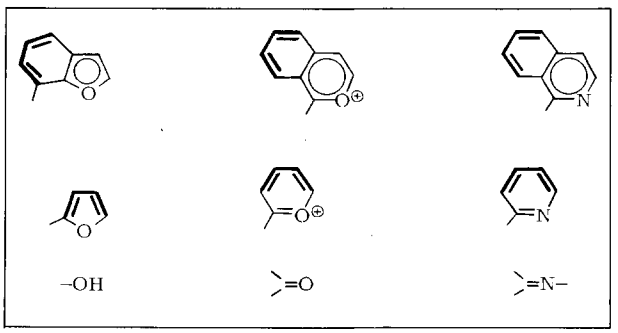
From the Principle of Areno-Analogy to Heterocyclopolyaromatic Compounds[**]

By Thomas Kauffmann[*]

Dedicated to Georg Wittig



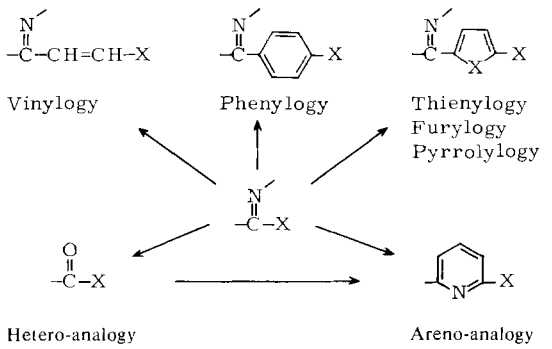
Organometallic linkage of heteroaromatic compounds provided a means of synthesizing complicated combinations of heteroaromatic compounds; not only nucleophilic aromatic substitution, but also "Ar—Cu/Ar—Hal linkage", "organometallic oxidative linkage", and "metal amide linkage" have been employed. The heterocyclopolyaromatic compounds are made of one, two, or three kinds of heteroaromatic species as ring members. These syntheses illustrate the construction of heterocycles from large, preformed structural units. Competition experiments showed that the reactivity typical of the individual species is enhanced in open-chain combinations $(Ar_{Nu})_n$ and $(Ar_E)_n$ (Ar_{Nu}, Ar_E: nucleo- and electrophilic heteroaromatic systems, respectively); the opposite situation is mostly encountered in the case of Ar_{Nu}—A_E combinations.—Cycloocta[1,2-*b*:4,3-*b'*:5,6-*b''*:8,7-*b'''*]tetrathiophene, the only heterocyclopolyaromatic system yet to have been studied in detail, proved surprisingly inclined to undergo monosubstitution reactions.

1. Motivating Influence of the Principle of Areno-Analogy

The existence of nucleophilic and electrophilic functional groups permits highly selective reactions to be performed in organic chemistry and biochemistry. Carbon chains furnished with groups of one kind or the other can be linked together without interference by formation of side products (*e.g.* ester formation from carboxylic acids and alcohols).

A second set of nucleophiles and electrophiles is available in the nucleophilic and electrophilic heteroaromatic compounds (π-electron-excess and π-electron-deficient heteroaromatic compounds[1]). With regard to their reactions and the effect on their substituents, they show a clear resemblance to nucleophilic and electrophilic functional groups (see below) and thus call for analogous applications in organic synthesis (principle of areno-analogy[2,3]).

The underlying reason for the relationship between heteroaromatic compounds and functional groups—the analogy between pyridine and the carbonyl group had already been pointed out prior to the formulation of the principle of areno-



Scheme 1. Functional groups and their areno-analogs.

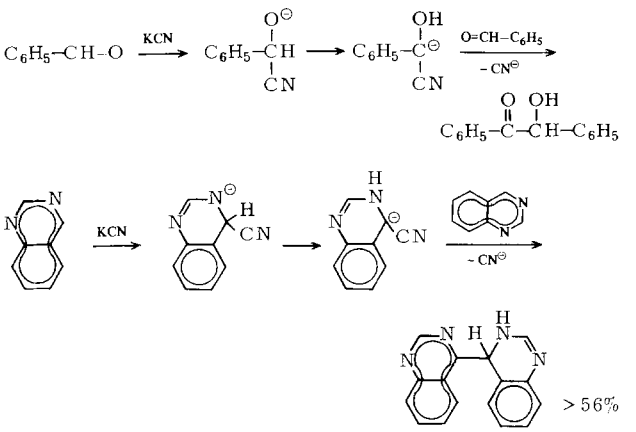
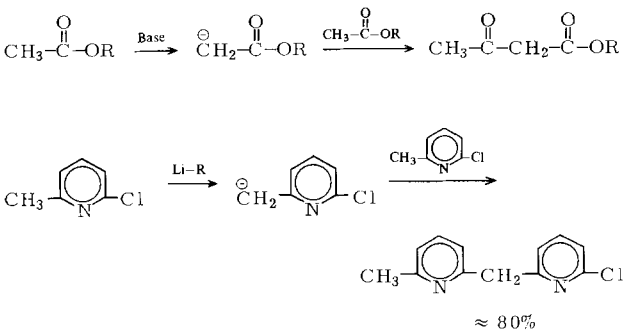
[**] Heterocyclopolyaromatic Compounds, Part 8.—Part 7: ref. [40a].



analogy[4]—can be considered[3] to lie in the possibility of formally deriving the simple heteroaromatic systems from the functional groups by incorporation of a C_4 unit possessing 4π electrons (Scheme 1). Although this leads to a drastic modification of the properties of the system, its nucleophilic or electrophilic activity and other essential features[2, 3] are retained.



As may be seen in Scheme 2, areno-analogy corresponds rather to hetero-analogy than to vinylogy. We therefore prefer the term "areno-analogy" over the originally chosen term "arenology"[2, 3]. Scheme 2 also underlines the difference between areno-analogy and phenylogy, thienylogy, *etc.* (see Section 2.2).

Scheme 2. Heuristically valuable analogies as illustrated for the CN double bond.

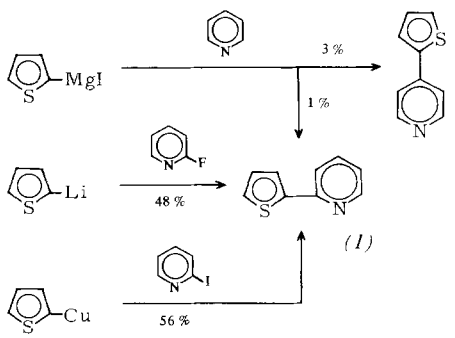
Use of the principle of areno-analogy often involves several conceptual steps; the pairs of reactions shown in Scheme 3 serve as examples. If classical heteroaromatic compounds

Scheme 3. Normal and areno-analogous benzoin and Claisen condensations [5, 3].

are viewed as higher homologs of functional groups, a number of interesting questions arise: Is the reactivity of the individual systems altered on linking heteroaromatic compounds to give open-chain or macrocyclic compounds in the same way as in the case of functional groups (see Section 2.2)? Are there hetero-aromatic counterparts of important specific reactions of organic molecules containing functional groups (see Scheme 3)? What heteroaromatic groups are particularly well suited for the linkage of hydrocarbon chains to give compounds such as Alk—Ar_{Nu}—Ar_E—Alk (see Section 2.1.4)? Can the bond between a nucleophilic and an electrophilic heteroaromatic unit be broken specifically (see Section 3.3.3)?

Questions of this kind and the favorable synthetic scope to be expected from the very existence of nucleophilic and electrophilic heteroaromatic compounds instigated the studies surveyed in the present article[6].

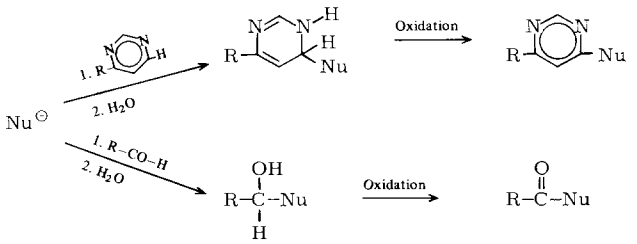
2. Heteropolyaromatic Compounds



2.1. Syntheses

2.1.1. Linkage of Heteroaromatic Units by Nucleophilic Substitution

Unlike functional groups, nucleophilic and electrophilic heteroaromatic compounds do not react together without prior activation. However, the activity of the nucleophilic heteroaromatic systems can readily be enhanced by introduction of a metal atom; such an example is seen in the reaction of thiophene with *n*-BuLi to give 2-lithiothiophene or with *n*-BuLi+CuCl to form 2-cuprothiophene. This enhancement of nucleophilicity is straightforward because nucleophilic heteroaromatic compounds exhibit a relatively high CH acidity and—in contrast to electrophilic heteroaromatic compounds—show no tendency to add the metalation reagent or the product of metalation.



Addition of one of the more strongly electrophilic heteroaromatic systems to a lithiated nucleophilic heteroaromatic unit generally leads to fast specific linkage.

At the outset of our studies seven years ago, little was known about the combinations of nucleophilic and electrophilic heteroaromatic compounds. The simplest uncharged representative, *viz.* 2-(2-furyl)pyridine was unknown and *(1)*, the corresponding thiophene derivative, was accessible in only about 1% yield (Scheme 4)[7]. Replacement of the magnesium iodide group by lithium[8, 9] or copper[10], as well as an H atom of the electrophilic component by halogen significantly raised the yield of *(1)* (Scheme 4).

Scheme 4. Synthesis of 2-(2-thienyl)pyridine *(1)*.

While the reaction of anionic nucleophiles such as 2-lithiothiophene with *halogenated* electrophilic heteroaromatic compounds like 2-fluoropyridine is known to proceed in full analogy to nucleophilic substitution with addition-elimination mechanism of *acyl halides*, the reaction of *non-halogenated* electrophilic heteroaromatic substances corresponds to the nucleophilic substitution of *aldehydes* which is much less familiar to the organic chemist (Scheme 5): in each case a stable adduct is formed which must be oxidized to regenerate the 6π- and 2π-electron system. Regeneration of the 6π system is usually easier (oxidation with nitrobenzene or with $KMnO_4$ in acetone) and sometimes even occurs of its own accord. Substitution with aldehyde-analogous electrophilic heteroaromatic compounds is of great importance in heteropolyaromatic chemistry; pyrimidine, quinoxaline, and quinoline are particularly well suited for this purpose.

Scheme 5. Nucleophilic substitution in non-halogenated electrophilic heteroaromatic compounds.

As may be seen in Table 1 (second line), *electrophilic* heteroaromatic compounds can be linked analogously if one of the two components—preferably that of lower electrophilicity—is first subjected to "umpolung". In contrast to the carbonyl compounds[11], *direct* umpolung generally proceeds without difficulty at low temperatures. However, the yields

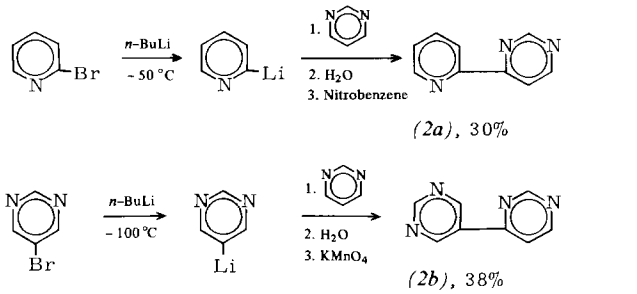


Table 1. Proven methods of linking heteroaromatic units.

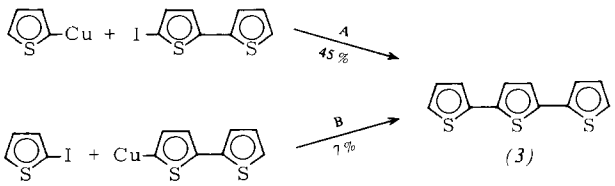
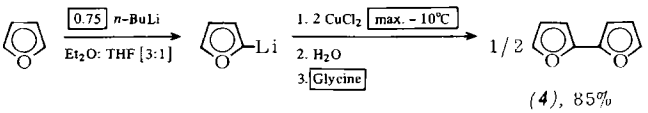


Kind of linkage	Reactants	Product
Nucleophilic aromatic substitution	Ar_{Nu}—Li + Ar_E (or Hal—Ar_E) Ar_E—Li + $Ar_{E'}$ (or Hal—$Ar_{E'}$)	Ar_{Nu}—Ar_E Ar_E—$Ar_{E'}$
Ar—Cu/Ar—Hal linkage	Ar_{Nu}—Cu + Hal—Ar_E (Hal = Br, I) Ar_{Nu}—Cu + Hal—$Ar_{Nu'}$ (Hal = Br, I)	Ar_{Nu}—Ar_E Ar_{Nu}—$Ar_{Nu'}$
Organometallic oxidative linkage	Ar_{Nu}—M + transition metal halide (M = Li, MgX) Ar_E—M + transition metal halide	Ar_{Nu}—Ar_{Nu} Ar_E—Ar_E
Metal amide linkage	Ar_E + $LiN(iPr)_2$	Ar_E—Ar_E
Areno-analogous benzoin condensation (see Scheme 3)	Ar_E + KCN	Ar_E—Ar_E

of linkage products are mostly lower than from corresponding substitutions with lithiated *nucleophilic* heteroaromatic compounds.

The syntheses of *(2a)*[12] and *(2b)*[13] are examples of substitutions with electrophilic heteroaromatic compounds after umpolung.

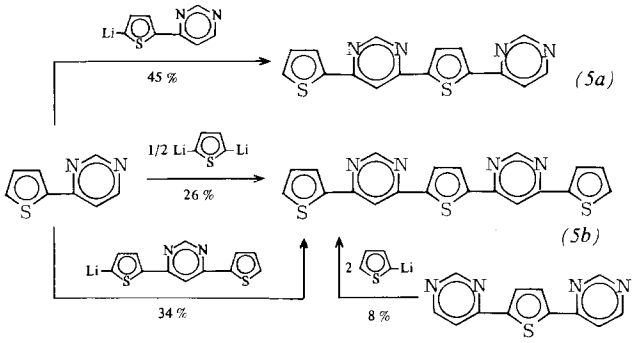


2.1.2. Other Methods of Linking Heteroaromatic Units

Ar—Cu/Ar—Hal linkage[14], the mechanism of which has still not been elucidated[15], has been used primarily by *Nilsson et al.*[16] to join nucleophilic aromatic compounds (benzene and its derivatives, nucleophilic heteroaromatic compounds) symmetrically and unsymmetrically. We found the method to be suitable for the synthesis of Ar_{Nu}—Ar_E combinations too[17] (an example is shown in Scheme 4), and to permit a convenient ring-linking synthesis of *all*-α-terthiophene *(3)*[10,18] (Scheme 6): pathway A proves much more favorable than B for reasons that are still not fully understood.

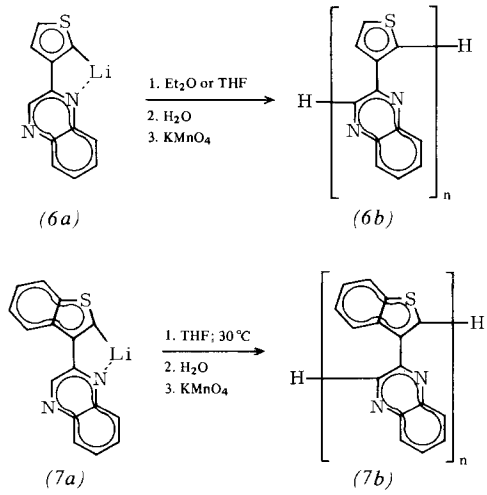
Scheme 6. Ring-linking synthesis of terthiophene.

Organometallic oxidative linkage is employed for symmetrically uniting nucleophilic heteroaromatic compounds. The reaction is normally accomplished smoothly by reaction of the lithium or magnesium compounds with $CuCl_2$, $CuCl/O_2$, $NiCl_2$, or $FeCl_3$ (for a survey, see ref. [6c]). Ring-linking synthesis of 2,2'-bifuran *(4)* (yield 85 %)[19], the best synthesis presently available for this sensitive compound[20], is particularly instructive: the reaction temperature should be about −10 °C; *n*-BuLi may only be used in the given molar ratio in order to ensure its complete consumption and to preclude its participation in the linkage process. Moreover, the bifuran-copper complex formed must be decomposed under mild conditions (addition of glycine). Analogous linkages led to the formerly unknown *all*-α-quaterfuran (53 %)[19], but for poorly understood reasons not to *all*-α-octifuran[21] (for further applications, see Sections 2.1.4, 3.2, and 3.4).



After umpolung, *electrophilic heteroaromatic compounds* can be linked analogously[6c] (a recent example is the synthesis of 5,5'-bipyrimidine, see Section 3.4).

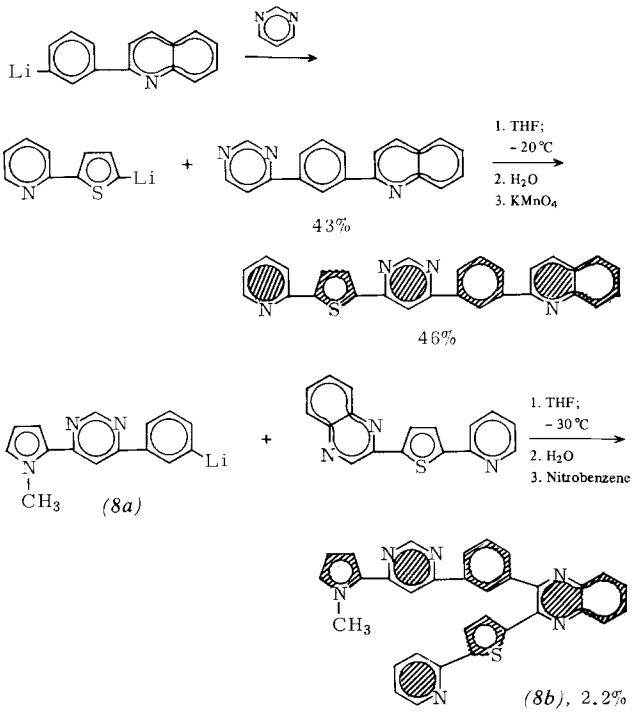
Metal amide linkage permits linkage of electrophilic heteroaromatic compounds (pyridine, quinoline, isoquinoline) by reaction with $LiN(iPr)_2$ in tetrahydrofuran (THF)/hexamethylphosphoric triamide (HMPA) according to *Clarke, McNamara*, and *Meth-Cohn*[22]. Analogous linkages of quinoxaline ($NaNH_2$ in dimethylaniline[23]) and 3-fluoropyridine ($NaNH_2$ in liquid NH_3[24]) have been described on previous occasions. The formation of a carbanion assumed to occur in the initial reaction step (*e.g.* formation of 2-lithiopyridine) should then



initiate a nucleophilic addition or substitution[22, 30]. However, trapping experiments failed to reveal carbanionic intermediates[22]. We have applied the linkage reaction with $LiN(iPr)_2$ to 3-bromopyridine, -quinoline (see Section 3.2), 5,5′-bipyrimidine, 3,3′-bi- and 4,4′-bipyridine, and to the tri- and tetraaromatic compounds *(52)* and *(49a)* (see Section 3.4). In some case a dihydro-product, requiring oxidation to the aromatic system, was formed, while in other cases the desired aromatic system is obtained directly. In spite of modest yields, these linkages are of preparative value because they provide ready access to suitable starting materials for heterocyclo-polyaromatic compounds and to such compounds themselves.

2.1.3. Linkage of Several Nuclei

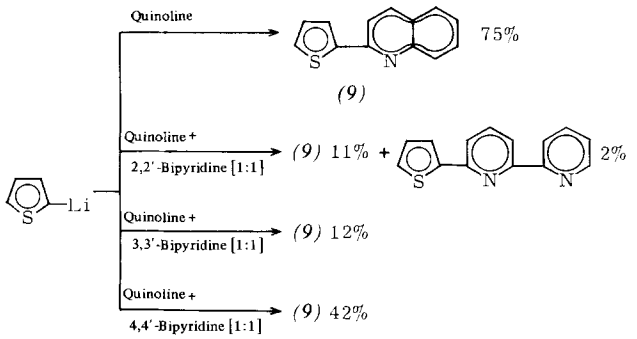
It is relatively easy, by means of the methods described in Section 2.1.2, to prepare heteropolyaromatic compounds. Apart from compounds having *nucleophilic nuclei of the same kind*, which are conveniently preparable by organometallic oxidative linkage (see Sections 2.1.2 and 2.1.4), combinations of heteroaromatic systems having an *alternant* arrangement of nucleophilic and electrophilic nuclei are most readily accessible. The pyrimidine and quinoxaline systems are especially suited as electrophilic structural units, and thus permitted preparation of, *e.g.*, the yellow thiophene-pyrimidine combinations *(5a)* and *(5b)*[13] and the likewise yellow thiophene-quinoxaline combinations *(6b)*, $n = 2$—6 (yields 22, 12, 13, 9, 5 %)[25], and benzo[*b*]thiophene-quinoxaline combinations *(7b)*, $n =$ 2—4 (yields 24, 11, 4 %)[26, 27] (Schemes 7 and 8).



Scheme 7. Alternant thiophene-pyrimidine combinations.

Scheme 8. Alternant thiophene-quinoxaline and benzo[*b*]thiophene-quinoxaline combinations (see Section 3.3.1 regarding the mechanism of oligomerization).

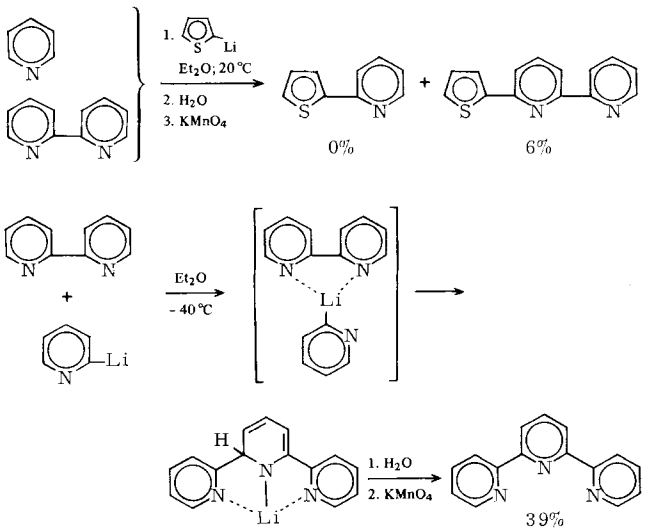
Attempts to link four, five, or even six different aromatic species, undertaken with the aim of developing the synthetic approach, gave the desired products[12, 28] (Scheme 9). The resulting compounds, which contain a benzene ring (hatching in the formulae emphasizes the alternance between Ar_{Nu} and Ar_E) show the term "heteropolyaromatic" to be a more fitting general designation than "polyheteroaromatic".



Scheme 9. Heteropolyaromatic compounds made up of many different components.

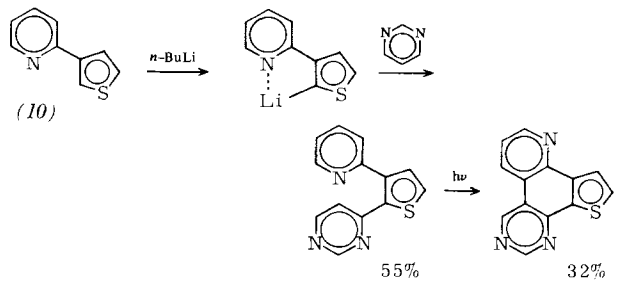
The low yield of the hexaaromatic compound *(8b)* is probably due, at least in part, to crowding on the quinoxaline group[29]. Crowding on the quinoxaline group appears to have a much less pronounced effect in the synthesis of the polyaromatic compounds *(6b)* and *(7b)* and of the protophane formulated in Scheme 14, possibly due to the greater mobility of the groups: in the synthesis of compounds *(6b)* and *(7b)* $n-1$ quinoxaline groups are present in the dihydro form prior to the oxidation step.

2.1.4. Fundamental Difficulties Besetting Synthesis



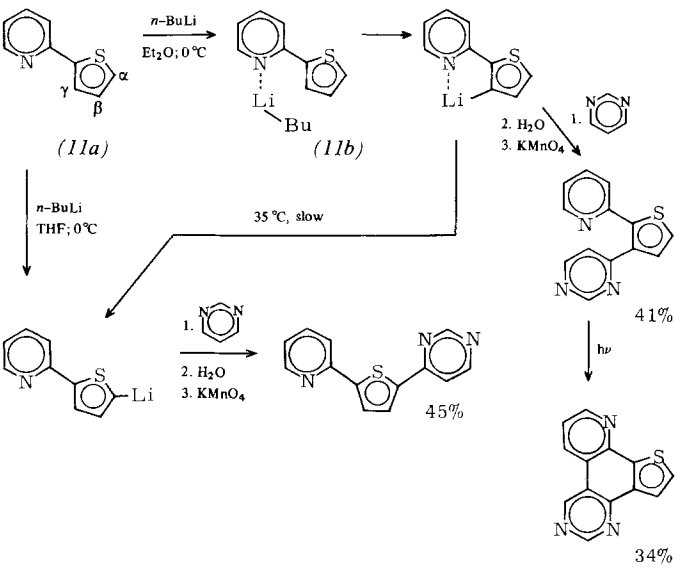
Deactivation by complexation: On attempted linkage of a lithiated nucleophilic heteroaromatic system with a combination of two or more heteroaromatic compounds, it was not uncommon for the lithiated species to be deactivated by complexation. This danger is particularly acute when two electrophilic heteroaromatic nuclei are joined together directly in the substrate.

Scheme 10 illustrates the deactivation of 2-lithiothiophene by bipyridines: the reaction with quinoline to give *(9)* is largely suppressed by addition of 2,2′- and 3,3′-bipyridine. The reason is undoubtedly to be sought in complexation since hardly any thienyl-bipyridine is formed.



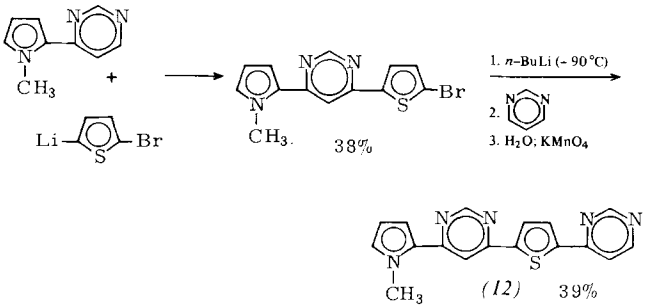
Scheme 10. Deactivation of 2-lithiothiophene by bipyridines [9].

Complexation of 2-lithiothiophene by 2,2'-bipyridine also explains why this diaromatic species, although extremely reactive towards *n*-BuLi (see Section 2.2), shows a similar resistance towards 2-lithiothiophene as pyridine (Scheme 11)[9]. Lithiated *electrophilic* heteroaromatic compounds appear to be less readily deactivated by 2,2'-bipyridine and similar systems than are lithiated nucleophilic heteroaromatic compounds. Thus, attempts to link lithiated pyridine with 2,2'-bipyridine by nucleophilic substitution are relatively successful (Scheme 11)[30, 31].



Scheme 11. Reactivity of 2,2'-bipyridine towards lithiated heteroaromatic compounds.

Nonspecific lithiation: If the nucleophilic component to be activated in a synthesis consists of two or more heteroaromatic units, then specific lithiation of a single position often proves impossible because two or more CH bonds of comparable acidity are present. This does not apply to compound *(10)* because lithiation at C-2 of the thiophene ring gives a thermodynamically stable chelated lithium compound. This phenomenon can be utilized in the synthesis of condensed heteroaromatic compounds[33, 34].

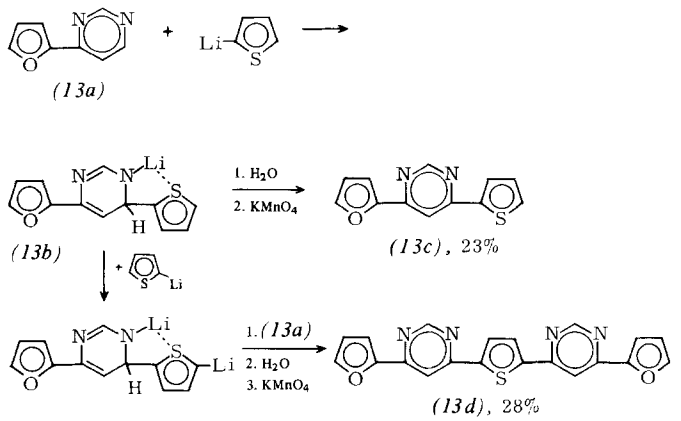


In contrast, the diaromatic compound *(11a)* possesses two positions of comparable acidity. The site of lithiation is strongly influenced by the solvent: in THF *n*-BuLi metalates almost exclusively in the α- position, and in ether mainly in the γ-position (γ:α-lithiation = 62:13)[32, 34]; *t*-BuLi even effects exclusive γ-lithiation in ether[34]. The lithioalkanes are presumably first attached as shown in *(11b)* and then effect H/Li exchange at the spatially proximate γ-C atom. It appears plausible that the tendency to form complex *(11b)* is reduced on use of the better-coordinating solvent THF. On heating of the ethereal solution of the γ-lithiation product to boiling, the lithium atom gradually shifts to the α-position, thus indicating kinetic control of γ-lithiation[35].

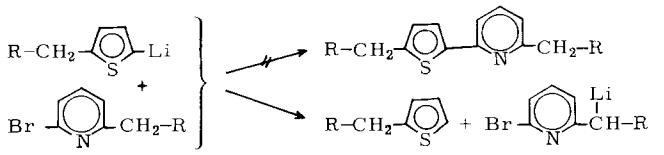
Solvent-controlled lithiations permit synthesis of the isomeric triaromatic compounds shown in Scheme 12[32, 34], as well as the photocyclization product[33, 34] (for further solvent-dependent lithiations and preparative applications, see ref. [32, 36]).

Scheme 12. Solvent-controlled α- and γ-lithiation of 2-(2-thienyl)pyridine.

Polyaromatic compounds containing more than two heteroaromatic members usually possess several CH groups of comparable acidity. In such cases, it is advisable to introduce the lithium atom in the manner shown for the synthesis of *(12)*[13], *i.e.* by *halogen/Li exchange* (essentially quantitative in this example; other examples are given in ref. [13]).



Transmetalation: Translithiations frequently impair the yields of heteropolyaromatic syntheses, and lead to undesired



side products. In the synthesis of the triaromatic compound *(13c)* selected as example, the less acidic five-membered ring was first linked to pyrimidine, thus hindering further complication due to translithiation. Nevertheless, there is some interference from a transmetalation reaction: the adduct *(13b)* is lithiated by 2-lithiothiophene and reacts to give the side product *(13d)*[13].

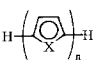
Translithiation is a very real danger when dealing with *alkyl*-substituted *electrophilic* heteroaromatic compounds. Instead of linkage between heteroaromatic compounds, translithiation usually occurs (Scheme 13, below) and initiates secondary reactions. The linkage of two alkyl groups according to

$$Alk{-}Ar_{Nu}{-}Li + Ar_E{-}Alk \rightarrow Alk{-}Ar_{Nu}{-}Ar_E{-}Alk$$

which is areno-analogous to the formation of carboxylic esters or carboxamides (see Section 1) is possible only in exceptional cases[6a, 37].

Scheme 13. Interference by translithiation.

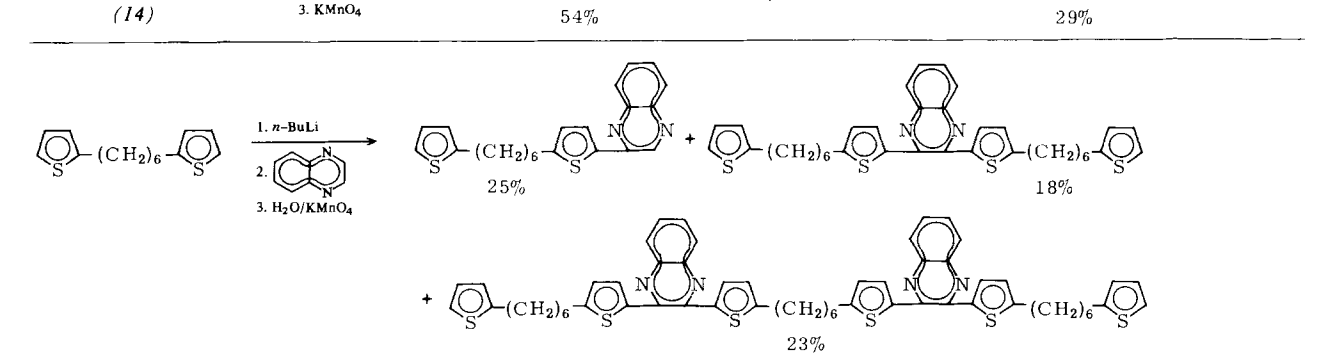
In contrast, alkyl groups attached to *nucleophilic* heteroaromatic systems do not have any interfering effect in organometallic syntheses of polyaromatic systems owing to their modest acidity. Thus alkyl groups can be joined *via* a group of three heteroaromatic nuclei ($Ar_{Nu}{-}Ar_E{-}Ar_{Nu}$) (Scheme 14, above)[9], which is areno-analogous to the formation of carboxylic diesters according to



$$2\,Alk{-}OH + Cl{-}O{-}Cl \rightarrow Alk{-}O{-}CO{-}O{-}Alk$$

It also follows from Scheme 14[38] that this mode of linkage can be utilized in protophane syntheses.

Sparing solubility: Organometallic syntheses of heteropolyaromatic compounds have often been thwarted by the sparing solubility of the polyaromatic precursors in THF, benzene, or ether. Thus it proved impossible to effect oxidative linkage of *all*-α-octithiophene to give *all*-α-sexidecithiophene[39]. *all*-α-Octi(*N*-methylpyrrole), which is much more soluble owing to the methyl groups, underwent linkage to give the hexadecamer (Table 2). In general, alkyl groups attached to Ar_{Nu} rings, and thus non-acidic, should help to overcome solubility problems in organometallic syntheses of heteropolyaromatic compounds.



all-α-Poly(*N*-methylpyrrole) (Table 2), of which only the representative having $n=2$ was formerly known[16c], differ not only in their solubility but expectedly also in their melting points (Table 2) and UV spectra (Fig. 4) from the *all*-α-polythiophenes known as far as the octamer.

Table 2. Melting points of *all*-α-polythiophene [41] and *all*-α-poly(*N*-methylpyrroles) [40].

n	M.p. [°C] X=S	M.p. [°C] X=NCH3	X=NCH3, yield [%] $CuCl_2$ [a]	X=NCH3, yield [%] $NiCl_2$ [a]

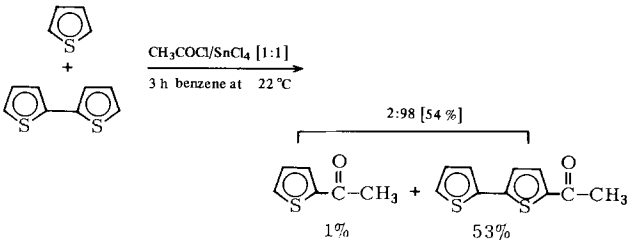
Scheme 14. Linkage of alkyl groups *via* heteroaromatic groups and protophane syntheses.

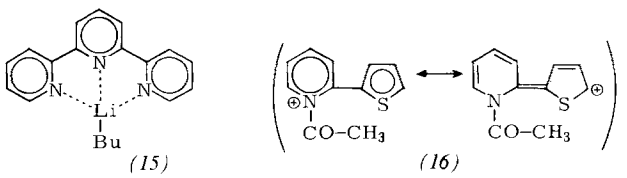
2.2. Reactivity[42]



Combinations of functional groups are of considerable significance in organic chemistry. The results compiled in the upper part of Scheme 15 thus belong to the basic armamentarium of the organic chemist: linkage of groups of the same kind (nucleophilic or electrophilic), for instance of amine or carbonyl functions, leads to an enhancement of the reactivity typical of the individual group; on linkage of a nucleophilic group with an electrophilic one, however, the reactivity of individual groups is lowered by mesomeric interaction. In this connection, the reader's attention is called to the pronounced electrophilicity of triketones, which is manifested in their tendency to add water at the central carbonyl group.

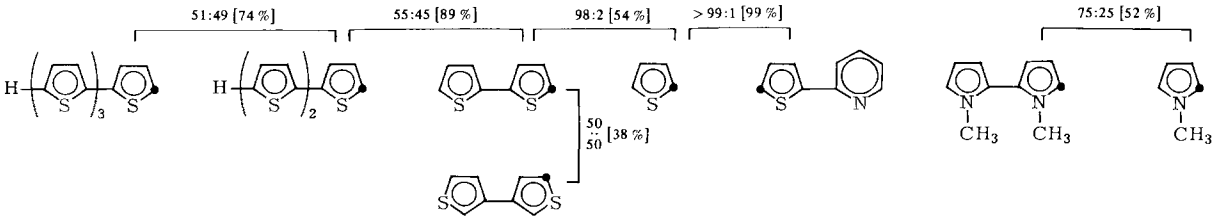
Scheme 15. Relative reactivity of combinations of functional groups and of heteroaromatic compounds.

Our studies have shown that the question, raised in the Introduction, whether an analogous situation is encountered in heteroaromatic combinations can be answered essentially in the affirmative if *thiophene* and *pyridine* are chosen as representative systems and acetyl chloride/$SnCl_4$ and *n*-BuLi as reagents. The only deviation from the situation described in the upper part of Scheme 15 is that *all*-α-terpyridine lies between pyridine and 2,2'-bipyridine on the electrophilicity scale. This deviation is probably due to the formation of the very stable *n*-BuLi-terpyridine complex *(15)* and the *m*-position of the terminal nuclei on the central ring of terpyridine, which hinders mesomeric interaction between the terminal rings.



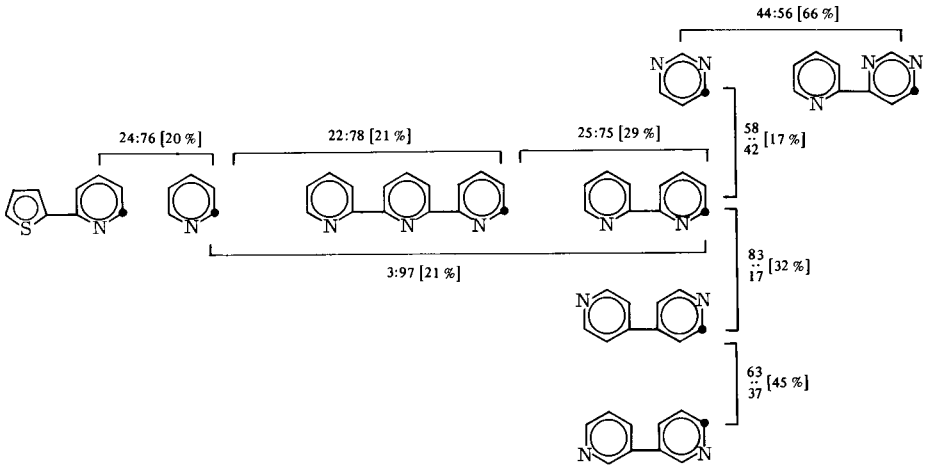
The information shown in the lower part of Scheme 15 was gained in competition experiments with the reagents mentioned according to Scheme 16, giving practically only monosubstitution products. The individual results are shown in Schemes 17—20. The figures above the brackets are the ratios in which the monosubstitution products are formed in the competition experiments (slow dropwise addition of reagent

Scheme 16. Typical competition experiment [43].



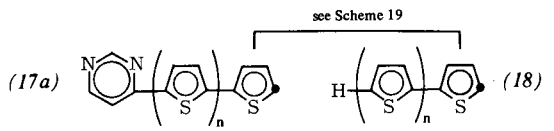
solution to the aromatic pair[42]); the overall yields of the two monosubstitution products are given in square brackets.

We attribute the apparent drastic weakening of the *nucleophilic* activity in the combination of nucleophilic and electrophilic nuclei as compared with thiophene (Schemes 17 and 19) to the formation of *N*-acetyl compounds, *e.g. (16)*, in which the electron-withdrawing effect of the electrophilic nucleus is greatly increased. Accordingly, acetylation of one mole



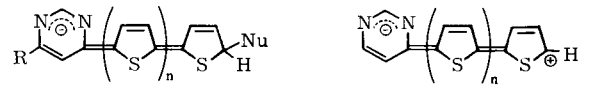
(15) *(16)*

of this combination requires two moles of acetyl chloride (but only one mole of $SnCl_4$)[43].

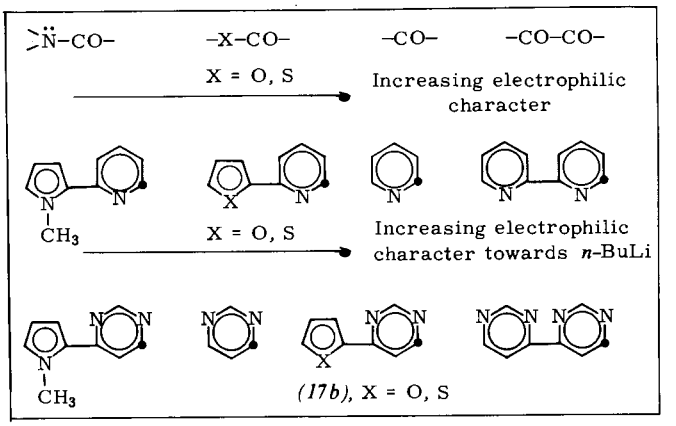


Scheme 17. Competition experiments with $CH_3COCl/SnCl_4$ as reagent (acetylation at ●).

Scheme 18. Competition experiments with *n*-BuLi as reagent (butylation at •).



Scheme 19 shows that the drop in nucleophilicity at the thiophene nucleus of *(17a)*, $n=0$, due to the pyrimidine nucleus can extend over two further thiophene nuclei and is completely attenuated only after the third additional nucleus[39]. The ratio of 32:68 almost corresponds to the statistical ratio since *(17a)*, $n=3$, possesses *one* nucleophilic α-position whereas *(18)* has *two* such positions; acetylation is apparently subject to kinetic control.



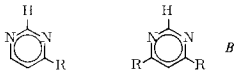
Scheme 19. Competition experiments on "thienylogous pyrimidines" with $CH_3COCl/SnCl_4$ as reagent (acetylation at •) [39].

$n=0$	$n=1$	$n=2$	$n=3$
<1:99 [99 %]	<1:99 [99 %]	24:76 [49 %]	32:68 [96 %]

Compounds *(17a)* can be regarded as thienylogs of pyrimidine (cf. Scheme 2). The nucleophilicity of their terminal thiophene nuclei does not exhibit umpolung under the influence of the pyrimidine nucleus—no formation of adducts *(19a)* has been observed so far—but is significantly lowered, partly due to charge shifts according to *(19b)*.

Further results of competition experiments are summarized in Scheme 20 (for details see ref. [42]): the increase in carbonyl activity on going from left to right in line 1 has long been known. The "pyridine activity" (towards *n*-BuLi) of the compounds in line 2 show a similar gradation. However, the "pyrimidine activities" (towards *n*-BuLi) in the compounds of line 3 do not correspond entirely to expectation, for reasons yet unknown[44], since in competition experiments with pyrimidine *(17b)* the diaromatic compounds *(17b)* underwent butylation almost to the same extent as pyrimidine although they have only one site susceptible to attack by *n*-BuLi compared with the two of pyrimidine[45].

Scheme 20. Electrophilicity of carbonyl compounds and areno-analogous systems (butylation at •) [42].



It was established in the competition experiments with $CH_3COCl/SnCl_4$ that the resulting monoacetyl compounds are stable under the experimental conditions. In competition experiments with *n*-BuLi the lithium derivatives of dihydroheteroaromatic compounds appear as primary products, and have to be hydrolyzed and oxidized for the synthesis of the aromatic monosubstituted products. Presumably the lithiated dihydroheteroaromatic species are largely stable under the experimental conditions and are transformed into the substitution products on hydrolysis and oxidation. However, this assumption has yet to be confirmed.

2.3. Spectra

2.3.1. NMR Spectra[49]

The diminished chemical reactivity of Ar_{Nu}—Ar_E combinations usually observed on comparison with the individual aromatic compounds suggests that electron density is transferred from the nucleophilic to the electrophilic nuclei. This can be confirmed by ^{1}H-NMR spectroscopy[46]. The 2-H atom of the pyrimidine nucleus is particularly suitable as a probe because its signal (Table 3) is hardly ever masked by other proton signals[13,43].

Table 3. ^{1}H-NMR signal of 2-H in pyrimidine derivatives *A* and *B* (*ca.* 0.12 M solution, TMS as int. standard, 20°C, in $CDCl_3$) [43].

R	*A* δ	*B* δ
2-(*N*-Methylpyrrolyl)	9.04	8.94
2-Thienyl	9.13	9.03
2-Furyl	9.14	9.00
H	9.22	9.22
2-Pyridyl	9.29	
2-Pyrimidinyl	9.35	

The redistribution of electron density is even clearer in the ^{13}C-NMR spectra[47]: the chemical shifts shown in Figures 1 and 3 can be viewed, to a first approximation, as a measure of the change in electron density at the C atoms. The signals of C-3 and C-5 of the pyridine ring (Fig. 1) and of C-5 of the pyrimidine ring (Fig. 2) are shifted upfield owing to enhanced electron density and those of the nucleophilic heteroaromatic nuclei downfield. The effects are very pronounced in the triaromatic systems of Figure 2 because a stronger acceptor nucleus is linked to two donor nuclei.

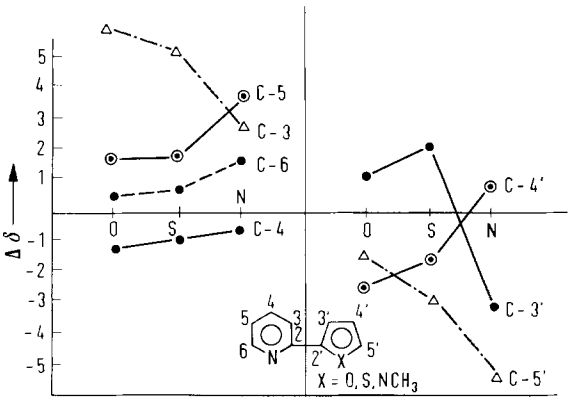


Fig. 1. ^{13}C-NMR of diaromatic compounds: chemical shifts relative to furan, thiophene, *N*-methylpyrrole, or pyridine (*ca.* 0.4 M solution, 20°C, in [D_6]dimethyl sulfoxide, standard TMS, upfield shift shown positive) [47].

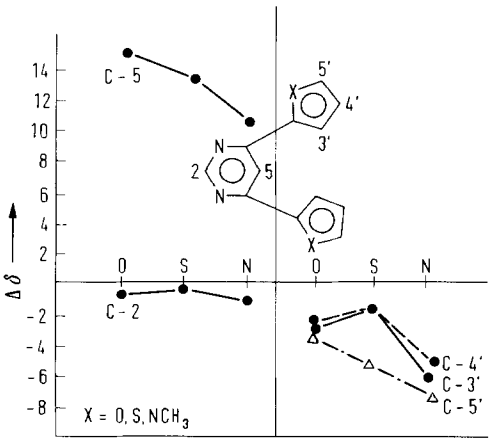

Fig. 2. ^{13}C-NMR of triaromatic compounds: chemical shifts relative to furan, thiophene, *N*-methylpyrrole, or pyrimidine (*ca.* 0.4 M solution, 20°C, in [D_6]dimethyl sulfoxide, standard TMS, upfield shift shown positive) [47].

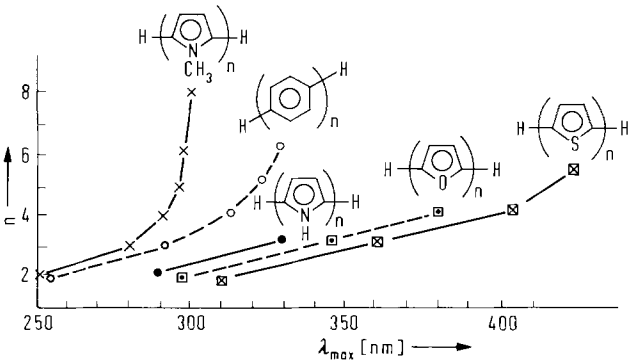
2.3.2. UV Spectra

In this Section mention is made only of the difference in spectra between *all*-α-poly(*N*-methylpyrroles)[40] on the one hand and *all*-α-polythiophenes[48], -furans[19], and -pyrroles[48] on the other (Fig. 3). The convergence of the absorption wavelengths in *all*-α-poly(*N*-methylpyrroles), which is more pronounced than in the case of the poly-*p*-benzenes[48], is due to the greater torsional angle between the planes of adjacent nuclei.



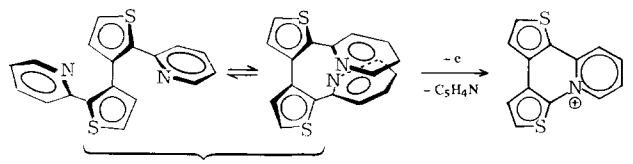


Fig. 3. λ_{max} in the UV spectrum of combinations $(Ar_{Nu})_n$; solvent $CHCl_3$.

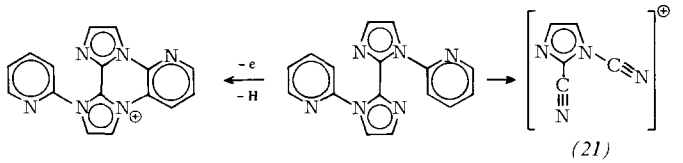
2.3.3. Mass Spectra[49]



The mass spectra (70 eV) of heteropolyaromatic compounds do *not* normally contain fragment ions indicating the elimination of individual aromatic nuclei; intranuclear bonds are apparently broken much faster than internuclear ones. Exceptions are encountered in heterotetraaromatic compounds with terminal nuclei in the *o,o'*-position relative to the central internuclear bond ("*o,o'*-linkage"). In such a case, *e.g.* in *(20)*, an intense $(M^+ - Ar)$ peak regularly appears which is usually also the base peak (Table 4). Knowledge of this phenomenon is useful in structure elucidation.

The mass number of the $(M^+ - Ar)$ peak of tetraaromatic compounds which consist, like *(20)*, of two kinds of aromatic species, show that one *terminal* nucleus each is eliminated. A fused aromatic compound is probably formed, for an intense peak for $(M^+ - Ar)$ occurs only if cyclization to give a condensed aromatic molecule is formally possible (further arguments, see [49]).

(20) [49]

Heterotetraaromatic compounds having *o,o'*-linkage in which the terminal nuclei are attached by CN bonds to the central portion also eliminate a terminal nucleus in the mass spectrometer (Table 4). However, the $(M^+ - Ar)$ peaks are relatively weak owing to competition by more favorable decomposition pathways [H elimination, HCN elimination, formation of fragments such as *(21)*].

(21)

Table 4. ($M^+ - Ar$) peaks in the mass spectra of heteroaromatic compounds with "*o,o'*-linkage".

Compound	Relative intensity [%]

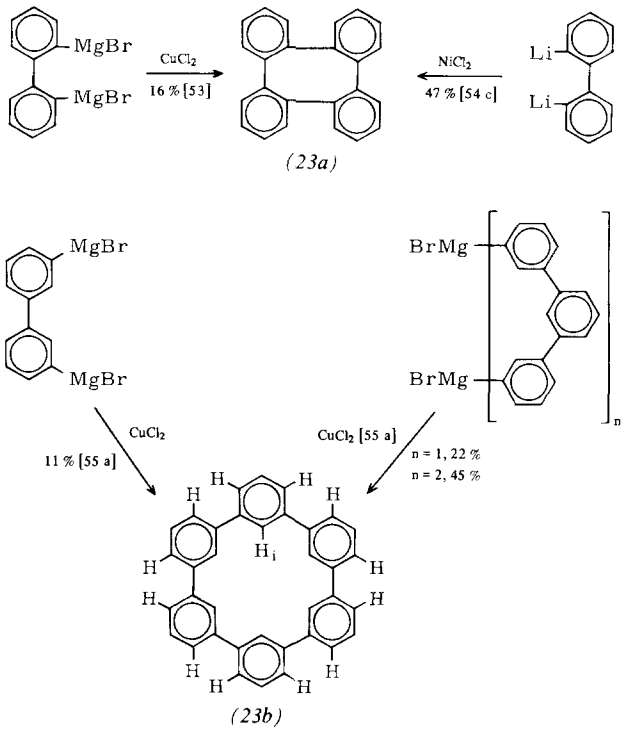
3. Heterocyclopolyaromatic Compounds

3.1. An Unattractive Class of Compounds?

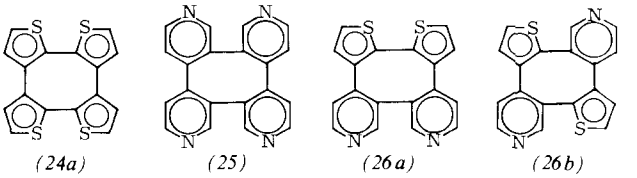


In contrast to the field of organoelement compounds, there are probably only few regions left to be discovered in the field of organic compounds proper. Nevertheless, the well-populated class of heterocyclopolyaromatic compounds was still unknown in 1973, apart from the heterocyclodiaromatic[52] compounds such as (*22a*)[50] or (*22b*)[51].

(*22a*) (*22b*)

Carbocyclic cyclopolyaromatic compounds have been known for several decades. The first example, cyclotetrabenzene (tetraphenylene) (*23a*) was prepared in 1943 by *Rapson, Shuttleworth*, and *van Niekerk*[53] by oxidative coupling of a di-Grignard compound (Scheme 21). Further syntheses and studies were performed primarily by research teams led by *Wittig*[54] and *Staab*[55]. The carbocyclic compounds were obtained mainly in modest yield by oxidative linkage of metalated starting compounds with transition metal halides; the properties of the products, *e.g.* (*23b*), correspond largely to expectations.

We attempted to gain an entry to heterocyclopolyaromatic compounds, which promise to be more interesting than their carbocyclic analogues with regard to their chemical reactivity because they are also expected to exhibit the interactions between neighboring nuclei (see Section 2.2) observed in open-chain heteropolyaromatic compounds. It might be expected that the reactivity typical of the individual nuclei would be enhanced in (*24a*) and (*25*), whereas mutual deactivation

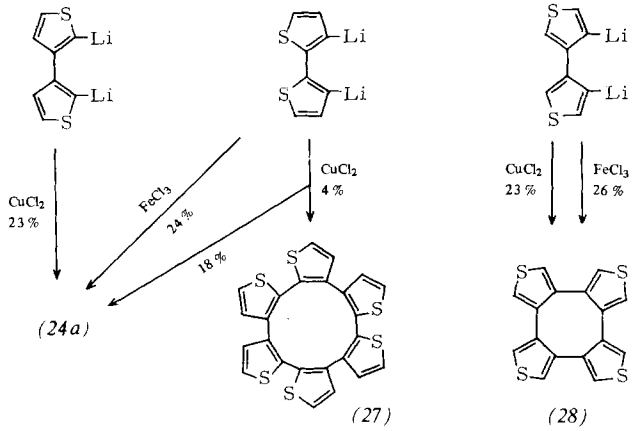


(*23a*)

(*23b*)

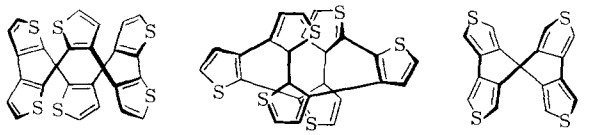
Scheme 21. Cyclopolybenzenes (polyphenylenes).

of the aromatic nucleophiles and electrophiles constituting the ring members could occur in (*26a*) and especially (*26b*).



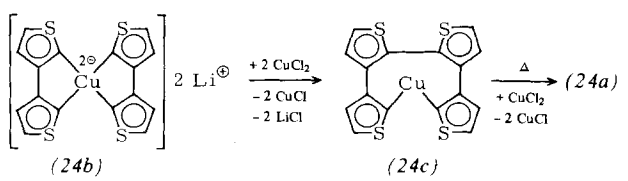
(*24a*) (*25*) (*26a*) (*26b*)

3.2. Organometallic Oxidative Linkage as Cyclization Step

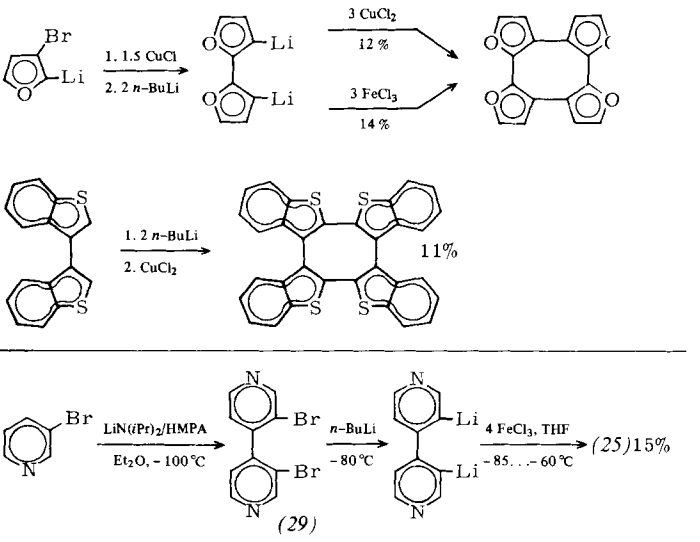


3.2.1. Similar Aromatic Ring Members

The method of oxidative linkage which proved of value in the preparation of cyclotetrabenzene was successfully applied to heterocyclic starting materials. Starting from the dibromides[56], Br/Li exchange and oxidative coupling initially gave the cyclotetrathiophenes *(24a)* and *(28)* (Scheme 22)[9, 13, 57, 58]. Cyclohexathiophene *(27)* was formed as side product in one case. Cyclodithiophenes, *i.e.* products analogous to *(22a)*, could not be detected.



Scheme 22. Cyclopolythiophene syntheses.

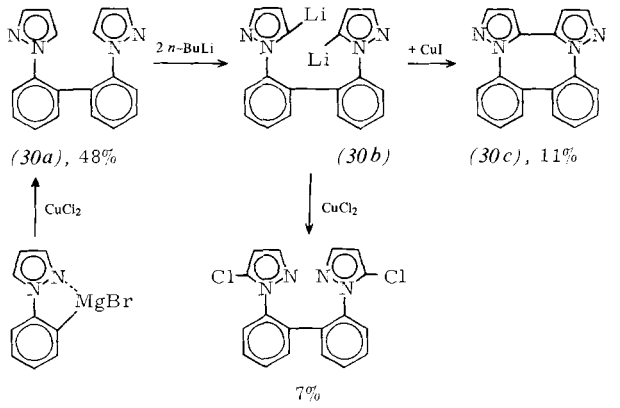


The three-dimensional structure *(28')* was found for *(28)* by X-ray structure analysis[59]. The angle between the planes of adjacent nuclei is 53.7° and is thus considerably smaller than in cyclotetrabenzene *(23a)* (*ca.* 70°)[60]. This complies with expectations, because less deformation of the bond angles is required to planarize *(28')* than *(23a)*. Analogous nonplanar structures are assumed for *(24a)* and the other heterocyclotetraaromatic compounds synthesized. The ^{1}H-NMR spectrum of the cyclohexathiophene *(27)* is almost identical with that of *(28')*. Hence *(27)* probably has the three-dimensional structure *(27')* rather than *(27'')*[61].

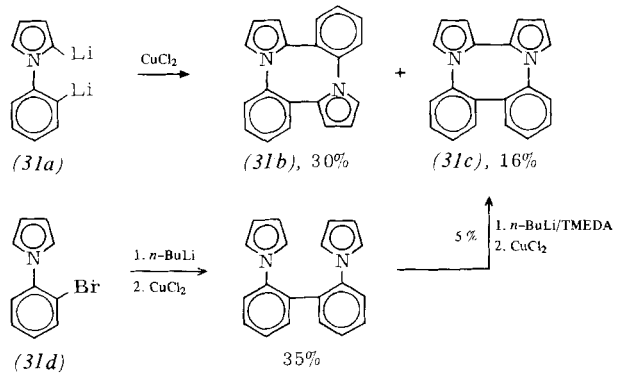
The mechanism of the linkages leading to *(24a)* and analogous compounds is still unclear. A reaction route analogous to that proposed and experimentally supported by *Wittig et al.*[54c] for the formation of cyclotetrabenzene would involve the intermediacy of the ate complex *(24b)* and metallocyclic species *(24c)* in the formation of *(24a)* by oxidation with $CuCl_2$.

Two further nucleophilic cyclotetraaromatic compounds (Scheme 23) could be prepared analogously[9, 13, 57, 58] from known precursors[62, 63]. The difficult synthesis of cyclotetrafuran[64] could be reproduced only after several attempts[65].

Scheme 23. Further homotypic [66] heterocyclotetraaromatic compounds by oxidative coupling: Top, aromatic nucleophiles as ring members; bottom, aromatic electrophiles as ring members.



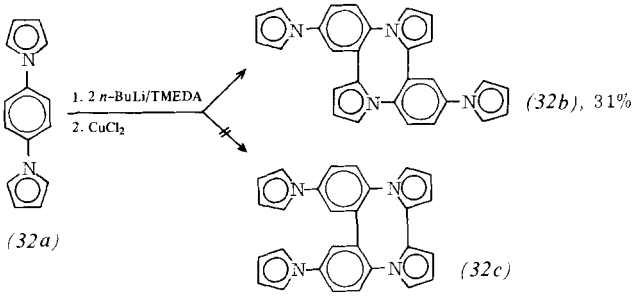
Analogous attempts to synthesize cyclopolyaromatic compounds made up exclusively of heteroaromatic *electrophiles* as ring members have so far succeeded only in the case of cyclotetrapyridine *(25)*. Metal amide linkage of 3-bromopyridine (cf. Section 2.1.2) led to *(29)*[31], which reacted with *n*-BuLi to form the corresponding dilithium compound. Addition of $FeCl_3$ gave the cyclotetrapyridine *(25)*. In contrast, only traces of *(25)* were formed on use of $CuCl_2$[67].



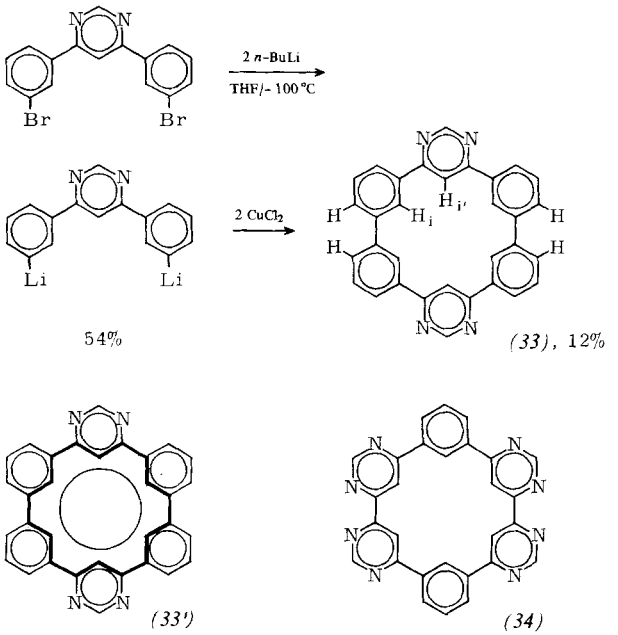
3.2.2. Two Different Kinds of Aromatic Ring Members

On synthesis of *(30c)*, the first heterocyclopolyaromatic compound containing unlike aromatic ring members (Scheme 24)[68, 69], selective linkage of pyrazole and benzene proved feasible because 1-phenylpyrazole is metalated specifically at the phenyl group by Grignard compounds[70] and the tetraaromatic compound *(30a)* specifically at the pyrazolyl group by *n*-BuLi[68]. $CuCl_2$, which is usually the reagent of choice for oxidative linkage *via* organocopper compounds, fails to effect cyclization of the dilithium compound *(30b)*; it acts as a chlorinating agent instead. There is a danger of explosion when cyclization is performed with CuI/O_2[71].

Cyclic pyrrole-benzene combinations were much more readily accessible (Scheme 24, below). On linkage of the dilithium compound *(31a)*, which arises almost quantitatively on reaction of 1 mol of 1-phenylpyrrole with 2 mol of *n*-BuLi/tetramethylethylenediamine (TMEDA)[40b, 72], the question whether *(31b)* or *(31c)* is formed preferentially was of particular interest. It is still unclear why the macrocycle with alternant arrangement of the nuclei happens to predominate. Structural assignment of the two cyclization products[40b] proved possible only after the isomer *(31c)* had been synthesized from *(31d)*[73].



It was not possible to isolate the expected cyclohexaaromatic analog of *(36b)* or the cyclotetraaromatic compound *(32c)* from the mixture obtained on reaction[40b] of the triaromatic

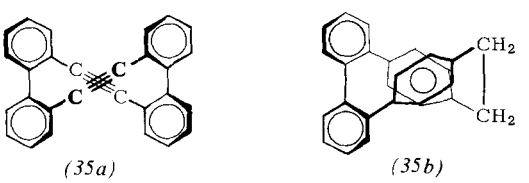


Scheme 24. Heterotypic [66] heterocyclotetraaromatic compounds by oxidative linkage.

species *(32a)*[73]. Compound *(32c)* should be formed less readily for steric reasons than the colorless, fairly soluble isomer *(32b)* formed in relatively good yield; the compound has the basic ring system of *(31b)*.

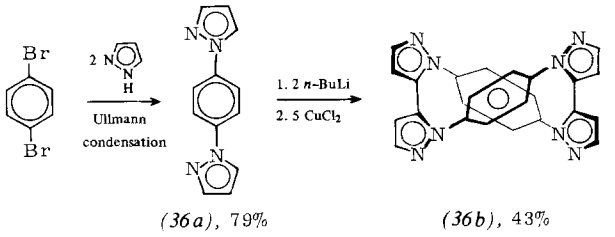
On synthesis of *(33)* (Scheme 25)[69, 74], the first heterocyclo*hexa*aromatic compound having different kinds of ring members, the double Br/Li exchange shown in the scheme must be carried out with cooling owing to the competing *n*-BuLi addition at the pyrimidine nucleus.

While the planes of adjacent benzene rings are twisted by *ca.* 30° relative to each other in hexa-*m*-phenylene *(23b)* (Scheme 21)[75], the corresponding angle in tetraazahexa-*m*-phenylene *(33)* is shown by X-ray structure analysis[76] not to exceed 1°. This is probably because six pairs of *o,o'*-protons in the outer sphere of *(23b)* hinder planarization while only two such pairs are present in the tetraaza compound. Intramolecular hydrogen bonds from benzene moieties to nitrogen atoms may also be effective.

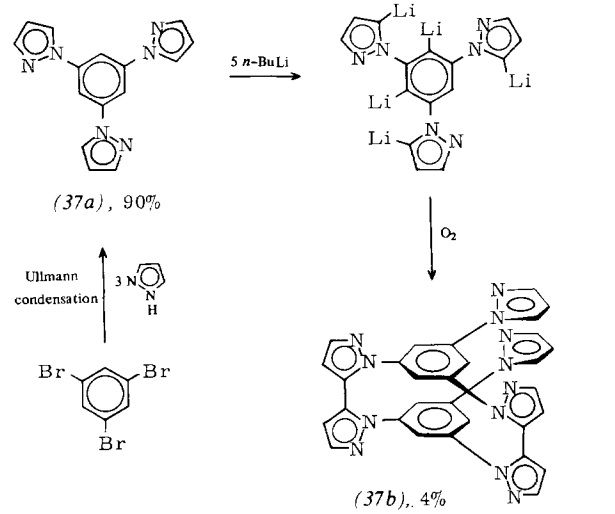


Scheme 25. Heterocyclohexaaromatic compounds with a crown-type structure.

X-Ray structure analysis of *(33)* also shows that a clear distinction in bond length remains (C—$C_{aromatic}$: 1.38 Å; C—$C_{internuclear}$: 1.40 Å) in the internal ring, which formally corresponds to an [18]annulene ring. Thus, as expected, the aromatic character of the individual benzene rings is not weakened in favor of an aromatic [18]annulene system. Any formulation as a condensed aromatic system *(33')* is therefore erroneous.



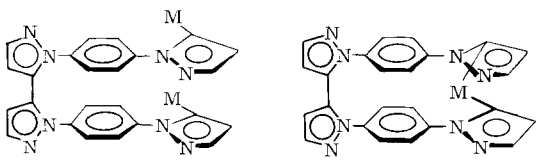
The ^{1}H-NMR spectrum of hexa-*m*-phenylene *(23b)* (Scheme 21) contains the signals of the internal protons at $\delta = 8.85$. The corresponding signals of the tetraaza compound *(33)* at $\delta = 9.42$ (H_i) and 9.51 ($H_{i'}$) show a significant downfield shift. This is probably partly due to the stronger mutual interaction (van der Waals). In the case of octaazahexa-*m*-phenylene *(34)* (synthesis in Section 3.4), the signals of the internal protons H_i and $H_{i'}$ appear at $\delta = 9.75$, *i.e.* even further downfield. This cyclohexaaromatic compound should therefore also be planar, which is understandable in view of the absence of steric hindrance between external *o,o'*-pairs of protons.



Since compounds *(35a)* and *(35b)* are known[77, 78], it was to be expected that not only crown-type cyclohexaaromatic compounds (Scheme 25) should be possible in which two nuclei are arranged face to face. The question of their chemical and spectroscopic properties makes such compounds interesting synthetic objectives.

It proved possible to synthesize compound *(36b)* as the first representative of this type in acceptable yield (Scheme 26)[40]. Attempted preparation of an analogous heterobicyclooctaaromatic compound having benzene rings linked *via* three bispyrazolyl bridges did not give the desired product but instead a disubstituted cyclohexaaromatic compound to

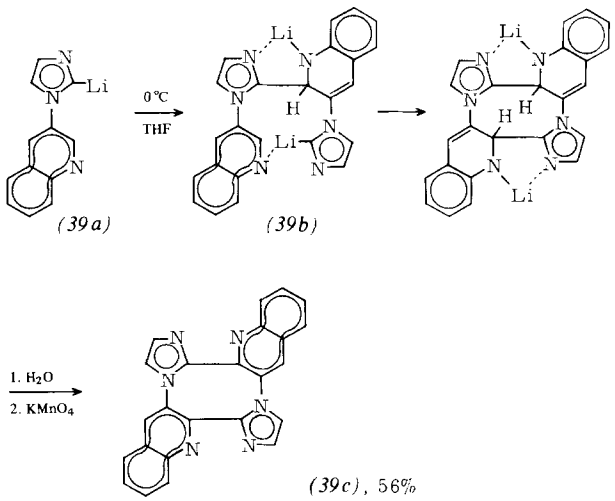
which we assign structure *(37b)*[79]. The yield of *(37b)* was only 1 % on oxidative coupling of the precursor with $CuCl_2$ instead of with O_2[40b].



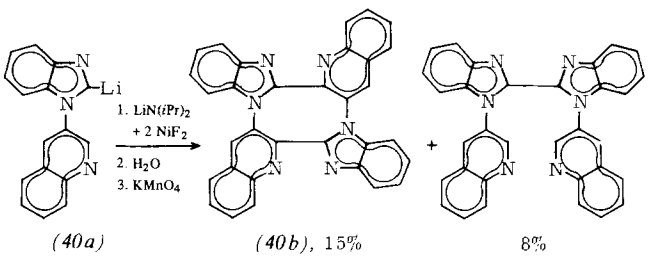
Scheme 26. Heterocycloaromatic compounds with face-to-face arrangement of two rings.

The signals of the phenylene protons (singlet, $\delta = 6.97$) in the ^{1}H-NMR spectrum (in $CDCl_3$) of *(36b)* are distinctly shifted upfield relative to those of the precursor *(36a)* ($\delta = 7.80$). This corresponds to the situation in [2.2]paracyclophane[80], in *(35b)*[78], and in other phanes, and can be explained in terms of the anisotropic effect of the neighboring phenylene group[80].

In the syntheses of heterocyclopolyaromatic compounds by oxidative linkage considered so far, the yield of the cyclization step was at most 31 %. The high yield of *(36b)*—43 %—is therefore surprising. Since the two CC bonds will hardly be formed simultaneously, we have to assume that the intermediate hexaaromatic compound occurs in the cisoid conformation *(38a)* or as metallocycle *(38b)*, or readily transforms into these structures (cf. ref. [49]).



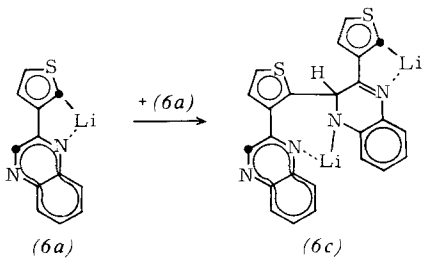
3.3. Nucleophilic Aromatic Substitution as Cyclization Step



3.3.1. 2+2 Linkage

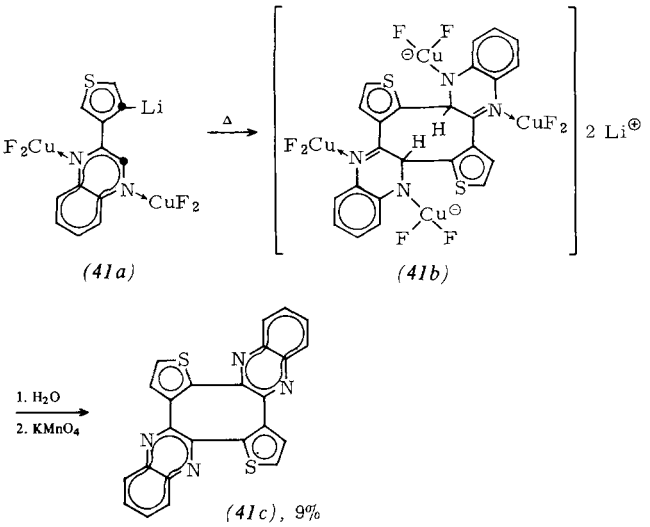
Since linkage of a heteroaromatic nucleophile with an electrophile is particularly facile (see Section 2.1.1), the cyclization of two molecules of a monolithiated diaromatic compound appears highly promising if it contains a strongly nucleophilic and a strongly electrophilic center like *(39a)*. This kind of cyclization proved successful in four cases.

Especially smooth cyclization was observed with lithiated 3-(1-imidazolyl)quinoline *(39a)* (Scheme 27)[68,81,82]. A contributory role is probably played by the chelate bridge assumed to occur in the intermediate *(39b)* which forces the terminal nuclei into spatial proximity. Unlike the syntheses of *(40b)*, *(41c)*, and *(42)*, that of *(39c)* fails to give better yields on addition of CuF_2 or NiF_2.

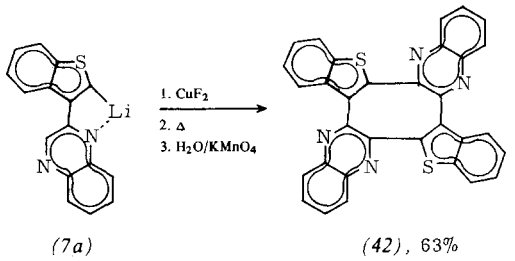


The analogous benzimidazole derivative *(40a)* gives the cyclotetraaromatic compound mentioned in a yield of only 3 %, for reasons which are still unknown; addition of 2 equiv. of NiF_2 *(vide infra)* to the reaction mixture raises the yield to over 15 %[68,81]. The higher electrophilicity of benzimidazole, compared with imidazole, is probably responsible for formation of the above side product (addition of *(40a)* to the corresponding nonlithiated compound).

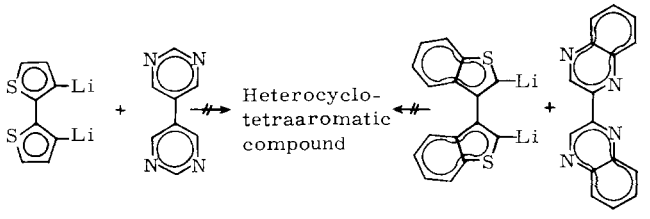
Scheme 27. Cyclization of imidazolide-analogous [83] diheteroaromatic compounds.



The corresponding cyclization of the lithiated thiophene-quinoxaline combination *(6a)* could not initially be performed since only the open-chain oligomers *(6b)* mentioned in Section

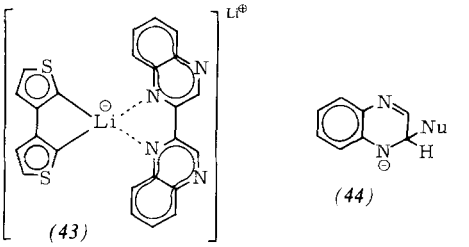


2.1.3 were formed on heating. We attribute this to the chelate bridges in *(6a)* and *(6c)* and analogous intermediates because they fix the two active centers (marked by a point) in the *trans* orientation which is unfavorable for cyclization.

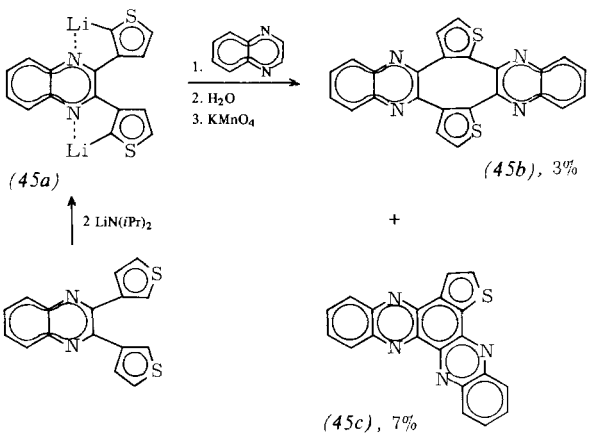


The desired cyclization to *(41c)* (yield 9%) occurred only on treatment of the THF solution of *(6a)* with 2 equiv. of CuF_2 (Scheme 28)[26, 27]. The effect of the CuF_2 can be rationalized by assuming it to complex the N atoms of the quinoxaline system according to *(41a)*, which should overcome the fixing of the "wrong" conformation of *(6a)* and also raise the electrophilicity. The speculative formula *(41b)* should illustrate the complexity of the reaction course.

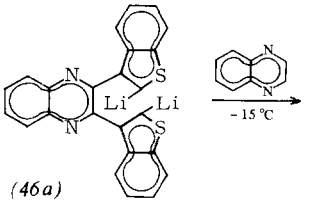
The benzohomolog *(7a)* likewise mentioned in Section 2.1.3 also cyclizes without addition of CuF_2. Addition of 2 equiv. of anhydrous CuF_2 or NiF_2[84] raised the yield of cyclization product *(42)* from 12% to 63 and 26%, respectively[26, 27]. 63% is the highest yield yet obtained in a heterocyclopolyaromatic synthesis. It is remarkable that this yield and the second-best one [56% of *(39c)*] were both achieved by Ar_{Nu}—Ar_E linkages, which have also proved especially valuable in the synthesis of open-chain systems (cf. Section 2.1.3).



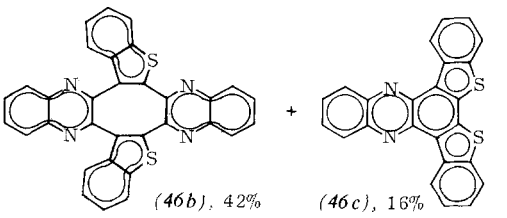
Scheme 28. CuF_2-assisted cyclotetraaromatic syntheses.



Scheme 29. Unaccomplished cyclizations [13, 26].

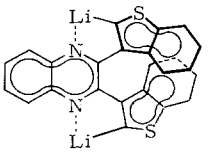


The reaction of a dilithiated nucleophilic diaromatic compound with an electrophilic diaromatic species, *e.g.* according to Scheme 29, also appeared promising as a method for the synthesis of heterocyclotetraaromatic compounds, but all attempts to carry out this reaction were unsuccessful. We suspect the dilithium compound to be deactivated by complexation, *e.g.* according to *(43)* (cf. Section 2.1.4).

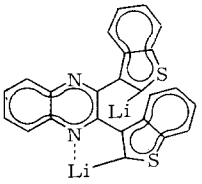


3.3.2. 3+1 Linkage

The quinoxaline system, whose adjacent electrophilic centers make it appear to be such a favorable structural unit for cyclotetraaromatic syntheses, is particularly advantageous for the critical cyclization step in cyclotetraaromatic syntheses. If one of the two electrophilic centers is attacked with formation of an adduct *(44)*, then the electrophilicity of the second center increases, since the "aromatic" CN double bond has been transformed into a "normal" CN double bond. Thus special measures are required (very slow addition of nucleophile to quinoxaline[85]) if single nucleophilic addition to the



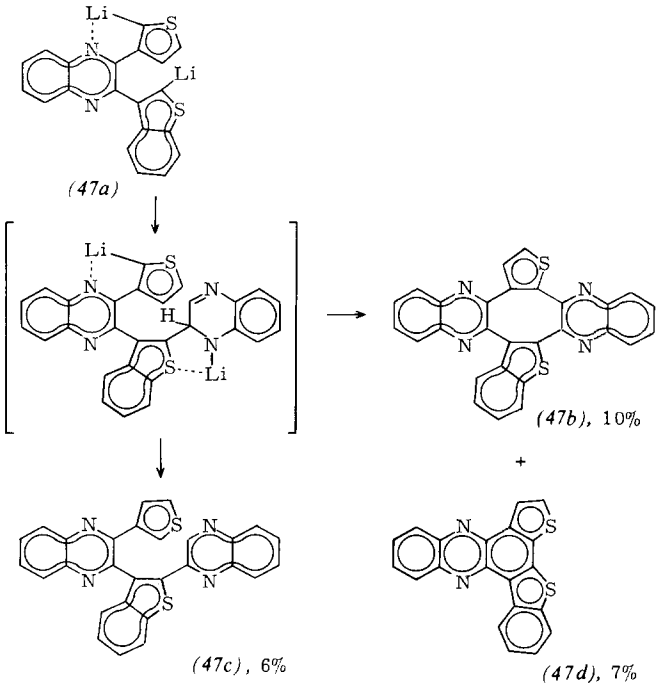
Scheme 30. Heterocyclotetraaromatic syntheses with dilithium compounds.



quinoxaline system is to be accomplished rather than double addition. Reaction of the lithiated triaromatic compound *(45a)* with quinoxaline does lead to the desired compound *(45b)* (Scheme 30), but only in poor yield[26].

The dilithium compound *(46a)* prepared analogously is a far better starting material[26,69]. Presumably, crowding of groups in the conformations *(46a')* and *(46a'')* leads to population of conformation *(46a)* which is more favorable for cyclization. The reaction temperature has a marked influence on the product ratio: at 20 instead of −15 °C (Scheme 30) the yield of *(46b)* and *(46c)* is 18 and 69 %, respectively. X-Ray structure analysis[76] confirms the expected double-boat structure analogous to *(28')*.

Reaction of *(47a)* with quinoxaline gives *(47b)*, the first heterocyclotetraaromatic compound to contain three kinds of ring members (Scheme 31)[26]. The by-product *(47c)* justifies the conclusion that the benzothienyl group is initially linked to the quinoxaline. This is expected, because chelation



(46a')

(46a'')

to an N atom of the quinoxaline leading to a drop in nucleophilicity is more likely for steric reasons in the case of the thienyl group of *(47a)* than for the benzothienyl group.

(47a)

(47c), 6%

(47d), 7%

Scheme 31. Heterocyclotetraaromatic compound having three different kinds of ring members.

3.3.3. 4+0 Linkage

The yield obtained on cyclization of the lithiated tetraaromatic compound *(48)* to give the compound *(45b)* already mentioned was surprisingly low[26]. This may be partly because lithiation with lithium diisopropylamide leading to *(48)* does not occur specifically at the site given (cf. Section 2.1.4)[86]. A further detrimental effect on the yield is exerted by the unusual intramolecular nucleophilic substitution leading to the fused system *(45c)*, in which a 3-thienyl group replaces a 2-quinoxalinyl moiety (Scheme 32). Elimination of a nucleus from *(48)* (two terminal nuclei located in an *o,o'*-relationship to the central internuclear bond) is comparable with elimination of nuclei in the mass spectrometry of structurally analogous tetraaromatic compounds (cf. Section 2.3.3).

(48)

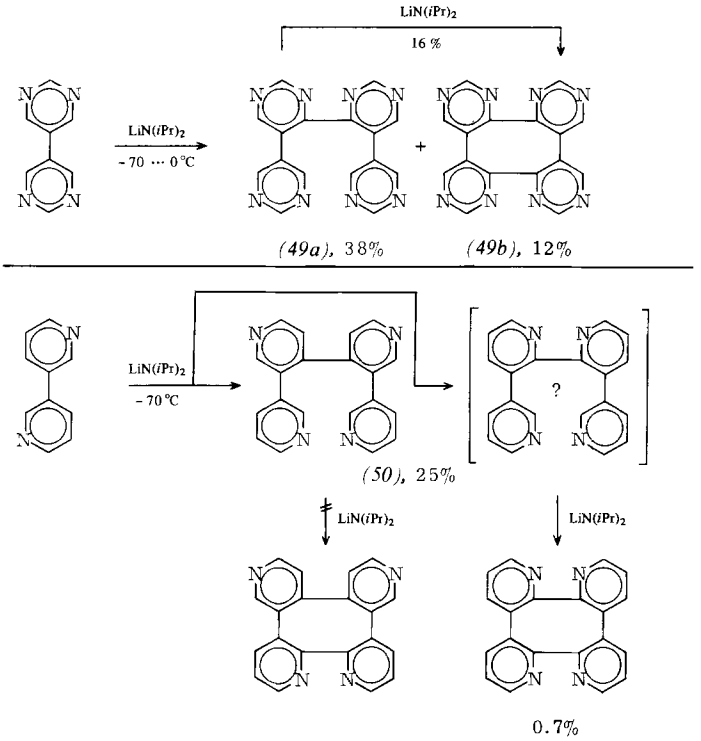
(45b), 12%

(45c), 7%

18%

Scheme 32. Cyclization of tetraaromatic compounds and replacement of one nucleus by another (see also Scheme 30).

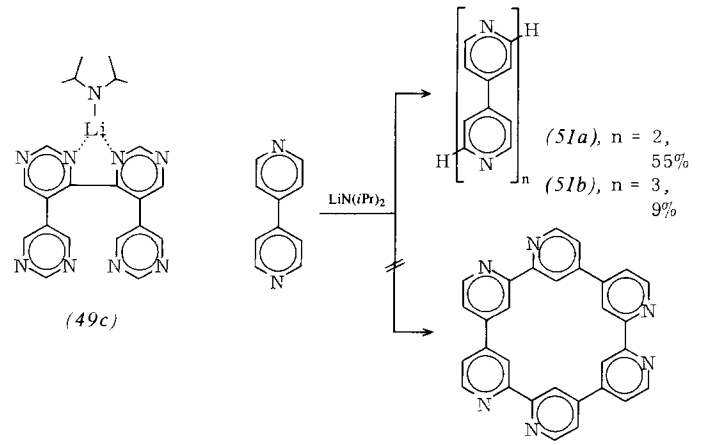
In only one other case have we observed a similar nuclear substitution: the by-product *(45c)* of the reaction formulated in Scheme 30 must have been formed in this way. That such reaction must also be able to proceed intermolecularly follows from the 1-pyrazolyl/2-thienyl exchange shown in the bottom part of Scheme 32[87]. A common feature of these substitutions, which probably proceed *via* an addition-elimination mechanism, is their occurrence at a strongly electrophilic nucleus.



3.4. Metal Amide Linkage as a Cyclization Step[*]

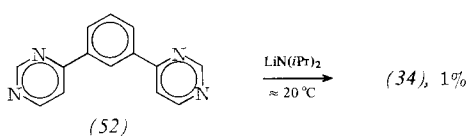
The 5,5'-bipyrimidine obtained (57 %, Scheme 33)[13,57b,58] by oxidative linkage of 5-lithiopyrimidine[88] was transformed into quaterpyrimidine *(49a)* and cyclotetrapyrimidine *(49b)* on addition of lithium diisopropylamide. On further reaction with lithium diisopropylamide[13,57b,58], *(49a)* underwent cyclization, possibly involving fixation of the cisoid conformation by complexation with lithium diisopropylamide according to *(49c)*. This would explain why quaterpyridine *(50)*, which lacks the two nitrogen atoms required for such a complexation, cannot be cyclized analogously[31].

Linkage of 3,3'-bipyridine[31,57b] led to only a very modest yield of cyclotetrapyridine (Scheme 33). The much more readily



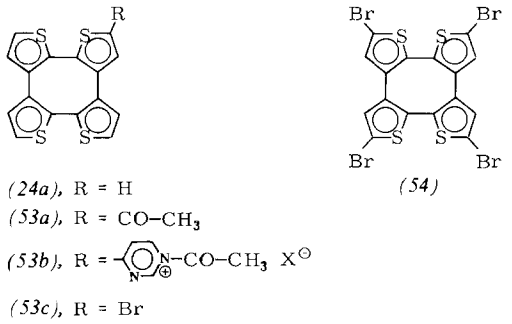
[*] Cf. Section 2.1.2.

accessible cyclotetrapyridine *(25)* was mentioned in Section 3.1.

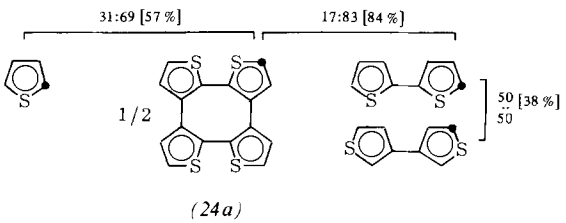


Scheme 33. Cyclization of electrophilic heterodiaromatic compounds.

Attempts to obtain cyclohexapyridine *(51c)* by treatment of 4,4'-bipyridine, alone or in admixture with *(51a)*, or of sexipyridine *(51b)* with lithium diisopropylamide were unsuccessful. Linkage gave only open-chain polypyridines[67].



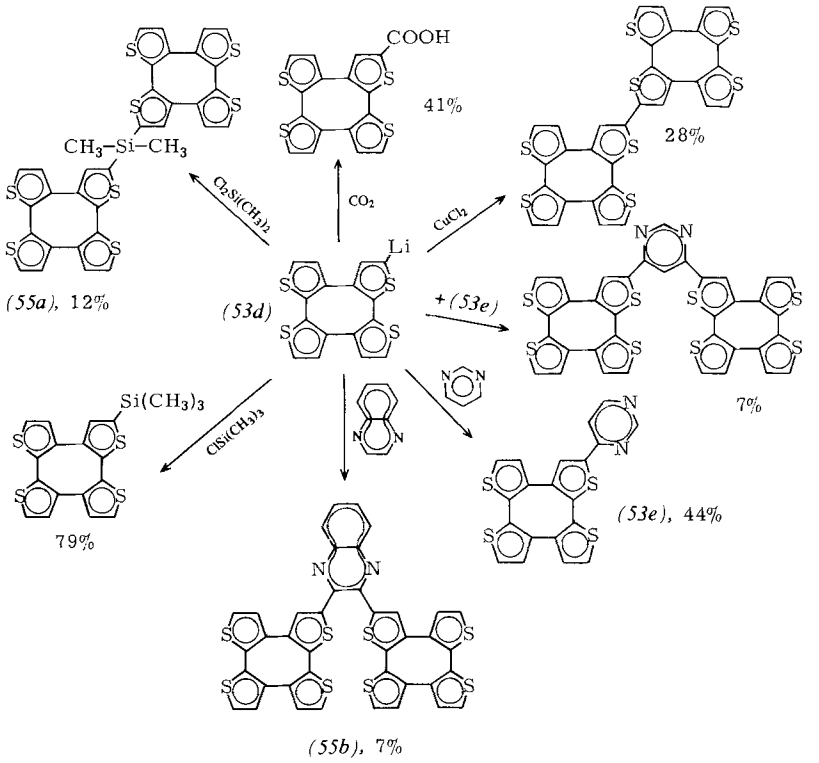
In contrast, the triaromatic compound *(52)* reacts to give octaazahexa-*m*-phenylene *(34)* already mentioned (see Section 3.2.2)[74]. The product of linkage was obtained directly in the "fully aromatic" form, albeit in very low yield.



3.5. Detailed Studies on the Heterocyclotetraaromatic Compound *(24a)*

Among the heterocyclotetraaromatic compounds synthesized, only the cyclotetrathiophene cycloocta[1,2-*b*:4,3-*b'*:5,6-*b''*:8,7-*b'''*]tetrathiophene *(24a)* has been studied in detail. Nonavailability of suitable crystals precluded X-ray structure analysis; however, the three-dimensional structure will no doubt closely resemble that found for the isomer *(28)*[59] (see Section 3.2.1). In the UV spectrum ($CHCl_3$) of *(24a)* λ_{max} is observed at 278 nm, and thus lies between λ_{max} of 3,3'-bithiophene (263 nm) and of 2,2'-bithiophene (297 nm). Noncoplanarity of the nuclei apparently prevents extensive interaction between the π-electrons.

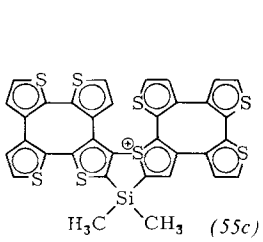
Reaction of *(24a)* with one mol. equiv. each of acetyl chloride and $SnCl_4$ leads to a 45% yield of the monoacetyl compound *(53a)*; less than 3% of diacetyl compounds were formed[89, 90]. Introduction of the electron-attracting acetyl group thus significantly reduces the nucleophilic character, not only of the acetylated thiophene ring but of the entire macrocycle, which seems surprising in view of the markedly nonplanar structure.—Competitive experiments with acetyl chloride/$SnCl_4$ show (Scheme 34) that *(24a)* lies between thiophene and 2,2'-bithiophene[89] on the nucleophilicity scale (regarding experimental conditions, see ref. [42]).



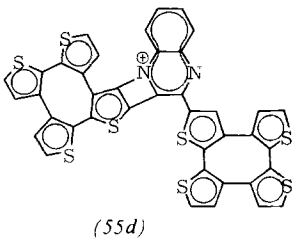
Scheme 34. Relative nucleophilicity towards acetyl chloride/$SnCl_4$: results of competitive experiments analogous to Scheme 16 [91].

The deactivating effect of electron-withdrawing substituents on the entire macrocycle manifests itself even more clearly in the failure of an excess of acetyl chloride and $SnCl_4$ to acetylate even one of the C atoms of the macrocyclic system of the pyrimidinyl-substituted cyclotetrathiophene *(53e)* (Scheme 35), whereas the pyrimidinyl-substituted (open-chain) quaterthiophene *(17a)*, $n=3$, is readily acetylatable under the same conditions (see Section 2.2). This is probably due to the formation of the *N*-acetyl compound *(53b)* and the resulting strongly enhanced electron attraction of the pyrimidinyl group.

While 2-bromothiophene effectively cannot be obtained by the action of bromine on thiophene, owing to fast incorporation of further bromine atoms[92], the reaction of *(24a)* with one mol. equiv. of bromine leads to a 29% yield [48% based on reacted *(24a)*] of the monobromine derivative *(53c)*. Reaction with an excess of bromine under more drastic conditions gave the tetrabromide *(54)* in 82% yield[89].



Weak electrophiles can be linked to the macrocycle by reaction with lithiated *(24a)*. It is most fortunate that the reaction of *(24a)* with one equivalent of n-BuLi surprisingly affords essentially only a monolithium derivative[9,89]. It also proves possible, *via* this compound *(53d)*, to oxidatively link two molecules of *(24a)* or to join them together by way of a linking group[89] (Scheme 35).



The mass spectrum of the bridged products, *e.g. (55a)* and *(55b)*, contain intense peaks suggestive of cyclization[89]; *(55c)* and *(55d)* (each of relative intensity 100%) are two

Scheme 35. Products obtained from lithiocyclotetrathiophene *(53d)*.

characteristic examples. We may expect that uncharged metallocycles analogous to *(55a)* will one day become readily accessible on a preparative scale from heterocyclopolyaromatic compounds.

The information obtained from a detailed study of cyclotetrathiophene *(23a)* is encouraging: although this macrocycle contains two sets of four equivalent nucleophilic and CH acid positions, monosubstitution products could be obtained with a surprising degree of selectivity by direct electrophilic substitution, by lithiation, or by electrophilic substitution of the lithiation product. The nonplanar structure endows the molecule with a relatively good solubility (*e.g.* 29.4 g/l in $CHCl_3$[93]), while still not effecting mutual isolation of the nuclei which would be of disadvantage on substitution of equivalent positions by random attack. The results suggest that selective and hence preparatively valuable reactions are also possible with other heteropolyaromatic compounds.

4. Outlook

The principle of areno-analogy, which prompted our investigations, will continue to stimulate research into organic chemistry. Developing trends can be seen in protophane (see Section 2.1.4) and phane syntheses[6], in which heteroatoms linked *via* carbon chains serve as nucleophilic and electrophilic functional groups; however, transmetalation reactions (see Section 2.1.4) could set narrow limits to the utility of these reactions. A further limitation comes from the generally irreversible nature of linkages between two heteroaromatic groups (exception: see Scheme 32), which contrasts with the linkage of most functional groups.

It should be mentioned in connection with the heterocyclopolyaromatic compounds that the large number of known hetero- and carbocyclic aromatic compounds and the great variety of possible linkages must, in principle, give rise to thousands of such compounds. In the long term, chemists will not wish to forgo this enormous potential. The years

to come will therefore see the synthesis of many new compounds of this kind. After introduction of suitable substituents to raise their solubility, some compounds of this class may also exhibit interesting physiological properties.

As shown in Section 3.5, monosubstitution does not cause any fundamental difficulties. Concerning the introduction of several substituents or side chains, we can expect that tetrasubstituted derivatives of *(24a)* should be preparable, *e.g.* from the tetrabromo compound *(54)*, by Br/Li exchange and reaction with electrophiles. Apart from subsequent introduction of substituents, it should also be possible to cyclize substituted di- and triaromatic compounds.

All the syntheses carried out so far are organometallic in nature, and often unsatisfactory with regard to yield. Thus, another future task is the development of less complicated, productive syntheses.

The pathway leading to heterocyclopolyaromatic compounds was smoothed by a team of capable co-workers, whose names are mentioned in the references cited. This report is their report. I wish to express my gratitude to all of them.—Thanks are also due to Prof. Dr. H. G. von Schnering, Max-Planck-Institut für Festkörperforschung, Stuttgart, and Priv.-Doz. Dr. H. Irngartinger, Organisch-chemisches Institut der Universität Heidelberg, for X-ray structure analyses. I am indebted to H. Niewind, Organisch-Chemisches Institut der Universität Münster, for preparation of starting materials.—Financial support of this work by the Deutsche Forschungsgemeinschaft (Ka 144/27 and Ka 144/30), the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen[94], and the Fonds der Chemischen Industrie is gratefully acknowledged.

The Art of Titration

From Classical End Points to Modern Differential and Dynamic Analysis[**]

By Ruthild Winkler-Oswatitsch and Manfred Eigen[*]

Gerold Schwarzenbach in memoriam

Titration represents the quantitative determination of a chemical change in response to the variation in concentration of a standard. Information on reaction parameters is usually obtained from an analysis of the shape of the titration curve. In this paper the derivatives of titration functions with respect to concentration variables and with respect to equilibrium parameters are compared with one another. The latter can be determined directly from amplitudes and time constants of the dynamic responses to equilibrium perturbations, brought about by fast alterations of temperature, pressure or electric field.

Three general situations have to be distinguished: 1. If the interaction is very strong (*i.e.* the complex stability is high: $K \rightarrow \infty$), the (average) number of sample particles can be counted directly by means of their reaction with a calibrated number of standard particles.—2. If, on the contrary, the interaction is weak (*i.e.* the complex stability is low), the sample will react quantitatively only in the presence of a large excess of standard; the half-way point of which provides a direct measure of the binding constant.—3. Only for moderate interactions can individual curves characteristic of the binding strength be observed. The limiting cases 1 and 2 yield titration curves which reflect only the general class to which the system belongs.

The dynamical procedures are fairly insensitive in case 1, which represents the classical end-point situation and is most suitable for quantitative analysis, *i.e.* for a determination of sample concentrations. For case 2, the classical and dynamical techniques yield comparable information: mass-action parameters are obtained from the extrema of the curves, which occur only in the presence of an excess of the standard. In case 3 the dynamical treatment provides a more direct access to the equilibrium constants, and also to the enthalpies or volumes of reaction as well as to the rate constants. The advantage of the dynamic method is due to the fact that in the two derivatives of the titration function $\mathrm{d}T_i/\mathrm{d}\ln q$ and $\mathrm{d}T_i/\mathrm{d}\ln p$ (where q is the titration variable, *i.e.* the ratio of standard and sample concentration, and p the mass-action parameter, *i.e.* a reduced binding constant) the terms resulting from a differentiation with respect to p are more closely related to the reaction parameters than those following from a variation of q.

The dynamic analysis is generalized for applications to multiple-step titration processes, where it allows for the measurement of equilibrium and rate parameters of *individual* steps. A uniform representation utilizing trigonometric functions was chosen which expresses clearly the singular character of the end-point. The relations are summarized in tabular form. They provide in conjunction with the illustrations the basis for a comparative discussion.

1. Introduction

Any complex system of matter is completely characterized by the spatial and temporal distribution of its various individual constituents, expressed in terms of their population densities. The determination of the population densities of the various molecular parts of the system is one of the fundamental tasks of chemistry. This is usually effected by "counting" utilizing chemical turnover: The species present in unknown number is allowed to react with a known or measurable number of specific partners. This procedure is called *titration.*

The *classical method* of titration is based on a more or less *complete turnover* of the sample to be analyzed yielding a well defined *end-point.* Of course, the only reactions suitable for titration are those which occur rapidly enough, *i.e.* within the time of observation. The "completeness" of the turnover is then solely determined by the magnitude of the equilibrium stability constant. In fact, a quantitative establishment of this parameter is very often the final object of the titration. It is therefore necessary to measure precisely the *concentrations of individual partners and products* involved in the reaction.

An alternative procedure for determining stability constants is to measure an *extensive thermodynamic quantity* as a function of the weighed-in concentrations of the reaction partners. It requires the precise measurement either of Gibb's free energy or of any of its first or higher derivatives with respect to

[*] Prof. Dr. M. Eigen, Dr. R. Winkler-Oswatitsch
Max-Planck-Institut für Biophysikalische Chemie,
Abt. Biochemische Kinetik
D-3400 Göttingen (Germany)

[**] This work is based on a thesis [1] carried out at the Max-Planck-Institut für Physikalische Chemie, Göttingen, and submitted at the Technische Hochschule, Wien, im November 1969.

an *intensive variable* (such as temperature T, pressure P, electrical field density $\boldsymbol{E}$).

The aim of the present paper is *to demonstrate the particular advantages of dynamic titration methods for the determination of binding constants from the time-dependent chemical increments of extensive thermodynamic functions*, and *to compare the results of the dynamical approach with those obtained by classical titration procedures.*

This article is particularly addressed to the chemist who has experienced that titration is by no means a matter of routine, requiring rather a procedure optimally adapted to suit each problem. For this purpose an understanding of the physical basis is necessary, and its principles will be developed in this paper. The "Art of Titration" is as little related to the mechanical execution of recipes as is the "Art of Cooking".

2. Binary Complex Formation

2.1. Stability Constants and Titration Curves

The progress of a chemical reaction can be followed (almost) instantaneously, if reaction partners and products show detectable changes in their electromagnetic properties upon reaction. As an example let us consider the binary association-dissociation process

$$A + B \rightleftharpoons AB \tag{2.1-1}$$

where A and B may represent an acid and a base, a metal ion and a ligand, an enzyme and a substrate, an antibody and a hapten, or any kind of reaction partners involved in a general coordination process. The example embodies equally the processes of electron, proton or ligand exchange, although these processes belong to the category of substitution rather than addition reactions.

If both weighed-in concentrations c_A^0 and c_B^0 are known, the law of mass action adopts the form

$$K = K_0 \Pi f \approx \frac{c_{AB}}{(c_A^0 - c_{AB})(c_B^0 - c_{AB})} \tag{2.1-2}$$

where K_0 is the thermodynamic equilibrium constant at the given values of the intensive thermodynamic variables, and $\Pi f = f_A f_B / f_{AB}$ is a term involving the activity coefficients of the reaction partners and products.

In the following we shall not deal explicitly with the term Πf. Its changes during the titration occurring especially when there is charge neutralization, can be taken into account wherever it turns out to be necessary; it is negligible at low concentrations of A, B and AB, or, in the presence of an excess of inert electrolyte, it can be included in K as a constant factor.

Eq. (2.1-2) provides explicit expressions for the equilibrium concentrations of all individual species in terms of c_A^0, c_B^0 and K:

$$c_{AB} = \frac{c_A^0 + c_B^0 + K^{-1}}{2} - \frac{1}{2}\sqrt{(c_A^0 + c_B^0 + K^{-1})^2 - 4 c_A^0 c_B^0} \tag{2.1-3}$$

$$c_A = c_A^0 - c_{AB} \tag{2.1-4}$$

$$c_B = c_B^0 - c_{AB} \tag{2.1-5}$$

Let A and/or B, upon its conversion into AB, show a measurable shift in the absorption spectrum, characterized by the (finite) difference of extinction coefficients: $\varepsilon_A + \varepsilon_B - \varepsilon_{AB}$. The optical density per unit length (E/l) can then be written as

$$\begin{aligned} E/l &= c_A \varepsilon_A + c_B \varepsilon_B + c_{AB} \varepsilon_{AB} \\ &= c_A^0 \varepsilon_A + c_B^0 \varepsilon_B + c_{AB}(\varepsilon_{AB} - \varepsilon_A - \varepsilon_B) \end{aligned} \tag{2.1-6}$$

If we denote the limiting values of the optical density for $c_{AB} = 0$ as:

$$E_0/l = c_A^0 \varepsilon_A + c_B^0 \varepsilon_B \tag{2.1-7}$$

or for $c_B = 0$, *i.e.* after complete conversion of B into AB in presence of an excess of A as:

$$E_\infty/l = c_A^0 \varepsilon_A + c_B^0(\varepsilon_{AB} - \varepsilon_A) \tag{2.1-8}$$

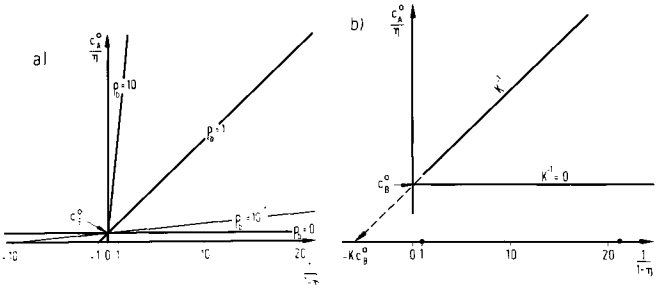
then the "degree of complexation" can be expressed by measurable extinction values as

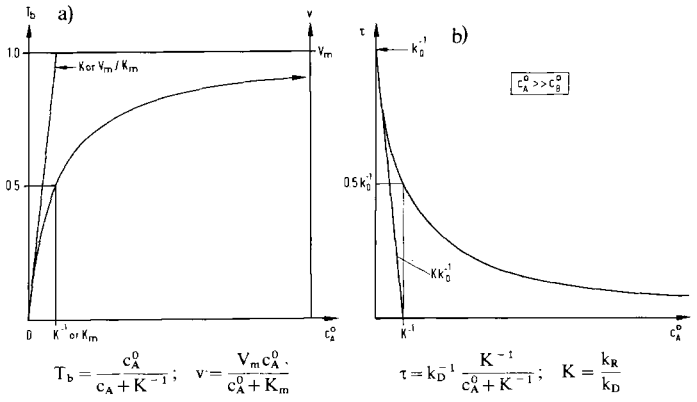
$$\frac{c_{AB}}{c_B^0} = \frac{E - E_0}{E_\infty - E_0} \equiv \eta \tag{2.1-9}$$

Eq. (2.1-9), in combination with the law of mass action, provides useful relations for the determination of equilibrium constants from titration curves, *e.g.* the Hildebrand-Benesi equation or similar forms[2]:

$$\frac{c_A^0}{E - E_0} = \frac{c_B^0}{E_\infty - E_0} + \frac{K^{-1}}{E_\infty - E} \tag{2.1-10}$$

If we plot $c_A^0/(E - E_0)$ *versus* $1/(E_\infty - E)$ (cf. Fig. 1a), a straight line is obtained. Its slope yields the dissociation constant K^{-1}. Such a diagram does not even require a precise knowledge of c_B^0, which results from the intercept of the obtained line.





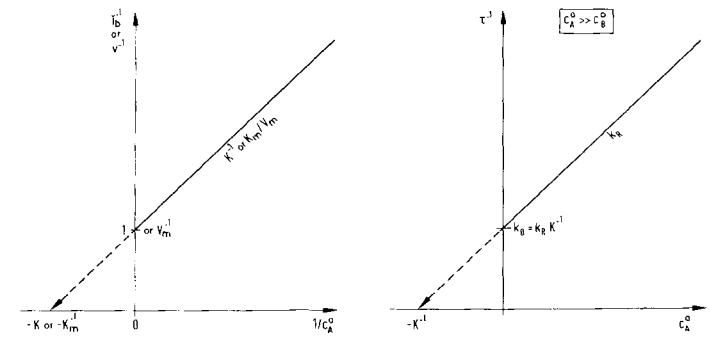


Fig. 1. a) Hildebrand-Benesi plot providing stability constants (K) from extinction ratios η or $1-\eta$ resp. (variation of c_A^0- or $q_b = c_A^0/c_B^0$- at constant c_B^0; parameter to be determined: $p_b = K^{-1}/c_B^0$). For η-values close to one or zero, the detection becomes insensitive. If p_b is large, the ratio $q_b = c_A^0/c_B^0$ can be adjusted to comparatively large values, which represent the sensitive range for changes of η. If p_b is small, however, there will be almost no change of c_A^0/η within the corresponding region of η (*i.e.* $\eta \sim c_A^0$). Hence very small values of p_b cannot be evaluated (cf. also Fig. 3).

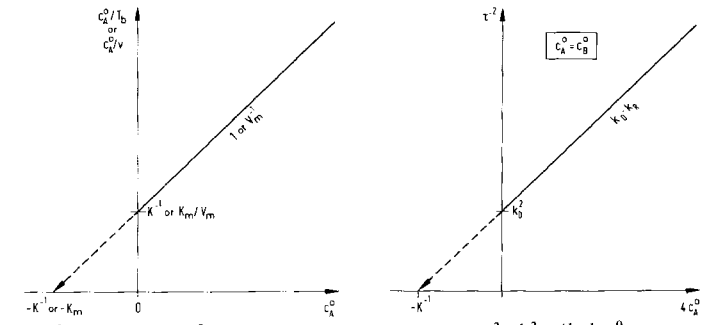
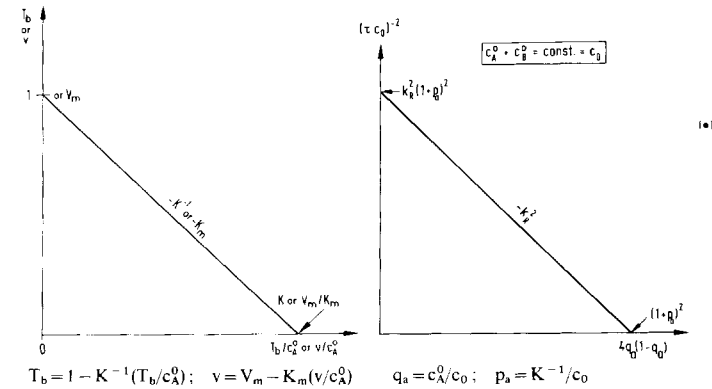
b) The range between the two dots on the abscissa is most suitable for measurements.

A variety of similar equations may be derived which offer specific advantages (*e.g.* a suitable extrapolation in cases where $(E_\infty - E_0)$ is unknown), or which refer to parameters other than those of extinction. Biochemists have been especially successful in inventing all sorts of related plots for enzyme-



$$T_b = \frac{c_A^0}{c_A + K^{-1}}; \quad v = \frac{V_m c_A^0}{c_A^0 + K_m} \qquad \tau = k_D^{-1}\frac{K^{-1}}{c_A^0 + K^{-1}}; \quad K = \frac{k_R}{k_D}$$



$$T_b^{-1} = K^{-1} c_A^{0\,-1} + 1 \qquad \tau^{-1} \approx k_R c_A^0 + k_D$$

$$v^{-1} = \frac{K_m}{V_m} c_A^{0\,-1} + V_m^{-1}$$

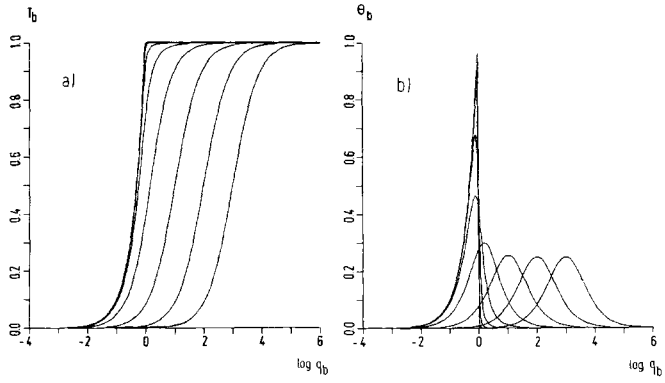
$$\frac{c_A^0}{T_b} = c_A^0 + K^{-1}; \quad \frac{c_A^0}{v} = \frac{1}{V_m} c_A^0 + \frac{K_m}{V_m} \qquad \tau^{-2} = k_D^2 + 4k_D k_r c_A^0$$

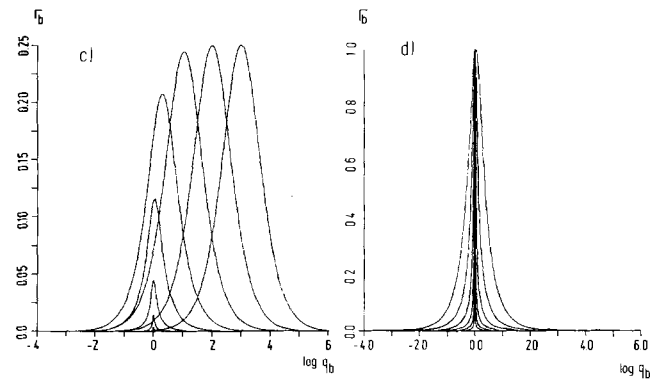
$$T_b = 1 - K^{-1}(T_b/c_A^0); \quad v = V_m - K_m(v/c_A^0) \qquad q_a = c_A^0/c_0; \quad p_a = K^{-1}/c_0$$

$$(\tau c_0)^{-2} = k_R^2[(1+p_a)^2 - 4q_a(1-q_a)]$$

Fig. 2. a) Illustrative plots for binding (T_b) and steady state rates (v), popular in enzymology. Various names are associated with such plots (from top to bottom): Michaelis-Menten, Lineweaver-Burk, Woolf, Angustinsson. All these plots suppose the concentration of free substrate to be known, which is fulfilled, if the total substrate concentration is large compared to total enzyme concentration, *i.e.* $c_A^0 \gg c_B^0$.

b) Analogous plots for the evaluation of relaxation times (τ). Again restricting assumptions—as quoted with the curves—are involved. (Note that similar linear plots do not hold for Γ_b, which can be expressed as a product of τ_b and T_b and therefore cannot easily be represented in a linear form.)





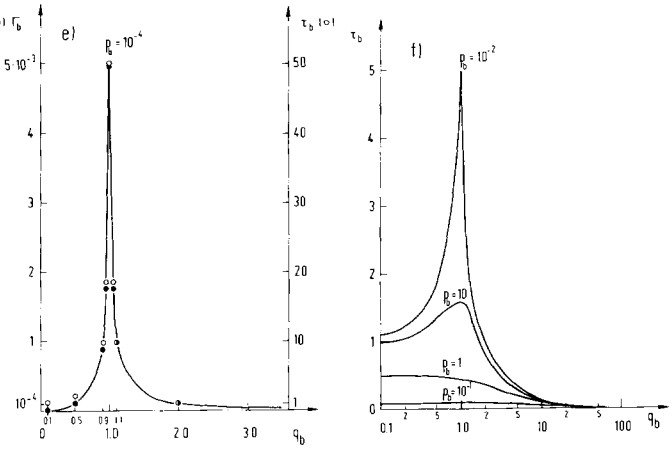


Fig. 3. a) Classical titration curves: plot of degree of binding (T_b) *vs.* logarithm of concentration ratio ($q_b = c_A^0/c_B^0$), A being the standard and B the sample (c_A^0 = const., c_B^0 = variable), for different parameters p_b (cf. Table 1).

b) Slopes of titration curves: $\theta_b = \mathrm{d}T_b/\mathrm{d}\ln q_b$. As is seen for $p_b > 1$, the position of the maximum slope, indicating the inflection point of the titration curve, is a direct measure of p_b. For $p_b \to 0$, however, a limiting curve is approached. The curve shapes show only relative differences, which cannot be improved by signal amplification.

c) For comparison, the amplitude factor $\Gamma_b = \partial T_b/\partial \ln p_b$ is plotted in the same way as θ_b. For $p_b \gg 1$ identical curves result for Γ_b and θ_b. Amplitude factors can be detected *directly* from relaxation amplitudes and do not have to be derived by differentiation procedures. For $p_b < 1$ the absolute values decrease in proportion to $1/\sqrt{p_b}$, but at the same time the curve shapes change characteristically. Signal amplification can truly enhance such effects to a level where they provide a sensitive measure of p_b.

d) The shifts of Γ_b with p_b amplified to the same maximum value (cf. Table 1).

e) Γ_b and τ_b (not normalized) plotted on a linear concentration axis for one example ($p = 10^{-4}$).

f) τ_b for various parameters p_b plotted on a logarithmic concentration axis (see also Table 1).

substrate interactions (cf. [3, 4]), usually supposing the substrate to be in excess of the enzyme ($c_S \approx c_S^0$). A compilation of those plots can be found in Figure 2a.

Useful as all those relations may be—wherever they apply—their validity with respect to a precise determination of stability constants becomes severely limited whenever K reaches excessively large values or, explicitly if

$$K(c_A^0 + c_B^0) \gg 1 \tag{2.1-11}$$

This can be immediately seen from Figure 1b, and even better from Figure 3a, where titration curves for different stability constants ($K c_B^0$ as parameter) are plotted against the logarithm of the titration variable $q_b = c_A^0/c_B^0$. These curves—or their first derivatives (Fig. 3b)—show that for $K c_B^0 \gg 1$ the region sensitive to K is more and more restricted to the close vicinity of the equivalence point ($c_A^0 \approx c_B^0$).

In fact, only the second derivative of the titration curve:

$$\frac{d^2 c_{AB}}{dc_A^{0\,2}} = -\frac{2c_B^0 K^{-1}}{[(c_A^0 - c_B^0 + K^{-1})^2 - 4c_B^0 K^{-1}]^{3/2}} \tag{2.1-12}$$

shows a direct proportionality to K^{-1}. For $K^{-1} \to 0$ there exists a true singularity; the slope of the titration curve then switches abruptly from one to zero:

$$\frac{dc_{AB}}{dc_A^0} \to \frac{1}{2}\left[1 - \frac{c_A^0 - c_B^0}{|c_A^0 - c_B^0|}\right] \tag{2.1-13}$$

($|c_A^0 - c_B|$ is the absolute amount, which is always a positive quantity, whereas $c_A^0 - c_B^0$ assumes negative values for $c_B^0 > c_A^0$).

It is the differential change of this slope, the curvature of the titration function, which—for large K-values—has to be viewed in comparison with the differential changes brought about by perturbation of a thermodynamic (intensive) parameter. This problem is treated in detail in the next section.

2.2. Relaxation Amplitudes and Time Constants

We shall consider the variation of c_{AB} resulting from a perturbation of the chemical equilibrium by the alteration of an intensive parameter. Here, rather than changing c_B^0 (or a combination of c_A^0 and c_B^0) at constant K, we vary K under fixed conditions of c_A^0 and c_B^0. The quantity, we are interested in, is the differential-quotient $\partial c_{AB}/(\partial \ln K)$ which can be directly detected in a relaxation experiment[5].

Any small perturbation—*e.g.* brought about by an alteration of temperature, pressure or electrical field density—will in general result in a linear relaxation effect. A stepwise shift of the force will cause an exponential temporal response of the concentration variable:

$$\delta_t c_{AB} = \delta_\infty c_{AB}(1 - e^{-t/\tau}) \tag{2.2-1}$$

where $\delta_\infty c_{AB}$ represents the concentration shift after complete equilibration ($t \to \infty$) and τ is a characteristic time constant, the *relaxation time of chemical equilibration.*

For sinusoidal periodic variation, the response can be written in complex notation:

$$\delta_\omega c_{AB} = \frac{\delta_0 c_{AB}}{1 + i\omega\tau} \tag{2.2-2}$$

where $\delta_0 c_{AB}(\omega \to 0)$ again is the concentration shift corresponding to *complete* equilibration. The complex form of eq. (2.2-2) indicates a frequency dependence of the true amplitude (*i.e.* the maximum value of $\delta_\omega c_{AB}$) and a phase relationship between $\delta_\omega c_{AB}$ and $\delta_0 c_{AB}$. Accordingly eq. (2.2-2) can be rewritten as

$$\delta_\omega c_{AB} = \frac{\delta_0 c_{AB}}{\sqrt{1 + \omega^2\tau^2}} e^{-i\varphi} \tag{2.2-3}$$

where $\varphi = \arctan(\omega\tau)$ represents the phase angle, while the square root term describes the frequency-dependent reduction of the amplitude. It should be noted that owing to the periodic variation of force $\delta_0 c_{AB}$ is a periodic function of time: $\delta_0 c_{AB} = a_{AB} e^{i\omega t}$. The amplitude a_{AB} depends on equilibrium parameters only and is determined by the amplitude of the periodically varied force.

If z is an intensive variable, such as temperature, pressure or electrical field density, $\delta_0 c_{AB}$ can be expressed as:

$$\delta_0 c_{AB} = \left(\frac{\delta c_{AB}}{\partial \ln K}\right)_z \left(\frac{\partial \ln K}{\partial z}\right) \delta z = \frac{\Gamma \Delta Z}{RT} \delta z \tag{2.2-4}$$

where δz includes the externally imposed change in intensity (*e.g.* periodic, steplike), while $\Gamma = (\partial c_{AB}/\partial \ln K)_z$ is an amplitude factor, having the dimensions of concentration, and $\Delta Z = RT\ \partial \ln K/\partial z$ defines the extensive reaction quantity complementary to z. For $z = T$ and P, ΔZ is given by $\Delta H/T$ and $-\Delta V$ respectively, ΔH being the enthalpy and ΔV the volume of reaction. The general thermodynamic treatment of relaxation phenomena is briefly outlined in Appendix 1.

Of special interest is the amplitude factor Γ in relation to c_A^0, c_B^0 and K. For the binary complex equilibrium it reads:

$$\Gamma = \frac{c_A c_B}{c_A + c_B + K^{-1}} = \frac{K^{-1}}{2}\left[\frac{1}{\sqrt{1 - 4c_A^0 c_B^0/(c_A^0 + c_B^0 + K^{-1})^2}} - 1\right] \tag{2.2-5}$$

Γ shows a maximum at the equivalence point which parallels the maximum in the logarithmic derivative of the titration function (cf. Fig. 3c, d). For $K^{-1} \ll c_A^0 + c_B^0$ the peak becomes very sharp and its shape represents a sensitive measure of the stability constant.

Although $\delta_\infty c_{AB}$ and $\delta_0 c_{AB}$ are parameters related to the *equilibrium*, their identification usually will require a complete recording of the time or frequency dependence of the concentration shift δc_{AB}. Since the perturbation is brought about by an alteration of the external intensive variable, it may not only result in a shift of the chemical composition, but also in changes of volume (*e.g.* thermal expansion) or of the parameters (*e.g.* extinction coefficients) which are utilized for a detection of the chemical effect. With $c = n/V$ (n = number of moles, V = volume), δc_{AB} can be essentially approximated by two terms: $(\delta c_{AB})_{chem}$ and $-c_{AB}(\delta V/V)$. Only the term $(\delta c_{AB})_{chem}$ refers to the true chemical change, which is characterized by the relaxation time τ. The physical effects of the perturbation (*e.g.* the volume change δV) usually respond much faster. They may actually be assumed to occur "instantaneously" within the limits of resolution. However, all these influences contribute to the final amplitude and hence can be separated only with the help of the characteristic time dependence of the chemical effect. (An example will be shown in Section 2.4). Owing to this fact a dynamical approach

is most appropriate for a correct determination of equilibrium chemical shifts. In addition, the time or frequency dependence offers access to the measurement of the kinetic parameters of equilibration. Such a procedure is straightforward only in the linear domain of expansions, *i. e.* for small perturbations.

At equilibrium the rate of recombination of A and B equals the rate of dissociation of AB:

$$v = k_R c_A c_B = k_D c_{AB} \tag{2.2-6}$$

where v is called the equilibrium exchange rate.

In Appendix 1, it is shown that the relaxation time τ is related to the amplitude factor Γ *via* the exchange rate v. The reciprocal of τ is given by:

$$\tau^{-1} = k_R(c_A + c_B + K^{-1}) \tag{2.2-7}$$

or in explicit form:

$$\tau^{-1} = k_R\sqrt{(c_A^0 + c_B^0 + K^{-1})^2 - 4c_A^0 c_B^0} \tag{2.2-8}$$

For $K^{-1} \ll (c_A^0 + c_B^0)$,—in analogy to Γ—τ reaches a sharp maximum at the equivalence point. Illustrative plots for τ or τ^{-1} are compiled in Figure 2b.

Such simple functional relationships do not exist for Γ, which is a product of the exchange rate and relaxation time, and hence of the two functions c_{AB} and τ (see Appendix 1).

2.3. Relaxation Amplitudes and Time Constants Contrasted with Titration Functions

We are now ready for a more detailed discussion of methods for the determination of stability constants based on the variation of c_{AB} in relation to c_A^0, c_B^0 or K. First we notice that there is, of course, a symmetry for any change of c_{AB} with respect to c_A^0 or c_B^0. Titration techniques usually involve the variation of only one of the concentrations (c_A^0 or c_B^0), while the other is kept at a fixed value. An alternative procedure—better adapted to the symmetry of the functional relations—would be to keep constant the sum of c_A^0 and c_B^0, but to vary their proportion. Both concepts may offer advantages in particular cases and will therefore be treated separately.

For an intuitive description and comparative analysis of the various mathematical expressions it proves useful to substitute the quantity

$$Q \equiv \frac{2\sqrt{c_A^0 c_B^0}}{c_A^0 + c_B^0 + K^{-1}} \equiv \sin\alpha \tag{2.3-1}$$

This substitution is of purely formal nature and has been chosen only for the sake of a uniform mathematical representation.

The angle α thus defined can vary between 0 and (nearly) $\pi/2$. It has its maximum at the equivalence point ($c_A^0 = c_B^0$ or $c_A^0 + K^{-1} = c_B^0$ respectively), where it would reach $\pi/2$ only in the limiting case $K(c_A^0 + c_B^0) \to \infty$. For any finite K-value α will always remain below $\pi/2$.

We now derive expressions for

1) the titration function,
2) its first derivative, *i. e.* the slope,
3) its second derivative or curvature,
4) the relaxation amplitude and
5) the relaxation time,

distinguishing the two cases

a) $c_A^0 + c_B^0 = \text{const.}$
b) $c_B^0 = \text{const.}$

In Table 1 alternative expressions are listed for each of these five quantities, one showing the explicit dependence on the two variables p and q, involving c_A^0, c_B^0 and K for either the constraint a) or b), the other based on the substitution eq. (2.3-1). in the latter case several ways of representation are possible. For uniformity the expressions are given throughout in the form of functions of $\tan(\alpha/2)$.

The presence of a term $[1 - \tan^2(\alpha/2)]^{-1}$ then signifies the appearance of a singularity in the limit of $\alpha \to \pi/2$, (*i. e.* $K \to \infty$). This results in abrupt changes in the values of the various functions if $K(c_A^0 + c_B^0) \gg 1$. The normalized[*] relaxation amplitudes and time constants as functions of the titration variable q_a have here characteristic forms, whereas among the titration functions only the second derivative of T_a or T_b (for $p_a < 1$) shows this behavior. For $K \to \infty$ the normalized curves for Γ, τ and T'' have the appearance of the delta function. Such

Table 1. Binary (1 : 1) complex formation:
Titration function and its various derivatives with respect to overall concentrations and equilibrium parameters. We refer to the complex equilibrium (2.1-1) and to the parameters introduced with eq. (2.1-2).

Two procedures are distinguished.

a) $c_A^0 + c_B^0 = \text{const.}$	b) $c_B^0 = \text{const.}$
K as parameter	K as parameter
Variation of c_A^0 requires a corresponding compensation of c_B^0.	c_A^0 is the variable, common to classical titration procedures.

It is convenient to introduce the following abbreviations:

a)	b)
$p_a \equiv \frac{K^{-1}}{c_A^0 + c_B^0}$	$p_b \equiv \frac{K^{-1}}{c_B^0}$
$q_a \equiv \frac{c_A^0}{c_A^0 + c_B^0}$	$q_b \equiv \frac{c_A^0}{c_B^0}$
$(1 - q_a) \equiv \frac{c_B^0}{c_A^0 + c_B^0}$	
equivalence point:	(apparent) equivalence point:
$q_a = 0.5$, *i.e.* $c_A^0 = c_B^0$	$q_b = 1 + p_b$, *i.e.* $c_A^0 = c_B^0 + K^{-1}$

In these notations the variable Q as defined by eq. (2.3-1) will read:

$Q = \frac{2\sqrt{q_a(1-q_a)}}{1+p_a}$	$Q = \frac{2\sqrt{q_b}}{1+p_b+q_b}$
or for $p \to 0$	
$Q_0 = 2\sqrt{q_a(1-q_a)}$	$Q_0 = \frac{2\sqrt{q_b}}{1+q_b}$

We substitute formally $Q \equiv \sin\alpha$

$$\cos\alpha = \sqrt{1-Q^2}; \quad \tan\alpha = \frac{Q}{\sqrt{1-Q^2}}; \quad \tan\frac{\alpha}{2} = -\frac{1-\sqrt{1-Q^2}}{Q}$$

and obtain the functions compiled below, according to the definitions given.

[*] Cf. Section 2.4.

The range of existence of α is limited due to: $1/(1+p_a) \geq \sin\alpha \geq 0$: (*i.e.* $1/p_a(2+p_a) \geq \tan^2\alpha \geq 0$, or: $1+p_a-\sqrt{p_a(2+p_a)} \geq \tan(\alpha/2) \geq 0$.) α reaches $\pi/2$ only in the limit of $p_a = 0$. The same holds for the case b, where the range of existence of α is given by $1/\sqrt{1+p_b} \geq \sin\alpha \geq 0$.

The parameters for curves 1 to 8 are:

1) p = 0
2) p = 10^{-4}
3) p = 10^{-3}
4) p = 10^{-2}
5) p = 10^{-1}
6) p = 1
7) p = 10
8) p = 100

1. Classical titration function:

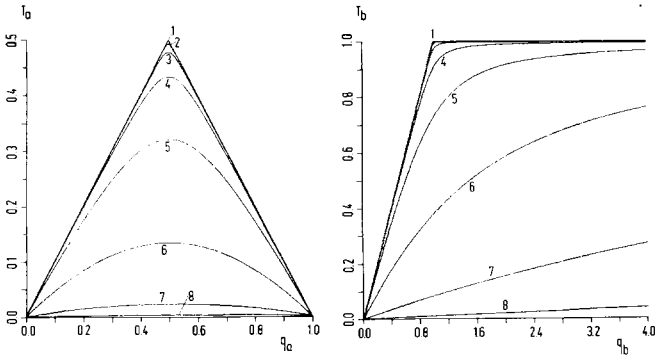
a)
Definition:

$$T_a = \frac{c_{AB}}{c_A^0 + c_B^0}$$

Expression I:

$$\frac{1}{2}(1+p_a)\left[1-\sqrt{1-\frac{4q_a(1-q_a)}{(1+p_a)^2}}\right]$$

Expression II:



$$(1+p_a)\,\frac{\tan^2\left(\frac{\alpha}{2}\right)}{1+\tan^2\left(\frac{\alpha}{2}\right)}$$

b)

$$T_b = \frac{c_{AB}}{c_B^0}$$

$$\frac{1}{2}(1+p_b+q_b)\left[1-\sqrt{1-\frac{4q_b}{(1+p_b+q_b)^2}}\right]$$

$$(1+p_a+q_b)\,\frac{\tan^2\left(\frac{\alpha}{2}\right)}{1+\tan^2\left(\frac{\alpha}{2}\right)}$$

2. Slope of titration function:

a)
Definition:

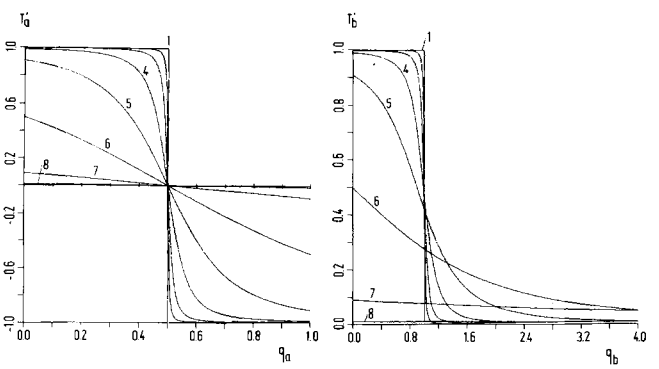
$$\frac{dT_a}{dq_a} \equiv T_a'$$

Expression I:

$$\frac{1}{\pm\sqrt{1+p_a(2+p_a)/(1-2q_a)^2}}$$

Expression II:

$$\frac{\pm\sqrt{1-p_a(2+p_a)\tan^2\left(\frac{\alpha}{2}\right)}}{1+p_a}$$



b)

$$\frac{dT_b}{dq_b} \equiv T_b'$$

$$\frac{1}{2}\left[1-\frac{1}{\sqrt{1+4p_b/(p_b+q_b-1)^2}}\right]$$

$$\frac{1-(p_b+q_b-1)\tan^2\left(\frac{\alpha}{2}\right)\Big/\left(1-\tan^2\left(\frac{\alpha}{2}\right)\right)}{1+p_b+q_b}$$

For q_b and $p_b \gg 1$, the classical plot of T_b *vs.* the logarithm of the titration variable will be of advantage. The slope, *i.e.* $\theta_b = dT_b/(d\ln q_b) \approx q_b/p_b/(1+q_b/p_b)^2$ (for q_b and $p_b \gg 1$) will have an extremum at $q_b = p_b$ (standard curve shapes, if plotted *vs.* q_b/p_b).

3. Curvature of titration function:

a)
Definition:

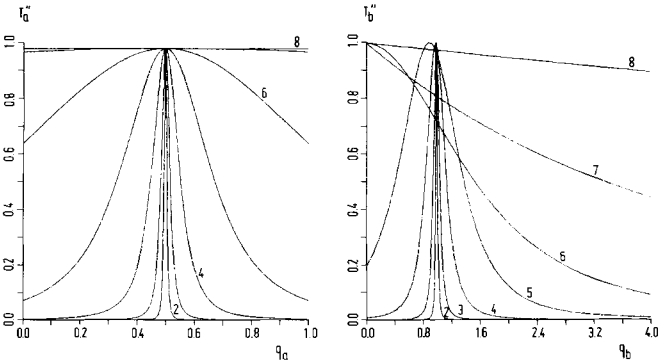
$$\frac{d^2T_a}{dq_a^2} \equiv T_a''$$

Expression I:

$$-\frac{2p_a(2+p_a)}{[p_a(2+p_a)+(1-2q_a)^2]^{3/2}}$$

Expression II:

$$-\frac{2p_a(2+p_a)}{(1+p_a)^3}\left[\frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}\right]^3$$



b)

$$\frac{d^2T_b}{dq_b^2} \equiv T_b''$$

$$-\frac{4p_b}{[(1+p_b+q_b)^2-4q_b]^{3/2}}$$

$$-\frac{4p_b}{(1+p_b+q_b)^3}\left[\frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}\right]^3$$

Notes on evaluation:
1) T_a and T_a' will always show extrema at the equivalence point; $q_a = 0.5$.
2) For T_b' an extremum is present only if $p_b < 1$. It will occur at $q_b = 1 - p_b$.
3) The half point: $T_b = 1/2$ will always occur at $q_b = 1/2 + p_b$.

4. Reduced relaxation amplitude factor (Γ according to eq. 2.2-4):

a)
Definition:

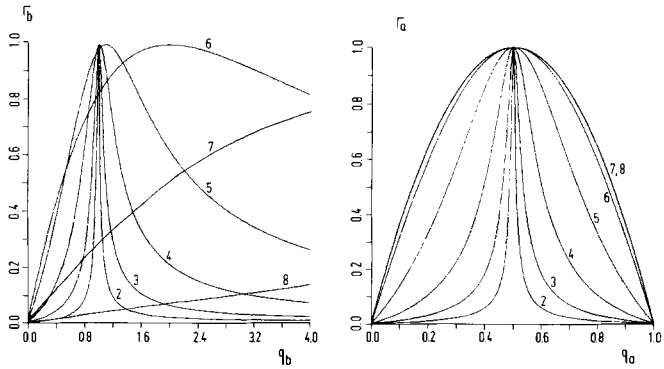
$$\Gamma_a = \frac{dT_a}{d\ln p_a} = \frac{\Gamma}{c_A^0 + c_B^0}$$

Expression I:

$$\frac{p_a}{2}\left[\frac{1}{\sqrt{1-4q_a(1-q_a)/(1+p_a)^2}}-1\right]$$

Expression II:

$$p_a\,\frac{\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$$



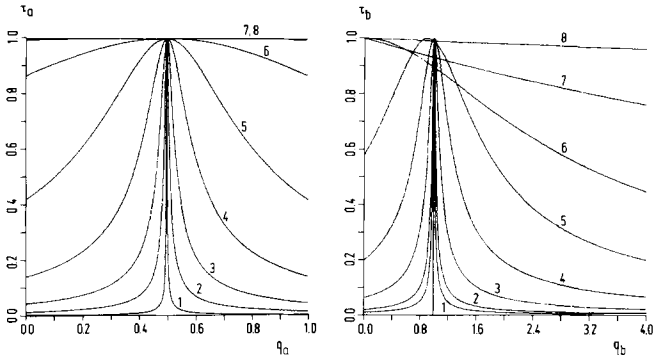
b)

$$\Gamma_b = \frac{dT_b}{d\ln p_b} = \frac{\Gamma}{c_B^0}$$

$$\frac{p_b}{2}\left[\frac{1}{\sqrt{1-4q_b/(1+p_b+q_b)^2}}-1\right]$$

$$p_b\,\frac{\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$$

For p_a and $q_a \gg 1$ there is a close analogy between $\theta_b = dT_b/d\ln q_b$ and $\Gamma_b = dT_b/d\ln p_b$.



5. Reduced relaxation time (τ according to eq. 2.2-7).

a)	b)
Definition:	
$\tau_a = \tau k_R (c_A^0 + c_B^0)$	$\tau_b = \tau k_R c_B^0$
Expression I:	
$\frac{1}{\sqrt{p_a(2+p_a)+(1-2q_a)^2}}$	$\frac{1}{\sqrt{(p_b+q_b-1)^2+4p_b}}$
Expression II:	
$\frac{1}{1+p_a} \cdot \frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$	$\frac{1}{1+p_b+q_b} \cdot \frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$

One may define a complementary reduced relaxation time as:

$$\tau^* = \tau k_D = \tau_a p_a = \tau_b p_b = \frac{\Gamma_i}{T_i}$$

(T_i being T_a or T_b if $\Gamma_i = \Gamma_a$ or Γ_b, resp.)

Notes on evaluation:

1) Maxima for Γ_a and Γ_b occur always at the equivalence points a) $q_a = 0.5$ and b) $q_b = 1 + p_b$.
2) The same is true for τ_a, while τ_b—due to its relation to T_b—has its maximum at $q_b = 1 - p_b$, *i. e.* present only for $p_b < 1$.
3) Method a) is impracticable for $p_a \gg 1$, while method b) is straightforward to yield p_b from the apparent equivalence point $q_b \approx p_b$. The functions $\theta_b = d\,T_b/d\ln q_b$ and $\Gamma_b = d\,T_b/d\ln p_b$ show equivalent behavior in this situation.
4) Note that for τ the inverse square yields linear plots which can be easily evaluated.

an "end-point"-property is most suitable for the purpose of titration and, in this form, allows a determination of the stability constant K as well.

Graphic *representations* of some key functions used in Table 1 are also given in Figure 4. For practical use numerical tabulations are available. The illustrations in Figure 4 are self-explanatory. They stress the need for an exact calibration of the titration variable q_a (or q_b), and emphasize the importance of relative (rather than absolute) accuracy of calibration in the vicinity of the equivalence point.

If we compare the two procedures: a) $c_A^0 + c_B^0 =$ constant and b) $c_B^0 =$ constant, we notice the advantage of the conservation of symmetry in the former case. Method b) reflects the classical procedure, aiming at a determination of the unknown sample concentration (c_B^0) with the help of a standard A of known concentration c_A^0. This method has later been adapted to yield also the stability constant of the reaction product AB and is straightforward as long as the inverse of the stability constant is larger than or comparable with the sample concentration However it becomes increasingly insensitive for $K^{-1} \ll c_B^0$. Under these circumstances method a) offers advantages. Of course, this method requires a knowledge of c_A^0 as well

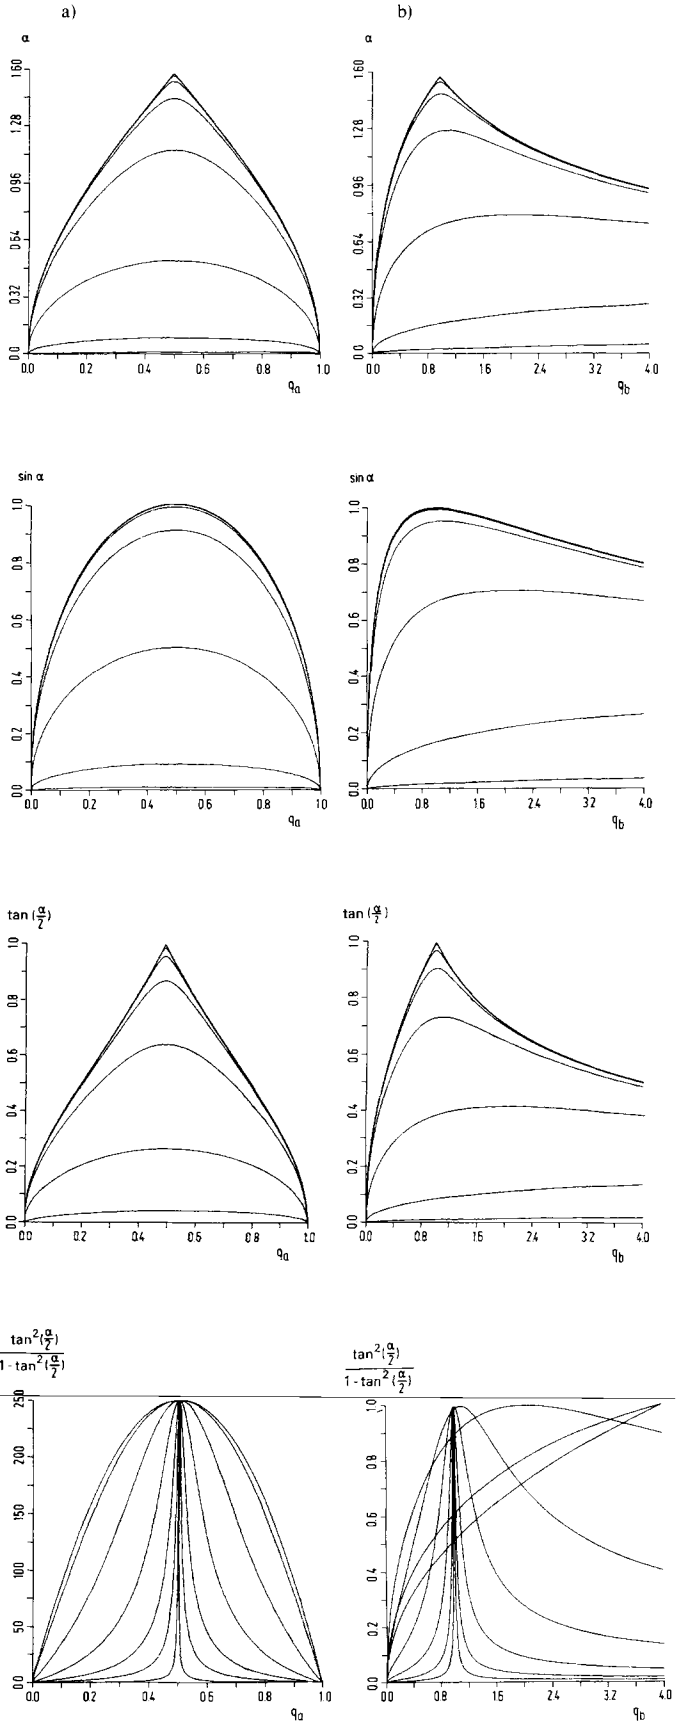


Fig. 4. Some key functions used in Tables 1a and 1b.

as c_B^0, because their sum is to be kept constant. Thus if both concentrations can be adjusted independently it is most natural to have $c_A^0 = c_B^0$ and to use varying fractions of the two solutions. Their combination—apart from possible small non-additive effects showing up only at higher concentrations—does not alter the total number of particles (A *and* B) in any given volume element.

Method a) was introduced by *Job*[6] in complexometry as the *method of continuous variation*. A critical review on related techniques and a survey of the relevant literature can be found in a monograph by *F. J. C. Rossotti* and *H. Rossotti*[7]. The use of this method in relaxation studies is strongly recommended. The symmetry expresses itself most clearly in the trigonometric representation uncovering a unique relationship between relaxation amplitude and time, which is absent in case b). From the expression in Table 1 we see that

$$\tau_a = \frac{1}{1+p_a} + \frac{2\Gamma_a}{p_a(1+p_a)} \tag{2.3-2}$$

or

$$\tau = \frac{1}{k_R(c_A^0 + c_B^0 + K^{-1})} + \frac{2}{k_R(c_A^0 + c_B^0 + K^{-1})K^{-1}\Delta Z}(\Gamma\Delta Z) \tag{2.3-3}$$

The experimental procedure is to vary q_a at constant $(c_A^0 + c_B^0)$ and to plot the measured relaxation time *versus* the respective relaxation amplitude containing the product of Γ_a and ΔH or ΔV (*i.e.* $\Gamma\Delta Z$ in eq. (2.3-3)). The intercept of the straight line (cf. Fig. 5) simply yields the reciprocal of $k_R(c_A^0 + c_B^0 + K^{-1})$ whereas the ratio of intercept and slope is equal to $K^{-1}\Delta Z/2$. Measurement at different fixed values of the sum $(c_A^0 + c_B^0)$ will thus permit a separate detection of all parameters involved. *The elegance of this method lies in the concomitant establishment of k_R, k_D, K and ΔH or ΔV from simple linear plots.*

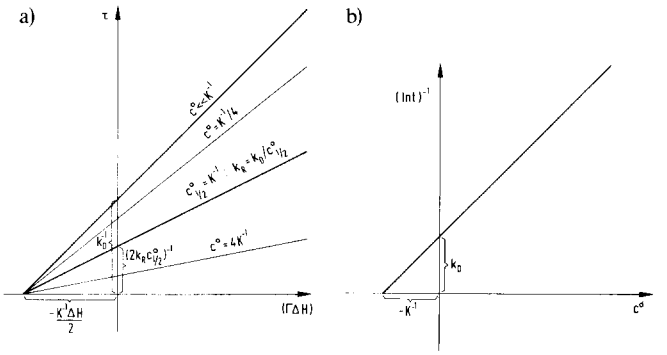

Fig. 5. a) Plot of relaxation time τ *versus* amplitude factor $\Gamma\Delta H$ at constant $c^0 = c_A^0 + c_B^0$.

Both quantities (τ and $\Gamma\Delta H$) can be evaluated from experimental data. At least two series of measurements have to be carried out, each of which refers to a different c^0. Within each series $c^0 = c_A^0 + c_B^0$ is kept constant while the ratio c_A^0/c^0 is varied. From the slopes and intercepts all parameters, such as k_R, k_D, K and ΔH can be determined. If K^{-1} is small or large as compared to c^0, the ordinate intercept yields either $k_R \times c^0$ or $k_R \times K^{-1} \equiv k_D$. Combination with any absolute value for τ at a given ratio c_A^0/c^0 will supplement the other rate constant and hence K, while ΔH follows from the abscissa intercept. $c^0_{1/2}$ refers to the half-value of the slope and is given by $c^0_{1/2} \equiv K^{-1}$.

b) Plot of reciprocal ordinate intercepts $(\mathrm{Int})^{-1}$, obtained from Fig. 5a, as function of the concentration c^0.

The main advantage of dynamic over static titration techniques becomes most evident in studies of multiple-step binding processes. Consider a sequential reaction, typical for the binding of a substrate to an enzyme, which may exist in several conformations:

$$A + B \rightleftharpoons AB_1 \rightleftharpoons AB_2 \tag{2.3-4}$$

Classical titration will yield one "overall binding parameter":

$$\bar{K} = \frac{c_{AB_1} + c_{AB_2}}{c_A \cdot c_B} \tag{2.3-5}$$

Only the dynamical technique can distinguish the two constants referring to the individual reaction steps:

$$K_1 = \frac{c_{AB_1}}{c_A \cdot c_B}; \qquad K_2 = \frac{c_{AB_2}}{c_{AB_1}} \tag{2.3-6}$$

which in the overall constant appear as the combined term.

$$\bar{K} = K_1(1 + K_2) \tag{2.3-7}$$

Two relaxation times (τ_I and τ_{II}) can be measured, both being concentration dependent. In the form of $1/\tau_I + 1/\tau_{II}$ and $1/\tau_I \cdot 1/\tau_{II}$ they can explicitly be expressed in terms of the titration variable $q_a = c_A^0/(c_A^0 + c_B^0)$ or $q_b = c_A^0/c_B^0$, the sum being the trace and the product the determinant of the matrix of rate coefficients. Both functions pass through a sharp maximum, which occurs at $q_a = 0.5$ or $q_b = 1 - p_a$ if (and only if) there is a 1:1 complex formation between A and B. In this way the number of binding sites can be identified. Analysis of the curves yields the four rate constants, which include the individual equilibrium parameters (cf. Table 2).

Table 2. Binary (1:1) complex formation involving additional first order transformations.

Reaction schemes:

1)	2)
$A + B \underset{k_D}{\overset{k_R}{\rightleftharpoons}} AB_1 \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} AB_2$	$A_2 + B \underset{k_{12}}{\overset{k_{21}}{\rightleftharpoons}} A_1 + B \underset{k_D}{\overset{k_R}{\rightleftharpoons}} A_1B$

Both reactions yield titration curves formally identical with those discussed in Table 1 and referring to the overall stability constants $\bar{K}$:

1)	2)
$\bar{K} = \frac{c_{AB_1} + c_{AB_2}}{c_A \cdot c_B} = K_1(1 + K_2)$	$\bar{K} = \frac{c_{A_1B}}{c_B(c_{A_1} + c_{A_2})} = \frac{K_1}{1 + K_2}$
$K_1 = \frac{c_{AB_1}}{c_A \cdot c_B} = \frac{k_R}{k_D}$	$K_1 = \frac{c_{A_1B}}{c_{A_1} \cdot c_B} = \frac{k_R}{k_D}$
$K_2 = \frac{c_{AB_2}}{c_{AB_1}} = \frac{k_{12}}{k_{21}}$	$K_2 = \frac{c_{A_2}}{c_{A_1}} = \frac{k_{12}}{k_{21}}$

T_1 and T_2 can be written in explicit form. For the overall concentrations the conservation relations read:

1)	2)
$c_A + c_{AB_1} + c_{AB_2} = c_A^0$	$c_{A_1} + c_{A_1B} + c_{A_2} = c_A^0$
$c_B + c_{AB_1} + c_{AB_2} = c_B^0$	$c_B + c_{A_1B} = c_B^0$

There are two relaxation times associated with each of the reaction schemes. They can be obtained from the original (linearized) rate equations by a normal mode analysis as outlined in Ref. [5]. Sum and product of the

two time constants for each scheme can be expressed in terms of overall concentrations, equilibrium and rate parameters as:

$\tau_I \cdot \tau_{II}$

1)

$$\frac{X}{\sqrt{(c_A^0+c_B^0+\bar{K}^{-1})^2-4c_A^0c_B^0}}$$

2)

$$\frac{X'}{\sqrt{(c_A^0+c_B^0+\bar{K}^{-1})^2-4c_A^0c_B^0}}$$

$\tau_I + \tau_{II}$

1)

$$Y+\frac{Z}{\sqrt{(c_A^0+c_B^0+\bar{K}^{-1})^2-4c_A^0c_B^0}}$$

2)

$$\frac{Y'}{X'}+\frac{Z'-\bar{K}^{-1}\cdot Y'}{X'\sqrt{(c_A^0+c_B^0+\bar{K}^{-1})^2-4c_A^0c_B^0}}$$

with the constants being:

1)

$X=[k_R(k_{12}+k_{21})]^{-1}$

$Y=(k_{12}+k_{21})^{-1}$

$Z=k_R^{-1}+(k_{12}+k_{21})^{-1}K_2\bar{K}^{-1}$

$\bar{K}^{-1}=\frac{k_D}{k_R}\frac{k_{21}}{k_{12}+k_{21}}=k_Dk_{21}\cdot X$

2)

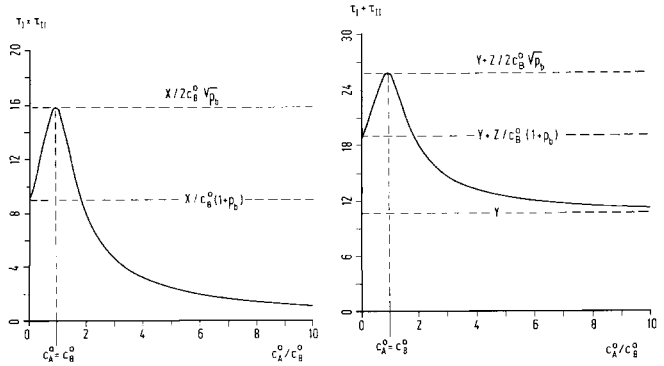
$X'=k_R\cdot k_{21}$

$Y'=k_R\cdot\frac{1+K_2/2}{1+K_2}$

$Z'=k_D+k_{12}+k_{21}$ (for $c_A^0=c_B^0$)

If $c_A^0\neq c_B^0$, a term

$-k_R\frac{K_2/2}{1+K_2}(c_A^0-c_B^0)$

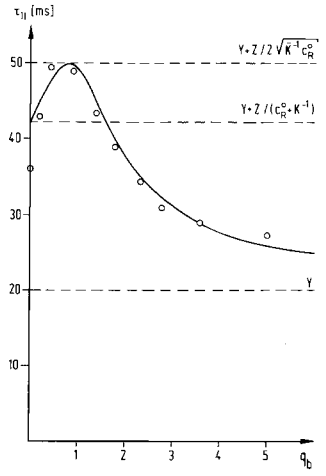


is to be added to Z'.

$\bar{K}^{-1}=\frac{k_D}{k_R}\frac{k_{12}+k_{21}}{k_{21}}=k_D(k_{12}+k_{21})/X'$

For an evaluation one may proceed in the same way as in Table 1, introducing the variables $q_a=c_A^0/c_A^0+c_B^0$ (for $c_A^0+c_B^0=$const.) or $q_b=c_B^0/c_A^0$ (for $c_B^0=$const.) and accordingly $p_a=\bar{K}^{-1}/(c_A^0+c_B^0)$ or $p_b=\bar{K}^{-1}/c_B^0$. The binding parameter p_a then follows immediately from the shape of the $\tau_I\cdot\tau_{II}$-curves. The square root terms can then be calculated and may serve as a variable in reciprocal plots in order to obtain $\tau_I+\tau_{II}$. For case 2) a further concentration factor appears in Z' if $c_A^0\neq c_B^0$. It is suggested that one could apply the condition $c_B^0=$const. only for a determination of $\bar{K}$ using the relation for $\tau_I\cdot\tau_{II}$, but then change to the condition $c_A^0=c_B^0$ (variable) in order to evaluate the sum $\tau_I+\tau_{II}$. Such a difficulty does not arise in case 1). If one of the two steps (in each scheme) is fast with respect to the other, separate expressions for τ_I and τ_{II} can be derived and evaluated accordingly. However, if the first order step is the fast one, the two first order rate constants cannot be discriminated any longer since they enter as a sum, not involving any concentration dependent term.

The concept outlined in this table can be generalized to include a whole sequence of first order transformation steps. The Gaussian method of representing combinations of eigenvalues (such as sum and product in case of two time constants) by the coefficients of the characteristic polynomial leads to a form, which easily yields the single step parameters.



Examples of two step systems are discussed in Sections 2.3 and 4.2. Schematic representations of the curves reflecting the product and sum of the time constants τ_I and τ_{II} are shown for the case 1). The parameters X, Y, and Z are defined in the text at the top of Table 2. The curve shapes are calculated for $\bar{p}_a=\bar{K}^{-1}/c_B^0=10^{-2}$.

Example of an evaluation of measured relaxation times τ [14]. The example refers to the binding of acetylcholine (A) to its receptor (R) (which exists in two conformations) according to the mechanism:

$$A+R\underset{k_D}{\overset{k_R}{\rightleftharpoons}}AR_1\underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}}AR_2$$

Two relaxation times, associated with this mechanism have been determined. They turned out to be easily separable due to $\tau_I\ll\tau_{II}$. Here, τ_{II} is plotted as a function of $q_b=c_A^0\cdot c_R^0$. As a consequence of the condition $\tau_I\ll\tau_{II}$ the quantity Z is given by $K^{-1}\cdot K_2\cdot Y$ (cf. mechanism 1). Values for k_R and k_D (*i.e.* also for K_1) resulted from the data of τ_I, which refers to the fast binding step. Therefore a complete identification of all four rate constants (and hence of both equilibrium constants) was possible, yielding: $k_R=2.4\ (\pm0.5)\times10^7\ M^{-1}\ s^{-1}$, $k_D=144\ (\pm30)\ s^{-1}$, $k_{12}=43.5\ s^{-1}$ and $k_{21}=6.5\ s^{-1}$ ($K_1=1.7\times10^5\ M^{-1}$, $K_2=6.7$).

This representation can be extended to any further sequences of first order steps, using the Gaussian method of correlating combinations of the different eigenvalues with the coefficients of the characteristic polynomial. For $\bar{K}\gg1$, at least some of the combinations of eigenvalues will show sharp maxima at the equivalence point. *The dynamic titration procedure thus yields a much deeper insight into the binding mechanism than any of the classical complexometric techniques.*

2.4. Evaluation of Data and Some Experimental Examples

The absolute value of a relaxation amplitude depends on the magnitude of the mass action parameter p_a. For *high complex stabilities*, as reflected by small p_a-values, both classical titration and relaxation measurements require a high resolution of the recorded signal. There is, however, an important difference, if we compare the two procedures. *Conventional titration* calls for a *high relative accuracy* in the calibration of concentrations. The desired information is hidden in (small) deviations from a standard curve. Signal amplification does not reduce any relative error, unless some kind of double-differential recording is applied, *e. g.* a direct recording of the second derivative of the titration function. Relaxation amplitudes and times, on the other hand, are related to p_a or K in a more straightforward way. Here *the absolute magnitude* of the signal is of importance. The amplitude vanishes if p_a approaches zero. Therefore, amplification of the signal leads to a true enhancement of resolution, ultimately limited only by the noise introduced by the recording equipment.

Considerable progress in the development of relaxation instruments has been made in recent years. As a consequence,

the dynamic amplitude technique promises to become a powerful new tool in analytical chemistry. The possibility of such applications has been mentioned long ago. In fact, one of the first studies of chemical relaxation effects[8, 9] started from a quantitative estimate of amplitudes and their concentration dependence. The utilization of relaxation amplitudes has until recently been hampered by the inadequate sensitivity of earlier instruments. A combination of the presently-available relaxation techniques with devices for an automatic control of concentration will open a wide range of application in complexometry[*].

The essential information about the stability constant (contained in the parameter p_a) will be obtained from curve *shapes* for T'', Γ and τ as functions of the titration variable q_a rather than from *absolute* values. For an evaluation of data it is, therefore, practical to *normalize* the curves, *i.e.* to divide them by their maximum value. These normalized curves are to be distinguished from the *reduced* terms quoted in Table 1. The latter still contain some unknown factors (p_a or a function thereof), apart from the fact that the reduced form of Γ cannot be detected directly, since relaxation amplitudes contain also ΔH or ΔV. The normalized curves, on the other hand, can be obtained immediately from experimental data (*i.e.* by dividing them by the maximum term). They do not reflect the absolute magnitude of the measured signal. Fitting them with the theoretical curves (cf. Table 1) will allow an assignment of the parameter p_a (or K). Then a further evaluation of the recorded *absolute* signals with respect to rate constants, reaction enthalpies *etc.* can be undertaken.

As an example let us consider a T-jump experiment. Usually, some optical signal is detected which represents a shift in extinction occurring upon perturbation of the equilibrium. For a calibrated perturbation (*i.e.* a T-jump of precisely fixed magnitude and known characteristics of the detection equipment) the amplitude of the relaxation effect can be correlated with δc_{AB}, supposing the difference in the extinction coefficients ($\varepsilon_{AB}-\varepsilon_A-\varepsilon_B$) to be known. The unknown factors of the measured amplitude are Γ or p_a and ΔH. After assignment of p_a from the shape of the normalized curve the absolute number at the maximum can be used to determine ΔH as well. Expressed in terms of δc_{AB} the maximum value is given by:

$$\text{a)}\quad (c_A^0+c_B^0)\frac{p_a}{2}\left[\frac{1+p_a}{\sqrt{p_a(2+p_a)}}-1\right]\frac{\Delta H}{RT}\cdot\frac{\delta T}{T} \tag{2.4-1}$$

$$\text{b)}\quad c_B^0\frac{p_b}{2}\left[\sqrt{1+\frac{1}{p_b}}-1\right]\frac{\Delta H}{RT}\cdot\frac{\delta T}{T} \tag{2.4-2}$$

[a) and b) referring to Table 1].

Both maxima reduce for $p_a\rightarrow 0$ to the same limiting value

$$\frac{1}{2}\sqrt{K^{-1}c_B^0}\;\frac{\Delta H}{RT}\cdot\frac{\delta T}{T} \tag{2.4-3}$$

In a similar way the relaxation times can be analyzed, plotting τ/τ_{max} as a function of q_a, with τ_{max} being

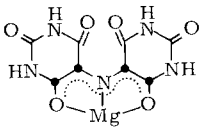
$$\text{a)}\quad [k_R(c_A^0+c_B^0)\sqrt{p_a(2+p_a)}]^{-1} \tag{2.4-4}$$

and

$$\text{b)}\quad [2k_R c_B^0\sqrt{p_b}]^{-1} \tag{2.4-5}$$

With respect to a determination of k_R and k_D, this is just an alternative to plotting $1/\tau^2$ as a function of c^0 (Figure 2b, third diagram from top), which is based on the condition $c_A^0=c_B^0$. For T'', *i.e.* the second derivative of the titration function, such an evaluation using normalized curves is not necessary, since in this case p_a is the only unknown, fixing the shape as well as the maximum value (Table 1). It may nevertheless be of advantage, if T'' is directly detected with the help of a double differential method, and the recorded signals involve any unknown factor. At its maximum T'' is given by:

$$\text{a)}\quad -\frac{2}{\sqrt{p_a(1+p_a)}}\xrightarrow{p_a\rightarrow 0}-2\sqrt{Kc_B^0} \tag{2.4-6}$$



and

$$\text{b)}\quad -\frac{1}{2\sqrt{p_b(1+p_b)^3}}\xrightarrow{p_b\rightarrow 0}-\frac{1}{2}\sqrt{Kc_B^0} \tag{2.4-7}$$

For T_b''—as for τ_b—a maximum is present only if $p_a<1$ and appears at $q_b=1-p_b$.

In conclusion to this section on binary (1:1) complexes some examples of the experimental determination of relaxation amplitudes and time constants and their evaluation for rate and equilibrium parameters are discussed.

The first example[11] deals with the formation of a metal complex between Mg^{2+} and the anion of purpuric acid (murexide) in methanol.

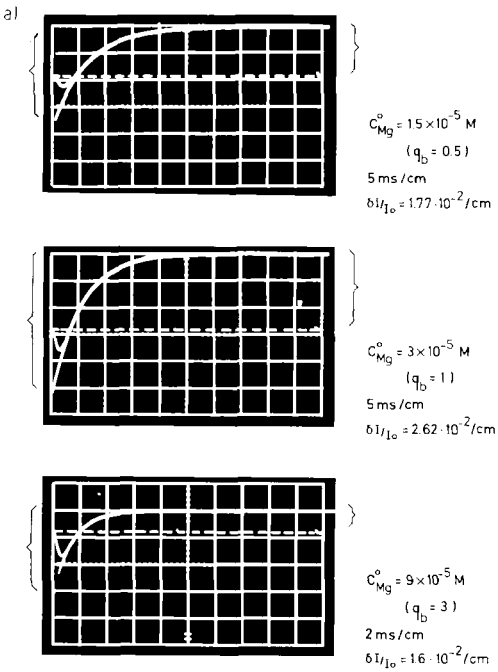
Three independent sources of data, (classical) titration, relaxation amplitudes and time constants, are available for a determination of the stability constant. Oscillograms of the relaxation effects are shown in Figure 6. They demonstrate clearly why a dynamic recording is of advantage. The total change of extinction contains two parts: an instantaneous shift caused by the thermal expansion of the sample, and a chemical relaxation effect occurring with a finite time constant. The chemical effect on which the evaluation of Γ is based would not result directly from any static experiment. A simple static recording of the temperature dependence—due to the superposition of the effects of thermal expansion—could lead to quite erroneous explanations.

The sensitivity of the differential technique is very high. Conventional ratio recording spectrophotometers do not reach any comparable resolution. Titration functions, relaxation amplitudes and time constants are represented in Figures 6c and 6d in the form of normalized plots.

The second case describes a reaction involving two competitive steps, the addition of sulfate and water to 4-pyridinecarbaldehyde, studied by *Schuster et al.*[13].

[*] Only few examples of this technique are known so far; cf. [1, 10—12].

The overall equilibrium constant of complex formation is $\bar{K} = K_1/(1+K_2)$.



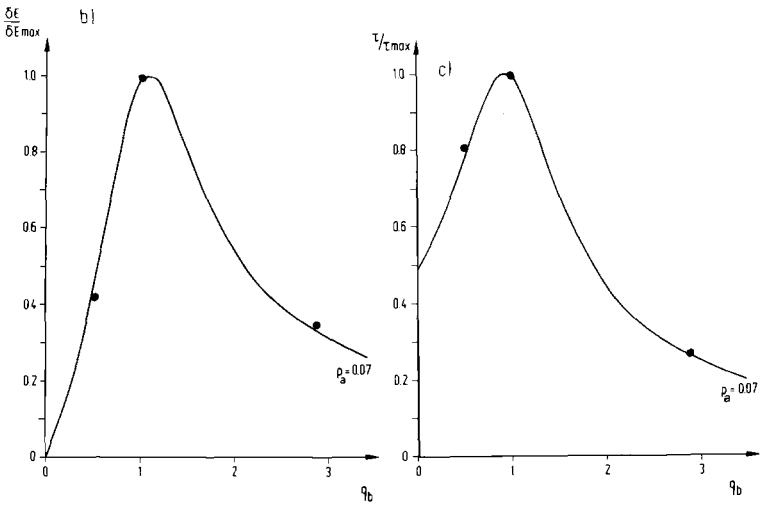


Fig. 6. a) Relaxation curves from *T*-jump experiments (oscillograms) for the system Mg/murexide in methanol;
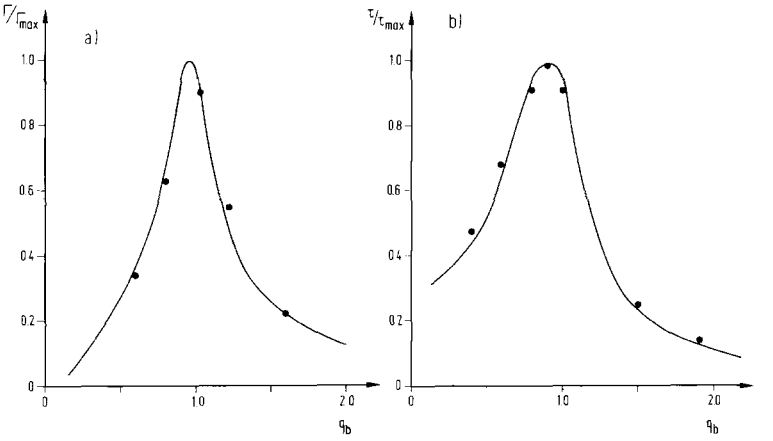
$c^0_{Mu} = 2.9\times10^{-5}$ M
Note the differences in sensitivity ($\delta I/I_0$). With uniform sensitivities the second oscillogram would show almost twice as large an amplitude. The true amplitudes, resulting from an extrapolation of the dynamic response and indicated by a bracket at the left side of the pictures, differ strikingly from the "static" shifts (indicated by the right hand brackets). The baseline (dashed) indicates the initial position of the temperature jump induced concentration shift.

b) Normalized relaxation amplitudes *versus* titration variable q_b. (Experimental data taken from Ref. [1].)

c) Normalized relaxation times *versus* titration variable q_b. (Experimental data taken from Ref. [1].)

Evaluation of the data with $c^0_{Mu} = 4.2\times10^{-5}$ M yields: $K = 3.5\times10^5$ M^{-1}; $k_R = 8.0\times10^6$ M^{-1} s^{-1}; $k_D = 23$ s^{-1}; $\Delta H = +7.3$ kcal/mol.

The dynamic measurements, however, refer to the sulfate reaction only, since the hydrate is formed (much more) slowly.



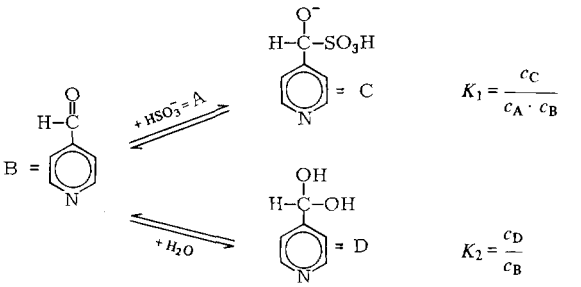


Fig. 7. a) Normalized relaxation amplitude Γ/Γ_{max} as a function of the titration variable $q_b \equiv c^0_A/c^0_B$ for the sulfite/4-pyridinecarbaldehyde system (after [13]). The data are fitted with a curve referring to $K_1 = 6.5\times10^5$ M^{-1} with c^0_B being 1×10^{-3} M (hydrogen sulfite) and pH = 7. Due to the protonation of hydrogen sulfite the maximum does not appear at exactly $q_b = 1$ (cf. Ref. [13]).

b) Normalized relaxation time (τ/τ_{max}) as a function of q_b (data cf. Fig. 7a).

Normalized amplitudes Γ_b (from *T*-jump experiments) as a function of $q_b = c^0_A/c^0_B$ (accounting for the first step only) are shown in Figure 7.

3. Substitution Methods

The applicability of the titration principles described in Section 2 is based essentially on two facts:

There is a measurable shift of properties—such as extinction, fluorescence etc.—occurring upon combination of A *with* B,

and

the stability of the complex AB *is of a magnitude which allows the recording of finite signals.*

What can we do if one of these conditions is not fulfilled? We may use an auxiliary system, *e.g.* an indicator which competes for combination with one of the reaction partners (A or B) and exhibits unique optical (or other) qualities in order to compensate for the absence of detectable changes of the sample. The stability of such a competitor has to be similar to that of the complex under investigation.

In enzyme chemistry an analogous case is that of competitive inhibition. Straightforward expressions are obtained if substrate and inhibitor are in large excess of the enzyme (Figure 8). Such simplifying assumptions, however, will not be made in the following treatment.

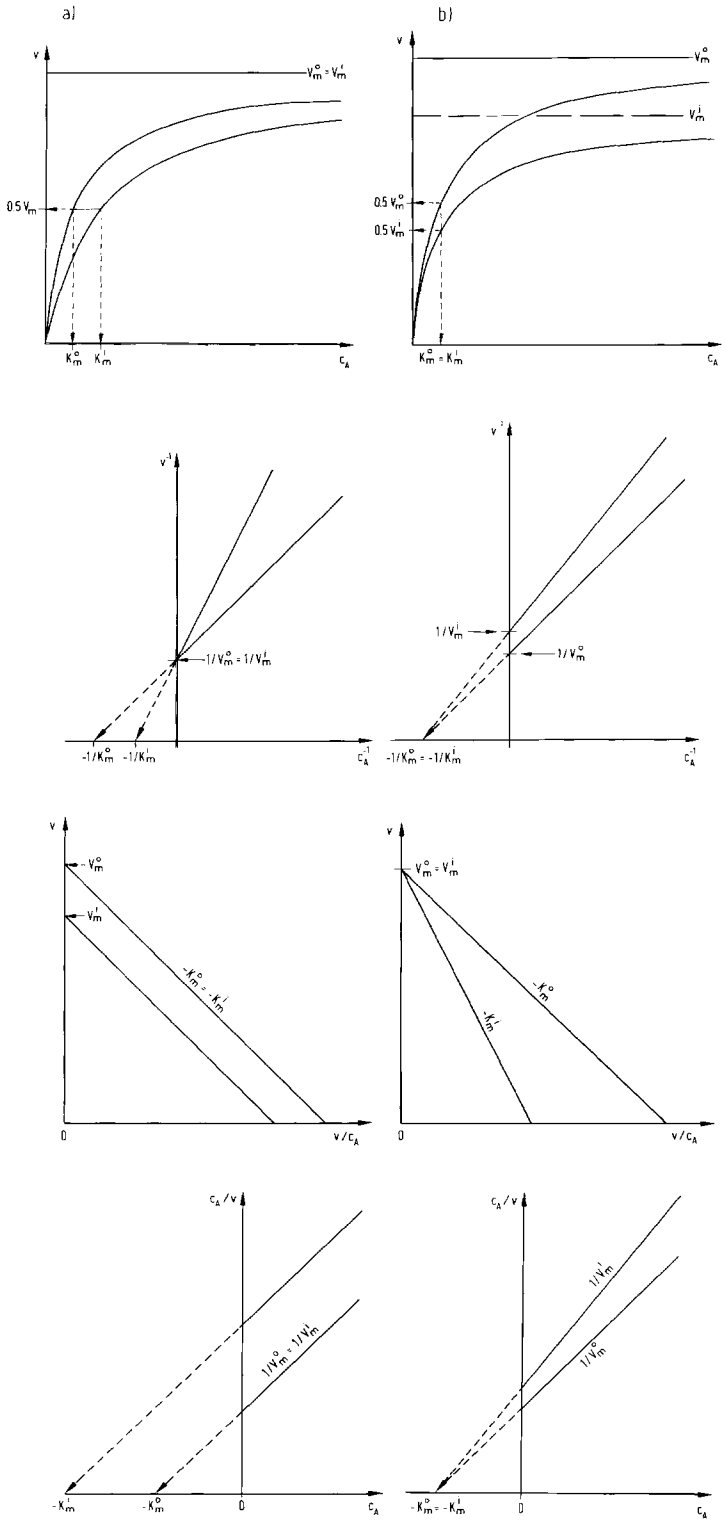

Fig. 8: Simple linear plots—analogous to those shown in Figure 2—for coupled binding processes: a) competitive inhibition, b) non-competitive inhibition. (Data from *Dixon and Webb*[3].)

The plots are based on the relation (cf. Figure 2a):

$$v = V_m^i c_A/(c_A + K_m^i)$$

where V_m^i and K_m^i have the following meaning:

a) competitive	b) non-competitive
$V_m^i = V_m^0$	$V_m^i = V_m^0/(1 + K_i c_i)$
$K_m^i = K_m^0(1 + K_i c_i)$	$K_m^i = K_m^0$

K_i being the stability constant of the enzyme-inhibitor complex, c_i the inhibitor concentration. V_m^0 and K_M^0 are the maximum velocity and Michaelis constant, respectively in absence of the inhibitor, and c_A is the substrate concentration.

Let us introduce the auxiliary system as an indicator I, which undergoes complex formation with one of the reactants, say B:

$$I + B \rightleftharpoons IB$$

in competition with

$$A + B \rightleftharpoons AB$$

A complete description of the dynamic properties requires two coupled differential equations, the solutions of which refer to certain normal modes of reaction. With respect to applications in complexometry it is sufficient to consider the overall-equilibration.

Two limiting cases are of special interest:

1. The stability of both complexes AB and IB is so high that free B is not present to any detectable extent. The reaction equation then can be written:

$$AB + I \rightleftharpoons A + IB$$

2. The auxiliary system is used as a true indicator without essentially influencing the sample equilibrium. This means I and IB are present at relatively low concentrations—still allowing optical or any other kind of detection—while the amount of B is similar to that of A and AB.

3.1. Complete Exchange of a Ligand B

The first mentioned case represents a true one-step reaction.

$$AB + I \underset{k_{-S}}{\overset{k_S}{\rightleftharpoons}} A + IB$$

We define the equilibrium and rate parameters as:

$$\frac{c_A \cdot c_{IB}}{c_{AB} \cdot c_I} = K = \frac{k_S}{k_{-S}} \tag{3.1-1}$$

Furthermore we have the conservation conditions:

$$\begin{aligned} c_A + c_{AB} &= c_A^0 \\ c_I + c_{IB} &= c_I^0 \\ c_{IB} + c_{AB} &= c_B^0 \end{aligned} \tag{3.1-2}$$

(Note that c_B is assumed to be negligibly small.)

From these equations we can calculate the explicit expressions for all individual concentrations at equilibrium, *e.g.*

$$c_{IB} = \frac{c_A^0 - c_B^0 + K(c_B^0 + c_I^0)}{2(K-1)}\left[1 - \sqrt{1 - \frac{4K(K-1)c_B^0 c_I^0}{[c_A^0 - c_B^0 + K(c_I^0 + c_B^0)]^2}}\right] \tag{3.1-3}$$

Several ways of performing the experiments are possible. For instance:

- We may start with a given amount of I (in its uncomplexed form) and add aliquots of A and B, such that always $c_A^0 = c_B^0$, or:
- We fix the concentration of IB (*i.e.* $c_I^0 = c_B^0$) and add varying amounts of (uncomplexed) A.

Mathematically, we do not have to distinguish between these procedures explicitly because we can deduce one from the other taking into account the symmetry of the substitution process in which the symbols of I and A can be interchanged. Using the *conditions* (3.1-2) we can derive c_{AB} from expression (3.1-3) for c_{IB}. The various cases then refer to either c_{IB} or c_{AB} under the secondary requirement $c_A^0 = c_B^0$. The resulting formulae are always symmetrical with respect to c_I^0 and c_B^0, *i.e.* we could alter one and keep the other constant or—in analogy to the method a) in Table 1—fix the sum of c_I^0 and c_B^0 and vary their proportions.

It is therefore sufficient to quote one example only. Let us choose the conditions

$$c_I^0 = \text{const.}; \quad c_A^0 = c_B^0 = \text{variable}$$

Hence we define the titration variable $q_b \equiv c_B^0/c_I^0$ and the titration function $T_b \equiv c_{IB}/c_I^0$. The reciprocal of the (dimensionless) equilibrium constant will be called $p_b (= K^{-1})$ in analogy to the nomenclature in Table 1. We obtain

$$T_b = \frac{1+q_b}{2(1-p_b)}\left[1 - \sqrt{1 - \frac{4(1-p_b)q_b}{(1+q_b)^2}}\right] \tag{3.1-4}$$

This titration function is similar to the one already described. For $p_b \to 0$ it approaches the limiting linear form:

$$T_b = \frac{(1+q_b) \pm (1-q_b)}{2} \quad \text{or} \quad T_b = \begin{cases} q_b & \text{for } q_b < 1 \\ 1 & \text{for } q_b > 1 \end{cases} \tag{3.1-5}$$

T_b changes abruptly at $q_b = 1$. For $p_b = 1$ it simply reads

$$T_b = \frac{q_b}{1+q_b} \tag{3.1-6}$$

while for $p_b \gg 1$ again a limiting form with respect to a generalized variable will result:

$$T_b \to \frac{q_b}{2p_b}\left[\sqrt{1 + \frac{4p_b}{q_b}} - 1\right] \tag{3.1-7}$$

The point of half transition ($T_b = 0.5$) will always be found for $q_b = (1 + p_b)/2$.

From this it follows that the choice of the particular titration procedure depends on the magnitude of p_b and upon the purpose of the titration experiment. If it is the concentration of a sample (c_I^0 or c_A^0) which is to be measured one fixes the concentration of the weaker and varies the concentration of the stronger complex. In this case, corresponding to $p_b \ll 1$, one reaches a sharp end-point, indicated by a (quasi) singularity in the curvature of the titration function T_b (more precisely the transition is singular only in the limiting case $p_b \to 0$). If, on the other hand, the object is a determination of K or p_b it may be advisable to titrate with the weaker complexing agent and to calibrate precisely the excess of c_A^0 over c_B^0 necessary to reach the half-point [where $q_b = (1 + p_b)/2$]. The added substance, of course, should not be identical with the indicator, since its concentration may have to be varied over several orders of magnitude.

Note that—owing to the symmetry of the substitution reaction—one could equally as well designate a complementary titration function T_{-b} based on c_{AB} rather than c_{IB}. With $T_{-b} = c_{AB}/c_I^0$ we have $T_{-b} = q_b - T_b$ and $T'_{-b} = -T'_b$, $T''_{-b} = -T''_b$. Furthermore, utilizing the symmetry of T_b with respect to c_I^0 and c_B^0, one may also introduce $T_b = c_{IB}/c_B^0$, so that $T_{-b} = c_{AB}/c_B^0 = 1 - T_b$. This definition is to be preferred if $c_A^0 = c_B^0$ is kept constant while c_I^0 is the variable.

Often one is not free to choose the ideal substance. The most frequently encountered problem in titration is the *solubility* limit. The alternative "method of continuous variation", in which the sum of c_I^0 and c_B^0 (or c_A^0) is fixed, then offers advantages. Again the essential information about the equilibrium constant may result from small variations of q_a in the neighborhood of the equivalence point ($q_a = 0.5$).

Expressions for the titration function, its first and second derivative, as well as for relaxation amplitudes and time constants under the requirement $c_I^0 + c_B^0 = \text{const.}$ and $c_A^0 = c_B^0$ are compiled in Table 3. Again, owing to the symmetry of the substitution scheme, the symbols I and A are convertible. For reasons of comparative representation, the introduction of trigonometric functions proves to be especially useful. In this treatment a *formal* complication arises owing to the fact that the term $\sqrt{(1-p_a)}$ appears in all expressions. Since p_a can be larger than one those terms may become imaginary. We therefore have to distinguish the following cases:

$p_a < 1$
$p_a = 1$
$p_a > 1$

For $p_a < 1$, $\sin\alpha$ can be introduced in the same straightforward way as before. For $p_a > 1$ we have to remember that $-i\sin(ix) \equiv \sinh x [\sinh x = (e^x - e^{-x})/2]$. Here all trigonometric functions have to be replaced by the corresponding hyperbolic ones.

Table 3 shows that there is only a *formal* correspondence between the expressions for $p_a < 1$ and $p_a > 1$. Although the form of the expressions is (nearly) conserved if we substitute hyperbolic terms for the trigonometric ones, the functional relationships with respect to q_a and p_a vary considerably. For $p_a < 1$ the angle α can vary between 0 and $\pi/2$ (reaching $\pi/2$ only in the limiting case $p_a \to 0$), while for $p_a > 1$, α can assume any value, *i.e.* any multiple of $\pi/2$ with the limit ∞ for $p_a \to \infty$. Hence for $p_a \to 0$, $\tan(\alpha/2)$ steeply approaches unity if α gets close to $\pi/4$, yielding sharp maxima wherever the term $1/(1 - \tan^2(\alpha/2))$ is involved. On the other hand,

Table 3. Substitution reactions $I + AB \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} IB + A$ at constant $(c_I^0 + c_{AB}^0)$. Titration function and its derivatives, relaxation amplitude and time constants. The equilibrium constant K is defined according to eq. 3.1-1), and the conservation conditions (3.1-2) hold. Furthermore, the procedure requires $c_A^0 = c_B^0 \equiv c_{AB}^0$ and $c_I^0 + c_{AB}^0 = \text{const.}$, *i.e.* a positive variation of c_{AB}^0 is compensated by an equivalent negative variation of c_I^0.

It is useful to define the dimensionless parameters in analogy to Table 1:

$$p_a = K^{-1}; \quad q_a = \frac{c_{AB}^0}{c_I^0 + c_{AB}^0}; \quad 1 - q_a = \frac{c_I^0}{c_I^0 + c_{AB}^0}$$

The reduced quantities are given as:

1) Titration function: $T_a = \dfrac{c_{IB}}{c_I^0 + c_{AB}^0}$

2) Slope of titration function: $T'_a = \dfrac{dT_a}{dq_a}$

3) Curvature of titration function: $T''_a = \dfrac{d^2 T_a}{dq_a^2}$

4) Relaxation amplitude factor: $\Gamma_a = \frac{\Gamma}{c_I^0 + c_{AB}^0}$

5) Relaxation time $\tau_a = \tau k_S (c_I^0 + c_{AB}^0)$

$\tau_{-a} = \tau k_{-S} (c_I^0 + c_{AB}^0) \equiv p_a \tau_a$

One may also derive complementary titration functions:

$$T_{-a} = \frac{c_{AB}}{c_I^0 + c_{AB}^0} = q_a - T_a; \quad T'_{-a} = -T'_a; \quad T''_{-a} = -T''_a$$

Explicit expressions for reduced quantities:

1) $T_a = \frac{1}{2(1-p_a)} [1 - \sqrt{1 - 4(1-p_a) q_a (1-q_a)}]$

2) $T'_a = \frac{1 - 2q_a}{\sqrt{1 - 4(1-p_a) q_a (1-q_a)}}$

3) $T''_a = -\frac{2p_a}{[1 - 4(1-p_a) q_a (1-q_a)]^{3/2}}$

4) $\Gamma_a = \frac{p_a [1 - \sqrt{1 - 4(1-p_a) q_a (1-q_a)}]^2}{4(1-p_a)^2 \sqrt{1 - 4(1-p_a) q_a (1-q_a)}}$

5) $\tau_a = \sqrt{1 - 4(1-p_a) q_a (1-q_a)}$

In analogy to Table 1 the explicit relations can be represented by formal substitution of suitable trigonometric or hyperbolic functions, in which form their interrelations become more easily seen. However, three cases have to be distinguished.

$p_a < 1$ $\qquad$ $p_a = 1$ $\qquad$ $p_a > 1$

Formal Definitions

$\sin\alpha \equiv 2\sqrt{(1-p_a) q_a (1-q_a)}$ $\qquad$ — $\qquad$ $\sinh\alpha \equiv 2\sqrt{(p_a - 1) q_a (1-q_a)}$

Range of Existence of α

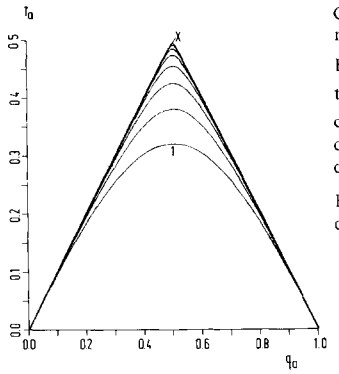
$0 \le \sin\alpha \le \sqrt{1-p_a}$ $\qquad$ $0 \le \sinh\alpha \le \sqrt{p_a - 1}$

$0 \le \tan\alpha \le \sqrt{\frac{1-p_a}{p_a}}$ $\qquad$ $0 \le \tanh\alpha \le \sqrt{\frac{p_a - 1}{p_a}}$

$0 \le \tan\frac{\alpha}{2} \le \frac{\sqrt{1-p_a}}{1+\sqrt{p_a}} = \frac{1-\sqrt{p_a}}{\sqrt{1-p_a}}$ $\qquad$ $0 \le \tanh\frac{\alpha}{2} \le \frac{\sqrt{p_a - 1}}{1+\sqrt{p_a}} = \frac{\sqrt{p_a - 1}}{\sqrt{p_a - 1}}$

Reduced Functions

$T_a = \frac{1}{1-p_a} \cdot \frac{\tan^2\left(\frac{\alpha}{2}\right)}{1+\tan^2\left(\frac{\alpha}{2}\right)}$ $\qquad$ $T_a = q_a(1-q_a)$ $\qquad$ $T_a = \frac{1}{p_a - 1} \cdot \frac{\tanh^2\left(\frac{\alpha}{2}\right)}{1-\tanh^2\left(\frac{\alpha}{2}\right)}$



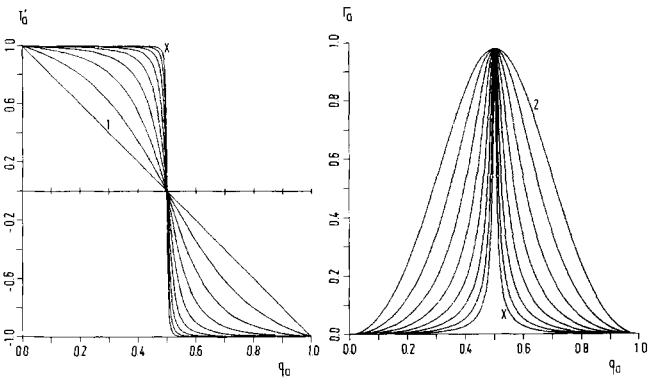
$T'_a = \sqrt{1 - \frac{p_a}{1-p_a} \tan^2\alpha}$ $\qquad$ $T'_a = 1 - 2q_a$ $\qquad$ $T'_a = \sqrt{1 - \frac{p_a}{p_a - 1} \tanh^2\alpha}$

$T''_a = -2p_a \left[\frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}\right]^3$ $\qquad$ $T''_a = -2$ $\qquad$ $T''_a = -2p_a \left[\frac{1+\tanh^2\left(\frac{\alpha}{2}\right)}{1-\tanh^2\left(\frac{\alpha}{2}\right)}\right]^3$

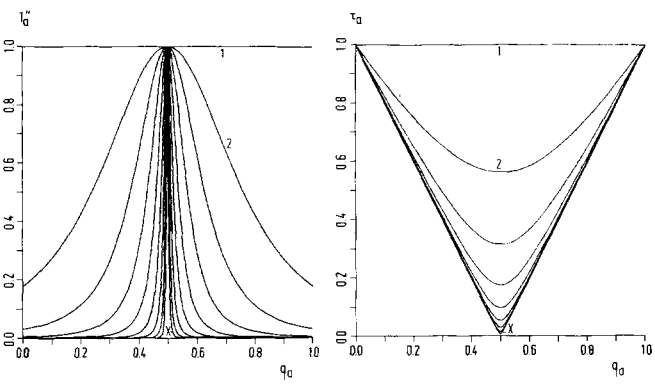
$\Gamma_a = \frac{p_a}{(1-p_a)^2} \cdot \frac{\tan^4\left(\frac{\alpha}{2}\right)}{1-\tan^4\left(\frac{\alpha}{2}\right)}$ $\qquad$ $\Gamma_a = T_a^2 = [q_a(1-q_a)]^2$ $\qquad$ $\Gamma_a = \frac{p_a}{(1-p_a)^2} \cdot \frac{\tanh^4\left(\frac{\alpha}{2}\right)}{1-\tanh^4\left(\frac{\alpha}{2}\right)}$

$\tau_a = \frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$ $\qquad$ $\tau_a = 1$ $\qquad$ $\tau_a = \frac{1+\tanh^2\left(\frac{\alpha}{2}\right)}{1-\tanh^2\left(\frac{\alpha}{2}\right)}$

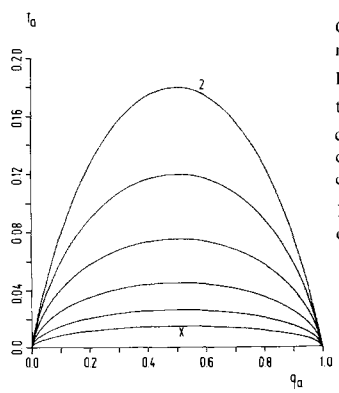
As compared to Table 1 the very pronounced dependences should be emphasized. It appears most clearly in T'_a. The dissymmetry for $p_a < 1$ and $p_a > 1$, expressed by a transition from trigonometric to hyperbolic functions is most obvious for Γ_a and τ_a. The trigonometric forms show much sharper transitions, especially for small p_a-values. For τ_a the dependences are inverted at $p_a = 0$.



Graphic representation of the five mentioned functions:



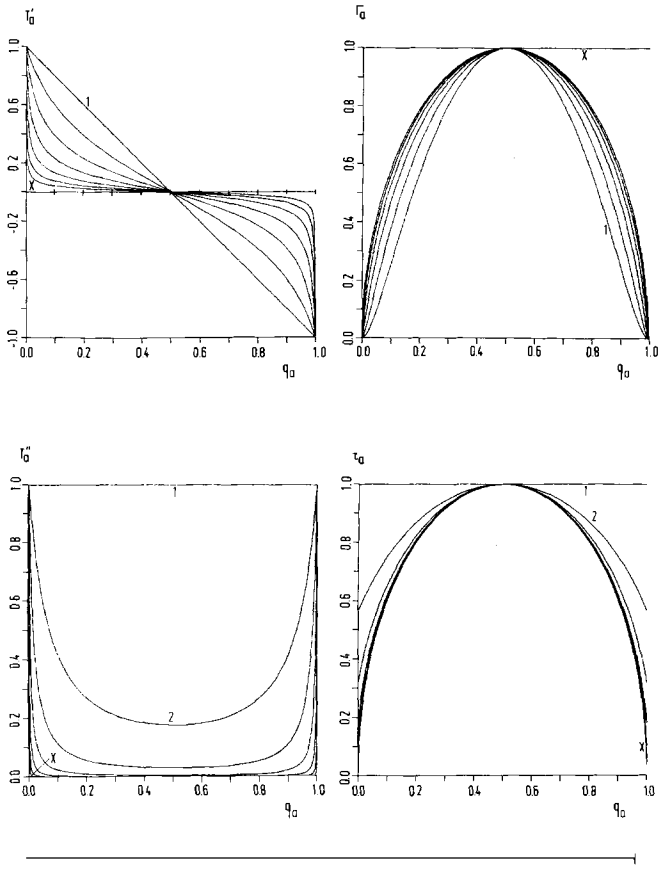
For the case: $p_a \le 1$.



the parameters are

curve 1: $p_a = 1$
curve 2: $p_a = 10^{-0.5}$
curve x: $p_a = 10^{-1}$

For the curves between 2 and x p_a changes by the factor $10^{-0.5}$.



Graphical representation of the five mentioned functions.

For the case: $p_a \ge 1$.

the parameters are

curve 1: $p_a = 1$
curve 2: $p_a = 10^{0.5}$
curve x: $p_a = 10^{3}$.

For the curves between 2 and x p_a changes by the factor $10^{0.5}$.

tanh α for large p_a approaches unity asymptotically, allowing only rather flat extrema around the equivalence point.

This abstract description may be illustrated by the following example: We start with a solution of I at the concentration c_I^0. Adding aliquots of AB and replacing equivalent amounts of I will keep $c_I^0 + c_B^0$ constant, while $c_A^0 = c_B^0$. For large p_a the equilibrium distribution is such that only relatively little B is transferred from AB to I. This minor exchange starts quite early and does not alter substantially if one comes close to the equivalence point, since c_I^0 decreases steadily while c_A^0 increases. However, a quite different situation is met for small p_a values. Here almost all B available converts into IB upon addition of AB until the equivalence point is reached, where the relative proportion of IB starts abruptly to decrease, since all I has been converted to IB and only AB will accumulate. Correspondingly the curvature of the titration function shows a sharp peak at $q_a = 0.5$ in contrast to the former case (cf. the graphical representation in Table 3.)

If we compare the expressions for T_a'', Γ_a and τ_a in Table 3 with those in Table 1 we notice the even sharper q_a-dependence of Γ_a relative to T_a'' and τ_a since $\tan^2(\alpha/2)$ in Γ_a is replaced by $\tan^4(\alpha/2)$, while τ_a and T_a'' formally remain unchanged (note, however, the difference in the definition of α). As a consequence the relation between relaxation amplitude and time constant now assumes a different form. It is most obvious for the complementary relaxation time τ_{-a} (cf. Table 3), reading explicitly:

$$\tau_{-a} = p_a + 2(1-p_a)\sqrt{\Gamma_a \tau_{-a}} \tag{3.1-8}$$

The quantities available from experiments are the relaxation time τ and the amplitude factor $\Gamma\Delta H$. A plot of τ *versus* the square root of the products of τ and $\Gamma\Delta H$ at constant $c_I^0 + c_{AB}^0$ should give a straight line with an intercept at: $[k_S(c_I^0 + c_{AB}^0)]^{-1}$ and a slope of

$$\frac{2(1-p_a)}{c_I^0 + c_{AB}^0}\sqrt{\frac{1}{k_S p_a \Delta H}} \tag{3.1-9}$$

This relation is not quite as useful for a separate determination of equilibrium parameters as is the corresponding one for association-dissociation reactions [see eq. (2.3-3)], though the intercept in this case yields directly the rate constant k_S.

3.2. Coupled Reaction System: Sample-Indicator

The second limiting case to be discussed in this section is the use of an auxiliary system as indicator in the presence of finite concentrations of free B-particles ($c_I^0 \ll c_A^0, c_B^0$). The two stability constants:

$$K_A = \frac{c_{AB}}{c_A \cdot c_B} \quad \text{and} \quad K_I = \frac{c_{IB}}{c_I \cdot c_B} \tag{3.2-1}$$

now have to be distinguished explicitly.

Let us assume that any shift of extinction (or other detectable parameters) can be solely attributed to the indicator, so that—in analogy to our previous treatment outlined in Section 2.1—we have for the extinction ratios:

$$\frac{E - E_0}{E_\infty - E_0} \equiv \eta = \frac{c_{IB}}{c_I^0} \quad \text{or} \quad \frac{E_\infty - E}{E_\infty - E_0} \equiv (1-\eta) = \frac{c_I}{c_I^0} \tag{3.2-2}$$

The amount of uncomplexed B is then uniquely defined by the extinction ratio if K_I is known:

$$c_B = \frac{\eta}{1-\eta} K_I^{-1} \tag{3.2-3}$$

Any derivation of an explicit expression for c_{IB}, based on the conservation conditions

$$c_I^0 = c_I + c_{IB}; \quad c_A^0 = c_A + c_{AB}; \quad c_B^0 = c_B + c_{AB} + c_{IB} \tag{3.2-4}$$

would involve the solution of a cubic equation. However, with the help of relation (3.2-3) we can easily deduce an implicit form, correlating the extinction ratios with the overall concentrations, which for known K_I provides the value for the unknown K_A:

$$\frac{\eta}{1-\eta} + K_I(c_A^0 - c_B^0 + \eta c_I^0) = \frac{K_I^2}{K_A}\left(c_B^0 \frac{1-\eta}{\eta} - c_I^0(1-\eta)\right) - \frac{K_I}{K_A} \tag{3.2-5}$$

A straightforward procedure of substitution titration is to start with a given amount of I ($c_I^0 = \text{const}$) and add A and B in stoichiometric aliquots ($c_A^0 = c_B^0$). Assuming that the indicator concentration is small compared with K_I^{-1}, $c_I^0 \ll K_I^{-1}$, eq. (3.2-5) will reduce to the very convenient form

$$\frac{\eta}{1-\eta} = \frac{K_I^2}{K_A}\frac{1-\eta}{\eta} c_B^0 - \frac{K_I}{K_A} \tag{3.2-6}$$

A plot of the extinction ratio $\eta/(1-\eta)$ *versus* its reciprocal multiplied by c_B^0 will yield a straight line, having the following features:

slope: K_I^2/K_A
abscissa intercept: K_I^{-1} (3.2-7)
ordinate intercept: $-K_I/K_A$

An experimental example[11] is shown in Figure 9. Both K_A and K_I can be determined by this simplified procedure of substitution titration, which is somewhat analogous to the Hildebrand-Benesi method and represents an especially advantageous technique of complexometry.

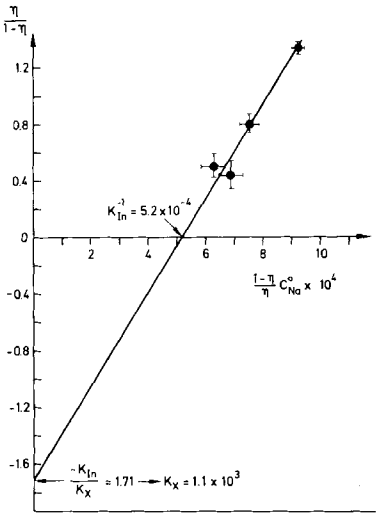


Fig. 9. Substitution titration method according to eq. (3.2-6) as applied to the complexation of dinactin (–) with Na^+ in methanol (data from Ref. [15b]). The obtained value for K is 1.1×10^3 M^{-1}.

It should be emphasized that the general principle of an indicator—a chemical tool of enormous practical importance—is based on the existence of relations such as (3.2-3), or (2.1-10) and (3.2-6). These show how a substance (I), whose physical properties allow the determination of its binding state with respect to a particular reaction partner, can be used in order to characterize the binding states of *any* other compound (A) with which it has this reaction partner (B) in common. Since the partner (B) is the link between the two equilibria, the detection of its concentration [*e.g.* with the help of the extinction ratio (2.2-3)] permits a decoupling of both mass action relations and hence reduces the problem of determining the binding state of the unknown compound (A) to an evaluation of simple mass balance equations (such as, *e.g.* $c_B^0 = c_B + c_{IB} + c_{AB}$).

In this respect an ideal indicator and an ideal buffer are complementary to each other. Both lead to an assignment of the coupling factor, the concentration of the common reaction partner B. The indicator, present at relatively low concentrations, does not fix c_B, but allows its measurement (eq. 3.2-3). The buffer, on the other hand, fixes c_B by its presence at very high concentration compared with that of any of the competitors.

The procedure just outlined applies equally well to an *evaluation of relaxation amplitudes.* Relaxation measurements have to be carried out in the absence and in the presence of the sample AB:

The corresponding implicit expressions are:

$$\delta c_{IB} = \Gamma_I(\delta \ln K_I) \tag{3.2-8}$$

$$\delta c_{IB}^{\pm} = \Gamma_I^{\pm}\left(\delta \ln K_I - \frac{\Gamma_A}{c_B}\delta \ln K_A\right) \tag{3.2-9}$$

where Γ_I, Γ_A and $\Gamma_I^{\pm}$ are defined as:

$$\Gamma_I = \frac{c_I \cdot c_B}{K_I^{-1} + c_B + c_I}; \quad \Gamma_A = \frac{c_A \cdot c_B}{K_A^{-1} + c_B + c_A} \tag{3.2-10}$$

$$\Gamma_I^{\pm} = \frac{c_I \cdot c_B}{K_I^{-1} + c_B + c_I\left(1 - \frac{\Gamma_A}{c_B}\right)} \tag{3.2-11}$$

Thus the A-system influences the amplitude δc_{IB} in two ways. One appears to be a buffering effect and hence shows up in $\Gamma_I^{\pm}$; the other reflects the finite shift of the AB-equilibrium due to a finite $\delta \ln K_A$ which, *via* the concentration change of B, is coupled with the indicator equilibrium. The buffering action is of especial importance, whenever A, AB, I and IB are in large excess of free B. This very case was treated in the first part of this section. Here we are concerned with the other case, where the indicator is present at small concentration, in particular $c_I \ll K_I^{-1} + c_B$ (c_B being controlled by the AB-system). Γ_I and $\Gamma_I^{\pm}$ then become identical, because the c_I-term is negligible, and the difference amplitude $\Delta(\delta c_{IB}) = \delta c_{IB}^{\pm} - \delta c_{IB}$ is simply given by:

$$\Delta(\delta c_{IB}) = -\frac{\Gamma_I \Gamma_A}{c_B}\delta \ln K_A \tag{3.2-12}$$

Γ_I is taken to be known, since it can be either calculated from K_I or detected independently in absence of the AB-system.

Γ_A/c_B for small c_I^0 is identical with the expression obtained for an uncoupled system:

$$\Gamma_A/c_B = \frac{c_A}{c_A + c_B + K_A^{-1}} = \frac{1}{2}\left[1 - \frac{1}{\sqrt{1 + \frac{4K_A^{-1} \cdot c_A^0}{(K_A^{-1} + c_B^0 - c_A^0)^2}}}\right] \tag{3.2-13}$$

or with the convenient assumption $c_A^0 = c_B^0$,

$$\Gamma_A/c_B = \frac{1}{2}\left[1 - \frac{1}{\sqrt{1 + 4K_A \cdot c_A^0}}\right] \tag{3.2-14}$$

This expression, of course, cannot be directly recorded. The quantity yielded by the experiment, according to eq. (3.2-12), is

$$f_{exp} = \frac{\Gamma_A}{c_B}\delta \ln K_A \tag{3.2-15}$$

where $\delta \ln K_A$ is given by $(\Delta H_A/RT)(\delta T/T)$ in case of a T-jump. There is a simple trick for evaluating the measured quantity f_{exp} (if one does not want to leave it completely to a computer).

We guess a value for $\delta \ln K_A$ (*e.g.* for ΔH_A) and then consider the factor

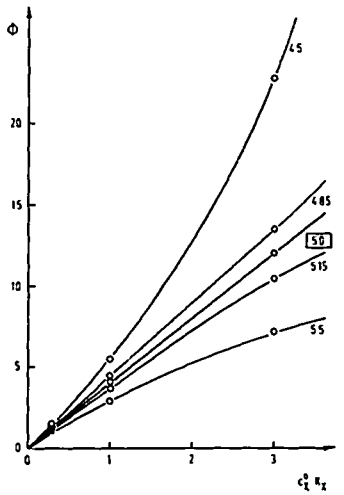
$$\frac{f_{exp}}{(\delta \ln K_A)_{guessed}} = f^* = \frac{1}{2}\left[1 - \frac{1}{\sqrt{1+4K_A \cdot c_A^0}}\right] \qquad (3.2\text{-}16)$$

which can be rearranged to:

$$\phi = (1-2f^*)^{-2} - 1 = 4K_A c_A^0 \qquad (3.2\text{-}17)$$

A plot of ϕ *versus* c_A^0 should yield a straight line with a slope of $4K_A$, if (and only if) we have guessed the correct value for $\delta \ln K_A$.

What happens if our guess was not correct is illustrated in Fig. 10. For excessively large values of $(\delta \ln K_A)_{guessed}$ all curves bend downwards, whereas for small values they bend upwards. Hence we have a *converging* method for iterative guesses which leads finally to the correct number for $\delta \ln K_A$ (i.e. ΔH_A or ΔV_A *etc.*) and also for K_A itself, resulting from the slope of the interpolated straight line.



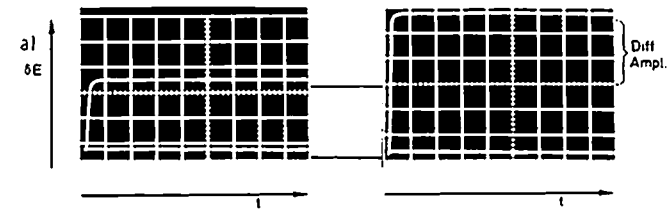


Fig. 10. Evaluation of stability constants and reaction enthalpies from relaxation amplitude-differences, using the substitution method described in the text. The function ϕ which is based on the experimental data, but contains also a guessed value for ΔH, is plotted *versus* the concentration c_X^0 (here given in reduced units: $c_X^0 K_X$). The numbers at the curves refer to the guessed ΔH values [kcal/mol].

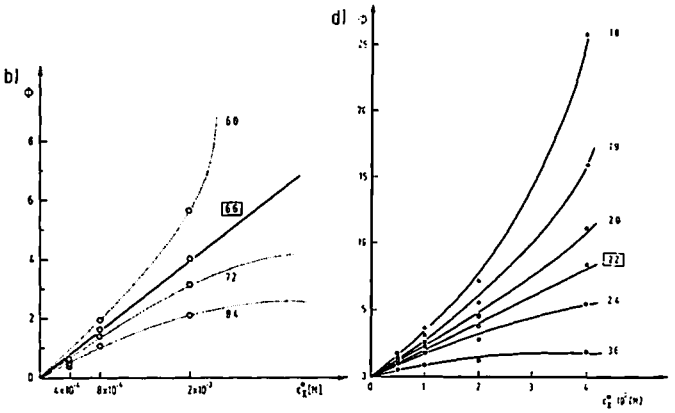
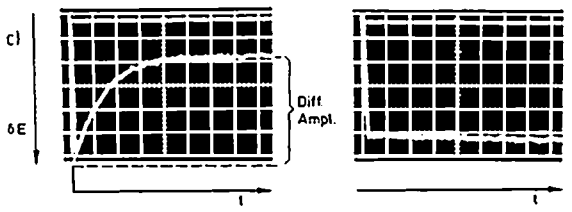
The curves converge into a straight line for the correct ΔH value of 5.0 kcal/mol. The slope of this line yields $4K_X$.



The example in Figure 10 shows how sensitive this method is with respect to a determination of ΔH. For the conventional van't Hoff plots one has to scan through a quite substantial temperature range in order to obtain comparably precise values for ΔH. Many compounds—especially enzymes which may undergo conformational changes or even denaturation—do not tolerate large temperature variations. The relaxation procedure described here works with a relatively small temperature shift δT (*e.g.* ≈ 5 to 10°C) around a suitable reference state.



How convenient both substitution methods are, may be seen from Figures 11a—d, where some experimental data resulting from studies of alkali metal complexes with antibiotics[11] and related substances[15a] are presented. Further applications are to be found in a joint paper with *P. B. Chock* and *F. Eggers*[15b].

With monactin:
$4 \cdot 10^{-5}$ M murexide
$2 \cdot 10^{-3}$ M monactin
$2 \cdot 10^{-3}$ M sodium (total)
$\delta E = 1.5 \times 10^{-3}$/large division
time base: 10 ms/large division

Without monactin:
4×10^{-5} M murexide
1.3×10^{-3} M sodium (total)
$\delta E = 1.5 \times 10^{-3}$/large division
time base: 10 ms/large division

With antamanide:
4×10^{-5} M murexide
1×10^{-3} M antamanide
1×10^{-3} M sodium (total)
$\delta E = 3.5 \times 10^{-4}$/large division
(compensated to 6.03×10^{-3})
$\tau = 2.3$ ms

Without antamanide:
4×10^{-5} M murexide
0.75×10^{-3} M sodium (total)
$\delta E = 3.7 \times 10^{-4}$/large division
(compensated to 6.34×10^{-3})

(Note, that the sensitivities of measurements for δE in both cases are somewhat different. The initial (fast) extinction changes are almost identical in both cases.)

Fig. 11. Experimental data exemplifying the amplitude substitution method.

a) and c) relaxation oscillograms of the Na^+-monactin [1] and Na^+-antamanide [15a] systems in methanol under the specified conditions. The amplitudes in the presence and in the absence of monactin or antamanide, respectively, are measured under exactly equal concentrations of free sodium ions and indicator (murexide).

b) and d) show the evaluation according to the method described in Fig. 10. The resulting values are at $T = 293$ °K.

Na^+-monactin: $K = 5 \times 10^2\ M^{-1}$ $\Delta H = -6.6$ kcal/mol
Na^+-antamanide: $K = 5 \times 10^2\ M^{-1}$ $\Delta H = -2.2$ kcal/mol

4. Multiple Step Systems

The theoretical considerations as well as the practical procedures discussed above lead to some generalizations. We have already mentioned that it is not the aim of this paper to deal with general theoretical aspects of the dynamics of

complex reaction systems near equilibrium. The linear algebra required for the solution of this problem is well known[5, 16]. In the present paper we want to discuss primarily the application of dynamical methods to analytical chemistry. The desired information about the properties of an individual complex reaction system can only result from a detailed analysis of the particular mechanism involved.

Three cases of more general interest for complexometry will be treated in this section.

1. Two reaction partners are specified which form a complex:

$$A + B \rightleftharpoons AB$$

Each of the two partners is further involved in a series of binding steps with auxiliary systems. We may, for instance, consider a typical problem of complexometric titration. A metal ion (or general electrophile) in buffered solution is titrated with a ligand which exists in various protonated forms. The buffer also binds to the metal ion, in various proportions, and simultaneously controls the pH of the system.

2. A center A binds a certain number of ligands B:

$$A + B \rightleftharpoons AB;\ AB + B \rightleftharpoons AB_2;\ldots;AB_{n-1} + B \rightleftharpoons AB_n$$

Under such particular conditions a sequential binding process can be characterized by one equilibrium parameter, as follows:

2a) The intrinsic binding constant for each step is degenerate:

$$K_1 = K;\quad K_2 = 2K;\ldots;K_n = nK$$

An example is provided by an allosteric enzyme which consists of several identical subunits, each of which can independently bind a substrate.

2b) The intermediates (AB_i for $1 \leq i < n$) have a low stability and hence are present at a very low concentration. The overall process can then treated as if it were one single step:

$$A + nB \rightleftharpoons AB_n$$

2c) The individual steps differ so strongly in their binding constants that for any given concentration range of B, one complex is always present in large excess. If the mid-points of those transitions can be reached at finite concentrations of uncomplexed B, we have just a series of separate steps of binary complex formation *e.g.*

$$AB_{k-1} + B \rightleftharpoons AB_k$$

as have been discussed in Section 2.

If, alternatively, the stability of all steps is so high that the concentrations of free ligand particles B is small compared with the complex concentrations, the particular reaction may be written as a disproportionation:

$$AB_{k-1} + AB_{k+1} \rightleftharpoons 2AB_k$$

3. The complex-forming agent A is assumed to be involved in several competitive 1 : 1 association reactions with different ligands X, Y, Z. Significant examples are the ternary systems: {sample, buffer, indicator} or {sample 1, competing sample 2, indicator}.

In fact, most other cases of general multiple complex formations may be reduced to any one of these principal mechanisms.

4.1. Complexometric Titration

This Section heading resembles the title of *Gerold Schwarzenbach*'s famous monograph[17], in which the prototype of a multiple step complexation reaction was considered. Adopting *Schwarzenbach*'s notation we call the metal ion $M^{+\nu}$, the ligand used for titration $Y^{-\mu}$, and the auxiliary complex partner L. The latter may be the buffer providing constant pH, which must naturally be in sufficient excess. All changes associated with the ML- and HY-equilibria have to occur rapidly in comparison with the complexation reaction M + Y under study. Examples outlined by *Schwarzenbach* include various di- and trivalent metal ions, the complex partner ethylenediaminetetraacetic acid, and the auxiliary buffer system NH_3. One may determine the concentration of MY spectroscopically if Y shows detectable optical or electrical properties. Otherwise an additional system may be added as indicator, which has to be present at appropriately low concentration, in order not to interfere with any of the conservation relations. The indicator, furthermore, has to react rapidly in comparison with the sample. If these conditions are not fulfilled, the indicator must be treated as an additional reaction partner, as set out in Section 4.2 or 4.3.

Taking into account the two chains of equilibria

$$M + L \rightleftharpoons ML,\ldots,\ ML_{n-1} + L \rightleftharpoons ML_n \tag{4.1-1}$$

and

$$Y + H \rightleftharpoons YH,\ldots,\ YH_{m-1} + H \rightleftharpoons YH_m \tag{4.1-2}$$

we define the apparent concentrations:

$$\begin{aligned} c'_M &= c_M + c_{ML} + \cdots + c_{ML_n} \\ &= c_M(1 + K_1 c_L + K_2 c_L^2 + \cdots + K_n c_L^n) \equiv \beta_L c_M \end{aligned} \tag{4.1-3}$$

where β_L is a constant at fixed c_L^0 (for a large excess of L).

Likewise

$$\begin{aligned} c'_Y &= c_Y + c_{YH} + \cdots + c_{YH_m} \\ &= c_Y(1 + K_1 c_H + K_2 c_H^2 + \cdots + K_m c_H^m) \equiv \alpha_H c_Y \end{aligned} \tag{4.1-4}$$

with α_H being a constant at given pH (*i.e.* in a buffered solution). Then for the complex formation between M and Y we have:

$$K_{MY}^{App} = \frac{c_{MY}}{c'_M \cdot c'_Y} = \frac{c_{MY}}{c_M \cdot c_Y} \cdot \frac{1}{\alpha_H \beta_L} = \frac{K_{MY}}{\alpha_H \beta_L} \tag{4.1-5}$$

The conservation relations

$$c_M^0 = c_{MY} + c'_M \text{ und } c_Y^0 = c_{MY} + c'_Y \tag{4.1-6}$$

contain the missing link for an explicit solution in terms of the titration function, which—as was described in Section 2—follows from a quadratic equation:

$$\frac{c_{MY}}{(c_M^0 - c_{MY})(c_Y^0 - c_{MY})} = \frac{K_{MY}}{\alpha_H \beta_L} \qquad (4.1\text{-}7)$$

The solution has precisely the form of T_b introduced in Table 1. The constant $K = K_{MY}/\alpha_H\beta_L$ is now—with the help of α_H and β_L—an adjustable quantity. In a similar way all the other expressions, such as T_b'', Γ_b and τ_b can be derived from the solution of eq. (4.1-7). Details are to be found in Section 2.1 to 2.3. Applications of the titration function T_b were discussed by *Schwarzenbach*[17].

4.2. Sequential Complex Formation and Ligand Exchange

Three limiting cases have been distinguished in the introduction to Section 4. The first two are: 2a) *degeneracy* of intrinsic binding parameters for homotropic sites, and 2b) *all-or-none* binding at multiple sites—possibly mediated by concerted conformational changes. These are typical for multi-subunit protein molecules. The classical titration procedures, such as the well-known methods of *Bjerrum*[18], *Scatchard*[19] and others (as detailed in the monograph by *Edsall* and *Wyman*[4]) easily yield the number of binding sites per molecule (for a survey of plots cf. Figure 12). In a similar way the relaxation

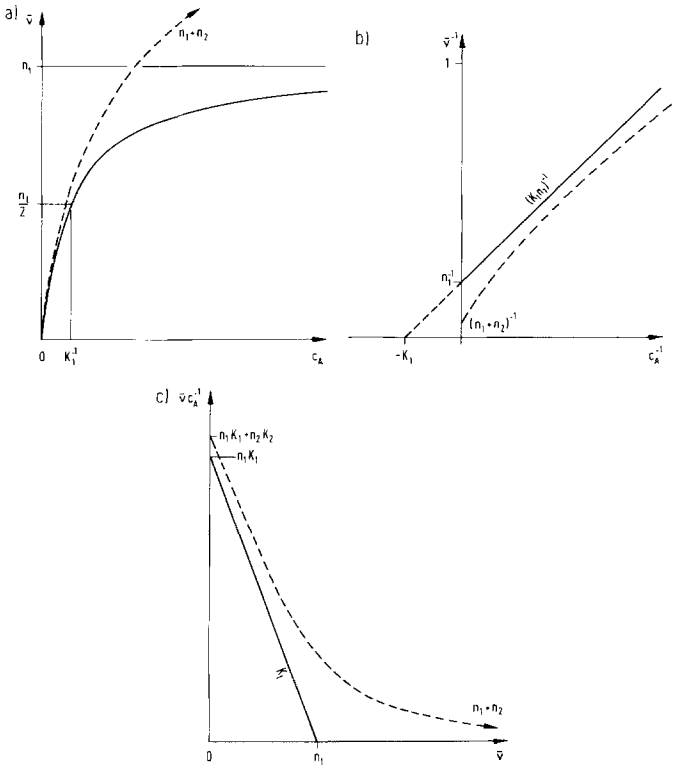


Figure 12. Conventional plots of binding functions in the presence of several groups of equivalent binding sites. The full line refers to appearance of only one group of n_1 equivalent sites, while the broken line indicates the presence of two groups with n_1 and n_2 sites, respectively, having binding constants K_1 and K_2 ($<K_1$). Data taken from *Edsall* and *Wyman* [4]. a) correspond to the Michaelis-Menten plot and b) to the Linewaver-Burk plot (see Fig. 2). c) is named after *Scatchard* [19].
For a) the following relation holds $\bar{\nu} = \sum n_i c_A/(K_i^{-1} + c_A)$; n_i = number of equivalent binding sites of sort i, K_i = respective binding constant and c_A = (free) ligand concentration. In the case b) the relations are: $1/\bar{\nu} = [(1/n_1) + (1/K_1 n_1 c_A)]f_{12}$ with

$$f_{12} = \frac{n_1 K_1 (1 + K_2 c_A)}{n_1 K_1 + n_2 K_2 + (n_1 + n_2) K_1 K_2 c_A}, \quad (f_{12} = 1 \text{ for } K_2 = 0)$$

and for c) $\bar{\nu}/c_A = K_1[(n_1/f_{12}) - \bar{\nu}]$.

