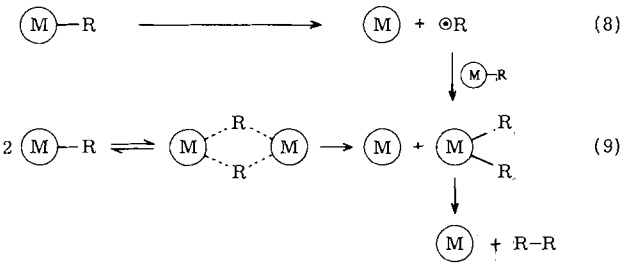
The two last-mentioned processes presently rate among the greatest challenges of organometallic chemistry. In particular, the activation of aliphatic hydrocarbons at transition metal centers [eq. (5)] is on the verge of a development which is raising great expectations.

As is evident from these examples, a central problem is the labile and reactive metal-to-carbon σ-bond, particularly with regard to the most probable decomposition pathways, for preliminary data concerning bond-dissociation energies[3,4] have meanwhile demonstrated that metal-to-carbon σ-bonds in the transition groups are no less stable than those involving main group elements. We therefore turn our attention to the question, under which conditions alkyl metal compounds become kinetically unstable.

1.2. σ-Methylmetal Compounds

In order to circumvent β-elimination as the dominant decomposition mode of alkylmetal complexes, we employ organic groups CH_2—X (X = H, C_6H_5, $C(CH_3)_3$, $Si(CH_3)_3$, *etc.*)[5,6]. However, in the simplest case of the methylmetal complexes there are still further decomposition pathways accessible; a methyl group attached to a basic metal center providing an empty coordination site can rearrange *via* proton migration to give a hydride-carbene function.



(6)

(7)

This *α-elimination* was established comparatively recently[6] while the reverse reaction (6) has been known longer[7]. The double bond formulation of the carbene fragment illustrates that the equilibrium (6) essentially differs from the acid-base equilibrium (7) only in that the base in (7) approaches from the outside while the deprotonation is intramolecular with the metal base in (6).

(8)

(9)

Further possibilities are a radical process (8) or a dismutation reaction (9) involving transfer of alkyl groups. Unlike (9), reaction (8) does not initially require a vacant coordination site; the reaction essentially depends on the appearance potential of the radical ⊙R. In this sense benzylmetal compounds are more labile than the corresponding methyl compounds.

The approach chosen here for the stabilization of methyl complexes of nickel, cobalt, and iron is based upon the assumption that it is possible to block all coordination sites of these metals in all their common oxidation states by using small ligands which can occupy all sites given by the inert gas rule (18-electron rule) without encountering steric problems.

Furthermore in complexes of catalytically active metals, the lowest possible reactivity of the coordinated ligand is desirable.

1.3. Trimethylphosphane

The principle of permethylated primary compounds has a long tradition in organometallic chemistry[8]. It is profitably applied to the phosphanes which proved to be good ligands for transition metals: Trimethylphosphane is the sterically least demanding of the triorganophosphanes. It forms stable metal complexes, reactions of the coordinated ligand are essentially unknown, and its high symmetry in complexes (local C_{3v}) facilitates spectroscopic investigations (IR, NMR).

Tolman[9] has defined the steric requirements of phosphane ligands by the vertex angle θ of a cone with its vertex at the metal which encloses the van der Waals boundaries of the substituents at the phosphorus atom. The value given for trimethylphosphane in nickel(0) complexes, $\theta = 118°$ for $d(NiP) = 228$ pm[9], is much smaller than for other trialkylphosphanes: $P(C_2H_5)_3$, $\theta = 132°$; $P(C_6H_5)_3$, $\theta = 145°$. In cobalt and iron complexes [$d(CoP) = 218$ pm[10], $d(FeP) = 224$ pm[11]] larger values of θ have to be taken into account. Nevertheless, salts of a stable cation $FeCH_3L_5^{\oplus}$ ($L = PMe_3$)[12] can be obtained. However, it is difficult to estimate the minimum spatial requirements of a phosphane ligand which are important to the preparative chemist.

