Another obvious method is the retention of spherical orientation averaged atomic pair correlation functions in molecular liquids (the average over all orientations has to be formed at fixed atom-atom distance). For a molecule consisting of n non-equivalent atoms, there are $(1/2)\ (n^2+n)$ such functions. Knowledge of the g-coefficients allows the calculation of these functions[69]. The converse, however, is impossible. Sometimes the calculation of thermodynamic data using these functions proves to be very complicated, as shown *e. g.* by the relations describing the pressure[70]. Of course, atom pair correlation functions may also be obtained by computer simulations; then one extracts less complete information from the respective simulation. Apart from the publications cited above computer simulations of the systems H_2O, C_6H_6, NH_3, CCl_4 (all summarized in reference [71]) and CH_4[72] should be mentioned. If a hard sphere potential is chosen to describe the interatomic interactions, an analytical calculation of the atomic pair correlation functions is possible with the aid of a modified Percus-Yevick theory (RISM-theory)[73]. A comparison with X-ray and neutron experiments can easily be performed, because the formulas describing the scattering, if expressed by atomic pair correlation functions according to eq. (15), contribute additively to the total scattering intensity. The combination of various scattering experiments (electron, X-ray and neutron scattering), or, the use of different isotopes in neutron experiments, allows also in this case a separation into the individual contributions[52, 53, 56].

To obtain structural information from a single scattering experiment, or from one of the integral relations for $G^{(1)}$, $G^{(2)}$, or T_1, one needs very detailed models. The work concerned with the latter topics has not been discussed here. The reader is referred to recent reviews on the results from X-ray scattering experiments[74] and nuclear magnetic relaxation measurements[75].

A great deal of work has still to be done before our knowledge of molecular liquids is as detailed as our knowledge of atomic liquids. On the other hand, present activities in this field are promising. In particular, one may hope that simply applicable statistical mechanical methods for structural calculations will be developed, so that one is not entirely committed to computer simulations. Only then will more and more realistic potentials be developed by comparison with the previously described experiments, which then allow the calculation of all measurable quantities. At present, the situation is delightful for the experimentalists, for one cannot renounce their measurements.

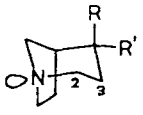
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

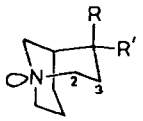
Inductive, CC-Hyperconjugative, and Frangomeric Effects in Solvolytic Fragmentation Reactions

By *Cyril A. Grob, Martin Bolleter,* and *Walter Kunz*[*]



1-Azabicyclo[3.2.1]octyl *endo*-4-*p*-toluenesulfonate *(1a)*, 1-azabicyclo[3.3.1]nonyl *endo*-4-*p*-toluenesulfonate *(2a)*, and the equatorial[1] 4-bromo-1-azaadamantane *(3a)* undergo quantitative fragmentation in 80% ethanol to give the methyleneimmonium salts *(7)*, *(8)*, and *(9)*, respectively[2]. Moreover, they react some 10^3, 10^4, and 10^5 times faster than the nitrogen-free parent compounds *(4a)*, *(5a)*, and *(6a)*. This comparison demonstrates the pronounced frangomeric acceleration of the ionization of *(1a)*, *(2a)*, and *(3a)*[3]. The azabicyclics thus react by a concerted mechanism, as was to be expected from the antiperiplanar arrangement of the C(4)—R′ bond and the electron pair at N(1) relative to the C(2)—C(3) bond[3].

On the other hand, the axial[1] epimer *(1b)* in which this stereoelectronic condition is not fulfilled (cf. ref.[3]) reacts slower than the parent compound *(4b)*, giving the substitution and elimination products *(1c)*, *(1d)*, and *(12)*, respectively, along with the fragmentation product *(7)*. The fivefold slower reaction of *(1b)* relative to *(4b)* and the formation of several products suggest the intermediacy of the cation *(10)*, whose formation is rendered more difficult by the electron-withdrawing inductive ($-I$) effect of the nitrogen atom (SOH = solvent).



Surprisingly, the likewise axial[1] epimer *(2b)* reacts twice as fast, and *(3b) even 1230-times as fast* as *(5b)* and *(6a)*[5], respectively, although the stereoelectronic conditions for a concerted fragmentation are again not fulfilled[4]. In the case of *(2b)* and *(3b)*, fragmentation forming *(8)* and *(9)*, respectively, is accompanied by substitution giving *(2c)* and *(3c)*, and with *(2b)* by elimination giving the olefin *(13)*; this indicates occurrence of the cationic intermediates *(11)* and *(14)*, respectively. This assumption is supported by the observation that addition of ten mol. equiv. of sodium azide to an aqueous solution of *(3b)* hardly affects the reaction rate, while the yield of *(9)* falls from 75 to 58%. The question thus arises as to how the nitrogen atom accelerates the ionization of the axial bromide *(3b)* to form *(14)*.

Fundamental studies by *Schleyer et al.*[6] have shown that nucleophilic participation of the solvent in the ionization of secondary *p*-toluenesulfonates (S_N2 with intermediate) is highly dependent upon steric hindrance at the rear of the reaction site. This hindrance is only slight in simple acyclic tosylates, significantly stronger in the cyclic compounds, and so strong in 2-adamantyl *p*-toluenesulfonate *(6b)* that nucleophilic participation of the solvent is no longer detectable[7]. This participation should therefore be practically ruled out in the ionization of the axial 4-bromo-1-azaadamantane *(3b)* but not in the case of *(1b)* and *(2b)*.

However, since the positive charge at the reaction site is largely transferred to the solvent by nucleophilic solvation, the electron deficiency at C(4) is only slight in the ion pairs *(10)* and *(11)* so that only the $(-I)$ effect of the nitrogen atom should be effective. But if access of solvent is hindered, as in *(14)*, then the positive charge spreads over the molecule, and particularly to the nitrogen atom if, as in *(15)*[8], it is hyperconjugated *via* a CC single bond with the cationic site at C(4)[9]. This also applies to the equatorial epimers *(1a)*, *(2a)*, and *(3a)*, in which nucleophilic solvation is likewise hindered but which can undergo concerted fragmentation. Thus exclusion of solvent triggers a reaction-promoting hyperconjugative or frangomeric effect. However, the stereoelectronic requirements for CC hyperconjugation are evidently less rigorous than for concerted fragmentation, and also less rigorous than conventional orbital models would suggest.

$(R_2NPO)_3$: A Novel Heterocycle with λ^3-Phosphorus by Trimerization of an Aminooxophosphane[**]

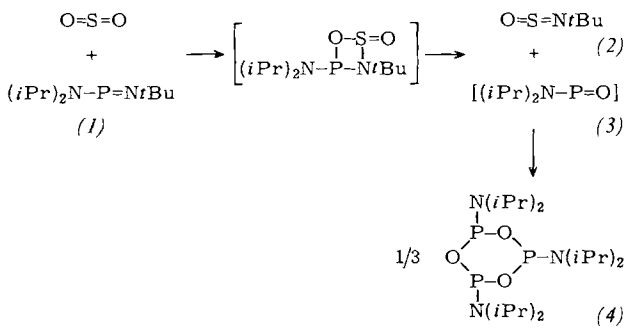
By *Edgar Niecke, Hans Zorn, Bernt Krebs*, and *Gerald Henkel*[*]

The Staudinger iminophosphorane/carbonyl reaction and its sulfinyl variant[1] are of preparative importance for the coupling of nitrogen-carbon and nitrogen-sulfur double bonds, respectively.

X = C, S

In the case of iminophosphanes, however, this reaction provides a possible approach for the generation of phosphorus compounds with $p_\pi(P)$—$p_\pi(O)$ bonding. This class of compounds is gaining more and more interest in connection with investigations on highly reactive species containing element-element multiple bonds[2].

We report here on a pseudo-Wittig reaction of the iminophosphane *(1)*, which leads to the previously unknown 1,3,5-trioxa-2λ^3,4λ^3,6λ^3-triphosphorin system.



Diisopropylamino-*tert*-butyliminophosphane *(1)* already reacts with sulfur dioxide at $-25\,^\circ C$[3] to give *tert*-butyliminosulfur oxide *(2)* and a product of the composition

[**] Phosphazanes of Coordination Number 2 and 3, Part 18. This work was supported by the Fonds der Chemischen Industrie. We thank Dr. *T. Wirthlin*, Varian AG, Zug/Switzerland for carrying out the NMR measurements.—Part 17: *E. Niecke, D.-A. Wildbredt*, Chem. Ber. *113*, 1549 (1980).

"R_2NPO", which proved to be the trimer *(4)* of the aminooxophosphane (phosphinidene oxide) *(3)*.

Presumably, in the initial step of the reaction a [2+2]-cycloaddition product is formed, which decomposes to kinetically labile *(3)*. Compound *(3)* is stabilized by coordinative saturation at the phosphorus to give the trioxatriphosphorin *(4)*—a reaction which can be formally compared with the observed cyclization in the isoelectronic XSN-system ($3XSN \rightarrow (XSN)_3$[4]).

The phosphorus-oxygen heterocycle *(4)* is a colorless, crystalline solid (m.p. 109 °C), sensitive to atmospheric moisture and oxygen. The composition and structure are secured by elemental analysis, mass spectrum[5], and NMR data, as well as by X-ray structure analysis (Fig. 1).

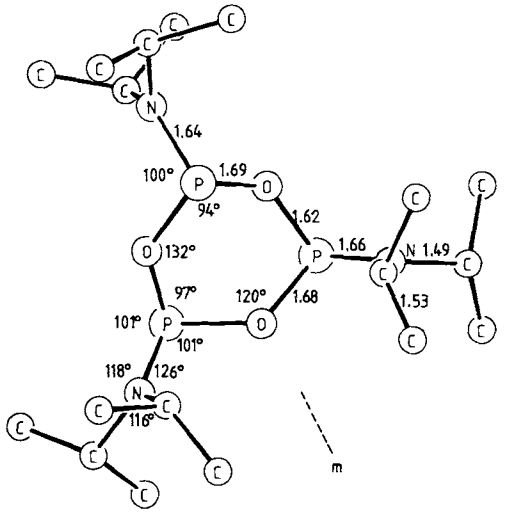

Fig. 1. $P_3O_3[N(i\text{-}C_3H_7)_2]_3$ *(4)* in the crystal, with average bond lengths [Å] and angles (σ *ca.* 0.012 Å and ca. 1.0°, resp.). *(4)*: space group $P2_1/n$, $a = 10.092(4)$, $b = 36.848(15)$, $c = 7.484(3)$ Å, $\beta = 106.54(3)°$, $Z = 4$ (at −133 °C).

The $^{31}P\{^1H\}$-NMR spectrum (30% solution in C_6D_6; H_3PO_4 ext.; 25 °C) shows the preferred population of only one isomer (>98%)[6] with two types of stereochemically different phosphorus atoms ($\delta A = 140.3$, $\delta B_2 = 131.3$, $^2J_{P_AP_B} = 13.5$ Hz), whose signals lie in the same region as those of 2-amino-1,3,2-dioxaphosphorinanes[7]. In accord with the ^{31}P-NMR spectrum, the ^1H-NMR spectrum (30% solution in CH_2Cl_2: TMS int.; 25 °C) shows two multiplets, each (2:1) for the methyl- and methine-protons: $\delta = 1.21$ ($^3J_{HH} = 6.8$ Hz), 3.59 ($|^3J_{HP_B} + {}^5J_{HP_B}| = 10.8$ Hz $[P_BN(CHMe_2)_2]$), 1.24 ($^3J_{HH} = 6.8$ Hz), 3.83 ($^3J_{HP_A} = 11.5$ Hz $[P_AN(CHMe_2)_2]$).

In the solid state the heterocycle *(4)* has, to a close approximation, C_s-symmetry. The sterically homogeneous molecules are disordered in the unit cell. Surprisingly, the heterocycle has almost ideal boat conformation in the crystal, whereby the transannular P...O distance (3.01 Å) between the ring atoms in the mirror plane of the molecule can possibly be seen as an indication of a 1,4-dipole-dipole interaction. The ligands take up the equatorial position at the phosphorus atoms, in which both a 1,3 repulsion of the ligands is minimized and a more effective $p_\pi(N)$—$d_\pi(P)$ interaction is achieved. The transfer of electrons from the nitrogen to the phosphorus manifests itself in the relatively short P—N bonds (1.64 and 1.66 Å) as well as in the planar arrangement of the ligands at the nitrogen atoms.

The molecule *(3)* can be trapped by complexation[8].

Procedure

About 180 mmol SO_2, dried with $CaCl_2$, is passed into a solution of *(1)* (9.5 g, 47 mmol) in ether (15 ml) at −25 °C under N_2. Immediately after passage of SO_2 is complete the excess SO_2 is removed under further cooling. The reaction solution is then warmed up to room temperature, and the solvent and any *(2)* that is formed are removed. Finally, the solid product is recrystallized twice from benzene; yield 2.8 g *(4)* (41%), colorless needles, m.p. 107 °C.

Complex-Stabilization of an Aminooxophosphane (Phosphinidene Oxide)[**]

By *Edgar Niecke, Monika Engelmann, Hans Zorn, Bernt Krebs*, and *Gerald Henkel*[*]

While stable methylenephosphanes *(1)* and iminophosphanes *(2)* have been reported recently, the existence of the phosphorus-oxygen $(p\text{-}p)_\pi$ bond, such as in *(3)*, has not been verified, although trapping reactions would indicate the formation of such a species[2]. Recently, reaction of aminoiminophosphane *(4)* and sulfur dioxide yielded the trioxatriphosphorine *(6)*, which is presumably formed by stereospe-

cific cycloaddition of the intermediate aminooxophosphane (phosphinidene oxide) *(5)*[1]. By application of the SO_2-reaction to the iminophosphane complex *(7)* we have now succeeded in trapping the aminooxophosphane as complex *(8)*.

The compounds *(7)* and *(8)* are pale yellow crystalline solids which are sensitive to atmospheric moisture and oxygen. Their composition and constitution are confirmed by elemental analysis, IR, Raman, NMR and mass spectral data, and by complete X-ray structure analyses.

The mass spectrum (Varian 311A, 70 eV, direct sample introduction) of *(7)* (L = $(iPr)_2NPNtBu$) and of *(8)* (L = $(iPr)_2NPO$) show the molecular ion $LCr(CO)_5^+$ [*m/e* = 394 (3%) and 339 (4%), resp.] and the fragments $LCr(CO)_n^+$ (*n* = 4—0) resulting from successive cleavage of CO, with the LCr^+ fragment (*m/e* = 257 and 199, resp.) as base peak. In the IR and Raman spectra (Table 1) of *(7)* and *(8)* five bands appear in the expected ν(CO) range which can be considered as resulting from a strong perturbation of the local C_{4v} symmetry of the $Cr(CO)_5$ group. The frequency shift to high wave numbers observed in the case of *(8)* is possibly due to the stronger π-acceptor properties of the aminooxophosphane ligand.

Table 1. Characteristic IR [a] and Raman data [b] of compounds *(7)* and *(8)*.

(7) IR	*(7)* Raman	*(8)* IR	*(8)* Raman	For (C_{4v})

1340 m, br.	1344 s, br. [c]	1198 m	1203 s [d]		

[a] Nujol mull. [b] Solid. [c] ν(P=N). [d] ν(P=O).

The broad intense Raman line at 1344 cm^{-1} in *(7)*, as in the case of other iminophosphane complexes[3], can be ascribed to strengthening of the P=N-bonding [in *(2)*: 1242 cm^{-1}[4]] by coordination. In *(8)* a Raman band of comparable intensity appears at 1200 cm^{-1}; accordingly, it should arise from a stretching vibration with predominant P=O character.

The ^1H- and $^{13}C\{^1H\}$-NMR spectra of *(7)* and *(8)* show the expected groups of signals (Table 2). In the ^{31}P-NMR spectrum of *(7)* the coordination of the iminophosphane results in an upfield shift of the ^{31}P resonance signal[3,5] [δ = 224.0; for comparison, 295.2 in *(4)*]. On the other hand, the replacement of the *tert*-butyl imino-group in *(7)* by oxygen as in *(8)* leads to strong deshielding of the phosphorus atom (δ = 319.2), from which it can be concluded that the phosphorus in *(7)* is considerably more electrophilic than in *(4)*. These findings are consistent with an extremely reactive "free" aminooxophosphane.

Figure 1 shows the molecular structure of the complex *(8)*[6]. The central phosphorus atom is trigonal-planar

Table 2. ^{31}P-, ^1H- and ^{13}C-NMR data of the compounds *(7)* and *(8)* [a].

	(7)	*(8)*
$\delta(^{31}P)$	224.0	319.2
$\delta(^1H)$ (J_{HP} [Hz])		
*t*Bu	1.40	—
*i*Pr	1.17, 3.77 [b] (15.3)	1.23, 3.25 [b] (13.5)
$\delta(^{13}C)$ (J_{CP} [Hz])		
*t*Bu	33.5 (5.9), 57.0 (1.9)	—
*i*Pr	22.2 (3.3), 48.9 (9.6)	22.4 (3.3), 50.2 (10.3)
CO_{eq}	215.1 (16.0)	213.9 (18.7)
CO_{ax}	220.3 (3.6)	218.2

[a] 20% solution in $CDCl_3$; H_3PO_4 ext. (^{31}P) or TMS (^1H, ^{13}C) int.; 25 °C. [b] $^3J_{HH}$ = 6.7 *(7)*, 5.9 Hz *(8)*.

coordinated, as it is in the complexes $(CO)_5CrL$ [L = $(Me_3Si)_2NP{=}NtBu$, $tBuHNP{=}NSiMe_3$][3c], whose structures were analyzed previously. The extremely short $P—N_{amine}$ distance[7] and the P=O bond length, which is comparable with that in trimethylphosphane oxide[8], are compatible with a pseudoallylic $R_2\overset{+}{N}\cdots P\cdots\bar{O}$ interaction.

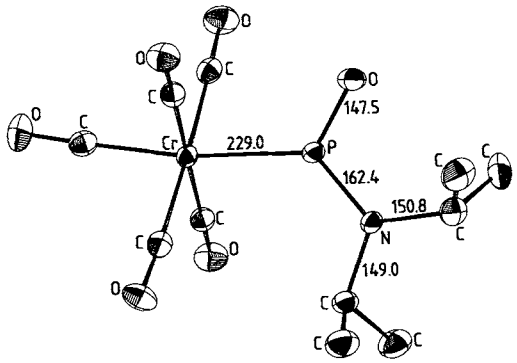

Fig. 1. Molecular structure of *(8)* (without H atoms; vibration ellipsoids with 50% probability) with important bond lengths (pm; σ = 0.2 pm). Further bond data: O—P—N 120.6(1)°, O—P—Cr 111.4(1)°, N—P—Cr 128.0(1)°; Cr—C_{ax} 188.4(2) pm, Cr—C_{eq} 190.2—191.4(2) pm.

This is in accord with an almost planar arrangement of the C_2N—P=O moiety; the dihedral angle between the C_2N- and NPO-plane is only 1.6°. The P—Cr distance is significantly shorter than in the corresponding iminophosphane complexes[3c], which should be attributed to better π-acceptor properties of the aminooxophosphane ligand. These properties result from the higher orbital electronegativity of the phosphorus in *(8)* in comparison with that in the iminophosphanes.

Procedure

All reactions are carried out in anhydrous solvents under N_2. *(7)*: A solution of *(4)* (4.4 g, 22 mmol) and $Cr(CO)_6$ (5.0 g, 23 mmol) in tetrahydrofuran (THF) (250 ml) is irradiated in a photoreactor at −5 °C until about 2/3 of the calculated amount of CO has been formed. The solution is then concentrated to 50 ml and unreacted $Cr(CO)_6$ is filtered off. The residue after removal of solvent is recrystallized twice from *n*-hexane; yield 2.8 g (32%) *(7)*, m.p. 95—98 °C (dec.).

(8): About 15 mmol SO_2, dried over $CaCl_2$, is passed into a solution of *(7)* (2.1 g, 5.3 mmol) in ether (20 ml) at −30 °C. Unreacted SO_2 is removed at −30 °C and the reaction solution warmed to room temperature. The crude product [*ca.* 80% *(8)*] after removal of solvent and any *t*BuNSO that is

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0909-0711 $ 02.50/0

formed is purified by sublimation at 50 °C/0.1 torr; yield 0.9 g (43%) *(8)*, m.p. 93—96 °C (dec.).

An Amino-Protecting Group for Use in Peptide Synthesis Which Can Be Introduced Electrochemically[**]

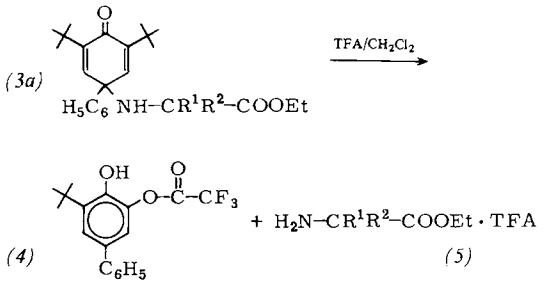
By *Mohamed Hassen Khalifa, Günther Jung,* and *Anton Rieker*[*]

In acetonitrile, sterically hindered phenols of type *(1)* can be electrochemically oxidized to phenyloxylium ions which form *p*-quinols or *p*-quinol derivatives in the presence of nucleophiles (water, alcohols and amines)[1,2]. The specificity and yield of this synthesis are usually far higher than normally attained in chemical oxidation.

We now report the application of electrochemical oxidation of 2,4,6-trisubstituted phenols to the synthesis of new *N*-protected amino acids and peptide derivatives. A suitable reagent is 3,5-di-*tert*-butyl-4-biphenylol *(1a)* which is readily accessible by reaction of 2,6-di-*tert*-butyl-1,4-benzoquinone with phenylmagnesium bromide and subsequent reduction with zinc/HCl[3,4]. Introduction of the new protecting group 3,5-di-*tert*-butyl-4-oxo-1-phenyl-2,5-cyclohexadienyl (PCHd)

(a), R = C_6H_5
(b), R = $C(CH_3)_3$

is accomplished by anodic oxidation of *(1a)* in dichloromethane in the presence of the free amino acid esters *(2)* at an anode potential of +1300 mV *vs* Ag/0.01 M $Ag^{\oplus}$ at a platinum electrode in an undivided cell.



The *N*-(PChd)-amino acid esters *(3a)* (Table 1) are usually formed cleanly, with high selectivity, and without racemization. Polyfunctional amino acids have to be completely blocked except for the amino group to be protected.

Table 1. Yields and physical data of selected PChd-protected amino acids *(3a)* and peptides derivatives.

N-PChd derivative	Yield [%]	M.p. [°C]	$[\alpha]_D^{20}$ [e]	R_F [g]
PChd-Gly-OH	90 [a]	167—168	—	0.30 (II)
PChd-L-Ala-OH	94 [a]	181—183	−125.9	0.45 (II)
PChd-Aib-OEt	97 [b]	88—89	—	0.26 (I)
PChd-Aib-OH	94 [c]	169—171	—	0.48 (II)
PChd-L-Leu-OBzl	89 [b]	86—87	−169.5	0.41 (I)
PChd-L-Leu-OH	60 [c]	131—133	−185.3	0.69 (II)
PChd-L-Pro-OBzl	59 [b]	144—145	+ 55.3	0.29 (I)
PChd-L-Pro-OH	57 [c]	81—82	+183.8	0.56 (II)
PChd-L-Leu-Gly-NH_2	85 [d]	148	+ 51.3 [f]	0.58 (II)
PChd-L-Pro-L-Leu-Gly-NH_2	75 [d]	116—118	+ 70.5	0.54 (II)

[a] Based on *(1a)* after hydrolysis of *(3)*. [b] Based on *(1a)* (on reaction of H-Aib-OEt with *(1a)* in a molar ratio of 1:1 the yield is 82%). [c] Based on hydrolysis of *(3)*. [d] Based on coupling of PChd-Leu-OH and PChd-Pro-OH, respectively. [e] $c = 1$, ethanol. [f] $c = 0.4$. [g] (I) Dichloromethane/light petroleum (3:2), (II) chloroform/methanol (8:1).

The alkali-stable PChd group can be quantitatively removed by 50% trifluoroacetic acid (TFA) in dichloromethane within 15 min at 25 °C. The protecting group regenerates a phenol *(4)*[5] which can easily be separated from the amino acid ester *(5)* by extraction with diethyl ether.

These mild acidolysis conditions permit selective use of this protecting group alongside benzyloxycarbonyl, benzyloxy, and benzyl ester protecting groups, even in syntheses involving repeated coupling and deblocking steps.

Particularly useful is the quantitative hydrogenolytic removal with Pd/C (10%) in methanol which regenerates the protecting group in its original form *(1a)*. This method of removal permits its use alongside all hydrogenolysis-stable protecting groups, *e.g.* the Boc group.

The applicability of the PChd protecting group in peptide synthesis has been tested in the case of the MSH inhibitor H-L-Pro-L-Leu-Gly-NH_2[6] (see Table 1). Coupling of PChd-L-Leu-OH with H-Gly-NH_2 by the DCC/HOBt method afforded PChd-L-Leu-Gly-NH_2. The H-L-Leu-Gly-NH_2 generated both by acidolysis as well as hydrogenolysis was then reacted with PChd-L-Pro-OH by the same method to give well-crystalline, unequivocally characterized PChd-L-Pro-L-Leu-Gly-NH_2 which, on hydrogenolysis, gave chromatographically pure, racemate-free H-L-Pro-L-Leu-Gly-NH_2. Thus the new protecting group fulfils the requirements of unequivocal peptide syntheses[7]. The PChd group also facilitates ready fast monitoring of the course of reaction by means of UV detection. Easy recovery of the phenol *(1a)* after hydro-

genolytic removal of the protecting group should prove valuable, above all when working on a large scale.

Anodic oxidation of the phenol *(1b)* in the presence of amino acid esters *(2)* afforded *N*-(1,3,5-tri-*tert*-butyl-4-oxo-2,5-cyclohexadienyl)amino acid esters; however, the yield obtained is lower (<50%). Removal of this protecting group can only be accomplished by catalytic hydrogenation. Finally, the PChd group can also be introduced electrochemically to protect the carboxy group of *N*-protected amino acids.

General procedure

(1a) (2.82 g, 10 mmol), *(2)* (20 mmol), and 2,6-dimethylpyridine (2.14 g, 20 mmol) are dissolved in dichloromethane (150 ml) which is 0.1 M in Et_4NBF_4. After saturation with N_2 the mixture is electrolyzed at Pt gauze electrodes in an undivided cell[2]. The initial anode potential is chosen (*ca.* +1000 mV *vs* Ag/0.01 M $Ag^{\oplus}$) such that the current lies below 130 mA. In the course of electrolysis the current falls off; the electrode potential is then increased stepwise to +1300 mV and the reaction continued until *(1a)* has been completely consumed. The solvent is removed *in vacuo* and the residue washed repeatedly with diethyl ether. The oily residue of PChd-amino acid ester *(3a)* and 2,6-dimethylpyridine, obtained after removal of the ether, can be separated by a single filtration over silica gel (light petroleum 60—90 °C/dichloromethane 2:1 as eluent) and crystallization from alcohol. Oily PChd-amino acid esters (Gly, Ala) can also be hydrolyzed with 0.2 N NaOH in CH_3OH/H_2O (4:1) immediately upon extraction.

The Ambiphilicity of 1,1-Diethoxy-4,4,4-trifluoro-3-(trifluoromethyl)-1,2-butadiene[**]

By *Rolf W. Saalfrank, Winfried Paul,* and *Heide Liebenow*[*]

Electron-rich or electron-deficient allenes, *e.g.* tetrakis(dimethylamino)allene or allenetetracarboxylic acid tetraethyl ester, respectively react at the central atom C^2 with electrophiles or nucleophiles to give dipolar products[1]. Ambiphilic carbenes, *e.g.* chloro(methoxy)carbene, exhibit electrophilic and nucleophilic selectivity, respectively, towards electron-rich and electron-deficient olefins[2]. If the donor substituent (Do) in an ambiphilic carbene *(1)* is replaced by a stabilized

(1) *(2)* *(3)*

anion, and the acceptor substituent (A) is replaced by a stabilized cation, then one obtains a dipolar carbene *(2)* which can also be regarded as allene *(3)*. We have now found that such donor/acceptor-substituted allenes are likewise ambiphilic, *i.e.* can react at the central atom C^2 both electrophilically as well as nucleophilically.

Reaction of hexafluoroacetone *(4)* with (2,2-diethoxyvinylidene)triphenylphosphorane *(5)* affords the thermally surprisingly stable 3-(diethoxymethylene)-2,2,2-triphenyl-4,4-bis(trifluoromethyl)-1,2λ^5-oxaphosphetane *(6)*[3] (yield 92%; m.p. 109 °C, dec.), which only decomposes above 100 °C into triphenylphosphane oxide and 1,1-diethoxy-4,4,4-trifluoro-3-(trifluoromethyl)-1,2-butadiene *(7)*. The characterization of *(6)* as a derivative of pentavalent phosphorus was achieved $^{31}P\{^1H\}$-NMR spectroscopically (Table 1). The $^{13}C\{^1H\}$-NMR spectrum contains only four signals (Table 1) for the three phenyl groups. The equilibration of the apical and equatorial positions of the trigonal-bipyramidal structure *(6)* already takes place rapidly (^{13}C-NMR time scale) at room temperature by a ligand-rearrangement process.

Table 1. Some characteristic spectroscopic data of the compounds *(6)—(12)* [a].

[**] Donor/Acceptor-Substituted Allenes, Part 5. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 4: *R. W. Saalfrank, E. Ackermann, H. Winkler, R. Böhme*, Chem. Ber., in press.

A simplified flash thermolysis of the primary product *(6)* opens a facile entry to the allene *(7)* (yield 79%; m.p. $\approx -5\,^{\circ}C$), which is storable in the cold for some time, but rapidly ($\tau_{1/2} \approx 5$ min) forms a crystalline center-center dimer[4] at room temperature. The spectral data of *(7)* (Table 1) confirm the proposed structure.

Characteristic for the ambiphilic donor/acceptor allene *(7)* is the finding that it can be attacked both nucleophilically as well as electrophilically at the carbon atom C^2. For example, nucleophilic attack with Grignard reagents and subsequent elimination of a fluoride ion affords the 1,3-butadiene derivatives *(8)* [*(8a)* and *(8b)*: yield 66% and 70%, resp.; b.p. 87 and 35 °C/0.5 torr, resp.], while electrophilic attack with water or ethanol furnishes the addition products *(9)*. *(9a)* spontaneously loses ethanol to give the ethyl 4,4,4-trifluoro-3-trifluoromethylcrotonate *(10)* [yield 78%; b.p. 127 °C (126—127 °C[5])], whereas the ethyl 4,4,4-trifluoro-3-trifluoromethylorthocrotonate *(9b)* (yield 74%; b.p. 30 °C/0.3 torr) can be isolated.

Addition of phenyl isocyanate to the allene *(7)* affords the 1:1 cycloadduct *(11)* (yield 64%; m.p. 48 °C). As in other similar cases, a polar two-step process[6] is assumed for this [2+2]-cycloaddition of an electrophilic reagent to an electron-rich π-system. The ^{1}H-NMR spectrum of the β-lactam *(11)* shows two equivalent ethyl groups, the ^{19}F-NMR spectrum two non-equivalent trifluoromethyl groups (Table 1).

Further proof of the structure of *(11)* is provided by its acid hydrolysis to the ester *(12)* (yield 75%; m.p. 142 °C).

Procedure

(6): 1.7 g (10.0 mmol) of *(4)* is fed into a solution of *(5)*[7] (3.8 g, 10.0 mmol) in anhydrous ether (40 ml) at −78 °C in the absence of moisture. After warming to room temperature the solvent is distilled off and the residue [*(6)*] recrystallized from dichloromethane/ethyl acetate (1/10).

(7): *(6)* (5.4 g, 10.0 mmol) is decomposed in a Schlenk tube by immersion in an oil-bath heated to 150 °C at 0.5 torr; the allene *(7)* that distils over is frozen in a trap cooled to −78 °C.

Photoreactions of Stilbene with Caffeine: Known, and New Types of Reactions[**]

By *Gerd Kaupp* and *Heinz-Willi Grüter*[*]

The kinetic, spectroscopic and stereochemical detection of diradicals in cyclovinylogous additions (or reversions)[1] enabled a planned search for new types of reactions. It is to be expected that diradicals not only stabilize themselves by cycloadditions (or cycloreversions)[1] and H-shifts[2], but also by substituent migrations and fragmentations with carbene formation. We report on three new types of reactions which occur alongside the usual [2+2]-[3] and [4+2]-photocycloadditions[4] and which are particularly easy to detect because of the ^{1}H-NMR key signals of the methyl groups when caffeine *(2)* traps electronically excited stilbene *(1*)*. The products *(3)*, *(4)* ([2+2]-addition), *(5)* ([4+2]-addition followed by methylamine elimination), *(6)*, *(7)*, and *(8)* are formed in the

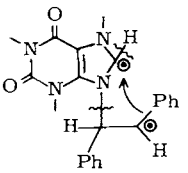
[a] Irradiation (λ=250; 290 nm) at 293 K and 83 K rapidly leads to decomposition to *(1)* and *(2)*. [b] Without resolution of the long-range couplings. [c] On irradiation the *Z*-isomer absorbing at longer wavelengths is formed photoreversibly. [d] Consistent with data in the literature (*K. Bhushan, J. H. Lister*, Aust. J. Chem. *29*, 891 (1976)). [e] M.p. 176—178 °C (*H. Goldner, G. Dietz, E. Carstens*, Justus Liebigs Ann. Chem. *692*, 134 (1966)); 185 °C (*F. Yoneda, T. Nagamatsu*, J. Chem. Soc. Perkin I *1976*, 1547; we thank Prof. *Yoneda* for communicating his ^{1}H-NMR data, which are in complete agreement with ours).



The formation of *(6)* [substitutive addition with phenyl migration and cleavage of the double bond of *(1)*], of *(7)* [substitutive addition with the cleavage of the double bond of *(1)*] and of *(8)* [intermolecular exchange of vinyl substituents] are without precedence. Their formulation is especially simple and clear if one assumes initial formation of 1,4-diradicals *(9)*, *(10)* and *(11)*, as in the cycloadditions[1] to give *(3)*, *(4)* (initial attack at C-4 or C-5)[3] and *(5)* (initial attack at C-5 or C-8)[4]. The indicated rearrangements and bond cleavages would then have to take place in order to form the products[6].

(9)

(10)

(11)

The experimental results show that hitherto unknown types of reactions predominate and enable the synthesis of interesting products such as that of the oxidizable and acylatable *(6)* from the rare class of enediamines, without well-known reactions such as the formation of [4.3.2]propellanes[3] [*(3)* and *(4)*] being completely suppressed[7]. The new types of reactions are applicable to other heterocycles. Thus, the photoreaction of *(1)* with benzothiazole leads predominantly to 2-benzylidene-3-phenylbenzothiazoline [analogous to *(6)*] and 2-(1,2-diphenylethyl)benzothiazole (H-migration) in the ratio 1:1[7].

Procedure

A solution of *(1)* (1.0 g, 5.5 mmol) and *(2)* (10 g) in dichloromethane (150 ml) under N_2 is irradiated for four days with a mercury high-pressure lamp (Philips HPK 125 W) using a Solidex filter (λ>300 nm)[8]. The solvent is removed by evaporation and the residue is extracted with 3 × 100 ml hot benzene. Unreacted *(2)*, which precipitates on cooling the combined extracts, is filtered off and the residue from the mother liquor (2.3 g) is separated by preparative TLC on 300 g SiO_2, firstly with cyclohexane [400 mg *cis*-stilbene, 95 mg unreacted *(1)*, 70 mg stilbene dimers[2]] and finally with ethyl acetate. 350 mg (17%) of *(6)*, 230 mg (11%) of *(3)* and 60 mg (4%) of *(7)* were isolated (cryst. in heptane and isopropanol). Repeated preparative TLC furnishes 60 mg (4%) *(8)* and 20 mg (1%) *(5)* (cryst. in methanol). *(4)* (50 mg, 2.5%) is purified by preparative HPLC [pre-packed column (Knauer: length 25 cm, diameter 32 mm, 10 μm-LiChrosorb RP-18), 73% methanol] (cryst. in heptane).

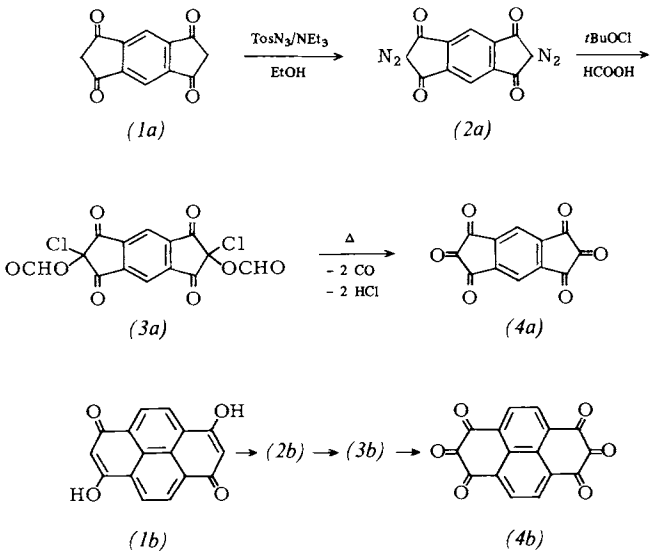
[8] The same products are formed on more selective irradiation (λ>315 nm), but the reaction is hindered because the content of *cis*-stilbene [in photoequilibrium with *(1)*] increases.

1,2,3,5,6,7-*s*-Hydrindacenehexone and 1,2,3,6,7,8-Pyrenehexone—Two New Strong Acceptors[**]



By *Rolf Gleiter* and *Peter Schang*[*]

Dedicated to Professor David Ginsburg on the occasion of his 60th birthday

The properties of vicinal triketones[1] suggest that compounds containing two or more vicinal tricarbonyl groups should be strong acceptors. In order to test this hypothesis, we have synthesized 1,2,3,5,6,7-*s*-hydrindacenehexone *(4a)* and 1,2,3,6,7,8-pyrenehexone *(4b)* from the tetraoxo com-

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

pounds *(1a)* and *(1b)*, respectively[2], which were transformed into the bis(diazo) compounds *(2a)* and *(2b)*[3], respectively.

The reaction of *(2a)* and *(2b)* with formic acid and *tert*-butyl hypochlorite[4] afforded the bis(α-chloro-α-formyloxy) β-diketones *(3a)* and *(3b)*. Pyrolysis of *(3a)* and *(3b)* gave the bis(triketones) *(4a)* and *(4b)*, which were characterized by elemental analysis and their IR, UV/VIS, and mass spectra (see Table 1).

Table 1. Physical data of the new compounds *(4a)* and *(4b)*.

Cpd. Yield [a]	UV [b] λ [nm] (log ε)	IR [c] [cm^{-1}]	$\varepsilon_{1/2}^{-}$ [d] [V]
(4a) 53%	620 sh (1.72), 265 (4.43), 246 (4.31), 217 (4.14)	1782, 1750, 1728	0.15
(4b) 60%	533 sh (2.10), 355 (4.15), 342 (4.15), 266 (4.04), 234 (4.67), 203 (4.36)	1746, 1703, 1690	0.11

[a] Overall yield starting from *(1a)* and *(1b)*. [b] In acetonitrile. [c] In KBr. [d] In acetonitrile *vs.* SCE.

The half-wave potentials measured on polarographic reduction (see Table 1) provide an indication of the good acceptor properties of *(4a)* and *(4b)*. The values found resemble that of tetracyanoquinodimethane ($\varepsilon_{1/2}^{-}=0.19$ V)[5]. 1:1 complexes of pyrene and *(4a)* and *(4b)* have been isolated[6].

Procedure

(4a): Compound *(1a)* (2.0 g, 9.3 mmol) is dissolved in ethanol (500 ml) + triethylamine (2.8 ml, 20 mmol) and treated with tosyl azide (4.0 g, 20 mmol). After 48 h *(2a)* is obtained as grayish-blue crystals[7], yield 2.2 g (89%). Reaction of *(2a)* (2.0 g, 7.5 mmol) in formic acid (60 ml) with *tert*-butyl hypochlorite (1.8 g, 16.5 mmol) with cooling in an ice bath affords *(3a)*[8] (2.35 g, 85%). Vacuum pyrolysis (0.01 torr/180–200 °C) of *(3a)* gives *(4a)* in *ca.* 70% yield.

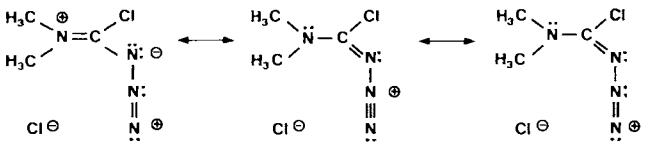
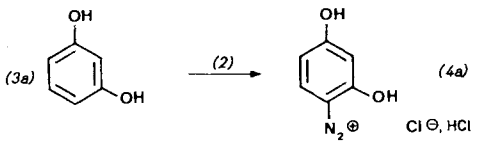
Iminium-Activated Azides—New Reagents for the Transfer of Diazonium or Diazo Groups[**]



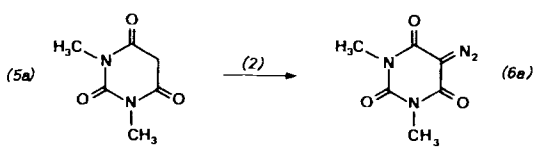
By *Bruno Kokel* and *Heinz Günter Viehe*[*]

Replacement of chlorine in the phosgeniminium salt *(1)* by the N_3-group affords (azidochloromethylene)dimethylammonium chloride *(2)*[2], whose reaction with primary amides to give aminotetrazoles has been described[2].



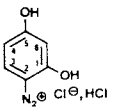
(1) *(2)*

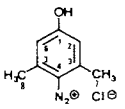
As the limiting structures of *(2)* show, this compound is expected to react as a powerful ambident electrophile either on the iminium carbon or on the azide-nitrogen.

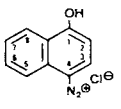


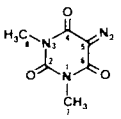
(2)

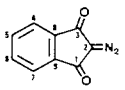
We have found that *(2)* reacts with a variety of CH-acidic compounds by diazo- or diazonium group transfer. Thus, resorcin *(3a)* in dichloromethane produces already at room temperature the diazonium chloride *(4a)* in almost quantitative yield.

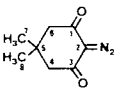


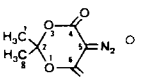












Compounds with carbonyl-activated methylene groups such as *N,N*-dimethyl barbituric acid *(5a)* readily react at room temperature with *(2)* to give good yields of the corresponding diazo compounds such as *(6a)*.

Table 1 illustrates the potential of this new reagent in the well-known field of diazo group transfer[3], which generally occurs under basic or neutral conditions.

To our knowledge, the only diazo group transfer reagents which work under acidic conditions are the less readily accessible azidinium salts such as *(7)*[4,5]. *(7)*, like *(2)*, belongs to the class of reactive but stable heterosubstituted (azidomethylene)ammonium salts.

(7)

Experimental

(4): *(3)* (10 mmol) is added to a solution of *(2)* (12 mmol) in 100 ml of CH_2Cl_2. After 5—8 hours' stirring at room temperature the salt *(4)* precipitates out.

(6): *(5)* (10 mmol) is added to a solution of *(2)* (12 mmol) in 100 ml of CH_2Cl_2. This solution is refluxed with stirring for about 4 h. After removal of the greater part of the solvent, the residue is treated with ether, filtered, and evaporated down. After rubbing the oily residue with 2-propanol, *(6)* is isolated and dried.

Photochemical Reductive *cis*-Elimination in *cis*-Diazidobis(triphenylphosphane)platinum(II) Evidence of the Formation of Bis(triphenylphosphane)platinum(0) and Hexaazabenzene[**]

By *Arnd Vogler, Robin E. Wright,* and *Horst Kunkely*[*]

Reductive *cis*- and *trans*-eliminations in transition metal complexes not only take place thermally, but also photochemically. Two $X^{\ominus}$ ligands are oxidized, which, in the first step of the photoreaction split off, either as $X^{\odot}$ radicals or cleave directly as a new energy-poorer molecule X_2. On steric grounds, in *trans*-eliminations the formation of radicals $X^{\odot}$ should be favored, in *cis*-eliminations, on the other hand, the departure of X_2. Both types of reaction have been observed. Irradiation of *trans*-$[Pt(CN)_4(N_3)_2]^{2\ominus}$ leads to $[Pt(CN)_4]^{2\ominus}$ and $N_3^{\odot}$ radicals, which were detected by ESR spectroscopy[1]

and flash photolysis[2]. In contrast *cis*-$[IrClH_2(PPh_3)_3]$ photolyzes directly to $[IrCl(PPh_3)_3]$ and H_2 without the intermediary formation of H atoms[3].

We have now been able to show that the complex *cis*-$[Pt(N_3)_2(PPh_3)_2]$ also undergoes a photochemical *cis*-elimination. At the same time evidence was also found that the azide ligands are cleaved off as N_6 molecule (hexaazabenzene) with concomitant formation of $[Pt(PPh_3)_2]$.

It was already known that $[Pt(C_2O_4)(PPh_3)_2]$ undergoes reductive photoelimination. The bidentate oxalate ligand is oxidized to CO_2, and $[Pt(PPh_3)_2]$ is formed. This was detected, not directly but only as the stable dimer $[Pt(PPh_3)_2]_2$[4].

Irradiation[5] of *cis*-$[Pt(N_3)_2(PPh_3)_2]$[6] at room temperature with shortwave light ($\lambda = 280$ nm)[7] in solvents such as ethanol or tetrahydrofuran likewise leads to $[Pt(PPh_3)_2]_2$, with evolution of N_2. To gain an insight into the reaction behavior, low-temperature photolyses were carried out. For analysis of the photoproducts in glasses of organic solvents at 77 K, ESR and luminescence spectroscopy were resorted to. The latter is especially suited for the identification of platinum(0)-phosphane complexes[8].

Irradiation of *cis*-$[Pt(N_3)_2(PPh_3)_2]$ and $[Pt(C_2O_4)(PPh_3)_2]$ in ethanol or methyltetrahydrofuran at 77 K leads to photoproducts which fail to give ESR signals, but in both cases an intense emission peak is observed at $\lambda = 445$ nm. On warming the photolyzed glasses to room temperature $[Pt(PPh_3)_2]_2$ was formed, which was identified by its intensely red luminescence ($\lambda_{max} = 665$ nm) at 77 K. In the low-temperature photolysis of the oxalate complex the organic glass remained colorless, whereas in the case of the azide complex a yellow coloration rapidly occurred (absorption maximum at $\lambda = 380$ nm), which on warming the matrix immediately disappeared with simultaneous evolution of N_2.

On the basis of these observations we suggest that the photolysis of the azide complex proceeds according to the equation

$$cis\text{-}[Pt(N_3)_2(PPh_3)_2] \rightarrow [Pt(PPh_3)_2] + N_6$$

Oxalate and azide complex form a common photoproduct (emission at $\lambda = 445$ nm) stable only at low temperatures; this can only be $[Pt(PPh_3)_2]$. On warming and melting the glasses it affords the stable dimer $[Pt(PPh_3)_2]_2$[4]. The reactive complex $[Pt(PPh_3)_2]$ is assumed to occur as intermediate in many reactions of platinum-triphenylphosphane complexes, but has so far not been isolated[9]. However, other $[Pt(PL_3)_2]$ complexes containing sterically demanding ligands L have been isolated[10].

While the ESR spectra of the products of low-temperature photolysis of *trans*-$[Pt(CN)_4(N_3)_2]^{2\ominus}$ clearly indicated that azide radicals were formed[11], the formation of such radicals from *cis*-$[Pt(N_3)_2(PPh_3)_2]$ could not be demonstrated. In analogy to the H_2-elimination from *cis*-$[IrClH_2(PPh_3)_3]$[3] we therefore assume that the azide ligands are cleaved from *cis*-$[Pt(N_3)_2(PPh_3)_2]$ as a N_6-molecule. We ascribe the yellow coloration to N_6, which is stable only at low temperatures and decomposes to N_2 on heating the matrix.

As extension of our studies in this field we carried out flash photolyses of *cis*-$[Pt(N_3)_2(PPh_3)_2]$ in ethanol and methyltetrahydrofuran at room temperature. Although no $N_3^{\odot}$ radicals[11] could be detected, an intermediate was observed which absorbed at $\lambda = 380$ nm and decomposed according to a reaction of first order with $k = 1.66 \times 10^2\ s^{-1}$ (Fig. 1).

The possible existence of N_6 (hexaazabenzene) has been discussed in a number of theoretical papers[12]. The lability of N_6 is generally regarded as being due to compensation of the resonance stabilization of an aromatic N_6-ring by repulsion of the lone pairs of electrons at the N atoms. According to one published paper, N_6 should decompose without activation energy[12c]. Other calculations lead to the conclusion

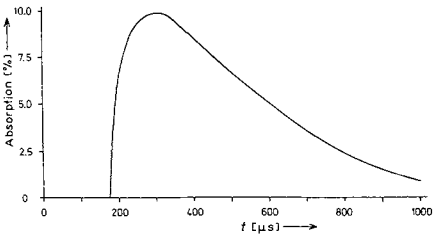

Fig. 1. Decomposition curve of a transient ($\lambda_{abs} = 380$ nm) in the flash photolysis of *cis*-$[Pt(N_3)_2(PPh_3)_2]$ (7×10^{-5} mol/l) in ethanol; flash energy 900 J.

that N_6 is slightly stabilized[12b] and therefore can certainly be stable at low temperatures.

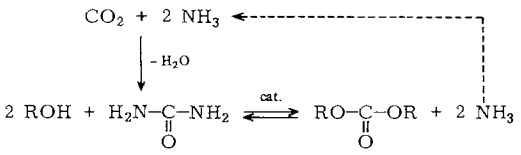
Carbonates and Polycarbonates from Urea and Alcohol[**]

By *Peter Ball, Heinz Füllmann*, and *Walter Heitz*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

Carbonates and polycarbonates are conventionally prepared by reaction of alcohols and diols, respectively, with phosgene.



$$2\,ROH + COCl_2 + 2\,NaOH \rightarrow RO{-}CO{-}OR + 2\,NaCl + 2\,H_2O$$

This reaction creates safety problems (use of phosgene) and is energetically unfavorable: the chlorine required for the synthesis of phosgene ends up in NaCl.

In order to circumvent these disadvantages an attempt could be made to use CO_2[1–4] or another derivative of carbonic acid as starting material. Urea (Scheme 1) reacts with alcohols to form carbonates and ammonia. The industrial synthesis of urea starts from CO_2 and ammonia, *i.e.* the ammonia liberated in the carbonate synthesis can be recycled and only CO_2 and alcohol are therefore consumed.

Scheme 1

In the reaction of esters with amides, the equilibrium is largely on the side of the amides. However, if amides are treated at high temperatures with alcohols and the resulting ammonia is removed from the reaction mixture then the synthesis of esters can be successfully accomplished.

Paquin discovered that alcohols react with urea to form carbamic esters[5]. Yields of 50 to 90% are obtained on catalysis with zinc acetate. On use of the catalysts reported by *Paquin* small amounts of carbonate can be detected by gas chromatography if the reaction time is prolonged. Many catalysts effect loss of more than the amount of ammonia corresponding to formation of carbamic ester; but reaction products of isocyanic acid—cyamelide and cyanuric acid—are also formed. In other words, the carbamic ester decomposes to isocyanic acid and alcohol. We have found that combinations of a weak Lewis acid and a Lewis base accelerate carbonate formation to such an extent that the competing liberation of isocyanic acid is suppressed (Scheme 2). Examples are shown in Table 1.

Scheme 2

Table 1. Catalysts for reaction of 2-ethyl-1-hexanol and urea to give bis(2-ethylhexyl) carbonate (see Scheme 2).

Catalyst [a]	Amount [b]	Yield [%] [c]
$Mg(OCH_3)_2/PPh_3$	3/3	41
$Fe(acac)_3/PPh_3$	3/3	76
$CeCl_3 \cdot 3H_2O/PPh_3$	3/3	36
$LaCl_3 \cdot 7H_2O/PPh_3$	3/3	40
$CoCl_2 \cdot 6H_2O/PPh_3$	3/3	54
$Cd(OAc)_2/PPh_3$	3/3	64
$Al(iBu)_2H/PPh_3$	0.5/0.5	87
$Al(iBu)_2H/P(OPh)_3$	1.5/0.95	90
$Al(iBu)_2H/P(OPh)_3$	3/1.6	94
$Al(iBu)_2H/P(NMe_2)_3$	1.5/2.0	94

[a] Both compounds in equimolar amounts. [b] Mol.-% of catalyst component relative to urea. [c] Based on urea.

Kinetic studies have shown that the reaction proceeds in two steps. 50% of the ammonia are liberated fast, *i.e.* the carbamic ester is formed fast. Even on raising the temperature from 165 to 180 °C the rate of the second step remains much lower than that of the first.

The carbamic esters can also be treated directly with alcohols to form carbonates; the same catalysts prove effective. The catalysts differ in the nature of the by-products obtained. The principal side reaction is ether formation. Use of diisobutylaluminum hydride/tributyl phosphite leads in the case of 2-ethyl-1-hexanol to the formation of 3.5% of bis(2-ethylhexyl) ether; the ether content increases with increasing Al/P ratio in the catalyst.

On treatment with urea primary and secondary alcohols can be converted into carbonates (Table 2). With low boiling alcohols the required reaction temperature can be attained, without altering the pressure, by addition of the alcohol.

Table 2. Reaction of alcohols with urea to give carbonates; diisobutylaluminum hydride/triphenylphosphane as catalyst.

ROH	Yield [%] [a]	RO—CO—OR B. p. [°C/torr]
1-Pentanol	81	115/12 [c]
Cyclohexanol	78	
3-Methylcyclohexanol	82	
2-Ethyl-1-hexanol	87	168—170/12
Isononyl alcohol [b]	73	

[a] Based on urea. [b] Isomeric mixture of primary isononanols. [c] 127 °C/15 torr [6].

The reaction is also suitable for the preparation of polycarbonates. It was applied to long-chain primary aliphatic diols and primary cycloaliphatic diols. Addition of monofunctional alcohols initially generates oligomeric carbonates whose low viscosity permits quantitative separation of the ammonia. The molecular weight of the product is then increased by transesterification. The reaction temperatures of up to 270 °C show that aliphatic polycarbonates are more stable than reported in the literature.

Procedure

Dipentyl carbonate: Urea (24 g), 1-pentanol (35.3 g), triphenylphosphane (0.795 g) and DIBAH-T solution (2.5 ml; 20% solution of diisobutylaluminum hydride in toluene (Schering)) are heated together at 135—150 °C for 5 h. The NH_3 escaping *via* a Vigreux column is collected by titration or by freezing. The temperature is increased to 185 °C during the following 2 h. 1-Pentanol (35.3 g) is added, the mixture is heated to 185—197 °C for 10 h, and the product is isolated by distillation.

Bis(2-ethylhexyl) carbonate: Dry urea (180 g), 2-ethyl-1-hexanol (1200 g), triphenylphosphane (4 g), and DIBAH-T solution (18 ml) are heated together to *ca.* 160 °C. The liberated ammonia is collected in a cold trap. The reaction temperature is raised to 270 °C in the course of 16 h. The cold trap than contains 93 g of NH_3 (91% yield). After removal of the excess alcohol by distillation, 743 g of the product remains.

Poly(oxycarbonyloxymethylene-1,4-cyclohexylenemethylene): Urea (15 g), cyclohexanedimethanol (30.3 g), isononyl alcohol (34 g), triphenylphosphane (0.34 g), and DIBAH-T solution (1.2 ml) are heated together to 170 °C; the temperature is then raised to 225 °C within 45 min and subsequently to 260 °C at a steady rate over 2.5 h. Excess isononyl alcohol, some diol, and diisononyl carbonate are distilled off under water pump vacuum and then oil pump vacuum. The polycarbonate (32.8 g) is not crystalline; $M_n = 11\,000$ (determined by vapor pressure osmometry), $\eta_{rel} = 1.26$ (measured as a 0.5% solution in CH_2Cl_2, 25 °C).

N-Ethynylamines of the Type R—NH—C≡C—H[**]

By *Hans-Wilhelm Winter* and *Curt Wentrup*[*]

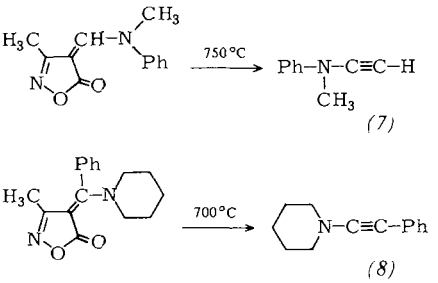
Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

Aminoacetylenes carrying secondary or primary amino-groups were previously unknown because of their tautomerization to ketenimines and nitriles, respectively. We have now developed a method which permits the preparation of such compounds, and report here on the first examples.

Flash vacuum pyrolysis of 4-methyleneisoxazol-5(4*H*)-ones is known to produce vinylidenes, which rearrange efficiently to acetylenes[1]. The starting material required for the preparation of *N*-ethynylaniline *(4)*, 4-(anilinomethylene)-3-methylisoxazol-5(4*H*)-one *(2)* has been obtained[2] by reaction of 4-benzylideneisoxazol-5(4*H*)-one with *N,N'*-diphenylformamidine. However, enamines of the type *(2)* can be obtained in a much simpler and general manner by reaction of the free isoxazolone *(1)* with amines and ortho-esters[3].

(1) *(2)* *(3)* *(4)* *(5)* *(6)*

Thus, *(2)* was obtained in 70% yield in less than 5 min by heating an equimolar mixture of *(1)* and aniline in triethyl orthoformate. The initial pyrolyses of *(2)* were carried out using an externally heated quartz tube (32 × 2 cm) as previously described[4]. *(2)* was stable toward pyrolysis up to *ca.* 450 °C (10^{-5} torr). Between 450 and 650 °C increasing amounts of CO_2 and acetonitrile were formed and identified by IR spectroscopy of the volatile pyrolysis products. Work-up of the products at room temperature afforded *N*-phenylketenimine *(5)* (50% at 650 °C/4 × 10^{-5} torr). *(5)* was identified by IR and NMR spectroscopy, and by hydrolysis to acetanilide. Furthermore, a 4.5% yield of indole *(6)* was isolated from the 650 °C pyrolysis. The formation of *(6)* is ascribed to a cyclization of the vinylidene (carbene) *(3)*. Similar cyclizations of other vinylidenes have been reported[5].



The isolation of *(5)* from the above pyrolyses indicated that *N*-ethynylaniline *(4)* had been formed initially. In order to isolate and observe *(4)* a pyrolysis apparatus equipped for IR spectroscopy was used[6]. This consisted of a quartz tube incorporating a 5-cm sublimation zone and a 10-cm pyrolysis zone, mounted in a water-jacketed stainless steel housing. The pyrolysis products were condensed directly on a KBr target attached to a turnable liquid nitrogen cryostat and housed in a vacuum shroud equipped with KBr windows[7]. In this manner, the pyrolysis of *(2)* at 650 °C/10^{-5} torr gave *(4)*, which was stable at −196 °C and identified by strong IR absorptions at 2120 (C≡C) and 3290 (C≡C—H) cm^{-1}; the latter absorption was superimposed by a broad NH-band at *ca.* 3200—3300 cm^{-1}. These absorptions disappeared on warming the sample to *ca.* −70 to −60 °C, when new, strong signals due to the ketenimine *(5)* at 2020 and 2040 cm^{-1} appeared in their place.

(4), R = H

(4a-d), R = CH_3, OCH_3, OC_2H_5, NO_2

Other aminoacetylenes related to *(4)* have been obtained in a similar manner [*(4a)*: 2125 cm^{-1}; *(4b)*: 2123 cm^{-1}; *(4c)*: 2125 cm^{-1}; *(4d)*: 2136 cm^{-1}] and isomerized to the corresponding ketenimines on warming[8]. The tautomerization to ketenimines can, of course, be prevented by using *N,N*-disubstituted 4-(aminomethylene)-3-methylisoxazol-5(4*H*)-ones[3] as starting materials. Examples of pyrolysis products are the acetylenes *(7)* (2130 cm^{-1}) and *(8)* (2220 cm^{-1}).

(7) *(8)*

Experimental

(5): 670 mg of *(2)* was pyrolyzed at 650 °C/4 × 10^{-5} torr by sublimation from a sample flask held at 125 °C. The products were collected in a U-tube cooled in liq. N_2. After pyrolysis was complete, distillation of the products *in vacuo* below 0 °C afforded CO_2 and acetonitrile. Further distillation at 25 °C afforded *(5)* (50%): IR (CCl_4): 2040 vs, 2020 vs, 1600 s, 1500 s, 700 s cm^{-1}; ^{1}H-NMR (CCl_4): δ = 3.4 (s, 2H), 7.2 (m, 5H). *(5)* was identical with a sample prepared according to *Staudinger*[9].—In a separate experiment, the cold pyrolysis products were treated with 50 ml of 10% HCl and then allowed to stand for 2 h at room temperature. The mixture was extracted with ethyl acetate, the extract washed with water, dried over $MgSO_4$, concentrated, and chromatographed on SiO_2/$CHCl_3$. Elution with $CHCl_3$ followed by $CHCl_3$/CH_3OH (9:1) gave indole (4.5%), starting material *(2)* (13%), and acetanilide (43%).

New Dihydrido-Bridged Binuclear Platinum-Iridium Complexes[**]

By *Attilio Immirzi, Alfredo Musco, Paul S. Pregosin,* and *Luigi M. Venanzi*[*]

Carbonyl complexes having bridging hydrogen atoms are rather common in transition metal chemistry[1]. Recently, bridging hydrido complexes not containing CO ligands have received considerable attention[2]. Whereas a number of hydrido-bridged bi-homometallic complexes have been reported[1], only few examples of heterometallic complexes are known[3,4]. We report here the synthesis and structural characterization of the stable mixed Pt—Ir cations *(1)* and *(2)* containing double hydrido bridges.

(1a), R = C_6H_5; *(2a)*, R = H[1]

(1b), R = C_6H_5; *(2b)*, R = H[1]

The cations *(1)* and *(2)* are formed as follows:

$$trans\text{-}[PtR(CH_3OH)(PEt_3)_2]^+ + [IrH_5(PEt_3)_2] \rightarrow (1) \text{ or } (2) + H_2$$

As shown in the above equation the reaction occurs with transfer of a phosphane ligand from platinum to iridium, a rather uncommon phenomenon in the absence of free ligand[5] The rather novel nature of the above complexes prompted us to undertake the X-ray structure determination of *(1a)* [BPh_4] (Fig. 1)[6]. The molecular geometry of the cation *(1a)* is consistent with a square planar Pt^{II} and an octahedral Ir^{III} with two bridging H atoms between them and one terminal H atom on Ir. The atoms Pt, P1, C1, Ir and P2 are nearly coplanar with P1 and P2 in a cisoid arrangement. The axial ligands Et_3P3 and Et_3P4 are slightly bent towards the bridging hydrogens thus reducing the steric interaction with the equatorial phosphane ligand Et_3P3. The Pt···Ir distance is practically identical with the Pt···Pt distance (2.692(3) Å) in $[(Cy_3P)(Me_3Si)Pt(\mu\text{-}H)_2PT(Me_3Si)(Cy_3P)]$ (Cy = cyclohexyl)[7] and slightly longer than the Ir···Ir distance (2.518 Å) in $[(Ph_3P)_2(H)Ir(\mu\text{-}H)_3Ir(H)(Ph_3P)_2][PF_6]$[8], as expected for a compound with three bridging hydrogens.

Support for the presence of the terminal and bridging hydride ligands in *(1)* and *(2)* is provided by ^{1}H-NMR spectroscopy. The ^{1}H and ^{31}P-NMR spectra of *(1a)* in CD_2Cl_2, *dissolved and measured at −60 °C,* are assigned as follows: δ = −7.05 (H2, ^1J(PtH) = 671 Hz), −9.04 (H3, ^1J(PtH) = 662 Hz), −15.27 (H4); 16.3 (P1, ^1J(PtP1) = 3656 Hz,

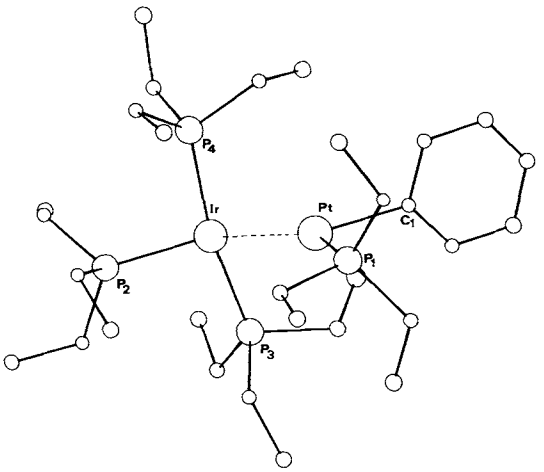

Fig. 1. Molecular structure of the cation *(1a)*. Bond lengths [Å]: Pt···Ir 2.687(2), Pt—C 2.08(2), Pt—P1 2.213(6), Ir—P2 2.323(5), Ir—P3 2.354(6), Ir—P4 2.341(6); bond angles [°]: Pt—Ir—P2 138.2(1), Pt—Ir—P3 86.6, Pt—Ir—P4 91.2(1), Ir—Pt—C1 133.0(3), Ir—Pt—P1 140.7(1), P2—Ir—P3 96.6, P2—Ir—P4 94.5(2), P3—Ir—P4 165.7(1); torsion angles (°, avg. error ~1°): P1—Pt—Ir—P2 −2, P1—Pt—Ir—P3 94, P1—Pt—Ir—P4 −100; P2—Ir—Pt—C1 −178, P3—Ir—Pt—C1 −82, P4—Ir—Pt—C1 84.

^4J(P1P2) = 43 Hz, ^4J(P1P3) = 4 Hz), 6.0 (P2, ^2J(P2P3) = 18 Hz), −4.5 (P3, ^3J(PtP3) = 40 Hz). On warming to −30 °C a new set of signals appear and these are assigned to isomer *(1b)*: δ = −4.18 (H2 or H3, ^1J(PtH2 or H3) = 826 Hz), −11.64 (H3 or H2, ^1J(PtH3 or H4) = 525 Hz), −14.61 (H4), 18.7 (P1, ^1J(PtP1) = 3349 Hz), ^4J(P1P3) = 4 Hz), 5.6 (P2, ^2J(P2P3) = 18 Hz), −2.3 (P3, ^3J(PtP3) = 36 Hz). At this temperature a 1:1 mixture of *(1a)* and *(1b)* is obtained in *ca.* one hour. The same isomeric composition is observed at room temperature. Of special interest in isomer *(1a)* is that: (a) the appearance of H3 immediately allows its assignment since this hydrogen is *trans* to *two* PEt_3 groups and therefore, shows two large ^2J(P1H3) and ^2J(P2H3) values (66 Hz)[9] and (b) H2 does not show large (>20 Hz) ^2J(P1H2 or P2H2) couplings. In isomer *(1b)*, however, both H2 and H3 show *one* strong ^2J(PH) coupling (*ca.* 74 Hz).

Similar spectral observations and structural assignments have been made for *(2a)* and *(2b)*.

Experimental

(1a) [BPh_4]: A solution of $AgBF_4$ (0.143 g, 0.73 mmol) in 3 ml of methanol was added to a suspension of *trans*-$[PtCl(C_6H_5)(PEt_3)_2]$ (0.400 g, 0.73 mmol) in 5 ml of methanol and the AgCl filtered off. $[IrH_5(PEt_3)_2]$ (0.319 g, 0.73 mmol) in 5 ml of methanol was added to the colorless filtrate. The resulting yellow solution was treated with a solution of $NaBPh_4$ (0.252 g, 0.73 mmol) in 5 ml of methanol. A yellow microcrystalline solid *(1a)* [BPh_4] precipitated and was collected by filtration (0.663 g, 72% yield). *(1a)* may be recrystallized from CH_2Cl_2/CH_3OH. *(2a)* [BPh_4] was prepared in a similar fashion starting from *trans*-$[PtCl(H)(PEt_3)_2]$.

The =PCN Group as a Pseudochalcogen; Cyanophosphinidene-Substituted Heterocycles[**]

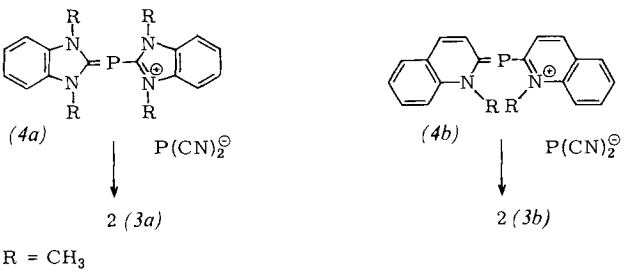
By *Alfred Schmidpeter, Wolfgang Gebler, Franz Zwaschka,* and *William S. Sheldrick*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

The "cyano displacement principle"[1a] suggests the $-P(CN)_2$ group to have the character of a pseudohalogen, and the =PCN group to have the character of a pseudochalcogen. The pseudohalogen character has been shown in the ions $P(CN)_2^-$, $P(CN)_2Br_2^-$, and $P(CN)_2I_2^-$[1]; we sought to establish the pseudochalcogen character by means of cyanophosphinidene analogues *(3)* of the oxo- or thioxo derivatives of nitrogen heterocycles. The synthesis of these new compounds can be accomplished *via* the dicyanophosphide ion by reductive removal of CN developed for the production of $P(CN)_2^-$[1a]. In the case of *(3a)* this reaction starts initially from benzimidazolone, so that *(3a)* really is formed by O/PCN exchange, not just formally.

The tetrafluoroborates *(1)*[2] obtained by methylation of the 2-chloroheterocycles with $HC(OMe)_2BF_4$ react with [18]crown-6-sodium dicyanophosphide or triethylammonium dicyanophosphide[1] to give the respective 2-(dicyanophosphino) chlorides *(2)* (Table 1). Treatment with sodium diethylphosphite generates the cyanophosphinidene-heterocycles *(3)*.

The cyanophosphinidene-heterocycles *(3)* (Table 1) occupy a connecting position between the phosphamethinecyanine cations synthesized by *Dimroth* as the first (—P=C—) compounds[3] and the dicyanophosphide anion[1a]. In a metathetic reaction these ions afford the salts *(4)* (Table 1) which have the same composition as compounds *(3)*. They are stable as crystals, but surprisingly rearrange in solution even at room temperature, *e.g.* on attempted recrystallization, affording *(3)*. The exchange could proceed *via* a diphosphetane betaine *(5)*[4].



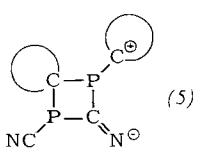


Table 1. Compounds of types *(2)*, *(3)*, and *(4)*.

Cpd.	Color	M.p. [°C]	ν_sCN	ν_{as}CN [cm^{-1}]	λ_{max} [nm]	$\delta(^{31}P)$ [a]	$\delta(^1H)$ [b]
(2a)	vermilion	130—132	2195	2180			
(2b)	greenish yellow	106—109	2190	2165		− 44	
(3a)	yellow	155—157		2105	356	−133	3.87
(3b)	brick red	162 (dec)		2115	448	− 38	3.77 [c]
(4a)	yellow	122—123			415	−103, −193	
(4b)	brown	248—252			588	56.5, −193	

[a] In CH_3CN; *(3a, b)* in tetrahydrofuran. [b] Methyl protons. [c] $^4J_{PH} = 2.5$ Hz.

The cyanophosphinidene-heterocycles *(3)* form air-stable acicular crystals. The ^{31}P chemical shifts lie roughly in the middle between those of $P(CN)_2^-$ and those of the corresponding phosphamethine cyanine cation, *i.e.* between the two $\delta(^{31}P)$ values of *(4)*. Their CN stretching vibration is shifted by about 75 cm^{-1} to longer wavelengths relative to that of cyanophosphines but is close to that of $P(CN)_2^-$[1a] and

[**] Cyanophosphorus Compounds, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: *W. S. Sheldrick, A. Schmidpeter, F. Zwaschka, K. B. Dillon, A. W. G. Platt, T. C. Waddington,* J. Chem. Soc. Dalton Trans., in press.

thus indicates a negative charge of the PCN group. This negative charge corresponds to a positive charge of the heterocycle, as is manifested in the chemical shift of the N-methyl protons which lies half way between that in the neutral and in the cationic heterocycle.

The considerable contribution of the resonance formula *(B)* is underscored by the interatomic distances found on X-ray structure analysis of *(3a)* (Fig. 1). *(3a)* forms orthorhombic crystals, space group $Pna2_1$, $Z=4$[5]; the cyano group is disordered (occupation factors = 0.50). The arrangement of the methyl protons rules out the possibility that the molecule lies on a crystallographic symmetry plane (as would be required for Pnam).

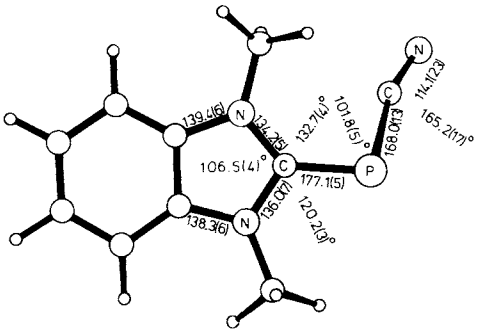

Fig. 1. Structure, bond lengths [pm], and bond angles of 2-(cyanophosphinidene)-1,3-dimethylbenzimidazoline *(3a)* (average values are given for the disordered PCN group) [5].

In contrast to what is suggested by resonance formula *(A)* without formal charges, the PC bond in the PCN group is considerably shorter than the $PC_{imidazole}$ bond. However, this observation should not be regarded as evidence for a conjugational dependence of the two parts of the molecule, which the resonance *(A)*↔*(B)* seems to suggest. The two moieties (PCN and P-heterocycle) are actually not coplanar in *(3a)*[6]; their PC distances resemble those in the dicyanophosphide ion (167—169 pm[7]) and in the phosphamethinecyanines (176—181 pm[3]). The consistently strong bond in the PCN unit confirms its classification as pseudochalcogen.

Procedure

(2): *(1)* (10 mmol) and [18]crown-6-$NaP(CN)_2$[1a] (10 mmol), each in CH_3CN (10 ml each) are cooled to −20 °C and united. *(2)* precipitates in 70—90% yield.

(3): Compound *(2)* (10 mmol) is suspended in a solution of an equimolar amount of $NaPO(OEt)_2$ in tetrahydrofuran (20 ml) and stirred for 12 h. Compound *(3)* crystallizes from the concentrated filtrate; yield 20—40%.

(4): To a solution of [18]crown-6-$NaP(CN)_2$[1a] (10 mmol) in CH_3CN (40 ml) is added an equimolar amount of the corresponding phosphamethinecyanine tetrafluoroborate in CH_3CN (125 ml). *(4)* is obtained in about 50% yield. The rest of the mixture is converted into *(3)* and can be separated from the mother liquor by concentration. *(4)* is transformed into *(3)* on attempted recrystallization from CH_3CN or CH_2Cl_2.

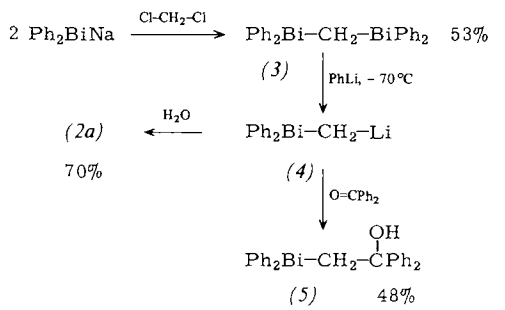
The Diphenylbismuthyl Group—A Potential New Auxiliary Group in Organic Synthesis[**]

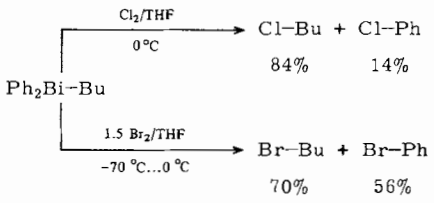
By *Fritz Steinseifer* and *Thomas Kauffmann*[*]



Organoelement groups have acquired considerable importance in organic synthesis as "mobile functional groups"[1]. Our own observations suggest that the diphenylbismuthyl group is also suitable for this purpose:

1) Alkyldiphenylbismuthanes *(2)*, which to our knowledge have not been previously reported[2], could now be synthesized in very good yields. Although air-sensitive, compounds *(2)* show surprising thermal stability (can be distilled almost without decomposition at 100—190 °C) and differ from trialkylbismuthanes by not being pyrophoric.

(2a), R = CH_3, 0 °C, 89%
(2b), R = n-C_4H_9, −70 °C, 91%
(2c), R = n-C_6H_{13}, −70 °C, 91%



2) The diphenylbismuthyl group can be introduced into organic compounds by means of Ph_2BiNa and $Ph_2Bi—CH_2Li$ *(4)*. The Ph_2Bi/Li exchange reaction *(3)*→*(4)* reveals that the diphenylbismuthyl group can stabilize a carbanionic center like other organo-heavy metal groups[3].

[**] New Reagents, Part 16. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 15: *A. Rensing, K.-J. Echsler, Th. Kauffmann*, Tetrahedron Lett. *1980*, 2807.

3) Whereas halogenolysis of alkyldiphenylarsanes or -stibanes or of alkyl phenyl selenides (alkyl = CH_2R) requires relatively high temperatures (*e.g.* bromolysis: 130 °C[4], 220 °C[5], and 80 °C[6], respectively), halogens cleave alkyldiphenylbismuthanes below 0 °C. Bromine and, in particular, chlorine selectively rupture the Bi-alkyl bond, thus favoring applications in organic synthesis[7].

4) As shown by the reactions *(3)*→*(4)*→*(2a)*, the diphenylbismuthyl group can be replaced by lithium—provided the resulting lithium compound is stabilized[8]—or hydrogen under mild conditions.

The diphenylbismuthyl group therefore offers a combination of favorable properties that is so far unique.

The structures of the new compounds (Table 1) have been confirmed by elemental analysis, ^{1}H-NMR and mass spectrometry.

6-Oxoverdazyls[**]

By *Franz A. Neugebauer* and *Hans Fischer*[*]

The reaction of 2,4-dimethylcarbonohydrazide *(1)*[1] with aldehyde *(2)* in the molar ratio 1:1 gives colorless hexahydro-*s*-tetrazines *(3)* as major product. The structural assignment is based on ^{1}H-NMR spectra. Dehydrogenation of *(3)* (*e.g.* with Ag_2O, $K_3Fe(CN)_6$, PbO_2) afforded stable monomeric radicals, *viz.* 6-oxoverdazyls *(4)*. The radical *(4a)* crystallizes from ligroin as yellow needles. Figure 1 shows the ESR spectrum (benzene): $a(N_{2,4}) = 6.50$, $a(N_{1,5}) = 5.19$, $a(H_{CH_3}) = 5.45$ (6 H), $a(H_{CH}) = 0.78$ G, $g = 2.0036$. *(4b)* forms red crystals from methanol: ESR (benzene): $a(N_{2,4}) = 6.5$, $a(N_{1,5}) \approx a(H_{CH_3}) \approx 5.3$ G, $g = 2.0036$.

(7)

Hydrogenation of the radicals *(4)* (0.5 mol H_2, Pd) leads to the leuco compounds *(5)* which are again dehydrogenated to *(4)* on exposure to air. Alkylation of *(5)*, *e.g.* methylation, yields stable tetrahydro-*s*-tetrazine derivatives *(6)*.

This radical preparation is not limited to monoaldehydes such as *(2)*. Analogous reaction of *(1)* with glyoxal bis(sodium hydrogen sulfite) hydrate gave the C-3, C-3′ linked diradical *(7)*, as black crystals from chloroform. On the basis of its ESR half-field resonance, *(7)* is seen to have a zero field splitting parameter of $D' \approx 320$ G.

The 6-oxoverdazyls *(4)* and *(7)* are sufficiently soluble in water for ESR studies. Their isolation demonstrates that the *N*-aryl substituents of the verdazyls[3] can be replaced by methyl groups without any significant loss of stability.

Selected physical data of the compounds synthesized are listed in Table 1.

Table 1. Compounds *(3)* to *(7)*. All the compounds gave a molecular peak of 100% intensity in their mass spectra.

Asymmetric Synthesis of Amines by Carbon-Carbon Coupling in the α-Position to Nitrogen

By *Michael Kolb* and *Jacqueline Barth*[*]

We recently reported on the asymmetric synthesis of α-substituted α-amino acids with (*S*)-1-(dimethoxymethyl)-2-(methoxymethyl)pyrrolidine [SDMP, *(9)*] as chiral agent[1]. We describe here the use of *(9)* for the asymmetric synthesis of the amines *(7)* and *(8)* and their secondary products. The key reaction is the diastereoselective coupling of the carbon-carbon bond at the α-position to the amine nitrogen.

Propargylamine *(1)* is first converted into the amidine *(2)*[2a] (colorless oil). H/Li exchange at the acetylene function in *(2)* with *n*-butyllithium (5 min) leads, after addition of freshly distilled trimethylsilyl chloride, to the 3-silylated propargylamine derivative *(3)*[2b]. The so protected amine *(3)* is metalated with *n*-butyllithium to *(4)* (30 min). After addition of the electrophile R^1X at −78 °C, the reaction mixture is allowed to warm to room temperature. Aqueous workup affords the substituted amidines *(5)*. The completely alkylated derivative *(6)* is obtained from *(5)* by repeating the metalation and alkylation with R^2X (see Scheme 1). ^{1}H-NMR and IR spectra show that *(4)* reacts regioselectively with RX at C-1. Neither allene products (alkylation at C-3) nor enyne products (alkylation at the amidine C) were observed.

The α-substituted propargylamines *(7)* and *(8)* are obtained from *(5)* and *(6)*, respectively, by hydrolysis of the amidine function with hydrazine hydrate and cleavage of the silyl protecting group with sodium methoxide (see Scheme 1). The pyrrolidine derivative (*S*)-*(10)* liberated from *(5)* and *(6)* can be reconverted into *(9)*.

Scheme 1. a) *(1)*:*(9)* = 1:1; without solvent, 3 h, 80 °C oilbath temperature. b) *(2)*: *n*-BuLi = 1:1.1; in tetrahydrofuran (THF), −78 °C. c) 1.1 equiv. Me_3SiCl, 5 min at −78 °C, then 30 min at 25 °C. d) *(4)*: R^1X = 1:1.1. e) *(5)*: R^2X = 1:1.1. f) *(5)* or *(6)*: $H_2NNH_2 \cdot H_2O$ = 1:5—10; in anhydrous ethanol, 2—4 h, reflux. g) 1 equiv. CH_3ONa in CH_3OH, 2—3 h, 25 °C. h) RuO_2, $NaIO_4$.

The yield and optical rotation of the reaction products are collected in Table 1. The enantiomeric purity of the amines *(7)* and *(8)* was determined by oxidation to the corresponding amino acids *(11)* and *(12)*, respectively[3]. The asymmetric induction increases with increasing size of the electrophile (see Table 1, α-methylphenylalanine and α-methylnorleucine). As to be expected, the preferred configuration at the asymmetrically substituted carbon atom in *(8)* changes if the electrophiles R^1X and R^2X are added in the reverse order.

n-C_4H_9I	CH_3I	77 [g]	−36	56	−4.9 [c, g]	(*R*) [8]
C_6H_5—CH_2Br	CH_3I	79		77	+4.5 [e]	67 (*R*) [9]

[a] Yield of isolated, analytically pure product. [b] $c = 2$, benzene. [c] $c = 2$, H_2O. [d] L-norleucine·HCl: $[\alpha]_D^{20} = +13.8$ ($c = 2$, H_2O). [e] L-phenylalanine: $[\alpha]_D^{20} = -12.5$ ($c = 2$, H_2O). [f] $c = 1$, H_2O. [g] The yield in the alkylation step and in the asymmetric induction does not change if the solution of *(4)* in THF prepared at −78 °C is stirred for 20 min at 25 °C before addition of the electrophile.

The propargylamine derivatives *(7)* and *(8)* synthesized are configuratively related, since the chelates *(4)* in the configuration depicted in Scheme 1 are preferably alkylated from the upper side. This is in complete contrast to the described asymmetric synthesis of α-alkylated α-amino acids with the same reagent SDMP, whereby preferred alkylation from the lower side has been observed[1].

The method described here for the preparation of the optically active propargylamines *(7)* and *(8)* is not only of importance for the enantioselective synthesis of α-alkylated α-amino acids. The ethynyl group in the products corresponds to a d^1/d^2-synthon[4], *i.e.* an extremely versatile function[5], which in combination with the asymmetric synthesis describe here offers numerous possibilities for the enantioselective preparation of nitrogen compounds.

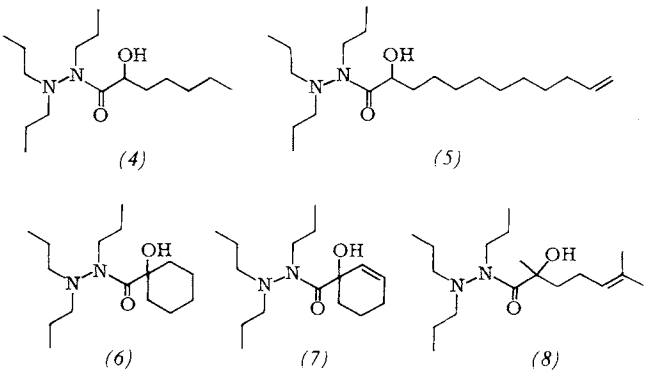
Tripropylcarbazoyllithium

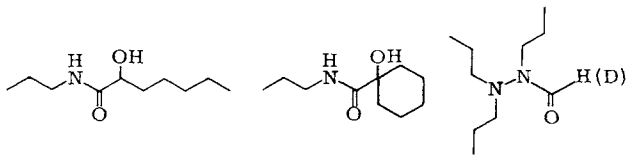


By *Valentin Rautenstrauch* and *François Delay*[*]

Can structural modifications lead to synthetically useful acyllithiums[1]? To answer this question further[2] we have investigated the preparation and reactions of tripropylcarbazoyllithium *(3)*.

(1) *(2)* *(3)*

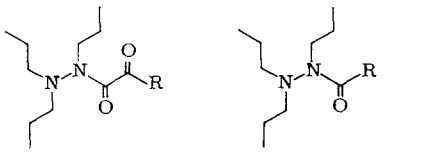
(3) is readily obtained by carbonylation of lithium tripropylhydrazide *(2)* in tetrahydrofuran (THF)/hexane solution[3] (*ca.* 0.5 M) at *ca.* −75 °C and normal pressure, as demonstrated by its reactions. *(2)* is prepared by lithiation of tripropylhydrazine *(1)*[4] with *n*-butyllithium. *(3)* is inert towards CO (cf. [1c]), but reacts rapidly[5] and cleanly, at −75 °C, with aldehydes and ketones: Addition of the reactants [0.7—1.2 mol per mol of *(1)*] to the solution of *(3)* and subsequent hydrolysis leads to the hydroxycarbohydrazides *(4)*—*(8)* [high-boiling oils, yields 60—85%]. Under these simplest experimental conditions [*e.g.* without inverse addition of *(3)*], *(3)* does *not* react with the hydrazide function of the



(4) *(5)* *(6)* *(7)* *(8)*

alcoholates of *(4)*—*(8)* (cf. [1c]). Although the hydrazide function of the adducts *(4)*—*(8)* is greatly hindered, they can be smoothly cleaved, by reaction with lithium in liquid NH_3/THF and subsequent hydrolysis, to give the unhindered propylamides [cf. [1d], *e.g. (4)*→*(9)*, m.p. 88—89 °C, yield *ca.* 90%; *(6)*→*(10)*, m.p. 105—106 °C, yield *ca.* 85%].

Addition of water to the solution of *(3)* gives the formohydrazide *(11)* and addition of D_2O gives the labeled hydrazide



[*] Dr. V. Rautenstrauch [+], Dr. F. Delay

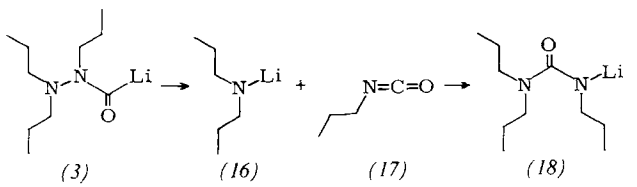
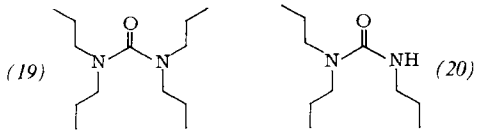
[+] Author to whom correspondence should be addressed.

[D_1]-*(11)*, along with traces of *(11)* [[D_1]-*(11)*:*(11)* = 94:6[6a], yields of *(11)*, [D_1]-*(11)* *ca.* 40%].

(9) *(10)* *(11)*/[D_1]-*(11)*



(3) reacts in a 1:1 molar ratio with esters: addition of 1.1 equiv. of ethyl acetate or isobutyrate to the solution of *(3)* at *ca.* −75 °C and work up with water gives the oxocarbohydrazides *(12)* [yield *ca.* 35%, unidentified minor products] and *(13)* [yield *ca.* 55%], respectively.



(12), R = CH_3 *(14)*, R = CH_3

(13), R = $(CH_3)_2CH$ *(15)*, R = n-C_3H_7

Methyl iodide (1.1 equiv.) methylates *(3)* slowly[5] (4 h) at *ca.* −75 °C to give the acetohydrazide *(14)* [yield *ca.* 60%]. Propyl iodide alkylates *(3)* very slowly[5] at *ca.* −75 °C to give the butyrohydrazide *(15)* [*ca.* 30% conversion in 15 h]; hydrolysis with D_2O shows that, in parallel, *(3)* slowly[5] reacts with the medium to give *(11)* [→[D_1]-*(11)* + *(11)*, 78:22[6b]]. In the alkylations, *(3)* does not react with *(14)* and *(15)* (cf. [1c]). Addition of hexamethylphosphoramide (2 equiv.) at *ca.* −75 °C accelerates the alkylations, but also, and more strongly, the reaction with the medium to give *(11)*; hydrolysis with D_2O shows that *(3)* does not survive [→unlabeled *(11)*[6b]].

(3) *(16)* *(17)* *(18)*

(19) *(20)*

The alkylations cannot be accelerated by raising the temperature, because *(3)* rearranges to give the *N*-lithiourea *(18)*. In the presence of *e.g.* propyl iodide, mixtures of tetrapropylurea *(19)* and the hydrazide *(15)* are then formed. In the absence of an alkylating agent, warming the solution of *(3)* to 0—5 °C for 2 h and subsequent hydrolysis affords tripropylurea *(20)* as the main product, along with some *(11)* and many unidentified minor products; hydrolysis with D_2O shows that *(11)* is again partially formed by prior reaction of *(3)* with the medium [→[D_1]-*(11)* + *(11)*, 69:31[6b]]. Presumably, *(3)* dissociates to give lithium dipropylamide *(16)* and propyl isocyanate *(17)* and the pair *(16)*/*(17)* then recombines to give *(18)*.

(3) can also be obtained by lithiation of the formohydrazide *(11)* with lithium diisopropylamide at *ca.* −75 °C (cf. [1a]), but the equilibrium seems to be unfavorable: exposure of *(11)* to 1.2 equiv. of the base [in the medium used for the carbonylation of *(2)*, starting concentration of *(11)* *ca.* 0.4 M, 10 min—5 h] and subsequent hydrolysis with D_2O affords a 63:37 mixture[6b] of [D_1]-*(11)* and *(11)*. The carbonylation of *(2)* is the better method.

Procedures

Solutions of *(3)*: A hexane solution (1.5—1.6 M) of *n*-butyllithium (3.2 mmol) is added to a solution of *(1)*[4] (3.2 mmol) in 5 ml THF [or 2.5 ml THF and 2.5 ml 1,2-dimethoxyethane (DME)[3]] at *ca.* −75 °C under an inert gas and after 5 min stirring, CO is passed (*ca.* 3 l/h) at *ca.* −75 °C for 4 h through the stirred solution.

Reaction of *(3)* with aldehydes, ketones, and esters: The reactants (0.7—1.2 equiv.) are added at once to the solution of *(3)*. After 1—2 h stirring at *ca.* −75 °C, H_2O (*ca.* 22 °C) is added.

Hydrolysis of *(3)* with D_2O: 1 ml of D_2O (*ca.* 22 °C) is added to the solution (*ca.* −75 °C) of *(3)* [from 3.2 mmol of *(1)*]. After 3 min stirring in an ice-bath, the mixture is diluted with H_2O.

Cleavage of the hydroxycarbohydrazides: A solution of the educt (0.8 mmol) in 6 ml THF is added dropwise with stirring to 6 ml of liquid NH_3 at *ca.* −75 °C. Li (3.1 mmol) is then added to the mixture (blue solution or suspension) which is then warmed with stirring until the blue color disappears (*ca.* −50 °C). More Li (3.1 mmol) is then added, and the mixture is kept at reflux for 30 min (blue solution or suspension), and is finally treated with NH_4Cl (20 mmol). The NH_3 is then evaporated and H_2O is added.

All compounds are isolated by extraction with ether, concentration, and distillation. Analytically pure samples are obtained by gas chromatography or recrystallization.

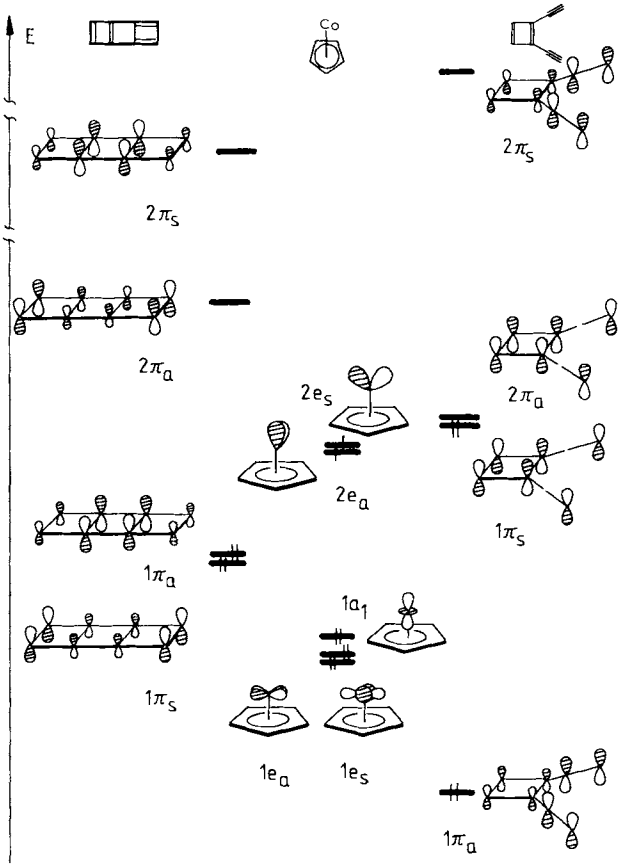
A Theoretical Investigation of the Diethynylcyclobutadiene(cyclopentadienyl)cobalt Rearrangement[**]

By *Peter Hofmann* and *Thomas A. Albright*[*]



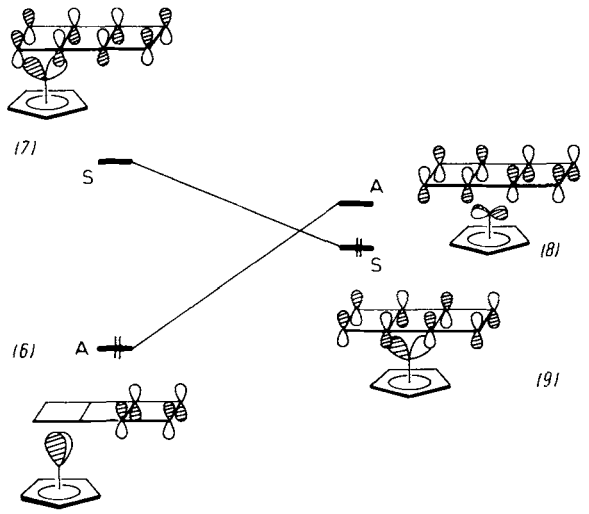
A recent fascinating development in the area of alkyne metathesis has been the synthesis and interconversion of η^4-dialkynylcyclobutadiene-η^5-cyclopentadienylcobalt complexes by *Vollhardt* and *Fritch*[1]. Subjected to flash pyrolysis conditions, such compounds [*(1)* in scheme 1, R = $SiMe_3$] isomerize to *(1')*. This rearrangement[1b] has been proposed to occur by intervention of a novel complex *(2)*[1a], which could undergo a haptotropic shift[2] of the CoCp fragment leading first to *(2')* and finally to the observed product *(1')*.

Scheme 1. Possible rearrangement pathways of η^4-diethynylcyclobutadiene-η^5-cyclopentadienylcobalt complexes (Ref. [1a]).

Another conceivable process (Scheme 1, lower part) involves the retrocycloaddition of *(1)* to a bis-alkadiyne complex *(4)* and a shifting of the CoCp fragment *via (5)* to *(4')*; cycloaddition again would yield *(1')*. We show here that, based on theoretical results, both mechanistic alternatives are highly improbable. This forms part of a general theoretical analysis for the propensity of an ML_n unit to migrate in polyene-ML_n complexes[3]. Along with these haptotropic rearrangements we have initiated an investigation of the electronic requirements of retrocycloaddition *(1)*→*(4)* as well as of the cycloadditions *(1)*→*(2)* and *(4')*→*(1')* which are closely related to the mechanism of alkyne metathesis and of transition metal catalyzed alkyne oligomerizations. Our MO calculations are of the Extended Hückel type[4].

The relevant orbitals of tricyclo[4.2.0.$0^{2,5}$]octa-1(6),2,4,7-tetraene ("bicyclobutadienylene"), the CoCp-fragment[5] and of diethynylcyclobutadiene are presented in Scheme 2.

Scheme 2. Relevant valence orbitals of tricyclooctatetraene (left), CoCp (middle) and diethynylcyclobutadiene (right).



For structure *(2)*, the $2e_s$ and $2e_a$ frontier orbitals of the CoCp unit make the dominant contribution to the bonding of the polyene ligand. $2e_s$ finds a good match in symmetry and energy to interact with the $1\pi_s$ orbital of the tricyclooctatetraene ligand. The situation with $2e_a$ is a bit more complicated: $2e_a$ forms a bonding combination with $1\pi_a$, sending $1\pi_a$ to lower energy, the antibonding combination of $1\pi_a$ and $2e_a$ strongly mixes into itself $2\pi_a$, the LUMO of the tricyclooctatetraene. This mixing takes place in a bonding way with respect to $2e_a$, forming *(6)* as an occupied but practically nonbonding orbital. The $1a_1$, $1e_s$ and $1e_a$ orbitals of the CoCp fragment are largely nonbonding levels, localized at the cobalt center.

A shift *(2)*→*(3)* of the CoCp fragment as a plausible step of the interconversion *(1)*→*(1')* causes an orbital crossing between the HOMO *(6)* of the complex and its LUMO *(7)*, the antibonding combination of $1\pi_s$ and $2e_s$. In other words, the conversion *(2)*→*(2') via (3)* is symmetry forbidden. To see how this comes about note that it is the bonding combination of $2\pi_a$ with $2e_a$ which keeps the HOMO *(6)* from rising to a

[**] Haptotropic Rearrangements of Polyene-ML_n Complexes, Part 1. This collaboration was made possible by a NATO Scientific Affairs Grant. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie (P. H.), the Robert A. Welch Foundation and the Petroleum Research Foundation (T. A. A.). T. A. A. is Camille and Henry Dreyfus Scholar Teacher (1979–1984).

high energy. For geometry *(3)* this interaction is lost by symmetry and, thus, during the CoCp transit, *(6)* rises to high energy, ultimately becoming MO *(8)* of structure *(3)* (predominantly $2\pi_a$ in character). On the other hand, the antibonding between $2e_s$ and $1\pi_s$ vanishes so that the LUMO *(7)* is lowered in energy and in addition begins to mix into itself $2\pi_s$ in a bonding fashion with respect to $2e_s$, so that finally MO *(9)* results.

The symmetry imposed barrier of the CoCp migration is calculated as 47 kcal/mol. The relatively high temperatures used in the experiments and the fact that the CoCp unit need not remain on the mirror plane bisecting the tricyclooctatetraene (which technically avoids the HOMO-LUMO correlation) would still make the pathway *via (3)* an attractive process. However, the conversion of *(1)* to *(2)* is also strongly symmetry forbidden. The orbitals of the diethynylcyclobutadiene ligand are shown on the right side of Scheme 2. Of these $1\pi_s$ and $2\pi_a$ form ideal bonding combinations with $2e_s$ and $2e_a$, respectively. The π-orbitals of both valence isomers of the pure ligand correlate with each other nicely during the cycloaddition and, therefore, they must as well in the CoCp-complexes. The problem lies in the orthogonal ("in plane") π- and π^*-orbitals of the two ethynyl groups of *(1)*, the S and A combinations of which are easily constructed. Of these orbitals two are important, the S-combination of the π^*-levels and the A-combination of the π-levels. As the two ethynyl groups approach each other to cycloadd to a four membered ring, the symmetric combination of the π^* orbitals finally becomes a bonding σ-orbital, the A-combination of the alkyne π-MO's correlates to an antibonding σ^*-orbital of the new ring. The transformation of *(1)* into *(2)* therefore is not unlike the symmetry forbidden $[{}_{\pi}2_s + {}_{\pi}2_s]$ dimerization of ethylene[6]. The activation barrier found for the rearrangement *(1)*→*(1')* of 37 kcal/mol[1b] seems to be too small for the process to occur by way of *(2)* and *(3)*. It can also be shown, that the direct conversion of *(1)* into *(3)* [CoCp migration and simultaneous ring closure] is doubly symmetry forbidden: two occupied A-levels become empty, while two unoccupied MO's of S symmetry correlate to occupied orbitals of the product.

The direct retrocycloaddition of *(1)* to *(4)* is also strongly symmetry forbidden. A σ^*-orbital of the cyclobutadiene ring develops into a filled π-level of the alkyne ligands, a σ-MO correlates to π^* orbitals. The reverse of this process has been treated by *Mango et al.* in qualitative terms[7]. Our preliminary calculations furthermore put a higher barrier on going from *(4)* to *(4')* (60 kcal/mol) than that for the rotation of an alkyne ligand *via (10)* (23 kcal/mol). Thus, one would expect, that if the energy manifold leading from *(1)* to *(4)* were accessible, then "cross products" of the type given by *(11)* should be observed. Such is not the case for $R = D$[1a], and when $R = SiMe_3$[1b] *Vollhardt* and *Fritch* find *(11)* to be formed with a higher activation energy than that for the *(1)*→*(1')* rearrangement. The reason for the enormous energetic requirements of a CoCp shift *(4)*→*(4')* lies in the fact, that all dominant frontier orbital interactions in *(4)* between $2e_s$ and $2e_a$ of CoCp and the highest occupied π and the lowest unoccupied π^* orbitals of two diacetylenes break down for symmetry reasons in *(5)*.

(10) (11) (12)

Our preliminary results therefore make all pathways of a diethynylcyclobutadiene-CoCp rearrangement as shown in Scheme 1 appear rather improbable.

A further mechanistic hypothesis for this unusual reaction could involve the direct conversion of *(1)*, $R = H$, to *(12)*, mentioned as "structural and electronic counterpart" of *(3)* by *Vollhardt* and *Fritch*[1a].

Characterization by Mössbauer Spectroscopy of Iron Carbide Phases in a Highly Active Carbon Matrix Catalyst for Medium Pressure Fischer-Tropsch Synthesis[**]

By *Hartwig Schäfer-Stahl*[*]

As crucial intermediates in the synthesis of hydrocarbons from CO and H_2 on heterogeneous catalysts containing iron, cobalt, and nickel (Fischer-Tropsch synthesis), the formation of metal carbide phases was reported as long ago as the 1920's by *F. Fischer et al.*[1], partly on the basis of results of

hydrolysis experiments with such catalysts (cf. also [2]). This concept is still a matter of controversy[3,4]. We now report observations on a highly active matrix catalyst which show that the catalytically active sites are formed at iron carbide crystallites.

Reduction of iron halide-graphite intercalation compounds leads to destruction of the ordered host lattice, giving a carbon layer matrix with a greatly increased surface area in which highly dispersed iron particles are embedded whose diameter is shown by Mössbauer spectroscopy and electron microscopy[5,6] to be smaller than 2000 pm (20 Å). This matrix catalyst mediates Fischer-Tropsch synthesis at temperatures as low as 140 °C in the medium pressure range[7].

Under these conditions the original iron particles undergo complete transformation. Superparamagnetic iron oxide and, above all, ferromagnetic ε- and χ-iron carbide phases are recognizable in the Mössbauer spectrum. If the temperature of Fischer-Tropsch synthesis is raised to 185 °C then the unstable iron oxide phases disappear and only magnetically ordered ε- and χ-iron carbide phases are present in the catalyst. The activity of the catalyst increased concomitantly. Subsequent heating to 320 °C in a gas mixture having a high concentration of H_2 effects complete phase transition to the χ-iron carbide phase (magnetically ordered at room temperature) which is then also stable at 140 °C (Fig. 1). This χ-iron carbide phase is the most active form of the investigated matrix catalyst in the temperature range around 140 °C. Since the phase is magnetically ordered at room temperature but fails to show sharp X-ray reflections, the particle diameter can be estimated as between several tens and several hundreds of Å.

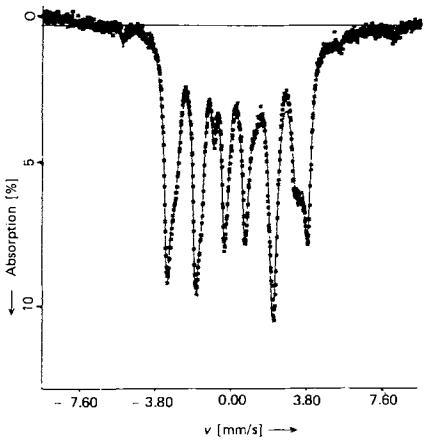

Fig. 1. Mössbauer spectrum of the matrix catalyst after 600 h operation at 140 °C in its most active form. Almost the entire iron content is present in the form of ferromagnetic χ-carbide. (Recorded under protective gas with an ELSCINT AME40 instrument, calibration with Ne-He laser interferometer and α-Fe foil. Chemical shift relative to center of gravity of the α-Fe spectrum.)

However, if the catalyst is heated to 320 °C in a gas mixture having a low H_2 content then the χ-iron carbide phase is partly degraded to ferromagnetic Fe_3O_4; it no longer exhibits Fischer-Tropsch activity at 140 °C. A residual catalytic activity can be detected at 185 °C; in the course of several days the χ-iron carbide phase is regenerated with a concomitant increase in catalytic activity. A similar increase in activity is observed when the partially oxidized catalyst is reduced with hydrogen before it is re-used. After such regeneration small amounts of ferromagnetic Fe_3O_4 and of α-Fe are recognizable in the Mössbauer spectrum. Accordingly, the original activity of the pure χ-iron carbide phase is not quite reached. This oxidation-reduction cycle is reproducible.

The correlation between catalytic activity and content of iron carbide phases, and particularly the χ-iron carbide phase, observed in all the operations described above can be regarded as unequivocal proof that such carbide phases are the actual catalytically active component, at least below 200 °C.

The matrix catalyst under investigation is particularly suitable for a structure-reactivity correlation. Owing to the extremely low diameter of the particles, which are essentially isolated from one another by the disordered carbon layer matrix and the exceptionally low reaction temperatures thus possible, the formation, transformation, and growth of the reactive phases can be recognized from the sequence of magnetically disordered iron, superparamagnetic iron oxide alongside ε-iron carbide, iron carbide mixtures, and ultimately pure χ-iron carbide. Our results differ in this point from those of similar studies on α-Fe particles[3,8] whose larger diameters necessitated higher formation temperatures, at which the temperature-dependent sequential formation of oxide and carbide phases and their varying catalytic activities are unobservable.

The high proportion of surface atoms in the highly dispersed particles described above also has the effect that the periphery of the particles makes a significant contribution to the Mössbauer spectra relative to the bulk. Since none other than carbide phases, and especially no α-Fe phase[3,8], can be observed at maximum activity, it may be assumed that χ-iron carbide is also present in the periphery of the reactive particles. It remains to be established how the carbide centers activate the CO molecule for reduction and chain propagation reactions and whether analogies exist with recently described reactions of CO at iron carbide clusters in homogeneous solution[9].

Procedure

All operations were performed in an argon atmosphere with exclusion of air and moisture. Flattened and comminuted lithium wire (11 g) and biphenyl (65 g) are stirred in tetrahydrofuran (THF) (500 ml) at −80 °C until dissolution is complete. $FeCl_3 \cdot C_{6.8}$ (50 g) is cautiously added with further cooling. If the green color of the solution disappears further lithium wire is added until the green color is retained. After 10 minutes' stirring at room temperature the solvent and volatile components are stripped off *in vacuo* and sublimed off up to 100 °C, respectively.—Some 20 $cm^3 = 10$ g of the matrix catalyst prepared with biphenyllithium and having an iron content of 0.98 g (≙ 0.0175 mol Fe) is examined with regard to its catalytic activity.

The Fischer-Tropsch reaction was carried out in a differential reactor with a membrane pump in the external synthesis gas cycle at pressures between 10 and 32 bar and a flow rate of 18 l/h. The reactivity of the matrix catalyst follows from the decrease in pressure of the synthesis gas with time. The product spectrum (GC-MS) was similar to that obtained on use of standard precipitation catalysts; it did not alter significantly during the catalyst transformations described above.

Facile Synthesis of α- and β-*O*-Glycosyl Imidates; Preparation of Glycosides and Disaccharides[**]

By *Richard R. Schmidt* and *Josef Michel*[*]

Glycosides and saccharides are largely synthesized *via* haloses and their activation by heavy metal salts—especially silver salts[1,2]. The disadvantages of this method are self-evident. Simplification of this approach should come from the synthesis of sterically pure, readily isolable intermediates with other leaving groups not requiring activation by heavy metal salts[2,3]. Suitable candidates would seem to be, *e.g.*, α- and β-glycosyl imidates, since β-glycosyl imidates—prepared from α-haloses with silver salts—undergo acid-catalyzed reaction to give good chemical and stereochemical yields of α-glycosides and α-saccharides[4]. Thus a facile synthesis of α- and β-glycosyl imidates is called for[5].

Ketenimines and nitriles containing electron-withdrawing substituents are known to afford imidates directly on reaction with alcohols[6]. We shall now demonstrate for the case of the C-1-unprotected glucopyranose *(1)* that this reaction can be applied to cyclic hemiacetals. Use of sodium hydride as base and aryl-substituted ketenimines gave exclusively the β-imidates *(2)*—*(5)* whereas the same reaction both with benzyl- and with acetyl-protected glucopyranose *(1)* and trichloroacetonitrile led diastereospecifically to the α-imidates *(6)* and *(7)* (Table 1). Both the β-imidates and the α-imidates, now prepared for the first time, could be conveniently isolated.

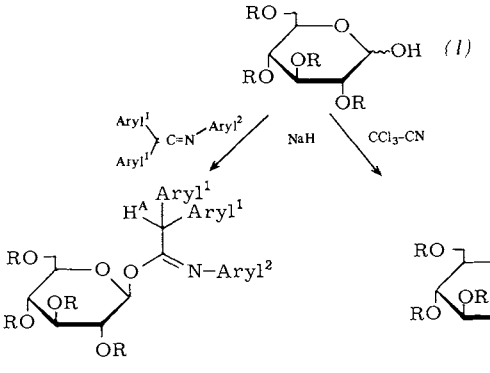

Table 1. *O*-Glycosyl imidates *(2)*—*(7)* prepared [a].

Déléris et al.[2] and *Sharpless et al.*[3] have independently published analogous results and presented some interesting possible applications of the 2-alkenesulfinamides *(4)* they have synthesized. In a systematic investigation[4] of the structure-reactivity relations of the enophiles of type *(2)* and the ene components *(1)* we have now found that the enophilicity of *(2)* and similar *N*-sulfinylsulfonamides can be further markedly enhanced by incorporation of strongly electron-attracting groups R^6.

[a] All compounds *(5)* gave correct analyses. [b] Start of melting (intervals generally 1 K; as a rule decomposition with evolution of gas and red coloration). [c] KBr disk. [d] δ values, measuring frequency in the case of *(5a)—(5c)* and *(5g)*: 200 MHz; in the case of *(5f)*: 60 MHz; solvent in the case of *(5a)—(5e)* and *(5g)*: CD_3CN; in the case of *(5d)*: $(CD_3)_2CO$, in the case of *(5e)—(5f)*: $CDCl_3$ (internal standard: TMS). [f] Mixture of diastereoisomers.

Thus, *N*-sulfinylnonafluorobutanesulfonamide *(3)*[5] (obtained from nonafluorobutanesulfonyl fluoride in three steps) is about 10^3—10^4 times more reactive than *(2)* (see Table 1).

This finding has parallels in the dramatic increase in dienophilicity of C=C and C≡C bonds by trifluoromethanesulfonyl-[6] or nonafluorobutanesulfonyl-substitution[7]. A surprising feature is the extremely marked effect of varying the residue R^6, which is "insulated" from the reaction center by the sulfonyl group. With *(3)*, very "electron-deficient" alkenes *(1)* can also undergo the ene-reaction which do not react any further [*e.g. (1d)*] or only very slowly and in moderate yields [like *e.g. (1c)* and *(1f)*] with *(2)*. Some characteristic data of 2-alkenesulfonamides *(5)* synthesized so far are given in Table 2.

Procedure

(5): A solution of *(3)* (3.45 g, 10 mmol) in anhydrous tetrachloromethane (5 ml) is treated at −20 °C under dry N_2 with 11 mmol *(1)*. After the requisite reaction time (Table 1) either the precipitate is filtered off under N_2 or the reaction mixture is treated with anhydrous pentane until clouding occurs and the product brought to crystallization at −78 °C. Purification is achieved by dissolution in diethyl ether at 20 °C, addition of pentane, and cooling to −78 °C. The products *(5)* can be stored for a few months at −20 °C in the absence of moisture.

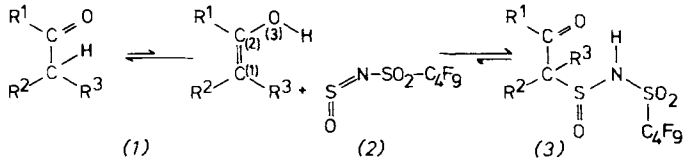
3-Oxa-Ene Reactions of *N*-Sulfinylnonafluorobutanesulfonamide with Alkanones—General Synthesis of 2-Oxoalkanesulfinic Acid Derivatives[**]

By *Günter Kresze* and *Reinhard Bussas*[*]

We have found that *N*-sulfinylnonafluorobutanesulfonamide *(2)* reacts with alkyl-substituted alkanones and cycloalkanones within minutes at 20 °C, and with 1-aryl-2-alkanones within a few hours (direct ^{1}H-NMR spectrometric observations) to give *N*-(nonafluorobutanesulfonyl)-2-oxoalkanesulfinamides *(3)* (see Table 1, cf. [1a]). This finding is of interest, *inter alia*, in connection with the mechanism of oxidation of carbonyl compounds and alkenes with SeO_2[1b].



We propose that the enol form of *(1)* reacts in a 3-oxa-ene reaction with *(2)*. This hypothesis is supported by the following observations:

Non-enolizable alkanones such as diphenylmethanone, 1,1,1,3,3,3-hexachloro-2-propanone, and 1-phenyl-2,2,2-trifluoro-1-ethanone do not react with *(2)* at 20 °C[2].

The C—H acidity of *(1)* and analogous compounds[3], which would be decisive in the alternative mechanism of an HX addition[4], plays no significant role, since compounds much more strongly acid than the alkanones presented here

The formation of *(3)* is reversible: on allowing a solution of the product *(3)* to stand, the signals of the educts *(1)* appear in the NMR spectrum.

3-Oxa-ene reactions have previously been observed on only few occasions, *e.g.* in the cyclization of alkenones[5], in the reaction of 1-(1,3,5-triazin-2-yl)-2-propanone with enophiles[6], and in the reaction of 1,3-dicarbonyl compounds with 2-oxopropanedinitrile[7]. In our opinion the formation of *N*-fluorosulfonyl-β-oxocarboxamides from α-methylene ketones and fluorosulfonyl isocyanate can also be regarded as a 3-oxaene reaction[8].

The isolation of product *(3)* now confirms the possibility of such a mechanism also for the oxidation of *(1)* with SeO_2; moreover, the reaction *(1)*→*(3)* opens up a facile entry to 2-oxoalkanesulfinic acid derivatives which were previously reported unobtainable[9a] or only obtainable in certain cases (without α-H atom)[9b].

Procedure

(3): A solution of *(2)* (3.45 g, 10 mmol) in anhydrous CCl_4 (5 ml) is treated with 11 mmoles of *(1)* at 20 °C [in the case of *(1a)*, *(1m)*, *(1o)*—*(1r)* at 0 °C] under dry nitrogen. After the requisite reaction time (Table 1) either the precipitate is filtered off under N_2 or the reaction mixture is treated with anhydrous pentane until clouding occurs and then brought to crystallization at −78 °C. Purification is achieved by recrystallization from diethyl ether/pentane. The products *(3)* can be stored for months at −20 °C in the absence of moisture.

Direct Detection of Dicyanoketene in the Gas Phase[**]

By *Alfred Hotzel, Richard Neidlein, Reinhard Schulz*, and *Armin Schweig*[*]

Cyanoketenes are exceptionally reactive and are therefore regarded as highly unstable[1]. Evidence for their existence could only be gained indirectly by trapping reactions, except in the case of sterically stabilized *tert*-butyl- and *tert*-pentylcyanoketenes. Dicyanoketene itself was also postulated in 1978 on the basis of trapping products[2].

We now wish to report the generation of free dicyanoketene *(2)* in the gas phase and its characterization by UV photoelectron spectroscopy and mass spectrometry.

(1) *(2)*

On slow warming of 2,5-diazido-3,6-dicyano-1,4-benzoquinone *(1)*[3] to 60 °C *in vacuo* ($p < 5 \times 10^{-2}$ mbar) a gas mixture could be pumped off over a longer period of time whose PE spectrum (Fig. 1) showed it to contain not only nitrogen and a small amount of carbon dioxide[4] but also a further compound having the vertical ionization energies ① 10.56 eV, ② 13.25 eV and 13.49 eV. Band ① is split into partial vibrational bands separated by 1150 cm^{-1} and its shape resembles that of the lowest-energy $^2B_1$ PE band of ketene[5].

The high intensity of band ② is attributable to superposition of several ionizations. PERTCI calculations[6] with MNDO wave functions[7] permit assignment of the bands ①/$^2B_1(\pi)$ and ②/$^2B_2(\sigma)$, $^2A_1(\sigma)$, $^2A_2(\pi)$, and $^2B_2(\sigma)$ to ionizations of dicyanoketene *(2)*.

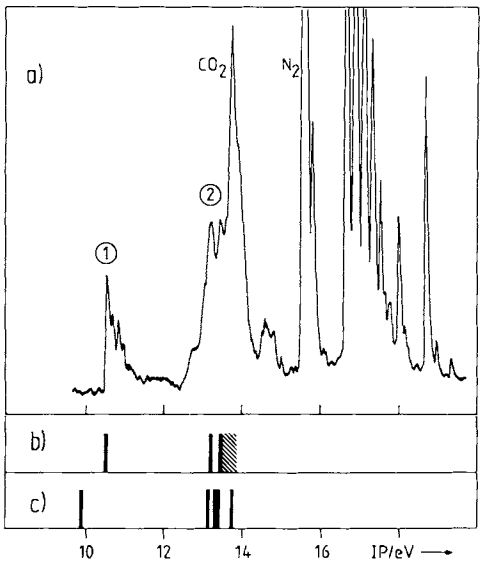

Fig. 1. a) He-I photoelectron spectrum of the gaseous product mixture obtained on heating 2,5-diazido-3,6-dicyano-1,4-benzoquinone *(1)* to 60 °C/$< 5 \times 10^{-2}$ mbar; b) experimental, and c) calculated (MNDO-PERTCI) vertical ionization energies of dicyanoketene *(2)*.

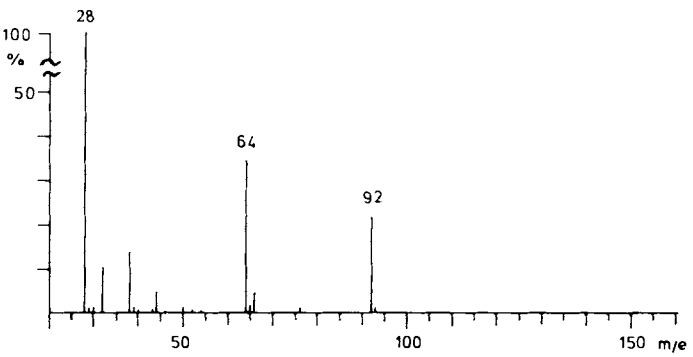
In view of the unusual reaction conditions—the highly reactive dicyanoketene is pumped off from the surface of the decomposing quinone *(1)* which does not itself go into the gas phase even in a high vacuum—further independent evidence appeared desirable.



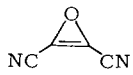


Fig. 2. 100-eV mass spectrum of the dicyanoketene *(2)* obtained together with nitrogen on heating 2,5-diazido-3,6-dicyano-1,4-benzoquinone *(1)* to 85 °C in the ion source.

To this end we slowly heated the quinone *(1)* in the ion source of a mass spectrometer until vigorous evolution of nitrogen occurred (85 °C). The mass spectrum (Fig. 2) unequivocally confirms the formation of dicyanoketene *(2)*. High resolution spectra of the two characteristic peaks at the mass numbers 92 (M^+) and 64 ($M^+ - CO$) afforded the empirical formula C_4N_2O (calc. 92.0011, exp. 92.0011) and C_3N_2 (calc. 64.0061, exp. 64.0060). Fragmentation of the molecular cation with loss of CO is characteristic of ketenes[8] and rules out the two C_4N_2O isomers *(3)* and *(4)* as possible competing products in the decomposition of *(1)*. This is in agreement with MNDO calculations (standard enthalpies of formation: *(2)* 52 kcal/mol; *(3)* 118 kcal/mol; *(4)* 101 kcal/mol).

[3] We are grateful to Dr. R. Gartner for the preparation of 2,5-dichloro-3,6-dicyano-1,4-benzoquinone, from which (1) was obtained according to [2]. The premature deflagration of (1) in the experiments described could be suppressed by preparation of (1) in the presence of roughly twice the amount of finely divided calcium carbonate ("solid state dilution"). The mixture of (1) and $CaCO_3$ was thoroughly dried at 0 °C and 10^{-6} mbar prior to each experiment.

[4] It could be demonstrated by mass spectrometry that carbon dioxide is formed on thermal decomposition of the (di- or polymeric?) byproducts. This reaction becomes increasingly pronounced with rising temperature, but plays only a minor role below 100 °C. Increasing temperature considerably strengthened the mass peak at $m/e = 44$ after that at $m/e = 92$ had disappeared almost completely.

Direct Detection of Dicyanothioketene in the Gas Phase[**]

By *Reinhard Schulz* and *Armin Schweig*[*]

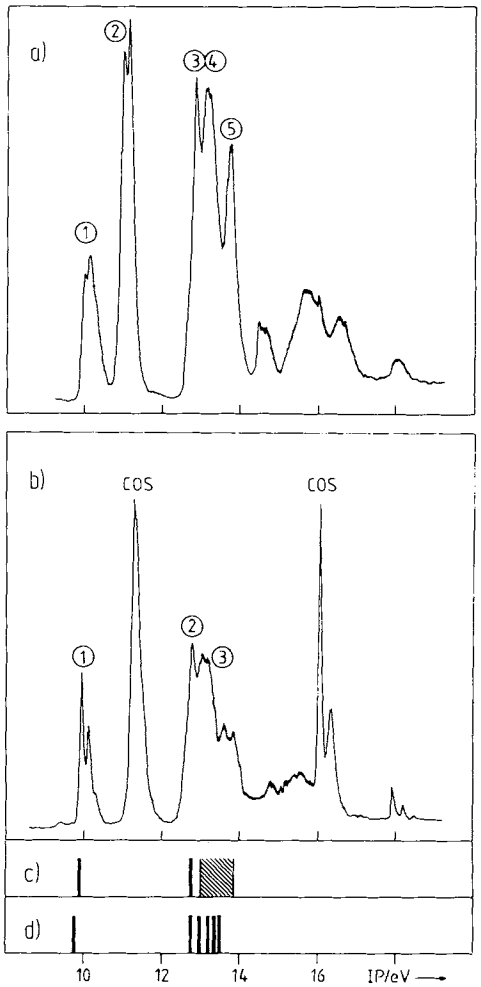
Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

Dicyanothioketene (2) has been formulated as an intermediate on several occasions[1]; however, all attempts to isolate this species or to detect it by spectroscopy have so far failed. Not even monocyanothioketenes have yet been identified directly[2].

We have now succeeded in directly detecting this apparently highly reactive molecule by variable temperature photoelectron spectroscopy (VTPES)[3] on gas phase pyrolysis of 2-(4-oxo-1,3-dithietan-2-ylidene)malonitrile (1)[1a]. A previous attempt to generate (1) in the gas phase by this reaction and to isolate it in solution at low temperature afforded only dimeric and polymeric material[4].

(1) (2)

The reaction (1)→(2) was performed in a flash pyrolysis reactor (stainless steel tube, 20 × 0.6 cm; *ca.* 5×10^{-2} mbar) directly above the ionization region of a modified PS 18 photoelectron spectrometer and went to completion at 470 °C. The PE spectrum of the starting material (1) (Fig. 1a) shows bands at ① 10.00 eV/$^2B_1(\pi)$, ② 10.95—11.10 eV/$^2A_2(\pi)$ and $^2B_2(n)$, ③ 12.80 eV/$^2B_1(\pi)$, ④ 13.08 eV/$^2B_2(\sigma)$ and $^2A_1(\sigma)$ and ⑤ 13.70 eV/$^2A_2(\pi)$[5]. The PE spectrum of the pyrolysis products (Fig. 1b) contained not only the known bands of carbon oxide sulfide[6] but also the new bands at ① 9.94 eV/$^2B_1(\pi)$, ② 12.79 eV/$^2B_2(\sigma)$, ③ 13.00—13.8 eV/$^2B_1(\pi)$, $^2B_2(\sigma)$, $^2A_1(\sigma)$ and $^2A_2(\pi)$[5a]. Band ① is split into vibrational partial bands separated by 1500 cm^{-1} and expectedly[7]



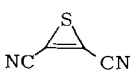


Fig. 1. He-I photoelectron spectrum of a) the starting material (1) and b) its pyrolysis products at 470 °C; c) experimental and d) calculated (MNDO-PERTCI) vertical ionization energies of dicyanothioketene (2).

shows the same fine structure as the energetically lowest-lying $^2B_1(\pi)$ band in the PE spectrum of thioketene[8]. The identity of dicyanothioketene (2) follows not only from the extremely clear-cut reaction but also from the good agreement between the experimental vertical ionization energies and those predicted by MNDO[9a]-PERTCI[9b] calculations (Fig. 1). The ionization energies are expectedly smaller than for dicyanoketene[10]. The energy difference between the $^2B_1(\pi)$ states of dicyanoketene and dicyanothioketene (0.7 eV) is in excellent agreement with the corresponding difference in the case of the ketene/thioketene pair[8].

(3)  NC–≡–S–CN (4)

Hans-Meerwein-Strasse, D-3550 Marburg 1 (Germany)

[**] Part 90 of Theory and Application of Photoelectron Spectroscopy. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 89: [10].

Among the three isomers *(2)*, *(3)*, and *(4)*, MNDO calculations with optimized molecular geometries show dicyanothioketene *(2)* to have the lowest energy content (standard enthalpies of formation: *(2)* 110 kcal/mol; *(3)* 134 kcal/mol; and *(4)* 122 kcal/mol). These values suggest that it might well be possible to generate thiirenedicarbonitrile *(3)* by photochemical methods.

Like dicyanoketene[10], free dicyanothioketene *(2)* is stable in the gas phase at low pressure. Unlike dicyanoketene, however, *(2)* can readily be generated continuously over a prolonged period in a flow system by gas phase pyrolysis.

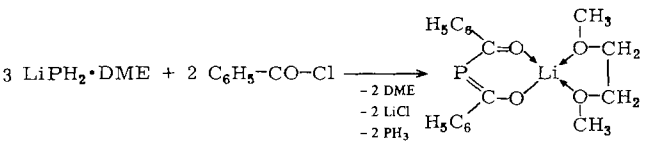
Lithium Dibenzoylphosphide · 1,2-Dimethoxyethane —A New 2-Phospha-1,3-dionate[**]

By *Gerd Becker, Matthias Birkhahn, Werner Massa*, and *Werner Uhl*[*]



Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

The diacylphosphanes *(1)*, $R = CH_3$, $(CH_3)_3C$, synthesized so far show a remarkable keto-enol tautomerism and resemble 1,3-diketones in their properties[1]. According to X-ray structure analyses of nickel bis(dipivaloylphosphide)·DME[2] (DME = 1,2-dimethoxyethane) and of aluminum tris(dibenzoylphosphide)[3a] this similarity is also shown by 2-phospha-1,3-dionates; the metal ions are not coordinated to the phosphorus atoms but in chelate rings to the oxygen atoms of the anions.

(1)

In order to synthesize the hitherto unknown dibenzoylphosphane *(1)*, $R = C_6H_5$, we treated monolithium phosphide·DME[4] with benzoyl chloride in DME. However, instead of the expected monobenzoylphosphane, lithium dibenzoylphosphide·DME *(2)* was formed with slow evolution of phosphane.

(2)

The reaction course can be rationalized by assuming formation of the monosubstituted compound, subsequent lithium/hydrogen exchange, and renewed reaction with an excess of benzoyl chloride. The resulting dibenzoylphosphane reacts with lithium phosphide to form *(2)*.

Compound *(2)* was characterized by elemental analysis and by its NMR and IR data. The ^{31}P- and ^{13}C-NMR signals of the C—P—C group show a downfield shift[5] as has been observed in similar compounds[1b,3]. Since the poor solubility in apolar solvents containing no DME precluded determination of the molecular size and constitution, we investigated *(2)* by an X-ray structure analysis (see Fig. 1).

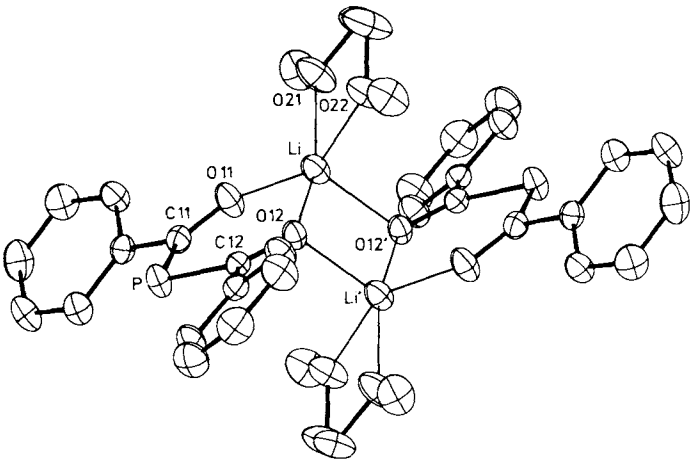


Fig. 1. ORTEP plot of the molecular structure of dimeric lithium dibenzoylphosphide·1,2-dimethoxyethane. The vibrational ellipsoids correspond to 50% probability. *(2)*, space group $P2_1/c$, with $a = 1907.1(7)$, $b = 762.6(7)$, $c = 1259(2)$ pm; $\beta = 104.5(1)°$; 4 formula units. 1907 independent, observed ($F > \sigma$) reflections recorded on an automatic four-circle diffractometer CAD4 (Enraf-Nonius) at $-80\,°C$ ($Mo_{K\alpha}$ radiation, $4° < 2\theta < 48°$) and corrected in the conventional way; $R_w = 0.034$.

(2) exists as 2-phospha-1,3-dionate; the lithium ion is bonded to all oxygen atoms of the ligands. No monomer is present in the solid state; by the inversion as a crystallographic symmetry operation the molecules are linked pairwise to form dimers (Fig. 1). The coordination number of lithium is raised to 5 by bonding to a further oxygen atom O12′ belonging to the inverse dibenzoylphosphide ion; the two lithium atoms of the dimer are located 45 pm above the basal planes of two edge-linked, somewhat distorted square pyramids of O atoms. Although the Li—Li distance (283 pm) is shorter than in the element (304 pm)[6a], metal-metal interaction can be ruled out at a covalent radius of 134 pm[6b]. Similar association is observed in other 1,3-dionates[6c].

[**] Part 14 of Acyl- and Alkylidenephosphanes. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. 13. Mitteilung: *G. Becker, W. Uhl*, Z. Anorg. Allg. Chem., in press.

As in phosphamethinecyanines, λ^3-phosphorins[7], and phosphaferrocenes[8], the third valence of the phosphorus is involved in partial double bonds in the conjugated system of *(2)*. The bond lengths and angles (Table 1) in the dibenzoylphosphide ion are similar to those of the aluminum compound[3a]. The larger ionic radius of the lithium ion (59 pm), however[9], results in an increase of the intramolecular O11—O12 distance ("bite") to 279 pm. The bond lengths of the differently coordinated oxygen atoms O11 and O12 differ only slightly. As expected, the formally singly negatively charged phosphide anion is bound by shorter bonds to the lithium than the uncharged DME. Both chelate rings are not planar; lithium (72 pm) and phosphorus (11 pm) are located above the plane of the six-membered ring formed by the atoms C11, O11, O12, and C12.

Table 1. Selected structural parameters of *(2)*. For clarity, in Figure 1 the carbon atoms of the phenyl groups as well as C8n and C9n of the DME ligand have not been labeled. Atoms from the inverse molecule are marked with an apostrophe.

Bond lengths [pm]			Bond angles [°]	
	n=1	n=2		
P—C1n	181.5(3)	179.6(3)	C11—P—C12	101.8(1)

Li—Li′	283.2	—	O11—Li—O22	147.3(3)
			O12—Li—O21	159.7(3)

Procedure

All operations must be performed under highly pure Ar with dry (Na, $LiAlH_4$) solvents.—A solution of monolithium phosphide·DME (20.3 g, 156 mmol) in DME (200 ml) is added dropwise to a stirred, cooled (−35 °C) solution of benzoyl chloride (14.6 g, 104 mmol) in DME (50 ml). The mixture is then warmed to +20 °C and stirring is continued until evolution of phosphane has ceased (*ca.* 12 h). The precipitated lithium chloride is filtered off and washed with small amounts of DME. The solvent is vacuum distilled from the filtrate and the residue is dissolved in DME. At −25 °C, air-stable, orange-red, hexagonal prisms crystallize from the solution: yield 15.1 g (44.7 mmol, 86%), dec. p. 308 °C (under argon).

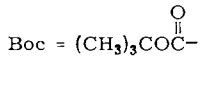
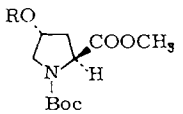
Direct Method for the Synthesis of *N*-Boc-L-3,4-didehydroproline[**]

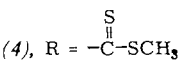
By *Jean-Robert Dormoy, Bertrand Castro, Georges Chappuis, Ulrich Stefan Fritschi*, and *Peter Grogg*[*]



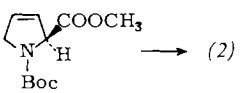
The incorporation of L-3,4-didehydroproline *(1)* into biologically active peptides very seldom results in loss of activity[1-3]; in fact, in some cases the activity even increases, with reduced toxicity of the product[3,4]. Deuterium and tritium can also be incorporated into biologically active peptides *via* dehydroproline[1,3].



(1)



(2)



Hitherto, *(1)* had to be prepared by resolution[1,5] from the technically difficultly accessible racemic educt[6]. We have now succeeded in synthesizing *N*-Boc-L-3,4-didehydroproline *(2)* directly from the naturally occurring L-4-hydroxyproline.

(3), R = H

(4), R = 

(5)

N-Boc-L-4-hydroxyproline methyl ester *(3)*[7] was converted (90%) into the *S*-methyl xanthogenate *(4)*[8], which on Tschugaeff pyrolysis[9] gave the protected 3,4-didehydro ester *(5)* in 64% yield together with some protected 4,5-didehydro ester (3—5%) and educt *(3)* (5—9%). Hydrolysis of *(5)* afforded *(2)* in (70%) yield (see Procedure).—The 250-MHz ^{1}H-NMR spectra of the compounds *(4)* and *(5)* and of the 4,5-didehydro ester are given in Table 1.

Table 1. 250-MHz ^{1}H-NMR shifts of the ring protons in the compounds *(4)*, *(5)* and in the 4,5-didehydro isomer of *(5)* (δ values, in $CDCl_3$, TMS int., multiplets).

Dehydroxylation of Hydrogen Zeolites: Conditions for the Preparation of Thermally Stable Catalysts

By *Laszlo Marosi*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Hydrogen zeolites of Y type are finding increasing use as industrial catalysts for transformations of hydrocarbons; they are produced by thermal decomposition of the ammonium form[1]. However, catalytically inactive products may also arise. One possible reason for the loss of activity might be the elimination of the catalytically active hydroxyl groups (as water) together with ammonia on heating. The mechanism of this scientifically and industrially important dehydroxylation process is still a matter of controversy. In particular, it is unclear whether elimination of water in a shallow bed involves formation of tricoordinated (Si^+Al) sites or of oxoaluminum cations[2]. Our studies on the thermal dehydroxylation of HX and HY zeolites showed that elimination of water *in vacuo* or under shallow bed conditions[3] proceeds in two steps with formation of Lewis acid centers having different properties.

The first step affords partially dehydroxylated zeolites whose properties are compatible with the presence of tricoordinated silicon and aluminum in the crystal lattice.

In the second step framework aluminum atoms migrate into the intracrystalline pore system. This can give rise to a variety of products having differing crystallinity and ion exchange capacity, including products resembling deep bed-calcined Y zeolites in their thermal properties.

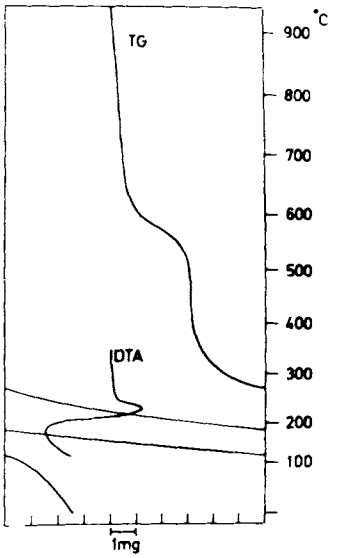

Fig. 1. Thermogravimetric diagram for the thermal decomposition of NH_4Y zeolite (Si/Al = 2.0).

Up to about 320 °C, physically bound water and ammonia are liberated, affording the hydrogen zeolite. Only a slow loss of weight is observed in the first dehydroxylation step from 320 to 550 °C. No changes are seen in the X-ray diffraction pattern. Nevertheless, precise evaluation of the thermogravimetric diagram (Fig. 1) shows that 40% of the hydroxy groups are eliminated in this step.

The second dehydroxylation step is characterized by a fast elimination of water at 550 to 630 °C. The lattice constant decreases from 24.70 to about 24 Å. Moreover, lattice distortions occur, leading to complete disruption of the crystal lattice on further increasing the temperature.

For detailed studies NaX and NaY zeolites with different Si/Al ratios were prepared by known methods[4], transformed into the ammonium form, and calcined under shallow-bed conditions at a temperature below that of lattice destruction (Fig. 2).

The residual content of hydroxy groups (α) decreases with increasing aluminum content, and the lattice constant remains unchanged. The ion exchange capacity after partial dehydroxylation, determined by fourfold exchange with a 0.1 M solution of $AgNO_3$, always corresponds to the sum of the sodium content and the residual proton content.

The resulting Lewis acid centers do not possess ion exchange properties. The contribution of this step to the overall dehydroxylation can be estimated from a simple scheme: the faujasite structure consists of cuboctahedra made up of six four-membered rings of tetrahedra. At a molar ratio of Si/Al = 3, *i.e.* the composition of the silicon-richest Y zeolite, each of the four-membered rings contains an aluminum

[*] Dr. L. Marosi
Ammoniaklaboratorium der BASF AG
D-6700 Ludwigshafen (Germany)

atom. Replacement of further silicon atoms leads to neighboring pairs of aluminum atoms in opposite corners of the four-membered rings whose contribution increases with increasing aluminum content. It can be deduced from the experimental results shown in Figure 2 that for HX and HY

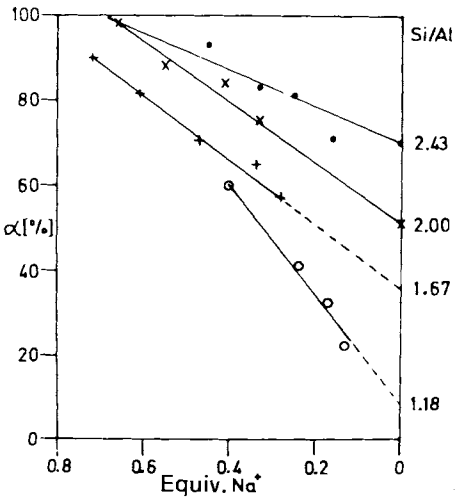

Fig. 2. Decrease in content of hydroxy groups (α) on heating of sodium-containing NH_4 zeolite: 60 h at 470 °C (●); 15 h to 470 °C (×); 8 h to 470 °C (+); 4 h to 530 °C (○).

zeolites the number of eliminated water molecules in the first dehydroxylation step is in agreement with the number of pairs of aluminum atoms for a given Si/Al ratio (Table 1).

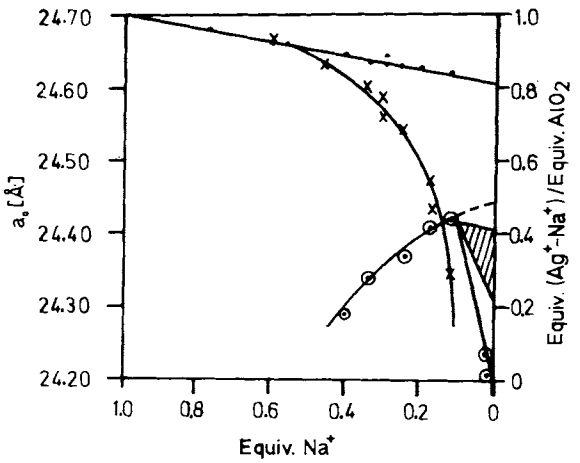
Table 1. Relationships between the calculated amount of neighboring aluminum atoms and the experimentally determined extent of dehydroxylation for HX and HY zeolites having various Si/Al molar ratios.

Si/Al	Neighboring Al atoms [%]	Dehydroxylation [%]
3.0	0	
2.43	28.50	30
2.0	50	50
1.67	66	63
1.18	91	90

It must therefore be assumed that in the first dehydroxylation step water is eliminated from those hydroxy groups which are coordinated to neighboring framework aluminum atoms. Remarkably, the same number of hydroxy groups prove to be non-acidic on amine titration[5].

The second step of dehydroxylation always involves migration of framework aluminum atoms into the intracrystalline pore system. This leads to products having an ion exchange capacity considerably greater than their respective sodium content; this suggests formation of AlO^+ ions during the elimination of water (see Fig. 3).

The elimination of water becomes increasingly slower with increasing sodium content; even after complete dehydroxylation the samples are still crystalline. The influence of the dehydroxylation rate on the crystallinity can also be demonstrated for Si-rich HY zeolites. For instance, if the sample is heated at a rate of 0.1 °C/min between 500 and 600 °C then the crystal structure is retained to over 1000 °C. Samples of this kind obtained by controlled dehydroxylation resemble deep-bed calcined Y zeolites in their properties[3]. They possess a high thermal stability and—as demonstrated by the hatched region in Figure 3—exhibit a considerable ion exchange capacity. Their lattice constant lies between 24.30 and 24.50 Å.



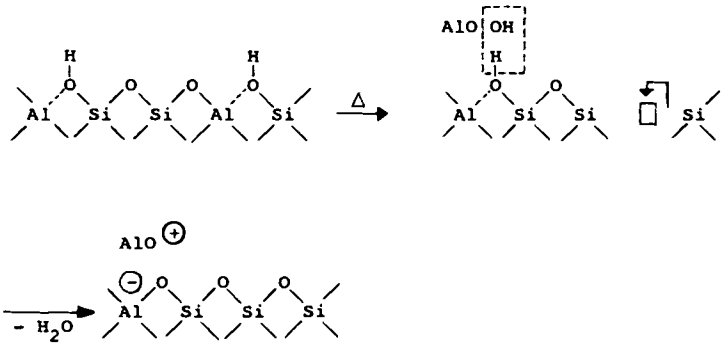


Fig. 3. Lattice constant a_0 of NaHY zeolite (Si/Al = 2.43) (●) and the corresponding completely dehydroxylated products (×) and the increase in ion exchange capacity (○). The sample was heated to 750 °C for dehydroxylation. Hatched: ion exchange capacity.

Since the migration of the framework aluminum atoms into the intracrystalline pore system also takes place *in vacuo* it cannot be interpreted as a result of hydrolysis. It appears more likely that the AlO(OH) skeletal units swing out in the course of their thermal motion and under subsequent cationization according to the following scheme. (The vacancy at the AlO(OH) is occupied by silica, *e.g.* from peripheral regions.)

Whether, and to what extent, the AlO(OH) groups are cationized depends upon the relative rate of swinging and cationization. Too fast a heat-up rate between 500 and 600 °C causes most of the aluminum atoms to leave the crystal framework. The lattice then collapses. Depending upon the rate of dehydroxylation a variety of products can arise which differ in their crystallinity and ion exchange capacity and also contain defect sites. By a suitable choice of calcination conditions it is possible to balance these two processes such that the products have a particularly high thermal stability. This mechanism of water elimination in the second dehydroxylation step can also be applied to shallow-bed and deep-bed dehydroxylation and thus permits a coherent view of the processes occurring under different dehydroxylation conditions.

Amorphous Zeolites

By *John M. Thomas* and *Leslie A. Bursill*[*]

Crystalline zeolites possess a wide range of properties that make them industrially important. It is less widely known that imperfectly-ordered (quasi-crystalline or semiamorphous) zeolites also exist, and that these, too, possess potentially attractive properties. There is, however, some difficulty in characterizing these amorphous variants; and it is rather puzzling that a material which lacks long-range order can nevertheless exhibit marked cation-exchange capacity and catalytic activity, which in the case of the crystalline varieties, arise because of the unit-cell level porosity of the aluminosilicate. Our communication focuses on these two points; and, in particular, describes how high resolution electron microscopy (h.r.e.m.) helps rationalize these problems.

We have recently shown[1] that it is possible, notwithstanding their beam-sensitivity, to record direct structural images, at a resolution close to 3 Å, of crystalline zeolites such as Na-A, Na-X, Na-Y and ZSM 5. During the course of examination the zeolites gradually become amorphous; but advantage may be taken of this fact since both the course of the process of amorphization as well as the various degrees of quasicrystallinity may be analyzed by direct (real-space) imaging. (The reliability of the images taken by h.r.e.m., both for crystalline and amorphous materials, is known from computer simulation procedures that are described fully elsewhere[2,3].)

Considerable insight is gained from the study of amorphous zeolites in this way. This is illustrated with reference to Fig. 1 which is a high-resolution image of a dehydrated crystal of Na-A (idealized formula $Na_{12}Al_{12}Si_{12}O_{48}$) that has been appreciably converted to an amorphous condition[4]. There are several noteworthy features:

(i) A 'raft' (*ca.* 10^4 Å^2 in projected area) of crystalline material consisting of an ordered array of so-called supercages[2]—*ca.* 10^2 in all—is surrounded by essentially amorphous aluminosilicate.
(ii) A smaller 'raft' (*ca.* 3×10^3 Å^2 in area), less well-ordered than the other and not in registry with it, consisting of some 30 supercages, is also surrounded by amorphous material.
(iii) Several isolated supercages, one of which is arrowed, may be identified in the amorphized background.

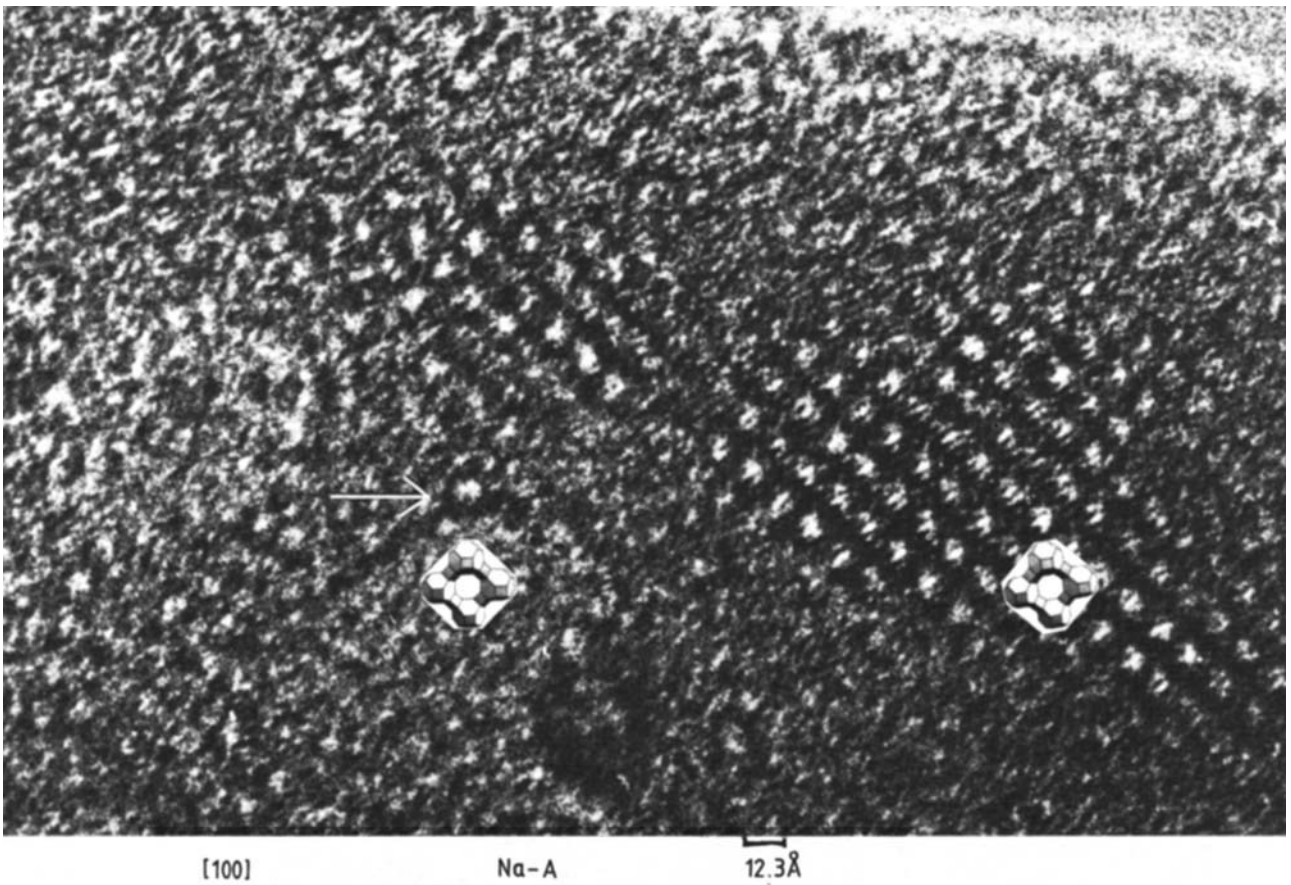

Fig. 1. High resolution electron micrograph of a thin film (<40 Å thick) of quasi-crystalline zeolite A, showing the supercages as white dots. For details see text.

[*] Prof. Dr. J. M. Thomas, Dr. L. A. Bursill [**]

Lensfield Road, Cambridge, CB2 1EP (England)
[**] On leave from Department of Physics, University of Melbourne (Australia)

We may now appreciate how amorphous zeolites can retain much of their cation-exchange capacity: even though clusters of sodalite cages (which circumscribe the supercage—see inset) are detached from the parent crystal, thereby generating

a structure the long-range order of which is disrupted, these sub-unit cell fragments still possess the basic attribute that confers upon them their exchange capacity and catalytic activity.

Clearly h.r.e.m. can play a useful role in the characterization of microcrystalline and amorphous zeolites, more so perhaps than other solids since the individual units (in this case the cubo-octahedra) are more readily discernible, and hence the interpretation of image detail more straightforward.

Bis(η-cyclopentadienyliron-μ,η-thiadiborolene)iron—Structure of a η-C_5H_5 Tetradecker Sandwich Complex[**]

By *Walter Siebert, Christian Böhle,* and *Carl Krüger*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

Triple-decker complexes with terminal carbon monoxide or thiaborolene ligands are cleaved by cyclopentadienide into anionic mononuclear compounds which form tetradecker complexes with transition-metal halides[1]. An analogous cleavage of the η-cyclopentadienyl triple-decker sandwich *(3)*[2] fails because of its short Fe...Fe distance. By reacting the compound $[(C_5H_5)Fe(C_8H_{12})]_2Zn$, recently described by *Jonas et al.*[3], with 1,2,5-thiadiborolene to give the trinuclear complex *(1)* (58% yield) we have now found a route for the synthesis of the long-sought sandwich anion *(2)*[4]. We report here on the first η-cyclopentadienyl-μ-thiadiborolene tetradecker sandwich complexes *(4)* and *(5)* which we obtained in 53 and 42% yield, respectively, from the anion *(2)* and $FeCl_2$ and $CoCl_2$.

Direct reaction of *(1)* with $CoCl_2$ leads, as a result of ligand exchanges, to $(C_5H_5)Co(C_2B_2S)$ (83%), $(C_5H_5)_2Fe$ (70%) and traces of *(3)*. Reaction of *(1)* with $FeCl_2$ in boiling tetrahydrofuran (THF) affords besides *(3)* and *(4)* (19%) the hydride complex $[(C_5H_5)Fe(H)(C_2B_2S)]$, which contains a Fe—H—B 3z/2e bond [$\delta^{11}B(CS_2) = 0.3$ (br. s, 1), 34.7 (s, 1)]. This compound is also obtained on reaction of *(1)* with HCl-gas; the isomeric hydride complex $[(C_5H_5)(C_2B_2S)Fe—H]$ [$\delta^{11}B(CS_2) = 25.3$ (s, 1), 38.7 (s, 1); $\delta^1H(CS_2) = -7.4$ (Fe—H)] is formed initially and is then converted thermally into the compound with the Fe—H—B bridge[4].

The constitution of *(4)* follows from the spectroscopic data [$\delta^1H(CS_2) = 3.52$ (s, 10), 3.1 (m, 4), 1.9 (m, 4), 1.79 (s, 12), 1.22 (t, 12); $\delta^{11}B(CS_2) = 19.2$; MS: $m/e = 630$ (M^+, 100%) (70 eV)]. The ^{11}B signal indicates four equivalent boron atoms as well as bifacial coordination of the thiadiborolene ligands. The B—CH_3 signal is consistent with a *trans* arrangement of the μ-ligands, which, as for the trinuclear complexes $[(CO)_3Mn(C_2B_2S)]_2Fe$[5] and $[(C_2B_2S)Co(C_2B_2S)]_2Fe$[1], is confirmed by the crystal structure analysis[6] (Fig. 1).

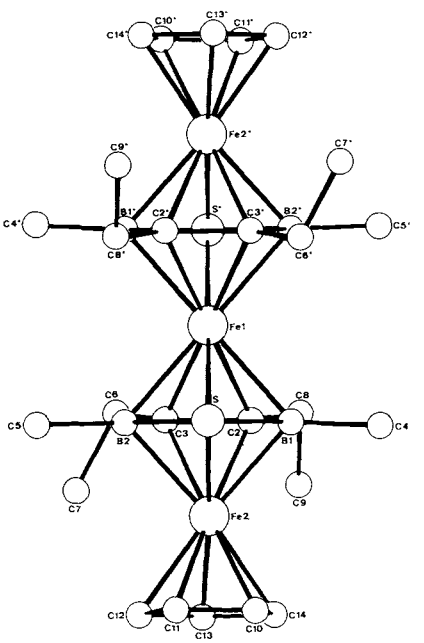

Fig. 1. Molecular structure of the complex *(4)* in the crystal.

The distances between the ring atoms in the μ-ligands are C—C = 1.461(3), B—C = 1.564(3), 1.556(3) and B—S = 1.909(2), 1.913(2) Å, and in the η-ligands C—C = 1.405(4)—1.417(4) Å. Fe1 occupies an inversion center, the Fe1—Fe2 distance (3.272(1) Å) is only slightly longer than in *(3)* (3.236(1) Å).

The distances between the metal atoms and the best planes of the ligands (D) [Fe—D(C_5H_5) = 1.67, Fe—D(C_2B_2S) = 1.63, and Fe1—D(C_2B_2S) = 1.64 Å] are similar. In contrast, strongly deviating distances (1.69, 1.60, and 1.93 Å) were found in the tetradecker sandwich complex

[**] Tetradecker Complexes, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 2: [1].

$[(C_2B_2S)Co(C_2B_2S)]_2Fe$ *(6)*[1]. The different influence of the d^7 fragments $(C_5H_5)Fe$ and $(C_2B_2S)Co$ on the $(C_2B_2S)Fe(C_2B_2S)$ unit is manifested in the expansion of the central sandwich from 3.28 in *(4)* to 3.86 Å in *(6)*; the expansion reflects the enhanced acceptor character of the terminal thiadiborolene ligands. Consequently, there are no drastic changes in the ligand/metal bonding relationships on incorporation of the 12-valence-electron "stack" $[(C_2B_2S)Fe]$ into the tripledecker *(3)* to give the tetradecker *(4)*. Therefore $(C_5H_5)Fe[(C_2B_2S)Fe]_n(C_5H_5)$ complexes with $n>2$ should also be stable.

(4), with a $(4\times\pi^6+3\times d^6)$ arrangement, is the parent member of the series of tetradecker sandwich complexes (42 to 48 valence electrons). The cobalt compound *(5)* with a total of 43 valence electrons is accordingly paramagnetic and has an 8-line ESR spectrum ($\langle g\rangle=2.087$, $\bar{a}(^{59}Co)=45$, 2 G).

Procedure

(1): A mixture of $[(C_5H_5)Fe(COD)]_2Zn$[3] (1.9 g, 3.63 mmol) and 3,4-diethyl-2,5-dimethyl-1,2,5-thiadiborolene (1.9 g, 11.4 mmol) in *n*-hexane (25 ml) is heated under reflux for 1 h. After filtration through a frit the solution is concentrated by evaporation to 10 ml and cooled to −78 °C. The red crystals which are formed are washed with ether and dried in a high vacuum. Yield 1.35 g *(1)* (58%); m.p. 182—184 °C; $\delta^{11}B(CS_2)=14.6$; MS: $m/e=639$ (M^+, 15%).

(4): A solution of *(1)* (0.95 g, 1.49 mmol) in THF (25 ml) is allowed to react with mirror potassium (0.22 g, 5.64 mmol) for 64 h. Excess potassium is separated off and the solution treated with 0.4 g (1.49 mmol) $FeCl_2\cdot 2THF$. After 16 hours' stirring and removal of THF, the residue is taken up in toluene (20 ml), filtered, evaporated down to 5 ml, and allowed to stand for 16 h at −78 °C. Yield 0.5 g (53%) *(4)* as black needles, m.p. 209—211 °C (dec.). *(5)* is obtained analogously (0.4 g, 42%): m.p. 218 °C (dec.).

BOOK REVIEWS

Integriertes Organisches Praktikum. By *S. Hünig, G. Märkl,* and *J. Sauer*. Verlag Chemie, Weinheim 1979, xlvii, 739 pages, bound, DM 112.00.

It is comforting to know that students taking organic chemistry will bear the imprint of the practical hand book that they use, and that in comparison with this any reforms bandied about at official levels are only of marginal importance. After generations of students trained on "Gattermann", the "Organikum" appeared in the mid-sixties and its design still determines the character of a practical organic handbook. However, it would be a miracle if after almost two decades new demands were not made for a "modern" book, and above all for the application of the now routine spectroscopic methods. This is where the "Integriertes Organisches Praktikum" comes in.

"Integrated" should mean the equal and simultaneous treatment of synthesis, isolation in pure form, and structure determination. This statement of the aims defines a new type of practical handbook that of necessity cannot replace the textbook. Thus, at the beginning of each chapter there is a short general introduction, and at the end a block with an index of working methods used. Each experiment is divided into sections as follows: theoretical preparations (with information on the subjects to be studied), performance of the reaction, isolation, and purification, realization of the experiment, evaluation of the results, and conclusions. With the aid of a formal summary that he must complete and augment, the student learns to view the experimental results within a broader context. Interspersed exercises, problems, and questions should stimulate further thought on the subject.

The external appearance of the book is characterized by many illustrations of the IR and NMR spectra of educts and products and by apparatus symbols, which do more to illustrate every working step than a lengthy description. Sources of danger are particularly indicated and hints on first aid are appended (many an unnecessary repetition could be easily avoided by the consistent use of "pointing hands").

The present book can switch the points. It has succeeded in its aim, is well thought out, is complete in itself, and is impressive in the sheer elegance of its didactic construction. The authors' years of experience and their love of detail are palpable on every page. Its scope corresponds to a single-semester course, and the book thus fits well into the study plans currently under discussion. Provided that adequate assistance is available—which is particularly important with this more school-oriented practical handbook—the student will know in his bones "what organic chemistry is" after this relatively short period. He learns very early to proceed in the manner that will be demanded of him later in his undergraduate and postgraduate studies. The intellectual requirement is greater and the attractiveness—the book is not like a collection of cooking recipes—correspondingly higher. However, it is necessary not to waste the advantages of the earlier practical groundwork (syntheses performed in accordance with the universally held "Organikum" precepts) by anchoring them more firmly in a subsequent advanced practical course.

The present book offers a chance and deserves a positive response. The spirit of an "Integrated Organic Practical Handbook" will prevail sooner or later, and the practical instructors are called upon to test to what extent the new concept is becoming established in their field.

One obstacle should not be underestimated: the call is to seek out *new* paths. Can this hurdle be overcome? Let us hope so.

Günther Maier [NB 518 IE]

Pharmaceutical Chemistry Today—Changes, Problems, and Opportunities

By Horst König[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Dissatisfaction with empirical methods, high expectations of the public, poorly harmonized international regulations, and rising costs have induced pharmaceutical research to search for new approaches. As a consequence, the medicinal chemist's professional activity is in a state of change. His synthetic strategy is being increasingly influenced by the reasoning of molecular biology. Novel classes of biologically active compounds demand the development of new synthetic methods beyond the scope of modern preparative organic chemistry: enzymes and microorganisms, cell cultures, and genetic engineering are harnessed to supply highly complex structures. Major efforts are devoted to the development of reliable structure-activity relationships to rationalize his work. Thus the field of medicinal chemistry stretches from physical and physical organic chemistry far into the realm of biosciences, and the interdisciplinary character of this research is rapidly increasing. The author endeavors to convey an impression of this complex subject with the aid of selected examples.

1. Introduction: Is Pharmaceutical Research Still Worthwhile?

This question is frequently posed in a dual sense. On the one hand, it is often assumed that a sufficient number of drugs is already available and that new ones are not needed. On the other hand, cost analyses indicate that the development of a new drug has become extremely expensive. Only few products have the potential to recover the necessary investment of 50—150 million $ in a short period and thus to contribute quickly to the financing of new research projects[1].

However, this questioning of the usefulness of pharmaceutical research must be answered from both aspects in a clearly affirmative sense. Firstly, satisfactory therapy is available only for about a third of all ailments[2]. Widespread and dangerous diseases (cancer, virus infections, circulatory disorders, just to mention a few) will require great efforts to develop hopeful beginnings into reliable cures.

Secondly, products that initiate a therapeutic breakthrough are generally rewarded by economic success[*]. And finally, where else can chemistry solve important problems with such small consumption of costly energy and scarce raw materials.

[*] Prof. Dr. Horst König
Pharma-Sparte, BASF Aktiengesellschaft
D-6700 Ludwigshafen (Germany)

[*] New products for rare diseases are developed as a social and ethical obligation. Their costs must be carried by other drugs.

2. The Status Quo

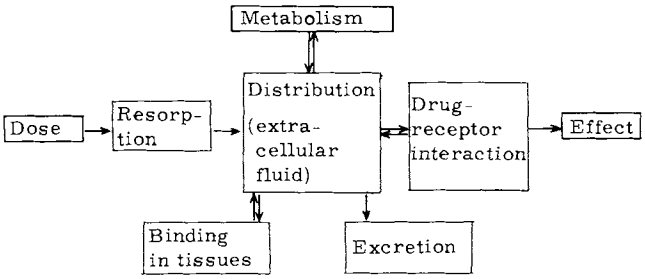
The discovery of penicillin and the subsequent dramatic success of other antibiotics in the fifties heralded in an era of great optimism. Novel, highly active drugs were developed in rapid succession and the solution to most therapeutic problems appeared to be just around the corner. However, sudden disillusionment followed in the sixties. The widespread use of drugs logically had led to the more frequent observation of side effects. The miracle weapon of antibiotics was in danger of being blunted by the development of microbial resistance. Strict governmental regulations were called for by the public. As the detrimental consequences of introducing a new drug with unexpected severe side effects are much more obvious than the consequences of unduly blocking use of an effective drug for therapy, the requirements for testing and registration became enormous. For example, the documentation for a single new product in 1973 filled 45 volumes (1.5 tons of paper!) describing expensive biological experiments[3]. These quite often could only prove the exactness of the regulatory agency and the assiduity of the developing company but produced no new criteria.

Simultaneously, one was no longer satisfied with therapeutic success alone, but sought to clarify the biological action of drugs on a causal basis. Biological model conceptions have gained great importance for the medicinal chemist and guide his synthetic work wherever possible. "Rational drug design" circumscribes this effort to utilize our still scarce, but fortunately growing knowledge of molecular biology for the development of new drugs. Medicinal scientists try to orient their work on the molecular mechanisms of physiological and pathophysiological processes. Huge scientific gaps in many areas of medicine and biology still tend to frustrate this effort. Thus pharmaceutical research is passing through a difficult period where former guidelines prove unsatisfactory and new ones have to be established with the expenditure of great effort.

A promising new alley was opened by the discovery of novel classes of biological mediators. This research provides the medicinal chemist with new model substances. However, it has also demonstrated the complexity of biological signal systems and thus the difficulty of controlled therapeutic interference. Prostaglandins, for instance, or the hypothalamic peptides are frequently produced in minimal concentrations and in small defined areas[*] to elicit a specific physiological response. The same substance may trigger totally different responses in different tissues. Obviously, systemic therapy with such a substance must encounter problems of specificity.

3. Scope and Objectives of Current Pharmaceutical Research

From a chemical point of view the human organism is a highly complex arrangement of many, often specialized, molecules which cooperate in vital functions under the guidance of a well balanced system of electrophysiological and chemical signals. Disruption of the molecular network or a disturbance in the transmission of signals are experienced as an ailment. Thus pharmaceutical research looks for substances which can compensate for the disorder or, ideally, provide a causal cure. This latter, optimal treatment, however, is still rare in practice. Chemotherapy of infectious diseases is one of the most successful examples, because the extermination of the infective agent usually eliminates the disorder and reestablishes normal functions.



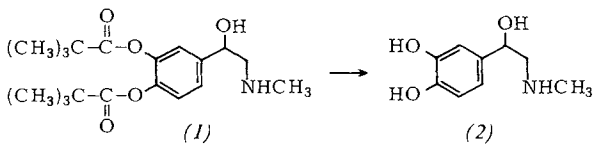


Fig. 1. Active substances and the human organism interact in many ways, the sum of all effects determines the practical value of a drug.

Figure 1 illustrates the various requirements of a drug: The desired therapeutic effect is usually accomplished by a specific binding of the active ingredient to defined structures of the target cell. These receptors are usually proteins or glycoproteins (in membranes or enzymes) and feed the cell information on its surroundings to regulate its activity. The molecules of the drug should enhance signals that have become too weak (agonist) or reduce excessive signals (antagonist). This modulation can only be precisely calibrated if a well defined number of drug molecules reach the target cells. This requirement poses a problem. Only in rare cases will it be possible to administer the drug directly to the inflicted area, as in the case of superficial wounds or infections. Usually the diseased organ or tissue is situated inside the body and systemic application of the drug is necessary to reach it *via* the blood stream. This is also true in the therapy of generalized infections where a sufficient concentration of therapeutic agent must be established in the majority of body cells. Resourceful formulation can help to ensure a sufficient resorption of the drug. For instance, an acid resistant coating may shield a drug that would be destroyed by gastric juices and allow its absorption in alkaline regions of the intestines. Slow-release formulations are designed to guarantee a steady supply of the agent over a prolonged period of time. Release from the formulation is defined as "pharmaceutical availability". After resorption into the blood-stream—for instance by passage through mucous membranes or directly by injection into veins—the drug's active ingredient will be distributed in the extracellular fluid. Binding in various tissues is to some extent determined by the lipophilicity of the substance and can establish depots (desired or otherwise).

Most substances can be chemically modified by the body's enzymes. If the products of these transformations are biologically inactive, this process mainly influences the lifetime of the drug. The same is true if the metabolite has the same type

[*] Detection and quantitative determination of unstable substances in picogram or nanogram quantities could only be accomplished by special analytical methods: immunoassays plus electrophoresis, isotope labeling, sensitive techniques of mass spectroscopy, *etc.*

of activity as the parent drug. If, however, metabolites with undesirable effects are formed, the usefulness of a drug is often destroyed. Finally, parent compound and degradation products must leave the body in a reasonable period of time. Quite often the first passage of a drug substance transported in the bloodstream through liver or lung will result in a decisive metabolic transformation (first pass effect). The chemist can save some drugs from this fate by masking sensitive functional groups, for example by ester or amide formation in the case of a carboxylic acid. The product, a prodrug, ideally should have no significant activity of its own but should release the active substance for instance by enzymatic hydrolysis after passage through the "threatening" organs. Prodrugs can also profit from their specific physicochemical properties (like greater lipophilicity than the parent compound) and thus ensure a different distribution. Furthermore, their toxicity may be reduced. For example, cytotoxic substances have been modified in such a way that they have little effect on normal cells but are reactivated by the different and faster metabolism in tumor cells.

(1) (2)

Fig. 2. Appropriate chemical "masking" of drugs yields prodrugs, which are reactivated by metabolic unmasking. For example, the dipivalate of epinephrine *(1)* is more active and has less side effects than epinephrine *(2)* itself in the topical treatment of glaucoma.

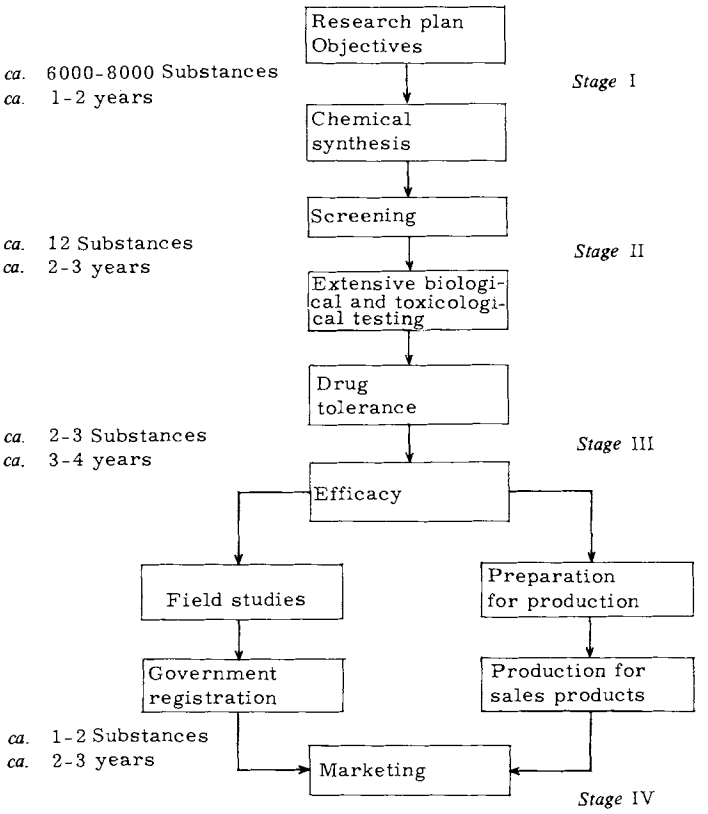
One important property of a drug is its bioavailability, *i. e.* the amount of active substance present after resorption. It is much more convenient for the patient to take a pill or receive an injection only once a day rather than at short time intervals. On the other hand, there must be a way of interrupting the treatment at short notice if advisable. Halflife times of 4—12 h are usually a reasonable compromise. Most important, a reliable and therapeutically efficient concentration of the drug at the target organ must be guaranteed between applications.

It is obvious that *in-vitro* test models, such as cell cultures, can provide only limited information with regard to resorption, distribution, metabolism, and excretion. *In-vivo* models are necessary to obtain these pharmacokinetic data and most pharmacodynamic parameters which describe the action of the drug on the organism. This is especially true for ailments with a systemic character, like hypertension.

4. Stages of Drug Development

The development of a new drug requires interdisciplinary cooperation of principally chemists, biologists, physicians, and pharmacists.

A simplified scheme of drug development is presented in Figure 3. The first stage is the synthesis of new substances with a promise of useful effects, or their isolation from natural materials, according to a research strategy. In a screening procedure those candidates are selected which possess the desired biological activity. The test models are designed to



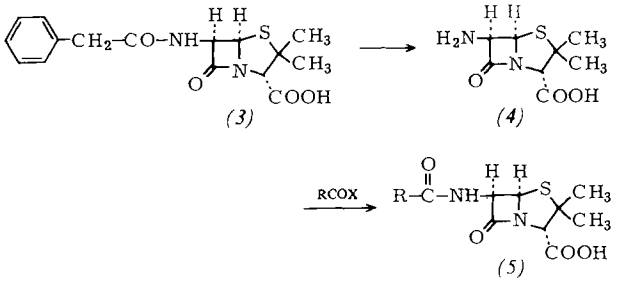


Fig. 3. Many professional disciplines cooperate in the development of a new drug which requires about 10 years of intensive work. Very few of the many substances tested are found sufficiently effective and safe for therapy. Stage IV comprises continued monitoring of therapeutic success and side effects.

simulate diseases and therapeutic processes as well as possible.

Subsequent thorough studies in pharmacology, biochemistry, and toxicology determine the risk/benefit ratio of the potential new drug. A substance may not be applied in human medicine without convincing evidence that the therapeutic benefit promises to outweigh any undesired side effect. A variety of toxicological studies are therefore carried out over prolonged periods of time and decide the fate of a test substance. Nevertheless, great care is exercised when a substance is finally studied in man, as no other species is completely comparable. A small dose is first checked with regard to tolerance in healthy volunteers. If no undesirable effects can be observed, the dose is slowly increased into the expected therapeutically effective range. Then the efficacy is tested in patients in comparison with established drugs or placebos (if warranted). Finally, field studies have to prove the reliability of the new drug in a great number of patients. These studies are also designed to reveal rare side effects which are encountered only in particularly predisposed individuals. Of course, the severity of the disease under study will influence the evaluation. A passing nausea may be tolerated for a lifesaving antibiotic while it could lead to rejection in the case of a sleep inducer. This stepwise development of a drug is regulated by detailed national laws[4]. To eliminate subjective factors in clinical trials for instance, double blind studies are prescribed where neither patient nor doctor know which trial group is receiving the experimental drug and which one the established drug.

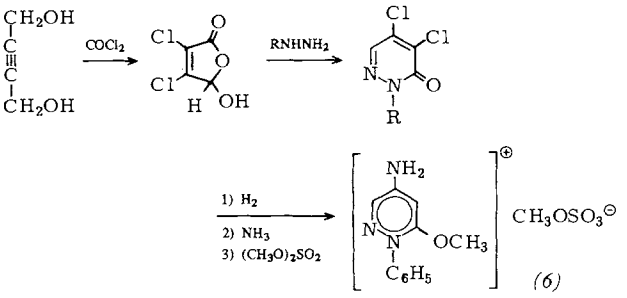
The majority of test substances is eliminated during stages II and III. At present, only one out of approximately every 10000 new compounds is introduced into therapy after a trial period of, on average, 10 years. After the initial synthesis the chemist has to provide increasing amounts of test substance in a high and defined quality for the later stages of development. Finally, a technical process must be developed that guarantees high quality at reasonable costs.

Stereochemical uniformity often plays an important role. The separation of enantiomers or chiral synthesis is therefore of great interest in medicinal chemistry. The excellent specificity of enzymes is increasingly utilized in the synthesis of drugs: Penicillin-amidase, for instance, can be employed with great success to cleave Penicillin G *(3)*. The resulting 6-aminopenicillinic acid *(4)* is then routinely used as a synthon for semisynthetic penicillins *(5)* with superior therapeutic properties.

(3) *(4)* *(5)*

For many years, fermentation of molasses with yeast has been employed to provide active acetaldehyde and catalyze its stereospecific addition to benzaldehyde in a chiral production process of ephedrine[5].

Antibiotics are produced on a large scale and in excellent yields by fungal strains that have been developed by mutation and adaptation from wild strains which are not very effective.



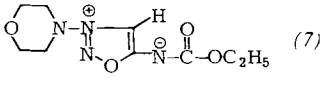
The synthesis of complicated structures like the glycoproteins of the interferon family with 166 amino acids requires the interplay of several enzymes. This can be achieved in cell cultures of fibroblasts for instance. As microorganisms in general can be fermented in simpler ways and reduplicate faster, human genes for hormones or other active substances have been spliced into bacterial genomes. Expression of these genes could be achieved by various techniques and offers a fascinating new approach for the production of very complicated chemical structures. The pharmaceutical industry therefore invests considerable research efforts in this spectacular but difficult field.

5. Synthesis in Medicinal Chemistry

At the very beginning of the development of a new drug the chemist has to select promising target structures (and a synthetic strategy to obtain them). Whenever possible he will try to utilize structure-activity considerations. In general, this means that he will start from a lead structure and try to improve its biological profile by molecular variations.

5.1. The Search for New Lead Structures

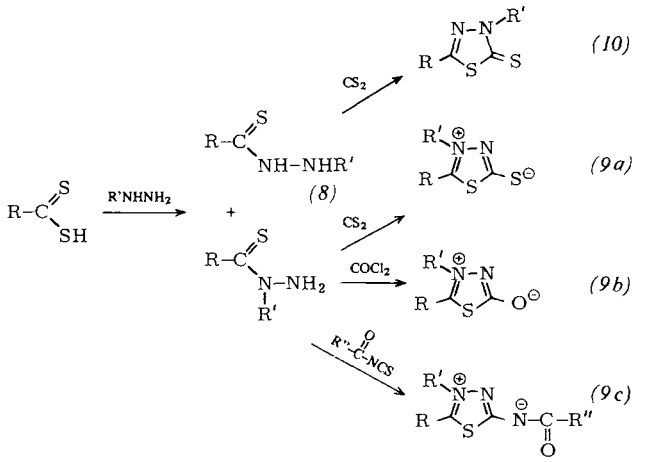
The problem consists in finding new structures that can serve as a starting point for variation. Chemical novelty can be a reasonable criterion if a well organized and broad pharmacological screening department cooperates closely with an effective and creative group of synthetic chemists. Chances are comparable with those in a lottery, with many blanks and few but substantial winners. Most substances will drop out in the screening process, but with some luck new classes of active compounds will be discovered. One example from BASF research are pyridazones. They are based on 2-butyne-1,4-diol, an important product of Reppe acetylene chemistry.



(6)

Its chlorination affords dichloromalealdehydic acid, a useful four-carbon synthon for heterocycles. Condensation with hydrazines, for instance, produces dichloropyridazones in excellent yields that can be further derivatized in many directions to provide dyestuffs or pesticides, for example. The pyridazones also appeared to be of interest in medicinal chemistry, though no structure activity relations were known to guide the molecular variation.

Thus, structural subgroups of 10—20 substances were synthesized and tested in a broad array of screening models. It soon became obvious that the 4-amino substitution established interesting biological activity. 4-Amino-6-methoxy-1-phenylpyridazinium salts in particular possess a pronounced antihypotensive effect. A thorough pharmacological analysis revealed that the stabilizing effect on blood pressure is due to a novel combination of inhibitory actions involving a specific monoaminoxidase and reuptake of norepinephrine into neuronal depots[6]. Thus the signal of the mediator norepinephrine on vascular tonus regains sufficient strength to produce a normal blood pressure. Furthermore, ameziniummetilsulfate *(6)* also displays good activity after oral application and is thus distinguished from other antihypotensive drugs. As all stages of development have been passed successfully, the product should be soon available for therapy.



Mesoionic thiadiazolium compounds *(9)* provide a second example of a chemically motivated successful search for new classes of medicinally useful substances. To date very little is known about the pharmacological properties of mesoionic heterocycles. So far apparently only a single sydnone derivative morsydomin *(7)* has been introduced into therapy[7].

(7)

Our interest concentrated on five-membered heterocycles with sulfur and two nitrogen atoms, as the key intermediates *(8)* were readily available and the published methods for cyclization promised a wide variability[8].

The only major problem to solve was a rapid and definitive structural assignment of expected isomers. High energy photoelectron spectroscopy (ESCA)[9] in combination with ^{13}C-NMR was applied wherever ^{1}H-NMR, UV, or IR were not conclusive. The pharmacological test program produced no useful effects for compounds with exocyclic nitrogen *(9c)*

R = Aryl; R' = Alkyl, Aryl; R'' = Alkyl, Aryl

or oxygen *(9b)*, nor for the thiadiazolethiones *(10)*. The thiadiazolium sulfides *(9a)*, however, showed remarkable anticonvulsive activity. By systematic variation of the aromatic and aliphatic group, the effect could be improved considerably[10]. The outstanding substances of this research project raise considerable hopes of becoming new antiepileptic drugs.

It should not be overlooked that while new structures may implicate a genuine therapeutic advantage they also require especially careful preclinical studies, as there is no experience to be used as guidelines[11]. This is true for the mode of therapeutic action as well as for possible side effects. The thorough evaluation of risk-benefit ratios often slows down such projects.

5.2. Optimization of Lead Compounds

Chances of success are better calculable if a project can be based on some known structure-activity relationship. The objective of such work is to improve the therapeutic quality of lead compounds. Is such work useless and redundant as has been claimed by critics of the pharmaceutical industry? Nobody would be foolish enough to regard *Henry Ford*'s Tin Lizzy as the ultimate solution for a motor car. It is equally unrealistic to expect optimal therapeutic results from prototypes of drugs. The desired properties can be enhanced and undesired effects must be minimized. It is a legitimate and desirable goal in its own right if nothing more can be accomplished than a reduction in dosage[12]. The organism will then have to cope with less foreign material and the danger of serious side effects arising from rare individual metabolic anomalies will be diminished.

5.2.1. Natural Products as Lead Substances

Natural products are the most important source of lead substances (see Table 1). A number of alkaloids provide excellent examples for the successful entry of folk medicine into modern therapy.

The search for new lead substances from microorganisms has been extremely useful. The scientific era of antibiotics began with penicillin research and still produces new and highly effective drugs for the treatment of infectious diseases and also of cancer. The impressive role of antibiotics could not be stopped by the "instant success" experience that had caused physicians and patients to use antibiotics much too often and carelessly. The shocking observation of increasing resistance has caused a much more sophisticated and effective therapeutic use of antibiotics.

Research into mammalian natural products has provided a better understanding of normal and pathophysiological processes and their regulation. The important role of steroids as sexual hormones or regulators in inflammatory processes or of blood pressure has caused the development of many drugs as well as contraconceptives ("the pill"). Prostaglandins and peptide hormones may become equally useful in medicinal chemistry, as will be discussed a little later.

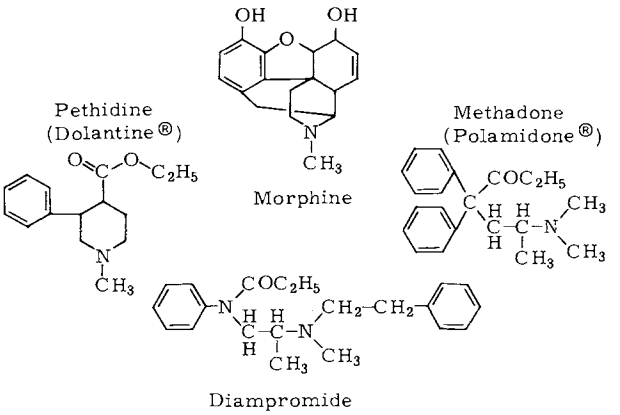
Table 1. Some examples of drugs derived from natural products.

Plants		*Animals*	
Quinine	Malaria	Steroids	Inflammation
Reserpine	Hypertension		Conception
Codeine	Cough	Peptide	Growth
Digitalis	Cardiac insufficiency	hormones	Diabetes
Microorganisms		*Marine organisms*	
Penicillin, Streptomycin, Adriamycin	Infectious diseases, Cancer	Algae, Fishes, Jellyfish	?
		Corals	Prostaglandins

At present a thorough search is going on for new lead substances from marine organisms. The underlying logic is that marine biotopes, with a high halogen ion concentration and—in deeper regions—high pressures may cause the formation of unusual structures. So far, the search has produced mostly halogenated derivatives of well-known structural classes and an impressive therapeutic product is still missing[13]. Some toxins (tetrodotoxin) from certain species of fish or from dinoflagellates (saxitoxin), however, are useful in pharmacological models as they selectively block the transport of Na^+ in nerve membranes. A peptide (53 amino acids) from a sea anemone, anthopleurine-A, influences the contractile force of cardiac muscle and has thus aroused scientific interest[14].

Usually, a natural product of pharmacological interest will first be isolated and characterized. If possible, a total synthesis will then be developed to ensure independence from natural sources, as they can vary widely in quantity and quality. This synthetic process is often designed to allow variations of the parent structure as the activity of natural products is often either too low or too unspecific to be useful as drugs. One typical example is provided by morphine alkaloids. Their analgesic activity is accompanied by side effects on respiration, the intestines, and most of all by their great addiction potential.

Many variations and simplifications of the morphine structure have proved that the analgesic power is obviously linked to a structural element that consists of a phenyl ring, a



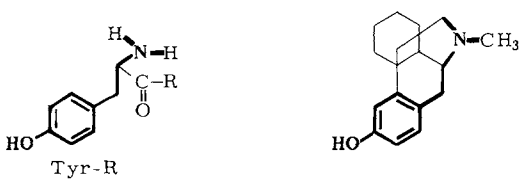


Fig. 4. Variations of the morphine structure retain the analgesic properties of the parent compound only if the structural element consisting of phenyl-$C_{quart.}$—C—C—NR_2 is not lost. At most the quarternary C-atom can be replaced by a tertiary nitrogen as in diampromide.

quaternary carbon atom (or tertiary nitrogen), a two-carbon chain, and a tertiary amine in that order with stereospecificity[15]. These structural requirements suggested receptors[16] but no natural mediators had been detected until very recently.

5.2.2. New Biological Mediators Serving as Lead Structures, Peptides

In 1975, however, a direct search for the natural mediators of the opiate receptors ended in a surprise[17]. Small peptides, a class of compounds very different from morphine alkaloids, turned out to function as the body's own analgesics. However, a N-terminal tyrosine molecule was found in these two pentapeptides, methionine-enkephalin *(11a)* and leucine-enkephalin *(11b)*[11]. It apparently plays an important role in opiate receptor affinity and Figure 5 shows clearly that the important substructure of morphine analogues mentioned above can be superimposed on this tyrosine and is obviously essential for binding to opiate receptors.

(11a), R = Gly-Gly-Phe-Met
(11b), R = Gly-Gly-Phe-Leu

(12)

Fig. 5. Comparison of enkephalins *(11)* with the morphine derivative levorphanol *(12)* clearly shows common structural features.

In the past decade or so, a number of other peptides have been discovered that consist of only a few amino acids and still are able to direct important and divergent bioprocesses. A picture of common features is emerging from this research. A number of different active peptides can apparently be derived from a single precursor peptide. Enzymes appear to cleave its chain at specific sites if a certain substructure is called for by regulatory mechanisms. It is not surprising that similar partial amino acid sequences are found in different peptide mediators[18].

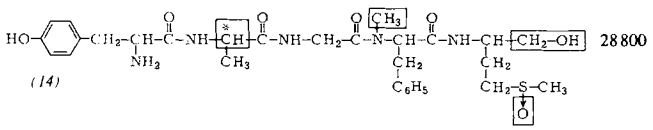
Table 2. β-Lipotropine consists of a chain of 91 amino acids and contains the sequence of a number of peptide mediators. The terminal amino acids are indicated by their number in the β-lipotropine sequence and the usual symbols.

Peptide	Amino acid sequence
β-Lipotropine	1 37 47 58 61 65 76 77 79 91 NH_2-Glu-Ala-Met-Asp-Tyr···Met—Thr-Leu-Lys—Glu-OH
Methionine-enkephalin	61-65
α-Endorphine	61-76
γ-Endorphine	61-77
δ-Endorphine	61-79
β-Endorphine	61-91
β-MSH [a]	37-58
ACTH (4—10) [b]	47-53

[a] Melanocyte stimulating hormone (melanotropine). [b] Partial sequence (Met-Glu-His-Phe-Arg-Trp-Gly) of adrenocorticotropic hormone. Recent work suggests an ever bigger peptide (Big ACTH) as a common precursor of ACTH and β-lipotropine [19].

The same principle can be recognized in other examples: the antagonist of MSH, the inhibiting factor MIF, consists of a sequence of three amino acids that is part of the oxytocin structure *(13)* and is set free by enzymatic cleavage[20]. While oxytocin acts on the uterus and the mammary glands, MIF influences pigment formation and, interestingly, the low dopamine levels encountered in Parkinson's disease.

(13) Cys-Tyr-Ile-Glu-Asn-Cys-Pro-Leu-GlyNH$_2$
MIF



Some properties of these natural products are obviously a disadvantage for practical therapy: the biological signal is often regulated by short term variations of local concentrations of the mediator. The halflife of regulatory substances is therefore, in general, short. Furthermore, they are usually not stable towards digestive enzymes and thus cannot be administered orally. Finally, identical chemical substances are utilized as mediators in different organs or tissues and are there often involved in very different physiological processes[21]. The specificity of signals is then guaranteed by a localized biosynthesis of the mediator. This repeated occurrence may reflect evolutionary processes.

For the synthetic chemist it means a chance and a challenge. By alteration of the natural structure he can inhibit degradation by enzymes and obtain products with useful lifetimes for therapy. At the same time, structural variations may promote a more selective tissue distribution or better specificity in receptor binding. The same family of receptors apparently can have subgroups with small specific variations in structure. For the opiate receptor, for instance, a subgroup of μ-receptors has been found in the central nervous system

that has a higher affinity for morphine derivatives than the δ-receptor in the gut which shows a preference for the enkephalins. More subgroups are emerging from current research. A longer lifetime and better receptor binding can also mean better efficacy[*].

Again the enkephalins provide a good example of successful synthetic chemistry. The natural peptides *(11)* exhibit all effects that can be expected for a mediator of the opiate receptor: They are analgesics, act as antagonists to morphine narcotics; like the latter, they influence behavior and may therefore cause addiction. It was interesting to learn that enkephalin levels apparently rise under the influence of acupuncture. This old Chinese technique of eliminating pain sensations may thus have found a modern explanation. The pentapeptide Met-enkephalin has been systematically derivatized by exchanging three of the amino acids that are not essential for receptor binding for new structural elements[22] (Table 3).

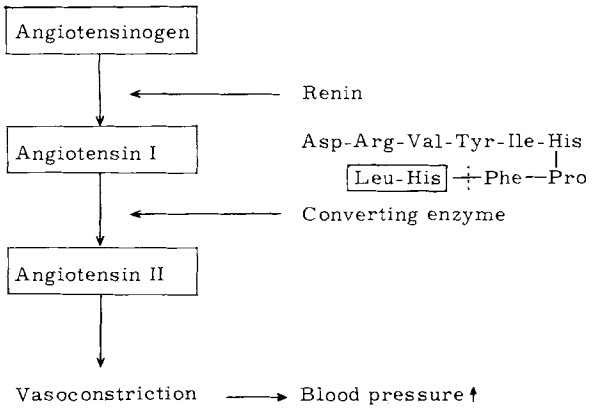
Table 3. Chemical variation of the enkephalin structure accomplishes stabilization towards enzymatic degradation and enhances analgesic activity.

Structure	Analgesic activity [a]
Morphine → Tyr—Gly—Gly—Phe—Met	33
Tyr—[D-Ala]—Gly—Phe—Met	1
Tyr—[D-Ala]—Gly—Phe—Met-[ol]	100
Tyr—[D-Ala]—Gly—Phe—Met-[(o)]-[ol]	1600
Tyr—[D-Ala]—Gly—[MePhe]—Met-[(o)]-[ol]	9600
(14) 	28800

[a] In this model the substance is directly applied to certain regions of the brain.

Replacement of glycine by D-alanine resulted in a 100-fold increase of activity. Reduction of the *C*-terminal methionine to the primary alcohol and oxidation of its thioether to the sulfoxide gained another two powers of ten. Finally, a peptide bond was modified by *N*-methylation of phenylalanine. All variations together increased the analgesic power of *(14)* by 10^4. In connection with the recent progress of peptide synthesis similar results may be expected for other peptide mediators.

At present, the role of peptides in the regulation of blood pressure commands great interest[23]. For example, angiotensinogen, a globulin protein, is cleaved by the enzyme renin to give a decapeptide angiotensin I. This, in turn, is the precursor of angiotensin II, an octapeptide that acts as a vasoconstrictor and thus elevates blood pressure (Fig. 6)[24]. The converting enzyme, which splits off the C-terminal dipeptide histidylleucine from angiotensin I, can be blocked by the pentapeptide Pyr-Lys-Trp-Ala-Pro from snake venom as was shown by a research group at Squibb[25]. This results in an antihypertensive effect.



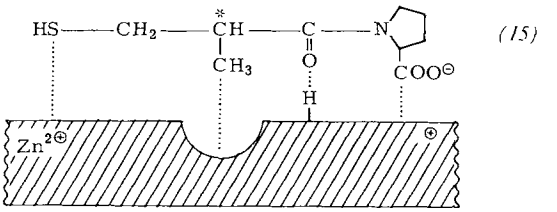


Fig. 6. The renin-angiotensin system of blood pressure regulation presents various possibilities of therapeutic interference. Antagonists of the angiotensins and enzyme inhibitors exhibit clinically useful properties.

Synthetic variations of the angiotensin structure also led to peptides that block the converting enzyme and thus lower blood pressure. Systematic slimming down of the lead structure ultimately afforded *N*-(3-mercapto-2-methylpropionyl)-L-proline *(15)* (SQ 14225, see Fig. 7) that obviously still fits excellently to the angiotensin converting enzyme[26]. *(15)* is active in man, even on oral administration. As Captopril® it has undergone extensive clinical testing and promises to become an antihypertensive of therapeutic value[27].

(15)

Fig. 7. Model concepts of receptor-substrate interactions served as guidelines in the development of simple molecules like *(15)* (SQ 14225) as inhibitors of angiotensin converting enzyme.

Very recently, evidence has been gathered in pharmacological and medical studies that these angiotensin-converting enzyme inhibitors may exert their hypotensive effect mainly by increasing levels of bradykinin[28], another peptide mediator. Certain prostaglandins[29] also appear to be involved in the effects of Captopril® on blood pressure. It is possible that once again a scientific hypothesis has led to progress by opening new research paths without being completely correct.

An important chapter of peptide research began with studies on release factors. They are formed in the hypothalamic region of the brain and reach the pituitary *via* specific channels. There they trigger or inhibit the release of pituitary hormones.

The signal cascade then includes the hormones from peripheral glands and these finally modulate physiological processes. The hypothalamic peptides are of great practical interest by virtue of their comparatively simple structures.

[*] The concept of receptor differentiation has been extremely successful in recent years. Drugs have been developed that influence various α- and β-receptors for epinephrine and norepinephrine (*e.g.* β-receptor blockers for cardiovascular therapy). A search for substances that selectively block the H_2-receptor of histamine has overcome early setbacks and resulted in a very successful drug (Tagamet®, SKF).

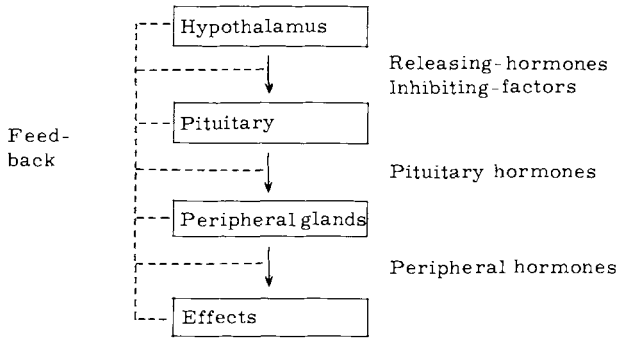

Fig. 8. Hypothalamic peptides, hormones from the pituitary and hormones of peripheral glands form a signal cascade with feedback mechanisms.

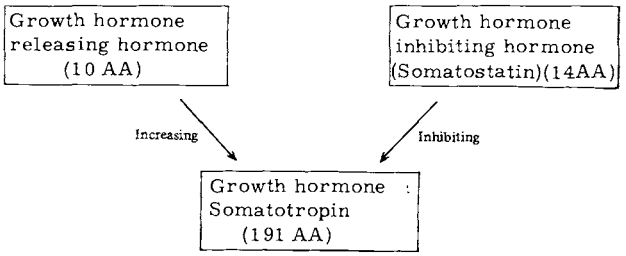
Thus human growth hormone (191 amino acids)[30] is released under the influence of a decapeptide[31]. The complementary inhibiting factor is somatostatin *(6)*[32], a sequence of 14 amino acids. Growth hormone itself is available either



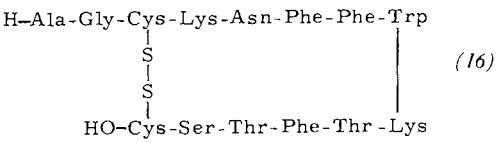


Fig. 9. The formation of pituitary hormones is modulated by release and inhibiting factors that consist of rather short peptide sequences, as shown for growth hormone (AA = amino acids).

by a multistep and difficult total synthesis[33] or *via* gene-manipulation by a biotechnical route[34]. Obviously, both its hypothalamic modulators present an economic and therapeutic alternative.

(16)

The state of the art in peptide chemistry and biology is illustrated well by somatostatin *(16)*. This cyclic disulfide *(16)* has been discovered in such divergent organs as brain and pancreas. As mentioned above, it inhibits the release of growth hormone. In addition, however, it also inhibits the secretion of insulin and its counterpart glucagon and is probably of great importance for the metabolism of glucose[35] and in diabetic disorders. Furthermore, somatostatin inhibits the secretion of gastric juices. Experience shows that such a variety of biological activities is a limiting factor for therapeutic application of a natural product[36]. Indeed, side effects were observed in most trials.

Somatostatin *(16)* was the first reported example of a human hormone that was produced by a microorganism and thus heralded a new era of gene technology. For the first time, a synthetic human gene had successfully been implanted into the genome of *E. coli* bacteria and expressed by a suitable operator[37]. Although somatostatin is also available by total synthesis[38], synthetic variations may be more important if they prove to be orally active and more specific than the parent compound[39].

Table 4. Peptides of quite different size and structure act as hormones or mediators in many organs of the human body.

Peptide		Number of amino acids
Hypothalamic releasing factors (release hormones)		
for luteinizing hormone	LRH	10
for follicle stimulating hormone	FRH	10
for thyreotropin	TRH	3
for growth hormone	GRH	10
Pancreatic hormones		
	insulin	51
	glucaton	29
	(somatostatin)	(14)
Pituitary hormones		
adrenocorticotropic hormone	ACTH	39
melanocyte stimulating hormone	MSH	13
	oxytocin	9
	vasopressin	9
Endorphins		>5
Enkephalins		5
Tissue hormones		
	bradykinin	9
	angiotensin II	8
	gastrin	17
	secretin	27
"Immune hormones"		
	factor thymique	
	serique	9
	thymosin α_1	28
	thymopoietin II	49
	fragment (32—36)	5

A selection of peptides that are currently under investigation in many laboratories is listed in Table 4. Our knowledge of tissue hormones and peptides involved in immunological processes is still very incomplete. There is sufficient evidence, however, that peptides participate in the process of expressing immune competence in B-cells and T-cells. As the entire immune system is very complicated, it may take some time before results from this type of peptide research can routinely be used in therapy. Selective stimulation of killer and helper cells would be of great importance for the treatment of cancer. Suppressor cell activation might help to control autoimmune diseases. Rheumatoid polyarthritis and some rare, but life-threatening diseases obviously involve immune defects of this kind (Fig. 10).

6. Molecular Biology in Drug Development: Prostaglandins

Extraordinarily intensive research activities were started when it became obvious that prostaglandins are formed almost ubiquitously in the human organism and participate in many physiological and pathophysiological processes. Many research teams[40] have contributed to our present knowledge about biogenesis, activity and metabolism of these short-lived substances (Table 5).

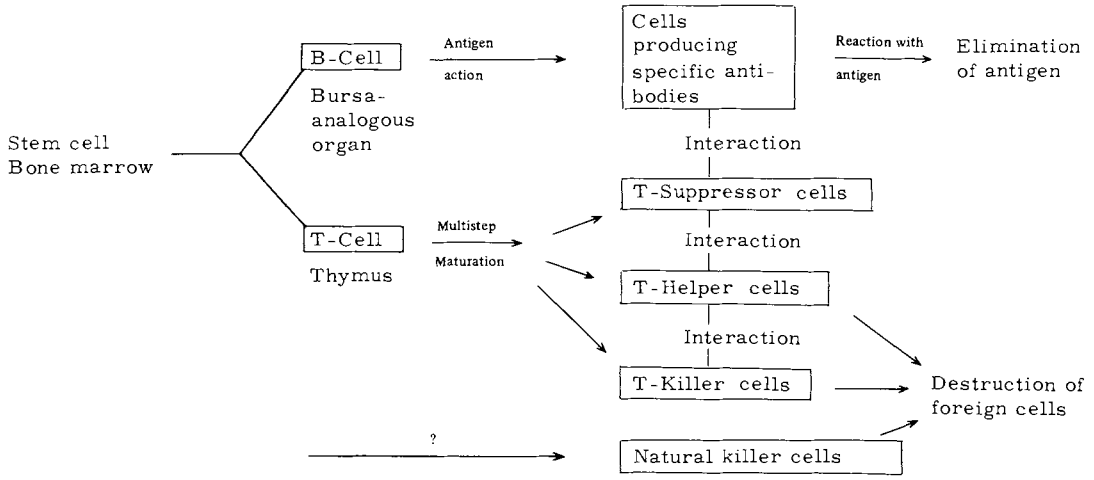

Fig. 10. Maturation of immune competent cells and their interactions are complex processes that are not yet completely understood. Here a highly simplified scheme is presented.

Table 5. Biological actions of prostaglandins.

Triggering:	Inflammation, pain
Regulating:	Neurotransmission in the vegetative peripheral nerve system, body temperature, birth, stomach secretion, bronchial resistance, function of blood platelets, microcirculation

It has been elucidated that polyunsaturated fatty acids, mainly arachidonic acid (Fig. 11), are enzymatically peroxidized to cyclic peroxides PGG_2 and PGH_2[41] that exhibit physiological activities in their own right but are rapidly transformed to give the so-called primary prostaglandins of the E, F, B, A, and D series[42].

As prostaglandins influence many important medicinal areas like blood pressure regulation, inflammatory processes, and pain a wealth of synthetic work was instigated. Brilliant syntheses made all natural prostaglandins available, despite their complex stereochemistry[43]. Structural variations were aimed at an increased specificity and at retardation of metabolic breakdown (Fig. 12). Nonetheless, the wide distribution and the diversity of physiological effects have so far proved a handicap for the therapeutic utilization of prostaglandins and their analogues.

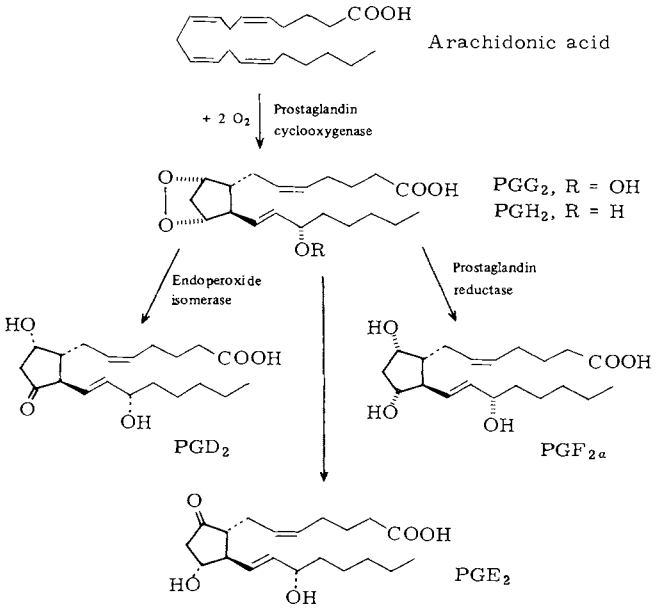

Fig. 11. Primary prostaglandins, *e.g.* PGD_2, PGE_2, $PGF_{2\alpha}$ are biogenetically formed *via* the "arachidonic acid cascade". They are not stored but are locally synthesized *de novo* and reach plasma or tissue levels in the order of ng/ml.

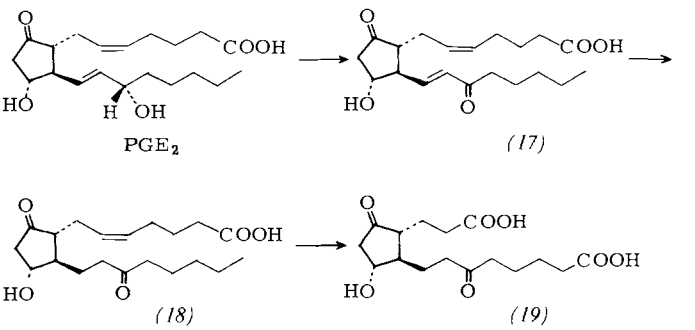

Fig. 12. In man, prostaglandins, *e.g.* PGE_2, are metabolized *via* oxidation to *(17)* by the enzyme 15-hydroxyprostaglandin-dehydrogenase and reduction of the double bond at C-13 to *(18)*. Once the keto group has been formed at C-15, all biological activity is lost. The half-lives of active prostaglandins range from seconds to a few minutes. Steric hindrance, for example by methyl groups at C-16, can retard the metabolic breakdown. β- and ω-oxidation transform *(18)* into *(19)*, the main metabolite in human urine.

In a period of initial resignation, fresh hopes were raised by the discovery of new very short-lived products of the arachidonic acid cascade. These substances are also formed from the endoperoxides and appear to play a major role in the regulation of blood pressure and function of blood platelets.

According to present knowledge, prostacyclin[44] is predominantly formed in the innermost endothelial lining of arteries and acts as a vasodilator and thus lowers blood pressure. At the same time it inhibits the adhesion of circulating platelets to the vessel wall and their aggregation. Under normal physiological conditions PGI_2 thus guarantees unhindered blood flow. On the other hand, TXA_2[45] is formed in platelets. It causes blood vessels to contract and platelets to aggregate. These functions acquire great importance if a vessel is injured. When blood flows through the lesion into the

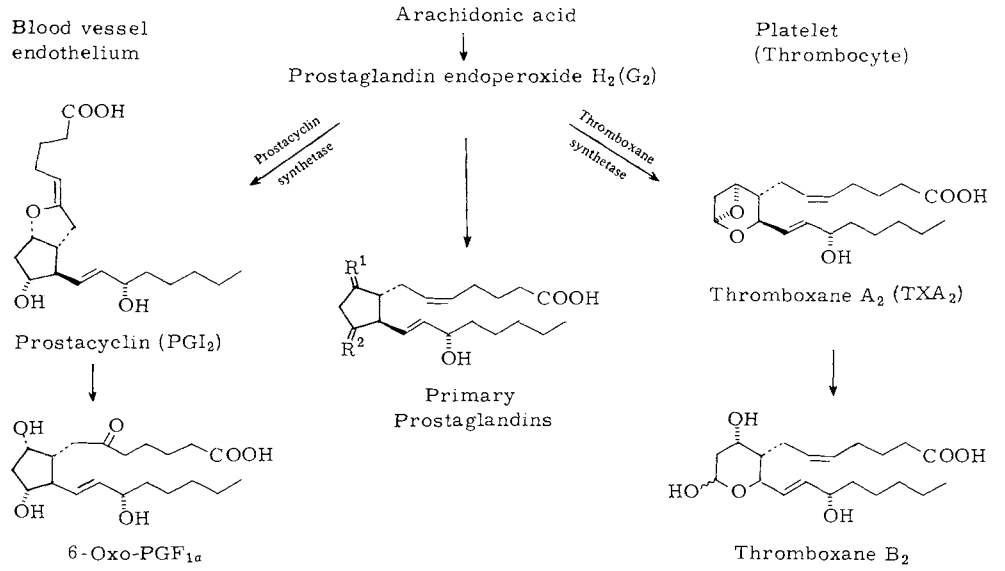

Fig. 13. In different locations—*i. e.* vessel wall and platelets—prostacyclin and thromboxane are formed from common precursors that are in turn derived from arachidonic acid. PGI_2 and TXA_2 have counteracting activities. They are rapidly degraded to inactive derivatives.

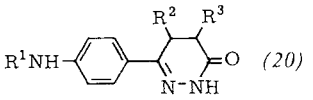

surrounding tissue, platelets contact the lower collageneous layers of the vessel. This contact triggers platelet aggregation. At the same time, local concentrations of prostacyclin have been lowered by destruction of the endothelial lining of the vessel. Thus the effects of thromboxane become predominant. The vessel contracts, platelets aggregate and thus the bleeding is stopped. Under the protective thrombus the vessel wall starts to regenerate.