Table 4. Relations for general ligand exchange

$n-1 \le q_a \le n+1$	$n-1 \le \frac{1}{q_b} \le n+1$
$0 \le \sin\alpha \le \sqrt{1-4p_a}$	$0 \le \sin\alpha \le \sqrt{1-4p_b}$
or $0 \le \tan\frac{\alpha}{2} \le \frac{1-2\sqrt{p_a}}{\sqrt{1-4p_a}}$	or $0 \le \tan\frac{\alpha}{2} \le \frac{1-2\sqrt{p_b}}{\sqrt{1-4p_b}}$

a)
$$\begin{cases} T_a = \dfrac{1}{1-4p_a}\left\{1-\sqrt{1-(1-4p_a)[1-(q_a-n)^2]}\right\} \\ T_a = \dfrac{1}{1-4p_a}\cdot\dfrac{2\tan^2\left(\frac{\alpha}{2}\right)}{1+\tan^2\left(\frac{\alpha}{2}\right)} \end{cases}$$

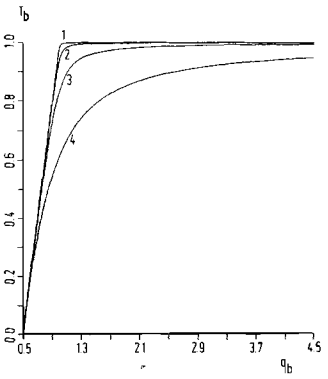
$$T_a' = -\frac{q_a - n}{\sqrt{1-(1-4p_a)[1-(q_a-n)^2]}}$$

$$T_a'' = -4p_a\left[\frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}\right]^3$$

$$\Gamma_a = p_a T_a^2 \tau_a = \frac{4p_a}{(1-4p_a)^2}\cdot\frac{\tan^4\left(\frac{\alpha}{2}\right)}{1-\tan^4\left(\frac{\alpha}{2}\right)}$$

$$\tau_a = 1-(1-4p_b)[1-(q_a-n)^2]^{-1/2} \qquad \tau_a = \frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$$

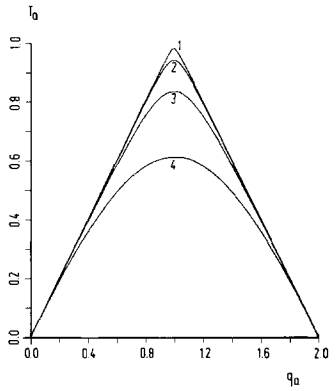
b)
$$\begin{cases} T_b = \dfrac{q_b}{1-4p_b}\left\{1-\sqrt{1-(1-4p_b)\left[1-\left(\frac{1}{q_b}-n\right)^2\right]}\right\} \\ \dfrac{T_b}{q_b} = \dfrac{1}{1-4p_b}\cdot\dfrac{2\tan^2\left(\frac{\alpha}{2}\right)}{1+\tan^2\left(\frac{\alpha}{2}\right)} \end{cases}$$



$$q_b T_b' = -\left[\frac{\left(\frac{1}{q_b}-n\right)}{\sqrt{1-(1-4p_b)\left[1-\left(\frac{1}{q_b}-n\right)^2\right]}} - T_b\right]$$

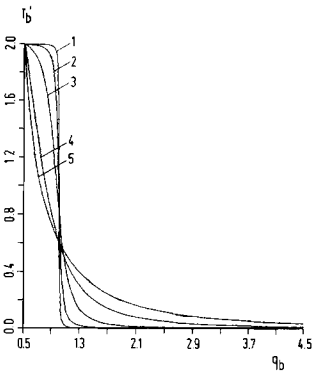
[*] For $4p_a > 1$, substitution of hyperbolic functions analogous to Table 3

$$q_b^3 T_b'' = -4 p_b \left[\frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)} \right]^3$$

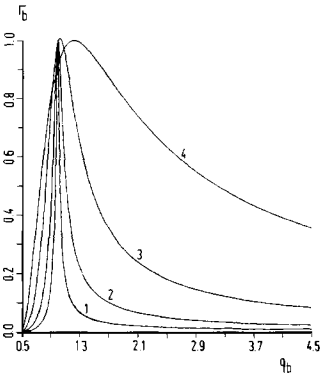


$$\frac{\Gamma_b}{q_b} = \frac{p_b (T_b/q_b)^2}{\sqrt{1-(1-4p_b)\left[1-\left(\frac{1}{q_b}-n\right)^2\right]}} = \frac{4p_b}{(1-4p_b)^2} \frac{\tan\psi\left(\frac{\alpha}{2}\right)}{\left(1-\tan^4\left(\frac{\alpha}{2}\right)\right)}$$

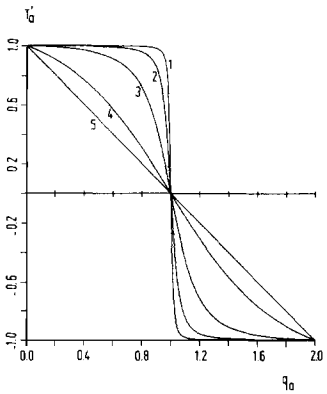
$$\tau_b q_b = \frac{1+\tan^2\left(\frac{\alpha}{2}\right)}{1-\tan^2\left(\frac{\alpha}{2}\right)}$$

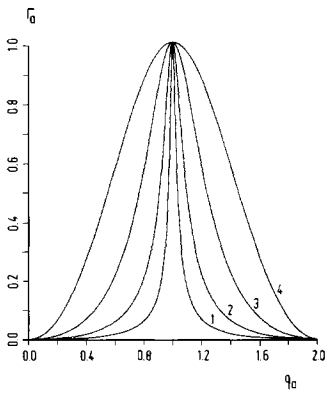


For the case n = 1 the parameters are:

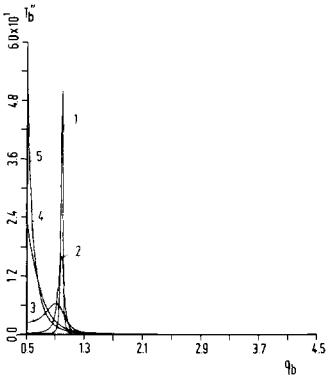


curve 1: $p_b = 1 \times 10^{-4}$
2: $p_b = 1 \times 10^{-3}$
3: $p_b = 1 \times 10^{-2}$
4: $p_b = 1 \times 10^{-1}$
5: $p_b = 2.5 \times 10^{-1}$

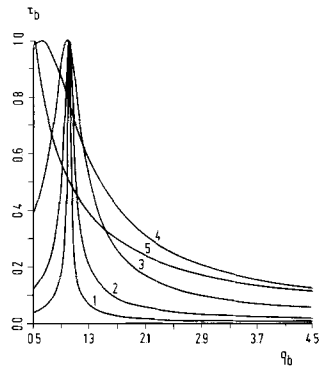


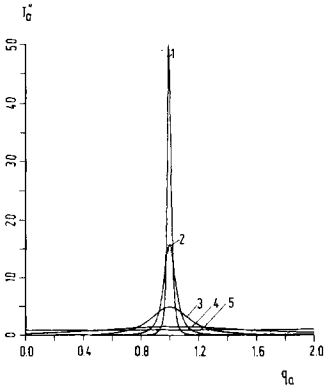


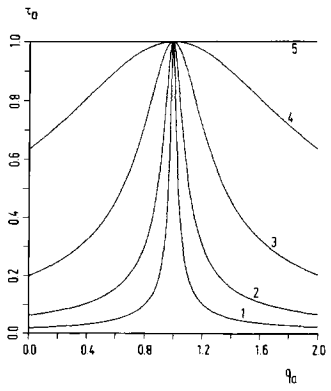
For the case n = 1 the parameters are:

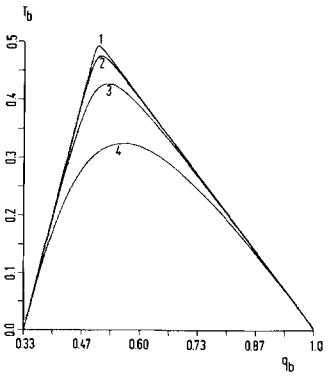


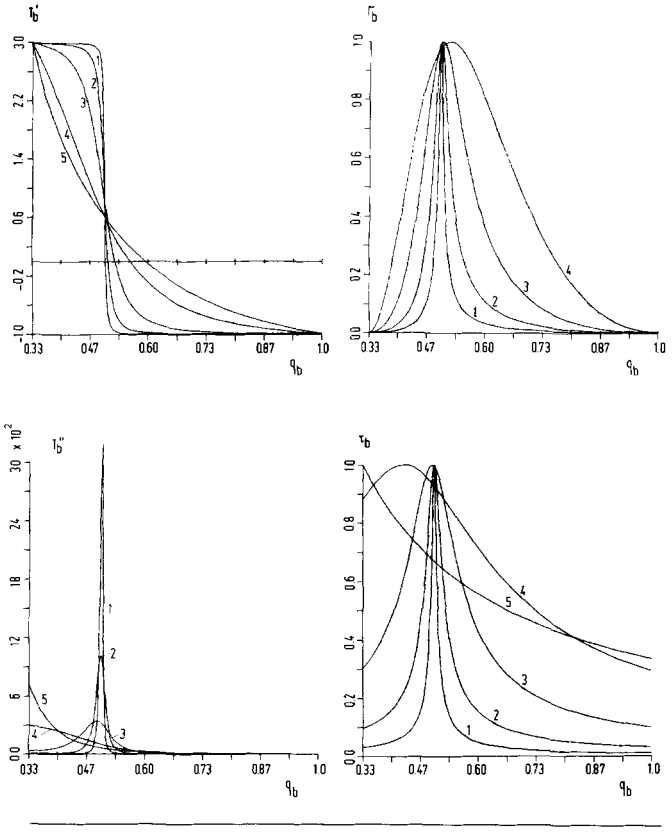
curve 1: $p_a = 1 \times 10^{-4}$
2: $p_a = 1 \times 10^{-3}$
3: $p_a = 1 \times 10^{-2}$
4: $p_a = 1 \times 10^{-1}$
5: $p_a = 2.5 \times 10^{-1}$











For the case n = 2 the parameters are:

curve 1: $p_b = 1 \times 10^{-4}$
2: $p_b = 1 \times 10^{-3}$
3: $p_b = 1 \times 10^{-2}$
4: $p_b = 1 \times 10^{-1}$
5: $p_b = 2.5 \times 10^{-1}$

parameters can be evaluated, using the principles outlined in Table 1. For n equivalent sites per molecule the term c_B^0 has simply to be replaced by $n c_B^0$, shifting the maxima for Γ_a, Γ_b, τ_a, T_a'' to the equivalence points:

a) $c_A^0 + n c_B^0 = 0.5$

and

b) $c_A^0 = n c_B^0 + K^{-1}$

and for τ_b and T_b'' to $c_A^0 = n c_B^0 - K^{-1}$.

Any deviation from the standard curve shapes, *e.g.* dissymmetries, will indicate the presence of nonequivalent binding sites. There will be as many relaxation times as groups of nonequivalent sites. If they are independent of each other, the evaluation is straightforward (cf. Table 4). An example of an enzyme with (at least) two independent nonequivalent groups, each containing 6 degenerate sites, is provided by glutamic dehydrogenase[20]).

The more complex relations for the relaxation parameters of systems with nonequivalent and interacting sites—including some common models for allosteric enzymes[21, 22]—will be discussed in a forthcoming paper[23].

True cooperativity is mainly confined to macromolecular species, such as proteins, nucleic acids or membrane vesicles. In fact, for most other sequential binding processes involving polyfunctional entities of lower molecular weight just the opposite is true. One might call their behavior "negatively cooperative". It is the first ligand which, in general, is most strongly bound, while with increasing number of ligands one finds a gradual decrease of binding strength. Exceptions to this rule usually involve a more complex mechanism. For instance, the two phenolic protons in phenolphthalein have identical pK's (*i.e.* dissociate in the same pH range) as a consequence of the superimposed quinone-lactone transformation.

If the binding constants of individual groups differ sufficiently one may treat each step separately as outlined in Section 2. Difficulties appear if all binding constants are high, so that all sites are (almost) saturated, which means that their concentrations are in large excess of the free ligand concentration. The essential process at any given stage then has to be formulated as a ligand exchange reaction:

$$AB_{n-1} + AB_{n+1} \underset{k_{-n}}{\overset{k_n}{\rightleftharpoons}} 2\,AB_n \qquad (4.2\text{-}1)$$

The explicit expressions of all functions (T_b and its higher derivatives, Γ_b and τ_b) with respect to the titration variable are very similar to those given in Section 2, and especially in Table 2, although minor modifications show up due to the n-fold appearance of B in AB_n.

The equilibrium constant is defined as

$$K = \frac{c_{n-1} \cdot c_{n+1}}{c_n^2} = \frac{k_{-n}}{k_n} \qquad (4.2\text{-}2)$$

The indices n−1, n and n+1 refer to the species AB_{n-1}, AB_n and AB_{n+1}, respectively. The conservation conditions read:

(4.2-3)

$$c_A^0 \approx c_{n-1} + c_n + c_{n+1}; \qquad 2c_{n+1} = c_A^0 + c_B^0 - n c_A^0 - c_n$$

$$c_B^0 \approx (n-1)c_{n-1} + n c_n + (n+1)c_{n+1}; \quad 2c_{n-1} = c_A^0 - c_B^0 + n c_A^0 - c_n$$

The explicit expression for c_n can then be obtained as the solution of a quadratic equation

$$c_n = \frac{c_A^0}{1-4K}\left\{1 - \sqrt{1-(1-4K)(1-[(c_A^0/c_B^0)-n]^2)}\right\} \qquad (4.2\text{-}4)$$

The most convenient and simple procedure is to maintain the overall concentration of the complex forming agent c_A^0 and to vary c_B^0, which has to be present in about n-fold excess of c_A^0. The constancy of the c_A^0 factor in the prebracket-term leads to very symmetrical relations for $T_a \equiv c_n/c_A^0$, $\Gamma_a = \Gamma/c_A^0$ and $\tau_a = \tau k_n c_A^0$ [analogous to case a) quoted in Tables 1 and 3] which are easy to handle. However, mathematical convenience is not always identical with practical applicability. If the complexes are very strong, and the strength decreases with increasing n, it may be preferable to add aliquots of A to the B-sample, where c_B^0 = const. The highest stages AB_n will then be populated immediately, as long as B is still in (more than) n-fold excess. But as soon as c_A^0 becomes larger than c_B^0/n, there will be a competition for the ligands according to the scheme (4.2-1). This competition will shift steadily to lower n-values with increasing c_A^0. Here we refer to the fixed concentration c_B^0 defining: $T_b \equiv c_n/c_B^0$, $\Gamma_{nb} = \Gamma_n/c_B^0$ *etc.*

The results for both treatments are compiled in Table 4. Their correspondence with the expressions listed in Tables 1 and 3 is most obvious if the trigonometric form of representation is chosen.

Amplitude recording (*i.e.* Γ or T'') offers exciting new opportunities for complexometry, especially for sequential ligand

binding. Using the titration variable q_a in the range from (below) 1/n to (above) 1 means scanning through a number of well defined sharp peaks, each being characteristic of one of the n steps of ligand binding. The search for a method yielding singularities pays off particularly where a series of ligand binding processes shows up in a narrow range of concentration variation, and where ordinary binding curves just exhibit a more or less broad transition.

To illustrate the usefulness of the dynamic techniques let us consider two examples of multiple step titration.

The first case is that of complex formation involving the substitution of solvent by two ligands in the inner coordination sphere of a metal ion.

$$M + 2L \rightleftarrows ML + L \rightleftarrows ML_2 \qquad (4.2\text{-}5)$$

If the individual stability constants are so high that at the lowest detectable level of ligand concentration both complexes are already formed, it is advisable to apply method b), *i.e.* to fix c_L^0 and titrate with the metal ion. If Γ or T_b' is recorded for $c_M^0 \approx c_L^0/2$, a maximum appears, which is due to the formation of ML_2. This maximum vanishes when c_M^0 becomes larger than $c_L^0/2$, but soon a second peak shows up caused by the—now dominating—exchange reaction (4.2-1) which, of course, is only present if the binding strength for the first ligand is higher than that for the second one. Figure 13 illustrates

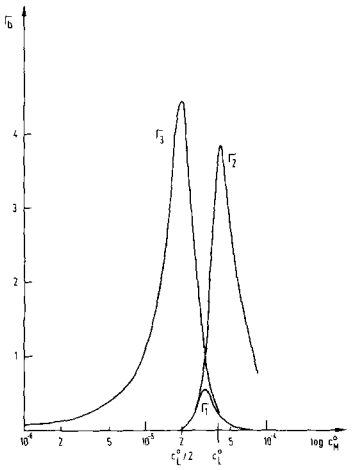


Fig. 13. Reduced amplitude factor for a two step dissociation process according to eq. (4.2-5). The two sharp maxima are responsible for the two processes:

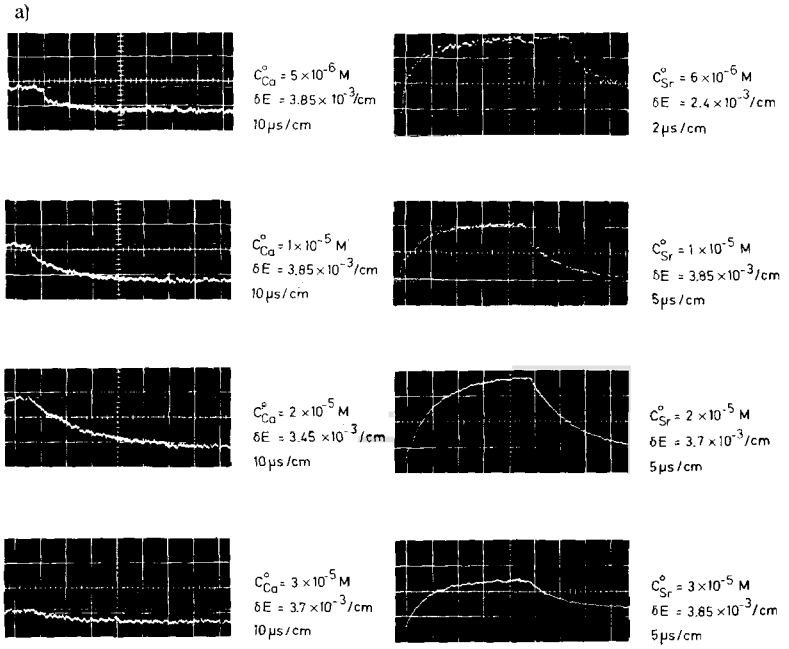
1) $L + ML \rightleftarrows ML_2$
2) $ML_2 + M \rightleftarrows 2ML$

The parameters for the scheme



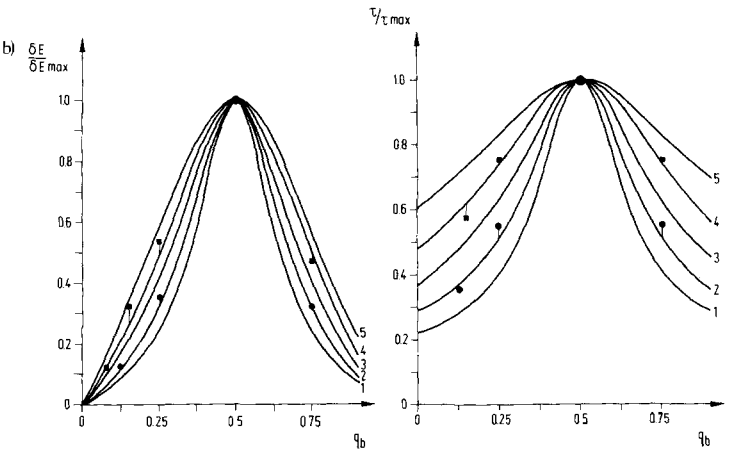
$$M + 2L \underset{}{\overset{K_1}{\rightleftharpoons}} ML + L \overset{K_2}{\rightleftharpoons} ML_2$$

$$ML_2 + M \underset{K_3}{\rightleftharpoons} 2ML \underset{K_4}{\rightleftharpoons} 2M + 2L$$

are:

$K_1 = 10^8\ M^{-1}$
$K_2 = 10^6\ M^{-1}$
$c_L^0 = 4 \times 10^{-5}\ M$

this type of behavior for Γ_b. The sensitivity expressed by the sharpness of peaks is striking. Experimental recordings of this kind have been obtained with the murexide-complexes of Ca^{2+} and Sr^{2+} in methanol[11]. Both relaxation amplitudes and time constants could be determined by electric field-pulse and temperature-jump measurements. Examples of oscillograms and their interpretation are shown in Figure 14.



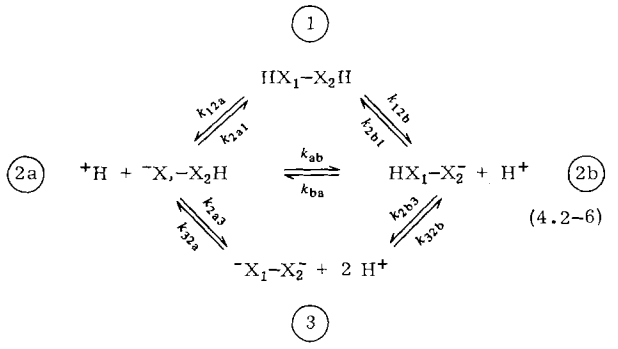


Fig. 14. Relaxation curves from electric field pulse measurements for the systems Ca-murexide and Sr-murexide in methanol. The data refer to the step $ML + L \rightleftarrows ML_2$. The maxima of Γ and τ occur at $c_M^0 = \frac{1}{2} c_L^0$. A second (slower) relaxation effect occurring at higher concentrations of M refers to the step $ML_2 + M \rightleftarrows 2ML$.

a) Oscillograms.

b) Normalized plots for $\Gamma(E)$ and τ. The evaluation of the data yields for Ca: $K_2 = 5\times10^5\ M^{-1}$ and for Sr: $K_2 = 1.5\times10^5\ M^{-1}$. c_M^0 refers to the total concentration of the metal ion. c_L^0 for both series was fixed at 4×10^{-5} M. 1–5 refers to: 1) 1.0×10^6, 2) 5.6×10^5, 3) 3.1×10^5, 4) 1.8×10^5, and 5) 1.0×10^5.

Only if saturation of M with L occurs in distinct concentration ranges of L, with $c_L^0 \gg c_M^0$ for both steps, may one scan through those ranges at constant c_M^0 and monitor the signals characteristic of the individual steps of complex formation according to scheme (4.2-5). Evaluation in this case would simply follow the procedure of Section 2.

The second example is concerned with the titration of a dibasic acid. So far only little reference has been made in this paper to pH-titration, since straightforward procedures using suitable buffers throughout the pH-scale are usually

(4.2-6)

available. The case of polybasic acids, however, involves a problem, which has not yet found a completely satisfactory solution. It is the problem of the so-called "microscopic" dissociation constants[4]. What is meant by these constants, can immediately be seen from the reaction scheme (4.2-6).

The two pK-values resulting from titration refer to the overall equilibra (1)–(2a)–(2b) and (3)–(2a)–(2b).

$$\frac{c_{HX_1-X_2H}}{c_H \cdot (c_{X_1-X_2H} + c_{HX_1-X_2})} = K_1 \text{; and } \frac{c_{X_1-X_2H} + c_{HX_1-X_2}}{c_H \cdot c_{X_1-X_2}} = K_2 \qquad (4.2\text{-}7)$$

These pK-values may differ by orders of magnitude, but this fact does not necessarily imply that the intrinsic pK's of the individual groups X_1 and X_2 are greatly dissimilar. Strongly differing pK-values are also found for identical groups X_1 and X_2, and are due to neighboring group effects attributed to a change of the state of ionization. In order to have access to the true or "microscopic" constants, one needs to know—in addition to pK_1 and pK_2—the constant of the isomerization equilibrium (2a)⇌(2b). A straightforward assignment would require an experimental identification of the two states (2a) and (2b), *e.g.* by spectroscopy. Usually, this is very difficult and often involves certain more or less valid assumptions concerning spectral or other analogies with similar (*e.g.* methylated) compounds. Because of the rapid interconversion between states (2a) and (2b), it is impossible to quench the exchange and titrate one of the states separately using a specific reaction.

With the help of the dynamic method, we can in principle identify the isomerization step in the relaxation spectrum, In other words: there is a time constant in the spectrum which in the right pH range refers directly to the first-order conversion (2a)⇌(2b). Unfortunately, first-order steps yield concentration-independent time constants and amplitudes[5], and there is no straightforward way (other than by using analogies), either of evaluating the measured relaxation time in terms of both rate constants, or of splitting the relaxation amplitude into the unknown quantities: equilibrium constant, reaction enthalpy or volume and recording parameter (such as difference of extinction coefficients for the state (2a) and (2b)). Thus here again is an interpretation only possible under simplifying assumptions.

One way out of the difficulty could be to record carefully the whole relaxation spectrum and evaluate the concentration dependences of time constants and amplitudes. The reaction scheme under appropriate pH-conditions may be reduced to one of the triangles (low pH: (1)–(2a)–(2b); high pH: (2a)–(2b)–(3)). However, this method also has its difficulties, since protolytic reactions are generally diffusion-controlled, *i.e.* fast and not readily discernible in their rate (so that steps (1)–(2a), and (1)–(2b), or (2a)–(3) and (2b)–(3) cannot directly be discriminated).

A more elegant solution of the problem is offered by a little trick. Starting from situations where the states (2a) and (2b) predominate, one adds a specific reaction partner which interacts with only one of the states a or b (for example, for $HS-R-NH_2$ a specific SH-reagent). This interaction, of course, must *not* be an irreversible one, nor should it be slow as compared with the first-order reaction. In other words, the auxiliary system must not remove one of the states, but rather equilibrate quickly and hence couple with the isomerization a⇌b. For such a system, the relations derived in Table 4b apply. The evaluation of data requires nothing but the knowledge of measurable quantities (*e.g.* two relaxation times and the weighed-in concentrations of the sample as well as that of the auxiliary system). In fact, the addition of sulfite to 4-pyridinecarbaldehyde, discussed earlier, belongs to this category of reactions. In Section 2.4 we were only concerned with the—fast and hence separately occurring—second-order step. The terms for the slow first-order hydration reaction in presence of sulfite now in fact contain concentration dependent factors so that all rate and equilibrium parameters could be assigned. Although these slow hydration processes can be studied by other means, the example demonstrates a very useful application—especially for biochemistry.

4.3. Ternary Systems

In relaxation studies a sample has to fulfill two requirements: firstly, it has to respond to the enforced change of an intensive parameter (T, P, E), and secondly, it must provide a suitable signal for recording the shift of equilibrium. The extent of perturbation depends on the magnitude of the reaction parameters, such as enthalpy (ΔH) or volume of reaction (ΔV). If those parameters for a given sample are too small one may still enforce an equilibrium perturbation *via* an auxiliary system which possesses typical buffer properties and is more sensitive to the external force. This principle may be of special importance in the application of strong electric fields in perturbation methods. A measurable dissociation field effect is present only if both reaction partners carry excess charges. Metal complexes with neutral ligands do not fulfill this condition. However, "secondary" field effects can be induced with the help of competing charged ligands which buffer the concentration of free metal ions and hence influence their interaction with the neutral reaction partner.

Binary equilibria have already been discussed in detail in Section 3, but under certain circumstances there may be a demand for two auxiliary systems, a buffer *and* an indicator. A generalization of this procedure is therefore of common interest and will be given explicitly for two kinds of ternary systems. An example in Appendix 2, furthermore, will demonstrate how to generalize the treatment for any number of reaction partners—metal ions or ligands—by iteration.

4.3.1. Sample, Buffer, Indicator

Let three different types of ligands, X, Y and Z, compete for the same metal ion M. Intentionally it is not yet specified, which of the three substances represents the sample, the buffer or the indicator, in order to keep the treatment as general as possible. Later on, of course, it is necessary to identify the properties of each of the three compounds, since they fulfill their particular role only under selected conditions of concentration. For the corresponding equilibria:

$$\begin{array}{l} M+X \rightleftharpoons MX \\ M+Y \rightleftharpoons MY \\ M+Z \rightleftharpoons MZ \end{array} \qquad (4.3\text{-}1)$$

the following mass action relations hold:

$$\frac{c_{MX}}{c_M c_X} = K_X; \quad \frac{c_{MY}}{c_M c_Y} = K_Y; \quad \frac{c_{MZ}}{c_M c_Z} = K_Z \qquad (4.3\text{-}2)$$

to which are attributed the amplitude factors:

$$\Gamma_X = \frac{c_M c_X}{K_X^{-1} + c_M + c_X}; \Gamma_Y = \frac{c_M c_Y}{K_Y^{-1} + c_M + c_Y}; \Gamma_Z = \frac{c_M c_Z}{K_Z^{-1} + c_M + c_Z} \qquad (4.3\text{-}3)$$

Assuming that only one system, the indicator, shows detectable changes upon complex formation, its concentration shift is the quantity monitored. In absence of X and Y this shift is given by:

$$\delta c_{MZ} = \Gamma_Z \delta \ln K_Z \qquad (4.3\text{-}4)$$

In Section 3.2 it has been shown that the presence of the X-system will modify the recorded signal to:

$$\delta c_{MZ}^{\pm} = \Gamma_Z^{\pm} \left(\delta \ln K_Z - \frac{\Gamma_X}{c_M} \delta \ln K_X \right) \qquad (4.3\text{-}5)$$

where

$$\Gamma_Z^{\pm} = \frac{c_M c_Z}{K_Z^{-1} + c_M + c_Z(1-\Gamma_X/c_M)} = \Gamma_Z \frac{1}{1-\Gamma_Z \Gamma_X / c_M^2} \qquad (4.3\text{-}6)$$

If the Y-system is also included, an expression symmetrical with respect to the parameters of X and Y is obtained:

$$\delta c_{MZ}^{\pm\pm} = \frac{\Gamma_Z}{1-\Gamma_Z \Gamma_{XY}/c_M^2} \left\{ \delta \ln K_Z - \frac{\Gamma_X/c_M(1-\Gamma_Y/c_M)}{1-\Gamma_X\Gamma_Y/c_M^2} \delta \ln K_X - \frac{\Gamma_Y/c_M(1-\Gamma_X/c_M)}{1-\Gamma_X\Gamma_Y/c_M^2} \delta \ln K_Y \right\} \qquad (4.3\text{-}7)$$

with

$$\Gamma_{XY} = \frac{\Gamma_X + \Gamma_Y - 2\Gamma_X\Gamma_Y/c_M}{1-\Gamma_X\Gamma_Y/c_M^2} \qquad (4.3\text{-}8)$$

Since the indicator Z is the only substance contributing a finite signal for detection, c_M is given by $K_Z^{-1} \cdot \eta/(1-\eta)$, where $\eta/(1-\eta)$ is the extinction ratio $(E-E_0)/(E_\infty - E)$ introduced in Section 2.1. For a perturbation brought about by a T-jump, we have:

$$\delta c_{MZ}^{\pm\pm} = \frac{\Gamma_Z}{1-\Gamma_Z\Gamma_{XY}/c_M^2} \left\{ \Delta H_Z - \frac{(\Delta H_X \Gamma_X + \Delta H_Y \Gamma_Y)/c_M - (\Delta H_X + \Delta H_Y)\Gamma_X\Gamma_Y/c_M^2}{1-\Gamma_X\Gamma_Y/c_M^2} \right\} \frac{\delta T}{RT^2} \qquad (4.3\text{-}9)$$

So far no particular discrimination between X and Y has been made. We see that even if one of the reaction enthalpies happens to be zero, the influence of a secondary shift still allows both systems to contribute to the amplitude. Complete buffering of M by the X- as well as by the Y-system means:

$$c_X, c_{MX}, c_Y, c_{MY} \gg c_M \qquad (4.3\text{-}10)$$

or explicitly

$$c_X \gg c_M + K_X^{-1}; \quad c_Y \gg c_M + K_Y^{-1} \qquad (4.3\text{-}11)$$

$$\Gamma_X \simeq \Gamma_Y \simeq c_M; \quad \Gamma_{XY} \simeq 1 \qquad (4.3\text{-}12)$$

The response depends on the relative strength of the two buffering effects, represented by the magnitude of the ratio

$$\frac{c_i}{c_M + K_i^{-1}} \gg 1 \qquad (4.3\text{-}13)$$

where i refers either to X or Y. If one buffer (i) is much stronger than the other, eq. (4.3-7) simplifies to:

$$\delta c_{MZ}^{\pm\pm} = \frac{c_M c_Z}{c_M + K_Z^{-1}} (\delta \ln K_Z + \delta \ln K_i) \qquad (4.3\text{-}14)$$

The properties of the competitor of i cannot then be recorded any more. If, on the other hand, X and Y exhibit identical buffering behavior, then—independent of their absolute strengths—they both contribute to the amplitude:

$$\delta c_{MZ}^{\pm\pm} = \frac{c_M c_Z}{c_M + K_Z^{-1}} (\delta \ln K_Z + \frac{1}{2} \delta \ln K_X + \frac{1}{2} \delta \ln K_Y) \qquad (4.3\text{-}15)$$

The trick of obtaining finite sample signals consists of selecting a buffer with a complex stability comparable with that of the sample. If only one of the two competitors X or Y acted as a strong buffer, its equilibrium constant could not be determined from the relaxation signal. The fact that the signal shows up only in the presence of *both* X *and* Y characterizes the overall reaction as a substitution process.

The possibility of inducing "secondary" shifts opens a new and very general applicability of the relaxation techniques to the determination of stability constants. For instance, it can be used for a study of the interaction of alkali ions with electrically neutral antibiotics acting as ion-carriers. In this very case a "secondary" field effect is to be produced with the help of electrically active ionophores, such as nigericin or monensin.

4.3.2. Indirect Monitoring of Concentration

While general competition involving more than three partners is of only minor practical relevance, another binary system may play a more important role in titration: two substrates A and B compete for the same binding site P (*e.g.* at an enzyme), but one of them, say B, can also react

with a competitor of P, which may be an indicator (I) changing its absorption spectrum upon binding with B. An alternative but formally similar situation is found if B does not complex with the indicator, but transfers some particle, for instance a proton, an electron or a metal ion to I. A titration procedure based on this kind of reaction may be of great value since quite often neither the protein nor the substrate is discernible by suitable optical properties. On the other hand, one may be able to find a substance which at the same time binds to the protein *and* to some indicator as well. Many proteins lose a metal ion upon association with a substrate. Ca^{2+}, for instance, is released upon binding of acetylcholine to its receptor[14]. None of the three components (Ca^{2+}, acetylcholine or the receptor) offers optical shifts convenient for detection. However, Ca^{2+} may couple to an indicator such as murexide and thereby yield information about its competition with acetylcholine (see Table 2 and Fig. 4). There are many similar cases in protein chemistry and also in complexometry, so that more details about this problem are desirable.

For simplicity the protein is denoted by P, the indicator by I, and the two competitors by A and B respectively.

The binding equilibria and their corresponding (simplified) mass action relations are:

$$\left.\begin{array}{ll} A+P\rightleftharpoons AP & K_A=\dfrac{c_{AP}}{c_A\cdot c_P} \\ B+P\rightleftharpoons BP & K_B=\dfrac{c_{BP}}{c_B\cdot c_P} \\ B+I\rightleftharpoons BI & K_I=\dfrac{c_{BI}}{c_B\cdot c_I} \end{array}\right\}$$

or

$$B+I'\rightleftharpoons B'+I \qquad K_I=\frac{c_{B'}\cdot c_I}{c_{I'}\cdot c_B}$$

The overall composition is conserved:

$$c_P^0=c_P+c_{AP}+c_{BP} \qquad c_B^0=c_B+c_{BP}+c_{BI}$$
$$c_A^0=c_A+c_{AP} \qquad c_I^0=c_I+c_{BI}$$

or $c_I^0=c_I+c_{I'}$ and $c_I=c_{B'}$, if the sum $c_{I'}+c_{B'}$ also equals c_I^0.

Note that with respect to the symbols including a "prime", whatever it means (*e.g.* a proton or electron) the conservation law must be fulfilled as well. The above equations then only hold as long as no other acceptor for the "prime" is present and the "prime" itself cannot exist as a free particle (at least not to any extent comparable to c_I and c_B).

In the scheme above, the two brackets indicate how the competitions for P and for B are related to one another.

The indicator species I and IB, or I and I′ respectively, are the only ones which contribute to the measurable absorption. Hence c_B is directly given by the extinction quotient:

$$c_B=K_I^{-1}\frac{\eta}{1-\eta} \qquad \text{or} \qquad c_B=K_I^{-1}\cdot c_I^0\frac{\eta^2}{1-\eta}$$

with

$$c_{IB}=\eta\, c_I^0 \quad \text{and} \quad c_I=(1-\eta)c_I^0 \text{ (cf. Section 3.2)}$$

or

$$c_I=\eta\, c_I^0 \quad \text{and} \quad c_{I'}=(1-\eta)c_I^0$$

Further progress requires a suitable combination of the different terms, leading to a correlation between the *measurable* extinction ratios or their differential shifts, the overall concentrations (to be chosen suitably) and the stability constants which are to be determined. Appendix 3 contains a compilation of the formulae obtained. The relaxation amplitudes are written in an implicit form. The general relations are of fairly complicated structure and must therefore be analyzed in detail in order to be applied optimally.

The existence of two overlapping competing systems restricts severely the choice of conditions. K_A and K_B should not differ too much, and the indicator must be in a concentration range where the shifts of c_B can be monitored most sensitively. Furthermore, c_A, c_B, and c_P have to be adjusted with special reference to K_A^{-1} and K_B^{-1}.

The expression for the amplitude $(\delta c_{BI})_{III}$ is given in Appendix 3. The simplest way of measuring K_A would be to record the corresponding relaxation time τ_{III} at an excess of c_A^0. The linear plot—as in the examples shown in Figure 2b—will yield the two rate constants, the ratio of which defines K_A. The equation of $(\delta c_{BI})_{III}$ indicates where finite signals can be recorded.

In general, the application of secondary indication demands thorough understanding of the theoretical basis, rather than a schematic realization of a recipe.

5. General Comments on Application

The chemist's interest in titration is naturally more of a practical than of a fundamental theoretical nature. It is therefore appropriate, in conclusion, to give a brief critical review on the practical merits of the different kinds of titration principles. No attempt is made to provide anything like a complete description of the various procedures or of the necessary properties of complexing agents, indicators, buffers *etc.*, which can be found in the literature (*e.g.* in the excellent monographs by *F.* and *H. Rossotti*[17] and by *Schwarzenbach*[17]).

A good titration curve is characterized by its sharpness of transition signifying a well defined end-point. In the extreme limit such an end-point is a true discontinuity. In real cases, within a critical concentration range around the equivalence point the addition of a minute amount of standard solution changes the concentration of unreacted sample—or any function thereof—by orders of magnitude. Wherever one can arrange for such a situation—assuming the aim is quantitative analysis—the conventional method of titration is unbeatable. If, on the other hand, the object is a determination of the complex stability constant rather than of the sample concentration, an extreme sharpness of transition does not offer any advantage. On the contrary, the transition should here occur more smoothly, since it is the deviation from discontinuous change which contains all the information about K. As the titration curve becomes broader the mid-point of the change monitored will shift along the concentration axis, until for $Kc_B^0 \ll 1$ its position becomes a direct measure of K^{-1}. If T_b is then plotted *versus* the logarithm of the standard concentra-

tion (c_A^0) the inflection point occurs at exactly $\log c_A^0 = -\log K$. In this limit the curve assumes again a standard shape (cf. Fig. 3). The classical plots of enzyme chemistry—including the applications of steady state kinetics—usually refer to those circumstances (cf. Figures 2, 8 and 12). Obviously, the requirement for such a situation, $c_{standard} \gg c_{sample}$, can be fulfilled only for complexes which are not too strong. Most detection methods cease to be sufficiently sensitive for concentrations below 10^{-4} to 10^{-6} M. This is certainly true for polarimetry (ORD and CD), spectrophotometry—supposing even strongly absorbing substances—and for conductometry in aqueous media. Fluorimetry[*], insofar as it is applicable, may permit some further extension to lower concentrations ($<10^{-6}$ M), and with regard to a *selective* recording of very small concentrations polarography and other electrochemical techniques deserve particular attention. Nevertheless, if one wants to use these methods for the titration of very strong complexes, it is necessary to provide auxiliary systems and to proceed according to the rules of the substitution scheme.

The dynamic titration techniques apply to all situations in which the more conventional static procedures have been used thus far. The information they yield is in fact more directly related to the equilibrium (and kinetic) parameters and is much more detailed, if multiple step processes are involved. In such cases dynamic analysis may offer solutions to problems which were not accessible by classical methods (cf. Table 2, Figs. 7 and 11).

For binary complex formation with $K^{-1} \gg c_{sample}$ the logarithmic derivatives $\partial T_b/\partial \ln K$ and $\partial T_b/\partial \ln c_{standard}$ are very similar. In this case, it is the position of the maximum on the $c_{standard}$ axis (Fig. 3) which yields the information about the stability constant K, otherwise hidden in the uniform curve shape. For $K^{-1} \ll c_{sample}$, the situation is quite different. Actually the concentration dependence of the amplitude and, even more, of the time constants then resembles closely the second derivative of T_b with respect to $c_{standard}$. In a way, the use of higher derivatives of T_b may be considered as a mobilization of all the information which the end-point can provide about stability constants. We therefore have to concentrate on those relations which signify the approach of a singularity. In trigonometric representation, these are especially the functions which contain the term $1-\tan^n(\alpha/2)$ in the denominator, n being an integer ≥ 1. They correlate an equilibrium parameter with some distance on the concentration axis, *e.g.* the half-width of the bell-shaped curves for T'' and Γ or τ, or a distance between two peaks for Γ', (Γ' being the derivative of Γ with respect to the concentration variable). The sharper the end-point, the smaller these distances and therefore the higher the demands for signal amplification, signal/noise resolution and calibration of concentrations. For multiple-step schemes, differential recording offers considerable advantages. It is solely the sharpness of the peaks occurring in the functions Γ, Γ', τ or T'' which leads to the discrimination of several closely superimposed reaction steps, otherwise appearing as a continuum in the titration function.

In this context we should focus our attention on the differential concentration shift δc itself. Since total concentrations are known only within certain limits of accuracy, this difference should be calibrated in the most direct way. For this purpose—whatever the particular relaxation or observation technique is—two identical cells should be filled with the *same* standard solution, so that no differences can arise owing to dissimilar compositions. Small, exactly calibrated equal amounts of standard are now added to both cells, but the perturbation of equilibrium is applied only to one cell. The differential response to such a dissymmetry of perturbation is monitored as a function of the amount of standard added. Procedures of this kind are well known in the field of polarography[24]. Usually it is not necessary to know the *absolute* values of concentrations; if the relative variations of the concentration are exactly calibrated, one may reconstruct the equivalence point uniquely from the curve shapes (*i.e.* their maxima and points of inflection).

The dissymetry of perturbation in the two cells may also refer to the concentration change δc^0 rather than to the change in the intensive variable δz. Only for the direct determination of the relaxation amplitude is the alteration of z ($= T$, P or E) (as was mentioned just before) applied to just one of the cells. If the second derivative of the titration function is to be measured, one keeps both solutions at a fixed finite difference of c_A^0 while adding the same (small) amounts of standard solution concomitantly to both cells. With this technique a differential recording of relaxation amplitudes is possible as well. The external perturbation (*e.g.* a T-jump) may then be applied simultaneously to *both* cells, which, however, are not congruent with respect to their standard content.

The two latter approaches differ in one important aspect. The determination of the curvature of the titration function T'' requires the recording of a second order differential shift $\delta^2 c_A^0$, while the differential recording of amplitudes (*i.e.* Γ') involves only a first order difference in the concentration variable. The shift of the intensive parameter δz is independent of δc_A^0 and can be adjusted in order to yield the largest possible signals. This shows that one of the decisive limiting factors, *i.e.* δc_A^0, influences the two procedures in a quite different manner. For large K-values minute additions of c_A^0 have to be made since all observable changes appear in the close vicinity of the equivalence point. Hence the absolute magnitude of δc_A^0 becomes the limiting factor of accuracy, imposing quite different error limits on both methods.

These considerations lead to the essential question:

Which method is best for which problem?

On the basis of the preceding discussion we can say that for a determination of equilibrium constants the dynamic amplitude techniques are clearly superior, especially when the system has high stability constants, *i.e.* small p-values or sharp endpoints. This advantage holds for all kinds of reactions, *i.e.* binary (1:1) complex formation, substitution or—especially—any of the multiple-step transformations. Moreover, the relaxation amplitudes include additional information on derivatives of the equilibrium constants, such as ΔH or ΔV, and on rate parameters.

On the other hand, relaxational titration requires quite sophisticated techniques for dynamic recording, usually not available as standard laboratory equipment. One may think also of using a static method, *e.g.* a difference recording of the titration function in two cells held at slightly different

[*] A comprehensive review of fluorimetric techniques for both titration and relaxation studies has appeared (*T. Jovin* [12]).

temperatures. However, as was shown in section 2.4 the inevitable corrections for physical effects such as thermal expansion are of a magnitude similar to that of the expected chemical effects, and have to be carried out by suitable calibration.

Among the different *relaxation* techniques we may come to special preferences in order to achieve the optimal response of the system upon variation of T, P or E. In absence of a direct response, a suitable buffer may aid in providing a sufficiently large perturbation of equilibrium.

The very pronounced curve shapes of T'', Γ and τ demand a careful selection of the optimal concentration range in which the differential studies are to be carried out. Otherwise one may not obtain any finite signal at all. In relaxation measurements, both the amplitude as well as the time range have to be taken into consideration. For binary complex formation *Brubacher*[25] has proposed a plot of reduced amplitudes *versus* reduced time constants, under particular constraints concerning c_A^0 and c_B^0, in order to find out the optimal conditions. The representation by trigonometric functions, chosen in this article, serves the same purpose. The various plots shown in previous sections are in this respect self-explanatory. They also show where the method of continuous variation, in which the sum of overall sample and standard concentrations is kept constant, is to be preferred. The interrelations between several functions (T_a, Γ_a, τ_a, T_a' *etc.*) become especially simple in symmetrical cases and suggest applications hitherto unexplored, such as Γ *versus* τ plots (Fig. 5) in which the parameters to be determined can be directly read off from the slopes and the intercepts of a family of lines. This procedure can be especially well adapted to microtitration.

There is no limitation as to the kind of problems to be studied by any of the methods discussed in this article. Dynamic amplitude titration has proven to be of great advantage in complexometric investigations, yet acid-base, electron donor-acceptor and—in particular—enzyme-substrate interactions may equally well be objects of study.

Finding the optimal approach to each problem means mastering the art of titration.

We are greatly indebted to Miss Ursula Wisniewski and Dipl.-Phys. Gerhard Kessling for writing the computer programs and providing graphical representations of the calculated functions.

We wish to thank also Prof. Peter Schuster, Prof. Eberhard Neumann, and Dr. Heinz Winkler for providing us with yet unpublished experimental data. Dr. Paul Woolley was kind enough to revise the English manuscript.

Appendix 1. Outline of the Thermodynamic Treatment of Chemical Relaxation Phenomena[*]

The concentration variable is represented by the extent of reaction ξ, which correlates the stoichiometric changes of reactants and reaction products: $d\xi = dn_i/\nu_i$. n_i is the mole number and ν_i the stoichiometric coefficient of compound i (being positive for reaction products and negative for reactants). If related to a reference value of n_i, ξ is identical for all participants of a given reaction, *e.g.* $dn_{AB} = -dn_A = -dn_B$. Complementenary to ξ is the affinity A, defined by

$$A = -(\partial G/\partial \xi)_z$$

where G denotes Gibbs' free energy. Referring to general intensive variables z (T, P *etc.*) the total equilibrium shift can be expressed as

$$\delta\xi = \left(\frac{\partial \xi}{\partial z}\right)_A \delta z = -\frac{(\partial A/\partial z)_\xi}{(\partial A/\partial \xi)_z}\,\delta z$$

Maintenance of equilibrium during the variation of ξ with respect to z is indicated by the subscript A, which in particular means $A = \text{const.} = 0$. The term $\partial A/\partial z)$ corresponds to the Δ-term, *e.g.* for $z = T$: $\Delta H/T$ or for $z = P$: $-\Delta V$. The reciprocal of $-(\partial A/\partial \xi)_z$ yields the amplitude factor Γ_z divided by RT. This factor—appearing also in the relaxation time τ—is dependent on the variables z kept constant during the variation of ξ, *e.g.* $\Gamma_{T,P}$ and $\tau_{T,P}$ if the process refers to sufficiently slow equilibration under atmospheric pressure and thermostatic control. For solutions, however, we may well omit these subscripts since the factors discriminating differing external conditions—Γ_{SV}, Γ_{TP} *etc.*—are negligibly small. In ionic solutions which are highly diluted or where the ionic strength is kept constant, activity coefficients do not have to be taken into account explicitly. Then Γ simply reduces to the form

$$\Gamma^* = \frac{1}{\sum_i \frac{\nu_i^2}{c_i}}$$

which is valid for any kind of reaction order. The sum has to include all reactants and products involved in the equilibration process. It is positive since ν_i enters as a square term. If activity coefficients contribute measurably to the change of affinity A with respect to the extent of reaction ξ, Γ is to be replaced by

$$\Gamma = \frac{\Gamma^*}{1 + \Gamma^*(\partial \Sigma \nu_i \ln f_i/\partial \xi)_z}$$

Γ^* being identical with the expression quoted above.

Relaxation time τ and amplitude factor Γ are correlated *via* the exchange velocity v, which for a general reaction process

$$\nu_1 A_1 + \nu_2 A_2 \ldots \nu_k A_k \underset{\overleftarrow{k}}{\overrightarrow{k}} \nu_{k+1} A_{k+1} + \cdots \nu_n A_n$$

reads

$$v = \overrightarrow{k} \prod_{i=1}^{k} c_{A_i}^{\nu_i} = \overleftarrow{k} \prod_{i=k+1}^{n} c_{A_i}^{\nu_i}$$

For a non-diffusion-controlled process k contains the essential part of the equilibrial activity coefficients $\prod f_i^{\nu_i}$.

τ, Γ and v are related to each other by

$$\tau = \Gamma/v$$

As was pointed out by *Katchalsky* [26], there is a formal similarity between electrical and chemical networks. The linearized rate equation—as a relation between a chemical flux (turnover rate) and force (affinity)— defines the chemical analogue of a resistance R_{Chem}, and the dependence of a temporal derivative of the force on the flux allows the introduction of a "chemical capacitance" C_{Chem}. The comparison yields

$$R_{Chem} C_{Chem} = \tau$$

$$R_{Chem} = \frac{RT}{v}$$

$$C_{Chem} = \frac{\Gamma}{RT}$$

Both "resistance" and "capacitance" in a chemical "circuit" have a quite obvious physical meaning [27].

Appendix 2. Generalization for Multiple Ligand Competition

a) Ligands L_1, $L_2 \ldots$ + complexing partners M

Given a number of ligands 1, 2, ..., n, which can competitively interact with a common complexing partner (or binding site) in forming such a 1 : 1 complex.

[*] Cf. also [5] and [16].

The common complexing partner may be denoted by M (usually being some metal ion) and the ligands by $L_1 \ldots L_n$: The mass action relations are written as:

$$\begin{aligned} M + L_1 &\rightleftharpoons ML_1 \quad K_1 = \frac{c_{M_1}}{c_M \cdot c_1} \\ M + L_2 &\rightleftharpoons ML_2 \quad K_2 = \frac{c_{M_2}}{c_M \cdot c_2} \\ &\vdots \\ M + L_n &\rightleftharpoons ML_n \quad K_n = \frac{c_{M_n}}{c_M \cdot c_n} \end{aligned} \tag{1}$$

where the concentrations c_i or c_{M_i} refer to the corresponding ligand L_i or metal complex ML_i, respectively. The conservation conditions for any perturbation are:

$$\delta c_i = -\delta c_{M_i} \tag{2}$$

for $i = 1,2,\ldots n$

and $$\delta c_M = -\sum_{k=1}^{n} \delta c_{M_k} \tag{3}$$

Expansion of any of the mass action relations yields:

$$\delta c_{M_i} = \Gamma_i \delta \ln K_i - \gamma_i \sum_{k \neq i} \delta c_{M_k} \tag{4}$$

with the usual definitions:

$$\Gamma_i = \frac{1}{\frac{1}{c_M} + \frac{1}{c_i} + \frac{1}{c_{M_i}}} = \frac{c_i c_M}{c_M + c_i + K_i^{-1}} \tag{5}$$

and

$$\gamma_i \equiv \frac{\Gamma_i}{c_M} = \frac{c_i}{c_M + c_i + K_i^{-1}} \tag{6}$$

The sum $\sum_{k \neq i}$ is taken over all partners k = 1 to n except for k = i. An explicit expression for $\sum_{k \neq i} \delta c_{M_k}$ can be derived by iteration. According to eq. (4) one may write:

$$\begin{aligned} \delta c_{M_1} &= \Gamma_1 \delta \ln K_1 - \gamma_1 \delta c_{M_2} - \gamma_1 \sum_{k \neq 1,2} \delta c_{M_k} \\ \delta c_{M_2} &= \Gamma_2 \delta \ln K_2 - \gamma_2 \delta c_{M_1} - \gamma_2 \sum_{k \neq 1,2} \delta c_{M_k} \end{aligned} \tag{7}$$

Combination results in:

$$\delta c_{M_1} + \delta c_{M_2} = \bar{\Gamma}_{12} \delta \ln \bar{K}_{12} - \bar{\gamma}_{12} \sum_{k \neq 1,2} \delta c_{M_k} \tag{8}$$

with

$$\bar{\Gamma}_{12} \delta \ln \bar{K}_{12} \equiv \frac{\Gamma_1(1-\gamma_2)\delta \ln K_1 + \Gamma_2(1-\gamma_1)\delta \ln K_2}{1 - \gamma_1 \gamma_2} \tag{9}$$

and

$$\frac{\bar{\Gamma}_n}{c_M} \equiv \bar{\gamma}_{12} \equiv \frac{\gamma_1(1-\gamma_2) + \gamma_2(1-\gamma_1)}{1 - \gamma_1 \gamma_2} \tag{10}$$

The sum $\sum_{k \neq 1,2}$ now contains all terms δc_{M_k} for k from 3 to n (*i.e.* all, except k = 1 and k = 2). A corresponding expression would hold for any two partners i and j. The same procedure can be iterated for inclusion of any further partner suggesting a general expression:

$$\sum_{k=1}^{m} \delta c_{M_k} = \bar{\Gamma}_{1\ldots m} \delta \ln \bar{K}_{1\ldots m} - \bar{\gamma}_{1\ldots m} \sum_{k=m+1}^{n} \delta c_{M_k} \tag{11}$$

with

$$\bar{\Gamma}_{1\ldots m} \delta \ln \bar{K}_{1\ldots m} = \frac{\bar{\Gamma}_{1\ldots m-1}(1-\gamma_m)\delta \ln \bar{K}_{1\ldots m-1} + \Gamma_m(1-\bar{\gamma}_{1\ldots m-1})\delta \ln \bar{K}_{1\ldots m-1}}{1 - \bar{\gamma}_{1\ldots m-1}\gamma_m} \tag{12}$$

and

$$\frac{\bar{\Gamma}_{1\ldots m}}{c_M} \bar{\gamma}_{1\ldots m} = \frac{\bar{\gamma}_{1\ldots m-1}(1-\gamma_m) + \gamma_m(1-\bar{\gamma}_{1\ldots m-1})}{1 - \bar{\gamma}_{1\ldots m-1}\gamma_m} \tag{13}$$

The validity of this form can be shown by complete induction, which in this case is a simple extension of the procedure applied above for k = 1 and 2. Starting from eq. (11) with a split sum term:

$$\sum_{k=1}^{m} \delta c_{M_k} = \bar{\Gamma}_{1\ldots m} \delta \ln \bar{K}_{1\ldots m} - \bar{\gamma}_{1\ldots m} \delta c_{M_{m+1}} - \bar{\gamma}_{1\ldots m} \sum_{k=m+2}^{n} \delta c_{M_k} \tag{14}$$

and adding eq. (4), written as:

$$\delta c_{M_{m+1}} = \Gamma_{m+1} \delta \ln K_{m+1} - \gamma_{m+1} \sum_{k=1}^{m} \delta c_{M_k} - \gamma_{m+1} \sum_{k=m+2}^{n} \delta c_{M_k} \tag{15}$$

leads to the general form of eq. (11) for m + 1.

Finally one has to derive an explicit form for eq. (4), valid for any complexing agent. Substituting the sum term in eq. (4) according to eq. (11), by:

$$\sum_{k \neq i} \delta c_{M_k} = \bar{\Gamma}_{k \neq i} \delta \ln \bar{K}_{k \neq i} - \bar{\gamma}_{k \neq i} \delta c_{M_i} \tag{16}$$

where the index $k \neq i$ means (n − 1)-fold iteration from k = 1 to n, except for k = i (*e.g.* i = n, iteration 1 to n − 1. Note that the way of numbering is arbitrary).

The explicit form of eq. (4) then reads:

$$\delta c_{M_i} = \frac{\Gamma_i}{1 - \bar{\gamma}_{k \neq i}\gamma_i} (\delta \ln K_i - \bar{\gamma}_{k \neq i} \delta \ln \bar{K}_{k \neq i}) \tag{17}$$

in which the ternary system treated in the text reflects only a special example, where the combination term with the index $k \neq i$ involves the contributions of the buffer and the sample, while i represents the indicator.

Explicit expressions for c_i can be obtained if we combine the respective mass action and conservation relation for each ligand.

$$c_i + c_{M_i} = c_i^0 \tag{18}$$

$$\frac{c_{M_i}}{c_i} = K_i c_M \quad \frac{c_i^0 - c_i}{c_i} = K_i c_M \tag{19}$$

$$c_i = \frac{c_i^0}{1 + K_i c_M} \tag{20}$$

$$c_{M_i} = c_i^0 \frac{K_i c_M}{1 + K_i c_M} \tag{21}$$

If c_M can be determined uniquely (*e.g. via* an extinction ratio) a complete representation in weighed-in concentrations, and measurable parameters is possible.

Three possible ways of evaluation result:

1) All but one K_i values are known (natural system)

2) Successive addition of ligand 1...n (practical for not higher than ternary systems)

3a) Time constants differ sufficiently so that successively all steps can be determined (dynamic analysis)

3b) Binding constants differ markedly so that by addition of M one may scan through all binding ranges (often identical with 3a).

b) Ligand L + macromolecule P with several binding sites

The same general concept can be applied to the case of general ligand binding by a macromolecular reactant P, usually being a protein. The titration procedure was discussed by *Edsall* and *Wyman*[4]. The common ligand L is bound at different sites, 1,2...n, each characterized by a specific affinity, expressed in terms of binding constants, $K_1 \ldots K_n$:

$$K_1 = \frac{c_{PL_1}}{c_L \cdot c_{P_1}}; \quad \ldots \quad K_n = \frac{c_{PL_n}}{c_L \cdot c_{P_n}} \tag{22}$$

As is seen, the common ligand L now plays the same role as the metal ion M in the first example, whereas the various binding sites 1...n at P resemble the former ligands. The mass action and conservation relations hence are of completely analogous form. In Ref. [4] an equation for the degree of binding, was given

$$\bar{\nu} = \frac{\sum_{k=1}^{n} c_{PL_k}}{\sum_{k=1}^{n} c_{PL_k} + \sum_{k=1}^{n} c_{P_k}} \tag{23}$$

which in our (slightly differing) terminology reads:

$$\bar{\nu} = \frac{\sum_{k=1}^{n} \frac{K_k c_L}{1 + K_k c_L}}{n} = \frac{\bar{K}_{1\ldots n} c_L}{1 + \bar{K}_{1\ldots n} c_L} \tag{24}$$

n may or may not include groups of m-fold degeneracy, *i.e.* m-sites having identical binding constants. $\bar{K}_{1-n}$ is defined as above:

$$\bar{K}_{1\ldots n} = \frac{\sum_{k=1}^{n} c_{PL_k}}{c_L \sum_{k=1}^{n} c_{P_k}} \tag{25}$$

and related to individual binding constants by the iteration formula:

$$\bar{K}_{1\ldots i+1} = \frac{\sum_{k=1}^{i} c_{P_k}}{\sum_{k=1}^{i+1} c_{P_k}} \bar{K}_{1\ldots i} + \frac{c_{P_{i+1}}}{\sum_{k=1}^{i+1} c_{P_k}} K_{i+1} \tag{26}$$

The general amplitude relationship, derived in the first part of this appendix holds analogously for the perturbation of $\bar{\nu}$:

$$\delta\nu = \frac{\bar{\Gamma} \ln \bar{K}_{1\ldots n}}{\sum_{k=1}^{n} c_{PL_k} + \sum_{k=1}^{n} c_{P_k}} \tag{27}$$

As *Edsall* and *Wyman* point out, these equations include "endless possible sets of n's and K's, and it would be hopeless to attempt any general discussion of all these possibilities". It should be emphasized, however, that especially in such cases of multiple binding processes, the relaxation amplitude techniques offer new possibilities of obtaining individual, rather than only overall or average binding parameters. Several examples are given in the text, and a more detailed analysis applying to allosteric proteins will be given in a forthcoming paper [23].

Appendix 3. Secondary Indication

a) Indication by Complex Formation

The general correlation between extinction ratios, overall concentrations and equilibrium parameters is

$$\left\{\frac{c_A^0}{K_B^{-1} + K_I^{-1}\frac{\eta}{1-\eta} - c_P^0/U}\right\} + \{u\} = -\frac{K_B}{K_A} \tag{1}$$

with

$$u = K_I \frac{1-\eta}{\eta}(c_B^0 - \eta c_I^0) - 1 \tag{2}$$

or explicitly:

$$\left\{c_A^0 - c_P^0 + \left(c_B^0 - \eta c_I^0 - K_I^{-1}\frac{\eta}{1-\eta}\right)\left(1 + K_B^{-1} K_I \frac{1-\eta}{\eta}\right)\right\}$$
$$= -\frac{K_B}{K_A}\left\{K_I^{-1}\frac{\eta}{1-\eta} - \frac{c_P^0}{K_I \frac{1-\eta}{\eta}(c_B^0 - \eta c_I^0) - 1}\right\} - K_A^{-1} \tag{3}$$

which reduces for $K_B^{-1} \ll K_I^{-1}$, K_A^{-1} to

$$\left\{c_A^0 + c_B^0 - c_P^0 - \eta c_I^0 - K_I^{-1}\frac{\eta}{1-\eta}\right\} + K_I^{-1} =$$
$$= -\frac{K_B}{K_A}\left\{K_I^{-1}\frac{\eta}{1-\eta} - \frac{c_P^0}{K_I \frac{1-\eta}{\eta}(c_B^0 - \eta c_I^0) - 1}\right\} \tag{4}$$

or for K_A^{-1}, $K_B^{-1} \ll K_I^{-1}$

$$\left\{K_I \frac{1-\eta}{\eta}(c_B^0 - \eta c_I^0 + c_A^0 - c_P^0)\right\} = \frac{K_B}{K_A}\left\{\frac{c_P^0}{c_B^0 - \eta c_I^0 - K_I^{-1}\frac{\eta}{1-\eta}}\right\} + 1 - \frac{K_B}{K_A} \tag{5}$$

The brackets in each equation denote which combinations of terms have to be plotted against each other. Further simplifications are obtained for $c_B^0 = c_P^0$ and for $c_I^0 \ll c_A^0$, c_B^0, or $c_B^0 K_I \gg 1$.

Overall amplitude:

$$(\delta c_{BI})_{tot.} = \frac{\Gamma_I}{1 - \gamma_I\gamma_B - \gamma_A\gamma_B'}\left[(1 - \gamma_A\gamma_B')\delta \ln K_I - \gamma_B \delta \ln K_B + \gamma_A\gamma_B \delta \ln K_A\right] \tag{6}$$

with

$$\gamma_I \equiv \frac{\Gamma_I}{c_B} = \frac{c_I}{c_I + c_B + K^{-1}}; \quad \gamma_B \equiv \frac{\Gamma_B}{c_B} = \frac{c_P}{c_P + c_B + K_B^{-1}}$$
$$\gamma_B' \equiv \frac{\Gamma_B}{c_P} = \frac{c_B}{c_P + c_B + K_B^{-1}}; \quad \gamma_A \equiv \frac{\Gamma_A}{c_P} = \frac{c_A}{c_P + c_A + K_A^{-1}} \tag{7}$$

The implicit terms can be expressed by overall-concentrations and extinction ratios according to:

$$c_{BI} = \eta c_I^0; \quad c_I = (1-\eta)c_I^0; \quad c_B = K_I^{-1}\frac{\eta}{1-\eta}; \tag{8}$$

$$c_P = K_B^{-1} u; \quad u \text{ according to eq. (2)} \tag{9}$$

$$c_A = c_A^0 - c_P^0 + u\left\{K_B^{-1} + K_I^{-1}\frac{\eta}{1-\eta}\right\} \tag{10}$$

Amplitude differences can be determined, as was pointed out in Section 4. Under identical conditions with respect to c_I^0, c_P and c_B the amplitudes are measured in presence and absence of the A-system.

If the equilibration of the A-system is the slowest step, *i.e.* if reactant and competitor B equilibrate sufficiently fast, the lowest time constant τ_{III} provides information about K_A. In systems

$$A + P \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} AP$$

this (reciprocal) time constant reads:

$$\tau_{III}^{-1} = k_{34}\{c_A + c_P + K_A^{-1}\} f_{ABI} \tag{11}$$

with

$$f_{ABI} = \frac{1 - \gamma_I\gamma_B - \gamma_A\gamma_B'}{1 - \gamma_I\gamma_B} \to 0 \quad \text{for} \quad K_B c_B \to 0 \tag{12}$$

This time constant is associated with a relaxation amplitude

$$(\delta c_{BI})_{III} = \Gamma_A \frac{\gamma_I\gamma_B}{1 - \gamma_I\gamma_B - \gamma_A\gamma_B'}\left\{\delta \ln K_A - \frac{\gamma_B'}{1 - \gamma_I\gamma_B}(\delta \ln K_B - \gamma_I \delta \ln K_I)\right\} \tag{13}$$

b) Indication *via* exchange reactions

The same sample and competitor binding equilibria as in a) are supposed. Indication, however, is effected by an exchange process

$$B + I' \rightleftharpoons B' + I \tag{14}$$

All expressions of case a) apply, if the extinction ratio $K_I^{-1}\,\eta/1-\eta$ is replaced by

$$K_I^{-1} \cdot c_I^0 \eta^2/(1-\eta)$$

using the definitions given in the text.

The amplitude factor of the indicator equilibrium is defined as

$$\Gamma_I = \frac{1}{\frac{1}{c_I} + \frac{1}{c_{B'}} + \frac{1}{c_{I'}} + \frac{1}{c_B}} = \frac{c_{B'} c_I}{c_{B'} + c_I + K_I(c_B + c_I)} \tag{15}$$

and

$$\gamma_I = \frac{\Gamma_I}{c_B} = \frac{K_I c_{I'}}{c_{B'} + c_I + K_I(c_B + c_I)} \tag{16}$$

Plastics as Optical Materials

By Helmut Dislich[*]

The principal material used in optics is glass. Plastics can only gain acceptance in optics if they have properties not encountered with glass or if a desired article can be produced more rationally from a plastic. An example of the first case is provided by UV light guides consisting of a quartz glass core surrounded by a plastic cladding; there is no glass with a sufficiently low refractive index. Examples of the second case are viewfinder optics for cameras and lenses for sunglasses and industrial safety spectacles.

1. Introduction

"Plastics in optics"—when considering this topic it is inadvisable to start from the annual production of 1000 tons because even the potentially interested reader is likely to feel his interest wane at the thought of such unusually low production figures. The turnover of high-value products made possible by new plastics and plastics technologies would appear to attract much more attention. In many cases the user is unconscious of the application of plastics, unless he notices it by way of the price which may be very low (example: high quality viewfinder optics) or very high (example: spectacles worn after removal of a cataract or UV fiber optics). In the former case, use of plastics is dictated by the market, in the second case by the optical and other properties of the plastics.

The most comprehensive report about the use of plastics for optical purposes appeared in 1945[1]. At that time, however, many of the plastics of interest nowadays were unknown. Widely acclaimed surveys were subsequently authored by *Schreyer*[2–4]. Optical properties are listed in Landolt-Börnstein[5, 6]. An exceptional wealth of detail is given in a review by *Torbin* and *Daminov*[7].

In the present article, the optical properties of plastics will be correlated with their chemical structure wherever possible. Rather exotic plastics hardly known outside the realm of optics sometimes prove particularly interesting. Mass produced plastics—in optics, these include poly(methyl methacrylate) or polycarbonate—are of interest with regard to the possibilities of working them. Combinations of plastics with glasses were frequently the logical consequence of studies on the optical scope of plastics.

Any consideration of optics compels us to look at glass, because glass was, and still is, the classical material of optics, and any plastics making an inroad into this field will be measured against glasses. In view of the well established position of glass, serious consideration must be given to the question of the motivation for the intense work being done on plastics for optical purposes, particularly by an author in a glass-house who, as the saying goes, may not throw stones with impunity. There are two simple answers:

1) A desired article can be produced more rationally from plastics;

[*] Dr. H. Dislich
JENAer Glaswerk Schott & Gen., Mainz
Postfach 2480, D-6500 Mainz (Germany)

2) some plastics have—urgently required—properties not shown by glasses.

2. Glasses and Plastics

In this article, glass is taken to mean a fused inorganic product, and plastic an organic high polymer, produced, for example, by polymerization, polycondensation, or polyaddition of low-molecular starting materials. We shall restrict our attention to glass-clear, preferably more recent plastics.

2.1. Comparison of Optical Properties

Essential properties always employed as initial selection criteria are the spectral transmittance, the refractive index n_d, and the Abbe number

$$\nu_d = \frac{n_d - 1}{n_F - n_C}$$

n_F, n_C = refractive indices for the F and C lines, respectively.

2.1.1. Transmittance

In the case of glasses the ranges of high transmittance extend from the ultraviolet region (silica glass) *via* the visible (many optical glasses often having very high transmittance owing to extremely high homogeneity and purity) to the infrared region (chalcogenide glasses)[8].

The transmittance ranges are somewhat more limited in the case of plastics. Apart from the good transmittance in the visible range, the UV transmittance of poly(methyl methacrylate), methylpolysiloxanes, and perfluorinated polymers deserves mention; some perfluorinated polymers, *e.g.* the copolymer of tetrafluoroethylene and hexafluoropropylene (Teflon FEP®), are also transparent to IR up to about 6 μm (Figs. 1 and 2).

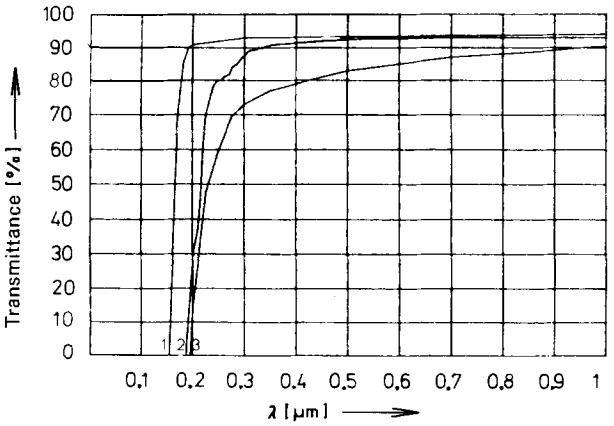

Fig. 1. Spectral transmittance of (1) silica glass (Suprasil W), 1.0 mm; (2) methylpolysiloxane (Glass Resin 650), 1.04 mm; (3) polytetrafluoroethylene-hexafluoropropylene copolymer (Teflon FEP®), 0.02 mm.

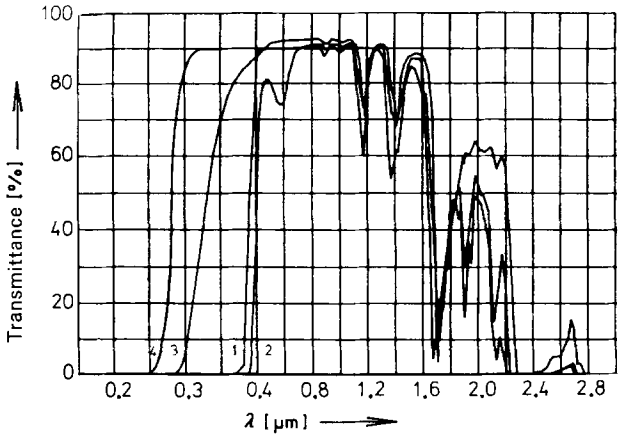
A monomethyl polysiloxane ("Glass Resin 650") produced mainly from methyltrialkoxysilane[9], can be designated as



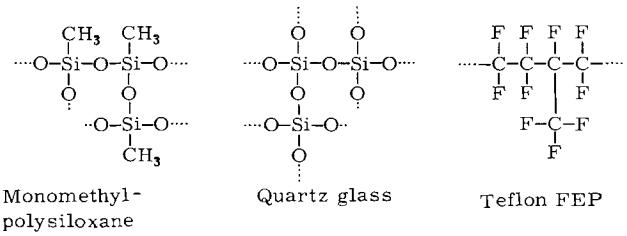


Fig. 2. Spectral transmittance of (1) poly(methyl methacrylate) (Plexiglass® 201 with UV absorber), 3 mm; (2) poly[*p*-(*p*-hydroxy-α,α-dimethylbenzyl)-phenyl hydrogen carbonate] (Makrolon, Lexan®), 3 mm; (3) poly(diethylene glycol diallyl biscarbonate) (CR39), 3 mm; (4) poly(methyl methacrylate) (pure), 3 mm.

"monomethylated quartz glass", which is suggestive of its high transmittance resembling that of quartz glass.

As a result of their high IR transmittance, fluorinated polymers can be used as embedding agents in IR spectroscopy. FEP®, which is glass-clear as thin films, owes its special position as a largely non-crystalline, and hence non-scattering, perfluorinated polymer (in contrast to polytetrafluoroethylene) to the branching arising from copolymerization, which inhibits crystallization.

The reflection losses of plastics having higher refractive indices, such as polystyrene or polycarbonate, can be reduced by coating with a layer of material having a lower refractive index such as MgF_2 and their transmittance consequently enhanced[10], as is common practice with glasses.

2.1.2. The $n_d - \nu_d$ Diagram

The "optical position" of transparent plastics and glasses[11] is normally represented in a $n_d - \nu_d$ diagram. Figure 3 shows some examples.

The plastics region overlaps with the glass region but appears more extensive at the bottom. The extremely low refractive indices of Teflon FEP® (point 19) and methylpolysiloxane (point 5) permit their use as optical coatings for silica glass fibers and rods[12, 13]; no alternative glass is foreseen.

Correlation of the "optical position" with the chemical structure of polymers leads to simple relationships with which new plastics always comply. Directed syntheses of tailormade products would be readily feasible. In practice, however, one

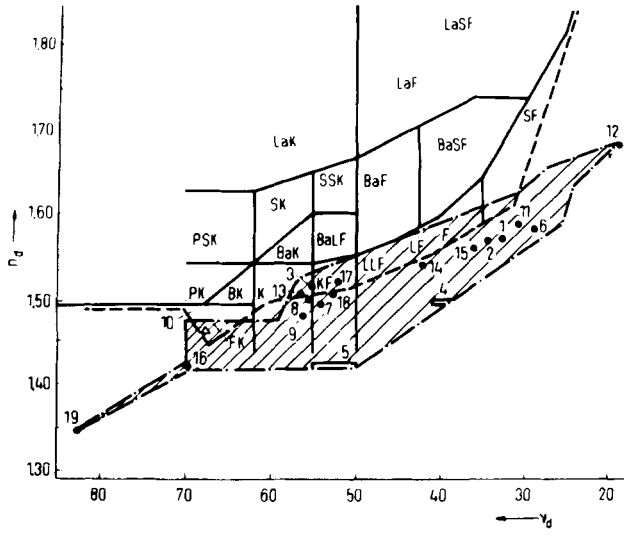

Fig. 3. Glass region and plastics region in the $n_d - \nu_d$ diagram. ---: present limit of the glass region; ·····: present limit of the region of transparent plastics. △ quartz glass, ● plastics 1—19. 1 = styrene-acrylonitrile copolymer, 2 = poly(*o*-diallyl phthalate), 3 = poly(methyl α-chloroacrylate), 4 = methylphenylpolysiloxane, 5 = methylpolysiloxane, 6 = poly[*p*-(*p*-hydroxy-α,α-dimethylbenzyl)phenyl hydrogencarbonate], 7 = poly(methyl methacrylate), 8 = poly(diethylene glycol diallyl biscarbonate), 9 = cellulose acetate, 10 = cellulose propionate, 11 = polystyrene, 12 = poly-*N*-vinylcarbazole, 13 = poly(cyclohexyl methacrylate), 14 = poly(vinyl chloride), 15 = epoxy resin (Araldite Cy 206), 16 = poly(2,2,2-trifluoroisopropyl methacrylate), 17 = methyl methacrylate-α-methylstyrene copolymer, 18 = methyl methacrylate-acrylonitrile copolymer, 19 = tetrafluoroethylene-hexafluoropropylene copolymer.

searches through known materials, applying possible corrections by copolymerization.

Highly aromatic plastics, such as polystyrene, poly(aryl carbonates), or even poly-*N*-vinylcarbazole, have high refractive indices and low Abbe numbers; fluorinated, and especially perfluorinated, plastics have low refractive indices and high Abbe numbers.

By means of the Lorentz-Lorenz equation[2, 11]

$$R_M = \frac{n^2-1}{n^2+2}\frac{M}{d}$$

R_M = molar refractivity, M = molecular weight, d = density, n = refractive index

it is possible to estimate the limits of plastics, including hypothetical polymers: as far as can be seen nowadays no polymers will become available with refractive indices much in excess of $n_d = 1.73$ or below $n_d = 1.33$. Plastics fail to reach the center of the glass region. Thus the terms of competition between optical glasses and transparent plastics are defined, as are the limitations of their combinations.

2.1.3. Effects of Thermal and Mechanical Properties of Plastics on Optical Properties

The lower specific gravity of plastics (≈1.0 to 1.5) often gives them an advantage over glasses (≈2.2 to >3). The coefficient of linear thermal expansion of plastics is roughly ten times greater than for glasses; this is a disadvantage since the optical properties become strongly temperature dependent. The refractive index of a plastic decreases with increasing temperature[14]. The drawback of being less hard or less resistant to wear is less serious because it can be at least partly overcome by mechanical protection or coating.

The greater impact resistance of plastics can be of advantage since the danger of fracture is reduced. Their low thermal conductivity can lead to deformation on fast changes in temperature.

The effects of these properties are accurately known[4]; it may therefore be predicted whether the required tolerances can be met for any given application.

The main plastics used are polymers and copolymers of methyl methacrylate, styrene, diethylene glycol diallyl biscarbonate, and acrylonitrile, as well as polycarbonate, cellulose acetate, and cellulose acetobutyrate. Polymethylpentene TPX should also be mentioned in passing. Let us turn our attention specifically to poly(methyl methacrylate) (PMMA) and polystyrene among this relatively sparse selection. Their optical positions (see Fig. 3) are sufficiently different to lead to achromatism in an optical system. PMMA then corresponds to the crown glasses and polystyrene to the flint glasses.

2.2. Comparison of Production Techniques

2.2.1. Glasses

According to the ASTM definition, glass is "an amorphous inorganic usually transparent or translucent substance formed by cooling and solidifying a molten mass without crystallization", and has been prepared in this way for some 4000 years. The ingredients of glass, frequently oxides, are mixed and heated until they melt (usually above 1000°C), reactions between the components leading to formation of the glass melt. On cooling, the melt solidifies to a glass without crystallizing. This cooling can be carried out in a mold. The optical component (lens, prism, disk, *etc.*) is then fashioned from the casting by grinding and polishing.

2.2.2. Plastics

The starting materials are monomers which are transformed into polymers by polymerization, polycondensation, or polyaddition. These reactions take place at relatively low temperatures. It is of considerable importance that conversion into the polymeric state can occur in the mold (casting process) and so immediately lead to the finished component. As an example we can consider the polymerization of diethylene glycol diallyl biscarbonate to give spectacle lenses as described in Section 3.1.2. This "one-step process" is by no means highly rationalized because polymerization must be performed slowly and under careful control in order to ensure formation of a homogeneous optical component of reproducible geometry. The mold, which is usually rather complicated, is blocked during this time.

The relatively short treatment given to plastic optical components produced by injection molding or similar processes should not disguise the fact that this is actually the largest market. Several reports have already been published on this topic. Combined Optical Industries Ltd. in England were pioneers in this field.

Whenever possible the polymer is converted into granules and shaping is by standard injection molding processes. Thus

lenses and prisms for the viewfinder optics of a camera are molded from poly(methyl methacrylate), as are reflectors, Fresnel lenses, and many other similar objects. Without doubt this is still the most rational method for the production of large numbers of objects.

Injection molding of lenses requires a high, but nowadays attainable, degree of precision; the accuracy obtainable with ground and polished glass lenses is greater. The material used for the injection mold and the quality of its surface play an important role along with other parameters. A recent development is the use of glass molds[17].

Injection pressing, stamping, and extrusion are included in this section as broadly similar processes starting from a polymeric material. For example, pressing and stamping techniques are used to manufacture thick-walled lenses of large diameter, reflector optics, traffic signals, mirrors, and aspherical optics.

Apart from injection molding, machining of plastic blocks is used for the production of large Fresnel lenses which can hardly be manufactured from glass.

Adhesive layers of epoxy resins, consisting of resin and curing agent (amine or anhydride), are often used to join two halves of a component. Alkylpolysiloxanes are used mainly as layers on substrates. The starting material is often methyltrialkoxysilane, which is hydrolyzed by atmospheric moisture, according to

$$CH_3Si(OR)_3 + 3\,H_2O \rightarrow CH_3Si(OH)_3 + 3\,ROH$$

With increasing temperature, methylsiloxanes are formed by polycondensation.

The method of choice for manufacturing a given product depends upon the technical possibilities and requirements, and also on the manufacturing runs involved[15].

2.2.3. Synthesis of Glasses by Polycondensation

While the production techniques for glasses and plastics do show a certain resemblance (thermoplastic processing), this does not appear to apply to the synthesis of glasses and of plastics. It therefore appeared most challenging to synthesize a glass by one of the principles used in the synthesis of plastics, *i.e.* by polycondensation.

An analogy was seen in the synthesis of a silica glass[18] according to

$$Si(OR)_4 + 4\,H_2O \rightarrow [Si(OH)_4] + 4\,ROH$$

$$[Si(OH)_4] \xrightarrow{-2\,H_2O} SiO_2$$

which proceeds *via* polyorgano(hydroxy)siloxanes.

In fact, numerous oxide glasses—and also crystals—containing many elements from various positions in the periodic table can be synthesized without having to go through the molten phase if the highly reactive and invariably hydrolyzable alkoxides of several elements are allowed to react with one another in alcohol. Hydrolysis and polycondensation ultimately lead to the pure multicomponent oxide, *i.e.* a glass[19]. This reaction is illustrated for the known glass Duran 50 in Figure 4[20].

$$m\,Si(OR)_4 + n\,B(OH)_3 + p\,Al(OR)_3 + q\,NaOR + r\,KOR \rightarrow$$

$$[(Si_mB_nAl_pNa_qK_r)(OR)_{4m+3p+q+r}(OH)_{3n}] \xrightarrow{H_2O}$$

$$[(Si_mB_nAl_pNa_qK_r)(OH)_{4m+3p+q+r+3n}] \xrightarrow{\Delta,\ -H_2O}$$

$$[Si_mB_nAl_pNa_qK_rO_{(4m+3p+q+r+3n)/2}]$$

Fig. 4. Synthesis of a borosilicate glass Duran 50 by polycondensation (schematic).

This approach can be exploited for the production of thin oxide layers by a dipping process[21].

3. Plastics for Optical Applications

Glass still reigns supreme in the field of optics, and will continue to do so. Nevertheless, there are narrow yet interesting areas which plastics have already conquered and will conquer in the future. Information supplementing that in [1–7] will be found in[22–24]. In the following, examples will be given in which plastics are chosen because of their optical properties such as transmittance or refractive index, because of more rational production methods, or even because of their non-optical properties such as specific gravity, impact resistance, ease of coloring.

Once again the reader is reminded that poly(methyl methacrylate) plays a dominant role among plastics, and has even been described as "organic glass". However, all this is so well known (see, *e.g.* [25]) that it will only be mentioned in passing.

3.1. Spectacle Lenses

3.1.1. Thermoplastics

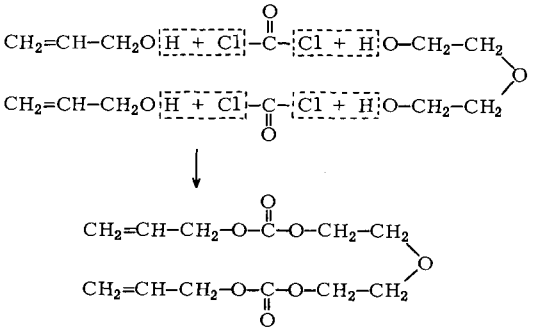
Most people have had close contact with lenses made of plastics such as poly(methyl methacrylate), cellulose acetate, or polycarbonate in sunglasses and safety spectacles. Rational production and impact resistance are of advantage. A disadvantage of thermoplastics is their sensitivity to scratching and wiping. Attempts have been made in the last five years to reduce the sensitivity to wiping by aftertreatment. One approach employed vacuum condensation with inorganic materials[26]—often glass—and another involved dip coating, preferentially with methylpolysiloxanes. Many of these developments were apparently promoted by the Glass Resin 650 of Owens Illinois[9], and led to specific formulations by various companies (Degussa, Toray, Daicel, Resart, Röhm, *etc.*).

Du Pont's Abcite® layers employ a copolymer of partly hydrolyzed vinyl acetate and tetrafluoroethylene which is crosslinked with a silicic ester. Curing is performed thermally or with hard radiation[27]. The search for new markets for large transparent plastic sheets as a substitute for glass, *e.g.* in buses as is promoted by present legislation in the USA, has had a stimulating effect on this very active field.

The prospects[28] of producing integral spectacles—frame and lenses injection-molded as a single unit—are very interesting, in order to meet the needs of those countries where normal medical care will remain impossible for years to come owing to the lack of any infrastructure. A lens which roughly satisfies requirements is said to be far better than no aid at all.

3.1.2. Duroplastics

The properties of poly(diethylene glycol diallyl biscarbonate) are ideal for spectacle lenses—whether correcting or non-correcting. Apart from its very good optical quality, it has the best wiping properties of all the transparent plastics produced as bulk solids. Its optical data (see 8 in Fig. 3) lie in the glass region and thus permit true competition between glass and plastic. The refractive index $n_d = 1.499$ can be modified as desired by copolymerization. The specific weight of 1.32 is roughly half that of glasses, which is of great advantage in lenses of high focal power; it shatters far less readily than the usual glasses.



The material developed by Pittsburgh Plate Glass[29] in the 1940's (CR 39, from "Columbia Resin 39") has long been accepted on the market and certainly promoted by legislation in the USA. On the other hand, the spectacle glass industry has taken up the challenge and marketed silicate glasses hardened by ion exchange which comply with legal requirements, as defined in a ball-impact test.

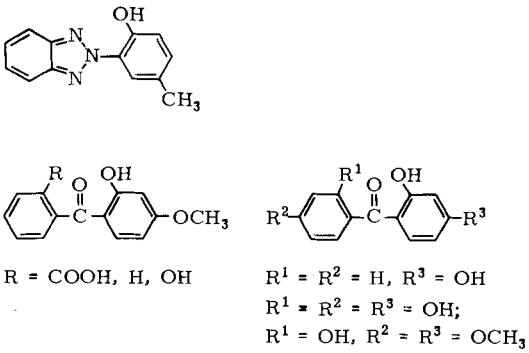
Of greater significance is the negative cosmetic effect in the case of plastics. Lenses produced from the lower refractive index material CR39 must have a greater curvature then those made of more refractive glass. Highly refractive but lighter glass, which has recently become available by replacement of the heavy element lead by titanium[30], will probably lower the market potential of CR39 in some areas[31].

Moreover, trends in fashion play a role in the spectacle market. Thus allyl carbonate (there are many trade names corresponding to the multitude of manufacturers) is coming to the fore because of numerous possibilities of bulk and surface coloring by diffusion processes. A diffusion technique is also used to produce a continuously changing transmission from the bottom to the top of the lens (graded spectacles). Glass is an excellent substance for making photochromic lenses whose transmission adjusts to the brightness of incident light.

Despite all improvements to CR39 (*e.g.* condensed SiO_2 coating), glass remains far more resistant to scratching, and lower weight becomes significant only with very thick spectacle lenses. Wearers of plastic spectacles must still forego the comfort of photochromism. Photochromic plastics remain reversible for only very limited periods.

CR39 monomer is synthesized from allyl alcohol, phosgene, and diethylene glycol and subjected to crosslinking polymerization at the two allyl groups with the aid of a dialkyl peroxydicarbonate, *e.g.* diisopropyl- (IPP) or dicyclohexyl peroxydicarbonate.

C R 39-Monomer



IPP

The monomer is introduced, together with 3—4 % of peroxide into a mold consisting of two glass half-molds with an optically perfect internal surface separated by an elastic spacer ring. On polymerization, induced by heating, the volume contracts by 14 %; the two half-molds to which the polymer tends to adhere—a problem in its own right—follow the contracting mass. There results a lens which requires no aftertreatment provided that it is of low focal power. In the range of medium focal power, it proves possible to impart the final curvature to only one side. The other receives its ultimate shape by grinding and polishing. At high focal powers, deviations from the shape of the mold are so large that only a rough casting can be produced by polymerization. Polyfocal lenses can also be produced by polymerization[32].

High-quality sunglass lenses are produced analogously from CR39. Polymerization may take hours. Since the mold is tied during this time, considerable costs result. For this reason, non-correcting lenses are preferably produced from large flat sheets of CR39 about 2 mm thick which are then sawn and worked similarly to glass. The disks are softened by heating and pressed or sucked into a curved mold; they retain this shape on cooling. When in use, their temperature should not be allowed to attain values leading to restoration of the original flat shape.

The UV stability of CR39 and the UV opacity of a spectacle lens can be adjusted in the finished product by several minutes' immersion in a boiling aqueous suspension of UV absorber (Fig. 5).

R = COOH, H, OH

$R^1 = R^2 = H$, $R^3 = OH$
$R^1 = R^2 = R^3 = OH$;
$R^1 = OH$, $R^2 = R^3 = OCH_3$

Fig. 5. Examples of UV absorbers based on hydroxyphenylbenzotriazole and hydroxybenzophenone.

The absorber diffuses a few μm into the surface where it is retained so strongly that it cannot be removed by water[33]. The depth of penetration is controlled by the nature of the substituent(s) at C-4 (and C-4'), and the position of the UV absorption edge by the number and position of the OH groups. This is a very apt example of "doubly tailored molecules".

The advantage of this method lies in its versatility, speed, and effective protective action (UV barrier), and also in the saving in expensive UV absorber and avoidance of a certain yellow tinge observed on bulk UV stabilization of optical material. The process can also be applied to other plastics. Choice of an inert solvent, which may not lead to swelling of the plastic, is of critical importance; water is often ideal for this purpose[34].

CR39 will probably retain its distinctive role mainly in the case of correcting glasses, variations being possible by copolymerization. Preliminary studies on epoxy resins have revealed various advantages with regard to rates of curing and coloring; a serious disadvantage is the sensitivity of the surface to wiping which is greater than that of CR39 and this has to be overcome by coating[35]. Epoxy resin lenses can be cast in plastic molds to which they do not adhere[36].

3.2. Other Products[22, 24, 37, 38]

3.2.1. Photographic Optics

The use of plastics [poly(methyl methacrylate), polycarbonate (which is increasingly replacing polystyrene), and polystyrene-acrylonitrile copolymers] in the image-forming optical system of a camera is limited to simpler cameras. The image-producing units in high-quality cameras remain a domain of glass owing to the temperature dependence of optical properties. The viewfinder optics of even expensive equipment is nowadays made almost entirely of plastic (lenses, Fresnel lenses, *etc.*). Practically the only exception is the bulky pentaprism of single lens reflex cameras. The narrow tolerances of the angles and the planarity of the surfaces are unattainable with plastics. A possible solution could lie in the use of a hollow prism.

A balanced mixture of plastic and glass is used in camera production. However, a trend toward the use of plastics cannot be denied, especially in "integral plastic optics" in which the optical components as well as mounting and centering components are produced in one piece. A classical example is the "Polaroid Land Super Swinger Camera", in which the transition to plastics is reported to have incurred cost saving of up to 95% for the optical system[16]. Viewed realistically savings of 30% can be expected. It is of considerable significance that aspherical plastic lenses are very easy to produce; just one such lens is said to replace several spherical glass lenses in many applications. (Pro's and con's are compiled in[23].)

3.2.2. Lighting Optics

Lighting optics is a field of application for plastics provided that high temperatures are not involved, such as occur in studio lighting[4].

3.2.3. Strain Optics

Transparent plastics having various strain-optical constants have proved of value[1].

3.2.4. Signal Optics

Plastics (frequently PMMA owing to the resistance to weathering often required) have cornered a considerable market and have replaced glass (*e.g.* automobile reflectors, warning signs, traffic signs). The colored disks of traffic lights can also be produced from polycarbonate by injection molding. Good flow properties of plastics permit highly rational production methods.

3.2.5. Polarization Optics

Poly(vinyl alcohol) and poly(vinyl acetate) films colored with iodine and stretched have long been in use[1]. Plane polarizers made of plastic have also been described for the infrared and ultraviolet spectral regions[39].

3.2.6. Filter Optics

Apart from colored transparent plastic disks, photographic filters are also made in sandwich form, consisting of a colored gelatin or cellulose acetate filter between glass layers, *e.g.* Kodak Wratten filters[40]. The variety of spectral transmission and the possibility of precise adjustment are considerable (for recent improvements see Section 4).

Protective welding spectacles having the required high IR absorption also belong in this Section. Again, plastics are seeking to penetrate into a domain of glass. Cast PMMA is used for protective glasses for electric welding, while injection-molded cellulose propionate is employed in those for autogeneous welding. It would appear that only American Cyanamid produces organic IR absorbers that can be used—to a limited extent—in practice. Protective glasses for welding are often coated with a transparent layer of gold to reflect strong IR radiation.

Goggles affording protection against laser light are produced from plastics by Glendale Optical Corp., USA. Dyes having extremely high extinction coefficients are incorporated into the plastics[41].

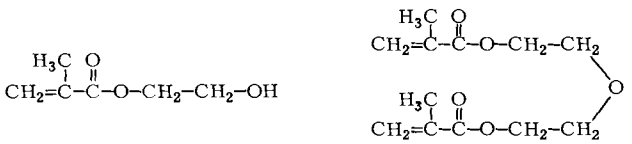
Narrow bandpass filters have been developed for the region between 2000 and 3000 Å[42]. For this purpose, organic absorbers are dissolved in partly condensed methylpolysiloxane which is then cured. This plastic was selected as "host material" owing to its high UV transmission.

3.2.7. Grating Optics

Original diffraction gratings are produced with extreme precision by scratching of glass and metal and may bear up to several thousand lines per millimeter. Plastic replicas of the valuable originals are made, *e.g.* gelatine replicas, which in turn serve as masters for the production of polyester replicas. Styrene or methyl methacrylate may also be polymerized in contact with the original gratings. The fidelity of reproduction is excellent (see also Section 4).

3.2.8. Fresnel Optics

Fresnel lenses, prisms, and mirrors are produced both by injection and by machining; these techniques are suitable for plastics. The principal material used is poly(methyl methacrylate).



3.2.9. Optical Cements

The classical optical cement, Canada balsam, can be replaced by plastics. Presumably the epoxy resins already used for this purpose will find wider use. Examples are cemented glass filter packs. Such cements can be formulated as desired in considerable variety from numerous combinations of resin and curing agent. Their good adhesion to glass, attributable to chemical reaction of the Si—OH groups of the glass surface with the epoxy or OH groups of the resin, can be further

enhanced by admixture of specific adhesion promoters (silicon compounds having "glass-functional" and "resin-functional" groups). On cementing lenses with non-thermoplastic cements, the elegant possibility of "fine adjustment" in the warm state is renounced.

3.2.10. Contact Lenses

Apart from hard plastics used as contact lenses, particular interest attaches to the hydrogels developed by *Wichterle*[43] which permit the production of soft lenses[44]. Crosslinking copolymerization of hydroxymethyl methacrylate with, *e.g.*, diethylene glycol dimethacrylate, reduces the water solubility of the former to water swellability.

Silicone rubber with a hydrophilized surface has also recently been used as a contact lens material[45]. Its high permeability to oxygen represents a considerable advantage.

3.2.11. Laser Optics

Even though numerous laser effects of rare earth chelates in solid solution are known, *e.g.* in PMMA, as are other laser-active organic compounds (metal phthalocyanines and dyes), we have to assume that the significance of "plastic lasers" made in this way will remain limited to special scientific problems. Some 50 organic dyes provide overlapping coverage of the range between 3900 and 10000 Å, and this range of variation is where their strength lies. Plastics have proved of value as "host material" for laser dyes, *e.g.* rhodamine G in polyurethane films[46,47].

3.2.12. Aspherical Optics

While the production of aspherical glass lenses requires time-consuming working of individual components, an aspherical steel mold will provide large numbers of aspherical plastic lenses. The economic advantages of plastic lenses become particularly significant with very large lenses (680 mm diameter)[16,28].

3.3. Light Guide Optics

In light guides, a rod or fiber of transparent material with a high refractive index (n_1) is surrounded with a transparent cladding of lower refractive index (n_2). Light falling on the end surface is conducted through the guide as a result of total reflection (Fig. 6).

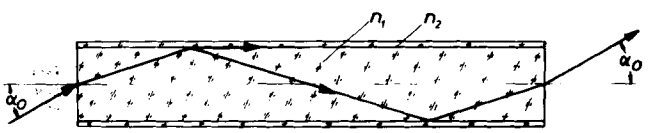


Fig. 6. Principle of light guide optics.

In order to ensure high light transmission and large aperture angle, the core material should have excellent transmittance, the likewise transparent coating should be in excellent contact with the core, and the difference between the refractive indices $n_1 - n_2$ should be as large as possible for it determines the aperture angle $2\alpha_0$, according to

$$n_0 \cdot \sin\alpha_0 = \sqrt{n_1^2 - n_2^2}$$

where n_0 is the refractive index of the surrounding medium.

Although light guide optics, and especially fiber optics, is a domain of glass, the contribution of plastics can no longer be overlooked.

The $n_d - \nu_d$ diagram (Fig. 3) shows the availability of several suitable and industrially accessible "pairs of plastics". Thus polystyrene core fibers ($n_d = 1.59$) have been cladded with poly(methyl methacrylate) ($n_d = 1.49$).

Better known are the Crofon® light guide fibers manufactured by Du Pont[48], which are produced from poly(methyl methacrylate) core fibers by extrusion and stretching. The cladding is applied continuously in a coating bath. Since the PMMA preferentially used as core material for optical reasons already has a relatively low refractive index, none of the mass-produced plastics can serve as cladding (with a necessarily lower refractive index). Use is therefore made of fluorinated esters of acrylic and methacrylic acid[49] (see Section 4.1).

Sheath and core should not absorb nor scatter light, *i.e.* should be noncrystalline or only slightly crystalline. According to *Schreyer*[4], scattering losses account for the major part of losses in plastic light guides. Absorption losses are effective mainly in the ultraviolet and the infrared spectral region. Optical contact is said to be good in Crofon®.

The development of fibers for communications has led to further optimization of plastic light guides. Meanwhile, glass-glass communications fiber optics having extremely low losses of only a few dB/km are available[50].

Plastics cannot meet these extreme requirements, at least as core material. Use of plastics as sheath material is considered in Section 4.1. Whereas Crofon® cables exhibit losses of 1100 dB/km, values of 470 dB/km have been reported for the new PFX fiber produced by Du Pont[51].

Plastic light guides are used mainly for control and illumination purposes.

Planar waveguides made of plastics have proved of interest for integral optical systems[46]. To this end, thin films are produced from solution or by plasma polymerization. Although the energies in the plasma are so high that only relatively inert structures have a chance of survival, this underinvestigated field would appear to offer numerous possibilities. Alkylpolysiloxanes and fluorinated polymers have been examined in more detail; they afford glass-clear films of low pore density.

4. Glass-Plastics Combinations for Optical Applications

4.1. Light Guide Optics

4.1.1. UV Fiber Light Guides

The fundamentals are presented in Section 3.3. Fiber optics have long been used for conducting visible light; until recently,

however, conduction of UV light was possible only by classical methods using lenses and prisms made of silica glass. UV fiber optics cannot be made from combinations of glass with glass or plastic with plastic; only glass-plastic combinations offer this possibility.

The only material transparent down to wavelengths of 200 nm that can be drawn out to fibers is silica glass having refractive indices of $n_{546} = 1.460$, $n_{365} = 1.475$, and $n_{255} = 1.506$. A glance at Figure 3 shows that there is no glass with a sufficiently low refractive index to serve as a possible cladding material, while plastics have such refractive indices. Since this cladding material should also be UV transparent and nonscattering, two readily accessible materials appear likely candidates from Figure 1, *viz.* methylpolysiloxane and Teflon FEP: in more general terms, alkylpolysiloxanes and extensively, if possible completely, fluorinated polymers insofar as they are glass-clear. The wavelength dependence of the refractive indices of Teflon FEP is shown in Figure 7[52].

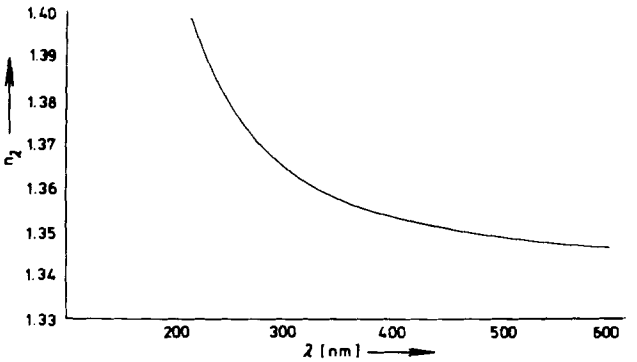

Fig. 7. Refraction by a Teflon film as a function of wavelength.

On this basis, JENAer Glaswerk Schott & Gen., Mainz, produced UV fiber optics[11-13] which provided the first means of conveniently handling UV light, and represent a new tool for use in medical technology, medicine, and numerous technical and scientific applications. The spectral transmittance is shown as an essential property in Figure 8. Further information will be found in company literature[11, 53] which also gives details concerning development.

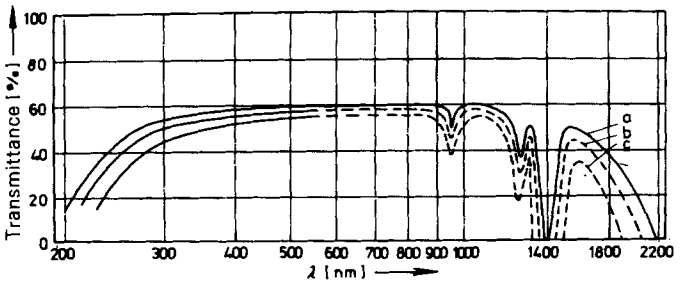

Fig. 8. Spectral transmittance of flexible UV light guides made of silica glass coated with Teflon FEP. Length of light guide: (a) 500 mm, (b) 1000 mm, (c) 1800 mm.

4.1.2. Communications Fibers

After this, to our knowledge the first, application of coatings made of transparent plastic on glass core material[12, 13], developments were reported which were aimed at producing low-loss fibers for transmission of information by the same principle[54-58]. The light to be conducted is usually 800 to 1060-nm radiation from a laser source; the excellent transparency of certain silica glasses is exploited and a low-refractive-index material is therefore required as coating; the same problem has already been solved in the case of UV fiber optics. Accordingly, the same plastics (fluoropolymers and alkylpolysiloxanes) are described as cladding for these (step index) communications fibers. Other plastics are unsuitable. Examples are shown in Figure 9.

$CF_2{=}CF_2$	Tetrafluoroethylene
$CF_2{=}CF{-}CF_3$	Hexafluoropropylene
$CH_2{=}CHF$	Vinyl fluoride
$CH_2{=}CF_2$	Vinylidene fluoride
$CF_3{-}O{-}CF{=}CF_2$	Perfluorovinyl methyl ether
$CF_2{=}CClF$	Monochlorotrifluoroethylene
$CH_2{=}C(CH_3){-}CO{-}O{-}CH(CF_3)_2$	Hexafluoroisopropyl methacrylate
$CH_2{=}C(CH_3){-}CO{-}O{-}CH(CF_3)CH_3$	Trifluoroisopropyl methacrylate

Fig. 9. Fluorinated monomers for optical cladding.

To our knowledge the resulting fibers having exceptionally low losses of a few dB/km are not in technical use. We can expect considerable investment in scientific and technical development in this "hotly contested" field in the near future. The two classes of compounds are fixed; however, variations are possible within these classes.

In conclusion, it should be mentioned that glass-plastic combinations are not essential in this field. The best prospects exist for glass-glass systems, in the form of gradient fibers. It is interesting to note that after achieving 470 dB/km with their PFX fiber[51], Du Pont has switched to the glass-plastic area and so far achieved 80 dB/km[59]. The core of these fibers consists of undoped silica glass and the cladding of an unnamed polymer. The price of this PFX-S-108-RO2 cable is presently 5 dollars per meter.

4.2. Grating Optics

The reader is referred to Section 3.2.7 for a description of the production of plastic gratings. Owing to the high thermal expansion of plastics, the line separations are dependent upon temperature. Some glass ceramics show practically no thermal expansion over a wide range of temperatures. If a drop of monomeric diethylene glycol diallyl biscarbonate is polymerized between a block of a glass ceramic and an original glass grating (Fig. 10) one obtains a plastic grating which is likewise not subject to expansion. In order to separate the original grating from the replica, the former is "siliconized", *i. e.* treated with methylchlorosilanes, prior to copying (Fig. 11). This procedure is rendered possible by the Si—OH groups of the glass. These groups are also responsible for the very firm adhesion between the plastic and the glass ceramic by copolymerization of "grafted" vinyl groups (Fig. 11)[60]. There results a plastic lattice some μm thick which is chemically bonded to the substrate.

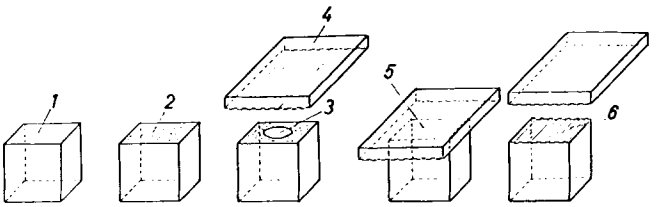

Fig. 10. Bonding of a grating of polymeric diethylene glycol diallyl biscarbonate to a glass support. 1 = glass block, 2 = vinylation of the surfaces, 3 = drop of diethylene glycol diallyl biscarbonate, 4 = original glass grating with a methylated surface, 5 = polymerization of the drop after spreading, 6 = plastic grating bonded to the glass block.

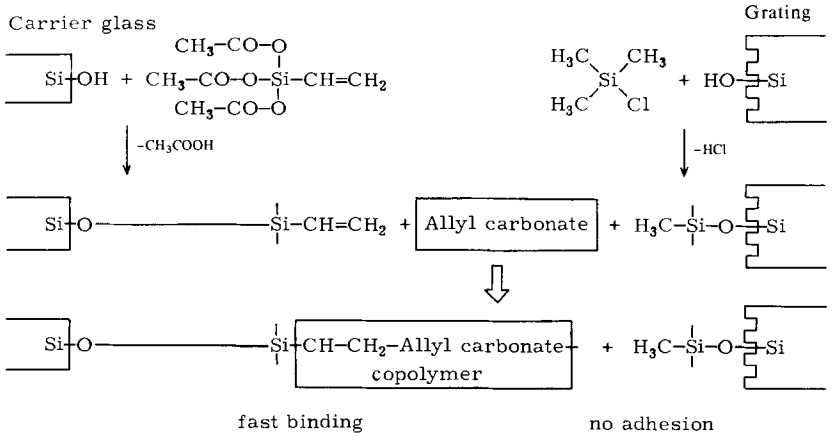

Fig. 11. Polymerization of diethylene glycol diallyl biscarbonate ("allyl carbonate") between the vinylated surface of a glass support and the methylated surface of a glass grating (schematic).

This example[61], which is not employed in practice, illustrates the chemistry of a glass-plastic composite and its potential.

4.3. Filter Optics

Optical filters for photographic or scientific purposes can be made from glass or plastic. Glass filters generally meet all the optical requirements made of them and stability requirements. Certain limitations do apply to their spectral scope, particularly if other properties are desired simultaneously, *e.g.* lack of fluorescence.

Plastics have almost unlimited spectral possibilities, but are less robust in use and prone to scratch. Moreover, plastic filters cannot be produced with the same high degree of planarity as ground and polished glass filters.

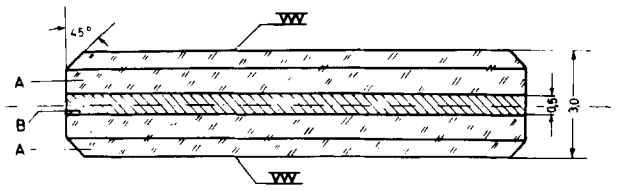

Fig. 12. Glass-plastic composite filter. A = cover glass, B = plastic composite layer, VVV high polish.

A glass-plastic composite filter as shown in Figure 12 combines the advantages of both materials. In their production, methyl methacrylate is treated with soluble dyes, silane adhesion promoters of the kind described in Section 4.2, and catalysts, and polymerized between two glass sheets separated by spacer strips. Owing to the ready oxidation of many dyes, azodiisobutyronitrile is used as initiator in place of the usual peroxides. These composites produced as large sheets are so firm, that filters can be produced with conventional glass-working machines[62]. Thus maximum planarity and scratch-resistance are ensured, as is resistance to climatic, and even tropical, conditions[63]—properties not found with plastic filters.

On the other hand, plastics offer ideal means of introducing absorbing materials which are impossible with glass. For example, a series of extremely sharp-edged UV suppression filters can be produced with extremely narrow tolerance with regard to the wavelength of the absorption edges, and having very low intrinsic fluorescence (Fig. 13)[64].

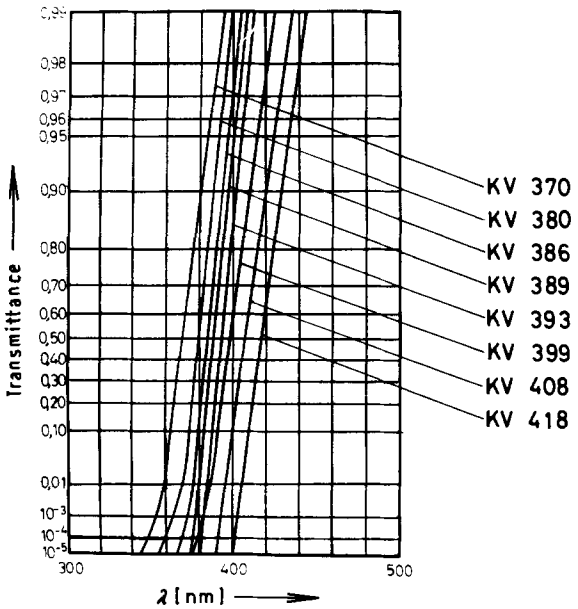

Fig. 13. UV suppression filter. KV 370 to KV 418 signify the values of internal transmission = 0.50.

Such combinations are accordingly suitable as UV suppression filters, as fluorescence suppression filters, as filters for the study of excitation conditions, and as conversion filters[65].

While plastic is protected by glass in these filters, we shall now consider cases in which inorganic material requires protection by plastic. This is the case with IR-transparent materials such as single crystals or polycrystals of alkali or alkaline earth halides. These products, which are often very expensive, are sensitive to moisture. They can be protected by coatings which, however, must also be IR-transparent.

For example, a polycrystalline lithium fluoride disk, which is transparent down to about 5—6 μm acquires excellent protection against water from a film of Teflon FEP just a few μm thick, which is applied as a dispersion, without losing its IR transparency[66]. Films applied in this way enclose LiF disks so well that they can be kept for years under water. The protective layer of Teflon FEP can be also applied by sputtering (see, *e.g.* [67]). As a rule, however, this leads to far-reaching structural changes.

4.4. Insulating Windows

It may appear surprising to find mention of windows in an article about optical materials. And yet, in these days of rising energy prices, a window no longer merely fulfills the function of mechanical protection against the whims of nature through which light falls and people can look out. Its protective function has meanwhile also become optical in nature, *e.g.* sunshielding glasses in high-rise buildings which reduce the load on air conditioning plant on sunny days or conversely prevent the escape of longwave IR radiation in winter. Reflecting coatings best serve both purposes, *e.g.* layers of TiO_2 at interference layer thicknesses or of metals such as Au, Ag, Cu[68]. Of course, this is a domain of glass. Triply-glazed windows, of which one pane may also bear a reflecting coating, have very low heat transfer coefficients (k values). The third pane, which leads to considerably greater weight and greater thickness of the overall system, can be replaced by a coated plastic film. Thus a doubly-glazed window is transformed into a triply-glazed window without any significant increase in weight; coating of the film and carefully chosen gas filling of the intermediate spaces leads to very low heat transfer and—where desired—affords protection against sunlight[69]. Table 1 shows the astonishing extent to which the k value of such a "film window" can be reduced. The k value of 0.65 kcal m^{-2} h^{-1} K^{-1} corresponds to a 0.5-m solid brick wall.

Table 1. k values of window glazing.

Kind of glazing	k [kcal m^{-2} h^{-1} K^{-1}]
Single glazing	5.0
Double glazing (12 mm air)	2.6
Triple glazing (2 × 12 mm air)	1.8
Double glazing (12 mm air) (gold)	1.55
Double glazing (12 mm krypton) (gold)	1.06
Film window (metal) (2 × 6 mm air)	1.46
Film window (metal) (2 × 12 mm air)	0.95
Film window (metal) (2 × 6 mm krypton)	0.79
Film window (metal) (2 × 8 mm krypton)	0.65

Such windows have been made on an experimental basis; however, many questions still surround their use in practice.

It was the author's intention to close a rather sober account of plastics in optics with a somewhat futuristic section, in order to show that plastics can often provide solutions for freshly occurring problems in spite of all their limitations. It is not the material itself which should be placed in the foreground, but the solution of problems. The question of the material—plastic or glass—is admittedly important, but nevertheless secondary.

While thanking many colleagues for their kind support, I would like to mention two co-workers specifically. Karl-Heinz Wiesner has promoted the entire development of plastics thanks to his dedicated engagement and understanding, and Paul Hinz has done the same for the unorthodox glass synthesis and the coating processes. The author wishes to express his particular thanks to them and their co-workers for more than ten years of cooperation.

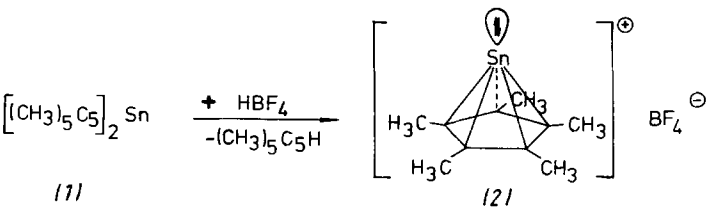
COMMUNICATIONS



Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis and Structure of the *nido*-Cluster $(CH_3)_5C_5Sn^+$ [**]

By *Peter Jutzi, Franz Kohl*, and *Carl Krüger*[*]

Species of the type $R_5C_5Sn^+$ have previously only been observed in the mass spectra of dicarbonyl(η^5-cyclopentadienyl)ferriostannanes[1] and some cyclopentadienyl compounds of divalent and tetravalent tin[2]. We have now been able to isolate for the first time such an ion as the tetrafluoroborate and to elucidate its structure by X-ray crystallography.

Treatment of bis(pentamethylcyclopentadienyl)tin *(1)*[2d] with tetrafluoroboric acid leads to formation of pentamethylcyclopentadiene and the salt $(CH_3)_5C_5Sn^+BF_4^-$ *(2)*, whose cation exists in the form of an axially symmetric pentagonal bipyramidal *nido*-cluster:

(1) *(2)*

Compound *(2)*, which is isolable as colorless crystalline needles, is air- and moisture-sensitive and rapidly turns violet on exposure to daylight. On the other hand, no decomposition is observed over several weeks when it is stored at −20°C and in the dark. *(2)* is readily soluble in strongly aprotic solvents (acetonitrile, nitromethane, dichloromethane). ^{1}H-NMR (in CH_2Cl_2): $\delta CH_3 = 2.15$ (s); ^{11}B-NMR (in CD_3CN, ext. $BF_3 \cdot OEt_2$): $\delta BF_4^- = -0.53$ (s); ^{19}F-NMR (in CD_3CN, ext. $CFCl_3$): $\delta BF_4^- = 146.8$ (s). Conductivity (in CH_3NO_2, 20°C): $\Lambda = 127.4\ \Omega^{-1}\ cm^2\ mol^{-1}$ (1.035×10^{-3} M) [comparative measurement on $C_6H_5CH_2N(C_2H_5)_3^+Cl^-$: $\Lambda = 130.5\ \Omega^{-1}\ cm^2\ mol^{-1}$ (1.010×10^{-3} M)]. Molecular weight determination (cryoscopic in HMPT): 175 [M_r for *(2)* = 340.7].

The orbital and electron requirements for clusters are predicted from MO considerations and established rules[3]. The new cation in *(2)* can be placed quite neatly in the series

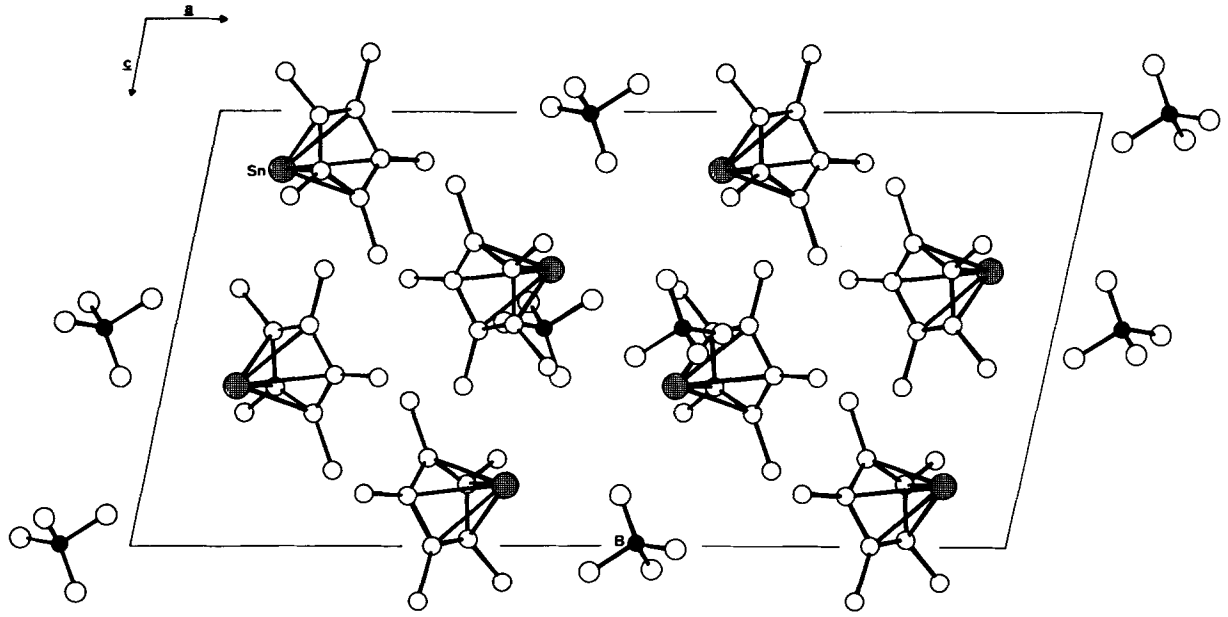

Fig. 1. Crystal structure of η^5-pentamethylcyclopentadienyltin(II) tetrafluoroborate *(2)*.

of well-known pentagonal-pyramidal *nido*-clusters[4]. As in the case of comparable cyclopentadienyl systems the accuracy of the X-ray structure analysis[5] of *(2)* is reduced because of rotational disorders which manifest themselves in high thermal vibration parameters of the lighter atoms.

The Sn—C bond length in *(2)* ($2.462 \pm 0.016 \times 10^{-10}$ m) is considerably shorter than in Cp_2Sn[6] (2.71) or CpSnCl[2b] (2.61 mean value); in the ring the average bond length is 1.39 ± 0.03, the C-methyl bond length 1.51 ± 0.03. Surprisingly[7], the methyl groups are oriented away from the central atom in the same fashion, and are bent at an average angle of $\theta = -4°$ (corresponding to 0.11) to the plane through the Cp ring (planar ± 0.01). The shortest SnB distance in the lattice is 3.590 (Sn—F 2.97—2.99).

Experimental

A 54 % ether solution of HBF_4 (14.3 mmol) is added dropwise with stirring to a solution of *(1)* (5.59 g, 14.4 mmol) in 300 ml diethyl ether cooled to −78 °C. After concentration of the mixture to *ca.* 50 ml the resulting pale yellow precipitate is filtered off, recrystallized from toluene and dried in a high vacuum. Yield: 1.50 g (31 %) of *(2)*, m.p. 210—218 °C (decomp).

Bis(trimethylsilyl)zinc and -cadmium[**]

By *Lutz Rösch* and *Gerald Altnau*[*]

Organozinc derivatives number among the first organometallic compounds to be synthesized and are well established reagents in preparative chemistry. In contrast, the homologous silylzinc derivatives were hitherto virtually unknown; the first representative of this series of compounds, bis(triphenylsilyl)-zinc was only briefly described in 1963[1].

We have now been able to synthesize the first alkylsilylzinc compound bis(trimethylsilyl)zinc *(1)* by reaction of zinc chloride or zinc acetate with lithium tetrakis(trimethylsilyl)aluminate[2] in diethyl ether.

$$2\,MX_2 + LiAl(SiMe_3)_4 \cdot 2DME \xrightarrow{Et_2O} 2\,M(SiMe_3)_2 + \cdots$$

X = Cl, CH_3COO — *(1)*, M = Zn
DME = 1,2-Dimethoxyethane — *(2)*, M = Cd

The pale yellow crystalline product *(1)*, which is isolable by vacuum sublimation, ignites spontaneously and is readily soluble in ethers, benzene and pentane. On treatment with dilute hydrochloric acid, a strongly exothermic reaction ensues with formation of trimethylsilane. The composition of *(1)* was confirmed by elemental analysis and by the mass spectrum (molecular peak with calculated isotope distribution). The ^{1}H-NMR spectrum (benzene) shows a sharp signal at $\delta = 0.20$. Only one absorption band is observed in the expected range for the ZnSi stretching vibration, both in the IR spectrum (305 cm^{-1}) and in the Raman spectrum (330 cm^{-1}). These findings indicate that the molecule is linear, *i. e.* the structure corresponds to that of the homologous bis(trimethylsilyl)mercury[3]. Compound *(1)* is not very stable thermally; slow decomposition with separation of metal takes place even at room temperature. However, it can be stored for *ca.* three weeks at −20 °C.

Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Bis(trimethylsilyl)cadmium *(2)*, which was likewise previously unknown, can be synthesized in the same way. Its properties are similar to those of the zinc compound. However, it is even less stable thermally; at $-20°C$, *(2)* decomposes within *ca.* 2 days with precipitation of the metal. The ^{1}H-NMR spectrum contains only one signal near that of the TMS standard, which still shows no splitting at $-10°C$. This signal would be expected to be flanked by two satellite bands [coupling with ^{111}Cd (13 %, $I=1/2$) and ^{113}Cd (12 %, $I=1/2$)]. The absence of satellites points to rapid exchange of the trimethylsilyl groups, as observed in the case of dimethylcadmium[4] and divinylcadmium[5]. According to the IR spectrum (CdSi stretching vibration at 320 cm^{-1}), *(2)* should also be a linear molecule; a Raman spectrum could not be recorded because the compound is very sensitive to light.

The preparatively important bis(trimethylsilyl)mercury can also be conveniently synthesized by reaction of lithium tetrakis(trimethylsilyl)aluminate with mercury acetate. We are presently investigating the general utility of this synthetic route as a method for the preparation of trimethylsilylmetal compounds.

Experimental

All operations must be carried out in the absence of air and moisture (argon as inert atmosphere).

(1): $Zn(OOCCH_3)_2$ (0.9 g) is added portionwise at room temperature to a vigorously stirred solution of $LiAl(SiMe_3)_4 \cdot 2DME$ in Et_2O (50 ml) with continuous passage of argon. After one hours' stirring, the solvent is removed at 0 °C in an oil-pump vacuum. Sublimation of the residue (room temperature/$-20°C$) from the reaction flask affords pale yellow star-shaped crystals, which immediately ignite and decompose on exposure to air. Yield 0.23 g (25 %).

(2): $CdCl_2$ (1.8 g) is allowed to react in the same way as above. $Cd(SiMe_3)_2$ is obtained in the form of yellow crystals, yield 0.35 g (27 %). This compound is also light-sensitive, and can be stored for only short periods in an ice-box.

Coordination Number 3 in Co^{II}: $Na_{10}[Co_4O_9]$, an Oligooxocobaltate(II)[1]

By *Wilfried Burow* and *Rudolf Hoppe*[*]

In the newly prepared oxide $Na_{10}[Co_4O_9]$ we find the first example of cobalt coordinated in an almost trigonal planar environment. Lustrous red, robust single crystals of $Na_{10}[Co_4O_9]$ are obtained on heating an intimate mixture of Na_2O and "active" CoO in a cobalt tube[2] [Na:Co = 2.2:1, 500 °C, 30 d]. The crystals are extremely sensitive towards moisture (hydrolysis) and immediately deliquesce on exposure to air. The reaction product was therefore handled under absolutely dry argon, and single crystals were selected and picked out under the microscope.

According to Weissenberg photographs $Na_{10}[Co_4O_9]$ crystallizes triclinically with $a=12.18_1$, $b=8.52_7$, $c=8.32_2$ Å; $\alpha=119.96_7$, $\beta=87.89_1$, $\gamma=116.75_7°$; $Z=2$ (four circle diffractometer data). The structure was determined with 4928 symmetry independent reflections (Mo-Kα, graphite monochromator, $3° \leq \theta \leq 34°$)[3] by direct methods[4] and interpretation of the three-dimensional Patterson synthesis. Refinement with anisotropic temperature parameters for all particles gave for 3364 reflections the R value 6.10 % (space group $P\bar{1}$).

lengths 1.86—1.96 °A) and terminal O atoms (Co—O bond lengths 1.76—1.82 Å)]. In contrast, not all Na particles are coordinatively equivalent. This follows obligatorily from the composition if it is presupposed that all Co atoms have the coordination number (C.N.) 3 and all Na atoms and O atoms must as far as possible be coordinatively equivalent (cf. Table 1). One Na particle and one O particle (Na^5 and O^4) each differ coordinatively from the others. The equivalence of all the remaining Na towards O, as given in Table 1, refers only to the coordination number, not to the function of Na as bridge between various $[Co_4O_9]$ groups. Seven Na particles each link three asymmetric $[Co_4O_9]$ groups; Na^3, Na^5 and Na^9 each link four such groups, while Na^3 and Na^4 are unique insofar as they do not belong to any bridging oxygen.

Secondary structure: In a $[Co_4O_9]$ group the bridging O atoms form O—Co—O angles of 116.47, 96.32 and 115.99° with the Co atoms. The conformation of the group is difficult to explain: one half of the group (with Co^1 and Co^2) is almost planar, the other half (with Co^3 and Co^4) is both twisted with respect to the first as well as being twisted itself.

Tertiary structure: In the projection along [001] the assumed valency bonds between each two Co atoms of a $[Co_4O_9]$ group are almost parallel to [010]. It thus follows that the $[Co_4O_9]$ groups are also parallel [010] but out of phase with each other. This results in the formation of channels along [001] in which Na particles reside. The Madelung Part of the Lattice Energy (MAPLE[5] = 15843.3 kcal/mol) agrees with the sum of the MAPLE values of the binary oxides (15654.6 kcal/mol, Δ MAPLE = 1.1 %).

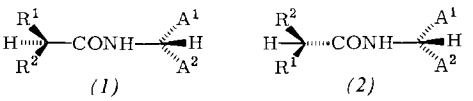
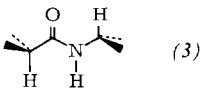
Extreme Liquid Chromatographic Separation Effects in the Case of Diastereomeric Amides Containing Polar Substituents[**]

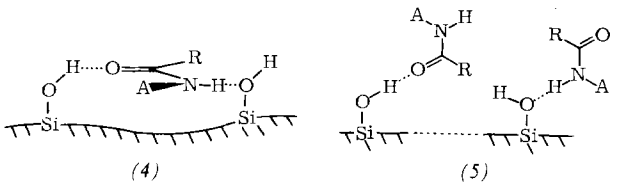


By *Günter Helmchen, Günter Nill, Dieter Flockerzi, Willi Schühle*, and *Mohamed S. K. Youssef*[*]



In contrast to the classical method *via* fractional crystallization of diastereomeric salts the separation of the enantiomers of chiral carboxylic acids and amines can be carried out by liquid adsorption chromatography of diastereomeric amides in a directed way, *i. e.* with pre-estimation of separation effects[1a] and with simultaneous determination of the enantiomeric purity[1b] and absolute configuration[1c]. Besides the low efficiency of the—now superseded—conventional column chromatography[2], non-optimal separation factors and especially the extreme difficulty of amide hydrolysis[3] were obstacles to wider preparative application of the method.

We have now developed reagents which not only ensure very high separation factors but also ready hydrolysis (cf. [4]).



Particularly well suited for demonstrating the effects are the diastereomeric amides *(1)/(2)*, since their conformation in solution, the starting point of our model considerations, is well defined[1a] and the substituents R and A can be easily varied. From chromatographic data (adsorbent: silica gel[5]) four simple postulates were derived which serve as guidelines in the search for structural features necessary for high separation effects.

1. The conformation of the amides is the same in the dissolved state and in the adsorbed state[6]. In cases *(1)/(2)*, for both diastereomers it is determined by the planar structural element *(3)* (common plane) provided neither R^1 nor R^2 form a hydrogen bond to the amide group[7].

2. Binding to silica gel preferentially takes place *via* hydrogen bonding[9]. Hence the contribution of the amide group, which can be bound as described by *(4)* and *(5)*, is particularly high.

3. Significant diastereoselectivity is to be expected only for the state *(4)*. This arrangement is perturbed in favor of unbound or states *(5)* by substituents R and A with weak affinity to the silica gel. The perturbing effect of a substituent must be determined empirically. We assess it formally by the designations chromatographically large (cL) and small (cS), since for alkyl and aryl groups it approximately parallels the steric bulk in the direction perpendicular to the amide plane[9].

4. (Configuration rule) The groups R^1 and R^2 as well as A^1 and A^2 are classified according to their perturbing effect as R^{cL} and R^{cS} and A^{cL} and A^{cS}. Due to the better shielding of the amide group, the diastereomer whose R^{cL}/A^{cL} groups are situated on opposite faces of the common plane is eluted first.

Which structural features, according to these postulates, ought to lead to particularly good separating effects, as assessed by the separation factor α? Postulate 3 implies that α increases with the difference in steric bulk between A^1 and A^2 or R^1 and R^2. This is so for the amides *(a)* and *(b)* (cf. Table 1) but not in the series *(c)—(e)*, even though postulate 4 remains correct. Apparently the proportion of diastereoselectively acting states *(4)* decreases for *both* diastereomers with increasing size—especially broadening—of the apolar substituents. An extreme case is *(f)*.

(p)	$(CH_2)_2OH$	Ph	CH_2OH	Ph	5.77	1031	0:1
(q)	CH_2CO_2Me	Ph	CH_2OH	Ph	3.36	713	1:1

[a] Apparatus: see [1b]; pressure: 150 bar; inert substance: pentane; column: 30 × 0.3 cm for *(a)*–*(f)*, 20 × 0.3 cm for *(g)*–*(q)*, packed with Merckosorb SI 60, 5 µm. [b] All the new compounds were prepared diastereomerically pure and gave correct analyses and spectra; the configuration of *(l)* and *(o)* was confirmed by ^{1}H-NMR (method: *G. Helmchen*, Tetrahedron Lett. *1974*, 1527), otherwise by synthesis. [c] The composition of the eluent could not be held constant because of the difference in polarity of the compounds. As shown by case *(i)*, α decreases with increasing content of ethyl acetate. [d] $\alpha = (t_2 - t_0)/(t_1 - t_0)$; t_1, t_2: retention time of the first and second eluted amide, respectively; t_0: retention time of pentane. [e] $\Delta(\Delta G) = -RT\ln\alpha$.

In order to counteract this undesirable effect polar groups were introduced for the stabilization of *(4)*. The OH group proved particularly effective for this purpose. Thus, the series *(g)*–*(i)* corresponding to *(c)*–*(e)* shows (comparison of $A^1 = CH_3$ with $A^1 = CH_2OH$) not only a considerably higher α-level but also the expected increase with increasing difference in bulkiness of the apolar substituents. Equally favorable as that of the amine moiety is a polar group of the acyl moiety; compare *(a)* with *(j)* or *(k)*.

As to be expected on the basis of the proposed structure *(4)* the influence of the polar group is dependent upon its position. This manifests itself for the OH group in the series *(j)*–*(l)* and for the ester group, whose overall effect is weaker, in the series *(m)*–*(o)*. That the effect is particularly large in the case of a hydroxyl group in the γ position relative to the carbonyl C makes it "chemically" useful.

A further increase is observed with compounds containing polar groups in both moieties; see *(p)* and *(q)*. The postulates 1–4 are valid also for these extreme cases regarding separation if the polar groups are formally assigned to the cS class.

Separation factors $\alpha > 2$ are rarely found, even for cyclic diastereomers. The significance of such values in practice must be judged in relation to the number of theoretical plates of the chromatographic system[2]. Assuming typical conditions ($k'_2 = 5$), with $\alpha = 1.05$, 1.2, 1.5, 2.0, and 5, *ca.* 15000, 1200, 300, 130, and 50 theoretical plates, respectively, are necessary[8] for a baseline separation ($R_s = 1.2$). Accordingly, separations with α above ≈ 2 can be readily carried out even on primitive columns.

[2] Reproducible long-lived (> 1 year) preparative glass columns (45 × 4 cm; 300 g silica gel Merck LiChroprep 15–25 µm) with 10000 ± 1000 theoretical plates (naphthalene, hexane/ethyl acetate (95:5), 50 ml/min) can even be prepared by beginners: *B. Glatz, G. Helmchen*, unpublished. Under the same test conditions conventional open columns have 50–300 theoretical plates, TLC plates or Merck-Lobar columns 600–1200.

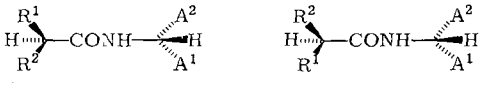
[3] Previously, the only alternative to the hydrolysis was the rearrangement of the corresponding nitrosamides, in which the amine is destroyed: *G. Helmchen, V. Prelog*, Helv. Chim. Acta 55, 2599 (1972); see in particular p. 2601, paragraph 1.

[4] a) *G. Helmchen, G. Nill, D. Flockerzi, M. S. K. Youssef*, Angew. Chem. *91*, 65 (1979); Angew. Chem. Int. Ed. Engl. *18*, 63 (1979); *G. Helmchen, G. Nill, ibid. 91*, 66 (1979) and *18*, 65 (1979).

[5] For other adsorbents, especially reversed phases, the postulates must possibly be modified.

[6] We are well aware that this postulate might excite contradiction; but in many more than 100 cases so far investigated it has been found to be valid without exception. The Ugi-Ruch method which does not contain the concept of conformation was shown to be inapplicable here: *H. Völter*, Dissertation, Universität Stuttgart 1978.

[7] According to IR and NMR spectra none of the compounds listed in Table 1 shows hydrogen bonding of this kind.



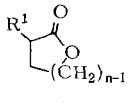
[8] *L. R. Snyder*: Principles of Adsorption Chromatography. Marcel Dekker, New York 1968.

[9] The repulsive perturbation effect of aryl groups towards alumina is smaller; it is known that arenes are also adsorbed on alumina much more strongly than on silica gel [8].

Preparative Scale Directed Resolution of Enantiomeric Carboxylic Acids and Lactones *via* Liquid Chromatography and Neighboring-Group Assisted Hydrolysis of Diastereomeric Amides[**]

By *Günter Helmchen, Günter Nill, Dieter Flockerzi*, and *Mohamed S. K. Youssef*[*]

The diastereomeric amides *(1)*/*(2)* with OH groups located in the γ or δ position to the carbonyl group [R^1 or $R^2 = (CH_2)_nOH$ and/or A^1 or $A^2 = (CH_2)_{n-1}OH$, $n = 2, 3$] show high, in certain cases extreme separation factors in liquid absorption chromatography[1]. We now report that these amides also have favorable chemical properties. Their cleavage takes place under acidic conditions mild enough, so that relati-



(1) *(2)*

vely sensitive compounds can be worked with, but not under such mild conditions that reaction occurs on the weakly acidic adsorbent silica gel. In cases where R^1 or $R^2 = (CH_2)_nOH$, $n = 2$, 3, reaction with 0.5–1 N mineral acid at 50–90 °C leads to formation of lactones *(3)*, $n = 2$, 3[2] and amines

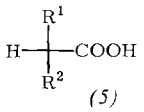
[**] Directed Resolution of Enantiomers *via* Liquid Chromatography of Diastereomeric Derivatives, Part 5.– This work was supported by the Deutsche Forschungsgemeinschaft (Projekt He 880/6).–Part 4: [1].



(4). In cases where A^1 or $A^2 = (CH_2)_{n-1}OH$, $n = 2, 3$, *N,O*-acyl transfer[3] occurs, followed by ester hydrolysis to give the carboxylic acids *(5)* and amines *(4)*. Depending upon the properties of R^1 and R^2, 0.5–3 N mineral acid is necessary at *ca.* 50–100 °C. As a rule the yields are almost quantitative.

(3)

(4)

(5)

(4a) $A^1 = CH_2OH$, $A^2 = Ph$
(4b) $A^1 = CH_3$, $A^2 = Ph$

These results thus demonstrate that the sought-after method (see [1]) for directed resolution of enantiomeric carboxylic acids or amines has in principle been realized, as has also a method for the separation of enantiomeric lactones:

1. Racemic carboxylic acids *(5)* *via* the usual activated derivatives (acyl chlorides, imidazolides *etc.*) can be reacted with amino alcohols *(4)*, A^1 or $A^2 = (CH_2)_nOH$, $n = 1, 2$, to give the diastereomeric amides *(1)/(2)*, which can be separated chromatographically and subsequently hydrolyzed. (−)-(*R*)-phenylglycinol *(4a)* is a suitable reagent here, since it is UV-active (chromatographic detection), is commercially available[4], and is easily recoverable almost quantitatively (cf. Table 1 and Experimental). Other compounds that can be prepared from amino acids, *e.g.* phenyl alaninol, alaninol, valinol, leucinol, and amides or esters of serine also give good results[5]. The nitrosamide rearrangement, an alternative for the hydrolysis in the case of extremely sensitive carboxylic acids, can also be employed in the case of *N*-acyl derivatives of amino alcohols, cf. *(5d)* in Table 1.

2. Racemic lactones *(3)* can by direct reaction with amines *(4)* be converted into amides *(1)/(2)*, R^1 or $R^2 = (CH_2)_nOH$, $n = 2, 3$ (catalyst: 2-hydroxypyridine[6]). Since these amides show high separation factors even in the case of apolar substituents A^1, A^2[1], amines such as (−)-(*S*)-1-phenylethylamine *(4b)*[7] are sufficiently good separating reagents. Cleavage of the chromatographically separated amides affords (apart from in the case where $R^1 = Ph$) enantiomerically pure lactones *(3)* (cf. Experimental and Table 1).

Such lactones have a strong tendency to racemization. We have therefore determined the enantiomeric purity of the particularly sensitive lactone *(3c)* in the following way: (+)-*(3c)* (for data see Table 1) was treated with hydrogen bromide/glacial acetic acid and then with zinc/glacial acetic acid; the 2-benzylbutyric acid formed was > 99.9 % enantiomerically pure [HPLC of the diastereomeric amides with *(4b)*][8].

3. Enantiomerically pure lactones *(3)* are now readily available for the first time. However, they are not suitable as separating reagents for amines since they partially racemize upon direct conversion to amides (for a solution to this problem see [9]).

Experimental

(1)/(2) from *(5)*: 1 mol *(5)* is converted with oxalyl chloride into the crude acyl chloride, whose solution in anhydrous dioxane is added dropwise to a solution of 1.0 mol *(4a)* and 1.2 mol triethylamine in dioxane at 5–10 °C. After removal of the solvent 1 N hydrochloric acid is added and the amides *(1)/(2)* are extracted with methylene chloride.

(1)/(2) from *(3)*: A solution of 1 mol *(3)*, 2 mol *(4a)* or *(4b)* and 1 mol 2-hydroxypyridine in 0.5 l anhydrous toluene is heated to boiling for 25 h under an inert gas, then partially evaporated down and the residue partitioned between CH_2Cl_2 and 0.5 N hydrochloric acid.

Separation of *(1)* and *(2)*: The crude mixture of *(1)/(2)* is chromatographed, either on a column as mentioned in Ref.[1] or on a Merck-Lobar column (UV detection, eluent: petroleum ether (low-boiling)/ethyl acetate in a ratio shown to be optimal by TLC). Alternatively, the mixture can be fractionally crystallized with TLC monitoring of the separation progress (in all cases widely separated spots).

Amide cleavage: For recovery of *(3)* the vigorously stirred mixture of 1 mol of the diastereomerically pure *(1)* or *(2)* and 2 l 1 N H_2SO_4 in dioxane/water (1:1) is heated at 80–90 °C for 16 h then diluted with water and extracted with methylene chloride to afford *(3)* in the neutral part. The recovery of *(5)* is carried out analogously, but as a rule up to 3 N H_2SO_4 is used and the mixture is heated to boiling. Since the rate of reaction varies greatly with the nature of the acyl group (reaction time a few minutes to several hours) the conversion

Table 1. Separation of enantiomeric lactones *(3)* and carboxylic acids *(5)* by chromatography of diastereomeric amides *(1)/(2)* ($A^2 = Ph$, $A^1 = CH_2OH$ or CH_3) and their cleavage under acid conditions (cf. Experimental).

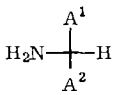
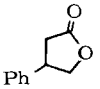
Preparative Scale Directed Resolution of Enantiomeric Amines *via* Liquid Chromatography of Diastereomeric 4-Hydroxybutyramides[**]



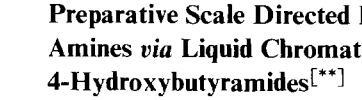
By *Günter Helmchen* and *Günter Nill*[*]

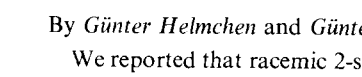
We reported that racemic 2-substituted butyrolactones *(1)*, R ≠ aryl, can be readily resolved into enantiomers by converting them with an enantiomerically pure amine *(2)* into diastereomeric 4-hydroxybutyramides, separating these by liquid chromatography and cleaving the separated products under mild acidic conditions back into lactone and amine[1]. In view of the practical importance of optically active amines *(2)* the converse of this method, the separation of enantiomeric amines by reaction with an enantiomerically pure lactone is of great interest. However, the realization of this concept was at first thwarted by the fact that enantiomerically pure 2-alkylbutyrolactones [investigated for the cases: *(1)*, $R = CH_2C_6H_5$ and *n*-butyl] partially racemize under the influence of catalysts (*e.g.* 2-hydroxypyridine) required for the direct reaction with amines.



The most advantageous of several solutions[2] to this problem achieved so far was gained from investigations of diastereomeric amides in which the distances between the chirality centers were varied. As can be seen from Table 1, shifting the chirality center of the acyl group from the α- to the β-position with respect to the carbonyl group leads to only a slight decrease in the separation factor α, while displacement to the γ-position leads to a very large decrease in the separation factor. Consequently, not only α- but also β-substituted carboxylic acids and lactones can be separated quite easily *via* diastereomeric amides. Conversely, β-substituted lactones must be suitable reagents for the resolution of amines *(2)*, since they are stable towards racemization.

(1)





(2)

(3)

We have investigated 3-phenylbutyrolactone *(3)*, the first example of this new class of separating reagents. The preparation of *(3)* and the separation into two pure enantiomers [*via* the diastereomeric amides *(6a, b)*, cf. Table 1] are described in the Experimental section[3].

Table 1. Liquid chromatographic separation factors [a] of diastereomeric amides having differently spaced chirality centers (23 °C; silica gel; hexane/ethyl acetate (1:1); 150 bar).

	R = OH, R′ = H	α	R = H, R′ = OH	α
	(4a, b)	2.81	*(8a, b)*	2.56
	*(5a, b)*	2.83	*(9a, b)*	2.20
	*(6a, b)*	2.07	*(10a, b)*	1.93
	*(7a, b)*	1.10		

[a] For definition of the separation factor α and description of the measuring apparatus see [1a] Table 1.

Directed resolutions of the enantiomers of amines *(2)* are carried out with (−)-*(R)*-*(3)* [or with (+)-*(S)*-*(3)* in the "mirror image" way] according to the method summarized in Scheme 1 (for examples see Table 2). The configurational relationships were determined as follows: 1. The chromatographic model presented in [1] can be applied to the case of the diastereomeric amides with a chirality center in the β-position to the carbonyl group, since the conformation of compounds $R^1R^2CH(CH_2)_nCONHA^1A^2$ (R^1, R^2 = alkyl, aryl, $n \neq 0$) can generally be given[4]. 2. A^{cL} and A^{cS} represent the "chromatographically larger and smaller", respectively, of the groups A^1, A^2 of *(2)* (for the definition of these terms see [1]). 3. The separation of the enantiomers of *(3)* *via* the diastereomeric amides *(6a, b)* already constitutes a directed resolution according to Scheme 1 and establishes the configuration of *(3)*. For unequivocal confirmation (−)-*(R)*-*(3)*, $[\alpha]_D^{20} = -50°$ ($c = 4.7$, MeOH) was converted with hydrogen bromide in glacial acetic acid into 4-bromo-3-phenylbutyric acid, and this in turn with zinc in glacial acetic acid into (−)-*(R)*-3-phenylbutyric acid[5], $[\alpha]_D^{25} = -55°$ ($c = 2$, benzene).

Experimental

Separation of the enantiomers of *(3)*: A mixture of 28.9 g *(3)*[6], 17 g 2-hydroxypyridine, 43.2 g (−)-*(S)*-1-phenylethylamine, $[\alpha]_D^{22} = -40.36°$ (neat), enantiomerically pure, and 50 ml anhydrous toluene is heated under an inert gas at 120 °C

[a] Chromatographically pure compounds; maximum difference between *(11a)* and *(11b)*: 2%. [b] Neutral sulfate: $[\alpha]_D^{20} = -13.1°$ (*c* = 2, water); cf. *F. M. Jaeger, W. Froentjes*, Proc. Nederl. Acad. Wetenschap. *44*, 140 (1941): $[\alpha]_{589} = -13.5°$ (*c* = 2, water). [c] *N*-acetyl derivative: $[\alpha]_D^{20} = +136.6°$ (*c* = 3.7, MeOH); cf. *O. Cervinka, V. Dudek, L. Hub*, Collect. Czech. Chem. Commun. *35*, 724 (1970): $[\alpha]_D = +72.3°$ (*c* = 3.8, MeOH). [d] According to *F. G. Mann, J. W. G. Porter*, J. Chem. Soc. *1944*, 456: $[\alpha]_D^{17} = +4.67°$ (*c* = 6.23, MeOH). [e] Yield of distilled amino alcohols: (+)-*(2e)* 92%, (−)-*(2e)* 95%. [f] From first eluted *(11)*: $[\alpha]_D^{22} = +1.30°$ (neat), from second eluted *(11)*: $[\alpha]_D^{22} = -1.31°$ (neat); HPLC determination of the enantiomeric purity with *O*-methylmandelic acid according to *G. Helmchen, W. Strubert*, Chromatographia *7*, 713 (1974) gave > 99.5% for (+)-*(2e)*. These facts contrast with the literature data; cf. *G. Habermehl, H. Andres*, Justus Liebigs Ann. Chem. *1977*, 800: $[\alpha]_D^{22} = +3.4°$ (neat) for (*S*)-*(2e)*.

for 26 h. Dichloromethane (1 l) is then added and the solution extracted several times with 1 N hydrochloric acid and water. The crude product after evaporation of the organic phase is chromatographed in 4 g portions (column: see [1a]; eluent: ethyl acetate, flow-rate: 40 ml/min; UV detection at 254 nm): baseline separation, $t_R(6a) = 22$ min, $t_R(6b) = 35$ min. 25.2 g (100%) of *(6a)* and 23.3 g (92%) of *(6b)* are obtained.

A vigorously stirred mixture of 22.7 g *(6b)* and 160 ml 2 N sulfuric acid/dioxane (1:1) is heated under an inert gas at 90°C for 14 hours. The mixture is then worked up in the same manner as described above. 12.95 g (100%) of (−)-(*S*)-*(3)* is obtained. For the elemental analysis a sample is distilled bulb-to-bulb (70—80°C/0.001 torr): m.p. 61—61.5°C, $[\alpha]_D^{20} = +50.4°$C (*c* = 5, methanol). (−)-(*R*)-*(3)* is obtained in an analogous way from *(6a)*.

Separation of enantiomeric amines *(2)*: The same procedure as above (or as is described in [1b]) is employed, but with lactone/hydroxypyridine/amine in the molar ratio (2:2:1). The excess lactone is recovered quantitatively from the front fraction on chromatographic separation of the amides. The amines are isolated in the usual way from the acidic aqueous phases after hydrolysis.

Scheme 1. Directed resolution of the enantiomeric amines (±)-*(2)* *via* diastereomeric amides *(11a)* and *(11b)*. The oxygen of the Z amide group (with its plane perpendicular to the plane of the paper) is pointing upwards.

[6] Freshly distilled 2-oxo-2-phenylethyl acetate is allowed to react with diethyl(methoxycarbonyl) phosphonate according to the standard method, the crude reaction product subjected to catalytic hydrogenation (5% Pd/C/glacial acetic acid), and (once again the crude product) lactonized with 4 N sulfuric acid/dioxane (1:1). The total yield of *(3)* after purification by distillation is 80—90%.

$Xe(OTeF_5)_6$, A Deep-Colored Noble Gas Compound, and $O{=}Xe(OTeF_5)_4$—The Existence of $Kr(OTeF_5)_2$[**]

By *Dieter Lentz* and *Konrad Seppelt*[*]

Since the —OTe_5 group has been shown to have fluorine-like ligand properties[1a] we have tried using it for the synthesis of nobel-gas compounds having the highest possible oxidation states. Recently, the stable $Xe(OTeF_5)_4$ was reported[1b].

We have now succeeded in synthesing $Xe(OTeF_5)_6$ *(1)*: XeF_6 reacts very slowly with $B(OTeF_5)_3$[2] (molar ratio 1:2) in perfluoro-*n*-pentane at −40°C with liberation of BF_3 and precipitation of *(1)* as a reddish violet finely crystalline solid. The xenon hexakis(pentafluorotellurate(VI)) was characterized by its defined decomposition to $Xe(OTeF_5)_4$ and F_5TeOO-TeF_5. This decomposition can be induced either thermally at −10°C or by exposure to daylight at temperatures as low as −230°C. The photolysis is analogous to the decomposition of XeF_6 into XeF_4 and F_2 by UV light[3]. Yet $Xe(OTeF_5)_6$ decomposes in UV light to one part Xe and 3 parts $F_5TeOOTeF_5$.

$$XeF_6 + 2\,B(OTeF_5)_3 \xrightarrow[n\text{-}C_5F_{12}]{-40°C} 2\,BF_3 + \underset{(1)}{Xe(OTeF_5)_6}$$

$$(1) \xrightarrow{-10°C;\ h\nu(VIS)} Xe(OTeF_5)_4 + F_5TeOOTeF_5$$

$$(1) \xrightarrow{h\nu(UV)} Xe + 3\,F_5TeOOTeF_5$$

The sensitivity of *(1)* makes spectroscopic investigations difficult. Apart from the recently described species Xe_2^+ (green)[4],

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fond der Chemischen Industrie.

no other deeply colored noble-gas compounds have previously been reported, where the color is due to the noble gas. The color of *(1)* must be a consequence of the bonding of the hexavalent xenon, which has a lone pair of electrons; the tellurium compound $Te(OTeF_5)_6$[5] has no lone pair and is colorless. From the color we conclude that *(1)* exists as a monomeric molecule with covalent bonds and does not form intermolecular bridges, as have been observed in the case of XeF_6, both in the liquid and the solid state[6]; so, even monomeric XeF_6 is pale yellow in color. An accurate X-ray structure analysis of *(1)* would thus also allow conclusions to be drawn about the structure of monomeric XeF_6.

In contrast to XeF_6 the new compound $Xe(OTeF_5)_6$ is moderately stable towards hydrolysis, presumably because of the shielding effect of the large $OTeF_5$ groups. The first isolable product of hydrolysis, $O{=}Xe(OTeF_5)_4$ *(2)*, is a colorless, remarkably stable compound (m. p. 56 °C, subl. 35 °C/10^{-2} mbar) which can be obtained better directly from $XeOF_4$.

$$3\,XeOF_4 + 4\,B(OTeF_5)_3 \xrightarrow[n\text{-}C_5F_{12}]{-30\,^\circ C} 4\,BF_3 + 3\,O{=}Xe(OTeF_5)_4 \quad (2)$$

$$XeOF_4 + (2) \rightleftharpoons O{=}XeF_3(OTeF_5) + \textit{cis}\text{-}O{=}XeF_2(OTeF_5)_2 + \textit{trans}\text{-}O{=}XeF_2(OTeF_5)_2 + O{=}XeF(OTeF_5)_3$$

The identity of *(2)* was easily established by spectral data [MS (75 eV): $m/e = 871$ $OXe(OTeF_5)_3^+$, 646 $O_2Xe(OTeF_5)_2^+$ *etc.*; Raman (cm^{-1}): *inter alia* 886 $\nu_{Xe=O}$, 667 ν_{TeF_4}, 477 $\nu_{Xe=O}$; ^{19}F-NMR: AB_4 spectrum with $\delta_A = 47.8$, $\delta_B = 35.3$, $J_{AB} = 183$ Hz] and elemental analysis. Of particular importance is the ^{129}Xe-NMR spectrum (Fig. 1)[7].

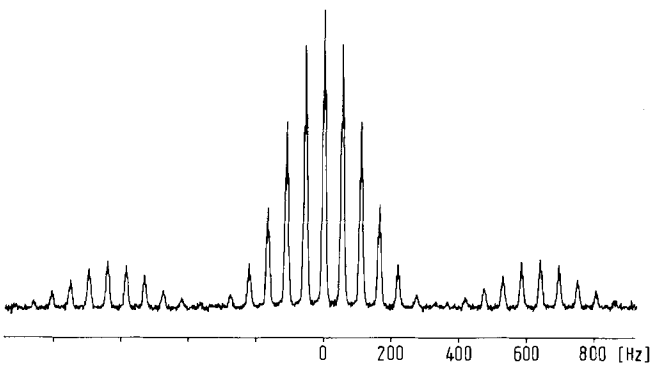

Fig. 1. ^{129}Xe-NMR spectrum (55.33 MHz) of $O{=}Xe(OTeF_5)_4$, dissolved in $C_2F_4Cl_2$: $\delta = -5121$ rel. Xe; $^3J_{Xe-F_{ax}} = 4$ Hz, $^3J_{Xe-F_{eq}} = 55$ Hz, $^2J_{Xe-^{125}Te} = 1281$ Hz.

Coupling is observed with the 16 equatorial fluorine atoms and with the four axial fluorine atoms, and also with the tellurium isotope ^{125}Te (7 % natural abundance, nuclear spin 1/2). Since the pentafluorotellurates are the most stable xenon derivatives after the fluorides [decomp.: $Xe(OTeF_5)_2$ 130 °C[8] > $O{=}Xe(OTeF_5)_4$ 90 °C > $Xe(OTeF_5)_4$ 72 °C[1b] > $Xe(OTeF_5)_6$ −10 °C] we tried to synthesize an analogous krypton compound.

$$3\,KrF_2 + 2\,B(OTeF_5)_3 \xrightarrow[FClO_3]{-100\,^\circ C} 2\,BF_3 + 3\,[Kr(OTeF_5)_2] \quad (3)$$

$$(3) \xrightarrow{-100\,^\circ C} Kr + F_5TeOOTeF_5$$

Even under the most carefully controlled reaction conditions only $F_5TeOOTeF_5$ could be detected besides krypton. Since, however, the peroxide is the typical decomposition product of all xenon derivatives, we assume intermediary formation of $Kr(OTeF_5)_2$ (or $FKr{-}OTeF_5$). Indeed, the reaction proceeds in a very clear fashion and, despite the extremely powerful fluorinating property of KrF_2, no TeF_6 can be detected. Reactions with the $OSeF_5$ ligands proceed analogously. It would appear, therefore, that the synthesis of a compound containing a krypton-oxygen bond is impossible with todays state of synthetic chemistry—apart perhaps by means of the matrix technique. KrF_2 so far remains the only compound of krypton, and it can be converted into the ions KrF^+ and $Kr_2F_3^+$[9].

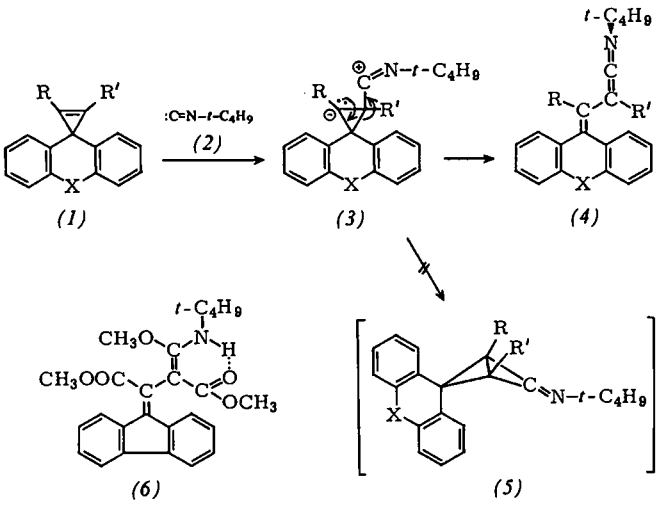
Vinyl Ketenimines by Nucleophilic Ring Cleavage of Cyclopropenes with *tert*-Butyl Isocyanide[**]

By *Günter Ege* and *Karlheinz Gilbert*[*]

Dedicated to Professor Hans Plieninger on the occasion of his 65th birthday



Isocyanides react with activated double[2] and triple bonds[3] to give primary products, which nearly always add to further isocyanide or also to the multiple bond, with formation of cyclic compounds.

On reaction of the cyclopropenes *(1)*[4], activated by electron-acceptor groups, with *tert*-butyl isocyanide *(2)* in benzene solution at room temperature and allowing the reaction mixture to stand for several days in the dark we obtained the vinyl ketenimines (1-aza-1,2,4-pentatrienes) *(4)* which showed characteristic ketenimine bands in the IR spectrum at 2025 to 2060 cm^{-1}. Boiling under reflux shortened the reaction time, but reduced the yields.

The vinylketenimines *(4a)*—*(4d)* (Table 1) could be purified by chromatographic methods. On attempted crystallization, *(4b)* added one equivalent of methanol on standing to give the vinylketene *O,N*-acetal *(6)*[5]. Though *(4e)* could be separated by column chromatography it has so far not been obtained in the pure state.

R = $COOCH_3$

in the dark. After removal of all volatile components in a rotary evaporator at 30°C the crude oil is separated on a silica gel medium-pressure column with anhydrous petroleum ether (60—70°C)/ether (2:1). The main fraction (IR band at 2060 cm^{-1}) is evaporated in a rotary evaporator; the resulting colorless oil crystallizes. *(4a)*, yield after recrystallization from anhydrous petroleum ether (60—70°C)/ether (1:1) 1.6 g (82%), melts at 146—148°C.

[a] Yellow glassy mass. [b] Not pure.

The reaction is initiated by nucleophilic attack of the *tert*-butyl isocyanide *(2)* at the reactive double bond of the cyclopropene *(1)*. The dipolar compound *(3)* is formed, in which the negative charge on the cyclopropane ring is stabilized by the electron acceptor R. Subsequent opening of the cyclopropane ring in *(3)* leads to the conjugated ketenimine *(4)*. This ring cleavage opens up a new entry to vinylketenimines *(4)*, only one example of which has hitherto been described in the literature[6].

The constitutionally specific ring-opening of the adduct *(3)* rules out intermediary formation of a bicyclobutanone imine *(5)*: the unsymmetrically substituted *(3e)* affords exclusively *(4e)*. The structure of *(4e)* follows from the long-wave position of the ketenimine band at 2025 cm^{-1} [*(4a)*—*(4d)*: 2050 to 2060 cm^{-1}] and the downfield position of the ^{1}H-NMR signal of the $COOCH_3$ group at δ = 3.90 [*(4b)*: δ = 3.95 and 3.77].

Experimental

Synthesis of *(4a)*: *(1a)*[1] (1.54 g, 5 mmol) is dissolved in anhydrous benzene (30 ml), treated with 0.42 g (5 mmol) *(2)* and allowed to stand for three days at room temperature

Oxidation of Hydrocarbons with Benzyl(triethyl)ammonium Permanganate

By *H.-Jürgen Schmidt* and *Hans J. Schäfer*[*]

CH bonds can be oxidized with permanganate ions; however, the use of this method is greatly restricted by the insolubility of the alkanes in aqueous solution[1]. A further disad-

[*] Prof. Dr. H. J. Schäfer, Dipl.-Chem. H.-J. Schmidt

Orléans-Ring 23, D-4400 Münster (Germany)

vantage is that alkylarenes are degraded to arenecarboxylic acids[2]. The advantages of oxidation in organic solvents have hitherto been exploited only in isolated cases. Olefins can be cleaved to carboxylic acids with potassium permanganate in benzene, if the potassium ion is complexed with a crown ether[3]. In pyridine, alcohols and aldehydes can be oxidized to carboxylic acids with tetrabutylammonium permanganate[4].

We report here on the oxidation of alkanes with benzyl(triethyl)ammonium permanganate *(1)* in dichloromethane or glacial acetic acid (Table 1). *(1)* precipitates as a violet salt on treatment of an aqueous solution of the corresponding chloride with potassium permanganate[5]. It is thermally stable at 100°C, resistant to shock, and readily soluble in dichloromethane and glacial acetic acid (0.3—0.5 mol/l), in which it is relatively stable.

Table 1. Products of the oxidation of alkanes with benzyl(triethyl)ammonium permanganate *(1)*.

Alkane	Oxidation products, Yields [a]
Cumene *(2)* [b]	2-Phenyl-2-propanol, 28 % (98 %); acetophenone, 1 %
sec-Butylbenzene *(3)* [c]	2-Phenyl-2-butanol, 12 % (61 %); acetophenone, 1 %; propiophenone, 1 %; (1-methyl-1-phenylpropyl)acetate, 2 % (12 %)
Isobutylbenzene *(4)* [d]	Isobutyrophenone, 26 % (51 %); 2-methyl-1-phenyl-2-propanol, 3 %; (α,α-dimethylphenethyl)acetate, 20 % (38 %)
n-Butylbenzene *(5)* [e]	*n*-Butyrophenone, 44 % (61 %); (1-phenylbutyl)acetate, 26 % (37 %)
3-Ethylpentane *(6)* [f]	3-Pentanone, 12 % (25 %); 3-ethyl-2-pentanone, 13 % (25 %); 3-ethyl-3-pentanol, 12 % (24 %); (1,1-diethylpropyl)acetate, 5 % (10 %)
Methylcyclohexane *(7)* [g]	1-Methylcyclohexanol, 23 % (72 %); 2-methylcyclohexanone, 3 %
trans-Decalin *(8)* [h]	*trans*-9-Decalol, 11 % (37 %); *trans*-1-decalone, 13 % (43 %); *trans*-2-decalone, 3 %
cis-Decalin *(9)* [h]	*cis*-9-Decalol, 33 % (67 %)

[a] Chromatographically determined yields, based on original amount of alkane and (in brackets) on consumed alkane. [b] 50 mmol *(2)*, 52 mmol *(1)*, 6 mmol pyridine, 3 d at 40°C in CH_2Cl_2. [c] 50 mmol *(3)*, 50 mmol *(1)*, 2 d at 40°C in glacial acetic acid. [d] 50 mmol *(4)*, 10 mmol *(1)*, 100 mmol $KMnO_4$, 4 d at 30°C in glacial acetic acid. [e] As in [d] but only 2 d. [f] As in [d] but at 50°C. [g] As in [d] but 2 d at 60°C. [h] as in [d] but only 3 d.

Benzylic methylene groups [*(4)*, *(5)*] are oxidized to the ketone; cleavage to benzoic acid is suppressed. Tertiary benzylic CH-groups [*(2)*, *(3)*] are smoothly transformed into tertiary alcohols. Some aliphatic methine groups [*(4)*, *(6)*—*(9)*] require higher reaction temperatures and activation of the permanganate by glacial acetic acid as solvent, whereupon the alcohol formed is partially dehydrated and/or secondary methylene groups are also oxidized. Hydroxylation of the decalins [*(8)*, *(9)*] proceeds stereospecifically with retention of configuration.

In the oxidation of alkanes with *(1)* the yields obtained are not as high as those achieved by dry ozonolysis[6]; however, the former method appears to be advantageous for the oxygenation of alkylarenes, which are degraded to alkylcarboxylic acids by ozone[7].

Experimental

Preparation of benzyl(triethyl)ammonium permanganate *(1)*[5]: A solution of benzyl(triethyl)ammonium chloride (227.8 g, 1.00 mol) in 200 ml water is added dropwise and slowly to a solution of potassium permanganate (158.0 g, 1.00 mol) in 4.7 l water. The violet crystals are recovered by filtration and dried at 40°C/0.2 torr. Yield of *(1)* 294.8 g (0.947 mol, 95 %; over 99 % pure (iodometrically)); m.p. (decomp.) 127—129°C.

Oxidation of Ethers with Benzyl(triethyl)ammonium Permanganate

By *H.-Jürgen Schmidt* and *Hans J. Schäfer*[*]

Ruthenium tetraoxide has long been known to be a particularly suitable reagent for the oxidation of alkyl ethers[1]. Other oxidizing agents have also been used. For example, chromium trioxide[2] and trichloroisocyanuric acid[3] oxidize ethers to esters and lactones, respectively. Reaction with bromine[4], uranium hexafluoride[5], lead tetraacetate[6] or ozone[7], as well as anodic oxidation[8], leads *via* oxidative cleavage of the ethers to carboxylic acids, ketones and alcohols. Ruthenium tetroxide is, of course, only suitable for the oxidation of dialkyl ethers, since aryl groups are oxidatively degraded. This disadvantage is overcome on oxidation with benzyl(triethyl)ammonium permanganate *(1)*, which oxidizes ethers cleanly and chemoselectively to esters (Table 1).

Table 1. Products of the oxidation of ethers with benzyl(triethyl)ammonium permanganate *(1)*.

Ether	Oxidation products, Yields [a]
Dibutyl ether *(2)* [b]	Butyl butyrate, 58 % (80 %)
Dibenzyl ether *(3)* [c]	Benzyl benzoate, 80 % (84 %); methylene dibenzoate, 8 %

The esters formed from the unsymmetrical ethers and the reaction times and temperatures indicate the following reactivity sequence for the individual CH-bonds: benzyl > phenylalkyl > *primary*-alkyl > *secondary*-alkyl, methyl > phenyl. In phenyl ethers the phenyl group deactivates the CH-group of the alkyl residue.

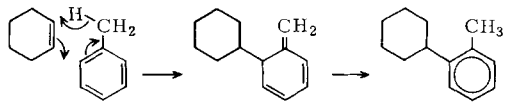
Intermolecular Ene Reactions in a High-Pressure/High-Temperature Flow Apparatus[**]

By *Jürgen Metzger* and *Peter Köll*[*]

In the thermal degradation of chitin in supercritical acetone[1] we were able to demonstrate the presence of large amounts of diacetamide *(1)*, which can be formed by dimerization of the acetamide molecules in the sense of an ene reaction.



(1)

This finding encouraged us to investigate some ene reactions[2], as example of the numerous types of thermal pericyclic reactions[3], in the same high-pressure/high-temperature apparatus ("HP-HT" apparatus)[1], which enables relatively unproblematical operation at pressures of up to *ca.* 500 bar and temperatures of up to *ca.* 700 K, and is readily built from commercially available HPLC and GC equipment. The apparatus offers all the advantages of a flow reactor, such as exceptionally rapid withdrawal of sensitive products from the reaction zone and the possibility of quickly changing the reaction parameters with slightest consumption of substances.

Whereas numerous *intra*molecular ene reactions, even with *nonactivated* enophiles, have already been reported[4], *inter*molecular ene reactions generally require *active* enophiles[2]. It was predicted, however, that if the latter reactions were to be carried out at high pressures, besides the usual conditions employed for ene reactions, namely high temperatures and long reaction times, then *inter*molecular ene reactions with *nonactivated* enophiles should also be possible. Thus, the reactions carried out at high temperatures under pressure by *Nemtsov et al.*[5] in 1938 with the aim of polymerizing olefins may be regarded as ene reactions. The reaction of acetylene as moderately active enophile with olefins at 623 K and 170 bar to give 1,4-dienes—likewise in a flow reactor—also demonstrates the influence of pressure in such reactions[6].

In all the examples so far investigated by us (cf. Table 1) the expected products were seen to be formed in the overall main reaction. Even toluene was found to react as "deactivated" ene component with non-activated enophiles; reaction with cyclohexene afforded *o*-cyclohexyltoluene *(2)*.

(2)

The yields quoted in Table 1 are not optimized and might easily be increased to preparatively satisfactory values by increasing the residence time of the reactants (incorporation of a longer reaction capillary or reduction in the rate of flow of reactants). A typical example here is the synthesis of 3-cyclohexylcyclohexene from cyclohexene (see Experimental). Such a dimerization apparently proceeds regiospecifically, corresponding to the expected pericyclic mechanism. (With longer residence times, however, about 5 % of the primary product isomerizes to 1-cyclohexylcyclohexene.) Thus, the thermal olefin-dimerization and the alkylation of toluene described here are superior to the catalytic methods, at least as far as regioselectivity is concerned.

Table 1. Some intermolecular ene reactions with non-activated enophiles. Reaction conditions: 673 K, 450 bar, 10 min residence time, ene:enophile = 10:1, conversion based on enophile. Characterization of the products by GC-MS.

Ene	Enophile	Reaction product(s)	Conversion [%]
1-Hexene	1-Hexene	Mixture of isomeric dodecenes	5
Cyclohexene	Cyclohexene	3-Cyclohexylcyclohexene	4.5
Acetone	Cyclohexene	Cyclohexylacetone	0.5
Toluene	Cyclohexene	*o*-Cyclohexyltoluene	1.2
Toluene	Tolan	1,2-Diphenyl-1-tolylethylene	15

Experimental

Synthesis of 3-cyclohexylcyclohexene: Cyclohexene (20 g) is pumped through the "HP-PT" apparatus[1] at 673 K and 460 bar at a flow-rate of 0.12 ml/min and with a residence time of *ca.* 50 min. A 15-m long stainless steel capillary (O.D. 1.6 mm, I.D. 0.7 mm) can be used as reactor. Unreacted cyclohexene (16 g) is removed by distillation. The residue (3.4 g, 17 %) mainly consists of pure 3-cyclohexylcyclohexene, which is further purified by distillation: b.p. 98 °C/10 torr, $n_D^{20} = 1.4912$ (b.p. 224 °C/760 torr, $n_D^{20} = 1.4941$[7]). The IR, NMR, and mass spectra are consistent with the given structure.

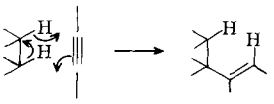
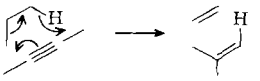
Thermal Pericyclic Reaction between Alkynes and Alkanes[1]



By *Jürgen Metzger* and *Peter Köll*[*]

From results of intermolecular ene reactions[2] in a high-pressure/high-temperature flow reactor ("HP-HT" apparatus) it was predicted that hitherto presupposed but unobserved thermal pericyclic reactions ought to be realizable at high pressures and temperatures with rapid removal of reaction products. We first examined the reaction of 1-hexyne in *n*-hexane (1 : 10) under such conditions, expecting to observe not only the trimerization of the alkyne to benzene derivatives but also a dimerization in the sense of an ene reaction, which should lead to allene derivatives. A hexyne dimer was indeed detectable in small amounts by combined GC-MS. Surprisingly, however, we obtained alkenes as major products (0.9 % octene, 0.9 % nonene, 1 % decene, 6 % dodecene, 2.6 % tributylbenzene; in each case isomeric mixtures; yields based on starting 1-hexyne). These alkenes could only have been formed by reaction of 1-hexyne with *n*-hexane.



To check the possible generalization of this surprising observation we examined the reaction of cycloalkanes with alkynes in the same HP-HT reactor[3]. As shown in Table 1, in each of the cases investigated the alkenylcycloalkanes are formed as major products in a remarkably uniform reaction.

Owing to the extremely drastic reaction conditions free radicals were assumed to be involved in the reaction, particularly since the formation of vinylcyclohexane is known to take place in the presence of radical-forming species[4, 5]. Addition of radical scavengers, however, did not influence the yield of main product. In our opinion, this finding rules out a radical chain reaction.

The reaction is apparently another novel type of thermal pericyclic reaction, which also ought to be possible on theoretical grounds[6]. The formation of the major products can best be described by the general scheme:

As side reaction an alkyl group obviously can migrate (with cleavage and reformation of a CC σ-bond) instead of a hydrogen atom. This would explain the formation of octene, nonene, and decene in the reaction of *n*-hexane with 1-hexyne, as well as the fact that undecene is not observed:

The new pericyclic reaction might be of interest both for the functionalization (vinylation) and for the fragmentation (thermal non-radical cracking) of alkanes to alkenes.

General Procedure

The alkynes are dissolved in an excess of alkane; in the case of gaseous alkynes, the alkane is saturated in an autoclave with the alkyne. The solution is pumped through the HP-PT apparatus[3]. As reactor for the present series of experiments we used a stainless steel capillary (length 12 m, O.D. 1.6 mm, I.D. 0.7 mm). The following reaction conditions proved to be suitable: $T = 623$—673 K, $p = 350$—500 bar, flow rate 1—3 ml/min.

Table 1. Reactions of alkanes and alkynes (reaction conditions: $T = 673$ K, in the case of Nos. 1 and 2, 633 K; $p = 400$ bar). The products were identified by GC-MS and determined gas chromatographically using an internal standard. The major products were isolated by distillation (Nos. 2, 4, 5) or by preparative thin-layer chromatography (No. 3) and investigated by NMR and IR-spectroscopy.

No.	Alkane	Alkyne	Alkane : Alkyne	Residence time [min]	Main product(s)	Yield [%] [a]
1	*n*-Hexane	1-Hexyne	10 : 1	4	Dodecene isomers	6
2	Cyclohexane	1-Hexyne	20 : 1	2	*trans*-1-Cyclohexyl-1-hexene	7.5
					cis-1-Cyclohexyl-1-hexene	2.6
					2-Cyclohexyl-1-hexene	0.8

General Synthesis of Potentially Antiviral α-Adamantyl Carbonyl Compounds[**]

By *Manfred T. Reetz, Wilhelm F. Maier, Konrad Schwellnus,* and *Ioannis Chatziiosifidis*[*]

Recently, it was discovered[1] that certain α-adamantyl carbonyl compounds are considerably more active as antiviral agents and a great deal less toxic than 1-aminoadamantane[2]. The multistep syntheses which were described in [1] are based on phenols as starting materials, and are therefore restricted to the cyclohexanone framework. We wish to report that our method of α-*tert*-alkylation of carbonyl compounds can be applied generally to the introduction of 1-adamantyl groups[3]. Silylenol ethers *(2a)—(2h)*, which are easily obtained from ketones *(1a)—(1h)*[4], react smoothly with 1-bromoadamantane in the presence of titanium tetrachloride at −40 °C to −50 °C to afford the desired α-adamantyl ketones *(3)* in good yields (Table 1). Table 1 shows that structurally

	R^1	R^2	R^3	Yield [%] [a]
a		$-(CH_2)_3-$	H	66 (78)
b		$-(CH_2)_4-$	H	89 (95)
c		$-(CH_2)_6-$	H	73 (90)
d	$(CH_3)_2CH$	CH_3	CH_3	62 (75)
e	$-(CH_2)_2-$	$-CHCH_3-CH_2-$	H	72 (80)
f	C_2H_5	CH_3	H	75 (80)
g	$(CH_3)_3C$	H	H	82 (89)
h		[b]		70 (80)
i	OCH_3	$-(CH_2)_5-$		80
j	OCH_3	CH_3	H	47
k	OCH_3	C_2H_5	H	77
l	OC_2H_5	$(CH_3)_3C$	H	70 [c]

[a] The yields are based on isolated products in the reaction *(2)* → *(3)*; the values in brackets were determined by ^{1}H-NMR spectroscopy. [b] 1-Trimethylsiloxy-4-methyl-3,4-dihydronaphthalene *(2h)* → 2-(1-adamantyl)-4-methyl-1-tetralone *(3h)*. [c] Yield *(1l)* → *(2l)*: 84%.

quite different ketones can be alkylated. Also noteworthy is the smooth adamantylation of diisopropyl ketone *(1d)*, which affords the derivative *(3d)* having two neighboring *quaternary* carbon atoms.

In a similar manner carboxylic acid alkyl esters *(1i)—(1h)* can be adamantylated *via* the corresponding ketene ketals *(2i)—(2l)*[5], using catalytic amounts of zinc chloride as Lewis acid at room temperature. Compounds containing *two* tertiary groups on *one* carbon atom can also be prepared, *e.g. (3l)*.

According to *Dubois et al.*[6] it is possible to convert bulky carboxylic acid esters into ketones *via* the corresponding acid chlorides on using Grignard reagents in the presence of copper salts. Combination of the methods allows the synthesis of ketones having adamantyl groups in specific positions.

Concerning the antiviral activity of the compounds *(3)*, *in vitro* tests with viruses of the Newcastle disease show that for example 2-(1-adamantyl)-4-methylcyclohexanone *(3e)* is about three times more active and half as toxic as 1-aminoadamantane[1].

Experimental:

Synthesis of 2-(1-adamantyl)cyclohexanone *(3b)*: A cooled solution (−50 °C) of 3.8 g (20 mmol) titanium tetrachloride in 10 ml dry methylene chloride is added within two minutes to a cooled mixture (−50 °C) of 3.5 g (20 mmol) 1-trimethylsiloxycyclohexene and 4.5 g (20.9 mmol) 1-bromoadamantane in 60 ml of dry methylene chloride. The reaction mixture is stirred for 30 minutes, hydrolyzed, and the solvent of the organic phase evaporated off. Recrystallization of the residue from methanol affords 3.5 g of pure 2-(1-adamantyl)cyclohexanone as well as 1.0 g from the mother liquor: yield 89%; m.p. 86 °C; ^{1}H-NMR (CCl_4): $\delta = 1.72$ (s, 15H), 1.42—2.4 (m, 9H); IR (KBr): 2960, 2930, 2895, 2840, 1695, 1445, 1345, 1310, 1205, 1130, 1120, 1110, 1065 cm^{-1}.

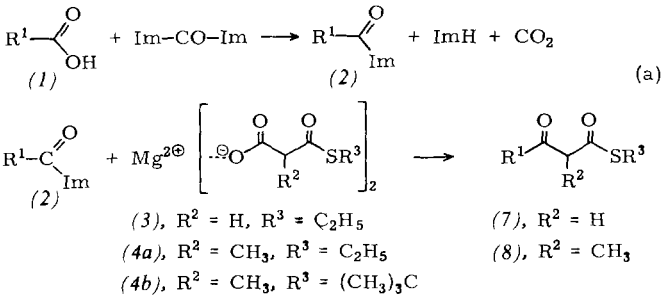
C-Acylation under Virtually Neutral Conditions[**]

By *Dee W. Brooks, Linda D.-L. Lu,* and *Satoru Masamune*[*]

During the course of studies directed toward the total synthesis of macrolide antibiotics, the pressing need for an efficient method of *C*-acylation on acid- and base-sensitive synthetic intermediates became evident[1]. We wish to describe here a practical solution of this fundamental problem.



The method is operationally very simple; it involves successive addition of two reagents to a carboxylic acid *(1)* in tetrahydrofuran (THF) [reaction (a)]. Carbonyldiimidazole converts the acid *(1)* into the corresponding imidazolide *(2)*[2], which, without isolation, is treated with the *neutral* magnesium salt of a malonic or methylmalonic acid half thiol ester of type *(3)* or *(4)*. The condensation proceeds in excellent yields and under mild conditions (see Table 1). The β-ketothiol esters of type *(7)* and *(8)* which are obtained are apparently

Because of the slightly enhanced reactivity of a primary hydroxy group toward carbonyldiimidazole as compared with a secondary hydroxy group, the above method requires modification when applied to ω-hydroxycarboxylic acids. Thus, treatment of 8-hydroxyoctanoic acid *(1i)* (1.0 mmol) in 4 ml THF with excess imidazole (4.4 mmol) and trifluoroacetic acid anhydride (2.1 mmol) gave the imidazolide *(12)*, which in turn was allowed to react with 1.2 mmol *(4a)* or *(4b)*. Methanolysis in the presence of sodium acetate (25°C for 2h) afforded the ω-hydroxy-β-ketothioester in 90% yield [reaction (c)].

(1i) *(12)*

(c)

(8i), $R^3 = C_2H_5$
(8k), $R^3 = (CH_3)_3C$

The efficient *C*-acylation resulting from reaction of the *neutral* magnesium compounds of type *(3)* or *(4)* with an acid imidazolide *(2)* is surprising and offers distinct advantages in many respects over an earlier, superficially similar method which involves reaction of the *basic* magnesium enolate *(11)* with an acid chloride or imidazolide[3]. With this earlier method, *e.g.*, the acid derivatives of *(1d)* and *(1e)* provided, at best, 25—32% yields of the corresponding products listed in Table 1. Protection of the hydroxy group is normally required before the reaction with *(11)* (cf. entries 12 and 14 in Table 1). Furthermore, the present *C*-acylation proceeds unaffected by the presence of 1 equivalent of cyclohexanecarboxaldehyde, which is recovered intact.

The use of malonic acid half thiol esters patterns the scheme proposed for a similar process involved in the biosynthesis of fatty acids[4]. Early and recent model studies for the enzymatic process[5] have aided us in developing the present synthetically useful procedure.

Experimental

Synthesis of *(4a)*: Magnesium ethoxide (0.49 g, 5 mmol) is added to a solution of methyl malonic acid half ethanethiol ester (1.62 g, 10 mmol) in THF (25 ml) and the mixture is stirred for 1 h. The solvent is removed at reduced pressure (25°C/0.1 torr) to give a slightly hygroscopic white salt which is used directly.

Synthesis of *(8a)* (Table 1, entry 7): Carbonyldiimidazole (180 mg, 1.1 mmol) is added to a solution of levulinic acid *(1d)* (116 mg, 1.0 mmol) in THF (5 ml). After stirring at room temperature for 6 h, the magnesium salt *(4a)* prepared above (380 mg, 1.1 mmol) is added. The mixture is stirred for 18 h at 25°C and then the solvent is removed at reduced pressure. The residue is partitioned between ether (20 ml) and aqueous 0.5 N HCl (20 ml) and the layers are separated. The aqueous phase is further extracted with ether (10 ml). The combined ether extracts are washed with aqueous saturated $NaHCO_3$ (20 ml), dried over anhydrous Na_2SO_4, and filtered. The solvent is evaporated at reduced pressure to give 185 mg (85%) of the β-ketoester *(8d)*; ^{1}H-NMR ($CDCl_3$): $\delta = 1.26$ (t, 3H, $J = 7.5$ Hz), 1.38 (d, 3H, $J = 7.0$ Hz), 2.16 (s, 3H), 2.75 (m, 4H), 2.91 (q, 2H, $J = 7.5$ Hz), 3.82 (q, 1H, $J = 7.0$ Hz); MS: $m/e = 216.0819 = C_{10}H_{16}O_3S$ (M^+).

Cyclooligocondensation of Amino Acids: Macrocyclic Amides of β-Alanine[**]

By *Manfred Rothe* and *Dietger Mühlhausen*[*]

The formation of large ring molecules—in competition with polymer formation—from monomers in macrocyclization equilibria or from polymers by degradation has recently attracted increasing theoretical interest[1]. We have investigated the system β-alanine/cyclooligo(β-alanyls)/poly-β-alanine, which is of interest with respect to the industrial production of fiber-forming poly-β-amides (nylon 3) from β-lactams[2].

We first synthesized cyclic oligoamides of β-alanine *c*-$(NHCH_2CH_2CO)_n$ *(2)* up to the hexamer ($n=2$—6) in crystalline form by stepwise synthesis of the linear oligoamides $H(NHCH_2CH_2CO)_nOH$ *(1)*, $n=2$—6, according to the methods of peptide chemistry (*via* mixed anhydrides with isobutyl chloroformate, benzyloxycarbonyl protecting group removed with HBr/glacial acetic acid) and ring closure of *(1) via* active esters $H(NHCH_2CH_2CO)_n\ SC_6H_5$ in dimethylformamide or phosphorous anhydrides $H(NHCH_2CH_2CO)_n—O—P(OR)_2$ in diethyl phosphite (DEP) according to the dilution principle. With the exception of cyclo-di-β-alanyl *(2)*, $n=2$[3] (m.p. 298—299 °C), the cyclic amides *(2)* decompose without melting only above 350 °C.

The results of the cyclization of the linear oligoamides *(1)* in the form of their active phosphite derivatives are listed in Table 1. These findings cannot be explained in terms of a specific "doubling" resulting from antiparallel association of two oligoamide chains with formation of hydrogen bonds[4], but by polycondensation with subsequent cyclization, especially as an alternative reaction to formation of strained medium-sized rings. Consequently, higher ring homologues are also formed.

We subsequently condensed the "monomeric" amino acid β-alanine according to the phosphite method[5] in moderately dilute solution in DEP ($c=0.1$ mol/l) with *o*-phenylene chlorophosphite (*o*-phenylene phosphorochloridite) at 140 °C. After removal of the linear oligoamides *(1)* with ion exchangers in aqueous solution a cycloamide mixture was obtained which could be separated by gelchromatography (Merckogel PGM 2000/water) into a homologous series of polymeric rings with up to 44 ring atoms [*(2)*, $n=2$—11]. The assignment of the peaks was accomplished with the aid of the synthesized authentic cycloamides by plotting the elution volumes of the gel chromatograms against the logarithm of the molecular weight (in homologous series of polymers a straight line is obtained within a certain range), and by mass spectrometry of the isolated compounds.

Table 1. Cyclization of phosphite derivatives of the linear oligoamides $H(NHCH_2CH_2CO)_nOH$ *(1)* in 0.01 M solution.

Remarkably, the monomeric four-membered ring (β-propiolactam) *(2)*, $n=1$, could not be detected, even at larger dilutions; and also the eight-membered ring *(2)*, $n=2$, containing two *cis*-peptide bonds (detected IR spectroscopically: NH 3195, 3080; amide I 1660; amide II 1440; amide III 1330 cm^{-1}) was formed in only moderate yields. In each case the cyclo-tri- and cyclo-tetraamide (12 and 16 ring atoms, respectively; Table 2) were obtained as the main products.

Table 2. Cyclization of β-alanine according to the phosphite method [a]. The yields of *(2)* are given in %.

[a] Conditions: see Experimental procedure b.

The formation of macrocyclic rings can be compared with that of large rings containing up to 63 ring atoms during the polymerization of caprolactam[6]. According to X-ray structure investigations[7] such very large rings are present—at least in the nylon-6 series—as parallel chains, closed at the ends. They therefore resemble the linear polymers in their physical properties, especially in their spectra and solubility. Hence their separation from the chains, and even their detection is always problematical with increasing ring size. Nevertheless, our previous studies (cf. Ref. [6, 8]) show that very large ring molecules are obviously always formed—besides the simplest small rings—during the formation of polymers. Heteroatoms[9] as well as increasing temperature and concentration favor the formation of large rings.

The chromatographic separation of the rings could be achieved quantitatively (baseline separation) up to the heptamide or octamide (after repeated GPC). Complete separation of the tri- and tetramide can be carried out by GPC on Biogel P2. Thus, cycloamides with up to eight amide groups

[**] Linear and Cyclic Oligomers, Part 25. This work was supported by the Fonds der Chemischen Industrie.—Part 24: *M. Rothe* in *J. Brandrup, E. J. Immergut*: Polymer Handbook. 2nd Edit. Wiley-Interscience, New York 1975, VI-1.

were readily made available in a one-step reaction. The cycloamides *(2)* can be converted by reduction with $LiAlH_4$ in THF suspension into cycloamines $c\text{-}(NHCH_2CH_2CH_2)_n$ of the same size, which as aza-crown ethers form alkali metal ion complexes. This method of formation—also starting from other ω-amino acids—may constitute the simplest route to such ring compounds.

Experimental

a) Cyclization of tri-β-alanine *(1)*, $n=3$: *(1)*, $n=3$, 695 mg (3.0 mmol) is dissolved with warming and stirring in 500 ml DEP, treated with 7 ml diethylethylene pyrophosphite, and heated for 2 h at 140°C under nitrogen. All but 10 ml of the solvent is removed *in vacuo*, and the crystalline precipitate filtered off and washed with acetone; yield of crude product 579.1 mg (91%). After gel chromatographic purification (Sephadex G 10/H_2O) 156.1 mg (65%) of *(2)*, $n=3$, 30.7 mg (13%) of *(2)*, $n=6$, and 5.9 mg (2.5%) of *(2)*, $n=9$, are obtained. Cyclo-tri-β-alanyl *(2)*, $n=3$, crystallizes from H_2O as long entangled needles which sublime above 280°C and do not melt below 350°C.

b) Cyclooligocondensation of β-alanine: 223 mg (2.5 mmol) of dried and sieved β-alanine is dissolved by heating in 25 ml DEP at 140°C. After addition of a twofold molar excess of *o*-phenylene chlorophosphite (873 mg) and subsequent addition of a threefold molar excess of anhydrous triethylamine (1.05 ml) the solution is allowed to stand under N_2 for 30 min. The DEP is removed in a rotary evaporator (oil pump vacuum), the residue dissolved in 30 ml H_2O and neutralized with strongly basic ion exchanger and then passed through cationic and anionic exchangers (Merck I, Amberlite IRA 410). The colorless eluate is removed in a rotary evaporator *in vacuo* and the crystalline cycloamide mixture (64%) separated by gel chromatography on Merckogel PGM 2000/H_2O, the tri-/tetraamide fraction being subsequently separated on Bio-Gel P2.

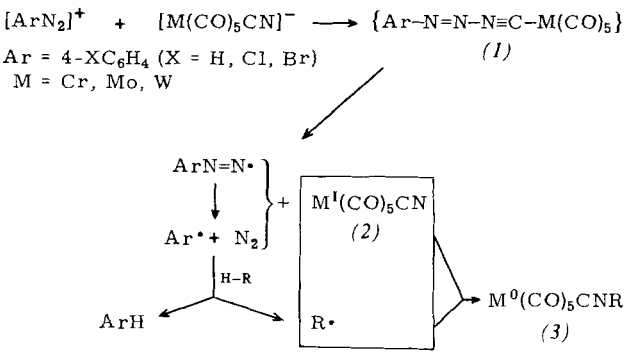
Thermolysis of Arenediazonium Pentacarbonylcyano-6A-metalates in Various Media: A Route to Novel α-Functionalized Isocyanides[**]



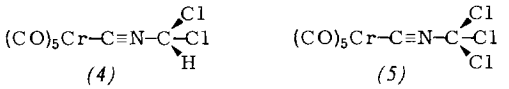
By *Wolf Peter Fehlhammer* and *Fritz Degel*[*]

The stability of diazonium salts is strongly dependent on the nature of the anion. In general, replacement of simple anions (*e.g.* Cl^-) by complex ions such as $SbCl_6^-$, $Fe(CN)_6^{3-}$, $PtCl_6^{2-}$, or $HgCl_3^-$ has a stabilizing effect[1]. Conversely, however, it is also known that even traces of oxidizable anionic metal complexes may catalyze the decomposition of diazonium compounds; this is, in fact, the basic principle of the Sandmeyer reaction[2].

We have now found that pentacarbonylcyano-6A-metalate ions also have a strong labilizing effect on diazonium compounds and have exploited this for the *synthesis of novel isocyanides within metal complexes.*

At temperatures between −50 and −20°C nitrogen is already released from mixtures of $Na[M(CO)_5CN]$ (M = Cr, Mo, W) and arenediazonium chlorides ($[4\text{-}XC_6H_4N_2]Cl$; X = H, Cl, Br) either dissolved or suspended in various media. Reaction in tetrahydrofuran of stoichiometric amounts of these compounds afforded crystalline, sublimable products, which, on the basis of their IR spectra and their fragmentation pattern in the mass spectrometer (−5 CO, $[ML-27(HCN)]^+$, $[MCNH]^+$), were identified as (pentacarbonyl)isocyanide complexes. Surprisingly, these complexes—independent of the arenediazonium components employed—contain the same alkyl isocyanide ligands, the alkyl side chain R of which has been recognized as α-tetrahydrofuranyl by ^{1}H-NMR spectroscopy [*(3)*, M = W: δ (in $CDCl_3$) = 2.28 (m, CH_2, 4H), 4.16 (m, OCH_2, 2H), 5.58 (t, CH, 1H)] and thus originates from the solvent.

For the formation of this novel isocyanide complex we suggest the mechanism outlined in Scheme 1: An electron transfer takes place between diazonium cation and cyanometalate anion, possibly *via* a diazoisocyanide intermediate *(1)* whose existence has, as yet, not been demonstrated[3]. By its stepwise homolytic decomposition (or directly[4]) an energy-rich aryl (or aryldiazenyl) radical is formed, which immediately reacts with the solvent with H abstraction, together with a relatively stable organometallic radical *(2)* which combines with the main radical of the solvent—here an α-tetrahydrofuranyl radical[5].



Scheme 1.

Actually, in addition to the isocyanide complexes *(3)* we were also able to detect the reduction product ArH of the diazonium component in each case (Scheme 1). This reaction mechanism is further supported by a) the characterization and controlled thermal decomposition of *p*-dimethylaminobenzenediazonium pentacarbonylcyanochromate[6], b) the earlier isolation of the paramagnetic chromium(I) compound *(2)*[7], and c) the ESR and ^{1}H-NMR spectroscopic detection of paramagnetic species in the reaction solution[6].

If Scheme 1 holds, each change of solvent RH should lead to new isocyanide complexes. This is confirmed by the reactions in di- and trichloromethane, which afford the complexes *(4)* and *(5)* in 25 and 60% yields, respectively.

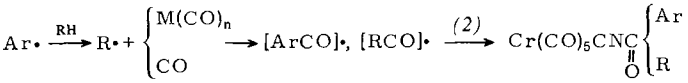
[**] Isonitrile Syntheses at the Metal, Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. -Part 3: *W. P. Fehlhammer, A. Mayr, M. Ritter*, Angew. Chem. *89*, 660 (1977); Angew. Chem. Int. Ed. Engl. *16*, 641 (1977).



(4) *(5)*

The isocyanides thus formed at the metal are characterized by a high reactivity of the chlorine atoms which can be exploited synthetically. The IR spectra of the two complexes, in particular their low ν(CN)- and high ν(CO) [E]-frequencies, reflect the marked acceptor properties of the dichloro- and trichloromethyl isocyanide ligands.

Characteristic IR data (*n*-pentane; cm^{-1}) of $Cr(CO)_5CNCCl_nH_{3-n}$

		ν(N≡C)	ν(CO) [A_1, E]	
	$n=1$	2135 w	2050 w,	1960 vs
(4)	$n=2$	2122 m	2055 m,	1976 vs
(5)	$n=3$	2120 m	2088 m,	1983 vs

The "radical alkylation of cyano complexes" according to Scheme 1 thus opens up an entry to isocyanides bearing strongly electronegative substituents which are not accessible by the usual methods. The monochloro derivative ($n=1$) still missing from the series $Cr(CO)_5CNCCl_nH_{3-n}$ has so far been detected only in traces by IR and mass spectroscopy. Here, as in other cases where particularly short-lived radicals occur and the volatility of RH necessitates working under pressure, large amounts of *aroyl* and *acyl isocyanide*-metal complexes [*e.g.* $Cr(CO)_5CNCOC_6H_4Cl$, $Cr(CO)_5CNCOCH_2Cl$] are formed instead of the expected products *(3)*. The problem

of whether this variant involves a sequence of free-radical reactions or whether aryl and, correspondingly, aroyl *cations* play a role can only be resolved by further investigations (also under CO pressure).

The reactions in dibromomethane or benzene no longer conform to Scheme 1.

The characterization of all the products clearly shows that, in this instance, bromo- or phenyldediazonization processes occur instead of H abstraction from the solvent.

$CH_2Br_2 + Ar^{\bullet}/Cr^{I}(CO)_5CN \rightarrow ArBr + Cr^{0}(CO)_5CNCH_2Br$
$C_6H_6 + Ar^{\bullet}/Cr^{I}(CO)_5CN \rightarrow ArC_6H_5 + Cr^{0}(CO)_5CNH$

Experimental

Pentacarbonyl(trichloromethyl isocyanide)chromium(0) *(5)*: $Na[Cr(CO_5)CN]$[8] (885 mg, 3.67 mmol) and $[p\text{-}ClC_6H_4N_2]Cl$ (640 mg, 3.67 mmol) are mixed with stirring in 100 ml anhydrous alcohol-free trichloromethane under nitrogen at −78 °C and the mixture allowed to warm to room temperature within 3—4 h. Evolution of gas is observed as soon as the temperature reaches −50 °C. After evolution of gas has subsided the solvent is removed and the solid residue is extracted several times with 20 ml portions of *n*-pentane. Removal of solvent and purification of the crude product by sublimation (30 °C, high vacuum) affords 740 mg of a finely crystalline yellow solid (60 %; decomp. pt 99 °C), which can be stored almost indefinitely at −35 °C.

Reversible Opening of a Trinuclear Heterometal Cluster[**]

By *Gottfried Huttner, Josef Schneider, Hans-Dieter Müller, Gerhard Mohr, Joachim von Seyerl*, and *Lidwina Wohlfahrt*[*]

Despite numerous investigations on the homogeneous catalytic activity of metal clusters[1], very little is known about their mode of reaction. We have now succeeded in demonstrating for the first time[2] that clusters can add substrates reversibly with opening of metal-metal bonds. Addition of a substrate molecule with rupture of a metal-metal bond, and elimination of the modified substrate with formation of a metal-metal bond, could therefore be the first and last steps, respectively, of a catalytic cycle with cluster participation.

The heterometallic, closed tetrahedral cluster *(1)*[3] can be converted at 20 °C under 2 bar carbon monoxide *via* cleavage of a Mn—Fe bond into the half-closed cluster *(2a)*[4].

(1) *(2a)*, L = CO
(2b), L = $P(C_6H_5)_3$

The yield of *(2a)* is 90 %. At 80 °C under 1-bar N_2, *(1)* is regenerated from *(2a)* quantitatively. At 40 °C and 40 bar CO both Mn—Fe bonds of *(1)* are opened and the metallacyclophosphane complex $C_5H_5(CO)_2MnP(C_6H_5)Fe_2(CO)_8$[5] is formed, which likewise is completely converted into *(1)* under 1 bar N_2 at 80 °C.

(1) reacts analogously with triphenylphosphane: In toluene solutions containing equimolar amounts of *(1)* and PPh_3, the adduct *(2b)* is present to the extent of 73 % at 50 °C, whereas at 80 °C only 31 % of *(2b)* is present in equilibrium with 69 % of *(1)*. The addition of *(1)* to PPh_3 is a second order

[*] Prof. Dr. G. Huttner, J. Schneider, Dr. H.-D. Müller, Dr. G. Mohr, Dipl.-Chem. J. von Seyerl, L. Wohlfahrt
Lehrstuhl für Synthetische Anorganische Chemie, Fachbereich Chemie, der Universität Konstanz
Postfach 7733, D-7750 Konstanz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

reaction, its activation enthalpy is small; the decomposition of *(2b)* to *(1)* and PPh_3 is first order, the activation enthalpy $\Delta H^{\neq} = 115\,kJ\,mol^{-1}$. Overall, the opening of the cluster *(1)* to *(2b)* with $\Delta H = -81\,kJ\,mol^{-1}$ is exothermic. That the structure of the adduct *(2b)* is analogous to that of *(2a)*[4] was confirmed by an X-ray structure analysis[6].

Experimental

All operations must be carried out under an inert atmosphere in anhydrous solvents [mass spectrum: Atlas CH7, direct inlet; structure determination: Syntex P3 diffractometer, λ-Mo = 71.069 pm, graphite monochromator; solution: Syntex-XTL, conventional; kinetic data: Cary 17 UV spectrometer].

Synthesis of (2b): A mixture of *(1)* (300 mg, 0.532 mmol) and PPh_3 (1 g, 3.8 mmol) in 200 ml toluene is stirred for 20 h at 40 °C. The originally red solution gradually takes on the green color of the complex *(2b)*. The crude product is absorbed on 5 g silical gel and gently dried. Chromatography at −10 °C (column 20 × 2.5 cm, silica gel Merck 0.063—0.200 mm, pentane) with *n*-pentane/toluene (1 : 1) affords a small yellow front followed by a broad green zone of *(2b)*; unreacted *(1)* can subsequently be washed from the column with *n*-pentane/toluene (1:2). Recrystallization from 5 ml CH_2Cl_2 and 5 ml *n*-pentane affords 380 mg (86.5 %) of analytically pure *(2b)* as green crystals, m.p. 153 °C (red coloration at 80 °C). The mass spectrum of *(2b)* shows only the molecular ion of *(1)* and its fragments.

Catalytic Alkylation of Benzene with CO and H_2: A Homogeneously Catalyzed Fischer-Tropsch Synthesis

By *G. Henrici-Olivé* and *S. Olivé*[*]

Alkylbenzenes, $C_6H_5(CH_2)_nH$, with $n = 1$—5 (maximum at $n = 2$) are formed in a Fischer-Tropsch type synthesis, if a homogeneous solution of $W(CO)_6$ and $AlCl_3$ in benzene is treated in an autoclave with CO and H_2 under pressure, at 200 °C. No xylenes are detected in the reaction solution, but small amounts of methane, ethane and ethylene are generally present in the gas phase. The yield of alkylbenzenes is increased by the addition of a chelating tertiary phosphane, such as ethylenebis(diphenylphosphane), (diphos), or bis(2-diphenylphosphinoethyl)phenylphosphane, (triphos), in a molar ratio phosphane/tungsten of 1—2. Under otherwise comparable conditions, the catalyst turnover (defined as the number of moles CO converted to side chains, per mole of $W(CO)_6$) increases linearly with the ratio p_{H_2}/p_{CO}, as shown in Table 1. Blank runs under identical conditions except for the omission of either $W(CO)_6$ or $AlCl_3$ result in no detectable production of alkylbenzenes.

Table 1. Catalyst turnover in the $W(CO)_6$ catalyzed formation of alkylbenzenes from C_6H_6, CO and H_2, as a function of the ratio p_{H_2}/p_{CO}. $[W(CO)_6] = [triphos] = 4.7 \times 10^{-3}$ mol/l; $[AlCl_3] = 0.25$ mol/l; $T = 200$ °C; $t = 3$ h.

p_{CO} (atm)	p_{H_2} (atm)	p_{H_2}/p_{CO}	Turnover CO/W
100	20	0.2	7
11	9	0.8	38
60	60	1.0	11 [a]
60	60	1.0	44
60	60	1.0	82 [b]
10	30	3.0	105
20	100	5.0	230

[a] No phosphane added. [b] $t = 14$ h.

Table 1 indicates also that the reaction rate decays with time: after 14 hours, the turnover is only roughly twice that observed after 3 hours. The catalyst, $W(CO)_6$, is retained quantitatively in the reaction solution after the reaction. The decrease in reaction rate is assumed to be due to exhaustion of $AlCl_3$ which is enclosed in Friedel-Crafts type, solid, condensed aromatic byproducts.

The inverse dependence of the turnover on the CO pressure indicates ligand CO dissociation prior to the formation of the catalytically active species—similarly as is known from hydroformylation catalysis[1]. The action of the phosphane appears to be to hold this species in solution. Other metal carbonyls, such as $Rh_6(CO)_{16}$, $Ru_3(CO)_{12}$, $Cr(CO)_6$ and $Co_2(CO)_8$, also catalyze the reaction, but with decreasing turnover in this sequence.

The insertion of CO into an aromatic C—H bond, destabilized by $AlCl_3$, was first reported as early as 1897 by *Gattermann et al.*[2]; *Heck*[3] achieved the insertion of CO into the C—X bond of halogenated arenes with $Ni(CO)_4$; *Casey et al.*[4] were able to carbonylate the phenyl ligand of the complex $[(CO)_5WC_6H_5]^-$. However, in no case was reduction of the inserted $>C{=}O$ to $-CH_2-$ reported, which would be the obvious premise for further chain growth according to a Fischer-Tropsch type reaction.

We suggest that HCl, formed in the reaction

$$AlCl_3 + C_6H_6 \rightleftharpoons HCl + C_6H_5AlCl_2$$

is oxidatively added to the tungsten catalyst; this assumption is based on the observation that the catalytic reaction is inhibited by the presence of a HCl scavenger, such as $CaCO_3$. Ligand exchange between the tungsten center and $C_6H_5AlCl_2$ (Cl versus C_6H_5) may then give an arylated tungsten species, where coordinated CO is inserted into the metal-carbon bond. Further steps in the synthesis of alkylbenzenes are assumed to be analogous to those suggested previously for the heterogeneous Fischer-Tropsch reaction[5].

The Fischer-Tropsch type growth of the alkyl chains is corroborated by their chain length distribution. In the "classical", heterogeneous Fischer-Tropsch catalysis, the primary products have a Schulz-Flory distribution[5a, c]. Table 2 shows the chain length distribution of alkylbenzenes obtained in

[*] G. Henrici-Olivé and S. Olivé
Monsanto Triangle Park Development Center, Inc.
P.O. Box 12274, Research Triangle Park, N.C. 27709 (USA)

two parallel runs with the $W(CO)_6$ system at $p_{CO}=20$ atm, $p_{H_2}=100$ atm (cf. Table 1). This distribution was computed from the gas-chromatographic analysis of the alkylbenzenes. In the Schulz-Flory diagram[6] (Fig. 1) the measurements lie on a reasonably straight line. Interestingly, the points corresponding to ethylbenzene lie considerably above the straight line. Evidently, ethylbenzene is produced by more than one mechanism.

Table 2. Weight distribution of C_nH_{2n+1} chains of alkylbenzenes; conditions as in Table 1, last line.

Length of chain, P	[Alkylbenzene] (10^2 mol/l)	[Alkyl chains] (g/l)	Weight fraction m_P	m_P/P
1	25.3	3.79	0.240	0.240
2	39.0	11.31	0.715	0.357
3	1.3	0.56	0.035	0.012
4	0.11	0.06	0.0038	0.001
5	0.13	0.09	0.0057	0.001
1	23.4	3.51	0.207	0.207
2	42.0	12.18	0.719	0.359
3	2.3	0.99	0.058	0.019
4	0.26	0.15	0.009	0.0022
5	0.17	0.12	0.007	0.0014

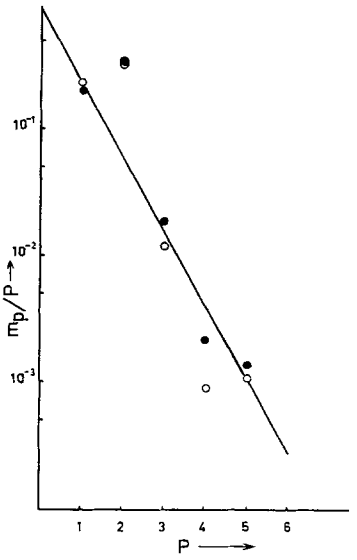

Fig. 1. Chain length distribution of the alkyl chains; graphical representation of data of Table 2 according to $\log(m_P/P)=\log(\ln^2\alpha)+P\log\alpha$ [Schulz-Flory equation, α = probability of chain growth, P = number of carbon atoms in the chain, m_P = weight fraction of chain with length P].

Evidence for homogeneous Fischer-Tropsch catalysis is still scarce. Hydrogenation of CO to hydrocarbons with soluble transition metal-cluster compounds, at low pressure, did not proceed further than to C_2, and with a low turnover[7]; at higher pressures, oxygenated compounds were also produced with soluble clusters[8]. These results led to the assumption[7] that clusters are indispensable for mimicking the solid surface of "classical" Fischer-Tropsch catalysts. However, the recent methanol synthesis by *Rathke* and *Feder*[9], using $HCo(CO)_4$ at 200 °C and 300 atm, is the first example of the catalytic hydrogenation of CO on a soluble, mononuclear species. Some higher alcohols were also found, but were shown to be the products of secondary reactions of methanol, and not of a Fischer-Tropsch type carbon-carbon bond formation.

The synthesis of alkylbenzenes from benzene, CO and H_2 represents the first actual Fischer-Tropsch type chain growth on a soluble, mononuclear catalyst. In contrast to the heterogeneous Fischer-Tropsch catalysts, where chain initiation is assumed to take place at a metal-hydrogen bond[5], the presently described chain growth requires an aryl-metal species to start with. The observed predominance of ethylbenzene, on the other hand, indicates that this particular compound is produced by more than one mechanism. Since small amounts of C_1 and C_2 hydrocarbons are generally found in the reaction gases, it is assumed that ethylene is generated by the "classical" route. (The metal-H bond resulting from the suggested oxidative addition of HCl to the soluble metal complex may be responsible for the initiation of this route.) Ethylene then alkylates the benzene in a Friedel-Crafts reaction.

Ring-Opening of 5-(Bromomethyl)-2-isoxazolines to β,γ-Enoximes—A New Principle for the γ-Substitution of Allyl Bromides by α-Functionalized Alkyl Groups[**]

By *Volker Jäger, Hartmut Grund, and Wilfried Schwab*[*]

2-Isoxazolines represent functionalized carbon skeletons which can be assembled from alkenes and nitrile oxides. This reaction is synthetically useful if suitable methods for the ring cleavage are available[1]. We report here on the ring-opening of 5-(bromomethyl)-[5-(iodomethyl)-]2-isoxazolines *(3)* by reductive elimination: key step of a sequence for the controlled γ-substitution of allyl bromides *(1)*[3] by α-functionalized alkyl groups.

5-(Bromomethyl)-2-isoxazolines *(3)* are accessible in good yield (see Table 1) from *(1)* and chlorooximes as precursors of nitrile oxides *(2)*[4]. On treatment of *(3)* with zinc or zinc/copper [in the case of *(3e)* and *(3f)* after conversion into the iodide], bromine-oxime ether cleavage takes place to furnish β,γ-enoximes *(4)* with the configuration as preconceived in *(3)*. Obvious subsequent reactions are deoximation to *(5)*[5] and oxime reduction to *(6)*, thus completing *acylation* and *α-aminoalkylation* sequences, respectively.

The β,γ-enones *(5a)* and *(5b)* were obtained in $\gtrsim 70\%$ yield *without appreciable isomerization* (see Table 1); the reaction *(4d)*→*(5d)* has so far not been accomplished; likewise the (*E*,*E*)-β-damascone oxime *(7)* (m.p. 123—124 °C), formed

[a] Method A: *(2)* from chlorooxime/triethylamine in ether at ≈0°C [4]; B: *(2d)* from β-cyclocitral oxime/*N*-bromosuccinimide/$NaOCH_3$/dimethylformamide (DMF), 0–25°C [9]; C: Zn/80% ethanol, reflux, 1–4.5 h; D: Zn/Cu, DMF/H_2O (3:1), 16 h at ≈25°C; E: NaI, acetone, 6 h reflux [*(3e)*], 110°C [*(3f)*], then Zn/Cu, tetrahydrofuran (THF/H_2O) (4:1), 7h at room temperature; F: $TiCl_3/NH_4OAc$ buffer [5a] H_2O/DMF/pentane (7:1:4), 15h at ≈25°C; G: Al/Hg, THF/H_2O (9:1) [7b], 0–≈25 or 40°C [*(6e)*]. Structures are secured by elemental analyses and spectral data. To our knowledge *(3b)*–*(3f)*, *(4a)*–*(4d)*, *(6b)* and *(7b)* are new compounds. [b] Kugelrohr distillation, bath temperature. [c] Main fraction, m.p. 54–56°C. [d] *(5a)*: α,β-isomer ≲5%; *(5b)*: ≲3% (^{1}H-, ^{13}C-NMR). [e] *(4c)* is configurationally labile: freshly prepared after distillation (*Z*):(*E*)≈7:1 [(*E*)-*(4c)*: δ(CH_2)=3.03; δ(CH_3)=19.5, δ(CH_2)=33.6; (*Z*)-*(4c)*: δ(CH_2)=3.24; δ(CH_3)=13.4, δ(CH_2)=40.3 (in $CDCl_3$)]; after 5 months at 4°C 1:2; using method C a 43:57 (*Z*)/(*E*) mixture was obtained in ≈50% yield. [f] Reduction and conversion into free amino acids, see [7a], yield w.r.t. *(4e)* and *(4f)* 67 and 71%, respectively [7a]. [g] Not optimized.

in 70% yield on isomerization of *(4d)* with hydrochloric acid in 1,4-dioxane, could not be converted into an enone[6].

Enoximes *(4)* activated by phenyl or alkoxycarbonyl[7a] are smoothly converted into the homoallyl amines *(6)* on reduction with aluminum amalgam (see Table 1). This synthesis of the γ,δ-unsaturated α-hydroxyimino esters *(4e)* and *(4f)* (whose reduction has already been described[7a]) constitutes a new entry to γ,δ-unsaturated amino acids; such compounds frequently function as amino acid antagonists inhibiting the growth of microorganisms[8].

Experimental

(5a) from *(3a)*: A mixture of *(3a)* (2.40 g, 10 mmol) and zinc dust (3.27 g, 50 mmol) in 50 ml of 80% ethanol is heated under reflux for 4 h, then evaporated down, treated with water, and twice extracted with ether. The solution is filtered (short column filled with Na_2SO_4) and concentrated in a rotary evaporator. The residue is dissolved in 40 ml of pentane and stirred with a solution of 25 ml $TiCl_3$ (15% in 4% HCl)/12 g NH_4OAc/70 ml water/10 ml DMF for 15 h under argon. For work-up, the mixture is treated with pentane, extracted twice with pentane, washed with H_2O, saturated $NaHCO_3$ solution, again with water, and then dried over Na_2SO_4. Fractionation (rotary evaporator, then Kugelrohr; see Table 1) affords 1.03 g (71%) of *(5a)* as a pale-yellow liquid.

(6b) from *(4b)*: Amalgamated aluminum foil (540 mg, 20 mmol) is added in small pieces (0.5–1 cm^2) to a solution of *(4b)* (360 mg, 2.05 mmol) in 20 ml THF/2 ml H_2O. Vigorous evolution of gas is moderated by ice-cooling; the stirred mixture is then allowed to warm up to 25°C overnight. On completion of reaction (≈27 h, TLC control) the mixture is treated with 20 ml of THF/Na_2SO_4, allowed to stand for 90 min, filtered, and the solids carefully washed with THF/ether and extracted for 24h with refluxing ether. The dried solutes (Na_2SO_4) are evaporated to afford 344 mg of crude product. Distillation of 244 mg thereof yields 231 mg (98%) of pure *(6b)* as a colorless liquid [b.p. ≈60°C (bath temp.)/0.1–0.2 torr; ^{1}H-NMR ($CDCl_3$): δ=1.73 (CH_3), 1.87 (NH_2), 2.3 ("d", J≈7 Hz; CH_2), 4.03 ("t", J≈7 Hz, CHN), 4.8 (=CH_2), 7.3 (C_6H_5).

Six-Coordinate Hydrogen: Structure of $[(Ph_3P)_2N]^+[HCo_6(CO)_{15}]^-$ by Single-Crystal Neutron Diffraction Analysis[**]

By *Donald W. Hart, Raymond G. Teller, Chiau-Yu Wei, Robert Bau, Giuliano Longoni, Stefano Campanella, Paolo Chini*, and *Thomas F. Koetzle*[*]

Interstitial H atoms are normally found in the structures of binary metal hydrides. In these materials, it has been shown that H atoms may occupy octahedral and/or tetrahedral sites in the metal lattice[1a], and that intermediate sites of lower symmetry may be occupied as well[1b]. For covalent molecular complexes, however, examples of such "interstitial" hydride ligands are rare[2]. We report here the characterization, *via* single-crystal neutron diffraction measurements, of an interstitial hydride ligand (a six-coordinate H atom) in the metal carbonyl cluster complex $[HCo_6(CO)_{15}]^-$.

The complex anion $[HCo_6(CO)_{15}]^-$ can be prepared by the protonation of $[Co_6(CO)_{15}]^{2-}$, which in turn is formed in the pyrolysis of $Co_2(CO)_8$ in ethanol[3a]. We recently became interested in the structure of $[HCo_6(CO)_{15}]^-$ when it was reported that the ^{1}H-NMR signal of the unique proton in that complex occurred at $\delta = 23.2$[3b], which is unusual for a metal hydride complex. Normally, for hydridometal complexes δ values in the range 0 to -40 are measured[4]. This anomalous downfield shift found here suggested that the H atom in $[HCo_6(CO)_{15}]^-$ might be located in the vicinity of the carbonyl ligands, similarly as in $H_2Fe_3(CO)_{11}$[5].

[**] This research was carried out under contract with the U.S. Department of Energy (Division of Basic Energy Sciences), and supported by Grant CHE-77-00360 (to R. B.) from the National Science Foundation. We thank Mr. *J. Henriques* for technical assistance.

$[(Ph_3P)_2N]^+[HCo_6(CO)_{15}]^-$ was prepared by addition of concentrated HCl to an aqueous solution of $K_2[Co_6(CO)_{15}]$, followed by metathesis of the precipitated $K[HCo_6(CO)_{15}]$ with $[(Ph_3P)_2N]Cl$ in acidified isopropyl alcohol. The IR spectrum of this compound (in CH_2Cl_2) consists of the following bands: 2060 (w), 2005 (s), 1975 (ms) and 1830 (ms) cm^{-1}. Salts of $[HCo_6(CO)_{15}]^-$ are unstable in most of the usual solvents where, at room temperature, rapid decomposition to a mixture of $[Co_6(CO)_{15}]^{2-}$, $[Co(CO)_4]^-$ and eventually $Co_4(CO)_{12}$ is observed. The most stable solutions are obtained in diisopropyl ether, and to a somewhat lesser extent in dichloromethane.