In a number of cirulatory diseases the balance between prostacyclin and thromboxane A_2 is obviously disturbed. An increase in platelet aggregability has been observed in connection with arteriothrombotic disease and may be the result or even a causative factor of atheriosclerosis and infarctions[46]. Widely distributed risk factors like smoking, obesity, high blood pressure, diabetes make diseases of this type a frequent cause of premature invalidity or death. In consequence, major efforts are devoted to the search for structural analogues that act as agonists of PGI_2 or as antagonists of TXA_2[47]. Again prolongation of action is one of the important issues. This research effort has been encouraged by preliminary clinical results: Infusions of prostacyclin have caused a significant improvement of thrombotic disorders[48].

It is most interesting that substances with a very different structure possess biological activities which parallel those of prostacyclin. Substituted 6-aryl-4,5-dihydro-3(2*H*)-pyridazinones, especially derivatives bearing a *p*-aminophenyl or *p*-acylaminophenyl function *(20)*, were first investigated because of their excellent antihypertensive effects (Table 6).

This antihypertensive effect could be significantly increased by systematic variation of the basic structure and simultaneous biological testing. At the same time, an excellent inhibitory action on platelet aggregation was produced. Acetylsalicylic acid which is therapeutically used as inhibitor of prostaglandin endoperoxide synthetase, has been surpassed by more than four powers of ten.

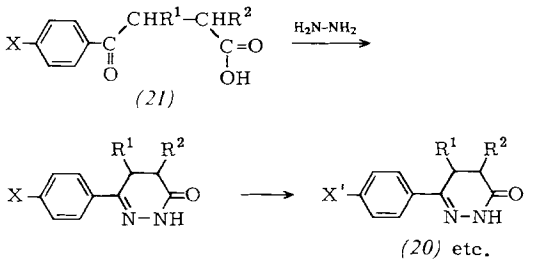

Table 6. Dihydropyridazinones *(20)* exert a pronounced inhibitory effect on platelet aggregation and lower the blood pressure by peripheral vasodilation. EC 50% = efficient concentration, which produces 50% of the measurable effect. ED 20% = efficient dose which produces 20% of the measurable effect.

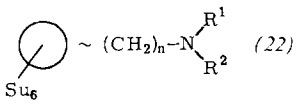
(20)

Compound			Inhibition of platelet aggregation [a]			Antihypertensive action [b]	
			Collagen		ADP		
R^1	R^2	R^3	EC 50% [mg/ml]	RE	EC 50% [mg/ml]	ED 20% [mg/kg]	RE
H	H	H	14.75	33	46.44	0.180	1.89
CH_3CO	H	H	1.09	453	1.00	0.197	1.73
C_2H_5CO	H	H	0.74	667	0.64	0.060	5.67
CH_3CO	H	CH_3	6.31	11	46.40	15	0.02
$CH_3CHClCO$	CH_3	H	0.031	15900	0.099	0.0079	43.0
Acetylsalicylic acid			494	1.00	—	—	—
Dihydralazine			149	3.32	310	0.34	1.00

[a] Human platelets, *in vitro*, RE = relative efficiency, acetylsalicylic acid ≡ 1. [b] Rats, urethane narcosis, intraperitoneal application, RE = relative efficiency, dihydrazine ≡ 1.

(21)



(20) etc.

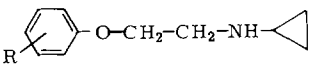
Fig. 14. A great variety of biologically active substituted 6-aryldihydropyridazinones, *e.g. (20)*, can be obtained by cyclization of suitable γ-oxocarboxylic acids *(21)* with hydrazine and modification of the aromatic substituents.

Flexible synthetic pathways have been worked out for *(20)* and similar compounds (Fig. 14). They facilitate the search for compounds with either predominant antihypertensive or platelet aggregation inhibiting properties[49]. *In vitro* test models utilizing isolated thrombocytes[50] and the enzymes of the arachidonic acid cascade[45,51] are very useful for selecting these substances.

7. Structure-Activity Relationships in Synthetic Strategy

This last example showed once more the importance of structural variations of a new lead substance. Today, the enormous variety of preparative methods will allow the talented chemist to synthesize almost any substance he desires. However, economic considerations impose limitations. This can be illustrated by a simple calculation: The variation of a ring system *(22)* that is to be substituted at six positions by 50 different substituents (Su) and linked to a dialkylamine by a methylene chain of 1—10 units would require $50^6 \times 10 \times 30^2 = 140625 \times 10^9$ substances if 30 different alkyl substituents are to be considered.

(22)



Obviously, costs of a few thousand dollars for the chemical synthesis and at least the same amount for a basic screening of one compound rule out such an approach. Great efforts are therefore devoted to methods that are able to limit the number of test compounds in a reasonable way. Many different methods[52] have been developed to establish quantitative structure-activity relationships[*].

So far, the relatively simple Hansch model and its variations have had the greatest success[53]. It is based on the plausible assumption that drugs have to pass lipophilic membranes and hydrophilic areas (for example, plasma) before reaching their receptor and that the binding to the receptor will also be influenced by hydrophobic interactions. In the Hansch model, biological activity is therefore correlated with the partition coefficient P (between H_2O and octanol) or the related factor π.

$$\log \frac{1}{BR} = k + a \log P + b (\log P)^2 + c\sigma + dE_s$$

BR = Biological activity (ED_{50} molar); k, a, b, c, d = constants; P = partition coefficient H_2O/octanol; σ = Hammett constant (electronic factor); E_s = Taft parameter (steric factor).

In addition, the Hammett constant can be considered as a measure of electronic factors and the Taft parameter as an indication of steric effects. If the structural variations are kept within rather narrow limits, Hansch analysis provides good predictions on the basis of even a small number of experimental data. An excellent example in point are the inhibitors of a monoaminooxidase[*] from the group of *N*-(phenoxyethyl)cyclopropylamines *(23)* (Fig. 15).

(23)

Experimentally determined equation:

$$\log(1/c) = 0.154\,\pi + 0.674\,E_s + 1.760\,\sigma + 4.226$$
$$r = 0.942,\ n = 16$$

Predictions:

R	calc.	observed
4-N=NC$_6$H$_5$	7.28	7.56
4-NH$_2$	4.57	4.40

Fig. 15. In the framework of well defined structural classes the Hansch model and its variations allow good predictions for structure activity relationships, specially for specific *in vitro* test models. c = concentration of test substance which produces a 50% inhibition of the enzyme monoamine oxidase. r = correlation coefficient, n = number of test substances.

The planning of a set of test compounds can profit greatly from use of the Craig diagram, which orders the functional groups common in medicinal chemistry by their contributions to the partition coefficient and to the Hammett parameter (Fig. 16).

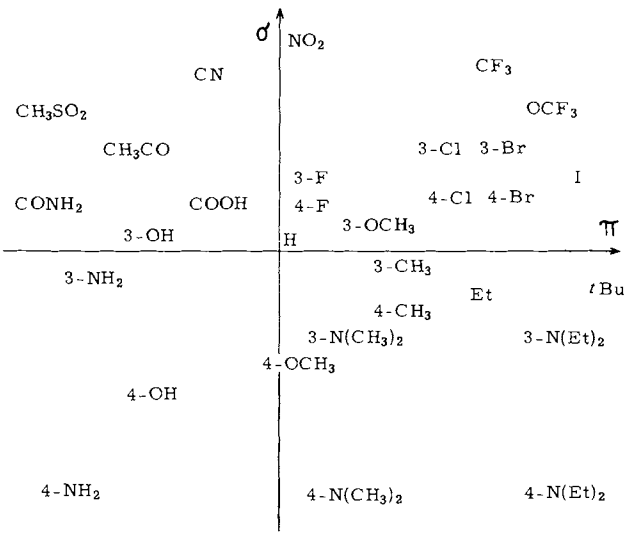


Fig. 16. The Craig diagram [54] facilitates selection of the most promising functional groups in the variation of aromatic substructures of drugs as it indicates the importance of π and σ parameters (see text).

[*] Hansch, Free-Wilson, discriminance, cluster analysis, pattern recognition, drug receptor mapping; quantum chemistry calculations.

[*] This enzyme degrades catecholamines such as epinephrin. MAO inhibitors have been clinically used as antidepressants.

One first selects a few examples from each quadrant formed by π and σ as coordinates. These compounds are synthesized and tested, and further synthetic work is then focused on substituents from that quadrant which produced the best test results.

The Topliss scheme[55] also assists in the systematic planning of test compounds by similar reasoning. For aromatic substructures, one synthesizes first the unsubstituted phenyl ring and then the *p*-chloro derivative. If the latter is more active this can either be attributed to a greater lipophilicity or an electron deficit in the aromatic ring. If a further increase in activity can be achieved with the 3,4-dichloro derivative, then lipophilicity is the more important factor. Logically, the dibromo or the iodo derivative are the next candidates for syntheses. If, however, the 3,4-dichloro derivative is less active than the *p*-chloro compound, 4-nitro substitution will tell if σ is the predominant factor. Corresponding considerations guide the synthetic work if the 4-chloro derivative is less active than or equiefficient with the unsubstituted phenyl derivative. The importance of quantitative structure activity relationships, such as the Hansch equation, lies mainly in selecting priorities for synthesis and in the assurance, that no reasonable compound in the area of the calculated optimum of biological activity has been overlooked. At this point, further improvement of activity can only be expected from a more profound variation of the lead structure. This, of course, then means that the equation used so far will no longer be valid and a new one will have to be developed.

A strategy for the rational development of new drugs could therefore be defined in the following way:

1) define a clear-cut goal;
2) select a lead substance based on biochemical considerations;
3) form a cooperative, multidisciplinary team;
4) apply relevant biological tests;
5) work out new lead substances by carefully designed variations;
6) check the significance of results and apply Hansch analysis, Topliss approach or Free-Wilson analysis to optimization wherever possible;
7) compare the results of structure activity analyses with the model ideas about the molecular mechanism of biological action;
8) utilize the refined model for future strategy of synthesis.

The application of these principles cannot guarantee success, but at least it improves the chances and reduces the dependance on serendipity in medicinal research.

8. Outlook

Until very recently, the organic chemist had little information about the reciprocal effects of molecules approaching each other and the detailed role of solvents and other components of a reaction medium. Frontier orbital calculations, and the study of membranes or other boundary surfaces, however, have increased our knowledge. The mutual influences between a bioactive substance and its receptor are much more complex, as biopolymers are flexible structures and intra- as well as extracellular body fluids have a complexity by far greater than most solvents used in organic chemistry.

Realistically, only a gradual reduction of effort can be expected in the search for new lead substances and their optimization to become useful drugs. For some time to come, therefore, the success of a medicinal chemist will depend on a combination of synthetic talent and versatility in the neighboring disciplines of biology and medicine. *Paul Ehrlich* was already aware of the importance of money, talent, patience, and good luck. Indeed, it often takes many years before a medicinal chemist knows with certainty whether his efforts were successful. He is compensated by the wide range of chemical methods and structures at his disposal. As the daily dose of most drugs is in the range of some milligrams to a few grams, even complex and therefore expensive substances can be acceptable. For life-saving drugs price considerations should be secondary in any case. This, of course, does not exclude great efforts to lower the costs of drug production. For instance, penicillins are available today at a fraction of the original costs.

The most important incentive for many medicinal researchers is the opportunity to alleviate the suffering of human beings. That this has been achieved to a considerable degree is well documented by the increase in life expectancy in civilized countries.

But much has still to be done to conquer further diseases. Speculation has no room in medicinal research. The danger of disappointment for the hopeful patient is too great. But some areas of interesting scientific progress may be mentioned. The intensive search for effective and well-tolerated drugs for the treatment of viral infections and/or malignant tumors may experience a breakthrough with the new results of interferon research. The clinical evaluation of these glycopeptides was made possible by recent progress in cell culture techniques. Methods of genetic engineering are also currently investigated to secure the supply of interferons should a routine therapy become feasible.

The study of trace elements[56] produces new insights as to their role in life processes and may trigger the development of new drugs.

The biological importance of fat soluble vitamins has been known for a long time; only recently, however, did we gain detailed information about their mode of action. Thus vitamin A and derivatives[57] apparently play an essential part in the differentiation of epithelial cells. They therefore offer new hopes for therapy and prevention of epithelial tumors (including cancer of the lung, the intestines, bladder, kidney, mamma, and skin)[57].

The transformation of such observations into the development of new drugs starts with the synthesis of substances that are more active, better tolerated and have a practical duration of action. Medicinal chemistry will therefore continue to be a challenge and an opportunity for talented and persevering chemists.

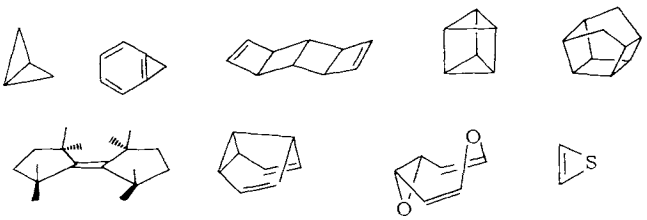
The Synthesis of Unusual Organic Molecules from Azoalkanes

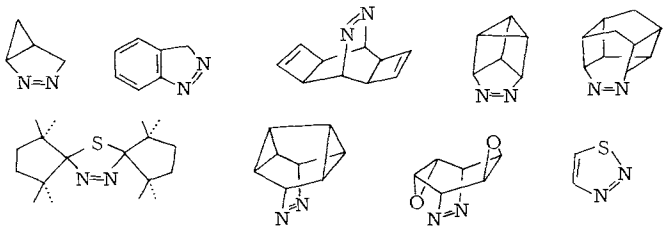
New synthetic methods (33)



By Waldemar Adam and Ottorino De Lucchi[*]

Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday

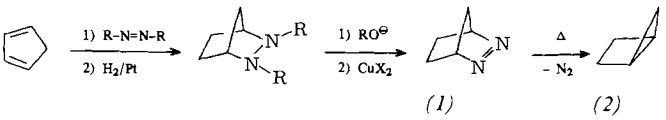
The thermal or photochemical denitrogenation of azoalkanes constitutes an effective and convenient method for the preparation of unusual organic molecules, including highly ring-strained, sterically crowded, fluxional, antiaromatic and other interesting structures. The importance of this synthetic approach is that the azo linkage serves as a means of introducing the critical (usually last) bond in the complex target molecule. This article presents a cross-section of such elegant synthetic utilization of azoalkanes for fused-, bridged- and spiro-cyclization. Our coverage of the large body of literature has been directed by the complexity and novelty of the products. Azoalkanes are usually prepared *via* cycloaddition of azo dienophiles to appropriate substrates.



1. Introduction

Complex and unusual organic molecules such as the set of examples shown in Scheme 1, including ring strained, sterically crowded, fluctuating and antiaromatic structures, have captivated the organic chemist's curiosity and interest especially during the last two decades[1]. On the one hand, such molecules represent a formidable preparative challenge and allow us to sharpen and shape our synthetic tools; on the other hand they provide abundant opportunities for mechanistic and structural investigation and thereby permit us to enrich our knowledge of physical organic chemistry.

Scheme 1



Although the illustrated set of unusual molecules displays great structural diversity, they share a common synthetic history. Specifically, the crucial step involved thermal and/or photochemical extrusion of molecular nitrogen from the corresponding azo compounds shown in Scheme 2. Clearly, the usefulness and convenience of this synthetic strategy cannot be overemphasized.

Scheme 2

Am Hubland, D-8700 Würzburg (Germany)

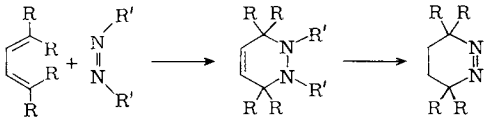
Criegee's elegant synthesis of bicyclo[2.1.0]pentane *(1)*[2] from the azoalkane *(2)* marks the beginning of this synthetic approach[3]. Not only was bicyclo[2.1.0]pentane *(1)* just about the most strained molecule that existed at the time,

(1) *(2)*

and thus provoked interest among the organic chemists to hunt for still more abused organic structures, but this sequence also laid down the essential *modus operandi* for the preparation of such unusual organic structures. During the last two decades, many interesting molecules have indeed been prepared *via* the elegant and convenient Criegee route.

In this article we report accomplishments and progress in this field. After surveying the various methods available for the preparation of azoalkanes[*], we shall illustrate the diversity of unusual molecules that can be prepared from the azoalkanes by thermal or photochemical extrusion of nitrogen. Complexity and novelty of the structures have dictated our choice of examples.

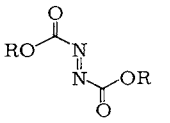
2. Synthesis of Azoalkanes



2.1. Cycloaddition of Azo Dienophiles

By far the most important method for the preparation of azoalkanes is Diels-Alder addition of azo dienophiles to appropriate diene substrates and subsequent oxidative hydrolysis of the resulting adduct (Scheme 3). In fact, the cycloaddition of azo dienophiles to 1,3-dienes marked the beginning of the famous Diels-Alder reaction[4]. The synthesis of 2,3-diazabicyclo[2.2.1]hept-2-ene *(2)* by *Criegee*[2] represents a specific application of this general synthetic pathway, which is of great importance in the present context.

The acyclic azodicarboxylates *(3a, b)* have often been employed as useful azo dienophiles[5]. However, the hydrolysis of the cycloadducts to the hydrazo compounds is frequently



[*] The term "azoalkanes" is also taken to include unsaturated compounds.

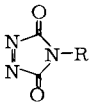
Scheme 3

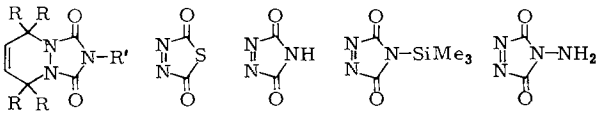


problematic, especially when sensitive functionalities are present. For this reason the more elaborate derivatives *(3c)*[6] and *(3d)*[7] were designed which permit cleavage under mild conditions. Recently, special techniques have been develop-

(3a), R = Me
(3b), R = Et
(3c), R = CH_2CH_2OTs
(3d), R = CH_2CCl_3

ed, *e.g.* with lithium methyl sulfide in hexamethylphosphoric triamide[8] and trimethylsilyl iodide or trimethylsilyl chloride and NaI[9], which facilitate cleavage of adducts derived from *(3a)* or *(3b)* under mild conditions.

More effective, and presently more widely used dienophiles are the 1,2,4-triazoline-3,5-diones (TAD) *(4)*. Particu-



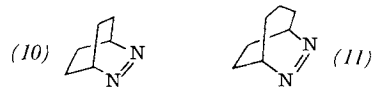
(4)
TAD

R = Et, *t*Bu, *n*Bu, *c*-C_6H_{11}, $PhCH_2$, *p*-MeC_6H_4, *p*-$NO_2C_6H_4$, *p*-ClC_6H_4, 3,4-$Cl_2C_6H_3$

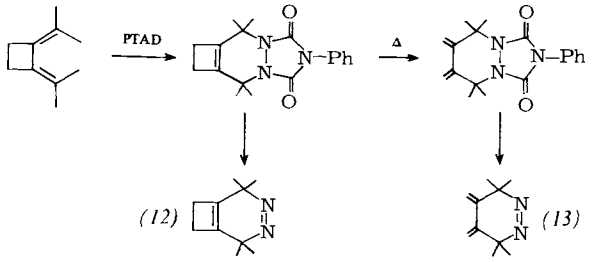
R = Me (MTAD); R = Ph (PTAD)

larly popular are the *N*-phenyl (PTAD) and *N*-methyl (MTAD) derivatives[10]. An extensive mechanistic study[11] has revealed that the TAD derivatives *(4)* are among the most reactive dienophiles known. Furthermore, solvent and substituent effect show that the cycloaddition process is a typical concerted Diels-Alder reaction.

One of the serious disadvantages of the triazolinediones *(4)* is the difficulty of hydrolyzing the resulting urazoles *(5)*. The development of mild and selective hydrolytic methods for such urazole products will greatly widen the scope and synthetic potential of this excellent reagent. In order to cir-



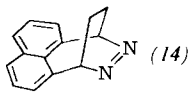
(5) *(6)* *(7)* *(8)* *(9)*



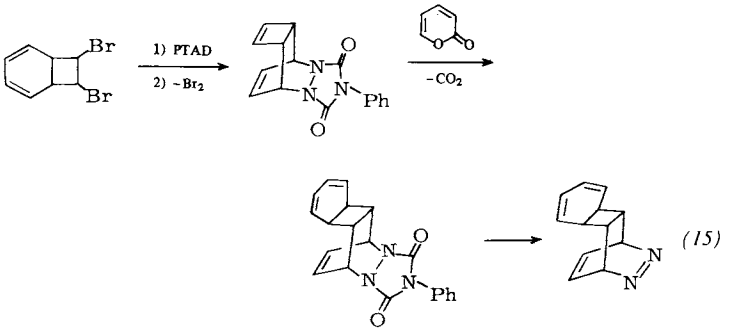
cumvent this problem, for example, the sulfur analogue *(6)* has been utilized as dienophile since the resulting cycloadduct can be hydrolyzed with great ease[12]. Unfortunately, *(6)* is rather unstable even under ambient conditions, and can only be employed for the most reactive Diels-Alder substrates. Also the parent triazolinedione *(7)*, formed *in situ* from its urazole, has been shown to undergo Diels-Alder reaction[13]. We feel that oxidative methods can be developed to transform the resulting unsubstituted urazoles *(5)*, R = H, into the corresponding azoalkanes. In the same vane, the *N*-silyl and *N*-amino derivatives *(8)* and *(9)*[14] might be useful, but no work has so far been reported along these lines.

2.1.1. Cyclic 1,3-Dienes

These remarks concerning the Diels-Alder reaction of azo dienophiles will now be illustrated by suitable examples. Let us first consider 1,3-dienes. By analogy with the preparation[2] of 2,3-diazabicyclo[2.2.1]hept-2-ene *(1)* from cyclopentadiene, 1,3-cyclohexadiene[15,16] and 1,3-cycloheptadiene[16] were converted into the corresponding azoalkanes *(10)* and *(11)*, respectively.

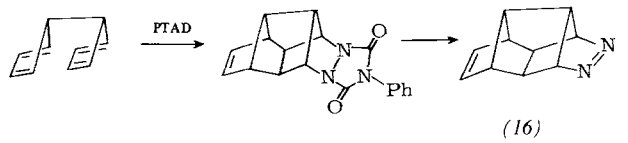


Interesting examples have been the preparation of azoalkanes *(12)* and *(13)*, obtained by the cycloaddition of PTAD with 1,2-diisopropylidenecyclobutane (dimethylallene dimer)[17]. Thus, hydrolysis and oxidation of the initial PTAD

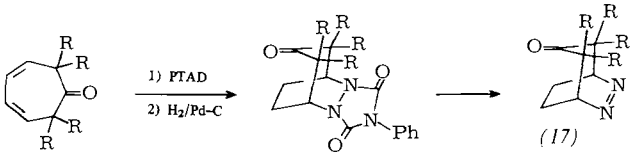


cycloadduct gave the very labile azoalkane *(12)*, while first thermal isomerization and subsequent hydrolysis and oxidation of the resulting urazole led to the considerably more stable azoalkane *(13)*.

The rather strained azoalkane *(14)* was prepared from pleiadiene by cycloaddition of ethyl azodicarboxylate, followed by hydrogenation, hydrolysis and oxidation[18].



Among the more amazing applications are the preparation of the polycyclic azoalkanes *(15)* and *(16)*. The former commences with the cycloaddition of PTAD to the bicyclic dibromide[19]. The azoalkane *(16)* was prepared by PTAD cy-

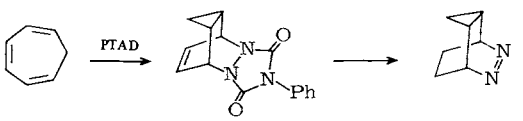


cloaddition to 1,1'-bicyclopentadienyl *via* the ingenious domino-Diels-Alder process[20].

The synthetic value of PTAD cycloaddition is clearly apparent. An unexpected example comes from our own work.

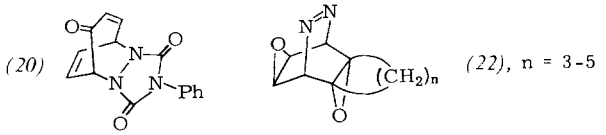
(16)

While 3,5-cycloheptadienones either isomerize or are unreactive towards the common dienophiles including azodicarboxylates, PTAD reacts smoothly to afford the corresponding urazoles, which are readily converted into their azo compounds *(17)*[21].



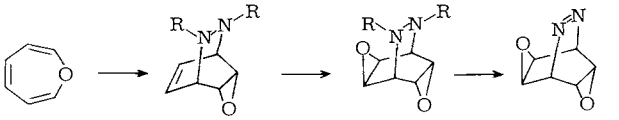
(17)

Numerous interesting PTAD cycloadditions have been performed which could be potentially useful for the preparation of exotic azoalkanes; however, the corresponding urazoles have not been converted into their respective azo compounds. Specific examples are the PTAD cycloadducts derived from dienic substrates[22a] such as divinylallene[22b], cyclopentadienone[23], isobenzofulvene[24], 1,2-dihydropyridines[25], phosphole sulfides[26], 2,3-dihydro-1,2-diazepines[27], 2,7-dihydrothiepin[28a], and homoheptafulvene[28b].



2.1.2. Cyclic Polyenes

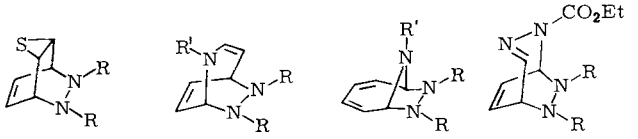
One of the earliest cyclic polyenes to be employed was cycloheptatriene. Although ethyl azodicarboxylate[29] exclusively undergoes ene-reaction, PTAD[30] gives the norcaradiene adduct *(18)* in high yield. We have shown[31] that irre-



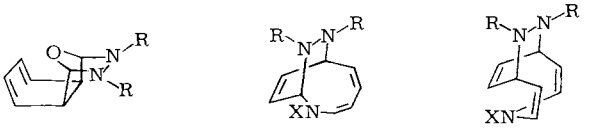
(18) (19)

spective of the electronic nature of the substituent at the 7-position, *i.e.* whether electron-withdrawing such as CO_2Me, CHO, CN, or Ph, or electron-donating such as MeO or Me, the exclusive product is the norcaradiene-type adduct *(18)*. Transformation of the urazole *(18)* into the azoalkane *(19)* has been accomplished in the usual way[15]. As expected, tropone gives the tropilidene-type PTAD adduct *(20)*[32a,b].

(20) (22), n = 3-5



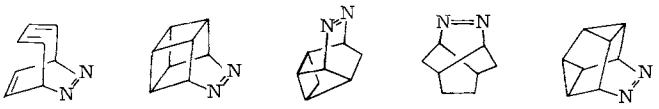
Among the hetero-analogues of cycloheptatriene, oxepin or benzene oxide has been converted into the bis(epoxy)azoalkane *(21c)*[33]. The difficult conversion of *(21b)* into *(21c)*, was accomplished with bis(trichloroethyl) azodicarboxylate as dienophile[7] which permits reductive cleavage under very mild conditions. The bridged azoalkanes *(22)*, $n=3$—5, have been prepared *via* a similar sequence[34]. Other unsaturated heterocycles forming adducts with azo dienophiles include thiepin [adduct *(23)*][35], azepine [adduct *(24)*][32], diazepine [adduct *(25)*][36], and heterocyclic polyenes *(26)*[37].



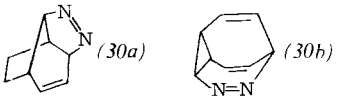
(21a) (21b) (21c)

R = $Cl_3CCH_2OC(=O)-$

Cyclooctatetraene has been a favored polyenic substrate for cycloaddition with azo dienophiles; for example, it is the



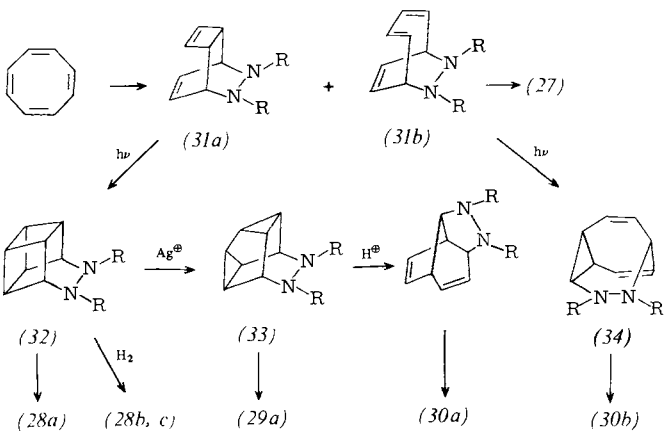
(23) (24a) (24b) (25)



(26a) (26b) (26c)

X = $CONH_2$, COMe

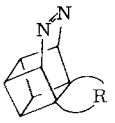
precursor of azoalkanes *(27)*—*(30)*. Thus, early work[30,38] showed that PTAD leads to the [4.2.2.$0^{2,5}$]-product *(31a)*;



(27) (28a) (28b) (28c) (29a)

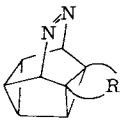
(30a) (30b)

however, on more careful examination[39], *(31b)* was also isolated and characterized. Photochemical isomerization gave the urazole *(34)* which was transformed into the azoalkane



(31a) (31b) (27)

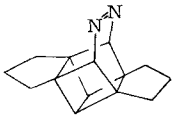
(32) (33) (34)



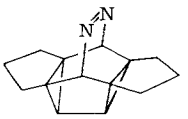
(28a) (28b, c) (29a) (30a) (30b)

(30b) (diazabullvalene)[39]. On the other hand, catalytic hydrogenation of the $Fe(CO)_3$-complex (protection of the diene moiety) of urazole *(31b)* and subsequent hydrolysis and oxidation afforded the azoalkane *(27)*[40a]. Furthermore, the $Fe(CO)_3$-complex of cyclobutadiene afforded the expected cycloadduct with ethyl azodicarboxylate, which was transformed into the useful azoalkane 2,3-diazabicyclo[2.2.0]hex-2-ene[40b].

Acetone-sensitized photocyclization of urazole *(31a)* produced *(32)* which was transformed into the interesting azoalkane *(28a)* (diazabasketene)[41]. However, silver ion-catalyzed rearrangement of the urazole *(32)* produced the snoutene derivative *(33)* which served as precursor to the azoalkane *(29a)* (diazasnoutene) and *(30)*[42]. Following this general synthesis, the structurally still more elaborate diazabasketene and diazasnoutene derivatives *(35)* and *(36)*, respec-

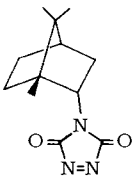


(35)



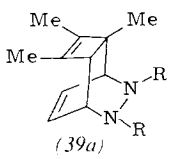
(36)

R = $-(CH_2)_n-$, (n = 3, 4, 5),
$-CH_2-CH=CH-CH_2-$,
$-CH_2-O-CH_2-$,
$-CH_2-NR-CH_2-$,
$-CH_2-SO_2-CH_2-$,
$-CH=CH-CH=CH-$

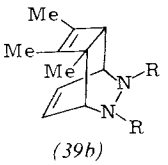


tively, have been prepared[43]. In fact, the doubly bridged diazabasketene *(37)* and diazasnoutene *(38)* could be synthesized in this way[44].

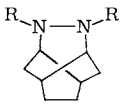
(37)



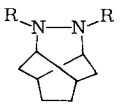
(38)



BTAD

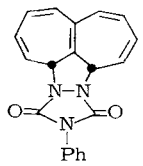


A potentially most valuable observation has been the very high degree of asymmetric induction when the optically pure (−)-4-(*endo*-2-bornyl)-1,2,4-triazoline-3,5-dione (BTAD) was allowed to cycloadd to cyclooctatetraene derivatives[45].

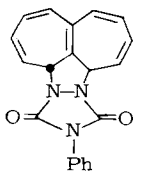


(39a)

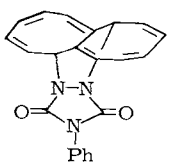
(39b)



(39c)

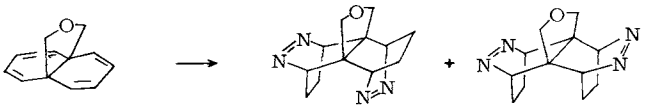


(39d)



The optically pure urazoles *(39a, b)* could be isolated and converted into their labile azoalkanes in the usual way. No doubt, this ingenious application of the cycloaddition with azo dienophiles should be of great synthetic value and convenience.

(40a)

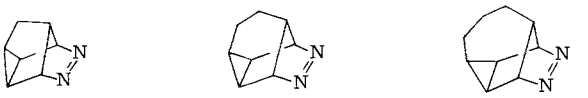


(40b)

(41)

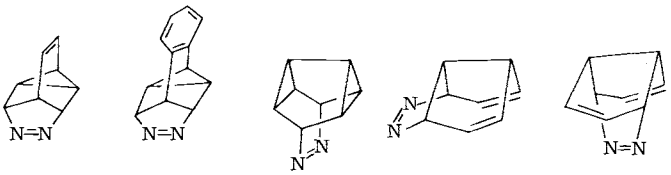
Heptalene affords the isomeric PTAD adducts *(40a, b)*[46] while octalene gives the intriguing adduct *(41)*[47]. None of these urazoles has yet been transformed into the corresponding azoalkane.

Finally, bridged annulenes have also received some attention in terms of cycloaddition with PTAD. For example, the isomeric bis(azoalkanes) *(42a, b)* have been prepared *via* the



(42a) *(42b)*

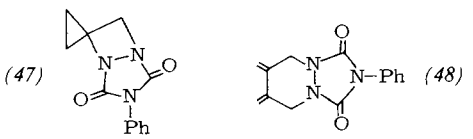
PTAD route[48]. A number of other bridged annulenes have been shown to give similar PTAD adducts, but they have not been converted into the corresponding azo compounds[49].



2.1.3. Cyclic 1,4-Dienes

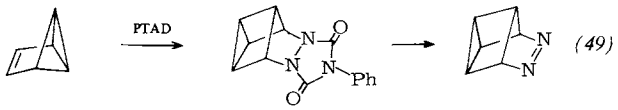
The homo-Diels-Alder cycloaddition of azo dienophiles with 1,4-cyclodienes was first accomplished with bicyclo[2.2.1]heptadiene, affording the azoalkane *(43)* after the usual manipulations[30,50]. The congeners *(44)* and *(45)* were

(43) *(44)* *(45)*



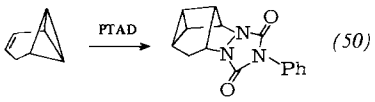
synthesized similarly[51]. Barrelene and benzobarrelene serve as precursors of azoalkanes *(46a, b)*[52]; semibullvalenes afford the exotic azoalkanes *(29)*[53].

(46a) *(46b)* *(29a)* *(29b)* *(29c)*



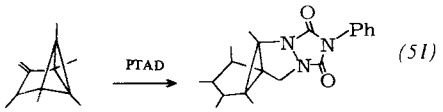
2.1.4. Strained Cycloalkenes

The ability of azo dienophiles, particularly TAD, to undergo [2+2]-cycloaddition with electron-rich olefins *via* dipolar intermediates is quite well established[54]. However, strained alkenes such as alkylidene- and alkenylidenecyclopropanes also give the urazoles *(47)*[55] and *(48)*[56], respectively.



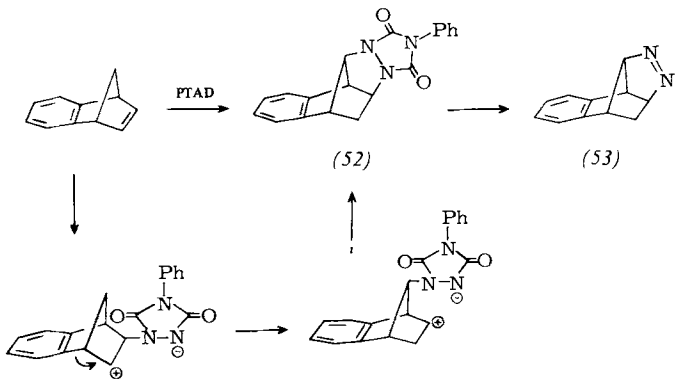
(47) *(48)*

A very clever application of such cycloaddition of PTAD has been the preparation of azoalkane *(49)* from benzval-



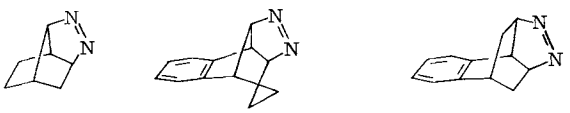
(49)

ene[57a]. Similarly, homobenzvalene has been converted into the urazole *(50)*[58] and isohomobenzvalene into urazole *(51)*



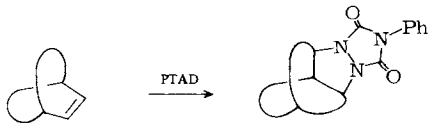
(50)

with PTAD[59]. Obviously some rather deep-seated rearrangements *via* dipolar intermediates are taking place in these intriguing cycloadditions.



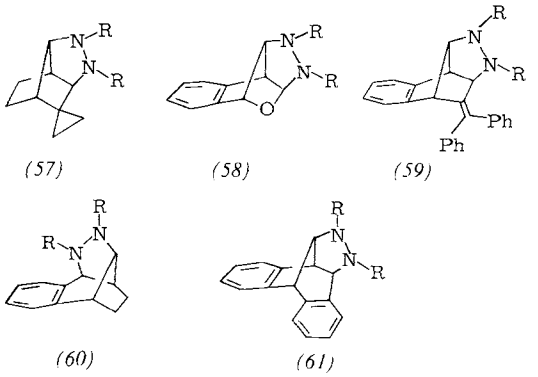
(51)

Along these lines, we have recently been able to demonstrate that benzonorbornadiene cycloadds with PTAD to give the interesting urazole *(52)* which has been converted into its azoalkane *(53)* in the usual way[60]. We rationalize that this fascinating reaction takes place *via* rearrangement of dipolar intermediates shown in Scheme 4. In a similar



Scheme 4

manner the azoalkanes *(54)*—*(56)* could be prepared from norbornene, 7,7-dimethylenebenzonorbornadiene, and 6,7-benzobicyclo[3.2.1]nona-2,6-diene, respectively[60,61]. In fact,

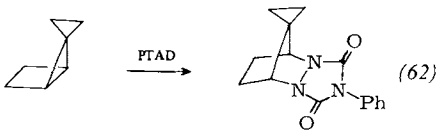


(54) *(55)* *(56)*

we could show that this dipolar addition to strained bicycloalkadienes is of general scope (5), allowing us to prepare the urazoles *(57)*—*(61)*[60–62]. However, bicyclo[2.2.2]octene

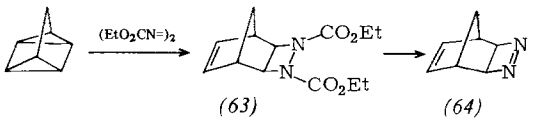
Scheme 5

did not react and the cyclopentadiene dimer gave exclusively ene-reaction.



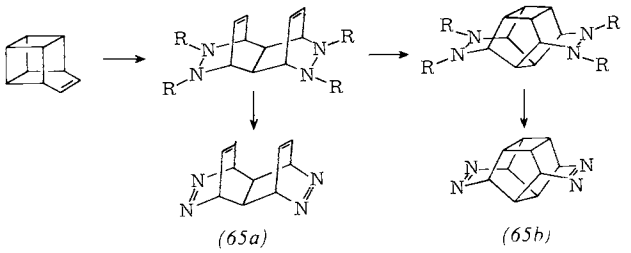
(57) *(58)* *(59)*

(60) *(61)*



2.1.5. Compounds with Strained σ-Bonds

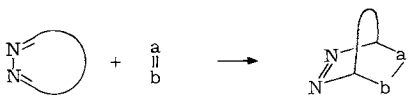
In view of the great reactivity of azo dienophiles, compounds with strained σ-bonds will undergo cycloaddition reactions. For example, 5,5-dimethylenebicyclo[2.1.0]pentane affords the urazole *(62)*[63]. Quadricyclane reacts with



(62)

ethyl azodicarboxylate to give the unusual cycloadduct *(63)*, which has been converted into azoalkane *(64)*[64]. Finally,

(63) *(64)*

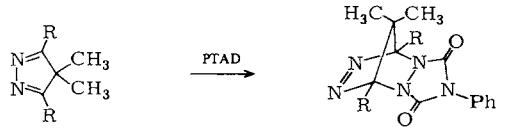


basketene is the precursor of the interesting bis(azoalkanes) *(65a, b)* formed on cycloaddition with ethyl azodicarboxylate[65].

(65a) *(65b)*

2.2. Cycloadditions to Cyclic 1,2-Diazadienes and Their Derivatives

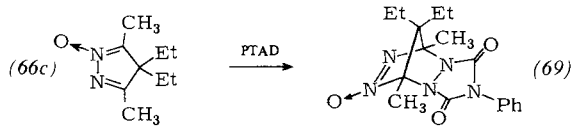
This synthetic approach for the preparation of azoalkanes also utilizes the Diels-Alder reaction, but the azo linkage is created through the cycloheterodiene partner (Scheme 6).



Scheme 6

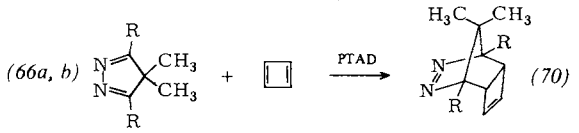
Two heterodiene partners that have been employed for this purpose are the diazacyclopentadiene *(66)* and the tetrazine *(67)*[66].

(66) (67)



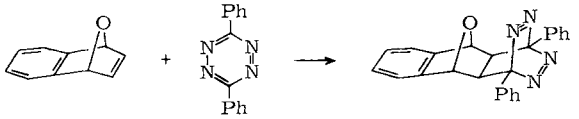
The preparation of the azoalkane *(68)* by addition of PTAD to *(66)* was one of the first examples of this synthetic

(66a), R = CH_3
(66b), R = Ph



(68)

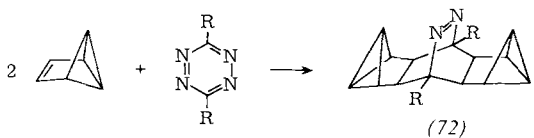
concept[67a-c]. Also the *N*-oxide derivative *(66c)* cycloadds PTAD to give the corresponding azoxy product *(69)*[67d].



(66c) *(69)*

Furthermore, addition of cyclobutadiene to *(66)* affords the synthetically valuable azoalkane *(70)*[68].

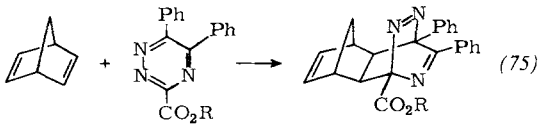
(66a, b) *(70)*



Some fascinating and elaborate azoalkanes have been prepared from tetrazines *(67)* as heterodienic cycloaddition partners. An early application was the synthesis of the bis(azoalkane) *(71)*[69]. A beautiful example is the double addition of benzvalene to *(67)* to afford the azoalkane *(72)*[70].

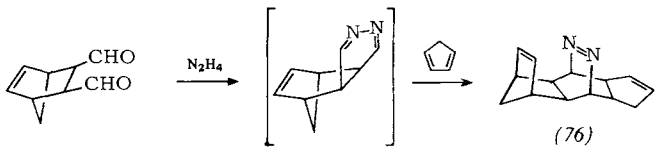
(67a) *(71)*

Similarly, the azoalkanes *(73)* and *(74)* are obtained by double addition of cyclobutadiene[71] or dimethylcyclopropene[72], respectively, to the tetrazine *(67)*.



Related results are the preparation of azoalkane *(75)* by cycloaddition of bicyclo[2.2.1]heptadiene to a 1,2,4-triazine[73a]. Similar triazine cycloadditions have been reported recently with benzocyclopropene[73b] and cyclopropene[73c];

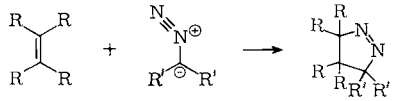
(67) *(72)*



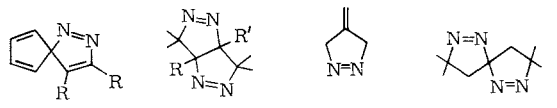
(73), R = Me, Ph, CO_2Me *(74)*

(75)

however the expected azoalkanes denitrogenate *in situ* to annulenes and azepines, respectively. Finally, the formation of azoalkane *(76)* in the reaction of the bicyclic dialdehyde with



(76)



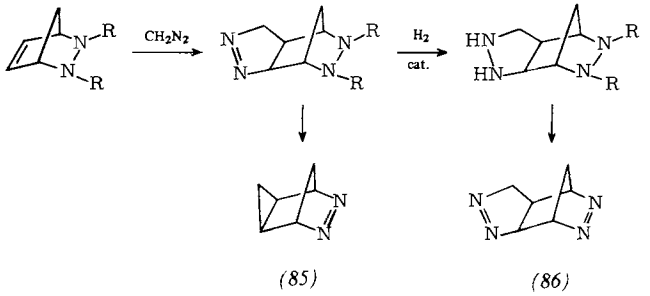
hydrazine presumably goes through the intermediary heteroiene[74]; the cyclopentadiene is produced *in situ* by retro-Diels-Alder of the heterodiene.

2.3. Cycloaddition with Diazoalkanes

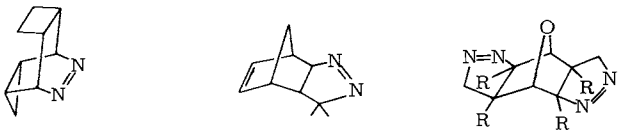
A convenient and effective direct synthesis of cyclic azoalkanes by dipolar cycloaddition of diazoalkanes[75] is shown in its most generalized form in Scheme 7. To cite some interesting representative examples from the vast body of literature on this topic, acetylenes afford the azoalkanes *(77)*[76] and *(78)*[77] by single and double addition, respectively. Al-

Scheme 7

(77) *(78)* *(79)* *(80)*



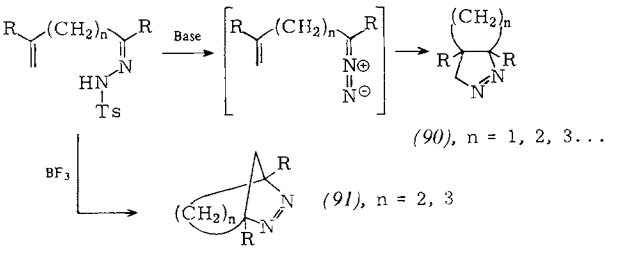
(81) *(82)* *(83)* *(84)*



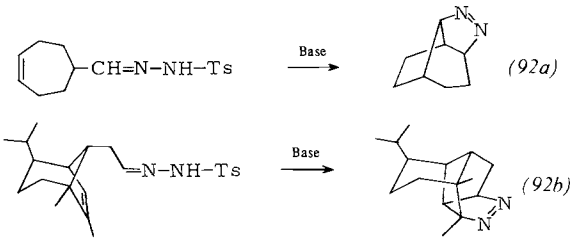
lene and diazomethane (and -propane) afford the azoalkane *(79)*[78] (and *(80)*[79]) again *via* the single and double addition of the diazoalkane. Butadienes lead to the azoalkanes *(81)* on reaction with 3-diazo-1-propene[80]. Cyclopropene[81], cyclobutene[82], and even cyclopentene[83] give the azoalkanes *(82)*, *(83)*, and *(84)*, respectively, with diazoalkanes.

The dipolar cycloaddition of diazoalkanes has also been applied successfully for the preparation of tricyclic and tetra-

cyclic azoalkanes. For example, the azoalkanes *(85)* and *(86)* have been prepared[84]. The azoalkanes *(87)*—*(89)* were prepared similarly by diazoalkane dipolar addition with 1,3,5-cyclooctatriene[85], with bicyclo[2.2.1]heptadiene[86], and 7-oxabicyclo[2.2.1]heptadiene[87].



(85) *(86)*

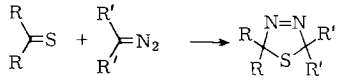


(87) *(88)* *(89)*

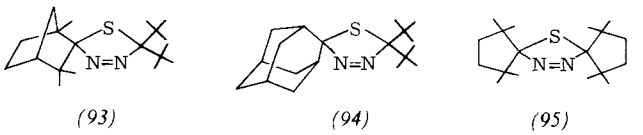
Interesting bicyclic azoalkanes are available through intramolecular diazoalkane cycloaddition. In these cases the diazo functionality is generated *in situ*, usually from the tosylhydrazone[88]. For example, bicyclo[*n*.3.0]-type azoalkanes *(90)* are prepared in this manner[89]. In this context it is of interest to mention that BF_3-catalyzed cyclization of such tosylhydrazones leads to the bicyclo[*n*.2.1]azoalkanes *(91)* instead[90]. Obviously the mechanism cannot involve a diazoalkane intermediate as in the base-catalyzed process. As more elaborate intramolecular cyclizations we cite the preparation of the azoalkanes *(92)*[91].

(90), n = 1, 2, 3...

(91), n = 2, 3



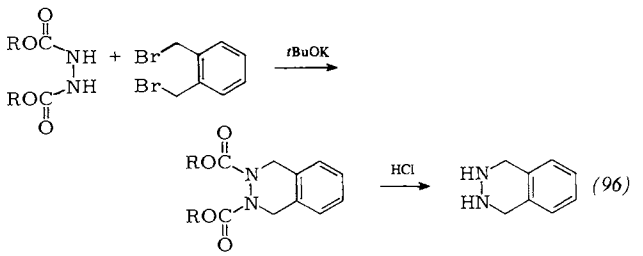
(92a)



(92b)

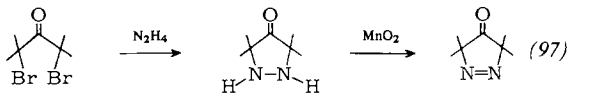
Finally, it should be noted that diazoalkanes cycloadd to thioketones to generate the sulfur-containing azoalkanes

Scheme 8



(Scheme 8). For example, the sterically hindered azoalkanes *(93)*[92], *(94)*[93], and *(95)*[94] have been prepared in this way.

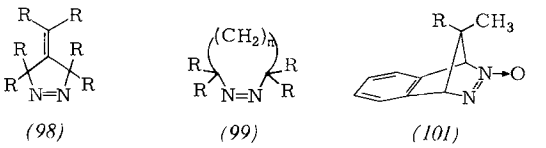
(93) *(94)* *(95)*



2.4. Cyclizations with Hydrazine and Derivatives

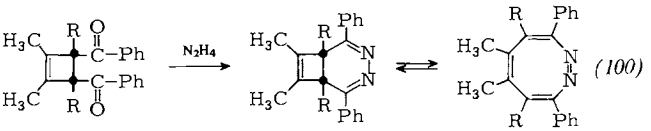
The 1,2-cycloalkylation of hydrazine and its derivatives constitutes a useful method for the preparation of hydrazo

(96)



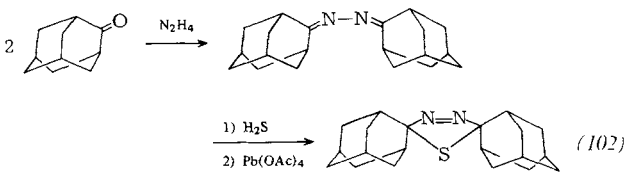
precursors to azoalkanes, as illustrated for the hydrazo compound *(96)*[95]. On the other hand, the interesting azoalkane

(97)



Scheme 9

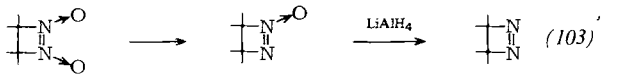
(97) was prepared (Scheme 9) *via* the direct reaction of hydrazine and subsequent oxidation of the hydrazo product[96]. Derivatives of azoalkane *(98)* were prepared similarly, but



(98) *(99)* *(101)*

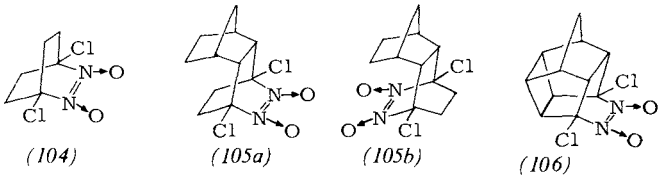
using ethyl hydrazodicarboxylate[97]. The sequence in Scheme 9 proved useful for the preparation of a number of azoalkanes *(99)*[98]. Diazocyclooctatetraene *(100)* was prepared

(100)



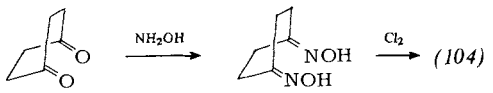
with hydrazine *via* elimination of water[99]. The azoxyalkanes *(101)* could be prepared from the corresponding 1,3-dibromoindans[100], and the azo compound *(102)* from adamantanone[101].

(102)



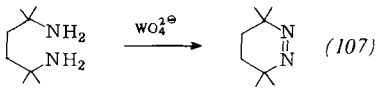
2.5. Miscellaneous Methods

We shall close this section with a potpourri of interesting preparations of azoalkanes which cannot be readily classified in any of the previous categories, but which are of synthetic potential. For example, the diazetine 1,2-dioxide[102] could be deoxygenated[103] to the diazetine *(103)*.



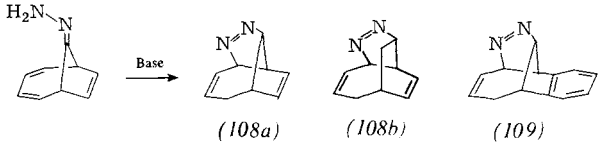
(103)

The fascinating azoalkane dioxides *(104)*[104], *(105)*, and *(106)*[105] have been prepared *via* the sequence illustrated for



(104) *(105a)* *(105b)* *(106)*

(104). The latter has been reduced to its azoalkane. Thus, an effective method is at hand for further exploitation.



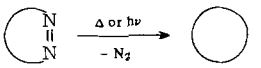
A convenient direct synthesis of azoalkane *(107)* (21% yield) is by tungstate oxidation of the corresponding diamine[104]. Clearly, this convenient transformation should be of

(107)

synthetic value, especially since it constitutes a convenient alternative for the iodine pentafluoride oxidative coupling of amines to form azoalkanes[106].

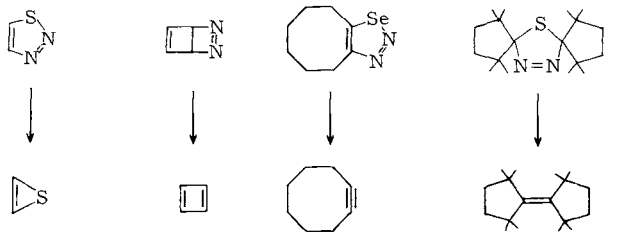
(108a) *(108b)* *(109)*

Of interest is the formation (75% yield) of the tricyclic azoalkane *(108a)*[107] and *(108b)* and the benzo-derivative *(109)*[108].



3. Denitrogenations of Azoalkanes

3.1. General Aspects



We are now ready to illustrate the usefulness and convenience of azoalkanes as precursors of unusual organic structures *via* thermal and photochemical denitrogenation. In view of the diverse repertory of synthetic methods that have been presented, it is assumed that the required azoalkanes can be made. Consequently, in this section we will not describe specifically the synthetic origin of the azoalkanes used.

Furthermore, the synthetic utilization of azoalkanes is so extensive that we are obliged to limit the scope of this article to cyclization reactions (Scheme 10). In other words, the very

Scheme 10

important applications for the introduction of double bonds, *e.g.* the preparation of antiaromatic thiirene[109] and cyclobutadiene[6], strained cyclooctyne[110,3a], or sterically congested bis(2,2,5,5-tetramethylcyclopentylidene)[94] (Scheme 11), will only be briefly considered. In fact, among the numerous cyclization reactions, we will be particularly concerned with bicyclizations leading to fused, bridged, and spiro structures (Scheme 12). The value of azoalkanes as synthons for unusual and complex structures will become quite apparent.

Scheme 11

Before taking up specific examples of azoalkane denitrogenations as a synthetic tool, we shall consider a number of practical aspects. For example, the range of activation energies for the pyrolytic extrusion of molecular nitrogen covers values as low as 15—20 kcal/mol to as high as 40—45 kcal/mol[3a]. This wide range of E_a values translates into decomposition temperatures as low as $-100\,^{\circ}C$ to as high as $+300\,^{\circ}C$. Many of the thermal denitrogenations are conducted in solutions of inert and thermally stable solvents. However, flash vacuum thermolysis (FVT) techniques are particularly convenient and have been used more and more frequently in recent years[3a,111].

Scheme 12 Fused Bridged Spiro-linked

Among the photochemical techniques either direct and/or sensitized photolysis have been used[3a,112]. From the spectral characteristics[113] of the *cis*-azoalkanes, which are of interest for our discussion, it is clear that the excitation process is $n_- \rightarrow \pi^*$ derived and lies in the 300—400 nm range. Although the $n_- \rightarrow \pi^*$ transition is much weaker (*ca.* 100-fold) than the $\pi \rightarrow \pi^*$ transition ($\varepsilon \approx 10^4$ to 10^5), the former is convenient for photoextrusion of nitrogen from azoalkanes. This

convenient long wavelength excitation is $n_- \rightarrow \pi^*$ in character and corresponds to the antisymmetric combination of the two nitrogen lone pair orbitals (Fig. 1). The corresponding $n_+ \rightarrow \pi^*$ excitation (from the symmetric combination) is at a considerably shorter wavelength and can fall below the $\pi \rightarrow \pi^*$ transition.

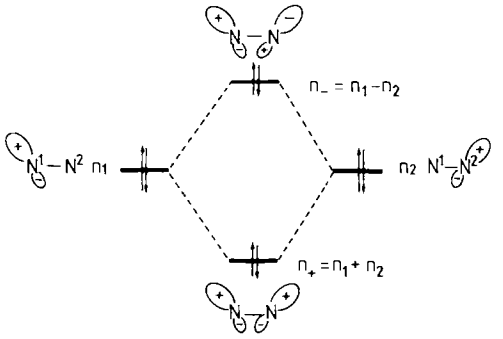


Fig. 1. Orbital diagram for azoalkanes.

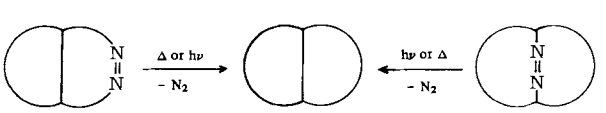
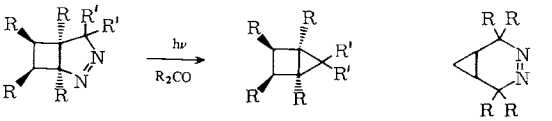
The singlet states of the $n_- \rightarrow \pi^*$ transition have excitation energies E_S of *ca.* 70—90 kcal/mol and for the triplet states E_T is *ca.* 50—60 kcal/mol. Thus, triplet sensitization can be conveniently and effectively performed with the usual carbonyl sensitizers (acetone, benzophenone, benzil, *etc.*).



The quantum yields Φ for the photo-extrusion of nitrogen depend greatly on the structure of the azoalkane, ranging from as high as unity to essentially zero. In the latter case the azoalkane is termed a "reluctant" substrate for photodenitrogenation. For example, azoalkanes for which the —N=N— bond is contained in a five-membered ring photo-eliminate nitrogen efficiently (Φ *ca.* unity), while azoalkanes whose —N=N— bond is contained in a six-membered ring are reluctant (Φ *ca.* zero) towards photolysis.

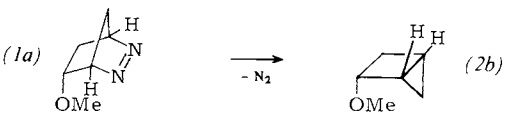
The choice of thermal *vs.* photochemical activation depends on the structure of the particular azoalkane. This will now be illustrated by some representative examples, but our focus and emphasis will be on synthetic utility rather than mechanistic insight. In particular, we intend to demonstrate that the denitrogenation of azoalkanes is a viable route for fused, bridged, and spiro bicyclizations in organic synthesis.

3.2. Cyclizations to Give Fused Rings



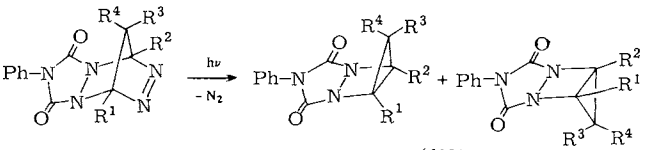
3.2.1. Bicyclic Structures

Cyclodenitrogenation from two structural types of azoalkanes, namely the fused and bridged azobicycloalkanes *(110)* and *(111)*, respectively, have been employed to construct



(110) *(111)*

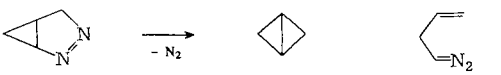
fused-ring bicycloalkanes. In fact, the preparation of bicyclo[2.1.0]pentane *(2)* from 2,3-diazabicyclo[2.2.1]hept-2-ene *(1)* by *Criegee* and *Rimmelin*[2] demonstrated for the first time the viability and convenience of this synthetic concept for the construction of highly strained compounds[1c].



(83a) *(2a)* *(83b)*

The alternative route starting from a 2,3-diazobicyclo[3.2.0]hept-2-ene *(83a)* has been shown[82] to afford bicyclo[2.1.0]pentanes *(2a)* in high yield (50—100%) on photosensitized denitrogenation with triplet ketones. However, the isomeric 3,4-diazabicyclo[4.1.0]hept-3-ene *(83b)* eliminates nitrogen with great ease, leading to 1,4-dienes in a stereospecific concerted process[114] and such compounds are, therefore, not useful azo-synthons for bicyclization. While the stereochemistry at the bridgehead carbons in *(1)* is retained when the fused *(83a)*[115] serves as substrate[82], double inversion can predominate with the bridged [2.2.1]azoalkanes *(1a)* depending on the reaction conditions[116].

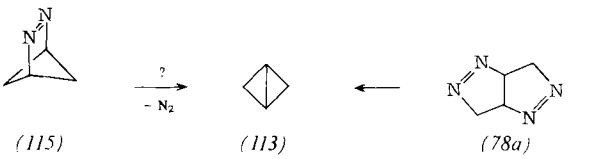
(1a) *(2b)*



In a similar manner, the heterocyclic bicyclo[2.1.0]pentane *(112)* was prepared from the azo compounds *(68)*[66]. The in-

(68a), R = Me, $PhCH_2$, Ph *(112)*

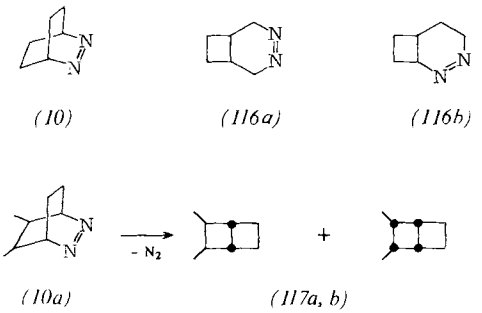
termediacy of the 1,3-diradical precursor of these urazoles *(112)* was established by ESR, using matrix isolation techniques.



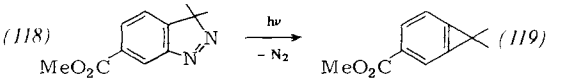
Substituted bicyclo[1.1.0]butanes *(113)*, the smallest and most strained fused bicycle, have been prepared by nitrogen extrusion from the fused 2,3-diazabicyclo[3.1.0]hex-2-enes *(82a)*[81a,116]. The yields of *(113)* are moderate (*ca.* 20—50%)

(82) *(113)* *(114)*

since the major products are isomeric 1,3-dienes. The mechanism of this denitrogenation is complex, since it has been shown that the diazoalkene *(114)*, generated by cycloreversion of *(82a)*, intervenes as precursor of the products[81,116,117].

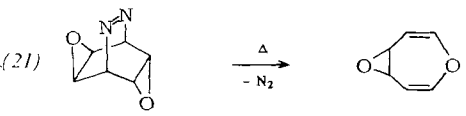


Use of the alternative route starting from the [2.1.1]azoalkane *(115)* seems not to have been reported. Presumably it is difficult to come by the highly strained *(115)*. However, double nitrogen extrusion from the fused bis(azoalkane) *(78)* takes place on heating or irradiation, affording the bicy-

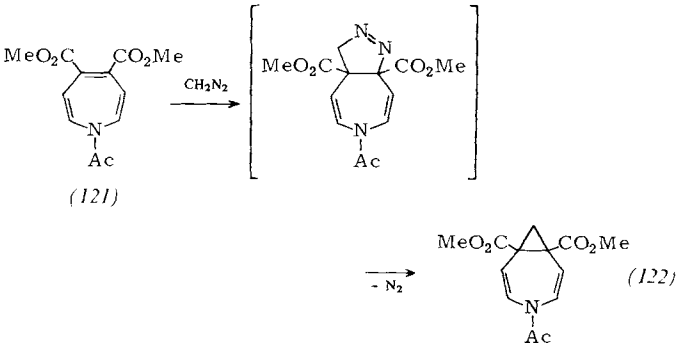


(115) *(113)* *(78a)*

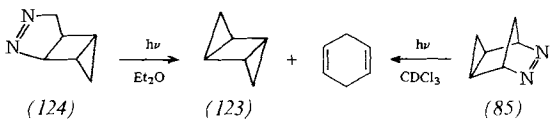
clo[1.1.0]butane *(113)* in poor yields (15—20%)[77,118]. It was shown that nitrogen loss is stepwise, first leading to *(82)*. Again, diazoalkenes *(114)* are intermediates in this transformation and are the cause for the low yields of *(113)*.



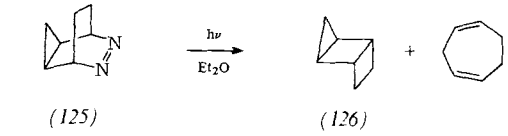
For the synthesis of bicyclo[2.2.0]hexanes *(117) via* denitrogenation, the [2.2.2]system *(10)* and the two [4.2.0]isomers *(116)* can serve as potential azo synthons. Thus, although the parent system *(10)* has been reported[15a] to give only 1,5-hexadienes, *i.e.* the acyclic product, the 5,6-dimethyl derivative *(10a)* afforded[119] the desired bicyclo[2.2.0]hexanes *(117)*. However, the [4.2.0]fused azoalkane *(116a)* gave exclusively[120] the 1,5-hexadienes *via* a stereospecific disrotatory cycloreversion process involving anchimeric assistance by cyclobutane. The isomer *(116b)* appears not to have been studied as a source of *(117)*.



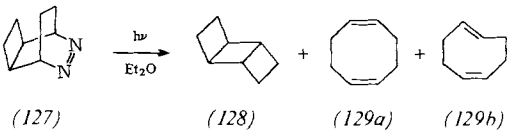
Fusion of a cyclopropane ring to an aryl moiety leads to highly strained compounds. For example, the benzopyrazole *(118)* photo-eliminates nitrogen to give *(119)*[121].



The bicyclo-fusion of heterocycles *via* azoalkanes has recently been accomplished, providing a convenient synthesis of *syn*-oxepin oxides *(120)*[33,122]. The bicyclo-fusion of a cyclopropane ring to a heterocycle is illustrated by *(121)*→*(122)*. Presumably an azoalkane formed as intermediate readily denitrogenates to yield the product *(122)*[123].

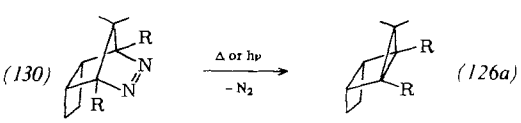


3.2.2. Polycyclic Compounds

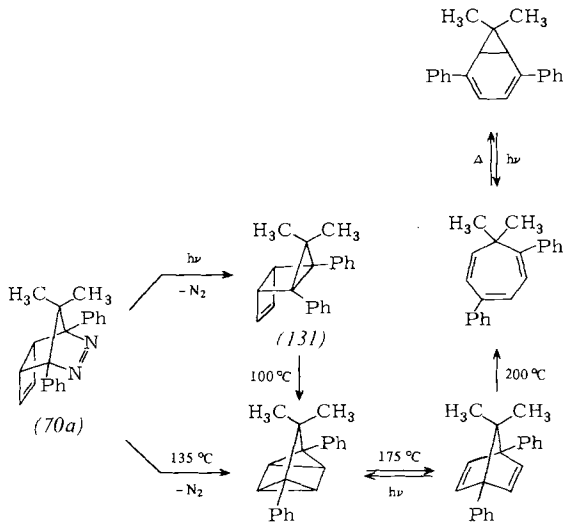


The smallest tricyclic system with fused rings that has been prepared by denitrogenation of azoalkanes is tricyclo[3.1.0.0^{2,4}]hexane *(123)*[84]. Thus, from the fused azotricycle *(124)* a *ca.* 10—15% yield of the *syn*-tricycle *(123)* was obtained along with minor amounts of the 1,4-cyclohexadiene.

Similarly, photolysis of the bridged azotricycle *(85)* gave a low yield (*ca.* 6%) of *(123)* and mostly (*ca.* 92%) 1,4-cyclohexadiene[124]. The latter was the exclusive product in the thermolysis of either *(85)* or *(124)*[84].

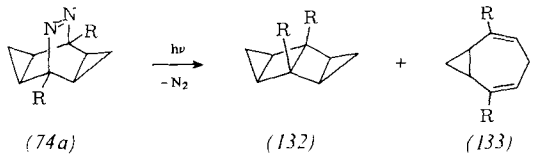


In analogous manner, thermolysis of the bridged azotricycle *(125)* gave only 1,4-cycloheptadiene[125], but photolytic denitrogenation[124] led to *ca.* 20% of the fused *anti*-tricycle *(126)* and 60% 1,4-cycloheptadiene. The fusion of three four-membered rings afforded the tricycle *(128)* from azoalkane *(127)*[124]. A more recent study showed[126] that in the photolysis as well as thermolysis the expected (1*Z*,5*E*)-1,5-cyclooctadiene *(129b)* is the major product, which thermally isomerizes to the *Z*,*Z*-isomer *(129a)*.

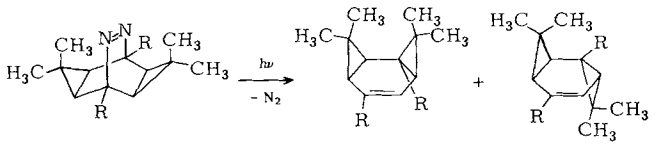


It is interesting to observe that in all three cases, *i.e.* tricycles *(123)*, *(126)*, and *(128)*, the rings are *anti* in the product, although in the azo precursors *(85)*, *(125)*, and *(127)* they were initially *syn* to the incipient cyclobutane bridge. This double inversion is apparently a general stereochemical course in the denitrogenation of such *syn*-azoalkanes. Furthermore, in this stereochemical arrangement of the reactants, denitrogenation is greatly enhanced through anchimeric assistance[15,51,84,127]. This concerted elimination affords the cyclic 1,4- or 1,5-diene as major product.

In contrast, when the azo-linkage and the cyclobutane ring are *syn* as in the bridged azo-tricycle *(130)*, the thermal (140 °C in $CHCl_3$) and photolytic nitrogen extrusions give essentially *quantitatively* the expected fused *anti*-tricycle *(126a)*[68a]. At higher temperatures (*ca.* 200 °C) *(130)* and/or *(126)* decompose into the corresponding ethylene and cyclo-

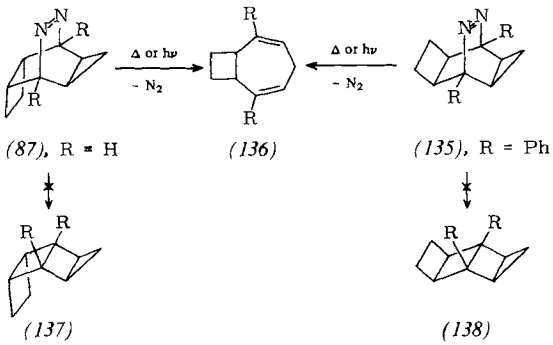


pentadiene. Similarly, the azoalkane *(70a)* photo-denitrogenates to give the fused tricycle *(131)* quantitatively[68b]; however, on thermolysis, the quadricyclane, norbornadiene, or



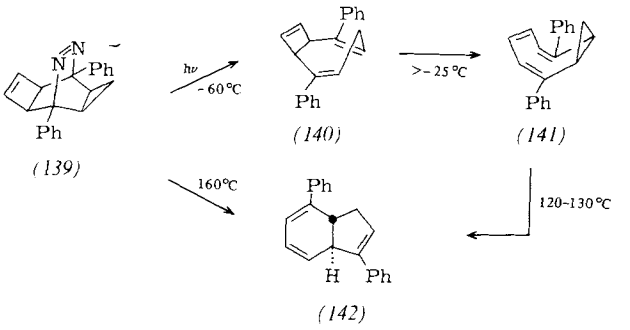
the cycloheptatriene valence isomers are produced, depending on the temperature. Other derivatives of type *(70)* lead to even more complicated product mixtures[68].

Four fused rings are present in the tetracycle *(132)* prepared from *(74a)*. Depending on the photolysis conditions,



(132) is formed in high yield (90%), along with the homotropilidene *(133)*[72a,c]. However, when the cyclopropane rings are disubstituted as in *(74b)*, then for steric reasons the bishomobenzenes *(134)* are produced[72d].

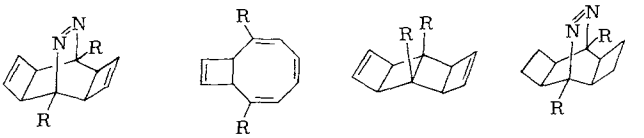
(74b), R = CN, CO_2Me, CO_2H, COCl, $CONH_2$ *(134)*



The isomeric azo compounds *(87)* and *(135)* on heating or irradiation afforded the bicyclodiene *(136)* rather than the expected tetracycles *(137)* and *(138)*, respectively[85,128]. The

(87), R = H *(136)* *(135)*, R = Ph

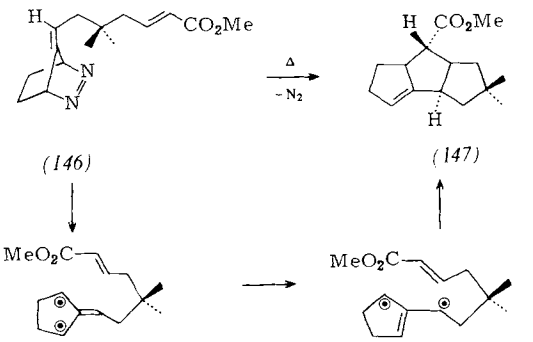
(137) *(138)*



unsaturated analogue of *(135)*, *i.e.* azoalkane *(139)*, did also not furnish the corresponding tetracycle[128]. Instead, on photolysis at −60 °C the triene *(140)* was formed which above

(139) *(140)* *(141)* *(142)*

−25 °C valence-isomerized to *(141)*. The latter rearranged at 120—130 °C to the 3a,7a-dihydroindene *(142)*, the thermolysis product of azoalkane *(139)* at 160 °C.

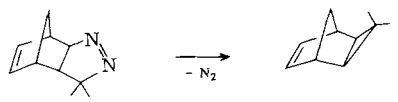


Thermal and photochemical denitrogenation of the azoalkane *(73)*, R = Ph[129], afforded complex product mixtures which can be rationalized *via* the intermediary bicycle *(143)*,

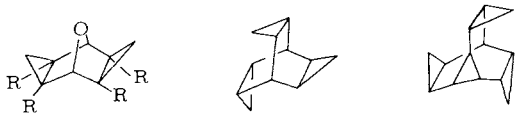
(73) *(143)* *(144)* *(145)*

R = Ph. However, a recent reinvestigation of *(73)*, R = Me, CO_2Me, Ph, confirmed that the tetracycle *(144)* is indeed produced[71]. The saturated analog *(145)* was reported[129] to give only the ring-opened product, *i.e.* the analogue of *(143)*.

A most ingenious fused tricyclization was executed recently *via* intramolecular trapping of a trimethylenemethane di-



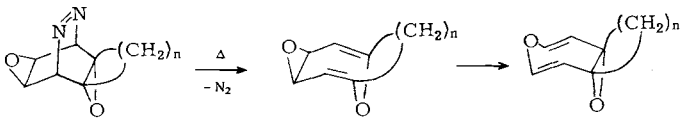
(146) *(147)*



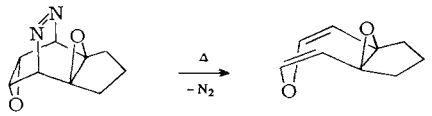
radical[130]. Thermal loss of N_2 leads to the diradical, which then undergoes regio- and stereoselective intramolecular cyclization to give the tricyclic product *(147)*.

3.2.3. Bridged Structures

The following examples concern cyclizations on substrates possessing bridged bicyclic skeletons. For example, denitrogenation of the azoalkane *(88)* leads to the tricycles *(148)*[86]. Quite analogously the complex polycyclic structures *(149)*, *(150)*, and *(151)* were prepared respectively from the azoalkanes derived from diazomethane addition to 7-oxabicyclo[2.2.1]hepta-2,5-diene[87] and homobarrelene and bullvalene[131].



(88) (148)



(149) (150) (151)

Finally, analogous to the preparation of *syn*-oxepin oxide *(120)*, the bridged oxepin oxides *(152)* and their valence isomers *(153)* have been prepared from azoalkanes *(22)*[34].

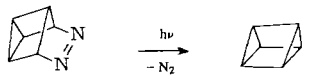
(22) (152) n = 3-5 (153)

For $n=3$, 4 the valence isomer *(152)* prevails, but for $n=5$ it is *(153)*. However, *(153)*, $n=3$, could be made from the isomeric azoalkane *(154)*. Clearly, a three-membered ring that is *anti* to the departing N_2 is essential to obtain a particular oxepin oxide[34].

(154) (153), n = 3

3.3. Cyclizations Foming Bridged Bicyclics

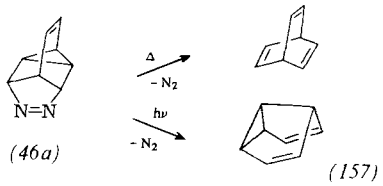
3.3.1. Cage Structures



Quadricyclane *(155)*, synthesized *via* denitrogenation of the appropriate azoalkane, was one of the earliest target molecules in bridged bicyclization. First *Moriarty*[50b] reported that the caged azoalkane *(43)* gave a 35% yield of the quadricyclane *(155)* on thermolysis; however, *Allred* and *Johnson*[51]

(43) (155) (64)

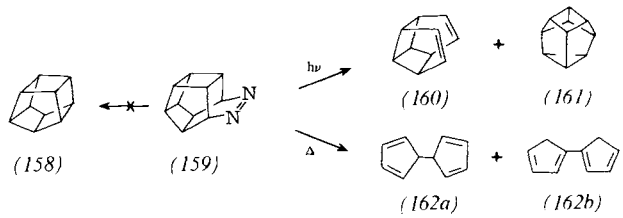
showed that thermolysis of *(43)* did not afford quadricyclane *(155)*, but rather its valence isomer norbornadiene. These thermolysis results were recently[132] confirmed by *Turro et al.*; however, the quadricyclane was the major product. For example, triplet sensitized photolysis of *(43)* gave as much as 90% quadricyclane. It is of interest to mention in this context that the azoalkane *(64)* also served as an efficient source of quadricyclane. While in the thermolysis only *ca.* 5% of quadricyclane are produced[64], direct and triplet sensitized photolysis of *(64)* give a *ca.* 90% yield of this strained cage product[132].



Another much studied and intriguing example is the synthesis of prismane *(156)* from the azo precursor *(49)*[57]. On heating at 130—150 °C, the caged azoalkane *(49)* quantitatively affords benzene instead of the desired prismane[133]. However, on singlet excitation in a nitrogen atmosphere *ca.* 10% of prismane was formed, accompanied by *ca.* 30% ben-

(49) (156)

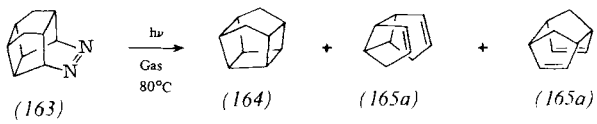
zene, 45% Dewar benzene, and 3% benzvalene[57a,134]. The triplet sensitized process led to diazacyclooctatetraene, but these rearrangement processes of azoalkanes without denitrogenation are taken up in a later section.



The caged azoalkane *(46a)* derived from barrelene did not produce the caged product, either on thermolysis or on photolysis[52]. Thus, on heating at 60—80 °C, *(46a)* smoothly lost N_2 to afford quantitatively barrelene, while triplet sensitized photolysis quantitatively afforded semibullvalene *(157)*, the

(46a) (157)

di-π-methane rearrangement product of barrelene. On direct photolysis of *(46a)* both barrelene (24%) and semibullvalene (73%) were formed along with cyclooctatetraene (3%). Analogous results were observed for the benzo- and naphtho-annelated derivatives.

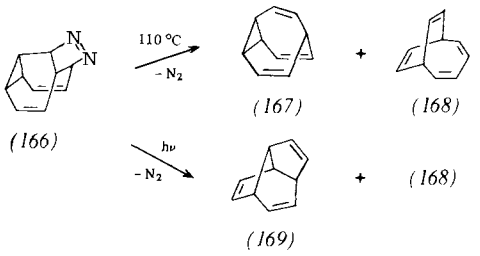


The synthesis of pentaprismane *(158)* was attempted by denitrogenation of the caged azoalkanes *(159)* and *(65a)*, but did not lead to this highly symmetrical and strained product. For example, on direct photolysis *(159)* gave the hydrocarbons *(160)* and *(161)* in 10% and 12% yields, respectively[135].

(158) (159) (160) (161) (162a) (162b)

Flash vacuum pyrolysis at 430 °C produced the isomeric dihydrofulvalenes *(162a, b)*. Similarly, the bis-azoalkane *(65a)* gave the dihydrofulvalene *(162a)*[65b].

On the other hand, *Turro et al.*[136] recently showed that the photo-reluctant azoalkane *(163)* gave the desired cage hydrocarbon *(164)* in 60% yield, together with the isomeric

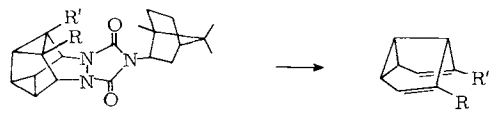


(163) (164) (165a) (165a)

cyclopentadiene dimers *(165a)* and *(165b)* in 22 and 5% yields, respectively. Clearly, the synthesis of caged hydrocarbons from suitable azo precursors *via* bridged bicyclization

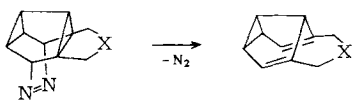
on denitrogenation is a viable synthetic approach to such complex structures.

3.3.2. Fluxional Structures



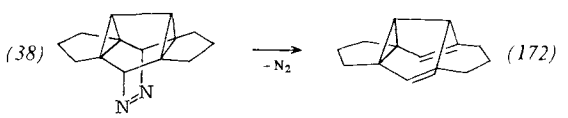
Bullvalene *(167)*, the best-known fluxional molecule, was prepared[137] *via* the azoalkane *(166)* by thermal extrusion of nitrogen. At 110 °C the bullvalene was formed in 46% yield

(166) *(167)* *(168)* *(168)* *(169)*



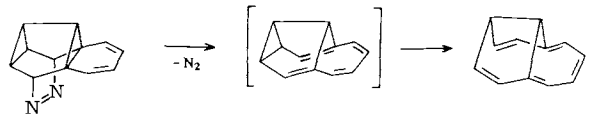
along with the bicyclic compound *(168)* (53% yield). However, on photolysis *(168)* and the tricyclic product *(169)* were formed instead of bullvalene.

Essentially simultaneously the elegant synthesis of semibullvalene *(157)* was accomplished *via* thermal denitrogenation of 9,10-diazasnoutene *(29a)* by *Askani*[42a], *Moriarty*[42b] and *Paquette*[42c]. A large number of 1(5)-, 2(4)-, and 3-substituted semibullvalenes *(157)* have been prepared in this way by *Paquette et al.*[42c] from the corresponding derivatives



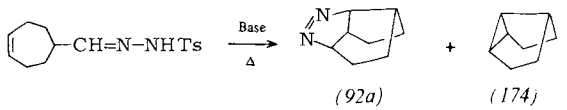
(170a), R = H; R' = CH_3
(170b), R = CH_3; R' = H

of *(29a)*[42d] with substituents such as CH_3, C_6H_5, CH_2OCH_3, CH_2OH, F, and CHO. Also, the absolute configuration and chiroptical properties of 2(4)-methylsemibullvalene were recently reported[43c]. Furthermore, a variety of fascinating 2,8-bridged semibullvalenes *(171)* could be synthesized from the corresponding bridged 9,10-diazasnoutenes *(36)* in this manner[43]. Particularly intriguing is the doubly bridged semibull-



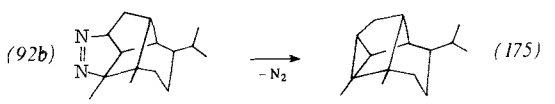
(36) *(171)*

valene *(172)*[44]. The semibullvalenes have been invaluable in providing essential information on the dynamics of such fluxional structures. For example, the fascinating 2,8-(1,3-



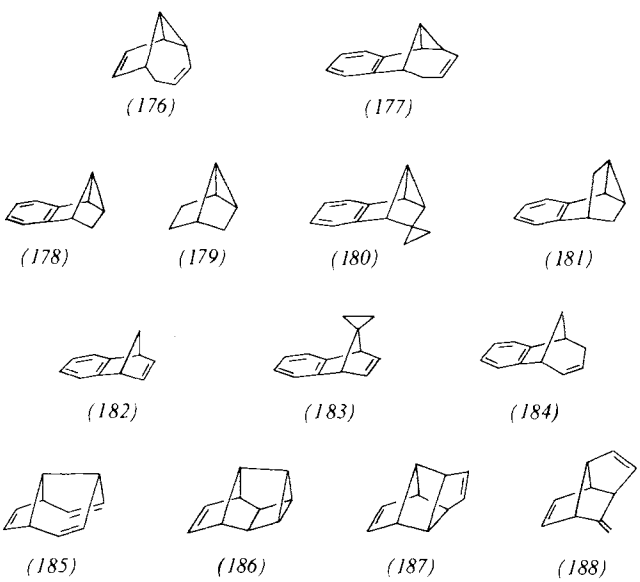
butadienylene)-bridged semibullvalene *(173)*, which was generated from the azoalkane *(36a)* on loss of nitrogen[138], exists exclusively as the bridged pentaene valence isomer *(173a)*.

(36a) *(173)* *(173a)*



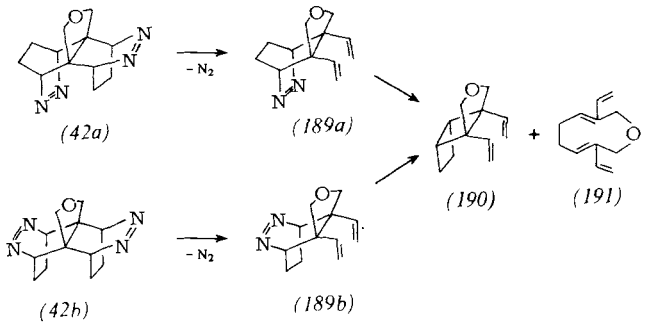
3.3.3. Miscellaneous Systems

To terminate this section, let us consider a number of azoalkane denitrogenations which lead to synthetically interesting molecules, but which cannot be classified as caged or fluctuating structures. Thus, the perhydro-semibullvalene *(174)* is formed in the base-induced decomposition from the tosylhydrazone, presumably *via* the azoalkane *(92a)*, which



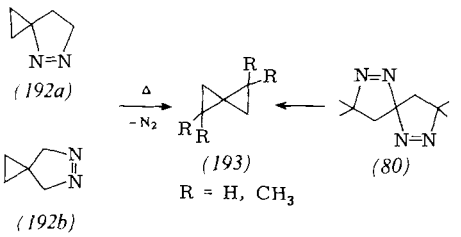
(92a) *(174)*

in turn results from intramolecular dipolar cycloaddition of the intermediary diazoalkane[91,42d]. Similarly, azoalkane *(92b)* afforded the tetracyclic product *(175)*[91b] on photo-de-



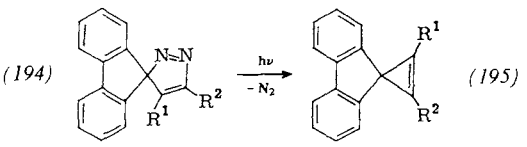
nitrogenation. Furthermore, the tricycloalkadiene *(176)* and its benzo-analogue *(177)* were obtained from the respective azoalkanes *(108)*[107] and *(109)*[108]. We have shown[139] that

(176) *(177)* *(178)* *(179)* *(180)* *(181)* *(182)* *(183)* *(184)* *(185)* *(186)* *(187)* *(188)*



the azo compounds *(53)*—*(56)* afford the corresponding cyclopropanated products *(178)*—*(181)* on thermal and/or photochemical extrusion of molecular nitrogen. Of course, it should be recognized that these polycycloalkanes are, with the exception of *(179)*, the di-π-methane rearrangement products of the corresponding polycycloalkadienes *(182)*—*(184)*[140]. In fact, significant amounts (*ca.* 18—20%) of *(184)* are formed in the thermolysis and photolysis of *(56)*, providing valuable information on the mechanism of the di-π-methane rearrangement[139].

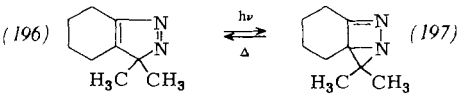
An amazing example is the photo-denitrogenation of the azoalkane *(16)* which gave the unusual products *(185)*—*(188)*[20]. Finally, the bis(azoalkanes) *(42a, b)* on short (20 min) irradiation led to the monoazoalkanes *(189a, b)*, respectively, and on long (3.5 h) irradiation the fully denitrogenated products *(190)* and *(191)*[48].



3.4. Cyclizations Forming Spiro Compounds

Two excellent recent reviews have been published on this topic, one on spiroalkanes in general[141] and the other on spiro-conjugated systems[142]. For this reason we will only mention an example of each for illustration. Thus, spiropentane *(193)* was prepared in two ways, by thermal and photolytic denitrogenation of (i) the isomeric spiroazoalkanes *(192a, b)*[143] and (ii) the bis(azoalkane) *(80)*[79]. In fact, the

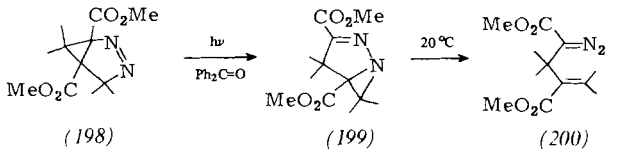
monoazoalkane *(192a)* was an intermediate in the denitrogenation of *(80)*. Interestingly, photolysis with circularly polarized near-UV light caused *ca.* 5% asymmetric enrichment in the starting material on incomplete denitrogenation[79].



On the other hand, denitrogenation of azoalkane *(194)* gave the spiro-conjugated product *(195)*[144]. Many other examples of such highly strained molecules have been prepared in this way[142].

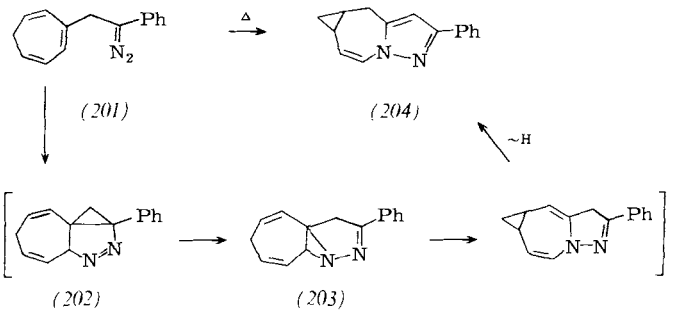
4. Transformations of Azoalkanes without Loss of Nitrogen

Azoalkanes do not always expel molecular nitrogen on thermal or photochemical activation. Instead, they can suffer rearrangements or retro-Diels-Alder reactions. Again we shall consider only those examples which may be of synthetic utility.



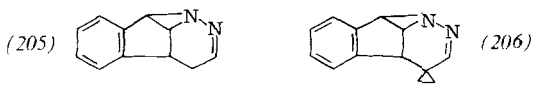
4.1. Rearrangements

An early example was observed by *Closs et al.*[145] in the photolysis of the fully alkylated 3*H*-pyrazoles *(196)*. Thus,



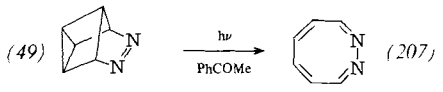
while photolysis of *(196)* at −60 °C in *n*-pentane gave the expected cyclopropene as major product on loss of nitrogen, photolysis of *(196)* at −60 °C in methanol gave exclusively the valence tautomer *(197)* on rearrangement. The 1,2-diazobicyclo[2.1.0]pent-2-ene skeleton *(197)* is unstable, and on warming to room temperature reverts to *(196)*.

A related example is the rearrangement of azoalkane *(198)* into the aziridine derivative *(199)* on benzophenone-sensitized photolysis[118b]. On standing at 20 °C, the thermally la-

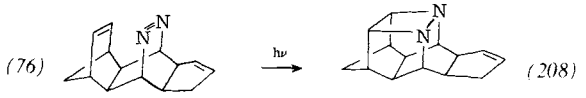


bile *(199)* retrocyclizes into the diazo derivative *(200)*. Analogously, the thermal transformation of the diazo compound *(201)* into *(204)* might involve the rearrangement of the in-

termediary azoalkane *(202)* into the aziridine derivative *(203)*, although a different pathway was preferred[146].



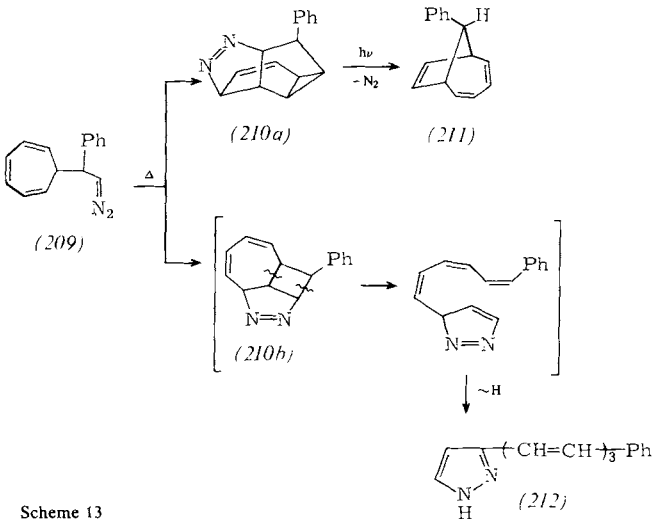
We recently observed similar rearrangements of the bridged azoalkanes *(53)* and *(55)*. While direct photolysis afforded the expected tricycloalkanes *(178)* and *(180)*, respectively, benzophenone-sensitized photolysis gave quantitatively the stable and isolable aziridines *(205)* and *(206)*, respectively[139]. It appears, therefore, that this type of azoal-



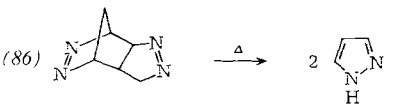
kane rearrangement may be general and of synthetic value since such aziridines would be difficult to prepare *via* classical methods.

An interesting and unexpected rearrangement was observed with the azoalkane *(49)* on attempted photo-denitrogenation. On direct photolysis, *(49)* afforded the expected prismane *(156)* in low yield[134a]. The major product, espe-

cially on acetophenone-sensitized photolysis (*ca.* 67%), however, was the 1,2-diazo-2,4,6,8-cyclooctatetraene *(207)*[134].

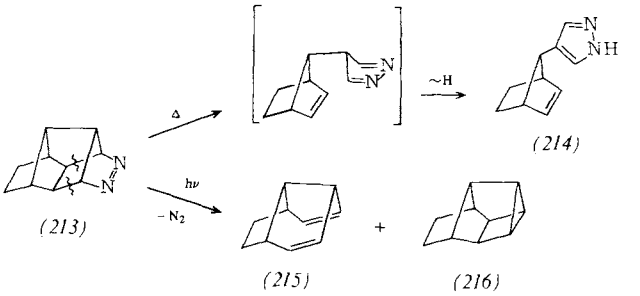


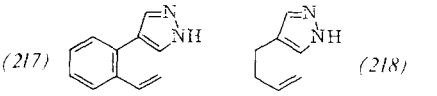
Also quite surprising was the intramolecular cycloaddition of the azo linkage to the juxtaposed C=C bond in the azoalkane *(76)* to give the caged product *(208)*[74]. This example appears to be unique!



4.2. Cycloreversions

One of the earliest examples of interest is shown in Scheme 13[147]. The diazoalkane *(209)*, produced *via* thermal decomposition of its tosylhydrazone precursor, gave the azoalkane *(210a)* and the pyrazole *(212)* as products. The formation of the unexpected pyrazole *(212)* was rationalized in terms of the intermediary azoalkane *(210b)* *via* [2+2]-retrocyclization and 1,3-hydrogen shift. Azoalkane *(210a)* afforded the bicycloalkatriene *(211)* on photo-denitrogenation.

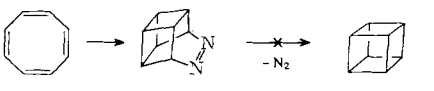


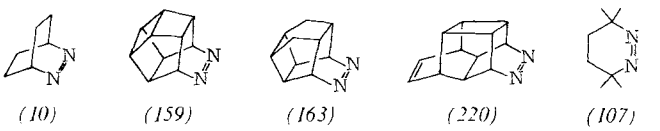


Scheme 13

Analogous to the thermal retrocyclization of the cyclopentadiene dimer, the bis(azoalkane) *(86)* decomposes into two moles of pyrazole. The intermediary 3*H*- and 4*H*-pyrazoles isomerize to the more stable 1*H*-tautomer[148].

A similar [4+2]-retrocyclization was observed by *Paquette et al.*[149a] on pyrolysis of azoalkane *(213)* at 370 °C, leading quantitatively to the pyrazole *(214)*. Again a 1,3-hydrogen shift gave the more stable tautomer. In contrast, photolysis of *(213)* afforded the hydrocarbons *(215)* and *(216)*[149b]. Finally, we recently observed[139] that the azoalkanes *(53)* and *(54)* undergo analogous [4+2]-retrocyclizations on flash vacuum pyrolysis at *ca.* 400 °C, leading quantitatively to the respective pyrazoles *(217)* and *(218)*.





5. Reluctant Azoalkanes

The majority of azoalkanes lose molecular nitrogen on either thermal or photochemical excitation; only a few undergo transformations retaining the nitrogen. Both categories are, however, of synthetic utility and interest. Most frustrating is the third category of azoalkanes, namely the "reluctant" azoalkanes, which are essentially inert to denitrogenation, especially toward the photolytic variant. The term "reluctant" signifies that the quantum yields for denitrogenation are low (*ca.* 5% or less)[150]. Thus, an elegant synthetic sequence may falter at its last step, when attempts to introduce the last carbon-carbon bond by nitrogen extrusion are thwarted by the azoalkanes resistance to denitrogenation.

An early classical example is the attempt to prepare cubane *(219)* from cyclooctatetraene *via* diazabasketene *(28a)*.

Thus, prolonged photolysis afforded a low yield of cyclooctatetraene, while flash vacuum pyrolysis gave diazacyclooctatetraene[151]. Other "reluctant" azoalkanes are shown in Scheme 14[150].

Scheme 14

The interesting common structural feature of these "reluctant" azoalkanes is that the azo-linkage is part of a six-membered ring. 3,3,6,6-Tetramethyl-1,2-diazacyclohex-1-ene *(107)* is the simplest system possessing this structural feature and is itself a "reluctant" azoalkane[152].

Recently, much mechanistic work has been invested in order to gain an understanding of why such azoalkanes lose nitrogen reluctantly, in the hope of developing remedies when a synthetic sequence fails in the last critical step of denitrogenation. Some progress has been made along these lines. For example, denitrogenation of *(10)* was enhanced *ca.* 25-fold by introducing substituents which stabilize radical sites, such as cyano, vinyl, *etc.*, at the α-carbon to the azo linkage or by introducing strain into the ring containing the azo-linkage through cyclopropane ring-fusion[150]. Alternatively, vapor phase photolysis at elevated temperatures proved to be successful in denitrogenating *(163)*[136].

Clearly, the electronically excited "reluctant" azoalkane possesses an activation energy (*ca.* 2—10 kcal/mol) towards nitrogen elimination. Consequently, denitrogenation no longer takes place on the lowest energy path and photophysical or photochemical energy dissipation, *e.g.* fluorescence[136, 150] or *cis-trans* isomerization[152], respectively, can become competitive.

Recently[153] it was demonstrated that the reluctant azoalkanes *(10)*, *(28a)*, and *(107)* smoothly denitrogenate on irradiation at 185 nm. While *(10)* and *(107)* led to the expected hydrocarbons, *(28a)* afforded cyclooctatetraene in good yield. In the latter case it still needs to be established whether cubane is an intermediate. It was suggested that either n_+, π^* or π,π^* excitation of the reluctant azoalkane is responsible for the greatly enhanced photo-elimination[154]. However, more mechanistic work will be necessary in order to understand "reluctance" sufficiently to overcome this menacing problem in the synthesis of unusual organic molecules from azoalkanes.

We acknowledge generous financial support by the National Science Foundation (CHE-78-12621), National Institutes of Health (GM-00141-05 and RR-8102-07), and the Petroleum Research Fund (11022-ACI), administered by the American Chemical Society, for our own work in this area.

Mechanistic Aspects of Diels-Alder Reactions: A Critical Survey

By Jürgen Sauer and Reiner Sustmann[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The question of concerted or consecutive bond formation arises in all types of cycloaddition reactions. Stereochemical investigations and studies of regiospecificity as well as intensive kinetic investigations with regard to substituent and solvent effects, and the dependence of the reaction on temperature and pressure permit in many cases mechanistic conclusions concerning the Diels-Alder reaction. Efforts towards a theoretical interpretation, *ab initio* and semiempirical calculations, the application of frontier molecular orbital theory (FMO) as well as thermochemical measurements permit a description of the energy hypersurface of these [4+2]-cycloadditions. An attempt is made here to draw a line of distinction between the mechanistic alternatives—one-step reaction *versus* two-step reaction—considering all experimental and theoretical criteria.

1. Introduction

On reading the first publication in the series "Synthesen in der hydroaromatischen Reihe" by *Otto Diels* and *Kurt Alder*[1], one anticipates there having been a door opened to virgin preparative territory:

"Bei der Ähnlichkeit im Verhalten der Azoester mit den Chinonen gegen Cyclopentadien und andere Kohlenwasserstoffe erschien es nicht ausgeschlossen, daß sich die Letzteren auch mit den Anhydriden der Malein-, Citracon- und Itaconsäure zu beständigen Verbindungen vereinigen würden. ... wir haben nun festgestellt, daß in der Tat Maleinsäureanhydrid, aber auch die freie Maleinsäure, ferner Citracon- und Itaconsäureanhydrid sich – meist schon bei gewöhnlicher Temperatur – glatt an Cyclopentadien und Butadien, aber auch an komplizierte Kohlenwasserstoffe mit einem System konjugierter Doppelbindungen, wie z. B. Cyclo-Hexadien oder Phellandren in der selben Weise wie Azoester und die Chinone anlagern. Die doppelte Bindung der genannten ungesättigten Anhydride oder Säuren öffnet sich, und es kommt in allen Fällen zu einer Angliederung der freien Valenzen in 1,4-Stellung an die betreffenden Kohlenwasserstoffe, wobei sich die neue Doppelbindung zwischen den Kohlenstoffatomen 2 und 3 bildet.

Die so entstehenden zahlreichen Produkte sind keineswegs "Molekülverbindungen", sondern festgefügt und stabil. Ein Teil von ihnen hat sich durch Überführung in altbekannte Stoffe identifizieren lassen"[**].

[**] "Since the behavior of azoesters and quinones towards cyclopentadiene and other kinds of hydrocarbons is similar, it seemed possible that the latter would also react with the anhydrides of maleic, citraconic and itaconic acid to give stable compounds ... we have now found that, in fact, not only maleic acid anhydride but also the free maleic acid and even citraconic acid and itaconic acid anhydride add—in most cases at normal temperatures, without any problem—to cyclopentadiene and butadiene in the same way as azoesters and quinones; moreover, they also add to more complex hydrocarbons having a system of conjugated double bonds, as for example cyclohexadiene or phellandrene. The double bond of the above mentioned unsaturated anhydrides or acids is broken, and in all cases the free valences in the 1,4 position link to the respective hydrocarbons, with the new double bond being formed between the carbon atoms 2 and 3. The various products thus generated are in no way "molecular complexes", but stable and definite compounds. Some of them could be identified by conversion into well-known products".

In retrospect, the subsequent communications by these two authors, published in short succession, reveal that this memorable publication constitutes a milestone in organic chemistry, the hour of birth of cycloaddition reactions[2]. The [4+2]-cycloadditions[3], named after their discoverers, were later joined by [2+1]-, [2+2]-, [3+2]-cycloadditions (1,3-dipolar cycloadditions), and those leading to more extended ring systems.

Diels and Alder were already able to identify essential characteristics of the [4+2]-cycloaddition:

1. The addition reactions take a *stereospecific* course resulting in a *cis*-addition.
2. In the case of cyclic dienes the *endo principle* is often followed.
3. Unsymmetrically substituted reactants combine *regiospecifically* to give the cycloadduct.
4. With maleic acid anhydride, valued in those days as the most reactive test dienophile, electron releasing groups in the diene accelerate the reaction, while electron withdrawing groups in the diene retard it. Kinetic measurements[4-8] quantified the so-called *"Alder-rule"*, formulated by *Alder*.

A preparatively useful extension of the cycloaddition was provided by the discovery of its catalysis by Lewis-acids[9], which, with retention of stereospecificity, accelerates the rate of addition by several powers of ten. In the presence of Lewis-acids, *endo*-products and the normally favored regioisomers were formed even to a higher extent.

Concepts of the mechanisms of the Diels-Alder reaction were most strongly influenced by the Woodward-Hoffmann rules[10-13]. If in those days the experimental results were consistent with a simultaneous formation of both bonds, the selection rules of Woodward and Hoffmann appeared to apodictically exclude the two-step mechanism (see Scheme 1 in Section 3).

Theoretical predictions, *ab initio* calculations[14-18], approximation methods[19] and the FMO-theory[20-26] stimulated further detailed discussion of the mechanism of the cycloaddition and made it possible to give a more satisfactory interpretation of many phenomena, including *e.g.* relative sequences of reactivity and regiospecifity in the Diels-Alder reaction.

It is a legitimate aspiration of the chemist to incorporate as many experimental facts as possible into a uniform, mechanistic picture. Very often, however, and not only in the case of Diels-Alder reactions, one succumbed to the danger of trying to interpret all reactions of a given type in a uniform way. The controversial "here, one-step bond formation", "there, two-step reaction pathway with a biradical or zwitterionic intermediate", both with a claim to exclusivity, has proven to be more of a hindrance than a help in discussions on the mechanism of the Diels-Alder reaction.

Today, it would seem to be undisputable that many [4+2]-cycloadditions are best described in terms of a symmetry-allowed one-step mechanism. In principle, however, a two-step mechanism cannot be ignored. The experimental results suggest that the two-step mechanism is in most cases energetically more demanding; but in so far as simultaneous bond formation may be hindered, for example by steric or electronic effects, the two-step mechanism might be able to compete energetically.

An attempt is made to critically analyze all those mechanistic results which are relevant for a decision regarding these alternatives. In particular we shall make comparisons with [2+2]-cycloadditions[27,28] and [3+2]-cycloadditions[29-33]. On the basis of the selection rules of *Woodward* and *Hoffmann*, we have to expect biradical or zwitterionic intermediates in [2+2]-cycloadditions; in contrast, [3+2]-cycloadditions ought to take place by a one-step mechanism in the same way as the Diels-Alder reaction. Many reviews have been written which facilitate general access to cycloaddition reactions, and particularly to [4+2]-cycloadditions[3,4,10,11,13,20,28,34-42].

2. Attempted Theoretical Interpretations

The aim of a theoretical analysis of a reaction mechanism is to gain a detailed description of the energy hypersurface, which connects reactants with reaction products. However, owing to the complexity of the problem—the participation of N atoms implies $3N-6$ degrees of freedom of vibration on a hypersurface of the same dimension—all methods of interpretation are limited from the outset, on the one hand by the selection of simple model reactions and, on the other, by the approximations which are necessary in the case of selected theoretical procedures. Also solvent effects are generally not considered, because theoretical models are normally developed for isolated molecules in in the gas phase. The fact that these limitations can lead to a false interpretation of experimental results, has been demonstrated on a number of occasions in recent years, particularly with regard to vapor phase-acidity and basicity experiments[43].

Conclusions drawn from such investigations must always be examined carefully in the light of these approximations. *Herndon*[21] gives a survey of the results obtained up to the beginning of the seventies concerning cycloadditions.

2.1. MO-Methods

2.1.1. *Ab initio* and Semiempirical Calculations

As prototype of a cycloaddition, the Diels-Alder reaction has on several occasions been the subject of quantum chemical calculations of energy hypersurfaces. The increased efficiency of modern computers and the further development of theoretical methods has enabled more and more detailed investigations. Despite this progress, however, attention has been confined almost exclusively to the formation of cyclohexene from butadiene and ethylene and the corresponding reverse reaction. With these two reactants a [4+2]-cycloaddition could certainly be verified, but it is not the typical example.

Presently there are two contradictory mechanistic interpretations. *Ab initio* calculations[14,16] lead to a reaction profile with a symmetrical transition state without any intermediate (distance between the planes of the reactants about 2.2 Å[16]). Semiempirical calculations of *Basilevsky et al.*[44] are in agreement with this, whereas another approach, using SINDO[45] certainly indicates an unsymmetrical transition state, but no intermediate. Calculations according to MINDO/2[46] and MINDO/3[19] contradict these results in preferring an unsymmetrical, diradicaloid transition state and a biradical

as intermediate. The experimentally determined energy of activation of the reaction is approximately reproduced by all calculations. This is not the case, however, with older CNDO/2 calculations[47], where an energy minimization is not undertaken. This condition is best complied with in semiempirical calculations by *Dewar et al.*[46,19].

Arguments can be presented against all these investigations. May a method parametrized for ground states (MINDO) be applied to the exploration of transition state geometries? It is at least questionable. Is the quality of the *ab initio* methods really good enough to distinguish between a synchronous and a two-step reaction?[48] The delimitation of both reaction pathways explored by *Salem et al.*[16] is not sufficiently rigorous; it seems possible that an improvement of the *ab initio* methods will perhaps lead to a different result. A detailed discussion of these problems on the basis of the cycloaddition of fulminic acid with acetylene is to be found in ref. [18]. *Basilevski et al.*[44] as well as *Houk et al.*[17] attributed the tendency to unsymmetrical transition states in MINDO to the ZDO approximation. The neglect of overlap favors the unsymmetrical transition state. Thus indeed a reason for diverging behavior is realized, but the actual quality of theoretical calculations does not allow a definite statement about the "real" reaction course. Besides, this reaction path would refer only to one non-typical case of a Diels-Alder reaction. A study (MINDO/2 and MINDO/3) using 1-hydroxybutadiene and acrolein as reactants tries to remedy this shortcoming[49]. But a mechanistic decision is also not possible here, for the reasons already discussed.

Thus the *ab initio* and semiempirical calculations are hardly a decisive help in defining the mechanism.

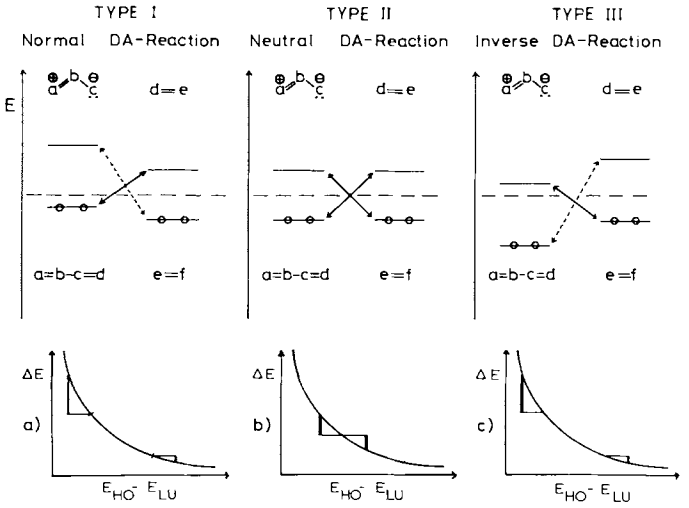
2.1.2. Approximate Theoretical Models

Despite rapid development in the field of computer techniques, the interest attached to qualitative reactivity models has not waned. Initially, simple reactivity indices were in the foreground of discussions about reactivity problems[21,50], whereas the Woodward-Hoffmann-rules[10] represented the first attempt at obtaining information about energy hypersurfaces on the basis of non-numerical methods. The analysis of symmetry relations provides an indication of the course of pericyclic reactions[13,43,51,52]. Orbital-, configuration-, and state-correlation diagrams would infer that the suprafacial approach $[{}_{\pi}2_s + {}_{\pi}4_s]$ of diene and dienophile is, as a ground state reaction, symmetry allowed and consequently can be a synchronous reaction. For most of the known Diels-Alder additions this conclusion seems to be correct (see Section 5). The same conclusions were drawn from the theory of the aromatic or antiaromatic transition state[53,54]. Also other directions of approach—$[{}_{\pi}2_s + {}_{\pi}4_a]$, $[{}_{\pi}2_a + {}_{\pi}4_s]$ and $[{}_{\pi}2_a + {}_{\pi}4_a]$—can be analyzed by the rules of orbital symmetry. However, it seems that there is still no definite experimental proof of these types of reaction of dienophile and diene.

Excellent summaries of these ideas can be found in papers by *Woodward* and *Hoffmann*[10], by *Herndon*[21] (literature up to 1971) and by *Houk*[55] (who considers all contributions up to 1977).

2.1.3. Frontier Molecular Orbital (FMO) Method

The search for a simple as possible description of the reactivity and the regioselectivity in Diels-Alder reactions led to the application of frontier-orbital theory[20,56]. The restriction to the molecular orbitals of the reactants most important for the reactivity allowed the classification of Diels-Alder reactions into three types[23,57] (Fig. 1). This classification is based on an analysis of eq. (a), which describes mathematically the interaction of both pairs of frontier orbitals in the HMO model[20].



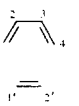


Fig. 1. Types of Diels-Alder (DA) reactions according to the frontier orbital (FMO) model. a)—c) see text.

$$\Delta E = \frac{(c_{1HO}\cdot c_{1'LU}\cdot \beta_{11'} + c_{4HO}\cdot c_{2'LU}\cdot \beta_{42'})^2}{E_{HO(diene)} - E_{LU(dienophile)}} + \frac{(c_{1LU}\cdot c_{1'HO}\cdot \beta_{11'} + c_{4LU}\cdot c_{2'LU}\cdot \beta_{42'})^2}{E_{HO(dienophile)} - E_{LU(diene)}} \quad \text{(a)}$$

Figure 2 illustrates more generally this relation for the interaction of two cycloaddition partners K and L[*] forming the adduct K—L. The following conclusions can be drawn from Figure 2:

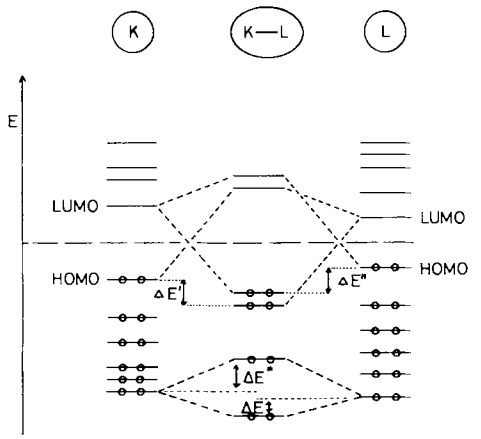

Fig. 2. MO-interaction diagram for two molecules K and L.

[*] The symbols K and L for the cycloaddition partners have been arbitrarily chosen.

1. *The interaction of occupied orbitals of K and L leads to a destabilization of the reaction complex.* The increase ΔE^* is larger than the decrease ΔE.
2. *Only the interaction of occupied orbitals of one reactant with vacant MO's of the other molecule leads to a stabilization of the system.*
3. *The extent of the interaction of two MO's is inversely proportional to their energy separation, i.e.* the more comparable the energies are, the greater is the interaction. The prerequisite for such an interaction is of course the same symmetry behavior of the molecular orbitals concerned.

These are basic statements of the qualitative perturbation theory; they do not only apply to cycloadditions[58-60] but are also fundamental for the orbital symmetry rules of *Woodward* and *Hoffmann*.

The classification of Diels-Alder reactions is to be seen in Figure 1.

As *Type I* we designate all those reactions whose $HOMO_{diene}$-$LUMO_{dienophile}$ separation is smaller than the second HOMO-LUMO separation. According to our above statements the $HOMO_{diene}$-$LUMO_{dienophile}$ separation is more important and dominates the reactivity.

For *Type II* both HOMO-LUMO separations are similar and therefore both must be considered.

Type III is just the converse of Type I. Here the $HOMO_{dienophile}$-$LUMO_{diene}$ separation governs the reactivity.

This classification makes it possible to describe the reactivity pattern of Diels-Alder reactions in a qualitative and, as we shall see later, also in a semiquantitative way; for application of this model, one has to know how substituents normally used in organic chemistry influence orbital energies. *Houk et al.*[61] have proposed a useful classification.

In a reaction of Type I with participation of a diene with a high lying HOMO, one expects that substituents which strengthen the dominant frontier orbital interaction increase the reactivity. For example, electron withdrawing substituents in the dienophile (Z-substituents according to *Houk*) or electron releasing substituents in the diene (X-substituents) are effective in this way. This situation is illustrated in Figure 1. The interaction energy is inversely proportional to the HOMO-LUMO separation. Suppose that a Z-substituent lowers the HOMO and LUMO of the dienophile by the same amount; one of the frontier orbital energy separations is enlarged, the other one is reduced. As a consequence of the inverse proportionality of stabilization and orbital separation the stabilization exceeds the destabilization, so that the overall-effect must be an acceleration of reaction. For Type I this is shown in a plot of ΔE against the HOMO-LUMO separation (Fig. 1a). The vertical lines indicate the extent of stabilization and destabilization, respectively, if the smaller HOMO-LUMO separation is shortened (left) by the same amount as the greater one (right) is lengthened. Type I represents the *normal Diels-Alder addition.*

The situation for Type II is demonstrated in Figure 1b. Both interactions are equally important. This diagram clearly illustrates the effect of a Z-substituent which decreases the HOMO and LUMO levels of a dienophile by the same amount. By strengthening one interaction the gain in stabilization is greater than the loss by weakening the other one, *i.e.* electron withdrawing substituents (Z-substituents) in the dienophile increase the reactivity. The same applies for electron releasing substituents (X-substituents), since the HOMO and LUMO will now be raised. The overall-result for Type II, which we have called a *neutral Diels-Alder reaction*[57] is: Any kind of substitution in the components effects an increase in the reactivity.

Type III is the converse of Type I (see Fig. 1c). The dominant interaction is increased by electron releasing substituents in the dienophile. This corresponds to the *Diels-Alder reaction with inverse electron demand.*

The equation for the frontier orbital interaction [eq. (a)] can be simplified to eq. (b)[23]. In doing so we assume that the value of the numerator in eq. (a) in discussing a reactivity series, *e.g.* the reaction of the same diene with several dienophiles, is constant to a first approximation. Thus, reactivity differences can be solely attributed to modifications of frontier orbital energies.

$$\Delta E = K\left[\frac{1}{E_{HO(diene)} - E_{LU(dienophile)}} + \frac{1}{E_{HO(dienophile)} - E_{LU(diene)}}\right] \quad (b)$$

As far as discussion of the Type I or Type III Diels-Alder reaction is concerned one can go one step further [eq. (c)] and restrict the discussion to the contribution of the dominant FMO-interaction. One should now expect an approximately linear correlation

$$\Delta E \approx \frac{1}{E_{HO} - E_{LU}} \quad (c)$$

between $1/(E_{HO} - E_{LU})$ and ΔE. The $\log k_2$-values of cycloaddition reactions represent an experimental measure of ΔE (see Section 5).

The numerator of eq. (a) contains information about the regiochemistry of the cycloadditions. This connection first mentioned by *Herndon et al.*[62] was later generalized[61,63]. Knowing the relative sizes of the eigenvector coefficients of the dominant HOMO-LUMO interaction, the favored orientation can be predicted. It is determined by the fact that those atoms of diene and dienophile unite which have the greatest and smallest coefficient, respectively, in the HOMO and LUMO. Generalized frontier orbital coefficients for dienes and olefins allow a simple mnemonic rationalization of orientation phenomena. Figure 3 depicts the generalized structures of frontier orbitals of dienes and dienophiles[22,56,61].

A perturbation theory, limited to frontier orbital interactions, can lead at best from a qualitative to a semiquantitative description of reaction patterns. There have been many attempts to extend the perturbational treatments[21]. *Klopman* and *Hudson*[64] developed an equation which enables description, not only of orbital interactions but also charge and steric effects. We undertook similar attempts on the basis of the ZDO approach[65,66]. These attempts were taken up by *Bachler* and *Mark*[67] and applied to specific Diels-Alder reactions[68]. *Salem*[69] enlisted similar considerations and applied them to the dimerization of acrolein[70]. Apart from the recognition that cycloadditions are not solely governed by frontier orbitals, the value of these efforts lies in the fact that specific examples, for instance the dimerization of acrolein[68] or the *endo*-addition of cyclopropene to cyclopentadiene[65], can be investigated more exactly. The interplay of

various factors, such as electronic, polar, and steric effects, can be estimated in this way. Though these numerical methods demand more exact assumptions about the structure of the reaction complex, they do not possess the simple applicability and elegance of the FMO-model.

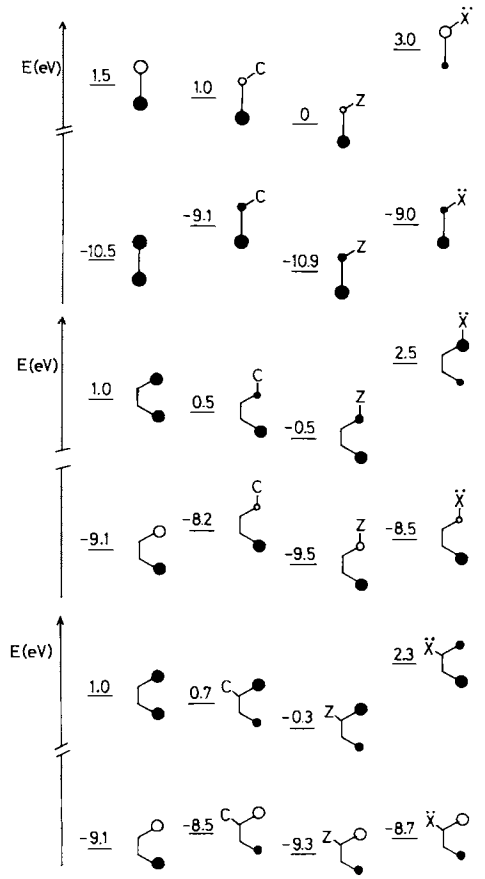

Fig. 3. Generalized frontier orbital energies and coefficients for monosubstituted alkenes (dienophiles) and dienes (C: $CH{=}CH_2$, Ph, *etc.*; Z: CHO, CN, *etc.*; X: alkyl, OR, NR_2, *etc.*).

The easier applicability of qualitative, theoretical concepts led to a further development of the ideas of *Woodward* and *Hoffmann*. *Halevi*[71] introduced the OCAMS method, which, as an orbital correlation procedure, does not lead to any fundamentally new conclusions for the Diels-Alder reaction. Interesting is the remark[72,73] that particularly the interaction of antisymmetric frontier orbitals should favor the concerted character of Diels-Alder additions. This concept would predict for the normal Diels-Alder addition a higher degree of synchronous character than for the cycloaddition with an inverse electron demand.

An exact description of the course of a cycloaddition demands an investigation of the energy hypersurface. The necessity of theoretical investigations of energy hypersurfaces was first demonstrated in the field of photochemical reactions[74,75], but in the meantime it has also proved to be a valuable extension to our theoretical interpretations of ground state reactions[75-77]. There have been several attempts to understand these problems in a quantitative manner[66,78-81]. These efforts are based essentially on the description of the reaction course as a linear combination of various electron configurations of the reaction complex [eq. (d)].

$$\Psi_{KL} = C_0\Psi_0 + \sum_{m(K)}^{occ.}\sum_{p(L)}^{unocc.} C_{m\to p}\cdot\Psi_{m\to p} + \sum_{p(L)}^{occ.}\sum_{m(K)}^{unocc.} C_{p\to m}\Psi_{p\to m} + \sum_{i(K)}^{occ.}\sum_{j(K)}^{unocc.} C_{i\to j}\Psi_{i\to j} + \sum_{r(L)}^{occ.}\sum_{s(L)}^{unocc.} C_{r\to s}\Psi_{r\to s} \quad (d)$$

Ψ_0 comprises only the molecular orbitals of the two cycloaddition partners K and L being occupied in the ground state. The second and third term of eq. (d) consist of contributions of electron configurations in which an electron has been transferred from K to L or L to K, the so called charge-transfer configurations. The last two terms of the linear combination include locally excited configurations. Each configuration in the equation is provided with a coefficient C, indicating the square of the weight of this configuration in the linear combination. This formalism can be evaluated and leads to formulas applicable for calculations[66,78].

Of great importance, is the fact that we can gain an understanding of the reaction course from the qualitative analysis of this formalism[77]. Figure 4 illustrates this by an example. For the sake of simplicity Ψ_{KL} is supposed to be a linear combination only of the ground state configuration and a charge-transfer configuration. The full lines show the energies of the configurations Ψ_0 and $\Psi_{K^+L^-}$ as a function of the separation R of the molecules K and L; these we can designate as a diabatic potential hypersurface[77]. Configuration interaction (CI) results in the adiabatic reaction course drawn with dotted lines. E_a is the activation energy of the reaction.

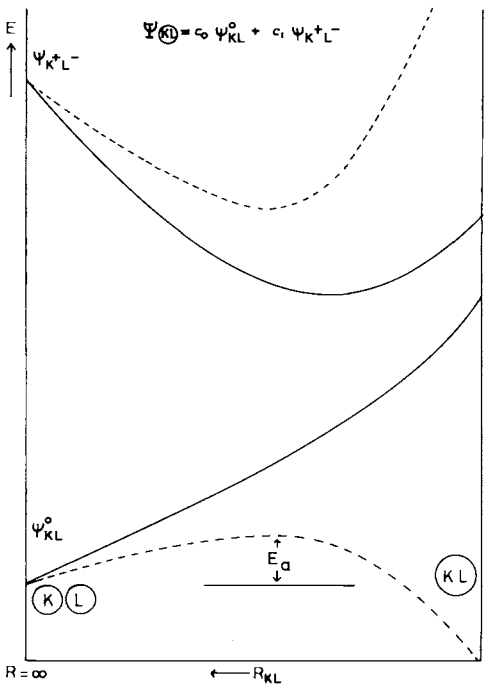

Fig. 4. Energies of the ground state configuration Ψ^0_{KL} and of a CT-configuration $\Psi_{K^+L^-}$ as a function of the separation R of K and L (full lines). Dotted lines: energy after configuration interaction (CI) between Ψ^0_{KL} and $\Psi_{K^+L^-}$

In the case of $R=\infty$, $\Psi_{K^+L^-}$ possesses a certain energy which must be on a higher level than Ψ^0_{KL}, because energy has had to be taken in order to transfer an electron from K to L. The complex $\Psi_{K^+L^-}$ is a radical ion-pair, whose energy content decreases with decreasing distance owing to the Coulomb-attraction; after passing through a minimum the ener-

gy increases again owing to steric interactions. The energy difference between Ψ^0_{KL} and $\Psi_{K^+L^-}$ corresponds to the charge-transfer excitation energy, which is thus a function of the separation of K and L. The dotted lines indicate that the mutual interaction of the two configurations leads to a stabilization and destabilization, respectively. Two states are arising; each of them contains, either in bonding or anti-bonding manner, a small amount of the other electron configuration. The size of E_a, that is the turning point of the lower, dotted curve depends on the energy separation between Ψ^0_{KL} and $\Psi_{K^+L^-}$. The smaller this is, the lower is E_a. At this point the relationship between FMO-model and CI-method becomes evident.

The FMO-model uses properties of the ground states of K and L for the discussion of the reactivity, which is identical with the assumption of an infinite separation of the reactants. In the extended model the contributions of the different configurations to the total energy are computed assuming a finite distance[79, 80]. Applications of these procedures to cycloadditions have already been described[66, 79, 81].

The chemist has already developed a feeling for orbitals and orbital correlation diagrams; it is essential that he now also gains a qualitative understanding of states and state correlation diagrams. Furthermore, apart from the aspect of correlation, an understanding of the energetics and the possibilities of influencing them must be fostered. Contributions to a qualitative understanding of energy hypersurfaces have recently been reported[82].

2.2. Thermochemical Analysis and Empirical Exploration of Hypersurfaces

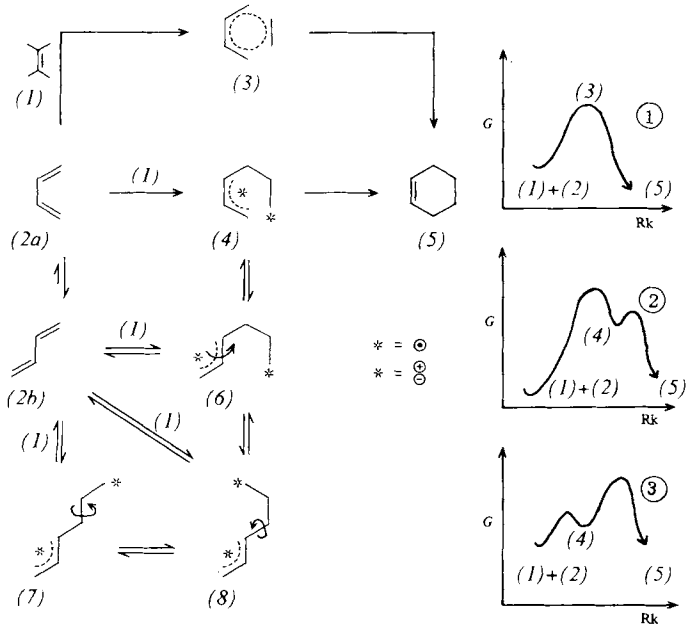
After exact execution, the quantum-chemical scanning of an energy hypersurface supplies its precise shape. The pathway of lowest energy from starting compounds to end products defines the mechanism. The thermochemical analysis of reactants, intermediates, and end products offers another possibility of determining specific points of the hypersurface. With the aid of these distinct positions an approximate hypersurface can be constructed. Since the thermochemical increments for enthalpies of formation of isolated molecules are applicable in the vapor phase, only a comparison with experimental values obtained in the vapor phase is possible. This method was mainly developed by *Benson*[83].

In the meantime, there are many examples of such a treatment of Diels-Alder additions and retro-Diels-Alder reactions. The mechanistic alternative to the concerted reaction in the vapor phase is the reaction *via* a biradical. Thus, arguments focus on the question whether experimentally obtained activation parameters are in agreement with thermochemical data for a biradical mechanism. Table 1 lists Arrhenius parameters for Diels-Alder reactions in the vapor phase.

Whereas the data for the reaction of cyclopentadiene with acetylene and ethylene seem to be interpretable in the sense of a concerted process[83, 96, 97], and *Frey et al.* draw the same conclusions for the reaction of butadiene with ethylene[98], the reactions of cyclohexadiene with propene and with acrolein are interpreted as two-step processes[93–95]. Opinions about the dimerization of butadiene are varied[5, 84–86, 99]. Also the dimerization of *cis,cis*-1,4-dideuterio-1,3-butadiene—the stereochemistry of the adducts was investigated in this system—did not enable a definite decision[100]. For the dimerization of *trans,trans*-deuterio-1,3-pentadiene[101], however, the concerted character of the reaction seems to be the most plausible interpretation for the formation of the Diels-Alder adduct. This short discussion already shows the difficulties of this method, and the quotation of *Benson* seems appropriate at this juncture[83]: "Thermochemical analysis can be definitive in demonstrating the incompatibility of a biradical path with observed Arrhenius parameters, but it cannot prove the occurrence of a biradical path. It can only demonstrate the compatibility of kinetic parameters with thermochemical data".

A conclusion can be drawn from the existing investigations. The concerted reaction pathway and the biradical

Table 1. Arrhenius-parameters for Diels-Alder Reactions in the gas-phase.



Diene	Dienophile	T [K]	log$A$ [l mol^{-1} s^{-1}]	E_A [kcal/mol]	Ref.

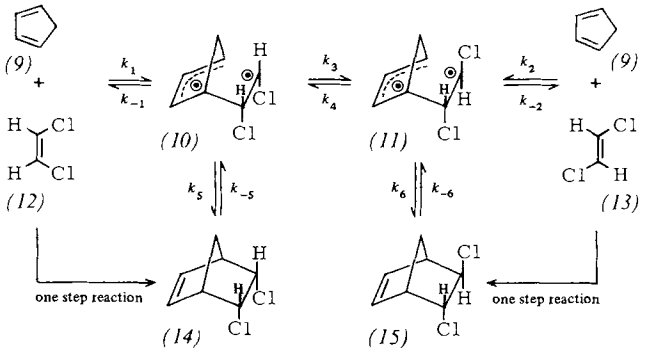
Cyclopentadiene	Ethylene	521—570	7.59	23.7	[97]

mechanism in some of the cases examined—formal Diels-Alder reactions—are very similar energetically, so that a traversing of both kinds of reaction paths seems to be possible, depending on the structure of the reactants. It seems at least questionable whether all these reactions can be described by one and the same mechanism.

In connection with thermochemical procedures there are those which describe the energy hypersurface by means of empirical mathematical functions[102,103]. Starting from fixed points on the hypersurface, an attempt is made to establish the reaction coordinate by means of the experimentally obtained activation parameters. This results in determining the fraction of various "limiting mechanisms" in the true reaction course. As an empirical method this procedure seems attractive, but it is not very clear to what extent mechanistic conclusions are permitted. *Gajewski*[104] has recently analyzed the reaction of cyclopentadiene with cyanoethylenes in this way.

3. Stereospecificity of Diels-Alder Reactions



A simultaneous closure of the two new σ-bonds between diene and dienophile, with involvement of a transition state *(3)*, predicts a stereospecific reaction (Scheme 1, energy profile 1). A two-step mechanism with a zwitterionic or biradical intermediate *(4)* (Scheme 1), however, leads to a non-stereospecific reaction if rotations about single bonds in the intermediate *(4)* (Scheme 1) are faster than ring closure to the cycloadduct (energy profiles 2 and 3); if, on the other hand, rotations are slower than the very fast ring closure reaction, also a two-step reaction can take place stereospecifically. Thus a two-step reaction does not exclude *a priori* a stereospecific reaction.

Scheme 1.

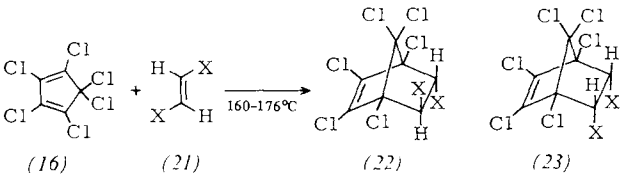
Apart from the possibility of a reaction of the *s-cis* diene *(2a)*, Scheme 1 shows also the reaction of the *s-trans* diene *(2b)*. This reaction pathway cannot be excluded *a priori*, for most open-chain dienes exist mainly in the *s-trans* configuration. But, if cycloaddition of the *s-cis* form is 100 times faster and the *s-cis*→*s-trans* transformation occurs rapidly, this reaction pathway should not be realized. After attack of an olefin at the *s-trans* form the formation of a six-membered ring cannot take place in one step; biradicals or zwitterions must be the intermediates. To attain the conformation *(4)* favorable for ring closure, rotations about single bonds in *(7)* and *(8)*, and about an allylic bond in *(6)* have to take place. Whereas the first are energetically favorable, the latter have to surmount higher barriers. This however depends also on whether it is a radical[105] or an ionic allyl structure[106,107]. Since the rotation about the allylic bond in *(6)* needs more energy than rotation about single bonds in this molecule the [4+2]-addition *via* this route should be non-stereospecific.

The above statement is illustrated by the cycloaddition of the stereoisomeric 1,2-dichloroethylenes *(12)* and *(13)* to cyclopentadiene *(9)*[108] (Scheme 2). On starting from pure *cis*- and *trans*-dichloroethylene *(12)* and *(13)*, no stereochemically "false" [4+2]-adduct could be detected within the error

Scheme 2.

limit of gaschromatography (0.5%) at 180 °C; this observation is consistent with simultaneous bond formation. The presence of biradical intermediates *(10)* and *(11)*, respectively, not improbable energetically, is thus rather unlikely; k_3 and k_4 would have to be considerably smaller than k_5 and k_6.

Halogenated olefins take a special position with respect to cycloadditions to dienes; six-membered ring products as well as four-membered ring products are formed to various extents by way of biradical intermediates. In connection with the problem of one-step *versus* two-step formation of the six-membered ring product, the additions of *cis*- and *trans*-1,2-dichloro-1,2-difluoroethylene to *trans,trans*-2,4-hexadiene[109] are of great importance. It could be unequivocally demonstrated that the six-membered ring products, formed to 16.8% and 19.4%, respectively, were formed not only in a synchronous (85%) but also in a two-step process (15%) (see Scheme 14). Comparison of the partial loss of stereochemistry of the dienophile in the product with the corresponding results in the purely biradical cycloaddition of the same dienophiles to butadiene clearly shows that in these reactions the energy surfaces of both reaction pathways are comparable. In spite of the partial two-step reaction, the stereochemistry of the *trans,trans*-2,4-hexadiene is completely preserved in the adduct. This is an example for a reaction in which one rotation, namely about the C—$\overset{\ominus}{C}$ClF bond, is faster than the ring closure, and another rotation, about the



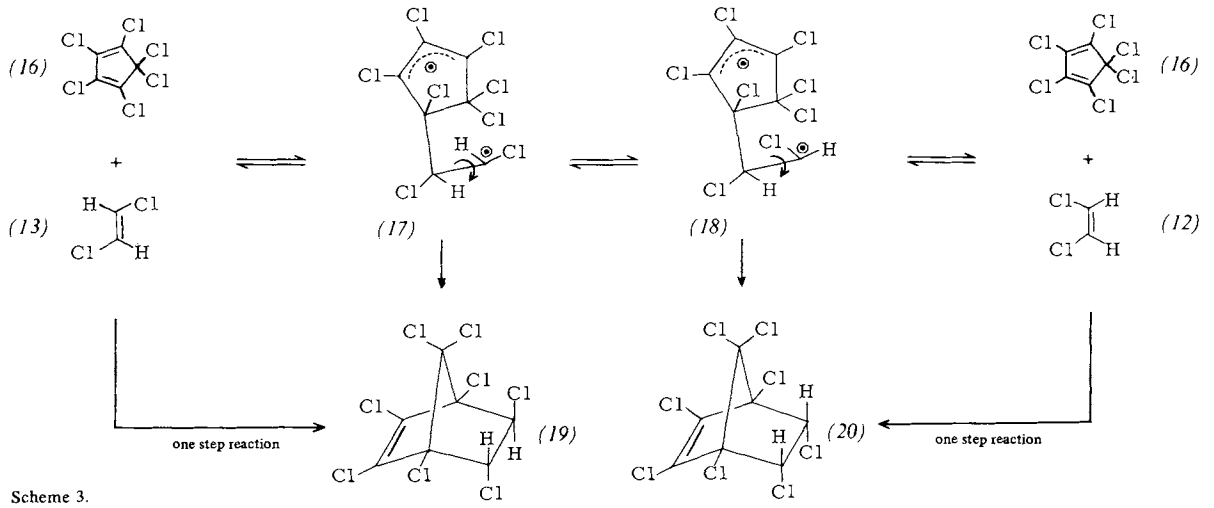
C—$\overset{\oplus}{C}$HCH $\cdot$CHCH$_3$ bond, is slower than the ring closure (see Scheme 14).

A perusal of the literature[3,4,36] shows, however, that only few Diels-Alder reactions have been investigated so precisely from the stereochemical standpoint. The proof of stereospecifity for many cycloadditions of this type refers to only 90–95%, which corresponds to the isolated yield of the pure product; however, this does not necessarily mean that the mother liquor contains the "wrong" stereoisomer, proving a two-step reaction. In any case more precise investigations of selected systems with improved analytical procedures would be desirable. With the above restriction, however, *the stereospecific [4+2]-cycloaddition in Diels-Alder reactions seems to be the rule,* as is proven by a plethora of examples.

When can one expect the two-step mechanism, and thus perhaps a non-stereospecific reaction? According to what has been mentioned in Section 2.1.3 the symmetry allowed suprafacial-suprafacial cycloaddition is fast if the separation $HOMO_{diene}$-$LUMO_{dienophile}$ or $LUMO_{diene}$-$HOMO_{dienophile}$ is small and the steric conditions allow a cisoid conformation of the diene and thus a smooth reaction in the 1,4-position.

Conversely, a large HOMO-LUMO separation as well as unfavorable steric factors slow down the rate of the synchronous reaction to such an extent that perhaps a slower two-step reaction becomes possible. Also substituents capable of stabilizing intermediates will favor the two-step mechanism; the small influence of solvents on the reaction rate in Diels-Alder reactions (Section 5.3) excludes completely zwitterionic intermediates. The examples, already described in the literature concerning non-stereospecific Diels-Alder additions seem to confirm these considerations. Similar arguments are given by *Houk*[55].

these results on the basis of biradical intermediates *(17)*⇌*(18)* would seem obvious. The geminal position of two bulky chlorine atoms in hexachlorocyclopentadiene *(16)* impede a synchronous [4+2]-cycloaddition; furthermore, the substitution by chlorine should increase the stabilization of the intermediates *(17)* and *(18)*. The steric factor mentioned here is also shown in the breakdown of the relation of reactivity and selectivity on going from 1,2,3,4-tetrachlorocyclopentadiene to hexachlorocyclopentadiene[111].

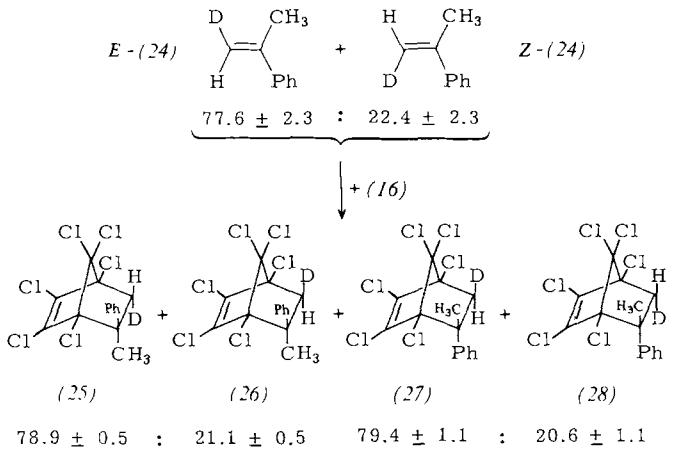


(16) *(21)* *(22)* *(23)*

Scheme 4.

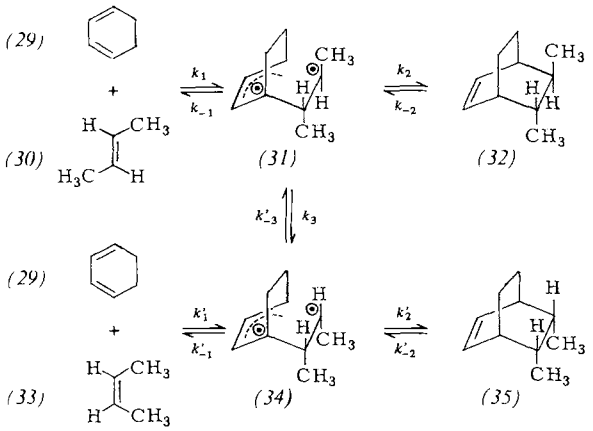
(21), X=	*(22)* :	*(23)*
Cl [≡ *(13)*]	5 [≡ *(19)*] :	95 [≡ *(20)*]
CN	57 :	43
C_6H_5	71 :	29
CO_2CH_3	73 :	27
CH_3 [≡ *(30)*]	≈100 :	≈ 0

The non-stereospecific reaction of dichloroethylene as dienophile is not a singular example[110]; the values in the Table under Scheme 4 show the effect in a slightly reduced way for fumaronitrile, stilbene, and fumaric acid dimethyl ester; only *trans*-2-butene reacts in a stereospecific way. All dienophiles, except 2-butene, possess electron withdrawing substituents,



(16) *(13)* *(17)* *(18)* *(16)* *(12)* *(19)* *(20)*

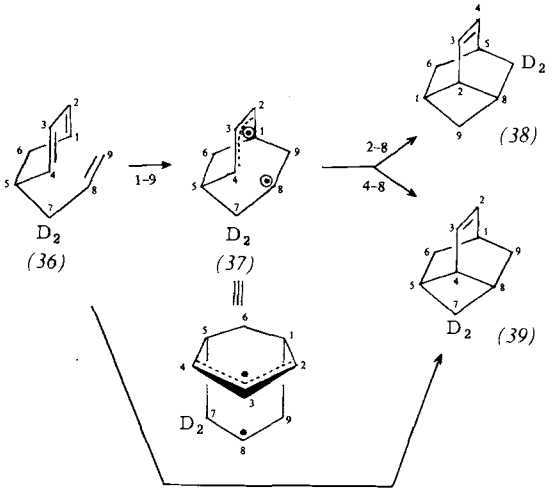
Scheme 3.



Mark[110] found that the kinetically controlled reaction of hexachlorocyclopentadiene *(16)* with *trans*-1,2-dichloroethylene *(13)* affords the [4+2]-adducts *(19)* and *(20)* in the ratio 5:95; recovered dichloroethylene contained 39% *cis*-isomer *(12)* (Scheme 3).

The Diels-Alder reaction of *(16)* and *(12)*, on the other hand, leads exclusively to *(20)* together with very small portions of the *cis-exo*-isomer; a *cis-trans* isomerization of unreacted dienophile *(12)* did not take place. An explanation of and in each case good radical stabilizers. It is difficult to make the above discussed steric effects responsible for the non-stereospecific reaction of fumaronitrile. An alternative explanation is provided by the assumption that combination of an electron deficient dienophile with an electron deficient diene (see Section 2.1.3) handicaps the one-step reaction as a result of the large HOMO-LUMO separation; moreover in this special case, steric factors as well as substituents favor a reaction *via* a biradical intermediate.

Scheme 5.



Interestingly, the cycloaddition of a mixture of 77.6 ± 2.3% *E*- and 22.4 ± 2.3% *Z*-β-deuterio-α-methylstyrene *(24)* with hexachlorocyclopentadiene *(16)* proceeds, within the limit of error, stereospecifically to the four products *(25)*—*(28)*[108, 112] (Scheme 5). Regarding the data of Scheme 3 we are not able to decide whether these results can be interpreted in favor of a simultaneous bond closure or whether the intermediates *(17)*/*(18)*, formed by analogy, close the ring faster than they interconvert by rotation (*(17)*⇌*(18)*).

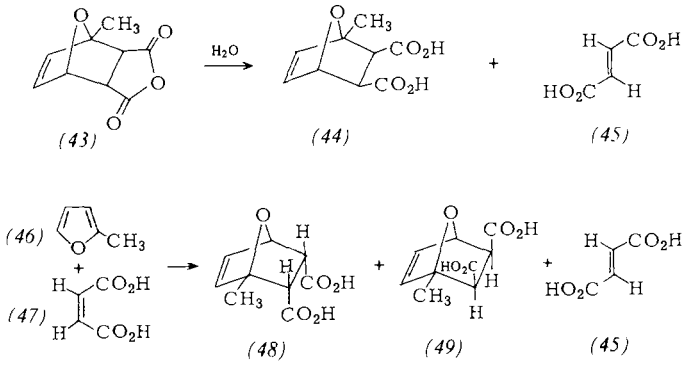
Scheme 6.

	(31)	(34)
Cycloreversion / Ring closure	$\frac{k_{-1}}{k_2} = \cong 220$	$\frac{k'_{-1}}{k'_2} \cong 25$
Cycloreversion / Rotation	$\frac{k_{-1}}{k_3} \cong 100$	$\frac{k'_{-1}}{k'_3} \cong 6.6$

Also the cycloaddition of *cis*- and *trans*-2-butene *(30)* and *(33)*, respectively, to 1,3-cyclohexadiene and the cycloreversion of the Diels-Alder adducts *(32)* and *(35)* seem to be partially non-stereospecific[113] (Scheme 6). The kinetically controlled cycloaddition was followed to 2% conversion, the cycloreversion to 6% conversion. In the authors' opinion the accurate gaschromatographic analysis supports the kinetic system of Scheme 6 with biradical intermediates *(31)* and *(34)*. Interestingly the reverse reaction of the intermediates to the educts is faster than the ring closure (see energy profile 3, Scheme 1) and likewise faster than rotations *(31)*⇌*(34)*. Also in the case of the reaction of 1,3-cyclohexadiene and 2-butene we are dealing with a system with large HOMO-LUMO separation favoring according to the above mentioned ideas a successful competition of a two-step mechanism with a symmetry allowed one-step cycloaddition; the high reaction temperature (327 °C) certainly also favors the two-step mechanism over the one-step addition with notoriously small $\Delta H^{\neq}$-values. The relatively easy reverse reaction of the intermediates *(31)* and *(34)* explains the *cis-trans*-isomerization of *(30)* and *(33)*, observed by the authors in the presence of 1,3-cyclohexadiene.

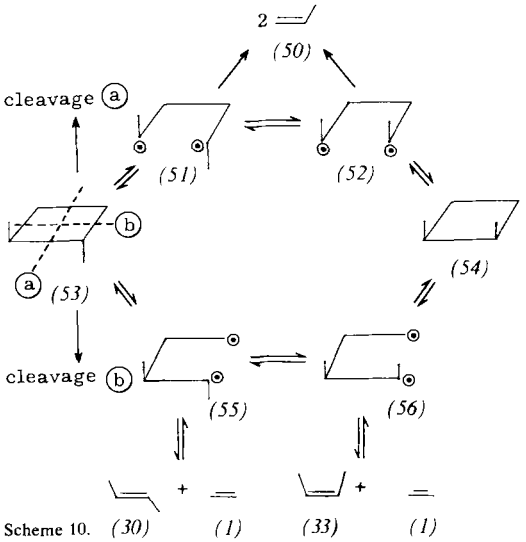
Scheme 7.

A large HOMO-LUMO separation does not guarantee a two-step mechanism, as is shown by interesting experiments by *Krantz*[114] (Scheme 7). The 5-allyl-1,3-cyclohexadiene *(36)* dideuteriated in position 7 yields exclusively the [4 + 2]-adduct *(39)* at 184 °C, corresponding to synchronous bond formation in position 1—9 and 4—8. A symmetrical, biradical intermediate *(37)* would lead to a 1:1 distribution of the D-labels [*(38)* + *(39)*]. Estimations of the rates indicate that the two-step mechanism at 184 °C is less favorable by about 4 kcal/mol. At higher temperatures a slight distribution of the labels can be observed, which, in the opinion of the author, must not be exclusively explained in terms of biradical intermediates.



Scheme 8.

The mechanisms of dimerization of 1,3-dienes have been investigated intensively[99]. According to investigations by *Stephenson et al.*[100] the dimerization of the specifically deuteriated butadiene *(40)* does not lead exclusively to the products *(41)* and *(42)* (Scheme 8), corresponding to the one-step

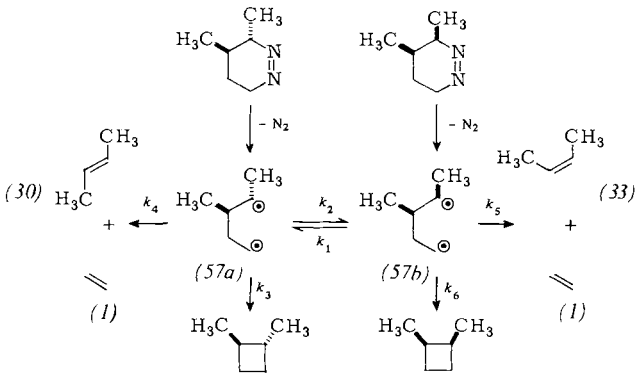


mechanism, but also to about 10% of a cycloadduct which has the vinyl group and the deuterium in positions 4 and 5 in *trans*-orientation. Although an explanation by way of a biradical intermediate is in principle possible, the authors discuss also a forbidden $[_{\pi}4_s + _{\pi}2_a]$ reaction. Even a seemingly slight structural variation of the diene, however, leads to a completely stereospecific reaction, as *Berson et al.* convincingly showed by means of *trans*-1-deuterio-1,3-pentadiene[115]. A dimerization with biradicals as intermediates is suggested for 1,3-diphenyl-substituted butadienes. An accelerating factor $>10^6$ compared with the dimerization of the unsubstituted butadiene is not compatible with a synchronous mechanism[116].

A final example of a non-stereospecific cycloaddition and cycloreversion is taken from the reactions of substituted furans (Scheme 9), whose reversible cycloadditions with maleic

Scheme 9.

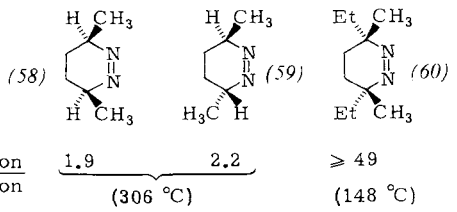
anhydride and its derivatives are well known[117]. Thus, the cycloaddition of maleic acid to 2-methylfuran affords, besides the expected *endo*- and *exo*-adducts *(48)* and *(49)*, up to 17% fumaric acid *(45)*, which is also formed during the hydrolysis of the *exo*-maleic acid anhydride adduct *(43)*. In the analogous reactions of furan itself and its 2,5-dimethyl derivative, on the other hand, *no* fumaric acid is formed. The authors would explain this *cis-trans*-isomerization in terms of a reversible formation of a zwitterionic intermediate. The alternative explanation—by an isomerization as consequence



Scheme 10.

of a Michael-type addition in competition with the cycloaddition—can in our opinion not be ruled out, according to the experimental data.

Whereas in the case of the *symmetry allowed [4+2]-cycloadditions* the *stereospecific* reactions, as already mentioned, represent the *normal case,* and the above discussed *non-stereospecific* ones seem to be the exception, the non-stereospecific reaction in accordance with the Woodward-Hoffmann rules seems *to be the rule for [2+2]-cycloadditions.*

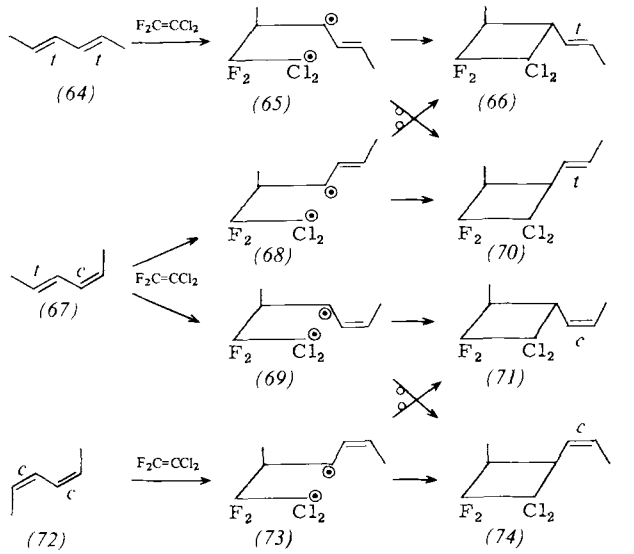


The cycloadditions of ethylene *(1)* to *cis*- and *trans*-2-butene *(33)* and *(30)*, respectively[118], as well as the cycloreversion reaction of the corresponding cyclobutane derivatives[119] have been intensively investigated in the vapor phase at 400 °C. The exact analysis of the kinetic data and product studies support Scheme 10; again rotations can compete in the biradical intermediates, not only with ring closure to the cycloadduct but also with the cleavage to the educts. The independent formation of the same biradical intermediates by thermolysis of cyclic azo compounds under the same conditions leads to the same mechanistic conclusions[120] (Scheme 11). The rate of rotation in the biradical

Scheme 11.

	(57a)	(57b)
Cleavage / Ring closure	$\frac{k_4}{k_3} = 1.4$	$\frac{k_5}{k_6} = 1.8$
Ring closure / Rotation	$\frac{k_3}{k_2} = 1.9$	$\frac{k_6}{k_1} = 0.7$

depends on its structure; progressive alkyl substitution of the radical centers hinders the rotation, as shown by the increase in the ratio retention/inversion for the formation of cyclobutane in the thermolysis of azo compounds *(58)*—*(60)*[120] (Scheme 12). The differing reaction temperatures, however, must be mentioned.



Schema 12

Also the cycloaddition of the isomeric 2-butenes *(30)* and *(33)* to tetrafluoroethylene *(62)*[121] is extremely non-stereospecific (Scheme 13).

Schema 13.

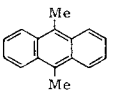
The already classical investigations by *Bartlett*[121,122] have considerably increased our knowledge about the mechanistic course of [2+2]-cycloadditions and also contributed indirectly to the mechanistic conceptions concerning the Diels-Alder reaction. 1,1-Dichloro-2,2-difluoroethylene ("1,1,2,2") reacts with the stereoisomeric 2,4-hexadienes *(64)*, *(67)* and *(72)* in a non-stereospecific way *via* intermediates *(65)*, *(68)*, *(69)* and *(73)* to give the cyclobutane derivatives *(66)*, *(70)*, *(71)* and *(74)*; rotations about single bonds successfully compete with ring closure reactions, the configuration of the allyl radical structure in the intermediates is preserved (Scheme 14)[123]. Kinetic measurements show only very small positive influences of solvents[122] on the reaction rate, consistent with a non-polar biradical intermediate. Competition experiments and a comparison of the relative rate constants so obtained

Schema 14.

with rate constants of Diels-Alder reactions of the same dienes with maleic anhydride (MAA) and tetracyanoethylene (TCNE) reveal obvious differences[124]. This finding is taken as an argument against biradical intermediates in these special cases of [4+2]-cycloadditions, for similar substituent effects would be expected if analogous biradical intermediates did occur (Table 2).

In some cases *Bartlett et al.* observed with "1,1,2,2" and with the stereoisomeric 1,2-dichloro-1,2-difluoroethylenes ("1,2,1,2"), as well as with α-acyloxyacrylonitrile, competing [2+2]- and [4+2]-cycloadditions[125]. Are these two products formed by way of the same biradical intermediate? In all cases a definite decision is not possible; some facts may be cited. Thus substituents in the 2-position of the diene influence in the reaction with "1,1,2,2" the fraction of [4+2]-addition, which increases with the size of the substituent in the diene[126]; also in the Diels-Alder reaction of MAA, *Craig et al.*[127] noticed an increase in rate with increasing size of the 2-substituent. The reaction of cyclopentadiene with the stereoisomers of "1,2,1,2" affords the [2+2]-cycloadduct in a non-stereospecific reaction, whereas it gives the [4+2]-cycloadduct in a stereospecific fashion[121]; in this case a common biradical intermediate must be ruled out. α-Acetoxyacrylonitrile predominantly undergoes a stereospecific [4+2]-cycloaddition with the stereoisomeric 2,4-hexadienes, the fraction of [2+2]-addition is diminished to 0.4%; also in this case [4+2]- and [2+2]-cycloadditions seem to occur *via* different energy profiles.

Apart from biradical intermediates it is also possible to detect zwitterionic ones in [2+2]-cycloadditions[27,28,123]. A non-stereospecific reaction, a strong influence of solvent, and high ρ-values prove beyond doubt the zwitterionic intermediate, for example in the reaction of enol ethers with cyanoethylenes. The fact that the relative reaction rate of cyanoethylenes in [4+2]-cycloadditions can be excellently correlated by the HOMO-LUMO model[23] and that in the analogous [2+2]-cycloadditions this relation fails[128] proves the difference in mechanism (Table 3); the rate-differentiation of cyanoethylenes in the reaction with enol ethers is in complete agreement with the expected stabilization of the zwitterionic intermediate.



The competition between [2+2]- and [4+2]-cycloaddition of 1,1-disubstituted 1,3-dienes *(75)* as well as of *cis*-1-substituted 1,3-dienes often cited in the literature has recently been investigated by *Nishida et al.*[129]. Exact product analyses and kinetic studies, including the dependence of the reaction rate on solvents, are compatible with the mechanistic picture of Scheme 15. The kinetically controlled reaction furnishes, *via* the zwitterionic intermediate *(76)*, the thermodynamically unstable four-membered ring adduct *(77)*, which then trans-

Table 2. Relative rate-constants k_{rel} of different dienes for the [2+2]-cycloaddition with 1,1-dichloro-2,2-difluoroethylene and for the [4+2]-cycloaddition with maleic anhydride MAA and tetracyanoethylene TCNE [124, 125].

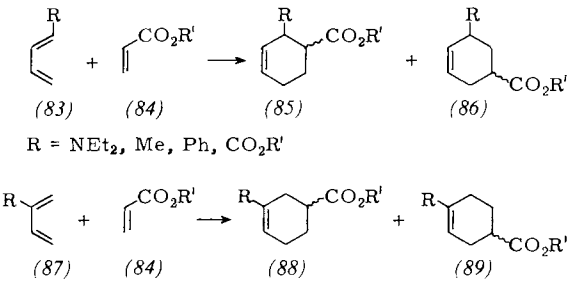
forms into the stable cyclohexene derivative *(78)* by way of *(76)* and *(79)*. The dipole *(76)* could be intercepted by thiophenol; an intramolecular course of the transformation *(77)*→*(78)* is secured. In so far as the [4+2]-adduct, as well as the [2+2]-product, is formed, the fraction of cyclobutane derivative increases with increasing amount of transoid diene-conformer. At high temperature (120 °C, cyclohexane) a cleavage, presumably *via* the diradical *(80)* to *(81)* and *(82)*, is observed.

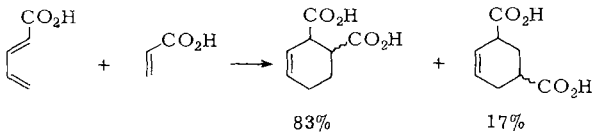


Schema 15.

These results support the concept of four-membered ring formation as consequence of an attack on the transoid diene, as already mentioned in the discussion of Scheme 1. The fact that dienophiles which are very active in normal Diels-Alder additions yield in the reaction with transoid fixed dienes vinyl-cyclobutane derivatives *via* a zwitterionic intermediate, has also been observed in other studies[121,130]. This also conforms with the above discussed halogenated olefins.

4. Regiospecificity of Diels-Alder Reactions

In the same way as the related 1,3-dipolar cycloadditions Diels-Alder additions show a strong preference for the formation of specific regioisomers[3,131,132]. For a long time, efforts have been made to interpret this finding by means of the combination of "electronic" and "steric" effects, however without finding a satisfactory solution. Only the application of simple perturbation theoretical considerations led to a breakthrough[61-63]. The present discussion is based on the generalized frontier orbitals of dienes and olefins by *Houk*[61].

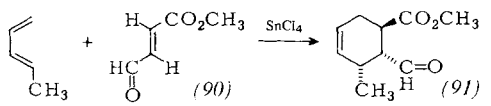


1-Substituted dienes, independently of the nature of the substituent (Scheme 16), preferably give the *"ortho"*-isomer *(85)* with electron-poor dienophiles like methyl acrylate or with phenyl substituted olefins. In contrast, 2-substituted dienes mainly afford the *"para"* isomer *(89)*, also independently of the substituent. All these reactions are $HOMO_{diene}$-$LUMO_{dienophile}$ controlled. By means of Figure 3 it is easily determined which isomer should preferably be formed: the HOMO of the diene has to be brought to an interaction with the LUMO of the dienophile in such a way that the larger and smaller coefficients, respectively, can lie side by side. Instead of considering all four eigenvector coefficients of the reacting C-atoms of HOMO and LUMO one can restrict the discussion to the larger ones[63].

Scheme 16.

The energies of the generalized frontier orbitals by *Houk* have been determined as average values of ionization potentials or electron affinities of appropriately substituted olefins and dienes. The eigenvector coefficients originate from calculations, mainly of the *ab initio* or CNDO/2 type. The eigenvector coefficients calculated according to the Hückel-method[63], conform with the other values, with the exception of electron-poor olefins (Z-substituted) and Z-substituted dienes. The structures of the frontier orbitals of *Epiotis*[133] correspond to those of *Anh et al.*[63]. *Anh et al.* and *Houk et*

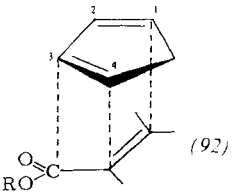
al.[61] arrive at the same conclusions in spite of the discrepancy in the cases already mentioned, *e.g.* for the reaction of 2,4-pentadienoic acid with acrylic acid[134], since evaluation of the two HOMO-LUMO stabilizations in the Hückel-model leads to the same result as consideration of the stronger interaction based on the values of *Houk*.



Epiotis[133], who deduced the preferred orientation solely from the size of the coefficients of the dominant HOMO-LUMO pair and relied upon Hückel-calculations, suggests that the discrepancy between theory and experiment in these cases demands a two-step reaction *via* a biradical. A detailed discussion of the results of various calculation methods for the determination of eigenvector coefficients can be found in ref.[135].

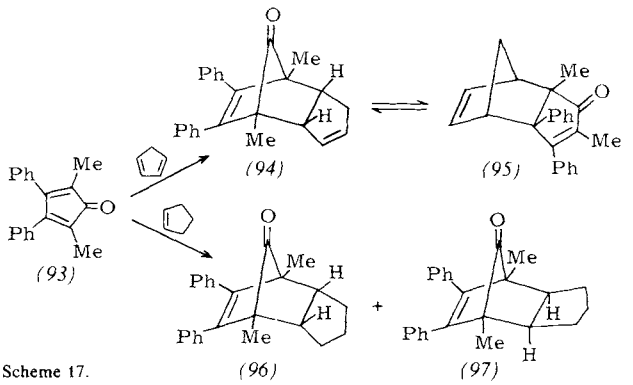
Which mechanistic conclusions enable interpretation of the regiochemistry by means of the FMO-model? Apart from the rare controversial examples, the accordance of FMO theory with experiment lends support for a multicentere mechanism. However, with respect to the different size of the eigenvector coefficients an unsymmetric transition state is suggested even during a simultaneous formation of the new bonds, as postulated by *Woodward* and *Katz*[136]. But this discussion cannot provide a mechanistic decision.

The generalized orbitals discussed by *Houk et al.*[61] are noteworthy, for they are easy to remember. On the other hand, in the case of multisubstitution of the diene or in the case of hetero multiple bonds their applicability is rather limited. Explicit HMO-calculations for a multitude of different dienes and dienophiles, even with hetero multiple bonds as for example in nitroso compounds[137], extend the range of applicability[63]. The qualitative agreement of theory and experiment in more than 100 examples emphasizes the usefulness of FMO-theory for the interpretation of regiochemistry.



At this juncture it might also be pointed out that catalysis by Lewis acids can influence the regiochemistry of Diels-Alder reactions[138]. Thus the reaction of *(90)* with *trans*-1,3-pentadiene under non-catalytic conditions leads to a mixture of three adducts in the proportion 5:3:1. Addition of tin tetrachloride, however, effects exclusive formation of the main isomer *(91)*[139] also formed in the non-catalyzed reaction. The complexing of dienes and dienophiles by Lewis acids changes the energetic position and the structure of the frontier orbitals[140-142], and thus it affects the regiochemistry.

Apart from the relative magnitudes of the eigenvector coefficients of the dominant HOMO-LUMO interaction, secondary orbital interactions are cited as additional modifying factors for the regiochemistry[142-145]. They are supposed to enhance the orientation behavior indicated by primary interactions. The importance of such forces manipulating the regioselectivity is controversial[134].

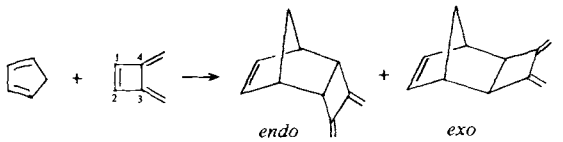


Besides the formation of *"ortho"* or *"para"* products in cycloadditions of unsymmetrical reactants, *Alder et al.* already observed the *preferred formation of endo-addition products*[146]. The experimental facts and attempts at their interpretation have been discussed on several occasions[3,37,131]. In this connection it was also pointed out that the energies determining the steric course of the addition are of the order of 0 to about 3 kcal/mol, corresponding to a 1:1 mixture and to a 100:1 preference for one isomer[3]. It is well known that the *endo/exo* ratios are both solvent[37,147] and temperature dependent[3,148]. The comparative interpretation of experimental data, very often obtained under different conditions, can only be effected very cautiously.

In recent years mainly secondary orbital interactions have been resorted to for such interpretations. This approach was initiated by *Woodward* and *Hoffmann*[149] and taken up by others[70,150,151]. For the normal Diels-Alder addition this

(92)

means that the $HOMO_{diene}$-$LUMO_{dienophile}$ interaction is not only limited to the reacting C-atoms but also includes interactions as are indicated in *(92)* between C-3 and the carboxyl C-atom. The importance of secondary orbital interactions follows from elegant experiments by *Houk*[152] who reacted 2,5-dimethyl-3,4-diphenylcyclopentadienone with cyclopentadiene and with cyclopentene (Scheme 17). Whereas the conjugated diene formed only the *endo*-adduct *(94)*, in the reaction of cyclopentene the two isomers *(96)* and *(97)* are produced in the ratio 1:1. *(94)* is in equilibrium with its rearrangement product *(95)* at higher temperatures.



Scheme 17.

The Diels-Alder addition of 3,4-dimethylenecyclobutene with cyclopentadiene also points to the importance of secondary orbital interactions[153]. The smallness of the eigenvector coefficients in the 3- and 4-position of this triene is regarded as responsible for the fact that the reaction with cyclopentadiene results in a 1:1 mixture of *endo*- and *exo*-compounds.

The exclusive formation of *endo*-adducts in the reaction of cyclobutadienes[154-156] can be explained, on the other hand, by eigenvector coefficients which are increased in the 3- and

4-position. Therefore more intense secondary orbital interactions are possible.

The reaction of maleic acid anhydride with furan did not seem, for a long time, to corroborate the importance of secondary orbital interactions; first of all only the *exo*-product was isolated[157], but later on, however, it was found[158] that both *endo*- and *exo*-product are produced simultaneously and furthermore that the *endo*-adduct rearranged to the *exo*-product by reversible cleavage in the components. Recently, however, it has been shown[117] that the original *endo*-addition takes place 500 times faster than the *exo*-reaction. Thus it seems that secondary orbital interactions decide the regiochemistry also in the case of furan, since steric hindrance by the oxygen atom during *exo*-addition cannot be invoked.

The addition of cyclopentadiene to cyclopentene, resulting only in the *endo*-adduct[159], seems to underline the foremost importance of the CH_2-group of cyclopentadiene as an *endo* directing effect. This influence, which is only sterically justifiable, could perhaps be responsible for the fact that propene supplies mainly *endo*-adduct[160]. Cyclopropene[161] and cyclobutene do not make an exception in this series, as long as they are only substituted at the double bond[162]. But if one introduces substituents into the 3-position of cyclopropene[163-166] and into the 3- or 3- and 4-position of cyclobutene[162,167-169], the situation can change. Bulky substituents impair the formation of the *endo*-transition state such that the less favored *exo*-addition also gets a chance. The fact that the *endo*-addition of cyclopropene is due to steric hindrance in the *exo*-transition state, could be shown by SCF perturbation calculations[65].

The explanation of the orientation behavior in the reaction of cyclopentadiene with the dienophiles listed in Table 4 is controversial. A Japanese research group[170], on the one hand, concludes an attracting interaction between the methyl group of the dienophile and the π-system of the diene from the special position of the methacrylic acid derivatives, *i.e.* from the preferred *endo*-position of the methyl group in the adduct. On the other hand, it has been pointed out[171] that such a special behavior is not observed with 2,5-dimethyl-3,4-diphenylcyclopentadienone *(93)* as diene. It seems that the steric effect of the CH_2-group of cyclopentadiene is responsible for the preference of the *endo*-position of the methyl group. This fact is impressively confirmed by an analysis of the *endo/exo*-selectivity of these dienophiles by *Konovalov et al.*[172]; the *endo/exo*-selectivities found by the Russian group conform with those given in ref.[170]. In Figure 5, $\log k_x$ (k_x = *exo*-addition rate constant) is plotted against $\log k_n$ (k_n = *endo*-addition rate constant)[172]. One can see that the dienophiles of the acrylic acid and crotonic acid type lie on one regression line ($r = 0.997$), while those of the methacrylic acid type (5—8) occupy a special position. Common to all three types is the sequence of relative reactivities. A dotted straight line of gradient 1 is also drawn, which holds for $\log k_n = \log k_x$. It is very interesting that the deviation from the dotted line increases with increasing reactivity. This would point to the previously established higher selectivity at higher reactivity, interpretable by means of the FMO-model. It is important that the *endo/exo*-selectivity is not a phenomenon in itself but is coupled with the absolute reactivity of the dienophiles. The more reactive the dienophile, the greater the differences in the selectivity ought to be. The comparison of crotonic acid with acrylic acid derivatives is

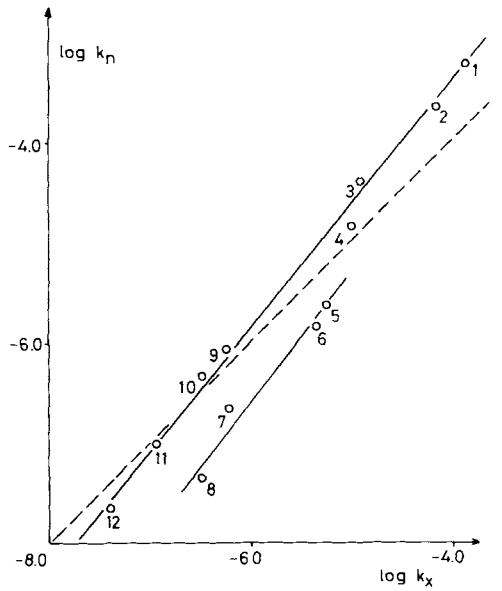


Fig. 5. Plot of $\log k_x$ against $\log k_n$ for the reaction of the dienophiles of Table 4 with cyclopentadiene.

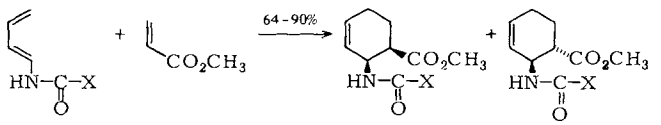
an indication in this direction. The exceptional position of methacrylic acid derivatives is also explained by the Russian authors in terms of the steric effect of the CH_2-group of the cyclopentadiene.



This explanation is confirmed by comparison of the reactivity of 2,3-dimethylbutadiene with the same dienophiles. But there exist arguments against this explanation by means of a steric effect[173], and there are also perturbation-theoretical objections[174].

Another regiochemical aspect of Diels-Alder reactions consists in the observation of *syn-anti*-addition of cyclopentadiene derivatives mono-substituted in the 5-position[175]. The selectivity in these reactions can be influenced by addition of Lewis-acids as catalysts[176]. *Anh*[177] interpreted the experiments by means of steric effects, van-der-Waals-London forces and by orbital interactions.

5. Kinetic Investigations

5.1. Influence of Diene and Dienophile Structure on the Reactivity

The preferred reaction of electron-rich dienes with electron-poor dienophiles with formation of six-membered carbocycles has represented the prototype of these cycloadditions since the original works of *Diels* and *Alder*. Various examples illustrate these facts[3,37,178]. The FMO-model provided a theoretical interpretation, by relating the high reactivity to the dominant influence of the $HOMO_{diene}$-$LUMO_{dienophile}$ separation[23,57]. Equation (c) describes this correlation in a quantitative way disclosing either a linear correlation of $1/(E_{HO(diene)} - E_{LU(dienophile)})$ with $\log k_2$—the latter as a measure of E_A—or a hyperbolic relation of $E_{HO(diene)} - E_{LU(dienophile)}$ with $\log k_2$. Of course in the case of a constant diene or dienophile in a reaction series it is also possible to consider only the orbital energy concerned in the substitution. A hyperbolic correlation was recognized for the reactions of substituted dienes with tetracyanoethylene and maleic anhydride[179]. That this kind of correlation becomes linear in a small section of the hyperbola is demonstrated by the reaction of 1-acylaminobutadienes with methyl acrylate[180].

X = CCl_3, OC_2H_5, OC_6H_5, SC_6H_5, -N⬡

Figure 6 shows the plot of $1/(E_{HO(diene)} - E_{LU(dienophile)})$ against $\log k_2$ for cycloadditions of cyclopentadiene and 9,10-dimethylanthracene, respectively, with cyano-substituted ethylenes[181]; kinetic data elaborated earlier by us[7].

Whereas Figure 6 is a good confirmation of the reactivity model, Figure 7, containing a plot of $\log k_2$ values against $1/(E_{HO(diene)} - E_{LU(dienophile)})$ for cycloadditions of substituted dienes with tetracyanoethylene, seems to contradict it[124]. An exact analysis of the rate data listed in Table 5 solves this problem.

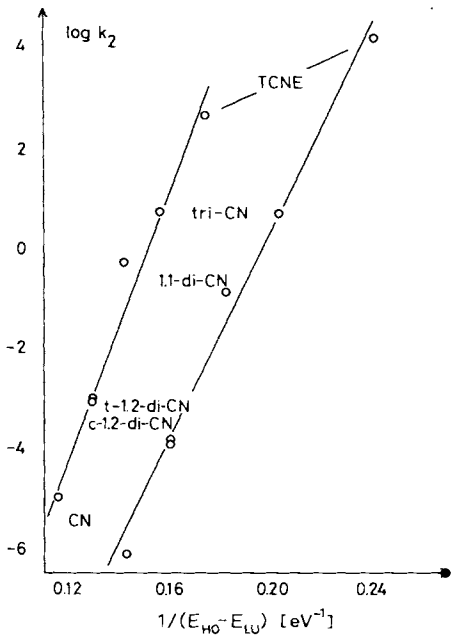


Fig. 6. Correlation of $\log k_2$ (20 °C) against $1/(E_{HO(diene)} - E_{LU(dienophile)})$ for the cycloaddition of cyclopentadiene (left curve) and 9,10-dimethylanthracene (right curve) to cyano-substituted ethylenes [181].

The reactivity in Diels-Alder reactions is not only controlled by orbital interactions but is also influenced by other effects, above all for example, by conformational effects in the diene. *Eisler* and *Wassermann*[182] have already drawn attention to the fact that the equilibrium of *s-cis*- to *s-trans*-diene influences the reaction rate. This holds true irrespective of whether the second conformation—being in equilibrium with the *s-trans*-diene in question—is a *cis*- or a *gauche*-conformation[183]. The dienes of Table 5 carry one or

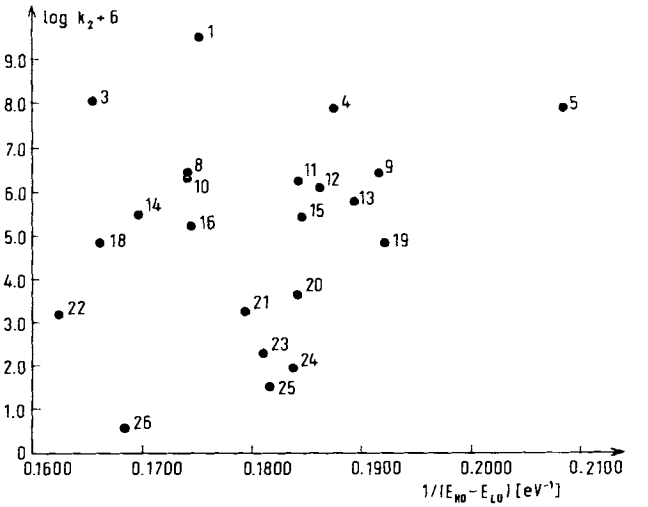

Fig. 7. Plot of $1/(E_{HO(diene)} - E_{LU(TCNE)})$ against $\log k_2$ for cycloadditions of substituted dienes to tetracyanoethylene (for numbering see Table 5).

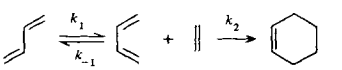

Table 5. Kinetic data for the reaction of substituted dienes with tetracyanoethylene [124] (TCNE) at 20 °C and maleic acid anhydride (MAA) at 30 °C.

[a] k-values in [l mol^{-1} s^{-1}]. [b] The k-values refer to the [4+2]- and [2+2]-cycloaddition.

more substituents in various positions of the molecule or are even cyclic. Hence the energy content of the *s-cis* form and its fraction in the equilibrium are greatly varied and therefore influence the rate. The very small reactivity of *cis*-1-substituted and 1,1-disubstituted dienes emphasizes this finding; for these dienes, however, the question is justified whether actually a *s-cis*-conformation can exist? Why should a [4+2]-cycloaddition not be possible based on a *gauche*-conformation? In connection with these conformational effects it is to be recognized, that as far as *cis*-1-substituted and 1,1-disubstituted dienes are concerned a [2+2]-cycloaddition takes place in competition with a [4+2]-cycloaddition (see Section 3). Figure 8 attempts to illustrate this relationship.

Normally the transition state of the [4+2]-addition is lower than that of the [2+2]-cycloaddition. The dotted lines show how the transition state changes if the *s-cis* form becomes energetically more unfavorable. It then may happen that it is higher or similar in energy to the transition state of the [2+2]-addition, as it originates from the *s-trans* form. [4+2]- and [2+2]-addition then take place in competition. This implies mechanistically that the four-membered ring formation does not result from the cisoid diene. This seems to be plausible because the transition state of the four-membered ring formation originating from the *s-cis* diene ought to be energetically higher by an amount which corresponds to the energy difference between *s-cis* form and *s-trans* diene and therefore should not be competitive.

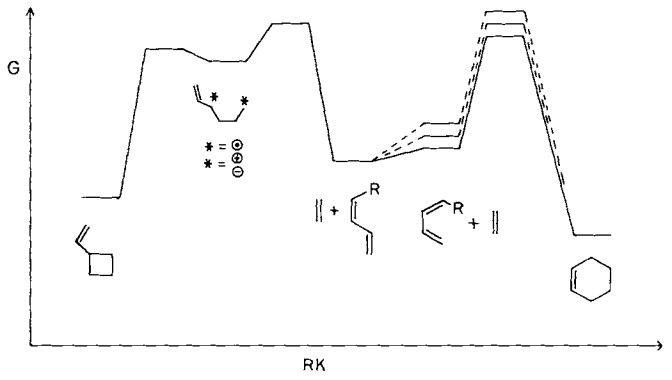

Fig. 8. Influence of the energy content of the *s-cis*-form of dienes on the ratio of a four-membered to six-membered ring formation, schematic (see text; R has been omitted from the products).

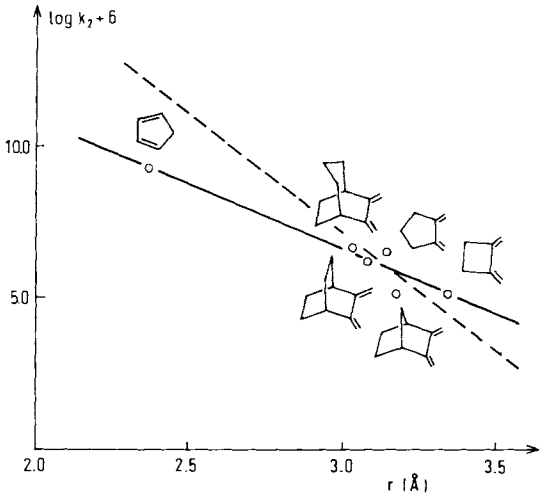
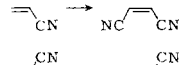
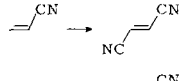
Is a mechanistic implication contained herein? Primarily not; however, a zwitterionic reaction path was definitely proved for the [2+2]-addition of a transoid fixed diene with TCNE by the kinetic investigations of *Huisgen* and *Ortega*[130]. Similar results were obtained in stereochemical investigations by *Bartlett* on [2+2]-cycloadditions which take place *via* biradicals[121]. *Stewart*'s observation[184] that the portion of four-membered ring product in the reaction of 4-methylpentadiene (1,1-dimethylbutadiene) with TCNE increases if the solvent polarity rises, indicates that the four-membered ring and the six-membered ring originate from two different path ways. The fact that cisoid fixed dienes in the reaction with TCNE do not produce any four-membered ring product points in the same direction.

The $\log k_2$-values of the reaction of cisoid fixed dienes with TCNE depend on the 1,4-distance in the diene[185,186]; they can be correlated linearly with this distance[186] (Fig. 9). Variation of the 1,4-distance by more than 1.0 Å leads to changes of several powers of ten in the reaction rate. The regression line is obtained by incorporating cyclopentadiene, the dotted line results when cyclopentadiene is omitted. The dotted line supports the fact that cyclopentadiene ought to react faster by virtue of its 1,4-distance. Obviously the CH_2-group is a handicap. The functional relationship of 1,4-distance and reaction rate can be a hint of a concerted cycloaddition. In the transition state, the *interaction with both centers*







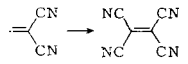


Fig. 9. Dependence of $\log k_2$-values on the 1,4-distance in dienes in the reaction with TCNE.

forming the new σ-bonds is important. This is in accordance with the FMO-model. This finding is only compatible with a two-step mechanism, if the ring closure of zwitterionic intermediate or a biradical is rate determining. However, experimental verifications of this possibility do not exist.

The kinetic data of Table 5 provide further support for the significance of the FMO-model. The higher reactivity of 1-substituted compared to the corresponding 2-substituted dienes results directly from the fact that the diene-HOMO has a greater eigenvector coefficient in the 1- than in the 2-position[57, 124].

Does the fact that the kinetic data for normal Diels-Alder reactions can be interpreted by the FMO-model, suggest the synchronous character of the cycloaddition? At least the example of cyano-substituted ethylenes shows that a cyano substituent influences the rate of a two-step four-membered ring cycloaddition[104] differently than in the Diels-Alder reactions: here one does not find a linear correlation between $\log k_2$ and the inverse HOMO-LUMO separation. *Huisgen et al.*[128] even see this different behavior as a new mechanistic possibility for differentiating between synchronous and multistep reactions.

Table 6. [4 + 2]-Cycloadditions of cyclopentadiene and 9,10-dimethylanthracene (20 °C, dioxane): influence of substituents on variation of the dienophile [7, 8, 97].

No.	Dienophile-Variation 1→2	k_2/k_1 for reaction with Cyclopentadiene	9,10-Dimethyl-anthracene
1		117000	—
2		88	147
3		78	156
4		44000	143000
5		10	46
6		≈950	100000

In the literature[19] kinetic data of the reaction of cyanoethylenes with dienes[7] were valued as proof for a biradical intermediate within the scope of a two-step mechanism. Table 6 contains the k_2-values, quoted as they are in ref. [7], in the form of rate ratios k_2/k_1 on successive introduction of nitrile functions into the dienophile. The k-value for the reaction of cyclopentadiene with ethylene was computed from data in ref. [97]. Without doubt, an unsymmetrical substitution of the dienophile (No. 1 and 4, Table 6) has the greatest influence on the ratio k_2/k_1 and seems to call for a biradical intermediate. However, the FMO-model supports the same effect as consequence of the reduction of the HOMO-LUMO separation and the modification of the eigenvector coefficients. A substitution of the second dienophilic C-atom (No. 2, 3, 5, and 6 in Table 6) is also linked to a rate increase; furthermore, in agreement with the FMO-model, the greater effect is observed for the more reactive diene. In the case of a biradical intermediate one should expect a decrease in the ratio k_2/k_1 due to loss of conjugation.

Table 5 contains $\log k_2$-values not only for the reaction of dienes with TCNE but also with maleic acid anhydride (MAA). Generally one finds, that the differences in reactivity for the dienes is smaller for MAA as dienophile than for TCNE. Similar results are obtained in the cycloaddition of substituted anthracenes with MAA[187] and TCNE[188]. Here, a higher selectivity at higher reactivity is reflected; it can be interpreted by the FMO-model[23]. Russian authors[189] arrived at the same conclusions for Diels-Alder reactions of acenes with *N*-arylmaleimides. This behavior deviates from normal reactivity-selectivity relationships (for a discussion see [190]).

Decreasing reactivity in normal Diels-Alder reactions as a consequence of the increasing orbital-energy separation $HOMO_{diene}$-$LUMO_{dienophile}$ signifies an increasing energy of the energy hypersurface. The contribution of the CT-configuration to the energy surface, which connects educts with products, diminishes. As a consequence it may be that alternatives on the potential energy surface become feasible and the original reaction path is prevented. Perhaps it is possible in this way to interpret the behavior of halogenated olefins, whose cycloadditions have been investigated by *Bartlett et al.* in a series of elegant studies[109, 121]. The promotion of the synchronous pathway by CT-interaction, as given for TCNE, does not exist anymore. However halogens, particularly the higher ones, have a marked ability to stabilize radical centers. Hence the direct, concerted route to the products is hindered, whereas the route *via* a biradical offers a favorable alternative. Unlike the findings in the reaction of TCNE with 1,1-disubstituted dienes[124, 129, 191], where the six-membered ring is formed without a zwitterionic intermediate, the results of the reaction of 1,1-dichloro-2,2-difluoroethylene with butadiene and 2,4-hexadienes[109] point to the six-membered rings arising at least partly by way of a biradical. The reaction coordinate might be similar to that in Figure 10.

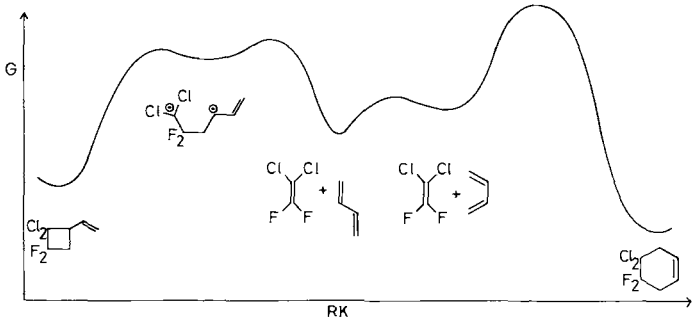

Fig. 10. Reaction coordinate for the reaction of 1,1-dichloro-2,2-difluoroethylene with butadiene.

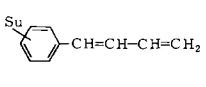
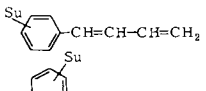
The reactivity of dienophiles, and thus their selectivity, can often be enhanced by Lewis-acid catalysts. The numerous results collected by *Inukai* and *Kojima*[192] can be interpreted by means of the FMO-model[140, 141]. Complexing of the dienophiles with Lewis-acids has the effect of a strong electron withdrawing substituent, decreasing the LUMO level and thereby reinforcing the $HOMO_{diene}$-$LUMO_{dienophile}$ interaction.

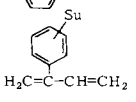
5.2. Normal, Neutral, and Inverse Diels-Alder Reactions

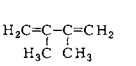
As already mentioned in Section 2.1.3 (see also Fig. 1) one has, in principle, to expect three different types of cycloadditions according to FMO-theory:

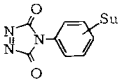
Normal reactions (Type I) with $HOMO_{diene}$-$LUMO_{dienophile}$-control.

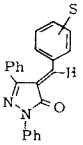


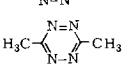












Neutral reactions (Type II), in which both HOMO-LUMO interactions must be considered; the characteristic of this reaction type is that not only the introduction of electron releasing substituents but also substitution by electron withdrawing groups in diene or dienophile leads to a rate acceleration.

Inverse reactions (Type III) with $LUMO_{diene}$-$HOMO_{dienophile}$-control.

In 1,3-dipolar cycloadditions kinetic experiments revealed examples for all three types of reaction[23]. What is the situation for Diels-Alder reactions?

Table 7 offers a selection of ρ-values for [4 + 2]-cycloadditions with CC-, NN-, and NO double- and CC-triple bonds as dienophiles. The sign of the ρ-values shows the systems 1.1—1.8 of Table 7 to be definitely *normal* Diels-Alder reac-

Table 7. Electronic substituent effects in [4 + 2]-cycloadditions: ρ values. As substituents (Su) *e.g.*, $N(CH_3)_2$, OCH_3, Cl, NO_2, CN were used.

tions. In an analogous way the signs of the ρ-values for the systems 2.1—2.7 of Table 7 show the *inverse type of cycloaddition.* In the system 2.3 the $\log k$ values correlate in a linear way with the redox potentials of diaryltetrazines[206]. In so far as they have been investigated, the ρ-values decrease with increasing temperature. The absolute value of ρ is normally small and indicates only small partial charges in the rate determining transition state. Only for reactions of substituted nitrosoarenes (No. 1.6 and 1.7) is an unsymmetrical transition state with higher partial charges indicated. Likewise one can find a ρ-value exceeding the average in the cycloadditions of dehydrobenzene with substituted arenes (No. 1.4, Table 7); in this case the C-1-atom of the diene is directly substituted, whereas in the other examples of Table 7 the substituent is separated by a phenylene group from the diene system. In some cases, the Hammett-relation is only obeyed if σ^+ values are used. Other examples concerning the influence of substituents have been investigated particularly by *Konovalov et al.*[193].

What mechanistic importance do these ρ-values have? Transition states with higher partial charges, for example in solvolyses[194] or in electrophilic aromatic substitutions, show ρ-values below -3 to -4. Thus, nitration of benzene derivatives exhibits a ρ-value of -6.53. Also the [2+2]-cycloadditions of cyanoethylenes *via* zwitterionic intermediates show very high negative ρ-values[27]; for instance *Bartlett* found for the [2+2]-cycloaddition of substituted styrenes to TCNE on evaluation according to the Yukawa-Tsuno-equation, a ρ-value of -7.1 ± 0.5 (25 °C). The small ρ-values of the Diels-Alder reactions investigated so far thus exclude a two-step reaction *via* a zwitterionic intermediate. The FMO-model also makes it possible to interpret the existence of ρ-values not equal to zero in concerted cycloadditions[195,196].

From *Konovalov*'s research group stem the first examples of *Type II Diels-Alder reactions,* which could recently be confirmed by *Kanematsu et al.*[209]. Table 8 contains some typical examples. In the case of tetrachloro- and tetrabromo-*o*-ben-

zoquinone as O=C—C=O-diene the minimum reaction rate is found for *p*-chlorostyrene, compared to styrene itself for the other dienes. It is interesting that in the cyclopentadienone series as well as in other systems a transition from Type II to Type I is possible by introduction of appropriate electron withdrawing substituents into the diene in accordance with theoretical predictions. Whereas pentacene represents Type I (normal Diels-Alder reaction[193]), two chlorine atoms in positions 6 and 13 of the molecule modify the reaction to Type II (neutral Diels-Alder reaction). The plot of $\log k_2$ *versus* E_{HOMO} of the dienophile displays for the reaction with phenacyclone a U-shaped curve as expected for Type II[209]. Figure 11 shows the data collected by *Kanematsu*[209]. The rate-data for substituted styrenes result in a linear Hammett-plot with a minimum for R = H only if σ^+ values are used; the ρ-values change sign. One finds for $\sigma_p^+ < 0$ that the *p*-chloro-substituted diene reacts fastest whereas for $\sigma_p^+ > 0$ the *p*-methoxy-derivative shows the lowest reactivity (Fig. 11).

5.3. Solvent Effects

Investigation of the dependence of reaction rates on solvents enable conclusions to be drawn about changes in the polarity on going from educt to transition state; an increase in the reaction rate with increasing solvent polarity proves, for example, that the transition state is more polar than the ground state. In the case of [4 + 2]-cycloadditions also the influence of solvents has been studied intensively in connection with systematic kinetic investigations. Tables 9—16 show a selection of kinetic data. They contain a variation of the diene and dienophile components corresponding to many powers of ten in the absolute reaction rate. Besides the *k*-values corresponding to $\Delta G^{\neq}$ a splitting of the $\Delta G^{\neq}$ term into $E_A/\log A$ or $\Delta H^{\neq}/\Delta S^{\neq}$ can be found in some cases.

Dioxane	6.8	49
$C_6H_5CH_3$	6.6	44

The following conclusions can be drawn from the data of Tables 9—16:

1. In general the influence of the solvent on the reaction rate—independently of the systems investigated—is relatively small and even if greater polarity changes are covered it is rarely above a factor of 10. Only in the reactions of TCNE (Table 11) and 4-phenyl-1,2,4-triazolinedione (Table 14) is the acceleration factor greater.
2. The nature of the dienophile (CC-, NN-, and NO-dienophiles) has just as little influence on the solvent dependence as that of the diene. Unsymmetrical educts (Table 13) certainly reveal an increase in the absolute reaction rate, for example in the reaction of 1,1-dicyanoethylene with anthracene, 9-methylanthracene and 9,10-dimethylanthracene; the solvent influence on the k_2-values however is comparatively small in all the systems of Table 13.
3. As far as investigations are available, [4+2]-cycloadditions seem to occur as fast in the vapor phase as in nonpolar solvents. Table 17 lists values for the dimerization of cyclopentadiene and butadiene[37].

Table 17. Solvent influence on the dimerization of 1,3-cyclopentadiene (20 °C) and 1,3-butadiene (82 °C) (cf. also Table 9) [37].

	1,3-Cyclopentadiene $10^7 \times k_2$ [l mol^{-1} s^{-1}]	1,3-Butadiene $10^9 \times k_2$ [l mol^{-1} s^{-1}]
Gas phase	5.3	24
Liquid phase	4.1—5.0	21

4. The same small solvent dependence is also observed in both normal (see Tables 6—15) as well as inverse Diels-Alder reactions (Table 16).

A plausible interpretation of the influence of the solvent, particularly in combination with the remaining mechanistic criteria, is provided by the synchronous bond formation in the [4+2]-cycloaddition step; this, however, proceeds with the formation of partial charges in the transition state which show up in the ρ-values (see Section 5.2), and also in the solvent effects. Zwitterionic intermediates, however, are definitely excluded by the small solvent dependence of the k-values; in analogous kinetic studies on [2+2]-cycloadditions proceeding *via* zwitterionic intermediates[27,28] acceleration effects of several powers of ten are observed if the polarity of the solvent is increased. Biradical intermediates cannot be excluded completely by means of the solvent influence on the reaction rate. Interestingly the solvent influence in the reaction of TCNE with anthracene is completely analogous[215] to that of the reaction of the same dienophile with bicyclo[2.2.1]heptadiene (symmetry allowed [2+2+2]-cycloaddition with simultaneous bond formation)—a further indication of the same reaction mechanism, *i.e.* a simultaneous bond formation in the Diels-Alder reaction.

Thermochemical investigations by *Haberfield* and *Ray*[220] and by *Konovalov et al.*[216] present an interesting aspect; they measured the enthalpies of solvation for educts and products of a series of systems already studied kinetically[187,221]. Some energy diagrams resulting from these thermochemical data and the kinetic data (see Fig. 12) show that reasons for the difference in enthalpy between ground state and transition state on changing the solvent may be quite different for different systems. Thus TCNE and *N*-aryltriazolinediones show very strong CT-interactions, particularly with aromatic solvents, which strongly modify the reactivity of these dienophiles[216]. Undoubtedly a new mechanistic discussion of solvent effects on the reaction rate must take into consideration these aspects. Entropy effects which are likewise able to affect the k-values are, of course, not taken care of in these considerations; the examples investigated in Figure 12 show differences in the $\Delta S^{\neq}$-values of up to 6—8 entropy units.

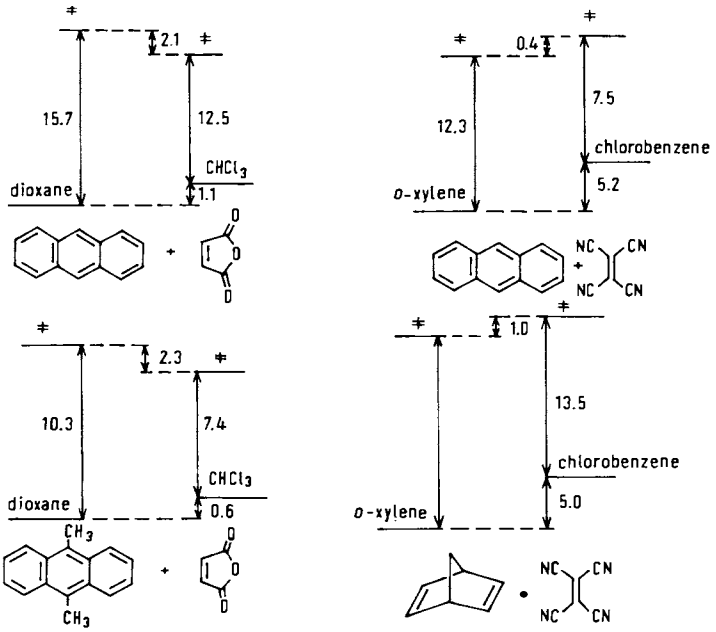

Fig. 12. Relative enthalpies [kcal/mol] of the educts and transition states of some cycloadditions in various solvents [220].

5.4. Activation Parameters

According to *Arrhenius* the temperature dependence of the rate constants discloses the values of the activation energy E_A and the frequency factor $\log A$, and according to *Eyring* it discloses the analogous quantities activation enthalpy $\Delta H^{\neq}$ and activation entropy $\Delta S^{\neq}$. Whereas the mechanistic interpretation of E_A and $\Delta H^{\neq}$ values, which are generally small for Diels-Alder reactions, is rather difficult, the quantities $\log A$ and $\Delta S^{\neq}$ offer criteria for a mechanistic discussion. In Table 18 representative values of the activation entropy $\Delta S^{\neq}$ for a total of 16 different systems are listed with approxi-

mately 150 individual examples. The reaction rates of the systems studied differ by many powers of ten; as dienophiles, systems with CC-double and triple-bonds as well as hetero-multiple bonds were employed; the structure of the dienes was also extensively varied. Furthermore there are ΔS^{+} values for reactions in very different solvents.

The following conclusions can be drawn from Table 18:

1. The ΔS^{+} values are largely independent of the absolute reaction rate. Modifications of the reaction rate are normally reflected in the energy term E_A (or ΔH^{+}).
2. Structural factors in the diene and dienophile do not substantially influence the ΔS^{+} values.
3. The solvent has only little influence on the rate constants (see Section 5.3) and on the ΔS^{+} values. The dimerization of cyclopentadiene in the vapor phase and in solution shows comparable log A and ΔS^{+} values. The same conclusion follows from Table 1, which lists comparable log A values for a larger number of reactions in the gas phase. In discussing these values and comparing them with those in Table 18 the difference in temperature, in part considerable, must be taken into account.
4. The absolute values for ΔS^{+} are in the range of about −40 to −30 entropy units. This means that on going from the ground state to the transition state an extensive restriction of degrees of freedom must be considered. A highly ordered transition state, required by the simultaneous bound formation in [4 + 2]-cycloadditions, is consistent with these data. Zwitterionic intermediates as explanation are excluded by the generally very small influence of solvent and substituents on the reaction rate. A biradical intermediate for these Diels-Alder reactions would certainly be in accordance with substituent- and solvent-effects, but would be opposed in most cases to the stereochemical results; the biradical intermediate could be preserved only if in all cases a fast cleavage of the intermediate to the educts and a rate determining ring closure to the Diels-Alder adduct is postulated. Under this assumption also very negative ΔS^{+} values for a two-step reaction involving a biradical intermediate are expected.

Unfortunately the present experimental material concerning the ΔS^{+} values for [2 + 2]-cycloadditions is not very extensive. In [2 + 2]-cycloadditions of ketenes to enol ethers the reaction rate shows a strong dependence on the solvent; highly negative ΔS^{+} values are expected which, however, do not constitute evidence against simultaneous bond formation in [4 + 2]-cycloadditions. The dimerizations of tetrafluoroethylene, trifluoroethylene, as well as the mixed [2 + 2]-cycloaddition between tetrafluoroethylene and trifluorochloroethylene which were investigated in the vapor phase show ΔS^{+} values between −26.5 to −29.2[222]. Whether these few examples possessing on the average less negative ΔS^{+} values than [4 + 2]-cycloadditions, can be taken as a proof of a different mechanism, remains to be seen.

Obviously the greatest portion of the ΔS^{+} value has to be ascribed to the formation of one bond (abolition of translational degrees of freedom) whereas the prevention of a rotation, as required for a one-step reaction in the transition state, contributes only to a small extent. Thus one can find an overlapping area for the ΔS^{+} values of one-step [4 + 2]-cycloadditions of the Diels-Alder type and of two-step [2 + 2]-cycloadditions. Recently *Berson et al.* referred to this aspect in connection with the study of the cycloaddition of singlet- and triplet-trimethylene biradicals[223]. It is certainly necessary to explore some further systems in the field of [2 + 2]-cycloadditions with regard to the ΔS^{+} values; in these studies also [4 + 2]-cycloadditions should be included which were shown to react in a non-stereospecific way.

5.5. Pressure Dependence of the Cycloaddition: Activation Volumes[41]

During the last 10—15 years the industrially well developed high-pressure technique found more and more access to organic chemical laboratories. Reactions which involve a decrease in volume (for example cycloadditions as prototypes for bimolecular reactions) profit from a rise in pressure, *i.e.*

the reaction rate (k-value) increases. In accordance with the theory of *Eyring* one can determine the activation parameter ΔV^{+} (difference of volume between transition state and ground state) from the pressure dependence of the k-value:

$$\left(\frac{\partial \ln k}{\partial \ln p}\right)_T = -\frac{\Delta V^{+}}{RT}$$

The absolute values of ΔV^{+} and their signs as well as a comparison with the values ΔV of the decrease in volume for the overall reaction permit important mechanistic conclusions; a different extent of bond formation, specific solvent influences and other factors are reflected for example in ΔV^{+}. For the closure of one bond one has to expect a value for ΔV^{+} of about 10—15 [cm³/mol], provided that there is no electrostriction in non-polar solvents.

Earlier measurements by *Walling*'s group[226] seemed to demand a two-step mechanism for [4+2]-cycloadditions. ΔV^{+} was found to be only half as large as the total volume decrease ΔV (Table 19). These values, however, had to be revised[227,228]. The improvement of the experimental technique—nowadays the ΔV^{+} values are reliable to ± 1 [cm³/mol]—has made these activation parameters an important mechanistic criterion.

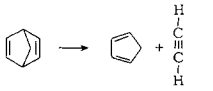
Table 19. Early ΔV^{+} values for Diels-Alder reactions.

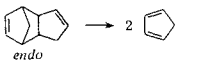
	Reaction	ΔV^{+} [cm³/mol]	ΔV [cm³/mol]	Ref.
1.	Isoprene dimerization	−24.3	−45.5	[226a]
2.	Cyclopentadiene dimerization	−22.3	−32.2	[226a]
3.	2,3-Dimethylbutadiene + Butyl acrylate	−22.6	−42.2	[226b]

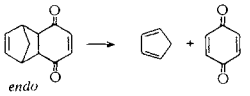
Table 20 presents a selection of ΔV^{+} and ΔV values for various systems with partly very different reactivities; solvent effects were investigated in a number of cases. Several characteristics can be gathered from the ΔV^{+} values:

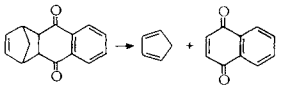
1. The ΔV^{+} values are generally very large for [4+2]-cycloadditions and exceed the order of magnitude expected for the closure of *one* bond in non-polar solvents.
2. In some cases when maleic acid anhydride is the dienophile, ΔV^{+} exceeds (No. 1—4) the value of ΔV considerably. One can therefore conclude that the transition state requires a smaller volume than the reaction products. In the literature this phenomenon, particularly observed in the case of maleic acid anhydride, is attributed to the strong *endo* orientation, as postulated for the transition state of a one-step [4+2]-cycloaddition[3]. Normally, ΔV^{+} is only slightly larger or smaller than ΔV (No. 6—9).
3. Solvent influences on the reaction rate of [4+2]-cycloadditions are normally small compared with corresponding influences on [2+2]-cycloadditions with zwitterionic intermediates[27,28] (see Section 5.3); also in system No. 2, ΔV^{+} responds only insignificantly to a variation in solvent. In contrast $\Delta\Delta V^{+}$ is larger for the more polar system No. 4 with distinctly discernible electrostriction. Here one has to expect a more polar transition state; in the analogous reaction with 2-methoxybutadiene the electrostriction of $\Delta\Delta V^{+} = 6$—7 is significantly smaller.
4. For the $AlCl_3$-catalyzed reaction of acrylic acid butyl ester with 2,3-dimethylbutadiene one finds $\Delta V^{+} = -26$ and $\Delta V = -29$ [cm³/mol] (non-catalyzed reaction: $\Delta V^{+} = -28$, $\Delta V = -32$) cm³/mol[234]). Thus the ΔV^{+} values for catalyzed and non-catalyzed reaction differ only negligibly.

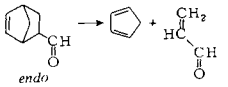
What mechanistic conclusions can be drawn? Obviously in [4+2]-cycloadditions we have a highly ordered transition state, very similar to the products with regard to space requirements. This is consistent with a *simultaneous* formation of *both* bonds in the transition state. If one wants to save the concept of a two-step bond formation for the examples of Table 20, this is only possible by supposing that the second step is rate determining in all cases; only then can one expect ΔV^{+} values of similar order of magnitude. The fact may be recalled here that such an assumption can hardly be reconciled with the small solvent influence on the reaction rate and the results of stereochemical investigations.