The compound $[(Ph_3P)_2N]^+[HCo_6(CO)_{15}]^-$ crystallizes in the monoclinic space group $P2_1/n$, with $a = 17.922(3)$ Å, $b = 17.524(4)$ Å, $c = 16.329(8)$ Å, $\beta = 92.27(2)°$, $Z = 4$ (unit cell parameters measured at -193°C). The neutron diffraction analysis was carried out on a crystal of approximate dimensions $3.0 \times 2.2 \times 0.5$ mm [Brookhaven High Flux Beam Reactor, $\lambda_n = 1.0373(1)$ Å (KBr, $a = 6.6000$ Å, -193°C)]. The positions of the non-hydrogen atoms in the molecule had been determined from an earlier X-ray analysis and this model, together with phenyl H atoms placed in calculated positions, was used to phase the neutron data. A subsequent difference-Fourier synthesis revealed the position of the unique H atom in the anion. Several cycles of least-squares refinement (based on F^2) were then carried out, in which all atoms in the anion were refined anisotropically, and phenyl rings were treated as rigid groups with individual isotropic temperature factors. Final agreement factors are $R(F) = 0.071$, $R(wF) = 0.042$, $R(F^2) = 0.107$ and $R(wF^2) = 0.081$[6] for 3574 unique reflections having $F^2 > 3\sigma(F^2)$.

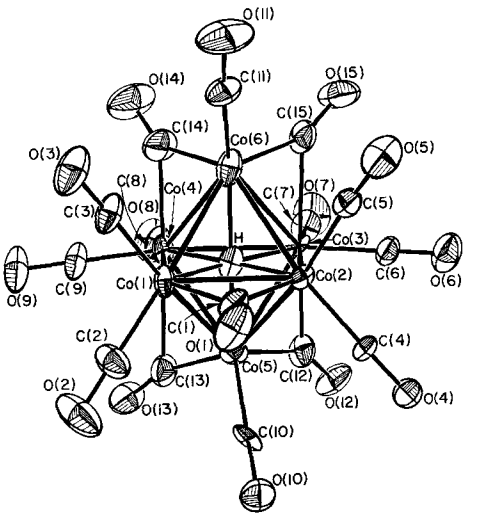

Fig. 1. A molecular plot of the $[HCo_6(CO)_{15}]^-$ anion, showing the six-coordinate H atom at its center. The cluster has approximate C_{2v} symmetry, with ten terminal, one symmetrically bridging and four asymmetrically bridging carbonyl groups. Average H—Co and Co—Co distances are 1.82(1) Å and 2.58(1) Å, respectively.

The structure of the $[HCo_6(CO)_{15}]^-$ anion is shown in Figure 1, which indicates that the lone H atom is located not on the carbonyl ligands but at the center of the Co_6 octahedron. The H—Co distances are nearly equivalent [1.80(2), 1.80(2), 1.81(2), 1.81(2), 1.85(2), 1.87(2) Å; average = 1.82(1) Å], and the H atom is displaced less than one standard deviation from the geometric center of the metal cluster. Co—Co distances range from 2.50(2) to 2.67(2) Å, with an average of 2.579(15) Å, resulting in an apparent radius for the interstitial H atom of $1.82 - (2.58/2) = 0.53$ Å. An interesting observation

is that the insertion of a H atom into the cluster has caused a small but appreciable swelling of the octahedron: the average Co—Co distance increases from 2.509(8) Å in $[Co_6(CO)_{15}]^{2-}$[7] to 2.579(15) Å in $[HCo_6(CO)_{15}]^-$. This was also noticed in the structures of $[HNi_{12}(CO)_{21}]^{3-}$ and $[H_2Ni_{12}(CO)_{21}]^{2-}$: the individual Ni—Ni distances for octahedral holes containing H are 0.02—0.07 Å longer than those for holes without H[2b].

There are ten terminal, one symmetrically bridging and four asymmetrically bridging carbonyl groups in the cluster. The $[(Ph_3P)_2N]^+$ cation is in the usual bent form[8], with a P—N—P angle of 142.9(4)°.

We now return to the observation which originally attracted us to $[HCo_6(CO)_{15}]^-$: the anomalous ^{1}H-NMR chemical shift of $\delta = 23.2$[3b]. This signal (a moderately broad singlet) is observable at −100 °C in acetone, when the solution is prepared at low temperature, or in dichloromethane. At −70 °C, a broad signal is present, but at −50 °C no signal could be observed. The signal reappears by cooling again to −100 °C. The finding that the signal is absent when the compound is dissolved in [D$_6$]acetone would suggest that, in solution, the H atom may leave the cluster and exchange with the solvent. Further evidence that the H atom may quite easily enter and leave its "metal cage" is provided by the simple protonation of $[Co_6(CO)_{15}]^{2-}$, and the converse reaction of $[HCo_6(CO)_{15}]^-$ observed on simple dissolution in solvents such as water, methanol or even tetrahydrofuran[9]. This borderline ability to accommodate the interstitial hydride observed between solid state and solution is in fair agreement with the predicted trend that decreasing the number of interstitial holes present in the cluster leads to decreased stability of the hydride[3b]. It should be noted that $[HRu_6(CO)_{18}]^-$, which is suspected from X-ray analysis to contain an interstitial H atom[10], also shows a ^{1}H-NMR signal with similar downfield shift ($\delta = 16.4$), whereas the signals of the larger interstitial clusters $[HNi_{12}(CO)_{21}]^{3-}$ ($\delta = -24.0$), $[H_2Ni_{12}(CO)_{21}]^{2-}$ ($\delta = -18.0$)[2b], $[H_2Rh_{13}(CO)_{24}]^{3-}$ ($\delta = -26.7$), and $[H_3Rh_{13}(CO)_{24}]^{2-}$ ($\delta = -29.3$)[2c, 2d] are all found at the expected high-field positions. It is clear that more results, both spectroscopic and crystallographic, will be needed before we can successfully correlate structural information with the NMR chemical shifts of atoms embedded within metal clusters.

[(triphos)Co(δ-P$_3$)Cr$_2$(CO)$_{10}$]: A Trinuclear Heterometal Complex Containing *cyclo*-Triphosphorus as μ$_3$-Ligand

By *Stefano Midollini, Annabella Orlandini*, and *Luigi Sacconi*[*]

The first sandwich metal complex of *cyclo*-triphosphorus *(1)*[11] contains a central cobalt atom bound to six phosphorus atoms, three of which belong to the η^3-P$_3$ unit and three to the tridentate tritertiary phosphane $CH_3C(CH_2PPh_2)_3$(triphos). We have found that this complex possesses Lewis base properties due to the three donor phosphorus atoms of the P$_3$ unit. Indeed *(1)* reacts with Cr(CO)$_6$ in the molar ratio 1:1 or 1:2 to give the binuclear *(2)* and the trinuclear complex *(3)*.

(1)

$\xrightarrow[h\nu]{Cr(CO)_6}$ (triphos)Co(η^3-P$_3$)Cr(CO)$_5$ *(2)*

(triphos)Co(η^3-P$_3$)Cr$_2$(CO)$_{10}$ *(3)*

Even on treating *(1)* with an excess of Cr(CO)$_6$, it was not possible to isolate any compound containing more than two Cr(CO)$_5$ groups. This is probably due to the bulkiness of these coordination units.

A complete X-ray structure analysis performed on the complex *(3)* (Fig. 1) shows the structure of the donor complex

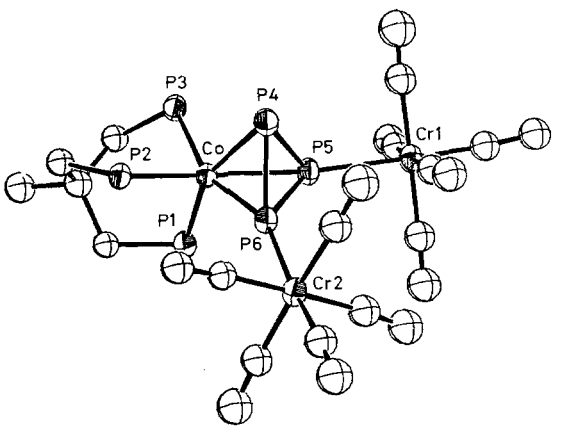

Fig. 1. Inner skeleton of *(3)* [ORTEP diagram]. Monoclinic, space group C2/c, $a = 36.48(2)$, $b = 13.45(1)$, $c = 26.59(1)$ Å, $\beta = 105.0(1)°$, $Z = 8$. Data collection: Philips PW 1100 automatic diffractometer, refined from 3725 observed reflections with $I \geq 3\sigma(I)$ to $R = 0.08$. Bond lengths: P—P(ring) = 2.14, Cr—P = 2.42 Å (av.). Bond angles: Cr1—P5—P6 = 132.8°, Cr1—P5—P4 = 123.3°, Cr1—P5—Co = 165.4°, Cr2—P6—P5 = 138.1°, Cr2—P6—P4 = 129.6°, Cr2—P6—Co = 157.1°.

(1) to be almost unchanged on bonding to the two Cr(CO)$_5$ groups. Each Cr atom is six-coordinate and is bound to a P atom and to five CO groups in a distorted octahedral geometry. The values of the CrPCo and CrPP angles, which range from 123.3 to 165.4°, show that the Cr—P bonds lie out of the plane of the P$_3$ ring. The Cr—P distances, 2.42 Å, are equal to the Cr—P distance in the complex $Ph_3PCr(CO)_5$[12]. This suggests that the coordination properties of the P atoms in the *cyclo*-P$_3$ unit are similar to those of the phosphorus in triphenylphosphane.

Via J. Nardi 39, I-50132 Florence (Italy)

The IR spectra in $CHCl_3$ solution of the complexes *(2)* and *(3)* in the CO region are essentially similar. The 2058 w, 1990 vw, 1945 s, and 1917 m cm^{-1} bands (attributable to A_1^1, B_1, E, A_1^2 modes, respectively, in the complex *(2)*) are those expected for a $LCr(CO)_5$ complex in which the local symmetry is reduced by the lower symmetry of the L group[3].

While the cobalt atom formally accepts three electrons from the three phosphorus atoms of the μ_3-bonded P_3 unit, each chromium atom receives an electron pair from one P atom. Thus each metal atom in the trinuclear complex has a closed-shell electronic structure with consequent diamagnetism.

Procedure

A solution of *(1)* (300 mg, 0.39 mmol) in THF (40 ml) is added under nitrogen to solid $Cr(CO)_6$ (600 mg, 2.7 mmol) in a quartz vessel. The mixture is refluxed under UV light for 4 h. The red-brown solution is then evaporated and the unreacted $Cr(CO)_6$ removed by sublimation. The residue is dissolved in THF and mixed with dibutyl ether. After concentration, 150 mg of *(3)* is obtained. If only 87 mg (0.39 mmol) of $Cr(CO)_6$ is employed, compound *(2)* is obtained.

Preparation of a New Series of Trinuclear Metallophthalocyanines and -porphyrins

By *Shinzi Kato, Ippei Noda, Masateru Mizuta*, and *Yuji Itoh*[*]

Polynuclear metalloporphyrin complexes are well known[1], whereas the corresponding phthalocyanine complexes, have so far never been described in the literature. We report here on the synthesis of novel trinuclear metallophthalocyanines and -porphyrins of the type (A), M, M' = metal.

The compounds *(4a)* and *(4d)* listed in Table 1 where obtained on reaction of dichloro(phthalocyaninato)tin(IV) *(1a)*, $Sn(Pc)Cl_2$, or dichloro(5,10,15,20-tetraphenylporphyrinato)tin(IV) *(1d)*, $Sn(TPP)Cl_2$ with decacarbonyldirhenium *(3)* at 180 °C. It is interesting that reaction of *(3)* with complexes possessing no axial ligands such as Zn(Pc) *(2b)* or Mg(TPP) *(2f)* likewise leads to the trinuclear compounds *(4)*.

The structures proposed for *(4a)*—*(4g)* are in accord with the results of elemental analysis and UV/VIS, IR and Raman spectroscopic data. The UV/VIS absorption spectra contain characteristic bands or a Soret band; the maxima are very similar to those of the starting complexes *(1)* or *(2)*, thus suggesting the presence of the phthalocyaninato- or porphyrinatometal moiety. In the mass spectra, no chloride ion was detected. The infrared spectra of the complexes in the solid state show characteristic intense bands in the region of the metal carbonyl stretching bands and resemble quite closely those of $TPP[Re(CO)_3]_2$[2]; this would suggest the presence of two $Re(CO)_3$ groups, one located above and the other below the plane of the Pc- or TPP-ligand. No characteristic absorption bands appear in the FIR region of 150—250 cm^{-1}, in which the metal-metal stretching vibrations of tin-transition metal complexes are to be observed[3].

Though the existence of metal-metal bonds in the complexes *(4)* could not be proven, we assign the structures[4] of type (A) to these compounds on the basis of the spectral data mentioned above, and the results of an X-ray structure analysis on the complex $[Sn(TPP)\{Re(CO)_3(C)\}_2]$[5], obtained according to a similar procedure at 160—165 °C.

Experimental

A mixture of *(1a)* (70.2 mg, 0.1 mmol) and *(3)* (326 mg, 0.5 mmol) in *o*-dichlorobenzene (6 ml) was heated at 180 °C for 7 h. Two characteristic bands in the VIS spectrum at 631 and 696 nm (in CH_2Cl_2) disappeared and new bands appeared at 644 and 712 nm (in CH_2Cl_2). After removal of solvent *in vacuo* and subsequent vacuum sublimation of excess

A Metalloporphyrin Containing Carbyne-like Carbido Carbon: 5,10,15,20-Tetraphenylporphyrinato[bis(μ-carbidotricarbonylrhenium)]tin(IV)[**]

By *Ippei Noda, Shinzi Kato, Masateru Mizuta, Noritake Yasuoka*, and *Nobutami Kasai*[*]

The green 5,10,15,20-tetraphenylporphinato[bis(tricarbonylrhenium)]tin(IV) *(3)*[1] is formed on reaction of the dichloro compound *(1)* with decacarbonyldirhenium *(2)* at 180°C. Interestingly, however, we have found that the same reaction at 160–165°C affords a dark red complex *(4)*, showing similar IR spectroscopic data to those of *(3)*. An X-ray structure analysis[3] of *(4)*, revealed it as being, to our knowledge, the first metalloporphyrin containing carbido-carbon ligands.

The compound *(4)* was prepared by a procedure similar to that used previously[2], from *(1)* and *(2)* by 240 hours' heating at 160–165°C [$\lambda_{max}(CH_2Cl_2)$: 402 sh, 420 (Soret), 512, 552, 591 and 628 nm; ν(C≡O) (KBr): 2000, 1995, and 1920 cm^{-1}]. Small single crystals of *(4)* for X-ray crystallographic analysis were obtained on allowing a solution of the complex in *o*-dichlorobenzene to stand for several weeks. As shown in Figure 1 the centrosymmetric molecule contains two $Re(CO)_3$ groups, one located above and one below the plane of the porphyrin ring which is centered by the tin atom. Surprisingly, the tin and rhenium atoms are linked by a carbido-carbon atom, which is bound carbyne-like to the rhenium atom. The Re—C1 length (1.75 Å) is close to the Re≡C distance (1.747 Å) which might be predicted from the sum of the covalent radii [using half the Re≡Re distance (1.145 Å) in $Re_2Cl_5 \cdot \{MeS(CH_2)_2SMe\}_2$[4] and half the C≡C

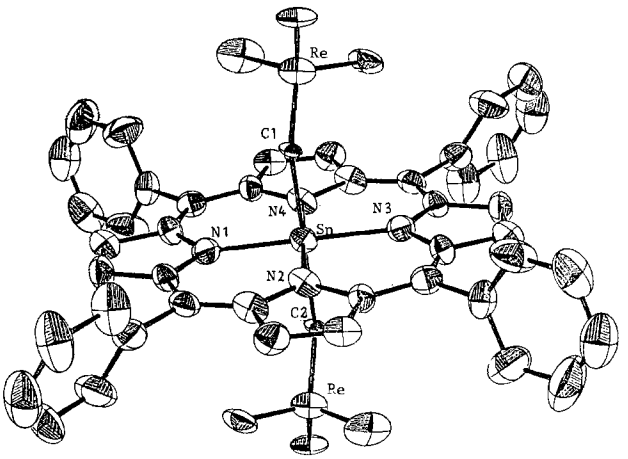

Fig. 1. Structure of the carbido complex *(4)* [3].

distance (0.603 Å)[5] in common acetylene compounds]. The Sn—C1 length (2.14 Å) is in good agreement with the length of the Sn—C single bonds in $Me_2ClSnSC(S)NMe_2$[6] [2.17(5) and 2.20(5) Å]. Further, it is interesting that the Sn—C1≡Re angle is 138.5(8)°. Thus, the Sn—C≡Re linkage is nonlinear. We connot as yet offer a reasonable explanation for this finding. The angles N1—Sn—C1 and N2—Sn—C1 are 89.4(5) and 90.6(5)°, respectively. The porphyrin ring is planar within 0.7 Å; Sn, N1, N2, N3 and N4 lie in a plane. Two Sn—N lengths [2.07(2) Å] are equal, the N—Sn—N angles are 89.3(6) and 90.1(6)°, and the other bond lengths and angles also have values in the usual range. At the present time, it is unclear whether *(4)* is converted into *(3)* or not on heating to 180°C[7].

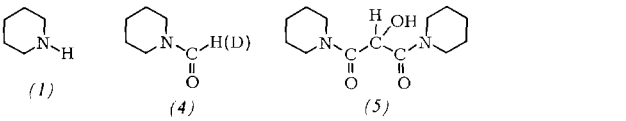
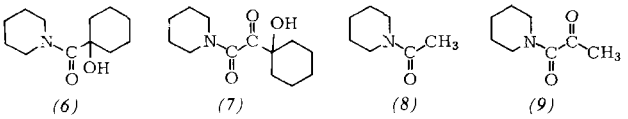
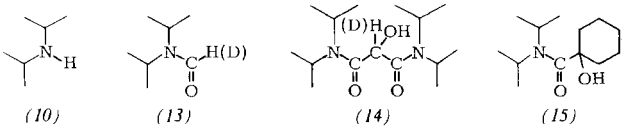
metal compounds. Only certain carbamoyllithiums (CAL-s) with presumably ionic, bent structures appear to be largely persistent in solution[2–5] and thus represent an unexplained "island of stability" in the area of acyl anions. Of the reported modes of formation—namely (A) the addition of carbon monoxide to lithium dimethylamide[2a] or *tert*-butylamide[2b, 6], (B) the transmetalation between butyllithium and bis(diethylcarbamoyl)mercury[3], and (C) the lithiation of dialkylformamides with lithium diisopropylamide[4] or *tert*-butyllithium[5]—the simplest, method (A), has been the least studied, with contradictory results (cf. [2]). We have investigated method (A) in detail and report typical findings with two lithium dialkylamides[6].



(2) *(3)*

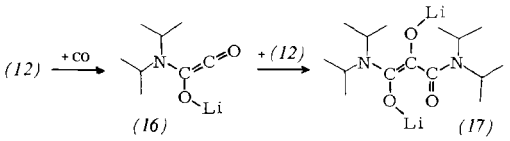


(11) *(12)*



Passing CO into a *ca.* 0.6 M solution of lithium piperidide *(2)* in 1,2-dimethoxyethane (DME)/tetrahydrofuran(THF)/hexane at *ca.* −75 °C under standard conditions [Procedure (PR)] affords a solution of the corresponding CAL *(3)*, detectable by trapping reactions. Hydrolysis leads to the formamide *(4)* [yield based on *(2)* 20—30 %[7a]], hydrolysis with D_2O and workup with H_2O to the labeled formamide $[D_1]$-*(4)* along with small amounts of *(4)* [85:15 to 90:10[7b]]. Reaction with cyclohexanone (0.6 equiv., PR) and hydrolysis gives the hydroxycarboxamide *(6)* [m.p. 121—122 °C] and in addition the hydroxy(oxo)carboxamide *(7)* [m.p. 116—117 °C; molar ratio ≈4:1, yield *(6)* + *(7)* *ca.* 85 %[8a]]. Similarly, reaction with methyl iodide (PR) and hydrolysis affords the acetamide *(8)* and the α-oxopropionamide *(9)* [≈1:1, yield *(8)* + *(9)* *ca.* 65 %[8a]]. Reaction with *(8)* instead of methyl iodide under otherwise the same conditions and subsequent hydrolysis likewise leads to *(9)*: addition of *(3)* to *(8)* thus competes with the methylation of *(3)*; protonation of the secondary adduct leads to cleavage to give *(9)* and *(1)*. *(7)* (and *(1)*) must be formed analogously, by addition of *(3)* to the initially formed alkoxide of *(6)*, protonation of the secondary adduct, and cleavage. *(3)* apparently does not react further with the secondary adducts.

(1) *(4)* *(5)*



(6) *(7)* *(8)* *(9)*

(10) *(13)* *(14)* *(15)*

Passing CO into a solution of lithium diisopropylamide *(11)* at *ca.* −75 °C (PR) analogously affords a solution of the corresponding, hindered CAL *(12)*. On reaction with cyclohexanone, the secondary addition is suppressed, and after hydrolysis *(15)* is obtained [m.p. 137–138 °C, yield *ca.* 50 %[8a, b]]. Hydrolysis affords the formamide *(13)* [yield based on *(11)* 20—40 %[7a]]; hydrolysis with D_2O and workup with H_2O gives the labeled formamide $[D_1]$-*(13)* along with small amounts of *(13)* [84:16 to 98:2[7b, 9]].

Both on prior (partial) trapping of *(3)* and *(12)* with cyclohexanone and subsequent hydrolysis [→ *(6)* + *(7)* and → *(15)*] and on direct hydrolysis, the hydroxymalonamides *(5)*[8c] [m.p. 81—82 °C] and *(14)* [m.p. 102—103 °C; yield based on *(11)* or *(10)* (stoichiometry: 2 *(10)* + 3 CO → *(14)*, 10—20 %[7a]] are isolated[10] along with the formamides *(4)* and *(13)*. When CAL *(12)* is generated *via* method (C), without introduction of CO, *via* the equilibrium *(11)* + *(13)* ⇌ *(10)* + *(12)*, in concentrations comparable with those obtained here on carbonylation (starting from *ca.* 0.5 M solutions of *(11)* and *(13)*) and in the same medium, none of *(14)* is found on hydrolysis after leaving the reaction mixtures for 5 min *(4b)* to 4 h[9] at *ca.* −75 °C. This suggests that the anionic precursors of *(14)* and *(5)* are formed by twofold addition of the CAL-s *(12)* and *(3)* to CO: the yield of *(14)* [*ca.* 35 % together with 20 % of *(13)*] indeed increases when more CO is introduced (PR, introduction of CO for 9 instead of 4 h)[11]. For this reason we have not attempted to convert the lithium amides *(2)* and *(11)* completely. Even more *(14)* [yield *ca.* 40 %] is isolated when the carbonylation is carried out at *ca.* 5 °C (otherwise according to PR). *(12)* presumably reacts with CO to give a short-lived adduct *(16)*, which rapidly adds *(12)* to give the dianion *(17)* of *(14)* (formation of the dianion of *(5)* analogous). Hydrolysis with D_2O[9] and workup with H_2O indeed leads to labeled $[D_1]$-*(14)*[12].

(12) *(16)* *(17)*

Most lithium dialkylamides should react analogously with CO to give CAL-s. Their synthetic utility is primarily limited by 1) the reaction of the CAL-s with CO; 2) the incomplete conversions of the amides [in part due to 1]; 3) the secondary additions of unhindered CAL-s to primary adducts.

Procedure

20 mmol of *n*-butyllithium (1.5—1.6 M) in hexane is added to 20 mmol of *(1)* or *(10)* in DME (10 ml) and THF (10 ml)[13] at *ca.* −75 °C under an inert gas and after 5 min CO is passed (*ca.* 3 l/h) at *ca.* −75 °C for 4 h through the stirred solution. Hydrolysis: the solution (*ca.* −75 °C) is poured into *ca.* 100 ml of H_2O (*ca.* 22 °C). Hydrolysis with D_2O[9]: 3 ml of D_2O (*ca.* 22 °C) is added at once to the stirred solution (*ca.* −75 °C) and the resulting mixture is diluted with H_2O. Reaction with cyclohexanone or methyl iodide: 0.6 mol of the substrates per mol of *(1)* or *(10)* is added at *ca.* −75 °C, and the resulting mixtures are stirred for 3 h ($C_6H_{10}O$) or 1 h (CH_3I) at −75 °C and finally for 1 h at *ca.* 5 °C; hydrolysis as above. Isolation: The hydrolysates are diluted to *ca.* 250 ml with H_2O and continuously extracted with ether for 48 h. The extracts are concentrated and roughly fractionated. Pure substances are obtained by gas chromatography and/or recrystallization.

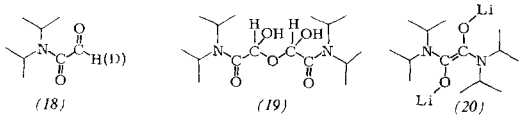
Gleiter, ibid. 77*, 964 (1965), and *4*, 951 (1965).



[5] *A. S. Fletcher, K. Smith, K. Swaminathan*, J. Chem. Soc. Perkin Trans. I *1977*, 1881.

[6] For the carbonylation of lithium monoalkylamides according to [2b] see *V. Rautenstrauch, M. Joyeux*, Angew. Chem. *91*, 73 (1979); Angew. Chem. Int. Ed. Engl. *18*, 85 (1979).

[7] a) Several runs. The variations in the yields are probably caused by variations in the CO flow and by incomplete extraction (PR). b) Several runs. Control experiments with $[D_1]$-*(4)* and $[D_1]$-*(13)* show that no D/H exchange takes place during the isolation; *(4)* and *(13)* are probably formed *via* method (C), on incomplete lithiation of the amines *(1)* and *(10)*.

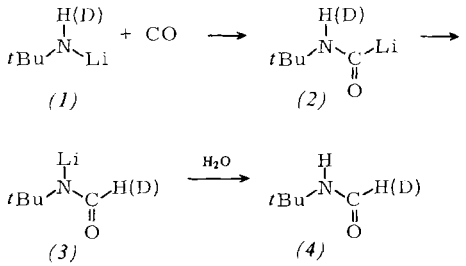
[8] a) Yield not optimized. – b) The hydrolysate contains *(13)* and cyclohexanone, which probably reacts in part with unconsumed *(11)* to give the enolate. – c) Yield not determined, of the same order as that of *(14)*.

[9] On hydrolysis of the solutions of *(12)* with a relatively small amount of H_2O or D_2O (PR, hydrolysis with D_2O) the glyoxylamides *(18)* and $[D_1]$-*(18)*, respectively (cf. [4d]) [yield up to 15% based on *(11)*; only partially survives the extraction (PR)] or their readily formed hemihydrates *(19)* and $[D_2]$-*(19)* [m.p. 103–106°C (loss of water to give *(18)* and $[D_1]$-*(18)*, *meso*-form)] are obtained in varying yields, which long confused us: control experiments show that *(18)* (and/or *(19)* and/or the hydrate of *(18)*) is formed after the addition of H_2O or D_2O in the two-phase system consisting of the aqueous phase and the cold (*ca.* –75°C) DME/THF/hexane solution, which contains *(11)*, *(12)* (?), *(10)*, *(13)* and LiOH. *(18)* is *not* formed when the solutions are poured into a large excess of H_2O (PR, hydrolysis); it is also not formed in method (C), *via* addition of *(12)* to *(13)*. Thus *(18)* is neither derived from *(16)*, nor from a dimer *(20)* of *(12)*.

(18) *(19)* *(20)*

[10] Two further, not fully identified compounds are found in the hydrolysate of the solution containing *(3)*.

[11] Without further passage of CO, the CO still present in the solution reacts slowly with *(11)* and *(12)* on standing for 20–48 h at *ca.* –75°C (yield of *(13)* after hydrolysis *ca.* 20%, of *(14)* 20–40% [7a]; hydrolysis with D_2O gives $[D_1]$-*(13)*:*(13)* ≈ 97:3). We do not know whether the carbonylations under these conditions are reversible, as is the case at elevated temperatures: *J. C. Powers, R. Sneider, T. G. Parsons*, Tetrahedron Lett. *1965*, 1713.

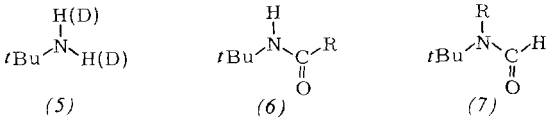


[12] 50–80% $[D_1]$-*(14)* several runs, 50–20% *(14)*; $[D_1]$-*(14)* apparently undergoes partial H/D exchange during isolation.

[13] With THF alone a jelly is formed which is converted into a normal solution by addition of DME.

Carbonylation of Lithium Monoalkylamides to Give *N*-Lithio(alkyl)formamides

By *Valentin Rautenstrauch* and *Michel Joyeux*[*]



We report that the carbamoyllithium *(2)* which formed when carbon monoxide is passed into solutions of lithium *tert*-butylamide *(1)*[1] rearranges rapidly to give the *N*-lithioformamide *(3)*, as expected on the basis of the pK_a values of *(2)*.

(1) *(2)* *(3)* *(4)*

Passing CO into *ca.* 0.6 M solutions of lithium dialkylamides in 1,2-dimethoxyethane/tetrahydrofuran/hexane at *ca.* –75°C under standard conditions affords the corresponding carbamoyllithiums[3] which are persistent in solution; hydrolysis leads to the *N*,*N*-dialkylformamides, hydrolysis with D_2O and workup with H_2O to the labeled $[D_1]$-formamides[3].

Reaction of the lithium monoalkylamide *(1)* with CO under these conditions (Procedure[3]) and subsequent hydrolysis also affords the *N*-alkylformamide *(4)* [yield based on *(1)* *ca.* 30%], but hydrolysis with D_2O and workup with H_2O leads to unlabeled *(4)* [yield *ca.* 50%[4]]. Analogous carbonylation of the labeled amide $[D_1]$-*(1)*—prepared from labeled *tert*-butylamide ($[D_2]$-*(5)*, $[D_1]$-*(5)*, *(5)*)[5], contaminated with *(1)*—and hydrolysis yields the labeled formamide

(5) *(6)* *(7)*

R = $SiMe_3$, $GeMe_3$, $PbMe_3$

$[D_1]$-*(4)* (91%) and a small amount of *(4)* (9%; yield of $[D_1]$-*(4)* + *(4)* *ca.* 15%[4, 5]). The ratios $[D_1]$-*(1)*:*(1)* and $[D_2]$-*(5)*:$[D_1]$-*(5)*:*(5)* were not determined independently, because D/H exchange is difficult to avoid during manipulation and analysis; $[D_1]$-*(1)*:*(1)* can at best have been ≥ 96:4[5] and may have dropped to ≥ 91:9 by D/H exchange. These experiments alone afford proof—which is more convincing when contrasted with the corresponding experiments with authentic carbamoyllithiums[3]—that *(2)* and $[D_1]$-*(2)* are shortlived primary products and rearrange to give *(3)* and $[D_1]$-*(3)*, respectively. This result can be generalized as formulated in the title. The derivatives described in [1] therefore did not have structures of type *(6)* most likely are the structures of type *(7)*[5].

[4] The variations in the yields are probably caused by variations in the CO flow, by incomplete extraction, and in the case of $[D_1]$-*(1)* by inaccurate weighing of ($[D_2]$-*(5)*, $[D_1]$-*(5)*, *(5)* [5]).

[5] *(5)* and D_2O were mixed in a molar ratio of 4:96; the mixture ([D_2]-*(5)*, [D_1]-*(5)*, *(5)*) formed by exchange was distilled into the reaction flask under argon and lithiated to give a mixture of [D_1]-*(1)* and *(1)* as, in [2] but with excess butyllithium so as to convert any entrained D_2O, HOD, H_2O into LiOD and LiOH. On complete exchange with the D_2O, without D/H exchange during distillation, and neglecting kinetic isotope effects in the lithiation [D_1]-*(1)* and *(1)* should have been formed in a molar ratio of 96:4.

BOOK REVIEWS

Optoacoustic Spectroscopy and Detection. Edited by *Yoh-Han Pao*. Academic Press, New York—London 1977. xi, 244 pp., numerous figs., and tables, bound, $ 19.00.

Optoacoustic or photoacoustic spectroscopy is one of the most recent procedures in instrumental analysis, although the underlying physical phenomenon was reported as long ago as 1880 by *Alexander Graham Bell*. It is a variant of classical absorption spectroscopy in the UV/visible and IR regions, in which a microphone is used as the detector. This combination of optics with acoustics has led to the designation optoacoustic or photoacoustic spectroscopy. In this, the first monograph on the new procedure nine authors, including *L. B. Kreuzer* and *A. Rosencwaig* who are accounted pioneers in the field, report on the physical principles, design of the apparatus, and the possible applications, in eight independent chapters each with its own bibliography.

An introductory chapter on signal production and detection is followed by sections on energy transfer, the principles underlying the optoacoustic spectrometer, on tunable light sources in the UV/visible and the IR region, and on the optoacoustic spectroscopy of gases and solids.

The individual chapters are very clearly written and are provided with a wealth of illustrations. The literature review is probably the most complete that exists at present for this field. The book can be recommended to all who are interested in this new process of instrumental analysis and are active in teaching and research or in the application of this area of absorption spectroscopy.

Principles of Colloid and Surface Chemistry. By *P. C. Heimenz*. Undergraduate Chemistry: A Series of Textbooks, Vol. 4. Marcel Dekker, New York—Basel 1977. 1st edit., xi, 516 pp., bound, SFr. 64.00.

Important aspects of the extensive field of colloid chemistry are treated in eleven chapters with the physical considerations placed in the foreground.

After the introduction of the important experimental values, Chapters 1—4 give an extensive treatment of viscosity, sedimentation, and diffusion (the fundamental mathematical derivations are given in every case), and a discussion of osmotic phenomena. Chapter 5 discusses light scattering theoretically and with numerous experimental examples. There follow chapters on surface tension and adsorption from the liquid phase, starting consistently with the Gibbs equation. The description of adsorption isotherms is placed as the central point of Chapter 8, which deals with adsorption from the gas phase. Unfortunately, this chapter is confined to physisorption, whereas in view of the demanding title of the book at least a brief illustration of the very important area of chemisorption could have been expected. Chapter 9 is devoted to electrochemistry (electrode processes, Debye-Hückel and Gouy-Chapman theory), while van der Waals interaction and its significance for flocculation phenomena of colloidal particles are treated in Chapter 10. The final chapter contains information on electrophoresis and other electrokinetic phenomena.

All in all, the book covers an astonishingly wide field and offers many details; it is forcefully and clearly written, but also includes strict mathematical derivations wherever these are necessary. It is designed for chemists who wish to enter the field of colloid chemistry, though specialists too will find the occasional useful detail.

Klaus Christmann [NB 439 IE]

Methodische Fortschritte im medizinischen Laboratorium (Progress in Methods used in the Medical Laboratory). Vol. 3: **Akute Syndrome** (Acute Syndromes). Edited by *A. Englhardt* and *H. Lommel*. Verlag Chemie, Weinheim—New York 1978. 1st edit., viii, 288 pp., 35 figs., 138 tables, plastic, DM 62.00.

It is unfortunate that the subtitle "Laboratory diagnostics of acute internal diseases" does not appear on the cover, for what is the uninformed or even just the curious reader to make of an "acute syndrome"? Certainly not a "group of related acute symptoms" as given in textbooks and dictionaries.

In their foreword the editors indicate that the plan of the book was based on the following concepts:

1. All modern methods of an emergency laboratory are to be treated.
2. The book should be a reference work for acute situations that call for rapid treatment.
3. Detailed references should provide a review of clinical symptoms, diagnoses, and differential diagnoses.
4. Clearly laid out tables should give side by side clinical pictures and laboratory investigations.

The book contains the following chapters, written by a number of individual authors: acute endogenous intoxications, acute exogenous intoxications, acute cerebral processes: apoplexy and its differential diagnosis, acute disturbances of the cardiovascular system, acute disturbances of hemostatis: acute bleeding, acute disturbances in the abdominal region: the acute abdomen, acute inflammatory organ disorders, acute disturbances of the defense system against infections, acute hemolytic crisis.

It must be emphasized that the clinicochemical part determines the value of the book. All essential data on methods are described in detail or references are given to customary test methods. In view of the progress in the field of clinical chemistry this method of presentation will soon make necessary a supplementary volume or even a new edition.

The book contains a section (p. 281) on "Enzyme immunoassays for the detection of drugs in serum and urine", but the keyword "Enzyme immunoassay" does not appear in the index. There are many similar cases. This is indeed a pity, since a book on emergency medicine is naturally only as good as its index.

The clinician will regret particularly the omission of, *inter alia*, the following signs of acute pictures: diarrhea, unconsciousness due to lactacidosis, coma paraproteinaemicum, and pulmonary embolism.

The strength of the book lies in the emphasis on laboratory diagnostics, so that it can be recommended particularly to users in this field.

Friedrich Willig [NB 436 IE]

Structure Reports. Edited by *J. Trotter* for the International Union of Crystallography. Bohn, Scheltema & Holtema, Utrecht. Vol. 40B (part 1+2) for 1974. Organic Section. Publ. 1976, 1227 pp., bound, fl. 272.00; Vol. 41A for 1975, Metals and Inorganic Section. Publ. 1977, 477 pp., bound, fl. 127.50; 60-Year Structure Index 1913—1973. A. Metals and Inorganic Compounds. Publ. 1976, 229 pp., bound, fl. 68.00; Supplement for 1974—1975. Publ. 1977, 47 pp., bound fl. 10.00; 60-Year Structure Index 1913—1973. B. Organic and Organometallic Compounds. Publ. 1976, 437 pp., bound, fl. 161.50; Strukturbericht (Structure Report). Cumulative Index for Vol. 1—7 (1913—1939). Publ. 1976, 91 pp., bound, fl. 42.50 (Price to Subscribers).

X-Ray structure determinations enable the most extensive statements to be made about the structure of chemical compounds and are used increasingly because of the enormous development of automatic measuring procedures and of elegant methods of calculation. The volume of the results is increasing accordingly, but only their technically correct collection and ease of retrieval enable them to be rationally evaluated by the many potential users, be they crystallographers, chemists, biologists, mineralogists, physicists, metallurgists, or others.

Therefore, in 1956, the International Union of Crystallography continued as "Structure Reports" the "Strukturberichte" begun in 1931 by *P. P. Ewald* and *C. Hermann*; with the volumes listed above it was possible to catch up with the current literature, insofar as this is ever possible in a traditional abstracts publication.

Whereas at the beginning of the series each paper of "structural interest" was abstracted critically and in detail, the data have had to be reduced to the core of the structural information: chemical formula, name of the substance, literature citation (with reference to older papers), unit cell, space group, conditions of measurement, description of structure (sometimes with illustration), atomic distances and bond angles (selected values), and atomic coordinates (only for the simpler structures). Nowadays each volume contains the structures published in the year specified, provided that the data named above can be taken from the paper.

In the volumes of series A the structures are arranged in order of increasing complexity but with regard to the chemical relationships (*e.g.* alloys, sulfides, oxides, phosphates, silicates). In the volumes of series B a division into classes has been attempted (*e.g.* aliphatic amines, N-heterocycles, metal complexes (N-ligand)). Structures for which the data are incomplete are collected in a table.

The reader obtains a stimulating review, the user is thrown back on the indexes: author's name index, substance name index (rational and mineral names), and the molecular formula index. Since the year of publication is second in importance for the purposes of a structure search, the new 60-year indexes are a very considerable help to the owner of all the volumes. An attempt to increase the usefulness has been made by means of a classified index. In Part A the index for some classes is according to the molecular formula, for others according to the periodic system. In addition, this volume contains an alphabetical index of mineral names and a structure-type index after *Pearson* for metallic substances. Part B contains, besides the usual molecular formula index a classifying molecular formula index, sorted according to organic-chemical classes and according to compounds of the transition metals.

Since further structural information was provided in the first volumes of the series (Strukturbericht 1—7), these volumes have additionally their own collective index, which contains special subject and substance indexes taken from the original indexes after modernization and translation into English.

The value of a collection of abstracts must be measured by the criteria of completeness, reliability, variety of entry points, and the period covered. Although the yearly volumes are a great help and often make it unnecessary to go to the original literature, yet in the important 60-year indexes many things can be sought in vain. Many molecular formulas given in the individual indexes are lost. In the classifying indexes the compounds are entered only once, but one does not know where. For instance, "tricarbonyl(hexaethylborazine)chromium(0)" is found among the metal-π-complexes (arenes) but not among boron compounds. In the more detailed classifying index of inorganic compounds the variable nomenclature makes searching still more of a problem. Thus, $Cu_2In_2O_5$ occurs not among the indates, like *e.g.* $CdIn_2O_4$, but among cuprates as "copper indium oxide"; $CuAl_2O_4$ not among the aluminates, like *e.g.* $NiAl_2O_4$, but among cuprates as "copper(II) aluminate". No one should be deceived by the simple, apparently obvious division into classes (nitrates, tellurides, *etc.*) into thinking that the chemical relations are completely reproduced. Search for compounds containing several relevant components requires great care; one finds the Roussin compounds $CsFe_4S_3(NO)_7(H_2O)$ among sulfides, $Fe_4(NO)_4S_4$ among nitrosyls, and $(C_2H_5)_2(Fe_2(NO)_4S_2)$ in the organic part among metal complexes with a sulfur ligand.

To aid a search for crystal structures of organic and organometallic compounds better indexes are available; for metals and inorganic compounds the present book is, in spite of its failings, currently the most complete work of reference. Particularly noteworthy is the structure-type index (after *Pearson*), containing nearly 2000 compounds.

That the problem of finding and displaying large quantities of data can also be handled in a modern way is shown by the work "Molecular Structure and Dimensions"[*].

Günter Bergerhoff [NB 440a IE]

Liquid Fuels from Coal. Edited by *R. T. Ellington*, Academic Press, New York—London, 1977. 1st edit., xvii, 273 pp., numerous figs. and tables, bound, $ 14.50.

A great deal of R & D work has been done in the USA on the liquefaction of coal in the past few years, and the subject was discussed in detail at the 172nd National Meeting of the American Chemical Society in 1976. This book contains 17 studies, each preceded by a short introductory note by the editor. The following topics are discussed:

Dissolution and liquefaction of coal: effect of the solvent; liquefaction with mixtures of H_2 and CO; influence of various catalyst-carriers and of the mineral fraction of coal.

Kinetics of various reactions: hydrogenation over Co/Mo

[*] Cf. Angew. Chem. Int. Ed. Engl. *17*, 872 (1978).

catalysts; general criteria for catalyst development; regeneration and abrasion of the catalyst in the H-coal process; kinetics of coal hydrodesulfurization; solubility of hydrogen and the kinetics of the hydrogenation of coal; short contact time liquefaction of coal.

Separation of solid products: modification of the particle size of inorganic coal components in the liquid product; coagulation and filtration of the ash components in the Synthoil process.

Analytical methods: separation procedures and development of methods for product analysis; application of high-pressure liquid chromatography; petrographic classification of solid residues.

The experimental equipment is generally described accurately and the results are detailed in tables and diagrams. The book is well worth recommending. The results are of interest not only for the liquefaction of coal, but also for the processing of heavy petroleum residues.

K. Hedden [NB 434 IE]

Ullmanns Encyklopädie der technischen Chemie. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), and *W. M. Weigert* (deceased). Volume 13: Hormone bis Keramik (Hormones to Ceramics). Verlag Chemie, Weinheim—New York 1977. 4th Edit., xv, 735 pp., bound DM 380.00.—Volume 14: Keramische Farben bis Kork (Ceramic Colors to Cork). Verlag Chemie, Weinheim—New York 1977. 4th Edit., xv, 717 pp., bound DM 380.00.

Volumes 13 and 14 of "Ullmann" continue the series of alphabetically arranged volumes of the new edition of this reference work.

Among the many keywords of Volume 13, the following ones catch the eye, partly on account of the size of the corresponding entries: Hormones (71 pages), insecticides (65 pages), ion exchangers (68 pages), rubber (129 pages). The last-named article impressively underlines the comprehensive and thorough treatment typical of "Ullmann". The entry is subdivided into five sections entitled: Introduction and natural rubber; synthetic rubber; rubber chemicals and additives; processing and regeneration; testing. Each of these sections is preceded, like every other entry, by a clear list of contents which reveals, for example, that the wealth of industrial and technical information presented is also accompanied by purely chemical material. In this case, for instance, the chemical composition of latex is considered under the heading "natural rubber".

Mention should be made of the following organic intermediates dealt with in Volume 13: hydroquinone (4 pages); aliphatic hydroxy- and keto carboxylic acids (9 pages); aromatic hydroxy carboxylic acids (6 pages); imidazole (3 pages); isocyanates (12 pages); isoprene (10 pages). Topics from inorganic chemistry include: hydrazine (13 pages); hydrides (25 pages); the elements indium (10 pages), iodine (8 pages), and potassium (66 pages), including their compounds; electrical insulators (19 pages), chalk (12 pages), ceramics (25 pages). Dyes are represented by the keywords indigo and indigoid dyes (5 pages), indicator dyes (14 pages), and cationic dyes (10 pages), and pharmaceuticals by cough medicines (12 pages), interferons (4 pages), and the article on hormones mentioned above. Various other keywords not assignable to specific substances also warrant attention: hydrogenation and dehydrogenation (13 pages); natural isotopes and isotope separation (31 pages); heterogeneous catalysis and catalysts (53 pages); and the keyword ion exchangers, in which there unfortunately appears to be some slight lack of coordination between the various authors. A further remark is also called for here: the so-called liquid ion exchangers are used not only in uranium recovery but also for the enrichment of other metals such as copper on an industrial scale (see also Volume 2, p. 571).

Volume 14 is dominated by two keywords which have become highly topical: nuclear engineering (167 pages) and coal and coal refining (282 pages). The article on nuclear engineering is largely devoted to the numerous chemical problems of this field; however, a well-balanced survey of the entire field is also given, as follows from the individual section headings: Historical and introduction; power reactors, general; thermal reactors (converters); breeders; fuel cycle; nuclear fusion. Of particular interest to the chemist is the section on the fuel cycle which could also contribute important factual material for restoring the current public discussion of nuclear power stations to a less emotional level. Precisely this keyword of nuclear engineering beautifully illustrates the way in which the presentation of a large field of study in the new Ullmann becomes a terse monograph in the best sense of the word. The same can be said of the keyword coal and coal refining. A preliminary general section considers, *inter alia*, the origin, occurrence, chemical structure, mining and processing of coal; methods of refining coal are also surveyed before being considered in separate sections: Fischer-Tropsch synthesis; gas production; hydrogenation; carbonization and coking of lignite; carbonization and coking of coal. The section on gas production considers not only gasification of coal but all other processes for the production of gas containing CO and H_2, as well as synthetic natural gas, *i.e.* processes using petroleum fractions (naphtha, heavy oil) and natural gas as raw materials. Thus all the problems connected with the production of these gases, which are of interest both as chemical raw materials and as energy sources, are surveyed in a comprehensive manner, as are purification operations.

Other large entries in Volume 14 include: adhesives and dispersions (42 pages), carbon (57 pages), hydrocarbons (62 pages, including the section on their separation). Furthermore, the keywords ketenes (9 pages), aliphatic ketones (31 pages), aromatic ketones (4 pages), and carboxylic esters (3 pages) represent organic intermediates, while inorganic materials include cobalt (18 pages), carbon dioxide (13 pages), and carbon monoxide (68 pages), and color chemistry is represented by ceramic colors (12 pages).

Summarizing, it may be said that the two volumes live up to the high standard already set by previous volumes with regard to quality of presentation and production.

Structure and Bonding in Cyclic Sulfur-Nitrogen Compounds

By Herbert W. Roesky[*]

The coordination number of sulfur is used in this review as a classification principle; cyclic sulfur-nitrogen compounds in which the sulfur is di-, tri-, and tetracoordinated are discussed. Compounds with sulfur (and nitrogen) of coordination number 2 are electron-rich combinations of elements whose π-electrons are extensively delocalized. A correlation between the coordination number and the bond length can be observed in certain compounds containing tri- and tetracoordinated sulfur.

1. Introduction

As a rule, the formal oxidation number of the sulfur atom is used for the description of sulfur compounds[1]. However, in many cases this formalism does not correctly reflect reality; thus, for S_4N_4 a mean oxidation number of +3 is obtained for the sulfur. As an alternative to the oxidation number, which cannot be measured, one can consider the coordination number, which is an observable.

2. Concept for the Description of Cyclic Sulfur-Nitrogen Compounds

Solely on the basis of the coordination numbers of two, three, and four there are 13 possible arrangements of the sulfur atom in ring systems (Table 1).

A graph-type notation can be selected to distinguish between these varieties[2]. For example, the six-membered ring *(1)*, which contains three sulfur atoms of type *a*, can be described by (*aaa*). Correspondingly, for the derivative *(2)* we obtain the notation (*kkk*). The notation (*abl*) corresponds to six-membered sulfur-nitrogen rings *(3)* with three types of sulfur

Table 1. Sulfur atoms as ring members with coordination numbers of two, three, and four. The 13 possibilities are indicated by lower-case letters.

(2) (kkk)

atoms[3]. The sulfur-sulfur bonds in such rings are indicated by a bar placed over the corresponding identifying letters, *e.g.* ($\bar{a}\bar{e}b$) for the S_3N_2 derivative *(4)*.

The range of sulfur-nitrogen compounds is wide, since by starting with the 13 basic building blocks more than 100 chemically reasonable six-membered rings can be constructed. Only a few of these possibilities have so far actually been synthesized.

(3) (abl)

(4) ($\bar{a}\bar{e}b$)

It now becomes easy to understand that a useful nomenclature for sulfur-nitrogen compounds can be achieved in terms of coordination number alone.

Assuming the feasibility of classifying sulfur-nitrogen compounds by the coordination number, is it also possible to correlate chemical and physical properties with the coordination number? Before attempting to establish such relationships with the aid of examples, we shall describe certain representative syntheses of these types of compounds.

3. Selected Processes for the Synthesis of Sulfur-Nitrogen Compounds

In general, sulfur-nitrogen compounds are prepared from sulfur-halogen compounds and ammonia. A large variety of products is usually formed in such reactions. Some of the redox reactions involved, such as those in the synthesis of S_4N_4, are still not fully understood[4]. The best yield is obtained in the case of S_4N_4 when the S and the Cl are used in the ratio of 1:3; this can be accomplished by addition of elemental chlorine to SCl_2[5, 11]:

$$4SCl_2 + 2Cl_2 + 16NH_3 \rightarrow S_4N_4 + 12NH_4Cl$$

S_4N_4 (see Fig. 9) is a key compound for the preparation of SN-rings[6]. Reaction of S_2Cl_2 with NH_4Cl or urea affords $S_3N_2Cl^+Cl^-$ in good yield[7, 8].

What happens when the relatively stable N—H bond in the NH_3 molecule ($D^{298} = 390\,kJ\,mol^{-1}$) is replaced by the substantially weaker Sn—N bond in $N[Sn(CH_3)_3]_3$ ($D^{298} = 167\,kJ\,mol^{-1}$ in $(CH_3)_3SnN(CH_3)_2$)? In place of S_4N_4

$$4\ S_2Cl_2 + 4\ N[Sn(CH_3)_3]_3 \longrightarrow$$

$$\left[\begin{array}{c} CH_3 \\ N\text{–}Sn\text{–}CH_3 \\ S \quad | \\ N\text{–}S \end{array}\right]_2 + 2\ (CH_3)_4Sn + 1/2\ S_8 + 8\ (CH_3)_3SnCl$$

(5)

we obtain the tin compound *(5)* with two-coordinate sulfur and nitrogen atoms (see Fig. 1).

Depending on the temperature, S_4N_4 reacts with $N[Sn(CH_3)_3]_3$ to give the sulfur diimide *(6)* and sulfur:

$$S_4N_4 + 2N[Sn(CH_3)_3]_3 \rightarrow 3(CH_3)_3Sn\text{—}N{=}S{=}N\text{—}Sn(CH_3)_3 + {}^1/_8S_8$$

(6)

At higher temperatures the sulfur obtained acts as a nucleophilic reagent; the tin compound *(5)* is again formed[9, 10]:

$$2(6) + {}^1/_4S_8 \rightarrow (5) + 2(CH_3)_4Sn$$

Sulfur diimide *(6)* is an ideal starting material for the preparation of linear and cyclic SN compounds with a low coordination number of the sulfur, since the tin-nitrogen bond can very easily be cleaved by halides.

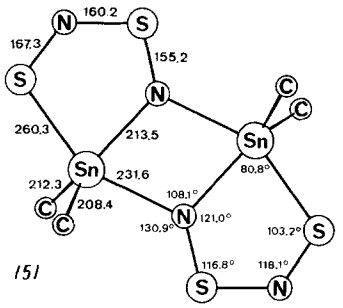

Fig. 1. Structure of dimeric $S_2N_2Sn(CH_3)_2$ *(5)*. Bond lengths in pm [25].

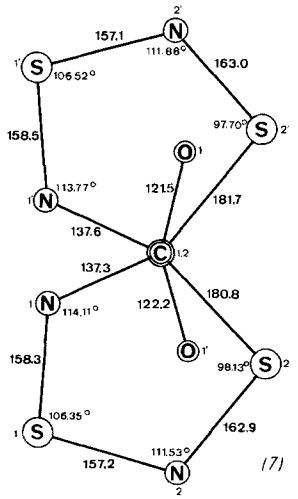
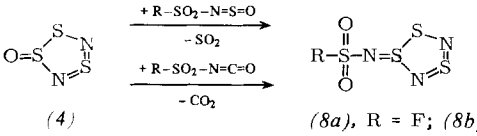
X-ray structure analysis of *(5)* (Fig. 1) reveals that the molecule is dimeric and planar in the solid state. The molecule consists of two five-membered rings and one four-membered ring, with fivefold-coordinated tin; coordination takes place *via* nitrogen and not *via* sulfur. Molecular-weight determinations reveal that the dimer is also present in solution[11].

The tin atom in compound *(5)* can easily be replaced. Thus, COF_2 will react to form cyclic ketone *(7)* (Fig. 2), while with SOF_2 the five-membered sulfur-nitrogen oxide S_3N_2O *(4)* is obtained, in which the sulfur atoms have coordination numbers of two or three.





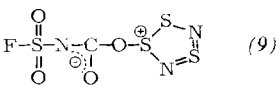


Fig. 2. Structure of S_2N_2CO *(7)* [27]. The molecules are arranged in pairs. Bond lengths in pm.

The ketone *(7)* is a yellow, crystalline solid that sublimes without decomposition in a vacuum; on UV irradiation it liberates CO to form S_4N_4. S_3N_2O *(4)* is a red, oily liquid which does not wet glass and which forms a plastic noncrystalline solid at low temperatures. S_3N_2O can be prepared very easily by hydrolysis of $S_3N_2Cl^+Cl^-$ with anhydrous formic acid[8]. On reaction of S_3N_2O *(4)* with iminosulfur oxides or isocyanates, SO_2 or CO_2 respectively is evolved and substituted sulfur-nitrogen five-membered rings of type *(8)* are obtained provided that the groups R are electron-attracting substituents.

(4) *(8a)*, R = F; *(8b)*, R = CF_3
(8c), R = n-C_4F_9

The above-mentioned reactions lead to the conclusion that the S_3N_2 ring structure is preserved during the reaction. When FSO_2NCO reacts with *(4)* an adduct is first formed, to which the structure *(9)* has been assigned on the basis of its IR spectrum. This suggests that compounds of type *(8)* may

(9)

also be obtained by cleavage of SnN or SiN bonds with $S_3N_2Cl^+Cl^-$[12–14].

Amides react with $S_3N_2Cl^+Cl^-$ with liberation of hydrogen chloride. While $CF_3SO_2NH_2$ gives rise to the five-membered ring *(8b)*, sulfamide ($H_2N—SO_2—NH_2$) gives the eight-membered ring $S_4N_4O_2$ (see Fig. 11)[8]. This reaction first made $S_4N_4O_2$ ready accessible; like S_4N_4 (see Fig. 9), it can react with a variety of reagents to give new ring systems. $S_4N_4O_2$ is a key compound for the preparation of SN rings with variously coordinated sulfur atoms[3].

However, S_4N_4 is still important in the synthesis of SN compounds with low coordination numbers of the ring atoms. Thus, its reaction with tetraalkylammonium azides[15] gives $N_3S_3^-$, while with the Lewis acid SbF_5 it gives the cation $S_4N_4^{2+}$[16]. From S_4N_4 and trifluoromethanesulfonic acid anhydride or AsF_5 we can isolate the radical-cation $N_2S_3^+$ in the form of a salt, so that its crystal structure can be determined (see Fig. 5c)[17, 18]. Since most reactions with SN compounds are of a radical nature, $N_2S_3^+$ is very important as an intermediate.

4. Sulfur-Nitrogen Compounds with Sulfur and Nitrogen of Coordination Number Two

Sulfur and nitrogen have very similar radius-to-charge ratios, assuming that both elements have a coordination number of two. The Mullikan electronegativity[19] of sulfur in its s^2p^4 valence state is 2.28, and that of nitrogen in its s^2p^3 valence state is also 2.28. An SN bond system of this type can be regarded as largely nonpolar. The six valence electrons of sulfur in such an SN unit can formally be classified as follows: two electrons are shared in σ-bonds, two form the lone pair, and two are left over for the formation of π-bonds. In nitrogen, one π-electron is left over. The number of π-electrons in the molecule can be increased systematically by adding further sulfur and nitrogen atoms. If the electron density within an SN rings is not too high, we can always expect to find planar rings with delocalized electrons. The electron density can be diminished by transforming the neutral molecule into the cation. These relationships will be demonstrated for rings of various sizes in the remaining part of this article.

4.1. Four-Membered Rings

The smallest SN ring known at present with coordination number 2 at the sulfur and nitrogen atoms is S_2N_2 (Fig. 3)[20, 21], which has a 6 π-electron structure.

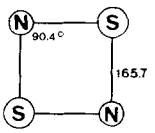

Fig. 3. Molecular structure of S_2N_2. Bond lengths in pm.

As expected, this molecule has SN bonds of approximately the same length and is square-planar. The bonding can be described by a four-center π-electron system. According to a simple Hückel MO treatment, the molecule has one pair of bonding π-electrons, four electrons are in nonbonding π-orbitals, while the π*-orbital is unoccupied (Fig. 4). S_2N_2 is isoelectronic with the planar S_4^{2+} cation[22, 23].

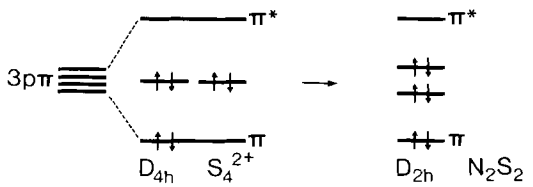

Fig. 4. Distribution of the four 3pπ atomic orbitals in S_2N_2; compare with S_4^{2+}.

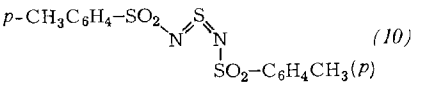

The square-planar D_{4h} symmetry of the S_4^{2+} ion is lowered to the D_{2h} symmetry of S_2N_2. With $SbCl_5$, S_2N_2 forms a 1:2 adduct; this implies an exchange interaction with the nonbonding π-electrons. From this we may conclude that the S—N bonds are not lengthened in the adduct. Molecular structure analysis confirms this assumption[24].

For the so far unknown $S_2N_2^{2+}$, isoelectronic with the P_4 molecule, we can postulate in advance a tetrahedral or planar structure with two localized double bonds.

4.2. Five-Membered Rings

What changes in bonding can be expected on going from four-membered to five-membered SN rings? Here we must consider whether the fifth member of the ring participates in the π-bonding. If we examine the bond lengths and angles in a series of five-membered rings with different atoms or groups X, comparison of the numerical values (Table 2) reveals no immediately obvious relationship. The atoms or groups X have no significant influence upon the S—N bond lengths. The mean bond lengths ($\overline{SN}$) in all three sulfur-nitrogen compounds are approximately constant. Evidently in the S_2N_2

part there is an electron-density distribution reminiscent of "electron billiards", as a consequence of slight differences in energy levels. Even the cations $N_2S_3^+$ (Fig. 5c) and $N_2S_3Cl^+$, in which the electron density is very much lower, give $\overline{SN}$ values that scarcely deviate from those of the neutral molecules. Further numerical values are given in Figure 5a.

(10)

favorable[30]. Both the *cis,trans*[31] and the *trans,trans* configuration[32] are known in complexes. However, besides the N-

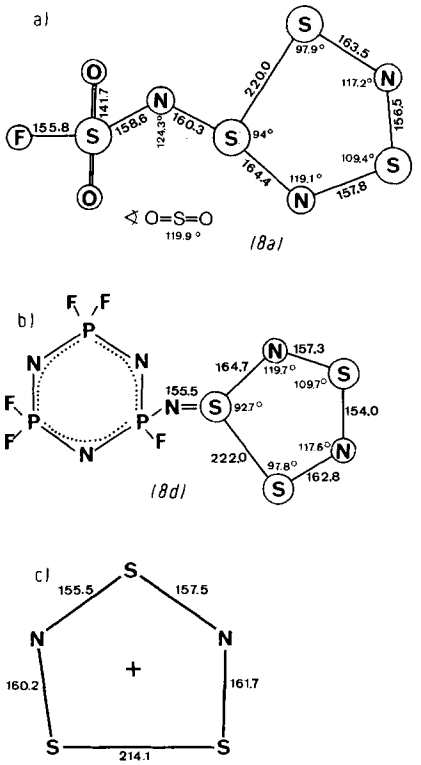

Fig. 5. Molecular structure of a) $S_3N_3SO_2F$ *(8a)*, b) $S_3N_3P_3N_3F_5$ *(8d)* obtained from the PN-ring with $N[Sn(CH_3)_3]_2$ substituents and $S_3N_2Cl^+Cl^-$, c) $S_3N_2^+$ [18, 25]. Bond lengths in pm.

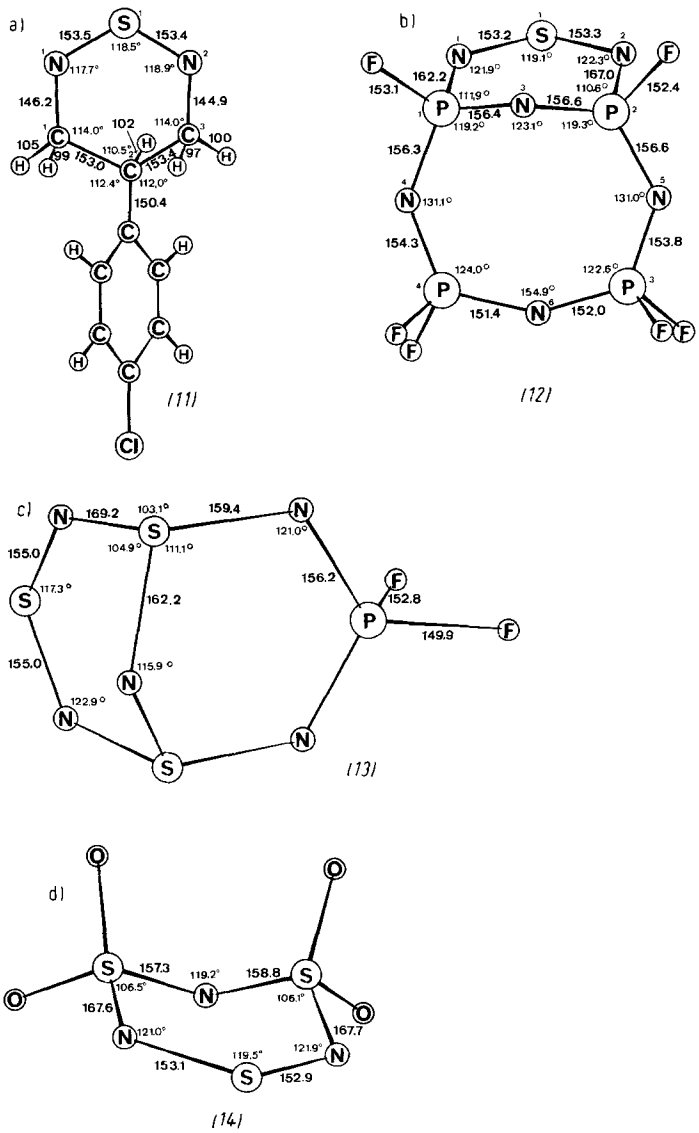
All of the above five-membered rings can be described as 6 π-electron systems[28, 29]; they are almost planar.

4.3. Six-Membered Rings

Of the six-membered rings that contain sulfur and nitrogen with a coordination number of two, the sulfur diimide derivatives are very suitable for comparison purposes since they provide several well-investigated examples.

According to quantum-mechanical calculations, the *cis,trans* form of bis(*p*-tolylsulfonyl)sulfur diimide *(10)* is the most



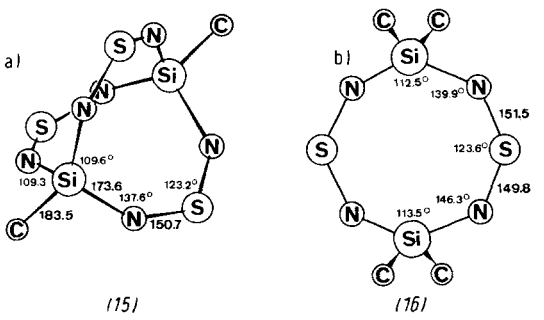


Fig. 6. Molecular structures of a) 4-(4-chlorophenyl)-4,5-dihydro-3*H*-1λ^4,2,6-thiadiazine *(11)* [34], b) $SN_2N_4P_4F_6$ *(12)* [35, 38], c) $S_3N_5PF_2$ *(13)* [37], d) $S_3N_3O_4^-$ *(14)* [36]. Bond lengths in pm.

atoms, the sulfur atom of the sulfur diimide can also act as a coordination site; examples of this are provided by the pentacarbonyl complexes of chromium and tungsten[33]. The *cis,cis* arrangement is attained in sulfur diimides by cyclization[34-42].

We shall consider the compounds *(11)*–*(14)* as representative examples, in which the sulfur diimide group is bound to tetracoordinated carbon[34], tetracoordinated phosphorus[35,38], or tri- or tetracoordinated sulfur[36,37] (Fig. 6). (The last two of these compounds do not, strictly speaking, belong in this section.)

The common feature of all the above-mentioned substituents on the nitrogen atoms of the SN_2 system in *(11)*–*(14)* is that they show no π-exchange interaction with this system. The substituents act as barriers to full conjugation with the 4 π-electron skeleton; only hyperconjugation is conceivable. This accounts for the almost identical S—N bond lengths and angles, which are not influenced even by a negative charge as in $S_3N_3O_4^-$ (Fig. 6d)[36] or by the electron-attracting action of fluorine atoms (Figs. 6b and 6c). Furthermore, it can be deduced that the S—N bond lengths are independent of the substituent so long as no π-interactions take place. The sulfur diimide group, including also the neighboring atoms, is planar. The nitrogen atoms of the SN_2 groups have bond angles of approximately 120° in all the compounds. On the basis of these results it is to be expected that the S—N bond will be shorter when the electron density between S and N is increased by an increase of the angle at the nitrogen or at the sulfur. In fact, we find that in both of the silicon-bridged SN_2 derivatives *(15)* and *(16)*[25,43-45] the S—N bonds are shortened to 150 pm (Fig. 7).

(15) *(16)*

Fig. 7. Molecular structure of a) $(CH_3)_2Si_2N_6S_3$ *(15)*, b) $(CH_3)_4Si_2N_4S_2$ *(16)*. Bond lengths in pm.

Compound *(16)* contains the shortest known bond between sulfur and nitrogen of coordination number two (149.8 pm). The reason for this shortening may be an alteration of the electron density in the σ-skeleton; this effect is known to occur with silicon atoms[46]. As expected, the Si—NSN—Si structure in *(15)* and *(16)* is planar. The bonding in cyclic SN_2 compounds can best be described if, in addition to the sulfur-nitrogen σ-bonds, one assumes a 3-center-4-electron π-bonding. Of the 16 valence electrons, 6 are σ-electrons, 4 are π-electrons, and 6 are nonbonding electron pairs.

4.4. Larger Rings

Gleiter[47] investigated the symmetry properties of a planar eight-membered ring with a D_{4h} configuration. Figure 8 shows the HMO diagram for a planar S_4N_4 ring.

Fig. 8. HMO diagram for planar S_4N_4.

Assuming that each nitrogen and each sulfur atom in S_4N_4 has a lone pair and that the SN units are linked to one another by σ-bonds, 12 π-electrons are left over. These will be distributed in such a way that two are in each of the five lowest orbitals (a_{2u}, e_g, b_{2u}, b_{1u}), while each e_g orbital will have one electron, with parallel spin, according to Hund's rule. There results a triplet ground state for a molecule with D_{4h} configuration. The degeneracy of the two highest occupied orbitals will be eliminated by Jahn-Teller distortion. The desired splitting is obtained on considering interactions between opposite sulfur atoms; this is how the cage-like structure of S_4N_4 comes about (Fig. 9). The D_{2d} structure with two S—S σ-bonds is thus preferred, since calculations show it to yield the lowest total electron energy for the singlet ground state of S_4N_4[48].

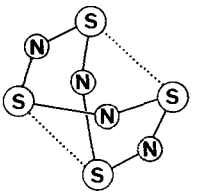

Fig. 9. Molecular structure of S_4N_4.

Taking the MO diagram for planar S_4N_4 as a starting point, and using $S_4N_4 \cdot SbCl_5$ as an example, *Gleiter* has shown that Lewis acids can exert a decisive influence on the structure of S_4N_4. To a first approximation we can assume that the electron-attracting effect of Lewis acids acts only on a single atom. This eliminates the degeneracy of the two highest occupied orbitals. It is not necessary to have exchange interactions between opposite atoms in order to obtain a singlet ground state. The 10 π-electron system $S_4N_4^{2+}$ actually has a planar configuration[16]. However, the resonance stabilization for the planar arrangement cannot be very important, since in other S_4N_4 derivatives, *e.g.* $[S_4N_4][SbCl_6]_2$, a distorted, nonplanar form has been found. These examples show that slight alterations of the ring electron density can have a drastic influence

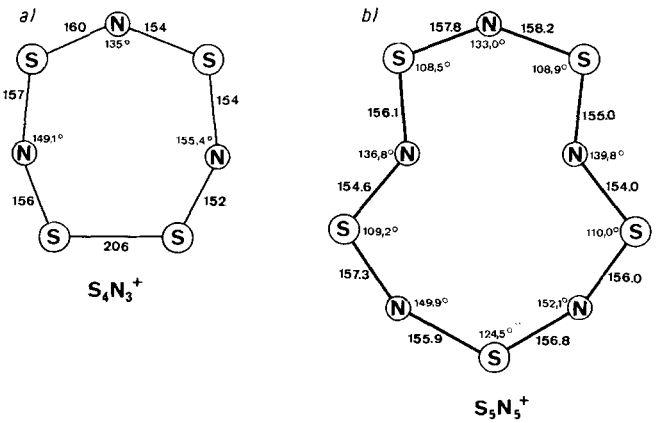

Fig. 10. Molecular structures of a) $S_4N_3^+$ and b) $S_5N_5^+$. Bond lengths in pm.

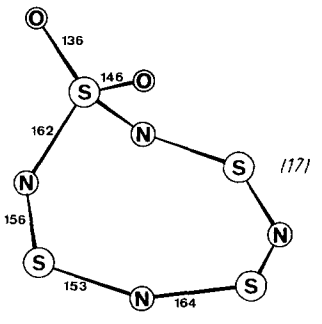


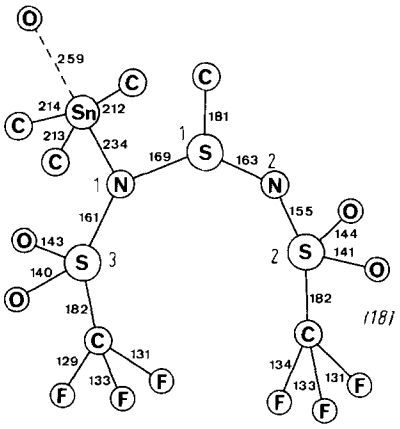
on the structure. The structures of $S_4N_4 \cdot SbCl_5$ or $S_4N_4 \cdot SO_3$ can be considered as transitions between the $S_4N_4^{2+}$ ring and the S_4N_4 cage. The cations $S_4N_3^+$ and $S_5N_5^+$ also have planar structures (Fig. 10).

$S_4N_3^+$ can be described as a 10π-, and $S_5N_5^+$ as a 14π-electron system. In $S_5N_5^+$, apart from the azulene-like structure (Fig. 10b), a heart-shaped structure is known. Comparison of the six possible $S_5N_5^+$ structures on the basis of MO considerations shows that the azulene structure should be preferred[49].

The deviation of the angle at the nitrogen from the angles in the corresponding regular polygon can be regarded as characteristic of the cyclic delocalized π-electron systems under discussion. Thus, the angle at the nitrogen has the following mean values: in $S_3N_2^+$ (Fig. 5c, Table 2) 120° (instead of 108°); in $S_4N_3^+$ (Fig. 10a) 146.5° (instead of 129°), and in $S_5N_5^+$ (Fig. 10b) 142.5° (instead of 144°). The size of the angle at the sulfur will not be further discussed here, since it is known that in carbon-sulfur compounds an increase of the angle at doubly-coordinated sulfur from 65.8 to 113° produces no change in the bond length[50, 51]. The essential information concerning this class of compounds can be summarized as follows: sulfur-nitrogen rings in which both elements have a coordination number of two can be classified as cyclic, delocalized, π-electron systems; as a rule they are planar when they comprise six, ten, or fourteen π-electrons and so obey the Hückel rule. The number of ring members and the size of the angles have little effect upon the S—N distances. The most favorable energy state is attained by an optimal electron distribution. Planar structures can also be found in compounds that do not obey the Hückel rule, *e.g.* in the 8π-electron system $S_4N_4O_2Sn_2(CH_3)_6$.

5. Sulfur-Nitrogen Compounds with Higher Coordination Numbers of the Sulfur

We have already discovered for $S_3N_3O_4^-$ *(14)* (Fig. 6d) that higher coordination numbers of the sulfur impede electron delocalization. This is also evident in $S_4N_4O_2$ *(17)* (Fig. 11).

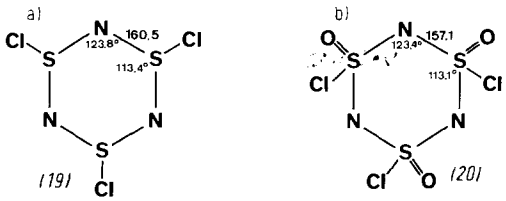


(17)

Fig. 11. Molecular structure of $S_4N_4O_2$ *(17)*. Bond lengths in pm.

Whereas the S_3N_2 moiety is planar, the NSO_2N group assumes a tetrahedral configuration. The tetracoordinated sulfur and the neighboring nitrogens are pulled out of the plane of the ring. This sulfur atom no longer contributes to electron delocalization.

There is an obvious correlation in compound *(18)*—a noncyclic derivative—between the bond lengths and the coordination numbers of the atoms involved (Fig. 12)[52]. At the shortest S—N distance, (S2—N2: 155 pm), the sulfur has a coordination number of four and the nitrogen a coordination number of two. This is not surprising, since the increase in the coordination number will give rise to a contraction of the orbital; this leads to better overlapping which, in turn, strengthens the bond. Concomitantly, the increase in the coordination number (CN) at N1 leads to a lengthening of the S3—N1



(18)

Fig. 12. Molecular structure of $(CF_3SO_2N)_2Sn(CH_3)_3SCH_3$ *(18)*. Bond lengths in pm.

distance, to 161 pm. By analogy, the S1—N2 distance is found to be shorter than the S1—N1, so that the following sequence of increasing bond lengths is obtained:

$$S(CN=4)—N(CN=2) < S(CN=4)—N(CN=3) \approx$$
$$S(CN=3)—N(CN=2) < S(CN=3)—N(CN=3)$$

For a comparison of the S—N bond lengths as functions of the coordination numbers, we turned our attention to the cyclic compounds $N_3S_3Cl_3$ *(19)* and $N_3S_3O_3Cl_3$ *(20)* (Fig. 13).

(19) *(20)*

Fig. 13. Molecular structure of a) $N_3S_3Cl_3$ *(19)* and b) $N_3S_3O_3Cl_3$ *(20)*. Bond lengths in pm.

In accordance with the above considerations, the S—N bond in *(20)* [S(CN=4)—N(CN=2)], 157.1 pm, is shorter than that in *(19)* [S(CN=3)—N(CN=2)], 160.5 pm, as expected.

The alternance of S—N bond lengths (154 and 166 pm) in $N_4S_4F_4$ fits this scheme perfectly, since the mean value is as large as the S—N distances in $N_3S_3F_3$[1, 5, 53]. The rule is also obeyed by the molecules NSF and NSF_3. The S—N distance in NSF (144.6 pm) is—as expected—longer than that in NSF_3 (141.6 pm). The rule no longer applies when a nitrogen atom is substituted by a system capable of conjugation, since in this case the electron density distribution, and with it the separation, are modified.

These conclusions make it clear that one can speak of neither "single" nor "double" bonds, and that there is little

point in comparing bond lengths in sulfur-nitrogen compounds unless the coordination number is taken into account[54]. These phenomena should also apply to combinations of other elements.

My thanks go first to my associates who took part in the preparation of this review, and also to my colleagues Prof. B. Krebs, Dr. A. Gieren, and Prof. A. Simon, who allowed me to use their unpublished results. I am indebted to the Fonds der Chemischen Industrie, Hoechst AG, and the Deutsche Forschungsgemeinschaft for generous support, which made these studies possible in the first place.

Empirical Parameters of Solvent Polarity as Linear Free-Energy Relationships

By Christian Reichardt[*]

Although the effect of solvent on the rate and the position of equilibrium of chemical reactions has been known since the last century, there are still no reliable and exact methods for a quantitative description and prediction of such solvent effects. Empirical parameters of solvent polarity are of great value in this respect and can be derived with the aid of the principle of "linear relationships between free energies" (LFE relationships). The present article deals with the possibilities of establishing reaction and absorption series using solvent-dependent standard reactions or standard absorptions of organic compounds. Particular attention is merited by the summary of the 24 most important empirical parameters of solvent polarity and the table of $E_T(30)$ values for 151 solvents. In addition to examples of the application of these values, attempts to improve the LFE correlations of singular empirical parameters of solvent polarity with the aid of multiparametric equations are described.

1. Introduction

When a chemist wishes to carry out a specific liquid-phase chemical reaction in the laboratory, he not only has to prepare the intended reagents and select a suitable reaction vessel and appropriate temperature but must also decide on a reaction medium, the correct choice being of major importance to the success of the planned reaction. The effect of solvents on chemical reactivity has been known for over a hundred years[**]; every chemist is therefore well aware that solvents can exert a considerable influence on reaction rates and on the position of chemical equilibria. Since at present there are some three hundred solvents in common use[3] (quite apart from the infinite number of possible solvent mixtures), a chemist requires not just experience and intuition but also qualitative rules (*e.g.* "like dissolves like") and quantitative data (*e.g.* boiling point, dielectric constant, refractive index) to enable him to make this generally difficult choice.

One of the most important selection criteria in this connection is a property of solvents generally known as "solvent polarity". Although the expression "polarity of a solvent" is often used, it is in fact not easy to define this property precisely, and it is still more difficult to assess it quantitatively. The simplicity of electrostatic solvation models has resulted in the effect of the dielectric constant (ε) and the permanent dipole moment (μ) being given prominence over other factors and ascribed a special role as parameters of solvent polarity. In fact, however, the dielectric constant describes only the change in the electric field intensity that occurs between the plates of a condenser when the latter is removed from vacuum and placed in a solvent. This induces a dipole moment in apolar solvent molecules (displacement polarization) and the now dipolar molecules are aligned (orientation polarization). The dielectric constant therefore describes the ability of a solvent to separate electrical charges and orient its dipolar molecules. However, the total sum of the interactions between the solute and solvent molecules is much more extensive and complicated: in addition to the nonspecific coulombic, directional, inductive, and dispersion interactions, there are also specific hydrogen bond, electron pair donor (EPD)/electron pair acceptor (EPA), and solvophobic interactions. Hence from a practical point of view it would seem expedient to take "solvent polarity" to mean the over-all solvation ability of a solvent, this in turn being determined by the sum of all the molecular properties responsible for the interactions between the solvent and the solute. It stands to reason that solvent polarity as thus defined cannot generally be described quantitatively by a single physical parameter (ε, μ, *etc.*). This fact and the difficulty of calculating rates and equilibrium positions of chemical reactions in solution with such physical data have led to the parameters of solvent polarity being determined by purely empirical means. The procedure is to start with well known, easily measured, and strongly solvent-dependent processes, which are investigated as reference processes in the greatest possible number of solvents: the rate or the position of equilibrium of a carefully selected model reaction or the spectral absorption of a suitable standard dye. From the rate or equilibrium constants or the absorption maxima thus obtained it is then possible to derive empirical parameters of solvent polarity which generally provide a more comprehensive measure of the over-all solvation ability of the solvent than individual physical data (cf. [1, 2, 4–10] for reviews). The model processes selected can be compared with probes to determine the effect of the solvent in the molecular-microscopic region.

This approach is characteristic of the experimental chemist, but it is regarded with mistrust rather than goodwill by theoreticians. However, organic chemistry has since its very beginning made use of the qualitative, empirical rule that similar compounds react in similar ways and that similar changes in the structure and the reaction medium produce similar changes in the reactivity of the compounds. As the application of this rule and the selection of suitable model reactions naturally leaves room for subjective decisions, the rather derisory remark that organic chemistry is not a science but an art would appear to be not wholly unfounded[11].

The principle of "linear free-energy relationships" (LFE relationships) occupies a position of central importance in the mathematical description and theoretical interpretation of empirical observations[12-14]. In what follows it will first be demonstrated that the empirical parameters of solvent polarity can be understood as the result of such LFE relationships. A table summarizing the most important solvent parameters known at present and their application and expansion in the form of multiparametric equations complete the review. A more detailed description will be found in an earlier monograph[2].

2. Linear Free-Energy Relationships

Consideration of a series of reactions (*i.e.* a group of reactions in each of which one of the reaction partners has its molecular structure changed slightly in one detail or in which the reaction medium is changed while the functional group—the reaction center—remains unchanged), often reveals that the rate or equilibrium constants k_i of a reaction series A correlate with the corresponding constants of a related reaction series B in which the structure of the reaction partners or the medium was changed in the same way as in series A. This correlation is generally, although not necessarily, linear and can be described by Eq. (1),

$$\lg k_i^B = m \cdot \lg k_i^A + c \tag{1}$$

in which the subscript i stands for the same structural or solvent-determined variation in the two reaction series. However, the prerequisite is that all the other experimental conditions such as the second reaction partner, pressure, temperature, reaction mechanism, *etc.* are kept constant while one parameter is systematically varied.

As the logarithm of the equilibrium constant K of a chemical reaction is proportional to the change in the free energy of reaction ΔG^0 in accordance with Eq. (2),

$$\lg K = -\frac{\Delta G^0}{2.3 \times R \times T} \tag{2}$$

and the logarithm of the rate constant k, according to *Eyring*'s theory of absolute reaction rates, is proportional to the free energy of activation ΔG^* (Eq. (3)),

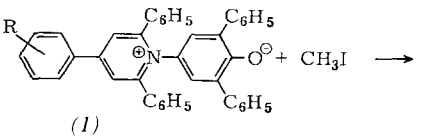
$$\lg\left(\frac{k}{R \cdot T/N \cdot h}\right) = -\frac{\Delta G^*}{2.3 \times R \times T} \tag{3}$$

Eq. (1) in fact describes a linear relationship between free energies. If one relates the rate constants or the equilibrium constants within a series of reactions to a standard reaction (with standard substituent or standard solvent; subscript o), Eq. (1) becomes Eq. (4):

$$\lg(k_i^B/k_o^B) = m \cdot \lg(k_i^A/k_o^A) \tag{4}$$

LFE relationships of this type are useful in two respects. On the one hand the LFE correlation of experimental data from a new reaction series with those of a known series documents a mechanistic similarity between the two series, which can be useful in explaining reaction mechanisms[15]. On the other hand, LFE relationships can be used to predict the rate and equilibrium constants that will be produced by changes in the reactant structure or in the reaction medium.

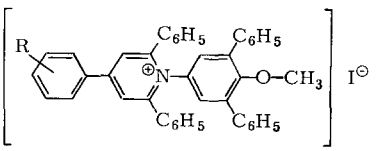
If one looks at a reaction between a substrate S and a reagent R[*] in a medium M, which leads *via* an activated complex to the product P,



$$(S)_M + (R)_M \rightleftarrows [S \ldots R]^{\ddagger}_M \rightarrow (P)_M \tag{5}$$

then a reaction series can be established in three ways by making small changes:

a) *Variation of the substrate S by the introduction of substituents.* In the case of substituted benzene derivatives this results in the well-known Hammett equation (6)[16],



$$\lg k_X - \lg k_o = \sigma \cdot \rho \tag{6}$$

in which k_X is the rate or equilibrium constant of *meta*- or *para*-substituted aromatic substrates, σ is the substituent constant, and ρ is the reaction constant[**]. Eq. (6) describes

(1)

(1a), R = H

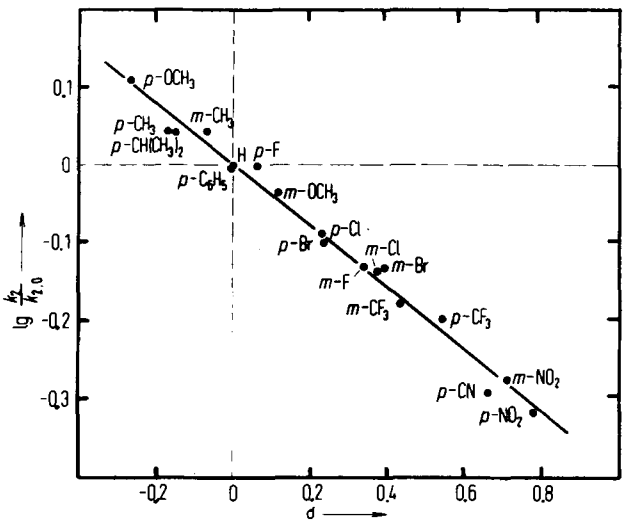


Fig. 1. Hammett correlation of the substituent constants σ with the logarithms of the relative rate constants $\lg(k_2/k_{2,o})$ of the S_N2 alkylation of substituted pyridiniophenolates of type *(1)* with methyl iodide in chloroform at 25°C [17]: $\lg(k_2/k_{2,o}) = -0.40 \cdot \sigma$ (number of value pairs $n = 18$; correlation coefficient $r = -0.993$).

[*] The designation of one reactant as the *substrate* and of the other as the *reagent* is not entirely arbitrary. In general the substrate is structurally varied in a reaction series while the reagent remains unchanged. A catalyst is always regarded as a reagent.

[**] $\rho = 1$ applies for the standard equilibrium reaction

$$C_6H_5{-}CO_2H + H_2O \rightleftarrows C_6H_5{-}CO_2^{\ominus} + H_3O^{\oplus}$$

in water at 25°C.

the effect of *meta*- and *para*-substituents on the rates and the equilibria of reactions in the side chain of benzene derivatives. A typical Hammett correlation is shown in Figure 1[17].

As was to be expected, and as documented by the negative sign of ρ, electron-attracting substituents reduce the rate of the S_N2-alkylation of pyridiniophenolates of type *(1)* while electron-releasing substituents increase this rate.

b) *Variation of the reagent R.* An example of this is the catalysis relationship of *Brønsted* and *Pedersen*, according to which the effectiveness of a catalyst in a generally acid- or base-catalyzed reaction is proportional to its acid or base strength[18]. This quantitative relationship, formulated already in 1924, was the first example of an LFE relationship[11-14].

c) *Variation of the medium M.* Finally, variation of the reaction medium while all the other reaction conditions are kept constant yields the desired empirical parameters of solvent polarity, provided that the standard reaction selected, whose rate or position of equilibrium is determined in various solvents, is sufficiently solvent-dependent. If one regards the solvent molecules of the solvation shell surrounding the substrate and the reagent as loosely bound substituents, then the analogy between the modification of the chemical reactivity of the substrate produced by the introduction of substituents and the modification produced by changing the reaction medium is particularly striking. While substituents can change the chemical reactivity of a substrate only discontinuously, a variation of the medium (particularly when solvent mixtures are used) makes it possible to produce a virtually continuous effect on substrate reactivity[19].

If one develops the concepts of "chemical reaction" and "reagent" further, then it is also possible to formulate the "reaction" of a photon $h \cdot \nu$ with a substrate S, dissolved in medium M, in a similar way to Eq. (5):

$$\underset{\text{ground state}}{(S)_M} + h \cdot \nu \rightleftharpoons \underset{\text{excited state}}{(S)_M^*} \qquad (7)$$

LFE relationships can therefore be derived not only in the form of relationships between rate or equilibrium constants but also with the aid of spectroscopic studies of members of a reaction series in different spectral regions (UV/VIS[20], IR[20], NMR[21a], *etc.*). On the basis of Eq. (7) a reaction series (or better an absorption series) can be established in two ways:

a) *Variation of the substrate S by the introduction of substituents.* This procedure results in a spectroscopic Hammett equation which is most expediently formulated for the spectral excitation of substituted dyes in the UV/VIS region according to a suggestion by *Kosower*, *Wallenfels*, and *Hoffmann* as follows[21b]:

$$\frac{E_{T,R} - E_{T,0}}{2.3 \times R \times T} = \sigma \times \rho_A \qquad (8)$$

$E_{T,R}$ and $E_{T,0}$ are the transition energies (kcal/mol or kJ/mol) of the compound substituted by R or the reference compound (generally R = H), R is the gas constant, T is the absolute temperature, σ is the usual Hammett substituent constant, and ρ_A is the absorption constant[22,23]. The difference between the transition energies is divided by $2.3RT$ to bring it into the same order of magnitude as the Hammett substituent constants, which were obtained primarily from equilibrium or rate constants. In addition, ρ_A is then a dimensionless number, just like the reaction constant ρ [Eq. (6)]. The absorption constant ρ_A is a measure of the susceptibility with which the position of the absorption band of a dye reacts to a change in the substituent R. A typical example of such a UV/VIS spectroscopic Hammett correlation is shown in Figure 2[23] (for further examples cf. [20, 22, 24, 25]).

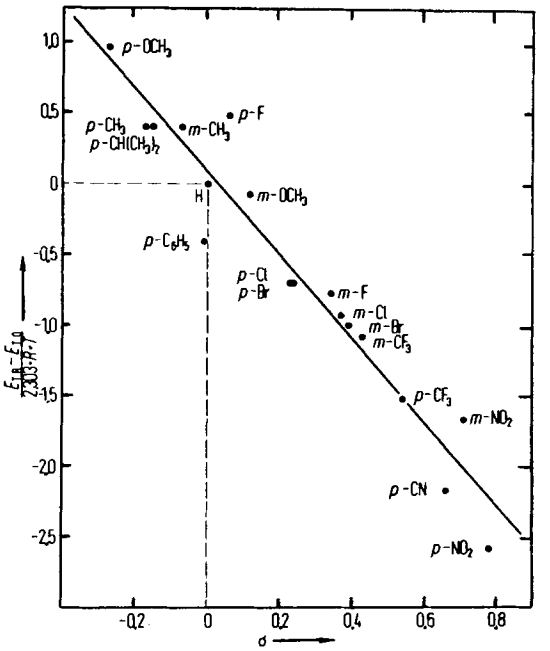

Fig. 2. Hammett correlation of the substituent constants σ with the modified transition energies $(E_{T,R} - E_{T,0})/2.3 \cdot R \cdot T$ of the longest-wavelength π-π^*-absorption band of substituted pyridiniophenolates of type *(1)* in methanol at 25 °C [23]: $(E_{T,R} - E_{T,0})/2.3 \cdot R \cdot T = -2.97 \cdot \sigma + 0.08$ ($n = 18$; $r = -0.962$).

In accordance with the negative sign of the absorption constant ρ_A in the case of pyridiniophenolates of type *(1)*, electron-attracting substituents produce a bathochromic shift in the longest-wavelength π-π^* band (which can be regarded as an intramolecular charge transfer band[*]), while electron-releasing substituents give rise to a hypsochromic shift. A value of $\rho_A < 0$ should always be maintained if a lower π-electron density is present in the electron ground state at the absorption center[**] than in the first excited state[23].

If the substrate is kept constant in Eq. (7), a series of reactions can also be produced by introducing substituents into the solvent M, for example by varying R in the homologous series of aliphatic alcohols R—OH which interact with the substrate (*e.g.* by hydrogen bonding). An example of this can be found in [23].

b) *Variation of the medium M.* If the absorption band of a standard substrate S is sufficiently solvatochromic (*i.e.* if its position depends on the solvent), a systematic variation of the solvent makes it possible to introduce empirical param-

[*] The excitation of π-electrons corresponding to the longest-wavelength absorption band of pyridiniophenolates of type *(1)* is accompanied by a reduction of the permanent dipole moment of approximately 30×10^{-30} C m (*ca.* 9 D), which corresponds to an intramolecular charge transfer from the phenolate to the pyridinium group [26].

[**] By "absorption center" is meant that atom of the molecular skeleton with which the perturbation in the π-electron system of the dye caused by the substituent R is associated.

eters of solvent polarity spectroscopically. The UV/VIS absorption spectrum of a negatively solvatochromic standard dye of this type is shown in Figure 3[27-29]. The longest-wavelength absorption maximum of pyridiniophenolate *(1a)* is shifted hypsochromically by 357 nm when the solvent is changed from diphenyl ether to water, this corresponding to a change in the electron transition energy by 28 kcal/mol (117 kJ/mol). The transition energies E_T calculated according to Eq. (9) can be used either directly as empirical parameters of solvent polarity

$$E_T\,[\text{kcal/mol}] = hc\tilde{\nu}N = 2.859 \times 10^{-3} \times \tilde{\nu}\,[\text{cm}^{-1}] \qquad (9)^{[*]}$$

or in the form of a relative measure of solvent polarity *RPM* (relative polarity measure) defined by Eq. (10), as suggested by *Dähne et al.*[30]

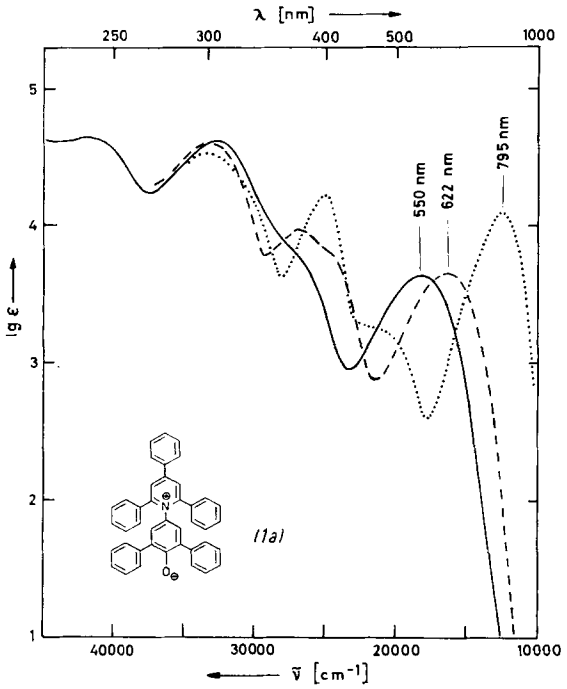

Fig. 3. UV/VIS absorption spectrum of 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridinio) phenolate *(1a)* in ethanol (——), acetonitrile (- - - - -), and 1,4-dioxane (.....) at 25°C [27, 28].

$$RPM = \frac{E_T(n\text{-hexane}) - E_T}{E_T(n\text{-hexane})} \qquad (10)$$

One of the advantages of using the dimensionless *RPM* values of Eq. (10) is that spectroscopic polarity parameters obtained with various solvatochromic standard substrates can more readily be compared with one another. Regardless of the nature of the indication of the solvent polarity, the *RPM* value of *n*-hexane (as the least polar solvent) is always equal to zero. Positively solvatochromic standard dyes yield positive *RPM* values and negatively solvatochromic dyes negative *RPM* values; however, for correlation analyses it is sufficient to use absolute |*RPM*| values. The choice of an *n*-hexane solution instead of the gas phase as the reference state within a reaction series is made for experimental reasons: because of the low volatility of solvatochromic dyes, their absorption spectra cannot usually be recorded in the gas phase. The relative polarity function *RPM* is not only applicable to solvent-determined band shifts in the UV/VIS absorption region; it can also be used for other wavelength regions (IR, NMR, ESR).

When substituent or solvent effects as described above are interpreted with the aid of model processes that yield the same or similar effects, the thermodynamic parameters that are compared are generally free energies. However, the empirical and generally linear LFE relationships obtained are not derived from the laws of formal thermodynamics and are therefore also referred to as "extrathermodynamic relationships"[19]. These relationships are obtained by combining molecular-microscopic detailed model reactions with the formal parameters of thermodynamics and hence are also not as rigorous as macroscopic thermodynamic laws. Since LFE-relationships are not restricted to correlations between thermodynamic parameters, but can also encompass other physicochemical properties (*e.g.* optical excitation energies), their use is often also referred to more generally as "correlation analysis"[13, 14].

3. Empirical Parameters of Solvent Polarity

Table 1 gives a selection of empirical parameters of solvent polarity that have been obtained by determining solvent-dependent equilibrium constants, rate constants, or absorption maxima (in the UV/VIS, IR, NMR, or ESR region) within a series of reactions in which only the solvent was systematically varied. A more comprehensive description of *all* the empirical solvent parameters known at present is given in a monograph[2].

Negatively and positively solvatochromic dyes are particularly suitable as standard substances for the determination of empirical solvent parameters[*], and of these, by virtue of the exceptionally large extent of its solvatochromism, the negatively solvatochromic pyridiniophenolate *(1a)* (cf. Fig. 3) is especially suitable[27-29]. Its $E_T(30)$ values have so far been determined for 151 pure solvents[27, 58] and for many binary solvent mixtures[28, 63-66][**]. Table 2 summarizes all the $E_T(30)$ values known at present, including the dimensionless relative polarity measure calculated from them according to Eq. (10).

The position of the longest-wavelength absorption maximum of this pyridiniophenolate *(1)* depends not only on the solvent (solvatochromism) but also on temperature (ther-

[*] The units [kcal/mol] were selected for E_T so that the latter could be compared directly with free reaction energies and free activation energies. As E_T values have already found wide application in the literature, we decided not to convert them into kJ/mol in this review in order to avoid confusion. In the SI system the following applies instead of Eq. (9):

$E_T\,[\text{kJ/mol}] = 1.196 \times 10^{-2} \times \tilde{\nu}\,[\text{cm}^{-1}]$.

[*] With increasing solvent polarity the solvent-dependent absorption band is shifted bathochromically in the case of positively solvatochromic dyes and *vice versa*. For the theoretical interpretation of the solvatochromism of organic compounds that in most cases belong to the group of merocyanine dyes see also [59—62].

[**] Further $E_T(30)$ values of organic solvents were recently determined by *J. Hormadaly* and *Y. Marcus*, J. Phys. Chem., in press. The author is indebted to Prof. *Marcus*, Hebrew University, Jerusalem, for sending in still unpublished results.

Table 1. Empirical parameters of solvent polarity.

Symbol (name)	Physical quantity measured	Solvent-dependent standard process	n [a]	Ref.
From equilibrium measurements				
L (desmotropic constant)	equilibrium constant	keto-enol tautomerism equilibrium of ethyl acetoacetate at *ca.* 20 °C	13	[31]
$-\Delta G^0_{OCH_3}$	free energy of the reaction in standard state	conformation equilibrium between *cis*- and *trans*-2-isopropyl-5-methoxy-1,3-dioxane at 25 °C	17	[32]
$-\Delta G^0$	free energy of the reaction in standard state	NH/OH tautomerism equilibrium of Schiff bases of pyridoxal-5'-phosphate at 25 °C	8	[33]
DN (donor number)	reaction enthalpy $-\Delta H_{EPD\cdot SbCl_5}$	1:1 adduct formation between antimony(V) chloride as standard EPA and EPD solvents in 1,2-dichloroethane at 25 °C	40	[10, 34]
From measurements of reaction rates				
Y	relative rate constant k_1	S_N1 solvolysis of *tert*-butyl chloride at 25 °C	11	[35, 36]
$\lg k_1$, $\lg k_{ion}$ W [b]	rate constant k_1	solvolysis of 2-(4-methoxyphenyl)-2-methylpropyl tosylate at 75 °C	15	[37, 36]
X	relative rate constant k_2	S_E2 reaction of tetramethyltin with bromine at 20 °C	7	[38]
$\mathscr{S}$ ($\lg k_2$)	rate constant k_2	S_N2 Menshutkin reaction between tri-*n*-propylamine and methyl iodide at 20 °C	78	[39, 40]
Ω	*endo*-/*exo*-product ratio	Diels-Alder $[\pi 4_s + \pi 2_s]$ cycloaddition of cyclopentadiene to methyl acrylate at 30 °C	14	[41, 42]
From spectroscopic measurements				
Z	molar transition energy	charge-transfer absorption of 1-ethyl-4-methoxycarbonyl-pyridinium iodide at 25 °C	46	[43]
E_T, $E_T(30)$ [c]	molar transition energy	π-π*-absorption of pyridiniophenolate (*1a*) at 25 °C (cf. Fig. 3)	151	[27—29]
χ_R	molar transition energy	π-π*-absorption of a positively solvatochromic undecamethinemerocyanine dye at 25 °C	58	[44]
χ_B	molar transition energy	π-π*-absorption of a negatively solvatochromic nonamethinemerocyanine dye at 25 °C	12	[44]
E_T, PM [d]	molar transition energy	π-π*-absorption of 5-dimethylamino-2,4-pentadienal		[30]
$\Phi(F)$	wave number difference	n-π*-absorption of saturated aliphatic ketones	23	[45]
E_K	molar transition energy	d-π*-absorption of tetracarbonyl [*N*-(2-pyridylmethylene) benzylamino]molybdenum(0)	40	[46]
E_T^{SO}	molar transition energy	n-π*-absorption of *N*,*N*-dimethylthiobenzamide *S*-oxide	35	[47]
π^*	absorption wave number	π-π*-absorption of several compounds, particularly nitro-substituted arenes (*e.g.* 4-nitroanisole (1-methoxy-4-nitrobenzene))	70	[48]
S	equilibrium constant, rate constant, molar transition energy	mixed parameter, calculated from various solvent-dependent processes	47	[49]
G	relative wave number difference	IR stretching vibration absorption of X=O and X—H···B groups (X=C, S, N, O, or P, B=solvent) in the gas phase and in solution	20	[50]
B	wave number difference	IR stretching vibration absorption of O—D and O—H groups in CH_3OD or C_6H_5OH in the gas phase and in solution	55 [51] 198 [52]	[8] [51, 52]
$\mathscr{A}_N$	splitting constant a^{14N}	^{14}N-HFS splitting in the ESR spectra of three dialkylaminyl oxide radicals	31	[53, 54]
P	relative ^{19}F-NMR chemical shift	^{19}F-NMR absorption of 1-fluoro-4-nitrosobenzene	52	[55, 56]
AN (acceptor number)	relative ^{31}P-NMR chemical shift	^{31}P-NMR absorption of triethylphosphane oxide	34	[10, 57]

[a] Number of pure solvents for which the empirical parameter was obtained. [b] "W" stands for "Winstein's parameter", following the proposal by *P. D. Bartlett*, J. Am. Chem. Soc. *94*, 2161 (1972). [c] Since the standard dye (*1a*) was numbered 30 in [27], its molar transition energies were designated by $E_T(30)$. [d] Cf. Eq. (10).

[a] Standard dye: 2,6-diphenyl-4-(2,4,6-triphenyl-1-pyridinio) phenolate (*1a*). Since its formula was numbered 30 in [27], its molar transition energies were designated as $E_T(30)$ values. [b] Conversion to SI units gives 1 kcal/mol = 4.184 kJ/mol. [c] *RPM* (relative polarity measure) = $[E_T(n\text{-hexane}) - E_T]/E_T(n\text{-hexane})$; cf. Eq. (10). [d] Calculated on the basis of the linear correlation between $E_T(30)$ and Z from Kosower's Z values, using $Z = 1.41 \cdot E_T(30) + 6.92$ [58]. [e] *E. M. Kosower, H. Dodiuk*, J. Am. Chem. Soc. *98*, 924 (1976). [f] *E. M. Kosower, H. Dodiuk, K. Tanizawa, M. Ottolenghi, N. Orbach*, J. Am. Chem. Soc. *97*, 2167 (1975). [g] Value at 30 °C. [h] This $E_T(30)$ value was determined by *G. Collier* (personal communication from *J. Shorter* of June 21, 1978). The author wishes to thank *G. Collier* and *J. Shorter*, University of Hull (England), for communication of their unpublished results. Cf. also *A. G. Burden, N. B. Chapman, H. F. Duggua, J. Shorter*, J. Chem. Soc. Perkin Trans. II *1978*, 296. [i] From the corresponding Z-value calculated by *T. G. Beaumont, K. M. C. Davis*, J. Chem. Soc. *B1968*, 1010. [k] *W. Jeblick, K. Schank*, Justus Liebigs Ann. Chem. *1977*, 1096.

uents and by the solvent (Fig. 1)[17]. Hence it was possible, with *one and the same* standard substrate, to establish no less than three LFE relationships (cf. Figs. 1—3). The extreme sensitivity with which pyridiniophenolates of type *(1)* react to slight changes in the surrounding medium can be compared to the behavior of *Hans Christian Andersen*'s "princess and the pea"[69].

Although the empirical parameters of solvent polarity shown in Table 1 were obtained with very different standard processes, there are satisfactory linear relationships between most of them, particularly when solvents with highly specific interaction capabilities (*e.g.* protic solvents) are correlated separately[2, 4, 29, 70]. Nevertheless, the use of individual solvent parameters to predict solvent effects should be limited in the first approximation to largely analogous processes (reactions, absorptions), since only then is the proportion of intermolecular forces in the interaction between the solvent and the substrate roughly the same as in the interaction between the solvent and the standard substrate. Even when the Hammett equation (6) is used different σ-scales are often selected depending on whether, for example, one is concerned with the effect of the substituent on reactions of substituted aromatic substrates (σ, σ^+, σ^-, σ^0) or aliphatic compounds (σ^*, Taft equation)[13, 14].

Hence the empirical Koppel-Pal'm solvent parameter B shown in Table 1 and defined according to Eq. (11) should be primarily a measure of the Lewis basicity of the solvent against CH_3OD as the standard substrate[8, 51, 52].

$$B = \Delta\tilde{\nu}_{OD} = \tilde{\nu}^0_{CH_3OD} - \tilde{\nu}_{CH_3OD\cdot B} \qquad (11)$$

$\tilde{\nu}^0_{CH_3OD}$ and $\tilde{\nu}_{CH_3OD\cdot B}$ are the wave numbers of the O—D stretching vibration band in the IR spectrum of monomeric CH_3OD, measured in the gas phase ($\tilde{\nu}^0_{CH_3OD} = 2720\,cm^{-1}$[51]) and in a solvent B. EPD solvents reduce $\tilde{\nu}_{CH_3OD\cdot B}$; the wave number difference $\Delta\tilde{\nu}_{OD}$ is proportional to the strength of the HBD/EPD interaction[*].

[*] EPD = electron pair donor; EPA = electron pair acceptor; HBD = H-bond donor; HBA = H-bond acceptor. HBA solvents are also EPD solvents, HBD solvents correspond to protic solvents.

Of particular importance to the determination of the Lewis basicity or nucleophilicity of a solvent are the donor numbers *DN* introduced by *Gutmann et al.*[10, 34], defined according to Eq. (12) as the negative enthalpies of the reaction of EPD solvents with antimony(v) chloride as the standard acceptor in a highly diluted 1,2-dichloroethane solution.

$$\text{EPD} + SbCl_5 \xrightleftharpoons[\text{in } Cl{-}CH_2CH_2{-}Cl]{25\,^\circ C} \text{EPD} \rightarrow SbCl_5$$

$$DN \equiv -\Delta H_{\text{EPD}\cdot SbCl_5}\,[\text{kcal/mol}] \qquad (12)$$

The donor number is a molecular property that reflects the entire interaction of an EPD solvent with the electron pair acceptor and is of particular significance in predicting coordination-chemical reactions in solution[10, 71].

In protic solvents the $E_T(30)$ values of Table 2 should reflect above all their HBD properties and hence the electrophilicity or Lewis acidity of these solvents. In the electron ground state the pyridiniophenolate *(1a)* with the phenolate oxygen has a strongly basic, anionic HBA center, while the positive charge is delocalized over the pyridine ring and screened by the phenyl groups. Since the electron excited state is much less dipolar owing to intramolecular charge transfer absorption[26], the molecule will only exhibit extra stabilization by protic solvents compared with aprotic solvents in the electron ground state. Hence the $E_T(30)$ values of protic solvents are generally greater than those of comparable dipolar aprotic solvents (cf. Table 2).

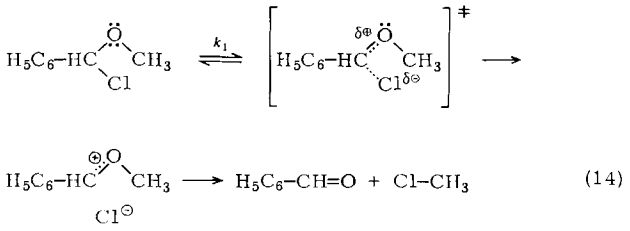
Similarly, the electrophilic properties of solvents can be characterized by the acceptor number *AN* (cf. Table 1), which is defined according to Eq. (13) as the relative ^{31}P chemical shift of triethylphosphane oxide[10, 57].

$$(Et_3P{=}O \leftrightarrow Et_3P^{\oplus}{-}O^{\ominus}) + \text{EPA} \rightleftharpoons Et_3P^{\delta\oplus}\cdots O^{\delta\ominus} \rightarrow \text{EPA}$$

$$AN \equiv \frac{\delta_{corr}}{\delta_{corr}(Et_3PO{-}SbCl_5)} \cdot 100 = \delta_{corr} \cdot 2.348 \qquad (13)$$

δ_{corr} is the solvent-dependent ^{31}P chemical shift of triethylphosphane oxide extrapolated to infinite dilution, referred to *n*-hexane, and corrected for the difference between the volume susceptibilities of *n*-hexane and the solvent in question. The ^{31}P chemical shift of the 1:1 adduct $Et_3PO{-}SbCl_5$ dissolved in 1,2-dichloroethane is used as the reference state within this series; it is set arbitrarily as equal to 100. The acceptor numbers of organic solvents lie accordingly between 0 (*n*-hexane) and 100 ($Et_3PO{-}SbCl_5$). As was to be expected, they give a satisfactory linear relationship with the $E_T(30)$ values of Table 2[57]: $AN = 1.56 \times E_T(30) - 48.9$ ($n = 29$; $r = 0.940$)[58].

In 1976 *Kamlet* and *Taft*[72] established an α-scale of solvent HBD acidities and a β-scale of solvent HBA basicities by a UV/VIS spectroscopic method they called the solvatochromic comparison method. To determine the β values the absorption wave number shifts of 4-nitroaniline relative to *N,N*-diethyl-4-nitroaniline were measured in a series of HBA solvents. Both standard compounds are capable of acting as H-bond acceptors (*via* the oxygen atoms in the nitro group) in protic HBD solvents, but only 4-nitroaniline can also act as an H-bond donor in HBA solvents (*via* the amino group). Taking the $\Delta\Delta\tilde{\nu}$-value of 2800 cm^{-1} measured in hexamethyl-



phosphoric acid triamide (a particularly strong HBA solvent) as a reference point ($\beta_1 = 1.000$) it was possible to obtain an LFE scale of HBA basicities (=Lewis basicities) for 30 HBA solvents. By the same principle, using 4-nitroanisole (1-methoxy-4-nitrobenzene) and the pyridiniophenolate *(1a)* (Fig. 3), an α-scale of the HBD acidities for eleven protic solvents was derived[72].

Owing to the peculiarities of the selected standard processes, the above-mentioned parameters are no longer true characteristics of general solvent polarity but rather ones of the electrophilic and nucleophilic properties of organic solvents (cf. Section 5).

4. Applications

The application of empirical parameters of solvent polarity will be demonstrated with the aid of three examples. Many other correlation analyses can be found in [2, 10, 29].

The first-order thermolysis of α-chlorodialkyl ethers gives rise in aprotic solvents only to aldehyde and alkyl halide, but not, as in the gas phase, to HCl-elimination products[73]. Concerted one- and two-stage mechanisms proceeding *via* a cyclic, isopolar, activated complex, a radical mechanism,

(14)

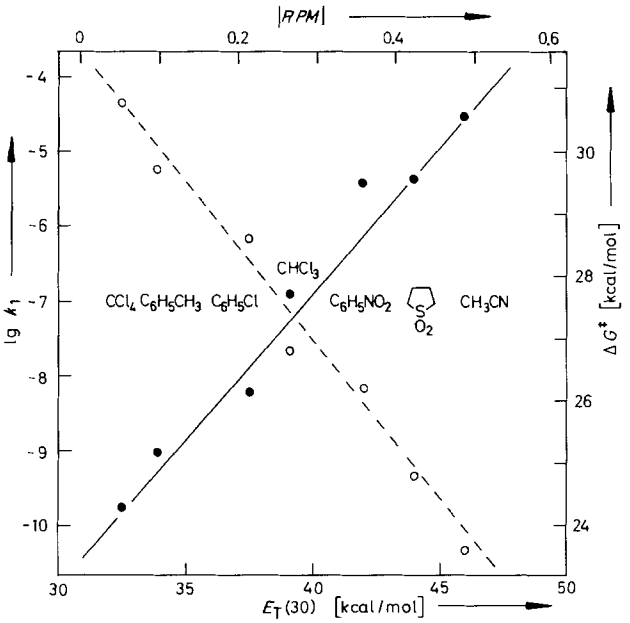


Fig. 4. Correlation between $E_T(30)$ and $\lg k_1$ (●) and $\Delta G^{\neq}$ (○) of the thermolysis of α-chlorobenzyl methyl ether in aprotic solvents at 25 °C in accordance with Eq. (14) [73]:

$\Delta G^{\neq} = -0.51 \cdot E_T(30) + 47.4$ ($n = 7$; $r = -0.991$).

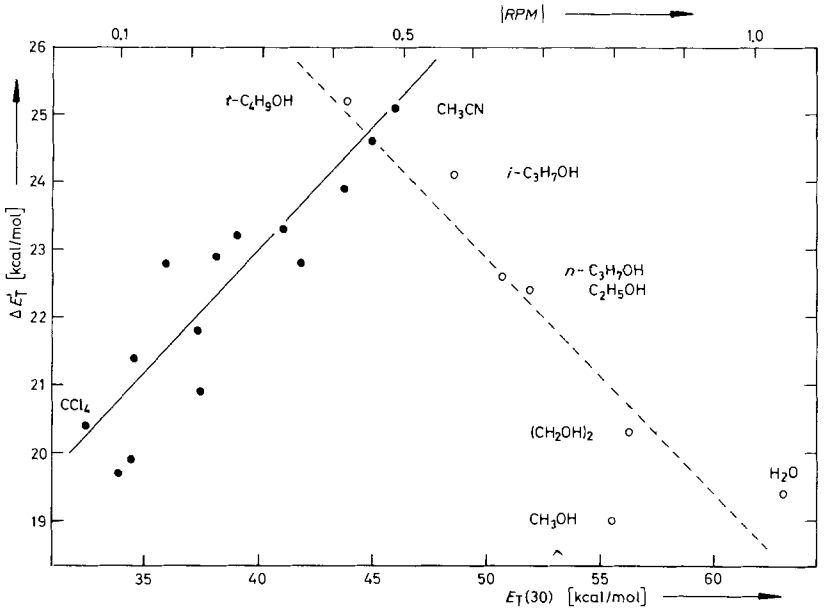
and an ion-pair mechanism with a dipolar activated complex have been suggested for the reaction in solution[73].

The exceptionally marked acceleration of the reaction obtained during the thermolysis of α-chlorobenzyl methyl ether with increasing solvent polarity ($k_1(CH_3CN)/k_1(CCl_4) = 1.7 \times 10^5$; $\Delta\Delta G^{\neq} = 7.2$ kcal/mol) and the linear correlation between the logarithms of the rate constants or the free activation energies of this reaction and the $E_T(30)$ values (cf. Fig. 4) indicate beyond all doubt a reaction taking place *via* a dipolar, cryptoionic activated complex as shown in Eq. (14)[73].

Figure 5 shows the correlation between $E_T(30)$ values and the differences between the transition energies $\Delta E_T'$ of sodium 4-nitrophenolate and 4-nitroanisole measured in 21 solvents[74]. To increase the solubility of the sodium salts in nonpolar solvents the cryptand [15]crown-5-ether was added in all cases as a cation solvator. The longest-wavelength solvatochromic absorption band of the 4-nitrophenolate ion is ascribable to a π-π^* transition with intramolecular charge transfer character. Because of the same type of solvation of the 4-nitrophenyl part of the molecule, 4-nitroanisole was used as the reference substance. A striking satisfactory correlation is then found between $E_T(30)$ values and $\Delta E_T'$, although two different straight lines with opposing slopes are obtained for protic and aprotic solvents, indicative of different solvation mechanisms in the two solvent series. Protic solvents are good anion solvators, which solvate the 4-nitrophenolate ion specifically *via* H-bridges, the intensity of their action increasing with increasing HBD character of the protic solvents used. Accordingly an increasing hypsochromic shift of the longest-wavelength absorption band of the 4-nitrophenolate ion relative to that of 4-nitroanisole ($\hat{=}$ reduction of $\Delta E_T'$) is observed in the solvent series $(CH_3)_3COH$ < i-C_3H_7OH < n-C_3H_7OH < C_2H_5OH < $HOCH_2CH_2OH$ < CH_3OH ≈ H_2O (cf. also the α-scale of HBD acidities in [72]). Aprotic solvents, in contrast, are poor anion solvators, and in these solvents the effect of the solvent on the longest-wavelength absorption band of sodium 4-nitrophenolate must be interpreted by increasing dissociation of the ion pair and the resultant steady reduction of the cation-anion interaction, which gives rise to a bathochromic shift[74]. Results of this type are also of significance to the solvent-determined varying chemical reactivity of ambident phenolate ions to alkylating agents[75].

Finally, it should be mentioned that a linear correlation can even be found between $E_T(30)$ values and the molecular ellipticities $[\theta]$ taken from CD spectra of a solution of 2-benzoylbenzoic acid and (−)-(*R*)-amphetamine in eleven solvents (cf. Fig. 6)[76].

The achiral 2-benzoylbenzoic acid in benzene has an absorption band at 322 nm ($\varepsilon = 111$) which is due to the n-π^*-absorption of the carbonyl group. The addition of an equimolar amount of (−)-(*R*)-amphetamine induces more strongly positive circular dichroism in the region of the n-π^*-absorption, its magnitude depending on the solvent: as the solvent polarity increases, the induced circular dichroism is reduced (from $[\theta] = +1320$ in CCl_4 to $[\theta] = 0$ in CH_3OH). The cause of this induced circular dichroism is assumed to be the formation of a 1:1 salt *(2)*, which is initially present in nonpolar solvents as a (possibly H-bonded) ion pair. With increasing solvent polarity *(2)* dissociates *via* solvent-separated ion pairs into free solvated ions, in which the contact between the γ-keto acid and the chiral gegenion is virtually lost and hence also



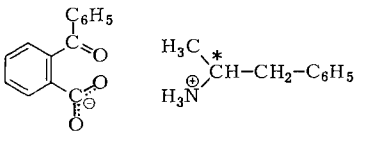


Fig. 5. Correlation between $E_T(30)$ and the difference between the transition energies ΔE_T^* of sodium 4-nitrophenolate and 4-nitroanisole, measured in protic (○) and aprotic (●) solvents in the presence of [15]crown-5-ether [74].

(2)

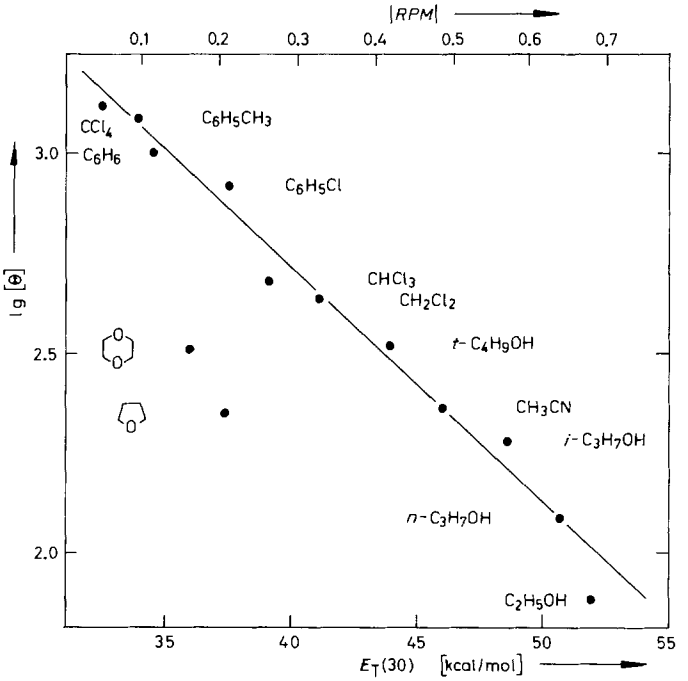

Fig. 6. Correlation between $E_T(30)$ and the logarithms of the molecular ellipticities $[\theta]$ of the 1:1 salt (2) from 2-benzoylbenzoic acid and (−)-(*R*)-amphetamine, measured in dilute solution (*ca.* 10^{-3} M) at 25°C [76]: $\lg[\theta] = -0.06 \cdot E_T(30) + 5.1$ ($n = 11$; $r = -0.989$).

the induced circular dichroism[76]. The deviation of the points for the ethereal solvents 1,4-dioxane and tetrahydrofuran from the straight correlation lines can easily be explained by competitive H-bridge formation between the γ-keto acid and the HBA solvent.

5. Multiparametric Equations

Despite the large number of very good to satisfactory LFE correlations between the empirical parameters of solvent polarity given in Table 1 and numerous other solvent-dependent processes, there is an at least equal number of examples where no such simple correlation can be found. The simple definition of "solvent polarity" as a solvent characteristic that can be universally determined and applied with the aid of singular empirical parameters is obviously too great a simplification. The solvation of solute molecules by the solvent, generally classified somewhat arbitrarily into specific and nonspecific solvation, is the result of very diverse and complex interactions and is therefore as a rule more complicated than, for example, the interaction between substrate and substituent. It is therefore truly amazing that despite the multiplicity of possible substrate-solvent interactions reasonable correlations can be obtained in so many cases with singular empirical solvent parameters. However, with a view to assessing several aspects of the substrate-solvent interaction there has recently been no shortage of attempts to establish LFE relationships in the form of multiparametric equations like Eq. (15).

$$A = A_0 + b \times B + c \times C + d \times D + \cdots \qquad (15)$$

A stands for a solvent-dependent, physicochemical parameter ($\lg K$, $\lg k$, E_T, *etc.*), determined for a specific reaction or absorption in a series of solvents, A_0 is the corresponding parameter in the gas phase or in an inert solvent taken as the reference state. The terms *B*, *C*, *D*,... represent independent but complementary solvent parameters that can be used as quantitative characteristics for different substrate-solvent inter-

actions; b, c, d, ... are regression coefficients that describe the susceptibility of A to the respective substrate-solvent interactions and have the significance of statistical weighting factors. Naturally, it is only possible to obtain such multiparametric correlation for a solvent-dependent process if measurements are available for a sufficiently large number of solvents and suitable statistical evaluation methods are used[5, 14]. A statistical method suitable for this purpose is factor analysis, in which reciprocal relationships between a large number of variables can be calculated in the form of multiparametric equations. A review of the principles and applications of factor analysis in organic chemistry can be found in[77]. The separation of solvent polarity into several interaction parameters as implied in Eq. (15) is initially purely formal and does not necessarily even have a theoretical basis, since the intermolecular interactions are coupled with one another, *i.e.* cannot be independent. Nevertheless, in a factor analysis the aim is in a second step to identify the initially still abstract factors B, C, D, ... and to determine their relationships to known parameters, thereby obtaining information about the proportion of the total solvent effect accounted for by individual interactions. Multiparametric equations of type (15) designed to provide a better quantitative description of the solvent effect on chemical reactions and light absorptions have been established over the last few years in particular by *Katritzky et al.*[78], *Koppel* and *Pal'm*[5, 8, 79], *Fawcett* and *Krygowski*[80], *Dougherty*[81], *Kamlet* and *Taft*[48], and *Mayer*[81a]. In this context we shall merely mention that efforts have also been made to improve the description of the effect of substituents on chemical reactivity with the aid of multiparametric equations[13, 82].

Katritzky et al.[78] tried out several multiparametric equations consisting of linear combinations of available empirical solvent parameters. The most successful proved to be a two-parameter combination of $E_T(30)$ values and functions of the dielectric constant or the refractive index. A more recent example of this is the S_N2 reaction between benzyl chloride and aniline, studied in twelve solvents, the solvent-dependent rate constant being found to correlate best in statistical terms with $E_T(30)$ values and the Kirkwood parameter $(\varepsilon-1)/(2\varepsilon+1)$ according to Eq. (16)[83]:

$$\lg k_2 = 0.0865 \times E_T(30) + 10.87 \times (\varepsilon-1)/(2\varepsilon+1) - 13.125 \qquad (16)$$

On the basis of a separation of specific and nonspecific substrate-solvent interactions, *Koppel* and *Pal'm*[5, 8, 79] suggested the four-parameter equation (17):

$$A = A_o + y \times Y + p \times P + e \times E + b \times B \qquad (17)$$

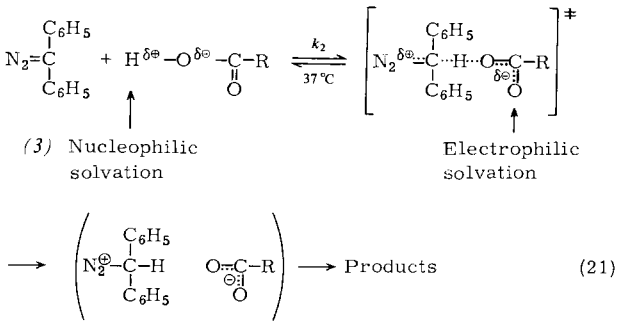
Here A and A_o have the same meaning as in Eq. (15). The nonspecific parameters Y and P are parameters for the polarization and polarizability of the solvent in accordance with classical dielectric theory, and E and B are specific parameters for the Lewis acidity (electrophilic solvation ability) and Lewis basicity (nucleophilic solvation ability) of the solvent. The dielectric constant ε is the basis for the polarization parameter Y and is used in the form of the Kirkwood functions $(\varepsilon-1)/(2\varepsilon+1)$ or $(\varepsilon-1)/(\varepsilon+2)$. The corresponding function $(n_D^2-1)/(n_D^2+2)$ of the refractive index n_D is used as a solvent polarizability parameter P. The parameters used for the Lewis acidity E are the $E_T(30)$ values of pyridiniophenolate *(1a)* (Fig. 3), although these were corrected to take account of nonspecific interactions by subtracting the polarization term $(y \times Y)$ and the polarizability term $(p \times P)$ according to Eq. (18) (using $E=0$ for the gas phase):

$$\begin{aligned} E &= E_T(30) - E_T^0(30) - y \times Y - p \times P \\ &= E_T(30) - 25.37 - 14.39 \times Y - 9.08 \times P \end{aligned} \qquad (18)[*]$$

By definition, in Eq. (17) $e=1$ stands for the basic reference process, *i.e.* the π-π^*-absorption of pyridiniophenolate *(1a)*. The parameters used for the Lewis basicity B were the wavenumber differences of the OD-stretching vibration band of monomeric CH_3OD defined in Eq. (11) (using $B=0$ for the gas phase). By definition, in Eq. (17) $b=1$ then stands for this reference process.

By way of example, the S_N1 solvolysis of *tert*-butyl chloride studied in 23 protic and aprotic solvents at 25°C correlates well according to Eq. (19) with the terms Y, P, and E of Eq. (17) (multiple correlation coefficient $R=0.982$), the E-term being predominant[8]:

$$\lg k_1 = -19.89 + 13.89 \times Y + 13.46 \times P + 0.378 \times E \qquad (19)$$



The relative contribution of the individual terms of Eq. (19) to the total solvent effect, as determined by the regression coefficients y, p, and e, reflects quantitatively the high sensitivity of this S_N1 reaction to a change in polarity (expressed by $Y=(\varepsilon-1)/(2\varepsilon+1)$, in the polarizability (P), and in the electrophilicity (E) of the solvent. In contrast, the nucleophilic properties of the solvents used can be totally disregarded (absence of the $b \times B$ term in Eq. (19) because $b=0$), as one would expect for an S_N1 reaction. The positive value of y is consistent with the increasing charge separation during the transition from the neutral starting molecule to the dipolar activated complex $[Me_3C^{\delta+}\ldots Cl^{\delta-}]^{\neq}$. The sign of e is also positive, and this indicates an additional stabilization of the activated complex relative to Me_3C—Cl by electrophilic solvation in protic solvents (by H-bond formation in accordance with $[Me_3C^{\delta+}\ldots Cl^{\delta-}\ldots H\text{—}S]^{\neq}$). Finally, the positive sign of p indicates that the activated complex of this S_N1 reaction would have a higher polarizability than the starting compound[8].

As more recent examples of correlation analysis with the aid of the Pal'm-Koppel equation (17) we shall mention only the second-order reactions between benzenesulfonyl chloride and imidazole[85], between benzaldehyde and aniline[85a], and between carboxylic acids and diazodiphenylmethane *(3)* in aprotic solvents[86]. In the last case there is a significant correlation between $\log k_2$ (determined in 43 aprotic solvents) and all four parameters of Eq. (17) in accordance with Eq. (20) $(R=0.979)$[86]:

$$\lg k_2 = -3.190 + 4.463 \times Y + 12.330 \times P + 0.210 \times E - 0.0181 \times B \qquad (20)$$

The finding that in Eq. (20) b has a negative sign and e a positive one can be best explained by nucleophilic stabilization of the carboxylic acid used and electrophilic stabilization of the activated complex in accordance with the simplified reaction scheme (21)[86].

[*] On the basis of more recent $E_T(30)$ values Eq. (18) and the E-scale of Lewis acidity defined by it were expanded and improved in 1974 [84].

(21)

A much simpler but equally successful two-parameter equation (22) was proposed by *Fawcett* and *Krygowski*[80]:

$$A = A_0 + \alpha \times E_T(30) + \beta \times DN \qquad (22)^{[*]}$$

According to this, all it is necessary to know to describe the effect of a solvent on the parameter A is the solvent's Lewis acidity (assessed with the aid of the $E_T(30)$ values; Table 2) and Lewis basicity (measured by the donor numbers DN; cf. Eq. (12) and Table 1). The regression coefficients α and β accordingly describe the relative dependence of A on the electrophilic or nucleophilic properties of the solvent in which A is measured. As the $E_T(30)$ and the DN values for a specific solvent series do not vary numerically to the same extent, the α and β values are normalized using partial regression coefficients α' and β' according to Eqs. (23a) and (23b):

$$\bar{\alpha} = 100 \times \alpha'/(\alpha' + \beta') \qquad (23a)$$
$$\bar{\beta} = 100 \times \beta'/(\alpha' + \beta') \qquad (23b)$$

$\bar{\alpha}$ and $\bar{\beta}$ can then be interpreted as the percentage contribution of solvent acidity and solvent basicity to the total solvent effect obtained. Some results of the application of Eq. (22) to solvent-dependent processes (including processes used to establish singular empirical solvent parameters) are summarized in Table 3.

predominantly by the Lewis acidity of the solvent ($\bar{\alpha} = 88$ or 85%). The corresponding α-coefficient according to Eq. (22) has a negative sign in both cases, which represents a reduction of the reaction rate with increasing Lewis acidity of the solvent. The azide ion is evidently more highly stabilized as an H-bond acceptor in protic solvents than the anionic activated complex, in line with the smaller charge density of the latter. The linear relationship between the ^{23}Na-NMR chemical shifts of $NaClO_4$ solutions and the donor number DN found by *Popov et al.*[89] is consistent with the higher $\bar{\beta}$-value of 93%, which indicates that it is predominantly the nucleophilic properties of the solvent that determine cation solvation.

Many further applications of the two-parameter Eq. (22)—including the solvent-dependent solvent activity coefficients, ionic solvation enthalpies, standard reduction potentials of organic molecules, molar heats of solution, *etc.*—can be found in [80].

Another semiempirical multiparametric equation (24) for calculating the solvent dependence of chemical reactions using the donor numbers DN[10, 34] and the acceptor numbers AN[10, 57] was published recently by *Mayer*[81a]:

$$\Delta G^S - \Delta G^R = a \cdot (DN^S - DN^R) + b \cdot (AN^S - AN^R) + c \cdot (\Delta G_{tp}^{oS} - \Delta G_{tp}^{oR}) \qquad (24a)$$

$$\Delta\Delta G = a \cdot \Delta DN + b \cdot \Delta AN + c \cdot \Delta\Delta G_{tp}^{o} \qquad (24b)$$

ΔG is the free standard reaction energy or the free activation energy ($\Delta G^{\neq}$), and ΔG_{tp}^{o} represents the free standard vaporization energy in a solvent S and a reference solvent R. The coefficients a and b are then related to the donor and acceptor strengths of the reaction participants relative to the reference compounds $SbCl_5$ and $(C_2H_5)_3PO$. Some of the successful applications of Eq. (24) have been in calculating the solubilities of alkali metal halides in several solvents, the solvent dependence of complex formation and ion association equilibria, and the solvent dependence of an S_NAr reaction[81a].

Table 3. Application of the complementary Lewis acid/base description of solvent effects according to Eq. (22) [80].

Solvent-dependent process	n [a]	$\bar{\alpha}$	$\bar{\beta}$	R [b]	Ref.
S_N1 solvolysis of *tert*-butyl chloride (Y)	5	80	20	0.909	[35, 36]
S_N1 solvolysis of 2-(4-methoxyphenyl)-2-methylpropyl tosylate ($\lg k_{ion}$)	13	99	1	0.908	[37]
S_N2 reaction $N_3^- + n$-C_4H_9Br	10	88	12	0.905	[87]
S_NAr reaction $N_3^- + 4$-NO_2—C_6H_4F	11	85	15	0.969	[88]
Diels-Alder cycloaddition cyclopentadiene + methyl acrylate (Ω)	7	91	9	0.961	[41]
CT absorption of 1-ethyl-4-methoxycarbonylpyridinium iodide (Z)	16	98	2	0.970	[43]
n-π^*-absorption of ketones (F)	7	84	16	0.956	[45]
$\bar{\nu}_{O\ D}$ of CH_3OD (Koppel-Pal'm parameter B)	15	22	78	0.954	[8]
^{23}Na-NMR chemical shift of $NaClO_4$ ($c = 0.05$ mol/l)	8	7	93	0.984	[89]

[a] Number of solvents considered. [b] Multiple regression correlation coefficient.

Comparison of the $\bar{\alpha}$ and $\bar{\beta}$ values in Table 3 shows that the empirical solvent parameters Y, $\lg k_{ion}$, Ω, Z, and F indicate above all the electrophilic solvation ability of the solvent, while the Koppel-Pal'm parameter B with a $\bar{\beta}$ value of 78% characterizes predominantly the nucleophilic solvation ability of the solvent. The two second-order substitution reactions with the azide ion as the nucleophile are also determined

Finally, we should also present a multiparametric equation for the assessment of ionic solvation that describes the substrate-solvent interaction as an interaction between the highest occupied orbitals (HOMOs) of ions and solvent and the corresponding lowest unoccupied orbitals (LUMOs) of solvent and ions. If one approximates the energies of these orbitals with the aid of the ionization potential IP and the electron affinity EA, then according to *Dougherty*[81], given certain simplifications, it is possible to formulate Eq. (25) for the ion-solvent interaction energy:

[*] Because of the consistency with Eq. (15), the letters A and A_0 were used in Eq. (22) instead of Q and Q_0 as in the original paper [80].

$$\delta E_{solv} = C_1 \times (IP_{solv} + EA_{solv}) + C_2 \times (IP_{solv}) + C_3 \times (EA_{solv})^2 + C_4 \quad (25)$$

The term $(IP_{solv} + EA_{solv})$ can be interpreted as an expression of the ionization ability of the solvent. The term (IP_{solv}) reflects the nucleophilicity of the solvent and the $(EA_{solv})^2$ represents its electrophilicity. Owing to the lack of sufficient data on electron affinities, it has so far only been possible to test Eq. (25) in very few solvent-dependent processes[81]. Thus, the Winstein-Grunwald parameter Y (solvolysis of *tert*-butyl chloride)[35, 36], for example, is controlled predominantly by the $(IP_{solv} + EA_{solv})$ term.

There is only space here merely to mention other multiparametric equations for the description of solvent effects on heterogeneous catalytic reactions (hydrogenation of C=C double bond systems, reduction of aromatic nitro compounds)[90] and on cationic copolymerization reactions (of *p*-substituted styrenes and alkyl vinyl ethers)[91].

Finally, it should be pointed out that the use of multiparametric equations instead of single-parameter equations has in many cases produced a dramatic improvement in the correlations between solvent-dependent processes (reactions, absorptions) and inherent solvent properties, since they take better account of the multiplicity of the substrate-solvent interactions than a singular parameter of solvent polarity. Nevertheless, the question in what way, and on the basis of what model concepts, the polarity or solvation ability of a solvent can best be broken down into a number of complementary interaction parameters as independent of each other as possible is still far from being answered. In this respect multiparametric equations have still not proved themselves.

6. Conclusion

Although LFE relationships of the type described above do not follow from the laws of thermodynamics, their appearance indicates the existence of real relationships between the parameters correlated, for whose nature there is in most cases a plausible explanation. On the basis of the extent to which the effect of a solvent on a standard process used to determine an empirical solvent parameter is understood, it is also possible to give a reasonable interpretation of the effect of a solvent on a series of reactions or absorptions correlating with this parameter. The method of LFE correlations is still the simplest and most practical method of predicting the effects of solvents (and substituents) on the rate and position of equilibrium of chemical reactions and also on spectral absorptions of organic molecules. The criticism that the procedure is far too empirical can be countered by saying that not only are the basic postulates of the LFE relationships (additivity and separability of the effects obtained) of theoretically acceptable form, but the selection of suitable standard processes to determine empirical parameters of solvent polarity also makes use of a number of theoretical considerations.

The author's own papers mentioned as examples were sponsored by the Fonds der Chemischen Industrie, for which the author would like to express his gratitude.

New Applications of Computers in Chemistry

By Ivar Ugi, Johannes Bauer, Josef Brandt, Josef Friedrich, Johann Gasteiger, Clemens Jochum, and Wolfgang Schubert[*]

The mathematical model of constitutional chemistry described here is based on a concept of isomerism which has been extended from molecules to ensembles of molecules. A chemical reaction is the conversion of an ensemble of molecules into an isomeric ensemble. An ensemble of molecules is representable by an atomic vector and an associated bond and electron (BE)-matrix, and a reaction by a reaction (R)-matrix. These BE- and R-matrices serve as a basis for computer programs for the deductive solution of chemical problems. We present here algorithms and computer programs based on the theory of BE- and R-matrices. They enable the classification and documentation of structures, substructures and reactions, the prognosis of reaction products, the design of syntheses, the construction of networks of mechanistic and synthetic pathways and the prediction of chemical reactions.

1. Approaches to the Deductive Solution of Chemical Problems

In chemistry the use of computers has been customary for a long time. Nevertheless, only a modest part of the inherent capabilities of modern computers is utilized for the solving of chemical problems. Numerical problems are solved, such as the ones encountered in quantum chemistry, and in the collection and evaluation of experimental data, or large sets of data are subjected to storage and retrieval operations. The challenge to solve chemical problems by algorithms which simulate human intelligence in the sense of decision processes and deductive thought was felt at a rather early stage. It led to studies in a direction which is now associated with the term "artificial intelligence".

This development began more than ten years ago with computer programs for the elucidation of molecular structures from measured physicochemical data[1] (*e.g.* mass spectra), and also with retrieval oriented computer assisted synthesis design[2]. In the latter type synthesis design programs, stored information on chemical reactions is used to generate the precursors of a given synthetic target molecule. Here the structural features of the target molecule are perceived and analyzed in order to determine which of the reactions in a library of stored known reactions may lead to the target. For such reactions the corresponding precursors of the target are generated.

A theory of constitutional chemistry is needed for the development of synthesis design programs which are also able to propose -- without detailed knowledge of chemical reactions —synthetic pathways containing unprecedented steps. This theory should be the basis for finding the molecular systems from which a given system may be formed by chemical reactions, or into which it may be converted.

Such a theory would not only serve as a suitable foundation for synthesis design programs, but it would also enable the solution of a great variety of other chemical problems.

Deductive computer programs which are based on mathematical representations and models of logical structures will play an essential role in future chemistry. With this approach, one is not restricted to the retrieval and manipulation of stored empirical data. Instead, the *whole set of conceivable solutions* of a chemical problem can be taken into account by *deduction* based on a suitable theory. There is no need to refrain from making use of relevant empirical data; it is possible and meaningful to condense these into the form of general selection rules which are applied in the analysis and evaluation of the intermediate and final results.

In this article a mathematical model of constitutional chemistry is described, and its use as a theoretical basis of deductive computer programs is demonstrated by some examples. This *mathematical model of constitutional chemistry*[3] is based on the consequent use of the equivalency concept in the representation and classification of molecular systems.

The basis for the additional treatment of stereochemical aspects has been discussed before[4].

2. A Mathematical Model of Constitutional Chemistry

As an introduction to representing the logical structure of constitutional chemistry by a mathematical model[3], we observe that: An ensemble of molecules (*EM*)[5, 6] consists of molecules which may be chemically different, or indistinguishable. Just like a molecule, an *EM* has an empirical formula. It is the union of the empirical formulas of the molecules belonging to the ensemble.

2.1. The Extended Concept of Isomerism

The above statement leads directly to an extension of the concept of isomerism to ensembles of molecules:

Ensembles of molecules (*EM*) are isomeric, if they have the same empirical formula. The empirical formula describes the collection **A** of atoms which the *EM* contains. All *EM*'s which can be formed from **A** have the same ensemble empirical formula $\langle \mathbf{A} \rangle$.

Accordingly, an *EM*(**A**) consists of one or more than one molecule that can be obtained from **A** by using each atom belonging to **A** exactly once.

An *FIEM*(**A**), the *family of the isomeric ensembles of molecules* which contains the atoms of **A**, is the collection of all

[*] Prof. Dr. I. Ugi, Dipl.-Inform. J. Bauer, Dr. J. Brandt, Dipl.-Inform. J. Friedrich, Dr. J. Gasteiger, Dr. C. Jochum, Dr. W. Schubert

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0202-0111 $ 02.50/0*

EM(**A**). An *FIEM* is simply determined by the empirical formula $\langle \mathbf{A} \rangle$ of the collection **A** of atoms.

A chemical reaction, or a sequence of chemical reactions, is the conversion of an *EM* into an isomeric *EM*. An *FIEM* contains all *EM*'s which are chemically interconvertible, as far as stoichiometry is concerned. Thus the *FIEM*(**A**) contains the whole chemistry of the collection **A** of atoms. Since any collection of atoms may be chosen here, a theory of the *FIEM* is a theory of all of chemistry.

The left-hand sides and the right-hand sides of the "chemical equations" (1) to (4) are pairs of isomeric *EM*'s whose empirical formulas are given in brackets. The addition of eqs. (1) to (3) results in eq. (4) for the overall reaction.

$$HCN + Cl_2 = ClCN + HCl \qquad \langle CHCl_2N \rangle \qquad (1)$$

$$NH_3 + ClCN = H_2NCN + HCl \qquad \langle CH_3ClN_2 \rangle \qquad (2)$$

$$H_2NCN + H_2O = H_2NCONH_2 \qquad \langle CH_4N_2O \rangle \qquad (3)$$

$$HCN + Cl_2 + NH_3 + H_2O = H_2NCONH_2 + HCl + HCl \qquad \langle CH_6Cl_2N_2O \rangle \qquad (4)$$

The *EM*'s which participate in the reactions (1) to (4) can be imbedded into the *FIEM* $\langle CH_6Cl_2N_2O \rangle$ when the ensembles of the reacting molecules are supplemented by those molecules that do not participate directly in the reactions [eq. (5)].

$$HCN + Cl_2 + NH_3 + H_2O \rightarrow ClCN + HCl + NH_3 + H_2O \rightarrow H_2NCN + HCl + HCl + H_2O \rightarrow H_2NCONH_2 + HCl + HCl \qquad (5)$$

2.2. BE-Matrices

Seen chemically, atoms consist of a core (atomic nucleus and the electrons of the inner orbitals) and the valence electrons (electrons of the outer orbitals). In molecules the cores are held together by the valence electrons. The chemical constitution of a molecular system is described in terms of its *covalently* bonded pairs of cores. The distribution of the "free" valence electrons which do not belong to covalent bonds can also be considered as part of the constitution. Customarily, the chemical constitution is described by constitutional formulas. In these the atomic cores are represented by element symbols, and covalent bonds by lines connecting the element symbols. The placement of the free valence electrons is generally indicated by dots next to the element symbols.

In our model, the chemical constitution of an *EM* is represented by its atomic vector, which corresponds to the atoms in **A**, and by the associated bond and electron (BE)-matrix, whose rows and columns belong to the individual atomic cores. The off-diagonal entries are the formal covalent bond orders, and the diagonal entries are the numbers of the free valence electrons[3-13].

In the past, some other matrix representations of the chemical constitution have been introduced: The adjacency matrix **J**, which originates in graph theory, indicates only, which atoms are bonded. *Spialter*[14] defined the connectivity matrix **C**, whose off-diagonal entries are the formal covalent bond orders; the diagonal entries contain the atomic vector. *E. Meyer*[15] used topological matrices for documentation purposes. *Yoneda*[16] uses a matrix representation for the treatment of heterogenous catalysis. The reactive centers of the reactants and the catalysts are accounted for on the diagonal.

The adjacency matrix **J**(HCN) (6) and the connectivity matrix **C**(HCN) (7) of hydrogen cyanide may serve as an illustration.

H—C≡N:

$$\mathbf{J}(HCN) = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \qquad (6)$$

$$\mathbf{C}(HCN) = \begin{pmatrix} H & 1 & 0 \\ 1 & C & 3 \\ 0 & 3 & N \end{pmatrix} \qquad (7)$$

The BE-matrix **B** of an *EM*(**A**) with a set of n arbitrarily indexed atoms $\mathbf{A} = \{A_1, \ldots, A_n\}$ is an $n \times n$ matrix whose i-th row and column belong to the i-th atomic core A_i. The off-diagonal entry b_{ij} of the i-th row and j-th column is the formal bond order of the covalent bond from A_i to A_j. Since this corresponds to a bond with the same formal order from A_j to A_i, we have $b_{ij} = b_{ji}$. Thus the BE-matrices must be symmetric. The i-th diagonal entry b_{ii} indicates the number of free valence electrons of the atom A_i. For *EM*'s with closed valence shells and spin paired valence electrons all diagonal entries are even.

The BE-matrices **B**(HCN) and **B**(HNC) correspond to the formulas of hydrogen cyanide and hydrogen isocyanide.

$H^1—C^2 \equiv \ddot{N}^3$ $\qquad$ $H^1—\overset{\oplus}{N}^3 \equiv \overset{\ominus}{\ddot{C}}^2$

$H^1C^2N^3$ $\qquad$ $H^1C^2N^3$

$$\mathbf{B}(HCN) = \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 3 \\ 0 & 3 & 2 \end{pmatrix} \begin{matrix} H^1 \\ C^2 \\ N^3 \end{matrix} \qquad (8) \qquad \mathbf{B}(HNC) = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 2 & 3 \\ 1 & 3 & 0 \end{pmatrix} \begin{matrix} H^1 \\ C^2 \\ N^3 \end{matrix} \qquad (9)$$

In **B**(HCN) the entries $b_{12} = b_{21} = 1$ stand for the H—C bond, the entries $b_{23} = b_{32} = 3$ for the C≡N triple bond, and $b_{33} = 2$ for the pair of free electrons on the nitrogen atom.

As can be seen from the example, a BE-matrix is a representation of a resonance structure in the sense of the valence bond theory.

The number of valence electrons s_i which belong to the atom A_i is the sum over the entries of the i-th row or column of a BE-matrix:

$$s_i = \sum_{j=1}^{n} b_{ij} = \sum_{j=1}^{n} b_{ji} \qquad (10)$$

The formal electrical charge of the atom A_i is the core charge minus s_i. For the second row or column of **B**(HNC) we have $s_2 = 0 + 2 + 3 = 5$. It follows that the C-atom of HNC with a core charge of $+4$ has a formal electrical charge of -1. The cross sum

$$\hat{s}_i = 2s_i - b_{ii}$$

over a diagonal entry b_{ii} comprises the entries in the i-th row and column, *i.e.* all entries b_{ij} and b_{ji} whose indices include an i. This is twice the row/column sum s_i, minus the diagonal entry b_{ii}. The cross sum $\hat{s}_i$ is the number of

electrons in the valence orbitals of the atom A_i. For the C-atom of HNC we find

$$\begin{aligned} s_2 &= b_{21}+b_{22}+b_{23}+b_{12}+b_{23} \\ &= 0+2+3+0+3 = 2s_2-b_{22} \\ &= 2\times 5-2=8 \end{aligned} \tag{11}$$

i.e. this atom fulfils the octet rule.

The row of a BE-matrix describes the distribution of valence electrons at the respective atomic core. For a given core, only a limited number of such distributions (valence schemes) is permissible. These may be collected in a list of acceptable valence schemes[13].

The sum

$$S = \sum_i s_i = \sum_{ij} b_{ij} \tag{12}$$

over all entries of a BE-matrix is the number of valence electrons which the *EM* contains. This sum S has the same value for all *EM*'s belonging to the same *FIEM*.

The BE-matrices of all relevant resonance structures, or BE-matrices with fractional formal bond orders, may be used for the description of the constitution of chemical compounds which are not representable in terms of localized bonds, such as systems capable of resonance, or systems with multicenter bonds.

The n atoms of an *EM* can be numbered in up to $n!$ different ways, thus leading to up to n! distinguishable but equivalent BE-matrices. By appropriate rules *one* of these numberings can be declared canonical[17]. This numbering is important when dealing with stereochemical aspects.

2.3. R-Transformations

A chemical reaction is the conversion of an *EM* into an isomeric *EM* by the redistribution of valence electrons. Here the following invariances hold which are based on the conservation laws of matter and charge:

1. The atomic cores of an *EM* are preserved.
2. The total number of the valence electrons of an *EM* is preserved.

From 2 it follows that the conversion of the starting materials *EM*(**B**) into the final products *EM*(**E**) through a chemical reaction

$$EM(\mathbf{B}) \rightarrow EM(\mathbf{E}) \tag{13}$$

is representable by those transformations $\mathbf{B}\rightarrow\mathbf{E}$ of BE-matrices in which the sum over all entries (S) [see eq. (12)] is maintained.

2.3.1. *R*-Matrices

We define the *R-matrix* (reaction matrix) **R** through the transformation:

$$\mathbf{B}+\mathbf{R}=\mathbf{E} \tag{14}$$

The addition of an R-matrix to a BE-matrix may be interpreted as the action of an operator $\mathbf{R}_{op}$ on **B**:

$$\mathbf{R}_{op}(\mathbf{B})=\mathbf{B}+\mathbf{R}=\mathbf{E} \tag{15}$$

Since **B** and **E** have the same sum S of entries:

$$S = \sum_{i,j} b_{ij} = \sum_{i,j} e_{ij} = \sum_{i,j} b_{ij} + \sum_{i,j} r_{ij} \tag{16}$$

the sum of the entries $r_{ij}=e_{ij}-b_{ij}$ of the matrix $\mathbf{R}=\mathbf{E}-\mathbf{B}$ must be zero:

$$\sum_{i,j} r_{ij} = 0 \tag{17}$$

The matrix must be symmetric, because $\mathbf{E}=\mathbf{B}+\mathbf{R}$ is a BE-matrix, and must thus by definition be symmetric, *i.e.* from $b_{ij}=b_{ji}$ and $e_{ij}=e_{ji}$ follows $r_{ij}=r_{ji}$.

The off-diagonal negative entries $r_{ij}=r_{ji}=-1$ reflect the breaking of a covalent bond A_i—A_j; a negative diagonal entry r_{ii} indicates the number of free valence electrons that the atom A_i loses by a chemical reaction. Correspondingly, positive off-diagonal entries show how many bonds between A_i and A_j are made, and a positive diagonal entry shows how many free valence electrons the atom A_i gains during the reaction.

When **R** represents the reaction $EM(\mathbf{B})\rightarrow EM(\mathbf{E})$ according to $\mathbf{B}+\mathbf{R}=\mathbf{E}$, then its inverse $\bar{\mathbf{R}}$ describes the *retroreaction* $EM(\mathbf{E})\rightarrow EM(\mathbf{B})$ according to:

$$\mathbf{E}+\bar{\mathbf{R}}=\mathbf{E}-\mathbf{R}=\mathbf{B} \tag{18}$$

The entries of $\bar{\mathbf{R}}$ are thus given by:

$$\bar{r}_{ij} = -r_{ij} \tag{19}$$

For example, the reaction

$$HCN \rightarrow HNC$$

is represented by:

$$\begin{array}{ccccc} \mathbf{B}(HCN) & + & \mathbf{R} & \rightarrow & \mathbf{B}(HNC) \\ \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 3 \\ 0 & 3 & 2 \end{pmatrix} & + & \begin{pmatrix} 0 & -1 & +1 \\ -1 & +2 & 0 \\ +1 & 0 & -2 \end{pmatrix} & = & \begin{pmatrix} 0 & 0 & 1 \\ 0 & 2 & 3 \\ 1 & 3 & 0 \end{pmatrix} \end{array} \tag{20}$$

The inverse matrix $\bar{\mathbf{R}}=-\mathbf{R}=\mathbf{B}(HCN)-\mathbf{B}(HNC)$ corresponds to the reaction HNC→HCN.

The R-matrices of reactions belonging to the chemistry of valence shells with paired electrons have in the diagonal zeros, or even numbers only. The R-matrices belonging to the octet chemistry of molecules without formally charged atoms have only zero entries in the diagonal. Such R-matrices exist only from $n\geq 4$ onwards. From this it follows, that one cannot obtain from any collection of three atoms more than *one* molecule or *EM* which belongs to the octet chemistry, and that no product of a reaction of this *EM* can also belong to octet chemistry[3].

2.3.2. The Basis Elements of *R*-Matrices

An R-matrix of the type

$$\mathbf{U}^{ij} = \begin{array}{c} \begin{matrix} & i & & j & \end{matrix} \\ \begin{pmatrix} \cdots & +1 & \cdots & 0 & \cdots \\ & \vdots & & \vdots & \\ \cdots & 0 & \cdots & -1 & \cdots \end{pmatrix} \begin{matrix} i \\ \\ j \end{matrix} \end{array} \tag{21}$$

with all entries = 0, except $u_{ii}^{ij} = +1$ and $u_{jj}^{ij} = -1$, describes an elementary *redox reaction*

$$A_i + {}^{\bullet}A_j \rightarrow {}^{\bullet}A_i + A_j \tag{22}$$

by which an electron is transferred from A_j to A_i. The elementary *homoapsis* according to

$${}^{\bullet}A_i + {}^{\bullet}A_j \rightarrow A_i\text{—}A_j \tag{23}$$

is represented by the R-matrix

$$\mathbf{V}^{ij} = \begin{array}{c} \begin{matrix} & i & & j & \end{matrix} \\ \begin{pmatrix} \cdots & -1 & \cdots & +1 & \cdots \\ & \vdots & & \vdots & \\ \cdots & +1 & \cdots & -1 & \cdots \end{pmatrix} \begin{matrix} i \\ \\ j \end{matrix} \end{array} \tag{24}$$

in which $v_{ij}^{ij} = v_{ji}^{ij} = +1$ and $v_{ii}^{ij} = v_{jj}^{ij} = -1$ are the only non-zero entries.

The R-matrix $-\mathbf{V}^{ij}$ describes the retroreaction, *i.e.* the elementary *homolysis*

$$A_i\text{—}A_j \rightarrow {}^{\bullet}A_i + {}^{\bullet}A_j \tag{25}$$

An R-matrix with the entries r_{ij} and the i-th row sum

$$r_i = \sum_j r_{ij} \tag{26}$$

is uniquely represented (up to sequence) as a sum of the R-matrices $\mathbf{U}^{in}$ and $\mathbf{V}^{ij}$.

$$\mathbf{R} = \sum_{i<j} r_{ij}\mathbf{V}^{ij} + \sum_{i<n} r_i \mathbf{U}^{in} \tag{27}$$

The set of the $\mathbf{U}^{in}$ and the $\mathbf{V}^{ij}$ forms a *basis* for the R-matrices. Since the R-matrices may be interpreted as vectors belonging to $\mathbb{R}^{n^2}$, the $\mathbf{U}^{in}$ and $\mathbf{V}^{ij}$ are also called the *basis vectors*.

The vector basis of the R-matrices of reactions within the chemistry of valence shells with paired electrons only (with $r_{ii} = 0, \pm 2, \ldots$) consists of R-matrices of the type $(\mathbf{U}^{ij} + \mathbf{V}^{ij})$ and $2\mathbf{U}^{in}$. The basis vector $(\mathbf{U}^{ij} + \mathbf{V}^{ij})$ represents reactions of the types (28) and (29):

$$A_i + :A_j \rightarrow A_i^{\ominus}\text{—}A_j^{\oplus} \tag{28}$$

$$A_i^{\oplus} + :A_j^{\ominus} \rightarrow A_i \text{—} A_j \tag{29}$$

The R-matrix from eq. (20) may serve to illustrate the decomposition of R-matrices into their basis vectors.

$$\mathbf{R}(\mathrm{HCN} \rightarrow \mathrm{HNC}) = -(\mathbf{U}^{12} + \mathbf{V}^{12}) + (\mathbf{U}^{13} + \mathbf{V}^{13}) \tag{30}$$

$$\mathbf{R}(\mathrm{HCN/HNC}) =$$

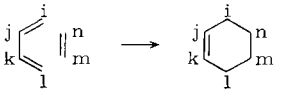
$$\begin{pmatrix} 0 & -1 & +1 \\ -1 & +2 & 0 \\ +1 & 0 & -2 \end{pmatrix} = -\begin{pmatrix} 0 & +1 & 0 \\ +1 & -2 & 0 \\ 0 & 0 & 0 \end{pmatrix} + \begin{pmatrix} 0 & 0 & +1 \\ 0 & 0 & 0 \\ +1 & 0 & -2 \end{pmatrix} \tag{31}$$

2.3.3. Fitting Conditions for R-Matrices

The transformation of a BE-matrix **B** by the addition of an R-matrix **R** according to $\mathbf{B} + \mathbf{R} = \mathbf{E}$ corresponds to a chemical reaction only, if we have for all entries:

$$e_{ij} = b_{ij} + r_{ij} \geq 0 \tag{32}$$

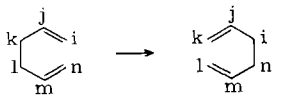
since, by definition, a BE-matrix cannot contain any negative entries. Thus the negative entries of an R-matrix must be chosen to satisfy



$$|r_{ij}| \leq b_{ij} \quad \text{for} \quad r_{ij} < 0 \tag{33}$$

Further, the entries e_{ij} of the resulting matrix **E** must have values which agree with the acceptable valence chemical schemes of the respective chemical elements.

With a given BE-matrix **B**, one can thus use its positive entries b_{ij} to determine the negative entries r_{ij} of the *mathematically fitting* R-matrices. The positive entries are then chosen to yield R-matrices with $\sum_{i,j} r_{ij} = 0$. Among these, one selects those R-matrices which are acceptable with respect to the valence chemical boundary conditions for **E**. The transformation properties of the BE-matrices, and the known valence chemical properties of the chemical elements can thus be used to predict all the conceivable reactions and their products for a given *EM*. The action of all fitting R-matrices on a single BE-matrix leads to the BE-matrices of the whole family of isomeric ensembles of molecules (*FIEM*).



On investigating the conceivable reactions of HCN through the transformation properties of the BE-matrix **B**(HCN), one finds, *e. g.*, a fitting R-matrix with $r_{12} = r_{21} = -1$ and $r_{33} = -2$. Taking into account the structure of the R-matrices, as defined above, and the valence chemical properties of the elements H, C, and N, one finds that $r_{13} = r_{31} = +1$ and $r_{22} = +2$ are suitable as the complementary positive entries. The result is the R-matrix of eq. (20).

In general, there may be several BE-matrices having the required mathematical and valence chemical properties to fit a given R-matrix. Therefore an R-matrix represents a whole category of chemical reactions which have in common the "electron redistribution pattern" as given by the R-matrix and some features of the participating bond systems.

(34)

The reaction scheme (34) describes a Diels-Alder diene synthesis, while scheme (35) describes a Cope rearrangement.

(35)

The addition of an R-matrix of the form

$$\mathbf{R} = \begin{array}{c} \begin{matrix} i & j & k & l & m & n \end{matrix} \\ \begin{bmatrix} . & -1 & . & . & . & +1 \\ -1 & . & +1 & . & . & . \\ . & +1 & . & -1 & . & . \\ . & . & -1 & . & +1 & . \\ . & . & . & +1 & . & -1 \\ +1 & . & . & . & -1 & . \end{bmatrix} \end{array} \begin{matrix} i \\ j \\ k \\ l \\ m \\ n \end{matrix} \qquad (36)$$

to a BE-matrix corresponds to a Diels-Alder synthesis, or a Cope rearrangement, depending on the chemical constitution which this BE-matrix represents [cf. reactions (34) and (35)].

Any two R-matrices **R** and **R'** belong to the same R-category and represent similar reactions if there exists an R-matrix **R''** which can be transformed into **R** by row/column permutations, and which is convertible into **R'** by removal, or addition of rows and columns of zeros. Any two chemical reactions belong to the same R-category if they are represented by BE-matrix transformations of the same R-category.

In those reactions that are important for organic syntheses, generally a redistribution of electrons takes place in which up to six atoms participate and through which up to three covalent bonds are broken or made. The formal charge may increase by one unit at one of the atoms while decreasing by one unit at another atom, through participation of free valence electrons. Such reactions correspond to R-matrices with up to three pairs of negative and positive off-diagonal entries $r_{ij}=r_{ji}=-1$ and $r_{kl}=r_{lk}=+1$, respectively. The non-zero diagonal entries $r_{ii}=\pm 2$ are chosen to make all row/column sums of the R-matrix zero, except one pair of rows/columns with $r_i=\sum_j r_{ij}=\pm 1$.

2.4. Chemical Metric

An $n\times n$ BE-matrix **B** can also be represented as a vector **b** with n^2 components

$$\mathbf{b}=(b_{11},\ldots,b_{1n};\ b_{21},\ldots;\ \ldots b_{n1},\ldots,b_{nn}) \qquad (37)$$

This results in an imbedding of the BE-matrices **B** of an *FIEM* into $\mathbb{R}^{n^2}$, *i.e.* an n^2-dimensional metric space over the field of real numbers. The entries b_{ij} of **B** can also be interpreted as the cartesian coordinates of a point P(**B**) in $\mathbb{R}^{n^2}$, or as the components of a vector in $\mathbb{R}^{n^2}$. We call P(**B**) the BE-*point* of the BE-matrix **B**.

Since the BE-matrices are symmetric, any BE-matrix **B** can further be associated with a BE-point b in $\mathbb{R}^{n(n+1)/2}$, a space with fewer dimensions, by writing the upper triangle of **B** as a vector. In order to account for the constancy of the overall number of valence electrons, the lower triangle must be added to the upper one:

$$\mathbf{b}=(b_{11},2b_{12},\ldots,2b_{1n},b_{22},\ldots,2b_{n-1n},b_{nn}) \qquad (37a)$$

Accordingly, all resonance structures of the diatomic hydrogen fluoride are already representable in three dimensional space $\mathbb{R}^3$ (Fig. 1).

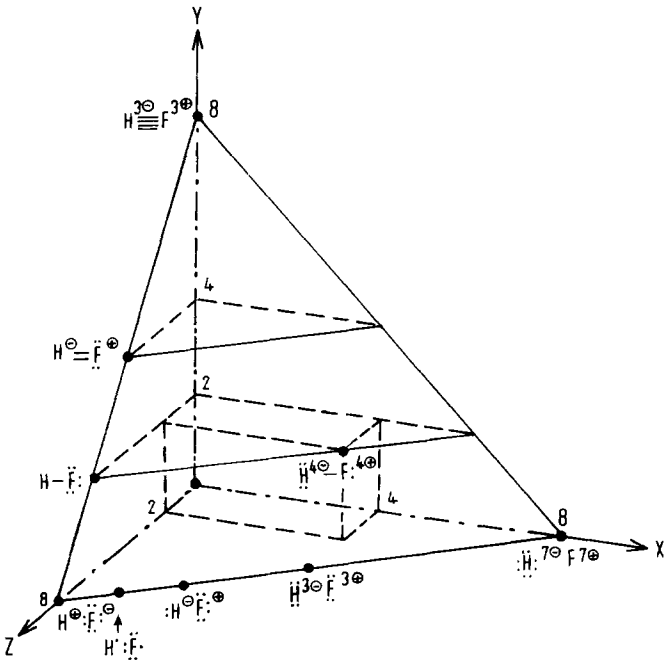


Fig. 1. The resonance structures of hydrogen fluoride lie on a plane which intersects the coordinate axes at 8 (= the number of valence electrons).

Similarly an R-matrix **R** corresponds to a vector **r** in $\mathbb{R}^{n^2}$. A chemical reaction as given by $\mathbf{B}+\mathbf{R}=\mathbf{E}$, is represented by the vector **r** from P(**B**) to P(**E**). The sum

$$D(\mathbf{B},\mathbf{E})=\sum_{i,j}|b_{ij}-e_{ij}|=\sum_{i,j}|r_{ij}| \qquad (38)$$

over the absolute values of the entries of **R** is twice the number of valence electrons which are redistributed during the reaction, since these are taken into account by the negative, as well as the positive entries of **R**.

We call D(**B**, **E**) the *chemical distance*[3] between **B** and **E**, and also between *EM*(**B**) and *EM*(**E**). By D(**B**, **E**) a metric is defined in the space $\mathbb{R}^{n^2}$ which is equivalent to the euclidean metric. The chemical distance is thus a genuine distance function for the BE-matrices of an *FIEM*. The origin of the coordinate system in $\mathbb{R}^{n^2}$ corresponds to the $n\times n$ zero matrix, **0**. The sum over the entries $S=\sum_{i,j} b_{ij}$ is the number of valence electrons, and has the same value for all BE-matrices of an *FIEM*. Therefore an *FIEM* can be mapped into a lattice of points with integral positive coordinates, on a surface with a "radius" S = D(**B**, **0**). Note that the chemical distance D(**B**, **E**) refers directly to the representation space $\mathbb{R}^{n^2}$.

3. Algorithms and Computer Programs Based on BE- and R-Matrices

A BE-matrix contains the complete constitutional information about a molecular system, including the placement of the free valence electrons. An R-matrix represents the "electron redistribution pattern" underlying a chemical reaction.

Documentation of structures and reactions: The BE-matrices are most suitable for the documentation of molecular structures and substructures (see Section 3.1.1).

A hierarchic order and documentation of chemical reactions is for the first time feasible, through the R-matrices which describe the reactions directly, in contrast to the customary methods by which the reactions are described in terms of the reactants only (see Section 3.1.2).

The transformation of BE-matrices by the addition of R-matrices leads to novel deductive methods for the solution of chemical problems with computers. One needs a universal model of the logical structure of chemistry, as described here, for the deductive approach by which the solutions of the individual problems are derived from general principles. Our model affords the following general ways to treat the dynamic aspect of chemistry:

One BE-matrix is given: It is possible to start from a given ensemble of molecules (*EM*) with the BE-matrix **B**, *EM*(**B**), and to generate the R-matrices which fit **B** mathematically within the valence chemical boundary conditions. This is one basis for programming the design of syntheses and the prediction of products which may be obtained from given starting materials (see Section 3.2).

Two BE-matrices are given: With two given BE-matrices, **B** and **E**, belonging to the same family of isomeric ensembles of molecules (*FIEM*), the expansion of the R-matrix $\mathbf{R}=\mathbf{E}-\mathbf{B}$ into its components $\mathbf{R}_1, \mathbf{R}_2, \ldots, \mathbf{R}_r$ according to $\mathbf{R}=\mathbf{R}_1+\mathbf{R}_2+\cdots\mathbf{R}_r$ yields information on the chemical pathways which lead from *EM*(**B**) to *EM*(**E**). Computer programs on this basis generate networks of reaction pathways which may consist of conceivable reaction mechanisms, or syntheses (see Section 3.3).

An R-matrix is given: The determination of all pairs (**B**,**E**) of BE-matrices which mathematically fit a given R-matrix, under the valence chemical boundary conditions, enables us to predict chemical reactions in a systematic manner (see Section 3.4).

3.1. Classification and Documentation

3.1.1. Structures and Substructures

In chemical documentation systems molecular structure is only one of many keys of access to further information, such as the contents of publications, and patents, as well as data on the properties of compounds. It is typical for chemical documentation systems that the key information is structured in a characteristic manner.

On the one hand, the structure of a chemical compound is subject to a variety of rules, in particular to valence chemical rules. On the other hand, it always contains substructures (functional groups, ring systems *etc.*), which may also serve as keys of access in their own right. This holds for applications such as

- searching files for molecules with a given substructure (pure retrieval)
- correlation of substructures with molecular properties (substructure/activity correlation)
- analogy search based on incomplete structural information (search for "similar" structures)
- recognition of substructures which target molecules of syntheses have in common with starting compounds
- documentation and analysis of spectroscopic data.

A documentation system capable of doing this must have the capacity for complete storage and retrieval of structural information. It must, however, also perform special manipulations, such as fragmentation, valence chemical plausibility checks, and afford access to substructures.

The representation of constitutional properties on the basis of a mathematical model is a prerequisite for the performance of such operations (see Section 2).

The treatment of chemical reactions is thus possible within the framework of a unified theory. It is described in more detail in the following sections. Firstly, the manipulation of chemical data on the basis of BE-matrices, which are defined as part of the mathematical model, is discussed.

Matrix representations of chemical constitution, *e.g.* the adjacency and connectivity matrices[14, 15], have been used in various documentation systems. Such matrices afford the basic services of a documentation system, *i.e.* storage and retrieval of data, but generally speaking they are not directly usable for valence chemical checks and the manipulation of data in the sense of chemical conversions.

The entries in any row of a BE-matrix must conform to at least one of the valence chemically acceptable electron distribution schemes of the respective atomic core. The permissible valence schemes for any given atomic core can be listed, and they determine the range of chemistry which is admitted for a particular purpose for the chemical element under consideration. The valence schemes afford effective plausibility checks on input data, or on recoding of foreign data. They are particularly useful when older data banks that represent a considerable investment are supplemented or tested for consistency. In such collections of data some of the structural information has been suppressed by the form of coding used. The information that is lacking must sometimes be reconstructed. Often the information on free electrons and formal electrical charges is missing. A comparison with the allowable valence schemes yields one or more proposals for the required supplementary data. These are further processed according to additional information, or, in exceptional cases, subjected to a manual selection procedure. In any case, this balance of the valence electrons ensures that only acceptable and complete constitutional information enters the collection of data. For documentation systems such perfect representation by BE-matrices has the unique advantage that the types of problems which may be of interest in the future do not have to be known when the system is implemented.

Hitherto, documentation systems usually have been so designed as to cope with the solution of particular problems. This approach frequently leads to some constitutional information being neglected. This is especially true for the widely used fragment codes.

On the basis of such a complete representation of chemical constitution, an interactive system for the filing and retrieval of chemical structures and substructures has been implemented.

The methods for plausibility checks, of fragmentation, and of substructure access have been realized in a FORTRAN program study. A more advanced system is being implemented

in PL/1. It offers higher performance in substructure retrieval and in substructure/activity correlation.

In order to cope with the conflicting requirements of semantic assistance (for example in synthesis design: recognition of functional groups and common substructures), minimal memory space, and minimal access time, the retrieval of substructures has been segmented into a time consuming fragmentation phase, and a fast retrieval phase.

By fragmentation (phase one) we mean the decomposition of molecular structures into partial structures (fragments) which are generated by breaking one bond, or lowering a bond order. Each particle which is thus obtained is associated with a reference to its immediate precursor (*father* reference), and *vice versa*: The molecule is tagged with references to the partial structures directly generated from it (*son* reference). This process of direct fragmentation is recursively applied to the partial structures, until single atoms are encountered as fragments. Thus one obtains a network in which the molecules and their fragments are the nodes, and the references are the oriented lines.

When the next molecule is fragmented, usually only rather large new substructures are found, while the smaller substructures are recognized as already being documented. They do not need further dissection.

Thus, the production of fragments leads to saturation of the substructure file (Fig. 2).

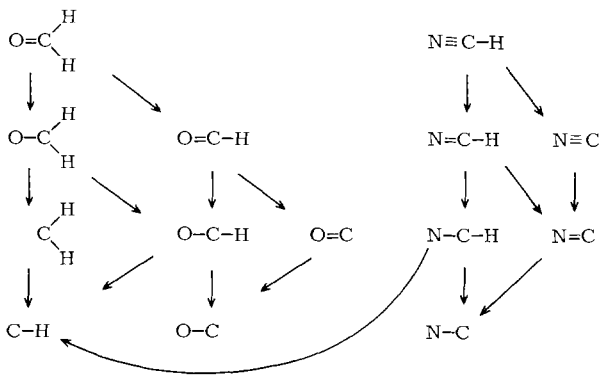

Fig. 2. Fragmentation of formaldehyde and hydrogen cyanide with son references.

A typical request for retrieval of a substructure is treated in the retrieval phase (phase two) as follows: The fragment to be retrieved (*e.g.* C—H) is brought into canonical form. Its memory address is computed from its canonical representation. This enables one to enter the network of references and follow the father references up to the molecule level. Because of the design of the reference network from phase one, the molecules arrived at contain the query fragment as a partial structure.

In the retrieval phase of an analysis of substructure/activity relations one is interested in the substructures common to those molecules which have a certain activity (*e.g.* antioxidant, fungicidal, bacteriostatic). Here, the program tracks the son references which originate from molecules with the considered activity, until, *via* many generations of sons, substructures are found which occur, with statistical significance, more often in the active molecules than in the other molecules[18].

3.1.2. Reactions

The systematics and nomenclature of chemical reactions are far less elaborate than those of chemical structures. It is symptomatic that the customary description of chemical reactions is still largely based on trivial names.

Hitherto, chemical reactions have been represented by their educts and products, wholly in the sense of a statically oriented approach based on structures. Traditional documentation systems for chemical reactions have been designed on this basis.

In terms of the mathematical model of chemistry, this means that two points in the vector space of an *FIEM* are used to describe a reaction. A description by the vector between these points was lacking.

In the description of a chemical reaction we begin with the underlying scheme of electron redistribution. This is represented by an R-matrix. Knowing that a chemical reaction can be represented by matrices of a certain kind (the R-matrices), and that this representation is in itself structured, affords the required generalization. The steps of the generalization are (for chemical reactions): irreducible R-matrices (nucleus of the reaction; see below) ⊃ nucleus of the reaction with associated atomic vector ⊃ BE-matrix of the nucleus ⊃ atomic vectors and BE-matrices of the spheres adjacent to the nucleus.

A given electron redistribution pattern may describe many different reactions which belong to the same R-category (see Section 2.3.2). A collection of chemical reactions grouped in this manner has been published recently (*cf.* Fig. 3)[19].

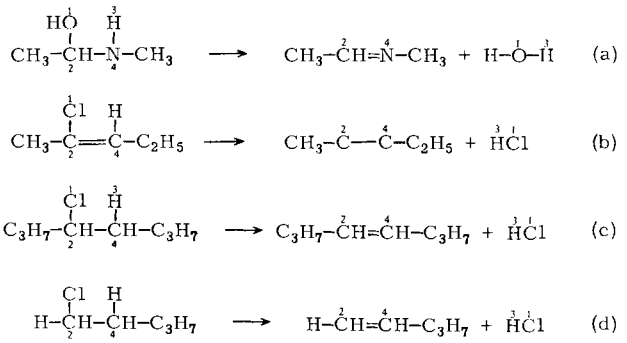

Fig. 3. Four reactions which belong to the same R-category. (a) differs from (b), (c), and (d) by different entries in the atomic vector at the nucleus of the reaction: O, C, H, N in (a), and Cl, C, H, C in (b), (c), (d) (same "RA-type"); (b) differs from (c) and (d) by differences in the BE-matrix at the nucleus of the reaction: $b_{24} = 2$ in (b), $b_{24} = 1$ in (c) and (d) (same "RB-type"); (c) and (d) differ only with respect to the vicinity of the nucleus. The R-matrix of this R-category is

$$\mathbf{R} = \begin{pmatrix} 0 & -1 & 1 & 0 \\ -1 & 0 & 0 & 1 \\ 1 & 0 & 0 & -1 \\ 0 & 1 & -1 & 0 \end{pmatrix}$$

It follows from the mathematical model that only a certain number of irreducible R-matrices can exist within given limits. Each one of these irreducible R-matrices defines an R-category, and any chemical reaction belongs to one of these R-categories. Some limited number of valence schemes may be associated with an R-category. These determine atomic vectors that fit an R-matrix. Here, only those atoms are taken into account which belong to the nucleus of the reaction, *i.e.* the atoms which do not correspond to any one of the all-zero rows/columns of the R-matrix. The distinct atomic vectors partition

an R-category into reaction types which we call the RA-types. These are, in turn, partitioned according to differences in bonding between the atoms of the reacting nucleus, *i.e.* by the differences in the entries in that block of the BE-matrix which belongs to (the atomic vector of) the reacting nucleus. Further specific classifications may be obtained by considering some additional neighboring spheres of the reacting nucleus. With this formalism, reactions may be coded in a general form. This opens new possibilities in the retrieval of reactions having unknown features.

3.2. Prediction of Reaction Products, and the Design of Syntheses

Designing syntheses usually involves analysis of the target molecule of the synthesis for those structural moieties which can be formed through known reactions, and one uses the retroreactions of these for the construction of the synthetic precursors. The realization of such an approach in a computer program would require a data bank of individual chemical reactions. Progressive improvement of such synthesis design programs would necessitate continuous maintenance, updating and extension of the reaction library—and yet a program of this kind could only reproduce known reactions.

Our mathematical model affords an entirely different approach in the design of syntheses[8, 20–22]. The application of R-matrices to BE-matrices of given molecules and *EM*'s leads to the BE-matrices of the reaction products into which they are convertible. The R-matrices may, however, not only be used to describe the conversion of some reactants into products, but they may also be interpreted as retroreactions which lead from the products to the educts. Beginning with the target molecule of a synthesis, one can thus infer the precursors which lead to that target molecule.

3.2.1. Operations with R-Matrices

The program EROS (Elaboration of Reactions for Organic Syntheses)[20] generates, by the action of R-matrices, from the BE-matrix of an ensemble of molecules (*EM*) the BE-matrices of further *EM*'s Depending on the direction in which the reactions are considered, forward or reverse, —this is a matter of formulation—EROS can be used to predict the products which are formed from given compounds, or it may serve in the design of syntheses.

If an *EM* consists of one molecule only, the program generates the products of rearrangements and fragmentations. Further molecules must be added if other types of reactions are to be included; the choice of the supplementary reactants depends on the problem at hand.

An investigation of the products which may be obtained from a given molecule requires the addition of its potential reaction partners: In a study of the products which may be formed from a chemical (*e.g.* an agricultural chemical) in the environment, these are H_2O, O_2, O_3, CO_2 *etc.* When searching for the potential uses of an industrial by-product some readily available chemical can be added as the supplement.

In the design of syntheses, the molecules by which the target molecule is to be augmented cannot be easily determined. A detailed study of the synthetically relevant reactions has shown that here mostly small molecules form the coproducts. One encounters again and again some low-energy species, like H_2O, HCl, NaCl, NH_3, CO_2, N_2. In a retrosynthetic approach, molecules of this kind are combined with the target into an *EM*. Thus those synthetic reactions are accounted for in which these molecules are the coproducts.

Since the mathematical model affords the elaboration of all conceivable reactions, the problem now is their meaningful evaluation from the standpoint of the given problem. A substantial part of the evaluation can be accomplished by the program itself. Physicochemical and heuristic criteria are used for this.

Multiple bonds and bonds involving heteroatoms, as well as their neighboring bonds are broken with preference. Parameters for 1,2- and 1,3-interactions are obtained from thermochemical data, and are used to estimate the enthalpy of the reactions[23].

Several models for estimating the activation parameters of reactions are being tested. The effect of steric influences of a reaction can be determined by looking at the bond lists of the participating atoms. Certain unfavorable combinations of atoms may be recognized through electronegativity considerations[24].

Since syntheses generally involve many steps, the problem of synthesis design cannot be solved by merely generating—from a target *EM* through R-matrices—the precursors of the first level, and subsequently evaluating these. Instead, the precursors of the first level are reintroduced into the program and used to generate precursors of a further level. Repetition of this procedure leads to a "synthesis tree" whose root is the target, and whose nodes are reactions, or molecules, respectively (see Fig. 4).

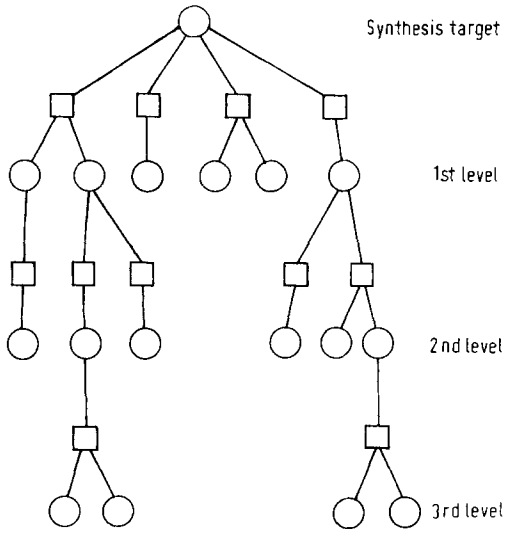

Fig. 4. "Synthesis tree"; ○ molecules; □ reactions.

A reaction may involve more than one precursor. The development of a synthetic pathway is complete when all required precursors can be identified as available starting materials.

In the evaluation of syntheses, it does not suffice to look at the individual steps, *i.e.* the individual synthetic reactions. Each branch of the synthesis tree must be considered as a whole, because success in a synthesis depends on the quality of all steps and the availability of all required compounds.

The program EROS has been used to study the formation of products from given *EM*'s, as well as the design of

syntheses, using examples from the fields of organic synthesis, industrial chemistry, and biochemistry. With such examples the flexibility and prediction capability of EROS could be demonstrated.

The synthetic pathway A encompasses the last two steps of the biosynthesis. Pathway B corresponds to the first two steps of Traube's synthesis of uric acid; its further development involving dicyanamide and glycine ester is novel. It has not

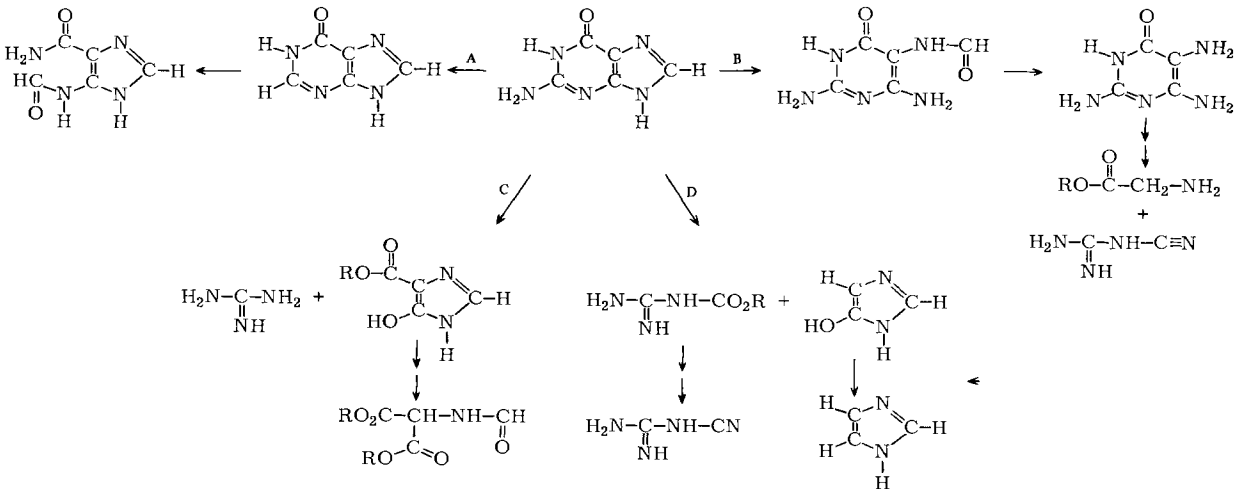

Fig. 5. Selected synthetic pathways which were generated by the program EROS for guanine.

A study of the syntheses of guanine may serve as an illustration. Figure 5 contains a selection of the proposed syntheses.

been checked in the literature whether there is precedence for pathways C and D. In order to influence the direction of

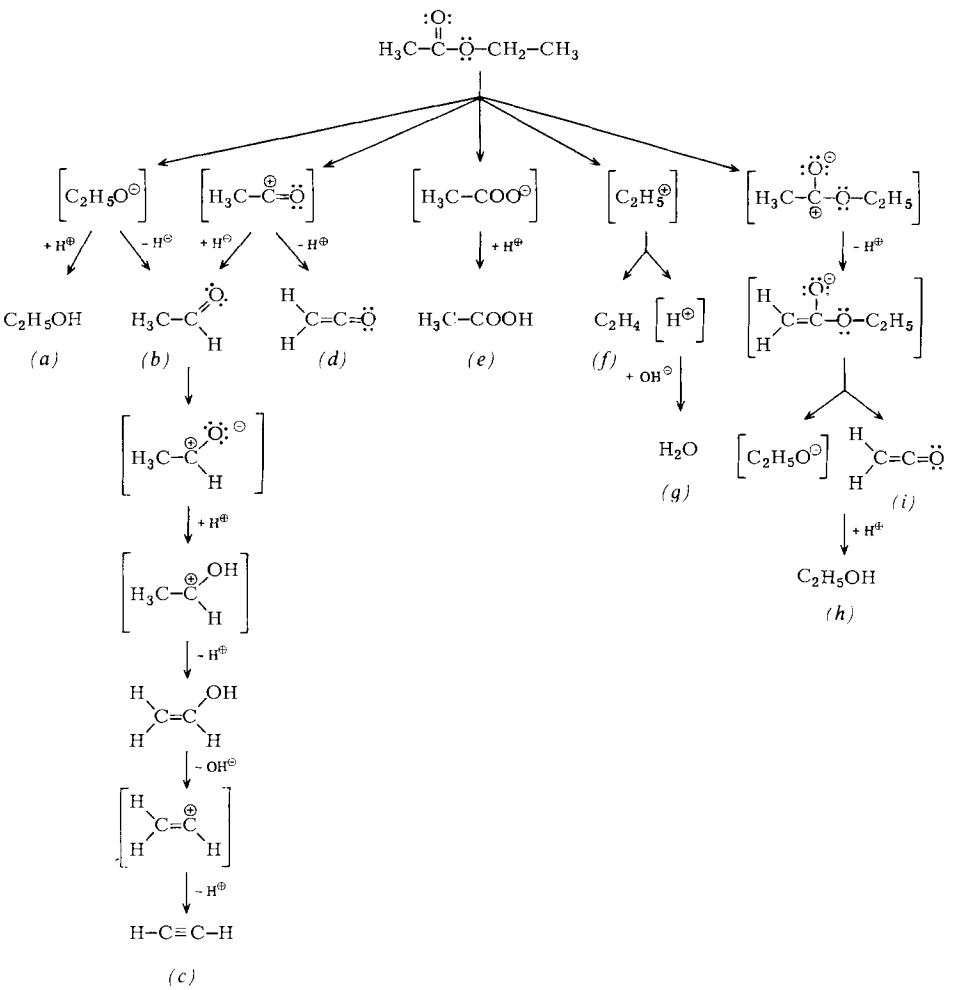

Fig. 6. Synthetic pathways from ethyl acetate which were generated with the basis elements of R-matrices by program system ASSOR. (a)+(e): esterification of acetic acid with ethanol; (b): dimerization of acetaldehyde (*Tischtschenko*); (c): addition of water to acetylene to form acetaldehyde; (a)+(d) or (h)+(i): addition of ethanol to ketene (*Wacker*); (f)+(g): addition of water to ethylene to form ethanol.

the syntheses favorably, it may be necessary to activate some of the reactive sites, and to protect others during certain synthetic steps.

3.2.2. Operations with Basis Elements of R-Matrices

Presently we are developing a program ASSOR[21] which does not use R-matrices as linear combinations of basis elements (see Section 2.3.1), but operates with the basis elements themselves in the simulation of chemical reactions. These basis elements form the simplest *complete* set of R-matrices by which *all* conceivable reactions can be represented. Since a reaction is simulated by the basis elements in terms of its elementary mechanistic steps, it is possible to decide through plausibility checks after any one of these steps whether or not the pathway should be pursued any further. This yields a network of reactions which consists of mechanistic steps. Such a network is free of mechanistically unrealizable branches. Besides this selection, which is associated with the generation of the pathways, further evaluation is still necessary in order to avoid too many proposals.

The result of a trial run with ethyl acetate as the target molecule and water as the coproduct is shown in Figure 6.

3.3. Networks of Reaction Mechanisms and Synthetic Pathways

Reaction mechanisms and synthetic pathways are equally well represented by the mathematical model of constitutional chemistry described above. In the investigation of a reaction mechanism the equation

$$\mathbf{B}+\mathbf{R}=\mathbf{E} \tag{14}$$

describes the overall reaction of the educts to the products. In the treatment of syntheses, eq. (14) refers to the union of all starting materials (**B**), and all products formed (**E**). Thus, in one case **R** indicates the bonds to be broken and made by a single reaction, whereas in the other case it represents all the bonds to be broken and made by the reactions of a whole pathway. Therefore, reaction mechanisms and synthetic pathways can mathematically be treated in rather a similar way. Only when the overall reaction matrix **R** is expanded into the matrices of individual steps, are a reaction mechanism or a synthesis treated differently (see below).

3.3.1. Shortest Reaction Pathways

We know by experience that chemical reactions tend to proceed with the redistribution of a minimal number of valence electrons. We therefore postulate: When a reaction is given in terms of its educts and products, the associated redistribution of electrons corresponds to an overall R-matrix which is close to the minimal chemical distance (D)[25].

If the atoms in the educts and products, *EM* (**B**) and *EM* (**E**) of a chemical reaction are indexed in an arbitrary manner, the mutual assigment of the atoms by their respective indices may falsely indicate a more complex reorganization of bonds and electrons (b) than is actually taking place (a) (Fig. 7).

The aim is to isolate the actual redistribution of bonds and electrons from such formal processes: in *EM* (**E**) the indexing of the atoms of the same chemical element must be permuted in such a manner that the reaction is formally achieved with

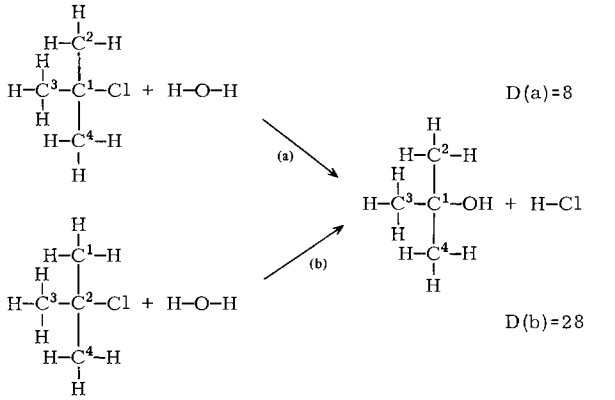

Fig. 7. To illustrate the postulate of minimal redistribution of electrons.

redistribution of a minimal number of electrons. This is equivalent to minimizing the chemical distance (see Section 2.4).

Mathematically, this means a permutation matrix **P** must be found for which the function

$$F(\mathbf{P})=D(\mathbf{B},\mathbf{PEP}^{T}) \tag{39}$$

has a minimal value.

Ansatz: Even with the use of modern computers and problems of moderate size performing all permutations is too time consuming. In the case of educts and products with 10 C-atoms more than three million permutations would have to be carried out.

We are therefore presently studying the applicability of some methods of integer optimization, namely quadratic assignment algorithms[26, 27], to this problem (see Fig. 8). In order to avoid excessive computation time, these methods need to start with a permutation **P**′ for which F(**P**′) is already close to the minimum. We have developed heuristic methods for finding such an approximate solution **P**′. These are based on a comparison of the vicinities $U(A_i,A_j)$ of the atoms A_i in *EM*(**B**) with A_j in *EM*(**E**). Here the attempt

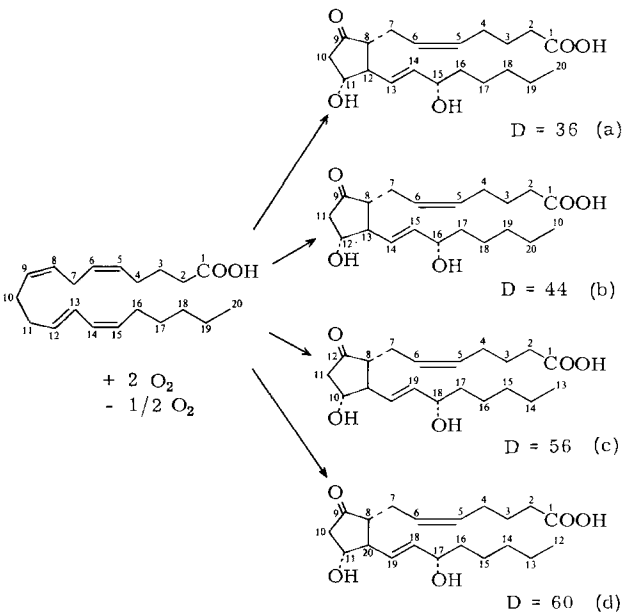

Fig. 8. The formation of prostaglandin E_2 from 5,8,12,14-eicosatetraenic acid and oxygen involving reactions which differ in chemical distance; (a) shows the correlation of the atoms at minimal chemical distance; (b) to (d) are examples for the many correlations near minimal chemical distance.

is made to map the atoms of *EM* (**B**) onto the atoms of *EM* (**E**), such that the vicinities "match" as well as possible.

Once the minimal chemical distance has been determined, we obtain a minimal reaction matrix $\mathbf{R}_{Min}$ by the formula

$$\mathbf{R}_{Min} = \mathbf{PEP}^T - \mathbf{B} \tag{40}$$

A suitable expansion of $\mathbf{R}_{Min}$ into components $\mathbf{R}^i$ with

$$\mathbf{R}_{Min} = \sum_i \mathbf{R}^i \tag{41}$$

leads to a description of the shortest reaction pathways.

3.3.2. Construction of Networks

Let *EM*(**B**) and *EM*(**E**) be some given initial and final *EM*. By minimization of the chemical distance D(**B**, **E**) (see above) we obtain a minimal reaction matrix $\mathbf{R}_{Min}$ which satisfies the equation

$$\mathbf{B} + \mathbf{R}_{Min} = \mathbf{E} \tag{42}$$

In order to find the reaction mechanisms or synthetic pathways by which *EM*(**B**) is convertible into *EM*(**E**), the overall reaction matrix is expanded into sums S^k of components:

$$S^k: \mathbf{R}_{Min} = \sum_i {}^k\mathbf{R}^i \quad (k = 1, \ldots, m) \tag{43}$$

This corresponds to an expansion of an overall reaction into partial reactions. In the elucidation of reaction mechanisms rather small partial reactions may be chosen (*e.g.* a basis vector, or a sum of a few basis vectors), because as many as possible intermediates should be considered, the unstable ones, too. When synthetic pathways are determined the ${}^k\mathbf{R}^i$ are chosen to yield intermediates only. For both types of problems those R-matrix components are also admissible whose entries cancel in the overall matrix, *i.e.* along some reaction pathway certain bonds are broken and remade, and appear as unchanged by the overall reaction.

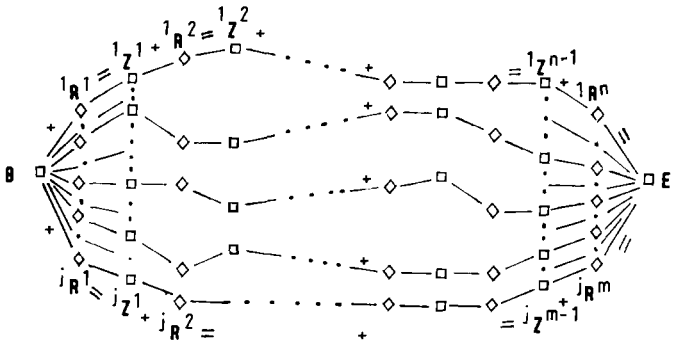

Fig. 9. Construction of a network of synthetic pathways between the educts and products **B** and **E**.

A network of intermediates ${}^k\mathbf{Z}^i$ is constructed from such components of R-matrices (Fig. 9). The components of the reaction matrices must, however, be chosen to yield intermediates that lie close to a shortest pathway within a network of reaction or synthetic pathways. This is so, because, on the one hand, the actual reactions proceed presumably close to a minimal pathway, and on the other hand, synthetic pathways must be rejected as wasteful if they are too remote from a minimal pathway.

3.4. Prediction of Chemical Reactions

In the preceding section we discussed the construction of R-matrices which are acceptable when pairs of BE-matrices are given. Now the opposite approach is described, namely the generation of all reactions which "fit chemically" a given electron redistribution scheme. This means the search for pairs of BE-matrices which "fit" a given R-matrix, The creative aspect of this approach lies in the fact that it leads to a complete set which also contains the reactions without precedence.

To generate *all combinatorially* possible reactions is neither chemically meaningful, nor feasible with present computer technology. Instead, one must restrict the solution space to some domain through suitable boundary conditions. Within

Given reaction scheme

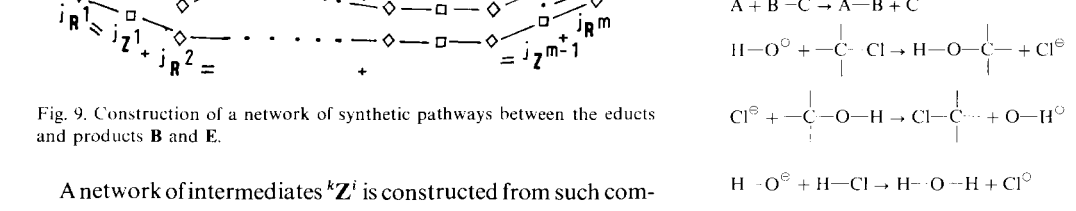
:A + B– C → A—B + :C

Equivalent R-matrix:

$$\mathbf{R} = \begin{pmatrix} -2 & 1 & 0 \\ 1 & 0 & -1 \\ 0 & -1 & 2 \end{pmatrix} \begin{matrix} \text{A} \\ \text{B} \\ \text{C} \end{matrix}$$

Extract from a list of valence schemes:

No.	Symbol	Valence scheme f, s, d, t	Elements
v1	:Ẍ:	8, 0, 0, 0,	Cl; Br; I;
v2	–Ẍ:	6, 1, 0, 0,	O; Cl;, Br; I;
v3	–Ẍ—	4, 2, 0, 0,	O;
v4	—X—	0, 4, 0, 0,	C;
v5	—X	0, 1, 0, 0,	H;



f = number of free electrons; s, d, t = number of single, double, triple bonds, respectively

Possible valence scheme pairs and element assignment:

A	v1→v2	Cl; Br; I;	O; Cl; Br; I;
	v2→v3	O;	
B	v2→v2	O; Cl; Br; I;	O; Cl; Br; I; C; H;
	v3→v3	O;	
	v4→v4	C;	
	v5→v5	H;	
C	v2→v1	Cl; Br; I;	O; Cl; Br; I;
	v3→v2	O;	

Worked out examples:

A + B –C → A—B + C

etc.

Fig. 10. Simplified example for the representation of reactions belonging to the same R-category. The atomic vectors which are compatible with a list of valence schemes (here appreciably abbreviated) describe the whole set of the conceivable reactions, regardless whether or not they are realizable.

this domain exhaustive treatment of the problem is feasible, and desirable. For the R-matrices this can be achieved through suitable restrictions. The BE-matrices can then be generated according to the valence schemes. Such valence schemes are mappings of the individual rows in the BE-matrices. Suitable BE-matrices are constructed from these row by row. The addition of a corresponding row of an R-matrix yields a new valence scheme. Each chemical element is assigned to one or several valence schemes. Each row of the initial, and of the final BE-matrix results in a *pair* of valence schemes. If such a pair is contained in the list of valence schemes of some chemical element, this element may occupy the site in the atomic vector which corresponds to the row in question. As a result one obtains for each site of the atomic vector a list of all allowable element assignments (see Fig. 10). These combinations of element assignments are further restricted by additional valence chemical, physicochemical and heuristic rules.

4. Perspectives

In chemistry, progress is achieved through the results of experiments which have been initiated by heuristically valuable hypotheses. The need for a universal theory with predictive power has not yet been satisfied. As a theoretical foundation of chemistry, quantum theory, too, has not attained the impact which had been expected because of the comprehensive nature of its approach. Up to now, inductive inference and reasoning by analogy have dominated in the interpretation and planning of chemical experiments. When proceeding in this way progress depends very much on chance. In order to open up new possibilities in a systematic manner, it is necessary to supplement the known approaches by deductive procedures. For this the prerequisite is a theory which permits one to take into account all of the conceivable solutions for a wide variety of problems[28].

The theory of *a family of isomeric ensembles of molecules*, as presented in this article, satisfies these requirements. In the mathematical formulation of this theory BE-matrices are used to represent the chemical constitution. The electron redistribution schemes of the chemical reactions are expressed by R-matrices. A chemical reaction is then described by the addition of an R-matrix to a given BE-matrix, according to the master equation

$$\mathbf{B}+\mathbf{R}=\mathbf{E} \qquad (14)$$

of the model.

In this equation **B** stands for the ensemble of molecules at the beginning of the reaction, and **E** for the ensemble on termination of the reaction.

It is essential for the applications of the master equation that it can be solved when one of the matrices is known. This is possible, using our theory. In order to select from the set of all conceivable solutions of the master equation those which are likely to be relevant to the issue, without discarding valuable information, one needs selection rules. These rules must be based on chemical experience. Thus empirical data are used to *restrict, and not to generate*, the solutions of the problems[28].

For the deductive chemical computer programs chemical literature is not only a source of general selection rules; in the form of suitably organized files on chemical compounds and reactions, chemical literature can also be used to determine whether a computer generated solution of a problem is already known. For future developments this approach is particularly promising, because it comprises access to the literature, and it enjoys the advantages of the mathematical model which enables one to take into account all of the conceivable possibilities. As a computer operation, matrix addition is much more effective than the manipulation of data based on published reactions.

The programs which have hitherto been implemented, and the results obtained with them, have demonstrated that computer programs for the deductive solution of chemical problems in combination with suitably organized documentation, will relieve the research chemist in his routine information and planning work, and will call to his attention possibilities which he might otherwise have overlooked. This will never replace the chemist; with the computer and its new applications, however, he has a tool which will help him to perform his tasks more effectively.

We acknowledge gratefully the financial support of our work by Stiftung Volkswagenwerk e.V. (development and testing of mathematical models, in particular in stereochemistry), the Deutsche Forschungsgemeinschaft (synthesis design), the European Communities (Contract Nos. 115-74-10-ENV-D and 310-77-5-ENV-D, documentation and ecology) and the Bundesministerium für Forschung und Technologie, project administrator: Gesellschaft für Information und Dokumentation (classification of reactions). We wish to thank Profs. J. Dugundji, Los Angeles, and R. E. Burkard, Köln, for helpful discussions and stimulating suggestions. The Institut für Plasmaphysik (Garching), and the Leibniz-Rechenzentrum kindly provided us with computer time.

Activation Analysis—Its Present State of Development and Its Importance as an Analytical Tool

By Viliam Krivan[*]

Activation analysis is one of the most important methods available for the determination of traces of elements and of isotopes. One special advantage of activation analysis is its ability to cope with the simultaneous determination of many elements with very high detection sensitivity—for many elements lying below the ppb level. In some cases as little as 10^{-14}—10^{-15} g of an element can be detected. A number of sources of systematic errors common to other analytical procedures, mainly those caused by the blank, are eliminated in activation methods. The disadvantages may be seen as the inconvenience of handling radioactive materials, the dependence on large irradiation facilities, and sometimes the unavoidably long irradiation and cooling periods. On account of its unique capabilities activation analysis finds applications in all fields of endeavor where minute amounts of elements are of significance, from materials research through medicine to archaeology. Further improvements in performance and increases in scope are seen to lie in the development of new radiation sources, activation techniques, measurement systems, and separation procedures.

1. Introduction

A knowledge of the occurrence and content of trace elements in various materials is often absolutely necessary for the success of the actual investigations in fields such as medicine, environmental studies, and life, earth, and materials sciences[1–5]. In many branches of industry trace analysis of elements has already become a routine procedure.

Activation analysis has always played an important role in the determination of trace elements. Following its tempestuous development in the post-war years, the attraction and significance of activation analysis lay primarily in the uniquely high sensitivity which it offered for the detection of many elements. The subsequent introduction of high-resolution Ge(Li) detectors in the sixties opened the way for instrumental multi-element analysis.

In the sixties and seventies, some powerful methods based on atomic spectroscopy and other techniques were developed in addition to activation analysis, and sometimes with comparable sensitivities. It is only since analysts have had access to several high-performance techniques, that they have been able to assess the reliability and accuracy of the individual methods. Comparisons of analytical results obtained by various techniques and in particular of interlaboratory results obtained from collaborative investigations—so-called round-robins—have revealed the real limitations of all these methods[6–8]: the lower the levels of the elements being determined, the greater the deviations of the results obtained by individual laboratories from the mean experimental value, or from the "true" value. At the ppb level and below, deviations of several orders of magnitude are by no means uncommon.

The main problem in element trace analysis is undoubtedly that of the accuracy of the results, *i. e.* the problem of systematic

errors and their elimination. Other criteria such as detection limits, precision, and cost in terms of equipment and manpower are of course very important, but the decisive factor is the extent to which the sources of systematic error can be identified and then eliminated. False conclusions based on spurious analytical results can have far-reaching consequences. The squandering of substantial financial and manpower resources would not even be the greatest evil: "Unfortunately, too many situations exist in which the price of some analytical errors, no matter how infrequent, is measured in lives, and therefore is unacceptable"—this was how *Hirschfeld* described the situation[9].

It is precisely in connection with these problems that activation analysis has begun to reassert itself, for one of its special advantages lies in the complete absence of a number of sources of error characteristic for other methods. Moreover, there are some trace analytical problems which can only be solved by activation methods, such as the determination of oxygen in the lower ppb range. In spite of these special advantages of activation analysis, its significance should not be overestimated and it should rather be considered as just one of the indispensible tools of modern analytical chemistry.

2. Principle of Activation Analysis

Activation analysis constitutes a method for the determination of elements and isotopes (standard texts, see [10–15]). It is based on the conversion of the stable nuclides of the element to be determined into radioactive nuclides of the same element or of a neighboring element with a difference in atomic number of ± 1 or 2. These reactions are induced by irradiating the sample with neutrons, charged particles, or high-energy photons. The indicator radionuclide produced in such a nuclear reaction decays with a known half-life, which process is accompanied by the emission of characteristic radiation. Indicator radionuclides can be identified by these two properties and, considering the appropriate reaction type, they can be attributed to the presence of particular stable nuclides in the original sample. Quantitative determination is based on the linear relationship between the activity of the indicator radionuclide produced and the amount of the element present in the sample. After irradiation, the activity of the sample is measured either directly (instrumental activation analysis) or after prior radiochemical separation processes (radiochemical activation analysis). The principal steps in an activation analysis are summarized in Figure 1.

The relationship between the activity of the indicator radionuclide produced, the amount of the element being determined, and the activation and decay parameters involved is given by:

$$A = \Phi\sigma(m/A_r)h N_A(1 - e^{-0.693 t_B / t_{1/2}}) \quad (1)$$

where A is the activity of the indicator radionuclide (disintegrations per second), Φ is the projectile flux (per cm^2 and s), σ is the activation cross-section (in cm^2), m is the weight of the element present (in g), A_r is the atomic weight of the element, h is the relative abundance of the reacting nuclide, N_A is Avogadro's number, t_B is the irradiation time, and $t_{1/2}$ is the half-life of the indicator radionuclide.

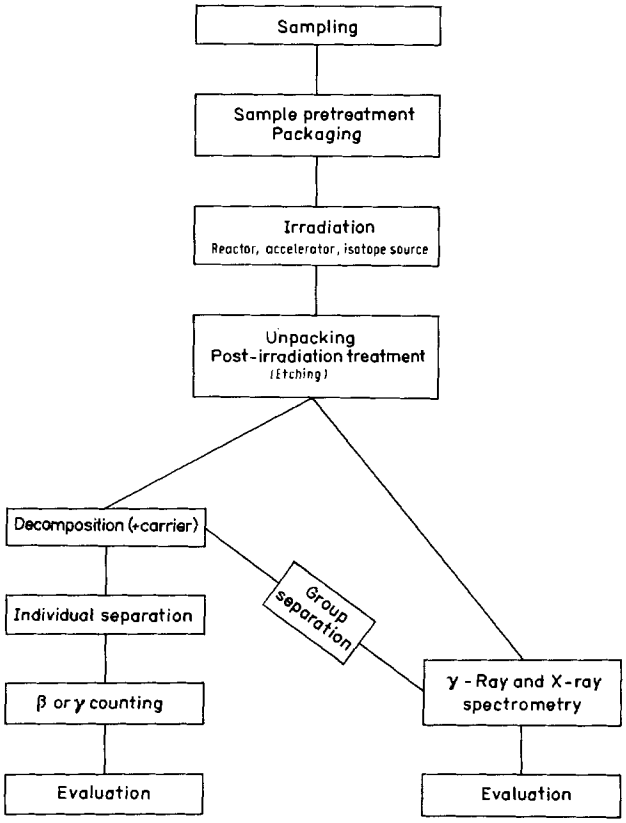

Fig. 1. The sequence of steps in an activation analysis.

The factor which in most cases decides the analytical sensitivity of a given nuclear reaction is the product $\Phi\sigma$. The saturation factor (the term in parentheses) accounts for the decay of the resulting radioactive nuclide during the irradiation period. Figure 2 illustrates the variation of activity with time from the beginning of irradiation to the end of the measurement.

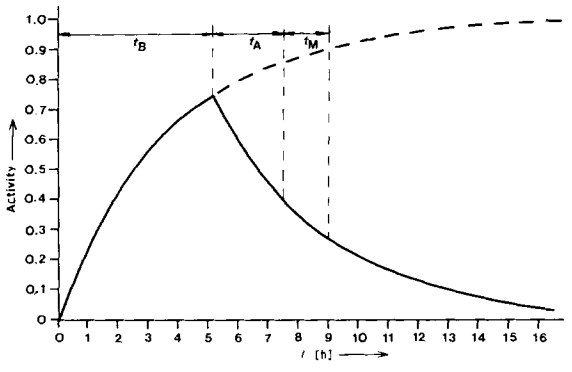

Fig. 2. The radioactivity of ^{56}Mn ($t_{1/2} = 2.58$ h) during and after the irradiation of manganese. The activity is in arbitrary units. t_B = irradiation time, t_A = cooling time, and t_M = measurement time.

The form of the activation equation given by (1) is only valid for cases where the particle flux Φ and the activation cross-section σ can be expressed in discrete values, as for example in activation analysis with thermal neutrons in a reactor or with 14-MeV neutrons. If the energy distribution and the angular distribution of the particles have to be taken into consideration, as in the case of fast neutrons produced by a cyclotron or bremsstrahlung photons, then the product of these two quantities must be integrated over the whole

energy spectrum of the particles and over the relevant solid angle.

Apart from the activation process itself, specific detection of the indicator radionuclide is of fundamental importance for activation analysis. Table 1 summarizes the possible modes of decay, and the types of radiation emitted which may be used for detection of the indicator radionuclides. α-decay is not considered here; it is only of interest for nuclides with $Z > 83$.

Table 1. Possible decay processes of indicator radionuclides and the types of emitted radiation.

Decay process	γ-photon emitted	Possible types of radiation emitted: Particles	Photons
${}^{A}_{Z}X \xrightarrow{\beta^-} {}^{A}_{Z+1}X + \beta^- + \bar{\nu}$	no	β-rays with continuous energy spectrum	bremsstrahlung with continuous spectrum
	yes	β-rays with continuous energy spectrum	mono-energetic γ-rays
		mono-energetic conversion electrons from γ-rays	characteristic X-rays from conversion electrons
			bremsstrahlung with continuous energy from conversion electrons
${}^{A}_{Z}X \xrightarrow{\beta^+} {}^{A}_{Z-1}X + \beta^+ + \nu$	no	positron emission with continuous energy spectrum	511 keV annihilation radiation (gamma) bremsstrahlung with continuous energy from positrons (β^+)
	yes	positron emission with continuous energy spectrum	mono-energy γ-rays
		mono-energetic conversion electrons from γ-rays	511 keV annihilation radiation
			characteristic X-rays from conversion electrons bremsstrahlung with continuous energy from conversion electrons and positrons
Electron capture ${}^{A}_{Z}X + e^- \rightarrow {}^{A}_{Z-1}X + \nu$	no	none	characteristic X-rays from electron capture
	yes	mono-energetic conversion electrons from γ-rays	mono-energetic γ-rays
			characteristic X-rays from electron-capture and conversion electrons
			bremsstrahlung with continuous energy from conversion electrons
Isomeric transition ${}^{Am}_{Z}X \rightarrow {}^{A}_{Z}X + \gamma$ (delayed emission of excitation energy)	only yes	mono-energetic conversion electrons from γ-rays	mono-energetic γ-rays
			characteristic X-rays from conversion electrons
			bremsstrahlung with continuous energy from conversion electrons

β-particles can be detected very easily; however, their continuous energy spectrum generally precludes identification of a radionuclide unless an appropriate chemical separation precedes counting. On the other hand, γ-photons are emitted with discrete energies characteristic for each radionuclide. This is the basis of gamma spectrometry — nowadays the most important counting technique for instrumental activation analysis. The characteristic X-rays associated with each electron capture or internal conversion process can also be used as a means of detection measurement in many cases.

Quantitative determinations can be performed either by the relative (comparative) method or by the absolute standardization method.

In the absolute method[16–18], the amount of element present is calculated from the activities measured with a gamma-ray spectrometer calibrated in absolute terms by using equation (1). Considerable systematic errors can, however, creep in when this approach is used, largely due to the uncertainty in the values for the nuclear constants taken for the calculations[19]. The absolute method should therefore be used with great caution.

For the same reasons, the more time-consuming relative method is mostly used in practice: the sample is irradiated simultaneously with a separate standard for each of the elements to be determined, then both sample and standards are counted. The amount of the element present in the sample is calculated by simple proportions using the ratio of the counting rates of sample and standard and the amount of the element present in the standard. The standards may be purely synthetic, prepared to contain the desired elements, or may be similar materials to the samples, but of known composition. Use of the relative method requires no knowledge of the projectile flux or the detector efficiency.

The time-saving single-standard procedure is being increasingly used in neutron activation analysis[20–23]. In this approach only one element is irradiated as the standard, *e.g.* cobalt, gold, ruthenium, or zirconium, and the amounts of other elements present in the sample are calculated using the previously experimentally determined *k*-factors relating the sensitivities of the chosen standard to that of the element in question.

Finally, it may be possible to use one of the elements present in the sample itself as the standard, provided that suitable radionuclides are produced from this element on activation[24–26].

3. Characteristic Features of Activation Analysis

An impressive array of powerful methods based on a variety of physical principles is available nowadays for the determination of the elements: the analytical procedures using them

can be classified as direct instrumental procedures, or as combined procedures in which dissolution, separation, and sometimes other operations precede the actual measurement step.

The direct procedures for trace analysis, such as optical emission spectroscopy with spark or arc sources, X-ray spectroscopy, and spark-source mass spectrometry permit determination of elements at levels down to the order of 10 to 0.1 ppm, depending on the method, the element, and the matrix composition.

Below these levels, however, the analyst has to rely mainly on the combined procedures of trace analysis. The problem in these methods is to take the μg-, ng-, and pg-amounts of the elements to be determined through all steps of the procedure from sampling to detection without introducing systematic errors. These systematic errors include blanks and losses.

On going to lower trace concentrations, the blank not only determines the limits of detection but also becomes the predominating factor affecting the accuracy in each wet chemical combined method. Recent experience has shown[27, 28] that it is only possible to obtain correct results in extreme trace analysis if extensive precautions are taken to reduce the blank values, such as working in dust-free clean rooms and/or clean benches and using specially purified reagents as has been done, for example, in the analytical laboratories of the U. S. National Bureau of Standards in Gaithersburg[27], and in the Laboratory for High-Purity Materials at the Max Planck Institute in Schwäbisch Gmünd[29]. This is a general principle to be applied in all combined procedures whatever the principle upon which the determination step is based.

Activation analysis occupies a special position in connection with the problem of the blank, even when radiochemical separations are involved. Depending on the nature of the sample, the blank can be almost entirely or largely eliminated. At present, this would seem to be the principal advantage of activation analysis.

The problem of the blank does not occur at all when the samples are compact solids. For example, the contamination on the surface of a metal sample arising from handling before and during irradiation can be removed by etching after irradiation (Figure 1). However, the possibility of enrichment of the trace elements during the etching procedure should not be overlooked[30]. Contamination is no longer possible after the irradiation step; indeed it is common practice to add inactive carriers (1—10 mg) to facilitate execution of radiochemical operations.

In the case of samples which cannot be etched, such as many environmental and biological samples, it is not possible to eliminate all sources of contamination contributing to the blank, but at least the most important—that of contamination from reagents used for dissolution and separation—can be avoided. Possible contamination or losses incurred during sampling, pretreatment and storage, however, must be taken into account in activation analysis as with other approaches. There is also the possibility of contamination from the capsule in which the sample is irradiated[31].

Of all trace analytical methods for the determination of elements, then, activation analysis would seem best to meet the stringent requirements and to offer the best chance of obtaining correct results for elements at extremely low concentration levels, *i. e.* in the ppb range and below.

Another characteristic feature of activation analysis is its high sensitivity: for many elements it is the most sensitive method of determination available. If one considers all the various means of activation, separation of the radionuclides, and counting, and also the possibility of employing short-lived indicator radionuclides, then one can say that practically every naturally occurring element can be determined in ng-amounts or at the ppb level (see Section 4). At the same time the technique offers a high degree of selectivity, since each radionuclide is identified on the basis of two characteristic properties: the energies of the gamma rays or of the X-rays emitted, and the half-life. No other analytical technique offers such a combination of decisive advantages for determinations at the extreme trace level.

Activation analysis employed as a typical multi-element analytical technique can often be carried out nondestructively, which can be of importance when only minute amounts of sample are available. The extent to which the nondestructive approach can be adopted depends on the elemental composition of the sample. However, one has to consider that the analysis is nondestructive only with respect to the elemental composition of the sample material but not with respect to its structure and physical properties which can change as a result of radiation effects during the bombardment. Our experience in activation analysis with thermal and fission neutrons in a reactor, with fast neutrons produced by a cyclotron and with charged particles, has shown that element contents < 0.1 ppm can only occasionally be determined reliably by the nondestructive approach in conjunction with high-resolution gamma spectrometry. Other multi-element instrumental methods would seem to offer similar limits of detection (*e. g.* spark-source mass spectrometry) or worse, even by two or three orders of magnitude (*e. g.* direct optical emission spectroscopy or X-ray fluorescence analysis). In some special cases, the decisive factor may be that activation techniques can be employed for analysis *in situ* and *in vivo*, as well as for localization microanalysis and surface analysis.

Like any other technique activation analysis also has its problems and its limitations. As the information provided by activation analysis is gained *via* nuclear processes and properties, valid analytical conclusions can be drawn only about the amounts of elements or isotopes present, and not about the state of chemical combination. A possible exception involves analytical use of the Szilard-Chalmers reactions which, however, are difficult to handle[32].