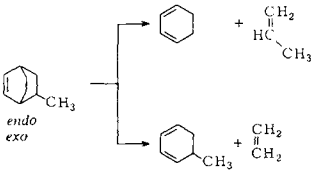


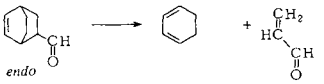


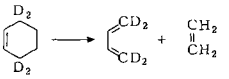


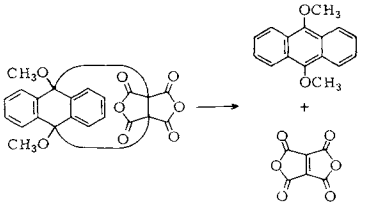


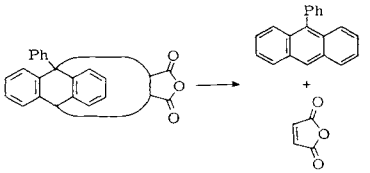












Stewart[235] studied the product spectrum and the pressure dependence of the dimerization of 2-chlorobutadiene to products of the formal [2+2]-, [4+2]- and [4+4]-cycloaddi-

Table 20. ΔV^{+} and ΔV values for different Diels-Alder reactions.

No.	Reaction	Solvent	T [°C]	ΔV^{+} [cm³/mol]	ΔV[cm³/mol]	Ref.

9	Dimethyl acetylenedicarboxylate + Cyclopentadiene	CH_3CO_2Et	10	−30.2	−33.9	[232]

tion. The pressure dependence of the product distribution led him to the conclusion that in this case two different mechanisms are competing; the two-step [2+2]-reaction, probably involving a biradical intermediate ($\Delta V^{+} \approx -22$ [cm^3/mol]), and the one-step [4+2]-cycloaddition to cyclohexene derivatives ($\Delta V^{+} = -29$ to -31 [cm^3/mol]). For [2+2]-cycloadditions with zwitterionic intermediates[27,28] one also finds very negative ΔV^{+} values of about -30 to -40 [cm^3/mol]. This, however, can be explained by the strong electrostriction in the transition state which manifests itself also in a strong solvent dependence of the reaction rate[236].

Table 21. Values of activation entropy ΔS^{+} for Retro-Diels-Alder reactions.

No.	System	Conditions	ΔS^{+}	Ref.
	Cyclopentadiene adducts			
1		Gas phase, 257—297 °C	+ 3.7	[97]

6. Retro-Diels-Alder Reactions

In the [4+2]-cycloaddition step two π bonds are transformed into two σ bonds. On the basis of bond energies one expects for Diels-Alder additions highly exothermic reactions in the order of $\Delta H = 30$–40 kcal/mol. Thermochemical measurements[237–240] confirm this. Depending on the structure of educts and products, ΔH values of 15—40 kcal/mol are found for the reactions with TCNE and MAA. Thus, for a cycloreversion one has to expect relatively high ΔH^{+} values, signalizing high reaction temperatures.

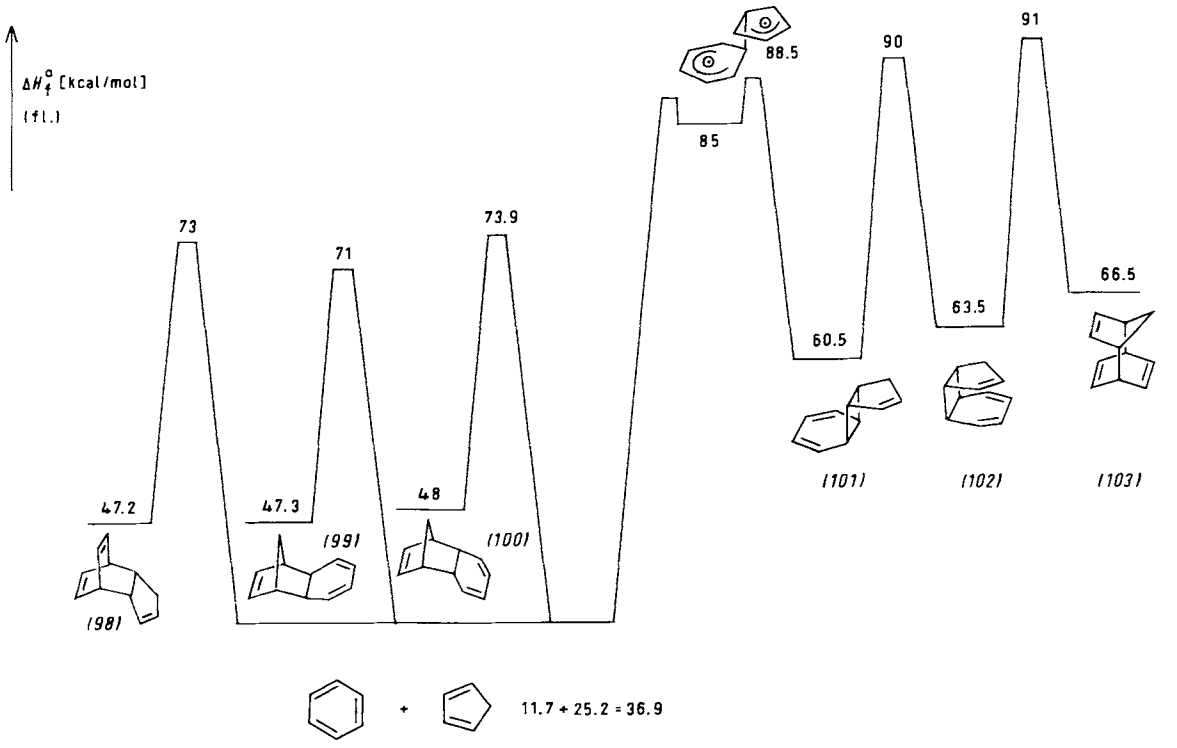
Retro-Diels-Alder reactions were used mainly from a preparative point of view for syntheses of new compounds or of molecules which are difficult to obtain by conventional procedures[35]. Mechanistic studies, however, are less frequent. The criterion of stereospecificity can only be applied in a limited way in Retro-Diels-Alder reactions, since either the Diels-Alder adducts themselves or the *cis-trans*-isomeric dienophiles, originating from the cycloreversion, isomerize under the drastic reaction conditions. In Section 3 reference has already been made to the cleavage of the adducts of 1,3-cyclohexadiene and *cis*- or *trans*-2-butene, which according to the literature[113] is partly non-stereospecific. The isotope effects investigated in Retro-Diels-Alder reactions will not be discussed here, for no new mechanistic findings have been published in the literature since the last review[3,4,36].

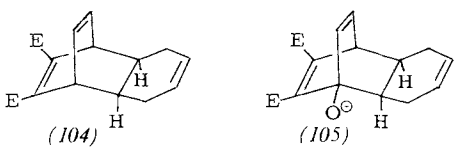
The literature contains a number of kinetic studies of [4+2]-cycloreversions. A selection of data, particularly with respect to the magnitude of the ΔS^{+} value, is presented in Table 21. In all cycloreversions performed in the gas phase a homogeneous reaction was secured.

The ΔS^{+} values of Table 21 are relatively uniform and allow some mechanistic conclusions:

1. The magnitude of ΔS^{+} is not influenced systematically by the fact that the reaction takes place either in solution or in the gas phase. Here too, as in the studies of the cycloaddition itself (see Section 5.3), it is evident that the rate determining transition states are just as polar as the ground states; at best small partial charges can occur.
2. The ΔS^{+} values normally cover a range of about -5 to $+6$ entropy units. One can conclude from this that there are no important modifications of rotational or vibrational degrees of freedom in the transition state. From the "entropy viewpoint" the transition state of the cycloreversion is comparable to the product, as expected for simultaneous bond formation in the addition step or for bond cleavage in the reversion step. A sandwich structure for the transition state is discussed in the literature.
3. Remarkably the ΔS^{+} values for those cyclopentadiene adducts (No. 3—6) which are formed in a relatively strong *endo*-mode are nearly always negative. The analogous picture for the ΔV^{+} values (Section 5.5) increases the credibility of this interpretation; there too, particularly negative ΔV^{+} values were found in those cases partly exceeding the total volume decrease ΔV of the reaction.

Are the present mechanistic criteria adequate for a decision between one-step or two-step reaction? Does one have to expect more positive ΔS^{+} values for a two-step cleavage *via* a 1,6-biradical? The literature does not yet offer definitive help for this decision. The kinetically well studied cycloreversion of *cis*- and *trans*-1,2-dimethylcyclobutane *(54)* and *(53)*, respectively[118], which involves a biradical intermediate provides an example (see also Scheme 10); the ΔS^{+} values determined by the authors (temperature range 390—430 °C) for the [2+2]-cycloreversions, which are marked in Scheme 10 as ⓐ and ⓑ are on the average between 8.5 to 9.1





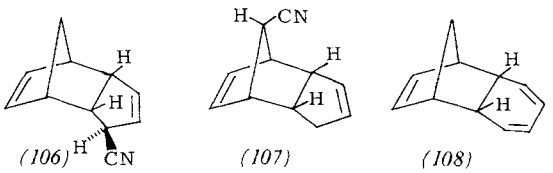


Fig. 13. Energy diagram of the cycloreversion of benzene-cyclopentadiene adducts *(98)*—*(103)*.

entropy units. Thus they are on the higher side of the data of Table 21 and slightly exceed the average; with caution they are used as an argument for simultaneous bond formation in the [4+2]-cycloaddition. As for the cycloaddition step (see Section 5.4) there obviously exists an overlapping area for ΔS^{+} values of [2+2]- and [4+2]-cycloreversion.

Kinetic and thermochemical data of *Grimme et al.*[249] allow interesting mechanistic conclusions for a number of [2+2]-, [4+2]- and [4+4]-cycloadducts of benzene and cyclopentadiene (see Fig. 13). The educts *(98)—(100)*, in which a symmetry allowed, *simultaneous* bond cleavage takes place pass transition states which energetically lie maximally 36 kcal/mol above the reaction products benzene and cyclopentadiene; in contrast the transition states for the cleavage of the [2+2]- and [4+4]-cycloadducts *(101)—(103)*, which should have a biradical as intermediate, lie more than 15 kcal/mol higher. For the [4+2]-cycloreversions explored by *Grimme* a simultaneous bond cleavage seems to be the simplest interpretation. It should be mentioned that this conclusion can not be applied uncritically to all Retro-Diels-Alder reactions. As already pointed out in Section 4 one has to expect that for systems with a large HOMO-LUMO separation under certain conditions the two-step reaction *via* a biradical intermediate will become compatible; in these cases one evidently has to assume for the cycloreversion a two-step mechanism in accordance with the principle of microscopic reversibility.

Recently, *Grimme et al.*[250] found an interesting acceleration effect in the decomposition of anionic Diels-Alder adducts. For example ΔG^{+} for the cycloreversion is lowered by about 9 kcal/mol in proceeding from *(104)* to *(105)*. Also the cleavage of *(106)* and *(107)* in presence of bases (formation of anions) occurs significantly faster than that of *(108)*.

In both cases the transition state takes advantage of the stability of the products (phenolate ion and cyclopentadienide ion, respectively). These results, too, are in agreement with simultaneous bond cleavage in the cycloreversion step.

7. Conclusion and Outlook

It is certainly justified to finally ask whether a reaction like the Diels-Alder cycloaddition, which was discovered more than 50 years ago, is still of general interest. The several hundred original publications appearing regularly each year on this topic give a positive answer. The preparative potential of these [4+2]-cycloadditions has not been exhausted yet. The almost unlimited possibility to vary the diene- and dienophile-components provides in many cases the simplest access to cyclohexene- and 1,4-cyclohexadiene derivatives; the possibility of using *cyclic* compounds, heterodienes and heterodienophiles opens up access in "one pot syntheses" to monocyclic, bicyclic and polycyclic carbocycles and heterocycles. The high preparative value of [4+2]-cycloadditions follows—not only from the mostly very high yields—but also from the stereospecific and generally regiospecific course of the reaction; the catalysis by Lewis acids reinforces stereo- and regiospecificity, so that often nearly exclusively one reaction product is formed. The recent systematic studies of *intramolecular* Diels-Alder reactions[40,251] provided a new impact.

The preparative exploitation of a reaction optimally succeeds if the reaction mechanism is known in detail. This review has revealed that considerable progress has been made during the last 10—15 years in the mechanistic area. In particular the FMO-model has provided the experimental chemist with a distinct and relatively simple aid for selecting his educt from the viewpoint of optimum reactivity and regiospecificity. The HOMO-LUMO model will increasingly permit semi-quantitative estimations when electron affinities and ionization potentials or redox potentials are known. Last but not least it would seem most important to be able to define clearly the factors which are responsible for a one-step orbital symmetry-allowed [4+2]-cycloaddition or for a two-step reaction involving an intermediate.

Many thanks go to all our collaborators cited individually in this article for their interest and valuable cooperation. We are indebted to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, as well as many other individual companies who have generously supported this work.

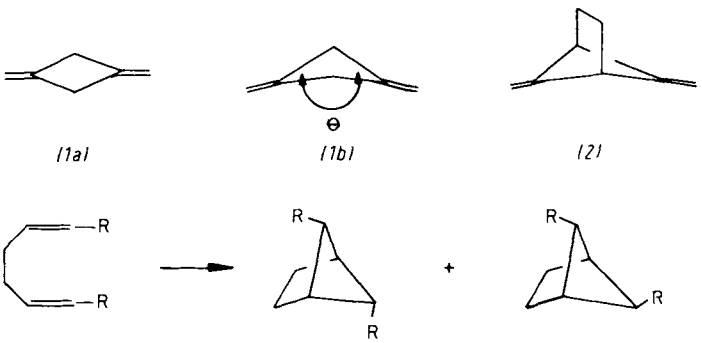
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Diagonal Interaction in the Four-Membered Ring. Experimental Demonstration of a Dominating Circumannular Conjugation: 5,6-Dimethylenebicyclo[2.1.1]hexane[**]



By *Hans-Dieter Martin, Mirjana Eckert-Maksić,* and *Bernhard Mayer*[*]

Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday

Diagonal interaction in the four-membered ring, with its chemical[1] and spectroscopic[2] consequences, is one of the most interesting transannular relationships. From UV and PE spectroscopic investigations, *Vala* and *Klessinger* (cf. [2]) concluded the involvement of a considerable amount of through-bond coupling (circumannular conjugation) in 1,3-di-π-substituted cyclobutanes. We report here on an experimental determination of the orbital sequence in planar 1,3-dimethylenecyclobutane *(1a)* using the reference compounds *(2)*, *(10)*[3], and *(12)*, with a procedure proposed by *Heilbronner*[4] being used in the case of *(10)*.

The splitting of the first two ionization potentials of *(1a)*[2] cannot be independent of the dihedral angle θ. A diminution of θ, as in *(1b)*, however, has different consequences depending on whether the sequence S > A (circumannular) or A > S (transannular) in *(1a)* predominates. In the former case a diminution in the splitting is to be expected, in the second case an increase (Fig. 1, columns a—d). The PE spectroscopic investigation of *(2)*, whose dihedral angle in the model is 130°, can answer this question.

(3) is photochemically cyclized to a mixture (35:65) of *(4a)* and *(4b)*[5]. Hydrolysis ($KOH/CH_3OH/H_2O$) and reaction

(3), R = $COOCH_3$ (4a)–(9a) (4b)–(9b)

(4), R = $COOCH_3$; (5), R = COOH; (6), R = COCl; (7), R = $CON(CH_3)_2$;

(8), R = $CH_2N(CH_3)_2$; (9), R = $CH_2\overset{\oplus}{N}(CH_3)_2$

with thionyl chloride affords—*via* carboxylic acids *(5a)/(5b)*, which are separable by fractional crystallization—the acid chlorides *(6a)/(6b)* (1:3). Reaction with dimethylamine (ether, 0 °C) furnishes *(7a)/(7b)*, from which ($LiAlH_4$, tetrahydrofuran) the gas-chromatographically separable amines *(8a)* and *(8b)* are obtained. Oxidation (30% H_2O_2, CH_3OH, room temperature) leads to the hydrated amine oxides *(9a)/(9b)*, which are dehydrated at 120 °C/12 torr, and at 180 °C/12 torr give the diene *(2)* (yield 40—55%). Table 1 contains ^{1}H-NMR data. The first two ionization potentials of *(2)* ($IP_{1,v}=9.25$, $IP_{2,v}=9.65$ eV, Fig. 1, column e) show that only the sequence S > A in *(1a)* (column c) is consistent with the experimental findings (column e). This experiment alone provides no information about the sequence in *(2)*.

In Figure 2 the same sequence S > A for *(1a)* (column e) leads *via* the experimental result for *(11)*[6] (column f) to a prediction of the orbital sequence in *(10)* (column g), which is in excellent agreement with the observed ionization potentials of *(10)* (column i) [$IP_{1,v}(\pi_S)=8.50$, $IP_{2,v}(\pi_A)=9.75$, $IP_{3,v}(\sigma)=11.00$, $IP_{4,v}(\pi_S)=11.40$ eV]. The assumption A > S for *(1a)* (column d), on the other hand, leads to a contradiction (columns b and c). Finally comparison of *(10)* with 3-

methylene-1,4-pentadiene *(12)*[7] [$IP_{1,v}(\pi_s) = 8.80$, $IP_{2,v}(\pi_A) = 9.95$ eV] shows that the sequence derived for *(10)* in Figures 1 and 2 is in very good agreement with that of the structurally related triene *(12)*. All three reference compounds *(2)*, *(10)*, and *(12)* demonstrate that in *(1a)* the circumannular through-bond conjugation (sequence S > A) dominates over the transannular through-space interaction (sequence A > S)[8].

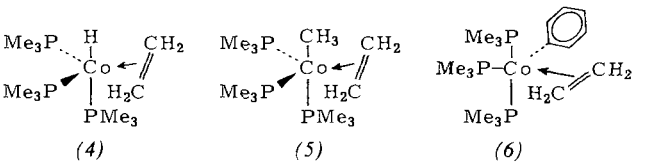
Olefin-Insertion into Cobalt(d^8) Complexes—Structure of Ethylene(phenyl)tris(trimethylphosphane)cobalt[**]

By *Hans-Friedrich Klein, Reinhard Hammer, Joachim Gross*, and *Ulrich Schubert*[*]

The formal insertion of olefins into transition metal-hydrogen or -carbon bonds is a cardinal problem of organometallic chemistry and the principal feature of important industrial processes[1].



(1) *(2)* *(3)*

While the σ-π rearrangement *(1)*⇌*(2)*, a reversible β-elimination, is relatively well established[2], there is only little experimental evidence supporting the practically irreversible insertion *(3)*→*(2)*[3].

As potential insertion precursors, we have prepared the three pentacoordinated cobalt(I) complexes *(4)*—*(6)*, which contain a Co—H or Co—C bond in the *cis* position to the equatorially bound ethylene ligand.

[*] Prof. Dr. H.-F. Klein, Dr. R. Hammer, Dipl.-Chem. J. Gross, Dr. U. Schubert
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

(4) *(5)* *(6)*

The new olefincobalt complexes were synthesized from known compounds[4] according to eqs. (a) and (b); propene or cyclopentene can also be used, instead of ethylene.

$$K[Co(C_2H_4)(PMe_3)_3] \xrightarrow[-\,CH_3OK]{+\,CH_3OH} CoH(C_2H_4)(PMe_3)_3 \quad (a)$$

(4), 60%

$$CoCl(PMe_3)_3 + LiR \xrightarrow[-\,LiCl]{+\,C_2H_4} CoR(C_2H_4)(PMe_3)_3 \quad (b)$$

(5), R = CH_3, 63%
(6), R = C_6H_5, 55%

The diamagnetic ethylenecobalt(I) complexes *(4)*—*(6)* were crystallized from pentane solutions. The complexes gave correct elemental analyses. The crystals can be stored under Ar at 20 °C, but rapidly decompose on exposure to air.

(4) forms greenish yellow leaflets, which sublime with decomposition at 35–40 °C/0.1 mbar and are stable up to 95 °C under 1 bar Ar. The brownish-yellow crystals of *(5)* sublime at 60—65 °C/0.1 mbar, likewise with decomposition; m.p. 115—117 °C (dec.). *(6)* was obtained as well-formed orange-yellow crystals, dec. > 99 °C.

The dynamic ^1H- and ^{31}P-NMR spectra of *(4)*—*(6)* evidence anisochronic ^{31}P nuclei (2:1) for the ground state, and thus indirectly the *cis* relationship of anionic ligands and ethylene. An axial position of the hydride ligand in *(4)* cannot be deduced from the spectra; the structure *(4)* was formulated in analogy to the structure of the methyl compound *(5)*. A comparison of the NMR data of *(5)* with those of $CoCH_{3(ax)}(PMe_3)_4$[4c] indicates an axial position for the CH_3 ligand, consistent with a theoretical postulate[2c,5].

All three complexes behave differently in solution. On using CH_3OD for the synthesis of *(4)* according to eq. (a), IR spectroscopy reveals a nearly random distribution of the deuterium over five positions of the product: four sites in ethylene (ν_{CD} 2100 cm^{-1}) and one at the cobalt (ν_{CoH} 1850 cm^{-1}). Solvent-free 1-pentene is catalytically isomerized by *(4)* (0.5 mol-%, 20 °C, 48 h) to 2-pentene (*cis*:*trans* = 9:1)[6], thus demonstrating σ-π rearrangement in the 18-electron compound *(4)* (Scheme 1).

$$L_3CoH(CH_2{=}CH_2) \rightleftharpoons L_3Co{-}CH_2{-}CH_3$$
(4)

$$L_3CoR(CH_2{=}CH_2) \rightleftharpoons L_3Co{-}CH_2{-}CH_2R \rightleftharpoons L_3CoH(CH_2{=}CHR)$$
(5), *(6)*

Scheme 1. L = PMe_3; R = CH_3, C_6H_5.

In contrast, a thermal isomerization into the complex of type *(4)* (Scheme 1) in the sense of an insertion-β-elimination reaction sequence[7] is not observed in the case of *(5)*; 1-pentene is not isomerized by *(5)*.

$$(6) \rightarrow Co(C_2H_4)(PMe_3)_3 + 1/2\,C_6H_5{-}C_6H_5$$
(7)

On warming, ethylene-saturated solutions of *(6)* (*e.g.* in toluene, 1 bar C_2H_4, 50 °C, 8 h) furnish biphenyl and paramagnetic ethylenetris(trimethylphosphane)cobalt(0) *(7)*[4a] in quantitative yield. Styrene and hydridocobalt complexes, as by-products of an insertion reaction (Scheme 1), were not detected.

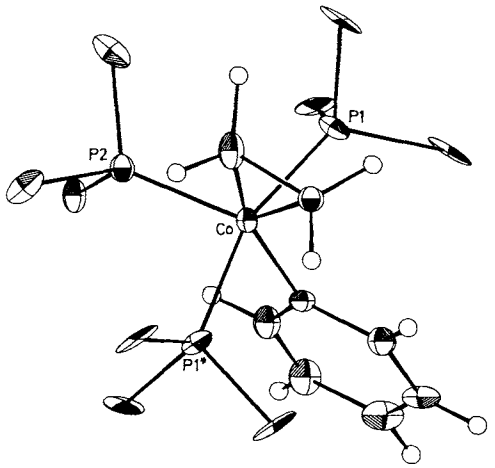


Fig. 1. ORTEP diagram of the molecule *(6)* in the crystal. The hydrogen atoms have been omitted for sake of clarity. Co—P1 219.2(3), Co—P2 221.5(2), Co—C(Ph) 199.9(6), Co—C(Eth) 204.0(7), 205.6(7), C—C(Eth) 143(1) pm. P2—Co—C(Ph) 111.7(2), P2—Co—Eth 110.4(2), C(Ph)—Co—Eth 137.9(2), P1—Co—P1* 160.26(8), P1—Co—P2 97.91(7), P1—Co—C(Ph) 81.6(2), P1—Co—Eth 92.6(2). Eth = center of the C=C bond in the ethylene ligand. *(6)* crystallizes orthorhombically, $a = 1342(1)$, $b = 1301(4)$, $c = 2423(4)$ pm; $V = 4230$ pm^3; ϱ(calc.) = 1.23 g/cm^3; space group Cmca; $Mo_{K\alpha}$ radiation, ($\lambda = 71.069$ pm, graphite monochromator); 1800 independent reflections ($2° \leq 2\theta \leq 50°$). $R_1 = 0.041$, $R_2 = 0.046$ for 1169 structure factors with $F_0 \geq 3.92\sigma(F_0)$.

The X-ray structure analysis of *(6)*, however, revealed that the configuration is favorable for the insertion step, at least in the solid state (Fig. 1). The complex has crystallographic C_s-symmetry with coplanar arrangement of all C-atoms of phenyl and ethyl ligands and of the vector of the Co—P2 bond in the mirror plane. Thus, a reaction path is available which involves minimal rearrangement of the participating atomic centers. The reason for insertion not taking place lies either in the unfavorable orbital symmetries[2c] or unknown thermodynamic quantities. The complex *(6)* is markedly distorted from a trigonal pyramidal coordination (P1 and P1* axial) in the direction of a square pyramidal coordination with P2 in the axial position. This distortion could be caused by the strong steric interaction between ethyl- and phenyl-ligand, which results from their coplanarity.

Procedure

(6): A 0.90 M solution (1.62 ml) of LiC_6H_5 in ether is pipetted into a suspension of $CoCl(PMe_3)_3$[4c] (470 mg, 1.46 mmol) in ether (20 ml) at −78 °C under 1 bar ethylene. The stirred mixture is warmed to 20 °C and stirring continued for a further 1 h. The volatile components are removed in a vacuum and the brown residue is extracted twice with 10 ml pentane. On slowly cooling over dry-ice, orange-yellow crystals of *(6)* separate out; yield 310 mg (55%).

The Nitrile Function of Tetracyanoethylene as Dienophile in Diels-Alder Reactions[**]

By *Klaus Burger* and *Herbert Goth*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Cycloaddition reactions to tetracyanoethylene (TCNE) proceed with high site selectivity at the CC double bond[1]. Examples of [3 + 2]-cycloaddition reactions, in which one of the nitrile groups functions as reaction partner, are rare[2], and no examples of Diels-Alder reactions have, to our knowledge, been reported[3].

We have found that the 1-thia-3-aza-1,3-pentadienes *(2)*[4], accessible by electrocyclic ring opening from 2,2-bis(trifluoromethyl)-2*H*-1,3-thiazete derivatives *(1)*, react with TCNE already at 120 °C (bath temperature). A [1:1]-adduct can be isolated from the product mixture in 50—60% yield (Table 1).

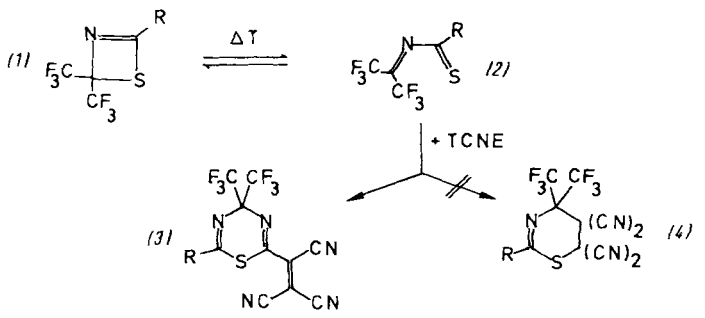

Table 1. Yields, melting points, and IR data of compounds *(3)*.

(3)	R	Yield [%]	M.p. [°C]	IR [cm^{-1}] (KBr)
a	C_6H_5	60	162—163	2233, 1658, 1578
b	*p*-$CH_3C_6H_4$	55	158—160	2232, 1657, 1607
c	*p*-ClC_6H_4	53	140—141	2233, 1660, 1642, 1584

The color of the products, an IR absorption at 1655—1660 cm^{-1}, and a singlet representing six fluorine atoms at $\delta = -2.1$ in the ^{19}F-NMR spectrum[5] indicate reaction of one of the nitrile functions. The mass spectrometric fragmentation pattern, which reveals the electron-impact induced retro-Diels-Alder processes[6] $[M - RCN]^{\oplus}_{\odot}$ and $[M - TCNE]^{\oplus}_{\odot}$ of comparable intensity and intense lines for the fragmentation ions $[(CN)_2C{=}C(CN)C{\equiv}S]^{\oplus}$ and $[RC{\equiv}S]^{\oplus}$, confirms the constitution of a 4*H*-1,3,5-thiadiazine *(3)*. The possible conversion into a symmetric [2:1]-adduct on subsequent heating in the presence of *(1)* is also consistent with structure *(3)*. The [2:1]-adducts are present in minor amounts in the crude products of the reaction of *(1)* with TCNE, even on using twice the amount of *(1)*. Compounds of type *(2)* with oxygen instead of sulfur do not react with TCNE under comparable reaction conditions.

Organisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Procedure

A mixture of *(1)*[4] (10 mmol) and TCNE (1.28 g, 10 mmol) in anhydrous xylene (25 ml) is heated to 120 °C—130 °C (bath temperature) for 48 h under an atmosphere of N_2. After removal of the solvent by distillation *in vacuo*, the 4,4-bis(trifluoromethyl)-4*H*-1,3,5-thiadiazines *(3)* are obtained from the crystalline product mixture by fractional digestion with ligroin (fraction 90—110 °C).

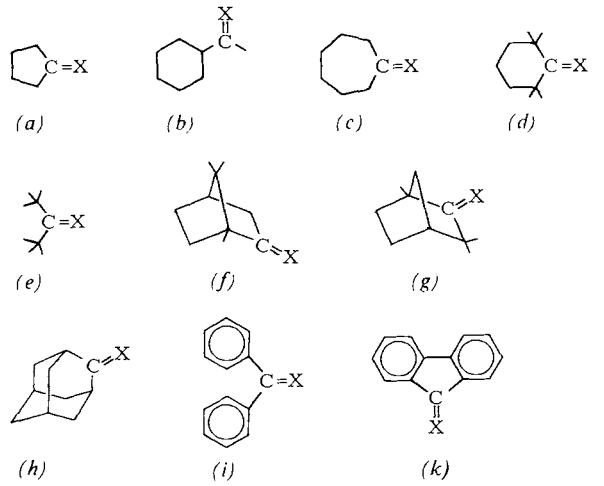
^{13}C-NMR Study of Protonated Thioketones in Superacidic Media: Significance of Mercaptocarbenium Ion Contributions[**]

By *George A. Olah, Tadashi Nakajima*, and *G. K. Surya Prakash*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In general, thioketones have been studied less thoroughly than the parent ketones[1], and only very few ^{13}C-NMR spectroscopic studies of the thiocarbonyl group have been reported[2,3].

We now wish to report the ^{13}C-NMR spectroscopic study of a series of thioketones *(1)*[2,4] and their protonation under superacidic conditions[5]. The chemical shifts obtained are tabulated in Table 1, along with those of their carbonyl analogues *(3)* and *(4)*. For comparison, we have also obtained ^{13}C chemical shifts of the hindered selenoketones *(5e)* and *(5g)*[6].



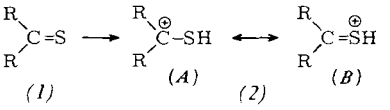


Table 1. ^{13}C-NMR data [a] of thioketones *(1)*, ketones *(3)*, selenoketones *(5)*, as well as thioketones *(2)* and ketones *(4)*.

Cpd. \ C=X	*(1)* C=S [b]	*(2)* C=S$^{\oplus}$H [c]	*(3)* C=O [b]	*(4)* C=O$^{\oplus}$H [c]	*(5)* C=Se [b]
(a)		285.0	215.5	260.5	
(b)	262.7	279.3	212.7	249.4	
(c)	261.4	282.7	205.8	253.4	
(d)	279.8	300.4	222.3	263.1	
(e)	279.8	298.5	216.0	259.4	291.4
(f)	273.2 [d]	284.4	216.7	253.8	
(g)	281.8	291.2	224.4	257.2	291.7
(h)	272.5	286.0	219.9	257.2	
(i)	240.1	228.0	195.2	211.9	
(k)	229.5	217.0	195.0	205.5	

[a] δ values tetramethylsilane external. [b] In $CDCl_3$ at room temperature. [c] In $FSO_3H:SbF_5/SO_2ClF$ or FSO_3H/SO_2ClF at −70 °C. [d] Cf. [3a].

In general, the thiocarbonyl carbon of *(1)* is deshielded by 35—63 ppm, compared to the analogous carbonyl carbon in *(3)* (this is valid for aromatic and aliphatic systems). The magnitude of the deshielding of the C=S$^{\oplus}$H atoms relative to the C=S atoms in *(1)* decreases dramatically in the case of protonated thioketones *(2)*. In fact, a shielding effect of *ca.* 12 ppm is observed for protonated aromatic thiocarbonyl carbons *(2i)* and *(2k)* relative to their neutral precursors *(1i)* and *(1k)*. This effect can be rationalized only by considering a significant mercaptocarbenium ion *(A)* contribution to the protonated thioketone structure, the resultant change in bond order causes a decrease in the deshielding effect. The shielding observed in the case of protonated aromatic thioketones *(2)* is due to the extensive charge delocalization[7] into the aromatic ring through the mercaptocarbenium ion form. In contrast, the contribution of hydroxycarbenium ion forms in related protonated ketones *(4)* is small[8].

[**] Stable Carbocations, Part 227. Support of our work by the National Science Foundation is gratefully acknowledged. *G. A. O.* thanks the Alexander von Humboldt foundation for a senior U. S. Scientist Award which facilitated part of this work and Professor *P. v. R. Schleyer* for his hospitality and stimulating discussions.— For Part 226: *G. A. Olah, M. I. Watkins*, Proc. Natl. Acad. Sci. USA *77*, 703 (1960).

Attempted correlation of the ^{13}C chemical shifts of the corresponding thiocarbonyl carbons with those of carbonyl carbons shows only a very poor fit, demonstrating the importance of steric effects on the functionality. However, excellent correlations have been reported earlier in the case of relatively unhindered thioureas and thiocyanates, *etc.*[3b,c].

The strong deshielding of the thiocarbonyl carbon relative to the carbonyl carbon is rather interesting, considering the relative dipole moments of C=S and C=O bonds and relative electronegativities of sulfur and oxygen[9]. It has been argued that contributions to the paramagnetic term (σp) are responsible for such behavior[3]. The paramagnetic term σp is inversely proportional to the mean excitation energy (ΔE), and ΔE is considerably smaller for the >C=S bond than the >C=O bond. The above concept is also supported by the fact that thioketones *(1)* are more strongly colored, and $n\rightarrow\pi^*$ transitions occur at higher wavelengths than for ketones *(3)*[3]. However, π-electron densities[3c] obtained by simple Hückel molecular orbital calculations did not reproduce the ^{13}C chemical shift trend in thioureas.

This kind of deshielding effect appears to be even more pronounced in seleno ketones *(5)*. In fact, the ^{13}C chemical shifts of di-*tert*-butyl selenoketone *(5e)* and selenofenchone *(5g)* represent the most deshielded carbon shifts ever observed in neutral molecules. All our attempts to protonate selenocarbonyls under a variety of superacidic conditions failed, however, and resulted only in polymeric materials.

Thioketones containing α-hydrogen atoms tend to exist in their thioenolic form[1]; hence, it was necessary to obtain the spectra of cyclohexyl methyl thioketone *(1b)* and cycloheptanethione *(1c)* immediately after their synthesis. We were unable to record the chemical shift of cyclopentanethione *(1a)*, as it enolized rather rapidly. Protonation of such thioenols, however, also leads to protonated thioketones.

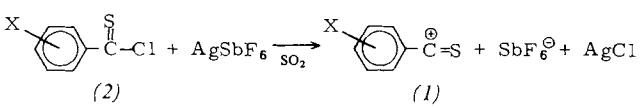
Thiobenzoyl Cations[**]

By *George A. Olah, G. K. Surya Prakash,* and *Tadashi Nakajima*[*]



Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In contrast to extensive chemical and spectroscopic investigations[1] on acyl cations, thioacyl cations have so far remained practically unexplored although they were postulated as intermediates in the Friedel-Crafts reactions of thiobenzoyl and thioamidoyl chlorides, *O*-aryl chloro(thioformates) and *S*-alkyl and *S*-aryl chloro(thioformates) with benzene[2]. The only synthesis of thioacyl cation was reported by *Lindner* and *Karmann*[3] in 1968, who prepared the thiobenzoyl hexafluoroantimonate from the reaction of thiobenzoyl chloride and silver hexafluoroantimonate in SO_2 solution. Although no conclusive spectral data were obtained for the thiobenzoyl cation *(1a)*, the structure was indicated by the CS vibrational stretching in its IR spectrum at 1332 cm^{-1} (shifted considerably from that of its precursor thiobenzoyl chloride *(2a)* at 1250 cm^{-1}), by conductivity measurements and its ability to thiobenzoylate benzene to the corresponding thiobenzophenone. *Lindner* and *Karmann*[3] also stated "the $[C_6H_5CS]^{\oplus}$ cation can thus be said to exist mainly in two mesomeric limiting forms, which have approximately equal importance so that the mean bond order for G—S is 2.5."

In continuation of our study of acyl cations we now wish to report the preparation and ^{13}C-NMR characterization of the parent *(1a)* and a series of substituted thiobenzoyl cations *(1b)*—*(1g)*. Attempts[4] to generate thioacyl cations *via* cleavage of protonated alkyl and aryl dithioesters and dithioacids under a variety of superacidic conditions were unsuccessful. Some of the protonated dithioacids were found to be stable up to 100 °C in the superacidic media[4a].

Although thiobenzoyl chlorides are well characterized in the literature[5], the corresponding aliphatic counterparts are still unknown, except for perfluorinated analogues. Hence our research effort was directed to the generation of thiobenzoyl cations *(1)* from the readily available[5] thiobenzoyl chlorides. Experiments carried out to generate the thiobenzoyl cation *(1a)* by ionizing thiobenzoyl chloride either in $FSO_3H:SbF_5/SO_2$ or SbF_5/SO_2 solution were unsuccessful and resulted in a complex mixture (according to ^{13}C-NMR spectra). Application of the metathetic silver salt method[1] of preparation of acylium salts, also utilized by *Lindner* and *Karmann*[4], turned out to be of general utility for generating thiobenzoyl cations. The thiobenzoyl chloride *(2)*[5b] was treated with a tenth molar excess of freshly prepared silver hexafluoroantimonate in SO_2 solution at −78 °C. Warming the solution to −20 °C effected precipitation of silver chloride and led to a burgundy colored solution.

(1g)	4-CF_3	191.8	115.9	143.7	127.8	161.6 *J*(C—C—F) = 37.0 Hz	127.8	143.7	CF_3 = 122.2 *J*(C—F) = 271.0 Hz

[a] δ values, TMS as external standard.

The 20 MHz ^{13}C-NMR spectrum of the solution of *(1a)* was distinctly different from that of thiobenzoyl chloride *(2a)*[6]. In the spectrum the thiocarbonyl peak of *(1a)* was observed at δ 195.5, about 6.5 ppm more shielded relative to that in the chloride *(2a)*[5b]. This observation, together with the remarkable upfield shift of C-1 [$\approx$30 ppm relative to *(2)*] as well as substantial deshielding of C-2,6 and C-4, clearly proves the formation of thiobenzoyl cation *(1a)* with considerable delocalization of positive charge into the aryl ring through thioketene-like resonance forms. Comparing the observed chemical shifts to those of the benzoyl cation[1] shows similarities between the species, but the carbonyl carbon and C-1 are shielded by 51 and 25 ppm in *(1a)*. The deshielding of the thiocarbonyl carbon relative to the carbonyl carbon is readily rationalized by contributions from paramagnetic terms[7] as well as by the lack of contribution of the sulfonium type form ($C_6H_5C\equiv\overset{\oplus}{S}$) in the thiobenzoyl cation *(1a)*.

(1a)

We also prepared a series of thiobenzoyl cations *(1b)*—*(1g)* with both electron releasing and electron withdrawing substituents on the aryl ring. Their ^{13}C-NMR data are summarized in Table 1. The chemical shift of the thiocarbonyl carbon ranges from δ 198.3 for *(1b)* and *(1c)* to δ 191.8 for *(1g)* (a range of 7.5 ppm). A larger spread of 12 ppm is observed for the shift of C-1. However, it is apparent[8] that there is no linear correlation of thiocarbonyl carbon chemical shifts with the σ^+ substituent parameters of the substituent on the aryl ring. Even in the case of *para*-fluoro and *para*-chloro substituents [*(1f)* and *(1e)*], there is significant stabilization of the positive charge through back donation of the halogen atoms *via para*-quinonoid forms in accordance with the significance of thioketene-like forms.

Our present ^{13}C-NMR spectroscopic study constitutes the first structural characterization of thiobenzoyl cations under long-lived stable ion conditions. The study shows that contribution of thioketene-like resonance forms to the thiobenzoyl cation structure is significant, whereas, in contrast to benzoyl cations, the sulfonium ion type involvement is negligible.

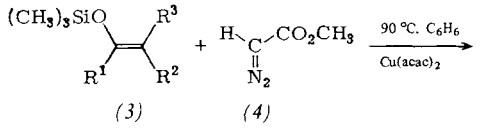
Donor-Acceptor Substituted Cyclopropanes: Synthesis and Ring Opening to 1,4-Dicarbonyl Compounds[**]

By *Hans-Ulrich Reissig* and *Elisabeth Hirsch*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Cyclopropanes are playing an increasingly important role in the synthesis of carbon skeletal structures[1]. A survey of the utility of "oxycyclopropanes" *(1)* and *(2)* has recently been published[2]. The donor-acceptor substituted cyclopropanes *(2)*, which are obtained from diazocarbonyl compounds and alkylenol ethers, and which, as masked 1,4-dicarbonyl compounds, are valuable precursors for the synthesis of cyclopentane, furan, and lactone systems, would appear to be especially versatile.

(1), R' = Alkyl, H
(2), R' = $CO_2C_2H_5$, COAlkyl



However, the scope of application of *(2)* is limited by the following disadvantages: 1. The alkylenol ethers required for synthesis of *(2)* are frequently only obtained under drastic conditions (usually acetal pyrolysis at 160—200 °C) and without regioselectivity; 2. the yield of *(2)* is only about 50%; 3. the ring-opening must be performed in strong acid medium (1 M or conc. hydrochloric acid).

Silylenol ethers *(3)*, on the other hand, are often regioselectively accessible by comparatively mild methods[3]. We obtained the siloxy-substituted cyclopropanes in good, synthetically useful yields by copper salt-catalyzed cyclopropanation of *(3)* with methyl diazoacetate *(4)* (Table 1)[4]. The

[a] *cis/trans* Mixture. [b] Yields isolated after bulb-to-bulb distillation; all the new compounds gave satisfactory elemental analyses and characteristic spectra. [c] Bath temperature. [d] Yields of crude product (NMR spectroscopically pure).

The removal of the trimethylsilyl group with ring opening of the cyclopropane to give the 1,4-dicarbonyl compounds *(6)* could be achieved smoothly with fluoride ions[5] under essentially neutral conditions. *(6)* is most conveniently liberated by the readily accessible triethylammonium fluoride[6]. This gentle method (1 h, 25 °C, tetrahydrofuran) also enables straightforward synthesis of the aldehyde esters *(6b—d)* and of the alcohol *(6h)*.

Procedure

(5): A solution of methyl diazoacetate *(4)* (1.28 g, 12.8 mmol) in anhydrous benzene (50 ml) is added dropwise in 3 h to a suspension of copper(II) pentanedionate in *(3a)* (2.00 g, 11.6 mmol) kept at 90 °C. After cooling and removal of solvent the residue is dissolved in pentane and filtered through 35 g aluminum oxide (neutral, activity grade III). On evaporation of the eluate there remains 2.58 g (91%) *(5a)* as a colorless, NMR spectroscopically pure oil. Bulb-to-bulb distillation at 65 °C/0.1 torr furnishes 2.47 g (87%) of analytically pure *(5a)*.

Competing [3+4]- and [2+4]-Cycloadditions of Allenyl Cations[**]

By *Herbert Mayr* and *Inge K. Halberstadt*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The number of synthetic applications of cationic cycloadditions is steadily increasing. Whereas [3+4]-cycloadditions[1] of allyl cations are already one of the most widely used synthetic approaches to seven-membered carbocycles[2], the first [2+2]-cycloaddition of a solvolytically generated vinyl cation to cyclohexene has only just been accomplished[3]. The acid catalyzed cyclodimerization of acetylenes and allenes to give cyclobutanes also proceeds *via* vinyl cations[4].

We recently demonstrated the formation of [3.2.1]bicyclic compounds by treatment of propargyl halides *(1)* and cyclopentadiene with equimolar amounts of silver trifluoroacetate; this reaction was rationalized in terms of [3+4]-cycloadditions of intermediate allenyl cations[5].

(1)

R = H, CH_3

We now report that trisubstituted allenyl cations can be generated more easily from propargyl halides *(3)* and catalytic amounts of zinc chloride; the type of cycloaddition depends upon the nature of the substituents.

Vinyl halides *(2a, b)* and *(4c—h)* were obtained in 20—65% yield from propargyl halides *(3a—h)* and cyclopentadiene (molar ratio 1:1—2) at −30 to −50 °C in the presence of zinc chloride-ether, a complex soluble in dichloromethane (Table 1). Apart from higher-molecular-weight compounds, the only side products observed were enynes *(9)* and *(10)* arising from hydrogen chloride elimination from *(3e)* and *(3h)*. Spontaneous increase of temperature could not be avoided when the reactions were carried out under heterogeneous conditions (suspension of zinc chloride in dichloromethane) and only traces of the addition products could be isolated.

The bicyclooctadienes *(2)* have ^{1}H- and ^{13}C-NMR spectra similar to 3-chloro-4,4-dimethyl-bicyclo[3.2.1]octa-2,6-

diene[5]. Whereas the two bridgehead protons of both *(2a)* and *(2b)* show similar chemical shifts ($\delta = 2.48$—2.63), H-4 is considerably more deshielded than H-1 in the norbornenes *(4)* (Table 2). The significant upfield shift of one methyl

(9) *(10)*

group in the 5-(α-halobenzylidene)-6,6-dimethylnorbornenes *(4)* indicates the presence of the (*E*)-isomers; steric interactions prevent a coplanar arrangement of the phenyl group with the exocyclic double bond so that one methyl group moves into the positive shielding zone of the benzene ring[6]. Reaction of *(4c)* with silver trifluoroacetate in boiling ether and alkaline work-up affords *exo*- and *endo*-*(11)* with a carbonyl band at 1670 cm^{-1}.

We propose that the propargyl halides *(3)* initially dissociate under the influence of zinc chloride to give the allenyl cations *(5)*. Cyclopentadiene then attacks the sp^2 carbon of *(5)*, forming the cyclopentenyl cation *(7)* which cyclizes to the vinyl cations *(6)* or *(8)*. A concerted mechanism with unequal extent of bond formation in the transition state is also conceivable. Addition of a halide ion gives the vinyl chlo-

rides *(2)* and *(4)*; *(8)* is selectively attacked from the sterically less hindered side, resulting in the exclusive formation of *(E)-(4)*.

According to force-field calculations, bicyclo[3.2.1]octa-2,6-diene [type *(2)*] is 9 kcal/mol more stable than the isomeric 5-methylene-2-norbornene [type *(4)*][7]. This energy difference is responsible for the formation of the cyclic vinyl cation *(6)* when R^1 = alkyl even though the ideal geometry of the vinyl cation fragment cannot be achieved[8]. In contrast, an aryl group R^1 directly attached to the cationic center stabilizes *(8)* to such an extent that the higher strain energy of the norbornene is overcompensated.—The formation of *(4)* cannot be due to isomerization of *(3)* to haloallenes which then might undergo Diels-Alder reaction with cyclopentadiene: non-activated allenes do not react with 1,3-dienes at low temperatures[9]. Furthermore, 3-chloro-3-methyl-1-butyne does not undergo zinc chloride-catalyzed reaction with cyclopentadiene but yields 1-chloro-3-methyl-1,2-butadiene, which is stable under these conditions.

Procedure

$ZnCl_2$ (1.2 g) was dissolved in ether (1.5 ml), diluted with CH_2Cl_2 (30 ml), and cooled to −40 °C. A solution of *(3f)* (5.2 g, 25.0 mmol) and cyclopentadiene (1.65 g, 25.0 mmol) in CH_2Cl_2 (20 ml) was added dropwise with stirring. After 1 h (−40 °C) the catalyst was washed out with conc. aqueous ammonia and the organic phase was dried over $CaCl_2$. Filtration over silica gel (10 g) afforded *(4f)* (2.62 g, 38%) as NMR-pure oil which crystallized from a solution in light petroleum on scratching (colorless prisms).

Oxopropenylation of Grignard Compounds with 3-Ethoxyacroleins[**]

By *Klaus Rustemeier* and *Eberhard Breitmaier*[*]

Dedicated to Professor Rudolf Tschesche on the occasion of his 75th birthday

3-Ethoxyacroleins *(2)* are versatile C_3 building blocks, especially in heterocyclizations[1]. We have now found that they are suitable in a general way for the introduction of the oxopropenyl moiety. For this purpose they are allowed to react with an alkyl, aryl, or heteroarylmagnesium bromide *(1)*; after work-up in acid solution one obtains the corresponding α,β-unsaturated aldehydes *(6)* in yields between *ca.* 30 and 60% (Table 1). Comparable reactions with enols[2a], with enol ethers[2b], and with open-chain enamino aldehydes[2c] have already been described.

That the oxopropenylation proceeds *via* the alcohol *(4)* is supported by the isolation of the intermediates *(4x)* and *(4y)* (R^1 = 2-pyridyl, R^2 = methyl or ethyl), which are stabilized by an intramolecular hydrogen bond. The hydrolysis of the alcohol *(4)* to the aldehyde *(6)* on heating in 2 N sulfuric acid is almost quantitative. The alcohol *(4)* can also be detected NMR spectroscopically in the product mixture obtained on gentle hydrolysis of other Grignard reagents *(3)* (*e.g.* in ice-cold ammonium chloride solution).

The compounds *(6)* synthesized were identified by elemental analysis, ^{1}H- and ^{13}C-NMR spectroscopy, and by mass spectrometry. Compounds *(6)* are found to exist in the *E*-form, though the isopropyl-substituted compounds, in particular, contain small amounts of the *Z*-form (NMR data).

Procedure

(1): 2 g of magnesium turnings are covered with 20 ml of the solvent quoted in Table 1. 0.055 mol of the bromide is then added dropwise, such that the solution constantly boils. After addition of the total amount of bromide the solution is boiled under reflux for a further 30 min and then allowed to cool.

(6): The solution of *(1)* is added dropwise with stirring to an ice-cooled solution of *(2)* (0.05 mol) in diethyl ether (100 ml). The mixture is stirred for 2 h at room temperature, cooled with ice and then treated dropwise in the cold with

Table 1. 3-Alkyl-, 3-aryl-, and 3-heteroarylacroleins *(6)*; physical data and yields. *(1)* is generated with stoichiometric amounts of R^1Br.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

1 N sulfuric acid (60 ml). The organic phase is washed with saturated sodium hydrogen carbonate and dried over magnesium sulfate. After removal of solvent *in vacuo* the residue is distilled and the distillate redistilled or recrystallized.

(1), R^1 = 2-pyridyl: A small amount of ethyl bromide is added to 5 g magnesium turnings in 20 ml tetrahydrofuran. As soon as reaction commences a solution of 5 g ethyl bromide and 16 g 2-bromopyridine in 100 ml tetrahydrofuran is added dropwise such that the mixture just boils. After completion of addition the mixture is heated for a further 2 h under reflux and then allowed to cool.

(4x, y): A solution of *(1)*, R^1 = 2-pyridyl, is added dropwise to an ice-cold solution of *(2)* (0.15 mol) in diethyl ether (150 ml) and the mixture is stirred at room temperature for 2 h. The ice-cold product mixture is then hydrolyzed with 100 ml 2 N sulfuric acid. The organic phase is separated off and washed twice with a little 2 N sulfuric acid. The combined acid extracts are rended alkaline with ammonia and extracted with ether. After removal of ether from the extract the residue is distilled and finally recrystallized. The almost colorless tabular crystals of *(4x)* and *(4y)* are stable for long periods only when stored in a refrigerator; b.p. 98 °C/0.05 torr and 100—105 °C/0.40 torr, m.p. 51 °C and 42 °C, yield 50 and 54%, respectively.

(6x, y): *(4x, y)* is dissolved in 2 N sulfuric acid and heated to 50 °C with stirring for 2 h. After addition of aqueous ammonia until alkaline and subsequent extraction with ether, *(6x)* and *(6y)* can be isolated almost quantitatively. Crystalline *(6x)* is stable for some time at room temperature, while *(6y)* solidifies only when stored in the refrigerator, and rapidly decomposes on heating.

Benzophenonedilithium as Complex with Tetrahydrofuran and Tetramethylethylenediamine

By *Borislav Bogdanović, Carl Krüger*, and *Bernd Wermeckes*[*]

While the structure and reaction behavior of alkali metal adducts of aromatic hydrocarbons are already well documented[1], only spectroscopic data are available on the structure and composition of the alkali metal ketyls and the dianions of aromatic ketones and thioketones[2]. We report here the synthesis and structure of a benzophenonedilithium compound which contains one molecule each of complexed tetrahydrofuran (THF) and tetramethylethylenediamine (TMEDA).

Our investigations are connected with studies on poly(alkali metal) complexes of 1,6,6aλ⁴-trithiapentalene[3] and related compounds. Crystalline complexes of this sort could previously not be isolated; benzophenonedilithium appeared to us to be the simplest model compound of these polymetalated systems. For the synthesis of the model compound *(1)*,

(1)

benzophenone was allowed to react with lithium sand in the molar ratio 1:40 in THF at 0 °C. In 7 d the ratio of lithium to ligand in the red solution slowly increased to 3.6:1. After removal of excess lithium, concentration of the now deep-violet solution, and addition of TMEDA, the mono-THF-

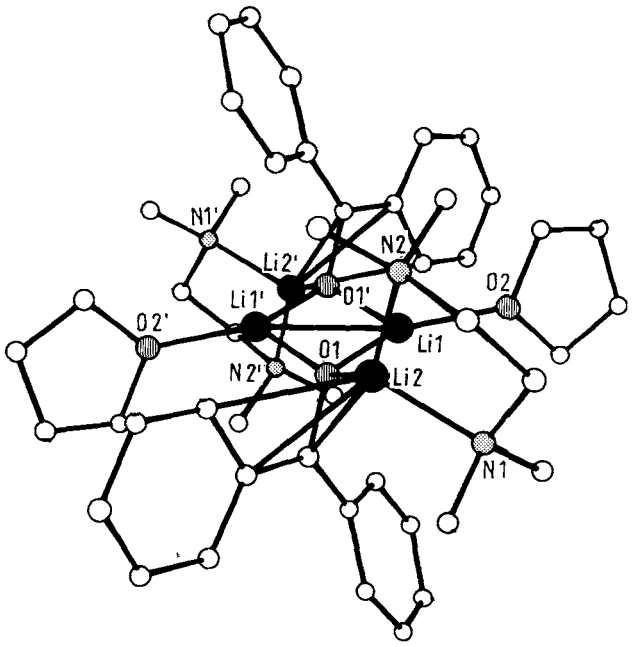

Fig. 1. Structure of the dimer of *(1)* in the crystal.

mono-TMEDA adduct of benzophenonedilithium *(1)* precipitates (yield 71%). It can be recrystallized from THF/TMEDA and forms violet crystals which are extremely sensitive to air and hydrolysis.

Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim-Ruhr 1 (Germany)

According to the X-ray structure analysis[4] *(1)* is a dimer (Fig. 1) with symmetry $\bar{1}$ (C_i). The oxygen atoms of the symmetry-related benzophenone moieties (O1, O1′) are bridged by a metal-metal contact of bonding dimensions (Li1—Li1′: 2.452(10) Å)[5] (see Fig. 2). The Li—O distances within this planar four-membered ring are equal (1.867(8) Å); the dihedral angle between the planar four-membered ring and the plane of the benzophenone moiety (O1C1C2C8) is 110.4°. Hence both lithium atoms (Li1, Li1′) of this metal-metal system interact with one lone pair of the carbonyl oxygen (three-center bonding), while the other lone pair is directed towards one of the "unique" lithium atoms (Li2). The latter, however, has an additional ion-pair interaction with the central planar part of the carbon skeleton of the benzophenone (C1, C2, C7) (dihedral angles O1C1C2C7: 2.7°, O1C1C8C13: 23.5°). Bonds of this type, with similar lengths, also exist in benzyllithium[6] or triphenylmethyllithium[7]. As expected Li1—O2 (1.919(8) Å) is shorter than Li—C (2.21—2.54). Two coordination sites on the almost tetrahedral Li2 are occupied by the nitrogen atoms of one TMEDA molecule, while a slightly angularly oriented THF molecule occupies a free site at Li1 and at Li1′.

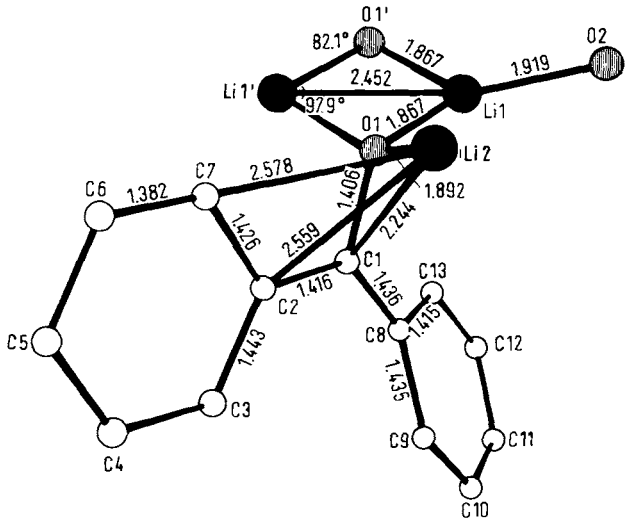

Fig. 2. Principal bond lengths [Å] and angles in *(1)* (substructure).

Catalytic Synthesis of Magnesium Hydride under Mild Conditions

By *Borislav Bogdanović, Shih-tsien Liao, Manfred Schwickardi, Peter Sikorsky,* and *Bernd Spliethoff*[*]

The direct synthesis of magnesium hydride from the elements requires extremely long reaction times and drastic conditions[1]. Since hydrides of magnesium and its alloys and hydrides of intermetallic magnesium compounds are of potential use in reversible hydrogen storage devices[2], great efforts have already been directed at improving the hydrogenation of magnesium by addition of foreign metals or by alloying[1e, 2, 3]. In contrast, little is known about the use of homogeneous transition-metal catalysis for the hydrogenation of magnesium[4][***]. We report here on such a synthesis, which for the first time affords highly reactive magnesium hydride under mild conditions and which can also be carried out on a large scale.

Combinations of organic compounds of the main group elements with transition metal halides serve as suitable catalysts, which if necessary are activated by polycyclic arenes or amines; particularly active catalysts are obtained by reaction of anthracenemagnesium[5] with chromium, titanium, or iron halides in tetrahydrofuran (THF)[6]. Olive-green (Cr, Fe) or violet (Ti) THF solutions are formed, which already catalyze the hydrogenation of magnesium over days at 20 °C and normal pressure. To increase the rate of hydrogenation the catalysis can be carried out at 40—70 °C under H_2-pressure. As shown for the chromium catalyst (Fig. 1), for example, with this method and with a molar ratio of Mg:catalyst of 100:1 or 200:1, magnesium can be converted quantitatively into magnesium hydride within *ca.* 10 or 16 h, respectively, at 60—70 °C/80 bar.

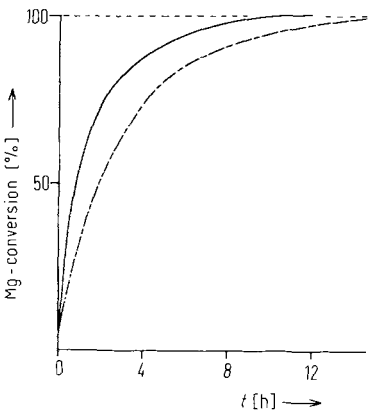

Fig. 1. Hydrogenation of magnesium with an anthracenemagnesium/$CrCl_3$ catalyst at 60—70 °C/80 bar; (——) Mg:Cr = 100:1, [Cr] = 0.086 mol/l; (– – – –) Mg:Cr = 200:1, [Cr] = 0.043 mol/l.

[**] Alexander-von-Humboldt Fellow; permanent address: Institute for Chemical Physics of the Chinese Academy of Sciences, Talien (The Peoples Republic of China).

[***] In US-Pat. 3167218 (*E. van Tamelen, R. Fechter*, 1968) the production of alkali metal hydrides from the metals and hydrogen in the presence of, *e.g.* naphthalene and titanium tetraisopropylate is claimed, but only that of sodium hydride is described as example (as also in the later publication J. Am. Chem. Soc. *90*, 6854 (1968)). In the general description also the possibility of the hydrogenation of the alkaline earth metals and of aluminum is mentioned, as well as a series of further catalyst combinations. According to our own experiments, however, the catalysts recommended therein are unsuitable for the hydrogenation of alkaline earth metals and aluminum.

According to preliminary kinetic measurements the rate of hydrogenation is nearly proportional to the concentration of chromium or titanium catalyst and corresponds to a reaction of first order referred to magnesium[7]. In the case of the chromium catalyst (0.086 mol Cr/l) the rate of hydrogenation increases only slightly with increasing hydrogen pressure between 5 and 80 bar.

The following experimentally verified reactions may be regarded as possible steps of the homogeneously catalyzed hydrogenation of magnesium: (i) metallic magnesium reacts with anthracene in THF at 20 °C or above in the molar ratio 1:1 to give orange, sparingly soluble anthracenemagnesium *(2)* [eq. (a)]; (ii) in the reaction of *(2)* with $CrCl_3$ or $TiCl_4$ in THF, which leads to formation of the catalytically active species, free anthracene *(1)* is formed [eq. (b)]; (iii) in presence of the dissolved chromium or titanium catalyst, *(2)* is hydrogenated by hydrogen (at 30—60 °C/80 bar) to magnesium hydride [eq. (c)], with liberation of *anthracene (1)* (only small amounts of 9,10-dihydroanthracene were detected).

(1) *(2)* (a)

$$(2) + CrCl_3(TiCl_4) \xrightarrow[THF]{20\text{–}30\,^\circ C} Cr(Ti)\text{-cat.} + (1) \qquad (b)$$

$$(2) + H_2 \xrightarrow[THF]{Cr(Ti)\text{-cat.}} MgH_2 + (1) \qquad (c)$$

The reaction sequence eq. (a) and eq. (c) represents a catalytic cycle of magnesium hydrogenation *via* anthracenemagnesium *(2)* as intermediate. This assumption is supported by the experimental finding that the hydrogenation of *(2)* [eq. (c)] according to our method is considerably faster than the hydrogenation of elemental magnesium.

Thus, in this method a magnesium hydride/magnesium system is obtained which, because of the high dehydrogenation/hydrogenation rate (at 200—350 °C/1—50 bar) and high content of reversibly bound hydrogen in the magnesium hydride so produced (*ca.* 7 wt-%), is particularly suitable as a hydrogen storage system.

Procedure

All reactions carried out under argon. A suspension of magnesium powder (73.2 g, 3.0 mol) (Riedel-de Haën) in anhydrous THF (350 ml) is treated with ethyl bromide (0.3 ml) and, after 30 minutes' stirring, with 5.35 g (30.0 mmol) of *(1)*. After three hours' stirring (during which time *(2)* is formed) anhydrous $CrCl_3$ (4.75 g, 30.0 mmol) is added and stirring continued for a further 15—30 min until cessation of the weakly exothermic reaction. The olive-green suspension is transferred to a 1 l autoclave fitted with glass insert and magnetic stirrer and hydrogenated at 60—65 °C external temperature and a H_2-pressure of 80 bar; the rate of hydrogenation (Fig. 1) is measured *via* the drop in pressure in a hydrogen storage vessel. On completion of reaction the light-gray suspension is filtered through a glass frit (D4, diameter 9 cm)[8], and the MgH_2 washed twice with THF and pentane and dried in a high vacuum at 20 °C. One obtains 76.0 g of a pyrophoric magnesium hydride which is free from elemental magnesium; according to the elemental analysis and the amount of hydrogen liberated by hydrolysis the MgH_2 is *ca.* 94% pure (rest: THF, $MgCl_2$, catalyst[9].

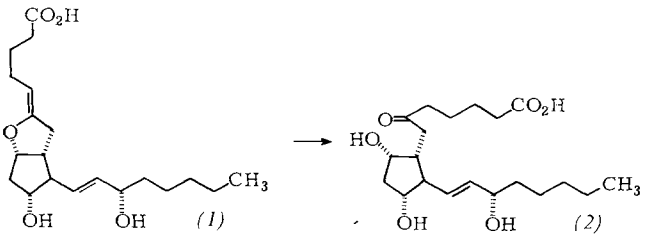
[7] The kinetic measurements were carried out in a 2 l autoclave fitted with stirrer.

[8] The filtration is laborious; a much quicker filtration, particularly in experiments on a larger scale (up to 0.7 kg Mg), is possible with a pressure filter (Polypropylene cloth 2832, Verseidag).

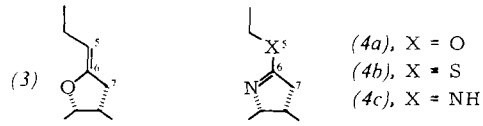
[9] The procedure for the production of MgH_2 with $TiCl_4$ or $FeCl_2$ is analogous; the product is somewhat coarser and more easily filterable.



New Prostacyclin Analogues

By *Wilhelm Bartmann, Gerhard Beck, Jochen Knolle*, and *R. Helmut Rupp*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



Prostacyclin (PGI_2) *(1)*[1] has been found in animal and human experiments to lower the blood pressure and to hinder platelet aggregation after intravenous administration[2]. Since it is less rapidly biologically deactivated than the "classical" prostaglandins E_2 and $F_{2\alpha}$ it has been considered as a circulating hormone affecting the circulation[3].

Aqueous solutions of pure *(1)* have a halflife of only 3 min at pH 7.5 and 37 °C[4]; *(1)* is hydrolyzed to 6-oxo-$PGF_{1\alpha}$ *(2)*.

It has been a preparative goal of various laboratories to synthesize chemically more stable analogues of *(1)*[5]. As far as can be seen, the biological action of *(1)* is closely connected with the electronic and steric parameters of the enol ether structure. Prostacyclin analogues differing considerably from the natural product in this partial structure are biologically less active[6].

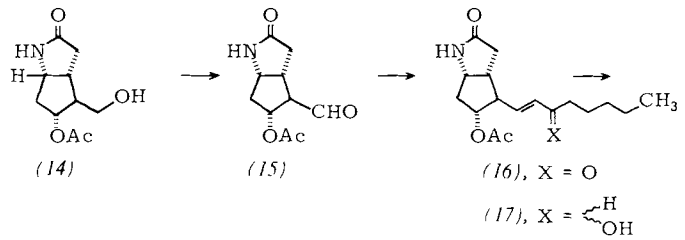
(3) (4a), X = O; (4b), X = S; (4c), X = NH



We now wish to describe the synthesis of prostacyclin analogues *(22)*, *(24)*, and *(26)* in which the enol ether structure *(3)* has been replaced by a β-hetero-imino group *(4)*.

Replacement of the C=C double bond by a C—X single bond should permit adoption of conformations resembling the *Z*-configuration of the natural product. It was expected that compounds having the partial structures *(4b)* and *(4c)* would be more resistant to acids than *(1)*. The starting material for the synthesis should be industrially available.

Scheme 1.

Scheme 1 shows the transformation of the known synthon *(5)*[7] into the analogues *(22)*, *(24)*, and *(26)*.

After protection of the alcohol function in *(5)* (benzyl bromide/sodium hydride/50 °C) the lactone *(6)* is aminolyzed in methanol (autoclave, 36 h/130 °C/ammonia) and the resulting hydroxyamide *(7)* oxidized according to *Jones* to form the oxoamide *(8)* ($CrO_3/H_2O/H_2SO_4$/acetone/ −20 °C). Compound *(8)* slowly tautomerizes to the hydroxylactam *(9)*. Mild removal of the hydroxy group is accomplished by conversion of *(9)* into the phenylthio compound *(10)* which is also directly accessible from *(8)* (C_6H_5SH/$ClSi(CH_3)_3$/pyridine/CH_2Cl_2/reflux). Compound *(10)* can be desulfurized at room temperature with Raney nickel in *tert*-butyl alcohol to form *(11)* which gives the alcohol *(12)* on keeping for 5 h at 50 °C or on treatment with Pd/C/hydrogen in methanol at 25 °C.

After esterification of the alcohol function of *(12)* to form *(13)* (Ac_2O/pyridine/5 °C) and methanolysis of the tetrahydropyranyloxy group (CH_3OH/*p*-toluenesulfonic acid/ 25 °C) compound *(14)* is oxidized to *(15)* (dimethyl sulfoxide/oxalyl chloride/CH_2Cl_2/ −60 °C) and the crude product condensed according to *Horner-Emmons-Wittig* with dimethyl (2-oxoheptyl)phosphonate to produce the enone *(16)* (NaH/dimethoxyethane (DME)/25 °C). Reduction to *(17)* and its esterification (Ac_2O/pyridine/5 °C) led to the diacetate *(18)*, which affords the lactim ether *(22)* on reaction with ethyl ω-bromobutyrate (Ag_2O/xylene/120 °C) followed by removal of the acetate groups (K_2CO_3/CH_3OH/25 °C) from the product *(21)*.

The thiolactim ether *(24)* can be obtained by transformation of *(18)* into the thiolactam *(19)* (P_4S_{10}·4 pyridine/pyridine/80 °C), alkylation with ethyl ω-bromobutyrate (NaH/DME/25 °C) to form *(23)* and removal of the acetate groups (K_2CO_3/CH_3OH/25 °C).

The *S*-methyl thiolactim ether *(20)* preparable from *(19)* (NaH/DME/CH_3I/25 °C) is treated at 80 °C in methanol with γ-aminobutyric acid to form *(25)*. Hydrolysis of the acetate groups (K_2CO_3/CH_3OH/25 °C) leads to the amidine *(26)*.

Compounds *(22)*, *(24)*, and *(26)* exhibit interesting biological properties. Thus *(24)*, for example, inhibits platelet aggregation with an IC_{50}[9] value of 5×10^{-10} [M] and is more acid-resistant than prostacyclin *(1)*[8]. The three analogues were characterized by ^{1}H-NMR, IR, and mass spectra: *(22)* ($CDCl_3$): δ = 5.53 (2H, m, H—C=C), 4.25 (1H, m, H—C—N=C), 4.1 (1H, m, H—C—O), 3.8 (1H, m, H—C—O), 3.77 (3H, s, CO_2CH_3), 3.67 (2H, m, CH_2—O); *(24)*: ($CDCl_3$): δ = 5.58 (2H, m, H—C=C), 4.38 (1H, m, H—C=N—C), 4.08 (1H, m, H—C—O), 3.81 (1H, m, H—C—O), 3.67 (3H, s, CO_2CH_3), 3.1 (2H, m, CH_2—S); *(26)*: ($(CD_3)_2SO/CF_3CO_2D$): δ = 5.46 (2H, m, H—C=C), 4.31 (1H, m, H—C—N=C), 3.89 (1H, m, H—C—O), 3.8 (1H, m, H—C—O), 3.23 (2H, m, CH_2—N).

2-Vinylidene-2*H*-indene[**]

By *Reinhard Schulz, Armin Schweig, Curt Wentrup,* and *Hans-Wilhelm Winter*[*]

Until now, only one 2*H*-indene (isoindene), *viz.* 2,2-dimethyl-2*H*-indene, has been isolated and characterized[1]. Although the 2-methylene derivative (isobenzofulvene) is known as a reactive intermediate in dilute solution[2], no isolation or spectroscopic identification has been reported. However, the blue 2-(dimethylaminomethylene)-1,3-diphenyl-2*H*-indene stabilized sterically (and/or electronically) by substituents in positions 1 and 3 has been isolated[3].

We now wish to report the gas-phase and low temperature isolation of 2-vinylidene-2*H*-indene *(2)*. When cyclopropa[*b*]naphthalene *(1)*[4] was subjected to flash vacuum pyrolysis (30 × 2 cm quartz tube; 10^{-3}—10^{-4} torr), an intensely blue compound was collected at −196 °C on a cold-finger situated immediately after the exit from the oven. The blue color appeared at pyrolysis temperatures above *ca.* 400 °C, reached a maximum at *ca.* 600 °C, and had almost completely disappeared at 850 °C. The blue compound dimerized and/or polymerized as soon as diffusion commenced, *e.g.* in an ether matrix at −116 °C, or in the solid state at −100 °C (fading of the color in the course of *ca.* 5 min on warm-up between −100 and −80 °C).

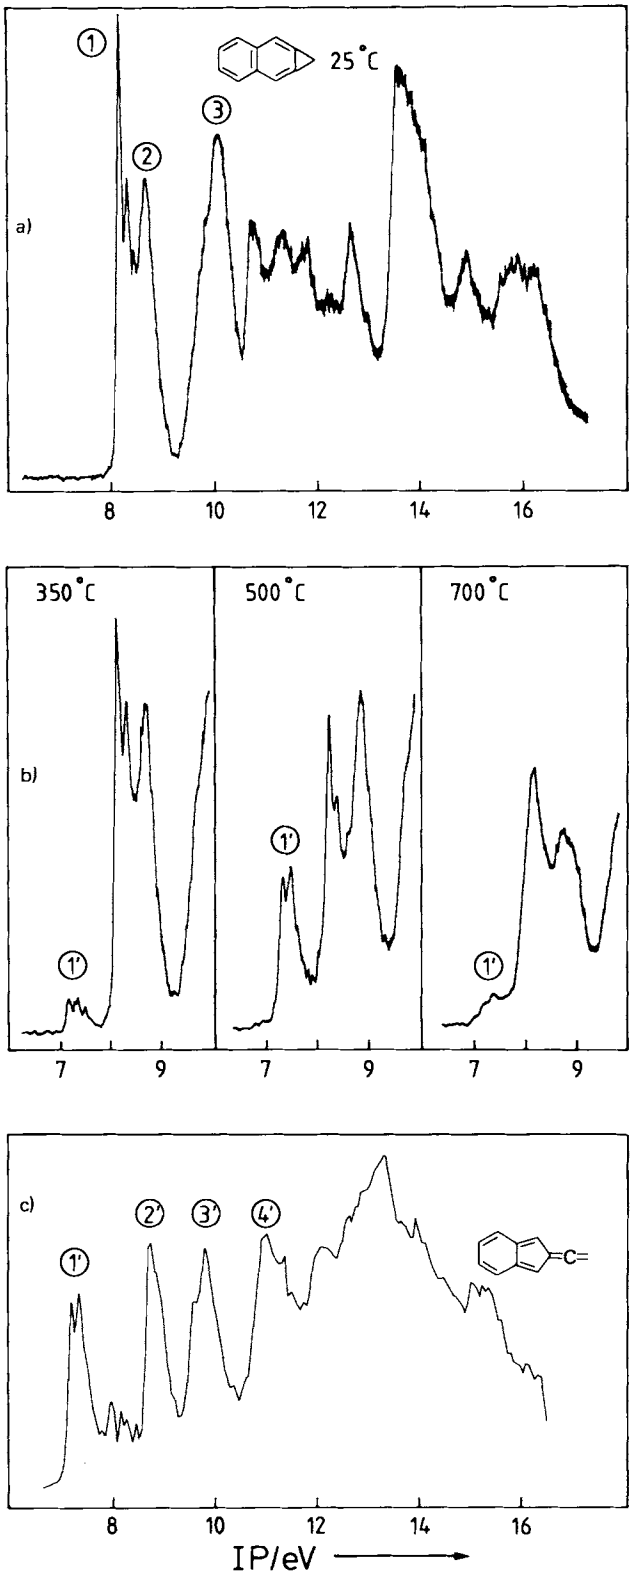
(1) *(2)*

The blue compound was characterized by its IR spectrum at −196 °C, using a modified apparatus (10 × 1 cm pyrolysis tube) in which the products were condensed directly onto a turnable KBr disk attached to a liquid nitrogen cryostat (IR (−196 °C): 3030 w, 2960 w, 1935 vs, 1890 (sh), 1470 s, 1425 s, 905 s, 840 s, 800 vs, 745 s, 725 m cm^{-1}).

The very intense allene absorption at 1935 cm^{-1} is in agreement with the structure *(2)*. When the cryostat was warmed to −96 °C by the addition of toluene (room temperature), the 1935 cm^{-1} band disappeared with a halflife of *ca.* 8 min[5]. At the same time, the blue color disappeared.

The structure of *(2)* was obtained by variable temperature photoelectron spectroscopy (VTPES)[6]. For this purpose, the reaction *(1)*→*(2)* was carried out in the reactor (20 × 0.6 cm stainless steel pyrolysis tube; *ca.* 5×10^{-2} torr) of a modified PS18 photoelectron spectrometer. The mixture of pyrolysis product and starting material was ionized immediately after the exit from the reactor.

Figures 1a and 1b show the photoelectron spectra obtained at reactor temperatures of 25, 350, 500, and 700 °C. The spectrum of the starting material *(1)* has bands at ① 8.03 eV ($^2A_2(\pi)$), ② 8.54 eV ($^2B_1(\pi)$), and ③ 9.95 eV ($^2A_2(\pi)$, $^2A_1(\sigma)$) (assignment by CNDO/S[7] calculations). At pyrolysis temperatures above 350 °C, a new band ①' at 7.25 eV appeared. This reached a maximum at 500 °C, and had almost entirely disappeared again at 700 °C. The temperature dependence of this band largely parallels that of the formation of the blue allenic compound.



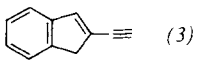


Fig. 1. He-I photoelectron spectra a) of *(1)* at 25 °C; b) of mixtures of *(1)* and *(2)* at 350, 500, and 700 °C; and c) of *(2)*. The last spectrum in Fig. 1c was calculated from the 500 °C spectrum by subtraction of the spectrum of *(1)*.

The formation of *ca.* 50% of the rearrangement product at 500 °C can be estimated from the relative band intensities. The remainder is largely unchanged starting material *(1)*. The spectrum of the rearrangement product was obtained by subtraction (Fig. 1c). It has bands at ①' 7.25 eV, ②' 8.83 eV, ③' 9.63—9.89 eV, and ④' 11.02 eV. The possibility that the species observed was 2-ethynyl-1*H*-indene *(3)*, the high-tem-

perature rearrangement product of *(1)*[8], was excluded by recording a spectrum of this compound (8.04 eV ($^2A''(\pi)$), 9.03 eV ($^2A''(\pi)$), and 10.09–10.31 eV ($^2A''(\pi)$, $^2A'(\pi)$); assignment by MNDO[9] calculations).

(3)

The identification of the rearrangement product as 2-vinylidene-2*H*-indene *(2)* follows from the excellent agreement between the measured vertical ionization potentials (VIP) and those calculated for *(2)* by several methods[7, 9, 10] (Fig. 2).

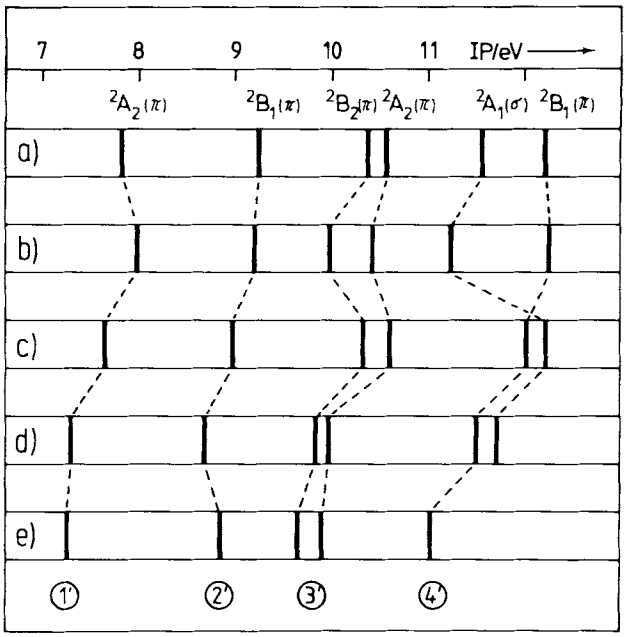

Fig. 2. Vertical ionization potentials (VIP) of *(2)*; calculated by a) CNDO/S [7]-Koopmans; b) CNDO/S PERTCI [10a]; c) LNDO/S [10b]-Koopmans; [d] LNDO/S PERTCI; and e) measured (see Fig. 1c).

Synthesis of Cyclic Compounds from Triphenyl(phenyliminovinylidene)phosphorane and Carboxylic Acids

By *Hans Jürgen Bestmann, Gerold Schade*, and *Günther Schmid*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

Triphenyl(phenyliminovinylidene)phosphorane *(1)*[1] adds carboxylic acids *(2)*, primarily to give the nonisolable phosphoranes *(3)*, which are converted by $O \rightarrow N$-acyl migration into compounds *(4)*. On heating to 60 °C, compounds *(4)* rearrange by intramolecular *C*-acylation into acyl-*N*-phenylcarbamoyl ylides *(5)*[2].

When *(5)* is heated in boiling toluene it cleaves off phenyl isocyanate *(7)* in an equilibrium reaction, and the acyl ylide *(6)* is formed. *(7)* can be removed from the equilibrium by addition of an alcohol, so that the reaction sequence *(1)* + *(2)* → *(6)* is a general preparative method for the synthesis of acyl ylides *(6)* from free—inactivated—carboxylic acids *(2)*[3]. Table 1 shows some examples.

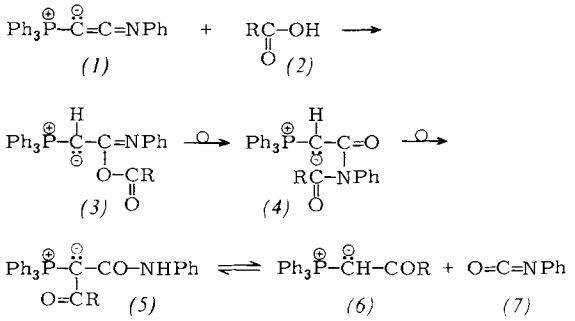

Table 1. Phosphoranes *(4)*, *(5)*, and *(6)* from ylide *(1)* and carboxylic acids *(2)* (yields not optimized).

	R	*(4)* M.p. (dec.) [°C]	*(4)* Yield [%]	*(5)* M.p. (dec.) [°C]	*(5)* Yield [%] [a]	*(6)* M.p. [°C]	*(6)* Yield [%]
a	CH_3	123	72	178	72	202	62
b	C_3H_7	131	71	162	71	162	54
c	Ph—CH=CH	116	51	192	51	148	59
d	Ph	[b]		182	74	181	69

[a] Referred to *(2)*. [b] Cannot be isolated pure.

Substituted carboxylic acids *(2)*, whose substituents can react with an ylide function, *e.g.* oxocarboxylic acids *(8)*, ought to occasion intramolecular ring closure reactions at the stage of *(9)*, *(10)*, or *(12)* [corresponding to *(3)*, *(4)*, *(6)*] on reaction with *(1)*. In the case of *(8)* these are intramolecular Wittig reactions. These cyclizations (ring closures A, B, C) lead to compounds of the type *(13)*, *(14)*, and *(15)*. From our findings the following general rules can be derived:

In the reaction of *(1)* with α-oxo acids the cyclization can proceed according to route A or B. One obtains either the isoimide *(13)* (X = null) or imide *(14)* (X = null) of a 2-substituted maleic acid. We found that the compounds *(13)* (X = null) can be quantitatively rearranged into *(14)* (X = null) with catalytic amounts of sodium azide in anhydrous methanol. The reaction of *(1)* with α-oxo acids thus opens up a general route for the synthesis of 2-substituted *N*-phenylmaleimides.

(8h), *n* = 4	173—174	80	*C*		*(15h)*	50/0.02	75
(8i), *n* = 3	167—169	82	*C*		*(15i)*	40/0.02	60
(8j), *n* = 4	177—179	72	*C*		*(15j)*	60/0.01	85
(8k), *n* = 3	167—170	74	*C*		*(15k)*	60/0.05	67
(8l)	173—175	64	*C*		*(15l)*		
					(16)	38—39	82
(8m)	203—205	95	*C*		*(15m)*	65—66	55

[a] Known compounds are identical with authentic reference material; correct elemental analyses and molecular spectroscopic data (IR, NMR, mass spectra) for all unknown compounds. [b] *(14a)*, R′ = CH_3, and *(14b)*, R′ = Ph, were obtained from *(13a)* and *(13b)* by reaction with NaN_3/CH_3OH; m.p. 97 and 117 °C, respectively.

On reaction of *o*-formylbenzoic acid and *(1)*, 2-phenyl-2-benzazepine-1,3-dione *(14e)* is formed *via* ring closure B.

γ-Oxo acids react with *(1)* to give compounds of type *(11)*, which on heating immediately cyclize *via* acyl ylides *(12)* to cyclopentenones [ring closure C to type *(15)*, X = $(CH_2)_2$]. δ-Oxo acids can be analogously converted into cyclohexenones [type *(15)*, X = $(CH_2)_3$]. The annelations to *(15h—k)* are superior to other methods, *e.g.* the Robinson annelation, because the products are free from double-bond isomers[4] and of compounds which are formed by retro-aldol condensations[5]. Reaction of the oxocarboxylic acid *(8l)* proceeds *via* the corresponding compound *(11l)* to give the acyl ylide *(12l)*, which surprisingly reacts to give the "anti-Bredt" α,β-unsaturated ketone *(15l)*. Compound *(15l)* immediately adds the ethanol used for trapping the isocyanate to give the end product *(16)*[6] (see Table 2).

The finding that the acyl ylide *(12m)* formed in the reaction of *(8m)* forms the enol ether of a cyclic 1,3-diketone by Wittig reaction at the ester carbonyl group[7] is of special preparative interest.

Procedure

(15i): A suspension of *(1)* (10 g, 26.5 mmol) in anhydrous ethyl acetate (200 ml) is treated with a solution of 2-oxocyclopentaneacetic acid *(8i)* (3.8 g, 26.8 mmol) in ethyl acetate (20 ml). The solution is heated under reflux for 3 h. On cooling 11.3 g of *(11i)* crystallize out.

A solution of *(11i)* (10 g, 19.3 mmol) in 80 ml of anhydrous toluene, which contains 5 ml ethanol, is heated under reflux for 12 h. The solvent is removed and the residue digested with 50 ml pentane. Precipitated Ph_3PO is separated off and the previously unknown 4,5,6,6a-tetrahydro-2(1*H*)-pentalenone *(15i)* (1.41 g) isolated by bulb-to-bulb distillation.

First Insertion Reaction of Carbon Monoxide into a Rhenium-Carbon σ-Bond[**]

By *Ekkehard Lindner* and *Günter von Au*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

Carbon monoxide has great importance as a reactant in the hydroformylation of olefins[1]; this reaction is catalyzed by carbonyl-metal derivatives[2]. The lengthening of the C-chain of the metal-bound olefin occurs *via* labile σ-alkyl complexes, which insert CO into their M—C σ-bond. Such insertions with corresponding carbonyl-rhenium compounds have not previously been described[3]. We successfully performed this reaction with the six-membered rhenacycles *(3)* which we were able to obtain by heterolytic cleavage of the Re—Re bond in the dianionic, binuclear complexes *(1)*[4], with neopentylene bis(trifluoromethanesulfonate) *(2)*.

The colorless, thermally stable metallacycles *(3)* sublime in a high vacuum and are soluble in all common organic solvents. They were characterized by complete elemental analysis, IR, MS (Table 1), and ^{1}H-NMR spectra [*(3a)*, *(3b)* (C_6D_6 rel. to TMS): δ = 0.89, 1.01 (s, C(CH_3)$_2$), 0.92, 1.04 (d, J = 2.5, 3.1 Hz, P—Re—CH_2), 3.19, 3.51 (d, J = 17.6, 17.3 Hz, P—O—CH_2)], as well as by crystal structure analysis of *(3b)*[5].

P2—Re3	239.9(2)	O1—P2—Re3	116.0(2)

(3b) has a distorted chair conformation with a dihedral angle of 115.4° between the C5, C6, O1 plane and the approximate plane through O1, P2, Re3, C4, and C5. Thus the tetrahedral angle at C6 is only slightly enlarged. Due to the steric effect of both methyl groups, the same applies to the angle at C5, resulting in a considerable expansion of the tetrahedral angle at C4. This indicates a considerable ring strain, which leads to greater reactivity.

[**] Preparation and Properties of, and Reactions with Metal-Containing Heterocycles, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 5: *E. Lindner, H.-J. Eberle*, J. Organomet. Chem. *191*, 143 (1980).

Although in *(3b)* the Re3—C4 distance is clearly greater than the sum of the single bond radii, and SO_2 can easily cleave the Re—C σ-bond with ring expansion to thermally stable *(4b)*, the insertion of CO will not proceed until 100 °C

and 800 bar. However, if the metal-coordinated carbon monoxide in *(3b)* is activated with a Lewis acid, such as $AlBr_3$[6], then the colorless adduct *(5b)*, obtained in toluene, takes up CO at 20 °C without pressure. Subsequent hydrolysis with cleavage of the aluminum group, leads to the colorless, ring-expanded, insertion product *(6)*, which is thermally labile. In solution, CO is eliminated at 20 °C. In the spectra of *(4b)* and *(6b)*, in contrast to *(3b)*, ν(CO) is shifted characteristically to higher frequencies. *(4b)*, *(5b)*, and *(6b)* are soluble only in more strongly polar organic solvents.

Experimental

(3a, b): A solution of *(1a)* or *(1b)* (1.23 mmol) in dimethoxyethane (DME) (50 ml) is added dropwise to *(2)* (1.10 mmol) and K_2CO_3 (2 mmol) in DME (20 ml) at −10 °C [*(3a)*] or 20 °C [*(3b)*], and is heated for 10 h at 60 and 84 °C, respectively. After filtration (D4), *(3a)* and *(3b)* are purified on a chromatographic column (l = 0.3 m, diam. = 25 mm, silica gel, act. III, eluent: *n*-hexane). Final purification is by distillation (20 °C/10^{-2} torr) and recrystallization from *n*-hexane. Yield: 12—27%.

(4b): *(3b)* (0.38 mmol) in liquid SO_2 (10 ml) is left to react for 1 h at −40 °C. After removal of SO_2, analytically pure *(4b)* remains in quantitative yield.

(6b): *(3b)* (0.21 mmol) and $AlBr_3$ (0.21 mmol) are dissolved in toluene (20 ml) in the absence of air and moisture. After several minutes, when *(5b)* has formed, CO is bubbled through the solution for 1 h at room temperature. The solvent is removed and the solution hydrolyzed with aqueous $CHCl_3$, then filtered (D4). The solvent is removed under vacuum at −10 °C, and the residue of *(6b)* is washed with *n*-hexane. Yield: 45%.

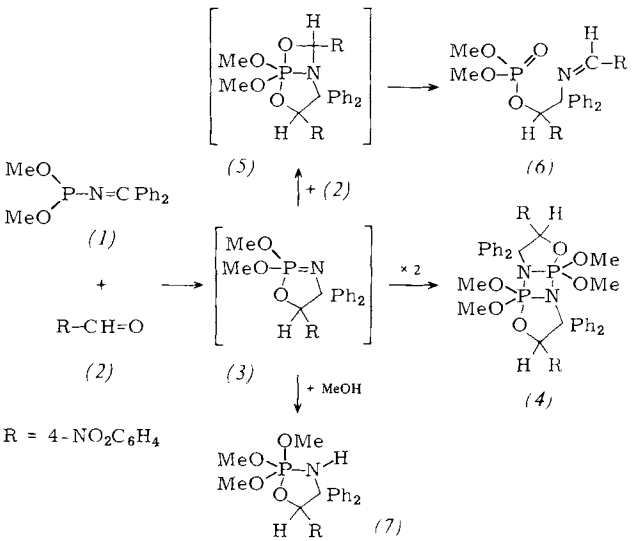
Double Cycloaddition Yielding a Tricyclic Diphosphorane[**]



By *Alfred Schmidpeter, Werner Zeiss, Dietmar Schomburg,* and *William S. Sheldrick*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In criss-cross addition to a dienic four-membered chain, the first [3 + 2]-cycloaddition is followed by a second one, and a five/five-membered bicyclic species results. In the case of double addition to the three-membered chain of an enephosphane described below, the second addition is likewise a necessary consequence of the first one. The role of the second ene is assumed by P^{III} which increases its coordination number by two and becomes the P^{V} bridgehead of a four/five-membered bicyclic species.

(Methyleneamino)phosphanes[1] such as *(1)* represent a special case of 1,3-dipoles free of formal charges. They react with electron-deficient olefins and acetylenes *via* [3 + 2]-cycloadditions to form 1,2-azaphospholes and 1,2-azaphospholines, respectively[2]. Their reaction with carbonyl compounds is more complicated. We found that dimethoxy(diphenylmethyleneamino)phosphane *(1)* and *p*-nitrobenzaldehyde *(2)* afford a 2:2 and a 1:2 addition product in 40 and 30% yield, respectively, which prove to be the tricyclic diphosphorane *(4)* and the methyleneaminoethyl phosphate *(6)*. Both compounds must be regarded as the result of double cycloadditions: a [3 + 2]-addition forming the thermodynamically favorable PO bond leads, contrary to kinetic expectations, regiospecifically to the 1,3,2λ^5-oxazaphosphol-

[**] Four- and Five-Membered Phosphorus Heterocycles, Part 46. This work was supported by the Fonds der Chemischen Industrie.—Part 45: *K. C. Dash, H. Schmidbaur, A. Schmidpeter*, Inorg. Chim. Acta *46*, 167 (1980).

ine *(3)*. As a result of the proclivity of its P,N bond to undergo addition[3], compound *(3)* reacts further *via* [2+2]-cycloaddition with itself to form the dimer *(4)*[5], and with further *(2)* in the manner of a Wittig reaction[4] *via (5)* to give *(6)*[5].

If the reaction of *(1)* and *(2)* is performed in the presence of methanol (molar ratio 1:1:1), then *(3)* is trapped by addition of methanol to the P,N bond[6] forming the stable phosphorane *(7)*[5].

The tricyclic title compound *(4)* formed in one step from four acyclic building blocks is identified by the upfield shift of the phosphorus signal, $\delta^{31}P = -57.9$ and by the proton signals of the *cis*- and *trans*-OCH_3 groups which each constitute the X part of $[AX_3]_2$ spin systems: $\delta^1H = 2.92$ ($N = J(POCH) + J(PNPCOH) = 13.6$ Hz) and 3.63 ($N = 12.5$ Hz); OCHR: $\delta^1H = 5.88$ ($N < 1.5$ Hz). Assuming the bridgehead phosphorus to have trigonal-bipyramidal coordination and an axial-equatorial arrangement of all the rings, then three possible configurations (equivalent with regard to the polarity rule) result for *(4)*, *viz. A, B,* and *C* with equatorial, *trans*-axial, and *cis*-axial fusion, respectively; moreover, R may be in a *cis*- or a *trans* position (not shown).

The ^{1}H-NMR spectrum is compatible with each form and also with a mobile equilibrium between *A, B,* and *C*. X-ray structure determination[7] shows that *A* predominates in the crystal, although there is slight distortion towards *C* (Fig. 1).

The four-membered ring is planar and the five-membered rings exhibit an envelope conformation. The *cis* relationship of the groups R and the ring atoms on which they are located corresponds to the *cis* fusion of the five-membered rings (Fig. 1b). As a result of the small internal angles in the four- and five-membered ring at the phosphorus atom, the angle between the two methoxy groups is decreased. The mutual dependence of these two quantities[8] is confirmed by a comparison of the angles at the two crystallographically independent phosphorus atoms.

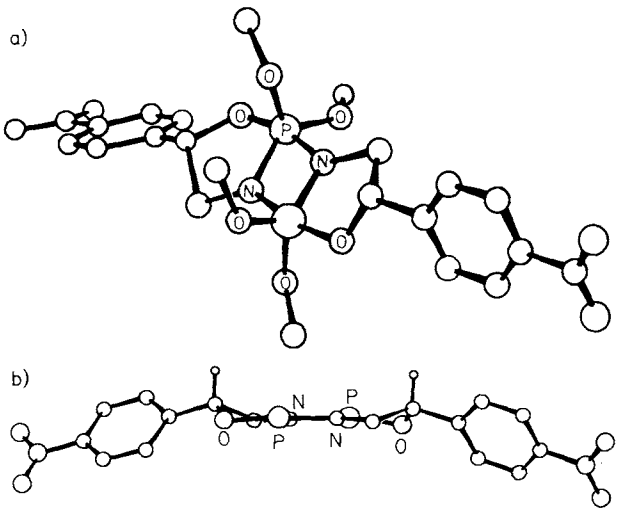

Fig. 1. Two views of the molecular structure of *(4)*. For the sake of clarity, the phenyl groups have been omitted, as have the methoxy groups in (b). The principal bond lengths [pm] and angles [°] are (standard deviations 0.4 pm and 0.2°; the two columns refer to the two crystallographically independent halves of the molecule):

Procedure

(4): (1)[1] (20 mmol) is stirred together with *(2)* (20 mmol) in ether (50 ml) under N_2 for 20 h. Compound *(4)*, which is sparingly soluble also in other solvents, precipitates as crystals which are separated and washed with ether until colorless; m.p. 175—176 °C.

(6): the evaporated filtrate is dissolved in dichloromethane and chromatographed on Al_2O_3. Compound *(6)* crystallizes from the concentrated eluate on stirring with pentane/ether; m.p. 195—196 °C.

(7): (1) (20 mmol) and methanol (20 mmol) in ether (50 ml) are stirred for 20 h with *(2)* (20 mmol). After concentration of the solution to one quarter of its volume, compound *(7)* precipitates as colorless crystals (45% yield); m.p. 135—140 °C (dec.) after recrystallization from dichloromethane with methanol.

Synthesis of Norbornenes from Cyclopentadiene and Allyl Alcohols in an Acidic Two Phase System[***]

By *Heidrun Ernst* and *H. M. R. Hoffmann*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Following the synthesis of bicyclo[3.2.1]oct-6-enes[1] from allyl cations and cyclopentadiene, a wide variety of seven- and five-membered rings has become accessible by combination of appropriate π systems[2]. Frequently, although by no means necessarily, the key electrophilic intermediate in these reactions has been a 2-alkoxyallyl cation or a related organometallic species.

We now report that another type of allyl cation, which lacks the potentially electron-releasing substituent at the central carbon of the allyl moiety but has stabilizing terminal substituents, reacts with conjugated dienes in a different manner. The two allyl cations investigated, *i.e.* the α,α,γ-trimethylallyl cation *(2a)* and the $\alpha,\alpha,\gamma,\gamma$-tetramethylallyl cation *(2b)* attack cyclopentadiene to give bridged cyclohexenes. For the sake of brevity only the reaction of 2,4-dimethyl-3-penten-2-ol *(1b)* and cyclopentadiene will be outlined here. Cation *(2b)* was generated in a novel way from the alcohol *(1b)* in a two-phase system consisting of aqueous acid and hydrocarbon solvent. Although cyclopentadiene has long been known to be very acid sensitive[3] and prone to dimerization and polymerization, it survived our experimental conditions at least partially to react with *(2b)*. The main products (30—40%) were the epimeric norbornene type alcohols *(5)* and a mixture of isomeric monocyclic allyl alcohols *(8)*, whereas the two bicyclic olefins *(11)* and *(12)* were formed in traces at 0—25 °C. The structures of *(5)*, *(11)*[4], and *(12)* were secured spectroscopically and by independent synthesis. $AlCl_3$-catalyzed reaction of mesityl oxide and cyclopentadiene gave the corresponding *endo/exo* Diels-Alder adduct[5] which was methylated with methylmagnesium iodide to give *(5)* and also methylenated to give *(12)*. Our reaction scheme is further supported by isolating the product alcohols *(5)* and *(8)*, subjecting them to the reaction conditions, and invoking the principle of microscopic reversibility. For example, when *(5)* was allowed to react with aqueous acid under two phase conditions at higher temperature, *i.e.* 50 °C, the bicyclic olefins *(11)* and *(12)*, cyclic ether *(10)*, and a tricyclic alcohol were formed as comparatively stable products. Significantly, another consecutive product was monocyclic alcohol *(8)* and its dehydration products *(9a, b)*. On the other hand, heating *(8)* at 50 °C under two phase conditions gave compounds *(11)* and *(12)*, the above-mentioned tricyclic alcohol, and the ether *(10)*.

Does the postulated allyl cation intermediate *(2b)* undergo cycloaddition to cyclopentadiene to give the bridged cation *(3)* having a seven-membered ring, analogous to the cycloaddition of the 2-methylallyl cation to cyclopentadiene[1a]? Reduction of 2,2,4,4-tetramethylbicyclo[3.2.1]oct-6-en-3-one[6] with $LiAlH_4$ gave the secondary alcohol *(4)*, which was not dehydrated after 1 h under two phase conditions (reflux). Forcing conditions (heating with $POCl_3$ and pyridine at 117 °C) gave 2,3,4,4-tetramethylbicyclo[3.2.1]octa-2,6-diene, formed by 1,2-methyl shift, and ring-contracted olefin *(12)*[1b]. As we found no trace of *(4)* in the product of the two phase reaction, we believe that the secondary carbenium ion *(3)* is not involved here, and that in any event, its formation would be energetically unfavorable. The formation of the norbornene type alcohol *(5)* is therefore formulated as a stepwise, Diels-Alder-like reaction with an allyl cation as a "dienophile". Presumably, the present work is also related mechanistically to recent studies of 1-alkoxydehydroallyl type cations (generated from propiolic ester and $AlCl_3$), which have been shown to attack appropriate π systems with formation of six-membered and also four-membered rings[7]. Finally, our simplified two phase procedure for generating allyl cations from allyl alcohols is of general preparative interest.

Experimental

(1b) (2.85 g, 25 mmol) and cyclopentadiene (3.3 g, 50 mmol) in pentane (5 ml) are stirred with water (5 ml) containing *p*-toluenesulfonic acid (2.4 g, *ca.* 13 mmol). After 7 h

[***] Cycloadditions of Allyl Cations, Part 23. We thank the Fonds der Chemischen Industrie and Deutsche Forschungsgemeinschaft for support of our work.—Part 22: *H. M. R. Hoffmann, J. Matthei*, Chem. Ber., in press.

at 0 °C (or 4 h at room temperature) the reaction solution is neutralized with aqueous $NaHCO_3$, the organic phase is separated and the aqueous layer is extracted three times with pentane. The combined organic phase is washed with water, dried (Na_2SO_4) and the solvent is evaporated to leave an oil which is filtered through silica gel (25 g) using pentane as an eluent (200 ml). Elution of the more polar alcohols with ether and bulb-to-bulb distillation gives the following typical composition of products: alcohols *(5)* and *(8)* (1.65 g, 37%, *(5)*:*(8)* = 1:2.4); *(8)* consists of at least three monocyclic isomers (GC, carbowax 20 M), *(5)* is an epimeric mixture (*endo*:*exo* = 2.5:1). The less polar olefin fraction (0.70 g) (from elution with pentane) contains mainly dicyclopentadiene, *(11)* (1%), *(12)* (1%), and two substituted cyclopentadienes *(9a, b)*.

endo-(12) and *exo-(12)* were synthesized independently by methylenation[8] of 6-acetyl-5,5-dimethyl-2-norbornene[5].

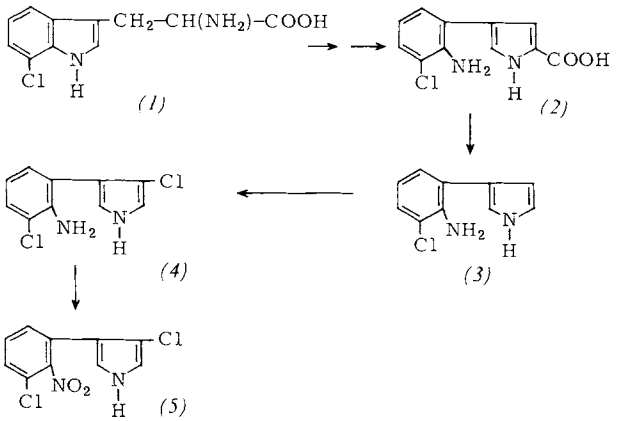
Formation of Pyrrolnitrin and 3-(2-Amino-3-chlorophenyl)pyrrole from 7-Chlorotryptophan



By *Karl-Heinz van Pée, Olga Salcher,* and *Franz Lingens*[*]

Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday

Several phenylpyrrole derivatives have been isolated from gram-negative *Pseudomonas* species and have been characterized; these include the antibiotic pyrrolnitrin *(5)*, aminopyrrolnitrin *(4)*[1] and 4-(2-amino-3-chlorophenyl)-2-pyrrolecarboxylic acid *(2)*[2]. 7-Chlorotryptophan *(1)*[3] was postulated as direct precursor of *(2)*[2]. At which stage of the biosynthesis is the second chlorine atom incorporated?

We report here on the formation of ^{36}Cl-labeled pyrrolnitrin from 7-chlorotryptophan *(1)* and on the isolation and characterization of the new phenylpyrrole derivative 3-(2-amino-3-chlorophenyl)pyrrole *(3)* from *Pseudomonas aureofaciens*, strain P[4].

Precultured cells from the early stationary growth phase of this strain of bacteria[4] were shaken with 2×10^{-3} M *(1)* and $Na^{36}Cl$ or D-tryptophan and $Na^{36}Cl$ for 5 days at 30 °C.

Ethyl acetate extracts were evaporated *in vacuo* and chromatographed on a silica gel 60-F_{254} precoated TLC plate with toluene as eluent. The pyrrolnitrin *(5)* that is formed can be determined with a UV thin layer scanner (calibrated with authentic *(5)*). The spots containing *(5)* were removed from the plate and the radioactivity measured in a dioxane liquid scintillator. The radioactivity of *(5)*—generated respectively by addition of *(1)* and $Na^{36}Cl$ and of D-tryptophan and $Na^{36}Cl$ to the cells—was in the ratio 54:100, *i.e.* one or two ^{36}Cl atoms, respectively, had been incorporated. Under otherwise equal conditions but in the absence of NaCl, the phenylpyrrole derivative *(3)* could be isolated. After an $OD_{560} = 2.0$ had been reached, 2.4×10^{-4} M 7-chlorotryptophan *(1)* was added. The fermentation was terminated after a further 24 h and the cell-free medium brought to pH 8.5 with ammonia. The ethyl acetate extract was evaporated *in vacuo* and chromatographed on silica gel 60 with toluene as eluent. The fractions with $R_f = 0.29$ in TLC (silica gel HF_{254}60, eluent toluene) and $R_f = 0.59$ (eluent toluene/dioxane (10:1), green color-reaction with van Urk's reagent[5]) were purified further by chromatography on silica gel 60 with toluene/dioxane (10:1) as eluent.

The band at longest wavelength in the UV spectrum of the new metabolites *(3)* shows—like the corresponding absorption of *(4)* and *(2)*—a strong hypsochromic shift on going from neutral to acidic medium. λ_{max} in MeOH, MeOH/0.1 N NaOH, and MeOH/0.1 N HCl is 303, 303, and 269, and 221, 221, and 230 nm, respectively.

The NH stretching vibration at 3300 cm^{-1} provides evidence of a pyrrole ring. In the mass spectrum (GC/MS)[6] the molecular ion appears as a doublet at $m/e = 192/194$ (intensity ratio 3:1). This is characteristic for a monochloro-substituted compound with an even number of N atoms.

From the spectral findings and the fact that compound *(3)* is formed by *P. aureofaciens* from 7-chlorotryptophan *(1)* we deduce the structure 3-(2-amino-3-chlorophenyl)pyrrole. *(3)* could be formed in the pyrrolnitrin biosynthesis from *(2)* by decarboxylation and chlorinated to aminopyrrolnitrin *(4)*. The proposed biosynthetic pathway must still be confirmed by enzymatic investigations of the individual steps.

UV Irradiation of Nucleic Acids and Their Components in the Presence of Air[**]

By *Egon Fahr, Peter Fecher, Georg Roth,* and *Peter Wüstenfeld*[*]

Dedicated to Professor Alfred Roedig to the occasion of his 70th birthday

The UV irradiation of nucleic acids and their components has been investigated in great detail *in vitro* and *in vivo*[1]. Essentially, addition of water to the 5,6-double bond of the pyrimidine bases and dimerization of the latter to cyclobutane derivatives is observed. With few exceptions these investigations were carried out in the absence of air.

We have now been able to show that the UV irradiation of nucleic acids and of pyrimidine components of nucleic acids with the usual Hg low-pressure and medium-pressure lamps proceeds completely differently if carried out in aqueous solution in the presence of air.

Very little has been reported in the literature about the UV irradiation of these educts in the presence of air or oxygen. In the case of thymine, thymidine, uracil, uridine, and other pyrimidine derivatives no oxidation products were detected[2]. *Wang* and *Alcantara*[3a,c] report that thymine is oxidized to uracil *via* 5-hydroxy(methyl)uracil, 5-formyluracil, and 5-uracil carbonate. In the case of 1,3-dimethyluracil and 1,3-dimethylthymine CO-elimination to give *N,N*-dimethylmalonodiamide and *N,N*-dimethylmethylmalonodiamide could be demonstrated[4] (see also [3b]).

We have found that photochemical addition of water to cytosine *(1)*, uracil *(2)*, and thymine *(3)* affords the 6-hydroxydihydropyrimidine derivatives *(4)*, *(5)*, and *(6)*, respectively, of which *(4)* is converted by deamination into the corresponding uracil derivative *(5)*. Photochemical oxidation of *(5)* leads *via* barbituric acid *(8)* to alloxan *(10)*; that of *(6)* to methylbarbituric acid *(9)*. Photochemical elimination of CO from *(9)* and *(10)* affords methylhydantoin *(14)* and parabanic acid *(12)*, respectively. The photochemical hydrolysis of *(12)* gives oxamide *(15)*, oxalic acid monoamide *(16)*, and urea *(17)*, that of *(9)* methylmalonamide *(11)* and that of *(8)* malonamide *(7)*. The photochemical oxidation of *(14)* leads to acetylurea *(13)*.

Cytosine *(1)* affords the same irradiation products as uracil *(2)*, since it is either converted *via (4)* into *(5)* or by direct photochemical oxidation into uracil *(2)*. *(2)* can be detected in the irradiation solution of *(1)*.

The photochemical CO-elimination observed here is also displayed by cytidine, uridine, and thymidine as well as the pyrimidine components of polyuridylic acid and DNA, but not by the purine components of nucleic acids (adenine, guanine, adenosine, and guanosine were investigated).

In the earth's atmosphere there are *ca.* 400 million tons CO, which decomposes with a halflife of *ca.* 3 months (CO cycle of the earth's atmosphere[5]). CO emission into the atmosphere is 1.3—1.5 thousand million tons per annum, of which *ca.* 300 million tons originate from biological processes.

The formation of CO by higher plants, fungi, algae and microorganisms and their dependence on light has been demonstrated on a number of occasions[6]; the reactions responsible, however, are largely unknown. Possibly the photochemical elimination of CO from nucleic acids described here contributes to this CO production.

Experimental

Ca. 10^{-3} M solutions of the educts in water, through which a stream of filtered air was passed, were irradiated with VG-NN-15/22 Hg low-pressure lamps or TQ 718 Hg medium-pressure lamps (Original Hanau, Quarzlampen-Gesellschaft, Hanau). Wavelengths <210 were eliminated by filter-solutions.

The identification of the compounds *(1)—(3)*, *(7)*, and *(9)—(17)* in the irradiation mixtures was achieved by GC and TLC comparison with authentic material and by the use of precision mass spectrometry. The 6-hydroxydihydropyrimidine derivatives *(4)* and *(5)* were detected by cleavage of H_2O to give *(1)* and *(2)*, respectively. *(6)* cannot be detected directly. Its intermediary formation follows from the secondary products *(9)* and *(11)*. Barbituric acid *(8)* is oxidized photochemically to alloxan *(10)* so rapidly that it cannot be found in the irradiation mixture. CO-detection tubes (Drägerwerk AG, Gasanalysentechnik, Lübeck) were employed for the detection of CO.

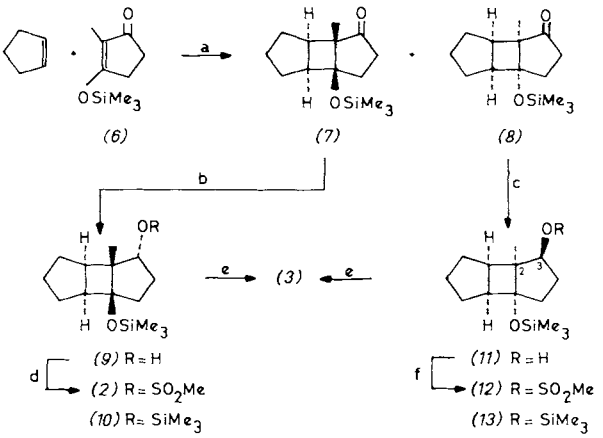
Fluoride-Induced Fragmentation of Trimethylsilyloxysulfonates to Form *cis*-Coupled Hexahydroazulenones[**]

By *Lutz-F. Tietze* and *Ulrich Reichert*[*]

Cleavage reactions of the heterolytic fragmentation type[1] have great importance in the stereoselective synthesis of olefins[2], in the preparation of cyclic compounds of medium ring size[3], and in the formation of substituted ring systems of definite configuration[4]. A general and simple method is the base-induced fragmentation of the monosulfonates of 1,3-diols. However, this method has the great disadvantage that condensations[4] and isomerizations at the α-position to the newly formed carbonyl group can occur in a strongly basic reaction medium[5]. Thus, in the fragmentation of compounds of the structural type *(1)* with potassium *tert*-butoxide or potassium hydroxide mainly the thermodynamically stable *trans*-coupled bicyclic system of type *(4)* is formed. The fluoride-induced fragmentation[6] of the silyl ether *(2)*, on the other hand, leads exclusively to the *cis*-coupled hexahydroazulenone *(3)*. *(3)* corresponds to the substructure of the sesquiterpene of the eregoyazine type[7].



(1) R = H
(2) R = $SiMe_3$

(3) R = α-H
(4) R = β-H

(5)

For the synthesis of *(2)* a 35:1 mixture of cyclopentene and the trimethylsilyl ether *(6)*, which can be prepared in 91% yield by reaction of 2-methylcyclopentane-1,3-dione with hexamethyldisilazane/imidazole, was photolyzed at −60 °C (Scheme 1). After chromatography the cyclobutane derivatives *(7)* and *(8)* are obtained in a ratio of *ca.* 3:2 (total yield 51%). *(7)* and *(8)* were reduced to the crystalline alcohols *(9)* (m.p. 74 °C) and *(11)* (m.p. 71 °C)[8a], which on reaction with methanesulfonyl chloride gave the sulfonates *(2)* and *(12)*[8b]. In the case of *(11)* the reaction proceeded very slowly owing to strong steric shielding, and was still not complete after 100 h.

Reaction of *(2)* and of *(12)* with potassium fluoride in the presence of [18]crown-6 in dichloromethane gave the *cis*-coupled bicycle *(3)* as sole product in 78% and 76% yield, respectively. Thus, for the synthesis of *(3)* it is not necessary to separate *(7)* and *(8)*. The formation of the (*Z*)-C=C double bond in *(3)* is consistent with the *trans* arrangement of the substituents on C-2 and C-3 in *(2)* and *(12)*.

(6) *(7)* *(8)*

(9) R = H
(2) R = SO_2Me
(10) R = $SiMe_3$

(11) R = H
(12) R = SO_2Me
(13) R = $SiMe_3$

Scheme 1. a: high-pressure mercury lamp, quartz apparatus, 4 h, −60 °C; chromatography on silica gel with ether/pentane (1:3); 31% *(7)*, $R_F = 0.56$; 21% *(8)*, $R_F = 0.58$.—b: $LiAlH_4$, ether, 3 h, 42 °C (83%).—c: $LiAlH_4$, ether, 3 h, 42 °C (90%).—d: $MeSO_2Cl$, pyridine, dimethylaminopyridine (DMAP) [9], 8 h, 20 °C (86%).—e: KF, [18]crown-6, CH_2Cl_2, 4 h, 20 °C (78/76%).—f: $MeSO_2Cl$, pyridine, DMAP [9], 100 h, 20 °C (68%). The yields refer to isolated and analytically pure products.

(3) did not isomerize under the given reaction conditions, even after 48 h. Treatment of *(3)* with potassium *tert*-butoxide, on the other hand, led to a 1:4-mixture of *(3)* and *(4)*. The structures of *(3)* and *(4)* are in agreement with the analytical data (cf. [10]).

Experiments with other nucleofugal groups were less clear-cut. Thus, reaction of *(9)* with trifluoromethanesulfonic anhydride/pyridine gave the fragmentation product *(3)* directly in 50% yield together with 35% *(10)*; *(11)* afforded 46% *(3)* and 35% *(13)*. Presumably the trifluoromethanesulfonates are initially formed, at least partially, and then these fragment to *(3)* by nucleophilic attack of the trifluoromethanesulfonate ion at the silyl group. The trimethylsilyl trifluoromethanesulfonate formed in this reaction could then silylate unreacted *(9)* and *(11)* to *(10)* and *(13)*, respectively.

The scope of the above fragmentation reaction appears to be limited to strained cyclic systems. Thus the silyl ether *(5)*[11] does not react with potassium fluoride/[18]crown-6 within 24 h at 20 °C.

Thermal [2+2]-Cycloadditions of Tetracyanoethylene to Cyclic Thioenol Ethers[**][1]

By *Siegfried Fries* and *Klaus Gollnick*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Thermal [2+2]-cycloadditions of tetracyanoethylene *(1)* to *acyclic* thioenol ethers have recently been the subject of numerous reports[2].

We have now found that thermal [2+2]-cycloadditions of *(1)* to the *cyclic* thioenol ethers *(2a, b)* (3,4-dihydro-2*H*-thiopyrans) and *(2d-f)* (2,3-dihydrothiophenes) occur—*via* spontaneously formed, deep-blue CT complexes which disappear within minutes at room temperature and at about $-20\,^\circ C$, respectively—to give the corresponding tetracyanocyclobutane derivatives *(4)*, which generally crystallize analytically pure in 85—95% yield[3].

	n	X	R^1	R^2
a	2	S	H	H
b	2	S	CH_3	H
c	2	O	H	H
d	1	S	H	H
e	1	S	CH_3	H
f	1	S	CH_3	$CH(CH_3)_2$
g	1	O	CH_3	H

The oxygen analogues *(2c)* and *(2g)* react with *(1)* to give red CT complexes which are stable at $-20\,^\circ C$, but cyclize at $+20\,^\circ C$ within 4 h and ≈ 1 min, respectively, to the corresponding tetracyanocyclobutanes *(4c)* and *(4g)*. Obviously, 3,4-dihydro-2*H*-thiopyrans such as *(2a)* and 2,3-dihydrothiophenes such as *(2e)* react with *(1)* much more rapidly than their oxygen analogues. Under otherwise equal conditions the rates of cycloaddition (determined as the time elapsed up to disappearance of the CT complexes) of *(1)* to the cyclic thioenol ethers increase along the series *(2a)* < *(2b)* < *(2d)* < *(2f)* ≤ *(2e)*. Thus, 2,3-dihydrothiophenes react faster than 3,4-dihydro-2*H*-thiopyrans, and the methyl-substituted derivatives such as *(2b)* and *(2e)* react better than their unsubstituted parent compounds *(2a)* and *(2d)*, respectively. The relatively bulky isopropyl group in *(2f)* only moderately retards the rate of cycloaddition. Increasing solvent polarity promotes the cycloaddition; thus, the reaction rates of *(1)* + *(2a)* in tetrahydrofuran (E_T[4] = 37.4), dichloromethane ($E_T = 41.1$), and acetonitrile ($E_T = 46.0$) are in the ratio of about 1:2:10.

Increasing solvent polarity promotes not only the cycloaddition, but also the dissociation of the cyclobutane derivatives *(4d, f, g)* to their educts. The cycloreversion is easily recognized by the characteristic color of the CT complexes which appear on dissolution of the cyclobutanes in dimethyl sulfoxide or acetonitrile. Furthermore, elimination of hydrogen cyanide occurs; compounds *(5)*, however, were not intercepted. Formation of HCN is also observed in the reaction of *(1)* with the 2,3-dihydrothiophenes in acetonitrile at room temperature, whereas with 3,4-dihydro-2*H*-thiopyrans only cycloaddition reactions occur.

Our results can only be explained by assuming that in the rate-determining step zwitterionic intermediates of type *(3)* are formed, as is the case in the reaction of *(1)* with enol ethers [5]. Depending upon the solvent polarity, the zwitterions *(3)* then undergo competition reactions to give the cycloadducts *(4)* or eliminate HCN with formation of *(5)*. Alkyl substituents R^1 (such as CH_3) stabilize an intermediate carbenium ion and thus lower the energy of the transition state which leads to the zwitterion. The reaction of *(1)* with cyclic thioenol ethers is therefore accelerated by an α-methyl group as is the dissociation of the cycloadducts. The increased rate of cyclization of thioenol ethers with *(1)* and the enhanced cycloreversion of their cycloadducts as compared to the reactions of the corresponding oxygen derivatives are then due to the fact that sulfonium ions *(3)*, X = S, are more resonance-stabilized than the corresponding oxonium ions *(3)*, X = O. Since all steps of the cycloaddition reactions are reversible, we assume that the cycloadducts *(4)* exhibit the thermodynamically more stable *cis*-fusion of the rings.

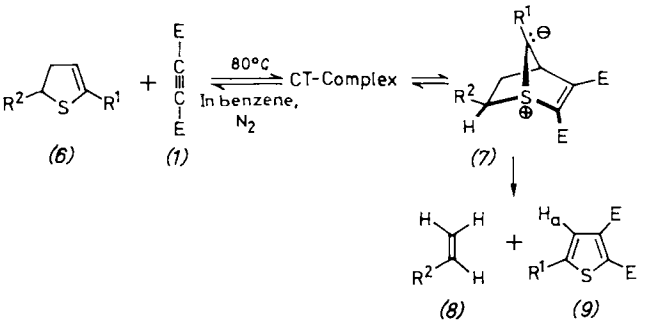
Thermal Cycloadditions of Dimethyl Acetylenedicarboxylate to Cyclic Enol Ethers and Thioenol Ethers[**]

By *Klaus Gollnick* and *Siegfried Fries*[*]

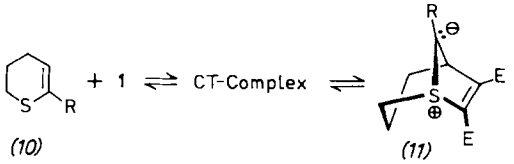
Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



Cyclic enol ethers and thioenol ethers cycloadd to tetracyanoethylene (TCNE) in high yields under mild conditions[1]. On attempting to react dimethyl acetylenedicarboxylate *(1)*, $E = CO_2CH_3$, with 3,4-dihydro-2*H*-pyran, 2,3-dihydrofuran, or 5-methyl-2,3-dihydrofuran *(2)*, only the α-methylated enol ether *(2)* proved to be reactive enough to give *via* a pale yellow CT complex the [2+2]-cycloproduct *(4)*[2] as well as dimethyl 2-(2-methyl-4,5-dihydro-3-furyl)fumarate *(5)*[3].

Formation of *(5)* from the cycloadduct *(4)* is ruled out, since *(4)* is stable even in boiling toluene (110 °C). We assume that a zwitterionic intermediate *(3)* is formed from the CT complex, as was similarly discussed for [2+2]-cycloadditions with TCNE. Only then is the formation of *(5)* easily explained by prototropy in the dipole. The remarkable reaction-promoting influence of a methyl group, which has also been observed in the [2+2]-cycloaddition of *(1)* to 2-alkoxy-3,4-dihydro-2*H*-pyrans[4] and of TCNE to enol ethers and thioenol ethers[1], is then due to a stabilization of the oxonium ions of type *(3)*; alkyl groups thus lower the transition states which have to be passed in the rate-determining step that leads to the zwitterion.

The thioenol ethers *(6a—c)* and *(10a, b)* form yellow CT complexes on reaction with *(1)* in benzene. However, whereas the 3,4-dihydro-2*H*-thiopyrans *(10a, b)* are recovered unchanged from boiling benzene, the 2,3-dihydrothiophenes react with *(1)* in boiling benzene within several hours to give the alkenes *(8)* and dimethyl 2,3-thiophenedicarboxylates *(9)*[5].



Of the three 2,3-dihydrothiophenes, *(6c)* reacts most rapidly. 3-Methyl-1-butene *(8b)* is apparently a better leaving group than ethylene. This was shown also in an attempt to react *(6a—c)* with methyl propiolate in boiling xylene

(6a), $R^1 = R^2 = H$ → *(8a)*, $R^2 = H$ + *(9a)*, $R^1 = H$
(6b), $R^1 = CH_3$, $R^2 = H$ → *(8a)*, $R^2 = H$ + *(9b)*, $R^1 = CH_3$
(6c), $R^1 = CH_3$, $R^2 = i\text{-}C_3H_7$ → *(8b)*, $R^2 = i\text{-}C_3H_7$ + *(9b)*, $R^1 = CH_3$

(140 °C), in which only *(6c)* underwent olefin elimination to give *(8b)*.

The results may be easily explained in terms of a *[2+3]-cycloaddition* of *(1)* to the thioenol ethers *(6)* to afford the bicyclic sulfonium ylides *(7)*, which subsequently react according to a retro-[2+3]-cycloaddition by elimination of an alkene *(8)* to give a 2,3-thiophenedicarboxylic acid ester *(9)*. The sulfonium ylide *(7)* may be stabilized by an overlap of the sp^3 anion orbital with a sulfur d-orbital[9]; in the oxygen analogue of *(7)*, however, the formation of a (p-d)π bond is impossible. The reaction of *(1)* with *(2)* therefore appears to prefer the energetically favored route *via* the 1,4-dipole *(3)*. *(1)* should also react with the 3,4-dihydro-2*H*-thiopyrans *(10a, b) via* CT complexes to give sulfonium ylides *(11)*, but this route proves to be a dead end, since the stabilization by a retro-[2+3]-cycloaddition to give *(1)* + *(10)* is apparently far more effective than by a fragmentation to 2,3-thiophenedicarboxylic ester + cyclopropane.

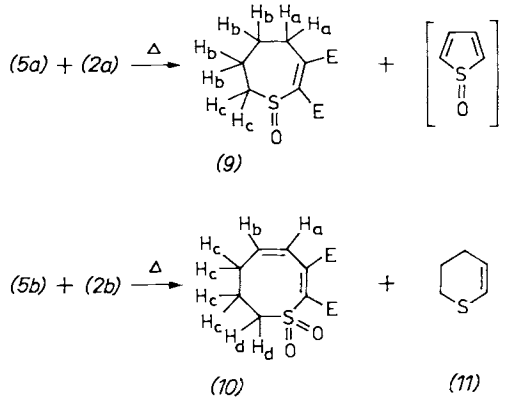
Thermal Additions of Dimethyl Acetylenedicarboxylate to Cyclic Thioenol Ether 1-Oxides with Ring Expansion[**]

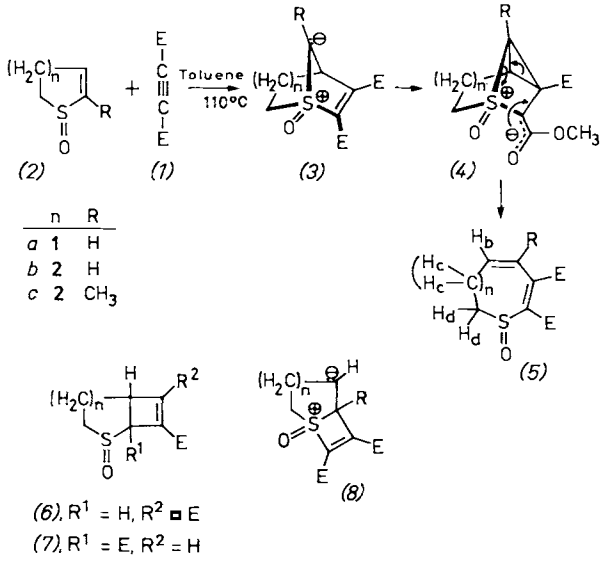
By *Klaus Gollnick* and *Siegfried Fries*[*]



Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Cyclic thioenol ethers react with tetracyanoethylene (TCNE) to give [2+2]-cycloadducts[1a]. With dimethyl acetylenedicarboxylate *(1)*, $E = CO_2CH_3$, however, they undergo [2+3]-cycloaddition reactions to form unstable sulfonium ylides[1b].

Like their parent cyclic thioenol ethers, the 1-oxides afford colored CT complexes with TCNE; however, [2+2]-cycloadditions do not occur. With *(1)* and the 1-oxides of 2,3-dihydrothiophene *(2a)*, 3,4-dihydro-2*H*-thiopyran *(2b)* and its α-methyl derivative *(2c)* colored CT complexes are no longer observed. If, however, the components are heated for several hours in benzene at 80 °C or in toluene at 110 °C, dimethyl 6,7-dihydrothiepin-2,3-dicarboxylate 1-oxide *(5a)*, dimethyl 3,4-dihydro-2*H*-thiocin-7,8-dicarboxylate 1-oxide *(5b)* and its 6-methyl derivative *(5c)*[2], respectively, are isolated in about 10% yield (benzene) or 35% yield (toluene) (after chromatographic purification).



[2+2]-Cycloadditions to give cycloadducts of type *(6)* (with subsequent rearrangement *via (7)* to give *(5)*), and presumably also of type *(8)* are ruled out as a mode of formation[3]. On the other hand, a [2+3]-cycloaddition of *(1)* to *(2a—c)* to give the sulfonium ylide *S*-oxide *(3)* appears to be an attractive reaction route; in a similar way reactions of *(1)* and cyclic thioenol ethers afford bicyclic sulfonium ylides[1b]. However, whereas the latter undergo only retro-[2+3]-cycloadditions, the ylides *(3)* should be able to react further in an intramolecular Michael addition to give the tricyclic sulfonium ylide *S*-oxides *(4)*[4]. The tricycles *(4)* then rearrange to the monocyclic sulfoxides *(5)*. With the formation of *(3)* as the rate-determining step the observations that *(2c)* reacts essentially slower than *(2b)*, and that 2-isopropyl-5-methyl-2,3-dihydrothiophene 1-oxide no longer reacts, become intelligible[3].

The sulfoxides *(2a—c)* are stable for longer periods even in boiling xylene (140 °C). On the other hand, in the absence of solvents they rapidly disproportionate at higher temperatures into the thioenol ethers and the thioenol ether 1,1-dioxides. On heating 1:1 mixtures of the sulfoxides *(2b)* and *(5b)* in the absence of solvents, oxygen transfer takes place exclusively from *(2b)* to *(5b)* to give dimethyl 3,4-dihydro-2*H*-thiocin-7,8-dicarboxylate *(10)*[5] and the thioenol ether *(11)*. Under the same conditions, sulfoxides *(2a)* and *(5a)*, however, disproportionate by hydrogenation of *(5a)* to dimethyl 4,5,6,7-tetrahydrothiepin-2,3-dicarboxylate 1-oxide *(9)*[6] and by dehydrogenation of *(2a)* to the as yet unobtained monomeric thiophene 1-oxide[7]. Heating of the sulfoxides *(5a)* and *(5b)* above their melting points results only in resinification. These reactions may drastically lower the yields of *(5)*.

A Cationic Ethylene(hydrido)iridium(III) Complex

By *Bernhard Olgemöller* and *Wolfgang Beck*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Hydridoolefin complexes of cobalt(III), rhodium(III), and iridium(III) occur as intermediates in the catalytic hydrogenation and hydroformylation of olefins[1]. We have been able to isolate the cationic iridium complex *(2)* by substitution of the tetrafluoroborate ligand in the hydride *(1)* by ethylene. Compound *(1)* has been prepared by oxidative addition of HBF_4 to the Vaska compound *trans*-$(Ph_3P)_2Ir(CO)Cl$[2].

The salt *(2)* is thermolabile (decomposition above 0 °C) and sensitive to moisture. The structure of its cation can be established unequivocally by ^{1}H-NMR spectroscopy. The signal of ethylene coordinated in *(2)* ($\delta_{C_2H_4}=4.37$ in CD_2Cl_2 rel. to $CHDCl_2=5.33$ at −43 °C) appears upfield from that of free ethylene ($\delta_{C_2H_4}=5.38$). The hydride absorption is observed as a triplet ($^2J_{PtH}=11$ Hz) at $\delta_H=-7.35$. A square-planar ethylene-hydrido complex, *viz. trans*-$[(Et_3P)_2Pt(C_2H_4)H]^{\oplus}$, has been known for some time[3]. Hydrido-d^6-metal compounds of—generally cyclic—oligoolefins have been reported on several occasions[4]. A cationic ethylene hydrido complex of rhodium[5] and dihydrido-monoolefin-iridium compounds have recently been described[6].

Reaction of the cationic iridium complex *(2)* with pentacarbonylrhenate(−1) in tetrahydrofuran leads in a reductive elimination *via* an isolable pale yellow intermediate to pentacarbonyl(ethyl)rhenium (MS: $m/e=355.97$, calc. 355.967)[7]:

$$(2) + Re(CO)_5^{\ominus} \xrightarrow[-BF_4^{\ominus}]{} C_2H_5Re(CO)_5 + (Ph_3P)_2Ir(CO)Cl$$

We assume the intermediate to have the structure of a bis-metalated ethane, as has been found for $(CO)_5ReCH_2CH_2Re(CO)_5$[8].

Synthesis of carbonyl(chloro)ethylene(hydrido)bis(triphenylphosphane)iridium(III) tetrafluoroborate (2)

All operations were performed under dry argon in dry solvents.—Dry C_2H_4 (molecular sieve) is passed at −40 °C through a suspension of *(1)* (750 mg, 0.86 mmol) in CH_2Cl_2 (10 ml). A clear solution is formed within 30 min, which is kept at this temperature for 1 h. On addition of cold *n*-pentane (40 ml), *(2)* precipitates as a colorless, finely crystalline powder. It is washed twice with *n*-pentane (2 × 10 ml) at −40 °C and dried at −30 °C *in vacuo*. The compound decomposes to ethylene and *(1)* above *ca.* 0 °C.

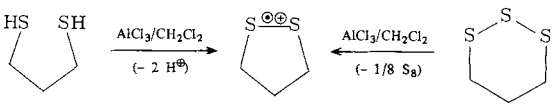
One-Electron Oxidation of 1,2-Dithiacycloalkanes[**]



By *Hans Bock* and *Udo Stein*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The electron-rich sulfur-sulfur bond in disulfides XSSX changes considerably with the substituents X and the dihedral angle ω (XS—SX)[1-3]: thus the bond length d_{SS} varies between 188 and 222 pm (FSSF with $\omega=88°$ and S_7O with $\omega=6°$)[1,2] and the splitting of the sulfur electron pair ionization energies $\Delta IE_{1,2}$ between 0.2 and 1.8 eV (H_3CSSCH_3 with $\omega=85°$ and α-lipoic acid with $\omega=35°$)[1,3]. Donor-substituted disulfides exhibiting small dihedral angles should therefore be oxidizable to stable radical cations[4] in solution: during this transformation the electron density in the RS—SR bond is lowered and a favorable charge distribution is established by structural modifications such as bond contraction $\Delta d_{S^{\oplus\cdot}S}$ and flattening $\omega(RS^{\ominus\oplus}SR)\rightarrow 0°$[5].

The five-membered ring disulfide 1,2-dithiolane will be presented as an example (Fig. 1). Its unknown dihedral angle should be *ca.* 30°[3], the splitting $\Delta IE_{1,2}$ reaches 1.75 eV (!), and the "vertical" first ionization energy $IE_1^v=8.22$ eV is lowered by about 0.5 eV relative to diethyl disulfide[3]. Oxidation can be accomplished with $AlCl_3/CH_2Cl_2$—which generally requires $IE_1^v<7.9$ eV[6]—because "adiabatic" structural changes in solution effect additional stabilization of the incipient 1,2-dithiolate radical cation and thus lower the oxidation potential.

The energetically favorable 1,2-dithiolane radical cation is also formed on $AlCl_3/CH_2Cl_2$ oxidation of 1,3-propanedithiol with ring closure or of 1,2,3-trithiane with deposition of sulfur and ring contraction:

The equivalence of the adjacent methylene protons of the oxidized five-membered ring disulfide $(CH_2)_3S_2^{\odot\oplus}$ at 300 K (Fig. 1) confirms time-averaged planarity of the $CS^{\odot\oplus}SC$ group, and the large *g* factor of 2.0183 as well as the large ^{33}S isotope coupling constant evidence a pronounced spin density at the sulfur centers[7,8]. This interpretation of the ESR data is supported by INDO open-shell calculations; the bond contraction Δd_{S-S} should amount to about 10 pm[1].

Disulfides containing six- and seven-membered rings can be oxidized to the homologous 1,2-dithiane and 1,2-dithie-

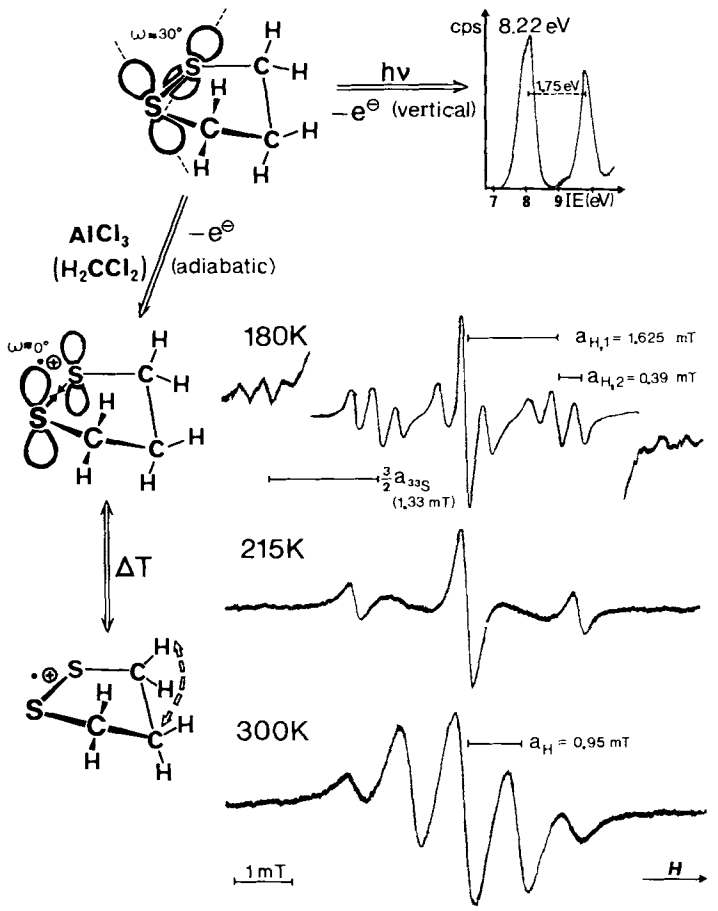
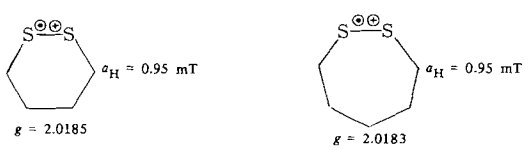
[**] Radical Ions, Part 44.—Part 43: *W. Kaim, H. Tesmann, H. Bock*, Chem. Ber., in press.





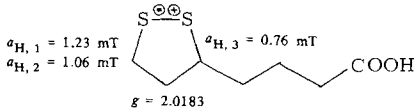


Fig. 1. The unstable compound 1,2-dithiolane can be prepared in benzene solution by oxidation of 1,3-propanedithiol with iodine in the dark and with addition of the polymerization inhibitor Et_3N. After removal of the solvent at 300 K, it can be evaporated into a photoelectron spectrometer by rapid heating to 350 K [1]. The first PE band with a "vertical" maximum at 8.22 eV is separated by 1.75 eV from the second ionization likewise assigned to sulfur electron pair combination, and its low energy foot extends to about 7.3 eV. One-electron oxidation with $AlCl_3/CH_2Cl_2$ affords a persistent radical cation whose $CS^{\oplus\oplus}SC$ skeleton is shown by optimized-geometry INDO open-shell calculations to be completely planar. The low temperature spectrum shows a triplet of triplets corresponding to the two different pairs of adjacent methylene protons. On edge amplification, the ^{33}S isotope coupling constants of 1.33 mT become visible; the factor $g = 2.0183$ is considerably higher than that for the free electron $g = 2.0023$. The central methylene bridge begins to invert above 200 K, and at 300 K a quintet is observed due to the four neighboring protons which are now equivalent on the NMR time scale. The temperature dependence of the line shape permits estimation of the activation barrier for the 1,2-dithiolane radical cation as 8 kJ/mol [1].

pane radical cations, which expectedly—the positive charge largely localized in the disulfide bridge is partly transferred by hyperconjugation to the adjacent methylene groups—exhibit comparable ESR spectra:

However, differences become apparent on replacement of H_2C by $(H_3C)_2C$ chain members: 4,4-dimethyl substitution of the 1,2-dithiolane radical cation raises the activation threshold for molecular fluctuation (Fig. 1) from 8 to 18 kJ/mol. Such a stiffening of the molecular skeleton is especially pronounced in the 4,4,6,6-tetramethyl-1,2-dithiepane radical cation, which merely shows a triplet for the two adjacent axial methylene protons at 300 K.

Selective $AlCl_3/CH_2Cl_2$ oxidation also permits transformation of biologically active compounds, such as α-lipoic acid which plays an important role as coenzyme in pyruvate decarboxylation[9], into their radical cations:

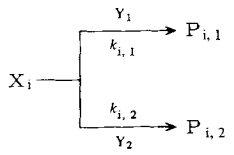
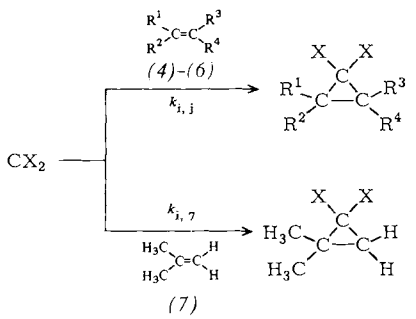
The Significance of Isoselective Temperatures for the Existence of Linear Free-Energy Relationships[**]



By *Bernd Giese* and *Woo-Bung Lee*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In many cases of competing reactions of molecules X_i with the reaction partners Y_1 and Y_2 a coincidence of the selectivities $\log(k_{i,1}/k_{i,2})$ is observed in a narrow temperature range, the isoselective temperature T_{is}[1]. Above and below T_{is} the order of selectivities of the molecules X_i is exactly reversed.



[*] Prof. Dr. B. Giese, W.-B. Lee
Institut für Organische Chemie und Biochemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

If the competing pair Y_1/Y_2 is left unchanged, then different isoselective temperatures are observed for various classes of substances X_i. Thus T_{is} drops from 360 through 310 to 210 K in radical halogen abstractions in the $BrCCl_3/CCl_4$ competition system if there is a transition from alkyl radicals of the π-type *via* sp^2-hybridized σ-radicals to sp^3-hybridized bridgehead radicals[1,2].

The influence of the variation of reaction partners Y_j of the competing system on the isoselective temperature was previously unknown. To answer this question we have investigated the cycloadditions of the dihalocarbenes *(1)—(3)* with various pairs of the alkenes *(4)—(7)*[3].

(7)

X		R^1	R^2	R^3	R^4	
F	*(1)*	CH_3	CH_3	CH_3	CH_3	*(4)*
Cl	*(2)*	CH_3	CH_3	CH_3	H	*(5)*
Br	*(3)*	CH_3	H	H	CH_3	*(6)*
		CH_3	CH_3	H	H	*(7)*

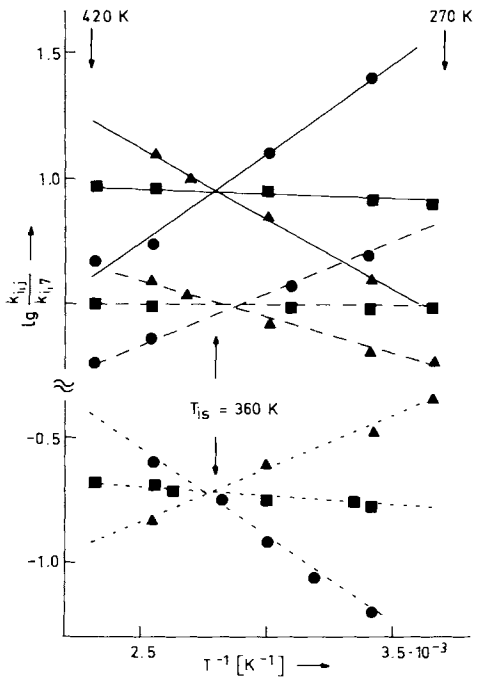


Fig. 1. Selectivities of the carbenes CF_2 (●), CCl_2 (■), and CBr_2 (▲) in cycloadditions with the alkene pairs *(4)/(7)* (solid lines), *(5)/(7)* (dashed lines), and *(6)/(7)* (dotted lines) between 270 and 420 K.

In Figure 1 the carbene selectivities measured between 270 and 420 K are plotted against T^{-1}. The three groups of lines show that different isoselective relationships exist for different alkene pairs[1]. Surprisingly, however, the selectivity lines for each competition pair intercept at 360 ± 10 K. Hence the substituents on the alkenes *(4)—(7)* have an influence on the isoselective relationship, but no influence on the isoselective temperature.

These astonishingly constant isoselective temperatures can only be due to special substituent effects. In fact, the reactivity of alkylated alkenes in cycloadditions with singlet carbenes at 298 K obeys a common linear free-energy relationship, as found by *Skell*[4] and *Moss et al.*[5]. If this dependence stems from a structure-reactivity correlation, then a linear relationships between these series of reactivities must also exist at other temperatures.

At the isoselective temperature the variation of the alkenes has exactly the same effect on the selectivity of the carbenes *(1)—(3)*. An interception of the carbene selectivities for a specific alkene pair must therefore be repeated in each of the other competing systems if there is a common linear free-energy relationship for the substituent effects.

Together with the results of radical substitutions in the $BrCCl_3/CCl_4$ competition system[2,6], these cycloadditions of the carbenes demonstrate that isoselective temperatures must be of the same order, if series of reactions between X_i and Y_j are to be correlated linearly. Thus, the determination of isoselective temperatures opens up an accurate and generally valid method for testing the description of substituent effects by linear free-energy relationships.

(Trifluoromethyl)fluorogermanates

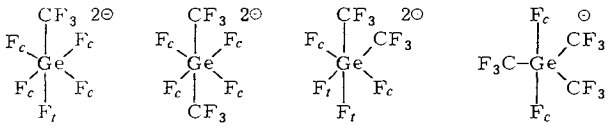
By *David J. Brauer, Hans Bürger*, and *Reint Eujen*[*]

Since it was first synthesized, CF_3GeF_3 has been shown to react with excess aqueous KF forming $K_2[CF_3GeF_5]$[1]. We have now found that other trifluoromethylgermanium halides $(CF_3)_nGeX_{4-n}$, $n = 1—4$, X = F, Cl, Br, I[2,3] are remarkably stable towards H_2O and are decomposed only by $OH^{\ominus}$ with formation of HCF_3. Their miscibility with H_2O decreases with increasing CF_3 content n. They may be extracted undecomposed from the aqueous phase by organic solvents, such as ether.

The halide $X^{\ominus}$ (X = Cl, Br, I) may be precipitated quantitatively from aqueous solution as AgX without the CF_3Ge moiety being attacked. The addition of $F^{\ominus}$ *via* NaF or NH_4F leads to readily soluble (trifluoromethyl)fluorogermanates:

[*] Prof. Dr. H. Bürger, Dr. R. Eujen, Dr. D. J. Brauer
FB 9—Anorganische Chemie, Gesamthochschule-Universität
Gaussstr. 20, D-5600 Wuppertal 1 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/1010-0836 $ 02.50/0



$$(CF_3)_nGeX_{4-n} \xrightarrow{F^{\ominus}} (CF_3)_nGeF_{6-n}^{2\ominus}$$

(1), $n=1$; *(2)*, $n=2$

$$(CF_3)_3GeX \xrightarrow{F^{\ominus}} (CF_3)_3GeF_2^{\ominus}$$

(3)

With $F^{\ominus}$ in excess, the intermolecular F-exchange is so slow that the coupling between CF_3- and GeF-groups is observable in the ^{19}F-NMR spectra (Table 1). The coupling patterns of the spectra, which are more readily interpretable than are those of the isoelectronic fluorophosphates[4], indicate that the six-coordinate, octahedral structures *(1)* and *(2a)* and five-coordinate, trigonal-bipyramidal structure *(3)* exist in solution.

(1) *(2a)* *(2b)* *(3)*

Table 1. ^{19}F-NMR spectra of (trifluoromethyl)fluorogermanates [a].

	$\delta(CF_3)$	$\delta(F_c)$	$\delta(F_t)$	$^3J(FF_c)$	$^3J(FF_t)$	$^2J(F_cF_t)$
(1)	−14.05	45.4	42.1	14.6	<0.3	23.7
(2a)	−14.13	47.1	—	14.5	—	—
(3)	−15.10	60.5	—	9.5	—	—

[a] Chemical shifts rel. CF_3COONH_4 int.; coupling constants in Hz.

In solution, the dianion *(2)* is present to more than 90% as the *trans*-isomer *(2a)*. The NMR evidence for the presence of the *cis*-isomer *(2b)* is uncertain because of the complexity of the $A_2BB'X_3X_3'$ spectrum; however, the moderately soluble potassium salt of *(2b)* could be crystallized from the mixture and characterized by an X-ray structure analysis. Solutions of *(3)* have to be saturated with NH_4F in order to suppress F-exchange. Only then are a triplet and decet observed in the ^{19}F-NMR spectrum in the ratio 9:2, with chemical shifts which deviate markedly from those of the hexacoordinated species *(1)* and *(2a)*. On dissolution in saturated NH_4F solution $(CF_3)_4Ge$ slowly decomposes, mainly to *(3)*. However, because of the F-exchange the NMR signal $\delta(CF_3) = -18.4$ shows no structurally diagnostic fine structure.

The X-ray structure analysis of $K_2[cis\text{-}(CF_3)_2GeF_4]$[5] shows that the distorted octahedral anion *(2b)* (Fig. 1) and the two cations have crystallographic symmetry C_2. The nearly identical GeF bond lengths are longer than in K_2GeF_6 (1.77 Å[6]); furthermore, the GeC bond lengths and FCF angle are respectively 0.052(5) Å longer and 4.5(3)° smaller than corresponding r_α values in $Ge(CF_3)_4$[7]. Each K

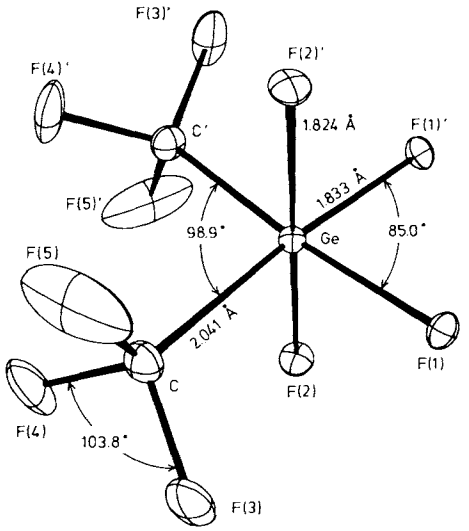


Fig. 1. Structure of *(2b)* in the crystal $K_2[cis\text{-}(CF_3)_2GeF_4]$.

atom has 10 nearest F atoms as neighbors, namely four or six F(Ge) atoms at 2.644(2) to 2.798(2) Å, and six or four F(C) atoms at 2.973(3) to 3.269(4) Å.

Procedure

A solution of NaF (235 mg, 5.6 mmol) in H_2O (2 ml) is treated with 650 mg (1.4 mmol) $(CF_3)_2GeI_2$. On vigorous shaking, the liquids slowly mix. After removal of the H_2O *in vacuo*, the solution is washed free of $I^{\ominus}$ with ethanol and the residue is dried in a vacuum. Yield: 380 mg (82%) $Na_2[(CF_3)_2GeF_4]$.

Grundlagen der Kalorimetrie [Principles of Calorimetry]. By *W. Hemminger* and *G. Höhne*. Verlag Chemie, Weinheim 1980. xiv, 256 pp., bound, DM 88.00.

In view of the fact that no book in the German language dealing exclusively with calorimetry has appeared since *W. Roth* and *F. Becker*'s monograph (1956), although the importance of this method of measurement has been increasing continuously, the appearance of this book can only be welcomed.

The declared aim of this monograph is to provide information about the technical state of commercial apparatus and, with the aid of examples, to encourage the application of calorimetric methods. Accordingly, the book is divided into two parts, the first part being devoted to calorimetry and the second to calorimeters. The first part is preceded by a clear systematic classification of calorimeters subdivided according to the measurement principle, method of operation, and type of construction. This introductory matter must be welcomed, since it assists in throwing light on the jungle of nomenclature used in publications both as regards calorimeters themselves and the measurement principles. Other points of emphasis in the first part are the descriptions of the instruments for recording the measurements and the presentation of the thermodynamic principles, heat-transport phenomena, and the ambient and operating conditions. Finally, the evaluation of the measured curves is discussed in full. The second part is devoted to historical and current commercial apparatus. It is clear that the fundamental ideas in the field of calorimetry go back to such well-known workers as *Bunsen* and *Eucken*, and it is not a criticism to report that descriptions of individual examples of special apparatus available only to small research groups are not given.

The last section is intended to assist in the selection and evaluation of the suitability of calorimeters. Here there are some valuable pointers on the basis of which apparatus best suited to the solution of particular problems can be selected. The decision is helped by a list of addresses of the suppliers and associations concerned.

The book does not assume any special knowledge and is directed at practical research workers, advanced students, and interested industrial workers. Detailed and comprehensive accounts of individual solutions to problems cannot, therefore, be expected. However, for the group at which it is aimed this book is recommended reading.

Horst Klump [NB 519 IE]

Semisynthetic Proteins. By *R. E. Offord*. John Wiley & Sons, New York 1980. xi, 235 pp., bound, £ 17.00.

Protein semisynthesis is the use of fragments of naturally occurring proteins as easily available intermediates for building up proteins with new types of structures. If, for example, it is desired to investigate the effect of a single amino acid on the biological activity of a protein molecule, it is not necessary to build up the entire molecule step by step. Semisynthesis should always be considered in such cases if the molecular fragment to be replaced is located in a strategically favorable position of the amino-acid sequence, *e.g.* at the N-terminus; this end can be degraded stepwise, *e.g.* by the Edman method, and be replaced by acylation with suitable amino-acid and peptide derivatives (permutation). *Offord* is a pioneer in protein semisynthesis, and the present monograph summarizing his experience and that of his many friends and associates is therefore highly welcome. In it he has succeeded not only in presenting the theoretical principles of protein semisynthesis clearly and critically, but also in greatly facilitating the entry of newcomers into this field with proven laboratory procedures. The book is divided into eight chapters: Synthesis and Semisynthesis, Protecting Group Tactics for Splitting off Fragments, Cleavage and Separation of Protein Fragments, Protecting Group Tactics after Cleavage, Methods of Coupling, Cleavage of Protecting Groups and Purification, and Review of Published Papers on Protein Semisynthesis.

The book is most warmly recommended to biochemists, molecular biologists, pharmacologists, and chemists who wish to work in the field of protein semisynthesis.

Helmut Zahn [NB 521 IE]

Ullmanns Encyklopädie der technischen Chemie [Ullmann's Encyclopedia of Industrial Chemistry]. Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), *W. M. Wiegert* (deceased), and *E. Weise*. Vol. 18: Petrolsulfonate bis Plutonium [Petroleum Sulfonates to Plutonium]. Verlag Chemie, Weinheim 1979. 4th edit., xvi, 738 pp., bound, DM 475.00.

Another volume[*] of the new edition of Ullmann has arrived. Its most comprehensive entries are on Pharmaka [Pharmaceuticals], Phosphor und seine Verbindungen [Phosphorus and its Compounds], Photographie [Photography], and Pigmente [Pigments]; together they make up two-thirds of the contents. The entry on Pharmaceuticals (107 pages) begins with a general part which, in addition to an introductory section on the action of pharmaceuticals, deals with the testing of drugs and the statutory regulations concerning their registration and marketing. This is followed by special entries on individual areas such as Antiepileptika [Antiepileptics], Kontrazeptiva [Contraceptives], Muskelrelaxantien [Muscle Relaxants], and Psychopharmaka [Psychopharmaceuticals]; here it must be observed that other, more extensive, areas of pharmaceuticals, *e.g.* antibiotics or heart and circulation agents, appear in other volumes under their own entries in accordance with their positions in the alphabet. Pharmazeutische Technologie [Pharmaceutical Technology] (25 pp.), *i.e.* the science of preparation forms of drugs (liquids for injection, tablets, ointments, *etc.*), an important field that is also known under the name of Galenik [Galenics], is also treated on its own. The entry on Photography (102 pp.) treats photographic chemistry in the form of a monograph, the processes of colour photography being illustrated in color. The Pigments entry (a total of 150 pp.) contains special sections on several inorganic and organic pigments, dealing not only with manufacturing processes but also with applications and toxicology. Among other things, it states that the world consumption of the most commonly used white pigment, titanium dioxide, in 1976 was 1.85×10^6 tons! Under Phosphorus and its Compounds (a total of 115 pp.) we find, besides elemental phosphorus, the phosphorus oxides, phosphorus acids, and phosphates, as well as the other organic and inorganic phosphorus compounds. The present volume also includes entries on Platinmetalle [Platinum Metals] and their compounds (32 pp.), Plutonium (10 pp.),

[*] Cf. Angew. Chem. Int. Ed. Engl. *19*, 148 (1980).

Phthalocyanine [Phthalocyanins] (20 pp.) (or interest particularly as dyestuffs), Phenolharze [Phenolic Resins] (13 pp.), and several intermediates (Phenol und seine Derivate [Phenol and its Derivatives], Phosgen [Phosgene], Phthalsäure und ihre Derivate [Phthalic Acid and its Derivatives]). We may also mention Pflanzenschutz, Toxikologie [Plant Protection, Toxicology] (37 pp.), an entry in which all toxicological aspects of the use of plant-protection agents are treated comprehensively; the toxicological characteristics of a large number of plant-protection agents are particularly interesting.

As usual with the Ullmann Encyclopedia, the individual entries have been written by outstanding specialists. Again as usual, the subdivision within the entries is clear and easy to understand, so that it is easy to find information on specific points. It is almost unnecessary to mention that the contents are always up to date (with some literature references up to 1979!).

All in all, a recommended and useful source of information for any chemist.

Ulfert Onken [NB 522 IE]

Chemistry through Models. By *C. J. Suckling, K. E. Suckling,* and *C. W. Suckling.* Cambridge University Press, Cambridge 1980. xii, 321 pp., bound, £ 5.95.

The use of models is so firmly rooted in our way of thinking that we often use models without being aware of the fact. Chemists in particular are forced to use models in many situations. However, "Chemistry through Models" appears to be the first attempt at a comprehensive account of the use of models in chemistry, an attempt that may be considered as successful.

Models are constructions of alternative, and usually simpler, forms of objects or concepts called prototypes. A piece of wood floating in water is a very simple physical model of the prototype "ship". The ideal gas law $pV = nRT$ is a conceptual model of the prototype "real gas", in which some important factors such as the interactions between the individual gas molecules and their intrinsic volumes are neglected. It can therefore be used only within an accurately delimited region to describe the properties of real gases.

The present book begins with two very detailed chapters in which models are defined, hints are given on their construction, and the advantages of the use of models are discussed, as are the dangers of their incorrect use. This is followed by chapters on conceptual models in chemistry (*e.g.* quantum-mechanical models such as the VB and the MO theories, linear free energy relationships, functional groups in organic chemistry, the periodic system of the elements in inorganic chemistry), and models of reacting systems (collision theory, transition-state theory, reaction mechanisms in organic chemistry, Woodward-Hoffmann rules, *etc.*). The use of models in the planning of syntheses, in spectroscopy, and in the elucidation of structures is explained next. The concluding chapter deals with models in biochemistry (biosynthesis, biomimetic reactions, study of complex enzyme systems, *etc.*), in the planning of new manufacturing plants, and in the development of new commercial products.

This review of the contents hopefully gives an idea of the broad scope of the book. Obviously, in view of the diversity of subjects treated, it was not possible to give an in-depth account of the problems in every case, but this disadvantage can be partly overcome by resorting to the literature references cited.

"Chemistry through Models" is a good introduction to the use of models in all fields of chemistry. It can be recommended to all chemists and advanced students who want an interesting guide to a complicated subject.

Chemistry in Compressed Solutions

By William J. le Noble and Hartwig Kelm[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

Contrary to "common sense" impression, modest pressures often have quite large effects on reactions in solution.—The volume profile of a chemical reaction in solution is easily measurable with considerable precision by means of the effect of pressure on the rate and equilibrium constant. The factors that govern the magnitude of these pressure effects are similar to those that affect the entropy changes and there is a rough correlation between them; however, the volume parameters are much less subject to apparently random fluctuations, have much greater appeal to the solution chemist's intuition, and most important, the activation volume is the only transition state property that can readily be determined in absolute terms (rather than as a difference value). In this paper we outline the experimental approach to the measurement of volume changes in wet chemical reactions, interpret the volume quantities, discuss a number of simple model equilibria and reactions, point out a number of contributions in both mechanistic and synthetic chemistry, and make an attempt to foresee future developments.

1. Introduction

The application of high pressure to chemical reactions is based on a knowledge of physical properties in compressed media. Investigators in this area are especially indebted to Professor *E. U. Franck* and his collaborators for their efforts to measure the pressure response of virtually the entire gamut of physical properties of a variety of materials. A sample of their outstanding work and references to earlier reports may be found in Ref. [1].

1.1. Some Erroneous Impressions

The application of pressure to chemical reaction systems is indeed a very common one, both in the laboratory and in manufacturing plants. To those only superficially acquainted with this fact, the objective in these applications is almost always assumed to be an increase in the rates of the reactions, and/or a shift in the equilibria in the desirable direction. Indeed, in the gas phase, the rate and equilibrium changes can to a first approximation be calculated on the basis of two assumptions: that the rate and equilibrium constants are independent of the pressure, and that the ideal gas laws apply. Furthermore, in many instances the reaction may be occurring in a solution in equilibrium with a gas phase; in that case, Henry's law may allow evaluation of the concentrations of the reactants in the solution. Since it is also common knowledge that liquid compressibilities—and therefore, pressure-induced concentration changes in solution—are orders of magnitude smaller than the corresponding gas-phase properties, many chemists permanently retain the impression that no significant effects can be expected from the compression of liquid reaction systems. This impression is in fact invalid; indeed, rather large effects by relatively modest pressures are the rule rather than the exception in such systems, and it is the purpose of this paper to describe these effects

and their uses. It is intended primarily to convey an impression of the premises supporting the use of pressure on chemical reactions in solution, the methods employed, the results achieved, and the applications made possible by it; it is not intended to instruct the new practitioner in the technical details. Those desiring such instruction are referred to the Proceedings of the 1978 NATO Advanced Study Institute on High Pressure Chemistry[1], and to a comprehensive listing[2] of and comments on volume changes in chemical reactions[3].

1.2. Units and Physical Properties

It has become customary in high pressure chemistry in recent years to record pressure in MPa (megapascal) and GPa (gigapascal) units, the pascal being the new IUPAP unit of pressure. Accordingly, this paper will make use of these units. We note, perhaps superfluously, that a pascal equals one newton/m^2, and that 1 MPa equals 0.01 kbar, or about 10 atmospheres.

Almost all compounds have lower *densities* in the liquid state than in the solid and accordingly, pressure has the effect of *raising melting points.* This phenomenon is described by the well-known Clausius-Clapeyron equation. In most instances, the *melting point* is increased by a few tenths of a degree per MPa. As a consequence, a number of common solvents such as benzene, dimethyl sulfoxide, *tert*-butyl alcohol and others with freezing points near room temperature have only limited use in experiments under pressure; furthermore, it becomes virtually impossible to maintain the liquid state at room temperature with any fluid much above 5 GPa. Fortunately, the effects of interest to most chemists are steepest in the low end of the pressure range. Another fortunate circumstance is that water, the most common solvent of all, is more dense than ice at 0 °C and hence its *freezing point* is *lowered* by pressure; only at about 300 MPa does this trend reverse itself.

The *boiling point* is likewise raised, and in fact, very much more so than the melting point because of the relatively huge increase in density associated with this phase change. Pressure effects on the liquid *solubilities* of solids and gases are closely related to those on melting and boiling points. Thus, it would obviously be unwise to use saturated or nearly saturated solutions of solids under pressure; conversely, pressure is often used to keep effervescent gases in solution.

The *viscosity* of liquids is one of the most pressure-sensitive physical properties: it increases exponentially with pressure. This effect especially makes itself felt in diffusion-controlled reactions, in which the generation of lattice holes for the molecules of interest to move into is part of the activation process. Under high pressure conditions this step is obviously impeded, and such reactions are strongly retarded. Examples here are the termination step of polymerizations[4] and the energy transfer step in certain photophysical processes[5]. Under ordinary conditions, most bimolecular processes are totally independent of viscosity and, in fact, there is only one known instance of a reaction losing this independence under pressure: the displacement of bromide ion from ethyl bromide by eugenoxide ion in isopropyl alcohol-eugenol mixtures. This reaction, which is accelerated over most of the pressure range, as displacements normally are (see below), drops precipitously in rate when the pressure exceeds 2 GPa[6].

The increase in *liquid densities* at ambient temperatures in response to pressure is describable by the Tait equation

$$(V_0 - V_p)/V_0 = C\log(1 + B/P),$$

where B and C are constants characterizing the substance[7]. The effect is generally greatest in the more tenuous nonpolar liquids; increases up to 40% are observed for saturated hydrocarbons of low molecular weight at 1 GPa. Water, on the other hand, increases its density by only 20% over the same range; this fact may be attributed to the cohesion already present between the water molecules by virtue of their hydrogen bonds, which leads to a relatively high density even under atmospheric conditions. Water is said to possess a high internal pressure ($(\partial E/\partial V)_T$), and some efforts have been reported to relate solvent effects and pressure effects in nonionic reactions on the basis of simple additivity[8]; however, these attempts generally fail when their extrapolation to polar species is attempted. The assumption inherent in such correlations, *i.e.,* that a reacting molecule experiences a pressure from its solvent neighbors equal to that prevailing in the bulk solvent, is then bound to be inadequate.

Pressure causes increases in *dielectric constant* which can be described in terms of the Owen-Brinkley equation[9]; this has essentially the same form as the Tait equation. These changes are small but not unimportant: they allow a better test of the many supposed correlations between the rate and dielectric constants than measurements of solvent response, in which the chemical environment is also changed.

1.3. Apparatus

Generation and determination of pressure up to several GPa can be achieved without much effort. The apparatus normally employed consists of a generator, at least one manometer, a separator, and a pressure vessel. An intensifier is often used to produce the highest pressures. The scheme of a simple high pressure apparatus is shown in Figure 1.

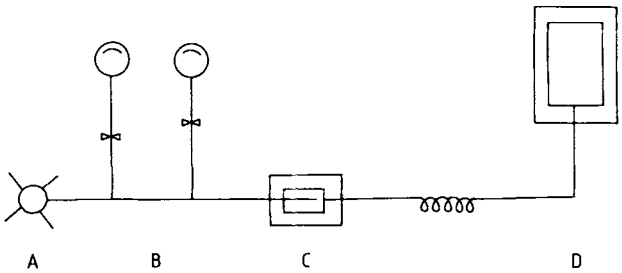

Fig. 1. Scheme of high pressure apparatus. A: generator; B: manometers; C: separator; D: reactor vessel.

Commercially available hand or motor driven generators usually produce pressures up to several tenths of a GPa, which in turn can be intensified by a factor of ten. For most studies in the liquid phase such pressures are sufficient. The pressures obtained are determined with the help of manometers also commercially available for various pressure ranges.

Oil is commonly used as a hydraulic fluid on the pressure generation side of the apparatus, whereas another fluid may be desired on the reactor side. In such cases a separator is

used that transfers pressure practically without loss. A piston system, a flexible tube or bellows, or the intensifier can be used for this purpose.

The solution to be studied is contained in a sample vessel, which must be made of inert materials, and which must completely separate the solution from the hydraulic fluid and yet transmit the pressure from the latter to the former while automatically adjusting its capacity. Its construction principle and size are determined by the method of analysis. The simplest version of such a vessel is a syringe containing the reacting solution, the pressure being transmitted *via* the plunger. Analytical samples can be taken from the syringe by means of a fine dosage valve. Pressure losses and interruptions of temperature constancy can—if desired—be avoided by slow pumping[10].

A large number of methods described in the literature can be used in conjunction with commercially available analytical instruments such as spectrophotometers for *in situ* analysis[11]. Ultraviolet-visible spectroscopy is perhaps the technique most frequently used; only small amounts of dilute reaction solutions (*ca.* 1—3 cm^3) are then required. A typical high pressure photometer cell is shown in Figure 2.

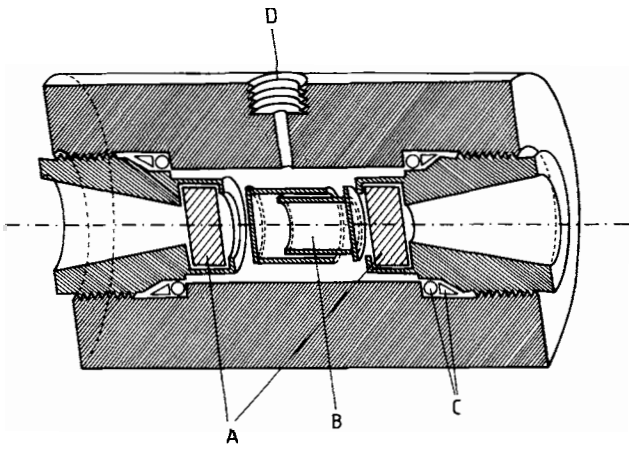

Fig. 2. Scheme of a high-pressure spectrophotometer cell (capacity *ca.* 1 to 3 cm^3): A: sapphire or quartz windows; B: "pillbox" containing reaction fluid; C: packings; D: hydraulic fluid.

It will be clear that charging the vessel and establishment of a constant pressure and temperature requires some time, perhaps 5 to 10 minutes. For reactions with half-lives below this range, special constructions have been proposed. These are essentially high pressure variations of the stopped-flow or relaxation methods[12]. The mixing of reagents under pressure is also possible[13]. In recent years NMR and ESR high pressure measurements have been employed for the study of fast degenerate reactions and equilibria[14].

No unusual safety precautions are necessary. In spite of the high pressures, the elastic energy that can be stored in liquids is relatively small when it is compared to gases, and when a leak develops it is usually more difficult to find it than to hide from it. Nevertheless, a complete and sudden rupture could under the worst circumstances pose a hazard that should not be ignored.

It should be pointed out that the high-pressure apparatus need not to be massive. Since the strength of vessels and tubing is determined by the ratio of external to internal diameter, it will be obvious that the size of the equipment is a function not only of the pressure but also of the sample size. Thus the mass of a vessel of several hundred cm^3 capacity designed for 2 GPa may weigh in the order of a hundred kilograms. The vessel shown in Figure 2 weighs only a few kilograms and the diamond cells designed for pressures of tens of GPa but very small (mg) samples may be carried in one's pocket.

1.4. Determination and Interpretation of Volume Changes

The pressure effects on chemical equilibria and reaction rates are described by the well-known equations:

$$(\mathrm{d}\ln K/\mathrm{d}P)_T = -\Delta\bar{V}/RT; \quad (\mathrm{d}\ln k/\mathrm{d}P)_T = -\Delta\bar{V}^{+}/RT$$

in which K and k represent the equilibrium and rate constants, $\Delta\bar{V}$ and $\Delta\bar{V}^{+}$ the reaction and activation volumes, respectively. Pressure-independent concentration units must be used for the calculation of the constants; if needs be, appropriate corrections have to be made.

The plots of $\ln K$ or $\ln k$ *versus* pressure may appear to be linear within experimental error, or they may show a more or less pronounced curvature. Since a theoretical description of these pressure dependencies is not possible at present, a number of empirical and semi-empirical functions have been proposed in order to describe the experimental data[1]. Depending on the type of function used and the statistical weight given to the individual points, one obtains slightly different results for the volume term at ambient pressure. Such variations are, however, seldom larger than the experimental error and choice of the evaluation procedure is not crucial.

In any molecular interpretation of $\Delta\bar{V}^{+}$, it should be remembered that the observed rate constant (k_{obs}) may represent a composite quantity because of the complexity of the mechanism. Even as simple a system of two opposing first order reactions

$$\mathrm{A} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{B}$$

leads to $k_{obs} = k_1 + k_{-1}$. The combination of a fast pre-equilibrium (*e.g.* a pre-protonation) with a rate determining step k_2

$$\mathrm{A} + \mathrm{B} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{C} \xrightarrow{k_2} \text{products}$$

leads to $k_{obs} = k_1 k_2/k_{-1} = K k_2$. In such situations, the pressure dependencies of the equilibrium constants *and* of the rate constants are needed in order to give a complete description of the volume profile.

It has furthermore turned out to be advantageous and valid to a first approximation to split the individual volume quantities into an intrinsic and a solvation contribution:

$$\Delta\bar{V} = \Delta V_{intr} + \Delta V_{solv}; \quad \Delta\bar{V}^{+} = \Delta V^{+}_{intr} + \Delta V^{+}_{solv}$$

The intrinsic part results from the motion of the nuclei of the reacting species during the formation of the products or the transition state, *i.e.* from the formation or cleavage of bonds. This term represents the change in bond lengths and angles.

A change in polarity of the reactants during these processes causes the superimposed solvation contribution. Clearly the formation of a covalent bond between two atoms leads to a negative intrinsic contribution, whereas bond cleavage is characterized by a positive volume change; thus, bond-making processes are accelerated by pressure whereas bond-breaking is retarded.

If one considers the cleavage of a bond between two carbon atoms, the distance between them has to increase from *ca.* 1.5 Å to *ca.* 3.0 Å (the van der Waals distance). Given the cross section, for example, of a hydrocarbon chain, the increase in volume is about $+10$ Å^3, or about 10 cm^3 mol^{-1}. A more precise value cannot be given, because at the molecular level, the reaction will usually be accompanied by changes in bond angles and in void structure of the solution.

The intrinsic parts of the volumes of activation can be estimated in a similar manner, keeping in mind, however, that bonds are only partially formed or broken. Furthermore, the transition state does not necessarily lie midway in the reaction coordinate between reactants and products. There are, indeed, indications that covalent bond cleavage often occurs early and bond formation late; we return to this question in Sections 3.2 and 3.4. The normally expected contributions of $\Delta V^{\neq}_{intr}$ for these two processes range from $+3$ to $+8$ cm^3 mol^{-1} and from -7 to -12 cm^3 mol^{-1}, respectively.

Whenever such bond-making or bond-breaking processes are accompanied by the quenching or creation of charges or dipoles, the volume effects arising from them must also be estimated, since then not only the atoms of the reaction center are involved, but also an unknown number of solvent molecules in the neighborhood of these centers.

An exact appraisal of the ΔV_{solv} and $\Delta V^{\neq}_{solv}$ contributions would permit one to quantitatively describe solvent effects on equilibria and rates under pressure. Such a description is not possible at present, and one has to rely on estimates and experience.

The very short range interactions due to induced dipoles are very small; the volume effects can as a rule be neglected. The solvation contributions from the interactions of functional groups, *e. g.* hydrogen bonds, are larger; their quantitative estimation is based mostly on experimental data obtained with model systems.

The effects that stem from the appearance or disappearance of ionic charges and dipole moments can be estimated at least with respect to sign and even in a semiquantitative manner with the equations proposed by *Born* and *Kirkwood,* or rather by means of their pressure derivative given by *Drude* and *Nernst*[15]:

$$V_e = -(q^2/2rD^2)(dD/dP)$$

and

$$V_e = -(\mu^2/r^3)(3/(2D+1)^2)(dD/dP)$$

where V_e is the so-called electrostriction, q is the charge of the ion, μ the dipole moment, r the respective radius, and D is the dielectric constant. Based on the known value of (dD/dP) for water, the volume effect calculated is of the order of -1 to -2 cm^3 mol^{-1} for the development of a single ionic charge (or of a dipole moment of *ca.* 10 D); it becomes larger in nonaqueous solvents like methanol (-4 to -6 cm^3 mol^{-1}), acetone (-5 to -8 cm^3 mol^{-1}) or benzene (-20 to -30 cm^3 mol^{-1})[16]. Clearly charge delocalization reduces this effect. Such predictable solvation contributions will be shown to correspond to experimentally obtained volume data in later sections.

It may be worth while to point out that neither charges nor bond lengths and angles (and hence dipole or multipole moments) are influenced under pressure, as indicated by experimental evidence[17].

In the interpretation of volume data, it is vitally necessary to estimate the solvation contributions quantitatively in order to appraise the intrinsic part, the latter being the main criterion in the assignment of mechanisms. Additional caution should prevail when volume data to be used and compared were obtained at different temperatures.

1.5. Determination of Partial Molar Volumes and Partial Molar Volume Differences

When the density d is known for a solution of concentration c and for the solvent d_0, one can calculate the apparent molar volume ϕ of the solute in that solvent by means of

$$\phi = \frac{M}{d} - \frac{d-d_0}{d_0}\frac{1000}{c}.$$

The value obtained is often found to be somewhat dependent on the concentration. Such deviations are caused by solute-solute interactions which can be substantial if the mass fraction of the substrate is relatively large, or if the solute is charged. With large molecules, this may be the case even at low concentrations. For this reason, the partial molar volume at infinite dilution is used (ϕ^{∞}); it is obtained by extrapolating ϕ to zero concentration. With modern densimeters it is possible to measure the term $(d-d_0)$ to concentrations as low as 10^{-3} M, and to obtain ϕ^{∞} to an accuracy of the order of a few tenths of a cm^3 mol^{-1}. When the solute molecules are subject to association or dissociation, linear extrapolation can be expected only if the appropriate power function of c is used in the plot. For the best procedure to be employed, the original literature should be consulted[18].

Reaction volumes $\Delta\bar{V}$ for an equilibrium

$$A + B \rightleftharpoons C + D$$

can thus be determined if the necessary density data are available for all components. No high pressure measurements of K are necessary then, and in fact, the initial response of K to pressure changes $(d\ln K/dP = -\Delta\bar{V}/RT)$ can be calculated from such data. In many instances in which the reaction volumes have been determined either by means of the pressure dependence of the equilibrium constant, or from density data, the results agree very well. The density route is not available if substantial equilibration cannot be prevented.

For the ionization of weak electrolytes, the inescapable need for counterions actually supplies a solution to this problem: thus, the partial molar volumes of sodium acetate, hydrochloric acid, sodium chloride and acetic acid in water can be combined so as to yield the ionization volume:

$$\Delta\bar{V}_i = \bar{V}_{NaOAc} + \bar{V}_{HCl} - \bar{V}_{NaCl} - \bar{V}_{HOAc}$$

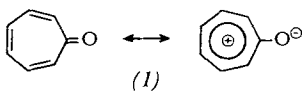
In other instances, however, one is obliged to make high-pressure measurements of the equilibrium constant. Spectroscopic techniques are the method of choice for covalent equilibria, and for ionic equilibria if the indicator approach is chosen; in that instance, one needs independent information concerning the volume profile for the ionization of the indicator itself. It is of course also desirable to verify that pressure does not modify the spectral characteristics of the pure components. Likewise, if the conductance method is to be used, one needs to keep in mind that other relevant properties of the system are sensitive to pressure too (the dielectric constant of the medium and the cell constant, to mention only two). However, these difficulties have largely been surmounted, and very extensive compilations of ionization volumes are now available[19]. Reaction volumes for reactions which essentially go to completion can be obtained either from partial molar volume data or by means of dilatometry.

2. Reaction Volumes

All chemical reactions approach an equilibrium composition. In some this composition is such that all components, including the starting materials, are simultaneously detectable in the final mixture; in others, the reaction is for all practical purposes complete. The method to be used in determining the reaction volume must be chosen according to the magnitude of the equilibrium constant, the rate of equilibration, the stability of the components *etc.* In this section, we discuss together, without further distinction, the reaction volumes both of traditional equilibria and complete reactions. Additional examples of reaction volumes are mentioned in Section 3, where they are compared with activation volumes.

2.1. Complexation

The small diameter of covalently bound hydrogen and the substantial length of the hydrogen bond combine to produce only a small volume decrease in the formation of such a bond: $\Delta\bar{V} = -4$ cm^3 mol^{-1}, on the average. This result was first deduced by *Drickamer et al.*[20] from the effect of pressure on the infrared spectra of alcohol solutions in hydrocarbons, and it has since then been confirmed by *Suzuki*'s studies of the complexation of phenol with dioxane[21], and of the dimerization equilibrium of carboxylic acids[22].



Similarly, small negative volume changes occur upon charge transfer complexation between neutral aromatic molecules such as chloranil and hexamethylbenzene[23]. Values of $\Delta\bar{V}$ of -5 to -10 cm^3 mol^{-1} are typically observed. They are in agreement with simple volume calculations based on X-ray data; since these calculations neglect electrostriction, the amount of charge transferred must be quite small.

The dominant effect of electrostriction on volume changes in solution first manifests itself when the members are charged. Thus, pressure strongly *inhibits* the complexation between *N*-methyl-4-carbomethoxypyridinium and iodide ions; $\Delta\bar{V}$ for this equilibrium is $+16$ cm^3 mol^{-1}[24]. Clearly, in this case the normal volume decrease that is expected upon complexation is more than offset by the release and relaxation of solvent molecules that occur when the charged members approach and in a sense neutralize one another. When only one of the members is charged, no pressure effect is observed at all ($\Delta\bar{V} \cong 0$); thus, the complexation of pentakis(methoxycarbonyl)cyclopentadienide ion with trinitrobenzene, and that of tropylium ion with hexamethylbenzene are pressure-independent equilibria[24]. The loss of solvation that occurs when one side of the ion is stripped to make room for the neutral partner compensates for the volume decrease that takes place in the complexation process.

2.2. Covalent Bond Formation

Covalent bonds are shorter than those produced by the weaker interactions discussed above, and more sizable volume decrease and pressure effects are observed, even with molecules of small diameter. Equilibrium studies of the hydration of carbonyl compounds under pressure have revealed that volume changes of -10 cm^3 mol^{-1} are quite typical[25]. Somewhat greater shrinking characterizes ketalization[26] and methanol addition to benzonitrile[27]. The addition of water to fumarate ion has a reaction volume of -10 cm^3 mol^{-1}[28], and so it is comparable to the hydration of the carbonyl functionality. The dimerization of NO_2 is greatly favored by pressure: $\Delta\bar{V} = -20$ cm^3 mol^{-1}. This pressure effect is larger than can be accounted for on the basis of covalent bond formation between two such small molecules, and it seems likely that the dimeric molecule contains local dipoles whose solvation may contribute to the overall result[29].

The molar volume decreases become much greater still when more than one covalent bond is formed. In the Diels-Alder reaction, for example, two new bonds result. The reaction volume has been determined in many instances—in some, by means of dilatometric experiments and in others, by means of partial volume determinations of the reactants and products. In the large majority of cases the shrinkage is as large as 30 to 40 cm^3 mol^{-1}[30–32]. Interestingly, the intrusion of electrostatic effects once again can greatly alter these numerical results. The cycloaddition product resulting from the reaction of cyclopentadiene with tropone, for example, appears to be only barely less voluminous than the compounds from which it was made: $\Delta\bar{V} = -5$ cm^3 mol^{-1}. The feature responsible for this exceptional case was revealed by individual partial molar volume measurements, which

(1)

showed tropone *(1)* to occupy much less space in solution than what is expected on the basis of a completely covalent structure; clearly, this molecule has a highly dipolar if not zwitterionic character, and the loss of the dipole counteracts the shrinkage due to bonding[33].

2.3. Ionization

The ionization volume of water has been determined as -22 cm^3 mol^{-1}[34]. This may seem impossible at first sight: the molar volume of water being only 18 cm^3 mol^{-1}. What happens is not that the ionizing molecules themselves shrink in any significant way, but that the bulk solvent around the newly formed ions solvates. This is a universal phenomenon;

there is no known instance in which a reaction producing ions from neutral molecules fails to lead to volume contraction.

A very large number of weak acids have been similarly examined[2], and the results can qualitatively be understood in terms of the aforementioned Drude-Nernst equation. Thus, the first ionization volume for hydrogen sulfide equals -16 $cm^3\ mol^{-1}$; clearly, a larger ionic size leads to less contraction. The q^2/r dependence manifests itself when delocalization of the charge characterizes the anion: phenol has an ionization volume of $-18\ cm^3\ mol^{-1}$, that of *p*-nitrophenol equals -10 $cm^3\ mol^{-1}$, and that of acetic acid, $-13\ cm^3\ mol^{-1}$; the much larger second $\Delta\bar{V}_i$ values of diprotic acids (phosphoric acid: $\Delta\bar{V}_{i,I}$: -14, $\Delta\bar{V}_{i,II}$: $-24\ cm^3\ mol^{-1}$) point in the same direction. The large solvent dependence of the ionization volume (embodied in the dielectric constant term) is shown by the fact that the values in methanol roughly double those in water. It is difficult to carry out such measurements in solvents much less polar than simple alcohols; however, in nonpolar media the volume decreases due to ionic solvation can be shown to become enormous (see Section 3.5).

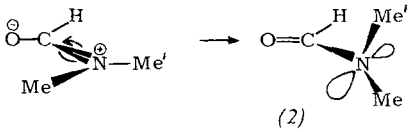
An interesting aspect of the behavior of carbonic acid under pressure is that the volume change observed ($-27\ cm^3\ mol^{-1}$) indicates a process quite different from that of the otherwise closely related carboxylic acids. The difference is that the greatly increased ionization of carbonic acid under pressure reflects the effect of bond formation as well:

$$CO_2 + 2H_2O \rightleftharpoons HCO_3^{\ominus} + H_3O^{\oplus}$$

The base strengths of a large number of amines under pressure are also known, and since these data generally confirm but do not add to the conclusions just drawn, they need not be mentioned here.

Ion-pair equilibria are sensitive to pressure for the same reasons as acid-base equilibria, and the effects implicate the same factors. Monovalent ion-pairs in water are not known, but a number of divalent ion-pairs such as $MnSO_4$ and $MgSO_4$ have been studied in that solvent. The volume change that accompanies the dissociation of these pairs is about $-7\ cm^3\ mol^{-1}$[35]. If we consider ionization in terms of the Winstein Scheme

$$A-B \rightleftharpoons A^{\oplus}, B^{\ominus} \rightleftharpoons A^{\oplus} \,||\, B^{\ominus} \rightleftharpoons A^{\oplus} + B^{\ominus}$$



then according to the Drude-Nernst equation, the dissociation volume of a monovalent ion-pair in water should be only about -3 to $-4\ cm^3\ mol^{-1}$. This is but a small fraction of the ionization volume of a neutral monovalent species (generally about $-15\ cm^3\ mol^{-1}$); evidently, most of the electrostriction occurs in the first stage of the Winstein scheme.

The very large volume effects that accompany the charge separation in nonpolar solvents have been demonstrated by means of several ion-pair reactions. Thus, it has been deduced from the effect of pressure on the sodium hyperfine coupling constant that a volume contraction of $-15\ cm^3\ mol^{-1}$ occurs when naphthalenesodium tight ion-pairs in dimethylformamide are allowed to become loose[36]. This is a remarkably large value, if one considers that the ions are already formed at the start, that one of them must be highly delocalized, and that the separation is a minor one. Similar results have been obtained with alkali-metal fluorenides[37]. Complete separation brings about a proportionately larger volume decrease; thus, the dissociation of tetra-*n*-butylammonium picrate in ether has been claimed to have a $\Delta\bar{V}_d$ of $-125\ cm^3\ mol^{-1}$[38].

3. Activation Volumes

3.1. Conformational Changes

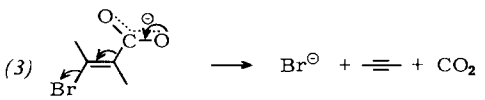
Only small pressure effects are observable when bonds undergo only partial deformations such as stretching and bending (biphenyl racemization[39]), or conformational changes (cyclohexane inversions[40]); the activation volumes are generally between $+2$ and $-2\ cm^3\ mol^{-1}$. In one instance, the methyl equilibration in dimethylformamide *(2)*, $\Delta\bar{V}^{\neq}$ is rather larger ($\sim +10\ cm^3\ mol^{-1}$). It would logically seem to be related to the partial loss of the dipole in the transition state;

(2)

however, the authors did not observe large solvent effects on this value, and they attribute the result at least partially to a pre-evacuation of the space needed to carry out the rotation[41].

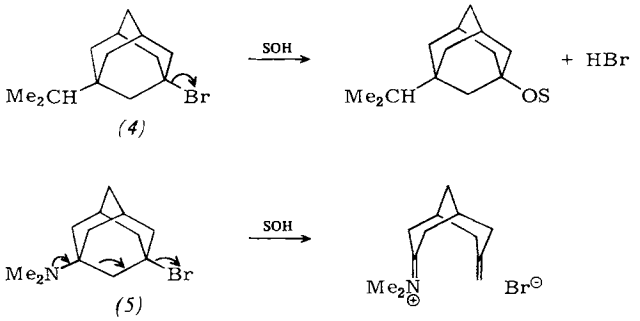
3.2. Covalent Bond Formation and Cleavage

There are relatively few examples of such reactions that occur without large concomitant changes in dipole moment. The propagation step in free-radical polymerization is one of them. This reaction has been studied under pressure, especially by *Nicholson et al.*[4], *Weale*[3], and *Ogo et al.*[42] and their conclusions in general agree: the activation volume for this reaction is about $-10\ cm^3\ mol^{-1}$. While there are of course variations depending on the monomer involved, it is clear that the bond being formed is quite short already when the transition state is reached.



It might be supposed that the termination reaction of radicals should also be accelerated by pressure, but that is not so; it is in fact severely retarded. The reason for this is that this part of the polymerization reaction is diffusion controlled[4], and therefore inhibited by pressure in spite of the fact that the actual bond formation step is characterized by the usual volume decrease: the combination of radicals already together in a cage is accelerated. For instance, $\Delta\bar{V}^{\neq}$ for the recombination of *tert*-butoxy radicals equals $-4\ cm^3\ mol^{-1}$[43].

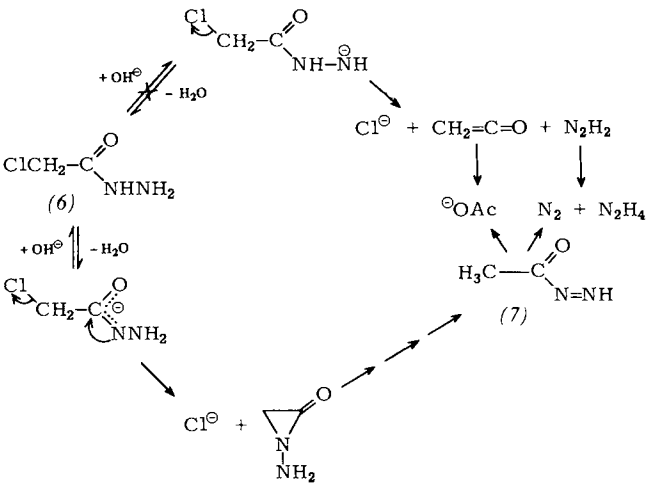
Covalent bond cleavage is retarded as expected; thus, the decomposition of di-*tert*-butyl peroxide is a well-known example with an activation volume of about $+10\ cm^3\ mol^{-1}$[44]. Since this type of reaction is often used to initiate polymerizations, it may be noted in passing that the pressure responses to all three steps in polymer formation (initiation, propagation, and recombination) conspire to generate fewer chains that grow more rapidly and are taken out of circulation less readily—in other words, to form polymers of greater density and higher molecular weights. This fact may find ap-



plication in the production of special polymers for which there are limited but critically important uses.

Bond cleavage in ions is complicated by the fact that the charge is often translocated in the process; however, experience has shown that this is a secondary consideration as long as no charge is neutralized, or new charges are formed. As an example one might mention the studies on decarboxylation by *Brower et al.*[45]: the loss of CO_2 from such ions as trichloroacetate has an activation volume of +6 to +10 cm^3 mol^{-1}, depending on the substrate.

Multiple bond fractures should show correspondingly larger volume changes. That is, *if* these bond reorganizations are concerted; if only one bond breaks in a rate controlling initial step, there is no reason to expect an unusually large volume increase in the transition state. Several results now available seem to bear this out. Thus, the fragmentation of 3-bromo-2-methylisocrotonate *(3)* has an activation volume of +18 cm^3 mol^{-1}[46]; when it is remembered that $\Delta\bar{V}^{\neq}$ in simple decarboxylation reactions averages +6 to +10 cm^3 mol^{-1}[45], concertedness in the reaction is clearly indicated.

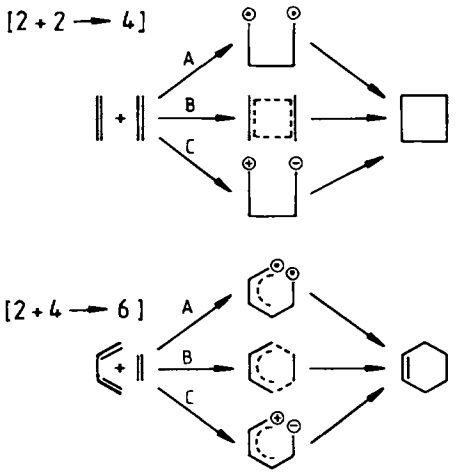


In the solvolysis of δ-aminoalcohol derivatives, the products are indicative of fragmentation, and the fact that the rate is up to 50000 times faster than the solvolysis rates of the corresponding carbon homomorphs (in spite of the induction by the nitrogen atom) strongly suggests that the bond cleavages are concerted[47]. Since charge formation occurs simultaneously, negative activation volumes are expected, but they should be less negative in the fragmentations than in the solvolyses.

This difference is indeed observed. Whereas the simple solvolysis of *(4)* (in 80% aqueous alcohol at 40 °C) has an activation volume in the range of -21 ± 2 cm^3 mol^{-1}, the fragmentations [*e.g.* of *(5)*] have one of -13 ± 2 cm^3 mol^{-1}[48] (SOH = alcoholic solvent). In one instance, the *N*-compound upon dissolution in aqueous alcohol does not lead to fragmentation products, but to substitution and elimination[47]. The rate is ten times slower than that of the carbon analog, and the activation volume is -23 cm^3 mol^{-1}[48].

In one fragmentation, the pressure effect was found to be opposite in sign to that expected: in aqueous alkaline solution, chloroacetyl hydrazide *(6)* fragments to chloride and acetate anions, and to nitrogen and hydrazine, *via* what was presumed to be a concerted fragmentation of the β-anion[49,50] similar to that of the anion *(3)*. However, $\Delta\bar{V}^{\neq}$ is -5 cm^3 mol^{-1}. A subsequent conventional investigation based on the effect of *N*-methyl substitution and on stopped flow experiments revealed that the reaction takes place *via* the α-anion and rate-limiting internal displacement. The intermediate acetyldiazene *(7)* was directly observed[51]. This is a nice example of the fact that deviations from expected pressure effects justify reinvestigations of reactions whose mechanisms have already been "established".

Very similar arguments can of course be applied in the case of the cycloaddition reactions. The schemes shown in Figure 3 for [2+2]- and [2+4]-cycloadditions indicate the three conceivable mechanisms for these reactions. The two-step process (A) with a biradical intermediate should result



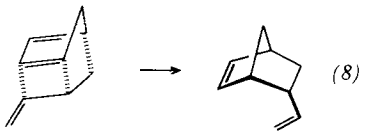


Fig. 3. Possible reaction mechanism of [2+2]- and [2+4]-cycloaddition reactions. A, B, C (see text).

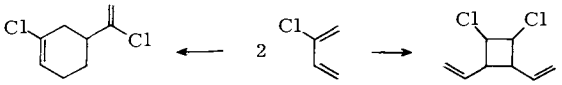
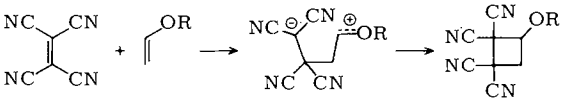
in a moderately negative volume of activation accompanied by little or no solvent effect. The concerted route (B) is also nonpolar. A fairly large negative $\Delta\bar{V}^{\neq}$ is expected with no solvent variation. Finally, the polar two-step path (C) with the zwitterionic intermediate should lead to negative volumes of activation which in their magnitude depend on the solvent. Thus high pressure kinetics combined with solvent variation should in principle offer a possibility to differentiate between the three mechanisms.

It was already known in the thirties that the Diels-Alder reaction is unusually sensitive to hydrostatic pressure; the mechanistic implications have been discussed, especially by



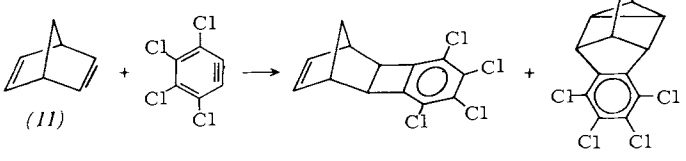
Walling and *Eckert*[52–55]. In fact, in recent years the Diels-Alder reaction has often been carried out under high pressure for synthetic reasons[56]. Evidently the reacting molecules have in the transition state already advanced well beyond the half-way point to the final volume; the reaction is indeed concerted.

Eckert's experiments in fact contain evidence for the unique feature of the secondary orbital interaction[57]: a weak bonding feature which is present in the transition state but not in the final product. It is thought that this feature is responsible for the predisposition of many of these reactions to produce *endo* products such as *(8)*, even though these are often the more hindered ones. In a number of such reactions, *Eckert* reported that the transition state is even smaller than the product.



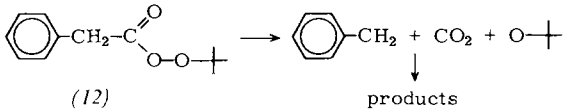
(8)

In some cases, allowed and forbidden cycloadditions occur in competition, and one can compare the rate of the presumably concerted cycloaddition directly with that of a stepwise analog. Indeed, *Stewart* has shown[58] that in the dimerization of chloroprene *(9)*, which produces both [2+4]- and [2+2]-products, pressure favors the former by a wide margin: $\Delta\Delta\bar{V}^{+} \approx 10$ cm^3 mol^{-1}.



(9)

While the pressure effect appears to be a promising approach to the question of concertedness, one should be aware of the following pitfalls. For one, it is assumed that no zwitterionic character is present in either reactant, product, or transition state. That is not always true. For instance, in the cycloaddition of tetracyanoethylene to enol ethers, known to be stepwise and to involve a zwitterionic intermediate *(10)*[59], the activation volume in nonpolar solvents may have values as large as -50 cm^3 mol^{-1}[60]. That these large negative values are due in part to electrostriction and not to covalent bond formation is clear from the fact that the *reverse* of



(10)

the last step also has a negative activation volume; this reaction is therefore less akin to homolysis than to solvolysis[61]. For similar reasons, in the competing cycloadditions of norbornadiene *(11)* and tetrachlorobenzyne, the [2+2]- is favored over the [2+4]-isomer[62]. If the zwitterionic character is present in one of the reactants, the disappearance of this feature as the cycloaddition progresses may make $\Delta\bar{V}^{+}$ less negative than would otherwise be expected. This is evidently the case in the 1,3-dipolar [4+6]-cycloaddition of tropone *(1)* to cyclopentadiene[33]. Although this is known to be a concerted reaction[63,64], the activation volume (-7 cm^3 mol^{-1}) is exceptionally small for a cycloaddition. Measurement of both the reaction volume and the partial molar volumes of all of the participating molecules, then showed that the tropone is responsible for the exceptionally small pressure enhancement of the rate: as noted in Section 2.2, the dipolar nature of this reactant disappears on the way to the transition state, and the volume decrease is accordingly reduced. This is a nice example of one of the principal advantages of the use of the activation volume over that of the other activation parameters: the availability of the corresponding initial state information makes it possible, when anomalous pressure effects are observed, to decide whether the anomaly is due to the initial or transition state.

(11)

It should not be assumed that bond cleavage is always characterized by large volume increases of 10 cm^3 mol^{-1} or more. Thus, it may be obvious from the near equality of the activation and reaction volumes in the Diels-Alder reaction that the corresponding cycloreversions would have quite modest activation volumes. This question is clearly related to the location of the transition state along the reaction coordinate. *Neumann et al.*[65] have found, for example, that the decomposition of peresters such as *(12)* may have activation volumes as low as 1 cm^3 mol^{-1} even though two bonds are breaking.

(12)

These fragile molecules obviously decompose with early transition states. The activation volumes for product formation in radical decompositions are much larger (>10 cm^3 mol^{-1}) in those cases in which the initial step is reversible, so that diffusion out of the initially formed cage is then part of the activation process.

The relation between $\Delta\bar{V}^{+}/\Delta\bar{V}$ and the transition state location in concerted reactions is a close though not a linear one. Both the volume changes *and* the location along the reaction coordinate are obviously related to the nuclear positions in the reacting molecules; on the other hand, the volume profile of the reaction may involve a "non-least motion" extremum that rules out the use of any linear relation between the two. Nevertheless, activation volumes are often used to make estimates, for example, of bond elongations in the transition state. *Hamann*[66] estimates on that basis that 25—50% extensions are common. Even now, however, one frequently encounters the rule of thumb that only a 10% extension occurs. The users of this rule are generally unaware that it originated with *Eyring et al.*[67], and that it, too, was based on a few of the earliest activation volume measurements!

In this connection, it may be useful to point out that there is a possible source of confusion in the terms "early" and "late", or "reactant-like" and "product-like", since these ex-

pressions depend on what parameter is used to make the comparison. The Diels-Alder reaction is a good example. This is generally described by organic chemists[68], because of its low activation energy, as a textbook example of a reaction with an early transition state; yet the fact that $\Delta\bar{V}^{\neq}$ and $\Delta\bar{V}$ are comparable requires that the transition state is late so far as nuclear locations are concerned. It seems evident that the nuclei are virtually already in place when the electrons begin to flow to form the new bonds. The Hammond postulate is another important principle related to transition state location; its connection with high pressure results is considered further in Section 3.4.

3.3. Neutral Displacement

In neutral displacement reactions

$$X—Y + Z \rightarrow \{TS\}^{\neq} \rightarrow X + Y—Z$$

the transition state is characterized either by an additional bond between Y and Z (S_N2- or A-mechanism) or by a broken Y—X bond (S_N1- or D-mechanism). Between these extreme configurations, a continuum of concerted bond-making/bond-breaking processes (interchange or I-mechanisms) can occur in which the more dominant of the two concurrent steps is often indicated by either an I_a- or I_d-symbol.

Since no major polarity changes are expected for this type of substitution reaction, the volumes of activation experimentally obtained consist mainly of the intrinsic contribution.

Among the examples, there are many radical abstraction reactions; for instance, the abstraction of a hydrogen atom from phenols by diphenylpicrylhydrazyl has an activation volume of -13 cm^3 mol^{-1}[17]. For the removal of a chlorine atom from CCl_4 by hydrocarbon radicals, $\Delta\bar{V}^{\neq}$ equals -15 cm^3 mol^{-1}[69]. The magnitude of these results suggests a rather close approach of the two reactants, *i.e.* a S_N2-like situation.

A rather impressive demonstration of the usefulness of the volume of activation as a mechanistic criterion was presented by *Merbach et al.*[70], who investigated the fast ligand exchange reactions

$$MX_5L + L^* \rightarrow MX_5L^* + L$$

for the systems M = Nb or Ta and X = Cl or Br. When L is an oxygen-ether, the complexes react *via* a dissociative mechanism with $\Delta\bar{V}^{\neq}$ values between $+15$ and $+30$ cm^3 mol^{-1}, whereas thio-, seleno-, and telluro-ethers indicate an associative behavior with $\Delta\bar{V}^{\neq}$ varying from -10 to -20 cm^3 mol^{-1}.

3.4. Displacements Involving Ions

In view of the large volume changes due to ionic solvation (electrostriction), considerable variations may be expected in pressure effects on ionic displacements depending on the charge type.

Those examples in which there is *no* net change in the number of charges would be expected to resemble neutral displacements. In coordination chemistry, the exchange of neutral ligands belongs to this type of reaction. The more labile solvent complexes, $MS_6^{2\oplus}$, of the divalent cations cobalt and nickel are believed to react *via* dissociative mechanism. In solvents like methanol, dimethylformamide and acetonitrile, the volumes of activation for the ligand-solvent exchange reactions turned out to be positive, ranging, indeed, from $+9$ to $+11$ cm^3 mol^{-1}[71].

Within the series of the rather stable complex ions $M(NH_3)_5OH_2^{3\oplus}$ (with M = Co, Rh, Ir, Cr), the volumes of activation for the corresponding water molecule exchanges amount to $+1.2$, -4.1, -3.2, and -5.8 cm^3 mol^{-1}[72-74], respectively. From these results it was proposed that contrary to earlier concepts, only the complexes of trivalent cobalt react by a dissociative mechanism (I_d), while the other central ions force an associative character on the substitution processes.

When both reactants are charged, the volumes of activation of ligand substitution reactions need to be interpreted in terms of their intrinsic and solvation contributions. In most cases, one can estimate the total volume of activation with respect to both sign and magnitude, for either a dissociative or an associative mechanism, and compare it with the experimentally obtained quantity. This allows one to make a decision as to the character of the rate determining step. For instance, the stepwise anation of $Cr(OH_2)_6^{3\oplus}$ by oxalate was investigated at pH 2.7, where only the aqua form of the complex is present and the oxalate exists mainly as $HC_2O_4^{\ominus}$. The volumes of activation for the formation of $Cr(C_2O_4)(OH_2)_4^{\oplus}$, $Cr(C_2O_4)_2(OH_2)_2^{\ominus}$, and $Cr(C_2O_4)_3^{3\ominus}$ turn out to be -2.2, -8.2, and -10.0 cm^3 mol^{-1}, respectively[75]. In case of a prevailing dissociative mechanism, each of the rate determining steps should be represented by a similar Cr—OH_2 bond breaking, resulting in a positive contribution to $\Delta V^{\neq}_{intr}$ and a negligible $\Delta V^{\neq}_{solv}$. An associative mechanism, preceeded possibly by an ion association, however, should lead to a negative $\Delta V^{\neq}_{intr}$ with a superimposing $\Delta V^{\neq}_{solv}$ varying in sign and magnitude. The experimental results can, in fact, only be reconciled with the second possibility.

A supplemental example of this line of reasoning is the anation of the pentacyano(aqua)cobaltate(III) ion:

$$Co(CN)_5(OH_2)^{2\ominus} + X^{\ominus} \rightarrow Co(CN)_5X^{3\ominus} + H_2O$$

For X = Br, I, NCS the volumes of activation were found to be $+8.4$, $+9.4$, and $+8.2$ cm^3 mol^{-1}[76]. Here only the common dissociative rate determining step of a Co—OH_2 bond cleavage is compatible with the results, since negative values are definitely expected for an associative mechanism.

The difficulty in interpreting high pressure effects of this type of reaction for organic substrates lies in the several complicating features, such as the effect of the dispersion of charge in the transition state and the degree of association of the ions in nonaqueous media. That charge dispersion is an important factor is clear from the effect of pressure on the displacement of bromide ion from ethyl bromoacetate by the dinegative thiosulfate ion: $\Delta\bar{V}^{\neq}$ is $+3.2$ cm^3 mol^{-1} in that case[77].

In displacement reactions in which charged products are formed from neutral substrates, electrostriction and covalent bond formation combine to produce pronounced shrinking. The best known example of this type is the Menschutkin

reaction; all of the numerous cases studied were accelerated by increased pressure. While many of these instances could be quoted as supporting the general impressions recorded above, special mention deserves to be made of three studies which have yielded particularly interesting results.

Two of these concern the solvent effect[78,79]: once again, Drude-Nernst behavior is observed, with the least polar media producing the greatest contractions. Figure 4 shows the variation of $\Delta\bar{V}^{+}$ with solvent for two Menschutkin reactions plotted as a function of the electrostriction parameter q_p. It can be seen that the contribution ΔV^{+}_{solv} is largest in nonpolar solvents, whereas ΔV^{+}_{intr} depends on the structure of the reactants.

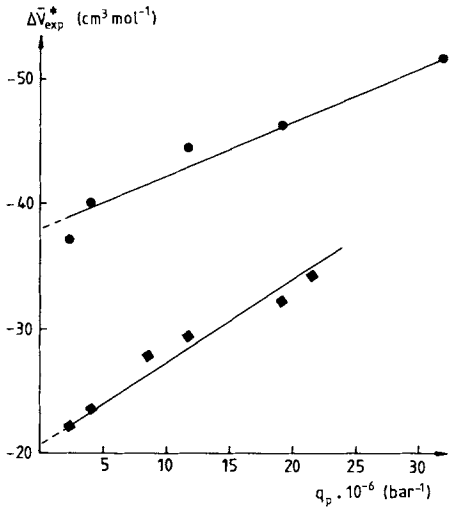


Fig. 4. Solvent dependence of $\Delta\bar{V}^{+}$ for the Menschutkin reactions: ● triethylamine + ethyl iodide and ■ pyridine + methyl iodide. The electrostriction parameter q_p is defined according to *Drude-Nernst*[15] as: $q_p = (3/(2D+1)^2)(dD/dP)$ with D being the dielectric constant of the solvent.