A disadvantage is that activation analysis for very low levels requires large and expensive irradiation sources, either to be used in nuclear research centers, or to be purchased at considerable expense. The latter is increasingly the case, although irradiation facilities are generally well organized for use by outside parties at nuclear research centers, particularly at reactor centers.

The necessity of handling radioactive materials certainly complicates experimental work, and sometimes long irradiation and cooling times (up to a few weeks) are required to obtain the desired sensitivities or to be able to process the sample in the post-irradiation steps, all of which can lead to delays in evaluation of the analytical results.

The financial cost of activation analysis largely depends on the source of radiation required and on the time involved (instrumental or radiochemical procedures). The desired preci-

sion and the numbers of elements to be determined and of samples also affect the final cost. If the irradiation is carried out in a nuclear reactor followed by instrumental multi-element analysis (*e.g.* for a rock sample), the cost may be as low as 15 DM per element per sample[33]. When a large accelerator is used for the irradiation, the time factor is most critical as the cost can run to 500 DM per hour. In some cases, then, the high performance of activation analysis must be paid for dearly.

4. The Activation Process

The sources which provide the projectiles usable for activation analysis, and their most important properties, are summarized in Table 2. Three properties of these projectiles are of fundamental significance for activation analysis: the type of particle, the energy, and the intensity. The projectiles of interest are of three types: neutrons, charged particles, and photons. The analytical reaction taking place, and therefore also the indicator radionuclide produced, are determined by the type of projectile used, which is illustrated in Table 3 for copper. For most elements one has a choice of a number of sensitive reactions which can be used, depending on the availability of the radiation sources.

sensitivity is proportional to this factor, as can be seen from equation (1).

Table 3. Some analytically interesting nuclear reactions induced by various particles in copper.

Projectile	Reaction	Cross-section [barn]	Product half-life $t_{1/2}$
Thermal and epithermal neutrons	$^{63}Cu(n,\gamma)^{64}Cu$	4.5	12.7 h
14-MeV neutrons	$^{63}Cu(n,2n)^{62}Cu$	0.52	9.76 min
	$^{65}Cu(n,p)^{65}Ni$	0.024	2.52 h
Protons	$^{63}Cu(p,n)^{63}Zn$	0.56 [a]	38.4 min
Deuterons	$^{63}Cu(d,p)^{64}Cu$	0.30 [a]	12.7 h
^{3}He-particles	$^{65}Cu(^3He,2n)^{66}Ga$	0.28 [a]	9.3 h
α-Particles	$^{65}Cu(\alpha,2n)^{67}Ga$	0.52 [a]	78.3 h
Photons	$^{63}Cu(\gamma,n)^{62}Cu$	0.07 [a]	9.76 min

[a] Maximum of the excitation function.

The type of radiation used also determines the maximum volume of sample which can be handled, the uniformity of the activation of the sample, the necessary cooling during irradiation, and the irradiation time. The accessibility of the source, the cost of irradiation, and other factors should also be taken into consideration.

Table 2. Survey of different activation techniques.

Projectiles and source	Mode of projectile production	Projectile energy	Typical analytical reaction	Projectile flux [$cm^{-2}\ s^{-1}$]	Range of analytical application
Neutrons					
Nuclear reactor	fission	fission spectrum	(n,γ)	high, 10^{12}—10^{15}	trace to extreme trace components with $Z>10$
Neutron generator	$^3T(d,n)^4He$	14 MeV	(n,p), (n,α) (n,2n)	medium, 10^8—10^{10}	main to trace components
Cyclotron	d + Be → n	variable spectrum	(n,p), (n,α) (n,2n)	high, 10^{10}—10^{12}	trace to extreme trace components
$^{252}Cf/^{235}U$	spontaneous and neutron fission	fission spectrum	(n,γ)	medium, 10^8—10^{10}	minor to trace components, elements with $Z>10$
^{252}Cf	spontaneous fission	fission spectrum	(n,γ)	low, 10^6—10^8	main and minor components, elements with $Z>10$
(α,n)-sources	(α,n)-reaction	medium energies, 4—6 MeV	(n,γ), (n,p) (n,α), (n,2n)	low, 10^5—10^6	main and minor components
Charged particles					
$\tau = p,d,^3He,\alpha$ Cyclotron, linear accelerator	acceleration	variable	(τ,n), (τ,2n) (τ,p), (τ,γ)	high, 10^{13}—10^{14} [a]	trace to extreme trace components
Photons					
Electron accelerator	bremsstrahlung production	variable spectrum	(γ,n), (γ,p)	high, 10^{13}	trace to extreme trace components

[a] Number of particles per second; beam intensity = 1 μA = 6.2×10^{12} singly charged particles per second.

Some of the sources listed in Table 2 yield particles with variable energy. This is often a very important aspect, since, in each particular case, optimum projectile energy can be chosen with regard to the sensitivity of the analytical reaction, to the occurrence of interfering reactions, and/or to the instrumental performance of the analysis. The projectile flux (or the beam intensity) is of course also important, since the

4.1. Activation with Neutrons

Since neutrons carry no electrical charge they can easily penetrate the sample material. This facilitates (i) uniform irradiation throughout the sample and (ii) standardization since both sample and standard can be irradiated simultaneously. The high penetrating power of neutrons brings with it further

important advantages: the samples can be irradiated in closed containers (made, *e.g.*, from high-purity quartz or polyethylene) which prevent the escape of volatile substances and reduce the risk of contamination to a minimum. The sample material is not heated to high temperatures during the irradiation, which may be advantageous for biological materials, for example.

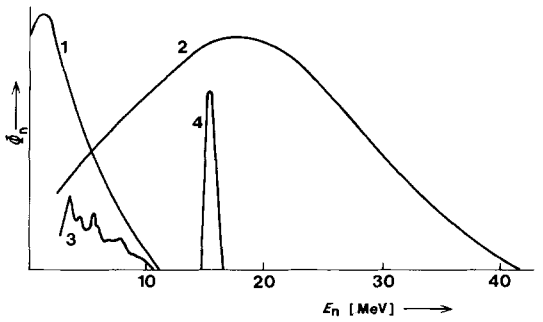

Fig. 3. Energy spectra of neutrons from different sources 1, nuclear reactor and ^{252}Cf isotope source; 2, cyclotron: beryllium target bombarded with 40-MeV deuterons; 3, ^{241}Am/Be isotope source; 14-MeV neutron generator. Φ_n = neutron flux (arbitrary scale).

Neutron sources for activation analysis are nuclear reactors, particle accelerators, and radioactive nuclides. The neutrons from these sources differ markedly in both energy spectrum and flux (see Figure 3 and Table 2) and therefore permit a differential approach to activation analysis.

4.1.1. Activation with Reactor Neutrons

Nuclear reactors are the most intense sources of projectiles. According to design, they can provide steady fluxes of up to 10^{15} neutrons cm^{-2} s^{-1} or pulsed neutron fluxes of up to 10^{18} neutrons cm^{-2} s^{-1}. For most reactors, the steady fluxes lie in the range 10^{12}—10^{14} neutrons cm^{-2} s^{-1}.

There has been notable recent progress in the development of nuclear reactors for use in activation analysis. Small reactors of the new generation are good value for money, easy to handle, reliable in operation, and yet relatively powerful. For example, fluxes of 3.5×10^{12} neutrons cm^{-2} s^{-1} can be achieved in the mini-TRIGA reactor, and 10^{12} neutrons cm^{-2} s^{-1} in the recently developed Slowpoke-2 reactor[33a]. Pneumatic sample-handling facilitates the speedy transfer of samples into and out of the irradiation position. These small reactors are in many instances well suited to the requirements for good sensitivity in trace analysis, as has been shown by the analyses of biological, environmental, and other samples[34, 35].

With few exceptions, activation analysis using nuclear reactors is based on the production of radionuclides *via* (n,γ) reactions with thermal neutrons (energies E_n ranging from zero to 0.2 eV) and with epithermal neutrons (E_n between 0.2 eV and 0.5 MeV), while the (n,p) and (n,α) threshold reactions caused by fast neutrons ($E_n > 0.5$ MeV) must be considered as possible primary interfering reactions. The thermal activation cross-section σ_{th} and the activation resonance integral I vary considerably from one target nuclide to the next[36]. Values of σ_{th} lie between 2.4×10^{-5} barns for the reaction ^{15}N(n,γ)^{16}N and 5300 barns for ^{151}Eu(n,γ)^{152g}Eu.

In principle, it is possible to carry out activations in a reactor using neutrons of varying energies[12, 37], since the spectrum of fission neutrons at the irradiation positions of the reactor normally includes thermal, epithermal, and fast neutrons. In such irradiations the highest flux of thermal neutrons can be achieved, and hence also the highest sensitivity for the determination in question, since the contribution of thermal neutrons is responsible for the (n,γ) reactions; however, the epithermal neutrons can also contribute to production of the indicator radionuclide by way of (n,γ) resonance activation. For this reason irradiation with fission neutrons is most commonly employed in activation analysis.

When the analysis is carried out instrumentally, the limits of detection can often be considerably improved by eliminating the thermal neutrons and activating only with resonance neutrons. Sometimes instrumental activation analysis is possible only by this approach, for example when irradiation with resonance neutrons suppresses the production of interfering activity from the nuclides of the matrix elements and leads to a relatively increased production of indicator radionuclides from the element to be determined. Activation by the thermal neutrons, the flux of which is generally much higher than that of the others, can be eliminated by surrounding the sample with a filter of cadmium or of boron[38] as these elements absorb the thermal neutrons almost completely while transmitting the resonance neutrons practically without attenuation. Activation using resonance neutrons has been used in recent years for the analysis of geological[39–42], biological[43–46], and environmental[47] samples, with limits of detection considerably lower than had previously been attainable, *e.g.* lower by a factor of about 20 for the determination of U, Th, Mo, W, As, and Sb in granitic rocks.

Activation analysis in a reactor is characterized by a very high sensitivity of detection for most elements. The figures quoted in Table 4 give some impression of the detectabilities which can be achieved using reactor neutrons, 14-MeV neutrons, and photons.

The methodology of activation analysis with reactor neutrons is well established, and as far as the activation step is concerned, is unlikely to be improved on much. It is possible to make good estimates of the limits of detection and nuclear interferences for determinations of all the elements. Significant improvements are only likely to be made in the separation and measurement techniques involved in the post-irradiation steps.

4.1.2. Accelerators as Sources of Fast Neutrons

For the determination of a number of elements, activation with fast neutrons *via* threshold reactions of the (n,p), (n,α), (n,2n), and (n,n'γ) types is a well suited technique since such reactions lead to the production of suitable indicator radionuclides in relatively high yields.

The most important source of fast neutrons is the neutron generator[13], in which 14-MeV neutrons are produced in the reaction ^{3}T(d,n)^{4}He. To induce this reaction, an intense beam of deuterium ions is produced, with energies in the range 50 to 600 keV, and focused onto a tritium target from which the neutrons are emitted with a fairly uniform 4π angular distribution. The commercially available generators provide neutron fluxes of the order of 10^9 neutrons cm^{-2} s^{-1}.

These fluxes, together with acceptable activation cross-sections, which are now quite well characterized[36] and exhibit

systematic trends[48,49], enable an impressive number of elements to be determined with good sensitivity (see Table 4). However, 14-MeV activation analysis is limited by the following three factors: by the relatively low neutron flux (compared with reactor fluxes), by the invariable, and for many elements unfavorable, neutron energy of 14 MeV, and by the limited operating life of the tritium target and the resulting operating cost.

Recently, a high-power neutron generator has been developed at the Nuclear Research Center at Karlsruhe which yields 5×10^{12} neutrons s^{-1}[50], from which a flux of 6×10^{10} neutrons cm^{-2}s^{-1} can be achieved for irradiating samples up to 25 cm^3 in volume. The working life of the tube was several hundred hours. Work is in progress[51] at the Sandia Laboratories on a high-power neutron generator which is designed to yield 5×10^{13} neutrons s^{-1} and fluxes of up to 5×10^{11} neutrons cm^{-2}s^{-1}. These new generators now make it possible to apply activation analysis with fast neutrons to the determination of elements even below the ppm level. In some cases it will be possible to make use of nuclear reactions not previously used for analytical purposes, such as, for example, in the determination of silicon *via* the reaction ^{29}Si(n,p)^{29}Al ($t_{1/2}$ for ^{29}Al = 6.6 min) which does not suffer from any interfering reactions, while in the reaction previously employed ^{28}Si(n,p)^{28}Al the indicator radionuclide can also be produced by two other reactions, namely ^{27}Al(n,γ)^{28}Al and ^{31}P(n,α)^{28}Al.

Very promising development possibilities are offered by the use of a cyclotron to produce fast neutrons of variable energy. Though in principle a large number of reactions could be used to produce neutrons[52-54], bombardment of a thick beryllium target with high-energy deuterons has proved to be best suited[55,56]. The neutrons are produced largely as

Table 5. Characteristic parameters for cyclotron-produced neutrons emitted in the forward direction [55, 56].

E_d [MeV]	Neutron yield [n s^{-1} μA^{-1}] [a]	Energy distribution maximum [MeV]	FWHM of the energy distribution [MeV]	FWHM of the angular distribution [b] [°]
18	1.2×10^{10}	6	8.3	31.6
23	1.8×10^{10}	7.5	10.5	27.4

45	5.1×10^{10}	18	17.3	19.5
53	7.3×10^{10}	22	19.0	19.0

[a] For neutrons with energy $E_n \geq 2$ MeV and angular range $0 < \varphi < 20°$ (see Figure 5).
[b] Relative to the original direction of the deuteron beam.

a result of stripping and break-up processes, and are emitted preferentially in the forward direction distributed as a cone. The sample is positioned so as to lie in this cone of neutrons as indicated in Figure 4. Figure 5 illustrates the energy spectra for neutrons in the forward direction over a range of angles $0 < \varphi < 20°$ resulting from bombardment with deuterons of different energies. Table 5 summarizes the fluxes which are attainable at the sample position, along with other characteristic parameters, for various energies of deuterons. As the deuteron beam current available usually lies in the range 10—50 μA, the fluxes of fast neutrons which can be achieved from this source are higher than those which can be produced by other sources.

All this makes it possible to achieve exceptionally high sensitivities and correspondingly low limits of detection by the use of cyclotron-produced fast neutrons. Approximations based on systematics of the excitation functions[57] have indicated that the limit of detection attainable when 14-MeV neutrons are used (with a flux of 10^{10} neutrons cm^{-2} s^{-1}) can be improved by a factor of between 20 and 100[55]. The experimentally determined sensitivities and limits of detection

terons. In each particular case the energy spectrum of the neutrons can be optimized with respect to the sensitivity of the determination and the minimization of interfering reactions, *i.e.* the maximum in the energy distribution of the neutrons can be made to coincide with the maximum in the excitation function for the analytical reaction.

Activation using cyclotron-produced neutrons has recently been made use of for the determination of fluorine in a variety of samples, including geological ones, *via* the $^{19}F(n,2n)^{18}F$ reaction with subsequent separation of the ^{18}F (limit of detection = 2.5 ng), for multi-element analyses (K, Ca, Ti, Fe, Rb, Sr, Hg, Pb) of several Bowen and NBS reference standards[59], and for the determination of oxygen in metals[60].

4.1.3. Radioisotope Sources of Neutrons

The radioactive neutron sources possess a number of noteworthy advantages. They are entirely reliable systems with no mechanical or electrical components, and they are simple, clean, and cheap. Two types of isotopic neutron sources are in use: the spontaneous fission emitters and the two-component sources. The most important of these are listed in Table 7.

Table 6. Limits of detection for activation analysis with cyclotron-produced neutrons and 14-MeV neutrons for the elements Mg, Al, Si, P, Zr and Mo.

Analytical reaction	Limit of detection in g [a] Cyclotron neutrons [b]			
	E_d = 15 MeV	E_d = 30 MeV	E_d = 45 MeV	14-MeV neutrons [c]
$Mg + n \rightarrow {}^{24}Na$	1.1×10^{-6}	1.1×10^{-7}	3.8×10^{-8}	1.1×10^{-5}
$^{27}Al(n,p)^{27}Mg$	1.1×10^{-7}	1.7×10^{-8}	5.8×10^{-9}	2.1×10^{-6}
$Si + n \rightarrow {}^{28}Al$	4.8×10^{-8}	6.9×10^{-9}	2.2×10^{-9}	7.5×10^{-7}

$Mo + n \rightarrow {}^{97}Nb$	1.1×10^{-4}	2.3×10^{-6}	2.9×10^{-7}	7.4×10^{-4}

[a] Activity assumed to be necessary for detection of indicator radionuclide: 0.1 nCi for $t_{1/2} > 30$ min and 0.5 nCi for $t_{1/2} < 30$ min at the end of the irradiation. [b] Deuteron beam current = 10 μA. [c] Neutron flux = 10^9 n cm^{-2} s^{-1}.

for Mg, Si, Al, P, Zr, and Mo activated by cyclotron-produced fast neutrons and by 14-MeV neutrons are compared in Table 6[58].

A further advantage in using cyclotron-produced neutrons for the activation is that the mean energy of the neutrons can be varied by varying the energy of the accelerated deu-

For a number of years the availability of ^{252}Cf has made it possible to produce quite a powerful source of fission neutrons in a very small volume (see Tables 2 and 7). The energy spectrum of the neutrons resembles that of fission neutrons

Table 7. Characteristics of the principal radionuclide neutron sources.

	Cf	Am/Be	Pu/Be	Ac/Be	Sb/Be

from ^{235}U, so that the resulting reactions are usually of the (n,γ) type. These ^{252}Cf sources have already found employment in a number of laboratories[61–64].

A recent development utilizes ^{235}U as a neutron multiplier surrounding the ^{252}Cf source. Each neutron reaching the shield produces further neutrons, which are in turn moderated by passage through polyethylene or water. The use of such subcritical systems can lead to thermal fluxes being multiplied by factors between 25 and 100. As an example one might quote a source consisting of a milligram of ^{252}Cf surrounded by 1.4 kg of 93.4 % enriched ^{235}U, which, with a multiplication factor of 33, produces a thermal neutron flux of 4×10^{8} neutrons $cm^{-2}\ s^{-1}$[65]. A similar source with 2 mg of ^{252}Cf was installed in the laboratories of Eastman Kodak[66]. The most intense source of this kind has recently been developed at the Battelle Laboratories in Richland (USA) and commissioned specially for use in activation analysis[67]. This installation consists of six ^{252}Cf sources with a total weight of 105 mg which are positioned in a subcritical lattice of rods of 93.2 % enriched uranium, and produces a thermal neutron flux of 3.5×10^{10} neutrons $cm^{-2}\ s^{-1}$ (see Figure 6).

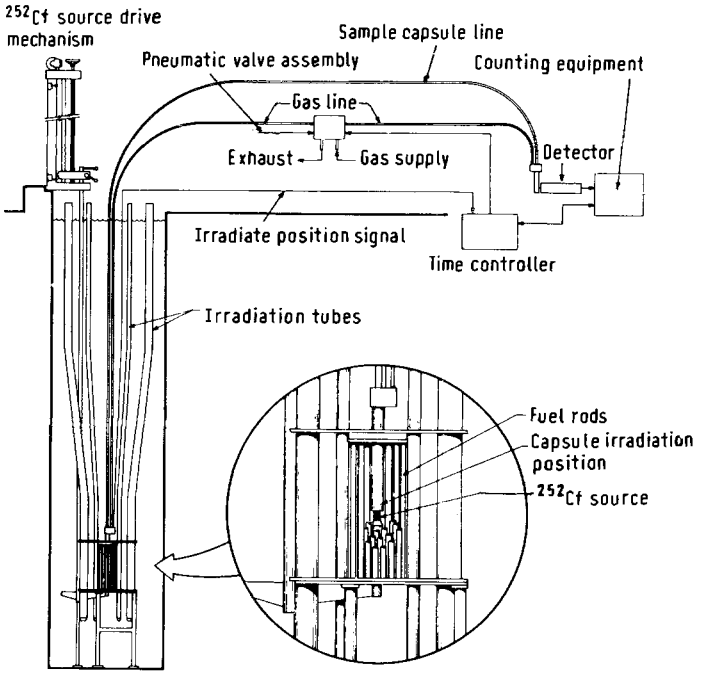

Fig. 6. A ^{252}Cf neutron source with ^{235}U neutron multiplier shield capable of producing a thermal neutron flux of $3.5\times10^{10}\ cm^{-2}\ s^{-1}$ [67].

Thanks to the constancy of the neutron flux and of its energy spectrum it is possible to work with short-lived indicator radionuclides with repeated cyclic irradiations so as to improve the limits of detection. Table 8 presents some limits of detection which have been achieved using the source at the Battelle Laboratories just mentioned.

Table 8. Limits of detection for activation analysis with neutrons produced in a subcritical assembly containing 105 mg of ^{252}Cf with 93.2 % enriched ^{235}U as neutron multiplier [67].

Limit of detection, in ppm [a]	Element
0.001	Eu, Dy
0.001— 0.01	Mn, In, ^{129}I, Ir, Au, Lu, Ho, Sm, Re
0.01 — 0.1	Na, Sc, Co, Ga, Br, Ag, Sb, I, Cs, La, Pr, Tm, Yb, Ta, W, Pt, As, Se
0.1 — 1.0	Ar, K, Cr, V, Cu, Cd, Ce, Nd, Gd, Tb, Er, Hg, Hf, Ge, Sr, Na
1.0 — 10	Cl, Zn, Mo, Ru, Rh, Pd, Te, Ba, Os
10 — 100	F, Mg, Al, Ti, Ni, Sn, Rb, Y
100 —1000	Ca, Fe, Zr
1000	Pb, O, S

[a] Based on the assumptions: amount of sample = 1 g, activity measured = 200 counts, efficiency of the Ge(Li)-detector = 15 %. The lowest limit of detection was selected from those given by four combinations of irradiation time t_B, cooling time t_A, counting time t_M, and number of cycles:
1) 6 s, 1 s, 6 s, for 50 cycles
2) 1 h, 5 min, 30 min, 1 cycle
3) 1 d, 1 h, 30 min, 1 cycle
4) 7 d, 1 h, 30 min, 1 cycle.

These new neutron sources certainly offer an alternative to the large irradiation facilities (nuclear reactors) for many applications, and are well suited for use in universities, research centers, industrial laboratories, and hospitals.

The two-component sources[68, 69] consist of an alpha- or gamma-emitting isotope and beryllium, in which the neutrons are produced in (α,n) or (γ,n) reactions. Neutron fluxes from such sources can only reach values of between 10^5 and 10^7 neutrons $cm^{-2}\ s^{-1}$, and they are therefore suitable only for the determination of major or at best minor components. On the other hand, because the stability of these sources is so good, both with respect to time and to spatial distribution of the neutron flux, the results obtained from their use in activation analysis can show high precision and accuracy[70, 71].

4.2. Activation with Charged Particles

In contrast to the behavior of neutrons and photons, charged particles are quickly slowed down and stopped when they hit the sample (see Figure 7). This has many consequences, not least for the question of standardization. It makes a difference whether the samples to be irradiated are thick or thin. The necessary mathematical treatments have been performed for both cases, which take into account the degradation of energy of the particles and the way in which this affects the activation processes: these are the procedure of the equiva-

lent thickness, for thin samples[73], and the procedure of the average cross-section, for thick samples[74]. In the case of thin samples, sample and standard are irradiated simultaneously. In the more usual case of irradiation of thick samples, the activation is achieved with a continuous energy spectrum between the original particle energy on the surface of the sample and the threshold energy for the given reaction at the depth corresponding to the effective penetration of the particles in the sample. Since, however, the cross-section is strongly dependent on the energy of the particles, the amount of indicator radionuclide produced exhibits a distribution depending on the depth in the sample. An example of this is shown in Figure 8. With thick samples, simultaneous irradiation of sample and standard is only possible with some kind of rotating arrangement, which, however, results in a lowering of the activity produced. Because of this the sample and the standard are usually irradiated separately, and the intensity of the particle beam is measured with a Faraday cup or a monitor foil.

The rapid deceleration of the fast particles can result in the sample being heated up, and therefore necessitates efficient cooling of the sample during the irradiation. Even then, beam currents over 10 μA can rarely be used.

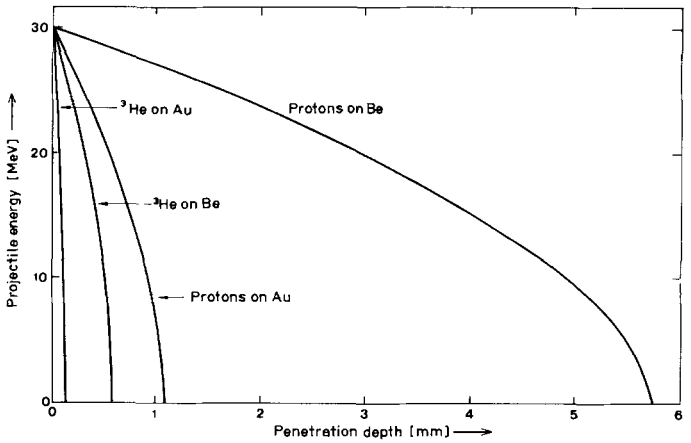

Fig. 7. Energy degradation of 30-MeV protons and ^{3}He-particles when they penetrate targets of beryllium or gold [72].

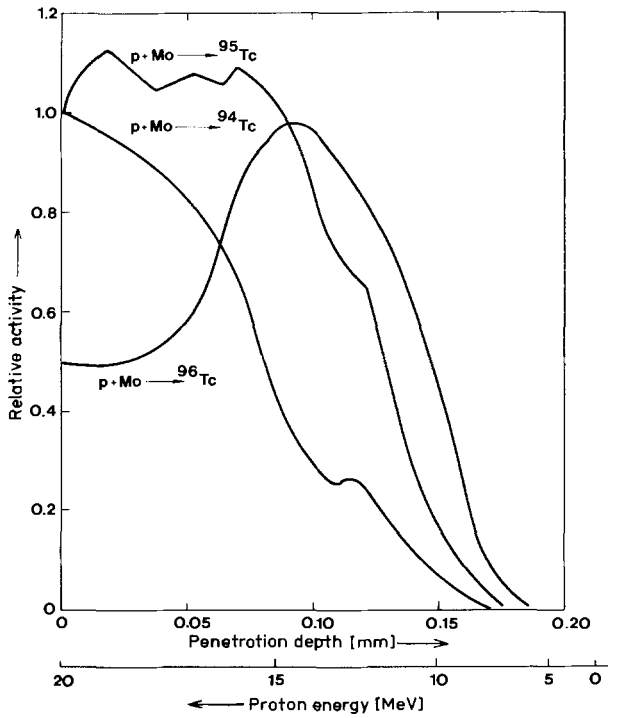

Fig. 8. Irradiation of a thick molybdenum target with 20-MeV protons: relative distributions of the radionuclides ^{94}Tc, ^{95}Tc, and ^{96}Tc as a function of the penetration depth of the proton beam.

Table 9. Survey of the most important data for projectiles and analytical reactions used in activation analysis with charged particles.

Particle/ binding energy [MeV]	Most important reaction types	σ_{max} [mbarn]	Position of maximum [MeV]
p	(p,n)	100—900	8—15
	(p,2n)	200—1300	17—27
	(p,pn)	100—600	23—43
	(γ,α)	20—200	7—23
d	(d,n)	30—400	2—13
2.2	(d,2n)	200—1100	11—17
	(d,p)	100—500	4—15
^{3}He	(^{3}He,n)	10—100	5—13
7.7	(^{3}He,2n)	20—300	15—25
	(^{3}He,p)	40—400	6—17
	(^{3}He,pn)	100—700	12—20
	(^{3}He,α)	20—400	6—22
α	(α,n)	50—1000	12—23
28.3	(α,2n)	100—1300	25—33
	(α,p)	100—600	16—30
	(α,pn)	50—1000	27—42

Table 9 summarizes a number of important parameters for the commonly used charged particles. One can see that for any given target nuclide and any given type of particle, a number of reactions is possible, so that for practically every element at least one, and usually several sensitive nuclear reactions can occur and give rise to the production of indicator radionuclides with suitable properties. Tritons (^{3}H nuclei)[75] and heavy particles[76] have also been used to induce analytical reactions. Thanks to the relatively high cross-sections for such activation processes (several hundred millibarns) and the high beam intensities which can be used (10^{12} to 10^{14} particles per second) trace elements can be determined at the ppb level and lower. It is a great advantage that the most suitable particle and the optimum energy can be selected for each application. Typical limits of detection for a number of elements are given in Table 10.

The most suitable source of charged particles for use in activation analysis is the cyclotron[84, 85]—particularly the recently developed compact cyclotrons with variable energy of the external beam. These machines are small, simple to operate, and considerably cheaper to buy than the big cyclotrons of the old generation. Figure 9 shows as an example the CV-28 compact cyclotron (Cyclotron Corporation, Berkeley) which can produce particle energies in the external beam in the following ranges: protons, 2—24 MeV, deuterons, 4—14 MeV, ^{3}He, 6—36 MeV, and alpha particles, 8—28 MeV. These compact cyclotrons are suitable for use, besides activation analysis, also in other fields of applied research and in nuclear medicine. In the Federal Republic of Germany alone, seven compact cyclotrons have been installed in recent years, four of them of the variable energy type, and similar

Table 10. Limits of detection for activation analysis with charged particles for the light and some heavy elements.

Element	Activation reaction	Particle energy [MeV]	Limit of detection in ppb [a]	Ref.
Li	$^{7}Li(p,n)^{7}Be$	15	19.4	77
Be	$^{9}Be(^{3}He,n)^{11}C$	20	4.9	78

Pb	$^{206}Pb(p,n)^{206}Bi$	22	12.9	84

[a] Beam intensity = 5 μA, irradiation time = $2\,t_{1/2}$ or at most 5 h. The limit of detectability of the indicator radionuclide is based on 0.1 nCi for $t_{1/2} > 30$ min, and 0.5 nCi for $t_{1/2} < 30$ min.

Fig. 9. The variable-energy compact cyclotron model CV-28 (produced by Cyclotron Corporation (Berkeley)).

developments can be observed in other industrial countries. They are therefore quite likely to find increasing application in the field of activation analysis.

4.3. Activation with Photons

Photon activation analysis represents an interesting extension of the techniques discussed so far. It offers good sensitivities for a large number of elements (see Table 4) and combines some of the advantages of neutrons with those of charged particles for carrying out the activation. Samples are effectively transparent to high-energy photons, as they are to neutrons, thus simplifying standardization. The similarity with charged particles lies in the possibility of varying the energy spectrum of the bremsstrahlung photons.

The determination of most elements depends on (γ,n) type reactions[86, 87]. This has the disadvantage that practically all the radionuclides produced by such reactions are positron emitters, in which case the annihilation process giving rise to a line at 511 keV in the gamma spectrum can cause difficulties. For a number of elements the (γ,p) and (γ,γ') type reactions can also be of analytical interest.

Photon activation analysis requires a beam of gamma rays of variable energy up to about 30 MeV. The only way to produce a beam of these high-energy photons with an adequate intensity is to bombard a metal target of high atomic number with high-energy electrons, thus giving rise to the emission of bremsstrahlung radiation. The bremsstrahlung photons show a continuous spectrum, the maximum energy of which corresponds to the energy of the accelerated electrons (Figure 10). The shape of the energy spectrum depends on the target material and on the energy of the electrons. The spatial distribution of the photon beam shows a sharp maximum in the forward direction relative to the direction of the electron beam[88].

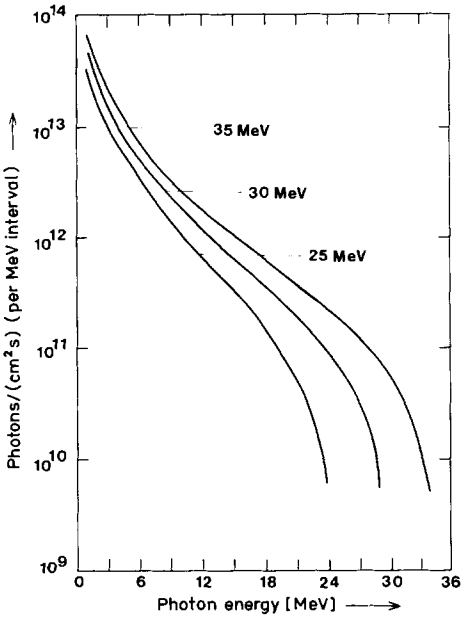

Fig. 10. Bremsstrahlung spectra produced by bombarding a tungsten target with 25-, 30-, and 35-MeV electrons [87]. Electron beam current assumed to be 100 μA.

The most important type of electron accelerator capable of producing a beam of electrons of sufficiently high energy and intensity (up to about 100 μA) is the Linac (linear accelerator)[89, 90]. It is also possible to accelerate electrons to the energies required in a betatron, but this type of machine provides neither an adequate intensity nor a sufficiently stable energy required for activation analysis.

The practical application of photon activation analysis is therefore restricted by the very small number of suitable linear accelerators which are available for such work: in the whole of the Federal Republic of Germany and West Berlin, for example, there is only one, at the Bundesanstalt für Materialprüfung in Berlin.

4.4. Interfering Nuclear Reactions

Several kinds of nuclear reactions can occur in the activation which can upset the expected proportionality between the activity of the indicator radionuclide and the amount of the element to be determined. If these interfering reactions are not taken into consideration they can be the cause of very serious systematic errors in analyses. We differentiate between

primary and secondary interfering reactions, and second-order interfering reactions.

Table 11. Examples of primary interfering reactions.

Projectile	Analytical reaction	Threshold energy [MeV]	Primary interfering reaction	Threshold energy [MeV]
Fission neutrons	$^{23}Na(n,\gamma)^{24}Na$	0	$^{24}Mg(n,p)^{24}Na$	4.9
			$^{27}Al(n,\alpha)^{24}Na$	3.2
Fast neutrons (14 MeV)	$^{28}Si(n,p)^{28}Al$	4.0	$^{31}P(n,\alpha)^{28}Al$	2.0
			$^{27}Al(n,\gamma)^{28}Al$	0
Protons	$^{51}V(p,n)^{51}Cr$	1.6	$^{55}Mn(p,\alpha n)^{51}Cr$	9.6
			$^{52}Cr(p,pn)^{51}Cr$	12.3
^{3}He-particles	$^{16}O(^3He,p)^{18}F$	0	$^{19}F(^3He,\alpha)^{18}F$	0
	+	3.8	$^{20}Ne(^3He,\alpha p)^{18}F$	3.1
	$^{16}O(^3He,n)^{18}Ne$		$^{23}Na(^3He,2\alpha)^{18}F$	0.4
	$\beta^+ \rightarrow {}^{18}F$		$^{24}Mg(^3He,2\alpha p)^{18}F$	13.5
			$^{27}Al(^3He,3\alpha)^{18}F$	11.5
Photons	$^{12}C(\gamma,n)^{11}C$	18.7	$^{14}N(\gamma,t)^{11}C$	22.7
			$^{16}O(\gamma,\alpha n)^{11}C$	26

Primary interfering reactions are those in which the indicator radionuclide is produced in nuclear reactions between the original bombarding particles and nuclei of other elements in the sample than the one being determined. Table 11 shows some examples of such interferences for the different activation techniques. These interfering reactions can often be eliminated by suitable choice of particle energy. The primary interfering reactions in activation analysis with reactor neutrons are easily predicted and can in the main also be evaluated by calculation using the appropriate nuclear data, and to a large extent this is also true for activation with 14-MeV neutrons[91]. For the other activation techniques the excitation functions are generally not known with sufficient accuracy for corrections to be carried out purely by calculation[92]. The contribution from these interfering reactions is therefore normally determined experimentally from activation curves. Figure 11 shows an example.

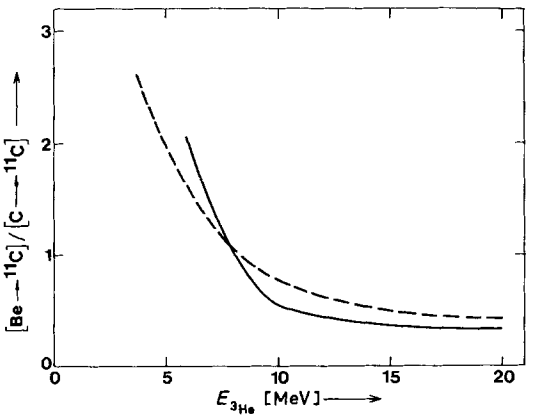

Fig. 11. The extent of interference by beryllium on the determination of carbon by activation analysis with ^{3}He as a function of the ^{3}He energy, $E_{^3He}$. Comparison of the calculated ---- [92] and experimentally found —— [93] ratio of the amount of ^{11}C formed from beryllium and from carbon. The amounts of beryllium and carbon present are assumed to be equal.

Secondary interfering reactions are those in which the indicator radionuclide is produced in nuclear reactions between secondary particles and nuclei of other elements in the sample than the one of interest. They arise almost exclusively in the case of activation with high-energy projectiles. The secondary particles can be produced in reactions between the primary projectiles and the sample material or its surroundings (see Table 12). Activation with charged particles[52-54, 80] or with photons[94] sometimes gives rise to considerable neutron fluxes (see Section 4.1.2). When organic matter is irradiated with fast neutrons, protons are produced by collisions between neutrons and hydrogen atoms. For instance, the interfering reaction $^{16}O(p,\alpha)^{13}N$ occurring in the determination of nitrogen by the reaction $^{14}N(n,2n)^{13}N$ can cause errors equivalent to several hundred ppm[95].

Table 12. Examples of secondary interfering reactions.

Projectiles	Analytical reaction	Production of secondary particles	Interfering reaction
Fast neutrons	$^{14}N(n,2n)^{13}N$	p-knock-out	$^{13}C(p,n)^{13}N$
			$^{16}O(p,\alpha)^{13}N$
Protons	$^{15}V(p,n)^{51}Cr$	(p,xn)	$^{50}Cr(n,\gamma)^{51}Cr$
			$^{52}Cr(n,2n)^{51}Cr$
Deuterons	$^{12}C(d,n)^{13}N$	Stripping, break-up, and (d,xn)	$^{14}N(n,2n)^{13}N$
Photons	$^{25}Mg(\gamma,p)^{24}Na$	(γ,xn)	$^{23}Na(n,\gamma)^{24}Na$
			$^{27}Al(n,\alpha)^{24}Na$

Second-order interfering reactions are those involving the products of the primary reactions. They fall into two categories:

1) The decay product of a radionuclide, arising from activation of a neighboring element also present in the sample, can be identical with the target nuclide of the element being determined or with its indicator radionuclide. For example, if phosphorus is to be determined in silicon *via* the reaction $^{31}P(n,\gamma)^{32}P$, then the interference arising from the processes

$$^{30}Si(n,\gamma)^{31}Si \xrightarrow[2.6\,h]{\beta^-} {}^{31}P(n,\gamma)^{32}P$$

must be taken into consideration when the phosphorus level lies below 0.1 ppm[96]. Similar interferences have been reported in about 65 cases of activation with thermal neutrons[97–100].

2) The quantity of indicator radionuclide produced can be reduced substantially if it has a high effective cross-section (say 10^3—10^4 barns) for the (n,γ) reaction. This phenomenon is known as double capture. As an example one might mention the determination of tantalum *via* ^{182}Ta as the indicator radionuclide, where, at long irradiation times, ^{183}Ta is produced *via* the processes

$$^{181}\text{Ta} \xrightarrow[21\ \text{barn}]{n,\gamma} {}^{182}\text{Ta} \xrightarrow[8200\ \text{barn}]{n,\gamma} {}^{183}\text{Ta}$$

by which an error of up to 10% can be introduced[101]. This type of interfering reaction need only be considered for very long irradiation times with high projectile fluxes, *i.e.* only in the case of activation with reactor neutrons.

The attenuation of the projectile flux within the sample itself has also to be taken into account as a possible source of systematic errors. This effect is particularly significant in activation with thermal or epithermal neutrons, since a number of elements have very high total effective capture cross-sections for these entities. As a rule, this effect must be considered when the sample contains more than one gram of a matrix element with a cross-section greater than about one barn. The attenuation of the flux can be estimated satisfactorily by calculation or by graphical correction procedures[102–105]. Similar correction procedures have also been worked out for activation with 14-MeV neutrons[106–107], or with photons[86,108]. When charged particles are used for activation, the problem to be considered is their decrease in energy as they pass through the sample[109].

5. Instrumental Activation Analysis

Whether the indicator radionuclides produced during the irradiation can be detected by purely instrumental means or must first be subjected to a radiochemical separation from the matrix elements (see Figure 1) will depend on the irradiation and cooling, on the composition of the matrix, on the decay characteristics of the activation products, and on the measuring equipment available.

5.1. Gamma-Ray and X-Ray Spectrometry

Gamma-ray spectrometry provides the basis for instrumental activation analysis[110–112]. As it involves the use of much the same equipment, X-ray spectrometry can be seen as an extension of this field. Figure 12 shows schematically the construction of a gamma-ray spectrometer. At the present time, high-resolution semiconductor detectors, such as Si(Li), Ge, and Ge(Li) detectors, are used almost exclusively. The most important performance criteria for a detector system are the energy resolution, the efficiency, the peak-to-Compton ratio, and the linearity between the pulse height and the energy of the gamma photons. Each of these three detectors exhibits its optimum performance in a different energy region of the gamma-ray spectrum, but all three offer excellent linearity.

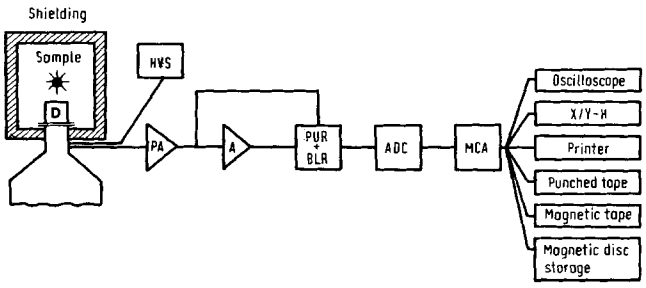

Fig. 12. Schematic construction of a gamma-ray spectrometer: D = detector; HVS = high-voltage supply; PA = pre-amplifier; A = linear amplifier (main amplifier); PUR = pile-up rejector; BLR = baseline restorer; ADC = analog-to-digital converter; MCA = multi-channel pulse-height analyzer.

The Si(Li) detectors possess exceptionally good efficiency for photon energies in the range 1—30 keV, and also offer the best energy resolution. For energies between 30 keV and about 150—200 keV small intrinsic germanium or planar Ge(Li) detectors are most suitable. An additional advantage of the intrinsic germanium detectors is that they can be stored at room temperature, while the lithium-drifted detectors must be kept permanently cooled with liquid nitrogen. These low energy photon detectors give relatively low background due to Compton scattering from gamma-rays of higher energy and permit attainment of enhanced peak-to-background ratios in the low energy region.

Gamma rays with energies higher than 150—200 keV are normally counted with a Ge(Li) detector. Large lithium-drifted germanium detectors have recently become available with an energy resolution down to 1.7 keV (FWHM) for 1.33 MeV photons, an efficiency over 30% of that of a 3×3″ NaI(Tl) crystal detector, and a peak-to-Compton ratio up to over 50:1, though they are not cheap. The efficiency depends not only on the size but also on the shape of the detector. For a given size, the maximum efficiency is obtained with a well-type detector[113,114]. However, it must be kept in mind that both the peak-to-Compton ratio and the energy resolution are lowered with this type of detector.

Users should be aware that semiconductor detectors can themselves be sources of systematic errors, due for example to the counting geometry being wrong[115], to the efficiency decreasing with time[116] or varying from one part of the detector to another[117].

The capabilities of a high-resolution gamma-ray spectrometer depend also on the electronic system[118,119], since the energy resolution, the peak symmetry, the linearity, and the time resolution are dependent both on the detector itself and on the amplification and analysis circuitry. Modern gamma-ray spectrometer systems use a FET pre-amplifier followed by a linear amplifier with "pole-zero control", "pile-up rejector", and "baseline restorer" circuits. At energies > *ca.* 100 keV and at counting rates up to around 10^4 per second, using the above-mentioned equipment, the energy resolution depends largely on the detector. In low-energy photon detection, the energy resolution has been considerably improved by using preamplifiers with "pulsed optical feedback". For example, with a lithium-drifted silicon detector or an intrinsic germanium one, a resolution of 145 eV can be achieved for photons of 5.9 keV. Inserting a "pile-up rejector" in the amplification circuit effects a significant improvement of the energy resolution at high counting rates[120], as this arrangement

permits distinction between the undistorted pulses which are accepted and the distorted ones which are rejected. An example is shown in Figure 13. It should be added, however, that the pile-up effect cannot be completely eliminated using the pile-up rejector.

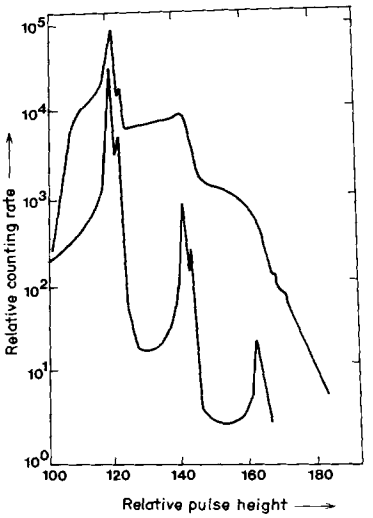

Fig. 13. Spectra of ^{55}Fe recorded without (above) and with (below) pile-up rejector, using a Ge(Li) detector system at a counting rate of 40000 cps [121].

A gamma-ray spectrometer system recently developed[122,123] is capable of producing high-quality spectra with input counting rates as high as 10^6 counts/s, with the energy resolution for the ^{60}Co peak at 1.33 MeV remaining constant up to 3.2×10^5 counts/s (see Figure 14). Electronic systems such as these are going to become of increasing importance for instrumental activation analysis, since in the detection of short-lived radionuclides high energy resolution and high counting rates are conflicting requirements.

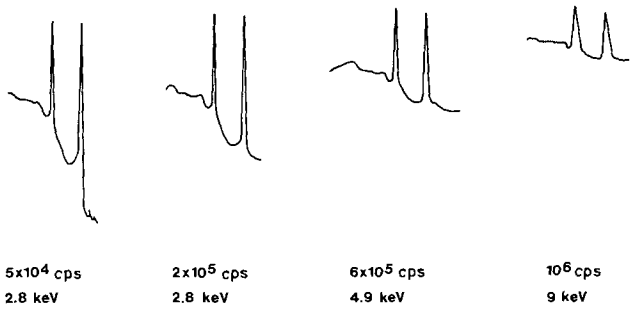

Fig. 14. Sections from gamma-ray spectra of ^{60}Co recorded with an improved high-performance gamma spectrometer system for different counting rates [123]. The energy resolution for the 1.33-MeV line is given for each case.

Computer-controlled multichannel analyzers are nowadays considered indispensible for the measurement, evaluation, and interpretation of gamma-ray spectra. The most important aspects of practically all spectrum evaluations are smoothing, peak-finding, determining the position and the net area of the peaks, peak fitting, resolving complex peaks, identifying the radionuclides present, and calculating the amount of the element present in the sample, along with limits of detection and error analysis. Numerous evaluation procedures and programs have been developed to computerize activation analysis (for a critical review, see [124]).

Because of the complexity and the great amount of data measured, efforts have been made to automate the evaluation and interpretation of gamma-ray and X-ray spectra, and even the entire measurement procedure, by incorporating an automatic sample-changer[125–127].

5.2. Special Counting Techniques

The presence of Compton continua in the spectra still presents a major problem in gamma-ray spectrometry as it can often drastically impair the limits of detection of an activation analysis procedure. The scope of instrumental activation analysis can be broadened considerably if special counting techniques are used which are highly specific or which suppress the Compton background.

Coincidence counting arrangements allow the selectivity to be improved and the limit of detection to be lowered. The two-channel system normally used consists of two detectors. Two (or more) gamma-rays to be observed in the two detector circuits are selected using two timing single-channel analyzers. Use of the coincidence technique makes it possible to employ instrumental activation analysis even at the ppb level and sometimes lower than that. The disadvantage of this technique is the considerable reduction of the counting rates and therefore the necessity of long counting times. A further inconvenience is that only one radionuclide can be measured at any one time as the equipment is effectively a single-channel spectrometer.

The performance of gamma-ray spectrometry can be significantly improved if the contribution of the Compton-scattered gamma-rays to the pulse-height spectrum is suppressed by the use of anticoincidence counting techniques[128–130]. In this technique the Compton scattering radiation in one detector is compensated for by a second detector. The electronic circuitry is so arranged that only those pulses are selected and stored which do not coincide with events in the second detector. The extent to which the Compton background can be suppressed depends very much on the size, design, and geometrical arrangement of the two detectors. Very good results can be obtained with an asymmetric arrangement like that depicted in Figure 15. As the example in Figure 16 shows, it is possible with modern anticoincidence spectrometers to reduce the Compton background by a factor of up to 20 in the low-energy part of the spectrum where it is normally most serious, and thus to improve significantly

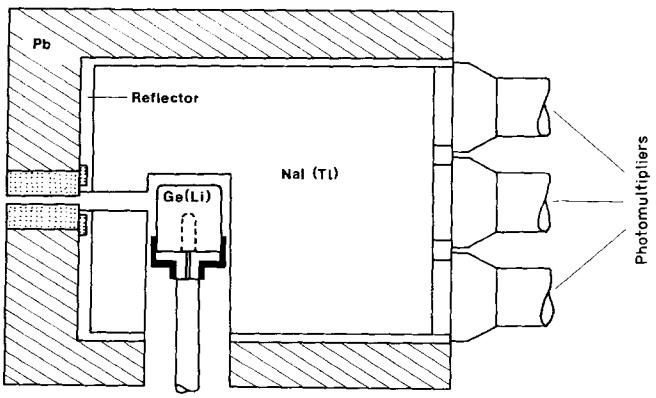

Fig. 15. Construction of a detector system for anticoincidence spectrometry.

the limit of detection of instrumental activation analysis[131]. This approach has been used with success in the analysis of biological and evironmental samples[129, 130], of meteorites and lunar samples[132], and of high-purity materials[133]. In contrast to the limitations of coincidence counting techniques, anticoincidence techniques do allow the simultaneous detection of many radionuclides in the whole energy region of interest, and, furthermore, the use of the anticoincidence principle does not cause any considerable losses in peak intensity.

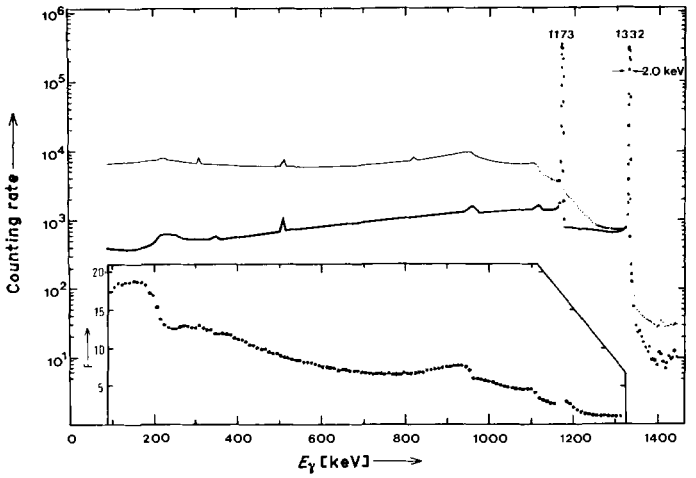

Fig. 16. Spectra of ^{60}Co, taken with a conventional gamma-ray spectrometer (upper spectrum) and taken with an anticoincidence spectrometer (lower spectrum) [131]. The Compton suppression factor F as a function of gamma energy is shown in the lower part of the figure. A 100-cm^3 Ge(Li) detector and a 9 × 9" NaI(Tl) detector were used. The numbers over the peaks are the energies of the gamma photons in keV.

A further problem in X-ray and gamma-ray spectrometry is presented by the interference due to β-particles. They give rise to bremsstrahlung which contributes significantly to the background in the low energy part of the spectrum, increase the dead-time, and impair the energy resolution of the spectrometer system. It is possible to place a magnet between the sample and the detector so that the electrons are deflected from their path and their interference is largely eliminated[133a,133b]. The background can be reduced by up to 99% by this means (see Fig. 17).

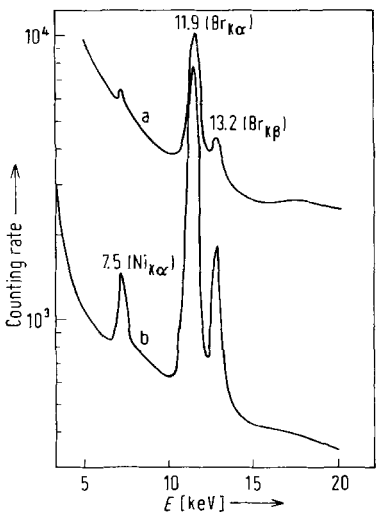

Fig. 17. X-ray spectra from a sample of hair irradiated with reactor neutrons [133b]. Sample size = 90 mg, irradiation time = 30 min, measuring time = 40 min. Curves were recorded a) without and b) with a magnetic field being used to deflect beta rays away from the detector.

6. Radiochemical Separations

The limitations of instrumental activation analysis by gamma-ray spectrometry are, as we have seen, determined largely by Compton and bremsstrahlung background, by the relatively low efficiency of the semiconductor detectors used, and by possible overlapping of gamma spectral lines from different radionuclides. For these reasons, radiochemical separations are often unavoidable.

All the common separation techniques used in trace analysis, and a few special ones as well, can be applied to activation analysis. According to the function of the separation step a distinction is to be made between a) separation of the radionuclides produced from the matrix, b) separation of groups of elements, and c) selective individual separations. The most important criteria for choice of a separation technique are high speed—dependent on the half-life of the radionuclide being determined—high yield, and high selectivity.

6.1. Removal of the Radionuclides Produced from the Matrix Elements

It is often sufficient to eliminate the activity of the matrix, or any other predominating activity, by a suitable single separation and to rely on the gamma-ray or X-ray spectrometer for subsequent resolution of the minor components. As an example we can consider the application of activation analysis to the determination of trace impurities in high-purity selenium: the ^{75}Se produced in extremely high yield from the matrix element can be removed up to 99.9999% by bromination and distillation of volatile $SeBr_4$, leaving 14 trace elements to be determined by gamma-ray spectrometry with a Ge(Li) detector[134].

When biological samples are activated by reactor neutrons, it is the ^{24}Na which is responsible for most of the activity – up to 99% in some cases. If the activity of the sodium can be specifically removed, then many elements can be determined simultaneously by gamma-ray spectrometry. Several procedures, utilizing a variety of separation principles, have been suggested for separating the sodium from the other elements, but the simple approach of *Girardi et al.*[135, 136], in which the sodium is adsorbed onto hydrated antimony pentoxide while 58 other ions are quantitatively eluted with 12 M hydrochloric acid (yields in the range 97–100%), is probably of the greatest practical importance. Almost all the essential and the toxic trace elements are included in this number. For some samples it may be necessary to remove ^{32}P, ^{82}Br, and ^{42}K before the trace elements are determined, but procedures similar to that outlined for sodium have been developed for such cases[137–139].

6.2. Group Separations

If it is not possible to tackle an analytical problem by the direct instrumental approach or by preliminary removal of the matrix activity, it may be helpful to try a group separation scheme: the radionuclides produced by activation are

separated into groups, each of which can then be examined by gamma-ray spectrometry.

When developing such separation schemes one attempts to collect in each group indicator radionuclides of similar activities but with well separated gamma energies and sufficiently different half-lives. Many useful schemes have been developed over the years, which depend on a number of basic separation principles, or combinations of these, such as liquid-liquid extraction, ion-exchange, column chromatography, and distillation. Some examples are given in Table 13. Group separation schemes have in common the advantage over individual separation procedures that they are quicker to carry out and relatively easy to automate.

Table 13. Examples of group separations used in activation analysis.

Elements and groups	Separation techniques	Typical sample material	Ref.
[Br,I,Os] [Ir,Mo,Pa,W] [Cd] [Zn] [Fe,Ca,In] [Co,Cu,Np] [Hf,Sc,Zr] [Ag] [Cr,Mn,Ni] [Ba,Ca,Mg,Sr] [Cs,K,Rb] [Na,P] [Au,Hg,Re,Tc] [Sb,Sn] [As,Se] [Lanthanoids]	Distillation, ion-exchange, extraction-chromatography	Biological	[152]
[Ag,Cl,Br] [Au,Ba,Pt,Ta] [Mn] [In] [Cu,As,Se,Sb,Pd] [Fe] [Cr,Hf,Sc] [Ni] [Co,Ga,Zn] [Ca,Sr] [K,Rb,Cs] [Lanthanoids]	Liquid-liquid extraction, precipitation	Geological	[153]
[As,Br] [Na,Ta] [Zn,Sb,Hg] [Fe,Co,Cu,Ga,Np,W,Mo] [Hf,Zr,Sc,Pa] [K,Rb,Cs,Sc,Ba,Sr,Cr,Ca] [Lanthanoids]	Distillation, adsorption, ion-exchange, liquid-liquid extraction	Geological and biological	[154]

6.3. Individual Separations

Maximum efficiency can be attained in activation analysis in terms of limit of detection, accuracy, and number of elements which can be determined when the respective indicator radionuclides are selectively separated from each other after the irradiation. The activity of each nuclide can then be measured with a simple but efficient detector system using for example a Geiger-Müller tube or a sodium iodide well-type crystal scintillation counter. This type of procedure is capable of exploiting to the full the very high potential sensitivity of activation analysis.

6.3.1. Individual Separations with Determinations of Yield

In these procedures, a known amount of carrier (1—10 mg) is added to the sample after its irradiation to assist the separation of the desired indicator radionuclide. Thus it is possible to separate a relatively high and always constant amount of the component in question—assuming that the amount of the element in the sample is negligibly small in comparison to the amount of carrier added. After chemical equilibration, the carrier is separated from the mixture of nuclides: this separation need not be quantitative, as long as the yield is determined by some conventional chemical method such as gravimetry, titrimetry, spectrophotometry, or atomic absorption spectrometry. It is even possible to add another radionuclide—a radioisotope not produced by irradiation under the conditions used for the sample—in order to check the yield. When this approach is adopted, activation analysis combined with individual separation and determination of the carrier recovery yield is capable of giving correct results even for very low concentrations of elements, at or below the ppb level.

The disadvantage of the individual separation procedure with yield determination is the high cost in terms of man-hours and use of ancillary equipment.

6.3.2. Substoichiometric Separations

The necessity of determining the yield can be avoided by making use of the principle of substoichiometry in separation[140]. In this approach the sample and the standard are irradiated simultaneously and are then treated in exactly the same way. After the irradiation and dissolution steps, the same amount of inactive carrier is added to both the sample and the standard solutions and then a fixed amount is recovered following the addition of an equal and substoichiometric amount of reagent to each solution. The relative activities of the two portions are then measured under the same conditions and the amount of the element present in the original sample is calculated on the basis of the measured activities, without the need for a yield determination.

Most of the published substoichiometric procedures involve liquid-liquid extraction of metal chelates using complexing reagents to effect the separations[141–143]; but some procedures use other separation techniques including precipitation, ion-exchange, and electrolytic deposition with equal success.

One important condition must be fulfilled when less than the stoichiometric amount of reagent is added: the reagent must still react quantitatively with the carrier element. The need to meet this condition often causes problems connected with the danger that the reagent can also react with other species present. Recently a new and universally applicable substoichiometric procedure has been developed[144] which represents a significant advance for radiochemical activation analysis, especially when one considers how simply elements even at the ppb level can be determined both precisely and accurately. In this development, similar amounts of all the matrix elements are added to both sample and standard after the irradiation step. The addition of the same amount of non-irradiated sample to the standard irradiated is the simplest and most elegant way of ensuring identical chemical conditions for the separation step on both sample and standard. The interferences which may arise do so to the same extent for

both, and the determination remains free from the unknown error. As an example one might cite the determination of traces of gold in the presence of gallium, which normally interferes strongly, in samples of silica. The exceptionally high precision for the gold value of 26.6 ± 0.3 ng could be obtained when the amount of gallium in sample and standard was varied over the range 0—2.5 mg.

6.3.3. Other Separations

In addition to the procedures just described, isotope-exchange procedures[145] and mass separators[146, 147] have been employed for certain specific separations of indicator radionuclides. The results obtained in the development of very rapid separation methods[147a, 147b] give grounds to hope that the capability of activation analysis by way of short-lived indicator radionuclides can yet be significantly improved.

6.4. Separation and Enrichment Prior to Irradiation

There are some applications in which activation analysis can only be used successfully when combined with a separation or enrichment step preceding irradiation.

Separation before irradiation is unavoidable when activation produces only a low activity of a short-lived indicator radionuclide but large activities of interfering radionuclides with a similar or even longer half-life, and when no simple, rapid dissolution and separation procedure is available.

Enrichment before irradiation is necessary if the contents of the elements to be determined are very low and therefore very large volumes of samples must be irradiated in order to achieve enough activity of the indicator radionuclides for measurement. The maximum volume of sample which can be taken for irradiation is, however, in most sources limited for technical reasons, and prolonged irradiation of liquid samples is not possible. Such problems may be encountered with a variety of samples of natural origin including water, air, and blood. Drying, ashing, chromatography, ion-exchange, extraction, coprecipitation, and other procedures have been employed for enrichment of trace elements[148].

The determination of trace elements in glacier ice samples by neutron activation analysis can serve as an example of enrichment prior to irradiation[149]. The drilled core ice pieces are melted and filtered through a membrane filter. The filtrate is treated with a small amount of ammonium nitrate as carrier for dissolved trace elements, and is then freeze-dried. The dried residue is then taken for analysis. Instrumental activation analysis is used for the determination of Al, V, Ca, Cl, Mn, Na, K, and Br, while radiochemical separations precede the determinations of Cu, Mo, Cd, Zn, As, Sb, Fe, Co, and Se along with the lanthanides. The amounts determined lie between 2×10^{-6} g for cobalt and 2×10^{-11} g for samarium.

Trace levels of Ba, Ca, Cd, Ce, Co, Cr, Cu, Fe, La, Mg, Mn, Se, V, Y, and Zn have been determined in samples of sea and fresh water by neutron activation analysis following pre-concentration of the ions on a mixture of Chelex-100[*] and glass powder[150]. Active charcoal[151] and other carrier substances have also been used as collectors for the enrichment of trace elements in water samples.

[*] The ion-exchanger Chelex-100 is a styrene-divinylbenzene copolymer containing aminodiacetic acid groups.

The wide use of this approach should not detract from the fact that the unique advantage of activation analysis in having virtually no blank or errors through losses is discarded the moment any separation or enrichment step is introduced prior to irradiation. For this reason, such procedures should be avoided whenever possible.

7. Special Activation Analysis Procedures

7.1. Activation Analysis Using Very Short-Lived Indicator Radionuclides

The technical requirements for the use of very short-lived indicator radionuclides with $t_{1/2} < 1$ s have been fulfilled in recent years. Ultra-high-speed transport systems incorporating automatic separation of the sample from the transporting capsule have been developed[155, 156] which permit measurement to be started only 30 ms after the end of irradiation; the transport time is reproducible to within $\pm 1.5\,\%$.

Another important factor upon which the detection of short-lived radionuclides depends has been the development of gamma-ray spectrometers capable of handling the extremely high counting rates involved[122, 123] (see Section 5.1). The use of such high-speed transport systems and counting equipment, together with pulsed reactors, 14-MeV neutron generators, and cyclotrons has made it possible to determine 34 elements *via* indicator radionuclides with half-lives $t_{1/2} < 1$ s, 18 of them, including Li, Be, and B, by neutron activation. These three elements, for example, cannot be determined by conventional neutron activation analysis. Table 14 presents some data for analytically interesting reactions of this type. The hard β-rays are detected by a Cherenkov counter, or by coincidence counting using two thin discs of plastic scintillator material[157]. Good limits of detection have been achieved in some cases, for example 0.5 μg for lead using reactor activation[156], and < 1 ppm for Li, B, and C using activation by charged particles[157].

Table 14. Nuclear reactions producing radionuclides with half-lives < 1 s, and properties of the reaction products.

Reaction	$t_{1/2}$ [ms]	E_{max} of the β [MeV]	E_γ [MeV]

7.2. Analyses Involving Detection of Prompt Radiation

The detection of new particles or of gamma photons formed during a nuclear reaction has now become an important extension of conventional activation analysis. The so-called prompt radiation is usually emitted within 10^{-14} s following the particle capture event leading to the creation of a compound nucleus.

The measurement of prompt gamma rays following neutron capture has made it possible to determine numerous elements with low limits of detection[158]. The gamma rays have energies lying between 50 keV and about 10 MeV. The gamma-ray spectra are relatively complex, as a result of numerous intermediate energy levels, but are nevertheless characteristic for each target nuclide. The sensitivity of the technique depends only on the product $\Phi\sigma$ (see Section 2), and the nuclear properties of the product nuclide, which can also be stable, do not affect the performance. This technique is of special interest for those elements which cannot be determined by conventional activation analysis (or can, but with very poor sensitivity) because of the unfavorable properties of indicator radionuclides produced. As an example we can quote boron, which cannot be determined at all by conventional methods, but which can be determined with high sensitivity if the prompt gamma photons are counted. Table 15 presents essential data for a few elements which can be determined successfully by this technique. Prompt gamma measurement techniques are also of interest for *in situ* analyses (see Section 8.2). It is also possible to detect prompt charged particles produced in nuclear reactions arising from neutron irradiation, which opens up yet another range of applications.

Table 15. Limits of detection for analysis by detecting prompt gamma radiation from neutron-capture processes [158].

Element	Low energy region		High energy region	
	E_γ [MeV]	Limit of detection in g [a]	E_γ [MeV]	Limit of detection in g [a]
B	0.477	2×10^{-10}	—	—
Cl	1.163	4.6×10^{-8}	6.111	5×10^{-7}
Sc	0.228	2.4×10^{-8}	8.175	1.6×10^{-6}
Ti	1.378	1×10^{-7}	6.759	1×10^{-6}
Mg	0.212	2.8×10^{-7}	7.243	2.4×10^{-6}
Fe	0.353	8×10^{-7}	7.631	6×10^{-6}
Co	0.230	2.6×10^{-8}	6.877	1.5×10^{-6}
Ni	0.465	3×10^{-7}	8.999	2.0×10^{-6}
Cu	0.279	2.2×10^{-7}	7.914	4.3×10^{-6}
Rh	0.181	1.1×10^{-8}	5.917	7.0×10^{-6}
Ag	0.198	1.6×10^{-8}	—	—
Cd	0.559	7×10^{-10}	5.824	2×10^{-7}
In	0.276	5.3×10^{-9}	—	—
Gd	0.182	1×10^{-10}	6.749	8×10^{-8}
Ir	0.217	1.2×10^{-8}	5.958	5.4×10^{-6}
Au	0.216	6.5×10^{-8}	6.252	3.2×10^{-6}
Hg	0.371	2.9×10^{-9}	5.967	2.5×10^{-7}

[a] Estimate based on a thermal neutron flux $= 1.5 \times 10^{10}$ neutrons cm^{-2} s^{-1}; counting time = 20 min.
Limit of detection is taken as being that amount of an element which gives rise to a counting rate equal to twice the standard deviation of the background.

If charged particles are used to bombard the sample, analyses can be carried out by measuring the elastically scattered original particles[159-162], the new charged particles produced as a result of a nuclear reaction[163,164], neutrons, γ-rays[165,166], or the emitted X-rays[167,168]. Each of these types of prompt radiation can be identified by its energy, characteristic of the nuclide from which it originates, and this permits their analytical utilization. The latest developments in this field involve the use of different kinds of detectors so as to be able to observe several different processes occurring simultaneously by looking at the different kinds of radiation emitted. Figure 18 is a diagrammatic representation of such an arrangement.

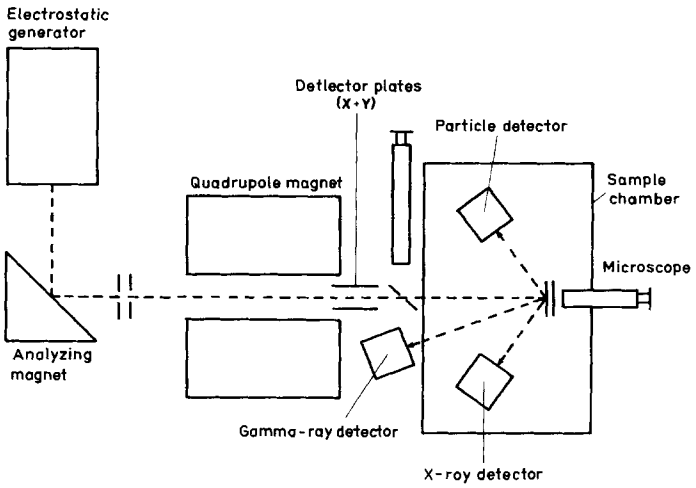

Fig. 18. Schematic construction of a nuclear microprobe [169].

8. Applications

Activation analysis occupies an important position, indeed very often a key position, in all those areas of science, industry, and medicine where the most minute amounts of elements have to be determined. Table 16 summarizes the most important fields of application and also the individual scope of the various activation techniques.

8.1. High-Purity Materials and Reagents

Activation analysis is probably the most effective analytical technique known for characterizing high-purity materials and reagents in terms of the trace element contents. For the determination of elements with $Z > 11$, activation with reactor neutrons has the greatest practical significance. There is hardly a single type of material of scientific or technological interest which has not been investigated by this technique[170]. Multi-element analyses of many high-purity materials have been carried out for trace impurities at the ppb and ppt[*] level: *e.g.* silica[171], optical glasses[172], aluminum[173], titanium[174], selenium[134], palladium, platinum, rhodium and gold[175], gallium phosphide[176], various reagents[176-178], and catalysts[179]. A procedure involving a long irradiation in a medium flux reactor followed by specific separation of the indicator radionuclides made it possible to determine 25 ppt of chromium, 7 ppb of iron, and 19 ppt of cobalt in high-purity niobium[179a]. The use of an anti-Compton spectrometer permitted the determination of 24 elements in high-purity lead at levels < 1 ppm by instrumental neutron activation analysis[133].

[*] ppt = parts per trillion = 10^{-12} g/g.

Table 16. Applications of activation analysis. MEA = multi-element analysis; ● technique very well suited; ○ technique only suitable under certain conditions; — technique has little to offer.

Surface and local microanalysis	—	—	—	—	●	—

For some trace analytical problems activation with charged particles is more appropriate than that with reactor neutrons. Thus, while cobalt can be determined with very high sensitivity by neutron activation analysis (the limit of detection for cobalt in niobium is about 4 ppt[179a]), proton activation analysis can be used to determine 14 elements nondestructively in a cobalt matrix[180]. Instrumental proton activation analysis has been employed in the analytical characterization of tantalum[180a], rhodium[180b], aluminum[180c], various semiconductors[180d], niobium[181], and other materials. In the case of niobium, as little as 0.2 ppb of chromium and 5 ppb of iron can be detected if radiochemical proton activation analysis is used[181a].

Activation with charged particles is the only technique which can be used for the determination of practically all the light elements (H, Li, Be, B, C, N, O, and F) at the ppb level (see Table 10). Some very thorough investigations into the systematic errors from surface oxygen and recoil oxygen[182–185] have made it possible to determine oxygen at the 1-ppm level with an accuracy of around $\pm 10\%$[186]. The elements C, N, O, and F can, however, also be determined satisfactorily by photon activation analysis[187,188]. The most suitable technique for the determination of oxygen at levels above 1—5 ppm would seem to be activation with 14-MeV neutrons[13,189,190], a technique which is now used routinely in industry for this application. A precision of 1% relative is attainable by this means[191].

8.2. Geochemical and Cosmochemical Applications

Neutron activation analysis is one of the most important analytical tools for these branches of science[192–195]. Of the 74 elements which have been detected in the standard rocks G-1 and W-1, 63 have been determined by activation analysis, seven of them only by this means[196]. At least 60 elements have so far been determined in stony and iron meteorites by the same approach.

Activation with reactor neutrons followed by radiochemical separation has enabled a number of elements to be determined even at the ppt level: *e.g.* 4 ppt iridium in basalt BCR-1, a U.S. Geological Survey silicate rock standard, or 9 ppt in andesite AGV-1[197]. Radiochemical separation procedures have been used for the determination of 39 elements in geological samples[153], 42 elements in lunar samples[198], and 38 in meteorites[199]. Very often instrumental analysis can make a useful contribution: depending on the type of sample, up to over 20 elements can be determined simultaneously, *e.g.* 23 in U.S. Geological Survey standards (a sub-alkaline basalt and rhyolite)[200], 24 in granitic rocks[201], 25 in plagioclases, pyroxenes, and magnesite[202], and 23 in iron meteorites[203].

If the activity of the irradiated sample is measured not only with a conventional Ge(Li) detector but also with a planar low-energy Si(Li) detector or an intrinsic germanium detector, then it is possible to obtain results with a better precision and accuracy, and to increase the number of elements which can be determined instrumentally, *e.g.* in basaltic rocks up to 34 elements[204]. Sometimes, activation with epithermal neutrons can be advantageous[39–42]. Activation with 14-MeV neutrons is a well suited technique for the determination of O, F, Si, Al, and P[190].

In situ measurement techniques are playing an increasingly important role in the earth sciences. Probes with a diameter

Fig. 19. A mobile field laboratory (Mobil Research and Development Corporation, Dallas) for activation analysis with 14-MeV neutrons using a bore-hole probe consisting of a pulsed 14-MeV neutron generator, a gamma-ray detector, and a neutron detector.

of only 4.3 cm have been developed for lowering down test bore-holes, which have a pulsed 14-MeV neutron source and both gamma-ray and neutron detectors[204]. Such probes offer particular advantages as far as the problem of radiation protection is concerned. Similar probes have been constructed using ^{252}Cf sources: one containing 170 μg of ^{252}Cf and a planar intrinsic germanium detector with an area of 200 mm^2, has an overall diameter of 7.3 cm and a length of 1.7 m[205]. Borehole probes such as these can be used as mobile analyzers (Figure 19) for investigating the porosity, mineral composition, and ore-metal content of rocks in geological prospecting[204–207], as well as for studying deep-sea sediments[208]. The successful surface analysis of other planets is of course one of the more striking examples of the kind of work these probes can accomplish[209].

Activation with charged particles has been used for the determination of lithium and boron[210, 211], while up to 30 elements may be determined in garden soil samples by photon activation analysis[212].

8.3. Environmental Analysis

Instrumental neutron activation methods are being used on an increasing scale for carrying out elemental analysis of environmental samples. The potential of activation analysis for analyzing atmospheric samples has been widely studied (*e.g.* [213–221]). If the samples are irradiated twice (for 5 min and then later for 7—21 h) in a neutron flux of 10^{12} neutrons cm^{-2} s^{-1} and left for three different cooling times before counting, then 33 elements can be determined by instrumental means, including most of the toxic ones such as arsenic, antimony, and mercury[213]. In another approach, three cycles of irradiation, cooling, and counting (2 min + 10 min, 10 min + 10—15 h, and 7 days + 1—3 weeks) employing a neutron flux of 9×10^{13} neutrons cm^{-2} s^{-1} enabled 42 elements to be determined in atmospheric aerosols, again by instrumental techniques. Silicon and oxygen were determined separately by irradiation with 14-MeV neutrons[221]. If it is necessary to improve the limit of detection and/or the accuracy of any of the determinations, then one or more radiochemical separations can be introduced. Instrumental neutron activation analysis has also been used to look for trace elements in hair, to see to what extent it can be used as a monitor for the pollution of the environment by inorganic toxins as far as it affects people[35, 221a].

Instrumental and radiochemical neutron activation procedures have often been used for multi-element analyses of drinking water[222–224], rain water[225, 226], river water[218, 222, 227], lake water[222], seawater[225, 228], and various other water samples[218, 229].

Other environmental samples which have been investigated have included fly ash and similar industrial emissions[230–232], automobile exhaust emissions[233], and cigarette smoke[234].

Activation with photons[235–238] and with charged particles[239–242] has also been used to advantage in some special environmental problems.

8.4. Biological and Medical Applications

It is now recognized that in addition to the principal body-building elements, a number of trace elements, including F, Si, V, Mn, Cr, Fe, Co, Ni, Cu, Zn, Se, Mo, Sn and I, are essential for growth and health in mammals both animal and human. Just as important, however, is the recognition that some elements are toxic for the same group of species, *e.g.* Li, Be, As, Br, Ag, Cd, Sb, Ba, Pb, and Bi, though to widely differing extents. Activation analysis with reactor neutrons, having proved to be a very effective method for the determination of most of these trace elements in biological samples, is nowadays widely used for this task[243–247]. Researchers have so far been able to determine 43 elements in such samples by direct instrumental activation analysis. Separation procedures can of course be incorporated if need be for particularly awkward cases[248] (see Section 6). The outstanding sensitivity of activation analysis comes into its own for the investigation of biopsy samples, which are normally only about 2—10 mg in total: this is an excellent example of multi-element micro-trace analysis.

With the help of this technique, samples from nearly every part of the human body have been analyzed: whole blood, blood plasma and serum[249, 250], urine[251], lung[252], liver[253], kidney[254], placenta[240], bone[255], and hair[256] for example. The collaboration between activation analysts and medical researchers has resulted in a much deeper understanding of the function of trace elements in the body, and of the correlation between the amounts present and the occurrence of different diseases. Because of this, activation analysis can now play a role in diagnostic medicine[257], particularly in diagnosing certain diseases which give rise to significant changes in the levels of some trace elements in the blood or in the tissue of specific organs. It is easy to see how important the accuracy of these analytical results is for establishing the "normal" values for these elements, and even more so when actual clinical samples are being handled. As is the case with most biological samples, the factors involved in taking the sample so as to ensure its homogeneity and that it is representative of the whole are added to the usual problems of sample handling for all trace analyses[258, 259, 259a].

Various kinds of samples from animals[260–263], plants[264, 265], and foodstuffs[266–269] have also been subjected to activation analysis. A more recent application of activation techniques has been to aid in the elucidation of the pathways of trace elements from the environment into the human body[270].

A special field of application of activation analysis has been the determination of trace elements *in vivo*, making use of neutrons from isotope sources[271–274], 14-MeV neutrons[275], and cyclotron-produced neutrons[276–278]. The elements N, Na, P, Cl, Ca, Cu, Cd, and I have been the ones usually determined, either in specific organs or in whole-body analyses. The *in vivo* technique creates problems for the researcher, however, both ethical (concerning the acceptable radiation dose) and experimental (concerning standardization procedures), but it nevertheless seems to be developing into a useful analytical tool. The problems of standardization associated with whole-body analyses are to some extent being overcome by the use of anthropomorphic "phantoms" of the same size, shape, and approximate elemental composition as the human body[278a].

In addition to activation with neutrons, activation with photons[279, 280] and with charged particles[281] also offer interesting possibilities in this field, and significantly extend

the number of elements which can be determined. As an example, the lead content of teeth can be determined by activation with ^{3}He projectiles[282].

8.5. Other Applications

Other fields in which problems have been solved by means of activation methods are archaeometry[283], archaeology, and history of art[284–287], forensic science[288], and isotopic analysis[289,290].

8.6. Local Microanalysis and Surface Analysis

While the total amount of an element present in a sample has usually been the main point of interest in the past, increasing attention is now being paid to the spatial distribution of the traces in a matrix. In many cases, physical and mechanical properties of materials are strongly dependent on local variations in the levels of trace constituents. Such problems can often be studied by combining activation analysis with autoradiography[30,291,292]. Figure 20 shows an example of such an application. A significant advance in the evaluation of the two-dimensional pictures has been the use of colored autoradiograms[293]. The continuous shades of gray in the conventional autoradiograms are transformed into different color shades by a special process. The quantitative relationship between concentration of the element present and the color shade is found by treating standards in the same way as the samples. The technique has been used to investigate the distribution of doping elements and of contaminants in silicon, and of tantalum and tungsten in high-purity niobium to be used as a superconductor: concentrations of impurities at the ppb level can be detected this way, *e.g.* of phosphorus and gold in silicon. The same combination of activation by irradiation with neutrons followed by autoradiography has been applied to the study of distributions of elements in geological and biological materials.

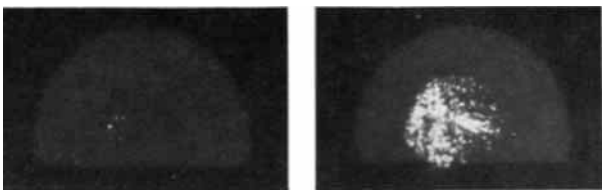

Fig. 20. Autoradiograms of silicon doped with iron, after neutron activation [30]. Left: beginning of iron deposition; right: pronounced iron deposition. Distance apart of the samples in the silicon rod was 5 cm.

In recent years the nuclear microprobe has been developed for investigating variations in concentrations of elements across a sample. A beam of accelerated charged particles can be focused by a quadropole magnet to a diamater of about 3 μm in such instruments[294–296]. The analytical measurement can be based on any of four principles: 1) on the conventional activation process, with the activity of the indicator radionuclide being measured, 2) on the measurement of new particles or gamma photons released in the nuclear reaction, 3) on the measurement of the elastically scattered primary particles, and 4) on the measurement of X-rays excited in the irradiation.

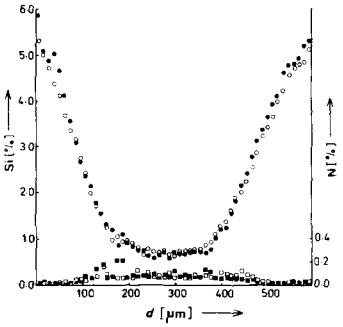

Fig. 21. Silicon and nitrogen profiles in a 20/25 niobium steel after contact with Si_3N_4 at 1000°C for 1173 hours, taken with a nuclear microprobe [169]. ○, ● silicon values, 1st and 2nd measurement; □, ■ nitrogen values, 1st and 2nd measurement. d = distance from the surface of the sample.

When this approach is applied to surface analysis[162,164,297–299], limits of detection of 0.01 μg cm^{-2} are attainable, with a resolution in depth of 10—20 μm, and all the light elements including hydrogen can be determined. Some examples are given in Table 17, and Figure 21 shows as an example a concentration profile determined by this means. Yet another example of this approach is given by the determination of concentration profiles of some elements in human teeth[300].

8.7. Industrial Applications

Many branches of industry are already making use of activation analysis, not only in research and development, but also on the production line, to monitor raw materials, intermediates, and finished products as well as environmental samples. The principal field of application of activation analysis is the metallurgical industry[301], although it plays a useful part in other areas of industry[302,303] including those concerned with electronics, oil processing, nuclear materials, building

Table 17. Examples of surface analysis by measurement of prompt radiation during bombardment with charged particles.

Element to be determined/ Target nuclide	Reaction	Particle energy [MeV]	Sample	Limit of detection
H/^{1}H	^{19}F,α	16.3–17.5	Lunar materials	Resolution in depth = 10 nm
N/^{14}N	d,p	1–3	Iron	0.01 μg/cm^2
O/^{16}O	d,p	1.2–3	Various metals	0.01 μg/cm^2
Al/^{27}Al	p,γ	2.5	Oxides	Resolution in depth = 10 nm
S/^{32}S	p,p′	3–4	GaSb	2×10^{18} atoms/m^2

materials, paper, textiles and foodstuffs, often for solving specific analytical problems, but sometimes also for automatic process control work. Many highly specialized problems have also been solved through activation methods, for example in an investigation of mass transfer on low-current contacts of electrical switches[304]. There are many irradiation facilities with associated laboratories in nuclear research centers which are available for use by industrial concerns (see Table 18),

Table 18. Radiation facilities with associated laboratories for use by industrial concerns in the European community [305].

Radiation source	Number available
Reactors	25
Isotope sources	15
14-MeV neutron generators	17
Cyclotrons	9
Low-energy particle accelerators	6
Linear accelerators	4

though a number of companies have purchased their own reactors specifically for analytical purposes (such as the mining and metallurgical complex at Noril'sk in the USSR[306] and the Dow Chemical Co in the USA[307]). While a reactor may be considered something of a luxury by most companies, many have invested in 14-MeV neutron generators, isotope neutron sources, and Van de Graff generators.

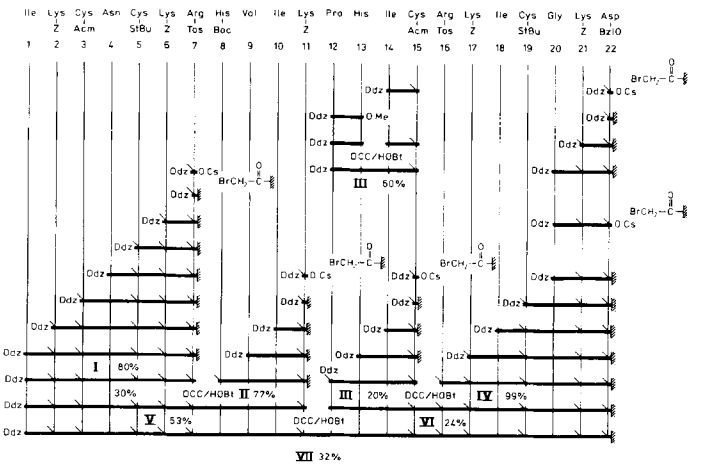
COMMUNICATIONS



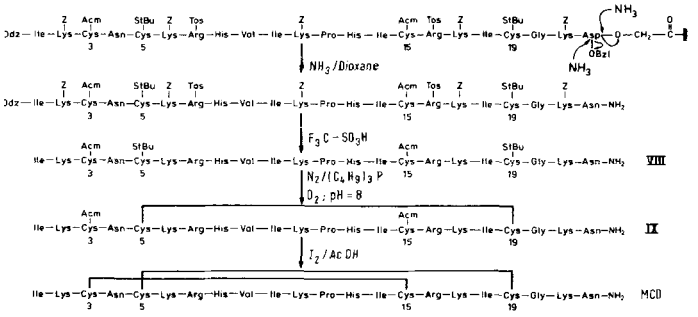
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis of the Mast Cell Degranulating (MCD) Peptide from Bee Venom[**]

By *Christian Birr* and *Margot Wengert-Müller*[*]

The mast cell degranulating peptide (MCD peptide) is a minimal component (1—3 %) of bee venom[1]. The single-stranded sequence consisting of 22 amino acids[2] (Scheme 2) has two disulfide bridges and contains 5 lysine, 2 arginine, and 2 histidine residues; the isoelectric point lies near pH 12. At low dosage (<0.1 mg/kg) the natural product effects release of histamine (degranulation) in mast cells[1] which is overcompensated at higher dosages (1 mg/kg) by an anti-inflammatory effect[3]. The MCD peptide appears to have an anti-inflammatory activity exceeding that of all known pharmaceuticals without being neurotoxic. This property endows the compound with therapeutic interest in the case of rheumatic processes[4], and also for allergic reactions, and kindled our interest in the total synthesis of this compound.

In order to synthesize the MCD peptide (see Scheme 1), four fragments (I—IV) were produced by an extensively modified Merrifield method[5] on a polystyrene gel phase (<0.5 % crosslinked): thanks to the spectroscopic properties of the acid-labile Ddz protecting group, each operation could be continuously monitored by photometry for complete reaction and plotted visually[6]. None of the fragment syntheses was programmed with regard to sequence length. Rather, the automatic synthetic process was stopped when the reactions on the polystyrene gel phase fell below 70 % average yield. This gave heptapeptides as the longest sequences. As a result of the ready basic cleavage of the 2-oxo ethyl ester bond —O—CH_2—CO-Polymer of the peptides on the polystyrene phase (0.1 N benzyltrimethylammonium hydroxide in dry methanol/dioxane 1:3, v/v) the peptides could be removed from the support for intermediate purification and subsequently condensed on the solid phase to give larger fragments. Thus



Scheme 1. Synthesis of the fragments and carrier-bound completely protected MCD peptide (fragment VII). The yields of I—IV are based on the initial loading of the gel phase. The fragment III obtained in 60 % yield was additionally produced in solution. Protecting groups: Acm, acetamidomethyl; Boc, *tert*-butyloxycarbonyl; Bzl, benzyl; Ddz, 3,5-dimethoxy-α,α-dimethylbenzyloxycarbonyl; StBu, *tert*-butylthio; Tos, toluenesulfonyl; Z, benzyloxycarbonyl.

I and II reacted on the carrier to form V (53 % based on II-gel polymer) and III and IV reacted on the carrier to give VI (24 % based on IV-gel polymer). V was again released from the carrier, purified, and combined with VI on the carrier to give the fully protected final product VII (32% based on VI-gel polymer). The scheme of fragment syntheses and the formation of the fully protected sequence VIII has already been briefly described[7].

Scheme 2. Liberation of the MCD peptide from carrier-bound final product VII.

The product VII of the Merrifield synthesis was released from the carrier as the diamide by treatment with ammonia-saturated dioxane (Scheme 2). The release of VII from polystyrene gel was practically complete (98.5 %) and after chromatography on Sephadex LH 20/DMF resulted in completely protected MCD peptide (MW 4067). All the benzyloxycarbonyl and toluenesulfonyl groups were removed with trifluoromethanesulfonic acid, the sulfur-protecting groups being left intact in positions 3, 5, 15, and 19. No aromatic protons were detected in the ^{1}H-NMR spectrum, while the signals of the sulfur-protecting groups remained unchanged.

After ion exchange and gel chromatography, 507 mg of Cys(Acm)^{3,15},Cys(StBu)^{5,19}-MCD peptide (VIII) was obtained (71 % based on the amount of VII released from the carrier).

Reduction with tributylphosphane[8] selectively removed the StBu protecting groups in positions 5 and 19, and the disulfide bridge 5—19 was formed by air oxidation at pH 8; there resulted 276 mg of Cys(Acm)^{3,15}-MCD peptide (IX) (61 % based on VIII).

In order to bring about selective linkage of the 3—15 disulfide bridge, the Acm protecting groups were removed from 126 mg of IX by iodine in acetic acid solution[9]. Oxidation was halted with ascorbic acid and the final product immediately chromatographed on Sephadex G25 with 0.1 N acetic acid. The fraction containing the most synthetic MCD peptide initially gave 16 mg of pure product after purification. It was shown by electrophoresis (paper, polyacrylamide normal and SDS gel) and chromatography (HPLC, Zorbax ODS; acetonitrile/water 35/65, isocratic) to be identical with the natural product. Amino acid analysis (calculated values given in parentheses): Cys 4.2(4); Ile 4.0(4); Lys 5.0(5); Arg 2.3(2); His 1.8(2); Val 0.8(1); Pro 1.4(1); Gly 1.5(1); Asp 2.4(2).

In the CD spectrum, the synthetic MCD peptide shows the same four bands between 190 and 240 nm as the natural product; however, the spectra are not congruent. This suggests gradual racemization of particularly endangered sites (histidine, cysteine). The degranulating effect of the synthetic product was tested on rat mast cells. The synthetic MCD peptide exhibited 35 % of the histamine-releasing activity of the natural product.

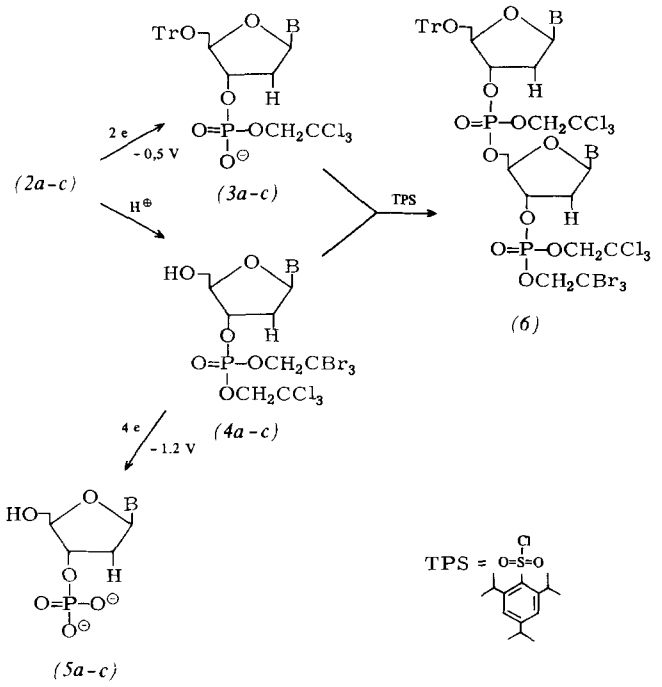
Selective Electrochemical Removal of Protecting Groups in Nucleotide Synthesis

By *Joachim Engels*[*]

In the synthesis of nucleotides by the triester method[1] a completely protected nucleoside-3′-phosphate in the triester form *(2)* can be used as synthon for construction of the oligonucleotide chain. A major problem in the synthesis is the selective cleavage of an ester moiety. We report here on the selective deprotection of such synthons by controlled potential electroreduction[2]. Two important advantages make this approach attractive: Firstly, the 2,2,2-trichloro- and -bromoalkyl esters of phosphoric acid are quite stable towards both basic and acidic hydrolysis[3], so that a wide range of acid- and alkali-labile protecting groups can be used on the sugar and on the base. Secondly, owing to the reaction mechanism[4], the danger of an isomerization during cleavage of an ester function is far less than during attack of the reagent at phosphorus.

The protected nucleosides *(1a—c)* were allowed to react with 2,2,2-trichloroethylphosphoric dichloride[5] and then with 2,2,2-tribromoethanol. The triesters *(2a—c)* can be isolated in 85—90 % yield by chromatography on silica gel.

(1a-c) *(2a-c)*



(a), B = Thyminyl
(b), B = N^4-Benzoylcytosyl
(c), B = N^6-Benzoyladenyl

Tr = Trityl or monomethoxytrityl

The detritylation of *(2a—c)* was achieved with 1% trifluoroacetic acid in CH_2Cl_2 or with BF_3Et_2O/MeOH in CH_2Cl_2[6]; the resulting crystalline esters *(4a—c)* are stable and can be lengthened in the 5′-direction. It is possible to cleave the tribromoethyl protecting group quantitatively from *(2a—c)* by controlled potential electroreduction[7] at a mercury cathode at −0.5 to −0.6 V. The reaction is carried out in acetonitrile/pyridine with $LiClO_4$ as supporting electrolyte; the diesters *(3a—c)* which are formed can be used for the condensation reaction directly after extraction with $CHCl_3$. Reaction of TPS with the triesters *(4a—c)* afforded *(6)*. The reactions proceed very smoothly. The nine possible combinations of

(6) can then be cleaved by selective electroreduction and lengthened in the 3'-direction or be used for block condensation after acid cleavage at the 5'-terminal. Complete electrochemical deprotection to give the free phosphates was carried out on the diesters *(4a—c)*. On reduction in dimethylformamide (DMF) with tetrabutylammonium tetrafluoroborate as supporting electrolyte, *(4a)* and *(4c)* can be smoothly reduced at -1.2 to -1.4 V to *(5a)* and *(5c)* respectively in 90% yield. The dichloroethyl ester, *i.e.* the byproduct cited in [4], is formed to the extent of 2% at most and is virtually inseparable from the trichloroethyl ester (reactant).

Experimental

Reduction of *(2a—c)*: The reduction is carried out at room temperature under nitrogen in a partitioned electrolytic cell[8] (Pt-anode, Hg-cathode, Ag-wire; Nafion 125 membrane) using a 0.5 M solution of $LiClO_4$ in pyridine/CH_3CN (1:5) and 0.5—1 mmol *(2a—c)* as catholyte and 0.5 M $LiClO_4$ and 1—2 mmol pyridine as anolyte. The cathode potential is potentiostatically adjusted to -0.5 V (Ag-wire) and the uptake of electrons monitored coulometrically. When the current has reached its residual value the reaction is complete. After removal of solvent, partition of the residue between water and chloroform, extraction with chloroform, and drying of the chloroform phase with Na_2SO_4 followed by filtration and removal of solvent, *(3a—c)* is obtained and can be used directly for further reaction in pyridine.

Reduction of *(4a—c)*: The reduction is carried out at room temperature under nitrogen in the same type of cell as described above using 0.5 M tetrabutylammonium tetrafluoroborate in DMF/CH_3CN (1:1) and 0.5—1 mmol *(4a—c)* as catholyte and the same anolytes as above plus an additional 1—2 mmol 2,6-lutidine. The cathode potential is adjusted to -1.2 V (Ag-wire). On completion of reaction, extraction of the supporting electrolyte with chloroform and chromatography of the aqueous phase on RP8 or RP18 silica gel with water or water/ethanol as eluent affords *(5a—c)*.

Di-*tert*-Butyl Acetylenedicarboxylate and Its Cyclotrimerization

By *Wolfgang Sucrow* and *Fritz Lübbe*[*]

For the synthesis of ene-hydrazines[1] we required as starting material di-*tert*-butyl acetylenedicarboxylate *(2)*, which, surprisingly, had previously not been described in the literature. Following the procedure used for the preparation of tert-*butyl* propiolate *(1)*[2] we have now been able to obtain *(2)* as a crystalline product, m.p. 35—36°C [^{1}H-NMR (90 MHz, $CDCl_3$): singlet, $\delta = 1.50$] from acetylenedicarboxylic acid and isobutene.

In spite of the bulky *tert*-butyl residue the esters *(1)* and *(2)* can be trimerized with dicarbonylbis(triphenylphosphane)nickel(0)[3]. *(1)* furnishes tri-*tert*-butyl trimellitate *(3a)* [oil, b.p. 165—170°C (bath)/0.03 torr, Kugelrohr] and tri-*tert*-butyl trimesitate *(4a)* [from petroleum ether, m.p. 218°C (dec)] in the ratio 6:1, while, according to the NMR spectrum, the known trimethyl esters are formed in the ratio 12:1. The total yield of *(3a)* and *(4a)* after chromatographic separation is 55%.—Under somewhat more severe conditions, *(2)* trimerizes to hexa-*tert*-butyl mellitate *(5a)* in 44% yield [^{1}H-NMR (90 MHz, $CDCl_3$): singlet, $\delta = 1.59$]. The crystals obtained from petroleum ether/chloroform decompose without melting above 180°C into mellitic acid *(5b)* and isobutene. In the case of the ester *(4a)* complete decomposition to *(4b)* takes place following previous melting.

In contrast to *(1)*, compounds *(2)* and *(3a)* also decompose to acetylenedicarboxylic acid and *(3b)*, respectively, on attempted distillation above 165°C and 204°C under normal pressure.—The new compounds *(2)*, *(3a)*, *(4a)*, and *(5a)* gave correct elemental analyses.

As shown by the cyclotrimerization, the *tert*-butyl groups in *(2)* do not give rise to much steric hindrance. The numerous reactions realizable with dimethyl acetylenedicarboxylate can thus presumably also be carried out with the di-*tert*-butyl ester *(2)*. This offers advantages, *e.g.* easy cleavage of the ester without use of bases.

Procedure

Synthesis of *(2)*: Conc. sulfuric acid (0.15 ml) is added dropwise under nitrogen at −10 °C to a stirred mixture of acetylenedicarboxylic acid (2.0 g, 17.5 mmol), ether (10 ml), and isobutene (55 ml) in an ampoule. The ampoule is sealed at −195 °C and then allowed to stand for 4 days at room temperature. After removal of solvent *in vacuo* the residue is chromatographed with petroleum ether/6 % ether on 50 g silica gel and the product distilled at 80—82 °C (bath)/0.05 torr in a Kugelrohr [2.9 g (73 %), m.p. 35—36 °C].

Synthesis of *(5a)*: A solution of *(2)* (0.25 g, 1.1 mmol) in benzene (0.4 ml) is added dropwise at 70 °C to a suspension of $[(C_6H_5)_3P]_2Ni(CO)_2$ (0.10 g) in benzene (0.5 ml). The benzene is then removed by distillation (almost complete when the temperature reaches 115 °C), a further 0.05 g of catalyst is added to the product, and the resultant mixture stirred for 2 h at 115 °C. Chromatographic separation with petroleum ether/30 % ether on 30 g of silica gel and crystallization from petroleum ether/5 % $CHCl_3$ affords 0.11 g (44 %) of *(5a)* as colorless platelets.

Synthesis and Properties of Tetrabutylammonium Octaiododirhenate(III), $[(n\text{-}C_4H_9)_4N]_2[Re_2I_8]$

By *Wilhelm Preetz* and *Lutz Rudzik*[*]

Dinuclear complexes $[Re_2X_8]^{2-}$ (X = Cl, Br) containing a Re···Re quadrupole bond were first prepared by *Cotton et al.*[1] as long ago as 1965. Compounds of Mo and Tc having the same type of structure have also been reported[2]. They can also contain organic moieties as ligands[3]. Detailed spectroscopic and X-ray crystallographic investigations have already been carried out on the alkali-metal and tetraalkylammonium salts of the octachloro- and octabromo-complexes[4].

We have now been able to prepare for the first time the previously unreported[7] octaiodo-complex *via* a simple route, namely by reaction of the tetrabutylammonium salt with hydrogen iodide in dichloromethane:

$$[(n\text{-}C_4H_9)_4N]_2[Re_2X_8] + 8\,HI \xrightarrow[CH_2Cl_2]{20\,^\circ C} [(n\text{-}C_4H_9)_4N]_2[Re_2I_8] + 8\,HX$$

The new compound[7], owing to the large I-ligand, is of interest from the point of view of its structural chemistry and bonding. It is immediately hydrolyzed in aqueous media, but is stable in organic solvents and in the solid state. On reaction with the corresponding tetrabutylammonium halides in CH_2Cl_2 it is reconverted into the octachloro- or octabromo-compound. It is also suitable for the preparation of other already known derivatives.

The absorption spectra[5] (Fig. 1) measured at about 10 K show systematic band shifts for the three homologous compounds. The $\delta \rightarrow \delta^*$ transition, which in the case of the chloro- (*ca.* 14500 cm^{-1}) and bromo-compound (*ca.* 14100 cm^{-1}) displays a vibration fine structure of the Re_2 group, appears at 12800 cm^{-1}. The ReRe bond length in the octaiodocomplex is thus estimated to be 2.27 Å[6].

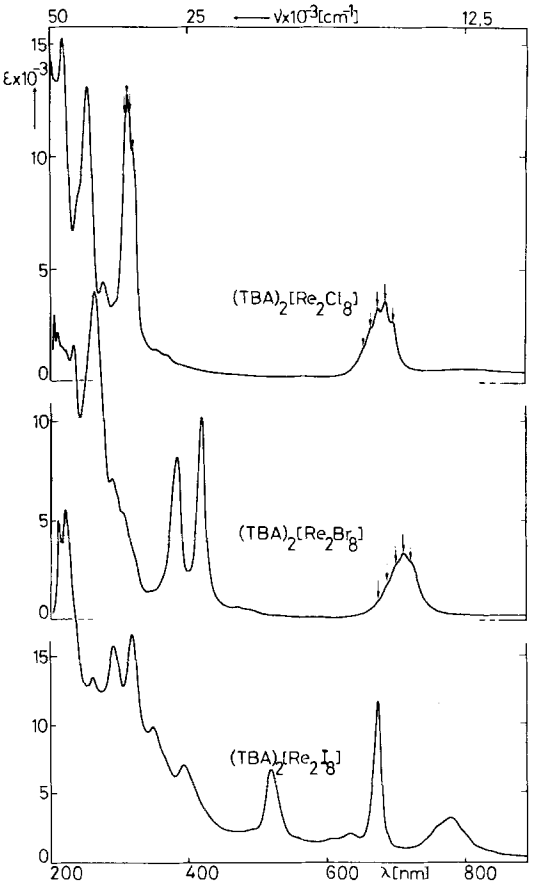

Fig. 1. UV/VIS spectra of the tetrabutylammonium octahalodirhenates(III), recorded on tablets of the corresponding rubidium halides at 10 K.

The IR spectrum shows only one intense Re—I stretching vibration at 184 cm^{-1}. In the Raman spectrum the Re—Re stretching vibration at 257.7 cm^{-1} is by far the most intense. It can be determined very accurately since on excitation in the region of the charge-transfer band at 522 nm several overtones occur as a result of the resonance-Raman-effect as well as a series of combination tones with the symmetric Re—I stretching vibration at 153 cm^{-1}. The Re—Re vibrations of the octachloro- (277 cm^{-1}) and octabromo-complex (279 cm^{-1}) appear distinctly higher. Weak skeletal and lattice vibrations occur at 195, 119, 107 and 98 cm^{-1}.

Experimental

Anhydrous, iodine-free hydrogen iodide is passed into a solution of about 500 mg of $[(n\text{-}C_4H_9)_4N]_2[Re_2Cl_8]$ in 250 ml of freshly distilled CH_2Cl_2, previously dried over a molecular sieve. The color of the solution immediately changes from light blue to deep violet. On removal of solvent by evaporation $[(n\text{-}C_4H_9)_4N]_2[Re_2I_8]$ precipitates in the form of dark-violet to black crystals. Double recrystallization from CH_2Cl_2 affords the very pure compound in 50—70 % yield. On elemental

analysis the sum of the contents of C, H, N, I and Re amounted to 99.35%. The solid complex salt thermally decomposes at *ca.* 200°C. It is moderately soluble in benzene, toluene, and ethanol, and readily soluble in dichloromethane and acetone.

Long-Chain Alkylammonium Ions as Phase Transfer Reagents for the Synthesis of Mixed-Ligand Complexes of the Platinum Metals

By *Ashok Kumar Shukla* and *Wilhelm Preetz*[*]

The transfer of anionic reactants from a polar phase into an apolar phase by lipophiles has recently gained increasing importance in synthetic chemistry. In two-phase liquid/liquid or solid/liquid systems, complete reaction of organic compounds with inorganic anions can be achieved merely with the aid of a few mol-percent of transfer reagent, a process now commonly referred to as phase transfer catalysis (PTC)[1]. Crown ethers were first used for this purpose, but the more readily accessible quaternary alkylammonium salts are equally suitable reagents[2]. To our knowledge the application of PTC to "inorganic reactions" has so far not been reported in the literature.

In the case of kinetically inert hexahaloosmates(IV) ligand exchange processes take place 10^2 to 10^4 times more rapidly in weakly polar or apolar solvents than in aqueous systems[3]. Exploiting this fact in the application of phase transfer processes it is possible to carry out substitution reactions under mild conditions. Though only the heavier halogen ligands X = Cl, Br, I can be mutually substituted in complexes of the type $[MX_6]^{2-}$, M = Os, Ir, Pt, (Re), in aqueous acidic media[4], we have now been able to prepare the first fluorine-containing mixed-ligand complexes of the type $[MF_nX_{6-n}]^{2-}$, $n = 1-5$, in organic solvents. Hitherto, platinum metal complexes could be fluorinated only with BrF_3 or XeF_2 and in KHF_2 melts[5]. But all Br and I ligands are cleaved under such reaction conditions.

Tridodecylammonium, $[(C_{12}H_{25})_3NH]^+$ (A^+), the hydrogen sulfate of which is readily available in very pure crystalline form, has proven to be a suitable lipophilic phase-transfer reagent. Substitution can be carried out both in homogeneous organic phases as well as in two phases using the PTC method. The principle steps of such substitutions are as follows:

1. *Ion-pair extraction.* The complex anions and the halide ions are transferred separately or together from the aqueous solution or the solid salt into the organic phase (benzene or toluene) with the aid of A^+.

$$2A^+HSO_{4\,org}^- + [MX_6]_{aq}^{2-} \rightleftharpoons A_2^+[MX_6]_{org}^{2-} + 2HSO_{4\,aq}^-$$

$$A^+HSO_{4\,org}^- + NaY_{solid\ or\ aq} \rightleftharpoons A^+Y_{org}^- + NaHSO_{4\,solid\ or\ aq}$$

2. *Ion-pair reaction.* The ion pairs undergo stepwise ligand substitution. An equilibrium between several mixed-ligand complexes ensues in dependence of their concentrations. The presence of solid NaY favors the ligand exchange if X is a lighter halide then Y; owing to the high lattice energy solid NaX is formed by PTC.

$$A_2^+[MX_6]_{org}^{2-} + nA^+Y_{org}^- \rightleftharpoons A_2^+[MY_nX_{6-n}]_{org}^{2-} + nA^+X_{org}^-$$

3a. *Precipitation as sparingly soluble complex salt.* Benzene forms a homogeneous organic phase with a solution of potassium acetate in glacial acetic acid. The ion pairs undergo double conversion with precipitation of the complex potassium salts, which are readily soluble in water.

$$A_2^+[MY_nX_{6-n}]_{org}^{2-} + 2K^+AcO_{org}^- \xrightarrow{C_6H_6/AcOH} K_2[MY_nX_{6-n}]\downarrow_{solid} + 2A^+AcO_{org}^-$$

3b. *Complex-ion extraction* ("stripping"). The complex anions can be extracted into an aqueous phase in exchange with larger, less hydrolyzed anions (*e.g.* ClO_4^-, CCl_3COO^-).

$$A_2^+[MY_nX_{6-n}]_{org}^{2-} + 2ClO_{4\,aq}^- \xrightarrow{C_6H_6/H_2O} [MY_nX_{6-n}]_{aq}^{2-} + 2A^+ClO_{4\,org}^-$$

4. *Separation of mixtures of complexes.* Hexahalo complexes of tetravalent platinum metals, whether containing the same or different ligands, are kinetically inert in aqueous acidic solutions at low temperatures. The individual species of the $[MY_nX_{6-n}]^{2-}$ mixtures can be isolated in pure form by separation on cellulose ion-exchangers[6]. Of the many mixed-halo complexes accessible in this way, the new fluorine-containing compounds are of special interest. The reaction conditions for a selection of such compounds are listed in Table 1.

Table 1. Synthesis of fluorine-containing hexahalo complexes by ion-pair reactions in benzene.

Reactants	T [°C]	t [min]	Main product (yield %) [a]
$A_2^+[OsCl_6]^{2-}$, A^+F^-	80	60	$[OsFCl_5]^{2-}$ (40), $[OsF_2Cl_4]^{2-}$ (30)
$A_2^+[OsCl_6]^{2-}$, A^+F^-	80	180	$[OsF_2Cl_4]^{2-}$ (40), $[OsF_3Cl_3]^{2-}$ (20)
$A_2^+[OsBr_6]^{2-}$, A^+F^-	80	10	$[OsFBr_5]^{2-}$ (40), $[OsF_2Br_4]^{2-}$ (40)
$A_2^+[OsBr_6]^{2-}$, A^+F^-	80	60	$[OsF_3Br_3]^{2-}$ (50), $[OsF_4Br_2]^{2-}$ (20)
$A_2^+[OsI_6]^{2-}$, A^+F^-	20	10	$[OsF_2I_4]^{2-}$ (20), $[OsF_3I_3]^{2-}$ (10) [b]
$A_2^+[OsCl_5I]^{2-}$, A^+F^-	80	30	$[OsFCl_4I]^{2-}$ (60), $[OsF_2Cl_3I]^{2-}$ (30)

[a] Low yields of other mixed-ligand complexes; [b] losses by hydrolysis.

The hexahalometalates(IV) of Ir, Pt and Re react similarly. The method is not restricted to the mutual exchange of F,

Detection of Large-Ring Sulfur Molecules in Liquid Sulfur: Simple Preparation of S_{12}, α-S_{18}, and S_{20} from S_8[1]

By *Ralf Steudel* and *Hans-Joachim Mäusle*[*]

On melting at 120°C, *cyclo*-octasulfur is slowly converted into an equilibrium mixture of S_8 and π-sulfur (S_π); the solidification temperature (triple point) is therefore *ca.* 5°C lower than the melting temperature; the S_π content increases from 5.5 wt-% at 115°C to 12% at 159°C[2]. It has already been shown by vibrational spectroscopic analysis that S_π contains S_6, S_7, and S_{12}[3a], and S_7 can be preparatively isolated from quenched sulfur melts[3b]. We now report the simple preparation of pure S_{12}, α-S_{18}, and S_{20} from liquid sulfur, in yields comparable with those obtained[6] in the condensation reactions[4, 5] previously employed for the synthesis of these rings. The separation of S_{12}, α-S_{18}, and S_{20} from excess S_8 was accomplished by flotation (in the case of S_{12}) and by fractional crystallization (solutions of S_{18} and S_{20} in CS_2 tend to supersaturation).

S_{12} was identified by its crystal shape, melting point, and Raman spectrum[7], α-S_{18} and S_{20} by their melting points, color, crystal shape, densities, and lattice constants (both crystallize orthorhombically). The α-S_{18} isolated was free from β-S_{18}. The hitherto unrecorded vibrational spectra of α-S_{18} and S_{20}, which are best suited for the rapid characterization and differentiation of these species from other sulfur modifications, are given in Table 1. Owing to the low molecular symmetry (α-S_{18}: C_{2h}; S_{20}: C_2[4b]) the spectra show many lines.

Table 1. Raman and IR spectra of solid α-S_{18} and S_{20} (in cm^{-1}; Cary 82 Raman spectrometer with krypton laser, 647.1 nm, sample temperature −80°C, slit 1.5 cm^{-1}, relative intensities in brackets; Perkin Elmer 325 IR spectrometer, range 200—600 cm^{-1}, CsI pellets, 25°C).

Apart from the three above-mentioned components, which are stable at 25°C, we have now isolated for the first time an orange-yellow resin-like substance from S_π which may be regarded as a mixture of large S_x rings. S_x is very soluble in CS_2 at 25°C; at −78°C the solubility is 4 g/100 g CS_2. This solution can be stored for weeks at 25°C, whereas neat S_x decomposes within a matter of days at 25°C into polymeric sulfur (*ca.* 60%), S_8 (*ca.* 40%), and traces of S_{12}; no decomposition occurs at −78°C. S_x is practically insoluble in benzene toluene, trichloro-, dichloro-, and dibromomethane. The relative molecular mass of S_x, determined osmometrically in CS_2, corresponds to 25 atoms per molecule; however the Raman spectrum is consistent with a complex mixture of homocycles, since a continuum (due to numerous closely adjacent lines) instead of discrete lines is observed in the region of the SSS deformation vibrations (285—100 cm^{-1}) while, on the other hand, only few SS stretching vibrations occur. Column chromatography on silica gel 60 at −40°C, with partial (10%) decomposition of S_x to S_8, gave only partial separation into six S_8-free fractions with relative molecular masses corresponding to $x = 23$ to 34 (column length 120 cm, solvent CS_2). Under the same conditions, S_6/S_{12} mixtures were separated almost quantitatively.

These findings confirm earlier presumptions[2] that liquid sulfur contains both smaller as well as larger S_n rings ($n = 6$, 7, 12, 18, 20, >20) besides S_8; however, there is no evidence available as yet for the presence of S_9, S_{10} and other medium sized sulfur rings ($n = 13$—17). The view expressed in recent work[8] that S_π consists of S_8 rings in a conformation deviating from that of the normal (D_{4d}) conformation is thus refuted.

Experimental

Preparation of S_x: 400 g of a sulfur melt previously heated to 155—159°C for 3 h and then quenched by pouring into liquid nitrogen is extracted with 250 ml of CS_2 for 1 h at 25°C, and the filtered extract allowed to stand for 20 h at −78°C. The solution is separated from precipitated S_8 and S_{12} by rapid decantation, warmed to 25°C, and treated with an equal volume of *n*-pentane. After 10 min the solution is carefully decanted from the oily S_x. Reprecipitation of the CS_2-containing S_x five times—by dissolution in 40 ml CS_2, treatment with 40 ml *n*-pentane and careful decantion—affords the resin-like product free from S_8, S_7 and S_6. Yield 1.2 g.

Preparation of α-S_{18} and S_{20}: The 5 × 80 ml CS_2/pentane mixture remaining after reprecipitation of the S_x is stored for 3 d in a closed flask at 25°C. The lemon-yellow precipitate is recovered by decantation and extracted with 50 ml CS_2 for 30 min at 25°C. The extract is concentrated to 5 ml and allowed to stand for 1 h. The precipitated sulfur is recrystallized by dissolution in 40 ml CS_2 and concentration of the resulting solution to 3 ml. After 3 h, 150 mg of a mixture of α-S_{18} (intense yellow rhombic platelets) and S_{20} (pale yellow prismatic rods) crystallize out. For separation a small portion of the roughly ground mixture is added to a mixture of 14 ml $CHBr_3$ and 20 ml $CHCl_3$ in a separating funnel and the density of the mixed solvent adjusted by dropwise addition of further $CHBr_3$ (*ca.* 0.25 ml) so that S_{20} ($\rho = 2.01$ g·cm^{-3}) floats on the solution and α-S_{18} ($\rho = 2.09$ g·cm^{-3}) sinks, while small amounts of S_{18} and S_{20} (*e.g.* intergrown crystals) remain suspended in the liquid. On addition of all the remaining

S_{18}/S_{20} mixture, the α-S_{18} separates from S_{20} and each fraction is recrystallized from CS_2. Yields: 80 mg α-S_{18}, 40 mg S_{20}.

Preparation of S_{12}: 400 g of S_8 is heated to *ca.* 200 °C for 5—10 min in a 500 ml flask. The melt is then allowed to cool within 15 min to 140 °C, poured into liquid nitrogen and the product recovered after decantation extracted with 250 ml CS_2 for 1 h at 25 °C. The filtered solution is stored for *ca.* 20 h at −78 °C and then rapidly decanted. The precipitate of S_8 and $S_{12}\cdot CS_2$ is warmed to 25 °C, vigorously shaken with 50 ml CS_2 and the solution rapidly decanted off; the suspended, colorless powdery $S_{12}\cdot CS_2$ is carried over with the solution and is thus separated from the large S_8 crystals. The $S_{12}\cdot CS_2$ is recovered from the solution by filtration, and the filtrate returned to the S_8/S_{12} mixture for further recovery of $S_{12}\cdot CS_2$ by extraction, decantation, and filtration. This procedure is repeated a further three times. The crude product is dissolved in 200 ml CS_2 at 25 °C and recrystallized at −78 °C. Yield: 1.0 g $S_{12}\cdot CS_2$, after prolonged exposure to air 0.85 g S_{12} of m.p. 146—148 °C.—If the sulfur melt is not heated to 200 °C and then cooled to 140 °C but allowed to reach equilibrium at 140 °C within 3 h, the yield of S_{12} is only 0.25 g.

^{23}Na-NMR Study of the Competition of Biogenic Amines with Sodium Ion for Binding to Lasalocid (X-537A)[**]

By *Jean Grandjean* and *Pierre Laszlo*[*]

Lasalocid (X-537A) *(1)*[1], a linear carboxylic polyether antibiotic ionophore, is remarkable for its multiple functions. Not only does it complex and transport a wide variety of ions (alkali and alkaline earth[2], rare earth, transition metal ions) across membranes but has the same action on biogenic amines[3]. Furthermore, it also stimulates thromboxane or prostaglandin synthesis and thus affects calcium metabolism[4].

(1)

Through direct observation of the sodium ion, we have demonstrated competitive binding of Na^+ and biogenic amines (cf. Table 1) with lasalocid *(1)*. This conclusion is in accord with the very similar structures found for both types of complexes (cf.[7]). Given the significantly greater binding constants of the amines with *(1)* in a membrane-like environment[3c, 6b], the transport of the amines across biological membranes can be rationalized as follows: after crossing the membrane, *(1)* disgorges its organic load at the water interface as it recomplexes with alkali and alkaline earth cations, whose physiological concentrations are far greater than those of the catecholamines.

Solvent polarity is an important parameter: whereas one molecule of lasalocid complexes one ion in polar solvents[2b, 2e, 5], two molecules of lasalocid sandwich the alkali or alkaline earth ion in nonpolar media[2a, 2c, 2d] and in the crystal. In such nonpolar environments, the free acid *(1)* assumes a hydrogen-bonded cyclic structure virtually identical to that of the Na^+ complex[2d, 6a]. The binding constants for biogenic amines drop by one or two orders of magnitude when the solvent is changed from isooctane to octanol, and become negligible in methanol solution[6b].

We have chosen a binary mixture of methanol and *n*-hexane (71 : 29 v/v) as solvent in order to mimic the lipid membrane-aqueous solution interface, and to ensure formation of 1 : 1 complexes between *(1)* and Na^+[2e] or the biogenic amines[7]. The ^{23}Na-NMR data[8a] were evaluated in the manner already described[8b].

Addition of biogenic amines to 10^{-2} M solutions of *(1)* as the sodium salt (= 1 : 1 complex of *(1)* and Na^+) induces a narrowing of the observed ^{23}Na resonance. In the absence of amines, the band width decreases upon raising the temperature, as befits fast chemical exchange of the sodium cation between the free state in solution and the bound state in the Na^+/*(1)* complex. The sodium chemical shift does not depend upon the amine concentration. Therefore, the observed relaxation rate $1/T_2$ is simply the weighted average of the relaxation rates in the free (F) and in the bound (B) state, respectively:

$$\frac{1}{T_2} = \frac{p_F}{T_{2F}} + \frac{p_B}{T_{2B}}, \quad \text{with} \quad \frac{1}{T_{2F}} \ll \frac{1}{T_{2B}}$$

The calculated stability constant K_{Na} of the sodium complex is $500 \pm 100\ l\,mol^{-1}$, a value in agreement with the expected solvent effect[2c, 6b]. Addition of the biogenic amines, by displacement of sodium cations from the 1 : 1 complex they form with *(1)*, increases the mole fraction p_F at the expense of p_B, leading to the observed narrowing of the linewidth. The stability constants K_{amine} of the amine complexes (Table 1) have been determined from the following equation:

$$K_{amine} = \frac{[\text{amine}]_F[Na^+]_B}{[\text{amine}]_B[Na^+]_F} K_{Na}$$

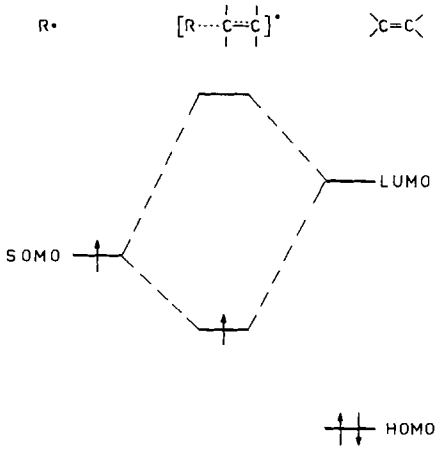
Reversal of the Selectivity Principle in Free-Radical Additions to Alkenes[**]

By *Bernd Giese* and *Jürgen Meixner*[*]

It has previously been assumed that the nucleophilic properties of alkyl radicals in additions to alkenes[1] and arenes[2] can be described in terms of the dominant interaction between



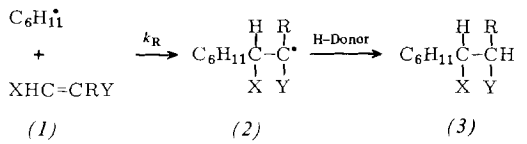


Fig. 1. Frontier orbital interaction between the singly occupied orbital (SOMO) of a radical and the unoccupied orbital (LUMO) of an alkene.

[*] Prof. Dr. B. Giese, Dipl.-Chem. J. Meixner
Institut für Organische Chemie und Biochemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the singly occupied orbitals (SOMO) of the radicals and the lowest unoccupied orbitals (LUMO) of alkenes[3].

Substituents which lower the difference in energy between the SOMO and LUMO ought to increase both the reactivity as well as the selectivity of the radicals and the alkenes, owing to the better frontier orbital interaction. We have now observed this contradiction of the selectivity principle[4] in the reaction of the cyclohexyl radical with the alkenes (*1*): If generation of the C_6H_{11} radical from $C_6H_{11}HgOAc$ and $NaBH_4$ is carried out in the presence of (*1*) the adduct radicals (*2*) capture H to give the product (*3*) in almost quantitative yield[1a, 5].

(*1*) (*2*) (*3*)

In reactions with pairs of alkenes the relative rate constants k_H (R = H) and k_{CH_3} (R = CH_3) can be measured[5].

Table 1. Relative rate constants k_H (R = H) and k_{CH_3} (R = CH_3) (mean error ± 10 %) and competition constants k_H/k_{CH_3} of the cyclohexyl radical with the alkenes (*1*) at 293 K [a] in $CHCl_3$.

Alkene	k_H [b]	k_{CH_3}	k_H/k_{CH_3}
Styrene	≡ 1.0		1.1
α-Methylstyrene		0.92	
Methyl acrylate	6.7		1.3
α-Methyl methacrylate		5.0	
Acrylonitrile	24		1.8
Methylacrylonitrile		13	
Fumarodinitrile	310		4.4
Methylfumarodinitrile		70	
Maleic anhydride	730		5.0
Methylmaleic anhydride		145	

[a] Preliminary experiments show that the reactivity sequence does not alter on varying the temperature.
[b] The k_H values are rate constants per attacked vinylic C-atom. The reactivity of fumarodinitrile and maleic anhydride is twice as large as the k_H value.

The measured values listed in Table 1 show that the statistically corrected rate constant k_H increases by a factor of 730 on going from styrene to maleic anhydride, while in the series of α-methylated alkenes the addition constant k_{CH_3} increases by a factor of only 145.

The raising of the energy of the LUMO by a vinylic methyl group has almost no effect in the case of the less reactive competing pair styrene/α-methylstyrene ($k_H/k_{CH_3} = 1.1$). In contrast the rate constant of the more reactive maleic anhydride is decreased by a factor of 5.0 by introduction of a methyl group (Table 1). Thus, the more reactive the reaction partners, the greater the influence of the substituents.

Together with the gradation in selectivity and reactivity of the primary, secondary and tertiary radicals[1b, 5] this substituent effect clearly demonstrates that the free-radical addition to alkenes can be satisfactorily explained in terms of the frontier orbital theory. If steric effects play a subordinate role[6] the selectivity increases with increasing reactivity of the radicals and alkenes. This finding is of great importance in radical polymerization.

Only in the case of α-methylstyrene are the products of disproportion and O_2-capture formed along with the H-capture product *(3)* from the adduct-radical *(2)*. This has been taken into account in the calculation of the relative reactivities.

[6] The k_K/k_{CH_3} value of 1.1 for the competing system styrene/α-methylstyrene shows that steric shielding by a methyl substituent on the neighboring vinylic C-atom has little influence on the addition of cyclohexyl radicals. In contrast the steric effect of a methyl group is of great importance for the regioselectivity of radical additions. *B. Giese, J. Meixner*, Tetrahedron Lett. *1977*, 2779. Table 1 contains alkenes from fumaronitrile which bear a CN or C(O)O group on the carbon atom which is attacked; although the steric effect of these groups is extremely small, without such shielding the reactivities ought to be somewhat greater.

A New Cationic Binuclear Trihydrido Complex Containing One Four- and One Five-Coordinate Platinum Atom[**]

By *Gustav Bracher, David M. Grove, Paul S. Pregosin*, and *Luigi M. Venanzi*[*]

As part of our programme concerned with the chemistry of platinum hydrides we have characterized several derivatives containing a monohydrido bridge, *e.g. (1)*[1]. In an extension of this work we have prepared, and now report, the unusual binuclear platinum trihydrido complex *(2a)* which contains both a dihydrido bridge and a terminal hydride ligand. This is the first example of a class of binuclear platinum hydrides containing one four- and one five-coordinate metal center. The recently reported dimeric complex $[Pt_2(\mu H)_2(SiEt_3)_2(PCy_3)_2]$[2] (Cy = cyclohexyl) also contains a dihydrido bridge, but here both metal centers are equivalent and four-coordinate.

The synthetic route to *(2a)* is shown below:

$$[Pt(cod)_2] + 2Ph_3P + H_2 \rightarrow \text{"hydride intermediate"}, \quad (3)$$

$$(3) + trans\text{-}[PtH(MeCOMe)(Ph_3P)_2][BF_4] \rightarrow (2a) \quad (4)$$

(cod = 1,5-cyclooctadiene)

The reaction of $[Pt(cod)_2]$ with two moles of phosphane and subsequent treatment with gaseous hydrogen is known to afford bisphosphanedihydridoplatinum complexes[3,4].

In our case intermediate *(3)* was directly reacted with *(4)* to give the trihydrido complex *(2a)*, which was isolated from the reaction mixture as a pale-yellow air-stable solid. Its microanalytical data are consistent with the molecular formula shown and its infrared spectrum shows a weak band at 2205 cm^{-1}, which we assign to the terminal $Pt_B—H_B$ stretching vibration.

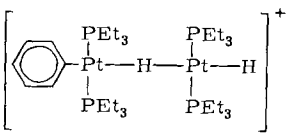
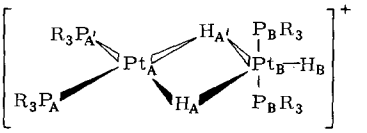
[**] This work was supported by the Swiss National Science Foundation.

The molecular structure of complex *(2a)* was deduced from the ^1H-, ^{31}P- and ^{195}Pt-NMR spectroscopic data.



The ^1H-NMR spectrum [$(CD_3)_2CO$, 360 MHz] has, in addition to the resonances due to the aromatic protons of the PPh_3 ligands, a complex set of resonances in the region to high field of TMS. The appearance of these hydride resonances is indicative of a system containing strongly coupled spins and the spectral data were analyzed by computer simulation and iteration[5].

For the purposes of discussion the resonances are conveniently divided as follows:



1. A terminal hydride resonance [$\delta H_B = -4.75$], of relative intensity one, which is coupled to two distinct platinum atoms [$^1J(H_BPt_B) = 1197$ Hz, $^3J(H_BPt_A) = 226$ Hz], two bridging hydride atoms [$^2J(H_AH_B) = 14$ Hz] and two equivalent phosphorus atoms [$^2J(H_BP_B = 25$ Hz].

2. A bridging hydride resonance, H_A, of relative intensity two, which is centred at $\delta = -3.20$ and coupled to two distinct platinum atoms [$^1J(H_APt) = 601$ and 397 Hz], four phosphorus atoms and the terminal hydride ligand. The division of this resonance into two well-separated multiplets arises from the large value of $\{^2J(H_AP_A) + {}^2J(H_AP_{A'})\}$ which is 110 Hz. This results from the fact that the values of $^2J(PH)$ for platinum complexes are large (> 100 Hz) for *trans*- and small (< 25 Hz) for *cis*-geometries[6].

A $^{195}Pt\{^1H\}$-NMR study showed resonances attributable to two distinct metal centers [CD_2Cl_2: $\delta Pt_A = -5104$, $\delta Pt_B = -4756$][7] each of which was coupled to two equivalent directly bound phosphorus atoms. The magnitude of the observed platinum-platinum coupling [$^2J(Pt_APt_B) = 325$ Hz] is comparable to that found for *(1)* (366 Hz) and is in accord with values found for other dimeric complexes containing bridging ligands[8].

BPh_4^- *(1)*

BF_4^-

(2a), R = C_6H_5
(2b), R = C_2H_5
(2c), R = $c\text{-}C_6H_{11}$

The $^{31}P\{^1H\}$-NMR spectrum of *(2a)* shows the expected resonances for the two types of phosphorus atoms with appropriate couplings to platinum [CD_2Cl_2: $\delta P_A = 31.9$, $^1J(P_APt_A) = 3008$ Hz, $^3J(P_APt_B) = 42$ Hz; $\delta P_B = 26.6$, $^1J(P_BPt_B) = 2803$ Hz, $^3J(P_BPt_A) = 18$ Hz][7]. An "off-resonance" ^1H-decoupling experiment resulted in a large residual splitting of the signals attributable to P_A confirming our proposal of a *trans* phosphorus-hydride arrangement about Pt_A.

Experimental

To a stirred toluene solution of PPh_3 (525 mg, 2 mmol) under a N_2 atmosphere at 0°C was added $[Pt(cod)_2]$ (411 mg, 1 mmol) to produce a clear orange solution. A separate solution of *trans*-$[PtH(MeCOMe)(PPh_3)_2]^+BF_4^-$ (865 mg, 1 mmol) was prepared at 0°C and saturated with H_2. The two solutions were mixed together at 0°C and then stirred under a H_2 atmosphere for ½ h. After removal of solvent *in vacuo* the mass was washed with methanol and the brown-yellow solid collected and dried. An acetone extract of this solid was treated

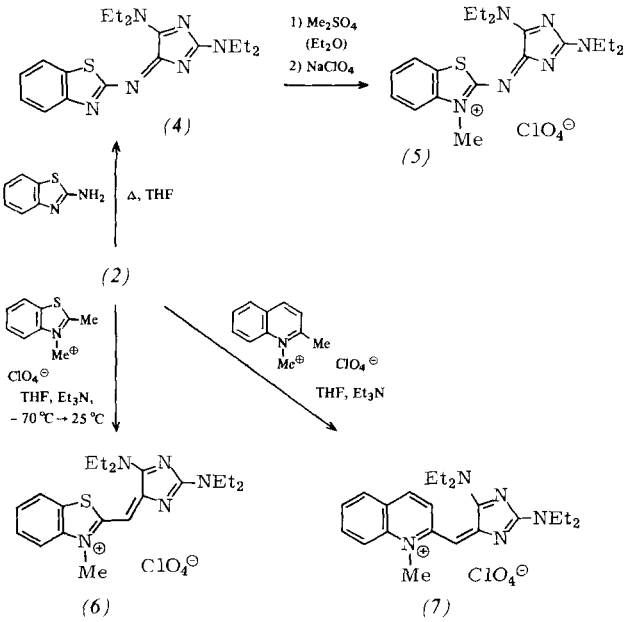
Stable Aza- and Diazacyclopentadienylium Salts[1]

By *Rudolf Gompper* and *Klaus Bichlmayer*[*]

Consistent with expectations from aromaticity criteria it has already been demonstrated experimentally that cyclopentadienyl cations are antiaromatic (resonance destabilized)[2]. From investigations on azacyclobutadienes[3, 4] it may be concluded—with supporting evidence from MO calculations[5]—that the antiaromatic character of aza- and 1,3-diazacyclopentadienyl cations is weaker than that of cyclopentadienyl cations. Moreover, donor groups, especially dialkylamino groups, also ought to have a stabilizing effect in all cyclopentadienyl cations.



Treatment of tetrachloro-2*H*-imidazole *(1)*[6] in tetrahydrofuran with an excess of diethyl(trimethylsilyl)amine, first at

(1) *(2)* *(3)*

−70°C and then at room temperature, leads to separation of fine, bright-yellow needles whose composition, according to analytical and spectroscopic data and chemical behavior, has been established as 2,4,5-tris(diethylamino)-1,3-diazacyclopentadienylium chloride *(2)* (Table 1). The salt-like character of *(2)* is confirmed, *inter alia*, by the fact that it can be converted into the, likewise yellow, perchlorate *(3)* without any noticeable change in properties (Table 1).

Hydrolysis of *(2)* with aqueous hydrochloric acid affords, as expected, parabanic acid. Of preparative interest are the reactions of *(2)* with 2-aminobenzothiazole, 2,3-dimethylbenzothiazolium perchlorate, and 1,2-dimethylquinolinium perchlorate, which, respectively afford the orange merocyanine *(4)*, the red cyanine dye *(6)*, and the red quinolinium salt *(7)*. *(4)* reacts with dimethyl sulfate to give the orange azacyanine dye *(5)* (Table 1).

An Example of the Equilibrium Ethylenehydridometal ⇌ Ethylmetal Complex[1]

By *Helmut Werner* and *Rainer Feser*[*]

It is generally assumed that both the insertion of C_2H_4 in a M—H bond as well as the reverse of this reaction proceed *via* an intermediate of the type *(1)*.

$$L_nMH + C_2H_4 \rightleftarrows \underset{(1)}{L_nMH(C_2H_4)} \rightleftarrows L_nM(C_2H_5)$$

Very few examples of stable isolable ethylenehydridometal complexes have previously been reported in the literature[2].

After having prepared $C_5H_5Rh(PMe_3)_2$ *(2)*[3] we have now also synthesized its monocarbonyl- *(3)* and ethylene-derivative *(4)* and investigated their behavior as Lewis bases.

$$\underset{(2)}{C_5H_5Rh(PMe_3)_2} + CO \rightarrow \underset{(3)}{C_5H_5Rh(CO)PMe_3} + PMe_3$$

$$[(C_2H_4)(PMe_3)RhCl]_2 + 2TlC_5H_5 \rightarrow \underset{(4)}{2C_5H_5Rh(C_2H_4)PMe_3} + 2TlCl$$

While *(2)* even reacts with NH_4PF_6 to give the complex $[C_5H_5RhH(PMe_3)_2]PF_6$, the stronger acid HBF_4 (in propionic anhydride) is necessary for the protonation of *(3)* and *(4)*; this is one case where the influence of the ligand—PMe_3 is a much better donor than CO or C_2H_4—on the basicity of the metal atom is more marked.

$$\underset{(3),(4)}{} + HBF_4 \rightarrow \underset{\substack{(5),\ L=CO \\ (6),\ L=C_2H_4}}{[C_5H_5RhH(L)PMe_3]BF_4}$$

The products *(5)* and *(6)* form light-brown, extremely air-sensitive crystals which are readily soluble in polar organic solvents such as *e.g.* CH_3NO_2.

As shown by the ^{1}H-NMR spectrum (cf. Table 1) *(5)* also exists in solution as the carbonylhydrido complex; evidence for insertion of the CO ligand in the Rh—H bond is not observed. In contrast, however, the temperature-dependence of the spectrum of *(6)* indicates, in this case, that an equilibrium is set up between ethylenehydrido- (a) and ethyl complex (b), where the free coordination site in the latter could possibly be occupied by a solvent molecule.

$$\underset{(a)}{[C_5H_5RhH(C_2H_4)PMe_3]^+} \rightleftarrows \underset{(b)}{[C_5H_5Rh(C_2H_5)PMe_3]^+}$$

In CD_3NO_2-solutions of *(6)* at room temperature only the signals of the C_5H_5- and PMe_3-protons are sharp, while those of the hydridic H atom ($\delta \approx -10.5$) and of the C_2H_4-protons ($\delta \approx 3.3$) appear as broad humps. At $+10$°C the signal at $\delta \approx 3.3$ splits into two less broader signals, which on further cooling to -20°C give two multiplets at $\delta = 3.0$ and 3.52. As expected, at -20°C a doublet of doublets (Table 1) is observed for the RhH signal. The signals of the C_5H_5- and PMe_3-protons remain unchanged on lowering the temperature[4].

Table 1. ^{1}H-NMR data for *(3)*—*(11)* (δ values, TMS int.; J in Hz; solvent for neutral complex: C_6H_6, for ionic compounds: CD_3NO_2).

0570-0833/79/0202-0157 $ 01.00/0

^{1}H-NMR signals for the RhH and C_2H_4 protons disappear. If the solution of *(6)* in D_2O is treated with KOH and the resulting product extracted with benzene, the ^{1}H-NMR spectrum of the benzene extract is identical—except for the signals for complex-bound ethylene—with that of *(4)*. The mass spectrum of the product remaining after removal of solvent shows the line of highest intensity in the range $m/e = 270$—280 at $m/e = 276$, which corresponds to an ion of composition $C_5H_5Rh(C_2D_4)PMe_3^+$; the occurrence of weak lines at $m/e = 277$ to 281 indicate that reaction of D_2O with *(6)* can lead to deuteration not only of the ethylene but also, at least partially, to deuteration of the cyclopentadienyl ligand (the relatively low intensity of the C_5H_5-signal in the ^{1}H-NMR spectrum supports this assumption; cf. also [5]).

The equilibrium between ethylenehydrido- and ethyl-complex is also reflected in the reactivity of *(6)*: the ethylene of the complex can be replaced by CO or by P(*i*-Pr)$_3$. Reaction with C_2H_4 leads to formation of *(8)*, from which *(6)* can be regenerated, both in the solid state as well as in solution with elimination of C_2H_4; the formation of *(8)* could be formulated as involving an addition of ethylene to the free coordination site of the cation $[C_5H_5Rh(C_2H_5)PMe_3]^+$.

$$(6) + L \rightarrow [C_5H_5RhH(L)PMe_3]BF_4 + C_2H_4$$
$$(5),\ L = CO$$
$$(7),\ L = P(iPr)_3$$

$$(6) + C_2H_4 \rightleftharpoons [C_5H_5Rh(C_2H_5)(C_2H_4)PMe_3]BF_4$$
$$(8)$$

Analogously as with ethylene, *(6)* also reacts with NaCl, NaBr or NaI to give neutral complexes *(9)*—*(11)*, which have been characterized by elemental analysis, ^{1}H-NMR data and mass spectra. In the reaction of *(6)* with NaF (in water or nitromethane) a deprotonation of the ethylenehydrido-metal cation takes place and *(4)* is obtained.

$$(6) + NaX \rightarrow [C_5H_5Rh(C_2H_5)(PMe_3)X] + NaBF_4$$
$$(9),\ X = Cl$$
$$(10),\ X = Br$$
$$(11),\ X = I$$

$$(6) + NaF \rightarrow C_5H_5Rh(C_2H_4)PMe_3 + HF + NaBF_4$$
$$(4)$$

To our knowledge these findings provide the first evidence that an ethylenehydridometal complex can exist in equilibrium with an ethylmetal complex under normal conditions in solution. This finding is of general importance for an understanding of the insertion of olefins in M—H bonds.

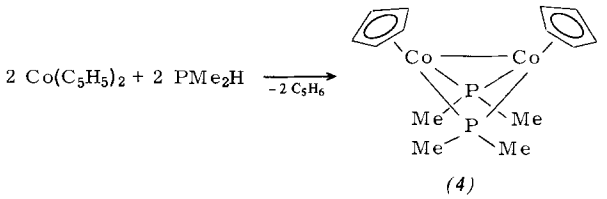
Stepwise Addition of a Lewis Acid and a Lewis Base to a Metal-Metal Bond[1]

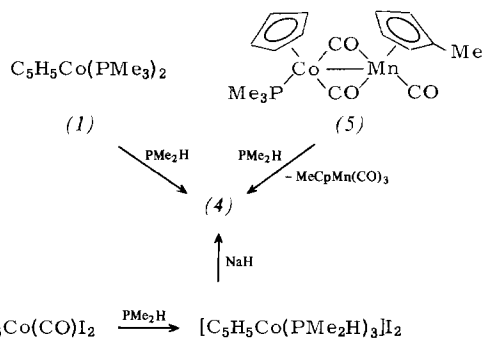
By *Helmut Werner* and *Werner Hofmann*[*]



$C_5H_5Co(PMe_3)_2$ *(1)* reacts with methyl iodide and ethyl iodide to give ionic compounds of the type *(2)*[2a], and, surprisingly with isopropyl bromide and *tert*-butyl bromide to give compounds of type *(3)*[2b].

(2), R = Me, Et *(3)*, R' = *i*Pr, *t*Bu

If it is correct that steric factors are responsible for the different reaction course, it could be possible for a complex $C_5H_5CoL_2$—or even $C_5H_5Co(PMe_3)L$—containing a ligand L which is *smaller* than PMe_3 to react with *i*PrBr or *t*BuBr to give a cation with a stable Co—R' bond. We therefore attempted the preparation of $C_5H_5Co(PMe_2H)_2$ and/or $C_5H_5Co(PMe_3)(PMe_2H)$.



The bis(phosphite) complexes $C_5H_5Co[P(OR)_3]_2$ (R = Me, Et, Ph)[3a] as well as *(1)*[3b] are accessible from cobaltocene. Dimethylphosphane also reacts cleanly with $Co(C_5H_5)_2$, giving quantitatively the binuclear complex *(4)*; the half-sandwich complex $C_5H_5Co(PMe_2H)_2$ expected as intermediate has so far not been detected.

(4)

The bis(μ-*diphenyl*phosphido) complex analogous to *(4)* is accessible by reaction of $C_5H_5Co(CO)_2$ with P_2Ph_4[4]. Attempts to prepare *(4)* in this way have proved unsuccessful; reaction of $C_5H_5Co(CO)_2$ with P_2Me_4 afforded the μ-diphosphane complex $C_5H_5(CO)Co(PMe_2PMe_2)Co(CO)C_5H_5$[4].

Our attempts to synthesize $C_5H_5Co(PMe_3)(PMe_2H)$ also led to *(4)*. Its formation from *(5)* is noteworthy insofar as the (*Co—Mn*)-binuclear complex *always* reacts with other Lewis bases L (PPh_3, $P(OMe)_3$, $P(OPh)_3$, alkenes, alkynes *etc.*) to give $C_5H_5Co(PMe_3)L$ and $MeC_5H_4Mn(CO)_3$[5].

(4) is also formed on reduction of the dication $[(C_5H_5Co(PMe_2H)_3]^{2+}$, which—similarly to $[C_5H_5Co(PMe_3)_3]^{2+}$[1,2a]—is obtainable in good yield by reaction of $C_5H_5Co(CO)I_2$ with PMe_2H in methanol.

According to MO calculations[6] for $[(CO)_nM(\mu\text{-}PPh_2)]_2$ the σ-electron pair of the metal-metal bond occupies the HOMO of this molecule. Should this also be the case for *(4)* its Co—Co bond ought to have nucleophilic character and react with electrophiles. It does not react with MeI at room temperature. On the other hand, *(4)* reacts rapidly and quantitatively with trifluoroacetic acid to give a cationic μ-hydridocobalt complex, which on precipitation with NH_4PF_6 affords the corresponding hexafluorophosphate *(6)* as dark-brown, air-stable crystals[7].

(4) $\xrightarrow[(NH_4PF_6)]{CF_3COOH}$  PF_6

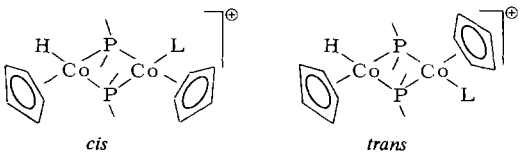
(6)

We assume that the cation of *(6)* has a triple-decker-like structure[8]. According to *Hoffmann* et al.[9], binuclear complexes of this type ought to be stable when the two metal atoms possess 30 or 34 valence electrons; in the case of *(6)* the 34-electron rule applies. Consistent with the suggested bridged structure the NMR signal of the CoHCo proton is observed at much higher field ($\delta = -21$!) than that of the CoH proton of $[C_5H_5Co(PMe_3)_2H]^+$[2a]. The marked broadening of the signal is due to the fact that the bridge H-atom is bound to *two* Co nuclei (which have a quadrupole moment).

Like the 34-electron complex $[Ni_2(C_5H_5)_3]^+$[8], *(6)* also reacts with Lewis bases: reactions with PMe_3 and $P(OMe)_3$ afford the compounds *(7)* and *(8)*, respectively, in very good yields (>80%). The red crystals of *(7)* and *(8)* are readily soluble in acetone or nitromethane and are only slightly sensitive to air.

(6) + L ⟶ $[C_5H_5(L)Co(\mu\text{-}PMe_2)_2Co(H)C_5H_5]PF_6$

(7), L = PMe_3



(8), L = $P(OMe)_3$

The opening of the CoHCo bridge during the formation of *(7)* and *(8)* is confirmed by the ^{1}H-NMR spectra (Table 1). For example, the hydride signal in the spectrum of *(7)* is shifted 7.7 ppm *downfield* compared to the same signal in the spectrum of *(6)* and appears in a similar region as for $[C_5H_5Co(PMe_3)_2H]^+$. While the reaction of *(6)* with PMe_3 gives essentially only one product, the NMR spectrum of *(8)* indicates the presence of two isomers—probably *cis/trans* isomers.

Table 1. ^{1}H-NMR data of the complexes *(4)*, *(6)*, *(7)* and *(8)* (δ values, TMS int.; *J* in Hz).

Complex	Solvent	C_5H_5	μ-PMe_2	Co—H	L

[a] Mixture of two isomers (see text); [b] overlapping of four virtual triplets.

cis *trans*

Trimethylphosphane is bulkier than trimethyl phosphite[10] and can therefore attack a cobalt atom of *(6)* only from the more sterically favorable side. The NMR data of *(7)* give no indication in this case whether the *cis*- or corresponding *trans*-isomer is present.

No addition takes place on reaction of *(6)* with anionic Lewis-bases such as H^- or Me^-: The reactions with NaH (in tetrahydrofuran) or with $LiCH_3$ (in ether) lead quantitatively to the neutral complex *(4)*.

Our observation that the *stepwise* addition of a Lewis acid and a Lewis base to a metal-metal bond is possible, *without disturbing the binuclear structure*, could be of general importance. Thus, the increased reactivity of carbonylmetal clusters (*e.g.* $Ir_4(CO)_{12}$) in the presence of Lewis acids such as $AlCl_3$[11] could be due to the initial opening of an M—M bond and the subsequent reaction of the intermediate with a Lewis base such as *e.g.* CO. *Vahrenkamp*[12] has recently pointed out the possibility that ligand substitution in binuclear complexes or clusters is initiated by cleavage of an M—M bond.

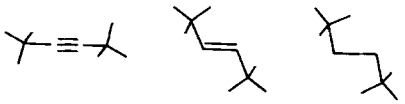
Hindered Rotation at the Triple Bond



By *Philippe Koo Tze Mew* and *Fritz Vögtle*[*]

While rotation about the C—C single bond in ethanes is hindered even by small substituents[1a,1b], it is foreseeable that bulkier substituents are necessary to bring about such

[*] Prof. Dr. F. Vögtle, Dipl.-Chem. P. Koo Tze Mew

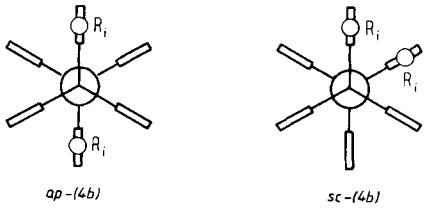
© *Verlag Chemie, GmbH, D-6940 Weinheim, 1979* *0570-0833/79/0202-0159 $ 01.00/0*

hindrance in the case of the extended triple-bond system *(1)*[1c]. We have found that suitably substituted triptycene groups hinder rotation not only in butynes *(1)* but also in butenes *(2)* and butanes *(3)*.

(1) *(2)* *(3)*

DNMR spectroscopic investigation of the *un*substituted ditriptycenyl-ethyne *(4a)*, -ethene *(5a)*[2], and -ethane *(6a)* (see Table 1) revealed detectable steric interactions only for the ethane system at low temperature.

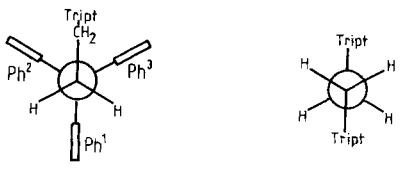


(4) *(5)* *(6)*

(a): $R_i = R_a = H$

(b): $R_i = R_a = CH_3$

Hindrance to rotation could, however, be achieved also in the ethyne system *(4)* by incorporation of internal substituents R_i[3]: for the internal methyl groups $(CH_3)_i$ of *(4b)* a broadened absorption is already observed at room temperature[4]; at higher temperatures it converts into a sharp singlet ($\delta = 2.80$ at 70°C, in $C_2D_2Cl_4$), and on cooling it splits into two singlets ($\delta = 2.66$, 3.16, in CD_2Cl_2) (coalescence temperature $T_c = +10$°C), the intensity ratio of which is temperature dependent. We interpret this behavior as indicative of the presence of two conformers at lower temperature, and their interconversion at higher temperature. We assign the more intense singlet to the antiperiplanar conformation (*ap-4b*), the less intense singlet to the synclinal conformation (*sc-4b*). On cooling, the population of the more stable *ap*- compared to the *sc*-conformer increases from 2.7:1 (0°C) to 7.6:1 (−80°C). Taking into account the difference in population of the conformers the threshold of the rotation is approximately[5]: $\Delta G_c^{\ddagger} = 63.1$ kJ/mol (15.1 kcal/mol) for the *sc*→*ap* conversion and 65.2 kJ/mol (15.6 kcal/mol) for the *ap*→*sc* conversion.



ap-(4b) *sc-(4b)*

Thus, in *(4b)* we have an obvious case of steric hindrance of the "nonbonded interaction" type by (methyl) substituents, which touch each other face-to-face without substantial steric contributions from neighboring groups[6, 7].

While the methyltriptycene-substituted ethene *(5b)* and the analogous ethane *(6b)* do not show temperature-dependent ^{1}H-NMR spectra, in the case of *un*substituted ditriptycenylethane *(6a)* a sharpening of the multiplets of the arene protons and singlet of the methylene protons compared to the singlet of the bridgehead protons is observed on increasing the temperature. Cooling to −20°C leads to increased broadening of the multiplets of the arene protons, especially of the multiplet of H-1, H-8 and H-13. At −40°C H-1, H-4 and H-2, H-3 split at $\delta = 7.42$ and 7.00 in the intensity ratio 1:1. These findings are consistent with free rotation of the triptycenyl groups about the C-9—CH_2 bond in *(6a)* at room temperature and the freezing out of rotation at lower temperature, for Ph^1 in the conformation *(6aA)* differs from the equivalent phenylene groups Ph^2 and Ph^3[8]. At −30°C the free energy of activation is $\Delta G^{\ddagger} = 58.5$ kJ/mol (14 kcal/mol)[9].

The sharp singlet of the four *methylene* protons in *(6a)* at room temperature indicates time-averaged predominance of the sterically more favorable antiperiplanar conformation *(6aB)* with equivalent methylene protons. The increased broadening with decreasing temperature (down to −80°C) indicates a slowing-down of the to-and-fro rotation of the triptycenylmethylene groups about the central CH_2—CH_2 bond. In the process *sc*-conformers can be formed, but the *sp* barrier is not crossed.

(6aA) *(6aB)*

Consistent with these explanations is the temperature-independence of the proton resonances of *(5b)* and *(6b)* which

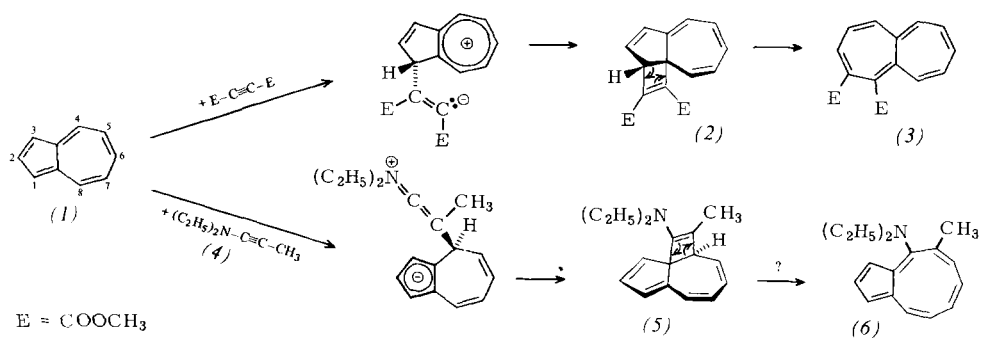
Surprising Transformation of Azulene by Cycloaddition with 1-(Diethylamino)propyne[**]

By *Klaus Hafner, Hans Jörg Lindner*, and *Werner Ude*[*]

Azulene *(1)* reacts as the prototype of nonbenzenoid "aromatic" hydrocarbons[1] with electrophiles and nucleophiles *via* substitution at positions 1(≡3) and 4(≡8), respectively, or 6. With electron-poor alkynes such as dimethyl acetylenedicarboxylate, *(1)* can undergo not only additive substitution[2a] but—like electron-rich alkenes[2b] also thermally induced dipolar cycloaddition at the five-membered ring; subsequent valence isomerization of the primary adduct *(2)* yields the next-higher homologue of *(1)*, *viz.* the heptalene derivative *(3)*[2c]. We have now attempted reaction of *(1)* with electron-rich alkynes such as 1-(diethylamino)propyne *(4)* in order to obtain the adduct *(5)* *via* (presumably also dipolar) cycloaddition to the seven-membered ring. Valence isomerization of *(5)* could lead to the hitherto unknown cyclopentacyclononene system *(6)*[3].



Surprisingly, *(1)* and *(4)* give a colorless crystalline 1:1 adduct *(7)*, m.p. 76 °C, even at room temperature. Compound *(7)* was isolated after 20 d in 83 % yield (based on reacted azulene)[4]. The constitution of the bridged spiro[4.5]decatetraene *(7)* has been confirmed by X-ray structure analysis[5] and ^{1}H- and ^{13}C-NMR spectra (Table 1). Thus *(7)* exists in the crystal as a dimer *(8)* formed by [4+2] cycloaddition of its cyclopentadiene moiety whereas a rapid retro-Diels-

Alder raction to give *(7)* occurs in solution (benzene, trichloromethane). This indicates only low activation energy for dimerization of *(7)* and for the cycloreversion of *(8)* (E_a < 25 kcal/mol)[6].

Formation of *(7)* probably involves the primary adduct *(5)* containing the structural unit of a spiro[3.4]octa-1,5,7-triene, which has been shown by *R. D. Miller et al.*[7] to resist isolation at −10 °C, partly due to a presumably 1,5 sigmatropic ring expansion to form a dihydropentalene. Analogous rearrangement of the 1,3-diene-bridged derivative *(5)* should lead to *(7)*.

In the presence of catalytic amounts of glacial acetic acid at room temperature, *(7)* undergoes fast isomerization in solution (CH_3OH)—possibly by renewed 1,5 sigmatropic alkyl shift—to give 20 % of the 1,8a-dihydrocyclopent[*c,d*]azulene derivative *(9)* (lemon yellow needles, m.p. 87 °C; see Table 1), which is transformed under the same reaction conditions

within *ca.* 3 h to give 2-(diethylamino)-1-methyl-3,4-dihydrocyclopent[*cd*]azulene *(10)* (brown platelets, m.p. 52 °C, yield 80 %; see Table 1). In boiling tetralin, on the other hand, *(7)* gives *(10)* directly in 30 % yield. The same tricyclic com-

pound also results from reaction of *(1)* with *(4)* in boiling tetralin (yield 17%), probably also *via (7)* as intermediate.

In contrast to *(1)*, 4,6,8-trimethylazulene *(11)* reacts with *(4)* only in boiling tetralin; cycloaddition is hindered by the alkyl groups in positions 4 and 8.

The major product isolated was found to be 15% of the dihydrocyclopentaindene derivative *(14)* (yellow platelets,

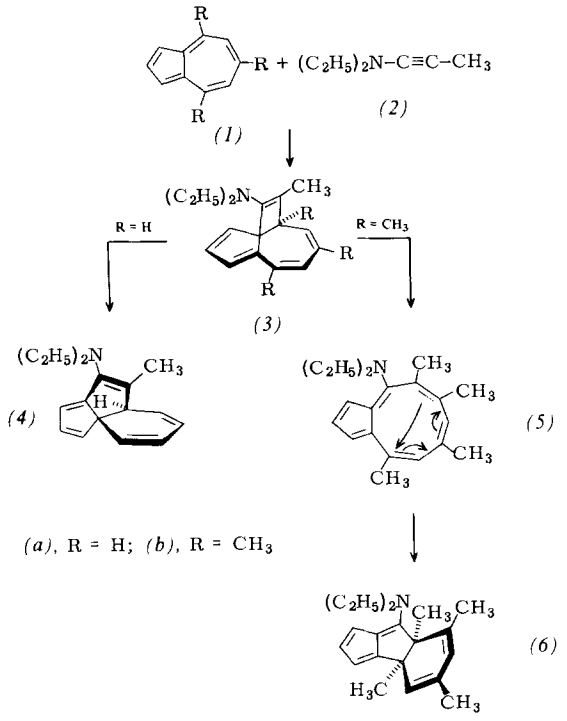
Facile Ring Enlargement of Azulene to Give the Cyclopentacyclononene System by Dipolar Cycloaddition[**]

By *Klaus Hafner, Hans Jörg Lindner*, and *Werner Ude*[*]



Azulene *(1a)* and 4,6,8-trimethylazulene *(1b)* react with 1-(diethylamino)propyne *(2)* to form 1,3-diene-bridged spiro-[3.4]octa-1,5,7-triene derivatives *(3)*, which undergo stabilization by 1,5 sigmatropic ring enlargement to bridged spiro-[4.5]decatetraene *(4)* or by valence isomerization *via* the cyclopentacyclononene *(5)* to give the dihydrocyclopentaindene derivative *(6)*[1a]. Owing to the valence isomerization characteristic of cyclononatetraenes[1b], the azulene-homologous cyclopentacyclononene system could not yet be isolated. This result prompted a study of cycloadditions of *(2)* with azulenes bearing substituents which hinder or rule out valence isomerization of the nine-membered ring in *(5)*. Inspection of models suggested that the readily accessible 1,2-dihydrocyclopent[*cd*]azulene *(7)*[2] should be particularly suitable for this purpose.

The bridged azulene *(7)* reacts like azulene with *(2)* at room temperature to give a brownish red crystalline 1:1

adduct[3] of m.p. 127—129 °C [43 % yield based on reacted *(7)*]. According to X-ray structure analysis (Fig. 1)[4] and spectroscopic results, the expected 1,10-ethano-bridged 4-(diethylamino)-5-methylcyclopentacyclononene *(9)* is indeed formed.

The five-membered ring of the "6-amino-1-vinylfulvene system" present in *(9)* is planar, with an exocyclic double bond twisted through about 30° and a 1-vinyl group twisted only slightly out of the plane of the ring. The bond lengths in this partial structure lie in the region characteristic of 6-aminofulvenes[5] and suggest extensive π-electron delocalization. The resulting weakening of the exocyclic double bond of the fulvene system is manifested in the relatively large twisting of this bond. The torsional angles of the other single bonds in the nine-membered ring (53, 83, 93°) are extremely large. The conformation of this ring resembles the tub form of cyclooctatetraene and thus corresponds to that of 1-(dimethylcarbamoyl)-azonine[6].

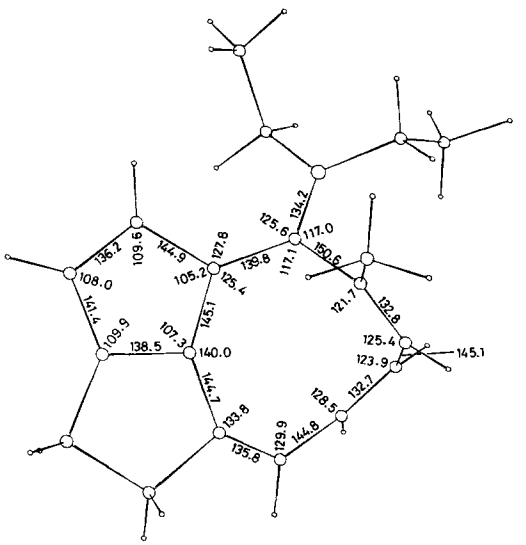

Fig. 1. Molecular structure of *(9)* with bond lengths [pm] and bond angles [°] of the cyclopentacyclononene system (standard deviations $\sigma_r = 0.4$ pm; $\sigma_\alpha = 0.4°$).

UV/VIS and NMR spectra of *(9)* are in accord with this structure[7]. The UV spectrum corresponds to that of 6-(dimethylamino)-1-(2-methoxyvinyl)fulvene[8].

The novel ring system *(9)*, presumably resulting by valence isomerization of the primary adduct *(8)*, is the first cyclononatetraene derivative which is thermally stable and inert towards atmospheric oxygen, and is not stabilized by benzo-annelation[9]. No isomerization of *(9)* takes place in boiling toluene or in the presence of protic acids. Reversible protonation of *(9)*, presumably occurring at one of the ring C atoms, is possible in 2 N H_2SO_4 and conc. acetic acid.

3-Bromo-3-methyl-2-trimethylsiloxy-1-butene—A New Cycloaddition Reagent[1]

By *Hideki Sakurai, Akihiko Shirahata*, and *Akira Hosomi*[*]

We have found that 3-bromo-3-methyl-2-trimethylsiloxy-1-butene *(1)* can be obtained in good yield from 3-bromo-3-

methyl-2-butanone, and is a useful reagent for synthesis of seven- and five-membered cyclic ketones from 1,3-dienes and olefins, respectively.

The reaction of *(1)* with 1,3-dienes in dichloromethane in the presence of zinc chloride gives cycloheptenones, *i.e.* [3+4] cycloadducts, in good to excellent yields (Table 1). With isoprene (experiment no. 4), karahanaenone *(2)*[2] was obtained in 33% yield with its regio isomer *(3)*.

With isoprene and 1,3-butadiene, [3+2] cycloadducts were also obtained in small amounts.

Styrene derivatives gave [3+2] cycloadducts as major products (Table 1). For example, 2-(*p*-methylphenyl)-1-propene (experiment no. 7) afforded the aromatic sesquiterpene (±)-α-cuparenone *(4)*[3] and its regio isomer *(5)*. Zinc chloride was again the most satisfactory catalyst examined.

R = *p*-CH_3–C_6H_4

[3+4] and [3+2] cycloadditions have been reported for α,α′-dibromoketones with zinc-copper couple[4] or carbonyl-iron compounds[5] as catalysts and using 2-methoxyallyl bromide with silver perchlorate as catalyst[6]. However, the new reagent *(1)* generally gives higher yields, and the reactions would appear to have important mechanistic implications.

Procedure

To a solution of lithium diisopropylamide, prepared from diisopropylamine (12.1 g, 0.12 mol) in THF (100 ml) and 1.0 M *n*-butyllithium in *n*-hexane (120 ml, 0.12 mol) is added 3-bromo-3-methyl-2-butanone (16.5 g, 0.10 mol) dropwise at −78 °C. The mixture is stirred for 30 min at −78 °C and then chlorotrimethylsilane (13.0 g, 0.12 mol) is added to the mixture. The cooling bath is removed and the mixture is stirred for 6 h at room temperature. After the solvent has been stripped, *(1)* (16.5 g, 70% yield) is distilled at 63 °C/9 torr. ^{1}H-NMR (CCl_4): δ = 0.40 (9H, s), 1.95 (6H, s), 4.10 (1H, d, J = 2 Hz), 4.60 (1H, d, J = 2 Hz); IR (film): 1620 cm.

Facile Regeneration of Carbonyl Compounds from 1,3-Dithiane 1-Oxides *via* 1-Ethoxy-1,3-dithianium Salts[**]

By *Ingfried Stahl, Jürgen Apel, Rainer Manske*, and *Jürgen Gosselck*[*]

Carbonyl compounds can be protected as 1,3-dithiane 1-oxides *(1)*; they are usually released again in an acid medium[1]. We have found that *(1)* can be alkylated regioselectively at the O-atom with triethyloxonium tetrafluoroborate *(2)*, even at 0 °C (CH_2Cl_2, argon), to give the hitherto unknown 1-ethoxy-1,3-dithianium tetrafluoroborates *(3)*, which are isolable in high yields.

(1) *(2)* *(3)*

(4) *(5)*

The salts *(3)* rapidly cleave in aqueous neutral medium at 5 °C, giving the carbonyl compounds *(4)* and propylene disulfide *(5)* in high yields (over 60%). The observed separation of *(5)*, which was also isolated in the acid hydrolysis of *(1)*[2], confirms the postulated reaction mechanism *via* hydroxydithianium ions.

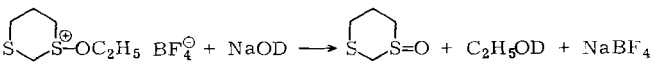
This hydrolytic variant for the cleavage of 1,3-dithiane 1-oxides *(1)* *via* *O*-ethyl derivatives *(3)* constitutes a novel and preparatively simple method.

As precursors for the preparation of *(3)* we used the *trans*-2-substituted sulfoxides *(1)* (Table 1) (content of *trans* isomer >90%), which we synthesized from the 1,3-dithianes[3] by monooxidation with $NaIO_4$[4].

Table 1. Some new 1,3-dithiane 1-oxides *(1)* [a].

	R	Yield [%]	*trans*/*cis*	M.p. [°C]	^{13}C-NMR, δ-values [b]
(1e)	C_6H_4-OCH_3-(*p*)	90	92:8	166	68.8, 29.2, 31.2, 54.4, 55.0 (OCH_3)
(1f)	C_6H_4-NO_2-(*p*)	83	91:9	176–177	68.6, 29.2, 31.0, 54.7
(1g)	C_6H_4-CH_3-(*p*)	94	92:8	165	68.8, 29.0, 30.8, 52.2, 20.7 (CH_3)

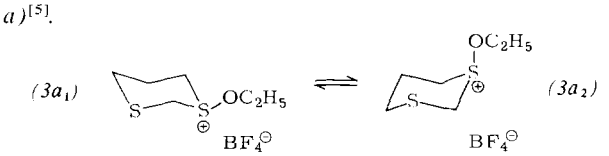
[a] *(1a)*, R = H; *(1b)*, R = CH_3; *(1c)*, R = $C(CH_3)_3$; *(1d)*, R = C_6H_5 are known. [b] ^{13}C-NMR of the *trans*-compounds (23 MHz, $CDCl_3$, TMS = 0); the signals are given in the sequence C-2, C-4, C-5, C-6 [5].



The tetrafluoroborates *(3)* were characterized as 2,4,6-trinitrobenzenesulfonates *(3')* (Table 2).

Table 2. Some 1-ethoxy-1,3-dithianium tetrafluoroborate salts *(3)* and -2,4,6-trinitrobenzenesulfonates *(3')*. All compounds gave correct C, H, N values. The rearrangement of *(1e)* into *(3e)*, R = C_6H_4-OCH_3-*p*, led to an insufficiently pure product.

	R	Yield [%]	M.p. [°C] (dec.)	^{1}H-NMR, δ-values [a]
(3a)	H	80	115	5.16, 4.96 d, $^2J = -12$ Hz; 4.64 q; $(CD_3)_2CO$
(3a')	H	75	145	4.90, 4.62 d, $^2J = -12$ Hz; 4.48 q; CD_3CN
(3b')	CH_3	67	103	4.90, 5.05 q; 4.49, 4.46 q; CD_3CN
(3c')	$C(CH_3)_3$	75	92	5.20, 5.05 s; 4.50; CD_2Cl_2
(3d)	C_6H_5	80	77–80	6.05 s; 3.87 q; CD_2Cl_2
(3d')	C_6H_5	75	101–104	5.97 s; 3.85 q; CD_3CN
(3f')	C_6H_4-NO_2-(*p*)	47	101	6.25 s; 3.90 q; $(CD_3)_2CO$
(3g')	C_6H_4-CH_3-(*p*)	52	75–78	6.00 s; 3.85 q; CD_3CN

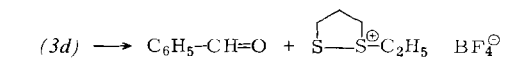


[a] The signals are given in the order S–CH_2–$S^{\oplus}$ or S–CH–$S^{\oplus}$; O–CH_2 [6].

Evidence for the regioselective ethylation at the *O*-atom of *(1)* is provided, *inter alia*, by the quantitative nucleophilic cleavage of the S–O bond of *(3a)* with NaOD in the NMR experiment. *S*-alkoxysulfonium salts behave analogously[7].

(3a) *(1a)*

We carried out a ^{13}C-NMR analysis on the parent compound *(3a)*. The signals of the ring-C-atoms were assigned on the basis of selective ^{1}H-^{13}C decoupling, those of the ethyl-C-atoms were locatable under off-resonance conditions [^{13}C-NMR (CD_3CN): δ = 75.1 (OCH_2); 46.7 (C-6); 45.8 (C-2); 29.0 (C-5); 27.2 (C-4); 15.5 (CH_3)]. The sequence of the ring-C-atom signals corresponds to that of the starting sulfoxide *(1a)*[5].



(3a$_1$) *(3a$_2$)*

A low-temperature ^{1}H-NMR experiment [in $(CD_3)_2CO$; *T* up to −106 °C] provided no evidence of a conformational process in the sense of the equilibration *(3a$_1$)* ⇌ *(3a$_2$)*. The splitting of the A-resonance of the AB doublet of the C-2 protons ($J_{2e6e} = 2.5$ Hz) at lower field strength, the size of the geminal coupling constant ($^2J_{AB} = 12$ Hz)[8], and the separation of H_{6e} and H_{6a} by *ca.* 0.4 ppm in the ^{1}H-NMR spectrum (100 MHz) indicate almost exclusive participation of the conformer *(3a$_1$)*.

Conformationally fixed forms are also present in the salts *(3b)*–*(3g)*; *(3b)* and *(3c)* contain small proportions of *cis* isomers.

A novel intramolecular decomposition has been observed in the case of *(3d)*. In anhydrous dichloromethane at room temperature it cleaves quantitatively within about 1 h into benzaldehyde *(4d)* and 1-ethyl-1,2-dithiolanium tetrafluoroborate *(6)*.

(3d) *(4d)* *(6)*

The salt *(6)* was isolated as the 2,4,6-trinitrobenzenesulfonate *(6')* (dec. pt. 153–154 °C) [^{1}H-NMR (CD_3CN) of *(6')*:

1.41 (t, 3H), 2.74 (t of t, 2H), 3.32 (q, 2H), 3.75 (t, 2H), 3.99 (t, 2H), assignment by proton decoupling]. The spectral pattern corresponds to that of 1,2-dithiolane 1,1-dioxide[9].

General Procedure

Synthesis of *(3)*: *(1)* (6 to 8 mmol) is dissolved in anhydrous CH_2Cl_2 in the absence of moisture and the solution treated with 2 g of molecular sieve (4 Å, MERCK). An equimolar amount of *(2)* in 10 ml of anhydrous CH_2Cl_2 is then added at 0 °C and the mixture stirred for up to 3 h under argon. The salt *(3)* is precipitated with anhydrous ether, the solution decanted off, and the crude product *(3)* dried over P_4O_{10} at 0.1 torr/25 °C. The salts *(3')* are first obtained by addition of a concentrated ethanolic solution of picrylsulfonic acid to the crude *(3)* and then reprecipitated from acetonitrile/ether or CH_2Cl_2/ether.

Regeneration of *(4)*: The dried crude tetrafluoroborate *(3)* is treated with water (5 °C). After a few minutes the precipitate of *(5)* is removed by filtration and the aldehyde worked-up or precipitated as the 2,4-dinitrophenylhydrazone derivative.

Bond Switch with Participation of π-Bonded S^{IV} in Thiathiophthene-Analogous Systems[**]

By *Kin-ya Akiba, Shin-ichi Arai, Tohru Tsuchiya, Yohsuke Yamamoto*, and *Fujiko Iwasaki*[*]

In the thiathiophthenes, a class of stable π-hypervalent molecules, the S—S bonds are influenced by substitution or introduction of heteroatoms into the ring[1]. Both iminothiadiazolines[2a] and iminooxadiazolines[2b] react with activated acetylenes with cycloaddition-elimination; the elimination is probably due to the great difference in electronic nature of the two five-membered rings of the intermediate π-λ^4-sulfurane. In all these reactions, the original S-heteroatom bond is opened, while the newly formed five-membered ring remains intact, *i.e.* bond switch is observed at π-hypervalent sulfur.

We report here on a simple and typical example of bond switch. When 3,4-disubstituted 5-imino-Δ^2-1,2,4-thiadiazoline *(1)*[3] is heated with excess imidate at 60—80 °C without solvents, ethanol is eliminated and the 1:1 adduct *(3)* of *(1)* and the nitrile R^3—CN is obtained in good yields (in Table 1).

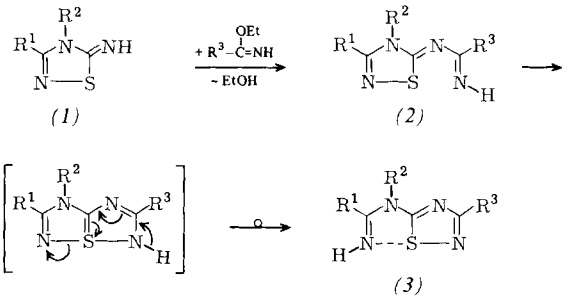

Table 1. Some 1,2,4-thiadiazole *(3)*. (^{1}H-NMR data: δ values, $CDCl_3$, Me_4Si int. [4]).

	R^1	R^2	R^3	M.p. [°C]	Yield [%]
a	Me 2.36 ± 0.03 [a]	Me 3.69 ± 0.13	Me 2.54 ± 0.03	139.2–140.2	66
b	Me	Me	Ph 7.2–7.6 (m, 3H) 8.0–8.4 (m, 2H)	182.2–183.7	80
c	Et	Me	Me	149.2–150.2	77
d	Ph 7.48 ± 0.02	Me	Me	174.1–175.1	48

[a] Coupling with NH (δ = 9.5, J = 1.5 Hz).

The structure of the adduct *(3)* was deduced by comparison of its NMR spectral data with those of related compounds[5]. The IR spectra contain characteristic absorptions at 3250 (ν = NH) and 1630—1640 cm^{-1} (νC=NH)[6a].

We also synthesized *(3a)*, *(3c)* and *(3d)* *via* an independent route by heating the nitriles R^1—CN with the thiadiazole *(4)*[5] to 80—100 °C in the presence of $AlCl_3$; the yield of *(3)* was about 20%[7].

Finally, the structure of *(3a)* was determined by an X-ray structure analysis on a single crystal. The molecule is almost planar (dihedral angle between the "rings": 174.7°); the N···S and N—S bond lengths are 2.500 and 1.668 Å, respectively, thus confirming intramolecular N···S interaction.

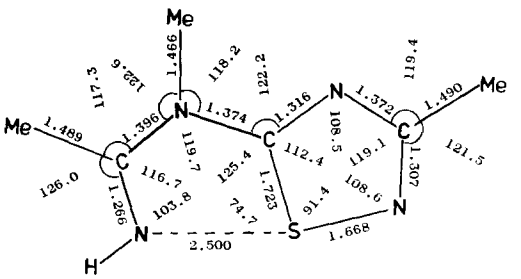

Fig. 1. Bond lengths [Å] and angles [°] in compound *(3a)* (Details: *F. Iwasaki, K. Akiba*, unpublished).

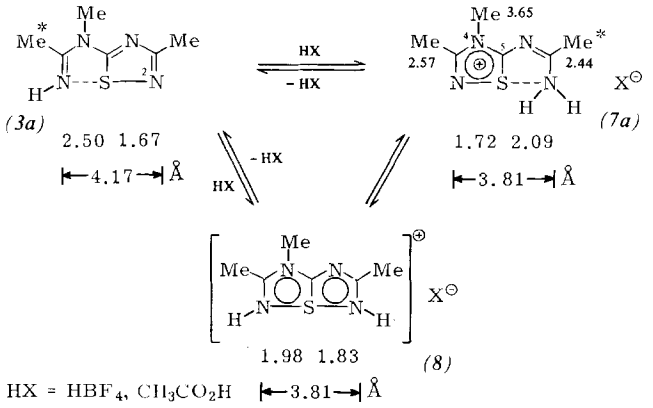

Surprisingly, the salt formation of the bases *(3)* proceeds *via* bond switching. Thus the tetrafluoroborates of *(3a)* and *(3c)* have the structures *(7a)* and *(7c)*, respectively, derived as shown below by long range coupling with the NH proton (the position is marked by an asterisk). This is supported by the finding that the protons of the three analogous methyl

groups in the salts *(7a)*, *N*-methyl-*(7a)* and *N,N*-dimethyl-*(7a)*[8] give almost identical NMR signals (δ values, in [D_6]-dimethyl sulfoxide ([D_6]-DMSO), Me_4Si int.). On addition of excess trifluoroacetic acid (TFA) to *(3a)* and *N*-methyl-*(3a)* in $CDCl_3$ the same chemical shifts occur for the corresponding methyl protons as in *(7a)* and *N*-methyl-*(7a)* (both BF_4^- salts). The remarkable red shift and hyperchromism in the UV spectrum of *(7a)* compared to that of the base *(3a)* clearly demonstrates that *(7a)* is a salt with a conjugated thiadiazolium ion. *N*-Methyl-*(7a)* behaves similarly.

When about a half-molar amount of TFA was added to the base *(3a)* in $CDCl_3$/[D_6]-DMSO at 34 °C, only three methyl signals were observed between those of *(3a)* and *(7a)*. Under the same conditions *N*-methyl-*(3a)* is half converted into *N*-methyl-*(7a)* (eight methyl signals). This finding indicates the presence of a rapid equilibrium between *(3a)* and *(7a)*. The equilibrium was confirmed by the fact that a linear relationship was observed between the chemical shift of the Me* protons in *(3a)* and the amount of TFA added.

The bond switch is thus explained in terms of the protonation of *(3a)* at N-2[6b] and affords the 6aλ^4-thia-1,3,4,6-tetraazapentalenium tetrafluoroborate *(8)*, which is converted by prototropy into the thermodynamically more stable compound *(7a)*. Rapid equilibrium is effected by deprotonation with the residual free base *(3a)* and/or X^-.

Finally, let us consider the bond lengths. In *(3a)* (see Fig. 1) and *N,N*-dimethyl-*(8)*[9] they have been determined by X-ray crystallography. The N—S bond length in *(7a)* can be estimated on the basis of the data for an isothiazolium salt of analogous structure to be 1.72 Å[10]. The S···N bond length in *(7a)* then becomes 2.09 Å, if it is assumed that the NSN distances in the singly positively charged compounds *(7a)* and *(8)* are the same. It can then be visualized that the central sulfur atom moves back and forth rapidly along the N—S···N bond in the range between 0.78 Å [maximum: 4.17 − (1.72 + 1.67)] and 0.26 Å [minimum: 3.81 − (1.72 + 1.83)], most probably *ca.* 0.40 Å.

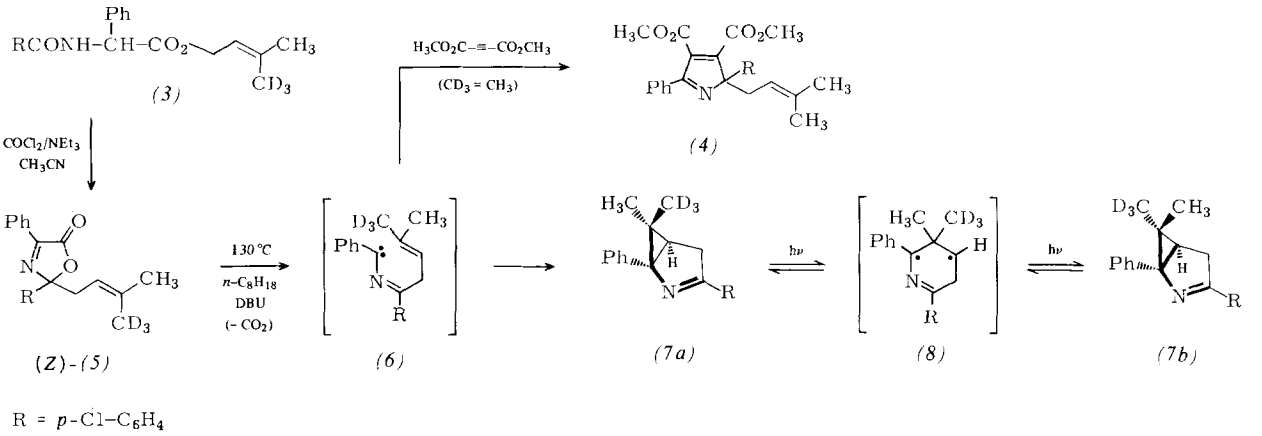
Synchronous Mechanism of the 1,1-Cycloaddition of Nitrile Ylides to C=C Double Bonds[1]

By *Janos Fischer* and *Wolfgang Steglich*[*]

On irradiation of both (*E*)- and (*Z*)-2-(2-butenyl)-2-methyl-3-phenyl-2*H*-azirine [(*E*)-*(1)* and (*Z*)-*(1)*, respectively], *Padwa* and *Carlsen*[2] obtained *endo*-3,6-dimethyl-1-phenyl-2-azabicyclo[3.1.0]hex-2-ene *(2)* by intramolecular 1,1-cycloaddition of the intermediary nitrile ylide. The lack of stereospecificity and formation of mixtures of isomeric azabicyclohexenes in

closely related cases led the authors to postulate a stepwise addition of the 1,3-dipole to the double bond, with generation of a trimethylene intermediate ("six-membered ring dipole") [cf. *(8)*]. Since this mechanism is in direct contrast to the well-documented synchronous mechanism of 1,3-dipolar cycloadditions[3] and singlet-carbene additions[4], and since photochemical effects cannot be ruled out, we have reinvestigated the stereochemistry of 1,1-cycloaddition with thermally generated nitrile ylides.



A suitable model for this purpose is the trideuteriated 3-oxazolinone *(5)*; the thermolysis of the unlabeled compound to 2-azabicyclo[3.1.0]hex-2-ene *(7)* (CH_3 instead of CD_3) has already been described[11]. *(5)* was prepared by cyclization

of (*Z*)-*N*-(*p*-chlorobenzoyl)-2-phenylglycine 3-trideuteriomethyl-2-butenyl ester *(3)*[5] with phosgene/triethylamine in acetonitrile[6]. According to the ^{1}H-NMR spectrum ($CDCl_3$) a 9:1 mixture of the (*Z*/*E*) isomers was formed [(*Z*)-*(5)*: $\delta_{CH_3}=1.61$; (*E*)-*(5)*: $\delta_{CH_3}=1.53$].

R = *p*-Cl–C_6H_4

When a mixture of (*Z*)-*(5)* in *n*-octane and some added diazabicycloundecene (DBU) was heated under reflux for 2 h, a 9:1 mixture of the *endo*- and *exo*-CD_3 isomers of the 2-azabicyclo[3.1.0]hex-2-ene [*(7a)*: $\delta_{CH_3}=0.94$; *(7b)*: $\delta_{CH_3}=0.89$] was formed in good yield. The ratio of epimers remained unchanged even after chromatography of the crude product and recrystallization from methanol (m.p. 85—87 °C). The configuration at C-6 follows from the ^{13}C-NMR spectrum ($CDCl_3$)[8]: the intense signal at $\delta=23.4$ is assigned to the *exo*-CH_3 group of *(7a)*, the weak signal at $\delta=13.4$ to the *endo*-CH_3 group of *(7b)*, whose resonance is shifted to higher field owing to the γ effect[9].

The result of the thermolysis experiment shows, within the accuracy of measurement, that the 1,1-cycloaddition of the thermally generated nitrile ylide *(6)* proceeds with retention of configuration. This provides evidence against the stepwise addition and in support of a synchronous mechanism.

On irradiation with an immersion lamp (Philips HPK 125, Vigor filter) in benzene the 9:1 ratio of *(7a)* to *(7b)* changes within 4 min to 7:3. Hence the epimerizations and isomerizations of the 2-azabicyclo[3.1.0]hex-2-enes *(7)* observed in the photolysis of azirines could be due to photochemical secondary reactions, probably involving a trimethylene intermediate [*e.g. (8)*][2]. That the nitrile ylide *(6)* is in fact generated in the thermolysis of *(5)* is demonstrated by trapping with dimethyl acetylenedicarboxylate (toluene, 6 h reflux), whereupon the oily 2*H*-pyrrole derivative *(4)* is obtained *via* 1,3-dipolar cycloaddition[3] [^{1}H-NMR (CCl_4): $\delta=1.37$, 1.48 (each br. s, 6H); 3.13 (m, 2H); 3.62, 3.66 (each s, 6H); 4.45 (br. t, 1H) 7.2—7.5 (m, 3H); 7.8—8.1 (m, 2H); 7.40, 8.03 (AA'BB' system, 4H)].

S_2^{2-} as Simultaneous End-on and Side-on Bonded Ligand in the Novel Transition-Metal Complex $[Mo_4(NO)_4S_{13}]^{4-}$

By *Achim Müller, Werner Eltzner*, and *Nageswaran Mohan*[*]

Interesting coordination compounds (*e.g.* with metal-metal bonds, unusual coordination numbers, or polynuclear metal-sulfur bonding systems)[1] can be synthesized by reaction of H_2S or S_n^{2-}[2] with solutions of oxometalates of the transition metals in the presence of other ligands. In the case of molybdenum mainly polynuclear sulfur complexes are formed.

Reaction of molybdate ions with ammonium polysulfide in aqueous solution in the presence of hydroxylamine led to the formation of the orange-red crystalline compound $(NH_4)_4[Mo_4(NO)_4S_{13}]\cdot 2H_2O$ *(1)*, which was characterized by elemental analysis, DTA, TG, and magnetic measurements, as well as by ESCA and IR spectra and a single-crystal X-ray structural analysis[3]. *(1)* is diamagnetic, soluble in H_2O, and shows principal IR absorptions (cm^{-1}) of the anion at *ca.* 1520 (br, s) [ν(NO)], 615/600 (m) [δ(NO), ν(MoN)], 548 (w), 533 (w) [ν(SS)], 342 (w), 327 (w) [ν(MoS)].

The most important structural features (cf. Fig. 1) of the new compound are two equilateral triangular arrays of Mo

[*] Prof. Dr. A. Müller, Dipl.-Chem. W. Eltzner, Dr. N. Mohan
Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld 1 (Germany)

atoms (Mo—Mo 3.375(2) Å) "joined" by a common edge (angle between triangular arrays 127.59°) with two triply bonded sulfur atoms normal to each Mo-triangle (Mo—S 2.501(5) Å) and one further sulfur atom bonded to each of the four Mo atoms (Mo—S 2.616(5) Å) and situated on the other side of the triangular arrays. Four of the total of five S_2^{2-} ligands each function as unsymmetrical bridges between two Mo atoms, one S atom being bound to only one Mo center (Mo—S 2.465(5) Å), and the other to both Mo centers (Mo—S 2.492(5) Å). The distances in the S_2^{2-} ligands are almost equal (S—S 2.048(7) Å). In the functional group {MoNO} the N—O and Mo—N distances are 1.219(22) Å and 1.742(16) Å, respectively.

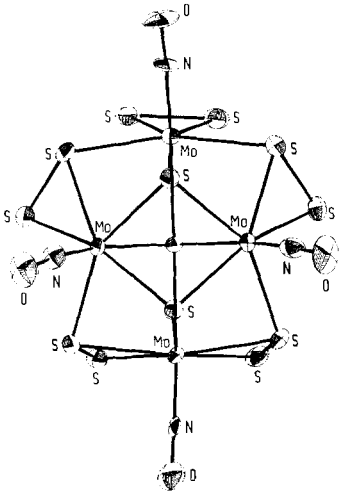

Fig. 1. Structure of the complex anion $[Mo_4(NO)_4S_{13}]^{4-}$.

(1) contains sulfur in *five different bonding states* and thus provides an example of the significance of S_2^{2-} ligands for the stabilization of unusual coordination compounds of the transition metals[4]. Particularly noteworthy here are the four S_2^{2-} ligands, each of which is coordinated *both end-on* (to one Mo atom) *as well as side-on* (to another Mo atom).

Procedure

An aqueous solution (10 ml) of $NH_2OH \cdot HCl$ (2.1 g) is added with stirring to a solution of 2.5 g of $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and 15 g of $(NH_4)SCN$ in 40 ml of water. The yellow suspension is warmed to 80°C for 1 h, then, after addition of an equal volume of ammonium polysulfide solution, allowed to stand for *ca.* 10 h at 60°C in a closed vessel (any black precipitate that is formed is removed by filtration). On slow cooling, orange-red crystals of *(1)* precipitate out. These are washed with methanol, carbon disulfide, ether, and then dried over P_4O_{10} (yield 0.5 g).

Bis(chlorophenylphosphoranediyl)methane[1]

By *Rolf Appel* and *Karl Waid*[*]

"Carbodiphosphoranes" substituted at P by halogen are potential building blocks for the synthesis of theoretically interesting phosphorus-carbon ring systems[2]. Having previously prepared the partially halogenated compound (chlorodiphenylphosphoranediyl)(triphenylphosphoranediyl)-methane[3], we have now also been able to synthesize the symmetrical bis(chlorodiphenylphosphoranediyl)methane *(2)*. It is formed on reaction of tetrachloromethane with trimethylsilylmethylenebis(diphenylphosphane) *(1)* with elimination of (trichloromethyl)trimethylsilane and trichloromethane.

The yellow solid *(2)* undergoes smooth 1:1 addition with hydrogen chloride to give the salt *(3)*, which on reaction with alcohols undergoes a double Arbuzov rearrangement with cleavage of alkyl chloride to give the bis(diphenylphosphinoyl)methane *(4)*[4]. The dioxide *(4)* can also be obtained directly from *(2)* and alcohol.

Procedure

To a solution of *(1)*[5] (4.6 g, 10 mmol) in anhydrous dichloromethane (15 ml) is added CCl_4 (4.6 g, 30 mmol). The solution rapidly turns yellow and warms up. After 50 min the brown solution is evaporated down at reduced pressure, whereupon a yellow solid suddenly precipitates. Pentane (40 ml) is added, the mixture is filtered, washed with pentane (10 ml), and dried: yield 4.1 (90%) of $C_{25}H_{20}Cl_2P_2$ *(2)*, dec. pt. 150°C; M^+ at $m/e = 452$; $^{31}P\{H\}$-NMR (C_6H_6/C_6D_6, H_3PO_4 ext.): $\delta = +20.7$ (s); ^1H-NMR (CD_2Cl_2): $\delta = 7—8.5$ (m).

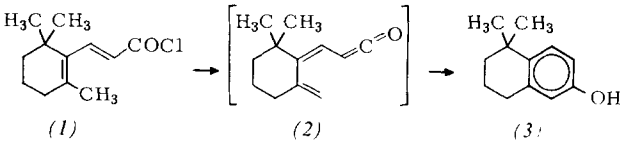
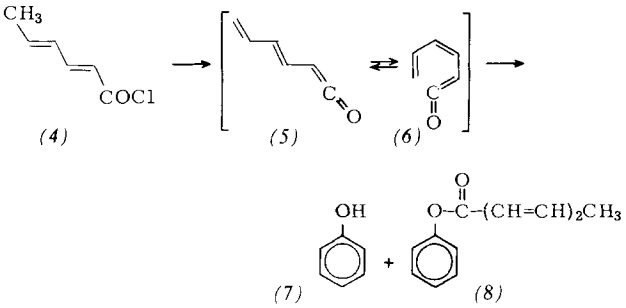
Flash Vacuum Thermolysis of Doubly Unsaturated Acyl Halides to Give Phenols[**]

By *Eckehard V. Dehmlow* and *Marion Slopianka*[*]



Dienylketenes have hitherto been observed and trapped only as products of $n \rightarrow \pi^*$ excitation of *ortho*-blocked cyclohexadienones at low temperatures[1]. In the absence of strong nucleophiles, recyclization occurs on warming to room temperature, yielding cyclohexadienones and in some cases bicyclo[3.1.0]hexenones[2] too.

It appeared interesting to know whether dienylketenes with R^1, $R^2 = H$ can be obtained from α,β,γ,δ-unsaturated acyl chlorides and whether their rearrangements to phenols can compete with possible polymerization.



Treatment of doubly unsaturated acyl chlorides with triethylamine in dry ether always led to tars. *Schiess et al.*, however, showed that unsaturated ketenes with one conjugated and one nonconjugated double bond could be formed pyrolytically, *inter alia*, from acyl halides[3].

With the aim of preparing short-lived dienylketenes, we have performed flash vacuum thermolysis experiments in an apparatus of the kind developed by *Seybold*[4, 5]. *trans*-3-(2,6,6-Trimethyl-1-cyclohexenyl)propenoyl chloride *(1)* (*ca.* 5 mmol) was pyrolyzed at 660 °C/6×10^{-5} Torr. The pyrolyzate was condensed at −196 °C and then slowly warmed up to room temperature. The presumed intermediate ketene *(2)* contains two double bonds in an arrangement suitable for ring closure to give *(3)*. In fact, *(3)*[6] is the main product (yield 53 %) accompanied by traces of hydrocarbons and by unreacted *(1)*. Thermolysis of *(1)* at normal pressure gave mainly polymer besides *ca.* 10 % of *(3)*.

(1) *(2)* *(3)*

The expected primary pyrolysis product of sorboyl chloride *(4)* is the *trans*-dienylketene *(5)*. However, only isomer *(6)* is capable of ring closure. Experimentally, phenol *(7)* and phenyl sorbate *(8)* are obtained from *(4)* in 42 and 25 % yield, respectively, under the conditions defined above. Thus, the simplest possible dienylketene→phenol rearrangement has been accomplished.

(4) *(5)* *(6)* *(7)* *(8)*

Bicyclo[3.1.0]hexenones were not observed on flash thermolysis of *(1)* and *(4)* in spite of the fact that the bicyclic species possibly formed from *(1)* would not be readily transformed into *(3)*.

Koordinationschemische Katalyse organischer Reaktionen (Coordination-Chemical Catalysis of Organic Reactions). By *H. Pracejus*. Technische Fortschrittsberichte, Band 64 (Industrial Progress Reports, Vol. 64). Verlag Theodor Steinkopff, Dresden 1977. 287 pp., 174 figs., 12 tables, bound, *ca.* DM 50.00.

Pracejus has undertaken to set out in less than 300 A5 pages a summary, in the German language, of the whole field of coordination catalysis from the point of view of the organic chemist, and in this he has been successful. The mechanistic features are presented only as the principle for the arrangement of the text, and the kinetic investigations that form the basis for mechanistic representations are intentionally reported only in a secondary manner.

The book contains an introduction (21 pages), followed by chapters on hydrogenation and dehydrogenation (18), isomerization and disproportionation (12), oxidation (21), nonoxidative formation of C-heteroatom bonds (14), dimerization and oligomerization (44), polymerization (42), and syntheses by means of C_1 compounds (60); the last chapter concerns the relationships between homogeneous and heterogeneous catalysis by coordination catalysts (carrier-fixed complex compounds as catalysts (1), methods for carrier fixation (8), and special features of carrier-fixed complex catalysts (3)). Finally, the coordination-chemical phenomena observed in the catalysis by metals and metal oxides are described in 6 pages.

Facts are clearly presented, and what is still unclear is often plainly described as such. The main target of the book is to draw the still incomplete directions of research to the attention of advanced Students, post-graduate students, and interested specialist colleagues. Tables and clear diagrams facilitate orientation.

Admittedly, anyone wanting to know how polyethylene is in fact manufactured nowadays must search through the original and patent literature with the aid of the relatively complete citation of review articles, and there he will find "that the patent literature describes thousands of combinations of transition-metal compounds with maingroup metal alkyls, among which almost every transition metal is mentioned".

I failed to find any reference to the importance of Mg alkyls for Ziegler catalysts, to the system $TiCl_3 \cdot {}^1/_3 AlCl_3$, to the work of *B. Diedrich* [Appl. Polym. Symp. *26*, 1 (1975)] that leads to true high-yield catalysts, to the process review by *Weissermel et al.* [J. Polym. Sci. *C 51*, 187 (1975)], or to the book "Coordination Polymerisation" edited by *J. C. W. Chien*, Academic Press, New York 1975.

The setting is clean, structural formulas are cramped but clear, the quality of the paper still gives good legibility (slight transparency), and the binding permits frequent handling, which it is certain to receive.

Every interested person should obtain the book; several copies should be in every Institute's library.

Hansjörg Sinn [NB 437 IE]

Fundamentals of Chemical Relaxation (Monographs in Modern Chemistry 10). By *H. Strehlow* and *W. Knoche*. Verlag Chemie, Weinheim 1977, 1st edit., x, 133 pp., 41 figs., 12 tables, bound, DM 68.00.

Although relaxation methods (essentially based on *Eigen*'s work) as a tool for the measurement of the rates of fast reactions have greatly extended our knowledge of the kinetics and mechanisms of chemical reactions, they have only found passing mention in physical chemistry textbooks, even in those dealing with chemical kinetics. For this reason the authors' efforts to provide a comprehensive survey of relaxation methods are highly welcome.

The authors enter into the theory of the methods only insofar as it is necessary for understanding, without neglecting the necessary accuracy. For this reason the monograph can be readily understood even by the less advanced student.

The authors deal with the temperature, pressure, and field jump methods, and also with the "steady-state" methods based on ultrasonic absorption and dielectric loss. In each case not only the theory but also experimental details are described and exemplary calculations are given. Comparisons of the different relaxation methods with one another and with other methods for fast reactions indicate which method to choose for a given purpose. The following chapters, on the basis of theory and some selected practical examples, show what information can be obtained from relaxation methods under optimal experimental conditions.

A first-rate book, clear and precise despite its restricted presentation. The price, however, in no way appears appropriate.

Ulrich Schindewolf [NB 450 IE]

Collision Spectroscopy. Ed. by *R. G. Cooks*. Plenum Press, New York—London 1978, 1st edit., xiv, 458 pp., bound, $ 54.60.

Molecular beam experiments have long been known to physicists; more recently, in the variant form of ion beam processes, they have won a firm place in the repertoire of methods used by chemists and physical chemists. The information gained from such experiments relates to apparently differing aspects, *e.g.* the structure determination of gaseous ions, the analysis of reaction mechanisms, and the description of the dynamic relationships of ion/molecule reactions in the gas phase. A summary of the current state of the theoretical knowledge and a thoughtful discussion of the experimental probes available today were thus urgently needed, and the editor has filled this gap in no uncertain fashion with the aid of competent colleagues. The seven chapters not only reflect the most important literature published up to 1974 (altogether 650 references, which in part also cover the 1975/76 literature); the book also reflects the skill of its authors. It is very much more than a collection of seven mini-books (though each chapter can be read separately). In increasing order of complexity, the book deals first with ion beam experiments on atoms and on diatomic and polyatomic systems. A very wide range of interactions is discussed: electronic excitation, charge exchange, and dissociative excitation (collision-induced decomposition). There is a wealth of clear pictorial material, and mathematical symbolism is kept within limits.

In Chapter 1 (71 pages, 110 references), *Park* describes collision-induced excitation processes (experimental probes, theory) on simple systems (small atoms, diatomic molecules). In Chapter 2 (55 pages, 87 references) *Johnson* and *Böring* discuss in detail the theory of charge-transfer reactions. The advantages and the disadvantages of the currently available experimental methods are clearly outlined. In Chapter 3 (79 pages, 120 references), *Kessel*, *Pollack* and *Smith* present the latest experimental techniques, and also the consistent use of correlation diagrams for ion beam experiments on atoms. Multielectron transfers (with the possibility *e.g.* of a relatively precise determination of higher ionization potentials) are dis-

cussed by *Appell* (Chapter 4, 29 pages, 55 references). In Chapter 5 (31 pages, 24 references), *Kemp* and *Cooks* describe the various means by which ion/molecule reactions can be used to produce modified types of mass spectra, from which information on ionic structure may be obtained. In Chapter 6 (67 pages, 120 references), *Los* and *Gevers* demonstrate very convincingly the theoretical and methodological aspects of collision-induced decompositions of diatomic ions ($H_2^{+\bullet}$, $HHe^{+\bullet}$, $N_2^{+\bullet}$). These brilliantly written chapters are followed by an excellent discussion on the qualitative aspects of these processes with larger molecules (Chapter 7, 93 pages, 149 references). *Cooks* deals with topics as different as structure determination of thermochemical data, and isomerization of cations, without ever becoming superficial.

The book will prove useful to the expert, but it can also be unreservedly recommended to any scientist wishing to become acquainted with the wide-ranging field of gas-phase chemistry.

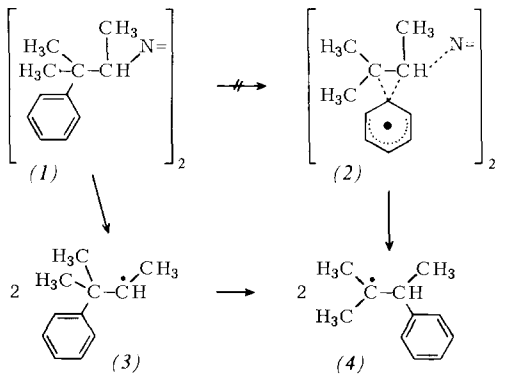
Anchimerically Accelerated Bond Homolyses

By Manfred T. Reetz[*]

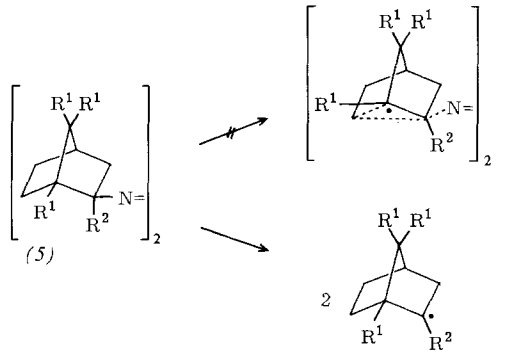
Radical reactions of the type R^1—a—b—$R^2 \rightarrow {}^{\bullet}$a—b—$R^1 + {}^{\bullet}R^2$ are feasible if the new bond formed between b and R^1 is considerably stronger than the old bond between a and R^1. Furthermore, both the radical fragments formed must be resonance stabilized. An example of this reaction type is the thermolysis of benzyl trimethylsilylmethyl ethers, in which the trimethylsilyl group (with empty orbitals) migrates to the oxygen atom (with lone pairs). Assumption of a cyclic reactive intermediate with pentacoordinated silicon explains the observed intramolecular nature and the negative entropy of activation of such homolyses.



1. Introduction

In organic chemistry substituent effects are generally transmitted through bonds or through space. However, substituents can also influence reactions by bonding with the reaction center, thereby stabilizing transition states or intermediates[1]. This effect is called *neighboring group participation*, and may, but need not, result in rearranged products. If the neighboring group stabilizes the transition state in the rate determining step, one speaks of *anchimeric*[**] acceleration[2]. Once the phenomenon of anchimeric participation had been shown to be general in the field of carbocation chemistry, as evidenced by numerous examples, the search for analogous effects in *radical* processes began in the fifties. It turned out that a number of unimolecular[3] homolytic reactions failed to show anchimeric effects, in spite of the fact that the neighboring group in corresponding cationic systems exerts a pronounced accelerating effect.

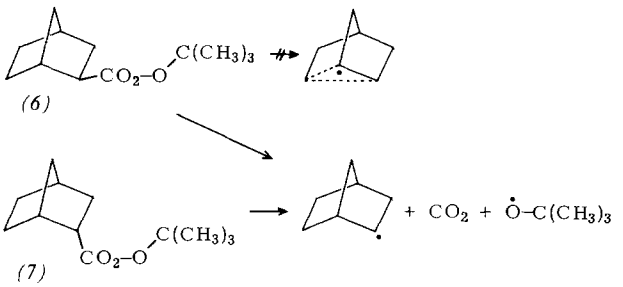
[*] Doz. Dr. M. T. Reetz
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg (Germany)
Present address: Institut für Organische Chemie und Biochemie der Universität,
Gerhard-Domagk-Strasse 1, D-5300 Bonn (Germany)



[**] The term "anchimeric" (Greek *anchi* near, *meros* part) was coined by *Winstein* [2].

For example, in his studies concerning the thermal decomposition of azo compounds *(1)*, *Overberger et al.*[4] excluded the participation of phenyl groups in the transition state of radical formation according to *(2)*. The generation of rearranged products was explained by a secondary phenyl group migration *(3)* → *(4)*.

Radical decomposition reactions of other azo compounds also show no appreciable anchimeric effects[5–7]. Among them are the thermolyses of bornyl and norbornyl derivatives *(5a)* and *(5b)*, respectively, studied by *Berson et al.*[5] and *Rüchardt et al.*[6].



© *Verlag Chemie, GmbH, D-6940 Weinheim, 1979* *0570-0833/79/0202-0170 $ 01.00/0*

(5)

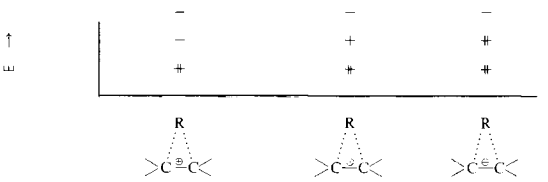
(a), $R^1 = CH_3$, $R^2 = H$; (b), $R^1 = H$, $R^2 = CH_3$

According to *Bartlett et al.*[8], thermal decomposition of the *tert*-butyl peroxynorbornanecarboxylates (6) and (7) proceeds at normal rates ($k_{exo}/k_{endo} = 4.1$). Again, the norbornyl framework induces no nonclassical effects. The search for anchimeric acceleration in the thermal decomposition of other peroxyesters as well as in other homolytic processes also remained fruitless[1, 9–13].

(6)

(7)

Why do carbenium ions and radicals behave differently? Apart from possible effects during the formation of carbenium ions and radicals, Wagner-Meerwein rearrangements proceed much more rapidly than analogous radical 1,2-sigmatropic shifts. The latter are in fact rare[14]. A simple explanation based on MO theory was published by *Zimmerman et al.*[15] in 1961 and later refined by *Jaffé* and *Orchin*[16]. The cyclic transition state is treated as a three-center bond with two, three, or four electrons, which gives rise to appreciable energy differences for carbenium ions, radicals and carbanions, respectively (see Fig. 1). Therefore, the participation of a neighboring group in a bonding manner during the formation of radicals will usually be of no energetic advantage.



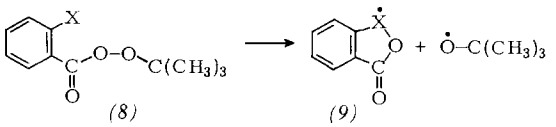


Fig. 1. MO scheme for 1,2-sigmatropic shifts in carbocations, radicals, and carbanions.

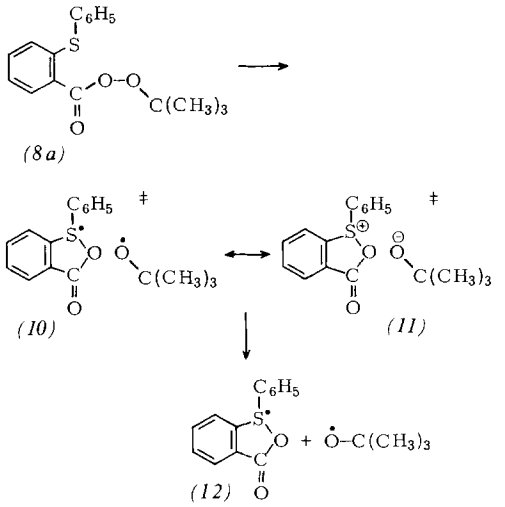
2. Thermolysis of *ortho*-Substituted *tert*-Butyl Peroxybenzoates

The above results suggest that appreciable anchimeric effects may at best be found in compounds that contain hetero atoms having low-lying empty orbitals and/or lone pairs. Such a system was described by *Leffler et al.*[17], and was generalized and mechanistically studied by *Martin*[18] in an impressive series of papers. It was observed that peresters of type (8) as well as corresponding dibenzoyl peroxides[13] undergo homolytic decomposition to (9) at different rates, depending upon the nature of the substituent X (Table 1).

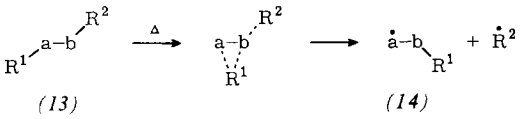


(8) (9)

Table 1. Kinetic data [18] of the radical fragmentation of *tert*-butyl perbenzoates (8). Chlorobenzene as solvent.

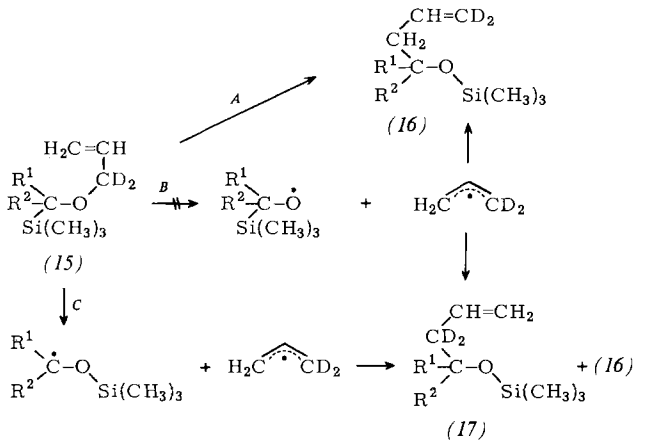
	X	k_{rel}	$\Delta H^{\neq}$ [kcal/mol]	$\Delta S^{\neq}$ [e.u.]
a	C_6H_5S	6.5×10^4	23.0	− 3.4
b	$CH{=}C(C_6H_5)_2$	150	26.3	− 5.0
c	I	80	28.0	− 0.8
d	$C(CH_3)_3$	2.4	34.4	+12.5
e	H	1.0	34.1	+10.0

In particular, sulfur gives rise to an enormous anchimeric effect (see Table 1). *Martin* postulates a transition state (10) for the rate determining step of the fragmentation of (8a) in which sulfur coordinates with oxygen, thereby weakening the O—O bond. Resonance forms (10) and (11) were proposed to describe the transition state. They explain the radical reaction path and the pronounced dependence of the fragmentation rate on solvent polarity. It is not quite clear whether (11) is also an *intermediate* on the way to (12)[19, 20]. However, there is no doubt that radicals are indeed generated, as shown by trapping experiments[18] and ESR studies[21].



(8a) (10) (11) (12)

3. Thermolysis of Alkyl Silylmethyl Ethers



The reactions studied by *Martin* involve neither three-center transition states nor complete migration of the assisting group to the radical reaction center. In contrast, our own studies started from a completely different standpoint. We speculated that anchimerically accelerated homolyses of the type (13) → (14) may be possible if the new bond b—R^1 is consider-

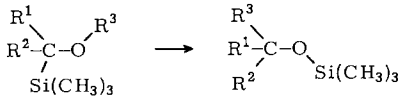
ably stronger than the old bond a—R^1, and if the radicals generated are resonance stabilized.

(13) *(14)*

This working hypothesis evolved in 1974 from the observation that the dyotropic rearrangement[22] of allyl silylmethyl ethers *(15)* → *(16)* (Path *A*), which proceeds with allyl inversion, is accompanied by a radical reaction[23, 24]. Thermolysis (160—190 °C) affords 80% of *(16)* and 20% of the "wrong" isomer *(17)*. Formation of the latter can be explained by postulating the formation of allyl radicals. The overall yield of rearrangement product drops to 60% in the presence of a radical trapping agent. Importantly, it then contains 97% of *(16)*. Under these conditions the greater portion of the suspected allyl radicals are trapped.

(15) *(16)* *(17)*

$R^1 + R^2$ = 2,2'-Biphenylylene

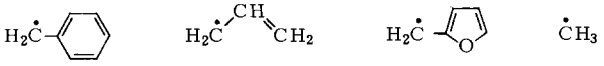


(15) and similar derivatives ($R^1 = R^2 = C_6H_5$; $R^1 = C_6H_5$, $R^2 = C_{10}H_8$) were found to rearrange with astonishingly low activation energies ($E_a \approx 33$ kcal/mol). Thus the hypothesis of allyl radical formation appeared rather dubious, since the homolysis of C—O bonds, generating resonance stabilized radicals usually requires *ca.* 50 kcal/mol[25]:

For these reasons, a simple radical cleavage of the C—O bond of *(15)* (Path *B*) was excluded[24]. In contrast, a mechanism was proposed in which the silyl group provides anchimeric assistance by migrating toward oxygen and initiating radical fragmentation (Path *C*). The formation of the very strong Si—O bond (110—130 kcal/mol)[26] as well as the generation of resonance stabilized radicals correspond to the general scheme *(13)* → *(14)*. In order to study these unusual and intruiging effects more closely, a number of alkyl silylmethyl ethers were synthesized which are *incapable* of allyl inversion (*e.g.* benzyl ethers)[27].

3.1. Structural Prerequisites for Radical Fragmentation[27, 28]

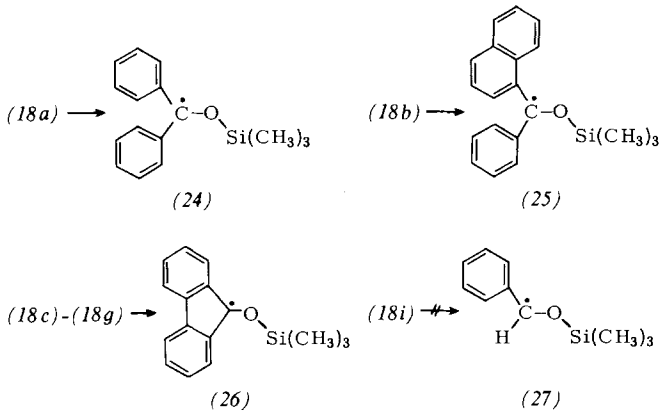
In order to ascertain the effect of R^1, R^2, and R^3 on the rate of decomposition of alkyl silylmethyl ethers, the kinetics of the rearrangement *(18)* → *(19)* were studied (Table 2). First order kinetics were found in all cases. The yield of rearrangement products is 85—98%.



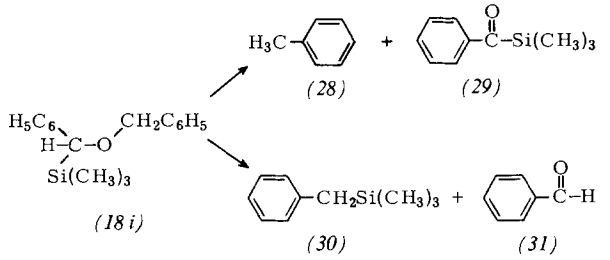
(18) *(19)*

Table 2. Kinetic data of radical fragmentation of alkyl silylmethyl ethers *(18)* to siloxy compounds *(19)* at 185 °C. Solvent: benzene.

	R^1	R^2	R^3	$k_{rel} \pm 0.05$
a	C_6H_5	C_6H_5	$C_6H_5CH_2$	0.3
b	C_6H_5	1-Naphthyl	$C_6H_5CH_2$	0.9
c	2,2'-Biphenylylene		$C_6H_5CH_2$	1.0
d	2,2'-Biphenylylene		p-CH_3—C_6H_5—CH_2	1.5
e	2,2'-Biphenylylene		p-CH_3O—$C_6H_5CH_2$	2.2
f	2,2'-Biphenylylene		p-NO_2—$C_6H_5CH_2$	0.2
g	2,2'-Biphenylylene		Furfuryl	0.3
h	2,2'-Biphenylylene		CH_3	—
i	H	C_6H_5	$C_6H_5CH_2$	$<10^{-4}$



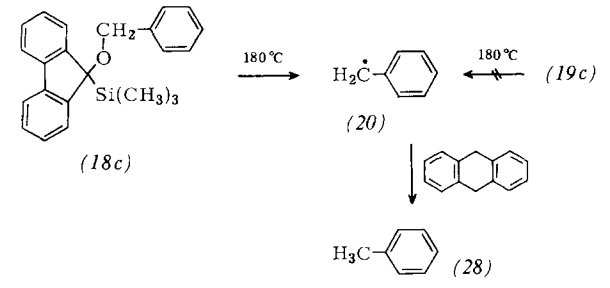
Within the fluorenyl series ($R^1 + R^2$ = 2,2'-biphenylylene) the benzyl and furfuryl ethers react with comparable rates, whereas the methyl ether *(18h)* is completely stable under the reaction conditions. This reflects the relative ability of the substituents R^3 to function as a radical leaving group. Whereas (substituted) benzyl[29], allyl[29] and furfuryl radicals[30] *(20)*, *(21)*, and *(22)*, respectively, are resonance stabilized, this fails to apply to the high energy methyl radical *(23)*[29].



(20) *(21)* *(22)* *(23)*

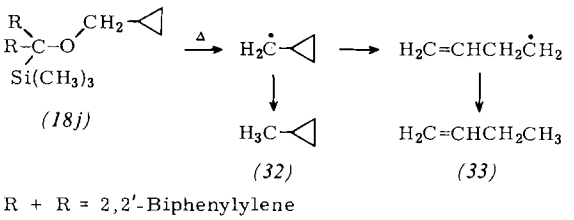
The relative rates in relation to the nature of the substituent at the carbon atom (R^1 and R^2) are equally revealing. Di-aryl-substituted benzyl ethers *(18a)*—*(18g)* react at similar rates. However, if one of the arene groups is substituted by hydrogen, no rearrangement is observed; *(18i)* is stable between 150 and 195 °C. At 230 °C competing β-eliminations set in, so that only a lower limit of the theoretically possible radical fragmentation rate can be approximated: $k_{(18i)}/k_{(18c)} < 10^{-4}$. Assuming the intermediate formation of ketyl radicals (see ESR experiments, Section 3.4), a resonance effect can be invoked once more. Whereas *(24)*, *(25)*, and *(26)* are stabilized by two aromatic substituents, the potential radical *(27)* contains only one group capable of resonance. Therefore, competing β-eliminations leading to *(28)*, *(29)*, *(30)*, and *(31)* dominate.

Although the presence of bulky groups is known to significantly affect the rate of unimolecular homolyses[31, 32], steric acceleration could be ruled out as the dominating factor in the above cleavage. The *tert*-butyl derivative benzyl 9-*tert*-butyl-9-fluorenyl ether analogous to *(18c)* remains unchanged at 195 °C for several days. In sharp contrast, the half-life of the rearrangement *(18c)* → *(19c)* under identical conditions amounts to a mere 18 minutes. This underlines the dramatic influence of the trimethylsilyl group and is in line with the low activation energy of 32 kcal/mol and the negative



entropy of activation $\Delta S^{+} = -8.6$ e. u. for *(18c)*→*(19c)*. The entropy factor suggests a reduction in the number of degrees of freedom in the transition state.

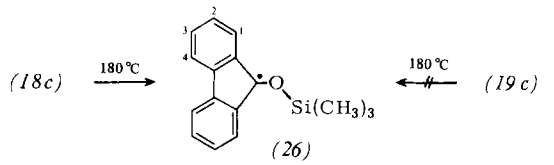
3.2. Crossover Experiments[33]



Crossover experiments using labeled compounds show that the silyl groups migrate 100% *intra*molecularly. On the other hand, the benzyl groups undergo *ca.* 25% *inter*molecular migration. These observations are also in accord with the postulated radical mechanism.

3.3. Radical Trapping Experiments[33]

If the thermolysis of *(18)* indeed leads to R^3 radicals, it should be possible to prove this by the use of appropriate trapping agents. The thermolysis of *(18c)* in the presence of an excess of 9,10-dihydroanthracene does in fact lead to toluene (59%) and anthracene. The thermolysis of independently synthesized rearrangement product *(19c)* does not generate benzyl radicals, *i.e.* no trace of toluene is observed under identical conditions.



A similar experiment was performed with the cyclopropyl methyl ether *(18j)* which reacts considerably slower. If (cyclopropyl)methyl radicals are in fact formed, they should undergo rapid rearrangement to 4-butenyl radicals, as described by *Kochi*[34]. Thus, two different trapping products are to be expected. Indeed, methylcyclopropane *(32)* and 1-butene *(33)* were identified in a ratio of 1:74.

R + R = 2,2'-Biphenylylene

3.4. ESR Experiments[33]

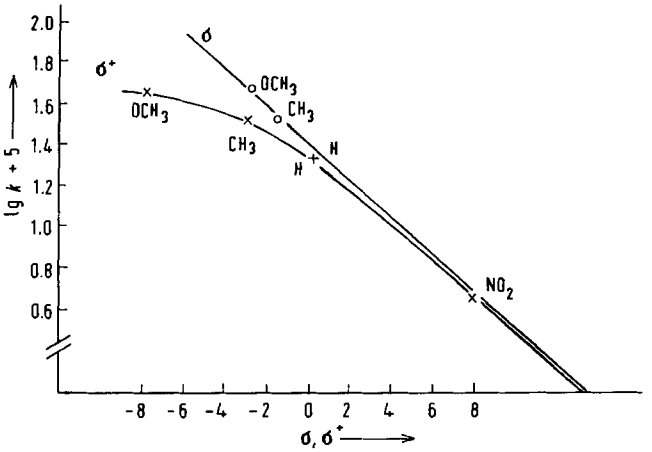
The intermediate formation of ketyl radicals was proved directly by ESR spectroscopy. Heating *(18c)* to 180°C in an ESR spectrometer results in a well resolved spectrum with $a^{H} = 3.48$, 0.83, 3.78 and 0.83 G for the protons H-1, H-2, H-3, and H-4 of the fluorenyl ring in *(26)*. The values correspond to those of *Neumann et al.*[31], who prepared *(26)* by a different route. Under identical conditions the rearrangement product *(19c)* does not give rise to ESR signals. This control experiment again shows that the theoretically possible reverse reaction is *not* responsible for radical formation.

3.5. Solvent Effects[33]

In order to determine the influence of solvent polarity on the rate of decomposition, kinetic measurements were carried out in solvents having different E_T values (E_T values are empirical parameters of solvent polarity.) Utilizing *(18c)* at 185°C, the results point to a very small effect: k_{rel} (based on benzene) is 1.4 in *o*-dichlorobenzene and 2.2 in acetonitrile. The fact that the activation parameters of *(18c)* → *(19c)* do not change significantly in going from benzene to acetonitrile as solvent is mechanistically significant[23]. The intermediacy of ions or zwitterions is quite unlikely.

3.6. Influence of Substituents and Secondary Kinetic Isotope Effects in the Radical Leaving Group[27, 33, 35]

In order to examine possible electronic effects in the radical leaving group, a Hammett study utilizing (substituted) benzyl ethers *(18c)*—*(18f)* was undertaken. The k_{rel} values lie closely together (see Table 2). Whereas the application of σ constants leads to a good correlation ($\rho = -0.92$), no straight line results with σ^{+} values (Fig. 2). Thus, radical formation has not advanced to a significant degree in the transition state, *i.e.*, the C—O bond is not stretched much. The values can be explained on the basis of a small polar effect[27].



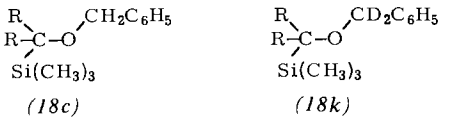


Fig. 2. Hammett plot for thermolysis of the (substituted) benzyl ethers *(18c)*—*(18f)* to *(19c)*—*(19f)* (see Table 2).

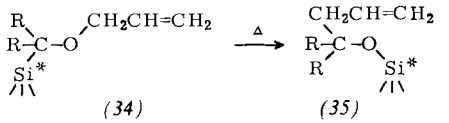
The above results are in line with the observation[35] that the secondary kinetic deuterium isotope effect at 150°C is rather small: $k_{(18c)}/k_{(18i)} = k_H/k_D = 1.04 \pm 0.03$.

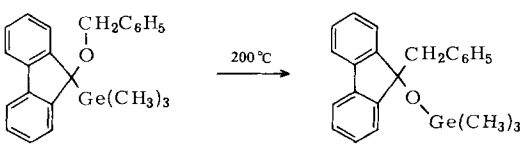


(18c) *(18k)*

R + R = 2,2'-Biphenylylene

3.7. Stereochemistry at the Migrating Silyl Group[24,36]

Although allyl ethers react only in part by a radical mechanism [cf. *e.g. (15)*], the stereochemistry at the silicon atom was investigated for the total rearrangement process. For this purpose a complete Walden cycle involving *(34)* and *(35)*, which contain an asymmetric silicon atom, was transversed. It turned out that the silyl group migrates from carbon to oxygen with >96% *retention* of configuration. This means that not only the concerted rearrangement, but also the radical rearrangement, proceeds stereospecifically.

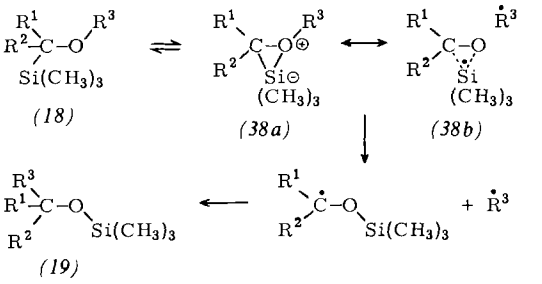


(34) *(35)*

$\overset{*}{\text{Si}}$ = Methyl(α-naphthyl)phenylsilyl

3.8. Replacement of Silicon by Germanium[37]

In order to study the role of the neighboring group more closely, the (germylmethyl) ether *(36)* analogous to *(18c)* was synthesized and thermally rearranged to *(37)*. *(36)* reacts much slower than the silicon analogue: $k_{(36)}/k_{(18c)} \approx 4 \times 10^{-5}$. At first glance this seems surprising, since in sigmatropic 1,5 rearrangements involving the cyclopentadienyl framework



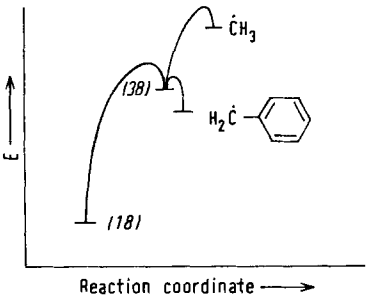
(36) *(37)*, 66%

germyl groups migrate *faster* than the analogous silyl moieties[38]. Apparently the strength of the new bond to oxygen plays an important role. The Ge—O bond (*ca.* 85 kcal/mol[39]) is weaker than the Si—O bond (110—130 kcal/mol)[26].

3.9. Mechanism of Radical Formation[33,40]

It is clear that the presence of the silyl group induces radical formation under mild conditions. But how does this neighboring group act? Rate-determining complexation between silicon and oxygen leading to the generation of a reactive intermediate[41] having cyclic three-membered structure *(38a)* in which the R^3—O bond is weakened [see resonance form *(38b)*], is in line with all presently known observations. This *may* involve d_π-p_π interaction. Rapid homolytic decomposition then leads to the complete formation of the strong Si—O bond and the generation of resonance stabilized radicals. If the potential radical is not sufficiently stabilized [for example in the case of the methyl ether *(18h)*], the complex merely reverts back to starting material, since an additional energy barrier would have to be overcome (see Fig. 3).

(18) *(38a)* *(38b)* *(19)*



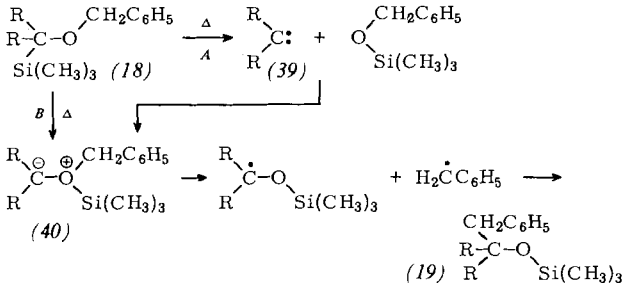


Fig. 3. Possible reaction profile for thermolysis of the ethers *(18c)* and *(18h)*.

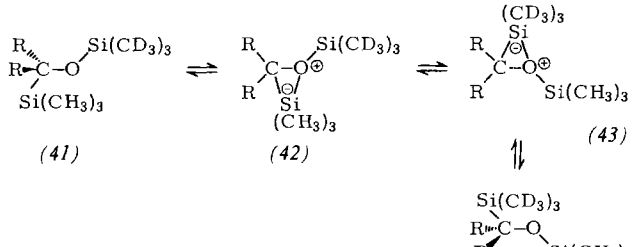


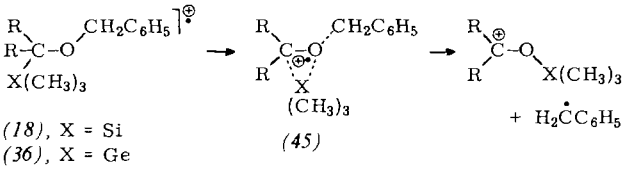
The formation of species *(38)* with pentacoordinated silicon is not only consistent with the intramolecularity and stereochemistry of silyl group migration, but also with the negative entropy of activation, the small kinetic deuterium isotope effect, and the results of the Hammett study. However, the existence of the reactive intermediate *(38)* cannot yet be proved beyond all doubt. Concerted fragmentation of *(18)* into radicals does not involve any local energy minimum along the reaction coordinate. The difference between the two-step and concerted mechanism is thus rather small. In both cases the motion of the neighboring group is far advanced compared to that of the leaving group. The pronounced affinity of silicon for oxygen is the driving force of the reaction and is responsible for the relatively low activation energy. The germanium analogue *(36)* rearranges slower, since the Ge—O bond is considerably weaker.

Since alternative mechanisms have been discussed in detail elsewhere[24, 33], only two of the most important possibilities are mentioned here. Path *A* involves rate-determining α-elimination affording carbene *(39)*. Related α-eliminations are known[42], but involve formation of stabilized nucleophilic carbenes. Path *A* appears unlikely because trapping experiments fail to afford carbene adducts[24].

It is more difficult to disprove the direct ylide mechanism (Path *B*), which represents anchimerically accelerated homolysis, just like the previously discussed mechanism involving *(38)*. The difference between the ylide *(40)* and the three-membered ring *(38)* has to do with the fact that in the former there is no bonding between silicon and carbon. Is it possible to detect this difference experimentally? Perhaps the formation of a genuine oxygen ylide would result in a larger solvent effect.

The main counterargument is more subtle. We observed that the dyotropic valence isomerism[43] of silyl methylsilyl ethers *(41a)*⇌*(44a)* occurs *without* radical formation[44, 45]. The silyl groups interchange their places strictly intramolecularly at 160—190°C with retention of configuration, whereby an equilibrium is reached. However, the activation parameters and solvent effects are almost identical to those of the radical fragmentation *(18)*→*(19)*. This suggests a similar transition state, namely rate-determining coordination between silicon and oxygen. It necessarily follows that the energy surface is characterized by a double minimum *(42)*⇌*(43)*. A mechanistically significant observation is that the benzhydryl derivative *(41b)* is completely stable under normal thermolysis conditions (160—190°C). Only at *ca.* 230°C does *slow* silyl-silyl exchange occur, along with considerable amounts of decomposition products.

(a), R + R = 2,2'-Biphenylylene
(b), R = Phenyl



The dramatic difference between *(41a)* and *(41b)* ($k_{(41b)}/k_{(41a)} \approx 10^{-5}$) can only be explained by a steric model. The motion of the silyl group in *(41b)* from oxygen to the backside of the carbon atom in the reactive intermediates *(42)* and *(43)* is rapid only if the R-substituents do not give rise to steric inhibition, *e.g.*, as in flat fluorenyl derivatives and similar systems[44]. Such is not the case in the benzhydryl derivatives.

This effect was *not* found in radical reactions, where the benzhydryl and fluorenyl compounds [*e.g. (18a)* and *(18c)*] fragment at comparable rates. This is not surprising, since intermediate *(38)* has an "escape route", namely homolytic fragmentation which does not involve concerted backside attack. The strikingly different behavior of *(18)* and *(40)* in going from fluorenyl to benzhydryl derivatives *is not consistent with an ylide or a carbene mechanism.* However, it is in line with the formation of structurally related reactive intermediates *(38)* and *(42)*.

It remains to be explained why the rearrangement *(18)*→*(19)* proceeds with such surprisingly high yield, *i.e.*, without the formation of dimerization products such as bibenzyl. Relevant is the fact that preferred cross-dimerization is a common phenomenon in radical chemistry. In our case a somewhat enhanced concentration of ketyl radicals which trap just about all the benzyl radials could be the cause.

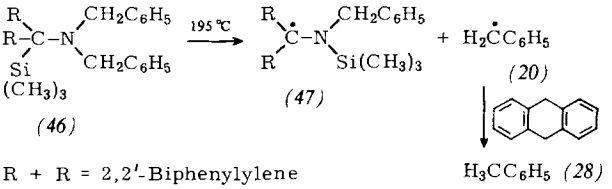
3.10. Comparison of Thermal, Electron-Impact Induced, and Photolytic Behavior

Surprisingly, silylmethyl- and germylmethyl ethers *(18)* and *(36)* as well as related compounds show very intense mass spectral peaks at $e/m = [M - CH_2C_6H_5]^+$[46]. Since electron-impact induced cleavages of C—O bonds with elimination of radicals and fixation of charge on the oxygen moiety are high energy processes which rarely afford intense fragment ions[47], a neighboring group effect was postulated. Migration of the metal from carbon to oxygen prevents charge localization.

(18), X = Si
(36), X = Ge

Indeed, further studies utilizing DADI spectra show that this new type of electron-impact induced ether cleavage occurs if the transition state *(45)* is stabilized by anchimeric participation of the silyl or germyl group[48]. Relevant and significant is the observation that in case of the *tert*-butyl analogue of *(18c)* (C in place of Si) the genesis of $[M - CH_2C_6H_5]^+$ does not come about, in spite of the fact that a stabilized benzyl radical could be generated. Thus, in this case there is a strict correspondence between thermal and electron-impact induced behavior.

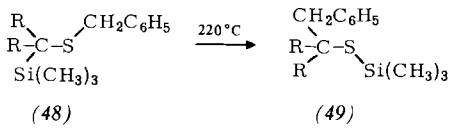
These and other experiments confirm the decisive role of the silyl and germyl groups and also demonstrate that generation of ions by an alternative migration of the C^9—C^{10} σ-bond of the fluorenyl skeleton to the oxygen, which involves ring expansion, offers no competition. The observation that hydrogen scrambling processes—which are otherwise very evident in the low energy spectra of arenes—do not take place (deuterated allyl derivatives loose only $C_3H_3D^+$) also suggests a fast process facilitated by migration of the adjacent metal groups[48].



The differing rates of thermal fragmentation of *(18c)*, *(18h)*, and *(18i)* have no quantitative parallels in the mass spectrum.

The radical R^3 liberated on electron-impact induced decomposition is not necessarily resonance stabilized. Moreover, just *one* stabilizing group on the stationary C atom is sufficient [cf. *(18i)*]. The germyl compound shows effects of similar magnitude although it undergoes thermal fragmentation much slower than the silicon analogue.

It was of interest whether the above anchimerically accelerated ether cleavages can also be induced photochemically. Such a process would require specific photochemical excitation of the C—Si bond. The direct excitation of a certain σ-bond is generally difficult. *(18c)* was chosen as experimental substance[28] because the fluorenyl skeleton is a suitable chromophore in which the absorbed light energy can "flow" into the α-positioned σ-bond. Experiment (Hg high-pressure lamp, Pyrex filter) showed that the C—O bond, rather than the C—Si bond, reacts preferentially[28]: normal ether cleavage was detected. The experiments underline the fundamental difference between thermal and photolytic behavior.



4. Thermolysis of Benzyl(silylmethyl)amines and Benzyl Silylmethyl Thioethers[49, 51]

If the hetero atom with a lone pair does in fact play a crucial role in the radical fragmentation of alkyl silylmethyl ethers, then the analogous amines should likewise undergo anchimerically assisted homolyses. Of course, the strength of the Si—N bond amounts to only *ca.* 85 kcal/mol[50]. The radical fragmentation of *(46)* does indeed proceed more slowly than that of the corresponding ether: $k_{(46)}/k_{(18c)} \approx 10^{-5}$. In the presence of 9,10-dihydroanthracene as a radical trapping agent, 76% of toluene is formed. A mechanism according to *(46)* → *(47)* + *(20)* is therefore likely[49]. In the absence of radical trapping agents a number of products are formed, among them bibenzyl (15%). In its mass spectrum *(46)* shows a low-intensity $[M-CH_2C_6H_5]^+$ peak[48], in contrast to the oxygen analogue *(18c)*. Hence there exists a parallel between thermolysis and electron impact.

These results underscore the central role of the heteroatom, with the strength of the new bond to silicon being of prime importance for the subsequent reactions. *Brook* has noted similar effects in the base-induced sigmatropic silyl migration in α-silyl alcohols and α-silylamines; the latter rearrange considerably slower[50].

The thioether *(48)* analogous to *(18c)* was also synthesized and thermolyzed in order to study possible anchimeric effects[51]. Although the mechanistic studies have not been completed, it is clear that the reaction *(48)* → *(49)* is much slower than *(18c)* → *(19c)*: $k_{(48)}/k_{(18c)} \approx 6 \times 10^{-6}$. Again, this observation supports the working hypothesis according to which the strength of the new bond to the neighboring group is decisive for the rate of radical fragmentation: $E_{Si-O} - E_{Si-S} \approx 30$ kcal/mol[52,53].

5. Summary

The rearrangements described in Sections 3 and 4 are the first known examples of anchimerically accelerated homolyses involving three-center bonds in the transition state as well as the migration of the neighboring group to the radical reaction center. The conjecture that such processes are possible if a strong new bond is made and if both radical fragments are resonance stabilized has been confirmed so far. Rate-determining complexation between the neighboring group having empty orbitals and a heteroatom having a lone pair is presently a useful working hypothesis. Some degree of correspondence is observed in many cases between thermal and electron-impact induced behavior. Further parallels are found in recent studies, *e.g.* on thermolysis and behavior of silyl methylacetates in the mass spectrometer[48, 54]. It remains to be seen whether groups other than SiR_3 (*e.g.*, phosphorus or boron) are also capable of anchimeric assistance.

This review was written by the author during his stay as guest professor at the Department of Chemistry, University of Wisconsin (Madison). I would like to thank the members of the department for their hospitality and for interesting discussions. Particular thanks are due to my co-workers Dr. M. Kliment, Dr. N. Greif, Dipl.-Chem. A. Maaroufi, and M. Plachky. Our work was generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

New analytical methods (15)

Liquid Column Chromatography with Chemical Derivatizations after Separation

By Georg Schwedt[*]

Modern liquid column chromatography (high-pressure liquid chromatography, HPLC) has evolved in the last few years into a highly efficient and versatile separation technique. The selectivity of an analytical process that depends upon a previous separation step can in many cases be increased considerably by chemical derivatizations after the separation. In addition, lower detection limits can be achieved in this way than in detection without derivatization. The physicochemical principles of these combined processes involving chromatographic separation and chemical derivatization prior to detection (coupling of HPLC and a reaction detector) are presented and discussed. The state of development is outlined, with a survey of the more important applications so far described in the literature.

1. Introduction

The essential problems of modern analytical chemistry are to increase the sensitivity and selectivity and to improve the detection limits of analytical processes used to detect and determine trace elements and low contents of organic substances in complex mixtures. During the last two decades progress in this direction has been made possible mainly with the help of physics and physical methods of measurement, namely by novel analytical applications of physical effects and by improvements in the available apparatus.

While the development of analytical chemistry up to about 1960 was mainly characterized by the analytical application of chemical reactions and the discovery of new reagents for the classical gravimetric, volumetric, colorimetric, and photometric methods, it seems that the most significant part in further development is nowadays played by physical methods of measurement, for example spectroscopic methods.

In chromatography too, improvements in the equipment, above all in the fields of gas and liquid chromatography, have been responsible for a decisive improvement in separation performances and hence in selectivity. Technological advances in the manufacture of column packings with particle diameters below 10 μm, and improvements in pumping techniques that enable a constant pulsation-free delivery of the mobile phase against high pressures, have in the last ten years transformed classical liquid chromatography into the incomparably more efficient high-pressure liquid chromatography (HPLC). However, compared to the analytical side of HPLC, the detection stage has, as yet, not reached the same high level of sophistication as far as sensitivity, detection limits, and selectivity are concerned. Nevertheless, developments are appearing that

once more endow the chemical side, *i.e.* chemical reactions and reagents, with greater significance.

2. Reaction Detectors

2.1. Principles and Designs of the Analytical System

UV and fluorescence detectors with flow-through cells are at present the most usual, and from the point of view of instrumentation the best-developed detectors used with HPLC[1]. To improve the sensitivity and in particular the detection limits it is often recommended that the substances to be determined should be modified chemically to give compounds with higher molar extinction coefficients for UV detection, or compounds that can be detected fluorimetrically down to lower detection limits than can be attained by UV detection. Such derivatization can be performed either before or after the chromatographic separation[2].

Derivatization prior to a chromatographic analysis, with the aim of achieving more selective separations, and in particular lower detection limits than is possible with the original compounds, has been successfully applied in chromatography for some time[2, 3]. For this purpose the chemical derivatizations should be as quantitative as possible, and should lead to one definite product. In contrast, if the substances are to be derivatized after the separation step, reactions that do not proceed to completion may suffice, even if they yield several products, provided only that the signals to be measured are strong and reproducible. Moreover, in this case there is no longer any need for the sample preparation required with derivative formation before the separation, which is often laborious, time-consuming, and associated with losses of material.

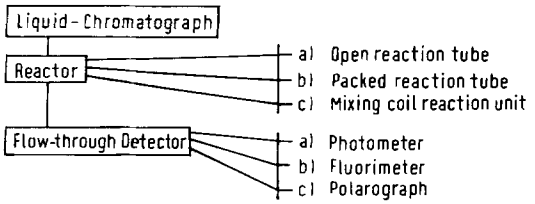

Fig. 1. System for liquid chromatographic analyses with chemical reactions after the separation step. The combination of a reactor and flow-through detector is called a reaction detector.

The analytical systems for liquid chromatography with chemical reactions after the separation consist of a liquid chromatograph, a reactor, and a flow-through detector (Fig. 1, cf. also [4]). The chemical reaction and the detection of the separated substances take place in on-line coupling after the chromatographic separation. In conformance with current practice, in what follows we shall refer to the reactor and the flow-through detector as the (chemical) reaction detector[5]. The reactor can consist of an open reaction tube (a capillary tube), a packed reaction tube (a tube of greater diameter than a capillary, packed with small particles such as glass beads), or a mixing coil reaction unit such as those used in equipment for automatic wet chemical analyses (AutoAnalyzers®). In this reaction unit a peristaltic pump is used for pumping the solutions through manifold tubes into the mixing coils. The liquid stream is divided into segments with air bubbles (see Fig. 2).

2.2. Diffusion Effects in the Reactors

In all reactors the chromatographically separated substances exhibit "band broadening" caused by diffusion effects, which can be described quantitatively.

The band broadening of a signal recorded in the detector in the form of a Gaussian distribution curve can be described in terms of the standard deviation σ or the variance σ^2. The variances of individual parts of the analytical system are additive (cf. Table 1):

$$\sigma_t^2 = \sigma_{tc}^2 + \sigma_{tv}^2 + \sigma_{td,g}^2 \text{ [s]} \tag{1}$$

(c: column, v: connections, td,g: total detection system, *i.e.* the reactor and flow-through detector).

2.2.1. Open Reaction Tube

In an open capillary tube connected to the outlet of the HPLC column *via* a T-piece, the variance as a function of the reaction time (according to [6, 7]) is given by:

$$\sigma_{td}^2 = \frac{d_t^2 t}{96 D_m} \tag{2}$$

Thus, for a given diffusion coefficient D_m the band broadening σ is proportional to the tube diameter d_t and to the square root of the reaction time t. Differences in band broadening between ideal and geometrically deformed tubes have been investigated by *Halász* and *Walkling*[6].

2.2.2. Packed Reaction Tube

Packed reaction tubes correspond to packed separation columns in chromatography, but they do not have any retaining action. The dependence of the variance upon the reaction time is here:

$$\sigma_{td}^2 = \left[\frac{\varepsilon \cdot D_m \pi^2 d_t^4}{8 F_l^2} + \frac{\pi d_t^2 \lambda_1 \cdot \lambda_2 d_p}{4 F_l [1 + \lambda_2 d_t (\pi D_m / d_p)^{1/2}]}\right] t \tag{3}$$

(The equation used in [8] has been rearranged.) The abbreviations are explained in Table 1. In this type of reactor the band broadening can be reduced by using finer particles, a higher flow-through rate, and a smaller tube diameter.

2.2.3. Mixing Coil Reaction Unit

In units of this kind the liquid stream is segmented by air bubbles (Fig. 2) and the band broadening resulting from diffusion effects in the longitudinal direction is thus reduced to a minimum[5, 9, 10].

The following equation, due to *Snyder*[5], gives the variance as a function of the reaction time:

$$\sigma_{td}^2 = \left[\frac{538 d_t^{2/3} (F_l + 0.92 d_t^3 n)^{5/3} \eta^{7/3}}{\gamma^{2/3} F_l D_{w,25}} + \frac{1}{n}\right] \times \left[\frac{2.35 (F_l + 0.92 d_t^3 n)^{5/3} \eta^{2/3}}{\gamma^{2/3} F_l d_t^{4/3}}\right] \cdot t \tag{4}$$

The optimal segmentation frequency n can in each case be determined as a function of the diameter of the mixing coil. The influences exerted by the flow rate F_l, viscosity

η of the reaction mixture, and surface tension γ have been investigated thoroughly by *Snyder*[5]. (For the abbreviations in eq. (4), see Table 1.)

Table 1. Explanation of the abbreviations used and some definitions.

c_{max}	Concentration of a substance at the band maximum [g·cm^{-3}]
c_0	Concentration of a substance in the sample solution [g·cm^{-3}]
d_f	Mean liquid-film thickness on the walls [cm]
d_i	Internal diameter of connectors or tubes
d_p	Particle diameter [cm]
d_t	Tube diameter [cm]
D_m	Molar diffusion coefficient [cm^2·s^{-1}]
$D_{w,25}$	Molar diffusion coefficient in water at 298 K [cm^2·s^{-1}]
F_l	Flow rate down the column, space velocity [cm^3·s^{-1}]
F_R	Flow rate of the reagent [cm^3·s^{-1}]
H	Height of a theoretical separation plate [mm]
k'	Capacity-, mass distribution ratio
l_s	Length of a liquid segment [cm]
L	Column length [cm]
m_s	Mass [g]
n	Segmentation frequency [s^{-1}]
N	Number of theoretical separation plates
p	Pressure [bar]
q	Free cross section of a separation column
r	Radius of mixing coil
R	Resolution of two bands
R_{max}	Maximum resolution
t	Reaction time [s]
t_R	Over-all retention time [s]
u	Linear flow velocity [cm·s^{-1}]
V_0	Sample volume [cm^3]
β	Ratio of liquid length/sum of liquid and gas lengths [*]
γ	Surface tension [dyne·cm^{-1}]
ε	Porosity: fraction of the free cross section available to the eluent
λ	Geometric constants for the packed reaction tube
η	Viscosity [dyne·s·cm^{-2}]
σ_t, σ_v	Band broadening [s] or [cm^3]
σ_{tc}	Band broadening in the column [s]
σ_{td}	Band broadening in the reactor [s]
$\sigma_{td,g}$	Band broadening in the whole detection system [s]
σ_{tv}	Band broadening in the connectors [s]

Sensitivity of a method: slope of calibration curve
Detection limit of a process: concentration for the measured quantity from blank value plus three times its standard deviation

[*] By "liquid length" and "gas length" are meant the lengths of the liquid and the gas segments, respectively.

Deelder and *Hendricks*[11] give the following relationship for the dependence of the variance on the mean thickness of the liquid film d_f on the walls and on the length l_s of a liquid segment (Fig. 2):

$$\sigma_{td}^2 = \frac{2\pi^2 d_f l_s L r^3}{F_l} \qquad (5)$$

According to *Hrdina*[12], the following relation exists for the value of 4σ:

$$4\sigma = 2\sqrt{n t d_f/(\beta d_t)} \qquad (6)$$

Here β represents the ratio of the liquid length to the sum of the liquid and gas lengths (see Table 1).

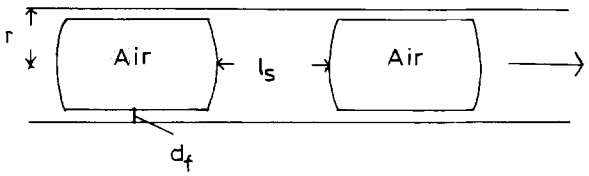

Fig. 2. Schematic representation of the segmentation of the liquid stream in a mixing spiral reaction unit. r: radius of the glass tube (of the mixing coil); d_f: mean liquid-film thickness on the walls; l_s: length of a liquid segment.

Eq. (4)[5] makes it possible to calculate the band broadening from directly measurable or known magnitudes of the reactor, while the application of the simpler relationships (5) and (6) requires knowledge of the mean thickness of liquid-film on the walls.

Further investigations concerning the dynamics of the analysis with continuously segmented flow have been performed *e.g.* by *Begg*[13], *Thiers et al.*[14], and *Walker et al.*[15], and on band broadening in columns by *Halász et al.*[16] and by *Huber* and *Hulsman*[17].

2.3. Comparison of the Reactors and General Relationships

If we compare the variances or the band broadening for several types of reactors in relation to the reaction time (Table 2), the mixing coil unit proves to be best. In practice, however, additional broadening occurs as a result of diffusion in the connections of the mixing coil to the chromatographic column, in the air separator, and in the connection to the detector (see, for example, [11]). Experimental values of σ for several reactors are shown in Table 3.

An open reaction tube is also suitable for very rapid reactions lasting a few seconds. Indeed, when mixing coil reaction units are used, greater band broadening than the calculated value is observed due to the connectors; nevertheless, this type of reactor is preferred to the two others for long reaction times, particularly when several reaction steps are involved.

Table 2. Parameters for the calculation of band broadening σ_t in several reactor types.

	Open reaction tube	Packed reaction tube	Mixing coil reactor
Internal tube diameter d_t [cm]	0.05	0.5	0.1
Diffusion coefficient D_m [cm^2·s^{-1}]	2×10^{-5}	2×10^{-5}	$D_{w,25}$: 3.5×10^{-5}
Flow rate F_l [cm^3·s^{-1}]	—	0.025	0.025
Viscosity η [dyne·s·cm^{-2}]	—	0.004	0.004
Surface tension γ [dyne·cm^{-1}]	—	—	25
Packing particle diameter d_p [cm]	—	1.6×10^{-3}	—
Segmentation frequency n [s^{-1}]	—	—	7.3
Constants λ_1	—	11	—
λ_2	—	18	—
Calculated variance as a function of reaction time [s^2]	σ_t^2 $1.30t$	$5.14\times10^{-2}t$	$4.97\times10^{-3}t$

Table 3. Examples of experimentally obtained band broadenings σ_t and σ_v in several types of reactor.

Open reaction tube (after [21])

Determination of thioridazine in blood. Chromatography: partition with ternary phases; reaction: oxidation with potassium permanganate; detector: fluorimeter.

	$\sigma_v \cdot 10^{-3}$ [cm^3]
System: Sample loop + flow-through cell	36
Sample loop + flow-through cell + open reaction tube	120

Conditions: $t=5$ [s], $F_1=2$ [cm^3 min^{-1}], $d_t=0.04$ [cm], $L=150$ [cm]

$\sigma_t=3.6$ [s] (calculated from σ_v)

Packed reaction tube (after [70])

Determination of isoenzymes. Chromatography: in a modified cellulose exchanger; reaction: transformation with lactate/NAD$^+$; detector: photometer or fluorimeter.

System: column packed with nonporous glass beads.

Conditions: $L=30$ [cm], $d_t=0.41$ [cm], $p=7$ [bar], $d_p=5\times10^{-5}$ [cm], $u=0.4$ [cm^{-1}], $t=75$ [s]

$\sigma_t=3.1$ [s] (calculated from Fig. 3 in [70] with $H=0.5$ [mm]) [*]

Mixing coil reaction unit (after [11])

Determination of cyclohexanone. Chromatography: partition with ternary phases; reaction: transformation with 2,4-dinitrophenylhydrazine; detector: photometer.

		σ_{td}^2 [s^2]
System: Mixing coil I: $L=2$ [m], $d_t=0.24$ [cm]		16
Mixing coil II: $L=1$ [m], $d_t=0.24$ [cm]		6
Connectors		11
	Total	33 ($\sigma_{td,g}^2$)

Conditions: $t=180$ [s], $u=0.15$ [cm·s^{-1}], $k'=0.3$ $R_{max}=3$ (without a reactor), $R=2.4$ (with a reactor): $\sigma_{tc}>7$ [s] decreases the resolution R by less than 20% [11].

$\sigma_t=5.7$ [s] (calculated from $\sigma_{td,g}^2$)

[*] σ_{td}^2 amounts to only one-third of the value when the same reaction is carried out in an open capillary tube 15.25 m long and with an internal diameter of 0.05 cm [70].

Only at high temperatures does the packed reaction tube seem to offer advantages[18], since no tubing or plastic connections such as in the mixing coil reaction unit are required. In more recent publications, *Frei et al.*[19, 20] have compared the various possibilities of post-column derivatization.

For the ratio of the resolution of two signals, recorded in the flow-through detector, and the resolution R_{max} attained by the chromatographic system with $\sigma_t=\sigma_{tc}$ and $\sigma=0$, we have (according to [8, 11]):

$$R/R_{max}=[1+\sigma_{td}^2/\sigma_{tc}^2]^{-1/2} \tag{7}$$

If a decrease of 5% in the resolution R_{max} is allowed for, then $\sigma_{td}=0.33\,\sigma_{tc}$. From this condition we obtain a minimum retention time of

$$t_{R2}=2\sigma_{td}\sqrt{N} \tag{8}$$

(Example: $\sigma_{td}=2$ [s], $N=10000$, $t_{R2}=400$ [s]) at a given resolution R for a pair of substances in dependence on the number of theoretical separation stages N.

The dilution effect in liquid chromatography can be expressed as the ratio of the concentration of a substance at the band maximum c_{max} to its concentration in the sample c_0 (after [11]):

$$\frac{c_{max}}{c_0}=\frac{V_0}{q(1+k')\sqrt{2\pi LH}} \tag{9}$$

The product $c_0 V_0$ corresponds to the quantity of the sample.

In the reactor the sample solution is further diluted by the addition of reagents and the band broadening[11]:

$$\frac{c_{max}}{c_0}=\frac{F_1}{F_1+F_R}\cdot\frac{\sigma_{tc}}{\sigma_t}\cdot\frac{V_0}{q(1+k')\sqrt{2\pi LH}} \tag{10}$$

With the assumption of a Gaussian distribution, we have for c_{max} (see [21]):

$$c_{max}=\frac{m_v}{\sqrt{2\pi}\sigma_v} \tag{11}$$

3. Examples of Application

Most of the so far described liquid chromatographic analyses involving a reaction detector are related to the fields of organic chemistry or biochemistry. The analysis of amino acids has already been carried out successfully for about 20 years, using a chromatographic separation (ion exchange) directly coupled to a chemical reaction stage before the detection, in automatic reaction systems (with mixing coil reaction units)[22]. Apart from the classical ninhydrin[18, 23], phthalaldehyde[29–32], fluorescamine[29, 37, 38] and pyridoxal[40] have been used for the photometric or fluorimetric determination of amino acids (see Table 4).

Peptide separations have also been combined with a reaction step using phthalaldehyde[34] or fluorescamine[39]. In part, these methods have been extended to the determination of amines[24–27, 30, 33]. In the analysis of biogenic amines such as catecholamines, special chemical reactions are carried out in mixing coil reaction units after the chromatographic separation: a) transformation with ethylenediamine[4, 41, 42] and b) oxidation to fluorimetrically detectable trihydroxyindoles[43–48]. Owing to the selective reaction to trihydroxyindoles, with the aid of reversed-phase HPLC it is even possible to determine the catecholamines in urine directly without preliminary separation ([48], see also [85]).

Other oxidizing agents such as potassium permanganate[21], Ce(IV) sulfate[49–54], chromic acid[56, 57], and periodate[56, 57] find application in the fluorimetric and absorption-spectrometric determination of various organic substances in combination with liquid chromatography (see Table 4). Oxidizing compounds such as hydroperoxides are transformed with sodium iodide; the iodine released is determined photometrically in the through-flow[8]. Redox indicators such as tetrazolium blue and neocuproine are suitable for the analysis of reducing sugars[58, 59].

Carboxylic acids can be detected using acid-base indicators after ion-exchange chromatographic separation[60–62].

Further reagents are listed in Table 4. For chromatographically separated and chemically modified substances one can also use electrochemical detection methods, such as the detection of citrals with semicarbazide[69].

Special reagents and reaction systems have been described for enzyme analysis[70, 71]. In environmental analysis, the enzymatic inhibition of cholinesterase is used as an indication

4. Outlook: Development Trends

Selective chemical reactions with a variable flow-through detector in combination with high-performance separation systems offer the possibility of direct and sensitive analyses of individual substances in complex mixtures such as urine or blood without sample preparation.

Table 4. Examples of (chemical) reaction detector applications.

Reagent	Substance or group of substances	Detection [a]
Ninhydrin	amino acids [18, 23], amines [24, 25], polyamines [26, 27], γ-aminobutyric acid [28]	F, A
Phthalaldehyde	amino acids [29—32], amines [30, 33], catecholamines [33], peptides [34], 5-hydroxyindoleacetic acid [35], *N*-methylcarbamate [36]	F
Fluorescamine	amino acids [29, 37, 38], peptides [39]	F
Pyridoxal	amino acids [40]	F
Ethylenediamine	catecholamines [4, 41, 42]	F
Oxidizing agents		
a) Potassium hexacyanoferrate(III)	catecholamines [43—48]	F
b) Potassium permanganate	thioridazine and metabolites [21]	F, A
c) Cerium(IV) sulfate	arenecarboxylic acids [49—51], carbohydrates [52, 53], phenols [54], 5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide [55]	F, A
d) Chromic acid	hydroxycarboxylic acids [56, 57]	F, A
e) Periodate	hydroxycarboxylic acids [56, 57]	F, A
Sodium iodide	hydroperoxides [8]	A
Tetrazolium blue	sugar [58]	A
Neocuproine	reducing sugars [59]	A
Acid-base indicators	carboxylic acids [60—62]	A
Carbazole	hydroxycarboxylic acids [56, 57], uronic acids [63]	A
Phenol	carbohydrates [64]	A
Sulfanilic acid/*N*-(1-naphthyl)ethylenediamine	nitrosamide [65]	A
7-Chloro-4-nitrobenzofuran (NBD-chloride)	proline, hydroxyproline [66]	F
2,4-Dinitrophenylhydrazine	cyclohexanone [11]	A
Acids (hydrochloric, sulfuric, acetic)	glycosides [20], carbohydrates [67], estrogens [68]	F
Semicarbazide	citral [69]	E
6,6′-Dinitro-3,3′-dithiodibenzoic acid	enzymes [70]	A
p-Nitrophenyl-*p*-guanidinobenzoate	enzymes [70]	A
Lactate/NAD^+	enzymes [70, 71]	A, F
Cholinesterase	organophosphorus compounds, carbamates, insecticides [72, 73]	A

4-(2-Pyridylazo) resorcinol (PAR)	metal ions [75, 76]	A
Luminol	metal ions [77—79]	F
Zincon	zinc [80]	
Ce(IV) sulfate	polythionates [81]	

[a] A: absorption measurements; F: fluorescence measurements; E: electrochemical detection.

for organophosphorus compounds, carbamates, and insecticides[72,73].

In inorganic analysis too, reactions after ion-exchange chromatographic separations with molybdate, metal reagents, or even Ce(IV) sulfate find some application[74–81].

The examples set out in Table 4 are not differentiated in terms of classical or modern HPLC in columns. According to *Engelhardt*[82], the borderline between HPLC and classical liquid chromatography is defined by a packing particle diameter greater than 50 μm for the latter. *Snyder* and *Kirkland*[83] characterize modern column chromatography as high-speed or high-performance liquid chromatography with a high separation power and short separation times ranging from a few minutes up to an hour. Further examples of reactions in systems with continuous through-flow in combination with classical column chromatography are given in a monograph by *Foreman* and *Stockwell*[84].

Examples of such applications of reaction detectors have been described, among others, for carbohydrates in urine and serum[52], for free proline and hydroxyproline in serum[66], and for free epinephrine and norepinephrine in urine[48] (Fig. 3). Further examples are the direct determinations of dopamine and serotonin in brain homogenates by reversed-phase chromatographic separation and reaction with phthalaldehyde (Fig. 4) (see also [85]).

Such analytical processes, especially when they are used for the trace analysis of organic substances, are mainly effective in reducing problems connected with separation from the material and the stability of the substances or derivatives prepared for the liquid chromatography. Moreover, they shorten the analysis time compared to a process comprising separation, derivatization of the test substance, and chromatographic analysis. Another objective of such systems that combine HPLC and (chemical) reaction detectors is the separation

and determination of as many materials as possible in a single operation. Examples of this are provided mainly by the analysis of amino acids, of carbohydrates, and of metallic ions, which are derivatized by means of group reagents and thereby determined all together after a chromatographic separation (see Table 4). The precondition for the applicability of this process

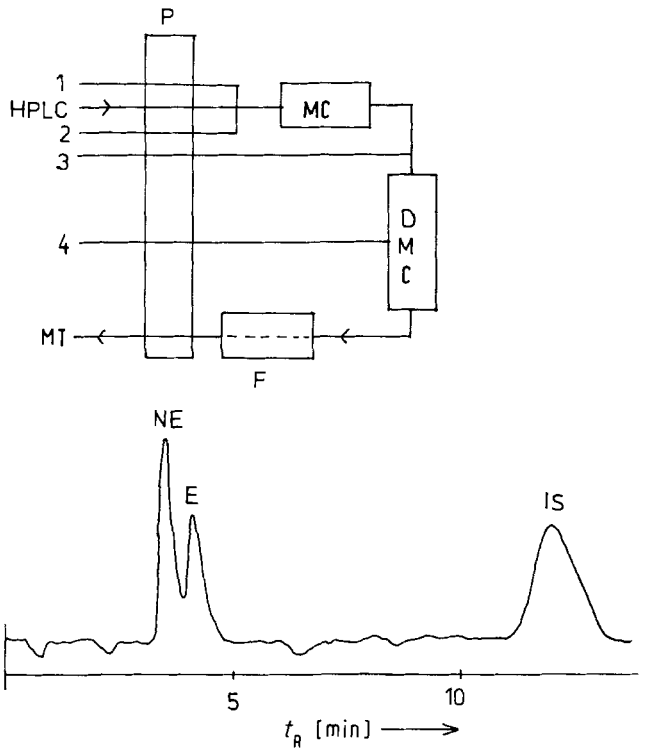

Fig. 3. Direct determination of epinephrine (E) and norepinephrine (NE) in 200 µl of urine by a combination of reversed-phase chromatography (column: LiChrosorb RP 18, mobile phase: 0.05 M phosphate buffer pH 3, flow rate: 1.5 ml·min^{-1}, pressure: 60 bar) with a (chemical) reaction detector. IS denotes internal standard.
Flow diagram: 1: Oxidizing solution: 0.3 M formate buffer pH 4/0.1 M boric acid/0.1 % potassium hexacyanoferrate(III)/2·10^{-3} % copper acetate (tube: d_i 0.76 mm); 2: Air (tube: d_i 1.42 mm); 3: Reducing solution: 5 % mercaptoethanol in water/20 % sodium sulfite in water/10 M caustic soda, proportions by volume 1:1:1 (tube: d_i 0.76 mm); 4: 4 M acetic acid/4 % boric acid (tube: d_i 1.14 mm); MT: Main tube d_i 1.85 mm; P: Peristaltic pump, F: Fluorimeter (excitation wavelength 405 nm, fluorescence-edge filter 450 nm, sensitivity 0.03 µA/full scale); MC: Mixing coil, DMC: Double mixing coil (d_i 2.4 mm). Urine sample: 14.5 ng epinephrine/ml and 59 ng norepinephrine/ml (corresponding to 2.9 ng epinephrine and 11.8 ng norepinephrine in the column).

is a selective chromatographic system with a high separating efficiency. Thanks to developments in modern liquid chromatography, the analysis time in the case of amino acids has been reduced from over 12 h[22] to less than 1 h[38].

Moreover, with the systems described, the accuracy of analytical results can be checked, as can be seen from the following example:

For the analysis of biogenic amines in biological material, interference-free analytical processes combining separation and enrichment processes (ion exchange, liquid-liquid partition) with selective chemical reactions have been developed. Considering the example of serotonin, HPLC and chemical reaction with fluorimetric measurement after the separation have shown that with urine samples the separation processes with *n*-butanol usually used for brain specimens give erroneous (high) values. In the chromatogram alongside the

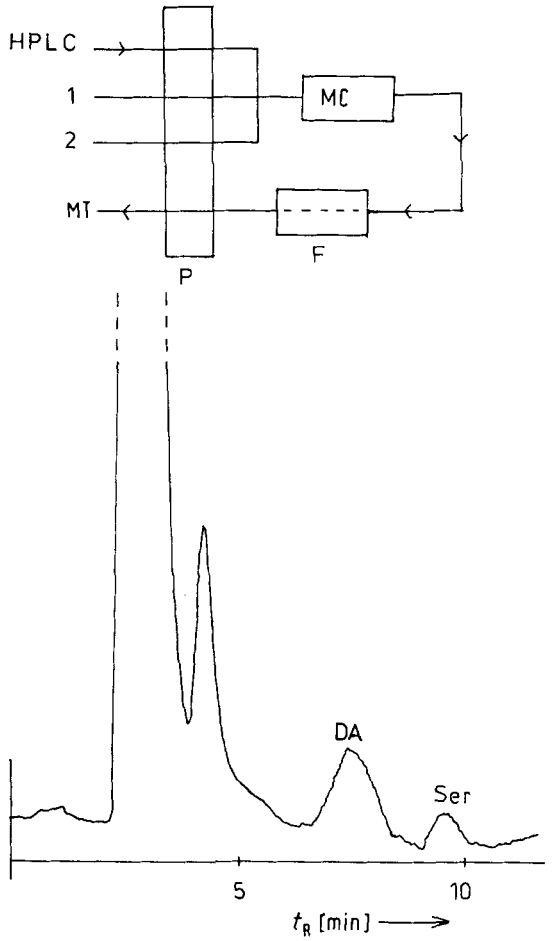

Fig. 4. Direct determination of dopamine (DA) and Serotonin (Ser) in 50 µl of brain homogenate (1.5 g of rat brain homogenized in 10 ml of 0.1 N hydrochloric acid) by a combination of reversed-phase chromatography (column: Li-Chrosorb RP 18, mobile phase: 20 % methanol in an aqueous solution of 0.4 M acetic acid/boric acid pH 3.2, flow rate 1.2 ml·min^{-1}, pressure: 80 bar) with a (chemical) reaction detector.
Flow diagram: 1: Reagent: phthalaldehyde, 0.02 wt-%/0.05 vol-% mercaptoethanol in 0.2 M borate buffer pH 9 (tube: d_i 0.76 mm); 2: Air (tube: d_i 0.76 mm); MT: Main tube (d_i 1.14 mm); P: Peristaltic pump; F: Fluorimeter (excitation wavelength 365 nm, fluorescence edge filter 450 nm, sensitivity: 0.3 µA/full scale); MC: mixing coil.

serotonin signal a further signal was recorded, which is measured as serotonin when no separation has been performed, in spite of the selective reaction (with phthalaldehyde in hydrochloric acid at 80 °C)[86].

Structural Chemistry of Fluorides and Oxide Fluorides of Nonmetals

By Konrad Seppelt[*]

The structural features of the nonmetal fluorides and oxide fluorides can now be explained and useful predictions can be made. The same applies in part to the chemistry of this class of compounds. Statements concerning structures can easily be made on the basis of the electron pair repulsion model (VSEPR theory). Some rules for the number of ligands provide structural predictions for larger units than isolated molecules or ions. This is important for the fluorides and oxide fluorides of the heavier elements. This class of compounds has its limits in the lighter noble gases which, even with fluorine, form only weak bonds or no bonds at all.

1. Introduction

The number of research papers on the fluorides and oxide fluorides of the nonmetals runs into thousands. A complete survey of the literature cannot be given in this article—for this the reader may be referred, for example, to specialist review periodicals[1–3]. Here we shall be considering common features in the structural chemistry of this class of compounds.

Simple rules are now known which help us to predict the structures of compounds. If we confine the discussion to the nonmetals, and permit only oxygen and fluorine as ligands, we are in a position to make almost complete structural

[*] Priv.-Doz. Dr. K. Seppelt

Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)

predictions. These predictions can often be extended to the reactivity of the compounds. In the case of monomeric compounds of types AF_x or AO_xF_y the structure is obtained from the electron pair repulsion model (VSEPR theory; VSEPR = *V*alence *S*hell *E*lectron *P*air *R*epulsion). Although this model is not based on bonding theory considerations (which is actually its strength), all known structures can be explained with its aid and its predictions have been found to be correct. However, in the case of high coordination numbers and other ligands, such as chlorine, the VSEPR model encounters increasing difficulties (cf. Section 2). Nevertheless, cations and anions such as SF_3^+ or $IO_2F_2^-$ fit well into the scheme. With such species complications arise only because of the impossibility of distinguishing between molecular-ionic and bridged-polymeric structures, since the boundary between them is not rigid. Structures in which molecular fragments can no longer be recognized, *i.e.* salts, are of course rare in the class of substances under consideration.

For the first row of the periodic table the octet rule is obeyed. An analogous duodecet rule for the second and possibly even the third rows must, however, be taken with a pinch of salt. Here again modern MO theory best explains the bonding. Although the physical reality is questionable, it is visually attractive to include the d-orbitals in the consideration, particularly in the case of higher-valent fluorides and oxide fluorides[4, 5] (see Section 4).

It is known that only some of the nonmetal fluorides and oxide fluorides exist in the form of monomers. Nothing of strict validity can be said about tendencies to undergo dimerization, oligomerization, and polymerization, but much can be explained by comparisons, and even predictions are possible. An early attempt to elucidate this problem was the formulation of the double-bond rule (only first row elements will form double bonds) which can no longer be used in such a simple form.

2. The Electron Pair Repulsion Model (VSEPR Theory)

This simple model dates back to 1939[6, 7] and was refined in 1957[8]. A detailed description can be found in [9].

According to the VSEPR theory the molecular state of a compound AF_x or AO_xF_y is determined by the repulsion of the bonding and nonbonding valence electron pairs. The electron pairs, and hence the ligands, arrange themselves in such a way that they are as far from one another as possible. Thus definite structures are obtained, such as triangles (BF_3, COF_2), tetrahedra (CF_4, SO_2F_2, NF_3), trigonal bipyramids (PF_5, SF_4, ClF_3), octahedra (SF_6, IF_5, XeF_4), *etc.* In the case of molecules with different ligands the positions with the smallest available space are always occupied by the most highly electronegative ligands. This is particularly important in the case of the trigonal bipyramid. Deviations from ideal bond angles can also be plausibly explained in many cases. The structural properties of the known nonmetal fluorides and of their cationic and anionic derivatives fit into this scheme without any gaps, particularly if sixfold coordination is not exceeded. The same structural predictions can be obtained by simple Hückel approximation calculations[10]; the advantage of the VSEPR method is mainly its didactic simplicity.

The "steric effect of the nonbonding electron pair"—a unique feature of the VSEPR model—decreases with increasing size and increasing number of ligands. This is clear in the case of compounds such as XeF_6, XeF_8^{2-}, or $TeCl_6^{2-}$: in the presence of eight fluorine or six chlorine ligands the free electron pairs cease to have more than a slight steric effect. Thus, the ions $SeCl_6^{2-}$, $TeCl_6^{2-}$, $PoCl_6^{2-}$, $SbCl_6^{3-}$, and $BiCl_6^{3-}$ have an octahedral structure ("sterically inactive s-electron pair"). However, many of these salts show effects that can be explained by a dynamic distortion of the octahedron[11].

The existence of nonrigid transitions here is shown by the series of tellurium chlorides: $TeCl_3^+$ has a pyramidal structure with complete steric activity of the electron pair (and also has three more remote chlorine atoms in the vicinity). Tetrameric $TeCl_4$ has a cubane-like structure and $TeCl_5^-$ is polymeric. In this sequence, tellurium increasingly achieves an octahedral environment by means of six chlorine ligands[12–15]. Finally, $TeCl_6^{2-}$ has an almost or completely octahedral structure[11]. The same transition can be observed in the case of XeF_5^+, XeF_6, and XeF_8^{2-} (see Section 10).

3. Discontinuities in Group-Homologous Compounds

Nonmetals of the first row of the periodic system always have only four orbitals available in the valence shell (*"octet rule"*), which means that the number of ligands and the number of nonbonding valence electrons cannot exceed four. No exceptions to this rule are known[16]. Thus, while the ion NF_4^+ does exist, the hypothetical NF_5 appears to be realized only in the form of $NF_4^+F^-$. *Siebert* pointed out as early as 1953 and *Gillespie* repeated in 1964 that elements of the second and third rows obviously have available only the equivalent of six single bonds[17–19]: the bond orders of the nonmetal-oxygen bonds in the anions PO_4^{3-}, SO_4^{2-}, and ClO_4^- have been calculated as 1.41 (P), 1.52 (S), and 1.48 (Cl).

It seems that a bond order of 1.5 (times 4 = 6 single bonds) is the upper limit for these elements: chlorine cannot achieve the equivalent of seven single bonds. If fluorine is taken in place of oxygen, the situation is still clearer: the ions ClF_6^+ and BrF_6^+ exist, but neither ClF_7 nor BrF_7 has yet been obtained. Thus, six bonds are permitted in the second row, but not seven: AlF_6^{3-}, SiF_6^{2-}, PF_6^-, SF_6, and ClF_6^+ are known.

Exceptions occur in the third row: BrF_6^- and $SeCl_6^{2-}$ exist. It is interesting to note that only SeF_5^- is observed and not SeF_6^{2-}. An explanation is that five fluorine ligands in SeF_5^- imply a strong steric activity of the nonbonding electron pair; here, therefore, the quasi-octahedral arrangement is achieved. Although chlorine is larger than fluorine, because of the greater Se—Cl distance there is more space around the selenium atom, so that a $SeCl_6^{2-}$ species becomes possible. The nonbonding electron pair is supposed to be sterically not very active. For a discussion about BrF_6^-, see Section 9.

In the fourth period of the periodic system the limit of six ligands is finally exceeded: TeF_8^{2-}, IF_7, IF_8^-, and XeF_8^{2-} exist. So far, nine has been found as the maximum number of ligands plus nonbonding electron pairs.

Discontinuities have been observed not only in the maximum coordination number but also in the bond energy, *i.e.* the energy that must be supplied to decompose a gaseous

compound completely into atoms. The bond energy can usually be given accurately for binary compounds.

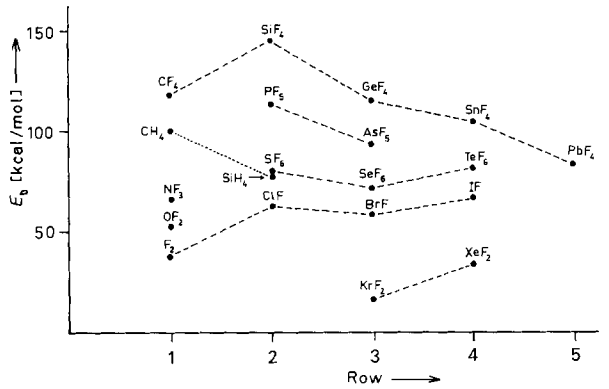

Fig. 1. Mean bond energies E_b of some fluorides (and hydrogen compounds) per bond [20]. The "M" form, with maxima at the elements of the second and fourth period, is characteristic. This is a superposition of size effects (transition-metal contraction, lanthanoid contraction), orbital effects, and increase in metallic character (decrease in electronegativity).

It is appropriate to divide this energy by the number of bonds. If this mean bond energy of some fluorides is plotted in a diagram, the following peculiarities are observed (see Fig. 1): the bond energy passes through two maxima, one at Si, P, S, and Cl, and another—less pronounced—at Sn, Te, I, and Xe. This discontinuity in the bond energy parallels the irregular change in electronegativity (*e.g.* C 2.5, Si 1.7, Ge 2.0, Sn 1.7, Pb 1.8; after *Allred* and *Rochow*).

Some chalcogen fluorides are discussed as examples of further discontinuities. The sensitivity to hydrolysis is found to be $SF_6 \approx SeF_6 \ll TeF_6$. It appears that SF_6 and SeF_6 are similarly insensitive to hydrolysis and the greater instability of SeF_6 must be ascribed simply to its easier reducibility. Thus, SeF_6 is as stable as SF_6 towards concentrated alkali, but not in the presence of I^-[21]. The oxidizing power of the oxo-anions also follows a very irregular sequence: $SO_4^{2-} \ll SeO_4^{2-} > H_4TeO_6^{2-}$. The instability or actual nonexistence of $FOTeF_5$ ($FOSF_5$ and $FOSeF_5$ have long been known) could also be a consequence of atomic size: on attempted synthesis, $FOTeF_5$ decomposed into TeF_6 and $\frac{1}{2}O_2$[22]. By comparison, $FOCF_3$ exists while $FOSiF_3$ does not as yet.

In the series of oxide fluorides F_5SOSF_5, $F_5SeOSeF_5$, and $F_5TeOTeF_5$, the last one shows the greatest bond angle and also the most pronounced shortening of the chalcogen-oxygen bond[23, 24] (see Section 8).

The amine $H_2N—TeF_5$ is less basic than $H_2N—SF_5$, in spite of the lower electronegativity of tellurium[25, 26]. A comparative investigation of the acid strengths of $HOSF_5$, $HOSeF_5$, and $HOTeF_5$ has so far foundered on the corrosiveness of $HOSeF_5$ and the instability of $HOSF_5$[27, 28]. In this connection, mention should be made of the extreme Lewis acidity of the boron compound $B(OTeF_5)_3$[29] in comparison with that of the boron halides. Unfortunately, there are no analogous sulfur and selenium compounds.

The following explanation is offered for these irregular features.

Because of the transition-metal and lanthanoid contraction, the sizes of the atoms change irregularly (see Table 1). The filled d-electron levels just before the elements Ga to Kr and the filled f-electron levels before Hf to Rn lead to a contraction of the atomic volumes.

Table 1. Transition-metal and lanthanoid contraction as shown by the atomic volumes of some main-group elements at 0 K. Volumes in cm^3/g-atom [30].

Mg	Al	Si	P	S	Cl	Ar

Ba	**Tl**	**Pb**	**Bi**	**Po**		
37.0	16.0	17.9	21.0	22.4		

Thus, for spatial reasons alone an expansion of the coordination sphere is more difficult for the elements of the third and fifth rows, as compared with those of the elements of the second and fourth rows. The first filling of relatively diffuse 3d- and 4f-orbitals also leads to ineffective screening of the nuclear charge, so that the electrons in the smaller and spherically symmetrical 4s- and 6s-orbitals are bound particularly strongly. Consequently, the oxidation states of five for arsenic and bismuth, six for selenium, and seven for bromine are more unstable than for the group-homologous elements. Indicative of this phenomenon is the fact that the preparation of the perbromates and of arsenic pentachloride was achieved only a few years ago[31–33].

The above-mentioned explanation for discontinuities in group-homologous compounds is a physical reality. Conversely, it is also possible to make the first participation of d- and f-orbitals responsible for the strengthening the bonds of the preceding elements (and not the weakening of the bonds of the following elements; see above). We thus arrive at the bond model of full hybridization.

By means of this model it is possible to explain the properties of the elements Si to Cl by the first appearance of d-orbitals. These can be used to expand the coordination sphere (SiF_6^{2-}) or for a (p→d)π-back bonding (SiF_4). Many peculiarities of Si chemistry, as compared with C chemistry, can be explained in this way; for example, differences in the bond angles or basicities in comparable compounds. (The "reality" of the involvement of d-orbitals will be discussed in Section 4.)

If the abrupt change between the third and fourth rows is to be described by the same bond model, it must be argued that now 4f-orbitals become available for the first time. However, the influence of the f-orbitals has not yet been accurately studied for main group elements. Yet all those arguments which are employed in the dispute concerning the participation of d-orbitals can be used for or against f-orbital involvement. Thus it is conceivable that in a molecule such as TeF_6 because of the high charge of the tellurium, the 4f-orbitals are in an energetically more favorable position than the 5d-orbitals. In an octahedral field, the seven f-orbitals are divided into the classes A_{2u}, T_{1u}, and T_{2u}. In TeF_6, T_{1u}

could give a σ-bond and T_{2u} σ- and π-bonds, while the A_{2u} orbital would be suitable only for a δ-bond. Bonds in more highly coordinated compounds such as TeF_8^{2-} can also be easily explained.

The picture of f-orbital participation must be used with great caution and it should be regarded only as an aid to the understanding of the abruptly changed bonding behavior.

4. Bonding Problems

The participation of d-orbitals in the bonds between main-group elements has received considerable attention in the last twenty years[34-54,61,62]. Some of the arguments have been collected in book form[34]. More precisely, the question is to what extent are d-orbital included in the molecular orbitals of compounds of main-group elements, and how strongly bonding are they? This question is far from physical reality as the description of the total electronic structure of a compound in terms of molecular orbitals is already a simplification. Although no definite judgment can yet be made the following answer may be allowed. The participation of d-orbitals in bonds is very small and becomes appreciable only in compounds that contain the main-group elements in the highest oxidation states[4,5,55]. An indication of d-orbital participation appears to be given by the peculiar structures of F_5SOSF_5 and its homologs[23,24,28] (see Section 8).

The best description of bonding properties is today achieved by using molecular orbitals. This will be shown for the hexafluorides SF_6, SeF_6, and TeF_6. The arrangement of the molecular orbitals with respect to energy has been calculated by several methods. The degree of degeneracy of the orbitals is always obtained from the symmetry of the molecule. However, the MO description is clear only in simple molecules, and in any case it is only a model. Figure 2 shows the MO scheme for SF_6[48]; the arrangement of very close molecular orbitals varies, depending on the method of calculation.

Some check on the calculations is provided by photoelectron spectroscopy, and this method seems to confirm the MO scheme for SF_6, SeF_6, and TeF_6[56,57], assuming the validity of Koopmans' theorem. Figure 2 shows the nonbonding electron pairs at the fluorine atoms ($1e_g$, $1t_{1g}$, $3t_{1u}$, $1t_{2u}$) as well as strong σ-bonds which form the octahedral skeleton ($1a_{1g}$, $1t_{1u}$, $2a_{1g}$, $2t_{1u}$). $1t_{2g}$ and $2e_g$ are weakly bonding; however, it is just these orbitals that contain sulfur 3d-contributions. The d-orbital participation becomes particularly clear in the case of $2e_g$: if no d-character is permitted in the calculation, $2e_g$ lies above $1t_{1g}$[48]. Symmetry requires that $2e_g$ forms a σ-bond and $1g_{2g}$ a π-bond ((p→d)π-back donation).

When the d-orbitals are included in the calculation, the bond becomes less polar. In that respect the expression "back donation" is quite appropriate.

Turning to SeF_6, it is striking that the distance between $2a_{1g}$ and $2t_{1u}$ ("s-p splitting") is substantially greater than that in SF_6; the inadequate screening of the nuclear charge by 3d-electrons is visible here ("transition-metal contraction").

Figure 2 does not show the antibonding orbitals, the lowest of which is probably $3a_{1g}^*$. Since this one is lowered in energy like $2a_{1g}$, the ready reducibility of the selenium compound becomes understandable.

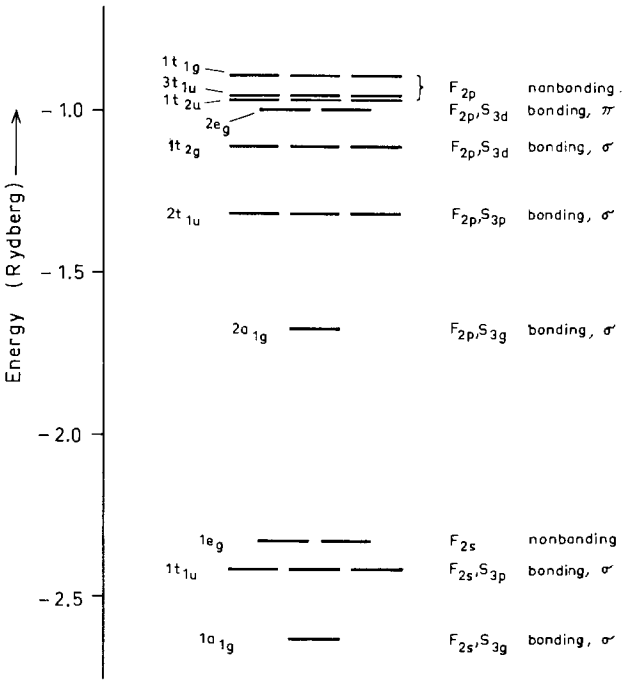

Fig. 2. MO scheme for SF_6 [48]. The figure shows only the occupied orbitals; inner shells (F_{1s}, S_{1s}, S_{2s}, S_{2p}) have been omitted. The distances between the orbitals vary according to the method of calculation; an approximate assignment of the upper orbitals to ionization energies of SF_6 is possible. The main contributions of fictitious atomic orbitals to molecular orbitals are written on the right side. Bonding occurs mainly through $1a_{1g}$, $1t_{1u}$, $2a_{1g}$, and $2t_{1u}$, while $1e_g$, $1t_{2u}$, $3t_{1u}$, and $1t_{1g}$ act as nonbonding electron pairs on the fluorine atoms. A graphical representation of all orbitals, although based on older CNDO calculations omitting the S_{3d} contributions, can be found in [50]. d-Atomic orbitals of sulfur are involved only in $1t_{2g}$ and $2e_g$, and for reasons of symmetry $1t_{2g}$ must be a π-bond [(p→d)π-back-donation] which is energetically lower than $2e_g$ (σ-bond with d-orbital participation).

In TeF_6, the $2a_{1g}$—$2t_{1u}$ distance is normalized again. All the orbitals are now closer together. Taking the 4f-orbitals into account will perhaps enhance this effect still further. However, because of the atomic size of tellurium, the MO calculations must be regarded with great caution.

5. Stability of the Fluorides and the Oxide Fluorides

It can be deduced from the mean bond energies that the bond strengths of the fluorides and oxide fluorides decrease with increasing electronegativity of the central atom (see Fig. 1). The resistance of a compound to decomposition into the elements is also affected by the atomization energies of the elements. The contribution of fluorine (dissociation energy 37 kcal/mol) is the same for all fluorides. The high dissociation energy of oxygen (118 kcal/mol), on the other hand, explains the visibly lower stability of the oxide fluorides and oxides as compared with the pure fluorides. This effect can be seen in the pair XeF_4 (stable) and XeO_4 (explosive). Another example is the decomposition of IOF_5:

$$IOF_5 \xrightarrow{\Delta} IF_5 + \tfrac{1}{2}O_2$$

This reaction clearly demonstrates the high formation tendency of molecular oxygen, which manifests itself in spite of the fact that the I—O bond is stronger than the I—F bond. Since the atomization energy of the noble gases is

zero, XeF_2, XeF_4, and XeF_6 are stable in the presence of one another: reactions such as

$$2\,XeF_2 \rightarrow XeF_4 + Xe$$

therefore have such small heat effects because Xe—F bonds are always approximately equal in strength and the liberation of xenon yields no energy[58]. These reactions are therefore mainly entropy-directed. The case is quite different for the sulfur fluorides: the unstable SF_2 decomposes rapidly into sulfur and SF_4, the driving force being the polymerization energy of the sulfur ($8\,S \rightarrow S_8$)[59]. This phenomenon explains the instability of many fluorides of elements in a lower valence state, such as IF, IF_3, BrF, SF_2, S_2F_2, SeF_2, and Se_2F_2.

6. Bridge Formation and Coordination Problems

CF_4 is a monomer, but under normal conditions CF_2 is a polymer; there are similar pairs, such as IF and $(IF_3)_x$, and SOF_4 and $(TeOF_4)_2$. It is easy to predict approximately whether a given nonmetal fluoride or oxide fluoride will have a monomeric, oligomeric, polymeric, or ionic structure, but accurate predictions are another matter altogether. Furthermore, transitions exist which are observed, in particular, in the case of monomeric molecules with high dipole moments (IF_5). There are also several types of polymeric structures: F-bridged (SbF_5, BrF_3), O-bridged ($Se_2O_2F_{10}$, $I_2O_4F_6$), and central-atom-bridged ($(CF_2)_2$, $(SiF_2)_n$, B_3F_5). Apart from the latter exceptions, the fluorides polymerize through fluorine bridges, while in the case of the oxide fluorides oxygen bridges prevail. However, in the case of the oxide fluorides of the *subgroup* elements fluorine bridges are formed preferentially to oxygen bridges[60].

The weakly interacting molecules found almost exclusively among the fluorides and oxide fluorides of the highest-valent nonmetals are particularly fascinating (see Tables 2 and 3).

Table 2. Weakly interacting fluorides of nonmetals in their highest valence states. Boiling points in °C.

BF_3	−100.4	CF_4	−128.0						
AlF_3	+1272	SiF_4	−95.0	PF_5	−84.0	SF_6	−63.8		
		GeF_4	−36.5	AsF_5	−52.9	SeF_6	−46.6		
		SnF_4	+705	SbF_5	+150	TeF_6	−38.9	IF_7	+4.8
		PbF_4		BiF_5	+550	PoF_6			

Since the replacement of two fluorine atoms by oxygen decreases the coordination number, the weakly interacting monomeric molecules are rarer in the oxide fluorides.

Table 3. Weakly interacting oxide fluorides of nonmetals in their highest valence states. Boiling points in °C.

$(BOF)_3$	COF_2	−83.1	NOF_3	−90.0			
	$(SiOF_2)_n$		POF_3	−39.8	SOF_4	−48.5	
			$(AsOF_3)_n$		$(SeOF_4)_2$		
			$(SbOF_3)_n$		$(TeOF_4)_{2,n}$	IOF_5	<4 XeO_2F_4

Monomeric compounds with central atoms of lower valence frequently have a greatly reduced volatility. The reason for this is a high dipole moment (BrF_5) or dynamic fluorine bridges (SeF_4, XeF_6) (Tables 4 and 5). The transition to fluorine-bridged solids is not rigid, *e.g.*

$$SF_4\ (\text{gaseous}) - SeF_4\ (\text{liquid}) - TeF_4\ (\text{solid})$$

Table 4. Monomeric but strongly interacting fluorides of nonmetals in lower valence states. Boiling points in °C.

$(CF_2)_{2,n}$	NF_3	−129.0						
$(SiF_2)_n$	PF_3	−101.8	SF_4	−40.4	ClF_5	−13.1		
GeF_2	AsF_3	+63	SeF_4	+106	BrF_5	+41.3		
SnF_2	SbF_3	+376	TeF_4		IF_5	+104.5	XeF_6	+75.6
PbF_2	+1293	BiF_3						

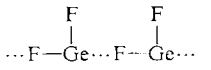

Table 5. Monomeric but strongly interacting oxide fluorides of nonmetals in lower valence states. Boiling points in °C.

CO	−191.5	NOF	−59.9	SOF_2	−43.7	$ClOF_3$	+27 to +29
(SiO)		(POF)		$SeOF_2$	+126	$BrOF_3$	?
(GeO)		$(AsOF)_x$		$(TeOF_2)$		IOF_3	$XeOF_4$ +105

If a molecule is still unknown, its physical properties can be estimated from related compounds. However, care must be taken. Thus, SF_6, SOF_4, and SO_2F_2 and also SeF_6 and even SeO_2F_2 are weak-interaction compounds, but the long-sought $SeOF_4$ appears under normal conditions as the dimer (see Section 8). Fivefold coordination seems to be particularly unfavorable. Accordingly, the dimeric structure of $(IO_2F_3)_2$ was analogous to related selenium and tellurium compounds and was to be expected *a priori*, in contrast to monomeric ClO_2F_3 (see Section 9).

Radical changes in physical properties are most pronounced in the third and fourth groups of the periodic system: thus, BF_3 boils at −100.4 °C and AlF_3 at 1272 °C. CF_4 is such an inert gas that it was possible to detect it as an atmospheric "krypton isotope"[61]. Although SiF_4 and GeF_4 already show a tendency towards expansion of the coordination sphere as in SiF_6^{2-} and GeF_6^{2-}, they are still gases. SnF_4 is the first species to have the structure of a solid with quasi-octahedral environment of the tin by fluorine, as has PbF_4[62].

The difluorides of this group also show interesting transitions. Monomeric CF_2 and SiF_2 are short-lived (SiF_2: 150 s at 0.2 torr)[63]. Both molecules are bent (CF_2 105°, SiF_2 101°)[64–66] and also exist in the isomeric triplet form with two unpaired electrons[67–69]. Polymerization takes place through C—C and Si—Si bonds to give $(CF_2)_n$ and $(SiF_2)_n$. On the other hand, GeF_2 is a fluorine-bridged polymer which can be described approximately as [70]:

The bond angles are in the neighborhood of 90° and the steric activity of the nonbonding electron pair is evident (see Fig. 3). Ge—Ge bonds cannot be detected.

In SnF_2 a highly distorted octahedral environment around the Sn is observed, again with a detectable steric effect of the nonbonding electron pair[71]. PbF_2 exists as a salt (CaF_2 type), with an ionic lattice, where eight fluorine atoms surround each lead atom.

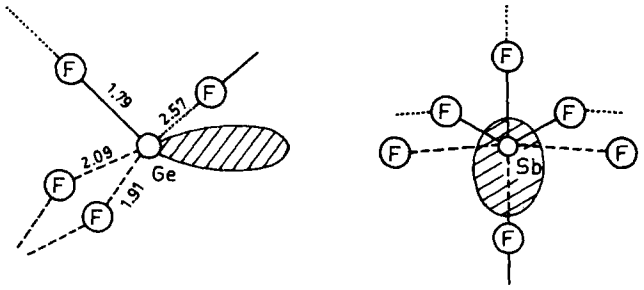

Fig. 3. Solid-state structures of GeF_2 [71] and SbF_3 [91] as examples of the difficulties in the definition of a coordination number. Only one central atom with its coordination sphere is shown. In both cases, the steric effect of a nonbonding electron pair is indicated by hatching. In GeF_2 only one fluorine atom is bound closely to the central atom but still belongs as a bridge to the sphere of another central atom. The environment of the germanium is best described as (distorted) trigonal-bipyramidal. The environment of antimony in SbF_3 is initially pyramidal, as in PF_3, but when three more remote fluorine atoms are taken into account a distorted octahedral arrangement appears.

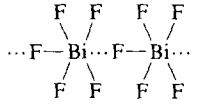
The structures of GeF_2, and still more that of SnF_2, point out a basic difficulty in the interpretation of crystal structures: it is often impossible to strictly define the environment of the central atom in the form of a coordination number, as it is in the case of molecular compounds and salts. In the lattice the fluorine may occur as a singly bound ligand, as bridge fluorine, and even as a fluoride ion. Depending on the point of view, in GeF_2 and SnF_2 a coordination number of four to five (Ge) or four to seven (Sn) can be given, including the sterically active electron pair in both cases. *Hoppe* has dealt with this general problem in a review[72]. The difficulty of determining the coordination number occurs almost invariably in cationic and anionic derivatives, and particularly seriously in the case of derivatives with heavy elements. Nevertheless, it can be stated that even the more remote coordination sphere is governed by electron-pair repulsion. Nonbonding electron pairs can be detected as free space in the nearer and more distant environment. A well investigated example is, among others, $XeF_3^+Sb_2F_{11}^-$ (see Section 10).

Although there is a very strong double bond in COF_2, no monomeric $SiOF_2$ exists under normal conditions; just as, in general, double bonds of silicon have been detected hitherto only in short-lived intermediates. This appears to be mainly a problem of the coordination sphere: while in POF_3 and SO_2F_2 formal double bonds form without difficulty, since the coordination number remains four, this is not possible in the case of silicon for simple arithmetical reasons. A tetrahedral configuration means either four fluorine ligands (SiF_4) or the formation of oxygen bridges $(-F_2Si-O-SiF_2-O-)_n$. Argumentation by orbital theory is therefore not necessary when the absence of double-bonds at a silicon atom has to be explained. The fact that a similar phenomenon occurs in tellurium (in contrast to sulfur and selenium) with the prohibition of a double bond for the maintenance of the coordination number six (see Section 8) indicates the validity of this argument.



7. Fluorides and Oxide Fluorides of Elements of the Fifth Main Group

NF_5 does not seem to exist, a fact that confirms the octet rule. From the point of view of bonding theory a covalent NF_5 would be conceivable if electron-deficient bonds were permitted. Assuming that the existence of $NF_4^+F^-$ is confirmed[73], this unstable compound is a salt of the NF_4^+ cation[74].

PF_5 is well known; like AsF_5, it has a trigonal-bipyramidal structure[75, 76]. The axial and equatorial bonds are of almost the same length. The axial-equatorial ligand exchange generally takes place the faster, the more equal the bond lengths are; this ligand exchange has been demonstrated by nuclear resonance[77, 78]. In the case of PF_5 and AsF_5 it has not yet been possible to "freeze" this intramolecular fluorine exchange. Ions such as PF_4^+ and PF_6^- are derived from PF_5, while only AsF_6^- is known from AsF_5.

AsF_5, because of its strong Lewis acid character and because of its high volatility, is a valuable reagent in fluorine chemistry. SbF_5, which is probably the strongest Lewis acid, is a high-boiling viscous liquid; NMR investigations have shown that SbF_5 exists in solution as a *cis*-bridged polymer[79–81]. Even in the gaseous state, SbF_5 is still partially polymeric[82–85]. Solid SbF_5, like the ions $Sb_3F_{16}^-$ and $Sb_4F_{21}^-$ in solution, has a *cis*-bridged structure[81, 86], while the salt $Br_2^+Sb_3F_{16}^-$ contains a *trans*-$Sb_3F_{16}^-$ ion[83]. The angles at the bridge fluorine atom vary between 141 and 173°[86–88]. A discussion of the bond angle of fluorine bridges is not profitable.

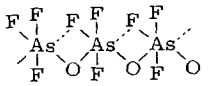
BiF_5 is a solid, made up of chains of the type[89, 90]:

An exact knowledge of the structure of this fluoride (as also of PbF_4) is important for predicting the properties of the fluorides of polonium, astatine, and radon, which are accessible only with difficulty (see Section 11).

The transitions that have already been described several times appear equally clearly in the case of the trifluorides: NF_3 and PF_3 are pyramidally built gases; AsF_3 is a monomeric liquid whose dipole forces are already sufficient for association, as is frequently the case when nonbonding electron pairs are present at the central atom; SbF_3, a solid, still has the pyramidal structure in the crystal, but already with three additional bridging fluorine atoms which are more distant[91] (see Fig. 3). The Bi atom in BiF_3 is surrounded by eight fluorine atoms, and the free space of the nonbonding electron pair is still visible[92–94]. Many ions are also derived from these trifluorides. The ion $Sb_2F_7^-$ has the form of two axially linked trigonal bipyramids[95], while $Sb_2F_9^{3-}$ consists of two apex-linked octahedra[96] (including the nonbonding electron pairs in each case).

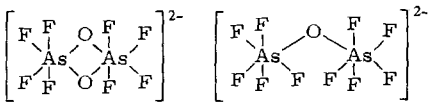
Fluorides of lower molecular weight are known particularly in the case of nitrogen[97]: N_2F_4 exists both in the *trans* and in the *gauche* form[98–101]; even at room temperature it is in equilibrium with $^{\bullet}NF_2$, one of the few stable fluoride free radicals. Fluorine azide N_3F decomposes with formation of N_2 and N_2F_2. The latter exists in *cis* and *trans* forms. Interestingly, the *cis* form is the more reactive and also thermodynamically more stable one[102, 103]. $N{=}NF_2$ is also conceivable[104], but has not yet been isolated. Phosphorus forms P_2F_4[105, 106], which, in contrast to N_2F_4, occurs only in the *trans* form[105, 107], presumably because the small P—P—F

angle in any *cis* or *gauche* form would hinder the fluorine atoms.



Six nitrogen oxide fluorides have been described: FNO, FNO_2, $FONO_2$, NOF_3, $ONNF_2$, and O_2NNF_2, and some others are also conceivable[108,109]. NOF is of great value as a strong gaseous Lewis base (like AsF_5 as a Lewis acid). The fact that the bonded fluorine is readily given off as F^- is explained directly by the structure of NOF the N—F bond is extremely long (1.51 Å as against 1.36 Å in NF_3), while the N—O bond is extraordinarily short (1.13 Å)[109,110].

NOF_3 is of theoretical importance. It was discovered fairly late[111-113]. The structure can be described formally as $\bar{O}$—$\overset{+}{N}F_3$. However, it must be emphasized that according to the vibrational spectra the molecule has a very strong NO bond; the situation must therefore be explained by hyperconjugation:



$$O^-—N^+F_3 \leftrightarrow O{=}\overset{+}{N}F_2F^-$$

Indeed, the N—F bonds are weaker than in NF_3. Such problems do not occur in the case of POF_3: the bond to the oxygen can be regarded as a true double bond and the PF bonds in POF_3 (1.52 Å) are actually somewhat shorter than in PF_3 (1.57 Å)[114,115]. It is therefore unnecessary to invoke for POF_3 an ionic-covalent resonance as in NOF_3—formally an indication of the participation of more than four orbitals in the bonds. For a lower phosphorus oxide fluoride with an oxygen bridge, $F_2P—O—PF_2$, cf. [105].

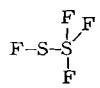
The synthesis of the monomeric $AsOF_3$[116] has not been confirmed. However, it has been possible to obtain polymeric $(AsOF_3)_n$, the structure of which is not yet known in detail[117]. In view of the structures of $(SeOF_4)_2$ and $(TeOF_4)_2$, oxygen bridging should be expected here as well:

This becomes still clearer if the structures of the anions $(AsOF_4)_2^{2-}$ and $F_5AsOAsF_5^{2-}$ are compared[118-120]:

Solution of this problem requires an X-ray structure analysis of solid $(AsOF_3)_n$. Taking into account the marginal existence of monomeric $SeOF_4$, it should perhaps be possible to trap monomeric $AsOF_3$ which, like $SeOF_4$, should polymerize readily. The evidence in favor of a monomeric $AsOF_3$ is the more stable tetrahedral configuration as compared with the trigonal-bipyramid structure of $SeOF_4$. The evidence against its monomeric form is that arsenic is larger than selenium and the polymeric hexacoordination is therefore still more highly favored[*].

The likelihood of monomeric $SbOF_3$ is poor: a polymeric $SbOF_3$ has been obtained[117]. The structural problem is the same as in the case of the arsenic compound—an indication that in the case of the oxide fluorides the similarities between the third and fourth rows are sometimes more pronounced than those between the second and third rows. The anion $(SbOF_4)_3^{3-}$ is trimeric with a ring structure and an octahedral environment around the Sb[121]. It is possible to explain why $(AsOF_4)_2^{2-}$ is dimeric and $(SbOF_4)_3^{3-}$ trimeric. Two forces are in competition: forces of repulsion within a four-membered ring and forces of deformation of the octahedron around As or Sb. Because of its size, antimony can deform the octahedral bond angle—as is necessary for trimerization—more readily than arsenic: a six-membered ring is formed. The smaller arsenic must accept a four-membered ring and the angular deformation of the oxygen in exchange[121].

The anion $F_5SbOSbF_5^{2-}$ has the same structure as the arsenic analogue[121]. Nothing is known about the structure of $BiOF_2$[122]. There are still other oxide fluorides of phosphorus ($F_2PO—O—POF_2$, $(PO_2F)_n$), which all have a tetrahedral structure[123].



8. Fluorides and Oxide Fluorides of Elements of the Sixth Main Group

The number of fluorides and especially of the oxide fluorides reaches a maximum in the 6th main group. Relatively simple fluorides are formed by oxygen: the certain ones are OF_2 and O_2F_2, and also the radicals OF and O_2F. The existence of O_3F_2 is unclear[124,125], and there is some evidence for the existence of O_4F_2, the dimer of the O_2F radical. O_5F_2 and O_6F_2[126], and also O_3F and O_4F[127], are still less certain; the compounds are said to contain oxygen chains. The synthesis and the properties of the oxygen fluorides have already been reviewed on several occasions[128-130]. The highest formal oxidation state of oxygen so far, +2, has been found in OF_2. However, the existence of $OF_3^+SbF_6^-$ does not appear to be impossible; its formal oxidation number would be +4.

Sulfur fluorides are still more numerous: SF_2, SSF_2, FSSF, FSSSF, FSSSSF, FS—SF_3, SF_4, SF_6, and S_2F_{10}[131]. The general instability of the lower sulfur fluorides has already been explained (see Section 5).

SSF_2 is the sulfur analogue of thionyl fluoride and the existence of two isomers FSSF/S=SF_2 has no parallel in the cases of ClSSCl, HSSH, and ClSSF. These findings have also been confirmed by CNDO calculations[132].

SF_2 has a monomeric structure, and the angle at the sulfur atom (98° 16′)[133] is understandably somewhat smaller than that in OF_2 (103° 4′)[134]. S_2F_4 is not dimeric SF_2, but FS—SF_3, a derivative of SF_4 with the structure:

as has been shown by nuclear magnetic resonance[135,136]. Hindered rotation about the S—S axis is necessary to explain the nonequivalence of the two axial fluorine atoms. A conceivable tetragonal arrangement is probably reserved for the transition state according to the Berry mechanism; FS—SF_3 reacts spontaneously with oxygen to give SOF_2[135].

SF_4 has the expected trigonal-bipyramidal structure with the nonbonding electron pair in the base. Intramolecular fluorine exchange can be frozen out at −20 °C if the last traces

[*] *Note added in proof: A. J. Downs* has presented evidence for monomeric $AsOF_3$ in a matrix: 6th European Fluorine Symposium, Dortmund, 1977.

of HF are eliminated[137]. The ligand exchange takes place strictly by the Berry mechanism[138]. The pentacoordination of SF_4 also determines its chemistry: it converts many oxygen compounds into fluorides with no change in valence; the driving force is the tendency toward the formation of sulfinyl fluoride SOF_2 (with formal tetrahedral configuration). Another variant of the change in coordination is the abstraction of F^- to give SF_3^+ (pyramidal structure) or the addition of F^- to give SF_5^- (with the IF_5 structure).

The kinetic stability of SF_6 can be ascribed to complete screening of the sulfur by the fluorine atoms. Another interesting derivative is $F_5S{-}SF_5$ with a sulfur-sulfur bond, which has no selenium or tellurium analogues so far.

The sulfur oxide fluorides are very numerous (see Table 6). This is because oxygen can form a double bond or a bridge, and because both the tetrahedral and the octahedral arrangements are particularly stable. SOF_4 constitutes the only exception with a coordination number of five. It has a trigonal-bipyramidal structure with the oxygen in an equatorial position. It has not yet been possible to freeze out the intramolecular fluorine exchange. Derivatives such as $SOF_3^+SbF_5^-$ and $Cs^+OSF_5^-$ are known. The anion OSF_5^-, like the homologs $OSeF_5^-$ and $OTeF_5^-$, contains a strong oxygen-sulfur bond which is best explained by ionic-covalent resonance (hyperconjugation)[140-142]. In general, hyperconjugation appears to be possible as an explanation if a double bond is implied.

The noteworthy feature is that the axial fluorine atom, especially in OSF_5^- and $OSeF_5^-$, and to a smaller extent in $OTeF_5^-$, accepts the bulk of the negative charge, and the middle resonance form is therefore particularly important: *trans* effect in the octahedron.

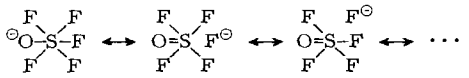


Table 6. Oxide fluorides of hexavalent sulfur [139]. CN = coordination number.

CN	
4	SO_2F_2, FSO_2OSO_2F, $FSO_2(OSO_2)_nOSO_2F$, $FOSO_2F$, FSO_2OOSO_2F, $FOOSO_2F$
5	SOF_4
6	$FOSF_5$, F_5SOSF_5, F_5SOOSF_5, $F_5S{-}OSF_4{-}OSF_5$ (*cis*), $SF_5{-}OSF_4{-}OOSF_5$, $SF_5{-}OSF_4{-}OOSF_4{-}OSF_5$
4+6	FSO_2OSF_5, $F_5SOSO_2OSF_5$, $FSO_2{-}OSF_4{-}OSO_2F$ (*cis*)

The $O{-}SF_4{-}O$ grouping, or in general the $X{-}SF_4{-}X'$ grouping, may occur in the *cis* or the *trans* form. No systematic explanation can yet be given, although there are many examples[143-147]. Any explanation should take into account both the thermodynamic stabilities and the kinetically controlled modes of formation. Thus, it is striking that the radical mode of formation leads predominantly to *cis* systems[148]. The intermediate radical $X{-}O{-}SF_4^{\bullet}$ exists and reacts only in the *cis* form (see Section 12). Most systems with sulfur as the central atom behave similarly. For example, *cis*-$F_5S{-}OSF_4{-}OSF_5$ arises by a radical mechanism[139], while the mode of formation of the homologous *cis*-$F_5Se{-}OSeF_4{-}OSeF_5$ has not yet been elucidated but is presumably not radical[149]. The *trans* isomers of these two compounds are unknown, while the two isomeric tellurium compounds *cis*- and *trans*-$F_5Te{-}OTeF_4{-}OTeF_5$ are produced together by a radical mechanism. These do not undergo rearrangement even at elevated temperatures[150,151]. However, in the case of nucleophilic substitution in TeF_5X to give TeF_4XX' a preferred *cis* orientation has been found[152-154].

Lower selenium and tellurium fluorides have not as yet been reported[*]. Fluorine analogues of the subchlorides, subbromides, and subiodides of tellurium have not yet been found either[155,156].

In contrast to SF_4, SeF_4 is a high-boiling liquid. Fluorine bridges certainly exist. It has been possible to freeze out the fluorine exchange at $-140°C$ and to detect the SeF_4 in dilute solution as a monomer. Thus the SF_4-analogous structure was unambiguously demonstrated[157,158]. SeF_4 forms SeF_3^+ and SeF_5^-; salts of this anion are clearly more stable than SF_5^- salts.

The oxide fluorides of selenium show some special features: coordination numbers smaller than six are rare. $SeOF_4$ exists as a monomer, and the structure is probably the same as that of SOF_4[159,160]. Above $-100°C$, $SeOF_4$ dimerizes to $F_4SeO_2SeF_4$, the structure of which is derived from that of SeF_6 by the edge linkage of two octahedra[160-162], in the same way as $F_5SeOSeF_5$ arises by the apex-linkage of two octahedra[163,164].

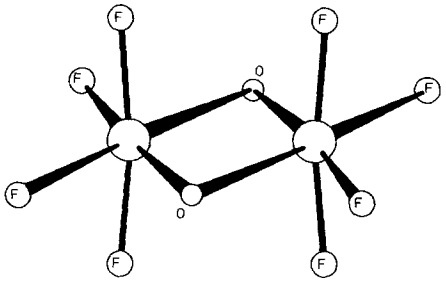

Fig. 4. Molecular structure of $F_4SeO_2SeF_4$ (and $F_4TeO_2TeF_4$), as determined by electron diffraction [162]. In spite of the proximity of the two chalcogen atoms a transannular bond is unlikely.

The dimer $Se_2O_2F_8$ soon became a model substance for other oxide fluorides such as $Te_2O_2F_8$ and $(IO_2F_3)_2$; in addition, the anion $As_2O_2F_8^{2-}$, which has the same structure, was already known. Four-membered ring units of this type appear to occur more frequently than is generally assumed. The long-known salt $K_3Se_2O_6H_3F_2$ also probably has the same type of structure[165]. In fluorine-free systems this structural principle is realized in the anions $[Te_2O_8(OH)_2]^{6-}$ and $[I_2O_8(OH)_2]^{4-}$[166,167].

SeO_2F_2 has the same tetrahedral structure as SO_2F_2, but not its chemical resistance. Already with HF the coordination sphere is enlarged to $HOSeF_5$[168,176].

The other selenium oxide fluoride with a formal tetrahedral structure is $SeOF_2$. Strong dipole forces and fluorine exchange raise the boiling point to 125°C (SOF_2: $-40°C$).

Other oxide fluorides of selenium with an octahedral structure are $F_5SeOOSeF_5$, *cis*-$F_5Se{-}OSeF_4{-}OSeF_5$, $FOSeF_5$, and $F_5SeO{-}SeO{-}OSeF_5$[149,161,162,169-171].

In the chemistry of tellurium the octahedral structure dominates completely. According to the crystal structure analysis, TeF_4 consists of TeF_4 units with steric activity of the nonbonding electron pair linked in the form of chains, and thereby reaches a quasi-octahedral environment around

[*] *Note added in proof: A. Haas* and *H. Willner* report the matrix isolation of unstable SeF_2, Se_2F_2, and FSeSeF: Z. Anorg. Allg. Chem., in press.

Te[172]. Monomeric TeF_4 with an SF_4-type structure has been detected only in a matrix[173]. Steric activity of the nonbonding pair of electrons is also found in the anion TeF_5^-, which, moreover, is a good example of the orientation of even the more remote coordination sphere according to the electron pair repulsion model[174, 175].

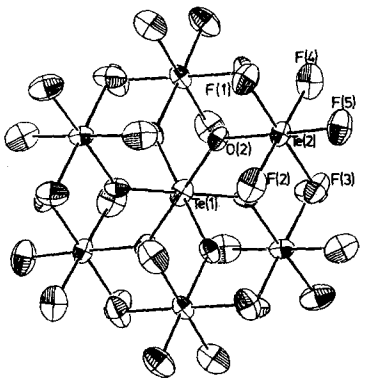
TeF_6 is a relatively inert gas, but by no means as resistant to hydrolysis as SF_6 and SeF_6. The hydrolysis takes place in steps[152, 176]. TeF_6 can widen its coordination sphere, forming TeF_7^- and TeF_8^{2-}. These ions probably have pentagonal-bipyramidal and square-antiprismatic structures, respectively[177, 178]. No Te_2F_{10} (with the structure of S_2F_{10}) has so far been reported: the fraction arising by the fluorination of Te/TeO_2 has proved to be $F_5TeOTeF_5$ with a certain amount of $F_5TeOOTeF_5$[22, 179, 180].

All oxide fluorides of tellurium are derived from the octahedral structure (see Table 7 and Figs. 4 and 5). Doubly-bonded oxygen has never been observed here. Hexavalence and hexacoordination alone are responsible for the diversity of the chemistry of purely covalent tellurium compounds.

Table 7. Tellurium oxide fluorides [151].

$F_5TeOTeF_5$	$FTe(OTeF_5)_5$
$F_5TeOOTeF_5$	$Te(OTeF_5)_6$
$F_4TeO_2TeF_4$	$(TeOF_4)_n$
	$Te_6O_5F_{26}$
	$Te(OTeF_5)_4$
trans-$F_5Te{-}OTeF_4{-}OTeF_5$	
cis-$F_4Te(OTeF_5)_2$	
trans-$F_2Te(OTeF_5)_4$	
cis-$F_2Te(OTeF_5)_4$	

The oxygen bridge angle in the oxide fluorides of hexavalent tellurium (with the exception of $F_4TeO_2TeF_4$) is very constant and large—in $F_5TeOTeF_5$ it is 145.5°[23, 24]—but only slightly larger than in $F_5SeOSeF_5$ (142—143°). Since, in spite of steric problems, neighboring fluorine atoms on different chalcogen atoms coincide and the chalcogen-oxygen bonds appear shortened, a possible explanation is $(p\rightarrow d)\pi$ back-donation, which is strongest in the case of $F_5TeOTeF_5$.



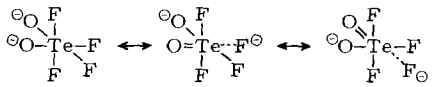


Fig. 5. Crystal structure of $Te(OTeF_5)_6$ [151]. The octahedral environments of the central and peripheral tellurium atoms yield a perfectly screened structure. As a result this oxide fluoride is chemically as inert as TeF_6.

In *trans*-$F_2Te(OTeF_5)_4$ and $Te(OTeF_5)_6$[151, 181, 182] the angle at the oxygen atom is also $139\pm1°$. As in the case of $F_5TeOTeF_5$, this large angle is not caused by steric hindrance.

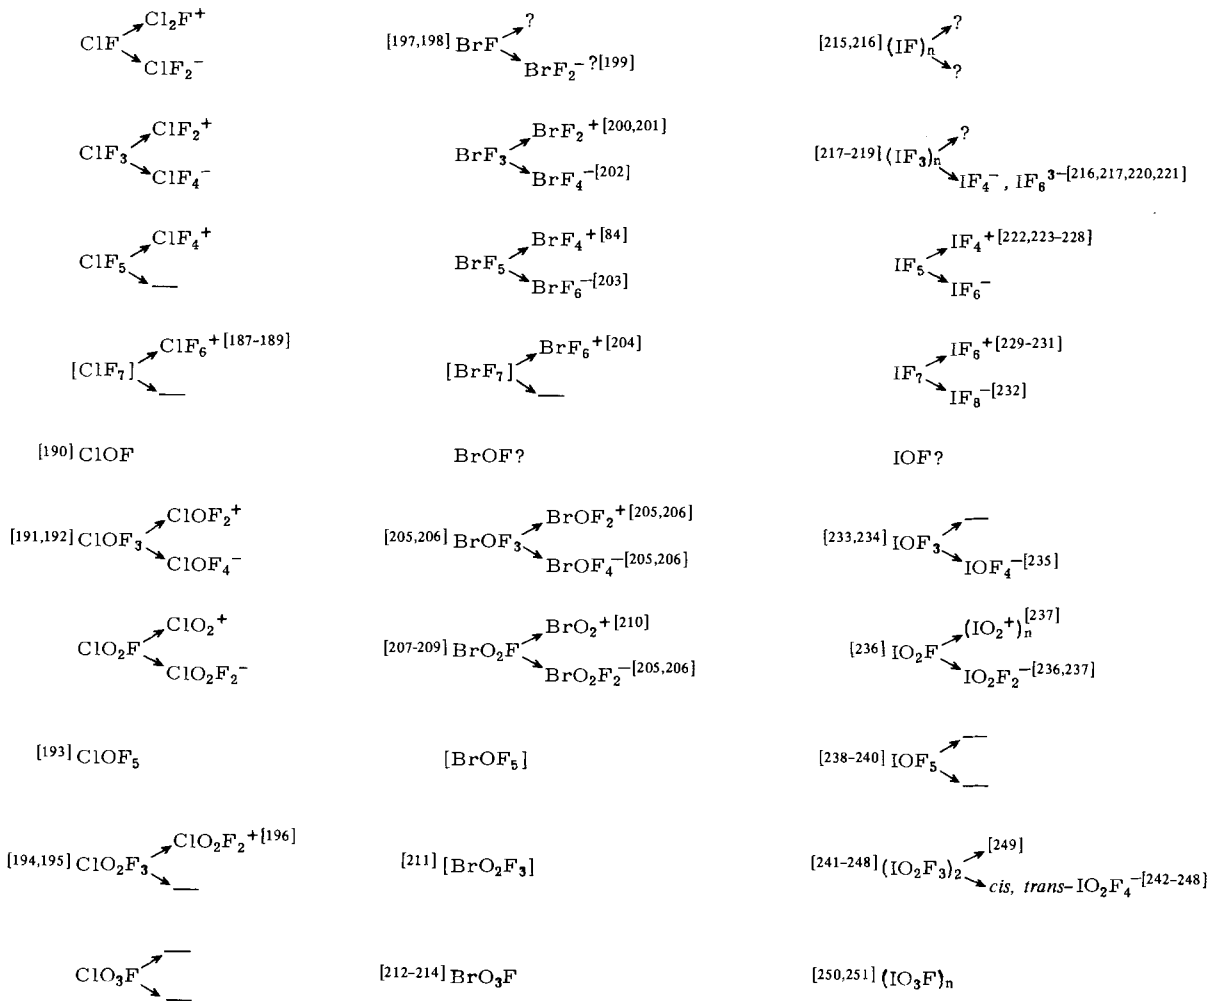
Monomeric $TeOF_4$ (with doubly-bonded oxygen) does not appear to exist; only the dimer $F_4TeO_2TeF_4$ or a polymer $(TeOF_4)_n$ is observed[29, 160, 183]. However, it is useful to assume formally doubly-bonded oxygen in the form of hyperconjugation in anions such as $TeOF_5^-$ and $TeO_2F_4^{2-}$. The *cis* arrangement of the oxygens in $TeO_2F_4^{2-}$ is best explained by the assumption that a shift of the negative charge to fluorine atoms in the *trans* position is possible only in the *cis* anion[152, 160, 184]. (The electron pair repulsion theory in fact

predicts the *trans* arrangement for the $TeO_2F_4^{2-}$ anion.) On the other hand, $TeOF_4^{2-}$ again has the expected $XeOF_4$-analogous structure[185].

The prohibition of a double bond in hexavalent tellurium must also be regarded as being analogous to prohibition of a double bond on silicon: a double bond leads to a decrease in the size of the coordination sphere (five ligands in the case of "$TeOF_4$", three ligands in the case of "$SiOF_2$") and this decrease appears to be difficult or impossible. Double bonds are easily formed when the favorable coordination number remains six (IOF_5, XeO_2F_4).

9. Fluorides and Oxide Fluorides of Elements of the Seventh Main Group

Among the halogen fluorides and oxide fluorides the wealth of structures decreases. In particular, compounds with oxygen bridges occur only rarely (exceptions are $O_3ClOClO_3$ and $(IO_2F_3)_2$).



On the other hand, oxidation states of 1 to 7 are now possible, so that the number of compounds is again large (see Table 8). In their structural relationships all the compounds obey the VSEPR theory—an astonishing success of this method. Cationic or anionic derivatives of most of the compounds are known (see Table 8).

Chlorine, bromine, and iodine form fluorides of the types XF, XF_3, and XF_5, and iodine also forms IF_7. ClF is the best source of partially positive chlorine and is therefore gaining increasing importance for preparative chemistry. However, pure Cl^+ does not occur. Thus, ClF reacts with fluoride acceptors not to form $Cl^+SbF_6^-$, but $Cl_2F^+SbF_6^-$[252, 253]. The cation Cl_2F^+ is unsymmetrical and bent:

ClF_5, first discovered in 1963[254], appears to be coordinatively saturated as is indicated by the low boiling point[255]. It liberates a fluoride ion to give ClF_4^+[256, 257], but in contrast to BrF_5 and IF_5 it does not form ClF_6^-. If ClF_7 (and BrF_7) is ever prepared, it may not have a pentagonal-bipyramidal structure as does IF_7[258]. Only the octahedral cation ClF_6^+ is known[187–189].

Chlorine oxide fluorides have been well investigated but not exhaustively. ClOF probably exists only as an unstable species[190], while ClO_2F is the first detectable hydrolysis

Table 8. Fluorides and oxide fluorides of the halogens [186].

product of the chlorine fluorides[259]. $ClOF_3$ like ClF_5, was discovered not long ago[191,192]. The controversy concerning its structure has now been resolved in favor of the expected quasi-trigonal-bipyramidal structure with one fluorine atom, the oxygen atom, and the nonbonding electron pair in the base[260].

The chemical properties of ClO_3F are unexpected. It shows substantial kinetic resistance to hydrolysis; however, it has been possible to replace the fluorine atom. Also $ClOF_5$ has been reported[193], even though a strict proof of its existence is still lacking[186]. The nuclear magnetic resonance spectrum of $ClOF_5$ cannot be predicted with certainty. Because of the almost octahedral structure of the molecule, a considerable line broadening by quadrupole relaxation, as in ClO_3F, is conceivable. The preparation of $ClOF_5$ in a pure state is desirable because it stands in a similar relationship to the well-known IOF_5 as does NOF_3 to POF_3 (see Section 7). The chlorine-oxygen bond is probably strengthened at the expense of the axial fluorine-chlorine bond.

ClO_2F_3 and its cation $ClO_2F_2^+$ have been thoroughly studied[194-196]. To prepare ClO_2F_3 or its cation, ClO_2F must be fluorinated with PtF_6. The anion $ClO_2F_4^-$ does not appear to be stable[195,196].

The nature of the unstable blue, violet, and green reaction products of O_2F_2 with ClF (or BrF_3 or SF_4) is still obscure. They are probably radical oxygen-fluorine compounds[261-264].

The bromine fluorides are thermodynamically more stable than the chlorine fluorides, but BrF cannot be obtained in a pure state because it decomposes into bromine and bromine trifluoride[197,198].

BrF_3, a high-boiling yellow liquid, is also strongly bridged in the liquid state. In contrast to ClF_3 and SeF_4 it has not yet been possible to freeze the fluorine exchange out by a suitable choice of the solvent; only one signal is always found. On the other hand, fluorine exchange ("self-dissociation") makes BrF_3 a good solvent that in a broader sense can be included among the "water-like solvents". The same applies to IF_5, SeF_4, and XeF_6.

As a quasi-octahedral molecule, BrF_5 gives up a fluoride ion only with difficulty and forms $BrF_4^+Sb_2F_{11}^-$; fluoride acceptors other than SbF_5 are not strong enough. The nonbonding electron pair in the BrF_4^+ cation can be detected because of angular deformation in spite of the presence of two fluorine bridges[88]. It is surprising that BrF_5, in contrast to ClF_5, also accepts F^- to form BrF_6^-[203]. Unfortunately, little is

known about the structure of this anion apart from the fact that it is not an octahedral one. If BrF_6^- does actually exist as an isolated anion with a nonbonding electron pair, this will be the only one of the derivatives described here, in which an element of the third period has a higher coordination number than six. Possibly, however, it represents an adduct, $BrF_5 \cdot F^-$. The BrF_6^- ion is isoelectronic with XeF_6, which in the solid state can also be regarded as $(XeF_5^+F^-)_n$. In any event, a complete crystallographic investigation of $Cs^+BrF_6^-$ would be of great interest.

BrF_5 is important as a strong fluorinating agent that is nevertheless easy to handle because of its low boiling point. Still, it can itself be fluorinated with KrF^+ (or $Kr_2F_3^+$) to the cation BrF_6^+[204]. This fluorination cannot be performed with PtF_6 (which fluorinates ClF_5 to ClF_6^+), which shows once again the difficulty of achieving the heptavalent state of bromine. BrF_6^+ has a strictly octahedral structure. The synthesis of BrF_7 from BrF_6^+ proved impossible; the report of a direct fluorination of BrF_5 to BrF_7 is probably erroneous[265].

The bromine oxide fluorides have not been investigated completely; they appear to be equivalent to those of chlorine. The lower resistance of BrO_3F to hydrolysis may be a coordinative effect of the somewhat larger bromine. There is already a mass-spectroscopic indication of the existence of BrO_2F_3[211]. Since it is a homologue of ClO_2F_3, $(IO_2F_3)_2$, and $(SeOF_4)_2$, it could exist either in the monomeric form (like ClO_2F_3) or as a dimer with two oxygen bridges (like $(IO_2F_3)_2$).

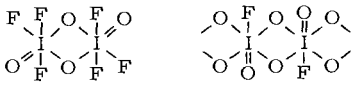
Among the iodine fluorides, IF and IF_3 have been investigated more closely only in the last few years[215-219]. Both are polymerized through fluorine bridges. It is also interesting that the yellow IF_3 first disproportionates into IF_5 and IF, the latter decomposing, in turn, into I_2 and IF_5. From IF_3 are derived not only an IF_4^- but also an IF_6^{3-}[220]; concerning its structure we know so far only that it is not octahedral.

IF_5, the least aggressive halogen fluoride, is a molecular compound. Dipole forces raise the boiling point to 104.5 °C. IF_5 has the well known tetragonal-pyramidal structure, like BrF_5 and ClF_5, the steric activity of the nonbonding electron pair being so great that it displaces the four fluorine atoms in the base appreciably toward the axial fluorine atom[266, 267]; axial and equatorial bonds are of almost the same length. IF_5 readily forms IF_4^+, IF_6^-, and $I_3F_{16}^-$ (see Table 8). IF_6^- is likewise not octahedral and certainly has a less symmetrical structure than BrF_6^-.

IF_7 is a completely unbridged compound. Because of an incomplete measurement of the IR spectrum and the low informative value of the ^{19}F-NMR spectrum, its structure was long disputed. Today it is clear that it has a pentagonal-bipyramidal structure[231, 268, 269]. The axial and equatorial fluorine atoms exchange rapidly even at very low temperatures. Therefore the ^{19}F-NMR spectrum shows no fine structure. The very broad resonance line must be ascribed to coupling with the nuclear spin of the iodine (5/2) which, because of the quadrupole relaxation of the almost spherical IF_7 molecule, leads only to a broadening with a weak structure. The contour of this signal resembles that of ClO_3F and MnO_3F[270]. IF_7 forms a stable cation IF_6^+, which—as expected—shows a distinct ^{129}I-^{19}F coupling sextet in the ^{19}F-NMR spectrum[229-231]. The preparation of IF_8^- was finally achieved in 1974; its structure is still unknown, but it may be a tetragonal antiprism[232]. The solid-state structure of IF_7 should be redetermined. It will be interesting to know how the molecule is arranged in the crystal; it probably does not decompose into $IF_6^+F^-$[271] as does the related species XeF_6 in the solid state.

The ^{19}F-NMR spectra of the iodine fluorides IF_5, IOF_5, IF_7, and IF_6^+ show a clear transition from faster to slower quadrupole relaxation of the ^{127}iodine nucleus:

IF_5: Asymmetric structure → rapid relaxation → sharp lines without ^{19}F-^{127}I coupling, but because of the rigid structure F_{ax}-F_{eq} coupling with corresponding fine structure.



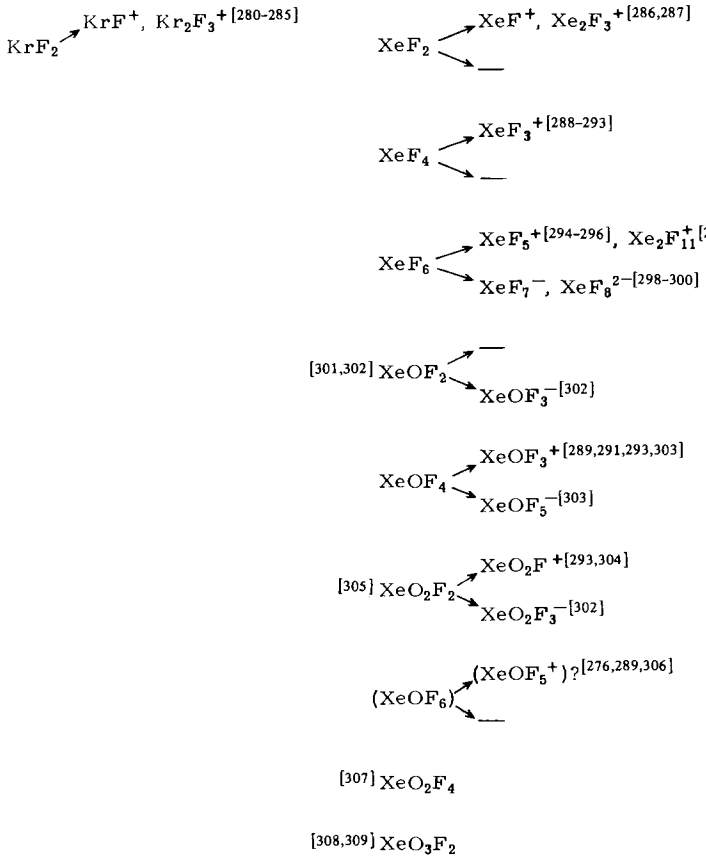
IOF_5: Almost octahedral → slower relaxation → line broadening, $^{19}F_{ax}$-$^{19}F_{eq}$ coupling still visible[238-240, 272].

IF_7: Nonrigid molecule with a (time-averaged) spherically surrounded iodine nucleus → slow relaxation → indication of ^{19}F-^{127}I resolution; because of nonrigidity, no F_{ax}-F_{eq} coupling[272].

IF_6^+: Regular octahedron → very slow relaxation → sharp lines with clear ^{19}F-^{127}I coupling.

With the exception of IOF_5, all iodine oxide fluorides are bridged. The crystal structure of IOF_3[233, 234] still shows molecular IOF_3 units, but at the same time bridges can be observed, so that a coordination number between five and eight may be assumed.

According to the crystal structure analysis, IO_2F_3 is dimeric[241], and the same applies to the compound in the gaseous state[244].



The structure of $(IO_2F_3)_2$ has given rise to much discussion, since the compound was first believed to be monomeric[242, 243], while the nuclear magnetic resonances indicated a trimer[245]. IO_3F[238, 239] probably also has a four-membered ring structure, such as has been proposed for meta-periodic acid[273].

10. Fluorides and Oxide Fluorides of the Noble Gases

The fluorides and oxide fluorides of the noble gases are surprisingly similar in their structural and chemical behavior to the corresponding halogen compounds; hitherto only xenon compounds have been studied extensively. Probably the only accessible argon fluoride would be the cation ArF^+ (perhaps with SbF_6^- as anion)[274]. ArF_2 itself would probably be very unstable. KrF_2 is nowadays easily prepared by a photolysis reaction[275]. KrF_2 and still more its cation KrF^+ are the strongest fluorinating agents known. Thermodynamically, KrF_2 is a fluorinating agent about 13 kcal/mol stronger than elemental fluorine. The use of KrF_2 enabled BrF_6^- and AuF_5 to be prepared for the first time[204, 276]. A report on the detection of KrF_4[277] has proven to be erroneous[278]; likewise krypton-oxygen compounds do not exist; their supposed observation must obviously be ascribed to xenon contamination of the krypton gas used[279].

Table 9. Fluorides and oxide fluorides of the noble gases.

Surprisingly XeF_2 and XeF_4 do not form anions. The hypothetical XeF_3^- will probably be T-shaped[310]. The crystal structures of many xenon-fluorine cations again show the problem of the coordination number in the solid state very distinctly[72]. Compounds of the type $XeF_2 \cdot AF_5$ exhibit all transitions between $F—Xe^+ \cdots AF_6^-$ (ion), $F—\overset{\delta+}{Xe}\cdots\overset{\delta-}{F}\cdots AF_5$ (bridge), and $F—Xe—F \cdots AF_5$ (adduct). The coordination number (including the three nonbonding electron pairs of xenon) thus ranges between four and five. In XeF_3^+ and XeF_5^+ the steric activity of the nonbonding electron pairs is indirectly visible from the the space that is avoided by any F atoms even at relatively large distances from the xenon atom[290,292].

The chemistry of tetravalent xenon has been investigated the least. Pure XeF_4 can now be prepared in quantitative yield by irradiating XeF_6[311]. The oxide fluoride $XeOF_2$ is very unstable; most likely, the oxygen atom forms a bridge instead of a double bond[301,302].

The structure of XeF_6 has roused much controversy. The structure of the gaseous (monomeric) XeF_6 molecule is certainly not octahedral (see Fig. 6a). The most probable structure is one in which the nonbonding electron pair is located on a surface or an edge of an octahedron and correspondingly distorts the octahedral arrangement to C_{3v} and C_{2v} symmetry. These structures interconvert very rapidly with very low potential barriers. Because of this nonrigid arrangement, the xenon is on average in an almost spherical environment. All physical properties are in agreement with this structural model[312]. The other explanation of the structure, in which XeF_6 forms three electronic isomers[313] which are transformed into one another in times reckoned in minutes, can probably be rejected. In the liquid state XeF_6 is fluorine-bridged; XeF_5^+ and XeF_7^- ions certainly occur as intermediates[314]. In dilute solutions in chlorofluorocarbons or similar solvents a tetramer Xe_4F_{24} with equivalent xenon and fluorine atoms is observed (Fig. 6b)[311,315,316]. This is supported by ^{19}F- and ^{129}Xe-NMR spectroscopy and confirmed by measurements on enriched $^{129}XeF_6$[316]. The structure of the tetramer is probably tetrahedral; the magnetic equivalence of 24 fluorine atoms is explained by a rapid rearrangement of all the fluorines in the manner of a cog-wheel mechanism. The cohesion of the tetramer can be explained in terms of flexible fluorine bridges and probably also of

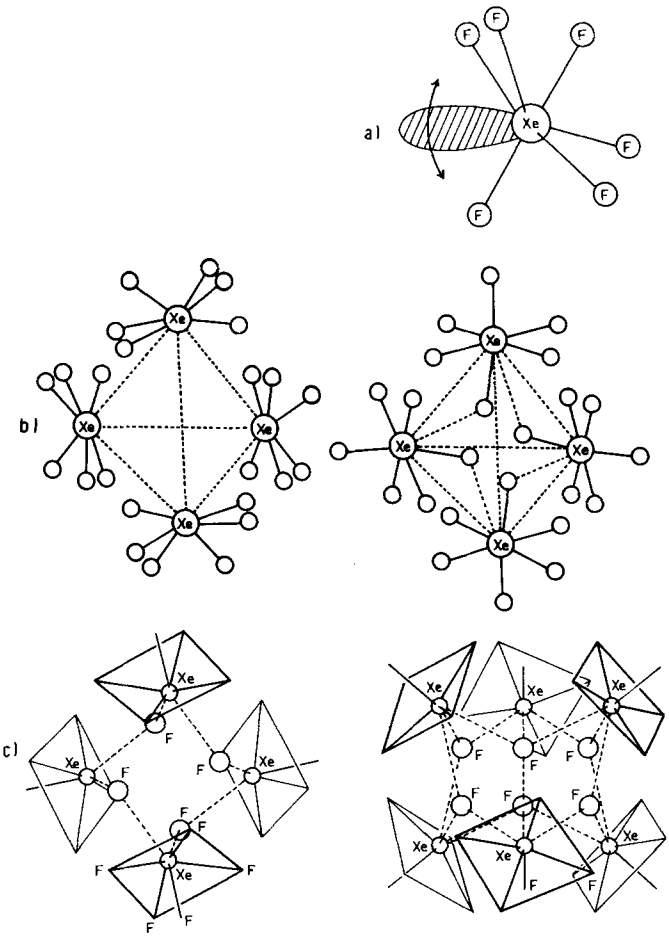


Fig. 6. The structure of XeF_6.
a) In the gaseous state the directed free electron pair moves mainly between a position over a face and over an edge of the dynamically distorted octahedron [312].
b) Tetramerization takes place in non-bridging solvents (CF_2Cl_2, CF_3Cl, SO_2ClF, F_5SOSF_5). The xenon atoms probably form a tetrahedron. The 24 fluorine atoms are all found to be magnetically equivalent. It follows that all the fluorine atoms take part in a rearrangement, but do not leave the sphere of the tetrahedron. The cohesion of the Xe_4F_{24} cluster must be ascribed not only to dynamic fluorine bridges but perhaps also to (weak) xenon-xenon interactions [311, 315, 316]. The high-temperature form of $Rh_4(CO)_{12}$ has a comparable dynamic structure (*F. A. Cotton, C. Kruczynski,* and *B. C. Shapiro,* J. Am. Chem. Soc. *94*, 6191 (1972); *J. Evans, B. F. G. Johnson, J. Lewis, J. R. Norton,* and *F. A. Cotton,* J. Chem. Soc. Chem. Commun. *1973*, 807).
c) Crystal structure of XeF_6. Here the tetrameric Xe_4F_{24} units are frozen out and are best described as $(XeF_5^+F^-)_4$. Hexameric units $(XeF_5^+F^-)_6$ also occur in the cubic modification [318—320].

xenon-xenon interactions. Thus, electron-deficient bonds on the tetrahedral surfaces can be assumed, as in B_4Cl_4, or the problem can be treated according to a simple MO model for four-atom polyhedra[317]. The structure in the liquid state has some correspondence with the crystal structure (Fig. 6c)[318-320]. Four crystalline modifications are known; the cubic one has been investigated in detail[320]. $(XeF_5^+F^-)_4$ and $(XeF_5^+F^-)_6$ units are observed, the xenon atoms occupying the corners of the tetrahedra and octahedra. The other three modifications appear to be constructed of tetrahedral units only. This common tetrahedral unit can be regarded as a frozen cluster of the dynamic liquid structure Xe_4F_{24}. In its complexity, the structure of XeF_6 has no analogues among any of the structures presented in this paper. The steric activity of the free electron pair, dominating in XeF_5^+ and still visible in XeF_6, nevertheless disappears almost completely in XeF_8^{2-}[299]. XeF_8, although reported[321], does not seem to exist[322]; it can be estimated that it would in fact decompose into XeF_6 with liberation of two fluorine atoms, so that any kinetic stability is questionable.

The oxide fluorides of octavalent xenon are also very unstable. The reaction of XeO_4 with XeF_6 gives both XeO_3F_2[308,309] and XeO_2F_4[307]; the latter has been detected only by mass spectroscopy. The cation $XeOF_5^+$, a derivative of the hypothetical $XeOF_6$[289], proved to be the adduct $XeF_5^+ \cdot XeOF_4$[276,306]. The octavalent state of xenon is obviously very difficult to achieve except in the stable perxenates.

11. Fluorides and Oxide Fluorides of Polonium, Astatine, and Radon

Bismuth is followed by three radioactive elements which have been little studied because of their short half-lives. By analogy with tellurium, polonium should form a tetrafluoride and perhaps also a hexafluoride. While a substantially ionic structure may be expected for the tetrafluoride, the hexafluoride, if it exists at all, could exist both in monomeric form and also dimerized or polymerized through fluorine bridges. Because of the high α-activity of all long-lived polonium isotopes, self-decompositions may also be observed (as in the case of plutonium hexafluoride)[323].

^{210}Po, which is readily obtained in a reactor ($t_{1/2}=138$ days) could not be fluorinated to PoF_6[324]. On the other hand, ^{208}Po ($t_{1/2}=2.9$ years) has apparently been fluorinated successfully to give a volatile fluoride, *i.e.* a hexafluoride[325]. Since a relatively stable ^{209}Po ($t_{1/2}=103$ years) can be obtained from bismuth in a cyclotron[326], our knowledge in this field could improve.

The same certainly does not hold for astatine. The longest-lived isotope, ^{210}At, has a half-life of only 8.3 h. If ^{211}At ($t_{1/2}=7.2$ h) is treated with ClF_3, a nonvolatile fluoride is obviously formed, *i.e.* not AtF_7[327]. The stability of the highest valence states apparently falls off steadily in the lowest row of the periodic system: $TlF_3 > PbF_4 > BiF_5 > PoF_6$, as a consequence of the deficient screening by the complete 4f shell (lanthanide contraction). We cannot, therefore, expect an RnF_8. When ^{222}Rn ($t_{1/2}=3.8$ days) is fluorinated under the most diverse conditions, obviously the same radon fluoride is always formed[328], probably RnF_2. The chemical behavior of radon fluoride is similar to that of XeF_2. Thus, it reacts with water to give elemental Rd, it forms no oxo-anions, and it always coprecipitates with XeF_2[329]. The Rn—F bond is unquestionably more ionic than the Xe—F bond. This also explains why, presumably, no RnF_4 is formed, since it must be kinetically very difficult to fluorinate a substantially ionic RnF_2[330]. The application of relativistic quantum mechanics to the bonding problem of radon fluorides confirms the highly ionic nature of radon difluoride[331,332]. Whether monovalent ionic fluorides Rn^+F^- or $^{118}E^+F^-$ exist, as discussed in this theoretical paper, is uncertain. The radical fluorides KrF and XeF are very unstable; however, they do not have an ionic structure[333,334]. If radon fluoride does in fact contain monovalent radon, this could be easily detected by ESR spectroscopy.

Suggestions have already been made that cesium or francium could occur in valence states higher than 1. Francium appears to be less suitable for this than cesium if the chemistry of xenon is compared with that of radon, but even a CsF_3 would decompose spontaneously into CsF and F_2[335]. Only $Cs^+F_3^-$ has so far been detected *in* matrix[336].

12. Free Radicals

The hypothesis concerning Rn^+F^- reminds us that free radical fluorides also exist.

Only a few stable radicals are known: NF_2[97], SO_3F[337-339], and perhaps also O_2F[340] and PF_2[105]. These exist in equilibrium with the dimers N_2F_2, $FSO_2—O—O—SO_2F$, O_4F_2, and P_2F_4. The O_2F radical, from which the stable cation O_2^+ is derived[341,342], is perhaps stable even at room temperature[343]. The radical PO_2F_2 has not yet been confirmed[344]; the UV spectrum published is identical with that of ClO_2.

Most other free radicals have only been detected in matrix. A good review of this technique and the results is given in [345]. The large number of unstable free radicals has mainly been produced in matrix by γ or UV radiation and detected by ESR, IR, or Raman spectroscopy.

The present discussion will be limited to a few cases. In the photolysis of a $ClF/F_2/Ar$, $ClF/F_2/N_2$, or ClF_3/Ar matrix at 15 K it is possible to detect ClF_2[346]. On the basis of the chlorine isotope splitting in the IR spectrum a bond angle of about 136° may be assumed. This bond angle lies between that in ClF_2^+ (about 100°) and that in ClF_2^- (180°)[347-349]. It therefore appears that here again the VSEPR theory applies, *i.e.* that even a single electron is sterically active, although not so strongly as a nonbonded electron pair. A nonplanar structure (similar to that of SF_4) would then be expected for ClF_4, even though the deviation from planarity should be smaller than that from linearity in ClF_2, because the spatial requirements of the four fluorine atoms can be satisfied better in a more planar structure. Indeed, ClF_4 has been detected[350]; the ESR results are, however, compatible with a planar structure. The free radical ClF_6[351,352] and the free radicals BrF_6 and IF_6[352] probably have an almost or a completely octahedral structure. Dynamic effects like those operative in XeF_6 and $TeCl_6^{2-}$ are difficult to detect by ESR.

In the cases mentioned, as well as in the isoelectronic species SF_6^-, SeF_6^-, and TeF_6^-[354], it can be shown by means of the hyperfine structure in the ESR spectrum that the unpaired

electron undergoes an interaction with the central atom and the fluorine ligands. In the related free radicals $SeOF_5$ and $TeOF_5$, however, which are stable to $-30°C$, the unpaired electron is mainly localized on the central atom and on the oxygen[22].

As assumed, the free radical SF_5 has a square-pyramidal structure, and the same arrangement is obtained for CF_3—OSF_4, the ligand O—CF_3 assuming an equatorial position. A consequence of this structure is that this free radical reacts to form the *cis* isomer CF_3O—SF_4—X[353] (see Section 8).

Free radicals always seem to have qualitatively the same structure as their parent molecules or ions which have one more electron[345]. Pairs like ClF_2/ClF_2^-, NO_2/NO_2^-, and SF_5/SF_5^- prove this rule. A more detailed study of this point would be of general interest.

13. Outlook

As shown by this survey, the field of main group fluorides and oxide fluorides has been extensively investigated and an overall picture of the structural problems is clearly emerging. Gaps in this picture are, for example, the compounds of heptavalent bromine, such as BrO_2F_3 and $BrOF_5$, while the existence of BrF_7 and ClF_7 seems unlikely. It is also not entirely understandable why the chemistry of radon is so underdeveloped compared with that of xenon, even though octavalent compounds of radon are not to be expected. The synthesis of an argon compound would be an important synthetic breakthrough. However, the solution of all these problems is fraught with grave experimental difficulties. Each one of these problems will require the development of a highly sophisticated experimental method.

Many of the fluorides and oxide fluorides described are starting compounds for an extensive chemistry; the ligands —OSO_2F, —$OTeF_5$, —$OSeF_5$, —$OPOF_2$, and —ClO_3 may be cited as examples. The use of PF_5, AsF_5, and SbF_5 as fluoride ion acceptors has already become a standard procedure.

With few exceptions, new developments are to be expected not so much in the synthesis of individual compounds of this class, but rather from their chemical applications.

Many colleagues deserve my gratitude for their contributions to valuable discussions. The author's own work cited here has been generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Annulenoannulenes

By Masazumi Nakagawa[*]

Annulenoannulenes formally consist of two annulenes fused together. Hitherto, almost all the known representatives of this class of compounds were the strongly dehydrogenated forms, containing a few triple bonds and several cumulated double bonds. Besides *ortho*-annelated dehydroannulenoannulenes also such compounds containing bridges made up of two or four carbon atoms ("acetylene-cumulene" annulenoannulenes) were obtained by multistep syntheses. Most dehydroannulenoannulenes are stable and form colored crystals. In addition to dehydro[$4n+2$]annuleno[$4n+2$]annulenes with 14-, 18-, and 22-membered individual rings, two dehydro[$4n$]annuleno[$4n+2$]annulenes with 16- and 14-, and 16- and 18-membered rings have also been synthesized. Planar combinations of two [$4n$]-rings of this type and size are not known.—The dehydrogentated [14]annuleno[14]annulene containing a bridge of two carbon atoms has been studied in detail; however, the problem of the induction of a diamagnetic ring current in compounds of this type has still not been completely clarified.

1. Introduction

Parallel with the amazing developments recently made in the chemistry of monocyclic and bridged annulenes[1, 2], macrocyclic annulenes fused with benzenoid rings (*e.g.* benzo- and naphthoannelated annulenes) have received a great deal of attention and interesting results have been reported by several research groups[1g, 3–5]. In view of the interesting properties of polycyclic aromatic compounds, annulenoannulenes, fused systems made up of two annulene nuclei, *i.e.* naphthalene-like systems, have deservedly also received considerable attention.

The first examples of macrocyclic annulenoannulenes were reported in 1975 independently by *Cresp* and *Sondheimer*[6] and by the author's group[7].

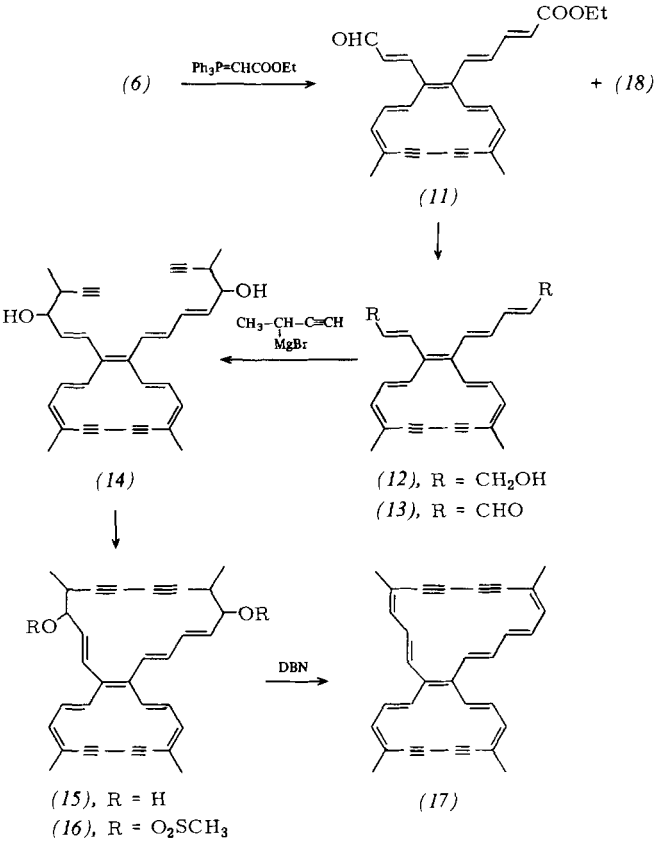
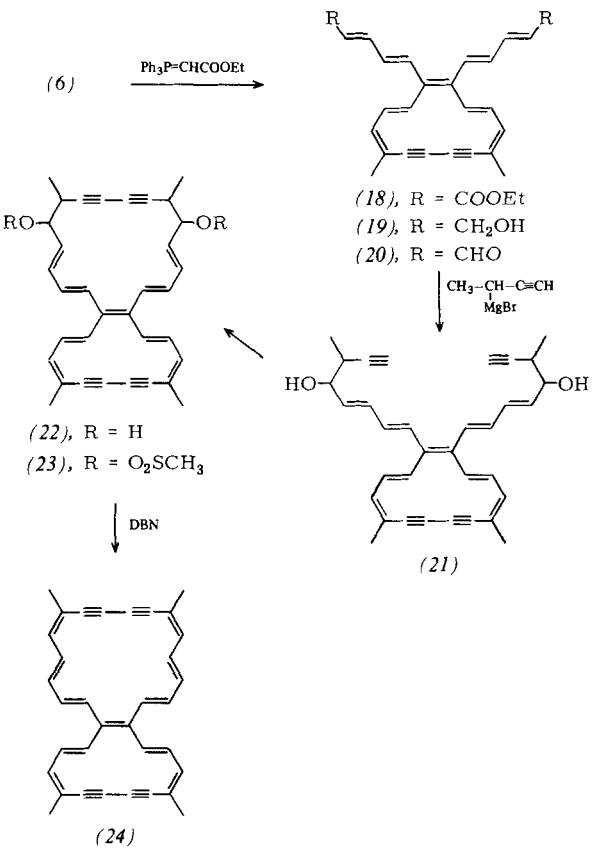
2. Syntheses



2.1. *ortho*-Annelated Annulenoannulenes[6][*]

The dimethylbisdehydro[14]annuleno[c]furan *(1)*[8], prepared by an improved method, served as starting material for the synthesis of the tetrakisdehydro[14]annuleno[14]-annulene *(10)*. Treatment of *(1)* with lead tetraacetate in acetic acid furnished the diacetate *(2)*, which on hydrolysis gave the hemiacetal *(3)*. Reaction of *(3)* with an excess of (ethoxycarbonylmethylene)triphenylphosphorane afforded

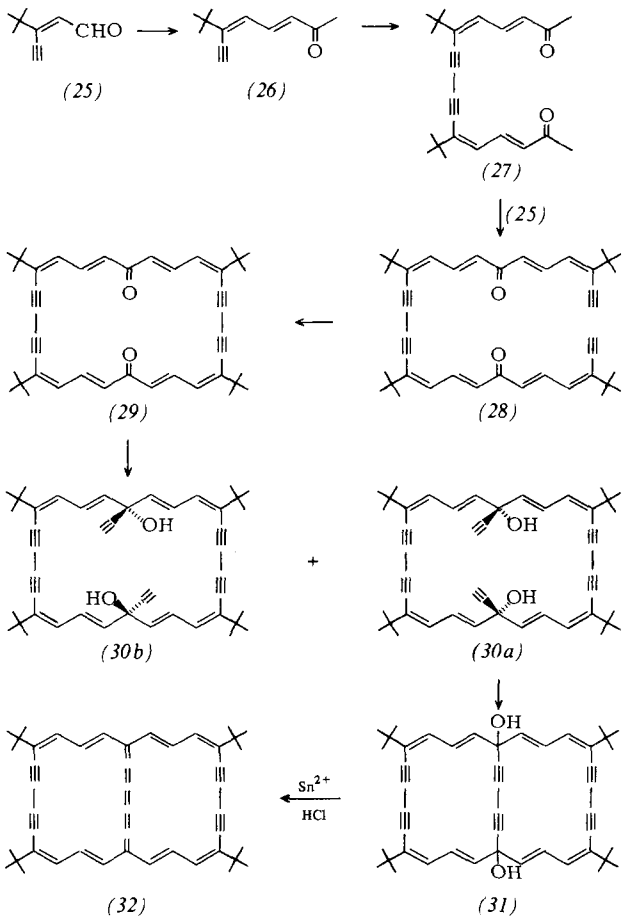


the diester *(4)* (deep-orange crystals). The newly formed double bonds in *(4)* were found to be almost entirely in the desired *trans* configuration. Reduction of the diester *(4)* with diisobutylaluminum hydride and oxidation of the resulting diol *(5)* with manganese dioxide yielded the dialdehyde *(6)* (orange needles). Reaction of *(6)* with the Grignard derivative of 3-bromo-1-butyne[9] led, *via* chain lengthening, to a mixture of the stereoisomeric diols *(7)*. Oxidative coupling of *(7)* with copper(II) acetate in dimethylformamide yielded the bicyclic diol *(8)*. The crude diol *(8)* thus obtained was converted into the corresponding bis(methanesulphonate) *(9)*, which on treatment with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) was converted into the required tetrakisdehydro[14]annuleno[14]annulene *(10)*[**] [dark red-brown prisms, yield *ca.* 5% based on *(6)*].

The dialdehyde *(6)* was used as starting material for the synthesis of the tetrakisdehydro[14]annuleno[16]annulene *(17)*[6b]. Reaction of the dialdehyde *(6)* with one equivalent

of (ethoxycarbonylmethylene)triphenylphosphorane gave the aldehydic ester *(11)* in 56% yield together with 9% of the corresponding diester *(18)*. The aldehydic ester *(11)* was reduced by diisobutylaluminum hydride to the diol *(12)*.

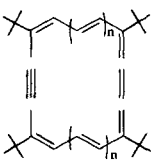
[*] For the nomenclature of the annulenoannulenes according to *Sondheimer* see [6b].



[**] Systematic name of *(10)* according to IUPAC rule A-31: 5,10,18,23-tetramethylbicyclo[12.12.0]hexacosa-1(14),2,4,10,12,15,17,23,25-nonaene-6,8,19,21-tetrayne.

The dialdehyde *(13)*, obtained by the manganese dioxide oxidation of *(12)*, was converted into the diol *(14)* by reaction with the Grignard derivative of 3-bromo-1-butyne. The bicyclic diol *(15)*, obtained by the oxidative coupling of *(14)* with copper(II) acetate in pyridine/ether, was converted into the bis(methanesulphonate) *(16)*, which was transformed on treatment with diazabicyclononene (DBN) into the tetrakisdehydro[14]annuleno[16]annulene *(17)*[*] [deep-purple prisms, yield 3% based on *(13)*].

Compound *(24)* was obtainable in essentially the same manner as *(17)*. The Wittig reaction of *(6)* with an excess of (ethoxycarbonylmethylene)triphenylphosphorane gave the diester *(18)*, which was converted *via (19)* into *(20)* [cf. *(4)*→*(6)*]. The yield of *(20)* was 82% based on *(18)*. The dialdehyde *(20)* could be converted *via* the acyclic diol *(21)*, the cyclic diol *(22)* and the bis(methanesulphonate) *(23)* into the fairly stable tetrakisdehydro[14]annuleno[18]annulene *(24)*[**] (deep-violet crystals, overall yield 20%).



2.2. 'Acetylene-cumulene'-annulenoannulenes[7,15,18,19,25]

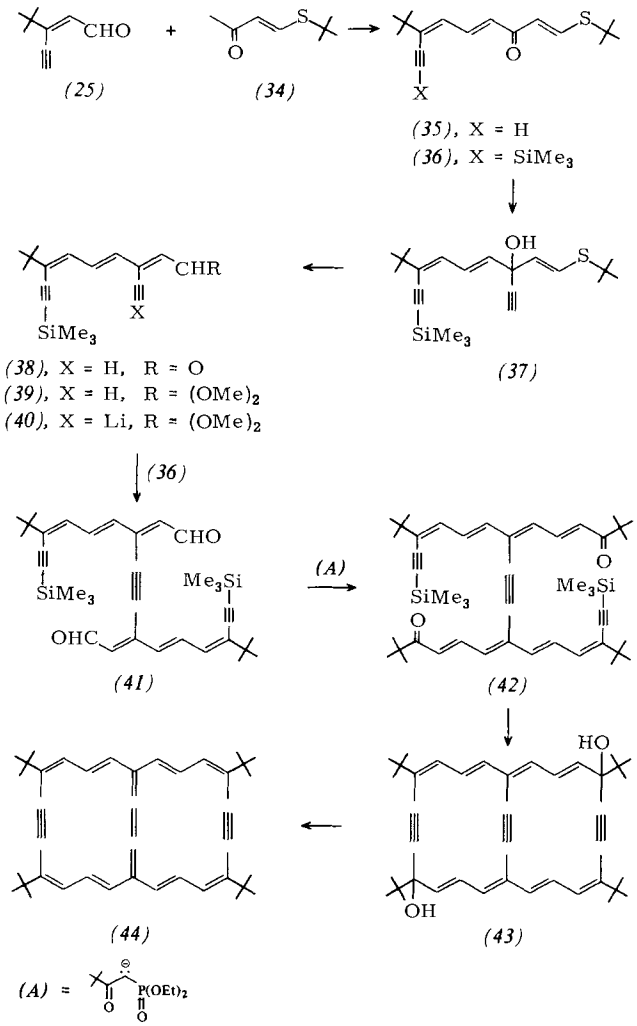
In view of the high conformational stability and the strongly diatropic[***] nature of 'acetylene-cumulene'-dehydroannulenes[1g], it was of considerable interest to prepare annulenoannulenes consisting of two fused 'acetylene-cumulene'-dehydroannulenes. For reasons of synthetic convenience, the hexakisdehydro[18]annuleno[18]annulene *(32)* was first synthesized[7]. The ethynyl ketone *(26)*, obtained by the aldol condensation of 3-*tert*-butyl-2-penten-4-ynal *(25)*[10] with acetone, was oxidatively coupled with copper(II) acetate in pyridine to give the diketone *(27)*. Treatment of the diketone *(27)* with an excess of the enyne aldehyde *(25)* in the presence of sodium ethoxide yielded the acyclic diketone *(28)* in 92% yield. Oxidative coupling of *(28)* with copper(II) acetate in pyridine, methanol and ether under high dilution conditions resulted in formation of the 26-membered cyclic diketone *(29)* in almost quantitative yield. Bisethynylation of *(29)* with lithium acetylide-ethylenediamine complex[11] in tetrahydrofuran saturated with acetylene gave a mixture of the diastereomeric cyclic diols *(30a)* and *(30b)* in 88% yield. Subsequent chromatographic separation on alumina yielded a high melting and a low melting isomer (≈4:1). Oxidation of the high melting isomer *(30a)* with copper(II) acetate in pyridine/methanol/ether under high dilution conditions afforded the bicyclic diol *(31)* in 61% yield. In contrast, the low melting isomer *(30b)* gave no bicyclic diol upon attempted oxidative coupling under the same reaction conditions; only the starting material *(30b)* was recovered in 62% yield. The failure of intramolecular oxidative coupling of the low melting isomer *(30b)* is attributable to the unfavorable *trans* disposition of the ethynyl groups in the molecule. (On this basis, we assign the structure *(30a)* to the high melting isomer in which the ethynyl groups are favorably positioned for intramolecular oxidative coupling.)

A solution of *(31)* in ether was mixed at −60°C with a solution of tin(II) chloride dihydrate in ether saturated with hydrogen chloride. The hexakisdehydro[18]annuleno[18]annulene *(32)*[*] was obtained as fairly stable dark-green crystals in 79% yield. The annulenoannulene *(32)* gave a 1:1 CT complex with 2,4,7-trinitrofluorenone.

Since tetra-*tert*-butylbisdehydro[4*n*+2]annulenes *(33)*, *n*=1—5, have already been prepared by the author's group[1f,1g], the synthesis of annulenoannulenes consisting of two bisdehydro[4*n*+2]annulenes *(33)* attracted interest in view of comparing their properties with those of the corresponding monocyclic systems *(33)*.

(33), n = 1,2,3,4,5

The *tert*-butylthiovinyl methyl ketone *(34)*, obtained by the addition of 2-methyl-2-propanethiol to ethynyl methyl ketone in the presence of Triton B[12], was condensed with the *tert*-butylenyne aldehyde *(25)* to give the ethynyltriene ketone *(35)*. Successive treatment of the ethynyl ketone *(35)* with lithium diethylamide in tetrahydrofuran at −78°C and with chloro(trimethyl)silane gave the trimethylsilyl derivative



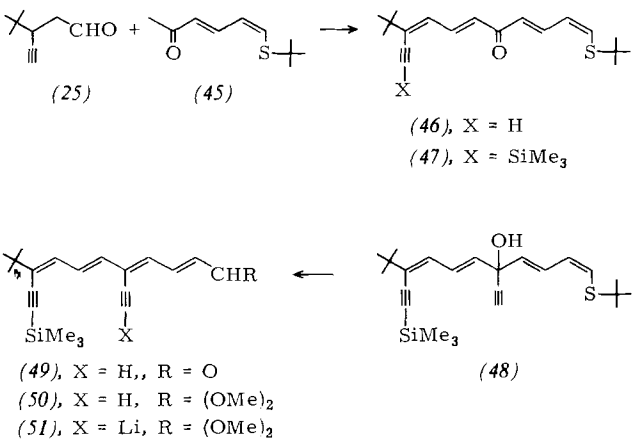
[*] Systematic name of *(17)*: 7,12,20,25-tetramethylbicyclo[14.12.0]octacosa-1(16),2,4,6,12,14,17,19,25,27-decaene-8,10,21,23-tetrayne.

[**] Systematic name of *(24)*: 7,12,22,27-tetramethylbicyclo[16.12.0]triaconta-1(18),2,4,6,12,14,16,19,21,27,29-undecaene-8,10,23,25-tetrayne.

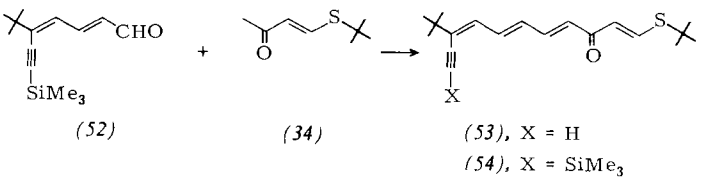
[***] Molecules whose NMR spectra reveal the effect of a diamagnetic ring current are called *diatropic* [1c].

[*] Systematic name of *(32)*: 5,10,18,23-tetra-*tert*-butylbicyclo[12.12.4]triaconta-1(27),2,4,10,12,14(30),15,17,23,25,27,28,29-tridecaen-6,8,19,21-tetrayne.

(36), which was allowed to react with lithium acetylide in tetrahydrofuran[13]. The product *(37)* was treated with an acid to give the aldehyde *(38)*, whose dimethyl acetal *(39)*



could be lithiated with butyllithium to *(40)*. Reaction of the lithium derivative *(40)* with the trimethylsilyl ketone *(36)*, followed by rearrangement and hydrolysis with an acid, yielded the dialdehyde *(41)* (yellow crystals). Chain-lengthening to give the diketone *(42)* could be achieved by reaction with the carbanion *(A)* derived from diethyl 3,3-dimethyl-2-oxobutanephosphonate[14]; *(42)* (yellow crystals) was obtained in 81% yield. Although cleavage of the trimethylsilyl groups was found to be difficult under the usual conditions, the desired intramolecular reaction could be realized by treatment of the bis(trimethylsilyl) diketone *(42)* with potassium hydroxide in liquid ammonia. A mixture of the diastereomeric bicyclic diols *(43)* (yellow crystals, 94% yield) was obtained.

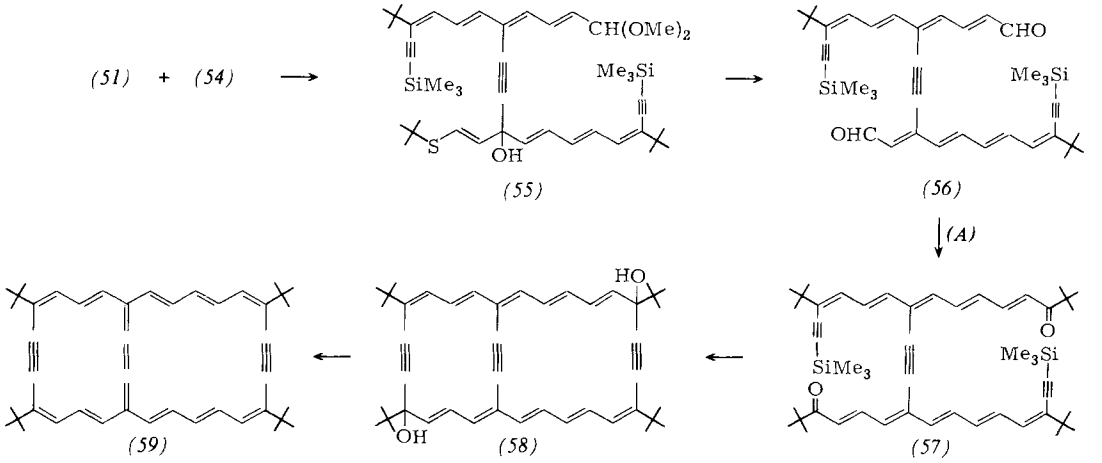


Treatment of *(43)* with tin(II) chloride in ether saturated with hydrogen chloride yielded the trisdehydro[10.10.2][14]-annuleno[14]annulene *(44)*[*] (stable reddish-purple crystals) in 77% yield[15]. The annulenoannulene *(44)* gave a 1:1 CT complex (purple crystals) with 2,4,7-trinitrofluorenone[15].

The successful synthesis and the interesting properties of the [14]annuleno[14]annulene *(44)* (see, Sections 3.1 and 3.2) encouraged us to prepare other members of this series of annulenoannulenes.

tert-Butylthiobutadienyl methyl ketone *(45)* was prepared by addition of 2-methyl-2-propanethiol in the presence of Triton B to 3-hexen-5-yn-2-one, which is readily accessible by the chromium trioxide oxidation of 3-hexen-5-yn-2-ol[16]. The aldol condensation of the diene ketone *(45)* with the enyne aldehyde *(25)*[10] afforded the tetraene ketone *(46)*, which was treated with lithium diethylamide followed by trimethylchlorosilane to give the trimethylsilyl ketone *(47)*. The ketone *(47)* was ethynylated with lithium acetylide in tetrahydrofuran[13] and the product *(48)* treated without isolation

with an acid to give the tetraene aldehyde *(49)* (orange-yellow crystals). The aldehyde *(49)* was converted into the dimethyl acetal *(50)* in the usual way and treated with butyllithium to give the lithium derivative *(51)*, which served as a moiety of construction of the [14]annuleno[18]annulene skeleton.

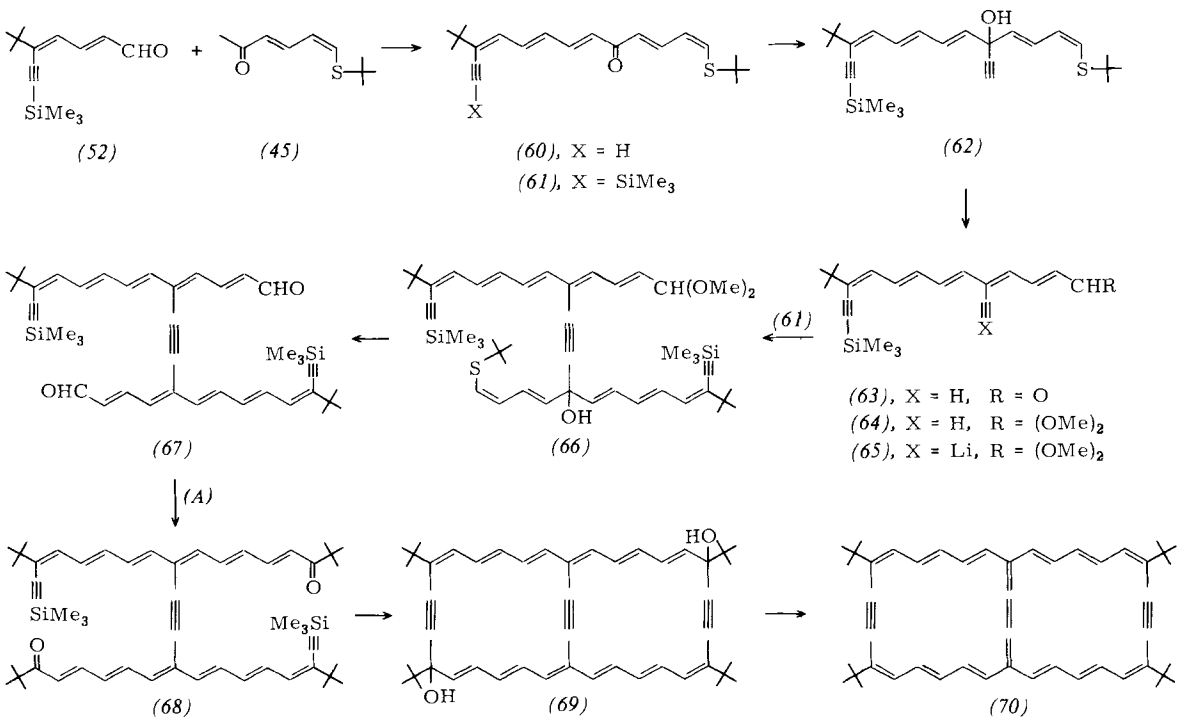


The tetraene ketone *(53)*, obtained by aldol condensation of the dienyne aldehyde *(52)*[17] with the methyl thiovinyl ketone *(34)*, could be silylated into the trimethylsilyl ketone *(54)* by the method used in the transformation of *(46)* to *(47)*. The product *(55)*, obtained by the reaction of *(51)* with *(54)*, was treated with an acid to give the dialdehyde *(56)* (yellow crystals, 68% overall yield). Reaction of *(56)* with the above mentioned carbanion *(A)* yielded the bis(trimethylsilyl) diketone *(57)* in 57% yield. Treatment of the diketone *(57)* without removal of the protective groups with a suspension of potassium hydroxide in liquid ammonia afforded the bicyclic diol *(58)* (yellow crystals 88% yield). The trisdehydro[14.10.2][14]annuleno[18]annulene *(59)*[*] was obtained in 90% yield on treatment of the bicyclic diol

[*] Systematic name of *(44)*: 5,8,16,19-tetra-*tert*-butylbicyclo[10.10.2]tetracosa-1(23),2,4,8,10,12(24),13,15,19,21,23-undecaen-6,17-diyne.

[*] Systematic name of *(59)*: 7,10,20,23-tetra-*tert*-butylbicyclo[14.10.2]octacosa-1(27),2,4,6,10,12,14,16(28),17,19,23,25,27-tridecaen-8,21-diyne.

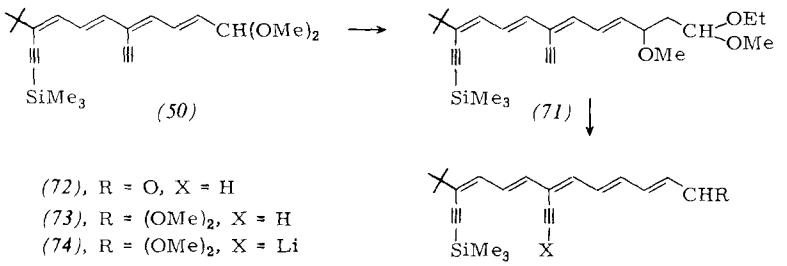
(58) with tin(II) chloride in ether saturated with hydrogen chloride at low temperature[18]. The annulenoannulene (59) (deep-purple crystals) was found to be a stable compound which forms a 1:1 CT complex (deep-green crystals) with 2,4,7-trinitrofluorenone[18].



acid. Chain-lengthening with the carbanion (A) afforded the bis(trimethylsilyl) diketone (68) (orange crystals, 65% yield) having the desired skeleton of carbon atoms. On addition of a solution of the diketone (68) in tetrahydrofuran to a suspension of potassium hydroxide in liquid ammonia, the

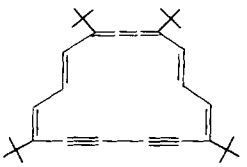
For the synthesis of the trisdehydro[18]annuleno[18]annulene (70), the pentaenyne ketone (60), obtained by aldol condensation of (52)[17] with (45)[18], was firstly converted into the trimethylsilyl derivative (61) (yellow crystals) by the above-mentioned procedure. The ethynyl alcohol (62), obtained by reaction of (61) with lithium acetylide in tetrahydrofuran[13], was then treated without isolation with an acid to give the aldehyde (63) (orange crystals, 83% yield). The dimethyl acetal (64), which was obtained from (63) in the usual way, could be converted into the lithium derivative (65) by treatment with butyllithium. The product (66) of

bicyclic glycol (69) (orange yellow crystals) was obtained in 69% yield. A solution of tin(II) chloride in concentrated hydrochloric acid was added to a diluted solution of (69) in dichloromethane/tetrahydrofuran (20:1) at *ca.* −10°C. The tetra-*tert*-butyltrisdehydro[14.14.2][18]annuleno[18]annulene (70)[*] was obtained as sparingly soluble and fairly stable deep-green crystals in 89% yield[19].



The tetraenedimethyl acetal (50) served as starting material for the synthesis of the trisdehydro[14]annuleno[22]annulene (82). (50) was allowed to react with ethyl vinyl ether in the presence of boron trifluoride etherate[20,21]. The resulting

the reaction of the lithium derivative (65) with the trimethylsilyl ketone (61) gave the dialdehyde (67) (orange crystals, 56% overall yield) on treatment without isolation with an



[*] Systematic name of (70): 7,10,22,25-tetra-*tert*-butylbicyclo[14.14.2]dotriaconta-1(31),2,4,6,10,12,14,16(32),17,19,21,25,27,29,31-pentadecaene-8,23-diyne.

methoxy acetal *(71)* was treated with diluted acetic acid containing sodium acetate to give the pentaene aldehyde *(72)*[21], which was converted in the usual way into the dimethyl acetal *(73)*. The lithium derivative *(74)* was obtained on treatment of *(73)* with butyllithium. The aldol condensation of the trimethylsilyltrienyne aldehyde *(75)*[17] with the thiovinyl

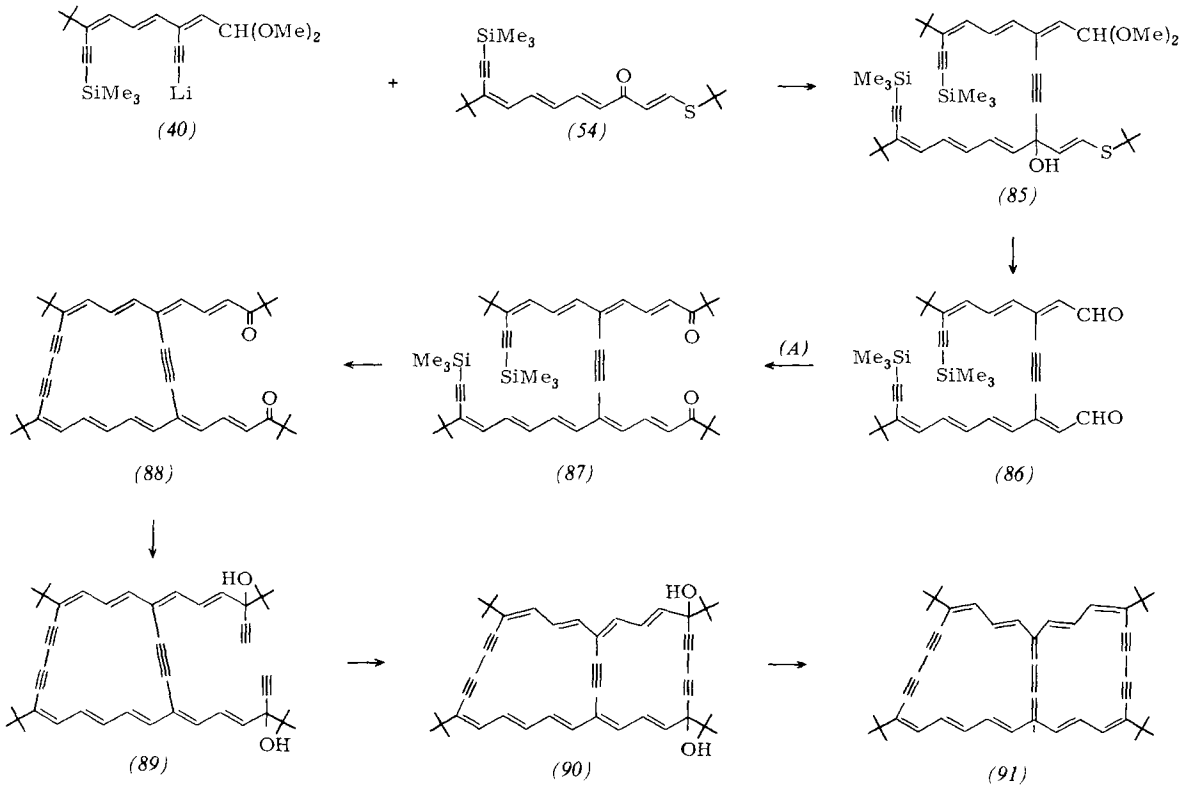
The bis(trimethylsilyl) diketone *(80)* (red crystals) was obtained in 63 % yield by reaction of *(79)* with the carbanion *(A)*. The bicyclic diol *(81)* (brownish-yellow crystals, 80 % yield) was obtained on treatment of *(80)* with a suspension of potassium hydroxide in liquid ammonia. Reductive dehydroxylation of *(81)* with tin(II) chloride in ether saturated with hydrogen chloride afforded the fairly stable tetra-*tert*-butyltrisdehydro[18.10.2][14]annuleno[22]annulene *(82)*[*] (deep blue-green crystals, 92 %)[22].



The lithium derivative *(40)* of the triene aldehyde dimethyl acetal *(39)*[15] was allowed to react with the tetraene ketone *(54)*[18] and the product *(85)* was treated with an acid to give the dialdehyde *(86)*. Reaction of *(86)* with the carbanion *(A)* yielded the diketone *(87)* (yellow crystals) in moderate yield. Oxidative coupling of the bis(trimethylsilyl) diketone *(87)* with copper(II) acetate in pyridine at 80—90 °C afforded

the cyclic triyne diketone *(88)* (orange-red crystals, 61 % yield), which could be bisethynylated with lithium acetylide in tetrahydrofuran[13] to give the monocyclic diol *(89)* (yellow liquid,

[*] Systematic name of *(82)*: 9,12,24,27-tetra-*tert*-butylbicyclo[18.10.2]dotriaconta-1(31),2,4,6,8,12,14,16,18,20(32),21,23,27,29,31-pentadecaen-10,25-diyne.

89 % yield). *(89)* was again oxidized with copper(II) acetate in pyridine to give the bicyclic diol *(90)* (orange brown crystals, 80 % yield). Treatment of the bicyclic glycol *(90)* with tin(II) chloride in ether saturated with hydrogen chloride gave the pentakisdehydro[14.12.2][16]annuleno[18]annulene *(91)*[*] in the form of fairly stable deep-green crystals[25].

3. Properties

3.1. Electronic Spectra

The tetramethyltetrakisdehydroannulenoannulenes *(10)*, *(17)* and *(24)* have been reported to give rather complex electronic spectra; the data are summarized in Table 1[6b]. It has also been pointed out that the location of the strongest absorption maxima of these annulenoannulenes resemble those of the monocyclic dehydroannulenes[26] with the same number of π-electrons. As illustrated in Figure 1, the electronic spectrum of the tetra-*tert*-butylhexakisdehydro-[12.12.4][18]annuleno[18]annulene *(32)* consists of three main absorption bands, clearly showing features characteristic of aromatic [4*n*+2]annulenes; *i.e.*, the spectrum of *(32)* was found to be closely related to that of tetra-*tert*-butylbisdehydro[18]annulene *(98)*[10] except for its showing a bathochromic shift and hyperchromism[7].

Table 1. Absorption maxima in the electronic spectra of *ortho*-annelated tetrakisdehydroannulenoannulenes *(10)*, *(17)* and *(24)* and the strongest absorption maxima of the corresponding monocyclic dehydroannulenes (see [26]); in ether.

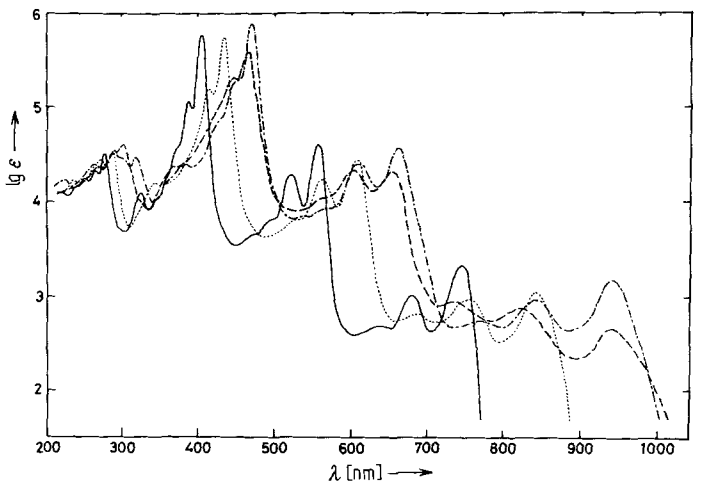
The UV/VIS spectral data of the trisdehydroannulenoannulenes *(44)*, *(59)*, *(70)* and *(82)* are listed in Table 2 together with those of bisdehydro[4*n*+2]annulenes *(33)* corresponding to the periphery of the annulenoannulenes[17,34,35]. It should be noted that the longest wavelength absorption maxima of these 'acetylene-cumulene'-annulenoannulenes show appreciable hypsochromic shift as compared with those of the corresponding bisdehydroannulenes *(33)*. The absorption curves of the trisdehydroannulenoannulenes *(44)*, *(59)*, *(70)* and *(82)* are illustrated in Figure 2.



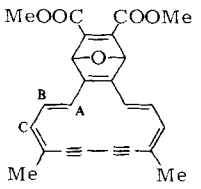


Fig. 2. Electronic spectra of trisdehydroannulenoannulenes [14][14] *(44)* (—), [14][18] *(59)* (·····), [18][18] *(70)* (– – –) and [14][22] *(82)* (-------) in tetrahydrofuran.

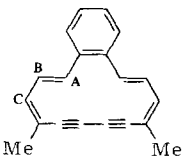
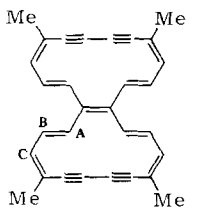


The electronic spectra of the 'acetylene-cumulene'-trisdehydroannulenoannulenes *(44)* and *(59)* exhibit a bathochromic shift and hyperchromism as compared with the spectra of the corresponding *ortho* annelated tetrakisdehydroannulenoannulenes *(10)* and *(24)*, presumably reflecting some difference in the π-electronic structure between the two series.

3.2. NMR Spectra



The effect of annelation on the diatropicity of the dimethylbisdehydro[14]annulene moiety in the *ortho*-annelated tetramethyltetrakisdehydroannulenoannulenes *(10)*, *(17)* and *(24)* has already been discussed[6b], comparing the ^{1}H-NMR

spectra with those of the reference substances *(92)*[27] and *(93)*[27]. The resonances of H^C, $H^{C'}$ and CH_3, CH_3' were used as a probe for the ring current, because these protons are furthest from the point of annelation, and must be conformationally stable. The ^{1}H-NMR parameters are summarized in Table 3. The fact that the inner protons move to higher field and the outer ones to lower field on going from *(93)* to *(10)* indicates that the diamagnetic ring current in the

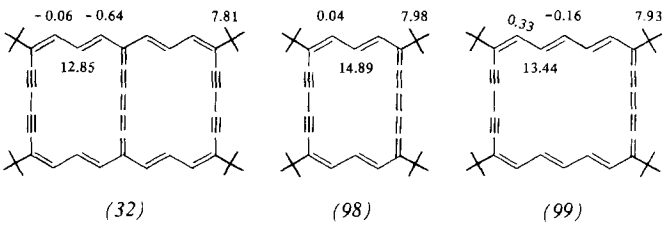
14-membered ring in *(10)* is greater than in *(93)*. It has been suggested that the equivalent Kekulé structures *(10a)* and *(10b)* may be responsible for the enhanced diatropicity of *(10)*[6b]. It is concluded that the diatropicity of the 14-mem-

(10a) *(10b)*

bered ring decreases with decreasing size of the annelated annulene [*(92)* > *(24)* > *(17)* > *(10)* > *(93)*][6b]. (Compound *(92)* is *not* an annulenoannulene.) The fact that the signals of H^A, $H^{A'}$ and H^B, $H^{B'}$ in the [14]annuleno[16]annulene *(17)* are at higher field than would be expected from the H^C, $H^{C'}$ and CH_3, CH_3' resonances is attributed to the shielding effect of the paramagnetic ring current in the 16-membered ring[6b].



The ^{1}H-NMR spectroscopic data of the bisdehydro[16]annulene moiety in the tetramethyltetrakisdehydro[14]annulene[16]annulene *(17)* and in the dimethylbisdehydrobenzo[16]annulene *(94)*[4e] and the A''' signal of the 1,3-bisdehydro[16]annulene *(95)* are given in Table 4. The 16-membered rings in *(17)* and *(94)* are clearly paratropic, showing the inner proton signals at low field and the outer proton signals at high field. However, marked suppression of paratropicity of the bisdehydro[16]annulene ring on annelation with a [4*n*+2]-membered ring was shown by comparison with the resonance of the A''' proton in the 1,3-bisdehydro[16]annulene *(95)*. The chemical shifts of the outer protons in *(95)* cannot be compared with the corresponding ones in *(17)* and *(94)*, since, in contrast to the conformational stability of *(17)* and *(94)*, *(95)* is conformationally mobile, as evidenced by the temperature dependent NMR spectra[28]. The fact that both of the inner and outer proton signals move to lower field and the magnitude of the low field shift decreases with increasing distance of the protons from the [4*n*+2]-membered rings should be ascribed to the deshielding effect of the diatropic rings. The negligible effect for the furthest removed protons ($H^{D'''}$, $H^{E'''}$, CH_3''' and CH_3'''') showed that the paramagnetic ring currents of the 16-membered rings in *(17)* and *(94)* are essentially the same, regardless of the size of the annelated diatropic rings. This is in contrast to the above-mentioned dependency of diatropicity of 14-membered rings on the size of the annelated rings.

The ^{1}H-NMR resonances of the 18-membered ring protons in the [14]annuleno[18]annulene *(24)*, in the dimethylbisdehydro[18]annulene *(96)*[4e], and in the "model" compound *(97)*[29] are given in Table 5. The high field inner proton signals and the low field outer proton resonances show the 18-membered ring in these compounds to be diatropic, although the diatropicity is clearly greatly reduced by the annelation of the 14- and 6-membered rings.

Table 5. Some ^{1}H-NMR parameters of dimethylbisdehydro[18]annulenes in $CDCl_3$ at 100 or 220 MHz (τ values; Me_4Si int.).

The ^{1}H-NMR parameters of the trisdehydro[4*n*+2]annuleno[4*n*+2]annulenes *(44)*, *(59)*, *(70)* and *(82)* are presented

together with those of the related monocyclic bisdehydro-[4n+2]annulenes in Figures 4 to 6.

The difference in chemical shifts between inner and outer protons ($\Delta\tau = \tau_i - \tau_o$) was regarded as an approximate measure of the diamagnetic ring current in the bisdehydro[4n+2]annulenes *(33)*, n=1—5[1g]. The decrease in $\Delta\tau$ could possibly be in agreement with the theoretical prediction of decreasing resonance energy per π-electron or increasing bond-alternation with increasing ring size[30]. It must be noted that the peripheries of the annulenoannulenes *(32)*, *(44)*, *(59)*, *(70)* and *(82)* are Hückel type [4n+2]π-electron systems.

As can be seen from Figure 4, the ^{1}H-NMR characteristics of the hexakisdehydro[18]annuleno[18]annulene *(32)* are also to be found in the spectrum of the trisdehydro[14]annuleno[14]annulene *(44)*: both the outer and the inner protons in *(44)* show a downfield shift as compared with those of the parent tetra-*tert*-butylbisdehydro[14]annulene *(33)*, n=1[1g, 31]. The $\Delta\tau$ values for the annulenoannulene *(44)* were found to be much larger than those for the bisdehydro[22]annulene *(33)*, n=3, which correspond to the periphery of *(44)*. The conformational stability of the bisdehydro-[22]annulene *(33)*, n=3, has been proven by the essentially temperature-independent NMR spectra[21]; the almost planar structure has been revealed by X-ray structure analysis[32]. Hence, the much higher $\Delta\tau$ values found for the annulenoannulene *(44)* cannot be attributed to an enhancement of rigidity of planarity of the molecular periphery of *(33)*, n=3, caused by the introduction of the acetylenic bridge at the central position.

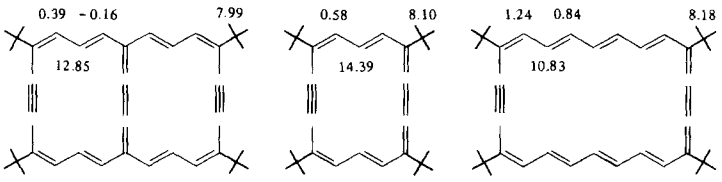

Fig. 4. ^{1}H-NMR parameters (τ values) of the trisdehydro[14]annuleno[14]annulene *(44)*, and the related bisdehydro[14]- and [22]annulenes *(33)*, n=1 and 3, respectively.

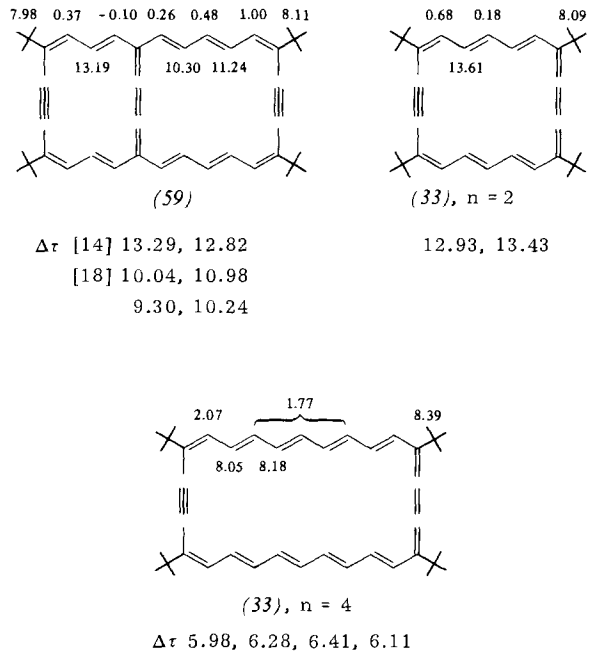

Fig. 5. ^{1}H-NMR parameters (τ values) of the trisdehydro[14]annuleno[18]annulene *(59)*, and the related bisdehydro[18]- and [26]annulenes *(33)*, n=2 and 4, respectively.

n=2 and n=4. The outer proton signals move to higher field as the distance from the bridge is increased. The same trend is observed in the chemical shifts of the inner protons in the 18-membered ring. It should be noted that the $\Delta\tau$ values in the 14-membered ring are much larger than in the 18-membered ring. As shown in Figure 5, the bisdehydro[26]annulene *(33)*, n=4[1g,33], which corresponds to the periphery of the annulenoannulene *(59)*, has much smaller $\Delta\tau$ values than *(59)*.

The ^{1}H-NMR parameters for the [18]annuleno[18]annulene *(70)*[19], the [14]annuleno[22]annulene *(82)*[22] and the bisdehydro[30]annulene *(33)*, n=5[1g, 34], are shown in Figure 6. As in the annulenoannulenes *(44)* and *(59)*, in *(70)* and *(82)* both the signals of the inner and the outer protons shift upfield with increasing distance from the bridge. The signal of an inner proton in the 22-membered ring in *(82)*

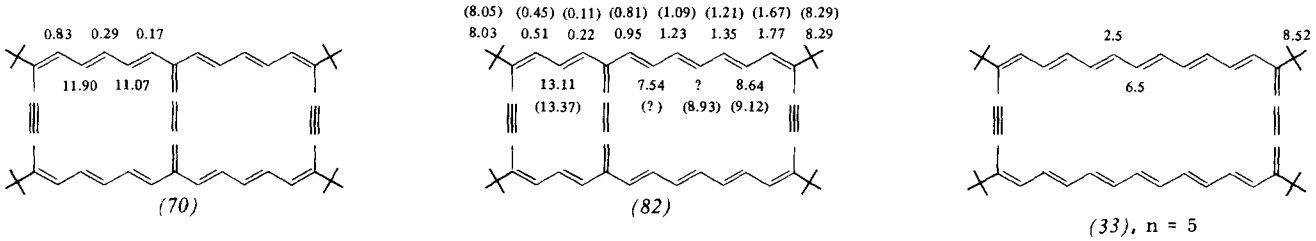

Fig. 6. ^{1}H-NMR parameters (τ values) of the trisdehydro[18]annuleno[18]annulene *(70)*, the trisdehydro[14]annuleno[22]annulene *(82)*, and the related bisdehydro[30]annulene *(33)*, n=5. The data in brackets for *(82)* are the τ values at −60 °C.

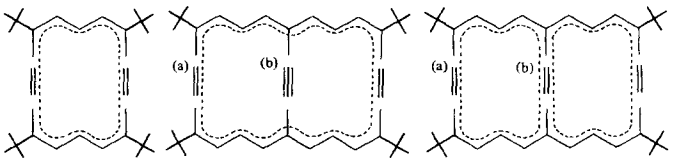
The ^{1}H-NMR parameters of the trisdehydro[14]annuleno[18]annulene *(59)*[18] are presented in Figure 5 together with those of the related bisdehydro[4n+2]annulenes *(33)*, is submerged under the tail of strong *tert*-butyl proton signals. As in *(44)* and *(59)* the $\Delta\tau$ values for the annulenoannulenes *(70)* and *(82)* are found to be much larger than that for



the bisdehydro[30]annulene *(33)*, $n=5$, which corresponds to the periphery of *(70)* and *(82)*. Both of the annulenoannulenes *(70)* and *(82)* were found to be fairly stable compounds, in sharp contrast to the extremely unstable nature of the [30]annulene *(33)*, $n=5$. The ^{1}H-NMR spectral behavior of the trisdehydro[14]annuleno[4n+2]annulenes *(59)*, $n=4$, and *(82)*, $n=5$, can be explained assuming the induction of diamagnetic ring currents of different intensity in each ring. The diamagnetic ring current in the 14-membered ring in *(59)* or *(82)* exerts a deshielding effect on all the protons of the 18- or 22-membered ring, respectively; the increase in the upfield shift of the signals with increasing distance from the 14-membered ring can be reasonably attributed to the diminishing deshielding effect upon remote protons. Similarly all the protons in the 14-membered ring suffer the deshielding effect of the 18- or 22-membered ring, resulting in a downfield shift.

It has been argued that diamagnetic ring currents of different intensity are induced in the neighboring benzene nuclei in polycondensed aromatic hydrocarbons such as anthracene and perylene[35]. The above-mentioned ^{1}H-NMR spectroscopic behavior of the annulenoannulenes *(59)* and *(82)* would seem to afford firm experimental evidence for the theoretical argument on the induction of ring currents of different intensity.

The trisdehydroannulenoannulenes *(32)*, *(44)* and *(70)* consisting of two equally sized dehydroannulenes exhibit quite similar ^{1}H-NMR spectroscopic characteristics to those of the annulenoannulenes *(59)* and *(82)* made up of two differently sized dehydroannulenes. The ring current of naphthalene has been considered to be confined to the 10π periphery, for if two identical ring currents were induced in both rings, the current across the common bond would have to be zero. If a trisdehydro[4n+2]annuleno[4n+2]annulene such as the trisdehydro[14]annuleno[14]annulene *(44)*, *i.e.* a bisdehydro[22]annulene, which is weakly perturbed by the acetylenic bridge, sustains the ring current along the periphery [see *(44a)*], it can be regarded as a resonance hybrid of two canonical forms *(44b)* and *(44c)*. Consequently, the sp-sp bond of the central bridge should have a higher acetylenic character than the other sp-sp linkages in the periphery. On the other hand, if the [14]annuleno[14]annulene *(44)* is an annelated system consisting of two independent diatropic 14π-electron systems [see *(44d)*] and can be regarded as a resonance hybrid of three main canonical forms *(44b)*, *(44c)* and *(44e)*, the mixed acetylene- and cumulene-character in the three sp-sp linkages should almost be the same.

The ^{13}C-NMR spectra of bisdehydro[14]-, bisdehydro[18]- and bisdehydro[22]annulenes *(33)*, $n=1$, 2 and 3, resp., show a single signal of the sp-hybridized carbon atoms, namely at $\delta=116.7$, 115.7 and 116.8, respectively, thus indicating the acetylene-cumulene hybrid nature of the sp-hybridized carbon atoms in the highly delocalized aromatic systems[36]. The observed ^{13}C chemical shifts agree fairly well with the arithmetical average of the chemical shifts of acetylene and cumulene carbon atoms of relevant reference compounds ($\delta=85$ and 153, respectively). The observed and weighted arithmetical mean values of the chemical shifts of sp-hybridized carbon atoms in the bisdehydro[14]annulene *(33)*, $n=1$, and the trisdehydro[14]annuleno[14]annulenes *(44a)* and *(44d)* are listed in Table 6. The good agreement between calculated and observed values for the shifts in *(33)*, $n=1$, would seem to reflect the hybrid acetylenic and cumulenic nature of the sp-hybridized carbon atoms (50:50). The weighted mean values based on the structure *(44d)* were found to be in good agreement with the observed values; however, this was not so in the case of *(44a)*.

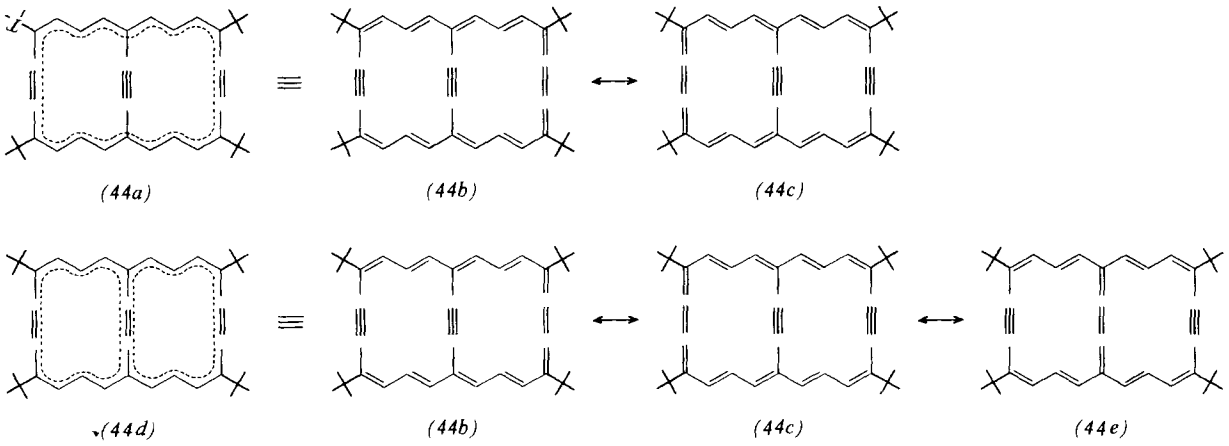


Table 6. ^{13}C-chemical shifts (δ values) of the sp-hybridized carbon atoms in the compounds *(33)*, $n=1$, and *(44a)* and *(44d)* [a].

(33), n = 1 *(44a)* *(44d)*

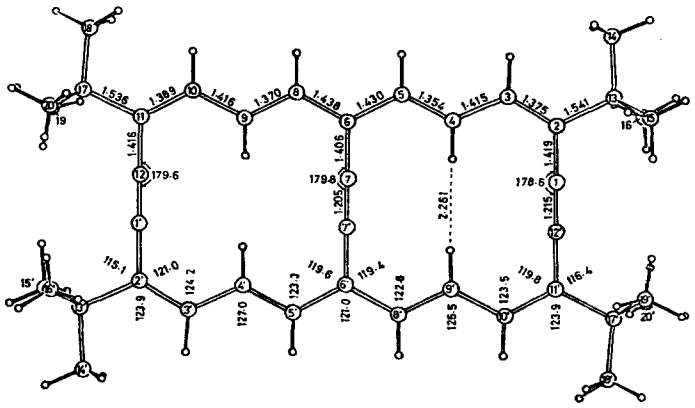
Cpd.	$\delta_{obs.}$	$\delta_{calc.}$
(33), $n=1$	116.7	(153+85)/2 = 119
(44a)	(a) 107.1	(153+85)/2 = 119
	(b) 102.4	(85+85)/2 = 85
(44d)	(a) 107.1	(153+85+85)/3 = 107.7
	(b) 102.4	(85+85+153)/3 = 107.7

[a] The following chemical shifts were used in the calculations: —C≡C—, $\delta=85$; =C=C=, $\delta=153$.

(44a) *(44b)* *(44c)*

(44d) *(44b)* *(44c)* *(44e)*

The lengths of the three sp-sp bonds in *(44)* have been determined by X-ray structure analysis (Fig. 7)[37]. Consistent with the ^{13}C-NMR spectral properties no appreciable differ-



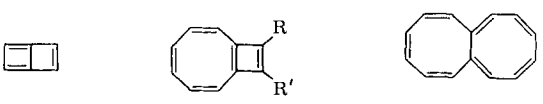


Fig. 7. Bond lengths [Å] and angles [°] in the trisdehydro[14]annuleno[14]annulene *(44)*.

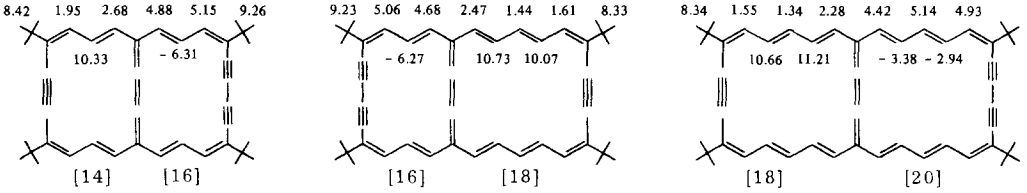
ence between these three sp-sp linkages could be observed. As pointed out previously, it seems to be difficult to explain the ^{1}H-NMR spectra of the annulenoannulenes consisting of two equally sized dehydroannulenes [*(32)*, *(44)* and *(70)*] on the basis of a ring current along the periphery. It would appear that the problem concerning the induction of a diamagnetic ring current in bicyclic systems made up of two annelated diatropic nuclei will have to await a more rigorous theoretical exploration.

The spectroscopic properties of the pentakisdehydro-[14.12.2][16]annuleno[18]annulene *(91)* are presently being studied. The annulene *(91)* sustains fairly strong paramagnetic and diamagnetic ring currents in each ring. However, further discussion would be premature at the moment.

4. [4*n*]Annuleno[4*n*]annulenes

[4*n*]Annuleno[4*n*]annulenes consisting of two annelated antiaromatic [4*n*]annulenes and containing a total of $[4n+2]\pi$-electrons are particularly interesting since they possibly represent a new class of nonbenzenoid aromatic compounds. The question as to whether they have antiaromatic or aromatic character has been the subject of experimental and theoretical studies. The formation and synthesis of lower members of the [4*n*]annuleno[4*n*]annulenes have been reported; *e.g.* generation of [4]annuleno[4]annulene (butalene) *(100)* has been confirmed by a trapping experiment[38], and derivatives of the [4]annuleno[8]annulene *(101)* have been synthesized and proved to have olefinic character[39]. Quite recently, [8]annuleno[8]annulene (octalene) *(102)* could be synthesized and characterized as a conformationally mobile olefinic compound[40].



(100) *(101)* *(102)*

A higher planar [4*n*]annuleno[4*n*]annulene is as yet unknown. We have attempted the preparation of a pentakisdehydro[12.12.2][16]annuleno[16]annulene (made up of two trisdehydro[16]annulenes *(83)*) and an analogous pentakisdehydro[16.16.2][20]annuleno[20]annulene. However, the precursors, *i.e.* the corresponding bicyclic diols, were found to persistently resist reductive dehydroxylation, which has been successfully applied in the preparation of $[4n+2]$annulenes, [4*n*]annulenes, $[4n+2]$annuleno$[4n+2]$annulenes and [4*n*]annuleno$[4n+2]$annulenes. However, no conclusions should be be drawn from these negative results.

5. Addendum

Recently the syntheses of a series of trisdehydro[4*n*]-annuleno$[4n+2]$annulenes have been achieved by our group[41]. Unexpectedly, their ^{1}H NMR spectra indicate that

the antiaromatic $4n\pi$ electron systems show a tendency to preserve their inherent paratropicity resulting in a marked suppression of diatropicity of the aromatic moieties (see the chemical shifts—τ-values—in the formulas). The same trend has been observed in the conformationally mobile pentakisdehydro[16]annuleno[18]annulene *(91)*.

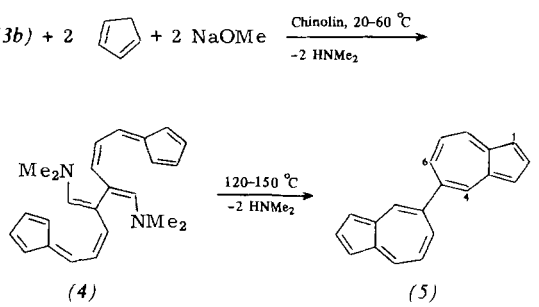
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



Synthesis of 5,5'-Biazulenyl[**]

By *Manfred Hanke* and *Christian Jutz*[*]

Directed synthesis of the hitherto unknown species 5,5'-biazulenyl *(5)* has been accomplished by the Ziegler-Hafner procedure[1] with the pentamethinium salt *(3b)*. Reaction of *(3b)* with cyclopentadiene and sodium methoxide in quinoline under nitrogen affords the deep-red bisfulvene *(4)* which undergoes *in situ* thermal cyclization to *(5)* with elimination

of dimethylamine[2]. Double electrophilic substitution of 1,4-bis(dimethylamino)-1,3-butadiene *(1)*[3] (which behaves under these circumstances as two non-coupled enamine units) with 3-chloroallylidene(dimethyl)ammonium chloride *(2)* (and subsequently with $HClO_4$) leads to fair yields of *(3b)*. The salt *(2)* was produced in the usual manner by treating 3-dimethylaminopropenal with oxalyl chloride.

The structure of *(5)* is confirmed by its ^{1}H-NMR spectrum. The pattern of signals closely resembles that of 5-methylazulene[4], the protons 4 (4') and 6 (6') adjacent to the linkage site expectedly appearing $\delta = 0.29$ and 0.21, respectively, downfield from those of 5-methylazulene owing to deshielding. The UV spectrum of *(5)* shows a relatively intense longwave ^1L_b band with vibrational structure and a distinct, remarkably longwave band at 716 nm.

Procedure

Synthesis of *(3b)*: Oxalyl chloride (8.7 ml, 0.10 mol) in chloroform (50 ml) is added dropwise to a stirred solution of 3-dimethylaminopropenal (12 g, 0.12 mol) in chloroform (250 ml) at −30 °C. Evolution of gas ensues (CO, CO_2) and a sludge of *(2)* precipitates; after 15 min, compound *(1)* (7.0 g, 0.05 mol) in chloroform (50 ml) is added dropwise to the cooled (−50 °C) sludge of *(2)*. The resulting dark-red solution is stirred for another 2 h, ultimately without external cooling, and ethanol (10 ml) is added before the mixture is evaporated down *in vacuo* without any heating. On addition of 70 % $HClO_4$ (14.3 g) in ethanol (30 ml) and ether (*ca.* 700 ml) the crude diperchlorate *(3b)* precipitates as a dark viscous oil. After repeated washing with ether and decanting off the ether layer the product is dissolved in a small volume of acetonitrile and ethanol is added until the onset of turbidity. When crystalline *(3b)* begins to precipitate, ether is added very slowly in small portions. Recrystallization of the dark salt (from ethanol in the presence of activated charcoal affords pure *(3b)* (11.3 g, 45 %); yellow needles, m.p. 219—223 °C (dec.); ^{1}H-NMR ([D_6]-DMSO, TMS int.): $\delta = 3.00$ (s, 12H, N—Me), 3.28 (s, 12H, N—Me), 5.33 (dd, $J = 12$ Hz, 2H), 7.40 (d, $J = 12$ Hz, 2H), 7.63 (s, 2H), 7.77 (d, $J = 12$ Hz, 2H); UV (ethanol): λ_{max} ($\log\varepsilon$) = 413 nm (5.00).

Synthesis of *(5)*: A *ca.* 3 N solution of sodium methoxide in methanol (8 mequiv.) is added, after prior addition of cyclopentadiene (0.58 g, 8.8 mmol), to a stirred solution of *(3b)* (2.0 g, 4 mmol) in quinoline (20 ml) under pure nitrogen. The dark-red reaction mixture is stirred at room temperature for 36 h and at 60 °C for 2 h, and heated to 120 °C and 150 °C for 3 h at a time. After stripping off the quinoline at *ca.* 1 torr, the dark residue is dissolved in CH_2Cl_2, filtered, and residual quinoline extracted with 1 N HCl and water. Chromatography, first in CH_2Cl_2 and then in *n*-hexane on Al_2O_3 (neutral, activity II) gives a blue fraction which affords small blue-black crystals (0.21 g, 21 %), m.p. 106 °C; ^{1}H-NMR ($CDCl_3$, TMS int.): $\delta = 6.88$ (dd, $J_{6,7} = J_{7,8} = 10$ Hz, 2H, H-7/7'), 7.27 (d, $J_{1,2} = J_{2,3} = 4$ Hz, 4H, H-1/1', H-3/3'), 7.56 (d, $J_{6,7} = 10$ Hz, 2H, H-6/6'), 7.72 (t, $J_{1,2} = J_{2,3} = 4$ Hz, 2H, H-2/2'), 8.07 (d, $J_{7,8} = 10$ Hz, 2H, H-8/8'), 8.41 (d, $J_{4,6} = 2$ Hz, 2H, H-4/4'); UV (ethanol): λ_{max} ($\log\varepsilon$) = 274 (4.49), 304 (4.78), 382 (4.20), 594 (3.04), 615 (3.03), 645 (3.04), 716 nm (2.74).

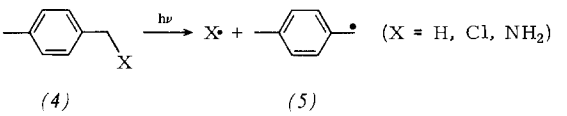
First Spectroscopic Detection of Diradicals in Photocycloreversions[**]



By *Gerd Kaupp, Eberhard Teufel*, and *Henning Hopf*[*]

Short-lived photointermediates can be detected kinetically in "allowed" and "forbidden" cycloadditions (-reversions)[1] and it is of practical utility[2] to call them 1,4-diradicals, as in the case of longer-lived intermediates exhibiting free[2b] or enforced[2c] internal rotations[3]. As the kinetic procedure does not allow any decision whether or not additional excimers or exciplexes will be formed before, after, or parallel to the diradicals[2c, 4], the direct spectroscopic detection of diradicals is of primary importance. For the first time we have now obtained spectroscopic evidence for diradicals in photocycloreversions. Upon appropriate execution of photochemical [6+6]-cycloreversions of [2.2]paracyclophanes[5], the process can be stopped at the 1,4-diradical[3a] stage. The weakly [*(2)*] or strongly [*(7)*] interacting benzyl radicals, which are linked together by an ethano-chain in the *p*-positions, are stable in glassy media at low temperatures and they can be readily recognized by their highly characteristic absorption and fluorescence spectra (see Fig. 1. and 2).

Irradiation of *(1)* (m.p. 285 °C) in a 2-methyltetrahydrofuran (MTHF) glass at 83 K with low pressure mercury lamps ($\lambda = 253.7$ nm) yields *(3)*[5] in competition with excimer fluorescence and phosphorescence. However, at 77 K *(2)* is formed rather than *(3)*. UV/VIS and fluorescence spectra are obtained which are very similar to those of *(5)*, which forms upon

corresponding irradiation of *(4)*[6] at 77 K (see Fig. 1). The spectra of *(2)* are almost as sharply structured as those of *(5)*. Therefore the mutual interaction of the benzyl radicals

in *(2)* must be weak. Its presence follows mainly from the increased UV absorption of *(2)* (but not of *(5)*) below 300 nm. Upon short thawing up to 100—120 K and recooling to 77 K both spectra of *(2)* disappear. If oxygen is carefully excluded[7] one obtains the UV bands of the cleavage product *(3)*[5], which does not fluoresce[8].

The cyclophane *(6)*[9] (intramolecular dimer) yields the intensely yellow species *(7)* in competition with excimer fluorescence upon irradiation at 83 or 77 K in MTHF. *(7)* exhibits sharply structured UV- and fluorescence spectra (see Fig.

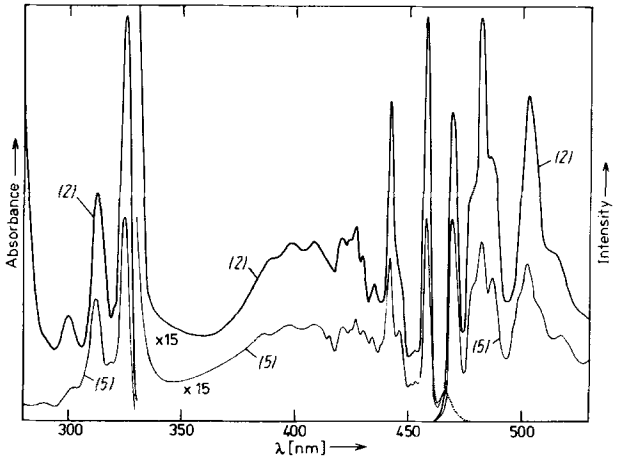

Fig. 1. UV-(excitation) and quantum corrected fluorescence spectrum of *(2)* (—) and *(5)* (—, halved scale) in MTHF at 77 K.

2). Both the absorption and emission of *(7)* are closely related to those of *(2)* and *(5)* but strongly bathochromically shifted. These observations underline the dimer (excimer after light absorption) character of *(7)*, which is enforced by the ethano-bridges.

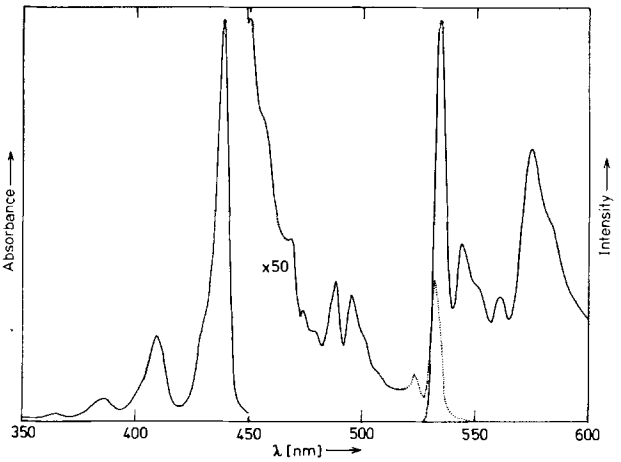

Fig. 2. UV-(excitation) and quantum corrected fluorescence spectrum of *(7)* in MTHF at 77 K.

It is only upon prolonged irradiation of *(7)* (77—83 K, $\lambda = 436$ nm), that one obtains the intramolecular dimers (excimers after light absorption) *(8)* and *(9)*. These exhibit strong or weak interaction, respectively, of the adjacent *p*-quinodimethane chromophores [UV spectra of *(8)*, *(9)*, and *(3)*, see Table 1]. *(9)* is obtained immediately upon short warming of *(7)* to 100—120 K and recooling to 77 K. It does not fluoresce, is photolabile at 77 K, and reacts thermally at 193 K to regenerate *(6)*.

[e] In benzene.

The spectroscopic detection of the 1,4-diradicals *(2)* and *(7)*[10] with presumably not-fully-extended as well as cisoid conformations profits from: (i) the relatively high stability of benzyl systems; (ii) the favorable position and intensity of the UV and the fluorescence spectra; and (iii) from barriers opposing geometrical changes, which are apparently high enough to be of significance even in the temperature range of 77—83 K. The sharp structure in the fluorescence spectrum of *(7)* is remarkable. Until now it was considered typical that intra- and intermolecular excimers or electronically excited "sandwich dimers" exhibit broad and structureless emission[11]. Therefore it may be predicted that the spectroscopic distinction between further 1,4-diradicals and dimer or complex (excimer, exciplex) structures (in particular instances perhaps at even lower temperatures) might meet with difficulties. In such cases ESR techniques should be helpful, provided these are not disturbed by radical side products (thus, there is a second fluorescence from the photolysate of *(1)* above 550 nm, which does not belong to *(2)*, but presumably to the [2.2]paracyclophanyl radical [*(1)*—H•]) or by secondary radicals involving solvent participation.

[10] Because of the ethano-links between the radicals, *(2)* and *(7)* are completely different from the *m*-quinodimethane or 1,8-naphthoquinodimethane triplets: *J.-F. Muller, D. Muller, H. J. Dewey, J. Michl*, J. Am. Chem. Soc. *100*, 1629 (1978); *M. Gisin, E. Rommel, J. Wirz, M. N. Burnett, R. M. Pagni, ibid*, in press; we thank Dr. *Wirz* for a preprint of this work and Professor *Michl* for a personal communication (Feb. 2, 1979), in which he corrects his singlet postulate of 1978 and now also assigns a triplet structure to the species he obtained.
[11] *J. B. Birks*: Organic Molecular Photophysics. Vol. 2. Wiley-Interscience, New York 1975, pp. 494ff. and further references therein; under our reaction conditions (MTHF, 77 K) the "sandwich dimer" formed from dianthracene [cf. *E. A. Chandross*, J. Chem. Phys. *43*, 4175 (1965)] also emits an unstructured fluorescence spectrum ($\tilde{\nu}_{max}^{corr} = 485$ nm); further examples in Table 1.

Elemental Sulfur/Alkali Metal Hydroxide/Dimethyl Sulfoxide—A New "Reagent" for Preparing Organic Sulfur Compounds[1]

By *Andrzej Jończyk*[*]

Elemental sulfur inserts smoothly into C—M bonds (M = Li, Na, MgX) to generate thiolates C—S^-M^+, which are transformed into thiols, thioethers, or thiol esters by treatment with acids, alkyl halides, or acyl halides, respectively[2]. However, α-alkylthio-substituted derivatives of nitriles, esters, ketones, *etc.* are usually prepared by reaction of the carbanions of these CH acids with disulfides, sulfenamides, sulfenyl halides, or thiocyanates[3]. We therefore examined the possibility of synthesizing these compounds *via* a simple reaction of carbanions with elemental sulfur and alkyl halides in the case of alkylated phenylacetonitriles *(1)*.

Preliminary experiments showed that compound *(1)* does indeed reacts to some extent with elemental sulfur and alkyl halides in the presence of 50% aqueous sodium hydroxide

(1) *(2)*

Table 1. Synthesis of α-(alkylthio)-nitriles *(2)* with the "reagent" S/NaOH/DMSO.

	R^1	R^2X	Yield [%]	B.p. [°C/torr]
a	CH_3	CH_3Br	72	78–80/0.35
b	CH_2=$CHCH_2$	*n*-C_4H_9Cl	71	96–98/0.1
c	*i*-C_3H_7	*n*-C_4H_9Cl	63	100–101/0.1
d	C_6H_5	CH_3Br	49 [a]	125–127/0.1 [b]

[a] Some 21% of $Ph_2C(CN)$—$C(CN)Ph_2$ is also formed, among other by-products. [b] M.p. 52–54 °C (53–54 °C [5c]).

Technical University (Politechnika)
Koszykowa 75, PL-00-662 Warszawa (Poland)

solution and benzyl(triethyl)ammonium chloride (TEBA)[4] to give α-alkylthio compounds *(2)*[5]; *e.g.* the yield of *(2b)* was *ca.* 10%. The process becomes of practical value on addition of DMSO [*ca.* 0.7 mol per mol of *(1)*] to the system (Table 1). The yields are about 5% lower without TEBA.

Peculiar transformations take place under these conditions when phenylacetonitrile *(1e)* reacts with sulfur and ethylene dibromide: the desired 2-phenyl-1,3-dithiolanecarbonitrile *(2e)* was accompanied, *inter alia*, by the *trans*-dinitrile *(3)*.

(1e) *(2e)*, 8% *(3)*, 14%

In the reactions between nitriles *(1)*, sulfur, and alkyl halides, polysulfides $R^2S_nR^2$ (mainly $n = 2$) were formed. We therefore treated alkyl halides directly with the S/NaOH/DMSO reagent, and obtained di- and trisulfides *(4)* (Table 2); the structure of the products depends on the reaction conditions and the alkyl halide. The yields of *(4)* were significantly improved by the use of powdered NaOH in DMSO (Table 2), though this variant requires fairly large quantities of DMSO.

Table 2. Synthesis of oligosulfides *(4)*. All reactions are performed in two steps: I, production of the "reagent" S/NaOH/DMSO; II, its reaction with RX.

RX	Base	Product	Yield [%]
n-C_4H_9Cl	50% NaOH aq	*(4a)*, $n = 1$	28 [a]
		(4a), $n = 3$	34 [a]
n-C_4H_9Cl	NaOH solid	*(4a)*, $n = 2$	56 [b, c]
n-C_4H_9Cl	NaOH solid	*(4a)*, $n = 1$	12 [a, d]
		(4a), $n = 2$	35 [a, d]
i-C_3H_7Cl	NaOH solid	*(4b)*, $n = 2$	43 [b, e]
n-$C_8H_{17}Cl$	NaOH solid	*(4c)*, $n = 2$	66 [b]

[a] By GLC. [b] Isolated. [c] Yield 50% in the presence of solid KOH. [d] Step I carried out at 90—100 °C/1 h. [e] Isopropyl bromide gives trisulfides and possibly higher polysulfides.

Procedure

Synthesis of *(2a)*: Methyl bromide (*ca.* 6 g, 0.067 mol) is bubbled through a stirred mixture of *(1a)* (2.6 g, 0.02 mol), sulfur (1.0 g, 0.031 mol), TEBA (0.1 g), DMSO (1 ml), and 50% aq. NaOH (10 ml) at 45 °C (exothermic reaction). Stirring is continued for 75 min, and the mixture is diluted with water and extracted with benzene. The organic extracts are washed with aq. NaCl, dried ($MgSO_4$), and distilled (yield 2.55 g, 72%).

Synthesis of *(4a)*, $n = 2$: Sulfur (1.6 g, 0.05 mol) is added to a stirred suspension of powdered sodium hydroxide (6.8 g, 0.17 mol) in DMSO (10 ml). Addition results in an exothermic reaction, during which the temperature is kept at 50 °C; after reaction the mixture is cooled to 25 °C. Butyl chloride (6.4 g, 0.069 mol) is added dropwise at 45 °C (cooling necessary). After being stirred for 45 min, the mixture is worked up as

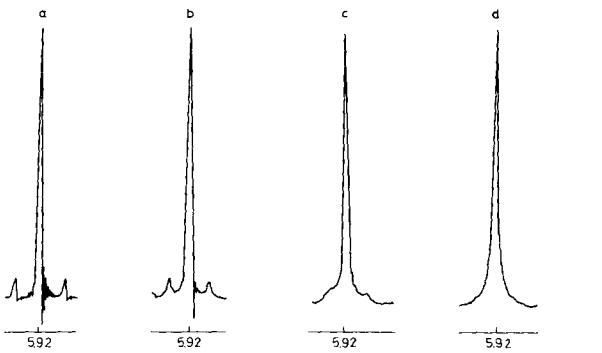
Intermolecular Exchange of Substituents *via* Ions (Ion Pairs) in Cyclopentadienyl- and Cyclononatetraenyl-trimethylstannane

By *Gernot Boche, Frank Heidenhain*, and *Brigitte Staudigl*[*]

The behavior of η^1-cyclopentadienyl derivatives of main groups IV and V, which is dynamic on the NMR time scale, has generally been recognized as an intramolecular orbital-symmetry controlled process or as one obeying the principle of least motion[1] [*(1')*⇌*(1)*]. We have found that, given suitable solvation, 1,3-cyclopentadienyl- and 1,3,5,7-cyclononatetraenyl-trimethylstannane *(1)* and *(3)*, respectively, can exist as ions (ion pairs) and exhibit intermolecular substituent exchange (Do = donor solvent or LiCl).

(1') *(1)* *(2)*



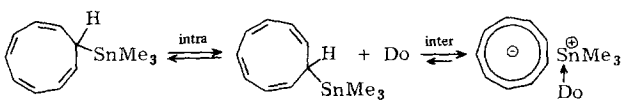


Fig. 1. ^{1}H-NMR spectra (δ values) of cyclopentadienyl-trimethylstannane *(1)* under various conditions (a—d, see Text).

Fast intramolecular exchange in the case of *(1)* in tetrahydrofuran (THF) (see Fig. 1a), dimethoxyethane (DME), trichloro-, dichloro-, or dichlorodifluoro-methane between 26 (Fig. 1a) and −70 °C is characterized, *inter alia*, by the sharp satellite bands of the signal of the five cyclopentadienyl protons at $\delta = 5.92$, which are due to ^{117,119}Sn-C-^{1}H coupling ($J = 22$ Hz)[2].

If the THF solution of *(1)* is treated at 26 °C with hexamethylphosphoric triamide (HMPT) (0.85 mol. equiv.), a broadening of the satellite signals is observed (Fig. 1b). Lowering the temperature of this sample leads to further broadening (−48 °C, Fig. 1c) and coalescence (−61 °C, Fig. 1d). A similar sequence of events occurs at constant temperature on increasing the concentration of HMPT, dimethylformamide (DMF), or lithium chloride. A spectrum like that in Figure 1d is obtained, *e.g.* with 0.54 mol. equiv. of LiCl in THF at 26 °C.

It is fully compatible with known ion-pair effects[4], and is adequately confirmed by the results obtained for cyclononatetraenyltrimethylstannane *(3)*, that the disappearance of the satellite signals with increasing concentration of donor solvent[3] or LiCl, and with falling temperature, should be due to an increasing shift of the equilibrium *(1)*⇌*(2)* in favor of the ion pair *(2)* (low concentrations) and thus to an *inter*molecular substituent exchange.

(3') *(3)* *(4)*

While *(3)* likewise exists as an olefinic η^1-compound with fast intramolecular substituent migration *(3')*⇌*(3)*[5] in solvents of low donor strength[3], the solvents DMF, HMPT, and dimethyl sulfoxide (DMSO) lead to a distinct shift of the ring protons from the olefinic region to that of the [9]annulene anion[6] (see Table 1). This is because the equilibrium *(3)*⇌*(4)* lies more on the side of the ion pair than in the case of *(1)*⇌*(2)* because of the easier ionization of the nine-membered ring derivative *(3)*[7]. Accordingly, valence isomerization to dihydroindenes, such as are common for cyclononatetraenes [*e.g. (3)*[5]], no longer occurs. The coupling constants $J(^{117,119}$Sn-C-^{1}H) also increase in parallel with the shift in equilibrium *(3)*⇌*(4)*. This is due to the stronger complexing ability of the above-mentioned donor molecules towards *(4)*[1c,8].

In a mixture of DME : DMF = 2 : 1, roughly the same population of *(3)* and *(4)* is attained, permitting determination of the temperature dependence of the equilibrium. The finding

Table 1. ^{1}H-NMR data of *(3)* in solvents of various donor strengths; δ values relative to TMS at 37 °C.

Solvent	Donor strength [3]	Ring-H (δ value)	$J(^{117,119}$Sn-C-^{1}H) [Hz]
$CDCl_3$	—	5.33	51
THF	20	5.35	51
DME	≈24	5.33	55
DMF	26.6	6.42	62
DMSO	29.8	6.72	65
HMPT	38.8	6.70	71

© Verlag Chemie, GmbH, D-6940 Weinheim, 1979 0570-0833/79/0303-0218 $ 02.50/0

that *(3)* is present at room temperature and that *(4)* predominates at $-40\,^{\circ}C$ corresponds to a reaction enthalpy of $\Delta H^{0} = -8.8$ [kcal mol^{-1}] and an entropy of reaction $\Delta S^{0} = -32$ [e. u.] for the transformation *(3)*→*(4)*, with the entropy term in particular confirming the solvation of the ion pair. Since only averaged spectra were recorded throughout the entire temperature range, the equilibrium *(3)*⇌*(4)* must be mobile ($\Delta G^{\neq}_{40\,^{\circ}C} \leq 10$ [kcal mol^{-1}]). Addition of 1 mol. equiv. of LiCl to a 0.4 M solution of *(3)* in THF leads to similar behavior: as the temperature falls the dynamic equilibrium *(3)*⇌*(4)* shifts reversibly to the side of the ion pair *(4)*.

(1) and *(3)* thus demonstrate that covalent trimethylstannyl compounds can be transformed by suitable solvents into ion pairs *(2)* and *(4)* which react differently from *(1)* and *(3)*[9].

"Multi-Loop Crown Ethers" with Multiple Selectivity[**]

By *Edwin Weber*[*]

While the chemistry of organic neutral ligands has made great advances with regard to the specific recognition of *individual types* of cations/anions and uncharged molecules[1], apparently, very little is known about receptors (host molecules) for the simultaneous selective complexation of several *different types* of alkali metal/alkaline earth metal and heavy metal ions. We report here on the first crown ether combinations "multi-loop crown ethers" of type *(1)*—*(5)*, in which several rings having tailor-made *cavity sizes* and *donor properties* are coupled *via* spiro C-atoms.

Such multi-loop crown ethers should not only be useful for the analysis of mixtures of salts[2] but also attract interest for the enzyme-analogous complexation of polyfunctional organic compounds and polyelectrolytes[3] and as models for cation contact, charge transfer, and energy transport processes[4]. The ligands having topologies *(1)*—*(5)*, *e.g. (6)* and *(7)* were synthesized using pentaerythritol[5] as starting substance (Tos = toluenesulfonyl, THP = tetrahydropyranyl).

The ligands *(6a)*—*(6e)* and *(7a)*—*(7d)* have been shown to be generally useful as hosts for the joint incorporation of *several* cations, and the ratio ionic radius/cavity volume of crown ether (donor number) for each ring can be adjusted at will.

The double-loop crown ether *(6b)* (colorless viscous oil)[6], for example, readily forms a 1:2 complex with NaSCN or with $Ca(SCN)_2$, *i.e.* each of the two similar "crown-5,5" rings[7] incorporate a metal ion—as in *(1)* (Table 1). The same applies for the bulkier "dicrown-6,6" ligand *(6c)* (colorless

Table 1. Complexes of the multi-loop crown ethers *(6)* and *(7)*.

Ligand No.	Ligand Type	Complex Stoichiometry Ligand:Salt	Complex Salt	M.p. [°C]

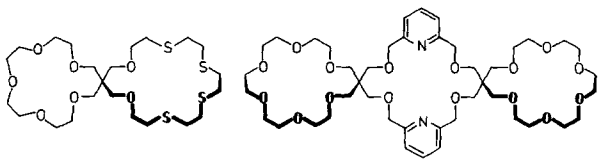
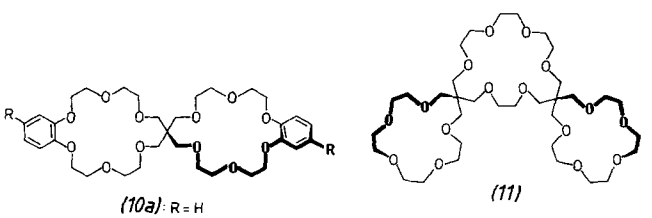
viscous oil) and BaI_2 and for *(6a)* (colorless crystals, m.p. 78—79°C) and LiI. Consistent with this finding, the triple crown ether *(7a)* (colorless viscous oil) incorporates a total of three K^+ ions in the spatially suitable "6,6,6" subunits and thus acts as a *trifunctional* cation receptor.



As a rule, with unfavorable cavity size/ionic volume ratios, for example if the cation is too large, no polynuclear complexes are formed: *(6b)* still forms only a 1:1 complex with KSN; in the case of $Ba(SCN)_2$ a stoichiometric 3:4 complex is formed.

Investigations on the separation of cations according to their charge were initiated by the finding that addition of 1:1 mixtures of NaSCN and $Ca(SCN)_2$ to a solution of the "5,5" ligand *(6b)* in acetone/ethyl acetate leads to precipitation of the 1:2 Na^+ complex in almost quantitative yield (see Table 1); in contrast, under the same conditions [15]crown-5 yields the 1:1 complex with $Ca(SCN)_2$. *(6b)* was also added to a solution of KSCN and $Ba(SCN)_2$ (2:1, acetone), whereupon the same Ba^{2+} complex (see Table 1) was formed as in the absence of K^+ ions. *(6c)* and $KSCN/Ba(SCN)_2$ (1:1, in acetone) led to a 1:2 complex with $Ba(SCN)_2$.

The *unsymmetrical* double-loop *(6d)*, *(6e)* [cf. *(3)*] and triple-loop crown ethers *(7b)*—*(7d)* [cf. *(4)*, *(5)*] should be able to incorporate several cations of various sizes: Thus, from a 1:1:1 mixture of *(6d)* (colorless viscous oil), LiI and BaI_2 in acetone/ethyl acetate an analytically pure complex is isolated which contains the components in a 1:1:1 ratio. Remarkably, this has only been achieved up to now with this combination of alkali metal and alkaline earth metal salts.



On attempting to exploit the different ring sizes of the "4,6" ligand *(6d)* to prepare mixed polynuclear complexes exclusively with alkali metal ions led—*e.g.* with LiI/KI (1:1, in acetone)—unexpectedly to a 1:2 complex with LiI. Apparently, for unequal occupation of the differently sized rings in *(6d)* differences in charge (or polarizability) as well as large differences in size of the metal ions are necessary.

On reaction of *(6d)* with BaI_2 (1:1) a 1:1 complex containing two H_2O molecules was isolated. It might incorporate the Ba^{2+} in the "6" compartment, while the "4" compartment could possibly take up the H_2O molecules coordinatively. Reaction of *(6c)* and LiI alone leads to a 1:2 complex containing four H_2O molecules. How the Li^+ ions are distributed, however, cannot be determined from the spectroscopic data.

(8) *(9)*

For further gradation of selectivity of the rings in *(6)* and *(7)* also *different* donor atoms were incorporated in the rings[8], as in *(8)* and *(9)*. *(8)* (colorless viscous oil) can provide one cavity for alkali metal/alkaline earth metal cations and one for transition metal ions, while *(9)* (colorless crystals, m.p. 123–125°C) can incorporate alkali metal/alkaline earth metal cations in two of its cavities and a heavy metal in its third cavity. With *(9)*, a mixed 1:2:1 (Ligand: K^+:Co^{2+}) $KSCN/Co(SCN)_2$ complex (m.p. 106–108°C) could be isolated, which most likely contains the Co^{2+} ion in the central ring.

(10a): R = H
(10b): R = CH_3

(11)

Further spiroskeleton/heteroatom combinations[8]—*e.g.* *(10a)* (colorless crystals, m.p. 77–78°C), the *chiral* ligand *(10b)* (colorless crystals, m.p. 55–57°C), and the *angularly* coupled *(11)* (colorless viscous oil)—serve to illustrate the synthetic utility of such complexes and the promising novel applications of the concept, *e.g.* in the simultaneous isolation precious metals from seawater.

η^5-Cyclopentadienyl(trinitrosyl)vanadium Hexafluorophosphate, $[CpV(NO)_3]PF_6$[**]

By *Max Herberhold, Reinhard Klein*, and *Paul D. Smith*[*]

In continuation of our work on highly nitrosylated metal cations[1] we have now synthesized $[CpV(NO)_3]^+$ *(1)*, thus completing the hitherto incomplete series of isosteric half-sandwich complexes of the type $[CpML_3]^+$ (L=CO or NO).