A second feature of great interest is that when Menschutkin reactions similar except in steric requirements are compared under identical conditions, the slower and more hindered reactions tend to be accelerated the most. Thus, a systematic study of the reactions of methyl, ethyl, and isopropyl iodides with pyridine, 2,6-dimethyl-, 2,6-diethyl-, 2,6-diisopropyl- and 2,6-*tert*-butylpyridines has revealed that $\Delta\bar{V}^{+}$ becomes steadily more negative as the hindrance is raised[80]; in fact, *Okamoto et al.*[81] have shown that the methylation of 2,6-di-*tert*-butylpyridine succeeds only under pressure. Several theories have been offered to account for this phenomenon; perhaps the most satisfying one is based on the fact that

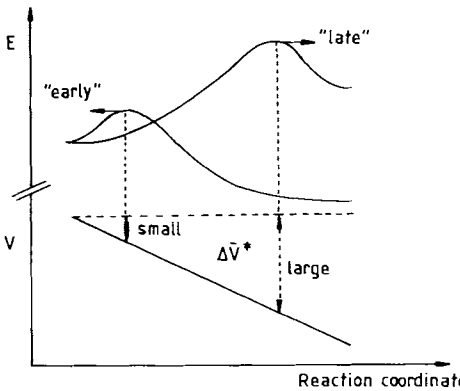

Fig. 5. Energy and volume profiles for an unhindered, fast Menschutkin reaction, and a hindered, slow one (with early and late transition state).

no anomalies are found in the initial and final state volumes[82]. Thus, the reaction volumes are all approximately the same, and the net result is that the activation volume becomes an increasingly larger fraction of the reaction volume as the crowding is raised. This suggests that the increase in hindrance leads to later transition states—precisely what is predicted on the basis of the well-known Hammond postulate (Fig. 5). It was subsequently found that in the corresponding reaction with methyl chloride, the $^{35}Cl/^{37}Cl$ isotope effect is indeed larger in the methylation of 2,6-lutidine than in that of pyridine[83].

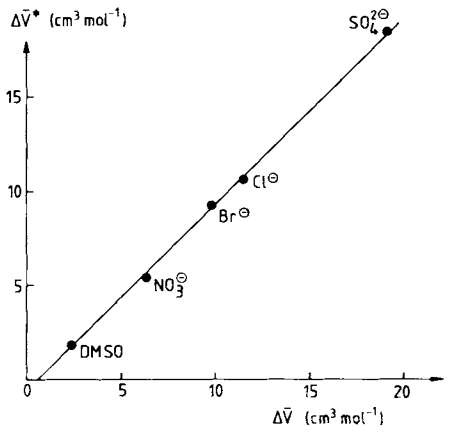
3.5. Solvolysis

The solvolysis reaction is a good example of the dominance of ionic solvation over covalent bond making and breaking where the volume is concerned: even though a bond breaks, pressure invariably accelerates the reaction, generally by a wide margin. Again, the dominant contribution from ΔV^{+}_{solv} depends on the factors given in the Drude-Nernst equation; it ranges from -10 to -35 cm³ mol⁻¹.

In inorganic chemistry, the system studied most involves the hydrolysis of acido(pentaammine)cobalt(III) complexes

$$Co(NH_3)_5X^{(3-n)\oplus} + H_2O \rightarrow Co(NH_3)_5OH_2^{3\oplus} + X^{n\ominus}$$

The activation volumes for a series of X lie between -5 to -17 cm³ mol⁻¹[84] despite the assumption that breaking of the Co—X bond is presumably the initial step of the hydrolysis, thus contributing a positive ΔV^{+}_{intr}. A linear relationship as depicted in Figure 6 exists between the $\Delta\bar{V}^{+}$ values for X = Cl, Br, NO_3, SO_4, and dimethyl sulfoxide (DMSO) and the corresponding overall reaction volumes, $\Delta\bar{V}$. The slope is close to unity indicating that the leaving ligand $X^{\ominus}$ is



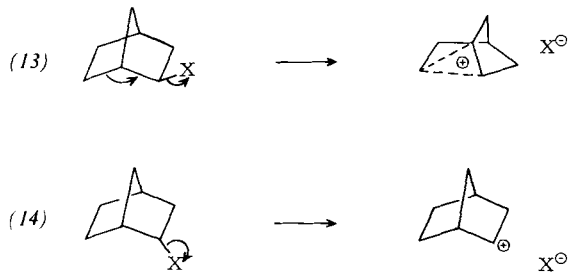


Fig. 6. Volume correlation $\Delta\bar{V}^{+}$ *versus* $\Delta\bar{V}$ for the hydrolysis reaction of $Co(NH_3)_5X^{(3-n)\oplus}$ (counterion: perchlorate).

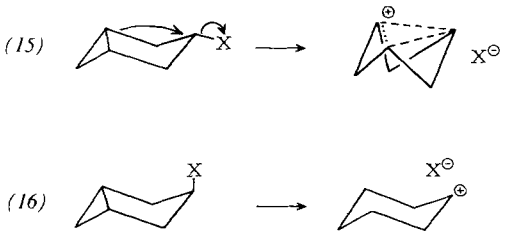
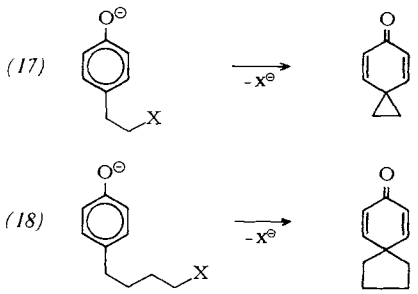
almost fully detached in the transition state; *i.e.* a dissociative-(D)-mechanism is prevailing. In this case the volume of the transition state or intermediate can be considered as the sum of the solvated ligand X, with $\bar{V}(X^{n\ominus})$, and the five-coordinate common fragment with $\bar{V}\{Co(NH_3)_5^{3\oplus}\}$. The activation volume, $\Delta\bar{V}^{+}$, can thus be expressed as follows[85]



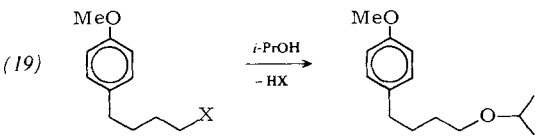
$$\Delta\bar{V}^{+} = \bar{V}\{Co(NH_3)_5^{3\oplus}\} + \bar{V}(X^{n\ominus}) - \bar{V}(Co(NH_3)_5X^{(3-n)\oplus})$$

The partial molar volumes of the individual ions $X^{\ominus}$ and $Co(NH_3)_5X^{(3-n)\oplus}$ can be determined by means of precision density measurements and by evaluation of the volumes of the respective counterions. This enables one to calculate the value of $\bar{V}\{Co(NH_3)_5^{3\oplus}\}$, which should be constant for the whole series if the D-mechanism is correct. In fact, it turns out to be 55 ± 1 cm^3 mol^{-1}. Thus, in this case of a predominantly dissociative mechanism, the combination of high pressure kinetics data with partial molar volume determinations permits the appraisal of the volume of reactive intermediates.

In this connection, high pressure has been brought to bear in an attempt to make a contribution to the question of the nonclassical ions. One of the highlights of organic chemistry of the nineteen sixties was the controversy about the validity of the concept of carbon participation in the formation of carbonium ions in solvolysis, and about the nature of the ions so formed. In some instances, this controversy has not been settled, even yet. As an example, we consider the 2-norbornyl derivative. Its *exo*-isomer *(13)* was claimed by *Winstein et al.*[86] to solvolyze with participation of other carbon atoms and formation of a symmetrical nonclassical ion, whereas the *endo*-isomer *(14)* behaves classically:



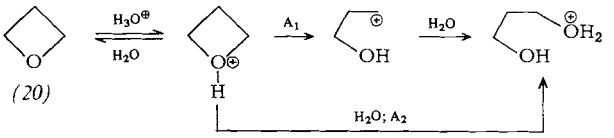
It is not possible here to take cognizance of the copious literature devoted to this question[87], and in this paper we can only allude to the pressure effect. In the *exo*-ion, the charge is dispersed between two carbon atoms, and hence that part of the activation volume that may be ascribed to the cation (roughly half) should be smaller than that of the *endo*-ion. The activation volumes for the two reactions were found to be about -14 and -18 cm^3 mol^{-1}, respectively, and hence this particular result supports carbon participation[88]. A similar result was found for the pair *(15)/(16)* shown below[89]:



In his last review of this topic, *Winstein* listed these observations among those he felt supported the concept of carbon participation[90]; however, they do have one weakness. An activation volume less negative than normal in such reactions is indicated only if the positive charge becomes evenly distributed over at least two centers. If it becomes largely or completely *transferred* to one other atom, it is again localized albeit at an atom different from the one originally bound to the leaving group; if that be the case, there is no reason to anticipate an activation volume less negative than normal. This criterion can therefore be applied impartially only in instances in which symmetry *demands* charge dispersal, such as is the case in the two instances cited. The difference $\Delta\Delta\bar{V}^{\neq}$ furthermore is rather small, and hence accurate measurements under identical conditions are essential; this fact also rules out cases in which the pair of interest has an unusually large rate ratio (*i.e.* 10^3 or more: it will then be difficult to measure the two under the same conditions).

Nevertheless, there are continued indications that the effect is real. Thus, in cases involving the so-called $Ar^{\ominus}$-participation, no positive charge is formed at all, and the reactions are essentially internal S_N2-types. The activation volumes of *(17)* and *(18)* are then in the range of 0 to -5 cm^3 mol^{-1};

this compares with about -20 cm^3 mol^{-1} for the reaction of *(19)*[91].

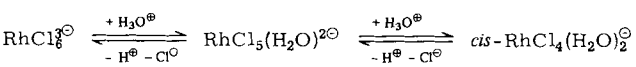


Sera has measured activation volumes of the solvolyses of *p*-substituted β-phenylethyl derivatives. In such reactions, it is now agreed, phenyl participation occurs when the substituent is an electron donor[92]. *Sera et al.*[93] find that the activation volume changes from -17 to -10 cm^3 mol^{-1} as the *p*-substituent is varied from *p*-nitro to *p*-methoxy. In a related experiment, the activation volume in the solvolysis of benzyl halides was found to become more negative when two large alkyl groups in the 2,6-positions interfere with the planarity and hence with charge dispersal.

3.6. Acid Catalyzed Solvolysis

Among the questions that have concerned high pressure chemists is that of solvent assistance, or whether the volume of activation can be used to probe solvolyses that may or may not be limiting. It does not appear to be so, with primary substrates such as β-cyclopentylethyl *p*-nitrobenzenesulfonate typically yielding $\Delta\bar{V}^{\neq}$ values quite similar to that of 2-adamantyl-*p*-nitrobenzenesulfonate[94] under identical conditions; the latter example is archtypical of secondary substrates hydrolyzing with a limiting S_N1-mechanism[95].

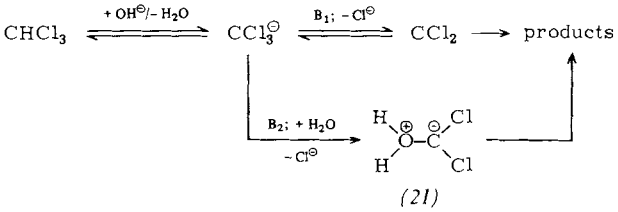
A closely related question has long puzzled organic chemists about the mechanism of acid-catalyzed hydrolysis of the CXC linkage in ethers, esters, acetals, amides, and so on:



does the protonated species undergo unimolecular (A_1) bond cleavage to give a free carbenium ion in the rate-determining step followed by rapid reaction with solvent, or are these steps combined in a single, bimolecular reaction (A_2)? These two pathways are demonstrated by means of oxetane *(20)* as an example; it may be noted that the rate law—as in solvolysis—offers no distinction between these possibilities. Several

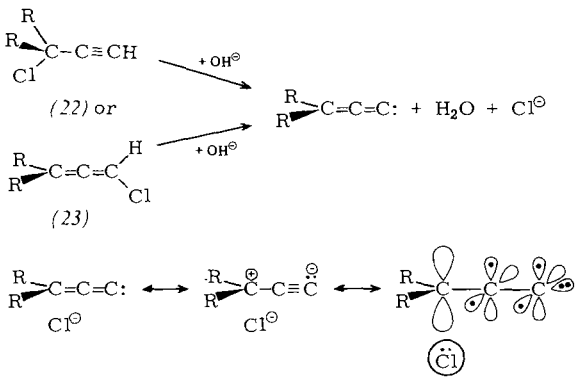
(20)

criteria have been applied to these reactions with this question in mind; among the more important are the solvent isotope effect (*i.e.* the use of D_2O) and the Hammett acidity function H_0. The results so obtained have never seemed very convincing; thus, in the case of oxetane, the use of these criteria led to the conclusion that it hydrolyzes *via* the A_1 mechanism[96]. That would mean a primary carbenium ion intermediate, in a solvent as nucleophilic as water. A straightforward prediction can be made on the basis of the pressure effect. The A_1 reaction is characterized by bond cleavage, and hence it should be pressure retarded; the A_2 pathway is basically one of displacement, and hence it should be promoted by hydrostatic pressure. This latter possibility is in fact observed; the activation volume is about -8 cm^3 mol^{-1}[97]. It may be noted in passing that the pre-equilibrium step involves no changes in either the total number of bonds or charges, and hence it should be affected by pressure in at most a minor way. A large number of cases has now been examined with this tool, especially by *Whalley et al.*, and a perfectly believable correlation between substrate and mechanism has emerged: while compounds such as ethers and simple esters solvolyze faster under pressure, others such as ortho-esters, acetals, *tert*-butyl ethers and so on are retarded[98]. The latter series is of course comprised of substrates capable of producing relatively stable carbenium ions.



Similarly to the situation with organic substrates, the question again arises whether stepwise acid hydrolysis of complex ions involves a direct attack by a solvent water molecule or a primary dissociation of a metal-ligand bond. Based on earlier chloride exchange studies and on the steric course of the reaction, a D-mechanism was proposed for the acid catalyzed hydrolysis of the $RhCl_6^{3\ominus}$ ion.

The volumes of activation for the first two chloride removal steps amount to $+21$ and $+14$ cm^3 mol^{-1}, respectively[99]. Although one has to allow for the charge dispersal that occurs during the bond-breaking process, thus contributing a positive ΔV^{+}_{solv}, the large and positive values of $\Delta \bar{V}^{+}$ certainly contain a positive ΔV^{+}_{intr} as well.



3.7. Base Catalyzed Solvolysis

A question similar to the one just considered arises in many base-catalyzed hydrolyses; the hydrolysis of chloroform may serve as example. In this case, the B_1 reaction would produce a free carbene, and the B_2 pathway would lead to a bound carbene (an oxygen ylide) *(21)*. It may be of interest to point out that *Hine*[100] in his classic paper on this reaction did not make a choice between these possibilities[100]. The observed rate constant was subsequently found to be proportional to the H_--function[101], which suggests that no solvent molecules become covalently bound in the transition state; but as noted above (Section 3.6), this criterion is subject to doubt. The activation volume is very large and positive, ($+16$ cm^3 mol^{-1}), so that it is certain that bond breaking must be taking place in the transition state[102]. The alternative B_2 path would in fact have led to a zwitterionic ylide *(21)* which because of its charges should be strongly solvated, and hence, characterized by contraction.

(21)

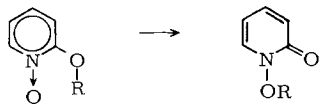
It is possible, of course, that carbenes are not always free molecules in all reactions in which carbenoid products form. The type of carbene considered, the solvent, leaving group and trapping agent all could conceivably alter the picture. These same studies have in fact unearthed one example of a complexed carbene[103]. The base-promoted solvolyses of tertiary propargyl halides *(22)* and of their isomeric allenic halides *(23)* are virtually unaffected by pressure, and it was concluded that these reactions produce not a free carbene, but one complexed with the leaving group in the same sense that ions are complexed in a pair. The zwitterionic character of the carbenic partner and the resulting electrostriction are thought to be responsible. In support of this conclusion, it was found that some internal return occurs; *i.e.*, during the

solvolysis of the acetylene derivative *(22)*, some of the allenic isomer *(23)* forms, and the yield of this product is almost independent of added chloride ions[104]. If the product *(23)* were formed *via* capture of chloride ions by a free carbene (external return), then the yield should have been increased by increasing the chloride ion concentration. The mechanism can of course also be tested stereochemically, and it has passed this test successfully[105].

The same question arises in other base-promoted reactions that produce interesting intermediates. *Brower* has employed

the high-pressure tool to demonstrate the freeness of dehydrobenzene in solution[106], and to dissect a number of carbanion reactions covering a spectrum of mechanisms[107]. We have used it to study the base-catalyzed reaction of chloramines. The evidence published in this case consists of base-catalyzed deuterium-exchange, correlation of the rate constant with the H_- function, and the fact that matrix-generated nitrene (NH) *does* react with water to produce hydroxylamine, which is the first observable product in the hydrolysis of NH_2Cl[108]. None of this evidence is completely convincing, however, and in fact, the rate law doesn't even rule out a simple S_N2 displacement reaction: the evidence that *Hine* had used to rule out such a mechanism for chloroform (a comparison of the rates of CH_xCl_{4-x}[100]) is not available in this instance. The activation volume is -3 cm^3 mol^{-1}. Furthermore, this same value applies to *N*-chloro(methyl)amine and *N*-chloro(dimethyl)amine; in the case of $(CH_3)_2NCl$, neither the B_1 nor the B_2 reactions are possible, and the conclusion is that the S_N2 mechanism is operating[109]. One might suppose that in analogy with the halomethanes, the B_1 pathway has its best chance among the halamines with the compounds NHX_2. It was found that difluoramine does indeed hydrolyze in aqueous base with an activation volume of about $+10$ cm^3 mol^{-1}[110]. Subsequent studies then showed that fluoronitrene (FN) could be trapped, that it is formed as a singlet, and that it has a triplet ground state[111]. The further fact that it is isoelectronic with oxygen makes it an enticing objective for further studies of its chemistry.

3.8. Rearrangements

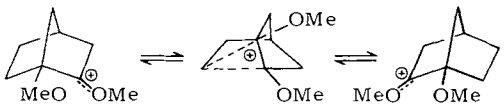


On the basis of the foregoing discussions, one should expect that pressure may either accelerate or retard rearrangements—the determining factor in whether bond-making or bond-breaking features dominate the mechanism. Simple steric changes and inversions, however, may be pressure independent.

Brower et al.[112] found that while the racemization of optically active sulfonium salts is usually virtually pressure-independent as might be expected from a simple sulfur inversion, in those instances in which a C—S fission could produce a stable carbenium ion— and hence in which an alternative mechanism for racemization might be operating—the racemization is indeed strongly inhibited by the application of pressure.

On the other hand, bond-making is clearly dominant in such concerted reactions as the Claisen[113] and Cope[114] rearrangements, which may be considered internal neutral displacements. $\Delta\bar{V}^{\neq}$ is about -15 cm^3 mol^{-1} in both cases.

The difference can be dramatically demonstrated with the rearrangement of ethers of type *(24)*.



(24)

Pre-dissociation into radicals is the first step in the reaction when $R = CH(C_6H_5)_2$; it is retarded under pressure, with a $\Delta\bar{V}^{\neq}$ of $+10$ cm^3 mol^{-1}[115]. This is in stark contrast to the acceleration observed when $R = CH_2C_6H_5$ ($\Delta\bar{V}^{\neq} = -30$ cm^3 mol^{-1}). These conclusions are supported by the observation of CIDNP in the former reaction but not in the latter[116]. Pressure is therefore an important tool to ascertain concertedness in sigmatropic shifts, as it is in cycloadditions.

If the bond-breaking is of an *ionic* nature, the solvation that accompanies the approach of the transition state produces a *negative* activation volume. This is clear from an interesting and revealing result turned up by *Brower*[117]. He finds that the linkage isomerization in benzhydryl isothiocyanate is strongly accelerated by pressure. This reaction—observable only in ionizing media—therefore mimicks the pressure response of a concerted sigmatropic shift.

Charge dispersal may become the dominant feature in concerted sigmatropic shifts in ionic species if the reaction involves a relocation of the charge. This is the case in degenerate Wagner-Meerwein rearrangements. The equilibration of the 1,2-dimethoxynorbornyl ion—known to be classical[118]—was examined under pressure; it was found that the equilibration rate (as calculated from the NMR line shapes) was depressed by the application of pressure: $\Delta\bar{V}^{\neq} \approx +8$ cm^3 mol^{-1}[119]. The transition state *(25)* has the nonclassical and charge-dispersed structure in this instance.

(25)

Coordination compounds exhibit three types of rearrangements: linkage isomerization, geometric isomerization, and racemization. Linkage isomerizations are encountered with ambidentate ligands like NO_2, SO_2, SCN *etc.* One of the systems more extensively studied is the nitrito/nitro rearrangement of octahedral complexes:

$$M(NH_3)_5ONO^{2\oplus} \rightarrow M(NH_3)_5NO_2^{2\oplus}$$

The earlier studies[120] at ambient pressure had shown that at least for the cobalt(III) complex, the linkage isomerization is much faster than the hydrolysis reaction, and no exchange occurs between the bond ligand and free, labeled nitrite ions. The volumes of activation for M = Co, Rh, and Ir were found to be similar, *i.e.*, -6 ± 1 cm^3 mol^{-1}, suggesting a common

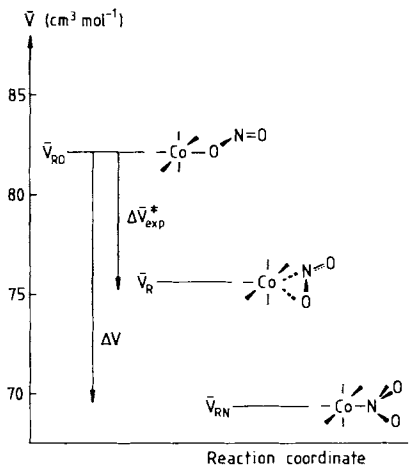


Fig. 7. Volume profile diagram for the linkage isomerization of $Co(NH_3)_5ONO^{2\oplus}$ (counterion: perchlorate).

mechanism[121]. Since the data are not at all similar to those obtained or expected for the corresponding hydrolyses reactions, an intramolecular rearrangement of the ligand is assumed with a transition state midway along the reaction coordinate, the overall volume of reaction being -12 cm^3 mol^{-1} for the cobalt complex ion. The total volume profile of the reaction emerging from these data is shown in Figure 7.

The linkage isomerization of the thiocyanato ligand attached to a planar four-coordinated palladium complex has been studied as part of a detailed investigation of this class of compounds. The two-pathway mechanism normally encountered for ligand substitution reactions of square planar complexes can be reduced to the solvolysis path (k_1) by steric crowding, *i.e.* by raising the bulkiness of the remaining ligands L (S = solvent):

$$ML_3X + S \xrightarrow{k_1} ML_3S + X$$

$$ML_3S + Y \xrightarrow{\text{fast}} ML_3Y + S$$

In fact, the rate constants and activation parameters for the solvolysis (or substitution through solvolysis) and the linkage isomerization of Pd(Et$_4$dien)SCN$^{\oplus}$ are identical, with $\Delta\bar{V}^{+}$ values of -10 ± 1 cm^3 mol^{-1}[122]. Unlike the nitrito/nitro isomerization, the linkage isomerization in this case proceeds through the well established hydrolysis route.

Conversions between the geometric *cis*- and *trans*-isomers of coordination compounds were studied with octahedral and square planar complexes as well. Isomerizations of *trans*-$Co(en)_2(OH_2)_2^{3\oplus}$ and *trans*-$Cr(C_2O_4)_2(OH_2)_2^{\ominus}$ were investigated in detail, with the result that the basic difference in mechanistic behavior between the complexes of trivalent cobalt and chromium was confirmed. Thus, the volume of activation for the isomerization of $Co(en)_2(OH_2)_2^{3\oplus}$ turns out to be $+6\pm1.5$ cm^3 mol^{-1} depending somewhat on ionic strength[123]. The relatively small and positive values were interpreted in terms of an I_d mechanism paralleling that of the water ligand exchange processes.

In contrast to this system, the isomerization of the *trans*-$Cr(C_2O_4)_2(OH_2)_2^{\ominus}$ shows a volume of activation of -16 cm^3 mol^{-1}[124]. This result could be conceived as an associative attack of a water molecule on the chromium center of the complex ion. However, the water exchange in this case is 150 times slower than the isomerization[125]. A rate-determining opening of an oxalato chelate ring with its charge concentration at the free end and a substantial contribution from electrostriction was therefore invoked.

Racemization reactions of a number of bis- and tris-oxalato complexes of chromium(III) show similar strong negative volumes of activation. Again, a ring-opening mechanism was suggested. The fact that all 12 oxygen atoms of $Cr(C_2O_4)_3^{3\ominus}$ were found to be equivalent in isotopic exchange studies supports the proposed mechanism[126].

Optically active cationic complex ions like $Cr(phen)_2(C_2O_4)^{\oplus}$, $Cr(bpy)_2(C_2O_4)^{\oplus}$, $Cr(phen)_3^{3\oplus}$, and $Cr(bpy)_3^{3\oplus}$ racemize with almost no pressure effect[127]. An internal twist mechanism is claimed to occur in which bonds are neither broken nor formed. This again shows that the volume of activation is an exceedingly useful criterion in mechanistic discussions.

3.9. Synthetic Applications

Pressure applications can be used to improve yields in those chemical syntheses in which the desired product formation has a markedly more negative volume of activation than the by-products; a difference in activation volume of *ca.* 10 cm^3 mol^{-1} can change a product ratio of 1:10 at ambient pressure into one of 10:1 at 1 GPa. Such circumstances may make a synthesis worthwhile.

And, in fact, examples of success are known: 0.7 GPa of pressure is enough to double the yield of *C*-alkylated phenols over *O*-alkylated isomer during the reaction of allyl chloride with aqueous sodium phenoxide[128]; the application of 1.4 GPa led to an increase from 2 to 65% in the cycloaddition of a steroidal diene in one instance[129]; as noted, *N*-methylation of 2,6-di-*tert*-butylpyridine, impossible altogether at atmospheric pressure, occurs with remarkable facility at 0.5 GPa, and so on. The Diels-Alder reaction in particular is one area that has attracted the attention of organic chemists as one that should be routinely considered a candidate for high-pressure execution[130]. Applications in inorganic synthesis have been reported by *Hagen et al.*[131].

4. Conclusions and Outlook

The principal uses of compressing chemical systems to date have been in mechanistic investigations. The volume of activation has intuitive appeal, a relatively favorable "signal to noise" ratio and an easy dissection into transition and initial state contributions, offering advantages over other activation parameters.

Additional possibilities now open to us include photochemistry[5, 132]. Thus, *Neuman et al.*[133] have already used high pressure to determine that α-fission has the greatest volume requirements among the various reaction paths into which carbonyl groups partition; *Weller et al.*[134] have determined that excimer formation prior to fluorescence can be diffusion controlled; *Hamann*[135] has calculated the ionization volume of excited *p*-nitrophenol from the effect of pressure on its Förster cycle, and it has been learned[136] that the pressure enhanced preference for covalent thermal [2+4]-cycloadditions over their [2+2]-analogs is reversed under photochemical conditions. Numerous other applications can be imagined and surely many are to be expected.

Something similar can be said for biochemistry[1, 137]. Some chemists are already using pressure to look for enzyme-mediated conversions subject to large-scale conformational changes in the catalytic process; others are scrutinizing the biomimetic catalysis of cyclodextrins and other enzyme models under pressure. There surely will be a useful high pressure input into problems surrounding the behavior of membranes; thus diffusion as revealed by spin labels is being investigated. The cyclization of squalene into steroid derivatives should benefit from high pressure conditions, as should numerous other forms of biomimicry.

The application of the next-higher-order pressures (of about 10 GPa where the $p\Delta\bar{V}^{+}$ term may well swamp the other parts of ΔG^{+}) is almost certain to lead to exciting new knowledge in even simple organic reactions[138]. The applications of relaxation and stopped-flow techniques under pressure are beginning to yield results[139], and the marriage of

high pressure and NMR techniques is sure to lead to knowledge of volume profiles in rapid degenerate equilibrations[14a]. Finally, small-scale technological applications are not ruled out either. Synthetic applications in the area of fine chemicals seem perfectly feasible; pharmaceuticals and special high molecular weight polymers are prominent among them.

The authors express their appreciation for the support of their own investigations in this field by the U. S. National Science Foundation (W. J. le Noble) and by the Deutsche Forschungsgemeinschaft (H. Kelm).

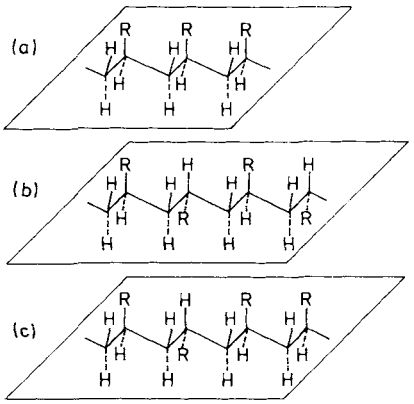
Stereospecific Polymerization of Propylene: An Outlook 25 Years after Its Discovery[**]

By Piero Pino and Rolf Mülhaupt[*]



In 1955 *Natta* and his co-workers from the Istituto di Chimica Industriale del Politecnico di Milano reported the properties of highly crystalline polypropylene and other poly-α-olefins[1] which possess, at least in long sections of the main chain, asymmetric carbon atoms of the same absolute configuration (isotactic poly-α-olefins). The discovery of the new crystalline polymers was judged at that time "revolutionary in its significance"[2] and heralded a new era in polymer science and technology. Indeed, crystalline polypropylene, because of its relatively high melting point and its outstanding mechanical properties, has found very extensive application in the field of plastics films and fibers.—25 years after this publication, it is worthwhile examining the further developments following this discovery which has had such a great scientific and industrial impact, and the problems which are still open concerning the structure of the catalytic centers and the mechanism by which practically completely stereoregular polypropylenes are formed.

1. Historical Background

The absence of crystallinity in vinyl polymers synthesized by radical polymerizations was first pointed out by *Staudinger* who attributed this phenomenon to the formation of a large number of diastereoisomers of the linear macromolecules[3]. Some attempts to synthesize stereoregular macromolecules were first carried out by *Marvel* and co-workers[4] who could not detect any differences in the poly(methyl methacrylates) synthesized using optically active or nonchiral radical initiators. It was *Schildknecht* and his co-workers[5] who first obtained two different types of poly(vinyl ethers) by cationic polymerization under different conditions, one of which showed some crystallinity. Unfortunately, they apparently were unaware of a paper published by *Bunn*[7] in 1942 who had postulated the possibility that the main chains of vinyl polymers having sterically equivalent monomeric units can assume helical conformations. Therefore *Schildknecht* and co-workers, in searching for possible structures of a stereoregular vinyl polymer (Scheme 1), attributed a zig-zag planar conformation like the one already known for linear paraffins, to the main chain of the poly(vinyl ethers) in the crystalline state. That is why they were compelled to attribute alternate (*R*) and (*S*) absolute configurations to the asymmetric carbon atoms of the main chain in order to eliminate strong steric interactions between the relatively bulky side chains.

In 1950 *Morton*[8] used his "alfin" catalyst to prepare a high molecular weight polystyrene but he did not investigate its structure. In 1956, after isotactic polystyrene had been obtained and its structure identified by *Natta* and co-workers[1], *Williams*[9] showed that the polystyrene obtained by *Morton* was isotactic.

The work of *Natta* and co-workers in the field of poly-α-olefins began in 1952, as a consequence of a report by *Ziegler*[10] describing the possibility of synthesizing relatively low molecular weight linear polyethylenes by reaction of ethylene with trialkylaluminum compounds. In *Natta*'s opinion, Ziegler's "Aufbaureaktion", whereby the monomer inserts between the growing chain and a metal atom, should

Scheme 1. Zig-zag planar conformation of the main chain of vinyl polymers having different types of stereoregularity. a) Isotactic chain [1]; b) syndiotactic chain [6]; c) atactic chain [6].

permit far better control of the polymerization process than is possible in the usual ionic or radical polymerizations which were believed to occur by the addition of the monomeric molecules to the free end of the growing chain.

By the end of 1953 *Ziegler* discovered[11] that high polymers of ethylene can be obtained on the addition of a transition metal salt (*e.g.* $TiCl_4$) to the alkylaluminum catalyst. At that time work on the "Aufbaureaktion" with alkylaluminum compounds was already in progress in Natta's laboratory. *Natta* interpreted the effect of transition metal halides on the "Aufbaureaktion" by supposing that the transition metals activate the ethylene molecules prior to the insertion, and therefore greatly enhance the rate of propagation, while the rate of the termination processes remains substantially unchanged. He thought that the same principle might apply to propylene, which in the "Aufbaureaktion" yielded only oligomers, and tried to use the new Ziegler catalytic systems

(metallorganische Mischkatalysatoren) to obtain linear polymers of propylene. Polymers of this kind were unknown at that time but were expected to have elastomeric properties resembling those of polyisobutylene[12]. Indeed, in March 1954, using a $TiCl_4/Al(C_2H_5)_3$ catalytic system, *Natta* and his co-workers obtained a rubber-like polymer of propylene in the very first experiments. However, the product was not homogeneous and contained some white solid particles. Fractionation by solvent extraction surprisingly afforded four very different fractions[13]: The first one was an oily product soluble in acetone; the second was a rubber-like product soluble in diethylether; the third was a partially crystalline solid soluble in boiling heptane; and finally a white highly crystalline powder was obtained, which had a melting point higher than 160 °C, was insoluble in boiling heptane, and represented 30—40% of the total polymer. The series of solvents and the extraction conditions chosen effected a fractionation which was very efficient indeed, as was recently shown by ^{13}C-NMR spectroscopy (Fig. 1, cf. also Fig. 2)[176].

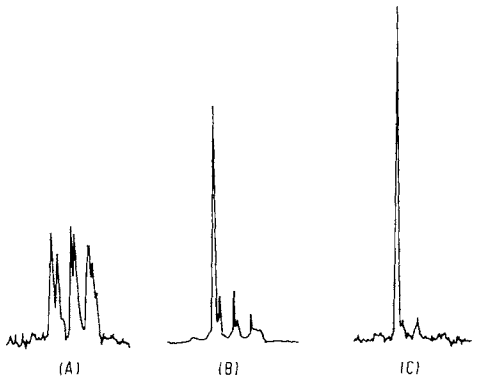

Fig. 1. ^{13}C-NMR spectra of polypropylene fractions obtained by extraction with solvents at their boiling temperature. (A) Acetone-insoluble, ether-soluble fraction; (B) ether-insoluble, heptane-soluble fraction; (C) heptane-insoluble fraction (solvent *o*-dichlorobenzene).

Initially the different properties of the fractions were attributed to differences in average molecular weight. However, thermal degradation of the crystalline fractions showed that low molecular weight polymers may also be crystalline[14]. The X-ray diffraction pattern of the crystalline products and density measurements showed that a zig-zag planar conformation of the main chain was not present in the solid state, and indicated the existence of a 3_1 helical conformation of the main chains[15]. Infrared spectra of the crystalline and amorphous fractions in solution and in the melt were very similar and indicated a head-to-tail structure of the main chain in both cases[1]. On the basis of the IR and X-ray data, it was possible to assign the correct structure of the new α-olefins polymers within a few months[16].

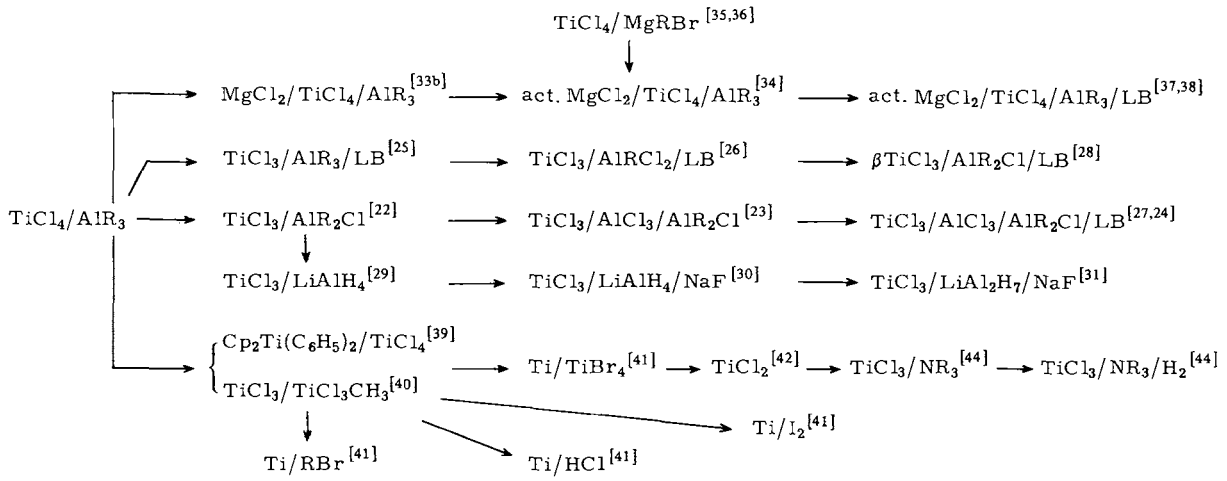
In the early fifties, propylene was polymerized with metal oxides in other laboratories[17-20]. However, only small quantities of the solid fractions were obtained, and it probably seemed uninteresting to invest too much time in investigating their structure. Furthermore, in one case, IR spectra, recorded only at room temperature on polymer films, were erroneously interpreted[19,20] and no X-ray studies were carried out. In another case[17,18], ethylene-propylene copolymers were often obtained as the major product, the ethylene very probably arising from propylene metathesis. Some of these polymers were characterized by X-ray diffraction and IR-spectroscopy but their structure was apparently not well understood[18].

It is interesting that, in 1955, *Natta*'s group[21] first proved the existence of isotactic polypropylene in the polymers obtained with various supported CrO_3 catalysts by comparing the spectroscopic and X-ray diffraction data of very small non-tacky polymer fractions thus obtained with the corresponding data already available in their laboratory for the polypropylenes prepared using the Ziegler catalyst.

2. Development of Catalysts for Polymerization of Propylene

The most frequently used catalysts for the synthesis of isotactic polypropylene is the product obtained by reacting a titanium halide with alkylaluminum compounds. However, partly to avoid conflict with existing patents and partly due to research efforts to clarify the polymerization mechanisms, a very large number of catalytic systems have been investigated.

We shall first outline the development of the classical Ziegler organometallic catalytic systems containing titanium halides and alkylaluminum compounds and then we shall briefly summarize some other types of catalytic systems which also produce isotactic polypropylene. The following discussion is by no means exhaustive and undoubtly reflects some personal biases of the authors about the relative importance of the approaches used by different groups.

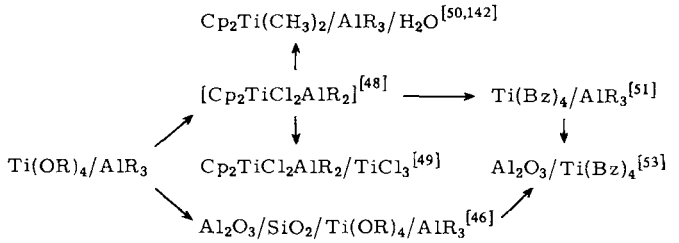


2.1. Development of Classical Titanium-Containing Catalytic Systems

An outline of the development of the catalytic systems, originally proposed by *Ziegler*[11], prepared from $TiCl_4$ and AlR_3 is presented in Scheme 2; in Scheme 3 a similar survey is shown for the $Ti(OR)_4/AlR_3$ catalytic systems.

The first important advance in the field[22] originated from *Natta*'s intuition that stereospecificity was connected with the regularity of the surface of the heterogeneous catalyst. Instead of preparing the catalyst by reaction of $TiCl_4$ with AlR_3, crystalline $TiCl_3$ prepared by reduction of $TiCl_4$ with hydrogen or with aluminum was suspended in a hydrocarbon medium and treated with a trialkylaluminum or a dialkylaluminum chloride. In this way the percentage of isotactic polypropylene in the polymerization product was increased from about 40% to about 90%.

A further improvement to this type of catalyst was made by researchers at Esso Research and Engineering Co., who used a solid solution of $AlCl_3$ in $TiCl_3$ instead of pure $TiCl_3$. Reacting this finely milled solid with aluminumalkyls gave a catalyst of higher activity[23]. A further increase in the percentage of isotactic polymer produced (up to 95%) was achieved by adding a Lewis base (*e.g.* an ester of an unsaturated carboxylic acid)[24] to the crystalline $TiCl_3$.



The use of Lewis bases to enhance catalytic activity was first proposed by *Razuvaev* and co-workers[25], and active catalytic systems were prepared from $TiCl_3$, $AlRCl_2$, and a Lewis base by *Coover* and co-workers[26]. More recently, treatment of the product resulting from reaction of $TiCl_4$ and $AlRCl_2$ with Lewis bases (mainly ethers) was found to give a

Scheme 2. Development of different types of titanium catalysts for the polymerization of propylene. LB = Lewis base.

$TiCl_3$-preparation with a larger surface area and with a much greater activity and high stereospecificity[27,28].

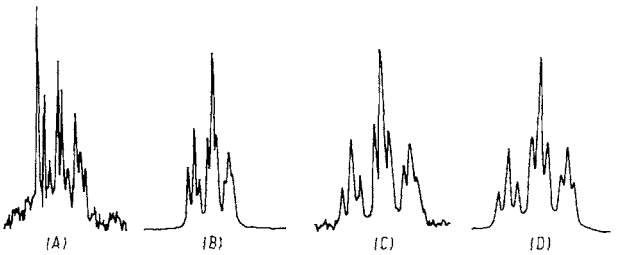
Catalysts of the same type which functioned at higher temperature (up to 200 °C) were obtained at Eastman Kodak[29] by reaction of $TiCl_3$ with $LiAlH_4$ and, in a further improvement, by adding NaF to the above mixture[30]. The best catalyst of this type seems to be a mixture of $TiCl_3$, $LiAl_2H_7$, and NaF[31].

Scheme 3. Development of different types of titanium catalysts for the polymerization of propylene. Bz = benzyl.

Parallel to the above developments, a series of attempts was made to support the $TiCl_4$ on different carrier materials. The first attempts were made with the classical large-surface supports used in heterogeneous catalysis, *i.e.* SiO_2[33a] or $MgCl_2$[33b]. However, no significant success was obtained along these lines until activated $MgCl_2$ was used as support[34-38].

Less important from an industrial point of view, but very interesting for the understanding of the nature of the catalytic centers, were the attempts to develop a catalyst containing only titanium as the metal component. Two groups[39,40] working independently obtained catalysts which are active in propylene polymerization by reacting $Cp_2Ti(C_6H_5)_2$ with $TiCl_4$[39] or by decomposing $TiCl_3CH_3$[40] to form a mixture of $TiCl_3$ with $TiCl_3CH_3$. Further developments in this field were the catalyst prepared by reacting elemental titanium with $TiBr_4$[41], with alkyl chlorides[41], with hydrogen chloride[41], or with iodine[41]. Also $TiCl_2$[42] and $TiCl_3$ treated with tertiary amines or with tertiary amines and hydrogen[43-45] were proposed as catalysts, but showed only very modest catalytic activity.

Among the original catalysts proposed by *Ziegler,* soluble systems, mostly containing no halogens, were examined in numerous investigations[50] (Scheme 3). This research finally led to the very active systems of the type $Cp_2Ti(CH_3)_2/AlR_3/H_2O$[142] which give the highest productivity for linear polyethylene (6×10^4 g polymer/g Ti × h × atm) and completely atactic polypropylenes (Fig. 2B). On the same line, catalytic systems were obtained from the reaction of $Ti(CH_2C_6H_5)_4$ with AlR_3[51] which yield organometallic complexes of relatively high molecular weight[52]. These complexes polymerize propylene and other α-olefins, yielding products containing a small amount of isotactic polymers.



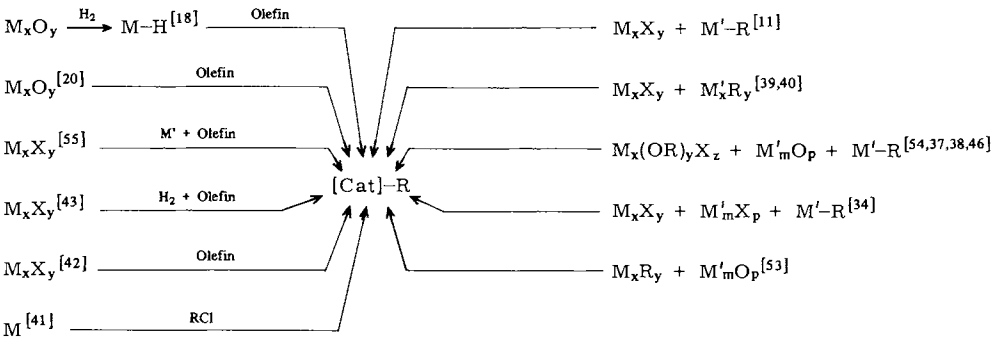


Fig. 2. ^{13}C-NMR spectra of ether-soluble polypropylenes. (A) Prepared with $MgCl_2/TiCl_4/Al(iC_4H_9)_3$/ethyl benzoate [176]; (B) prepared with $Cp_2Ti(CH_3)_2/Al(CH_3)_3/H_2O$ [142], product kindly made available by Professor *Sinn;* (C) atactic polymer prepared by epimerization of isotactic polypropylene with Pd catalysts at 270 °C (*U. W. Suter,* unpublished results); (D) calculated for a polypropylene with a Bernoullian distribution (molar fraction of m dyads corrresponding to the equilibrium composition is 0.48).

As soon as the activity of the soluble catalytic systems was recognized, attempts were made[46] to support the above soluble complexes. Titanium alcoholates and chlorotitanium alcoholates supported on Al_2O_3/SiO_2 in the presence of AlR_3 yielded small amounts of isotactic polypropylene, while only traces of polymer were obtained without support[46]. Highly crystalline polypropylene was obtained supporting the soluble complex $[Cp_2TiAl(C_2H_5)_2]_2$, which does not polymerize propylene, on $TiCl_3$[49]. Finally, an interesting class of catalytic systems was discovered in which Ti or Zr still attached to at least one benzyl group are chemically bound to the classical support Al_2O_3[53]. With these catalytic systems the use of organometallic compounds of aluminum can be avoided. The presence of a support increases the percentage of isotac-

tic polymer in the products; however, the synthesis of a high percentage of highly isotactic polypropylene has never been reported using this process. It is interesting to note that, with only the remarkable exception of the highly active soluble catalytic systems[50], all the other development lines finally led to catalysts in which titanium or, in general, the transition metal atoms are fixed to a solid support having a high surface area.

2.2. Pathways Leading to Stereospecific Catalysts for Olefin Polymerization

Scheme 4 summarizes the main pathways proposed to prepare catalysts for the synthesis of stereoregular poly-α-olefins. On the right side of the Scheme, catalysts containing in general more than one type of metal atom or ion are listed. Besides the typical Ziegler catalysts M_xHal_y/M'_mR_n[11] (M = transition metal; M' = main group metal), catalytic species supported on oxides[46] or on halides of the main group

Scheme 4. Methods of the synthesis of heterogeneous stereospecific catalysts [Cat]—R for the polymerization of α-olefins (M = transition metal; M' = main group metal; X = halogen).

elements have been proposed[34,54]. Furthermore, catalysts based on organometallic compounds of transition metals have been used in combination either with a halide of the same metal[39,40] as discussed for titanium catalysts in the previous section, or with a main group metal oxide[53].

On the left side of the Scheme 4, transition metals or transition metal compounds are shown which can form carbon-metal bonds *in situ*. In this family, $TiCl_4$ treated with aluminum and olefins[55], MoO_3/CoO pretreated with hydrogen[17,18], and CrO_3 supported on Al_2O_3/SiO_2[19,20] are, together with the $TiCl_4/AlR_3$ catalytic systems, the oldest representatives. Some catalysts of the above type are very active for ethylene polymerization but of no interest for propylene polymerization. In fact, although polymers of propylene were prepared very early with these catalysts, the yields of solid products were so low that they were not further investigated.

Other ways of producing catalysts for ethylene and α-olefin polymerization are the activation of metal halides with hydrogen and tertiary amines[43-45] or simply with olefins[42] and the activation of transition metals with alkyl halides[41].

3. Main Steps in the Development of Industrial Processes for Production of Isotactic Polypropylene

Despite the very large number of patents in the field, only relatively few have contributed to substantial progress in the industrial production of isotactic polypropylene[56-60]. In Table 1, some of the main improvements are listed in chronological order.

The original Ziegler catalytic systems had a relatively low productivity [up to *ca.* 20 g polypropylene/g Ti × h × atm][46]. A process based on this catalyst would have required three steps, *i.e.* polymerization, separation of the nonisotactic fractions (*e.g.* by solvent extraction), and purification of the isotactic polymers from the residues from the transition metal catalyst. The main improvements concern the increase of the polymer yield[32,61] and of the percentage of isotactic polymer[23,24,37] in the products, the medium in which the polymerization is carried out (saturated hydrocarbons, liquid monomer, gas phase[62]) and the regulation of the average molecular weight with H_2[63]. Further improvements concern the increase of the polymerization temperature[29-31] which, in principle, should allow the recovery of the polymerization enthalpy and finally the control of the polymer morphology.

The improvements connected with the developments on new catalysts have already been discussed in Section 2.1.

More recent developments concern mainly improvements in the catalyst productivity and have ultimately eliminated the need to purify isotactic polymers. A productivity of 520 g polymer/g Ti × h × atm was obtained by treating the $TiCl_3$ prepared from $TiCl_4$ and $AlCl_2(C_2H_5)$, with aliphatic ethers[27]. A greater improvement was obtained by supporting $TiCl_4$ on activated $MgCl_2$[37,38,61] or by producing a supported catalyst by reacting $TiCl_4$ with $Mg(OC_2H_5)_2$[54] or other magnesium compounds[35,36]. With these catalysts, a productivity of over 3000 g of polymer/g Ti × h × atm can be obtained; however, as with the non-supported catalyst, the percentage of isotactic polymer in the products is low (20—40%). A substantial improvement can be obtained by adding a Lewis base to the catalytic system (*e.g. N,N,N',N'*-tetramethylethylenediamine (TMEDA) in the solid component and ethyl benzoate in solution) (Table 2); in this way, the percentage of isotactic polymer can be increased to over 93%. In this case a productivity of 250 g polymer/g Ti × h × atm has been reported. In other cases productivities as high as 1300g/gTi × h × atm of polypropylene containing 90% isotactic polymer were reported[37].

Concerning the medium in which the polymerization is carried out, isotactic polypropylene is nowadays produced mainly in hydrocarbon suspension. However, as long ago as

Table 1. Important steps in the development of the industrial production of isotactic polypropylene with titanium catalysts.

[a] S, Polymerization in solvents; G, polymerization in the gas phase; F, polymerization in the liquid monomer. [b] A, Polymerization; B, separation of atactic fractions; C, purification of the isotactic polymers. [c] $\beta TiCl_3$ prepared from $TiCl_4$ and $AlCl(C_2H_5)_2$ and washed with aliphatic ethers.

in the fifties *Natta et al.* showed that propylene can be polymerized using a solid catalyst suspended in the gas phase[64] and, at the end of the sixties, a gas phase process for polypropylene was put into operation by BASF[62,65]. More recently, processes have come on stream in which the polymerization is carried out in liquid propylene; they seem to offer some advantages.

Table 2. Influence of Lewis bases on stereoregulation in propylene polymerization with supported $MgCl_2/TiCl_4/AlR_3$ catalytic systems.

Catalyst	Fraction of isotactic polypropylene [%]	g Polymer / g Ti × h × atm	Ref.
$TiCl_4/MgCl_2/Al(iC_4H_9)_3$	21	3840	[61]
$TiCl_4$(TMEDA)/$MgCl_2$/ $Al(C_2H_5)_3/C_6H_5COOC_2H_5$	93.5	250	[37]

Thanks to the outstanding properties of isotactic polypropylene[66,67] and improvements in the polymerization process, production is continuously growing and should reach a global level of well over 3×10^6 tons in 1980.

There are of course still many unsolved problems in the industrial production of polypropylene, the main one probably being the achievement of the control of the molecular weight distribution. This is connected with the preparation of catalysts in which the catalytic centers have similar chemical and steric structures. Highly active catalysts working at higher temperatures and giving a better control of polymer morphology would also certainly be welcome.

4. Fundamental Research on the Stereospecific Polymerization of Propylene and Other α-Olefins

Since the first announcement of the achievement of the stereospecific polymerization of propylene a large amount of fundamental research started all over the world with the aim of clarifying the two main novel aspects of this reaction, *i.e.* the mechanism of the reaction, which is characterized by an unusually high regiospecificity and stereospecificity, and the structure of the catalytic centers which are able to produce the stereoregular polymers.

To achieve the above aims, very different approaches have been adopted. They can be briefly summarized as follows:

A) Attempts to elucidate the mechanism of the reaction based on the investigation of
- Structure and stereochemistry of the synthesized polymers
- Model reactions
- Polymerization kinetics
- *"Ab initio"* or semiempirical calculations on models of catalytic centers

B) Attempts to elucidate the structure of the catalytic center based on the investigation of
- Reactions leading to the catalytic species
- Structure of the heterogeneous catalysts by various diffraction and spectroscopic techniques
- Synthesis of soluble coordination complexes having catalytic properties similar to the heterogeneous catalytic systems
- Relationship between structure of catalytic complexes and detailed structure of the polymers obtained

This effort has yielded a great amount of new knowledge not only in the field of polymer chemistry, but in many other fields of chemistry, such as organometallic chemistry, coordination chemistry, homogeneous and heterogeneous catalysis. However, although some features of the polymerization mechanism have been elucidated, important aspects of the polymerization reaction are still poorly understood and the detailed structure of the catalytic centers, not only in the heterogeneous polymerization catalysts but also in the homogeneous ones, is still unknown. The reasons for this lack of complete success are different for each of the approaches used, and will now be briefly summarized.

4.1. Polymerization Kinetics

Kinetic studies on heterogeneous catalytic reactions entail well known difficulties; in fact, kinetic measurements give only mean values for polymerization rates, from which it is impossible to determine the concentration of the active centers and the catalytic activity of each single catalytic center, which vary enormously from center to center.

The determination of the concentration of the catalytic centers has been attempted by several research groups[68-70]; only very few methods are available for such determinations, the one most commonly used being to poison the catalysts with radioactive carbon monoxide. Only a few catalytic systems (mainly based on Ti or V) have been investigated up to now.

Kinetic studies of polymerization in homogeneous phase[71,72] have shown that, even in the most thoroughly investigated catalytic complexes containing a bis(cyclopentadienyl)titanium group, the concentration of the catalytic species is too low to be detected by the available spectroscopic methods[71], and only precursors of the catalysts or non-catalytically active species in equilibrium with the catalytic centers can be studied.

Interesting reviews on the kinetic investigations have been published[73-77] and we shall not discuss this subject any further.

4.2. Spectroscopic and Diffraction Methods for the Investigation of Heterogeneous Catalysts

Although noteworthy progress has been made in the investigation of the structure of the surfaces of the heterogeneous catalysts during the past few years, the actual structure and the activity of single catalytic centers, even of the most stable heterogeneous catalysts, is far from being understood.

In the case of the typical Ziegler-Natta catalysts, the usual difficulties encountered in investigating heterogeneous catalysts are accompanied by further complications. Among these we mention only the relatively short life of the catalytic centers, compared with the catalyst lifetime, *e.g.* in ammonia synthesis, the continuous formation, at least in the $TiCl_3$ catalysts, of new surfaces by cleavage of the initial catalysts crystals, and the difficulty of investigating the catalyst after the reaction as it is often finely dispersed and completely buried in the bulk of the polymer.

Use of the various techniques and results obtained have been well documented in a number of papers and reviews[78-92] and will not be discussed here.

4.3. Theoretical Calculations on Models of the Catalytic Centers

Different types of calculations, including *ab initio*[97,98,101] calculations, semiempirical calculations[102], and calculations of nonbonded interactions at the active site[99,100] were attempted by different authors. The weak point of this approach, which was initiated by *Cossee* about 20 years ago[93-96], is the choice of the model on which calculations are made. As our knowledge of the structure of the catalytic centers is very scant (much scanter than the knowledge of the catalytic site of some enzymes), it only seldom happens that the calculations on models of catalytic centers lead to a better understanding of the experimental results and to the conception of new experiments. On the contrary, they offer very detailed explanations of the mechanism by which the models, that have been more or less arbitrarily chosen, could operate and they may give the impression to the unwary reader that the mechanism of stereospecific polymerization is fully known. Efforts along this line will become much more fruitful when more reliable models based on a better knowledge of the structure of the catalytic centers become available for these calculations.

4.4. Reactions Leading to the Catalytic Species

Great efforts in this direction were made especially in the period between the late fifties and the early seventies[103] but they did not bring any important advances in the understanding of the structure of the catalytic centers in the heterogeneous catalysts. The main difficulty here is that only a very few of the transition metal atoms (for Ti-containing nonsupported catalysts less than 1%) are actually catalytically active under steady-state conditions. In the reactions in which catalytic centers are formed, only the main products can be investigated, while products formed in smaller amounts (*e.g.* less than 1%) can hardly be investigated. Therefore a connection between the main reaction products must sometimes be postulated, or tacitly assumed, without actual proof that the main products and not small amounts of secondary products which form during the reaction, are in some way connected with the structure of the actual catalytic centers. This type of research will not be further discussed in this review.

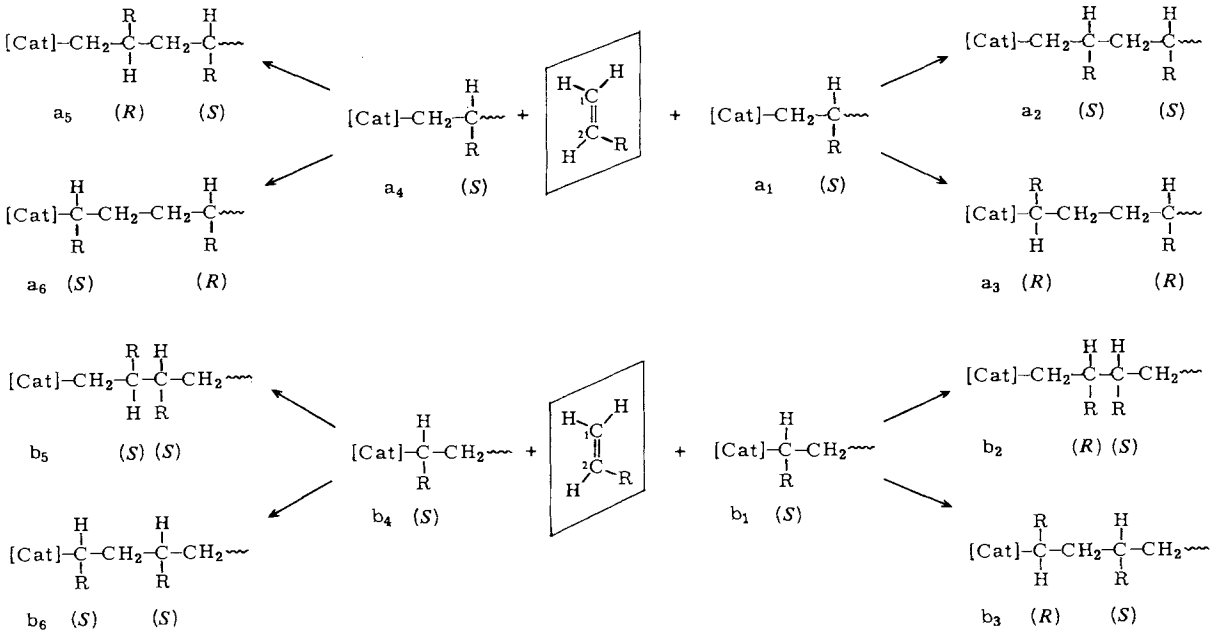
4.5. Model Reactions

Investigation of model reactions of the two steps (π-olefin complex formation and insertion of a double bond into a metal-carbon bond) which are generally assumed to play a role in stereospecific polymerization has certainly contributed very significantly to our present understanding of the mechanism of stereospecific polymerization.

The vast amount of literature in this field includes the oligomerization of ethylene and α-olefins with organometallic derivatives of transition metals[104], syntheses and equilibria between diastereomeric olefin complexes in which the olefin is a monosubstituted ethylene[105,106], and rotameric equilibria in the same complexes connected with the rotation of the olefin around the metal olefin bonds[107]. Finally simple additions of organometallic compounds to the double bonds[108-110] are of interest as model reactions. Some of these model reactions will be considered in the following sections of this review.

4.6. Structure and Stereochemistry of the Synthesized Polymers

This line of research has afforded, in our opinion, the most valuable information, not only on the polymerization mechanism, but also on the origin of the stereospecificity of the process and on the structure of the catalytic centers. It includes the determination of the nature of the terminal groups of the polymer chains, research on the stereochemistry of the insertion reaction, and, finally, spectroscopic investigations of structural and steric irregularities in the polypropylene main chain in low molecular weight models and in polymers and copolymers of racemic α-olefins. These aspects will be the main topic discussed in the following sections.



5. Research on the Mechanism of Stereospecific Polymerization Based on the Investigation of Structure and Stereochemistry of the Polymer Chains

5.1. Geometric Aspects of the Polymerization of α-Olefins

When ethylene dimerizes or polymerizes by an insertion reaction between a metal atom and the growing chain (*e.g.* as in the "Aufbaureaktion" discovered by *Ziegler*[10]), since ethylene is an olefin having D_{2h} symmetry, only one product can form in each step regardless of whether the stereochemistry is of the *cis* or *trans* type. The situation is completely different when an olefin having C_s symmetry undergoes the same reaction (Scheme 5). *Ziegler* had observed that in the dimerization of propylene the reaction is not completely regiospecific[112]; in fact, in the reaction of propylene with tri-*n*-propylaluminum, a small percentage of *n*-hexenes forms and therefore, small amounts of secondary alkylaluminum compounds must also be present in the reaction mixture in addition to primary alkylaluminum compounds. As practically no higher oligomers were formed, *Ziegler* did not consider the stereochemistry of the addition of the Al—R bond to an α-olefin, or the formation of corresponding diastereoisomers. Scheme 5 shows only the *cis* stereochemistry for the insertion reaction, which is the most probable in the addition of a M⇒C bond to a C=C double bond[113]; of course, a similar scheme could be conceived for an addition occurring with *trans* stereochemistry. Depending on the existence of a primary (a_1, a_4) or of a secondary group (b_1, b_4) bound to the metal (M) at the beginning of the step considered, a_2 and a_5 or b_2 and b_5 are formed by an insertion in which position 1 of propylene is linked to the metal atom of the catalyst and position 2 is linked to the growing chain end ("1—2" addition). a_3 and a_6 or b_3 and b_6 are formed by an insertion in which position 2 of propylene is connected with the metal atom of the catalyst ("2-1" addition). It is clear that a head-to-tail enchainment can be obtained by "1-2" addition to a primary metal alkyl (a_2 and a_5) or by a "2-1" addition to a secondary alkyl (b_3 and b_6). The type of enchainment is therefore regulated by the regioselectivity of the insertion reaction and the regularity of enchainment depends on regioselectivity at the two prochiral faces of the α-olefin, *i.e.* on the differences in energy between the activated complexes leading to a_2 or a_3, a_5 or a_6, b_3 or b_2, and b_6 or b_5.

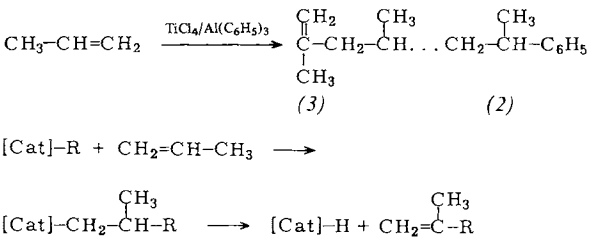
The absolute configuration of the new asymmetric carbon atom which forms in each step depends both on the prochiral face of the α-olefin which reacts and on the regioselectivity of the addition ("1-2" or "2-1" type). For instance, if the asymmetric carbon atom next to the metal atom has an (*S*) configuration (a_1 or a_4), the new asymmetric carbon atom can have different absolute configurations, depending on the face attacked (compare a_2 with a_5 or a_3 with a_6) or, if the products arising from the same prochiral face are considered, on the type of addition (compare a_2 with a_3 or a_5 with a_6). Complete stereospecificity is achieved, *e.g.* when the same prochiral face of the olefin is always attacked and when the type of insertion ("1-2" or "2-1") is always the same. The same configuration of the asymmetric carbon atom formed during the insertion can also be achieved when a change in the face of the olefin reaction is accompanied by a change in the type of addition (compare a_2 and a_6 or a_5 and a_3).

In discussing the stereospecific polymerization of vinyl monomers, both regioselectivity and steric order must be kept in mind; possible relationships between the two phenomena have not been completely elucidated as yet; however, it is known that in other asymmetric reactions involving prochiral olefins, the same reaction on the two faces of the olefin can occur with different regioselectivity[114].

Scheme 5. Geometric aspects of the "Aufbaureaktion" of poly-α-olefins assuming a *cis* addition of the metal containing moiety ([Cat]) and of the growing chain end to the double bond. R = CH_3; $(CH_2)_x$—CH_3. The rules proposed by the IUPAC Commission on Macromolecular Nomenclature [111] are used in the formulas.

5.2. Early Research on the Stereospecific Polymerization of Propylene Yielding Isotactic and Syndiotactic Polymers

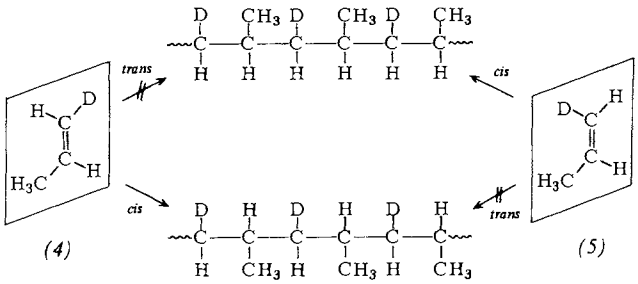
5.2.1. Isotactic Polypropylene



Although at the time of the discovery of the stereospecific polymerization the main aspects of the "Aufbaureaktion" in the presence of the alkyl derivatives of the metals of the three first groups of the Periodic Table were well understood, thanks to the research of *Ziegler* and of his co-workers, it was not obvious that the same mechanism should occur in the rapid polymerization of ethylene to very high polymers and particularly in the formation of stereoregular polymers of α-olefins in the presence of transition metals; in fact different hypotheses appeared in the literature in the fifties[115-120].

For the α-olefins the combination of X-ray and IR analyses showed very early that the polymers obtained with the Ziegler catalytic systems were substantially linear polymers with head-to-tail enchainments (absence of the IR band at 752 cm^{-1} corresponding to groups of type *(1)*). The regioselectivity was slightly lower for the amorphous than for the crystalline polymers.

(1) *(2)* *(3)*



That the polymers form through an insertion reaction of the monomer into a metal to carbon bond was shown very early[121] by an IR investigation of the end groups of the polymer chains. In fact, with catalysts prepared from $TiCl_4$ and $Al(C_6H_5)_3$, end groups of types *(2)*[*] and *(3)* were found (Scheme 6). These results showed that α-olefin polymerization occurs through an insertion reaction similar to the one observed in the "Aufbaureaktion" with alkylaluminum compounds and that the insertion is practically of the 1-2 type, regioselectivity being very high, probably greater than 95% in the synthesis of both isotactic and atactic macromolecules.

Scheme 6. Top: formation of end groups of types *(2)* and *(3)*; bottom: polymerization by insertion and chain termination by hydride transfer.

Concerning the stereochemistry of the addition, it was realized that, given the high regioselectivity, the type of addition in the synthesis of the isotactic chains must always be the same, but it was only when diisotactic[**] polymers of deuterated propylene were synthesized[123] and their IR[124] and NMR[125] spectra interpreted that the knowledge of the stereochemistry reached its present state.

If we assume that the metal atom of the catalyst bearing the growing chain and the growing chain end add synchronously to the double bond of the incoming monomer, and if we consider that an *erythro*-diisotactic deuterated polypropylene is obtained from *cis*-1-deuterio propylene *(5)*, and correspondingly a *threo*-diisotactic polymer from the *trans* isomer *(4)*, the insertion reaction must occur through *cis* addition to the double bond (Scheme 7). Further confirmation of the above type of stereochemistry can be found in the structure of the *cis*-2-butene/ethylene copolymer[126,127] and from the NMR spectra of deuterated polypropylenes[135].

Scheme 7. Stereochemistry of addition to the double bond of the deuterated monomers *(4)* and *(5)*.

5.2.2. Syndiotactic Polypropylene

Hydrocarbon polymers having a substantial content of syndiotactic structure have been obtained up to now only in the case of propylene[131] and in the "1-2" polymerization of butadiene[177]. Only some of the aspects of the synthesis of syndiotactic polypropylene will be briefly discussed here.

Syndiotactic polypropylene was isolated for the first time by elution chromatography using highly isotactic polypropylene as the support, from ether-insoluble, heptane-soluble fractions of the polymers obtained with $TiCl_4/LiC_4H_9$ catalytic systems[131]. Fractions containing large amounts of syndiotactic structures in the chain were obtained later with $TiCl_4$/Na-alkyl catalytic systems[132]; however, the best results were obtained with soluble catalytic systems of the type VCl_4/AlR_2Cl/anisole[133].

By analogy with the polymerization of propylene to isotactic polymers and on the basis of the presence in the polymers of the alkyl groups initially bound to aluminum, a "1-2" type insertion mechanism was first postulated also in this case[132]. Only at the end of the sixties did NMR experimental evidence appear that showed that the stereochemistry of the addition reaction is of *cis* type, as in the case of the synthesis of isotactic polymers[125].

At the same time, data began to appear in the literature[130] indicating that with catalytic systems of the type $VCl_4/Al(C_2H_5)_2Cl$ the propylene insertion could be of the "2-1" type. Further indications in this direction came from the IR investigation of the ethylene propylene copolymers obtained with $VCl_4/Al(C_2H_5)_2Cl$ catalytic systems[137]. Finally, the existence of the "2-1" insertion mechanism for the polymerization of propylene to syndiotactic polymers with soluble

[*] Surprisingly, this fact has been overlooked by some authors [122] who postulate a hydride transfer from the tertiary carbon atom of the last monomeric unit of the growing chain to the metal atom as an important step in stereospecific polymerization.

[**] Diisotactic polypropylenes differ from isotactic ones by the existence of two asymmetric carbon atoms in the monomeric unit[123].

$VCl_4/Al(C_2H_5)_2Cl$ catalysts was definitely proven by end group determination. As a matter of fact, by cleaving the polymerization mixture with tritiated strong acids[136] it was shown that organometallic bonds do indeed exist at the end of the chains in the low temperature polymerization of propylene with $VCl_4/Al(C_2H_5)_2Cl$ catalytic systems both in the presence and in the absence of Lewis bases. However, the end groups thus formed, were not isopropyl groups, as in the case of isotactic polypropylene, but *n*-propyl groups, thus confirming the prevalence[138] of a "2-1" addition type in the synthesis of syndiotactic polypropylene at least with the catalytic system used.

The nature of the end groups corresponding to the first monomer insertion and the M—C bond in the synthesis of syndiotactic polypropylene[130] still needs to be confirmed.

At the present it is not clear if syndiotactic sequences can be formed only through a "2-1" type addition or if this is the preferred type of addition exhibited with soluble vanadium containing catalysts, but not necessarily with the heterogeneous titanium catalysts previously described[131,132]. In fact, the type of insertion is probably dependent, not only on the structure of the alkyl group bound to the metal, but also on the type of metal bound to the alkyl group. For example, in the case of addition of propylene to alkyllithium compounds, the presence of an isopropyl group bound to the metal was first believed[109] to induce a "2-1" type of addition. However, a more accurate investigation of this reaction showed[110] that also in this case the main reaction product arises from a "1-2" type of addition.

The existence of a connection between "2-1" type of addition and formation of long syndiotactic sequences would explain the known fact that while isolated syndiotactic dyads form with all the linear α-olefins with a "1-2" type of addition long syndiotactic sequences form only in the case of propylene. As a matter of fact, a low steric hindrance would be required for an addition of "2-1" type which should make possible the formation of long syndiotactic sequences[154].

5.3. Present Views on Regioselectivity in the Polymerization of α-Olefins

The early observation by *Natta et al.* of the predominance of a "1-2" type of addition in the polymerization of α-olefins significantly influenced polymer chemists' views on this problem for about 15 years and the findings on propylene polymerization with catalysts prepared from $TiCl_4$ or $TiCl_3/AlR_3$ were unduly generalized to the broad field of stereospecific polymerization. However, some clues indicating the incomplete regioselectivity of the "Aufbaureaktion" and related reactions started to appear in the literature as early as the fifties. *Ziegler* showed in 1952[112] that propylene dimerization with alkylaluminum compounds was not completely regioselective, and in 1959 it was demonstrated that in the reaction between $Al(iC_4H_9)_3$ and styrene in the presence of $Ni(acac)_2$, 30% of the products arise from the "2-1" addition of styrene to the $(iC_4H_9)_2Al—H$, which is the probable intermediate[134]. Furthermore, it was clear from the research of *Wilke* and co-workers on the propylene dimerization with organometallic nickel catalysts[128] and, later, from that of *Henrici-Olivé* and *Olivé*[129] on the dimerization of propylene in the presence of palladium catalysts, that propylene dimerization with transition metals can be far less regioselective than the "Aufbaureaktion" in the presence of main group elements.

An important contribution to the investigation of the regioselectivity in stereospecific polymerization was carried out by *Suzuki et al.*[130] who, on the basis of stoichiometric reactions between 1-pentene and different types of Ziegler catalysts, proposed that the insertion of 1-pentene into M—C bonds is mainly of the "1-2" type with typical $TiCl_3/AlR_3$ catalysts but mainly of "2-1" type with catalytic systems of the type $VCl_4/Al(C_2H_5)_2Cl$ which, with propylene, yield mainly syndiotactic polymers.

Zambelli's NMR-spectroscopic investigations on the regioselectivity of polypropylenes obtained with different catalytic systems[139–140] have shown that regioselectivity is lower with catalytic systems prepared from VCl_4 and $Al(C_2H_5)_2Cl$ than with $TiCl_3/Al(C_2H_5)_2Cl$ catalysts and decreases with increasing temperature[139] (Table 3).

Table 3. Regioselectivity of various catalytic systems in propylene polymerization [139, 148].

Catalyst	*T* [°C]	Fraction [a]	(CH_2CH_2)-sequences [g/100 g polymer]
$\delta TiCl_3/Al(C_2H_5)_2Cl$	15	A	[b]
		B	1.5
		C	—
$\beta TiCl_3/Al(C_2H_5)_2Cl$	15	A	2.5
		B	1
		C	—
$VCl_3/Al(C_2H_5)_2Cl$	15	A	1.5
		B	1.0
		C	—
$VCl_4/Al(C_2H_5)_2Cl$	−78	—	2.1
	−58	—	2.4
	−38	—	3.5
	−18.5	—	2.8
$VCl_4/Al(C_2H_5)_2Cl$/anisole	−38	—	3.3
	−18.5	—	4.4

[a] A, boiling pentane-insoluble, boiling hexane-soluble fraction; B, boiling hexane-insoluble, boiling heptane-soluble fraction; C, boiling heptane insoluble fraction. [b] Not determined.

The regioselectivity of the heterogeneous catalytic systems seems, however, to differ considerably, depending on the actual structure of the individual catalytic centers. Recent experiments[149] have shown that in fact the highly isotactic polypropylenes obtained with conventional $TiCl_3/AlR_3$ catalysts at 200—220 °C do not show detectable amounts of head-to-head sequences in their chains. Only when the polymerization temperature reaches 240 °C do the head-to-head sequences in the isotactic heptane insoluble fractions reach a concentration detectable by ^{13}C-NMR.

From the ^{13}C-NMR spectra of the polypropylenes prepared by *Sinn* and *Kaminsky*[142] it appears that a high regioselectivity (>90%)[143] exists also with soluble catalytic systems. The type of insertion does not seem to have been investigated in this case; however, a "1-2" type of addition seems very probable in view of the completely atactic structure of the polymers (Fig. 2B).

The origin of regioselectivity in Ziegler-Natta catalysis has never been discussed in detail. As previously proposed for other reactions catalyzed by transition metals[140], it might be

connected with the position of conformational equilibria in π-olefin complexes, which have been postulated as the first intermediates in the coordination polymerization, and with the different activation energies for the insertion reaction in which the different rotamers of the π-complexes react further in the polymerization process.

In conclusion, it appears that, depending on the type of catalyst used, regioselectivity in the polymerization of α-olefins can vary between 95—99% of "1-2" type and over 85% of "2-1" type. Unfortunately, because of the lack of sufficient knowledge of the factors influencing regioselectivity both with heterogeneous and homogeneous catalysts we are still far from reaching a control of regioselectivity that would allow us to synthesize polymers with a predetermined molar fraction of head-to-head or head-to-tail sequences in the main chain.

5.4. Present Views on Stereospecificity in the Polymerization of α-Olefins

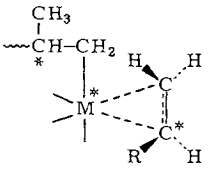
Even 25 years after its discovery, polymerization of propylene to give isotactic polymers remains a unique example of stereospecificity in organic nonenzymatic reactions. In fact, as in some enzymatic reactions, the highest limit of stereospecificity which can be achieved, as shown by the stereoregularity of the polypropylene fractions insoluble in *n*-decane, is still unknown because of lack of sufficiently accurate experimental methods to measure it. The maximum stereospecificity achievable by polymerization of propylene to syndiotactic polymers has not been thoroughly investigated, but in any case it is smaller than that obtained in the synthesis of isotactic polypropylene and, in general, does not reach 95%.

Stereoregulation in stereospecific polymerization of α-olefins can arise from the interaction between entering monomer and growing chain, as in free radical polymerization, or from the interaction between monomer and metal atom (including its environment) or, finally, from both factors.

According to the present views, the origin of stereoregularity appears to be different for isotactic and for syndiotactic polymers; hence the two cases will be discussed separately.

5.4.1. Origin of Stereospecificity in the Synthesis of Isotactic Polymers

Taking into account the practically complete regioselectivity, which is revealed by the nondetectability of head-to-head/tail-to-tail enchainments, and the *cis*-stereochemistry of the reaction, the stereospecificity in the polymerization of α-olefins to isotactic polymers must be connected to the ability of the catalyst-growing polymer chain system, which we shall refer to as the "catalytic center", to discriminate sharply between the two prochiral faces of the α-olefin. To do this, the catalytic system must possess one or more chirality centers.



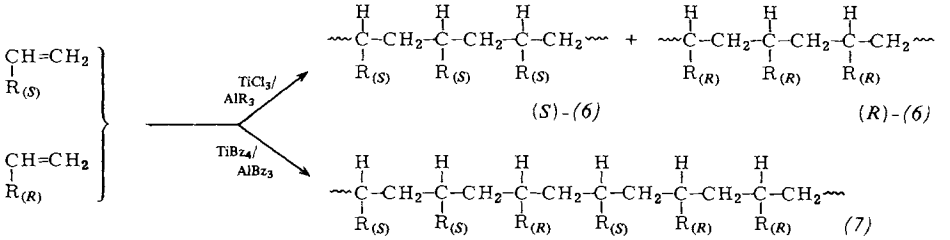


Fig. 3. Schematic representation of monometallic catalytic centers for isotactic polymerization. An asterisk indicates a chirality center.

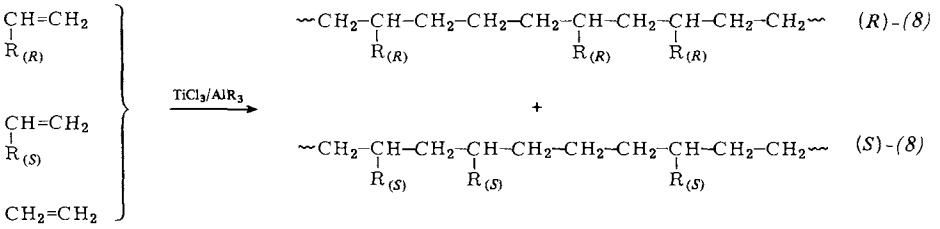
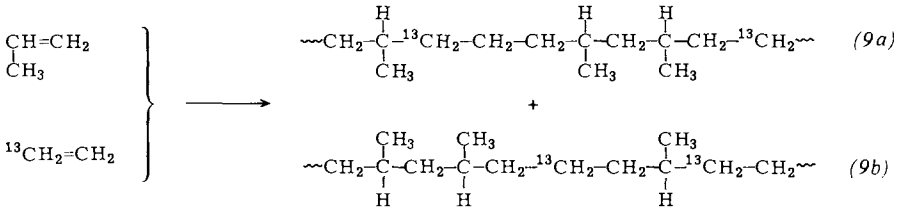
Considering the simplest model of a monometallic catalytic center (Fig. 3), a chiral carbon atom certainly exists in the growing chain in β-position with respect to the metal atom; furthermore, the metal atom itself can be a chirality center[141] which, being bound to a solid surface, could maintain its absolute configuration during the insertion reaction.

The following facts indicate that the metal atom in the catalytic center is indeed chiral[*] and that chirality at the metal atom is the main stereoregulating factor in the polymerization of olefins to isotactic polymers.

Stereospecific catalytic centers are able to distinguish between the two antipodes of a racemic monomer, as shown by the existence of stereoselectivity in racemic α-olefin polymerization[168]. Homogeneous Ziegler type catalysts, as *e.g.* $Ti(CH_2C_6H_5)_4/Al(CH_2C_6H_5)_3$, do not show this property[144] and copolymers of (*R*) and (*S*) monomer *(7)* are formed which cannot be resolved by elution chromatography on an optically active support.

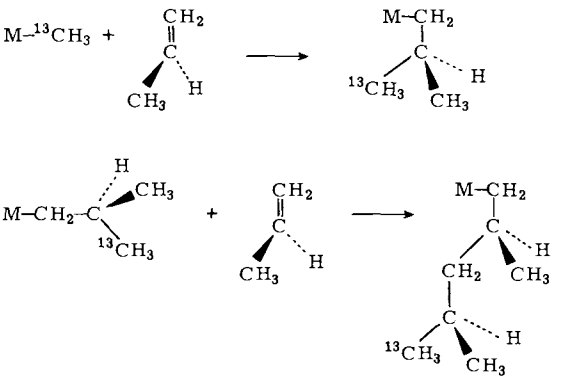


The copolymerization of racemic α-olefins with ethylene[145] is also stereoselective, *i.e.* it gives the copolymers (*R*)-*(8)* and (*S*)-*(8)* although the asymmetric carbon atom in the growing chain is at least δ-position with respect to the metal atom of the catalytic center.

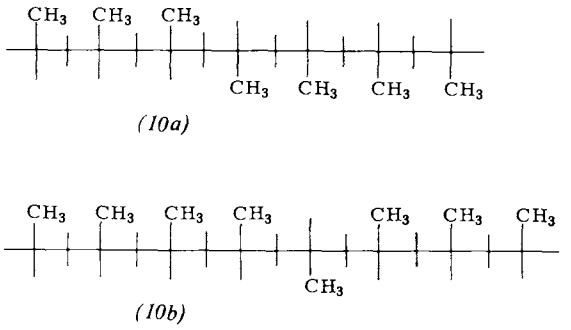


The copolymerization of a large excess of propylene with $^{13}CH_2{=}CH_2$ yields copolymers *(9a)* and *(9b)*, the ^{13}C-NMR spectrum of which shows only two bands attributable to isolated ethylene units. This fact indicates that the tertiary carbon atoms of the two propylene units separated by one ethylene unit arise from the addition of growing chain end and metal atom of the catalyst to the same prochiral face of the olefin[146].

When propylene polymerization is initiated with catalysts prepared from $TiCl_3$ and $Al(^{13}CH_3)_3$, the ^{13}C-enriched methyl group is present in the 2,4-dimethylpentyl terminal



[*] Of course a chiral catalyst does not need to be optically active and, in the usual catalysts, it is believed to be racemic.



groups, as shown by ^{13}C-NMR and the stereochemistry of the end groups[*] indicates that the attack of the alkyl group and of the metal atom of the catalyst occurs at the same type of prochiral face of both the first and the second inserted propylene molecule[147].

In isotactic polypropylene chains, a low concentration (*ca.* 4%) of mmmr, mmrr, and mrrm pentads are found, but practically no pentads of the type mrmm have been detected (see Table 4)[148]. If the main stereoregulating factor were the last asymmetric carbon atom of the growing chain, an occasional steric error would be perpetuated, giving rise to sequences of the type *(10a)* and hence to a prevalence of mrmm pentads.

On the contrary, if the chirality at the metal atom is the main stereoregulating factor, an occasional steric error not involving a change of configuration at the metal atom would remain isolated, giving rise to pentads of the type mrrm, *(10b)* which have indeed been found. The degree of isotacticity and the type of steric errors of heptane-insoluble polymers obtained by different catalytic systems are reported in Table 4.

(10a)

(10b)

[*] The tertiary carbon atom of the isopropyl group is to be regarded as asymmetric since it is bound to a $^{12}CH_3$ and a $^{13}CH_3$ group.

Although the main stereoregulating factor has been identified from the experiments described above, the way in which this factor operates is still not well understood, mainly because of a lack of knowledge of the reaction step or steps corresponding to the insertion reaction. It is clear that the energy difference between the transition states leading to an isotactic dyad (m) or to a syndiotactic dyad (r) is, for some catalytic centers, at least 3 kcal/mol. Some polymerization experiments carried out at 240 °C in the presence of $TiCl_3$/AlR_3 catalytic systems and still yielding highly isotactic polymers (mmmm pentads content >97%) show, however, that for some catalytic centers the above difference reaches at least 4.3 kcal/mol[149]. This energy difference is mainly attributed to steric factors, the details of which are still far from being understood.

Table 4. NMR investigation of the boiling heptane-insoluble fraction of polypropylene [148] (prepared with various catalysts) (polymerization temperature 15 °C); m = *meso* (isotactic) dyads; r = racemic (syndiotactic dyads).

Catalyst	Hept.-insol. fraction [%]	Amount of pentad sequences [%] mmmm	mrmm	mrrm
$\delta TiCl_3/Al(C_2H_5)_2Cl$	88.5	≥85	—	≤2
$\beta TiCl_3/Al(C_2H_5)_2Cl$	47.5	≈90	—	≈2
$VCl_3/Al(C_2H_5)_2Cl$	57.5	74	6 [a]	≈3
$CrCl_3/Al(C_2H_5)_2Cl$	98.5	≈90	—	≈2
$ZrCl_4/Al(C_2H_5)_3$	22.5	≈90	—	≈2

[a] mmrm + rrmr.

This information about the mechanism of stereoregulation would be extremely valuable not only for the synthesis of catalytic centers having similar structures and activities, and of polymers with predetermined stereoregularity, but also, more generally, for a better understanding of asymmetric catalysis. In fact, the existence of chiral racemic catalysts having a high stereospecificity, which is evidenced by stereospecific polymerization, could open the way to the preparation of very efficient heterogeneous optically active catalysts for different asymmetric syntheses.

5.4.2. Origin of Stereospecificity in the Synthesis of Syndiotactic Polypropylene

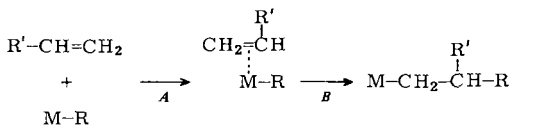
The problem of stereospecificity in the synthesis of syndiotactic polymers has been little investigated up to now. As already mentioned, according to *Suzuki et al.*[130], a "2-1" type of insertion into a primary metal-alkyl bond like M—C_2H_5 or M—CH_3 should predominate with soluble catalysts, producing prevailingly syndiotactic polypropylene. According to *Zambelli*, on the basis of ^{13}C-NMR spectra, the first insertion of propylene on a primary metal carbon bond with $VCl_4/Al(CH_3)_2Cl$/anisole catalytic systems should be of the "1-2" type and it should be followed by a "2-1" type of insertion[138].

It now seems that the experimental facts can be understood by assuming that the stereospecificity in the synthesis of syndiotactic polypropylene originates from the presence of an asymmetric carbon atom of a secondary alkyl group directly bound to a metal[150]. Configurationally stable secondary alkyl-metal compounds are known in the case of mercury[151], iron[152], and rhodium[153] derivatives, and the stability of the M—C bond of VCl_4/AlR_2Cl catalysts in the syndiotactic polymerization which is not cleaved by methanol[136], supports the view that configurationally stable vanadium alkyls are present as catalysts.

A detailed model explaining how steric interactions in this type of *sec*-alkyl-vanadium compounds and in the corresponding postulated π complexes can effect steric control in syndiotactic polypropylene synthesis has recently been proposed[154]. This model also explains why homopolymerization of higher olefins to syndiotactic polymers does not occur with the same catalytic systems. Further research is needed to understand steric control of the syndiotactic type of polymerization in other catalytic systems, particularly in the heterogeneous ones.

Like the regiospecificity, the stereospecificity is also not very high in the synthesis of syndiotactic polypropylene, the difference between the energies of the activated complexes yielding isotactic or syndiotactic dyads being at most 2 kcal/mol[155].

6. Some Remarks on the Mechanism of Stereospecific Polymerization



A thorough understanding of the origin of regioselectivity and stereospecificity in the polymerization of α-olefins would be necessary in order to rationally plan experiments to control the degree of stereoregularity, the average molecular weight, and the molecular weight distribution in the polymerization of α-olefins. To reach this understanding a more detailed knowledge of the reaction mechanism is required. Unfortunately, as in most catalytic processes, intermediates are very reactive and can only seldom be isolated. Most of our present knowledge is therefore based on indirect evidence and on investigations of model reactions. Regrettably, the scant experimental evidence is very often integrated into a large body of speculations and undue generalizations which further confuse the mechanistic picture.

We are not going to discuss in detail the mechanisms proposed up to now for the stereospecific polymerization, but we shall only present some facts mainly arising from the investigation of soluble catalysts and of model reactions and some speculations about the structure of the catalytic centers.

6.1. Experimental Evidence on the Mechanism of Propylene Polymerization with Ziegler Catalysts

Additions of organometallic compounds to olefins, which are the simplest models for the polymerization of α-olefins, are well described in the literature. They involve, in general, organometallic compounds of the metals of the first three groups of the Periodic System. In all these cases a planar four-center intermediate, as postulated for the addition of lithium alkyls to olefins[11], seems probable; however, a nonplanar intermediate complex has recently also been proposed[156]. An interaction between α-olefin and alkylmetal compound preceding the formation of the cyclic transition state and activating the olefinic double bond is conceivable, but has never been experimentally proved in the polymerization of α-olefins. Only in the case of alkylaluminum compounds has an interaction between a double bond present in one of the organic substituents and an aluminum atom been proven by IR spectroscopy[158].

To explain the much higher activity of Ziegler catalytic systems containing transition metal atoms, the possible activation of the olefinic double bond by chemiadsorption on the surface of a transition metal salt was already postulated by *Natta* in 1956[160]. Subsequently *Natta*[161], as well as *Ludlum et al.*[159] and *Carrick et al.*[157], proposed that the polymerization takes place through a coordination of the monomer to the catalyst followed by an insertion of the coordinated monomer into a metal to carbon bond (Scheme 8). *Cossee* then[93] proposed that the olefin forms a π-complex with a transition metal and is then inserted into one of its bonds with an alkyl group[93].

Scheme 8. Postulated two-step polymerization *A*, complexation; B, insertion.

Among the questions posed by experimental studies on the mechanism the following will be briefly discussed:

a) The type of metal atom on which the polymer chain is growing.
b) Formation of an olefin-catalyst complex.
c) Relative values of the activation energy for formation of the olefin-catalyst complex and for the actual insertion reaction.

a) In the original Ziegler catalytic systems, both transition metal atoms (*e.g.* Ti) and main group metal atoms (*e.g.* aluminum) were present. Therefore, the polymer chain can, in principle, grow either on the transition metal atom or on the main group metal atom. It was already shown in 1958[39,40]

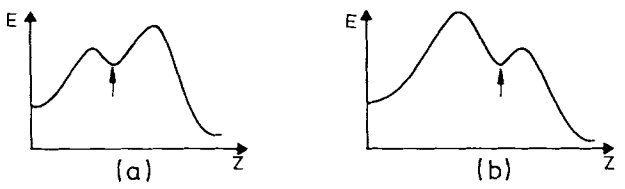
that catalysts containing only titanium as metal component could polymerize both ethylene and propylene. This does not necessarily demonstrate that when, *e.g.*, titanium and aluminum are present in the catalyst, the chain still grows on titanium. It must be emphasized that simple titanium compounds like $Cl_3Ti—CH_3$ are not active in the stereospecific polymerization of propylene if $TiCl_3$ is not present, and that the classical Ziegler catalysts prepared from $TiCl_4$ and AlR_3 are much more active than the catalysts containing only titanium as the metal component. This problem has recently been solved, at least for the polymerization of ethylene with a soluble catalyst prepared from Cp_2TiCl_2 and $Al(C_2H_5)Cl_2$. In fact, using ^{13}C-enriched ethylene it was shown[71] that a complex containing titanium and aluminum is present and that the polymer chain grows by insertion of ethylene molecules into a Ti—C bond and not into an Al—C bond. From this and other experiments it now appears very likely that the polymer chain grows on the transition metal present in the catalyst; however, the question remains open if the olefin to be inserted is complexed to the same metal atom on which the chain grows.

b) Experimental evidence on the existence of a catalyst-olefin complex is very poor. No complex of this type has been isolated; among the indirect evidence appearing in the literature, we shall mention only the fact that in the stereospecific polymerization of substituted styrenes which is supposed to occur according to an anionic mechanism, a rate increase is found when electron donating substituents are present in a *para* position, contrary to what is known for anionic polymerization[163]. This fact indicates that the rate depends on the formation of a transition metal-monomer complex which is favored by electron donating substituents.

As a direct evidence for olefin π complex formation, *Ballard*[162] found an equilibrium constant of 0.01 for the equilibrium between the soluble catalytic complex *(11)* + ethylene shown below, however, for other systems, and particularly for heterogeneous catalysts, the situation could be very different.

$$Zr[CH_2—Si(CH_3)_3]_4 + C_2H_4 \rightleftharpoons [\text{Catalyst-Olefin complex}]$$
(11)

In the case of ethylene polymerization with the catalytic system $Cp_2TiCl_2/Al(C_2H_5)Cl_2$, *Fink*[71] was not able to detect by spectroscopic methods the formation of a π-complex, the concentration of which is therefore in this case lower than 1%.



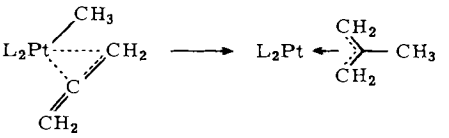


Fig. 4. Possible reaction paths for ethylene polymerization. a), b) see text. Arrow indicates catalyst-olefin complex.

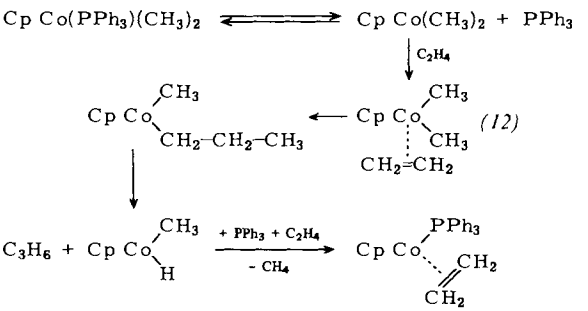
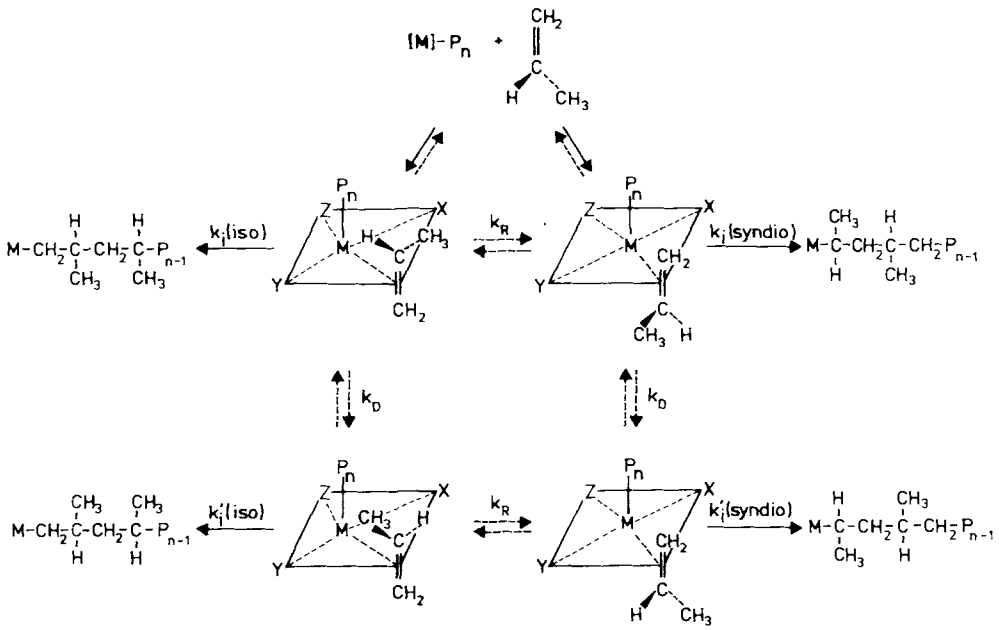


The failure to isolate an olefin catalyst complex, if it really is formed, can be explained in two ways (Fig. 4); either a rapidly established equilibrium exists between olefin-catalyst complex and free olefin and catalyst which, however, is largely displaced towards the dissociated species (Fig. 4a), or the activation energy for the insertion reaction of the π-complex is so low that the olefin-catalyst complex disappears at a rate which is very high, the steady state concentration of the olefin-catalyst complex being therefore very low (Fig. 4b).

c) To distinguish between the two possibilities of Figure 4, a knowledge of the relative activation energies for the catalyst-olefin complex formation and for the insertion of the complexed olefin is necessary. Unfortunately, very little is known about the insertion of a complexed olefin into a metal-to-carbon bond. The existence of a relatively high activation energy for an insertion reaction of a double bond into a metal-to-carbon bond was observed in the intramolecular reaction of a π-complexed allene molecule with a $Pt—CH_3$ bond (Scheme 9)[164]. However, since in the starting complex, the methyl group and the allene molecule are bound to the platinum atom in the *trans* position, it is not clear if the high activation energy is really required for the insertion reaction or if it is necessary to bring the two reacting moieties into the *cis* position.

Scheme 9. Insertion of a π-complexed allene into a $Pt—CH_3$ bond [164].

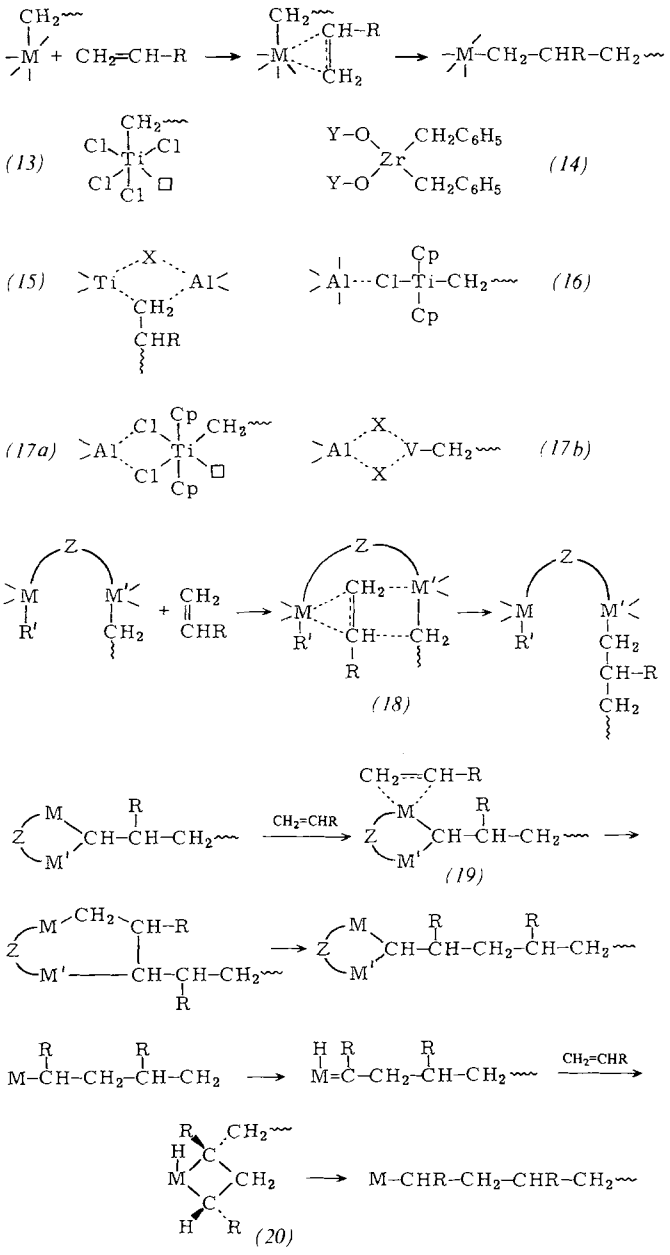


No insertion of a π-complexed ethylene into a $Co—CH_3$ bond was observed in the $[(CH_3)_3P]CoCH_3(C_2H_4)$[165]. However, such insertion into a $Co—CH_3$ bond was observed for the related complex *(12)* at 76 °C (Scheme 10)[166].

Scheme 10. Insertion of a π-complexed ethylene into the $Co—CH_3$ bond of complex *(12)* [166].

At present we can conclude that a two-step mechanism is very likely for the stereospecific polymerization even if not proven, and that a higher activation energy than that for the olefin-catalyst complex formation should be foreseen for the insertion reaction.

The working hypothesis we are using at the present is shown in Scheme 11; the double arrows correspond to reversible reactions, but not necessarily to rapidly achievable equilibria. According to this scheme, the position of diastereomeric and rotameric equilibria in the π-complexes and/or activation energy for the insertion reaction of the π-complexed olefin could cause the large regioselectivity and enantioface discrimination necessary for the synthesis of stereoregular poly-α-olefins.



Scheme 11. Possible diastereomeric π-complexes and insertion reactions leading to isotactic or syndiotactic polypropylene; P_n = polymer chain, [M] = metal atom with ligands X and Y.

6.2. Speculations about the Structure of the Catalytic Centers and the Mechanism of their Catalytic Action

A great number of structures have been proposed for the catalytic centers[169,170]. The models are related to the different polymerization mechanisms proposed, which can be classified as shown in the Table 5 and Scheme 12. Monometallic centers such as *(13)* and *(14)* have been largely accepted, although compounds like $Cl_3Ti{-}CH_3$[39] and $Cp_2Ti(C_6H_5)_2$[40] are not catalytically active. Dimetallic models in which the growing polymer chain is linked to both metal atoms as in *(15)* were criticized by *Ziegler*[180] because in the "Aufbau-reaction" the monomeric trialkylaluminum that has no bridging alkyl groups is catalytically active, while the dimeric triethylaluminum bearing two such bridging alkyl groups is not catalytically active. Dimetallic centers of type *(17)* having two halogen bridges have been criticized since the titanium atom is not octahedrally coordinated in the soluble catalytic species obtained from Cp_2TiCl_2 and $AlC_2H_5Cl_2$[7]. Model *(19)* and the corresponding mechanism can be discarded because in the copolymerization of $CH_2{=}CD{-}CD_3$ and $CD_2{=}CD{-}CD_3$ with $TiCl_3/AlR_3$ catalysts only CH_2 and CD_2 were found in the isotactic polymer instead of the predicted CHD groups[167]. Model *(20)* can be criticized on the grounds that the synthesis of isotactic polypropylene occurs according to a "1-2" and not according to a "2-1" insertion, and for other reasons[147].

No direct proof exists to confirm the above structures, some of which are based on a series of interesting speculations and indirect evidence. While these structures have the merit of stimulating further experiments to prove some of their features, uncritical acceptance of one of them can hinder further progress in the field. Some of these structures might not be very far from the actual structure of some soluble nonstereospecific catalytic species; however, it is probable that the actual structures of the catalytic centers of the

Scheme 12. Models for catalytic centers and some proposed mechanisms for the α-olefin polymerization; M = M′ or M ≠ M′ X = Hal, Y = Si or Al, Z = org. or inorg. bridging ligands (see Table 5).

Table 5. Proposed mechanism and corresponding models of catalytic centers for the growth of the polypropylene chain (see Scheme 12).

Type of insertion reaction	Models for catalytic centers

Growing chain end bound by a double bond to the metal atom (carbene complex); insertion reaction through a metallacyclobutane intermediate [122]	Monometallic center *(20)* [122]

heterogeneous catalysts are much more complex and involve a greater number of metal atoms and ligands.

7. Trends in Research on Propylene Polymerization

Even now, most of the research in the field of propylene polymerization is carried out in industrial laboratories and only a small part of the work is published.

One of the main aims of industrial research is to obtain high purity polymers with very high yields and catalyst's productivity from processes that use higher polymerization temperatures, to facilitate temperature control in the reactors, and, eventually, to utilize the enthalpy of polymerization. Further aims are to control the molecular weight distribution and the morphology of the polymers and to synthesize poly-α-olefins that have a predetermined degree of stereoregularity.

The achievement of the above aims is mainly dependent on a better knowledge of the structure of the catalytic centers and on improved methods for their synthesis.

Research in this field is still mainly empirical in character; however, from the thousands of experiments that have been reported mainly in the patent literature, two main lines of research seem to emerge:

a) It is possible to obtain more active and more stable catalytic centers when the transition metal is bound to one or more —OX groups, where X is an element of the II, III, or IV group of the Periodic System.
b) It is possible, using suitable Lewis bases, to modify the stereospecificity of the catalytic systems. However, with most of the Lewis bases used, an increase in stereospecificity is often accompanied by a decrease in catalytic activity, especially in the case of supported catalysts.

Point a) has been mainly investigated by *Ballard* and co-workers[156,162] and by a few other authors[172,173], but some of the interesting results obtained by *Sinn* and co-workers[142] in the field of ethylene and propylene homogeneous polymerization might be related to it. Excellent reviews in this field have recently been published by *Sinn* and *Kaminsky*[50], by *Zacharov* and *Yermakov*[76], by *Ballard*[171] by *Caunt*[69], and by *Yamamoto* and *Yamamoto*[174].

Point b) has been the subject of a great number of patents and papers since the early days of stereospecific polymerization. The use of bases has also found important industrial applications: fluoride ion is used as a Lewis base in the Eastman Kodak propylene polymerization process[29,31] and carboxylic esters are used as the third component to improve the stereospecificity in some processes using the classical $TiCl_3/Al(C_2H_5)_2Cl$ catalytic system[24,25,32,37].

The dramatic effect of Lewis bases in improving stereospecificity has led to the use of the highly active Lewis base modified $TiCl_4/MgCl_2/AlR_3$ catalyst for the industrial synthesis of isotactic polypropylene[37,38] (Table 2).

The two main lines of research on the Ziegler type polymerization catalyst discussed in the present section must not be conceived as being completely separated; on the contrary, by overcoming possible psychological barriers, a fruitful cross-fertilization can take place, which might yield, in the near future, further progress in the field of the catalysts for the stereospecific polymerization of propylene.

8. Recent Investigations on the Role of Lewis Bases in Catalytic Systems Supported on $MgCl_2$

Some progress in the understanding of the role of the Lewis bases in this type of catalyst and of the nature of the catalytic centers has been made recently by investigating the stereoelective polymerization of racemic 4-methyl-1-hexene with $MgCl_2/TiCl_4/Al(C_4H_9)_3$ and (−)-menthyl anisate as chiral Lewis base[175]. The polymer obtained was separated into an amorphous (ethyl acetate-soluble) fraction and a crystalline (methylcyclohexane-soluble) fraction by solvent extraction (Table 6). The two fractions had optical activities of opposite sign, and the optical purity of the amorphous polymer increased, while that of the crystalline polymer decreased upon increasing the conversion. As expected, the optical purity of both fractions increased upon increasing the ratio of Lewis base to AlR_3.

These results indicate that catalytic centers having different stereospecificities exist in the above catalytic systems. Being of chiral-racemic nature, the highly stereospecific centers have different tendencies to complex the optically active Lewis base used. The complexation of the base decreases the activity of the catalytic centers; the centers forming less stable complexes and having one prevailing chirality polymerize one of the monomer antipodes more rapidly than the other. As a result, the synthesized polymer is optically active (stereoelective polymerization[181]).

The centers having a low stereospecificity have a larger Lewis acidity and are not stereoelective; therefore, they produce a stereoirregular polymer having the type of chirality prevailing in the nonpolymerized monomer and therefore opposite to that of the stereoregular polymers.

As found experimentally, the optical purity of both the nonpolymerized monomer and of the amorphous polymer must increase with increasing conversion.

Table 6. Stereoelective polymerization of racemic 4-methyl-1-hexene with $MgCl_2/TiCl_4/Al(iC_4H_9)_3/H_3COC_6H_4COO$-Ment [a] at 20—25 °C.

[a] % Ti = 2.0; Al/Ti = 40; Ment = (1*R*,2*S*,5*R*)-2-Isopropyl-5-methylcyclohexyl. [b] *B*, acetone-insoluble, ethyl-acetate soluble polymer fraction; *E*, diisopropyl ether-insoluble, methylcyclohexane-soluble polymer fraction. [c] In methylcyclohexane. [d] Enantiomeric excess (optical purity) of a monomer giving rise to a polymer fraction having the same $[\alpha]_D^{25}$ and the same solubility (cf. *P. Pino et al.*, Polym. Lett. 5, 307 (1967).

This hypothesis was applied to propylene polymerization with similar catalytic systems and indeed it was found[176] that, on increasing the Lewis base/AlR_3 ratio from 0.01 to 0.3, a dramatic decrease of the heptane-soluble fraction takes place, while the amount of isotactic polymer produced per g of Ti per hour decreases only by about 25% (Fig. 5).

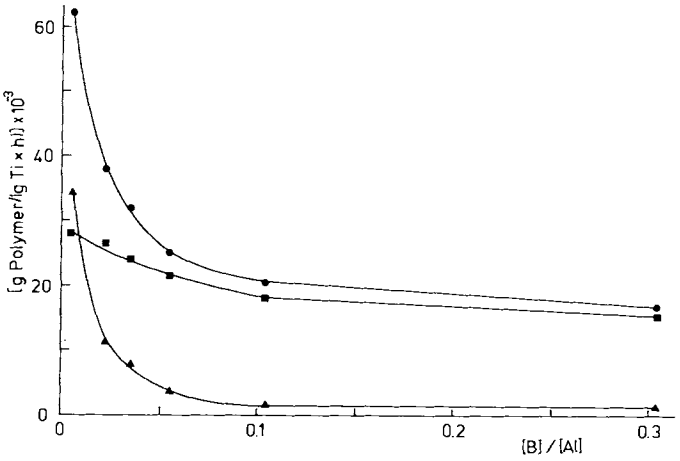

Fig. 5. Polymerization of propylene with the catalytic system $TiCl_4/MgCl_2/Al(iC_4H_9)_3$/ethyl benzoate. Catalyst's productivity at different ratios of [B]/[Al] [176]. [B] = molar concentration of ethyl benzoate; [Al] = molar concentration of triisobutylaluminum; ●, total polymer; ■, fraction insoluble in boiling heptane; ▲, fraction soluble in boiling heptane.

The ^{13}C-NMR spectra of the ether-soluble (Fig. 2A) and heptane-soluble fraction (Fig. 2B) obtained using different Lewis base/AlR_3 ratios shows that no fraction has a really atactic structure and that the ratio between the isotactic pentads (mmmm) and the syndiotactic pentads (rrrr) in the polymers significantly decreases when the Lewis base/AlR_3 ratio is increased (Fig. 6).

These results seem to indicate that even among the centers producing stereoirregular linear polypropylene, large differences exist in their Lewis acidity. The activity of the centers producing the (rrrr) pentads seems to be much less affected by the larger Lewis base/AlR_3 ratio, either because their Lewis acidity is smaller and they do not successfully compete with AlR_3 for the base present, or because they maintain their activity even after complexation with the base. We have already mentioned that some of the best catalysts for synthesizing syndiotactic polypropylene contain ethers[133].

These observations are in keeping with a competition between AlR_3 in solution and acidic centers on the solid surface for the complexation with the base, thus explaining why different Lewis base/AlR_3 ratios are necessary to obtain the same percentage of isotactic polymers, depending on the structure of the Lewis base and of AlR_3. These views are valid only for the catalytic systems mentioned above ($MgCl_2/TiCl_4/AlR_3$/Lewis base) and should not be extrapolated to similar catalytic systems without experimental confirmation. In fact, depending on the number of vacant sites in the catalytic centers, more than one base molecule per titanium atom might be necessary to stop the catalytic activity; in this case, centers containing only one molecule of base could still be catalytically active and could show a larger stereospecificity in the presence than in the absence of the Lewis base.

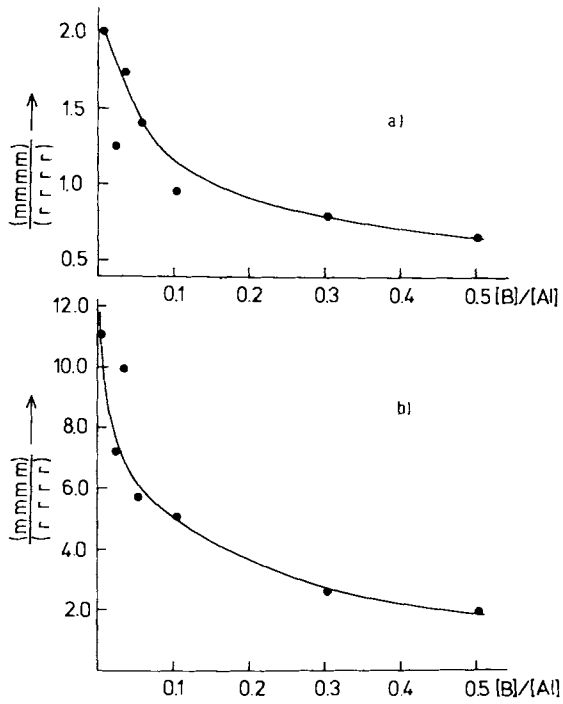

Fig. 6. Change in stereoregularity expressed as ratio of molar fractions of isotactic (mmmm) and syndiotactic (rrrr) pentads (a) in the ether-soluble and (b) in the heptane-soluble polypropylenes as a function of the ratio [B]/[Al] [176] (see legend of Fig. 5 for catalyst).

As shown by the above data, the $MgCl_2$-supported catalyst, despite the presence of the support which probably is far from being inert, yields interesting information on the nature of the catalytic centers, and Lewis bases can be used as probes to investigate their structure.

9. Final Remarks

The discovery of stereospecific polymerization of propylene has not only considerably stimulated the development

of polymer science, but also widely contributed to the development of various fields of chemistry.

In fact, due to the very early appreciation of the industrial relevance of propylene polymerization, numerous industrial laboratories have invested substantial efforts in the development of fundamental organometallic chemistry (in particular that of transition metals) and organometallic catalysis. Indeed, efforts to understand the mechanism of stereoregulation in stereospecific polymerization, although not comparable to the efforts devoted to the elucidation of enzymatic catalysis, have been much greater than those devoted to the understanding of other highly significant catalytic reactions, such as ammonia synthesis or the synthesis of hydrocarbons from carbon monoxide.

The knowledge of the existence of highly stereospecific catalysts for α-olefin polymerization could have stimulated the research on the possibility of application of similar catalytic systems to other organic syntheses. However, no significant progress has been reported in this field, with the exception of stereospecific dimerization and codimerization reactions. A possible reason for the delay of progress in this direction is the lack of sufficient knowledge of the factors on which stereospecificity is based.

Research on stereospecific polymerization has made a great contribution to our understanding of the relationships between homogeneous and heterogeneous catalysis; of interest for further progress in catalysis is also the idea of controlling the structure of the catalytic centers in heterogeneous catalysts by compounds (*e.g.* Lewis bases) which take part both in homogeneous equilibria (*e.g.* with Lewis acids) in solution and in heterogeneous equilibria (*e.g.* with groups having Lewis acidity) on the surface of an heterogeneous catalyst.

The contribution of the discovery of stereospecific polymerization to the development of polymer science is comparable to that provided by the understanding of free-radical polymerization and of polycondensation in the thirties. Besides the impetus to the development of new stereospecific syntheses of macromolecules, steric order in polymers afforded new parameters for acquiring a better knowledge of polymerization mechanisms.

Furthermore, the availability of a great number of new stereoregular polymers facilitated an understanding of the relationships between chemical structure and physical properties, including mechanical properties. In particular, the availability of polymers with perfectly defined chemical and steric structures allowed a better check on the results of conformational analysis and a better understanding of the significance of the conformational equilibria for the structure and properties of the polymers in crystalline state, in the melt, and in solution.

In spite of the great amount of research in the field of stereospecific polymerization that has been performed in the 25 years since its discovery, it appears that this subject will remain of paramount importance for the development of chemistry and of polymer science for a long time in the future.

Trinuclear Clusters of the Early Transition Elements

By Achim Müller, Rainer Jostes, and F. Albert Cotton[*]

Trinuclear clusters of the early transition elements, *i. e.* those elements situated on the left-hand side of the transition series, represent the simplest types of clusters. They characteristically have a pronounced formation tendency and high stability; they are therefore produced under a wide variety of conditions and their triangular M_3 skeleton is conserved in ligand exchange reactions. These clusters play a very important role in the chemistry of the respective elements, and especially those of the 4 d and 5 d series. Biochemical implications are of interest in connection with Mo^{IV}. This progress report presents a systematic account of the chemistry and the molecular and electronic structure of such compounds. A connection is also established with the crystal field treatment of mononuclear metal complexes.

1. Introduction

The chemistry of Werner complexes of type ML_n (M = a transition metal atom of the 3d series, L = a simple donor ligand without π-acceptor properties) is known in detail[1a]. Their molecular and electronic structures as well as ligand replacement reactions become intelligible with the aid of ligand field theory and related approximations as well as more rigorous treatments[1b]. Significantly, however, the early 4d and 5d metals in their lower oxidation states have virtually no aqueous chemistry (*e.g.*, $[M(H_2O)_6]^{2+}$ ions) comparable with that of the 3d transition series. It has not yet been properly emphasized in the chemical literature that under a variety of reaction conditions the heavier early transition elements very readily form isolated trinuclear clusters to which a variety of non-π-bonding ligands may be attached. The formation tendency for these trinuclear species, which dominate in the case of the early transition elements with intermediate oxidation states, is clearly very great. Numerous ligand substitution reactions are feasible at the central M_3 entity and the electronic energy levels may be discussed using relatively simple approximations comparable with crystal field analysis for mononuclear complexes. The formation of polynuclear structures with M—M bonds, especially by molybdenum, may be of importance in biochemistry, particularly because of the ready formation of these clusters in simple aqueous media at normal temperatures.

In this article we shall discuss the chemistry, structures, and bonding of these compounds in a systematic way. From an understanding of the electronic structure it is possible to elucidate the reactions and properties of the compounds. In view of the intense contemporary interest in all aspects of metal atom cluster chemistry, it seems pertinent to devote attention to these trinuclear clusters which are among the simplest and most accessible representatives.

2. Electron-Poor Trinuclear Clusters and Other Types of Transition Metal Clusters

We distinguish two broad classes of transition metal cluster compounds: "electron-rich" clusters formed by metals to the right side of the d-block in the periodic table, in which the metal atoms in low oxidation states are combined with π-acceptor ligands, and "electron-poor" clusters formed by the early transition elements, in which the metals atoms are in higher oxidation states and combined with ligands that are simple electron donors. The bonding in electron-rich clusters has been discussed in considerable detail[2], although not on the basis of quantitative calculations. Available theoretical treatments of the electron-poor clusters vary considerably in rigor. For many of them, essentially qualitative, symmetry-based analyses have been given[3-5] and in a few cases, namely $[Re_3X_{9+n}]^{n-}$ (X = Cl, Br; $n = 0, 3$)[6] and $[Mo_6Cl_{14}]^{2-}$ [6a] SCF-Xα-SW calculations have been carried out and the results tested against photoelectron spectroscopic data and other experimental facts. In a forthcoming article[7] the consist-

[+] To whom correspondence should be addressed.

ency of the simple and the more rigorous calculations will be discussed. For the clusters with which we are concerned in this article, however, no comprehensive work at any level of rigor has been published. An attempt to understand and calculate the electronic properties of some of these clusters using the Fenske-Hall method will be described elsewhere[8]. In this article we shall employ a more qualitative treatment, along the lines of the Cotton-Haas method[3], and treat all of the trinuclear electron-poor cluster compounds.

The term "electron-poor cluster" designates those clusters in which the number of metal-atom valence electrons is approximately equal to the number required to form single bonds between the adjacent pairs of metal atoms. For trinuclear clusters, this means a total of from five to eight electrons in the metal system, at least in a formal sense. In a simple, purely formal, shorthand, we may represent the M_3 system and the number of electrons, n, formally assigned to it as $\{M_3\}^n$. Clusters of this type are formed by the metals Ti, Zr, Nb, Ta, Mo, and W. The usual upper limit of $n=8$ for the number of electrons ($\{Mo_3\}^9$ cases are known but are rare) is significant because the next higher number of d-electrons in trinuclear clusters is 12 (as in Re_3X_9 and related species); in this case there is a clearly different electronic structure involving double bonds[6].

3. Preparation and Reactions of Cluster Compounds

Trinuclear clusters of the heavier early transition elements can be prepared by an *exceptionally varied range of reaction types*. Indeed, this characteristic in itself adds considerably to their significance for the chemistry of these elements.

In the case of *solid state structures*, stoichiometric amounts of the starting materials are usually caused to react at high temperatures. The following reaction types have been reported:

1) *Interaction of reactants containing the metals in the oxidation states required in the products:*

$$MoO_2 + M'O \rightarrow M'_2Mo_3O_8 \quad (M' = Mg,\ Mn,\ Fe,\ Co,\ Ni,\ Zn,\ Cd)^{[9,10]} \qquad (1)$$

2) *Comproportionation reactions:*

$$NbBr_5 + Nb \rightarrow Nb_3Br_8{}^{[11]} \qquad (2)$$

3) *Redox reactions:*

$$MoCl_3 + S_8 \rightarrow Mo_3S_7Cl_4{}^{[12]} \qquad (3)$$

Methods for preparing clusters *in solution* are of the following main types:

1) *Reactions of a compound whose metal is in the same oxidation state as the product:*

$$Mo^{IV}_{aq} + C_2O_4^{2-} \rightarrow [Mo^{IV}_3O_4(C_2O_4)_3(H_2O)_3]^{2-}{}^{[13]} \qquad (4)$$

2) *Solvolysis and oxidation of metal compounds in lower oxidation states:*

a) *Mononuclear reactants:*

$$W(CO)_6 + HOAc \rightarrow [W_3O_2(Oac)_6(H_2O)_3]^{2+}{}^{[14]} \qquad (5a)$$

b) *Binuclear reactants:*

$$W_2Cl_4(PnBu_3)_4 + HOAc \rightarrow [W_3O_3Cl_5(Oac)(PnBu_3)_3]^{[15]} \qquad (5b)$$

3) *Solvolysis and reduction of metal compounds in higher oxidation states:*

$$MoO_4^{2-} + S_x^{2-} \rightarrow [Mo_3S_{13}]^{2-}{}^{[16]} \qquad (6)$$

4) *Disproportionation reactions ($2M^V \rightarrow M^{IV} + M^{VI}$):*

$$(NH_4)_3[W_2O_4(C_2O_4)_{2.5}]\cdot 3H_2O + HF \rightarrow [W_3O_4F_9]^{5-}{}^{[17]} \qquad (7)$$

In addition, one may begin with a trinuclear cluster compound and carry out a ligand exchange reaction which preserves only the central M_3 unit or a redox reaction which preserves the central ligand sphere as well. An important example of a ligand exchange reaction is the following reversible process:

$$[Mo_3S_{13}]^{2-} \underset{S_x^{2-}}{\overset{+CN^-\ (-NCS^-)}{\rightleftharpoons}} [Mo_3S_4(CN)_9]^{5-}{}^{[18]} \qquad (8)$$

which may perhaps be a model reaction for the inhibition of xanthine oxidase by CN^-[19]. Neutral sulfur is transferred from the Mo—(S_2)—Mo bridges to CN^-, while the formal oxidation state of molybdenum is maintained (atom-transfer reaction from the activated S_2^{2-} ligand). Another noteworthy ligand exchange reaction allows the preparation of $[Mo_3S_{13}]^{2-}$ from $[Mo_3S_7Cl_4]$[12]:

$$Mo_3S_7Cl_4 \xrightarrow{+S_x^{2-}} [Mo_3S_{13}]^{2-}{}^{[20]} \qquad (9)$$

It should also be noted that molybdenum disulfur compounds with metal-metal bonds can undergo reductive elimination of S_2. This has been shown for $Cs_2[Mo_2(S_2)_6]$[21,22] which decomposes at relatively *low temperatures* accompanied by generation of S_2. The thermal decomposition of $(NH_4)_2[Mo_3S_{13}]\cdot nH_2O$ ($n=0$—2) leads to MoS_2, perhaps with coordinatively unsaturated trinuclear clusters as intermediates, without a change in the oxidation state of the metal[23] (the non-stoichiometric crystal water is lost at 50 °C).

On the basis of their electronic structures (see Section 5) it is to be expected that several clusters should undergo reversible redox reactions, as is clear, for example, from the existence of both $[Mo_3S_4Cp_3]^+$[24] and $[Mo_3S_4Cp_3]$[25]. The hexamethylbenzene derivatives of niobium and tantalum $[M_3X_6(C_6Me_6)_3]^+$ also show reversible redox reactions[26]; the oxidized, dipositive species is very reactive, but it can be isolated by crystallization with an oxidizing anion[27]. In solution, however, it dimerizes to form an octahedral cluster[26].

The variety of preparative methods shows that the trinuclear clusters are readily formed, and therefore play an important role in the chemistry of Nb, Mo, and W. This is especially evident from the ease with which they are formed from metal carbonyls, $Mo(CO)_6$ and $W(CO)_6$, by the action of organic acids [example (5a)][14,15], by reaction of MoO_4^{2-} with S_x^{2-} in H_2O [example (6)][16], or by reaction of $[Mo_3S_{13}]^{2-}$ with a large excess of CN^- [example (8)][18] (with retention of the central Mo_3S_4 unit!). The facile formation of $[Mo_3S_{13}]^{2-}$ under various conditions is a synergic effect of

the formation tendency of trinuclear Mo^{IV} clusters and the properties of S_2^{2-} ligands, which favor high coordination numbers and are suitable for stabilizing metal clusters by an optimum shielding[22]. $(NH_4)_2[Mo_3S_{13}]\cdot n\,H_2O$ ($n=0$—2) is even obtained *in nearly quantitative yield* by heating an aqueous solution containing MoO_4^{2-} saturated with $(NH_4)_2S_x$[16c]. Notable in this connection is also the formation of the cluster anion $[W_3O_4F_9]^{5-}$[17] through disproportionation of a W^V compound [example] (7)].

The species $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$[13] shown in example (4) demonstrates the tendency of Mo^{IV} in aqueous solution to form Mo_3 clusters in the presence of simple donor ligands. The extensive work of *Souchay, Lamache,* and coworkers and our own results[28] indicate that both hydrochloric acid and sulfuric acid solutions containing ≥ 3.5 M Mo^{IV} contain Mo_3 clusters (cf. also[57]). This is most clearly suggested by polarographic measurements, which show that Mo^{IV}_{aq} is reduced to Mo^{III} in two stages: reversible reduction by 2/3 electron per Mo precedes irreversible reduction by 1/3 electron per MO[28].

Our studies of the electronic structures of trinuclear clusters (see Section 5), especially those containing $[Mo_3O_4]$ central units, account for their stability in water in both the $\{Mo_3\}^6$ and $\{Mo_3\}^8$ configurations, namely, with both 2 and $2\frac{2}{3}$ electrons per Mo atom. The polarographic data are therefore to be understood in terms of the first, reversible reduction process taking the cluster from an $\{Mo_3\}^6$ configuration to an $\{Mo_3\}^8$ configuration, whereupon further reduction leads irreversibly to destruction of the cluster with formation of $[MoCl_6]^{3-}$. A trinuclear cluster structure for Mo^{IV}_{aq} cannot be excluded by EXAFS data[29]; however, a dinuclear complex was preferred. The first isolation of a crystalline substance, *viz.* $(NH_4)_5[Mo_3O_4F_9]\cdot NH_4F\cdot H_2O$[57], from mineral acid solution without addition of an additional complexing agent also suggests the presence of three-membered species.

Table 1 lists the known compounds together with their structural, optical, and magnetic properties, as well as a notation of the formal number of metal cluster electrons.

4. Complex Structures

For the trinuclear clusters under consideration there are three basic structures: without any μ_3-ligand, with one μ_3-ligand, and with two μ_3-ligands. These three structure types will henceforth be designated A, B, and C, respectively. Type B can assume two forms (B_1 and B_2), as will be seen.

Structure type A

This structure type, $[M_3X_6(C_6Me_6)_3]^{n+}$ with M = Ti, Zr, Nb, Ta and X = Cl, Br is depicted in Figure 1. The best-known representative of this type is $[Nb_3Cl_6(C_6Me_6)_3]^+$[26]. Each metal atom is coordinated in an approximately square-planar fashion with an additional η^6-C_6Me_6 ligand parallel to this plane.

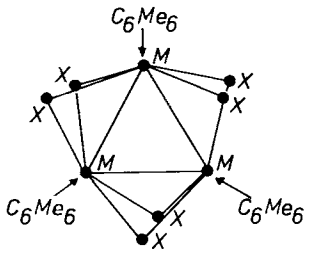

Fig. 1. Structure of clusters of formula $[M_3X_6(C_6Me_6)_3]$ (type A).

Table 1. Cluster compounds and their properties.

Compound	Structure type	Metal-metal distance [Å]	Number of electrons $\{M_3\}^n$	Electronic transitions [a] Color	Magnetism	Ref.
Ti_7Cl_{16}	B_1	2.954	6	black		[47] [b]

[a] 10^3 cm^{-1}; ε values [10^2 l mol^{-1} cm^{-1}] in parentheses. [b] *H. Schäfer*, personal communication. [c] Electronic absorption spectrum: see [37]. [d] The color can only be explained by additional absorption bands not reported in ref. [26]. [e] The color may be due to the anion $(TCNQ)_2^{2-}$. [f] Electronic absorption spectrum: see [39]. [g] $Zn_2Mo_3O_8$ is the best characterized example of this type of compound; $M_2Mo_3O_8$ with M = Mg, Mn, Fe, Co, Ni, Zn, Cd [9]. [h] Electronic absorption spectrum: *A. Müller* and *U. Reinsch*, unpublished. [i] The color may be due to the Cr^{3+} chromophore in the compound.

There has so far been no information bearing on the structure and bonding of the known titanium and zirconium compounds of this type[30] and they are not, therefore, included in Table 1.

Structure type B

Structure type B_1 is depicted in Figure 2. It occurs with clusters $[M_3(\mu_3\text{-}X)(\mu_2\text{-}Y)_3L_9]$ having M = Ti, Nb, Mo, and W. Possible ligands are: X = Cl, Br, I, O, OCH_2CMe_3, S; Y = Cl, Br, I, O, S; L = F, Cl, Br, I, O, H_2O, OEt, O_2CCMe_3, CN, 1/3 Cp, 1/2 C_2O_4, 1/2 acac, 1/2 Oac, PBu_3[*].

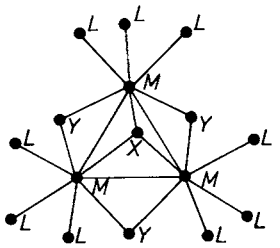

Fig. 2. Structure of clusters of formula $[M_3(\mu_3\text{-}X)(\mu_2\text{-}Y)L_9]$ (type B_1).

The coordination shell of each metal atom is a more-or-less distorted octahedron (MXY_2L_3 unit) as shown in Figure 3. A characteristic feature of the central unit $[M_3(\mu_3\text{-}X)(\mu_2\text{-}Y)_3]$ is that it can be regarded as an incomplete cube. A simple cluster of this kind, $[Mo_3S_4(CN)_9]^{5-}$ [18], is seen in Figure 4.

There is only one isolated cluster of type B that does not correspond to the general formula $[M_3(\mu_3\text{-}X)(\mu_2\text{-}Y)_3L_9]$,

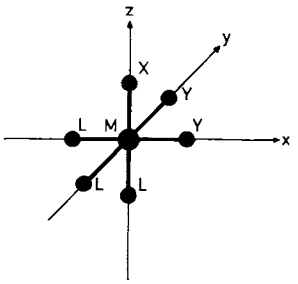

Fig. 3. Coordination and local coordination system of an isolated MXY_2L_3 unit.

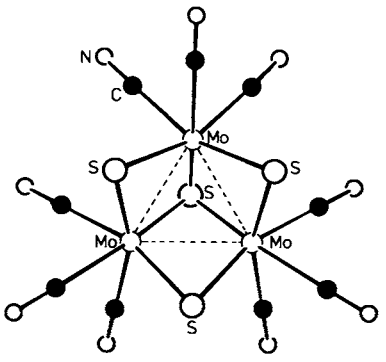

Fig. 4. Structure of $[Mo_3S_4(CN)_9]^{5-}$.

namely $[Mo_3S_{13}]^{2-}$, which has the central unit $[Mo_3(\mu_3\text{-}S)(\mu_2\text{-}S_2)_3]^{4+}$ and the structure presented in Figure 5. The

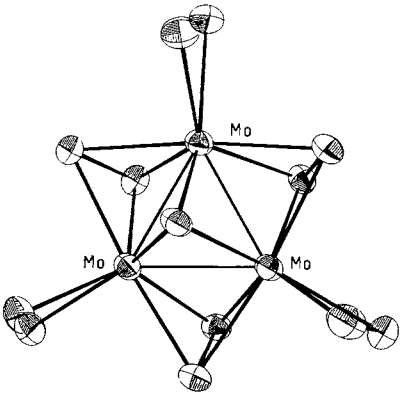

Fig. 5. Structure of $[Mo_3S_{13}]^{2-}$ (type B_2; ORTEP plot).

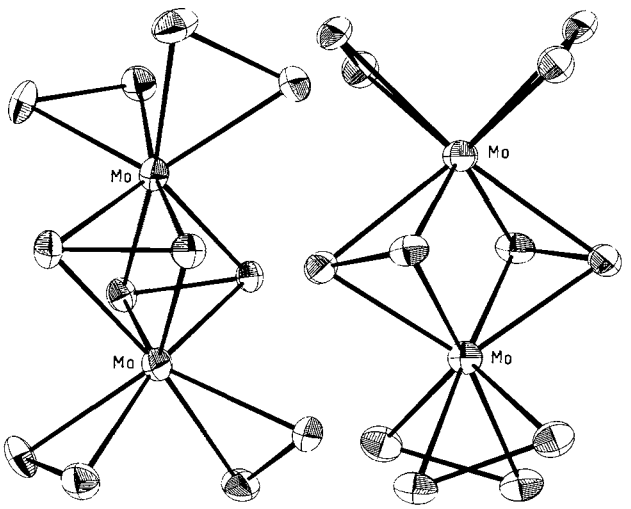
central unit just mentioned occurs also in a solid state structure[12]. If we neglect the M—M bonds, each molybdenum atom has a coordination number of seven. The shape of the coordination shell can be derived from the D_{2d} structure of $[Cr(O_2)_4]^{3-}$ [31] or $[Mo(O_2)_4]^{2-}$ [32], which is formed by two mutually perpendicular $M(O_2)_2$ units. The Mo atoms of the two different species of $[Mo_2(S_2)_6]^{2-}$ [33] found in the asymmetric unit of the crystal structure have nearly the same local symmetry, too (see Fig. 6).



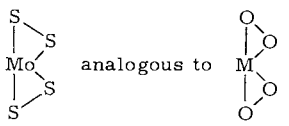


Fig. 6. Structure of the two independent anions $[Mo_2S_{12}]^{2-}$ in the asymmetric unit of the unit cell (ORTEP plot).

In $[Mo_3S_{13}]^{2-}$ we find a nearly planar unit

(with bridging S_2 groups) and, perpendicular to this, the planar unit

[*] When L = Cl, Br, I, or O, the ligands can form intermolecular bridges; when L = 1/2 C_2O_4, 1/2 acac or 1/2 Oac they form intramolecular bridges; L = CN or 1/3 Cp only for X = Y = S.

The occurrence of planar $M(X_2)_2$ units is fairly common with compounds having side-on bonded, diatomic ligands[34] (*e.g.* in $[Mo_4(NO)_4S_3(S_2)_5]^{4-}$[16c,35]). It should be noted that $[Cr^V(O_2)_4]^{3-}$ does exist as a monomeric complex, while a hypothetical $[Mo^V(S_2)_4]^{3-}$ (also with d^1 configuration) "dimerizes" under formation of $[Mo_2(S_2)_6]^{2-}$ with metal-metal bonds and sharing two S_2^{2-} ligands.

Structure type C

$[M_3(\mu_3\text{-}X)_2(\mu_2\text{-}O_2Y)_6L_3]$ clusters having the structure depicted in Figure 7 are known for the metals Mo and W[36]. Possible ligands are X = O, OEt; O_2Y = bridging bidentate ligands such as $MeCO_2$, $EtCO_2$, $tBuCO_2$; L = H_2O, $MeCO_2$, $tBuCO_2$.

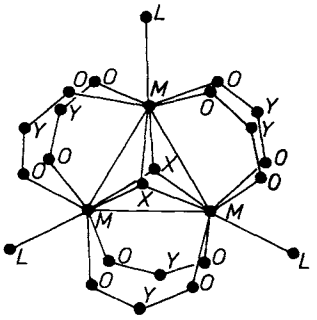

Fig. 7. Structure of clusters of formula $[M_3(\mu_3\text{-}X)_2(O_2Y)_6L_3]$ (type C).

The seven-fold coordination (*i.e.* neglecting M—M bonds) of each metal atom corresponds to that in the TaF_7^{2-} structure, namely, a capped trigonal prism (CTP) with C_{2v} symmetry, as shown in Figure 8.

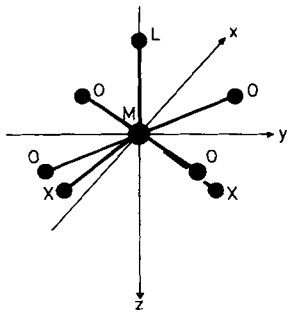

Fig. 8. Coordination and local coordination system of an isolated $MX_2(O_2Y)_4L$ unit.

5. Electronic Structures and Properties

Simplified MO calculations have been carried out for the observed structure types using a method much like that of *Cotton* and *Haas*[3] (see Section 8 for details). It can be shown (see ref.[8] for the full discussion) that this very simple method gives a satisfactory *qualitative* model for the bonding and explains most of the properties. Aside from the compounds $[Mo_3S_4Cp_3]^+$ and $[Mo_3S_4(CN)_9]^{5-}$ all the clusters of structure types B_1, B_2, and C are coordinated by ligands of the simple donor type. Ligands that are inherently capable of π-bonding (—O—, —S—, *etc.*) are, as a rule, in inter- or intramolecular bridging positions so that metal-ligand π-bonding may be neglected. This approximation makes it possible to subdivide the MOs into those which are responsible for metal-ligand bonding and those accounting for metal-metal bonding. With the compounds of structure type A such a subdivision is not possible because of the hexamethylbenzene ligands and therefore only compounds of structure types B_1, B_2, and C will be considered further. We may assume, however, that for clusters of structure type A the highest filled orbital has predominantly metal character; for $[Nb_3Cl_6(C_6Me_6)_3]^{2+}$ this is supported by the ESR spectrum[27].

Structure type B_1

A simplified description of the electronic structure of an MXY_2L_3 fragment as an octahedral complex shows that both the HOMO and the LUMO possess essentially metal d-character (corresponding to a crystal field splitting of the d orbitals into lower lying t_{2g} and higher lying e_g orbitals). While the e_g orbitals are directed towards the ligand atom centers the t_{2g} orbitals can interact only with the ligand π orbitals and if we neglect π bonding the t_{2g} orbitals may be regarded as pure metal orbitals. The three t_{2g} AOs (d_{xy}, d_{yz}, d_{xz}) on each metal atom can be combined within the symmetry (C_{3v}) of the entire molecule into the following symmetry-adapted MOs:

$1a_1$: $1/\sqrt{6}(d^1_{xz}+d^2_{xz}+d^3_{xz}+d^1_{yz}+d^2_{yz}+d^3_{yz})$
$2a_1$: $1/\sqrt{3}(d^1_{xy}+d^2_{xy}+d^3_{xy})$
a_2: $1/\sqrt{6}(d^1_{yz}+d^2_{yz}+d^3_{yz}-d^1_{xz}-d^2_{xz}-d^3_{xz})$
1e: $1/\sqrt{6}(2d^1_{xz}-d^2_{xz}-d^3_{xz})$; $1/\sqrt{2}(d^2_{xz}-d^3_{xz})$
2e: $1/\sqrt{6}(2d^1_{yz}-d^2_{yz}-d^3_{yz})$; $1/\sqrt{2}(d^2_{yz}-d^3_{yz})$
3e: $1/\sqrt{6}(2d^1_{xy}-d^2_{xy}-d^3_{xy})$; $1/\sqrt{2}(d^2_{xy}-d^3_{xy})$

Calculations of the orbital energies yield the MO scheme with three bonding MOs and one weakly bonding or nonbonding MO (Fig. 9).

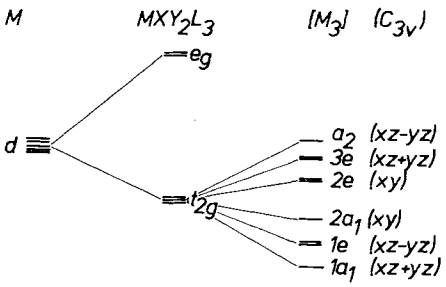

Fig. 9. MO scheme for the M_3 system of type B_1.

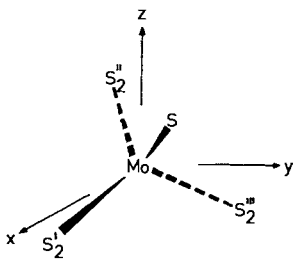
From the MO scheme it is understandable that clusters of structure type B_1 may exist with six, seven, or eight electrons in the metal system and that only those with seven electrons should be paramagnetic (with one unpaired electron). The estimated orbital energies suggest that electronic transitions within the metal system may cause absorption bands in the visible region. Such transitions are symmetry allowed and should, therefore, have higher intensities than the d-d transition of mononuclear species. Ligand→metal and metal→ligand charge transfer transitions are expected only at higher energies for the ligands that have been observed. In fact, clusters of structure type B_1, with six electrons, $\{M_3\}^6$, are red. For example, $[Mo_3O_4(C_2O_4)_3(H_2O)_3]^{2-}$ absorbs at 520 nm ($\varepsilon = 320$). On the other hand $[Mo_3OCl_3(Oac)_3(H_2O)_3]^{2+}$ with a $\{Mo_3\}^8$ configuration is blue. The observed colors

suggest the assignments $1e \rightarrow 2e$ for the transition causing the red color and $2a_1 \rightarrow 2e$ for that of the blue compound.



The existence of a low-lying unfilled metal cluster orbital in the $\{M_3\}^6$ cases is also indicated by the electronic absorption spectra of Nb_3Cl_8 and Nb_3Br_8 which show several bands in the near infrared and visible regions[37], by the black color of $Zn_2Mo_3O_8$[9], and by the weak paramagnetism of $Zn_2Mo_3O_8$[9,38] and $Zn_2W_3O_8$[38]. Because of the existence of six, seven, and eight-electron configurations, some degree of reversible redox behavior is to be expected for these compounds.

The observed increase in bond lengths on going from the $\{M_3\}^6$ to the $\{M_3\}^8$ configuration can be attributed mainly to ligand effects (see Section 6) and does not directly imply that the $2a_1$ orbital has antibonding character.

A description of the electronic structures of the compounds with strong ligands ($[Mo_3S_4Cp_3]^+$, $[Mo_3S_4(CN)_9]^{5-}$) using a simplified model of the isolated metal atom cluster is unlikely to be satisfactory for the same reason that a crystal field theory description of a mononuclear complex containing strong ligands is unsatisfactory. In both cases the strong π-bonding is too important to neglect. Because of appreciable delocalization of electron density out of the metal system and into π^* orbitals of the ligands there is a large increase (*ca.* 0.3 Å) in the metal-metal distances (see Table 1). The weaker metal-metal interaction leads to a red shift in the transitions of the metal system.

Structure type B_2

In the case of $[Mo_3S_{13}]^{2-}$ the coordination of each Mo atom can be regarded as a pseudotetrahedral arrangement of three S_2 groups and one S atom. (See also the detailed discussion of the molecular and electronic structure of $[Mo_3S_{13}]^{2-}$[39].) This pseudotetrahedral coordination implies that there should be a close similarity of the metal-ligand bonding to that in the tetrahedral MX_4^{n-} ions[40], such that the p_σ and p_π ligand orbitals of the MX_4^{n-} ion correspond to the π and π^* orbitals of the S_2^{2-} groups (see Fig. 10). On this basis there should be a splitting of the metal d orbitals,

S'_2—Mo—S''_2 103.05° S—Mo—S'_2 97.87°
S'_2—Mo—S'''_2 136.70° S—Mo—S''_2 120.05°
S''_2—Mo—S'''_2 103.05° S—Mo—S'''_2 97.82°

Fig. 10. Local coordination system of an individual $MoS(S_2)_3$ unit.

corresponding to that in a crystal field, into low-lying e and higher lying t_2 orbitals. The t_2 orbitals then point directly at the ligands, while the two e orbitals (d_{z^2} and $d_{x^2-y^2}$) on each metal center can be combined in accord with the C_{3v} symmetry of the whole molecule to give the following MOs:

a_1: $1/\sqrt{3}(d^1_{z^2} + d^2_{z^2} + d^3_{z^2})$
a_2: $1/\sqrt{3}(d^1_{x^2-y^2} + d^2_{x^2-y^2} + d^3_{x^2-y^2})$
1e: $1/\sqrt{6}(2d^1_{x^2-y^2} - d^2_{x^2-y^2} - d^3_{x^2-y^2})$; $1/\sqrt{2}(d^2_{x^2-y^2} - d^3_{x^2-y^2})$
2e: $1/\sqrt{6}(2d^1_{z^2} - d^2_{z^2} - d^3_{z^2})$; $1/\sqrt{2}(d^2_{z^2} - d^3_{z^2})$

A calculation of the orbital energies gives the MO scheme shown in Figure 11. Both clusters of structure type B_2 (cf. Table 1) have six electrons and these fill the bonding orbitals to give the configuration $1e^4a_1^2$. In this way the diamagnetism and the presence of Mo—Mo single bonds, as indicated by the vibrational spectrum and the interatomic distance, in $[Mo_3S_{13}]^{2-}$ are explained. The compound has been investigated by XPS, by means of which the oxidation state of the metal in this anion has been shown to be +4 (Mo $3d_{5/2}$: 230.1 eV). The Raman spectrum shows an intense line at 197 cm^{-1}, which has been assigned to a vibration with the character ν_s(Mo—Mo) + ν(Mo—S) by using ^{92}Mo and ^{100}Mo isotope substitution. The cyclic voltammogram shows two irreversible reduction waves, suggesting that the LUMO has antibonding character[39].

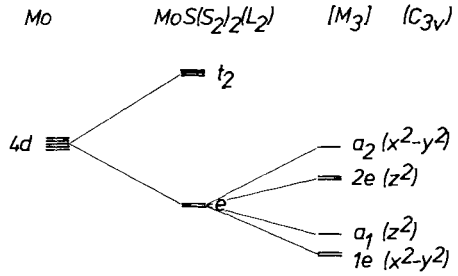


Fig. 11. MO scheme for the M_3 system of type B_2.

Explicit statements concerning the electronic structures of the type B_2 clusters are facilitated by the structural similarity between a Mo atom in $[Mo_3S_{13}]^{2-}$ and that of the Cr atom in $[Cr(O_2)_4]^{3-}$. According to an *ab initio* calculation[41] the highest (half) filled orbital of the latter ion is a nearly pure metal d orbital whose spatial orientation corresponds closely to that of a $d_{x^2-y^2}$ orbital. An orbital of this type on each of the three metal atoms in $[Mo_3S_{13}]^{2-}$ can be used to form bonding and antibonding MOs of 1e and a_2 types, respectively. The omission of one sulfur atom from a planar $Mo(S_2)_2$ fragment to leave a planar $MoS(S_2)$ unit makes another orbital of predominantly metal character available for metal-metal bonding. It is directed toward the center of the Mo_3 triangle and the three such orbitals can be combined to form a bonding a_1 MO and an antibonding 2e MO.

Structure type C

The local symmetry of one "triangular apex" ($MX_2(OY)_4L$) (cf. Fig. 7) is C_{2v}. Because of this low symmetry, a description of the electronic structure of such a cluster fragment is more difficult than for an octahedral one. According to a qualitative MO calculation[42], the CTP structure with C_{2v} symmetry has the d orbitals split into three higher-lying (but not, of course, degenerate) orbitals, $a_2(d_{xy})$, $a_1(d_{z^2})$, and $b_1(d_{xz})$, and two lower-lying orbitals, $b_2(d_{yz})$ and $a_1(d_{x^2-y^2})$. Within each group the energy ordering depends on the type of ligands and on the exact geometry. For a clus-

ter of structure type C the a_1 orbitals interact more strongly than the b_2 orbitals with the bridging O_2Y ligands and should therefore be higher in energy.

The d orbitals that should be most important for the metal-metal interactions can be combined under the restrictions of D_{3h} symmetry to form the following MOs:

d_{yz} a_2': $1/\sqrt{3}(d^1_{yz}+d^2_{yz}+d^3_{yz})$
$1e'$: $1/\sqrt{6}(2d^1_{yz}-d^2_{yz}-d^3_{yz})$; $1/\sqrt{2}(d^2_{yz}-d^3_{yz})$

$d_{x^2-y^2}$ a_1': $1/\sqrt{3}(d^1_{x^2-y^2}+d^2_{x^2-y^2}+d^3_{x^2-y^2})$
$2e'$: $1/\sqrt{6}(2d^1_{x^2-y^2}-d^2_{x^2-y^2}-d^3_{x^2-y^2})$; $1/\sqrt{2}(d^2_{x^2-y^2}-d^3_{x^2-y^2})$

The MO scheme for the entire metal cluster cannot be derived entirely unambiguously in this way because this would require a knowledge of the energy difference between the d_{yz} and $d_{x^2-y^2}$ atomic orbitals. Nevertheless, it is clear that the $1e'$ molecular orbital is the most strongly bonding and the $2e'$ molecular orbital is the most strongly antibonding. It is then understandable that six-electron systems (configuration $1e'^4a_1'^2$ or $1e'^4a_2'^2$) as well as eight-electron systems (configuration $1e'^4a_1'^2a_2'^2$) are both known. Clusters having either of these electron configurations should thus be diamagnetic.

While the electronic transition $a_1' \rightarrow a_2'$ is symmetry forbidden, the $a_1' \rightarrow 2e'$ and $a_2' \rightarrow 2e'$ transitions are symmetry allowed. This can explain why the compounds with $\{Mo_3\}^6$ configurations are yellow while those with $\{Mo_3\}^8$ configurations are red. For the $1e'^4a_1'^2a_2'^2$ configuration the HOMO is antibonding and in this way the longer metal-metal bonds in $[Mo_3(Oac)_6(OEt)_2(H_2O)_3]^{2+}$ compared to $[W_3O_2(O_2CR)_6L_3]$ may be understood.

6. Metal-Metal Distances

The metal-metal distances in the trinuclear clusters depend on the electron configurations $\{M_3\}^n$, on the coordination numbers, and definitely also on the type of ligands present. For instance, comparison of the Mo_3 and W_3 clusters with six-electron configurations and simple donor ligands (Table 2) reveals an increase of *ca.* 0.25 Å in the metal-metal bond lengths on going from those with coordination number 6 (average bond length 2.50 Å) to those with coordination number 7 (average bond length 2.75 Å). This can be attributed to the availability of more MOs with bonding character in the case of coordination number 6; in addition, somewhat better overlap makes the bonding orbitals somewhat lower in energy. The average bond lengths for similar Mo and W systems are very similar.

Table 2. Metal-metal bond lengths [Å] for the $\{M_3\}^6$ configuration—influence of the coordination number.

Coordination number	6	7
Mo	2.47—2.524	2.722–2.745
W	2.514—2.609	2.745—2.769

The influence of the electron configuration of the M_3 system can be seen by comparing the Mo_3 and W_3 clusters with coordination number 6 (Table 3). A change from the $\{M_3\}^6$ to the $\{M_3\}^8$ configuration appears to cause a slight increase, of about 0.05—0.10 Å, in the metal-metal distance. However, one must also be mindful of the fact that the ligands also influence the bond lengths. Thus, the Cl bridges in $[Mo_3OCl_3(Oac)_3(H_2O)_3]^{2+}$ apparently favor longer Mo—Mo distances than those in O-bridged systems. Similarly, in tungsten clusters of structure type B_1 a μ_3-O cap has a bond shortening effect as compared to a μ_3-OCH_2CH_3 cap. An extremely pronounced ligand effect on metal-metal bond lengths is seen along the series Nb_3Cl_8, Nb_3Br_8, Nb_3I_8.

Table 3. Metal-metal bond lengths [Å] for coordination number 6—influence of the electron configuration.

Electron configuration	$\{M_3\}^6$	$\{M_3\}^8$
Mo	2.47—2.524	2.550
W	2.514—2.609	2.610

Strong ligands exercise a very marked influence on the metal-metal bond lengths. While the typical bond lengths for B_1 type clusters with $\{M_3\}^6$ configurations are about 2.5 Å, the $[Mo_3S_4Cp_3]^+$ and $[Mo_3S_4(CN)_9]^{5-}$ clusters have bond lengths of around 2.8 Å (*i.e.* some 0.3 Å greater).

7. Summary and Outlook

In the presence of weak ligands without π-bonding properties the early transition elements—especially metals of the 4d- and 5d series in their middle oxidation states—form clusters. Frequently a d^n configuration leads to the formation of a dumbbell ($n=1$), triangle ($n=2$), tetrahedron ($n=3$), or octahedron ($n=4$)[16b].

As a group, the trinuclear clusters discussed in this article are distinguished by an exceptionally high formation tendency and high stability, so that they arise under very diverse conditions an preserve their integrity through various ligand-exchange reactions. These clusters are therefore of special significance for the chemistry of such transition elements in their middle oxidation states. For Mo^{IV} and W^{IV} the trinuclear clusters appear to be the most stable species in solution in the presence of non-π-bonding ligands. This may have biochemical implications for molybdenum. Niobium and probably tantalum clusters are found in solid state structures. Since the trinuclear clusters discussed here have chiefly anionic ligands they would have excessively high negative charges (*e.g.* $[Nb_3O_4X_9]^{8-}$) if they occurred as discrete species. Therefore, they occur preferentially as "polymeric" trinuclear clusters (as solids) which allows the total number of negative ligands (and hence negative charges) per metal atom to be smaller than for isolated species.

The clusters now known can be assigned to three structure types. It is interesting that those of types B_2 and C with $\{M_3\}^6$ configurations satisfy the 18-electron rule. A variety of properties (magnetic, optical, redox, and structural) can be systematically treated and understood using a simple MO scheme. Just as the metal-ligand interaction in mononuclear (Werner-type) complexes can be interpreted in terms of the electronic structure of one central atom, it is correspondingly possible to treat the trinuclear clusters by analyzing the electronic levels of the M_3 unit.

8. Appendix

In the method of *Cotton* and *Haas*[3] the energies of the molecular orbitals are expressed as functions of the overlap integrals and the valence orbital ionization potentials (VOIPs) for the metal atom orbitals. The overlap integrals were evaluated as linear combinations of the tabulated S_σ, S_π, and S_δ. Numerical values were calculated using a modified version of the programs written by *Cook*[43]. The following characteristic metal-metal distances were used: 2.50 Å for structure type B_1; 2.72 Å for structure type B_2; 2.75 Å for structure type C. Radial wave functions were those of *Roothaan* and *Synek*[44,45] of the multi-ζ-basis set type for the neutral Mo atom, and VOIPs for Mo 4d orbitals were the same ones as used for the calculation of MoS_2[46].

We thank the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Minister für Wissenschaft und Forschung (NRW) for financial support.

Chemistry of Thiazyl Fluoride (NSF) and Thiazyl Trifluoride (NSF_3): A Quarter Century of Sulfur-Nitrogen-Fluorine Chemistry

By Oskar Glemser and Rüdiger Mews[*]

In memory of Hans von Wartenberg on the centenary of his birthday[1]

Since the first sulfur-nitrogen-fluorine compounds were synthesized 25 years ago[2], great progress has been made in this field of covalent fluorine chemistry[3–9]. The two small molecules thiazyl fluoride (NSF) and thiazyl trifluoride (NSF_3), are key substances; nearly all sulfur-nitrogen-fluorine compounds can be derived from them.

1. Synthesis of NSF and NSF_3

NSF and NSF_3 can be synthesized by many methods, *e.g.* by fluorination of S_4N_4 with AgF_2 or HgF_2 in tetrachloromethane[2,10,11]. However, in this reaction numerous side-products are formed, which are often difficult to separate. The reaction of imino(triphenyl)phosphoranes $Ph_3P{=}NR$ ($R = H$, $SiMe_3$) with SF_4[12] is better. For production on a preparative scale, we prefer the decomposition of compounds which already contain the N—S—F group[**]:

$$FCO{-}NSF_2 \xrightarrow[CsF]{20\,^\circ C} NSF + COF_2 \quad [13,14] \qquad (1)$$

$$Hg(NSF_2)_2 \xrightarrow[HV]{110\,^\circ C} 2\,NSF + HgF_2 \quad [15] \qquad (2)$$

NSF_3 can be obtained from either NSF or directly from $OCF{-}NSF_2$ with AgF_2:

$$NSF + 2\,AgF_2 \xrightarrow{20\text{–}110\,^\circ C} NSF_3 + 2\,AgF \qquad (3)$$

NSF (m.p. $-89\,^\circ C$; b.p. $+0.4\,^\circ C$) is a colorless, pungent gas at room temperature and at $<0.4\,^\circ C$ is a pale yellow liquid. It is extremely hygroscopic and cannot be stored at room temperature without decomposition. NSF_3 (m.p. $-72.6\,^\circ C$, b.p. $-27.1\,^\circ C$), on the other hand, is kinetically very stable, both as a gas and as a colorless liquid; it reacts with metallic sodium only at *ca.* $200\,^\circ C$[10].

2. Properties of NSF

NSF is isoelectronic with SO_2; as expected it has, like SO_2, a bent structure (Fig. 1)[16]. The photoelectron spectra[17–19] show a similar sequence of orbitals in both molecules.

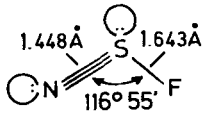

Fig. 1. Structure of NSF (not to scale). $f_{NS} = 10.94$ mdyn/Å [20–22]; dipole moment $\mu = 1.902$ D [20]; $\Delta H_f(NSF_{(g)}) = -20.92$ kJ/mol [23]; $\delta(^{19}F) = -234$ ($CFCl_3$) [22, 12].

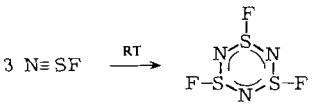
From the electron and molecular structures of NSF, we deduce three possible primary reactions:

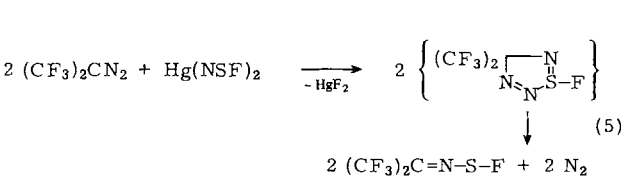
1. Reactions of the π-system (see Section 2.1): The S—N bond length is relatively short, and indicates multiple bonding, represented by the two canonical forms (*A*) and (*B*). We anticipate polymerization and addition reactions.



$$(A)\ :N{\equiv}S{-}F \longleftrightarrow {:}\overset{\ominus}{N}{=}\overset{\oplus}{S}{-}F\ (B)$$

2. Reactions with electrophiles (see Section 2.2): Electrophiles should be able to attack, as a consequence of the lone pairs on the N and S atoms. The relatively long and therefore strongly polar S—F bond should allow the addition of strong fluoro-Lewis acids.

3. Reactions with nucleophiles (see Section 2.3): Nucleophilic addition is favored at the coordinatively unsaturated S atom.

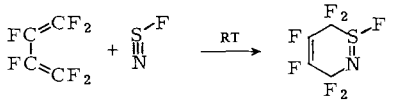


2.1. Reactions *via* the π-System

NSF forms a cyclic trimer at room temperature[11].

(4)

The reaction of the NSF-precursor, $Hg(NSF_2)_2$ [cf. Reaction (2)] with $(CF_3)_2CN_2$ is worthy of note. The primary step can be regarded as a dipolar addition of the diazo compound to the S—N bond of NSF; the stable product from reaction (5) contains sulfur with an oxidation number of $+2$[24]. Up to now, stable R=NSF compounds have not been obtained by any other method[25]. HgF_2 fluorinates $(CF_3)_2C{=}N{-}S{-}F$



(5)

[*] Prof. Dr. O. Glemser, Doz. Dr. R. Mews
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

[**] Abbreviations: HV = in vacuo, RT = room temperature, exc. = excess.

to give the sulfur difluoride imide $(CF_3)_2CF—N{=}SF_2$. $(CF_3)_2CN_2$ can also be regarded as a heterodiene instead of a 1,3-dipole. Genuine dienes, such as hexafluorobuta-1,3-diene, also react exothermically with cycloaddition[26] (alkylbutadienes react uncontrollably and ignite) [Reaction (6)].

(6)

Whether this [4+2]-cycloaddition is pericyclic, according to the Woodward-Hoffmann rules, or is a polar or nitrene-type addition in the primary step still needs clarification. It is interesting that on heating, the isoelectronic SO_2 adds chelatropically to the sulfur to form four-membered rings[27].

2.2. Reactions with Electrophiles

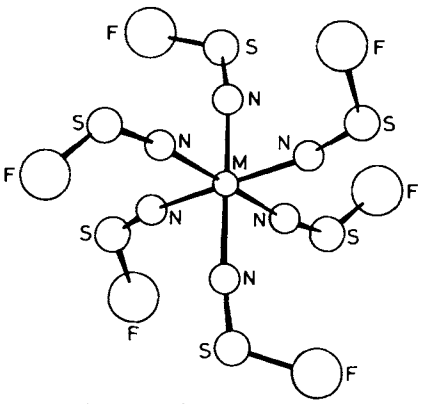
The site of electrophilic attack depends on the electrophile. Strong (hard) fluoro-Lewis acids attack at the fluorine to give thiazyl salts, for example:

$$NSF + BF_3 \rightarrow NS^{\oplus}BF_4^{\ominus}$$

According to *Pearson*, transition metal ions, $M^{2\oplus}$, can be classified as medium-hard acids. Here, the Coulomb interaction between the doubly-charged cation and the NSF dipole still dominates; these cations attack at the nitrogen. The HOMO/LUMO effect should be important only with soft acids, *e.g.* complexes of NSF with metals in low valencies; here an electrophilic attack on sulfur would be expected. However, we still lack proof of this type of reaction.

2.2.1. NSF as Complexing Ligand

Electrophilic attack on thiazyl fluoride by transition metal cations occurs at nitrogen[28,29]:



$$[M(SO_2)_2][AsF_6]_2 + 6\ NSF \xrightarrow[-2\,SO_2]{-20\,^{\circ}C} [M(NSF)_6][AsF_6]_2 \quad (7)$$
$$(M = Co, Ni)$$

A complex chemistry of this type using very weak bases and ligands sensitive to hydrolysis can be conducted in liquid SO_2. The solvent is bound—probably *via* S—to the central atoms only by weak σ-bonds; it can be concluded from the IR-data that hardly any π-back-bonding exists. Because of these weak bonds, SO_2 can be readily replaced—*e.g.* in Reaction (7) by NSF.

Table 1. S—N and S—F frequencies [cm^{-1}] as well as S—N and S—F distances [Å] of NSF and its Co- and Ni-complexes.

	NSF (g)	$[Co(NSF)_6]^{2\oplus}$	$[Ni(NSF)_6]^{2\oplus}$
ν_{SN}	361	1429	1438
ν_{SF}	641	655	655
d_{SN}	1.448	1.399(12)	1.404(5)
d_{SF}	1.643	1.569(12)	1.581(13)
∢ NSF [°]	116.5	115.0(0.7)	116.0(0.8)

From Table 1 it can be seen that the S—F and S—N bond frequencies are higher in the Co- and Ni-complexes than in NSF. Since this effect does not depend on mechanical coupling, it points to a reinforcement of the S—N and S—F bonds. This hypothesis was confirmed by X-ray structural analysis of the cations $[M(NSF)_6]^{2\oplus}$ (M = Co, Ni) (Fig. 2).

(M = Co, Ni)

Fig. 2. Structure of the cations $[M(NSF)_6]^{2\oplus}$ (M = Co, Ni) [28, 29]. See Table 1. Co—N = 2.093(11) Å, ∢Co—N—S = 170.8(10)°; Ni—N = 2.054(3) Å, ∢Ni—N—S = 168.6(2.5)°.

The central atom, M, is octahedrally coordinated by six NSF molecules *via* their N atoms. The decrease of the M—N distance on going from Co to Ni corresponds to the difference in the high-spin ionic radii. The M—N bond lengths are similar to those in the corresponding NH_3-complexes. The NSF angle alters little when complexed, in contrast to the S—N and S—F bonds, which are appreciably shortened. This unusual behavior is summarized (for some N—S—F compounds in different adducts), and explained in Section 3.1.1.

The introduction of NSF as a ligand into cationic carbonyl-metal compounds[30] is also achieved *via* SO_2-complexes:

$$[Re(CO)_5(SO_2)]^{\oplus}AsF_6^{\ominus} + NSF \rightarrow [Re(CO)_5NSF]^{\oplus}AsF_6^{\ominus} + SO_2 \quad (8)$$

The color of the deep-red cation $[Re(CO)_5NSF]^{\oplus}$ is due to a strong bathochromic shift of the NSF ligands, an effect which is not found with N-bound complexes (cf. Fig. 2). A similar shift occurs in the yellow starting material $[Re(CO)_5(SO_2)]^{\oplus}AsF_6^{\ominus}$ due to the SO_2 ligands, which are probably bound *via* sulfur. Whether this similar behavior indicates the same coordination of the atom, can only be clarified by X-ray structural analysis.

NSF is remarkably stabilized by complex formation. However, its reactivity is still so great that it reacts with both electrophiles and nucleophiles[31].

2.2.2. Formation and Reactions of the Cation $NS^{\oplus}$

Strong fluoro-Lewis acids, such as MF_5 (M = As, Sb) cleave NSF to give a fluoride ion and a thiazyl cation[32,33]; the reaction is best carried out in liquid SO_2[34].

$$NSF + MF_5 \xrightarrow{SO_2} NS^{\oplus}MF_6^{\ominus} \quad (M = As, Sb) \quad (9)$$

The S—N frequency is higher in $NS^{\oplus}$ than in NSF and, as expected, also higher than in the radical $NS^{\odot}$ (Table 2). Similar results are found with $NO^{\oplus}/NO^{\odot}$. Recently the formation of the cation $NS_2^{\oplus}$ was achieved[37].

Table 2. S—N frequencies [cm^{-1}] and S—N distances [Å] of NSF, $NS^{\oplus}$ and $NS^{\odot}$.

	NSF	$NS^{\oplus}$	$NS^{\odot}$
ν_{SN}	1361	1437	1205
d_{SN}	1.448	1.42(1)	1.4955
	[22, 16]	[35]	[36]
		1.44	
		[38—40]	

The thiazyl radical $NS^{\odot}$, ($X^2\pi$) has the electron configuration $1\sigma^2 2\sigma^2 3\sigma^2 4\sigma^2 1\pi^4 5\sigma^2 6\sigma^2 7\sigma^2 2\pi^4 3\pi^1$. The single electron is in an antibonding orbital; the expected bond strength increase occurs on ionization. A bond length of 1.44 Å was determined for $NS^{\oplus}$ ($X^1\Sigma^+$) from PE spectra[38], as well as from *ab-initio* calculations[39,40]. The X-ray structural analysis of $NS^{\oplus}Sb_2F_{11}^{\ominus}$ at −151.5 °C gave an N—S distance of 1.42 Å[35].

The cation $NS^{\oplus}$ is an interesting reagent for syntheses[34]. In $SOCl_2$ as solvent, $NS^{\oplus}$ reacts with S_4N_4 by insertion of an

$$S_4N_4 + NS^{\oplus}\ MF_6^{\ominus} \xrightarrow{SOCl_2} S_5N_5^{\oplus}\ MF_6^{\ominus} \quad (10)$$
(M = As, Sb)

$NS^{\oplus}$ moiety into the S—N bond of the starting material, to give a good yield of the yellow thiazyl salt (Reaction (10)). If liquid SO_2 is used as solvent, then a black polymer $(S_5N_5^{\oplus}AsF_6^{\ominus})_n$ is formed, along with other substances. The cation $S_5N_5^{\oplus}$ contained in the yellow salt, was first obtained by another method[41]. It has a planar ten-membered ring, which can be regarded as a 14π-electron system. An azulene-type molecular structure has been determined by X-ray analysis[42].

Insertion reactions into the polar S—Cl bonds occur with sulfenyl halides RSCl (R = CF_3, $(CF_3)_2C{=}N{-}$, Cl)[34], *e.g.* according to Reaction (11).

$$Cl{-}\overset{\delta\oplus}{S}{-}\overset{\delta\ominus}{Cl} + NS^{\oplus}\ MF_6^{\ominus} \xrightarrow{SO_2\,(l)} [N(SCl)_2]^{\oplus}\ MF_6^{\ominus} \quad (11)$$
(M = As, Sb)

The cation $[N(SCl_2)]^{\oplus}$ can also be obtained from NSF_3 and BCl_3 [see Reaction (48)][43]. In the yellow hygroscopic salts it has a planar *cis*-structure, *i.e.* the lone pairs on the N and S atoms are in a *cis*-configuration (Fig. 3).

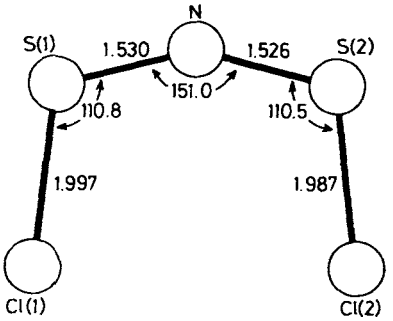


Fig. 3. Structure of the cation $[N(SCl)_2]^{\oplus}$.

The large SNS angle could indicate that the lone pair on nitrogen participates in the S—N bond[44].

2.3. Reactions with Nucleophiles

Nucleophilic attack occurs at the S atom, whereby either fluorine is substituted, or the coordination number is increased.

2.3.1. Substitution Reactions with Retention of the Formal S≡N Triple Bond

The formal triple bond is retained in only a few substitution reactions. So far only three compounds of the type N≡S—R (R = F, Cl, $ON(CF_3)_2$) have been reported; they all

$$2\ NSF + Hg[ON(CF_3)_2]_2 \xrightarrow[-HgF_2]{} 2\ N{\equiv}S{-}ON(CF_3)_2 \quad (12)$$
$$\downarrow$$
$$2/3\ \left[\begin{array}{l} \text{——}N{=}S\text{–} \\ \quad\quad | \\ (CF_3)_2NO \end{array}\right]_3$$

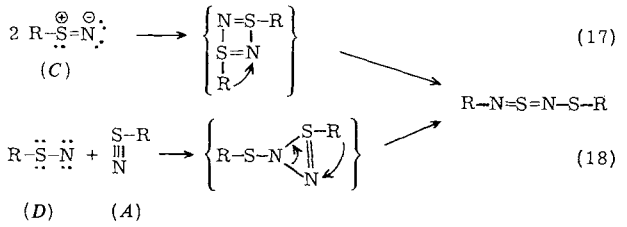
trimerize at room temperature [see also Reaction (4)]. The compound N≡S—$ON(CF_3)_2$ resulting from Reaction (12)[45], can, like NSF, be stabilized by being incorporated[46] into transition metal complexes [see *e.g.* Reaction (13)]. The orange-red salt is completely stable at room temperature.

$$[Re(CO)_5SO_2]^{\oplus}\ AsF_6^{\ominus} + N{\equiv}S{-}ON(CF_3)_2 \xrightarrow[-SO_2]{} [(CO)_5ReNSON(CF_3)_2]^{\oplus}\ AsF_6^{\ominus} \quad (13)$$

2.3.2. Nucleophilic Substitution and Subsequent Rearrangement

NSF was reacted with perfluoroalkenes[47,48] in the presence of CsF, in an attempt to replace the fluorine nucleophile by the perfluoro carbanion, to give disulfides and linear sulfenyl sulfur diimides [Reaction (14)].

$$N{\equiv}S{-}F + \rangle C{=}C\langle \xrightarrow{CsF} \{NSR_f\} \quad (14)$$
$$\downarrow$$
$$R_fN{=}S{=}N{-}S{-}R_f$$
$$(R_f = (CF_3)_2CF,\ (CF_3)_3C) \qquad + R_f{-}S{-}S{-}R_f + \cdots$$

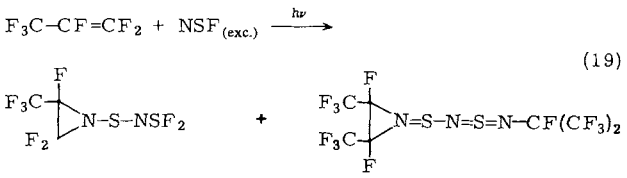


$$N{\equiv}S{-}F + F_3C{-}C{\equiv}C{-}CF_3 \xrightarrow{CsF} F_3C{-}CF_2{-}\overset{CF_3}{\underset{S{-}N}{\overset{|}{\underset{\|}{\overset{|}{N}}}}}{-}S + \cdots \quad (15)$$

If alkynes are used[49] [Reaction (15)], then cyclic sulfenyl sulfur diimides can be isolated, in which both ends of the —S—N=S=N— chain are bound to the same carbon atom. The electronegativity of R in thiazyl compounds RS≡N must obviously be high to enable a good overlap of the orbitals between N and S and the relatively short S—N distance for the formal triple bond. The bonding situation is illustrated by the canonical forms (*C*)—(*F*).

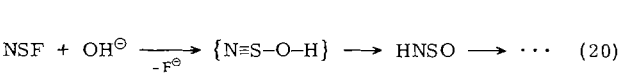
$$:N{\equiv}S{:}^{\oplus}\ R^{\ominus} \longleftrightarrow :N{\equiv}\ddot{S}{-}R \longleftrightarrow \ddot{N}^{\ominus}{=}\ddot{S}^{\oplus}{-}R \longleftrightarrow \ddot{N}{-}\ddot{S}{-}R \quad (16)$$
(*C*) (*D*) (*E*) (*F*)

As the electronegativity of R decreases, polar structures such as (*E*) and the nitrene structure (*F*) become important[50]. Even perfluorinated alkyl groups are incapable of stabilizing the formal triple bond. The secondary products from $\{R_fSN\}$ can be explained by the dimerization of polar or nitrene-type intermediates [Reactions (17) and (18)].



The formation of disulfides also indicates nitrene-type intermediates.

(17)



(18)

There is no clear evidence for nitrene reactions of NSF. Irradiation of excess thiazyl fluoride in the presence of hexafluoropropene[51] leads to sulfenylaziridenes [Reaction (19)].

(19)

Another type of rearrangement is found during hydrolysis. NSF is extremely hygroscopic and therefore somewhat difficult to handle. The coordinatively unsaturated sulfur atom is, as expected, easily attacked by the classic nucleophile water[52]; $F^{\ominus}$ is replaced by $OH^{\ominus}$. As shown by:

(20)

Thionylimide HNSO[10,53] is first formed, then hydrolytically cleaved. It decomposes *via* $S_2O_3^{2\ominus}$ to $HSO_3^{\ominus}$ and sulfur. The $HSO_3^{\ominus}$ ions then react with the remaining sulfoxylic acid to give trithionate $S_3O_6^{2\ominus}$ and hexathionate $S_6O_6^{2\ominus}$, both of which can be isolated as tetraphenylphosphonium salts.

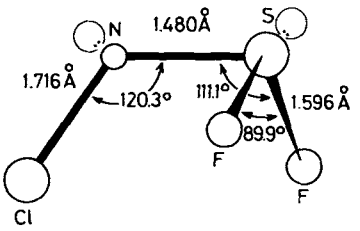
2.3.3. Nucleophilic Addition with Increase of the Coordination Number

Nucleophilic attack on NSF by $F^{\ominus}$ in the presence of CsF gives the salt $Cs^{\oplus}NSF_2^{\ominus}$[54]. In the presence of elemental chlorine, $ClNSF_2$[14] is produced, an example of the sulfur difluoride imides $RNSF_2$, of which many are known[8]. The halogen derivatives $XNSF_2$ (X = F, Cl, Br, I) are better[15] synthesized by:

$$Hg(NSF)_2 + X_2 \rightarrow 2XNSF_2 + HgF_2 \qquad (21)$$

$ClNSF_2$ (b.p. 23.7 °C) is the most stable compound in this series. $FNSF_2$[55] is an isomer of NSF_3. The structure of $ClNSF_2$ was determined by electron diffraction (Fig. 4)[56]. The Cl atom is *cis* to the SF_2 group. In other words: the *cis*-arrangement of the lone pairs on the N and S atoms is sterically more favorable than a *trans*-arrangement. This arrangement is also observed with $F_3C{-}NSF_2$[57] and with other S—N—X compounds, *e.g.* $[N(SCl)_2]^{\oplus}$, XNSO[53], $(NSX)_3$, X = F, Cl (cf. Section 4).

Numerous organic sulfur difluoride imides can be obtained by addition of $ClNSF_2$ or $BrNSF_2$ to C=C double bonds[8]. The radical $^{\circ}NSF_2$ postulated in this reaction has been identified in a matrix[58]. Organic sulfur difluoride imides can also be obtained by the reaction of SF_4 with *e.g.* primary amines, silylated primary amines, cyanides, cyanates or thiocyanates[8].



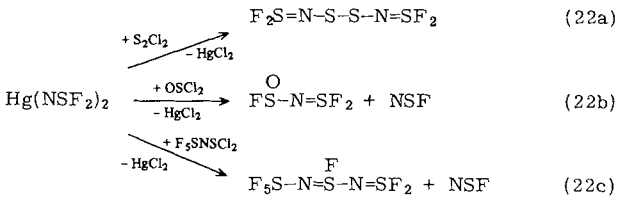


Fig. 4. Structure of $ClNSF_2$.

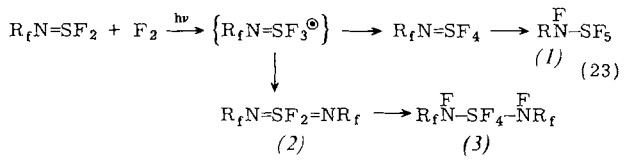
The NSF_2 group can also be directly transferred using $Hg(NSF_2)_2$[59] [Reaction (22)].



(22a)

(22b)

(22c)

In compounds of the type $RN{=}SF_2$, the N and S atoms are still coordinatively unsaturated. Therefore fluorination should lead to more highly coordinated species. We have recently[60] studied the photochemical reaction of $RN{=}SF_2$ ($R = C_2F_5$, SF_5) with fluorine in the gas phase, for which we postulate a radical mechanism [Reaction (23)]. Compounds *(1)* ($R_f = CF_3$, C_2F_5[61], FSO_2[62]) have already been prepared

(23)

by fluorination of $RN{=}SF_2$ in the presence of CsF. Compounds *(2)* were formed by uncatalyzed fluorination ($R_f = CF_3$, C_2F_5[61], SF_5[63]). Compounds with five-coordinate sulfur, such as $R_fN{=}SF_4$ are rare; however, we succeeded in isolating $C_2F_5N{=}SF_4$ (b.p. 25 °C) and in detecting traces of $F_5SN{=}SF_4$[64]. Compound *(3)* ($R_f = C_2F_5$) (b.p. 111 °C) is formed stereospecifically; only the *trans*-isomer is obtained.

The photochemical reaction of $RN{=}SF_2$ ($R = CF_3$, C_2F_5, iC_3F_7, $CF_2Cl{-}CF_2$, $CF_2Br{-}CF_2$, OCF) with OF_2[65] gives similar results. The $-N{=}SF_2$ group is isoelectronic with OSF_2, which reacts quantitatively with OF_2 to give O_2SF_2 and OSF_4[66]. Sulfur oxide difluoride imides and sulfur difluoride diimides are produced analogously by Reaction (24). $RN{=}SF_4$, isoelectronic with OSF_4, has been observed in only one case[65].

$$2\ RN{=}SF_2 + OF_2 \xrightarrow{h\nu} RN{=}\overset{O}{S}F_2 + \{RN{=}SF_4\} + RN{=}SF_2{=}NR + SF_4 \quad (24)$$

Compounds of type *(1)* [Reaction (23)] can also be produced according to Reaction (25), by low-temperature fluorination of NSF[14].

$$NSF + 3\ F_2 \xrightarrow{CsF} F_2N{-}SF_5\ (SF_6, NF_3) \quad (25)$$

In $F_2N{-}SF_5$, the sulfur is six-coordinate, and the nitrogen three-coordinate. The S—N bond of this compound is weak; this is confirmed by the relatively long S—N distance of 1.696 Å[67]. The molecule is therefore easily cleaved by further fluorination to give SF_6 and NF_3. On the other hand, the products and intermediates of Reactions (23)—(25) can also be regarded as derivatives of NSF_3 (cf. Section 3).

Derivatives of $RN{=}SF_2$ are easily produced by exchange of one or two F-atoms[68].

3. Properties of NSF_3

NSF_3 is isoelectronic with O_2SF_2, and like O_2SF_2 it has a distorted tetrahedral structure (Fig. 5) which was determined by *IR*[22,69], *NMR*[22], *Raman*[70] and *microwave* spectroscopy[71].

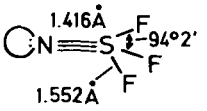


Fig. 5. Structure of NSF_3 (not to scale). $f_{NS} = 12.4$ mdyn/Å [22, 70, 72]; dipole moment $\mu = 1.91$ D [71]; $\Delta H_f^{\ominus}(NSF_{3(g)}) = -410$ kJ/mol [73]; $\delta(^{19}F)(CFCl_3) = 70.0$ [22, 74]; $\delta(^{14}N/^{15}N)(CH_3NO_2) = -243.4$ [74]; $J(F\text{-}^{14}N) = 26.4$ Hz; $J(F\text{-}^{15}N) = 37.5$ Hz.

From the electronic and molecular structures of NSF_3, we predict the following reaction possibilities:

1. Reactions with electrophiles (see Section 3.1): The lone pair on the N atom promotes electrophilic attack, so adducts are expected. The very short S—F distance, explained by π-back-bonding from occupied F(p) to empty S(d) orbitals, would hardly permit cleavage of $F^{\ominus}$ ions by strong fluoro-Lewis acids, as has been observed in the case of NSF. Therefore, NSF_3 should give adducts.

2. Reactions with the π-system (see Section 3.2): The very short S—N distance almost corresponds to a formal S≡N triple bond. Polymerization of the molecule, and addition to the S≡N triple bond should be observed.

Whilst NSF cyclotrimerizes to $(NSF)_3$, NSF_3 shows no similar reaction, *i.e.* the S—N bond behaves differently in NSF and NSF_3, although it can be described in both cases as a σ-bond and two π-bonds. The photoelectron spectra of NSF[17,18] and NSF_3[19] allow us to understand these results (Fig. 6).

The spectra are ambiguously interpreted in the literature; the following correlation would seem plausible: In NSF the HOMO is the σ-orbital of the lone pair on sulfur, then follow the two π-orbitals. NSF_3 has another set of orbitals: There are two degenerate π-orbitals as HOMOs and then a σ-orbital to which the lone pair on the nitrogen atom is assigned. Furthermore, it can be concluded from the measurements that the orbitals which contribute to the formal triple bond in NSF are on the N and S atoms, but in NSF_3 are more strongly concentrated on the N atom[19] (cf. also [75]). This difference in sequence and concentration of the orbitals in the two compounds probably causes the difference in chemical behavior.

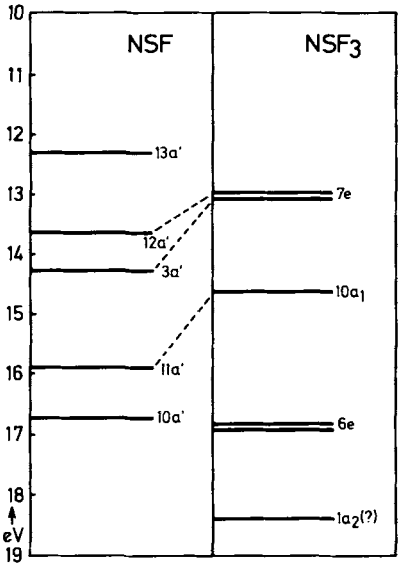

Fig. 6. Photoelectron spectra of NSF and NSF_3.

3. Reactions with nucleophiles (see Section 3.3): The partial charge of the S atom is lowered due to π-back-bonding, making nucleophilic attack on this still coordinatively unsaturated atom more difficult.

3.1. Reaction with Electrophiles

As with NSF, electrophiles such as fluoro-Lewis acids, cationic organometallic complexes and transition metal cations can be used. But the classic electrophile, the proton, as well as 'alkyl acids' ($R^{\oplus}$) are possible candidates. In all these reactions it is advantageous to use SO_2 as the solvent because it stabilizes the acids. NSF_3 is a stronger nucleophile, and so it displaces the SO_2 from these compounds. The given reactions are also valid for NSF_3-derivatives of the type NSF_2R.

3.1.1. Adduct and Complex Formation

In accordance with our prediction, fluoro-Lewis acids will only form adducts with NSF_3:

$$A + NSF_3 \rightarrow A{-}NSF_3 \quad (26)$$
$$(A = BF_3[76], AsF_5, SbF_5[133])$$

The stability of these adducts depends on the Lewis acid used. While liquid $F_3B{-}NSF_3$ completely dissociates into its components at room temperature, $F_5Sb{-}NSF_3$ is still not decomposed in the gas phase.

NSF_3 is thermally more stable than NSF, and therefore easier to incorporate into transition metal compounds as a ligand [Reactions (27)—(30)].

$$[M(CO)_5SO_2]^{\oplus}\,AsF_6^{\ominus} \xrightarrow[-SO_2]{+NSF_3} [M(CO)_5NSF_3]^{\oplus}\,AsF_6^{\ominus}\ [77] \quad (27)$$

(M = Mn, Re)

$$[C_5H_5Fe(CO)_2SO_2]^{\oplus}\,AsF_6^{\ominus} \xrightarrow[-SO_2]{+NSF_3} [C_5H_5Fe(CO)_2NSF_3]^{\oplus}\,AsF_6^{\ominus}\ [78] \quad (28)$$

$$[M(SO_2)_2]^{2\oplus}\,[AsF_6^{\ominus}]_2 \xrightarrow[-2\,SO_2]{+4\,NSF_3} [M(NSF_3)_4]^{2\oplus}\,[AsF_6^{\ominus}]_2\ [79] \quad (29)$$

(M = Mn, Fe, Co, Ni Cu)

$$AgAsF_6 + NSF_{3(exc.)} \xrightarrow{SO_2\,(l)} [Ag(NSF_3)_2]\,AsF_6 \xrightarrow[RT]{-NSF_3} [Ag(NSF_3)]\,AsF_6 \quad (30)$$

The $M^{2\oplus}$ ions bind a maximum of only four NSF_3 ligands (but six NSF ligands). According to Pauling's principle of electroneutrality, this could indicate that NSF_3 is a stronger σ-donor than NSF. A large increase in the S—N and S—F bond frequencies occurs in all adducts and complexes, an effect which we have already found with NSF complexes (where it is weaker), and which does not directly depend on the strength of the Lewis acid (Table 3).

Table 3. S—N and S—F frequencies [cm^{-1}] as well as S—N and S—F distances [Å] of NSF_3 and some of its complexes.

	NSF_3	$[Mn(NSF_3)_4]^{2\oplus}$	$[Re(CO)_5NSF_3]^{\oplus}$	$F_5As—NSF_3$
ν_{SN}	1515	1579	1643	1610
ν_{SF}	811, 775	880, 836	890, 847	888
d_{SN}	1.416	1.365(11)	—	1.383
d_{SF}	1.522	1.506(5)	—	1.439

This unusual effect points to a strengthening and shortening of *both* bonds in the adduct, since it cannot be explained by the coupling contributions[80]. Furthermore, we found that the stronger the bond between the central atom of the starting material and the N atom of NSF_3 is, the stronger the S—N bond becomes[81]. The X-ray structural analyses of $F_5As—NSF_3$ (Fig. 7)[82] and $[Mn(NSF_3)_4][AsF_6]_2$ (Fig. 8)[83] confirm the proposed shortening of the S—N and S—F bonds.

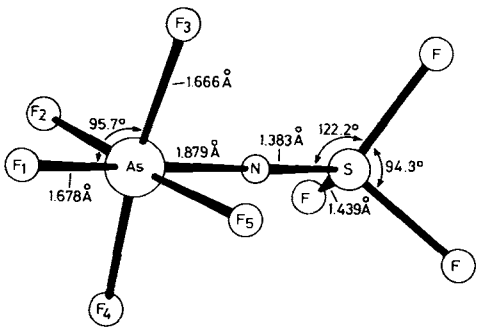

Fig. 7. Structure of $F_5As—NSF_3$.

According to preliminary results, there exists in $F_5As—NSF_3$ an exactly linear arrangement of F_{ax}—As—N—S with shorter S—N and S—F distances than in NSF_3[84]. In the octahedral complex $[Mn(NSF_3)_4][AsF_6]_2$, a Mn atom is located in the middle of a planar quadrangle formed by the N atoms of the four NSF_3 ligands. The fifth and sixth coordination positions are each occupied by fluorine atoms from the two AsF_6 groups. The S—N and S—F distances are considerably shortened. The Mn—N—S angle, like the Co—N—S angle (Fig. 2), deviates from 180°; further investigations will show whether or not this is due to steric factors. The As—F bond lengths indicate the presence of covalent interactions in the solid compound.

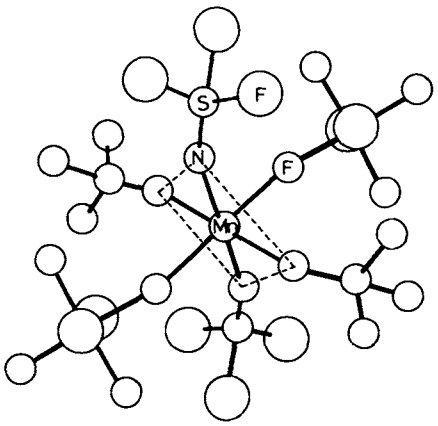

Fig. 8. Structure of $[Mn(NSF_3)_4][AsF_6]_2$. S—N = 1.365(11), S—F = 1.506(5), Mn—N = 2.187(8), Mn—F = 2.193(4), As—F_{ax} = 1.721(28), As—F_{eq} = 1.666(12) Å: ∢N—S—F = 121.4(1.3)°.

We explain the shortening of the S—N *and* S—F bonds in the NSF_3 adducts as follows: The lone pair on the N atom of NSF_3 has predominantly s-character. We assume, that when the adduct is formed, an sp-hybridization of the orbitals on the N atom occurs; this leads to a strengthening of the σ-bond and to a linear or almost linear central atom-S—N arrangement. Thus, charge-density is withdrawn from the S atom, whereby the S—F bond shortens due to further π-back-bonding. These considerations are also valid for the NSF complexes (Section 2.2.1).

3.1.2. Adducts and Complexes of NSF_3 Derivatives

Two types of NSF_3 derivatives (L), the species $N{\equiv}SF_2R$ ($R = NMe_2$, $(CF_3)_2CF$, OC_6H_5[85]) and $RNSOF_2$ ($HNSOF_2$[86], $H_3C—NSOF_2$[87], $NC—NSOF_2$[88], $NSF_2—NSOF_2$[85]), give the adducts F_5ML (M = As, Sb) and $[M(CO)_5L]^{\oplus}AsF_6^{\ominus}$ (M = Mn, Re).

The $N{\equiv}SF_2R$ group resembles the nitrile group in its ability to donate. In reactions with difunctional ligands, $N{\equiv}SF_2—NSOF_2$ or $N{\equiv}C—NSOF_2$, coordination takes place exclusively *via* the nitrogen of the $N{\equiv}S$ or $N{\equiv}C$ triple bond, respectively.

In the carbonyl transition-metal complexes of $N{\equiv}SF_2R$, the S—N and S—F frequencies, as in the NSF_3 complexes, are higher than in the uncomplexed molecules. This property leads to the conclusion that there is a linear or almost linear M—N—S arrangement, with shortened S—N or S—F distances. However, with fluoro-Lewis acids, such as AsF_5 or SbF_5, the S—F frequency increases, whilst the S—N frequency remains in the same region (Table 4).

We explain this as follows: In NSF_3 complexes the S atom apparently cannot accept a positive charge. In all cases the species $M—\overset{\oplus}{N}{\equiv}SF_3$ is formed, with a linear or almost linear M—N—S arrangement. However, substituents other than

Table 4. S—N and S—F frequencies [cm^{-1}] as well as $\delta(^{19}F)$ of NSF_2—$CF(CF_3)_2(L)$ and some of its adducts.

	L	$[Re(CO)_5L]^{\oplus}$	$F_5As \cdot L$	$F_5Sb \cdot L$
ν_{SN}	1502, 1475	1610, 1596	1496	1503
ν_{SF}	748, 722	832, 803	848, 819	863, 824
$\delta(^{19}F)$	−101.97	−92.00	−82.17	−79.3

fluorine lower the electronegativity of the SF_2R-group; the S atom is now able to accept a positive partial charge. Figure 9 shows the possible structures for adducts of NSF_2—NMe_2 with the strong acids SbF_5 and $CH_3^{\oplus}$.

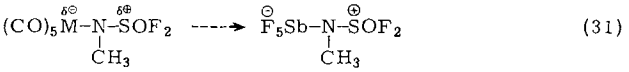

Fig. 9. Proposed structure for compounds with $-N{=}SF_2N(CH_3)_2$ groups.

Now the electron density on the S atom in $N{\equiv}SF_2R$ is certainly greater, and therefore the positive partial charge is smaller than in $N{\equiv}SF_3$. Weaker Lewis acids *e.g.* $[Re(CO)_5]^{\oplus}$ ions, cause a sp-hybridization of the orbitals of the N atom in $N{\equiv}SF_2R$, as in NSF_3; the influence on the bonding is the same. However, stronger Lewis acids of the type MF_5 (M = As, Sb), can withdraw more electron density from the bonding system of $N{\equiv}SF_2R$ than from NSF_3. The result is a sp^2-hybridization of the orbitals of the N atom (Fig. 9). A zwitterion is formed with the positive charge on the S atom of a non-linear M—N—S arrangement. As the partial positive charge is increased, ν_{SF} increases with increasing strength of the Lewis acid, and the S—F bond becomes shorter. There are two opposing effects regarding the S—N bond length: When the adduct is formed, the bond becomes shorter and stronger for the reasons discussed in Section 3.1.1. But, due to the altered hybridization of the orbitals on the N atom, the M—N—S arrangement becomes bent and the S—N bond longer.

Thus, the net result is that the length and strength of the S—N bond hardly alters.

The $RNSOF_2$ adducts all have nearly the same IR-spectra. That of H_3C—$NSOF_2$ has been chosen as an example and is given in Table 5. The coordination number of the N atom can be derived from the IR data. Furthermore, it can be seen that the bonding situation alters when the adduct is formed: The S—N bond contains more single bond character, ν_{NSO} becomes more or less decoupled, ν_{SN} is shifted to lower wavelengths, and $\nu_{as(NSO)}$ becomes more of a pure SO-vibration. This leads, depending on the acid strength, from compounds with partial charge to those with strongly zwitterionic character [arrow in (31)].

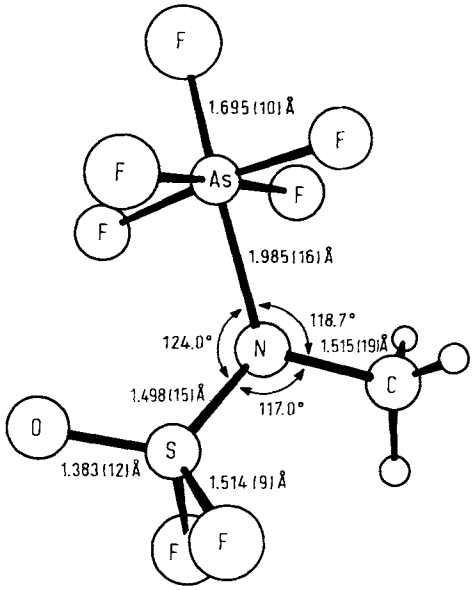
(31)

Table 5. IR data of H_3C—$NSOF_2$ (L) and some of its complexes [cm^{-1}].

	L	$[Mn(CO)_5L]^{\oplus}$	$F_5As \cdot L$	$F_5Sb \cdot L$
$\nu_{as(NSO)}$	1410, 1385	1390	1450	1450
$\nu_{sym(NSO)}$	1280	1215	1085	1092
$\nu_{as(SF)}$	920	940	948	950
$\nu_{sym(SF)}$	792	870	870	900

Again, as explained above, as the strength of the acid increases so the S atom becomes more positive, and the S—F bond becomes stronger—as shown by the trend of ν_{SF}[86].

The ideas developed here concerning the bonding in the adducts of H_3C—$NSOF_2$ have been confirmed by X-ray structural analysis[89] of F_5As—$N(CH_3)SOF_2$ (Fig. 10). The ligand is bound to the N atom, the S—N bond becomes longer in the adduct, the S—F bond shorter.



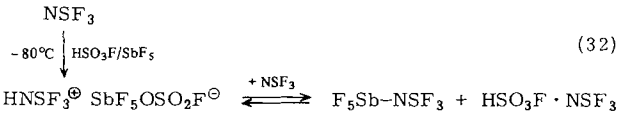


Fig. 10. Structure of F_5As—$N(CH_3)SOF_2$.

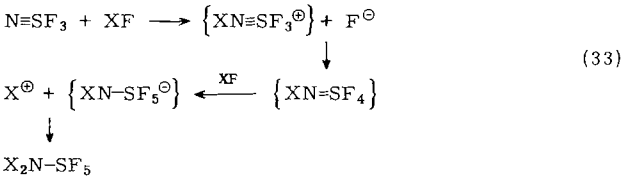
3.1.3. Formation of Cations from Thiazyl Trifluoride



Protonation of NSF_3 occurs in the superacid system HSO_3F/SbF_5 according to Reaction (32).

(32)

The $HNSF_3^{\oplus}$ cation is detectable by NMR spectroscopy only up to −80 °C, then the equilibrium (32) is quickly established[90].

Cations of the type $XNSF_3^{\oplus}$ are probably the primary products of the addition of polar reagents XF (X = H, Cl) to the $S{\equiv}N$ triple bond in NSF_3 [Reaction (33)][91, 102].

(33)

None of the postulated intermediate products of this reaction could be isolated; for example, the $XNSF_3^{\oplus}$ cation would be immediately attacked by the $F^{\ominus}$ nucleophile to form $XN{=}SF_4$. Pentafluorosulfur amines are formed as the stable end products (see Section 3.2).

If the electrophilicity of the cations is lowered by introduction of X = alkyl, and by choosing large, weakly nucleophilic anions, then it is possible to isolate salts of these cations[92,93].

$$NSF_3 + ROSO^{\oplus}MF_6^{\ominus} \rightarrow [R{-}NSF_3]^{\oplus}MF_6^{\ominus} \quad (34)$$
$(R = CH_3,\ C_2H_5)$

$$NSF_2R + H_3COSO^{\oplus}AsF_6^{\ominus} \rightarrow [H_3C{-}NSF_2R]^{\oplus}AsF_6^{\ominus} \quad (35)$$
$(R = N(CH_3)_2,\ CF(CF_3)_2,\ NSOF_2)$

Especially remarkable is the cation $H_3C{-}NSF_3^{\oplus}$, which has the hitherto highest known S—N frequency (1788 cm^{-1}). X-ray structural analysis will show whether it contains the correspondingly shortest S—N distance[94].

3.1.4. Sulfur Tetrafluoride Imides

The cation $H_3C{-}NSF_3^{\oplus}$, obtained according to Reaction (34), reacts with $F^{\ominus}$ ions to give the tetrafluoride[92] (b.p. 21.8 °C):

$$H_3C{-}NSF_3^{\oplus}\,AsF_6^{\ominus} + NaF \xrightarrow[HV]{160\,^{\circ}C} H_3C{-}N{=}SF_4 \quad (36)$$

The NSF_4 group is isoelectronic with OSF_4. The expected trigonal-bipyramidal structure was confirmed by electron diffraction[95] (Fig. 11).

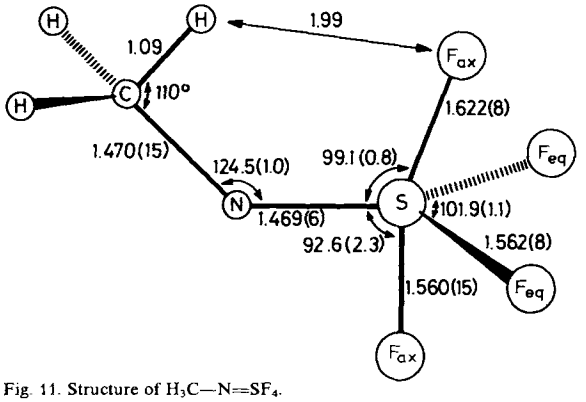


Fig. 11. Structure of $H_3C{-}N{=}SF_4$.

The $-CH_3$ group lies in the plane formed by the N and S atoms, and by the two axial fluorine atoms[96].

N-(perfluoroalkyl)sulfur tetrafluoride imides $R_f{-}NSF_4$, are accessible by fluorination of the corresponding sulfur difluoride imides $R_fN{=}SF_2$ [Reaction (23)] or by dehydrofluorination of *N*-(perfluoroalkyl)pentafluorosulfur amines $R_fNH{-}SF_5$[97]. It has recently been shown that perfluorinated sulfur tetrafluoride imide $FN{=}SF_4$ can be obtained from F_5S-NHF *via* this approach[97a].

3.2. Reactions *via* the π-System; Addition to the S≡N Triple Bond

Polar species such as XF (X = Cl, H)[91,102], add to the S≡N triple bond according to Reaction (33); according to the literature[102], also in the case of X = Cl only pentafluorosulfur amines are found, with no intermediate products such as sulfur tetrafluoride. However, if NSF_3 is used in excess, then cyclic $(ClNSF_4)_2$ is formed in small amounts [Reaction (37)]; this probably arises by dimerization of the monomeric tetrafluoride[98]. It is worth mentioning that sulfur in four-membered rings, as is the case here, has not yet been ob-

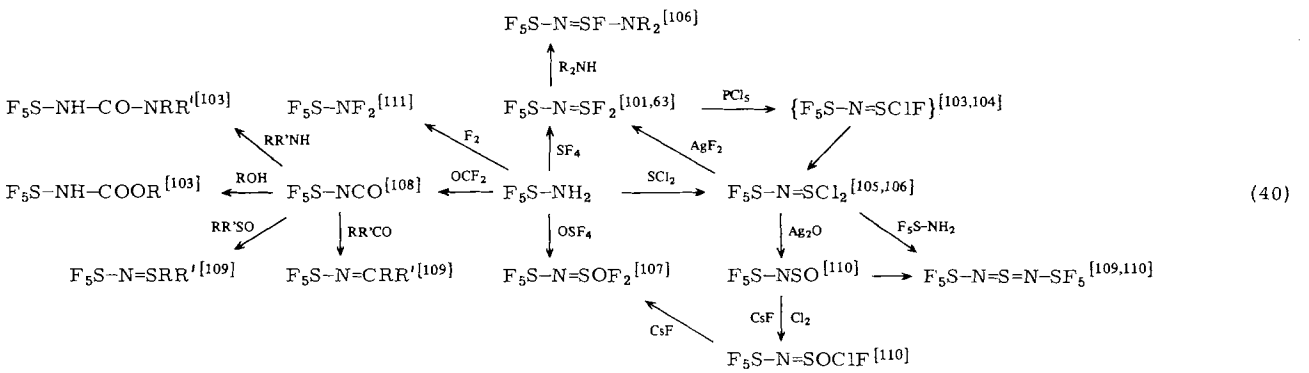
$$N{\equiv}SF_{3\,(exc.)} + ClF \longrightarrow \{Cl{-}N{=}SF_4\} \xrightarrow{ClF} F_5S{-}NCl_2 \quad (37)$$

$$1/2\ F_4S\begin{cases} Cl \\ N \\ N \\ Cl \end{cases}SF_4$$

served to have a coordination number of six. The proposed ring structure is supported by the ^{19}F-NMR spectrum, which has virtually two triplets at room temperature—originating from the axial and equatorial F atoms. The F atoms are coupled *via* the N atoms.

F_2 does not add in a similar manner. Surprisingly, fluorination of NSF_3 yields $F_5S{-}N{=}SF_4$, SF_6 and N_2[64] [Reaction (38)]. The compound $F_5S{-}N{=}SF_4$, can also be detected in traces in the photochemical reaction (23) of $F_5S{-}N{=}SF_2$ with F_2. A radical mechanism can thus be concluded for reaction (38)[99].

$$NSF_3 + F_2 \xrightarrow{RT} SF_6,\ N_2,\ F_5S{-}N{=}SF_4 \quad (38)$$



The bis(pentafluorosulfur) amines are obtained *via* $F_5S{-}N{=}SF_4$[100]:

$$(F_5S)_2NH \xleftarrow{HF} F_5S{-}N{=}SF_4 \xrightarrow{HgF_2} [(F_5S)_2N]_2Hg \quad (39)$$

The $(F_5S)_2N^{\ominus}$ ion, produced from the acid $(F_5S)_2NH$, is isoelectronic with the oxide $(F_5S)_2O$.

3.2.1. Other Pentafluorosulfur Amines

Pentafluorosulfur amine $F_5S{-}NH_2$, obtained by addition of HF to the S≡N triple bond of NSF_3 [Reaction (33)], serves as starting material for many further pentafluorosulfur amines, briefly summarized in Reactions (40).

(40)

$F_5S{-}N{=}SF_2$[101], $F_5S{-}N{=}SOF_2$[107], and $F_5S{-}NCO$[108] are synthesized directly from NSF_3 in the presence of HF; the reaction proceeds *via* $F_5S{-}NH_2$.

3.3. Reaction with Nucleophiles

Although $F^{\ominus}$ ions add to NSF to give $NSF_2^{\ominus}$ (Section 2.3.3), they do not add nucleophilically to NSF_3 to give stable $NSF_4^{\ominus}$ salts. However, NSF_3 reacts with F_2 in the presence of CsF, and with Cl_2 and HgF_2:

$$N{\equiv}SF_3 + CsF \longrightarrow \left\{Cs^{\oplus}NSF_4^{\ominus}\right\} \xrightarrow[-CsF]{F_2} F_5S{-}NF_2 \quad (41)$$

[112]

$$N{\equiv}SF_3 + HgF_2 \longrightarrow \left\{Hg(NSF_4)_2\right\} \xrightarrow[-HgCl_2]{Cl_2} F_5S{-}NCl_2 \quad (42)$$

[111]

The formation of $F_5S{-}NF_2$ by Reaction (41), and especially the simple synthesis of $F_5S{-}NCl_2$, are evidence for the NSF_4 anion being an intermediate.

In nucleophilic substitutions of NSF_3 with exchange of the fluorine atoms, the S≡N triple bond can be preserved (Section 3.3.1), or the primary product can rearrange (Section 3.3.2).

3.3.1. Substitution with Retention of the S≡N Triple Bond

Reactions of NSF_3 with amines[113,114] or with alcohols[114] give compounds which still contain the formal S≡N triple bond [Reactions (43) and (44)].

$$NSF_3 + 2\,R_2NH \xrightarrow[Et_2O]{20^{\circ}C} N{\equiv}SF_2{-}NR_2 + R_2NH \cdot HF \quad (43)$$

$$NSF_3 + C_6H_5OH \xrightarrow[Et_3N]{20^{\circ}C} N{\equiv}SF_2{-}O{-}C_6H_5 + Et_3N \cdot HF \quad (44)$$

S-Perfluoroalkyl derivatives can be synthesized by reaction with alkenes in the presence of CsF[115,48], *S*-aryl derivatives can be obtained *via* aryllithium compounds[116].

$$NSF_3 + \rangle C{=}C\langle + CsF \xrightarrow{90^{\circ}C} \left\{Cs^{\oplus}R_f^{\ominus}\right\} \xrightarrow{-CsF} N{\equiv}SF_2R_f \quad (45)$$

($R_f = (F_3C)_2CF$[115], $(F_3C)_3C$[48])

$$NSF_3 + ArylLi \xrightarrow[Et_2O]{-78^{\circ}C} NSF_2Aryl + LiF \quad (46)$$

The two alkyl derivatives rearrange at around 100 °C to give sulfur difluoride imides $R_fN{=}SF_2$. Very little is known about the physical and chemical properties of *S*-aryl compounds. The reaction with aryllithium compounds and lithium amides also leads to disubstituted derivatives of the type $NSFR_2$ (R = aryl, $N(C_6H_5)_2$) as well as to a bis(difluorothiazyl) compound [Reaction (47)][116].

$$2\,NSF_3 + Li{-}C_6H_4{-}Li \longrightarrow N{\equiv}S(F)_2{-}C_6H_4{-}S(F)_2{\equiv}N + 2\,LiF \quad (47)$$

3.3.2. Substitution with Rearrangement of the Primary Product

Stability of NSF_3: In contrast to NSF, NSF_3 is kinetically very stable; it resists hydrolysis by dilute acids and does not react with metallic sodium below *ca.* 200 °C[10]. NSF_3 closely resembles SF_6 in its behavior. In both fluorides there is a certain localization of electron density on the S atom, due to π-back bonding from the F atoms, which makes nucleophilic attack on this atom more difficult. However, electrophilic attack proceeds very rapidly. SF_6 reacts rapidly with $AlCl_3$[117], and NSF_3 reacts rapidly with BCl_3 [Reaction (48)] to give the cation $[N(SCl)_2]^{\oplus}$[43] [cf. Reaction (11)].

$$NSF_3 + BCl_3 \rightarrow [N(SCl)_2]^{\oplus}BCl_4^{\ominus} + (NSCl,\ N_2,\ Cl_2,\ BF_3,\ BF_2Cl) \quad (48)$$

$NSCl_3$ does not seem to be capable of existence, probably because the S—Cl bond energy is insufficient to incorporate all six valence electrons of sulfur.

Hydrolysis: A nucleophilic attack on the S atom in NSF_3 by $OH^{\ominus}$ ions, is possible using hot alkali [Reaction (49)][118].

$$N{\equiv}SF_3 \xrightarrow[-F^{\ominus}]{+OH^{\ominus}} \left\{\begin{array}{c} H \\ \uparrow\downarrow O \\ N{\equiv}S{-}F \\ F \end{array}\right\} \longrightarrow HN{=}S(=O){-}F \xrightarrow[-F^{\ominus}]{+OH^{\ominus}} \quad (49)$$

$$H_2N{-}SO_2F \xrightarrow[-F^{\ominus}]{+OH^{\ominus}} H_2N{-}SO_3H \xrightarrow[H^{\oplus}]{+H_2O} NH_4^{\oplus}\,HSO_4^{\ominus}$$

The first hydrolysis product is sulfur oxide difluoride imide $HNSOF_2$, whose presence was proven by precipitation of the tetraphenylphosphonium salt[119]. The second hydrolysis product, H_2NSO_2F, is related to $NSF_2{-}NHSO_2F$ [see Reaction (61)].

$HNSOF_2$ (Fig. 12a), which we described as a complex ligand (Section 3.1.2), is the parent compound of the $RNSOF_2$ series; R can be an inorganic as well as an organic group. As an acid, $HNSOF_2$ forms salts; worthy of note are the Cs[14], Ag[120] and Hg[121-123] salts, because they react with elemental halogens to give the *N*-halogen derivatives $XNSOF_2$ (X = F, Cl, Br, I)[14,121,124], for example:

$$Hg(NSOF_2)_2 + X_2 \rightarrow 2\,XNSOF_2 + HgF_2 \quad (50)$$

The halides $XNSOF_2$ and $XNSF_2$ have very similar properties. Thus, the structures of $ClNSOF_2$ (Fig. 12b) and $ClNSF_2$ (Fig. 4) are closely related to one another, and the structures of $HNSOF_2$ (Fig. 12a) and $ClNSOF_2$ (Fig. 12b) nearly agree. It should be pointed out that the structures of the isoelectronic species $HNSOF_2$, $OSOF_2$ and NSF_3 hardly differ from one another.

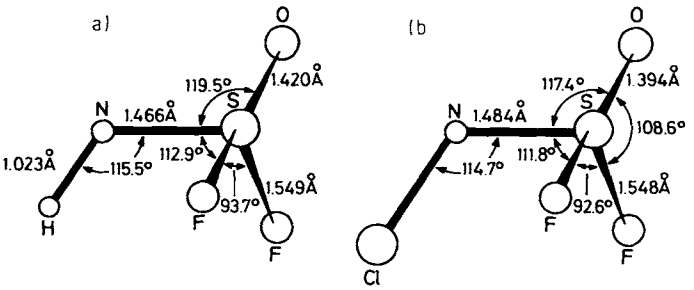


Fig. 12. Structure of a) $HNSOF_2$ (determined by microwave spectroscopy [127]) and b) $ClNSOF_2$ (determined by electron diffraction [126]).

In $HNSOF_2$ and $ClNSOF_2$, as in $ClNSF_2$, the —NH or ClN— group is *cis* to the SF_2— group, or: the lone pair on the N atom and the S=O double bond prefer the sterically favorable *cis*-arrangement. Many organic derivatives of sulfur oxide difluoride imide can be obtained by addition of $ClNSOF_2$ to C=C double bonds[128-130]. As with compounds of the type $RNSF_2$, organic sulfur oxide difluoride imides can also be produced by reaction of OSF_4 with, for example, primary amines, silylated amines, cyanates, and cyanides[8]. The reaction of $RN{=}SF_2$ with OF_2 [Reaction (24)] should also be mentioned.

Many inorganic sulfur oxide difluoride imides *e.g.* $B(NSOF_2)_3$, $[B(NSOF_2)_4]^{\ominus}$, $Sb(NSOF_2)_3$, $Si(NSOF_2)_4$, $OP(NSOF_2)_3$, and $SP(NSOF_2)_3$, can be synthesized *via* $Hg(NSOF_2)_2$—or often better *via* $AgNSOF_2$—with the corresponding chlorides[125,131-139].

$$MCl_n + n/2\ Hg(NSOF_2)_2 \xrightarrow{CH_2Cl_2} M(NSOF_2)_n + n/2\ HgCl_2 \quad (51)$$

The $NSOF_2$ group can also act as a ligand in transition metal complexes. Its tetraphenylarsonium derivative reacts with palladium acetate [140]:

$$4\ (C_6H_5)_4AsNSOF_2 + Pd(OAc)_2 \xrightarrow{CH_3OH} [(C_6H_5)_4As]_2[Pd(NSOF_2)_4] + 2\ (C_6H_5)_4AsOAc \quad (52)$$

The $NSOF_2$ group can be introduced into carbonyl transition metal complexes by using the silver salt $AgNSOF_2$[141] [Reaction (53)]. Below room temperature, $M(CO)_5NSOF_2$ (M = Mn, Re) is obtained. The Mn-compound dimerizes at

$$[Mn, Re](CO)_5Br + AgNSOF_2 \xrightarrow[<RT]{CH_2Cl_2} [Mn, Re](CO)_5NSOF_2$$

$$[Mn, Re](CO)_5NSOF_2 \xrightarrow{70\,^{\circ}C} [Mn(CO)_4NSOF_2]_2$$

$$[Mn, Re](CO)_5NSOF_2 \xrightarrow[90\,^{\circ}C]{\text{heptane}} [Re(CO)_4NSOF_2]_2 \quad (53)$$

room temperature with elimination of CO to give $[Mn(CO)_4NSOF_2]_2$, whose structure was determined[142,143] (Fig. 13). $[Re(CO)_4NSOF_2]_2$ m.p. 150 °C (decomp.) is formed analogously at 90 °C.

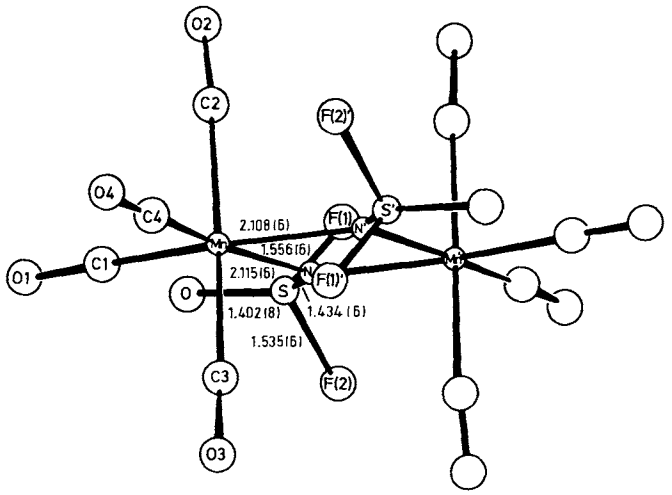

Fig. 13. Structure of $[Mn(CO)_4NSOF_2]_2$ (m.p. 130 °C, decomp.).

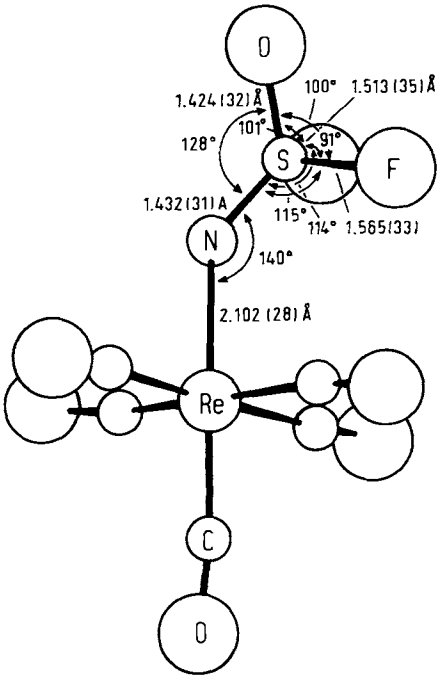
In the $NSOF_2$ bridges of the Mn compound (Fig. 13), the S—O and S—F distances are very short and similar to those in $HNSOF_2$ and $ClNSOF_2$ (Fig. 12), as well as in $Re(CO)_5NSOF_2$ (Fig. 14)[144]. The S—N distance is shorter



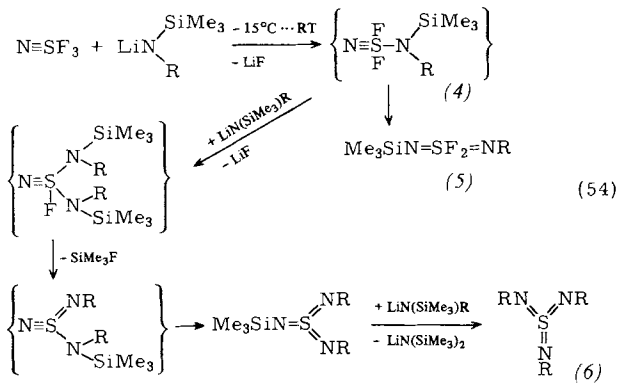


Fig. 14. Structure of $Re(CO)_5NSOF_2$ (m.p. 70 °C).

than in NSF and indicates strong (d-p)π bonds between sulfur and nitrogen. The central part of the structure containing the Mn, N and S atoms is nearly planar, the Mn_2—N_2 ring is exactly planar. All Mn—N bonds are equal and somewhat longer than the sum of the covalence radii. A Mn—Mn bond can be ruled out; the small NMnN' angle of 76° points rather to a repulsive interaction. The *cis*-arrangement of the $Re(CO)_5$— group to the F atoms in $Re(CO)_5NSOF_2$ is surprising. In this respect, the compound behaves like all $RNSOF_2$ and $RNSF_2$ species[145]. Reactions of $[Mn(CO)_4NSOF_2]_2$ which involve retention or opening of the four-membered Mn_2N_2 ring are known[146].

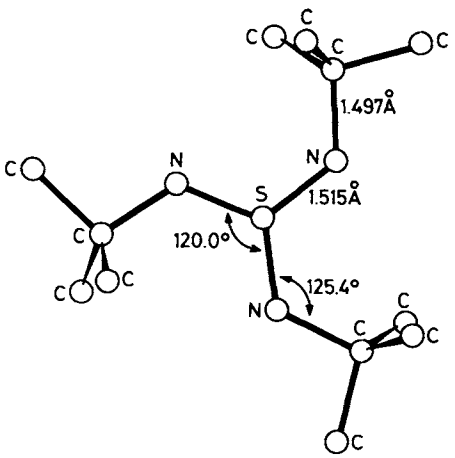
Other similar species, such as $C_5H_5Fe(CO)_2NSOF_2$ and $C_5H_5Cr(CO)_2NSOF_2$, can be produced from iodides or chlorides in accordance with Reaction (53)[147].

Reaction with LiN(SiMe$_3$)R, (R = SiMe$_3$, CMe$_3$)[148-150]: The reaction of NSF_3 with $LiN(SiMe_3)R$ gives $S(NSiMe_3)_3$ (b.p. 204 °C), $S(NCMe_3)_3$ (m.p. 52.5 °C), $S(NSiMe_3)(NCMe_3)_2$ (m.p. 110 °C), as well as $Me_3SiN{=}SF_2{=}NR$ (R = $SiMe_3$, b.p. 158 °C; R = CMe_3, m.p. 11 °C), according to choice of R and choice of reaction conditions. In this reaction, the NSF_3 molecule is attacked electrophilically at the F atom by Li, and nucleophilically at the S atom by the lone pair of the N atom, *i.e.* the silylated amide is acting as an acid as well as a base. We assume that an intermediate product *(4)* results from the cleavage of LiF; this then forms the very stable *(5)* by the migration of the $SiMe_3$ group.

With more silylated lithium amide, the intermediate product *(4)*, but not the diimide *(5)*, reacts. The final product is the sulfonylimide *(6)*, a derivative of the unknown sulfur triimide, which is isoelectronic with SO_3.

(54)

$(R_3SiN)_2SO$[151] occupies an intermediate position between SO_3 and sulfur triimide; it is obtained from OSF_4 and $LiN(SiR_3)_2$. The aza-analogues of the type $(R_3CN)_2S{=}NX$ (X = R'SO_2, F_5S, R_f[152], POF_2[153]) [Reaction (55)], are of interest; they all contain three-coordinate sulfur which has an oxidation number of +6, and have a "Y-triene" structure[154]. The bulky $SiMe_3$ group as well as the CR_3 group, stabilize low coordination states. Compounds $(RN)_3S$ with *e.g.* R = CH_3 or iC_3H_7, polymerize[150]. The molecular structure of $(tBuN)_3S$ was determined by X-ray structural analysis at −130 °C (Fig. 15)[149]. Here, as in the isoelectronic SO_3, the sulfur has a trigonal-planar coordination[155]. The σ-bonds between the S atom and the N atoms lie almost in a plane. This results in a sterically favorable arrangement for the formation of 3pπ(S)—2pπ(N) bonds. The S—N bond lengths vary between those of a single and a double bond.



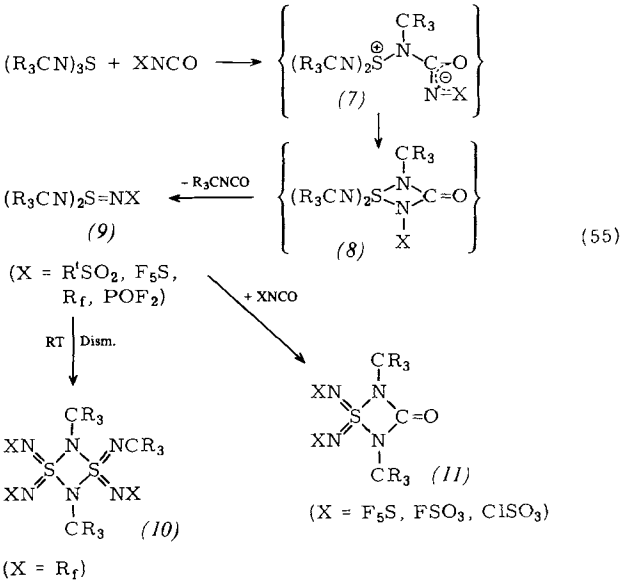


Fig. 15. "Y-triene" structure of $[(CH_3)_3CN]_3S$.

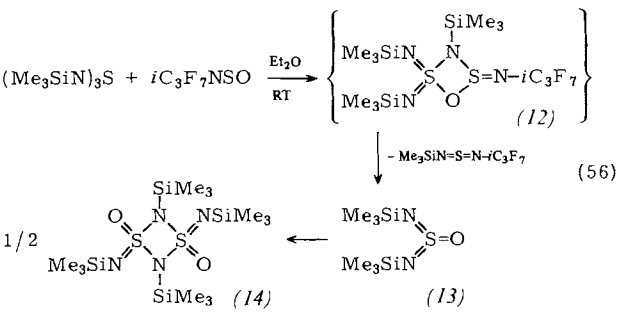
Reactions of $(Me_3SiN)_3S$ and $(R_3CN)_3S$: In both types of "Y-trienes", the S-atom is screened by the bulky Me_3Si or R_3C groups, so that its electrophilic character is ineffective. The characteristic reaction of three-coordinate sulfur compounds should—as known from SO_3—be an increase in coordination number. However, this only occurs if initially one of the N atoms is electrophilically attacked. Of interest are the reactions with isocyanates and *N*-sulfinylamines which lead to new four-membered SN-[156,157] or SNC-ring systems[152] *via* compounds with three-coordinate sulfur, *i.e.* Reactions (55) and (56).



The Y-trienes *(9)* are produced *via* the betaines *(7)* and unstable thiadiazetidinones *(8)*; they then react with excess XNCO to give the stable species *(11)*. Without a suitable co-reactant, the Y-trienes form cyclodiaza-λ⁶-thianes *(10)*.

(55)

(X = R_f)

The reactions with *N*-sulfinylamines proceed *via* similar intermediate products. The intermediate *(13)*, which is probably produced *via (12)*, dimerizes to *(14)*. The structure

(56)

of *(14)*, determined at −120 °C (Fig. 16)[157], is centrosymmetric and contains a planar S_2N_2 ring with transannular S...S and N...N distances of only 2.477 and 2.257 Å, respectively. The N atoms in the ring have pyramidal configurations. The geometry of the ring depends on the nature of the ligands; thus, the four-membered ring of derivative *(10)* is non-planar[157].

Reactions with $Me_3SiN{=}SF_2{=}NSiMe_3$: The cleavage of the Si—N bond in $Me_3SiN{=}SF_2{=}NSiMe_3$ by fluorides and

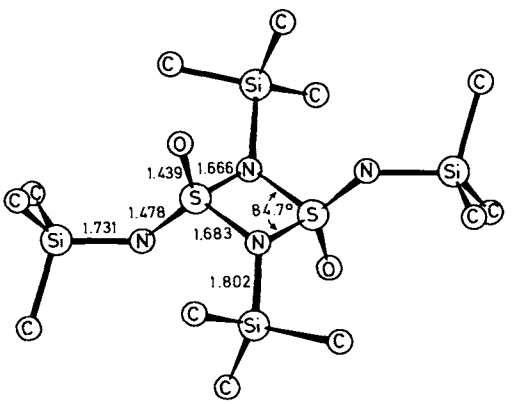


Fig. 16. Structure of the cyclodiaza-λ⁶-thiane (14).

acid anhydrides usually leads to sulfur difluoride diimides. For example, the reaction of $(F_2PO)_2O$ or $(CF_3CO)_2O$ is in accordance with Reaction (57). The monosubstituted products can be detected by NMR spectroscopy.

$$Me_3SiN{=}SF_2{=}NSiMe_3 + ROR \xrightarrow[-\,Me_3SiOR]{0\,^\circ C} \{Me_3SiN{=}SF_2{=}NR\} \quad (57)$$

$$\{Me_3SiN{=}SF_2{=}NR\} \xrightarrow[-\,Me_3SiOR]{+\,ROR} RN{=}SF_2{=}NR$$

(R = F_2P^{O} [158], F_3CC^{O} [159])

An essentially more complicated result is observed with COF_2[159], because the reactive OCF group is inclined to give secondary reactions [Reaction (58)].

$$Me_3SiN{=}SF_2{=}NSiMe_3 + OCF_2 \longrightarrow \{Me_3SiN{=}SF_2{=}NC(O)F\} \quad (58)$$

$$\{Me_3SiN{=}SF_2{=}NC(O)F\} \xrightarrow{+\,OCF_2} FC(O)N{=}SF_2{=}NC(O)F,\ FC(O)N{=}SF_2{=}N{-}C(O){-}N{=}SF_2{=}NC(O)F,$$

$$MeSiN{=}SF_2{=}N{-}C(O){-}N{=}SF_2{=}NSiMe_3$$

The difluoride diimide does not give the expected SF_3-derivative with SF_4, but *N*-(nitridodifluorosulfur) sulfur difluoride imide[160], the first sulfur-nitrogen compound containing single, double, and triple S—N bonds. This is probably formed according to Reaction (59), whose mechanism can be considered as the inversion of that of Reaction (54).

$$Me_3SiN{=}SF_2{=}NSiMe_3 + SF_4 \xrightarrow[-\,Me_3SiF]{RT} \left\{ F_3S(F)(N{-}SF)(N{-}SiMe_3) \right\} \quad (59)$$

$$\left\{ F_3S(F)(N{-}SF)(N{-}SiMe_3) \right\} \xrightarrow[-\,Me_3SiF]{RT} N{\equiv}SF_2{-}N{=}SF_2$$

The formation of the end product is easily understood from the geometry of the intermediate. An excess of SF_4 gives a mixture of *cis*- and *trans*-bis(difluorosulfinylimino)sulfur tetrafluoride $F_2SN{-}SF_4{-}NSF_2$ [Reaction (60)][161]. These compounds with six-coordinate sulfur, as

$$Me_3SiN{=}SF_2{=}NSiMe_3 \xrightarrow{+\,SF_4} \underset{trans}{F_3S(NSF_2)_2} + \underset{cis}{F_3S(NSF_2)_2} \quad (60)$$

$$N{\equiv}S{-}N{=}S(F)_2 \xrightarrow{+\,SF_4} F_3S(NSF_2)_2$$

well as $N{\equiv}SF_2{-}N{=}SF_2$, rapidly polymerize at room temperature and react explosively with water. The analogous $N{\equiv}SF_2{-}N{=}S(O)F_2$ (b.p. 93 °C) is formed from OSF_4 and $Me_3SiN{=}SF_2{=}NSiMe_3$; it attacks rubber and ignites with damp cellulose[162]. It reacts with SF_4 at 120 °C (CsF) to give a mixture of *cis*- and *trans*-$F_2SN{-}SF_4{-}NS(O)F_2$, which can be stored for days at room temperature in a glass vessel without decomposition[161].

Hydrolysis of NSF_2NSOF_2: Reactions of $NSF_2{-}NSOF_2$ offer an interesting comparison between the reactivity of the $N{\equiv}SF_2{-}$ and $NS(O)F_2{-}$ groups. When hydrolyzed[162], the $NS(O)F_2{-}$ group is attacked [Reaction (61)]; the hydrolysis product can be trapped as the tetraphenylarsonium salt. Three tautomeric forms (*G*), (*H*) and (*K*), can be formulated for the free salt, which has hitherto not been isolated. According to the bond lengths in the anion, determined by X-

$$N{\equiv}S(F){-}N{=}SF_2(O) \xrightarrow[-\,F^{\ominus}]{+\,OH^{\ominus}} \{N{\equiv}SF_2{-}NS(O)F(OH)\} \longrightarrow \quad (61)$$

$$N{\equiv}S(F){-}N{=}S(F)(O){-}OH \qquad N{\equiv}S(F){-}NH{-}S(F)(O){-}F \qquad HN{=}S(F){-}N{=}S(F)(O){-}F$$

(*G*) (*H*) (*K*)

ray analysis[163] (Fig. 17), (*H*) is the most important tautomer $[d(N_1S_1) < d(N_2S_2) < d(N_2S_1)]$. The two isoelectronic groups $N{\equiv}SF_2{-}$ and $-SO_2F$ form two tetrahedra connected by the same N atom; the structure is very similar to that of inorganic μ-oxoanions $X_2O_7^{y\ominus}$.

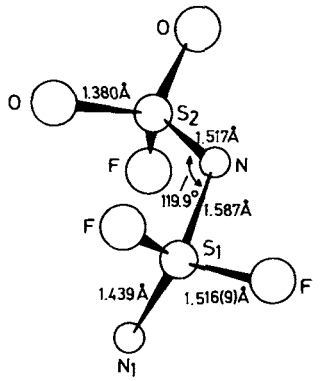

Fig. 17. Structure of the $NSF_2{-}NSO_2F^{\ominus}$ ion.

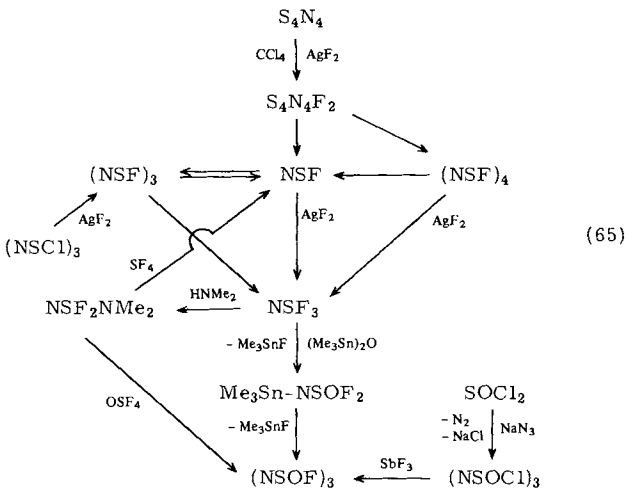
In this connection, one should remember the hydrolysis of NSF_3, which proceeds *via* the non-isolable $H_2N{-}SO_2F$ [Reaction (49)]. The acid generated by hydrolysis of $NSF_3{-}NSOF_2$ [Reaction (61)] can be formulated as $HNR{-}SO_2F$ with $R = NSF_2$; the structure of its anion (Fig. 17) can be regarded as proof of the occurrence of $H_2N{-}SO_2F$.

Just how versatile the chemistry of sulfur-nitrogen-fluorine acids, such as $NSF_2{-}NH{-}SO_2F$, can be, is shown for example, by the far better investigated isoelectronic $HN(SO_2F)_2$[164], which can also be produced by hydrolysis of $FSO_2{-}N{=}SOF_2$ (formed from H_2NSO_2F and OSF_4). The range of application reaches from organometallic to noble-gas chemistry. The $N(SO_2F)_2$ group can be introduced as a ligand into transition metal complexes *via* the silver salt[165, 166]. Substitution reactions using ligands such as

$$M(CO)_5Br + AgN(SO_2F)_2 \xrightarrow[-\,AgBr]{CH_2Cl_2} M(CO)_5N(SO_2F)_2 \quad (62)$$

(M = Mn, Re)

$$C_5H_5Cr(NO)_2Cl + AgN(SO_2F)_2 \xrightarrow[-\,AgCl]{} C_5H_5Cr(NO)_2N(SO_2F)_2 \quad (63)$$



CH_3CN, Ph_3P and Ph_3As[166], have been carried out on the complexes obtained by Reactions (62) and (63). The reaction with XeF_2 [Reaction (64)], gives the remarkable $FXeN(SO_2F)_2$, the first xenon species with a Xe—N bond[167].

$$XeF_2 + HN(SO_2F)_2 \xrightarrow[0\,^\circ C/4\ h]{CF_2Cl_2} FXeN(SO_2F)_2 + HF \quad (64)$$

4. Cyclic Compounds[3, 5, 8, 9, 168–171]

From the abundance of compounds containing sulfur, nitrogen and fluorine, we want to pick out $(NSF)_4$, $(NSF)_3$ and $(NSOF)_3$, since the chemistry of these three compounds is closely related to that of NSF and NSF_3, as shown by Reaction scheme (65).

Fluorination of S_4N_4 using AgF_2 in CCl_4, produces the eight-membered ring $(NSF)_4$[2], probably, as new work

(65)

shows, *via* the intermediate $N_4S_4F_2$[172]. Up to now, $(NSF)_4$ could only be synthesized from S_4N_4, which also has an eight-membered ring. At 300 °C *in vacuo*, or when heated in CCl_4, $(NSF)_4$ dissociates into NSF, which then trimerizes, as already known, to give the six-membered ring $(NSF)_3$[173]. Its formation by decomposition of $S_4N_4F_2$ is also conceivable. Preparatively, the Cl→F exchange of $(NSCl)_3$ using AgF_2[174], is better.

The fluorination of NSF and its cyclic derivatives gives NSF_3, which reacts with hexamethylstannoxane to give $Me_3Sn—NSOF_2$. The decomposition of this sulfur oxide difluoride imide at room temperature leads quantitatively to $(NSOF)_3$[132]. Other sulfur oxide difluoride imides decompose likewise under certain reaction conditions into $(NSOF)_3$ as well as polymeric rubber-like $(NSOF)_x$, which is isoelectronic with $(PNF_2)_x$[171].

$(NSOF)_3$ can be obtained by fluorination of $(NSOCl)_3$ using SbF_3. Furthermore, by starting from NSF_3, it is possible to obtain $(NSF)_3$ and $(NSOF)_3$ *via* the amine $NSF_2(NMe_2)$. The amine reacts with SF_4 as well as with OSF_4 to give $F_5S—NMe_2$ along with NSF in the first case, and $(NSOF)_3$ in the second[107].

Figure 18 shows the structures of $(NSF)_4$[175], $(NSF)_3$[176] and α-$(NSOCl)_3$[177], determined by X-ray analysis. The structure of α-$(NSOF)_3$ *(cis)* is not yet known, but it may correspond to the structure of α-$(NSOCl)_3$[178].

The $(NSF)_4$ molecule is a puckered eight-membered ring, with alternating S—N bond lengths of 1.66 and 1.54 Å; two F atoms are axial, two are equatorial. The structures of $(NSF)_3$ and $(NSOCl)_3$ are very similar to each another; the six-membered rings have a chair configuration with uniform S—N bond lengths of 1.593 and 1.571 Å, respectively. The halogen atoms are axial *(cis)*; the lone pairs on the N and S atoms of $(NSF)_3$ occupy equatorial *(trans)* positions, like the O atoms and lone pairs on the N atoms of $(NSOCl)_3$.

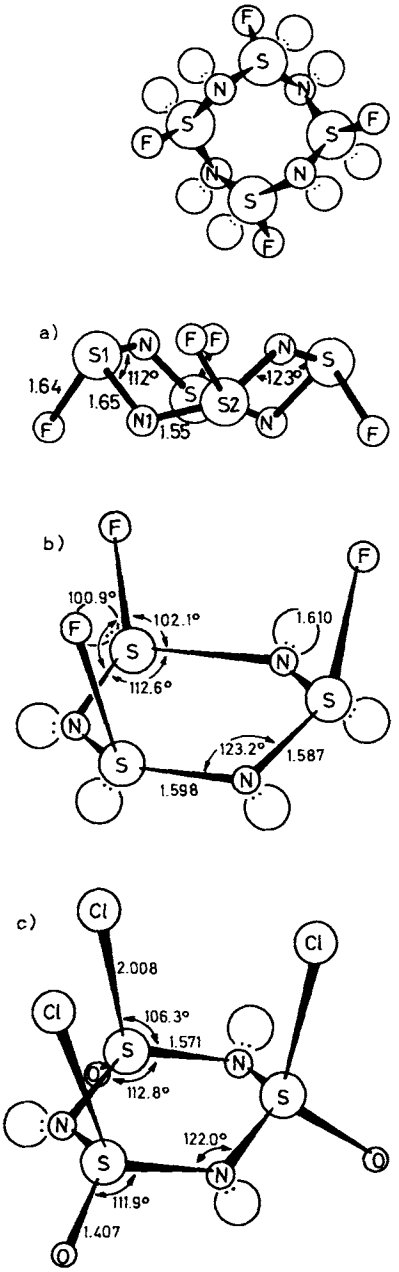


Fig. 18. Structure of a) $(NSF)_4$, b) $(NSF)_3$ and c) α-$(NSOCl)_3$.

The angles at the N and S atoms are almost the same in all three ring systems (similar hybridization of the orbitals). Thus, the chair configuration of the six-membered ring of $(NSF)_3$ becomes the puckered, compact structure of the eight-membered $(NSF)_4$ ring, which, for steric reasons has axial and equatorial F atoms. This is probably due to the repulsive effect of their lone pairs, which are somewhat displaced from one another (Fig. 18a), so that the NSF angles of 91.8° (F—S1—N1) and 106.2° (F—S2—N2) alternate. The same repulsive effect causes the lengthening of four of the eight S—N bonds[179].

The uniform S—N bond lengths in $(NSF)_3$ and $(NSOCl)_3$ could, according to *Dewar et al.*[180], be caused by three islands of delocalized SNS-π-bonds [(d-p)π][171], which originate from three-centered two-electron π-bonds between an N atom and two S atoms. Transannular interaction between the S atoms (Fig. 18) probably occurs in the rings[181].

The repulsive effect of the lone pairs, especially on the π-bonds of the ring, reaches a minimum in the *cis*-structure found for $(NSF)_3$. However, in $(NSOCl)_3$, the repulsive action of the electrons in the S=O double bond is certainly weaker than that of the lone pairs on the S atoms; *i.e.* $(NSOCl)_3$ can form other isomers than the *cis*-form. In accordance with this, only the *cis*-form is found for $(NSF)_3$, whilst in $(NSOCl)_3$ and $(NSOF)_3$, *cis*- and *trans*-isomers have been observed. The *cis*-isomer however, should be the most energetically favorable configuration. This we could prove by an isomerization reaction: At room temperature, in the presence of $F^{\ominus}$ ions (NH_4F, KF) in acetonitrile, pure *cis*- or pure *trans*-$(NSOF)_3$ gave an equilibrium mixture of 75% *cis*- and 25% *trans*-$(NSOF)_3$[182], by an S_N2 reaction with inversion at sulfur (Fig. 19). From the temperature dependency of the equilibrium constant, the conversion enthalpy was found to be $\Delta H_c = 5.5 \pm 1.4$ kJ/mol[182].

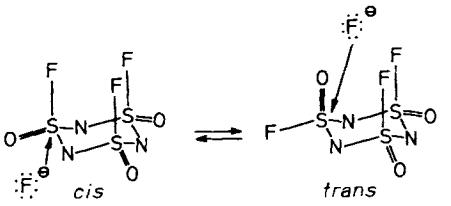

Fig. 19. Equilibrium mixture obtained from the isomerization of *cis*- or *trans*-$(NSOF)_3$.

$(NSF)_3$ should be more stable than $(NSF)_4$, due to the delocalized π-bonds. This was confirmed by the chemical behavior [see *e.g.* Reactions (66) and (67)].

$$(NSF)_4 + 2\,MF_5 \rightarrow N_3S_3F_2^{\oplus}MF_6^{\ominus} + NS^{\oplus}MF_6^{\ominus} \quad (66)$$

$$(NSF)_3 + MF_5 \rightarrow N_3S_3F_2^{\oplus}MF_6^{\ominus} \quad (67)$$

(M = As, Sb)

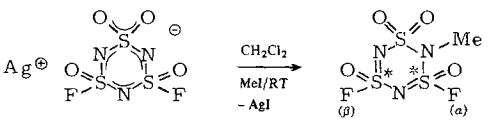
The cation $N_4S_4F_3^{\oplus}$ is unstable, the eight-membered ring loses an NS unit to form the more stable cation $N_3S_3F_2^{\oplus}$; only the $MF_6^{\ominus}$ salts of this cation are produced from the reaction of $(NSF)_3$ with Lewis acids MF_5[183]. However, $(NSF)_4$ is less sensitive than $(NSF)_3$ to hydrolysis. Nucleophilic attack on the S atom is more difficult with the tetramer than with the trimer, due to its compact structure. The trimer is, like its starting material NSF, strongly hygroscopic.

So far, our experiments show that of the three ring systems $(NSF)_4$, $(NSF)_3$, and $(NSOF)_3$, only the last is suitable for substitution reactions with retention of the ring structure[184]. The delocalized π-bond stabilizes the S—N ring; the S=O double bond and the eventual back-bonding by the F atoms produce a certain electron density on the S atom, which, as in the case of NSF_3, makes nucleophilic attack on this atom more difficult. Moreover, the S atom in $(NSOF)_3$ has a higher coordination number than in $(NSF)_4$ and $(NSF)_3$.

4.1. Some Reactions of $(NSOF)_3$[171]

Fluorination of $(NSOCl)_3$ by SbF_3 yields a mixture of *cis*- and *trans*-isomers of $(NSOF)_3$, along with a little $(NSOF)_2(NSOCl)$ and $(NSOF)(NSOCl)_2$, each of which form three isomers[185]. A mixture of *cis*- and *trans*-$(NSOCl)_3$ is best synthesized[186] according to Reaction (68). As was anticipated, $(NSOF)_3$ is relatively resistant to attack by water.

$$SOCl_2 + NaN_3 \xrightarrow[CH_3CN]{-35\,^{\circ}C} \{N_3SOCl\} + NaCl \xrightarrow[-N_2]{0\cdots30\,^{\circ}C} 1/3\,(NSOCl)_3 \quad (68)$$



Only boiling sodium hydroxide solution hydrolyzes it to amidosulfuric acid and ammonia[187]; an intermediate product can be precipitated as the tetraphenylphosphonium salt (*cis*- and *trans*-form) according to Reaction (69)[188, 189]:

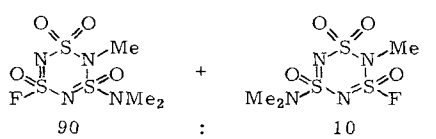
$$(NSOF)_3 + OH^{\ominus} + Ph_4PCl \xrightarrow[12\,h]{100\,^{\circ}C} Ph_4P^{\oplus}[N_3S_3O_3F_2O]^{\ominus} + HCl + F^{\ominus} \quad (69)$$

The remarkable cyclic anion $[N_3S_3O_3F_2O]^{\ominus}$ can also be obtained by alcoholysis of $(NSOF)_3$ in the presence of NMe_3.

$$(NSOF)_3 + MeOH + 2\,NMe_3 \xrightarrow[Et_2O]{-20\,^{\circ}C} NMe_4^{\oplus}[N_3S_3O_3F_2O]^{\ominus} + NMe_3HF \quad (70)$$

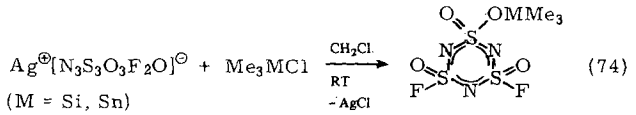
The free acid can be isolated as the oxonium salt $H_3O^{\oplus}[N_3S_3O_3F_2O]^{\ominus}$, by ion exchange and subsequent evaporation of the aqueous solution[188]. The silver salt is obtained with Ag_2CO_3; it reacts with alkyl iodides[190] according to Reaction (71).

(71)



The proposed structure is based on the ^{19}F-NMR spectrum[191]. The compound has two asymmetrical S atoms; their chirality was demonstrated with the help of the chiral 2-butanol[192] using ^{19}F-NMR.

An analogous reaction[193] to (70) is observed with the amino derivative $N_3S_3O_3F_2NMe_2$:

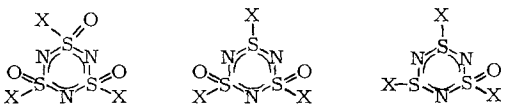


$$N_3S_3O_3F_2NMe_2 + MeOH + 2\,NMe_3 \xrightarrow[CH_3CN]{60\,^{\circ}C} NMe_4^{\oplus}[N_3S_3O_3F(O)NMe_2]^{\ominus} + NMe_3HF \quad (72)$$

After preparation of the free acid, and its conversion to the silver salt, it reacts with MeI to give two isomers in the ratio of 9:1 [Reaction (73)]. The principal isomer shows no coupling in its ^{19}F-NMR spectrum; therefore, the methyl groups on the ring and the SOF-group are in a 1,4-position.

$$Ag^{\oplus}[N_3S_3O_3F(O)NMe_2]^{\ominus} \xrightarrow[MeI/RT]{CH_2Cl_2} \quad (73)$$

The silver salt reacts in quite a different way with organometallic halides[193] [Reaction (74)], the cation $Me_3M^{\oplus}$ is bound to an O atom of the anion. The ^{19}F-NMR spectrum

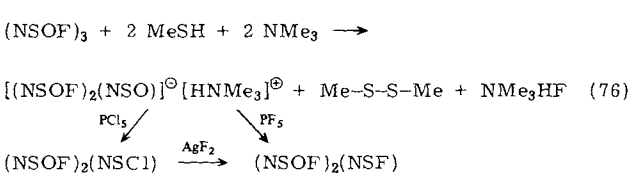


(74)

shows both F atoms to be equivalent (*cis* form), and in the ^{29}Si-NMR spectrum there is no coupling with fluorine. In addition, the chemical shift lies in the region for Si—O bonds. The O—M bond is energetically favorable here.

Ammonia in ether reacts with $(NSOF)_3$ to give $N_3S_3O_3F_2NH_2$, from which various derivatives $N_3S_3O_3F_2R$ can be made, with *e.g.* $R = NSF_2$, $NSOF_2$, $NSCl_2$, $NPCl_3$, $N{=}CHPh$[194, 195].

$(NSOF)_3$ reacts with secondary amines to give tri-, di-, and monosubstituted products[196, 197], depending on the experimental conditions; primary amines usually give only mono-, and rarely trisubstituted products. Primary amines form adducts with the substitution product; the free amine is obtained by cleavage of the adduct in an ether suspension, using hydrogen chloride[197]. Ring systems can be produced from $(NSOF)_3$, which contain sulfur with coordination numbers of three and four, with corresponding oxidation numbers of +4 and +6.



(75)

(15) *(16)* *(17)*

X = F, Cl	X = F, Cl	X = F, Cl
$(NSOX)_3$	$(NSOX)_2(NSX)$	$(NSOX)(NSX)_2$
$(NSOCl)_2(NSOF)$		
$(NSOCl)(NSOF)_2$		
cis-trans-isomers	*cis-trans*-isomers	no isomers

The ring system (15) was briefly mentioned in Reaction (68). The species *(16)* is obtained in good yield[188] by Reaction (76). An alternative method is the reaction of

(76)

$N_3S_3O_3F_2NH_2$ with $SOCl_2$[195]. Further compounds of the type *(16)* and *(17)* were obtained by reaction of $S_3N_2O_2$ with liquid chlorine[198, 199] and subsequent selective fluorination with SbF_3.

In agreement with our thoughts on the occurrence and non-occurrence of isomers of $(NSOF)_3$ and $(NSF)_3$, we find *cis-trans* isomers in the case of *(15)* and *(16)*, which, respectively contain three and two S(O)F groups; *(17)*, which only has one S(O)F group, forms no isomers.

5. Conclusion

The present review article identifies the two molecules NSF and NSF_3 as key compounds in sulfur-nitrogen-fluorine chemistry. Not only almost all known linear fluorinated "thiazenes" (azathienes), but also cyclic oligomers and polymers can be derived from them by addition reactions at the formal S≡N triple bond and by substitution and rearrangement reactions. The types of derivatives are multifarious: they embrace purely "inorganic" to "almost organic" species, organometallic compounds, complexes, and salts. The numerous possible reactions and the novel types of bonding that are observed give a good indication of how this area of chemistry is capable of extension, both from the standpoint of the chemistry of the main group elements—which has recently attracted revived interest—as well as by the use of sulfur nitrogen-fluorine compounds as unusual ligands in transition metal complexes. It is especially worth mentioning that reactions with these complex ligands are possible[31].

X-ray structural analyses and spectroscopic data provide information on the character of the bonding between sulfur and nitrogen. We have found relatively long as well as very short SN bonds; we plan to check which factors influence the SN bond length and those upon which the geometry of the R—SN moiety depends[200]. Finally, it should also be mentioned that the physiological properties of the species mentioned here have scarcely been investigated.

We thank the co-workers cited in our publications, who have contributed by their research to the development of this area. The work of our research group was supported by the Deutsche Forschungsgemeinschaft, the Stiftung Volkswagenwerk, the Fonds der Chemischen Industrie and the Akademie der Wissenschaften in Göttingen as well as by the Mittel des Landes Niedersachsen.

[31] A fluoride ion can be cleaved from the complex obtained by Reaction (8), as with free NSF, by using fluoro-Lewis acids at $-30\,^{\circ}C$ in liquid SO_2 (*R. Mews, C. S. Liu,* unpublished):

$$[Re(CO)_5NSF]^{\oplus}AsF_6^{\ominus} + AsF_5 \rightarrow [Re(CO)_5(NS)]^{2\oplus}[AsF_6^{\ominus}]_2$$

If silylamines or halides are used, the fluorine can be exchanged to form, for example, $[Re(CO)_5NSN(CH_3)_2]^{\oplus}$ or $[Re(CO)_5NSCl]^{\oplus}$ (*R. Mews,* unpublished).

Dalton Trans. *1976*, 928. The first given heart-shaped structure for $S_5N_5^{\oplus}$ can presumably be explained by a disordering of the azulene structure in the solid state: *A. J. Banister, J. A. Durant,* J. Chem. Res. (M) *1978*, 1931.

[43] *O. Glemser, B. Krebs, J. Wegener, E. Kindler,* Angew. Chem. *81*, 568 (1969); Angew. Chem. Int. Ed. Engl. *8*, 598 (1969). Furthur syntheses from SCl_2, $(NSCl)_3$ and MCl_3 (M = Fe, Al): *O. Glemser, J. Wegener,* Inorg. Nucl. Chem. Lett. *7*, 623 (1971); *G. G. Alange, A. J. Banister, P. J. Dainty, ibid. 15*, 175 (1979).

[44] The S—N distance and S—N—S angles in sulfur-nitrogen compounds should follow a linear function (*A. J. Banister, J. A. Durant,* J. Chem. Res. (M) *1978*, 1912). However, the values found for the cation $[N(SCl)_2]^{\oplus}$ do not fulfill a linear relationship. To conclude from this (like *Banister et al.*) that the structure determination is incorrect is unjustified, since on the one hand a strong deviation from linearity has been observed with other species, especially cations, and on the other an X-ray structural analysis of $[N(SCl)_2]^{\oplus}AlCl_4^{\ominus}$ (*O. Glemser, E. Kindler, B. Krebs, R. Mews, F. M. Schnepel, J. Wegener,* Z. Naturforsch. *B 35*, 657 (1980)) confirms the earlier reported structure [43]; cf. also *F. M. Sheppel,* Spectrochim. Acta, in press.

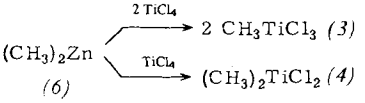
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Geminal Dialkylation of Ketones with Grignard Compounds and Methyltitanium(IV) Chlorides[**]



By *Manfred T. Reetz, Jürgen Westermann,* and *Rainer Steinbach*[*]

While alkyltitanium(IV) compounds are used in combination with alkylaluminum compounds as Ziegler-Natta polymerization catalysts, practically nothing is known concerning their utility as reagents in preparative organic chemistry[1a]. We describe here their use for the geminal dialkylation of ketones. Reaction of *tert*-alkyl chlorides *(2)*, which are readily accessible from the ketones *(1)*, with methyltitanium trichloride *(3)* or dimethyltitanium dichloride *(4)* at $-30\,^{\circ}C$ to room temperature leads to replacement of chlorine by the methyl group with formation of the desired product *(5)* containing a quaternary C-atom.

(1) *(2)* *(5)*

In order to optimize the decisive *tert*-alkylation *(2)*→*(5)* we have developed three methods (A, B, C). Although alkyltitanium(IV) compounds are accessible from titanium tetrachloride and the usual organometallic precursors such as alkyl-lithium and -magnesium compounds, we found it more

(6)

economical to use dimethylzinc *(6)*, which is readily obtainable from methyl iodide and zinc, and which reacts quantitatively with titanium tetrachloride to give *(3)* or *(4)*[1a]. The results of the reactions of *(2)* with *(3)* (method A), with *(4)* (method B), and with *(6)* in the presence of *catalytic* amounts of titanium tetrachloride (method C) are collected in Table 1.

Table 1. Geminal alkylation of ketones *(1)* via *tert*-alkyl chlorides *(2)* [a].

	(1)	R^3	Method [b]		*(5)*	Yield [%] [c]
(1a)	Cyclopentanone	Methyl	C	*(5a)*	1,1-Dimethylcyclopentane	88
(1b)	Cyclohexanone	Methyl	A	*(5b)*	1,1-Dimethylcyclohexane	80
(1b)	Cyclohexanone	Methyl	B	*(5b)*	1,1-Dimethylcyclohexane	85
(1b)	Cyclohexanone	Methyl	C	*(5b)*	1,1-Dimethylcyclohexane	93
(1b)	Cyclohexanone	*n*-Butyl	C	*(5c)*	1-Butyl-1-methylcyclohexane	95
(1b)	Cyclohexanone	Ethyl	C	*(5d)*	1-Ethyl-1-methylcyclohexane	90
(1b)	Cyclohexanone	Cyclohexyl	C	*(5e)*	1-Cyclohexyl-1-methylcyclohexane	66
(1c)	4-*tert*-Butylcyclohexanone	Methyl	C	*(5f)*	4-*tert*-Butyl-1,1-dimethylcyclohexane	86
(1d)	Cycloheptanone	Methyl	A	*(5g)*	1,1-Dimethylcycloheptane	70
(1e)	Cyclooctanone	Methyl	A	*(5h)*	1,1-Dimethylcyclooctane	72
(1f)	Cyclododecanone	Methyl	C	*(5i)*	1,1-Dimethylcyclododecane	90
(1g)	Acetone	*n*-Propyl	C	*(5j)*	2,2-Dimethylpentane	74
(1h)	3-Methyl-2-butanone	Methyl	C	*(5k)*	2,2,3-Trimethylbutane	63
(1i)	3-Pentanone	Ethyl	C	*(5l)*	3-Ethyl-3-methylpentane	78
(1j)	2-Hexanone	Methyl	C	*(5m)*	2,2-Dimethylhexane	77
(1k)	3-Hexanone	Methyl	C	*(5n)*	3,3-Dimethylhexane	79
(1l)	2-Heptanone	*n*-Butyl	C	*(5o)*	5,5-Dimethyldecane	95
(1l)	2-Heptanone	Methyl	B	*(5p)*	2,2-Dimethylheptane	83
(1m)	4-Heptanone	Methyl	C	*(5q)*	4,4-Dimethylheptane	85
(1n)	1-Adamantyl methyl ketone	Methyl	C	*(5r)*	1-*tert*-Butyladamantane	97
(1o)	*cis*- + *trans*-2-Decalone	Methyl	C	*(5s)*	*cis*- + *trans*-2,2-Dimethyldecalin	73
(1p)	3-Cholestanone	Methyl	C	*(5t)*	3,3-Dimethylcholestane	92
(1q)	2-Adamantanone	Methyl	C	*(5u)*	2,2-Dimethyladamantane	92

[a] The ketones *(1)* were conventionally converted by Grignardation and subsequent chlorination with HCl or PCl_5 into the *tert*-alkyl chlorides *(2)*. [b] Method A: with CH_3TiCl_3 *(3)*, B: with $(CH_3)_2TiCl_2$, C: with $(CH_3)_2Zn$ *(6)* + catalytic amounts of $TiCl_4$. Solvent: dichloromethane; 1,2-dichloromethane is also suitable. [c] Yield of isolated *(5)* based on *(2)*.

Table 1 clearly demonstrates that numerous ketones can be geminally dialkylated, methods B and C being more suitable than method A. Thus, 1,1-dialkylcycloalkanes as well as the derivatives of bi- and polycyclic ketones such as 2-decalone, 3-cholestanone, and 2-adamantanone are readily accessible for the first time. In case of open-chain branched *tert*-alkyl chlorides *(2)* the C—C coupling takes place exclusively

at the tertiary C-atom; this is not the case in Friedel-Crafts reactions with these compounds[2].

The advantage of the method is also evidenced by further examples[3]. In contrast, the few known reactions of *tert*-alkyl halides with alkyl-sodium[1b], -magnesium[1b] or -zinc compounds[1b] and with cuprates[4a] proceed, generally, only with preparatively poor yields (10—50%). A reaction of simple *tert*-alkyl halides with trimethylaluminum was not carried out on a preparative scale[4b]. Reaction of 2-chloro-2-methylheptane with triethylaluminum affords 3,3-dimethyloctane, which was isolated in 21% yield[5]. Related reactions with trialkynylaluminum compounds proceed in good yields, but have the disadvantage that only *one* organic group is transferred[6]. Noteworthy is also the exhaustive methylation of carbonyl compounds according to *Meisters* and *Mole,* which requires a large excess of trimethylaluminum under pyrolytic conditions (120—180 °C) and leads to moderate yields of product[7]. Other synthetic strategies are less productive or have only been tested on a few simple examples[8].

In generalizing our method we make use of the working hypothesis that the metal must be *an effective Lewis acid* and the organic group a *weak Lewis base.* The conventional alkyl-lithium, -sodium, or -magnesium compounds are unsuitable, since in the case of *tert*-alkyl halides they induce undesired olefin-forming HX elimination owing to their weak Lewis acid or strong Lewis base centers.

Procedure

(5i) according to Method C *via* 1-chloro-1-methylcyclododecane: A mixture of 1-methyl-1-cyclododecanol (23.8 g, 120 mmol) (obtained in 88% yield from cyclododecanone *(1f)*[9]) and zinc chloride (700 mg) in dry ether (50 ml) is saturated with HCl gas at 0 °C[10]. After one hours' stirring at 0 °C the mixture is treated with ice-cold water, neutralized with sodium carbonate, the aqueous phase extracted twice with ether, the combined organic phases dried over sodium sulfate, the solvent removed by evaporation and the residue recrystallized from ethyl acetate: 22.0 g (87%) 1-chloro-1-methylcyclododecane, m.p. 76 °C.

(6), obtained from methyl iodide and zinc[1c], is diluted to about 5 mol/l with dry CH_2Cl_2 at 0 °C in a flask fitted with a serum cap; this solution can be stored in a refrigerator for weeks[11].—To a solution of *(6)* (12 mmol) in CH_2Cl_2 at −30 °C is added 0.44 ml (4 mmol) of $TiCl_4$ and the mixture treated dropwise and slowly with a cold solution of 1-chloro-1-methylcyclododecane (4.34 g, 20 mmol) in CH_2Cl_2. After about 30 minutes' stirring the reaction mixture is poured into ice-water, the organic phase separated off, and the aqueous phase extracted twice with CH_2Cl_2. The combined organic phases are washed with sodium carbonate solution and dried over sodium sulfate. Distillation (136 °C/11 torr) affords 3.5 g (90%) *(5i)*; ^{1}H-NMR (CCl_4): $\delta = 0.81$ (s, 6H), 1.33 (m, 22H).

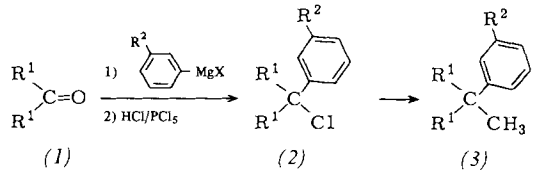
Chemoselective and Position Specific Methylation of *tert*-Alkyl Halides with Methyltitanium(IV) Chlorides[**]

By *Manfred T. Reetz, Jürgen Westermann,* and *Rainer Steinbach*[*]



tert-Alkyl chlorides obtainable from ketones are smoothly alkylated by methyltitanium(IV) chlorides[1]. We report here on continuing investigations being carried out, *inter alia,* on especially sensitive compounds. First, the chemoselectivity of the reactions of α,α-dialkylbenzyl chlorides [*(2)*→*(3)*] was investigated in which competing Friedel-Crafts self-alkylations as well as HCl-eliminations are to be expected. The conversion of *(2)* into *(3)* was carried out with methyltitanium trichloride (method A), dimethyltitanium dichloride (method B), or dimethylzinc in the presence of catalytic amounts of titanium tetrachloride (method C)[1] (Table 1).

Whereas method A at −30 °C to room temperature favors a reaction course leading to the aforementioned undesired reactions[2], at −78 °C the yields of the desired products are good to very good (Table 1). The reaction sequence *(1)*→*(2)*→*(3)* not only makes the geminal dialkylation of ketones possible, but also provides an easy access to the *meta*-substituted derivatives previously not obtainable by Friedel-Crafts alkylation.

Also worth noting is the chemoselectivity in case of alkyl chlorides which contain an additional *primary* or *secondary* alkyl chloride unit. Thus *(4a), (4b),* and *(6)* react according to method B *only* at the tertiary C-atom with formation of *(5a), (5b)* and *(7)* in 81, 74, and 61% yield, respectively.

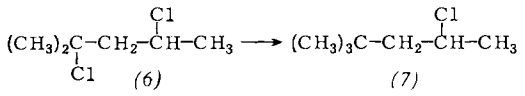
(1) (2) (3)

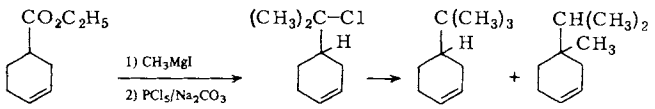
Table 1. Methylation of α,α-dialkylbenzyl chlorides *(2)* to *(3)* at −78 °C.

R^1	R^2	Method [a]	*t* [min]		Yield [%] [b]
CH_3	H	A	30	*(3a)*	70
CH_3	H	C	15	*(3a)*	91
CH_3	CH_3	A	20	*(3b)*	90
[c]	CH_3	C	20	*(3c)*	85
C_2H_5	H	A	20	*(3d)*	62
C_6H_5	H	C [d]	20	*(3e)*	95



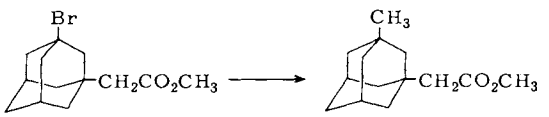
[a] Methods A, B, C, see text. [b] Yield of *(3)* isolated. [c] $-R^1-R^1-=-(CH_2)_5-$. [d] At 0 °C.

In order to check whether olefinic double bonds are also tolerated, the ester *(8)* was first converted by conventional methods into *(9)*. At −30 °C, method C (5 mol% $TiCl_4$) yields



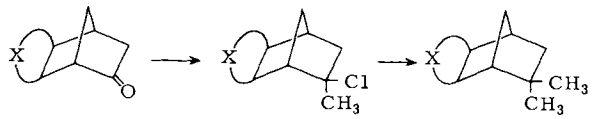
(4) *(5)*

(a), n = 2; *(b)*, n = 3



(6) *(7)*

1:1 mixtures of *(10)* and *(11)*. Although the double bond is not attacked, an undesired 1,2-hydride shift occurs. In contrast, at −78 °C a position specificity of 90% and a yield of *(10)* + *(11)* of 73% are realized. Hence, low temperatures and smallest possible amounts of effective Lewis acid ($TiCl_4$) suppress the 1,2-hydride shift almost completely.



(8) *(9)* *(10)* *(11)*

Alkylations are also possible in the presence of ester functions. However an additional equivalent of titanium tetrachloride is required to ensure that maximum yields are achieved, since otherwise methyltitanium trichloride is partially complexed or deactivated by the ester groups. Thus, *(12)* reacts with a 1:1 mixture of CH_3TiCl_3 and $TiCl_4$ chemoselectively to give *(13)* with a conversion of 95% (87% isolated), whereas without $TiCl_4$ only 10% of *(13)* is formed[2].

(12) *(13)*

Finally, we investigated the position specificity in the case of two further rearrangeable systems. The *tert*-alkyl chloride *(15a)*, readily obtainable from 2-norbornanone *(14a)*[3], reacts smoothly according to method B to give *(16a)* in 89% yield. Position specificity is also observed in the methylation *(15b)*→*(16b)* (87%); skeletal rearrangements to adamantyl derivatives[4] do not occur.

(14) *(15)* *(16)*

(a), X = 2 H; *(b)*, X = $-(CH_2)_3-$

Thus, the titanium-induced methylation of *tert*-alkyl halides constitutes a mild and general C—C coupling method. Not only ketones and carboxylates are suitable starting compounds, but also olefins which form *tert*-alkyl chlorides by HCl-addition.

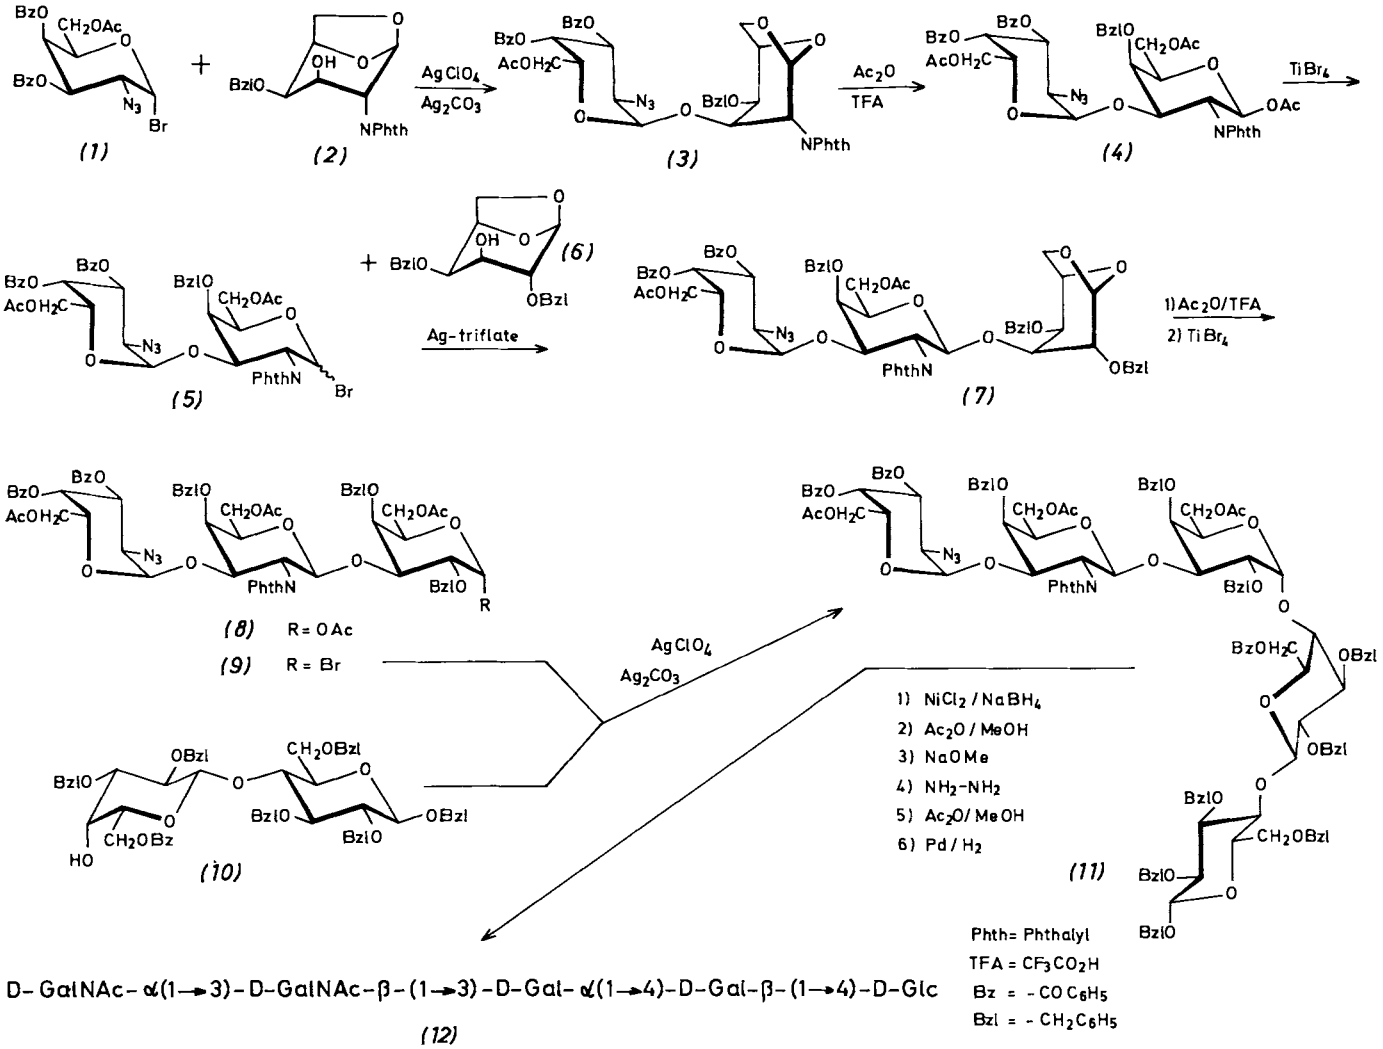
Synthesis of the Pentasaccharide Chain of the Forssman Antigen[**]

By *Hans Paulsen* und *Almuth Bünsch*[*]

The Forssman antigen[1] consists of a pentasaccharide chain and a ceramide moiety, which is anchored in the cell membrane[2]. It is assumed that, as a surface antigen, it regulates cell growth in mammals[3a]. For example, a deficiency of Forssman antigen was observed in uninhibited cell growth in hamsters[3b]. It also occurs on viruses[3c] and can therefore stimulate the formation of Forssman antibodies in infections in humans[3d]. The synthesis of the immunologically effective pentasaccharide chain *(12)* is therefore also of interest, because segments contained in it occur in many glycosphingolipids, *e.g.* globoside (P-antigen)[4], which are therefore likewise accessible[5].



We chose a novel block synthesis method, since we have now succeeded in satisfactorily converting also oligosaccharides with titanium tetrabromide into linkable pyranosyl bromides. The reaction was carried out in absolute methylene chloride/ethyl acetate and, after completion, the products were diluted with four volumes of toluene. It is important that the excess titanium tetrabromide is destroyed with anhydrous, powdered sodium acetate in order that the toluene-insoluble sodium bromide and titanium tetraacetate can be removed by filtration. Subsequently the pyranosyl bromide was obtained by removal of solvents under strictly anhydrous conditions. For the coupling of the two blocks a bonding site was chosen at which an α-glycosidic bond must be coupled, since high reactivity of the bromide and good stereoselectivity are then guaranteed. In the case of *(12)* this is the bond between the central galactose and the lactose unit, so a brominated trisaccharide has to be coupled with the disaccharide.

[**] Building Blocks of Oligosaccharides, Part 24.—Part 23: *H. Paulsen, H. Bünsch*, Tetrahedron Lett., in press.

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/1111-0902 $02.50/0*

For the synthesis of the trisaccharide block *(7)*, *(1)*[6] was coupled in the first step with *(2)* under the conditions of the α-glycoside synthesis. The phthalimido sugar *(2)* can be synthesized by selective ring opening of 1,6:2,3-dianhydro-4-*O*-benzyl-β-D-talopyranose[7] with potassium phthalimide. The

coupled pentasaccharide *(11)* (28% based on *(9)*, $[\alpha]_D^{20} = +74.2$). The deblocking of *(11)* is carried out stepwise as follows: reduction of the azide group with $NiCl_2/NaBH_4$ and *N*-acetylation, deacylation with sodium methoxide, cleavage of the phthalimide group with hydrazine and *N*-acetalation, disaccharide *(3)* obtained (66%, $[\alpha]_D^{20} = +179.5$) is acetolyzed with acetic anhydride/trifluoroacetic acid to the β-acetate *(4)*, which on reaction with titanium tetrabromide[8] affords the linkable bromide *(5)* in 90% yield. This is immediately coupled in the presence of silver trifluoromethanesulfonate (silver triflate)/collidine and complete absence of moisture with *(6)* with formation of the β-glycosidic bond[9] to give the trisaccharide *(7)* (68% based on *(5)*, $[\alpha]_D^{20} = +87.6$).

For functionalization, *(7)* is acetolyzed with acetic anhydride/trifluoroacetic acid to the α-acetate *(8)* (98%, $[\alpha]_D^{20} = +77.7$). Reaction of *(8)* with titanium tetrabromide affords the α-bromide *(9)* in 92% yield. As coupling component for *(9)* we used the selectively blocked lactose derivative *(10)*, obtainable from benzyl-2,3,6-tri-*O*-benzyl-4-*O*-(2,3-di-*O*-benzyl-β-D-galactopyranosyl)-β-D-glucopyranoside[10] by selective benzoylation with benzoyl cyanide.

The two synthesis blocks *(9)* and *(10)* can be selectively converted under the conditions of the α-glycoside synthesis in the presence of $Ag_2CO_3/AgClO_4$ into the α-glycosidically and finally hydrogenolytic cleavage of all benzyl groups. In this way the completely deblocked pentasaccharide *(12)* is obtained ($[\alpha]_D^{20} = +134$).

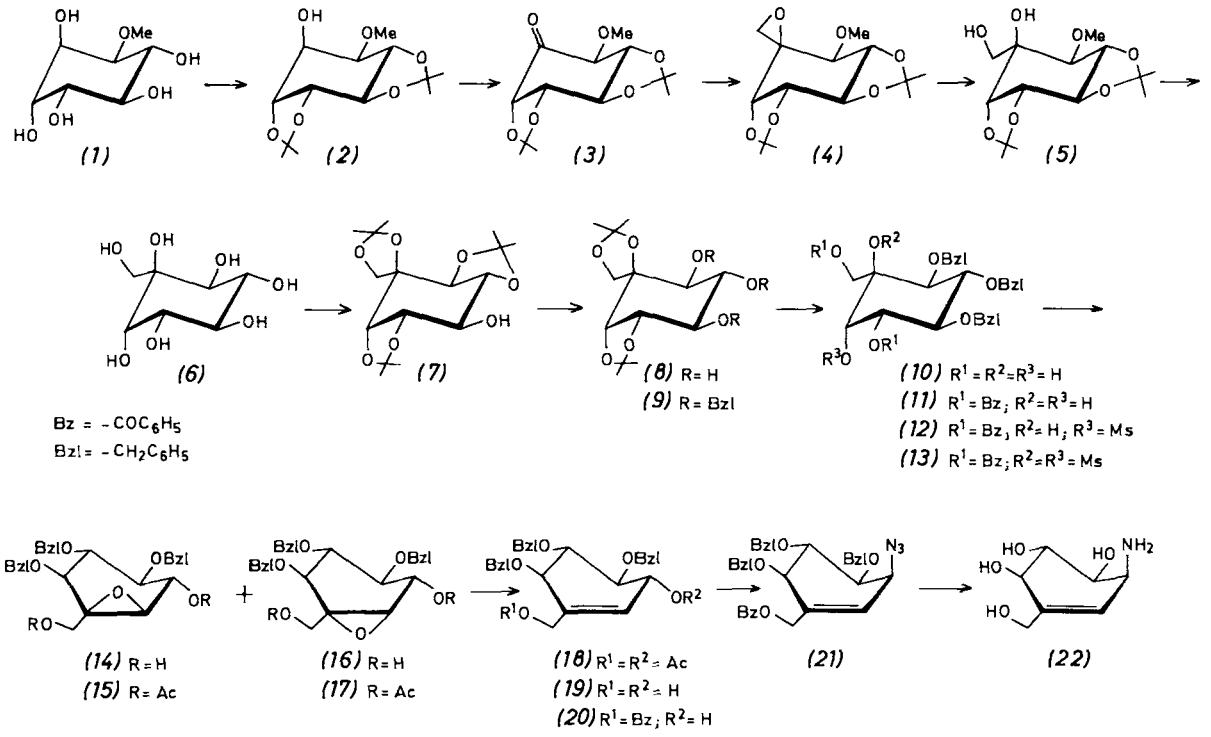
Synthesis of Chiral Valienamine[**]

By *Hans Paulsen* and *Fred R. Heiker*[*]

Valienamine *(22)*, an unsaturated amino-cyclitol derivative with side chain, is a component of the aminoglycoside antibiotics of the validamycin type[1], distinguished for its fungicidal action with low toxicity. Above all, however, valienamine is the cardinal building block of the oligosaccharide Acarbose®, in which it is coupled to a 6-deoxy-D-glucose unit, which in turn is bound to two glucose building blocks[2]. With Acarbose®, a highly effective inhibitor of the α-glucosidases in the human digestive tract, it is possible to delay the breakdown of ingested carbohydrates (sucrose, starch) and consequently to control the resorption of glucose from the intestines. Clinical studies of Acarbose® have been able to prove the usefulness of this new therapeutic principle through the treatment of diabetes mellitus[3]. We have now succeeded in carrying out the first synthesis of valienamine *(22)*, as the chiral compound.



As starting material we used quebrachitol *(1)* (2-*O*-methyl-L-chiroinositol), which is formed as byproduct in the production of natural rubber[4]. For incorporation of the side chain, *(1)* is converted with dimethoxypropane into the diisopropylidene compound *(2)*, which can be catalytically oxidized with ruthenium tetroxide/sodium periodate to the ketone *(3)* (63%, m.p. 86 °C, $[\alpha]_D^{20} = +1.6$). On reaction with dimethyloxosulfonium methylide[5], *(3)* stereoselectively forms the epoxide *(4)* (57%, m.p. 92 °C, $[\alpha]_D^{20} = 41.5$). Reaction of *(3)* with the anion of the dithiane analogue *N*-methylthioformaldine (5-methylperhydro-1,3,5-dithiazine)[6] affords—likewise stereoselectively—the product with the other (undesired) stereochemistry at the branching site. The ring-opening product *(5)* (89%, m.p. 86 °C, $[\alpha]_D^{20} = -4.1$) can be obtained by hydrolysis of *(4)* with aqueous alkali.

Since the stereochemistry of the side chain in *(5)* is fixed, the methyl ether can now be cleaved; on reaction with boron tribromide the completely deblocked product *(6)* is formed. Reaction of *(6)* with dimethoxypropane yields the triisopropylidene compound *(7)*. Selective hydrolysis of the *trans*-isopropylidene group leads to formation of *(8)*, from which the tribenzyl ether *(9)* (75%, $[\alpha]_D^{20} = -42.2$) can be obtained.

The benzoylation of the tetrol *(10)*, obtainable from *(9)* by acid hydrolysis, can be so steered that it selectively furnishes the dibenzoate *(11)* (82%, m.p. 162 °C, $[\alpha]_D^{20} = -18.5$). The OH group at the branching site and the 6-OH group are considerably less reactive. On mesylation of *(11)* one obtains an inseparable mixture of monomesylate *(12)* and dimesylate *(13)* (Ms = CH_3SO_3). Treatment of this mixture with sodium ethoxide affords a mixture of the epoxides *(14)* and *(16)*, which are isolated as the acetates *(15)* + *(17)*. The double bond is incorporated by reaction of *(15)* + *(17)* with sodium iodide followed by elimination with phosphorus oxide trichloride; this leads uniformly to the olefin *(18)* (69%, $[\alpha]_D^{20} = -85.9$).

For introduction of the amino group the side chain, after hydrolysis of *(18)* to *(19)*, is protected by selective benzoylation to *(20)*. It is now possible to convert the free hydroxy group at the allyl position into an azido group with hydrazoic acid/triphenylphosphane/azodicarboxylate[7] to give *(21)* (72%, $[\alpha]_D^{20} = +53.5$), which has the stereochemistry of valienamine. The azido group in *(21)* is converted with triphenylphosphane into the phosphinimide[8], which can be hydrolyzed to the amino group. Cleavage of the benzyl ether protecting groups is achieved with sodium in liquid ammonia: Valienamine *(22)* is isolated as the hydrochloride; its optical rotation is +48.6.

Proton and Hydrogen Affinity of Furan and the Site of Protonation in the Gas Phase[**]

By *Raymond Houriet, Helmut Schwarz,* and *Waltraud Zummack*[*]

The determination of molecular parameters such as adiabatic ionization energy (IE) or proton (PA) and hydrogen affinity (HA) provides direct information on some important *inherent* properties of molecules (*B*) when the experiments are carried out in the gas phase[1]. Thus, the ionization energy describes the nature of the bonding of an electron in B, while the proton affinity allows conclusions to be drawn about the readiness of *B* to share its electron density with a proton $H^{\oplus}$. The hydrogen affinity is a measure of the interaction of a $H^{\odot}$ atom with the radical cation $B^{\oplus\odot}$. Common to all parameters is the fact that they reflect the electronic properties of B under various experimental conditions. While IE and PA values [defined by eq. (a), (b)] are easily accessible by photoelectron (PE) and ion cyclotron resonance spectroscopy (ICR), respectively, the HA values [defined by eq. (c)] are most conveniently determined by a thermochemical cyclic process according to eq. (d).

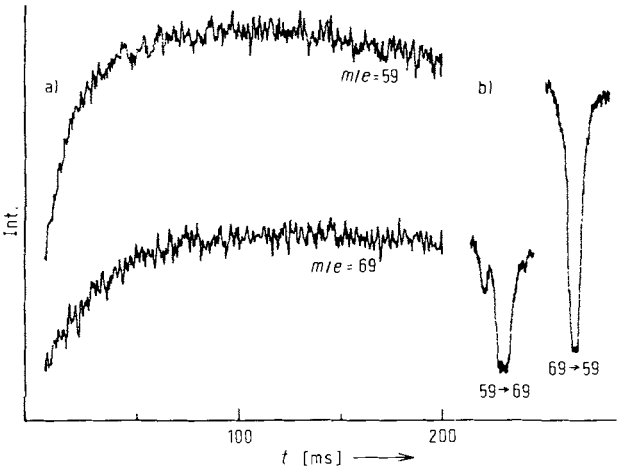
$$B \rightarrow B^{\oplus\odot} + e^{\ominus} \quad \Delta H_1 = IE(B) \qquad (a)$$
$$BH^{\oplus} \rightarrow B + H^{\oplus} \quad \Delta H_2 = PA(B) \qquad (b)$$
$$BH^{\oplus} \rightarrow B^{\oplus\odot} + H^{\odot} \quad \Delta H_3 = HA(B^{\oplus\odot}) \qquad (c)$$
$$HA(B^{\oplus\odot}) = PA(B) + IE(B) - IE(H) \qquad (d)$$

We report here our investigations on furan *(1)*, whose electrophilic substitution constitutes a fundamental type of reaction in organic chemistry. From ion cyclotron resonance (ICR) measurements[2] on the pair furan *(1)*/acetone *(2)*

(e)

(1-H)$^{\oplus}$ *(2)* *(1)* *(2-H)*$^{\oplus}$
m/e = 69 *m/e* = 59

(Fig. 1) we obtained $\Delta\Delta G = -0.59$ kcal mol^{-1} for the reaction (e)[3]. From this, and the entropy term $T \cdot R \ln 2$ [in contrast to *(2)*, *(1)* has *two* potential centers for protonation, *vide infra*] we calculated the proton affinity of *(1)* at 323 K to be PA *(1)* = 195.5 kcal mol^{-1}[4a]. Combination of this value with the adiabatic ionization energy of *(1)* (IE = 205.2 kcal mol^{-1}[5]) and that of the $H^{\odot}$ atom (IE = 313.6 kcal mol^{-1}) yields for $(1)^{\oplus\odot}$ a hydrogen affinity HA = 87 kcal mol^{-1}. The corresponding HA values for the radical cations of benzene and pyrrole are 84[4b] and 83.4 kcal mol^{-1}[1a], respectively. This means that the radical cation of furan is 3 kcal mol^{-1} *destabilized* compared to that of benzene, while the pyrrole radical cation experiences a stabilization of about 0.6 kcal mol^{-1}.



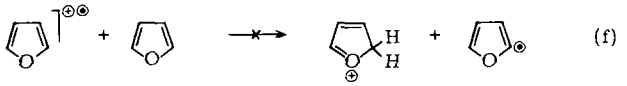


Fig. 1. a) Ion intensity as a function of time in a 1:1 mixture of furan *(1)* and acetone *(2)* (6×10^6 torr; 2.5 ms-pulse of 20 eV electrons); b) double resonance pulse at 200 ms.

The relatively small HA value of 87 kcal mol^{-1} for $(1)^{\oplus\odot}$ explains why reaction (f) is not observed. If one assumes that the (C—H) bonding energy of *(1)* is of the same order of magnitude as that of benzene (110 kcal mol^{-1}[6]), then the reaction (f) would be 23 kcal mol^{-1} *endothermic* and should therefore not take place. In fact, there is also no experimental evidence that $(1)^{\oplus\odot}$ reacts according to eq. (f). On the contrary: the concentration of $(1)^{\oplus\odot}$ remains virtually unchanged as a function of reaction time.

(f)

(1)$^{\oplus\odot}$ *(1)* *(1-H)*$^{\oplus}$ *(3)*

That the gas-phase protonation of furan—an electrophilic substitution *par excellence*—takes place exclusively at the α- and not at the β-position of the heterocycle is confirmed by investigations on the specifically [α-D]- and [β-D]-labeled furans *(1a)* and *(1b)*, respectively[7]. We find that a mixture of *(1b)* with *(2)* gives no signal at *m/e* = 60 (acetone-$D^{\oplus}$) alongside that at *m/e* = 59 under ICR conditions, even after

(1a) *(1b)*

200 ms, as must be the case if the β-position of the furan ring were to participate in the reversible H/D exchange between furan and acetone. Conversely, we find for mixtures of *(1a)* with *(2)* a signal ratio (*m/e* = 59)/(*m/e* = 60) of 47:53 after 200 ms[8]; *i.e.* the α-position[9] participates in proton exchange. Conclusion: in the prototype electrophilic reaction—the protonation—furan reacts as a typical arene and not as an enol ether, both in the gas phase as well as in the condensed phase[10].

Trimerization of an Azomethine Imine by Three Successive 1,3-Dipolar Cycloaddition Reactions[**]

By *Judith L. Flippen-Anderson, Isabella Karle, Rolf Huisgen,* and *Hans-Ulrich Reissig*[*]

The reaction of the electrophilic aryldiazocyanides and the nucleophilic diaryldiazoalkanes afforded the first class of stable, crystalline azomethine imines, *e.g., (1)* from *p*-chlorobenzene-*anti*-diazocyanide and diphenyldiazomethane[1]. Reactions of azomethine imines of this type served as an early test[2] for the synthetic potential of 1,3-dipolar cycloaddition; the reactions with olefinic[3] and acetylenic[4] dipolarophiles gave rise to pyrazolidines and 3-pyrazolines, respectively. The orange-yellow C,C,N^{α}-triaryl-N^{β}-cyanoazomethine imines of type *(1)* are stable in the crystal, but are converted in hot solution to colorless high-melting trimers[5]. Vapor pressure osmometry and the mass spectrum (300 °C) secured the molecular weight of the trimer of *(1)* (m.p. 288—289 °C). The monomer *(1)* incorporates the 1,3-dipolar azomethine imine system as well as the dipolarophilic cyano group. Conceivably, the trimerization consists of a succession of three 1,3-dipolar cycloadditions of which the concluding one takes place intramolecularly and produces *(2)*.

The structure *(2)* for the trimer has now been established by X-ray structure analysis on solvent-free single crystals, which were obtained from acetone/methanol in 6 weeks (Fig. 1).

The central ring of *(2)* is approximately planar with the three carbon atoms shifted slightly below this plane and the three nitrogen atoms shifted slightly above the plane. It is only the skeleton of the tetracyclic heterosystem in *(2)* which shows approximate three-fold symmetry. The symmetry vanishes, if one takes the aryl substituents into account. The iminium nitrogen of *(1)* becomes pyramidal in the cycloadduct

(1)

(2)

(2). Two of the *p*-chlorophenyl groups are located on one side of the average plane of the tetracyclic system, whereas the third projects out from the opposite side (Fig. 1). Some variations in the rotations of the remaining six phenyl groups can probably be accounted for by intra- and intermolecular forces. The bond length of 1.26 Å for the CN double bonds is shorter than "normal"[9], although one expects a bond order below 2 for the amidinohydrazine moiety in *(2)*.

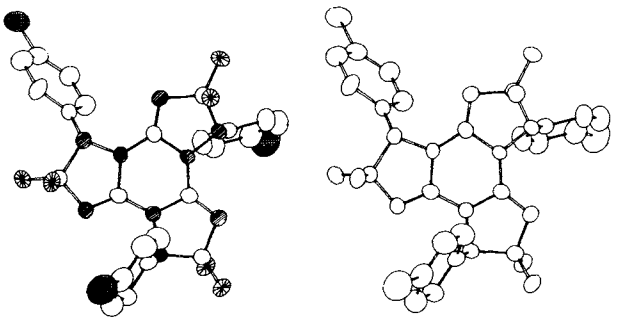

Fig. 1. Stereodrawing of the molecular structure of 1,5,9-tris(*p*-chlorophenyl)-1,2,5,6,9,10-hexahydro-2,2,6,6,10,10-hexaphenyl-tris[1,2,4]triazolo[1,5-*a*: 1′,5′-*c*: 1″, 5″-*e*][1,3,5]triazine *(2)*. The compound crystallizes in the body centered triclinic system with $a = 16.102$, $b = 24.894$, $c = 13.241$ Å, $\alpha = 96.7$, $\beta = 102.1$, $\gamma = 106.8°$ and $Z = 4$; the reduced cell dimensions are $a = 13.242$, $b = 13.558$, $c = 16.103$ Å, $\alpha = 108.5$, $\beta = 91.2$, $\gamma = 111.6°$ and $Z = 2$. The structure was solved by direct methods [6] and refined by a restrained least-square procedure [7] to a *R*-factor of 6.5% for 6053 independently measured intensities [8].—For ease of viewing the phenyl groups have been left out and their positions are indicated by ⊛. Chlorine atoms: ●, nitrogen atoms: ●.

The direction of addition revealed in *(2)* was also observed for the 1,3-dipolar cycloadditions of azomethine imines of type *(1)* to ethyl cyanoformate[10], whereas benzonitrile and acetonitrile fail to react.

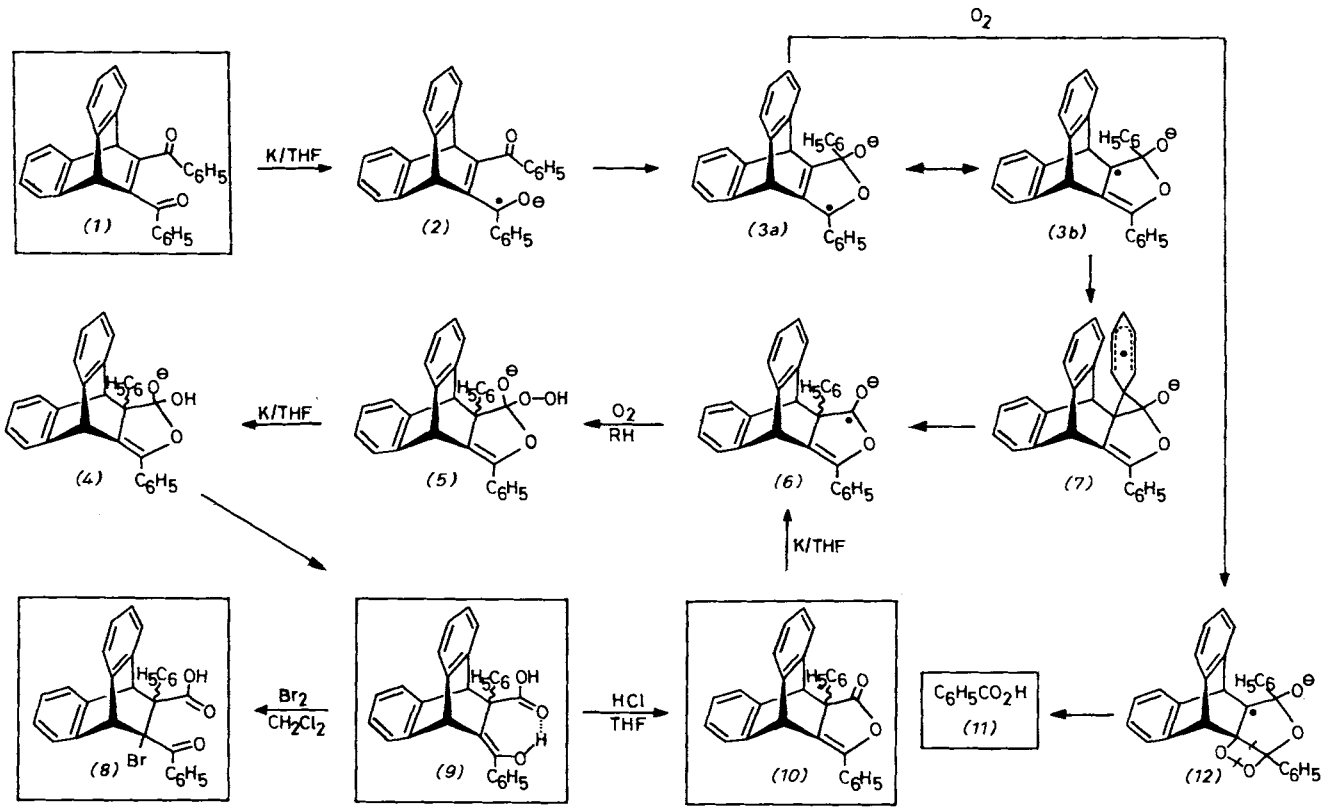
Alkali Metal-Induced Transformations of *cis*-1,2-Dibenzoylalkenes: Transformation of 11,12-Dibenzoyl-9,10-dihydro-9,10-ethenoanthracene

By *Bipin Pandey, M. P. Mahajan,* and *Manapurathu V. George*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Alkali metals add to 1,2-dibenzoylalkenes to give radical anion intermediates, which subsequently undergo different transformations, depending on the nature of the starting material and reaction conditions[1]. The reaction of *o*-dibenzoylbenzene with potassium, for example, has been reported to give a mixture of products consisting of 1,3-diphenylisobenzofuran, 10-hydroxy-10-phenyl-9-anthrone, 9-phenyl-9,10-dihydroanthracene-9,10-diol, anthraquinone and a dimeric reduction product[2,3]. In the present studies we have examined the reaction of 11,12-dibenzoyl-9,10-dihydro-9,10-ethenoanthracene *(1)* with potassium to determine the nature of products formed and to explore the synthetic utility of such reactions.



Treatment of a solution of *(1)* in tetrahydrofuran (THF) with potassium in a Schlenk tube for 10 h and subsequent work-up of the mixture by exposure to air, removal of the solvent under vacuum and chromatography over silica gel gave a mixture of products consisting of benzoic acid *(11)* (3%), anthracene (7%), and 12-(α-hydroxybenzylidene)-11-phenyl-9,10-dihydro-9,10-ethanoanthracene-11-phenyl-11-carboxylic acid *(9)* (35%) (see Table 1).

Passage of dry HCl gas through a solution of *(9)* in THF gave the lactone *(10)* in 59% yield (Table 1); treatment of *(9)* with bromine in dichloromethane gave a 42% yield of 12-benzoyl-12-bromo-11-phenyl-9,10-dihydro-9,10-ethanoanthracene-11-carboxylic acid *(8)*.

Table 1. Some physical data of the products *(8)*, *(9)*, and *(10)*.

(9) m.p. 171—172 °C; UV (methanol): $\lambda_{max} = 250$ nm ($\varepsilon = 7500$), 278 (3750), 330 (7300); IR: 3554 (CO*OH*), 3046, 3013, 1625 cm^{-1} (C=O); ^{1}H-NMR: $\delta = 3.45$ (s, 1H, COOH) [a], 4.3 (s, 1H [b]), 4.9 (s, 1H, [b]), 6.45—7.70 (m, 18H, aromatic), 16.4 (s, 1H, =CH*OH* [a]); MS: $m/e = 430$ ($10 = M^+$)
(10) m.p. 135 °C; UV (ethanol): $\lambda_{max} = 225$ nm ($\varepsilon = 5100$), 278 (2400); IR: 1795 cm^{-1} (C=O); ^{1}H-NMR: $\delta = 5.42$ (s, 2H [b]), 6.82—7.4 (m, 18H, aromatic); MS: $m/e = 412$ (20%, M^+)

[a] D_2O-exchangeable. [b] Bridgehead proton.

Scheme 1.

The formation of *(9)* on reaction of *(1)* with potassium may be rationalized in terms of the mechanism shown in Scheme 1. We assume that the dibenzoylalkene *(1)* accepts an electron from potassium to give initially the radical anion intermediate *(2)*, which then rearranges to a new radical anion intermediate *(3)*. Similar radical anion intermediates have been postulated in the reaction of *o*-dibenzoylben-

zene[3] and *o*-dimesitoylbenzene[4] with alkali metals in aprotic solvents. Subsequent rearrangement of *(3)*, involving a 1,2-phenyl migration leads to a new radical anion intermediate *(6)*, which on reaction with atmospheric oxygen gives the hydroperoxide intermediate *(5)*. Reduction of *(5)* with further potassium leads to the intermediate *(4)*, whose hydrolysis affords the final products *(9)*.

If a radical anion such as *(6)* is involved in the transformation of *(1)* to *(9)*, then it would be reasonable to assume that the lactone *(10)* which can generate the same intermediate *(6)*, by reaction with potassium, should also give rise to the same product *(9)*, under similar conditions. Reaction of *(10)* with potassium in THF, under conditions similar to those employed in the case of *(1)*, did indeed give *(9)* in 30% yield, thereby supporting the possible participation of *(6)*.

The formation of benzoic acid *(11)* in the reaction of *(1)* with potassium may be rationalized in terms of the dioxetane intermediate *(12)*, formed through the reaction of *(3a)* with oxygen; the formation of anthracene could be possible by retro-Diels-Alder fragmentation of one of the radical anions. Preliminary investigations have shown that *cis*-1,2-dibenzoylstyrene, 2,3-dibenzoylbicyclo[2.2.1]hepta-2,5-diene, and 2,3-dibenzoylbicyclo[2.2.2]octa-2,5-diene undergo similar transformations, on treatment with potassium.

Captodative Substituent Effects and the Chromophoric System of Indigo

By *Martin Klessinger*[*]

The principle of radical stabilization by captodative substitution recently discussed by *Viehe et al.*[1] is not only of importance regarding syntheses with radicals and radicophiles but proves to be a fundamental model for understanding many properties of organic compounds. This is demonstrated using as example the chromophoric system of indigo *(1)*, whose unusual color[2] can readily be explained in terms of the principle of captodative substitution. At the same time this example shows that the effect of captodative substitution can be very easily assessed with the simple HMO model.

(1)

The π-electron system of the chromophoric system of indigo can be formally constructed from two identical subsystems (Fig. 1), whereby the coupling of two radical centers affords one bonding and one antibonding π-MO of the central CC double bond which is substituted by two donor as well as by two acceptor groups. If the energetic splitting of these two MOs is sufficiently small they form the HOMO and the LUMO of the combined system, and the difference Δε of their orbital energies is responsible for the absorption of light of longest wavelength.

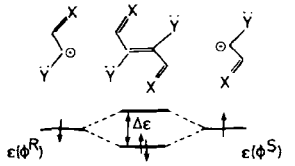

Fig. 1. Construction of the chromophoric system of indigo from two captodative stabilized radicals; interaction of the singly occupied π-MOs.

In the HMO approximation, according to the 1st order perturbation theory[3] the following applies:

$$\Delta\varepsilon = 2\, c_\rho^R\, c_\sigma^S\, \beta_{\rho\sigma}$$

Thus the orbital energy difference Δε is smaller, the smaller are the absolute values of the LCAO-MO coefficients c_ρ^R and c_σ^S of the singly occupied MOs ϕ^R and ϕ^S of the subsystems R and S at the coupling sites ρ and σ. The coefficients can also be estimated with the aid of perturbation theory as a function of the HMO parameters h_X and h_Y for the Coulomb integrals $\alpha_X = \alpha + h_X\beta$ an $\alpha_Y = \alpha + h_Y\beta$ of the heteroatoms X and Y[4]; starting from the butadienide ion as isoselectronic hydrocarbon we find

$$c_\rho^R = -0.372 + 0.184\, h_X - 0.304\, h_Y$$

Thus, c_σ^R is smaller the more electronegative X is, and the less electronegative Y is, *i. e.* the more pronounced are the acceptor and donor properties of the substituents —C=X and —Ÿ at the radical center. These are exactly the conditions corresponding to the greatest possible delocalization of the unpaired electron.

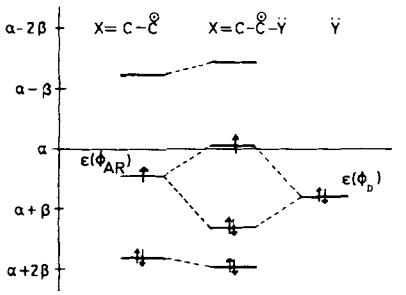

Fig. 2. Orbital energy correlation diagram for the captodative stabilization of a radical center by the substituents —C=X and —Ÿ (the data were obtained from a HMO calculation with $h_X = 1.0$ and $h_Y = 0.8$).

From the orbital energy correlation diagram (Fig. 2) it is clear that the intuitive condition of maximum delocalization of the radical electron agrees with the energetic criteria for an optimum captodative radical stabilization: As a 2nd order perturbation effect, the interaction between the radical center substituted by the acceptor group —C=X and the donor group —Ÿ is all the greater the smaller is the difference of the corresponding orbital energies[3], *i. e.* the closer are the singly occupied π-MO ϕ_{AR} of the radical X=C—Ċ and the doubly occupied donor MO ϕ_D. Starting from the allyl radical, 1st order perturbation theory yields the energy ε_{AR} of the singly occupied radical MO as $\varepsilon_{AR} = 1/2\, h_X\beta$, while the energy ε_D of the donor orbital is given by $\varepsilon_D = h_y\beta$; thus optimum

stabilization is reached for $h_Y = 1/2\,h_X$. A glance at the usual parameter values[5] shows that this situation cannot be reached with the the common heteroatoms (N, O, S, *etc.*) but is more nearly approached the greater h_X and the smaller h_Y, *i.e.* the more pronounced the donor and acceptor properties of the substituents.

Figure 2 shows, furthermore, that the stabilization of the system substituted by captodative groups is greater than the sum of the substituent effects: on using the given parameter values, the interaction of the radical center with the acceptor group —C≡X or with the donor group —Ÿ results in a stabilization of the π-system by 0.81β or 0.68β, respectively; the overall captodative stabilization is 1.67β, *i.e.* 0.18β greater than the sum of the individual effects.

A quantitative determination of the optimum radical stabilization on the basis of the donor and acceptor properties of the substituents taking into consideration electron-interaction effects is possible[7] with the LCFO model[6].

droperoxides, peracids, or iodosylbenzene[1]. Evidence has been presented for involvement of a high valency iron-oxo species as the active oxygen transfer agent[1,2]. Very few chemical systems are known to efficiently catalyze alkane hydroxylation under such mild conditions[1a]. Very recently, iron-porphyrins have been shown to catalyze iodosylarene-supported hydroxylations of nonactivated C—H bonds[3,4]. As a part of our effort to understand the mechanisms of the reactions between hemoproteins or metalloporphyrins and two-electron oxidizing agents[5], and to define good catalysts for hydroxylation of alkanes by readily available single oxygen donors, we have compared, in the present study, the abilities of various metalloporphyrins to catalyze cyclohexane hydroxylation by alkyl hydroperoxides[6].

Cumyl hydroperoxide, $C_6H_5C(CH_3)_2OOH$, is stable for days in benzene-cyclohexane (1:1) at 20 °C. Addition of a catalytic amount of *meso*-tetraphenylporphyrin-iron(III) chloride, Fe(TPP)Cl, to this mixture leads to fast decomposition of the hydroperoxide ($t_{1/2} \approx 1$ min) with formation of a nearly stoichiometric amount of cumenol, $C_6H_5C(CH_3)_2OH$, (95%) and acetophenone in minor quantities (≈2—4%). Study of the reaction mixture by HPLC and GLC also shows a concomitant formation of cyclohexanol and cyclohexanone with final yields (reached after about 10 min) of 40 and 20% based on starting hydroperoxide[7]. These products were also identified by IR and ^{1}H-NMR after distillation or silica gel chromatography of the reaction mixture. Visible spectroscopy shows that Fe(TPP)Cl is unchanged at the end of the reaction and therefore behaves as a true catalyst. Very similar yields of cyclohexanol and cyclohexanone are obtained under anaerobic conditions (argon), the reaction being only slightly faster than in the presence of O_2. Taking into account that two moles of oxidant are necessary for cyclohexa-

Metalloporphyrin-Catalyzed Hydroxylation of Cyclohexane by Alkyl Hydroperoxides: Pronounced Efficiency of Iron-Porphyrins[**]

By *Daniel Mansuy, Jean-François Bartoli, Jean-Claude Chottard,* and *Marc Lange*[*]

Cytochromes P450 are able to catalyze the hydroxylation of nonactivated alkanes, either by O_2 in the presence of a reducing agent, or by two-electron oxidants such as alkyl hydroperoxides, peracids, or iodosylbenzene[1]. Evidence has been presented for involvement of a high valency iron-oxo species as the active oxygen transfer agent[1,2]. Very few chemical systems are known to efficiently catalyze alkane hydroxylation under such mild conditions[1a]. Very recently, iron-porphyrins have been shown to catalyze iodosylarene-supported hydroxylations of nonactivated C—H bonds[3,4]. As a part of our effort to understand the mechanisms of the reactions between hemoproteins or metalloporphyrins and two-electron oxidizing agents[5], and to define good catalysts for hydroxylation of alkanes by readily available single oxygen donors, we have compared, in the present study, the abilities of various metalloporphyrins to catalyze cyclohexane hydroxylation by alkyl hydroperoxides[6].

Cumyl hydroperoxide, $C_6H_5C(CH_3)_2OOH$, is stable for days in benzene-cyclohexane (1:1) at 20 °C. Addition of a catalytic amount of *meso*-tetraphenylporphyrin-iron(III) chloride, Fe(TPP)Cl, to this mixture leads to fast decomposition of the hydroperoxide ($t_{1/2} \approx 1$ min) with formation of a nearly stoichiometric amount of cumenol, $C_6H_5C(CH_3)_2OH$, (95%) and acetophenone in minor quantities (≈2—4%). Study of the reaction mixture by HPLC and GLC also shows a concomitant formation of cyclohexanol and cyclohexanone with final yields (reached after about 10 min) of 40 and 20% based on starting hydroperoxide[7]. These products were also identified by IR and ^{1}H-NMR after distillation or silica gel chromatography of the reaction mixture. Visible spectroscopy shows that Fe(TPP)Cl is unchanged at the end of the reaction and therefore behaves as a true catalyst. Very similar yields of cyclohexanol and cyclohexanone are obtained under anaerobic conditions (argon), the reaction being only slightly faster than in the presence of O_2. Taking into account that two moles of oxidant are necessary for cyclohexanone formation from cyclohexane, 80% of the oxidizing equivalents of the hydroperoxide are used for cyclohexane oxidation. Neither ferric or ferrous chloride nor the free porphyrin ($TPPH_2$) gives any cyclohexane oxidation in the reaction conditions (Table 1) indicating that both the metal ion and its porphyrin ligand are necessary for the catalysis to take place.

Table 1 compares various metalloporphyrins[8] as catalysts for cyclohexane oxidation.

From these results, the metalloporphyrins studied can be divided into three classes. (i) The Cu^{II}-, Ni^{II}-, Zn^{II}-, Mg^{II}-, V^{IV}-, and Ti^{IV}-porphyrins are completely inactive in our conditions. (ii) Co(TPP) and Os(TPP)(CO)(py) are able to catalyze cyclohexane oxidation, the former even giving a slightly faster reaction and better yields than Fe(TPP)(Cl),

[**] We are indebted to Dr. *P. Battioni* for supplying Os(TPP)(CO)(py) and Ti(TPP)(O).

but appear greatly modified at the end of the reaction, exhibiting a decreased activity upon further hydroperoxide addition to the reaction mixture. (iii) Fe- and Mn(TPP)Cl are true catalysts found unchanged at the end of the reaction and exhibiting a constant activity upon new addition of hydroperoxide.

In reactions catalyzed by Fe(TPP)Cl, cumyl- and *tert*-butyl hydroperoxide give similar results but with better yields for the former; iodosylbenzene gives lower yields of oxidation products with a very different cyclohexanol/cyclohexanone ratio with an almost exclusive formation of the alcohol as reported previously[3] (Table 2). Moreover, an important irreversible oxidation of the porphyrin ring takes place with the latter oxidant[4] under our conditions.

Table 2. Cyclohexane oxidation by single oxygen donors catalyzed by Fe(TPP)Cl [a].

Oxidant	Yield [%] after 15 min		$t_{1/2}$ for reaction [min]
	$C_6H_{11}OH$	$C_6H_{10}O$	
$C_6H_5C(CH_3)_2O_2H$	40	20	1—2
t-BuO_2H	20	12	5
C_6H_5IO [b]	12	1	15

[a] Same conditions as Table 1. [b] Not completely soluble in the medium at the beginning of the reaction.

In biological systems, hydroperoxide reactions are generally catalyzed by iron-porphyrins; it is noteworthy that we also found an iron-porphyrin to be the best catalyst in our system[9].

[6] Preliminary results concerning *t*BuOOH supported hydroxylation of cyclohexane catalyzed by an iron-porphyrin have been recently mentioned: *J. T. Groves*, Symposium on Microsomes and Drug Oxidation, Ann Arbor 1979.

[7] Treatment of 50 mmol of cyclohexanol (in benzene) by 50 mmol of cumyl hydroperoxide in the presence of 2.5 mmol of Fe(TPP)Cl at 20 °C leads to cyclohexanone in 10—15% yield.

[8] a) *J. H. Fuhrhop, K. M. Smith* in *K. M. Smith:* Porphyrins and Metalloporphyrins. Elsevier, Amsterdam 1975, p. 757; b) *J. W. Buchler* in *D. Dolphin:* The Porphyrins. Vol. 1. Academic Press, New York 1978.

[9] Preliminary results show that $Ru(TPP)(PEt_3)_2$ is also an active catalyst leading to 35% cyclohexanol and 12% cyclohexanone within a few minutes at 20 °C under the conditions of Table 1, but appears partially modified at the end of the reaction.

Separation of the Enantiomers of 2-Hydroxycarboxylic Acids on Optically Active Stationary Phases

By *Wilfried A. König, Susanne Sievers,* and *Uwe Schulze*[*]

The direct gas chromatographic separation of optical antipodes on chiral stationary phases has already been achieved in the case of amino acids, amino alcohols, amines and 2-alkylcarboxamides[1,2]. In these cases the separation was attributed exclusively to selective hydrogen bonding interactions[2,3]. We have shown with several model species that *e.g.* also dipole-dipole interactions effect an enantiomer separation[4].

Stationary phases developed for the separation of amino acids[1,2], however, are not suitable for the separation of enantiomers of nitrogen-free compounds. We have now succeeded for the first time in separating also the trifluoroacetylated esters of 2-hydroxycarboxylic acids on some novel stationary phases. Acids of this type are metabolic products of higher organisms[5] and constituents of important brain glycolipids[6].

As stationary phases we used the L-(*S*)-mandelic acid derivatives *(1)—(4)* (Table 1), coated on the inner surface of glass capillary columns (borosilicate glass, 40 m, 0.2 mm internal diameter). The separation factors for the trifluoroacetylated compounds investigated are presented in Table 1. As expected, the respective (*S*)-enantiomers are always retarded on phases *(1)—(4)* which contain the (*S*)-mandelic acid as structural unit. The elution sequence was checked in the case of the enantiomers of mandelic acid, alanine, valine, valinol, 2-aminopentane, and α-phenylethylamine.

The amino acid enantiomers are eluted in the reverse order on the phase diastereomeric to *(1)*, with (*R*)-α-phenylethylamine. The separation factors are expectedly smaller than in the case of *(1)* (*e.g.* DL-mandelic acid: $\alpha = 1.007$ at 70 °C; DL-alanine: $\alpha = 1.012$ at 80 °C; DL-valinol: $\alpha = 1.013$ at 80 °C). It can be concluded from this behavior that both chiral centers of the stationary phase influence the separation. As shown by the results with phase *(3)*, a single asymmetic center can also suffice for "chiral recognition" (cf. Table 1).

Interestingly, phases *(1)* and *(4)* show a noticeable selectivity for the enantiomers of mandelic acid, while the homologous racemic 3-phenyllactic acid is separated only on phases *(2)* and *(3)*. This is an indication that "chiral recognition" is favored by a close structural relationship between the interacting chiral partners. Also on cyclohexyl *O*-benzyloxycarbonyl-(*S*)-mandelate as stationary phase, of the hydroxy acids only DL-mandelic acid is separated. Remarkably, in this case "chiral recognition" is even observed in a nitrogen-free system.

The phases *(2)* and *(3)*, on which also aliphatic hydroxy acids are separated, behave less specifically. Hydrogen bonding interactions are in any case of secondary importance for the selectivity of the phases *(2)* and *(3)* for hydroxy acids, since at most *one* hydrogen bridge can be formed between the phase and the substrate. This argument is further supported by the observation that the phases *(1)* and *(4)*, *i.e.* in the cases where *two* hydrogen bridge bonds are possible, show rather less selectivity towards hydroxy acids than the other two phases. On the other hand, an essential contribution of hydrogen bonding interactions cannot be ruled out for the separation of the amines on phase *(4)*.

The possibility of separating enantiomeric hydroxy acids on phases such as *(2)* and *(3)* or similar compounds extends the scope of gas chromatography as a rapid method for configurational analysis. The partial separation of the enantiomers of trifluoroacetylated 1-phenylethanol on *O*-benzyloxycarbonyl-(*S*)-3-phenyllactic acid *tert*-butylamide indicates that diastereomeric interactions can be exploited for the separation of enantiomers also in the case of other nitrogen-free compounds.

Preliminary results with polymer-based phases of this type for enantiomer separation indicate that this method of analysis will undoubtedly gain practical importance.

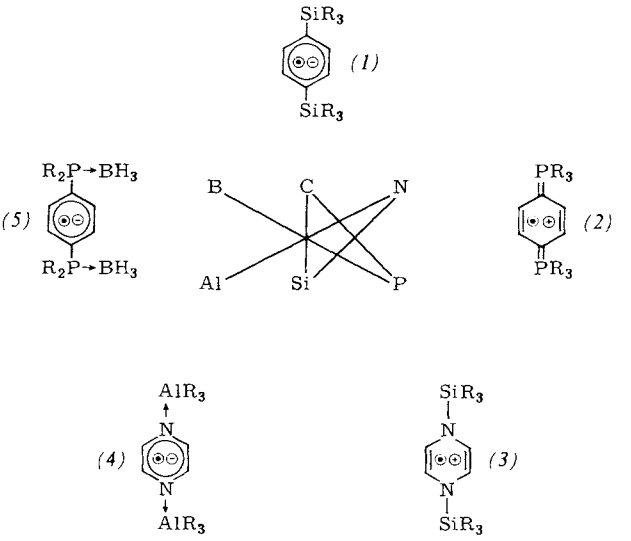
Isoelectronic Radical Ions and Redox Systems[**]



By *Wolfgang Kaim*[*]

Several systematic concepts have been developed regarding the stability and persistency of radicals and radical ions[1]. In this communication an additional route to stable open-shell systems is presented: The directed synthesis of isoelectronic radical ions[2] and redox systems.

The starting compound for the present isoelectronic series is 1,4-bis(trimethylsilyl)benzene, which, despite its low reduction potential of only −2.35 V[3], forms a stable anion *(1)*[3] and—on reaction with potassium at low temperature—also a dianion[4].

By combination of elements of the first (B, C, N) and second (Al, Si, P) periods of the periodic system four further redox systems isoelectronic to *(1)*[5] were devised; Scheme 1 shows the respective paramagnetic intermediates.

Scheme 1. Construction principle for five isoelectronic radical ions (R = CH_3). The radical ions were generated as follows: *(1)*, by reaction of 1,4-bis(trimethylsilyl)benzene with K in DME, *(2)* by cathodic reduction of 1,4-phenylenebis(trimethylphosphonium) diiodide in DMF, *(3)* by reaction of 1,4-dihydro-1,4-bis(trimethylsilyl)pyrazine with $AlCl_3$ in CH_2Cl_2 [4], *(4)* by reaction of pyrazine and $Al(CH_3)_3$ with K in benzene and *(5)* by alkali-metal reduction of 1,4-bis(dimethylphosphino)benzene in BH_3/THF.

All the radical ions *(1)*—*(5)* are persistent at room temperature and can be identified by ESR spectroscopy (Table 1). As representative example Figure 1 shows the spectrum of the N—Al compound[6] *(4)*.

Table 1. ESR coupling constants [mT] and g-factors of the radical ions *(1)*—*(5)*.

	(1)	*(2)*	*(3)*	*(4)*	*(5)*
a_1	0.179	0.195	0.313	0.262	0.188
a_2	[a]	[a]	[a]	0.22	[a]
a_3	0.9	[a]	0.664	0.677	0.92
a_4	0.535	1.310	0.279	0.221	0.908
a_5	0.027	0.030	<0.005	<0.005	[b]
g	2.0029	2.0028	2.0033	2.0035	2.0028

[a] Not observed. [b] Superposition of borane and methyl coupling constants.

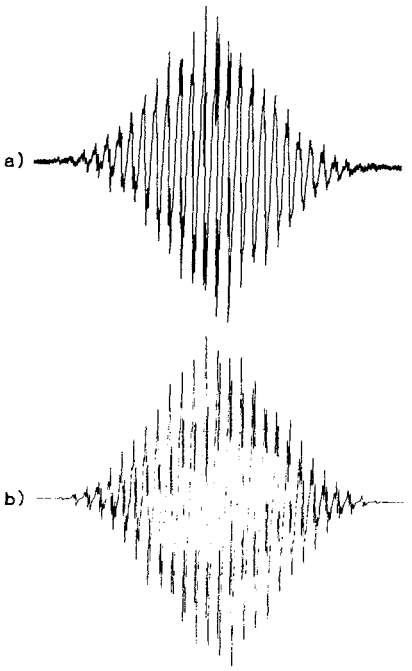

Fig. 1. a) ESR spectrum of the radical anion *(4)*; b) computer simulation.

The ESR parameters (Table 1) of the five isoelectronic radical ions reflect the structural differences: the pyrazine derivatives *(3)* and *(4)* have larger ring-proton and smaller methyl-proton coupling constants as well as higher g-factors than the benzene derivatives *(1)*, *(2)* and *(5)*.

The cations *(2)* and *(3)* are to be regarded as one-electron oxidation products of extremely electron-rich neutral compounds[8], but they can also be generated by reduction of the corresponding dications. The anions *(4)* and *(5)*, on the other hand, are the first examples of a new type of paramagnetic donor-acceptor complexes[9]; the strength of the complex bond is considerably influenced by the electron distribution.

Radical Cation Salts of Simple Arenes—A New Family of "Organic Metals"[**]

By *Christoph Kröhnke, Volker Enkelmann*, and *Gerhard Wegner*[*]

The charge transfer complexes of tetracyanoquinonedimethane (TCNQ) and tetrathiofulvalene (TTF) have been used as examples to formulate general principles which correlate the occurrence of metallic conductivity with structural parameters[1a,b]. The common structural principle of electrically conductive molecular crystals is the crystallization of the donor and acceptor in separated stacks with equal distance between the molecules within each stack[1c] but with only a partial transfer of charge[1a]. For synthesis of most of the previously known "organic metals" the charges are generated by a redox reaction between dissolved reaction partners, followed by crystallization[1d]. The low stability of the intermediary radical ions occurring in solution has hitherto limited the number of possible structures to pairs of heterocycles (*e.g.* TTF, phthalocyanine[1e]) and compounds containing heteroatoms (*e.g.* TCNQ).

Stable radical cations of arenes can be generated by anodic oxidation and can be separated at the anode in the presence of suitable anions as radical cation salts $[aryl_2]^{\odot\oplus}X^{\ominus}$ in the form of shiny black crystals, as has been shown by *Fritz et al.* for the example of $[naphthalene_2]^{\odot\oplus}PF_6^{\ominus}$ *(1a)*[2]. Crystals of this type represent a new class of organic metals.

We have synthesized the corresponding complexes of the radical cations of triphenylene, pyrene, perylene, fluoroanthene *etc.* with the anions BF_4^-, ClO_4^-, PF_6^-, AsF_6^- and SbF_6^- and investigated their conductivity (see also Table 1).

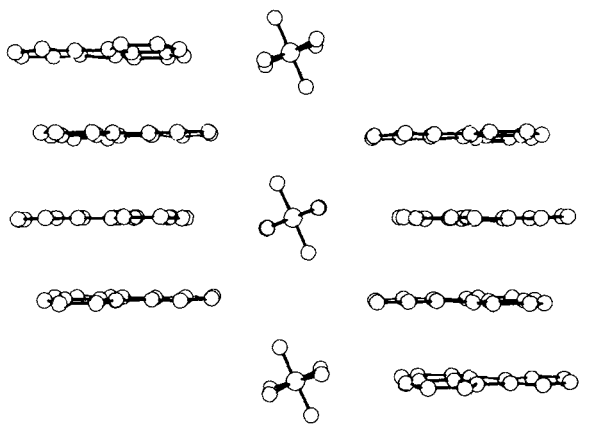

Fig. 1. Crystal structure of $[fluoroanthene_2]^{\odot\oplus}PF_6^{\ominus}$ *(2a)*.

[*] Prof. Dr. G. Wegner, Dr. C. Kröhnke, Dr. V. Enkelmann
Institut für Makromolekulare Chemie der Universität
Stefan-Meier-Str. 31, D-7800 Freiburg (Germany)

[**] This work was supported by Stiftung Volkswagenwerk.

All these complexes show a common structural principle. The arenes are packed in stacks with short distances of 320—325 pm between the molecular planes. The anions are located in the channels between the stacks. Anions of various sizes can be incorporated without essentially altering the structure. All organic molecules within a stack are crystallographically identical, *i.e.* the radical cation is not localized.

The extremely anisotropic ESR signals with linewidths of, in part, only 20 mG[3] also indicate strong interaction and a rapid charge transfer between the molecules within a stack. Figure 1 shows as example the structure of the complex $[\text{fluoroanthene}_2]^{\oplus}PF_6^{\ominus}$ *(2a)*, prepared by us for the first time. The isotropic conductivity σ measured on polycrystalline samples has a magnitude of *ca.* 0.1—0.001 $\Omega^{-1}\,\text{cm}^{-1}$ for all complexes at room temperature. The temperature dependence of σ for fluoroanthene with various anions is presented in Figure 2. The solid line was calculated according to an expression given by *Epstein* and *Conwell*[4]

$$\sigma_n = \sigma_T/\sigma_{295} = A \cdot T^{-\alpha} \exp\left(\frac{-E}{RT}\right) \qquad \text{(a)}$$

with $\alpha = 2.5$ and $E = 0$. The term $T^{-\alpha}$ describes the temperature dependence of the carrier mobility, E is the activation energy for generation of the charge carriers, A is a preexponential factor. In all cases the fitting of the measured curves gives $E = 0$. The counterion has only a small influence on the value of α. We are consequently dealing with organic metals in which the mobility of the charge carriers is strongly temperature-dependent.

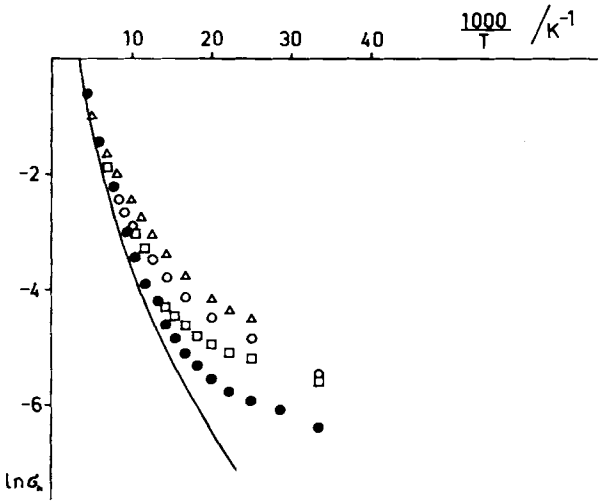

Fig. 2. Dependence of conductivity σ_n on T^{-1} for fluoroanthene radical cation salts *(2)* with various anions. The unbroken curve is calculated according to eq. (a). ●: $(FA)_2PF_6$ *(2a)*, □: $(FA)_2AsF_6$ *(2b)*, △: $(FA)_2SbF_6$ *(2c)* (FA = fluoroanthene), ○: $[\text{triphenylene}_2]^{\oplus}PF_6^{\ominus}$.

Below 150 K, phase transitions occur which imply the deviation of the measured values from the curve determined by eq. (a). Table 1 lists some of the distances between the molecular planes determined crystallographically by us, together with some conductivity values at room temperature.

A similar conductivity behavior is also observed in the case of polymers doped with strong oxidizing agents in the solid state; for example, polyacetylene[5] and poly-*p*-phenylene sulfide[6]. We assume that the transport of charge carriers also proceeds in these cases *via* complexes between individual segments of the polymers having the structure of radical cations. It is known that at least the radical cations of arenes can be obtained as unstable solids by reaction with typical "doping agents" such as $SbCl_5$[7].

Table 1. Distance *d* between the ring planes and isotropically measured specific conductivity σ_{295} in the salts $[\text{aryl}_2]^{\oplus}X^{\ominus}$.

	Aryl	X	*d*/pm	$\sigma_{295}/\Omega^{-1}\,\text{cm}^{-1}$
(1a)	Naphthalene	PF_6	320 [6]	0.12 [6]
(2a)	Fluoroanthene	PF_6	328	0.05
(2b)		AsF_6	330	0.02
(2c)		SbF_6	330	0.01
(3d)	Perylene	BF_4		$4\cdot10^{-4}$
(3a)		PF_6	335	0.04
(3b)		AsF_6		0.04
(3c)		SbF_6		$4\cdot10^{-3}$
(4a)	Pyrene	PF_6	320	
(4b)		AsF_6		$1\cdot10^{-3}$
(4c)		SbF_6		$1\cdot10^{-3}$
(5a)	Triphenylene	PF_6		$7\cdot10^{-3}$
(5b)		AsF_6		$3\cdot10^{-3}$

The salt $(TMTSF)_2PF_6$[8], which is superconductive at $T < 1$ K and pressures of $p > 12$ kbar, also has a packing related to that in the salts *(1)*—*(5)*.

Procedure

Crystals of $[\text{fluoroanthene}_2]^{\oplus}PF_6^{\ominus}$ *(2a)*: A solution of fluoroanthene (10 mmol) in CH_2Cl_2 (200 ml) is treated with tetrabutylammonium hexafluorophosphate (20 mmol). The solution is cooled to −30 °C and electrolyzed between Ni electrodes with a spacing of 1 cm and a current of 2 mA (20 V potential). Shiny black crystals of *(2a)* begin to grow on the anodes within a few minutes.

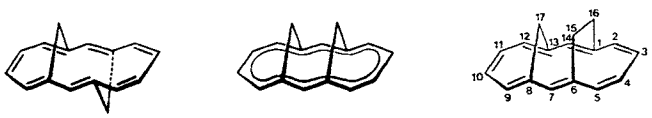
Geometrically Induced Loss of Aromaticity in Bridged [14]Annulenes: *syn*-1,6-Ethano-8,13-methano[14]annulene

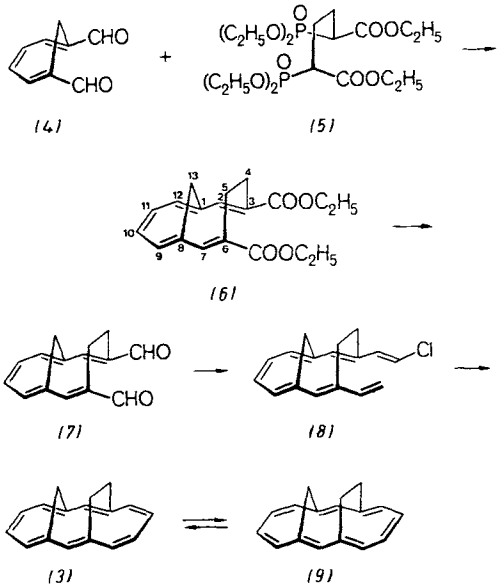


By *Emanuel Vogel, Hans M. Deger, Peter Hebel,* and *Johann Lex*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The rigid bridged [14]annulenes with acene perimeters are ideal substrates for investigations on the interrelation between aromaticity and molecular geometry, since the choice

[*] Prof. Dr. E. Vogel, Dr. H. M. Deger, Dipl.-Chem. P. Hebel, Dr. J. Lex
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)



of bridge type and steric arrangement of the bridges (*syn*- or *anti*-configuration) enables variation of the conformation of the annulene ring within relatively wide limits[1].

(1) (2) (3)

The influence of ring conformation on the π-electron structure of a bridged [14]annulene manifests itself most impressively in the case of the *syn*- and *anti*-1,6:8,13-bismethano[14]annulenes [*(2)* and *(1)*, respectively]. While *(2)* is aromatic, even though it contains a noticeably bent annulene ring[2a], *(1)* with its strongly puckered ring is an olefinic molecule with fluctional π-bonds[2b]. The absence of a geometrically induced loss of aromaticity in the case of *(2)* is consistent with knowledge gained from other bridged [14]annulenes, according to which a [4*n*+2]annulene tolerates considerable deformation of the ring skeleton without substantial weakening of the π-electron delocalization, provided that the torsional angles of the C_{sp^2}—C_{sp^2} bonds in the ring are not greater than *ca.* 45—55°[1a,3]. The maximum value of these torsional angles in the case of *(2)* is 34°, and in the case of *(1)* *ca.* 70°!

We have now found that the title compound, *syn*-1,6-ethano-8,13-methano[14]annulene, for which greater torsions in the annulene ring can be anticipated than in *(2)*[4], is, like *(1)*, an olefinic [14]annulene [*(3)* and/or *(9)*]. The preparation of the compound was accomplished using the recently developed building-block approach for the synthesis of bridged annulenes[5].

(4) (5) (6) (7) (8) (3) (9)

Reaction of *(4)*[5] with *(5)*[6] (for conditions see [5]) smoothly afforded the diester *(6)* (yield 69%, see Table 1), which by successive treatment with diisobutylaluminum hydride and manganese dioxide[5] could be transformed into the dialdehyde *(7)* [yield of diol and *(7)* 83 and 80%, respectively; dark yellow rhombs (ethyl acetate), m.p. 150—151 °C].

Table 1. Physical data of the diester *(6)* and of the *syn*-1,6-ethano-8,13-methano[14]annulene [*(3)*⇄*(9)*].

(6), M.p. = 88 °C (methanol); yellow needles; ^{1}H-NMR ($CDCl_3$): δ = 1.53 and 3.15 (AX system, *J* = 13.5 Hz, 2H, H-13), 2.17—2.78 (AA'BB' system, 4H, H-4,5), 6.45—6.85 (AA'XX' system, 4H, H-9,10,11,12), 7.77 (s, 2H, H-2,7), 1.33 and 4.23 (t and q, 10H, $2C_2H_5$); UV (dioxane): λ_{max} = 275 nm (ε = 41400), 356 (7650); IR (KBr): 1700 cm^{-1} (C=O); MS: *m/e* = 314 (M^+, 11%)

[*(3)*⇄*(9)*], dec. >250 °C (hexane); red, oblong-shaped crystals; ^{1}H-NMR (CCl_4): δ = 1.53 and 4.28 (AX system, *J* = 12.5 Hz, 2H, H-17), 1.90—2.82 (AA'BB' system, 4H, H-15,16), 5.98—6.55 (m, 10H, 10 perimeter-H); ^{13}C-NMR (CD_2Cl_2): δ = 141.7, 133.9, 133.7, 132.0, 128.4, 126.4, 123.6, 32.1, 29.9; UV (cyclohexane): λ_{max} = 287 nm (ε = 28000), 381 (3500); IR (CsI): 1599 cm^{-1} (C=C); MS: *m/e* = 220 (M^+, 30%), 205 (38), 191 (76), 178 (67), 165 (95), 152 (41), 142 (100), 128 (85), 115 (72), 91 (56)

For conversion into *(8)* (for procedure see [7]), *(7)* was allowed to react with methylene(triphenyl)phosphorane (molar ratio 1:1.3) to give the vinylaldehyde (6-vinylbicyclo[6.4.1]trideca-1(12),2,6,8,10-pentaene-3-carbaldehyde) [deep-yellow crystals (from ethyl acetate), m.p. 85 °C; yield 45%], which on treatment with chloromethylene(triphenyl)phosphorane afforded *(8)*. Owing to its strong tendency to polymerize, the chromatographically (silica gel, dichloromethane/hexane) separated *(8)* was "cyclodehydrochlorinated" by thermolysis (1 h) in boiling dimethylformamide without further purification. *syn*-1,6-Ethano-8,13-methano[14]annulene was formed stereoselectively as an easily isolable compound (yield 23% referred to the vinylaldehyde), which polymerizes relatively rapidly on exposure to air, but can be stored under an inert gas at low temperature.

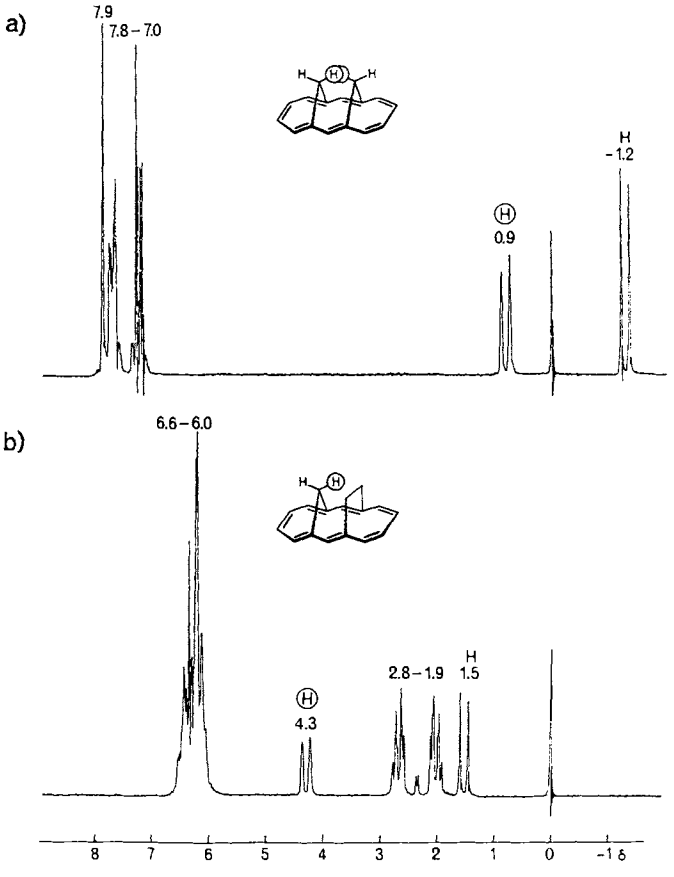


Fig. 1. 90-MHz ^{1}H-NMR spectra of a) *syn*-1,6:8,13-bismethano[14]annulene *(2)* and b) *syn*-1,6-ethano-8,13-methano[14]annulene [*(3)*⇄*(9)*] (in each case in CCl_4, TMS as internal standard).

Proof of structure was chiefly secured by a combination of its ^{1}H- and ^{13}C-NMR spectra (see Table 1). The 90-MHz ^{1}H-NMR spectrum immediately reveals the olefinic nature, for in comparison to the spectrum of *(2)* the resonances of the annulene protons are shifted upfield by *ca.* 1.2 ppm and those of the CH_2-bridge protons downfield by 2.7 (H_{exo}) and 3.4 (H_{endo}) ppm (see Fig. 1). The unusual deshielding of H_{endo} [by 1.7 ppm compared to the corresponding protons of *(1)*], together with a positive nuclear Overhauser effect can only be explained by the assumption that H_{endo} is sterically strongly compressed. It follows that the title compound must have *syn*-configuration. Since the ^{1}H-NMR spectrum does not completely rule out the valence isomer of *(9)* having a cyclobutane ring—the norcaradiene valence isomer of *(3)* is ruled out on the basis of the geminal coupling of the CH_2 protons—the ^{13}C-NMR spectrum was measured. Consistent with the annulene structure, a total of nine resonances is observed, of which seven belong to sp^2- and two to sp^3-hybridized carbon atoms. It was only by detailed analysis of the high resolution NMR spectra that the presence of *(3)* and *(9)* in rapid valence tautomeric equilibrium could be established (see [8]).

The title compound is characterized as an olefin also by its electronic spectrum. While *(2)* shows a spectrum consisting of three main bands[9], the ethano compound exhibits a two-band spectrum without vibrational fine structure.

The X-ray structure analysis of the new bridged [14]annulene gave a result which was surprising in view of the agreement between the NMR and electron spectral data. Though the analysis confirmed the *syn*-1,6-ethano-8,13-methano[14]annulene structure (transannular distances C1—C6 and C8—C13: 2.744 and 2.392 Å, respectively), C—C bond lengths (1.368—1.417 Å) were found for the annulene ring which would indicate the presence of an aromatic molecule. This contradiction is resolved if one assumes that *(3)* and *(9)* exist alongside each other at room temperature. A low-temperature X-ray structure analysis is planned.

Structure and Dynamic Behavior of *syn*-1,6-Ethano-8,13-methano[14]annulene[**]

By *Harald Günther, Henning von Puttkamer, Hans M. Deger, Peter Hebel*, and *Emanuel Vogel*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The bond length and bond order relationships of vicinal H,H-coupling constants[1] for cyclic π-systems have been so well investigated[2] that detailed structural information on unsaturated ring systems is accessible *via* ^3J(H,H) values. Whereas the chemical shifts generally only permit differentiation between diatropic, paratropic, or olefinic character, the ^3J(H,H) data provide additional information about the relative bond lengths and the conformation. We have now exploited this fact in structural investigations on the new 1,6-ethano-8,13-methano[14]annulene *(1)*[3]. Of particular interest here was a complete analysis of the ^{1}H-NMR spectrum, because the position of the proton resonances in the 90-MHz spectrum clearly indicated olefinic character, while the X-ray

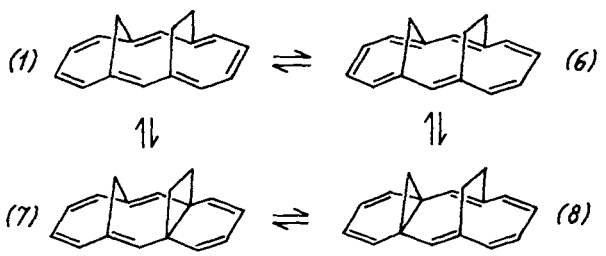
[**] Proton Resonance Spectroscopy of Unsaturated Ring Systems, Part 28. This work was supported by the Fonds der Chemischen Industrie.—Part 27: *H. Günther, M. E. Günther, D. Mondeshka, H. Schmickler, F. Sondheimer, N. Darby, T. M. Cresp*, Chem. Ber. *112*, 71 (1979).

structural data pointed to similar bond lengths and thus to a bond equalization due to delocalization—*i.e.* to aromatic character[3].

The strongly coupled spin system of the ring protons of *(1)* at 90 MHz is well resolved at 400 MHz and, besides the singlet for H(7, 14), shows two AA'BB' systems in the olefinic region (Table 1). The signals of the CH_2-bridge are observed as an AB system at higher field, those of the CH_2—CH_2-bridge as an AA'BB' system. Analysis of the ring-proton signals at 34 °C yielded the data given in Table 1, which on the whole are consistent with structure *(1)*, especially as a nuclear Overhauser effect of 20 and 28%, respectively, between the *endo*-methylene protons evidences the *syn*-position of the two bridges. *(1)* can therefore be regarded as a cyclic olefin with alternating double and single bonds.

The possible dynamic processes which must lead to an averaging of the NMR data.



The valence-tautomeric equilibria which are likely in the case of *(1)* are given in Scheme 1. It should be possible to demonstrate experimentally an interchange *(1)*⇌*(6)*, in particular *via* the temperature dependence of the H,H-coupling constants, and an interchange of the type *(1)*⇌*(7)* or *(1)*⇌*(6)*⇌*(8)* *via* the temperature dependence of the ^{13}C-NMR shifts of the quaternary C-atoms[5]. As the ^{13}C-NMR data show (Table 1), the influence of temperature here is only slight so that any mentionable participation of the valence tautomeric structures *(7)* and/or *(8)* can be ruled out. On the other hand, analysis of the ^{1}H-NMR spectrum at various temperatures gave changes in the H,H-coupling constants (Table 1) which clearly indicate a double bond shift of

The data of compounds *(2)*—*(5)*[4] can be taken as model values for the coupling constants of the cyclooctatriene and cycloheptadiene partial structures of *(1)* (Table 1). However, *(4)* and *(5)* are only of limited value for comparison, since they have C_2 symmetry and thus a twisted diene system, whereas a nearly coplanar arrangement of the C-9 to C-12

Scheme 1

fragment must be assumed for *(1)*. The J(H,H) values in the cyclooctatriene fragment of *(1)* are in good agreement with those of model compounds. Observation of practically the same ^3J(H,H) values in the cycloheptadiene fragment could, of course, be explained in terms of the aforementioned coplanarity, but at the same time motivated an investigation of the type *(1)*⇌*(6)*. In particular, the N-parameter of the two AA'BB' systems[6] of the ring protons is sensitive to the associated diene-triene isomerism[7] (Fig. 1). According to these results the equilibrium *(1)*⇌*(6)* shifts further to the side of

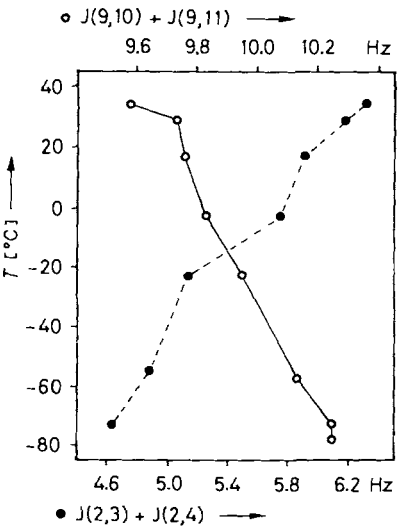

Fig. 1. Temperature dependence of the N-parameter [6] in the two AA'BB' systems of the ring protons H(2)—H(5) and H(9)—H(12) in *(1)*.

the stable *(1)* at lower temperatures. A rough estimate on the basis of the vicinal coupling $J(3,4)$ yields an equilibrium constant of $K \approx 2$ and thus a ΔG^0 of *ca.* 2 kJ/mol in favor of *(1)* at room temperature[8].

From the negative allylic coupling $J(2,4)$ and the relatively large homoallylic coupling $J(2,5)$ we conclude that a much greater dihedral angle C-1,2,5,6/C-2,3,4,5 exists for *(1)* than is suggested by the X-ray structure analysis for the solid[3,9]. On the other hand, the positive allylic coupling $J(9,11)$ and the decrease in the homoallylic coupling $J(9,12)$ on lowering the temperature are consistent with an essentially coplanar arrangement of the diene system, and the alternance of the vicinal coupling constants observed at $-73\,^{\circ}C$ is now in line with the overall picture.

1,3,2-Dithiaplumbocanes—Heterocycles with Lead(IV)—Sulfur Bonds[**]

By *Martin Dräger* and *Norbert Kleiner*[*]

Knowledge of the biochemical mode of action of lead compounds is essentially confined to the strong coordination of lead to sulfur and nitrogen, through which it can displace other metals from some enzymes[1]. This is true both for lead(II) ions as well as for organolead(IV) compounds which constitute the primary ecological burden[2], and which, moreover, can be bioalkylated by bacteria in sulfidic media[3]. This implication of the lead(IV)-sulfur bond in the biocycle of lead induced us to carry out structural investigations on compounds containing the $R_2Pb(S—)_2$ group; it was found that lead(IV) can form an astonishingly wide variety of coordinations with S, both in the solid state and in solution.

From diphenyllead diacetate *(1)*[4], which reacts more rapidly and smoothly than the dihalides[5] with disodium dithiolates, we obtained the five-membered 2,2-diphenyl-1,3,2-dithiaplumbolane *(2)* prepared previously[5] and the new eight-membered heterocycles 5,5-diphenyl-1,4,6,5-oxadithiaplumbocane *(3)* and 2,2-diphenyl-1,3,6,2-trithiaplumbocane *(4)*.

All three compounds are hydrolytically stable, but light-sensitive; *(3)*, and particularly *(4)* are thermally stable only below the temperature of dry-ice. *(2)* crystallizes from ethanol or methanol as colorless, very thin orthorhombic needles. *(3)* crystallizes dimorphically: from ether/ethanol (20:1) as pale yellow orthorhombic *(3a)*, from ether/methanol (20:1) as pale yellow triclinic parallelepipeds [*(3b)*]; *(3a)* and *(3b)* are colorless below $-25\,^{\circ}C$. No single crystals of the colorless *(4)* could be prepared because of its thermal lability. All decomposition products are intensely yellow.

The X-ray structure analyses (at $-160\,^{\circ}C$) of *(2)*, *(3a)* and *(3b)*[6] gave for the five-membered ring of *(2)* an envelope conformation, for the eight-membered ring of *(3)* in *(3a)* twice chair-chair conformation and in *(3b)* both a chair-chair conformation for one molecule and a boat-chair conformation for the other (Fig. 1). *(3b)* is the first example exhibiting both conformations of the eight-membered ring (chair-chair and boat-chair) in the same structure[7]. The occurrence of both conformations in *(3b)* supports the assumption based on NMR spectra that an equilibrium exists between both conformations in solution[8].

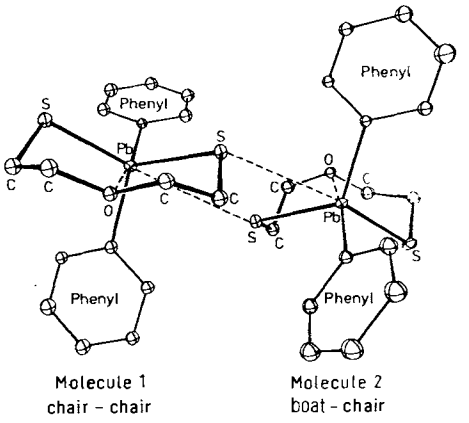

Fig. 1. Dimer pair of *(3)* in the triclinic modification *(3b)* with inter- and intramolecular coordinative bonds (broken lines).

In the crystal, *(2)* forms infinite chains *via* intermolecular Pb...S interactions; lead(IV) is coordinated trigonal-bipyramidally with one long and two short Pb—S distances (Table 1). *(3a)* contains isolated *(3)*-molecules in the crystal, but there is a clear 1,5-transannular Pb...O interaction within the eight-membered ring, so that lead(IV) in *(3a)* is penta-

[a] Pb^{IV}—C bond lengths 218—222 pm. [b] In $CDCl_3$ referred to $PbMe_4$, J in Hz.

coordinated (monocapped tetrahedra). There are also 1,5-transannular Pb...O interactions in *(3b)*; moreover, the two independent molecules of the asymmetric moiety are coupled *via* two intermolecular Pb...S bridges to form a dimer (Fig. 1). Lead(IV) is thus hexacoordinated (bicapped tetrahedra). The Pb^{IV}—S single bond in *(2)*, *(3a)* and *(3b)* has an average length of 250(2) pm.

In solution ($CDCl_3$), *(2)*, *(3)* and *(4)* were characterized by their ^{1}H-, ^{13}C- and ^{207}Pb-NMR spectra (Table 1). The strong downfield shift in the case of *(2)* and the smaller coupling constants show that *(2)* is monomeric in solution and contains tetrahedrally coordinated lead(IV). In the case of *(3)* and *(4)*, on the other hand, the pentacoordination observed in the crystal is retained (high-field shift of the Pb^{IV} signals[9] and stronger coupling).

Procedure

A solution of sodium (0.5 g, 22 mmol) in methanol (100 ml) is added to a solution of the dithiolate (10.4 mmol) in methanol (50 ml) and the mixture boiled for a few minutes. After cooling to 0 °C, a suspension of *(1)* (5.0 g, 10.4 mmol) in methanol (100 ml) is added with stirring. *(1)* is completely dissolved within a few minutes, while at the same time the product is partly precipitated. The solvent is removed *in vacuo* in a rotary evaporator and the residue is taken up in 150 ml of boiling ether. The filtered solution is evaporated in a vacuum until crystals separate. Yields: 3.2 g (68%) of *(2)*, 3.2 g (64%) of *(3)* and 2.6 g (51%) of *(4)*. Immediate work-up is necessary; on evaporation and recrystallization heating should be kept to a minimum and should be as brief as possible.

^{15}N-NMR Spectroscopic Detection of the Tetrazolo[1,5-*a*]pyrimidine/2-Azidopyrimidine Equilibrium[**]

By *William E. Hull, Michael Künstlinger,* and *Eberhard Breitmaier*[*]

The tetrazole-azide valence isomerism has hitherto been investigated by ^{1}H-NMR and by 1,3-dipolar cycloaddition[1]. A direct and very informative probe for the tetrazole-azide equilibrium is provided by ^{15}N nuclear resonance. However, its previous application was thwarted by the very low natural concentration of ^{15}N and the lack of sufficiently concentrated samples.

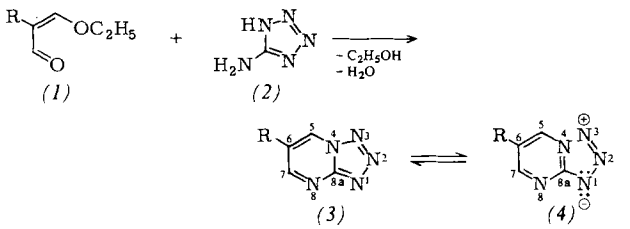

Table 1. Yields and characterization data of the heterocycles *(3)*⇄*(4)*.

lo[1,5-*a*]pyrimidines *(3)*, whose equilibrium with the 2-azidopyrimidines *(4)* (Table 1) can be detected particularly well in reasonable measuring time by high-field ^{15}N nuclear resonance (40.55 MHz).

Figure 1 shows the ^{15}N-NMR spectrum of the equilibrium mixture *(3f)* ⇄ *(4f)*, R = nC_4H_9, recorded without proton decoupling. The more intense signals of the tetrazolo[1,5-*a*]pyrimidine *(3f)* (85%) and the weaker ones of the 2-azidopyridine *(4f)* (15%) are easily recognizable. Table 2 lists the assignment of all the ^{15}N-, ^{13}C- and ^{1}H-signals. The assignment of the ^{15}N-signals is based on the known sequence of the signals of tetrazoles, pyridines and azides[2] and on the $^{2}J_{NH}$ coupling constants, which are larger (11—12 Hz) for nitrogen atoms of the pyridine type [N-8 in *(3)* and N-4,8 in *(4)*] than for nitrogen atoms of the pyrrole type [N-4 in *(3)*, not resolved][2].

Procedure

A solution of equimolar amounts of *(2)* and *(1)*[3] or malondialdehyde tetraethylacetal[3] in glacial acetic acid (10 equiv.) is heated under reflux for 1 h. After removal of the

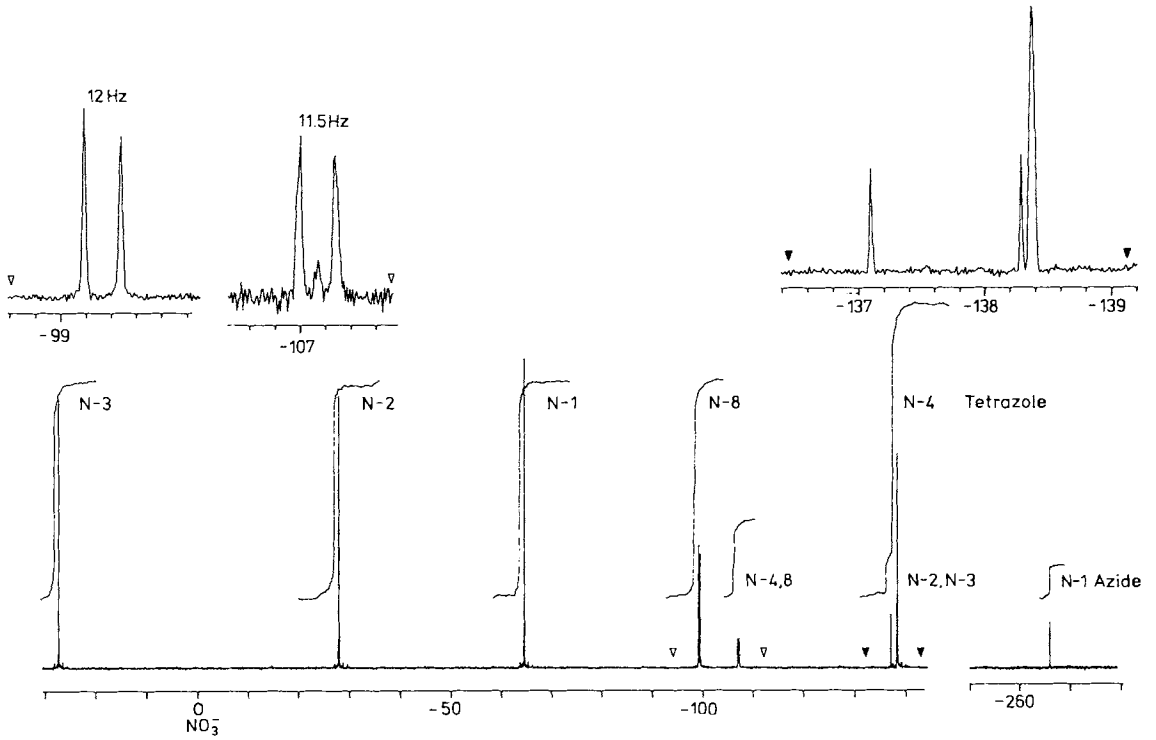

Fig. 1. ^{15}N-NMR spectrum of 6-*n*-butyltetrazolo[1,5-*a*]pyrimidine *(3f)* in equilibrium with 2-azido-5-*n*-butylpyrimidine *(4f)* without solvent. Recording conditions: 40.55 Hz, PFT technique, 45° pulses, delay time 30 s, 2500 scans; standard: $^{15}NH_4{}^{15}NO_3$ in D_2O (external); 15 mm-(∅) sample; spectrometer: WH-400 (Bruker).

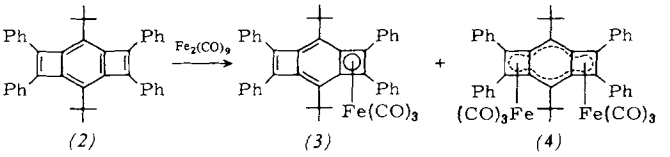
Complexation of a Benzodicyclobutadiene with $Fe_2(CO)_9$[**]

By *Thomas Butters, Fumio Toda,* and *Werner Winter*[*]

Up to now, only a few derivatives of monobenzoannelated [4]annulene (benzocyclobutadiene) have been isolated[1]. According to the results of three X-ray structure analyses, the best representation of the benzocyclobutadiene-framework is the valence-bond formula *(1)*[2].



(1)

Using *(1)*, with $R_1 = CH_3$ and $R_2 = tC_4H_9$, as example, we have already shown[3] that reaction with $Fe_2(CO)_9$ leads to a η^4-coordination of the four-membered ring. In this case, however, the outer double-bond of the four-membered ring is much more strongly coordinated to iron. Obviously, complexed *(1)* represents a compromise between an aromatic six-membered ring and an aromatic cyclobutadiene-$Fe(CO)_3$ unit.

Assuming this to be so, we have investigated the only benzodicyclobutadiene *(2)*[4] so far known in order to ascertain whether it likewise yields cyclobutadiene complexes, or whether it behaves more like a benzene derivative, the annelated double bonds of which undergo η^2-coordination.

When equimolar amounts of *(2)* and $Fe_2(CO)_9$ are heated for 4 h in xylene under reflux (N_2), subsequent work-up of the reaction mixture affords red crystals of the 1:1 complex *(3)* (yield 85%, m.p. 222—223 °C) and black-red crystals of the 1:2 complex *(4)* (yield 5%, m.p. 214—216 °C).

(2) *(3)* *(4)*

In order to establish the bonding properties, we have carried out X-ray structure analyses[5] on both *(3)* and *(4)*. It was established that the most suitable representation of the 1:1-complex is the valence-bond formula *(3)*: it is a 'real' cyclobutadiene complex with a square four-membered ring (C—C = 1.464(3) Å), and the iron atom is situated almost exactly above the middle of this ring. As a consequence of this strong coordination to the cyclobutadienic unit, the other C—C bonds in the whole ring system alternate between 1.354 and 1.509(3) Å.

The structure of complex *(4)* is surprising. The iron atoms are coordinated more strongly to the 'outer' double bonds, analogously to those in the iron complex of *(1)* (Fig. 1). The arrangement of both $Fe(CO)_3$ groups on the same side of the ligand is also surprising.

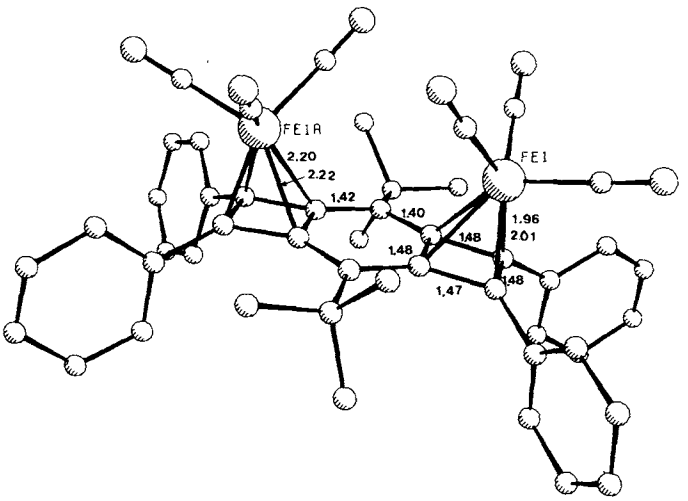


Fig. 1. Molecular structure of complex *(4)* (mean standard deviations of the bond lengths: 0.013 Å); since the molecule lies on a twofold crystallographic axis, it shows exact C_2 point symmetry.

The complexes *(3)* and *(4)* show, on the one hand, that the $Fe(CO)_3$-unit prefers a η^4-cyclobutadiene coordination and, on the other, that it is in fact possible to regard *(2)* as a benzo-*dicyclobutadiene* (at least from the point of view of the transition-metal).

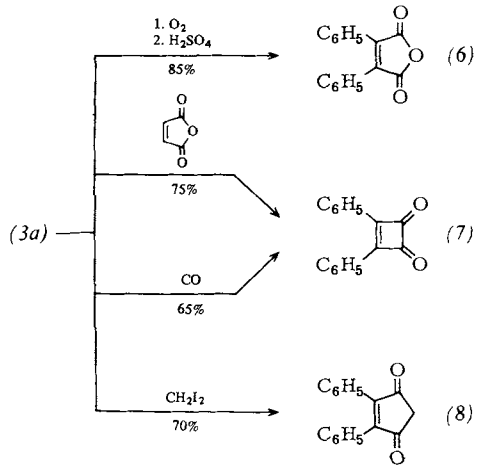
Nickelacyclopentene Derivatives from Nickel(0), Carbon Monoxide and Alkyne

By *Heinz Hoberg* and *Antonio Herrera*[*]

Alkynes and carbon monoxide are known to be activated by complexation with transition metals in such a way that they react to give open-chain or cyclic products *via* C—C linkage[1]. Unsaturated nickelacycles have been discussed as intermediates of the cyclization when $Ni(CO)_4$ is used as catalyst[1b,2], but to our knowledge they have so far not been isolated[3].

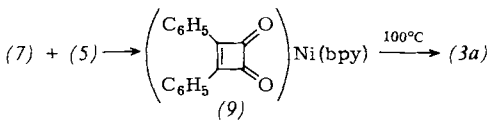
We describe here the synthesis and isolation of the nickelacyclopentene complex *(3)* stabilized by α,α'-bipyridine (bpy). Reaction of (bpy)Ni(CO)$_2$ with tolan *(2a)* and with butyne *(2b)* in tetrahydrofuran (THF) at 20 °C affords the nickelacyclopentenediones *(3a)*, R = C_6H_5, and *(3b)*, R = CH_3, in 60 and 25% yields, respectively.

(3a) can also be obtained without prior fixation of CO to nickel, *e.g.* by reaction of (bpy)Ni(tolan) *(4)* with CO (40% yield) or of (bpy)Ni(COD) *(5)* (COD = 1,5-cyclooctadiene) with CO and tolan *(2a)* (25% yield) (Scheme 1).



Scheme 1. Possible syntheses of *(3)*.

The compounds *(3a)* and *(3b)*, which crystallize as dark red lamellae[4], are diamagnetic and are thermally very stable in the absence of air [*(3a)*, m.p. 234 °C (dec.); *(3b)*, m.p. 224 °C (dec.)]. They are only sparingly soluble in the common solvents such as toluene, THF or diethyl ether.



The mass spectrum of *(3a)* shows only the fragment ions $m/e = 178$ ($(C_6H_5)_2C_2$), 156 (bpy) and 28 (CO). The IR spectrum (KBr) shows no characteristic bands above 1600 cm^{-1} (C=O region). The long-wave shift of the C=O vibration corresponds to a pronounced delocalization to *(3')*, which is also reflected in a lower chemical reactivity.

Thus, *(3a)* is hydrolyzed neither by water nor by 2 N H_2SO_4 (40 °C, THF, 12 h); protonolysis to the anhydride *(6)* only takes place after oxidation with atmospheric oxygen (20 °C, toluene). *(3a)* does not react with tolan *(2a)* (110 °C, toluene, 7 d), but maleic anhydride already effects a reductive elimination at 20 °C in THF after 2 h, giving the cyclobutenedione *(7)*, which with carbon monoxide at 80 °C and 1 bar is only complete after 10 h. Reaction of *(3a)* with diiodomethane affords the cyclopentenedione *(8)* (Scheme 2).

Scheme 2. Reactions of *(3a)*. The structure of the products *(6)*, *(7)* and *(8)* were determined spectroscopically (IR, MS, ^{1}H- and ^{13}C-NMR) and compared with the data of authentic samples [*(6)* [5], *(7)* [5], *(8)* [6]].

The reductive elimination of the C_4-ring in *(3a)* to give *(7)* is reversible: reaction of the cyclobutenedione *(7)* with (bpy)Ni(COD) *(5)* in THF (20 °C, 3 h) leads to the nickel(0) complex *(9)*, which already gives *(3a)* again within 1 h at 100 °C in toluene in the sense of an oxidative addition.

Procedure

A solution of tolan *(2a)* (7.42 g, 41.7 mmol) in THF (50 ml) is added dropwise to a solution of *(1)*[7] (11.0 g, 40.8 mmol) in THF (150 ml) at room temperature. The dark-red crystals which separates out after 24 h are filtered, washed with 30 ml THF, and dried; yield 10.9 g (59%) *(3a)*.

$Ru_3(CO)_{12}$-Catalyzed Synthesis of Vinylsilanes from Olefins and Hydrosilanes[**]

By *Yoshio Seki, Kenji Takeshita, Kazuaki Kawamoto, Shinji Murai,* and *Noboru Sonoda*[*]

Vinylsilanes have recently been shown to be versatile intermediates in organic synthesis[1], and they have usually been prepared from alkynes by hydroalumination of alkynylsilanes[2] or directly by hydrosilylation[3]. During the course of our investigations of catalytic reactions with hydrosilanes and carbon monoxide[4], we have now found a new method for the synthesis of vinylsilanes. The reaction of a fivefold excess of styrene *(1a)* with triethylsilane in the presence of catalytic amounts of $Ru_3(CO)_{12}$[5] affords (*E*)-β-triethylsilylstyrene *(2a)* in 93% yield (cf. [8]). The vinylsilanes *(2b)*—*(2i)* were obtained in high yields *via* the same route.

(1) *(2)*

[a] Reaction conditions: 50 mmol olefin, 10 mmol silane, 0.05 mmol $Ru_3(CO)_{12}$, 10 ml benzene, 80 °C, 5 h. [b] In CCl_4, signals of the olefinic protons $^3J = 19$ Hz. [c] $\nu_{C=C}$. [d] Determined gas-chromatographically. [e] 100 °C, 5 h, stainless steel autoclave. [f] $J = 19$ Hz, 4 Hz. [g] Without benzene, 50 °C, 12 h.

In the case of 3-phenoxy-1-propene, only traces (less than 3%) of the isomeric product, 1-phenoxy-3-triethylsilyl-1-propene, could be detected by GLC.

A large number of catalysts are known for the synthesis of alkylsilanes by hydrosilylation[6], but there are only few for the "dehydrogenative silylation" of olefins[6b,7]; the examples described in this connection are not suitable for the preparation of vinylsilanes.

Experimental:

(2a): A stirred mixture of *(1a)* (5.75 ml, 50 mmol), triethylsilane (1.16 g, 10 mmol) and $Ru_3(CO)_{12}$ (0.034 g, 0.05 mmol) in benzene (10 ml) was heated at 80 °C for 5 h under nitrogen. Analysis of the reaction mixture by GLC (Silicone OV-1, 5%, on Uniport KS, 3 m, 160 °C, internal standard: *n*-heptadecane) showed it to contain *(2a)* in 93% yield. Analytically pure *(1a)* was obtained by fractional distillation.

Spiropentene

By *Robert Bloch* and *Jean-Marc Denis*[*]

Spiropentene *(1)*, comprising a cyclopropane and a cyclopropene unit linked through a spiro carbon atom, was hitherto unknown. Its high strain (≈90 kcal mol^{-1}) probably accounts for the difficulties encountered in its synthesis[1]. Thus only two highly substituted derivatives of spiropentene *(1)* have been described so far[2]. In this communication we wish to report the synthesis of the parent compound and some of its properties.

4-Bromo-1,1-dimethylspiropentane reacts with an excess of potassium *tert*-butoxide in dimethyl sulfoxide (DMSO) at 25 °C to give 1,1-dimethyl-2-ethynylcyclopropane in 30% yield[3]. We have also observed the formation of ethynylcyclopropane *(2)* by reaction of gaseous bromospiropentane with solid KO*t*Bu supported on silica[4] [traces of spiropentene *(1)* are detected by NMR spectroscopy]. However, the slow addition of a solution of KO*t*Bu in DMSO to a hot solution (90 °C) of bromospiropentane in DMSO, under vacuum (80 torr) leads in 60—70% yield to spiropentene *(1)* together with 2—4% of *(2)*. Under these conditions, *(1)* is immediately extracted from the reaction mixture upon formation and can be dissolved in a solvent kept in a cold trap. Compound *(1)* is

(1) > 95% *(2)* < 5%

thus obtainable only as a chloroform solution with 2—4% of *(2)* and 10—15% of *tert*-butyl alcohol.

Although the hydrocarbon *(1)* is a highly reactive compound, which polymerizes in condensed phase even at −78 °C, its solution in chloroform containing a small amount of hydroquinone can be kept several days at −30 °C. Its spectroscopic data[5] resemble those of cyclopropane and cyclopropene. In particular the ^{13}C-H spin-spin coupling constants (158 and 225 Hz) compared to the coupling constants observed for cyclopropane and 3,3-dimethylcyclopropene (respectively 161 and 220 Hz)[6], suggest no difference in the states of hybridization of the corresponding C—H bonds. This would indicate that *(1)* is a normal spiro compound, and that the interaction between the cyclopropane Walsh orbitals and the cyclopropene π orbitals (pseudoconjugation)[7], if at all present, is not important. Confirmation by UV and PE spectroscopy has so far been precluded by the impurities present in *(1)*.

The high strain of *(1)* is revealed by its unusual chemical reactivity compared with that of 3,3-disubstituted cyclopropenes. As expected, the cyclopropene double bond is very

reactive toward nucleophiles; for example, *(1)* adds readily *tert*-butanol in the presence of *tert*-BuOK to give the spiro compound *(3)*[5]. Unlike 3,3-dimethylcyclopropene[8], spiropentene reacts rapidly and quantitatively, even at 0 °C, with cyclopentadiene and furan, respectively giving almost exclusively[9] the *endo* adduct *(4)*[5] and two adducts *(5a)*[5] and *(5b)* (1:3)[10]. Assignment of the configurations is based on the ^{1}H-NMR spectra. In particular, the bridgehead protons show neat coupling to the vicinal cyclopropyl hydrogens only for the *endo* configuration[10]. It appears also to be general that the olefinic protons of the endo-adducts are more shielded than the vinyl protons of the *exo* adducts.

Heating of the compounds *(4)* or *(5)* does not regenerate *(1)* (retro Diels-Alder rupture). *(5)* leads to several unidentified products, while *(4)* affords a unique compound *(6)* both in the vapor phase at 500 °C and in the condensed phase at 180 °C. The mass spectral data show that *(6)* is an isomer of the starting material *(4)*. The NMR spectrum has multiplets between $\delta = 0.1$ and $\delta = 2.0$, but no more absorption in the olefinic proton region. Such rearrangements *via* stabilized 1,3-diradicals, have been already observed in analogous systems[11].

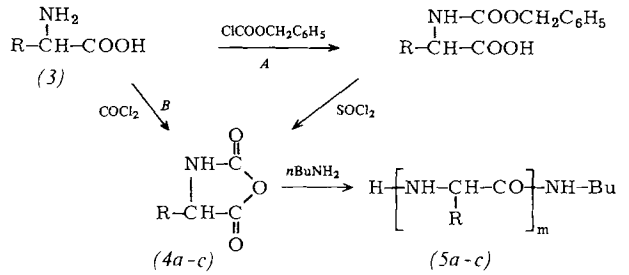
"Synthetic Enzymes". Highly Stereoselective Epoxidation of Chalcone in a Triphasic Toluene-Water-Poly[(S)-alanine] System[**]

By *Sebastián Juliá, Jaume Masana*, and *Juan Carlos Vega*[*]

The use of synthetic peptides as stereoselective catalysts in organic reactions is an attractive alternative to the use of enzymes[1]. However, many of the examples reported[2] have considerable disadvantages: optical yields may be too low[2a]; reaction times too long[2b], or the amounts of protein required too large[2c,d]. To our knowledge we report here the first example of a nearly stereospecific reaction by means of a triphase catalysis using readily available synthetic chiral polypeptides, which does not suffer from any of the drawbacks of the methods just mentioned. Thus, we have achieved the epoxidation of chalcone *(1)* to levorotatory *(2)* in optical yields higher than 90% and satisfactory chemical yields with poly[(*S*)-alanine] *(5a)*, poly[5-benzyl-(*S*)-glutamate] *(5b)*, and poly[5-butyl-(*S*)-glutamate] *(5c)* as catalysts.



Previously, epoxychalcone *(2)* was obtained in 34% optical yield by a phase-transfer method using benzylquininium chloride as catalyst[3]. Its absolute configuration has been recently determined[3]. The polypeptides were synthesized according to Scheme 1, method *A* being used for the preparation of polyalanine, and method *B* being preferred for the synthesis of polyglutamates[4].

The polymerization of the *N*-carboxy anhydrides *(4)*, was performed with *n*-butylamine (molar ratio 10:1). This assumes that the polymers contain an avarage of ten amino acids. IR data show both extended and helicoidal conformations to be present[5].

a, R = CH_3; *b*, R = $(CH_2)_2COOCH_2C_6H_5$;
c, R = $(CH_2)_2COO(CH_2)_3CH_3$
m = 10

Scheme 1

Experimental

Poly[(*S*)-alanine] *(5a)*: (*S*)-Alanine *N*-carboxyanhydride[4b] (11.39 g, 0.1 mol) is dissolved in acetonitrile (400 ml) (dried over P_2O_5). *n*-Butylamine (0.728 g, 0.01 mol) is added and the mixture is stirred for 4 d at room temperature. A white solid appears. The solvent is removed *in vacuo*, and the polymer is washed with diethyl ether. The polymer is dried *in vacuo*. Yield 7.5 g; m.p. >300 °C; IR (KBr): 3370, 3060, 1655, 1630, 1540 cm^{-1}; ^{1}H-NMR (CF_3COOH): $\delta = 7.3$ (—N*H*), 4.2 (—NH—C*H*—CO), 3.0 (—CH_2—R), 1.1 (CH_2—CH_2—CH_2—CH_3, and NH—CH(CH_3)CO), 0.5 $(CH_2)_3$—CH_3); $[\alpha]_{589}^{20} = -120.5$ ($c = 0.996$, CF_3COOH).

(−)-1,3-Diphenyl-2(*R*),3(*S*)-epoxypropan-1-one *(2)* (Table 1, exp. 3): To a solution of *(1)* (1.00 g, 4.8 mmol) in toluene (6.00 g) is added poly[(*S*)-alanine] (400 mg, 0.5 mmol; approx. mol. weight 783). The mixture is stirred for 30 min and a solution of NaOH in 30% H_2O_2 (0.08 g/ml) is slowly added dropwise. The mixture is stirred at room temperature for 48 h. The catalyst is filtered and washed with CH_2Cl_2 (50 ml). The organic phase is washed three times with water, dried over $MgSO_4$, and the solvent evaporated. The residue is purified by column chromatography, using 100 g of silica gel (Merck 0.2—3.0, 200 mm) and toluene as eluant. Yield 0.754 g (70%); $[\alpha]_{578}^{20} = -184$ ($c = 2.717$ in Cl_2CH_2), m.p. 59—61 °C. Spectroscopic data: IR, ^{1}H-NMR were satisfactory and in agreement with the literature[7]. Crystallization of this epoxide from *n*-hexane gave a product with $[\alpha]_{578}^{20} = -214$ °C, m.p. 63—65 °C. The m.p. and rotation remained unchanged after a second crystallization. The crude extract obtained in experiment 6 is divided into two parts before chromatography. One of them was chromatographed as described, yielding an epoxide of 93% o.p. The other one was directly crystallized from *n*-hexane yielding a product of 96% o.p. and m.p. 63—65 °C.

Table 1. Epoxidation of chalcone *(1)* in the presence of polypeptides *(5)*. Levorotatory epoxide *(2)* was formed in all cases *(2)* [a].

10	*(5b)*	1	8.8	26	1.3	1.3:1	144	8	11
11	*(5c)*	1	4.4	6	0.98	0.98:1	48	10	28

[a] For conditions of the reaction, see *Experimental*. [b] Solid NaOH in H_2O_2 30% (0.08 g/ml). [c] Product isolated by silica-gel chromatography. [d] $100 \times [\alpha]_{578}^{20}$ 214; maximum value $[\alpha]_{578}^{20} = -214$ ($c = 1.6$ in CCl_2H_2). [e] Polymer recovered after one experiment.

Our experiments are summarized in Table 1. From the results, the following inferences can be made:

a) Use of polyglutamates *(5b)* and *(5c)* instead of polyalanine *(5a)* lowers both the optical and the chemical yield significantly (exp. 8—11).

b) The polyalanine *(5a)* is necessary both for reaction to occur as well as for stereoselectivity to be observed. This implies that reaction takes place at the chiral interface (exp. 1).

c) The change in weight ratio chalcone *(1)*:polymer *(5)* does not seem to influence significantly the stereoselectivity (exp. 2, 3, 5 and 9,10), even though, optical yields higher than 90% were only obtained at a weight ratio of 1:0.8 (exp. 4—6, but not 7).

d) Polyalanine *(5a)* recovered from the reaction can be recycled[6] (exp. 7), giving rise to a decrease in chemical yield and optical purity, although the latter is still substantial.

e) The relative proportions in the liquid/solid/liquid phases seems to be important. For example, exp. 4 which gave a much lower chemical yield than exp. 3, used the same weight of aqueous phase and toluene while the weight of polymer was double. An increase in the proportion of toluene (compare exps. 8 and 10) resulted in a decrease in optical purity. The amount of aqueous solution does not appear to be crucial.

These results show that the use of simple polypeptides as "synthetic enzymes" may be a valuable tool for performing stereoselective organic reactions.

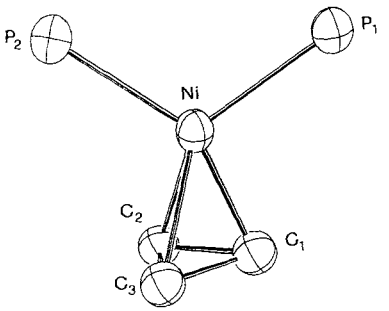
Upright Unsymmetrical Coordination in a Cyclopropenylnickel Complex: Synthesis and Structure of $[(C_3Ph_3)Ni(PPh_3)_2]PF_6$

By *Carlo Mealli, Stefano Midollini, Simonetta Moneti,* and *Luigi Sacconi*[*]

Unsymmetrical coordination of the cyclopropenylium ion has been found only in the complex $[(C_3Ph_3)Pt(PPh_3)_2]PF_6$[1]. Here the $C_3Ph_3^{\oplus}$ triangle has an isosceles shape with one large (1.58 Å) and two short (1.39 Å) sides. The PtP_2 fragment is displaced towards the base which lies approximately in the plane of the PtP_2 unit ("in-plane" conformation).

We have succeeded in preparing the analogous nickel complex $[(C_3Ph_3)Ni(PPh_3)_2]PF_6$ *(1)*, whose X-ray structure analysis shows that the $C_3Ph_3^{\oplus}$ unit is coordinated to the metal in an unprecedented unsymmetrical fashion (Fig. 1)[2].



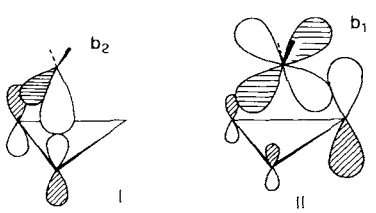


Fig. 1. ORTEP diagram of the skeleton of the complex cation in *(1)*. Important distances [Å] and angles [°] are: Ni—P1 = 2.242(4), Ni—P2 = 2.234(4), Ni—C1 = 1.91(1), Ni—C2 = 2.02(1), Ni—C3 = 2.07(1), C1—C2 = 1.46(2), C1—C3 = 1.44(2), C2—C3 = 1.34(2), P1—Ni—P2 = 107.4(2), C1—Ni—C2 = 43.7(5), C1—Ni—C3 = 42.1(5), C2—Ni—C3 = 38.4(4), C1—C2—C3 = 61.4(8), C1—C3—C2 = 63.4(9), C2—C1—C3 = 55.2(8).

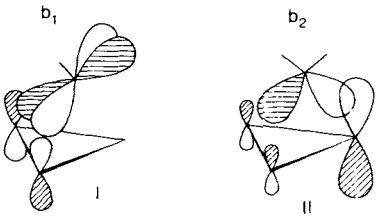

Also in this complex the cyclopropenylium ion has an isosceles shape but the base (1.35 Å) is shorter than the two other sides (1.43 Å). The nickel atom is located at 2.01 and 2.07 Å respectively from the two carbon atoms of the base and at 1.89 Å from the apical carbon atom. The plane of the NiP_2 moiety is almost perpendicular to the base of the triangle (84.09°). This can be named *upright* conformation and is just opposite to that of the platinum complex.

The bonding in both the metal complexes can be fairly well elucidated by considering the interactions of the b_1 and the b_2 orbitals of the MP_2 fragment (mainly metal d_{xz} and d_{yz} orbitals in nature) with the two π-set orbitals of the cyclopropenylium ion being the major bonding interactions in this complex[3].

[+] Author to whom correspondence should be addressed.

In the case of the platinum complex the b_2 orbital is favorably oriented for bonding interaction with the antibonding π^* orbital I of the cyclopropenylium ion, while overlap of b_1 with II falls to a very low value.

A reversed situation is observed in the nickel complex. The 90° rotation of the NiP_2 fragment with respect to the $C_3Ph_3^{\oplus}$ ring as well as the very short Ni—C(apical) distance favors a large overlap of b_2 with II and a lower overlap of b_1 with I. Also the very short distance (1.35 Å) between the two basal carbon atoms in the $C_3Ph_3^{\oplus}$ ring, which is only a bit larger than the C—C double bond in the free ethylene molecule (1.337(2) Å)[4], suggests that their engagement in bonding with nickel is strongly reduced. (For a discussion see also ref.[5].)

Experimental

All operations were performed under nitrogen and with oxygen-free solvents. Triphenylcyclopropenylium perchlorate (366 mg, 1 mmol) in methanol (20 ml) was added to a solution of $(C_2H_4)Ni(PPh_3)_2$ (611 mg, 1 mmol) in benzene (20 ml). On addition of $(n\text{-}Bu)_4NPF_6$ (386 mg, 1 mmol) in butanol (20 ml) and slow evaporation of the solvent, red crystals were formed: yield 75%.

Transition-Metal Complexes with Pyrazolyl Bridging Ligands between Very Different Metal Centers

By *Stephen R. Stobart, Keith R. Dixon, Donald T. Eadie, Jerry L. Atwood,* and *Michael D. Zaworotko*[*]

The structural characterization of transition-metal complexes with bridging pyrazolyl ligands[1] has thus far only

embraced systems incorporating homometallic bridged frameworks[2]. We wish to report the synthesis of some novel heterometallic analogues and the X-ray crystal structure of one of them.

(1) *(2)*

(a), $PR_3 = PEt_3$; *(b)*, $PR_3 = PMe_2Ph$

On UV irradiation (tetrahydrofuran, inert atmosphere) of the *cis*-bis(pyrazolyl)platinum(II) complexes *(1a)* and *(1b)* in the presence of $Cr(CO)_6$, the yellow compounds *(2a)* and *(2b)* were isolated. Molybdenum and tungsten analogues and the corresponding 3,5-dimethylpyrazolyl-bridged derivatives can be synthesized similarly[3]. The ^{1}H-NMR spectrum of *(2a)* (30 °C, CD_2Cl_2 solution) revealed that the methyl groups in the phosphane ligands are not magnetically equivalent; this is consistent only with a nonplanar conformation for the cyclic unit, and establishes that ring inversion for the latter is not rapid at ambient temperature. We subsequently determined the X-ray crystal structure of *(2a)*[4] (Fig. 1) and found a boat conformation for the central six-membered ring.

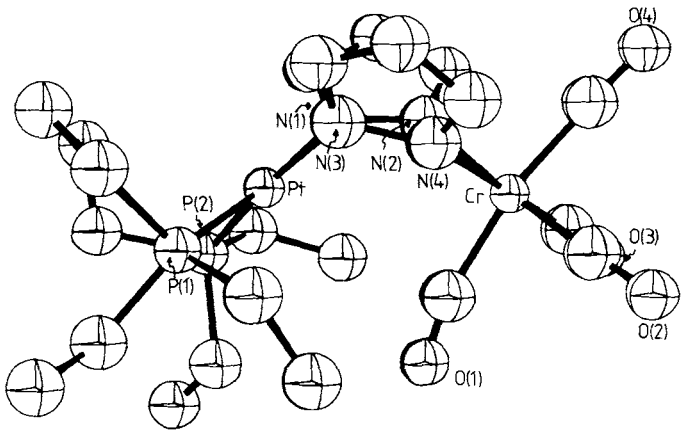

Fig. 1. ORTEP drawing of *(2a)* in crystal. Principal bond lengths [Å] and angles [°]:

Pt—N(1)	2.07(2)	N(1)—N(2)	1.39(3)
N(2)—Cr	2.14(2)	Cr—N(4)	2.16(2)
N(3)—N(4)	1.38(2)	Pt—N(3)	2.05(2)
Pt—N(1)—N(2)	121(1)	N(1)—N(2)—Cr	125(1)
N(2)—Cr—N(4)	85.6(7)	Cr—N(4)—N(3)	124(1)
N(4)—N(3)—Pt	120(1)	N(3)—Pt—N(1)	84.2(7)

These observations are of considerable current interest, in that structural data for related pyrazolyl-bridged complexes refer exclusively to homometallic molecules in which each metal atom has an identical environment. Such species exhibit a remarkable range of geometries from the chair conformation of $[(\eta^5\text{-}C_5H_5)_2Ti(\mu\text{-}C_3N_2H_3)]_2$[2a] through planar for $[Ni(NO)(\mu\text{-}C_3N_2HMe_2)]_2$[2b], to boat-shaped in a cobalt(I) analogue[2c]. In compound *(2a)*, whose pyrazolyl bridges link two dissimilar metal atoms in very different coordination environments and formal oxidation states, the central ring adopts a steep boat conformation in which the Pt—Cr distance is only 3.69 Å. This ability of the exobidentate pyrazolyl ligand to accommodate widely differing bridging configurations may be of considerable significance in relation to electrical or catalytic cooperativity effects between adjacent metal centers.

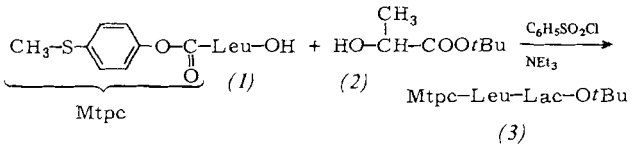
Full-matrix least-squares refinement of the model obtained from the subsequent difference Fourier phased on these atoms led to an R value of 0.088.

Synthesis of Alternating Depsipeptides with the 4-Methylthiophenoxycarbonyl Group as Protecting and Activating Group for the Amino Function[**]

By *Horst Kunz* and *Klaus Lorenz*[*]

Depsipeptides made up of alternating hydroxy and amino acids are of interest owing to their antibiotic properties and their ability to selectively complex ions. Methods from peptide chemistry[1] are employed to synthesize these compounds, although the ester bonds of the chain cause characteristic differences of reactivity relative to peptides.



In the case of depsipeptides having α-hydroxycarboxylic acid units, these ester groups not only lead to undesired hydrolyses but also react readily with free amino groups of the linkage partner or of the compounds own amino end group and thus cause error sequences and self-cyclization. In order to counter these effects, the drastic acyl chloride method is often used for chain-lengthening amide formation in depsipeptide synthesis[2]. In addition amino groups have to be liberated from the hydro salts during the condensation step.

During our studies on protecting groups[3] for peptide synthesis, we have found the 4-methylthiophenoxycarbonyl (Mtpc) group to combine protective and activation properties for the amino function which specifically meet the needs of depsipeptide synthesis. This group provides a means of avoiding the presence of free amino groups during the synthesis, of circumventing the extreme activation of the carboxy groups *via* the acyl chloride, and of combining carboxyl activation and condensation in a single step.

The Mtpc group is introduced by 4-methylthiophenyl chloroformate on reaction according to conventional methods with the amino acids in aqueous alkaline solution. This affords *e.g.* 4-methylthiophenoxycarbonyl-L-leucine *(1)* in 92% yield. Compound *(1)* is then coupled with *tert*-butyl L-lactate *(2)*[5] by the benzenesulfonyl chloride method[4] to give the Mtpc depsidipeptide ester *(3)* in 90% yield.

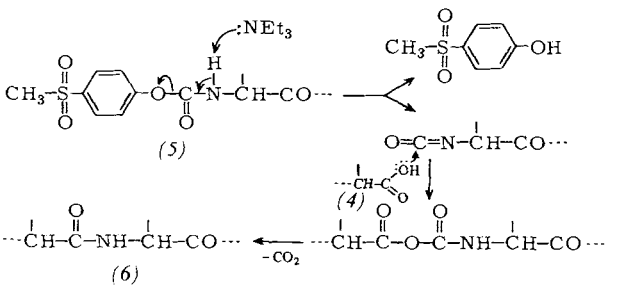
Mtpc (1) (2) Mtpc–Leu–Lac–OtBu (3)

The valuable properties of the Mtpc group for depsipeptide synthesis can be illustrated with the model compound *(3)*.

1) Mtpc protection is unaffected by trifluoroacetic acid, so that the C-terminal *tert*-butyl ester can be selectively removed.

2) The Mtpc group, which proved to be stable towards weak bases (pH = 12) under the conditions of its incorporation, can be easily oxidized by peracetic acid almost quantitatively to the base-labile 4-methylsulfonylphenoxycarbonyl (Mspc) group.



Mtpc–Leu–Lac–OtBu (3) → Mtpc–Leu–Lac–OH (4) + Mspc–Leu–Lac–OtBu (5) → Mtpc–Leu–Lac–Leu–Lac–OtBu (6)

Both reactions afford synthons useful for chain elongation. Coupled removal of the N-terminal protecting group and condensation with the next carboxylic component is accomplished by reaction of the N-terminal protected depsipeptide *(4)* with the N-terminally activated depsipeptide ester *(5)* in dichloromethane/pyridine/triethylamine. The N- and C-terminally protected tetradepsipeptide *(6)* is formed in a crude yield of 91%[6].

As with *(3)* the tetradepsipeptide *(6)* can be smoothly deprotected at the C-terminus (85% yield) and activated to the Mspc derivative at the N-terminal by treatment with peracetic acid (92% yield). Condensation of these derivatives under the same conditions as used for *(4)* and *(5)* furnishes a 93% crude yield of the octadepsipeptide Mtpc-(Leu-Lac)$_4$-OtBu. Purification by column chromatography gave an analytically pure yellowish oil (56%)[6].

Scheme 1 shows our concept of the reaction course. An analogous reaction sequence had already been utilized by *Gante*[7] for C-terminal chain elongation of peptides with *N*-(2,4-dinitrophenoxycarbonyl)amino acid esters.

The finding that the phenol is eliminated only from the Mspc form under the conditions employed is of decisive importance for depsipeptide synthesis by the Mtpc/Mspc principle.

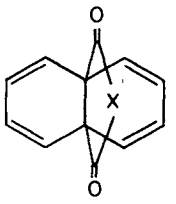
Cyclic Oligomers of Propellanes and Bridged Annulenes with Bis(triazolinediones) Studied by ^{252}Cf-Plasma Desorption Mass Spectrometry[**]

By *P. Ashkenazi, R. D. Macfarlane, W. A. Oertling, Heinrich Wamhoff, K. M. Wald*, and *David Ginsburg*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



For several years we have been studying the reaction of various polyenic propellanes of type *(1)* and bridged [10]annulenes with 1,2,4-triazoline-3,5-diones and have put forth rather convincing evidence that *syn*-attack (with reference to the hetero-ring) by the dienophile *(2)* occurs because of sec-

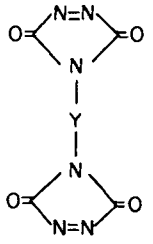
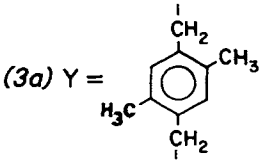
[**] Propellanes, Part 60. We are grateful to the National Science Foundation and the Robert A. Welch Foundation for support of the mass spectral work *(R. D. M.* and *W. A. O.)*, without which publication of these results would not have been possible. Support by the Deutsche Forschungsgemeinschaft and by Bayer AG is gratefully acknowledged *(H. W.* and *K. M. W.)*. We thank Prof. Dr. *A. Mandelbaum* for drawing our attention to ^{252}Cf plasma desorption mass spectrometry and Prof. Dr. *E. Vogel* for samples of bridged annulenes and his interest in this work. — Part 59: *I. M. Landheer, D. Ginsburg*, Heterocycles, in press.

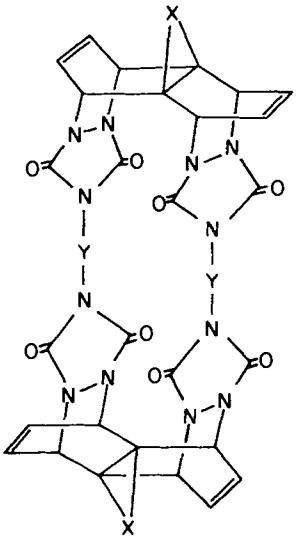
ondary orbital interactions between the π^* carbonyl orbitals in *(1)* (LUMO) and the n_--antisymmetric combination of nitrogen lone pair orbitals in *(2)* (HOMO)[1].



Perhaps our most exciting additional support for this thesis arose from the idea (suggested by *H. W.*) that we react our propellane substrates with bis(triazolinediones) *(3)*[2] in the hope that [2+2] cyclic oligomers be obtained. This hope was realized in the case of several 1,6-bridged [10]annulenes. Just as in the simpler reactions with *(2)*, exclusive *anti* attack occurs due to steric hindrance caused by the bridge, and the bis(triazolinedione) is able to form a [2+2] oligomer with an elliptical cavity *(4)*.



(1) *a* X = O
b X = NH
c X = NMe
d X = NPh



(2) R = Me, Ph

(3a) Y =

(3b) Y = $-(CH_2)_6-$

(4) X = CH_2, O
Y as in *(3)*

However, in the case of *(1)*, no [2+2] oligomers could be observed. The cavity in such a product is evidently not large enough to accommodate the peripheral structure. However, our hope was also realized in principle for *(1)*. We could easily demonstrate that certain substrates gave oligomers in the range [3+3] to [6+6] (Table 1). We exemplify this by structure *(5)*. When this as well as the analogous products obtained from substrates in Table 1 were irradiated in solution, all of the double bonds disappeared and the vinylic protons of *(5)* were replaced by the cyclobutane protons in *(6)*. We must however confess that the conformation exhibited by *(5)* and *(6)* has not been unequivocally proven as we have thus far not succeeded in obtaining crystals suitable for X-ray crystallography.

Although in one or two cases of 2:1 adducts (Table 1) a Rast molecular weight determination could be carried out (*e.g.* in camphor, borneol, or bornylamine), in all other cases temperature and solubility of the product did not permit this.

Table 2. Reaction of dienes obtained by 2:1 addition (see Table 1) with dienophiles in a molar ratio of 1:1.

[a] Photocyclization to cyclobutane derivatives.

The only method permitting interpretation of our findings was Cf-252 plasma desorption mass spectrometry[3]. Other mass spectral methods including field desorption could at most afford fragment peaks resulting from retro-Diels-Alder reactions, due to the low thermal stability of these molecules.

The chemical result we wish to emphasize is the photocyclization of compounds such as *(5)* → *(6)* in which a [4+4] oligomer was formed clearly stepwise, yet in the rapid reaction leading to it (instantaneous at RT) the bis-compound *(3)* is discerning enough to attack (on eight occasions!) *syn* to the imide ring. In *(3a)* + *(1d)*, this occurs on 12 occasions but six to eight is impressive enough. Calculations by *Gleiter* indicate that the attraction in the relevant secondary orbital in-

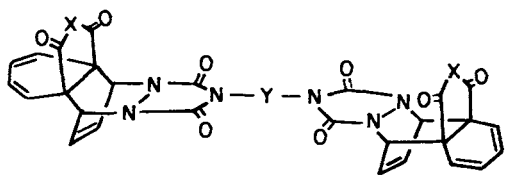
teraction is *ca.* 4—6 kcal/mol[4], of the order of a hydrogen bond. But the experimental results of the photocyclization (cf. [5]) are overwhelming support for secondary orbital interactions as the controlling factor in this *syn* attack.

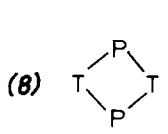
obtain products of type *(9)*, of which *(5)* is an example. This means that in the reaction between P—T_a—P and T_a (or T_b) or P—T_b—P and T_b (or T_a) the reactants must necessarily interact head (P) to tail (T) throughout, even when as many as



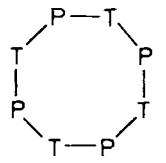
(5) X as in *(1)*
Y as in *(3)*

(6) X as in *(1)*
Y as in *(3)*

Perhaps the most interesting deduction from Table 2 is that the cavity in a [2+2] oligomer [from *(1)*] is evidently not big enough to sustain the structure and therefore the reactants prefer to react further, to the [4+4] stage or higher. The general structure of a [2+1] adduct obtainable from propellanes but not from bridged [10]annulenes (cf. also simpler cases in [5,6]) is given by formula *(7)*.



(7) X as in *(1)*
Y as in *(3)*



The central portion of formula *(7)* stems from the bis(triazolinedione) *(3a)* or *(3b)* (symbolized by T_a or T_b and its two side moities stem from the appropriate tetraenic propellane (symbolized by P); thus *(7)* may be abbreviated as, *e.g.* P—T_a—P or P—T_b—P (each P still has a cyclohexadiene ring capable of reacting with one end of T_a or T_b).

The course of reaction of P—T—P with T might be expected to lead to cyclic oligomers of type *(8)*, *i.e.* a [2+2] oligomer, but as we have seen in Table 2, it is more usual to

three P—T—P molecules are reacting with three molecules to give the dodecamers listed in Tables 1 and 2. Furthermore, the photoreaction [exemplified by *(5)*→*(6)*] indicates that these molecules are also aware of secondary orbital interaction, as exclusive *syn*-attack occurs throughout.

(8)

(9)

Because they react with dienophiles of type T in *anti-anti* sense with reference to the bridge, the Köln bridged annulenes are the only substrates able to form a [2+2] adduct with an elliptical cavity [type *(4)*], but Table 1 shows that they too may form [3+3] and [4+4] oligomers.

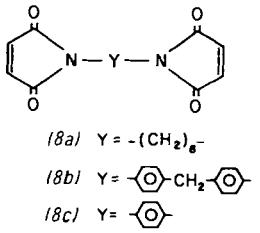
Mixed Oligomers of Propellanes and Bridged Annulenes with Bis(maleimides) and Bis(triazolinediones) Studied by ^{252}Cf-Plasma Desorption Mass Spectrometry[**]

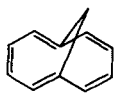


By *P. Ashkenazi, R. D. Macfarlane, W. A. Oertling, Heinrich Wamhoff, K. M. Wald,* and *David Ginsburg*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

On using propellanes as stereochemical models in various types of reactions, we discovered that for steric reasons simple substituted maleimides attack tetraenic propellanes from the side *anti*- to the heteroring[1]. In contradistinction to maleimides, substituted triazolinediones contain nitrogen atoms whose antisymmetric n_- combination of lone pair orbitals (HOMO) can undergo secondary orbital interactions with the CO π^* orbitals (LUMO) of the propellane hetero ring causing *syn*-attack with reference to the carbonyl-containing rings[2].

Before we began our work we knew that a tetraenic propellane mono-Diels-Alder adduct with a substituted maleimide, *e.g. (2),* will react with a simple triazolinedione such as *(3)* to give *(4)* and with another mole of a maleimide also to give the same type of *anti-syn*-bisadduct *(4)*. On the other hand, the monoadduct *(6)* with the substituted maleimide *(7)* does not afford a bisadduct even under forcing conditions[6].



In view of the results described in the preceding paper[3] and in view of the existence of bis(maleimides)[4] we decided to study mixed oligomers of tetraenic propellanes and bridged annulenes with both the bis(triazolinedione) type of dienophile *(12)*[3,5] and with the bis(maleimide) type *(8)*.

A Simple Method of Forming Metal-to-Metal Bonds[**]

By *Johann Plank, Doris Riedel*, and *Wolfgang A. Herrmann*[*]

Our studies on the acid-induced formation of trinuclear methylidynerhodium clusters from the methylene complex μ-$CH_2[(\eta^5\text{-}C_5H_5)Rh(CO)]_2$[1] and the smooth spontaneous formation of $(\eta^5\text{-}C_5H_5)_3Rh_3(\mu\text{-}CO)_3$ from the μ-hydrido complex $[(\eta^5\text{-}C_5H_5)_2Rh_2(CO)_3H]BF_4$ have demonstrated the activation of basic molecular centers to constitute a powerful alternative method of metal-metal bond making[2]. We now report the synthesis of a simple dinuclear rhodium compound which is accessible from its mononuclear precursor neither by thermal nor by light-induced reactions.

The action of tetrafluoroboric acid on diethyl ether solutions of dicarbonyl(η^5-pentamethylcyclopentadienyl)rhodium *(1)* effects fast and complete precipitation of an ionic, exceptionally base-sensitive dark brown complex *(2)*, which is thermally stable up to about 85 °C and is shown by its properties (Table 1) to be a cationic μ-hydrido complex (Scheme 1). The intermediacy of the primary protonation product $[(\eta^5\text{-}C_5Me_5)Rh(CO)_2H]BF_4$ in the formation of *(2)* is evidenced by independent protonation experiments carried out in *n*-pentane[9] and similar reactions of the cobalt complex $(\eta^5\text{-}C_5H_5)Co(PMe_3)_2$, related to *(1)* for which *Werner et al.* have observed a variety of surprising secondary reactions of the mononuclear hydrido complex $[(\eta^5\text{-}C_5H_5)Co(PMe_3)_2H]BF_4$[3].

The most striking property of the nitromethane-soluble compound *(2)* is its proclivity to undergo deprotonation, which is slow with basic solvents (dimethylformamide, dimethyl sulfoxide, acetonitrile) but *fast* and *quantitative* with sodium methoxide/methanol (Scheme 1); the violet-red neutral complex *(3)* is isolated which, strangely enough, was hitherto unknown (Table 1).

Scheme 1

Table 1. Physical and spectroscopic properties of the new rhodium complexes *(2)* and *(3)*.

(2): dark brown powder, can be stored indefinitely with rigorous exclusion of light and moisture, decomposes above *ca.* 85 °C (m.p. >240 °C, sealed capillary). Readily soluble and stable in nitromethane. Equivalent conductivity (CH_3NO_2, 21.6 °C, $c = 3.0 \times 10^{-4}$ mol/l): $\Lambda = 137$ cm^2 mol^{-1} Ω^{-1}. IR (νCO; cm^{-1}): 2010 vs, 1836 s (KBr) [a]; 2022 vs, 1834 vs (CH_3NO_2); 2026 vs, 1839 vs (CH_2Cl_2). ^{1}H-NMR (90 MHz; CD_3NO_2, −25 °C): $\delta = 2.03$ (s, 30H), −10.40 (t, 1H; $^1J_{Rh,H} = 19.2$ Hz)

(3): carmine red powder or violet-red, light-sensitive needles; stable in air for several days at room temperature in the dark. Sinters at 141—143 °C (sealed capillary) with weak evolution of gas and formation of the deep blue derivative *(4)*. Readily soluble in THF, CH_2Cl_2, and benzene; equivalent conductivity (THF, 21.6 °C, $c = 2.8 \times 10^{-4}$ mol/l): $\Lambda = 1.1$ cm^2 mol^{-1} Ω^{-1} (non-electrolyte). IR (νCO; cm^{-1}): 1947 vs, 1794 vs (KBr); 1952 vs, 1791 vs (THF); 1951 vs, 1778 vs (CH_2Cl_2). ^{1}H-NMR (90 MHz; [D$_8$]-THF, −10 °C): $\delta = 1.91$ ("s"); MS (12 eV); T_Q 140 °C, T_E 110 °C): $m/e = 560$ (M^+, 11%); 532 ([M−CO]$^+$, 100), 504 ([M−2CO]$^+$, 4), 476 ([M−3CO]$^+$, 1), 373 ($(C_5Me_5)_2Rh^+$, 82)

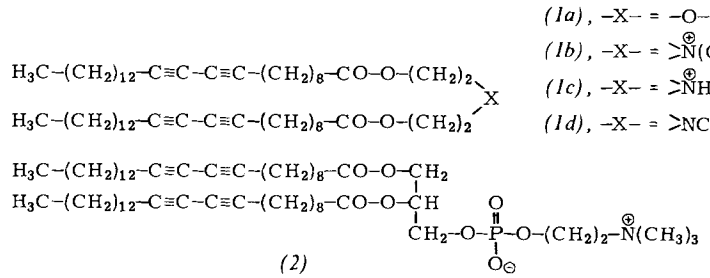
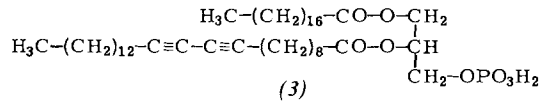
[**] Syntheses of Metal Carbonyls, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, Degussa Hanau and Hoechst AG.—Part 5: W. A. Herrmann, H. Biersack, J. Organometal. Chem. *191*, 397 (1980).



According to the data shown in Table 1, *(3)* has the same structure as the analogous cyclopentadienyl compound[4, 10] having no substituent in the five-membered ring. Complex *(3)* decomposes both thermally (150 °C, 1 h) and photochemically (tetrahydrofuran, Hg high-pressure lamp, $\lambda > 300$ nm) *via* carbonyl elimination to form *(1)* and the twofold carbonyl-bridged derivative *(4)*. *Maitlis et al.* obtained *(4)* by heating *(1)* (80—85 °C/10—20 torr)[5]; however, *(4)* does not form photochemically. Carbonylation of *(4)* under normal pressure essentially affords the starting material *(1)* along with very small amounts of *(3)*.

The carbonylrhodium compound *(3)* which in fact is inaccessible by thermal or photochemical (dimerizing) decarbonylation of *(1)* can readily be obtained by the protonation/deprotonation sequence presented in this communication. Owing to the basic character of *(1)* and analogous metal-carbonyl systems, their acid activation constitutes a clear-cut method for the facile construction of polynuclear complexes which can be obtained only with difficulty, in only low yields, or not at all by conventional methods[6].



Procedure[7]

(2): To a vigorously stirred solution of *(1)*[8] (294 mg, 1.0 mmol) in diethyl ether (20 ml) is added dropwise 54% HBF_4 (*ca.* 0.2 ml) in the same solvent. Towards the end of acid addition, compound *(2)* deposits as a dark brown floccular precipitate which is quickly filtered off on a D3 frit, washed with ether (4 × 6 ml), and dried for 3 h in a high vacuum; yield 298 mg (92%).

(3): Compound *(2)* (298 mg, 0.46 mmol) is treated with a saturated $NaOCH_3/CH_3OH$ solution (6 ml) in the dark at +20 °C, whereupon microcrystalline, carmine-red *(3)* (sparingly soluble in CH_3OH) is formed instantaneously. Compound *(3)* is *immediately* (!) filtered off on a D3 frit, quickly washed with methanol (3 × 6 ml) and dried in a high vacuum; yield 248 mg (97%). This product is already analytically pure but can be recrystallized from THF/ether (10: 1; −25 °C) *in the dark* (!).

[9] Reaction of $[\eta^5\text{-}C_5(CH_3)_5]Ir(CO)_2$ with HBF_4 (diethyl ether, 0 °C) affords the salt-like complex $[\{\eta^5\text{-}C_5(CH_3)_5\}Ir(CO)_2H]BF_4$ in a quantitative yield: IR(CH_3NO_2): 2111 vs, 2070 vs (νCO); ^{1}H-NMR (CD_3NO_2, int. TMS, −20 °C): $\delta = 2.43$ (s, 15H), −13.82 (m, 1H); equivalent conductivity: $\Lambda = 94.6$ cm^2 mol^{-1} Ω^{-1} (CH_3NO_2, 23.4 °C, $c = 10^{-4}$ mol/l). The complex can be reversibly deprotonated with $NaOCH_3/CH_3OH$. These findings support the assumption that the reaction *(1)*→*(2)* proceeds *via* the analogous mononuclear hydrido complex *(1)*-$H^{\oplus}BF_4^{\ominus}$. — Compound *(3)* is also protonated by CF_3SO_3H to form *(2)*, $CF_3SO_3^{\ominus}$ in place of $BF_4^{\ominus}$. The thermal and the photochemical disproportionation of *(3)* both follow the equation

$3\,(3) \rightarrow 2\,(1) + 2\,(4) + CO$

[10] *Note added in proof:* Meanwhile, an X-ray diffraction study of *(3)* has been carried out which confirmed the suggested structure; see Scheme 1 (*M. L. Ziegler, W. A. Herrmann, et al.*, unpublished results, 1980).

Polymerizable Phospholipid Analogues—New Stable Biomembrane and Cell Models[**]

By *Hans-Henning Hub, Bernd Hupfer, Horst Koch,* and *Helmut Ringsdorf*[*]

Biological membranes consist of phospholipids, proteins, and other compounds. Liposomes (vesicles)—artificially built up spherical particles with bimolecular membranes and aqueous cores—are particularly appropriate cell and membrane models[1]. One of the disadvantages of liposomes consisting of natural phospholipids is their short lifetime and especially their low stability in the interaction with natural cell systems. This hinders their application as models for cell-cell interactions as well as their use as carriers for drugs and other biologically active substances.

Initial attempts to work with model systems not composed of natural phospholipids have recently been described. These

synthetic liposomes consist either of long chain fatty acids[2a] ("ufasomes"), of fatty acid/lysophospholipid mixtures[2b], or of lipid analogous dialkyl compounds[2c]. Single-chain ammonium amphiphiles bearing two charged end groups and a rigid segment are able to form membrane-like assemblies as well[2d]. Yet all these models exhibit a limited lifetime.

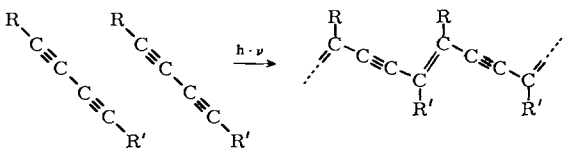
[**] Polyreactions in Ordered Systems, Part 20. We thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.—Part 19: [5b].



Novel, stable liposomes that are more suited as cell membrane models can be obtained *via* polymerization of the lipid bilayers of vesicles with retention of their structure. For this purpose lipid-analogous [*(1)—(3)*] and lysolipid analogous monomers *(4)* were synthesized containing polymerizable diacetylene moieties in the side chains (Table 1).

Table 1. Polymerizable lipid and lysolipid analogues; yields and melting points.

Compound	Yield [%]	M.p. [°C]	
(1a)	32 [a]	49.0—49.5	(ethanol)
(1b)	76 [a]	93.5—94.5	(acetone)
(1c)	80 [a]	109	(chloroform)
(1d)	85 [a]	47.5—48.5	[4a]
(2)	20 [a]	— [b]	
(3)	24 [a]	37—38	(acetone)
(4a)	55	68—69	(hexane)
(4b)	64	59—60	(hexane)
(4c)	86 [c]	79—82	(hexane)

[a] Based on *(4a)*. [b] Uncharacteristic m.p., in analogy to other synthetic lecithins [10]. [c] Based on *(4b)*.

Diacetylenes are known to be polymerizable topochemically by UV irradiation in the solid state[3a] and in oriented mono-[3b] and multilayers[3c,d]. The resulting polymers have a red color due to their conjugated enyne structure.

Prior to the investigation of the polymerization of compounds *(1)—(4)* in liposomes, we examined their surface pressure-area and polymerization behavior in monolayers at the gas-water interface[4] according to earlier investigations[3b,c]. In order to obtain vesicles, the lipid analogues *(1)—(3)* as well as the single chain lysolipid analogues *(4)* were sonicated as aqueous suspensions at 50 °C under nitrogen. Electron microscopy of the resulting clear, colorless solutions proves the formation of spherical vesicles of different diameters (up to several μm). Only after sonication for longer than 30 min the formation of small unilamellar liposomes occurs (diameter: approximately 100 nm, wall thickness: approximately 10 nm, Fig. 1).

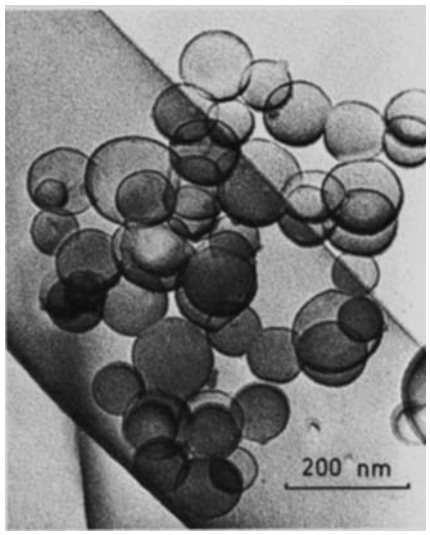


Fig. 1. Small unilamellar monomer vesicles of lipid analogue *(1a)* after 30 min of sonication, negatively stained with uranyl acetate. Philips EM 300 electron microscope, acceleration voltage: 80 kV.

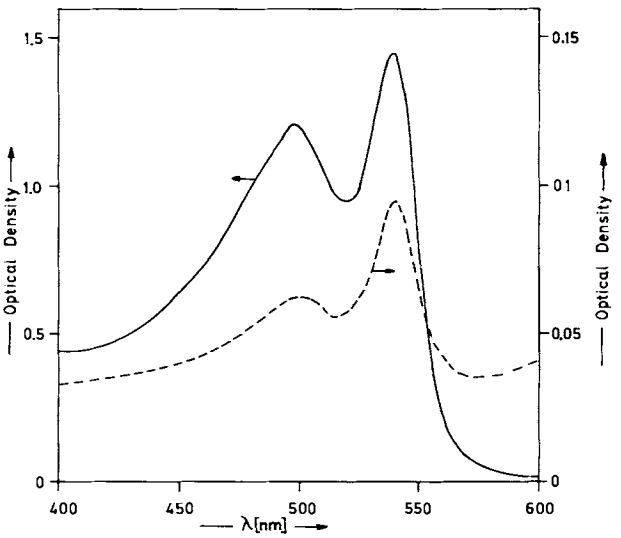
On UV irradiation, the vesicle solutions of the lipid analogues *(1a)—(1c)*, *(3)*, and of the lysolipid analogues *(4a)—(4c)* exhibit a color change from colorless *via* blue to red, which had already been observed in the solid state and in multilayers[5a]. The lecithin analogue *(2)* turns red without going through the blue intermediate. The absorption spectra of the polymer vesicles are qualitatively identical to those of the polymer monolayers[5b] (Fig. 2).



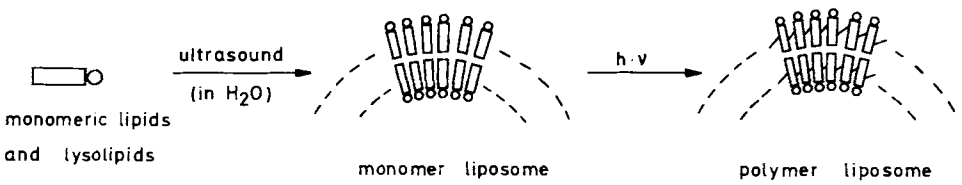


Fig. 2. UV spectrum of *(1b)* polymer liposomes after 15 min of UV irradiation (multichromatic light) (——), $c = 0.5$ mg ml^{-1}; reference spectrum of a polymer monolayer of *(1b)* after 60 min of irradiation [4b] (– – – –).

It can be shown by electron microscopy that the shape of the monomer vesicles is retained during the polymerization. Obviously a topochemical polymerization of diacetylenes is even possible in spherical liposomes. As far as we know, this is the first example of a transformation of defined monomer into defined polymer vesicles under complete retention of the orientation of the monomers and the structure of the vesicles (Scheme 1).

The polymeric character of these vesicles is also documented by their enhanced stability. In contrast to their monomeric analogues, aqueous dispersions of the polymeric liposomes are completely stable. Moreover, they cannot be destroyed by organic solvents: the dilution of a vesicle dispersion with 50% of ethanol does not lead to a precipitation. The spherical structure remains unchanged. A precipitation can be achieved by the addition of salts (KCl), but again it

Scheme 1. Formation of polymer liposomes from polymerizable lipid analogues.

has to be pointed out that the liposomes are not destroyed by the osmotic shock. Electron miscoscopy proved that the precipitate consisted of spherical vesicles.

In addition, the possibility of obtaining scanning electron micrographs of the polymer liposomes (Fig. 3) also hints at their great stability. In contrast, the monomer vesicles are destroyed during sample preparation.

These stable lipid bilayer vesicles could be of use as models for the study of cell-cell interactions or as carriers for biologically active substances. Preliminary experiments have already shown that mixed membranes consisting of polymerizable and natural lipids and proteins, respectively, can be realized at the gas-water interface. These mixed systems are of special interest for the investigation of interactions with natural cell systems. Synthetic lipids with different polymerizable groups[6] (vinyl and butadiene derivatives) can also be used for these experiments instead of the excessively rigid polydiacetylenes.

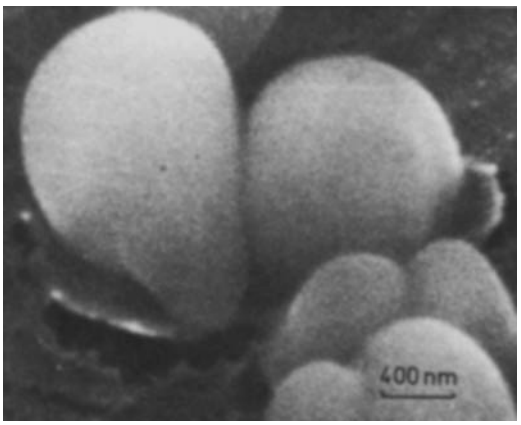

Fig. 3. Scanning electron micrograph of large, multilamellar *(1b)* polymer vesicles. ISI-40 scanning electron microscope, acceleration voltage 15 kV.