(1) *(2)*

The new complex *(1)* is formed according to proven methods[2] when the labile CO ligand in $CpV(CO)(NO)_2$[3] is replaced by the isoelectronic nitrosyl cation:

$$CpV(CO)(NO)_2 + NOPF_6 \xrightarrow[CH_3NO_2]{-25\,^\circ C} [CpV(NO)_3]PF_6 + CO$$

The composition of the green, diamagnetic salt $[CpV(NO)_3]PF_6$ is confirmed by elemental analysis and the

field desorption mass spectrum ($m/e = 206$ for $CpV(NO)_3^+$)[4]; in nitromethane solution it behaves as a 1:1 electrolyte. The pronounced electron deficit at the central metal of *(1)* is reflected in the high ν(NO) frequencies in the IR spectrum and in the strong deshielding of the cyclopentadienyl protons in the ^{1}H-NMR spectrum. Table 1 shows the characteristic spectroscopic data of the cations *(1)* and *(2)*[5] and of the corresponding neutral complexes from which they can be obtained by reaction with $NOPF_6$.

Table 1. IR and ^{1}H-NMR data [a].

Complex	IR [b] ν(CO)	IR [b] ν(NO)	^{1}H-NMR [c] δ(Cp)
$CpCr(CO)_2(NO)$	2025, 1948	1693	5.23
$[CpCr(CO)(NO)_2]PF_6$	2142	1875, 1789	6.25
$CpV(CO)(NO)_2$	2064	1723, 1629	5.71
$[CpV(NO)_3]PF_6$	—	1912, 1794	6.55 [d]

[a] All measurements in nitromethane. [b] Perkin-Elmer 297; cm^{-1}. [c] Jeol C-60-HL; δ values rel. TMS int., calibration with TMS/$CHCl_3$. [d] Measurement at −25°C.

In contrast to the now complete series of the isosteric cations $[CpML_3]^+$ (L = CO, NO), the analogous series of the neutral half-sandwich complexes, $CpML_3$, remains incomplete since the end-member $CpTi(NO)_3$ is still unknown.

Experimental[6]

$CpV(CO)(NO)_2$: $CpV(CO)_4$ (1.27 g, 5.6 mmol) is dissolved in tetrahydrofuran and reduced to $Na_2[CpV(CO)_3]$ with 1% sodium amalgam[3b, 7]. The salt is dried in a high vacuum at +70°C, suspended in 50 ml diethyl ether, and nitrosylated with *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide ("diazald") (2.38 g, 11.1 mmol; dissolved in 10 ml ether). The undissolved material is removed by filtration (G3 frit) and the solution evaporated to dryness; the resulting residue is then extracted with 5 × 20 ml pentane. Column chromatographic separation of the pentane solution on silica gel (pentane, 0°C) affords $CpV(CO)_4$ and $CpV(CO)(NO)_2$ in yields of 11% (0.14 g) and 34% (0.39 g), respectively.

$[CpV(NO)_3]PF_6$: A solution of $NOPF_6$ (0.32 g, 1.8 mmol) in 10 ml nitromethane is added dropwise to the orange-brown solution of $CpV(CO)(NO)_2$ (0.37 g, 1.8 mmol) in 50 ml nitromethane at −25°C. The resulting green solution is filtered through a G3 frit, cooled to −25°C, into 200 ml of cooled ether. After 12 h at −30°C, the resulting green crystals are separated from the mother liquor, washed several times with cooled ether and cooled pentane and then dried for 2 h at −70°C in a high vacuum. Yield 0.40 g (63%); decomposition above 160°C in a nitrogen-filled ampoule[8].

Asymmetric Synthesis of 2-Alkylcyclohexanones on Solid Phases[**]

By *Paul M. Worster, Colin R. McArthur*, and *Clifford C. Leznoff*[*]

Asymmetric syntheses of 2-alkylcyclohexanones[1a] have been recently described in which the optical yields were remarkably high[1b]. The key step is alkylation of an optically active alkoxyiminocyclohexanone.

Insoluble polymer supports have been used in the preparation of enantiomerically pure organic compounds in several ways. Crosslinked polymers containing optically active phosphane ligands have been used as catalysts in asymmetric synthesis[2]. Crosslinked polymers containing chiral cavities have been used for resolving specific organic racemates[3]. In both of these applications the polymer is the reagent and the product remains in solution. In the Merrifield synthesis, however, the reaction product is attached to the polymer and the excess reagents and catalysts are removed by simple filtration. The latter approach was used in the asymmetric synthesis of atrolactic acid on crosslinked polystyrene polymers containing a chiral sugar[4]. The chemical and optical yields were somewhat better than those obtained in solution.

We feel that significant advantages can be gained by performing asymmetric syntheses on insoluble polymer sup-

ports[5]. The expensive chiral reagent can be recovered by simple filtration at the end of the synthesis. In addition, the bulk of the polymer backbone and the reduced mobility of the polymer-bound substrate can mimic enzymatic reactions, giving high optical yields.

We were interested in determing whether the very high chemical and optical yields of the asymmetric synthesis of 2-alkylcyclohexanones[1b] could be achieved on solid phases. Merrifield's commercially available 1 % crosslinked divinylbenzene-styrene copolymer [*(1)*, containing 1.1 mmol of benzyl chloride groups/g of polymer] reacted with the potassium salt of (*S*)-2-phthalamido-1-propanol in benzene containing catalytic amounts of [18]crown-6 to give the polymer-bound phthalamido-blocked chiral amine *(3)*. Treatment of *(3)* with NaI in acetone and subsequent reaction with tri-*n*-butyltin hydride to remove the excess benzyl chloride groups[6] of *(3)*, followed by hydrazinolysis, gave the polymer-bound chiral amine *(4)*. Treatment of *(4)* with cyclohexanone *(5)* in benzene in a Soxhlet extractor [with 3-Å molecular sieves in the thimble] gave polymer-bound chiral alkoxyimine *(6)*. Acid cleavage[7] of *(6)* liberated 0.4 mmol of *(5)*/g of *(6)*. Treatment of *(6)* with lithium diisopropylamide (LDA) at 0 °C followed by the addition of methyl iodide *(7)* or propyl iodide *(8)* at 22 °C yielded the polymer-bound alkylated imines *(9)* or *(10)*, respectively. Mild acid cleavage[7] of *(9)* or *(10)* liberated *(4)* and (*S*)-2-methylcyclohexanone *(11)* ($[\alpha]_D^{26} = +15.5$) in 95% optical yield and 80% chemical yield or (*S*)-2-propylcyclohexanone *(12)* ($[\alpha]_D^{26} = +15.5$) in 60% optical yield and 80% chemical yield. The optical and chemical yields of *(11)* are at least as high as those reported[1b] for reactions performed in solution. The recovered chiral reagent *(4)* loses some of its capacity on recyclization, but the enantiomeric excesses of the product remain unchanged in subsequent cycles. We have thus demonstrated that asymmetric synthesis on solid phases is a practical reality which shows promise of high enantiomeric excesses of product comparable with those obtained in enzymatic systems.

Novel Glycals as Synthons for Saccharide Syntheses[**]

By *Joachim Thiem, Petra Ossowski,* and *Jens Schwentner*[*]

The sequential construction of long-chain oligodeoxyoligosaccharides and linkage to complex aglycons require readily accessible reactive saccharide precursors and a readily manageable method of coupling. A suitable technique consists in the reaction of glycals with alcohols in the presence of *N*-iodosuccinimide (NIS)[1]. As a potential method for the production of cardenolide oligosaccharides, increasing interest is being focused on a synthesis of D-digitoxal *(3a)*, which proceeds independently of the natural product[2] and of the conventional glycal syntheses[3].

The epoxide ring in methyl 2,3-anhydro-6-deoxy-α-D-allopyranoside *(1)*[4], which is easily accessible in six steps from methyl α-D-glucopyranoside by a standardizable method[5], undergoes smooth nucleophilic cleavage with lithium iodide dihydrate in pyridine with addition of acetic acid. According to the Fürst-Plattner rule[6], the *trans*-diaxial 2,6-dideoxy-2-iodo-α-D-*altro* cleavage product *(2)* predominates (80 % yield, see Table 1 for physical data). In addition, the *trans*-diequatorial 3,6-dideoxy-3-iodo-α-D-*gluco* product (20 %) is also formed.

The reaction of iodohydrin *(2)* with methyllithium in ether[7] has proved to be of considerable advantage. Chromatographic separation of the isomeric iodohydrins formed in the first step is not necessary for the preparation since the stable compound *(3a)*[2] crystallizes directly after reaction of the mixture with methyllithium.

(3a) was acetylated to *(3b)* which could be condensed with the epoxide *(1)* by the *N*-iodosuccinimide method[1]

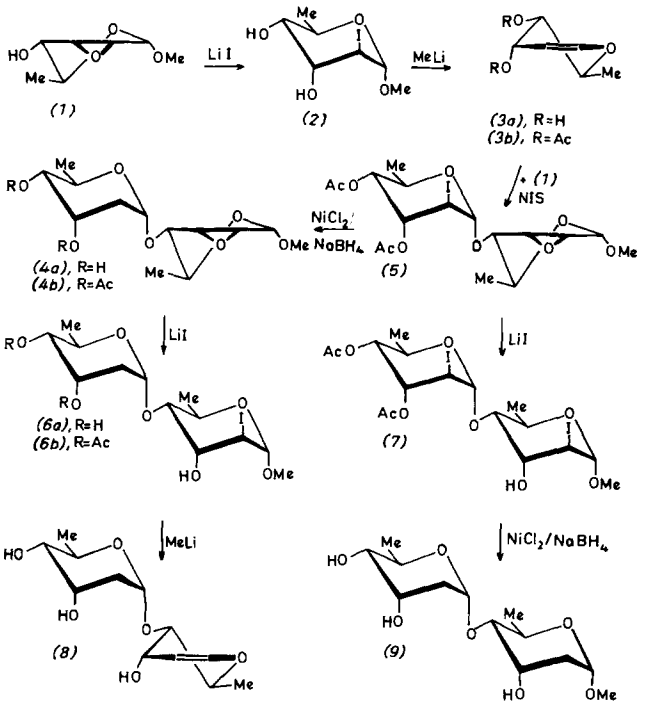

Table 1. Physical data (selection) of the sugar derivatives synthesized. ^{1}H-NMR at 270 MHz (Bruker WH 270) in $CDCl_3$ and CD_3OD.

to give *(5)* (72%). Opening of the epoxide ring of this α,1→4 linked disaccharide derivative with lithium iodide dihydrate gives, in addition to the *gluco-altro* isomer, the bis-*altro* compound *(7)* (56% yield) as the major product.

On reduction with $NiCl_2/NaBH_4$[1,5], compound *(7)* affords methyl 2,6-dideoxy-4-*O*-(2,6-dideoxy-α-D-*ribo*-hexopyranosyl)-α-D-*ribo*-hexopyranoside *(9)*[8], the glycoside of the terminal disaccharide unit of *neo*-digoxin[9]. The synthesis has not yet been optimized and the present yield of 34% should be open to considerable improvement. This synthetic approach provides a convenient entry to other oligodeoxyoligosaccharides.

Reductive removal of the iodine from *(5)* with $NiCl_2/NaBH_4$[1,5] gives the 2'-deoxy derivative *(4b)*. A series of hitherto unelucidated by-products lowers the yield to 32%. Epoxide ring cleavage of *(4b)* affords not only the *gluco-ribo* isomer but mainly the *altro-ribo* configurated derivative *(6b)* (43% yield); the ^{1}H-NMR data for its reducing saccharide ring are comparable with those of *(7)*.

When subjected to elimination reaction with methyllithium in ether[7], *(6b)* smoothly furnishes the disaccharide glycal *(8)*. The derivative *(8)* (45% yield) represents a disaccharide synthon, comparable with the monosaccharide synthon *(3a)*, which permits further synthetic reactions. Addition of methanol to *(8)* in the presence of *N*-iodosuccinimide affords *(6a)*, which was transformed into *(4a)* with sodium methoxide and characterized.

Formal Criss-Cross Cycloaddition of Sulfur Trioxide to Cyanogen[**]

By *Herbert W. Roesky, Nurul Amin, Graalf Remmers, Alfred Gieren, Uwe Riemann*, and *Bernhard Dederer*[*]

Cyanogen reacts with sulfur trioxide in the molar ratio 1:2 to give a compound which was formulated[1] as the (bis)adduct of a Lewis acid and a Lewis base. However, its sensitivity towards hydrolysis is incompatible with the properties of the known adducts of SO_3 with Lewis bases[2]. X-ray structure analysis has now shown this compound to be 1,2,3-oxathiazolo[4,5-*d*][1,2,3]oxathiazole 2,2,5,5-tetroxide *(1)*, the product of a formal criss-cross cycloaddition (1,3;2,4 cycloaddition)[3]. However, the reaction mechanism has yet to be elucidated. Neither SO_3 nor $(CN)_2$ has hitherto been found to undergo criss-cross cycloaddition. On bonding of *(1)* the SO_3 component is incorporated regiospecifically. No monoadduct could be isolated, even in the presence of an excess of cyanogen.

(1a)

(1b) *(1c)*

(1) forms monoclinic crystals, space group A2/a with $a=11.928(3)$, $b=6.818(2)$, $c=7.824(2)$ Å, $\gamma=96.37(2)°$, $Z=4$, $\rho_{calc.}=2.228\,g\,cm^{-3}$. Using an automatic single-crystal diffractometer (Siemens AED), 1968 independent reflections were measured with $Mo_{K\alpha}$ radiation ($\theta_{max}=40°$, $\theta/2\theta$ scan, 5-point measurement) of which 219 were regarded as unobserved ($I \leq 2\sigma_I$). After Patterson and Fourier synthesis, refinement (complete matrix) led to $R=0.049$. The molecule is centrosymmetric and in the crystal it deviates only slightly (mainly with regard to the exocyclic oxygen atoms) from the higher 2/m symmetry. The bicyclic skeleton is planar.

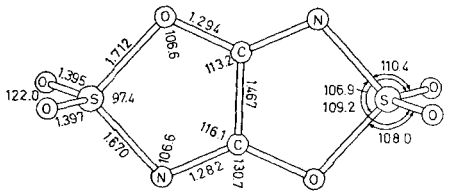

Fig. 1. Molecular structure of 1,2,3-oxathiazolo[4,5-*d*][1,2,3]oxathiazole 2,2,5,5-tetroxide *(1)* in the crystal. Standard deviations 0.002—0.003 Å for bond lengths and 0.1—0.2° for bond angles.

Compound *(1)* exhibits unusual bond lengths: the S—O bond in the ring is extremely long at 1.71 Å, while the exocyclic S=O bonds are shortened to 1.39 Å. This finding suggests a description of the molecule in terms of bond-non bond resonance [*(1a)*↔*(1b)*, *(1c)*], the resonance formulas *(1b)* and *(1c)* also providing some rationalization for the short C—O bond (1.29 Å).

Procedure

Cyanogen (0.1 mol) is passed into ice-cooled sulfur trioxide (0.15 mol) with exclusion of moisture. As soon as the solution has solidified to a gel, the excess of SO_3 is stripped off *in vacuo*. Vacuum sublimation gives colorless crystals of *(1)*; yield 80%. IR: ν(CN) and/or ν(CO) 1690, 1670 cm^{-1}. MS (70 eV): $m/e=106(100\%)M_r/2, 80\,SO_3, 64\,SO_2, 48\,SO, 42\,NCO$.

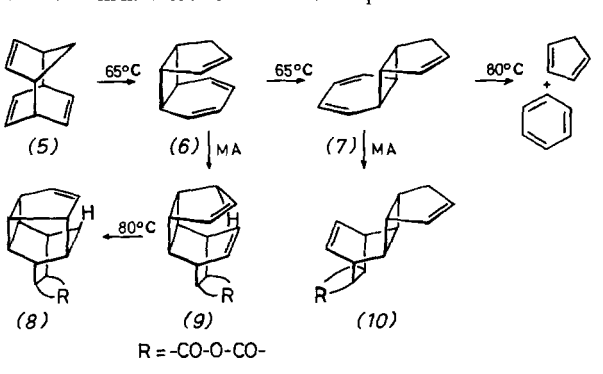
Tricyclo[4.2.2.1^{2,5}]undeca-3,7,9-triene, the [4+4]-Cycloadduct of Benzene and Cyclopentadiene. Reaction Sequence of Its Retro-Cleavage[**]

By *Wolfram Grimme*, *Wolfgang Mauer*, and *Gerd Reinhardt*[*]



Cycloreversions forming benzene readily proceed both as symmetry allowed [4+2]-[1] and as forbidden [2+2]-processes[2], and their kinetic and thermodynamic data can be determined quite easily. Since very little is known so far about the likewise forbidden [4+4]-cycloreversion[3] we have synthesized the title compound *(5)* and investigated its decomposition to benzene and cyclopentadiene. [2+2]-[2a] and [4+2]-cycloreversions[1a] to the same products are already well known.

The ketone *(1)*[4] is converted by treatment with diazomethane in methanol/ether in the presence of lithium bromide into the homologous compound *(2)* (85% yield; for physical data see Table 1). The enolate of *(2)*, generated by reaction with lithium diisopropylamide in hexane/tetrahydrofuran, is then allowed to react with diethyl chlorophosphate and tetramethylethylenediamine. Reduction of the resulting ester *(3a)* with lithium in liquid ammonia/tetrahydrofuran/*tert*-butanol according to the method of *Ireland*[5] affords, after gas-chromatographic separation, the C_9-homobasketene *(3b)* as volatile crystals (50%).

(4a), M = Rh(F$_3$acac)
(4b), M = Ag$^+$ClO$_4^-$

As expected[6], the tricyclo[4.2.0.0^{2,5}]octane moiety in *(3b)* can be opened by reaction with norbornadiene(trifluoro-2,4-pentanedionato)rhodium in chloroform at 60°C; the isomerization requires one equivalent of the reagent and yields the rhodium complex *(4a)*, which is purified by sublimation (100°C/10^{-2} torr) (87%). In benzene, *(4a)* is stable towards CO (5 atm), and only on addition of silver perchlorate does it split into the silver complex *(4b)* and dicarbonyl(trifluoro-2,4-pentanedionato)rhodium. Treatment of *(4b)* with ammonium nitrate in concentrated aqueous ammonia liberates the title compound *(5)*, which after chromatographic purification (diethylene glycol succinate, 0.5 m, 65°C) is obtained as volatile colorless crystals having a strong odor (26%).

Heating of the [4+4]-cycloadduct *(5)* of benzene and cyclopentadiene to 140°C leads to its complete retrocleavage; however, NMR spectroscopic monitoring of the reaction with stepwise increase in temperature shows that two separate rearrangements precede the decomposition: at 65°C a rapid Cope rearrangement ($t_{1/2}$ = 2 h) leads to the *syn-cis* [2+2]-adduct *(6)*, which can be separated gas chromatographically (diethylene glycol succinate, 0.5 m, 70°C). On prolonged warming at 65°C *(6)* is converted, as a result of reversible opening of the bicyclo[4.2.0]octa-2,4-diene moiety to the eight-membered ring[7], into the *anti-cis* isomer *(7)* (98%, $t_{1/2}$ = *ca.* 24 h). It is *(7)* which subsequently cleaves[2a] at higher temperatures into benzene and cyclopentadiene ($t_{1/2}$ = 35 h at 80°C). The reaction sequence of the retrocleavage of the [4+4]-cycloadduct *(5)* illustrates the energetic advantage of synchronous transition states over a diradical. The latter is obtained only from *(7)* at higher temperature and leads to the decomposition, while it plays no role in the two preceding direct processes.

Table 1. Physical data of the compounds *(2)*, *(3b)*, *(4a)*, *(5)*, *(6)*, *(8)*, *(9)*, and *(10)*. The ^{1}H-NMR spectra were recorded at 90 MHz in $CDCl_3$ [*(4)* and *(6)* in C_6D_6, *(5)* in CCl_4].

(2), m.p. 157°C; ^{1}H-NMR: δ = 6.5—7.3 (m, 8H), 2.17 (AB as doublets, Δ_ν = 24.7 Hz, J = 19.5 Hz, 2H, $COCH_2$), 1.80 (AB, Δ_ν = 16 Hz, J = 13.5 Hz, B-part split, 2H, CH_2); IR (KBr): ν_{CO} = 1700 cm^{-1}

(3b), m.p. 108°C; ^{1}H-NMR: δ = 6.12 (AA'XX' half spectrum, $J+J'$ = 5.4 Hz, J_A = 9.3 Hz, J_X = 0 Hz, 2 olefin-H), 3.1 (m, 4H), 3.0 (m, 2H), 2.6 (m, 2H), 1.48 (AB, Δ_ν = 21.5 Hz, J = 13.2 Hz, B-part as triplets J' = 5.4 Hz, 2H, CH_2); ^{13}C-NMR ($CDCl_3$, 20 MHz): δ = 129.75 (2 olefin-C), 44.83 (2C), 43.80 (2C), 34.70 (2C), 32.75 (1C, CH_2), 32.38 (2C)

(4a), m.p. 142°C; ^{1}H-NMR: δ = 5.97 (AA'XX'-half spectrum, $J+J'$ = 8.1 Hz, J_A = 7.8 Hz, J_X = 0 Hz, H-9,10), 5.57 (s, 1H, F_3acac), 5.17 (AA'XX' half spectrum, $J+J'$ = 8.4 Hz, J_A = 2.4 Hz, J_X = 0, H-7, 8), 4.65 (m, H-3, 4), 3.17 (m, H-1, 6), 2.07 (m, H-2, 5), 1.63 (s, 3H, F_3acac), 1.12 (AB, Δ_ν = 28.5 Hz, J = 11 Hz, A-part as triplets with J' = 4.5 Hz, H-11$_{anti}$, H-11$_{syn}$); MS: m/e = 400 (M^+), 334 ($M^+ - C_5H_6$), 181 ($-F_3$acac), 168 (100%, $RhC_5H_5^+$), 103 (Rh^+), 91 ($C_7H_7^+$)

(5), m.p. 90°C; ^{1}H-NMR: δ = 6.33 (A_2X_2 half spectrum, J = 6 Hz, H-9, 10), 6.20 (A_2X_2 half spectrum, J = 5 Hz, H-7, 8), 5.93 (s, H-3, 4), 2.97 (septet, J = 5 Hz, H-1, 6), 2.4 (m, H-2, 5), 2.09 (AB, Δ_ν = 37.6 Hz, J = 10.5 Hz, B-part as triplets with J' = 4.5 Hz, H-11$_{syn}$, H-11$_{anti}$); ^{13}C-NMR (CCl_4, ext. $CDCl_3$, 20 MHz): δ = 139.51 (2 olefin-C), 137.98 (2 olefin-C), 134.47 (2 olefin-C), 47.90 (C-11), 42.24 (2C), 39.44 (2C)

(6), ^{1}H-NMR: δ = 6.1—5.0 (m, 6 olefin-H), 3.3 (m, 4H), 2.48 (AB, Δ_ν = 47.4 Hz, J = 17.5 Hz, 2H, CH_2)

(8), m.p. 201°C; ^{1}H-NMR: δ = 6.02 (narrow m, 2 olefin-H), 3.5—3.0 (m, 4H), 2.9—2.0 (m, 6H), 1.68 (AB, Δ_ν = 123 Hz, J = 13.5 Hz, B-part as doublets with J' = 8 Hz, 2H, CH_2)

(9), m.p. 213°C; ^{1}H-NMR: δ = 6.07 (AA'XX' half spectrum, 2H), 5.55 (narrow m, 2H), 3.3 (m, 3H), 3.0 (d, J = 1.5 Hz, 2H), 3.1—2.0 (m, 5H)

(10), m.p. 207.5°C; ^{1}H-NMR: δ = 6.42 (AA'XX' half spectrum, 2H), 5.72 (narrow m, 2H), 3.3 (m, 3H), 2.90 (d, J = 1.5 Hz, 2H), 3.0—1.9 (m, 5H)

The *syn-cis* [2+2]-adduct *(6)* had already been postulated by us as an intermediate in the fragmentation of the *as*-homobasketene at *ca.* 180°C[8], since in the presence of an excess of maleic anhydride the addition compound *(8)* was formed. Reaction of the now accessible *(6)* with maleic anhydride confirms our assumption: At room temperature the Diels-Alder product *(9)* is formed (98%), which is converted at 80°C *via* an ene-reaction into *(8)* ($t_{1/2}$ = 15 h). The unusually low activation barrier for the secondary reaction *(9)* → *(8)* is explained in terms of the favorable fixation of the reaction centers in *(9)*. Reaction of *(7)* with maleic anhydride gives the adduct *(10)*.

Molecular Structure of Phe²-TRH, an Analogue of Thyrotropin-Releasing Hormone

By *John J. Stezowski, Claus Bürvenich*, and *Wolfgang Voelter*[*]

X-ray analysis of thyrotropin-releasing hormone (TRH) and analogous compounds has hitherto been impossible owing to the lack of suitable crystals. We have found that Phe²-TRH forms crystals suitable for X-ray analysis. Phe²-TRH is an analogue having a relatively high biological activity[1] and antidepressive action[2].

Figure 1 illustrates the methodological strategy for the synthesis of Phe²-TRH. Crystals of Phe²-TRH were obtained by

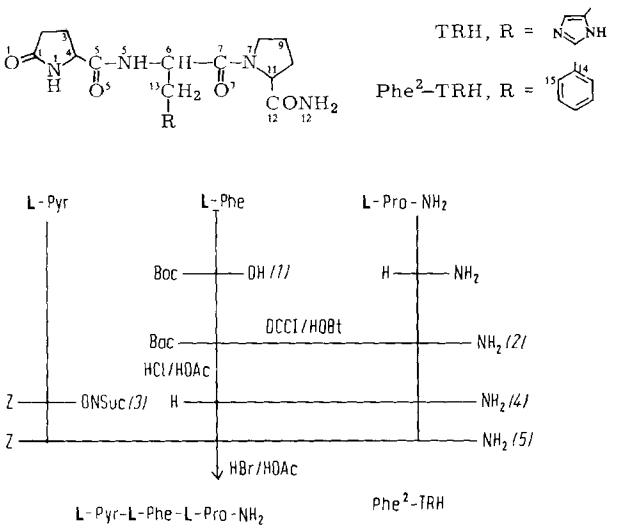

Fig. 1. Schematic diagram of the synthesis of Phe²-TRH. Pyr = pGlu = pyroglutamyl.

slow evaporation of aqueous or 2-propanol solutions; space group $P2_12_12_1$, with 4 Phe²-TRH·H_2O molecules per unit cell, cell constants[3a] at 120 K: $a = 14.831(4)$, $b = 11.440(2)$, $c = 11.448(2)$ Å. The original crystal-structure model[3b] was refined with high-resolution data ($T \approx 120$ K) to $R = 0.044$ (3162 observed reflections).

Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)
Prof. Dr. W. Voelter, Dipl.-Chem. C. Bürvenich
Institut für Organische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen (Germany)

Figure 2 shows the molecular structure of Phe²-TRH. The proline ring is present in two conformations in the crystal.

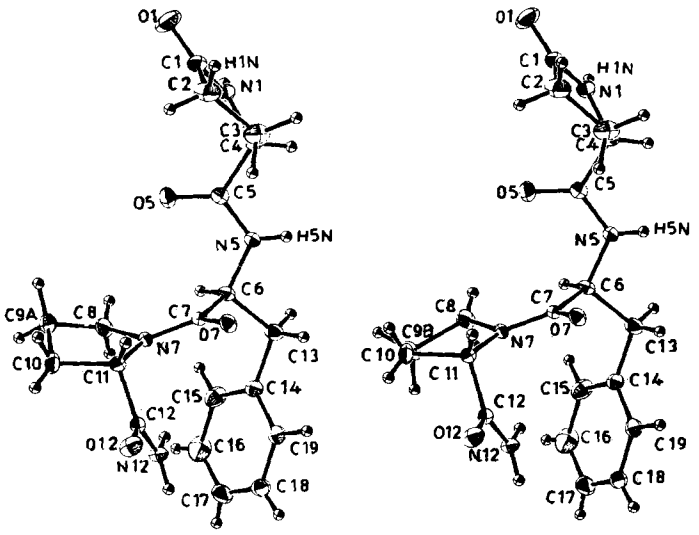

Fig. 2. Molecular structure of Phe²-TRH. The two conformations of the proline ring differ in the disposition of C(9). The rest of the molecule is presented stereoscopically. Dihedral angles: N(1)C(4)C(5)N(5) = 143.8°, N(5)C(6)C(7)N(7) = 132.1°, N(5)C(6)C(13)C(14) = 178.8°, C(6)C(13)C(14)C(15) = 62.5°, N(7)C(11)C(12)N(12) = −24.3°.

The two peptide bonds are *trans*-oriented. The water molecule is bonded *via* one of its protons to O(1) of one Phe²-TRH molecule and *via* its second proton to O(5) of another peptide molecule: its oxygen atom, however, has no acceptor function. H(1N) and H(5N) are bound *via* hydrogen bridges to O(12) of the next molecule. O(7) is coupled *via* a hydrogen bond with H(12N,1); H(12N,2) forms no hydrogen bonds in the crystal.

Experimental

The following amino acids and peptides were synthesized according to methods given in the literature: *(1)* (see Fig. 1)[4], Boc-L-Pro[4], Boc-L-Pro-NH_2[5], L-Pro-NH_2·HCl[6], Z-L-Glu[7a], Z-L-glutamic anhydride[7b], Z-L-Pyr·DCHA[7c], *(3)*[7d].

L-Phe-L-Pro-NH_2 *(4)*: A mixture of *(2)* (30 g) and 1.2 N HCl/HOAc (250 ml) is stirred for 30 min at room temperature. The solvent is then removed in a rotary evaporator and the residue extracted several times with methanol. After removal of the methanol by evaporation *(4)* is crystallized from the remaining oil with methanol/ether; yield 22.08 g (89 %), m. p. 60 °C (decomp.), $[\alpha]_D = -10.95°$ ($c = 1.13$/HOAc).

Z-L-Pyr-L-Phe-L-Pro-NH_2 *(5)*: A mixture of *(3)* (5 g), *(4)*·HCl (4.36 g) and *N*-ethylmorpholine (1.75 ml) is stirred for 24 h at room temperature. The reaction mixture is evaporated to dryness, taken up in ethyl acetate, washed several times with $NaHCO_3$ and water, dried with Na_2SO_4 and crystallized from anhydrous ether; yield 3.41 g (48 %) *(5)*, m. p. 70 °C (decomp.), $[\alpha]_D = -68.88°$ ($c = 1$, MeOH).

Phe²-TRH[8]: A mixture of *(5)* (3 g) and HBr/glacial acetic acid is stirred for 5 min at room temperature; the solvent is then removed and the residue washed several times with methanol. The residue recovered after subsequent evaporation to dryness is taken up in water and treated with ion-exchanger. After filtration the filtrate is concentrated by evaporation and passed through a Sephadex-G10 column and freeze dried.

Spherical Wrapping of a Linear Polyether around a Cation—1,20-Bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane·RbI[**]

By *Gabriela Weber, Wolfram Saenger, Fritz Vögtle*, and *Heinz Sieger*[*]

In addition to crown ethers and three-dimensional cryptands, linear polyethers are being increasingly used for complexing cations[1]. It is remarkable in this context that even 1,2-ethanediol forms crystalline complexes with alkaline earth metal ions[2] and that this property is enhanced by rigid aromatic end groups[1]. Depending upon the chain length of the polyether, various complex structures are obtained in the series of arene-$(OCH_2CH_2)_n$O-arene ligands: ligands with $n = 2$ wrap in a circular fashion around a cation[3], and extension of the ether chain by one or two OCH_2CH_2 units leads to helical structures[4, 5]. Two possible arrangements are conceivable for very long ligands: (i) helical polynuclear complexes could turn out as S-shaped arrangements, with a cation coordinated in each S loop, each cation being bound to an anion for geometrical reasons (see [6]), or (ii) a cation could be spherically wrapped in a long ligand with more than one turn and thus shielded from the anion. The possibility (ii) is actually found in the complex formed from 1,20-bis(8-quinolyloxy)-3,6,9,12,15,18-hexaoxaeicosane *(1)* and RbI.

(1)

Compound *(1)* was obtained by condensation of 8-hydroxyquinoline and heptaethylene glycol in alkaline medium, and the complex with RbI in boiling ethyl acetate/methanol. Synthesis of crystalline complexes with NaSCN, NH_4SCN, KSCN, $Ca(SCN)_2$, and $Ba(SCN)_2$ has so far proved unsuccessful. The ^{1}H-NMR spectrum of *(1)*·RbI does not exhibit any pronounced upfield shift of the α,β-quinoline protons (cf. [7]). Hence it may be deduced that the quinoline rings of *(1)*·RbI are located outside the region of mutual anisotropism.

Slow cooling of *(1)*·RbI in methanol/ethyl acetate yields single crystals (*ca.* $3 \times 1 \times 0.5\ mm^3$), space group C2/c, cell constants $a = 42.17$, $b = 10.80$, $c = 15.95$ Å, $\beta = 100.4°$. The intensities of 4672 independent reflections were measured with a four-circle diffractometer ($Cu_{K\alpha}$). After solving the structure by a combination of direct and Fourier methods, the structural data were refined to $R_w = 9.6\%$ by least-squares methods with anisotropic temperature factors for the heavy atoms and isotropic factors for C, N, O.

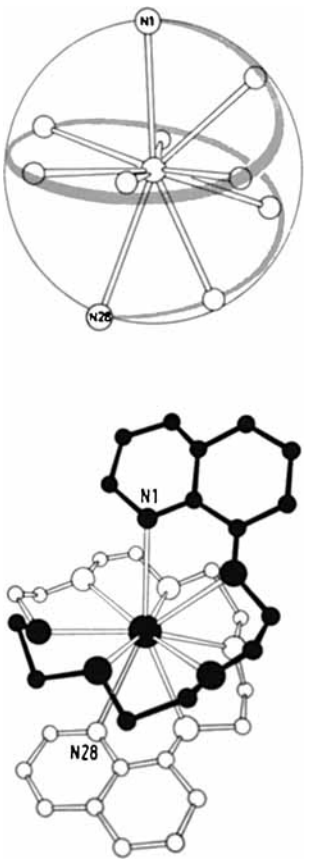

Fig. 1. a) Arrangement of heteroatoms of ligand *(1)* on the coordination sphere of Rb^+; b) structure of complex *(1)*·RbI. Since I^- is not coordinated it has been omitted.
Rb^+...heteroatom distances [Å] for the polar region: N(1), 3.201; N(28), 3.371; O(25), 3.086; for equatorial region: O(4), 2.993; O(7), 3.025; O(10), 3.038; O(13), 2.959; O(16), 2.974; O(19), 3.009; O(22), 3.147 (mean standard deviation ±0.008 Å).

In the complex *(1)*·RbI (Fig. 1), all the heteroatoms lie approximately on the surface of a sphere of radius ≈3 Å. Its poles are occupied by N(1) and N(28), in accord with the results of ^{1}H-NMR studies on the complex in solution. Starting from N(1) the ligand chain runs to the equator of

[**] Structures of Polyether Complexes, Part 7.—Part 6: *G. Weber, W. Saenger*, Acta Crystallogr., in press.

© Verlag Chemie, GmbH, D-6940 Weinheim, 1979 0570-0833/79/0303-0226 $ 02.50/0

the sphere, which it follows, before leaving to reach the other pole at N(28). This description is naturally somewhat idealized. The torsional angles OCCO along the polyether chain lie in the *gauche* region (±60°), whereas the angles CCOC and COCC are *trans*-oriented except for C(3)-O(4)-C(5)-C(6) (126°). +*gauche* and −*gauche* torsional OCCO angles alternate.

The Rb^+ cation is ten-coordinated if the $Rb^+ \cdots N$ and $Rb^+ \cdots O$ contacts of 3.371 and 3.147 Å are included. The ideal van der Waals distances are 2.97 and 2.87 Å, respectively: these values are not attained by any of the Rb...heteroatom contacts. Similar values are known for highly coordinated Rb^+[8], while other $Rb^+ \cdots$polyether complexes with smaller ligands show normal values[3, 4].

Since Rb^+ is completely enclosed by the ligand and thus shielded it cannot interact with I^-. In the unit cell I^- is located in cavities between the "spheres" of *(1)* and Rb^+ and is fixed by weak van der Waals forces only. This is probably the reason for its being twofold disordered.

Procedure

Synthesis of *(1)*: Heptaethylene glycol ditosylate[9] (50 mmol) in benzene/dimethylformamide (1 : 1, 60 ml) is added dropwise to a mixture of 8-hydroxyquinoline (100 mmol) and KOH (100 mmol) in boiling ethanol. After heating for 6 h under reflux, filtration and vacuum distillation of the filtrate, the residual oil is dissolved in $CHCl_3$, extracted several times with dilute caustic soda, washed with H_2O, dried over Na_2SO_4, concentrated to *ca.* 10 ml by distillation in vacuum, and chromatographed on alumina (Woelm, basic, activity I): 15.4 g (53 %) of *(1)*, viscous oil; ^{1}H-NMR ($CDCl_3$): δ = 9.2–9.0 (m, 2H, quinoline), 8.3–8.0 (m, 2H, quinoline), 7.6–7.1 (m, 8H, quinoline), 4.6–4.0 (m, sym, 8H, OCH_2), 3.9—3.6 (m, 20H, OCH_2); MS calc. 580.2785, exp. 580.2790; TLC ($CHCl_3$/ethanol 5 %, silica gel): $R_f = 0.5$.

Synthesis of *(1)*·RbI: *(1)* (0.2 mmol) in ethyl acetate (8 ml) and RbI (0.2 mmol) in methanol (4 ml) are heated together under reflux for ½ h. After cooling, the complex precipitates on addition of light petroleum (50—70 °C) as a viscous oil and is recrystallized from ethyl acetate/methanol: 84 mg (62 %) yellow prisms, m.p. 111—115 °C.

S-Shaped Binuclear Cation Complex of a Linear Polyether: 1,5-Bis{2-[5-(2-nitrophenoxy)-3-oxapentyloxy]-phenoxy}-3-oxapentane·2KSCN[**]

By *Gabriela Weber* and *Wolfram Saenger*[*]

Very long linear polyethers can adopt various arrangements on the coordination sphere of a cation. In contrast to the spherical wrapping of a decadentate ligand around Rb^+[1], the polyether *(1)* is S-shaped in the title compound[2] and binds a K^+SCN^- ion pair in each S-loop.

The complex *(2)*·2KSCN crystallizes from ethyl acetate/methanol as thin platelets, space group C2/c, cell constants $a = 23.184$, $b = 9.051$, $c = 22.235$ Å, $\beta = 114.43°$; m.p. 108—109 °[2]. 3438 diffractometer data were measured by $2\theta/\omega$ scanning with $Cu_{K\alpha}$ radiation up to $2\theta = 125°$. The structure was solved by direct methods and refined to a crystallographically weighted value of $R_w = 5.6$ % by least squares methods. In contrast to ref. [2], no water of crystallization could be detected.

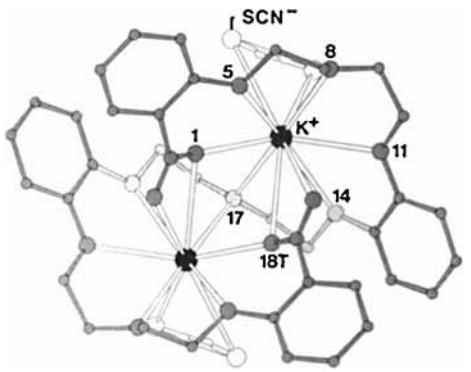

Fig. 1. Structure of the complex *(1)*·2KSCN. The two SCN^- ions are twofold disordered, such that the S and N atoms overlap. Since the C—S and C—N distances are unequal, the SCN^- ion is represented as (N)S—C—C—N(S). $K^+ \cdots$heteroatom distances [Å] for the polar region: O(1T), 3.113; O(18T), 3.180; N, S, 3.387 and 3.256; equatorial region O(5), 3.299; O(8), 2.684; O(11), 2.787; O(14), 2.815; O(17), 2.923.

In the complex *(1)*·2KSCN (Fig. 1) the polyether chain forms one S-loop around each K^+SCN^- ion pair. This arrangement of the ligand *(1)* is stabilized by coordination to K^+; the twofold coordination of O(1) and O(17) is probably the major factor involved. The central atom O(17) lies on a twofold crystallographic axis, *i.e.* the molecule is rotationally symmetric.

The coordination sphere of each K^+ can be divided into equatorial and polar regions. The equator is occupied by the heteroatoms O(1) to O(17) of one S-loop, and the nitro group belonging to the other loop covers one of the poles with O(1T) and O(18T). The other pole is free and can accommodate the SCN^- ion which is disordered for reasons of crystal packing.

[**] Structures of Polyether Complexes, Part 8. We are grateful to Professor *F. Vögtle*, Bonn, for the title compound.—Part 7: [1].

© *Verlag Chemie, GmbH, D-6940 Weinheim, 1979* *0570-0833/79/0303-0227 $ 02.50/0*

The K^+...O distances in the polar region are generally greater than in the equatorial plane. Nevertheless, the distances to O(1) (2.699 Å) and to O(5) (3.299 Å) deviate considerably from the ideal value of 2.87 Å[3] and reveal the inductive effect of the nitro groups. The fact that the bond to O(8) is shorter than that to O(11) and to O(14) complies with the rule[4] that O atoms of aliphatic ethers are more strongly coordinated by cations, owing to their greater electronegativity, than O atoms of aromatic ethers. The relatively long K^+...O(17) distance can be attributed to the double coordination of the two K^+ entities.

The torsional angles along the polyether chain have the generally preferred values[1, 4]. Only the angle C(7)—O(8)—C(9)—C(10) of 74° lies in the *gauche* instead of the *trans* range, probably in order to facilitate better coordination of O(11).

The nitro group is twisted through −42° relative to the phenoxy ring. Rotation through −13° can be explained due to steric repulsion between an O atom of the nitro group and the *ortho* ether oxygen (cf. [5]). The remaining rotation might possibly be attributable to improved coordination of the two nitro oxygen atoms with K^+.

Formation of a binuclear complex from *(1)* and KSCN probably has purely geometrical reasons. The twofold coordination of the terminal nitro group also appears to favor the binuclear complex. *(1)* and Na^+ and K^+ ions gave only 1:2 complexes. On the other hand, an analogous ligand containing 2,6-dimethoxyphenyl in place of *o*-nitrophenoxy groups gives a 1:1 complex with K^+ but can take up the smaller Na^+ ion in the ratio of 1:2[2].

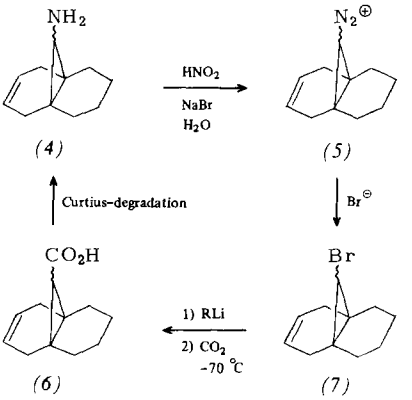
Stereochemistry of Nucleophilic Substitution at Cyclopropanediazonium Ions

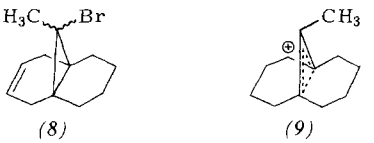
By *Wolfgang Kirmse* and *Theodor Engbert*[*]



According to MO calculations[11], S_N2-substitution with retention of configuration should be possible at small ring compounds. While inversion has been demonstrated in the case of cyclobutyl tosylates[2], cyclopropyl halides and sulfonates usually undergo ring-cleavage with formation of allyl derivatives[3]. We report here on the behavior of cyclopropanediazonium ions in nucleophilic substitution.

Substitution with retention of configuration: The decomposition of *exo*-7-norcaranediazonium ions *(1)* in the presence of sodium bromide yields *exo*-7-bromonorcarane *(3)* as major product[4]. The complete retention of configuration was explained in terms of formation of a partly opened cyclopropyl

(1) *(2)* *(3)*



cation *(2)*[3a, 5] as intermediate. It was also conceivable, however, that a "classical" norcarane cation gives only *exo* products for steric reasons, or that an S_N2-substitution with retention of configuration takes place. We therefore investigated a model in which steric discrimination was essentially inapplicable, but where partly opened intermediates are probable.

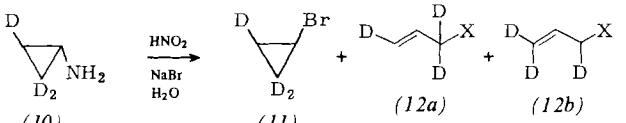
(4) *(5)* *(6)* *(7)*

(a), syn; (b), anti

The deamination of *syn*- and *anti*-11-aminotricyclo-[4.4.1.$0^{1,6}$]undec-3-ene *(4a, b)* in the presence of sodium bromide gave the bromides in high yields [*(7a)* up to 66%, *(7b)* up to 84%] and with 97—99% retention. As experiments in D_2O have shown, the small amounts (1—3%) of inversion products mainly stem from epimerization of the diazonium ions *(5a, b) via* the diazo compound. (In the inverted bromide, 11-H is replaced up to 85% by D, whereas the bromide formed with retention incorporated only 3—7% D.) The configurations of *(4)* and *(7)* were assigned *via* the carboxylic acids *(6)*. Only *(6a)* forms an iodolactone[6].

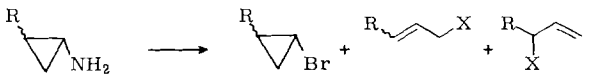
(8) *(9)*

The behavior of the diazonium ions *(5a, b)* corresponds to that of the tertiary bromides *(8)*, which on Ag^+-catalyzed methanolysis also react with predominant retention[7]. The cause of retention of configuration is very probably a partly opened cation. The delocalized structure *(9)*, which is nonplanar at C-11, could be identified by NMR spectroscopy in superacids[8].



Substitution with inversion of configuration: Cyclopropanediazonium ions, whose ring cleavage can proceed unhindered, give only low yields of cyclopropane derivatives. On deamination of (*E*)-[2,2,3-D_3]cyclopropylamine *(10)*[9] in the presence of sodium bromide we obtained 4% [2,2,3-D_3]cyclopropyl bromide *(11)* with 94±2% inversion. The stereochemistry of *(11)* follows from the D-decoupled ^{1}H-NMR spectrum: The coupling constant of the two protons in (*Z*)-*(11)* is 7.1 Hz, in (*E*)-*(11)* 3.8 Hz[9].

The deamination of *cis*-2-methylcyclopropylamine *(13a)* under analogous conditions gave 1.6—1.7% *trans*-1-bromo-2-methylcyclopropane *(14a)*; *cis*-2-methoxymethylcyclopropyl-



[*] Prof. Dr. W. Kirmse, Dr. Th. Engbert
Abteilung für Chemie der Universität
Postfach 102148, D-4630 Bochum 1 (Germany)

amine *(13b)* afforded 8.5% *trans*-1-bromo-2-methoxymethylcyclopropane *(14b)*.

(10) *(11)* *(12a)* *(12b)*

(13) *(14)* *(15)* *(16)*

(a), R = CH_3; *(b)*, R = CH_2OCH_3

The *trans*-amines *(13a,b)* yielded only traces of cyclopropyl bromides. This finding is consistent with a substitution with inversion, which in the case of the *trans*-diazonium ions is sterically hindered by the 2-substituents, so that it can no longer compete with ring cleavage.—The allyl alcohols *(12)*-OH and *(15)*-(OH) are formed stereospecifically *via* disrotation. The corresponding allyl bromides (X = Br) are not configurationally stable.

Our results refute—at least for nitrogen as leaving group—the concept of a retentive S_N2-substitution at the cyclopropane ring. Retention of configuration is only observed when the disrotatory cyclopropyl-allyl rearrangement is initiated, but cannot be led to completion owing to opposing ring strain; in these cases partly opened cyclopropyl cations are probably involved as intermediates. In the case of unconstrained ring cleavage the competing substitution at cyclopropanediazonium ions proceeds with inversion.

Dianion and Tetraanion of Octalene

By *Klaus Müllen, Jean F. M. Oth, Hans-Wilhelm Engels*, and *Emanuel Vogel*[*]

The ^{13}C- and ^1H-NMR spectra of octalene[1] recorded at −150°C reveal the molecule to show π-bond localization in the ground state and to exist in the double bond configuration depicted in formula *(1)*. Octalene is not planar, does not possess any element of symmetry, and is therefore chiral. Moreover, as temperature-dependent NMR studies (between −150 and +140°C) also show, octalene undergoes fast isodynamic processes: at very low temperatures the cyclooctatriene or/and the cyclooctatetraene ring inverts, and above *ca.* 70°C a π-bond shift occurs[2]. The olefinic nature of this potentially aromatic 14π-electron system is readily explained by the inadequacy of the delocalization energy to overcome the strain of flattening the eight-membered rings[3].

(1)

Mono- and polycyclic π-electron systems are subject to far-reaching changes in their π-bonding and geometry on electrochemically or alkali-metal induced reduction to anions[4]. In the case of octalene, the preparation of anionic derivatives appeared particularly attractive since the construction of this $(4n+2)\pi$-system from two $(4n)\pi$-cyclooctatetraene fragments permits various possible charge distributions in the ionic species and thus also various possible structures.

Measurement of the classical polarograms [dimethylformamide, tetra-*n*-butylammonium perchlorate as supporting electrolyte, calomel electrode (SCE), 1 N KCl as reference] shows that octalene can accept four electrons on reduction. Cyclic voltammetry and potential jump experiments also indicate that the first electron is transferred reversibly at $E_{1/2} = -1.67$ V and the three other electrons in a joint wave at $E_{1/2} = -1.70$ V. This second wave corresponds to chemically reversible processes since no secondary reactions are observed under strictly aprotic conditions; however, the electron transfers themselves are irreversible in that the reoxidation potentials are distinctly shifted towards more positive values relative to the reduction potentials. The electrochemical results[5] suggested that octalene *(1)* should form a radical anion $(1)^{\cdot-}$, a dianion *(2)*, a radical trianion $(2)^{\cdot-}$, and a tetraanion *(3)* on reduction by a metal.

We have therefore exposed octalene (in [D_8]tetrahydrofuran) to the action of lithium for defined periods of time and carefully checked the progress of reduction by recording the ^1H- and ^{13}C-NMR and ESR spectra. After brief contact, a radical anion can be detected in the solution which has turned from pale yellow to red. As shown by the ^1H- and ^{13}C-NMR spectra, the neutral and the radical species present are accompanied by a new diamagnetic compound to be regarded as the dianion *(2)*. The reduction can be interrupted at a stage where this ion is present exclusively. Figure 1 shows the relevant ^1H- and ^{13}C-NMR spectra (see also Table 1). The four signals in the ^{13}C-NMR spectrum of the dianion

[a] ^{13}C-NMR averaged spectrum [2] owing to fast ring inversion(s) at −80 °C. [b] Owing to the sparing solubility of the tetraanion *(3)* the resonance of the quaternary carbon atoms could only be observed at a low signal-to-noise ratio (2:1) and is therefore unreliable.

suggest D_{2h} molecular symmetry and hence structure *(2a)* with π-bond delocalization. In view of the total number of π-electrons ($14+2=16=4n$), structure *(2b)* containing a cyclooctatetraene dianion fragment would appear more likely. In such a case, the observed ^{13}C-NMR can only be rationalized by assuming a fast charge transfer coupled with a π-bond shift [*(2b)* ⇌ *(2b)*][6].

(2a) *(2b)* *(2b)*

Further reduction transforms the dianion *(2)* into a new diamagnetic anion which, like *(2)*, exhibits four signals in the ^{13}C-NMR spectrum (no ESR signals appear in the case of this reduction) and must therefore also have D_{2h} symmetry. After prolonged contact between the metal and the solution, which has meanwhile become dark brown, only the signals of this species are observed. Thus, it is reasonable to assume that the tetraanion *(3)* with a delocalized 18π-system is present.

(3)

Identification of the diamagnetic ions as dianion and tetraanion of octalene follows from the specific course of the reduction (*i.e.* the appearance and disappearance of the individual species), from the characteristics of the NMR spectra, and also from reoxidation experiments. Oxidation of the partially or completely reduced solution [*(2)* or *(3)*, respectively] with oxygen gave octalene as the sole identifiable product.

On going from *(1)* to *(2)* and *(3)*, the centroid of the ^{13}C-NMR signals underwent an upfield shift as expected from the known correlation of ^{13}C-NMR chemical shifts and π-charge densities[7]. Moreover, the observed sequence of assigned signals can be predicted on the basis of local π-charge densities. In contrast to ^{13}C-NMR chemical shifts, which mainly reflect the charge densities, the ^{1}H-NMR chemical shifts are also affected by field-induced ring currents. The surprisingly small upfield shift of the centroids of the ^{1}H-NMR signals seen on going from *(1)* to *(2)* ($\Delta\langle\delta\rangle = 0.41$) and from *(2)* to *(3)* ($\Delta\langle\delta\rangle = 0.07$) indeed suggests that the charge-induced upfield shift is largely compensated by the effect of a diamagnetic ring current.

In the $(4n+2)\pi$-system *(3)* the existence of a diamagnetic ring current complies with expectation, while this applies to *(2)* only if the anion has structure *(2b)* with a fast charge shift [structure *(2a)* would show a paramagnetic ring current[8]]. Attempts to elucidate this structural problem are currently in progress.

The ^{13}C- and ^{1}H-NMR spectra recorded during the reduction provide information about the relative energies of the octalene anions. When the ESR signals of the radical anion $(1)^{\cdot-}$ has reached maximum intensity, the ^{13}C- and ^{1}H-NMR spectra are each a superposition of the individual spectra of *(1)* and *(2)* (with only minimal line broadening). Hence it follows that the radical anion is extensively disproportionated and that the rate constants of all the bimolecular electron transfer reactions are slow on the NMR time scale. Similar arguments apply to the disproportionation of the radical trianion $(2)^{\cdot-}$ into *(2)* and *(3)*.

The fact that a relatively small molecule like octalene can accept four electrons at low (*i.e.* not very negative) potentials is surprising in view of the Coulomb forces involved[9]. According to the results described, the energy gain from delocalization of charges and π-bonds in the tetraanion *(3)* is so large that it overcompensates both the electrostatic energy and the strain energy associated with flattening of the molecule[2].

The new bicyclic $(4n+2)\pi$-species *(3)*, which is stable for several days at room temperature (in tetrahydrofuran with exclusion of air), can be regarded as an analogue of naphthalene: like the latter, it possesses a perimeter with π-bond delocalization and consists formally of two annelated $(4n+2)\pi$-fragments.

[8] On the basis of the ^{1}H-NMR chemical shifts of cyclooctatetraene and its dianion, an upfield shift of 0.05 would be predicted for the centroid of the signals of *(2)* [as structure *(2b)*] relative to *(1)*.
[9] A similar situation is encountered in the reduction of biscyclooctatetraenyl [*J. F. M. Oth, K. Müllen*, unpublished; see also *L. A. Paquette, G. D. Ewing, S. G. Traynor*, J. Am. Chem. Soc. *98*, 279 (1976)] during the course of which we were able to prepare the dianion and tetraanion (as the lithium salts) and to characterize them by ^{1}H-NMR and ^{13}C-NMR. In this molecule, which is suitable as a reference system for the understanding of the reduction of octalene [5], the Coulomb forces operative on formation of the tetraanion are less serious.

Stable Coordination Compounds of "Thiazyl Fluoride": Structure of $[Co(NSF)_6]^{2+}$ in the Crystal[**]

By *Bruno Buss, Peter G. Jones, Rüdiger Mews, Mathias Noltemeyer*, and *George M. Sheldrick*[*]

The simplest nitrogen-sulfur-fluorine compound, the monomeric "thiazyl fluoride" *(1)* is unstable at room temperature[1]. Stabilization of the molecule can be achieved, however, by incorporation as ligand in transition metal complexes:

$$\underset{(1)}{6\,NSF} + \underset{(2)}{[M(SO_2)_x](AsF_6)_2} \xrightarrow[-SO_2]{} \underset{\substack{(3a),\ M=Co\\(3b),\ M=Ni}}{[M(NSF)_6](AsF_6)_2}$$

The hexakis(thiazyl fluoride) complexes of Co^{II} and Ni^{II} are formed in almost quantitative yield on reaction of the hexafluoroarsenates *(2)* with an excess of NSF in liquid SO_2 below -20 °C. In the crystalline state the salts *(3)* are stable in dry glass vessels at room temperature, whereas in solution ligand-exchange takes place:

$$[M(NSF)_6]^{2+} + x\,SO_2 \rightleftharpoons [M(NSF)_{6-x}(SO_2)_x]^{2+} + x\,NSF$$
(4a), M = Co
(4b), M = Ni

The isolable salts then have a composition with $0 \le x \le 1$ [*(4a)*: $\nu_{as}(SO) = 1326$, $\nu_s(SO) = 1155\ cm^{-1}$; *(4b)*: $\nu_{as}(SO) = 1327$, $\nu_s(SO) = 1161\ cm^{-1}$].

The IR spectra of the complexes *(3a)* and *(3b)* show a strong shift of the SN stretching vibration to higher wave numbers; ν_{SF} also increases:

	ν_{SN} [cm^{-1}]	ν_{SF} [cm^{-1}]	d_{SN} [Å]	d_{SF} [Å]	∢NSF [°]
N≡S—F (Gas)	1361	641	1.446	1.646	116.5 [a]
$[Co(NSF)_6]^{2+}$	1429	655	1.399(12)	1.569(12)	115.0(7) [b]
$[Ni(NSF)_6]^{2+}$	1438	655	—	—	—

[a] Cf. [2]; [b] mean values.

The X-ray structure analysis of *(3a)* also indicates an increase in SN and SF bond strength. The central atom [on the special position (0, 0, 0)] is octahedrally coordinated; the Co—N bond length (mean value 2.093(11) Å) approximates to that in $[Co(NH_3)_6]^{2+}$ (2.114(9) Å)[3]. The NSF angle changes only slightly on formation of the complex; noteworthy is the pronounced shortening of the SF and SN bonds: *(3a)* shows the shortest SN bond so far recorded! The mean CoNS angle is 170.8(10)°. As can be seen from Figure 1, the S- and N-atoms are almost isotropic, although the F-atom vibrates anisotropically. This would indicate that appreciable librational shortening is to be expected only in the SF bond.

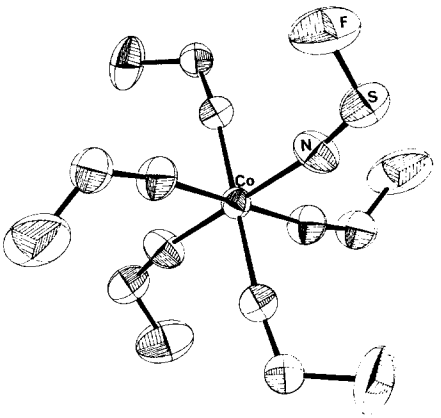

Fig. 1. Structure of the cation $Co(NSF)_6^{2+}$ in the salt *(3a)*, $M_r = 827.17$, monoclinic, $P2_1/n$, $a = 13.105(9)$, $b = 9.201(7)$, $c = 9.366(6)$ Å, $\beta = 90.43(4)°$, $V = 1129$ Å^3, $Z = 2$, $\rho_{calc} = 2.432$ g cm^{-3}, $\mu = 43$ cm^{-1} ($Mo_{K\alpha}$). Structure determination from diffractometer data by direct methods. Refinement, with structure factors of 1102 reflections corrected for absorption [$F > 4\sigma(F)$], to a current R value of 0.083.

Experimental

5 ml of SO_2 and a 10—20 % excess of NSF are condensed into 1—2 g (2—4 mmol) of the corresponding SO_2-complex *(2)*[4] at -196 °C. After stirring for 2—3 hours at -20 °C the reaction mixture is filtered and solvent and excess ligand reagent removed from the filtrate by evaporation. There remain the analytically pure products.

Facile Synthesis of Cyclopropylalkadienes[**]

By *Manfred Schneider* and *Angelika Rau*[*]

In contrast to the synthesis of cyclopropylalkenes there are only few methods known for the preparation of cyclopropylalkadienes. Their synthesis is of interest in connection with

Dictyopterene B Dictyopterene D Dictyopterene D'

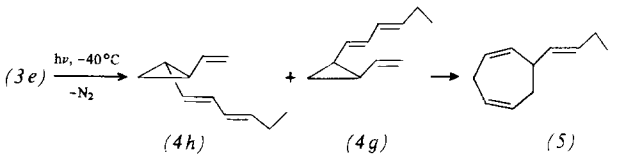
our search for simple routes to constituents of marine brown algae, *e.g.* the dictyopterenes B, D, and D′ (=ectocarpene)[1].

Cyclopropanizations of 1,3,5-trienes are of little synthetic value, since multiple additions and poor regioselectivity lead to mixtures and therefore small yields[2]. According to frontier orbital considerations, however, 1,3-dipolar cycloadditions of diazo compounds *(1)* to 1,3,5-trienes *(2)* should occur regiospecifically at the terminal double bonds of *(2)* with formation of 1-pyrazolines *(3)*. Their thermal or photochemical decomposition would produce the desired cyclopropylalkadienes *(4)* without side reactions.



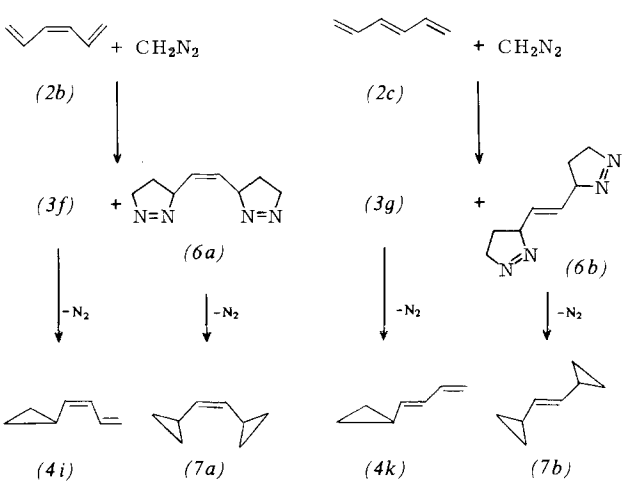
(1) *(2)* *cis/trans-(3)*

(4)

Indeed, the reactions of diazo compounds with (*E*,*E*)-1,3,5-octatriene *(2a)*[3] and the (*Z*)- and (*E*)-1,3,5-hexatrienes *(2b)* and *(2c)*[4] do in fact give the expected 1-pyrazolines *(3)* in satisfactory yields (Table 1). Similarly to other vinyl-substituted 1-pyrazolines[5], decompositions of *(3)* lead exclusively to the desired cyclopropylalkadienes *(4)* in almost quantitative yields (Table 1)[6]. Isolation and purification of the 1-pyrazolines *(3)* is not absolutely necessary; in all cases, photolysis or thermolysis of the crude products suffices. Since both the diazo and the triene components can be synthesized in great variety, the method provides access to a large number of different cyclopropylalkadienes.

Low-temperature photolysis of *(3e)* affords the *cis*- and *trans*-1-(*trans*-1,*trans*-3-hexadienyl)-2-vinylcyclopropanes *(4g)* and *(4h)*, respectively, in almost quantitative yield (isomeric ratio, see Table 1). Whereas *(4h)* is stable at room temperature, *(4g)* rapidly rearranges under these conditions *via* a $[_{\sigma}2_s + _{\pi}2_s + _{\pi}2_s]$ Cope rearrangement into 6-(*trans*-1-butenyl)-1,4-cycloheptadiene *(5)*.

Only *(4h)* and *(5)* are therefore isolated in the thermolysis of *(3e)*, which, similarly to 3,5-divinyl-1-pyrazolines[5], is already detectable at room temperature. *(4h)*, *(4g)*, and *(5)* are identical—apart from the configuration of the double bond in the side-chain—with the dictyopterenes B, D, D′ (=ectocarpene).



(4h) *(4g)* *(5)*

Two terminal double bonds are available for 1,3-dipolar cycloadditions of diazo compounds to *(2b)* or *(2c)*. However, the reaction of diazomethane with *(2b)* and *(2c)* in a 1:1 molar ratio affords only the isomeric 3-butadienyl-1-pyrazolines *(3f)* and *(3g)*, respectively, which decompose to the (*Z*)- and (*E*)-cyclopropylbutadienes *(4i)* and *(4k)*, respectively. Use of diazomethane and trienes in the molar ratio 2:1 does not only lead to *(3f)* and *(3g)* but also to *ca.* 15% *(6a)* and *(6b)*, respectively, from which the (*Z*)- and (*E*)-1,2-dicyclopropylethenes *(7a)* and *(7b)* are readily obtainable.

Table 1. Cyclopropylalkadienes *(4)* from diazo compounds *(1)* and 1,3,5-trienes *(2)*; intermediates: 1-pyrazoline *(3)*; *(2a)*: (*E*,*E*)-1,3,5-octatriene; *(2b)*: (*Z*)-1,3,5-hexatriene; *(2c)*: (*E*)-1,3,5-hexatriene.

General Procedure

The 1,3,5-triene *(2)* (25 mmol) is treated with *ca.* 50 mmol of the diazo compound *(1)* (dissolved in a minimum amount of ether, or as neat substance). The so obtained yellow to deep-red mixtures are stored at room temperature (on using 3-diazo-1-propene at +4°C) until completely colorless (8 h to 4 d depending on the reactivity of the diazo compound). The mixture is then taken up in *n*-pentane and the solution washed with water and dried over Na_2SO_4. After removal of solvents in a rotary evaporator at 0°C the remaining crude 1-pyrazolines *(3)* are photolyzed, without further purification, in a NORMAG photochemical reactor (Lamp: Hanau TQ150 or TQ718, pyrex filter, 18°C, 2—3 h) or pyrolyzed in sealed tubes (oil bath, 140°C, ca. 15 h). The products *(4)* are purified by conventional or trap-trap-distillation.

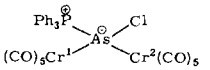
Stabilization of an Arsanediylphosphorane[**]

By *Joachim von Seyerl* and *Gottfried Huttner*[*]

Arsinidene complexes[1] contain a coordinatively unsaturated nitrene-homologous arsanediyl fragment as bridging ligand between two transition metal centers. Though the electron deficit at the trigonal-planar coordinated arsenic atom is largely compensated by back-bonding from the lone pairs of the metal atoms, attack at As by Lewis bases is still possible:



(1) *(2)*, B = PPh_3

UV: 16840 cm^{-1} (ε = 14000) UV: 26180 cm^{-1} (ε = 6300)

B = R_3N, R_3P, R_3As, R_2O, R_2CO

With triphenylphosphane as base (B) the equilibrium of adduct formation is shifted to the right, even at 20°C, while with weak nucleophiles such as esters or ketones the addition to *(1)* is easily reversed and the adduct consequently cannot be isolated at room temperature. In the case of the triphenylphosphane adduct a single-crystal structure determination[2] confirmed the formation of the addition compounds *(2)* and thus provided the first evidence for the existence of an arsanediylphosphorane ligand.

Bond lengths [pm]		Bond angles [°]	
As—Cr^1	246.6(2)	P—As—Cl	89.2(1)
As—Cr^2	249.9(2)	P—As—Cr^1	109.9(1)
As—P	240.1(2)	P—As—Cr^2	113.1(1)
As—Cl	225.6(2)	Cr^1—As—Cr^2	126.9(1)
Cr—C_{ax}	185.5(1)	Cl—As—Cr^1	102.9(1)
Cr—C_{eq}	190.7(1)	Cl—As—Cr^2	107.3(1)
P—C_{Ph}	180.5(1)	C—P—C	105.8—108.7(4)
		C—P—As	108.7—113.3(3)

The bond lengths in *(2)*, B = PPh_3, are consistent with a mesoionic formulation for the complex: The P—As bond length agrees very nearly with the sum of the covalent radii[3a], thus indicating the presence of a highly positive partial charge at the phosphonium center. This is further supported by the short P—C_{Ph} bond lengths and the large CPC angle[3b].

The positive partial charge on the phosphorus is confirmed by the ^{31}P-NMR signal, which, at δ = 11.8 (rel. H_3PO_4 ext.) shows a downfield shift compared to the signal of PPh_3 at δ = −7, as is characteristic for phosphonium salts[4a] and ylides[4b]. The corresponding negative charge appears to be essentially localized on the arsenic atom, since the Cr—C_{CO} bond lengths are only marginally shorter (189.7 pm) than in $Cr(CO)_6$ (190.9 pm)[5]. A small charge transfer is observed only for the axial carbonyl groups, whose Cr—C distances are shorter by about 5 pm than those in the equatorial groups.

The As—Cr bond lengths (mean length 248.2 pm) correspond with those of bonds typically found in carbonylchromium complexes containing arsenide-[6a] or arsane-[6b] ligands. The three-center 4π-system Cr···As···Cr of complexes of type *(1)* ($[Cr(CO)_5]_2AsPh$: As—Cr 238 pm)[1b] is no longer present in the adducts *(2)*; consequently, the characteristic absorption band for this system (*(1)*: 16840 cm^{-1}) is missing in the electron spectrum of *(2)*, whose longest wavelength absorption is observed at 26180 cm^{-1}.

Adduct formation is therefore recognized by a change in color, associated with the disappearance of the long-wave band of the arsinidene complex. We have been able to demonstrate spectroscopically that all the previously described phosphinidene-, arsinidene-, and stibinidene-complexes[1, 7] form analogous adducts according to *(1)*⇌*(2)*, even though in several cases the equilibrium lies well on the side of the starting complex even at −60°C. This reactivity has its parallel in the chemistry of the carbene complexes, where the coordinatively unsaturated carbene carbon atom is capable of ylide formation with phosphanes and amines[8].

Experimental

All operations must be carried out in anhydrous solvents under nitrogen.

A solution of triphenylphosphane (200 mg, 0.76 mmol) in CH_2Cl_2 (10 ml) is added dropwise to a solution of $ClAs[Cr(CO)_5]_2$ (300 mg, 0.6 mmol)[1c] in CH_2Cl_2 (20 ml) until the intense blue color has disappeared. After removal of solvent the residue is taken up in toluene and filtered through 2 cm of silica gel (Merck, particle size 0.063—0.200 mm, column: 0.5 × 10 cm). The eluate is evaporated and the residue recrystallized from dichloromethane in the cold. The orange crystals of *(2)*·CH_2Cl_2 already lose CH_2Cl_2 at 20°C; after drying, 400 mg (83 %) of analytically pure $Ph_3P(Cl)As[Cr(CO)_5]_2$,

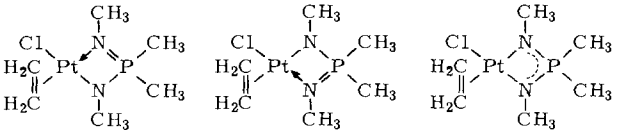
Synthesis of a Zeise Salt Derivative with a Phosphorus-Nitrogen Ylide as Chelate Ligand[**]



By *Otto J. Scherer* and *Andreas Nahrstedt*[*]

If we imagine a chloride ligand of Zeise's salt $K[PtCl_3(C_2H_4)]$ to be replaced by the aminoiminophosphorane ligand $[(CH_3)_2P(NCH_3)_2]^-$, then ring closure and elimination of KCl should lead to a type of complex in which the chelate ligand system could assume the function of the cation. This structure can indeed by accomplished starting from the lithium amide derivative *(1)*, according to

$$(CH_3)_2P(NCH_3)NCH_3Li \xrightarrow[-\,LiCl,\,-\,KCl]{K[PtCl_3(C_2H_4)]} [Cl(C_2H_4)Pt\{(NCH_3)_2P(CH_3)_2\}]$$

(1) *(2)*

The product *(2)* forms yellow crystals which are insoluble in pentane and hexane, and moderately soluble in ether and benzene. Its structure in solution[1] can be interpreted in terms of the resonance forms *(2a)*—*(2c)*.

(2a) *(2b)* *(2c)*

A mixture of *(2a)* and *(2b)* should be distinguishable by NMR spectroscopy, unless the two forms rapidly interconvert at room temperature, which would lead to structure *(2c)*. DNMR studies in deuterated toluene show only one modification of the original signal pattern down to −80°C. Below −30°C the rotation of the ethylene ligand becomes measurably slow. Worthy of note is the unusually large upfield shift of one CH_3N signal which we tentatively assign, on the basis of J_{PtNCH} reference data[2], to the chelate moiety bonded in the *trans* position relative to C_2H_4 (ligand with lower *trans* influence)[3]. Comparison of *(2)* with the related six-membered ring chelate system $Pt[(NCH_3)P(CH_3)_2NC(C_6H_5)(NCH_3)]_2$[4] shows a distinct downfield shift of $\delta(^{31}P)$ for the former compound; $^2J_{PtP}$ is almost three times as large (*(2)*, 259 Hz; six-membered ring chelate, *ca.* 90 Hz[4]). The slight difference in the coupling constants $^3J_{PH}$ (Table 1)[5] suggests structure *(2c)*.

Procedure

$(CH_3)_2P(NCH_3)NCH_3H$[6] (180 mg, 1.5 mmol), dissolved in benzene (20 ml) (25-ml centrifuge tube, N_2 atmosphere) is metalated at 10°C with an equimolar amount of n-C_4H_9Li/hexane and warmed to 55°C for 2 h. Solid pulverized $K[PtCl_3(C_2H_4)]$ (276 mg, 0.75 mmol) is added at room temperature and the mixture is stirred in the sealed centrifuge tube for 90 min. The suspension is centrifuged, the residue washed twice with benzene (2 × 20 ml), centrifuged once more, and the combined benzene solutions evaporated down in an oil pump vacuum. Yield: 205 mg of crude product which is washed with pentane (15 ml), centrifuged, and recrystallized from ether (20 ml) at −78°C to give 85 mg of *(2)* (30%); decomposes above *ca.* 85°C.

Table 1. NMR data of compound *(2)*.

PCH_3	$\delta(^1H)$, J [Hz] [a] NCH_3		C_2H_4	$\delta(^{31}P)$, J [Hz] [b]

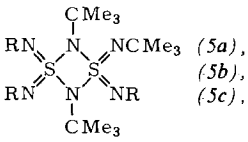
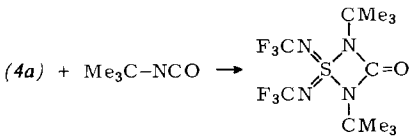
Cyclodiaza-λ^6-thianes—Syntheses and Structures[**]



By *Frank-Michael Tesky, Rüdiger Mews*, and *Bernt Krebs*[*]

Iminosulfur compounds of the "Y-triene" type $(RN{=})_3S$, with $R = SiMe_3$ *(1)*[1a] or CMe_3 *(2)*[1b] are stable at room temperature, whereas the derivatives *(3)* prepared from *(2)* by reaction with perfluoroalkyl isocyanates decompose within a short time. Thus *(3a)*—*(3c)* disproportionate, regenerating *(2)* and giving the highly reactive bis(perfluoroalkyl) derivatives *(4)* which cannot be isolated but immediately react with *(3)* present to give the cyclodiaza-λ^6-thianes *(5a)*—*(5c)*. Exceptionally, compound *(3d)* is stable.

$$(Me_3CN{=})_3S + R{-}NCO \longrightarrow RN{=}S(=NCMe_3)_2 + Me_3C{-}NCO$$
(2) *(3a-d)*, R = CF_3, C_2F_5, C_3F_7, i-C_3F_7



$$2\,(3) \longrightarrow (2) + \{Me_3CN{=}S(=NR)_2\}\ (4)$$

$+(3)\downarrow$

(5a), R = CF_3, m. p. 89 °C
(5b), R = C_2F_5, m. p. 91 °C
(5c), R = C_3F_7, m. p. 105 °C

The intermediate *(4)* can be detected by trapping reactions[2], *e.g.*:

(6), m. p. 77 °C

No structure determinations have hitherto been reported for cyclodiaza-λ^6-thianes[3]. Our studies on *(5b)* show the S_2N_2 skeleton to be nonplanar.

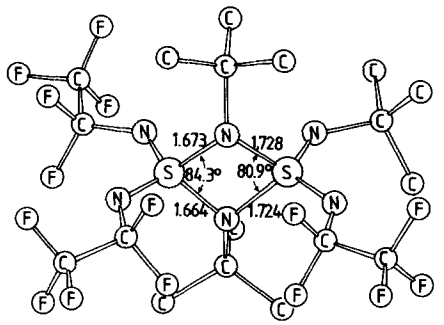


Fig. 1. Molecular structure of cyclodiaza-λ^6-thiane *(5b)* in the crystal with bond lengths and angles in the ring (σ = 0.007 Å and 0.3°).

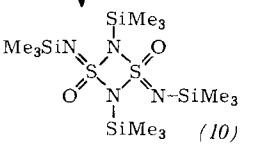
[*] Priv.-Doz. Dr. R. Mews, Dipl.-Chem. F. M. Tesky
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)
Prof. Dr. B. Krebs
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Compound *(5b)* forms monoclinic crystals ($P2_1/c$, $a = 10.802(3)$, $b = 16.501(3)$, $c = 18.948(4)$ Å, $\beta = 120.28(4)°$, $Z = 4$). X-Ray structure analysis ($R = 6.5\,\%$) revealed a nonplanar S_2N_2 ring with an SNS angle of 95.7(3)° and transannular S...S and N...N distances of 2.517(3) and 2.240(7) Å. The deviations of the ring S and N atoms from the averaged plane of the ring are +0.10 and −0.10 Å, respectively. Exocyclic bond lengths: 1.469(6)—1.532(7) Å, corresponding SNC angles: 125.4(6)—130.9(6)°.

The geometry of the S_2N_2 ring appears to be strongly dependent upon the nature of the ligand: unlike *(5b)*, the ring in the 1,3-dioxotetrakis(trimethylsilyl) derivative *(10)* is completely planar (cf. Fig. 2). Compound *(10)* is readily accessible from *(1)* and the perfluoroalkyl-*N*-sulfinylamine i-C_3F_7NSO:

$$2\,(1) + 2\,i\text{-}C_3F_7{-}NSO \longrightarrow 2\left\{\begin{array}{l} Me_3SiN{=}S(=O){-}N(SiMe_3){-}S{=}NC_3F_7 \\ \text{(7)} \end{array}\right\}$$

$$\longrightarrow 2\,(Me_3SiN{=})_2S{=}O\ (8) + 2\,Me_3SiN{=}S{=}NC_3F_7\ (9)$$

(10)

Judging by the isolable intermediate and by-product *(8)*[4] and *(9)*, this reaction should proceed *via* the oxadithiazetidine *(7)*.

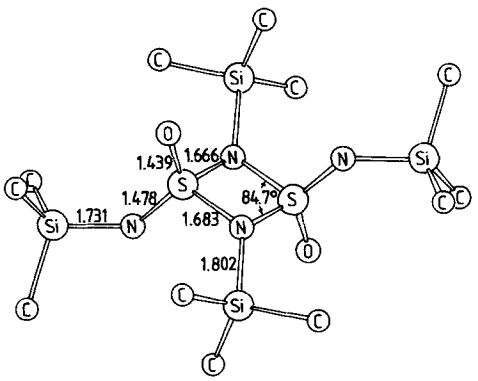


Fig. 2. Molecular structure of cyclodiaza-λ^6-thiane *(10)* in the crystal with bond lengths and angles (σ = 0.002 Å and 0.1°).

In crystalline *(10)* ($I4_1/a$ at −120 °C: $a = 20.231(4)$, $c = 12.199(3)$ Å, $Z = 8$; R factor for the structure determination performed at −120 °C: 3.0 %) the centrosymmetric molecule shows a planar S_2N_2 ring (S...S 2.477(1), N...N 2.257(4) Å. As in *(5b)*, the ring N atoms are pyramidally configurated. Other bond angles: $N_{exocycl.}$—S—O 120.8(1), S—$N_{exocycl.}$—Si 135.2(1)°.

Procedure

2,4-Bis(*tert*-butyl)-1-(*tert*-butylimino)-1,3,3-tris(pentafluoroethylimino)cyclodiaza-λ^6-thiane *(5b)*: Perfluoroethyl iso-

© *Verlag Chemie, GmbH, D-6940 Weinheim, 1979* *0570-0833/79/0303-0235 $ 02.50/0*

cyanate (1.9 g, 9.0 mmol) is condensed into a solution of *(2)* (1.0 g, 4.1 mmol) in diethyl ether (7 ml) at −196 °C. The temperature is allowed to rise from −50 °C to room temperature within 18 h, stirring is continued for 24 h, and the solvent and volatile products are removed *in vacuo*. The residue is dissolved in dichloromethane; on cooling to 0 °C, compound *(5b)* crystallizes (0.375 g, 27 %). ^{1}H-NMR: $\delta_{=NC(CH_3)_3} = +1.49$ (s), $\delta_{>NC(CH_3)_3} = +1.64$ (s). ^{19}F-NMR: $\delta_{CF_3} = -87.28$, −87.45, −87.67 (1:1:1), $\delta_{CF_2} = -85.86$, −88.33 (1:2).

1,3-Dioxo-2,4-bis(trimethylsilyl)-1,3-bis(trimethylsilylimino)cyclodiaza-λ^6-thiane *(10)*: Reaction of *(1)* (2.93 g, 10 mmol) with *i*-C_3F_7NSO (4.62 g, 20 mmol) in diethyl ether (7 ml) at room temperature gives, after three days' stirring, compound *(9)* (2.6 g, 86 %), b. p. 130 °C, and *(10)* (1.0 g, 23 %), m. p. 86 °C. Compound *(10)* is purified by recrystallization from pentane. ^{1}H-NMR: $\delta_{=NSi(CH_3)_3} = +0.21$, $\delta_{>NSi(CH_3)_3} = +0.415$; MS: $m/e = 444$ (18 %, M^+).

BOOK REVIEWS

The Chemistry of Cyclo-octatetraene and Its Derivatives. By *G. I. Fray* and *R. G. Saxton*. Cambridge University Press. Cambridge 1978. x, 492 pp., bound, £ 30.00.

Interest in cyclooctatetraene and its derivatives has been increasing steadily since the discovery and development of a catalytic synthesis by *W. Reppe* and co-workers in 1940. Although a number of reviews on various aspects of COT chemistry exist, there has been a need for a standard reference work to up-date the slim volume by *G. Schröder* which was first published in 1965. This need has now been admirably filled by *Fray* and *Saxton*'s book which certainly belongs in every chemical library. In view of the price it is doubtful, however, whether many individuals will purchase their own private copy.

Two relatively short chapters on the chemistry of cyclooctatetraene and substituted cyclooctatetraenes are followed by a mammoth chapter on "Further reactions of compounds derived from cyclooctatetraenes" in which the authors discuss the chemistry of such directly related species as semibullvalene, cyclooctatriene, 9-oxabicyclo[6.1.0]nona-2,4,6-triene and tricyclo[4.2.2.0^{2,5}]deca-3,6-diene. The book is rounded-off by a 50 page appendix which is referred to both in the text and in the index and which takes the literature coverage up to the end of 1976. The subject matter is well organized and both organometallic as well as organic aspects are discussed in detail. The lay-out makes it easy to find the relevant information while at the same time encouraging the reader to browse through related material.

P. W. Jolly [NB 446 IE]

Atlas of Metal-Liquid Equilibria in Aqueous Solutions. By *J. Kragten*. Ellis Horwood Ltd. and John Wiley & Sons, New York—London—Sydney—Toronto 1978. 1st Edit., 781 pp., numerous illustrations, bound, £ 35.00.

The book is concerned not with complexation equilibria in general but specifically with the heterogeneous equilibria set up when air-(oxygen and carbon dioxide)-saturated suspensions of sparingly soluble hydroxides, oxides, and carbonates of metals are treated with complexing agents in various concentrations. A total of 600 combinations of 45 metal ions and 29 inorganic and organic ligands are considered.

The work consists primarily of graphic representations from which the solubility of the precipitates in solutions of the complexing agent in the pH range 1 to 14 can readily be seen, as can the (reciprocal) amount of the non-coordinated metal ions present in the solutions. Only 25 pages are devoted to essential theoretical explanations. All the curves are computer-plotted with the aid of a suitable program on the basis of complexation constants and solubility products determined from other studies. In view of the general dependence of equilibrium constants on solution partners and that of solubility products on precipitation conditions, the data reported should be regarded merely as orientational aids.

This well produced book will be of interest mainly to readers involved in theoretical analytical chemistry. The more practically biased chemist could consult it if he wishes to prevent precipitation of metals from solutions of their salts.

Fritz Seel [NB 441 IE]

Verordnung über gefährliche Arbeitsstoffe. Vol. 2: Technische Regeln (TRgA) (Regulations on Dangerous Materials. Vol. 2: Technical Rules). By *E. Quellmalz*. Weka-Verlag, Kissing 1977. 1st edit., 309 pp., br., DM 36.00.

The subject of this book, by the fact that the author is experienced in industrial safety, might lead one at first to suppose it to be a reference book. Even a quick skim, however, will show the interested reader that this is not merely a book to be left on the library reference shelves. He will notice the author's absorbing and practical approach to legal rules and regulations, and will certainly make a careful study of the safety measures discussed, which cover the entire field of chemistry. For rapid information on a given Technical Rule for Dangerous Materials (Technische Regel für gefährliche Arbeitsstoffe, or TRgA) the reader will need to consult the contents list, since the publisher has not provided a subject index.

The work covers the TRgA from the introduction (001), the definition of concepts (101), the Technical Standard Concentration (TRK) for vinyl chloride and benzene, and the TRgA for these substances and also for aluminum powder, arsenic, hepatotoxic halogenated hydrocarbons, radiation agents, lead, fluorine, silicogenic dust, magnesium, fluxes, and ammonium nitrate, and also for various technologies. In many places the reviewer would have liked to see literature references to the available data. For example, the determination of the exposure conditions for fluorine by the detection of fluoride

© *Verlag Chemie, GmbH, D-6940 Weinheim, 1979* 0570-0833/79/0303-0236 $ 02.50/0

and the resulations for the investigation in the TRgA could have been even clearer if more references to the occupational hygiene literature, *e.g.* on analytical methods in the biological matrix, could have been quoted.

Part I is organized in a very clear fashion and helps the measures necessary in practice to be clearly recognized and realized. Part II offers an excellent presentation of the problems of characterization, with instructive tables. An impressive statistical proof of the necessity for characterization when dealing with dangerous materials is given. In Part III the working instructions (in accordance with §13, Section 6 of Arb. Stoff. V) are explained with many examples; this section is divided into "Information—actual operating instructions—protection instructions—first aid—unusual incidents—problems of waste".

The book belongs not only in the bookcase of the employer and the chief safety officer; the manager, the "local" safety officer, the works doctor and the responsible persons at universities and research institutes need it as well.

Hans Zorn [NB 458 IE]

Gas Chromatography with Glass Capillary Columns. By *W. Jennings*. Academic Press, New York 1978. 1st Edit., vii, 184 pp., bound, $ 16.50.

The book is intended as an introduction to the topic given in the title, and turns out to be a successful one. The reader senses that a practical chemist has committed his experience to paper. All that the beginner and more advanced user alike need to know about gas chromatography with glass capillary columns will be found in this book, starting from production of columns, drawing and coating, insertion of the column into the instrument, *via* a discussion of inlet system and retention time measurements, to sample preparation. *Jennings* has admirably presented the central problems of glass capillary gas chromatography; he considers possible errors and dangers, and how they can be overcome.

The last part presents selected solutions of problems. This section is somewhat short and the choice of material somewhat arbitrary. Nevertheless, purchase of this clearly written book can be wholeheartedly recommended.

Gerhard Spiteller [NB 443 IE]

Kirk-Othmer: Encyclopedia of Chemical Technology. Vol. 1. A to Alkanolamines. Edited by *H. F. Mark, D. F. Othmer, C. G. Overberger*, and *G. T. Seaborg*. John Wiley & Sons, London 1978. 3rd Edit. xxix, 967 pp., bound, £ 50.00.

This is the first volume of the third, completely revised edition of Kirk-Othmer.

This first taste of the new edition creates a very good impression in several respects. The editors have remained faithful to their principle of producing a tersely written and well arranged reference work serving as an excellent source of information for all manufacturers and users of chemical products. In the individual sections of the new edition, numerous aspects have been included which have attracted increasing interest during the past decade, such as energy considerations and data pertaining to safety engineering and toxicology. Moreover, SI units are now given side by side with British engineering units which will certainly facilitate use of the encyclopedia in many countries.

In the first volume both the sections with an engineering slant (*e.g.* Absorption, Adsorption, Air pollution) and those concerned with substances (*e.g.* Acetaldehyde, Acetic acid, Acetone, Acetylene, Acrylamide, Acrylic acid, Acrylic esters, Acrylic fibers, Acetonitrile, Alcohols) accurately reflect the present state of the art, and could hardly be improved in their clarity and presentation.

Thus the third edition of Kirk-Othmer will doubtless live up to its reputation of being the leading English-language reference work in chemical technology. Let us hope that the subsequent 24 volumes will be published in rapid succession.

R. Steiner [NB 444 IE]

Infrared and Raman Spectroscopy. Part A—C. Edited by *E. G. Brame* and *J. Grasselli*. Marcel Dekker, New York—Basle 1976, 1977. 1st edit., 1039 pp. in all, numerous tables and figures, the whole work SFr. 355.00.

The three parts of this work contain the following chapters: Introduction to Molecular Vibrations (*B. Crawford, D. Swanson*); Inorganic Materials (*R. L. Carter*); Organometallic Compounds (*W. F. Edgell*); Ionic Organometallic Solutions (*W. F. Edgell*); Computer Systems (*R. P. Young*); Organic Materials (*R. A. Nyquist, R. O. Kagel*); Environmental Science (*D. S. Lavery*); Food Industry (*A. Eskamani*); Petroleum (*P. B. Tooke*); Textiles (*G. Celikiz*); Biological Science (*G. J. Thomas, Y. Kyogoku*); Polymers (*S. C. Brown, A. B. Harvey*); Surfaces (*C. D. Craver*). A very broad picture is given of the vibrational spectroscopy of biological (156 pages), inorganic (139 pages), and organic (124 pages) systems. Fibers and textiles (16 pages), petroleum (34 pages), and even polymers (60 pages) come off badly.

I have seldom seen a handbook in which the individual chapters were so variable in quality as in the present work. The opening chapter often acts as a visiting card; were it so in this case, it would bide ill for the book. It is certainly not easy to write an original introduction to vibrational spectroscopy (they can be found in dozens of works). *Crawford* and *Swanson* have managed this—but how! "The nucleons within a nucleus, for example, do not exhibit such nice behavior"; "the practical spectroscopist in the real world"; "We chemists owe our good fortune to the fact that the forces between intramolecular particles ... are of Coulomb nature, and that the natural constants ... have the values they do"; these are just a few examples. Messrs. *Coulomb, Planck, etc.* are not thanked in the accompanying footnote; instead, *D. Dennison* is made responsible for this information. Colloquial nonsense like this makes the chapter no more than a source of amusement; fortunately, the following sections are more serious. (Regrettably, in the discussion of hydrocarbon analysis and group frequencies, no mention is made of the achievements of the Goubeau group.)

The chapter on the vibrational spectra of inorganic substances is competent. A large part is taken up with the section on symmetry and group theory (overlap with the first chapter); it is questionable whether this needs to be repeated in every book on spectroscopy. It is regrettable to find in Table 10 (NO_3^- vibrations) the terms "NO_2 symmetric and asymmetric stretch" (or "... bend") and "NO stretch"; the correct forms would have been found on p. 28. In the bibliography the emphasis is on *Siebert* (and his book); most of the other German-speaking spectroscopists are missing.

The two chapters by *Edgell* are important and interesting, and not only to specialists. In the first of these, $Ni(CO)_4$, $Mn(CO)_4Br$, and $(CH_3)_2SnCl_2$ are discussed in detail; there are also tables metal-hydrogen and metal-metal frequencies and information on vibration calculations. The second chapter gives information on the most important points on the structure of ionic organometallic solutions.

The chapter on computer systems is highly readable and informative, considering the new generation of "computerized grating spectrometers" and the Fourier interferometer. Perhaps the best part of this is the careful (and well explained)

use of "computer Chinese"; the informative illustrations and the extensive bibliography are also praiseworthy. The chapter on organic materials has a series of good spectra, an acceptable discussion, and a not very extensive bibliography (barely half the references by *Nyquist et al.*). The reviewer would have preferred here one of the good books on this topic. The chapter on IR and Raman methods in "Environmental problems" is essentially limited to the description of IR gas cells and their use in gas analysis. A rather wider outlook would have been useful (*e.g.* a comparison of the sensitivity of IR and mass-spectrometric methods). The excessively large calibration curves for some gases are of limited value, since data on the resolution, spectral slit width, and half-width value for the bands in question are missing. "Remote Raman" analysis with a pulsed laser Raman system, the laser IR system, and an IR technique which uses sunlight as a source are all briefly discussed. Analysis of water ranks six pages. The chapter on the application of IR spectroscopy in the food industry is useful. In particular, methods for the determination of water, carbohydrates, lipids, flavoring materials, and vitamins are discussed.

Perhaps the best chapter is the one on the IR and Raman analysis of biological systems. This is based on no fewer than 260 publications (up to 1975) and deals in some detail with proteins (oligopeptides and polypeptides), nucleic acids, lipids, and membranes. The methodology is also thoroughly discussed, including the resonance Raman effect. The illustrations have been carefully chosen; the numerous tables contain a wealth of information.

The physical appearance of the work is somewhat modest, considering its price. The paper is streaked with grey and translucent, and the contributions have been reproduced in manuscript form. The separate volumes appear almost identical in their outward appearance. Author and subject indexes for all three parts are placed at the end of Part C. The series deserves to be continued, though it might be useful if the editors checked the quality of the individual contributions more carefully than in the past.

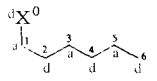
Methods of Reactivity Umpolung

By Dieter Seebach[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

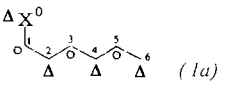
The past decade of organic chemistry may be characterized as a period of violent development of new synthetic methods. This was accompanied by a systematization of the analysis of synthetic problems (synthetic strategy). The planning of the synthesis of an organic target molecule is greatly facilitated by distinguishing between reagents $X(C)_n\ldots$ with normal reactivity (acceptor properties at $C^{1,3,5\cdots}$, donor properties at X, $C^{2,4\cdots}$) and with reactivity umpolung (acceptor properties at X, $C^{2,4\cdots}$, donor properties at $C^{1,3,5\cdots}$). In this context, reactivity umpolung turned out to be useful as a heuristic principle, as a classification scheme, and as an aid for locating so-called strategic bonds (synthon, transform, and antithesis according to *E. J. Corey*). There are six principal methods of umpolung: 1,2*n*-oxidation, heteroatom exchange and modification, homologation and its reversal, the cyclopropane "trick", use of acetylenes, and redox reactions; under certain circumstances none of these techniques is necessary in cases where direct umpolung is possible. Throughout the article, normal reactivity is indicated by green print; reactivity umpolung by red print.



1. Postulates and Nomenclature

Before describing and systematizing the methods of reactivity umpolung, the scope of the discussion, the nomenclature of synthetic methodology and the synthetic problem behind reactivity umpolung must be defined.

1. The reactions most frequently used in organic synthesis are *polar* in nature, *i.e.* nucleophilic or *donor* (**d**) and electrophilic or *acceptor* (**a**) sites are used to make and break bonds (Lewis acid base combinations)[1a, 1b].



2. The large majority of target molecules of organic synthesis contain the heteroatoms *nitrogen* and *oxygen* as functional groups (amino, imino, hydroxy, ether, carbonyl)[1a].

3. These heteroatoms impose an *alternating acceptor and donor reactivity pattern* (*1*) upon the carbon skeleton, *i.e.* acceptor properties or attack by donors at carbons $C^{1.3.5\cdots}$, and donor properties or attack by acceptors at carbons $C^{2.4.6\cdots}$; the heteroatom X^0 itself is a donor center d^{0}[1a].

(*1*), X = O, N

$a^{1,3,5\cdots}$- and $d^{0,2,4,6\cdots}$-reactivity

(*1a*)

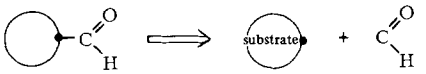
In order to clearly distinguish donor and acceptor reactivity from partial charge separation (⊕ or $\delta^{\oplus}$ and ⊖ or $\delta^{\ominus}$) we use the letters **d** and **a** throughout this article [see (*1*) [1c]]. The signs Δ for **d** and o for **a** [see (*1a*)] may also be employed and avoid additional letters to be written in more complex formulas. Green print indicates normal reactivity, red print reactivity umpolung (see definition 1.8).

4. A consequence and synthetic limitation is the fact that combination of components with reactivity (*1*) leads only

[*] Prof. Dr. D. Seebach
Laboratorium für Organische Chemie der Eidgenössischen Technischen Hochschule, ETH-Zentrum
Universitätstrasse 16, CH-8092 Zürich (Switzerland)

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0404-0239 $ 02.50/0*

to 1,3-, 1,5- ... 1,(2n+1)-disubstituted products (odd number of carbon atoms between the functional groups) [see *(2)* and *(3)*][1a].



a^3/d^0 or a^1/d^2 a^5/d^0, a^3/d^2 or a^1/d^4

(2) *(3)*

direct or vinylogous Prins-, aldol-, Claisen-, Mannich- and Michael reactions [1a, 2]; X, X' = O, N; double bonds where applicable

5. According to the original proposition, *synthons* are "structural units within a molecule which are related to possible synthetic operations"[3a]. Thus, the molecule *(4)* is related

(4) *(5)* *(6)*

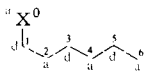
with the substrate synthon *(5)* and the formyl synthon *(6)*. This is irrespective of the type of reaction employed (polar, radical[1c], pericyclic, transition-metal mediated, photochemical, electrochemical).

6. An a^n- or d^n-synthon ($n \geq 1$) is, respectively, a synthon with an O- or N-heteroatom at C^1 and an acceptor or donor center at C^n[3b, 4]. Six such synthons are shown in *(7)*–*(9)*. An a^0- or d^0-synthon is an acceptor or donor heteroatom (O or N), respectively.

7. A *reagent* is the compound or intermediate actually used to carry out the synthetic operation. *Synthetically equivalent* reagents or series of reactions perform identical transformations (see Table 1 and definition 1.9)[3c].

a^1 d^1 a^1 d^1

(7a) *(7b)* *(8a)* *(8b)*



a^2 d^2

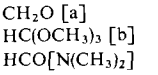
(9a) *(9b)*

8. A reagent has normal reactivity if it corresponds to a synthon of general type *(1)*.

Reactivity umpolung is present in a reagent in which **a**- and **d**-centers are reversed as compared to *(1)* [see general representation *(10)*; cf. *(7b)*, *(8b)*, *(9a)*]. Thus, a^{2n+1}- or

$a^{0,2,4,\cdots}$- and $d^{1,3,5,\cdots}$-reactivity

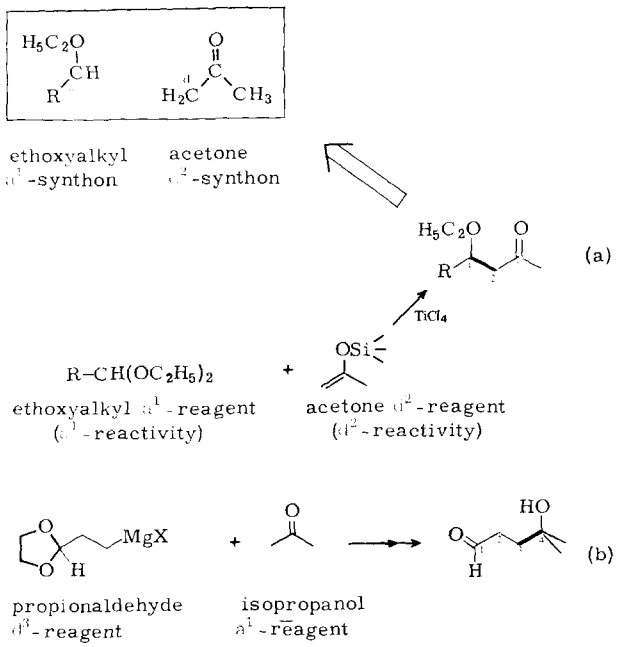
(10), X = O, N



d^{2n}-synthons correspond to reagents of normal reactivity, d^{2n+1}- or a^{2n}-synthons to those with reactivity umpolung (see Table 1).

Umpolung is also present if the alternation of reactivity is violated [see also query 4 in Section 2, and Section 3.5).

Finally umpolung is any *process* by which donor and acceptor reactivity of an atom are interchanged (see Sections 3.2 and 3.6).



9. When discussing particular transformations, the names of the structural units under consideration are used with the

Table 1. Preparations of an aldehyde R—CH_2—CH_2—CHO (target molecule).

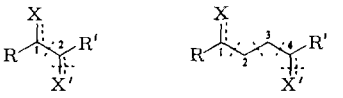
corresponding reactivity symbols; newly formed bonds are indicated in **bold type** [see eqs (a)[6] and (b)[7] and Table 1[3c, 5]].

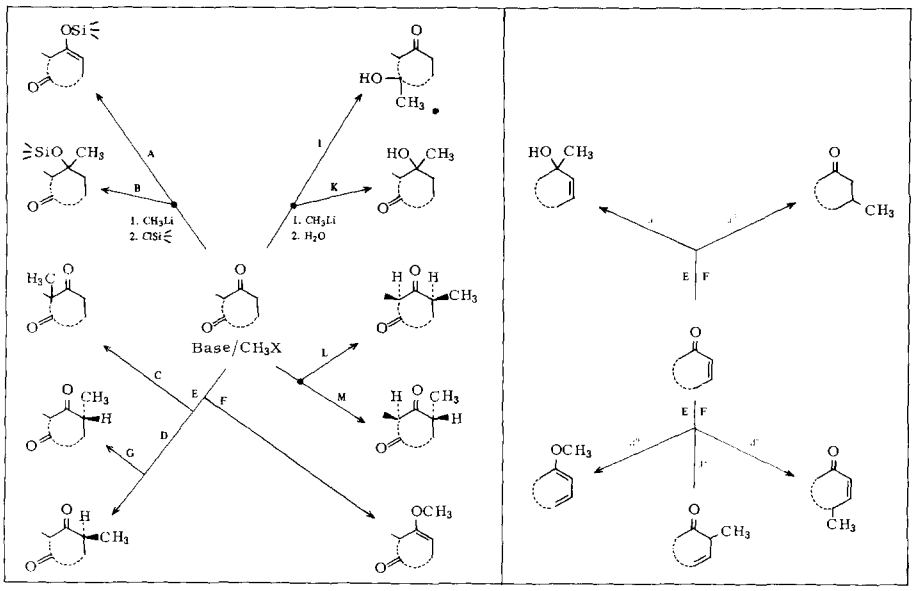


10. A reaction or reagent which differentiates between sites of identical reactivity in a conjugate system of type *(1)* or *(10)* is called *ambidoselective* (see selectivity nomenclature and examples in Table 2).

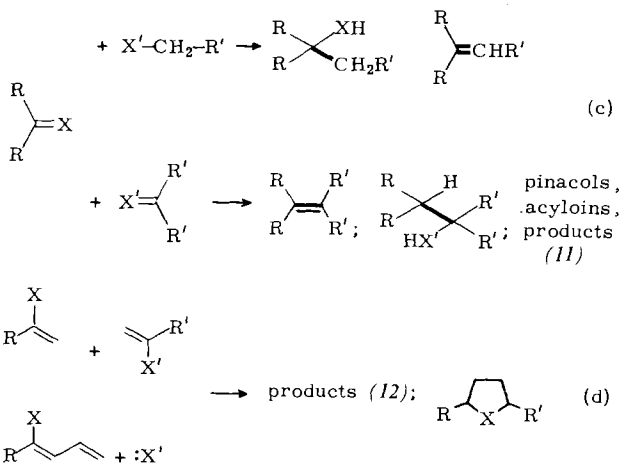
2. The Synthetic Problem

Four Views of Synthetic Situations Requiring Reactivity Umpolung

1. As stated in Section 1, the normal reactivity *(1)* does not enable us to construct 1,2*n*-disubstituted products (even number of carbon atoms between the functional groups). How are compounds of type *(11)* and *(12)* synthesized?



(11) *(12)*

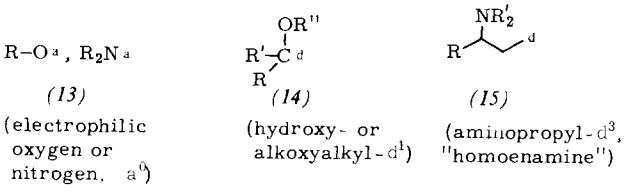


X, X' = NR''_2, OR'', NR'', O

2. We can rephrase this question in the following way: how do we couple two centers of identical polarity or affinity? [see eqs (c) and (d), X/X' = O, N].

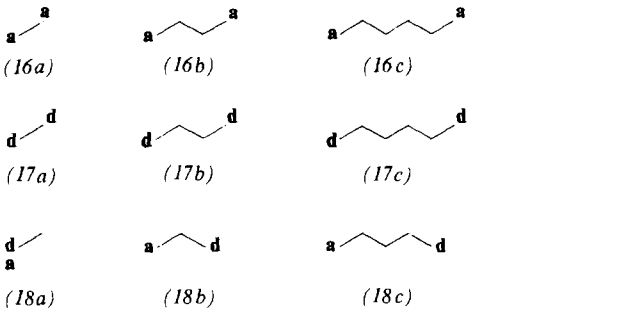
Table 2. Structural definition of selectivities.—Three principal selectivities are distinguished [a]: 1. *type* selectivity (*non*-isomeric products, mostly different types of reactions, *i.e.* substitution, addition, elimination, ... A/B); 2. *constitutional* selectivity (same kind of reaction, products are constitutional isomers; C/D, E/F, I/K); 3. *stereo*-selectivity (products are stereoisomers; diastereoselectivity L/M or enantioselectivity G/H [b, c]).—Constitutional selectivity is subdivided into *site* selectivity (differentiates unrelated functional groups in a molecule which can undergo the same type of reaction, I/K), *regio*-selectivity [d] C/D and *ambido*-selectivity E/F (see definition 1.10 [e]).

[a] The term *chemo*selectivity [*B. M. Trost, Th. N. Salzmann, K. Hiroi*, J. Am. Chem. Soc. *98*, 4887 (1976)] is not structurally defined, *stereospecificity* is an often criticized term [*H. E. Zimmermann, L. Singer, B. S. Thyagarajan, ibid. 81*, 108 (1959); *E. Ruch, I. Ugi*, Theoret. Chim. Acta *4*, 287 (1966)]; "specificity" should be dropped altogether. [b] See *Y. Izumi, A. Tai:* Stereodifferentiating Reactions, Academic Press, New York, 1977. [c] Of course, (G) and (H) are only enantioselective routes if the hydrogens of the α-keto CH_2-group are enantiotopic in the starting molecule of the present example; in L/M they must be diastereotopic. [d] See *A. Hassner*, J. Org. Chem. *33*, 2684 (1968). [e] This was part of the original definition of regioselectivity (see [d]). However, the term was rarely used to distinguish between 1,2- *vs.* 1,4-addition to an enone or *O*- *vs.* *C*-alkylation of an enolate [reviews: *J. d'Angelo*, Tetrahedron *32*, 2979 (1976); *R. Gompper, H.-U. Wagner*, Angew. Chem. *88*, 389 (1976); Angew. Chem. Int. Ed. Engl. *15*, 321 (1976); *L. M. Jackman, B. C. Lange*, Tetrahedron *33*, 2737 (1977)]. As evident from the lower part of Table 2, the **a**/**d**-nomenclature is very convenient in this connection.



(c)

pinacols, acyloins, products *(11)*



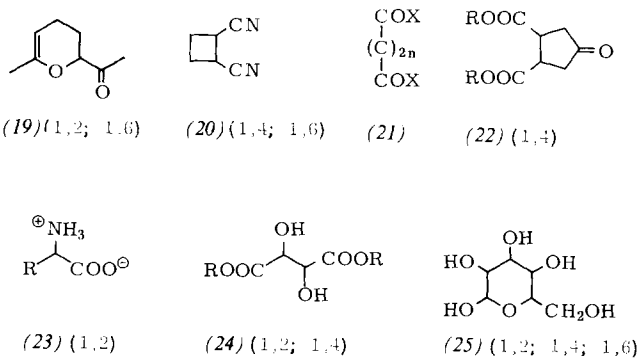
products *(12)*; (d)

3. How can we systematically achieve a reactivity umpolung or construct reagents which correspond to synthons such as *(13)*—*(15)*? [cf. postulates 1.6 and 1.8, *(10)* and Table 1].

R–O^a, R_2N^a		
(13)	*(14)*	*(15)*
(electrophilic oxygen or nitrogen, a^0)	(hydroxy- or alkoxyalkyl-d^1)	(aminopropyl-d^3, "homoenamine")

4. A fourth way of putting the question is: How do we generate equal reactivity in 1,(2*n*)- or opposite reactivity in 1,(2*n* + 1)-positions of a carbon framework? [see *(16)*—*(18)*].

(16a) *(16b)* *(16c)*



(17a) *(17b)* *(17c)*

(18a) *(18b)* *(18c)*

3. Methods of Reactivity Umpolung

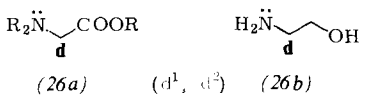
Although the problem has been recognized for a long time[14–16], and although numerous classical solutions are available, an intensive effort has been made in the past decade to answer the four questions in Section 2 in new ways. A confusing variety of apparently independent and unrelated methods has been conceived and demands classification. This is attempted in the following sections.

Prior to doing this, a very important *memo* is appropriate: The preparation of 1,2*n*-bifunctional starting materials such as the [2+4]-dimer *(19)* of methyl vinyl ketone[17] or the head-to-head [2+2]-dimer *(20)* of acrylonitrile[18] is not readily classified in the present context. Also, industrial and biochemical processes furnish readily available and often unusual compounds in large quantities, *e.g.* the dicarboxylic acid derivatives *(21)* (succinic, adipic, fumaric, maleic, phthalic)

(19) (1,2; 1,6) *(20)* (1,4; 1,6) *(21)* *(22)* (1,4)

(23) (1,2) *(24)* (1,2; 1,4) *(25)* (1,2; 1,4; 1,6)

Examples of molecules from the "black magic box".

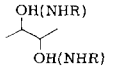


and *(22)* (from fumarate and cyanide[19,20]), furan and its derivatives, amino acids *(23)*, highly functionalized molecules such as tartaric acid *(24)* and carbohydrates *(25)*[21]. These may or may not arise along the lines described below. We might call these sources the "*black magic box*" of the synthetic organic chemist which should never be forgotten when planning the synthesis of a (chiral) molecule with complex functionality[21,22].

3.1. 1,2*n*-Oxidation

A process creating a 1,2*n*-oxygen and/or -nitrogen functionalized carbon skeleton without formation of a C—C bond is an oxidation (conservative conversion, non-connective). Some common transformations of this sort are listed in Table 3. As can be seen, many classical reactions and their recent improvements are among the examples: epoxidation (No. 1, 2), hydroxylation (No. 3, 4, 6, 7), oxygenation (No. 5, 8, 10, 11, 16), amination (No. 4), oximation and imination (No. 9), ozonolysis (No. 18), hydroboration /oxidation (No. 12), the Neber (No. 13), Bayer-Villiger (No. 17), and Criegee-Hock rearrangements (No. 19), the Hofmann-Löffler-Freytag (No. 14), and the Barton reaction (No. 15).

We are dealing with cases in which the heteroatoms oxygen and nitrogen have become acceptor (sextet or septet) sites *(10)* rather than acting as donors *(11)* [umpolung of heteroatom reactivity; a^0-synthons; equal polarity at adjacent heteroatoms R—O—O—R', R_2N—NR'_2, cf. *(17a)*]. Since the methodology of generating and selectively using reagents with electrophilic N or O is rather limited, there are numerous techniques which use other acceptor heteroatoms that are subsequently replaced by oxygen or nitrogen (see Section 3.2).



It is evident that all the products in Table 3, like the above mentioned black magic box molecules *(19)*—*(25)*, have a built-in reactivity umpolung: due to the 1,2*n*-functionalization, any of their normal reactions [*(11)*] with respect to one of the functional groups is an umpolung of reactivity [*(10)*] with respect to the other functionality. Thus, the enolate

(26a) (d^1, d^2) *(26b)*

of an amino acid derivative[4d,42] corresponds both to a d^2- *and* a d^1-synthon *(26)* (cf. the use of this type of reagent in the homologative approach, Section 3.3).

Table 3. Some reactions creating 1,2-doubly functionalized carbon skeletons without C—C-formation [23].

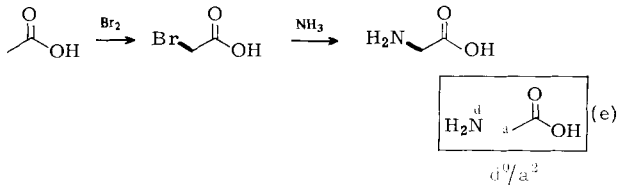
17		H_2O_2 [2, 18, 39]	
18		O_3 or $OsO_4/IO_4^{\ominus}$; $Pb(OAc)_4$ [40]	
19		TosCl [2, 41]	

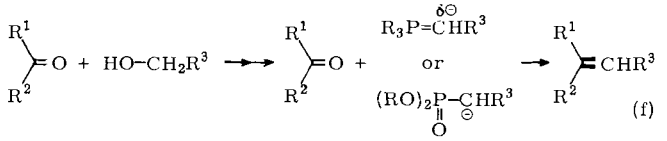


3.2. Exchange and Modification of the Heteroatom

Fortunately, organic chemistry is not restricted to the elements C, H, N, O! We can utilize all the elements of the periodic chart to achieve the goal of synthesizing C, H, N, O-containing products (see postulate 1.2) and to break out of the reactivity pattern *(1)* (see 1.3). The most common and best established systematic way of reactivity umpolung of N- or O-functionalized molecules is the *temporary exchange* of these heteroatoms by others which convey opposite reactivity to the carbon moiety. Thus, we use derivatives of other heteroatoms like a boat to cross a river.

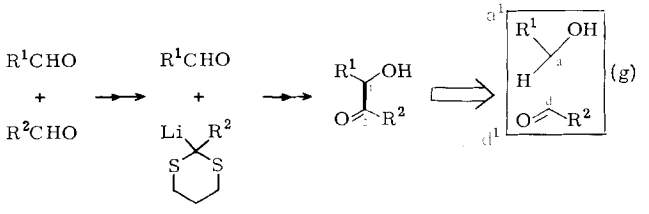
Furthermore, nitrogen, unlike oxygen, has so many oxidation states and occurs in a multitute of bonding situations that it can be "modified" to allow for jumping back and forth between the two reactivity patterns *(1)* and *(10)*.

3.2.1. Heteroatom Exchange



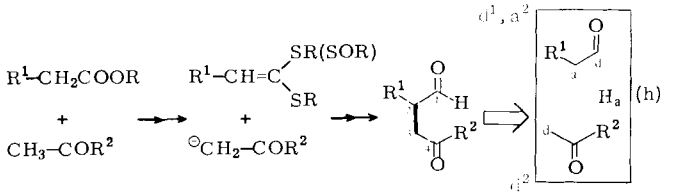
As stated above, there is a lack of methods which cleanly introduce nitrogen and oxygen at donor sites. The use of $Br^{\oplus}$ as an electrophilic substitute heteroatom is a classical solution to this problem [see eq. (e)]. When the desired C—N bond is formed, the nitrogen acts as a nucleophile, the α-car-

(e)



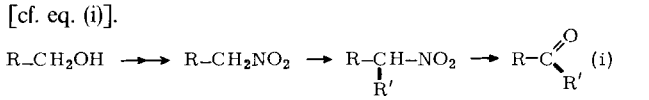
bonyl carbon as an electrophile; therefore the corresponding synthons are d^0 and a^2 (see also the 1,4-oxidation, entry 1 in Table 4). The use of α-chloronitrones (Table 4, entry 2) and of α-heter· ubstituted oximes[43] and hydrazones[44] as ketone a^2-reagents in C—C-bond forming processes has recently been demonstrated. The preparation of Grignard derivatives, the employment of tin-containing intermediates, and the use of certain acyl-metal and acyl-phosphorus compounds for reactivity umpolung are outlined in Table 4 (entries 3—5).

Especially versatile heteroatoms Y for this purpose are phosphorus, sulfur and selenium[4g,45]. They can be readily intro-



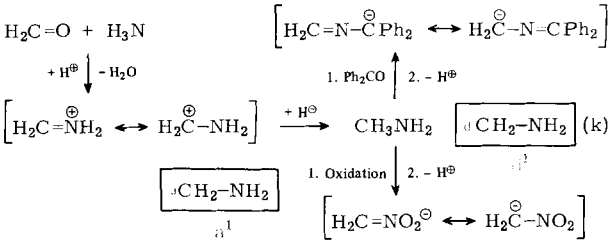
(f)

duced at electrophilic ($+R_nY^{\ominus}$) *and* at nucleophilic sites ($+R_nYX$). Sulfur in particular stabilizes positive *and* negative charges in the α-position, and there are numerous ways of removing all three heteroatoms from a molecule[4g]. Conversions associated with the names of *Wittig*, *Horner*, *Emmons*, *Wadsworth*, *Michaelis* and *Arbuzov*[2] allow the coupling of carbon atoms of the same polarity [cf. eqs. (c) and (f)]; recent improvements and promising developements in this general area are the so called redox condensations with phosphanes[46] and the conversion of NH_2 into the leaving group $N(SO_2R)_2$[47].



(g)

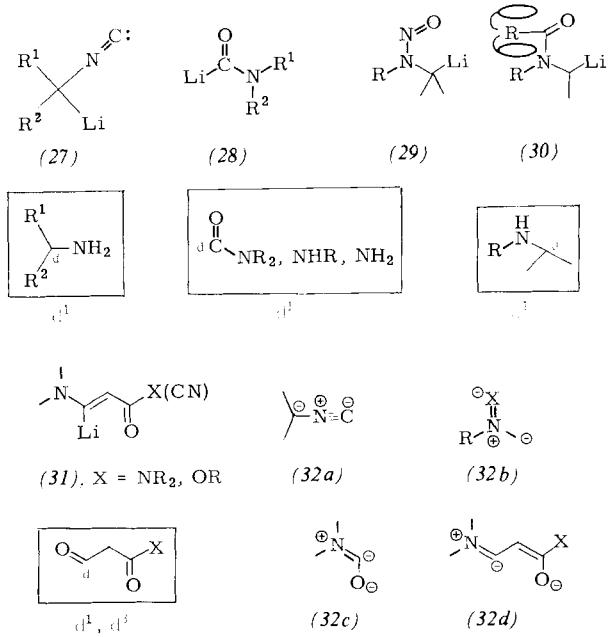
(h)



The temporary replacement of the heteroatom oxygen by sulfur for the preparation of 1,2-*n*-functionalized products is described in equations (g) and (h) [cf. eqs. (c) and (d); for further examples see Table 4, entries 6—8, and detailed reviews[4b, 4g, h, 12, 45]]. The interconvertibility of oxygen and nitrogen functions (functional group equivalence[13a]) renders the use of N-containing reagents with reactivity umpolung (see Section 3.2.2) a heteroatom exchange method for oxygen [cf. eq. (i)].

(i)

3.2.2. Heteroatom Modification



In sharp contrast to oxygen, which can hardly be modified to allow d^1- and a^2-reactivity as in *(10)*[48–50] (see Section 4.1) without the help of heteroatom exchange, nitrogen is a very rich heteroatom in this respect. There are two fundamental reasons for this: nitrogen can 1) make one more bond with carbon and thus be incorporated "in the middle" of conjugated systems, and 2) it has many more oxidation states; it can stabilize α-$C^{\oplus}$ in the lower ones and α-$C^{\ominus}$ in the higher ones. Thus, modification of the nitrogen of methylamine in the Schiff-base with benzophenone allows α-N—CH-deprotonation (cf. umpolung of amine reactivity with pyridoxal in Nature[51]) and converts the normal aminoalkylating a^1-

(k)

reactivity of iminium derivatives[52] into d^1-reactivity[53] [see eq. (k)]. On the other hand, we can convert the amine (oxidation state −3) into the nitronate (oxidation state +5) and use this as an aminomethyl d^1-reagent[41].

We need not go all the way to the nitro or diazo group to achieve α-N—CH acidification and α-N—C-donor properties. Any amine derivative which bears an electron-withdrawing group causing a partial positive charge on nitrogen appears to suffice under appropriate conditions [see the isocyanides *(27)*[54], the carbamoyllithium compounds *(28)*[50,55], the nitrosamines *(29)*[4d,56], the amides *(30)* with sterically pro-

tected but electronically effective carbonyl groups[48,49,57], and the vinylogous ureas, urethanes, and cyanamides *(31)*[58]. It is not entirely clear yet whether the dipolar anion stabilization indicated in *(32)* is the decisive effect causing the ready

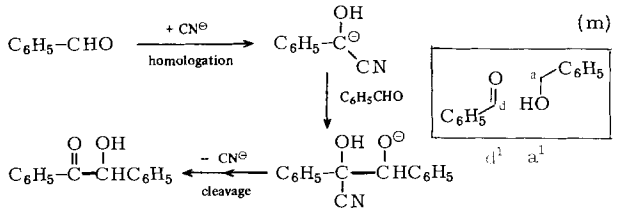
formation and unexpected stability of these systems[4d, 48, 49, 57]. An almost complete list of N-derivatives with nucleophilic α-carbons is found in a previous review (Table 3 in Ref. [4d]). The use of cyanide (Kolbe and Strecker syntheses[2], cyanohydrin formation), a recent example of incorporation of nitrogen into a conjugated system (cf. Section 3.5), and novel derivatives with "dipole stabilization" are listed in Table 4 (entries 9—13).

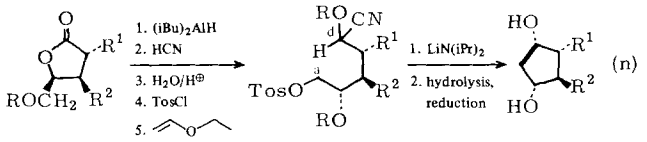
Examples of simultaneous heteroatom exchange *and* modification for the purpose of reactivity umpolung are the versatile reagent $TosCH_2NC$: (Tosmic[54, 59]) and the thiocarbamoyllithium derivatives $LiCSNR^1R^2$[60].



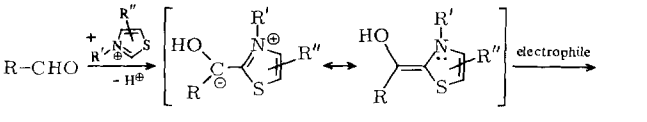
3.3. Homologation and Its Reversal

As stated in Section 3.1, any compound with a 1,2*n*-functionalization has the normal reactivity pattern *(1)* with respect to one of the two functional groups and reactivity umpolung *(10)* of the other one [cf. Section 3.1, *(26)*]. After a reaction with an acceptor at C^2, which in this case is at the same time a d^2- *and* a d^{2n-1}-center, the C—C bond leading to C^1 can be cleaved (reversal of homologation, degradation). This procedure then provides a reagent which corresponds to a d^{2n+1}-synthon. The extra functionalized carbon atom (C^1) can be specifically introduced (homologation) for the purpose of reactivity umpolung.

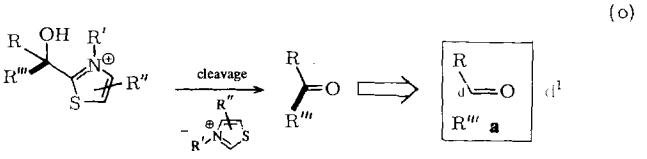
A d^1-reagent of this type has the general formula *(33)* where X and X′ may be oxygen and/or nitrogen, or other heteroatoms, and must fulfil three conditions: the C=X group is essential for anion stabilization, attack of the electrophile must occur on carbon, and the product must be amenable



(33)

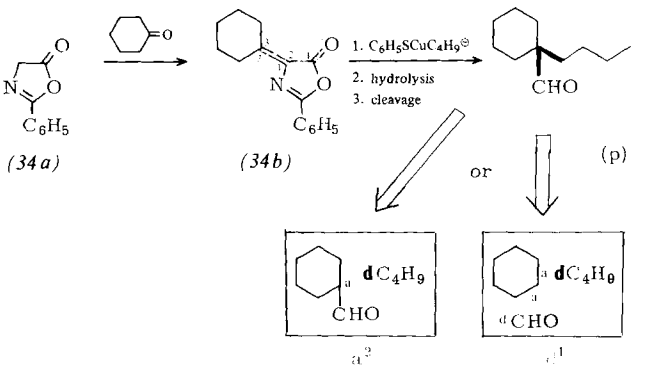


to cleavage to a carbonyl compound [see eq. (l) and Table 5]. Especially attractive are catalytic processes, the best known



example of which is the benzoin condensation [eq. (m)]. The Stork method[80] is conceived along these lines; it uses lithium derivatives of protected cyanohydrins (see Table 5) and is ingeniously applied to a prostaglandin synthesis as indicated in eq. (n)[81]. The method by which Nature performs nucleophilic acylations again involves a catalytic homologation, with

(n)

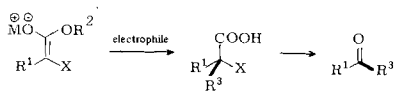


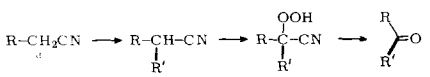
(o)

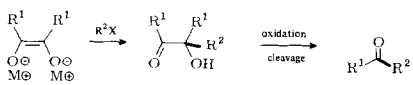
thiamine pyrophosphate[51,82], and was adopted by *Stetter et al.*[83] for laboratory scale preparations [eq. (o)].

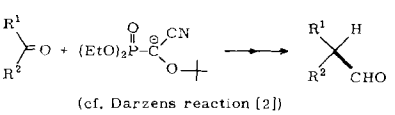
Further examples of devising d^1-reagents by the homologative approach are listed in Table 5.

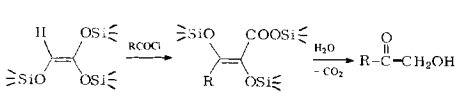
So far, we have discussed only cases in which d^1-reactions were performed with homologues of the actually required carbon framework. It is equally possible to use this method to supply a^2- and d^3-reagents [see eqs (p)—(r)]. In the first

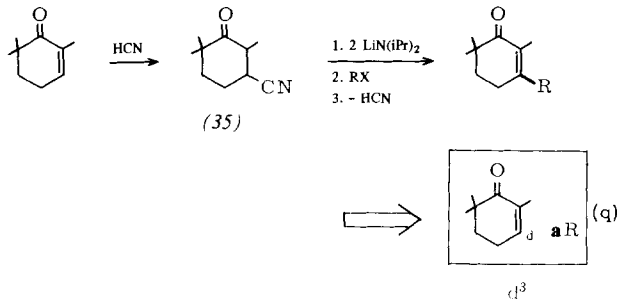












(p)

process a glycine derivative *(34a)* is used as a 1,2-bifunctional molecule[84]. Condensation with cyclohexanone gives a Michael acceptor (a^3) *(34b)*, which also is an enamine derivative (normal reactivity d^2, here a^2); the product obtained from the Gilman reaction[85] is hydrolyzed to the corresponding α-amino acid which is cleaved by lead tetraacetate (retrohomologation; the carbonyl carbon has "done its job"!) to give the final aldehyde product. If we consider the synthesis from cyclohexanone, the oxazolidone *(34a)* is a d^1-reagent (in the Dakin-West reaction[2] it is dCH_2NH_2); comparing *(34b)* with the aldehyde, we see that it is an a^2-reagent.

The reversible homologation of equation (q)[86] is vinylogous to the above mentioned use of cyanide for nucleophilic acylation and brings about a β-alkylation of an enone (cf. entries 7 and 9 of Table 4). The reaction sequence in equation (q) employs a 1,4-bifunctional intermediate *(35)*—like the classical Stobbe condensation[2] (and its many recent modifica-

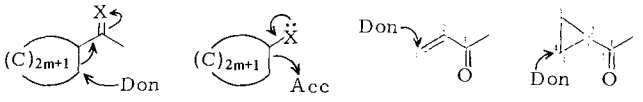
tions[87]; see also Section 3.4). As indicated in equation (r), the enolate derived from succinic ester corresponds to a d^3-synthon; the cyclopentenone annelation (route B) is part of a three carbon ring expansion method[88]. Some further

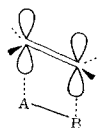


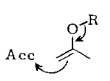
(r)

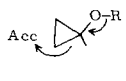
classical[2] reactions which can be used in homologative reactivity umpolung as defined here are the degradation methods according to *Baeyer-Villiger*, *Beckmann*, *Hofmann-Curtius-Lossen-Schmitt*, *Hunsdiecker* (all RCOR′ or RCOOH→ROH, RNH_2), and *Barbier-Wieland* ($R_2CHCOOH \rightarrow R_2CO$) in which carbon functions as a leaving group and is replaced by a heteroatom (N or O).

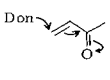
3.4. Use of Cyclopropanes

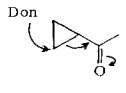
Opening of a cycloalkane with an odd number of carbon atoms and with substituents as indicated in *(36a)* and *(36b)* by donors and acceptors, respectively, constitutes yet another

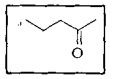


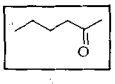


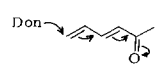


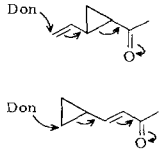


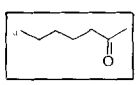




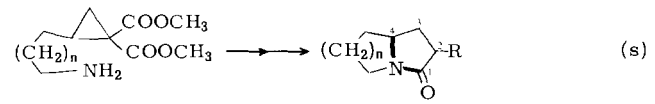






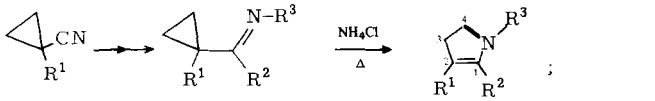


a^{2n}-reactivity d^{2n+1}-reactivity



(36a) *(36b)* *(37a)* *(37b)*

principal method of reactivity umpolung. It is related to the homologative method of the previous section by also rendering normal reactivity *(1)* [counting the short distance between the attacked and the functionalized carbon in *(36)*] identical with reactivity umpolung *(10)* [counting around the ring of *(36)*]; the resemblance becomes even closer if we consider that this kind of process is most likely to occur with cyclopropanes (110 kJ/mol strain release), the next higher homologues of "cycloethanes" [see *(37a)* and *(37b)*, and Table 6]. Most of the processes of this scheme were discovered some ten or more years ago[104] (d^3[105a], a^4[105b], a^6[105c]), but only recently have they been exploited systematically for this purpose; improved methodology of cyclopropanation[104,106] was a prerequisite. A fair coverage of the field is not possible in the present article[107]; only a few illustrative examples will be mentioned.



In the field of heterocyclic chemistry and natural product synthesis, the construction of pyrrolines, pyrrolidines, tetrahydrofurans, γ-lactones and γ-lactams is a problem of reactivity umpolung because in all of these five-membered rings, the chain of carbon atoms is 1,4-bifunctionalized. It is therefore not surprising that cyclopropanes have been widely applied in this area. One example each from *Danishefski*'s[108], *Stevens*'[109] and *Wenkert*'s[110] approaches is given in equa-

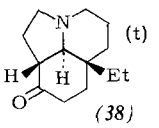


Table 6. Umpolung of carbonyl reactivity with cyclopropanes.

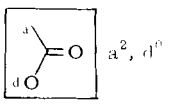
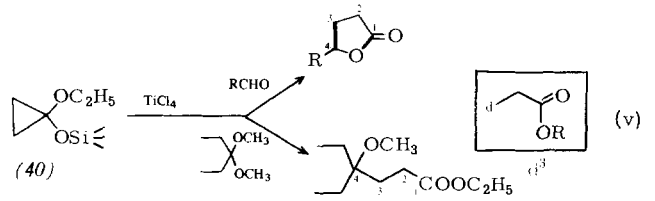
(s)

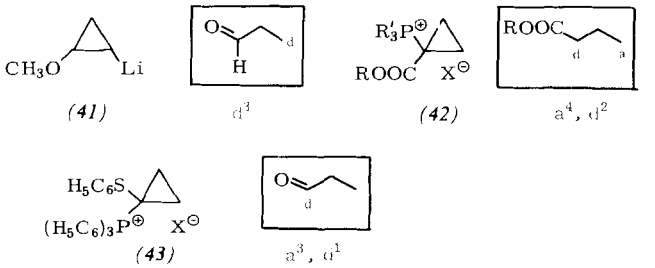


(t)



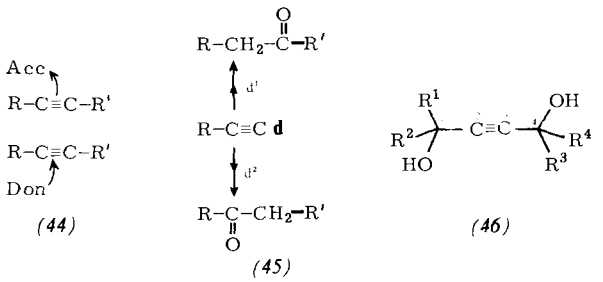
(39)

tions (s)—(u). In reactions of the type (s)[111] the three-membered ring is opened stereoselectively with inversion; they have been termed homoconjugative additions[108]. The general route outlined in equation (t) was followed in a synthesis of aspidospermine *via (38)*[112]; equation (u) outlines the key step of an eburnamonine synthesis[110,113]. Formally, the 1,4-relationships N—C_4—N and O—C_4—O have been established by an a^4-reaction with a nitrogen or oxygen atom donor in all three cases. The ring enlargements in equations (t) and (u) could also be classified as hetero analogues of the pericyclic vinylcyclopropane → cyclopentene rearrangement. The carbene used in equation (u) [cf. *(18a)*] corresponds to the a^2-synthon drawn underneath it; in *(39)* a pushing (or donor) effect of Ẋ is probably also involved [cf. *(36a) and (36b)*].



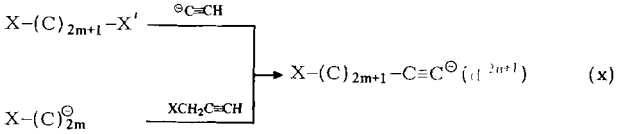
Stobbe-type conversions are possible with the cyclopropanone acetal *(40)*[114] [eq. (v)], a^0-reactivity was observed

(v)



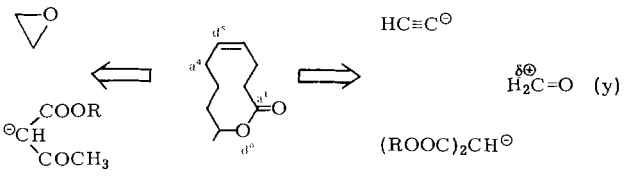
(w)

with the methyl(vinylcyclopropyl) ketone shown in equation (w)[115], methoxycyclopropyllithium *(41)* is a propionaldehyde d^3-reagent[116], and the phosphonium salts *(42)*[117] and *(43)*[118] are used in cyclopentane annelations to 1,3-dicarbonyl derivatives [cf. the synthons with *(18b)*; see also Section 5, *(77)—(82)*, eq. (av) and Table 9].



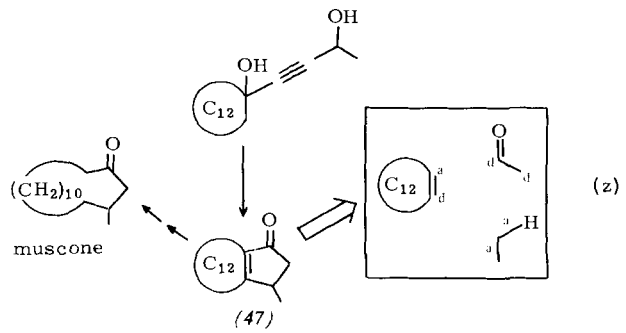
3.5. Acetylenes

Acetylenes are extremely versatile synthetic intermediates[119]. The highly reactive, "strained" triple bond can be attacked by electrophiles or nucleophiles [see *(44)*, and compare *(18a)*], terminal acetylenes are rather strong CH-acids, and the acetylides obtained by deprotonation are very good, non-hindered nucleophiles [*(45)*] (compare *(18a)*, acyl



d¹-reagents]. Acetylene itself is therefore a welcome moiety for the synthesis of 1,2*n*-bifunctional systems *(46)* [see *(17a)*]. An advantageous stereochemical aspect is that disubstituted alkynes can be selectively hydrogenated to (*E*) *or* (*Z*)-olefins.

If acetylene is attached to a molecule of normal reactivity (*1*), a carbon framework with reactivity umpolung (*10*) results [eq. (x)]. This principle is used if propiolic acid or propargyl

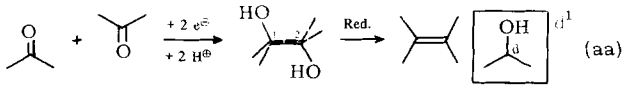


(x)

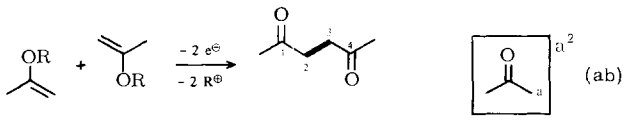
derivatives (aldehyde, alcohol, bromide) (d^3) or 4-pentynoic acids (d^5) are employed[120]. If one traces back the components of the synthesis of phoracantholide, one finds that the ultimate

(y)

reagents with reactivity umpolung are oxirane (see Section 3.1) and acetylene [see eq. (y)][121]. A recent muscone synthesis

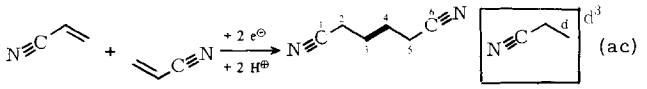


(z)



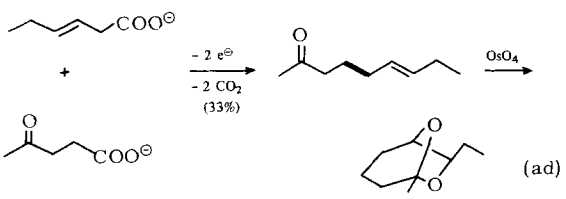
via (47) uses cyclododecanone, acetaldehyde and acetylene as components[122]; these are first joined to a 1,4-diol which is cyclized by sequential Rupe-Meyer-Schuster and Nazarov reactions[2]. Acetylene corresponds to a d^1,d^2-synthon [cf. eq. (z)].

3.6. Redox Reactions



Conceptually, the most simple method of reactivity umpolung is the addition or removal of electrons in a system which is electrophilic or nucleophilic, respectively. This will of course reverse the reactivity of the species (cf. also the formation of a Grignard reagent in Table 4, entry 3). Thus, we can reduce ketones and aldehydes to pinacols [eq. (aa)] and esters to acyloins[123] by electrochemical[124] or photochemical[125] methods or with metals[126]; further reduction leads to olefins which can now be obtained directly from ketones with low-

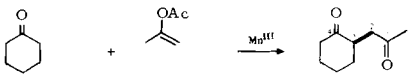
(aa)

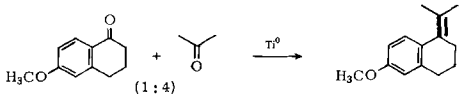


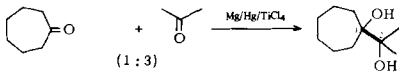
(ab)

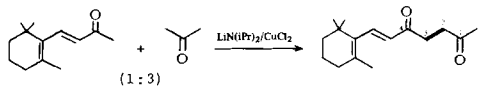
(ac)

alkali metal, is readily accomplished[126], while we do not normally cleave pinacols and olefins by such simple methods. The products mentioned—except for the olefin—are 1,2*n*-bifunctional and have been made by joining carbon atoms of the same polarity (cf. queries 1 and 3 in Section 2). We formally obtain these products, if we assume that half of the starting molecules are converted into reagents with reactivity umpolung [see the $d^{1,3}$- and a^2-synthons in eqs (aa)—(ac)] and then couple with the other half of normal reactivity. In reality, of course, radical anion or cation coupling (r-reactivity[1c]) furnishes the products in most cases. Therefore, it is difficult to prepare cross-coupling products in better than statistical amounts, unless we carry out intramolecular reactions[137]. Some exceptions to this statement are listed in Table 7; a confirmation is the still very short and efficient synthesis of the pheromone brevicomin[139,140] [equation (ad) (Kolbe carboxylate electrolysis[2])].

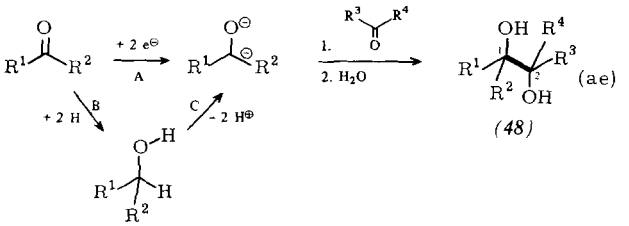








(ad)



exo-brevicomin

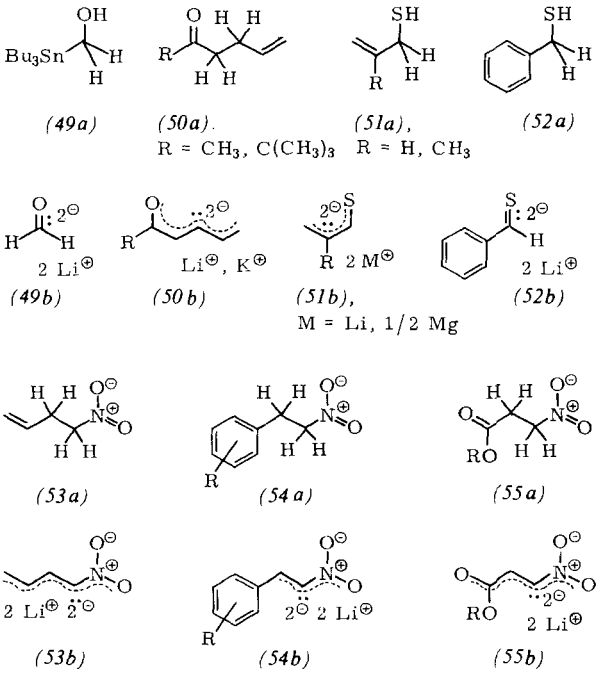
A way out of the problem of "self condensation" or scrambling, when *selective* cross coupling is desired, is being systematically investigated by our group[4f,65,142-148]. The principle

Table 7. Examples for cross-coupling of carbonyl derivatives to olefins, pinacols, and 1,4-dicarbonyl compounds.

Coupling reaction	Yield [%]	Ref.
		[141]
	20—35	[135]
 (1 : 4)	85	[138]
 (1 : 3)	75	[130]
 (1 : 3)	65	[134]

valent titanium[127-131]. Likewise, electrochemical or metal oxidation of enol ethers[132] or enolates[133-135], respectively, furnishes 1,4-dicarbonyl derivatives [eq. (ab)]; electrochemical processes of this type have been called cathodic umpolung[136]. A coupling reaction of industrial importance is the anodic dimerization of acrylonitrile to adiponitrile [eq. (ac)]. The converse of equation (ab), the cleavage of a 1,4-diketone with is described in the accompanying equation (ae). Instead of adding two electrons (A), the π-system is reduced (B) and the resulting dihydro compound is doubly deprotonated (C). The overall result is the same, and no intermediates are involved which could couple with each other. The derivative of the doubly reduced ("LUMO-filled") π-system thus obtained can be added to a different partner to give a "crosslinked

(ae)



(48)

dimer", for instance *(48)*. Only a one electron transfer during this latter step could prevent a clean cross-coupling and would lead to scrambling. In the conversion *via* route A, the formerly electrophilic carbonyl carbon has become nucleophilic, an umpolung ("polar reversal", "charge reversal") in the literal sense of the word [see also *(18a)*]. With more extended π-systems, there are several possible hydrogenated precursors to the desired dianion (see Table 8).

Table 8. Doubly reduced π-systems from hydrogenated precursors [see eq. (ae)].

Precursors	"LUMO-filled" π-system	
		2 atoms 4 electrons
		
		4 atoms 6 electrons
		
		
		
		
		6 atoms 8 electrons
		
		
		

The smallest system, the formaldehyde dianion *(49b)* could not be generated by double deprotonation of methanol; only tin/lithium exchange in *(49a)* was successful[65] (see also Table 4, entry 4). The other dianion derivatives *(50b)*—*(55b)* are accessible from the "hydrogenated" precursors *(50a)*—*(55a)* and strong base. They preferentially react in the ω-positions with electrophiles. Reagents *(50b)* correspond to d^5-synthons[144b,148]; the lithium compound *(51b)* is attacked at $C^3(d^3)$ by all types of electrophiles[4f,13,142,144], while the magnesium derivative adds to carbonyl compounds with >95 % α-selectivity (d^1); *(52b)* also reacts at the α-S-carbon. The doubly deprotonated nitroalkanes[41] are nitroolefins with reactivity umpolung: while 1-nitro-butadiene is known to accept donors at C^2 or C^4, its dianion *(53b)* (deep-red solution in THF/HMPT, stable at room temperature for a few hours) couples with acceptors (mainly **d^4**-reaction). Similarly, *(54b)* and *(55b)* react with alkyl halides, ketones, and aldehydes at the β-NO_2-position exclusively. It is interesting to note that the nitroolefin dianions *(53b)*—*(55b)* constitute reagents

(49a) *(50a)* *(51a)*, *(52a)*

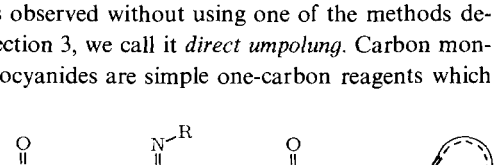
(53b) *(54b)* *(55b)*

with a double reactivity umpolung if they are used to prepare normal O, N-derivatives (see postulates 1.2—1.4): one is achieved by heteroatom exchange or modification, the other one by the redox method [see eq. (af), cf. eq. (i) and Section 5]. Some amine derivatives with umpolung achieved by going to the doubly reduced state can only be referred to here[149].



(53b)

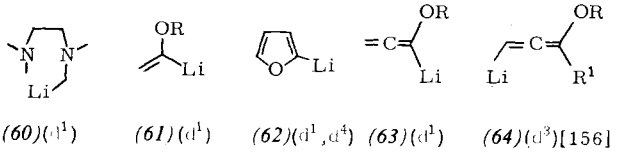
(af)

4. Direct Umpolung and Substrate Umpolung

4.1. Direct Umpolung

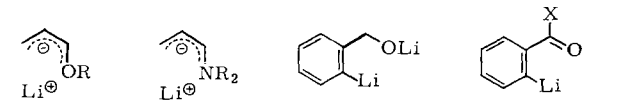
There are of course exceptions to postulate 1.3. If reactivity umpolung is observed without using one of the methods described in Section 3, we call it *direct umpolung*. Carbon monoxide and isocyanides are simple one-carbon reagents which

a d **a d**



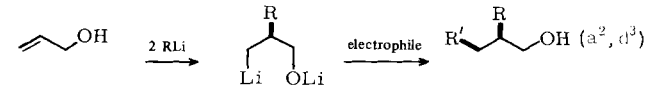
(56) *(57)* *(58)* *(59)*

can be attacked by a donor *and* an acceptor [see *(56)* and *(57)* and compare *(18a)*]. Thus, if carbon monoxide, an olefin and water combine to give a carboxylic acid under strongly



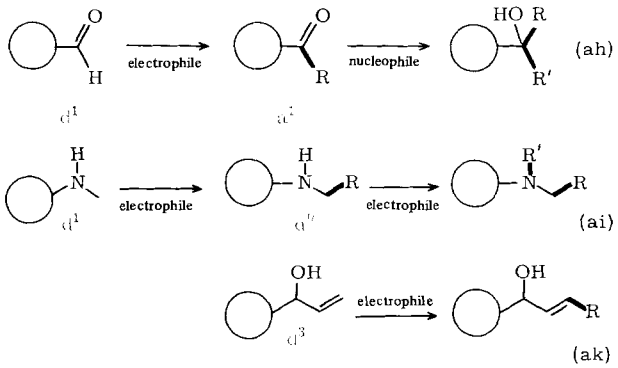
acidic conditions[10b], the CO-carbon atom formally combines with a carbenium ion (**a**/d^1) and $OH^{\ominus}$ (a^1/**d**). Isonitriles are used in the Passerini- and Ugi-reactions (see refs. in [4c]) to prepare α-hydroxy- and α-aminocarboxylic acid derivatives, respectively; given proper substitution in R of *(57)*, Grignard- and lithium-reagents can be added to the carbon atom (a^1) to give an iminoacyl anion derivative; subsequent reaction (d^1) with an electrophile and hydrolysis furnish aldehydes and ketones (Walborsky's method[150]). In the formose reaction[151], formaldehyde *(58)* oligomerizes to give carbohydrates when treated with alkali.

We realize that it is arbitrary to say that CO and CNR are reagents with direct umpolung while we put other, similar compounds [*(27)*—*(31)*, entries 9 and 11—13 of Table 4] into the section on reactivity umpolung by way of heteroatom modification; in *(56)* and *(57)*, not only the carbons but also O and N are in special bonding situations. This is also true of highly conjugated systems such as *(59)*[152]; C^{15} may "not care" whether it is attacked by a nucleophile or an electrophile.



Some unambiguous cases of direct umpolung are the generation of *(60)*—*(68)* directly from the CH-precursors and strong bases, without any of the manipulations described in Section 3. *(60)* is formed by metalation of TMEDA[153] and, like the other α-*O*- and α-*N*-lithium derivatives *(61)*, *(63)*, *(65)* and *(66)*[157], is surprisingly resistant towards Wittig-type rearrangements[154]; *(61)*—*(63)* are also obtained by depro-

(60)(d^1) *(61)*(d^1) *(62)*(d^1,d^4) *(63)*(d^1) *(64)*(d^3)[156]

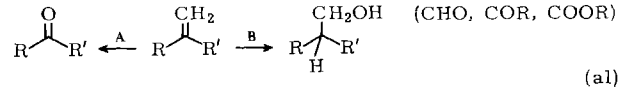


(65)(d^1 or d^3) *(66)*(d^3) *(67)*(d^3) *(68)*(d^3)

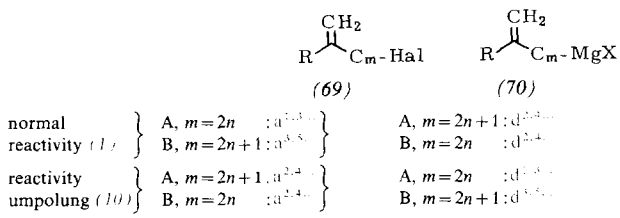
tonation[155]; the heterosubstituted allyllithium compounds *(65)* and *(66)* have been discussed in a recent review article[157]. The *ortho*-Li-derivative of benzyl alcohol and a variety of substituted analogues including α-tetralol[158] as well as *(68)*[159] are only two examples of a large number of similar reagents which are formed by direct *ortho*-metalation[160]. Equation (ag) shows a conversion in which allyl alcohol undergoes sequential a^2- and d^3-reactions[161].—It is important to note that in these cases the lithium is bonded to vinylic, arylic (both sp^2), or allylic carbon moieties and/or is internally complexed (chelation).

4.2. Substrate umpolung

By definition, umpolung must be reversible: the final goal is to make O, N-derivatives of normal reactivity. A reversible umpolung is a sequence of operations by which the reactivity of a functional group can be temporarily reversed, and this is not possible with all the methods mentioned in the previous sections. Should we arrive at a certain stage of a synthesis where we need to perform the conversions (ah)—(ak), this would be a task much more difficult than constructing a "small" reagent molecule with reactivity umpolung. We are here concerned with a more complex molecule whose functional groups must be compatible with all operations necessary to achieve the umpolung. Therefore, this may be called a *substrate umpolung*. Of the methods in Section 3 which fulfill this condition, we have to choose the mildest; the ones which require more stringent conditions will be applicable only for reagent umpolung or in the early stages of a synthesis when there is less complexity.



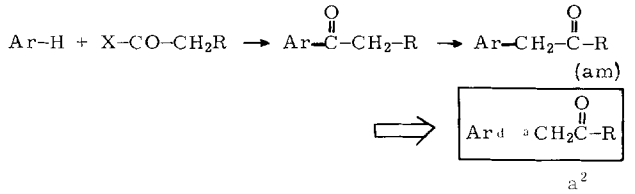
The reversible homologations through cyanohydrins [eq. (n)] and thiazolium derivatives [eq. (o)], and the heteroatom exchange method through thioacetal derivatives[4h] would appear the most promising for the realization of process (ah). The nitrosamine method[4d] [see *(29)*] might be applicable for (ai), and the allyl sulfoxide route[70] (entry 6 in Table 4) for (ak).



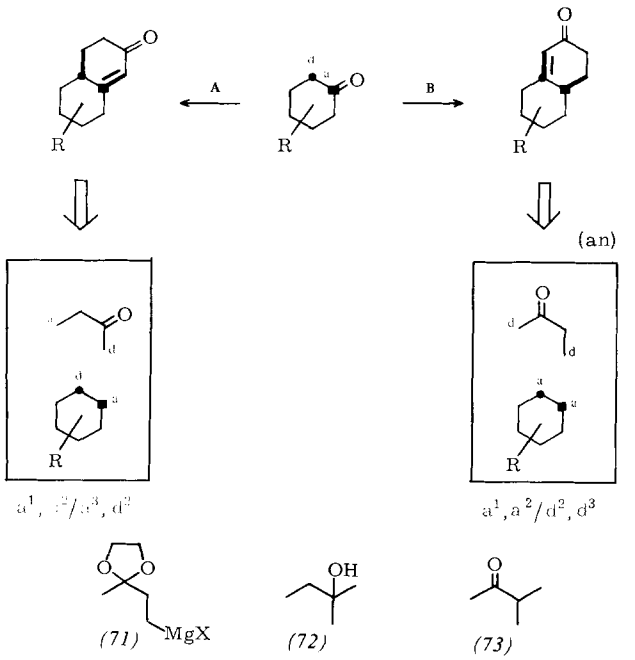
5. Analysis of Some Synthetic Methods

There are many possible combinations of the methods described in Sections 3 and 4.1 by which reactivity umpolung can be achieved. An interesting exercise is the analysis of the numerous ways of preparing 1,4-dicarbonyl compounds *(12)*. This has been a very active field because of the importance of jasmonoid, rethrolonoid, and prostanoid synthesis. Extensive review articles on this subject have appeared[113,162]. In the following discussion some reactions will be analyzed which use the six principal methods given in Section 3 in a more or less 'disguised' way.

One such case is the *use of ω-functionalized terminal olefins* (see *Lednicer*'s article on latent functionality in ref. [5])[163]. This method is based on the oxidative cleavage to a carbonyl



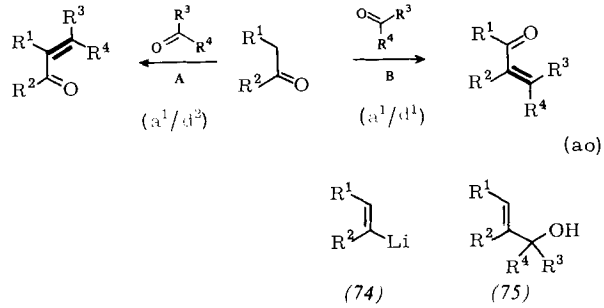
(al)



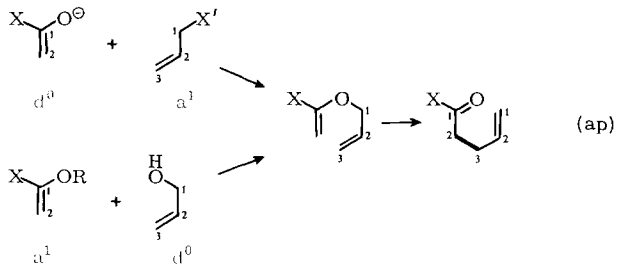
(69) *(70)*

compound, [eq. (al), route A], the anti-Markownikoff hydration [eq. (al), route B] or related reactions of olefinic double bonds, which make the halides *(69)* and the corresponding organometallic compounds *(70)* reagents of normal or reversed reactivity at will. If one also takes the preparation of the halides *(69)* into consideration, one realizes that a combination of heteroatom exchange (Section 3.2), homologation and its reversal (Section 3.3) and 1,2*n*-oxidation (Section 3.1) is at work. The same is true of reagents which contain RO-groups instead of the double bond[164].

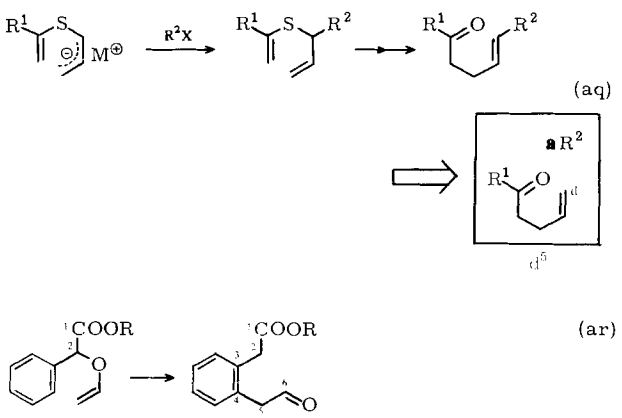
Another very useful approach is to combine normal reactivity *(1)* with a *1,2n-functionality transposition*[165] [a 1,(2*n*+1)-transposition will only shift reactivity *within* *(1)* or *(10)*, see below]. A simple example is outlined in equation (am): The 1,2-carbonyl transposition converts the product of the Friedel-Crafts acylation (a^1/d-) into the product of an a^2/d-combination (acylmethylation). All transpositions of this type



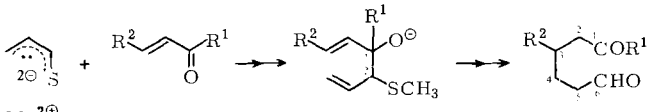
are 1,2*n*-oxidation-reduction processes (see Section 3.1). They either convert the C^1 carbon atom of *(1)* into a donor carbon or they transform d^0 or d^2- into a^0 or a^2-reactivity, respectively (see also Table 3). Two examples are given in equation (an), route B[166], and equation (ao), route B[167a], a "weird" Robinson-annelation [normal: eq. (an), route A][168] and aldol-condensation [normal: eq. (ao) route A][169], respectively. The first sequence of reactions necessitates twofold umpolung. The first one is achieved by heteroatom exchange to *(71)* (Section 3.2), the second one by a 1,2-functionality transposition *(72)* → *(73)* (carried out by dehydration, anti-Markownikoff



hydration, and oxidation) with an a^0-reagent (BH_3/H_2O_2 corresponds to the HO-a^0 synthon and the H-**d** synthon).

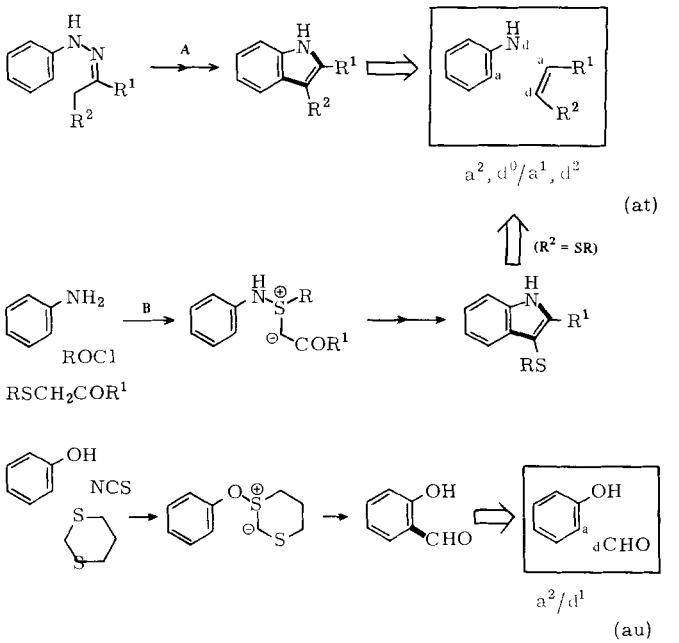


The enone synthesis in equation (ao) uses a reactivity umpolung of the carbonyl carbon [→*(74)*][45,72,167b] with heteroatom exchange methods (Section 3.2) and then a 1,3-transposition of oxygen functionality in *(75)*.



Bond shifts with C—C-formation are another important group of synthetic transformations. A [3,3]-shift does not change the relationship (*i.e.* the number of carbon atoms) between functional groups (whether odd or even). The classical Claisen rearrangement[2,170] converts an a^1/d^0- into an a^3/d^2-product [see eq. (ap)]. If a precursor is synthesized with reactivity umpolung [eq. (aq)][171] or from a compound which contains an even number of carbon atoms between the func-

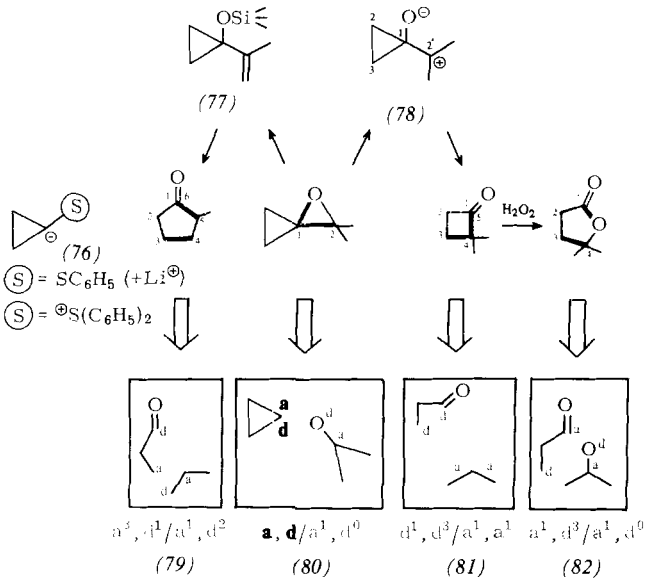
tional groups [eq. (ar)[172]], the "even relationship" is preserved in the rearrangement product. The first transformation is realized by the heteroatom exchange method and



a [3,3]-shift which converts the product of a d^1-reaction into that of a d^5-reaction. On the other hand, in equation (ar) one starts with a 1,2-product (see Section 3, "black magic-box" and 1,2*n*-oxidations), a mandelic acid derivative, and furnishes a 1,6-bifunctionalized compound. This is also true of the oxide-Cope rearrangement[2,173] described in equation (as)[4f,142,144]; the reactivity umpolung proceeds *via* heteroatom exchange (Section 3.2).

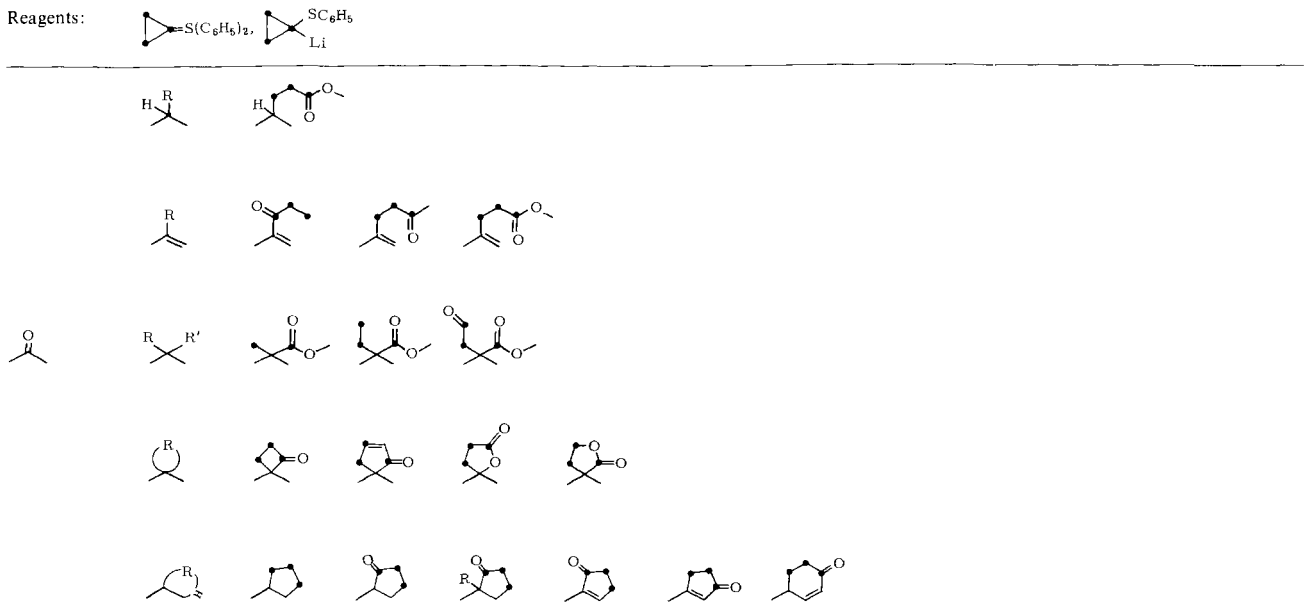
(as)

If a molecule contains X—X'-hetero-hetero bonds [R—O—O—R, R—O—NR_2, R—N=O, R_2C=N(O)R, RO—N=CR_2, R_2N—NR_2, R_2C=N—NR_2, RN=NR, ... or heteroatom exchange analogues], it has a built-in 1,2-oxidation (see Section 3.1 and Table 3), and thus a reactivity umpolung. Therefore, we can consider *Fischer*'s indole synthesis[2] and *Gassman*'s recent modification[174] as a^2/d^2-combinations leading to a 1,4-disubstituted carbon framework [see eq. (at), routes A and B]. The Reimer-Tiemann-type[2] reaction in equation (au)[175] is obviously an a^2/d^1-combination; both components have reactivity *(10)*, and we must necessarily obtain a

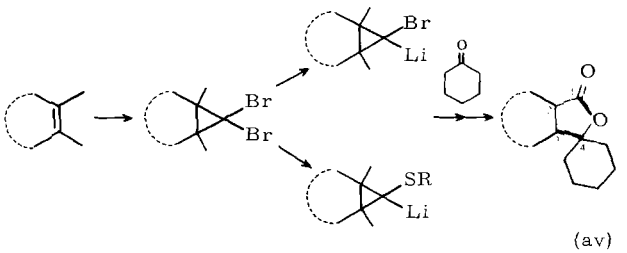


(at)

(au)



1,(2*n*+1)-bifunctional system—as in the reactivity pattern *(1)* (cf. postulate 1.4).



As is evident from Table 9, *Trost*'s cyclopropylidene sulfurane and phenylthiocyclopropyllithium *(76)*[176] are true synthetic chameleons; one can easily count ten different synthon combinations if one compares the products with the starting carbonyl compounds; all of them make at least one bond with reactivity umpolung [see *e.g. (79)—(82)*]. This plethora

of possibilities is obtained by a combination of: 1) heteroatom exchange [Section 3.2, see oxaspiropentane formation *(80)*], 2) the cyclopropane trick [Section 3.4, see *(77)* and *(78)* ($a^{2'}/d^3$)] and 3) the 1,2*n*-oxidation [Section 3.1, see *(82)*]. One limitation of the method, the general lack of availability of substituted reagents *(76)*, can be overcome[39b,177] by starting from dibromo cyclopropanes as outlined in equation (av); they are easily converted into Br/Li-carbenoids or RS-substi-

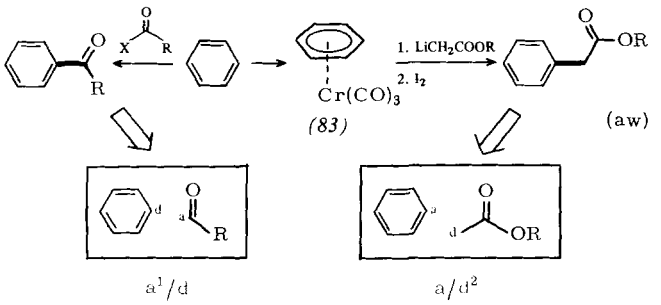


Table 9. Conversions of aldehydes and ketones with sulfur-substituted cyclopropyl nucleophiles of type *(76)*.

(av)

tuted·cyclopropyllithium derivatives, which may be up to tetrasubstituted, and which can be used just as the unsubstituted reagent *(76)*. In the overall reaction, the final product in *(46)* is made from cyclohexene, cyclohexanone, and bromoform, which illustrates that this approach constitutes a synthetic elaboration of the ketone *and* of the olefin [39b, 177]. The use of the Trost method for the preparation of 1,6- and 1,8-bifunctionalized carbon skeletons can only be alluded to here[178].

(aw)

As last example of a recent, useful development in the field of aromatic substitution with reactivity umpolung, *Semmelhack*'s method[179] is mentioned: formation of the benzene-(tricarbonyl)chromium complex *(83)* renders the benzene ring amenable to attack by nucleophiles; instead of the Friedel-Crafts products[2], aryl ketones, α-arylated carbonyl derivatives are formed [see eq. (aw), cf. eq. (am)]. The chromium metal atom decreases the electron density of the benzene ring (lowers the LUMO energy) sufficiently for nucleophilic attack to take place. At least formally, we may say that this is an umpolung by the redox method (Section 3.6).

6. Conclusion

The present article has tried to classify the methods by which reactivity umpolung can be achieved. Hopefully, it will help organic chemists to recognize the necessity of umpolung when planning a synthesis, to see new methods appearing in the literature in a systematic way, and to choose or even discover the best possible reagents for their synthetic problems. Reactivity umpolung is an essential part of synthetic strategy which is now also applied with the aid of computers[180]. It is still a controversial subject among synthetic chemists[181], but highly esteemed in many pharmaceutical and pesticidal industrial laboratories. A most important aspect of organic synthesis, stereochemistry, was naturally excluded from the present discussion, and it is appropriate to stress its importance by quoting: "Stereochemistry rears its ugly head" and "Multistage synthesis: logistics and stereochemistry combine to produce nightmares"[182].

I thank Miss R. Pfister, and Dipl.-Chem. E. Hungerbühler, M. Liesner, and Dr. N. Meyer for their most competent help in preparing the manuscript. Many valuable discussions with a number of colleagues, especially with Professor A. Eschenmoser are gratefully acknowledged. Our own work referred to in this article would not have been possible without the enthusiastic collaboration of my graduate students whose names are given in the list of references. We were generously supported financially by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the BASF AG (Ludwigshafen) and SANDOZ AG (Basel).

Alkenediazonium Salts: A New Chapter of Classical Organic Chemistry

By Kaspar Bott[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Whereas the protonation of α-diazo-β-diketones and α-diazo-β-oxo esters with hydrogen chloride and antimony pentachloride yields the corresponding hydroxyalkenediazonium hexachloroantimonates, the "acid-sensitive" α-diazomonocarbonyl compounds can be transformed into resonance-stabilized alkenediazonium salts by an analogous *O*-alkylation with triethyloxonium hexachloroantimonate. A general route for synthesizing these compounds consists in the transformation of the *p*-toluenesulfonylhydrazones of α-halogenated aldehydes and ketones with Lewis acids. Alkenediazonium ions which are not resonance stabilized can be isolated at room temperature only if their decomposition at higher temperatures leads, *via* evolution of nitrogen, to vinyl cations in particularly high energy levels. Facile substitution reactions at the CC double bond with anisole and methanol demonstrate the strongly electrophilic nature of alkenediazonium salts. When electron-donating substituents are attached to C2 of an ethylenediazonium ion, the bond order of the NN triple bond can be reduced to a level comparable with that in diazoacetic ester.

1. Introduction

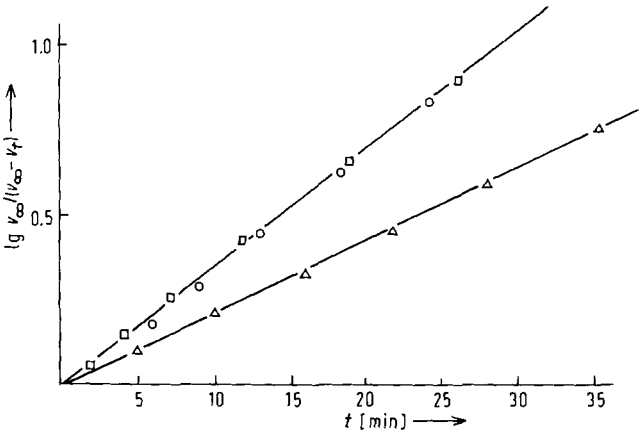
Since their discovery by *Griess* in 1858, aromatic diazonium compounds have acquired considerable industrial and scientific importance[1, 2]. In contrast, their aliphatic analogues, the alkenediazonium salts, were known for a long time only as short-lived intermediates[3–6] which, up to a few years ago, could not be utilized in syntheses. The main reasons for this are the remarkably strong structure-dependence of the thermal stability of the alkenediazonium ions and their high reactivity toward nucleophilic agents. This account intends to describe methods which have been developed for the synthesis of stable alkenediazonium salts. The differences in behavior of alkenediazonium salts and aromatic diazonium compounds will be demonstrated by various substitution reactions. The IR spectra of substituted ethylenediazonium ions provide a good insight into the bond character of the diazonium group.

2. Synthesis of Alkenediazonium Salts

2.1. Diazonium Salts from α-Diazocarbonyl Compounds

Since their discovery, α-diazo-β-dicarbonyl compounds have been known to survive dissolution in cold, concentrated mineral acids[7, 8]. However, subsequent attempts[9] to isolate the protonation products assumed to be present in such solutions were unsuccessful.

A kinetic study of the decomposition of diazomalonic ester with chlorosulfonic acid and methylsulfuric acid in 1,2-dichloroethane led to the assumption of a proton-adduct corresponding to the diazonium salt *(1)*, which decomposes according to a first-order rate law with the elimination of nitrogen. As shown by Figure 1, the rate of the volumetrically determined nitrogen evolution is largely independent of the concentration



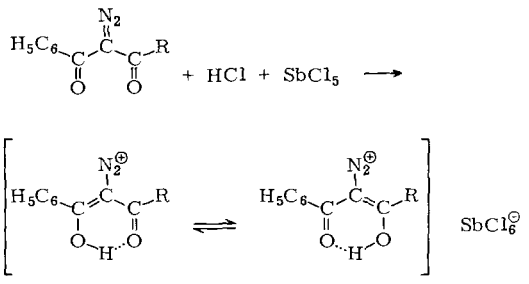


Fig. 1. Decomposition of diazomalonic ester at 16 °C in 1,2-dichloroethane (0.020 mol/l) with chlorosulfonic acid (△, 0.242 mol/l) or methylsulfuric acid (○, 0.238 mol/l; □, 0.443 mol/l).

and the strength of acid used in excess. Analogous measurements with α-diazo-β-disulfones have shown that, at the same temperatures and concentrations, chlorosulfonic acid reacts about 3000 times more rapidly than methylsulfuric acid[10].

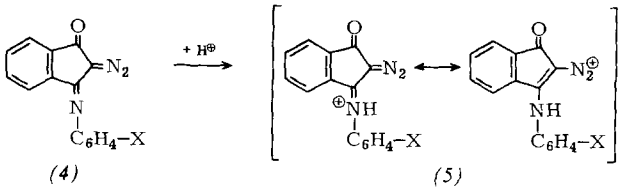
Dissolution of hydrogen chloride, antimony pentachloride, and methyl benzoyldiazoacetate, or benzoyldiazoacetone, or benzoyldiazoacetophenone in dichloromethane affords crystalline salts *(1)* of hexachloroantimonic acid with the diazo compound[11].

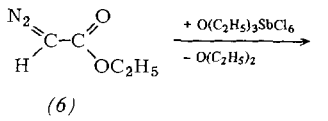


The colorless salts *(1)* contain diazonium ions derived from the enolic form of a β-oxo ester or a β-diketone. Because of the low vapor pressure of HCl (<1 torr at 25°C), it can be assumed that these hydroxyalkenediazonium ions have the *cis* configuration, with a strong intramolecular hydrogen bond[12]. The thermal stability of the salts *(1)* is remarkable; their chemical behavior is determined largely by their acidic character. Thus, the action of triethylamine leads to complete deprotonation and regenerates the α-diazo-β-dicarbonyl compounds.

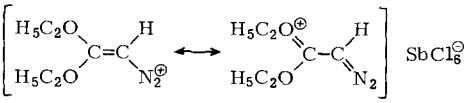
In the presence of hydrogen chloride and antimony pentachloride, diazomalonic ester does not add a proton, but reacts with two molecules of the Lewis acid[11]. Regarding the two structural possibilities, namely an addition complex *(2)* or a diazonium chelate *(3)* with salt character, measurement of the electrical conductivity in liquid sulfur dioxide provides evidence in favor of *(3)*.

(2) *(3)*

Boron trichloride and boron trifluoride also combine with dicarbonyl diazo compounds, to form 2:1 addition products, for which *Fahr* and *Hörmann*[9] suggest structures analogous to the complex *(2)*. The more strongly basic imines *(4)* are already protonated in ethanol/water by mineral acids yielding salts of type *(5)*, whose properties are in agreement with the two resonance structures, *viz.* diazoimonium ion and aminoalkenediazonium ion[13].

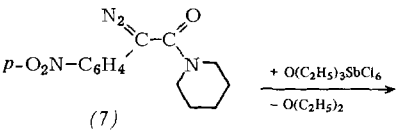


(4) *(5)*

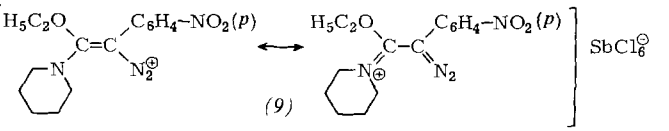


X = H, *p*-Cl, $-NO_2$, $-CH_3$, -I, $-OCH_3$

Although the acid-sensitivity of α-diazomonocarbonyl compounds such as diazoacetic ester *(6)* or *p*-nitrophenyldiazoacetic acid piperidide *(7)* excludes salt formation with strong protonic acids, the alkylation of the carbonyl oxygen with triethyloxonium hexachloroantimonate affords the substituted ethylenediazonium salts *(8)* and *(9)*[11], which can also be regarded as oxonium or as imonium compounds. *(8)* decomposes at 115°C and *(9)* at 127°C.



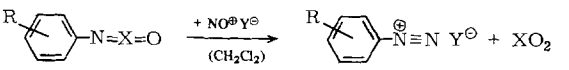
When *(6)* and *(7)* are transformed into the ions *(8)* and *(9)*, the frequencies of the respective NN stretching vibrations are shifted by 80 and 30 cm^{-1}. The magnitude of this frequency shift ($\Delta\tilde{\nu}$NN) and the position of the diazo absorption band



(6)

(8)

(7)



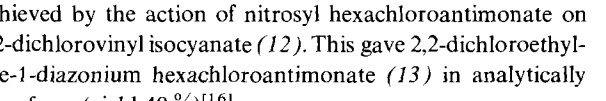
(9)

provide a simple means of estimating the approach to a real nitrogen-nitrogen triple bond (see Section 4).

2.2. Diazonium Salts from Isocyanates and Sulfinylamines

The observation crucial to the development of syntheses of ethylenediazonium salts without substituents at C2 capable of displaying resonance was that the salt *(8)* is resistant to acetic acid at room temperature but loses nitrogen spontaneously with methanol. This shows that methanol adds to the activated carbon-carbon double bond of *(8)*, to give a very short-lived alkanediazonium ion. The transformations selected as model reactions, namely those of nitrosyl salts with aryl isocyanates *(10a)* or arylsulfinylamines *(10b)* should permit preparation of arenediazonium ions in the absence of alcohols and water. Whereas the sulfinylamines *(10b)* are transformed almost quantitatively into aryldiazonium salts *(11)*[14], the desired reaction does not occur with phenyl isocyanate *(10a)*, R = H.

(10) *(11)*



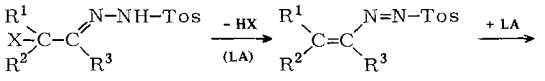
(10a), X = C, R = H

(10b), X = S, R = *p*-Cl, *p*-O_2N, *m*-O_2N

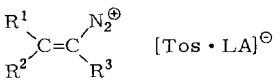
Y = $SbCl_6$, ClO_4

Our assumption that the nitrosyl cation preferentially attacks the benzene ring in the case of phenyl isocyanate was later confirmed by *Olah*[15]: alkyl isocyanates react with nitrosyl salts to give alkanediazonium salts, identified by their secondary products.

The analogous synthesis of an alkenediazonium salt was achieved by the action of nitrosyl hexachloroantimonate on 2,2-dichlorovinyl isocyanate *(12)*. This gave 2,2-dichloroethylene-1-diazonium hexachloroantimonate *(13)* in analytically pure form (yield 40%)[16].



(12) *(13)*

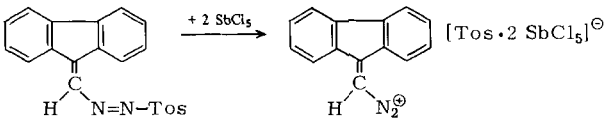


It still remains to be established whether other vinyl isocyanates are also suitable for these reactions. Vinylsulfinylamines, which could also be considered as potential starting materials, are still unknown.

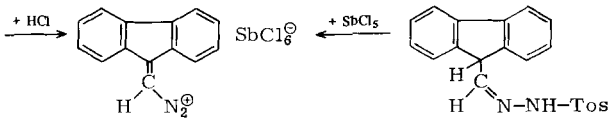
2.3. Alkenediazonium Salts from Sulfonylhydrazones

The action of Lewis acids on the *p*-toluenesulfonylhydrazones *(14)* of α-halo aldehydes or ketones constitutes a simple and efficient synthesis of alkenediazonium salts of the type *(16)*[17–19]. Suitable Lewis acids are antimony pentachloride, stannic chloride, and aluminum trichloride, and in this reaction sequence they fulfil several functions. They catalyze the elimination of hydrogen halide from the sulfonylhydrazones *(14)*, and they remove the *p*-toluenesulfinate anion from the azosulfone intermediate *(15)* in the subsequent step. Finally, they are necessary for the formation of the complex anion in the final product *(16)*. The hydrazones *(14)* can also contain an alkoxy or acyloxy group instead of the halogen, provided that their elimination is favored by geminal substituents R^1 and R^2.

(14) *(15)*



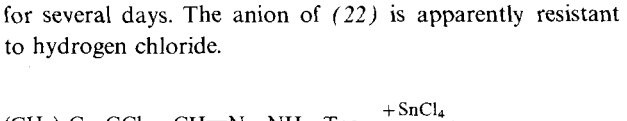
(16)



LA = Lewis acid
X = F, Cl, Br
Tos = *p*-CH_3–C_6H_4–SO_2

The rates of the formation of *(16)* parallel the well known sequence of strengths of the Lewis acids in Friedel-Crafts reactions[20], *i.e.* $AlCl_3 > SbCl_5 > SnCl_4$. As the first step of this sequence, hydrogen halide elimination can sometimes become rate-determining for the overall reaction, when relatively weak Lewis acids such as $SnCl_4$ are used. In such cases it is advantageous to produce the sulfonylazoalkene *(15)* separately, using a suitable base[21] (see Section 2.3.1).

Antimony pentachloride is preferred as the Lewis acid, since the diazonium hexachloroantimonates were found to be well-crystalline compounds. The salt *(18)*, which results from the azofulvene *(17)* and two molecules of $SbCl_5$, is transformed almost quantitatively into crystalline hexachloroantimonate *(19)* by the action of hydrogen chloride.



(17) [≡*(15a)*] *(18)*

(19) *(20)*

Furthermore, *(19)* arises directly from 9-fluorenecarbaldehyde *p*-toluenesulfonylhydrazone *(20)* and antimony pentachloride, the latter also acting as an oxidizing agent in this case.

2-Chloro-3,3-dimethyl-1-butene-1-diazonium tetrachloro(toluenesulfinato)stannate *(22)* crystallizes from a solution of 2,2-dichloro-3,3-dimethylbutyraldehyde tosylhydrazone *(21)* and stannic chloride in dichloromethane on standing for several days. The anion of *(22)* is apparently resistant to hydrogen chloride.

(21) *(22)*

2.3.1. Preparation of the Toluenesulfonylazoalkene Intermediate

The production of the azo compounds *(15)* which appear as short-lived intermediates in the synthesis of alkenediazonium salts can be considered as a variant of the Chattaway reaction[22]. The chemical behavior of *p*-toluenesulfonylazoalkenes *(15)* in the absence of strong acids has been investigated by several authors and was utilized for the synthesis of alkynes[23–25] or alkylidenecyclopropanes[26].

Table 1 shows a selection of azoalkenes *(15a–g)* accessible in pure form[19,21]. The reactions of *p*-toluenesulfonyl hydra-

[a] *(20a)* = 9-Acetylfluorene-*p*-toluenesulfonylhydrazone.

zide with α-halogenated aldehydes and ketones that also contain a C_α-aryl or -vinyl groups lead directly to the sulfonylazoalkenes [for example *(15a—c)*]. Apparently, aryl and vinyl groups strongly accelerate the subsequent reaction of the sulfonylhydrazones *(14)* to *(15)*, since this reaction occurs with a gain in resonance energy. The azoalkenes *(15a)* [≡ *(17)*] and *(15b)* can also be prepared by oxidation of the halogen-free sulfonylhydrazones according to a method described by *Schantl*[27].

Toluenesulfonylhydrazones of aldehydes and ketones bearing only halogen atoms or a halogen and *tert*-alkyl groups attached to C-2 require a base for elimination of hydrogen halide (*e.g.* triethylamine or aqueous sodium hydroxide). Among the azoalkenes *(15d—g)* synthesized by this route, *(15f)* and *(15g)* are stable at room temperature for only a few hours.

2.3.2. Diazonium Salts from Aldehyde Sulfonylhydrazones[19]

Table 2 lists the β-substituted ethylenediazonium compounds that have been prepared by the toluenesulfonylhydrazone method, in the order of decreasing decomposition temperatures. The stabilizing effect of chlorine is clearly evident. If one chlorine atom of *(13)* is replaced by hydrogen or

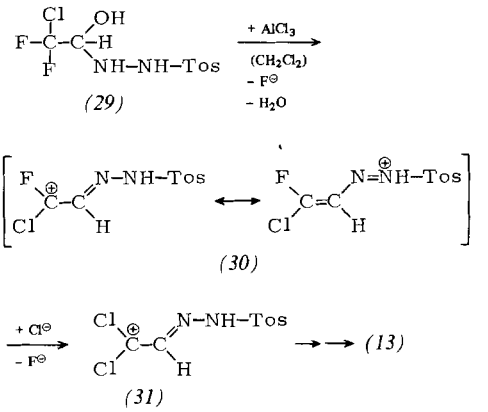
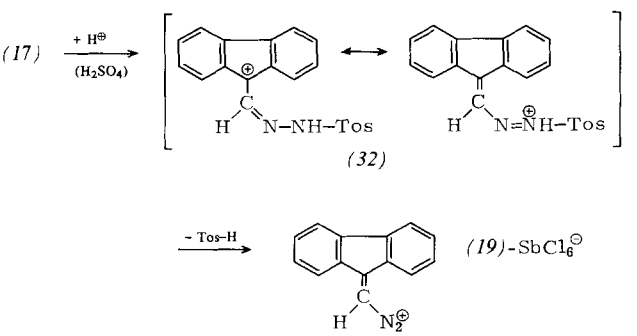
	H_5C_2	Cl	$SbCl_6$	[c]	—

[a] $CCl_2{=}CCl{-}CCl{=}CH{-}N_2^{\oplus}$ [$2SbCl_5$·Tos]$^{\ominus}$ decomposes at 90°C. [b] Compare *(23)*. [c] The compound can only be obtained as a solution (CH_2Cl_2) stable at room temperature.



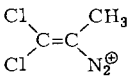
by a *tert*-butyl group, or if both chlorine atoms are replaced by a *tert*-butyl group and bromine, or by the 1-adamantyl substituent and bromine, the thermal stability of the resulting diazonium salt is decreased. A similar introduction of a trichlorovinyl or 2,2′-biphenylyl group decreases the stability to a smaller extent.

A plausible explanation for the different thermal stabilities of the β-substituted ethylenediazonium salts is that, in general, the elimination of nitrogen does not yield the particularly unstable primary vinyl cations [*e.g.* as in the case of *(13)*], but rather bridged cations such as *(26)*—*(28)*, which can already profit from the lower energy level of a completely rearranged intermediate[28–31]. Thus, it is not surprising that the alkenediazonium ions *(24)* and *(25)*, derived from 1-chlorocyclohexanecarbaldehyde- and α-chloroisobutyraldehyde toluenesulfonylhydrazone respectively, spontaneously eliminate nitrogen at temperatures as low as 5 to 10°C. The pronounced tendency of the cyclohexylidenemethanediazonium ion *(24)* to undergo decomposition corresponds to

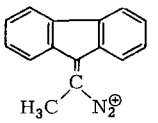


the accelerated solvolysis of cyclohexylidenemethyl trifluoromethanesulfonate, which undergoes ring expansion to give cycloheptanone, probably *via (27)*[32].

The influence of fluorine in the β-position upon the strength of the bonding of the diazonium group is of interest in this connection. While antimony pentachloride, antimony pentafluoride, or aluminum trichloride does not react with trifluoroacetaldehyde tosylhydrazone (as hydrate), reaction of the corresponding chlorodifluoro derivative *(29)* and aluminum trichloride in dichloromethane gives a solution of the 2,2-dichloroethylenediazonium ion. This ion is precipitated by the readily soluble isopentadecylammonium hexachloroantimonate as the salt *(13)*[33]. The replacement of fluorine by chlorine, necessary for the formation of *(13)*, probably takes place in the resonance-stabilized cationic intermediate *(30)*.



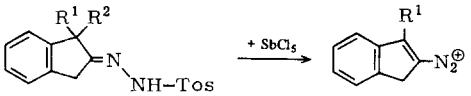
The protonation product *(32)* of the azo compound *(17)* [≡ *(15a)*], which corresponds to the short-lived intermediates *(30)* and *(31)*, can be observed directly in sulfuric acid, since transformation of the dark red *(32)* into the olive-green cation of *(19)* goes to completion only after one or two minutes even at room temperature.



2.3.3. Diazonium Salts from Ketone Sulfonylhydrazones[19]

The diazonium group plays an outstanding role[34] in the generation of carbenium ions by heterolytic bond fission because of the great ease with which a nitrogen molecule can be eliminated. This is why alkenediazonium ions with an alkyl or aryl substituent on the diazo carbon can exist under normal conditions only if the energy level of the resultant vinyl cations is raised by an opposing effect.

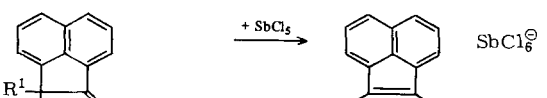
For example, in compounds *(13)* and *(19)*, replacement of the α-hydrogen by a methyl group leads to the ions *(33)* and *(34)*. The salts of the 1,1-dichloropropene-2-diazonium ion *(33)* can only be isolated and characterized at temperatures below −20 °C, since they decompose with evolution of



(33)

(34)

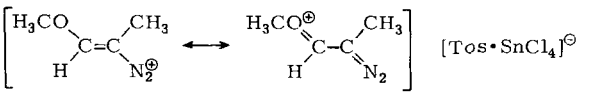
nitrogen even at −10 to 0 °C both as solids and in solution. Even at −20 °C, the reaction of the azo compound *(15b)* with antimony pentachloride gives no indication that *(34)* can exist for only a few minutes under these conditions.



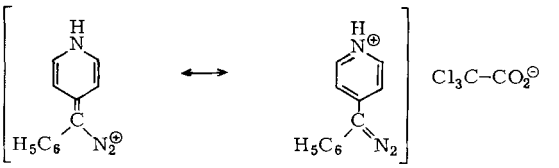
As shown by solvolyses of cyclic vinyl trifluoromethanesulfonates[35], vinyl cations with nonlinear σ-bonds are less stable than those with linear bonds. According to our investigations[36], however, the higher energy level of the 1-cyclopentenyl and 1-cyclohexenyl cations still does not permit the isolation of cyclopentene- or cyclohexenediazonium salts at 0 °C. Only in the indene-2-diazonium ion *(36a)*, and in its 3-phenyl derivative *(36b)*, does the five-membered ring become so rigid by the incorporation of four sp^2-centers that *(36a)* and *(36b)* fail to eliminate nitrogen at room temperature.

(35a, b) *(36a, b)*

(a), R^1 = H, R^2 = AcO
(b), R^1 = C_6H_5, R^2 = H



Reaction of the hydrazones *(37a)* and *(37b)* with antimony pentachloride yields the even more strained acenaphthylene-1-diazonium hexachloroantimonates *(38a)*, or *(38b)* with an aryl substituent at the diazonium carbon atom. The remarkable stability of *(38a)*, which is even greater in its derivative *(38b)*, due to fluorine substitution, arises for geometric reasons: in the diazonium ion *(38a)* the aryl substituent can only stabilize the vinyl cation resulting from loss of nitrogen when it is oriented perpendicularly to the σ-bond skeleton of the olefinic carbons. Such an orientation is completely ruled out because of the "fusion" of the five-membered ring with the naphthalene system. Likewise, the 3-phenyl-2-indenyl cation which corresponds to the indenediazonium ion *(36b)* is unable to lower its energy level by migration of the phenyl group to C-2.—"Aromatic" diazonium ions of acenaphthylene are still unknown.

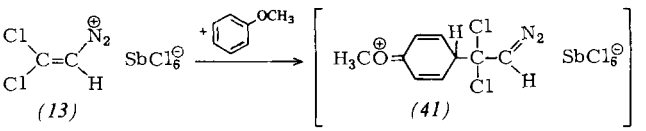


(37a, b) *(38a, b)*

	R^1	R^2	Decomposition of *(38)* at [°C]
(a)	H	OCH_3	140—141
(b)	F	F	187—188

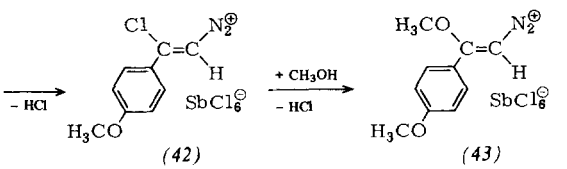
In addition, the stability of α-alkyl- or α-aryl-ethylenediazonium compounds can be increased by substituents capable of resonance with the diazonium group. Thus, the 1-methoxypropene-2-diazonium salt *(39)* obtained from 1,1-dimethoxyacetone tosylhydrazone and stannic chloride does not decompose below 95 °C.

(39)



(40)

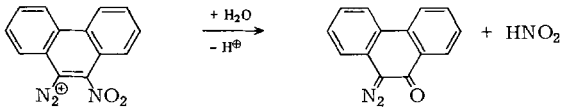
Both in the α-(*p*-nitrophenyl)ethylenediazonium salt *(9)* and in the salt *(40)*[37] (decomposition at 97 °C), promotion of nitrogen elimination by the phenyl substituent is completely suppressed by the resonance stabilization.



3. Reactions of Alkenediazonium Salts[19]

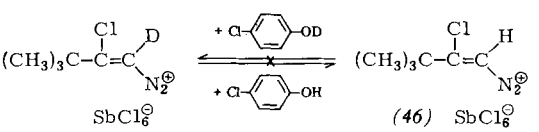
In contrast to the arenediazonium ions, the alkenediazonium ions can only exist with the anions of very strong acids, and they react spontaneously, even below room temperature, with water, alcohols, carboxylic acids, and other carbonyl compounds.

As shown by the substitution reactions of *(13)* and *(42)*, nucleophiles expectedly attack the β-carbon of the ethylenediazonium group. The particularly electrophilic salt *(13)* can enter the *p*-position in anisole at 0 to 20 °C. Subsequent elimination of hydrogen chloride forms the 2-chloro-2-(*p*-methoxyphenyl)-ethylene-1-diazonium salt *(42)*. While an excess of



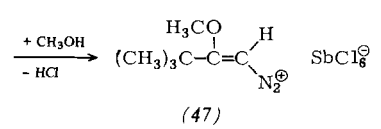
(13) *(41)*

(42) *(43)*



anisole does not react with *(42)*, the more strongly basic methanol can also substitute the second chlorine atom. The yields of the hexachloroantimonates *(42)* and *(43)*, isolated in an analytically pure state and free from isomers, are 61 and 56 %, respectively. The postulated intermediate *(41)* comprises a strong protonic acid and an acid-sensitive diazoalkane group united in a single molecule, but the usual displacement of nitrogen does not occur. The reaction *(42)*→*(43)* is expected to proceed *via* an analogous compound. This reaction requires two or three moles of methanol per mole of *(42)*, presumably because some of the alcohol is "bound" by the hydrogen chloride which is produced. Compound *(43)* ultimately decomposes on addition of yet more methanol.

The NO_2 group of the 10-nitrophenanthrene-9-diazonium ion *(44)*, whose C^9—C^{10} bond partly has an alkene-like character, is also displaced by water in dilute mineral acids, forming diazophenanthrone *(45)*[38].



(44) *(45)*

In the 2-chloro-3,3-dimethyl-1-butene-1-diazonium salt *(46)*, the addition of a nucleophilic agent at C-2 is strongly hindered by the bulky *tert*-butyl group. Thus, under the conditions mentioned earlier, neither anisole nor phenol can effect halogen exchange. However, the rapid transformation of *(46)* into 2-methoxy-3,3-dimethyl-1-butene-1-diazonium hexachloroantimonate *(47)* by methanol can be confirmed spectroscopically, since this reaction is accompanied by a characteristic shift of the diazo stretching band toward longer wavelengths (Section 4).

(46)

(47)

The strong deshielding effect of the *tert*-butyl group on the β-carbon in *(46)* provides a method of checking whether the acidity of the α-hydrogen atom is sufficient to establish an acid-base equilibrium in the presence of *p*-chlorophenol. In 1:3 mixtures of *(46)* with *O*-deuterated *p*-chlorophenol in 1,2-dichloroethane, the spectroscopically observed ratio of the two species of protons $[(CH_3)_3C—/{=}CH—N_2^{\oplus}]$ is still 9:1, even after three hours at room temperature.

In the light of the foregoing investigations, it is worth noting the observations by *Newman et al.*[5] and by *Kirmse et al.*[39] that the β,β-dialkylethylenediazonium ions *(24)* and *(25)*, obtained from *N*-nitrosooxazolidones, can be deprotonated to α-diazoolefins by sodium methoxide, and transformed into vinyl azides by alkali azides, in spite of their short lifetimes.

4. Diazo Stretching Vibrational Spectra

Taking the salts *(8)* and *(9)* as examples, it has already been mentioned that electron-donating substituents on C-2 of an ethylenediazonium ion are able to accept a positive charge and can thus reduce the bond order of the NN triple bond. Therefore, with increasing proportion of this resonance structure the frequency of the relevant diazo stretching vibration should decrease. Examples of this are shown in Table 3. 2-Chloroethylenediazonium hexachloroantimonate *(48)* and the next five compounds with halogens and *tert*-alkyl groups on C-2 exhibit diazo absorption bands with the shortest wavelengths. In the two subsequent compounds *(49)* and *(19)* a trichlorovinyl or biphenylylene group is involved in the resonance with the diazonium nitrogen. In the diazonium compounds *(47)*, *(39)*, *(42)*, *(43)*, and *(8)* the presence of *p*-methoxyphenyl and alkoxy groups leads to an even more marked shift of the NN vibrational frequencies. Owing to its long wave absorption maximum, the salt *(9)* can already be compared with diazoacetic ester ($\tilde{\nu}_{NN} = 2105\,cm^{-1}$), while Reimlinger salt *(40)* must be regarded as *N*-protonated phenyl-4-pyridyldiazomethane according to its IR spectrum.

Table 3. NN stretching frequencies of alkenediazonium salts $R^1R^2C{=}CR^3—N_2^{\oplus}Y^{\ominus}$.

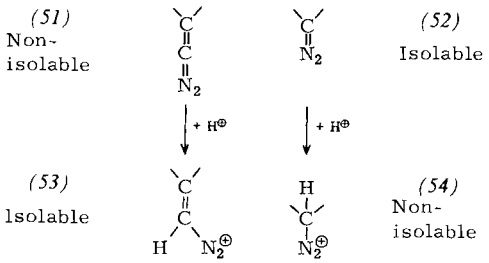
[a] Solid in Nujol. [b] In 1,2-dichloroethane. [c] In nitrobenzene. [d] KBr disk.

The influence of nuclear substituents in aromatic diazonium salts upon the position of the NN absorption bands has already been investigated[40]. The parent compound of the arenediazonium salts, benzenediazonium tetrafluoroborate, whose vibrational band is at 2280 cm^{-1}, should accordingly be placed at the head of Table 3.

5. Final Remarks and Outlook



From the various syntheses of alkenediazonium salts considered, we can conclude that those alkenediazonium ions are generally stable enough to be isolated which form high-energy vinyl cations on elimination of nitrogen. The only exceptions to this rule are the resonance-stabilized β-alkoxy- and β-dialkylaminoethylenediazonium salts. These compounds, products of the *O*-alkylation of α-diazocarboxylic acid amides, α-diazocarboxylic acid esters, α-diazoketones, and α-diazoaldehydes, are the links between real alkenediazonium ions and the uncharged aliphatic diazo compounds.

The vinyl cation *(50a)*, obtained in the decomposition of the resonance-stabilized alkenediazonium compound *(9)*,

assumes a similar transition state since, in another resonance form *(50b)*, it can also be regarded as an imonium ion with a β-alkoxycarbene partial structure. The gain in energy due to the resonance between *(50a)* and *(50b)* must however be considerably smaller than the loss in resonance energy that the alkenediazonium salt *(9)* must accept as a consequence of the elimination of the diazonium nitrogen. This was derived from the fact that in *(9)* the nitrogen is no longer the good leaving group that it normally is.

When alkenediazonium ions have an H-atom on the α-carbon, they can be regarded as protonated α-diazoalkenes. A comparison of the α-diazoalkenes *(51)* with the diazoalkanes *(52)* shows that in the first case only the protonated species *(53)* can be isolated, whereas the alkyldiazonium ions *(54)* derived from the isolable diazoalkanes *(52)* occur only as short-lived intermediates.

The introduction of the diazonium group into alkenes produces species surpassing even tetracyanoethylene in their electrophilic properties. For this reason the reactions of ethylenediazonium salts with other alkenes and "1,3-dipoles" most likely possess considerable synthetic potential. An indication of cycloadditions of alkenediazonium ions to the nitro group is provided by the observation that the particularly reactive compounds *(13)* and *(38a)* eliminate nitrogen in nitrobenzene solution even at room temperature.

Furthermore, alkenediazonium ions provide a means of investigating the stability of vinyl cations in a range that is inaccessible by the heterolysis of vinyl perfluoroalkanesulfonates. In this field, interest is centered mainly on the generation of primary vinyl cations which have so far only been unequivocally detected on the addition of 1-adamantyl cations to acetylene[41] or on the photolysis of iodoolefins[42].

Kinetics of Sorption, Desorption, and Diffusion in Zeolites

By Hans-Joachim Doelle and Lothar Riekert[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Sorption and desorption in zeolites (molecular sieves) have to be considered as complex processes, involving simultaneous diffusion in zeolite crystals, mass transfer in the intercrystalline voids of a pellet, and heat transfer between the zeolitic sorbent and its surroundings. The kinetics of sorption and desorption, respectively, of n-C_4H_{10} in zeolite X and of CO_2 in zeolite A have been investigated: only the initial rates of uptake or release of the sorbate are controlled by mass transfer alone whereas ultimately they also depend on the rate of heat transfer from the sorbent to its surroundings or *vice versa*. Diffusivities of the sorbate in the zeolite crystals can be obtained from the kinetics of mass transfer, provided the resistance due to viscous or Knudsen flow between the crystals of the zeolitic sorbent can be eliminated. A sample consisting of a monolayer of single crystals had to be used for this purpose in the n-butane/zeolite X system; the intracrystalline diffusivity obtained in this way is not in conflict with data obtained by NMR spectroscopy. The intracrystalline diffusivities obtained in this way—taking into account the coupling of several processes during sorption—are higher than values reported in the literature.

1. Introduction: Sorption, Diffusion, and Self-Diffusion in Zeolites

Zeolites (natural or synthetic crystalline aluminosilicates) have found important applications as sorbents and catalysts in commercial processes[1]. On conventional sorbents or catalysts adsorption takes place in a two-dimensional phase boundary whereas in zeolites guest molecules can penetrate into the relatively open crystal structures. These guest molecules can be considered as dissolved in a solid rather than being adsorbed at a surface, since the size of the "cavities" in the crystal structures (0.5—2 nm) is of the same order of magnitude as are the collision cross-sections of small molecules. At equilibrium, the sorbate will be distributed randomly in the crystal. The kinetics of sorption and desorption in zeolites as well as the activity and selectivity of zeolite catalysts may be strongly dependent on the rate of migration of the sorbate in the solid.

It therefore appears expedient to have some knowledge about the diffusivities of sorbed molecules in zeolite crystals when considering various applications. Zeolites can be synthesized as crystals with diameters of about 1 μm; crystal diameters up to 100 μm can be prepared by special methods. It is therefore not possible to measure diffusivities in zeolites *via* steady state rates of permeation—as for example in a foil of plastic material. Diffusivities can be deduced from material fluxes in zeolites only by observing rates of sorption or desorption, *i.e.* by studying non-steady-state kinetics. Information about the mobility of sorbed molecules in zeolites can also be obtained independently by NMR spectroscopy. Unfortunately, the results of several investigations along these lines appear inconsistent. For example, different values of the diffusivity of C_2H_6 in Na-mordenite have been found for sorption and desorption; the coefficient of diffusion thus depends on the direction of the net flux[2]. A diffusivity that is different by a factor of roughly 10^2 was found for the same system by a chromatographic pulse method[3]. The discrepancies between diffusion coefficients which have been found from observed rates of sorption on the one hand and coefficients of self-diffusion as obtained by the NMR spin-echo method on the other hand are even more striking.

The mean square displacement $\langle \Delta X^2 \rangle$ of a molecular species in sorption equilibrium during a given time interval Δt is observed by spin-echo experiments. $\langle \Delta X^2 \rangle$ will depend only on the random movement of the sorbate in the zeolite crystals if the amount of this substance in the gas phase is negligible compared to the amount which is sorbed in the solid, which will be the case at low temperatures. For sufficiently small time intervals Δt, the root mean square displacement $\langle \Delta X^2 \rangle^{1/2}$ will furthermore be small compared to the linear dimensions of the crystallites. Under these conditions the coefficient D^* of self-diffusion of the sorbate follows from $\langle \Delta X^2 \rangle$ and Δt as[4]:

$$D^* = \frac{\langle \Delta X^2 \rangle}{6 \Delta t}$$

This coefficient D^* characterizes the mobility of sorbed particles in a system where sorption equilibrium is established, the density of sorbed particles being constant in space and time. The diffusivity D as obtained from the kinetics of sorption or desorption on the other hand is defined by the diffusion equation

$$\frac{\partial c}{\partial t} = \operatorname{div}(D \operatorname{grad} c) \qquad (1)$$

(c = concentration of sorbate in a zeolite crystal) which is used in its integrated form to describe the net flux of material with respect to the coordinates of the solid. As long as the sorbed particles do not interact—their random movements thus being independent (at low degrees of saturation θ)—the

[*] Prof. Dr. L. Riekert, Dr. H.-J. Doelle

Postfach 6380, D-7500 Karlsruhe (Germany)

© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0404-0266 $ 02.50/0

coefficients D^* and D should be equal, whereas at higher degrees of saturation a simple theory of random movement of sorbed particles requires that D^* be smaller than D[5]. The same condition should be expected from a widely assumed relation (2) between the ratio D^*/D and the slope of the equilibrium isotherm

$$\frac{D^*}{D} = \frac{d\ln c}{d\ln p} = \frac{d\ln \theta}{d\ln p} \qquad (2)$$

which is (incorrectly) known as *Darken*'s equation. Within the linear range of the isotherm, equation (2) requires $D^* = D$, whereas at higher degrees of saturation (θ) its validity appears to be dubious[6]. Theory thus requires that D^* and D be of the same order of magnitude at least within a wide range of θ and also, that D^* should *not* be greater than D at a given temperature. Values of D^* obtained from NMR spectroscopy, however, are greater by factors between 10^3 and 10^5 than values of D found from sorption kinetics for the same sorbate-zeolite systems[7]. In view of these rather striking contradictions it was suspected that the kinetics of sorption in zeolites is not controlled exclusively by diffusion in the solid, and it has been proposed that coefficients of diffusion D in zeolites obtained from sorption kinetics be considered as compound quantities, which may also be influenced by processes other than the migration of the sorbate in the solid[7, 8].

In order to obtain "true" diffusivities of the sorbate in the zeolite crystals from sorption kinetics we have attempted to determine experimentally the relative influence of the following processes on the rate of uptake or desorption:

- mass transfer of sorbate in the gas phase and in the intercrystalline voids of the zeolite sample,
- transfer through the gas/solid phase boundary,
- diffusion in the volume of the crystals,
- heat transfer between solid and surroundings.

It was also a goal of this investigation[9] to gain some insight into the kinetics of sorption in commercial applications of zeolites, information which might perhaps be useful with respect to the optimal size, structure, *etc.* of zeolitic sorbents.

2. Experimental Investigation of Sorption Kinetics

The kinetics of sorption or desorption was observed in a system consisting of a gas phase and the solid, initially at equilibrium, the amount of sorbate in the solid being recorded following an increase or decrease of pressure in the gas at time zero. The gas phase consisted of only one component; any external resistance to mass transfer can thus arise only from the flux of the gas in the voids (macroscopic pores) between the crystals of the zeolite sample. The change of pressure at time zero should ideally be instantaneous, a condition which can only be approximated. The change of the gas pressure with time must be symmetrical in sorption and in desorption; otherwise different initial conditions could be responsible for an apparent discrepancy between the rate of sorption as compared to desorption. The finite rates of response of sensors and recording equipment has to be considered in evaluating the observations.

The apparatus shown schematically in Figure 1 has been used to determine sorption isotherms as well as the kinetics

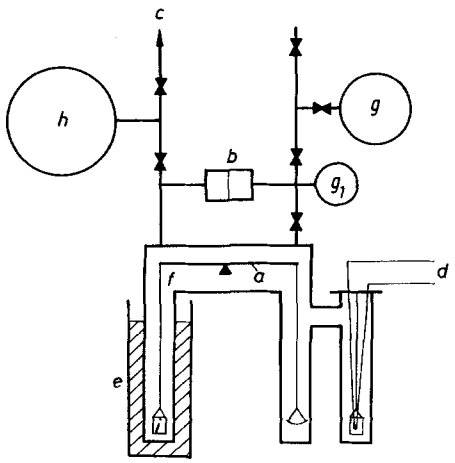

Fig. 1. Apparatus (schematic): a, balance (Cahn R 100); b, differential pressure transducer (MKS baratron 77); c, turbomolecular pump; d, thermocouple (Pt/PtRh, 0.1 mm diam.); e, constant temperature water bath; f, volume with sample and balance (3.075 l); g, storage vessel; g_1, storage vessel (0.285 l); h, evacuated buffer volume (50 l); i, sample pan.

of sorption and desorption. The zeolite sample in the form of either a bed of small crystals or a monolayer of larger single crystals was placed in the sample pan of an electric microbalance (sensitivity 0.5 μg); the pressure in the system was observed through a membrane-capacitance manometer. The overall time constants for the recording of changes of sample mass or pressure were found to be 0.15 s. The system was evacuated by a turbomolecular pump; the temperature of the glass leg containing the sample was kept constant within ±0.1 K during sorption experiments; an electric furnace was used for outgassing. The volume f containing the sample was connected at time zero for 0.2 s to the storage volume g_1 in order to obtain an increase in pressure; a decrease in pressure was obtained by connecting for 0.2 s to the evacuated vessel h. The change of the amount of sorbate in the solid was then recorded *via* the balance, the control volume of the closed system being always the same. The pressure p in the system changes linearly with the amount n of sorbate in the solid, because the total amount of substance either in the gas or in the solid is constant during each run. This condition had to be taken into account when diffusion coefficients were evaluated; solutions of the diffusion equation for this particular condition have been given by *Barrer*[10] and by *Crank*[11]. The variation of the temperature of the zeolite due to sorption or desorption was monitored in separate experiments but under identical conditions by a miniature thermoelement (0.1 mm diameter) embedded in the sample. The zeolite samples were degassed for 3 h at 573 K and $p < 10^{-2}$ Pa before starting the first sorption experiment.

Zeolites NaX and NaA were synthesized as relatively large crystallites (diameters ranging from 5 to 100 μm) by the method described by *Charnell*[12]. Crystal structures were verified by X-ray diffraction; the composition of the dry materials was analyzed as

zeolite NaX: $Na_2O \cdot Al_2O_3 \cdot (SiO_2)_{2.26}$
zeolite NaA: $Na_2O \cdot Al_2O_3 \cdot (SiO_2)_{2.0}$

Samples with a fairly narrow size distribution of the crystals (80±10 μm for NaX; 30±5 μm for NaA) were obtained by wet sieving. The gases used were *n*-butane (purity better than

99.8 mol %) and carbon dioxide (purity better than 99.995 mol %).

3. The *n*-Butane/Zeolite NaX System

Equilibrium isotherms of *n*-butane sorbed in NaX are shown in Figure 2 for temperatures between 25 and 40 °C. A constant isosteric heat of sorption $\Delta H_s = -39\,\mathrm{kJ\,mol^{-1}}$ follows from these data with the equation

$$\Delta H_s = RT^2 \left(\frac{\partial \ln p}{\partial T}\right)_{n/m}$$

for sorbate concentrations up to 6 wt %.

All kinetic observations were conducted in this range of saturation, where the isotherm at 25 °C can be represented with an accuracy of ±5 % by the linear relation

$$\frac{n}{m} = K \cdot p \text{ with } K = 3 \times 10^{-5}\ \mathrm{mol\ g^{-1}\ Pa^{-1}} \qquad (3)$$

(n = amount of sorbed butane, m = mass of sorbate-free, dry zeolite).

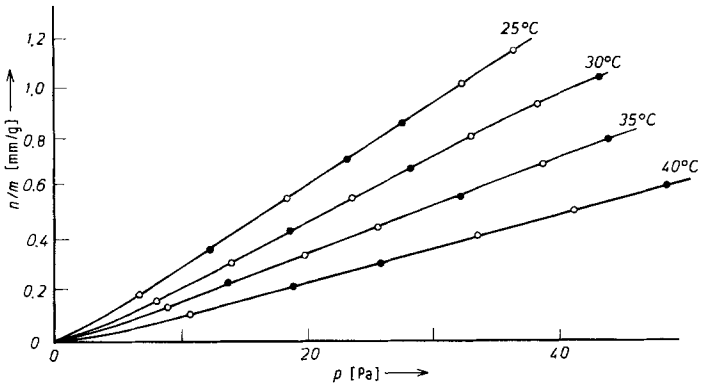

Fig. 2. Isotherms of *n*-butane in zeolite NaX; equilibrium reached in sorption (○) and in desorption (●).

The kinetics of sorption and desorption was studied with samples consisting of loose piles (beds) of the same crystals but of different heights, in order to find out whether mass transfer in the void fraction along the height of the bed has any influence on the observed rates. The observed kinetics are represented by plotting the dimensionless quantity $\Delta n/(\Delta n)_f$ as a function of time t or $\sqrt{t}$. $\Delta n/(\Delta n)_f$ gives the (positive or negative) change Δn of the amount n of sorbate in the solid as a fraction of the final change $(\Delta n)_f$

$$\frac{\Delta n}{(\Delta n)_f} \equiv \frac{(n)_t - (n)_{t=0}}{(n)_{t\to\infty} - (n)_{t=0}}$$

It will run from 0 to 1 in any sorption or desorption experiment. A plot of this quantity as a function of time must be independent of the height of the sample bed if mass-transfer resistance in the voids of the bed has no effect on the kinetics. In this case the composition (or pressure) of the gas will only change with time but must be independent of the location in the bed, being the same for each crystal. The reverse must be true if mass transfer through the bed causes appreciable gradients of concentration along its height.

Kinetic experiments have been conducted with three zeolite samples, all containing crystals of the same size:

(a) $m = 92$ mg, bed height 3 mm
(b) $m = 39.5$ mg, bed height 1.3 mm
(c) $m = 18$ mg, monolayer of crystals (≤80 μm)

Sample (c) was spread evenly in a special sample pan of large diameter and thus consisted of less than one monolayer of crystals; any mass-transfer resistance in the gas surrounding the crystals was excluded with this configuration.

The kinetics of sorption in samples (a)—(c) at 25 °C and at approximately the same final degree of saturation are shown in Figure 3; in Figure 4 the kinetics of sorption is compared with that of desorption. Experimental conditions are listed in Table 1.

Table 1. Conditions of kinetic experiments for the NaX/*n*-C_4H_{10} system.

Run no.	Sample weight m [mg] (bed height)	Initial/final loading [mmol/g]	Initial/final pressure [Pa]
1	92 (3 mm)	0/0.43	46.6/14.9
1′	92 (3 mm)	0.43/0.89	62.9/28.9
2	39.5 (1.3 mm)	0/0.41	27.3/14.4
3	18 (≤80 μm)	0/0.37	21.9/12.9
4	18 (≤80 μm)	0.49/0.82	34.0/26.3
5	18 (≤80 μm)	0.82/0.50	10.0/16.9
6	91 (2.9 mm)	0.74/0.90	43.5/37.0
7	91 (2.9 mm)	0.90/0.74	24.7/31.1

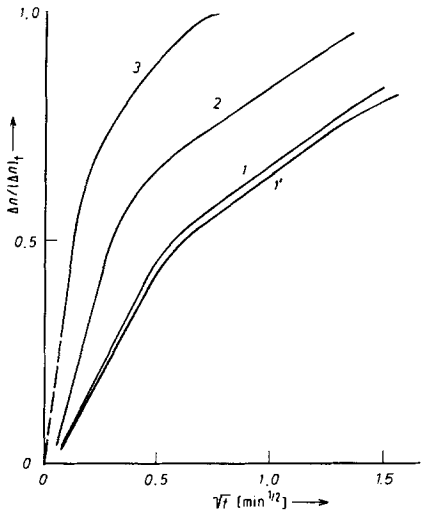

Fig. 3. Kinetics of sorption of *n*-butane in zeolite NaX at 298 K for three different samples of mass 92 mg (1 and 1′), 39.5 mg (2), and 18 mg (3).

The change Δn of the amount of sorbate is linear in $\sqrt{t}$ up to $\Delta n/(\Delta n)_f \approx 0.5$ within the accuracy of experimental observation[*]; its rate is independent of the direction of the flux, $\Delta n/(\Delta n)_f$ being the same function of t in sorption and desorption for a given sample configuration. This pattern—in particular

[*] The initiation of the change of pressure in the system was taken as the origin of the time axis ($t = 0$). Extrapolated curves of $\Delta n/(\Delta n)_f$ vs. $\sqrt{t}$ intersect with the line $\Delta n = 0$ at $\sqrt{t} \approx 3 \times 10^{-2}$ min$^{1/2}$, corresponding to a delay of 0.05 s due to the finite rate of response of balance and recorder.

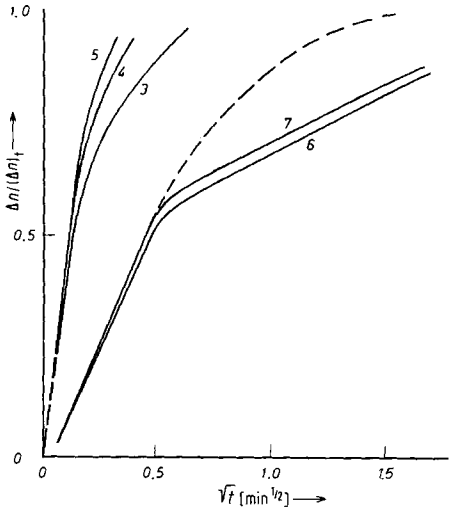

Fig. 4. Kinetics of sorption (3, 4, 6) and of desorption (5, 7) of *n*-butane in zeolite NaX at 298 K for two samples with mass 91 mg (6, 7) and 18 mg (3, 4, 5); broken line: advancement of $\Delta n/(\Delta n)_f$ as expected from the initial slope for run no. 7 on the basis of the diffusion equation with constant *D*.

the initially linear relation between Δn and $\sqrt{t}$—is generally to be expected if the rate-controlling flux of the sorbate in the sample is proportional to a gradient of concentration, no matter whether (laminar or Knudsen) flow in the voids of the sample-bed or diffusion in the crystals is rate controlling[13,14]. However, the initial slope of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$ was found to be nearly proportional to the inverse of the height of the bed (or sample mass) in runs no. 1, 2, 6, and 7—and thus depends on the geometric configuration of the bed.

This observation indicates that at least initially [for $\Delta n/(\Delta n)_f < 0.5$] mass transfer through the bed is rate controlling, whereas diffusion in the crystals was of only minor influence on the rates of sorption or desorption in these experiments. If mass transfer through the bed is rate controlling then in the limit every crystal in the bed would always be in equilibrium with the gas phase contingent to it and we would have to expect the same rate law as for diffusion and localized adsorption in a porous material[13,14], the individual crystals in the bed being analogous to sorption sites on the pore walls. This type of rate behavior was also observed for the sorption of *n*-butane in commercial pellets of zeolite X, the kinetics depending essentially on the macroscopic dimensions and on the macropore structure of the pellets[9].

Any external mass transfer resistance is excluded if the zeolite sample consists of a single crystal or a monolayer of crystals (runs no. 3, 4, and 5). In this case the observed rates can be controlled by diffusion of the sorbate in the zeolite crystals only if transfer through the solid/gas phase boundary causes no appreciable resistance to the flux. The diffusivity *D* of the sorbate in the zeolite can then be obtained from the observed initial slope of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$. This evaluation was based on the solution of the diffusion-equation for short times ($\Delta n/(\Delta n)_f < 0.3$), spherical geometry, and the appropriate initial and boundary conditions, *e.g.* sorption in a closed system and linear isotherm[10,11]:

$$\frac{\Delta n}{(\Delta n)_f} = \frac{12}{d}\left(\frac{1+E}{E}\right)\left(\frac{Dt}{\pi}\right)^{1/2} \tag{4}$$

with

$$E = \left(\frac{n_{gas}}{n}\right)_{equil.} = 2.4$$

d = crystal diameter = 8×10^{-5} m.

In runs no. 3, 4, and 5 the initial slope

$$\lim_{\Delta n \to 0}\left(\frac{1}{(\Delta n)_f}\frac{dn}{d\sqrt{t}}\right) \geq 0.59\,s^{-1/2} \tag{5}$$

was observed and from eq. (4) we have

$$D > 2 \times 10^{-7}\ cm^2\ s^{-1}$$

for *n*-butane in zeolite X at 298 K.

This value of *D* has to be regarded as a lower limit considering the finite rate of response of balance and recorder and a possible phase transfer resistance, sorption (or desorption) being 50 % complete after only 0.7 s.

The group D/d^2—which can be obtained from the initial slope of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$—should also determine the further progress of Δn with t according to the diffusion equation. However, all observed curves of Δn *vs.* $\sqrt{t}$ deviate considerably

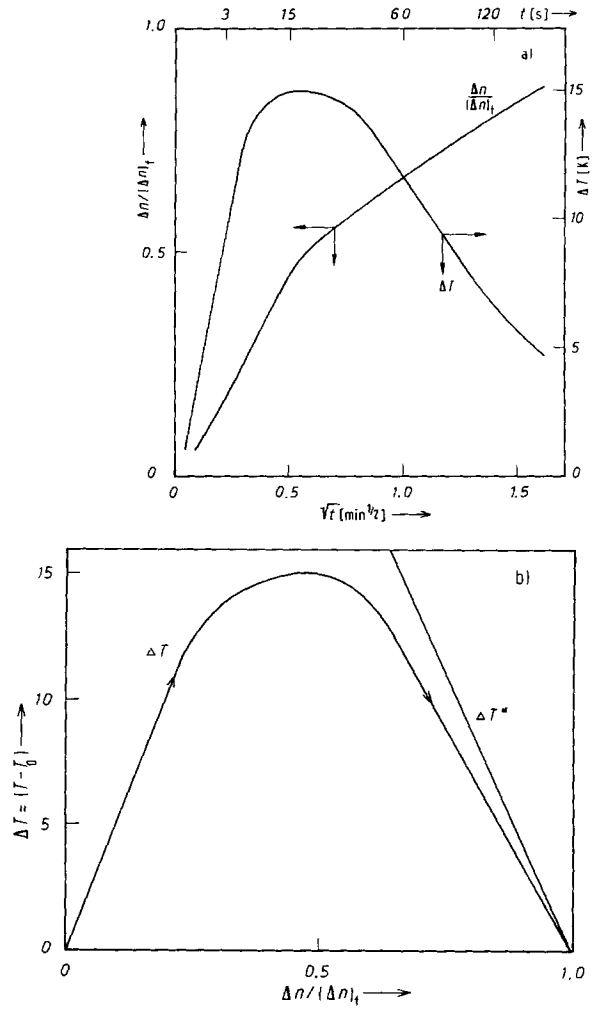

Fig. 5. Relative exchange $\Delta n/(\Delta n)_f$ of sorbate and temperature excursion ΔT in the n-C_4H_{10}/NaX system, conditions as in run no. 1 (see Table 1): a) as a function of $\sqrt{t}$; b) ΔT and equilibrium excess temperature ΔT^* as function of $\Delta n/(\Delta n)_f$.

from what should be expected (*e.g.* dotted curve for run no. 7 in Fig. 4) on this basis: a "bend" towards the $\sqrt{t}$-axis around $\Delta n/(\Delta n)_f \approx 0.5$ was found throughout, this bend being less pronounced for the monolayer configuration than for samples in form of a bed. This observation can *not* be explained as due to a concentration dependence of the diffusivity since the curves of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$ for a given sample are identical in sorption and desorption as well as for different ranges of sorbate concentration. The deviation of Δn from expectation—based on the laws of isothermal diffusion—appears to be due to temperature changes in the sample, sorption being an exothermic process whereas desorption is endothermic. The temperature in the sample during sorption has been monitored by a miniature thermocouple and is shown together with $\Delta n/(\Delta n)_f$ as function of $\sqrt{t}$ in Figure 5a for the conditions of run no. 1. In Figure 5b the temperature increase $\Delta T = T - T_0$ is plotted as a function of $\Delta n/(\Delta n)_f$, together with the temperature increase ΔT^* of the sample which would be necessary to establish sorption equilibrium in the closed system for any value of the independent variable $\Delta n/(\Delta n)_f$. In order to compute ΔT^* the constant K in Figure 3 was approximated as a linear function of T within the temperature interval under consideration. The temperature increase ΔT as a function of Δn approaches the equilibrium line ΔT^* (Δn) for $\Delta n/(\Delta n)_f > 0.7$. The observed kinetics is controlled by mass transfer in the range $\Delta n/(\Delta n)_f < 0.5$, whereas the kinetics of the final approach to equilibrium depends mainly on the heat transfer between the sample and its surroundings. Sorption equilibrium is nearly established in the range $\Delta n/(\Delta n)_f > 0.7$ ($\Delta T \approx \Delta T^*$), while the temperature of the sample is not in equilibrium with its surroundings until the closed nonadiabatic system has reached equilibrium at $T = T_0$ and $\Delta n = \Delta n_f$. The change of sample temperature with time will thus control the rate of sorption in this second stage of the experiment. Both the deviation of the amount of sorbate from its final value and the excess temperature ΔT of the sample decrease exponentially with time at this stage, the same time constant (1.8 min) being found independently from observations of either quantity. The bend in the plot of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$ was less pronounced with a sample consisting of a monolayer of crystals, the maximal temperature excursion being limited to $|\Delta T| < 6$ K due to the relatively important contribution of the sample pan to the combined heat capacity of the sample and its container.

It is possible to obtain diffusivities from the initial kinetics, in spite of the nearly adiabatic behavior of the system at small times ($\Delta n/(\Delta n) < 0.5$), since the kinetics of sorption or desorption is controlled by mass transfer in this range. The temperature diffusivity a of a zeolite crystal will be approximately

$$a = \frac{\lambda}{\rho c_p} \approx 5 \times 10^{-3} \text{ cm}^2 \text{ s}^{-1}$$

(with thermal conductivity $\lambda \approx 0.8$ W m^{-1} K^{-1}, density $\rho \approx 2$ g cm^{-3}, and specific heat $c_p \approx 0.75$ J g^{-1} K^{-1}); the Lewis number in the solid must thus be $Le = a/D \gg 1$ and temperature gradients in the crystals will be negligible. The crystal is therefore a heat sink (or source) of temperature T_0 at $t = 0$; the initial slope of Δn *vs.* $\sqrt{t}$ must be the same as in an isothermal system at T_0.

Comparing the thermal diffusivity in a bed of crystals with the apparent diffusivity of the sorbate in the bed leads to the conclusion that temperature differences within the bed will generally be less important than temperature differences between the bed and its surroundings. The rate of the final approach to equilibrium—which is controlled by heat transfer—will therefore depend on the thermal contact between the sample and the thermostat at T_0.

4. The Carbon Dioxide/Zeolite NaA System

Equilibrium isotherms for the CO_2/zeolite NaA system are shown in Figure 6; from these isotherms a constant heat of sorption of -44.7 kJ mol^{-1} is obtained for loadings up to 5 wt % CO_2, in good agreement with the value reported by *Barrer* and *Coughlan*[15].

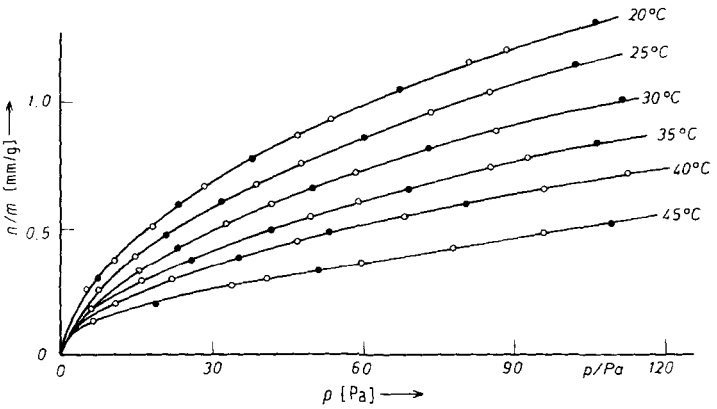

Fig. 6. Isotherms of CO_2 in zeolite NaA; equilibrium reached in sorption (○) and in desorption (●).

The kinetics of sorption and desorption was investigated at $T_0 = 293$ K using two samples of different weight (48.3 and 23.5 mg), the height of the beds being different by a factor of 15 since sample pans of different diameters were used.

Table 2. Conditions of kinetic experiments for the NaA/CO_2 system.

Run no.	Sample weight [mg] (bed height)	Initial/final loading [mmol/g]	Initial/final pressure [Pa]
1	48.3 (2.1 mm)	0/0.71	70.5/43.2
2	48.3 (2.1 mm)	0/1.01	118.4/89.8
3	23.5 (0.13 mm)	0/0.42	23.9/16.6
4	48.3 (2.1 mm)	0.82/0.61	23.9/33.3
5	48.3 (2.1 mm)	0.61/0.82	63.8/55.9

Experimental conditions are listed in Table 2; results are shown in Figures 7 and 8. The initial change of $\Delta n/(\Delta n)_f$ is always proportional to $\sqrt{t}$; it is independent of the direction of the flux, being the same for sorption or desorption over a given range of saturation of the sorbent. The initial slope of $\Delta n/(\Delta n)_f$ *vs.* $\sqrt{t}$ does not depend on the height of the bed; therefore the observed rate of mass transfer in the range $\Delta n/(\Delta n)_f < 0.4$ must be controlled by the uptake into or the release from the individual crystals, any influence of mass transfer in the voids of the bed being negligible in this case. The diffusivity D of CO_2 in zeolite A can hence be evaluated from eq. (4), on the basis of observations on a bed of crystals. Within the saturation range investigated we have $E = 2.1$ and

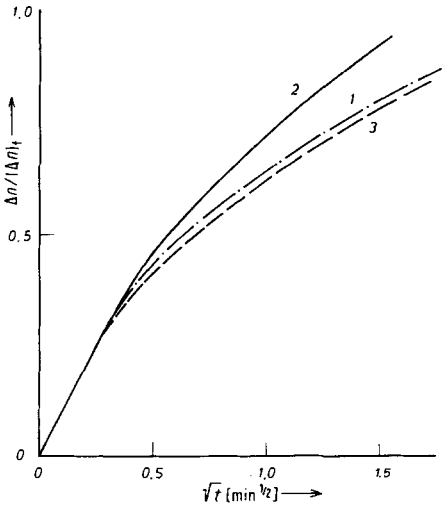

Fig. 7. Kinetics of sorption of CO_2 in zeolite NaA at 293 K for two samples with mass 43.3 mg (1, 2) and mass 23.5 mg (3).

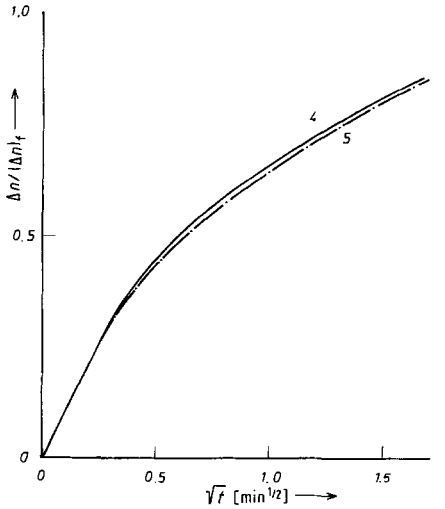

Fig. 8. Kinetics of sorption (5) and of desorption (4) of CO_2 in zeolite NaA at 293 K.

no. 1; the influence of an increase in thermal conductivity of the gas phase (due to increased pressure) on the kinetics is evident from Figure 7.

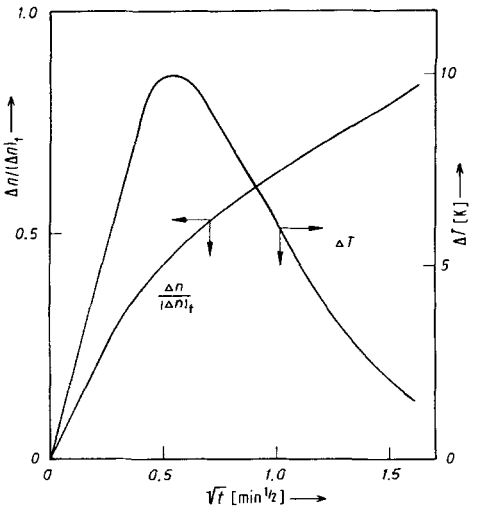

Fig. 9. Relative exchange $\Delta n/(\Delta n)_f$ and temperature excursion ΔT in the sample for sorption of CO_2 in NaA, conditions as in run no. 1 (see Table 2).

5. Discussion and Comments

Diffusivities D in the volume of zeolite crystals as obtained here from the kinetics of sorption and desorption are compared with values from the literature for the same or for similar systems in Table 3.

Diffusivities reported in the literature are considerably smaller than the values found here, with the exception of the coefficient of self-diffusion of *n*-butane in zeolite NaX as obtained from NMR experiments with the pulsed field gradient technique[4, 17]. Some of the values in Table 3 have been observed with the respective zeolites after partial or complete ion exchange of Na^+ against Ca^{2+}; however, this fact can hardly explain the appreciable discrepancies. Rather,

Table 3. Values of D, present results as compared to previous data.

Sorbate	Zeolite	T[K]	Method	Result [cm^2 s^{-1}]	Ref.
n-C_4H_{10}	$Ca_{0.42}Na_{0.16}X$	308	sorption	$D = 1.9\times10^{-14}$	[16]
n-C_4H_{10}	NaX	273	NMR spin-echo	$D^* = 10^{-5}$	[4, 17]
n-C_4H_{10}	NaX	298	sorption	$D > 2\times10^{-7}$	[a]
CO_2	CaA	298	exchange $^{12}CO_2/^{14}CO_2$	$D^* = 1.4\times10^{-11}$	[18]
CO_2	NaA	293	sorption	$D = 1.1\times10^{-9}$	[b]

[a] See Section 3; [b] see Section 4.

with $d = 3\times10^{-5}$ m a diffusity of $D = 1.1\times10^{-9}$ cm^2 s^{-1} follows for CO_2 in zeolite NaA at 293 K.

Excursion of the sample temperature and its re-equilibration is again of considerable influence on the kinetics of sorption or desorption when $\Delta n/(\Delta n)_f$ exceeds a value of 0.6. However, in the present system the final equilibration is not entirely controlled by heat transfer as was the case in the system *n*-C_4H_{10}/NaX. The excess temperature ΔT in the bed is shown in Figure 9 as a function of $\sqrt{t}$ under the conditions of run

it appears likely that the influence of external mass transfer and of mass transfer in the intercrystalline voids of pelleted sorbents on the kinetics has been underestimated in the work of *Ma* and *Lee*[16] and of *Sargent* and *Whitford*[18]. In both cases the gas phase consisted of a mixture of two components, pellets made from relatively small crystals (about 1 μm diameter) having been used as sorbents; the influence of external and intercrystalline mass transfer on the kinetics was evaluated from the shape of the curves of uptake or exchange *vs.* time

and not by experimentation with samples of different macroscopic sizes. The uptake as a function of time must follow the diffusion equation exactly if either intracrystalline or intercrystalline diffusion alone controls the rate of sorption or exchange; its shape will be identical in both limiting cases. Only in the intermediate case will isothermal uptake or exchange *not* follow the straightforward solution of the diffusion equation. However, the deviation should be most pronounced at the very beginning of an experiment, where it is difficult to measure the respective rate exactly.

A resistance due to the transfer through the phase boundary (crystal surface) will appear in the shape of the uptake *vs.* $\sqrt{t}$ curves also only as a "foot" near the origin, unless it controls the rate predominantly[19]. Such a resistance can be excluded on the basis of our experiments in the CO_2/NaA system; in the n-C_4H_{10}/NaX system it was not possible to obtain the exact shape of Δn *vs.* $\sqrt{t}$ near the origin. This is one reason for quoting only a lower limit for the diffusivity of n-butane in NaX, which as such is not in conflict with the coefficient of self-diffusion as reported by *Kärger* and *Pfeifer*[4] for the same system. It appears difficult, if not impossible, to measure diffusivities in zeolites greater than 10^{-7} $cm^2 s^{-1}$ by means of sorption kinetics, in view of the limitations of experimental equipment and of the size of synthetic zeolite crystals. Measurement of self-diffusion in zeolite crystals by means of NMR spectroscopy is limited to values of D^* above 10^{-7} $cm^2 s^{-1}$[20]; both methods thus complement each other.

Diffusivities can be obtained within this limit from the kinetics of sorption or desorption, no matter whether the system is adiabatic, nearly adiabatic, or isothermal, provided intracrystalline diffusion is rate controlling and the evaluation is based on proper boundary conditions. By observing certain precautions this condition can be fulfilled, at least for a limited range of the relative exchange $\Delta n/(\Delta n)_f$. In any case mass transfer into or out of a zeolite will necessarily cause an excursion of the temperature of the sample[21]. In the limit the kinetics of sorption can be entirely controlled by heat transfer; then it is of course not possible to obtain diffusivities from the respective rate data, as has been shown by *Wicke*[22]. The unsteady sorption or desorption in zeolites can never proceed strictly isothermally, a fact which seems important with respect to the interpretation of kinetic data as well as with respect to commercial applications.

Rather elaborate precautions were necessary in order to observe intracrystalline diffusion through sorption kinetics in the system n-C_4H_{10}/NaX. Intracrystalline diffusion may consequently not necessarily be relevant for the kinetics in this system under different conditions, *e.g.* in commercial operation. It appears that intracrystalline diffusion has frequently been assumed *a priori* to be rate determining in sorption or desorption in zeolites. This assumption seemed dubious after coefficients of self-diffusion have been found by NMR spectroscopy, which are orders of magnitude greater than those obtained from sorption kinetics. It is now evident that processes other than diffusion in the crystals but necessarily coupled with sorption or desorption—namely the flow in the intercrystalline voids and heat transfer—can be of considerable influence on the rate of mass transfer between a gas and a zeolitic sorbent. From this observation it follows that not only crystal structure and chemical composition but also crystallite size as well as dimensions and macropore structure of pellets can possibly be important for the properties of commercial sorbents and catalysts containing zeolites.

Dr. H.-J. Pätow's help in synthesizing large crystals of zeolites X and A as well as financial support from the Fonds der Chemischen Industrie are gratefully acknowledged.

Polymer Alloys—Their Structure, Morphology, and Properties

By Burghard J. Schmitt[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Polymeric materials with novel properties for new technological applications are increasingly obtained by combining existing polymers, while the synthesis of new monomers has receded into the background. These polymer combinations or "alloys" (polyblends) are characterized by their chemical composition, the conformation of the chain molecules, and the morphology, *i.e.* the state of order at supramolecular level. Multiphase constitution is a typical characteristic of these substances, with a decisive influence on their macroscopic properties. The morphology of multiphase polymer alloys can be controlled to a limited extent *via* the chemical composition of their components when homopolymers are mixed in the melt or as dispersions. Graft copolymerization, on the other hand, makes it possible to achieve the desired morphology at a given chemical composition. Furthermore, transparent two-phase polymer alloys can be obtained under certain conditions. In multiphase polymers the reduction of stress without fracture, caused by mechanical loading will be treated using models. Certain combinations of properties such as hardness and toughness are connected with the coexistence of disperse and continuous phases. Equilibrium thermodynamical criteria for liquid mixtures will be used to explain demixing phenomena in polymers. In the last few years it has become possible to determine the chain conformation experimentally using neutron scattering.

1. Basic Phenomena

Macromolecular materials with new technical properties can be obtained by the synthesis of new monomers, by new methods of polymerization, and by the combination of existing polymers[**] having various properties. Preparative chemistry has produced about 1000 compounds that can be polymerized in chain or stepwise reactions[***], forming the basic repeating units of the resulting polymers. About 50 of these monomers are used on an industrial scale, and this number has not increased in the past few years. In applied polymer research the interest has instead been turned more and more toward methods of polymerization and the combination of existing polymers. The simple idea behind this second method is to build up required composite industrial materials by combining known polymers[2-4]. For example, it seemed obvious to combine the hard and stiff, but at the same time brittle homo- and copolymers of styrene (repeating unit $-[CH(C_6H_5)-CH_2]-$) with the soft and resilient butadiene polymers (repeating units $(-[CH_2-CH=CH-CH_2]-$ or $-[CH_2-CH(CH=CH_2)]-)$ by polymerizing the former in the presence of prepolymerized butadiene to produce a material exhibiting hardness and stiffness as well as impact resistance. According to their composition, composites are to be regarded as polymer mixtures. They can be described as polymer alloys, because they often have qualitatively new characteristics not possessed by their constituents.

Figure 1 shows schematically the constitution of chain molecules. A polymer mixture or polyblend is obtained when in an assembly of polymer molecules some are present, whose chemical composition of the repeating unit differs from that of the remaining polymer molecules. By this definition, random copolymers are not polyblends. Random copolymers should be considered as polymer mixtures when polymer molecules with large differences in chemical composition are present. In block copolymers with sufficiently long sequences of one and then of the other repeating unit, the blocks behave like independent polymer molecules, so that they may be considered as analogous to polyblends[5].

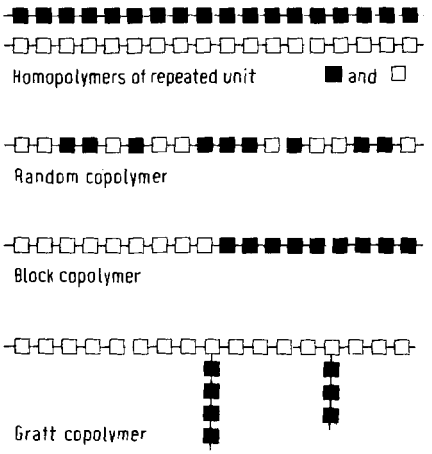

Fig. 1. Schematic representation of chain molecules.

The main characteristic of all polymer alloys is their multiphase constitution. A cross-section through such a material contains a number of regions that differ from one another in their characteristics such as chemical composition, density, refractive index, mechanical-dynamic properties, and softening temperature. These regions are separated from one another by phase boundaries. Generally there are two discrete phases: a continuous and a disperse phase. The dimensions of the disperse regions vary from 5 nm to a few thousand nm. It

[**] The term 'polymer' denotes an assembly of macromolecules which are built up of a large number of interconnected repeating units; the mechanism of the linking process is not specified.

[***] For the definition of these reactions, also called chain-growth and step-growth polymerization reactions, see [1].

© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0404-0273 $ 02.50/0

is unimportant whether the two phases are chemically different from each other, for according to the phase rules it is enough to have an abrupt change, amounting to a discontinuity, in a characteristic along the space coordinate, including therefore a change from the crystalline to the amorphous state alone, and a chemically homogeneous chain molecule can have both amorphous and crystalline sections at the same time[6].

When characterizing multiphase macromolecular materials, a distinction is made between structural features or elements of molecular dimensions and those of supermolecular dimensions[7]. The former are of a chemical nature and they impress their character on all the chain molecules, irrespective of the state of aggregation. They include the composition, molecular-weight distribution, steric arrangement of the substituents (tacticity), branching of the chains, and—in copolymers—the succession and amount of the repeating units.

The spatial arrangement of these chemical or molecular structural features according to crystallographic, kinetic, thermodynamic, and statistical rules is called morphology. This describes the state of order at the supermolecular level and largely determines the macroscopic properties of multiphase materials. Deliberate modification of the morphology offers a new degree of freedom at a given chemical structure of an assembly of macromolecules. In the case of polyblends the morphology is largely determined by phase-separation or demixing phenomena, *i.e.* by the separation of a homogeneous phase into at least two discrete phases.

No less important than the chemical structure is the physical form of the macromolecules, for example the different conformations of the chains in the amorphous and the crystalline domain (made possible by rotation around C—C bonds) and the mobility of chains, chain segments, and side groups. These mobilities are temperature-dependent, and they can all be frozen in at a sufficiently low temperature, *e.g.* at −130 °C for siloxanes, with the repeating unit $-[Si(CH_3)_2—O]-$, and the polymer is then either glassy and amorphous with no long-range order of the molecular chains, or it is partially crystalline, if it contains regions with a periodic order. When subjected to mechanical loads, these materials are almost elastic up to the point of brittle fracture. The slopes of the stress-deformation curves (see Fig. 35) are defined as moduli and give a measure of the stiffness (these slopes vary with the stresses to different extents). Polymers with frozen-in segmental mobilities have moduli of 10^5—10^7 N/cm^2, the modulus for steel being 10^8 N/cm^2.

Figure 2 shows schematically the temperature-dependence of the moduli of amorphous and partially crystalline polymers. Heating first produces a temperature region with secondary dispersion, where the side groups become mobile. This is followed by a relatively narrow temperature region in which the chain segments become mobile, the viscosity of the system falls by several orders of magnitude, and changes in the conformation of the macromolecules become possible; at the same time, there is a marked change in the temperature coefficients of the specific volume and the refractive index. Instead of a temperature range, one generally specifies a characteristic temperature—the glass temperature—for a polymer or a homogeneous polyblend. The glass temperature *e.g.* for polystyrene is about 100 °C, and that for polybutadiene is −85 °C.

Above the glass temperature, the polymer is soft and—unlike low-molecular liquids—still quite elastic, with moduli

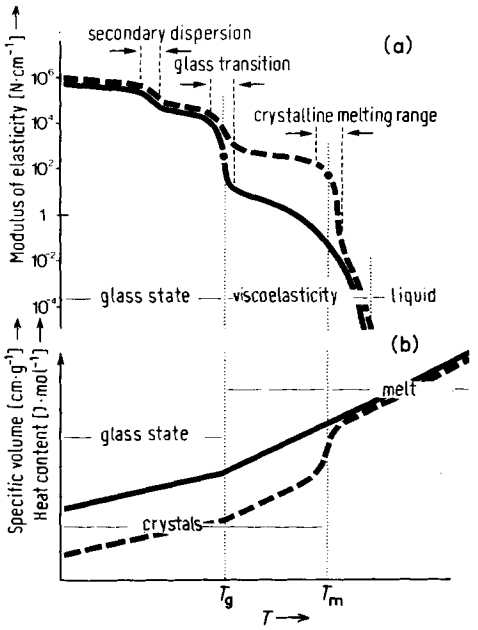

Fig. 2. a) Thermomechanical curves for amorphous (—) and partially crystalline (---) high molecular weight polymers (schematic), b) heat content and specific volume as a function of the temperature on melting and glassy solidification of high molecular weight polymers. T_g—glass temperature, T_m—crystalline melting point.

of 1—10 N/cm^2. This elasticity of softened polymers, called rubber-like or rubbery elasticity, stems from the network structure of the materials. Due to linkages between chain molecules either by chemical bonding, entanglement in amorphous domains or folds in crystalline domains, restoring forces come into operation on deformation. The coexistence of viscous and elastic properties is named viscoelasticity.

When the temperature is raised further, softened polymers become more and more like liquids, and the elasticity of the melt decreases. This is particularly noticeable in the melting region of crystallites. Figure 2 shows that the crystallites are formed from the melt. The state of glassy solidification below the glass temperature is not an equilibrium state with a minimum energy content, for the crystalline state has a lower energy than the glassy one. Yet the transition from the glassy state to crystallites occurs extremely slowly or not at all in practice, owing to the frozen-in segmental mobility. In polymers that do not crystallize because of insufficiently long sequences of the same tacticity one can observe only the transition from the glass amorphous state to the amorphous melt state. Polymers often fail, even at high temperatures, to reach the state of an ideal liquid without any elasticity, because they decompose before this would happen. A typical example of this is high-molecular poly(methyl methacrylate) with the repeating unit $-[CH_2—C(CH_3)\cdot(COOCH_3)]-$, which exhibits depolymerization and amorphous elastic behavior at about 200 °C.

The material properties of polymers show characteristic differences according to whether they exhibit a glassy state or rubber-like elasticity at a given temperature; crystallites can also be present in both cases. Multiphase polymeric materials can be arranged in a list according to their moduli[8, 9] (see Table 1). About 90 % of industrial polymers used today are multiphase materials; they include partially crystalline polymers and combinations with inert fillers such as glass fibers and air.

Table 1. Classification of multiphase polymeric materials.

Type of material	Disperse phase, with modulus G_D	Continuous phase, with modulus G_K	Relationship between moduli at room temperature
Reinforced rubber	inorganic filler	rubbery polymer	$G_D \gg G_K$
Thermoplastic elastomer	glassy amorphous or crystalline polymer	rubbery polymer	$G_D \gg G_K$
Reinforced thermoplastic	inorganic filler	glassy amorphous or partially crystalline polymer	$G_D > G_K$
Partially crystalline polymer	crystalline polymer	glassy amorphous polymer	$G_D \approx G_K$
Soft foam	gas	rubbery polymer	$G_D < G_K$
Impact-resistant stiff plastic	rubbery polymer	glassy amorphous or partially crystalline polymer	$G_D \ll G_K$
Rigid foam	gas	glassy amorphous polymer	$G_D \ll G_K$

The present review is restricted to polymer-polymer combinations. The designation "polymer alloys" used for these is not correct if it is intended to express an analogy with metal alloys, whose melts are homogeneous and whose products of solidification contain crystallites of the pure substances in a wide range of compositions. In polyblends, on the other hand, phase-separation phenomena must be borne in mind from the outset, the melts are often not homogeneous like a single phase, and the demixed phases are not pure substances but contain all the components in various concentrations. Pure substances occur as separate phases only in the case of partially crystalline polymers.

2. Preparation of Polyblends

The most direct way of preparing polyblends is to mix the preformed polymers in the molten state ("melt mixing"). The extent of mixing depends on the rate of diffusion of the chain molecules. *Bueche et al.* have measured the rate of diffusion of isotopically labeled polybutyl acrylate with the repeating unit $-[CH_2-CH(COOC_4H_9)]-$[10] and polystyrene[11] in a matrix composed of the same polymer in each case, as a function of the temperature and the molecular weight, while *Bresler et al.* have measured the rate of diffusion of labeled polyisoprene with the repeating unit $-[CH_2-C(CH_3)=CH-CH_2]$ in vulcanized rubber[12]. The diffusion coefficients lie in the range of 10^{-10}—10^{-13} cm^2/s, which means that the center of gravity of the chain molecules undergoes an average displacement of 10^{-5}—10^{-6} cm in the melt. This value is two orders of magnitude lower than that for the diffusion of low-molecular compounds in a polymeric matrix, and the thermodynamic equilibrium is established here considerably more slowly. Even so, the displacement is still about 10—100 times as great as the diameter of a polymer coil in the melt (cf. Section 4). The establishment of equilibrium is influenced by the time of mixing, the shear gradient, the temperature, and the rheological properties of the polymers[13–16]. A thorough mixing in molecular dimensions is possible only when the mobility of the chains is not frozen in, *i.e.* only above the glass temperature.

Strong shearing forces often decompose polymers, and the resulting radicals can then participate in cross-linking or in the formation of graft or block copolymers (cf. Fig. 1), leading to new chemical structures in the polyblend. For example, intensive kneading of polyisoprene with chloroprene rubber having the repeating units $-[CH_2-CH(CCl=CH_2)]-$ is enough to produce graft, block, and cross-linked copolymers even at low temperatures[17]. If the chemical structure is not to be changed, mixing in the melt must be restricted to thermally stable polymers and polymers that are not sensitive to shearing forces.

Polymer latexes are often combined by mixing. They consist of spherical or irregular polymer particles, emulsifiers, and dispersing agents such as water. The polyblend is obtained by coagulating the latex or evaporating the dispersing agent. When the mixture is dried, the components are present in the form of separate particles measuring 100—1000 nm. This method makes it possible to fix the particle size of the disperse phase without interfering with the properties of the components. The composition of the particles remains unchanged until the powder is melted, when again decomposition and grafting take place, with an increasing change in the particle composition. These changes, caused by the migration of one polymer component into the particles of the other, occur less often if cross-linking through chemical bonds has taken place in the latex particles. The electron micrographs in Figure 3 show increasingly sharper phase boundaries and phase contrast due to the reduced degree of mixing caused by increasing crosslinking, *e.g.* for a poly(butyl acrylate).

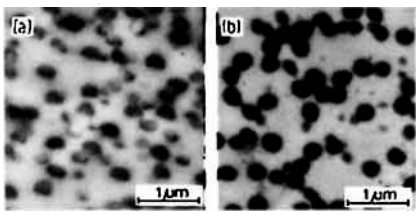

Fig. 3. Molten latex mixtures composed of poly(methyl methacrylate) and poly(butyl acrylate). a) Slightly cross-linked poly(butyl acrylate), b) strongly cross-linked poly(butyl acrylate). Contrast by electron etching, with the elastomeric phase as dark areas.

Another method is to mix the polymers in a mutual solvent, followed by precipitation and/or drying. The view that evaporation always leads to mixing at the molecular level, though occasionally encountered[18], is incorrect. Ternary systems consisting of two polymers and a solvent exhibit wide miscibility gaps[19–22]. Phase separation begins already at a polymer concentration of a few percent. As drying advances, a nonequilibrium state is frozen in. Coprecipitation also gives a heterogeneous material if the components have different solubilities.

Only through chemical bonds can polymer chains be fixed in a "forced" mixture. For this purpose the monomers are polymerized in the presence of a polymer prepared in advance. If the latter has functional groups such as hydroxyl or amino groups or halogen atoms at its ends, or if it comprises cations, anions, or free radicals, the monomer will add on there and block copolymers are formed. These can of course also be obtained by coupling reactions with preformed polymers. If the second polymer chain adds on not at the chain end but

at another site activated *e. g.* by double bonds, graft copolymers will be formed. This method is used to prepare a large part of rubber-reinforced thermoplastics. For example, polybutadiene is dissolved in the monomer which is to form the glassy component, and either bulk polymerization or solution polymerization in an inert solvent is then carried out. Alternatively, the reaction mixture is suspended in water after partial conversion, and the polymerization is completed with intense stirring[23, 24]. Pure glassy polymer and graft copolymer are formed side by side, *i. e.* a two-phase mixture is obtained directly. Many morphological variants can be prepared by an appropriate choice of the concentrations, the molecular weight of the polybutadiene, and the conditions of the preparation (cf. Section 5).

Graft copolymers are often prepared in emulsion. The monomers added to a chemically different polymer latex polymerize both on the surface and inside the latex particles. This method gives networks that penetrate into one another to various extents and are formed either by chemical bonds or by the looping-together of the chain molecules. Despite this fixation, the system exhibits demixing and a multiphase character with a domain structure within the dimensions determined by the latex particles (see Fig. 4).

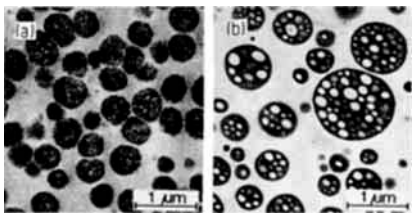

Fig. 4. Acrylonitrile-butadiene-styrene copolymers. a) Emulsion polymerization of styrene and acrylonitrile in the presence of a preformed polybutadiene latex, b) bulk polymerization of styrene and acrylonitrile in the presence of dissolved polybutadiene (for comparison). Dark areas: elastomeric phase.

3. Thermodynamics of Polyblends

Apart from mixing in the melt, all methods used for the preparation of polyblends are expected to lead initially to thermodynamically nonequilibrium systems, the attainment of equilibrium being inhibited by high viscosities and the network structure. In polymer melts, on the other hand, equilibrium states can be reached at sufficiently high temperatures. This is proved by a) the reversibility in the experimental determination of the turbidity limits, *e. g.* for mixtures of poly(methyl methacrylate) with styrene-acrylonitrile copolymers having the repeating units $-[CH(C_6H_5)-CH_2]-$ and $-[CH(CN)-CH_2]-$[25] (see also Fig. 9), and b) by reproducible adjustment of the molecular conformations according to the temperature in these mixtures and in mixtures of poly(methyl methacrylate) with poly(α-methylstyrene)[26]. Inspection under a light and an electron microscope shows directly that a multiphase system is formed in melts of poly(methyl methacrylate) and styrene-acrylonitrile copolymers in less than 1 minute if a sudden rise in the temperature transfers the system from the stable single-phase region to the multiphase region[27]. Annealing for 2 h simply makes the particles in the demixed regions twice as large. The finely dispersed state after phase separation favors the establishment of equilibrium concentrations in the demixed regions (for quantitative considerations see [28–30]).

The establishment of equilibrium is also inhibited in melts if the polymers are chemically cross-linked or the crystallites are not fully melted. In this second case, according to a widely confirmed model[31, 32], the number of possible chain segment conformations in the amorphous domains is reduced due to restrictions of the volume available for conformational changes because of crystallites of differing sizes (see Fig. 5).

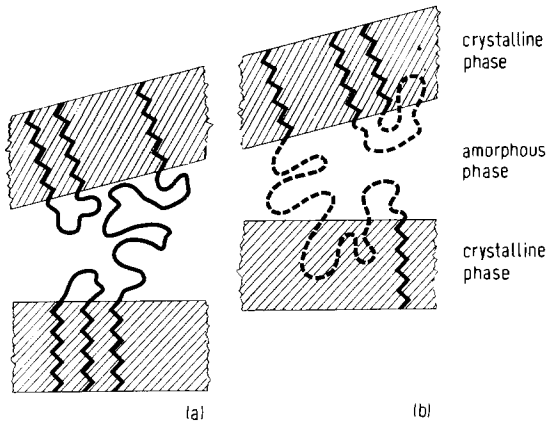

Fig. 5. Conformational restriction in the melting or crystallization of chain molecules (schematic). a) Possible conformations, b) conformations not possible, because of the excessively small volume of the amorphous phase.

Consequently the entropy contribution of a noncrystalline chain portion is smaller than that of a chain of the same length in an amorphous melt. During melting, the entropy changes not only for the repeating units changing phase but also for the entire noncrystalline chain sections. The entropy change per monomeric unit is therefore not constant, and partially crystalline polymers have a melting range rather than a fixed melting point:

$$T_S = \Delta H_S / \Delta S_S \qquad (1)$$

where ΔH_S is the enthalpy of melting and ΔS_S is the entropy of melting.

If the temperature of a melt mixture containing crystallizable polymers sinks below the melting range of one of the components, the latter will partially separate out as a solid crystalline phase and the composition of the remaining melt will be shifted. The free enthalpy of a polymer is lower in the crystalline state than in the melt, and the free enthalpy of the mixture is therefore reduced by partial crystallization. If the temperature is below the melting range of another crystallizable component, this component also crystallizes out in part. If two crystallizable polymers in the melt form a single-phase mixture, yet on crystallization form their own crystallites instead of mixed ones, plotting the melting temperature against the composition gives two curves that intersect at the eutectic point (see Fig. 6a)[33].

Figure 6b shows the phase diagram for a mixture of a crystallizable polymer and an amorphous polymer. Poly(vinylidene difluoride) with the repeating unit $-[CH_2-CF_2]-$ and poly(methyl methacrylate) form a homogeneous mixed melt[35], from which the former crystallizes out at any mixing ratio if the temperature is between the melting temperature of its crystallites and the glass temperature of the mixture.

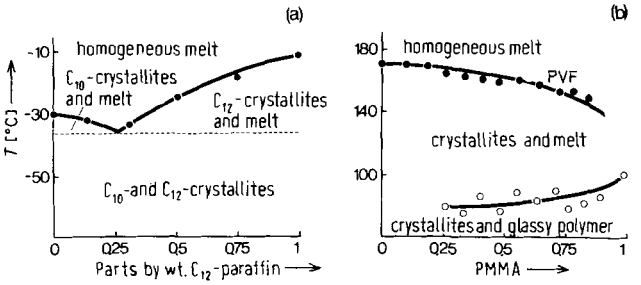

Fig. 6. Melting and glassy solidification of binary polymer mixtures. ●--Melting point; ○-- glass temperature. a) C_{10} and C_{12} paraffins as model polymers, both crystallizable (measurements by *Killian*) [33]; b) poly(vinylidene difluoride) (PVF) (crystallizable) and poly(methyl methacrylate) (PMMA) (amorphous) (measurements by *Nishi* and *Wang*) [35].

In the solid state we have the crystalline melting point and the glass temperature. Both depend on the ratio of the components in the mixture. As the amount of the poly(methyl methacrylate) is increased, the melting temperature of poly(vinylidene difluoride) decreases. The fact that the glass temperature of the mixture is lower than that of pure poly(methyl methacrylate) indicates that considerable amounts of uncrystallized poly(vinylidene difluoride) are still present[36]. It is now being investigated using neutron scattering whether this substance is mixed with poly(methyl methacrylate) in the form of a molecular dispersion[34]. When a homogeneous mixed melt is quenched below the freezing temperature, poly(vinylidene difluoride) remains in the amorphous state[36]. Since the condition for the homogeneous miscibility of chemically different polymers is rarely satisfied, this simple consideration can be used in few cases. Usually, crystallites are formed from which a non-crystallizable second component is omitted. However, the crystallites are in turn embedded in a multiphase amorphous matrix. Only a slow after-crystallization occurs near the glass temperature[37].

An equilibrium state reached in the melt at a high temperature can be frozen in by rapid cooling. There is then no equilibrium with respect to the lower temperature. The frozen-in systems are unstable and change with time even below the glass temperature[38]. For example, the moduli of elasticity increase during the storage of quenched melts of polycarbonates with the repeating unit $-[O-C_6H_4-O-CO]-$ and poly(methyl methacrylates)[39]. Since the changes with time are comparatively slow below the glass temperature and polyblends need to be melted in the case of thermoplastic processing, it has been recommended that the time-dependent effects should be ignored, and the criteria of the thermodynamics of mixtures should be used[20, 40-42]. If the parameters that determine the equilibrium state are known, it is possible to make predictions also for the nonequilibrium state as to the course of later changes. The magnitude, sign, and course of the free enthalpy of mixing[*], as a function of the composition, decide whether the polyblend gives a stable single-phase system or tends to separate into a number of phases under the given conditions. It is immaterial here in principle whether these states are actually established. However, conveniently, only the temperature range where the segmental mobility is not frozen in is observed since in practice an equilibrium state cannot be obtained at all below the glass temperature.

[*] This is defined as the difference between the free enthalpy of the mixture and the sum of the free enthalpies of the pure components.

The free enthalpy of mixing per mole is given by eq. (2) for two polymers 1 and 2 that are uniform with respect to the molecular weight:

$$\Delta G_m/(n_1+n_2)=RT[x_1\ln\Phi_1+x_2\ln\Phi_2+\chi_{12}\Phi_1\Phi_2(m_1x_1+m_2x_2)] \quad (2)$$

where x_1 and x_2 are the mole fractions and Φ_1 and Φ_2 the partial volumes of polymers 1 and 2, respectively, R and T have the usual meanings, n_1 and n_2 are the numbers of molecules, and m_1 and m_2 the numbers of segments per chain molecule (these numbers are relative to a reference volume that is the same for both polymers and approximately corresponds to the molar volume of the monomers). The correction term χ_{12} at first takes account only of the enthalpic interaction between a segment of polymer 1 and a segment of polymer 2. Equation (2) has been derived on the basis of a model in which the polyblend forms a three-dimensional lattice whose points are randomly occupied by the segments of the polymer chains (lattice theory)[43-45]. Figure 7 shows a two-dimensional model for mixtures of a polymer with a low-molecular compound and with another polymer. In the second case the number of possible arrangements in the given volume is considerably smaller, because of the linking of the polymer segments into chains. This is why the entropy of mixing (ΔS_m)

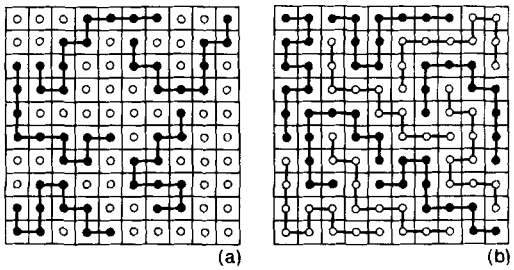

Fig. 7. Possible arrangements in binary mixtures of a polymer with a) a low-molecular weight compound, and b) another polymer (two-dimensional and schematic). Number of segments per chain molecule $m_1=m_2=10$.

reaches a lower value in the case of polyblends. A further reduction in the number of possible arrangements results from the stiffer chains[46, 47]. On the other hand, the number of contacts with neighboring segments is little affected, and the enthalpy of mixing (ΔH_m) is not so different for the two cases. The value of ΔH_m, which is positive for most polyblends[48, 49] is only partially compensated by ΔS_m[47] and ensures positive values for the free enthalpy of mixing ΔG_m on account of the relation:

$$\Delta G_m=\Delta H_m-T\Delta S_m \quad (3)$$

This gives a qualitative explanation for the increasing tendency toward demixing with increasing chain length of the components.

Figure 8 shows for a binary polyblend the variation in the free enthalpy of mixing with the composition (represented here by the mole fraction x_2 of polymer 2). If the curves have more than one minimum, there is a miscibility gap, despite the negative values of the free enthalpy of mixing over the whole range. The points of contact of the double tangents at the two minima of the individual curves lie on the binodal curve, which forms the boundaries of the area

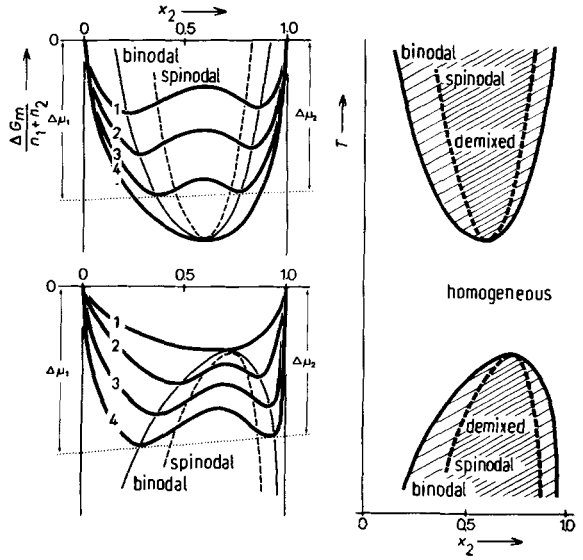

Fig. 8. Free mixing enthalpy ΔG_m, binodal and spinodal curves for binary polyblends with upper and lower miscibility gaps (schematic). T—temperature, n_1 and n_2—numbers of molecules, $\Delta\mu_1$ and $\Delta\mu_2$—chemical potentials, x_2 mole fraction of polymer 2. Curves 1—4 at T_1 to T_4; $T_1 > T_2 > T_3 > T_4$.

of stable homogeneous mixtures. This means that a homogeneous mixture is not stable within the enclosed area. Demixing shifts the free enthalpy of mixing toward the negative values. Connecting the points of inflection of the curves gives the spinodal curve, which acts as a boundary between the unstable and the metastable region. The main significance of the spinodal curve is that it can be calculated in the closed form from the expressions for the free enthalpy of mixing which cannot be done in the case of the binodal curve. The combination of eq. (2) with the condition for the point of inflection

$$\frac{\partial^2 \Delta G_m}{\partial x_1^2} = 0 \tag{4}$$

leads to

$$\chi_{12}^{Spin} = \frac{1}{2(m_1 \Phi_2 + m_2 \Phi_1)} \left[\frac{1}{\Phi_1 \Phi_2} + \frac{(m_2 - m_1)^2}{m_1 m_2} \right] \tag{5}$$

The spinodal curve shows the miscibility gap and its variation with the experimental conditions in qualitatively the same way as the binodal curve.

The components are miscible in any proportion if:

$$\left(\frac{\partial^2 \Delta G_m}{\partial x_1^2} \right)_{p,T=const.} > 0 \quad \text{for} \quad 0 < x_1 < 1 \tag{6}$$

If the value of this differential derivative is negative for a given interval of x_1, then there is a miscibility gap. This gives a thermodynamically exact definition of polymer compatibility and incompatibility, independently of the subjective assessment based on optical or mechanical properties of polyblends. The polymers of a mixture are said to be "compatible" if there is no miscibility gap anywhere in the composition domain at a given temperature and pressure; otherwise they are "incompatible". On the basis of equilibrium thermodynamics, there is no general incompatibility over the whole composition region in the case of amorphous polyblends: the miscibility gaps often extend to very small concentrations of one component, but they never encompass the pure substance. We therefore always have compatibility if one of the components is in a sufficiently large excess. A phase can form from just one of the components of the mixture only in the case of very extensively cross-linked or partially crystalline polymers[37].

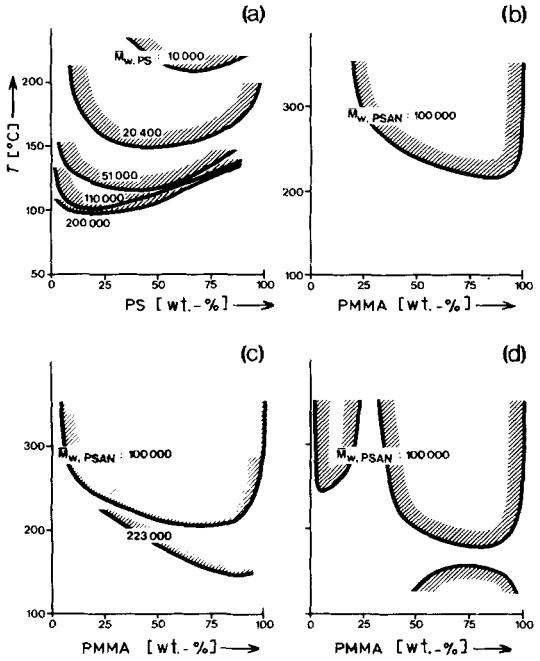

Fig. 9. Turbidity limits in quasibinary polyblends. a) Poly(methyl vinyl ether) ($\bar{M}_w = 51\,500$) and polystyrene (PS) (measurements by *Nishi* and *Kwei*) [50], b) poly(methyl methacrylate) (PMMA) ($\bar{M}_w = 100\,000$) and styrene-acrylonitrile copolymers (PSAN) with an acrylonitrile content of 26.8 wt.-%, c) 28 wt-%, and d) 28.7 wt-%. Curve for $\bar{M}_{w,PSAN} = 223\,000$, after [51]. $\bar{M}_w$ is the weight-average molecular weight; demixed regions are shaded.

Figure 9 shows the turbidity limits for mixtures of polystyrene and poly(methyl vinyl ether)[50] having the repeating unit $-[CH_2-CH(OCH_3)]-$ and for mixtures of poly(methyl methacrylate) and styrene-acrylonitrile copolymers[27,51]. There are certain differences here from mixtures of polymers and low-molecular compounds[52]: mixtures of high polymers always exhibit upper miscibility gaps, *i.e.* a diminished mutual solubility with increasing temperature. The position of the miscibility gaps in a temperature/composition diagram depends on the molecular weight to a great extent. In the case of copolymers there are drastic shifts in the turbidity limits even at small changes in the average composition. The upper and low miscibility gaps have also been found to merge. The lower miscibility gaps can be observed only if they lie above the glass temperature.

Mixtures of oligomers show strongly asymmetric and bimodal turbidity curves (see Fig. 10), as for example in the case of the oligomers of dimethylsiloxane and isobutylene with the repeating unit $-[CH_2-C(CH_3)_2]-$[53], or the oligomers of styrene and isoprene[20]. The mutual solubility increases with rising temperature as in the case of combinations with oligomeric glycols[54]. It is always lower miscibility gaps that are observed in oligomer mixtures.

Equation (2), derived from the lattice model, can be used for qualitative and quantitative description of the phase relationships in "liquid-liquid" systems of the type mentioned above. The first two terms account for the combinatorial

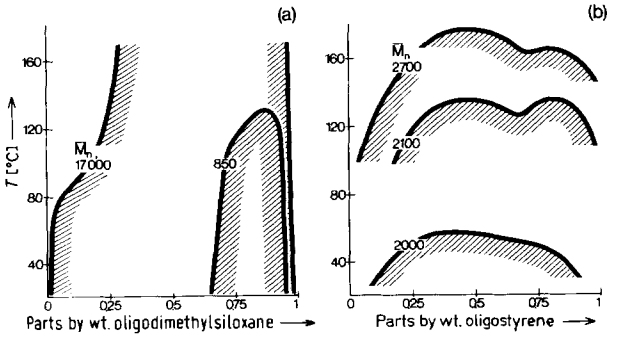

Fig. 10. Turbidity curves for binary oligomer mixtures. a) Oligoisobutylene ($\bar{M}_n \approx 250$) and oligodimethylsiloxanes ($\bar{M}_n = 17000$ and 850) (measurements by *Allen et al.*) [53]; b) oligoisoprene ($\bar{M}_n = 2700$) and oligostyrenes ($\bar{M}_n = 2700$, 2100, and 2000) (measurements by *Konigsveld et al.*) [20]. $\bar{M}_n$ is the number-average molecular weight; demixed regions are shaded.

entropy of mixing. As mentioned before, the correction term χ_{12} originally served only to describe the enthalpic interactions between a segment of polymer 1 and a segment of polymer 2. If this term is zero (when the interactions 1—2 are energetically equal to the sum of the interactions 1—1 and 2—2), the mixture is said to be athermal. The molecular nonuniformity, which is generally encountered with polymer components, is taken into account in the following multicomponent version of eq. (2)[55]:

$$\Delta G_m/(n_1+n_2) = RT\left[\sum_i x_{1i}\ln\Phi_{1i} + \sum_j x_{2j}\ln\Phi_{2j} + \chi_{12}\Phi_1\Phi_2\left(\sum_i x_{1i}m_i + \sum_j x_{2j}m_j\right)\right] \quad (7)$$

where $\Phi_1 = \sum_i \Phi_{1i}$ and $\Phi_2 = \sum_j \Phi_{2j}$

The subscripts i and j refer here to the chains with a number (m_i) of segments in polymer 1, and to the chains with a number (m_j) of segments in polymer 2, respectively. Since the full expression is unwieldy, the treatment is restricted to "quasi-binary" mixtures, and average values of the molecular-weight distributions of the two components are inserted for the relative chain lengths m_1 and m_2. This simplification at once means that a noncombinatorial entropy is assigned to the correction term χ_{12}. The lattice model can be used for the quantitative description of the phase relationships in amorphous polyblends as a function of the composition, temperature, pressure, molecular weight, and molecular-weight distribution only if suitable functional relationships for these factors are available for the correction term χ_{12}. The latter is then a largely empirical correction for the free enthalpy of the athermal mixture with an enthalpy component and a noncombinatorial entropy component. *Koningsveld et al.* have described bimodal turbidity curves for oligomer mixtures of isobutene and dimethylsiloxane with the aid of *e.g.* a quadratic concentration function of χ_{12}[20, 56, 57]. However, this method is merely descriptive and does not permit any predictions to be made about the mixing behavior of chemically different polymers.

On the other hand, *Hildebrand*'s solubility parameters δ permit such predictions to be made without the determination of χ_{12}, which is difficult with high-polymer mixtures[58]. These parameters are a measure of the internal heat of evaporation E needed for overcoming all the intermolecular forces in 1 mole of a liquid, the relevant relationship being:

$$\delta = (E/V_{mol})^{1/2} \quad (8)$$

where V_{mol} is the molar volume. For the change of enthalpy on mixing two liquids, we have that:

$$\Delta H_m = V_{tot}(\delta_1 - \delta_2)^2 \Phi_1 \Phi_2 \quad (9)$$

and using eq. (2), we obtain from this that:

$$\chi_{12} = \frac{V_{tot}}{RT(m_1 x_2 + m_2 x_2)}(\delta_1 - \delta_2)^2 \quad (10)$$

According to *Small*[59], the solubility parameter of a polymer i is obtained as:

$$\delta_i = \rho_i \sum \frac{F_i}{M_{0,i}} \quad (11)$$

where ρ_i is the density of the homopolymer, $M_{0,i}$ is the molecular weight of the repeating unit, and the F_i terms are the attraction constants of the chemical structural elements in the repeating unit (for numerical values, see [60]). The solubility parameters for copolymers are obtained by a linear combination of the partial volumes of the repeating units[61], while the change in the solubility parameter δ occurring when a reference temperature T_0 is replaced by a temperature T is taken into account with the aid of:

$$\ln(\delta_{T_0} - \delta_T) = -\alpha(T_0 - T) \quad (12)$$

where α is always the coefficient of thermal expansion that applies above the glass temperature. If δ is the same for two polymers, eqs. (10) and (2) show respectively that χ_{12} and ΔG_m are zero. A homogeneous single-phase mixture should then be stable. Although eq. (10) can be used only with positive enthalpies of mixing and fails both with partially crystalline polymers and with polymers containing hydrogen bonds, *Krause*[61] and *Casper*[62] have successfully used the concept of solubility parameters for an *a-priori* evaluation of the miscibility of polyblends of technical interest as a function of temperature, composition, and molecular weight. With mixtures of homopolymers and copolymers, the solubility parameter of the copolymer can be equalized with that of the homopolymer by choosing a suitable average composition for the copolymer. This was successful, for example with styrene-acrylonitrile copolymers and poly(methyl methacrylate) (see Fig. 11). The miscibility limits calculated *via* the solubility parameters[62] show at least a qualitative agreement with the experimental values. Although there are also numerous examples where this is not the case, the concept of solubility parameters is increasingly used with oligomer mixtures as well[54, 63].

Extended theories of polymer solutions include, *via* the degrees of freedom of the mobilities, non-combinatorial entropies of mixing as structural defects which for mixtures of liquids are due to differences in packing densities[64–69]. The free enthalpy of mixing is related to experimentally measurable quantities by relatively complicated expressions (thermal coefficients of expansion, compressibility, volume requirement of a chain segment). The property of the mixture can thus be found from the material characteristics of the pure components. In this way, *McMaster* has calculated the phase relationships in polyblends without any empirical correction

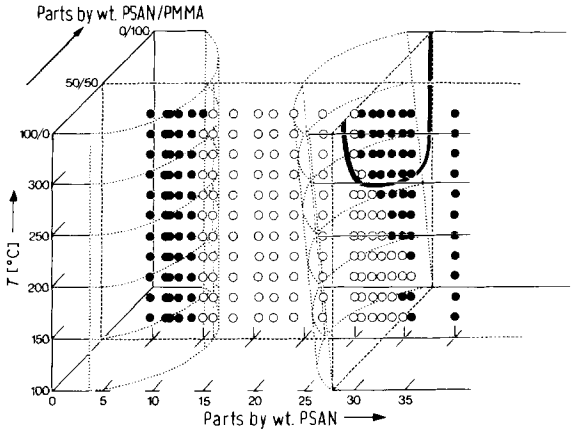

Fig. 11. Miscibility of poly(methyl methacrylate) (PMMA) with styrene-acrylonitrile copolymers (PSAN) as a function of temperature and composition. ○ = optically clear, ● = turbid. Unbroken curve: phase diagram for copolymer composition 72 wt-% styrene, 28 wt-% acrylonitrile (see Fig. 9). Concave surfaces: miscibility limits calculated according to [62] by means of solubility parameters.

terms[51, 70]. In agreement with experimental results, the calculation indicates both a close dependence of the turbidity limits on the molecular weight and the existence of upper miscibility gaps as the normal case for high-polymer mixtures. However, the thermodynamic material data needed for the calculation have been determined with sufficient accuracy only for a few substances. For this reason and because of the mathematics involved, these equations of state are not yet in frequent use.

Structural defects in a mixture, which are also regarded as changes in the free volume, can again be basically combined in the correction term χ_{12} featuring in Eq. (2)[70], in which case the first two terms in this equation remain unchanged[71, 72]. According to *Huggins*, however, we must consider the effect of the surroundings of the chain segments on the chain flexibility, in addition to the possibilities of arrangement, which—as mentioned before—are more limited here than in the case of low-molecular mixtures[73, 74]. The addition of stiff chains makes flexible chains less flexible, so that they will expand. According to *Silberberg*, it should be possible to formulate this effect in the form of a concentration-dependence of the radii of gyration in polyblends[75]. These corrections of *Huggins*' for the entropy of mixing can be combined with *Flory*'s equation of state[65] (changes in free volume on mixing), and they enable us to give a quantitative description of the thermodynamic properties of polyblends solely on the basis of molecular quantities that can be determined experimentally (for details, see [76, 77]).

Polyblends must tend toward a state of minimum free entropy if we are to apply equilibrium thermodynamic criteria to them. This is achieved in the case of demixing if the chemical potential of a component is the same in all the phases. The chemical potential is defined as the differential derivative of the free enthalpy of mixing ΔG_m with respect to the concentration of this component. We have from eq. (2) that:

$$\Delta\mu_1 = \frac{\partial(\Delta G_m/(n_1+n_2))}{\partial x_1} = RT[\ln\Phi_1 + (1-m_1/m_2)\Phi_2 + m_1\chi_{12}\Phi_2^2] \quad (13)$$

An identical chemical potential in demixed phases is indicated by a double tangent at the curve for the free enthalpy of mixing (cf. Fig. 8). This defines the compositions of the coexisting phases, which form the binodal curve at the temperature in question; this curve is identical with the turbidity limit in the case of strictly binary mixtures. It must therefore be ascertained whether the composition of the demixed phases in the miscibility gaps of "quasibinary" polyblends corresponds to the turbidity limit. This has been done successfully for the system composed of poly(methyl methacrylate) and styrene-acrylonitrile copolymer with the aid of broad-line nuclear magnetic resonance. The spectra were recorded for a pure polymer and for mixtures containing increasing amounts of the other polymer. In the miscibility region the spectra for the two pure polymer components are not additive. The homogeneous mixture with a specific composition must be regarded as an individual species with a characteristic spectrum. Just before the turbidity limit is exceeded, one obtains the spectrum of one of those polymer compositions the system is to give by decomposition in the nonmiscible region. Since in the case of immiscibility the nuclear resonance spectra are additive, we can accurately build up the spectra for the polymer compositions in the miscibility gap from the spectra for the polymer mixtures at the turbidity limits, provided that we know the proportions of the phases. The method and results for mixtures of styrene-acrylonitrile copolymers with poly(methyl methacrylate) are shown in Figure 12. The phases have been separated according to the rules of equilibrium thermodynamics for

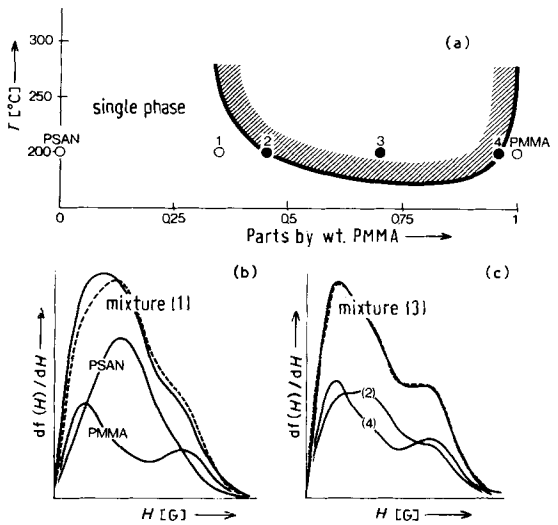

Fig. 12. Additivity and non-additivity of broadline NMR spectra of single- and multi-phase blends of poly(methyl methacrylate) (PMMA) and styrene-acrylonitrile copolymer (PSAN; 71.3 wt-% styrene, 28.7 wt.-% acrylonitrile). a) Turbidity curve, b) and c) resonance signals. Blend (1): PSAN/PMMA = 65/35, blend (3): PSAN/PMMA = 30/70 (phase ratio (2): 0.49, phase ratio (4): 0.51); — experimental curves, ---- curves calculated according to the composition (b), and using the stated phase ratios (c).

liquid mixtures. In quasibinary mixtures, however, the turbidity limit and the binodal curve do not coincide, on account of the inevitable molecular weight distributions[42], and the turbidity limit then by no means represents the composition of the coexisting phases (cf. [78, 79]).

The chemical potential $\Delta\mu_1$ of a component of a polyblend in the homogeneous single-phase region can be determined by small-angle neutron scattering. For this purpose all the hydrogen atoms in one part of the molecules of a component must be replaced by deuterium atoms. Since these isotopes differ in their scattering distances, a small-angle neutron scat-

tering, which—similarly to conventional light scattering—can be evaluated with the aid of eq. (14), is given by a dilute solution of the deuterated polymer in a nondeuterated matrix, or by the opposite system, which is simpler to use from the point of view of the scattering technique but is more difficult to prepare:

$$\frac{Kc_2}{R(\varkappa)} = \frac{1}{M_2 P(\varkappa)} + 2A_2 c_2 + \cdots \tag{14}$$

where $\varkappa$ [$=(4\pi/\lambda)\sin\theta$] is the scattering parameter, c_2, M_2, and A_2 are respectively the concentration, molecular weight, and the second virial coefficient of the polymer component present in the lower concentration, $R(\varkappa)$ is the ratio between the scattered and the incident intensities, $P(\varkappa)$ is *Debye*'s one-particle scatter function[80,81], λ is the neutron wavelength, and θ is the scattering half-angle. The constant K contains the scattering distances of hydrogen and deuterium as the most important quantities. The average scattering mass radius r of the polymer is calculated from $P(\varkappa)$ with the aid of:

$$P(\varkappa) = 1 - \langle r^2 \rangle_z \frac{\varkappa}{3} + \cdots \tag{15}$$

The conversion of $\langle r^2 \rangle_z$ into the weight-average scattering mass radius R_w is done in the usual way, on the assumption of a Schulz-Flory distribution. According to *Zimm*[82], we plot $Kc_2/R(\varkappa)$ against the sum of the concentration of polymer 2 and the square of the scatter parameter $\varkappa$. Extrapolation to $c_2 = 0$ and $\kappa = 0$ gives $P(\varkappa)$ and A_2, respectively. The intercept with the ordinate gives the reciprocal of M_2. Figure 13 shows such graphs for styrene-acrylonitrile copolymers in a matrix of perdeuterated poly(methyl methacrylate) at two temperatures[26]. The second osmotic virial coefficient of polymer 2 (here styrene-acrylonitrile copolymer) can therefore be obtained directly from experiment. It is connected by eq. (16) with the chemical potential $\Delta\mu_1$ of the polymer component 1 present in the higher concentration [here perdeuterated poly(methyl methacrylate)][52]:

$$\Delta\mu_1 = -RT\left[\frac{V_1}{M_2} c_2 + A_2 V_1 c_2^2\right] \tag{16}$$

where V_1 is the partial molar volume of polymer 1. If the chemical potential and the composition of the mixture are known, integration of eq. (13) gives also the value of the

Fig. 13. free enthalpy of mixing ΔG_m. The equation holds in this form only for dilute systems.

Neutron scattering experiments enable us to decide for the first time whether polyblends are molecular disperse in the optically clear domain. This cannot be done with certainty by means of the other methods used to determine whether the system is a multiphase one (dynamic and mechanical measurements, electron microscopy, and calorimetry). The state of the samples remains unchanged during scattering experiments; this method can be used at low concentrations and detects individual molecules. Molecular aggregates can be detected even at high dilutions. The molecular weights that the Zimm diagram (Fig. 13) gives for the styrene-acrylonitrile copolymer in a mixture with poly(methyl methacrylate) agree with the values obtained using conventional methods for the polymers employed. This indicates that in the range of compositions examined the mixtures are molecular disperse. Outside the miscibility gaps there is thorough mixing at the molecular level. Table 2 gives the numerical values for the molecular weights together with the other results obtained

by the neutron scattering method. As the temperature increases, the scattering mass radius R_w of the styrene-acrylonitrile copolymer decreases, as does the second osmotic virial coefficient A_2. This indicates a diminished dissolving power of poly(methyl methacrylate), in agreement with the existence of upper miscibility gaps. At the same time, when the miscibility limits are approached, the A_2 values decrease according to the acrylonitrile content of the copolymers, as an indication of the decreasing dissolving power of poly(methyl methacrylate) near these limits. The resolution of the A_2 values into an enthalpy term and an entropy term as in eqs. (17) and (18), which are valid for low concentrations[52]:

$$A_{2,H} = -T\left[\left(\frac{\partial A_2}{\partial T}\right)_p - \alpha_1 A_2\right] = -\frac{\Delta H_1}{RTc_2^2 V_1} \tag{17}$$

$$A_{2,S} = A_2 - A_{2,H} = \frac{\Delta S_1^E}{R c_2^2 V_1} \tag{18}$$

where α_1 is the coefficient of expansion, gives a negative sign for the heat of dilution ΔH_1 (indicating an exothermal interaction between the two polymers) and an excess entropy ΔS_1^E, which is surprisingly high for polyblends. The amorphous polyblend can therefore be treated as a liquid mixture.

In mixtures of styrene-acrylonitrile copolymers with a random constitution and various average compositions, the interaction between the two polymer components is endothermal. Despite the negative virial coefficients, the mixtures remain molecular dispersions until the variations in the acrylonitrile content of the component exceed about ±6 wt-%. As the deviation in the composition increases, the scattering mass radii decrease, and the second virial coefficient becomes more and more negative. Table 3 gives some relevant data obtained

Table 3. Neutron scattering by styrene-acrylonitrile copolymer mixtures with various average compositions of the components (monomer ratio in wt-%). $\bar{M}_w = 280000$. $T = 25\,^\circ C$. $\bar{R}_w$ = scattering mass radius. A_2 = second virial coefficient.

by the neutron scattering method[113]. Clusters are formed when the differences in the ratio of the repeating units of the components are large. The number of chain molecules per aggregate can be determined from the ratio between the molecular weight of the cluster and that of the initial copolymers.

4. Chain Conformation

The conformation of chain molecules in polyblends is basically the same as in homopolymers. Partially crystalline polymers are described by a two-phase model; crystalline regions are separated here by amorphous ones. Individual chain molecules belong partly to crystallites and partly to the amorphous phase. In the lamellar crystallites the chains are closely packed and have either a zigzag or a helical conformation. Owing to varying configuration of the main chains and because of branching, chain ends, and chemical heterogeneity, lattice defects occur in copolymers. As a result of these lattice defects and the amorphous regions, these systems give more or less diffuse X-ray diagrams, with broadened reflections, from which the unit cell for an ideal crystal without any lattice defects can be derived with the aid of stereochemical considerations. From this we can determine the equilibrium conformations of the chain molecules and derive the intramolecular and intermolecular interaction potentials. For example, *Natta et al.*[83] calculated in this way the potential surfaces for isotactic polypropylene with the repeating unit $-[CH_2-CH(CH_3)]-$ as a function of the angle of rotation between two successive monomer units.

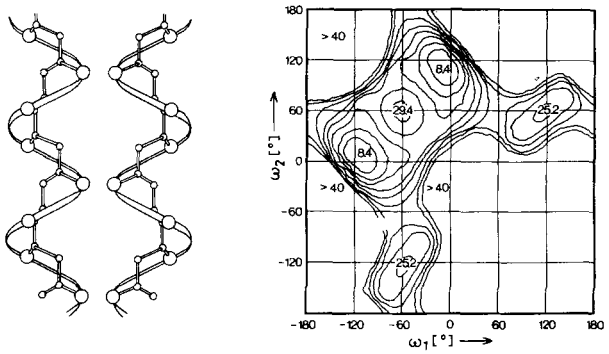

Fig. 14. Helical conformation and potential surfaces for isotactic polypropylene as a function of the angles of rotation ω_1 and ω_2 of two successive monomer units with respect to the main valence bond direction of the chain (after [83]). Numerical data in the diagram: conformational energies in kJ/mol. o $-CH_2-$ or $>CH_2$; O: CH_3.

Figure 14 shows two energy minima, one corresponding to a right-handed and the other to a left-handed triple helix, which have been detected by X-ray crystallography as well.

If the molecular chains continue parallel to the longer edge of the crystallites and if the disordered chain segments emerge from the shorter edge, fringed crystallites are formed as in native cellulose[84]. On the other hand, if the molecular chains run normal to the longer edge of the crystallites and if they emerge there from the crystalline domain and, either directly or after building a loose loop, enter the same or a neighboring crystallite they are called folded crystallites (see Fig. 15).

The periodic arrangement of crystalline and amorphous domains has been detected by small-angle X-ray scattering. The distance between the centers of gravity of the crystallites (the long period) is found from the position of the reflections. At the same time, these measurements show that the density of the non-crystalline domain is in general exactly the same as that of the purely amorphous polymer[85, 86]. However, this is significant only if we can ignore the dependence of the density of the amorphous and crystalline portions on

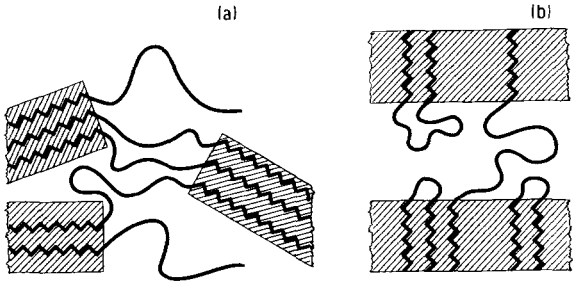

Fig. 15. Chain arrangement in a) fringed and b) folded crystallites (schematic).

the conditions of crystallization, which is difficult in the case of *e.g.* poly(ethylene terephthalate) with the repeating units $-[O-CH_2-CH_2-O-CO-C_6H_4-CO]-$[87]. The surface layer of single crystals of poly(1-butylene) with the repeating unit $-[CH_2-CH(C_2H_5)]-$ has the same glass temperature as the pure amorphous material[88]. Evidently the segmental mobility is frozen in in the cross-loops in the folding regions in the same way as in purely amorphous polymers.

Models for the structure of polymers crystallized from the melt[32] are often based on measurements on single crystals, which are best obtained by subjecting dilute solutions to crystallization. This gives regularly folded lamellar crystals or packets of such crystals; the degree of crystallinity is 80%. The material representing the other 20% goes preferentially to the boundary surfaces, which contain the folds (*i.e.* the loops between leaving and reentering of the chain in the crystallite, see Fig. 15). To elucidate the conformation of the chains in these regions, the sample is subjected to a chemical treatment such as hydrolysis (in the case of polysaccharides) or oxidation with concentrated nitric acid or ozone (in the case of polyethylene), whereupon the chains in the less closely packed folding regions preferentially react first, and the reaction rate falls when the boundaries of the crystalline region have been reached. Chain fragments corresponding to single and multiple traverses across the folding crystallite are obtained. The length of the chain folds in the amorphous domain is obtained in addition if the kinetics of the degradation are studied and the molecular-weight distribution of the decomposition products is determined[89]. This work shows that there is a chain-length distribution, with the greater part of the folds lying in a very narrow region.

The neutron scattering method offers a direct means for investigating the conformation of the chains in partially crystalline polymers. *Schelten et al.*[90, 91] have used this method on melt-crystallized mixtures of non-deuterated and perdeuterated polyethylene, obtained by quenching the melt relatively quickly. This prevents the aggregation of the deuterated material on crystallization and gives a mixture which is still in a state of molecular dispersion. The experimental radii of gyration (scattering mass radii) R_w surprisingly correspond to the conformation of random coils as found in polyethylene melts by *Fischer et al.*[92]. In particular, the dependence of the radius of gyration of the labeled polymer chain on the molecular weight, corresponding to the relationships in a Θ-solvent, cannot be reconciled with the complete insertion into a single folded crystallite. Therefore, *Schelten et al.* assume that the chain molecules crystallize out in their "entirety", with retention both of the coil dimensions of the melt and of the arrangement in which a polymer chain belongs to a number of crystallites and amorphous regions in between. *Yoon* and *Flory* have calculated the angle-dependence of the neutron scattering intensity of perdeuterated polyethylene in a deuterium-free matrix as a function of the proportion of back-folding of the chains into the same crystallite. The best agreement with the experimental values for the scattered intensity, the conformation of chains, and the degree of crystallinity is obtained when a model is used in which it is assumed that 70% of the chains fold back on themselves into the same crystallite[93]. Consequently, quenched melts of crystallizable polymers do not show the adjacent reentry that *Mandelkern*[94] has postulated in general.

If melts of crystallizable polymers are not quenched but are instead cooled slowly under pressure, crystallites with a thickness of up to a few thousand ångstroms are obtained, which thus reach the order of magnitude of fully stretched chain molecules. In recent neutron scattering measurements, *Ballard et al.*[95] have confirmed the stretched conformation in polyethylene crystallized in this way. The lengths of the stretched chains agree with the thickness of crystallites that is determined by the nondeuterated polyethylene matrix and has been found by degradation with nitric acid. The perdeuterated polyethylene molecules aggregate in the deuterium-free matrix, and the number of chain molecules per aggregate can be found from the molecular weight of the latter and that of the perdeuterated polyethylene. The radii of gyration of the aggregates change only slightly with the number of perdeuterated chain molecules in the aggregate. Besides, an increase in the molecular weight of the perdeuterated polyethylene does not lead to a marked increase in the radius of gyration, unlike in the case of the random coil conformation. Clearly, there is again back-folding of the chains into the same crystallite.

There are two models for the conformation and packing in homogeneous melts and solid amorphous polymers. *Flory*'s coil model[96] assumes a random conformation of the chain molecules, similarly to the case of dilute solutions of high polymers. In the unperturbed or Θ-state, the distances of the chain segments from the center of gravity of the coil follow a Gaussian distribution. The scattering mass radius or radius of gyration, which is normally specified, is the mean value of these distances. The coiled conformation leads to penetration of the chain molecules in the condensed state; the network is completely homogeneous. In the bundle models[97–99], on the other hand, it is assumed that the structure is characterized by a nonrandom short-range order, which is due to the parallel alignment of the chain sections and causes inhomogeneity and anisotropy at the molecular level. The situation is analogous either to the back-folding of chains or to the chain bundle in partially crystalline polymers, according to whether the parallel segments belong to the same or to different chain molecules. Because of the assumption of a parallel alignment of the chain sections, the bundle models are expected to give a different value for the radius of inertia from that suggested by the random-coil model. It should therefore be possible to find out which of these models is correct by measuring the radius of gyration as a function of the molecular weight (and in mixtures also of the concentration), as well as by investigating the short-range order at the molecular level to decide whether or not it is anisotropic.

Using the small-angle neutron scattering method, several authors have determined the radii of gyration in the glassy state, for poly(methyl methacrylate)[100, 101] and polystyrene[102–108], and in the melt state, for polyethylene[92, 107] and polypropylene[109], all the samples having been mixed with the corresponding deuterated polymer. Both the glassy state and the fluid state always have radii of gyration that agree with the "unperturbed" values in a Θ-solution. The angle-dependence of the scattered intensity can be described for random coils with the aid of *Debye*'s particle scattering function[92, 110]. Plotting the values in a Zimm diagram shows, with small deviations, a value of zero for the second osmotic virial coefficient, this value being typical of the Θ-state. The

required proportionality is found to exist between the weight-average molecular weight $\bar{M}_w$ and the square of the radius of gyration R_w. Since both the radius of gyration corresponding to the Θ-state and the experimental dependence on the molecular weight can be correctly calculated also for a meandering conformation of the type of a flat disk[111], *Fischer et al.*[92, 112] have tried to detect anisotropy at the molecular level and so to demonstrate the parallel alignment of the chain segments in amorphous polystyrene, poly(methyl methacrylate), and polycarbonate. Electron scattering experiments give a distance distribution for the chain segments in polyethylene melts without any sign of a parallel arrangement. Fluctuations in the density, determined by the small-angle X-ray scattering method, indicate no periodicity whatever. For amorphous polymers above the glass temperature the density fluctuations are fully analogous to those found in high-molecular and also low-molecular melts. The fluctuations at first decrease rapidly with falling temperature, then less rapidly as the temperature drops below the glass point, and finally—after the region of secondary dispersion has been reached—they are completely frozen in. The glassy amorphous state corresponds to a frozen-in melt without any additional order. Measurement of the magnetic birefringence and the scattering of depolarized light has revealed no orientation correlations typical of ordered domains. The anisotropy of the repeating units in the polymer is comparable to that in the monomer, and is a number of orders of magnitude smaller than is expected for parallel bundles of chains. The intermolecular short-range order of the chain segments can be attributed in its entirety to coiling. No additional orientation fluctuations occur in the glassy amorphous polymer. It follows, therefore, that the model predicting a coiled conformation has proven to be the correct one for the amorphous state.

The conformation of the chains in mixtures of various polymers has been determined by the neutron scattering method[26]. In accordance with the exothermal interaction, styrene-acrylonitrile copolymers are expanded with respect to the Θ-state when mixed with poly(methyl methacrylate). The graph obtained by plotting the radii of gyration R_w against the molecular weight (Fig. 16) shows a slope of 0.64 at 110°C and 0.61 at 130°C in the case of low concentrations of the copolymer, as compared to 0.5 for the unperturbed (Θ) state.

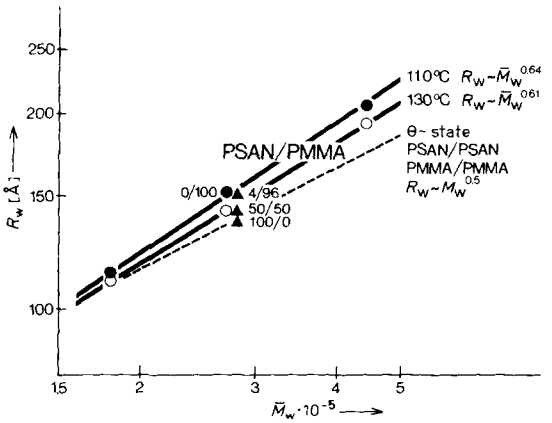

Fig. 16. Radius of gyration R_w of styrene/acrylonitrile copolymers (PSAN containing 19 wt-% acrylonitrile) as a function of the molecular weight $\bar{M}_w$ in blends with poly(methyl methacrylate) (PMMA). ○ = measurements at 130°C; ● and ▲ = measurements at 110°C. Values at points measured: extrapolation values for the composition of PSAN and PMMA in the Zimm plot (Fig. 13).

As the temperature is raised, the coil expansion decreases, and so does the parameter of the R_w *vs.* $\bar{M}_w$ function, indicating that the upper miscibility gap is being approached. The neutron scattering method has also been used to investigate mixtures containing the copolymer in other than very low concentrations[113]. For this purpose both polymers are deuterated with the exception of a small portion of one of the components. The system is then concentrated from the thermodynamic point of view but dilute from the neutron-optical point of view, and the measurements can be again evaluated with the aid of the scattering theory for dilute solutions. As more and more of the "solvent" [poly(methyl methacrylate)] is replaced by styrene-acrylonitrile copolymer the coil expansion decreases in the direction of the unperturbed dimensions of the Θ-state. The radius of gyration for the styrene-acrylonitrile copolymer in its own matrix falls precisely to the R_w *vs.* $\bar{M}_w$ curve for the Θ-state of the amorphous poly(methyl methacrylate).

The aggregation of the chain molecules on incipient phase separation can also be monitored with the aid of the small-angle neutron scattering method, as for example in the case of a mixture of poly(α-methylstyrene) and deuterated poly(methyl methacrylate)[26]. The amount of poly(α-methylstyrene) only has to be raised to above 0.5 wt-% to provoke a drastic increase in the scattered intensity, indicating molecular aggregations. At lower concentrations the mixture is still a molecular dispersion. The evaluation of the measurements in a Zimm diagram (cf. Fig. 11) gives the correct molecular weight and a radius of gyration that is close to the value for the collapsed coil. By analogy with the mixing of polymers with low-molecular compounds, we find that poly(methyl methacrylate) is not a solvent for poly(α-methylstyrene). Its coils are collapsed and tend to aggregate even at low concentrations. The existence of molecular dispersion at low concentrations supports the statement that there is no general incompatibility in the case of amorphous polymers.

5. Supermolecular Structure

The morphology of polyblends is determined by methods that indicate a heterogeneity in the region of supermolecular dimensions. Chemical methods rely on the different reactivities of the phases with special reagents, while physical methods differentiate between the phases on the basis of their different refractive indices, segmental and proton mobilities, polarizabilities, specific heats, and densities. The most frequently used tool is the electron microscope, employed in conjunction with ultrathin sections of the material (for details, see [114–121]).

Electron micrographs are used below to illustrate the effects of the chemical composition of the chain molecules, the temperature, the ratio between the components, and the method of polymerization or mixing on the magnitude, size distribution, and shape of the demixed zones. The system composed of poly(methyl methacrylate) and styrene-acrylonitrile copolymer is used again as an example of mixtures of amorphous polymers with similar freezing-in temperatures for the segmental mobility. The components are miscible at acrylonitrile contents of between 10 and about 30 wt-% in the copolymer, and there are upper miscibility gaps in the system. Figure 17 shows the morphological changes in the melt mixtures

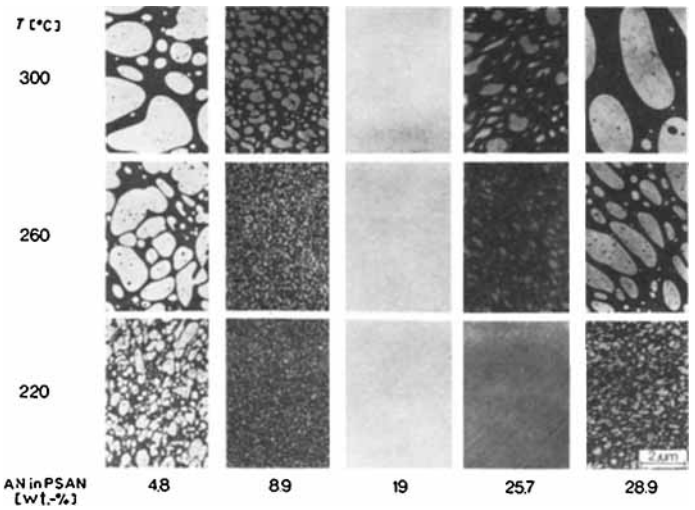

Fig. 17. Electron micrographs for 1 : 1 melt mixtures of poly(methyl methacrylate) and styrene-acrylonitrile copolymers (PSAN) with varying amounts of acrylonitrile (AN). Light areas: phase rich in poly(methyl methacrylate). T = temperature of the melt.

with the composition of the copolymer and the temperature. There are no visible inhomogeneities in the miscibility region[*], and after the miscibility limit has been exceeded the demixed regions become larger and larger and the phase boundaries sharper and sharper. The same occurs when the temperature is raised. The changing contrast of the phases proves that these are not pure substances but are themselves mixtures of the two polymers, with a large amount of poly(methyl methacrylate) (light areas) or of styrene-acrylonitrile copolymer (dark areas).

The combination of styrene-acrylonitrile copolymers with polybutadiene gives ABS polymers, which are important in industry. A characteristic feature of these is the great difference between the glass temperatures of the components. We have here a disperse elastomer phase embedded in a glassy amorphous matrix. Figure 18a shows the morphology of such a material, formed by the simple mixing of the styrene-acrylonitrile copolymer with polybutadiene[**]. The disperse phase is

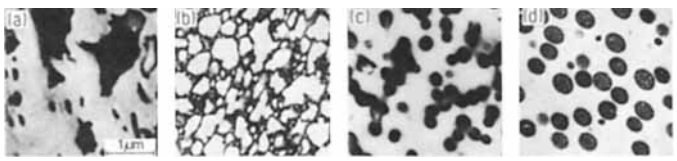

Fig. 18. Acrylonitrile-butadiene-styrene copolymers. a) Melt mixture with disperse elastomer phase, b) melt mixture with continuous elastomer phase, c) latex mixture, with the styrene-acrylonitrile copolymer as the continuous phase, d) emulsion graft copolymer, with the styrene-acrylonitrile copolymer as the continuous phase. Dark areas: elastomer phase.

present in regions of irregular shapes and sizes. The degree of dispersion seems to be fortuitous and depends to a great extent on the shearing forces applied in the mixing. By increasing the amount of the elastomer phase it becomes continuous, and one obtains a reinforced rubber with a morphology such as that shown in Figure 18b, for example.

[*] The globular structure often described in connection with many other amorphous polymers [168] is also absent here.

[**] The elastomer phase is not a butadiene homopolymer here but contains a few percent of acrylonitrile as a comonomer.

In the case of a polybutadiene component that is prepared by emulsion polymerization and is gradually cross-linked, the dispersion is less fortuitous. Figure 18c still shows the original spherical shape of the latex particles. The cross-linking hinders the coalescence of the latex particles, so that the styrene-acrylonitrile copolymer continues to be the continuous phase until its amount in the mixture is much smaller. Graft copolymerization of styrene and acrylonitrile onto preformed polybutadiene latexes gives systems with well-defined morphologies that are largely insensitive to shearing forces and heating to the processing temperature. These systems are stabilized and the latex particles cannot be either fused together or separated. The system shown in Figure 18d is a mixture of a random copolymer and a graft copolymer, illustrated in Figure 1.

The amount of monomers grafted on, the degree of crosslinking, and the particle size are important variables when the required morphology is fixed by emulsion polymerization[11,21]. Figure 19 shows a series of polybutadiene latexes, reacted with increasing quantities of styrene and acrylonitrile and then mixed with more styrene-acrylonitrile copolymer. The

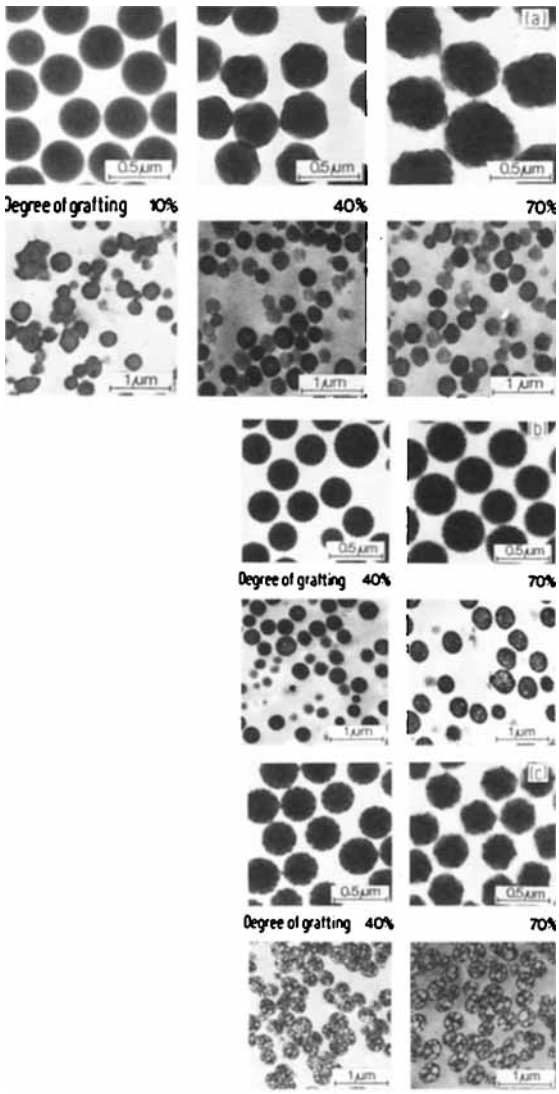

Fig. 19. Acrylonitrile-butadiene-styrene copolymers. Morphology of graft copolymer latexes (above) and of their mixtures with styrene-acrylonitrile copolymer (below), with various amounts of grafted-on monomers and with a) high, b) moderate, and c) slight cross-linking of the polybutadiene base rubber.

grafting monomers cause the latex particles of the basic dispersion to swell and polymerize out on these sites. Since polybutadiene and the graft polymer do not give a homogeneous mixture, a phase separation occurs in the latex particles. Grafted-on monomers can be concentrated in the outer zone of the latex by pre-crosslinking the latex particles (*e.g.* by the addition of a bifunctional comonomer), by introducing the monomers at a rate that is slow in comparison with the rate of polymerization, or by using an initiator that decomposes in an aqueous phase[4]. The result is a stronger envelope, which inhibits the agglomeration of the latex particles when these are mixed with the matrix polymer in the melt. The graft envelope is not visible in the mixture; the dimensions of the polybutadiene-rich phase are about the same as those of the ungrafted rubber particles. As the pre-grafting cross-linking of the latex particles is reduced, the graft envelope becomes less and less complete, even though the amount of the graft monomer remains the same; the graft component is inside the particles. The corresponding electron micrographs in Figure 19 clearly show a domain structure, owing to phase separation inside the particles. The open graft envelope then causes agglomeration of the polybutadiene-rich phase when the components are mixed in the melt. The mechanism and the kinetics of graft polymerization onto elastomeric substrates have been investigated in detail by *Riess* et al.[122–126].

The styrene polymers with a high impact strength, which are produced industrially on a large scale, are also built up of a rigid continuous phase and a soft disperse phase. Monomeric styrene is polymerized in the presence of non-crosslinked dissolved polybutadiene. The formation of homopolystyrene and the grafting of styrene onto polybutadiene proceed here simultaneously, and the result is a mixture of a homopolymer and a graft copolymer. The latter is formed preferentially if polybutadiene with double bonds in side groups is copolymerized with growing styrene chains. Double bonds in the main chain, on the other hand, tend to copolymerize only to a small extent[127] (see Fig. 20). A factor of secondary importance in the case of polybutadiene is the abstraction of allyl hydrogens by a growing polystyrene chain or by a primary radical of the initiator. The radical sites thus transferred to the polybutadiene chain might either become the starting points of a graft branch by the adding-on of further monomer, or they might lose their reactivity by recombination. By contrast, such transfer reactions are responsible for grafting and cross-linking in the case of other base polymers such as polyacrylates.

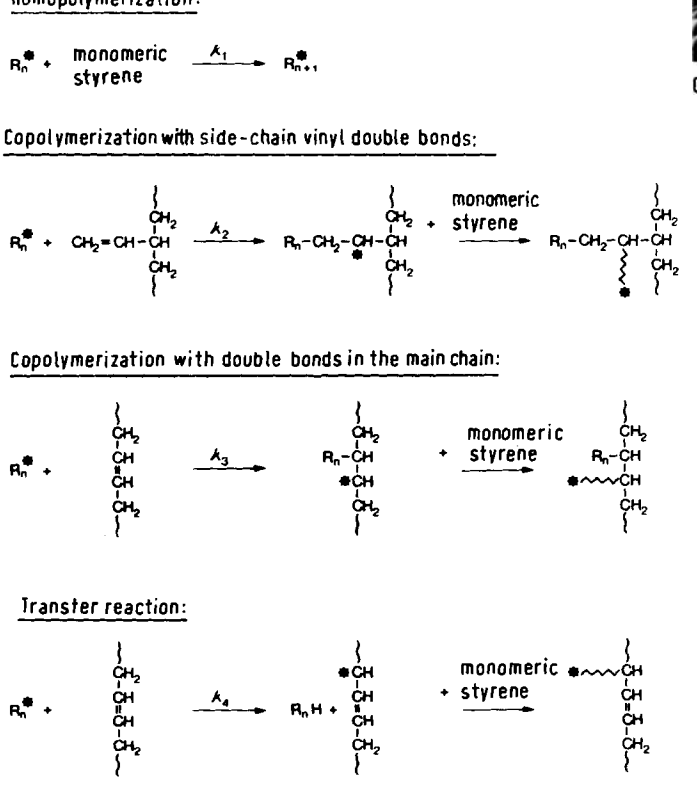

Fig. 20. Graft copolymerization onto polybutadiene (schematic). R_n^*—primary or macroradical, k —rate constant.

Unlike in emulsion polymerization, the attainment of the required morphology of multiphase polymers by grafting and cross-linking is complicated if bulk and suspension polymerization are carried out. If we start the polymerization with a single-phase solution of the base polymer (*e.g.* polybutadiene) in the monomer of the matrix (*e.g.* styrene), a phase separation occurs even at comparatively low conversions; a new disperse phase consisting of the dissolved matrix polymer is formed in the still continuous solution of the rubber in the monomer. The ratio between the volumes of the two phases continuously changes in favor of the matrix polymer until a reversal occurs for geometric reasons, and the phase rich in the matrix polymer coalesces to give a continuous phase (see Fig. 21). After the

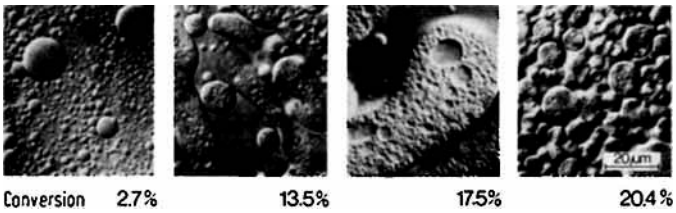

Fig. 21. Interference phase-contrast micrographs for a polymerizing solution of polybutadiene in styrene after a conversion of 2.7, 13.5, 17.5, and 20.4 %.

phase reversal, the graft copolymer formed in the meantime stabilizes the disperse polybutadiene-rich phase, which still contains numerous small polystyrene inclusions. Phenomena of this type were first observed by *Molau*[21,22]. Phase separation and phase reversal depend on the shearing forces in the reaction mixture, the ratio between the viscosities of the disperse and the continuous phase, the molecular weight of the polybutadiene starting material, and the ratio between the amount of styrene grafted on and the total amount of polystyrene formed. Graft copolymers formed before the phase reversal stay in the primary inclusions and do not participate in the phase reversal. Only the graft copolymers formed during or after the phase reversal act as emulsifiers for the disperse phase in the continuous phase[24]. The rheological properties of the reaction mixture largely determine the degree of dispersion and the particle-size distribution of the disperse rubber-phase, whose substructure depends on the chemical composition of the polybutadiene introduced. The substructure changes during the reaction as a result of grafting, and graft copolymers with a block structure are formed. The substructure of the disperse phase can therefore be controlled by adding a styrene-butadiene block copolymers.

Block copolymers form periodically ordered structures at the supermolecular level both in the solid state and in solution, these structures being determined by the ratio between the numbers of repeating units in the blocks (see [115, 128–131]). Figure 22 shows schematically such structures for two-block

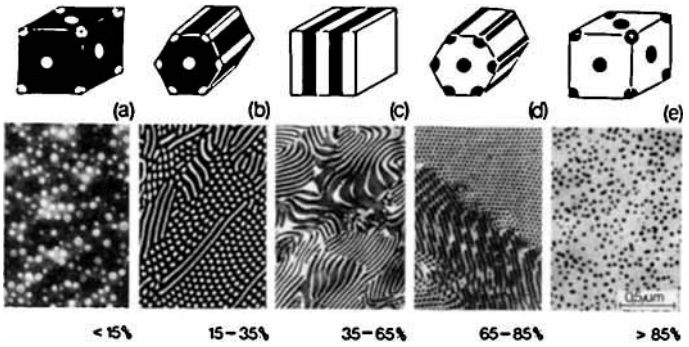

Fig. 22. Morphology of styrene-butadiene two-block copolymers in the solid state as a function of the composition (schematic, after [22]), together with the corresponding electron micrographs a) Polystyrene spheres in a polybutadiene matrix; b) polystyrene cylinders in a polybutadiene matrix; c) polystyrene and polybutadiene lamellae; d) polybutadiene cylinders in polystyrene matrix; and e) polybutadiene spheres in a polystyrene matrix. Dark: polybutadiene. The figures refer to the amount of styrene.

copolymers composed of butadiene and styrene (after *Molau*[22]), together with the corresponding electron micrographs. The polybutadiene-rich and the polystyrene-rich phases separate from each other. In mixtures of styrene-butadiene block copolymers and homopolystyrene, the latter penetrates into the domains of styrene blocks if their molecular weight exceeds that of the homopolymer[132, 133]. As the homopolystyrene portion is increased, the polystyrene-rich domains become larger and finally the morphology abruptly changes into the next type. If the molecular weight of the polystyrene blocks is smaller than that of the homopolymers then they demix to form a separate phase and the morphology of the two-block polymer is not changed but merely perturbed. Increasing the polystyrene content by grafting onto the blocks, on the other hand, always leads, irrespective of the molecular weight of the grafted chains, to a morphological change when the volume of the polystyrene-rich phase exceeds the threshold value to the next type. From the homo- and block-polymers of butadiene a considerable array of morphologies result—on the one hand, by mixing with polystyrene of higher molecular weight, and on the other, *via* the equivalent way of grafting and mixing with low molecular weight polystyrene; the "particle zoo" thus formed is shown in Figure 23.

In the case of block copolymers, the boundaries between the demixed phases do not increase their sharpness indefinitely but are instead characterized by a concentration profile of the repeating units involved, as is shown in Figure 24. Accord-

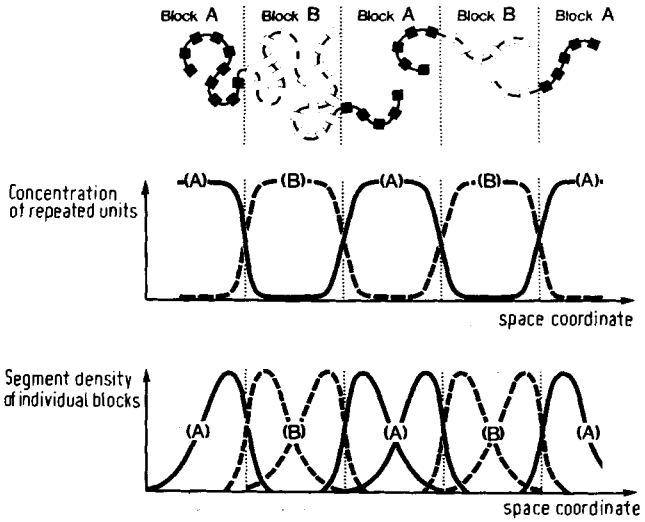

Fig. 24. Domain boundaries and segment-density distribution for two-block copolymers (schematic).

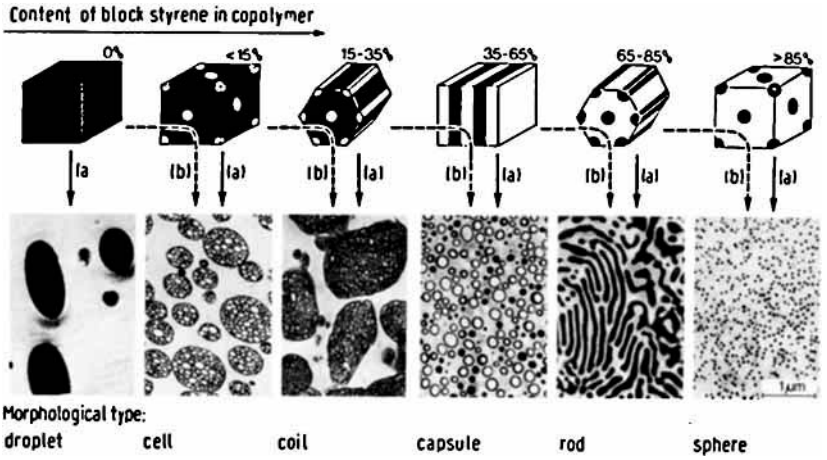
ing to the views on the conformation of the chains in amorphous polymers, a Gaussian curve can be assumed for the variation of the segmental density of the blocks in the area between the site of attachment and the phase boundary lying opposite. The coil dimensions are then fixed for a given molecular weight of the blocks. The size of the phase is limited, because the packing density of the homopolymers involved must be reached in the demixed phases (the temperature-dependent density variations can be neglected here). As a result, the dimensions of the demixed regions are nearly always smaller in block copolymers than in homopolymer mixtures. This readily explains the fact that on mixing a homopolymer in a block copolymer the former is excluded from the block domains when the molecular weight of the homopolymer is higher than that of the block. Homopolymers of lower molecular weight are incorporated in the block domains



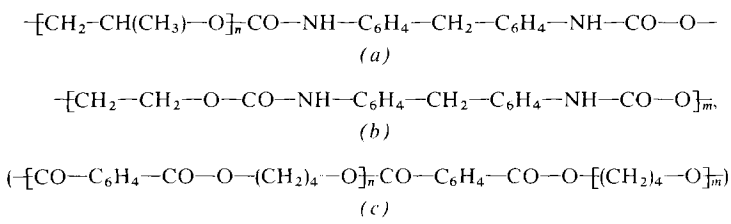


Fig. 23. Manufacture of high-impact polystyrene from ordered precursors (butadiene-styrene block copolymers of varying composition) a) by mixing with fairly high molecular weight polystyrene, b) by grafting in styrene solution.

because of their smaller coil dimensions. Quantitative relationships have been worked out by *Meier*[134–137] and by *Helfand*[138, 139].

As in the case of partially crystalline polymers, the number of possible arrangements of the blocks (and hence their entropy) is smaller in the demixed regions than in the case of free chains in homopolymers. Only the volume of the domains with the same chemical repeating units is available to the blocks, and the site of linkage between the blocks is always near the boundary of the domains. In the case of three-block copolymers there are two coupling sites at the phase boundaries and the entropy is then reduced even more. The diminished entropy of configuration in block copolymers at first opposes the demixing in domains with a high periodicity, but is compensated for by interfacial energies and blurred phase boundaries at the molecular level[140, 170].

Segmental copolymers can be distinguished from copolymers made up of high-molecular blocks, their "blocks" (segments) being much smaller. Polyurethan elastomers are the best known examples; in these, soft and flexible segments *(a)* of aliphatic polyethers or polyesters alternate with hard and stiff segments *(b)* containing the isocyanate linkages. Copolyesters are built up along the same lines; *e. g.* terephthalic acid-diol blocks are connected by soft segments *(c)* formed

(a)

(b)

(c)

by aliphatic polyethers. The hard segments combine to form crystallites, which act as physical cross-linking points. The crystallites melt when the temperature is raised, and re-form on cooling. These materials are therefore described as thermoplastic elastomers. The crystallites connected by soft segments form spherulitic superstructures. Figure 25 shows some typical

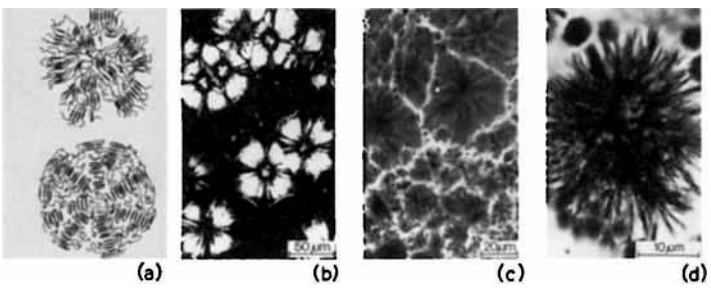

Fig. 25. Morphology of segmental copolymers. a) Schematic (after [141]), b) as seen under a polarization microscope, c) and d) as seen under an electron microscope. Light areas: soft phase.

micrographs, together with a schematic representation of the spherulitic structure after *Seymour*[141], based on light scattering in the small-angle region. The model showing a radial orientation of the crystallites and a tangential direction of the chains (top picture in Fig. 25a) is the more probable one of the two. The low-contrast regions between the spherulites are formed by amorphous material, which largely consists of soft segments and contains only a few short, noncrystallizable hard segments. These do not form a separate phase. In accordance with this morphology, segmental copolymers show, on thermomechanical analysis, a glass transition of the amorphous phase and melting of the crystallites. The dimensions of the crystallites and thus the melting point can be changed by altering the concentration of the hard segments, while the glass temperature and the partial volume of the amorphous phase can be controlled *via* the length of the hard segments[9, 140].

Partially crystalline polyolefin-containing mixed systems must be mentioned as the last example. By a selective reaction between the noncrystalline regions and chlorosulfonic acid, *Kanig* has rendered visible the lamellar crystallites that represent the most important morphological feature of these materials[118, 119]. As Figure 26a shows for linear polyethylene with

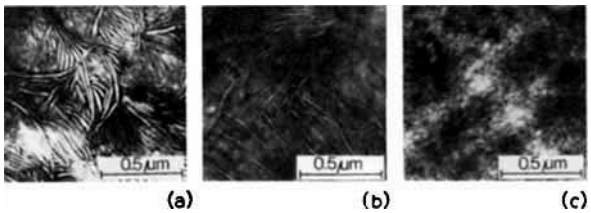

Fig. 26. Morphology of partially crystalline polyolefins (after [119]). a) Linear polyethylene, b) branched polyethylene, c) polypropylene. Dark areas: noncrystalline regions.

the repeating unit $-[CH_2-CH_2]-$, the lamellae are about 15 nm thick, bent, and matted together. As can be seen from Figure 26b, branched polyethylene with the repeating unit $-[CH_2-CH(C_nH_{2n+1})]-$ has thinner lamellae and an altogether less regular structure, somewhat like polypropylene, shown in Figure 26c. According to *Kanig*, this proves that the branching sites are not embedded into the lamellar crystallites but are instead located in the amorphous regions. Up to an ethylene content of about 70%, ethylene-propylene copolymers (possibly mixed with small amounts of nonconjugated dienes) which show a random sequence of the monomer repeating units give noncrystalline flexible thermoplastics that exhibit a high permanent set[169]. When the amount of ethylene is higher, the ethylene sequences form crystallites, which act as physical cross-linking sites and confer elastic properties on the material. The combination of polypropylene with polyethylene or with copolymers of both gives products that are both tough and elastic. Figure 27a shows inclusions in

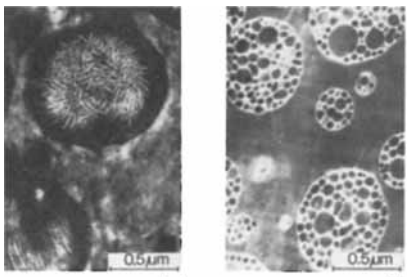

Fig. 27. Morphology of polyolefin copolymers (after [119]). a) Polypropylene with ethylene-propylene copolymer as disperse phase (dark areas: noncrystalline regions), b) polystyrene with cross-linked ethylene-propylene copolymer as the disperse phase (light areas: elastomeric phase).

a polypropylene matrix with small irregular lamellae; these inclusions consist of an outer shell made up of noncrystalline copolymer and of a central core of large polyethylene crystallites. Besides butadiene rubber and acrylate rubber, copolymers of about 30% of propylene, 60% of ethylene, and 10% of a diene are also used to modify the impact strength

of polystyrene. In accordance with this composition, the electron micrograph in Figure 27b shows no lamellar crystallites but instead the well-known picture of impact-resistant polystyrene with an amorphous elastic rubber component.

6. Optical Properties

For multiphase polymers turbidity is the rule and transparency the exception. However, the latter property is needed for certain technical applications. If the dimensions of the demixed phases are comparable to, or larger than, the wavelength of visible light, optically clear mixtures are obtained by equalizing the refractive indices of the various phases. For this, the components with different refractive indices must be mixed homogeneously within the phases. Use is often made of copolymers whose refractive indices are obtained from those of the corresponding homopolymers by linear combination, taking into account the partial volumes of the repeating units. Figure 28 shows the morphology of such copolymers,

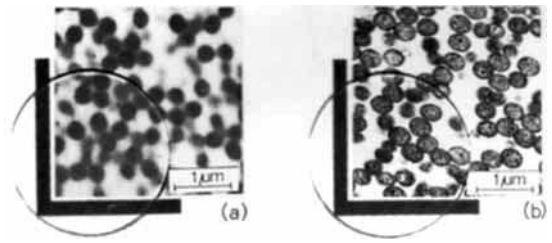

Fig. 28. Transparent elastomer-reinforced thermoplastics. Refractive index equalization between styrene-methyl methacrylate copolymer (continuous phase) and an elastomer phase composed of a) styrene-butyl acrylate copolymer, and b) styrene-butadiene copolymer.

together with disks made from them. Optically clear, elastomer-reinforced thermoplastics are obtained *e.g.* by embedding a random copolymer of butyl acrylate ($n_D = 1.467$[*]) and styrene ($n_D = 1.591$[*]), or by incorporating a copolymer of butadiene ($n_D = 1.515$[*]) and styrene into a styrene-methyl methacrylate matrix. The disperse phase can also contain inclusions of the isorefractive matrix material, as it does here in the second case. The matrix and the elastomer phase are linked by grafting.

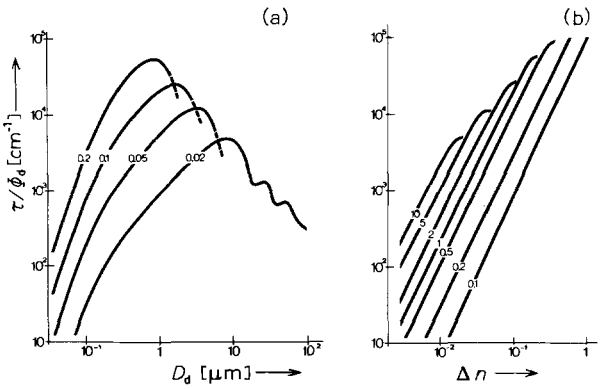

Fig. 29. Turbidity coefficient τ of two-phase mixtures after *Mie*, as a function of a) the diameter d_D of the disperse phase at various values of the refractive index contrast Δn and b) the refractive index contrast, at various values of the particle diameter in [µm]. The refractive index contrast is the difference between the refractive index of the continuous phase and that of the disperse phase, relative to the mean value of the refractive index, and Φ_d is the partial volume of the disperse phase. The curves are calculated at a wavelength of 0.55 nm and a refractive index of $n = 1.55$ for the disperse phase.

[*] These values refer to the homopolymers at 25°C.

The equalization of refractive indices is basically possible only for a single wavelength, and it must be borne in mind that these indices will not coincide if one changes over to other wavelengths. However, polymers with the same refractive index generally show the same wavelength-dependence of the refractive index [poly(vinyl chloride) is an exception], so that the system remains transparent over a wide spectral region. A critical factor is the variation of temperature, which can lead to changes in the phase compositions and thus to turbidity.

Figure 29 shows the turbidity (caused by one-particle scattering of the disperse phase) as a function of the "refractive index contrast" (defined as the difference between the refractive indices of the disperse and the continuous phase) and the magnitude of the phases, after *Mie*. The turbidity coefficient τ relative to the partial volume Φ_D of the disperse phase and defined by eq. (19) is used as a measure of the scattered intensity:

$$I(x)/I_0 = \exp[-(\varepsilon+\tau)x] \tag{19}$$

where I_0 is the intensity of the incident light, $I(x)$ is the transmission, ε is the absorption coefficient, τ is the turbidity coefficient, and x is the layer thickness. The turbidity always increases exponentially with the particle size (at a constant refractive index contrast) and with the refractive index contrast (at a constant particle size). Systems with a low refractive index contrast and small dimensions of the particles in the disperse phase have low turbidity values. For particle diameters of up to one-fifth of the wavelength of light, the refractive index of the disperse phase can be equalized with that of the matrix by grafting. Despite a core envelope structure, it is possible to specify a volume-average refractive index for graft copolymers, according to *Kerker*[142]. If the graft base exhibits a particle-size distribution, the ratio between the volume of the core and that of the envelope is not constant, and smaller particles, which have a larger specific surface area, are more strongly grafted. Thus we have a refractive index distribution after grafting and cannot obtain an accurate coincidence with the refractive index of the matrix polymer. This difficulty is reduced by using a monodisperse graft base. Figure 30 shows, for polybutadiene latexes with a monodisperse and bimodal distribution, the various graft envelopes composed of styrene, the corresponding particle-size distributions, and the transparency obtained after embedding into an isorefractive styrene-methyl methacrylate copolymer. The linking of the elastomeric graft copolymers with the chemically different matrix polymer is achieved by repeated grafting with the monomer of the matrix material. The degree of dispersion of the disperse phase can be controlled in this way.

When the disperse phase is not distributed homogeneously but forms agglomerates, it is particularly the angle-dependence of the scattered light that is modified. Figure 31 shows the scattered intensity I_s as a function of the angle of scattering ϑ in a Guinier plot for two elastomer-modified styrene-methyl methacrylate copolymers of different transparencies. In the case of homogeneous distribution the scatter is drastically reduced. The dimensions of the scattering centers can be found from the gradient of the linear portion of the graph[**]. The

[**] The nonlinear rise in the scattered intensity at small angles is caused by the presence of small amounts of impurities.

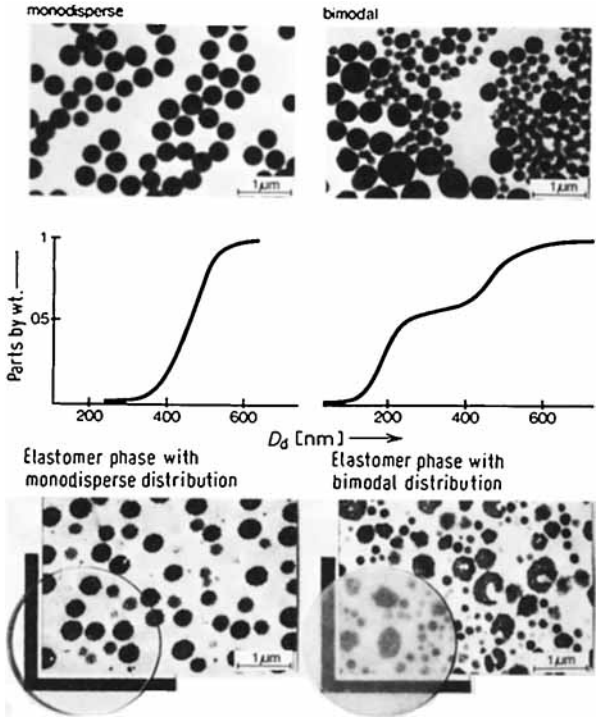

Fig. 30. Particle-size distribution and transparency of elastomer-modified styrene-methyl methacrylate copolymers (elastomer: polybutadiene-styrene graft copolymer). Top: graft dispersion; middle: integral particle-size distribution; bottom: mixture with the copolymer. D_d = particle diameter of the disperse elastomeric phase.

values obtained in the present case (a) are around 1300 nm, so that the scattering centers are not single rubber particles (whose size, found from electron micrographs, is about 100 nm), but larger clusters.

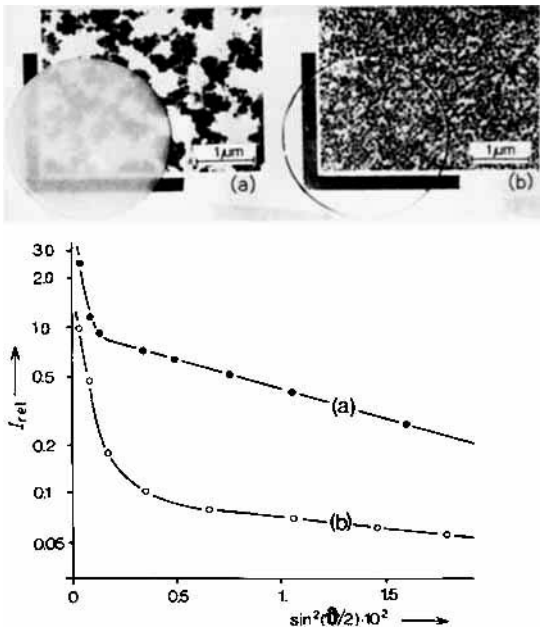

Fig. 31. Transparency and degree of dispersion of the disperse phase in elastomer-modified styrene-methyl methacrylate copolymers. Guinier plot of the relative intensity of the scattered light I_{rel} as a function of the scattering angle ϑ in the case of a) clustering and b) homogeneous dispersion of the elastomer phase. The intensities are relative to the scattering of optically clear samples at the smallest angle. Rubber phase: styrene-butadiene graft copolymer, approximately isorefractive with the continuous phase.

The dependence of the scattered intensity I_s on the angle of scattering ϑ is generally determined by the particle factor P^2 and the lattice factor L^2 in accordance with:

$$I_s(\vartheta) = P^2(\vartheta) \cdot L^2(\vartheta) \tag{20}$$

P^2 describes the scatter caused by single particles, while L^2 describes their superposition. The lattice factor is found from

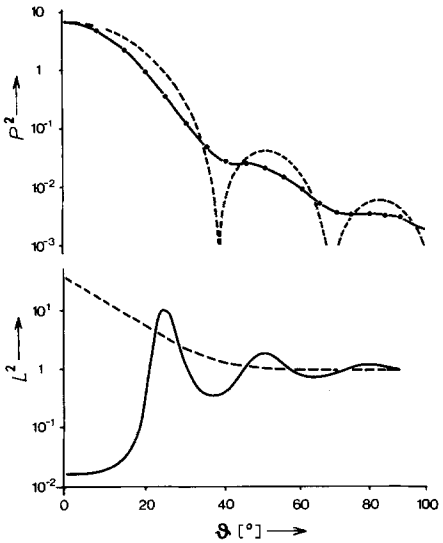

Fig. 32. a) Particle factor P^2 and b) lattice factor L^2 of the scattered intensity as a function of the scattering angle ϑ. a) Scattering centers with a particle-size distribution about the average diameter of 800 nm—experimental values (—); monodisperse scattering centers with a diameter of 800 nm, calculated after *Mie* (----); b) regular short-range order of the scattering centers (—) and Gaussian distribution of the distances (---).

the quotient of the scattered intensities at low and high concentration. Figure 32a shows schematically the variation of P^2 with the scattering angle in the case of particles with a diameter of about 800 nm. At a uniform particle size sharp minima and maxima are obtained, while a particle-size distribution gives a smoothed curve. The distribution of the distances between the scattering centers is represented by the lattice factor L^2 (see Fig. 32b). The variation of L^2 with the angle of scattering is clearly different for Gaussian distribution and for a regular short-range order. Increasing short-range order gives rise to sharp maxima and minima and to particularly low L^2 values in the first region, where P^2 is large. Multiplication of P^2 and L^2 as in eq. (20) gives the angle-dependent scattered light, whose volume integral—the turbidity—decreases with increasing short-range order.

As the distance between the scattering centers decreases, and as the particles become smaller, the curves for P^2 and L^2 shift toward larger angles of scattering. For example, in the case of an arrangement of monodisperse particles that

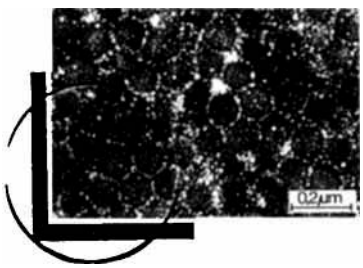

Fig. 33. Morphology and transparency of a polybutadiene latex ($n_D^{20} = 1.515$) and polystyrene ($n_D^{20} = 1.591$).

are in contact with one another and have diameters smaller than 150 nm, the first maximum of the lattice factor leaves the optical region at a scattering angle of 180°. L^2 is then very small in the entire optical region, and fully transparent two-phase systems are obtained (despite the large refractive index contrast), owing to the extinction of the scattered

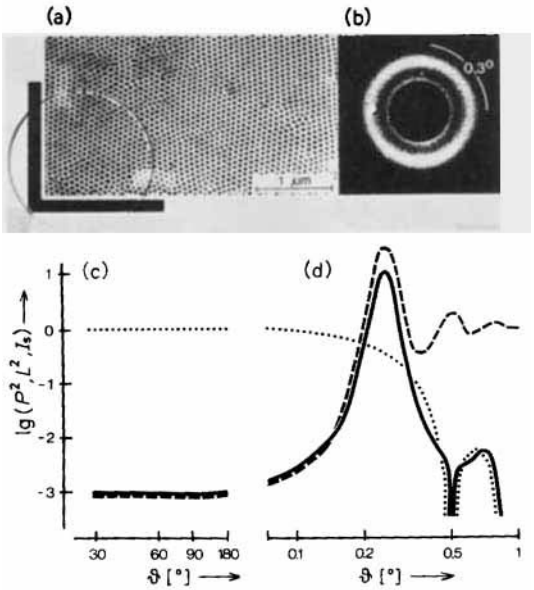

Fig. 34. a) Morphology and transparency of styrene/butadiene/styrene three-block copolymers. b) X-ray scattering of the lattice order in the small-angle region below 0.3°. c) Elucidation of particle scattering by the lattice factor in the light-scattering region ($\lambda = 546$ nm). d) Scattering in the X-ray small-angle region ($\lambda = 0.154$ nm). —— I_s, – – – L^2, ··· P^2. ϑ = scattering angle.

light[143]. Figure 33 shows by way of example a close-packed polybutadiene latex in a polystyrene matrix. Excellent examples of optically clear polymeric multiphase systems with considerable differences in the refractive index of the two phases are the highly ordered anionically polymerized two- or three-block copolymers of styrene and butadiene or isoprene. Demixing of the molecularly uniform blocks leads to domains on uniform size. Figure 34 shows the morphology, the change in the particle factor, the lattice factor, and the scattering intensity for the optical and the small-angle X-ray range. Practically no scattering occurs in the visible region; the copolymers are fully transparent. The high degree of order of the lattice of the demixed phases is made clear from the X-ray picture (Fig. 34b).

7. Mechanical Properties

From the technological point of view, multiphase polymers are of interest mainly because of their ability to withstand impacts without suffering brittle fracture. When a glassy amorphous polymer is subjected to deformation, the stress increases largely in proportion to the elongation and then leads to fracture. Polymers possessing rubber-like elasticity can undergo reversible elongations to several times their original length without fracture. The energy applied is harmlessly stored in the material, and the stresses are restricted. Figure 35 shows some typical tensile stress/elongation curves for glassy styrene-acrylonitrile copolymer, polybutadiene, and two ABS copolymers with different morphologies. Owing to the visco-elasticity of the material, the slope and the shape of

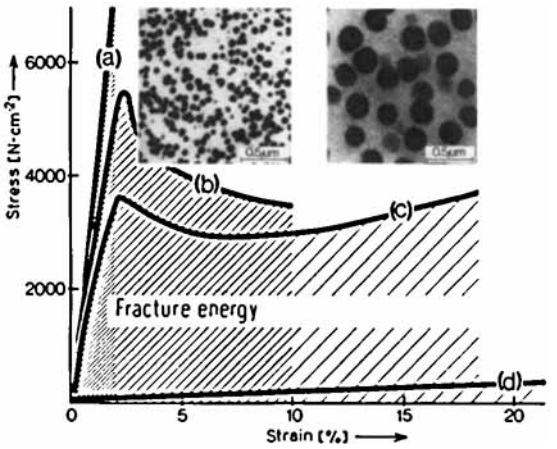

Fig. 35. Stress-elongation diagrams for a) glassy styrene-acrylonitrile copolymer, b) and c) acrylonitrile-butadiene-styrene copolymers with different morphologies, and d) polybutadiene. Electron micrographs: left: blend (b), right: blend (c).

the curves depend on the rate of deformation; as the latter is increased, the slope generally becomes greater and the elongation shorter. The usual impact strength tests correspond to very high rates of deformation. The energy of fracture, which is given by the area under the stress/elongation curve, is a measure of the impact strength. The pure elastomer component has a very low modulus. In contrast, the two-phase ABS polymers have a modulus that is only slightly lower than that of pure styrene-acrylonitrile copolymer and they clearly show the change from reversible elongation to permanent set or yield points.

The mechanical and dynamic properties of multiphase polymers emerge from the use of oscillating loads, the parameters being the shear modulus (a measure of the elastically stored energy of deformation) and the loss modulus (a measure of the dissipated energy). Figure 36 shows the variation of

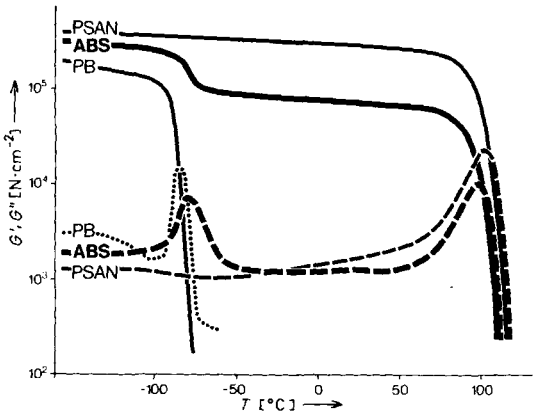

Fig. 36. Thermomechanical measurements on styrene-acrylonitrile copolymer (PSAN), acrylonitrile-butadiene-styrene copolymer (ABS), and polybutadiene (PB). Shear modulus G' (unbroken curve) and loss modulus G'' (dashed curve) as a function of temperature.

both these moduli with the temperature, again in the case of styrene-acrylonitrile copolymer, polybutadiene, and a two-phase ABS polymer. The curves for the first two are typical of the amorphous state: in the region of the glass temperature, the loss modulus G'' reaches a maximum, and the shear modulus G' drops from the value typical of glassy polymers to a value typical of rubber (cf. Fig. 2). Depending on the composition, copolymers with a random arrangement of the

repeating units show a corresponding curve in the region between the glass temperatures of the homopolymers. On the other hand, the curve for the two-phase polymer shows two damping maxima and a stepped fall in the shear modulus at both glass temperatures. The drop occurring at the glass temperature of the elastomer phase depends on the proportion of the latter and is comparatively low up to about 30 wt-%. Good use properties are obtained if the glass temperature of the elastomer phase is well below the temperature of use and the glass temperature of the matrix is well above the temperature of use. The impact strength is linked to the coexistence of a hard phase and an elastomer phase.

Partially crystalline two-phase polymers possess toughness in the sense of a continuous decomposition of the stress in the material without fracture on irreversible deformation. In the lamellar crystallites of these polymers, rearrangements and slip processes occur, which dissipate the energy introduced. Creep also occurs in limited regions in glassy amorphous polymers just before brittle fracture during the deformation process (see Fig. 37). This phenomenon leads either to shear bands (shear yielding) or to crazing. The former are sharply outlined regions of highly ordered chain molecules, with a density unchanged from that of the unoriented material. The chains align in the direction of the load, and the shear bands run at an angle to it, in the direction of the maximum shear stress. Owing to the homogeneous density, shear bands are not visible under the electron micrsocope, but can be observed only by polarization-optical means. The crazed state is characterized by gaps which run normal to the direction in which the load is applied and are filled with fibrils or lamellae, drawn out in the direction of the applied force, with numerous cavities between them. The density is much lower here than in the original material, and there is a volume dilatation, whose quantitative determination enables one to distinguish between shear bands and crazing during deformation[144]. The density fluctuation causes light scattering and is visible to the naked eye as a white fracture.

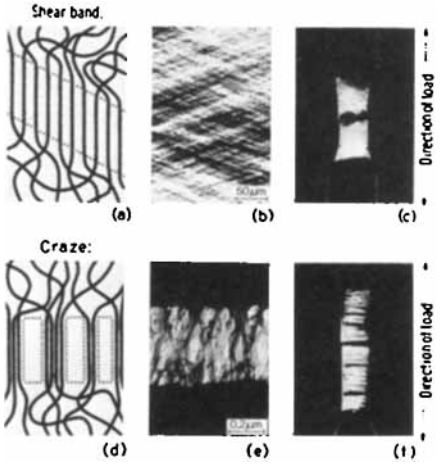

Fig. 37. Shear bands and crazing in glassy amorphous polymers. a) Shear band (schematic), b) under a polarization microscope, c) to the naked eye in polarized light, d) crazing (schematic), e) under an electron microscope [167], f) to the naked eye.

Cold drawing of the polymer chains[*] and the formation of internal surfaces are mechanisms of energy dissipation which decompose the stress and delay the fracture during the application of a load. It is believed that creep is triggered off by inhomogeneities, at which strain peaks cumulate during the application of an external force (for fundamental works see [145–152]). According to generally accepted views, a disperse elastomer phase causes a drastic increase in the initiation of these creep processes by strain peaks in the glassy amorphous matrix at the boundary with the elastomer. Figure 38 shows schematically that a uniaxially applied external force

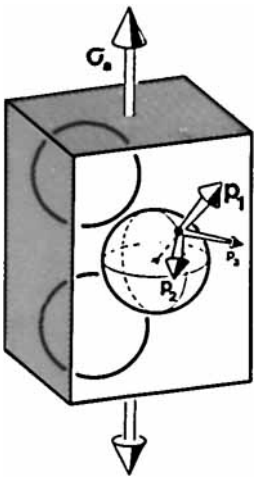

Fig. 38. Resolution of a uniaxial external force σ_a at the elastomer/matrix phase boundary into radial components and tangential components p_1 and p_2 and p_3, respectively.

σ_a produces multiaxial stress states at the boundary with a spherical elastomer phase. Two directions (p_2 and p_3) are tangential and one direction (p_1) is radial to the surface of the sphere. It is decisive for the toughness of the material which of the two types of plastic deformation takes place, which depends on the ratio between the stresses in the various directions; this ratio has different values at different points on the spherical surface. In a simplified model in which the direction of the external force is not taken into account, the total local stress is resolved into a dilatory isotropic component p (hydrostatic tension or hydrostatic pressure) and a shear component s, which causes deformations with a constant volume. The isotropic stress p and the shear stress s are defined by eqs. (21) and (22):

$$p = \frac{1}{3}(p_1 + p_2 + p_3) \tag{21}$$

$$s^2 = \frac{1}{6}[(p_1 - p_2)^2 + (p_2 - p_3)^2 + (p_3 - p_1)^2] \tag{22}$$

Sternstein et al.[153–155] investigated those combinations of the dilatory component and the shear component at which shear-induced creep, crazing, or brittle fracture occurs in the case of a polymethyl methacrylate that was not modified with an elastomer and presumably had a very high molecular weight. Deformation occurs in the form of crazing when the ratio between the dilatory and the shear component of the applied force exceeds 0.2 (at 60 °C). *Matsuo et al.*[156] have applied this result to two-phase systems and calculated the stress distribution in the surroundings of disperse elastomer spheres (for fundamentals, see [157]). With an external force

[*] Shock loads lead to a considerable rise in temperature locally, where the glass temperature is exceeded.

applied in the direction of the poles, the dilatory component of the stress has a maximum positive value at the equator of the sphere, whereas the shear component reaches its maximum at latitudes of 45° (see Fig. 39a). According to *Matsuo*,

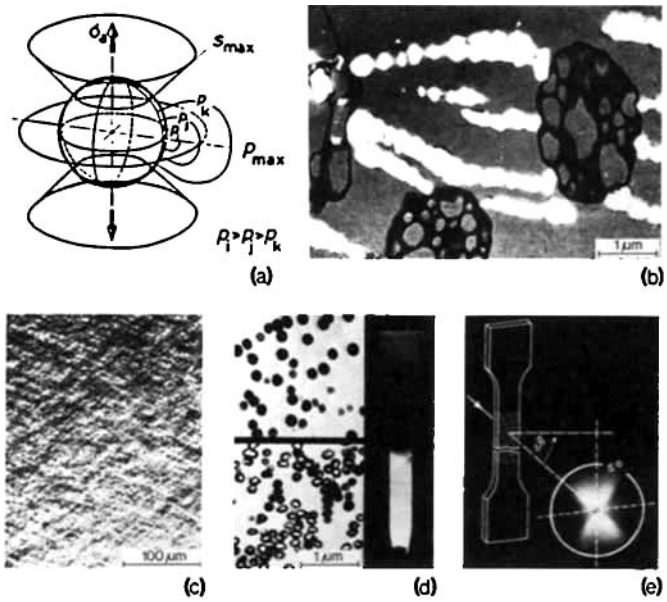

Fig. 39. Deformation mechanisms in rubber-modified thermoplastics. a) Maximum values of the shear component s and the dilatory component p of a uniaxial external force σ_A (schematic); b) crazing in polystyrene with a disperse elastomer phase; c) shear bands in poly(vinyl chloride) with a disperse elastomer phase; d) bursting of the elastomer phase under the influence of an external load; e) light scattering of the burst rubber particles in the small-angle region (ϑ = scattering angle).

the superposition of the force fields between neighboring spheres further increases the dilatory stress component in the equatorial plane. These results are qualitatively supported by the electron micrographs recorded for the deformed rubber-modified material (see Figs. 39b and 39c). Thus the crazing in the equatorial plane is triggered off vertically to the direction of the applied force, and the shear bands run at an angle to it. *Sternstein*'s results cannot be applied quantitatively to the force fields in a rubber modified system, because the experimentally determined craze limits must be assigned exclusively to surface-initiated crazes, and these are not formed at the same stress limits as those found in the bulk of the material[158]. Besides, the side groups of poly(methyl methacrylate) are already mobile at measuring temperatures of over 50 °C.

In Figure 39c, obtained for rubber-modified poly(vinyl chloride), the shear bands can be recognized only indirectly. The corresponding electron micrograph (Fig. 39d) shows cavities in the rubber particles, produced by splitting or bursting under the influence of the applied force. The volume dilatation therefore takes place in the disperse phase and not in the matrix. The light scattered at the cavities leads to a scatter pattern of high orientation, whose preferred directions represent the angle between the shear bands and the direction of the applied force (see Fig. 39e). The burst rubber particles, which act as scattering centers, are concentrated in the shear bands and form a rhomboid network with a lower density than that of the unsheared material[159].

The embedding of disperse rubber particles evidently promotes the creep process, which is also exhibited by the unmodified glassy amorphous matrix. Except for polystyrene, which has a pronounced tendency to crazing, most polymers seem to have a preference for the exclusive or at least the predominant formation of shear bands at high rates of stressing[160, 161]. Thus, practically no crazing can be observed in elastomer-modified poly(methyl methacrylate) whose molecular weight still permits processing *via* the melt; this is in contrast to the numerous published findings, presumably obtained for a high-molecular material.

To obtain a tough material, the disperse elastomer phase must adhere well to the surrounding matrix. The earlier view that the energy of deformation is transferred to the rubber phase *via* an adhesive layer, *e.g.* a graft shell, and is then absorbed there is incorrect, and it is enough to look at the stress-elongation diagram (Fig. 34) to realize that, in the usual elongation, the elastomer phase absorbs only a small proportion of the energy of fracture.

The cooling of a melt with a disperse elastomer phase first leads to the glassy solidification of the continuous phase. On further cooling this phase contracts in accordance with the coefficient of thermal expansion α, which is about 2×10^{-4} K^{-1} for amorphous polymers below the glass temperature. The elastomer phase still has the character of a liquid and contracts about three times as much as specified above. Since the elastomer phase is coupled to the matrix, the result is its unavoidable dilatation and the setting-up of a hydrostatic tension in the rubber[162]. This hypothesis is supported by the observation of the bursting of non-crosslinked polybutadiene inclusions in polystyrene on cooling[163] and on the lowering of the glass temperature of cross-linked polybutadiene graft rubbers below the value of the pure homopolymer[164–166]. This phenomenon is the reverse of the well-known one, where the glass temperature of elastomers rises during isotropic compression (hydrostatic pressure). It is often concluded that the hydrostatic tension of the drawn rubber is transferred to the surrounding matrix as a dilatory stress and promotes *a priori* crazing there. However, as *Breuer* has shown[161], while it is true that the hydrostatic tension in the rubber phase leads to an equal radial counter-stress in the matrix, there are at the same time some "arch stresses" lying tangentially to the boundary surface, as a result of which the sum of all the stresses is zero, and so there is no dilatory stress component in the matrix, according to eq. (21). Since the stress components in the various directions differ in their sign and magnitude, the difference between them gives the matrix a pure shearing stress exerted by the prestressed rubber, in accordance with eq. (22). Independently of this, an external force will then produce a dilatory stress, with a maximum round the equator of the rubber particles.

The author wishes to thank the following persons for their help with the preparation of the present review: Dr. K. Bergmann, Prof. Dr. G. Kanig, and Dr. W. Heckmann (Mess- und Prüflaboratorium der BASF-AG), Dr. J. Stabenow (Ammoniaklaboratorium der BASF-AG), Dr. H. Breuer, Dr. H. Naarmann and Dr. P. Wittmer (Kunststofflaboratorium der BASF-AG), and Prof. Dr. R. G. Kirste (Institut für Physikalische Chemie der Universität Mainz).

Chemical Vapor Deposition of Silicon Carbide and Silicon Nitride—Chemistry's Contribution to Modern Silicon Ceramics

By Erich Fitzer and Dieter Hegen[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Pure silicon carbide and silicon nitride have valuable properties in bulk pore-free form; however, their industrial exploitation has hardly been possible so far. Neither compound can be melted or sintered in pure form; hot pressing or sintering at normal pressure requires the presence of additives; and the reaction-sintering process in which only Si and C or Si and N are employed as additives affords porous materials.—The novel process of chemical vapor deposition has partly overcome the drawbacks of the previous methods. In the new process SiC is produced, *e.g.*, by pyrolysis of CH_3SiCl_3, and Si_3N_4 by reaction of $SiCl_4$ with NH_3. This technique can also be used for pore filling in objects made of SiC and Si_3N_4 (gas phase impregnation) and for producing extremely fine SiC and Si_3N_4 powder and SiC monofilaments suitable as components for SiC composites. Moreover, gas phase impregnation can also give fiber composites.

1. Introduction

The tempestuous advances in the field of physical metallurgy, solid state physics, and fracture mechanics have relegated the chemical basis of materials developments to a background role in modern materials science. It has become apparent, however, that for stringent technical demands greater attention should be focused on chemical aspects in the solution of problems. In the case of the silicon ceramics dealt with in this paper (SiC, Si_3N_4, silicon nitride solid solutions), which are considered for use in the manufacture of components for gas turbines and other topical high-temperature applica-

tions[1], chemical vapor deposition could provide new impetus because these materials cannot be produced by fusion methods (see Fig. 1[2-4]); moreover, standard techniques of powder metallurgy or ceramics lead not only to production problems but also to serious restrictions on quality.

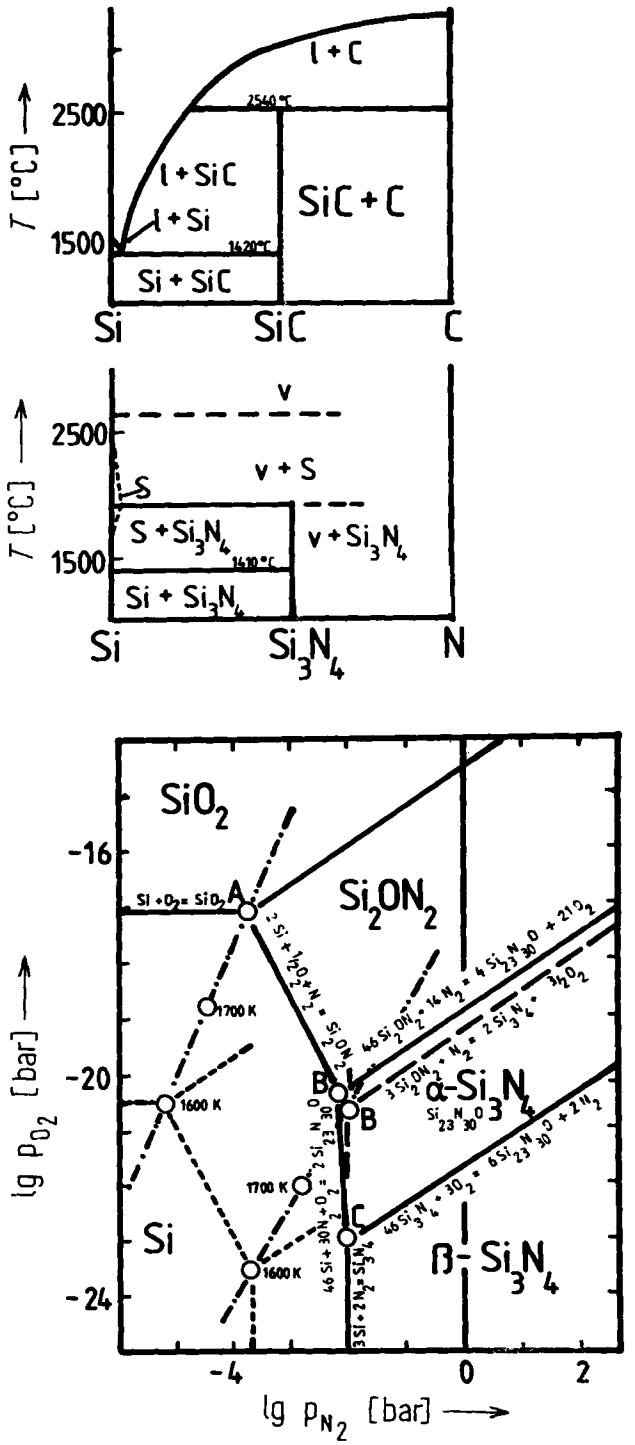

Fig. 1. Phase diagrams of the binary systems silicon/carbon [2] and silicon/nitrogen [3]; equilibrium diagram for the ternary system silicon/oxygen/nitrogen [4]. s = solid, l = liquid, v = vapor. A, B, C = equilibrium points of the phases at 1800 K.

2. Scope and Limitations of Silicon Ceramics

Silicon ceramics do not occur in nature; they are man-made inorganic materials, extending from metallic conductors, *viz.* silicides of transition metals of Group 4 and 5, *via* the stoichiometric covalent compounds SiC and Si_3N_4 having semiconductor properties, to the silicon nitride solid solutions (sialons)[5,6] in which the nitrogen and silicon have been partly substituted by oxygen and aluminum, respectively (see Fig. 1). The structures of the metallic silicides, of which molybdenum disilicide ($MoSi_2$) is the most significant technologically[7], show some resemblance to the interstitial structures of carbides and borides. However, the greater size of the silicon atom leads to lattice widening while still permitting direct Si—Si bonding which will modify the bonding character of the metallic host.

Silicon carbide is strictly stoichiometric and crystallizes, like elemental silicon, in a diamond type structure showing some range of variation of the stacking sequence. The strong covalent Si—C bond leads to a refractory nature, extreme hardness, and a very high theoretical Young's modulus which is indeed realized in industrial SiC monofilaments (up to 450000 MN/m^2). However, dislocation movement is blocked in these compounds, causing high temperature strength but also brittleness. This undesirable brittleness is reduced in silicon nitride and sialons, but at the expense of elasticity and high temperature strength (Table 1).

Table 1. Properties of SiC and Si_3N_4 (α = coefficient of thermal expansion) and strength (σ) of technical products made of these materials. The lower strengths are for reaction-bonded materials and the higher values for hot-pressed materials.

	Bonding strength [kJ/mol]	$\alpha \times 10^{-6}$ [K^{-1}]	$T_{dec.}$ [°C]	σ_{RT} [MN/m^2]	$\sigma_{1200°C}$ [MN/m^2]
SiC	437	5.8	2700	300—800	300—500
Si_3N_4	773	3.5	2200	150—700	150—600

The outstanding property of all of these refractory silicon compounds is their chemical inertness in an oxidizing environ-

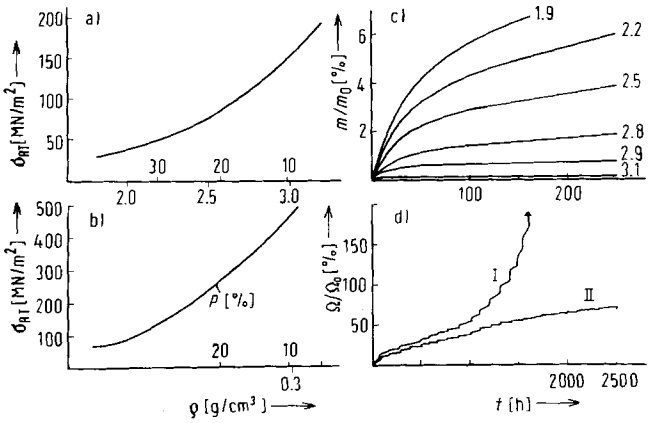

Fig. 2. Flexural strength σ_{RT} of a) reaction-bonded commercial SiC[8] and b) reaction-bonded commercial Si_3N_4 [9] as function of porosity (P) and density (ρ); weight increase (m/m_0) with time on oxidation of SiC at 1500 °C (the numbers next to the curves refer to the density ρ [g/cm^3] [8]); d) change in resistance Ω/Ω_0 of SiC on cycling between 20 °C and 1500 °C (I without glass layer; II with glass layer).

ment which is due to the high affinity of silicon for oxygen. In an aqueous environment, passivity results from reaction between silicon and oxygen. On thermal oxidation, for instance in air, glassy SiO_2 surface layers are formed which strongly suppress further oxidation. Oxidation was found to show a parabolic time dependence (Fig. 2)[8, 9]. Mass transport in such SiO_2 layers is effected solely by non-ionized oxygen, and is additionally hindered by counterdiffusion of volatile by-products of oxidation, such as CO and N_2 respectively.

Comparison of the temperature dependence of the overall oxidation rate of silicon, silicon nitride, silicon carbide, and $MoSi_2$ as well, reveals similar values for the activation energy,

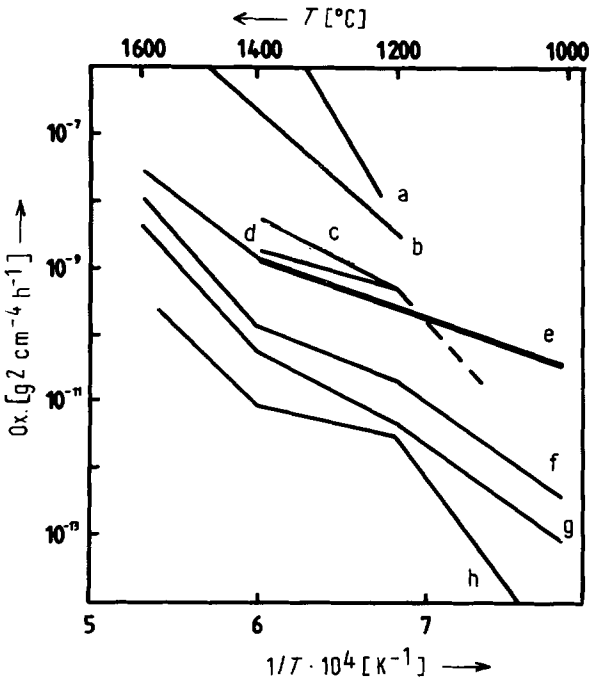

Fig. 3. Temperature dependence of oxidation rate constant (Ox.) of various silicon ceramics [10—12]. a) Si_3N_4 with 30% La_2O_3, air; b) Si_3N_4 with 5% MgO, air; c) sialon with 5—30% Al (air); d) sialon with 50% Al (air); e) $MoSi_2$ (air); f) SiC powder (O_2); g) SiC powder (air); h) Si_3N_4 powder (air).

and shows that the mechanism of the rate-controlling step is always the same (Fig. 3)[4, 5]. The activation energies are also comparable with that of oxygen permeation through SiO_2 glass films.

The blocking efficiency of the SiO_2 surface layers is greatly reduced by small quantities of foreign oxides. For instance, the oxidation rate of $MoSi_2$ is one order of magnitude higher than that of pure silicon carbide, because this compound forms a SiO_2 glass layer with small amounts of MoO_2[11], and does not form counterdiffusing by-products (Fig. 3)[10-12]. Nevertheless, the air oxidation of $MoSi_2$ at 1500°C is one order of magnitude slower than that of 20/80 Cr/Ni alloys at only 1000°C[13]. One can envisage the oxidation resistance of pure silicon carbide as being ten times better at 1400°C than that of today's best "superalloys" at their maximum temperature of application, which is still 1200°C. In such considerations, the superior resistance of silicon ceramics to "hot corrosion" resulting from attack by combustion products has not been taken into account[14].

The problem remains of how to utilize this chemical stability by provision of bulk materials without open porosity. In silicon ceramics having open pores, intercrystalline oxidation will occur, forming SiO_2 glass lamellae between the grains. This causes a deterioration of the material on cooling from the oxidation temperature because of the extremely low thermal expansion coefficient of SiO_2 glass ($\alpha = 0.5 \times 10^{-6}\,K^{-1}$) as compared with that of silicon carbide ($\alpha = 5 \times 10^{-6}\,K^{-1}$). Not only the mechanical properties, mainly impact strength and creep resistance, but also the thermal and electrical conductivity will be considerably impaired. The last mentioned effect is well known to the laboratory chemist from the increase in resistance of commercially available SiC heating elements in intermittently operated high-temperature combustion furnaces.

How can we produce pore-free SiC and Si_3N_4 bulk materials? Pure SiC and Si_3N_4 powders do not sinter in the conventional sense. In contrast, the silicides of the transition metals exhibit similarly high values of surface energy as are known for metals, and such silicides are therefore readily sinterable. Thus wire-wound or tubular $MoSi_2$ heating elements for working temperatures up to 1600°C can be produced by powder

Table 2. Comparison of manufacturing processes for silicon ceramics (RB = reaction bonded, HP = hot pressed, CP = cold pressed).

Process	Reaction sintering SiC	Reaction sintering Si_3N_4	Hot pressing SiC, Si_3N_4, Sialon	Pressureless sintering SiC
Starting materials	SiC powder + pitch binder	Si_3N_4 powder + Si powder	Si ceramic powder + Al_2O_3, MgO, Y_2O_3	Si ceramic powder + B, B_4C, C
Process steps	Molding or extrusion at RT Carbonization at $T = 1000$°C Siliciding at $T = 2000$°C	Molding at RT Nitriding at $T = 1500$°C	Molding at $T > 1500$°C	Molding at RT Sintering at $T = 2000$°C
Product	RB-SiC	Rb-Si_3N_4	HP-SiC, HP-Si_3N_4	CP-SiC
Properties	High porosity Low strength	High porosity Low strength	Low porosity but heterogeneous material High RT strength	Low porosity but heterogeneous material High HT strength
Remarks	Process well controlled Also suitable for complicated shaped sections Inexpensive raw materials	Process controlled Reaction usually incomplete Suitable only for thin-walled sections Inexpensive raw materials	Process difficult to control Suitable only for simple sections Expensive raw materials	Process not yet controlled Suitably only for simple sections Expensive raw materials

metallurgical techniques[15]. In the case of SiC and Si_3N_4 powders, even the finest grain sizes (<0.2 μm diam.) cannot be sintered in the absence of high melting, nonvolatile additives such as B_4C, MgO, Al_2O_3, or Y_2O_3[16-18]. Mechanical pressure is usually also applied during sintering (hot pressing at *ca.* 1600°C), imposing severe restrictions on the shapes and sizes of the products.

The most serious disadvantage introduced by such additives is their influence on oxygen transport within the SiO_2 surface layers (see Fig. 3), and furthermore on the creep behavior of the polygranular bulk material. Intercrystalline oxides will act as plastifiers at high temperatures. The sialons, which partly oxidize to Al_2O_3, exhibit a similar deterioration of their high temperature properties compared with pure silicon carbide and silicon nitride[10].

Silicon ceramics free from additives can be prepared by the reaction bonding (reaction sintering) process. Table 2 compares the process steps with those of other metallurgical processes. Reaction sintering starts with the pure carbide or nitride powder. As in ceramics the material is shaped prior to sintering with the aid of a temporary binder, which consists of one of the components of the silicon material (carbon in the case of SiC and silicon in case of Si_3N_4). This binder is converted into the final silicon compound, which should act as bridge or matrix connecting the primary powdered silicon compounds, at high temperatures (T>1500°C) by chemical reaction (siliciding with molten or vaporized silicon in the case of SiC; nitriding with volatile nitrogen compounds (N_2 or NH_3) in the case of Si_3N_4). This transformation amounts to an impregnation process; the compact must have open pores and a porous final structure is obtained. The pores can subsequently be filled by impregnation with an excess of molten silicon; however, a heterogeneous structure with impaired high temperature properties will result. Furthermore, grain growth is promoted at high temperatures by dissolution-reprecipitation cycles.

The novel process of chemical vapor deposition could at least partly eliminate or compensate the drawbacks of the reaction bonding technique:

1) Subsequent "gas impregnation" treatment densifies porous SiC and Si_3N_4 bulk materials and additionally seals the pore entrances on the surface[19].

2) Direct preparation of finest SiC and Si_3N_4 powder obviates the need for grinding processes for size reduction. Such grinding procedures always lead to surface passivation by oxygen adsorption and thus also inhibit sintering processes.

3) SiC monofilaments exhibiting extremely high Young's modulus and high tensile strength become available for reinforcement purposes.

4) Gas phase impregnation permits fabrication of pore-free, shaped objects, mainly fiber-reinforced composites.

Successful application of chemical vapor deposition requires an accurate knowledge of the kinetics of deposition and of the influence of the various process parameters.

3. Principles of Chemical Vapor Deposition of SiC and Si_3N_4

Chemical vapor deposition (CVD) can be considered as "precipitation" of a solid reaction product from a supersaturated fluid matrix. In contrast to the precipitation processes occurring from solid or liquid solutions, vapor deposition does not occur during cooling but during heating. The thermally activated process steps are mainly pyrolysis reactions having very complicated mechanisms. As in other heterogeneous chemical gas-solids reactions, transport steps can play a very important role during gas phase deposition[20].

With regard to the energy supply, we distinguish between two extreme alternatives: the "hot wall arrangement" in which

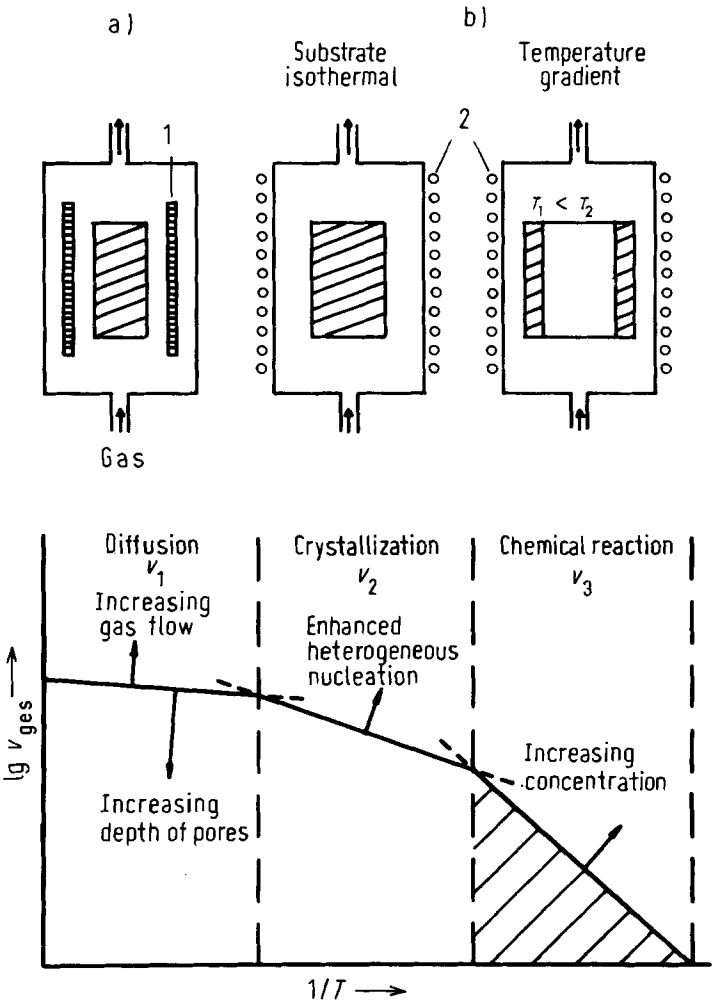

Fig. 4. a) Hot-wall and b) cold wall arrangements for chemical vapor deposition: 1, resistance heating elements; 2, induction coil. c) Rate-determining steps of chemical vapor deposition.

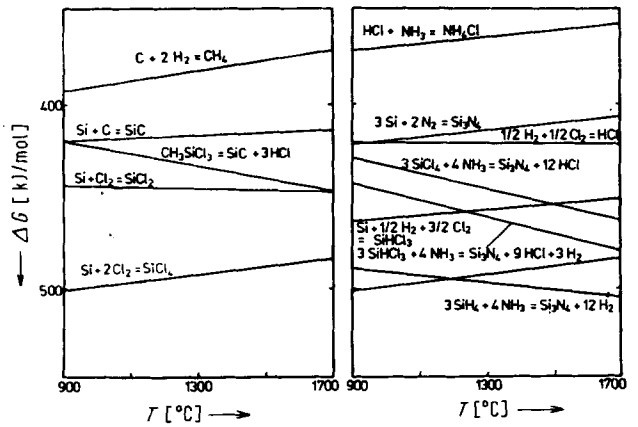
heating of the substrate, where deposition should take place, is performed by radiation from a surrounding heater, and the so-called "cold wall arrangement" with a heat source inside the substrate (Fig. 4a, b).

The mechanism of vapor deposition even on smooth planar surfaces is very complicated. Figure 4 shows a simplified Arrhenius plot from which it is seen that, especially at high temperatures (left-hand side of the diagram), the overall deposition rate will be controlled by mass transport in the outer gaseous surface layer (slowest consecutive step).

These limitations become more critical in case of chemical vapor deposition on inner surfaces because of the long diffusion

paths. Only by means of complicated experimental set-ups (temperature or pressure gradient)[21] is it possible to support diffusion by convective transport (cf. Fig. 4c). In order to achieve good impregnation, the overall deposition rate within the pores must never be controlled by the transport rate but only by the chemical reaction rate. Consequently, deposition must be performed at low temperatures, and low concentrations should be used. Furthermore, gas phase nucleation must be avoided. If finely powdered products are desired, however, high supersaturation is necessary to ensure spontaneous gas phase nucleation and very fast cooling to avoid crystal growth.

The driving force of chemical vapor deposition is the thermodynamic instability of the gaseous compounds used as precursors. Figure 5 shows data on the free energy of formation of some compounds involved in the deposition of SiC and Si_3N_4[22]. Chloro(methyl)silanes are mostly used for SiC deposition because easy control of the Si/C ratio in the feed can thus be achieved. However, cyclic silicon-carbon compounds ("carbosilanes") may be formed as intermediates[23] and deposit as tarry by-products in the cooler areas of the apparatus; on further heating they can initiate gas phase nucleation.



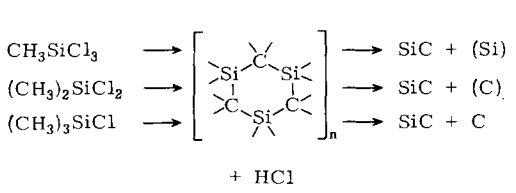


Fig. 5. Gibbs free energy of formation of various compounds arising during vapor phase deposition of SiC and Si_3N_4 [22].

The question whether a stoichiometric deposit or a deposit with an excess of silicon or carbon is obtained depends on the type of precursor. As SiC has practically no solubility for free silicon or carbon (Fig. 1), an excess of silicon or carbon can impart a heterogeneous structure to the deposit (see Fig. 7)[27]. However, the conditions during deposition will also influence the chemical composition of the deposit.

Figure 6[24] shows the yields of SiC and excess carbon deposited on a cold wall on decomposition of chloromethylsilanes. As can be seen, deposition of free carbon does not occur below 1000 °C whereas free silicon is often found even on use of CH_3SiCl_3, *i.e.* the compound with a 1:1 ratio of carbon and silicon[16, 26].

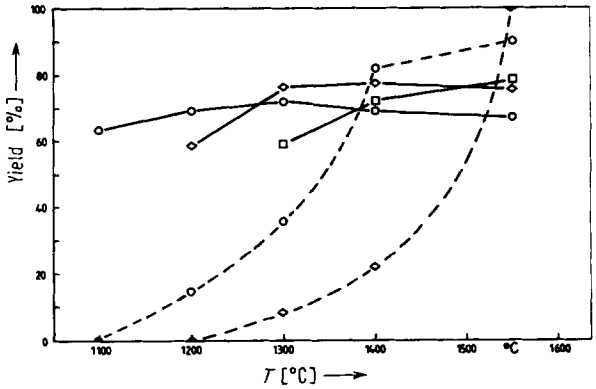

Fig. 6. Yield of SiC (—) and free carbon (---) during pyrolysis of various chloro(methyl)silanes CH_3SiCl_3 (□), $(CH_3)_2SiCl_2$ (◇), and $(CH_3)_3SiCl$ (○) [24].

Fig. 7. Alternating deposition of SiC and carbon caused by oscillating reaction [25]. The layers are about 0.5—1 μm thick.

In general, $SiCl_4$ and NH_3 are used as precursor compounds for the deposition of Si_3N_4 because they are inexpensive and easy to handle. As shown in Figure 5, however, NH_4Cl may be formed from the feed and the by-product HCl if backmixing of the reaction gases in not avoided.

Low deposition temperatures, which are necessary for reaction rate control of the overall kinetics, have the additional advantage of ensuring fine-grained and even amorphous structure of the deposits[20]. Scanning micrographs (Fig. 8) show the influence of deposition temperature on the morphology of chemical vapor-deposited SiC and Si_3N_4 for some typical examples[28].

The key to successful chemical vapor impregnation lies in a thorough comprehension of the deposition kinetics under various conditions. Figure 9a shows overall deposition rates of silicon carbide from trichloro(methyl)silane and of silicon nitride from tri- or tetra-chlorosilane and ammonia[28, 29] as a function of deposition temperature and gas concentration. These data were obtained with a hot wall arrangement. This is also the reason why we have found a maximum in the case of silicon nitride deposition; the fall in the deposition rate with further temperature increase is caused by gas phase nucleation which consumes the precursor before the gas flow

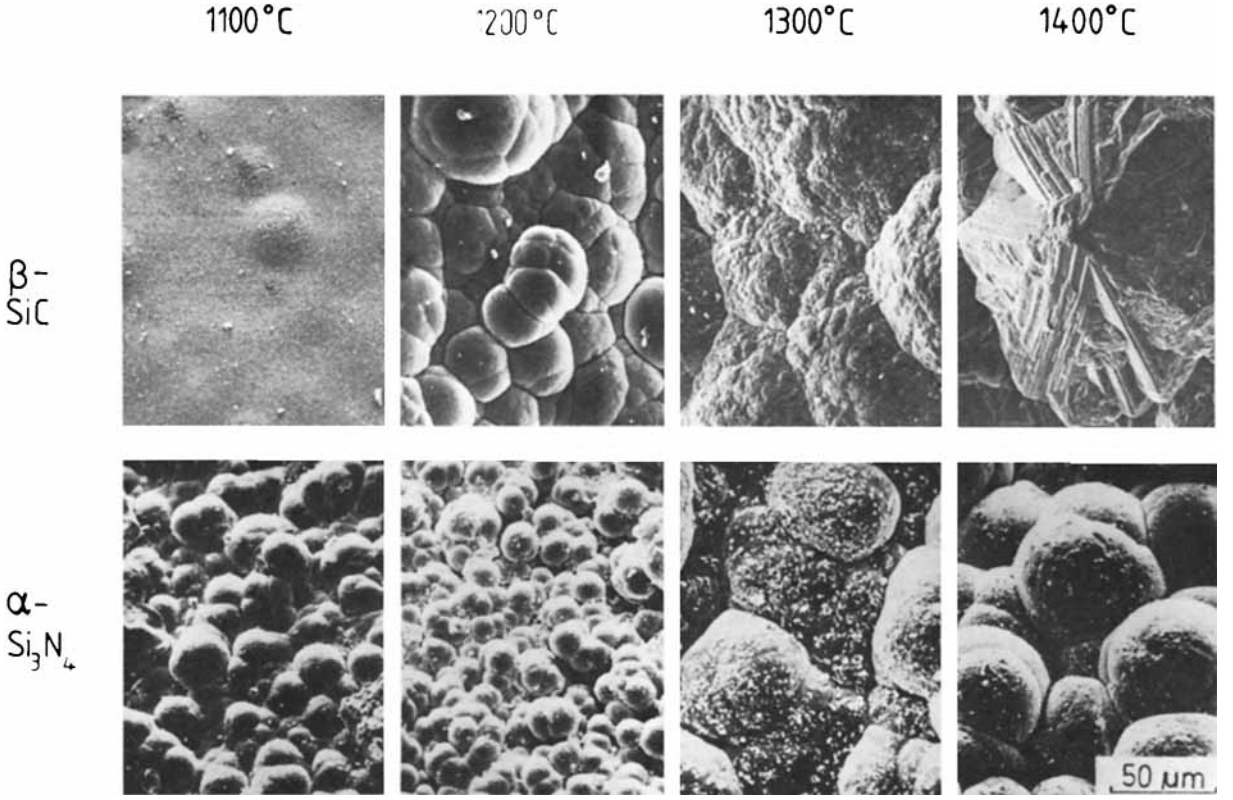

Fig. 8. Morphology of SiC and Si_3N_4 layers (secondary electron image) [28].

185510

reaches the surface of the substrate. The flattening of the rate of growth of SiC layers at high temperatures indicates mass transport control of the overall deposition rate, even on plane surfaces. This transition from reaction control to diffusion control is better recognized in the Arrhenius plot from the break in the curve. For cold wall silicon carbide deposition on plane substrate surfaces, this diffusion control starts at deposition temperatures above 1050 °C. The situation in a fluidized bed, *i.e.* a hot wall arrangement, is also shown for sake of comparison; diffusion control is then observed only above 1250 °C.

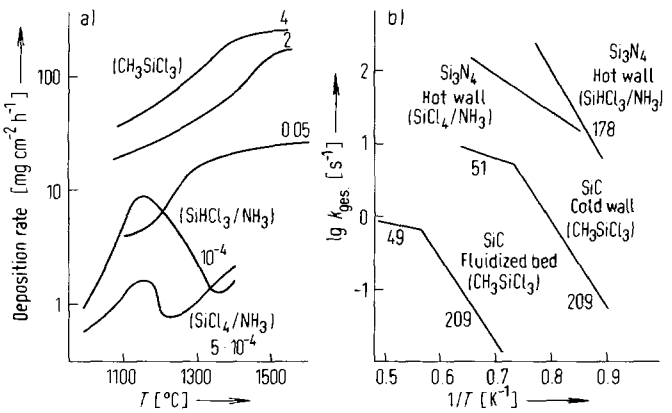

Fig. 9. Growth rates of SiC and Si_3N_4 layers deposited from the gas phase [28, 29]. a) The numbers next to the curves refer to the concentrations of the precursor compounds in the gas phase (in mol/l); b) the numbers next to the curves refer to the activation energies for decomposition (in kJ/mol).

The specific reaction rate for Si_3N_4 deposition is much higher than that for SiC. This is why very low concentrations are necessary in order to avoid gas phase nucleation.

4. Gas-Phase Impregnation of Porous SiC and Si_3N_4 Objects

If information is available about mass transport and reaction rates at various temperatures, the maximum impregnation depth can be predicted. In reaction kinetics, dimensionless numbers like the second Damköhler number Da_{II} and the Thiele number ϕ are used for calculations on diffusion in porous catalysts. Figure 10[30] shows the ratio η of the deposition rate in the pores to the deposition rate on the surface. In the interest of maximum possible impregnation, η should

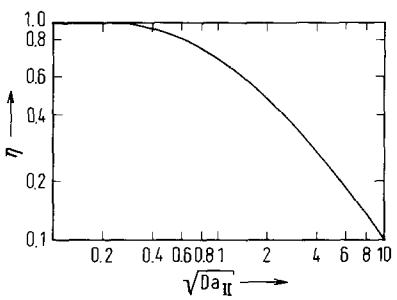

Fig. 10. Ratio η of the rate of deposition in the pores and on the surface as a function of the second Damköhler group Da_{II} [30]. $Da_{II} = k l^2/D$; k = rate constant, D = diffusion coefficient, l = depth of pores to be impregnated.

lie near the maximum value. l stands for the depth of the pores, which are assumed to be cylindrical.

We have precalculated such theoretical impregnation depths using the deposition rate as a measure of the reaction rate in the reaction rate-control regime (Fig. 9). The diffusion coefficients were calculated with data shown in Table 3.

Table 3. Diffusion coefficients in hydrogen of some gaseous species formed on chemical vapor deposition of SiC and Si_3N_4.

Cpd.	D [cm²/s] at T=			
	900 °C	1000 °C	1100 °C	1200 °C
CH_3SiCl_3	0.50	0.51	0.54	0.56
$(CH_3)_2SiCl_2$	0.49	0.50	0.52	0.54
$SiCl_4$	0.63	0.64	0.65	0.67
NH_3	0.95	0.96	0.97	0.98
CH_4	0.93	0.94	0.96	0.97
HCl	1.32	1.33	1.34	1.36

Attempts were made to test the results by model experiments on graphite samples with drilled holes as large model pores (Fig. 11)[28] and with polygranular graphite having a defined pore spectrum[31] (Fig. 12a) as substrate. At 1500 °C closing of the pore entrances is observed, even at very large diameters, owing to preferential surface deposition. In practical work, successful impregnation of substrates with smaller pore entrances requires much lower impregnation temperatures, *i.e.* about 800—900 °C.

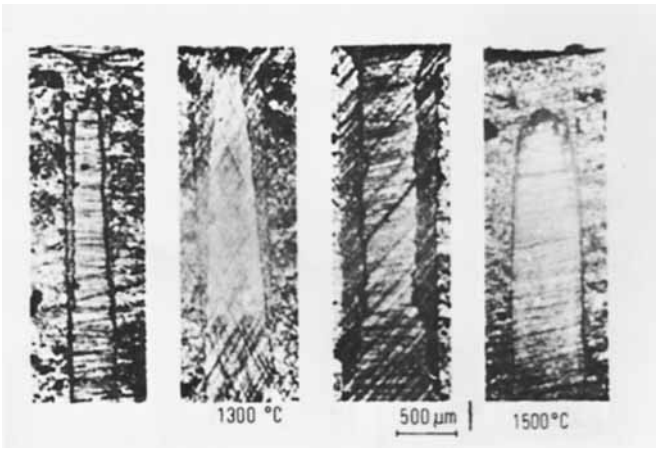

Fig. 11. Deposition of SiC in cylindrical model pores in graphite [28]. From left to right: d=400, 600, 800, 600 µm.

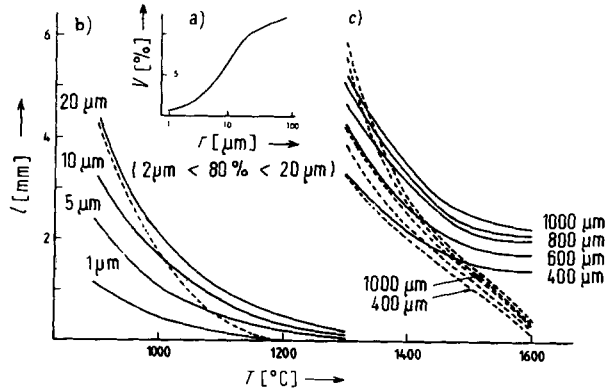

Fig. 12. a) Pore size distribution of porous graphite (V=pore volume, r=pore radius); b) calculated (—) and experimental (---) depth of impregnation l in porous graphite (see Fig. 12a), and c) in model pores. The pore radius is given next to the curves. Impregnation was with CH_3SiCl_3.

These predicted values were compared with experimentally observed impregnation depths in Figures 12b and 12c. The results confirm the applicability of such kinetic data for a precalculation of impregnation depths. The deviation of the experimental curves in the direction of lower impregnation depths is caused by a rapid narrowing of the pore entrances at the higher temperatures. However, there is an ever-present danger of merely converting open porosity into closed porosity by preferred deposition at the pore entrances. Thus, pore filling of originally open porosity can only be achieved in part.

We used five different types of reaction-bonded SiC and Si_3N_4 in our experiments on densification by SiC chemical vapor impregnation (CVI) (Fig. 13)[32,33]. They differed considerably in grain size and pore characteristics.

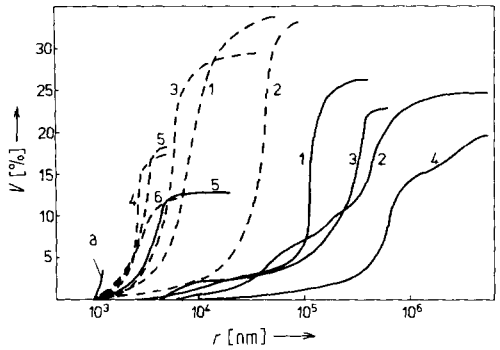

Fig. 13. Pore size distribution of reaction-bonded SiC (—) and Si_3N_4 (---) samples used as substrates [32, 33] (V= pore volume [vol. %], r = pore radius), a = experimental values after impregnation of SiC sample no. 2.

The results of CVI treatment with CH_3SiCl_3 are shown in Figure 14 for SiC sample no. 2. All open pores with radii larger than 1 µm are completely filled after 40 h. The volume fraction of open pores which can be filled by CVI depends strongly on the original pore spectrum. Impregnation yields up to 70 % have been achieved in the most favorable cases. Sample no. 5, the finest-grained sample of the series with only 12 % open porosity, was much more difficult to impregnate.

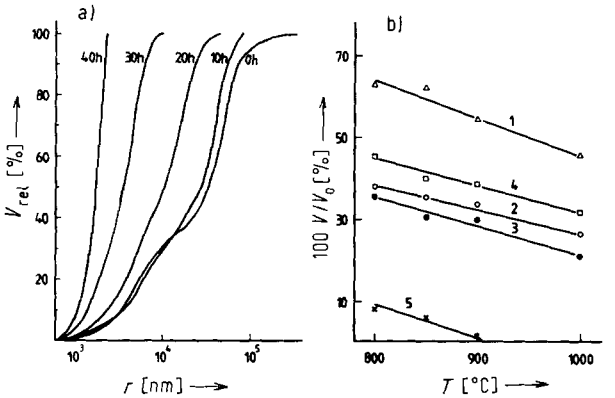

Fig. 14. Results of gas-phase impregnation of SiC with CH_3SiCl_3 at 800 °C. a) Pore size distribution of sample no. 2 (see Fig. 13) after impregnation for various periods; b) maximum degree of pore filling accomplished by impregnation (samples 1—5, see Fig. 13).

Table 4 shows that the strength of all samples, except no. 5, can be increased by densification. However, even in this last case, the surface properties are improved to the same

extent as with the other samples. The resistance to oxidation became the same as that of smooth SiC single crystal surfaces in all cases.

Table 4. Results of gas phase impregnation of five reaction-bonded SiC materials of various porosities. Samples 1—5, see Fig. 13. a is before, b after, impregnation. The values in the columns headed "Si" and "C" refer to wt.-% of free Si and C, respectively.

Sample	Si	C	Bulk density [g/cm³]		Flexural strength [MN/m²]		Oxidation constant [cm/h$^{1/2}$]	
			a	b	a	b	a	b
1	3.0	0.7	2.10	2.45	47	80	4.9×10^{-1}	8×10^{-5}
2	0.5	2.7	2.22	2.47	40	87	4.4×10^{-1}	8×10^{-5}
3	—	0.8	2.47	2.67	90	113	2×10^{-1}	8×10^{-5}
4	—	0.3	2.44	2.64	82	143	3×10^{-1}	8×10^{-5}
5	—	6.5	2.33	2.34	100	100	9×10^{-1}	8×10^{-5}

It was interesting to test how densification affects the high temperature strength. Figure 15 shows the improvement of the short time flexural strength and its variation with increasing testing temperature. It is not influenced up to 1400°C, but drops sharply with further increase of the testing temperature. Most striking is the effect of chemical vapor impregnation of RB-SiC on creep resistance (see Fig. 16).

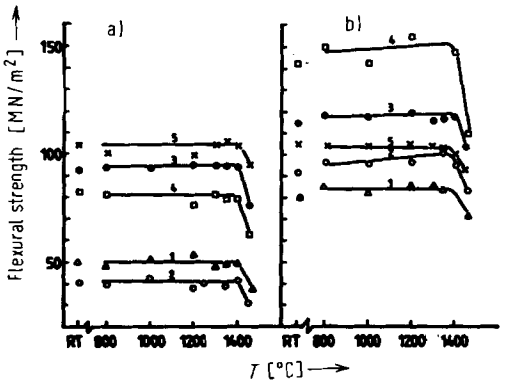

Fig. 15. High temperature flexural strength (short-time HT strength) of reaction-bonded SiC a) before and b) after impregnation with CH_3SiCl_3 (samples 1—5; see Fig. 13).

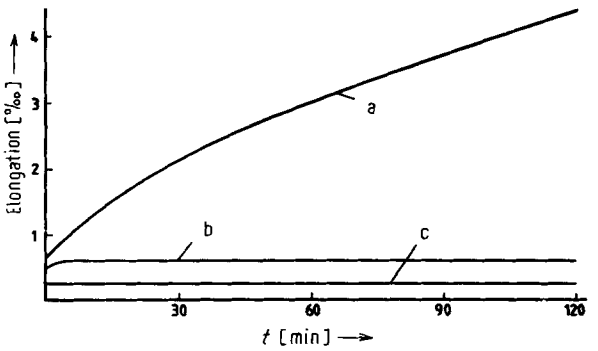

Fig. 16. Creep behavior of reaction-bonded SiC at 1350°C: a, before impregnation (load 30 MN/m²); b and c, after impregnation (load 50 and 30 MN/m², respectively). Sample no. 1, see Fig. 13.

The CVD of Si_3N_4 in general and the densification of porous RB-Si_3N_4 samples by CVI in particular are much more difficult. Not only does the reaction gas consist of two components but the reaction rate is also much higher. As the overall kinetics for CVI must be controlled by the reaction step, practical execution of in-pore deposition becomes very difficult. Furthermore, in the case of silicon nitride there is a high tendency for gas phase nucleation. The conditions for the gas-phase impregnation therefore have to be shifted not only to low temperatures (about 900°C—1000°C), but also to low gas concentrations. However, the latter condition increases the risk of diffusion control.

We selected a cold wall arrangement mainly in order to avoid gas phase reactions. We further used indirect heating with the aim of achieving a thermal gradient (see Fig. 4b)[33]. Finally, both reactive gases were introduced through separate tubes, and the flow of the gases was directed to the surface site from where impregnation should start[28]. In spite of all these preventive measures, we were unable to avoid preferential densification of the surface layers due to the very high deposition rate even at 1000°C. The maximum degree of impregnation was 20% on complete transformation of closed pores into sealed ones[33]. There is no increase in strength on Si_3N_4 gas-phase impregnation but the surface properties are decisively improved[34].

5. Preparation of SiC and Si_3N_4 Powders

Böcker and *Hausner*[35] recently described the preparation of sinter-active SiC powders with grain sizes in the submicron range by pyrolysis of CH_3SiH_3 in argon carrier gas at temperatures between 1000 and 1800°C but did not report the results of sinter experiments.

Previously described processes for the production of SiC powder by reaction of silicon halides[36] or silicon monoxide[37] with hydrocarbons do not give well-defined products. The transformation of amorphous into crystalline SiC by subsequent heat treatment (1800—2000°C) of the product obtained from pyrolysis of methylsilanes or chlorosilanes at 600—1100°C is described by *Enk* and *Nickl*[38].

Apart from the preparation of SiC powder by chemical vapor deposition, the plasma process can be used for the same purpose. *Neuenschwander*[39] described the reaction between $SiCl_4$ and hydrocarbon compounds in a direct current torch. *Kuhn*[40] used reactive anodes consisting of SiO_2 and carbon. *Fyans*[41] reported the reaction of solid SiO_2 with hydrocarbons. Only *Salinger*[42] used chloro(methyl)silanes as reactive compounds for cracking in a high frequency plasma.

The SiC powder used by *Prochazka*[43] in his first sintering experiments without applying mechanical pressure was apparently a powder prepared by the plasma process. The excess of carbon needed in these sintering experiments was probably necessary to reduce the oxides introduced by the plasma process.

Several methods of producing Si_3N_4 powder have already been described. *Mazdiyasni*[44] reported the pyrolysis of $Si(NH)_2$. *Morgan*[45] studied the reaction of $SiCl_4$ with NH_3. Inclusions of HCl were found to be unavoidable. *Prochazka et al.*[46] prepared Si_3N_4 powder from SiH_4 and NH_3 in a tubular reactor at temperatures above 1450°C. *Kijima*[47] introduced hydrogen into the same reaction gas. The resulting powder is finer than 0.1 μm.

Most interesting with respect to the sintering behavior of CVD Si_3N_4 powder is the work of *Thümmler et al.*[48]. The idea was to deposit β-Si_3N_4[28] and to utilize the β→α transformation occurring during sintering heat treatment to initiate and assist the sintering process. It is hoped to achieve products of high density without using high melting additives.

6. SiC Fibers and Fiber-Reinforced Composites

The first experiments on the preparation of SiC monofilaments were performed with W fibers as substrate using a technique already described for B fibers[49, 50, 51]. *Diefendorff*[52] reported tensile strengths up to 3500 MN/m² for fibers deposited from CH_3SiCl_3.

Our own studies were performed with carbon monofilaments as substrates[31, 53, 54]. The strength and flexibility of the monofilaments depend strongly on the deposition temperature. Coarse-grained products must be avoided. The tensile strength varies between 2500 and 3500 MN/m². A Young's modulus of up to 400×10^3 MN/m² can be reached[55, 56].

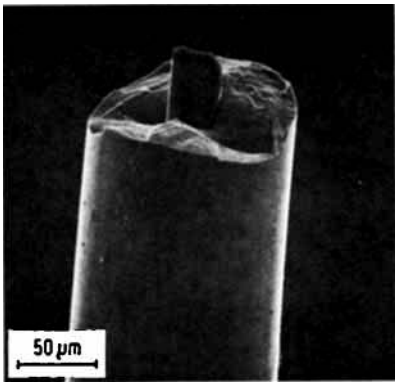

Fig. 17. SiC monofilament with carbon core.

SiC monofilaments with carbon cores (see Fig. 17) have superior high temperature properties to those with W cores because tungsten reacts with silicon carbide above 600°C. Similar results are described by *De Bolt*[57] and *McHenry*[58].

No literature is available on the formation of Si_3N_4 monofilaments. However, preliminary experiments have shown that it should be possible to coat carbon fiber yarn with Si_3N_4 by CVD[28].

Production of monolithic silicon ceramic objects from the gas phase is precluded by frozen-in stresses. However, CVD can be used for preparation of SiC-fiber and C-fiber reinforced composites with a SiC matrix. The steps involved are shown schematically in Figure 18. Such composites have a final closed porosity of 15—20%. The SiC matrix preferentially grows epitactically and thus increases the diameter of the core fiber (Fig. 19, left). Alternatively, a carbon fiber yarn may be impregnated from the gas phase with SiC (Fig. 19, right).

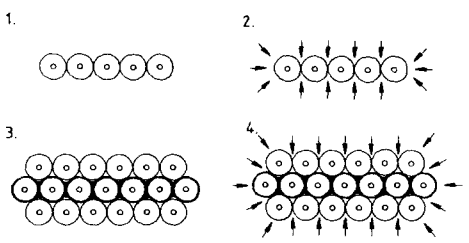

Fig. 18. Stepwise production of unidirectionally reinforced SiC composites (fiber-reinforced composites) by gas-phase impregnation.

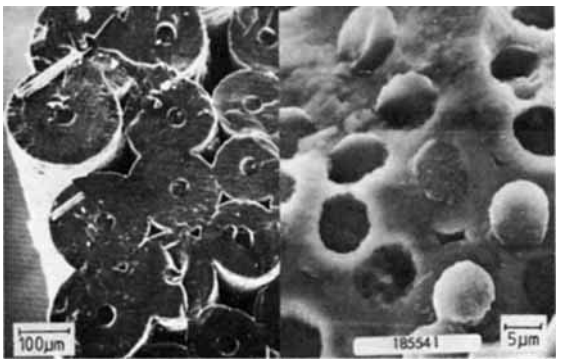

Fig. 19. Fracture of unidirectionally reinforced SiC/SiC (left) and C/SiC composites (right).

As shown in Figure 19, such unidirectionally reinforced composites are stronger than all other SiC materials, with flexural strengths up to 1000 MN/m². However, this strength is limited to the direction parallel to the fibers. Nevertheless, these composites are interesting and show promise for special future applications.

7. Outlook

Chemical vapor deposition promises improvements in the production and quality of silicon ceramics. For instance, comparison of the high temperature strength properties shows that chemical vapor impregnation of reaction-bonded silicon carbide materials (Fig. 20, e) with pure silicon carbide (Fig. 20, d) gives product having strengths formerly only achievable by liquid silicon impregnation (Fig. 20, c) which leads to silicon excess and attendant low creep resistance. In contrast, oxidation and creep resistance of vapor impregnated silicon carbide is enormously improved.

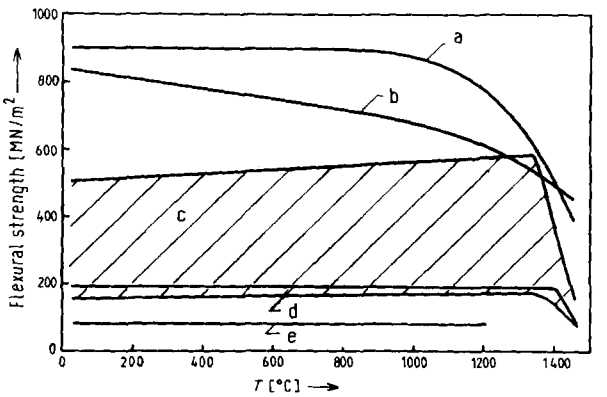

Fig. 20. High-temperature flexural strength of unidirectionally reinforced SiC/SiC and C/SiC composites (a) and gas-phase impregnated reaction-bonded SiC (d) compared with commercially available hot-pressed SiC (b) and reaction-bonded SiC with 5—15% excess of Si (c) and untreated reaction-bonded SiC (e).

Fiber-reinforced SiC composites (Fig. 20, a) exhibit high temperature strength data at 1400°C, superior to those of all today's leading hot pressed materials (Fig. 20, b).

The production of ultrafine powders by chemical vapor deposition could lead to a breakthrough of cold pressing techniques without mechanical pressure for high quality SiC and for Si_3N_4.

COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

A New Entry to Naphthalene Oxides[**]

By *Richard R. Schmidt* and *Rolf Angerbauer*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Arene oxides and dihydroarenediols are of considerable interest as metabolites of aromatic hydrocarbons[1]. The discovery of the pronounced carcinogenic nature of epoxytetrahydroarenediols[2] has prompted several recent syntheses[3].

In our work on the *de novo* synthesis of sugars *via* cycloaddition[4], we have now found a facile and productive method

for the synthesis of 1,4-dihydronaphthalene-*cis*-1,4-diol *(2)*[5], racemic epoxytetrahydronaphthalenediol *(4)*[6], and *syn*-naphthalene 1,2:3,4-dioxide *(5)*[7], which should also be applicable to other systems.

The Diels-Alder reaction of *trans,trans*-1,4-butadienylene diacetate with benzyne (from *o*-benzenediazoniumcarboxylate) gives *(1)* (53%, m.p. 88°C) (see Table 1 for NMR data). Compound *(1)* is readily deacetylated to *(2)*[5] (88%, m.p. 105°C) with Na_2CO_3 in methanol. *cis*-Hydroxylation of *(1)* with hydrogen peroxide and catalytic amounts of osmium tetroxide leads stereospecifically to *(3a)* (60%, m.p. 156°C) which undergoes facile transformation into the racemic monotosylate *(3b)* (75%, m.p. 141°C) with tosyl chloride in dry pyridine. On stirring with Na_2CO_3 in methanol, *(3b)* affords the racemic epoxy-diol *(4)*[6] (90%, viscous oil) almost quantitatively. This product has the stereochemistry characteristic for carcinogens of this type. The dimesylate *(3c)* (82%, m.p. 157°C) also readily accessible from *(3a)* specifically forms the *syn*-dioxide *(5)*[7] (90%, m.p. 170°C) on treatment with Na_2CO_3 in methanol. Unlike the *anti*-dioxide, the *syn* isomer cannot be prepared by direct oxidation of naphthalene[8].

(a), $R^1 = R^2 = H$
(b), R^1 = Tos, $R^2 = H$
(c), $R^1 = R^2 = SO_2CH_3$

Table 1. ^{1}H-NMR data [a] of the compounds *(1)*, *(3a)*, *(3b)*, and *(3c)* [b].

(3a):	5.99 (d; 2H, H-1, H-4), 4.16 (d; 2H, H-2, H-3), 2.10 (s; 6H, OAc), 7.20 (s; 4H, arom.), 3.45 (br. s; 2H, OH), $J_{1,2}=6$
(3b):	6.28 (d; 1H, H-1), 6.05 (d; 1H, H-4), 5.08 (dd; 1H, H-2), 4.32 (m; 1H, H-3), 2.70 (d; 1H, OH), 2.20 (s; 3H, CH_3), 2.12 (s; 3H, OAc), 2.00 (s; 3H, OAc), 7.20–7.90 (m; 8H, arom.), $J_{1,2}=7$, $J_{2,3}=2$, $J_{3,4}=5$, $J_{3,OH}=5$
(3c):	6.28 (d; 2H, H-1, H-4), 5.32 (d; 2H, H-2, H-3), 3.12 (s; 6H, CH_3), 2.17 (s; 6H, OAc), 7.37 (m; 4H, arom.), $J_{1,2}=5$

[a] 80-MHz spectra in $CDCl_3$ with TMS as internal standard; δ values, coupling constants in Hz.
[b] The NMR spectra of *(2)* [5], *(4)* [6], and *(5)* [7] agree with those reported in the literature. All new compounds gave correct elemental analyses.

Procedure

Synthesis of *(1)*: 1,3-Butadienylene diacetate (10 g, 58 mmol) and *o*-benzenediazoniumcarboxylate (10 g, 67 mmol) are heated to 60°C for 2 h with stirring in dry $CHCl_3$ (160 ml). After stripping off the solvent the residue is filtered on a short silica gel column and recrystallized from ethanol; yield 7.7 g (53%), m.p. 88°C.

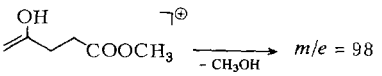
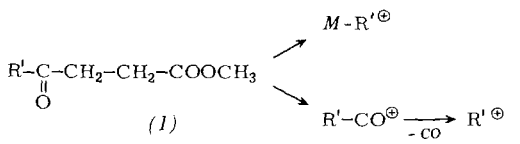
ω-Formyl- and 4-Oxocarboxylic Acids in Blood Plasma



By *Jürgen Pfordt* and *Gerhard Spiteller*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday



During workup of blood plasma with the aim of concentrating any dicarboxylic acids present, a fraction that was obtained after esterification with diazomethane was analyzed by combined glass-capillary chromatography and mass spectrometry. Besides the mono- and dicarboxylic esters already known to occur in plasma this fraction contained a series of homologous compounds whose mass spectra are characterized by key ions of mass 130 and 98. The key ions are formed by McLafferty rearrangement and subsequent elimination of methanol from the methyl 4-oxocarboxylates *(1)*.

(1)

Although molecular ions are absent the molecular weight can still be determined, *i.e.* from the $M-31$ ($M-OCH_3$) fragment. Further typical fragments are formed by rupture of the bonds in the neighborhood of the carbonyl group.

The structures derived from spectra for a 4-oxooctanoic, a 4-oxononanoic, and a 4-oxodecanoic methyl ester were confirmed by synthesis and subsequent comparative measurements of mass spectra and retention indices (Table 1).

Table 1. 4-Oxo- and ω-formylcarboxylic methyl esters.

Name	Retention index [a]	Key ions in mass spectrum
4-Oxooctanoic methyl ester ($M=172$)	1236	29 (47 %), 41 (42 %), 55 (60 %), 57 (100 %), 59 (28 %), 71 (5 %), 85 (67 %), 87 (16 %), 98 (50 %), 111 (9 %), 115 (61 %), 130 (36 %), 141 (23 %)
4-Oxononanoic methyl ester ($M=186$)	1336	41 (32 %), 43 (100 %), 55 (56 %), 59 (26 %), 71 (50 %), 87 (16 %), 98 (73 %), 99 (48 %), 111 (10 %), 115 (58 %), 130 (41 %), 155 (19 %)
4-Oxodecanoic methyl ester ($M=200$)	1436	41 (34 %), 43 (100 %), 55 (46 %), 57 (36 %), 59 (18 %), 71 (10 %), 85 (22 %), 87 (24 %), 98 (59 %), 113 (25 %), 115 (45 %), 130 (34 %), 169 (11 %)
7-Formyl-heptanoic methyl ester ($M=172$)	1288	41 (100 %), 43 (81 %), 55 (76 %), 57 (51 %), 59 (45 %), 69 (72 %), 74 (89 %), 81 (31 %), 87 (88 %), 97 (39 %), 101 (17 %), 111 (16 %), 129 (44 %), 141 (23 %), 144 (10 %)
8-Formyl-*octanoic* methyl ester ($M=186$)	1387	29 (42 %), 41 (74 %), 43 (63 %), 55 (81 %), 59 (37 %), 69 (33 %), 74 (100 %), 83 (43 %), 87 (64 %), 97 (10 %), 111 (21 %), 115 (7 %), 136 (5 %), 143 (29 %), 155 (19 %), 158 (11 %)

[a] Stationary phase OV-101, temperature program 2°C/min, initial temperature 80°C.

Two further compounds in the chromatogram were identified as acid aldehydes (ω-formylcarboxylic acids). Their mass spectra, like those of the long-chain fatty acid methyl esters, are characterized by key ions of mass 74 and 87. The molecular weight can be determined from an $M-31$ ($M-OCH_3$) fragment and an $M-28$ ion. These ions, as well as an $M-43$ fragment, are typical for methyl ω-formylcarboxylates[1, 2]. The structures of both the C_8 and the C_9 acid aldehydes were likewise confirmed by synthesis and comparative measurements (Table 1).

Isolation and workup

Blood plasma (5 ml) was diluted with five times its volume of physiological saline solution, and the resulting solution adjusted to pH = 1 with 6 N hydrochloric acid and extracted with 3 × 25 ml diethyl ether. The organic phase was concentrated to 1 ml and esterified with ethereal diazomethane solution. The dicarboxylic methyl ester fraction, which also contains the ω-formyl- and 4-oxocarboxylic methyl esters, can be isolated by chromatography on a silica gel column with petroleum ether/diethyl ether as eluent[3]. After separation in a coupled glass-capillary gas chromatograph/mass spectrometer, the compounds listed in Table 1 were identified by retention indices and mass spectra.

Diastereoselective Synthesis of β-Methyl Homoallyl Alcohols

By *Reinhard W. Hoffmann* and *Hans-Joachim Zeiss*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

The diastereoselective synthesis of the β-methyl alcohol units of macrolide antibiotics represents a similar challenge[1] to preparative organic chemistry today as did the stereoselective synthesis of carotenoids twenty years ago[2]. Significant achievements have been the *threo*-selective addition of (*E*)-2-butenyl-metal derivatives[3] and the *erythro*-selective addition of (*Z*)-metal enolates[4] to aldehydes. Starting from the effective addition of allylboronates to aldehydes[5, 6] we have found an *erythro*-selective addition of (*Z*)-2-butenylboronates *(3)* to aldehydes.

	R	*erythro*:*threo*
a	CH_3	97:3
b	C_2H_5	97:3
c	$(CH_3)_2CH$	94:6
d	C_6H_5	96:4

Only in the absence of Lewis acids do 2-butenylboronates prove to be *E*/*Z*-stable on heating[6a]. This is presumably the reason why direct reaction of (*Z*)-2-butenylpotassium *(1)*[6b] with chloro(dialkoxy)boranes led to *E*/*Z* mixtures of the 2-butenylboronates. We therefore used the weaker Lewis acid chlorobis(dimethylamino)borane[7] in tetrahydrofuran/hexane (−120 to 0°C) to convert *(1)* into 2-butenylbis(dimethylamino)borane *(2)*, which was shown by ^{13}C-NMR to be more than 95 % *Z*-configurated. *(2)* could be separated from minor amounts of the methylallylborane derivative also formed by distillation (70°C/15 torr) over a Spaltrohr® column. Reaction of *(2)* with pinacol followed by removal of dimethylamine led almost quantitatively to *(3)* (>95% *Z*), which was used immediately for the conversion[5b] of aldehydes *via (4)* into the β-methyl homoallyl alcohols *(5)* in crude yields of up to 92 %. The *erythro*/*threo* ratio[8] of the alcohols *(5)* has been determined by gas chromatography.

The reaction of *E*/*Z* mixtures of 2-butenyl(dimethoxy)borane with acetaldehyde or benzaldehyde gave β-methyl homoallyl alcohols in *erythro*/*threo* ratios[8] corresponding exactly to the *Z*/*E* ratios of the boronates used. It can therefore be concluded that not only the (*Z*)-2-butenylboronate but also the (*E*) isomer reacts diastereospecifically.

Bartlett*, personal communication 1977.

Economic Synthesis of Activated *N-tert*-Butyloxycarbonyl Amino Acid Esters[1]

By *Gerd Schnorrenberg* and *Wolfgang Steglich*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

We have found that 4,6-diphenylthieno[3,4-*d*][1,3]dioxol-2-one 5,5-dioxide *(1)*[2] permits an economic synthesis of activated Boc-amino acid esters *(5a)* if the reagent is used not only for activation of the Boc-amino acid *(3a)*[2] but also for introduction of the Boc group. To this end, activated *tert*-butyl carbonate *(2a)*[1] is heated with the amino acid and one equivalent of 1,1,3,3-tetramethylguanidine[3] in tetrahydrofuran (THF) until the amino acid has dissolved (variant A).

In the case of sparingly soluble amino acids, the components are stirred in dioxane/water at room temperature (variant B). After removal of the base with aqueous citric acid the Boc-amino acid *(3a)*, together with the sulfone *(4)*, is again treated with equimolar amounts of *(1)* and pyridine[5]. The sulfone *(4)* can be readily removed, and the crystalline activated ester *(5a)* (Table 1) is usually obtained analytically pure.

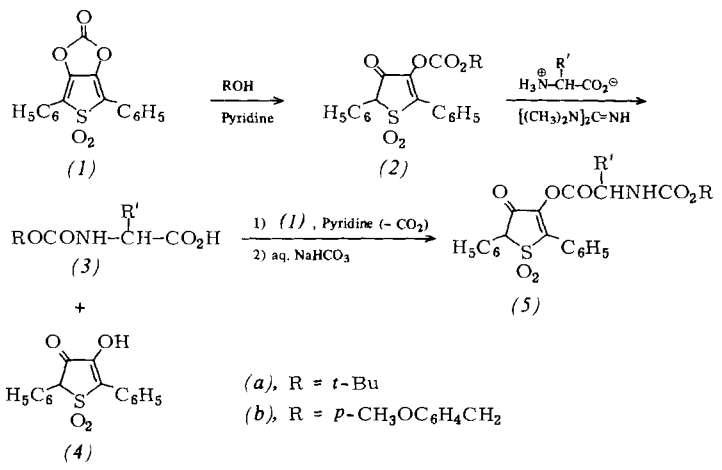

Table 1. Activated Boc- *(5a)* and Z(OMe) amino acid ester *(5b)* [a].

Activated ester *(5)* of	*t* [h] [b]	Variant	Yield [%] [c]	M.p. [°C] [d]
Boc-Ala	24	B	82	95
Boc-Cys(*S*-Bzl)	12	A	90	153
Boc-Gly	48	B	72	138
Boc-Leu	7	A	83	158
Boc-Phe	12	A	84	178
Boc-Pro	3	A	92	166
Boc-Ser(*O*-Bzl)	4	A	87	145
Boc-Trp	12	A	72	147
Boc-Val	18	A	87	160
Z(OMe)-Leu	4	A	85	138
Z(OMe)-Pro	3	A	76	146

[a] All compounds gave correct elemental analyses. [b] For reaction of the amino acids with *(2a)* or *(2b)*. [c] Based on amino acid. [d] Diastereomeric mixtures except for Boc-glycine derivative.

Unlike similar one-pot preparations of activated Boc-amino acid esters[4], our method avoids activation with dicyclohexylcarbodiimide and hence the difficulties of removing dicyclohexylurea. The yields are often higher than for conventional introduction of the Boc group. The activated esters *(5a)* are well suited for peptide syntheses[2].

Preparation of the esters *(5a)* was shown by gas chromatography[5] and polarimetry to proceed without racemization.

Reaction of *(1)* with *p*-methoxybenzyl alcohol gives the activated carbonate *(2b)* (m.p. 226°C after prior sintering with red coloration above 85°C) in 82% yield. Like *(2a)*, *(2b)* can be used for preparing the activated Z(OMe)-amino acid esters *(5b)*. Highly acid-labile alcohols such as triphenylmethanol or α,α-dimethyl-3,5-dimethoxybenzyl alcohol[6] cannot be converted into carbonates of *(2)*.

Procedure

Synthesis of *(2a)*: Compound *(1)*[2] (3.26 g, 10 mmol), dry *tert*-butanol (0.89 g, 12 mmol), and pyridine (0.81 ml, 10 mmol) are stirred together at 20°C for 1.5 h in dry dichloromethane (80 ml). The mixture is then washed twice with saturated $NaHCO_3$ solution, once with 20% citric acid solution, and once with water, dried over $MgSO_4$, and evaporated to dryness *in vacuo*; yield 3.60 g (90%), m.p. 158°C (dec.).

Synthesis of *(5a)*: variant A: Compound *(2a)* (4.00 g, 10 mmol), finely powdered amino acid (10 mmol), and 1,1,3,3-tetramethylguanidine (1.85 ml, 15 mmol) are heated under reflux in dry THF (100 ml) until the amino acid has dissolved. After evaporation *in vacuo*, the residue is taken up in dichloromethane, extracted four times with saturated $NaHCO_3$ solution; the pH of the aqueous extracts is then adjusted to 3 with solid citric acid or cold 1 N HCl before extracting three times with ethyl acetate. After washing with H_2O, drying over $MgSO_4$, and evaporation *in vacuo* the mixture is stirred with *(1)* (3.26 g, 10 mmol) and pyridine (0.81 ml, 10 mmol) in dry CH_2Cl_2 (80 ml) at 20°C for 30 min. The mixture is shaken three times each with 20% citric acid solution and saturated

$NaHCO_3$ solution, washed once more with citric acid solution and water, dried over $MgSO_4$, and evaporated. The esters *(5a)* can be used without further purification for peptide synthesis. For analysis, the product can be crystallized, if necessary, from ethyl acetate/light petroleum.—Variant B: The components are stirred in dioxane/water (2:1) (150 ml) at 20 °C for 1—2 days, the mixture evaporated down and treated as for variant A.

Electrophilic Behavior of Tri-*tert*-butylcyclobutadiene[1]

By *Günther Maier* and *Fritz Köhler*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

The cyclobutadiene *(1)*, which is readily accessible from 2,3,4-tri-*tert*-butylcyclopentadienone *via* the corresponding "housenone"[2], is extremely versatile in its reactions. It behaves both as a diene and as a dienophile[3a], as a nucleophile and as a base[3b], and as a potential diradical[3c]. No evidence of electrophilic properties has yet been reported for *(1)*, but our latest studies now close this gap. This chemical omnipotence of the cyclobutadiene 4π-system confirms its exceptional nature.

Reaction of *(1)* with *tert*-butyllithium in diethyl ether in the presence of *N,N,N',N'*-tetramethylethylenediamine at −78 °C smoothly affords the adduct *(2)*. Aqueous work-up gives a high yield (94 % based on the cyclopentadienone reactant) of 1,2,3,4-tetra-*tert*-butylcyclobutene *(3)*[4]. Treatment with D_2O gives only the monodeuterated derivative D_1-*(3)*. This means that addition does not proceed beyond the monoanion *(2)*; no deprotonation to give the "aromatic" dianion *(6)* occurs. The H/D NMR coupling constant in D_1-*(3)* proves the *trans* configuration[5].

A hydride ion is also added to *(1)*[6]. Both the direct action of lithium aluminum hydride on *(1)* and the circuitous route *via* the halogen adducts *(4a)*[4, 7] or *(4b)* [^{1}H-NMR ($CDCl_3$): $\delta = 1.18$ (9H), 1.20 (9H), 1.36 (9H), 5.13 (1H); ^{13}C-NMR ($CDCl_3$): $\delta = 28.24, 30.04, 31.10, 33.62, 34.31, 40.48, 58.60, 85.53, 149.89, 155.79$] lead to 1,2,3-tri-*tert*-butylcyclobutene *(5)*[4].

Nucleophilicity and basicity of *(1)* parallel the excellent donor properties of unsubstituted cyclobutadiene and its alkyl derivatives[8]. It is therefore all the more surprising that *(1)* should also show pronounced electrophilic character. The reason for this dualism is to be found in the pseudo-Jahn-Teller effect[9a] which gives rise to a low-lying LUMO and a high-energy HOMO, and thus endows *(1)* with the properties of a nucleophile and of an electrophile[9b]. The addition of *tert*-butyllithium—also known in the case of open-chain butadiene[10]—is even able to overcome the kinetic hindrance of three *tert*-butyl groups as a result of the energetic destabilization of the π-system.

Ester and Lactone Formation with the Reagent 1,2-Dihydro-4,6-dimethyl-2-thioxo-3-pyridinecarbonitrile

By *Ulrich Schmidt* and *Dieter Heermann*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Several synthetic routes affording entry to macrolactones have been described in recent years[1-4]. So far, however, no single method has proven universally satisfactory for the synthesis of complex macrolides.

We report here on the formation of esters with the readily accessible reagent 1,2-dihydro-4,6-dimethyl-2-thioxo-3-pyri-

dinecarbonitrile *(1)*[5], whose thiol esters *(3)* react with alcohols much more rapidly than the thiol esters of 2-thiopyridone, thus circumventing any necessary activation with silver ions[3].

The thiol esters *(3)* are formed within a few minutes on reaction of the disulfide *(2)*[6] with carboxylic acids and triphenylphosphane in toluene (concentration: 1 mol/l) at room temperature according to the method of *Mukaiyama*[7]. After addition of alcohol and 20 hours' heating at 100 °C, the esters *(4)* are formed in almost quantitative yields (isopropyl valerate >90 %)[8a].

Ring closure to the macrolactone was investigated in the case of 15-hydroxypentadecanoic acid. The acid was esterified with *(2)* and the thiol ester *(3)* (0.01 M in toluene) heated for 2 h; pentadecanolide[8a] was formed in 60 % yield together with *ca.* 10 % of dimeric lactone[8b]. Under moderate dilution conditions (dropwise addition of *(3)* in boiling toluene over 3 h) the yield of pentadecanolide was increased to 70 %[8a, c], under high dilution conditions (dropwise addition over 48 h) to 80 %[8a]. The yields do not alter if *(3)* is generated and lactonized in dilute solution (slow dropwise addition of *(2)* to a mixture of carboxylic acid and triphenylphosphane in toluene).

Owing to the sparing solubility of the thiopyridone *(1)*, the disulfide *(2)* and the thiol ester *(3)* are appreciably more reactive than the unsubstituted analogues. The thiol esters *(3)* react at rates comparable with the reaction rate of the thiol esters of 4-*tert*-butyl-1-isopropylimidazoline-2-thione[2], but they are less expensive and easier to obtain than the latter.

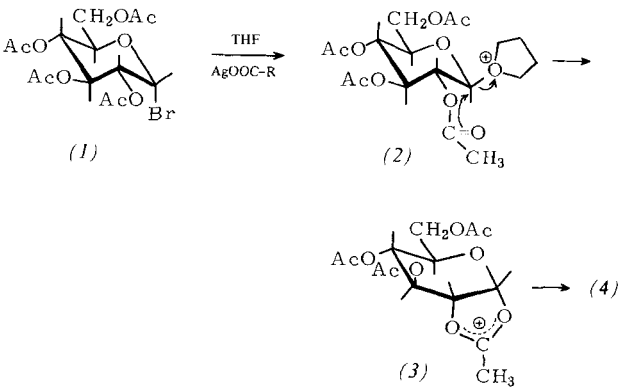
Directed Synthesis of Acyl Ortho Esters

By *Günter Wulff, Ulrich Schröder*, and *Wolfram Schmidt*[*]



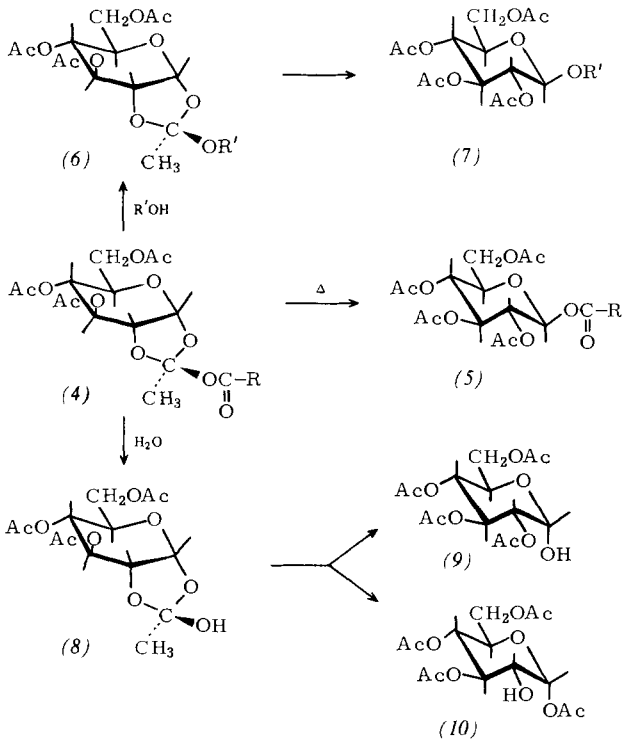
Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

The *trans*-glycosides [*e.g. (7)*] obtained from alcohols and peracetylated 1-halo sugars in the Koenigs-Knorr glycoside synthesis are usually accompanied by many undesired products, the main contaminants generally being 1-hydroxy sugars, *e.g. (9)*[2–4]. The formation of these hydroxy sugars has been attributed to reaction between the water entrained in or produced by condensation with the haloses[3]. However, it is doubtful that this should be solely responsible for their formation, since drying agents fail to suppress the reaction.

In order to investigate the mode of formation of the 1-hydroxy sugars we treated the halose *(1)* with cholesterol (as alcohol component) in the presence of silver propionate as acid acceptor since, unlike Ag_2O, Ag_2CO_3, or silver salts of hydroxy carboxylic acids, no water is formed in its reaction. Nevertheless, reaction in diethyl ether gave some 40 % of the monohydroxy sugars in addition to the expected 1-acyl sugars *(5a)* and the β-glycoside *(7c)* on conventional workup. Hydroxy sugars were also found to accompany *(5a)* in the absence of cholesterol.

It therefore appeared likely that the hydroxy sugars result from a reactive intermediate during workup. Direct ^{1}H-NMR examination of the anhydrous reaction mixture suggested the presence of the acyl ortho ester *(4a)* whose hydrolysis would lead to hydroxy sugars[5]. All attempts to isolate *(4a)* were thwarted by its ready decomposition. We therefore undertook the directed synthesis of this class of compounds.

The very first synthesis of an acyl ortho ester and the study of its properties were of interest for yet another reason. In their work on 1,2-disubstituted cyclohexane derivatives, *Winstein et al.*[6] examined the influence of neighboring acyl groups on the stereochemistry of substitution reactions and ascribed an essential role to intermediate acyl ortho esters; yet they were unable to synthesize or detect them directly[6, 7].



Since acylated haloses *(1)* are transformed almost quantitatively into acetoxonium ions *(3)* *via* the oxonium compound *(2)* in the presence of tetrahydrofuran[4], we treated *(1)* with silver propionate in tetrahydrofuran. This afforded the acyl ortho ester *(4a)* in some 70% yield; it could not be isolated pure owing to its reluctance to crystallize. Acyl ortho esters *(4)* of aromatic carboxylic acids are far more reactive and decompose faster. 4-(4-Biphenylyl)butyric acid proved more suitable; its derivatives crystallize readily. Reaction of its silver salt with *(1)* in tetrahydrofuran gave about 80 % of 3,4,6-tri-*O*-acetyl-1,2-*O*-{1-[4-(4-biphenylyl)butyryloxy]ethylidene}-α-D-glucopyranose *(4b)*[8], of which 67 % could be isolated in pure crystalline form. Crystalline *(4b)* is rather stable; m. p. 85—90 °C (dec.), $[\alpha]_D^{22} = +13.4°$ ($c = 3.5$, CH_2Cl_2). The structure follows unequivocally from its ^{1}H-NMR spectrum. The signals of H-1 ($\delta = 5.83$, $J_{1,2} = 5.6$ Hz), of H-2 ($\delta = 4.46$, $J_{2,3} = 2.8$ Hz; $J_{2,4} = 1.0$ Hz) and the protons of the methyl group attached to the dioxolane ring ($\delta = 1.97$) are expectedly shifted relative to the corresponding signals of other 1,2-ortho acetyl derivatives of glucose. However, the

[*] Prof. Dr. G. Wulff, Dipl.-Chem. U. Schröder, Dr. W. Schmidt
Institut für Organische Chemie und Biochemie der Universität
Gerhard-Domagk-Strasse 1, D-5300 Bonn 1 (Germany)

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0404-0309 S 02.50/0*

chemical shifts and the coupling constants of the other signals are nearly identical to those of alkyl ortho esters [*e.g. (6)*]. We found no signals corresponding to the *endo* form of *(4b)* in the ^{1}H-NMR spectrum.

(a), R = C_2H_5; *(b)*, R = $(CH_2)_3$- 

(c), R' = 3-Cholesteryl

The structure of *(4b)* also follows from its reactions. On heating to above its melting point or even on heating to over 60 °C in solution in the presence of 2,6-lutidine, *trans* cleavage of the dioxolane ring occurs, giving the *trans*-1,2-diacyl derivative *(5b)* almost quantitatively. The second conceivable *trans*-cleavage product of the mannose series could not be detected.

The reaction of *(4b)* with D_2O in [D_6]acetone in the presence of 2,6-lutidine was monitored by ^{1}H-NMR spectroscopy. It proceeds rather slowly (*ca.* 75 min until the signals of *(4b)* disappear) and affords (again followed by ^{1}H-NMR spectroscopy after trifluoroacetylation) about 60 % of the 1-hydroxy sugar *(9)* and 40 % of the 2-hydroxy sugar *(10)* *via* exclusive *cis* cleavage of the dioxolane ring. Thus both possible ring opening products are formed. The acidic ortho ester *(8)* has not yet been detected.

Reaction of *(4b)* with alcohols at room temperature for several hours gives the ortho ester *(6)*. Small amounts of trityl bromide considerably accelerate the reaction; the ortho esters of complex alcohols such as cholesterol are thus formed in goods yields. The trityl bromide probably transforms *(4b)* into the far more reactive acetoxonium ion *(3)*.

The acyl ortho ester *(4b)* also appeared suitable for 1,2-*trans*-glucoside synthesis by analogy with the use of 1,2-ortho esters according to *Kochetkov*[2]. Preliminary experiments using various kinds of Lewis acids gave modest yields of the 1,2-*trans*-glucoside *(7c)* from cholesterol and *(4b)*; the reaction proceeds preferentially *via* the ortho ester *(6c)*.

The mode of reaction of the acyl ortho ester is essentially in accord with the proposals of *Winstein et al.*[6].

It is seen that, in glycoside syntheses in the presence of silver salts, numerous side products, and especially an appreciable amount of hydroxy sugars, are formed *via* acyl ortho esters *(4)*. Similar intermediates must also be expected in the presence of other metal salts, as demonstrated by the occurrence of 3,4,6-tri-*O*-acetyl-1,2-*O*-(1-cyanoethylidene)-α-D-glucopyranose in the presence of $Hg(CN)_2$[9].

Procedure

Compound *(1)* (15 g, 36.5 mmol) was stirred with silver 4-(4-biphenylyl)butyrate in anhydrous tetrahydrofuran (under N_2) at room temperature for 7.5 h. After removal of silver salt on a reverse frit, the solution was evaporated to dryness *in vacuo* at room temperature and anhydrous diethyl ether (200 ml) was added. After a short time *(4b)* crystallized, and was collected on a reverse frit and dried at room temperature and 10^{-2} torr. Yield 13.9 g (67 %) of *(4b)*, shown to be homogeneous by analysis and spectroscopy.