Experimental[7]

(4c): (4b)[3d] (10 mmol) is added to $POCl_3$ (15 mmol) dissolved in anhydrous CCl_4 (25 ml). After standing stoppered overnight the mixture is refluxed for 6 h. The solvent and excess $POCl_3$ are evaporated *in vacuo*, and the residue is heated with water (50 ml) for 30 min. The mixture is extracted with ether and the product recrystallized.

(1a): (4a)[3d] is reacted with oxalyl chloride to obtain the acid chloride[8]. The acid chloride (10 mmol) dissolved in anhydrous chloroform (10 ml) are added dropwise at 0 °C to a mixture of tetraethyleneglycol (5 mmol) and anhydrous pyridine (15 mmol) dissolved in anhydrous chloroform (20 ml). The mixture is stirred overnight at room temperature and worked up with ether.

(1b): (1d) is obtained from *N*-methyliminodiethanol and the acid chloride of *(4a)* as described for *(1a)*. *(1d)* is quaternized with CH_3Br in anhydrous acetone at 0 °C.

(1c): A mixture of the acid chloride of *(4a)* and *N,N*-bis(2-hydroxyethyl)-2-aminoethanesulfonic acid in anhydrous chloroform/pyridine is refluxed overnight. *(1c)* crystallizes on chilling.

(2): 1,2-Bis(10,12-hexacosadiynoyl)glycerol, m.p. 65—66 °C (from light petroleum), was obtained using a general procedure described in ref. [9]. This product was acylated with β-bromoethylphosphoric dichloride according to *Eibl et al.*[10], hydrolyzed, and reacted with $N(CH_3)_3$ and Ag_2CO_3.

(3): 2-(10,12-Hexacosadiynoyl)-3-stearoylglycerol iodohydrin, m.p. 34—36 °C (ether/methanol), was obtained by stepwise acylation of racemic glycerol iodohydrin[11]. This product is phosphorylated with silver di-*tert*-butyl phosphate[12]. The *tert*-butyl protecting groups are removed by gaseous HCl in anhydrous $CHCl_3$[12].

Conversion of an Iodomethyl(phosphane)- into a Methylenephosphorane-Complex: Example of a Nucleophile-Catalyzed Isomerization Reaction[1]

By *Rainer Feser* and *Helmut Werner*[*]

Dedicated to Professor Fritz Seel on the occasion of his 65th birthday

The pronounced Lewis-base behavior of $C_5H_5Rh(PMe_3)_2$ *(1)* can be exploited for the synthesis of cationic hydrido-, alkyl-, and halo-complexes of the type $[C_5H_5RhR(PMe_3)_2]^+$ (R = H, Me, Et, MeCO, PhCO, Cl, I, *etc.*)[2]. We have now also attempted the preparation of a cationic iodomethyl complex. Such a compound containing a carbenoid ligand should be readily convertible into cations of the type $[C_5H_5Rh(CH_2L)(PMe_3)_2]^{2+}$ (L = PR_3, NR_3) and $[C_5H_5Rh(CH_2X)(PMe_3)_2]^+$ (X = halogen, OCH_3, *etc.*). Ylide complexes were hitherto prepared either by reaction of a

[*] Prof. Dr. H. Werner, Dipl.-Chem. R. Feser
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

suitable substrate with a free ylide[3] or of a methylene complex with a nucleophile[4].

The synthesis of the iodomethylbis(phosphane)-complex *(2)* was accomplished by the rapid, smooth reaction of *(1)* with diiodomethane.

$$C_5H_5Rh(PMe_3)_2 + CH_2I_2 \rightarrow [C_5H_5Rh(CH_2I)(PMe_3)_2]I$$
(1) *(2)*

The product is a colorless solid which is moderately soluble in polar organic solvents. *(2)* is stable for several days in CH_3NO_2 and CH_3OH, whereas in dimethyl sulfoxide a rapid reaction takes place, giving $[C_5H_5RhI(PMe_3)_2]I$.

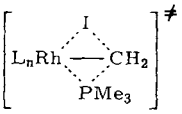
The lability of the carbon-iodine bond in *(2)* is confirmed by the reactions with various nucleophiles. Reaction with trimethylphosphane in nitromethane at room temperature leads after 30 h to almost quantitative formation of the dicationic methylenephosphorane complex $[C_5H_5Rh(CH_2PMe_3)(PMe_3)_2]^{2+}$:

$$(2) + PMe_3 \rightarrow [C_5H_5Rh(CH_2PMe_3)(PMe_3)_2]I_2$$
(3)

No reaction is observed with triphenylphosphane under the same conditions. With triethylamine the nitrogen-ylide complex corresponding to *(3)* is not formed, but surprisingly the compound *(4)* isomeric with *(2)*.

$$(2) \xrightarrow{(NEt_3)} [C_5H_5Rh(CH_2PMe_3)(PMe_3)I]I$$
(4)

The anion is apparently of no significance for this conversion: The complex $[C_5H_5Rh(CH_2I)(PMe_3)_2]BF_4$, obtained from *(2)* and $[CPh_3]BF_4$, likewise reacts smoothly with NEt_3, to give the ylide complex $[C_5H_5Rh(CH_2PMe_3)(PMe_3)I]BF_4$.



That not only neutral, but also anionic nucleophiles catalyze the isomerization *(2)*→*(4)*, is shown by the reaction of *(2)* with NaOMe in methanol. Instead of the expected product $[C_5H_5Rh(CH_2OMe)(PMe_3)_2]I$ (which is readily accessible *via* another route[5]), *(4)* is formed quantitatively. With the weaker base SMe^- a mixture of $[C_5H_5Rh(CH_2SMe)(PMe_3)_2]I$ *(5)* and $[C_5H_5Rh(SMe)(CH_2PMe_3)PMe_3]I$ *(6)* is formed; the latter mentioned compound is—as shown in an independent experiment—the product of a rapid secondary reaction of *(4)* with NaSMe.

The synthesis of the methylenephosphorane-metal complex from a phosphane-metal complex and dihalomethane is not new. Thus the reaction of $Co(PMe_3)_4$ with CH_2Cl_2 leads to $(Me_3PCH_2)_2CoCl_2$[6], and that of $Pt(PPh_3)_4$ with CH_2ClI to *cis*-$[(Ph_3P)_2Pt(CH_2PPh_3)Cl]I$[7]. As an important step in their one-pot synthesis of $(Me_3PCH_2)_2CoCl_2$, *Klein* and *Hammer*[6] postulated the formation of a halomethyl(phosphane)-complex which reacts very rapidly *via* $[Co(CH_2PMe_3)(PMe_3)_3Cl]$ as a further non-isolated intermediate to give the product.

Our investigations demonstrate for the first time the sequence

$$[L_nM(CH_2X)(PMe_3)]^+ \rightarrow [L_nM(CH_2PMe_3)X]^+$$

A remarkable feature of the conversion *(2)*→*(4)* is the migration of one of the two trimethylphosphane groups from rhodium to the carbon of the carbenoid ligand. In no case have we previously been able to demonstrate the dissociation of a Rh—PMe_3 bond in reactions of the cations $[C_5H_5RhR(PMe_3)_2]^+$ (R = H, Me, MeCO, *etc.*) either with nucleophiles or with electrophiles[2,5]. The possibility thus arises that the isomerization *(2)*→*(4)* proceeds intramolecularly, and formation of a four-center transition state

(with participatation of the catalyst) would be plausible.

Table 1. ^1H- and ^{31}P-NMR data of *(2)*—*(6)*, in CD_3NO_2 [δ values, TMS int. (^1H) and 85% H_3PO_4 ext. (^{31}P); J in Hz].

Tris(fluorosulfonyl)methane, $HC(SO_2F)_3$[**]

By *Gerhard Klöter, Hans Pritzkow,* and *Konrad Seppelt*[*]

Dedicated to Professor Fritz Seel on the occasion of his 65th birthday

In the course of a search for simple hydrocarbon derivatives bearing electronegative substituents we succeeded in preparing the title compound. Thus acetanilide reacts in oleum to form a species that can be precipitated as $HC(SO_3^-K^+)_3 \cdot H_2O$[1] on addition of potassium carbonate. The sulfonic acid $HC(SO_3H)_3$ can be liberated *via* the barium salt, and converted into the sulfonyl fluoride *(1)* by treatment with sulfur tetrafluoride.

$$H_3C{-}CO{-}NHPh \xrightarrow[2)\ K_2CO_3]{1)\ SO_3/H_2SO_4} HC(SO_3^-K^+)_3 \xrightarrow{Ba^{2+}}$$

$$HC(SO_3^-Ba^{+}_{1/2})_3 \xrightarrow{H_2SO_4} HC(SO_3H)_3 \xrightarrow{SF_4} HC(SO_2F)_3 \qquad (1)$$

The new compound *(1)* is a colorless, evil-smelling, crystalline solid (m.p. 44.5—45.5 °C, subl. 25 °C/10^{-2} mbar) with a considerable vapor pressure. Its structure is derived from its NMR spectra (^{1}H: quartet, $\delta = 6.85$; ^{19}F: doublet, $\delta = 67.6$, $J_{HF} = 1.8$ Hz).

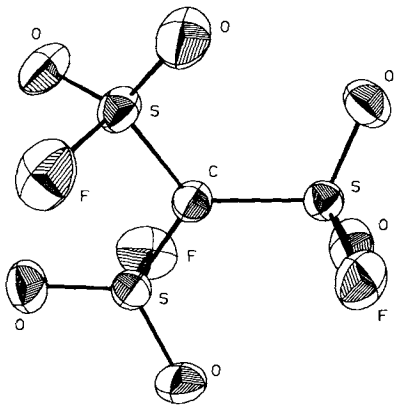

Fig. 1. Structure of the anion $C(SO_2F)_3^-$ in crystals of the salts with K^+ and Rb^+. The CS_3 skeleton is planar, the C—S distances (1.70 Å) indicate double bonding components. K salt: $P2_1/c$, $a = 7.899(1)$, $b = 11.729(2)$, $c = 18.557(3)$ Å, $\beta = 92.48(2)°$, $V = 1717.54$ Å^3, $Z = 8$, $\rho_{calc} = 2.323$, $\rho_{exp} = 2.32$ g/cm^3; 4637 reflections, $R = 0.039$. Rb salt: $R\bar{3}$, $a = 7.910(2)$, $c = 25.825(5)$ Å, $V = 1399.34$ Å^3, $Z = 3$; 557 reflections, $R = 0.043$.

The most striking property of *(1)* is its extreme acid character. Combination of this highly hygroscopic compound with water is extremely exothermic, with no hydrolysis of a fluorosulfonyl group being observed in a short period of time; after several weeks' standing a hydrate $HC(SO_2F)_2SO_3H \cdot nH_2O$ can be isolated. The aqueous solution of *(1)* proves to be a strong monobasic acid on titration with caustic alkali. Raman spectra of the equilibria

$$HC(SO_3F)_3 + K^+SO_3F^- \rightleftharpoons K^+C(SO_2F)_3^- + HSO_3F$$
$$HC(SO_3F)_3 + K^+NO_3^- \rightleftharpoons K^+C(SO_2F)_3^- + HNO_3$$

showed the acid strength to lie between the values for fluorosulfuric acid and nitric acid[2]. This remarkable finding is probably due to the mesomeric distribution of the negative charge in the anion.

Salts with K^+, Rb^+, and Cs^+ as counterions crystallize from water in order of decreasing solubility. Crystal structure analysis shows the CS_3 skeleton to be planar.

In order to determine the electronegativity of the $-C(SO_2F)_3$ group we prepared the methyl compound *(2)* (m.p. 145—146 °C, subl. −20 °C/10^{-2} mbar):

$$Ag^+C(SO_2F)_3^- + CH_3I \rightarrow AgI + CH_3{-}C(SO_2F)_3 \qquad (2)$$

The chemical shift of the methyl protons ($\delta = 3.125$) can be correlated with the electronegativity of the ligands[3], yielding a value of *ca.* 3.2.

The halogen derivatives $XC(SO_2)F_3$ were also synthesized:

$$HC(SO_2F)_3 \xrightarrow[CF_2Cl_2,\ -10\,°C]{XeF_2} Xe + HF + FC(SO_2F)_3 \qquad (3a)$$

$$Ag^+C(SO_2F)_3^- \xrightarrow[CH_2Cl_2]{X_2} AgX + C(SO_2F)_3$$

(3b), X = Cl
(3c), X = Br
(3d), X = I

The fluorine compound *(3a)* is a stable colorless liquid (b.p. 117—118 °C, m.p. −25.5 to −26.5 °C). No evidence for the existence of a compound containing a $Xe{-}C(SO_2F)_3$ link was obtained during the formation of *(3a)*. The chlorine and bromine compounds are colorless, evil-smelling solids [*(3b)*: m.p. 127—129 °C, subl. −20 °C/10^{-2} mbar; *(3c)*: m.p. 164 °C, subl. 0 °C/10^{-2} mbar]. Even the chlorine compound reacts with aqueous KI solution according to

$$(3b) + 2I^- \rightarrow C(SO_3F)_3^- + Cl^- + I_2$$

indicating the presence of a partial positive charge on chlorine. The yellow iodine compound [*(3d)*: m.p. 207—210 °C, subl. 35 °C/10^{-2} mbar] is unstable towards radiation; however, neither the $^{\bullet}C(SO_2F)_3$ radical nor its dimer could be detected during its decomposition.

All compounds were identified by complete elemental analysis and spectroscopic data (MS, IR, and Raman, ^{1}H and ^{19}F-NMR).

N-(Amidosulfonyl)hydroxylamine, H_2NSO_2NHOH[**]

By *Michael Boldhaus, Klaus Brink,* and *Claus Bliefert*[*]

Dedicated to Professor Fritz Seel on the occasion of his 65th birthday

While two amides of hydrazinesulfonic acid have already been described[1], not one unsubstituted amide of any of the five different hydroxylaminesulfonic acids has as yet been reported in the literature. Only two derivatives of the amide of hydroxylamine-*N*-sulfonic acid are known, namely $H_2N—SO_2—NHOCH_3$[2a] and $(CH_3)_2N—SO_2—NHOH$[2b].

Reaction of amidosulfonyl fluoride with hydroxylamine in ethanol leads to formation of *N*-(amidosulfonyl)hydroxylamine *(1)* (hydroxysulfamide).

$$H_2N—SO_2—F + 2\,H_2NOH \rightarrow H_2N—SO_2—NHOH + [H_3NOH]F$$
(1)

(1) is a colorless crystalline solid (m.p. 86—87 °C) which can be isolated in pure form only in small yields (*ca.* 2%). The new compound was identified by elemental analysis, molecular weight determination and spectroscopic data. Under normal conditions it is stable and non-hygroscopic. Its aqueous solutions react neutral. *(1)* is readily soluble in water and dimethyl sulfoxide, moderately soluble in methanol and ethanol, and only sparingly soluble in ether. Alkaline hydrolysis leads, as in the case of other sulfohydroxamic acids $R—SO_2—NHOH$[3] to monomeric hyponitrous acid (detection as $K_2[Ni(CN)_3NO]$[4]).

$$(1) \xrightarrow[-H_2O]{+2OH^-} SO_3^{2-} + NH_3 + HNO \rightarrow \tfrac{1}{2}(N_2O + H_2O)$$

Procedure

Amidosulfonyl fluoride (33.7 g, 0.34 mol) is added dropwise within 1 h to a stirred solution of hydroxylamine (45 g, 1.36 mol) in ethanol (750 ml) such that the temperature in the reaction vessel does not exceed 0 °C. The alcoholic solution, and thus large amounts of ethyl amidosulfonate that are formed, is decanted off. The remaining cloudy oil (*ca.* 80 g) is taken up in anhydrous sodium sulfate (120 g) and extracted with ether for 3 d in a Soxhlet apparatus. An oil (*ca.* 4 g) free of hydroxylammonium fluoride is obtained, from which *(1)* can be isolated as a colorless viscous liquid by renewed extraction with ethanol. *(1)* crystallizes out (0.8 g) after several days at room temperature.

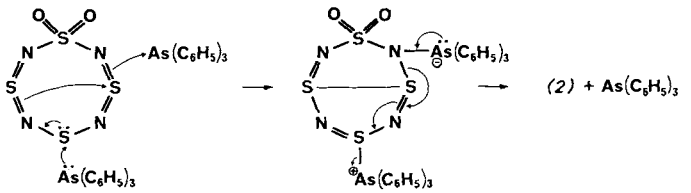
(8→5) Contraction of the Eight-Membered Ring of $S_4N_4O_2$[**]

By *Herbert W. Roesky, Michael Witt, William Clegg, Wilhelm Isenberg, Mathias Noltemeyer,* and *George M. Sheldrick*[*]



Dedicated to Professor Fritz Seel on the occasion of his 65th birthday

Degradation reactions of sulfur-nitrogen rings generally proceed in unclear fashion and sometime nonstoichiometrically[1]. We have now found that the reaction of $S_4N_4O_2$ *(1)*[2] with triphenylarsane affords the asymmetrically substituted sulfamide *(2)*.

(1) *(2)*

It was known[3] from mechanistic studies that nucleophilic reagents attack *(1)* at the S-5 atom located opposite the SO_2. The increase in electron density leads to formation of a central sulfur-sulfur bond between S-3 and S-7. Degradation of *(1)* would therefore appear to proceed *via* a transition state involving two molecules of triphenylarsane.

The molecular structure of *(2)* was determined by X-ray diffraction analysis of a single crystal[4] (Fig. 1). The five-membered ring in *(2)* is comparable with the rings in $S_3N_2{=}N—SO_2F$[5] and $S_3N_2{=}N—P_3N_3F_5$[6].

Triphenylarsoranediylaminosulfonylimino-1λ⁴,2,4λ⁴,3,5-trithiadiazole *(2)* cannot be sublimed without decomposition. The mass spectrum contains $(C_6H_5)_3AsS$, $m/e = 338$, as the highest fragment.

Procedure

A solution of $AsPh_3$ (7.6 g, 25 mmol) in benzene (50 ml) is added dropwise to *(1)* (5.4 g, 25 mmol) in benzene (100 ml).

The Pentafluoropyridine Cation $C_5F_5N^+$ [**]

By *Klaus Züchner, Thomas J. Richardson, Oskar Glemser,* and *Neil Bartlett*[*]

Dedicated to Professor Fritz Seel on the occasion of his 65th birthday

Salts of the hexafluorobenzene cation $C_6F_6^+$ were obtained by one-electron oxidation of C_6F_6 with $O_2^+X^-$ ($X^- = AsF_6^-$, SbF_6^-, $Sb_2F_{11}^-$) in WF_6[1]. Although numerous aromatic radical cations had already been detected in solution by spectroscopic data, this constituted the first isolation of such a paramagnetic species. We have now also accomplished the oxidation of pentafluoropyridine, as the first heterocycle, with $O_2^+AsF_6^-$ in SO_2ClF as solvent and moderator:

$$C_5F_5N + O_2^+AsF_6^- \xrightarrow[-45\,^\circ C]{SO_2ClF} C_5F_5N^+AsF_6^- + O_2$$

The suspended product, which is deep blue in the moist state, is only slightly soluble in SO_2ClF. Its ESR spectrum in SO_2ClF shows a broad singlet at $g = 2.0032$. Removal of the solvent and unreacted C_5F_5N at $-22\,^\circ C$ leaves a pale blue powder. This decomposes at 0 °C to give a white crystalline substance whose physical properties, especially the Raman and mass spectrum, are due to a 1:1 mixture of the molecular adducts $C_5F_5N \cdot AsF_5$[2] and $C_5F_7N \cdot AsF_5$ (cf. Table 1)[3] in accord with the disproportionation

$$2C_5F_5N^+AsF_6^- \rightarrow C_5F_5N \cdot AsF_5 + C_5F_7N \cdot AsF_5$$

Table 1. Raman data [cm^{-1}] of C_5F_5N and its derivatives.

sis of $C_5F_5N^+AsF_6^-$ in the following way: Since disproportionation occurs in the solid state and at relatively low temperature, only a slight activation energy will be required and the distribution of the molecules in the solid state will limit the possible reaction products. The first step is probably transfer of $F^\ominus$ from the anion to the cation, which is associated with a shift of the lone pair from the N to the As atoms:

$$C_5F_5N^\oplus AsF_6^\ominus \rightarrow C_5F_6N^\odot \cdot AsF_5$$

If this is valid, then the charge density values according to *Chambers et al.*[4a] would suggest that the $F^\ominus$ transferred to $C_5F_5N^\oplus$ is bonded to a carbon atom adjacent to the nitrogen atom. Redox reaction with the salt still present

$$C_5F_6N^\odot \cdot AsF_5 + C_5F_5N^\oplus AsF_6^\ominus \rightarrow C_5F_5N \cdot AsF_5 + C_5F_6N^\oplus AsF_6^\ominus$$

might be the next step.

The formation of C_5F_7N from $C_5F_6N^\oplus$ might similarly be initiated by a slight shift of $F^\ominus$ to $AsF_6^\ominus$, coupled with an acid/base interaction generating the $C_5F_7N \cdot AsF_5$ adduct.

Procedure

$O_2^+AsF_6^-$ (0.5 mol) is placed in a quartz- or Teflon FEP reaction vessel connected with a Monel vacuum apparatus. SO_2ClF (0.05 mol) and C_5F_5N (0.5 mol) are then condensed onto the solid at $-196\,^\circ C$. On warming to $-45\,^\circ C$, evolution of O_2 ensues. Decomposition of 1 mol of the salt at $-20\,^\circ C$ affords 0.5 mol of the original pentafluoropyridine and 0.5 mol of heptafluoro-1-aza-1,3-cyclohexadiene, both as AsF_5 adducts (1:1).

[2] Pure $C_5F_5N \cdot AsF_5$ was produced by tensimetric titration of the components. Its Raman spectrum and its Debye-Scherrer diagram are identical with those of the disproportionation product after the more volatile $C_5F_7N \cdot AsF_5$ has been removed *in vacuo*.
[3] The reaction of $O_2^+Sb_2F_{11}^-$ with C_5F_5N gave a product resembling $C_5NF_5^+AsF_6^-$. In contrast to the corresponding $C_6F_5^+$-fluoroantimonate(v), however, the thermal stability is not greater than that of hexafluoroarsenate.

Influence of Ionic and Polar Solutes upon $\Delta G^\ddagger$ and $\Delta V^\ddagger$ of the Amide Rotation in Aqueous Solutions of Dimethylacetamide[**]

By *Gerhard Völkel, Johann Hauer*, and *Hans-Dietrich Lüdemann*[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

The free activation energy for the rotation of the dimethylamino group in dimethylamides is altered strongly by variation of the substituent at the carbonyl group. Smaller but significant effects on $\Delta G^\ddagger$ are caused by changes in the polarity of the solvent[1].

The pressure dependence of $\Delta G^\ddagger$, defined by the activation volume $\Delta V^\ddagger$

$$\left(\frac{\partial \Delta G^\ddagger}{\partial P}\right)_T = \Delta V^\ddagger$$

however does not reveal any systematic dependence on the carbonyl substituents (R = H, CH_3, C_6H_5) or the solvent polarity (CCl_4, C_6D_6, $(CD_3)_2CO$, $(CD_3)_2SO$, CD_3CN, CD_3OD)[2]. For all solvents and substituents studied hitherto the activation volume is found to $\Delta V^\ddagger \approx 10$ cm^3 mol^{-1}, the only exception being the dilute aqueous solution ($x_{D_2O} > 0.98$) of the dimethylamides. In these dilute solutions, the rotation of the dimethylamino group becomes almost pressure independent (*e.g.* dimethylacetamide in D_2O, $x_{D_2O} = 0.99$, $\Delta V^\ddagger = 0.3$ cm^3 mol^{-1})[3].

The preliminary explanation for this unexpected result is the formation of an open hydration shell around the dimethylamino group, permitting amide rotation to occur without significant rearrangements of the water molecules in the first hydration layer. This attempted explanation predicts that the addition of polar or ionic solutes to the aqueous solutions, which alters the water structure, should lead to a significant increase of the $\Delta V^\ddagger$ observed.

In the first experiments dimethylacetamide (5% w/w) in aqueous solutions of sodium bromide and urea was studied. The results are given in Figures 1 and 2. Relatively small

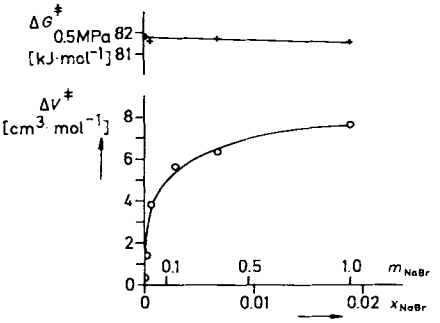

Fig. 1. $\Delta G^\ddagger$ and $\Delta V^\ddagger$ of the amide rotation in aqueous solutions of dimethylacetamide (DMA), $x_{DMA} = 0.012$ ($\approx 5\%$ w/w DMA), as function of the sodium bromide concentration. (In neat DMA, $\Delta V^\ddagger = 7.6$ cm^3 mol^{-1}.)

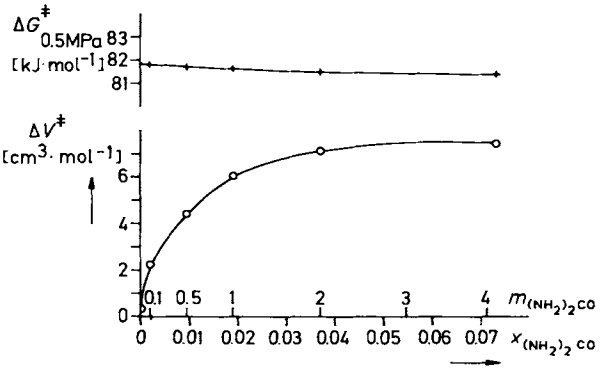

Fig. 2. $\Delta G^\ddagger$ and $\Delta V^\ddagger$ of the amide rotation in aqueous solutions of dimethylacetamide (DMA), $x_{DMA} = 0.012$ ($\approx 5\%$ w/w DMA), as function of the urea concentration. (In neat DMA, $\Delta V^\ddagger = 7.6$ cm^3 mol^{-1}.)

concentrations of sodium bromide do increase ΔV^+ significantly. 5% w/w of dimethylacetamide dissolved in a 0.14 molal solution of NaBr yields an activation volume of $\Delta V^+ = 5.6$ cm^3 mol^{-1}, which is fairly close to the results found in the common solvents. It must be concluded that the average distribution of the water molecules in the immediate vicinity of the dimethylamino group is drastically altered, and that the unique features of the binary aqueous solutions are destroyed almost completely by addition of small amounts of ionic solutes. The changes in ΔV^+ caused by comparable amounts of urea are smaller than the effects observed with NaBr. This might be explained qualitatively by the different influence of the urea molecules, which are incorporated into the hydrogen bond network of water and thus cause only local disturbance of the average water structure, while the electric charges of the sodium and bromide ions will cause longer-range changes in the water structure.

Our results show that the hydrophobic solvation of the apolar moieties of the dissolved molecules is significantly influenced by relatively small additions of ions, and indicate that the determination of ΔV^+ for the rotation of the dimethylamino group is a sensitive probe for structural changes of the hydrate structure.

The steepest increase of ΔV^+ is found in sodium bromide solutions with an ion/DMA ratio smaller than 1:6. It is thus unlikely that the effects observed can be explained by a preferential solvation of the ions by the DMA molecules. This assumption is further corroborated by the variation of x_{DMA} at constant x_{NaBr}. At $x_{DMA} = 0.012$ and $x_{NaBr} = 0.0003$ a value of $\Delta V^+ = 3.8$ cm^3 mol^{-1} is found. ΔV^+ remains essentially unchanged on lowering the DMA concentration to $x_{DMA} = 0.0024$.

ΔG^+ (cf. Fig. 1 and 2) is not influenced by the addition of NaBr or urea. This shows that the determination of ΔV^+ by high pressure studies can yield information about solvent structure which could not be obtained from the ambient pressure activation parameters ΔG^+, ΔH^+, and ΔS^+.

Experimental

ΔV^+ was derived from the pressure dependence of the ^{1}H-NMR signals of the N—CH_3 groups between 0.1 and 150 MPa. The rate of rotation was determined by computer simulation of the exchange broadened spectra in the region of the coalescence temperature (T_c: 370—380 K). Observation frequency: 100.1 MHz. Details of the high pressure apparatus and the simulation procedure have been published previously[2, 3].

BOOK REVIEWS

Physical Chemistry of High Temperature Technology. By *E. T. Turkdogan.* Academic Press, New York 1980. xv, 447 pp., bound, $ 49.50.

The author of this book has been active in applied research in the steel industry for over 30 years and was also involved in some basic work through numerous investigations. Here he gives a comprehensive account of the fundamental relationships and ideas in the form in which they are of immediate use in applied research, *i. e.* in the solution of technical problems. Such books are rare, and are therefore particularly valuable, for in general there is a gap between fundamental monographs, usually too detailed and too specialized for the practical man, and literature devoted simply to technical processes. A discussion of learned points of dispute is generally of little practical value. The present book confines itself first to the presentation of the physicochemical principles essential for understanding the processes in the smelting of solid and liquid chalcogenides, carbonates, and silicates, after which, in the second part, it shows examples of their application (mainly in the field of ferrous metallurgy). To this extent, the phrase "high temperature technology" as used in the title is not as wide as it seems.

The thermodynamics of metals, alloys, oxides, and silicates take up much of the first part, and in addition transport phenomena in particular are treated very exhaustively. In the second part, an account of the interplay of reaction and transport phenomena forms the basis for a discussion of the kinetics of individual processes (*e.g.* calcination, the blast-furnace process, steel production). 900 references indicate original papers and compilations of data (not only American) giving further information. The book constitutes a welcome supplementation of *Darken* and *Gurry*'s monograph; it is an introduction into an industrially particularly important field of applied chemistry that goes beyond the elementary principles.

1,5,-Electrocyclizations— An Important Principle of Heterocyclic Chemistry

By Rolf Huisgen[*]

Robert Burns Woodward—In Memoriam

The principle of orbital control of pericyclic reactions has deepened our understanding of reaction phenomena and provided an excellent classification of these one-step processes. The electrocyclic reaction of the *pentadienyl anion* ⇄ *cyclopentenyl anion* type is relatively unimportant in all-carbon systems and has not even been verified in the case of the parent compound. In the heterocyclic series, however, where up to five C-atoms of the pentadienyl anion are replaced by heteroatoms, a multitude of ring closures and ring openings find their ordering principle in the mentioned electrocyclic reaction. The replacement of the carbon atoms by heteroatoms can take place *isoionically, i.e.,* with retention of the anionic character, or *isoelectronically.* An isoelectronic replacement of CR_2 in position 1 by NR_2 or OR, and of CR in position 3 by NR or O leads to a charge-free resonance structure for the open-chain species; the migration of the charge during the electrocyclization results in a correlation with a cyclic zwitterion. Conversely, isoelectronic exchange of CR in position 2 by NR or O produces a conjugated 1,3-dipole, which cyclizes to a charge-free unsaturated five-membered ring. Twofold isoelectronic exchange allows the whole process to take place in a cation. Selected examples are to shed light on the classification and the thermodynamics of this electrocyclic reaction.

1. Introduction

The term "electrocyclic reaction" was coined by *Woodward* and *Hoffmann*[1]. A polyene (even-numbered) or a polyenyl (odd-numbered) system closes a ring in a process that can be described by a cyclic electron shift; its net result is the conversion of a π-bond into a σ-bond. Corresponding ring openings take place *via* the same energy profile. Electrocyclic ring closures and ring openings belong to the class of one-step "pericyclic reactions" which conform to the principle of conservation of orbital symmetry[2]. Electrocyclic reactions may benefit from the energetically favored concertedness only by taking the steric course defined by the *Woodward-Hoffmann* rules.

The fascination with the idea of orbital control led to a vigorous development of the chemistry of pericyclic reactions after 1965. At times, the mechanistic studies availed themselves of ingeniously conceived models, so inaccessible as to induce outsiders to raise the cry of "orchid chemistry". This is unjustified. On the contrary, pericyclic reactions offer an eminent classification principle[3] for a large number of well-known reactions, whose interrelation was frequently not recognized. The preparative and methodological gain tends to become effective only after the common mechanistic principle has been unveiled.

2. Reaction Scheme, Orbital Control, Stereochemistry

2.1. Overall Course and Charge Migration

The pentadienyl anion *(1)* has six electrons in five parallel π-orbitals. The resonance structures *(1a)—(1c)* illustrate the charge distribution over the carbon atoms 1, 3, and 5. The electrocyclic ring closure requiring a U configuration of the open-chain species is associated with a transformation of the terminal sp^2-hybridized centers into tetrahedral carbon atoms. The remaining four π-electrons emerge as an allyl anion group, *i.e.*, the lower vinylog of the pentadienyl anion, in the cyclopentenyl anion *(2)*. The reaction course is demonstrated by the cyclic shift of electrons depicted in *(1a)*.

(1a) *(1b)* *(1c)*

(2a) *(2b)*

This pattern of charge distribution can also be reproduced by the MO model, yet not in such a clear symbolism. The superiority of the MO model over the classical concept of resonance becomes evident in the *orbital control* of the steric course of electrocyclic processes.

2.2. Orbital Control of the Steric Course

The ring closure of *(1)* consists of coordinated deformation and twisting motions: two 90° rotations about the C1—C2 and C4—C5 bond axes are required, while carbon atoms 1 and 5 approach in order to create a new σ-bond from the former π-orbitals. *Woodward* and *Hoffmann*[1] found the inspection of the HOMO (highest occupied molecular orbital) symmetry to be the simplest treatment accounting for the steric course of electrocyclic reactions. According to Figure 1, phase consistent σ-overlap calls for one 90° rotation being clockwise and the second anticlockwise (disrotation). Similarly, conrotatory movements are derived from the symmetry properties of ψ_4 for the first excited singlet state of *(1)*.

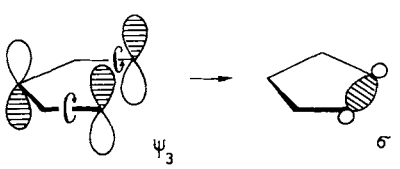

Figure 1. Derivation of disrotation for the cyclization of the pentadienyl anion from the HOMO symmetry.

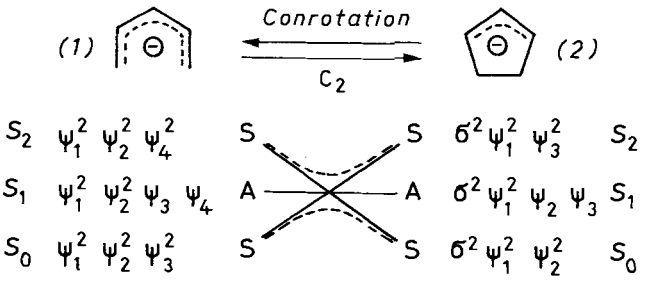
The *disrotatory* mode of the reaction can be described in terms of a symmetry plane (C_s) as a molecular symmetry element, whereas in the course of *conrotation* a twofold axis of symmetry is preserved. The MO symmetry correlation diagram[2] can be constructed on the basis of the transformation properties of the involved MO's (symmetric or antisymmetric) in relation to the above-mentioned symmetry element. Accordingly, for the disrotatory ring closure the occupied orbitals of the ground state of *(1)* are connected to those of *(2)* without encroaching on the antibonding side.



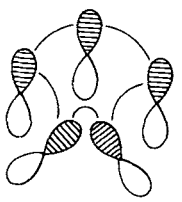


Fig. 2. Symmetry correlation diagram of molecular states for the conrotatory cyclization of the pentadienyl anion.

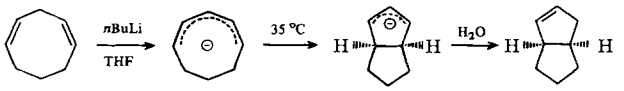
The *symmetry correlation of the molecular states*[4] furnishes a superior picture of the nature and energy requirement of the symmetry-forbidden reaction, as shown in Figure 2 for conrotation. The electronic configuration of the ground state of *(1)* is symmetry-connected with a higher excited state, S_2, of the cyclopentenyl anion; two electrons from ψ_2 of the allyl anion are promoted to ψ_3. Correspondingly, the ground state of *(2)* is correlated with a higher singlet excited state (S_2) of *(1)*. All the electronic configurations mentioned are symmetric with respect to a twofold axis of symmetry which dominates the conrotatory ring closure. Therefore, S_0 and S_2 of *(1)* and S_0 and S_2 of *(2)* enter into "configuration interaction" which with decreasing energy separation leads to an increasing admixture of S_2 in S_0 and *vice versa*. This interaction is the reason for the "non-crossing rule" which forbids the crossover of correlation lines between electronic configurations of the same symmetry. Thus, the cyclization of *(1)* in the ground state follows the dashed line and reaches S_0 of *(2)*, *i.e.*, the ground state; the forbiddenness of the thermal conrotation rests on the energy hill between the S_0 states of educt and product. Hence it is clear that "forbidden" does not mean that the reaction cannot take place, but rather that a higher activation energy is imposed on the process.

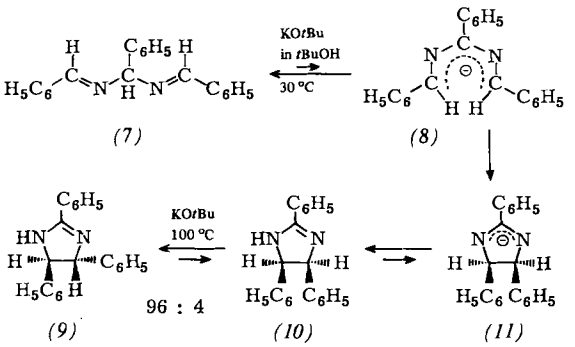
(3)



As an alternative treatment of orbital control, the *Evans-Zimmerman-Dewar* principle[5,6] shows the topology of the basis set of the atomic orbitals in the transition state to exhibit no phase dislocation; with 6 electrons, *(3)* characterizes an "aromatic" transition state for the disrotatory ring closure of *(1)*→*(2)*, symmetry not playing any part here.

This is noteworthy, since any substitution of the parent compound affects not only the symmetry of the molecule,

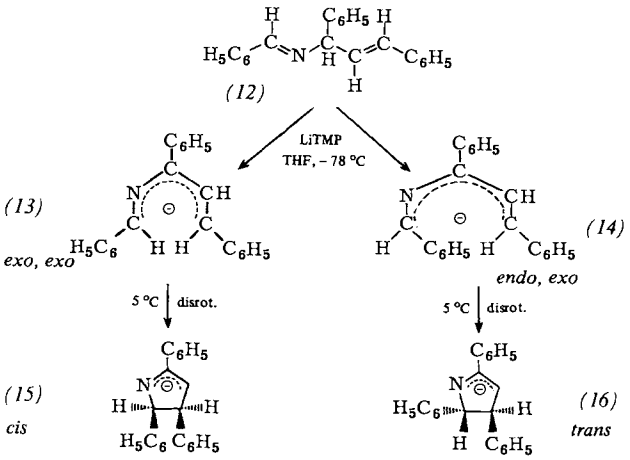
but *via* a change in the atomic orbital coefficients also that of the MO's involved in the reaction. The same applies to the replacement of carbon atoms by heteroatoms. Nevertheless, orbital control is retained qualitatively; the height of the symmetry-inflicted energy barrier of the forbidden reaction, however, can be strongly influenced by the substitution pattern.



2.3. Steric Course of the Reaction

According to *Bates* and *McCombs*[7], the deprotonation of 1,4-cyclooctadiene with butyllithium in tetrahydrofuran (THF)-hexane takes place at −78 °C. NMR observations show that the cyclization of the cyclooctadienyl anion *(4)* to the bicyclic allyl anion *(5)* proceeds with a half-life of 80 min at 35 °C. The uptake of a proton leads to bicyclo[3.3.0]oct-2-ene *(6)* with *cis*-linkage of the rings[8]. It is true that this is the disrotation permitted by orbital symmetry, but the fact that the *cis*-form *(6)* is the thermodynamically more stable configuration diminishes the evidential value for orbital control.

(4) *(5)* *(6)*



A diaza derivative permits further-reaching conclusions. As early as 1844, by heating hydrobenzamide *(7)* *Laurent*[9] obtained "amarine", later recognized as *cis*-2,4,5-triphenyl-1-imidazoline *(10)*. In an elegant study, *Hunter* and *Sim*[10] found the ring closure to be base-catalyzed; under the assumption that *(8)* with its *exo*-located terminal phenyls represents the most favorable U configuration of the heteropentadienyl anion, they deduced a disrotatory cyclization, *(8)*→*(11)*. Amarine *(10)* is the labile *cis*-4,5-diphenyl isomer. The rapid ring closure with potassium *tert*-butoxide (KO*t*Bu) at 30 °C was followed at 100 °C by a slow equilibration with isomarine *(9)* the *trans*-isomer.

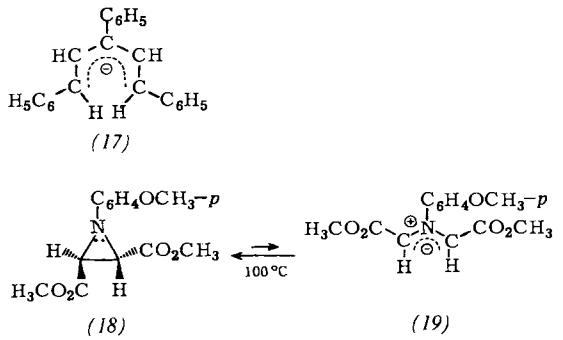
(7) *(8)* *(9)* *(10)* *(11)*

Reaction of lithium tetramethylpiperidide (LiTMP) with *(7)* in methyltetrahydrofuran at −130 °C afforded the purple anion *(8)*, whose cyclization to *(11)*—even at −130 °C too fast to be followed by NMR—occurred with better than 99.7% stereospecificity[11].

The persuasive power behind this finding for the orbital control is diminished by the lack of stereoselectivity in the ring closure of the monoaza compound *(12)*. The deprotonation of *(12)* with LiTMP in THF furnished a blue solution; under conditions of kinetic control the anions *(13)* and *(14)* cyclized to *(15)* and *(16)*, respectively, whose hydrolysis

(12)

(13) *exo, exo*



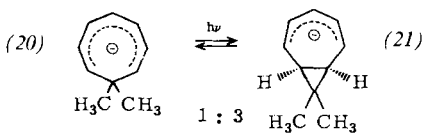
(14) *endo, exo*

(15) *cis*

(16) *trans*

yielded the *cis*- and *trans*-isomers of 2,4,5-triphenyl-1-pyrroline in a ratio of 1:1[12].

The key to an understanding of the difference in behavior of the diaza-anion *(8)* and the monoaza-anion of *(12)* is provided by the fact that cyclization of the former takes place approximately 10^6 times faster. The early transition state of the highly exothermic ring closure of *(8)* is structurally still in close relation to *(8)*. For reasons discussed in Section 3, a smaller reaction enthalpy is expected for the cyclization of the anion from *(12)*. If the reaction is almost thermoneutral, the later transition state at a higher energy level—cyclization takes place only above 0 °C—should receive contributions from the educt and the product. On the educt side the anion *(13)* will be more stable than *(14)*, since in the latter the *endo*-1-phenyl group disturbs the coplanarity. On the product side, however, the *trans*-anion *(16)* is preferred to the *cis*-anion *(15)*. It is conceivable that the transition states of the *two disrotations*, *(13)*→*(15)* and *(14)*→*(16)*, have the same energy level. The formation of *(15) and (16)*, therefore, does not necessarily involve an infringement of orbital control. In the case of the 1,3,5-triphenylpentadienyl anion *(17)*, cyclization is no longer observable; according to *Hunter et al.*[11], it might possibly be endothermic.



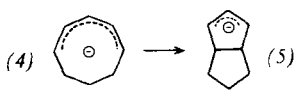
(17)

(18) *(19)*

Do the electrocyclic reactions of the lower and higher vinylogs of the pentadienyl anion—conrotation is expected for both in the ground state—follow the *Woodward-Hoffmann* rules? The steric course of the ring opening of substituted cyclopropyl anions to form allyl anions could not yet be observed directly, since equilibrium of the configurations was established by rapid subsequent rotation[13].

Symmetry-allowed conrotation has, however, been verified for the electrocyclic equilibration of the aziridine *(18)* with a small concentration of the azomethine ylide *(19)*[14,15];

these species are isoelectronic with the cyclopropyl anion and the allyl anion, respectively.

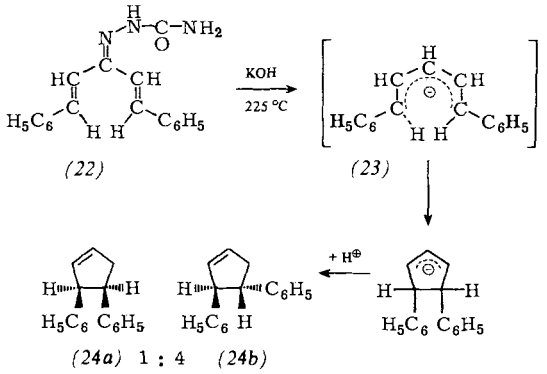


The heptatrienyl anion as the higher vinylog of *(1)* is incorporated in the 8-membered ring of *(20)*. Geometric constraints allow an intraannular ring closure only by disrotation which is symmetry-forbidden for the thermal electrocyclic reaction. Therefore, the equilibrium *(20)* $\rightleftharpoons$ *(21)* is not established thermally, but merely photochemically[16].

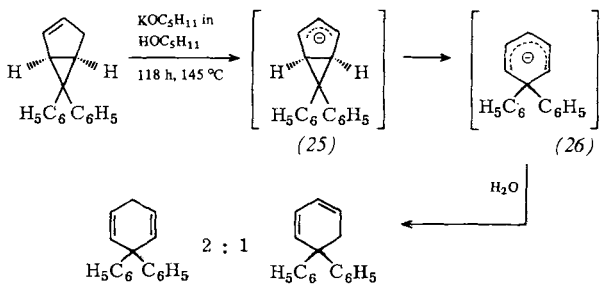
3. Thermodynamic and Kinetic Considerations

The different positions of the electrocyclic reaction equilibria have already been referred to. In the transformation of the cyclopropyl anion into the allyl anion a σ-bond is converted into a π-bond (+20 kcal mol^{-1}) and the ring strain (−28 kcal mol^{-1}) as well as the delocalization energy (−28 kcal mol^{-1}) are released, thus making the ring opening highly exergonic. No experimental value is available for the delocalization energy; it should be identical with the rotational barrier of the allyl anion for which an *ab initio* calculation (4-31 G) furnished 28 kcal mol^{-1} [13,17]. In addition, solvation and ion pairing will modify the energy balance. The reverse process has never been observed.

In the case of the higher vinylog, the heptatrienyl anion, the ring closure to form the low-strain cycloheptadienyl anion acquires driving force, since the energy gain in the transformation of a π-bond into a σ-bond (−20 kcal mol^{-1}) certainly exceeds the loss of delocalization energy. The cyclization of the unsubstituted heptatrienyl anion proceeds to completion in THF-hexane at −30 °C with a half-life of 13 min[18].

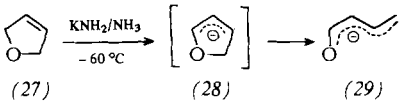


From a consideration of the above examples it can be assumed that the position of the electrocyclic equilibrium of pentadienyl anion $\rightleftharpoons$ cyclopentenyl anion depends on the substitution pattern. Let us first discuss the energy balance of the intraannular cyclization *(4)*→*(5)*.



π-bond→σ-bond	−20 kcal mol^{-1}
Increase in ring strain (estimated)	+ 4 kcal mol^{-1}
Decrease in delocalization energy	≤ +14 kcal mol^{-1}

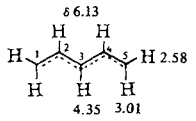
By attributing ≥2 kcal mol^{-1} to the exergonic cyclization[7], there is a decrease of ≤14 kcal mol^{-1} for the delocalization energy in going from the pentadienyl to the allyl anion.



In the cyclization of the *open-chain* pentadienyl anion a ring strain of approx. 7 kcal mol^{-1} [19] is built up. Furthermore, the conversion to the rigid cyclopentenyl anion causes a decrease of entropy during the cyclization. Indeed, no cyclization of open-chain pentadienyl anions has been observed so far, and it is still unclear whether this failure is due to thermodynamic or kinetic reasons. A single unexplained exception will be briefly discussed here.

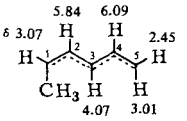
Shoppee and *Henderson*[20] achieved the conversion of the semicarbazone *(22)* into the cyclopentenes *(24)* with 12% yield by heating it with powdered potassium hydroxide or potassium *tert*-butoxide. The concepts of the mechanism of the Wolff-Kishner reduction suggest the intermediacy of the anion *(23)*. The equilibration of *(24a)* and *(24b)* under these conditions together with the conversion into the conjugated diphenylcyclopentenes prevents any conclusion about the steric course of the process. A cyclization of *(23)* was even less predictable due to the concomitant loss of phenyl conjugation energy. Moreover, the attempted cyclization was unsuccessful, when 1,5-diphenyl-1,4-pentadiene was heated with butyllithium to 190 °C. The ring closure *(22)*→*(24)* may possibly be ascribed to the changed solvation and protonation conditions on the surface of the solid potassium hydroxide or *tert*-butoxide at 225 °C.

In contrast, the anionic ring opening *(25)*→*(26)* which profits from the release of the cyclopropane ring strain is obvious[21].



No less apparent is the influence of heteroatoms on the electrocyclic equilibrium which is of prime importance here. Shortly after deprotonation of 2,5-dihydrofuran *(27)* with potassium amide in liquid ammonia, *Kloosterziel et al.*[22] observed the NMR spectrum of *(29)* in which the negative charge is mainly located on the oxygen. The butadienolate *(29)* is a weaker base than the pentadienyl anion *(1)* by about 20 pK units, which favors the ring opening *(27)*→*(29)* at −60 °C by about 20 kcal mol^{-1}. The resonance structures of *(1)* reveal that the replacement of carbon by heteroatoms of

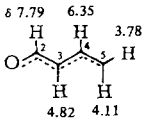
higher electronegativity in positions 1, 3, and 5 should provide the driving force for ring opening.



Replacement in position 2 or 4 acts in the opposite direction; by taking over the negative charge, heteroatoms in these positions effect stabilization not in the open-chain, but rather in the cyclic species. Transfer of the negative charge to the two nitrogen atoms of the 2,4-diazapentadienyl anion *(8)* makes the ring closure to *(11)* fast even at $-130\,^{\circ}C$. Amide anions are favored over carbanions. However, the monoaza substitution in *(13)* and *(14)* reduces the thermodynamic drive of the cyclization which is observed only above $0\,^{\circ}C$. This coupling of thermodynamic and kinetic reasoning is based on the *Hammond* postulate: in a family of mechanistically related reactions the transition state will resemble the educt structure all the more and require all the less activation enthalpy, the higher is the liberated reaction enthalpy.

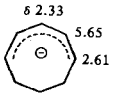
4. Charge Distribution and Configuration of the Pentadienyl Anion

Pentadienyl anions are conceivable in three idealized planar configurations, described as the W, S, and U forms. All three configurations can be established in cyclic derivatives. A comparison of the coupling constants in the ^{1}H-NMR spectra of the open-chain pentadienyl anions *(30)* and *(31)* with those of cyclic models permits the conclusion that *(30)* and *(31)* exist in the W form.



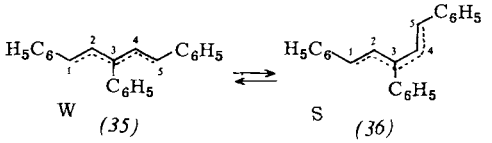
(30)

(31)



This conclusion is also supported by the symmetry of the parent system *(30)*, which can be generated by reaction of 1,4-pentadiene with potassium amide in liquid ammonia. According to *Kloosterziel et al.*[23], the chemical shift of the 2-H and 4-H of *(30)* shows the normal δ value for vinyl protons. The higher electron density on the carbon atoms 1, 3, and 5 is responsible for the shielding by several ppm, which is greater for 1- and 5-H than for 3-H. The δ values of the *cis*-1-methyl compound *(31)* bear witness to the electron-repelling effect of the methyl group.

(32)



(33)

(34)

The replacement of a terminal CH_2 in the pentadienyl anion by oxygen in *(32)* is accompanied by an increase in the δ-values of 3-H and 5-H by 0.5—1.2 ppm, corresponding to a reduction in the respective electron densities[23]. If *one* resonance structure is to be chosen for *(32)*, this should be the dienolate formula. In the anions *(33)* and *(34)*[23] the U configuration due to the ring structure exhibits a similar pattern of charge distribution as the W form of *(30)*. An even more sensitive probe for the charge distribution is provided by the ^{13}C-NMR shifts[24,25].

(35) *(36)*

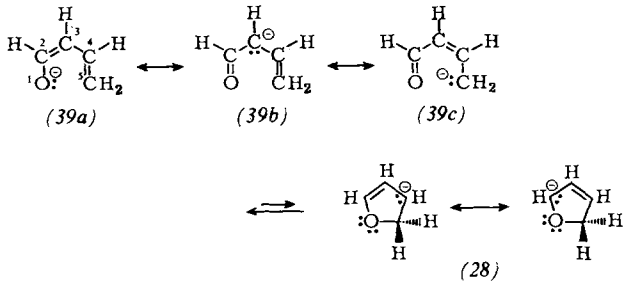
The configurational equilibrium of 1,3,5-triphenylpentadienyllithium in THF contains comparable amounts of the W and S forms: $\Delta G^{+} = 12$ kcal mol^{-1} for the transformation *(35)*⇌*(36)* was explained by *Hunter et al.*[26] in terms of a rotational barrier.

Whereas electrostatic considerations favor extended forms of the pentadienyl anion, the synphasic terminal atomic orbitals in two of the three occupied MO's were suggested as a factor which stabilizes the U configuration by bonding overlap[27]. Although the U form has not yet been detected experimentally, we nevertheless regard it as the *precursor of cyclization*. Only a simultaneous 180° rotation about the C2—C3 bond and 90° rotation about the C1—C2 bond in the S form *(36)* could yield a transition state of the ring closure reaction without passing through the sterically hindered planar U configuration.

5. Heterosubstitution and Charge Migration

The great importance of 1,5-electrocyclization becomes manifest in the hetero series. A distinction is made between *isoionic* and *isoelectronic* replacement by a heterofunction, which may be explained with nitrogen and oxygen as examples and applies *mutatis mutandis* to other heteroatoms.

5.1. Isoionic Replacement



The *isoionic* replacement of the carbanionic C-atom in the pentadienyl species *(1)* by an amide anion or an olate function according to *(37)* does in fact change the extent to which

(37) *(38)*

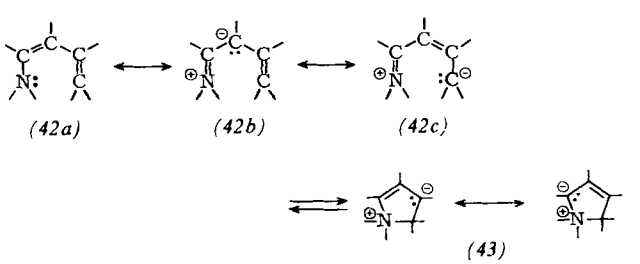
the individual resonance structures participate in the electron distribution of the ground state; however, the formal pattern of distribution of the negative charge is retained. The same applies to the replacement of the charge-free olefinic C-atom in the resonance structures of *(1)* according to *(38)* by imine nitrogen or carbonyl oxygen, which likewise bear no formal charge. Exchange of CRR′ by NR or O in positions 1 and 5 of the pentadienyl anion is conceivable, whereas in positions 2, 3, and 4 only the nitrogen atom can function as an exchange partner. The isoionic replacement can occur repeatedly without loss of the monoanionic character of the species.

The base-catalyzed ring opening of dihydrofuran *(27)* may again serve as an illustration. Only the oxapentadienyl anion profits from the isoionic replacement of CH_2 by O in position 1; the high electronegativity of oxygen stabilizes *(39a)*, but not the cyclic species *(28)*, and thus determines the electrocyclic equilibrium in the sense of *ring opening*.

(39a) (39b) (39c) (28)

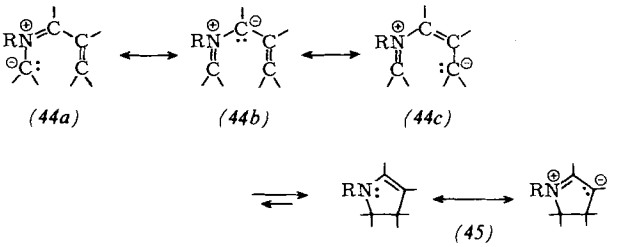
Are *two* 90° rotations about the terminal bond axes essential for electrocyclic processes? The availability of free electron pairs on the terminal olate oxygen or amide nitrogen enables *the rotations, e.g.,* in the ring opening reaction *(28)→(39), to be limited to one.* Presumably it is not the electron pair of the C—O σ-bond of *(28)* which enters into the pentadienyl π-system of *(39).* Instead, the dihydrofuran anion *(28)* contains a quasi-6π-system which is merely reorganized during ring opening. The stereoelectronics of the cyclization of the parent substance *(1)* is therefore drastically modified by the introduction of the heteroatom.

This also acts kinetically by lowering the activation barrier, since in the transition state a smaller amount of the bond energy of the reactants need be sacrificed. The ring opening *(28)→(39)* at as low a temperature as −60 °C may be ascribed to the highly exothermic character of the reaction as discussed in Section 3. However, we shall become acquainted in Section 8 with examples of thermoneutral cyclizations in which the equilibrium is established rapidly even at room temperature. In all these cases at least one sp^3-carbon of the cyclopentenyl anion *(2)* is replaced by a heteroatom with an unshared electron pair.



5.2. Isoelectronic Exchange

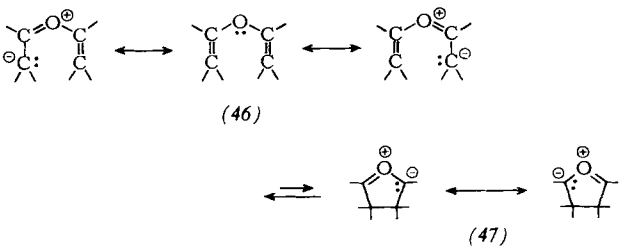
Amino nitrogen and ether oxygen have free electron pairs and, as per *(40),* are isoelectronic with the carbanion without harboring its negative charge. In accord with *(41),* the imin-



(40) (41)

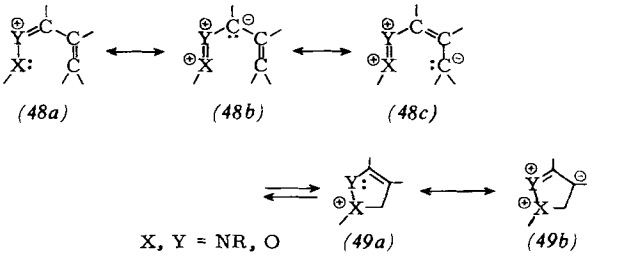
ium ion and the oxonium ion permit the ethylenic carbon atom in the resonance structures of *(1)* to be replaced isoelectronically. This exchange can occur in all positions of *(1),* although the consequences are very different.

(42a) (42b) (42c) (43)



Replacement of CH_2 in position 1 by an amino function permits us to expect the *charge-free* resonance structure *(42a)* along with the less important zwitterionic formulas *(42b)* and *(42c).* The charge migration associated with ring closure leads to the cyclic ammonium ion *(43),* which contains a normal allyl anion system. Stabilizing reactions may follow cyclization.

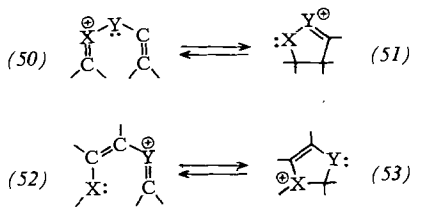
(44a) (44b) (44c) (45)



Isoelectronic replacement by NR in position 2 gives an iminium zwitterion *(44),* which delocalizes the carbanionic charge in its three all-octet structures *(44a)—(44c).* The ring closure is accompanied by charge compensation; a cyclic enamine *(45)* arises, the neutral and zwitterionic forms of which reveal the allyl anion structure.

The formulas *(44a)* and *(44b)* characterize a vinyl-substituted azomethine ylide. *(44)* acts as a representative for the large class of 1,3-dipoles of the allyl type conjugated with a CC or hetero double bond[28]. In Section 9 it will be shown that the cyclizations of conjugated 1,3-dipoles of the propargyl-allenyl type can be similarly treated. Here we are faced with the largest group of heteropentadienyl anion ring closures, whose range was recognized in *Reimlinger's* pioneering paper[29] in 1970 and which was called "1,5-dipolar cyclization". Recently, *Taylor* and *Turchi*[30] discussed this group in a review paper. The possibility of the stepwise replacement of all the carbons of the pentadienyl anion by heteroatoms—the exchange in position 2 is isoelectronic, the others are isoionic—makes the variations on this theme a polyphonic fugue.

(46) (47)



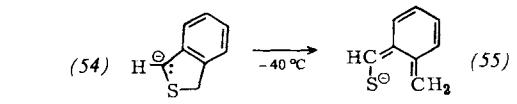
Like isoelectronic substitution in position 1, that in position 3—for a change, an oxygen has been introduced in *(46)*—leads to one resonance structure free of formal charges and two zwitterionic structures. Electrocyclization with its charge migration affords the carbonyl ylide *(47),* a cyclic 1,3-

(48a) (48b) (48c) X, Y = NR, O (49a) (49b)

dipole. Reactions of this type usually take place in the sense of a ring opening, unless subsequent processes follow the thermal or photochemical ring closure.

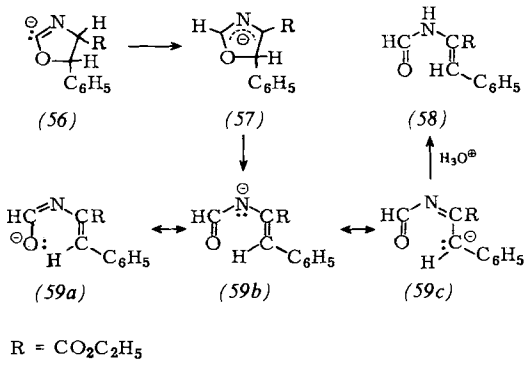
The multiplicity of possible 1,5-electrocyclizations is increased by *double isoelectronic exchange*; one can imagine that the cyclization of the pentadienyl anion type now takes place in the *cation*. *(48a)* shows this cation for the case of 1,2-disubstitution. The significance of the tripolar resonance structures *(48b)* and *(48c)* is all the smaller, since they violate the "adjacent charge rule". For this reason, *(49a)* dominates on the product side. Usually further steps follow, *e.g.*, proton shift.

Restricting attention to the forms with *one* positive charge, the systems with double isoelectronic replacement in the 2,3-position, *(50)*→*(51)*, and also in the 1,4-position, *(52)*→*(53)*, are schematically formulated; only a limited number of examples has been described. Naturally, the 1,3-, 1,5-, and 2,4-relationships of X and Y are also conceivable. Systems with triple isoelectronic replacement—here the process would take place in a dication—have to our knowledge not been reported so far.



In addition to the already mentioned reviews of 1,5-dipolar cyclizations[29,30], reference may be made to a short review by *Elguero*[31], who recognized the wide scope of the electrocyclic 6π principle for the construction of five-membered rings and placed the emphasis on reactions in the cation.

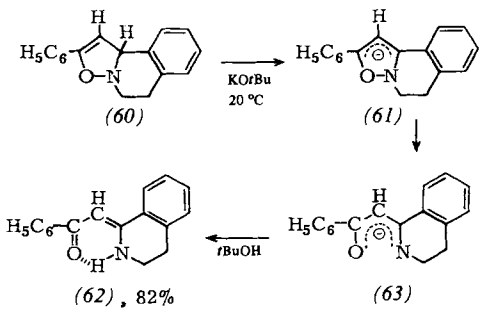
A complete coverage of the literature will not be attempted in this review. In our limited selection of examples we will give more weight to the didactic point of view than to that of a systematic account. So far the principles of charge distribution and charge migration have been illustrated with complete sets of resonance structures. In the following, we will prefer the short notation by delocalized structures; in other cases the most significant resonance formula serves as an illustration.



6. Heterosubstituted Pentadienyl Anions (Isoionic Replacement)

We have seen that the placing of the negative charge on a heteroatom which is more strongly electronegative than carbon decisively determines the direction of the electrocyclic reaction: heteroatoms in positions 2 and 4 of the pentadienyl anion favor ring closure, while in positions 1, 3, and 5 they promote ring opening.

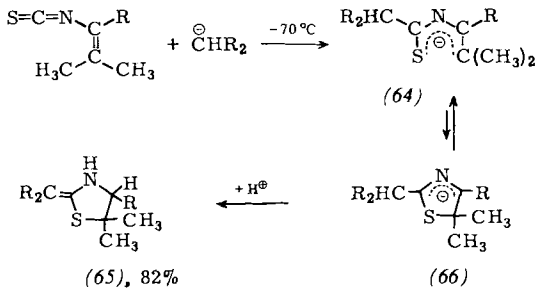
Reaction of potassium amide with 1,3-dihydrobenzo[*c*]thiophene generates the anion *(54)* which is of the benzyl type; *i.e.*, two of the carbon atoms of the allyl anion are part of a benzene ring. The NMR spectrum of the ring-opening product was substantially that expected for the *o*-quinodimethane structure *(55)*[32].



Naturally, *(54)* is not a 4π-system, but an 8π-system, and *(55)* is a 10π-system. In the classification of pericyclic reactions it is permissible to treat benzo-annelated systems as olefinic systems. This phenomenon, nowadays well understood, was one of the happy surprises in the early days of the *Woodward-Hoffmann* rules. Thus, *(55)* can be regarded not only as a pentadienyl anion but, with the inclusion of the double bonds of the 6-membered ring, as a nonatetraenyl anion; disrotation is also predicted for the ring closure of the latter. In the polyene series, the conrotatory ring-opening of *cis*- and *trans*-1,2-diphenylbenzocyclobutenes to the stereoisomeric *o*-quinodimethanes[33] offers an analogy to *(54)*→*(55)*.

R = $CO_2C_2H_5$

On treating α-isocyanoacetic ester with benzaldehyde and potassium *tert*-butoxide in THF, *Schöllkopf et al.*[34] isolated 85% of the formamide derivative *(58)*. The reaction presumably proceeds by the intermolecular proton shift *(56)*→*(57)* and electrocyclic ring opening to *(59)*. The ring cleavage gains high driving force by the distribution of the negative charge on the O- *and* N-atoms in *(59)*.

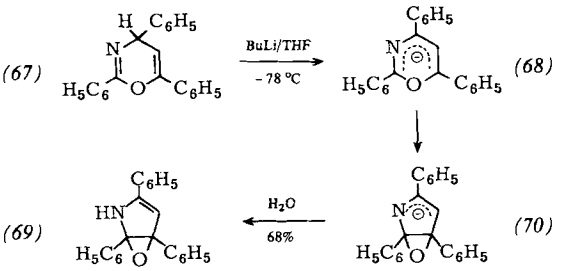


In the presence of potassium *tert*-butoxide in *tert*-butanol, the tricyclic 4-isoxazoline *(60)* undergoes an opening of the hetero-ring to give the enaminoketone *(62)*[35]. Not only the

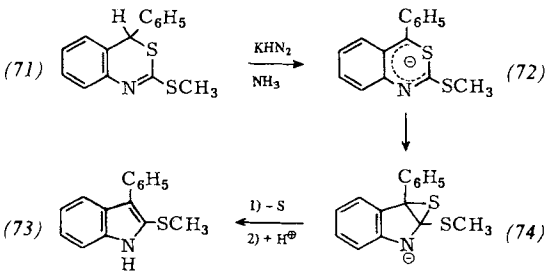
acquisition of the negative charge by O and N in the pentadienyl anion *(63)*, but also the weakness of the NO σ-bond (53 kcal mol^{-1}) in *(61)* favors the ring opening.

In *(63)* the heteroatoms occupy positions 1 and 5 of the pentadienyl anion. In *(61)* lone electron pairs on both heteroatoms are available for conjugation with the allyl anion system; only the pyramidalization at the nitrogen acts against the antiaromatic 8π-character. A rotation about the terminal bond axes is no longer necessary for the electrocyclic process to occur.

Even in the case of an unfavorable equilibrium a complete cyclization can be induced by favorable secondary reactions.

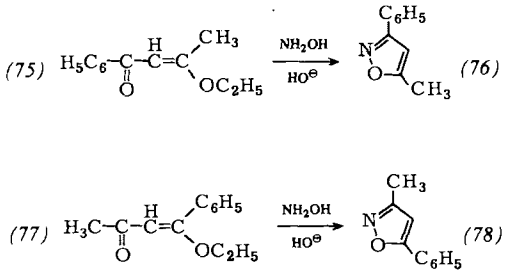


(64)

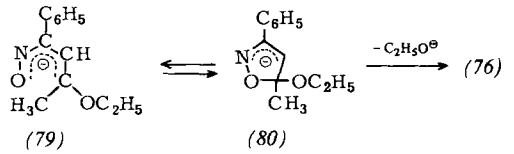


(65), 82% *(66)*

R = $CO_2C_2H_5$

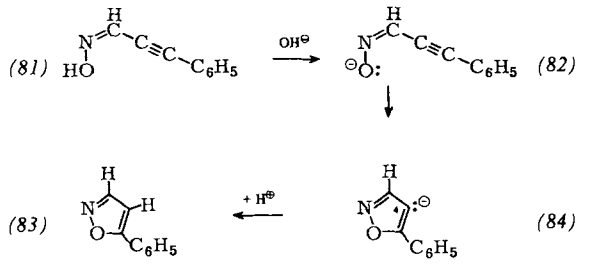


Treatment of potassium malonate with 2-isothiocyanatomethylcrotonic ester furnished the 2-methylenethiazolidine derivative *(65)*[36]. When the intermediate anion *(64)* closes the ring, the S and N atoms lose their portions of the charge. The formation of the cyclic allyl anion *(66)* must be endothermic; however, the subsequent shift of a proton from the malonic ester side chain to position 4 produces a favorable anion, in the stabilization of which the nitrogen atom again participates besides the two ester groups. The product *(65)* is an enamino-β,β-dicarboxylic acid ester.

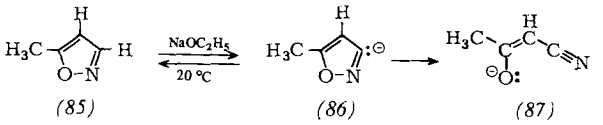


The special characteristic of the deprotonation of triphenyl-4*H*-1,3-oxazine *(67)* studied by *Schmidt et al.*[37] resides in the formation of the 8π-anion *(68)* with its cyclic conjugation. The deep blue color of *(68)* disappears rapidly at −78 °C and hydrolysis yields the bicyclic 2-pyrroline *(69)*. In *(68)* the nitrogen atom does not participate in the stabilization of the negative charge. The energetic preference for an aza-allyl anion and the disappearance of antiaromaticity promote the intraannular electrocyclization. These factors overcome the ring strain which is built up in the formation of the ethylene oxide ring in *(70)*. As in the case of the benzoannelated anions, the 8π-system of *(68)* is theoretically simplified by disregarding the oxygen atom which connects the termini of a pentadienyl anion system.

In the base-catalyzed ring contraction *(71)*—*(73)* according to *Lednicer et al.*[38], we encounter the benzo-annelated 8π-anion *(72)*, in which, in analogy with the preceding example, the S-containing ring is cleaved. Presumably the aromatic nature of the indole *(73)* prompts the cheletropic elimination of sulfur from the anion *(74)*.



By the action of hydroxylamine on the keto-enol ethers *(75)* and *(77)* in an alkaline medium, *Claisen*[39] obtained the isoxazoles *(76)* and *(78)*. Although the structures were later confirmed[40], many unexplained results[41] still make it doubtful whether the oximate anions, *e.g.*, *(79)*, are intermediates in the formation of *(76)*.

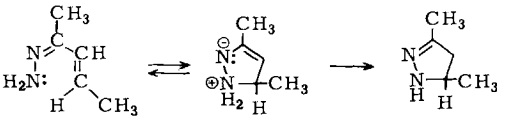


(79) *(80)*

With heteroatoms in positions 1 and 2 of the pentadienyl anion *(79)*, the negative charge migrates during the cyclization to *(80)* from the oxygen to the nitrogen atom. Ethoxide elimination from *(80)* effects aromatization.

The conversion of phenylpropiolaldoxime *(81)* to 5-phenylisoxazole *(83)* with a drop of caustic soda, which was observed by *Claisen*[42], offers an interesting borderline case. As in *(61)*→*(63)*, the rotational symmetry in the distribution of the π-electrons in the CC triple bond and the electronic configuration at the O-atom in *(82)* dispense with the necessity

of 90° rotations about the terminal bond axes. Ring closure leads to the isoxazole anion *(84)*, in which the n-orbital of the carbanionic electron pair is located within the ring plane and no longer maintains allylic resonance. The process *(81)*→*(83)* can be regarded as a nucleophilic *trans*-addition to the CC triple bond.

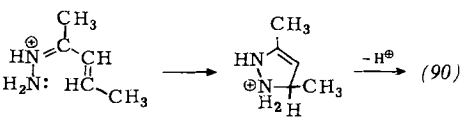


(85) *(86)* *(87)*

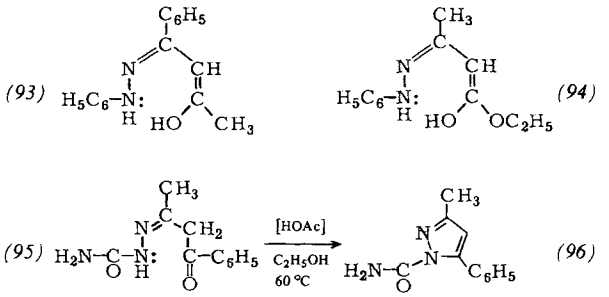
The base-induced ring cleavage of isoxazoles, likewise discovered by *Claisen*[43], constitutes a similar process in the opposite direction. Treatment of 5-methylisoxazole *(85)* with ethanolic sodium ethoxide yields the sodium salt of cyanoacetone *(87)*. Whether in this process the anion *(86)* occurs or the opening of the weak N—O bond is synchronized with deprotonation in position 3, is an open question. The whole process may be considered as a *trans*-elimination at the CN double bond of *(85)*.

7. Isoelectronic Exchange in Position 1 of the Pentadienyl Anion

Hydrazones of α,β-unsaturated carbonyl compounds are often not isolable, but isomerize to 2-pyrazolines even at room temperature as, *e.g.*, the hydrazone *(88)* of ethylideneacetone[44].



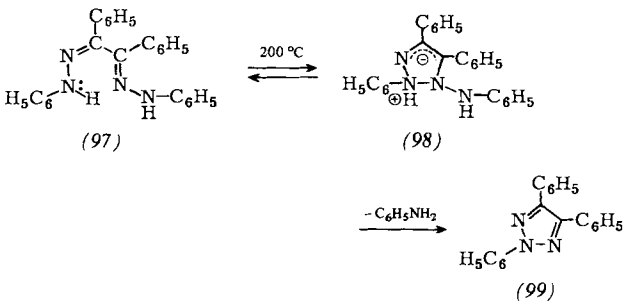
(88) *(89)* *(90)*



In *(88)* the anionic C-1 of the pentadienyl system *(1a)* is replaced by the isoelectronic amino group; the additional isoionic exchange of the CH in the 2-position by N does not affect the charge distribution. The cyclic zwitterion *(89)* which may exist in an electrocyclic equilibrium with *(88)* contains an aza-allyl anion. It is the subsequent prototropy or sigmatropic 1,4-shift which provides stabilization; the bond energy of the 2-pyrazoline *(90)* surpasses that of *(88)* by about 16 kcal mol^{-1}.

Cannot the formation of pyrazolines also be classified as a nucleophilic addition of the NH_2 group of *(88)* to the electrophilic α,β-unsaturated imine? This is an alternative description of one and the same process, differing only in the choice of words and not in its meaning from that given above. Like the electrocyclization of *(1)*, that of *(88)* requires the two 90° rotations about the axes of the terminal bonds.

The formation of pyrazolines from unsaturated hydrazones is subject to acid catalysis[45]. The role of the acid could consist in an acceleration of the subsequent prototropy, *(89)*→*(90)*. The hypothesis that the weakly basic imine nitrogen of *(88)* is protonated and the cation *(91)* undergoes ring closure to *(92)* is also conceivable, and is even preferred by some authors[45,46]. The cation *(91)* corresponds to *(48)* and differs from the pentadienyl anion by a *double isoelectronic* replacement.

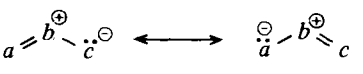


(91) *(92)* *(90)*

(93) *(94)*

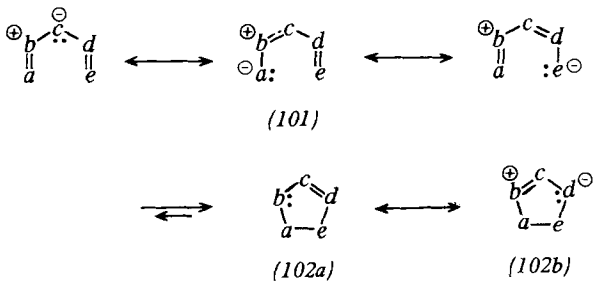
(95) *(96)*

According to *E. Fischer et al.*[47], the formation of 5-methyl-1,3-diphenylpyrazole from benzoylacetone and phenylhydrazine proceeds at 50 °C without the addition of acid *via* a labile crystalline intermediate. Dare we assume here an electrocyclization of the enol *(93)* with subsequent aromatization by elimination of water? Does Knorr's pyrazolone synthesis from phenylhydrazine and acetoacetic ester[48] involve a cyclization of the ketene hemiacetal *(94)*? The isolable benzoylacetone semicarbazone *(95)* is converted into *(96)* in the presence of a small amount of acetic acid[49]. Does the acetic acid merely establish the keto-enol equilibrium of *(95)*, or is the electrophilic activity of the carbonyl group increased by *O*-protonation? Mechanistic investigations of these classical syntheses of heterocycles are still lacking.



(97) *(98)* *(99)*

V. Meyer et al.[50] prepared 2,4,5-triphenyl-1,2,3-triazole *(99)* by heating benzil phenylosazone *(97)* to 200 °C. The formula *(97)* suggests a pentadienyl anion with an isoelectronic exchange in position 1 and a twofold isoionic replacement in positions 2 and 5. The cyclization *(97)*→*(98)* is probably endergonic, and it is the subsequent formation of the aromatic triazole *(99)* through elimination of aniline which makes up for the thermodynamic driving force.

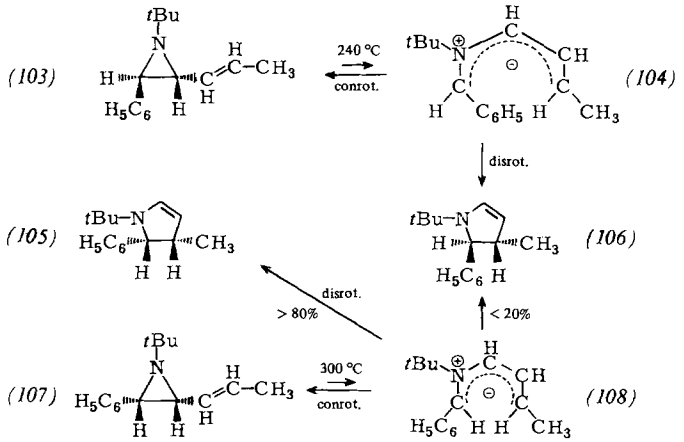


8. Isoelectronic Substitution in Position 2: Cyclizations of Conjugated 1,3-Dipoles of the Allyl Type

1,3-Dipoles are the $_{\pi}4$ reactants in concerted 1,3-dipolar cycloadditions. The all-octet resonance structures *(100)* char-

(100)

acterize 1,3-dipoles of the allyl type[28], which contain NR or O as the middle center *b*; CRR′, NR, and O are interchanged permutatively in the terminal centers *a* and *c*.

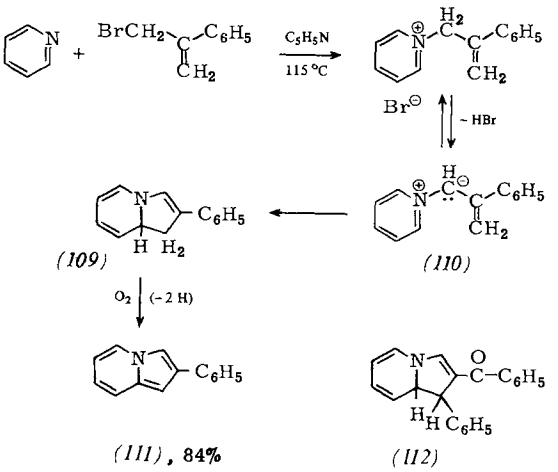


(101)

(102a) *(102b)*

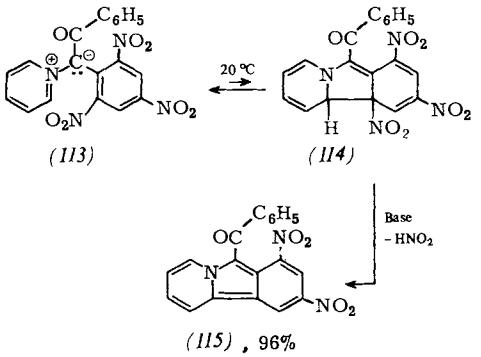
The octet formulas *(101)* of the 1,3-dipole which are conjugated with a double bond *d*=*e* reveal the resonance of pentadienyl anion type with a fixed onium center *b*. In the following the ring-closed product will be represented by the resonance structure *(102a)* which is free of formal charges, although the zwitterionic structure *(102b)* also contributes to a minor extent. With reference to the recent review[30], the plethora of cyclizations will be limited to a few examples.

8.1. Conjugated Azomethine Ylides



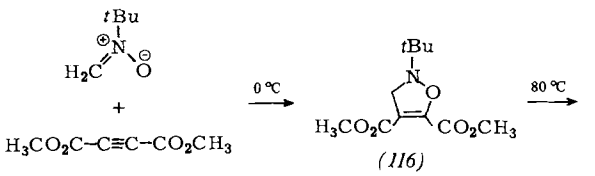
The electrocyclic ring opening of aziridines already discussed for *(18)*⇌*(19)* opens up a path to *vinyl*-substituted azomethine ylides. *Pommelet* and *Chuche*[51] have observed the exclusive formation of the *trans*-2-pyrroline *(106)* from

(103) *(104)* *(105)* *(106)* *(107)* *(108)*



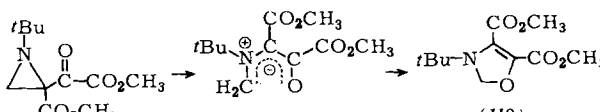
the *trans*-disubstituted aziridine *(103)* at 240 °C. This indicates a sequence of symmetry-allowed steps, namely a conrotatory ring opening of *(103)* and a disrotatory cyclization of *(104)*. Correspondingly, the aziridine *(107)* with *trans*-propenyl and phenyl in the *cis* positions afforded more than 80% of the *cis*-2-pyrroline *(105)*. The concomitant formation of the by-product *(106)* from *(107)* must be the result of a symmetry-forbidden electrocyclic step or a rotation. Only U configurations of the vinylazomethine ylide are presented in the formula scheme. Although W and S configurations may also be more stable in this case, the U configurations are inevitable precursors of the pyrrolines.

In the case of the well-documented pyridinium allylides, *e.g., (110)*, the CN quasi-double bond of the vinylazomethine ylide is part of the aromatic ring. *Pohjala*[52] obtained 2-phenylindolizine *(111)* in 84% yield after refluxing α-bromomethylstyrene in pyridine. The ring closure of *(110)* furnishes the dihydroindolizine *(109)* which is subject to autoxidation. The dihydroindolizine has been isolated in some cases, *e.g., (112)*. Consequently, cyclization does not lose its driving force when the pyridinium aromaticity has to be sacrificed.



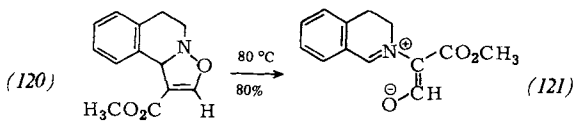
(109) *(110)* *(111)*, 84% *(112)*

In the deep violet isolable pyridinium betaine *(113)* the vinylazomethine ylide structure is embedded in two aromatic nuclei. The base-induced cyclization of this compound to the



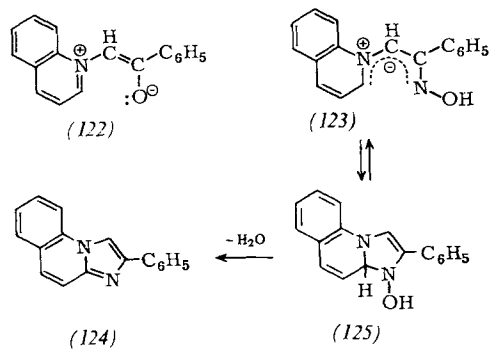
(113) *(114)* *(115)*, 96%

red benzo[*a*]indolizine *(115)* was discovered by *Augstein* and *Kröhnke*[53]. Conceivably, *(114)* is removed from an electrocyclic equilibrium by the elimination of HNO_2 with piperidine. The reaction may be described equally well by an intramolecular nucleophilic substitution of an aromatic nitro group *via (114)* as an intermediate σ-complex.



(116)

(117) *(119)* *(118)*



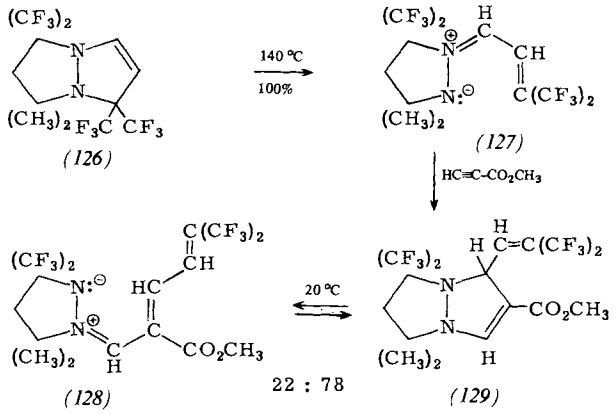
A multi-step sequence suggested by *Baldwin et al.*[54] for the isomerization of the 4-isoxazoline derivative *(116)* to the 4-oxazoline *(118)* calls for the inclusion of the *acyl*azomethine ylide *(119)* as an intermediate. Due to the weakness of the NO σ-bond, the isomerization *(116)*→*(118)* is exothermic

(120) (121)

by about 23 kcal mol^{-1}. The initiating ring contraction *(116)→(117)* probably corresponds in its mechanism to the rearrangement of vinylcyclopropane into cyclopentene.

Depending on the pattern of substitution, the reaction can be stopped at various stages[54,55]. The tricyclic 4-isoxazoline *(120)* that can be obtained from 3,4-dihydroisoquinoline *N*-oxide and propiolic ester isomerizes to the orange crystalline *(121)*[56]. Thus, a benzene ring, an aldehyde and an ester group stabilize the acylazomethine ylide *(121)* to such an extent that ring closure to a 4-oxazoline can no longer be ascertained. However, *(121)* still exhibits the activity of a 1,3-dipole, as disclosed by its cycloadditions to acetylenedicarboxylic ester and other dipolarophiles[55]. Many 4-oxazolines, moreover, maintain thermal equilibria with *C*-acylazomethine ylides[55,57].

(122) (123) (124) (125)

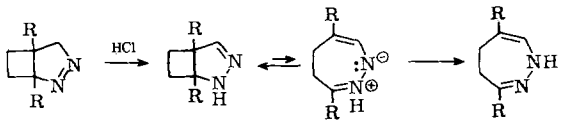


The phenacylquinolinium betaine *(122)* shows no inclination to close the ring. However, the replacement of the oxygen by an imino or oximino group again makes the cyclization energetically attractive. *Kröhnke* and *Zecher*[58] heated *N*-phenacylquinolinium bromide with hydroxylammonium chloride to 130 °C and isolated 87% of the imidazo[1,2-*a*]-quinoline *(124)*. Compound *(123)* may be considered an intermediate. *(125)* is perhaps removed from an equilibrium by elimination of water and rearomatization.

8.2. Conjugated Azomethine Imines

The conjugated double bond may be anchored to the carbon or nitrogen atom of the azomethine imine system. According to *Burger et al.*[59], the 1,5-diazabicyclooctene *(126)*, is accessible by "criss-cross" addition from hexafluoroacetone azine; on heating *(126)*, it is converted into the *C-vinyl*-azomethine imine *(127)*. The inductive stabilization of the anionic charge of *(127)* by the CF_3 groups affects the energy balance.

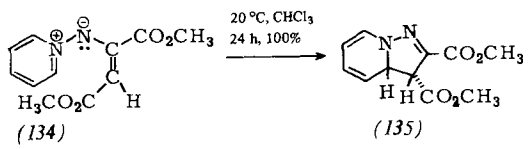
The 1,3-dipole *(127)* combines with methyl propiolate to give *(129)*, which in turn is subject to an electrocyclic opening of the new ring at room temperature and yields the heptatrienyl anion *(128)*; the CF_3 residues once again contribute to the charge stabilization[59].



1-Pyrazolines tautomerize under acid catalysis into 2-pyrazolines. The bicyclic diazomethane adduct *(130)*, upon tautomerization to *(131)*, undergoes a ring-opening to the monocyclic *N-vinyl*azomethine imine *(132)*, which is stabilized by prototropy. The direction of this process *(131)→(133)*, dis-

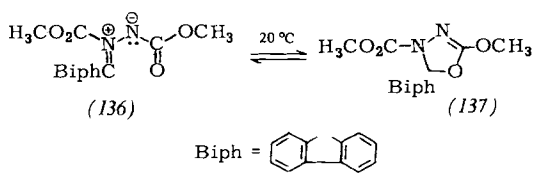
(126) (127) (128) (129)

22 : 78



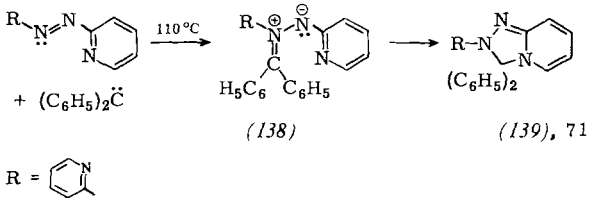
covered by *Prinzbach* and *Martin*[60], is determined by the release of ring strain (about −27 kcal mol^{-1}) which more than compensates the energy required for the conversion of a σ-bond into a π-bond (about +20 kcal mol^{-1}).

(130) (131) (132) (133)



R = CO_2CH_3

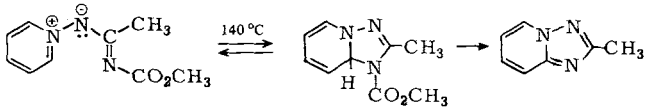
N-Aminopyridinium iodide and α-chlorofumaric ester are converted by potassium carbonate into the pyridinium betaine *(134)*, which according to *Sasaki et al.*[61], cyclizes to the dihydropyrazolo[1,5-*a*]pyridine derivative *(135)*.



(134) (135)

Nitrogen is set free in the reaction of diazoalkanes with electrophilic azo compounds, and azomethine imines are created, which occasionally can be isolated in crystalline form[62]. The product *(136)* from diazofluorene and dimethyl azodicarboxylate, as an *N-acyl*azomethine imine, closes the ring to form the 1,3,4-oxadiazoline *(137)*. Whereas *(137)* is present in the crystalline state, *Fahr et al.*[63] have revealed a mobile ring-chain tautomerism *(137)→(136)* in solution. Above 50 °C, *(136)* isomerizes irreversibly with acyl migration into fluorenone hydrazone-N^{β}, N^{β}-dicarboxylic ester.

(136) (137)

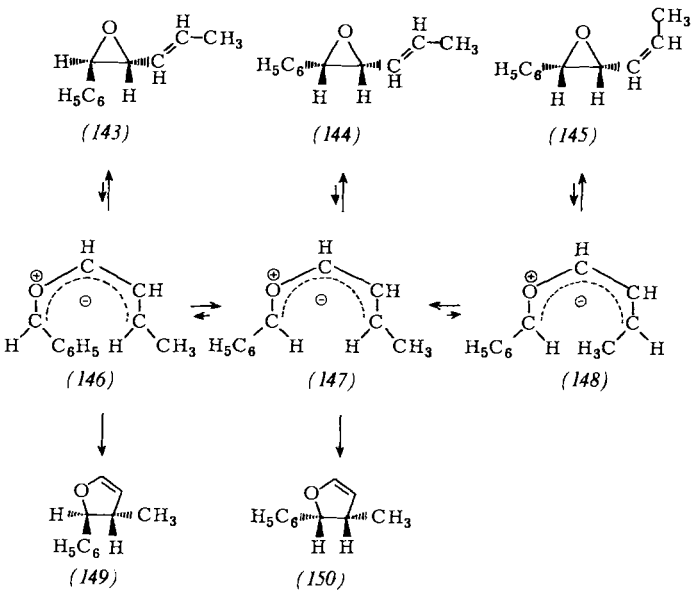


Biph =

(138) (139), 71%

R =

According to *Fahr et al.*[64], diphenyldiazomethane and 2,2′-azopyridine combine to form the dihydro-*s*-triazolo[4,3-*a*]pyridine *(139)*. Since the rate of the evolution of N_2 is that of the self-decomposition of diphenyldiazomethane, diphenylcarbene can be considered responsible for the formation of the *N-imino*-azomethine imine *(138)*.



(140) (141) (142), 60%

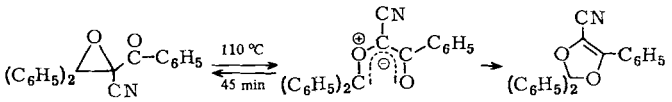
While in *(138)* the quasi-imino group belongs to a pyridine ring, in *(140)* the latter is integrated into the azomethine imine system. *Kakehi et al.*[65] observed that the electrocyclization *(140)*→*(141)* is followed by aromatization to give *(142)* with formal elimination of methyl formate.

8.3. Conjugated Carbonyl Ylides and Carbonyl Oxides

*Vinyl*carbonyl ylides are obtained by the thermal CC ring-opening of vinyloxiranes; as expected, they enter into electrocyclic ring closure to yield 2,3-dihydrofurans.

(143) (144) (145)

(146) (147) (148)

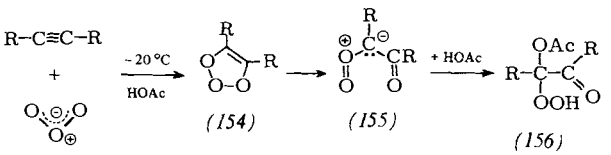


(149) (150)

Stereochemical studies of *Paladini* and *Chuche*[66] with 2-phenyl-3-propenyloxiranes have revealed a pronounced stereoisomerization of the oxiranes after short reaction times. For example, almost identical mixtures of products were reached after 3 h at 240 °C:

(143) → 30% *(143)*, 6% *(144)*, 62% *(150)*, 2% *(149)*
(144) → 30% *(143)*, 9% *(144)*, 61% *(150)*

Recyclization to oxiranes and 1,5-ring closure to dihydrofurans are competing reactions of the vinylcarbonyl ylides *(146)—(148)*. The predominance of the *trans*-oxirane *(143)* in the recovered starting material is due to its higher share in the equilibrium *(143)*⇌*(144)*. The stereoisomerization may be achieved by symmetry-allowed conrotation followed by rotation of the vinylcarbonyl ylide, *(146)*⇌*(147)*, or else through the combination of a conrotatory with a symmetry-forbidden disrotatory reaction step. In experiments at 400 °C, in addition, a low yield of *(145)* from *(144)* indicates a *trans-cis* isomerization in the propenyl side chain; this transformation must result from rotation about the 4,5-bond, *(147)*→*(148)*.



The preferred formation of the *cis*-dihydrofuran *(150)* would correspond to the allowed disrotatory ring closure of the vinylcarbonyl ylide *(147)*, *i.e.*, the sterically preferred U configuration with terminal *exo*-substituents. In view of the exergonic nature of the 1,5-cyclization, one may presume an early transition state; steric hindrance in the vinylcarbonyl ylide therefore affects the energy level of the transition state more strongly than steric factors in the dihydrofuran. The studies of *Eberbach et al.*[67] also support the conclusion that, as compared with the vinylazomethine ylides (Section 8.1), the vinylcarbonyl ylides exhibit greater configurative mobility and a smaller influence of orbital control on the ring closure.

(151) (152) (153), 100%

Since acyl residues and cyano groups stabilize carbonyl ylides better than vinyl and phenyl groups, the conversion of the acyloxirane *(151)* *via* the *acyl*carbonyl ylide *(152)* into the dioxole *(153)* proceeds at a lower temperature than *(143)*→*(146)*, according to *Foucaud et al.*[68].

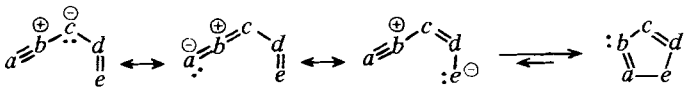
The key role of the carbonyl oxides within the framework of the *Criegee* mechanism for the ozonolysis of alkenes is no longer questioned nowadays[69,70]. The electrocyclic ring closure of *C-vinyl*carbonyl oxides has not yet been reported. On the other hand, *C*-acylcarbonyl oxides are postulated as intermediates in the ozonolysis of alkynes.

(154) (155) (156)

R = CH_2–O–C(=O)–C_6H_5

Criegee and *Lederer*[71] obtained the acetoxyhydroperoxide *(156)* in 83% yield by the action of ozone on 2-butynylene dibenzoate in the presence of acetic acid. The pathway through the 1,2,3-trioxole *(154)* and its electrocyclic ring opening to the acylcarbonyl oxide *(155)* is attractive. The conversion of a C—O bond (+86 kcal mol^{-1}) and an O—O bond (+35 kcal mol^{-1}) into a C=O double bond (−176 kcal mol^{-1}) more than compensates the energy of charge separation. The orbitals of the unshared electron pairs at the O-atoms eliminate the necessity for 90° rotations during the cleavage of the O—O bond.

9. Cyclizations of Conjugated 1,3-Dipoles of the Propargyl-Allenyl Type

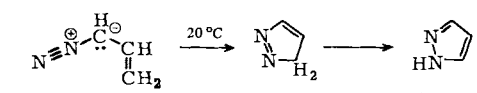


9.1. Mechanistic Considerations

The 1,3-dipoles *(157)* differ from *(100)* by an additional π-bond between *a* and *b*, which requires σ-bonds of the sp-hybrid type for *b*. With the possible exception of the nitrile ylides[72], all nitrilium and diazonium betaines[28] are linear.

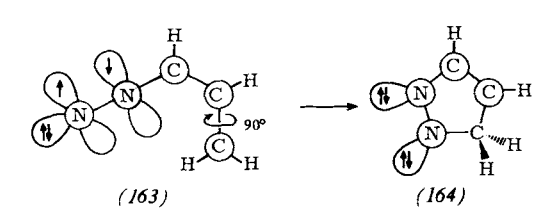
(157)

The π-orbitals of the extra bond between *a* and *b* are perpendicular to the molecular orbital of the allyl anion.



(158) *(159)*

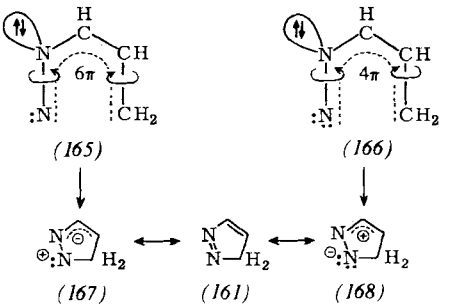
In *(158)* the allyl anion system of the 1,3-dipole of propargyl-allenyl type is extended by an additional double bond *d*=*e*. As in *(101)*, the octet structures *(158)* indicate the fixation of the formal positive charge on *b*, the central atom of the 1,3-dipole, which in this case must be a nitrogen atom; no other element of the first long period harbors an onium charge in the tetracovalent state. A methine group CR or another N-atom can take over the role of *a* in the nitrilium and diazonium betaines, respectively; *c* appears in the subclasses as ylide carbon or imine nitrogen. We are facing in *(158)* a pentadienyl anion with an isoelectronic exchange at *b* and up to four additional isoionic replacements.



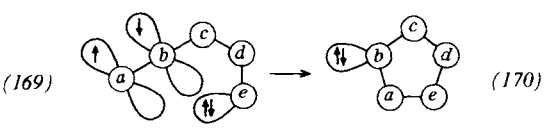
A glance at the scheme *(158)*→*(159)* suggests limitations to the abundance[29]. The conjugated double bond *d*=*e* cannot be located at the terminus *a* of *(157)*, since the resulting 5-membered ring would have to accomodate cumulated double bonds.

Like the concerted 1,3-cycloadditions of *(157)* to dipolarophiles, the cyclization of *(158)* demands the bending of the linear structure *a*—*b*—*c*. A new feature: the ring-closed product *(159)* lacks the allyl anion resonance of the cyclopentenyl anion *(2)*. The n-orbital of the unshared electron pair at *b* is in fact located *in the plane of the ring* and maintains no conjugation with the π-bond in *c*=*d*. Actually, *(159)* constitutes a cyclopentadiene derivative or a five-membered heteroaromatic ring if *e* is capable of conjugation.

Are the numerous known ring closures *(158)*→*(159)* still electrocyclic reactions of the pentadienyl anion type? The cyclization of vinyldiazomethane *(160)*[173] may serve as a model for the discussion of stereoelectronic pathways whose differentiation is, to some extent, more semantic than mechanistic. The 3*H*-pyrazole *(161)* first produced is transformed by prototropy into the aromatic pyrazole *(162)*.



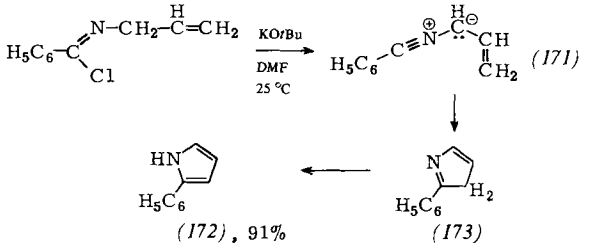
(160) *(161)* *(162)*



(163) *(164)*

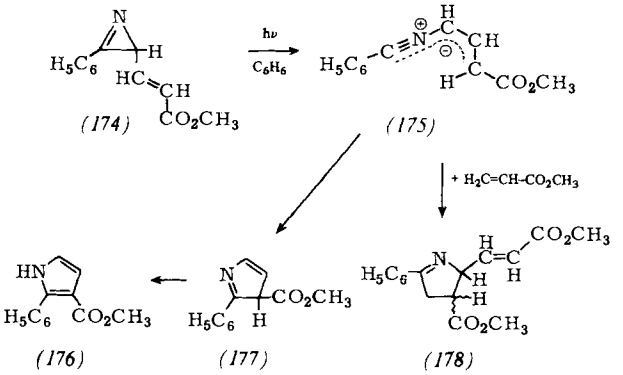
A. In *(163)* the circles demonstrate the 6π-electron system of the pentadienyl anion, the atomic orbitals of which are perpendicular to the plane of the σ-bonds. The extra π-bond of the diazonium group in *(163)*—orbitals in the plane of the paper—is electrophilic. Its two π-electrons are localized as an unshared pair at the inner nitrogen if a nucleophile attacks the outer N-atom. The terminal carbanionic CH_2 group can act as a nucleophile, *one* 90° rotation being required for the conversion *(163)*→*(164)*. Thus, it is not the NN fragment of the pentadienyl system that is involved in the formation of the new σ-bond, but rather the extra π-bond. Hence, of the five π-atomic orbitals that form the pentadienyl system of vinyldiazomethane in *(163) four* are retained during ring closure and constitute the 1,2-diaza-1,3-diene system of the 3H-pyrazole *(164)*.

(165) *(166)* *(167)* *(161)* *(168)*



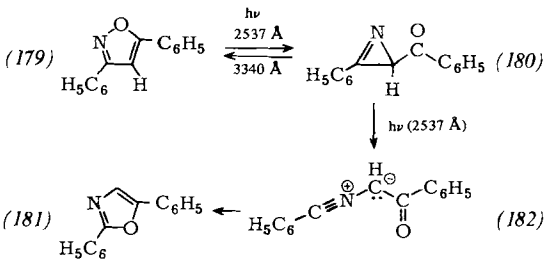
B. In a second model, two 90° rotations about terminal bonds are assumed and the continuous molecular motion is formally broken down into steps. The reaction begins with the bending of the linear diazomethane system of *(163)*; in *(165)*, the electrons of the extra π-bond appear on the inner nitrogen, and a nitrene function, *i.e.*, an electron sextet, arises on the terminal nitrogen. Now either a double-occupied or a vacant atomic orbital of this nitrene nitrogen enters into the pentadienyl system, which either closes the ring as a 6π-system in accordance with *(165)*→*(167)* or undergoes a 4π-cyclization of the pentadienyl cation type, *(166)*→*(168)*. The structures, among which *(167)* contains the allyl anion group and *(168)* that of the allyl cation, are minor resonance contributors of the 1,3-diene system of *(161)*. The distinction between the 6π- and 4π-route is probably only fictitious, particularly as the N-terminus rules out any differentiating between disrotation and conrotation.

(169) *(170)*



C. A ring closure without rotation is conceivable for *(158)*, *e*=NR or O. The unshared electron pair of the n-orbital at *e* functions as a nucleophile and creates a new σ-bond by overlapping the orbital of the extra π-bond at *a*. The 6π-system of the open-chain species *(169)* is preserved intact in the π-cloud of the aromatic ring *(170)*. A description of the process as a nucleophilic addition of *e* to the electrophilic onium bond $a{=}b^{\oplus}$ would be equivalent.

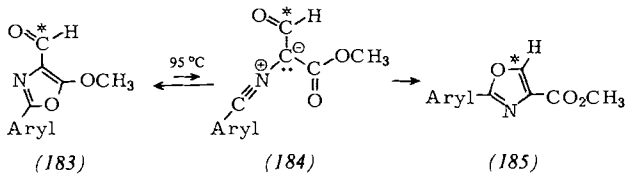
9.2. Conjugated Nitrile Ylides



(172), 91% (173)

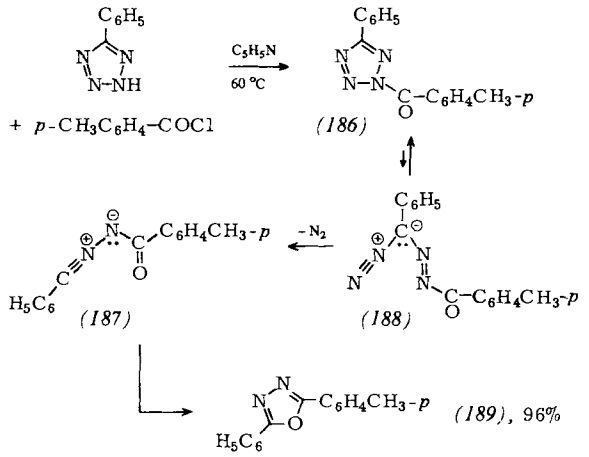
Nitrile ylides cannot be isolated so far. These 1,3-dipoles were first made available for *in situ* cycloadditions by elimination of HCl from imidoyl chlorides[74]. Recently *Steglich et al.*[75] have set free the benzonitrile *N*-allylide *(171)*, which, as a *vinyl* nitrile ylide, immediately closed the ring; *via* the 3*H*-pyrrole *(173)*, 91% of *(172)* was formed.

(174) (175) (176) (177) (178)



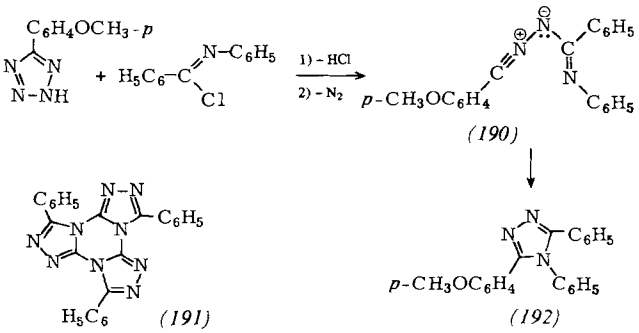
The light-induced electrocyclic ring opening of 2*H*-azirines offers an elegant method for the synthesis of the nitrile ylides. *Padwa et al.*[76] converted the 2*H*-azirine *(174)* into *(175)*, which formed the 3*H*-pyrrole ring *(177) in situ*; the aromatic tautomer *(176)* was isolated in 95% yield. On irradiation of *(174)* in the presence of methyl acrylate, intramolecular cyclization was suppressed in favor of the intermolecular 1,3-dipolar cycloaddition to give *(178)*.

(179) (180) (181) (182)



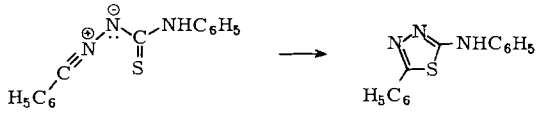
In the surprising photorearrangement of 3,5-diphenylisoxazole *(179)* into 2,5-diphenyloxazole *(181)*, *Singh* and *Ullman*[77] isolated 2-benzoyl-3-phenyl-2*H*-azirine *(180)* as an intermediate. The photochemical behavior of *(180)* is controlled by the wavelength of the light used. Whereas 3340 Å causes the reversal of the ring contraction, *(180)*→*(179)*, shorter wavelength light induces an electrocyclic ring opening to yield the *acyl* nitrile ylide *(182)*, which cyclizes in a dark reaction to the oxazole *(181)*.

Two acyl residues on the nitrile ylide carbon have such a successful stabilizing effect that a *thermal* equilibrium of 4-acyloxazoles with a small concentration of the diacyl nitrile ylide is established. *Cornforth*[78] was the first to observe thermal transformation of 5-methoxyoxazole-4-carbaldehydes *(183)* or -4-carboxamides into methyl oxazole-4-carboxylates *(185)* or their 5-amino derivatives. The interchange of the 5-C atom of the oxazole with the C-atom of the aldehyde or carboxamide side chain, as was to be expected for an intermediate nitrile ylide of type *(184)*, was demonstrated by ^{14}C-labeling[79].



(183) (184) (185)

9.3. Conjugated Nitrile Imines

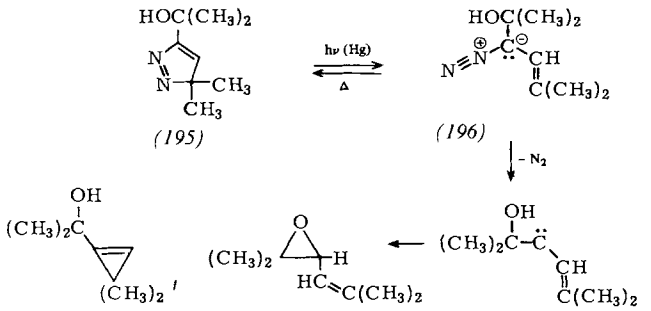


(186) (187) (188) (189), 96%

An excellent synthesis of 1,3,4-oxadiazoles which may bear aryl or alkyl substituents is based on the electrocyclic ring closure of *N-acyl* nitrile imines[80]. 5-Phenyltetrazole reacts with *p*-toluoyl chloride in pyridine to produce 96% of the oxadiazole *(189)*. The evolution of nitrogen obeys first-order kinetics[81], *i.e.*, the steps after the acylation to give *(186)* are rate-determining. The electrocyclic ring opening to the *acylazo* diazoalkane *(188)* probably takes place in an equilibrium that is continuously disturbed by the loss of N_2. For its part, the new *N-acyl* nitrile imine *(187)* closes the oxadiazole ring of *(189)*. The reaction scheme includes two electrocyclic steps of the pentadienyl type. This reaction scheme has been developed into a duplication process which affords polyaryls with alternating benzene and 1,3,4-oxadiazole units[82].

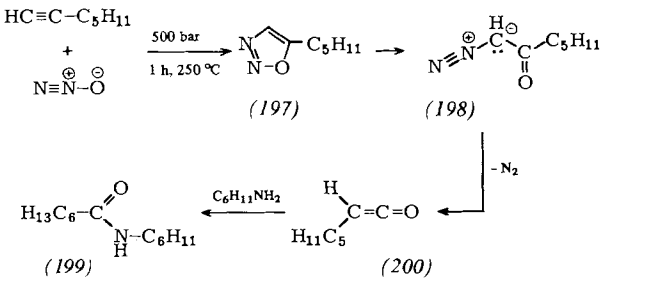
(190) (191) (192)

Imidoyl chlorides react analogously with tetrazoles, *e.g.*, 5-(4-methoxyphenyl)tetrazole with *N*-phenylbenzimidoyl chloride to give the 1,2,4-triazole derivative *(192)* in 99% yield[83]. The electrocyclization of *N-imino* nitrile imines of the type *(190)* provides the key step for this general synthesis of 1,2,4-triazoles. Cyanuric chloride, as a triple aromatic imidoyl chloride, combines with three equivalents of 5-phenyltetrazole to give 70% of *(191)*[84].



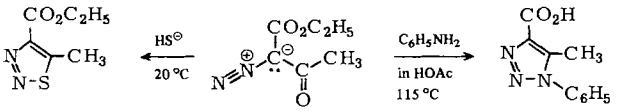
(193) *(194)*

5-Phenyltetrazole and phenyl isothiocyanate at 160 °C furnish the 1,3,4-thiadiazole derivative *(194)* in 64% yield *via* the *N-thiocarbonyl* nitrile imine *(193)*[84].



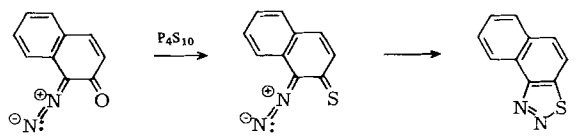
9.4. Conjugated Diazoalkanes

The spontaneous cyclization of *vinyl*diazomethane *(160)* to pyrazole *(162)*[73] has been discussed in Section 9.1; it takes place with a half-conversion time of 3.2 h at 25 °C[85]. *Ledwith* and *Parry*[86] found the photoconversion to be only three times faster than the thermal reaction, and considered it possible that the photochemical step is merely the tautomerization of the 3*H*-pyrazole *(161)* to *(162)*. The cyclization of *trans*-styryldiazomethane is accelerated only slightly by electron-donating substituents ($\rho = -0.40$); *Brewbaker* and *Hart*[85] concluded that there was only a slight loss of charge at the γ-carbon atom in the transition state.



(195) *(196)*

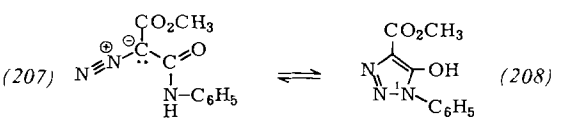
γ,γ-Disubstituted vinyldiazomethanes form the non-aromatic 3*H*-pyrazoles quite slowly. In their photolysis, *Closs* and *Böll*[87] found access to cyclopropenes; the transient red color suggested diazoalkanes to be intermediates. In the photolysis of *(195)*, *Day* and *Whiting*[88] detected spectroscopically up to 65% of the vinyl diazoalkane *(196)* as an intermediate; acetic acid converted *(196)* into the ester with evolution of N_2. Further irradiation of *(196)* is accompanied by the elimination of N_2. The recyclization *(196)*→*(195)* in the dark is slow.



(197) *(198)* *(199)* *(200)*

*Acyl*diazomethanes (diazoketones) are stable and do not undergo ring closure to form 1,2,3-oxadiazoles; this is due to the weakness of the NO σ-bond in the latter and the stabilization of the negative charge by the diazoketone oxygen. 1,2,3-Oxadiazoles are hypothetical, although plausible, intermediates in the 1,3-dipolar cycloadditions of dinitrogen oxide to alkynes. *Buckley* and *Levy*[89] studied the pressure reactions of N_2O with 1-heptyne in the presence of cyclohexylamine and isolated the *N*-cyclohexylamide of heptanoic acid *(199)* in 94% yield. The presumable pathway includes an electrocyclic opening of the 1,2,3-oxadiazole *(197)* to the diazoketone *(198)*. The latter decomposes at 250 °C with Wolff rearrangement, and the intermediate ketene *(200)* is intercepted by cyclohexylamine.

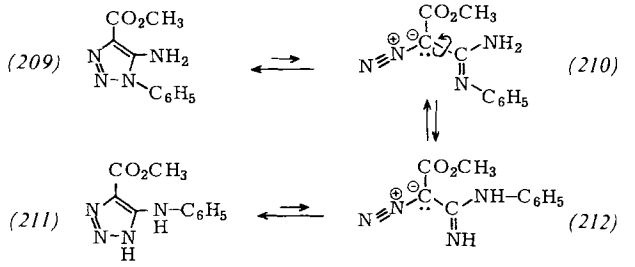
(201) *(202)* *(203)*



In contrast to the α-diazocarbonyl compounds, the *thiocarbonyl*diazoalkanes undergo ring closure immediately. In 1904, on treating α-diazoacetoacetic ester *(202)* with ammonium hydrogen sulfide, *Wolff* obtained 5-methyl-1,2,3-thiadiazole-4-carboxylic ester *(201)*[90]; the thioacyldiazoalkane probably occurred as an intermediate. The lower bond energy of C=S (128 kcal mol^{-1}) compared with C=O (179 kcal mol^{-1}) causes a shift of the energy balance in favor of the cyclic product.

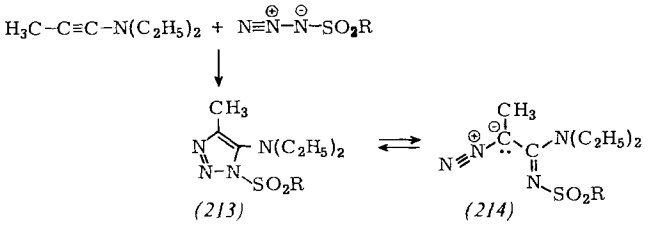
(204) *(205)* *(206)*

A similar situation is met in the aromatic series. "*o*-Quinone diazides" of type *(204)* exist in the diazoketone form[91]. *Bamberger et al.*[92] converted 1,2-naphthoquinone 1-diazide with P_4S_{10} into the naphthothiadiazole *(206)*, but were unable to isolate the thione *(205)*.



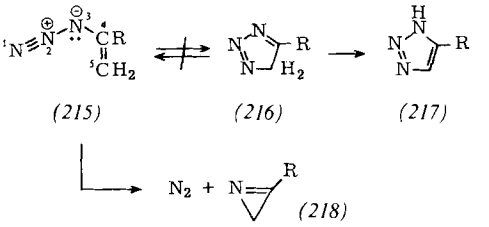
According to *Wolff et al.*, α-diazoacetoacetic ester *(202)* reacts with aniline in boiling acetic acid to give 5-methyl-1-phenyl-1,2,3-triazole-4-carboxylic acid *(203)*[93]. In their tendency to undergo ring closure, *imino*diazoalkanes occupy an intermediate position.

(207) *(208)*



A masterly investigation carried out by *O. Dimroth*[94] in 1910 revealed the tautomerism of the yellow diazomalonic ester anilide *(207)* with the colorless 5-hydroxytriazole-4-carboxylic ester *(208)*. The yellow compound was originally considered to be a triazolonecarboxylic ester, and a keto-enol tautomerism with *(208)* was proposed[95]. The open-chain diazo compound *(207)* was finally recognized without resorting to spectroscopic methods, which were still unknown in 1910.

Kinetic measurements have disclosed a relationship between the rate and the equilibrium constants for the ring opening of *(207)*, when the 1-phenyl in *(207)* is replaced by H, alkyl, or some other aryl residues. The more strongly the 1-substituent of the triazole *(208)* demands a share of the electron pair at N-1, the smaller is the concentration of the cyclic tautomer in the equilibrium mixture, and the rate constants of ring opening increase by a factor of 10^5 [94]. The well-investigated tautomerism *(207)*⇌*(208)* nevertheless still harbors a mystery. In *(207)*, is there an azo coupling with the anilino nitrogen, followed by prototropy to *(208)*, or does a proton shift of *(207)* to the iminol tautomer precede the electrocyclic ring closure?

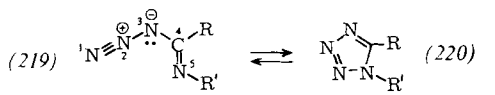


Another discovery of *Dimroth*'s concerns the equilibrium between the 5-amino-1-phenyl-1,2,4-triazole *(209)* and the 5-anilinotriazole *(211)*, which is established at 150 °C or at even lower temperatures with base catalysis, and which in methanol attains a ratio of 30:70 [94]. A migration of the phenyl residue was rigorously excluded, and a reaction pathway *via* the tautomeric amidines *(210)* and *(212)* was proposed.

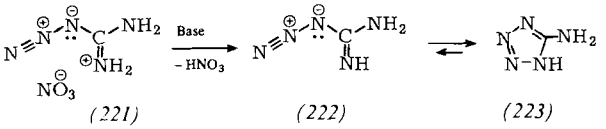
Lieber et al.[96] introduced substituents into the 1-phenyl residue of 5-amino-1,4-diphenyl-1,2,3-triazole, which is analogous to *(209)*, and observed for the "Dimroth rearrangement" a linear relationship between the logarithms of the rate and equilibrium constants. In a kinetic investigation of the acid catalysis of the isomerization *(209)*⇌*(211)*, *Brown, Hammick,* and *Heritage*[97] noticed a second-order reaction only at low acidities, whereas for pH > 4 a plateau value was reached. This indicates an acid catalysis of the amidine tautomerization, *(210)*⇌*(212)*.

The 1-sulfonyltriazoles arising from the cycloaddition of sulfonyl azides to 1-diethylaminopropyne are surprising in the mobility of the electrocyclic equilibrium with the *amidino*diazoethanes, *e.g. (213)*⇌*(214)*[98]. According to *Himbert* and *Regitz*[99], the equilibrium is established in cold chloroform and contains the following amounts of the triazole derivative *(213)*: 100% for R = $C_6H_4N(CH_3)_2$-*p*, 62% for C_6H_5, 30% for C_6H_4Cl-*p*, and 0% for $C_6H_4NO_2$-*p*. In the case of the 1-aryl-5-aminotriazoles of type *(209)*, the open-chain form *(210)* is not directly detectable. The fact that they are favored in the case of 1-sulfonyltriazoles of type *(213)* originates in a disturbance of the triazole resonance and in a stabilization of the negative charge in the amidinodiazoalkane *(214)* by the sulfonyl group.

9.5. Conjugated Azides



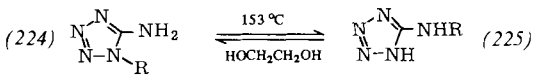
A negative experience may be more exciting than a wagonload of further confirmations of the general reaction scheme: *vinyl* azides *(215)* do not cyclize to 1,2,3-triazoles *(217)*! Instead, 2*H*-azirines *(218)* are formed with evolution of N_2[100], as was first uncovered by *Smolinsky*[101] for *(215)*, R = C_6H_5 (350 °C, gas phase).



Even if the cyclization *(215)*→*(216)* were deficient in thermodynamic driving force, which is unlikely, the subsequent aromatization of the 4*H*-triazoles, *(216)*→*(217)*, would overcome an unfavorable position of the equilibrium *(215)*⇌*(216)*. Is it conceivable that the prototropy *(216)*→*(217)* is slow enough to be exceeded by the nitrogen-eliminating process *(215)*→*(218)*? This seems all the less probable since *(216)* should be a stronger acid than the 3*H*-pyrazole *(161)* which is passed as an intermediate en route from vinyldiazomethane *(160)* to pyrazole *(162)*. The latter reaction in fact proceeds much faster (E_a = 22.6 kcal mol^{-1}) than the formation of azirines from vinyl azides, for which E_a values of 26.6—30.5 kcal mol^{-1} have been measured[102]. A 3,5-ring closure of *(215)* with simultaneous departure of N_2 (no free nitrene) is favored in the literature as pathway for the formation of 2*H*-azirines from vinyl azides.

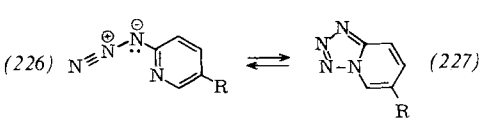
Leroy et al.[103] have carried out quantum-chemical calculations on the cyclization of vinyl azide, *(215)*→*(216)*, R = H, in which a 90° rotation about the terminal CC bond, but no rotation about the bond between N-1 and N-2 was assumed; this conforms to reaction path A of Section 9.1. Scanning of the hypersurface with an *ab initio* SCF method indicated an early transition state with a weak 1,5-bond and 25° rotation about the C4—C5 bond. The originally stretched azide system is bent to 129° in the transition state and the electrons of the extra π-bond between N-1 and N-2 are localized as lone pair on N-2. The activation energy was calculated with the STO-3G basis set as 33 kcal mol^{-1}, but with 4-31G as 41 kcal mol^{-1}; still greater is the discrepancy in the heats of the reaction (−56 and −11 kcal mol^{-1}). A comparative calculation of the cyclization of vinyldiazomethane would be desirable.

1,2,3-Triazoles can be obtained from vinyl azides by base catalysis. This conversion, taking place in the anion, will be described in Section 12.2.



When attempts are made to prepare *imino*azides *(219)* from imidoyl chlorides or nitrilium salts with the azide anion or in other ways, the tetrazoles *(220)* are isolated instead. The aromatic nature of the cyclic product *(220)* is probably responsible for the position of the equilibrium in this highly mobile system. Only electron-attracting substituents are capable of stabilizing the azide form; *inter alia (219)*, $R = CF_3$ and $R' = \beta$-naphthyl[104], and also $R = C_6H_5$, $R' = OH$ or OCH_3[105], have been reported.

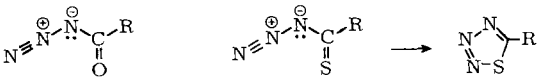
(221) *(222)* *(223)*



In 1892, in his investigation of aminoguanidines, *Thiele*[106] liberated "Amidotetrazotsäure", *i.e.*, 5-aminotetrazole *(223)*, with sodium acetate from "diazoguanidine nitrate" which *Hantzsch* and *Vagt*[107] correctly formulated as *(221)*. The cyclization of the *guanyl* azide *(222)* occurs in water at pH 9 and 0 °C with a half-conversion time of 2.2 min; the activation energy amounts to 17.8 kcal mol^{-1}[108].

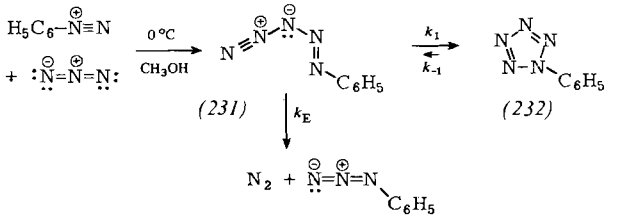
In the same way as for the cyclization *(215)*→*(216)*, R = H, *Leroy et al.*[109] carried out an *ab initio* calculation of the energy surface for the reaction *(219)*→*(220)*, R = R' = H. They based the cyclization on the simple reaction model C (Section 9.1): N-5 moves with its lone pair without rotation toward the extra π-bond located in the plane of the σ-skeleton. The transition state is reached when the azide system has bent to an angle of 136°. Here again the activation energy and the heat of reaction depend to an irritatingly large extent on the basis set: 12.3 and −66 kcal mol^{-1} for STO-3G as well as 24 and −18 kcal mol^{-1} for 4-31G[103].

(224) *(225)*



The Dimroth rearrangement of 1- and 5-substituted tetrazoles, *(224)*⇌*(225)*, proceeds *via* the substituted *amidino*azides. Their concentration in the equilibrium with *(224)* and *(225)* is so small that the rearrangement requires high temperatures. *Henry, Finnegan,* and *Lieber*[108] determined the following equilibrium proportions of the 1-substituted tetrazoles *(224)*: 96% for $R = CH_3$, 37% for $R = C_6H_5$, and 21% for $R = C_6H_4Cl$-*p*. Electron-attracting 1-substituents destabilize the tetrazole *(224)* as delineated in Section 9.4 for the 5-amino-1,2,3-triazoles, *(209)*⇌*(211)*. For R = aryl, the logarithms of the rate and equilibrium constants gave linear Hammett plots.

(226) *(227)*



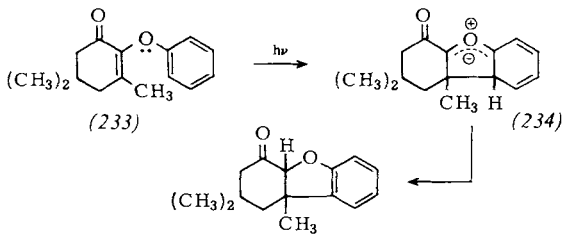
2-Pyridyl azide *(226)*, R = H, is unknown, but exists in the form of tetrazolo[1,5-*a*]pyridine *(227)*, R = H; on cyclization, the aromatic resonance is retained. A small equilibrium concentration of *(226)*, R = H, is exhibited in 1,3-dipolar cycloadditions to enamines[110] or to acetylenecarboxylic esters[111] at elevated temperatures.

Whereas *(227)*, $R = NO_2$, exists in the crystalline state, *Boyer* and *Miller*[112] in 1959 demonstrated the presence of a mobile equilibrium with *(226)*, $R = NO_2$, in solution. Since that time, imidazide-tetrazole equilibria have been observed and measured in so many heteroaromatics that it constitutes the most widely documented 1,5-dipolar cyclization. Electron-attracting substituents and electron-deficient N-heterocycles favor the azide tautomer for two reasons: a) The negative formal charge of the azide experiences additional delocalization; and b) the competing resonance destabilizes the annelated tetrazole ring. *Tišler*[113] and *Butler*[114] reviewed the topic.

(228) *(229)* *(230)*

Acyl azides *(228)* occur in the open-chain form, while *thioacyl* azides *(229)* cyclize completely to 1,2,3,4-thiatriazoles[115]; the analogous situation for acyl- and thioacyldiazomethanes (Section 9.4) indicates comparable resonance energies for azide and diazoalkane systems. Treatment of thioacyl hydrazides with HNO_2 yields 1,2,3,4-thiatriazoles *(230)*, and it is almost inconceivable that the azides *(229)* are not passed as intermediates. In the reaction of thiobenzoyl chloride with the azide anion at −100 °C, *(229)*, $R = C_6H_5$, was not detectable[115]; the electrocyclization to *(230)* is faster than the initial nucleophilic substitution.

(231) *(232)*



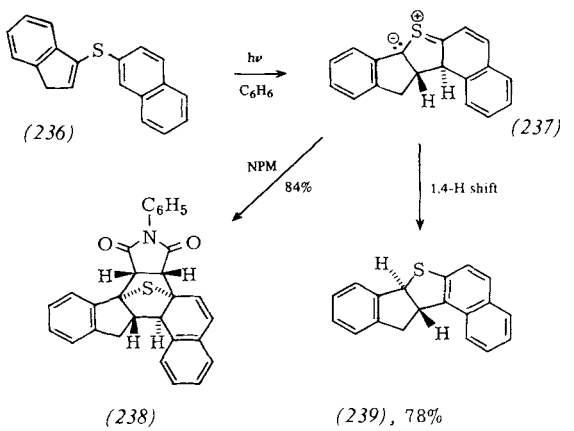
In the *imino* azides *(219)* one notices a pentadienyl anion with one isoelectronic exchange in 2-position and three additional isoionic replacements. With no carbon atom remaining, the *benzene diazo* azide *(231)* represents the logical extreme. Pentazoles are organic compounds *honoris causa*, because they figure as the end of the road in the aromatic azole family.

Prepared by azo coupling of benzenediazonium chloride with lithium azide in methanol, the benzene diazo azide *(231)* is rapidly channeled into two competing processes: The elimination of nitrogen (k_E) to give phenyl azide and the electrocyclic ring closure to *(232)* occur in a ratio of 76:24[116]. The phenylpentazole *(232)* decomposes *via* the open-chain diazo azide *(231)* into phenyl azide and nitrogen with a half-life of 14 min at 0 °C. Not only the fate of a ^{15}N label[116], but also the UV spectrum of the pure and crystallizable phenylpentazole[117] confirms the structure *(232)*. The rate of decomposition of the arylpentazoles depends on the nature of the aryl group in the same way as the rate of the Dimroth rearrangements, *(209)*→*(211)* and *(224)*→*(225)*. For *(232)*, $C_6H_4NO_2$-*p* instead of C_6H_5, the half-life decreases to 2 min, whereas for $C_6H_4N(CH_3)_2$-*p* and $C_6H_4O^{\ominus}$-*p* it increases to 69 and 127 min, respectively, at 0 °C[118].

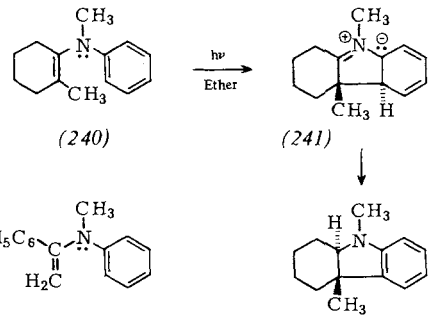
In an alternative description, the azide ion combines in a 1,3-dipolar cycloaddition with the benzenediazonium ion directly to *(232)*, and in a competing decomposition yields N_2 + phenyl azide *via (231)*. Within this second reaction model, the decomposition of the pentazole *(232)* involves a one-step 1,3-dipolar cycloreversion[119]. The analogy with the imino-azide-tetrazole system is so close that we prefer the scheme with the electrocyclic reaction *(231)*⇌*(232)*.

10. Isoelectronic Exchange in Position 3

10.1. Photocyclizations of Charge-Free Systems



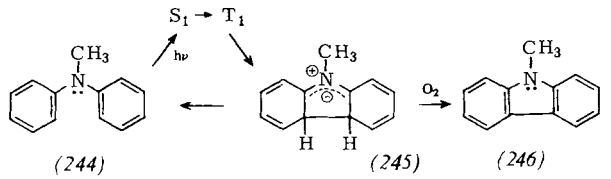
(233) *(234)* *(235)*, 95%



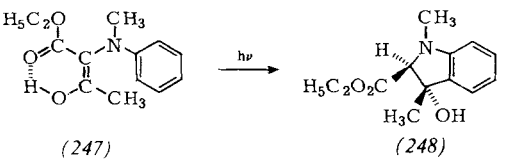
In *(233)* we recognize a derivative of divinyl ether which, for its part, is derived from the pentadienyl anion by isoelectronic replacement of the 3-CH by an oxygen atom. According to *Schultz* and *Lucci*[120], *(233)* undergoes a light-induced cyclization to the hydrobenzofuran derivative *(235)*; the cyclic carbonyl ylide *(234)* is stabilized by the neighboring carbonyl function and is a plausible intermediate. With a concluding prototropy the net process *(233)*→*(235)* may well be exergonic.

In contrast to divinyl sulfide, phenyl vinyl sulfide is subject to photocyclization, and in the presence of iodine it gives a small quantity of benzo[*b*]thiophene[121]. Acyl substitution contributes to stabilization of the thiocarbonyl ylide; compound *(233)* with S in place of the ethereal O on irradition gives *(234)*, S instead of O, in 91% yield[122]. The following example substantiates the conrotation of the electrocyclization that is prescribed by orbital control for the first excited singlet state.

According to *Schultz* and *De Tar*[123], 3-indenyl-2-naphthyl sulfide *(236)* in benzene undergoes a photorearrangement to yield 78% of the pentacyclic dihydrothiophene derivative *(239)*. The *trans* linkage of the five-membered ring in *(239)* is the expected result of a conrotatory photocyclization *(236)*→*(237)* with a subsequent suprafacial 1,4-H shift; the latter is a symmetry-allowed, thermal sigmatropic process. If the irradiation of *(236)* is carried out in the presence of *N*-phenylmaleimide (NPM) as a dipolarophile, the intermediate thiocarbonyl ylide *(237)* is trapped and is converted into the cycloadduct *(238)*. X-Ray structure analysis has elucidated the configuration *(238)* with *trans*-vicinal H atoms at the new σ-bond that is established during the electrocyclization *(236)*→*(237)*. Since triplet sensitizers have no effect, it was assumed that ring closure starts from the S_1 state of *(236)*. However, recent flash photolysis studies with related unsaturated sulfides suggested an excited triplet state as reactive intermediate[123a].



(236) *(237)* *(238)* *(239)*, 78%

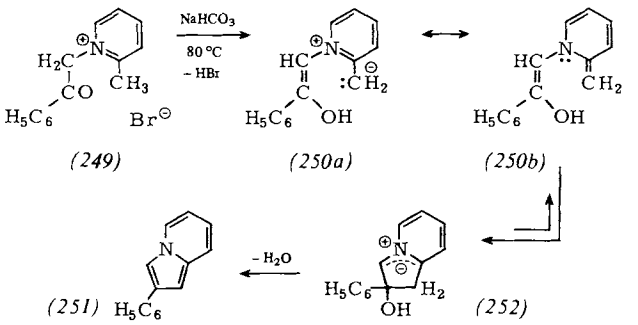


(240) *(241)* *(242)* *(243)*, 75%

Chapman et al.[124] studied the photocyclization of the *N*-cyclohexenylaniline derivative *(240)*, which yielded the tetrahydrocarbazole derivative *(243)*; *trans* linkage of the saturated ring was secured by X-ray structure analysis of a dibromo derivative of *(243)*. Here again the conclusion of conrotatory ring closure to the azomethine ylide *(241)* and a suprafacial 1,4-H shift is probable. An increase in the quantum yield by triplet sensitization was pointed out for another model, *N*-methyl-*N*-(α-phenylvinyl)aniline *(242)*. For direct irradiation a cyclization from the S_1 state seems possible, since triplet quenchers had no effect.

(244) *(245)* *(246)*

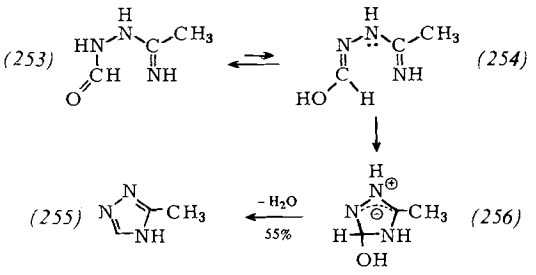
In the flash excitation of *N*-methyldiphenylamine *(244)*, *Grellmann et al.*[125] observed the appearance of an intermediate absorbing at 610 nm, which was ascribed to the azomethine ylide *(245)*. In a degassed cyclohexane solution, *(245)* reverted to *(244)* with a half-conversion time of 11 msec at 25 °C, while in the presence of O_2 *N*-methylcarbazole *(246)* was formed. Quantitative experiments revealed an inhibition of the formation of *(245)* by oxygen; a preceding excited triplet state was assumed.



(247) *(248)*

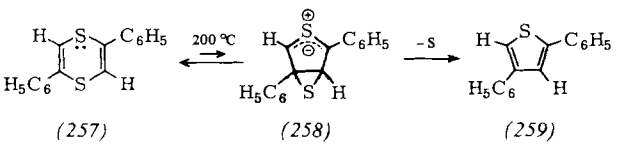
The light-induced cyclization of 2-(*N*-methylanilino)acetoacetic ester *(247)* to the dihydroindole derivative *(248)* is quantitative. The addition of some acetic acid to the medium caused the dehydration of *(248)* to 1,3-dimethylindole-2-carboxylic ester[126].

10.2. Thermal Cyclizations of Charge-Free Systems with Subsequent Reactions



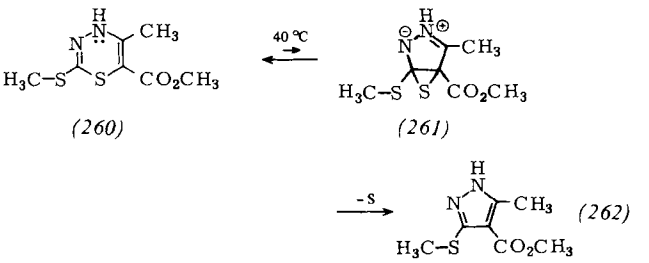
The Chichibabin synthesis of indolizines[127] by the reaction of α-picoline and derivatives with α-haloketones has been studied on hundreds of examples[128]. In the isolable picolinium salts, *e.g.*, *(249)*[127], the acidity of the methyl group is increased to such an extent that even sodium hydrogen carbonate brings about deprotonation.

(249) *(250a)* *(250b)* *(251)* *(252)*



In addition to the zwitterionic structure *(250a)*, the enol can be described by the charge-free formula *(250b)*. Electrocyclization leads to the azomethine ylide *(252)*, which achieves aromaticity by elimination of water to give 2-phenylindolizine *(251)*.

As long ago as 1933, noteworthy studies by *Kröhnke*[129] emphasized the similarity of *N*-acylalkylpyridinium salts to β-diketones and make the occurrence of the enolic form *(250)* plausible. Without mechanistic studies one cannot exclude an alternative in which the ketone form reacts in an aldol type condensation[130].

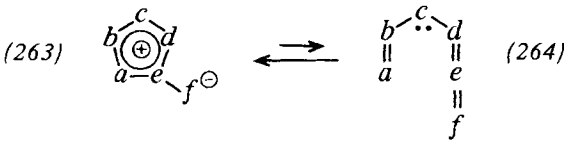


(253) *(254)* *(255)* *(256)*

Does the cyclization of the N^1-formylacetamidrazone *(253)* at 100 °C with the formation of 3-methyl-1,2,4-triazole *(255)*[131] take place *via* the iminol form *(254)*? The azomethine imine *(256)* would be aromatized by dehydration. However, a carbonyl addition starting from *(253)* offers a conceivable course without electrocyclization.

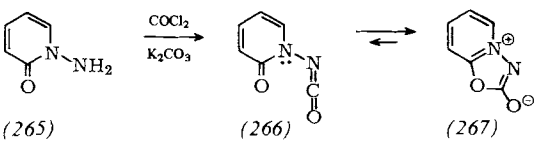
(257) *(258)* *(259)*

In 1954, *Parham* and *Traynelis*[132] observed the thermal loss of sulfur from 2,6-diphenyl-1,4-dithiin *(257)* giving rise to 2,4-diphenylthiophene *(259)* in 69% yield. An intraannular electrocyclization of the divinyl sulfide system present in *(257)* is an attractive pathway for the ring contraction; the thiocarbonyl ylide *(258)*, initially formed in small equilibrium concentration, gains aromaticity by elimination of sulfur; *cf. (74)→(73)* in Section 6. The corresponding ring contraction of 1,4-dithiin-2,3,5,6-tetracarbonitrile proceeds smoothly giving 98% of thiophenetetracarbonitrile[133]. The intermediate thiocarbonyl ylide, analogous to *(258)*, is here stabilized by two cyano residues.



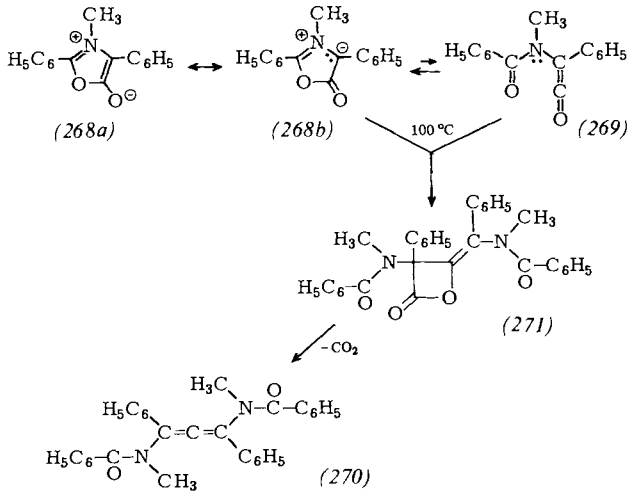
(260) *(261)* *(262)*

An N-function as an onium center should stabilize the cyclic 1,3-dipole more effectively than sulfur, since an iminium ion is better than a sulfonium ion. Several ring contractions of 1,2,4-thiadiazines are known, all based on the capacity of thiirane sulfur to undergo cheletropic elimination. According to *Beyer et al.*[134], even during recrystallization from organic media, the red *(260)* loses sulfur with the formation of the yellow pyrazole *(262)*. The bicyclic azomethine imine *(261)* is a reasonable intermediate.

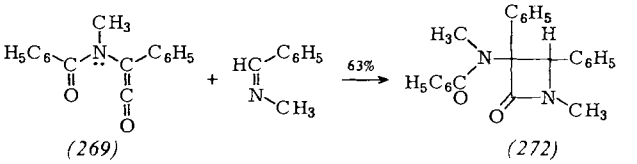


10.3. Formation and Ring Openings of Mesoionic Aromatics

For mesoionic compounds *(263)* of the so-called type A, *Ollis* and *Ramsden*[135] postulated a valence tautomerism with open-chain cumulated systems *(264)*, which contain a pentadienyl anion with isoelectronic replacement in position 3. The energy preference of the mesoionic heterocycle is so great that the spectroscopic detection of *(264)* in the thermal equilibrium with *(263)* has not yet been achieved.

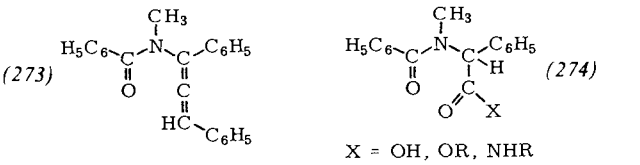


(263) *(264)*



In the first synthesis of an isosydnone, the bicyclic *(267)*, *Hoegerle*[136] treated *(265)* with phosgene and potassium carbonate in chloroform. The isocyanate *(266)* is a likely, though hypothetical intermediate. Analogous acylamino iso*thio*cyanates have been suggested by *Grashey et al.*[137] as intermediates for the formation of 1,3,4-oxadiazolium-2-thiolates from carboxylic acid hydrazides and thiophosgene.

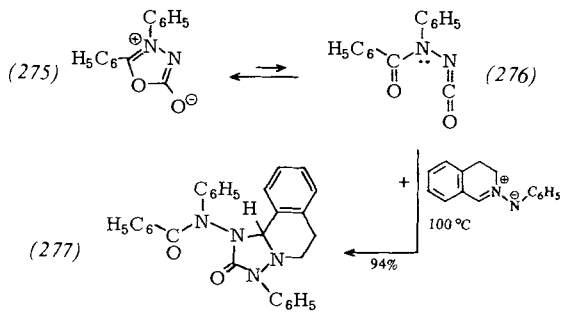
(265) *(266)* *(267)*



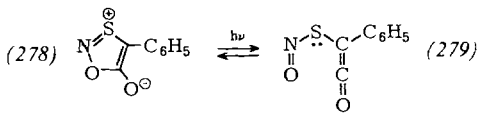
The mesoionic oxazolium-5-olate *(268)* reveals a cyclic azomethine ylide in the resonance structure *(268b)*. Thermolysis at 100 °C afforded the allene derivative *(270)* in 83% yield[138]. It is known that ketene dimers of the β-lactone type produce allenes on heating. More likely than the dimerization of the conjectured open-chain valence tautomer, the benzamidoketene *(269)*, is a combination of *(269)* with *(268)* to form the β-lactone *(271)*, which then loses CO_2. The ketene *(269)* must occur in such low concentrations that the IR absorption of the cumulated system did not become visible.

Further evidence for the intermediacy of the ketene tautomer *(269)* comes from the reaction of the "münchnone" *(268)*—the nomenclature recalls that of "sydnone"—with *N*-benzylidenemethylamine at 80 °C, which furnishes the β-lactam *(272)* in 63% yield[139]. The synthesis of β-lactams from ketenes and azomethines was discovered 70 years ago by *Staudinger*. Carbodiimides, enamines[139], and 3-dimethylamino-2*H*-azirines[140] intercept the ketene tautomer *(269)* in the same way as azomethines.

In contrast to the examples discussed in Section 10.2, the cyclic 1,3-dipole *(268)* is thermodynamically preferred to the open-chain species *(269)*. This can be ascribed to the aromaticity of the mesoionic ring *(268)* with its effective charge delocalization.



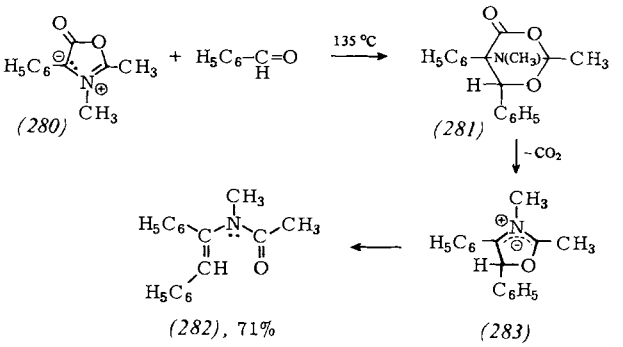
The formation of the allene *(273)* from the münchnone *(268)* with benzylidenetriphenylphosphorane likewise requires the valence-tautomeric ketene *(269)* as a reaction partner[141]. The conversion recalls one of the first carbonyl olefinations, the preparation of tetraphenylallene from diphenylketene and diphenylmethylene(triphenyl)phosphorane by *Staudinger* and *Lüscher*[142].



X = OH, OR, NHR

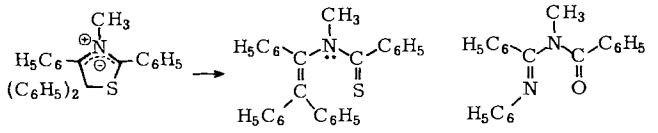
The yellow mesoionic compound *(268)* loses its color in methanol through the formation of *(274)*, X = OCH_3. Alcoholysis, hydrolysis, and ammonolysis find a simple explanation in the occurrence of the ketene form *(269)*[138].

Grashey and *Jänchen*[143] conjectured the isocyanate tautomer *(276)* to be in thermal equilibrium with diphenyl-1,3,4-oxadiazolium-2-olate *(275)* (isosydnone); the reaction with 3,4-dihydroisoquinoline gave rise to the adduct *(277)*,



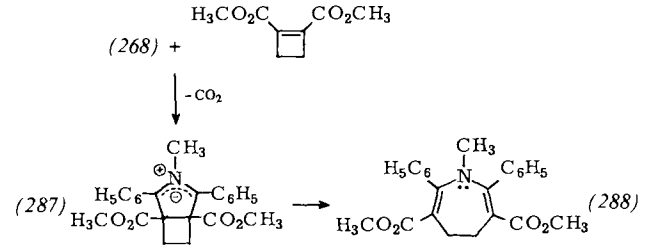
suggesting a 1,3-dipolar cycloaddition to *(276)*. The direction of the addition to *(276)* simulates that for the addition of the same 1,3-dipole to phenyl isocyanate.

The photolysis of the 1,3,2-oxathiazolium-5-olate *(278)* in a solid nitrogen matrix at 10 K[144] provides the only direct evidence for the open-chain cumulated system. The IR absorption at 2120 cm^{-1} was assigned to the ketene *(279)*.



10.4. Cyclic 1,3-Dipoles as Intermediates in Cycloreversions

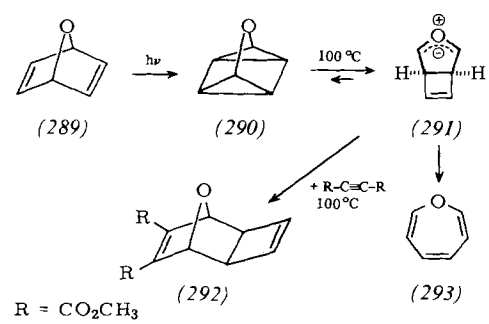
The above-mentioned mesoionic oxazolone *(268)* appears in the resonance formula *(268b)* as a cyclic azomethine ylide. It is indeed amenable to a variety of 1,3-dipolar cycloadditions[145]. The bicyclic primary adducts lose CO_2; *(268)* and acetylenic dipolarophiles yield pyrroles, whereas ethylene derivatives lead to 2-pyrrolines *via* new azomethine ylide intermediates.



A cyclic azomethine ylide *(283)* is also encountered in the reaction of oxazolium-5-olate *(280)* with benzaldehyde. The cycloaddition to the carbonyl group is followed by loss of CO_2 from *(21)* in a 1,3-dipolar cycloreversion. This leaves a new azomethine ylide *(283)* which, in contrast to *(280)*, is no

longer aromatically stabilized; the α-(*N*-acetyl-*N*-methylamino)stilbene *(282)* emerges from an electrocyclic ring opening[146]. Different substituents in positions 2 and 4 in *(280)* disclose the direction of the addition.

(284) *(285)* *(286)*



Thiocarbonyl compounds exceed carbonyl compounds in their dipolarophilic activity. Thiobenzophenone reacts with the münchnone *(268)* even at room temperature and, *via* the new azomethine ylide *(284)*, yields the thioenamide *(285)* quantitatively[147]. Nitrosobenzene also induces CO_2 evolution from *(268)* at 20 °C. A 97% yield of the *N*-benzoylamidine *(286)* was obtained[148]. In the initiating cycloaddition and the concluding electrocyclic ring opening the π- and σ-components of the dipolarophilic double bond become separated. Formulas *(282)*, *(285)*, and *(286)* illustrate this "cutting" of the dipolarophile.

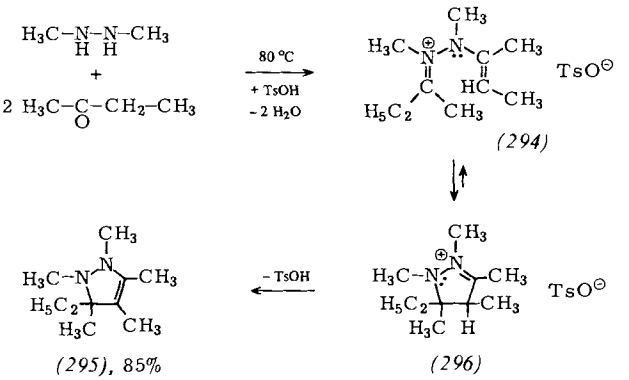
(287) *(288)*

Does this cleavage also take place with olefinic dipolarophiles? Here other stabilizations of the new cyclic azomethine ylide prevail: prototropy to a 2-pyrroline or the cycloaddition to a second molecule of the dipolarophile[149]. However, in the adduct of *(268)* to cyclobutene-1,2-dicarboxylic ester, the cleavage was observed by *Martin et al.*[150]. The strain release of the four-membered ring promotes the intracyclic ring opening of the azomethine ylide *(287)* leading to *(288)*.

A particularly elegant intramolecular variant is provided by the ring opening of the 3-oxaquadricyclane *(290)* studied by *Prinzbach et al.*[151]. The photochemical intramolecular [2+2]-cycloaddition of 7-oxanorbornadiene *(289)* is followed by a 1,3-dipolar cycloreversion resulting in the carbonyl ylide *(291)*. If we accept 101 kcal mol^{-1} as the ring strain of the quadricyclane[152] and estimate the strain remaining in *(291)* to be 38 kcal mol^{-1}, the liberation of a strain energy of

(289) *(290)* *(291)* *(292)* *(293)*

R = CO_2CH_3

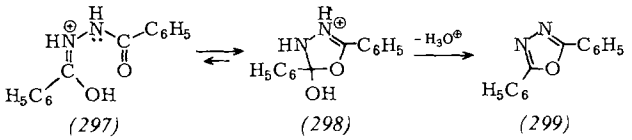


63 kcal mol^{-1} in the process *(290)*→*(291)* makes a reversal unlikely.

The isomerization of *(290)* to the oxepin *(293)* proceeds with a half-conversion time of 25 min at 100 °C[151] and constitutes an intraannular electrocyclic ring opening; *(293)*, in turn, maintains an equilibrium with benzene oxide[153]. The intermediacy of the carbonyl ylide *(291)* can be demonstrated by intercepting the 1,3-dipole with acetylenedicarboxylic ester and formation of *(292)*. The conversion of *(291)* into *(293)* does not involve a conrotatory opening of the cyclobutene ring, but a disrotatory opening of the cyclopentenyl anion type; the cyclobutene double bond does not change its position.

11. Systems with Twofold Isoelectronic Exchange

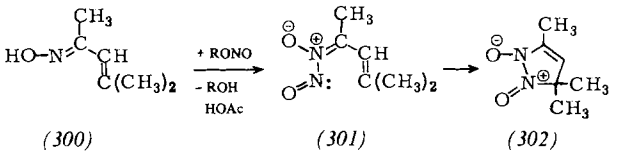
If the carbanionic function in *(1)* or *(2)* is replaced by a charge-free N-function or by an O atom, the resulting pentadienyl or cyclopentenyl systems are described by zwitterionic or charge-free resonance structures. A *second* isoelectronic exchange gives rise to systems which bear a net positive charge. Depending on the position of the exchange, the formulas harbor either a single cationic charge or two positive and one negative formal charge (Section 5.2).



A cyclization in the cation has been discussed above for the acid-catalyzed formation of pyrazolines from α,β-unsaturated hydrazones, *(91)*→*(92)*. An analogous pathway is very likely for the acid-catalyzed condensation of ketones with 1,2-dialkylhydrazines, which has been studied by *Elguero, Jacquier et al.*[154].

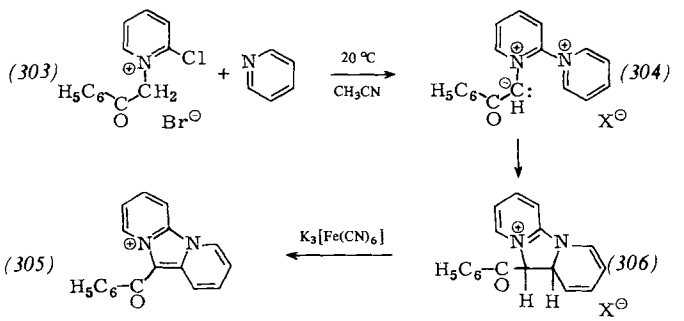
(294) *(295)*, 85% *(296)*

The hydrazinium ion *(294)* is the presumed intermediate from 2-butanone and 1,2-dimethylhydrazine in boiling benzene. The cationic character of *(294)* is retained during cyclization, the onium charge in *(296)* being shifted to the neighboring nitrogen. Deprotonation gives the persubstituted 3-pyrazoline *(295)*. The cation *(294)* is derived from the pentadienyl anion structure *(1b)* by isoelectronic exchange in positions 2 and 3, whereas the cation *(91)* shows the replacements in positions 1 and 2.



In 1899, *Stollé*[155] synthesized 1,3,4-oxadiazoles from *N,N'*-diacylhydrazines by elimination of water with zinc chloride. Later, polyphosphoric acid at 180 °C was recommended for the preparation of compound *(299)* from *N,N'*-dibenzoylhydrazine in a yield of 92%[156]. The initial protonation probably takes place at the oxygen as in the case of carboxamides with the formation of *(297)*; the proton can be replaced appropriately by other electrophilic agents. Cycliza-

(297) (298) (299)

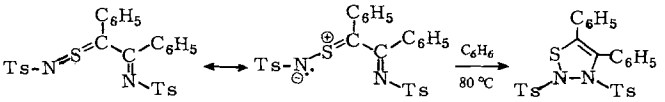


tion to *(299)* is again accompanied by the migration of the positive charge.

A compound obtained by *Harries et al.*[157] from mesityl oxide oxime *(300)* by nitrosation was recognized by *Free-*

(300) (301) (302)

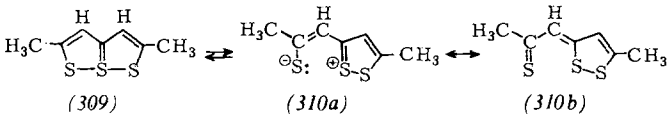
man[158] as trimethyl-5*H*-pyrazole 1,2-dioxide *(302)*. The open-chain precursor, the nitrosonitrone *(301)*, is a pentadienyl anion with double isoelectronic exchange; the onium charge is compensated by the anionic charge of the oxide oxygen on N-2. The reaction can also be regarded as an electrocyclic ring closure of a heterohexatriene (Section 12.5).



(303) (304) (305) (306)

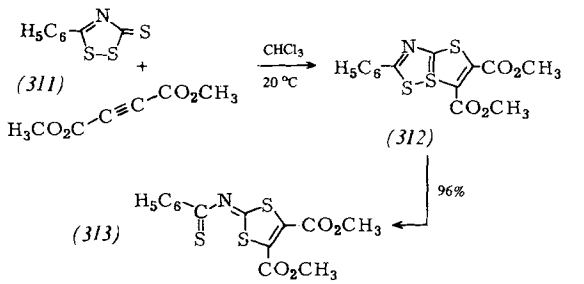
In the case of isoelectronic replacement of CH by NR in positions 2 *and* 4, the negative charge remains in positions 1, 3, and 5. The open-chain species therefore harbors two positive formal charges and a negative one; two of these charges cancel each other on ring closure. *Kröhnke et al.*[159] treated 2-chloro-1-phenacylpyridinium bromide *(303)* with two equivalents of pyridine. Quaternization is succeeded by deprotonation with a second mole of base leading to *(304)*. As a pyridinio-substituted aromatic azomethine ylide, *(304)* corresponds to the charge type mentioned. The cyclic dipyridodihydroimidazolium ion *(306)* was crystallized as perchlorate and dehydrogenated to the aromatic compound *(305)*.

12. Borderline Cases and Borderline Crossing



12.1. Isoelectronic Replacement by Elements of Variable Valence

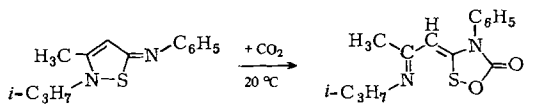
The thione *S*-tosylimide *(307)* resulting from a Wittig reaction can be depicted with tetravalent sulfur without a formal charge—see *(307a)*—or as a sulfonium zwitterion in formula *(307b)*. Viewed from *(307b)*, the ring closure to the Δ^4-1,2,3-thiadiazoline *(308)*[160] appears as the cyclization of an imino-conjugated 1,3-dipole, while in the formulation *(307a)*→*(308)* the transition from tetravalent to divalent sulfur compensates the charge migration in the course of electrocyclization.



(307a) (307b) (308)

A compound obtained by *Arndt et al.*[161] from 2,4,6-heptanetrione and P_4S_{10} was recognized by X-ray structure analysis[162] to be 2,5-dimethyl-6a-thiathiophthene *(309)*. The three sulfur atoms are arranged colinearly with equal distances of 2.40 Å. The terms "no-bond resonance" and "meribicyclo mesomerism" have been used to described a bonding

(309) (310a) (310b)

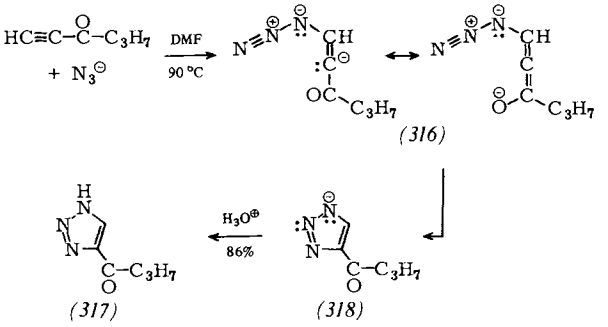


state that is best represented by tetravalent sulfur according to *(309)*. Most reactions of *(309)* find a simple explanation in the assumption of valence tautomerism with the monocyclic 1,2-dithiole structure *(310)*[163]. The ring opening of *(309)* is associated with a change of the valency state of the central sulfur, and the product can be described by a zwitterionic and a charge-free resonance contributor, *(310a)* and *(310b)*.

(311) (312) (313)

Many 1,3-cycloadditions of 1,2-dithiole-3-thiones and related ring systems to dipolarophilic multiple bonds give rise to products whose formation requires a bicyclic intermediate with tetravalent sulfur. *Behringer et al.*[164] treated 5-phenyl-1,2,4-dithiazole-3-thione *(311)* with acetylenedicarboxylic ester and obtained the 2-thiobenzoylimino-1,3-dithiole *(313)*. The ring opening *(312)*→*(313)* is again concurrent with a change in the valence of the sulfur, thus counteracting the effect of charge migration.

An amusing example is offered by 5-imino-3-isothiazoline *(314)* which, according to *Goerdeler et al.*[165], took up carbon

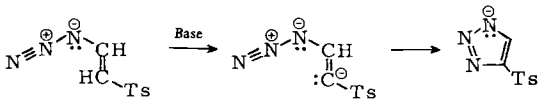


(314) (315), 67%

dioxide under pressure, thus closing a second five-membered ring; electrocyclic opening of the first ring furnished the 1,2,4-oxathiazolidin-5-one *(315)*.

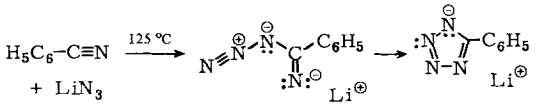
12.2. Additional Anionic Charge in a Conjugated 1,3-Dipole of the Propargyl-Allenyl Type

It has been mentioned in Section 9.5 that thermal electrocyclization of vinyl azides could not be achieved, but the reaction does take place in the deprotonated species.



Nesmeyanov et al.[166] treated 1-hexyn-3-one with sodium azide in dimethylformamide (DMF), *i.e.*, in an aprotic medium, and after acidification isolated 4-butyroyl-1,2,3-triazole *(317)*. The direction of the azide addition is dictated by the stabilization of the anion *(316)* as an allenolate. Phenylacetylene is also capable of forming triazoles with sodium

(316) *(317)* *(318)*

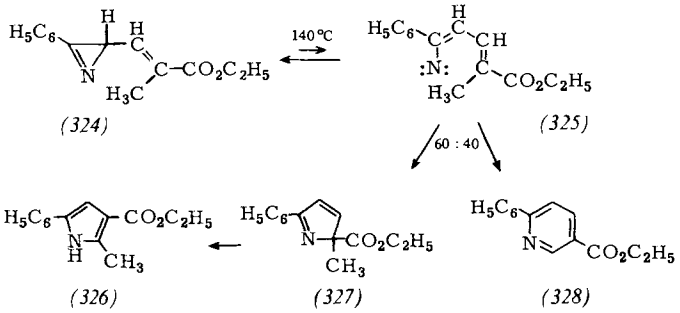


azide if the reaction is run in dimethyl sulfoxide for 160 h at 120 °C[167].

The anion *(316)* constitutes a vinyl azide from which a proton has been removed in position 5; the orbital of the unshared electron pair is located in the σ-plane of the pentadienyl system. This increases the nucleophilicity at C-5 and, furthermore, permits the direct formation of the aromatic triazole anion *(318)* on ring closure. The cyclization *(316)*→*(318)* probably obeys Scheme C of nucleophilic addition described in Section 9.1.

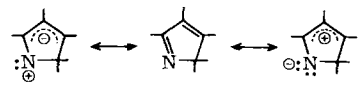
(319) *(320)* *(321)*

1-Azido-2-tosylethylene *(319)* can also be deprotonated with potassium *tert*-butoxide or with sodium toluenesulfinate to *(320)*, again followed by ring closure to the triazole anion *(321)*[168]. The alkaline H,D exchange of *(319)* confirms the acidity of the 5-CH.



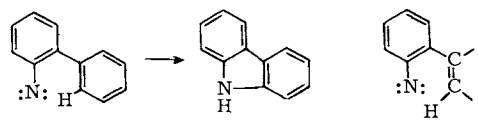
(322) *(323)*

The synthesis of 5-substituted tetrazoles by the 1,3-dipolar cycloaddition of hydrazoic acid to nitriles must often be carried out at elevated temperatures in an autoclave. Faster and less dangerous is the addition of the azide anion to the nitrile group; either ammonium azide in DMF[169] or lithium azide in glycol monoethyl ether at 125 °C[170] are suitable. Finally, the tetrazole is liberated from the salt by mineral acid. The conversion of benzonitrile *via* the anion *(322)* to the 5-phenyltetrazole anion *(323)* serves as an example. The pathway *via (322)* which is analogous to *(316)* and *(320)* deserves preference over a one-step 1,3-cycloaddition in which the reactants combine directly to *(323)*.



12.3. Cyclization of Butadienylnitrenes and Carbenes

The thermal formation of 2*H*-azirines from vinyl azides has been discussed in Section 9.5. These 2*H*-azirines apparently exist at elevated temperatures in equilibrium with vinylnitrenes.

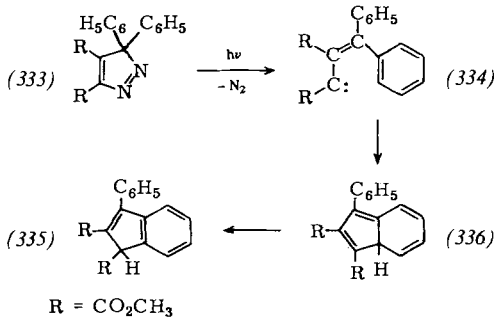


(324) *(325)* *(326)* *(327)* *(328)*

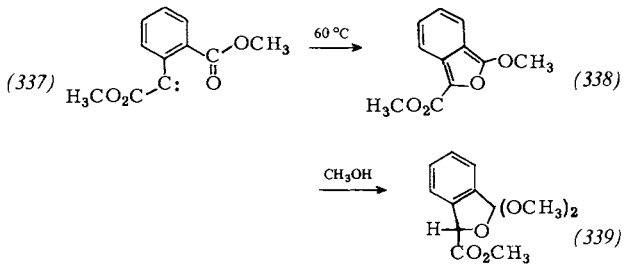
According to *Padwa et al.*[171], the 2*H*-azirine *(324)* rearranges in boiling xylene to the pyrrole derivative *(326)* and to 6-phenylpyridine-3-carboxylic ester *(328)*. The dienic nitrene *(325)* is presumed to be a common intermediate. Insertion into the terminal methyl group with subsequent loss of hydrogen is responsible for the formation of the pyridine derivative *(328)*. A competing process is the electrocyclization to the 2*H*-pyrrole *(327)*, which aromatizes to *(326)* by 1,5-sigmatropic migration of the ester group.

(329a) *(329b)* *(329c)*

The dienylnitrene *(325)* can participate in the electrocyclization as a 6π or a 4π system, depending on whether the nitrogen brings an occupied or an unoccupied orbital into the pentadienyl system. Since the formal cyclization products, *(329a)* or *(329c)*, are both insignificant resonance structures of the α,β-unsaturated imine *(329b)*, the distinction is not meaningful. The close connection with pathway B for the cyclization of vinyldiazomethane (Section 9.1) may be pointed out.



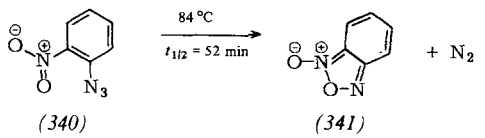
(330) *(331)* *(332)*



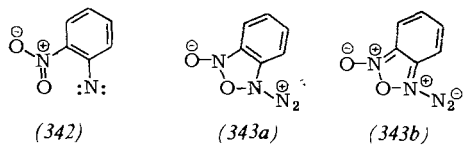
The ring closure of the dienylnitrene *(325)* is the prototype for a large number of cyclizations in which one or both of the ene systems are incorporated into aromatic rings. The synthesis of carbazoles by thermolysis of 2-azidobiphenyl (180 °C) and its derivatives, discovered by *Smith et al.*[172], finds a limit where *o*-substituents of the benzene ring interact with the intermediate nitrenes[173]. The singlet nitrene ap-

pears to be responsible for the ring closure *(330)*→*(331)* in the thermolysis and photolysis of the azide; the photosensitized reaction in fact mainly gives the dimer of *(330)*, 2,2'-azobiphenyl[174]. The deoxidation of 2-nitroso- or 2-nitrobiphenyl with triethyl phosphite also passes through *(330)*, as *Sauer et al.*[175] have established by the agreement of the competition constants in the formation of position-isomeric carbazoles. The synthesis of indoles *via* nitrenes of type *(332)*[176] is also important.

Besides the electrocyclic reaction through a nonaromatic 8a*H*-carbazole, a one-step CH-insertion can be envisaged for *(330)*→*(331)*. The latter is less likely, however. In fact, on thermolysis β,β-dimethyl-*o*-nitrostyrene gives 2,3-dimethylindole[176], which is evidence in favor of an electrocyclic reaction and a 2*H*-indole as an intermediate.

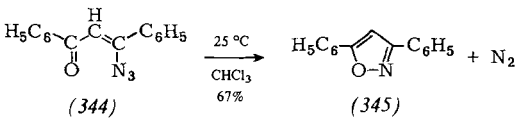


Among the various reaction possibilities, unsaturated carbenes relatively rarely choose pentadienyl cyclization. *Ege*[177] irradiated the 3*H*-pyrazole *(333)* and isolated the indene derivative *(335)* in 65% yield. Should *(334)* avoid the one-step CH insertion in favor of the two-step pathway *via* *(336)*, the analogy with the behavior of dienylnitrenes would be obvious.

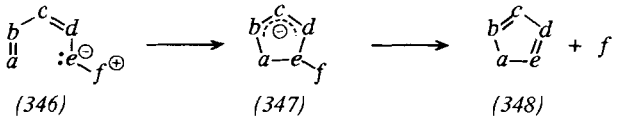


According to *Ibata et al.*[178], the copper-catalyzed decomposition of the corresponding diazo compound goes through the carbene stage *(337)* with pentadienyl cyclization to the benzo[*c*]furan derivative *(338)*. This *o*-quinonoid compound is trapped by the solvent methanol with formation of the cyclic orthobenzoate *(339)* or it may combine with *N*-phenylmaleimide to give the 1,3-cycloadduct.

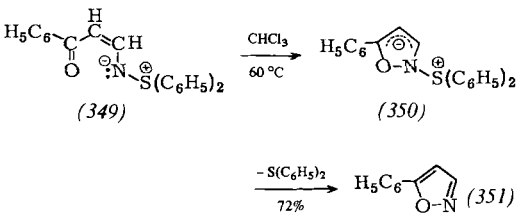
12.4. Coupling of Ring Closure with the Departure of a Group



Not all azide thermolyses pass through the free nitrene. In 1899, *Zincke* and *Schwarz*[179] stated that 2-nitrophenyl azide *(340)* loses nitrogen rapidly at 90 °C with the formation of benzofuroxan *(341)*. The elimination of nitrogen from *(340)* at 84 °C is 7000 times faster than that from phenyl

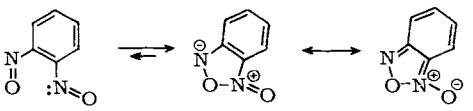


azide[180, 181], although *m*- and *p*-substituents exhibit only a slight influence. This indicates an interaction between the nitro and the azido groups in the rate-determining step and excludes *(342)* as an intermediate.



In addition to a one-step process, in which the leaving of N_2 is concerted with the closure of the O—N bond, a two-step sequence may also be assumed: the nitrophenyl azide *(340)* itself isomerizes by an electrocyclization to *(343)* and subsequently N_2 is eliminated to give *(341)*. Structures *(343a)* and *(343b)* differ only in their electron distribution; consequently, a distinction between electrophilic or nucleophilic attack of the nitro oxygen on the azide system is pointless. For illustration, we prefer *(343b)* since electrophilic agents usually attack the azide group at the inner nitrogen atom.

Olefinic azides behave analogously; the β-azido-enone *(344)* loses nitrogen already at 25 °C and gives 3,5-diphenylisoxazole *(345)*[182].



So far it has been impossible to distinguish experimentally the concerted process *(346)*→*(348)* from that with the intermediate *(347)*. On the other hand, it can be shown that leaving groups other than N_2 can take over the role of *f*.

According to *Tamura et al.*[183], the adduct *(349)* from benzoylacetylene and diphenylsulfilimine cyclizes to 5-phenylisoxazole *(351)* in boiling chloroform with elimination of diphenyl sulfide. The electrocyclization product *(350)* is a conceivable intermediate.

12.5. Cyclizations of Heterohexatrienes

Zincke and *Schwarz*[179] described the product of loss of N_2 from 2-nitrophenyl azide *(340)* as *o*-dinitrosobenzene *(352)*, but neither the lack of color nor the chemical properties of this compound are compatible with that structure. In 1903, *Wieland*[184] proposed the furoxan formula for the monocyclic compound, and this insight was later applied to benzofuroxan *(341)*. The cyclization of *(352)* is reversible, as is taught by the rapid isomerization, detectable with NMR, of substituted benzofuroxans[185, 186].

(352) *(341a)* *(341b)*

o-Dinitrosobenzene *(352)* can be regarded as a pentadienyl anion with an isoelectronic 5-exchange; cyclization affords the zwitterion *(341a)*. On the other hand, the resonance structure *(341b)* allows the formal description as a ring closure of the hetero 1,3,5-triene system in *(352)*. This ambiguity is already inherent in the cyclizations *(301)*→*(302)* and *(349)*→*(350)*.

Similar ring-closure reactions of numerous hetero-substituted 1,3,5-hexatrienes bearing carbon functions in positions 1 and 6 or 2 and 5 are associated with a 90° rotation about one of the terminal bond axes. The well-known electrocyclization of 1,3,5-hexatrienes to cyclohexadienes plays an important part also in the heterocyclic series[187]. The closure of *five*-membered rings constitutes a second electrocyclic reaction type of heterohexatrienes, the significance and scope of which has been recognized by *George et al.* and will be the subject of the following paper[188].

13. Epilogue

There is still a deplorable lack of studies on the kinetics and mechanism of 1,5-electrocyclizations. It is conceivable, if not probable, that not all the reactions compiled in this review are tailored after the same mechanistic model. In our discussion we often had to contend ourselves with speculation instead of undisputed knowledge. It is a matter of definition, to what extent the range of mechanisms can be generalized with the term *electrocyclic*.

In the pentadienyl anion cyclization we are undoubtedly facing an archetype which permits the collective description of a colorful variety of reactions. The classification system introduced is suitable to pigeon-hole hundreds of scattered examples from the literature. Hopefully, the knowledge of such a general reaction principle will stimulate further experimental activity.

The first papers on the rules of conservation of orbital symmetry prompted an almost unparalleled development of theory and practice. Should the concept of electrocyclizations of the pentadienyl anion type prove fruitful in heterocyclic chemistry, it would add to the great scientific harvest associated with the names of *R. B. Woodward* and *R. Hoffmann*.

Thermal and Photochemical Transformations of Hetero-1,3,5-hexatrienes into Five-Membered Rings—Possible Pericyclic Reactions[**]

By Manapurathu V. George, Abijit Mitra, and Kutikat B. Sukumaran[*]

Heterosubstituted 1,3,5-hexatrienes undergo thermal and photochemical cyclizations, most of which can be viewed as pericyclic reactions. Numerous cyclizations of this type have been reported in the literature. This article presents a systematic account of such reactions, classified according to the number and nature of the heteroatoms.

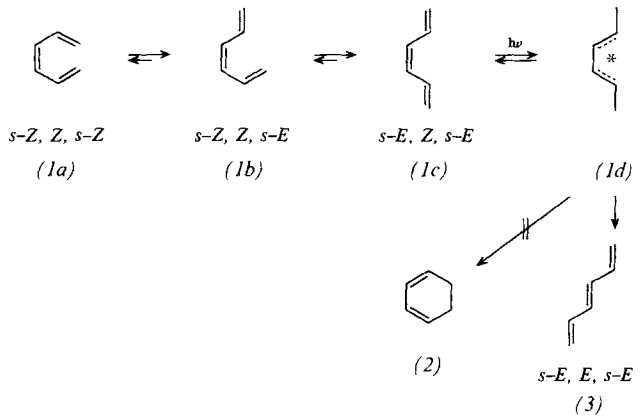
1. Introduction

The thermal and photochemical transformations of 1,3,5-hexatrienes to 1,3-cyclohexadienes and the analogous ring-opening reactions are well-known examples of electrocyclic reactions[1,2]. The principle of the conservation of orbital symmetry requires a disrotatory mode for the thermal ring closure of 1,3,5-hexatrienes, which is classified as a $[_\pi 2_s + _\pi 2_s + _\pi 2_s]$-process; the photocyclization follows the conrotatory mode. Numerous examples of such thermal and photochemical reactions are reported in the literature. A second conceivable mode of transformation of 1,3,5-hexatrienes is the intramolecular thermal cycloaddition to give bicyclo[3.1.0]hexenes, which as a $[_\pi 4_a + _\pi 2_a]$ reaction is also symmetry allowed. For photocyclizations, the Woodward-Hoffmann rules predict two routes for the formation of the same bicyclo[3.1.0]hexene system, namely $[_\pi 4_s + _\pi 2_a]$ or $[_\pi 4_a + _\pi 2_s]$.

Also, 1,3,5-hexatrienes containing heteroatoms such as oxygen, nitrogen, and sulfur, in principle, can undergo thermal electrocyclic reactions to give hetero-1,3,5-cyclohexadienes[3] or the $[_\pi 4 + _\pi 2]$-type to give heterobicyclo[3.1.0]hexenes or products derived there from. It is evident from the literature that, in addition to the above cyclizations, monocyclic five-membered rings can be formed from hetero-1,3,5-hexatrienes; these reactions can also be considered as pericyclic or electrocyclic reactions, respectively. In this review, selected examples of these types of reactions will be discussed particularly in order to stimulate further research and clarify mechanistic details.

2. Cyclizations of 1,3,5-Hexatriene and Hetero-1,3,5-hexatrienes

2.1. All-Carbon Systems



Generally 1,3,5-hexatrienes containing no heteroatoms undergo thermal electrocyclizations leading to 1,3-cyclohexadienes, and these reactions do not depend significantly on the preferred conformations of the 1,3,5-trienes. Thermal $[_\pi 4_a + _\pi 2_a]$-reactions leading to bicyclo[3.1.0]hexenes are rare.

In contrast, the photoreactions of 1,3,5-hexatrienes show a strong dependence on the conformational preferences of the

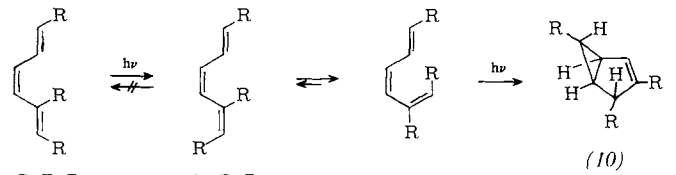
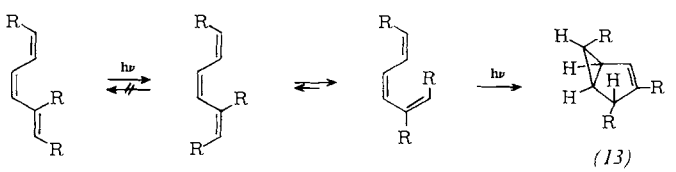
starting trienes. *Havinga* and co-workers[4,5] have shown that the product composition resulting from the irradiation of 1,3,5-hexatriene systems reflect both qualitatively and quantitatively the composition of the ground state conformational equilibrium. Thus it has been shown that the unsubstituted (*Z*)-1,3,5-hexatriene, which predominantly exists in the stretched *s-E,Z,s-E* form *(1c)*, does not give rise to any 1,3-cyclohexadiene *(2)*. The excited state relaxes back either to the (*Z*)-triene *(1)* or to the (*E*)-isomer *(3)*.



(4) s-Z, Z, s-Z *(5)*



(6) s-Z, Z, s-E *(7)*

In contrast, (*Z*)-2,5-dimethyl-1,3,5-hexatriene *(4)*, which exists predominantly in the *s-Z,Z,s-Z* form, cyclizes to *(5)* with a fair quantum yield. (*Z*)-2-Methyl-1,3,5-hexatriene, which exists predominantly in the *s-Z,Z,s-E* form, is transformed upon irradiation into 3-methylbicyclo[3.1.0]hex-2-ene *(7)*, along with other products.

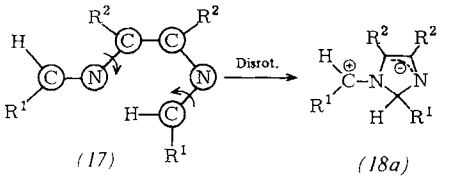
R = C_6H_5

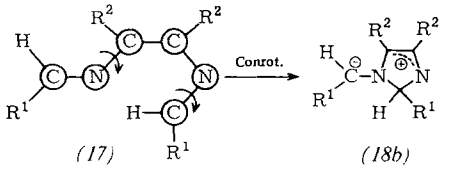
These photorearrangements are known to occur through the $\pi \rightarrow \pi^*$-singlet excited states, and a high stereospecificity is associated with these reactions. *Padwa et al.*[6] have shown that the formation of the bicyclo[3.1.0]hexene proceeds through the $[{}_\pi 4_s + {}_\pi 2_a]$-scheme. For example, the irradiation of (1*Z*,3*Z*,5*E*)-1,2,6-triphenyl-1,3,5-hexatriene *(8)* gives 4-*exo*,6-*exo*,3,4,6-triphenylbicyclo[3.1.0]hex-2-ene *(10)* as the major product, whereas the *Z,Z,Z*-isomer *(11)* under similar conditions gives preferentially the 4-*exo*,6-*endo*-bicyclo derivative *(13)*. It has been suggested that the trienes *(8)* and *(11)* undergo initial *cis,trans*-isomerization to give *(9)* and *(12)*. The thermodynamically favored conformers then photocyclize to *(10)* and *(13)*.

(14) *(15)* *(16)*

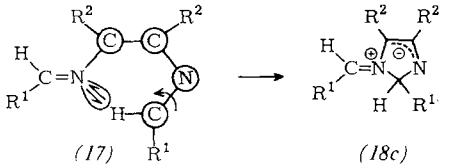
Dauben et al.[7,8] have also shown that the photorearrangement of conjugated trienes occurs from the *s-Z,Z,s-E* forms. These authors postulate a relaxation of the electronically excited state of *(14)* to the vibrationally excited zwitterion *(15)*, further reaction of which should occur from a conformation in which the central bond of the bisallyl system is twisted through 90°. An electrocyclization of the allyl anion moiety with subsequent ion recombination is considered responsible for the formation of the bicyclo[3.1.0]hexene *(16)*. Quantum chemical calculations by *Salem et al.*[9–12] support the view that zwitterionic intermediates are involved in these photoreactions.



Recent studies by *Courtot et al.*[13], however, have demonstrated the occurrence of cycloadditions of the $[{}_\pi 4_a + {}_\pi 2_a]$-type; these reactions might involve vibrationally excited ground states.

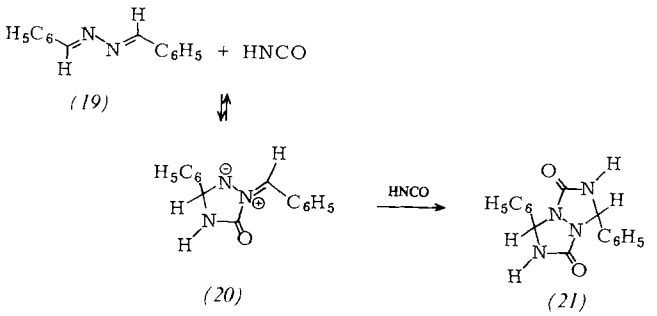


2.2. Heterosystems

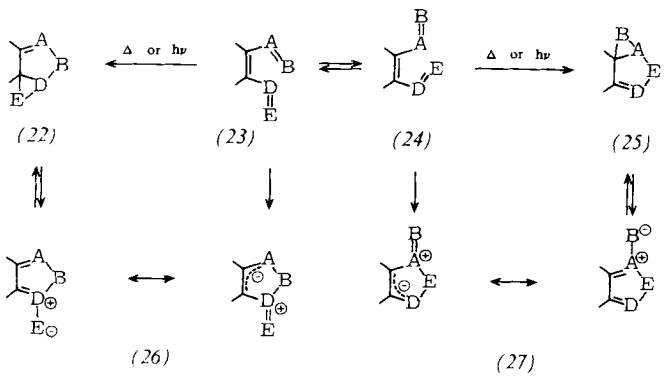


Cyclizations of hetero-1,3,5-hexatrienes to five-membered rings would also appear to proceed from the *s-Z,Z,s-E* form. The electron count for the one-step cyclization of hetero-1,3,5-hexatrienes allows several possible descriptions, which using the arbitrarily selected example *(17)*, are illustrated below.

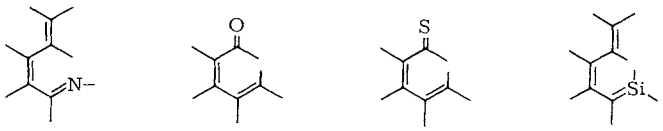
1) The formation of *(18a)* can be considered as a pentadienyl anion cyclization[14], which involves two 90° twists with disrotation.
2) In the case of a conrotatory cyclization of the pentadienyl cation type, 4π-electrons are involved in the electrocyclization, while the π-electrons of the CN double bond remain on the terminal C-atom of *(18b)*.
3) An intramolecular nucleophilic addition of the nitrogen lone pair to the heterodiene system involves only *one* 90°-twist, with the formation of *(18c)*.



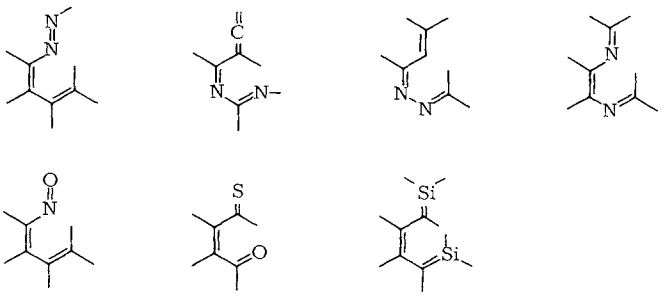
The electron count leads to three different resonance structures of the same species *(18)*. It is very difficult, if not impossible, to distinguish between these three reaction paths.



The same type of mechanistic problems and ambiguity were observed by *Huisgen*[14] for the electrocyclization of conjugated 1,3-dipoles of the propargyl-allenyl type.

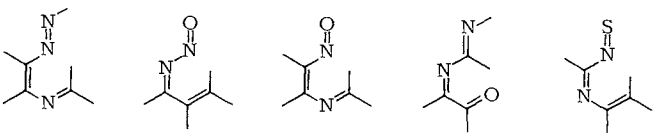


The close analogy to the first step of the "criss-cross addition" of unsaturated systems to azines[15] is also emphasized. For example, the formation of the bisadduct *(21)*[15a], is preceded by formation of a zwitterionic monoadduct from benzylideneazine *(19)* and cyanic acid; *(20)*, as an azomethine imine accepts a second molecule of HNCO in a 1,3-dipolar cycloaddition[16]. The diazadiene system in *(19)* reacts formally as an allyl anion.

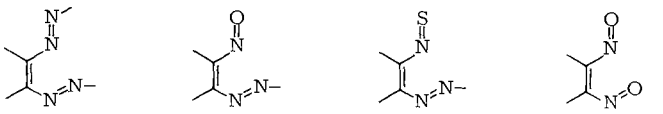


A further conceivable mode of cyclization for the hetero-1,3,5-hexatrienes *(23)* and *(24)* is the thermal $[_\pi 4_a + _\pi 2_a]$-cycloaddition, for which, however, no examples are known. At best, the heterobicyclo[3.1.0]hexenes *(22)* and *(25)* can be postulated as intermediates on the pathway to *(26)* and *(27)*; undoubtedly, there is a greater likelihood of the direct cyclization *(23)*→*(26)* and *(24)*→*(27)*. In contrast, the allowed photoadditions *(23)*→*(22)* and *(24)*→*(25)* of the type $[_\pi 4_s + _\pi 2_a]$ or $[_\pi 4_a + _\pi 2_s]$ are well documented.

Depending on the nature of the substrate and the type of heteroatoms, a variety of products can be formed from these reactions. Although the mechanistic similarities of the examples cited below are by no means certain, we prefer to base our description on the pericyclic reaction scheme. The skeletons of the hetero-1,3,5-hexatrienes discussed here are listed in Scheme 1.



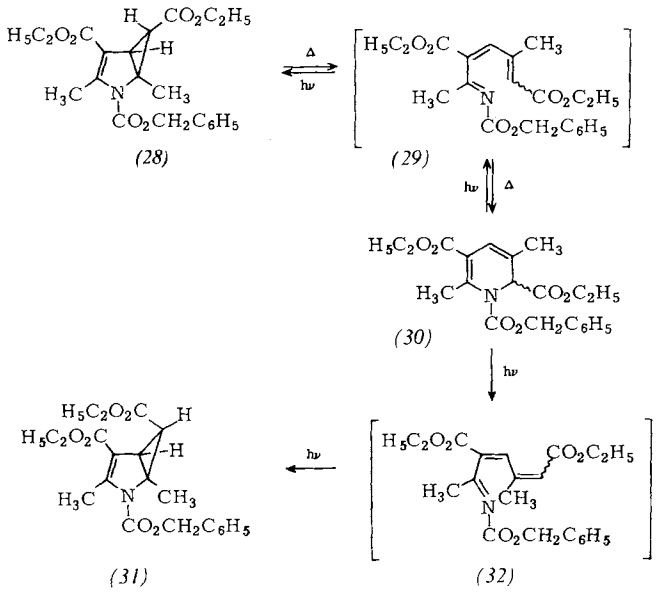
Systems with one heteroatom



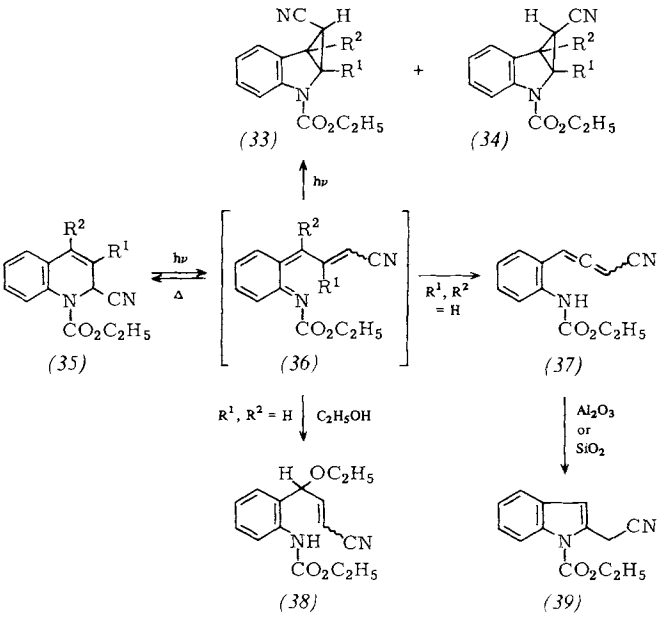
Systems with two heteroatoms

Systems with three heteroatoms

Systems with four heteroatoms



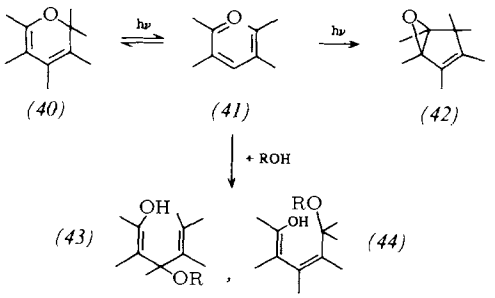
Scheme 1



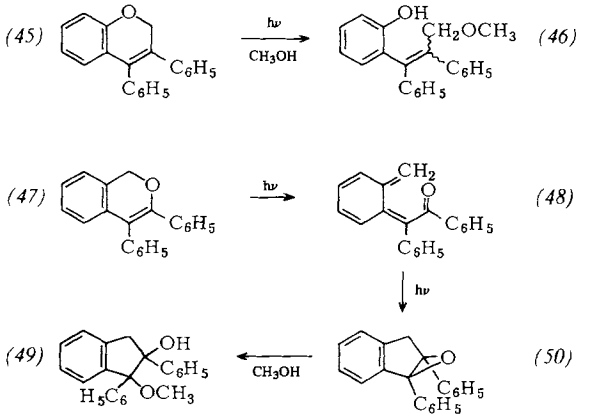
3. Triene Systems with One Heteroatom

3.1. One Nitrogen Atom

Biellmann and *Goeldner*[17] have shown that thermolysis of the homopyrrole *(28)* gives a nearly quantitative yield of the 1,2-dihydropyridine derivative *(30)*. Subsequent photolysis gives a mixture of the homopyrroles *(28)* and *(31)*. It has been suggested that the thermolysis of *(28)* initially involves a cycloreversion to the 1-azahexatriene derivative *(29)*,



which then undergoes a disrotatory electrocyclization. The formation of the homopyrrole on irradiation of *(30)* can be rationalized in terms of a sequence of two photoreactions. The conrotatory ring opening of *(30)*—clearly the steric course cannot be ascertained—is followed by a photocycloaddition of the types $[{}_{\pi}4_{s}+{}_{\pi}2_{a}]$ and $[{}_{\pi}4_{a}+{}_{\pi}2_{s}]$.

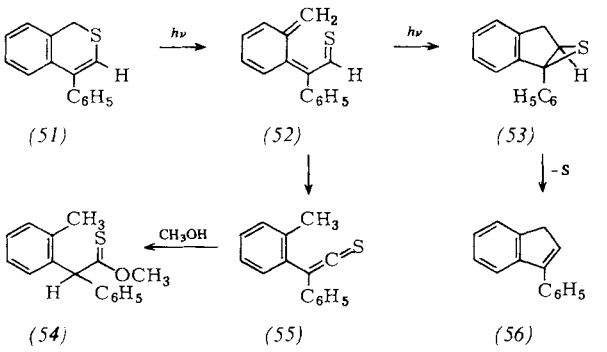


Ikeda et al.[18] have shown that the photolysis of the 2-cyano-1,2-dihydroquinoline-1-carboxylate *(35)*, $R^1=R^2=H$, in ethanol leads to a mixture of the allene *(37)* and the ethanol adduct *(38)*. The allene *(37)* as such could not be isolated, but rearranged to the 2-cyanomethylindole-1-carboxylate *(39)* on chromatography. The rearrangement of the energetically disfavored *o*-quinonoid system of *(36)* to the benzene derivative is responsible for both allene formation and alcohol addition. For certain 4-substituted or 3,4-disubstituted derivatives of *(35)*, *Ikeda* and co-workers[19] observed the photochemical transformation to the cyclopropa[*b*]indoles *(33)* and *(34)*; here also, the *o*-quinonoid 1,3,5-hexatrienes of type *(36)* would be involved as intermediates[20].

3.2. One Oxygen Atom

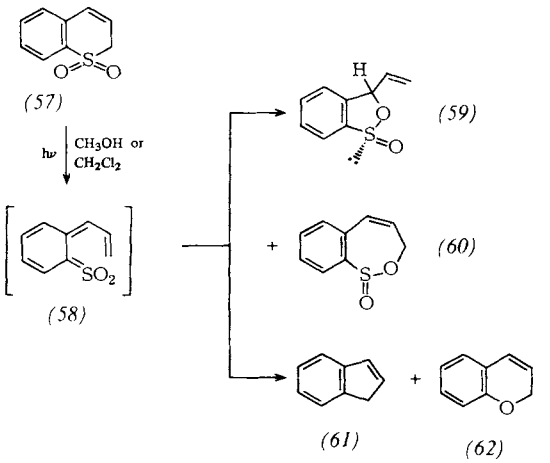
In a detailed investigation, *Padwa* and co-workers[21-25] have studied the phototransformations of chromenes, isochromenes, and chromanones. The 2*H*-pyran moiety *(40)* first undergoes an electrocyclic ring opening to the dienone

(41), which in certain cases cyclizes to the 6-oxabicyclo[3.1.0]hexene *(42)*. Additionally, solvent adducts of types *(43)* and *(44)* are formed.



As a specific example, the photolysis of the 2*H*-chromene *(45)* in methanol is chosen which affords, *via* the pathway mentioned earlier, *i.e.* through the dienone, the methanol adduct *(46)*[24]. In contrast, the irradiation of the isochromene *(47)* yields the indene oxide *(50)* and its methanol adduct *(49)*. The *o*-quinonoid dienone *(48)* is the logical intermediate. The independently demonstrated photolysis of the epoxide *(50)*→*(49)* in methanol makes the proposed reaction pathway plausible.

The ring-opening reactions of monocyclic 2*H*-pyrans *(40)* have been examined by different workers[26-28]. According to *Gosnik*, substituents exert an appreciable effect on the equilibrium *(40)*⇌*(41)*[27,28].

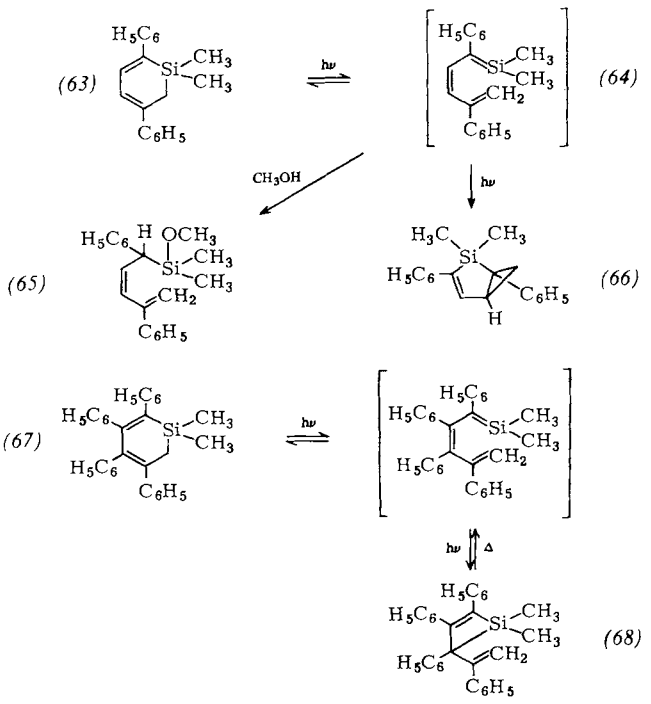


3.3. One Sulfur Atom

The photolysis of 4-phenylisothiochromene *(51)* in methanol, for example, which has also been studied by *Padwa et al.*[24], yields 3-phenylindene *(56)* and methyl α-phenyl-α-*o*-

(51) (52) (53) (54) (55) (56)

tolylthionoacetate *(54)*. The photo-ring opening to *(52)* and the subsequent photocyclization to *(53)* occur as described in the oxygen series; however, the thiirane *(53)* undergoes loss of sulfur. The heterohexatriene *(52)* can also undergo 1,5-H-shift to the thioketene *(55)*, which in turn immediately reacts with methanol to form the ester *(54)*.

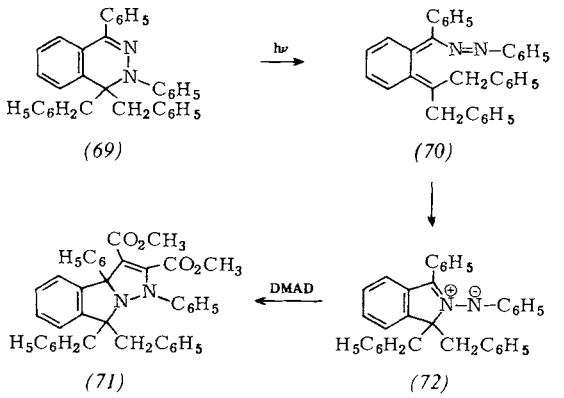


(57) (58) (59) (60) (61) (62)

According to *Hall* and *Smith*[29], the cyclic sulfone *(57)* can surprisingly also undergo electrocyclic photolysis to give the sulfene *(58)*. In any case, the formation of *(58)* enables one to explain the formation of the *cis*- and *trans*-sultines *(59)*, through an electrocyclization of the pentadienyl anion type, whereas the formation of the seven-membered sultine *(60)* is based on the heptatrienyl anion mode of cyclization. These processes profit from the restoration of benzenoid character, starting from the *o*-quinonoid *(58)*. The photochemical cleavage of SO_2 from *(58)* could lead to a carbenoid intermediate, whose 4π-electron system cyclizes to the indene *(61)*. The formation of the 2*H*-chromene *(62)* is based on formal loss of SO and is more difficult to explain.

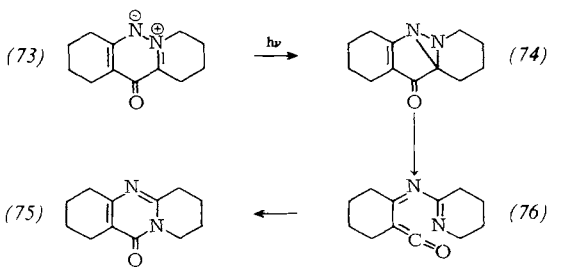
3.4. One Silicon Atom

It speaks for the generality of the electrocyclic reactions that both the photo-ring opening of the 1-sila-2,4-cyclohexadiene *(63)* and also the subsequent photocycloaddition with the formation of *(66)*, occur in a similar fashion, as shown by *Sakurai et al.*[30]. The intermediacy of the heterohexatriene *(64)* is demonstrated through the isolation of the methanol adduct *(65)*, which is obtained on photolysis in methanol/benzene, along with the 2-silabicyclo[3.1.0]hexene *(66)*. The photolysis of the tetraphenyl derivative *(67)* is an interesting silabutadiene cyclization to give *(68)*. The thermal reversion *(68)*→*(67)* profits from the loss of the silacyclobutene ring strain.



(63) (64) (65) (66) (67) (68)

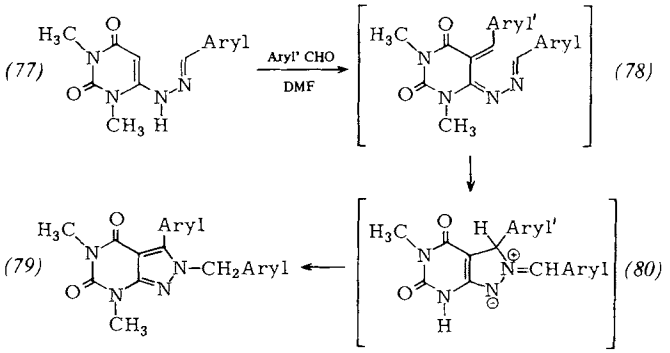
4. Trienes with Two Heteroatoms



4.1. Two Nitrogen Atoms

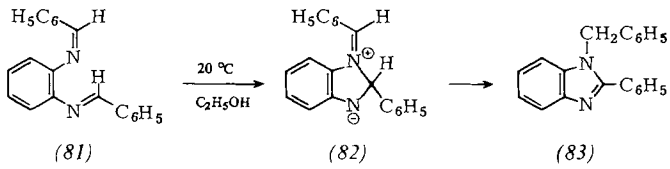
4.1.1. 1,2-, 1,3-, and 2,3-Diaza-1,3,5-hexatrienes

(69) (70) (71) (72)



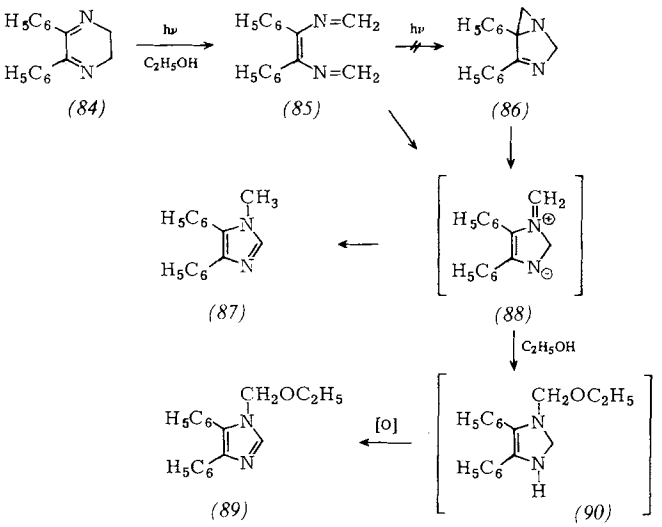
It has been observed by *Singh*[31] that 1,1-dibenzyl-2,4-diphenyl-1,2-dihydrophthalazine *(69)* photolyzes to the stable azomethine imine *(72)*, wherein the ring closure of the 1,2-

(73) (74) (75) (76)



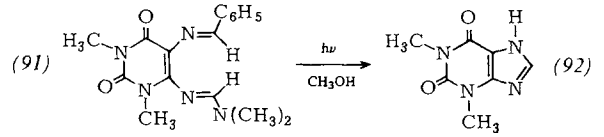
diazahexatriene *(70)* could well be a subsequent thermal reaction. The 1,3-dipole *(72)* reacts with suitable dipolarophiles; for example, with dimethyl acetylenedicarboxylate (DMA) the adduct *(71)* is formed.

Ning et al.[32] have reported that the cyclic azomethine imine *(73)* undergoes photoisomerization to the pyridoquinazolinone *(75)*. The electrocyclic ring closure *(73)*→*(74)*, the cycloreversion *(74)*→*(76)*, and the renewed electrocyclization form a plausible explanation, the last reaction probably being a thermal step.



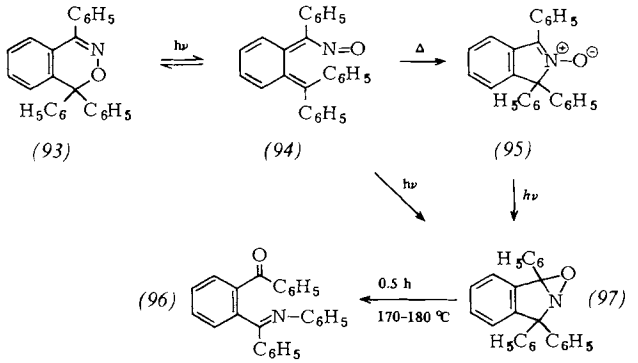
Yoneda et al.[33] have treated 6-(2-arylmethylenehydrazino)-1,3-dimethyluracil *(77)* with aromatic aldehydes in boiling dimethylformamide (DMF), whereby the 3-aryl-2-arylmethyl-5,7-dimethylpyrazolo[3,4-*d*]pyrimidines *(79)* are formed. One might suspect that the aldehyde reacts with the nucleophilic 5-position of the uracil derivatives and that the 2,3-diazahexatriene derivative *(78)* undergoes an electrocyclization to the azomethine imine *(80)*; *(80)* then tautomerizes to the aromatic pyrazole derivative *(79)*.

4.1.2. 2,5-Diaza-1,3,5-hexatrienes



A possible route to this system is provided by the reaction of *o*-phenylenediamines with aldehydes, which were investigated as early as 1877 by *Ladenburg* and co-workers[34]. In later studies by *Hinsberg*[35] and *O. Fischer*[36], the products were recognized as benzimidazoles which are formed through bis(azomethine) intermediates. For example, the reaction of *o*-phenylenediamine with benzaldehyde at −20 °C yields the bis(benzylidene) derivative *(81)*, which at room temperature undergoes cyclization to 1-benzyl-2-phenylbenzimidazole *via (82)*.