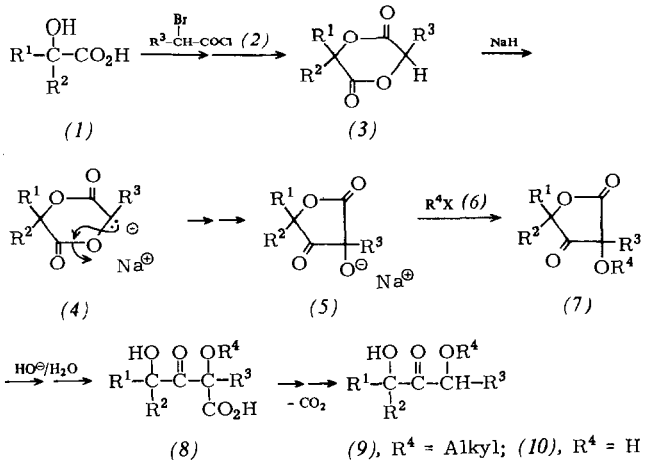
Lactide Contraction—A Method for the Synthesis of α,α'-Dihydroxy Ketones from α-Hydroxy Carboxylic Acids

By *Ulrich Schöllkopf, Wolfgang Hartwig, Uwe Sprotte*, and *Werner Jung*[*]



Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

α,α'-Dihydroxy ketones *(10)* and their derivatives *(9)* are of interest as versatile synthons and on account of their established or possible biological activity[1]. We now wish to report a method of synthesizing them from α-hydroxy carboxylic acids *(1)*. Compounds *(1)* react with a 2-bromoalkanoyl chloride *(2)* to give the lactides *(3)*, which afford the α-alkoxytetronic acids *(7)* on treatment with sodium hydride in the presence of an alkyl halide *(6)*. The sodium compounds *(4)* are intermediates; they form the sodium alkoxides *(5)* by lactide contraction. Since tetronic acids also exhibit biological activity[2], the α-alkoxytetronic acids *(7)* also warrant attention. Their basic hydrolysis, coupled with decarboxylation of the β-oxo acids *(8)*, yields the α-alkoxy-α'-hydroxy ketones *(9)*. Compounds *(9)*, $R^4 = C_2H_5OCH_2$ or CH_3OCH_2,

[a] The crude product is a mixture of diastereomers; m.p. may be that of only one diastereomer.

Procedure

Lactides *(3)*: A stirred equimolar mixture of (vacuum-dried) *(1)* and *(2)* is heated to 80 °C for 0.5—2 h (until evolution of HCl has ceased). The melt is allowed to cool and then dissolved in (P_4O_{10}-dried) acetone [150 ml for 0.2 mol of *(1)*], triethylamine (2 equiv.) is added portionwise, and the mixture stirred at 50—60 °C for 1 h. The solvent is removed in a rotary evaporator (4—6 torr), the residue extracted with aqueous $NaHCO_3$ and ether (or dichloromethane), the phases separated, and the aqueous phase extracted several times with ether (or dichloromethane). After drying over $MgSO_4$, work-up is as usual. The crude lactides *(3)* are purified by distillation or crystallization (from ether/light petroleum).—IR: $\tilde{\nu}$ = 1720—1740 cm^{-1} (C=O).

α-Alkoxytetronic acids *(7)*: A solution of *(3)* (20 mmol) and *(6)* (20 mmol) in dimethylformamide (DMF) (40 ml) is added dropwise over 5—10 min to a suspension of NaH (0.52 g, *ca.* 20 mmol) in DMF (40 ml, dried over 4-Å molecular sieve) and stirring is continued for 2—5 h. After removal of solvent at 4—6 torr (bath temp. 80—100 °C), the residue is dissolved in a small volume of ether and filtered over silica gel (20 g; ether as eluant). The tetronic acids *(7)* are purified by bulb-to-bulb distillation (b.p. ≈110 °C/0.05 torr).—IR (film): $\tilde{\nu}$ = 1740—1755 (C=O), 1770—1790 cm^{-1} (O—C=O).

α-Alkoxy-α'-hydroxy ketones *(9)*: Compound *(7)* (3 mmol) and a solution of Na_2CO_3 (NaOH or KOH with alkali-

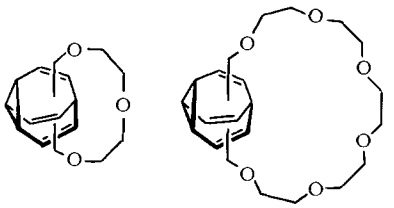
Crown Ethers with Fluctuating Ring Size ("Breathing Crown Ethers")[**]

By *Gerhard Schröder* and *Walter Witt*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday



The ring size of a cyclic system is generally determined by the number of ring members. We present here the first two examples of a class of compounds in which a supply of energy (E_a < 20 kcal/mol) suffices to vary the ring size reversibly. The bullvalene principle conceived by *Doering*[1] led us to the idea of fluctuating or "breathing" rings and inspired us to synthesize the bullvaleno[11—13]crown-3 *(1)* and bullvaleno[20—22]crown-6 *(2)*[2]. *(1)* and *(2)* are disubstituted

bullvalenes with two equal substituents. For such bullvalenes one can formulate twelve positional isomers, *i.e.* four each of the 1,2-, 1,3-, and 1,4-isomers[2, 3]. The ring size in the macrocyclic moiety of the "breathing" crown ethers *(1)* and *(2)* varies between the limiting values 11 and 13 and 20 and 22, respectively.

(1)

(3), R = Br
(4), R = CN
(5), R = CHO
(6), R = CH_2OH

The syntheses of *(1)* and *(2)* follow the conventional routes used for the preparation of crown ethers[4]. The key compound is bullvalenedimethanol *(6)*. Reaction of dibromobullvalene *(3)*[5] with sodium dicyanocuprate[6] in dimethylformamide in the molar ratio 1:2.4, followed by extraction with ether and chromatography on silica gel (ether/pentane 3:2) afforded the dinitrile *(4)*. Reduction of *(4)* with 2.2 equivalents of diisobutylaluminum hydride in toluene at 40°C led to formation of *(5)* in almost quantitative yield. Reduction of *(5)* with a suspension of 0.56 equivalents of $LiAlH_4$ in ether at −40°C, hydrolysis at −25°C and chromatography on silica gel (ether) generated bullvalenedimethanol *(6)*.

(6) is allowed to react with 1.0 equivalent of diethylene glycol ditosylate and 2.2 equivalents of NaH in dimethyl sulfoxide (DMSO) (4 days at 40°C). Extraction with dichloromethane and chromatography on silica gel (ethyl acetate) led to *(1)*. The crown ether *(2)* was obtained analogously by reaction of *(6)* with pentaethylene glycol ditosylate.

Table 1. Physical data of compounds *(1)*, *(2)*, *(4)*, *(5)*, and *(6)*.

(1): colorless crystals, m.p. 84°C (from ether/pentane); yield 9%; ^{1}H-NMR (160°C, [D$_6$]-DMSO): δ=4.18 (br. s, 8H, bullvalene-H), 3.91 (s, 4H, methylene-H), 3.60 (m, 8H, ethylene-H); ^{1}H-NMR (−40°C, CD_2Cl_2): δ=5.85 (narrow m, 4.3H, olef. H), 4.35—2.92 (m of many narrow bands of differing intensity, 12H, methylene- and ethylene-H), 2.78 (m, 0.9H, aliph. bullvalene-H), 2.19 (m, 2.8H, aliph. bullvalene-H); IR (KBr): 3030, 2940—2840, 1650 cm^{-1}; UV (methanol): λ=230 nm (ε=3800)

(2): colorless, highly viscous oil, b.p. 110°C/10^{-3} torr; yield 20%; ^{1}H-NMR (120°C, [D$_6$]-DMSO): δ=4.18 (br. s, 8H, bullvalene-H), 3.83 (s, 4H, methylene-H), 3.58 (s, 20H, ethylene-H); ^{1}H-NMR (−40°C, CD_2Cl_2): δ=5.85 (m, 4.5H, olef. H), 4.40—3.80 (m, 4H, methylene-H), 3.58 (m, 20H, ethylene-H), 2.65 (m, 0.8H, aliph. bullvalene-H), 2.20 (m, 2.7H, aliph. bullvalene-H); IR (film): 3020, 2860, 1630 cm^{-1}; UV (methanol): λ=230 nm (ε=3500)

(4): colorless needles, m.p. 134°C (from ether); yield 45%; ^{1}H-NMR (120°C, [D$_6$]-DMSO): δ=4.68 (br. s); ^{1}H-NMR (−30°C, CD_2Cl_2): δ=7.20—6.65 (m, 2H, olef. H), 6.35—5.70 (m, 2H, olef. H), 3.05—2.40 (m, 4H, aliph. H); IR (KBr): 2200, 1615 cm^{-1}; UV (methanol): λ_{max}=245 (ε=6300), 255 sh nm (5600)

(5): colorless crystals, m.p. 119°C (from toluene); ^{1}H-NMR (120°C, [D$_6$]-DMSO): δ=9.13 (s, 2H, aldehyde-H), 4.80 (br. s, 8H, bullvalene-H); ^{1}H-NMR (−30°C, CD_2Cl_2): δ=9.30 (s, 0.3H, aldehyde-H), 9.10 (s, 1.7H, aldehyde-H), 7.02—6.68 (m, 2H, olef. H), 6.15—5.55 (m, 2H, olef. H), 4.16 (split d, J=8 Hz, 0.6H, aliph. H), 3.50 (m, 0.6H, aliph. H), 2.95—2.50 (m, 2.8H, aliph. H); IR (KBr): 3010, 1670, 1625 cm^{-1}

(6): colorless oil, b.p. 100°C/10^{-3} torr; yield 92% based on *(4)*: ^{1}H-NMR (120°C, [D$_6$]-DMSO): δ=4.25 (s, 10H, bullvalene-H and OH), 3.78 (s, 4H, methylene-H); ^{1}H-NMR (−40°C, CD_2Cl_2): δ=5.83 (m, 4.5H, olef. H), 4.82 (br. s, 2H, OH), 4.25—3.56 (5 overlapping pseudo-s of differing intensity, 4H, methylene-H), 2.65—1.90 (m, 3.5H, aliph. bullvalene-H); IR (film): 3300, 3010, 2900, 2850, 1630 cm^{-1}; UV (methanol): λ=230 nm (ε=3200).

Like precursors *(3)* to *(6)*, the crown ethers *(1)* and *(2)* show temperature-dependent ^{1}H-NMR spectra (Table 1). Particularly strongly dependent upon temperature are the resonance signals of the bullvalene protons and, in the case of *(1)*, *(2)*, and *(6)*, also those of the protons of the methylene groups attached to the bullvalene system. In contrast to all other substituents the CH_2OH-, CH_2OCH_3-, and CH_2OAc-groups display no pronounced preference for definite positions at the bullvalene skeleton[7]. This finding, together with the ring size (which, according to model considerations, is sufficiently large for the macrocyclic moiety in *(1)* and *(2)*), and the temperature-dependence of the ^{1}H-NMR spectra are convincing enough reasons for us to describe *(1)* and *(2)* as "breathing" crown ethers[8].

A study of the temperature-dependent ^{1}H-NMR spectra of *(1)* and *(2)* in the presence of alkali-metal ions would be interesting. We presume that *(2)*, in particular, is capable of adapting itself to cations of various sizes.

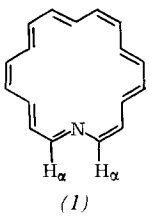
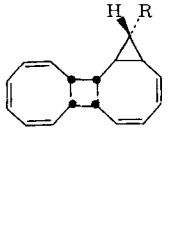
[7] *G. Schröder, H. Focke, J. F. M. Oth*, Tetrahedron Lett. *1975*, 2403. Our argument is as follows: the inductive effect of these three groups is virtually zero and therefore similar to the case of hydrogen.
[8] In this connection, the relatively rapid mixing process of the proton resonance signals of the bullvalenedicarboxylic anhydride should be mentioned. Because of the size of the anhydride ring the exchange process can only involve 1,2- and no 1,3- or 1,4-positional isomers; *E. Vogel, W. Grimme, W. Meckel, H. J. Riebel, J. F. M. Oth*, Angew. Chem. *78*, 599 (1966); Angew. Chem. Int. Ed. Engl. *5*, 590 (1966).



Aza[18]annulenes[**]

By *Walter Gilb* and *Gerhard Schröder*[*]



Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Higher membered *monocyclic* vinylogs of pyridine with $(4n+2)$ π-electrons were hitherto unknown. It may, however, be expected—as previously assumed[1]—that the range of validity of the Hückel rule in these compounds and in the carbocyclic annulenes is very similar.

Vogel et al.[2] and *Muchowski et al.*[3] recently described bridged aza[10]annulenes. We now report on the synthesis and properties of the aza[18]annulene *(1)*. The key step is the photolysis of the tetracyclic azide *(8)*.

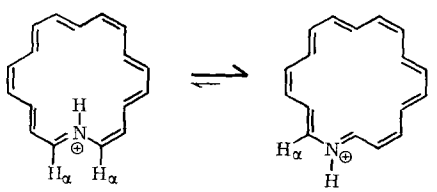
Reaction of the 2:2 dimer of cyclooctatetraene with diazoacetic ester in the presence of copper powder furnishes four isomeric monoadducts, of which *(2)* is the major product[4]. The carboxylic acid *(3)*[4] is allowed to react firstly with triethylamine and ethyl chloroformate and then with aqueous sodium azide solution to give the acid azide *(4)* (95%). Its transformation into the azide *(8)* proceeds analogously to the synthesis of cyclopropyl azide from cyclopropanecarbonyl azide[5]. Heating of *(4)* in benzene for 2h leads to the isocyanate *(5)* (96%), which is converted *via* the urea derivative *(6)* (94%, ether solution and NH_3) into the *N*-nitrosourea *(7)* (not isolated; with N_2O_4 in ether). Reaction of *(7)* with lithium azide in methanol, followed by column chromatography (SiO_2, pentane/ether = 19:1) affords *(8)* as a colorless oil [25% based on *(6)*].

Irradiation of *(8)* at −80°C in pentane (5×10^{-4} M) with a mercury low-pressure lamp yields, after concentration of the pentane phase and column chromatography (SiO_2, pentane/ether = 19:1) of the liquid residue, dark-green crystalline aza[18]annulene *(1)* (28%) (see Table 1).

Table 1. Physical data of the compounds *(1)*, *(4)*, *(5)*, *(6)*, *(8)*, *(9)*⇌*(10)*.

(1): black-green needles, m. p. ≥200°C (dec., from pentane); ^{1}H-NMR (28°C, $CDCl_3$): $\delta = -1.84$ (m, 5 H_i), 8.86 (m, 10 H_o), 10.05 (d, $J = 5.2$ Hz, 2 H_o = 2 H_α); UV (dioxane): $\lambda_{max} \approx 276$ ($\varepsilon = 7400$), 329 (sh, 20200), 349 (sh, 43000), 374 (140000), 410 (sh, 11400), 467 (11400), 611 (720), 682 nm (580); IR ($CHCl_3$): 3005, 1310, 950 cm^{-1}

(4): m. p. 74°C (dec.); ^{1}H-NMR ($CDCl_3$): $\delta = 1.25$ (m, 1H), 2.20 (m, 3H), 3.40 (m, 3H), 5.20—6.30 (m, 10H); UV (dioxane): $\lambda = 227$ nm (sh, $\varepsilon = 1600$); IR ($CHCl_3$): 2140, 1690 cm^{-1}



(5): yellowish oil, ^{1}H-NMR ($CDCl_3$): $\delta = 1.73$ (m, 2H), 2.28 (m, 1H), 3.38 (m, 4H), 5.12—6.16 (m, 10H); UV (dioxane): $\lambda = 260$ nm (sh, $\varepsilon = 3250$); IR (CCl_4): 2255 cm^{-1}

(6): m. p. 213°C (dec., from dioxane); ^{1}H-NMR ($CDCl_3$): $\delta = 1.78$ (m, 2H), 2.25 (d of a t, $J = 4.2$ and 1.0 Hz, 1H), 3.46 (m, 4H), 4.62 (br. s, 2H, NH_2), 4.77 (br. s, 1H, NH), 5.45—6.05 (m, 10H); UV (dioxane): $\lambda = 249$ nm (sh, $\varepsilon = 2100$); IR (KBr): 3480, 3180, 1674 cm^{-1}

(8): colorless oil, ^{1}H-NMR ($CDCl_3$): $\delta = 1.69$ (m, 2H), 2.56 (m, 2H), 3.42 (m, 3H), 5.13—6.40 (m, 10H); UV (methanol): $\lambda = 251$ nm (sh, $\varepsilon = 4000$); IR ($CHCl_3$): 2090 cm^{-1}

(9)⇌*(10)*: violet-black crystals, m.p. ≥180°C (dec.); ^{1}H-NMR ([D]$_7$-dimethylformamide, −50°C): $\delta = -4.24$ (m, 5 H_i), −3.60 (pseudo-t, $J = 12$ Hz, 0.8 H_i), −0.81 (br. s, 0.1—0.2 H, inner NH), 9.76—10.71 (m, 10 H_o), 10.90 (dd, $J = 12.6$ and 5.5 Hz, 0.8 H_o = 0.8 H_α), 11.49 (dd, $J = 13.5$ and 6.5 Hz, 0.4 H_o = 0.4 H_α), 19.0 (br. s, *ca.* 0.8 H, exterior NH)

The ^{1}H-NMR spectrum confirms the structure of *(1)*. The difference between the resonance signals for the 5 inner (H_i) and 12 outer protons (H_o) is *ca.* 11 ppm. Like [18]annulene[6] the molecule is strongly diatropic. The doublet of the two outer protons arises from the protons in the α-position to the nitrogen. The coupling constant proves the *cis* arrangement of H_α and H_β; the nitrogen thus occupies an internal position in the aza[18]annulene. The ^{1}H-NMR spectrum of *(1)* is practically temperature-independent. *(1)* thus behaves like 1,2-disubstituted [18]annulenes[7].

(9) *(10)*

Feeding dry hydrogen chloride into an etheral solution of *(1)* leads to precipitation of a black-violet crystalline hydrogen chloride derivative which is stable at room temperature in the absence of moisture (see Table 1).

The lower the temperature the more structured are the two broad singlets around $\delta = -0.81$ and 19.0 in the ^{1}H-NMR spectrum of the hydrogen chloride derivative. On irradiation at the frequency of these signals the double doublets at $\delta = 11.49$ and 10.90 each change to one doublet with $J = 6.5$ and 12.6 Hz, respectively. D_2O addition leads to the same result; in addition the two broad singlets disappear. The coupling constant $J = 6.5$ Hz corresponds to a *cis*-, that of $J = 12.6$ Hz to a *trans*-relationship between H_α and H_β. The ^{1}H-NMR spectrum thus provides proof of the structure of the aza[18]annulenium ions *(9)* and *(10)*, which presumably are present in equilibrium with each other (1:4 mixture). Addition of NH_3 at −50°C leads to deprotonation. A ^{1}H-NMR spectrum recorded immediately thereafter at this temperature revealed the presence of only *(1)*. Apparently the conjugate base of *(10)* rapidly isomerizes to the more stable *(1)*.

The Double Salt $Na_2S_2O_5 \cdot NaOOCH$ as Intermediate in the Formation of Sodium Dithionite by Reduction of SO_2 with Sodium Formate

By *Gert Ertl, Volker Kiener, Werner Ostertag*, and *Gerd Wunsch*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Sodium dithionite is of importance in vat dyeing and in bleaching. One method of industrial production consists in the reduction of sulfur dioxide by formate in aqueous methanol[1-3]:

$$NaOH + 2SO_2 + NaOOCH \rightarrow Na_2S_2O_4 + CO_2 + H_2O$$

Little has been reported on the mechanism of this reaction which proceeds in a three-phase system (solid, liquid, gaseous). *Yoshio et al.* assumed the intermediacy of $Na_2S_2O_5 \cdot HCOOH$ in the dithionite formation process[2]. We were unable to detect this compound, but found instead that the reaction proceeds *via* the isolable double salt $Na_2S_2O_5 \cdot NaOOCH$.

Our experiments were conducted in the following way: all the NaOH and half the amount of NaOOCH required

[*] Dr. G. Ertl, Dr. V. Kiener, Dr. W. Ostertag, Dr. G. Wunsch
Hauptlaboratorium der BASF AG
D-6700 Ludwigshafen (Germany)

© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0404-0313 $ 02.50/0

were suspended in aqueous methanol and a solution of SO_2 in methanol was added simultaneously with the rest of the sodium formate solution. The solid phases present were isolated from different experiments at various reaction periods and the content of Na_2SO_3, $Na_2S_2O_3$, $Na_2S_2O_4$, $Na_2S_2O_5$ and NaOOCH was determined. Figure 1 shows the composition of the solid samples as a function of reaction time.

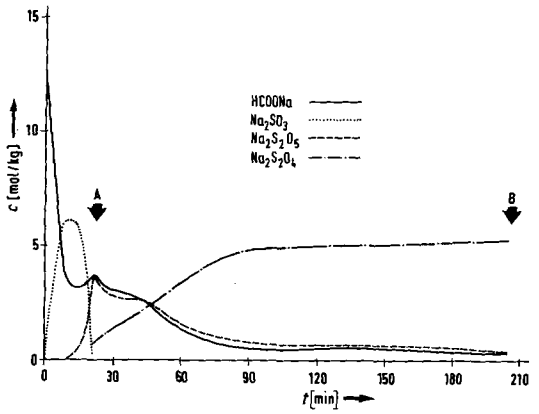

Fig. 1. Composition of solid material [mol/kg] as a function of the reaction time.

On progressive addition of SO_2, Na_2SO_3 is instantaneously formed and undergoes fast further reaction to give the disulfite at a rate depending on the decrease in pH:

$$2\,NaOH + SO_2 \rightarrow Na_2SO_3 + 2\,H_2O$$
$$Na_2SO_3 + SO_2 + H_2O \rightarrow 2\,NaHSO_3$$
$$2\,NaHSO_3 \rightarrow Na_2S_2O_5 + H_2O$$

The molar ratio of $Na_2S_2O_5$ to NaOOCH amounts to 1:1 within the limits of experimental accuracy once the reaction time exceeds 22.5 min (Fig. 1, sample A).

Our presumption that $Na_2S_2O_5$ might be present in the form of a double salt $Na_2S_2O_5 \cdot NaOOCH$ was confirmed by comparison of the X-ray diffraction diagrams[4] of the solid samples with that of the double salt obtained from an aqueous solution of $Na_2S_2O_5$ and NaOOCH (Table 1). An X-ray structure analysis[5] showed that the double salt forms monoclinic crystals with $a = 11.79_6$, $b = 5.47_6$, $c = 12.47_0$ Å, $\beta = 108.29°$.

Table 1. Characteristic d values of the double salt $Na_2S_2O_5 \cdot HCOONa$.

d [Å]	$I_{exp.}$	hkl
5.5865	5	200
4.7599	5	$11\bar{1}$
4.3182	8	111
3.5309	10	202
3.1783	4	$20\bar{4}$
2.8755	7	113
2.7987	10	$31\bar{3}$
2.0256	4	$22\bar{4}$
1.9463	3	420
1.6001	5	133

With the aid of the powder diagrams it was possible to trace the time dependence of the concentration of the double salt, with a maximum at 22.5 min (corresponding to sample A). As seen from Figure 1, dithionite formation only begins when significant amounts of the double salt are present; its concentration decreases at about the same rate as that of the dithionite increases. This also applies under the reaction conditions reported by *Yoshio et al.*[2]. The question whether dithionite formation takes place in the liquid phase or at the solid/liquid interface cannot be answered unequivocally. Evidence in favor of reaction at the interface is, however, provided by the following observations:

- The yield of dithionite decreases as the solubility of the intermediate compounds increases with increasing water concentration.
  Soluble dithionite is not stable under the above reaction conditions.
- Viewed under the microscope, the initially transparent crystals of the double salt become significantly cloudy with increasing conversion into the dithionite (Fig. 2a, b).
- Dithionite obtained from the "formate process" differs from that produced by the "zinc dust process" (crystallization from aqueous solutions) in its crystal habit (Fig. 2b, c) and is also shown by its X-ray diffraction pattern to exist in a different crystal modification.

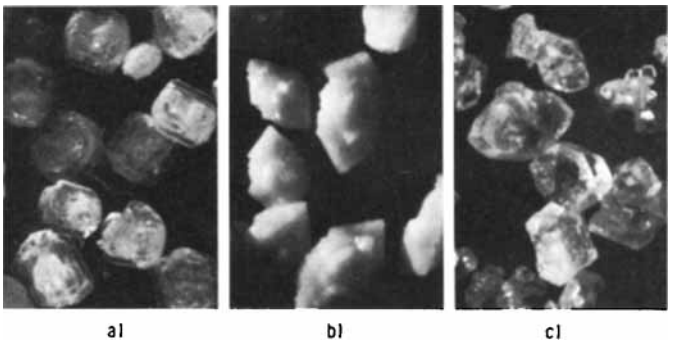

Fig. 2. Crystals of a) the double salt $Na_2S_2O_5 \cdot NaOOCH$ (solid sample obtained on stopping the reaction after 22.5 min, composition: $Na_2S_2O_5 \cdot NaOOCH$ 94.5 %, $Na_2S_2O_4$ 2.3 %, Na_2SO_3 3.0 %, $Na_2S_2O_3$ 0.2 %); b) sodium dithionite (formate process, corresponding to sample B, composition: $Na_2S_2O_5 \cdot NaOOCH$ 7.4 %, $Na_2S_2O_4$ 92.3 %, $Na_2S_2O_3$ 0.3 %); c) sodium dithionite (zinc dust process, from aqueous alkaline solution, precipitated with NaCl, composition: $Na_2S_2O_4$ 97.3 %, Na_2SO_3 1.9 %, $Na_2S_2O_3$ 0.4 %, NaCl 0.4 %).

Experimental

A solution of SO_2 (212 g) in methanol (636 g) and a solution of sodium formate (120 g) in water (106 g) are simultaneously added (50 % of each solution in 15 min and the rest within 7.5 min) to a suspension of sodium formate (120 g), NaOH(solid) (90 g), water (182 g), and methanol (402 g) in a 2-l glass flask fitted with a stirrer and two entry tubes; the temperature is kept at 67 °C during the addition. After cooling to 60 °C, the solid material is filtered off, washed with methanol, and dried. In this way, 211 g of a crystalline product is obtained which consists of $Na_2S_2O_5 \cdot NaOOCH$ (94.5 %), $Na_2S_2O_4$ (2.3 %), Na_2SO_3 (3.0 %), and $Na_2S_2O_3$ (0.2 %); the yield of $Na_2S_2O_5 \cdot NaOOCH$ is 46.7 % based on SO_2.

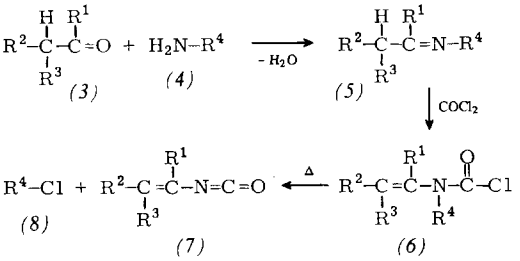
α,β-Unsaturated Isocyanates by Thermolysis of *N*-(1-Alkenyl)-*N*-alkylcarbamoyl Chlorides



By *Karl-Heinz König, Christian Reitel, Dietrich Mangold, Karl-Heinz Feuerherd*, and *Heinz-Günter Oeser*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

α,β-Unsaturated isocyanates should behave similarly to enamines[1] and are of interest for the synthesis of active substances and polymers. A method for the thermal dehydrochlorination of chlorinated alkyl isocyanates but giving only chlorinated α,β-unsaturated isocyanates[2] can be exploited in a new industrially useful method affording entry to this class of compounds.—Isocyanates *(2)* are formed on pyrolysis of the disubstituted carbamoyl chlorides *(1)*. The tendency for an alkyl group (R^1) to be cleaved increases with increasing branching at C_α in R^1[3].

$$\underset{(1)}{RR^1N{-}COCl} \xrightarrow{\Delta} \underset{(2)}{R{-}N{=}C{=}O}$$

Phosgenation of Schiff bases *(5)* provides access to polysubstituted α,β-unsaturated carbamoyl chlorides of type *(6)*[4]. The *N*-(1-alkenyl)-*N*-*tert*-alkylcarbamoyl chlorides *(6)* formed on catalyzed thermolysis[3] open up a novel and safe route for the production of α,β-unsaturated isocyanates *(7)*[5] (see Table 1). The reaction (R^4 = *tert*-alkyl) can be directed in such a

way that almost exclusively alkyl chlorides *(8)* are formed as cleavage products, but no alkenes and hydrogen chloride. This ensures high yields of the α,β-unsaturated isocyanates *(7)*, which are very sensitive towards halogen hydrides.—Vinyl isocyanate *(7a)* has already been prepared on a pilot-plant scale.

Table 1. α,β-Unsaturated isocyanates *(7)* prepared by thermal fragmentation of *N*-(1-alkenyl)-*N*-*tert*-butylcarbamoyl chlorides *(6)* R^1 = H, R^4 = $C(CH_3)_3$.

[+] Author to whom correspondence should be addressed.

In contrast to previous views[3], groups R^4 other than *tert*-alkyl are also readily cleaved. Thus, in the case of *(6)*, $R^1 = R^2 = R^3 = H$, R^4 = *sec*-butyl or cyclohexyl, and given sufficient activation of *(6)*, R^1 = H or CH_3, $R^2 = R^3 = H$, R^4 = benzyl, thermolysis leads to moderate or satisfactory yields of *(7)*.

The metal-salt-catalyzed thermolysis of the carbamoyl chlorides *(6)* can be carried out in the gas-phase on an industrial scale.

The observation (i) that isocyanates *(7)* are also accessible from *(6)*, R^4 = benzyl, and (ii) that our usual method of preparation from *(6)*, R^4 = *tert*-alkyl, gives almost exclusively the *tert*-alkyl chloride *(8)* besides *(7)*, would indicate the presence of a stabilized carbenium ion[6].

Procedure[5a, c]

Synthesis of *(5a)*: *tert*-Butylamine (12.8 kg, 175 mol) is added with stirring within 1.5 h at 10 to 15°C to a solution of acetaldehyde (9.8 kg, 223 mol) in *n*-pentane (technical) (70 l). After one hours' stirring and subsequent cooling to 0°C the aqueous phase is separated off and the pentane removed from the organic phase by distillation at a maximum internal temperature of 40°C. Yield of *(5a)* 16.5 kg (95 %).

Synthesis of *(6a)*: A solution of phosgene (25 kg, 252.5 mol) in CH_2Cl_2 (125 l) is treated at −5°C within 2 h with 16.5 kg (167 mol) of *(5a)* and 20.8 kg of *N*,*N*-dimethylcyclohexylamine. After 15 minutes' stirring at −5°C the excess of phosgene and CH_2Cl_2 is removed at +15°C. The phosgene is removed in a NaOH washing tower. The residue from the distillation is stirred with 165 l of *n*-pentane, the hydrochloride separated on a suction filter, and the combined filtrates distilled at 40°C (internal temperature) to remove the *n*-pentane. The crude *(6a)* is distilled at 2—4 mbar; yield 23.6 kg (88 %).

Synthesis of *(7a)*: *(6a)* (6 kg, 37.2 mol) is pumped within 4 h at 150°C/1—2 mbar through an evaporator into a reactor filled with a zinc salt fixed bed catalyst[5a,c] and decomposed at 120°C. The cleavage products are trapped by liquid nitrogen and separated by distillation; yield of *(7a)* 2.45 kg (96 %).

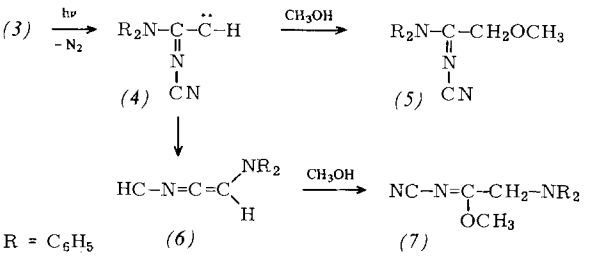
Iminocarbene/Ketenimine Rearrangement[**]

By *Bernhard Arnold* and *Manfred Regitz*[*]

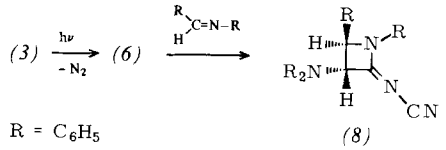
Dedicated to Professor Horst Pommer on the occasion of his 60th birthday



In contrast to α-oxocarbenes[1] little is known about α-iminocarbenes. They have so far only been generated by pyrolysis or photolysis of 1*H*-1,2,3-triazoles[2]. The synthesis of α-diazoamidines *(3)* by diazo group transfer to ynamines with electron-poor azides[3] opens an entry to carbenes of type *(4)*.

Reaction of the ynamine *(1)*[4] with cyanogen azide[5] in anhydrous acetonitrile afforded [most likely *via* the cycloadduct *(2)*] the α-diazoamidine *(3)* in 90% yield [m.p. 81°C; IR (KBr): 2180 (C≡N), 2100 (C=N_2), 1520 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$): δ=5.0 (1H, CH)].

R = C_6H_5



Irradiation of *(3)* in methanol (Duran-50 filter, Philips HPK-125W) and subsequent column chromatography furnished the amidine *(5)* [oil, IR (film): 2180 (C≡N), 1570 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$): δ=3.32 (3H, OCH_3), 4.23 (2H, CH_2)][6] and the imidate *(7)* [m.p. 72°C; IR (KBr): 2210, 2180, (C≡N), 1600 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$): δ=3.85 (3H, OCH_3), 4.82 (2H, CH_2)] in the ratio 1:3.

R = C_6H_5

The reaction branches at the carbene stage *(4)*, with the novel iminocarbene/ketenimine rearrangement *(4)*→*(6)* [which after addition of methanol to the heterocumulene leads to *(7)*] dominating over the insertion reaction *(4)*→*(5)*. Such extensive migration of a diphenylamino group has not yet been found in the related Wolff rearrangement[1].

Since neither aminoketenimines such as *(6)* nor cycloadducts of these heterocumulenes with azomethines were previously known, we have also trapped the photochemically generated *(6)* (in benzene) with benzylideneaniline; after chromatography on silica gel with chloroform the β-lactam imide *(8)* was obtained in 46% yield [m.p. 211°C; IR (KBr): 2180 (C≡N), 1650 cm^{-1} (C=N); ^{1}H-NMR ($CDCl_3$): δ=5.24, 5.45 (each d, $^3J_{H,H}$=2.0 Hz)].

R = C_6H_5 *(8)*

The magnitude of the H,H coupling constant is consistent with a *trans*-configuration of the hydrogen atoms; for *cis*-configuration a coupling constant of J=5—6 Hz would be expected[7]. The mass spectrometric fragmentation of *(8)* proceeds mainly in accord with the two conceivable [2+2]cycloreversions, reversion of the formation reaction predominating.

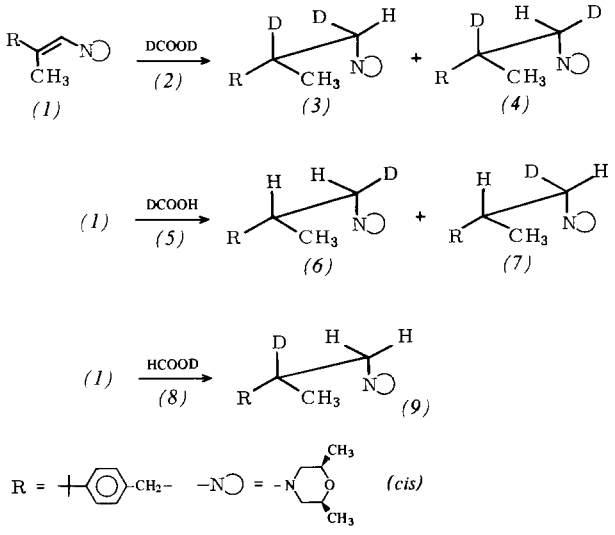
Selective Deuteration of Enamines with Deuterated Formic Acids

By *Walter Himmele, Wolfgang Bremser*, and *Hardo Siegel*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday



In some cases deuteration as well as ^{14}C-labeling can be used for monitoring and identifying the metabolites of active substances, provided it proceeds selectively and without H/D exchange. Such a deuteration can be achieved by the known reduction of enamines with formic acid[1] using deuterated formic acids [*(2)*, *(5)*, *(8)*].

Reaction of the enamine *(1)*[2] with stoichiometric amounts of variously deuterated formic acids at *ca.* 120°C in an inert solvent such as toluene leads to selective deuteration to *(3)* + *(4)*, *(6)* + *(7)*, and *(9)*, respectively, depending upon the formic acid employed.

0570-0833/79/0404-0320 $ 02.50/0

The deuteration pattern of the amines obtained indicates that the reaction proceeds, as previously suggested, *via* an immonium formate, which is then reduced by deuteride transfer to the amine.

Procedure

A solution of 3-(*p-tert*-butylphenyl)-2-methylpropanol (10.2 g, 0.05 mol) in toluene (70 ml) is treated with *cis*-2,6-dimethylmorpholine (6 g). After azeotropic removal of the water with toluene (which distills over until an internal flask temperature of *ca.* 120 °C is reached), 2.5 g of *(2)* in 5 ml toluene is slowly added and the mixture of amines *(3)* and *(4)* finally distilled at 142–145 °C/0.3 torr. In the case of *(6)* and *(7)* the $\{^1H\}$-noise-decoupled ^{13}C-NMR spectra show a triplet at $\delta = 64.77$, and in the case of *(9)* a triplet at $\delta = 31.82$; in all cases by coupling with the deuterium nucleus. *(3)* and *(4)* each show two triplets at $\delta = 64.53$ and 31.71. The ^1H-NMR spectra of *(6)* and *(7)* with signals at 7.3 (2, d), 7.1 (2, d), 3.7 (2, t), 2.8 (1, m), 2.7 (1, m), 2.35 (1, m), 2.2 (1, m), 2.15 (1, m), 2.0 (1, m), 1.7 (2, m), 1.3 (9, s), 1.15 (6, d) and 0.85 (3, d) confirm this assignment by the changing signal splitting; *(3)* and *(4)* as well as *(6)* and *(7)* are present as 40:60 mixtures.

Effects of Long-Chain Branches on the Degradation Kinetics of Polymers

By *Klaus H. Ebert, Hanns J. Ederer*, and *Arno Max Basedow*[*]

Dedicated to Professor Horst Pommer on the occasion of his 50th birthday

Experimental investigations on the kinetics of the hydrolytic degradation of dextran in solution[1] showed that small molecules are formed more frequently than should be the case in a random reaction. On assuming, firstly that the dextran molecules are unbranched, and secondly that the "individual" degradation constants ($K_{s,l}$) along the polymer chain vary according to a parabolic function, we could establish the curvature of this parabola as $b = 0.4$ from experimentally determined molecular-weight distributions *via* the combined polydispersity ratio $CPR = \bar{M}_w^2/(\bar{M}_n \cdot M_z)$ by mathematical simulation. This means that the polymer bonds at the ends of the molecule are about three times more reactive than in the center of the molecule. *Freudenberg, Kuhn, et al.*[2] likewise deduced a non-random degradation from the acid hydrolysis of cellulose and starch.

The assumption that the dextrans are unbranched is especially critical, since the experimentally determined molecular-weight distributions of the degradation products can in principle also be explained by long-chain branching and random degradation (see [1]).

Relatively little is known about branching in dextran[3,4]. Dextran obtained enzymatically from *Leuconostoc Mesenteroides* B 512 F has, at most, branching on 5% of its repeating units[5]. Of these at most 15% are longer than two glucose units[6], so that the proportion of branching points with side-chains longer than ten monomer units can be assumed to be about 0.1%, *i.e.* for every 1000 structural moieties there is one long-chain branch. Short-chain branches (side-chain lengths < five monomer units) do not influence the molecular weight distribution of the degradation products.

We have investigated the influence of long-chain branching on the product distribution in a random degradation reaction by mathematical simulations of various branched model molecules, which were generated by a Monte Carlo method. The results are expressed in terms of the dependence of $K_{s,l}$ on l. Here $K_{s,l}$ is the rate constant for the cleavage of a molecule having a degree of polymerization s into two fragments with degrees of polymerization l and s-l. For unbranched molecules, $K_{s,l}$ is a measure of the probability of cleavage at site l. These diagrams are identical with the molecular weight distributions obtained, assuming every molecule has undergone a simple chain rupture.

Our model calculations are based on molecules having a degree of polymerization of 1000 (Table 1). Model 1 is for singly branched molecules in which the length and position of the side-chain are randomly distributed. In models 2 and 3 the number of long-chain branches is increased respectively to three and seven, while the lengths and positions of the side chains are again randomly distributed; however, only one side chain can branch at each position of the main chain. Figure 1a shows that the curvature of the curves increases with increasing number of branches. The effect is very pronounced even with one side chain; the curve is almost parabolic with $b = 0.8$. The unbranched molecule gives a straight line parallel to the abscissa at 1.

Fig.	1a	1a	1a	1b	1b	1c	1c

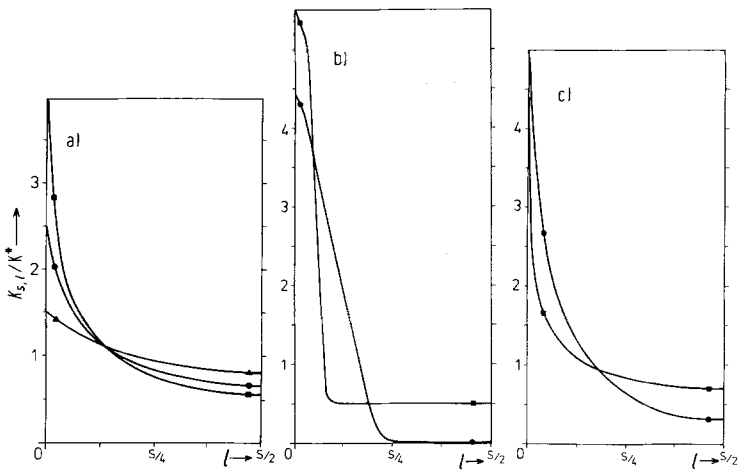

Fig. 1. Dependence of the rate constants $K_{s,l}$ on the degree of polymerization l of the fragment (K^* = experimental degradation constant). The curves are symmetric about $s/2$. a) ▲ model 1, ● model 2, ■ model 3; b) ■ model 4, ● model 5; c) ● model 6, ■ model 7.

Model 4 contains nine long-chain branches and the main chain is as long as the sum of the side chains; these were varied randomly between 30 and 80 monomer units. The branching points on the main chain were likewise randomly chosen. In model 5 the main chain was shortened to ten monomer units and the lengths of the side chains distributed randomly between 20 and 220. Model 4 can be regarded as a "comb", model 5 as a "star". Figure 1b shows that shorter side chains lead to higher $K_{s,l}$-values at small l-values; in the case of larger l-values (up to $s/2$) longer side chains and the main chain are decisive. The models 6 and 7 are "stars" with a greater distribution in the length of the side chains. Model 6 permits a random choice of $^2/_3$ of the residual monomer units available in the generating process, in the case of model 7 the lengths of the side chains are chosen randomly (Fig. 1c) from the total number of the residual monomer units (Table 1). Model 6 contains more side chains with average degrees of polymerization; hence the curve falls more slowly at low l-values. In the random model 7 the number of large fragments is greater; hence the larger values near to the center of the molecule $s/2$.

Our models cover all polymer molecules without compound branches as well as all molecules in which double branching is peripheral. More strongly branched or crosslinked molecules require more complicated models.

Our simultaneous show that long-chain branches have considerable influence on the distribution of the molecular weights of the products in degradation reactions. From the shape of the distributions, quantitative information can be gained about the number of branches and lengths of the side chains, and sometimes also about the main chain. Thus, *e.g.*, from our experiments on dextran it can be concluded, assuming random probability of cleavage, that the number of long-chain branches lies below 0.2%.—For a more accurate analysis of the long chain branching, the shape of the $K_{s,l}$ curve should be determined from the experimental molecular weight distributions, and not only from molecular weight averages and the CPR.

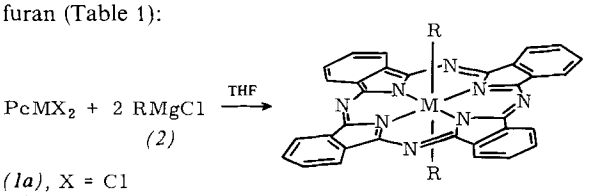
trans-Bis(1-alkynyl)-4B-metal Phthalocyanines[**]

By *Michael Hanack, Konrad Mitulla, Georg Pawlowski*, and *L. R. Subramanian*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Monomeric phthalocyanine derivatives of type *(3)* of elements of the 4th main group having two axial metal-carbon bonds are model substances for new polymer structures, which according to EHMO calculations ought to show pronounced electrical conductivity[1].

Octahedral silicon phthalocyanines having one axial Si—C bond have already been reported[2]; and the tin phthalocyanine *(3)*, R = C_6H_5, has been synthesized, but only in 1% yield[3]. Analogous *meso*-tetraphenylporphyrins were recently described[4].



We obtained *trans*-bis(1-alkynyl)-4B-metal phthalocyanines *(3)* in yields of about 90% by reaction of the corresponding

[a] M^+ with ^{28}Si, ^{74}Ge, ^{120}Sn. [b] THF, reflux. [c] Not analytically pure.

The products *(3)* were purified by extraction with acetone or methanol; their solubility in organic solvents is dependent upon the substituents R; *e.g.* the bis(3,3-dimethyl-1-butynyl) compounds *(3)*, M = Si, Ge, are readily soluble in tetrahydrofuran, acetone, or trichloromethane.

In contrast to the silicon- and germanium phthalocyanines *(3)*, the homologous tin compounds are difficult to isolate in pure form since they readily undergo reduction with formation of PcSn. Attempts to recrystallize the 4B-phthalocyanines from high-boiling solvents led to cleavage of the metal-carbon bonds[3]. Hydrolysis with THF/HCl/H_2O and with NaOH/H_2O respectively gave the chlorides *(1a)* and the corresponding dihydroxides *(1b)*[5], thus confirming the structure *(3)*.

Reaction of *(1a)* with organolithium compounds in diethyl ether likewise affords *(3)*, but the products are highly contaminated owing to uncontrollable side reactions.

General Procedure

(1a) (1 mmol) is added with stirring under nitrogen to a solution of *(2)* (6 mmol) in 50 ml of THF. On completion of reaction (cf. Table 1) the mixture is hydrolyzed with 10 ml of 5% hydrochloric acid, filtered, and the residue washed with water and dried. Insoluble products *(3)* were purified by extraction with methanol and then dried at 100 °C. Soluble products were isolated by fractional extraction with THF and concentration of the deep-blue solution with exclusion of light.

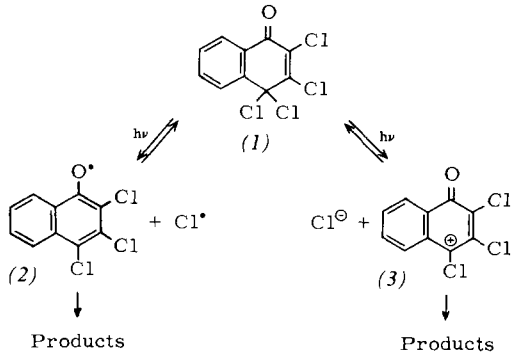
Characterization of Short-Lived Photoproducts by Pulse Raman Spectroscopy[**]

By *Walter Hub, Siegfried Schneider*, and *Friedrich Dörr*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

On the basis of a series of selected chemical reactions and from the similarity of the transient spectra observed in the visible spectral region on irradiating 2,3,4,4-tetrachloro-1-oxo-1,4-dihydronaphthalene ("β-TKN") *(1)* in the crystalline state or in solid solution, *Scheibe* and *Feichtmayr* concluded[1] that the phototropy first observed on this compound by *Marckwald* as long ago as 1899 cannot be explained in terms of physical interaction (crystal structure) but is due instead to photodissociation of *(1)*. The naphthoxyl radical *(2)* formed in this photodissociation disappears by recombination with a chlorine radical, by dimerization, or even by addition of an H atom abstracted from the solvent.



In contrast, *Zweegers*[2] reports to have been able to demonstrate that the cation *(3)* is formed as principal photoproduct by heterolytic cleavage of *(1)* on irradiation with light of wavelength $\lambda = 353$ nm in CCl_4 as solvent.

One of the difficulties in clarifying this problem is that according to quantum mechanical model calculations both products *(2)* and *(3)* show two bands of similar oscillator strength in the same spectral region. As in many cases this

means that the transient electronic spectrum obtained in a flash-photolysis experiment provides no decisive information. More characteristic differences are to be expected in the vibrational spectra, even in the case of similar compounds.

The aim of our present studies was to record the first highly time-resolved Raman spectra of transient photoproducts in order to determine their structure. For this purpose the light pulse of a N_2-laser (Lambda Physik M2000) is focused into the reaction cell. A dye laser (Zeiss 807103, 19000—21000 cm^{-1}) is triggered after a delay time of Δt ($\geq 0.2\,\mu s$); its beam follows the trace of the N_2 photolysis laser. The Raman light generated by the photoproduct is spectrally analyzed in a double grating spectrograph (Coderg UF 76). After amplification by an image converter (EMI 9912), which is externally gated during the "photoflash"[3], the spectrum is recorded with an optical multichannel analyzer (PAR 1205). The spectra can be immediately displayed or fed to a computer for further processing (*e.g.* for difference spectra).

The Raman spectrum of the transient from *(1)* in CCl_4 (300 K) was detected in the time interval 0.2 μs (apparatus limit) to 100 ms. Figure 1a shows the spectrum one obtains if the dye laser is triggered 4.5 μs after the N_2 photolysis laser; it contains contributions from the photoproduct, from unchanged starting material, and from the solvent. Figure 1b shows the spectrum recorded after spectrum 1a without photolysis laser; it corresponds with that of *(1)*, except for the broad CCl_4 solvent band at 1539 cm^{-1}. Finally, Figure 1c shows the difference spectrum, *i.e.* the Raman spectrum of the photochemically generated transient in the form in which it exists 4.5 μs after the photoflash.

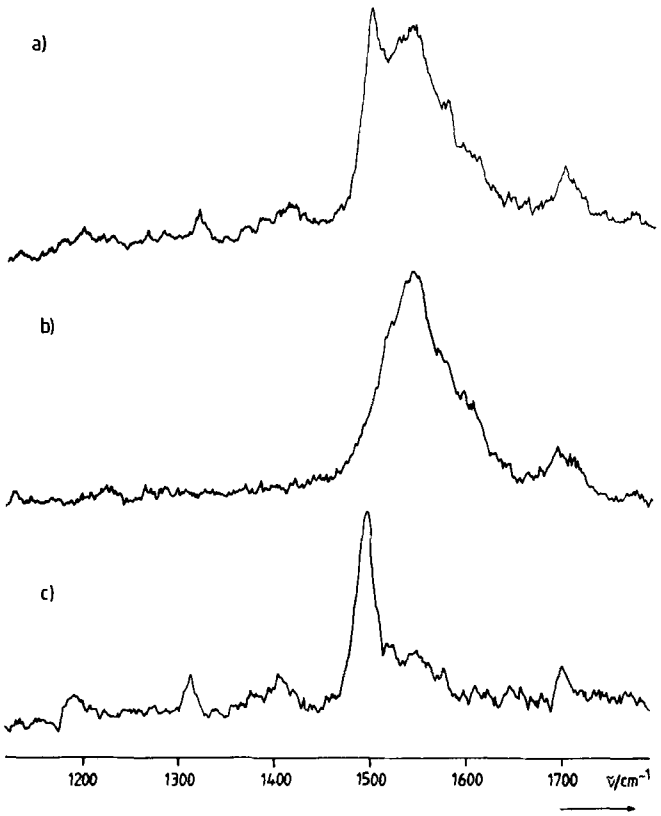

Fig. 1. Raman spectra of a 10^{-2} M solution of *(1)* in CCl_4: a) probe laser delay 4.5 μs ($\tilde{\nu}_L = 20576\ cm^{-1}$); b) without photolysis laser; c) difference spectrum.

In the spectrum of *(1)* in CCl_4, we assign the band at 1680 cm^{-1} to the C=O stretching vibration, and that at 1570 cm^{-1} to the non-aromatic C=C stretching vibration; the bands at 1600, 1296, 1260, and 1170 cm^{-1} are characteristic for the benzoyl moiety. The difference IR spectrum of *(1)* in an irradiated and an unirradiated KBr disc[4] reveals new bands at 1638 cm^{-1} [ν(C=O)] and at 1610, 1520, 1490, 1380, and 1284 cm^{-1} (decay time ≈2 h at 300 K). We assign these bands to the radical *(2)*, since according to model calculations its bond orders are similar to those of an unsubstituted naphthalene. In particular, the decrease in the frequency of the (C=O) stretching vibration is consistent with the smaller π-bond order of this bond in the radical. In contrast, the Raman spectrum of the photoproduct in CCl_4 (Fig. 1c) shows no substantial bands at frequencies appearing in KBr and assigned to the radical. The strongest line appears at 1495 cm^{-1}, others at 1190, 1320, 1400, 1575, and 1700 cm^{-1}. We thus conclude that two different photoproducts predominate in KBr and CCl_4, respectively. An increased C=O frequency (1700 cm^{-1}) compared to that observed for *(1)* would be in agreement with *Zweegers*'[2] assignment as cation *(3)*, since the model calculation yields a higher π-bond order. As yet, we cannot explain the high intensity of the line at 1495 cm^{-1}; whether a resonance effect is responsible is presently under investigation.

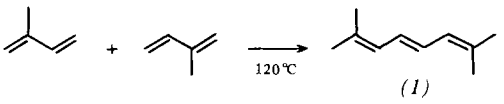
Homogeneously Catalyzed Dimerization of Isoprene to 2,7-Dimethyl-2,*trans*-4,6-octatriene at Chromium[**]

By *Heindirk tom Dieck* and *Alois Kinzel*[*]



Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

In our studies on homogeneously catalyzed oligomerizations of dienes on dad-modified metal catalysts (dad = 1,4-*diaza*-1,3-*diene*) we found that a chromium-dad system is able to transform isoprene in a highly specific manner into 2,7-dimethyl-2,*trans*-4,6-octatriene *(1)*. The reaction involves *tail-to-tail linkage with a double hydrogen shift.*

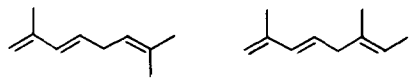
(1)

Open-chain dimers of isoprene are formed by numerous catalyst systems. The head-to-tail dimer 2,6-dimethyl-1,3,6-octatriene (5) is then formed—often only in poor yield. Only palladium[1] is found to give not only polymers but also 2,7-dimethyl-1,3,7-octatriene, which undergoes base-catalyzed rearrangement to (1) in modest yield.

The catalytic direct synthesis of (1) preferably starts with generation of the chromium(0) complex (3) from chromium(III) compounds and the dad-ligand *N,N'*-ethanediylidenebis(2,4-dimethyl-3-pentanamine) (2).



(2) (3)

R = $(CH_3)_2CH-\underset{|}{C}H-CH(CH_3)_2$

Activation of (3) with Et_2AlOEt in the presence of isoprene (molar ratio *ca.* 1:2:500) leads to the best result obtained so far: a small amount of trimeric (10%) and higher products is accompanied by 80% of (1).

In the simplified version of the reaction, compound (3) is not isolated. Reduction in THF is followed by evaporation to dryness, (3) is extracted from the residue with isoprene and then activated with Et_2AlOEt. A chromium(III) compound, the ligand (2), and AlR_3 as reducing agent also gives (1) as the sole dimer on reaction in a steel autoclave, admittedly together with much polymeric material; the yield of (1) is improved if ligand (2) is added in excess.

Chromium complexes of type (3) bearing other substituents R give less specific reactions; the products contain no (1). When R = cyclohexyl reaction gives *inter alia* 2,7-dimethyl-1,3,6-octatriene (4), the intermediate probably present before the final hydrogen shift, alongside the head-to-tail dimer 2,6-dimethyl-1,3,6-octatriene (5).

(4) (5)

The exclusive formation of the tail-to-tail dimer (1) on a catalyst system (3) suggests a strong steric interaction during the primary C—C linkage.

Similar steric control leading to tail-to-tail linkage in metal-diazadiene catalysis has also been observed in the $V(dad)_3/AlR_3$ system[2].

Compound (1), m.p. 35—37°C, b.p. 110—115°C/55 torr, forms the expected Diels-Alder adduct 3,3-dimethyl-6-(2-methyl-1-propenyl)-4-cyclohexene-1,1,2,2-tetracarbonitrile with tetracyanoethylene, while only a yellow-orange charge-transfer complex is formed with maleic anhydride. The nonuniform bromination gives *inter alia* 2,3,6,7-tetrabromo-2,7-dimethyl-*trans*-4-octene in *ca.* 10% yield[2].

Experimental

Synthesis of (3): Synthesis was successful only in flame-treated Schlenk tubes under re-purified argon in anhydrous solvents. Tris(2,4-pentanedionato)chromium(III) (3.49 g, 10 mmol), (2)[3] (5.04 g, 20 mmol), and sodium (0.69 g, 30 mmol) are stirred together in THF (150 ml) at room temperature for 20 h. The brown solution is evaporated to dryness, the residue taken up in *n*-hexane (150 ml), the solution filtered through a fine frit and evaporated down. Compound (3) precipitates in a freezer as a dark-brown solid which is washed with acetonitrile. It deliquesces, turning reddish brown, on exposure to air: MS: $m/e = 556$ (M^+), 304 ($dadCr^+$), 278 [$(dad)_2Cr^{2+}$], *etc.*; VIS spectrum (*n*-hexane): 13250, 15750, 17290 (sh), 21100 (sh), 24690, 28170 cm^{-1}.

Dimerization of isoprene to give (1): Dimerization was performed in a flame-treated glass ampoule in a steel autoclave under *n*-pentane back-pressure at 120°C. Compound (3) (265.1 mg) is transferred under argon into an ampoule. After freshly distilled isoprene (25 ml) and Et_2AlOEt have been pipetted into the ampoule, it is frozen, evacuated at oil-pump vacuum, and sealed. After 20 h at 120°C (volume contraction *ca.* 10%) the reaction solution no longer contains isoprene. Distillation affords 13 g (80%) of (1) and 1.8 g (11%) of trimer; the rest is undistillable. UV (cyclohexane): 34250, 35710, 37170 cm^{-1}; 270-MHz ^1H-NMR spectrum ($CDCl_3$, int. TMS): $\delta = 1.76$ (s, 6H), 1.78 (s, 6H), 5.78—6.35 (m, 4H, AA'BB' system); ^{13}C-NMR ($CDCl_3$, int. TMS): $\delta = 18.3$, 26.1 (CH_3), 125.7, 126.7 (=CH—), 134.3 (=C<).

Novel Titanium Halides Containing Metal-Metal Bonds: Ti_7Cl_{16} and Ti_7Br_{16}

By *Harald Schäfer, Reinhard Laumanns, Bernt Krebs*, and *Gerald Henkel*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Among the halides of titanium, no stoichiometric compound having a composition between TiX_2 and TiX_3 has so far been reported. The thermal disproportionation of $TiCl_3$ is usually formulated as involving formation of $TiCl_{4,g}$ and $TiCl_{2,s}$. However, it initially leads to low-order products of varying composition[1] before ending up as $TiCl_2$. The latter compound is also of low order and can spontaneously ignite in moist air. To explain this behavior it was assumed—as in the case of the $TiBr_3$ analogue[2]—that there is a large range of homogeneous solid solutions.

The observation that the trihalides already disproportionate at 400—500°C, *i.e.* at temperatures at which atoms could not be very mobile in the solid state, posed the question whether the equilibration can be improved with the aid of transport reagents such that well crystallized solid phases are formed. Aluminum halides are suitable as transporting agents for lower titanium halides; the gaseous complexes $TiAlCl_6$ and $TiCl_2 \cdot nAlCl_3$ are already well known[3]. Our experiments led to the discovery of the crystalline compounds Ti_7Cl_{16} and Ti_7Br_{16}.

[*] Prof. Dr. H. Schäfer, Dipl.-Chem. R. Laumanns, Prof. Dr. B. Krebs, Dr. G. Henkel
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

Ti_7Cl_{16} can be synthesized in several different ways, one of the most convenient being, *e.g.*, as follows: 400 mg of Ti foil and 50 mg of NH_4Cl are transferred to a cylindrical ampoule. After purging with nitrogen, sufficient Al_2Cl_6 (prepared from Al and Cl_2) is sublimed into the tube such that the Al_2Cl_6-pressure at 375 °C is *ca.* 5 atm; after further purging with nitrogen 100 mg of $TiCl_2$ (prepared according to the method of *Ehrlich et al.*[4]) is added and the ampoule sealed under a high vacuum. After three days' heating black crystals of Ti_7Cl_{16} (37.2 % Ti, 62.6 % Cl) are formed in the 350 °C-zone of the 400—350 °C temperature gradient. The X-ray diagram of this product differs from those of $TiCl_2$ and $TiCl_3$. The new compound Ti_7Cl_{16} is sensitive to hydrolysis and oxidation, but can be stored indefinitely in an inert atmosphere; treatment with dilute acids leads to evolution of H_2 and formation of brown solutions.

Ti_7Br_{16} can be prepared by reaction of Br_2 with an excess of Ti in the presence of Al_2Br_6 (conversion to $TiBr_3$ at 350 → 250 °C and then to Ti_7Br_{16} at 300 → 250 °C). This compound is also analytically pure.

Ti_7Cl_{16}, which according to Guinier photographs is isotypic with Ti_7Br_{16}, forms orthorhombic crystals ($a = 14.421$, $b = 9.987$, $c = 6.890$ Å), space group Pnnm, $Z = 2$. The molecule contains two sorts of Ti atoms, which we provisionally regard as Ti^{II} and Ti^{IV}. Trigonal Ti_3Cl_{13} units consisting of $Ti^{II}Cl_6$ octahedra coupled edge-to-edge and containing Ti—Ti bonds (2.954(2) Å) are present [equilateral Ti_3 triangles centered at *ca.* 1/6 1/3 1/2; 2/3, 1/6 0; 5/6 2/3 1/2 and 1/3 5/6 0]. The $Ti_3^{II}Cl_{13}$ groups are coupled three-dimensionally *via* octahedral edges without Ti—Ti bonds (Ti...Ti > 3.80 Å) with one another and with $Ti^{IV}Cl_6$ octahedra [in 0 0 0 and 1/2 1/2 1/2]. This is consistent with the formula $Ti^{IV}Cl_{6/3}[Ti_3^{II}Cl_{12/3}Cl_{6/2}]_2$ (= "$TiCl_4 \cdot 6TiCl_2$"). The Cl atoms form a distorted cubic close packing with layers parallel to (210).

A relationship is recognizable between the occurrence of Ti_3-units and the structures of Nb_3Cl_8, Nb_3Br_8, Nb_3I_8, and $Zn_2Mo_3O_8$[5]. Starting with an equal distribution of the Ti valence electrons the additional electrons necessary for the formation of the Ti_3-groups are provided by the "isolated" Ti.

Bis(dichloroboryl)silylamines and Tris(dichloroboryl)-amine

By *Theo Gasparis, Heinrich Nöth*, and *Wolfgang Storch*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

According to MO calculations, the D_{3h} molecule $N(BF_2)_3$ should be stable[1]; it was not examined, however, whether the expected decomposition products BF_3 and BN are thermodynamically more stable. Nevertheless, $N[B(CH_3)_2]_3$[2] exhibits considerable thermal stability—in contrast to the diborylamines $RN[B(CH_3)_2]_2$[3]—suggesting that tris(dihaloboryl)-amines would also show little tendency to decompose. And yet attempts to prepare $N(BF_2)_3$ and $N(BCl_2)_3$ have hitherto remained unsuccessful[4].

Although reaction of $N[Si(CH_3)_3]_3$ with CH_3BBr_2 leads to the *B*-halogenated diborylamine $Br(CH_3)_2SiN[BCH_3Br]_2$[5], only methylation of the boron halides is observed with BCl_3 or BBr_3[6]. In contrast, we have now found that Sn—N cleavage according to (a) predominates in the reaction of BCl_3 with $N[Sn(CH_3)_3]_3$ at low temperatures, while methylation of the reactant BCl_3 or the product $N(BCl_2)_3$ *(1)* only occurs at higher temperatures; an excess of BCl_3 prevents methylation of *(1)*. The bis(dichloroboryl)amines *(2)*—*(5)* are obtained analogously, increasingly high reaction temperatures being required along this series.

$$N[Sn(CH_3)_3]_3 + 3\,BCl_3 \rightarrow \underset{(1)}{N(BCl_2)_3} + 3(CH_3)_3SnCl \qquad (a)$$

$$RN[Sn(CH_3)_3]_2^{[7]} + 2\,BCl_3 \rightarrow \underset{(2)-(5)}{RN(BCl_2)_2} + 2(CH_3)_3SnCl \qquad (b)$$

Table 1. NMR data of the new dichloroborylamines *(1)*—*(5)*; standards $BF_3 \cdot OR_2$, $NaNO_3$, TMS.

$RN(BCl_2)_2$	R	$\delta^{11}B$	$\delta^{14}N$	$\delta^{1}H$
(1)	BCl_2	39.8	−218	—
(2)	$SiCl_3$	40.4	−238	—
(3)	$SiCl_2CH_3$	40.0	−240	1.2
(4)	$SiCl(CH_3)_2$	39.3	−242	0.78
(5)	$Si(CH_3)_3$	39.2	−242	0.43

All the new compounds are water-clear liquids that are extremely sensitive to hydrolysis. *(1)* exhibits remarkable thermal stability; it survives heating to 200 °C for 2 h. Nor do *(2)*—*(5)* decompose up to 100 °C. We regard this observation as further evidence that decomposition of the *B*-methylated diborylamines is initiated by intermolecular BN coordination. This step fails to occur with dichloroborylamines because the basicity of the nitrogen is greatly reduced by the Cl_2B groups. The very low field ^{14}N-NMR signals of a trigonal-planar nitrogen confirm the low electron density at this atom. Accordingly, the boron atoms in *(1)*—*(5)* experience only slightly greater shielding by BN-π interaction. The $\delta^{11}B$ values in the series $(Cl_3Si)_2NBCl_2$[8] (43.6) > *(2)* > *(1)* indicate that the Cl_2B group of *(1)* is least twisted relative to the $NB_{3-n}Si_n$ plane.

Synthesis of tri(dichloroboryl)amine (1)

Trichloroborane (21.5 g, 183 mmol) is condensed at −196 °C onto tris(trimethylstannyl)amine (15.2 g, 30 mmol) in *n*-pentane (30 ml). The mixture is thawed with stirring to −78 °C, warmed to −15 °C after 1 h, and then cooled again to −78 °C after 1.5 h. Insoluble material [$(CH_3)_3SnCl$ and $(CH_3)_2SnCl_2$] is filtered off, the filtrate is washed with cold pentane (−78 °C), and the solution evaporated down to 2/3 of its volume *in vacuo*. After removal of the precipitate formed at −78 °C, all volatiles are stripped off at −10 °C/10 torr and the product *(1)* isolated at 27 °C/1.5 torr (yield 3.4 g, 44 %).

Compounds *(2)*—*(5)* are prepared analogously. The reactions go to completion at 0—20 °C with *(2)*—*(4)*, and at 35 °C in the case of *(5)*. All compounds gave correct elemental

Complex-Stabilized Hydroxy(*p*-tolyl)acetylene by Reaction of *trans*-Chlorotetracarbonyl(tolylcarbyne)tungsten with Acetylacetone[1]

By *Ernst Otto Fischer* and *Peter Friedrich*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

The reaction of *trans*-halotetracarbonyl- or cyclopentadienyldicarbonyl-carbyne complexes with nucleophiles was observed to involve not only substitution of halogen and carbonyl but primarily specific transformations of the carbyne ligand ≡CR[2].

We have now discovered a new combined variant of the reaction by photochemical interaction of *trans*-chlorotetracarbonyl(*p*-tolylcarbyne)tungsten *(1)*[3] with acetylacetone. Fractional crystallization of the crude product yielded a dark blue complex (1:1 adduct with diethyl ether) which is air and temperature sensitive and readily soluble in polar solvents, but only sparingly soluble in pentane. On the basis of the analytical and spectroscopic data of the diamagnetic compound *(2)*, and the results of an X-ray structural analysis (Fig. 1), its formation can be envisaged as follows:

Two *cis* carbonyl ligands have been substituted by the acetylacetonate ion coordinated in *(2)* *via* the oxygen atoms. One of the two CO groups is evolved as carbon monoxide, whereas the second one combines with the tolylcarbyne ligand and a H atom to give a new ligand, *viz.* η^2-hydroxy(*p*-tolyl)acetylene, located *trans* to the halogen atom. 1-Hydroxy-1-alkynes were formerly regarded as incapable of existence, at least in the free state[4].

As shown by the crystal structure analysis of *(2)*, the two acetylenic carbon atoms are coordinated entirely symmetrically to the central atom; the W—C distances are 204(2) pm and thus, like the other bond lengths and angles in the Tol—C≡C—O fragment [$d_{C\equiv C}$ = 130(2) pm, ∢ C≡C—C = 141(1)°, ∢ C≡C—O = 138(1)°], closely resemble those in other η^2-acetylenetungsten complexes[5].

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. P. Friedrich
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

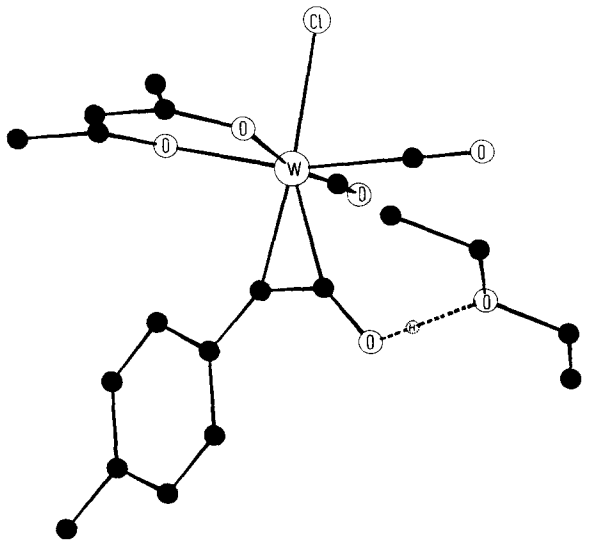

Fig. 1. Structure of the adduct *(2)*·$O(C_2H_5)_2$ in the crystalline state. Crystal data: monoclinic $P2_1/c$, Z = 4; a = 1069, b = 1716, c = 1547 pm, β = 126.8°, $V = 2272 \times 10^6$ pm^3, $\rho_{calc.} = 1.697$, $\rho_{exp} = 1.64$ g cm^{-3}. 2423 independent reflections. Syntex $P2_1$ four-circle diffractometer. Solution: Syntex XTL, conventional $R_1 = 0.042$.

A very short contact distance between the oxygen atom of the OH group in *(2)* and that in the solvate ether [257(1) ppm, ∢ C—O···O(Et_2) = 125(1)°] indicates strong hydrogen bonding, which is characteristic of NH or OH acidic systems such as carboxylic acids and phenols[6].

A ^{1}H-NMR signal of *(2)* at δ = 14.4 ([D_6]acetone, rel. to int. TMS, −80 °C), whose chemical shift and half-width are highly temperature dependent, is to be assigned to the hydroxyl H atom; the chemical shift reveals the acidic character of the proton[7]. The other signals (−20 °C) at δ = 7.63 (M, 4; C_6H_4), 5.78 (S, 1; C*H*(acac)[8]), 3.42 (Q, 4; $CH_2(Et_2O)$), 2.49 (S, 3; C_6H_4—CH_3), 2.16 (S, 6; CH_3(acac)), and 1.17 (T, 6; $CH_3(Et_2O)$) lie in the expected range.

The IR spectrum (KBr disc, room temperature) shows the ν_{CO} bands of the two *cis* carbonyl groups at 2060 (s) and 1960 cm^{-1} (vs). Absorptions at 1590 (s) and 1517 cm^{-1} (s) are assigned to the stretching vibrations of the acetylacetonate ligand[8]. A medium strength band at 1675 cm^{-1} is attributable in accord with other acetylenetungsten complexes[9] to the C≡C bond of the hydroxy(tolyl)acetylene ligand which is greatly weakened by coordination to the metal.

Procedure

All preparative work is carried out under N_2 and with oxygen- and moisture-free solvents.—Compound *(1)* (304 mg, 0.7 mmol) and acetylacetone (900 mg, 9 mmol) are dissolved in ether (250 ml) at −60 °C in a photochemical reactor fitted with a cold finger (UV mercury high-pressure lamp, 150 W, Hanau) and irradiated at that temperature with stirring until the evolution of CO has ceased. After stripping off the solvent at −20 °C and the excess of acetylacetone at −15 °C (cold finger), the violet residue is recrystallized several times from ether at low temperature. Analytically pure *(2)*·OEt_2 is isolated, yield 77 mg (19 %).

Photochemical Behavior of N_2-Complexes: Photoluminescence of *trans*-$(N_2)_2W(diphos)_2$ and *trans*-$(CO)_2W(diphos)_2$

By *Albert Caruana* and *Horst Kisch*[*]

Dedicated to Prof. O. E. Polansky on the occasion of his 60th birthday

In connection with our studies on the photochemical reactivity of complexed diazenes[1], we have now investigated dinitrogen-transition metal complexes. According to simple MO considerations the photochemical excitation of the ligand-field states (LF) should preferably lead to elimination of dinitrogen, while excitation of the charge-transfer state (CT), on the other hand, should increase the reactivity of the M—N_2 fragment[2]. Photochemical reduction[3] of complexed N_2 in the presence of suitable reagents should therefore preferably take place from CT states. A knowledge of the energies of the lowest excited states is therefore necessary in order to permit selective excitation.

On these grounds we report here on the electronic absorption and emission spectra of *trans*-$(N_2)_2W(diphos)_2$ *(1)*[4] and *trans*-$(CO)_2W(diphos)_2$ *(2)*[5] [diphos = ethylenebis(diphenylphosphane)] in 2-methyltetrahydrofuran. *(1)* is the first example of a photoluminescing N_2-complex.

On optical excitation of *(1)* ($\bar{\nu}_{excit} = 26000\,cm^{-1}$) at 77 K, a structured emission spectrum is observed with $\bar{\nu}_{max} = 17700\,cm^{-1}$ and a halfwidth $\Delta\bar{\nu}_{1/2} = 1500\,cm^{-1}$. The quantum yield of the emission is $\Phi = 0.08 \pm 0.02$[6] and the lifetime $\tau = 19\,\mu s$. The few other photoluminescing W^0-complexes all show unstructured emission bands: $W(CO)_5L$ (L = pyridines[7a], diazenes[1]), $W(CO)_4L_2$ (L_2 = α,α'-bipyridyl, phenanthroline[7b]) and $M(CNR)_6$ (M = Cr, W[7c]). Structured emission bands were previously observed only in the case of M^{II}- and M^{III}-complexes; *e.g.* $Ru(\alpha,\alpha'\text{-bipyridyl})_3^{2+}$[8]. In analogy to these complexes the emitting state of *(1)* probably has CT character (dπ*). The question of whether the observed vibrational fine structure arises from a δ(W—N_2) mode is currently being investigated by studies on the $^{15}N_2$ derivative.

The analogous *trans*-$(CO)_2W$ complex exhibits almost the same behavior. Under the same experimental conditions as in the case of *(1)*, an emission spectrum with $\bar{\nu}_{max} = 17600\,cm^{-1}$, $\Delta\bar{\nu}_{1/2} = 2400\,cm^{-1}$, $\Phi = 0.14$[6] and $\tau = 23\,\mu s$ is obtained. In contrast to the case of *(1)*, the low-energy side of the emission band of *(2)* is only weakly structured.

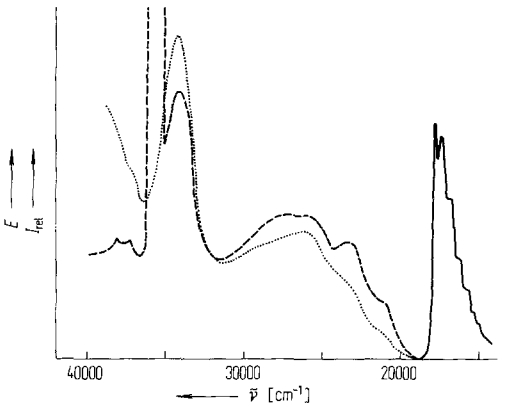

Fig. 1. Electronic spectrum of *trans*-$(N_2)_2W(diphos)_2$ *(1)* in 2-methyltetrahydrofuran: (.....) absorption at 143 K, (------) corrected excitation ($\bar{\nu}_{emiss} = 17700\,cm^{-1}$) at 77 K, (——) emission ($\bar{\nu}_{excit} = 26000\,cm^{-1}$) at 77 K.

The essentially equal energy of the emitting states of *(1)* and *(2)*, and the low-temperature (143 K) absorption spectra suggest that the two complexes have essentially identical electronic structures. The two lowest absorption bands (shoulders) of *(1)* and *(2)* at 20800 ($\varepsilon = 4000\,l \cdot mol^{-1} \cdot cm^{-1}$) and 23100 (6000), and at 20400 (2100) and 23200 (3600) respectively, are tentatively assigned to LF transitions; in *trans*-$Mo(N_2)_2(Et_2PCH_2CH_2PEt_2)_2$ these appear as isolated absorption bands at 20600 (589) and 21800 cm^{-1} (569)[9]. The broad, energetically higher band of *(1)* at 25800—27000 cm^{-1} (11000) is tentatively assigned to two superimposed CT transitions (dπ*); consistent with this assignment, *(2)* shows two separate maxima at 25600 (5400) and 27800 cm^{-1} (8400). The somewhat greater energy ($\approx 800\,cm^{-1}$) of the latter CT transition compared to that in *(1)* can be interpreted in terms of the higher energy of the lowest π* orbital or CO as compared to that of N_2, in analogy to the observed difference[2d] between *cis*-$[Os(NH_3)_4(N_2)_2]^{2+}$ and *cis*-$[Os(NH_3)_4(CO)(N_2)]^{2+}$.

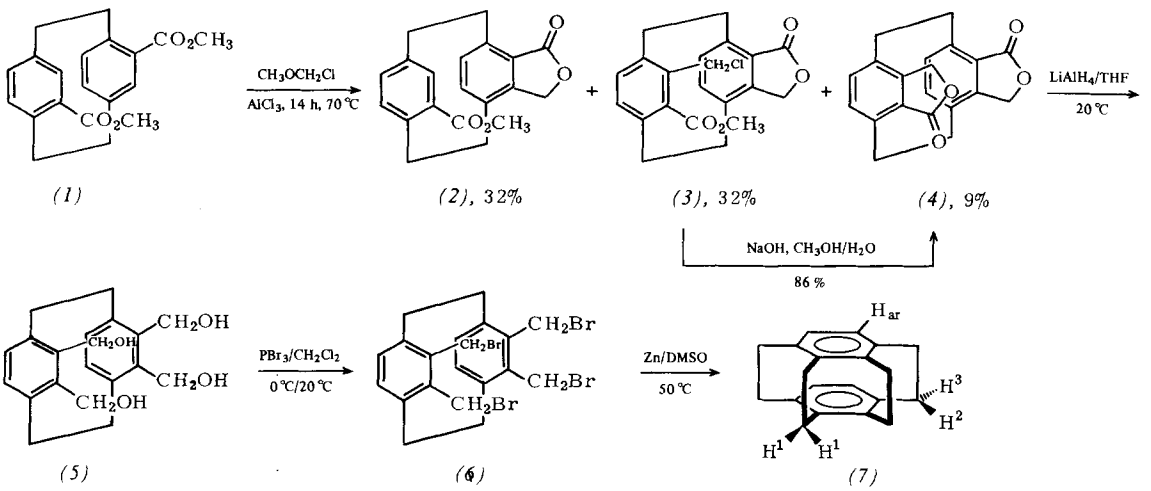
[2.2.2.2](1,2,3,4)Cyclophane[**]

By *Jürgen Kleinschroth* and *Henning Hopf*[*]

Dedicated to Professor Donald J. Cram on the occasion of his 60th birthday



Of the three possible [2.2.2.2]cyclophanes, the (1,2,4,5)-[1a] and the (1,2,3,5)-isomers[1b] are already known. In the present communication we describe the synthesis of the hitherto missing (1,2,3,4)-isomer *(7)*, the first phane system having four adjacent ethano bridges[2]. Multibridged phanes are of interest, *inter alia*, because the unusual properties of the parent compound [2.2]paracyclophane—*i.e.* extremely short distance between the (non-planar) benzene rings, and hence pronounced transannular interactions—ought to be more pronounced in such systems[3].

Reaction of the *pseudo-ortho* diester *(1)*[4] with chloromethyl methyl ether/aluminum trichloride at 70 °C[1] affords a mixture of the phthalides *(2)*—*(4)* in the yields shown in the reaction scheme (separation by column chromatography on Merck 60 silica gel with dichloromethane/ethyl acetate = 96:4)[5].

tion with activated zinc dust[7] in dimethyl sulfoxide (5 h, 50 °C) affords the desired hydrocarbon *(7)* (35 %).

The vibrational spectrum [(KBr): 3040 (w), 2940 (s), 2915 (s), 2890 (m), 1475 (s), 805 (m), 745 (m), 700 cm^{-1} (w)] and electronic spectrum [(ethanol): $\lambda_{max} = 200$ ($\varepsilon = 91150$), 225 (sh, 14100), 240 (sh, 3950), 283 (370), 297 nm (sh, 280)] of [2.2.2.2](1,2,3,4)cyclophane (prisms from pentane, m. p., 265 °C, dec. [5]) differ very little from those of its isomers[1]. However, the NMR-signal of the aromatic protons H_{ar} [$\delta = 6.32$ (4H)] appears at significantly lower field than the corresponding signals of the isomeric cyclophanes (H_{ar} at $\delta = 5.96$ in both cases[1]). Presumably this deshielding is brought about by non-parallel arrangement of the benzene rings in *(7)*. As molecular models show, the substituted ring carbon atoms in *(7)* are pressed still more closely than in [2.2]paracyclophane. At the same time the distance between the benzene rings on the unbridged side is larger: hence the arene protons no longer project so deeply into the anisotropy region of the oppositely placed rings and thus absorb at lower field. This interpretation is supported by the NMR spectrum of [2.2.2](1,2,4)cyclophane[3, 8]. The remaining protons of *(7)* absorb at $\delta = 3.22$ (m, 4H, H^3), 2.90 (s, 8H, H^1) and 2.58 (m, H, H^2).

Received: February 14, 1979 [Z 177 IE]
German version: Angew. Chem. *91*, 336 (1979)

Of particular importance for the subsequent synthetic steps is the observation that reaction of *(3)* with a boiling solution of sodium hydroxide in methanol/water (1:2) leads to formation of the bisphthalide *(4)*[5]. Reduction of *(4)* with $LiAlH_4$ in tetrahydrofuran at room temperature yields a mixture of several paracyclophane ethers and -alcohols, from which the *syn*-tetrakis(hydroxymethyl)-[2.2]paracyclophane *(5)*[5] can be isolated in 54 % yield. This alcohol differs markedly from the previously prepared *anti*-isomer in its spectroscopic and physical data[6]. Reaction of *(5)* with phosphorus tribromide in dichloromethane (initially at 0 °C, then at room temperature) leads to the tetrabromide *(6)* (65 %)[5], which on dehalogena-

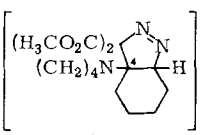
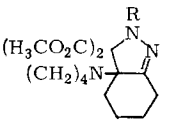
By *Rolf Huisgen* and *Hans-Ulrich Reissig*[*]



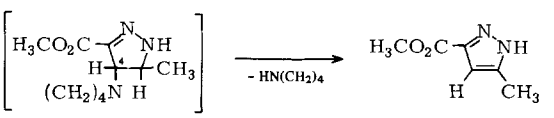
Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

Although diazomethane is inert towards enamines, α-diazo carbonyl compounds can undergo 1,3-dipolar cycloadditions with these compounds. *Piozzi et al.*[1] refluxed ethyl diazoacetate with *N*-(1-cyclohexenyl)pyrrolidine, -piperidine, or -morpholine for 2 h in $CHCl_3$, evaporated the mixture, and treated it for 15 min with 2 N HCl: they isolated the esters *(2)*, R = C_2H_5, in 55, 35, and 2% yield, respectively. Does cyclization of an open-chain precursor occur only after acid treatment?



(1) *(2)*

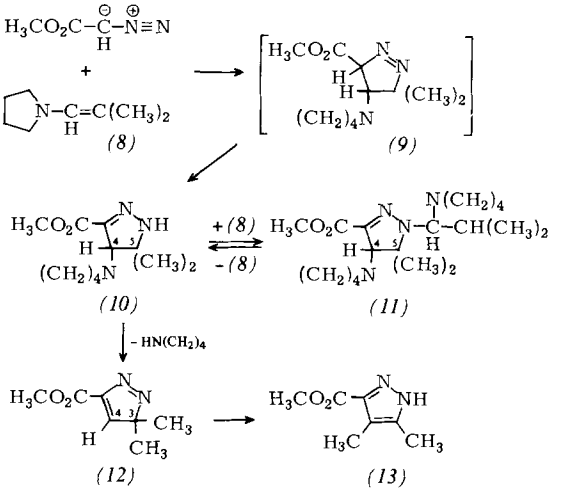
Such doubts proved groundless: we obtained compound *(2)*, R = CH_3 (82%), on reaction of methyl diazoacetate with *N*-(1-cyclohexenyl)pyrrolidine (3 weeks, 20 °C) without acidification. The analogous reaction with *p*-nitrodiazoacetophenone (1 h, 20 °C) gave 85% of *(2)*, *p*-$NO_2C_6H_4CO$ in place of RO_2C; pale yellow needles, m.p. 209—210 °C.



(3)

(4), R = H

(5), R = CO–NHC$_6$H$_5$



While aromatization induces elimination of HNR'_2 from *(1)*, this does not occur on reaction (4 d, 20 °C, ether) of dimethyl diazomalonate with *N*-(1-cyclohexenyl)pyrrolidine. The adduct (73% yield) was not *(3)* but its stable tautomer *(4)* (Table 1). The NH function of *(4)* is confirmed by reaction with phenyl isocyanate to give the phenylurea *(5)*. Compound *(4)* was transformed with HCl in boiling methanol into *(2)*, R = CH_3. The appearance of the NH function also establishes that the reactants are oriented according to *(3)* on cyclization; the primary product would not be able to tautomerize to the 2-pyrazoline *(4)* if the opposite orientation were to apply.

(6) *(7)*

Addition of methyl diazoacetate to freshly prepared *N*-(1-propenyl)pyrrolidine (*trans*:*cis* = 4:1, 3 d, 20 °C) was also followed by pyrrolidine elimination to give the pyrazole *(7)* (85% yield), whose synthesis from diazoethane and methyl propiolate served as structural proof. 3,5-Disubstitution left no doubt as to the intermediacy of *(6)*.

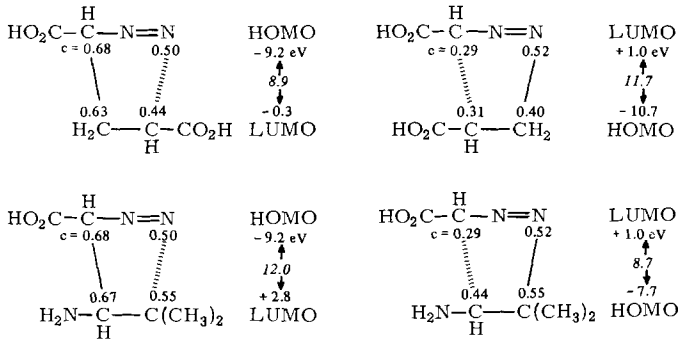
[*] Prof. Dr. R. Huisgen, Dr. H.-U. Reissig
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

(8) *(9)* *(10)* *(11)* *(12)* *(13)*

Use of a β,β-disubstituted enamine suppresses release of the secondary amine. Methyl diazoacetate combines with *N*-isobutenylpyrrolidine *(8)* (1:1, 8 h, boiling $CHCl_3$, 73%) to give the pyrazoline *(10)*[2]. Reaction in the ratio 1:2 (4 weeks, −5 °C, neat) gave the 1:2 adduct *(11)* (66% yield) which was also formed from *(10)* with further *(8)*. Just a little silica gel was sufficient to bring about the transformation *(11)* → *(10)*, whereas chromatography of *(10)* in ether over a large amount of SiO_2 afforded 92% of the 3*H*-pyrazole *(12)* with liberation of pyrrolidine [*(10)*—*(12)*, see Table 1]. Synthesis of *(12)* from methyl propiolate and 2-diazopropane[3] is known.

Table 1. Selected physical data of compounds *(4)*, *(10)*, *(11)*, and *(12)*.

Cpd.	M.p. [°C]	νNH [cm^{-1}]	^{1}H-NMR ($CDCl_3$), δ values
(4)	86—88	3360	6.15 (NH, disappears with D_2O), 3.74, 3.75 (2 s, 2 OCH_3)
(10)	64—66	3390	6.36 (s, br., NH), 3.83 (s, OCH_3), 3.88 (s, 4-H), 1.15, 1.28 (2 s, 2 CH_3)
(11)	62—68		3.82 (s, 4-H), 3.50 (s, OCH_3), 1.14, 0.70 (2 s, 2 5-CH_3), 1.03, 0.73 (2 d, 6 H, isopropyl-CH_3, J = 6.0 Hz) [a]
(12)	93.5—95		7.79 (s, 4-H), 3.98 (s, OCH_3), 1.52 (s, 2 CH_3)



[a] In C_6H_6.

On distillation of *(12)* (180–205 °C/12 torr) or on reaction with cold conc. sulfuric acid, van Alphen-Hüttel rearrangement[4] gave 63 and 57%, respectively, of the pyrazole *(13)*. It is also formed from diazoethane and methyl 2-butynoate.

The invariant orientation of the diazocarbonyl compound and enamines in the 1,3-dipolar cycloaddition is remarkable: 4-Aminopyrazolines [*(1)*, *(3)*, *(6)*, *(9)*] are the primary adducts. Addition to acrylic ester occurs in the opposite orientation, *i.e.* the ester group is located in position 3 of the adduct[5]. If cycloaddition were to proceed *via* a diradical intermediate[6], then the mentioned substituents on the dipolarophile should effect the *same* orientation in the adduct because the ester group, like alkyl or amino groups, can stabilize carbon radicals.

In concerted reactions, MO perturbation theory accounts for the observed *bidirectional behavior*. The second-order perturbation term gives the greatest bonding interaction for an orientation in which the atomic orbital coefficients are combined according to large-times-large and small-times-small. Only frontier-orbital interactions are considered in Scheme 1[8].

Scheme 1.

For diazoacetic acid + acrylic acid the two HOMO-LUMO interactions determine the opposite directions of addition; owing to the small energy difference HOMO(diazoacetic acid)-LUMO(acrylic acid) prevails, *i.e.* the 3,5-pyrazolinedicarboxylic ester is formed. With diazoacetic acid + *N*-isobutenylamine two HOMO-LUMO interactions cooperate in formation of the 4-amino compound.

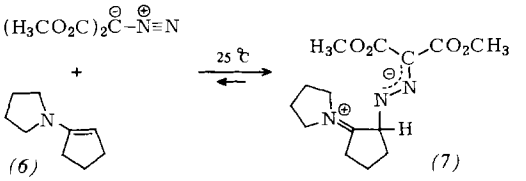
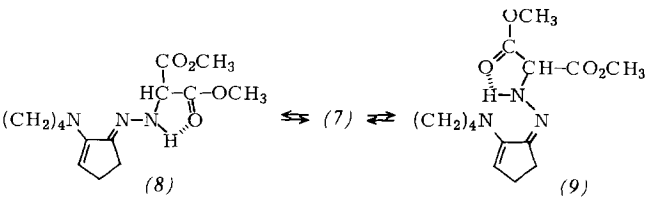
Azo Coupling of α-Diazo Carbonyl Compounds with *N*-(1-Cyclopentenyl)amines

By *Rolf Huisgen, Werner Bihlmaier*, and *Hans-Ulrich Reissig*[*]



Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

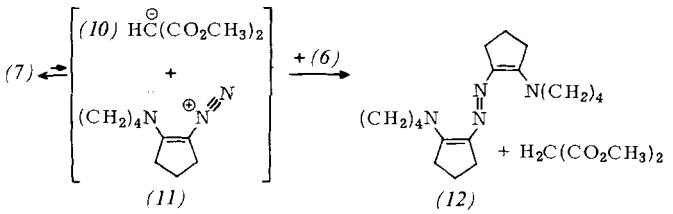
Combination of methyl diazoacetate with *N*-(1-cyclopentenyl)morpholine *(1)* (1 week, 20°C) gave a yellow crystalline 1:1 adduct, *viz.* enamine hydrazone *(4)*, in 51% yield [^{1}H-NMR ($CDCl_3$): δ = 4.2 (s, br. NH, vanishes with D_2O), 5.4 (t, J = 2.2 Hz, vinylic H, disappears with $D_3O^{\oplus}$), 3.95 (s, CH_2 of side chain) 3.70 (s, OCH_3)]. Compound *(4)* was accompanied by only 1—2% of the cycloadduct *(3)*; *(4)* could not be converted into *(3)*. The 1,3-dipolar cycloaddition[1] which dominates reaction of *N*-(1-*cyclohexenyl*)dialkylamines is suppressed by an azo coupling—presumably *via* the zwitterion *(2)*.



The enamine system of *(4)* added 4-nitrophenyl azide to give a triazoline (92% yield), which still contains the NH group ($\tilde{\nu}$ = 3290 cm^{-1}). Mild hydrolysis on silica gel transformed *(4)* into an oxo hydrazone with intramolecular NH bridge.

Dimethyl diazomalonate reacted with *(1)* even at −30°C in ether; an orange-yellow 65:35 mixture of crystalline enamine hydrazones *syn-(5)* and *anti-(5)*, respectively, (66% yield) could be precipitated with hexane. According to the ^{1}H- and ^{13}C-NMR spectra, the ester groups are equivalent [^{1}H-NMR (nitrobenzene): *syn-(5)* and *anti-(5)*, respectively, δ = 5.70 and 5.55 (NH), 5.12 and 4.98 (malonic ester H), 5.33 (vinylic H); all these protons exchange with $D_3O^{\oplus}$]. The UV maximum at 355 nm (log ε = 2.6, dioxane) reflects the conjugation of the enamine and the hydrazone system.

Are zwitterions of type *(2)* likely candidates as primary products? The zwitterion *(7)* obtained from the more nucleophilic species *N*-(1-cyclopentenyl)pyrrolidine *(6)* and diazomalonic ester is isolable. *(7)* was formed in ether or cyclohexane at 25°C in 93% yield; brick-red needles m. p. 89°C (dec.), which can be stored at −30°C; IR (KBr): $\tilde{\nu}$C=N$^+$ 1694, $\tilde{\nu}$C=O 1650 cm^{-1}. The color is due to intramolecular charge transfer interaction; λ_{max} ($CHCl_3$) 477 nm (log ε = 4.3). The weak diazomalonate absorption at 2135 cm^{-1} (in $CHCl_3$) indicated a dissociation equilibrium of *(7)* with the reactants. Distillation of *(7)* at 80—90°C/0.001 torr proceeded *via* retrocleavage and recombination; *(6)* was trapped by triazoline formation with 4-nitrophenyl azide placed in the receiver.



The IR solution spectra and the ^{1}H- and ^{13}C-NMR spectra of *(7)* also indicate equilibration with the *syn,anti* isomeric enamine hydrazones *(8)* and *(9)*. Their structural resemblance to the stereoisomers of *(5)* permitted assignment of the NMR signals to the zwitterion *(7)*. In pyridine at 32°C, 43% of *(7)* was present with 57% of *(8)* + *(9)* (in the ratio 1.4:1); the equilibrium is temperature dependent [in $CDCl_3$: 40% of *(7)* at −49°C, and 15% of *(7)* at +28°C]. The occurrence

[*] Prof. R. Huisgen, Dipl.-Chem. W. Bihlmaier, Dr. H.-U. Reissig
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

© Verlag Chemie, GmbH, 6940 Weinheim, 1979 0570-0833/79/0404-0331 $ 02.50/0

of two ester methyl signals ($\delta = 3.70$ and 3.75 in pyridine, 3.85 and 3.88 in $CDCl_3$) demonstrates the limited rate of equilibration[2].

Yet another equilibrium was indicated by the transformation of *(7)* in acetonitrile into orange crystals of $C_{18}H_{28}N_4$ (24 % yield), probably the azo-bis(enamine) *(12)*. We suspect a dissociation of *(7)*, with prototropic shift, into the anion *(10)* and the cation *(11)*, which combines with *(6)*, formed in the other dissociative equilibrium, to give *(12)*. Dimethyl

malonate could be detected. Such azo-bis(enamines) have been observed on reaction of dimesyl- and bis(phenylsulfonyl)diazomethane with substituted α-morpholinostyrenes[3].

Azo coupling of α-diazo carbonyl compounds with *N*-(1-cyclopentenyl)amines can be described in terms of MO perturbation theory by combination of the HOMO and LUMO centers with the greatest atomic orbital coefficients (cf. [1]). According to the ^{13}C-NMR spectra, C-4 has a somewhat greater charge density in cyclopentenylamines than in cyclohexenylamines. It could not be predicted, however, that this would lead to such drastic differences in reactions with α-diazo carbonyl compounds: azo coupling in the case of *N*-(1-cyclopentenyl)- and 1,3-dipolar cycloaddition with *N*-(1-cyclohexenyl)dialkylamines.

Oxidative Addition to a Quadruple Bond. The Complete X-ray Structure of $[Mo_2Cl_8H]^{3-}$ [**]

By *Avi Bino* and *F. Albert Cotton*[*]

The preparation of the $[Mo_2Cl_8H]^{3-}$ anion was first described about ten years ago[1] although the presence of the hydrogen atom was not then recognized. A few years later the bromo analog, $[Mo_2Br_8H]^{3-}$ was reported[2]. In 1976 the coordinated hydrogen atom was demonstrated by a combination of chemical observations, isotopic labeling experiments and infrared spectra[3]. The chemical process by which these ions are obtained was thus shown to be represented by eq. (1):

$$Mo_2^{II}(O_2CCH_3)_4 + 8\,HX \rightarrow [Mo_2^{III}X_8H]^{3-} + 3\,H^+ + 4\,CH_3CO_2H \quad (1)$$

This reaction appears to be quantitative when carried out (a) at temperatures of 60 °C and above, and (b) with exclusion of O_2. It had earlier[4] been shown that at 0 °C a simple metathesis takes place according to:

$$Mo_2^{II}(O_2CCH_3)_4 + 8\,HX \rightarrow [Mo_2^{II}X_8]^{4-} + 4\,H^+ + 4\,CH_3CO_2H \quad (2)$$

Reaction (1) constitutes the first unambiguous recognition of oxidative addition to a well-defined metal-metal multiple bond.

The $[Mo_2Cl_8H]^{3-}$ anions have since been shown to have interesting chemical properties[5]; however, their characterization remained incomplete in two respects: Direct structural evidence for the bridging hydrogen atom was lacking, and the conformation of the anion, when not constrained to occupy, in a disordered fashion, a position of D_{3h} symmetry, was unknown.

We report here experimental results that supply the above information. We have found that by modifying the reaction conditions and using cations other than those of the alkali metals, a great variety of well-crystallized salts of the $[Mo_2X_8H]^{3-}$ anions can be easily prepared. One of these new salts, the pyridinium salt $[C_5NH_6]_3[Mo_2Cl_8H]$, has been studied by X-ray crystallography and a complete structural characterization of the anion (including the location of the hydrogen atom) was achieved for the first time.

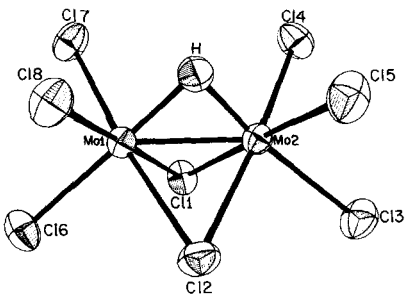

Fig. 1. The structure of the $[Cl_3Mo(\mu\text{-}Cl)_2(\mu\text{-}H)MoCl_3]^{3-}$ ion as it occurs in $[C_5NH_6]_3[Mo_2Cl_8H]$. Atoms are represented by their ellipsoids (sphere for H) of thermal vibration at the 50 % probability level.

The pyridinium salt crystallizes in the space group $P\bar{1}$ with $Z = 2$; the anion has no crystallographically imposed symmetry (Fig. 1). After a structural model omitting hydrogen atoms had been refined to convergence a difference electron density map revealed peaks corresponding to hydrogen atoms, one of which was in a bridging position in the anion. Hydrogen atoms for the three independent $[C_5NH_6]^+$ cations were placed at calculated positions and not refined, while the H atom in the anion was refined isotropically and the other atoms were all refined anisotropically. Using 2786 reflections with $I > 3\,\sigma(I)$ and 257 variables final discrepancy indices of $R_1 = 0.026$, $R_2 = 0.040$ and a goodness-of-fit parameter equal to 1.008 were obtained.

It is clear that in the previous structures the fact that the $[Mo_2X_8H]^{3-}$ anions were constrained to disordered occupation of sites of $\bar{6}m2$ (D_{3h}) symmetry obscured important details of their structure. The virtual symmetry of the $[Mo_2Cl_8H]^{3-}$ anion is mm (C_{2v}), where the mirror planes intersect at the μ-H atom; one contains the Mo atoms and the other the μ-Cl atoms. The terminal atoms *trans* to μ-H have a mean Mo—Cl bond distance (Table 1) significantly longer (0.10 Å)

Mo—H [Å]	—	1.74(1)
Mo'—H [Å]	—	1.62(1)
∢ Mo—H—Mo' [°]	—	89.6(3)

[a] Bonds *trans* to μ-Cl. [b] Bonds *trans* to μ-H.

than those *trans* to μ-Cl. The Mo—Mo and Mo—Cl_b distances and the mean Mo—Cl_b—Mo' are the same as those found before.

The μ-H atom refined as well as can be expected using X-ray data[6,7]. The mean Mo—H distance, the Mo—H—Mo' angle (Table 1) and an isotropic temperature parameter of 3.0 Å^2 for this atom are reasonable values and are consistent with the view that a symmetrically bridging hydrogen atom with appreciable hydride character is present.

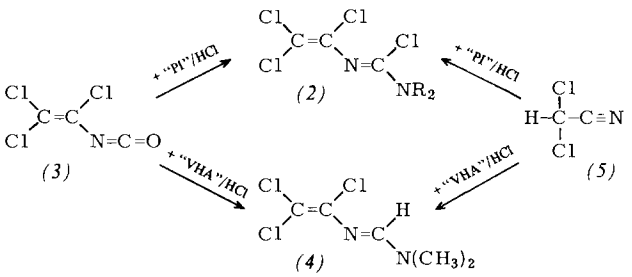
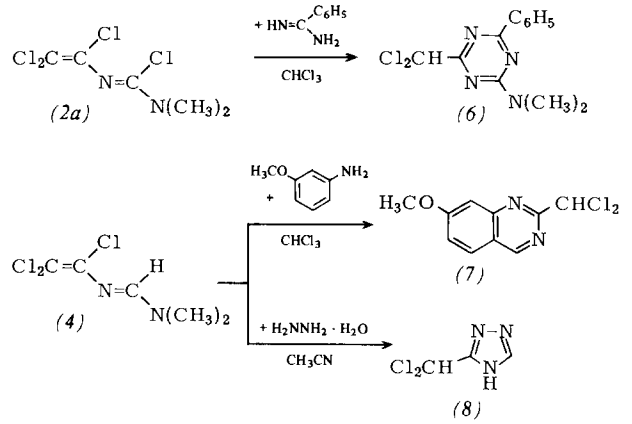
N^2-(Trichlorovinyl)amidines—New 1,3-Biselectrophilic Reagents[**]



By *Didier Van Broeck, Zdenek Janousek, Robert Merényi*, and *Heinz Günter Viehe*[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday.

Isocyanates and vinyl isocyanates behave as masked primary amines and vinylamines towards strongly electrophilic iminium salts in the presence of hydrogen chloride. The unstable carbamoyl chlorides *(1)* formed as intermediates suffer electrophilic attack by either phosgeniminium chloride [dialkyl(dichloromethylene)ammonium chloride] (PI)[1] or by the Vilsmeier-Haack-Arnold reagent (VHA)[2] with simultaneous loss of phosgene.



Thus, trichlorovinyl isocyanate *(3)* reacts smoothly both with PI and VHA/HCl to give the new N^2-(trichlorovinyl)-chloroformamidines *(2)* and N^1,N^1-dimethyl-N^2-(trichlorovinyl)formamidine *(4)*, respectively. An equally useful alternative route to *(2)* and *(4)* consists in using dichloroacetonitrile *(5)* as starting material[3].

Like trichlorovinyl isocyanate[4] both *(2)* and *(4)* are valuable 1,3-biselectrophilic reagents, especially for heterocyclizations.

Thus *(2a)* (R=CH_3) reacts with benzamidine to give the trisubstituted triazine *(6)* in 80% yield, while reaction of *(4)* with *m*-methoxyaniline affords the quinazoline *(7)* (50%), and with hydrazine hydrate the triazole *(8)* (55%).

Some physical data are listed in Table 1.

Table 1. Physical data of the compounds *(2a)*, *(4)*, *(4)*·HCl, *(6)*·HCl, *(7)* and *(8)*.

Experimental

(2a) from *(3)*: Dry HCl is slowly introduced into a refluxed suspension of 0.012 mol PI (R = Me) and 0.01 mol *(3)* in 60 ml dry $CHCl_3$ until all the PI has dissolved. The residue obtained after evaporation of the solvent is distilled in a Kugelrohr at 85—90 °C/0.01 torr; 2.03 g (86 %) of *(2a)* is obtained as a colorless oil.—Similarly, with PI, R = C_2H_5 and NR_2 = pyrrolidino, 93 % of *(2b)* and 90 % of *(2c)*, respectively, were obtained.—*(2a)* from *(5)*: A suspension of 0.045 mol PI (R = CH_3) and 0.04 mol dichloroacetonitrile in 100 ml anhydrous $CHCl_3$ is refluxed in the presence of gaseous HCl until all the PI has dissolved. Yield after workup (see above): 88 %.

(4) from *(3)*: A solution of 0.01 mol of *(3)* in 20 ml anhydrous CH_2Cl_2 is added to a stirred solution of 0.01 mol VHA in 40 ml of the same solvent at 0 °C, while anhydrous HCl is introduced slowly into the reaction mixture (about one hour at 0 °C). The solution is then refluxed for 30 min, the solvent is removed and the residue washed twice with ether. The yellow powder so obtained is treated with a concentrated solution of K_2CO_3 and extracted with CH_2Cl_2. After drying and removal of the solvent, *(4)* is obtained as a white powder. Yield: 65—75 %.—Hydrochloride of *(4)* from *(5)*: A solution of 0.03 mol *(5)* in 50 ml anhydrous CH_2Cl_2 is added dropwise to a solution of 0.03 mol VHA in 80 ml anhydrous CH_2Cl_2 saturated with dry HCl and cooled to −20 °C. After about two hours the mixture is allowed to slowly warm to room temperature. The solvent is partially removed in a rotary evaporator, whereupon yellowish needles crystallize out; yield 60—65 %.

BOOK REVIEWS

Einführung in die Pharmazeutische Chemie (Introduction to Pharmaceutical Chemistry). By *O. E. Schultz*. Verlag Chemie, Weinheim 1978. xvi, 460 pp., 15 figs., 83 tables, bound, DM 56.00.

New textbooks on pharmaceutical chemistry are welcome, since there are not many of them in German. As is appropriate for an introduction, the author has made a representative selection of the most important pharmaceuticals. The book is divided into six sections: Central Nervous System, Peripheral Nervous System, Disinfectants, Substances for the Chemotherapy of Infections and Cytostatics, Organs, and Vitamins. Each chapter in these sections is introduced by a brief pharmacodynamic or biological characterization of the group of pharmaceuticals, at times with notes on the action mechanism or on structure-activity relationships. This is followed by a tabular summary of the substances with tradename, chemical name, formula, and international abbreviation; next come synthesis or source (natural products), qualitative tests (identity and purity), and quantitative determination, together with data on activity and application.

Even though it is assumed that the reader has some basic chemical knowledge, reference to the classical reactions of organic chemistry (*e.g.* named reactions) is often missing, as to a certain extent is the clear application of the concepts of tautomerism and resonance. There is a note in the foreword stating that in the analytical sections the procedures and requirements of DAB 7, EuPharm, and some other national pharmacopeias have been taken into account; nevertheless, detailed information should still have been given in the text. In the same way, notes on the areas of agreement and disagreement between the pharmacopeias mentioned would have been desirable. Further important aspects of pharmaceutical chemistry are the stability of pharmaceuticals and pharmacokinetic parameters; the latter could stimulate the synthesis of derivatives.

The development of pharmaceutical chemistry from a collection of random observations to a system of systematic research is not taken into account, though from the didactic viewpoint this is just as important as the listing of research workers who have made fundamental contributions to this multidisciplinary field of research. This type of information could have been included as footnotes or in a table.

There are also some inorganic pharmaceuticals (*e.g.* lithium carbonate) that have not been mentioned. In addition (and this is possibly due to the structure of the book), some important groups of pharmaceuticals get too short a mention (*e.g.* anticoagulants) or no mention at all (*e.g.* analeptics, pentetrazole).

The style of the book is good; the few errors in structural formulae could easily be corrected in a later edition. The over-all impression is that this "Introduction" has successfully extended the range of textbooks in the field of chemistry.

K. E. Schulte [NB 462 IE]

Transient Techniques in Electrochemistry. By *D. D. MacDonald*. Plenum Press, New York—London 1977. 1st edit., xii, 329 pp., numerous illustrations, bound, $ 45.00.

This book deals with the relaxation phenomena that may be observed at the electrodes of galvanic cells as the voltage or current changes with time. Since one can specify either the current or the voltage as external parameters in a large number of ways, a variety of experimental techniques has sprung up, so that it is difficult even for the expert to remember them all. In this book the author gives an ordered presentation of such techniques, and in particular chronoamperometry, chrono-potentiometry, cyclic voltammetry, and alternating-current methods. He places special emphasis on an explanation of the mathematical principles for the analysis of the reaction couplings that lead to relaxation phenomena. A good summary of the expected time lapses is provided, and this will prove

© *Verlag Chemie, GmbH, 6940 Weinheim, 1979* *0570-0833/79/0404-0334 $ 02.50/0*

very helpful to readers wishing to familiarize themselves with theoretical deviations.

The final aim of such studies is to obtain information on the mechanism of the electrode reactions concerned from the analysis of the relaxation process. However, the book is not very helpful in explaining which method is most suitable for a specific purpose. The techniques are arranged one after the other without any evaluation. One of the most effective techniques, the current-pulse method (coulostatic method) is not even mentioned. Practical examples are rare. The book is suitable for readers who enjoy clear mathematical derivations and who already have practical experience, or who are prepared to turn to other sources for advice.

Heinz Gerischer [NB 452 IE]

Biochemistry—The Chemical Reactions of the Living Cell. By *D. E. Metzler*. Academic Press, New York 1977, xxxii, 1129 pp., bound, $ 24.95.

The simple anatomical classification of physiological chemistry—chemistry here, metabolic chains there, and one or two appended chapters on hormones, body fluids, and organs—was a historical consequence of its predominantly medical alignment. General biochemistry appeared as biology became more and more aware of its chemical basis and the dynamic nature of the body's building blocks. It culminated in the clever idea of *Fruton* and *Simmonds* that proteins (as biocatalysts) should be the central teaching point, with physicochemical considerations and the structure and metabolism of other biological molecules grouped around them. The more successful of their followers hardly changed this principle of a predominantly biological functional point of view, but chose different aspects to emphasize. Thus, *Lehninger* made energetics and *Styrer* made molecular information the main theme, while *Mahler* and *Cordes* took as their starting point the physical chemistry of cellular processes. In principle, it is possible to break down the network of cellular organization from many aspects. Each of these books, however, set a standard, and any new attempt must be measured against its predecessors, although as far as the chemist is concerned they all lack the chemical perspective. A comprehensive textbook, which is intended to lead biochemistry systematically back to chemical concepts, will therefore unavoidably be regarded with critical curiosity.

Such an attempt has now been undertaken by *Metzler* with his monumental work, and the goal is impressively well achieved, for the author not only has available a wide range of material but is also given authority by his own work in the field of the transfer from chemical reaction models to biological catalysis. Since the book is intended for readers without much basic biological expertise, although it also makes provision for the biologist, it starts with an introduction to cellular structure, together with the fundamentals of molecular energetics and subject-related thermodynamics (all data are given in SI units). The interactions between biomolecules and the internal organization of the cell are treated in detail, and the characteristics of enzyme catalysis are discussed in relation to the chemical reaction types, which are admittedly rather limited[*]. This knowledge is applied to a detailed description of the metabolic process. Optical analytical techniques are accommodated in the chapter on photobiology. Nitrogen metabolism has a chapter to itself; so do biochemical genetics and metabolic homeostasis. At the end of each chapter there are study questions, some of them never likely to be answered. The text is very attractively printed and easy ro read, vividly supplemented by structural and reaction formulas, flowsheets, and tables; anecdotal information in green-colored boxes (shown in the same way in the table of contents) is added as a spice to the basic blend.

It is unavoidable that even a system as well thought out and consistently applied as this one should have its weaknesses. For example, it has recently become easier to give a clear chemical description of the role of selenium in metabolism, and the reason why the respiration chain phosphorylation cannot be chemically coupled in the given stoichiometry can now be given more intelligibly; the principal criticism that can be raised, however, is that today chemistry is capable of more than bending electron arrows or perfecting nucleophilic and electrophilic attacks. Chemistry has become a highly sophisticated extrapolating science, and I can see little sign of it here. Why, for example, is cobalt suitable as the central metal of vitamin B_{12}; what is the reason for the structure of the respiration chain (which has now been largely clarified); what is the salient point of the chemical osmosis hypothesis as against the "protonated membrane" hypothesis; what requirements must be met by a cofactor that takes up electrons and protons simultaneously but separately; how can we link molecular motion with the charge distribution? And so it goes on. But perhaps we are asking too much of a textbook that is already very extensive; we really need a new medium, allied to cinematography; words, even symbols, make everything static, two-dimensional, consecutive. However, what is such nitpicking when applied to an attempt designed on a grand scale, and in the final analysis so successful, which also, because of the many and carefully collated literature references, amounts to far more than a textbook? It would be wonderful if the book not only met with acclaim among chemists but were also used by biologists and introduced them to the chemical foundations of biochemistry. Our comparison of textbooks can be summarized as follows: *Stryer* for appearance—*Lehninger* for feeling—*Metzler* for understanding—but there is still no book on biochemistry that meets all the requirements.

L. Jaenicke [NB 460 IE]

Singlet Oxygen, Reactions with Organic Compounds and Polymers. Edited by *B. Rånby* and *J. F. Rabek*. John Wiley & Sons, New York, 1978. 1st edit., 331 pp., bound, £ 15.00.

"Singlet oxygen" ($^1O_2$) is the term used to describe two short-lived and reactive electronic excitation states of oxygen ($^3O_2$). The present book contains 34 papers presented at the EUCHEM conference on "Singlet Oxygen Reactions with Polymers", held in Södergarn, Sweden, in September 1976.

A historical survey is followed by papers on the properties of $^1O_2$ and on the spectroscopic determination and the deactivation of $^1O_2$ species in the gas phase. The greater part of the book (16 papers, 187 pages) is devoted to the reactions of $^1O_2$ in solution. The kinetics of the formation of $^1O_2$ by energy transfer from electronically excited sensitizers to $^3O_2$ is the main point of two contributions.—*Belluš* gives an excellent survey on the mechanism and the rate constants of the deactivation of $^1O_2$ by organic substrates (50 pages). This topic is further discussed in two other short papers. Attention should also be drawn to the review by *Gollnick* (24 pages) on the reactions of $^1O_2$ with organic compounds. This is followed by ten short papers (76 pages) on the photooxidation of selected compounds.

The last third of the book (14 papers, 114 pages) deals with the reactions of polymers with $^1O_2$ and is introduced

[*] In connection with this I recall *H. Meerwein*'s disapproving comment: How can you limit your interest to biochemistry if you want to be a proper chemist? There is an air of monotony about the few reactions that are found there: water in and water out; hydrogen out and back in again ... Keep well away from it. In contrast, how wide-ranging are the possibilities of synthetic catalysis!

by a review by *Rånby* and *Rabek* (13 pages). The main interest of the papers lies in the mechanism of photo-oxidation and photochemical degradation of polymers (polyenes, polydienes, polystyrene, lignin), and in the resultant changes of physical properties. Two final papers deal with the action of photostabilizers.

The book offers the specialist a survey of the whole range of work with $^1O_2$ as it was in about the middle of 1976. Anyone wanting a detailed introduction to a specific topic would, however, do better to consult other monographs and review articles.

Permeability of the Outer Membrane of Bacteria

By Hiroshi Nikaido[*]

The outer membrane of Gram-negative bacteria is an attractive system for the study of the structure-function relationships in biological membranes. This membrane has, *inter alia*, the task of regulating the inflow of nutrients and outflow of waste products. Investigations with the aid of mutants showed that there are at least two general pathways for the diffusion of small molecules across the outer membrane: one for hydrophobic and one for hydrophilic compounds. In the case of the "hydrophobic pathway" the hydrophobic compound dissolves in the interior of the membrane and then crosses the membrane in accordance with the partition coefficient. In wild-type forms of enteric bacteria this pathway cannot be used—presumably owing to the absence of regions with phospholipid bilayers. Small hydrophilic molecules, on the other hand, penetrate the membrane through water-filled pores.

1. Introduction

Bacterial cells are usually covered by cell wall, which is located outside the cytoplasmic membrane. Under the electron microscope, thin sections of Gram-positive bacteria usually reveal the cell wall as a thick, diffuse, structureless layer. It consists mainly of murein (peptidoglycan). In contrast, thin sections of Gram-negative bacteria, *e.g. Escherichia coli* and *Salmonella typhimurium*, show that their cell wall is composed of at least two layers, an outer layer ("outer membrane") that gives a trilaminar image resembling any other biological membrane, and an inner, structureless layer that corresponds to the main component of Gram-positive cell wall, the murein[1] which is mainly responsible for the mechanical strength of the wall (Fig. 1).

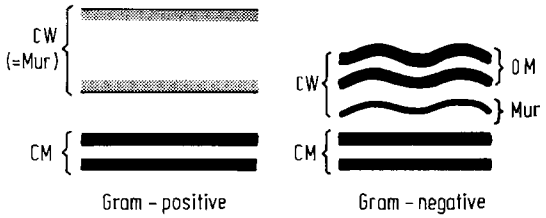

Fig. 1. Appearance of the surface layers of bacteria in thin sections. CW, cell wall; CM, cytoplasmic membrane; OM, outer membrane; Mur, murein (= peptidoglycan). Both Gram-positive and Gram-negative cells may contain extra layers of cell wall in addition to those shown here.

The outer membrane can be isolated from *E. coli* or *S. typhimurium*[2, 3], and was found to contain only a few major species of proteins (Fig. 2)[3–6]. These include (a) one to three proteins with molecular weights of 34000—36000, which are referred to as "porins", because they produce transmembrane diffusion channels (see Section 4), (b) usually one "heat-modifiable" protein (HMP, molecular weight of about 33000),

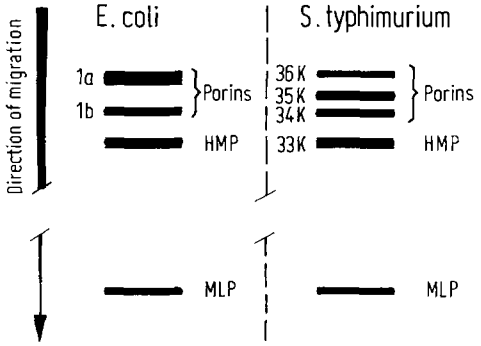

Fig. 2. Patterns of major proteins of the outer membrane as revealed by SDS-polyacrylamide gel electrophoresis. HMP, "heat-modifiable protein"; MLP, murein lipoprotein. Porins in *E. coli* have been called protein(s) 1, protein(s) I, "matrix protein", proteins b and c, and 0—9 and 0—8, in various laboratories. HMP in *E. coli* has been called protein 3a, II*, d, and 0—10. Porins in *Salmonella* have been called 36K, 35K, and 34K on the basis of their apparent molecular weights, and HMP, 33K (SDS = sodium dodecyl sulfate).

so called because its mobility in acrylamide gel electrophoresis changes in an unexpected manner upon heating, and (c) murein lipoprotein (MLP), a small protein containing 58 amino acid residues and covalently bound lipids[7]. About 30% of the lipoprotein is covalently linked to the underlying murein layer. It also contains two kinds of amphipathic molecules: phospholipids and lipopolysaccharides (LPS) (cf. also Fig. 15).

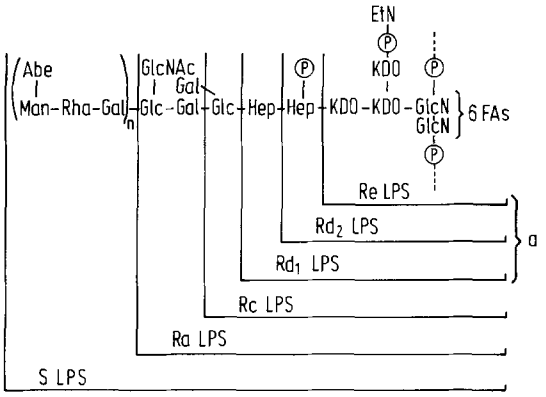

Fig. 3. Structure of lipopolysaccharides (LPS) from *S. typhimurium*. Biosynthesis proceeds generally toward the left in this figure. Thus wild-type cells complete the synthesis of the entire structure ("S-LPS"), whereas R mutants blocked at various steps of biosynthesis produce incomplete structures ("Ra through Re LPS"; a: deep rough mutants). Abbreviations: Abe, abequose; Man, D-mannose; Rha, L-rhamnose; Gal, D-galactose; GlcNAc, N-acetyl-D-glucosamine; Glc, D-glucose; Hep, L-*glycero*-D-*manno*heptose; P, phosphate; KDO, 3-deoxy-D-*manno*octulosonic acid (2-keto-3-deoxy-octonic acid); EtN, ethanolamine; and FA, fatty acid.

A series of genetic mutants producing LPS with variously defective polysaccharide chains are known; the structure of LPS produced by these mutants (Ra through Re) of *S. typhimurium* is shown in Figure 3[8, 9]. Mutants lacking one or more outer membrane proteins have recently been reported[10–14]. The availability of these mutants makes it possible to intentionally alter the composition of the membrane, and this possibility of "genetic engineering", together with the simple protein composition, makes the outer membrane an attractive system for the study of the structure-function relationships in biological membranes.

The lipid bilayer structure, in which the hydrocarbon chains are arranged approximately at right angles to the plane of the membrane and form its hydrophobic interior, seems to correspond to the basic continuum of the outer membrane as in other biological membranes. The data supporting this conclusion include the following:

(i) At least some of the lipid hydrocarbons of the outer membrane are arranged in one orientation, and the hexagonal quasi-crystalline packing of these chains disappears at high temperature through the process of cooperative "melting", as can be shown by X-ray diffraction[15, 16], as well as electron spin resonance performed after the insertion of spin-labeled probe molecules[17, 18].

(ii) With lipid bilayer membranes, freeze-fracturing produces cleavage in the center of the membrane[19]. Similar cleavage of the outer membrane has been observed repeatedly[20–23].

The major function of the outer membrane apparently is to serve as a penetration barrier and to protect the underlying murein layer from attack by hydrolytic enzymes (such as lysozyme) that are prevalent in Nature. This is suggested by the observation that during evolution the structure of the murein has undergone a tremendous diversification in Gram-positive bacteria, presumably owing to the selective pressure for novel, hydrolase-resistant structures, whereas in Gram-negative bacteria there is no sign of such an evolutionary diversification of the murein structure[23, 24]. The outer membrane should, however, also allow the passage of nutrients and waste products, *i.e.* it should possess a selective permeability, and in this respect should be similar to many other biological membranes. In the latter membranes, however, the transmembrane diffusion is often accomplished by the process of active transport, a process unlikely to operate in the outer membrane because of its location outside the cytoplasmic membrane.

Up to 1975 only a few scattered observations had been published on the selective permeability of the outer membrane. Thus, careful kinetic studies of the exit of β-galactosides from *E. coli* cells revealed the presence of a partial diffusion barrier "outside the cytoplasmic membrane"[25]. *Payne* and *Gilvarg*[26] found that *E. coli* could not utilize peptides exceeding a certain size limit, presumably because they were excluded by "a barrier located outside the cytoplasmic membrane". Since these results told us little about what molecules are excluded by, and what kind of molecules diffuse through, the outer membrane, or about the mechanisms involved in their exclusion or penetration, we decided to define systematically the selective permeability properties of the outer membrane, using mostly *S. typhimurium* and *E. coli*. But before such an attempt was undertaken, it was essential to know whether there are one or more pathways of transmembrane diffusion operating in the outer membrane. Studies on LPS mutants[27, 28] provided an important clue to this question.

2. Multiplicity of Diffusion Pathways

The availability of mutants with defined biochemical defects in LPS synthesis[8, 9] (Fig. 3) made it possible to experimentally alter the structure of a component of the outer membrane, and to study the effect of such alterations on the permeability of the membrane. These studies, initiated by *Roantree* and *Stocker*[27] as well as *Schlecht*, *Schmidt*, and *Westphal*[28], revealed the following: (a) Wild type strains of *Salmonella*,

E. coli, and other related bacteria are naturally sensitive to a number of antibiotics including neomycin, cycloserine, ampicillin, and cephalothin. The sensitivity to these antibiotics was not affected much by alterations in LPS structure. (b) On the other hand, these strains are much more resistant than most Gram-positive bacteria to some other antibiotics including actinomycin D, erythromycin, novobiocin, and rifamycin SV, to such dyes as crystal violet, and to such detergents as bile salts and sodium dodecyl sulfate. The sensitivity to these agents, however, increases drastically in "deep-rough" mutants of *Salmonella*[27,28] and *E. coli*[29] that produce extremely defective LPS of Rd_1, Rd_2, and Re-type (Fig. 3), and approaches the level seen in Gram-positive bacteria.

In addition to the approach described above, the structure of the outer membrane can be altered by removing up to 50% of LPS molecules by treating *Salmonella* or *E. coli* cells briefly with ethylenediaminotetracetic acid (EDTA)[30]. *Leive*[31] discovered that the partial removal of LPS increases the sensitivity of the organism toward actinomycin D. Subsequent studies[32] showed that the treated cells became sensitive also to polymyxin, novobiocin, rifampicin, long-chain fatty acids, and detergents.

Since the outer membrane is the only subcellular structure that contains LPS in substantial amounts[2,3], and since the targets of action of antibiotics and dyes examined are usually located in the cytoplasmic membrane or in the cytoplasm, the results described above suggest that the outer membrane normally acts as penetration barrier for certain kinds of molecules and that this barrier function can be diminished by the mutational alteration of LPS or by the removal of LPS with EDTA. Furthermore, the presence of another group of agents whose efficacy is not influenced by mutations in LPS synthesis suggests the multiplicity of the mechanism of diffusion across the outer membrane: thus there would be at least one diffusion pathway that is influenced by the structure or the amount of LPS in the outer membrane, and at least another that is not.

How, then, is any compound assigned to one of these pathways? A review of the structure of various compounds tested suggested to us that the compounds whose efficacy is increased in deep rough mutants and in EDTA-treated cells are usually hydrophobic. When the hydrophobicity of these compounds was determined quantitatively by measuring their partition coefficients in 1-octanol/phosphate buffer (pH 7.0), it was indeed found that the greater number of them had partition coefficients higher than 0.07[33] (Table 1). In contrast, the majority of the compounds whose efficacy was unaffected by LPS structure were quite hydrophilic, with partition coefficients lower than 0.02[33] (Table 1). The simplest explanation of these results is as follows: (a) There are at least two *general* pathways for the diffusion of small molecules across the outer membrane, one for hydrophilic compounds, and one for hydrophobic compounds. (b) The "hydrophilic pathway" is not affected much by the structure of LPS present. (c) The "hydrophobic pathway" is almost inactive in wild type strains producing complete LPS; it becomes fully active only in deep rough mutants or in EDTA-treated cells. The nature of this hydrophobic pathway is described in the next section.

Table 1. Hydrophobicity, molecular weight and relative efficacy (based on wild type = 1) of inhibitors against deep rough mutants [a].

Inhibitor Agent	Rel. efficacy	Hydrophobicity [b]	Mol. wt.
Actinomycin D	≥10	>20	1255
Novobiocin		>20	613
Phenol		>20	94
Crystal Violet		14.4	408
Rifamycin SV		8.8	698
Malachite Green		4.2	365
Nafcillin		0.31	414
Oxacillin		0.07	418
Vancomycin		> 0.01 [c]	≈3300
Penicillin G	0.5—1.0	0.02	334
Ampicillin		> 0.01	349
Cephalothin		> 0.01	395
Carbenicillin		> 0.01	378
Neomycin		> 0.01	615
Cycloserine		> 0.01	102
Chloramphenicol		12.4 [c]	323
Tetracycline		0.07 [c]	444

[a] Modified after ref. [33]. [b] Determined in a system containing equal volumes of 1-octanol and 0.05 M sodium phosphate buffer (pH 7.0) at 24°C. [c] For unknown reasons, these compounds do not follow the general tendency.

3. Barrier Properties against Hydrophobic Molecules

3.1. Measurement of Transmembrane Diffusion Rates

Most biological membranes are known to allow the transmembrane diffusion of small, hydrophobic compounds[34]; the outer membrane of deep rough mutants apparently behaves in a similar manner. In contrast, the results described in the preceding section suggest that the outer membranes of wild type *Salmonella* and *E. coli* constitute an exception in that they are not penetrated by many hydrophobic compounds.

These conclusions, however, were based on the inhibitory effects measured by using whole cells, and we could only infer that the difference in sensitivity reflected differences in penetration rates. A more direct approach was taken by *Gustafsson et al.*[35], who showed that the rates of uptake of crystal violet by intact cells were dependent on the nature of LPS present. These results, however, were complicated by the massive adsorption of the dye to unidentified cellular constituents. We have overcome this difficulty by using a high concentration of a semi-synthetic penicillin, nafcillin, as the permeant[33]. When nafcillin was added to thick suspensions of the cells of deep rough mutants, its extracellular concentrations at time $t=0$ and $t=\infty$ (actually 5 to 10 min at 22°C), determined on supernatants after centrifugation, were equal to those predicted on the assumption that nafcillin existed only in the extracellular space at $t=0$ and was distributed uniformly in extracellular and intracellular spaces at $t=\infty$. Adsorption, degradation, or active transport was therefore negligible under these conditions. Furthermore, the kinetics of diffusion followed a theoretical equation, and first-order rate constants for permeation could thus be calculated. These quantitative diffusion assays led us to the following conclusions[33]: (a) Permeation through the cytoplasmic membrane (measured with sphaeroplasts[*]) was at least ten times more rapid than the penetration rates into intact deep rough mutant cells. Thus in whole cells the permeation through the outer

[*] Sphaeroplasts are formed in the case of Gram-negative bacteria, *e.g.* by the action of lysozyme plus EDTA.

membrane is the rate-limiting step. (b) The permeation rate constants were low in the wild type (S) as well as in Ra and Rc mutants (see Fig. 3), but were much higher in deep rough (*i.e.* Rd_1, Rd_2, and Re) mutants (Fig. 4).

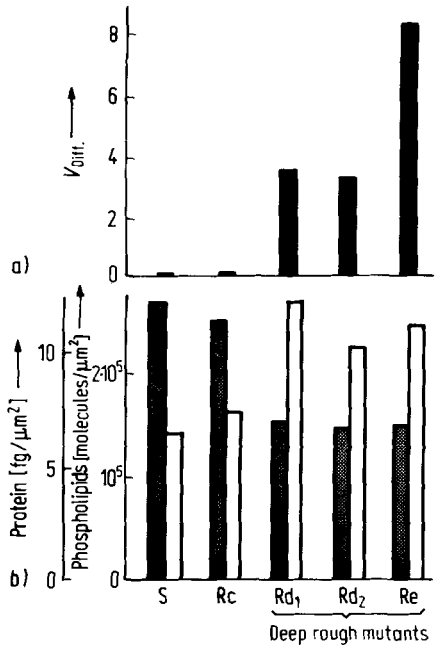

Fig. 4. a) Rate of diffusion of a hydrophobic solute, nafcillin, across the outer membranes of *S. typhimurium* strains (arbitrary units); b) composition of the outer membrane in these strains (after [22]). Rates of diffusion into intact cells were actually determined, but they reflect the diffusion rates across the outer membrane [33]. The diffusion rate does not increase significantly even when about 90% of the saccharide residues are lost as in the Rc mutant, but increase suddenly in correspondence with the increase in phospholipid content (and decrease in protein content) occurring in the deep rough mutants. In b), open and stippled bars represent phospholipids and proteins, respectively.

3.2. Mechanism of Diffusion of Hydrophobic Compounds

The mechanism of transmembrane diffusion of hydrophobic molecules has been studied extensively since the pioneering work of *Collander* and *Bärlund*[36], and it is known that the diffusion rates are faster with molecules of smaller size, with those of higher hydrophobicity, and at higher temperature[34,37–39]. The critical analysis of these results suggested that the permeant molecules first dissolve in the hydrophobic interior of the membrane, diffuse through the thickness of the hydrocarbon layer, and then cross the membrane by partitioning into the aqueous phase on the other side of the membrane[37]. In order to test whether hydrophobic substances penetrate through the outer membrane of deep rough mutants by a similar mechanism, we measured the influence of various conditions on diffusion rates, and obtained the following results: (a) Among compounds of similar size, the diffusion rate was faster with the more hydrophobic compounds. (b) The diffusion rates were extremely dependent on temperature, with a Q_{10} value (ratio of the rates at T°C and $(T-10)$°C) close to 10. (c) Compounds with fairly large size apparently penetrated the outer membrane by this mechanism, and there was no indication of a clear-cut size limit. These results strongly suggest that the hydrophobic compounds cross the deep rough outer membrane through dissolution into the membrane interior.

3.3. Structural Basis for the Lack of Permeability toward Hydrophobic Compounds

We have seen that the outer membrane of the wild type *Salmonella* is essentially impermeable to hydrophobic compounds. This is surprising, since small hydrophobic molecules diffuse rapidly across artificial phospholipid bilayers as well as most biological membranes[34,40]. Our first explanation was that the hydrophobic molecules could not diffuse through the hydrophilic surface layer that is composed of the saccharide chains of LPS. However, the outer membrane of Rc mutants, which are missing 80—90% of the saccharide residues found in the wild type (Fig. 3), is still impermeable to hydrophobic antibiotics, whereas Rd_1 mutants, which lack only one more sugar residue in LPS in comparison with Rc mutants (Fig. 3), produce an extremely permeable membrane. Thus there is a sudden and discontinuous increase in the hydrophobic permeability (Fig. 4a) when we compare strains producing LPS with saccharide chains of gradually diminishing chain length; these results are difficult to explain with the hypothesis presented above.

An important observation that later led us to an alternative hypothesis was made by *G. F.-L. Ames* in 1974[5]. She found that the protein content of the outer membrane remains more or less constant as the length of the saccharide chain of LPS becomes progressively shorter, down to the level of Rc LPS, but decreases suddenly and drastically in deep rough (*i.e.* Rd_1, Rd_2, and Re) mutants. A similar observation was made on an Re mutant of *E. coli* by *Koplow* and *Goldfine*[41]. Since some of the proteins presumably penetrate into the hydrophobic interior of the membrane, we expected that the reduction in proteins might be compensated for by an increase in either phospholipids or LPS. Quantitative analysis of outer membrane components in mutants producing Rc-, Rd_1-, Rd_2-, and Re-type LPS indeed revealed that in deep rough mutants there was a compensatory increase in phospholipids (Fig. 4b), while the number of LPS molecules per unit area of the outer membrane remained constant[22]. Furthermore, the absolute amount of phospholipids in the outer membrane of S and Rc strains was slightly less than that which was necessary to cover one side of the membrane as a monolayer. It was also known that practically all of the LPS molecules were located in the outer half of the outer membrane[42,43]. These results suggested a possible model in which the phospholipid molecules are distributed in an extremely asymmetrical manner in the outer membranes of S and Rc strains, being present *only* in the inner leaflet, the outer leaflet containing essentially only proteins and LPS molecules (Fig. 5a). Since this structure does not contain any phospholipid bilayer region, it can explain the lack of penetration by hydrophobic compounds if one assumes that these compounds cannot penetrate through the hydrophilic surface regions of the proteins and the hydrocarbon regions of LPS. The low permeability of the latter regions can be explained as follows: The hydrocarbon chains of LPS are likely to be tightly clustered together because at least six chains are connected to a single backbone structure and because unsaturated fatty acids are entirely absent. This idea is supported by spin labeling studies which showed that the motion of the segments of LPS hydrocarbon chains near the carboxyl end is severely restricted[18]. It is also consistent with the monolayer studies of *Romeo et al.*[44], who found

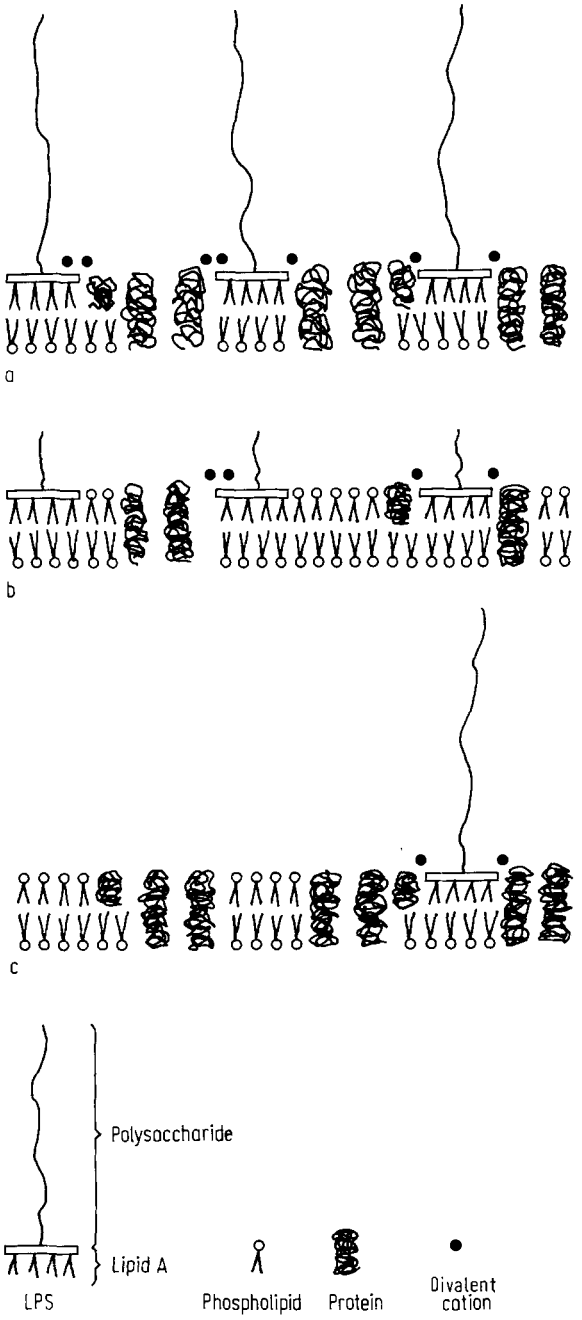

Fig. 5. Schematic structure of the outer membrane of *E. coli* and *S. typhimurium*. a) Wild type strains. b) "Deep rough" mutants producing LPS of Rd- or Re-type. c) Wild type strains after EDTA treatment (for details see text).

a smaller cross-sectional area for LPS hydrocarbons than for phospholipid hydrocarbon chains. Since a major portion of the resistance in the transmembrane diffusion of hydrophobic compounds arises because of the difficulty in making a hole between the associated hydrocarbon chains[39], it is easily seen that the presence of the tightly clustered hydrocarbon chains of LPS will drastically slow down the permeation process.

In deep rough mutants, the extremely abbreviated structure of LPS presumably hinders the proper interaction between LPS and proteins at the time of outer membrane assembly. This results in the decreased incorporation of outer membrane proteins, which in turn produces a compensatory increase in phospholipids, some of which are now found in the outer half of the membrane (Fig. 5b). Hydrophobic molecules can obviously diffuse through the "phospholipid bilayer" regions of this membrane.

The treatment of wild-type cells with EDTA releases LPS or LPS-protein complexes[30,45]. This selective removal of the components of the outer half of the membrane is presumably quickly followed by the flip-over of phospholipids from the inner half, or by the lateral diffusion of phospholipids from the inner membrane in a manner similar to that described by *Jones* and *Osborn*[46]. Thus "phospholipid bilayer" regions are generated also in this case (Fig. 5c), and the outer membrane will become permeable to hydrophobic molecules.

In order to examine whether phospholipid molecules are indeed distributed asymmetrically as predicted by our model, several experiments were performed[47]. In one approach, we attempted labeling the exposed head groups of phosphatidylethanolamine, the major phospholipid of *E. coli*, with a covalent labeling reagent. Since most of the previously developed "non-penetrating" reagents were expected to pass through the aqueous pores of the outer membrane (see Section 4) owing to their small size, we used BrCN-activated dextran as the covalent labeling reagent for amino groups (Fig. 6).

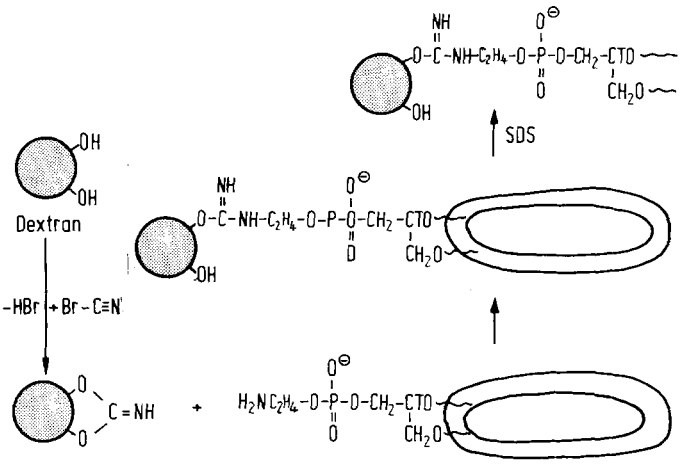

Fig. 6. Covalent labeling of phosphatidylethanolamine head groups on cell surface with a macromolecular reagent [47]: Soluble dextran was "activated" by treatment with CNBr, and the reagent was added to a suspension of intact bacterial cells. If phospholipids, the major portion of which is phosphatidylethanolamine in *Salmonella*, are located in the outer half of the outer membrane (cf. Fig. 5b), the reagent will become bound to the ethanolamine portion of the phospholipid through an amidine linkage. The dextran-phospholipid complex can be quantitated after dissolving the cells with SDS.

When intact cells were incubated with this reagent, with deep rough mutants a significant fraction of total cellular phospholipids became linked to the activated dextran in the medium, whereas with an S or Rc strain no such labeling took place. It must be emphasized that these results are difficult to explain in terms of the possible steric hindrance by the saccharide chains of LPS, as the transition occurred precipitously following the loss of a single sugar residue (compare Rc with Rd_1, Fig. 3).

The presence of this rather extreme form of asymmetry, LPS outside and phospholipids inside, is also supported by other observations: (1) Freeze-fracture of the outer membrane of *E. coli* and *S. typhimurium*[20,22] reveals a concave fracture face densely filled with particles, the major constituent of which was shown to be proteins (Fig. 7)[22]. In *Pseudomonas*

aeruginosa similar particles seen on the concave fracture face appear to be protein-LPS complexes, since EDTA treatment

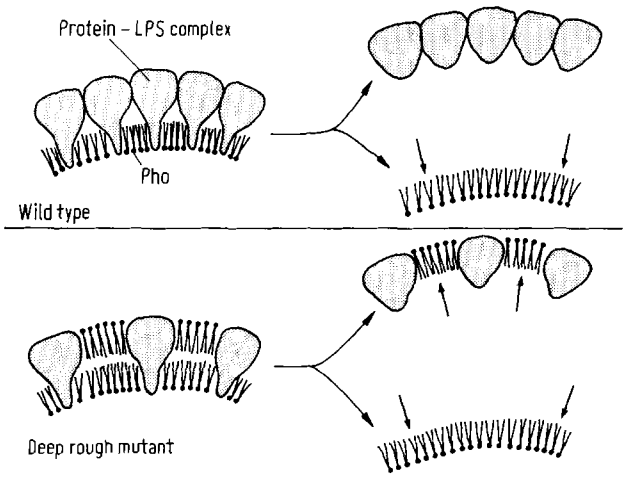

Fig. 7. Outer membrane after freeze-fracturing (schematic). When ice blocks containing cells are fractured, the fracturing occurs frequently through the middle of the membrane. This generates characteristic appearances on fracture faces. Thus the presence of smooth fracture faces (arrows), characteristic of the fractured halves of phospholipid bilayers, are seen on convex faces as well as on the concave face of deep rough mutants, but not on the concave face of the wild type cells.

which releases such complexes from the whole cell[45] results in the disappearance of a major fraction of these particles[21]. Thus it seems likely that the outer half of the outer membrane (corressponding to the concave fracture face) of *E. coli* and *Salmonella* is filled with protein-LPS complexes (or "particles"). It should be emphasized that smooth faces corresponding to the phospholipid monolayer were found abundantly on the convex face, but not on the concave face. However, such smooth faces were prominently seen on the concave fracture faces of deep rough mutants (Fig. 8)[23]. (2) Electron spin resonance studies with spin-labeled probes show that the hydrocarbon chains of LPS have rather low fluidity. Thus artificial mixed bilayers, with LPS molecules interdigitated among phospholipid molecules, exhibit significantly lower fluidity than the bilayers made of phospholipids alone[18]. Yet phospholipid hydrocarbon chains in the outer membrane have a level of fluidity very similar to that in the cytoplasmic membrane[16, 18], a result indicating that phospholipids in the outer membrane occupy a domain completely separated from LPS. This conclusion was also supported by the determination of the size of domains by exchange broadening of electron spin resonance line widths[18].

The low permeability of the outer membrane of wild type *E. coli* or *Salmonella* to hydrophobic molecules must confer an enormous selective advantage on these organisms, by making them resistant to bile salts and long-chain fatty acids that must be abundant in their usual habitat, the mammalian intestinal tract. There is no obvious reason, however, that all Gram-negative bacteria should produce hydrophobe-impermeable outer membranes. In fact, some non-enteric Gram-negative bacteria, for example *Neisseria gonorrhoeae*, are extremely sensitive to such hydrophobic agents as erythromycin, rifampin, acridine orange, and ethidium bromide[48], and it can be expected that these bacteria have an outer membrane of the phospholipid-bilayer-type.

4. Non-Specific Permeability toward Small, Hydrophilic Molecules

4.1. Equilibrium Studies with Intact Cells

Gram-negative bacteria are sensitive to a number of hydrophilic antibiotics (Table 1), which must penetrate through the outer membrane in order to reach their targets of action. Similar diffusion is required also for nutrients including sugars, amino acids, and inorganic salts, as well as for waste products of metabolism. These compounds penetrate through by a mechanism different from the "hydrophobic pathway" (Section 2), and we postulated the existence of a separate, hydrophilic pathway, a mechanism presumed to operate fully in wild type as well as in deep rough mutants. We studied the proper-

ties of this postulated pathway by using oligosaccharides as permeants[49].

In order to study the penetration through the outer membrane, it was necessary to use oligosaccharides that neither penetrated through nor were actively transported across the cytoplasmic membrane. Oligosaccharides of the saccharose-raffinose series fulfilled these conditions in *S. typhimurium*, and were used in most of our experiments. Since the space between the outer membrane and the cytoplasmic membrane (*i.e.* the "periplasmic space") is small, the diffusion into this space was difficult to measure[50]. We therefore expanded this space by "plasmolyzing" cells in 0.3 to 0.5 M NaCl or in 0.5 M saccharose solution[49]. Under these conditions, 40—50 % of the cell volume was occupied by the periplasmic space, and the extent of penetration of oligosaccharides into this space could easily be measured (see Fig. 9).

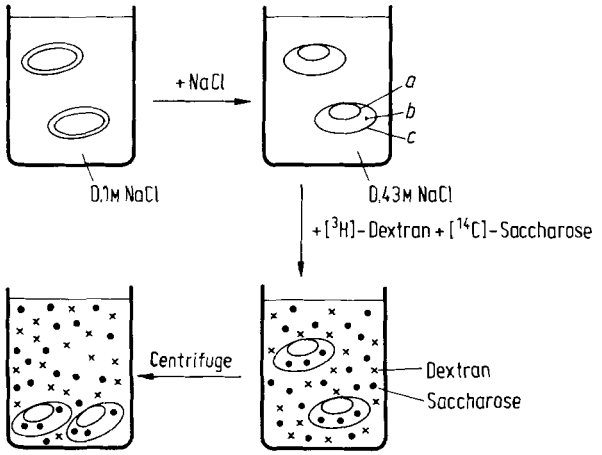

Fig. 9. Determination of permeability to oligosaccharides using plasmolyzed cells. Intact bacterial cells are suspended in a moderately concentrated solution of NaCl or saccharose. These solutes cross the outer membrane, but cannot penetrate through the cytoplasmic membrane (a). Water therefore flows out of the cytoplasm; the cytoplasm shrinks, but the mechanically rigid cell wall (c) does not, and in the "plasmolyzed" cell the space between the cell wall and cytoplasmic membrane ("periplasmic space" (b)) is greatly expanded. Addition of [^{3}H]-dextran and [^{14}C]-saccharose results in the penetration of saccharose, but not dextran, into the periplasmic space. This can be quantitated by centrifuging the cells down and by determining the ^{14}C- and ^{3}H-contents of the supernatant as well as the cell pellet.

These studies showed the existence of a clear size limit in the penetration process through this pathway[49]. Saccharose (342 daltons) and raffinose (504 daltons) penetrated fully into the periplasmic space after 5 min incubation at room temperature, but stachyose (666 daltons) and larger oligosaccharides showed only partial penetration. The partial penetration was apparently due to diffusion into damaged cells[49], and we conclude that the cell wall of *S. typhimurium* is permeable to a disaccharide (saccharose) and a trisaccharide (raffinose), but is essentially impermeable to tetrasaccharides and higher oligosaccharides. There thus seems to be a sharp exclusion limit around 550—650 daltons for the raffinose series of oligosaccharides.

It was gratifying to note that these results were consistent with the results of a pioneering study by *Payne* and *Gilvarg*[26], who found that peptides larger than about 600—650 daltons could not enter *E. coli* cells. However, neither the investigations by *Payne* and *Gilvarg* nor our results described above told us which of the two layers of the cell wall, the outer membrane and murein, acted as the limiting barrier for the penetration of hydrophilic molecules. Our later studies, however, clearly showed that the outer membrane, rather than the murein layer, acted as a limiting molecular sieve[52]. In one series of experiments, for example, the murein layer was degraded by lysozyme treatment or by growth in the presence of penicillin. The plasmolyzed cells or sphaeroplasts produced from these bacteria still showed the same molecular sieving properties seen before, despite absence of the intact murein layer.

How do the hydrophilic molecules pass through the outer membrane? As stated earlier, a mechanism involving dissolution in the membrane interior is impossible, as this would require breaking very many hydrogen bonds between the oligosaccharides and water molecules, thermodynamically a very unfavorable operation. The only possible mechanisms seem to be diffusion through water-filled pores, and carrier-mediated diffusion. We found that diffusion of oligosaccharides through the outer membrane was extremely rapid even at 0 °C[49], and this observation as well as the identical size limit for widely different kinds of compounds seemed to favor the aqueous pore mechanism. We sought a more definitive answer to this question through reconstitution studies, as described in the next section.

4.2. Reconstitution Studies

When the outer membranes are dissociated by detergents and then the detergents are slowly removed in the presence of Mg^{2+}, one observes the reformation of structures morphologically resembling the outer membrane[53]. These experiments established that the supramolecular structure of the outer membrane was ultimately determined by the structure and properties of the component molecules. However, they did not throw much light on the nature of interaction between the component molecules, or on the functions of individual components.

We carried out reconstitution experiments in order to determine the components that are responsible for the characteristic hydrophilic permeability of the outer membrane. Since both the hydrophilic permeability and the presence of LPS are unique attributes of the outer membrane, we first examined the possibility that LPS might be involved in the formation of pores. We prepared liposomes containing both LPS and phospholipids in the bilayer structure, by resuspending a dried film of phospholipids in an aqueous suspension of LPS, as described by *Kinsky et al.*[54]. These liposomes, bound by the mixed phospholipid-LPS bilayer were, however, as impermeable toward hydrophilic compounds as the liposomes made only of phospholipids[55]. These results led us to the alternative hypothesis that outer membrane proteins play an essential role in the formation of pores. This hypothesis was tested in our laboratory[56] by making liposomes in the presence of outer membrane proteins. For this purpose, the outer membrane proteins were extracted with the aid of detergents. Removal of detergents by extensive dialysis resulted in the precipitation of proteins, which were then recovered by centrifugation and resuspended in an aqueous buffer by sonication. Membrane vesicles were reconstituted by adding this protein suspension and an aqueous suspension of LPS to a dried film of phospholipids (Fig. 10). When the reconstitution medium contained both [^{3}H]-dextran and [^{14}C]-saccharose, both compounds were presumably present in intravesicular as well

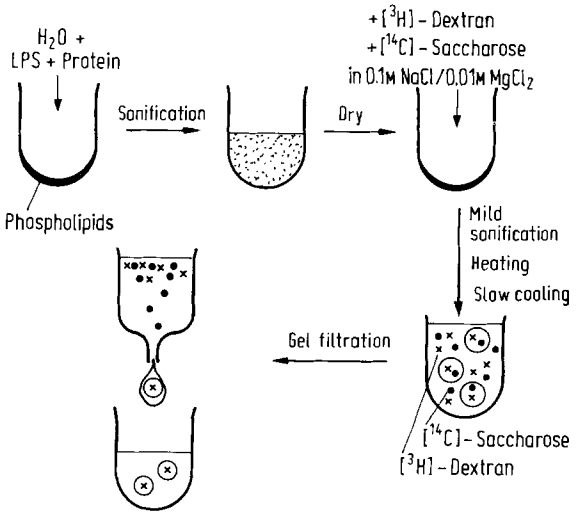

Fig. 10. Reconstitution of outer membrane vesicles. A dry film of phospholipids is resuspended with an aqueous suspension of LPS and proper proteins. After sonication to produce maximum dispersion and mixing, the mixture is dried as a film, and then resuspended in a salt solution containing [^{3}H]-dextran and [^{14}C]-saccharose. Heating and slow cooling of the suspension are carried out to ensure the maximal sealing of vesicles and the optimal rearrangement of membrane components. The vesicles, presumably containing both [^{3}H]-dextran and [^{14}C]-sucrose inside, are then applied onto a gel filtration column. They quickly become separated from the solutes in the extravesicular fluid. In addition, if the vesicle membrane is permeable to saccharose but not to dextran, [^{14}C]-saccharose will diffuse out of the vesicles during filtration, and the vesicles collected at the void volume will show a much higher $^3H/^{14}C$ ratio than the dextran-saccharose mixture originally added to the reconstitution system (see also Table 2).

as extravesicular space. When the vesicles were then separated from the medium by gel filtration through Sepharose 4B, a large portion of intravesicular [^{14}C]-sucrose diffused out through the protein-containing membrane during the filtration step, so that the $^3H/^{14}C$ ratio of the recovered liposome preparation was usually several times higher than the $^3H/^{14}C$ ratio in the initial reconstitution mixture. A control mixture lacking proteins produced liposomes essentially impermeable to saccharose, that is with hardly any increase in the $^3H/^{14}C$ ratio. In another control experiment, proteins from the red blood cell membranes of sheep were completely inactive in the production of saccharose-permeable pores. We conclude from these results that outer membrane proteins are essential in the formation of water-filled pores.

We then used partially purified preparations of outer membrane proteins for reconstitution, in order to identify the protein(s) involved in pore formation[57]. Treatment of *S. typhimurium* cell envelope with SDS at 37 °C leaves behind an insoluble complex that contains murein with covalently linked lipoprotein, as well as the major proteins of 34000—36000 daltons, *i.e.* the porins[58]. We found that the SDS-insoluble complex was much more active than the SDS-solubilized proteins in producing the pores. We then degraded the former with lysozyme and fractionated the products by gel filtration in SDS. This produced a protein aggregate containing only the porins from *S. typhimurium*[57] or from *E. coli* K12[59], and a similar oligomer composed only of the 36500 dalton porins from *E. coli* B[60], all of which were extremely active in producing pores in the reconstitution experiments (Table 2). *Inouye*[61] has proposed, on the basis of theoretical considerations, that oligomers of murein lipoproteins may contain aqueous channels in the center and thus produce pores by

Table 2. Result of a typical reconstitution experiment [a].

	[^{3}H]-Dextran [cpm]	[^{14}C]-Saccharose [cpm]
Activity in the reconstitution mixture	240000	260000
Activity in the vesicles after gel filtration		
Exp. I (without porin)	2400	2100
Exp. II (with porin oligomers, 10 μg)	3350	<30

[a] Membrane vesicles were reconstituted from 0.8 mg LPS and 0.8 mg phospholipids in the presence of [^{3}H]-dextran and [^{14}C]-saccharose, with or without porin oligomers [57]. Vesicles were recovered after gel filtration, which removed radioactive saccharides that were able to diffuse out through the vesicle membrane (see Fig. 10).

penetrating through the thickness of the outer membrane; our active complex, however, contained very few lipoproteins. In fact, the porin oligomer prepared from a lipoprotein-deficient mutant[14] of *E. coli* K12 was fully active[60]. Furthermore, aggregates containing mostly lipoproteins and little porin were only very weakly active in pore formation, and purified lipoprotein was completely inactive.

The pores produced by the addition of porins had the expected size, in that they allowed a free diffusion of saccharose and raffinose yet essentially excluded stachyose and larger oligosaccharides. The vesicles formed were also permeable to a wide variety of small, hydrophilic molecules, including galactose, glucosamine, glucose 1-phosphate, lysine, tryptophan, uridine, UMP, GDP, and polyethyleneglycol (600 daltons), but not to polyethyleneglycol (1540 daltons)[57]. Since complexes containing only one or three protein species can produce permeability to such a wide variety of substances, the mechanism of diffusion cannot be the facilitated diffusion that requires a specific carrier protein for each compound. This lack of specificity is indeed one of the strongest pieces of evidence suggesting the involvement of aqueous pores.

The channel-forming ability of the porin has recently been confirmed by a different approach. *Benz et al.*[62] added an extremely dilute (*e.g.* 0.5 ng/ml) solution of *E. coli* B porin to the aqueous solution in which a planar lipid bilayer membrane was bathed. Interestingly, the conductance increased in a stepwise manner, and the single incremental step of 1.7 nanosiemens (in 1 M KCl) was interpreted as resulting from the insertion of one molecule or oligomer of the porin into the membrane.

Reconstitution of hydrophilic pores has also been achieved by using outer membrane proteins of species other than *E. coli* or *S. typhimurium*[63,64]. A partial reconstitution from isolated phospholipids, LPS, and a small amount of outer membrane fragments has recently been performed by using components from *P. aeruginosa*[65]. Interestingly, the results suggest that the exclusion limit of *P. aeruginosa* pores is several thousand daltons, much higher than in the enteric bacteria.

4.3. Determination of Diffusion Rates with Intact Cells

If all the pores in the outer membrane are surrounded by porin molecules, the mutational loss of the porin is expected to be lethal. However, the loss of these proteins[11,13], or of all "major" proteins[12], did not produce any marked reduction in growth rates. The solution to this puzzle was provided in 1977 by studies utilizing two different methods of approach. Both of these methods enabled us to estimate the *rates* of

diffusion across the outer membrane, rather than the *equilibrium distribution* of solutes described previously (Section 4.1). In addition we gained new insights into the function of the outer membrane pores.

As described already, the diffusion rates across the outer membrane were too rapid to be measured with the equilibrium method described earlier. *Zimmermann* and *Rosselet*[66] recently devised an elegant method to measure these rates. They measured the rates of hydrolysis of β-lactam antibiotics (such as penicillins and cephalosporins) by intact cells as well as by broken cells of *E. coli*, containing a β-lactam-degrading enzyme, β-lactamase, in the periplasmic space. Thus, with intact cells the rate of diffusion across the outer membrane should be balanced, at the steady state, by the rate of hydrolysis in the periplasmic space. *Zimmermann* and *Rosselet*[66] made

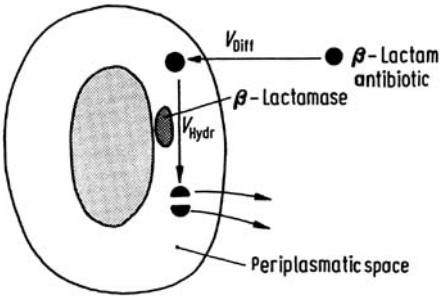

Fig. 11. Method of *Zimmermann-Rosselet* for the determination of outer membrane permeability. If we add substrates (*e.g.* β-lactam antibiotics) to intact bacterial cells that contain hydrolytic enzymes (*e.g.* β-lactamases) of known V_{max} and K_m in the periplasmic space, we can calculate the outer membrane permeability from the observed rates of hydrolysis. The efflux of the products of hydrolysis is expected to be much faster than the influx of the substrate—because of the smaller size of the products—and thus should have negligible effects on the kinetics at steady state.

a very important contribution in showing that the rates of hydrolysis by intact cells indeed followed this prediction and could be calculated by assuming that the diffusion and hydrolysis respectively followed Fick's law and Michaelis-Menten kinetics (Fig. 11). I should like to stress that this quantitative treatment is essential for the discussion of outer membrane permeability. For example, determination of "crypticity" (ratio of rates of hydrolysis in intact cells and in broken cells) at an arbitrarily chosen substrate concentration means very little, because the numerical values of "crypticity" can be altered freely, depending on the substrate concentration used[66].

We have followed the method of *Zimmermann* and *Rosselet* and determined the permeability coefficients of the outer membrane in various strains of *S. typhimurium*[67]. The results clearly show that the permeability of the outer membrane toward a hydrophilic β-lactam of 415 daltons, cephaloridine, decreases to less that 10% of that in the wild type in mutants with reduced levels of all three porins. Similar results were independently obtained with *E. coli* K12 by workers who approached the problem from the opposite direction, *i.e.* by examining membrane alterations in "cryptic" mutants. Intact cells of these mutants, studied by *Beacham et al.*[68], showed increased half-saturation (or Michaelis) constants (K_m) but unaltered maximal velocity (V_{max}) for the hydrolysis of nucleotides by periplasmic nucleotidases. When the outer membrane of these mutants was analyzed, it was found to have drastically reduced levels of porins[68].

In the approach described above, the inherent difficulty in the determination of diffusion rates across the outer membrane was solved by the use of enzymes that hydrolyzed substrates rapidly as they came into the periplasmic space. The prerequisite for this determination of outer membrane permeability is thus the efficient removal of diffusing substrates from the periplasmic space; only under these conditions will the overall rates of the process be determined predominantly by the diffusion rates across the outer membrane, and thus render the latter rates measurable. The removal of substrates can also be performed by active transport systems located in the cytoplasmic membrane. This forms the basis of the second approach to be described, *i.e.* the study of transport kinetics in intact cells. The diffusion rate (V) across the outer membrane is determined by Fick's law, and if we denote the substrate concentrations in the outside medium and in the periplasmic space by C_0 and C_p, respectively, then

$$V = P A (C_o - C_p)$$

where P and A are the permeability coefficient and the area of the membrane, respectively. The rate of active transport follows Michaelis-Menten kinetics, so that

$$V = C_p V_{max} / (K_m + C_p)$$

At steady state the two rates are equal, and thus we can eliminate C_p. This gives

$$V = \tfrac{1}{2}[V_{max} + P A K_m + P A C_o - \sqrt{(V_{max} + P A K_m + P A C_o)^2 - 4 C_o P A V_{max}}]$$

This equation looks rather unwieldy, but results of calculations using reasonable values of A, K_m, and V_{max} show that the decrease in outer membrane permeability (P) produces changes in the overall transport rate (V), changes suggesting an increased "K_m" value for the transport (K'_m) in intact cells without alteration in V_{max} (Fig. 12). This would suggest that the effect of porin deficiency on transport rates will become apparent only at low substrate concentrations (or high values of $1/C_o$). Furthermore, the effect will be difficult to detect even at low values of C_o, if the V_{max} of the active transport system (of the inner membrane) happens to be low.

Actually, mutants with the predicted change, *i.e.* increased "K_m" values for the transport of a number of substrates, were isolated some time ago by *von Meyenburg*[69] without the expectation of any outer membrane defect. These mutants were recently shown to be deficient in porins—in the 36.5 K porin in *E. coli* B/r and in both of the porins in *E. coli* K12[70]. Since the porin-deficient mutants have increased "K_m" for the transport of numerous compounds (various sugars, a sugar alcohol, a sugar phosphate, amino acids, a pyrimidine, and even inorganic anions like phosphate and sulfate)[73], this approach establishes the role of porins in the transmembrane diffusion of a very wide range of hydrophilic substrates. In addition, if we assume that the active transport systems in the cytoplasmic membrane have very high affinities (or low K_m values) for the substrate, we can estimate the minimal values of permeability coefficients for various substrates[74].

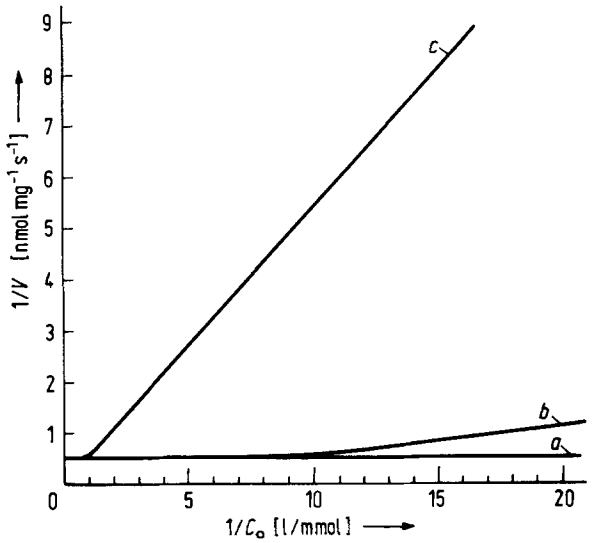

Fig. 12. Theoretically predicted behavior of transport systems in intact cells. Overall transport rates were calculated for different values of C_o (substrate concentration in the external medium), by assuming that the substrate first diffuses through the outer membrane with the permeability coefficient of value P, and then is transported actively by the underlying cytoplasmic membrane by a process characterized by the maximal rate (V_{max}) of 2 nmol/mg^{-1}/s^{-1} (based on dry weight), and the half-saturation (Michaelis) constant (K_m) of 1 μmol/l. The calculation was made for the P value of 1.4×10^{-2} cm/s (a "theoretical" value of permeability of *E. coli* outer membrane toward glucose [70]) (curve a, $K_m = 1.5$ μmol/l), and for P values corresponding to 1% and 0.1% of the value mentioned. The latter P values thus simulate situations in mutants producing 1% and 0.1% of the normal number of porins (curves b and c, $K'_m = 55$ and 550 μmol/l, resp.). It is seen that in mutants, the V_{max} of the overall transport process remains unchanged, but the apparent K'_m (*i.e.* the value of C_o giving the half-maximal rate of transport in intact cells) is increased. The plots are seen to follow straight lines except at very high values of C_o.

The transport studies and investigations with β-lactamase carried out in our laboratory have so far provided the following information:

(a) In contrast to the rate of diffusion of hydrophobic substances described in Section 3, the rate of diffusion of hydrophilic substances depends very little upon the temperature. Diffusion of a β-lactam antibiotic, cephaloridine, gave a Q_{10} value of about 2[71]; this low temperature dependence provides strong evidence for the permeation occurring through the water-filled pores.

(b) The most remarkable observation is the presence of a very large difference in permeability coefficients among permeable solutes. Thus, in wild type cells, the permeability coefficient of $\geq 1 \times 10^{-4}$ cm/s for lactose can be contrasted with a much lower coefficient for 6-aminopenicillanic acid (1.4×10^{-5} cm/s)[72], whose size (216 daltons) is actually smaller than that of lactose (342 daltons). We do not yet fully understand the factors that influence the rate of penetration through these pores, but a few parameters are already known to be important. The first factor is obviously the size of the solute molecule. In the "apparent transport K_m" experiments, the calculation of outer membrane P values on the basis of data on wild type cells gives only minimal values with a large margin of uncertainity. In contrast, the overall transport rates in intact cells of porin-deficient (*ompB*) mutants are essentially limited by the rates of diffusion through the outer membranes, especially at low values of C_o, and thus allow a fairly accurate calculation of P values[70]. Since the *ompB* gene is most probably a regulatory gene[73], the mutants are expected to produce smaller numbers of unaltered pores. Thus if we assume that hydrophilic solutes diffuse through the mutant outer membrane *via* the remaining porin channels, the data shown in Fig. 13 indicate clearly the effect of solute size. Furthermore,

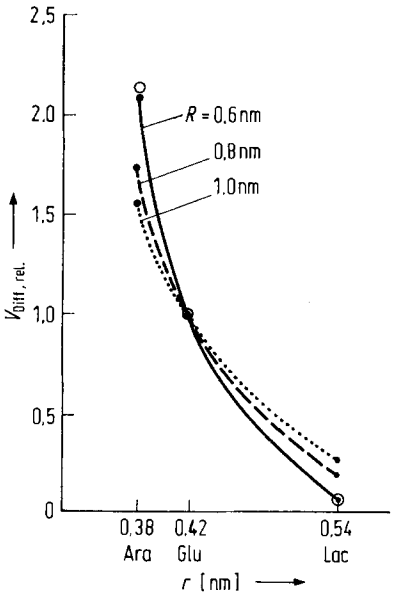

Fig. 13. Calculated and observed permeability toward solutes of various sizes. The calculated values (curves) were calculated by multiplying the free diffusion coefficients for arabinose (Ara), glucose (Glu), and lactose (Lac) by appropriate Renkin factors calculated for various pore sizes (hydration radii r see [75]). The observed permeability (○) was calculated from the "growth K_m" of porin-deficient (*ompB*) mutant CM7 on these carbon sources, and from the growth rate and growth yields (for details, see [70]). The relative diffusion rate $V_{diff,rel}$ serves as a measure of the permeability.

there is a reasonably good fit with the theoretical values calculated on the basis of the Renkin equation[74], which corrects for the hindrance caused by the collision of solutes of finite sizes with the rims of small pores, as well as for the viscous drag effect exerted by the pore wall.

The second factor is the hydrophobicity. Hydrophobic antibiotics cannot rapidly penetrate through the outer membrane of wild type *E. coli* or *S. typhimurium* even when their size is clearly below the exclusion limit of the pores[32]. This would suggest that the pores tend to exclude hydrophobic solutes,

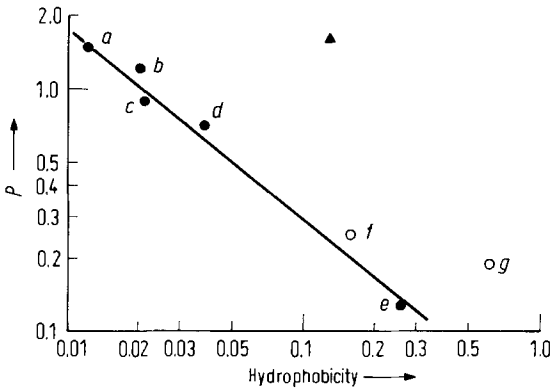

Fig. 14. Permeability (P, arbitrary units) of the pores as a function of hydrophobicity and charge. Rate of diffusion of β-lactam antibiotics across the outer membrane of *E. coli* (after [66]). The partition coefficients (as a measure of hydrophobicity) were determined in isobutanol/0.02 M phosphate buffer (pH 7.4) containing 0.9% NaCl, at 37°C. ●, monoanionic cephalosporins a: C 49288; b: C 49753; c: cephacetril; d: cephazolin, e: cephalothin; ▲, zwitterionic cephalosporin (cephaloridine), ○, monoanionic penicillins (f: ampicillin, g: benzylpenicillin).

an idea put to a direct test by *Zimmermann* and *Rosselet*[66]. They compared the outer membrane permeability to *E. coli* for a number of semisynthetic cephalosporin derivatives; their data (see Fig. 14) confirm the inverse correlation between hydrophobicity and transmembrane diffusion rates (through pores), at least for a series of monoanionic cephalosporins. At present it is not known why pores exclude hydrophobic molecules. An obvious possibility is that these hydrophobic antibiotics cannot penetrate into the pores because they form micelles. However, although these substances do indeed form micelles at very high concentrations, they seem to exist mostly as monomers at the concentrations used for permeability studies[71]. Perhaps the important thing to realize here is that the diameter of the pore is not much different from the diameter of solute molecules. Thus the walls of the pore are probably lined with hydrophilic or hydrogen-bonding structures, so that the transfer of hydrophilic solutes from bulk water to the interior of the pore can be achieved without the net breakage of many hydrogen bonds. In the "empty" pore, it is reasonable to expect that the structures on the wall are rather strongly hydrogen-bonded to water molecules in the pore, thus making the water in the channel more structured or more strongly hydrogen-bonded than the bulk water. Penetration of hydrophobic molecules into the pore will break this structure, and thus may be energetically unfavorable.

In this connection, the apparently larger pores found in *P. aeruginosa* may play a significant role in allowing the easier diffusion of hydrophobic molecules[65]. It is known that *P. aeruginosa* can grow on a number of organic acids and alcohols[76], and even on paraffinic hydrocarbons and camphor in the presence of a proper "degradative" plasmid[77]. Possibly a larger pore may permit the passage of hydrophobic molecules enveloped in a "cage" of structured water molecules, or even of micelles.

The third factor is the electrical charge. In the experiments of *Zimmermann* and *Rosselet*[66], the zwitterionic cephaloridine penetrated through outer membrane much faster than the monoanionic cephalosporins of comparable hydrophobicity (Fig. 14). It seems possible that the pore walls contain a number of anionic groups; in this connection we recall the observation that porins are the most acidic proteins found in the outer membrane, both in *E. coli*[58, 78] as well as in *S. typhimurium*[79]. However, a significant part of the resistance against anionic solutes may come from the fact that the periplasmic space contains many negatively charged macromolecules, and thus there exists a Donnan equilibrium favoring the exit of diffusible anions from the periplasmic space[51].

(c) These considerations help us understand the functions of porins in a physiological context. A very large number (about 10^5) of porins exist in a single cell. If we consider cells growing in a laboratory medium containing a typical concentration, say 0.2 %, of glucose, the porins are of course present in a large excess (perhaps 10^3-fold) over what is needed for the inflow of glucose at a rate needed for exponential growth at the doubling time of about 45 min (for calculation, see ref. [70]). But the production of these large numbers of porins is not wasteful, because they are needed under two conditions: Firstly, porins are needed for the diffusion of less permeable compounds. The Renkin equation predicts that the diffusion rates of disaccharide will be about 5 % of that of glucose. Hydrophobicity and electric charges will further reduce the diffusion rates by several orders of magnitude; this applies, for example, in some peptides that are a major source of nutrition for enteric bacteria in their natural habitat. It thus seems that for the diffusion of certain classes of compounds the presence of 10^5 copies of porins is indeed necessary. Secondly, the concentration of the nutrients is important. The passive diffusion rate is *proportional* to the concentration difference across the membrane. Thus although 10^5 copies of porins might seem an unnecessary excess in a medium containing 0.2 % (roughly 10^{-2} mol/l) glucose, all of these porins will become necessary if *E. coli* tries to keep growing at its maximal rate in the presence of only 10^{-5} mol/l glucose, apparently a condition *E. coli* is exposed to very frequently in its natural habitat[80].

In addition to the studies in our laboratory[70], other workers have found that porin-deficient mutants are less permeable to various nutrients and inhibitors such as Cu^{2+}, Ag^{+}, tetracycline, and chloramphenicol[81]. These results agree with the lack of specificity of porin channels observed in the reconstitution experiments, and suggest that most small, hydrophilic solutes cross the outer membrane through these channels (see, however, Section 5).

Both *E. coli* K12 and *S. typhimurium* LT2 synthesize more than one species of porins. Since the biosynthesis of the individual species is regulated by a specific set of environmental conditions[82], it seems possible that each species produces channels with slightly different properties from others. However, all reconstitution studies so far have indicated identical exclusion limits for the three species of *Salmonella* porins[83].

Inouye has proposed[61], on the basis of the amino acid sequence, that murein lipoprotein may form oligomers with a central channel, which would then serve as transmembrane pores. So far no experimental evidence favoring this hypothesis has been reported. Recently, by using a mutant lacking the lipoprotein[14], we have shown that the absence of this protein did not produce any reduction in the hydrophilic permeability of the outer membrane, measured by the diffusion of 6-aminopenicillanic acid[72].

4.4. Structural Basis of the Permeability toward Hydrophilic Molecules

We have seen that a special class of proteins, porins, make the outer membrane permeable to hydrophilic solutes. If these proteins form transmembrane channels, they should span the thickness of the membrane. Indeed, portions of the porins are exposed on the outside surface of the outer membrane, as seen from the binding of macromolecular labeling reagents[84], porin-specific bacteriophages[85] and antibodies[86]. At the same time the porins have a strong affinity toward the underlying murein layer[58, 87], and thus are believed to be exposed also on the inner surface of the membrane.

How are these proteins organized in the plane of the membrane? Porins solubilized in 0.1—0.2 % sodium dodecyl sulfate (SDS) at room temperature apparently exist as trimers, as revealed by cross-linking with bifunctional reagents[88] and by sedimentation equilibrium studies[89]. They seem to be organized as trimers also in the intact outer membrane, since cross-linking studies with cell envelopes produced predominantly dimers and trimers of porin[88].

These porin oligomers were "visualized" in the outer membrane by two techniques. Firstly, *Ueki et al.*[90] examined the small-angle X-ray scattering by oriented layers of intact outer membranes of *S. typhimurium*. The study revealed a series of in-plane reflections that appeared to correspond to regular protein aggregates of about 10 nm in diameter. A most interesting feature was the presence of a central electron-transparent area or a "hole" of about 5 nm in diameter. Since such reflections were absent in the outer membrane of a porin-negative mutant, these regular oligomers are formed only by the porins. Secondly, freeze-fracture electron microscopy revealed about 10^4 intramembranous "particles" on 1 μm^2 area of the concave fracture face of the outer membrane (see Fig. 7 and 8)[20-22]. From the total number of porin molecules per cell[58] and the surface area of an *E. coli* cell, one would expect about 10^4 porin trimers on 1 μm^2 area, and thus the majority of these particles are likely to correspond to porin trimers (or their complexes with LPS). Their size (8—10 nm) also agrees with the size of porin oligomers determined by X-ray scattering.

Does each monomer of porin contain a channel or does a channel get formed in the central space after the association of three subunits? A decisive answer is not available at present. So far it has not been able to reconstitute saccharose-permeable membranes by using monomeric porins[89]. On the other hand, some published results are at least consistent with the one-porin one-channel hypothesis. When the cell envelope of *E. coli* B is extracted with SDS at room temperature, murein sheets with hexagonally arranged oligomers of porin are left behind[58]. Because of this regular arrangement, *Steven et al.*[91] were able to use image-enhancement techniques in electron microscopy, and obtained the negatively stained picture suggesting that a trimer of proteins contains a central triplet of holes, each 2 nm in diameter. Although *Steven et al.* argued that these holes were probably occupied by lipoproteins, this sounds unlikely because the wall of the holes would then have to be hydrophobic and would repel the hydrophilic particles of the negative stains. If each of these holes corresponds to a channel, their size agrees very well with that predicted by the diffusion studies, *i. e.* about 1.2 nm in diameter (Section 4.3). Perhaps this triplet of channels could have appeared as a single large hole in the X-ray scattering study, because of the low resolution (about 2 nm) of the latter technique[90].

5. Specific Diffusion Processes

The discovery that some outer membrane proteins are involved in the specific transport of nutrients was made by *Bradbeer et al.*[92], when they found that a vitamin B_{12} binding protein, located in the outer membrane, is essential for the transport of this substrate into the cytoplasm. This discovery was rapidly followed by many other works describing various systems and defining their components (Table 3). Portions of the specific transporter proteins are expected to be exposed on cell surface, and indeed most of these proteins are used as "receptors" by various phages and colicins (Table 3).

We have observed in the previous section that the passive diffusion through porin channels is likely to become limiting if the solute has a large size or if the external concentrations of the solutes normally encountered are quite low, or if the rate of active transport is very high. We can thus expect that specific transport systems across the outer membrane will be needed for these cases, and it is gratifying to find that in all the cases listed in Table 3 one or more of the

Table 3. Outer membrane proteins involved in specific diffusion processes.

Facilitates the diffusion of:	Apparent mol. wt. of protein	Protein used as receptor by:	Ref.
Maltose and Maltodextrins	47000	λ	[93]
Ferrichrome	78000	T5, T1, Ø 80, colicin M	[94]
Fe^{3+}-enterochelin	81000	colicin B	[95]
Nucleosides	25000	T6, colicin K	[96]
Vitamin B_{12}	60000	BF23, E group colicins	[92, 97]

conditions above is satisfied. Thus iron-chelator complexes (ferrichrome, 740 daltons; Fe^{3+}-enterochelin, 746 daltons) as well as vitamin B_{12} (1357 daltons) are very large, and also exist in very low concentrations. Maltodextrin oligosaccharides are also large, and although maltose can diffuse through porin channels[93b] such diffusion becomes limiting for disaccharides if the external concentration falls below *ca.* 10^{-4} mol/l (see Section 4.3). Thus for the proper functioning of a maltose transport system, which has a very high affinity for maltose (K_{diss} of the periplasmic maltose binding protein is 2×10^{-7} mol/l for maltotriose[93b]) at low substrate concentrations, the porin channels are clearly insufficient. The presence of a specific protein for the transport of nucleosides which are not so large (less than 300 daltons) is somewhat unexpected, but is probably related to the fact that nucleoside transport is one of the most efficient transport systems in *E. coli* in terms of its high affinity combined with a very high velocity[80].

The maltose transporter, or the "λ-receptor", transports not only maltose but also maltotriose and possibly higher oligosaccharides[93b]. Since this protein shares several properties with porin[93c], it seems possible that it also acts essentially as a large pore with a discriminating mechanism in it. Consistent with this prediction is the observation that its presence allows the diffusion, albeit very slow, of glucose and lactose (but not of histidine) across the outer membrane of porin-deficient mutants[98]. Recently it was also shown that λ-receptor forms ion-permeable channels in planar lipid films[99]. The transport processes carried out by other specific transporter proteins may also involve pores, but little information is available on this point.

6. Penetration of Macromolecules

Under certain conditions, macromolecules can apparently cross the outer membrane barrier[100]. This situation is not correlated with any specific deficiency of the outer membrane components, but rather seems to occur whenever the stability of the outer membrane structure is decreased. It thus seems most likely that the "leakage" of this type occurs by the transient rupture and resealing of the membrane.

7. Conclusion

Owing to its location outside the cytoplasmic membrane, the outer membrane had to develop unusual permeability properties. Thus it is permeable to small hydrophilic molecules, and at least in *E. coli* and *Salmonella* essentially impermeable to hydrophobic molecules. Furthermore, it also had to develop specific diffusion mechanisms for exceptional compounds. We

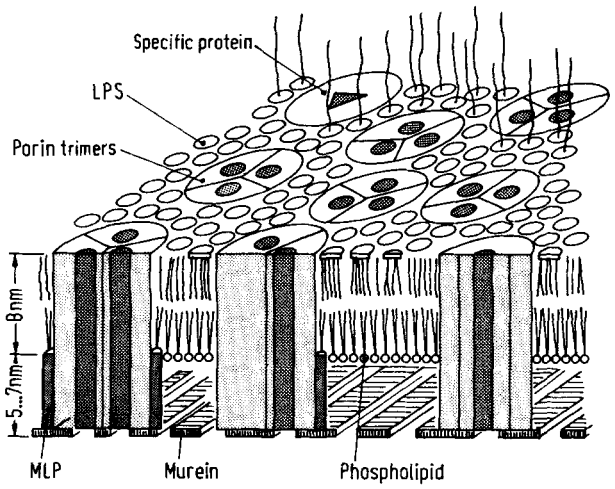

Fig. 15. Speculative model of the *E. coli* and *S. typhimurium* cell wall. Some features in this figure are highly speculative and have not been established experimentally: these include the assumptions that each porin molecule produces a channel, that murein lipoprotein is joined to the membrane only *via* its hydrocarbon chains, and that murein lipoprotein associates with porin. Spec. protein: protein which facilitates the diffusion of specific compounds; LPS: lipopolysaccharide; MLP: murein-lipoprotein.

now understand the structural basis of these permeability properties quite well at the molecular level. In fact, in terms of the correlation of structure with function, the outer membrane probably is the best understood among biological membranes. Since this membrane has a rather simple structure (Fig. 15) and a vast amount of data has already been accumulated on it, it seems likely that the outer membrane will remain a very useful object of study for the understanding of general principles of membrane structure and function[101].

The research in the author's laboratory has been supported by a U.S. Public Health Service research grant AI-09644 and an American Cancer Society research grant BC-20. I thank all my past and present coworkers who contributed ideas and hard work to this project, especially Taiji Nakae, Yoshiyuki Kamio, and John K. Smit.

A Model of Simple Liquids

By Werner A. P. Luck[*]

Dedicated to Professor Horst Pommer on the occasion of his 60th birthday

The intuitively clear hole defect model can be used for quantitative estimates and for understanding the properties of liquids. An ideal liquid is defined in analogy with an ideal gas and corrected for real liquids with hole defects. The good agreement permits an application of this approximation process to the understanding of some important material properties. The effective model fills a gap in the area of applied chemistry and of chemical teaching. It also leads to a correction factor for the failure of the theorem of corresponding states. The reasons for the applicability of such a simple model are demonstrated on the basis of the Lennard-Jones potential.

1. Introduction

One of the main problems of research and development in applied chemistry is the production of substances with predetermined properties (molecular engineering[1])—a problem for which the study of chemistry leaves one almost completely unprepared. For example, in dyestuffs research an average of 400 dyes are conceived, synthesized, and subjected to all-round testing before a new and better dyestuff is found; in pharmaceutical research the corresponding ratio is as large as 10000:1[1].

The yield of such an empirical process can be improved—if at all—only by a deeper understanding of the intermolecular forces in complicated systems. One example of this would be the structure of liquids, but its description with the aid of partition functions can hardly help the chemist.

The approximate description of the gaseous state by the "ideal gas equation" is generally recognized and used, although the model upon which this is based—of force-free point-size

molecules—cannot describe liquefaction, diffusion, thermal conductivity, or viscosity. Why have there been so few attempts at describing liquids, although it is with liquids that the chemist must deal most often? Below it will be shown how simply a useful model of liquids can be developed.

2. Ideal and Real Liquids

2.1. The Ideal Liquid

To avoid complications, we begin with two limitations:
1) We shall deal with nonpolar or only weakly polar substances.
2) We shall discuss the saturation states of the coexistence of liquids and vapors.

It must be mentioned in connection with 1) that for polar parts of molecules orientation-dependent components of the interaction must also be taken into account, as has been demonstrated for the extreme example of water[2] and also for methanol and ethanol[3] with a very simple but effective orientation defect model; and in connection with 2) that deviations from saturation due to an increase of the pressure can easily be included.

Like the ideal gas, the ideal liquid can be defined on the basis of the variables of state volume V or density ρ and temperature T. The upper curves in Figure 1 show the liquid saturation densities ρ_l and the lower curves the corresponding gas densities ρ_v. At low values of T the following expression holds for nearly all substances:

$$\rho_l = \rho_0 - AT; \quad T < T_b \tag{1}$$

where T_b is the boiling point.

Eq. (1), which applies strictly at low temperatures, also has a physical significance at high temperatures: it represents the geometric locus of the sum $(\rho_l + \rho_v)$[4, 5]—a situation that again applies to nearly all substances and is generally known

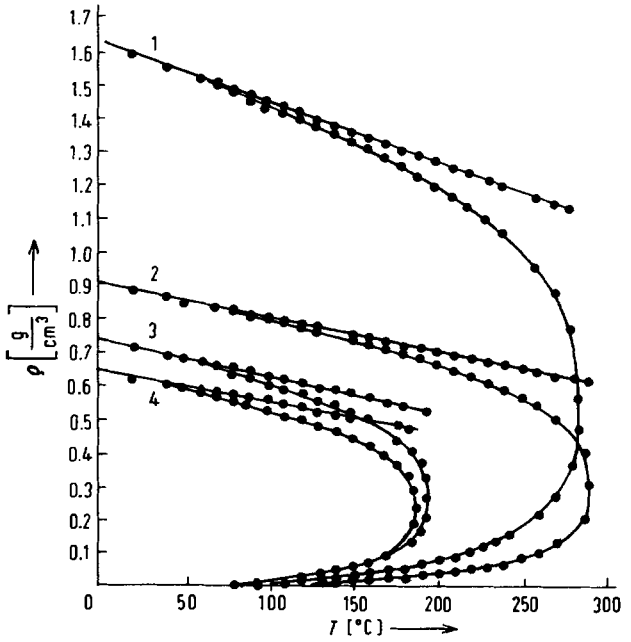

Fig. 1. Saturation densities: lower curves, vapor ρ_v; upper curves, liquid ρ_l; straight lines, $\rho_{id} = \rho_l + \rho_v$. 1, tetrachloromethane; 2, benzene; 3, diethyl ether; 4, 2-methylbutane.

for $(\rho_l + \rho_v)/2$ as the Cailletet-Mathias rule for testing critical characteristics (V_c, T_c).

We now define an ideal liquid by means of this straight line as a liquid whose volume, because of thermal oscillations about the equilibrium positions, increases with T in such a way that the relationship (1) applies exactly for its density $\rho_{id} = \rho_l + \rho_v$. While the ideal model gas corresponds the closer to reality the larger T/T_c becomes, the ideal model liquid thus defined approaches a real liquid the more closely the smaller is T/T_c.

2.2. The Real Liquid

Just as effective as the van der Waals corrections a and b for the gaseous state is the modification of the ideal model liquid by the assumption that hole defects appear in the real liquid with increasing T[4, 5]. We can give the number of hole defects for our model directly: the deviation of the density of the ideal liquid, which we have defined as $\rho_l + \rho_v$, from the density of the real liquid ρ_l is given exactly by ρ_v. Consequently, the hole-defect concentration in the model liquid must be equated with the concentration of molecules in the vapor. The fraction of hole defects is therefore determined by the expression

$$x_F = \frac{\rho_v}{\rho_l + \rho_v} \tag{2}$$

Figure 2 surveys the experimental values of x_F. A curve appears that applies to practically all organic compounds, but not to substances with low critical temperatures, such as He, Ne, and H_2. At T_c the value of x_F is 0.5, the number of

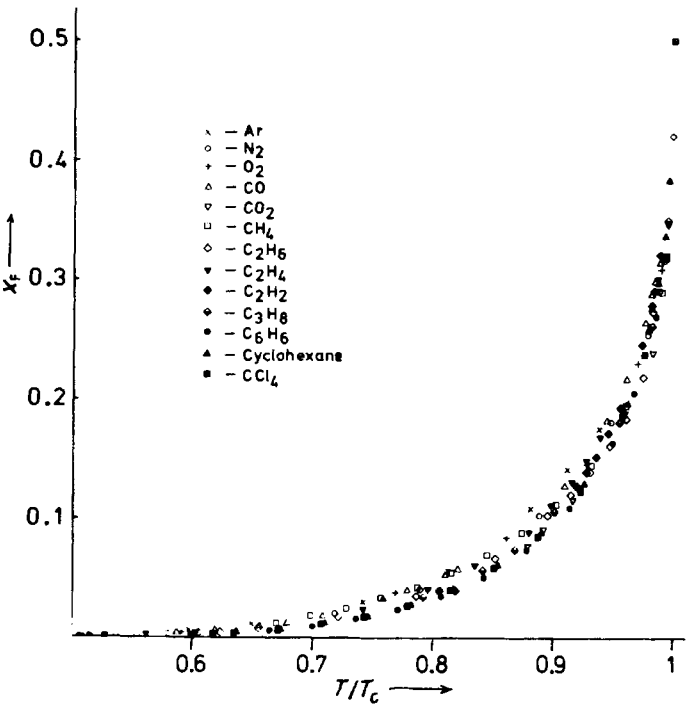

Fig. 2. Hole-defect concentration $x_F = \rho_v/(\rho_l + \rho_v)$.

hole defects in the liquid then being equal to the number of vapor molecules. The two phases have become indistinguishable.

Our model is in agreement with X-ray scattering data, which indicate that in liquids the distances between nearest neighbors increase only very slightly with increasing T, while the coordination numbers show a considerable decrease[6]. For example, for liquid argon at 149 K a mean distance between nearest neighbors of 5.27 Å would be expected on the basis of the density, while the X-ray scattering results show, in agreement with the hole model, a flat maximum of the pair distribution function at a distance of 4.1 Å; at T_c a coordination number of 6 is reached[6].

On the basis of the model, and in agreement with the X-ray results, we arrive at a simplified representation of a liquid (Fig. 3, left): a "crystal-like" structure, expanded at increased values of T and slightly distorted by the statistical oscillation volume; additional hole defects appear with rising T, their concentration being exactly equal to the vapor concentration.

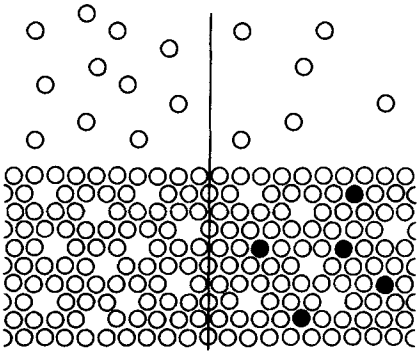

Fig. 3. Left: Hole defect model of a liquid: expanded crystal-like packing with the concentration of holes equal to the concentration of vapor. Right: model for *Raoult*'s law: dissolved particles having no intrinsic vapor pressure (black points) fill the holes and the vapor pressure of the liquid decreases in proportionality to the number of dissolved particles.

This model leads directly to *Raoult*'s law for the lowering of vapor pressure as a function of the concentration of dissolved foreign molecules. As in the thermodynamic derivation of this law, very laborious for most chemists, we presuppose that the dissolved molecules have no intrinsic vapor pressure. According to our model they will fill the holes in the liquid and therefore lower the vapor pressure proportionately. If the dissolved particles are much larger than the particles of the solvent, the well-known reduction in the lowering of the vapor pressure would be expected.

2.3. Zero-Point Density ρ_0

Figures 4 and 5 show, in reduced units, that the condition for the ideal liquid:

$$\frac{\rho_l + \rho_v}{\rho_c} = \frac{\rho_0}{\rho_c} - \left(\frac{\rho_0}{\rho_c} - 2\right)\frac{T}{T_c} \qquad (3)$$

is also satisfied for more complicated substances. The appreciable deviations in the case of H_2O and CH_3OH can be explained in terms of orientation defects[2] with lower density caused by the strong hydrogen bonding.

The slope of the straight lines represented by Eq. (3) is closely related theoretically and experimentally with the axial intercept ρ_0/ρ_c, because for $T/T_c = 1$, since $\rho_{v,c} = \rho_{l,c} = \rho_c$, we have: $(\rho_{v,c} + \rho_{l,c})/\rho_c = 2$.

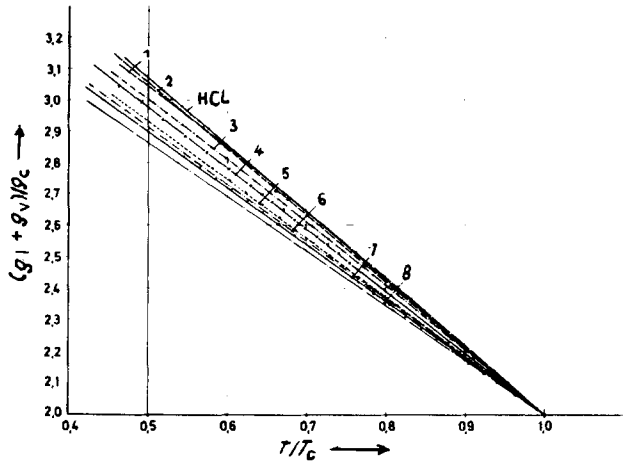

Fig. 4. Eq. (3) applies to HCl, but also for more complicated organic compounds such as 1, *n*-octane; 2, ethylamine; 3, *n*-heptane; 4, iodobenzene; 5, *n*-pentane; 6, dimethyl sulfide; 7, 2,3-dimethylbutane; 8, acetylene.

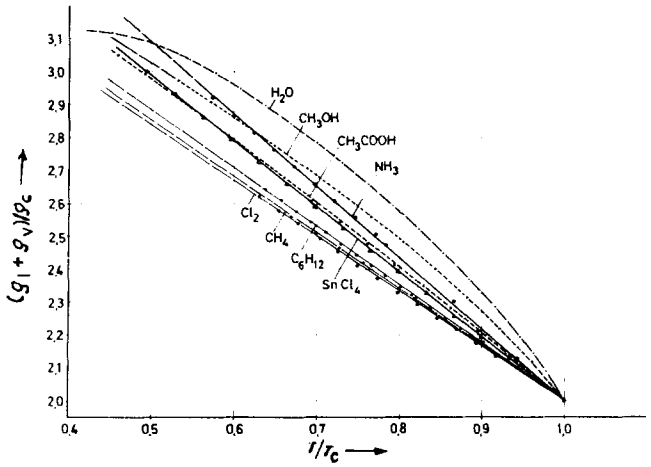

Fig. 5. Appreciable deviations from Eq. (3) occur only for substances with H-bonds.

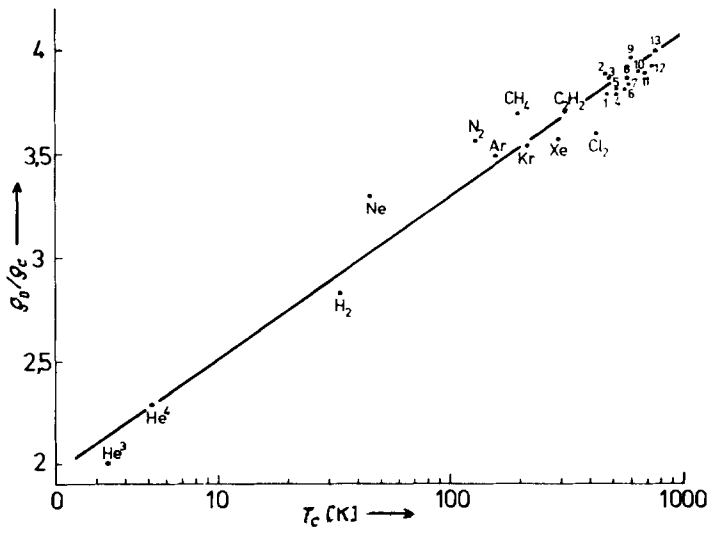

Fig. 6. Deviations from the theorem of corresponding states, ρ_0/ρ_c rises gradually with increasing values of the critical temperature (abscissa with logarithmic scale). 1, 2-methylbutane; 2, diethyl ether; 3, *n*-pentane; 4, dimethyl sulfide; 5, 2,3-dimethylbutane; 6, cyclohexane; 7, tetrachloromethane; 8, benzene; 9, tin tetrachloride; 10, chlorobenzene; 11, bromobenzene; 12, iodobenzene; 13, naphthalene.

Relation (3) does not correspond to the theorem of corresponding states; instead ρ_0/ρ_c rises slowly with T_c[7], *i.e.* with

the magnitude of the intermolecular forces[*] (Fig. 6). For organic vapors, whose critical temperatures T_c are generally lower than 500 K, $3.9 < \rho_0/\rho_c < 4$.

The van der Waals model with $V_c = 3b$ is most closely approached by H_2 with $\rho_0/\rho_c = 2.84$. In this case at T_c the mean distance of nearest neighbors $\bar{d}_c$ would be $\sqrt[3]{3}\,\bar{d}_0 = 1.44\,\bar{d}_0$, *i.e.* 1.44 times the closest packing. As Figure 7 illustrates, the mean distances $\bar{d}$ in the whole liquid range up to T_c are not very different from the distances in the crystal so that our model, in which the liquid below T_c is regarded as a close-packed melt, appears reasonable. In the hole model the distances of nearest neighbors would be even smaller than in Figure 7.

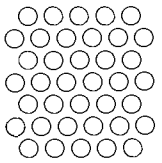

Fig. 7. Two-dimensional model of H_2 for mean particle separation $\bar{d}_c$ at the critical point.

The rise of the extrapolated zero-point density ρ_0/ρ_c with T_c is demonstrated in Figure 8 for noble gases with different

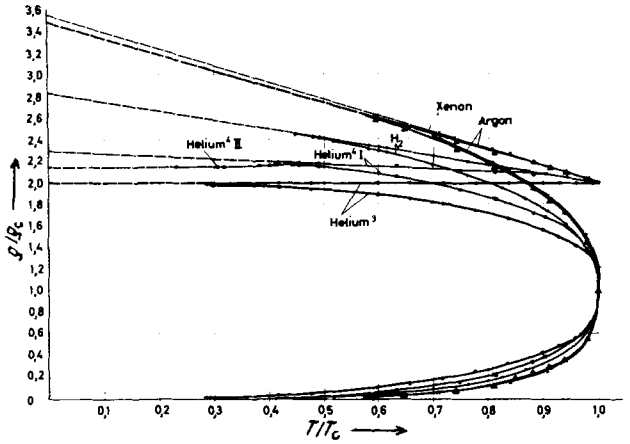

Fig. 8. $\rho/\rho_c = f(T/T_c)$; for ^{3}He and ^{4}He(II), $\rho_l + \rho_v$ is T-constant. Are there only holes, no vibration volumes?

T_c values. This shows the peculiarity that for the isotopes ^{3}He and ^{4}He(II) below the lambda point ρ_0/ρ_c is very close to 2 (for ^{3}He it is 1.9934). This means that the change in density of the ideal liquid $(\rho_l + \rho_v)$ is in this case almost zero. In our model this means that there are no oscillation volumes, and each rise in temperature merely causes an increase in the number of hole defects. A possible cause is the unusually high zero-point energy E_0 of the intermolecular degrees of freedom relative to the depth of the intermolecular potential $[(Z/2)(3/2)RT_c]$ for helium[9]:

	$3/2\,RT_c$ [cal/mol]	E_0 [cal/mol] [9]	$2E_0/Z$ [cal/mol]
^{3}He	10		
^{4}He	14	50—60	8.3—10

[*] This weak rise corresponds to the very similar rise of the critical coefficient $s = RT_c/P_cV_c$ with T_c and the small variation in $x_F(T/T_c)$ and $P\Delta V/RT_c$ with T_c [7].

In the last column E_0 has been corrected by the coordination number Z of nearest neighbors to value for the pair number $Z/2$ in order to be able to compare this value with the pair potential $(3/2)\,T_c$. Excitation of thermal oscillations in the intermolecular potential can therefore soon lead to a "dissociation" of aggregates.

3. Intermolecular Pair Potential

If the pair potential E_{pot} of the intermolecular forces and the arrangement of neighbors are known, it should in principle be possible to estimate the caloric properties of a liquid. However, can we estimate the pair potential for new substances?

The first and simplest indication of E_{pot} was the so-called Sutherland constant C, with which the temperature dependence of the gas-kinetic collision cross-section δ_T can be described:

$$\sigma_T^2 = \sigma_0^2\left(1 + \frac{C}{T}\right) \tag{4}$$

If two molecules are directly connected, then according to *Sutherland*[10]:

$$-C = \frac{2}{3R}E_{pot}; \quad -E_{pot} = \frac{3}{2}RC \tag{5}$$

For some substances, especially weakly polar ones, small deviations from the linearity of Eq. (4) are observed. We therefore redetermined the C values of all substances for which the gas-kinetic collision cross-sections are known in a sufficiently wide range of temperatures[11], and this as uniformly as possible in the neighborhood of T_c. As Figure 9 shows, the empirical relationship

$$C \approx 1.2\,T_c \tag{6}$$

was found for most substances. Consequently, according to Eqs. (5) and (6), the following relation is approximately valid:

$$-E_{pot} = \frac{3}{2}RC = 1.2\frac{3}{2}RT_c = f'\frac{3}{2}RT_c \tag{7}$$

This simple relationship permits estimation of the pair potential from T_c. Since, according to the Guldberg rule, the boiling point T_b is approximately equal to $2/3\,T_c$ and according to the Lorenz rule the melting point T_m is approximately equal to $2/3\,T_b = (2/3)^2\,T_c$, Eq. (7) shows the reason why substances can be very successfully characterized by T_b and T_m. With $3\,RT_c/2 = E_{kin}$ at T_c, Eq. (7) is reminiscent of *Kepler*'s laws of planetary motion, according to which a collision pair moves in a hyperbolic path for $|E_{kin}| > |E_{pot}|$ and in an elliptical path for $|E_{kin}| < |E_{pot}|$. Below T_c at sufficient density condensation to stable aggregates take place.

A factor with the order of magnitude of 1.2 frequently occurs in gas-kinetic derivations when the velocity distribution is neglected—as in the case of Eq. (5)[12].

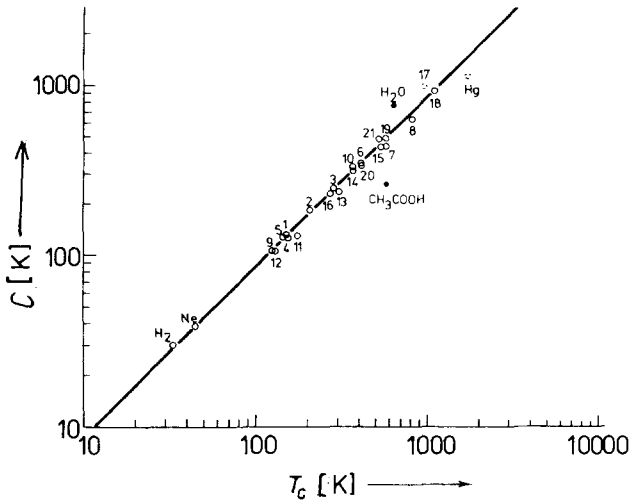

Fig. 9. Sutherland constant C and critical temperature T_c. The empirical relation $C \approx 1.2\,T_c$ holds for most substances. Consequently, T_c is a measure of the intermolecular pair potential. 1, Ar; 2, Kr; 3, Xe; 4, O_2; 5, F_2; 6, Cl_2; 7, Br_2; 8, I_2; 9, N_2; 10, H_2S; 11, NO; 12, CO; 13, CO_2; 14, COS; 15, CS_2; 16, SiH_4; 17, $HgCl_2$; 18, $HgBr_2$; 19, $SnCl_4$; 20, NH_3; 21, CH_3OH.

This estimation of E_{pot} from C and RT_c is supported by the fact that according to *van der Waals*

$$\frac{a}{3b} = \frac{a}{V_c} = \frac{9}{8} RT_c = 1.12\,RT_c$$

but empirically

$$\frac{a}{3b} \approx \frac{3}{2} CR$$

If T_c is unknown, its value can be estimated from T_b, T_m, or from group increments[7, 8].

4. Heat of Evaporation

On the basis of the hole model the heat of evaporation of a substance at constant volume, L_V, can be calculated. L_V is due to ΔH at constant pressure:

$$L_V = \Delta H - P\Delta V \tag{8}$$

For $T < T_b$, $P\Delta V = RT$. For $T > T_b$, ΔV must be calculated from measured densities; for organic vapors ΔV can be estimated from a (reduced) $P\Delta V/RT_c = f(T/T_c)$ diagram[7] or be determined by means of an approximate formula[7].

For L_V according to the hole model we have:

$$L_V = \frac{Zf}{2} R \left(\frac{3}{2} T_c - T\right)(1 - 2x_F) \tag{9}$$

Derivation: The potential energy between Z nearest neighbors is, according to Eq. (7):

$$-\frac{Z}{2} E_{pot} = \frac{3Z}{4} RT_c f'$$

At high temperatures and finite hole-defect concentrations, Z has to be corrected:

$$Z f'(1 - x_F)$$

In addition, the influence of more remote neighbors can be taken into account by a factor f'' (not exceeding 1.2[*])[2]. We combine the factors f' and f'' in f and write for the potential energy that is opposed to the forces of attraction on evaporation in vacuum:

$$\frac{3}{4} RT_c f Z(1 - x_F)$$

It must now be borne in mind that the molecular heat (molecular heat capacity) of all liquids is greater than that of the vapors because of intermolecular degrees of freedom. It has proved possible—insofar as experimental data are available—to express this heat content of the intermolecular degrees of freedom by the expression

$$\frac{fZ}{2}(1 - x_F)RT \tag{10}$$

in which for each pair of molecules an intermolecular degree of freedom is presumed. This component again becomes available on evaporation, and it must therefore be deducted from the potential energy in the calculation of L_V:

$$L_V' = \frac{Zf}{2} R \left(\frac{3}{2} T_c - T\right)(1 - x_F) \tag{11}$$

Comparison with experimental data shows good agreement for $T < T_b$, which becomes poorer at higher temperatures, where excessively high values are obtained. A value of L_V for evaporation in vacuum is calculated by means of Eq. (11); for $T > T_b$, however, the vapor pressure may rise to 100 atm and more, so that traces of intermolecular forces still remain in the real gas. On evaporation to the real gas state with a particle concentration x_F equal to the concentration of hole defects in the liquid this corresponds to a potential energy of the real vapor amounting to:

$$\frac{Zf}{2} R \frac{3}{2} T_c x_F$$

This component must be removed from Eq. (11) as unnecessary. In Eq. (11) we have deducted

$$\frac{Zf}{2} R\, x_F T$$

too much from the heat content of intermolecular degrees of freedom in the real gas, and this must therefore be added; altogether, we must subtract from L_V' the energy that would

[*] According to *Eucken*, f'' depends on the distance exponent n in $E_{pot} = f(1/r^n)$: $f''(n = 6) = 1.204$, and $f''(n = 12) = 1.01$ [12].

have to be exerted against intermolecular forces on transferring the real gas into vacuum:

$$\frac{Z}{2} fR\left(\frac{3}{2} T_c - T\right) x_F$$

In this way we obtain Eq. (9).

Testing: At low temperatures according to Eq. (9) the values of L_V correspond to a straight line whose intercept on the abscissa divided by the slope corresponds to a value of $3\,T_c/2$. This applies in all cases in which sufficient experimental data for L_V are available (Fig. 10). A magnitude of about 14 was to be expected for the product fZ[*]. We found the following values for fZ: $(C_2H_5)_2O$ 14.5, naphthalene 14.36, C_6H_5Cl 14.4, C_6H_5I 13.8, NH_3 13.8, C_6H_5Br 12.88, C_6H_6 12.82, CCl_4 12.4, and HCl 10.1. This is very good indeed. It means that our model can be used even for relatively large nonlinear molecules such as naphthalene, and even for polar molecules such as HCl.

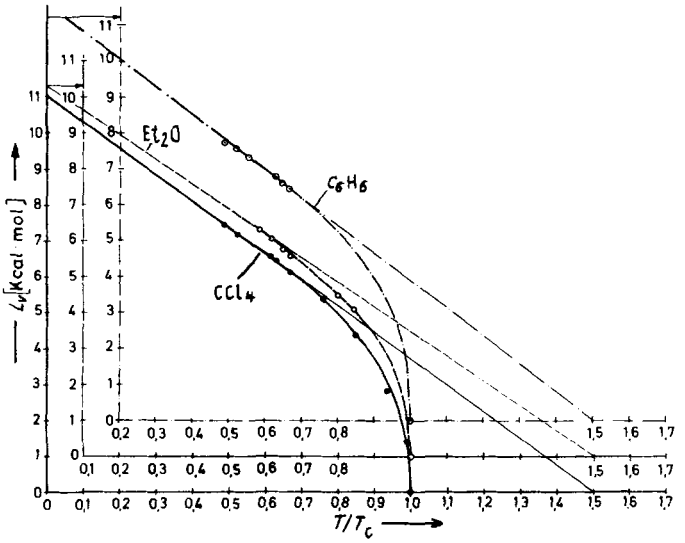

Fig. 10. Temperature dependence of the heats of evaporation L_V.

The straight lines required from Eq. (9) for low temperatures should intercept the abscissa for $L_V = 0$ at $3\,T_c/2$ (Fig. 10). The values of $L_V/(1-2x_F)$ also lie on the straight lines of Figure 10 within the accuracy of measurement of L_V. For nonpolar molecules we can therefore give: $12 < fZ < 14.5$. It is possible to determine the fZ very accurately, since it can be checked by two independent magnitudes—the slope and the intercept.

Figure 11 shows the interesting result that it is possible to understand deviations from the theorem of corresponding states on the basis of the factors fZ, which are a measure of the type of packing. The expression $L_V/fZ\,T = f(T/T_c)$ is generally valid. By measuring L_V at one temperature a value of fZ can be estimated for an unknown substance and thus the heat of evaporation can be given for all temperatures. In the range of error of 12 to 14.5, *i.e.* 20%, it is even possible to estimate heats of evaporation without making any measurement at all, provided that T_c is known or estimated with the aid of T_b.

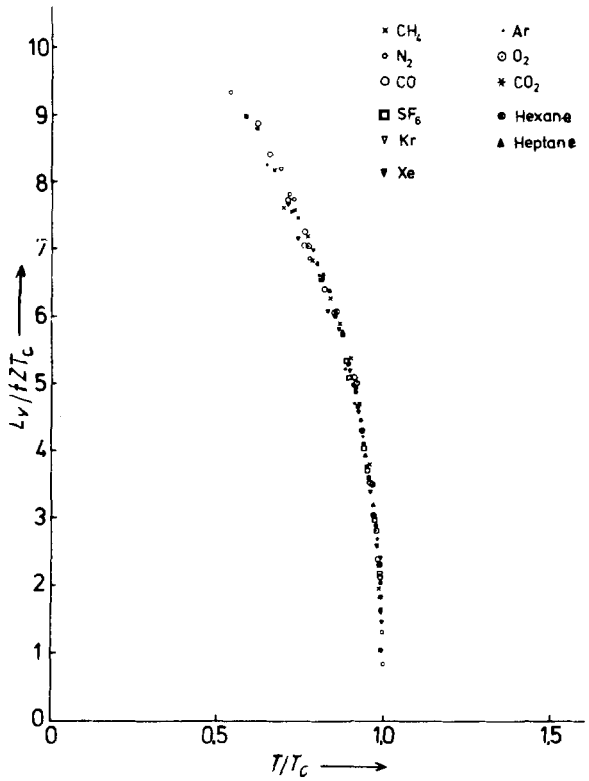

Fig. 11. $L_V/fZ\,T_c$ satisfies the theorem of corresponding states and is suitable for the estimation of unknown heats of evaporation L_V.

Eq. (9) leads not only to *Trouton*'s rule for L_V/T_b, or $\Delta H/T_b \approx 20$ cal/mol, but also explains the scatter round this value as again being due to the packing factor fZ. From Eq. (9) we obtain[5, 7] for

$$12 < fZ < 14.5$$
$$17 < \Delta H/T_b < 20$$

Deviations appear only in the cases of He, Ne, and H_2[7], which is explained by the relatively high zero-point energies E_0 of these elements; $17 < (\Delta H + E_0)/T_b < 20$ cal/mol[5].

5. Vapor Pressure Equation

The value of Eq. (9) can be demonstrated on the basis of two other facts, previously difficult to understand:

1) From the thermodynamic relation for the vapor pressure P:

$$\frac{\partial P}{\partial T} = \frac{\Delta H}{\Delta V} = \frac{L_V + P \cdot \Delta V}{T \cdot \Delta V} \tag{12}$$

it is possible to deduce as an approximation

$$\ln P = -\frac{\Delta H'}{RT} + \text{const} \tag{13}$$

in which $\Delta H'$ is constant over a wide range of T and is not identical with the T-dependent ΔH actually to be expected

[*] In the case of the closest packing of spheres, $Z = 12$. In the liquid state, because of the change in volume on melting, $Z = 0.8 \times 12 = 9.6$ and $9.6 \times f = 9.6 \times 1.2 \times 1.2 = 13.8 = fZ$.

$$\Delta H = \Delta H_0 + \int_0^T \Delta C_P \, dT$$

With

$$\Delta U_0 = \frac{3fZ}{4} RT_c \tag{14}$$

the heat of evaporation at $T=0$ it is possible to rearrange Eq. (9) in the following way:

$$L_V = \left(\Delta U_0 - \frac{fZR}{2} T\right)(1-2x_F) \tag{15}$$

In addition, the following relations hold (see eq. (2)):

$$(1-2x_F) = \frac{\rho_l + \rho_v - 2\rho_v}{\rho_l + \rho_v} = \frac{\rho_l - \rho_v}{\rho_l + \rho_v} \tag{16}$$

$$\Delta V = M\left(\frac{1}{\rho_v} - \frac{1}{\rho_l}\right) = M\frac{(\rho_l - \rho_v)}{\rho_l \cdot \rho_v} \tag{17}$$

It follows from Eq. (12) and Eqs. (14) to (17) that:

$$\frac{\partial P}{\partial T} = \left(\Delta U_0 - \frac{fZRT}{2}\right)\frac{(\rho_l - \rho_v)}{(\rho_l + \rho_v)} \cdot \frac{\rho_l \cdot \rho_v}{TM(\rho_l - \rho_v)} + \frac{P}{T}$$

$$= \left(\Delta U_0 - \frac{fZRT}{2}\right)\frac{\rho_l \cdot \rho_v}{(\rho_l + \rho_v)} \cdot \frac{1}{TM} + \frac{P}{T}$$

with $\rho_l \gg \rho_v$ and $\frac{\rho_l}{M} = \frac{1}{V_v} \approx \frac{P}{RT}$

$$\frac{1}{P}\frac{\partial P}{\partial T} = \frac{\Delta U_0}{RT^2} - \frac{fZR}{2RT} + \frac{1}{T}$$

$$\ln P = -\frac{\Delta U_0}{RT} - \left(\frac{fZ}{2} - 1\right)\ln T + \text{const} \tag{18}$$

$$\ln P \approx -\frac{\Delta U_0}{RT} + \text{const} \tag{19}$$

This corresponds to the proved Eq. (13), and shows that it contains ΔU_0, *i.e.* a T-independent magnitude.

From Eq. (18) we have also derived the improved empirical vapor-pressure equation due to *Kirchhoff*, *Hertz*, and *Dupré*[13] and to *Nernst*[14] with the characteristic summand $a \ln T$.

2) Empirically, a reduced vapor pressure equation

$$\ln \frac{P}{P_c} = g\left(\frac{T_c}{T} - 1\right) \tag{20}$$

has proved satisfactory; in this connection, *Nernst*[14] deduced the failure of the theorem of corresponding states on the basis of the material-dependent constant g.

If we write Eq. (19) for T_c and P_c and subtract this equation from the general equation (19), we obtain

$$\ln \frac{P}{P_c} = -\frac{\Delta U_0}{RT_c}\left(\frac{T_c}{T} - 1\right) \tag{21}$$

and ultimately, taking Eq. (14) into account,

$$\ln \frac{P}{P_c} = -\frac{3}{4} fZ\left(\frac{T_c}{T} - 1\right) \tag{22}$$

This is equivalent to Eq. (20) and shows that the substance-specific constant g is determined by the packing density fZ. The correction factor fZ for the theorem of corresponding states gives us a better insight into the properties of liquids.

6. Surface Energy U_σ

6.1. U_σ According to the Hole Model

Surface tension σ is defined as the energy necessary to increase a surface by 1 cm^2. Since the number of molecules per cm^2 is dependent on the material and the temperature, the molar surface energy σ_M must be used in discussions of structure[15, 16].

$$\sigma_M = N_A^{1/3} V^{2/3} \sigma \tag{23}$$

As isothermally measured work, σ_M is a free energy, and the surface enthalpy H_σ can be calculated from it by the Gibbs-Helmholtz equation:

$$H_\sigma = \sigma_M - T\frac{\partial \sigma_M}{\partial T} \tag{24}$$

In general, H_σ differs only very slightly from the surface energy U_σ.