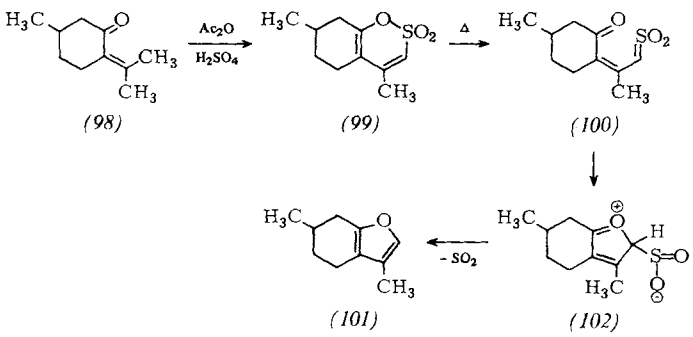
Open-chain 2,5-diazahexatrienes have been postulated as intermediates in the phototransformations of 2,3-dihydropyrazines[37,38]. *Beak* and *Miesel*[37] obtained a mixture of the 1-methyl- and 1-ethoxymethyl-5,6-diphenylimidazole *(87)* and *(89)* by the irradiation of the 5,6-diphenyl derivative *(84)* in ethanol. The ring opening to the bis(azomethine) *(85)* and its cyclization to the zwitterion *(88)* constitute a plausible explanation. Subsequent reactions are the tautomerization to *(87)*



and the addition of alcohol, which is followed by autoxidation to *(89)*. The authors did not observe any evidence for the occurrence of the diazabicyclohexene derivative *(86)*.

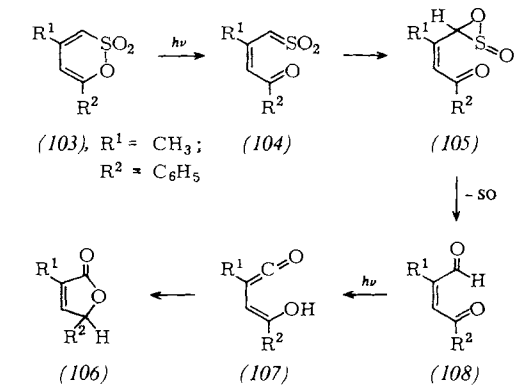
In the 2,5-diazahexatriene *(91)*, the CC-double bond is part of the uracil system. *Yoneda et al.*[39] obtained the theophylline *(92)*, upon irradiation in methanol. The reaction could occur *via* intermediates which correspond to *(88)* and *(90)*, wherein the N-methoxybenzyl and the dimethylamino group are probably removed by hydrolysis during work-up.

4.2. One Nitrogen and One Oxygen Atom



The action of light on 1,1,4-triphenyl-1*H*-2,3-benzoxazine *(93)* leads to the tricyclic oxaziridine *(97)*[40]; the nitroso intermediate *(94)* could undergo direct photocycloaddition or

might first be involved in the ring closure of the nitrone *(95)*, which then forms the oxaziridine *(97)* through a known photochemical reaction. This alternative pathway thus constitutes two electrocyclic steps. Upon heating of *(97)*, the anil of 1,2-dibenzoylbenzene *(96)* is formed, either directly or indirectly *via* the nitrone *(95)*.

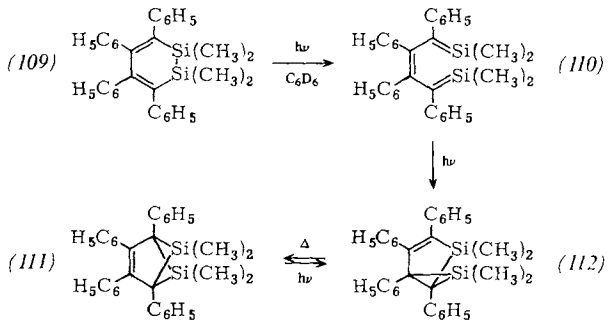


4.3. One Oxygen and One Sulfur Atom

Doubly unsaturated six-membered sultones behave like potential heterohexatrienes with O- and S-functions[41].

(98) *(99)* *(100)* *(101)* *(102)*

Triebs[42] observed a thermal SO_2 cleavage from sultones of type *(99)*—this can be prepared from the enone *(98)* with acetic anhydride and concentrated sulfuric acid—with the formation of the furan *(101)* in our example. The seemingly mysterious transformation finds a ready explanation in the three-step reaction pathway, which consists of electrocyclic ring opening to give *(100)*, closure of the five-membered ring in *(102)*, and an aromatization with loss of SO_2. Subsequent studies have shown that the pyrolysis of sultones constitute a synthetic route to furan derivatives[43].

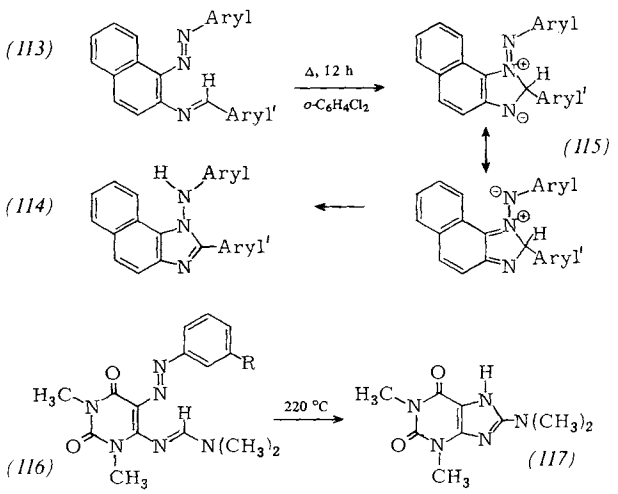


(103), R^1 = CH_3; R^2 = C_6H_5 *(104)* *(105)* *(106)* *(107)* *(108)*

The photolysis of sultones can take a different course with the formation of butenolides. *Gorewit* and *Rosenblum*[44] have shown that the carbon framework remains intact in the transformation of *(103)* into *(106)*. Several subsequent light-induced steps have been proposed: the α,β-unsaturated sulfene *(104)* should produce the diacylalkene *(108)* with SO loss, which in the next step induces a 1,5-H-shift to the enolketene *(107)*. Thermal intramolecular addition completes the process. We feel that a possible pathway for the transformation of *(104)*→*(108)* is through the intermediacy of the three-membered sultine *(105)*, which can readily undergo cheletropic SO elimination.

4.4. Two Silicon Atoms

The photolysis of 1,2-disila-3,5-cyclohexadiene *(109)* has been reported by *Sakurai et al.*[45] to give a quantitative yield of the bicyclohexene derivative *(112)*, presumably formed through the disilahexatriene intermediate *(110)*. Heating



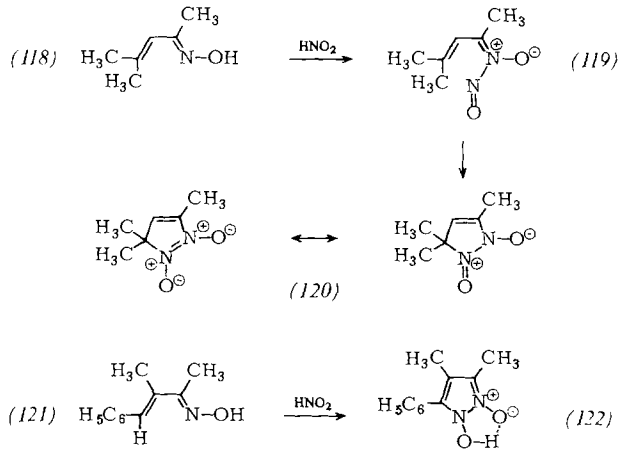
(109) *(110)* *(111)* *(112)*

(112) results in an allyl shift, which leads to the 5,6-disilabicyclo[2.1.1]hexene derivative *(111)*. Interestingly, irradiation of *(111)* causes the reverse isomerization to *(112)*.

5. Triene Systems with Three Heteroatoms

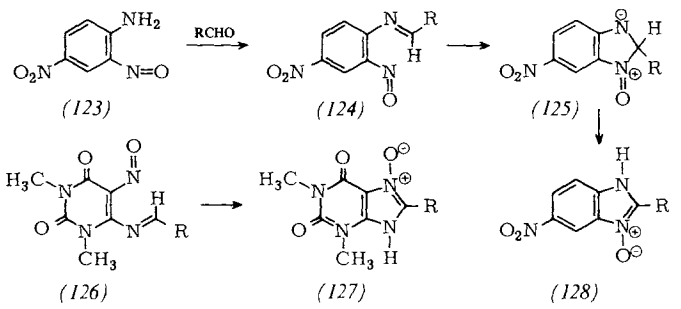
5.1. Three Nitrogen Atoms

On heating 1-arylazo-2-naphthylamines with aromatic aldehydes isomeric products were isolated instead of the azomethines *(113)*; they were identified as N-arylaminonaph-



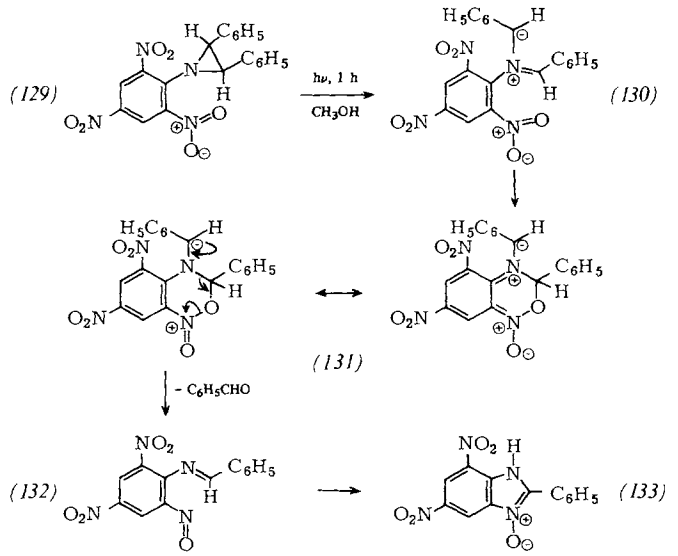
(113) *(114)* *(115)* *(116)* *(117)*

thoimidazoles *(114)* by *O. Fischer et al.*[46]. Under carefully controlled conditions, the heterotrienes *(113)* were isolable[47]; in solvents such as boiling toluene they rearrange smoothly to the imidazoles *(114)*, presumably through the intermediate *(115)*.

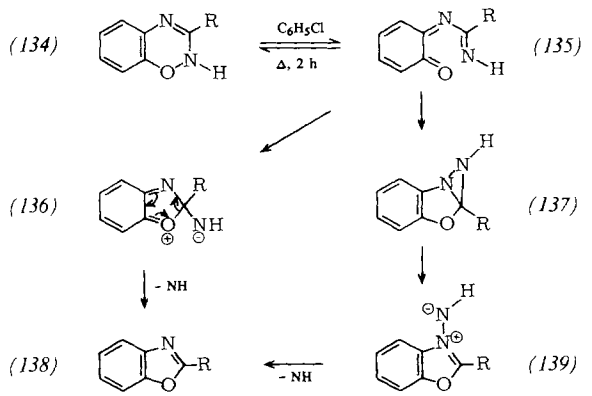


An analogous reaction pathway is presumably applicable to the transformation of 5-arylazo-6-aminouracil with dimethylformamide dimethylacetal, which yields the imidazole *(117)*; the amidine *(116)* reacting in the same way as the azomethine *(113)*; after cyclization, arylamine elimination allows the aromatization to *(117)*[33].

5.2. One Oxygen and Two Nitrogen Atoms

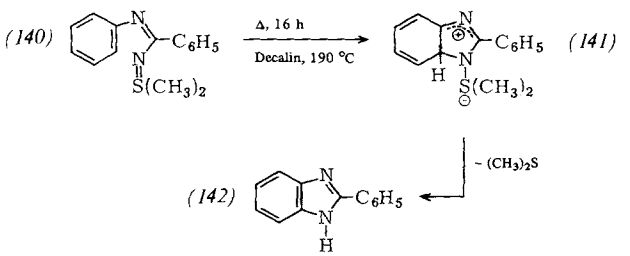


The product obtained from the reaction of mesityl oxide oxime *(118)* and nitrous acid was formulated as "nitrimine"[48] or as *N*-nitrosonitrone[49] *(119)*, until *Freeman*[50] characterized it as 3,3,5-trimethyl-3*H*-pyrazole 1,2-dioxide, which is



represented by two resonance structures in *(120)*. Ring closure of the nitroso compound *(119)* provides a plausible explanation. Treatment of the α,β-unsaturated ketoxime *(121)* with nitrous acid gives the 3*H*-pyrazole analogous to *(120)* which can tautomerize to the 1-hydroxypyrazole 2-oxide *(122)*[51].

On reaction of 4-nitro-2-nitrosoaniline *(123)* with benzaldehyde, the azomethine *(124)* cannot be isolated but cyclizes immediately *via (125)* to the benzimidazole *N*-oxide *(128)*[52]. A similar reaction pathway has also been described in the 6-amino-1,3-dimethyl-5-nitrosouracil series *(126)*, giving xanthine *N*-oxides *(127)*[53].

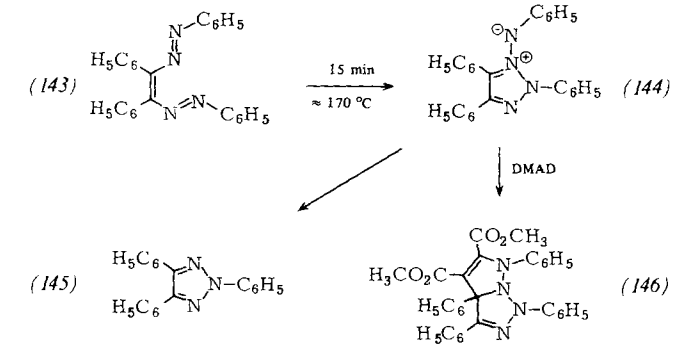


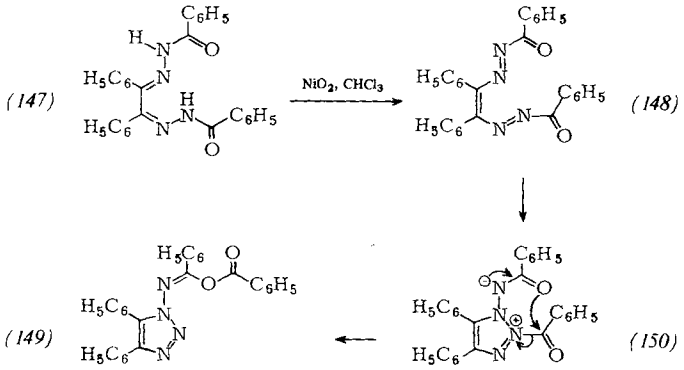
The phototransformations of *N*-*o*-nitrophenylaziridines into benzimidazole *N*-oxides, which have been studied by *Heine et al.*[54], deserve mention in connection with heterohexatrienes. The initial step in the irradiation of *(129)* might involve the well-documented electrocyclic ring opening to the azomethine ylide *(130)*. The electrocyclization to *(131)* is not adversely affected by the two onium centers in the heterohexatrine *(130)*. The subsequent elimination of benzaldehyde can be considered as a retro-Diels-Alder reaction. In the case of the nitrosoazomethine *(132)*, one obtains an intermediate which cyclizes in a manner analogous to *(124)*→*(128)*. It is not clear which steps in the reaction pathway besides the initial step are photochemical processes. The formation of the benzimidazole *N*-oxides from *o*-nitroanilines and aromatic aldehydes[55,56] could possibly occur through analogous pathways.

The transformation of 3-*p*-tolyl-2*H*-1,2,4-benzoxadiazine *(134)* into 2-*p*-tolylbenzoxazole *(138)* occurs in boiling chlorobenzene in 80% yield, as observed by *Rees et al.*[57]. The net loss of NH and the liberation of ammonia suggests the involvement of redox processes. As there are examples for the elimination of NH from azomethine imines, the authors proposed a stepwise reaction pathway, involving first the electrocyclic ring opening to the quinone imine *(135)*, followed by an intramolecular $[{}_{\pi}4_a + {}_{\pi}2_a]$ reaction in forming an NN bond. The diaziridine *(137)* then gives the azomethine imine *(139)*, which loses NH. In the more simple pathway through *(136)* also, the fate of NH is not clear.

5.3. One Sulfur and Two Nitrogen Atoms

The sulfimide *(140)* constitutes a heterohexatriene of this type. In refluxing decalin, *(140)* gives 2-phenylbenzimidazole *(142)* in 9% yield, presumably *via (141)* as intermediate; the major products are 2-phenylquinazoline (19%) and triphe-



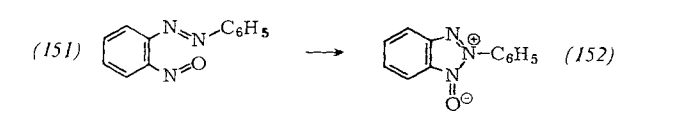


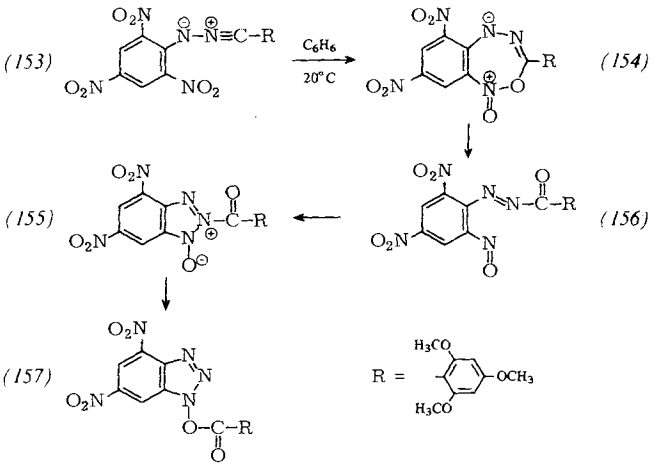
nyl-1,3,5-triazine (65%)[58]. The irradiation of *(140)* gives *(142)* in better yields (30%). *Gilchrist et al.*[58] formulated the reaction *via* a nitrene, which results from N=S cleavage; the pathway *via (141)* offers an alternative.

6. Triene Systems with Four Heteroatoms

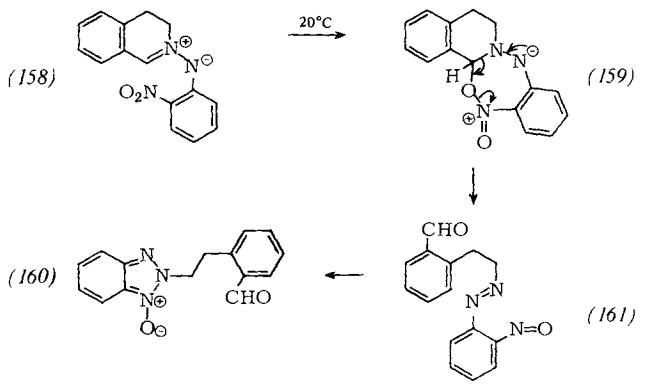
6.1. Four Nitrogen Atoms

1,2-Bis(phenylazo)alkenes are converted into 1,2,3-triazoles on heating or irradiation[59-61]. Thus, the stilbene derivative *(143)* at 170 °C yields 85% of 2,4,5-triphenyl-1,2,3-triazole *(145)*[59]. The intermediacy of the aromatic azomethine imine *(144)* has been demonstrated by trapping with suitable dispolarophiles—*(146)* is a typical cycloadduct[59].



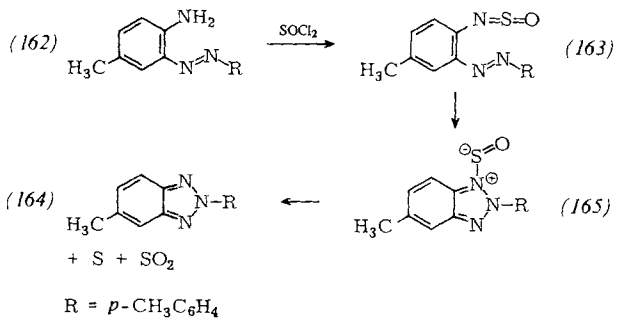


One would expect the bisazo compound *(148)* to be formed on oxidation of benzil bis(benzoylhydrazone) *(147)*. Instead, 26% of the triazole derivative *(149)* was isolated[62]. Here too, one can expect a heterohexatriene cyclization to give *(150)*, followed by an acyl shift with formation of *(149)*. The reactions of other 1,2-diketone bis(benzoylhydrazones) have also been studied[62,63].



6.2. One Oxygen and Three Nitrogen Atoms

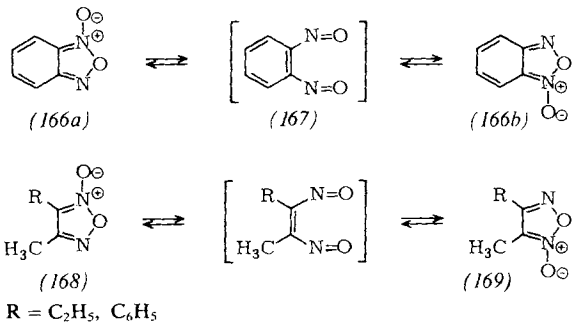
In an attempt to reduce *o*-nitrobenzene with sodium hydrogen sulfide to the *o*-nitroso compound *(151)*, *Bamberger* and *Hübner* obtained 2-phenylbenzotriazole 1-oxide *(152)*[64]. The formation of an aromatic heterocycle could significantly contribute to the driving force for cyclization.



Nitrilimines are unstable 1,3-dipoles which add *in situ* to dipolarophiles. In an attempt to liberate *(153)* from its precursor (hydrazidoyl halide), *Huisgen* and *Weberndörfer*[65] obtained a 71% yield of the 1-hydroxybenzotriazole derivative *(157)*. In the electrocyclic sequence *(153)*→*(154)*→*(156)*, an oxygen atom of the nitro group is transferred to the second side chain. The heterotriene *(156)* closes the five-membered ring according to the scheme observed from *(151)*, followed by the acyl shift *(155)*→*(157)*. The same multistep transformation was observed for *N*-(4-bromo-2-nitrophenyl)-*C*-phenylnitrilimine by *Barnish* and *Gibson*[66].

Azomethine imines of type *(158)* of the 3,4-dihydroisoquinoline series can be intercepted by dipolarophiles, with the formation of cycloadducts. In the absence of dipolarophiles, *(158)* isomerizes to the benzotriazole 1-oxide *(160)* in 80% yield, as reported by *Grashey*[67]. The apparently surprising reaction sequence consists of three electrocyclic steps; in the last step again there is an interaction between nitroso and azo groups.

6.3. One Sulfur and Three Nitrogen Atoms



In the treatment of the amine *(162)* with thionyl chloride *Michaelis* and *Erdmann*[68] isolated the benzotriazole deriva-

tive *(164)*, instead of the usual *N*-sulfinylamine *(163)*—which in this case is formed initially as well. The interaction of the heterocumulene with the azo group could proceed *via (165)*; S and SO_2 were observed as disproportionation products of the liberated SO.

6.4. Two Oxygen and Two Nitrogen Atoms

Substituted benzofuroxans have not been isolated as the expected isomers. The explanation is found in a fast equilibrium—illustrated in *(166a)* and *(166b)* for the unsubstituted species—*via* the heterohexatriene *o*-dinitrosobenzene *(167)*.

The temperature dependence of the NMR spectrum offers the key to the rate constant and activation enthalpy of this process[69,70]. Similar isomerisation equilibria are observed for the unsymmetrically substituted, mononuclear furoxans *(168)* and *(169)*[71].

7. Conclusion

In this brief review an attempt has been made to rationalize several reported reactions in terms of heterohexatriene cyclizations. It is needless to state that this analysis implying mechanistic uniformity is an oversimplication. Many of the described reactions may not proceed in a concerted manner, but may involve biradicals. Further work will be necessary to clarify these details.

The authors thank Professor Rolf Huisgen, Universität München, for carefully reading the manuscript and for numerous suggestions and helpful discussions, as well as for translating the text into German. The help rendered by Dr. S. Lahiri, Dr. V. Bhat, and Mr. Ch. Vijaya Kumar of the Indian Institute of Technology, Kanpur in preparing this manuscript is gratefully acknowledged. The preparation of this article was supported by the Department of Science and Technology, Government of India, Indian Institute of Technology, Kanpur and the Office of Basic Energy Sciences of the U. S. Department of Energy.

Reversible Topotactic Redox Reactions of Solids by Electron/Ion Transfer[**]

By Robert Schöllhorn[*]

Solids having suitable structural and electronic properties are able to form intercalation compounds by reversible redox reactions at room temperature *via* topotactic electron/ion transfer processes. The host lattices range from inorganic solids with different structural dimensionality to organic molecular solids. Similarly, depending on the host lattice type, the guest species may vary from protons and metal ions to large inorganic and organic molecular ions. The possibilities of a systematic "tailoring" of new stable or metastable compounds, the controlled modification of physical properties of solids, and the technical application of electronic/ionic conductors, provide a wide and attractive field for academic and applied research in an interdisciplinary area that involves solid state chemistry and physics, molecular chemistry, electrochemistry, and interface science.

1. Introduction

The formation of intercalation compounds by the uptake or exchange, respectively, of guest molecules, atoms and ions by host lattices having suitable structures is a well-known example for solid state reactions at low temperatures[1]. As concerns the mechanism of reaction, two different cases have to be distinguished: (a) host lattices which are insulators and whose effective lattice matrix charge remains constant in the course of intercalation or exchange reactions *e.g.* zeolites[2], sheet silicates[3], polyphosphates[4]; (b) host lattices with electronic conductivity, whose effective lattice charge may be altered by the intercalation, thus introducing a new dimension into the reaction mechanism. The intercalation is proceeding in this case under synchronous uptake of ions and electrons into the solid [cf. Section 2, eq. (1), Fig. 1]. The rapid development of the chemistry of intercalation compounds within the last ten years is essentially related to the latter mentioned type of reaction. Besides long known solids such as graphite[5], molybdenum sulfide[6] and tungsten trioxide[7], a large number of electronically conducting host lattices are accessible today; with respect to structure and composition their range extends from inorganic solids with framework lattices to organic solids with molecular lattices. A similar variety is found with regard to the (ionic) guest species which, depending upon the nature of the host lattice, include small ions like H^+, main group and transition metal ions, as well as large molecular ions (*e.g.* metal complex ions, heterocyclic ions, dye cations).

From the chemical standpoint the process associated with direct intercalation is to be considered as a reversible topotactic redox reaction by electron/ion transfer[8–11]. This concept enables the consideration of intercalation reactions which are correlated with a change in the electronic state of the host lattice under a common viewpoint, also in cases

[**] The term "topotactic" refers to solid state reactions which are characterized by the fact that defined lattice matrix elements specific to the original solid phase remain unaltered in the course of the reaction with respect to their structural organization (for semantic aspects cf. [13]).

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/1212-0983 $ 02.50/0

where neutral guest molecules are the only reacting species[12].

Topical interest in the type of reaction under consideration stems from different motivations. From a preparative point of view topotactic redox processes allow the systematic synthesis of an unusual variety of electron/ion conducting compounds *via* solid state reactions at ambient temperature; many of these materials are metastable and cannot be obtained by other preparative techniques. Investigation of the reaction mechanisms leads to new information on the relationship between structure, degree of order, and reactivity of solids. The possibility of a variation of redox state and composition provides a flexible model for the systematic modification of the physical properties of solids (optical and magnetic properties, transport phenomena, phase transitions, superconductivity) with conservation of the original host lattice matrix.

In connection with the problem of economic energy conversion and storage, topotactic redox systems with metal guest ions are of importance as electron/ion conducting reversible electrodes for high energy density secondary batteries. As regards application they are also of interest, *e.g.* in heterogeneous catalysis and electrocatalysis; metal oxide hydrogen bronzes are used as nonemissive optical display systems.

In the following review we shall first outline some of the general reaction principles and thereafter discuss the characteristics of particular systems using structural aspects as a guideline. Some special topics (ionic conductivity, physical properties, application) will also be briefly considered.

2. General Aspects

The principle of the process under discussion can be defined schematically as the bulk reaction of an electronically conducting host lattice (Z) that contains an intracrystalline system of accessible vacant lattice sites (□) with mobile guest ions (A) of an electrolyte phase which is in contact with the solid. Synchronously with the uptake of the guest ions—which diffuse from the interface host lattice/electrolyte into the bulk of the solid—an equivalent amount of electrons enters or leaves, respectively, the conduction band of the solid [eqs. (1) and (2)]. The electrons are provided and consumed by concurrent chemical or electrochemical reactions. It is understood that the process is reversible and that the host matrix retains its basic structural integrity during the course of foreward and backward reaction (topotactic process[13]).

$$x\,A^{\oplus} + x\,e + \square_x[Z] \rightleftarrows A_x^{\oplus}[Z]^{x\ominus} \quad (1)$$

$$x\,A^{\ominus} + \square_x[Z] \rightleftarrows [Z]^{x\oplus}A_x^{\ominus} + x\,e \quad (2)$$

While a large number of host lattices are known to undergo electron/cation transfer reactions [eq. (1), Fig. 1], there are few examples of reversible electron/anion transfer processes [eq. (2)], the most well-known being graphite, which is redox-amphoteric and is open to both types of reactions. It is clear for steric and energetic reasons that anion intercalation will be unfavorable in most cases. We shall therefore restrict our discussion to *electron/cation transfer*. In this case the solid can be described in the reduced state by a macroanion matrix $[Z]^{x-}$ with intercalated mobile guest cations A^+.

Equation (1) represents a homoionic process; the redox reaction may also proceed, however, by synchronous or consecutive cointercalation of different guest cations:

$$x\,A^{\oplus} + y\,B^{\oplus} + (x+y)\,e + [Z] \rightarrow A_x^{\oplus}B_y^{\oplus}[Z]^{(x+y)\ominus} \quad (3a)$$

$$x\,A^{\ominus} + x\,e + B_y^{\oplus}[Z]^{y\ominus} \rightarrow A_x^{\oplus}B_y^{\oplus}[Z]^{(x+y)\ominus} \quad (3b)$$

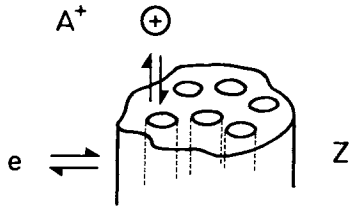

Fig. 1. Schematic illustration of reversible topotactic redox reactions by electron/cation transfer; Z = host lattice with accessible unoccupied lattice sites; A^+ = guest cation.

The intercalated compounds may in addition undergo cation exchange reactions according to

$$x\,A^{\oplus} + B_x^{\oplus}[Z]^{x\ominus} \rightarrow x\,B^{\oplus} + A_x^{\oplus}[Z]^{x\ominus} \quad (4)$$

With regard to the structural and physical properties of potential host lattices, there are a number of obvious requirements:

- In order to secure the stability of the host lattice matrix, the bonding between the atoms which constitute the matrix must be strong and has to include covalent (spacially directed) components. There are exceptions from this principle, *e.g.* in the case of rather small guest species such as protons, which may react reversibly even with molecular solids.
- A compound system of interconnected vacant lattice sites sharing polyhedral faces has to provide adequate space for the location and transport of guest cations.
- An energetically suitable conductivity band of the host matrix is required for the reversible uptake of electrons.
- The ionic mobility of the guest species must be high inside the solid, *i.e.* lattice positions have to be energetically approximately equivalent and the potential changes along the diffusion path should be small.

It is thus apparent that topotactic redox reactions of electronic/ionic conductors may essentially proceed only at intermediate temperatures: at high temperatures the matrix itself will become unstable, while at low temperatures the mobility of guest ions will be inhibited by large activation energy barriers for translation.

Independent of their chemical composition the host lattices may be divided into the following categories according to their essential structural characteristics (Fig. 2):

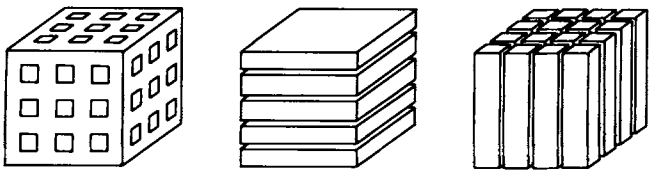

Fig. 2. Scheme of basic host lattice types with different structural dimensionality (see text).

Three-dimensional systems consisting of a framework host matrix that contains interconnected or isolated empty "channels" of unoccupied lattice sites which share polyhedral faces. There are naturally rather rigorous restrictions with respect to the dimensions of the guest cations which have to be below a critical radius that depends upon the host lattice.

Two-dimensional systems with neutral layered units as the matrix elements. The van der Waals gap between the layers represents a two-dimensionally infinite array of neighboring vacant lattice positions. As a consequence of the structural pecularities and the relatively weak coherence forces between the layer units, even large molecular guest ions may be accommodated *via* changes in the interlayer spacing. The flexibility of two-dimensional systems is characterized by the fact that complex solvated phases may form *via* the additional uptake of neutral polar molecules from the electrolyte medium [eq. (5)]. The solvated phases exhibit polyelectrolyte character, *i.e.* cation and solvate exchange properties.

$$x\,A^{\oplus} + x\,e + y\,\mathrm{solv} + [Z] \rightleftarrows (A^{\oplus})_x(\mathrm{solv})_y[Z]^{x\ominus} \qquad (5)$$

One-dimensional systems consisting of chain-type units separated by van der Waals gaps which provide neighboring empty lattice sites. Their structural flexibility is even higher as compared to layered lattices; they are, however, rather susceptible to lattice defects like all quasi one-dimensional systems[14].

Molecular solids have low lattice energies and low electronic conductivities; they may undergo topotactic redox reactions under certain conditions (cf. Section 7).

The majority of the host lattices investigated so far belong to the first two categories. With respect to chemical composition, the most variable group of host lattices are binary and multinary compounds of transition metals which easily undergo changes in the oxidation state with electronegative elements (chalcogenides, oxides). The formal oxidation state of the host matrix metal component is usually nonintegral in the reduced state. Thermodynamically unstable "empty" host lattices can be obtained by topotactic oxidation of ternary phases (prepared at high temperatures) which contain mobile metal ions (alkali ions, Cu^+, Tl^+) *e.g.* $CrSe_2$ from $NaCrSe_2$[15] or β-V_2O_5 from β-$Cu_xV_2O_5$[16]. For some ternary phases oxidation to zero negative charge on the host lattice is not possible [eq. (6)]; this may be due to electronic or structural reasons[17,18].

$$A_n^{\oplus}[Z]^{n\ominus} \rightleftarrows A_{n-x}^{\oplus}[Z]^{(n-x)\ominus} + x\,e + x\,A^{\oplus} \quad (x<n) \qquad (6)$$

Host lattices with framework structure intercalate only metal ions and protons. Host lattices with layer and chain structures may take up metal ions as well as molecular ions; both cation types can be solvated by neutral molecules *via* cation dipole interaction. The electronic conductivity of the host lattice may be either of semiconducting or metallic type and varies normally with the extent of reduction; considerable work has been devoted recently to the question of localized and delocalized electronic states[19,20].

Topotactic redox reactions can be performed either by chemical or electrochemical methods. The intercalation *e.g.* of lithium ions may be achieved by reaction of the host lattice with solutions of Li in liquid ammonia[19] or with butyllithium in aprotic solvents[21]; the electron donors are butyl carbanions or solvated electrons $e(NH_3)_x$, respectively. In aqueous electrolytes $S_2O_4^{2-}$, SO_3^{2-} *etc.* may be used as electron donors[8,9]; chemical reoxidation is performed *e.g.* with O_2, I_2, $[Fe(CN)_6]^{3-}$ as the electron acceptors. Direct thermal intercalation of neutral guest molecules into layered host lattices is well-known[22,23] and has recently been shown to proceed *via* molecular redox disproportionation[24,25].

A most important and versatile method for preparative as well as for analytical purposes is the electrochemical technique, which provides information on reversibility, intermediate stages, thermodynamic data and ionic mobility. Single crystal or polycrystalline host lattice electrodes can be intercalated and deintercalated by cathodic reduction or anodic oxidation in aqueous or nonaqueous electrolytes containing the appropriate guest ions [eq. (1), Fig. 3]. Cyclic voltammetry studies provide qualitative data on the reversibility of the

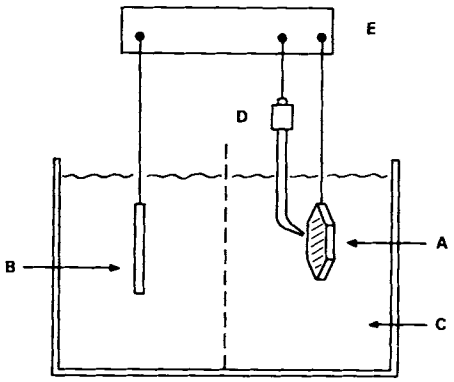

Fig. 3. Scheme of electrochemical reduction and oxidation of host lattice electrodes. (A) single crystal or polycrystalline working electrode; (B) counterelectrode; (C) aqueous or nonaqueous electrolyte containing guest cations; (D) Luggin capillary with reference electrode; (E) electronic equipment for control of potential and current.

reaction[8b,10,26,27]. Galvanostatic reduction and oxidation at constant current (coulometric titration) yields quantitative information on phase ranges and intermediate stages, provided equilibrium potential is maintained and side reactions are excluded. Thermodynamic data and chemical diffusion coefficients can be derived from EMF measurements at equilibrium potentials and from DC polarization studies, respectively[28]. *In situ* studies by X-ray and neutron diffraction methods provide evidence of structural changes and ordering states in the course of electrode reactions[29-32]. Lattice distortions, point defects and extended defects, which may be either inherent to the host lattice or develop during intercalation, strongly affect the kinetics, mechanism and extent of topotactic redox reactions; hysteresis phenomena and partial or total irreversibility are frequent consequences in such cases[33-35].

The general outline presented here does not account for the specific characteristics of particular systems; these will be discussed in the following sections with the dimensionality of the host lattice as the ordering scheme.

3. Host Lattices with Framework Structures

As discussed above solids with three-dimensional matrix will for steric reasons accept only metal guest ions, whose radii cannot exceed an upper critical value. The compounds investigated so far belong essentially to the transition metal oxides and chalcogenides. In terms of structure and reactivity they may be divided into systems with interconnected and with isolated channels.

3.1. Interconnected Lattice Channels

With respect to chemical reactivity the most versatile framework structures examined as yet are the rhombohedral molybdenum cluster chalcogenides Mo_6X_8 and $A_xMo_6X_8$ (X = S, Se; A = metal cation) which have gained considerable interest because of their remarkable physical properties (superconductivity, magnetic behavior, lattice instabilities)[36]. They are prepared from the elements at high temperatures (1300—1600 K), with the exception of Mo_6S_8 which was found to be formed on leaching of *e.g.* $Fe_2Mo_6S_8$ or $Ni_2Mo_6S_8$ with dilute mineral acids[37,38]. The structure of the binary phases can be described as a three-dimensional arrangement of Mo_6X_8 units which contain distorted octahedral Mo_6 metal clusters (Fig. 4). These units are joined *via*

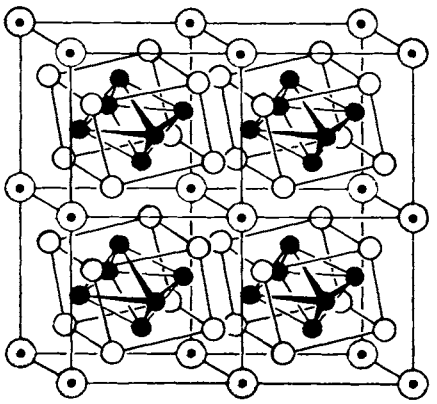

Fig. 4. Structure of Mo_6S_8. Dotted circles indicate unoccupied (channel) positions at the unit cell origin; ● = Mo, ○ = S.

Mo—S bonds to form a framework lattice that is characterized by intersecting infinite channels of neighboring vacant lattice sites running along the three rhombohedral axes. In the ternary phases the vancant lattice positions are (partially) occupied by the A metal atoms, whose location depends upon the stoichiometry x, the size and the oxidation state of A. X-Ray data established an unusually strong thermal motion for small A atoms[36].

Electrochemical studies on the molybdenum cluster chalcogenides revealed that they are able to undergo reversible topotactic redox reactions by electron/ion transfer at room temperature [eq. (7)][11,39,40]. Guest cations can be alkali, al-

$$x\,A^{\oplus} + x\,e + Mo_6X_8 \rightleftarrows A_x^{\oplus}[Mo_6X_8]^{x\ominus} \qquad (7)$$

kaline earth, transition and post transition metal ions; they all show rather high ionic mobility at 300 K. The upper critical guest ion radius corresponds to ≈ 120 pm for Mo_6S_8. Depending upon the guest cation line phases and nonstoichiometric phase ranges are observed (Table 1); some of these compounds are metastable phases.

Table 1. Ternary molybdenum cluster chalcogenides $A_xMo_6X_8$ obtained by cathodic reduction of the host lattice Mo_6X_8 in aqueous or organic electrolytes containing the guest cations A^{n+}; x_m = maximum stoichiometry observed.

Ternary Phase	Stoichiometry	Ternary Phase	Stoichiometry
$Li_x[Mo_6S_8]$	$x=0.8$; $2.4\leq x\leq 3.6$	$Zn_x[Mo_6Se_8]$	$x=1$; $x=2$
$Li_x[Mo_6Se_8]$	$x_m=3.6$	$Cd_x[Mo_6S_8]$	$x_m=2$
$Na_x[Mo_6S_8]$	$x_m=3.6$	$Cd_x[Mo_6Se_8]$	$x=1$; $x=2$
$Mn_x[Mo_6S_8]$	$x_m=1.3$	$Cu_x[Mo_6S_8]$	$0.7\leq x\leq 4$
$Fe_x[Mo_6S_8]$	$x_m=2$	$Cu_x[Mo_6Se_8]$	$0\leq x\leq 4$
$Co_x[Mo_6S_8]$	$x_m=2$	$Cu_x[Ag_{0.7}Mo_6S_8]$	$0\leq x\leq 3.3$
$Ni_x[Mo_6Se_8]$	$x_m=1.8$	$Zn_x[Ag_{0.7}Mo_6S_8]$	$x_m=1.65$
$Zn_x[Mo_6S_8]$	$x=1$; $x=2$	$Li_x[Ag_{0.7}Mo_6S_8]$	$x_m=3.2$

Because of their low redox potential, alkali and alkaline earth compounds decompose in H_2O; they can be obtained by cathodic reduction of Mo_6X_8 electrodes in aprotic organic electrolytes containing the guest ions. Chemical preparation is possible by reaction of Mo_6X_8 with the guest metals dissolved in liquid NH_3. In Figure 5 the potential/charge trans-

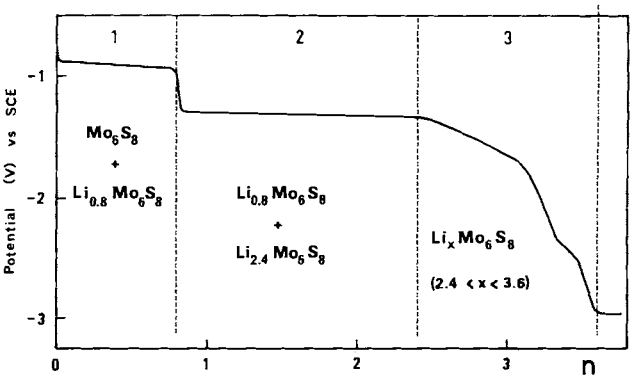

Fig. 5. Galvanostatic cathodic reduction of Mo_6S_8 in Li^+/propylene carbonate. Potential/charge transfer curve and phase diagram; n = integral charge transfer (mole/mol Mo_6S_8). 1, 2, 3 see text.

fer curve is given for the cathodic reduction of Mo_6S_8 in Li^+/dimethoxyethane. The charge transfer n (mole/mol Mo_6S_8) is numerically equivalent to the integral lithium content x in the overall reduction [eq. (8)]. Two potential

$$x\,Li^{\oplus} + x\,e + Mo_6S_8 \rightleftarrows Li_x^{\oplus}[Mo_6S_8]^{x\ominus} \qquad (8)$$

plateaus are observed (region 1, 2) as well as a region with continuous steep increase in potential (3). X-Ray studies showed that in agreement with thermodynamical considerations the plateau regions correspond to two phase ranges $Mo_6S_8/Li_{0.8}Mo_6S_8$ and $Li_{0.8}Mo_6S_8/Li_{2.4}Mo_6S_8$, while in region 3 a nonstoichiometric phase $Li_xMo_6S_8$ appears with $2.4\leq x\leq 3.6$[11,39,40] (Li metal deposition starts at $n=3.6$). The reversibility and the high ionic mobility of Li^+ is substantiated by cyclic voltammetry studies (Fig. 6) and by ^{7}Li-NMR data which show a rather low activation energy $E_A = 8.9$ kJ mol^{-1}.

It is remarkable that the molybdenum cluster chalcogenides are ionic conductors at ambient temperature even for

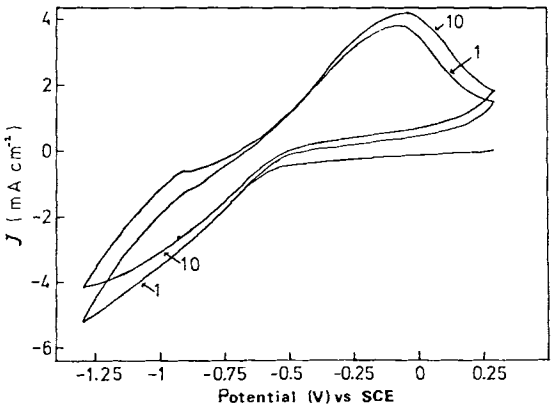

Fig. 6. Cyclic voltammogram of Mo_6S_8 electrode in Li^+/dimethoxyethane, $v = 300$ mV min^{-1} [11]. I = current density. The numbers on the curves indicate the cycle.

transition metal ions, *e.g.* Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}. The latter can be intercalated reversibly by cathodic reduction in aqueous electrolytes; they show solid solution ranges with triclinic lattice distortions at higher metal content. In contrast, line phases only with orthorhombic symmetry are observed for the bivalent post-transition metal ions Zn^{2+} and Cd^{2+}; values for the molar free energy ΔG^0 have been obtained from EMF measurements for zinc molybdenum selenides[41]:

$$Zn + Mo_6Se_8 \rightarrow ZnMo_6Se_8 \quad \Delta G^0 = -75.3 \text{ kJ/mol} \quad (9)$$
$$Zn + ZnMo_6Se_8 \leftarrow Zn_2Mo_6Se_8 \quad \Delta G^0 = -68.5 \text{ kJ/mol} \quad (10)$$

Large nonstoichiometric phase ranges are found for the copper compounds. They can be prepared either from aqueous Cu^{2+} or from organic electrolytes (Cu^+/CH_3CN). The oxidation state of Cu in the ternary chalcogenides is assumed to be $+1$[36]. For selenides $Cu_xMo_6Se_8$ the phase range is $0 < x < 4$, and a continuous change in lattice parameters is observed[41] (Fig. 7). Hysteresis phenomena are found for the

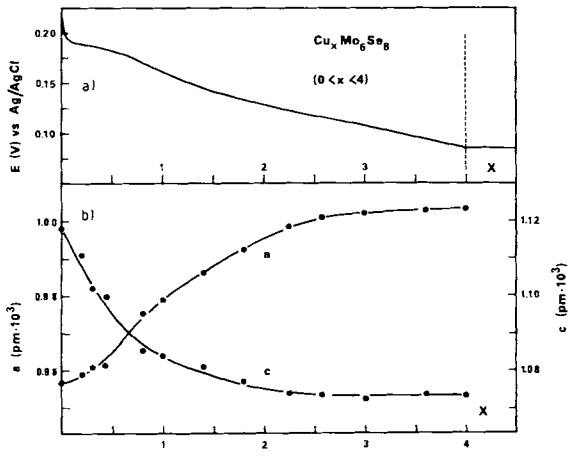

Fig. 7. Formation of $Cu_xMo_6Se_8$ by cathodic reduction of Mo_6Se_8 in Cu^{2+}/H_2O. (a) potential *vs.* composition, x = Cu content; (b) dependence of the hexagonal lattice parameters a, c on x.

sulfide $Cu_xMo_6S_8$: the lower phase limit corresponds to $x = 1.2$ on oxidation of $Cu_xMo_6S_8$ and to $x = 0.7$ on reduction of Mo_6S_8[39]. The hysteresis is reversible and is assumed to be related to the density anomaly of Mo_6S_8[42], to the fact that different positions can be occupied by Cu, and to small dimensional changes of the lattice positions with changes in the rhombohedral angle. A lower phase limit of $x = 1$ was reported in an X-ray study on the anodic oxidation of $Cu_2Mo_6S_8$ in aqueous electrolyte[43]; for thermally prepared phases the lower limit is $x = 1.2$[42].

An investigation on the system Cu/Mo_6S_8 in the temperature range $396\text{ K} < T < 443\text{ K}$ was performed recently in a solid state cell with doped CuBr as the electrolyte[44]. Partial copper ion conductivities and diffusion coefficients were determined as a function of copper content ($1.5 < x < 3.5$) and of temperature. The ionic transport properties were found to be excellent; the chemical diffusion coefficient amounts to 4.8×10^{-5} cm^2 s^{-1} at 441 K for $Cu_{3.3}Mo_6S_8$. From the dependence of the equilibrium EMF of the cell

Pt/Cu/Cu solid electrolyte/$Cu_xMo_6S_8$/Pt

on x and T the copper chemical potential, partial enthalpies and partial entropies were derived. The interpretation of the data is based on a model that takes into account the electronic configuration as well as the distribution of Cu between two types of lattice positions (Fig. 8).

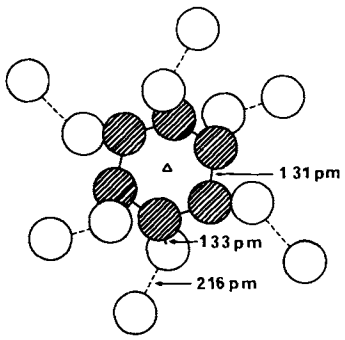

Fig. 8. Cluster of twelve partially occupied Cu^+ positions in $Cu_xMo_6S_8$ viewed along the threefold axis; Cu-1 sites shaded, Cu-2 sites unshaded. The six peripheral sites belong to nearest-atom positions of adjacent clusters [36, 44].

Ternary phases $Tr_xMo_6S_8$ ($x \approx 1$) with partial occupation of the channel sites by large cations, *e.g.* Ag^+, Sn^{2+}, Pb^{2+}, can be prepared only at high temperatures. The Tr^{n+} ions are located close to the origin of the unit cell and show no ionic mobility. There is, however, an excess of unoccupied channel lattice sites, and quaternary phases may be obtained by cathodic reduction of these compounds in electrolytes containing small guest ions A^{n+} [eq. (11)]. Data on the phase limits of $A_xAg_{0.7}Mo_6S_8$ are given in Table 1[41].

$$xA^{\oplus} + xe + TrMo_6X_8 \rightleftarrows A_x[TrMo_6X_8] \quad (11)$$

The "ionic-covalent" bonding model which has been proposed recently to explain the stabilizing effect of A^+ guest ions on the Mo_6X_8 lattice and to understand the influence of A^+ on changes in physical properties implies a maximum electron transfer to the host lattice matrix of ≈ 4 for sulfides and of ≈ 3 for selenides (*i.e.* $[Mo_6S_8]^{4-}$ and $[Mo_6Se_8]^{3-}$)[36]. This model is in agreement with the maximum stoichiometries observed for ternary phases prepared at high temperatures. From the data on selenides obtained at 300 K by cathodic reduction (Table 1) however, an electron transfer

corresponding to $[Mo_6Se_8]^{4-}$ is, calculated (*e.g.* $(Cu^+)_4[Mo_6Se_8]^{4-}$) which is inconsistent with the bonding scheme suggested.

The galvanostatic oxidation of the binary copper sulfide $Cu_{1+x}S$ has been studied in aqueous Cu^{2+} electrolyte; the phase diagram as well as thermodynamic data of intermediate phases were determined[45]. Bornite Cu_5FeS_4, which has a pseudocubic lattice, was shown to have a reversible redox region ($Cu_{5-x}FeS_4$) with $0<x<2$, *i.e.* a part of the Cu atoms are mobile and can be removed from the host lattice[46]. Alkali tungsten oxide bronzes A_xWO_3 with defect perovskite structure show high electronic conductivities[47]; the activation energy for alkali ion transport is, however, rather high. Li_xWO_3 can be used as a nonpolarizing electrode with β-alumina[48].

3.2. Isolated Parallel Lattice Channels

Among the binary and ternary compounds of sulfur and selenium with transition metals in lower oxidation states a series of phases is known which are semiconductors or metals and whose structures can be described in terms of a matrix M_yX_z that contains isolated parallel channels. These channels may be either empty or (partially) filled with large metal ions, *e.g.* Tl^+, K^+ (Table 2). Evidence that chalcogenide systems of this structure type may participate in topotactic redox reactions came originally from studies on Nb_3S_4 and Nb_3Se_4 which demonstrated that both compounds may act as host lattices with mono- or bivalent cations [eq. (12)][10, 16, 35]. The hexagonal niobium chalcogenides consist of a framework of NbX_6 octahedra joining common faces and edges with empty lattice channels of ≈ 130 pm diameter running in the direction of the c axis (Fig. 9)[49]. The metal atoms form Nb—Nb chains parallel to the c axis which are supposed to be responsible for the high electronic conductivity and the superconducting behavior[50]. Cyclic voltammetry studies indicate high ionic mobility in the lattice channels; lattice parameter changes on intercalation are very small as a consequence of the rigid lattice structure. The stoichiometries of the reduction products are, however, rather low ($Na_{0.2}Nb_3S_4$, $K_{0.2}Nb_3S_4$) which has been attributed to a restricted accessibility of the solid volume due to inherent lattice defects (Fig. 10). This assumption is supported by the observation that ternary phases $Na_xNb_3S_4$ and $K_xNb_3S_4$ prepared at high temperatures have considerably higher redox capacity, since the Nb_3S_4 structure is stabilized under thermal equilibrium conditions by the alkali cations[35]. Because of its small ionic radius the influence of defects should be less important for Li^+: cathodic reduction of Nb_3S_4 in Li^+/propylene carbonate leads in fact to $Li_xNb_3S_4$ with $x \approx 1$ (Fig. 11).

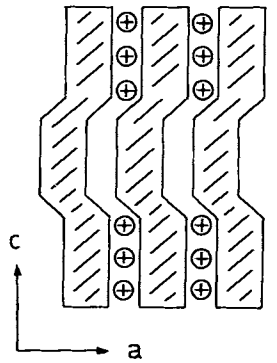

Fig. 10. Scheme of $A^+_x[Nb_3S_4]^{x-}$ structure with partially inaccessible channel volume originating from lattice defects (cross section parallel to channel axes, negative charges of the Nb_3S_4 matrix ommitted) [35].

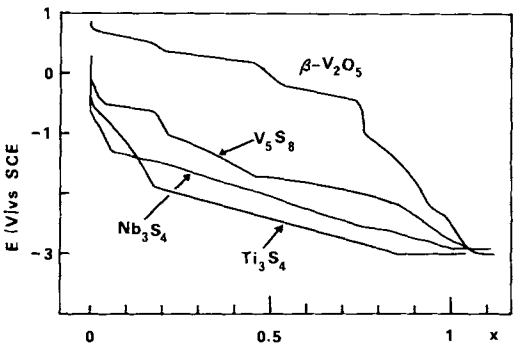

Fig. 11. Potential/charge transfer curve for cathodic reduction of Ti_3S_4, Nb_3S_4, V_5S_8 and β-V_2O_5 to the corresponding Li^+ phases. Electrolyte: 1 M Li^+/propylene carbonate, 298 K; x = e/unit formula [16].

The formation of $K_{0.3}Ti_3S_4$ has been reported recently[16]: its structure can be considered as a partially filled up version of the Nb_3S_4 type. The K^+ ions in the lattice channels are mobile at room temperature. On anodic oxidation in aqueous electrolytes the empty host lattice Ti_3S_4 is obtained which undergoes topotactic redox reactions with cations up to a radius of ≈ 130 pm. The upper limit for $Li_xTi_3S_4$ is equivalent to $x = 0.8$ (Fig. 11); variations of lattice parameters with x are rather small again due to the rigid host structure.

Large parallel channels filled up with Tl atoms are found in the titanium and vanadium chalcogenides $TlTi_5Se_8$, TlV_5S_8 and V_5S_8 (Table 2). Their monoclinic structure is, however, quite different from the Nb_3S_4 type; the structure consists of a distorted framework of MX_6 octahedra sharing faces and edges. The Tl atoms reside in large rectangular channels parallel to the b axis. TlV_5S_8 exhibits metallic conductivity; the Tl atoms are mobile and on anodic oxidation in aqueous electrolytes V_5S_8 is obtained[16]. The binary phase can be reduced and oxidized in electrolytes like Nb_3S_4—with clear changes, however, in lattice parameters due to the higher lattice flexibility. The upper stoichiometric limits for the copper and lithium phase are $Cu_{0.3}V_5S_8$ and $Li_{1.0}V_5S_8$, respectively.

A considerable number of transition metal oxide bronzes $A_xM_yO_z$ are known to have crystal structures with cations A (alkali cations, NH_4^+, Tl^+, Cu^+) positioned in channels inside the M_yO_z matrix[56,57]. Tetragonal tungsten bronzes Na_xWO_3 have been used as reversible electrodes in solid state cells with β-alumina as the electrolyte[58]. An NMR analysis of Li diffusion in the lithium vanadate β-$Li_xV_2O_5$ demonstrated a rather low activation energy of 6.4 kJ mol^{-1}[59]; it has been employed as reversible electrode material[60]. β-$Cu_xV_2O_5$ ($0.26<x<0.64$), which has a V_2O_5 network structure with Cu^+ in channel positions[61], may be oxidized anodically to the metastable binary oxide β-V_2O_5[16] with empty channels. On cathodic reduction in aqueous or organic electrolytes, alkali and transition metal ions can be reversibly inserted into the host lattice (Fig. 11). The high ionic mobility of guest ions can be attributed to the fact that the cations may occupy different positions[62].

Binary transition metal oxides MO_2 with rutile structure have empty lattice channels parallel to the tetragonal c axis and should be able to accept small ions such as Li^+. Metastable ternary phases Li_xMO_2 have actually been reported for the following oxides: TiO_2, VO_2, CrO_2, MnO_2, WO_2, RuO_2, OsO_2 and IrO_2[63–65]. Formation of ternary phases with Li^+ on electrochemical or chemical reduction has also been observed for a series of nonstoichiometric binary oxides of V, Cr, Mo, W with complex framework structures[66–68].

4. Host Lattices with Layered Structures

As compared to three-dimensional systems, host lattices with layer structures are characterized by their ability to intercalate besides metal ions a large variety of molecular species of different size and geometry with expansion of the lattice perpendicular to the layer planes. In addition they exhibit specific structural features on intercalation and deintercalation related to changes in the stacking sequence of the layer units; in extreme cases total one-dimensional disorder may be observed. We shall exclude here graphite from discussion, since its intercalation chemistry has been treated extensively in recent reports[69,70].

4.1. Layered Chalcogenides

A large number of transition metals M are able to form dichalcogenides MX_2 with the highly polarizable anions X = S, Se, Te which have hexagonal structures related to the CdI_2 type (Fig. 12, Table 3). The lattice can be described in terms of a stacking of elastic $(MX_2)_\infty$ sheets of ≈600 pm in thickness which are held together essentially by weak van der Waals interactions. The MX_2 layer units themselves consist of two anion sheets with the metal atoms in the central plane;

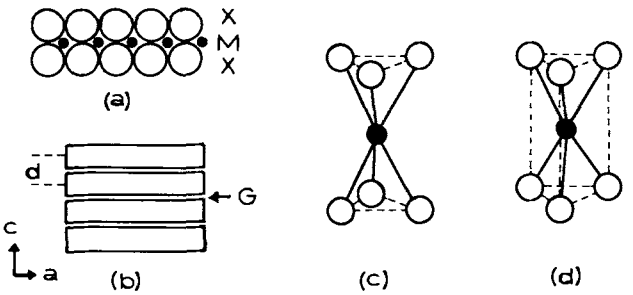

Fig. 12. Structure scheme of layered transition metal dichalcogenides MX_2. (a) X—M—X single layer, (b) layer stacking in the crystal lattice, d = interlayer spacing, G = van der Waals gap, (c), (d) octahedral and trigonal-prismatic coordination of M.

Table 3. Layered binary and ternary phases which undergo reversible topotactic redox reactions.

MX_2 [a]	Ta_2S_2C	MoO_3	$Li_xV_3O_8$
A_xMX_2 [a]	$K_2Ni_3S_4$	$Mo_{18}O_{52}$	FeOCl
MPX_3 [b]	$K_2Pt_4S_6$	V_2O_5	UO_2F_2
$CrPS_4$		ε-$Cu_xV_2O_5$	

[a] M = group 4—6 elements, Re, Sn; A = alkali metal, Ag, Tl, Cu; X = S, Se. [b] M = Mn, Fe, Ni, Zn; X = S, Se.

there is strong ionic/covalent bonding between M and X (Fig. 12). Modifications differ in the coordination of the intralayer metal atoms (octahedral or trigonal prismatic) and in the mode of stacking of the MX_2 layers[71,72].

The strong anisotropy of the layered transition metal dichalcogenides with respect to structure and physical properties extends also to their chemical reactivity. *Rüdorff* first observed alkali metal intercalation into dichalcogenides and proposed an ionic structure model[73]. Compounds with Lewis base molecules were prepared originally by *Weiss* and *Ruthardt*[74]. Intercalation by electrochemical methods was subsequently reported[8b,75,76] and interpreted as reversible topotactic redox reactions[8]. Recent investigations on the mechanism of thermal Lewis base intercalation established that these reactions also are correlated with redox processes and the formation of products with ionic structure[12,24,25].

In order to give an impression of the wide variety of topotactic reactions of layered dichalcogenides, a schematic overview on the characteristic reaction pathways (which also applies to other layered host lattices with redox properties) is shown in Figure 13. We shall divide here the reactions of dichalcogenides into three groups according to the guest species involved: intercalation of metal ions, intercalation of solvated ions, and intercalation of neutral molecules with Lewis base function.

The reversible formation of *intercalation compounds with metal ions* according to eq. (13) (Fig. 13) has been observed for the electropositive alkali and alkaline earth elements, Eu,

$$x\,A^{\oplus} + x\,e + MX_2 \rightleftarrows A_x^{\oplus}[MX_2]^{x\ominus} \qquad (13)$$

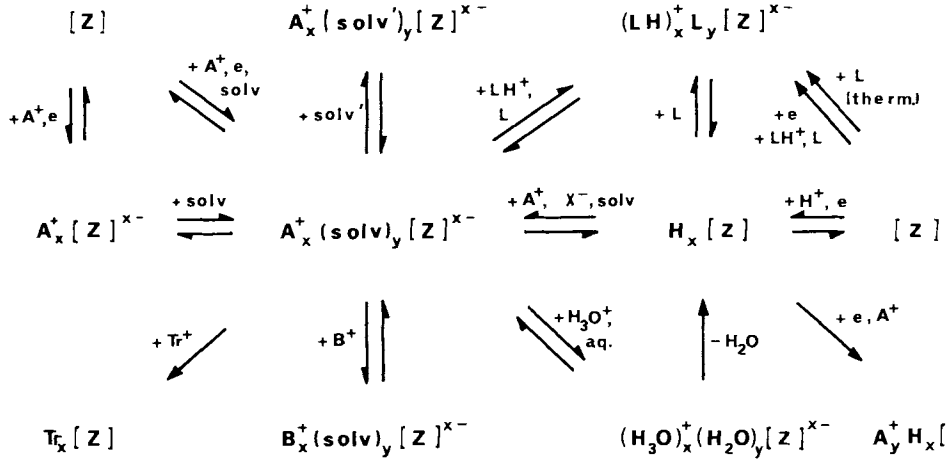

Fig. 13. Scheme of topotactic redox, exchange and solvation reactions of layered host lattices with electronic conductivity. Z = host lattice; A^+, B^+ = guest cations; solv = neutral polar solvent molecules (*e.g.* H_2O, NH_3, formamide); L = Lewis base (*e.g.* pyridine); R^- = anion base (*e.g.* OH^-, NH_2^-, CH_3O^-); Tr = cation with low solvation energy (Cu^+, Ag^+, Tl^+) [86].

Yb, and the post-transition metals Cu, Ag, Tl. Convenient ways of chemical preparation of the alkali compounds are the reaction of the dichalcogenides with alkali metal solutions in liquid NH_3[19,73] or with *n*-butyllithium solutions[21]. Electrochemical formation is achieved by cathodic reduction of MX_2 electrodes in nonprotolytic electrolytes, *e.g.* solutions of alkali ions in dimethyl sulfoxide or cyclopropylene carbonate[34,77]. The intercalation of the metal ions leads to an increase of the interlayer spacing *d* (distance between neighboring layers in the direction of the hexagonal c axis), which is related to the size of the guest ion. The upper limit for *x* in A_xMX_2 depends on the chalcogenide and on the guest metal ion. Several intermediate phase ranges were found for the larger alkali metals (Fig. 14). For low *x* values, higher stage phases are observed with the guest metal ions intercalated in

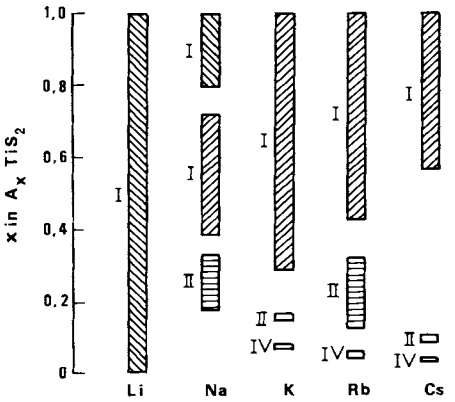

Fig. 14. Limits of A_xTiS_2 phases. I, II, IV = first, second and fourth stage compounds [19, 34].

only every second or fourth interlayer space. The intercalation is associated with changes in the stacking mode of the layers; Na^+, K^+, Rb^+ and Cs^+ may occupy either octahedral or trigonal prismatic sites depending upon the cation size, the cation concentration and the nature of the dichalcogenide[19]. The electronic band structure of the host lattice seems to play an important role in the stability of the ternary phases. While alkali compounds of dichalcogenides with a broad t_{2g} conduction band are rather stable (*e.g.* A_xTiS_2), it is found that compounds of chalcogenide host lattices with filled-up d_{z^2} band have low stability (*e.g.* A_xMoS_2[77,78], Fig. 15). Lithium compounds have been extensively studied because of their application as reversible battery electrodes[34].

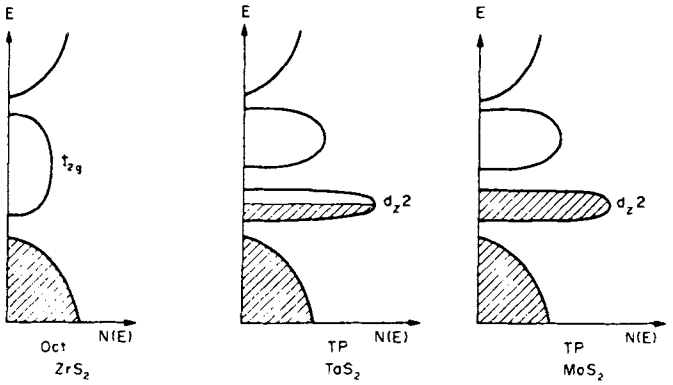

Fig. 15. Band structure scheme of layered dichalcogenides of transition elements of subgroups 4, 5 and 6 [19]. Examples ZrS_2, TaS_2 and MoS_2. Oct = octahedral, TP = trigonal prismatic.

In the case of Li_xTiS_2 a homogeneous phase range of $0 \leq x \leq 1$ has been observed[79]. Free energies and enthalpies of formation for Li and Na phases have been evaluated from electrochemical data[34,80].

Cu_xMX_2 and Ag_xMX_2 can be obtained from aqueous electrolytes; both cations reside in tetrahedral interlayer sites. The occupation is a function of temperature, and order-disorder transitions have been found for Cu_xNbS_2 and Cu_xTaS_2[81]. The existence of ordered intermediate structures (Fig. 16) in Na_xTiS_2 has been proven recently by X-ray investigations on the cathodic reduction of TiS_2 single crystals in NaI/propylene carbonate at 300 K[32]. Support for Li ordering states in Li_xTiS_2 follows from *in situ* X-ray investigations on TiS_2 electrodes[29], electrochemical potential stepping techniques[82], and perturbed angular correlation studies[83].

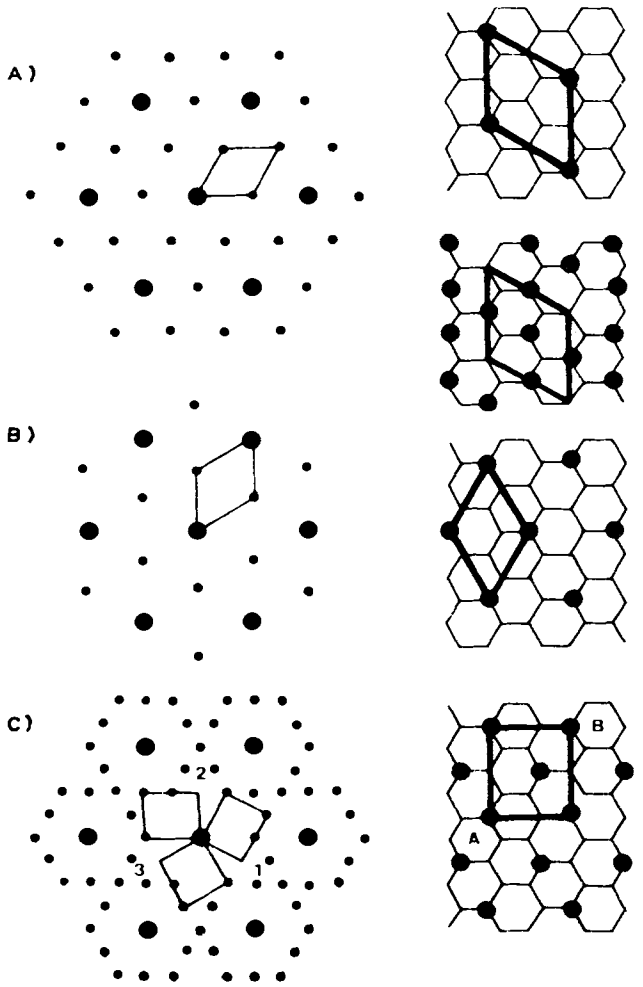

Fig. 16. Ordered states of Na_xTiS_2 phases at room temperature. Superstructure patterns and corresponding unit cells; n refers to stage number [32]. A) above: $a_A = 2a$, $n = 2$, $x = 1/8$; below: $a_A = 2a$, $n = 1$, $x = 3/4$; B) $a_B = a$, $n = 3$, $x = 1/9$; $n = 2$, $x = 1/6$; C) A = 2, B = $a\,|\,\bar{3}$; $n = 2$, $x = 1/4$, $n = 1$, $x = 1/2$.

Metastable layered binary sulfides and selenides may be prepared by oxidation of thermally stable ternary phases, *e.g.* $CrSe_2$, $Cr_{0.5}Ti_{0.5}S_2$ and VS_2 are obtained on oxidation of $LiVS_2$, $Na_{0.5}Ti_{0.5}Cr_{0.5}S_2$ and K_xCrSe_2[8a, 15, 84].

Cathodic reduction (or chemical reduction *e.g.* with $S_2O_4^{2-}$) of layered dichalcogenides in electrolytes with strongly polar solvents leads to uptake of neutral solvent molecules along with cations into the solid [eq. (14), Fig. 17].

$$x\,A^{\oplus} + x\,e + y\,\mathrm{solv} + MX_2 \rightleftarrows A_x^{\oplus}(\mathrm{solv})_y[MX_2]^{x\ominus} \qquad (14)$$

The resulting *solvated phases* exhibit polyelectrolyte character and consist of two-dimensional macroanions $[MX_2]_\infty^{x-}$ with mobile solvated cations in the interlayer space[8, 9, 85, 86]; they undergo ion and solvent exchange reactions (Fig. 13). An extraordinary variety of phases can be obtained by the choice of cation (*e.g.* main group and transition metal ions, metal complex ions, protonated amines and quaternary ions, cationic dyes) and solvent (inorganic and organic polar molecules). The solvate structures are principally governed by the ion/dipole interaction between cations and solvent molecules.

Hydrated chalcogenides $A_x^+(H_2O)_y[MX_2]^{x-}$ with alkali and alkaline earth ions show rather simple correlations between solvate structure and cation hydration energies. For cations with a charge/radius ratio $e/r < 1$ only monolayers of H_2O are observed, while cations with $e/r > 1$ are able to form hydrates with bilayers and monolayers of H_2O in dependence of the H_2O activity (Fig. 17, 18). The average lattice expan-

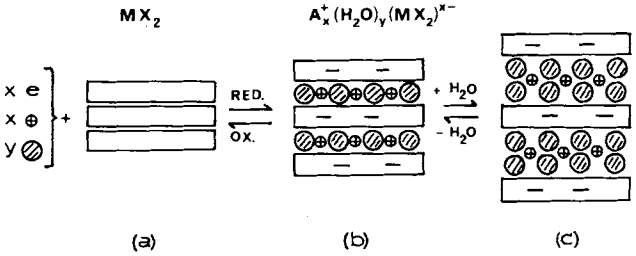

Fig. 17. Scheme of formation of hydrated layered chalcogenides by cathodic reduction of MX_2 in aqueous electrolytes. (a) host lattice; (b) monolayer hydrate; (c) bilayer hydrate; ⊕ = guest cation A^+; ◍ = H_2O.

sions of $\Delta d \approx 300$ pm and $\Delta d \approx 600$ pm are equivalent to one and two times, respectively, the van der Waals diameter of H_2O. Octahedral coordination of the cations by water was found for the bilayer hydrate $Na_{0.6}(H_2O)_2VS_2$[87], whereas trigonal prismatic sites could be established for H_2O and K^+ in the monolayer hydrates $K_{0.5}(H_2O)_{0.5}NbS_2$ and $K_{0.3}(H_2O)_yTaS_2$[88]. The position and anisotropic mobility of H_2O in monolayer hydrates is discussed in Section 8.

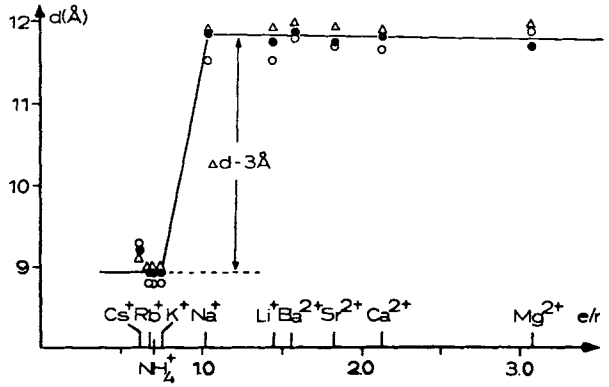

Fig. 18. Dependence of the interlayer spacing d of hydrated layered transition metal sulfides on the charge/radius ratio e/r of the guest cation [85].
○ = $A_{0.5/x}^{x+}(H_2O)_y[TiS_2]^{0.5-}$; ● = $A_{0.5/x}^{x+}(H_2O)_y[NbS_2]^{0.5-}$;
△ = $A_{0.3/x}^{x+}(H_2O)_y[TaS_2]^{0.3-}$.

The maximum reduction stage in aqueous electrolytes essentially depends upon the electronic nature of the host lattice and varies between $x \approx 0.25$ and $x = 0.5$ (*e.g.* $Na_{0.33}^+(H_2O)_y[TiS_2]^{0.33-}$, $K_{0.5}^+(H_2O)_y[NbS_2]^{0.5-}$). Hydrated sulfides $A_x(H_2O)_yMoS_2$ and $A_x(H_2O)_ySnS_2$ are rather unstable towards oxidation to the binary phases[78, 89, 90]; for chromium sulfides $A_x(H_2O)_yCrS_2$ a limited redox range $0.4 < x < 0.7$ is found which is likely to be due to the instability of Cr^{4+} in sulfides[17].

Evidence for the occurrence of intermediates in the cathodic reduction and anodic oxidation of dichalcogenide electrodes in aqueous electrolytes came from investigations on single crystal and polycrystalline MS_2 electrodes by cyclic voltammetry[8b]. This was confirmed by a recent *in situ* neutron diffraction study on the structural changes of 2H-TaS_2

electrodes in the course of galvanostatic reduction in K^+/D_2O[12,31]. The overall reaction proceeds according to equation (15) with formation of $K_{0.5}(D_2O)_{0.5}TaS_2$ as the final product.

$$x\,K^{\oplus} + x\,e + y\,D_2O + TaS_2 \rightleftarrows K_x^{\oplus}(D_2O)_y[TaS_2]^{x\ominus} \quad (15)$$

The potential/charge transfer curve shows three potential plateaus (regions 1—3) and a steep continuous rise in potential (region 4) (Fig. 19a). The neutron diffraction data obtained simultaneously with the reduction indicate the formation and disappearance of intermediate phases. Detailed

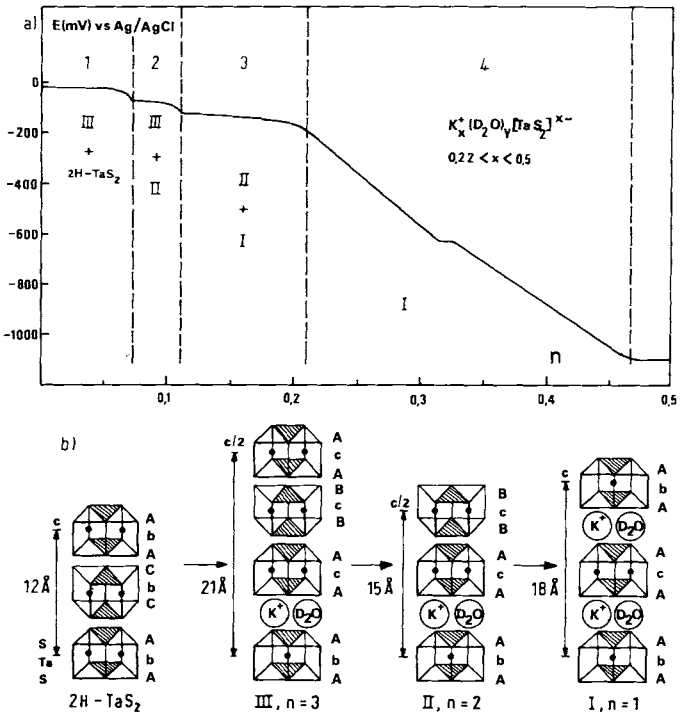

Fig. 19. Galvanostatic cathodic reduction of 2H-TaS_2 in K_2SO_4/D_2O. (a) potential/charge transfer curve and phase diagram, $n = e/TaS_2$; (b) scheme of structural transformations in the course of the reduction [31]. I, II, III = compounds of the first, second and third stage.

analysis revealed the existence of three two-phase ranges 1—3 with the formation of third stage, second stage and first stage hydrates (Fig. 19b):

$K^+_{0.21}(D_2O)_{0.79}[TaS_2]^{0.21-}_3$

$K^+_{0.22}(D_2O)_{0.78}[TaS_2]^{0.22-}_2$

$K^+_{0.21}(D_2O)_{0.79}[TaS_2]^{0.21-}$

In region 4 there exists a nonstoichiometric first stage phase. Anodic oxidation proceeds *via* the same stages in inverse sequence. The formation of higher stage intermediates was also observed for other MX_2 host lattices with different guest ions and seems to be a general phenomenon in topotactic electrode reactions of layered chalcogenides that is likely to be related to stable intermediate electronic states. Kinetic factors become of importance with increasing guest-ion size (*e.g.* large transition metal complexes, dye cations) and may prevent the isolation of pure intermediates[12,31].

The intercalation of protonated Lewis bases (amines, heterocycles) with low solvation energy in aqueous electrolytes results in the formation of homosolvated phases as a consequence of the equilibrium

$$LH^{\oplus} + H_2O \rightleftarrows L + H_3O^{\oplus}$$

On cathodic reduction of *e.g.* TaS_2 in aqueous pyridinium ion (pyH^+) solutions, $(pyH^+)_{0.25}(py)_{0.25}[TaS_2]^{0.25-}$ is obtained with pyridinium ions solvated by neutral pyridine molecules in the interlayer space [eq. (16)][8b,25,91]. Three intermediate phases have been identified with the pyridine ring planes either parallel or perpendicular to the host layer planes.

$$0.5\,pyH^{\oplus} + 0.25\,e + 0.25\,H_2O + TaS_2 \rightarrow (pyH^{\oplus})_{0.25}(py)_{0.25}[TaS_2]^{0.25\ominus} + 0.25\,H_3O^{\oplus} \quad (16)$$

Spontaneous intercalation is observed on reaction of dichalcogenides with aqueous base solutions, *e.g.* alkali hydroxides, NH_3, organic amines. The process involves partial hydrolysis of the host lattice layers with formation of H_2S, which itself acts as the electron donor yielding elemental sulfur[8c,85]:

$$\frac{x}{2}HS^{\ominus} + MX_2 \rightarrow \frac{x}{2}S + \frac{x}{2}H^{\oplus} + [MX_2]^{x\ominus} \quad (17)$$

A large variety of inorganic and organic *neutral molecular compounds with Lewis base character* (NH_3, hydrazines, amines, heterocycles, acid amides, *N*-oxides, phosphanes, *etc.*) are able to form *Lewis base intercalation compounds* L_yMX_2 with layered dichalcogenides by direct thermal reaction[22,23]. The lattice expansions are dependent upon size and arrangement of the guest molecules and interlayer spacings up to 5000 pm are measured for strongly anisometric guest species, *e.g. n*-alkylamines[92-94]. The interaction host lattice/guest molecule has been interpreted in terms of a charge transfer from the guest donor molecules to the acceptor host lattice[22,23,95,99]. Recent investigations led, however, to the hypothesis that the direct intercalation of Lewis base compounds generally proceeds *via* topotactic redox reactions to phases with ionic structures[12,24,25]. This concept is supported by studies on the mechanism of intercalation of NH_3 and pyridine. In contrast with previous models[96,97] (Fig. 20a), ^{1}H-NMR measurements on $TaS_2(NH_3)_{1.0}$ and $TiS_2(NH_3)_{1.0}$ established a position of NH_3 in the interlayer space with the C_3 axis oriented parallel to the layer planes (Fig. 20b)[95],

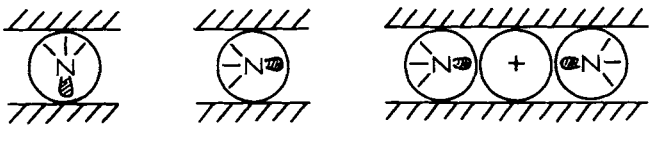

Fig. 20. Structure models for the position of NH_3 between the metal sulfide layers in $TaS_2 \cdot (NH_3)$. a, b: C_3 axis of NH_3 perpendicular and parallel to the layer planes, c: ionic model [12, 24].

which is obviously an unfavorable position for charge transfer between the nitrogen lone pair and the MX_2 layers. An investigation on the mechanism of NH_3 intercalation into TaS_2 demonstrated that a redox process is correlated with

this reaction that involves the oxidation of a fraction of the guest molecules with formation of N_2[24]. The electrons are transferred to the TaS_2 layers, while the protons are accepted by NH_3 molecules [eq. (18)—(20)].

$$2NH_3 \rightarrow N_2 + 6H^{\oplus} + 6e \quad (18)$$

$$xe + TaS_2 \rightarrow [TaS_2]^{x\ominus} \quad (19)$$

$$H^{\oplus} + NH_3 \rightarrow NH_4^{\oplus} \quad (20)$$

The resulting product $(NH_4^+)_x(NH_3)_{1-x}[TaS_2]^{x-}$ with $x \approx 0.1$ has ionic structure with NH_4^+ cations solvated by neutral NH_3 molecules. This bonding scheme explains *e.g.* the unusual orientation of NH_3 by conventional ion/dipole interactions (Fig. 20c). The thermal intercalation of pyridine in TaS_2 was found to proceed similarly *via* a redox process associated with a molecular disproportionation of a part of the guest molecules yielding dipyridine [eq. (21)—(23)]. The product has again ionic structure:

$$x\,py \rightarrow \frac{x}{2}(py\text{-}py) + xH^{\oplus} + xe \quad (21)$$

$$x\,py + xH^{\oplus} \rightarrow x(pyH^{\oplus}) \quad (22)$$

$$xe + TaS_2 \rightarrow [TaS_2]^{x\ominus} \quad (23)$$

$(py)_{0.5-2x}(pyH^+)_x(py\text{-}py)_{x/2}[TaS_2]^{x-}$ with the ring planes perpendicular to the hexagonal c axis ($x \approx 0.2$; Fig. 21d)[25, 98, 99]. The appearance of higher stage intermediates during thermal intercalation of NH_3 and pyridine has been investigated by neutron diffraction[100]. Less complex reaction mechanisms

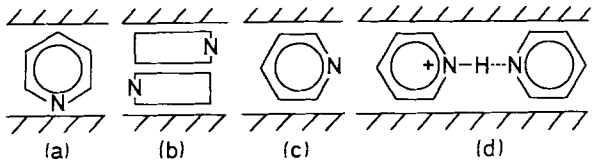

Fig. 21. Structure models for the position of pyridine in $MX_2(py)_{0.5}$ [12, 25, 99].

should be observed for guest species with low ionization potential and able to form stable radical cations, *e.g.* aromatic Lewis bases; indirect evidence for this process has recently been reported for phenylenediamine intercalation[83]. Direct ionization was assumed to occur in the thermal intercalation of metallocenes[101] which can also be obtained by cathodic reduction of MX_2 in electrolytes containing metallocenium ions[31].

A series of binary and ternary chalcogenides with layered structures related to the CdI_2 and $CrCl_3$ type have been reported to undergo topotactic redox reactions: tantalum sulfide carbide Ta_2S_2C[9, 102, 103], phosphorus sulfides MPX_3[91, 104, 105], $CrPS_4$[106] and the thiometallates $K_2Ni_3S_4$ and $K_2Pt_4S_6$[85, 86, 107]. Their reactivity is rather similar to that of the layered dichalcogenides.

4.2. Layered Oxides

As a consequence of the high electronegativity and low polarizability of oxygen, metal/oxygen bonds have more ionic character as compared to metal/sulfur bonds. The structures of oxides and sulfides are therefore generally quite different[72].

The binary oxide of molybdenum(VI) MoO_3 has a typical layer structure: edge- and vertex-sharing distorted MoO_6 octahedra form two-dimensional puckered $(MoO_3)_x$ units which are separated in the orthorhombic crystal lattice by van der Waals gaps (Fig. 22). The semiconducting MoO_3 is

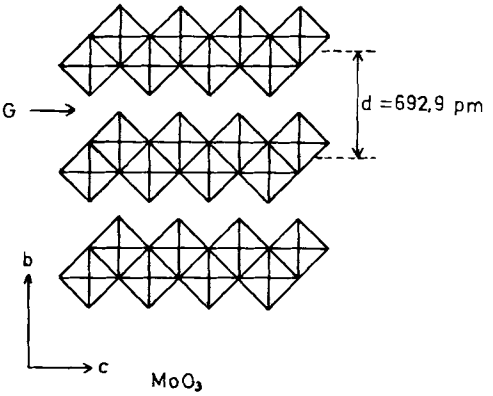

Fig. 22. Structure of MoO_3; cross section perpendicular to the layer planes; G = van der Waals gap.

able to undergo a wide range of topotactic redox and exchange reactions which are surprisingly similar to those observed for layered dichalcogenides (Fig. 13)[10, 67, 86, 108]. In aqueous electrolytes containing main group or transition metal ions dark blue hydrated phases with metallic luster are obtained [eq. (24)]. These reactions are strongly dependent upon pH values and may lead to the formation of mixed

$$xA^{\oplus} + xe + yH_2O + MoO_3 \rightleftarrows A_x^{\oplus}(H_2O)_y[MoO_3]^{x\ominus} \quad (24)$$

metal cation/hydrogen bronzes. To illustrate this, Figure 23 shows the potential/charge transfer curve for the cathodic re-

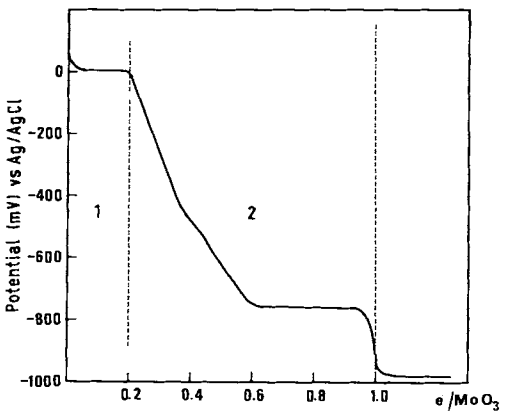

Fig. 23. Galvanostatic cathodic reduction of MoO_3 in Na^+/H_2O: potential/charge transfer curve.

duction of MoO_3 in 1 N Na_2SO_4 (pH = 6). The starting region 1 corresponds to a two-phase range with the formation of $H_{0.2}MoO_3$ at constant potential; in region 2, which exhibits a nonstoichiometric and a two-phase range, hydrated Na^+ and H_3O^+ ions enter the lattice simultaneously. After a charge transfer of $1\,e/MoO_3$ the potential of H^+ discharge is reached, the composition of the final product is $Na_{0.5}^+H_{0.5}^+(H_2O)_y[MoO_3]^-$. Oxidation/reduction cycles show a limited kinetically accessible reversible range of $0.4 \leq x \leq 1$ which is likely due to small structural distortions.

Transition metal complex ions as well as a large number of organic ions can be intercalated by cathodic reduction in aqueous and organic electrolytes. Thermal intercalation of Lewis base compounds can be achieved and is assumed to proceed as a molecular redox disproportionation[108].

MoO_3 is of interest as cathode material for organic electrolyte lithium batteries because of the high energy density of the couple Li/MoO_3[109]. As reaction product, the formation of lower molybdenum oxides has been proposed[110]; from X-ray data a ternary phase with a structure similar to high temperature Li_2MoO_3 was suggested as the product[63]. A study on the discharge reaction mechanism revealed that the process is in fact a reversible topotactic redox reaction [eq. (25)]; the kinetically accessible range corresponds to $0.1 < x < 1.5$[67].

$$x\,Li^{\oplus} + x\,e + MoO_3 \rightleftarrows Li_xMoO_3 \qquad (25)$$

$Mo_{18}O_{52}$ has a lattice structure closely related to the MoO_3 type and shows similar reactivity[67,108]. Several layered oxides of vanadium have been studied with respect to topotactic redox activity. The binary vanadium oxide V_2O_5 forms layered ternary phases $Li_xV_2O_5$ on cathodic reduction in organic Li^+ electrolytes and on reaction with butyllithium or LiI [eq. (26)][63,111,112]. Hydrated vanadium oxides

$$x\,LiI + V_2O_5 \rightarrow Li_xV_2O_5 + \frac{x}{2}\,I_2 \qquad (26)$$

$A_x^+(H_2O)_y[V_3O_8]^{x-}$ can be obtained from the ternary oxide $Li_xV_3O_8$ which show a limited redox range[113]. ε-$Cu_xV_2O_5$[114] yields on anodic oxidation in aqueous H_2SO_4 ε-$(H_3O^+)_{0.2}(H_2O)_y[V_2O_5]^{0.2-}$, which can be reversibly reduced in aqueous metal ion solutions to the hydrated phases ε-$A_x^+(H_2O)_y[V_2O_5]^{x-}$ $(0.2 < x < 0.8)$[115]. On cathodic reduction in A^+/(DMSO) the orthorhombic oxide chloride FeOCl forms solvated layered phases $A_x^+(DMSO)_y[FeOCl]^{x-}$ (A = alkali ion, H^+, $(CH_3)_4N^+$; $x = 0.1$—0.5)[116]. $Li_{0.5}FeOCl$ can be prepared by reaction of the oxide halide with butyllithium[117]. The thermal intercalation of metallocenes and of pyridine into the FeOCl lattice has been reported[117-119]. Analytical and mass spectrometric investigations on the reaction of pyridine with FeOCl to give $(py)_{1/3}FeOCl$ revealed the formation of bipyridyl and of chloropyridine; this would suggest a redox mechanism similar to that established for $MX_2(py)_{0.5}$ *(vide supra)* and a simultaneous topochemical modification of the host matrix[91]. On cathodic reduction of FeOCl in aqueous pyridinium solutions $(pyH^+)_x(py)_{1/3-x}[FeOCl]^{x-}$ is obtained ($x \approx 0.2$).

A large number of other layered materials exhibiting electronic conductivity have been described (metal chalcogenides, oxides, halides, carbides, nitrides, *etc.*[72]) and it is likely that many of them are potential candidates for topotactic redox reactions. Besides graphite, only few other host lattices are known so far which lead to products with inverse polarity $[Z]^{x+}A_x^-$ [eq. (2)]; interesting systems in this connection would be layered rare earth halides, *e.g.* PrI_2[72]—which is a metallic conductor $[PrI_2]^+(e)$ and should, in principle, be able to undergo electron/anion transfer reactions.

5. Linear Chain Systems

Relatively few studies have hitherto been devoted to host lattices with M_xX_y (M = metal, X = nonmetal) chains as the host lattice matrix. This is due, in part, to the low structural stability of one-dimensional elements and the ease of irreversible modification by chemical attack. Most investigations have concentrated on the transition metal trichalcogenides MX_3 (M = Ti, Zr, Hf, Nb, Ta; X = S, Se)[19,34]. The structure of $NbSe_3$ (Fig. 24) can be described geometrically by distorted $NbSe_6$ trigonal prisms sharing opposite trigonal faces to form $(NbSe_3)_\infty$ chains. The structures of the other compounds differ, in the main, with respect to the arrangement of the chains. Two of the chalcogen atoms are closer to each other with a X—X linkage, *i.e.* $M^{4+}X^{2-}(X_2)^{2-}$. The trichalcogenides can intercalate Li [eq. (27)] in organic electrolytes;

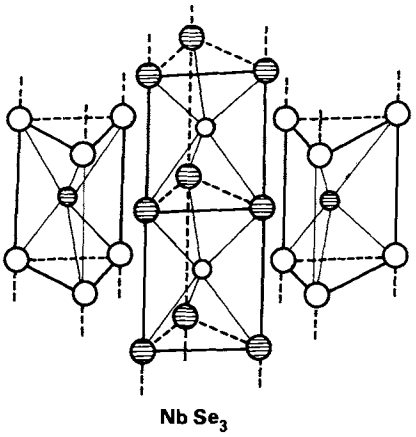

Fig. 24. Structure scheme of niobium triselenide with $(NbSe_3)_\infty$ chains. Large circles Se; small circles Nb.

$$x\,Li^{\oplus} + x\,e + MX_3 \rightarrow Li_x(MX_3) \qquad (27)$$

the reaction with *n*-butyllithium yields a maximum value of $x = 3$. Electrochemical studies on TiS_3 showed reversibility of the intercalation only for low values of x[63,120]. This has been attributed to irreversible attack at the polysulfide bridges which is probably associated with a change of the transition metal coordination from trigonal prismatic to octahedral coordination and with the formation of Li_2S. For $NbSe_3$, a larger reversibility range was observed; the higher stability of $NbSe_3$ may be related to the fact that Nb prefers trigonal prismatic coordination to octahedral coordination. Structural studies show strong line-broadening and extensive lattice disorder which is in part due to co-intercalation of solvent species.

The ternary alkali sulfides of iron $AFeS_2$ (A = K, Rb, Cs) consist of negatively charged chains built up of FeS_4 tetrahedra sharing opposite edges; the alkali ions occupy positions between the chains. Topotactic ion exchange of K^+ for alkaline earth ions in aqueos electrolytes has been reported[121]. The $AFeS_2$ structure contains vacant lattice sites between the chains, and in a recent electrochemical investigation the formation of Li_xKFeS_2 in organic Li^+ electrolytes was established with $x = 1$[122]. The initial reaction corresponds to a two phase region $KFeS_2/LiKFeS_2$ and the lattice symmetry changes from monoclinic to tetragonal. On subsequent oxidation/reduction cycling an extended nonstoichiometric phase region is found [eq. (28)]. X-Ray investiga-

$$LiKFeS_2 \rightleftarrows Li_{1-y}KFeS_2 + yLi^{\oplus} + ye \quad (28)$$

tions suggest a CuTe like structure for $Li_{1-y}KFeS_2$ ($0 \leq y \leq 0.75$). $Sr_{0.5}FeS_2$ and $Ba_{0.5}FeS_2$ also show reversible reactions with Li.

The structure of the niobium chalcogenide Nb_2Se_9 is also characterized by metal/sulfur chain elements[123]. Intercalation of Li with the formation of $Li_8Nb_2Se_9$ has been reported[124]. By thermal methods (iodine vapor transport) $NbSe_4I_{0.33}$ can be obtained; the iodine atoms are located between the $NbSe_4$ chains[125] and the structure may be described as $[NbSe_4]^{x+}[I_{0.33}]^{x-}$. It would be of interest to find out whether iodine is mobile in this compound, thus allowing topotactic electron/anion transfer [eq. (2)].

6. Hydrogen Bronzes and Electron/Proton Transfer

We shall here define hydrogen bronzes as solid compounds $H_x[Z]$ with electronic conductivity which contain mobile hydrogen atoms and are able to undergo reversible topotactic electron/proton transfer according to the formal scheme:

$$xH^{\oplus} + xe + [Z] \rightleftarrows H_x^{\oplus}[Z]^{x\ominus} \quad (29)$$

Hydrogen ions are the smallest guest ions available and strong pecularities are observed with respect to mobility, bonding and structural features as compared to other atomic and molecular guest ions. Because of their exceptionally small radius and consequent high charge density, protons polarize considerably their surrounding, which leads to partially covalent bonding to the host lattice. Besides line phases, large nonstoichiometric regions are frequently found; mixed metal cation/hydrogen bronzes may be obtained from electrolytes containing both H^+ and metal ions A^+ [eq. (30), Fig. 23].

$$xH^{\oplus} + yA^{\oplus} + (x+y)e + [Z] \rightleftarrows H_x^{\oplus}A_y^{\oplus}[Z]^{(x+y)\ominus} \quad (30)$$

A special type of reactivity is observed in the case of hydrogen bronzes with layered structure which may react as solid Brønsted acids with neutral or ionic Lewis bases [eq. (31), (32); Fig. 13].

$$H_x[Z] + L \rightleftarrows (LH^{\oplus})_x[Z]^{x\ominus} \quad (31)$$

$$H_x[Z] + xA^{\oplus} + xX^{\ominus} \rightleftarrows A_x^{\oplus}[Z]^{x\ominus} + xHX \quad (32)$$

(L = neutral Lewis base, *e.g.* H_2O, NH_3, pyridine; $X = OH^{\ominus}$, $NH_2^{\ominus}$, $OCH_3^{\ominus}$, *etc.*)

The first systematic studies were performed on H_xWO_3 and H_xMoO_3 by *Glemser*, who recognized the "genotypic" character and reversibility of the formation process[7, 126]. *Brénet et al.* and *Feitknecht et al.* observed a solid solution range H_xMnO_2 on the reduction of MnO_2[127, 128]. In recent years a considerable number of hydrogen bronzes have been prepared and characterized, most of them derived from transition metal oxides and chalcogenides with framework and layer structures (Table 4). Although the preparation of these phases is frequently possible by chemical reduction of the host lattice (*e.g.* Zn/HCl, N_2H_4, *etc.*) the most suitable way is the electrochemical technique (acid electrolytes), which also yields information on phase ranges and thermodynamic data and allows the convenient isolation of intermediates. Compounds with low stability at ambient temperature can be prepared by low temperature electrolysis in nonaqueous acid electrolytes. An indirect method of preparation for layered hydrogen bronzes is the dehydration of oxonium compounds $(H_3O^+)_x(H_2O)_y[Z]^{x-}$, which are readily accessible by ion-exchange with acids of the corresponding alkali phases (Fig. 13).

[a] 1T, 2H: stacking modifications of TaS_2.

Among the materials with framework host structures, tungsten(VI) oxide, which has a distorted ReO_3 type lattice, was studied in more detail. On reduction of WO_3 in aqueous HCl/Zn the color changes from faintly yellow to dark blue, with formation of H_xWO_3. The following nonstoichiometric phase ranges have been detected: tetragonal $0.15 < x < 0.23$, tetragonal $0.33 < x < 0.5$, and cubic $0.5 < x < 0.6$[7, 129]. Corresponding potential steps are found in potential/charge transfer curves on reduction of WO_3 in aqueous H_2SO_4; the upper composition limit on cathodic reduction is $x = 0.6$. Enthalpies of formation from $H_{2(g)}$ and $WO_{3(s)}$ at 298 K have been determined for $H_{0.18}WO_3$ (-4.8 kJ mol^{-1}) and $H_{0.35}WO_3$ (-9.6 kJ mol^{-1})[130]. Recent structural studies on the cubic phase show that the hydrogen atoms are attached to the WO_3 lattice by $-OH$ bonds[131].

The structurally related cubic oxide ReO_3 exhibits metallic conductivity and has been reported to yield a gold-colored orthorhombic hydrogen bronze $H_{0.15}ReO_3$ on reduction with ethanol or partial disproportionation in water[132]. Cathodic reduction of ReO_3 in aqueous H_2SO_4 was found to be reversible with an upper composition limit of $x = 0.8$; several potential steps occurring in the course of galvanostatic reduction indicate the presence of intermediate phases[115]. $BaRuO_3$, whose structure is also related to the perovskite type lattice, absorbs gaseous H_2 at room temperature to yield $H_{0.3}BaRuO_3$[133]; on (reversible) cathodic reduction of the ternary phase in 1 N H_2SO_4 the upper composition limit turns out to be $H_{0.4}BaRuO_3$[115]. Oxide hydrogen bronzes derived from host lattices with the more compact rutile type structure usually exhibit low x values except for H_xVO_2 and H_xMnO_2 (Table 4). Hydrogen bronzes of metal chalcogenides with framework structures seem to be rather unstable at ambient temperature; $H_{0.2}Ag_{0.7}Mo_6S_8$ can be prepared by cathodic reduction of $Ag_{0.7}Mo_6S_8$ at 230 K in CH_3OH/HCl electrolyte. The cluster halide Nb_6I_{11} is able to react with gaseous hy-

drogen to give HNb_6I_{11}; hydrogen is located inside the Nb_6 octahedra. The reaction seems, however, to be irreversible[134].

Of the hydrogen bronzes with layered structures H_xMoO_3 has been studied in most detail. Reduction of MoO_3 with *e.g.* Zn/HCl yields dark-blue bronzes. Four different phases have been reported: (I) blue orthorhombic $0.23<x<0.4$, (II) blue monoclinic $0.85<x<1.04$, (III) red monoclinic $1.55<x<1.72$ and (IV) olive green, $x=2$[126,135]. Electrochemical and X-ray studies revealed a strong influence of kinetics on oxidation and reduction[10,115]. On galvanostatic reduction of MoO_3 electrodes in 0.1 N H_2SO_4 a phase range of $0.25<x<0.5$ was observed for I; in the region $0.5<x<1.67$ potentials differ significantly from equilibrium values even at low current densities and a mixture of phases I, II and III is found. On reoxidation, however, pure phases III ($1.59<x<1.67$) and II ($0.94<x<1.01$) can be observed (Fig. 25). The reoxidation of phase I is kinetically hindered. The

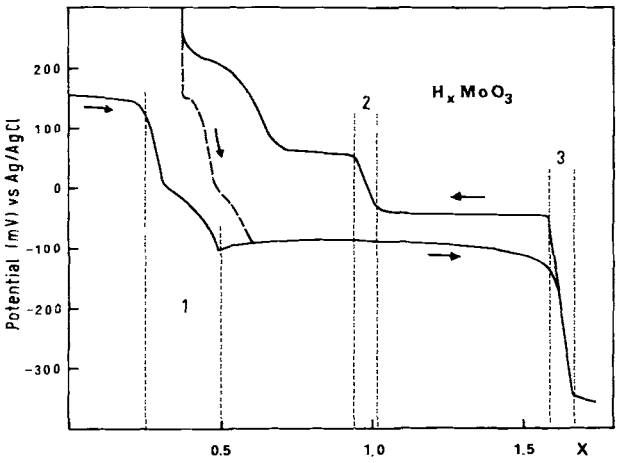

Fig. 25. Formation of H_xMoO_3 by cathodic reduction of MoO_3 in 0.1 M H_2SO_4: potential/charge transfer curve and phase diagram on reduction and reoxidation.

hysteresis found is fully reversible in the range $\approx 0.4<x<1.67$; it is obvious that structural reasons are responsible for this phenomenon. The line phase $H_{2.0}MoO_3$ can be obtained by cathodic reduction only in concentrated acid electrolytes. In the presence of metal ions mixed metal cation/hydrogen bronzes are formed[10] (Fig. 23). The enthalpies of formation of the four hydrogen bronzes H_xMoO_3 have been determined by solution calorimetry; the values (for formation from $H_{2(g)}$ and $MoO_{3(s)}$ at 300 K) are between -18.2 and -83.9 kJ mol^{-1}[136].

Elastic and inelastic neutron diffraction studies on $H_{0.3}MoO_3$ show hydrogen to be attached as —OH to bridging oxygen atoms within the MoO_3 layers, while peaks associated with —OH_2 groups appear in inelastic neutron scattering spectra of $H_{0.93}MoO_3$, $H_{1.86}MoO_3$, and $H_{2.0}MoO_3$[137,138].

H_xMoO_3 reacts as a solid Brønsted acid with Lewis bases (NH_3, N_2H_4, organic amines *etc.*) yielding the corresponding intercalation compounds [eq. (31)] with partially protonated bases, *e.g.* the pyridine compound of $H_{0.5}MoO_3$[10,108]:

$$(pyH^{\oplus})_x(py)_{0.3-x}[H_{0.5-x}MoO_3]^{x\ominus}$$

Neutralization with aqueous metal hydroxides leads in a reversible reaction to hydrated phases [eq. (32), Fig. 13][10,86]. The layered hydrogen bronzes $H_xMo_{18}O_{52}$, $H_xV_3O_8$ and ε-$H_xV_2O_5$ show analogous reactivity[108,113,115].

Hydrogen bronzes of layered transition metal dichalcogenides H_xMX_2 may be prepared either by cathodic reduction of binary chalcogenides in aqueous or nonaqueous solutions of strong acids [eq. (29)][12,30,139], or by dehydration of the oxonium compounds $(H_3O^+)_x(H_2O)_y[MX_2]^{x-}$[86]. Like the layered oxide bronzes they react as solid Brønsted acids with Lewis bases[85] and may form mixed metal cation/hydrogen bronzes.

Neutron diffraction and neutron scattering studies revealed characteristic differences for H position and bonding depending upon the coordination of the intralayer transition metal atoms in the host lattice. For 2H-TaS_2 and 2H-NbS_2 with trigonal prismatic environment of Nb and Ta hydrogen was found to be located *inside* the MX_2 layers in trigonal prismatic sites with hydrogen/metal four-center bonding[30] (Fig. 26). By way of contrast, in hydrogen bronzes derived from 1T-TaS_2 and TiS_2 with octahedral sites for Ti and Ta hydrogen is positioned close to the van der Waals gap approximately at the height of the sulfur atom planes[12].

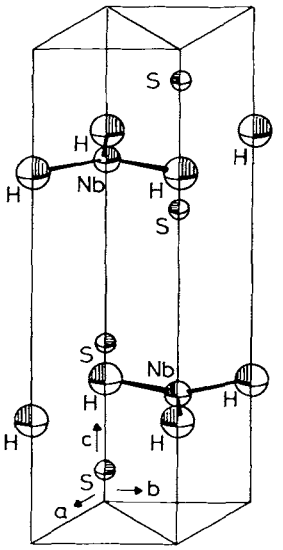

Fig. 26. Hexagonal unit cell of $H_{0.8}NbS_2$. Each hydrogen atom is bound to three Nb atoms in adjacent unit cells [30].

$H_{0.3}CrS_2$ and $H_{0.3}MoS_2$ (distorted MoS_2 lattice) are examples of metastable phases that can only be obtained from the corresponding ternary alkali sulfides A_xMS_2 *via* hydration and ion-exchange with acids[17,89]. Reversible electron/proton transfer in limited ranges correlated with partial protonation and deprotonation of guest cations is found for Lewis base intercalation compounds on oxidation and reduction[25,91], *e.g.*:

$$(pyH^{\oplus})_n(py)_m[TaS_2]^{n\ominus} + xe + xH^{\oplus} \rightleftarrows (pyH^{\oplus})_{n+x}(py)_{m-x}[TaS_2]^{(n+x)\ominus} \quad (33)$$

These systems, like the oxonium compounds, can be considered as solvated hydrogen bronzes.

Regarding the mobility of H in hydrogen bronzes, there is some disagreement on quantitative data in the literature. For polycrystalline samples of H_xWO_3 with $x<0.5$ a diffusion constant for hydrogen of $D=7\times10^{-6}$ cm^2 s^{-1} at 300 K with an activation energy $E_a=5.5$ kJ mol^{-1} was established by ^{1}H-NMR studies; rapid diffusion was reported even at 80 K[140]. Later ^{1}H-NMR studies on single crystals, however, showed lower values of $D\approx10^{-11}$ cm^2 s^{-1} and activation energies of 14—19 kJ mol^{-1} which seem to be more consistent with the proposed structures[131,141-143]. The lower diffusion coefficients were confirmed by inelastic neutron scattering data[131]. Similar values were established by electrochemical methods for H_xNiO_2 ($D\approx10^{-11}$ cm^2 s^{-1})[144]. For $H_{1.6}MoO_3$ an activation energy for H transport of 30 kJ mol^{-1} was found by NMR measurements[145]. Further data and a comparison of these with hydrogen mobilities in metal/hydrogen systems are urgently needed.

As regards their application, hydrogen bronzes are of present or potential future interest in several sectors: reversible electrode materials, electrochromic devices for nonemissive displays, heterogeneous catalysis, electrocatalysis (fuel cells, solar H_2O photolysis) *etc.* Some systems have been in use for a long time, *e.g.* manganese dioxide and nickel hydroxide as electrode materials in primary and secondary galvanic cells. In a simplified model, charge and discharge reactions can be described (for the topotactic range) by equations (34) and (35)[127,128,146,147]. Reversible deprotonation of intercalated H_2O molecules in hydrated layered nickel hydroxides may play an additional role.

$$MnO_2 + xH^{\oplus} + xe \rightleftarrows H_x[MnO_2] \quad (x_{max}\approx0.5) \quad (34)$$

$$H_{2-x}[NiO_2] + xH^{\oplus} + xe \rightleftarrows H_2[NiO_2] \quad (x_{max}\approx1.5) \quad (35)$$

Electron/proton transfer processes correlated with strong changes in color depending upon the oxidation state of the host matrix have been the subject of extensive studies in connection with their use as passive display devices[148]. The most promising system at the moment seems to be WO_3/H^+, which changes in color/bleaching cycles from faint yellow to dark blue due to the reversible formation of hydrogen bronzes:

$$WO_3 + xH^{\oplus} + xe \rightleftarrows H_x[WO_3] \quad (\text{yellow}\rightleftarrows\text{blue}) \quad (36)$$

The catalytic activity of H_xMoO_3 was first demonstrated in the reduction of NO by H_2[126]. H_xMoS_2 may play a role in hydrodesulfurization by activated MoS_2 catalysts. Studies on hydrogen spillover in metal/metal oxide systems have been reported[149], and the effect of hydrogen in TiO_2 photoanodes has recently been investigated[150]. It seems rather likely that in addition to interface reactions contributions of bulk topotactic electron/proton transfer processes play an important role in heterogeneous catalysis and electrocatalysis by semiconducting or metallic transition metal compounds. This is also the case for many related processes, *e.g.* corrosion, reduction of metal oxides by H_2 *etc.*; similarly, physical properties of solids may be altered significantly by small amounts of hydrogen in the lattice. Obviously, these aspects have not received adequate attention so far; one of the reasons for this is the fact that H concentrations and phase ranges in hydrogen bronzes can be very small and may thus escape detection by conventional analytical techniques.

A typical example for the important influence of minor amounts of hydrogen has been given lately in a study on the reaction mechanism of PbO_2 electrodes in lead acid batteries. The authors were able to show that the initial high current density observed on discharge is correlated with the formation of the hydrogen bronze H_xPbO_2, *i.e.* rapid electron/proton transfer in the solid phase[151] [eq. (37)]; x amounts to ≈0.02.

$$PbO_2 + xe + xH^{\oplus} \rightleftarrows H_x[PbO_2] \quad (37)$$

In conclusion it should be stated that investigation of the formation, reactivity, and properties of hydrogen bronzes is an attractive but largely undeveloped field which merits further systematic research both from the academic as well as the technological point of view.

7. Molecular Solids

We consider here molecular solids as lattices which consist of discrete neutral or ionic molecular units of low or medium molecular weight. They are characterized in general by low electronic conductivities and by modest lattice energies which consequently should prevent topotactic redox processes. Exceptions should be expected under the following conditions[155]: (a) extensive intermolecular electron delocalization, *e.g.* by charge transfer and metal d-orbital interaction[156,157], (b) small size of the guest ion resulting in minor steric perturbation of the host lattice and (c) appropriate intracrystalline diffusion pathways for guest ions with small activation energies. Obviously electron/proton transfer is thus expected to be the most likely type of reaction in molecular solids, though larger guest species have been found to intercalate.

Probably the earliest systems studied were solid oxygen-carrying metal chelates. [2,2'-Ethylenebis(nitrilomethylidine)diphenolato]cobalt(II) and substituted derivatives form red-brown crystals which turn black on exposure to air with reversible uptake of molecular oxygen[158-160]; depending upon the ligands, the cobalt/O_2 ratio is 2:1 or 1:1. The mode of stacking of the planar chelate molecules is such that large open channels are provided in one lattice direction for diffusion and location of oxygen. Cobalt(II) is oxidized on uptake of O_2, but the correct oxidation state has not yet been established. The cobalt chelates have been used for the generation of pure oxygen from air for welding purposes.

A large number of other planar metal chelates are known to have similar structures with columnar stacking of the complex units; their electronic conductivity parallel to the complex chains strongly increases on partial oxidation of the metal ions due to interaction between partially filled d-orbitals (one-dimensional metals and semiconductors). Bis(benzildioximato) complexes of nickel(II) and palladium(II) can be oxidized by halogens (Y=Br, I) to tetragonal columnar phases $[MR_2]Y$ with intermolecular metal-metal bonding; the halogen is located in channels parallel to the complex chains and is likely to be present principally as Y_3^- anions. Partial removal of the halogen under retention of the tetragonal lattice structure was observed over a large nonstoichiometric range for the bromine compounds [eq. (38); $z_{max}=0.8$]. Dynamic redox equilibria have been suggested

$$[MR_2]^{n\oplus}(Y)^{n\ominus} \rightleftarrows [MR_2]^{(n-x)\oplus}(Y_{1-z})^{(n-x)\ominus} + \frac{z}{2}Y_2 \quad (38)$$

for the lattice anions, *e.g.* $Y_2 + Y^- \rightleftarrows Y_3^-$[161]. One may assume that similar reactions will be observed for partially oxidized phthalocyanines[162]. It should be noted that phthalocyanines and related metal chelates have considerable electrocatalytic activity for oxygen reduction (fuel cells)[163] which may well be correlated to topotactic redox processes.

The migration of new phases from anode to cathode in applied electric fields has been observed on single crystals of the partially oxidized platinum complex salt $K_2[Pt(CN)_4]Br_{0.3}(H_2O)_{2.3}$, which has a columnar structure and behaves as a one-dimensional metallic conductor. Electron microprobe and X-ray analysis suggest the migration and discharge of Br^- to Br_2 at the anode with concurrent reduction of the metal[164]. Proton injection and reduction of the metal was found in a study on single crystals of $K_{1.46}[Pt(C_2O_4)_2](H_2O)_x$ under similar conditions. Solid state galvanic cells with electrodes of these materials using gelatine/HCl electrolyte produced open cell potentials of 0.33—0.52 V[165]. No details on structural changes have been reported.

Topotactic electron/proton transfer processes of tantalum halide cluster complexes and amminechloroplatinum complexes have recently been investigated[155]. The anodic oxidation of Magnus Green salt $[Pt(NH_3)_4][PtCl_4]$ electrodes in aqueous H_2SO_4 electrolyte proceeds in a two phase region. The structure of the tetragonal product can be described as consisting of chains of partially oxidized PtX_4 moieties with Pt—Pt bonding and hydrated HSO_4^- anions in the interchain space (Fig. 27). The compound shows a nonstoichiometric

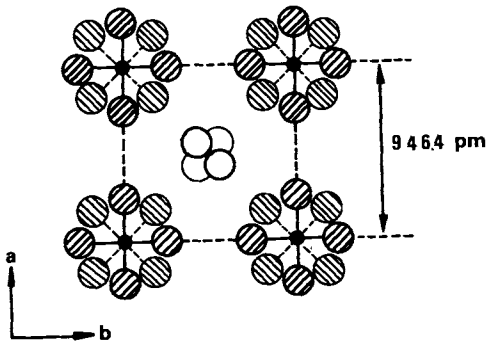

Fig. 27. Structure model of tetragonal $[Pt(NH_3)_4PtCl_4]^{0.5+}(H_{1.5}SO_4)^{0.5-}(H_2O)_y$ with partially oxidized PtX_4 chains and hydrated interchain anions (H_2O molecules not indicated). ● = Pt, ○ = O, ◍ = Cl, ◎ = NH_3.

phase region due to reversible electron/proton transfer [eq. (39), $0 \leq x \leq 0.1$]. Structurally related phases can be obtained

$$[Pt(NH_3)_4PtCl_4]^{0.5\oplus}(H_{1.5}SO_4)^{0.5\ominus}(H_2O)_y \rightleftarrows [Pt(NH_3)_4PtCl_4]^{(0.5+x)\oplus}(H_{1.5-x}SO_4)^{(0.5+x)\ominus}(H_2O)_y + xH^\oplus + xe \quad (39)$$

with other anions, *e.g.* BF_4^-, ClO_4^-, $H_2PO_4^-$ in the corresponding electrolytes; the isomeric Peyrones chloride *cis*-$Pt(NH_3)_2Cl_2$ reacts analogously.

The metal cluster halide $Ta_6Cl_{14}(H_2O)_8$ is able to undergo similar topotactic redox reactions in the solid state by anodic oxidation and cathodic reduction [eq. (40), $0 \leq x \leq 1.5$]. The accessible range for change of the oxidation state of Ta cor-

$$[Ta_6Cl_{14}](H_2O)_8 \rightleftarrows [Ta_6Cl_{14}]^{x\oplus}(OH^\ominus)_x(H_2O)_{8-x} + xH^\oplus + xe \quad (40)$$

responds to +2.33 to +2.58; proton transport is assumed to proceed *via* the hydrogen bond system that connects the cluster units. $Nb_6Cl_{14} \cdot 8H_2O$ may similarly be oxidized, but cathodic reduction is hindered for kinetic reasons[155].

Research on *organic molecular systems* with electronic conductivity has, in the last years, strongly centered on charge transfer complexes with columnar structures which behave as one-dimensional metals, *e.g.* tetracyanoquinone (TCNQ)/tetrathiofulvalene[157, 166]. Charge transfer complexes of this type have been studied as reversible galvanic cell cathodes; no structural data were reported[166, 167]. It is interesting to note, however, that water strongly influences the electrode processes. Recently, it could be demonstrated for the quinolinium salt of tetracyanoquinone that reversible electron/proton transfer may occur in these solids [eq. (41)][155].

$$(C_9H_7NH)^\oplus[(TCNQ)_2]^\ominus + xe + xH^\oplus \rightleftarrows (C_9H_7NH)^\oplus(H^\oplus)_x[(TCNQ)_2]^{(1+x)\ominus} \quad (41)$$

Semiconducting organic molecular solids with extended π bonding systems, *e.g.* dyes and salts of aromatic radical ions have been investigated with respect to their properties as electrochromic display materials[168]. There is little information on the reaction mechanism; since most of these systems are known to undergo electron/proton transfer in homogeneous solution[169], one may assume that this also holds for the solid state. The electronic conductivity of crystalline polyacetylenes has been shown to increase strongly by topotactic doping with oxidants[166, 170].

It has long been known that biological systems exhibit a degree of topological ordering on the molecular scale which is much higher than was originally assumed. Certain phenomena in living cells, *e.g.* energy conversion and storage, require fast electron/proton transfer over extended distances which is only possible in highly ordered domains; these processes may well be considered as topotactic redox reactions.

8. Fast Ion Transport and Molecular Dynamics

Interest in fast ion transport phenomena of cations and anions in solids at lower temperatures has focussed in the past decade essentially on insulator type electrolytes[171]. Systematic experimental research and theoretical studies[172] on electronic/ionic conductors have intensified only in recent years with the discovery of fast ion transport at room temperature in intercalation compounds of host lattices with alkali metals (Li, Na, K)[19, 34] as well as transition metals (Cu, Ag, Fe, Co, Ni, Zn)[10, 173]. NMR and electrochemical techniques have been used to obtain data for chemical diffusion coefficients and activation energies[28, 175]. For alkali ions in layered dichalcogenides A_xMX_2 the activation energies were found to depend upon the stoichiometric factor x, the site geometry of A^+ and the ionicity of the host structure[19]. Deviations from the ideal stoichiometry of the host lattice may strongly affect the guest ion mobility[33-35]. The existence of ordered domain structures has recently been proven by single crystal studies on Na_xTiS_2[32] and is also likely to occur in Li_xTiS_2[82, 83]. Chemical diffusion coefficients of 10^{-6} to

10^{-10} cm^2 s^{-1} in Li_xTiS_2 and Na_xTiS_2 were determined by electrochemical pulse techniques[33]. Electron microscopy and diffraction studies on Cu_xTaS_2 and Cu_xNbS_2 showed that the guest ions undergo order/disorder transformations which depend upon the Cu content; above $\approx$330 K the Cu ions behave as a two-dimensional liquid[81]. Chemical diffusion coefficients for Cu^+ in the solid solution range of $Cu_xMo_6S_8$ have been measured by the electrochemical pulse technique[44].

Regarding *molecular guest species,* investigations of the temperature dependent dynamics by NMR and inelastic neutron scattering may provide useful structural information. For the layered NH_3 intercalation compounds $TiS_2(NH_3)$ and $TaS_2(NH_3)$ strong anisotropic mobility of the guest molecules was found (Section 4, Fig. 20). Molecular diffusion and reorientation rates exceed 10^5 s^{-1} above 160 K; rotation about the C_3 axis of NH_3 continues down to $\approx$5 K with a rate of $\approx 10^8$ s^{-1}[95]. From inelastic neutron scattering data, an activation energy for translational motion of 9.6 kcal mol^{-1} could be derived[176]. A domain model for NH_3 diffusion in dichalcogenides has been proposed[174].

Extreme anisotropic mobility of water molecules at 300 K in monolayer hydrates $A_x^+(H_2O)_y[MX_2]^{x-}$ (A = alkali cation, M = Nb, Ta) was observed by ^{1}H-NMR studies[177]. The spectra show the calculated signal for an isolated two spin system which results from two-dimensional diffusion of H_2O in the interlayer space without activation of the rotation around the C_2 axis of H_2O (Fig. 28). The anisotropic motion

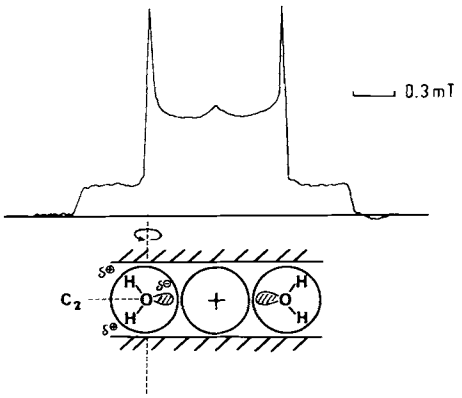

Fig. 28. ^{1}H-NMR spectrum of $K_{0.5}^+(H_2O)_{0.5}[NbS_2]^{0.5-}$ (integrated signal) at 290 K and below scheme of the orientation of H_2O molecules in the interlayer space.

is a consequence of the electrostatic interaction of the negatively charged $[MX_2]^{x-}$ layers with the positively polarized hydrogen atoms of water; the negative H_2O dipole ends are engaged in cation/dipole interaction with neighboring A^+ cations in the electrolyte layers. At temperatures of 370—420 K a single line spectrum is found indicating activation of the C_2 axis rotation; the transition to the rigid lattice at lower temperatures is dependent upon the hydration energy of the cations. pH-dependent structural changes in the two-dimensional electrolyte layers of hydrated chalcogenides have been investigated by H-NMR[12].

Proton spin-lattice relaxation time studies on $TaS_2(py)_{0.5}$ showed that the pyridine molecules form a rigid lattice with slow molecular motions up to 300 K[178]. Methyl group rotation down to low temperatures was observed by H-NMR techniques for monomethylpyridine intercalation compounds of TaS_2[179].

9. Physical Properties

The relationship between structural dimensionality and composition of solid compounds and the corresponding physical properties has been a major recent topic in solid state science. Extensive studies have been devoted particularly to anisotropy phenomena of quasi one-dimensional and two-dimensional systems[22,166]. An intriguing aspect in this context which has stimulated a great deal of research is the possibility of achieving systematic changes in physical properties of solids *via* topotactic redox reactions with conservation of the original host lattice structure.

Of the intercalation compounds of host lattices with two-dimensional structure, those of graphite have been widely studied[69,70] with respect to transport properties, electronic structure, optical properties, and lattice dynamics. Strong enhancement was found for basal plane conductivities σ_a in graphite on intercalation of acceptor host molecules. For $C_{16}AsF_5$ the conductivity $\sigma_a = 6 \times 10^{-5}\ \Omega^{-1}$ cm^{-1} exceeds that of copper metal, while the strong anisotropy is reflected in the ratio $\sigma_a/\sigma_c = 10^6$[180].

Marked anisotropy is similarly observed for layered dichalcogenides. Depending upon the nature of the guest species dramatic changes in the physical properties can occur. The intercalation of organic and inorganic cations in superconducting tantalum chalcogenides was found to strongly increase the critical temperatures T_c of the phase transition normal state/superconducting state[22,23]. The solvated alkali tantalum sulfides $A_x^+(solv)_y[TaS_2]^{x-}$ were shown to be superconducting polyelectrolytes[181]. The T_c enhancement was assumed to be related to the elimination of Fermi surface instabilities (charge density waves[182]) by the intercalation of guest species. Intercalated dichalcogenides are Type II superconductors and exhibit anisotropic critical field and current values; they represent the most anisotropic superconducting materials known. Measurements of magnetic proper-

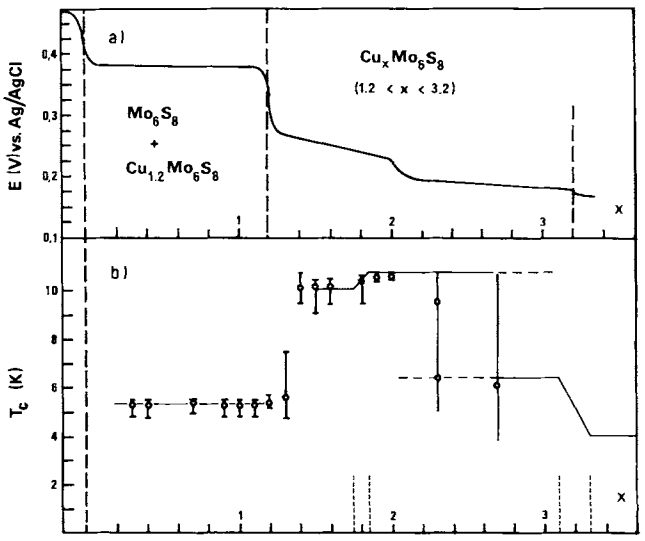

Fig. 29. Superconducting $Cu_xMo_6S_8$ phases prepared by reduction and oxidation of $Cu_2Mo_6S_8$. (a) potential/composition curve; (b) dependence of the critical transition temperature T_c on integral Cu content x [39].

ties and normal state conductivity also reveal strong anisotropy. The localization of the d-electrons in alkali metal compounds A_xMS_2 was found to increase in the series M = Ti, V, Cr[183]. Charge transfer to the host layers in dependence of type and concentration of the guest species has been studied by spectroscopic methods[22,83].

The correlation between composition, lattice parameter changes, electrochemical potential and superconducting transition temperatures of $Cu_xMo_6S_8$ prepared by electrochemical intercalation has recently been reported (Fig. 29)[39,43]. The structural transitions and T_c values were found to be close to those of samples obtained by thermal methods[36,42]. An increase in T_c of up to 7 K has been observed on the intercalation of K^+ ions into the empty lattice channels of Nb_3S_4[35].

10. Technological Application

Solids which undergo reversible topotactic redox reactions are of interest in several fields regarding application. One major area is the use of such systems as reversible cathodes for high energy density battery cells[34,46,63,67,184,185] *via* the formation of ternary phases with metal guest ions. It is obvious that topotactic battery electrode processes should be superior to electrode reactions correlated with the formation of new phases under complete structural reorganization. Basic requirements for cathode materials with topotactic reactivity are (a) high free energy of reaction, (b) little change in free energy over the composition range, (c) minor structural changes, (d) high mobility of the guest ions in the solid phase, (e) quantitative reversibility of the reaction, and (f) high electronic conductivity. Research has concentrated mainly on cells with Li anodes in organic electrolytes[26] because of the low specific weight of this element, the high mobility of Li^+ ions in host lattices, small structural changes on intercalation (small ionic radius of Li^+), and high free energies of formation of ternary phases with chalcogenides and oxides of transition metals in higher oxidation states (Table 5). Since higher maximum Li contents are usually observed

Table 5. Calculated energy densities of lithium organic cells with reversible topotactic cathode reactions.

Cathode	Energy Density (Wh/kg)
TiS_2	481
$V_{0.75}Fe_{0.25}S_2$	510
VSe_2	246
MoO_3	542
Cr_3O_8	940
MnO_2	530

for host lattices with two- and one-dimensional structures as compared to solids with framework structure, these have received favored attention. Examples of compounds which have been studied in more detail are the layered dichalcogenides MX_2[34], phosphorus sulfides MPX_3[104,105], transition metal trichalcogenides MX_3[120], and the oxides MoO_3[67], V_2O_5[63], Cr_3O_8[64], MnO_2[109], FeOCl[116,117].

Much work has been devoted to the development of Li/TiS_2 cells, since TiS_2 is the lightest in weight and the most economical among the layered dichalcogenides. The reaction $Li + TiS_2 \rightleftarrows Li_xTiS_2$ ($0 \leq x \leq 1$) takes place with a high free energy of formation of 206 kJ mol^{-1} and with little changes in lattice parameters and in free energy over the composition range (Fig. 30). The use of topotactic photointercalation electrodes for energy storage has been proposed recently[186].

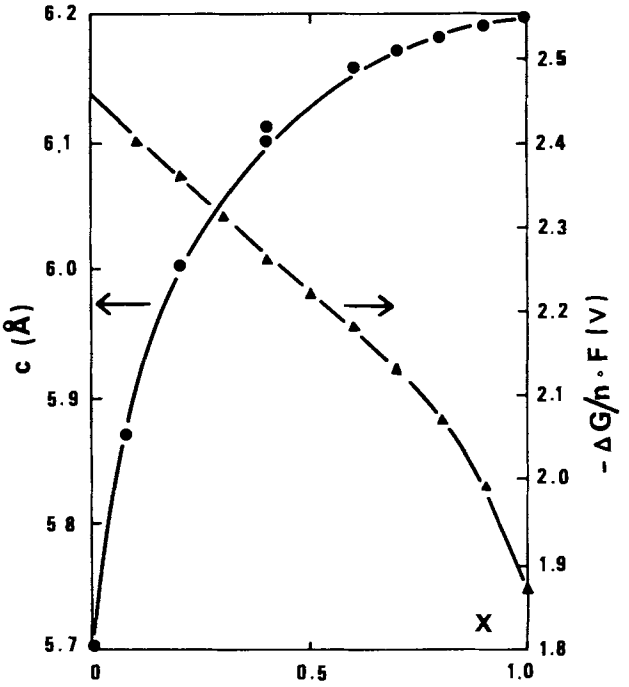

Fig. 30. Li_xTiS_2: variation of the hexagonal c axis lattice parameter and the partial molar free energy of formation with x [34].

The application of hydrogen bronzes and molecular organic solids liable to electron/proton transfer as nonemissive electrochromic display systems has been discussed in Sections 6 and 7.

Graphite donor and acceptor intercalation compounds have been studied because of their catalytic activity for a wide range of molecular reactions: NH_3-synthesis, reduction, oxidation, halogenation, polymerization and esterification of organic compounds, and Fischer-Tropsch synthesis[187]. Layered transition metal sulfides (MoS_2, WS_2) doped with Ni and Co are the major hydrodesulfurization catalysts in the petroleum industry; Ni and Co intercalation has been suggested to be involved in the catalytic activity. The formation of bipyridyl on the intercalation of TaS_2 and FeOCl with pyridine was shown to proceed at temperatures as low as 400 K[25,91]. Furthermore, it now seems likely that topotactic electron/proton transfer reactions may play an essential role in many heterogeneous catalytic and electrocatalytic processes (Section 6).

Graphite acceptor intercalation compounds with electronic conductivities higher than metallic copper have been already mentioned, as has also the strong increase in superconducting transition temperatures of layered and framework chalcogenides after intercalation; these two examples may suffice to illustrate further potential lines of future application of topotactic redox reactions *via* modification of materials properties.

11. Conclusions

In the present paper an attempt has been made to give an overview on a rapidly developing interdisciplinary field of research. The exciting variety of solid state redox reactions at room temperature and the corresponding changes in physical properties provide a wide and promising area for future research. Although the basic concept is clear now and presents a fairly consistent picture, extended systematic studies will be needed to elucidate particular points regarding *e.g.* the detailed description of changes in geometric and electronic structure in the course of topotactic redox reactions, the influence of lattice defects on kinetics, the temperature-dependence of transport properties, molecular dynamics and ordering states of guest species, thermodynamic correlations, and interfacial phenomena. The possibilities of a systematic "tailoring" of new metastable materials with unusual properties have been demonstrated and will certainly remain one important line of future investigations. It is also reasonable to predict that in addition to the systems already known, new ways for the practical application of solids with electronic/ionic conductivity will be perceived in the coming years.

With respect to his own contributions cited in the reference section the author is indebted to many co-workers for their support; this pertains also to the collaboration with several colleagues: Dr. J. O. Besenhard (Technische Universität München), Dr. A. Lerf (Institut für Tieftemperaturforschung Garching), Dr. C. Riekel (Institut Laue-Langevin Grenoble) and Dr. F. Sernetz (CERN Genf). The valuable experimental assistance of Herr K. Wagner is gratefully acknowledged. Thanks are also due to Prof. A. Weiss (Universität München), who succeeded many years ago to convince the author of the merits of research in solid state chemistry. Financial support has been provided by the Fonds der Chemischen Industrie, by the Ministerium für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Institut Laue-Langevin, Grenoble.

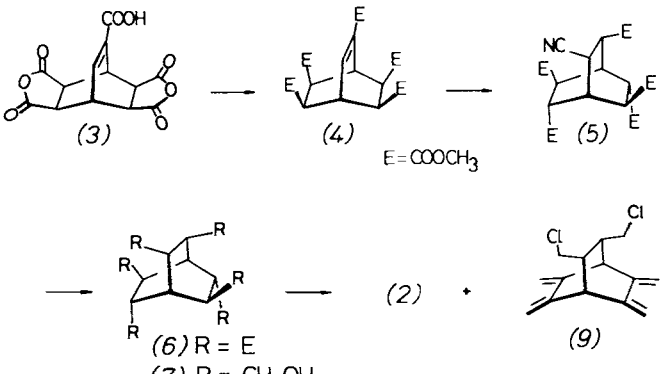
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

2,3,5,6,7,8-Hexakis(methylene)bicyclo[2.2.2]octane[**]



By *Olivier Pilet* and *Pierre Vogel*[*]

The 2,3,5,6-tetrakis(methylene)bicyclo[2.2.*n*]alkanes *(1)* have interesting spectroscopic[1] and chemical properties[2]. We report now the synthesis and a few properties of the hexaene *(2)*[3], a system ($D_3 \rightleftarrows D_3$ or D_{3h} symmetry) that occupies a place between barrelene[4] and triptycene[5].

Methyl bicyclo[2.2.2]oct-2-ene-2,3,5,6,7-pentacarboxylate *(4)* was obtained by heating a 3:1 mixture of maleic anhydride and coumalic acid to 200 °C without solvent, yielding *(3)* (65%)[6], followed by esterification (MeOH, $CHCl_3$, TosOH, 6 d, 87%). The all-*cis* configuration of the ester groups in *(4)* was indicated by $^3J_{H,H} = 2.0$ Hz between 2,6-H and 1 H and between 4-H and 3,5-H[7] and by $^3J_{C,H} \approx 2$ Hz between C-7, C-8 and 2,4,6-H and 1,3,5-H, respectively[8].

When *(4)* (50 g) was heated to 80 °C for 20 h with KCN (13 g), $(CH_3)_2C(OH)CN$ (13 g), and tetrabutylammonium cyanide (2 g) in dry CH_3CN (750 ml), *(5)* was obtained (>95%) which yielded the all-*trans* hexaester *(6)* (80% based on *(4)*) after hydrolysis (53 g in 500 ml 80% aq. AcOH + 15 ml H_2SO_4, 130 °C, 4 d) followed by esterification with MeOH ($CHCl_3$, TosOH). Reduction with $LiAlH_4$ (7 mol. equiv.) in THF (80 °C, 50 h) yielded *(7)* (41%). Chlorination with $SOCl_2$/pyridine (80 °C, 4 h) furnished *(8)* (45%). Treatment with potassium *tert*-butoxide (20 mol. equiv.) in THF (50 °C, 3 d) led to a 85:15 mixture (60%) of *(2)* and *(9)*. Compound *(2)* was isolated by fractional crystallization (hexane) as colorless crystals that polymerized upon heating under Ar.

(4): m.p. 137—138 °C; IR (KBr): 3010, 2970, 1740 cm^{-1}; ^{1}H-NMR (C_6D_6): $\delta = 2.54$ (dd, 3,5-H, $J = 10.4$, 2.0 Hz), 2.89 (dd, 2,6-H, $J = 10.4$, 2.0 Hz), 3.35, 3.37, 3.40 (s, 15H, CH_3OOC), 3.45 (m, 4-H, $J = 7.0$, 2.0 Hz), 3.99 (m, 1-H, $J = 2.1$ Hz), 7.79 (dm, 8-H, $J = 7.0$ Hz)

(6): m.p. 184—185 °C; IR ($CHCl_3$): 3010, 2960, 2860, 1740 (s), 1440, 1380, 1300 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 3.81$ (s, 18H), 3.71 (s, 2H), 3.13 (s, 6H)

(7): m.p. 290—294 °C; IR (KBr): 3330, 2960, 2940, 2900, 1480, 1450, 1380 cm^{-1}; ^{1}H-NMR (D_2O): $\delta = 1.33$ (m, 6H), 1.65 (m, 2H), 3.45 (m, 12H)

(8): m.p. 178—182 °C; IR (KBr): 3000, 2970, 2920, 1460, 1445, 1315, 1300 cm^{-1}; ^{1}H-NMR ($CDCl_3$): $\delta = 1.4$—2.0 (m, 6H); 3.3—4.0 (m, 12H); 5.13 (br. s, 2H)

Its structure was given by its spectra (Table 1) and its reactivity toward tetracyanoethylene (TCNE).

The UV absorption spectrum of *(2)* (Fig. 1) shows a relatively intense band at $\lambda_{max} = 247$ nm ($\varepsilon = 18\,500$) without the Franck-Condon fine structure usually observed for the rigid 2,3-bis(methylene)bicyclo[2.2.n]alkanes[9] and the tetraenes *(1)*[1a]. This suggests superposition of two allowed transitions of very similar energies (vibronic coupling?). The shoulder at $\lambda = 268$ nm might be due to the Franck-Condon contour of the lowest energy band or to a low intensity (perhaps symmetry forbidden) transition[10].

TCNE in excess added at 20 °C to *(2)*, gives the mono-, bis-, and trisadducts. Preliminary kinetic measurements gave $k_1 \approx 0.1$, $k_2 \approx 0.07$, and $k_3 \approx 0.0017$ l mol^{-1} s^{-1} at 27 °C in toluene. (Concerning the differences observed in the Diels-Alder reactivities, see[11].)

Oxygen Atoms Produced by Microwave Discharge: Reaction with Arenes[**]

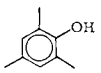
By *Elazar Zadok, Bonita Sialom*, and *Yehuda Mazur*[*]

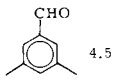
We recently found that ground state oxygen atoms produced by microwave discharge can be effectively used for preparative scale oxidations of unsaturated compounds in condensed phases[1].

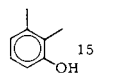
These oxidations involve passing O_2 or a mixture of N_2O and N_2 diluted with He in a flow system at 4 torr, through a microwave discharge and then onto the surface of a stirred substrate as neat liquid or in solution[1].

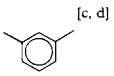
Using this method we have oxidized three mono- and three poly-substituted benzene derivatives (Table 1). The reactions were performed on 1—2 g of neat liquid substrate for 1—2 h, using O_2 discharge, and the conversions were *ca.* 30%. Products were identified after separation by preparative GC and their relative yields determined by analytical GC. The relative rates were established by reacting mixtures of substrates and comparison of the product yields. It was found that the product ratios were independent of reaction time.

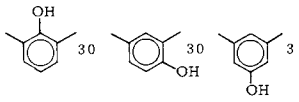
The products of these oxidations are mainly phenols derived from direct ring hydroxylation as well as from replacement of the substituent by the OH group. In the polymethylated arenes, minute amounts (less than 1%) of rearranged phenol products of 1,2-methyl migration were also formed. In addition, methyl substituents were partly oxidized to give benzyl alcohol and benzaldehyde or their respective derivatives. Similar products and in the same ratios were obtained when the source of ground state oxygen atoms was a mixture of N_2O and N_2.











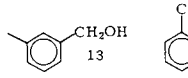


Table 1 shows that substituted arenes are hydroxylated mainly at the *ortho* positions, regardless of the size of the substituent. The substitution pattern and the relative rates for the ring substitution in the different substrates indicate that the ground state oxygen atom behaves as a radical reagent having a moderate electrophilic character[2].

The results of the oxidations in the condensed phase are similar to those obtained by *Grovenstein et al.*[3] in gas phase reaction, in which the ground state oxygen atoms were formed by photolysis of N_2O in the presence of Hg vapor[4]. A significant difference is, however, the absence in the gas

phase reaction of the rearranged phenols and of benzylic oxidation products[5]. Oxidation of naphthalene in solution with ground state oxygen atoms gave α- and β-naphthols in 7:1 ratio. The corresponding acetates were obtained in the same ratio when the reaction was performed in acetic anhydride in the presence of traces of sulfuric acid.

Experimental

Oxidation of naphthalene: A steady flow of O_2 and He (0.7 l/min, 7:1 ratio) at 4 torr was passed through a quartz U-tube containing a magnetically stirred methyl caproate solution of naphthalene (1 g in 5 ml). The side arm of the U-tube was connected by a gas discharge cavity to the microwave generator (Kiva MPG-2, 2450 MHz, 100 watt), which was placed 5 cm above the substrate surface. After reaction for 1 h at 5 °C the material was chromatographed on silica gel to give 600 mg starting compound, 280 mg of α-naphthol, 40 mg of β-naphthol, and small amounts of other oxidation products.

New Arene(dicarbonyl)chromium Chelates: Application to Asymmetric Synthesis of Amines

By *Arlette Solladié-Cavallo, Jean Suffert,* and *Jean-Luc Haesslein*[*]

We have found that arene(dicarbonyl)chromium chelates *(1a—d)* (synthetized by irradiation of arene(tricarbonyl)chromium complexes *(3a—d)* (Scheme 1) undergo, with alkyllithium compounds, nucleophilic addition on the azomethine carbon; hydrolysis of the intermediates then leads in good yields to the chiral amines *(2)* (Table 1).

(1a, b), n = 1,2 — *(1c)*

RLi / MeLi

$Ph-CH_2-(CH_2)_n-\underset{Ph}{\underset{|}{C}}R-NHPh$ — $Ph-(CH_2)_2-NH-\underset{Ph}{\underset{|}{C}}H-Me$

(2a), n = 1, R = Me
(2a'), n = 1, R = *n*Bu
(2b), n = 2, R = Me
(2c)

Table 1. Reaction conditions and yields of reactions of *(1)* with alkyllithium compounds.

Reactant (Chelate)	R in RLi	Reaction conditions T [°C]	t [h]	Yield [%]	Product (Amine)
(1a)	Me	0	16	98	*(2a)*
(1a)	*n*Bu	−30	15	40	*(2a')*
(1a)	1,3-Dithian-	0	15	0	—
	2-yl	50	10	0	—
(1b)	Me	0	16	60	*(2b)*
(1c)	Me	0	16	88	*(2c)*
(1*S*)-*(1d)* [1]	Me	0	16	98	*(2d)* [a]
(1*S*)-*(1d)* [1]	Me	−20	24	72	*(2d)* [b]

[a] $[\alpha]_D^{20} = -8.6$ ($c = 0.4$; $CHCl_3$); optical purity 77%, calculated with $[\alpha]_D^{20}$(max) $= \pm 11.2$. [b] $[\alpha]_D^{20} = -10.5$ ($c = 0.4$; $CHCl_3$); optical purity 94%, calculated as in [a].

A benzene solution of the chelate *(1)* is added dropwise, under argon, to a diethyl ether solution of the alkyllithium compound (see Table 1). Decomplexation occurs during work-up (H_2O/NH_4Cl), leading to the racemic amines *(2a–c)* which are purified by chromatography and identified by elemental analysis, mass spectra, IR, and ^{1}H-NMR (Table 2).

Chemical yields depend on reaction temperature but the absence of reaction with 2-lithio-1,3-dithiane may be ascribed mainly to steric hindrance.

When the optically pure chelate (1*S*)-*(1d)*[1] is used (Scheme 1), the amine *(2d)* obtained is up to 94% optically pure. Nucleophilic addition of alkyllithium compounds to the optically pure arene(tricarbonyl)chromium complexe (1*S*)-*(3d)* proceeds without asymmetric induction.

The new chelates *(1)* are good precursors of the chiral amines *(2)*; replacement of the phenyl groups on the azine methine function by alkyl groups or hydrogen should provide an efficient route to a large number of chiral amines.

Phosphorus Triiodide and Diphosphorus Tetraiodide, New Reagents for Deprotecting Acetals and Ketals[**]

By *Jean-Noël Denis* and *Alain Krief*[*]

On continuing our investigations on the reactivity of PI_3 and P_2I_4 towards organic molecules[1], we found that these reagents allow the transformation of ketals into aldehydes or ketones[2]. Only few nonaqueous deprotections have so far been reported for these protecting groups[3].

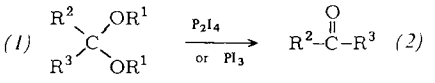

Table 1. Yields and conditions for reaction of aldehydes and ketones with P_2I_4 (method A) or PI_3 (method B).

R^1	R^2	R^3	Yield [%] [a]	Method	T [°C]	t [h]

61, rue de Bruxelles, B-5000 Namur (Belgium)

[**] The authors acknowledge award of a fellowship by Roussel Uclaf Company (France) to *J. N. D.* and financial support of this work by FNRS.

The reactions are particularly easy with dimethoxyalkanes *(1)*, $R^1 = CH_3$, which produce the corresponding carbonyl compounds *(2)* on stirring at room temperature for about 15 minutes in dichloromethane with 0.275 or 0.370 molar equivalent, respectively, of P_2I_4 (method A) or PI_3 (method B).

Work-up is usually performed by addition of water to the reaction medium, to solubilize the phosphorus by-products, and the organic phase is further extracted with water.

The diethoxyalkanes *(1)*, $R = C_2H_5$, are less reactive and require heating (60 °C, 2—4 h) to produce similar yields of *(2)* since appreciable amounts of intermediates, which decompose on heating, are formed at room temperature even in the case of ketones.

The behavior of ketals towards PI_3 or P_2I_4 differs from that of acetals: while the ketone is already present prior to the hydrolysis, the formation of the aldehyde requires the hydrolysis of an intermediate containing the phosphorus atom.

We also observed the concomitant formation of methyl- or ethyl iodide, depending on the nature of the starting ketal (≈ 0.8 mol per mol of protected carbonyl compound).

Water Gas Shift Reaction with the Aid of Selenium/Platinum Catalyst[1]

By *Nobuaki Kambe, Fumihiko Morimoto, Kiyoshi Kondo,* and *Noboru Sonoda*[*]

We recently reported[1] that carbon monoxide reacts with water and selenium in the presence of base to form selane (hydrogen selenide, H_2Se) and CO_2 [eq. (1)].

$$CO + Se + H_2O \rightarrow H_2Se + CO_2 \quad (1)$$

Meanwhile, we have found that selane (hydrogen selenide, H_2Se) decomposes to hydrogen and selenium on platinum black [eq. (2)].

$$H_2Se \xrightarrow{Pt} H_2 + Se \quad (2)$$

Reaction (2) was found to proceed smoothly at 200 °C, and at such a high temperature the reaction (1) did not require the presence of base. The combination of these two reactions (1) and (2) would thus provide a new system for the water gas shift reaction [eq. (3), Table 1].

$$CO + H_2O \xrightarrow{Se/Pt} CO_2 + H_2 \quad (3)$$

[*] Prof. Dr. N. Sonoda [+], Dr. K. Kondo [+], N. Kambe, F. Morimoto
Department of Petroleum Chemistry, Faculty of Engineering
Osaka University, Suita, Osaka 565 (Japan)
[+] Authors to whom correspondence should be addressed.

As shown by the control experiments using selenium or platinum black alone (runs 1, 7), both elements are necessary for catalytic formation of H_2 and CO_2. The experiment in run 1 corresponds to the reaction formulated in eq. (1). The conversion[3] of CO into CO_2 in run 4 after 20 h is 43%.

Table 1. Water gas shift reaction [a] catalyzed by selenium/platinum [a].

Run	Catalyst		Products	
	Se [mmol]	Pt [mmol]	H_2 [mmol]	CO_2 [mmol]
1	1	—	0.1	1.0
2	1	0.01	1.6	2.3
3	1	0.1	5.7	5.9
4	1	1	21.1	20.8
5	0.1	0.1	2.1	2.0
6	0.1	1	12.1	12.0
7	—	1	0.9	0.9

[a] See *Experimental* for reaction conditions.

The reaction of CO with H_2O in the co-presence of selane and platinum black under identical conditions likewise affords CO_2 and H_2 [eq. (4)].

$$CO + H_2O \xrightarrow{H_2Se/Pt} CO_2 + H_2 \quad (4)$$

Experimental

A) Water gas shift reaction (3), run 4 in Table 1: Metallic selenium (0.079 g, 1 mmol), platinum black (0.195 g, 1 mmol), and water (10 ml) are placed with a magnetic stirring bar in a glass tube inserted in a 50 ml stainless steel autoclave, and the apparatus is then flushed several times with carbon monoxide, and finally charged with CO at *ca.* 30 bar at room temperature. The reaction is carried out at 200 °C for 20 h with vigorous stirring. On completion of the reaction, the resulting gas is collected in a gas sampler and analyzed by gas chromatography: the resulting gas is found to consist of carbon monoxide (27.7 mmol), carbon dioxide (20.8 mmol), and hydrogen (21.1 mmol).

B) Decomposition of hydrogen selenide on platinum black (2): H_2Se (0.162 g, 2 mmol), platinum black (0.195 g, 1 mmol), and water (10 ml) are placed in the same apparatus as in (A) at room temperature under nitrogen (≈ 30 bar). After reaction at 200 °C for 1 h, 1.9 mmol of H_2 is found.

C) Water gas shift reaction (4): H_2Se (0.162 g, 2 mmol), platinum black (0.195 g, 1 mmol), and water (10 ml) are allowed to react at ≈ 30 bar as described in (A). The reaction is carried out at 200 °C for 20 h with vigorous stirring. The amounts of H_2 and CO_2 formed are 32.4 and 31.6 mmol, respectively.

Selenium-Catalyzed Reduction of Aromatic Nitro Compounds to Amines by CO/H_2O in the Presence of Triethylamine[1]

By *Toshiyuki Miyata, Kiyoshi Kondo, Shinji Murai, Tsuneaki Hirashima,* and *Noboru Sonoda*[*]

In the preceding paper[2] we described a new water gas shift reaction system using catalytic amounts of selenium and platinum black. In connection with this system, we now wish to report a new catalytic reduction of aromatic nitro compounds to aromatic amines with carbon monoxide and water in the presence of selenium and triethylamine [eq. (1)]. Examples are given in Table 1.

$$ArylNO_2 + 3CO + H_2O \xrightarrow{Se/Et_3N} ArylNH_2 + 3CO_2 \quad (1)$$

Table 1. Yields of isolated amines on Se-catalyzed reduction of nitrobenzenes according to eq. (1), based on nitrobenzene derivative.

No.	Aryl	Yield [%]
1	C_6H_5	86
2	p-$MeOC_6H_4$	40
3	p-ClC_6H_4	35
4	p-BrC_6H_4	25
5	p-MeC_6H_4	70

It is noteworthy that selenium, which is a main group element, catalyzes this reaction; until now however, only complexes of the transition metals rhodium[2,3], osmium[3], iridium[3], and iron[3] have been found to be effective catalysts for this reduction.

The yields of arylamines are moderate to good. The presence of triethylamine is essential for the reduction.

We have already reported two closely related reactions; (i) selenium/triethylamine catalyzed carbonylation of anilines with CO/O_2 to produce urea derivatives[4] and (ii) the selane/triethylamine promoted carbonylation of anilines with carbon monoxide to afford formanilides[5]. Under the present reduction conditions, subsequent carbonylation of aniline produced to diphenylurea was found to proceed only to a small extent; but the production of formanilide was not observed.

It is plausible that the most important reducing species in the present reaction system may be selane (hydrogen selenide, H_2Se)[6]. In a control experiment designed to test this assumption, reaction of nitrobenzene with selane under N_2 afforded aniline quantitatively [eq. (2)].

$$PhNO_2 + 3H_2Se \rightarrow PhNH_2 + 2H_2O + 3Se \quad (2)$$

Experimental

Freshly distilled nitrobenzene (1.23 g, 10 mmol), water (0.63 g, 35 mmol), metallic selenium (0.016 g, 0.2 mmol), and triethylamine (2.02 g, 20 mmol) in tetrahydrofuran (THF) (20 ml) are placed with magnetic stirring bar in a 50-ml stainless steel autoclave. The apparatus is then flushed several times with CO and charged with CO at 30 bar. The reaction is conducted at 80 °C for 5 h with vigorous stirring. After the reaction, CO is released and air is introduced into the reaction mixture to precipitate selenium. Filtration followed by evaporation gives a mixture of products shown by GLC analyses to contain aniline (0.80 g, 8.6 mmol) and diphenylurea (0.068 g, 0.34 mmol).

Photoreduction of Ketones and Aldehydes to Alcohols with Hydrogen Selenide[**]

By *Nobuaki Kambe, Kiyoshi Kondo, Shinji Murai,* and *Noboru Sonoda*[*]

Among the various photoreactions[1] of carbonyl compounds, the photoreduction of aldehydes and ketones is one of the best understood and, with few exceptions[2], usually affords 1,2-dihydroxy compounds[3]. We now wish to report the photoreaction of ketones and aldehydes with hydrogen selenide, H_2Se to give alcohols and selenium [eq. (1)].

$$\text{R, R'}{>}C{=}O + H_2Se \xrightarrow{h\nu} \text{R, R'}{>}C(OH)H + Se \quad (1)$$

Table 1. Reaction times and yields of photoreduction of carbonyl compounds according to eq. (1).

Carbonyl compound	t [h]	Yield [%]
Benzophenone	2	78 [a]
Acetophenone	0.33	98
Benzaldehyde	0.5	92
Cyclohexanone	18	93
Acetone	27	81
Cyclohexanecarbaldehyde	13	80
2-Acetonaphthone	3	70

[a] Accompanied by 7% of 1,1,2,2-tetraphenyl-1,2-ethanediol.

The photoreduction is achieved by irradiation of the substrates in tetrahydrofuran (THF) in a Pyrex reaction tube (15 °C/N_2); yields are good (Table 1).

The reduction of aryl-substituted carbonyl compounds proceeds more rapidly than that of alkyl-substituted carbonyl compounds. The following observations are important in relation to the mechanism of the early stage of this reduction. (i) H_2Se in THF has no absorption band in the 300–800 nm region; (ii) irradiation of H_2Se in the absence of carbonyl compounds in the same reaction apparatus used for the photoreduction causes no apparent change; (iii) acetophenone undergoes much slower photoreduction in the presence of diphenyl as a triplet quencher; (iv) 2-acetonaphthone, which is known to give π-π^* triplet on photoexcitation[2c,4], is reduced by H_2Se to 1-(2-naphthyl)ethanol in 70% yield (Table 1).

[**] Photoreaction of hydrogen selenide, Part 1.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/1212-1008 $ 02.50/0

Experimental

1-Phenylethanol: A well-degassed THF solution (3 ml) of acetophenone (30 mg, 0.25 mmol) in a Pyrex reaction tube is irradiated for 20 min by high-pressure mercury lamp (300 W) in the presence of H_2Se (0.45 mmol); selenium starts to deposit immediately. After oxidation of remaining H_2Se by introducing air into the reaction mixtures, metallic selenium is filtered off. The yield of 1-phenylethanol is 98% (GC and ^{1}H-NMR analyses).

Reduction of Carbonyl Compounds by Aluminum Telluride and H_2O or D_2O

By *Nobuaki Kambe, Kiyoshi Kondo, Satoru Morita, Shinji Murai*, and *Noboru Sonoda*[*]

Our studies on tellurium-catalyzed reaction of amines and carbon monoxide[1] led us to investigate hydrogen telluride as a potential intermediate. We found hydrogen telluride to have unique reducing ability toward carbonyl compounds. Thus reduction of benzaldehyde with hydrogen telluride proceeds at 0 °C under nitrogen to produce benzyl alcohol [eq. (1)].

$$PhCHO + H_2Te \xrightarrow{N_2,\ 0\,^\circ C} PhCH_2OH + Te \qquad (1)$$

Since the use of thermally unstable, air- and light-sensitive, gaseous hydrogen telluride requires troublesome experimental procedures, a convenient method has been developed for its *in situ* generation from aluminum telluride and water [eq. (2), Table 1].

$$\begin{matrix} R \\ \diagdown \\ C{=}O \\ \diagup \\ R' \end{matrix} + 1/3\ Al_2Te_3 + 2\ H_2O \longrightarrow \begin{matrix} R & H \\ \diagdown & \diagup \\ C & \\ \diagup & \diagdown \\ R' & OH \end{matrix} + Te + 2/3\ Al(OH)_3 \qquad (2)$$

Table 1. Isolated yields on reduction of carbonyl compounds with Al_2Te_3/H_2O (D_2O) [a].

The applicability of D_2O as deuterium source in the present reduction system is of vital importance, since all other deuterating reducing agents are extremely expensive. It is noteworthy that the reduction of α,β-unsaturated carbonyl compounds by H_2Te, generated *in situ*, proceeds in a highly selective manner[2] to the CC double bond [eq. (3), Table 2]; no allylic alcohols are detected in the products.

$$PhCH{=}CH{-}\overset{O}{\overset{\|}{C}}{-}R \xrightarrow[H_2O]{Al_2Te_3} PhCH_2{-}CH_2{-}\overset{O}{\overset{\|}{C}}{-}R \qquad (3)$$

Table 2. Isolated yields on the reduction of α,β-unsaturated carbonyl compounds with Al_2Te_3/H_2O.

R	Reactant: Al_2Te_3	*T* [°C]	*t* [h]	Yield [%] [a]
H	1:2	−15	0.3	89 (96)
Me	1:2	0	1	75 (90) [b]
Me	1:6	0	5	54 [c]
Ph	1:4	0	6	84

[a] Isolated yields; values in parentheses are yields determined by GLPC. [b] Accompanied by 2% of 4-phenyl-2-butanol (GLPC). [c] Together with 21% of 4-phenyl-2-butanol.

Experimental

A) Reduction of benzaldehyde with H_2Te[3]: H_2Te generated in a separate flask by the addition of a large excess of H_2O (2 ml) to Al_2Te_3 (2.19 g, 5 mmol) at 25 °C is introduced by a gentle stream of nitrogen into the reaction flask containing benzaldehyde (106 mg, 1 mmol) and tetrahydrofuran (THF, 10 ml) at 0 °C. Tellurium begins to deposit immediately. After 5 min, tellurium (0.29 mmol) is recovered by filtration, and the filtrate is shown by GLPC to contain benzyl alcohol (0.33 mmol) and benzaldehyde (0.67 mmol).

B) Reduction of benzaldehyde by Al_2Te_3/D_2O: D_2O (0.22 ml, 12 mmol) is added at −78 °C to a suspension of Al_2Te_3 (876 mg, 2 mmol) in THF (10 ml) containing benzaldehyde (106 mg, 1 mmol) with vigorous stirring. The temperature is raised to 0 °C in 30 min and maintained there for another 2 h. Filtration followed by evaporation of the solvent leaves essentially pure PhCHDOD (110 mg, 1.0 mmol) quantitatively.

It is noteworthy that nitrosobenzene gives hydrazobenzene as a major product while phenylhydroxylamine yields aniline quantitatively. This result might be taken to suggest that nitrosobenzene is not the intermediate in the reduction of nitrobenzene to aniline. Alternatively, however, the intermediacy of nitrosobenzene in the reduction of nitrobenzene is accommodated, if transiently formed nitrosobenzene undergoes rapid further reduction to give phenylhydroxylamine before the condensation[6] with phenylhydroxylamine. The reductions of both azoxybenzene and azobenzene by H_2Te afford good yields of hydrazobenzene, indicating that neither the azo nor the azoxy compound is the probable intermediate in the reduction of nitrobenzene.

Experimental

Powdered Al_2Te_3 (674 mg, 2 mmol), stored under N_2 in the dark, is added to a tetrahydrofuran (10 ml) solution of nitrobenzene (123 mg, 1 mmol) under N_2 at room temperature. Then the temperature is raised to 66 °C. To the vigorously stirred reaction mixture is slowly added an excess of water (0.43 ml, 24 mmol) dropwise by a syringe over a period of 40 min. The reaction mixture is refluxed for another 20 min and worked up. The yield of aniline is 90% (GC, ^{1}H-NMR, and IR).

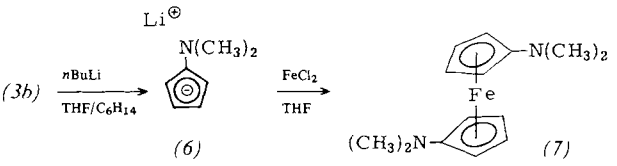
Electrophilic Amination of Cyclopentadienyllithium Compounds[**]

By *Michael Bernheim* and *Gernot Boche*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday



Although cyclopentadienyl compounds have found extraordinarily wide application as ligands of organometallic complexes and as synthons for natural products, *e.g.* prostaglandins, virtually nothing is known about cyclopentadienylamines[1]. We report here on the entry to this class of compounds by electrophilic amination of cyclopentadienyllithium compounds.

Reaction of cyclopentadienyllithium *(1)*[2] with *N,N*-dimethyl-*O*-(methylsulfonyl)hydroxylamine *(2)*[3] in tetrahydrofuran (THF) at −20 °C afforded *N,N*-dimethyl-1,3-cyclopentadienylamine *(3b)* in 47% yield (see Procedure).

From the ^{1}H-NMR spectrum of the $ABCX_2$-type [($CDCl_3$); $\delta = 2.90$ (s; 6H, $N(CH_3)_2$); 3.15 (m; 2H, H^5); 5.12 (mc; 1H, H^2); 5.77 (mc; 1H, H^4); 6.57 (mc; 1H, H^3)] it follows that the primary product of the amination *(3a)* is not present. An analysis of the apparently simple line shapes with the automatic program DAVINS[4] enabled assignment in favor of the isomer with the dienamine constitution *(3b)*[5]. Hydrolysis with a phosphate buffer (pH = 2) confirmed the spectral finding: Whereas *(3c)* should give exclusively 2-cyclopenten-1-one *(5b)*, a 94:6 mixture of 3-cyclopenten-1-one *(5a)* and *(5b)* is formed in 65% yield from *(3b)*[6,9]. It is still unclear whether the *(5b)*-part was formed from *(3b)*, *(3c)*, or by acid-catalyzed isomerization of *(3a)*[7].

Reaction with pentamethylcyclopentadienyllithium[10,2] instead of *(1)* affords *N,N*,1,2,3,4,5-heptamethyl-1,4-cyclo-

[*] Prof. Dr. G. Boche, Dipl.-Chem. M. Bernheim

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/1212-1010 $ 02.50/0

pentadienylamine *(4)* in 40% yield. In contrast to *(3a)*, *(4a)* cannot easily isomerize.

When a solution of *(3b)* in THF is allowed to react with *n*-butyllithium in hexane at −30 °C, the colorless *N,N*-dimethylaminocyclopentadienyllithium *(6)* precipitates out in almost quantitative yield [^{1}H-NMR ([D$_6$]-DMSO): $\delta = 4.90$ (mc; AA'BB' type; 4H, H^2—H^5); 2.40 (s; 6H, N(CH$_3$)$_2$)]. *(6)* is the first amino-substituted cyclopentadienide compound; it can be employed, *e.g.*, for the preparation of metallocenes. Thus, reaction with $FeCl_2$ in THF affords the dark-orange bis(dimethylamino)ferrocene *(7)*, m.p. 63—65 °C, in 55% yield [^{1}H-NMR ($CDCl_3$): $\delta = 2.55$ (s; 12H, N(CH$_3$)$_2$), 3.95 (mc, AA'BB' type; 8H, H^2—H^5, and H$^{2'}$—H$^{5'}$)]. To our knowledge, bis(dimethylamino) compounds of type *(7)* were hitherto unknown. We are currently investigating the chemistry of *(3b)* and *(6)*.

Procedure

A solution of *(2)* (4.17 g, 30.0 mmol) in THF (15 ml) was added at −20 °C to a solution of *(1)* [prepared from cyclopentadiene (2.52 ml, 30 mmol) and *n*-BuLi (20.1 ml, 30 mmol)] in THF (30 ml). After *ca.* 10 min the reaction solution turns cloudy. After 30 minutes' stirring at −20 °C the solvent was removed in a high vacuum at −20 °C and the residue digested with cold pentane. After filtration at −35 °C the pentane solution of *(3b)* was evaporated down in a high vacuum at −20 °C. There remained 1.53 g (47%) of a pale yellow oil. *(3b)* is extremely sensitive towards oxygen and water and decomposes within a few days even in the absence of air and moisture at −30 °C. MS (70 eV, direct sample introduction): $m/e = 109$ (100%, M^+), 108 (43), 94 (39, $M^+ - CH_3$), 58 (57), $(CH_3)_2N{=}CH_2^+$), 44 (74, $N(CH_2)_2^+$).

(6): A solution of *(3b)* (1.35 g, 12.4 mmol) in THF (10 ml) was treated at −30 °C with a solution of *n*-BuLi (10.0 ml, 15.0 mmol) in hexane, whereupon colorless *(6)* precipitated within 2 min. After 1 hours' stirring at −30 °C, *(6)* was filtered off under N_2 at room temperature, washed with pentane and dried in a high vacuum—the product turned light-brown in color. 1.32 g (93%) of *(6)* (dec. point 160 °C) was recovered. It immediately decomposes in air, but can be stored for weeks in a refrigerator in the absence of air.

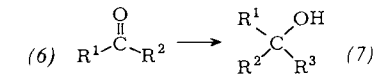
Chemo- and Diastereoselective Addition of Alkyl- and Aryltitanium(IV) Compounds to Aldehydes and Ketones[**]



By *Manfred T. Reetz, Rainer Steinbach, Jürgen Westermann*, and *Roland Peter*[*]

The addition of Grignard and alkyllithium reagents to carbonyl compounds is one of the important methods for C—C bond formation. However, it is known that aldehydes and ketones frequently react equally fast, thereby thwarting chemoselectivity[1], and that diastereoselectivity is limited[2]. As part of our studies concerning the use of alkyl- and aryltitanium(IV) compounds in organic synthesis[3], we have discovered that they (i) add smoothly to aldehydes and ketones, (ii) react with aldehydes faster than with ketones, and (iii) show high diastereoselectivity.

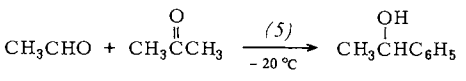
The reaction of methyltitanium trichloride *(1)*, dimethyltitanium dichloride *(2)*, methyltitanium triisopropoxide *(3)*, diphenyltitanium dichloride *(4)*, or phenyltitanium triisopropoxide *(5)* with carbonyl compounds *(6)* affords the alcohols *(7)* (Table 1)[4].

CH_3TiCl_3 *(1)* $(CH_3)_2TiCl_2$ *(2)* $CH_3Ti[OCH(CH_3)_2]_3$ *(3)*

(4) $(C_6H_5)_2TiCl_2$ $C_6H_5Ti[OCH(CH_3)_2]_3$ *(5)*

(6) → *(7)*

Table 1. Alcohols *(7)* by addition of titanium reagents *(1)*—*(5)* [4] to aldehydes and ketones *(6)* in dichloromethane.



Reactant	R^1	R^2	Titanium reagent [a]	*T* [°C]	*t* [h]	R^3	Product	Yield [%] [b]

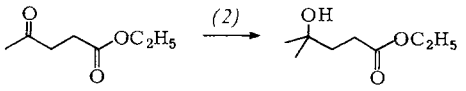
(6e)	Me	*n*Pent	*(3)*	22	48	Me	*(7f)*	0

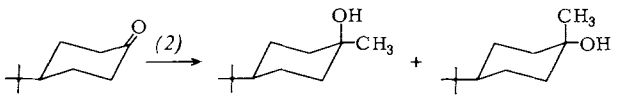
[a] In the reaction of *(2)* or *(4)* with aldehydes either 1:1 or 0.5:1 mixtures can be used, since both methyl or phenyl groups are transferred. In case of ketones 1:1 ratios are necessary. [b] Not optimized; the numbers given refer to conversion determined by NMR spectroscopy or gas chromatography. The values in brackets refer to isolated products.

Complete chemoselectivity is observed in the reaction of *(1)* or *(3)* with a 1:1 mixture of 3-methylbutyraldehyde *(6b)* and 2-heptanone *(6e)*. In each case the aldehyde adduct *(7b)* is the *sole* product (≈95% conversion). Similarly, *(5)* reacts with a 1:1 mixture of acetaldehyde *(8)* and acetone *(9)* to yield *(10)* (>90%) as the only addition product. In case of phenylmagnesium bromide a 1.5:1 mixture of *(10)* and $(CH_3)_2C(OH)C_6H_5$ is known to arise[5].



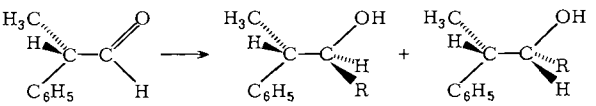
[*] Prof. Dr. M. T. Reetz, Dipl.-Chem. R. Steinbach, Dipl.-Chem. J. Westermann, R. Peter
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.



(8) (9) (10)

The reaction of levulinic acid ethyl ester *(11)* with *(2)* affords *(12)* (>90% conversion[6]), demonstrating that in such cases C—C bond formation occurs preferentially at the keto function.



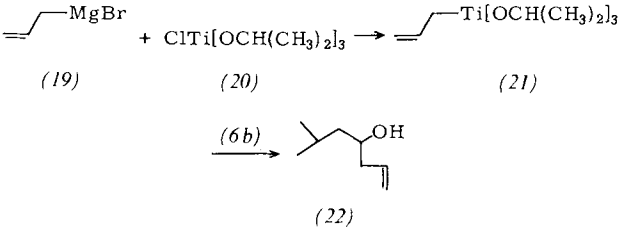
(11) (12)

Initial studies regarding diastereoselectivity in the addition of *(2)* to cyclic ketones were performed with 4-*tert*-butylcyclohexanone *(13)*. At −78 °C a mixture of the axial and equatorial alcohol *(14)* and *(15)* in a ratio of 82:18 (yield 92%) is formed. This is by far the best synthesis of *(14)*, since methylmagnesium bromide[7], dimethylmagnesium[7], and methyllithium[8] afford *(14)* and *(15)* with product ratios of only 60:40, 65:35, and 65:35, respectively.

(13) (14) (15)

The possibility of asymmetric induction in the addition of *(1)*—*(4)* to 2-phenylpropionaldehyde *(16)* was also investigated (Table 2). According to *Cram*, methyl- and phenylmagnesium halide[9] lead to the alcohols *(17a, b)* and *(18a, b)* with product ratios of 66:34 and ≈4:1, respectively[5]. Whereas *(4)* does not lead to an improvement (see Table 2), the diastereoselectivity in the addition of *(1)*, *(2)*, and *(3)* is remarkably high [*(17a)*:*(18a)* as 81:19, 80:20, and 88:12, respectively]. Such high values have not been previously found with any other organometallic compound[2,10]. A switch in solvent from dichloromethane to tetrahydrofuran has essentially no influence on the diastereoselectivity (Table 2).

(16) (17) (18)



(a), R = CH_3; *(b)*, R = C_6H_5

Table 2. Diastereoselectivity in the addition of titanium reagents *(1)*—*(4)* to 2-phenylpropionaldehyde *(16)* to form the alcohols *(17)* and *(18)*.

Titanium reagent	*T* [°C]	*t* [h]	Solvent	*(17)*:*(18)* [a]	R
(1)	−78	2	CH_2Cl_2	81:19	Me
(2)	−78	1	CH_2Cl_2	80:20	Me
(2)	−96	2	CH_2Cl_2	82:18	Me
(3)	[b]	4	CH_2Cl_2	88:12	Me
(3)	−10	2	CH_2Cl_2	85:15	Me
(3)	0	2	THF	88:12	Me
(4)	−78	0.5	CH_2Cl_2	80:20	Ph

[a] In all reactions, the conversion was >90%. [b] The reaction mixture was gradually allowed to warm up from −40 °C to 0 °C.

Finally, we note that a one-pot procedure starting from Grignard reagents is possible. For example, quenching allylmagnesium bromide *(19)* with chlorotitanium triisopropoxide *(20)* in tetrahydrofuran affords *(21)*[11], which reacts with 3-methylbutyraldehyde to form *(22)* (60% isolated).

(19) (20) (21) (22)

Typical procedure:

A cooled solution (−50 °C) of 2-phenylpropionaldehyde *(16)* (2.7 g, 20 mmol) in 50 ml of dry CH_2Cl_2 is added dropwise within 20 min to a mixture of dimethyltitanium dichloride *(2)*[4] (20 mmol) in CH_2Cl_2 (100 ml). After 1 h the mixture is poured onto ice water and treated with dilute HCl until the precipitate has dissolved. The organic phase is separated and aqueous phase extracted 3 times with CH_2Cl_2. The combined organic phases are dried over magnesium sulfate and the solvent removed. The crude product is studied by gas chromatography [*(17a)*:*(18a)* = 80:20] and distilled with a kugelrohr (80 °C/1 torr): 2.45 g (82%) of *(17a)*/*(18a)*[9].

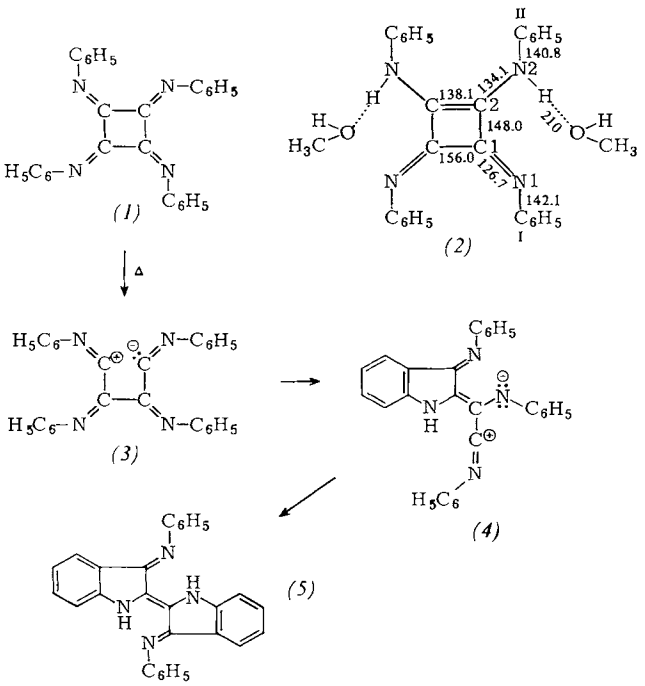
[9] *D. J. Cram, F. A. Abd Elhafez*, J. Am. Chem. Soc. *74*, 5828 (1952); slightly higher values are obtained depending upon the nature of the halogen in the Grignard reagent: *Y. Gault, H. Felkin*, Bull. Soc. Chim. Fr. *1960*, 1342.
[10] Our own experiments using a 1:1 mixture of Me_2Zn and $AlCl_3$ at −50 °C lead to *(17a)*/*(18a)* ratios of only 2:1.
[11] The precise nature of *(21)* in this reaction medium is not known since magnesium salts are present.

Thermal Rearrangement of Tetrakis(phenylimino)cyclobutane and Crystal Structure of Tetraphenylsquaramidine



By *Hans Jürgen Bestmann, Eberhard Wilhelm,* and *Günter Schmid*[*]

We recently reported the synthesis and crystal structure of tetrakis(phenylimino)cyclobutane (tetrameric phenyl isocyanide *(1)*[1]), which is readily reduced to tetraphenylsquaramidine *(2)* by alcohols. We have now found that besides polymeric phenyl isocyanide[2], also the blue indigo dianil *(5)*[3]

(m. p. 296—297 °C (dec.)), is formed on heating *(1)* to 150—200 °C in a high vacuum. One possible mechanism of rearrangement of *(1)* to *(5)* involves initial cleavage of a C—C bond in the cyclobutane ring to give *(3)*, which is then converted by twofold intramolecular, electrophilic aromatic substitution *via* the intermediate *(4)*, describable by several mesomeric forms, to *(5)*[4].

Furthermore, we have found that squaramidine *(2)* crystallizes from methanol with 2 moles of solvent of crystallization. According to X-ray structure analysis[5] the bond lengths and angles in the four-membered ring are comparable with those in other cyclobutene derivatives[6]. The four-membered ring, unlike that in *(1)*, is not completely planar. The greatest distance from the optimum plane is 6 pm for C2. The atom N1 lies 22 pm above, the atom N2 17 pm below this plane. If the nitrogen atoms are included in the calculation of the optimum plane, comparable values are obtained.—The C2—N2 bond is markedly shorter than a C—N single bond (average value 147 pm) and lies in the region of the C—N bond length in pyridine.

The phenyl groups are oriented at angles of 42° (phenyl I) and 34° (phenyl II), respectively, to the optimum plane of the four-membered ring. The two non-equivalent phenyl groups are at an angle of 70° to each other, while the two equivalent phenyl groups are almost parallel.

The two methanol molecules are oriented almost perpendicularly to the plane of the four-membered ring. The distance between H1 and O (210 pm) is indicative of hydrogen bonding. Owing to the C_2 symmetry the tetraphenylsquaramidine·2 methanol molecule has the structure given in Figure 1, suggesting the designation "man on the moon" molecule.

Synthesis under High Pressure: Michael Addition[**]

By *Kiyoshi Matsumoto*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The Michael reaction is perhaps one of the most important reactions in the field of organic synthesis due to its wide applicability. However, a variety of systems that do not undergo this condensation are known[1], although many improved methods, for example, employing enamines[2a], organolithium[2b] or organocopper[2c] compounds as carbanion sources and utilizing phase transfer reagents[2d] and organometallic complexes[2e] as catalysts have been reported. The factors responsible for the failure of the Michael condensation have not yet been investigated systematically. However, the presence of many substituents near the reaction center of the donor would appear to hinder both its deprotonation and the addition step[1].

[**] Molecular and Reaction Design Based on High Pressure Organic Reactions. Part 2. This work was supported by Research Grants from the Japanese Ministry of Education (Grant-in-aid, No. 284021 and 554146).—Part 1: *K. Matsumoto et al.*, Heterocycles *16*, No. 2, in press (1981).

I now report briefly high pressure assisted Michael addition[3], in which some of these difficulties can be overcome. As shown in Table 1, formerly unsuccessful Michael additions—except that of diethyl phenylmalonate—proceed in good yield when performed under pressure. The present reaction also appears amenable to asymmetric induction[4].

General procedure

Michael acceptor (3 mmol), donor (6 mmol), and triethylamine (0.5 ml) diluted with CH_2Cl_2 are placed in a 10 ml Teflon capsule and kept under hydrostatic pressure (*p* and *t*, see Table 1) at room temperature[5]. After evaporation of solvent and volatile materials at 15 torr, the products are isolated either by vacuum distillation or by chromatography.

Table 1. Reaction conditions and yields of Michael addition under high pressures at room temperature.

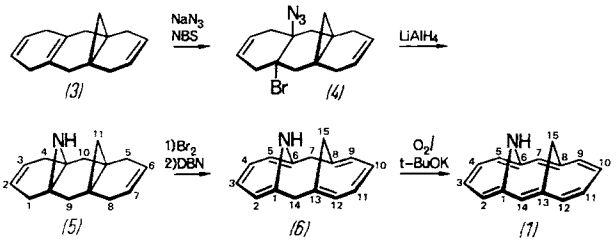
syn-1,6-Imino-8,13-methano[14]annulene

By *Emanuel Vogel, Ulrich Brocker,* and *Heinz Junglas*[*]



Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The versatile chemistry of 1,6-imino[10]annulene[1], dominated by a delocalized 10π-electron system (formation of substitution products[2]) and an azepine structural unit (production of 1*H*-1-benzoazepines and/or nitrenes[3]), has stimulated us to attempt the synthesis of the NH-bridged-[14]annulenes *syn*-1,6-imino-8,13-methano[14]annulene *(1)* and *syn*-1,6:8,13-bisimino[14]annulene *(2)*. Aromatic character can be predicted for both [14]annulenes, although the steric interaction of the bridges, which occurs in particular in the case of *(1)*, is likely to result in some bending of the annulene ring. The O-analogues of *(1)* and *(2)* have already been prepared[4]; we have now succeeded in synthesizing *(1)*.

(1) *(2)*

Reaction of the 1,4,5,8,9,10-hexahydro-4a,9a-methanoanthracene *(3)*[5] (obtainable by Simmons-Smith cyclopropanation of 1,4,5,8,9,10-hexahydroanthracene) with sodium azide and *N*-bromosuccinimide (Krief reagent)[6] (molar ratio 1:5:1.1) in dimethoxyethane/water at −15 to −20 °C gave a mixture of the *trans*-8aα-azido-10aβ-bromide *(4)*, the structural isomer *trans*-2α-azido-3β-bromide, and the hydrocarbon 1,4,9,10-tetrahydro-4a,9a-methanoanthracene [aromatization product of *(3)*]. Since losses are high in the isolation of *(4)*, the crude mixture was treated at −20 °C in tetrahydrofuran (THF) with $LiAlH_4$ and the reaction product worked-up by chromatography on aluminum oxide, first with hexane (separation of 1,4,9,10-tetrahydro-4a,9a-methanoanthracene) and then with hexane/dichloromethane. In this way an aziridine was obtained which on the basis of NMR spectroscopic and chemical findings proved to be *(5)* [colorless prisms (from ethanol), m.p. 67—68 °C; yield 13%]. The arrangement of the azide- and bromo-substituents in *(4)* conformed with the expectation that the, presumably ionic, addition of the Br/N_3 unit to the tetrasubstituted double bond of *(3)*, effected by the Krief reagent, is sterically controlled by the cyclopropane ring.

(3) *(4)* *(5)* *(6)* *(7)*

Reaction of *(5)* with two equivalents of bromine at −78 °C in dichloromethane afforded almost quantitatively a tetrabromide, which could be dehydrohalogenated with 1,5-diazabicyclo[4.3.0]non-5-ene in THF (room temperature 48 h) to *(6)*. Purification by chromatography on florisil and sublimation in vacuum afforded *(6)* as a lemon yellow, finely-crystalline solid (dec. above 75 °C; yield 26%). From the ^{1}H-NMR spectrum of *(6)* the resonances of the protons of the azepine structural unit—AA'BB'-system at relatively high field [δ = 5.13 and 5.93 (H-2,5 and H-3,4, resp.)] and broad singlet of the imino proton (δ = 3.33)—are underscored, for *(6)* is possibly the first 1*H*-azepine[7] without a substituent on the nitrogen. Attempts to dehydrogenate *(6)* to the NH-bridged annulene *(1)* with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone or noble metal catalysts were unsuccessful, yet such a conversion could be effected with potassium *tert*-butoxide/oxygen in THF (−5 to −10 °C, 30 min). Chromatography on aluminum oxide (hexane/dichloromethane 4:1) and recrystallization from ethanol furnished the air-stable *(1)* as brick red needles; m.p. 149—150 °C, yield 36% (for spectral data of *(1)*, *(5)*, *(6)*, and *(7)* see Table 1).

Table 1. Spectral data of compounds *(1)*, *(5)*, *(6)*, and *(7)*. C- and H atoms in *(7)* were numbered as in *(6)*.

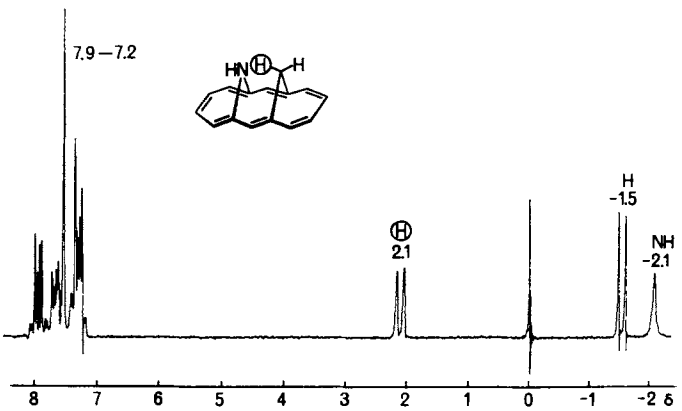
(1): ^{1}H-NMR (CCl_4): δ = −2.07 (br. s, N*H*), −1.52, 2.08 (AX, J_{AX} = 10.2 Hz, H-15$_{exo}$, H-15$_{endo}$), 7.45 (s, H-7,14), 7.23, 7.58 (AA'BB', H-2,3,4,5), 7.23, 7.87 (AA'BB', H-9,10,11,12); UV (EtOH): λ_{max} = 284 nm (ε = 30200), 314 (57100), 375 (9500), 518 (860); IR (CsI): 3330 cm^{-1} (N—H), 3055 (—C—H); MS (80 eV): *m/e* = 207 (*M*$^+$, 100%), 206 (53), 204 (34), 191 (24), 178 (32)

(5): ^{1}H-NMR (CCl_4): δ = 0.12 (br. s, N*H*), 0.24, 1.71 (AX, J_{AX} = 3.0 Hz, H-11$_{exo}$, H-11$_{endo}$), 1.68, 2.16 (AB, J_{AB} = 14.1 Hz, H-9,10), 1.82—2.43 (m, H-1,4,5,8), 5.45 (m, H-2,3,6,7); IR (CCl_4/CS_2): 3290 cm^{-1} (N—H), 1655 (C=C)

(6): ^{1}H-NMR ($CDCl_3$): δ = 1.95, 3.38 (AX, J_{AX} = 12.3 Hz, H-15$_{exo}$, H-15$_{endo}$), 2.93, 3.13 (AB, J_{AB} = 12.6 Hz, H-7,14), 3.33 (br. s, N*H*), 5.13, 5.93 (AA'BB', H-2,3,4,5), 6.03, 6.50 (AA'BB', H-9,10,11,12); UV (*n*-hexane): λ_{max} = 255 nm (sh, ε = 5550), 360 (sh, 170); IR (CsI): 3390 cm^{-1} (N—H), 1648 (C=C)

(7): ^{1}H-NMR ($CDCl_3$): δ = 1.48, 3.40 (AX, J_{AX} = 12.0 Hz, H-15$_{exo}$, H-15$_{endo}$), 3.27, 3.77 (AB, J_{AB} = 16.8 Hz, H-7,14), 3.38 (br. s, N*H*), 5.32, 6.13 (AA'BB', H-2,3,4,5), 6.07, 6.57 (AA'BB', H-9,10,11,12); UV (EtOH): λ_{max} = 269 nm (ε = 3380), 336 (sh, 355); IR (CsI): 3350 cm^{-1} (N—H), 1657 (C=C)

syn-1,6-Imino-8,13-methano[14]annulene *(1)* was recognized by its ^{1}H-NMR spectrum (see Fig. 1) as an aromatic compound. The resonances of the annulene protons—two partially superposing AA'BB' systems and a singlet—appear at relatively low field, while those of the exo CH_2- and the NH-bridge protons are observed at relatively high field. That the *endo*-CH_2-bridge proton is strongly deshielded—the difference in the chemical shifts between the two CH_2-protons is 3.6 ppm!—might be due to a considerable part to its steric interaction with the spatially very close NH-group (van der Waals effect)[8].



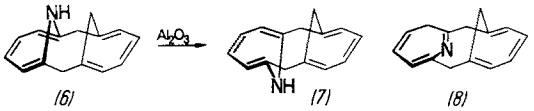


Fig. 1. 90-MHz ^{1}H-NMR spectrum of *syn*-1,6-imino-8,13-methano[14]annulene *(1)* (in CCl_4, TMS as internal standard).

Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

The NH-bridge proton is assigned the *exo* position with a high degree of certainty on the basis of its resonance at relatively high field. If this proton were to be in the *endo* position, then it would not only have to be markedly deshielded as a result of the H—H compression but also show a—not-present—nuclear Overhauser effect. Since the steric arrangement of the NH proton in *(1)* is of topical interest, in view of the much discussed problem of the relative sizes of the free electron pair and the H atom on the trigonal imino nitrogen[9], the assignment should be confirmed by an X-ray structure analysis.

The electronic spectrum of *(1)* has the same form as that of *syn*-1,6:8,13-bismethano[14]annulene, but the short-wave main absorption band shows a splitting, whose cause might be attributed to an interaction of the nitrogen electron pair with the 14π-electron system. Consistent with this explanation, the spectrum of the *N*-acetyl derivative[10] is almost superimposably identical with that of the hydrocarbon.

(6) *(7)* *(8)*

The dihydro[14]annulene *(6)*, characterized by its 1*H*-azepine structural unit, surprisingly isomerizes on chromatography on aluminum oxide (hexane/dichloromethane) to the *anti*-isomer *(7)*, whose structure is proven beyond doubt by the spectral similarity with *(6)* and by an X-ray structure analysis. The obvious idea of a thermal change of conformation can be ruled out, since *(6)* remains completely unchanged even on prolonged heating at 100 °C (in benzene). It may therefore be assumed that the *syn-anti* isomerization of *(6)* is brought about by Al_2O_3-catalyzed prototropic shifts *via* the 3*H*-azepine tautomer *(8)* of *(6)*/*(7)*.

An easy prototropy of *(8)* with formation of *(7)* or regeneration of *(6)*—first example of a reversal of a 1*H*-azepine/3*H*-azepine isomerization[11]—is readily explained by the relatively high strain of *(8)* (violation of the Bredt rule).

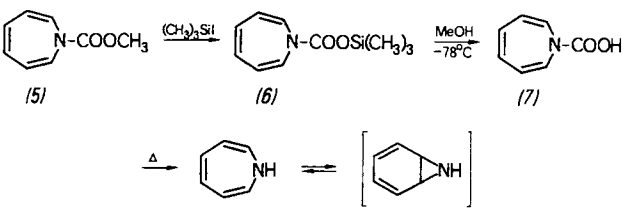
1*H*-Azepine: NMR Spectroscopic and Chemical Characterization

By *Emanuel Vogel, Hans-Josef Altenbach, Jakob-Matthias Drossard, Hans Schmickler*, and *Hartmut Stegelmeier*[*]

Dedicated to Professor Ralph A. Raphael on the occasion of his 60th birthday

1*H*-Azepine *(1)*, which was first generated by *Hafner*[1] by hydrolysis of ethyl 1*H*-azepine-*N*-carboxylate with potassium hydroxide and acidification of the resulting potassium salt of the acid *(7)*, has hitherto defied all attempts at detailed characterization owing to its high chemical reactivity[2]. Hence, the assumption, chiefly based on theoretical calculations, that *(1)* is thermodynamically much more favored[3] than the valence-tautomeric benzene imine *(2)* has long been awaiting experimental confirmation.



(1) *(2)*

The relative stability of the 1*H*-azepine and benzene imine derivatives *(3)*[4] and *(4)*[5] in neutral medium promted us to attempt the isolation of *(1) via* trimethylsilyl 1*H*-azepine-*N*-carboxylate *(6)*, which is readily accessible by reaction of the ester *(5)* with iodotrimethylsilane[6] in chloroform (room temperature, 24 h; b.p. 63 °C/0.02 torr, yield 71%).

(3) *(4)*

When a solution of *(6)* (3.14 g, 15 mmol) in pentane (10 ml) is treated with methanol (1.2 ml, 30 mmol), the carbamic acid *(7)*[7a] begins to precipitate within a few minutes; after 12 hours precipitation is complete. Subsequent washing with cold ether and drying for 12 h at 0.1 torr affords 1.5 g (74%) of pure *(7)*, a bright-yellow solid which is stable for a several days at −78 °C.

(5) *(6)* *(7)*

(1) *(2)* (<1%)

Decarboxylation of *(7)* in an NMR sample tube under the following conditions yields NMR spectroscopically pure 1*H*-azepine *(1)* (in solution): a solution of *ca.* 25 mg of *(7)* in 0.6 ml $CDCl_3$, prepared at −60 °C, is allowed to warm to

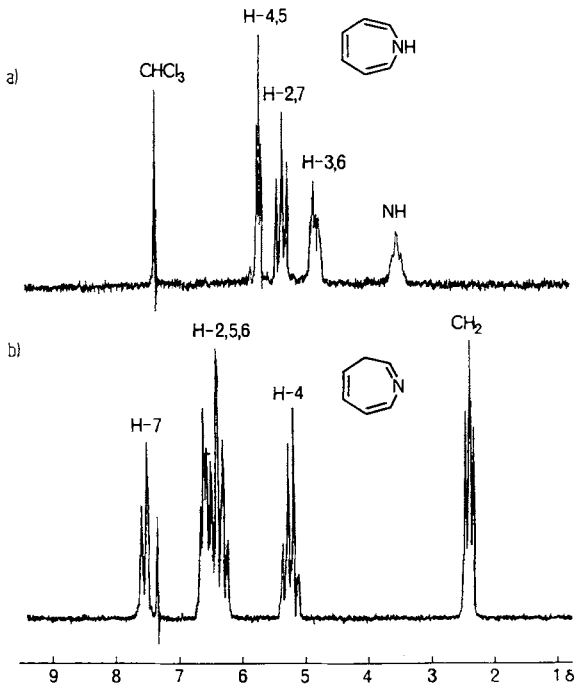
Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)



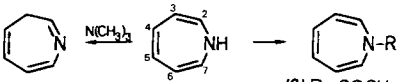


Fig. 1. ^{1}H-NMR spectra (90 MHz) of a) 1*H*-azepine *(1)* (−60 °C) and b) 3*H*-azepine *(8)* (32 °C) (in each case in $CDCl_3$, TMS as internal standard).

room temperature (duration 30—60 s); an intense red coloration is accompanied by gentle evolution of CO_2. The solution is cooled again to low temperature and the NMR spectrum of the sample is measured. Even at −78 °C *(1)* is stable for only a few hours in this solution[8].

Proof of the presence of 1*H*-azepine *(1)*— and of its existence as a seven-membered ring valence tautomer—is based on analysis of the ^{1}H- and ^{13}C-NMR spectra. The ^{1}H-NMR spectrum (Fig. 1), which is temperature independent in the range measured (−120 to −30 °C), and which could be assigned, partly by comparison with the spectrum of *(3)*, partly by double resonance experiments (localization of H-2,7 by irradiation at the frequency of the NH proton) affords the following arguments in favor of *(1)*: i) the chemical shifts of H-2,7 and H-3,6 correspond to those of the α- and β-protons, respectively, in enamines such as *N*-methyl-4,5-dihydro-1*H*-azepine[9a]; ii) the vicinal H—H coupling constants $J_{2,3}$, $J_{3,4}$ and $J_{4,5}$ are in good agreement with those of cycloheptatriene. This finding provides useful information, in that $J_{3,4}$ and $J_{4,5}$ change in the same characteristic way on going from *(1)* to *(4)* as in the transition from cycloheptatriene to the norcaradiene model tricyclo[4.3.1.0^{1,6}]deca-2,4-diene[9b].

The ^{1}H-NMR parameters, particularly the vicinal H—H coupling constants, although supporting the presence of *(1)*, are, however, too insensitive to allow detection of less than 10% of *(2)*. More accurate information about the position of the equilibrium *(1)*⇌*(2)* is provided by the likewise temperature independent ^{13}C-NMR spectrum which, in agreement with the symmetry of *(1)* and *(2)*, only comprises three resonance signals. As shown in Table 1, this spectrum is completely analogous to that of oxepin (at −134 °C) and—taking into account the influence of the electronegativity and resonance effect of the N atom on the chemical shifts—also with that of cycloheptatriene. Decisive for the detection of a small equilibrium concentration of *(2)* is the signal of C-2,7, since on the basis of the situation with cycloheptatriene/tricyclo[4.3.1.0^{1,6}]deca-2,4-diene and with oxepin/benzene oxide it may be assumed that *(1)* and *(2)* differ by no less than 80 ppm in the chemical shifts of C-2,7. From the finding that this signal clearly appears in the absorption region of olefinic protons and, on lowering the temperature of measurement to −120 °C, is neither shifted nor shows coalescence phenomena, the maximum amount of *(2)* at equilibrium can be reliably estimated as below 1%. 1*H*-Azepine *(1)* is thus in fact to be regarded, in agreement with prediction, as a practically uniform seven-membered ring valence tautomer.

Characteristic of the chemical behavior of 1*H*-azepine *(1)* is its ready tautomerization, usually accompanied by formation of polymers, by catalytic amounts of acids or bases (preferably trimethylamine) to the colorless 3*H*-azepine *(8)*, whose structure and uniformity is confirmed by the ^{1}H-NMR spectrum (double resonance experiments) (see Fig. 1). 3*H*-Azepine exhibits a somewhat smaller tendency to polymerization than *(1)*, so that it can be distilled in vacuum albeit with high losses[7b]. By reaction of *(1)* with ketene and with methanesulfonyl chloride/triethylamine it was possible to obtain *N*-acetyl-1*H*-azepine *(9)* (yield 20%) and *N*-methanesulfonyl-1*H*-azepine *(10)*, respectively[10] (yield 15%). Reaction with trimethylsilyl trifluoromethanesulfonate afforded the relatively stable, red *N*-trimethylsilyl-1*H*-azepine *(11)*[7c], which became only recently preparatively accessible by pyrolysis of the *N*,*N*′-disilyl derivative of 13,14-diazatricyclo[6.4.1.1^{2,7}]tetradeca-3,5,9,11-tetraene[12].

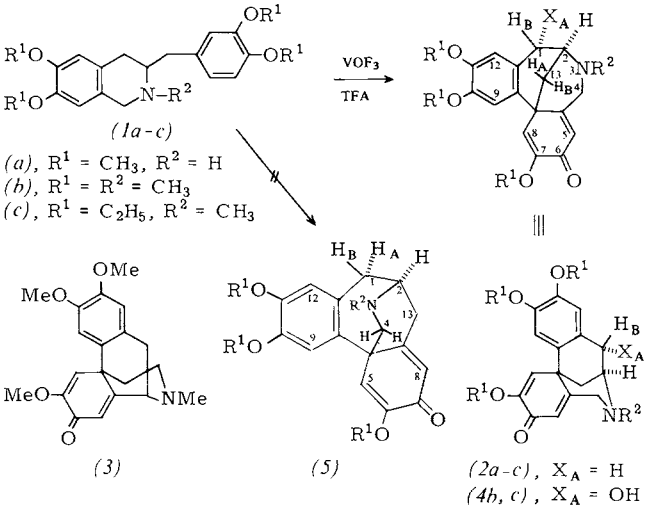
Intramolecular Oxidative Cyclization of 3-Benzyl-1,2,3,4-tetrahydroisoquinolines[**]



By *Johannes Hartenstein, Theo Heigl,* and *Gerhard Satzinger*[*]

In view of the supreme importance of 1-benzyl-1,2,3,4-tetrahydroisoquinolines for the biosynthesis of alkaloids[1], it is surprising that nature appears to have completely overlooked the 3-benzyl isomers. In the search for such "unnatural" alkaloids we have found that the non-phenolic oxidative coupling of 3-benzyl-1,2,3,4-tetrahydroisoquinolines *(1a—c)*[2] with VOF_3 in trifluoroacetic acid (TFA) at −15 to 0 °C leads smoothly and in high yields (>80%) to the previously unreported 1,2,3,4-tetrahydro-2,8a-methanodibenzo[*c,e*]azocin-6-ones *(2a—c)*[3,4] (Table 1).

The cyclization products *(2)* are closely related to the natural morphinandienones, *e.g. O*-methylflavinantine *(3)*.

The alternative structure *(5)*, the product of a *para*-coupling of the phenyl group with position 8a of the isoquinoline, could be ruled out by analysis of the 360-MHz ^{1}H-NMR spectra. Decoupling experiments with *(2a)* show that a remote coupling of 1 Hz exists only between the vinyl proton H-5 (δ = 6.09) and one of the aliphatic protons (H-4, δ = 3.39). Assuming structure *(5)*, then the demonstrated relation between a vinyl proton and an aliphatic proton by remote coupling would require an unusually large chemical shift of 3.36 for the C-13 methylene group. Also the positions of the signals at 1.91, 2.06 and 1.85 [Table 1, H-13$_B$ for *(2a)*, *(2b)*, and *(2c)*], respectively, would hardly be compatible with the chemical shift of protons of an allylic CH_2-group.

Besides the main products *(2a-c)*, very small amounts (<5%) of products of over oxidation are formed, namely the 3,4-didehydro derivative of *(2a)* in the cyclization of *(1a)*,

and the 1-hydroxy derivatives *(4b, c)* in the cyclization of *(1b, c)*. The hydroxy compounds *(4)* are formed regio- and diastereoselectively from *(2)* in analogy to the hydroxylation of aporphines[5]. Apart from the differences determined by the substituents, the signals for H-2, H-4 and H-13 in *(4)* correspond to those in *(2a—c)*. On the other hand, the ABX system of the H-1 methylene group is absent; instead a somewhat broadened singlet is observed at 4.85. Compatible with a dihedral angle of *ca.* 90° there is practically no coupling between H-1$_B$ and H-2. Moreover, H-12 is shifted downfield by *ca.* 0.2 ppm owing to the proximity of the hydroxy group.

Table 1. Some data of the compounds *(2a—c)*, 3,4-didehydro- *(2a)*, and *(4b)* [a].

Procedure

(±)-*(2b)*: 2-Methyl-6,7-dimethoxy-3-veratryl-1,2,3,4-tetrahydroisoquinoline *(1b)* (5.63 g, 15.74 mmol) is dissolved in TFA (60 ml) cooled with ice-water, and the stirred solution treated dropwise within 5 min at −15 to −10 °C under N_2 in the absence of moisture with a solution of VOF_3 (4.20 g, 2.5 equivalents) in TFA (200 ml). Stirring is continued for a further 1 h and then the solvent is removed at 20 °C/100 torr. The residue is treated with water and extracted with chloroform. The combined chloroform extracts are washed with semiconcentrated aqueous ammonia. Subsequent drying, removal of solvent, and crystallization of the residue from methanol furnishes 4.55 g (85%) of (±)-*(2b)*.

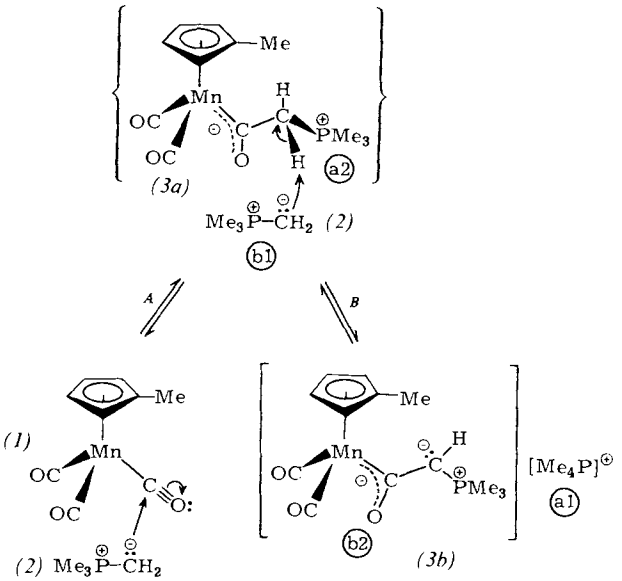
Total Reversibility of the Addition and Transylidation of Trialkyl(alkylidene)phosphoranes to Metal-Coordinated Carbon Monoxide[**]

By *Herbert Blau* and *Wolfgang Malisch*[*]



Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday

Nucleophilic phosphorus ylides add to the carbonyl carbon of carbonylmetal compounds that do not contain any ligands other than CO[1]. However, when trialkyl(alkylidene)phosphoranes[2] are used the reaction does not stop at the stage of the 1:1 adduct; instead, a rapid transylidation (with further phosphorane) takes place to give phosphorus ylide-substituted phosphoniummetal acylates[3].

We have now found for the first time that reaction of a carbonyl(cyclopentadienyl)metal compound, $MeC_5H_4Mn(CO)_3$ *(1)*, with trimethyl(methylene)phosphorane *(2)* in the molar ratio 1:2 leads, as with carbonylmetal compounds, in a two-step reaction to formation of phosphorus ylide substituted phosphoniummetal acylates, having quite novel and unusual properties. Thus, the product *(3b)*—an egg-yellow, extremely pyrophoric substance—obtained from *(1)* and *(2)* in pentane by addition and transylidation, completely regenerates the educts *(1)* and *(2)* on dissolution in tetrahydrofuran, or an ample amount of benzene, or pentane.

Consequently, *(3b)* can only be identified by IR spectroscopy (by two low-wavelength νCO bands, indicating the anionic character of the metal acylate), by analysis, and by secondary reactions[5].

Decisive evidence for the structure of *(3b)* is obtained from the product *(5)*, formed in the same fashion from $Et_3P{=}CHMe$ *(4)* and *(1)*; even in pure form, *(5)* is a non-crystallizable oil and can thus be measured NMR spectroscopically[6a].

Dissociation (on dissolution) and regeneration (on concentration of the solution) of *(3b)* and *(5)* can be repeated unlimitedly. Addition of the phosphorus ylide *(2)* to the carbonyl carbon of *(1)* (step A) and deprotonation of the adduct *(3a)* at the CH_2-bridge by further ylide *(2)* (step B) are accordingly completely reversible processes.

$$2\ Et_3P{=}CHMe + MeC_5H_4Mn(CO)_3 \longrightarrow$$
(4) *(1)*

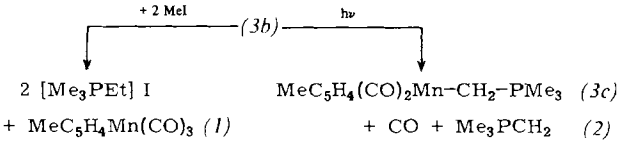
$$[Et_4P][(Mn)\text{–}C(O)\text{–}MeC{=}PEt_3]$$
(5)

$(Mn) = \eta^5\text{-}MeC_5H_4(CO)_2Mn$

Decisive for an understanding of this unusual phenomenon is the fact that in step B a transylidation equilibrium[7] is established between the corresponding acid/base pairs:

$[Me_4P]^{\oplus}$ (acid (a1))/Me_3PCH_2 *(2)* (base (b1))

and



$MePCH_2C(O)\text{–}(Mn)$ *(3a)* (acid (a2))/$[Me_3PCHC(O)\text{–}(Mn)]$ (base (b2))

The shift of equilibrium to the left on dissolution of *(3b)* begins with the deprotonation of the cation (a1) by the anion (b2) and is strongly favored, because the regenerated ylide adduct *(3a)* is extremely labile and is already spontaneously cleaved into *(1)* and *(2)* by the solvent. Since the reversibility of addition and transylidation is not observed in the case of metal systems bearing only CO[1,3] ligands, it has to be ascribed chiefly to the higher σ-donor/π-acceptor ratio of the methylcyclopentadienyl ligand in comparison to CO. It causes a) a lower electrophilicity of the carbonyl carbon and hence a lower stability of the primary product *(3a)*, b) a high electron density on the manganese, which increases the basicity of the ylide function in the metal acylate to such an extent that it can deprotonate the $[Me_4P]^{\oplus}$ counterion[8].

Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

[**] Presented in part at the Chemiedozententagung 1979 (Darmstadt), Referateband B47, and the IX. International Conference on Organometallic Chemistry 1979 (Dijon), Abstracts of Papers P32T. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The reversibility of formation of *(3b)* rationalizes its smooth transformation into the ylide complex *(3c)*[6b] on irradiation and into $[Me_3PEt]^{\oplus}I^{\ominus}$ and *(1)* on reaction with methyl iodide[9].

In both cases the products are formed from free *(1)* and *(2)*, which are generated from *(3b) via* steps B and A during the reaction.

Procedure

(3b): A solution of *(2)* (721 mg, 8.0 mmol) in pentane (15 ml) is added dropwise with vigorous stirring to a solution of *(1)* (872 mg, 4.0 mmol) in pentane (30 ml). A voluminous egg-yellow precipitate immediately separates out. After cooling the reaction mixture to 0 °C for 15 min, the precipitate is collected on a frit, washed with 20 ml ice-cold pentane, and briefly dried in a high vacuum at 25 °C; yield: 1.45 g (91%) *(3b)*. Above 114 °C *(3b)* is converted, with melting, into the educts[4].

(5): Pure *(4)* (1169 mg, 4.0 mmol) is added dropwise at 25 °C to liquid *(1)* (872 mg, 4.0 mmol). The reaction mixture immediately thickens to an orange-brown oil[6a].

(3c): A suspension of *(3b)* (1588 mg, 3.99 mmol) in benzene (60 ml) is irradiated until dissolution of *(3b)* (evolution of CO) and, after concentration of the solution to 30 ml, *(3c)* is precipitated with pentane (60 ml); yield: 994 mg (89%) of golden yellow, crystalline *(3c)*, m.p. 72—74 °C[6b].

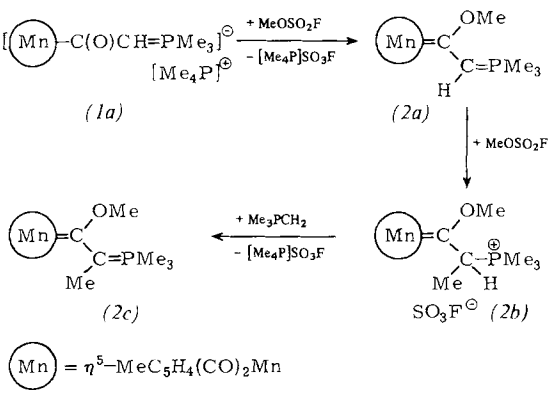
[7] Phosphonium salts can be regarded as Brønsted acids, alkylidenephosphoranes as the corresponding bases: cf. *H. J. Bestmann*, Angew. Chem. *77*, 609, 651, 850 (1965); Angew. Chem. Int. Ed. Engl. *4*, 583, 645, 830 (1965).

[8] We have meanwhile observed this effect on several carbonyl (cyclopentadienyl) and carbonyl(cyclopentadienyl)nitrosylmetal complexes; *W. Malisch, H. Blau*, Z. Naturforsch., in press.

[9] Analogous results are obtained in the case of reactions with $C_5H_5Mn(CO)_3$ instead of *(1)*. The ring substituent accordingly has no influence on the formation and reactivity of the compounds analogous to *(3b)* $[C_5H_5(CO)_2Mn—C(O)CHPMe_3][Me_4P]$; m.p. (with back dissociation) = 140 °C; photolysis affords $C_5H_5(CO)_2Mn—CH_2—PMe_3$, m.p. 110 °C.

Phosphorus Ylide Carbene Complexes of Manganese—Synthesis and Structure[***]



By *Wolfgang Malisch, Herbert Blau,* and *Ulrich Schubert*[*]

Dedicated to Professor Alfred Roedig on the occasion of his 70th birthday

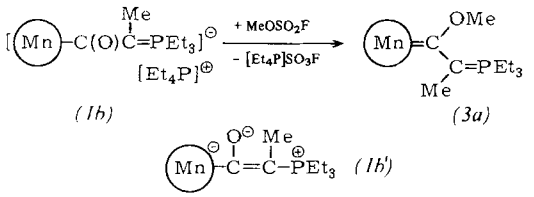
The pronounced tendency of phosphorus ylide-substituted tetraalkylphosphoniummanganese acylates

$R_4P[(Mn)—C(O)CR'=PR_3]$ *(1)* [*(1a)*, R = Me, R' = H; *(1b)*, R = Et, R' = Me] to regenerate phosphorus ylide and (Mn)-CO determines the products in the photoreaction of *(1)* and in its reaction with alkyl halides[1]. Reactions in which the manganeseacyl-phosphorus ylide skeleton remains intact can be realized with the *hard* alkylating reagent $MeOSO_2F$[2], but proceed in a complex fashion since *(1a)* has, with its acyl oxygen and ylide carbon two potentially nucleophilic centers. Moreover, even on reaction in substance or in a small amount of solvent *(1a)* affords $MePCH_2$[1], which interferes in the reaction.

Reaction of *(1a)* and an equimolar amount of $MeOSO_2F$ generates, *via* elimination of $[Me_4P][SO_3F]$[3], a mixture of the ylide-carbene complexes *(2a)* and *(2c)*.

Mechanistically this product formation can be interpreted in terms of the ambifunctional anion of *(1a)* being initially methylated at the *hard* oxygen[4], which bears most of the negative charge. *(2a)* then reacts partially with further alkylating agent to give the phosphoniumcarbene complex *(2b)*, which is only a short-lived intermediate in this reaction since it is immediately deprotonated to *(2c)* by Me_3PCH_2 [formed from *(1a)*]. *(2b)* is obtained in pure form on reaction of excess $MeOSO_2F$ with *(1a)*[5]. In a separate reaction with $MePCH_2$, *(2b)* can be converted quantitatively into *(2c)*, which can be protonated once again with ethereal HCl selectively at the ylide function to give

$[(Mn)—C(OMe)CHMePMe_3]Cl$, m.p. 120 °C.



On the other hand, it is not possible to control the successive methylation of the acyl oxygen [in *(1a)*] and ylide function [in *(2a)*] by $MeOSO_2F$ in such a way that the oxygen is

[***] Presented in part at the Chemiedozententagung 1979 (Darmstadt) Referatband B47, and the XI. International Conference on Organometallic Chemistry 1979 (Dijon), Abstracts of Papers P32T. This work was supported by the Fonds der Chemischen Industrie.

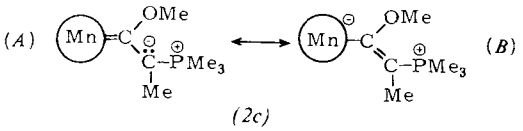
exclusively methylated. Such a reaction is realized only with the triethyl(ethylidene) homologue *(1b)*, which smoothly affords the *O*-alkylated product *(3)* as shiny golden yellow crystals, m.p. 84 °C.

(1b) *(3a)*

(1b')

This reaction tendency can be attributed to a steric hindrance of *C*-alkylation by the methyl ligands on the ylide carbon and/or to an increase in the electron density on the acyl oxygen by its donor activity and that of the ethyl groups on the phosphorus. For the anion of *(1b)* the resonance structure *(1b')* should be strongly favored[6].

Table 1. Spectroscopic data of the carbene-manganese complexes *(2a—c)* [a].



(2a): ^{1}H-NMR (C_6D_6): $\delta = 4.44$ (m, 4 ring-H), 1.96 (s, ring-CH_3), 4.73 (d, HC—P, $^2J_{HCP} = 34$ Hz), 4.04 (s, OCH_3), 0.74 (d, $P(CH_3)_3$, $^2J_{HPC} = 13.6$ Hz); IR (C_6H_6): $\nu CO = 1897$ vs, 1827 vs cm^{-1} [measured in admixture with *(2b)*]

(2b): ^{1}H-NMR (CD_3CN): $\delta = 4.93$ (m, 4 ring-H), 1.93 (s, ring-CH_3), 4.36 (s, OCH_3), 1.7 (dq, HCP, $^3J_{HCCH} = 7.6$ Hz, $^2J_{HCP} = 12.2$ Hz), 1.33 (dd, CH_3CP, $^3J_{HCCP} = 23$ Hz), 1.72 (d, $P(CH_3)_3$, $^2J_{HCP} = 14.2$ Hz); ^{31}P-NMR ([D_6]-DMSO): $\delta = 29.9$; IR (THF): $\nu CO = 1960$ vs, 1895 vs cm^{-1}

(2c): ^{1}H-NMR (C_6D_6): $\delta = 4.44$ (m, 4 ring-H), 1.94 (s, ring-CH_3), 2.28 (d, CH_3C, $^3J_{HCCP} = 16.2$ Hz), 4.00 (s, OCH_3), 0.80 (d, $P(CH_3)_3$, $^2J_{HCP} = 13.2$ Hz); ^{13}C-NMR (C_6D_6): $\delta = 236.19$ (CO), 257.6 (d, C—Mn, $^2J_{CP} = 7.77$ Hz), 101.9, 82.5, 81.1 and 14.4 (ring-C-1, -C-2,5, -C-3,4 and -CH_3), 58.14 (H_3CO), 17.81 (d, CH_3C, $^2J_{CCP} = 18.87$ Hz), 13.01 (d, CH_3P, $J_{CP} = 52.16$ Hz), 90.61 (d, C—P, $J_{CP} = 69.9$ Hz); ^{31}P-NMR (C_6D_6): $\delta = -4.49$; IR (C_6H_6): $\nu CO = 1898$ vs, 1830 vs cm^{-1}

[a] δ Values rel. TMS int. (^{1}H, ^{13}C) and H_3PO_4 ext. (^{31}P). ^{13}C- and ^{31}P-NMR ^{1}H-decoupled.

The composition and structure of *(2a—c)* and *(3)* are confirmed by elemental analysis and by IR and NMR spectra (cf. Table 1). In the case of *(2c)* its constitution was also confirmed by an X-ray structure analysis (cf. Fig. 1)[7]. This shows that the bonding in *(2c)* is best described by two resonance forms.

(A) *(B)*

(2c)

Fig. 1. Structure of *(2c)* in the crystal (important bond lengths in [pm]). Bond angles: Mn—C10—O10 123.5(7), Mn—C10'C11 129.0(8), O10—C10'C11 107.6(9), C10—C11—P 117.7(8)° [7].

(2c) differs from the $C_5H_5(CO)_2Mn$-carbene complexes known so far (resonance form A)[8] in that the length of the Mn—$C_{carbene}$ bond is extended by 7—10 pm, that of the $C_{carbene}O$ bond by 7—8 pm, and that the methyl group on O10 is no longer located in the coordination plane of the carbene carbon. The carbene carbon is electronically stabilized according to resonance form B, mainly by the ylide function; the methoxy group no longer participates[8]. Accordingly, the C10—C11 bond has strong double bond character, while the P—C11 bond (176.6 pm) is markedly longer than the corresponding bonds in phosphorus ylides. For comparison: The P—C_{sp^2} bond lengths in $[(Me_3P)_3C]I_2$ are 175 pm (formal bond order: 1.33)[9].

Procedure

(2b): *(1a)*, formed on reaction of $MeC_5H_4Mn(CO)_3$ (1.31 g, 6 mmol) with Me_3PCH_2 (1.08 g, 12 mmol) in pentane (15 ml) at 0 °C[1], is cooled, together with the solvent, to −78 °C. After addition of $MeOSO_2F$ (1.37 g, 12 mmol) and warming to room temperature the pale-yellow crystalline precipitate of *(2b)*, $[Me_4P]SO_3F$ and $[EtPMe_3]SO_3F$ is filtered off, washed with 3 × 5 ml benzene, and dried in a vacuum. Recrystallization from THF/CH_3CN (20 ml) affords 0.92 g (35%) of yellow *(2b)*, m.p. 99—100 °C.

(2c): A suspension of the above mixture of salts in benzene (40 ml) is treated dropwise at 8 °C with a solution of Me_3PCH_2 (0.45 g, 6 mmol) in benzene (10 ml). After 30 minutes' stirring the insoluble $[EtPMe_3]SO_3F$ and $[Me_4P]SO_3F$ are filtered off on a frit; the clear reaction solution is then evaporated down to 15 ml. After addition of pentane (30 ml) and cooling to 0 °C, 1.10 g (54%) of golden-yellow *(2c)*, m.p. 115—117 °C (dec.), crystallizes.

Metal-Assisted Reaction of Carbon Disulfide with the "Etriphos" Phosphane Ligand: Synthesis and Structure of $[(Etriphos)Fe\{S_2C(Et_2PCH_2)_2CMe_2\}](BF_4)_2$

By *Claudio Bianchini, Andrea Meli, Annabella Orlandini,* and *Luigi Sacconi*[*]

By reaction of CS_2 with hydrated iron(II) tetrafluoroborate in the presence of (neopentanetriyltris(diethylphosphane) ("Etriphos") *(1)*, we have obtained the iron(II) complex $[(Etriphos)FeZ](BF_4)_2$ *(2)*, where Z is the unprecedented six-membered heterocyclic zwitterion 1,1,3,3-tetraethyl-5,5-dimethyl-1,3-diphosphonia-2,2-cyclohexanedithiolate.

(1), etriphos

(2)

[*] Prof. Dr. L. Sacconi, Dr. C. Bianchini, Dr. A. Meli, Dr. A. Orlandini
Istituto di Chimica Generale e Inorganica dell'Università, Laboratorio CNR,
39 Via J. Nardi, I-50132 Firenze (Italy)

An X-ray structural investigation[1] on compound *(2)* (Fig. 1) has shown that the iron atom is five-coordinated by the three phosphorus atoms of the Etriphos ligand and by the two sulfur atoms of the zwitterion in a distorted square pyramid.

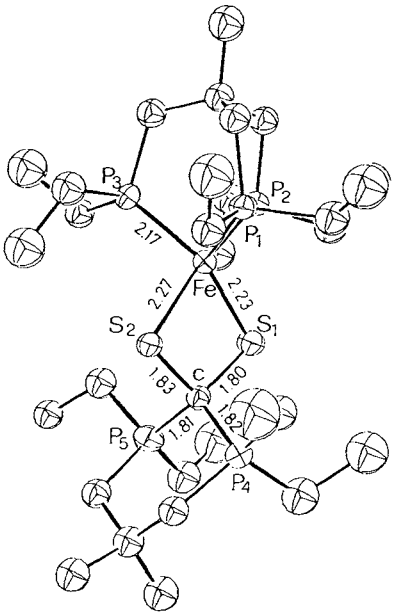

Figure 1. Perspective view of the complex cation $[(Etriphos)FeZ]^{2+}$ *(2)* (ORTEP diagram). Important bond lengths and bond angles: Fe—P(1—3) = 2.149—2.191(5) Å, S1—Fe—P3 = 150.1(2), S2—Fe—P2 = 163.7(2), S1—Fe—S2 = 77.8(2), S1—C—S2 = 101.7(9)° [1].

Some metal complexes with disulfido ligands containing *only one* quaternary phosphonium atom have already been reported[2], but no ring closure within the zwitterion has previously been observed. Definite conclusions have not been reached about the cleavage of a carbon-phosphorus bond in the third chain of the Etriphos rest.

The title compound *(2)* seems to be the first example of a five-coordinate iron(II) complex lying in a singlet ground state. Its diamagnetism can be ascribed to the very high $\sum n^0$ value of the P_3S_2 donor set[3], even higher than that of the P_4Br set in the complex $[Fe(P_4)Br]BPh_4$, which shows a singlet-triplet spin state equilibruim[4].
($P_4 = Ph_2P(CH_2)_2PPh(CH_2)_2PPh(CH_2)_2PPh_2$)

Procedure

All operations are performed under N_2 and with oxygen-free solvents. CS_2 is bubbled for 30 min through a hot mixture of *(1)*[5] (2 mmol) in dichloromethane (40 ml) and $Fe(BF_4)_2 \cdot 6H_2O$ (1 mmol) in ethanol (30 ml). The reaction mixture is maintained at reflux temperature for one hour. The resulting dark green solution is concentrated to give green crystals which are recrystallized from dichloromethane/ethanol; yield 40%.

Reversal of Stability in the Benzene/Dewar-Benzene System[1]

By *Günther Maier* and *Klaus-Albert Schneider*[*]

Dedicated to Professor Karl Dimroth on the occasion of his 70th birthday

In all previously investigated cases[2] the valence isomers of benzene and its derivatives under normal conditions[3] are higher in energy than the aromatic parent molecules. We have now found that crowding of very bulky groups can make the Dewar-benzene isomer more stable than the partner with an intact benzene ring.

Despite the great steric hindrance, tetra-*tert*-butylcyclobutadiene[4] reacts smoothly with acetylenedicarboxylate, even at room temperature, to give the symmetric Dewar-phthalate *(1)* (colorless crystals, m.p. 94—97 °C, 83%).

When *(1)* is heated to 120 °C a new, unsymmetrical Dewar-benzene isomer *(3)* is formed (colorless crystals, m.p. 98—100 °C, 51%) with another arrangement of the substituents. The structures assigned to *(1)* and *(3)* follow from the spectra (see Table 1) and the finding that both bicycles are

converted into dimethyl 3,4,5,6-tetra-*tert*-butylphthalate *(2)* [oil; from *(1)*: 24%; from *(3)*: 43%] on irradiation with 254-nm light.

The thermally induced rearrangement *(1)*→*(3)* is without precedent, and could proceed *via* a sort of $[{}_{\pi}2_a + {}_{\pi}2_a + {}_{\sigma}2_s]$-sigmatropic shift[6]. The interim appearance of the NMR signals of *(2)*, however, would rather suggest that *(1)* first of all opens to give *(2)*, which then cyclizes to *(3)*. This would indicate that the Dewar-benzene derivative *(3)* must be thermodynamically more favored than the benzene derivative *(2)*. This is in fact so. Compound *(2)* rearranges at 120 °C into *(3)* in 90% yield. The eclipsed position of the bulky substituents in *(2)*, the first benzene derivative with four directly adjacent *tert*-butyl groups, and their more favorable staggered orientation in the Dewar-benzene derivative *(3)* effect reversal of the usual order of stability.

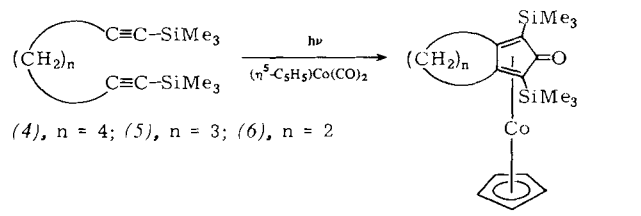
Cobalt Mediated [2+2+2]-Cycloadditions: A Simple Route to Substituted Cyclopentadienones[**]



By *Ernst R. F. Gesing, Jeffrey P. Tane*, and *K. Peter C. Vollhardt*[*]

Five-membered ring construction *en route* to cyclopentanoid natural products is an area of intensive current research effort[1]. Cyclopentadienones[2] have played no role in it due to their high reactivity in Diels-Alder reactions, avoidable only by introduction of synthetically disadvantageous bulky substituents, typically *tert*-butyl and phenyl. An attractive way to generate and stabilize the cyclopentadienone nucleus is by the transition metal-mediated cyclization of two alkynes with one molecule of carbon monoxide[3], but application of this method to organic synthesis has been hampered by low yields due to poor selectivity, the necessity for the presence of specific substituents or expensive metals, and the absence of mild demetalation methods.

We have found that irradiation of $(\eta^5\text{-}C_5H_5)Co(CO)_2$ in the presence of trimethylsilylacetylene *(1)* in tetrahydrofuran at −20 °C furnishes the dark red complexes *(2)* and *(3)* with pronounced chemo-[4] and regioselectivity (ratio 3:1) in good yield (Table 1). Higher temperatures lead to increasing alkyne trimer formation.

Interestingly, the more bulky η^5-$[C_5(CH_3)_5]Co(CO)_2$ reverses the product ratio (1:3.7) of the corresponding pentamethyl-analogs of *(2)* and *(3)*, an observation which might become valuable in synthetic applications.

(4), n = 4; *(5)*, n = 3; *(6)*, n = 2

(7), n = 4; *(8)*, n = 3; *(9)*, n = 2

Similar reaction with α,ω-diynes *(4)* and *(5)* yield the annelated cyclopentadienones *(7)* and *(8)*, whereas *(6)* requires different reaction conditions (irradiation with a GE projection lamp, 120 V, 250 W; refluxing *o*-xylene; syringe pump addition) to give the theoretically interesting[6] strained *(9)* in low yield (Table 1).

Table 1. Physical data of compounds *(2)*, *(3)*, *(7)*—*(18)*. All new compounds gave satisfactory analytical data and mass spectra. ^{1}H-NMR: δ values; IR: ν_{CO}; UV: λ_{max} (log ε), in cyclohexane.

[**] This work was supported by the NIH (GM22479). We appreciate preliminary experiments by Mr. *R. L. Brainard*. *E. R. F. G.* thanks the NATO/DAAD for a research fellowship (1979—1980). *K. P. C. V.* is a Fellow of the A. P. Sloan Foundation (1976—1980) and a Camille and Henry Dreyfus Teacher Scholar (1978—1983).

(7), and *(8)* constitute potentially valuable organic synthons, if decomplexation without dimerization were possible. The latter is achieved in nearly quantitative yields using ceric ammonium nitrate in a two-phase solvent system (CH_3CN/*n*-C_5H_{12}) to give *(11)*—*(13)* (Table 1). Under the same conditions at −20 °C, *(2)* yields the volatile *(10)* (11%) and its dimer *(14)* (54%) assigned the *exo*-configuration[7]. Dimerization of *(10)* occurs readily at 37 °C, but the monomer may be quantitatively regenerated by flash pyrolysis at 550 °C (10^{-4}—10^{-5} torr) (Table 1). This compound constitutes the first useful monomeric cyclopentadienone synthon.

(10) *(11)*, n = 4; *(12)*, n = 3; *(13)*, n = 2 *(14)*

The parent cycloalkane-annelated cyclopentadienones *(2)* and *(7)*—*(9)* were unknown. Their synthesis is of synthetic and theoretical interest since one may predict their respective rates of dimerization *to decrease* due to the increasing strain associated with the respective Diels-Alder adducts. Treatment of *(2)* and *(7)*—*(9)* with benzyltrimethylammonium fluoride (THF, 2 equiv. ethanol, reflux) gave the hydrated complexes *(15)*—*(18)* (Table 1) in 70—80% yield. Oxidation of *(16)* and *(17)* under the conditions employed in the preparation of *(10)*—*(13)*, gave ligand dimers, whereas in the case

(16), n = 4
(17), n = 3
(18), n = 2

of *(18)* a 1:1 adduct with acetonitrile of as yet unknown structure was obtained. This confirms that uncomplexed bicyclo[3.2.0]hepta-1(5),4-dien-3-one is reluctant to dimerize but is otherwise highly reactive.

Procedure

η^4-Cyclopentadienone-(η^5-C_5H_5)Co complexes *(2)*, *(3)*, *(7)*, *(8)*: 17 mmol of alkyne *(1)*, 6 mmol of *(4)* or 6 mmol of *(5)* and 3 mmol of (η^5-C_5H_5)$Co(CO)_2$ were irradiated in dry, degassed, THF (250 ml) at −20 °C with a Hanovia Hg medium pressure lamp (679 A36) for 5.5 h. The solvent was evaporated and the crude residue chromatographed (neutral Al_2O_3, Alfa CAMAG 95+%, −60 mesh, deactivated with 4.5% H_2O) to recover excess alkyne (elution with *n*-pentane) and subsequently the products (elution with ether). Recrystallization from ether/pentane, yields pure products.

Oxidative demetalations to form *(10)*—*(13)*: A 2.5×10^{-2} M solution of complexes *(2)*, *(7)*, *(8)*, or *(9)* in acetonitrile at 0 °C was covered with an equal volume of *n*-pentane and reacted with $(NH_4)_2Ce(NO_3)_6$ (1.5 equiv.) with stirring. After 30 min the yellow pentane layer was decanted, more cold pentane added, and the procedure repeated until the hydrocarbon layer stayed colorless. The solvent was removed and the product sublimed (10 °C/0.025 torr; −10 °C cold finger) or recrystallized (*n*-pentane).

Polymetallic Complexes: Complexation of the Triangular Faces of Clusters by the Tripod Ligand, $HC(PPh_2)_3$[**]

By *Anita A. Arduini, Ali A. Bahsoun, John A. Osborn,* and *Christian Voelker*[*]

Strategies for the synthesis of multimetallic complexes are of great interest but have not been widely developed[1]. We have sought therefore to bind several metal atoms in close proximity by use of suitably designed polydentate ligands. For the stabilization of triangular arrays of metal atoms of which metal cluster frameworks are mainly constructed, we have synthesized and studied the family of tripod ligands, $RC(L^1L^2L^3)$, where L^1, L^2, L^3 are donor functions such as PR_2, AsR_2, SR[2]. Models show the bite angle to favor the simultaneous binding of *three* metal atoms to the tripod ligand *(1)*, rather than chelation about one metal as found typically for other tripod ligands[3]. We illustrate here that the easily prepared[4], archetypal member of this ligand family, $HC(PPh_2)_3$, *(1)* (or tripod) can indeed complex three metal atoms on a cluster surface: This unusual binding mode can also be utilized for the stepwise synthesis of clusters[5].

Tetrahedral clusters of the type $M_4(CO)_{12}$ were chosen to test the complexation properties of *(1)* since no stereochemical problems on substitution were anticipated[6]. This expectation is borne out by experiment since reactions of *(1)* with $M_4(CO)_{12}$ clusters proceed cleanly to yield nearly quantitative yields of products *(2)*—*(7)* (Table 1). C_{3v} structures are proposed for these complexes, the tripod ligand complexing a carbonyl-bridged triangular face as shown for *(2)*, *(3)*, *(5)*, and *(7)*, whereas in *(4)* and *(6)* all carbonyls are terminal.

Table 1. Some spectroscopic properties of the complexes $M_4(CO)_9$(tripod) [a].

	M_4	Color	IR (ν_{CO} [cm^{-1}], CH_2Cl_2)	$^{31}P\{^1H\}$-NMR δ (rel. H_3PO_4)
(2)	Co_4	green	2050 s, 2000 s, 1975 s, 1780 m	44.3 (s)
(3)	Rh_4	deep red	2060 s, 2010 vs, 1990 s, 1805 s	18.0 (l, m), 14.4 (l, m), $J_{Rh\ P}$ = 133 Hz
(4)	Ir_4	yellow	2060 s, 2010 vs, 1970 s, 1950 m	−39.1 (s)
(5)	Co_2Rh_2	violet	2040 s, 2005 vs, 1985 s, 1845 w, 1805 m, 1785 m	33.0 (l, br), 29.0 (l, d), 25.2 (l, d), $J_{Rh\ P}$ = 137 Hz
(6)	H_4Ru_4	deep red	2065 s, 2015 s, 2000 s, 1960 w, br, 1940 w, br	35.9 (s)
(7)	$HFeCo_3$	deep violet	2045 s, 2035 s, 2010 vs, 1970 w, 1930 m, 1810 s, 1780 s	44.5 (br)

[a] Satisfactory elemental analyses were obtained for all the new compounds.

Several points are of note: a) The ^{13}C-NMR spectrum of *(3)* at 70 °C shows no sign of carbonyl exchange processes (merry-go-round or other)[7a], whereas the parent $Rh_4(CO)_{12}$ shows a limiting spectrum only at −65 °C[7b]. However, the exchange of ^{13}CO with *(3)* shows statistical incorporation to occur, indicating that intramolecular exchange is fast on a chemical time scale; b) in the reactions producing *(5)* and *(7)* the tripod ligand has selected only one of the two different faces to complex, *e.g.* for *(5)* the $CoRh_2$ face is complexed preferentially to the Co_2Rh face; c) these constrained clusters appear more resistant to fragmentation than the parent compounds, a property which may be useful if multimetal site catalysis is to be observed[8]. For example, refluxing *(2)* in toluene produces (π-toluene)$Co_4(CO)_6$(tripod)[9] in quantitative yield with no special precautions[10]. Also both *(2)* and *(3)* undergo no change in toluene at 100 °C under CO (30 bar) over 18 h whereas under such conditions the parent carbonyls (or their phosphane-substituted derivatives) are unstable[11].

Experimental

(1) (0.30 g, 0.53 mmol) in toluene (30 ml) was added dropwise with vigorous stirring to $Rh_4(CO)_{12}$ (0.38 g, 0.51 mmol) dissolved in hexane (80 ml) over 1 h. The solution then was stirred under a slow stream of argon for *ca.* 6 h. The deep red precipitate of *(3)* was filtered off, washed with hexane (2 × 25 ml), and dried *in vacuo*. Recrystallization from CH_2Cl_2/hexane gives *(3)* (0.50 g, 80%) as deep red crystals.

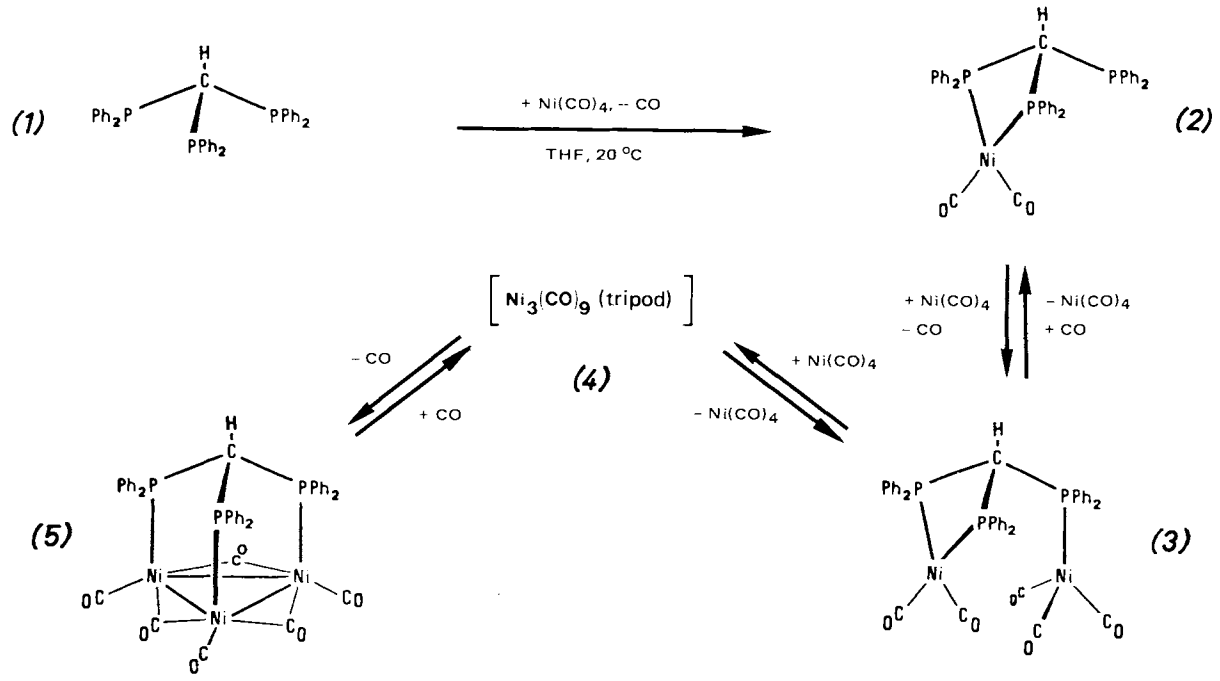
Template Synthesis of Clusters using the Tripod Ligand $HC(PPh_2)_3$ $Ni_3(CO)_6$(tripod)[**]

By *J. A. Osborn* and *George G. Stanley*[*]



We have shown[1] that the ligand $HC(PPh_2)_3$, *(1)*, (tripod) belongs to an unusual class of ligands which will bind three metals simultaneously in a triangular array. Here we illustrate how this property can be used for the construction of trinuclear clusters from mononuclear starting materials.

When *(1)* is reacted with an excess of $Ni(CO)_4$, a yellow solution is obtained, which on evaporation *in vacuo* turns orange and precipitates the light orange solid, $Ni_3(CO)_6$(tripod) *(5)*[2]. This compound has been characterized by elemental analysis and molecular weight measurements as well as infrared and ^{31}P-NMR spectroscopy (Table 1). Compound *(5)* has C_{3v} symmetry and is the first known nickel(0) trimer, the only other well characterized Ni(0) clusters being $Ni_4(CO)_6[P(CH_2CH_2CN)_3]_4$[3a] and $Ni_4(CNR)_7$[3b].

The mechanism of formation of *(5)* has been monitored by IR and ^{31}P-NMR studies. On addition of excess $Ni(CO)_4$ to *(1)*, only two tripod-containing species are initially observed: $Ni(CO)_2$(tripod) *(2)*[2] and a small amount of $Ni_2(CO)_5$(tripod) *(3)*[2]. In the mononuclear species *(2)*, which has been prepared separately, tripod functions as a bidentate ligand on one metal center[4]. The dimer *(3)*, which is formed by attack of $Ni(CO)_4$ on the free PPh_2 of *(2)*, has not been isolated[2]. Characteristically, the IR spectrum of *(3)* shows a simple superposition of nickel dicarbonyl and tricarbonyl moieties, consistent with the expected lack of a Ni—Ni bonding interaction. However, no trimer is observed in solution until vacuum evacuation to remove, paradoxically, the excess $Ni(CO)_4$ as well as the CO liberated. The explanation is that the presence of CO liberated in forming *(2)* and *(3)* disfavors the formation of trimer in the equilibrium and also inhibits the dissociation of $Ni(CO)_4$ to form $Ni(CO)_3$. This

latter reactive species is needed to open the chelate in *(3)* to form the trinuclear species *(4)*[5]. Decarbonylation of *(4)* occurs rapidly *in vacuo* to form three M—M bonds, yielding the trinuclear species *(5)*. We find that treatment of *(5)* with CO (1 bar) regenerates *(2)* and $Ni(CO)_4$; similar behavior has been observed with the related anionic nickel carbonyl clusters[6].

Hence *(1)* can act as a template for the stepwise formation of trinuclear clusters.

Experimental

All manipulations were performed under nitrogen. *(1)* (2.5 g, 4.4 mmol) dissolved in THF (160 ml) was added to $Ni(CO)_4$ (22 g, 130 mmol) in THF (30 ml) at 25 °C. The solution immediately turns light yellow with CO evolution. *(2)* can be isolated at this stage as a light yellow powder by precipitation with hexane. Alternatively, on evaporation of the original solution *in vacuo*[7] at 25 °C, the solution becomes deep orange and an orange precipitate of *(5)* forms at *ca.* half volume. Recrystallization of *(5)* from CH_2Cl_2/hexane yields orange crystals (2.0 g, 50%).

[4] The ν_{CO} vibrations in the IR spectrum of *(2)* are almost identical with those observed for $Ni(CO)_2(Ph_2PCH_2PCH_2)$; cf. *G. R. Van Hecke, W. Horrocks*, Inorg. Chem. *5*, 1960 (1966).

[5] A pale yellow complex can be precipitated out of concentrated reaction mixtures but it cannot be obtained pure. The IR spectrum in the solid state shows terminal carbonyl bands at 2060 and 1970 cm^{-1}, but on dissolving in CH_2Cl_2 to give an orange solution, these bands disappear to be replaced by those of *(2)*, *(5)*, and *(3)* and $Ni(CO)_4$. These observations indicate this species to be the trimer *(4)* formed before closure to *(5)* occurs and hence of formula $Ni_3(CO)_n$(tripod) where $n = 8$ or 9.

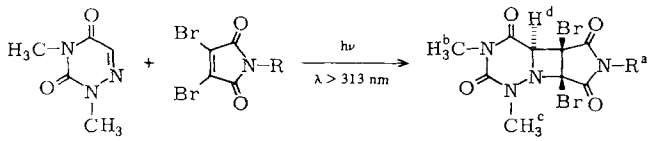
[6] *G. Longoni, M. Manassero, M. Sansoni*, J. Organomet. Chem. *174*, C41 (1979).

[7] The vacuum-evaporated $Ni(CO)_4$ is trapped in a liquid N_2 cooled cold trap in which Br_2 has previously been frozen. On warming $NiBr_2 + CO$ are formed. This reaction is very exothermic and for large amounts of $Ni(CO)_4$ appropriate precautions should be taken.

Novel Photocycloadditions of Dibromomaleimides to 1,3-Dimethyl-6-azauracil[**]

By *Géza Szilágyi* and *Heinrich Wamhoff*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



Photoreactions of cyclophilic molecules with pyrimidine bases and their aza analogues have great importance as model reactions for photochemotherapy[2]. So far, very few examples of photocycloadditions to the moderately reactive C=N double bond of heterocycles have been reported in the literature[3]. Dihalomaleic imides and anhydrides react photochemically with 1,3-dimethyluracil with $[_\pi 2_s + _\pi 2_s]$-cycloaddition and with 5-mono- and 5,5'-disubstitution, respectively[4]; we now report the surprisingly smooth photoaddition of the dibromomaleimides *(2a, b)* with 1,3-dimethyl-6-azauracil *(1)*.

After long-wave UV irradiation (Pyrex filter, $\lambda > 313$ nm) of *(1)*[5] with equimolar amounts of *(2a, b)* in various solvents, the [2+2]-cycloadducts *(3a, b)* can be isolated in high yields; photoalkylation products are not formed (Table 1), acetone serving both as solvent and as sensitizer.

The stereochemistry of the fusion of *(3a, b)* follows from the ^1H-NMR spectra (Table 2). The H^d resonance at $\delta = 5.23$ to 5.26 indicates a *cis-anti-cis* coupling, as is found in the cor-

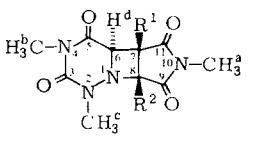
(3a), m.p. 206—207 °C; IR (KBr): 1780, 1710 (imide), 1730, 1660 cm^{-1} (C=O); ^{1}H-NMR: δ = 3.16 (s, 3H^c), 2.93, 2.91 (2 s, 3H^a and 3H^b), 5.23 (s, H^d); ^{13}C-NMR: 26.15 (C-10), 27.16 (C-4), 36.90 (C-2), 55.12 (C-7), 70.66 (C-6), 80.92 (C-8), 150.48 (C-3), 165.04 (C-5), 165.34 (C-9), 165.56 (C-11)



(3b), m.p. 184—187 °C; IR (KBr): 3450 (N—H), 1775, 1705 cm^{-1} (imide), 1735, 1660 cm^{-1} (C=O); ^{1}H-NMR: δ = 2.93 (s, 3H^b), 3.13 (s, 3H^c), 5.26 (s, H^d), ~12 (s, H^a)

(4), m.p. 215—216 °C; ^{1}H-NMR: δ = 3.18 (s, 3H^c), 2.93 (s, 3H^b), 2.91 (s, 3H^a), 5.26 (d, H^d), 4.48 (d, H$^{e'}$)

(5), m.p. 203—205 °C; ^{1}H-NMR: δ = 3.07 (s, 3H^c), 2.91 (s, 3H^b), 2.84 (s, 3H^a), 5.10 (s, H^d), 4.82 (s, H^e)

(6), m.p. 215—217 °C

Products following the photoreaction of *(1)* with *(2a)* are *(4)* and *(3)* (in dioxane, yields 0.3% and 6%, resp.), and *(6)* (in tetrahydrofuran (THF), yield 11%). *(4)* are *(5)* (Table 2) are formed by Br/H exchange with the solvent; *(6)* is obtained by acetone-sensitized substitution of THF[7]. The constitution and coupling of *(6)* are supported by ^{1}H- and ^{13}C-NMR data. Especially informative is the absence of a C-6,7,12 long range doublet splitting ($^3J_{CCC\cdots H}$-coupling); instead, a simple doublet is found for C-6 (64.1).

(4), R^1 = H$^{e'}$, R^2 = Br
(5), R^1 = Br, R^2 = H^e
(6), R^1 = Br, R^2 = 

Procedure

To a solution of *(1)* (10 mmol) and *(2a, b)* (10 mmol) in the solvent (200 ml) is added the sensitizer (in THF: 15 ml of acetone or 20 mg of benzophenone) and the is mixture irradiated with a Hg high-pressure lamp (Philips HPK 125). The course of the reaction is monitored by thin-layer chromatography (benzene/methanol 85:15). After the reaction in acetone the product *(3a, b)* is filtered off; in all other cases, the solvent is removed by evaporation and the residual oil chromatographed on silica gel in systems of increasing polarity (petroleum ether 60—90/acetone 10:1, 10:2, 10:3) and recrystallized from ethanol (see Table 2).

A Photochemical Route to (±)-Estrone[**]

By *Gerhard Quinkert, Wolf-Dietrich Weber, Ulrich Schwartz*, and *Gerd Dürner*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Estrone *(1)*, R = H, is an attractive synthetic target compound. The pathways leading to this goal are appealing if they open up uncharted areas of methodology. We now report[1] a convergent steroid synthesis based on the approach A + D → AD → ABCD (Scheme 1).

The phototransient *rac-(5)* plays a pivotal role in this concept. It undergoes intramolecular [4+2]-cycloaddition[2] to give the steroid *rac-(3)*, which forms *rac-(1)*, R = H, by dehydration, hydrogenation, and ether cleavage. The kinetically unstable *o*-quinodimethane derivative *rac-(5)* is accessible by regioselective electronic excitation and photoenolization[3] of the key compound *rac-(10)*. The Michael adduct *rac-(10)* (Table 1) is formed smoothly[4], from the inexpensive chemicals *m*-cresol methyl ether, dimethyl malonate *(6)*, R = CH_3, and (*E*)-1,4-dibromo-2-butene.

In order to prepare the achiral A ring building block, *m*-cresol methyl ether is allowed to react at 0 °C (in the presence of iron filings) with bromine in CCl_4 to give *(4)* (93%)[5]. The Grignard compound obtained *in situ* from *(4)* reacts at < −20 °C with dimethylformamide in tetrahydrofuran (THF) to give *(7)* (75%). The aldehyde *(7)* is transformed, by treatment with the Grignard compound obtained from 1-bromovinyl(trimethyl)silane[6] in THF at *ca.* 50 °C, into *(9)* (98%) which can be oxidized with chromic acid in a two-phase system, affording *(12)* (80%).

The synthesis of the racemic D ring component (2Ξ,3*RS*)-*(13)* begins with reaction of *(6)*, R = CH_3, at 55 °C with (*E*)-1,4-dibromo-2-butene in methanol containing sodium methoxide. The resulting dimethyl *rac*-2-vinylcyclopropane-1,1-

rac-(16), R = H: m.p. 198 °C (chloroform)

dicarboxylate *(RS)-(8)*, R = CH_3[7] (65%) affords, on treatment with dimethyl methylmalonate in methanol containing sodium methoxide (to which hexamethylphosphoric triamide has been added), the racemates of *(2Ξ,3RS,5Ξ)-(11)*, R = CH_3 (67%). The mixture of stereoisomers (no separation necessary) undergoes hydrolysis (10 h under reflux in aqueous/methanolic sodium hydroxide) and decarboxylation at pH ≈ 4.5 to form *(2Ξ,3RS)*-2-methyl-3-vinylcyclopentanone *(2Ξ,3RS)-(13)* (75%).

The A and D ring components *(12)* and *(2Ξ,3RS)-(13)* (no separation of isomers necessary) react at room temperature in a mixture of *tert*-butyl alcohol and ether containing sodium *tert*-butoxide to furnish *rac*-6,7;8,9-diseco-3-methoxy-1,3,5(10),7-estratetraene-9,17-dione *rac-(10)* [>60% relative to *(12)* or reacted *(2Ξ,3RS)-(13)*].

Irradiation [24 h for 1 g of *rac-(10)*] of a methylcyclohexane solution containing *rac-(10)*, pyridine, and mesitol, at 98 °C with UV light of $\lambda > 340$ nm yields a product consisting mainly of *rac-(3)*, and also containing *rac-(14)*[8]. The mixture left on removal of solvent is dissolved in benzene and the solution is refluxed for 20 min after addition of oxalic acid. The dehydration product obtained is a mixture of 95% *rac-(2)* (Table 1) and 5% *rac-(15)*[9]. It is isolated in 61% yield based on *rac-(10)* and does not have to be separated regardless of whether *rac*-estrone *rac-(1)*, R = H[10], *rac*-estradiol-17β *rac-(16)*, R = H[11], or *rac*-19-nor-4-androstene-3,17-dione *rac-(17)*[12] is the synthetic target compound.

The total steroid synthesis presented in this communication has the following characteristic features:

- it contains a photochemical key step;
- it starts from inexpensive chemicals;
- it proceeds with extremely high regio- and diastereoselectivity, and considerable overall yield[13];
- it can be directed asymmetrically to naturally occurring (+)-estrone *(1)*, R = H [and to *(16)*, R = H and *(17)*][1b]

[4] Under the conditions chosen *(vide infra)*, the thermodynamically more stable of the two enolate anions of the D ring component adds, in extremely regioselective manner, to *(12)*. The $(CH_3)_3Si$ ligand ensures that the reaction also produces *rac-(10)* in extremely high stereoselectivity.

[5] *m*-Cresol methyl ether (3-methylanisole) is brominated analogously to 3-ethylanisole: *D. J. Nelson, E. A. Uschak*, J. Org. Chem. *42*, 3308 (1977).

[6] *A. Ottolenghi, M. Friedkin, A. Zilkha*, Can. J. Chem. *41*, 2977 (1963).

[7] *rac-(8)*, $R = C_2H_5$, was synthesized by *R. W. Kierstead, R. P. Linstead, B. C. L. Weedon*, J. Chem. Soc. *1952*, 3613; we adopted to procedure of *J. M. Stewart, G. K. Pagenkopf*, J. Org. Chem. *34*, 7 (1969), but used *(6)*, $R = CH_3$. Concerning nucleophilic ring opening of cyclopropane derivatives activated by electron acceptors, see *S. Danishefsky*, Acc. Chem. Res. *12*, 66 (1979).

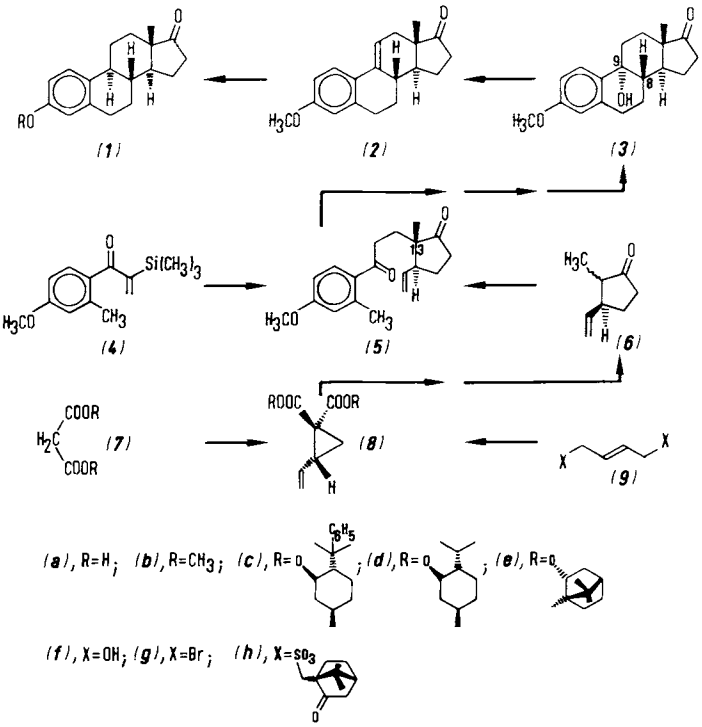
[8] The diastereomer of *rac-(5)* having Z-configurated 9,10-double bond traverses mainly that transition structure in which the dienophilic vinyl group approaches the *o*-quinonoid dienic moiety from the β-side, from the *exo* orientation: this affords *rac-(3)*. A competition reaction, of admittedly subordinate proportions, proceeds *via* that transition structure in which the vinyl group approaches the diene unit from the α-side, from the *endo* orientation: this gives *rac-(14)*. *rac-(3)* and *rac-(14)* are separated only for identification.

[9] *rac-(2)* and *rac-(15)* are separated only for identification.

[10] The mixture *rac-(2)* + *rac-(15)* is reduced by potassium in liquid ammonia in the presence of aniline and then oxidized by chromic acid to give *rac-(1)*, $R = CH_3$: *G. H. Douglas, J. M. H. Graves, D. Hartley, G. A. Hughes, B. J. McLoughlin, J. Siddall, H. Smith*, J. Chem. Soc. *1963*, 5072. *rac-(1)*, $R = CH_3$, is transformed, on heating with pyridine hydrochloride to 210 °C, into *rac-(1)*: *W. S. Johnson, D. K. Banerjee, W. P. Schneider, C. D. Gutsche, W. E. Shelberg, L. V. Chinn*, J. Am. Chem. Soc. *74*, 2832 (1952).

[11] The mixture *rac-(2)* + *rac-(15)* is reduced by potassium in liquid ammonia in the presence of aniline and then treated with diisobutylaluminum hydride *rac-(16)*; R = H: *J.-C. Hilscher*, DBP 2409991 (1976); Schering; Chem. Abstr. *84*, 59862v (1976).

[12] The mixture *rac-(2)* + *rac-(15)* is converted by Birch reduction into *rac-(17)* [by analogy with the procedure of *W. S. Johnson, W. A. Vredenburgh, J. E. Pike*, J. Am. Chem. Soc. *82*, 3409 (1960)].



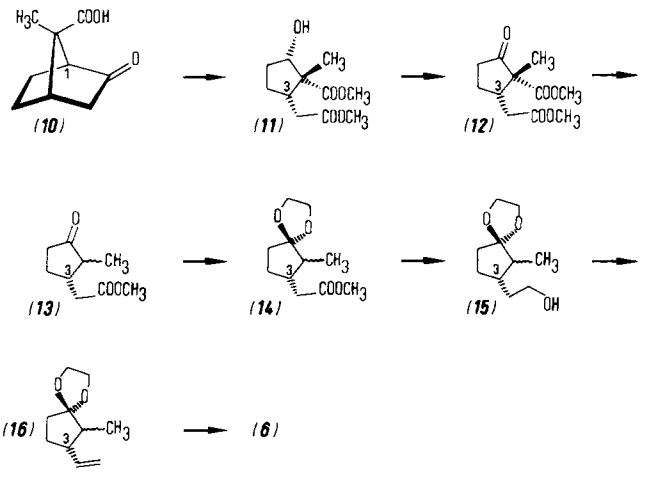
[13] Since *rac-(10)* undergoes at least 61% conversion into [*rac-(2)* + *rac-(15)*], the overall yield of this mixture is 22% for *m*-cresol methyl ether and 12% for (*E*)-1,4-dibromo-2-butene or dimethyl malonate.

Asymmetric Total Synthesis of (+)-Estrone[**]

By *Gerhard Quinkert, Ulrich Schwartz, Herbert Stark, Wolf-Dietrich Weber, Helmut Baier, Friedheld Adam*, and *Gerd Dürner*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

We have reported a steroid total synthesis which can be directed towards various racemic synthetic target compounds in considerable overall yield[1]. This synthesis contains a photochemical key reaction, starts from inexpensive chemicals, and proceeds largely regio- and stereoselectively. Of the four asymmetric C atoms of the title compound *(1a)*, three have been introduced with high diastereoselectivity: C-13 by a Michael addition, leading to the photo-enolizable key compound *rac-(5)*, C-8 and C-9 *via* an *o*-quinodimethanoid phototransient whose intramolecular Diels-Alder reaction[2] completes the steroid skeleton [of *rac-(3)*]. If the chiral dextrorotatory D ring component is used instead of the racemate (2Ξ,3*RS*)-*(6)*, then stereoselection is complete: natural (+)-estrone *(1a)* and its relatives thus become accessible by enantiomer selection (Scheme 1).



Scheme 1

The chiral, dextrorotatory D ring component has been obtained in three ways:

- According to Scheme 1, by ring expansion of the dextrorotatory three-membered ring compound *(R)-(8b)*, which is accessible from *(RS)-(8a)* by resolution with brucine[3,4];
- according to Scheme 2, by ring opening of the levorotatory bicyclic compound *(1S)-(10)*, obtained from *(1RS)-(10)* by resolution with (+)-1-phenylethylamine[5];
- according to Scheme 1, by ring expansion of the three-membered ring enantiomers *(R)-(8b)*/*(S)-(8b)* = 9:1, which are obtainable in this composition by asymmetric induction during diastereoselective cyclopropanation of *(7c)* and subsequent transesterification[6].

Table 1 indicates the extent of asymmetric induction, and shows (i) that the chiral substituent R greatly influences the

[**] Light Induced Reactions, Communication 22. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Hoechst AG. We are indebted to Prof. *R. Wiechert*, Schering AG, for kindly supplying large amounts of valuable steroids. *Marlies Dürr, Gabriele Stracke*, and *Sabine Beck* contributed greatly to optimization of the various reaction steps.—Communication 21: [1].

transformation of the malonic diesters *(7c)*, *(7d)*, and *(7e)* into products of type *(8)* and (ii) that the diastereoselective-asymmetric step of the synthesis is superior to the enantioselective-asymmetric alkylation [of *(7b)* by chiral *(9h)*[7] or by achiral *(9g)* in the presence of a chiral phase transfer catalyst[8]].

Table 1. Extent of asymmetric induction in the synthesis of *(8b)*.

Synthesis	Asymm. induction [%]
Diastereoselectively asymmetric	
(7c) + *(9g)*	76—80
(7d) + *(9g)*	52—54
(7e) + *(9g)*	39
Enantioselectively asymmetric	
(7b) + *(9h)*	13
(7b) + *(9g)*	<2

(*R*)-*(8b)* and (1*S*)-*(10)*, both obtained by resolution of racemates, represent reference compounds for the corresponding species from the chiral branch; *(5)* and *(2)*[9], which are obtained after introduction of (*R*)-*(8b)* and (1*S*)-*(10)* into the synthetic procedure (Scheme 1), are reference compounds for the corresponding species from the chiral trunk.

Table 2 shows that the optical yield of the diastereoselective-asymmetric synthesis is 80% on use of *(7c)*.

Table 2. Optical yield of the diastereoselectively asymmetric synthesis of *(2)* and intermediates [starting from *(7c)*] relative to reference compounds.

Opt. act. cpd.	$[\alpha]_D$ From the diastereoselectively asymmetric synthesis	Reference cpd.	Opt. yield [%]
(2)	+231.8 (dioxane)	+288.6	80
(5)	+ 21.2 ($CHCl_3$)	+ 27.1	80
(6)	+112.7 (CH_2Cl_2)	+149.0	76
(8b)	+ 43.9 (CCl_4)	+ 55.0	80

Table 3 contains some selected physical data of the compounds discussed above.

Table 3. Selected physical data of the identified chiral compounds. All formerly undescribed compounds and those synthesized by new methods exhibit correct molecular compositions and were characterized by IR and ^{1}H-NMR spectra.

(1a): m.p. 259 °C (ethanol); $[\alpha]_D^{20} = 164.8$ ($c = 0.501$ in dioxane)
(2): m.p. 143—144 °C (pentane); $[\alpha]_D^{20} = 288.6$ ($c = 0.506$ in dioxane).—*(2)* and *rac-(2)* [1] have similar IR spectra (KBr) but identical UV (methanol) and ^{1}H-NMR spectra ($CDCl_3$)
(5): $[\alpha]_D^{20} = 27.1$ ($c = 1.007$ in $CHCl_3$).—UV- (*n*-hexane), IR- (Film) and ^{1}H-NMR spectra ($CDCl_3$) of *(5)* and *rac-(5)* [1] were identical
cis-(6) + *trans-(6)* (8:92): $[\alpha]_D^{20} = 149.0$ ($c = 0.963$ in CH_2Cl_2)
(8b): $[\alpha]_D^{25} = 55.0$ ($c = 0.96$ in CCl_4)
(1*S*)-*(10)*: m.p. 206 °C (acetone, dec.); $[\alpha]_D^{20} = -76.1$ ($c = 0.992$ in ethanol)

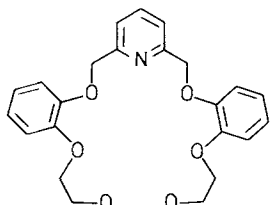
Selective Inclusion of Alcohols with a New Pyridino Crown[**]



By *Edwin Weber* and *Fritz Vögtle*[*]

Dedicated to Professor David Ginsburg on the occasion of his 60th birthday

Although several host/guest complexes of crown compounds with CH- and NH-acidic neutral molecules such as acetonitrile, nitromethane, and dimethyl sulfone have already been described[1], alcohols have so far defied all attempts at inclusion by compounds of this kind. Spurred on by the surprising complexation of uncharged guest molecules by the hexadentate dibenzopyridino crown *(1)*[1], our systematic study has now culminated in the discovery of the heptadentate tribenzopyridino crown *(2)* as a new host substance of this type. It is the first crown to form inclusion compounds—selectively—with aliphatic alcohols. Alcohol inclusion compounds of any kind were formerly very rare[2].

(1)

(2)

Our synthesis of *(2)* started from pyrocatechol monobenzyl ether *(3)*[3]; cyclization *(7)* + *(8)* → *(2)* could be accomplished by the dilution principle[4].

Compound *(2)* is obtained as a complex of exact 2:1 stoichiometry (ligand:guest) with *methanol* on recrystallization

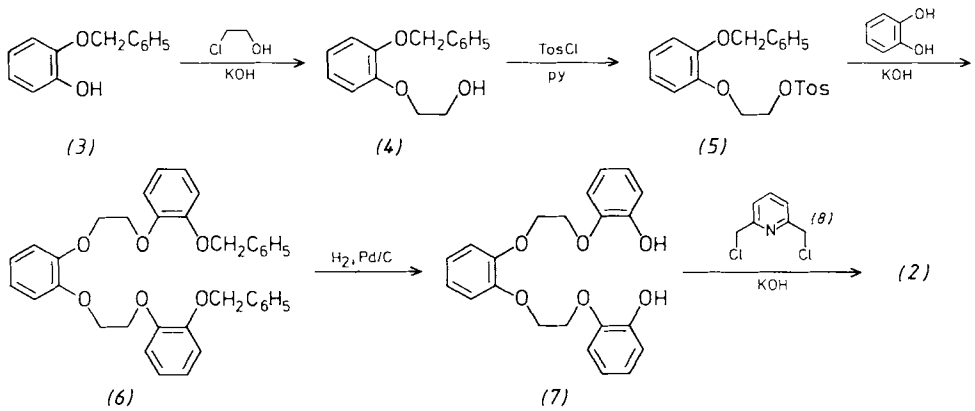
from this solvent[5]. The complex is so stable that it loses no methanol even on standing for weeks under normal conditions, or on drying for 1 d at 25 °C/15 torr. Heating to 48 °C leads to melting and slow decomposition with evaporation of the methanol, this process being complete at *ca.* 70 °C[5]. The melt then resolidifies. Renewed melting is observed at 102—104 °C—the melting point of the free ligand *(2)*.

The new ligand *(2)* binds not only *methanol* but also other alcohols to various extents, as is seen from the melting point, ^{1}H-NMR spectrum, and elemental analysis: while *ethanol* likewise gives a 2:1 complex, and is bound preferentially on recrystallization from a 1:1 *methanol/ethanol* mixture, the branched alcohols *isopropyl, isobutyl,* and *sec-butyl alcohol* do not give complexes but instead the free ligand.

In the homologous series of unbranched alcohols from *1-propanol* to *1-hexanol* complexes of various stability are obtained, some of which decompose already at 25 °C/0.2 torr. 1-Octanol no longer gives a complex. Maximum complexation is observed with ethanol and the limit lies at 1-heptanol. The 1-propanol complex is significantly less stable than those of ethanol and 1-butanol: it decomposes on standing under normal conditions.

The observed host/guest binding is thus selective with regard to chain length and branching of the guest molecule. The selectivity appears to be more pronounced than with trio-thymotide (TOT) which still includes cetyl alcohol[6a]. We assume that the guest molecules are accommodated, as in some TOT clathrates[6b]—and hence in contrast to crown complexes of acetonitrile[1], nitromethane[1], dimethyl sulfone[7], in which bonding is mainly by C—H···O interaction—in not particularly large *inter*molecular cavities of the crystal. However, since *(2)* does not include longer-chain alcohols, the host lattice appears to form only cages, and not cages *and* channels as in TOT[6b]. In contrast to the situation in the alcohol clathrates of the donorless TOT, the guest molecules in *(2)* are probably oriented since the OH group can form a hydrogen bond to the pyridine nitrogen[8].

Crown ethers such as *(2)* and *(1)*, and particularly the pyridino crowns which are symmetrically stiffened in TOT-like manner with aromatic rings[2a,9a], could possibly prove to be a treasure trove for systematically accessible new host molecules showing wide flexibility with respect to ring size, number of donors, and substitution, and capable of selectively complexing not only cations but also neutral organic molecules. The neutral host *(2)* is so far unique in that the structurally related heptadentate benzopyridino crowns *(9)*[1], *(10)* (m.p. 66—67 °C), and *(11)* (m.p. 99—100 °C)[4], also synthesized for the first time for purposes of comparison, do not form analogous alcohol inclusion compounds.



(9) *(10)* *(11)*

Procedure[4]

(4): KOH (14.0 g, 250 mmol) in boiling ethanol (250 cm^3) is stirred for 30 min with 2-benzyloxyphenol *(3)*[3] (50.0 g, 250 mmol); the temperature is maintained and ethylene chlorohydrin (20.1 g, 250 mmol) is then added dropwise. After 6 h under reflux the reaction mixture is filtered, the solvent removed in *in vacuo,* and the residue is dissolved in chloroform, washed with 0.2 N NaOH, and dried over Na_2SO_4. Distillation gives 29.3 g (48%) of colorless oil which crystallizes on standing; b.p. 167 °C/0.5 torr, n_D^{20} 1.5815, m.p. 40—41 °C (*n*-heptane).

(5): Compound *(4)* (24.4 g, 100 mmol) in pyridine is reacted under the usual conditions with toluenesulfonyl chloride (21.0 g, 110 mmol): 33.4 g (84%) colorless crystals, m.p. 44—46 °C (*n*-heptane).

(6): Catechol (4.40 g, 40 mmol), KOH (4.50 g, 80 mmol), and *(5)* (31.8 g, 80 mmol) are reacted as described for *(4)*. The solid residue is crystallized from ethanol: m.p. 91—93 °C, 65% yield.

(7): Compound *(6)* (14.0 g, 25 mmol) is hydrogenated in ethyl acetate for 4 h at room temperature under 3 bar H_2 over Pd/activated charcoal (10%). Yield 9.5 g (91%), colorless crystals, m.p. 116—118 °C (*n*-heptane).

Cyclization to (2): Compound *(7)* (7.65 g, 20 mmol) in dimethylformamide (250 cm^3), 2,6-bis(chloromethyl)pyridine *(8)*[9b] (3.52 g, 20 mmol) in *n*-butanol (250 cm^3), and KOH (2.25 g, 40 mmol) in ethanol (250 cm^3) are reacted under dilution principle conditions in boiling *n*-butanol (1000 cm^3). Evaporation *in vacuo,* washing with H_2O, dissolution in chloroform and chromatography (Al_2O_3, Woelm, basic, activity grade I) affords a glassy product which crystallizes immediately upon addition of methanol. Yield 2.43 g (26%), colorless scales of methanol adduct, m.p. 48 °C (incipient decomposition) to 60 °C; the melt generally solidifies at *ca.* 70 °C and remelts at 102—104 °C. ^{1}H-NMR ($CDCl_3$, TMS int. ref.): 5.12 (benzylic CH_2).

Cycloadditions with Silver Ion-Stabilized (2*RS*,3*RS*)-3-Methoxy-*trans*-Cycloheptene[**]

By *Heiner Jendralla*[*]

While compounds having a *trans* double bond in an eight-membered ring are as a rule stable at room temperature, no stable *trans*-cycloheptene or a corresponding bridgehead olefin could be prepared despite continued efforts[1]. Trapping experiments on photochemically generated *trans*-cycloheptene revealed that its lifetime at $-10\,^{\circ}C$ is 23 minutes[2].

"Normal" deamination of the nitrosourea *(1)* in weakly basic methanol led to the unstabilized title compound *(2)* as intermediate together with *(8)* as primary product[3]. Though *(2)* rapidly isomerizes to the *cis*-olefin *(7)* at room temperature[4], it can be trapped to the extent of 95% in the form of the cycloadducts *(3a)* and *(3b)* on deamination of *(1)* in methanol/furan[3].

On addition of silver perchlorate or trifluoromethanesulfonate (triflate) to a methanolic solution of *(1)* the deamination proceeds without the necessity of a base. If the reaction product is partitioned between ether and water, the ether extracts contain a mixture of the products *(7)*, *(8)*, and small amounts of *(9)*. If ammonia is now passed through the aqueous solution and the extraction is repeated, practically only *(7)* with small amounts of *(9)* and no *(8)* are found in the extract. Since the *cis*-olefin *(7)* forms no water-soluble silver perchlorate complex under the reaction conditions, this experiment indicates the reversible stabilization of the *trans*-olefin *(2)* as the water-soluble silver(I) complex *(6)*[5]. Removal of water *in vacuo* affords *(6)* as a colorless, thermally stable and moderately light-sensitive powder. The triflate complex could be isolated analytically pure by recrystallization (ethyl acetate/pentane/$-30\,^{\circ}C$)[6]. Elemental analysis gave an olefin/silver ratio of 1:1[9]. The *trans*-configuration of the double bond and the configuration of the methoxy group follow from the identical ^{1}H-NMR spectra of *(6a)* and *(6b)*. 1-H ($\delta = 5.80$) and 2-H (5.50) form an AB system; the large coupling constant $J_{1,2} = 17.9$ Hz confirms their *trans* orientation. 2-H also couples with 3-H ($J_{2,3} = 7.9$ Hz), whilst 1-H couples differently with the two protons on C-7 ($J_{1,7} = 9.2$ Hz, $J_{1,7'} = 4.3$ Hz). The magnitude of $J_{2,3}$ confirms the (2*RS*, 3*RS*)-configuration of *(2)*[7] previously deduced[3] from the adducts *(3a)* and *(3b)*. The very good agreement of the proton coupling constants of *(6a)* and *(6b)* with those of 3-methoxy-*trans*-cyclooctene[7] would suggest that the homologous olefins have a similar conformation. If one assumes that the olefin in *(6)* has the crown conformation ("eight-shaped loop") already demonstrated in the case of *trans*-cyclooctene[8], C-5 is found to be located exactly "behind" the double bond, *i.e.* should lie centrally in the shielding cone of anisotropism. The ^{13}C-NMR spectra of *(6a)* and *(6b)* contain four triplets. C-5 is shielded by about the same amount

[*] Dr. H. Jendralla
Institut für Organische Chemie, FB 9
Gesamthochschule, D-5600 Wuppertal 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Zentrale Verfügungsfonds der GH Wuppertal. I am indebted to Dr. *W. Dietrich* (Universität Bochum), who kindly recorded the ^{13}C-NMR spectra.

(8 ppm) compared to C-4 and C-6 as C-7 is deshielded due to its allylic position[9]. An X-ray structure analysis of *(6b)* is in progress.

The silver complex *(6a)* reacts with dienes at room temperature to give the corresponding cycloadducts *(3)* and *(10)*—*(13)*. Gas chromatographically, the sole impurity found in all cases was the *cis*-olefin *(7)* (2—13%). The following diastereomeric ratios *a/b* were determined by capillary gas chromatography: *(3)*: 4.4:1; *(11)*: 2.0:1; *(12)*: 2.4:1. The ratio *a/b* = 4.4:1 of the furan adducts *(3)* differs drastically from that found in the trapping of free *trans*-olefin *(2)* (*a/b* = 0.95:1)[3] and suggests that part of the cycloaddition takes place in the ligand sphere of the silver ion. The insolubility of *(6a)* in solvents suitable for anthracene hinders cycloaddition of the complex. However, *(13)* (m.p. 122 °C) was obtained when ammonia was passed into the stirred suspension of *(6a)* in the saturated anthracene solution in dichloromethane. Reaction of *(6a)* with *trans*-cyclooctene *(5)* gave tris(*trans*-cyclooctene)silver perchlorate *(4)*, m.p. 197 °C (decomp.). Preliminary experiments show that *cis,trans*-cycloheptadienes can also be stabilized as silver complexes.

[9] All the new compounds gave satisfactory ^{1}H-NMR spectra. *(6a)*: m.p. 157—159 °C (dec.) [6], ^{1}H-NMR (D_2O, TMS ext.): $\delta = 5.80$ (ddd, 1-H, $J_{1,2} = 17.9$ Hz, $J_{1,7} = 9.2$ Hz, $J_{1,7'} = 4.3$ Hz), 5.50 (dd, 2-H, $J_{1,2} = 17.9$ Hz, $J_{2,3} = 7.9$ Hz), 4.20 (m, 3-H), 3.50 (s, OCH_3), 2.73—1.30 (m, 8H); ^{13}C-NMR (D_2O, TMS ext.): $\delta = 123.0$ (d, C-1), 120.6 (d, C-2), 81.7 (d, C-3), 57.5 (q, OCH_3), 39.2 (t, C-7), 31.3 (t), and 31.1 (t) (C-4, C-6), 23.0 (t, C-5); essentially in agreement with MS of *(7)*. *(6b)*: m.p. 142—143 °C (dec.), ^{1}H-NMR: as *(6a)*; ^{13}C-NMR (D_2O/TMS ext.): $\delta = 121.7$ (d, $J_{CH} = 161.6$ Hz, C-1), 120.9 (q, $J_{CF} = 317.7$ Hz, CF_3), 119.9 (d, $J_{CH} = 161.6$ Hz, C-2), 81.3 (d, $J_{CH} = 150.4$ Hz, C-3), 57.2 (q, $J_{CH} = 142.6$ Hz, OCH_3), 38.9 (t, $J_{CH} = 129.4$ Hz, C-7), 31.0 and 30.7 (t, C-4, C-6), 22.6 (t, C-5).

$Li_{12}Si_7$, a Compound Having a Trigonal Planar Si_4 Cluster and Planar Si_5 Rings

By *Hans Georg von Schnering, Reinhard Nesper, Jan Curda,* and *Karl-Friedrich Tebbe*[*]

In a renewed study of the lithium-silicon system we were able to show[1] that the long-known violet compound "Li_2Si" actually has the composition $Li_{14}Si_6$ ($Li_{2.33}Si$). The metallic gray compound immediately adjacent on the silicon-rich side has now been identified as $Li_{12}Si_7$. This is the silicon-richest phase in the Li/Si system; it was formerly described as $Li_{13}Si_7$[2]. Preparation of the pure compound from the elements was accomplished in well baked-out, sealed tantalum ampoules at 1270 K. Syntheses under various conditions, thermal analysis, and coulometric titration demonstrate that $Li_{12}Si_7$ coexists in equilibrium with Si and $Li_{14}Si_6$. The compound has a almost negligible phase width ($1.69 \leq Li/Si \leq 1.71$); it melts congruently at 890 K and is extraordinarily sensitive to moisture and oxygen.

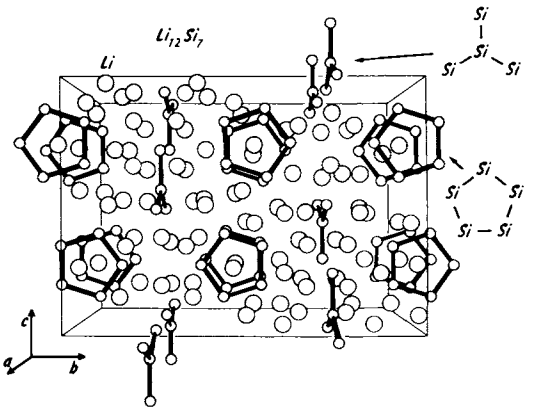

Fig. 1. Crystal structure of $Li_{12}Si_7$; projection of the unit cell along the *a* axis (Li, large circles; Si, small circles). Space group Pnma (No. 62); $a = 861.0(2)$, $b = 1973.8(4)$, $c = 1434.1(4)$ pm; 8 formula units in the unit cell; 2190 reflections *hkl*, $Mo_{K\alpha}$ radiation, $R = 0.035$ (anisotropic). None of the atoms shows anomalous coefficients U_{ij} or occupation densities. Subsequent ΔF synthesis is without notable contours [6].

$Li_{12}Si_7$ is unequivocally a semiconductor with a band gap of $E_G = 0.6$ eV and a specific conductivity at room temperature of $\sigma(298) = 10^{-6}\ \Omega^{-1}\ cm^{-1}$. The compound is diamagnetic with a considerably greater susceptibility than silicon ($\chi_{mol} = -23 \times 10^{-6}\ cm^3\ mol^{-1}$ for $Li_{1.714}Si$). These physical properties are important for an understanding of the bonding because they are indicative of a normal valence compound. The structure should therefore fulfil the rules of *Zintl* and *Klemm*[3] and of *Mooser* and *Pearson*[4].

$Li_{12}Si_7$ forms orthorhombic crystals (Fig. 1) with a surprising new kind of anionic Si_n cluster: Planar Si_5 rings—analogues are already known in the germanide $Li_{11}Ge_6$[5]—are accompanied by hitherto unknown star-shaped trigonal planar Si_4 clusters of 3/m-D_{3h} symmetry. The bond lengths d(Si-Si) in the Si_5 ring vary between 235.6 and 238.1 pm ($\bar{d} = 236.8$ pm) and those in the Si_4 star between 236.5 and 239.3 pm ($\bar{d} = 238.0$ pm); they are only slightly longer than the interatomic distance of a Si—Si single bond (235.1 pm).

Attempts to describe this structure in terms of the model of formal ions run into difficulties: for $Li_{24}Si_{14} \hat{=} (Li^+)_{24}(Si_4^{x-})(Si_5^{y-})_2$, the expression $x + 2y = 24$ would apply. The formal charge assigned to silicon (Si^{2-}) owing to the homonuclear divalency of the Si atoms in the Si_5 ring gives $y = 10$ as solution. However, this leads directly to Si_4^{4-}, a 20 e system normally found for the tetrahedrane structure of the isoelectronic P_4 molecule. Is the Si_4^{4-} star an excited tetrahedrane state then? Assuming an ($sp^2 + p$) configuration for all four Si atoms, a plausible description can be formulated with three three-center bonds and seven nonbonding electron pairs. Another remarkable variant results with the solution $x = y = 8$. The polyanion Si_4^{8-} would be isoelectronic with the carbonate anion CO_3^{2-} and the polyanion Si_5^{8-} with cyclopentene. We hope that this interesting structure will rouse the interest of theoreticians. The isostructural compound $Li_{12}Ge_7$ has likewise been prepared.

Planar Four-Coordinated Silicon?

By *Jack D. Dunitz*[*]

The announcement by *Meyer* and *Nagorsen*[1] that the bis(*o*-phenylenedioxy)silane molecule *(1)* is planar in the crystalline state is sufficiently novel and provocative that it can hardly avoid drawing critical attention to the evidence on which it is based. In the absence of a detailed X-ray analysis this evidence consists of a crystallographic symmetry argument: X-ray rotation and Weissenberg photographs led to a monoclinic unit cell with dimensions $a = 10.56$, $b = 5.60$, $c = 10.96$ Å, $\beta = 122°$, space group $P2_1/c$; with two molecules of $(C_6H_4O_2)_2Si$ per cell each silicon atom must occupy a crystallographic inversion center and hence must lie in a common plane with its four bonded oxygen atoms.

There are two weak points in this argument. In the first place, with a short *b* axis it may be dangerous to eliminate the alternative space group P2/c on the basis of a few systematically absent ($0k0$; $k = 2n+1$) reflections. If this space group is admitted as a possibility the silicon atoms could sit on twofold rotation axes instead of inversion centers and the symmetry argument for the planarity of the SiO_4 grouping would lose its force. In the second place, even if the space group $P2_1/c$ is accepted, the method of assigning molecular symmetry from space group arguments is not infallible because the molecular arrangement in the crystal may be disordered. There are many cases where molecular symmetries assigned in this way would obviously be in error. Perhaps the most famous case is that of azulene ($P2_1/a$, $Z = 2$)[2].

There is still another serious flaw in the experimental evidence: the chemical identity of the crystalline compound that was actually examined by X-ray diffraction is by no means proven. In fact the cell dimensions cited by *Meyer* and *Nagorsen* have a suspicious resemblance to those of catechol[3], a compound that might well be produced from *(1)* in the presence of traces of water.

In summary, the experimental evidence by *Meyer* and *Nagorsen*[1] is insufficient to establish *(1)* as the first compound with planar four-coordinated silicon. The theoretical arguments[1,4] of course retain whatever significance they had.

Planar Four-Coordinated Silicon—A Reply

By *Günter Nagorsen* and *Heinrich Meyer*[*]

The criticism leveled by *Dunitz*[1] at our communication[2] is partly justified. However, we had ourselves already emphasized that the space group determination is based on the absence of a few reflections and is hence not entirely compelling.

From 1975 to 1979 it proved impossible to again obtain suitable single crystals of the extremely sensitive monomeric bis(*o*-phenylenedioxy)silane *(1)*, and experimental results were therefore published only after supporting evidence had been obtained from model calculations[2,3].

The similarity between the lattice data of catechol and *(1)* appears remarkable at first sight, although *"a"* is significantly different. On closer examination, though, it actually provides powerful support for our structural model: for the H bond system linking two catechol molecules in *planar* fashion merely has to be replaced by silicon in a planar coordination, and the similarity in cell dimensions become entirely plausible.

Pure catechol melts at a temperature 8 °C lower than our substance and is stable to atmospheric moisture. Some of our (few) single crystals were hydrolyzed; catechol was identified alongside a gel of silicic acid. Within seconds of exposure to air, the lustrous crystals had become covered with a gel. Our identification of *(1)* was also based on mass spectrometry under the conditions of crystal growth.

We consider a possible disorder of the molecules in the crystal of *(1)* to be hardly applicable, since most of the cases cited by *Dunitz*[1] are (almost) planar, somewhat asymmetric systems whose disorder is explicable. Rather, it was precisely the lack of an isostructural relationship with the orthocarbonic ester that drew our attention to this structural problem.

SUBJECT INDEX

FP = Full paper (review article) SC = Short communication
G.E. = Reference to Volume 92 (1980) of the German Edition of Angewandte Chemie
References are given for Review Articles and Short Communications only.

ABSOLUTE configuration of the cancerostatic S(−)-isophosphamide (SC) 549 [G.E. 578]

Acetals, Phosphorus triiodide and diphosphorus tetraiodide, new reagents for deprotection of ~ and ketals (SC) 1006 [G.E. 1039]

Acetylene, Photochemically induced 1,2-bis(dialkylalumination) of diphenyl-~ (SC) 146 [G.E. 132]

Adamantane structure, $P_4(N\text{-}i\text{-}C_3H_7)_6$, a P_4X_6 molecule with and without ~ (SC) 571 [G.E. 563]

Addition, Total reversibility of ~ and transylidation of trialkyl(alkylidene)phosphoranes to metal-coordinated carbon monoxide (SC) 1019 [G.E. 1063]
Chemo- and diastereoselective ~ of alkyl- and aryl-titanium compounds to aldehydes and ketones (SC) 1011 [G.E. 1044]

Adenosine triphosphate, Structure and function of the energy-converting system of mitochondria (FP) 659 [G.E. 684]

Affinity gel, Phlorizin polymer as ~ for sugar-binding proteins (SC) 540 [G.E. 547]

Air pollution chemistry (Book Review) 330

Acetaldehyde as main product of the oxidation of ethylene oxide on a silver catalyst (SC) 407 [G.E. 389]

Alcohols, Photoreduction of ketones and aldehydes to ~ with selane (SC) 1008 [G.E. 1041]
Selective inclusion of ~ with a new pyridino crown (SC) 1030 [G.E. 1067]

Aldehydes, Coupling of solvolysis and C—C linkage: Promising synthetic route to functionalized carboxylic acids, ~, and ketones (FP) 171 [G.E. 169]
Photoreduction of ketones and ~ to alcohols with selane (SC) 1008 [G.E. 1041]
Reduction of carbonyl compounds by aluminum telluride and H_2O or D_2O (SC) 1009 [G.E. 1041]

Aldol condensation, Highly stereoselective ~ using an enantioselective chiral enolate (SC) 557 [G.E. 573]

Alkali metals, Catalytic graphite-intercalation with ~ in solution (SC) 491 [G.E. 476]

Alkali metal titanium sulfides, Nonstoichiometric ~ with channel structure (SC) 492 [G.E. 477]

Alkali metal-transition metal π-complexes (FP) 520 [G.E. 513]

Alkaloids, Intramolecular oxidative cyclization of 3-benzyl-1,2,3,4-tetrahydroisoquinolines (SC) 1018 [G.E. 1055]

Alkanes, Influence of isomerism of ~ on the thermodynamic properties of cyclohexane/alkane mixtures (SC) 223 [G.E. 209]

Alkanethiols, Addition of ~ to diketene (SC) 127 [G.E. 123]

1-Alkenes, Cycloadditions of diazoalkanes to ~ (SC) 202 [G.E. 198]

Alkylideneammonium ions, Collision induced fragmentation of ~ (SC) 541 [G.E. 548]

Alkyne cleavage, Biscarbyne clusters by ~: A general reaction (SC) 559 [G.E. 570]

Allenes, Acylated ketenimines and ~ from oxazol-5(4H)-ones and furan-2(3H)-ones (SC) 564 [G.E. 555]

Allenyl cations, Competing [3+4] and [2+4] cycloadditions of ~ (SC) 814 [G.E. 840]

Allyl cations, Synthesis of norbornenes from cyclopentadiene and allyl alcohols in an acidic two phase system (SC) 827 [G.E. 861]

Allylic compounds of magnesium, lithium and potassium: σ- or π-structures? (SC) 487 [G.E. 497]

Alumination, Photochemically induced 1,2-bis(dialkyl-~) of diphenylacetylene (SC) 146 [G.E. 132]

Aluminum compounds, First "small ring" in fluorometalates: $Ba_6F_4(F_4AlF_{2/2})_4$ = "$Ba_3Al_2F_{12}$" (SC) 489 [G.E. 476]

Aluminum telluride, Reduction of carbonyl compounds by ~ and H_2O or D_2O (SC) 1009 [G.E. 1041]
Reduction of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with hydrogen telluride from ~ and water (SC) 1009 [G.E. 1042]

Ambiphilicity of 1,1-diethoxy-4,4,4-trifluoro-3-(trifluoromethyl)-1,2-butadiene (SC) 713 [G.E. 740]

Amide rotation, Influence of ionic and polar solutes upon $\Delta G^{\neq}$ and $\Delta V^{\neq}$ of the ~ in aqueous solutions of dimethylacetamide (SC) 945 [G.E. 955]

Amides, Metal and metalloid ~ (Book Review) 656

N-(Amidosulfonyl)hydroxylamine, H_2NSO_2NHOH (SC) 943 [G.E. 957]

Amines, Mechanism of pyrylium/pyridinium ring interconversion. Mild preparative conditions for conversion of ~ into pyridinium ions (SC) 306 [G.E. 315]
Asymmetric synthesis of ~ by carbon-carbon coupling in α-position to nitrogen (SC) 725 [G.E. 753]
Selenium-catalyzed reduction of aromatic nitro compounds to ~ by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
Reduction of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with hydrogen telluride from aluminum telluride and water (SC) 1009 [G.E. 1042]
New arene(dicarbonyl)chromium chelates: Use in the asymmetric synthesis of ~ (SC) 1005 [G.E. 1038]

Aminoacetylenes, N-Ethynylamines of the type R—NH—C≡C—H (SC) 720 [G.E. 743]

Amino acids, Enantioselective synthesis of α-methylserines (SC) 212 [G.E. 205]

4-Aminobutyramide, New preparation of ~ (SC) 627 [G.E. 640]

3-(2-Amino-3-chlorophenyl)pyrrole, Formation of pyrrolnitrin and ~ from 7-chlorotryptophan (SC) 828 [G.E. 855]

Aminooxophosphane, $(R_2NPO)_3$: Novel heterocycle with λ^3-phosphorus by trimerization of an ~ (SC) 709 [G.E. 737]
Complex-stabilization of ~ (phosphinidene oxide) (SC) 710 [G.E. 738]

Amino-protecting group for use in peptide synthesis which can be introduced electrochemically (SC) 712 [G.E. 739]

Aminopyridines (SC) 388 [G.E. 390]

Ammonium ions, Collision induced fragmentation of alkylidene-~ (SC) 541 [G.E. 548]

Amphoterism, New variant of ~ of tin(II) hydroxide: $Sn(OH)_2$ as stannio complex ligand (SC) 553 [G.E. 561]

Analytical chemistry, Treatise on ~, Part I: Theory and practice (Book Review) 149

Analytical methods, Chromatographic resolution of racemates (FP) 13 [G.E. 14]
Kinetic and mechanistic evaluation of NMR spectra (FP) 411 [G.E. 445]
Physiochemical principles and applications of supercritical fluid chromatography (SFC) (FP) 575 [G.E. 585]

Annulenes, Synthesis of CH_2-Bridged [4n+2]-~ by a building-block approach (SC) 41 [G.E. 43]
syn-1,6-Ethano-8,13-methano[14]annulene (SC) 913 [G.E. 943]
Structure and dynamic behavior of syn-1,6-ethano-8,13-methano[14]annulene (SC) 921 [G.E. 944]
Mixed oligomers of propellanes and bridged ~ with bis(maleimides) and bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 936 [G.E. 972]
Cyclic oligomers of propellanes and bridged ~ with bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 933 [G.E. 970]
syn-1,6-Imino-8,13-methano[14]annulene (SC) 1015 [G.E. 1051]

Antimony compounds, Novel selenoantimonate(III) anions in $Na_4Sb_4Se_{11}$ (SC) 324 [G.E. 310]
Dimerization of S_6O to $S_{12}O_2$: Crystal structure analysis of $S_{12}O_2 \cdot 2SbCl_5 \cdot 3CS_2$ (SC) 325 [G.E. 313]

Anthracenemagnesium, Catalytic synthesis of magnesium hydride under mild conditions (SC) 818 [G.E. 845]

Arenes, Photochemical rearrangements and fragmentations of benzene derivatives and annelated ~ (FP) 243 [G.E. 245]

Aromaticity, syn-1,6-Ethano-8,13-methano[14]annulene (SC) 913 [G.E. 943]
Structure and dynamic behavior of syn-1,6-ethano-8,13-methano[14]annulene (SC) 921 [G.E. 944]

Arsenic compounds, Zintl phases with complex anions: $Sr_3Si_2As_4$ and $Sr_3Ge_2As_4$ (SC) 490 [G.E. 480]

Asymmetric catalysis, Conformational analysis of 1-phenylethyl substituents in metal complexes and their importance for ~ (SC) 641 [G.E. 645]

Asymmetric induction, Enhancement of 1,2-~ on C—C linkage by use of chiral 2-butenylboronic esters (SC) 218 [G.E. 218]

Asymmetric synthesis of amines by carbon-carbon coupling in the α-position to nitrogen (SC) 725 [G.E. 753]
New arene(dicarbonyl)chromium chelates: Use in the ~ of amines (SC) 1005 [G.E. 1038]
~ of (+)-estrone (SC) 1029 [G.E. 1062]

Aza[14]annulenes (SC) 207 [G.E. 204]

2-Azabarrelenone and 3-methoxy-2-azabarrelene (SC) 463 [G.E. 468]

Δ^3-1,2-Azaboroline, Preparation of 1-tert-butyl-3-methyl-2-phenyl-~ and utilization of its anion as a complex ligand analogous to cyclopentadienyl (SC) 54 [G.E. 61]

2-Aza-1,3-butadienes, 1,3-Bis-(dimethylamino)-~ from 1-alkyl-2-azavinamidinium salts (SC) 217 [G.E. 208]

6-Azauracil, New photocycloadditions of dibromomaleimides to 1,3-dimethyl-~ (SC) 1026 [G.E. 1066]

1H-Azepine: NMR spectroscopic and chemical characterization (SC) 1016 [G.E. 1053]

3H-Azepine, 1H-Azepine: NMR spectroscopic and chemical characterization (SC) 1016 [G.E. 1053]

Azides, Iminium-activated ~—New reagents for transfer of diazonium or diazo groups (SC) 716 [G.E. 754]

2-Azidopyrimidine, ^{15}N-NMR spectroscopic detection of the tetrazolo[1,5-a]pyrimidine/2-~ equilibrium (SC) 924 [G.E. 957]

Azoalkanes, Synthesis of unusual organic mo-

lecules from ~ (FP) 762 [G.E.] 815
β-Azolyl-α,α-dicarbonyl compounds (SC) 137 [G.E. 128]
Azomethine imine, Trimerization of an ~ by three successive 1,3-dipolar cycloaddition reactions (SC) 906 [G.E. 936]
Azulenesulfonium salts, Synthesis and rearrangement (SC) 621 [G.E. 635]

BARRELENE, 2-Azabarrelenone and 3-methoxy-2-aza-~ (SC) 463 [G.E. 468]
Benzene, Photochemical rearrangements and fragmentations of ~ derivatives and annelated arenes (FP) 243 [G.E. 245]
9,10-Benzotricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene—A Diels-Alder adduct of ~ and naphthalene (SC) 307 [G.E. 307]
Reversal of stability in the ~/Dewar ~ system (SC) 1022 [G.E. 1056]
Benzodicyclobutadiene, Complexation of a ~ with $Fe_2(CO)_9$ (SC) 926 [G.E. 952]
Benzophenonedilithium as complex with tetrahydrofuran and tetramethylethylenediamine (SC) 817 [G.E. 844]
9,10-Benzotricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene—A Diels-Alder adduct of benzene and naphthalene (SC) 307 [G.E. 307]
4,5-Benzotricyclo[4.1.0.0^{1,3}]hept-4-ene (SC) 631 [G.E. 641]
Benzotropylium tetrafluoroborate, Synthesis and intramolecular charge-transfer interaction in 1,4-dihydro-1,4-ethano-~ (SC) 545 [G.E. 566]
1,4-Benzoxazines, Oxidation of isatins to isatoic anhydrides and 2,3-dioxo-~ (SC) 222 [G.E. 196]
Benzvalene, Relation between orbital character and reaction product in the reaction of ~ and homobenzvalene with thiophenol (SC) 457 [G.E. 465]
Oxidation reactions of ~: Ozonolysis, cis-hydroxalation, epoxidation, and singlet oxygen addition (SC) 458 [G.E. 466]
Benzyl ligand, (1,2,5,6-η-1,5-Cyclooctadiene)(1,2,7-η-7-methylbenzyl)(7,8-η-styrene)rhodium(I)—Antarafacial fluctuation of the ~ and temperature-dependent-coordination of styrene (SC) 468 [G.E. 475]
3-Benzyl-1,2,3,4-tetrahydroisoquinolines, Intramolecular oxidative cyclization of 3-benzyl-1,2,3,4-tetrahydroisoquinolines (SC) 1018 [G.E. 1055]
Bicycloconjugation, Question of ~ in naphtho-fused 9-heterobicyclo[4.2.1]nona-2,4,7-trienes as examined by ^{13}C-NMR spectroscopy (SC) 639 [G.E. 657]
Bicyclo[3.2.0]hept-6-ene, New C_8H_{10} isomers: 2-Methylene-~[3.2.0]hept-6-ene and 3-methylenetricyclo[4.1.0.0^{2,7}]heptane—thermal and metal-catalyzed rearrangements (SC) 634 [G.E. 651]
Bicyclopropylidene, Three variants of the [2+2]-cycloadditions of ~ (SC) 387 [G.E. 387]
Biscarbyne clusters by alkyne cleavage: A general reaction (SC) 559 [G.E. 570]
1,3-Bis(dialkylamino)-1,3-butadiene from 1-methylvinamidinium salts (SC) 216 [G.E. 207]
1,2-Bis(dialkylalumination), Photochemically induced ~ of diphenylacetylene (SC) 146 [G.E. 132]
1,3-Bis(dimethylamino)-2-aza-1,3-butadienes from 1-alkyl-2-azavinamidinium salts (SC) 217 [G.E. 208]
Bis(maleimides), Mixed oligomers of propellanes and bridged annulenes with ~ and bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 963 [G.E. 972]
Bismuthanes, Diphenylbismuthyl group—A potential new auxiliary group in organic synthesis (SC) 723 [G.E. 746]
Bis(o-phenylenedioxy)silane, Planar tetracoordinated silicon? (SC) 1033 [G.E. 1070]
Planar tetracoordinated silicon—A reply (SC) 1034 [G.E. 1071]
Bis(triazolinediones), Cyclic oligomers of propellanes and bridged annulenes with studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 933 [G.E. 970]
Mixed oligomers of propellanes and bridged annulenes with bis(maleimides) and ~ studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 936 [G.E. 972]
Bituminous coal, ^{13}C-NMR spectroscopic studies on ^{13}C-methylated ~ (SC) 636 [G.E. 653]
Blood plasma, Chemistry and function of human plasma proteins (FP) 87 [G.E. 83]
Borates, Tetrakis(trimethylsilyl)borate and other trimethylsilyl-~ (SC) 58 [G.E. 65]
Boron compounds, Preparation of 1-tert-butyl-3-methyl-2-phenyl-Δ^3-1,2-azaboroline and utilization of its anion as a complex ligand analogous to cyclopentadienyl (SC) 54 [G.E. 61]
Stabilization of diborane(4) derivatives by tert-butyl groups: the first tetraalkyldiborane (4) (SC) 56 [G.E. 63]
Persistent tetraalkyldiboranes (4) (SC) 57 [G.E. 64]
Exceedingly mild desulfurization of thiols by sodium triethylhydroborate and transition metal chlorides (SC) 315 [G.E. 321]
Hexakis(dimethylamino)cyclohexaborane, a boron(I) compound without electron deficiency (SC) 482 [G.E. 481]
Boronic esters, Enhancement of 1,2-asymmetric induction on C—C linkage by use of chiral 2-butenyl-~ (SC) 218 [G.E. 218]
Boron sulfides, B_8S_{16}—An "inorganic porphine" (SC) 481 [G.E. 479]
Boron trifluoride: Crystal structure of a metastable phase (SC) 483 [G.E. 481]
Brefeldin, Novel entry to ~ A (SC) 472 [G.E. 486]
Bromination, Heterogeneously catalyzed gas-phase ~ of trifluoromethane (SC) 147 [G.E. 136]
~ with N-bromosuccinimide: solvent and selectivity (SC) 464 [G.E. 471]
N-Bromosuccinimide, Brominations with ~: solvent and selectivity (SC) 464 [G.E. 471]
1,2-Butadiene, Ambiphilicity of 1,1-diethoxy-4,4,4-trifluoro-3-(trifluoromethyl)-~ (SC) 713 [G.E. 740]
2-Butenylboronic esters, Enhancement of 1,2-asymmetric induction on C—C linkage by use of chiral ~ (SC) 218 [G.E. 218]
2-tert-Butyl-2H-isoindole: A partner for reactions with electrophiles (SC) 320 [G.E. 309]
Butyramide, New preparation of 4-amino-~ (SC) 627 [G.E. 640]

CAFFEINE, Photoreactions of stilbene with ~: Known, and new types of reactions (SC) 714 [G.E. 735]
Cage molecules, Cubane-type Sn_4N_3O cage (SC) 401 [G.E. 408]
Calcium isotope separation on an exchange resin having cryptand anchor groups (SC) 406 [G.E. 406]
Calorimetry, Grundlagen der Kalorimetrie (Book Review) 838
Cancerostatic, Absolute configuration of the ~ S(−)-isophosphamide (SC) 549 [G.E. 578]
Cannabinoids, Stereocontrolled intramolecular Diels-Alder reaction of heterodienes; studies on the synthesis of ~ (SC) 134 [G.E. 130]
Captodative substituent effects and the chromophoric system of indigo (SC) 908 [G.E. 937]
Carbamates, Lithiated allyl N,N-dialkyl-~ as homoenolate equivalents: Synthesis of protected 4-oxoalkanoates (SC) 625 [G.E. 637]
Carbamoyl halides, Synthesis of α-haloalkyl-~ (SC) 201 [G.E. 197]
Carbene-carbene rearrangement, 1,5-Dihydropentalene by tandem ~ (SC) 304 [G.E. 314]
Carbenecarbonylmetal complexes, Electrochemical oxidation of dicarbene complexes of the type (carbene)$_2$MoL(CO)$_3$: interconversion among three isomers via electrochemical redox process (SC) 538 [G.E. 550]
Carbene complexes, Structure of $[(CO)_5CrNEt_2]BF_4$, a key organometallic compound; reaction to give the carbene complex $(CO)_5CrC(AsPh_2)NEt_2$ (SC) 643 [G.E. 662]
Carbocations, Coupling of solvolysis and C—C linkage: A promising synthetic route to functionalized carboxylic acids, aldehydes, and ketones (FP) 171 [G.E. 169]
Carbocycles, Synthesis of cyclic compounds from triphenyl(phenyliminovinylidene)-phosphorane and carboxylic acids (SC) 822 [G.E. 856]
Carbodiimides, Cyclic ~ in nitrene rearrangements (SC) 566 [G.E. 556]
Carbodiphosphoranes, Ring-strained ~ (SC) 555 [G.E. 557]
Carbohydrates, L-Gulose or D-gluco-hexodialdose from D-glucurono-6,3-lactone by controlled reductions (SC) 546 [G.E. 552]
Pure D-gulose from D-gulono-1,4-lactone (SC) 547 [G.E. 553]
Simple new method for the synthesis of 2-deoxy-aldehydo-hexoses (SC) 548 [G.E. 553]
Synthesis of the pentasaccharide chain of the Forssman antigen (SC) 902 [G.E. 929]
Synthesis of chiral valienamine (SC) 904 [G.E. 930]
Carbon, Thermal degradation of polymers to polymeric ~—An approach to the synthesis of new materials (FP) 375 [G.E. 375]
Carbonates, Metal-catalyzed synthesis of cyclic ~ from carbon dioxide and oxiranes (SC) 317 [G.E. 302]
~ and poly-~ from urea and alcohol (SC) 718 [G.E. 742]
Carbon-carbon bond, Towards an understanding of the ~ (FP) 429 [G.E. 417]
Carbon-carbon coupling, Asymmetric synthesis of amines by ~ in the α-position to nitrogen (SC) 725 [G.E. 753]
Carbon disulfide, Metal-assisted reaction of ~ with "Etriphos" phosphane ligand: synthesis and structure of $[(Etriphos)Fe\{S_2C(EtPCH_2)_2CMe_2\}](BF_4)_2$ (SC) 1021 [G.E. 1055]
Carbon dioxide, Metal-catalyzed synthesis of cyclic carbonates from ~ and oxiranes (SC) 317 [G.E. 302]
Solubility of nonvolatile biochemical substances in compressed ~ (SC) 623 [G.E. 633]
Carbon disulfide, Nucleophilic addition of triphenylstannyllithium to ~ (SC) 220 [G.E. 227]
Carbon monoxide, ~/water as a reducing agent: formation of selane from selenium (SC) 308 [G.E. 317]
First insertion reaction of ~ into a rhenium-carbon σ-bond (SC) 824 [G.E. 843]
UV irradiation of nucleic acids and their components in the presence of air (SC) 829 [G.E. 858]
Carbon skeleton isomerization, Experimental and theoretical study of the degenerate ~ of the cyclopentyl cation in the gas phase (SC) 485 [G.E. 488]
Carbonyl groups, Distribution of terminal and bridging ~ in an anionic carbonylmetal cluster as a result of ion-pair formation. Crystal and molecular structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$ (SC) 404 [G.E. 441]
Carbonyl ylides, Intramolecular cycloadditions of ~ (SC) 47 [G.E. 48]
Carboxylic acids, Coupling of solvolysis and C—C linkage: A promising synthetic route to functionalized ~, aldehydes, and ketones (FP) 171 [G.E. 169]
Carbyne complexes, Double addition of a nucleophile to carbyne and carbonyl C-atom: S-phenyl 2-phenyl-2-(phenylthio)thioacetate from trans-bromotetracarbonyl(phenylcarbyne)chromium and thiophenolate (SC) 205 [G.E. 206]
Biscarbyne clusters by alkyne cleavage: A general reaction (SC) 559 [G.E. 570]

Catalysis, Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for homogeneous ~ (FP) 362 [G.E. 362]
Conformational analysis of 1-phenylethyl substituents in metal complexes and their importance for asymmetric ~ (SC) 641 [G.E. 645]
Catalysts, Catalysis of hydroformylation by $Co_4(CO)_{8-x}(\mu_2\text{-}CO)_2(PPh_3)_x(\mu_4\text{-}PPh)_2$, x = 0 or 2: clusters as ~ (SC) 478 [G.E. 494]
Dimerization of propylene with ~ exhibiting activities like highly-active enzymes (SC) 622 [G.E. 633]
Characterization by Mössbauer spectroscopy of iron carbide phases in a highly active carbon matrix catalyst for medium pressure Fischer-Tropsch synthesis (SC) 729 [G.E. 761]
Dehydroxylation of hydrogen zeolites: Conditions for the preparation of thermally stable ~ (SC) 743 [G.E. 759]
Metalloporphyrin-catalyzed hydroxylation of cyclohexane by alkyl hydroperoxides: Pronounced efficiency of iron-porphyrins (SC) 909 [G.E. 938]
Catechol, Planar tetracoordinated silicon? (SC) 1033 [G.E. 1070]
Planar tetracoordinated silicon—A reply (SC) 1034 [G.E. 1071]
CC bond formation, Chemo- and diastereoselective addition of alkyl- and aryltitanium compounds to aldehydes and ketones (SC) 1011 [G.E. 1044]
Cell models, Polymerizable phospholipid analogues—New stable biomembrane models and ~ (SC) 938 [G.E. 962]
^{252}Cf-Plasma desorption mass spectrometry, Mixed oligomers of propellanes and bridged annulenes with bis(maleimides) and bis(triazolinediones) studied by ~ (SC) 936 [G.E. 972]
Cyclic oligomers of propellanes and bridged annulenes with bis(triazolinediones) studied by ~ (SC) 933 [G.E. 970]
Chalcogran, Optically active ~ (2-ethyl-1,6-dioxaspiro[4.4]nonane) (SC) 630 [G.E. 640]
Chalcone, "Synthetic enzymes"-Highly stereoselective epoxidation of ~ in a triphasic toluene-water-poly[(S)-alanine] system (SC) 929 [G.E. 968]
Charge-transfer interaction, 1,4-Dihydro-1,4-bis(dicyanomethylene) triptycenes. Synthesis and intramolecular ~ (SC) 543 [G.E. 565]
Synthesis and intramolecular ~ in 1,4-dihydro-1,4-ethanobenzotropylium tetrafluoroborate (SC) 545 [G.E. 566]
Chemical distance, Principle of minimum ~ (PMCD) (FP) 495 [G.E. 503]
Chemisorption of gases on metals (Book Review) 76
Chemoreceptors, Differentiation between chiral pheromone analogues by ~ (SC) 475 [G.E. 492]
Chiral recognition, Separation of the enantiomers of 2-hydroxycarboxylic acids on optically active stationary phases (SC) 910 [G.E. 935]
Chloroformamidinium chlorides, Synthesis of carbocyclic and heterocyclic π-electron systems with pentafulvenoid ~ (SC) 199 [G.E. 202]
7-Chlorotryptophan, Formation of pyrrolnitrin and 3-(2-amino-3-chlorophenyl)pyrrole from 7-chlorotryptophan (SC) 828 [G.E. 855]
Chromatography, Chromatographic resolution of racemates (FP) 13 [G.E. 14]
Determination of morphological properties of swellable solids by size exclusion ~ (FP) 24 [G.E. 25]
Physicochemical principles and applications of super-critical fluid ~ (SFC) (FP) 575 [G.E. 585]
Liquid ~ of enantiomers: Determination of enantiomeric purity in spite of extensive peak overlap (SC) 469 [G.E. 490]
Phlorizin polymer as affinity gel for sugar-binding proteins (SC) 540 [G.E. 547]
Chromium, Ultratrace analysis: Determination of ~, Fe, and Co in the ppb and ppt range for checking the preparation of high-purity niobium (SC) 197 [G.E. 194]
Chromium complexes, Structural investigations on (η^{12}-[3.3]paracyclophane)chromium(0) and its cation in (η^{12}-[3.3]paracyclophane)chromium(I) triiodide (SC) 44 [G.E. 45]
Double addition of a nucleophile to carbyne and carbonyl C-atom: S-Phenyl 2-phenyl-2-(phenylthio)thioacetate from trans-bromotetracarbonyl(phenylcarbyne)-chromium and thiophenolate (SC) 205 [G.E. 206]
Complex stabilization of 3-oxopropadienylidene (C_3O) with pentacarbonylchromium(0) (SC) 225 [G.E. 224]
Structure of $[(CO)_5CrNEt_2]BF_4$, a key organometallic compound; reaction to give the carbene complex $(CO)_5CrC(AsPh_2)NEt_2$ (SC) 643 [G.E. 662]
Chromium compounds, Chromium(II)-catalyzed electrochemical dehalogenation of β-hydroxyhalides—convenient entry to deoxynucleosides (SC) 46 [G.E. 47]
Transition-metal complexes with pyrazolyl bridging ligands between very different metal centers (SC) 931 [G.E. 931]
New arene(dicarbonyl)chromium chelates: Use in the asymmetric synthesis of amines (SC) 1005 [G.E. 1038]
Chromophoric system, Captodative substituent effects and the ~ of indigo (SC) 908 [G.E. 937]
Citrate synthase reaction, (3R,S)-3,4-Dicarboxy-3-hydroxybutyl coenzyme A, an inhibitor of the ~ (SC) 136 [G.E. 133]
Citreoviridins from Aspergillus terreus (SC) 461 [G.E. 484]
Clusters, First optically active ~: resolution of enantiomers and absolute configuration of $SFeCoMoCp(CO)_8$ (SC) 65 [G.E. 66]
Activation and sulfur-atom transfer reaction of cluster-bonded S_2^{2-}-bridge ligands: synthesis of the new cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$ from $[Mo_3^{IV}S(S_2)_6]^{2-}$ and CN^- (SC) 72 [G.E. 69]
Trinuclear ~ of the early transition elements (SC) 875 [G.E. 921]
Polymetal complexes: Complexation of cluster triangular faces by the tripod ligand, $HC(PPh_2)_3$ (SC) 1024 [G.E. 1058]
Template synthesis of ~ using the tripod ligand $HC(PPh_2)_3$: $Ni_3(CO)_6$(tripod) (SC) 1025 [G.E. 1059]
Coal, ^{13}C-NMR spectroscopic studies on ^{13}C-methylated bituminous ~ (SC) 636 [G.E. 653]
Cobalt, Ultratrace analysis: Determination of Cr, Fe, and ~ in the ppb and ppt range for checking the preparation of high-purity niobium (SC) 197 [G.E. 194]
Cobalt clusters, Catalysis of hydroformylation by $Co_4(CO)_{8-x}(\mu_2\text{-}CO)_2(PPh_3)_x(\mu_4\text{-}PPh)_2$, x = 0 or 2: Clusters as catalysts (SC) 478 [G.E. 494]
Cobalt complexes, Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for homogeneous catalysis (FP) 362 [G.E. 362]
Distribution of terminal and bridging CO-Groups in an anionic carbonyl metal cluster as a result of ion-pair formation. Crystal and molecular structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$ (SC) 404 [G.E. 441]
Theoretical investigation of the diethynylcyclobutadiene(cyclopentadienyl)cobalt rearrangement (SC) 728 [G.E. 747]
Olefin-insertion into cobalt (d^8) complexes—Structure of ethylene(phenyl)tris(trimethylphosphane)cobalt (SC) 809 [G.E. 835]
Cobalt compounds, First optically active cluster: resolution of enantiomers and absolute configuration of $SFeCoMoCp(CO)_8$ (SC) 65 [G.E. 66]
Direct synthesis of the perfluoroalkanesulfinates of iron(II), cobalt(II), and nickel(II): SO_2-assisted addition of alkyl halides to transition metals (SC) 128 [G.E. 124]
Cobalt-mediated [2+2+2]-cycloadditions: A simple route to substituted cyclopentadienones (SC) 1023 [G.E. 1057]
Coenzyme A, (3R,S)-3,4-Dicarboxy-3-hydroxybutyl ~, an inhibitor of the citrate synthase reaction (SC) 136 [G.E. 133]
Complexes, Polarized low-temperature crystal spectra of inorganic ~ (FP) 290 [G.E. 290]
Compressed solutions, Chemistry in ~ (FP) 841 [G.E. 887]
Conformation, Rigid phenyl-group ~ in complexes (SC) 396 [G.E. 395]
Conformational analysis of 1-phenylethyl substituents in metal complexes and their importance for asymmetric catalysis (SC) 641 [G.E. 645]
Conjugation, Diagonal interaction in the four-membered ring. Experimental demonstration of a dominating circumannular ~: 5,6-Dimethylenebicyclo[2.1.1]hexane (SC) 807 [G.E. 833]
Coordination, Upright unsymmetrical ~ in a cyclopropenylnickel complex: Synthesis and structure of $[(C_3Ph_3)Ni(PPh_3)_2]PF_6$ (SC) 931 [G.E. 967]
Copolymerization parameters, Correlation between radical reactivities and ~ (SC) 206 [G.E. 215]
Copper complexes, MoS_4^{2-} and $MoOS_3^{2-}$ as structurally versatile and biochemically interesting ligands in crystalline multinuclear Cu- and Fe-complexes (SC) 654 [G.E. 665]
Corrinoids, Structure of metal-free ~ from Rhodopseudomonas sphaereoides (SC) 321 [G.E. 303]
Structure of yellow metal-free and yellow cobalt-containing ~ (SC) 321 [G.E. 304]
Crown ethers, Calcium isotope separation on an exchange resin having cryptand anchor groups (SC) 406 [G.E. 406]
Selective inclusion of alcohols with a new pyridino crown (SC) 1030 [G.E. 1067]
Crystal spectra, Polarized low-temperature ~ of inorganic complexes (FP) 290 [G.E. 290]
Cyanogen, Syntheses with ~—A simple route to 4,5-dichloroimidazoles (SC) 130 [G.E. 138]
Cyanophosphinidene, The ≡PCN group as a pseudochalcogen; ~-substituted heterocycles (SC) 722 [G.E. 767]
Cyclization, 1,5-Electrocyclizations—An important principle of heterocyclic chemistry (FP) 947 [G.E. 979]
Thermal and photochemical transformations of hetero-1,3,5-hexatrienes into five-membered rings—Possible pericyclic reactions (FP) 973 [G.E. 1005]
Cycloaddition, Mechanistic aspects of Diels-Alder reactions: A critical survey (FP) 779 [G.E. 773]
Intramolecular ~ of carbonyl ylides (SC) 47 [G.E. 48]
~ of diazoalkanes to 1-alkenes (SC) 202 [G.E. 198]
Three variants of the [2+2]-~ of bicyclopropylidene (SC) 387 [G.E. 387]
Competing [3+4] and [2+4] ~ of allenyl cations (SC) 814 [G.E. 840]
Double ~ yielding a tricyclic diphosphorane (SC) 825 [G.E. 860]
Thermal ~ of dimethyl acetylenedicarboxylate to cyclic enol ethers and thioenol ethers (SC) 832 [G.E. 848]
Thermal [2+2]-cycloadditions of tetracyanoethylene to cyclic thioenol ethers (SC) 831 [G.E. 848]
Cobalt-mediated [2+2+2]-~: A simple route to substituted cyclopentadienones (SC) 1023 [G.E. 1057]
~-s with silver ion stabilized (2RS,3RS)-3-methoxy-trans-cycloheptene (SC) 1032 [G.E. 1068]
Cyclobutadiene, Tetraphenyl-~-cycloalkene-nickel(0) complexes (SC) 145 [G.E. 131]

Theoretical investigation of the diethynylcyclobutadiene(cyclopentadienyl)cobalt rearrangement (SC) 728 [G.E. 747]
Cyclobutane, Tetrakis(phenylimino)-~ (tetrameric phenyl isocyanide) (SC) 136 [G.E. 134]
Cyclobutane derivatives, Thermal [2+2]-cycloadditions of tetracyanoethylene to cyclic thioenol ethers (SC) 831 [G.E. 848]
Cyclodextrin inclusion compounds in research and industry (FP) 344 [G.E. 343]
Cyclodimer distribution, Ligand-property control in the nickel(0)/butadiene/P-ligand catalytic system: "Electronic" factors in the control of ~ (SC) 570 [G.E. 569]
2,4,6-Cycloheptatriene-1-carbaldehyde, Dynamic behavior (SC) 301 [G.E. 316]
Cycloheptatriene trioxides, Stereospecific syntheses (SC) 48 [G.E. 54]
trans-Cycloheptene, Cycloadditions with silver ion-stabilized (2RS,3RS)-3-methoxy-~ (SC) 1032 [G.E. 1068]
Cyclohexane, Influence of isomerism of alkanes on the thermodynamic properties of ~(alkane mixtures (SC) 233 [G.E. 209]
Metalloporphyrin-catalyzed hydroxylation of ~ by alkyl hydroperoxides: Pronounced efficiency of iron-porphyrins (SC) 909 [G.E. 938]
Cyclopentadienones, Cobalt-mediated [2+2+2]-cycloadditions: A simple route to substituted ~ (SC) 1023 [G.E. 1057]
Cyclopentadienylamines, Electrophilic amination of cyclopentadienyllithium compounds (SC) 1010 [G.E. 1043]
Cyclopentyl cation, An experimental and theoretical study of the degenerate carbon skeleton isomerization of the ~ in the gas phase (SC) 485 [G.E. 488]
Cyclophanes, Structural investigations on (η^{12}-[3.3]paracyclophane]chromium(0) and its cation in (η^{12}-[3.3]paracyclophane)chromium(I) triiodide (SC) 44 [G.E. 45]
Tetrathiafulvalenopara-~ (SC) 66 [G.E. 49]
~ as diene components in Diels-Alder reactions (SC) 389 [G.E. 388]
Cyclopropanes, Heterocyclic analogues of methylene-~ (FP) 276 [G.E. 277]
Tetrachlorovinylcarbene from tetrachlorocyclopropene; facile synthesis of vinyl-~ (SC) 138 [G.E. 135]
Cyclopropane derivatives, Donor-acceptor substituted cyclopropanes: Synthesis and ring opening to 1,4-dicarbonyl compounds (SC) 813 [G.E. 839]
Cyclopropanimines by photolysis of pyrazolinimines: thermal reaction of an excited state (SC) 49 [G.E. 55]
Cyclopropenylnickel complex, Upright unsymmetrical coordination in a ~: Synthesis and structure of $[(C_3Ph_3)Ni(PPh_3)_2]PF_6$ (SC) 931 [G.E. 967]
Cyclopropyl ketone oximes, Rearrangement to 5,6-dihydro-4H-1,2-oxazines (SC) 199 [G.E. 195]
Cycloreversions, cis-/trans-Tris-[2.1.1]-σ-homobenzenes; synthesis and stereochemistry of [„2+„2+„2]-~ (SC) 567 [G.E. 575]
Cyclotri(phosphazenes) complexes with P-coordinated PdX_2 and PtX_2 (SC) 650 [G.E. 655]

DECARBOXYLATION, Thermal ~ of β-lactones: Steric hindrance of mesomerism as indication of a zwitterionic intermediate (SC) 465 [G.E. 469]
Decathiacyclotetradecane-6,7,13,14-tetraone, Synthesis and crystal structure analysis (SC) 125 [G.E. 122]
Dehalogenation, Chromium(II)-catalyzed electrochemical ~ of β-hydroxyhalides—convenient entry to deoxynucleosides (SC) 46 [G.E. 47]
Dehydroxylation of hydrogen zeolites: Conditions for preparation of thermally stable catalysts (SC) 743 [G.E. 759]
2-Deoxy-aldehydo-hexoses, Simple new synthesis (SC) 548 [G.E. 553]
Deoxynucleosides, Chromium(II)-catalyzed electrochemical dehalogenation of β-hydroxyhalides—convenient entry to ~ (SC) 46 [G.E. 47]
Depsipeptides, Synthesis of alternating ~ with the 4-methylthiophenoxycarbonyl group as protecting and activating group for the amino function (SC) 932 [G.E. 953]
Dermatoses, Photochemistry of sulfonamides and sulfonylureas: A contribution to the problem of light-induced ~ (SC) 648 [G.E. 647]
Desulfurization, Exceedingly mild ~ of thiols by sodium triethylhydroborate and transition metal chlorides (SC) 315 [G.E. 321]
Deuterium compounds, Reduction of carbonyl compounds by aluminum telluride and H_2O or D_2O (SC) 1009 [G.E. 1041]
Dewar benzene, Reversal of stability in the benzene/~ system (SC) 1022 [G.E. 1056]
Diacylphosphanes, Lithium dibenzoylphosphide·1,2-dimethoxyethane—A new 2-phospha-1,3-dionate (SC) 741 [G.E. 756]
Diagonal interaction in the four-membered ring. Experimental demonstration of a dominating circumannular conjugation: 5,6-dimethylenebicyclo[2.1.1]hexane (SC) 807 [G.E. 833]
Diastereoselective addition, Chemo- and ~ of alkyl- and aryl-titanium compounds to aldehydes and ketones (SC) 1011 [G.E. 1044]
Diazoalkanes, Cycloadditions to 1-alkenes (SC) 202 [G.E. 198]
Diazonium group transfer, Iminium-activated azides—New reagents for transfer of diazonium or diazo groups (SC) 716 [G.E. 754]
Dibenz[b,g]oxocinide ion, Direct observation of the ~; A non-aromatic (4n+2) species (SC) 393 [G.E. 402]
cis-1,2-Dibenzoylalkenes, Alkali metal-induced transformations of ~: Transformation of 11,12-dibenzoyl-9,10-dihydro-9,10-ethenoanthracene (SC) 907 [G.E. 939]
11,12-Dibenzoyl-9,10-dihydro-9,10-ethenoanthracene, Alkali metal-induced transformations of cis-1,2-dibenzoylalkenes: Transformation of ~ (SC) 907 [G.E. 939]
Diborane(4) derivatives, Stabilization by tert-butyl groups: the first tetraalkyldiborane(4) (SC) 56 [G.E. 63]
Persistent tetraalkyldiboranes(4) (SC) 57 [G.E. 64]
Dicarbamates, Syntheses with metalloid derivatives: Preparation of macrocyclic ~ (SC) 326 [G.E. 324]
1,4-Dicarbonyl compounds, Donor-acceptor substituted cyclopropanes: synthesis and ring opening to ~ (SC) 813 [G.E. 839]
1,2-Dichloroacenaphthylene, Ozonolysis (SC) 474 [G.E. 483]
4,5-Dichloroimidazoles, Syntheses with cyanogen—Simple route to ~ (SC) 130 [G.E. 138]
(3R,S)-3,4-Dicarboxy-3-hydroxybutyl coenzyme A, an inhibitor of the citrate synthase reaction (SC) 136 [G.E. 133]
Dicyanoketene, Direct detection in the gas phase (SC) 739 [G.E. 751]
Dicyanothioketene, Direct detection in the gas phase (SC) 740 [G.E. 752]
Dicyclobutabenzene, Complexation of a benzodicyclobutadiene with $Fe_2(CO)_9$ (SC) 926 [G.E. 952]
L-3,4-Didehydroproline, Direct method for synthesis of N-Boc-~ (SC) 742 [G.E. 761]
Diels-Alder adduct, 9,10-Benzotricyclo[6.2.2.$0^{2,7}$]dodeca-3,5,9,11-tetraene—A ~ of benzene and naphthalene (SC) 307 [G.E. 307]
Diels-Alder reactions, Mechanistic aspects: A critical survey (FP) 779 [G.E. 773]
Stereocontrolled intramolecular ~ of heterodienes; studies on the synthesis of cannabinoids (SC) 134 [G.E. 130]
Cyclophanes as diene components (SC) 389 [G.E. 388]
Nitrile function of tetracyanoethylene as dienophile (SC) 810 [G.E. 836]
Diene components, Cyclophanes as ~ in Diels-Alder reactions (SC) 389 [G.E. 388]
Dienophile, Nitrile function of tetracyanoethylene as ~ in Diels-Alder reactions (SC) 810 [G.E. 836]
Difluorosulfur imides, New aspects of reaction of ~ with fluorine (SC) 408 [G.E. 393]
5,6-Dihydro-4H-1,2-oxazines, Rearrangement of cyclopropyl ketones oximes to ~ (SC) 199 [G.E. 195]
1,5-Dihydropentalene by tandem carbene-carbene rearrangement (SC) 304 [G.E. 314]
Diisocyanide ligands, Template polymerization of rhodium(I) with rigid bent ~ (SC) 633 [G.E. 649]
Diketene, Addition of alkanethiols to ~ (SC) 127 [G.E. 123]
Dimethylacetamide, Influence of ionic and polar solutes upon $\Delta G^{\neq}$ and $\Delta V^{\neq}$ of the amide rotation in aqueous solutions of dimethylacetamide (SC) 945 [G.E. 955]
1,3-Dimethyl-6-azauracil, New photocycloadditions of dibromomaleimides to ~ (SC) 1026 [G.E. 1066]
5,6-Dimethylenebicyclo[2.1.1]hexane, Diagonal interaction in the four-membered ring. Experimental demonstration of a dominating circumannular conjugation: ~ (SC) 807 [G.E. 833]
1,4-Dioxanes with four fluorine and/or trifluoromethyl substituents on C^2 and C^3 from vicinal perfluorodicarbonyl compounds (SC) 126 [G.E. 123]
1,6-Dioxaspiro[4.4]nonane, Quantitative separation of the enantiomer pairs of the pheromone 2-ethyl-~ by complexation chromatography on an optically active metal complex (SC) 471 [G.E. 473]
Optically active chalcogran (2-Ethyl-~) (SC) 630 [G.E. 640]
Diphenylacetylene, Photochemically induced 1,2-bis(dialkylalumination) (SC) 146 [G.E. 132]
Diphenylbismuthyl group—A potential new auxiliary group in organic synthesis (SC) 723 [G.E. 746]
Diphosphoranes, Ring-strained carbo-~ (SC) 555 [G.E. 557]
Diphosphorus tetraiodide, Phosphorus triiodide and ~, new reagents for deprotection of acetals and ketals (SC) 1006 [G.E. 1039]
1,3-Dipolar cycloaddition, Trimerization of an azomethine imine by three successive ~ reactions (SC) 906 [G.E. 936]
Disaccharides, Facile synthesis of α- and β-O-glycosyl imidates; preparation of glycosides and ~ (SC) 731 [G.E. 763]
Distance, Principle of minimum chemical ~ (PMCD) (FP) 495 [G.E. 503]
Disulfenes, Perfluoro- and perchloro-~ (SC) 203 [G.E. 223]
1,2-Dithiacycloalkanes, One-electron oxidation of 1,2-dithiacycloalkanes (SC) 834 [G.E. 863]
1,3,2-Dithiaplumbocanes—Heterocycles with lead(IV)—sulfur bonds (SC) 923 [G.E. 950]
1,3-Dithietane 1,1,3,3-tetraoxide, Perfluoro- and perchlorodisulfenes 203 [G.E. 223]
Dithiolenes, Photolysis of water catalyzed by transition metal ~ (SC) 645 [G.E. 664]
Dithiomalonaldehyde, Transition-metal complexes of malonaldehyde and ~ (SC) 638 [G.E. 654]
Donor-acceptor substitution, Donor-acceptor substituted cyclopropanes: Synthesis and ring opening to 1,4-dicarbonyl compounds (SC) 813 [G.E. 839]
Drugs, Pharmaceutical chemistry today—Changes, problems, and opportunities (FP) 749 [G.E. 802]
Synthetische Arzneimittel (Synthetic ~) (Book Review) 229
Double cycloaddition yielding a tricyclic diphosphorane (SC) 825 [G.E. 860]
Dynamic NMR spectroscopy, Kinetic and mechanistic evaluation of NMR spectra (FP) 411 [G.E. 445]

ELECTROCHEMICAL oxidation of dicarbene complexes of type (carbene)$_2$MoL(CO)$_3$: Interconversion among three isomers via electrochemical redox process (SC) 538 [G.E. 550]
Electrochemistry, Chromium(II)-catalyzed electrochemical dehalogenation of β-hydroxyhalides—convenient entry to deoxynucleosides (SC) 46 [G.E. 47]
1,5-Electrocyclizations—An important principle of heterocyclic chemistry (SC) 947 [G.E. 979]
Electrolytes, Lithium nitride halides—New solid ~ with high Li^+ ion conductivity (SC) 74 [G.E. 72]
Electron acceptors, 1,2,3,5,6,7-s-Hydrindacenehexone and 1,2,3,6,7,8-pyrenehexone—Two new strong ~ (SC) 715 [G.E. 768]
Electron/ion transfer, Reversible topotactic redox reactions of solids by ~ (SC) 983 [G.E. 1015]
Electron microscopy, High-resolution transmission ~ re-examined as a tool in solid state chemistry (FP) 505 [G.E. 531]
Chemical applications of transmission ~ (Book Review) 148
Electron resonance spectroscopy, Multiple ~ (Book Review) 330
Electron transfer, Structure and function of the energy-converting system of mitochondria (FP) 659 [G.E. 684]
Outer sphere ~ reactions: A novel linear relationship between the selectivity and the normal potential of the reducing agents (SC) 558 [G.E. 580]
Electrophilic amination of cyclopentadienyllithium compounds (SC) 1010 [G.E. 1043]
Electrophilic reagents—Recent developments and their preparative application (FP) 151 [G.E. 147]
Enantiomers, Liquid chromatography of ~: Determination of enantiomeric purity in spite of extensive peak overlap (SC) 469 [G.E. 490]
Quantitative separation of the enantiomeric pairs of the pheromone 2-ethyl-1,6-dioxaspiro[4.4]nonane by complexation chromatography on an optically active metal complex (SC) 471 [G.E. 473]
Separation of ~ of 2-hydroxycarboxylic acids on optically active stationary phases (SC) 910 [G.E. 935]
Energy conversion, Structure and function of the energy-converting system of mitochondria (FP) 659 [G.E. 684]
Energy hypersurfaces, Reactions paths on multidimensional ~ (FP) 1 [G.E. 1]
Encyclopedia of chemical technology, Kirk-Othmer: ~ (Book Review) 228
Enethiolates, α-Carbamoyloxymethyl-substituted lithium ~ from 1-(N,N-dimethylcarbamoylthio)-2-methyl-1-propenyllithium (SC) 303 [G.E. 305]
Enol ethers, Thermal cycloadditions of dimethyl acetylenedicarboxylate to cyclic ~ and thioenol ethers (SC) 832 [G.E. 848]
Enophile, N-Sulfinylnonafluorobutanesulfonamide—A super-~ (SC) 732, 840 [G.E. 748]
Enzymes, Dimerization of propylene with catalysts exhibiting activities like highly-active ~ (SC) 622 [G.E. 633]
Epoxidation, Oxidation reactions of benzvalene: Ozonolysis, cis-hydroxylation, ~, and singlet oxygen addition (SC) 458 [G.E. 466]
"Synthetic enzymes". Highly stereoselective ~ of chalcone in a triphasic toluene-water-poly[(S)-alanine] system (SC) 929 [G.E. 968]
Ergochrome, Sequence analysis of ~—Biosynthesis by competitive incorporation (SC) 460 [G.E. 483]
Estrone, A photochemical route to (±)-~ (SC) 1027 [G.E. 1060]
Asymmetric total synthesis of (+)-estrone (SC) 1029 [G.E. 1062]
syn-1,6-Ethano-8,13-methano[14]annulene, Structure and dynamic behavior (SC) 921 [G.E. 944]
3-Ethoxyacroleins, Oxopropenylation of Grignard compounds with ~ (SC) 816 [G.E. 841]
Ethylene, Selective pathway from methanol to ~ and propene (SC) 126 [G.E. 125]
Unusually rapid cis-trans isomerization of a tetrasilylated ~: Generation of free radicals during rotation (SC) 620 [G.E. 632]
Ethylene(hydrido)iridium(III) complex, Cationic ~ (SC) 834 [G.E. 863]
Ethylene oxide, Acetaldehyde as main product of oxidation of ~ on a silver catalyst (SC) 407 [G.E. 389]
Ethylene(phenyl)tris(trimethylphosphane)cobalt, Olefin-insertion into cobalt (d^8) complexes—Structure of ~ (SC) 809 [G.E. 835]
N-Ethynylamines of the type R—NH—C≡C—H (SC) 720 [G.E. 743]
Etriphos, Metal-assisted reaction of carbon disulfide with "~" phosphane ligand: Synthesis and structure of $[(\sim)Fe\{S_2C(EtPCH_2)_2CMe_2\}](BF_4)_2$ (SC) 1021 [G.E. 1055]
Euglenapterin—An unusual new natural pteridine derivative from Euglena gracilis (SC) 473 [G.E. 474]

FISCHER-Tropsch synthesis, Characterization by Mössbauer spectroscopy of iron carbide phases in a highly active carbon matrix catalyst for medium pressure ~ (SC) 729 [G.E. 761]
Flash vacuum pyrolysis, 2-Vinylidene-2H-indene (SC) 821 [G.E. 846]
Fluctuating ligands, (1,2,5,6-η-1,5-Cyclooctadiene)(1,2,7-η-7-methylbenzyl)(7,8-η-styrene)rhodium(I)—Antarafacial fluctuation of the benzyl ligand and temperature-dependent coordination of styrene (SC) 468 [G.E. 475]
Fluid chromatography, Physicochemical principles and applications of supercritical ~ (SFC) (FP) 575 [G.E. 585]
Fluorine chemicals, Organo-~ and their industrial applications (Book Review) 230
Fluorine compounds, 1,4-Dioxanes with four fluorine and/or trifluoromethyl substituents on C^2 and C^3 from vicinal perfluorodicarbonyl compounds (SC) 126 [G.E. 123]
Direct synthesis of the perfluoroalkanesulfinates of iron(II), cobalt(II), and nickel(II): SO_2-assisted addition of alkyl halides to transition metals (SC) 128 [G.E. 124]
New aspects of the reaction of difluorosulfur imides with fluorine (SC) 408 [G.E. 393]
Ambiphilicity of 1,1-diethoxy-4,4,4-trifluoro-3-(trifluoromethyl)-1,2-butadiene (SC) 713 [G.E. 740]
N-Sulfinylnonafluorobutanesulfonamide—A superenophile (SC) 732 [G.E. 748]
The pentafluoropyridine cation $C_5F_5N^+$ (SC) 944 [G.E. 956]
N-Fluoroiminosulfur tetrafluoride, F—N=SF_4 (SC) 643 [G.E. 659]
Fluorometalates, The first "small ring" in ~: $Ba_6F_4(F_4AlF_{2/2})_4$ = "$Ba_3Al_2F_{12}$" (SC) 489 [G.E. 476]
Fluorophosphane ligands, General method for preparation of multidentate ~ (SC) 316 [G.E. 323]
Forssman antigen, Synthesis of the pentasaccharide chain of the ~ (SC) 902 [G.E. 929]
Fragmentation, Photochemical rearrangements and ~ of benzene derivatives and annelated arenes (FP) 243 [G.E. 245]
Collision induced ~ of alkylideneammonium ions (SC) 541 [G.E. 548]
Inductive, CC-hyperconjugative, and frangomeric effects in solvolytic ~ (SC) 708 [G.E. 734]
Fluoride-induced ~ of trimethylsilyloxysulfonates to form cis-coupled hexahydroazulenones (SC) 830 [G.E. 832]
Frangomeric effects, Inductive, CC-hyperconjugative, and ~ in solvolytic fragmentation reactions (SC) 708 [G.E. 734]
Free-energy relationships, Significance of isoselective temperatures for the existence of linear ~ (SC) 835 [G.E. 864]
6-Fulveneselone (SC) 69 [G.E. 52]
Fulvalenoparacyclophanes, Tetrathia-~ (SC) 66 [G.E. 49]
Fulvalenophanes, [2.2]- and [3.3]-tetrathia-~ (SC) 67 [G.E. 51]
Fungicides, 3-Phenylpropylamines. New class of systemic ~ (FP) 184 [G.E. 176]
Furan, Proton and hydrogen affinity of ~ and the site of protonation in the gas phase (SC) 905 [G.E. 934]
Furan derivatives, Thermal cycloadditions of dimethyl acetylenedicarboxylate to cyclic enol ethers and thioenol ethers (SC) 832 [G.E. 848]
Furan-2(3H)-ones, Acylated ketenimines and allenes from oxazol-5(4H)-ones and ~ (SC) 564 [G.E. 555]

GALLIUM compounds, Synthesis and properties of the first organosilyl-~ (SC) 55 [G.E. 62]
Gas chromatography, Separation of the enantiomers of 2-hydroxycarboxylic acids on optically active stationary phases (SC) 910 [G.E. 935]
Gas phase, Computer simulation of kinetics of complicated ~ reactions (FP) 333 [G.E. 331]
Gas-phase protonation, Proton and hydrogen affinity of furan and the site of (SC) 905 [G.E. 934]
Gel chromatography, theory, methodology, application (Book Review) 331
Germanium compounds, The $(Ph_4C_4GeMe)Fe(CO)_3$ cation: Synthesis, structure, and bonding (SC) 484 [G.E. 496]
Zintl phases with complex anions: $Sr_3Si_2As_4$ and $Sr_3Ge_2As_4$ (SC) 490 [G.E. 480]
(Trifluoromethyl)fluorogermanates (SC) 836 [G.E. 859]
α-D-Glucuronides of 1-(N-alkyl-N-nitrosoamino)alkyl alcohols (SC) 400 [G.E. 407]
D-Glucurono-6,3-lactone, L-Gulose or D-gluco-hexodialdose from ~ by controlled reductions (SC) 546 [G.E. 552]
Glycogen phosphorylases, Role of pyridoxal phosphate in catalysis of ~ (FP) 441 [G.E. 429]
Glycosides, Facile synthesis of α- and β-O-glycosyl imidates; preparation of ~ and disaccharides (SC) 731 [G.E. 763]
O-Glycosyl imidates, Facile synthesis of α- and β-~; preparation of glycosides and disaccharides (SC) 731 [G.E. 763]
Gold complexes, Synthesis and reaction of diorganophosphinite ~ (SC) 71 [G.E. 66]
Gold(I) dithioacetate, Gold(I)-gold(I) interactions. Tetrameric ~ (SC) 561 [G.E. 579]
Gold(I)-gold(I) interactions. Tetrameric gold(I) dithioacetate (SC) 561 [G.E. 579]
Graphite-intercalation, Catalytic ~ with alkali metals in solution (SC) 491 [G.E. 476]
Grignard compounds, Oxopropenylation of ~ with 3-ethoxyacroleins (SC) 816 [G.E. 841]
D-Gulono-1,4-lactone, Pure D-gulose from ~ (SC) 547 [G.E. 553]
Gulose, L-~ or D-gluco-hexodialdose from D-glucurono-6,3-lactone by controlled reductions (SC) 546 [G.E. 552]
Pure D-~ from D-gulono-1,4-lactone (SC) 547 [G.E. 553]

β-HALOETHYL groups, Vitamin B_{12} and a vitamin B_{12} model compound as catalysts of reductive removal of protecting ~ from acids (SC) 629 [G.E. 643]
Heme, A pyrazine-bridged ~ dimer absorbing at 800 nm (SC) 322 [G.E. 320]
Hericenes, 2,3,5,6,7,8-Hexakis(methylene)bicyclo[2.2.2]octane (SC) 1003 [G.E. 1036]
9-Heterobicyclo[4.2.1]nona-2,4,7-trienes, Question of bicycloconjugation in naphtho-fused ~ as examined by ^{13}C-NMR spectroscopy (SC) 639 [G.E. 657]

Heterocycles, 1,5-Electrocyclizations—An important principle of heterocyclic chemistry (FP) 947 [G.E. 979]
Thermal and photochemical transformations of hetero-1,3,5-hexatrienes into five-membered rings—Possible pericyclic reactions (FP) 973 [G.E. 1005]
Syntheses with metalloid derivatives. Preparation of ~ (SC) 327 [G.E. 325]
Synthesis of cyclic compounds from triphenyl(phenyliminovinylidene)phosphorane and carboxylic acids (SC) 822 [G.E. 856]
Hetero-1,3,5-hexatrienes, Thermal and photochemical transformations of ~ into five-membered rings—Possible pericyclic reactions (FP) 973 [G.E. 1005]
Hexaazabenzene, Photochemical reductive cis-elimination in cis-diazidobis(triphenylphosphane)platinum(II). Evidence of formation of bis(triphenylphosphane)platinum(0) and ~ (SC) 717 [G.E. 745]
Hexahydroazulenones, Fluoride-induced fragmentation of trimethylsilyloxysulfonates to form cis-coupled ~ (SC) 830 [G.E. 832]
1,2,3,7,8,20-Hexahydroporphyrin, an easily formed ligand system isomeric to porphyrinogens (SC) 141 [G.E. 141]
2,3,5,6,7,8-Hexakis(methylene)bicyclo[2.2.2]octane (SC) 1003 [G.E. 1036]
D-gluco-Hexodialdose, L-Gulose or ~ from D-glucurono-6,3-lactone by controlled reductions (SC) 546 [G.E. 552]
High temperature technology, Physical chemistry of ~ (Book Review) 946
History of science, Stereospecific polymerization of propylene: An outlook 25 years after its discovery (FP) 857 [G.E. 869]
German-Jewish pioneers in science 1900—1933 (Book Review) 573
Homobenzenes, cis-/trans-Tris-[2.1.1]-σ-~; synthesis and stereochemistry of [„2+„2+„2]-cycloreversions (SC) 567 [G.E. 575]
Homobenzvalene, Relation between orbital character and reaction product in reaction of benzvalene and ~ with thiophenol (SC) 457 [G.E. 465]
Homoenolate equivalents, Lithiated allyl N,N-dialkylcarbamates as ~: synthesis of protected 4-oxoalkanoates (SC) 625 [G.E. 637]
Homogeneous catalysis, Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for ~ (FP) 362 [G.E. 362]
Homotropone, "α,α,α"-, "α,β,α"-, and "α,α,β"-Trioxa-tris-σ-~ (SC) 214 [G.E. 216]
1,2,3,5,6,7-s-Hydrindacenehexone and 1,2,3,6,7,8-pyrenehexone—Two new strong acceptors (SC) 715 [G.E. 768]
Hydrido complex, Cationic ethylene(hydrido)iridium(III) complex (SC) 834 [G.E. 863]
Hydroformylation, Synthesis of intermediates by rhodium-catalyzed ~ (FP) 178 [G.E. 182]
Catalysis of ~ by $Co_4(CO)_{8-x}(\mu_2\text{-}CO)_2(PPh_3)_x(\mu_4\text{-}PPh)_2$, x = 0 or 2: Clusters as catalysts (SC) 478 [G.E. 494]
Hydrogen bonds, OH clusters with homodromic circular arrangement of ~ (SC) 398 [G.E. 404]
Novel proton-ordered, two-dimensional cross-linking of water molecules in pyridine trihydrate (SC) 552 [G.E. 559]
Hydrogen telluride, Reduction of carbonyl compounds by aluminum telluride and H_2O or D_2O (SC) 1009 [G.E. 1041]
Reduction of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with ~ from aluminum telluride and water (SC) 1009 [G.E. 1042]
Hydrogen zeolites, Dehydroxylation of ~: Conditions for preparation of thermally stable catalysts (SC) 743 [G.E. 759]
2-Hydroxycarboxylic acids, Separation of the enantiomers of ~ on optically active stationary phases (SC) 910 [G.E. 935]
β-Hydroxyhalides, Chromium(II)-catalyzed electrochemical dehalogenation of ~—convenient entry to deoxynucleosides (SC) 46 [G.E. 47]
Hydroxylamine derivatives, N-(Amidosulfonyl)hydroxylamine, H_2NSO_2NHOH (SC) 943 [G.E. 957]
Hydroxylation, Oxidation reactions of benzvalene: ozonolysis, cis-~, epoxidation, and singlet oxygen addition (SC) 458 [G.E. 466]
Metalloporphyrin-catalyzed ~ of cyclohexane by alkyl hydroperoxides: Pronounced efficiency of iron-porphyrins (SC) 909 [G.E. 938]

syn-1,6-IMINO-8,13-METHANO[14]ANNULENE (SC) 1015 [G.E. 1051]
4-Imino-1,2-oxazetidines, Stable ~ from N-neopentylidene-tert-butylamine N-oxide and isocyanides (SC) 45 [G.E. 46]
Inclusion compounds, Cyclodextrin ~ in research and industry (FP) 344 [G.E. 343]
Selective inclusion of alcohols with a new pyridino crown (SC) 1030 [G.E. 1067]
Inclusion reactions, Reversible topotactic redox reactions of solids by electron/ion transfer (FP) 983 [G.E. 1015]
Indigo, Captodative substituent effects and the chromophoric system of ~ (SC) 908 [G.E. 937]
Indole pigments from the fruiting bodies of the slime mold Arcyria denudata (SC) 459 [G.E. 463]
Industrial chemistry, Ullmanns Encyklopädie der technischen Chemie (Book Review) 838
Insertion, Olefin-~ into cobalt (d^8) complexes—Structure of ethylene(phenyl)-tris(trimethylphosphane)cobalt (SC) 809 [G.E. 835]
First insertion reaction of carbon monoxide into a rhenium-carbon σ-bond (SC) 824 [G.E. 843]
Intercalation complexes of metallocenes in iron oxide chloride (SC) 477 [G.E. 493]
Catalytic graphite intercalation with alkali metals in solution (SC) 491 [G.E. 476]
Iodine compounds, New dinuclear iridium(II) complexes arising by oxidative addition of I_2 to $Ir_2(\mu\text{-}StBu)_2(CO)_2L_2$ (SC) 551 [G.E. 572]
Iodomethyl(phosphane)complex, Conversion of an ~ into a methylenephosphorane-complex: Example of a nucleophile-catalyzed isomerization reaction (SC) 940 [G.E. 960]
Ion cyclotron resonance spectroscopy, Proton and hydrogen affinity of furan and the site of protonation in the gas phase (SC) 905 [G.E. 934]
Ion exchange, Calcium isotope separation on an exchange resin having cryptand anchor groups (SC) 406 [G.E. 406]
Ion pair formation, Distribution of terminal and bridging CO-groups in an anionic carbonylmetal cluster as a result of ~. Crystal and molecular structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$ (SC) 404 [G.E. 441]
Iridium complexes, New dinuclear iridium(II) complex arising by oxidative addition of I_2 to $[Ir_2(\mu\text{-}StBu)_2(CO)_2L_2]$ (SC) 551 [G.E. 572]
New dihydrido-bridged binuclear platinum-~ (SC) 721 [G.E. 744]
Cationic ethylene(hydrido)iridium(III) complex (SC) 834 [G.E. 863]
Iron, Ultratrace analysis: Determination of Cr, ~, and Co in the ppb and ppt range for checking the preparation of high-purity niobium (SC) 197 [G.E. 194]
Iron carbide phases, Characterization by Mössbauer spectroscopy of ~ in a highly active carbon matrix catalyst for medium pressure Fischer-Tropsch synthesis (SC) 729 [G.E. 761]
Iron complexes, Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for homogeneous catalysis (FP) 362 [G.E. 362]
First fixation of the unstable species sulfur monoxide in a cluster: Synthesis and structure of $Fe_3(CO)_9(S)SO$ (SC) 226 [G.E. 225]
Phthalocyaninatoiron with pyrazine as a bidentate bridging ligand (SC) 392 [G.E. 391]
The $(Ph_4C_4GeMe)Fe(CO)_3$ cation: Synthesis, structure, and bonding (SC) 484 [G.E. 496]
MoS_4^{2-} and $MoOS_3^{2-}$ as structurally versatile and biochemically interesting ligands in crystalline multinuclear Cu- and Fe-complexes (SC) 654 [G.E. 665]
Bis(η-cyclopentadienyliron-μ,η-thiadiborolene)iron—structure of a $\eta\text{-}C_5H_5$ tetradecker sandwich complex (SC) 746 [G.E. 758]
Iron compounds, First optically active cluster: resolution of enantiomers and absolute configuration of $SFeCoMoCp(CO)_8$ (SC) 65 [G.E. 66]
Direct synthesis of the perfluoroalkanesulfinates of iron(II), cobalt(II), and nickel(II): SO_2-assisted addition of alkyl halides to transition metals (SC) 128 [G.E. 124]
Metal-assisted reaction of carbon disulfide with "etriphos" phosphane ligand: Synthesis and structure of $[(Etriphos)Fe\{S_2C(EtPCH_2)_2CMe_2\}](BF_4)_2$ (SC) 1021 [G.E. 1055]
Iron oxide chloride, Intercalation complexes of metallocenes in ~ (SC) 477 [G.E. 493]
Isatins, Oxidation to isatoic anhydrides and 2,3-dioxo-1,4-benzoxazines (SC) 222 [G.E. 196]
Isatoic anhydrides, Oxidation of isatins to ~ and 2,3-dioxo-1,4-benzoxazines (SC) 222 [G.E. 196]
Isobacteriochlorin, Mutual interconversion of the chromophoric system of porphyrinogen and ~ (SC) 140 [G.E. 139]
Synthesis and transformation of 5-cyano-2,2,8,8,12,13,17,18-octamethyl-~ (SC) 143 [G.E. 143]
Isocyanates, Synthesis of α-haloalkylcarbamoyl halides (SC) 201 [G.E. 197]
Isocyanides, Stable 4-imino-1,2-oxazetidines from N-neopentylidene-tert-butylamine N-oxide and ~ (SC) 45 [G.E. 46]
Template polymerization of rhodium(I) with rigid bent diisocyanide ligands (SC) 633 [G.E. 649]
N-Isocyanoiminotriphenylphosphorane: Synthesis, coordination chemistry, and reactions at the metal (SC) 480 [G.E. 478]
2H-Isoindole, 2-tert-Butyl-~: A partner for reactions with electrophiles (SC) 320 [G.E. 309]
Isomerism, Influence of ~ of alkanes on the thermodynamic properties of cyclohexane/alkane mixtures (SC) 223 [G.E. 209]
Isomerization, Experimental and theoretical study of the degenerate carbon skeleton ~ of the cyclopentyl cation in the gas phase (SC) 485 [G.E. 488]
Base-catalyzed conversion of an equatorial into an axial methoxycarbonyl group due to a 1,5-long-range substituent effect (SC) 543 [G.E. 577]
Unusually rapid cis-trans ~ of a tetrasilylated ethylene: Generation of free radicals during rotation (SC) 620 [G.E. 632]
Conversion of an iodomethyl(phosphane)-into a methylenephosphorane complex: Example of a nucleophile-catalyzed ~ reaction (SC) 940 [G.E. 960]
Isophosphamide, Absolute configuration of the cancerostatic S(−)-~ (SC) 549 [G.E. 578]
Isoselective temperatures, Significance of ~ for existence of linear free-energy relationships (SC) 835 [G.E. 864]
Isotope separation, Calcium ~ on an exchange resin having cryptand anchor groups (SC) 406 [G.E. 406]

KETALS, Phosphorus triiodide and diphosphorus tetraiodide, new reagents for deprotection of acetals and ~ (SC) 1006 [G.E. 1039]

Ketenes, Direct detection of dicyanoketene in the gas phase (SC) 739 [G.E. 751]
Ketenimines, Acylated ~ and allenes from oxazol-5(4H)-ones and furan-2(3H)-ones (SC) 564 [G.E. 555]
Ketones, Coupling of solvolysis and C—C linkage: A promising synthetic route to functionalized carboxylic acids, aldehydes and ~ (FP) 171 [G.E. 169]
Functionalization of α-methylene ~ (SC) 131 [G.E. 138]
Photoreduction of ~ and aldehydes to alcohols with selane (SC) 1008 [G.E. 1041]
Reduction of carbonyl compounds by aluminum telluride and H_2O or D_2O (SC) 1009 [G.E. 1041]
Kinetics, Computer simulation of ~ of complicated gas phase reactions (FP) 333 [G.E. 331]

β-LACTAMS, Pyrrolizidines by rearrangement of ~ (SC) 129 [G.E. 126]
β-Lactones, Thermal decarboxylation of ~: Steric hindrance of mesomerism as indication of a zwitterionic intermediate (SC) 465 [G.E. 469]
2-Thietanimines from α-deprotonated ~ and phenyl isothiocyanate—A novel four-membered ring/four-membered ring recyclization (SC) 466 [G.E. 470]
Language, Symbolic ~ of the chemist (FP) 110 [G.E. 106]
Lead compounds, 1,3,2-Dithiaplumbocanes—heterocycles with lead(IV)—sulfur bonds (SC) 923 [G.E. 950]
Ligand-property control, ~ in the nickel(0)/butadiene/P-ligand catalytic system: Dominance of "steric" factors in the control of oligomer distribution (SC) 569 [G.E. 567]
~ in the nickel(0)/butadiene/P-ligand catalytic system: "Electronic" factors in the control of cyclodimer distribution (SC) 570 [G.E. 569]
Ligands, Coupling of well-established organotransition metal chemistry donor groups to multielectron ~ (SC) 328 [G.E. 321]
Rigid phenyl-group conformation in complexes (SC) 396 [G.E. 395]
Liposomes, Polymerizable phospholipid analogues—New stable biomembrane and cell models (SC) 938 [G.E. 962]
Liquid crystals, Handbook of ~ (Book Review) 656
Liquid metals and liquid semiconductors (FP) 593 [G.E. 598]
Liquids, Structure of simple molecular ~ (FP) 697 [G.E. 700]
Organic ~: structure, dynamics, and chemical properties (Book Review) 76
2-Lithio-2-methyl-1,3-dithiane, Crystal structure of ~·tetramethylethylenediamine (SC) 53 [G.E. 59]
Lithium compounds, Enantioselective synthesis of α-methylserines (SC) 212 [G.E. 205]
1,3-Bis(1-lithio-3-methyl-1-phenylpentyl)benzene, an organodilithium compound soluble in aromatic hydrocarbons (SC) 219 [G.E. 212]
Nucleophilic addition of triphenylstannyllithium to carbon disulfide (SC) 220 [G.E. 227]
Lithium bis(trimethylsilyl)methylene diphenylphosphoranide, a building block for the synthesis of bis(methylenephosphoranes) (SC) 243 [G.E. 206]
Distribution of terminal and bridging CO-groups in an anionic carbonylmetal cluster as a result of ion-pair formation. Crystal and molecular structure of $LiCo_3(CO)_{10}$·i-Pr_2O (SC) 404 [G.E. 441]
Allylic compounds of magnesium, lithium and potassium: σ- or π-structures? (SC) 487 [G.E. 497]
Lithiated allyl N,N-dialkylcarbamates as homoenolate equivalents: Synthesis of protected 4-oxoalkanoates (SC) 625 [G.E. 637]
Tripropylcarbazoyllithium (SC) 762 [G.E. 764]
Lithium compounds, $Li_{12}Si_7$, a compound having trigonal planar Si_4 cluster and planar Si_5 rings (SC) 1033 [G.E. 1070]
Lithium dibenzoylphosphide·1,2-dimethoxyethane—A new 2-phospha-1,3-dionate (SC) 741 [G.E. 756]
Lithium enethiolates, α-Carbamoyloxymethyl-substituted ~ from 1-(N,N-dimethylcarbamoylthio)-2-methyl-1-propenyllithium (SC) 303 [G.E. 305]
Lithium nitride halides—new solid electrolytes with high Li^+ ion conductivity (SC) 74 [G.E. 72]
Living polymers on polymerization with extremely productive Ziegler catalysts (SC) 390 [G.E. 396]
Luminescence spectroscopy (Book Review) 75

MACROMOLECULES. An introduction to polymer science (Book Review) 657
Magnesium compounds, Allylic compounds of magnesium, lithium, and potassium: σ- or π-structures? (SC) 487 [G.E. 497]
Magnesium hydride, Catalytic synthesis under mild conditions (SC) 818 [G.E. 845]
Malonaldehyde, Transition-metal complexes of ~ and dithio-~ (SC) 638 [G.E. 654]
Manganese compounds, Nucleophilic elimination-cycloaddition of α,ω-alkanediyl bis(triflates), a novel method for the synthesis of metallacycles with reactive metal-carbon bonds (SC) 73 [G.E. 70]
Total reversibility of addition and transylidation of trialkyl(alkylidene)phosphoranes to metal-coordinated carbon monoxide (SC) 1019 [G.E. 1063]
Phosphorus ylide carbene complexes—Synthesis and structure (SC) 1020 [G.E. 1065]
Mass spectrometry, Collision induced fragmentation of alkylideneammonium ions (SC) 541 [G.E. 548]
Matrix catalyst, Characterization by Mössbauer spectroscopy of iron carbide phases in a highly active carbon ~ for medium pressure Fischer-Tropsch synthesis (SC) 729 [G.E. 761]
Membrane, Vesicles with a monolayer, redox-active ~ (SC) 550 [G.E. 564]
Membrane models, Polymerizable phospholipid analogues—New stable biomembrane and cell models (SC) 938 [G.E. 962]
Mercaptocarbenium ion, ^{13}C-NMR study of protonated thioketones in superacidic media: Significance of ~ contributions (SC) 811 [G.E. 837]
Metal complexes in organic chemistry (Book Review) 656
Metallacycles, Nucleophilic elimination-cycloaddition of α,ω-alkanediyl bis(triflates), a novel method for the synthesis of ~ with reactive metal-carbon bonds (SC) 73 [G.E. 70]
Metallocenes, Intercalation complexes of ~ in iron oxide chloride (SC) 477 [G.E. 493]
Permethylated electron-excess ~ (SC) 640 [G.E. 658]
Metalloid derivatives, Syntheses with ~: Preparation of macrocyclic dicarbamate (SC) 326 [G.E. 324]
Syntheses with ~. Preparation of heterocycles (SC) 327 [G.E. 325]
Metalloporphyrin catalysts, Metalloporphyrin-catalyzed hydroxylation of cyclohexane by alkyl hydroperoxides: Pronounced efficiency of iron-porphyrins (SC) 909 [G.E. 938]
Metal polymers, Synthesis of organotrimetal polymers using trimetal vapor-fluid matrix techniques (SC) 402 [G.E. 409]
Metal-to-metal bonds, Simple method of forming ~ (SC) 937 [G.E. 961]
Methanol, Selective pathway from ~ to ethylene and propene (SC) 126 [G.E. 125]
Methoxycarbonyl group, Base-catalyzed conversion of an equatorial into an axial ~ due to a 1,5-long-range substituent effect (SC) 543 [G.E. 577]
(2RS,3RS)-3-Methoxy-trans-cycloheptene, Cycloadditions with silver ion-stabilized ~ (SC) 1032 [G.E. 1068]
Methylation, Geminal dialkylation of ketones with Grignard compounds and methyltitanium(IV) chlorides (SC) 901 [G.E. 931]
Chemoselective and position specific ~ of tert-alkyl halides with methyltitanium(IV) chlorides (SC) 901 [G.E. 933]
μ-Methylene complex, Synthesis of the first methylidyne-rhodium cluster by proton-induced H_2/CH_4-elimination from a ~ (SC) 651 [G.E. 660]
Methylenecyclopropanes, Heterocyclic analogues of ~ (FP) 276 [G.E. 277]
α-Methylene ketones, Functionalization (SC) 131 [G.E. 138]
Methylenephosphorane, $Ph(Me_3Si)C{-}P{-}Cl$, the first P-halofunctionalized ~ (SC) 556 [G.E. 578]
Methylenephosphorane-complex, Conversion of an iodomethyl(phosphane)- into a ~: Example of a nucleophile-catalyzed isomerization reaction (SC) 940 [G.E. 960]
Methylidyne-rhodium cluster, Synthesis of the first ~ by proton-induced H_2/CH_4-elimination from a μ-methylene complex (SC) 651 [G.E. 660]
Methyl ketones, Are α-oxothioacyl chlorides formed in the reaction of ~ with thionyl chloride? (SC) 563 [G.E. 559]
α-Methylserines, Enantioselective synthesis (SC) 212 [G.E. 205]
4-Methylthiophenoxycarbonyl group, Synthesis of alternating depsipeptides with the ~ as protecting and activating group for the amino function (SC) 932 [G.E. 953]
Methyltitanium(IV) chlorides, Geminal dialkylation of ketones with Grignard compounds and ~ (SC) 901 [G.E. 931]
Chemoselective and position specific methylation of tert-alkyl halides with ~ (SC) 901 [G.E. 933]
Micellar systems, Photophysical and photochemical processes in ~ (FP) 675 [G.E. 712]
Michael addition, Synthesis under high pressure: ~ (SC) 1013 [G.E. 1046]
Minimum chemical distance, Principle of ~ (PMCD) (FP) 495 [G.E. 503]
Mitochondria, Structure and function of the energy-converting system of ~ (FP) 659 [G.E. 684]
Models, Molecular and crystal structure ~ (Book review) 229
Chemistry through ~ (Book Review) 839
Molecular liquids, Structure of simple ~ (FP) 697 [G.E. 700]
Molten salts, Influence of density and temperature on properties of pure ~ (FP) 606 [G.E. 612]
Molybdenum compounds, First optically active cluster: resolution of enantiomers and absolute configuration of $SFeCoMoCp(CO)_8$ (SC) 65 [G.E. 66]
Activation and sulfur-atom transfer reaction of cluster-bonded S_2^{2-}-bridge ligands: synthesis of the new cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$ from $[Mo_3^{IV}S(S_2)_6]^{2-}$ and CN^- (SC) 72 [G.E. 69]
Electrochemical oxidation of dicarbene complexes of type $(carbene)_2MoL(CO)_3$: Interconversion among three isomers via electrochemical redox process (SC) 538 [G.E. 550]
MoS_4^{2-} and $MoOS_3^{2-}$ as structurally versatile and biochemically interesting ligands in crystalline multinuclear Cu- and Fe-complexes (SC) 654 [G.E. 665]
Morphological properties, Determination of ~ of swellable solids by size exclusion chromatography (FP) 24 [G.E. 25]
Multielectron ligands, Coupling of well-established organotransition metal chemistry donor groups to ~ (SC) 328 [G.E. 321]
Mutarotation, ^1H-NMR investigations on ~ rotation of N-acetyl-D-neuraminic acid (SC) 208 [G.E. 200]

NAPHTHALENE, 9,10-Benzotricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene—A Diels-Alder adduct of benzene and ~ (SC) 307 [G.E. 307]
(+)-(2R)-5,5′-Dimethyl-2,2′-spirobi(2,3-dihydro-1H-cyclopenta[a]-~)—A chiral spirohydrocarbon containing orthogonal ~ units (SC) 308 [G.E. 318]
Neuraminic acid, ^{1}H-NMR investigations on mutarotation of N-acetyl-D-~ (SC) 208 [G.E. 200]
Nickelacyclopentene derivatives from nickel(0), carbon monoxide, and alkyne (SC) 927 [G.E. 951]
Nickel complexes, Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for homogeneous catalysis (FP) 362 [G.E. 362]
Tetraphenylcyclobutadienecycloalkenenickel(0) complexes (SC) 145 [G.E. 131]
Photooxidation of the ligands of bis(o-semiquinonediimine)nickel(II) and -platinum(II) (SC) 221 [G.E. 228]
Ligand-property control in the nickel(0)/butadiene/P-ligand catalytic system: Dominance of "steric" factors in the control of oligomer distribution (SC) 569 [G.E. 567]
Ligand-property control in the nickel(0)/butadiene/P-ligand catalytic system: "Electronic" factors in the control of cyclodimer distribution (SC) 570 [G.E. 569]
Nickel compounds, Direct synthesis of the perfluoroalkanesulfinates of iron(II), cobalt(II), and nickel(II): SO_2-assisted addition of alkyl halides to transition metals (SC) 128 [G.E. 124]
Upright unsymmetrical coordination in a cyclopropenylnickel complex: Synthesis and structure of $[(C_3Ph_3)Ni(PPh_3)_2]PF_6$ (SC) 931 [G.E. 967]
Template synthesis of clusters using the tripod ligand $HC(PPh_2)_3$: $Ni_3(CO)_6$(tripod) (SC) 1025 [G.E. 1059]
Niobium, Ultratrace analysis: Determination of Cr, Fe, and Co in the ppb and ppt range for checking the preparation of high-purity ~ (SC) 197 [G.E. 194]
Nitrenes, Cyclic carbodiimides in nitrene rearrangements (SC) 566 [G.E. 556]
μ-Nitrido complex, $(AsPh_4)W_2NCl_{10}$, a ~ containing tungsten(V) and tungsten(VI) (SC) 220 [G.E. 211]
Nitroarenes, Selenium-catalyzed reduction of aromatic nitro compounds to amines by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
Reduction of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with hydrogen telluride from aluminum telluride and water (SC) 1009 [G.E. 1042]
Nitrogen compounds, Novel SN-ligand: Structure of $PtCl(S_4N_3)$ (SC) 653 [G.E. 644]
Reduction of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with hydrogen telluride from aluminum telluride and water (SC) 1009 [G.E. 1042]
Nitrosamines, α-D-Glucuronides of 1-(N-alkyl-N-nitrosoamino)alkyl alcohols (SC) 400 [G.E. 407]
Nitroso compounds, α-D-Glucuronides of 1-(N-alkyl-N-nitrosoamino)alkyl alcohols (SC) 400 [G.E. 407]
NMR spectroscopy, Kinetic and mechanistic evaluation of NMR spectra (FP) 411 [G.E. 445]
Extreme ^{13}C-NMR data as information on organometal radicals (SC) 479 [G.E. 487]
^{13}C-NMR spectroscopic studies on ^{13}C-methylated bituminous coal (SC) 636 [G.E. 653]
The question of bicycloconjugation in naphtho-fused 9-heterobicyclo[4.2.1]nona-2,4,7-trienes as examined by ^{13}C-NMR spectroscopy (SC) 639 [G.E. 657]
^{13}C-NMR study of protonated thioketones in superacidic media: Significance of mercaptocarbenium ion contributions (SC) 811 [G.E. 837]
Thiobenzoyl cations (SC) 812 [G.E. 838]
^{15}N-NMR spectroscopic detection of the tetrazolo[1,5-a]pyrimidine/2-azidopyrimidine equilibrium (SC) 924 [G.E. 957]
Norbornenes, Synthesis of ~ from cyclopentadiene and allyl alcohols in an acidic two phase system (SC) 827 [G.E. 861]
Normal potential, Outer sphere electron transfer reactions. Novel linear relationship between selectivity and ~ of reducing agents (SC) 558 [G.E. 580]
Nucleic acids, Viroids: A class of subviral pathogens (FP) 231 [G.E. 233]
UV irradiation of ~ and their components in the presence of air (SC) 829 [G.E. 858]
Nucleobases, UV irradiation of nucleic acids and their components in the presence of air (SC) 829 [G.E. 858]

OLEFIN-insertion into cobalt (d^8) complexes—Structure of ethylene(phenyl)-tris(trimethylphosphane)cobalt (SC) 809 [G.E. 835]
Oligomer distribution, Ligand-property control in the nickel(0)/butadiene/P-ligand catalytic system: Dominance of "steric" factors in the control of ~ (SC) 569 [G.E. 567]
Oligomers, Cyclic ~ of propellanes and bridged annulenes with bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectronomy (SC) 933 [G.E. 970]
Mixed ~ of propellanes and bridged annulenes with bis(maleimides) and bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectronomy (SC) 936 [G.E. 972]
One-electron oxidation of 1,2-dithiacycloalkanes (SC) 834 [G.E. 863]
Organic metals, Radical cation salts of simple arenes—A new family of "organic metals" (SC) 912 [G.E. 941]
Organisches Praktikum, Integriertes ~ (Book review) 747
Organofluorine chemicals and their industrial applications (Book Review) 230
Organometal radicals, Extreme ^{13}C-NMR data as information on ~ (SC) 479 [G.E. 487]
3-Oxabicyclo[4.3.0]non-1-en-9-one, (6R,7R)-(−)-7-Hydroxy-~. A readily accessible and highly versatile intermediate (SC) 628 [G.E. 639]
3-Oxa-ene reactions of N-sulfinylnonafluorobutanesulfonamide with alkanones—General synthesis of 2-oxoalkanesulfinic acid derivatives (SC) 737 [G.E. 750]
1,2-Oxazetidines, Stable 4-imino-~ from N-neopentylidene-tert-butylamine N-oxide and isocyanides (SC) 45 [G.E. 46]
Oxazines, Rearrangement of cyclopropyl ketone oximes to 5,6-dihydro-4H-1,2-~ (SC) 199 [G.E. 195]
Oxazol-5(4H)-ones, Acylated ketenimines and allenes from ~ and furan-2(3H)-ones (SC) 564 [G.E. 555]
Oxidation, Structural changes on ~: Flattening of the C_4-cluster of tetrahedrane (SC) 209 [G.E. 213]
Oxygen atoms produced by microwave discharge: Reactions with arenes (SC) 1004 [G.E. 1037]
Oxidative addition, New dinuclear iridium(II) complexes arising by ~ of I_2 to $[Ir_2(\mu\text{-}StBu)_2(CO)_2L_2]$ (SC) 551 [G.E. 572]
Oxiranes, Synthesis of monosubstituted (S)-~ in high optical purity (SC) 198 [G.E. 201]
Metal-catalyzed synthesis of cyclic carbonates from carbon dioxide and ~ (SC) 317 [G.E. 302]
2-Oxoalkanesulfinic acid, 3-Oxa-ene reactions of N-sulfinylnonafluorobutanesulfonamide with alkanones—General synthesis of ~ derivatives (SC) 737 [G.E. 750]
4-Oxoalkanoates, Lithiated allyl N,N-dialkylcarbamates as homoenolate equivalents: Synthesis of protected ~ (SC) 625 [G.E. 637]
3-Oxopropadienylidene, Complex stabilization of ~ (C_3O) with pentacarbonylchromium(0) (SC) 225 [G.E. 224]
Oxopropenylation of Grignard compounds with 3-ethoxyacroleins (SC) 816 [G.E. 841]
α-Oxothioacetyl chlorides, Are ~ formed in the reaction of methyl ketones with thionyl chloride? (SC) 563 [G.E. 559]
6-Oxoverdazyls (SC) 724 [G.E. 766]
Oxygen atoms produced by microwave discharge: Reactions with arenes (SC) 1004 [G.E. 1037]
Ozonolysis, Oxidation reactions of benzvalene: ~, cis-hydroxylation, epoxidation, and singlet oxygen addition (SC) 458 [G.E. 466]
~ of 1,2-dichloroacenaphthylene (SC) 474 [G.E. 483]

[2$_4$]-PARACYCLOPHANETETRAENE, Dianion and tetraanion of ~—New unusual perimeter systems (SC) 624 [G.E. 636]
Pentafluoropyridine cation, $C_5F_5N^+$ (SC) 944 [G.E. 956]
Pentasaccharide chain, Synthesis of ~ of the Forssman antigen (SC) 902 [G.E. 929]
Peptide synthesis, New ~ (SC) 133 [G.E. 129]
4-Sulfobenzyl, a new carboxy protecting group (SC) 394 [G.E. 394]
An amino-protecting group for use in ~ which can be introduced electrochemically (SC) 712 [G.E. 739]
Pericyclic reactions, Thermal and photochemical transformations of hetero-1,3,5-hexatrienes into five-membered rings—Possible ~ (FP) 973 [G.E. 1005]
PE spectroscopy, 2-Vinylidene-2H-indene (SC) 821 [G.E. 846]
One-electron oxidation of 1,2-dithiacycloalkanes (SC) 834 [G.E. 863]
Pharmaceutical chemistry today—Changes, problems, and opportunities (FP) 749 [G.E. 802]
Pharmacology, Foundation of molecular ~, Vol. 1 and 2 (Book Review) 409
Phenols, Oxygen atoms produced by microwave discharge: Reactions with arenes (SC) 1004 [G.E. 1037]
1-Phenylethyl substituents, Conformational analysis of ~ in metal complexes and their importance for asymmetric catalysis (SC) 641 [G.E. 645]
Phenyl-group conformation, Rigid ~ in complexes (SC) 396 [G.E. 395]
Phenyl groups, A very crowded molecule: X-Ray crystallographic analysis of bis(2,4,6-tri-tert-butylphenyl)phosphinic chloride (SC) 399 [G.E. 405]
Phenyl isocyanide, Tetrakis(phenylimino)cyclobutane (tetrameric ~) (SC) 136 [G.E. 134]
3-Phenylpropylamines. A new class of systemic fungicides (FP) 184 [G.E. 176]
Pheromone analogues, Differentiation between chiral ~ by chemoreceptors (SC) 475 [G.E. 492]
Pheromones, Quantitative separation of the enantiomer pairs of the pheromone 2-ethyl-1,6-dioxaspiro[4.4]nonane by complexation chromatography on an optically active metal complex (SC) 471 [G.E. 473]
Phlorizin polymer as affinity gel for sugar-binding proteins (SC) 540 [G.E. 547]
2-Phospha-1,3-dionate, Lithium dibenzoylphosphide·1,2-dimethoxyethane—A new ~ (SC) 741 [G.E. 756]
Phosphanes, General method for preparation of multidentate fluorophosphane ligands (SC) 316 [G.E. 323]
Metal-assisted reaction of carbon disulfide with "Etriphos" phosphane ligand: Synthesis and structure of $[(Etriphos)Fe\{S_2C(EtPCH_2)_2CMe_2\}](BF_4)_2$ (SC) 1021 [G.E. 1055]
Polymetal complexes: Complexation of cluster triangular faces by the tripod ligand, $HC(PPh_2)_3$ (SC) 1024 [G.E. 1058]

Template synthesis of clusters using the tripod ligand $HC(PPh_2)$: $Ni_3(CO)_6$(tripod) (SC) 1025 [G.E. 1059]
Phosphazenes, Cyclotri(phosphazene) complexes with P-coordinated PdX_2 and PtX_2 (SC) 650 [G.E. 655]
Phosphinidene oxide, Complex-stabilization of an aminooxophosphane (~) (SC) 710 [G.E. 738]
Phosphinite complexes, Synthesis and reaction of diorgano-~ of gold (SC) 71 [G.E. 66]
Phosphinous anhydride, Bis(di-tert-butylphosphino)tellurium(II). A derivative of ~ exhibiting umpolung (SC) 554 [G.E. 562]
Phospholane 1-oxides, Synthesis and structure of 3-chloro-4-hydroxy- and 3,4-epoxy-~ (SC) 132 [G.E. 127]
Phospholipid analogues, Polymerizable ~—New stable biomembrane and cell models (SC) 938 [G.E. 962]
Phosphonic anhydrides, New peptide synthesis (SC) 133 [G.E. 129]
Phosphorane, Lithium bis(trimethylsilyl)methylene diphenylphosphoranide, a building block for the synthesis of bis(methylenephosphoranes) (SC) 243 [G.E. 206]
N-Isocyanoiminotriphenyl-~: Synthesis, coordination chemistry, and reactions at the metal (SC) 480 [G.E. 478]
Synthesis of cyclic compounds from triphenyl(phenyliminovinylidene)-~ and carboxylic acids (SC) 822 [G.E. 856]
Double cycloaddition yielding a tricyclic di-~ (SC) 825 [G.E. 860]
Total reversibility of addition and transylidation of trialkyl(alkylidene)phosphoranes to metal-coordinated carbon monoxide (SC) 1019 [G.E. 1063]
Phosphorus compounds, A very crowded molecule: X-ray crystallographic analysis of bis(2,4,6-tri-tert-butylphenyl)phosphinic chloride (SC) 399 [G.E. 405]
Triple-decker sandwich complexes of 4d and 5d metals with cyclo-triphosphorus as μ,η^3-ligand: Structural and magnetic properties (SC) 405 [G.E. 412]
$Ph(Me_3Si)C{=}P{-}Cl$, the first P-halofunctionalized methylenephosphorane (SC) 556 [G.E. 578]
$P_4(N\text{-}i\text{-}C_3H_7)_6$, a P_4X_6 molecule with and without adamantane structure (SC) 571 [G.E. 563]
$(R_2NPO)_3$: Novel heterocycle with λ^3-phosphorus by trimerization of an aminooxophosphane (SC) 709 [G.E. 737]
Phosphorus triiodide and diphosphorus tetraiodide, new reagents for deprotection of acetals and ketals (SC) 1006 [G.E. 1039]
Phosphorylases, Role of pyridoxal phosphate in catalysis of glycogen ~ (FP) 441 [G.E. 429]
Photochemical degradation, UV irradiation of nucleic acids and their components in the presence of air (SC) 829 [G.E. 858]
Photochemical processes, Photophysical and ~ in micellar systems (FP) 675 [G.E. 712]
Photochemistry, Photochemical rearrangements and fragmentations of benzene derivatives and annelated arenes (FP) 243 [G.E. 245]
Cyclopropanimines by photolysis of pyrazolinimines. Thermal reaction of an excited state (SC) 49 [G.E. 55]
~ of sulfonamides and sulfonylureas: A contribution to the problem of light-induced dermatoses (SC) 648 [G.E. 647]
Photoreactions of stilbene with caffeine: Known, and new types of reactions (SC) 714 [G.E. 735]
Photochemotherapy, New photocycloadditions of dibromomaleimides to 1,3-dimethyl-6-azauracil (SC) 1026 [G.E. 1066]
Photocycloadditions, New ~ of dibromomaleimides to 1,3-dimethyl-6-azauracil (SC) 1026 [G.E. 1066]
Photolysis, Direct ~ of uranium hexafluoride as a preparatively utilizable endothermic reaction (SC) 227 [G.E. 226]
~ of water catalyzed by transition metal dithiolenes (SC) 645 [G.E. 664]
Cyclic water cleavage by visible light: Drastic improvement of yield of H_2 and O_2 with bifunctional redox catalysts (SC) 646 [G.E. 663]
Photooxidation of the ligands of bis(o-semiquinonediimine)nickel(II) and -platinum(II) (SC) 221 [G.E. 228]
Photoreduction of ketones and aldehydes to alcohols with selane (SC) 1008 [G.E. 1041]
Phthalocyaninatoiron with pyrazine as a bidentate bridging ligand (SC) 392 [G.E. 391]
Pigments, Developments in the field of inorganic ~ (FP) 190 [G.E. 187]
Plasma proteins, Chemistry and function of human ~ (FP) 87 [G.E. 83]
Platinum, Water gas shift reaction with the aid of selenium/~ catalyst (SC) 1007 [G.E. 1040]
Platinum complexes, Photooxidation of the ligands of bis(o-semiquinonediimine)nickel(II) and -platinum(II) (SC) 221 [G.E. 228]
^{195}Pt-NMR spectroscopy of catalytically active complexes. Extremely large spin-spin coupling between platinum and tin (SC) 316 [G.E. 323]
Photochemical reductive cis-elimination in cis-diazidobis(triphenylphosphane)platinum(II). Evidence of the formation of bis(triphenylphosphane)platinum(0) and hexaazabenzene (SC) 717 [G.E. 745]
Novel SN-ligand: Structure of $PtCl(S_4N_3)$ (SC) 653 [G.E. 644]
Platinum compounds, Transition-metal complexes with pyrazolyl bridging ligands between very different metal centers (SC) 931 [G.E. 931]
Platinum-indium complexes, New dihydrido-bridged binuclear ~ (SC) 721 [G.E. 744]
Polarography of molecules of biological significance (Book Review) 409
Polycarbonates and carbonates from urea and alcohol (SC) 718 [G.E. 742]
Polyethylene, "Living polymers" on polymerization with extremely productive Ziegler catalysts (SC) 390 [G.E. 396]
Polymerization, Stereospecific ~ of propylene: An outlook 25 years after its discovery (FP) 857 [G.E. 869]
Template ~ of rhodium(I) with rigid bent diisocyanide ligands (SC) 633 [G.E. 649]
Polymer-polymer miscibility (Book Review) 494
Polymers, Raw material-polymer interrelationships—Today and tomorrow (FP) 79 [G.E. 75]
Thermal degradation of ~ to polymeric carbon—An approach to the synthesis of new materials (FP) 375 [G.E. 375]
"Living ~" on polymerization with extremely productive Ziegler catalysts (SC) 390 [G.E. 396]
Synthesis of organotrimetal ~ using trimetal vapor-fluid matrix techniques (SC) 402 [G.E. 409]
Polypropylene, Stereospecific polymerization of ~: An outlook 25 years after its discovery (FP) 857 [G.E. 869]
Porphine analogues, B_8S_{16}—An "inorganic porphine" (SC) 481 [G.E. 479]
Porphyrinogen, Mutual interconversion of the chromophoric system of ~ and isobacteriochlorin (SC) 140 [G.E. 139]
1,2,3,7,8,20-Hexahydroporphyrin, an easily formed ligand system isomeric to ~-s (SC) 141 [G.E. 141]
Porphyrins, Metalloporphyrin-catalyzed hydroxylation of cyclohexane by alkyl hydroperoxides: Pronounced efficiency of iron-~ (SC) 909 [G.E. 938]
Potassium compounds, Allylic compounds of magnesium, lithium, and potassium: σ- or π-structures? (SC) 487 [G.E. 497]
Pressure, Chemistry in compressed solutions (FP) 841 [G.E. 887]
Synthesis under high ~: Michael addition (SC) 1013 [G.E. 1046]
Principle of minimum chemical distance (PMCD) (FP) 495 [G.E. 503]
Printing forms, New technologies for the filmless manufacture of ~ (FP) 99 [G.E. 95]
Propellanes, Cyclic oligomers of ~ and bridged annulenes with bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 933 [G.E. 970]
Mixed oligomers of ~ and bridged annulenes with bis(maleimides) and bis(triazolinediones) studied by ^{252}Cf-plasma desorption mass spectrometry (SC) 936 [G.E. 972]
Propene, Selective pathway from methanol to ethylene and ~ (SC) 126 [G.E. 125]
Prostacyclin analogues, New ~ (SC) 819 [G.E. 850]
Protecting group, 4-Sulfobenzyl, a new carboxy ~ (SC) 394 [G.E. 394]
Vitamin B_{12} and a vitamin B_{12} model compound as catalysts of reductive removal of β-haloethyl ~-s from acids (SC) 629 [G.E. 643]
Synthesis of alternating depsipeptides with the 4-methylthiophenoxycarbonyl group as protecting and activating group for the amino function (SC) 932 [G.E. 953]
Phosphorus triiodide and diphosphorus tetraiodide, new reagents for deprotection of acetals and ketals (SC) 1006 [G.E. 1039]
Proteins, Chemistry and function of human plasma ~ (FP) 87 [G.E. 83]
Phlorizin polymer as affinity gel for sugar-binding ~ (SC) 540 [G.E. 547]
Semisynthetic ~ (Book Review) 838
Propylene, Dimerization of ~ with catalysts exhibiting activities like highly-active enzymes (SC) 622 [G.E. 633]
Pseudochalcogen, The PCN group as ~: Cyanophosphinidene-substituted heterocycles (SC) 722 [G.E. 767]
Pteridines, Euglenapterin—An unusual new natural pteridine derivative from Euglena gracilis (SC) 473 [G.E. 474]
Pyrazine, A ~-bridged heme dimer absorbing at 800 nm (SC) 322 [G.E. 320]
Phthalocyaninatoiron with ~ as a bidentate bridging ligand (SC) 392 [G.E. 391]
Pyrazolinimines, Cyclopropanimines by photolysis of ~ thermal reaction of an excited state (SC) 49 [G.E. 55]
Pyrazolyl bridges, Transition-metal complexes with ~ between very different metal centers (SC) 931 [G.E. 931]
1,2,3,6,7,8-Pyrenehexone, 1,2,3,5,6,7-s-Hydrindacenehexone and ~—Two new strong acceptors (SC) 715 [G.E. 768]
Pyridine trihydrate, Novel proton-ordered, two-dimensional cross-linking of water molecules in ~ (SC) 552 [G.E. 559]
Pyridines, Amino-~ (SC) 388 [G.E. 390]
Pyridinium ions, Mechanism of the pyrylium/pyridinium ring interconversion. Mild preparative conditions for conversion of amines into ~ (SC) 306 [G.E. 315]
Pyridino crown ethers, Selective inclusion of alcohols with a new pyridino crown (SC) 1030 [G.E. 1067]
Pyridoxal phosphate, Role of ~ in the catalysis of glycogen phosphorylases (FP) 441 [G.E. 429]
Pyrolysis, Short-path ~: silabenzene (SC) 51 [G.E. 56]
Pyrrolizidines by rearrangement of β-lactams (SC) 129 [G.E. 126]
Pyrylium/pyridinium ring interconversion, Mechanism of ~. Mild preparative conditions for conversion of amines into pyridinium ions (SC) 306 [G.E. 315]
Pyrrolnitrin, Formation of ~ and 3-(2-amino-3-chlorophenyl)pyrrole from 7-chlorotryptophan (SC) 828 [G.E. 855]

RACEMATES, Chromatographic resolution of ~ (FP) 13 [G.E. 14]
Radical anion, Alkali metal-induced transformations of cis-1,2-dibenzoylalkenes: Transformation of 11,12-dibenzoyl-9,10-dihydro-9,10-ethenoanthracene (SC) 907 [G.E. 939]

Radical cation salts of simple arenes—A new family of "organic metals" (SC) 912 [G.E. 941]
Radical ions, Isoelectronic ~ and redox systems (SC) 911 [G.E. 940]
Radical reactivities, Correlation between ~ and copolymerization parameters (SC) 206 [G.E. 215]
Radicals, Unusually rapid cis-trans isomerization of a tetrasilylated ethylene: Generation of free ~ during rotation (SC) 620 [G.E. 632]
~ (Book Review) 229
Radionuclides, Radiotracers in agricultural chemistry (Book Review) 573
Raw materials-polymer interrelationships—Today and tomorrow (FP) 79 [G.E. 75]
Reaction paths on multidimensional energy hypersurfaces (FP) 1 [G.E. 1]
Reactions, Computer simulation of the kinetics of complicated gas phase ~ (FP) 333 [G.E. 331]
Rearrangement, Photochemical ~-s and fragmentations of benzene derivatives and annelated arenes (FP) 243 [G.E. 245]
Theoretical investigation of the diethynylcyclobutadiene(cyclopentadienyl)cobalt ~ (SC) 728 [G.E. 747]
Thermal rearrangement of tetrakis(phenylimino)cyclobutane and crystal structure of tetraphenylsquaramidine (SC) 1012 [G.E. 1045]
Recyclization, 2-Thietanimines from α-deprotonated β-lactones and phenyl isothiocyanate—A novel four-membered ring/four-membered ring ~ (SC) 466 [G.E. 470]
Redox reactions, Reversible topotactic ~ of solids by electron/ion transfer (FP) 983 [G.E. 1015]
Redox systems, Isoelectronic radical ions and ~ (SC) 911 [G.E. 940]
Reducing agent, Carbon monoxide/water as ~: Formation of selane from selenium (SC) 308 [G.E. 317]
Outer sphere electron transfer reactions. A novel linear relationship between selectivity and normal potential of ~-s (SC) 558 [G.E. 580]
Reduction, Selenium-catalyzed ~ of aromatic nitro compounds to amines by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
~ of carbonyl compounds by aluminum telluride and H_2O or D_2O (SC) 1009 [G.E. 1041]
~ of aromatic nitro, nitroso, hydroxylamino, azo, and azoxy compounds with hydrogen telluride from aluminum telluride and water (SC) 1009 [G.E. 1042]
Rhenium compounds, First insertion reaction of carbon monoxide into a rhenium-carbon σ-bond (SC) 824 [G.E. 843]
Rhodium clusters, Synthesis of the first methylidyne-~ by proton-induced H_2/CH_4-elimination from a μ-methylene complex (SC) 651 [G.E. 660]
Simple method of forming metal-to-metal bonds (SC) 937 [G.E. 961]
Rhodium complexes, μ-Arylthio- and μ-arylthio-μ-chlorodicarbonylbis(tri-tert-butylphosphane)dirhodium: dinuclear ~ with different bridging ligands (SC) 70 [G.E. 60]
(1,2,5,6-η-1,5-Cyclooctadiene)(1,2,7-η-7-methylbenzyl)(7,8-η-styrene)rhodium(I)—Antarafacial fluctuation of the benzyl ligand and temperature-dependent coordination of styrene (SC) 468 [G.E. 475]
Rhodium compounds, Synthesis of intermediates by rhodium-catalyzed hydroformylation (FP) 178 [G.E. 182]
Template polymerization of rhodium(I) with rigid bent diisocyanide ligands (SC) 633 [G.E. 649]
Ribonucleic acid, Viroids: A class of subviral pathogens (FP) 231 [G.E. 233]
Ring contraction, (8→5)Contraction of the eight-membered ring of $S_4N_4O_2$ (SC) 943 [G.E. 959]
Rotation, Unusually rapid cis-trans isomerization of a tetrasilylated ethylene: Generation of free radicals during ~ (SC) 620 [G.E. 632]
Ruthenium catalysts, $Ru_3(CO)_{12}$-catalyzed synthesis of vinylsilanes from olefins and hydrosilanes (SC) 928 [G.E. 974]

SALTS, Influence of density and temperature on the properties of pure molten ~ (FP) 606 [G.E. 612]
Sandwich complexes, Triple-decker ~ of 4d and 5d metals with cyclo-triphosphorus as μ,η^3-ligand: Structural and magnetic properties (SC) 405 [G.E. 412]
Bis(η-cyclopentadienyliron-μ,η-thiadiborolene)iron—Structure of a η-C_5H_5 tetradecker sandwich complex (SC) 746 [G.E. 758]
Selane, Carbon monoxide/water as a reducing agent: Formation of ~ from selenium (SC) 308 [G.E. 317]
Water gas shift reaction with the aid of selenium/platinum catalyst (SC) 1007 [G.E. 1040]
Selenium-catalyzed reduction of aromatic nitro compounds to amines by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
Photoreduction of ketones and aldehydes to alcohols with ~ (SC) 1008 [G.E. 1041]
Selectivity, Outer sphere electron transfer reactions. Novel linear relationship between ~ and normal potential of reducing agents (SC) 558 [G.E. 580]
1,2,3-Selenadiazoles, Reactions of cycloalkeno-~ with transition metal carbonyls (SC) 632 [G.E. 650]
Selenium, Carbon monoxide/water as a reducing agent: Formation of selane from ~ (SC) 308 [G.E. 317]
Water gas shift reaction with the aid of ~/platinum catalyst (SC) 1007 [G.E. 1040]
~-catalyzed reduction of aromatic nitro compounds to amines by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
Selenium bromide, Molecular and crystal structure of β-~ (SC) 645 [G.E. 646]
Selenium compounds, 6-Fulveneselone (SC) 69 [G.E. 52]
Unusually bridged tungsten complexes with $W(ER)_2W(ER)_3W$ skeleton (E=S or Se; R=C_2H_5, n-C_4H_9 or C_6H_5) (SC) 397 [G.E. 403]
Selenoantimonate(III) anions, Novel ~ in $Na_4Sb_4Se_{11}$ (SC) 324 [G.E. 310]
Semibullvalenes, One-pot synthesis of substituted ~ (SC) 456 [G.E. 464]
Semiconductors, Liquid metals and liquid ~ (FP) 593 [G.E. 598]
Semiquinone, Photooxidation of the ligands of bis(o-~-diimine)nickel(II) and -platinum(II) (SC) 221 [G.E. 228]
Short-path pyrolysis: silabenzene (SC) 51 [G.E. 56]
Si_4 clusters, $Li_{12}Si_7$, a compound having trigonal planar Si_4 cluster and planar Si_5 rings (SC) 1033 [G.E. 1070]
Silabenzene, Short-path pyrolysis: ~ (SC) 51 [G.E. 56]
~ (SC) 52 [G.E. 58]
Silica, Chemistry of ~ (Book Review) 230
Silicates, Amorphous silver ~, storage elements with low switching field strength (SC) 386 [G.E. 386]
Silicon compounds, Matrix isolation of OSiS: IR spectroscopic evidence for the Si=S double bond (SC) 323 [G.E. 310]
Zintl phases with complex anions: $Sr_3Si_2As_4$ and $Sr_3Ge_2As_4$ (SC) 490 [G.E. 480]
Unusually rapid cis-trans isomerization of a tetrasilylated ethylene: Generation of free radicals during rotation (SC) 620 [G.E. 632]
$Li_{12}Si_7$, a compound having trigonal planar Si_4 cluster and planar Si_5 rings (SC) 1033 [G.E. 1070]
Planar tetracoordinated silicon? (SC) 1033 [G.E. 1070]
Planar tetracoordinated silicon—A reply (SC) 1034 [G.E. 1071]
Silver catalyst, Acetaldehyde as main product of oxidation of ethylene oxide on a ~ (SC) 407 [G.E. 389]
Silver silicates, Amorphous ~, storage elements with low switching field strength (SC) 386 [G.E. 386]
Silyl derivatives, Synthesis and properties of the first organosilyl-gallium compounds (SC) 55 [G.E. 62]
Tetrakis(trimethylsilyl)borate and other trimethylsilylborates (SC) 58 [G.E. 65]
Singlet oxygen, Oxidation reactions of benzvalene: Ozonolysis, cis-hydroxylation, epoxidation, and ~ addition (SC) 458 [G.E. 466]
Size exclusion chromatography, Determination of morphological properties of swellable solids by ~ (FP) 24 [G.E. 25]
Slime mold, Indole pigments from the fruiting bodies of the ~ Arcyria denudata (SC) 459 [G.E. 463]
Solids, Reversible topotactic redox reactions of ~ by electron/ion transfer (FP) 983 [G.E. 1015]
Solid state chemistry, High-resolution transmission electron microscopy re-examined as a tool in ~ (FP) 505 [G.E. 531]
Solubility of nonvolatile biochemical substances in compressed carbon dioxide (SC) 623 [G.E. 633]
Solvolysis, Coupling of ~ and C—C linkage: A promising synthetic route to functionalized carboxylic acids, aldehydes, and ketones (FP) 171 [G.E. 169]
Spectroscopy, Polarized low-temperature crystal spectra of inorganic complexes (FP) 290 [G.E. 290]
Spirohydrocarbons, (+)-(2R)-5,5′-Dimethyl-2,2′-spirobi(2,3-dihydro-1H-cyclopenta[a]-naphthalene)—A chiral spirohydrocarbon containing orthogonal naphthalene units (SC) 308 [G.E. 318]
Spiropentene (SC) 928 [G.E. 969]
Squaramidine, Thermal rearrangement of tetrakis(phenylimino)cyclobutane and crystal structure of tetraphenyl-~ (SC) 1012 [G.E. 1045]
Stabilization, Cycloadditions with silver-ion stabilized (2RS,3RS)-3-methoxy-trans-cycloheptene (SC) 1032 [G.E. 1068]
Stereoselectivity, Highly stereoselective aldol condensation using an enantioselective chiral enolate (SC) 557 [G.E. 573]
"Synthetic enzymes". Highly stereoselective epoxidation of chalcone in a triphasic toluene-water-poly[(S)-alanine] system (SC) 929 [G.E. 968]
Steroid synthesis, Photochemical route to (±)-estrone (SC) 1027 [G.E. 1060]
Asymmetric total synthesis of (+)-estrone (SC) 1029 [G.E. 1062]
Stilbene, Photoreactions of ~ with caffeine. Known, and new types of reactions (SC) 714 [G.E. 735]
Strained hydrocarbons, Synthesis of unusual organic molecules from azoalkanes (FP) 762 [G.E. 815]
Strained organic molecules (Book Review) 75
Strontium compounds, Zintl phases with complex anions: $Sr_3Si_2As_4$ and $Sr_3Ge_2As_4$ (SC) 490 [G.E. 480]
Structure-activity relationships, Chemische Struktur und biologische Aktivität von Wirkstoffen. Methoden der Quantitativen Struktur-Wirkung-Analyse (Book Review) 572
Styrene, (1,2,5,6-η-1,5-Cyclooctadiene)(1,2,7-η-7-methylbenzyl)(7,8-η-styrene)rhodium(I)—Antarafacial fluctuation of the benzyl ligand and temperature-dependent coordination of ~ (SC) 468 [G.E. 475]
Substituent effect, Base-catalyzed conversion of an equatorial into an axial methoxycarbonyl group due to a 1,5-long-range ~ (SC) 543 [G.E. 577]

Sulfinates, Direct synthesis of the perfluoroalkane-~ of iron(II), cobalt(II), and nickel(II): SO_2-assisted addition of alkyl halides to transition metals (SC) 128 [G.E. 124]
N-Sulfinylnonafluorobutanesulfonamide—A superenophile (SC) 732, 840 [G.E. 748]
3-Oxa-ene reactions of N-sulfinylnonafluorobutanesulfonamide with alkanones—General synthesis of 2-oxoalkanesulfinic acid derivatives (SC) 737 [G.E. 750]
Sulfonamides, Photochemistry of ~ and sulfonylureas: A contribution to the problem of light-induced dermatoses (SC) 648 [G.E. 647]
N-Sulfinylnonafluorobutanesulfonamide—A superenophile (SC) 732, 840 [G.E. 748]
3-Oxa-ene reactions of N-sulfinylnonafluorobutanesulfonamide with alkanones—General synthesis of 2-oxoalkanesulfinic acid derivatives (SC) 737 [G.E. 750]
4-Sulfobenzyl, a new carboxy protecting group (SC) 394 [G.E. 394]
Sulfonium salts, Synthesis and rearrangement of azulene-~ (SC) 621 [G.E. 635]
Sulfonylureas, Photochemistry of sulfonamides and ~: A contribution to the problem of light-induced dermatoses (SC) 648 [G.E. 647]
Sulfur-atom transfer, Activation and ~ of cluster-bonded S_2^{2-}-bridge ligands: synthesis of the new cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$ from $[Mo_3^{IV}S(S_2)_6]^{2-}$ and CN^- (SC) 72 [G.E. 69]
Sulfur compounds, Crystal structure of 2-lithio-2-methyl-1,3-dithiane tetramethylethylenediamine (SC) 53 [G.E. 59]
Tetrathiafulvalenoparacyclophanes (SC) 66 [G.E. 49]
[2.2]- and [3.3]-Tetrathiafulvalenophanes (SC) 67 [G.E. 51]
Activation and sulfur-atom transfer reaction of cluster-bonded S_2^{2-}-bridge ligands: synthesis of the new cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$ from $[Mo_3^{IV}S(S_2)_6]^{2-}$ and CN^- (SC) 72 [G.E. 69]
Synthesis and crystal structure analysis of decathia-cyclotetradecane-6,7,13,14-tetraone, $S_{10}(CO)_4$ (SC) 125 [G.E. 122]
Addition of alkanethiols to diketene (SC) 127 [G.E. 123]
α-Carbamoyloxymethyl-substituted lithium enethiolates from 1-(N,N-dimethylcarbamoylthio)-2-methyl-1-propenyllithium (SC) 303 [G.E. 305]
Unusually bridged tungsten complexes with $W(ER)_2W(ER)_3W$ skeleton (E = S or Se; R = C_2H_5, n-C_4H_9 or C_6H_5) (SC) 397 [G.E. 403]
New aspects of the reaction of difluorosulfur imides with fluorine (SC) 408 [G.E. 393]
B_8S_{16}—An "inorganic porphine" (SC) 481 [G.E. 479]
N-Fluoroiminosulfur tetrafluoride, F—N=SF_4 (SC) 643 [G.E. 659]
A novel SN-ligand: Structure of $PtCl(S_4N_3)$ (SC) 653 [G.E. 644]
Sulfur-fluorine compounds, Tris(fluorosulfonyl)methane, $HC(SO_2F)_3$ (SC) 942 [G.E. 954]
Sulfur monoxide, First fixation of the unstable species ~ in a cluster: Synthesis and structure of $Fe_3(CO)_9(S)SO$ (SC) 226 [G.E. 225]
Sulfur-nitrogen-fluorine compounds, Chemistry of thiazyl fluoride (NSF) and thiazyl trifluoride (NSF_3): A quarter century of (FP) 883 [G.E. 904]
Sulfur-nitrogen rings, (8→5)Contraction of the eight-membered ring of $S_4N_4O_2$ (SC) 943 [G.E. 959]
Sulfur oxides, Dimerization of S_6O to $S_{12}O_2$: Crystal structure analysis of $S_{12}O_2 \cdot 2SbCl_5 \cdot 3CS_2$ (SC) 325 [G.E. 313]
Supercritical fluid chromatography, Physicochemical principles and applications (SFC) (FP) 575 [G.E. 585]
Superenophile, N-Sulfinylnonafluorobutanesulfonamide—A superenophile (SC) 732, 840 [G.E. 748]
Swellable solids, Determination of morphological properties of ~ by size exclusion chromatography (FP) 24 [G.E. 25]
Symbolic language of the chemist (FP) 110 [G.E. 106]
Synthetic enzymes. Highly stereoselective epoxidation of chalcone in a triphasic toluene-water-poly[(S)-alanine] system (SC) 929 [G.E. 968]
Synthetic methods, Synthesis of unusual organic molecules from azoalkanes (FP) 762 [G.E. 815]

TACTICITY, Stereospecific polymerization of propylene: An outlook 25 years after its discovery (FP) 857 [G.E. 869]
Tellurium compounds, Bis(di-tert-butylphosphino)tellurium(II): A derivative of phosphinous anhydride exhibiting umpolung (SC) 554 [G.E. 562]
Template polymerization of rhodium(I) with rigid bent diisocyanide ligands (SC) 633 [G.E. 649]
Template synthesis of clusters using the tripod ligand $HC(PPh_2)_3$: $Ni_3(CO)_6$(tripod) (SC) 1025 [G.E. 1059]
Tetra-tert-butylcyclobutadiene, Structure (SC) 211 [G.E. 214]
Tetracyanoethylene, Nitrile function of ~ as dienophile in Diels-Alder reactions (SC) 810 [G.E. 836]
Tetracyclo[6.2.1.$1^{3,6}$.$0^{2,7}$]dodecane, Synthesis of the epimeric 4-methyl derivatives of endo-endo- and exo-endo-~ (SC) 318 [G.E. 306]
Tetradecker complexes, Bis(η-cyclopentadienyliron-μ,η-thiadiborolene)iron—Structure of a η-C_5H_5 tetradecker sandwich complex (SC) 746 [G.E. 758]
Tetrahedrane, Structural changes on oxidation: Flattening of the C_4-cluster of ~ (SC) 209 [G.E. 213]
Tetrakis(phenylimino)cyclobutane (tetrameric phenyl isocyanide) (SC) 136 [G.E. 134]
Thermal rearrangement of ~ and crystal structure of tetraphenylsquaramidine (SC) 1012 [G.E. 1045]
Tetrathiafulvalene, Synthesis of a homologous ~ with central bicyclo[4.4.1]undeca-1(10),3,5,8-tetraene-2,7-diylidene group (SC) 204 [G.E. 199]
Tetrathiafulvalenoparacyclophanes (SC) 66 [G.E. 49]
Tetrathiafulvalenophanes, [2.2]- and [3.3]-~ (SC) 67 [G.E. 51]
Tetrazolo[1,5-a]pyrimidine, ^{15}N-NMR Spectroscopic detection of the ~/2-azidopyrimidine equilibrium (SC) 924 [G.E. 957]
Thermodynamic properties, Influence of isomerism of alkanes on ~ of cyclohexane/alkane mixtures (SC) 223 [G.E. 209]
Thiadiborolene, Bis(η-cyclopentadienyliron-μ,η-~)iron—Structure of a η-C_5H_5 tetradecker sandwich complex (SC) 746 [G.E. 758]
Thiazyl fluoride, Chemistry of ~ (NSF) and thiazyl trifluoride (NSF_3): A quarter century of sulfur-nitrogen-fluorine chemistry (FP) 883 [G.E. 904]
Thiazyl trifluoride, Chemistry of thiazyl fluoride (NSF) and ~ (NSF_3): A quarter century of sulfur-nitrogen-fluorine chemistry (FP) 883 [G.E. 904]
Thiepin derivatives, Thermal additions of dimethyl acetylenedicarboxylate to cyclic thioenol ether 1-oxides with ring expansion (SC) 833 [G.E. 849]
2-Thietanimines from α-deprotonated β-lactones and phenyl isothiocyanate—A novel four-membered ring/four-membered ring recyclization (SC) 466 [G.E. 470]
Thioacetate, Double addition of a nucleophile to carbyne and carbonyl C-atom: S-Phenyl 2-phenyl-2-(phenylthio)-~ from trans-bromotetracarbonyl(phenylcarbyne)-chromium and thiophenolate (SC) 205 [G.E. 206]
Thiocin derivatives, Thermal additions of dimethyl acetylenedicarboxylate to cyclic thioenol ether 1-oxides with ring expansion (SC) 833 [G.E. 849]
Thioenol ethers, Thermal [2+2]-cycloadditions of tetracyanoethylene to cyclic ~ (SC) 831 [G.E. 848]
Thermal cycloadditions of dimethyl acetylenedicarboxylate to cyclic enol ethers and ~ (SC) 832 [G.E. 848]
Thioenol ether 1-oxides, Thermal additions of dimethyl acetylenedicarboxylate to cyclic ~ with ring expansion (SC) 833 [G.E. 849]
Thioketene, Direct detection of dicyano-~ in the gas phase (SC) 740 [G.E. 752]
Thioketones, ^{13}C-NMR study of protonated ~ in superacidic media: Significance of mercaptocarbenium ion contributions (SC) 811 [G.E. 837]
Thiols, Exceedingly mild desulfurization of ~ by sodium triethylhydroborate and transition metal chlorides (SC) 315 [G.E. 321]
Thiomolybdates, MoS_4^{2-} and $MoOS_3^{2-}$ as structurally versatile and biochemically interesting ligands in crystalline multinuclear Cu- and Fe-complexes (SC) 654 [G.E. 665]
Thionyl chloride, Are α-oxothioacyl chlorides formed in the reaction of methyl ketones with ~? (SC) 563 [G.E. 559]
Thiophene derivatives, Thermal [2+2]-cycloadditions of tetracyanoethylene to cyclic thioenol ethers (SC) 831 [G.E. 848]
Thermal cycloadditions of dimethyl acetylenedicarboxylate to cyclic enol ethers and thioenol ethers (SC) 832 [G.E. 848]
Thermal additions of dimethyl acetylenedicarboxylate to cyclic thioenol ether 1-oxides with ring expansion (SC) 833 [G.E. 849]
Thiophenol, Relation between orbital character and reaction product in the reaction of benzvalene and homobenzvalene with ~ (SC) 457 [G.E. 465]
Thiopyran derivatives, Thermal [2+2]-cycloadditions of tetracyanoethylene to cyclic thioenol ethers (SC) 831 [G.E. 848]
Tin complexes, X-Ray structure analysis of bis(O,O'-diphenyldithiophosphato)tin(II), a bicyclic dimer held together by η^6-C_6H_5/Sn^{II} interactions (SC) 309 [G.E. 326]
Tin compounds, Nucleophilic addition of triphenylstannyllithium to carbon disulfide (SC) 220 [G.E. 227]
^{195}Pt-NMR spectroscopy of catalytically active complexes. Extremely large spin-spin coupling between platinum and tin (SC) 316 [G.E. 323]
Cubane-type Sn_4N_3O cage (SC) 401 [G.E. 408]
Tin(II) hydroxide, New variant of the amphoterism of ~: $Sn(OH)_2$ as stannio complex ligand (SC) 553 [G.E. 561]
Titanium compounds, Geminal dialkylation of ketones with Grignard compounds and methyltitanium(IV) chlorides (SC) 900 [G.E. 931]
Chemoselective and position specific methylation of tert-alkyl halides with methyltitanium(IV) chlorides (SC) 901 [G.E. 933]
Chemo- and diastereoselective addition of alkyl- and aryl-titanium compounds to aldehydes and ketones (SC) 1011 [G.E. 1044]
Titanium sulfides, Nonstoichiometric alkali metal ~ with channel structure (SC) 492 [G.E. 477]
Topotactic redox reactions, Reversible ~ of solids by electron/ion transfer (FP) 983 [G.E. 1015]
Total synthesis, Photochemical route to (±)-estrone (SC) 1027 [G.E. 1060]
Trace analysis, Ultratrace analysis: Determination of Cr, Fe, and Co in the ppb and ppt range for checking the preparation of high-purity niobium (SC) 197 [G.E. 194]
Transmission electron microscopy, High-resolution ~ re-examined as a tool in solid state chemistry (FP) 505 [G.E. 531]
Transition elements, Trinuclear clusters of the early ~ (SC) 875 [G.E. 921]
Transition metal π-complexes, Alkali metal-~ (FP) 520 [G.E. 513]

Transylidation, Total reversibility of addition and ~ of trialkyl(alkylidene)phosphoranes to metal-coordinated carbon monoxide (SC) 1019 [G.E. 1063]
1,2,3-Triazolo[4,5-d][1,3]thiazine, a new heterocyclic system (SC) 310 [G.E. 319]
Tricyclo[4.1.0.0^{2,7}]heptane, New C_8H_{10} isomers: 2-Methylenebicyclo[3.2.0]hept-6-ene and 3-methylene-~—Thermal and metal-catalyzed rearrangements (SC) 634 [G.E. 651]
Trifluoromethane, Heterogeneously catalyzed gas-phase bromination of ~ (SC) 147 [G.E. 136]
(Trifluoromethyl)fluorogermanates (SC) 836 [G.E. 859]
Trimethylphosphane complexes of nickel, cobalt, and iron—Model compounds for homogeneous catalysis (FP) 362 [G.E. 362]
Trimethylsilyloxysulfonates, Fluoride-induced fragmentation of ~ to form cis-coupled hexahydroazulenones (SC) 830 [G.E. 832]
Trioxa-tris-σ-homotropone, "α,α,α"-, "α,β,α"-, and "α,α,β"-~ (SC) 214 [G.E. 216]
Triphenyl(phenyliminovinylidene)phosphorane, Synthesis of cyclic compounds from ~ carboxylic acids (SC) 822 [G.E. 856]
Triphenylstannyllithium, Nucleophilic addition to carbon disulfide (SC) 220 [G.E. 227]
Triple-decker sandwich complexes of 4d and 5d metals with cyclo-triphosphorus as μ,η^3-ligand: Structural and magnetic properties (SC) 405 [G.E. 412]
Tripod, Polymetal complexes: Complexation of cluster triangular faces by the ~ ligand, $HC(PPh_2)_3$ (SC) 1024 [G.E. 1059]
Template synthesis of clusters using the ~ ligand $HC(PPh_2)_3$: $Ni_3(CO)_6(\sim)$ (SC) 1025 [G.E. 1059]
Tripropylcarbazoyllithium (SC) 762 [G.E. 764]
Triptycenes, 1,4-Dihydro-1,4-bis(dicyanomethylene)-~. Synthesis and intramolecular charge-transfer interaction (SC) 543 [G.E. 565]
Tris(fluorosulfonyl)methane, $HC(SO_2F)_3$ (SC) 942 [G.E. 954]
Tris[2.1.1]-σ-homobenzenes, cis-/trans-~. Synthesis and stereochemistry of [„2+„2+„2]-cycloreversions (SC) 567 [G.E. 575]
Tris(triazolo]triazine, Trimerization of an Azomethine imine by three successive 1,3-dipolar cycloaddition reactions (SC) 906 [G.E. 936]
Tungsten complexes, $(AsPh_4)[W_2NCl_{10}]$, a μ-nitrido complex containing tungsten(V) and tungsten(VI) (SC) 220 [G.E. 211]
Unusually bridged tungsten complexes with $W(ER)_2W(ER)_3W$ skeleton (E=S or Se; R=C_2H_5, n-C_4H_9, or C_6H_5) (SC) 397 [G.E. 403]

ULLMANN's Encyclopedia of Industrial Chemistry, Ullmanns Encyklopädie der technischen Chemie (Book Review) 148
Ultratrace analysis: Determination of Cr, Fe, and Co in the ppb and ppt range for checking the preparation of high-purity niobium (SC) 197 [G.E. 194]
Umpolung, Bis(di-tert-butylphosphino)tellurium(II). A derivative of phosphinous anhydride exhibiting ~ (SC) 554 [G.E. 562]
Uranium hexafluoride, Direct photolysis of ~ as a preparatively utilizable endothermic reaction (SC) 227 [G.E. 226]
Urea, Carbonates and polycarbonates from ~ and alcohol (SC) 718 [G.E. 742]

VALIENAMINE, Synthesis of chiral ~ (SC) 904 [G.E. 930]
Verdazyls, 6-Oxo-~ (SC) 724 [G.E. 766]
Vesicles with a monolayer, redoxactive membrane (SC) 550 [G.E. 564]
Vinamidinium salts, 1,3-Bis(dialkylamino)-1,3-butadiene from 1-methyl-~ (SC) 216 [G.E. 207]
1,3-Bis(dimethylamino)-2-aza-1,3-butadienes from 1-alkyl-2-aza-~ (SC) 217 [G.E. 208]
Vinylcarbene, Tetrachloro-~ from tetrachlorocyclopropene; facile synthesis of vinylcyclopropanes (SC) 138 [G.E. 135]
Vinylcyclopropanes, Tetrachlorovinylcarbene from tetrachlorocyclopropene; facile synthesis of ~ (SC) 138 [G.E. 135]
2-Vinylidene-2H-indene (SC) 821 [G.E. 846]
Vinylidene phosphorane, Synthesis of cyclic compounds from triphenyl(phenyliminovinylidene)phosphorane and carboxylic acids (SC) 822 [G.E. 856]
Vinylsilanes, $Ru_3(CO)_{12}$-catalyzed synthesis of ~ from olefins and hydrosilanes (SC) 928 [G.E. 974]
Viroids: A class of subviral pathogens (FP) 231 [G.E. 233]
Vitamin B_{12} and a vitamin B_{12} model compound as catalyst of reductive removal of β-haloethyl protecting groups from acids (SC) 629 [G.E. 643]

WATER, Carbon monoxide/~ as a reducing agent: formation of selane from selenium (SC) 308 [G.E. 317]
Photolysis of ~ catalyzed by transition metal dithiolenes (SC) 645 [G.E. 664]
A novel proton-ordered, two-dimensional cross-linking of ~ molecules in pyridine trihydrate (SC) 552 [G.E. 559]
Water cleavage, Cyclic ~ by visible light: Drastic improvement of yield of H_2 and O_2 with bifunctional redox catalysts (SC) 646 [G.E. 663]
Water gas, Selenium-catalyzed reduction of aromatic nitro compounds to amines by CO/H_2O in the presence of triethylamine (SC) 1007 [G.E. 1040]
Water gas shift reaction with the aid of selenium/platinum catalyst (SC) 1007 [G.E. 1040]

XANTHENIDE anion, Generation and direct observation of the ~.—A stable 4nπ-system (SC) 43 [G.E. 53]

YLIDE carbene complexes, Phosphorus ~—Synthesis and structure (SC) 1020 [G.E. 1065]
Ylide complexes, Phosphorus ylide carbene complexes—Synthesis and structure (SC) 1020 [G.E. 1065]
Ylides, Intramolecular cycloadditions of carbonyl ~ (SC) 47 [G.E. 48]

ZEOLITES, Dehydroxylation of hydrogen ~: Conditions for the preparation of thermally stable catalysts (SC) 743 [G.E. 759]
Amorphous ~ (SC) 745 [G.E. 755]
Ziegler catalysts, "Living polymers" on polymerization with extremely productive ~ (SC) 390 [G.E. 396]
Zintl phases with complex anions: $Sr_3Si_2As_4$ and $Sr_3Ge_2As_4$ (SC) 490 [G.E. 480]
Zirconium complexes, "Living polymers" on polymerization with extremely productive Ziegler catalysts (SC) 390 [G.E. 396]