Trimethylphosphane is a base ($pK_a = 8.65$; for comparison: Me_3N 9.80, pyridine 5.25). As a σ-donor, it is a good ligand in complexes of metals in high oxidation states, while from its position in the series of π-acids

$$CO \approx PF_3 > PCl_3 > AsCl_3 \approx SbCl_3 > P(OR)_3 > PPh_3 > PMe_3 > SMe_2 > RCN > NR_3 \approx ROH > H_2NCOR$$

no affinity for low valent metal centers is expected[13]. However, these insights which have emerged from investigations

of metal carbonyl complexes should not be applied directly to carbonyl-free systems because a change of central metal has to be considered as well as the sum of all ligand effects in a complex[14]. The σ-donor/π-acceptor properties of a ligand are not constant.

Reactions of trimethylphosphane with electrophiles are well known:

$$(CH_3)_3P \xrightleftharpoons{HX} [(CH_3)_3PH]^{\oplus}X^{\ominus} \quad (10)$$

$$(CH_3)_3P \xrightarrow{RX} [(CH_3)_3PR]^{\oplus}X^{\ominus} \rightleftharpoons R(CH_3)_2P{\cdot\cdot}CH_2 + HX \quad (11)$$

X = Halogen, *etc.*

The reversible protonation (10) corresponds to the quarternization (11) which upon action of base is not reversed but leads to alkylidenephosphoranes. Both reactions are more difficult at the coordinated ligand because of its phosphonium character.

Nucleophiles in general fail to react with trimethylphosphane. Only the strongest organometallic bases, *e.g. tert*-butyllithium, are able to abstract protons[15,16]. This reaction should be facilitated in the coordinated ligand. However, since the competing attack at the metal is usually faster, no report of a clear-cut proton abstraction from a trialkylphosphane ligand has yet appeared.

The oxidation of trimethylphosphane by oxygen to give trimethylphosphane oxide is a slow reaction under ambient conditions but is accelerated in metal complexes by oxidation-reduction catalysis. From some of these reactions peroxo complexes have been isolated[17], *e.g.* a triphenylphosphane complex in a reaction sequence according to eq. (12)[18].

$$Ni(PPh_3)_4 \xrightarrow[-2\,PPh_3]{O_2} (PPh_3)_2Ni\begin{smallmatrix}O\\O\end{smallmatrix} \quad (12)$$

$$\xrightarrow{4\,PPh_3} Ni(PPh_3)_4 + 2\,PPh_3O$$

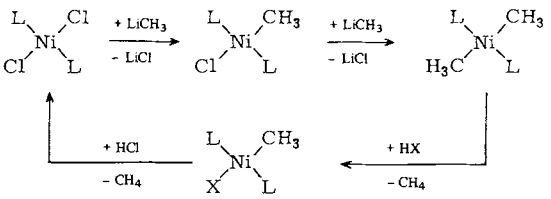
These reactions explain the air sensitivity of many phosphane complexes.

1.4. Preparation of Methyl Metal Compounds

A methylmetal function can be generated in two fundamentally different ways: (A) by an anionic alkylation, *e.g.* substitution of halide ligands by methyllithium or methylmagnesium bromide. Its counterpart is a cationic methylation (B) using reagents such as methyl iodide or tosylate. If both synthetic routes are to give identical products, route (B) requires a complex anion $M^{\ominus}$ in an oxidation state which is lower by two units (d^{n+2}) because in a formal heterolytic cleavage the bonding electron pair is transferred to the *C*-bonded ligand. For this reason reaction (B) is called an oxidative addition.

Substitution

$$d^n: (M)\text{—}X \xrightarrow[-X^{\ominus}]{+CH_3^{\ominus}} (M)\text{—}CH_3 \quad (A)$$



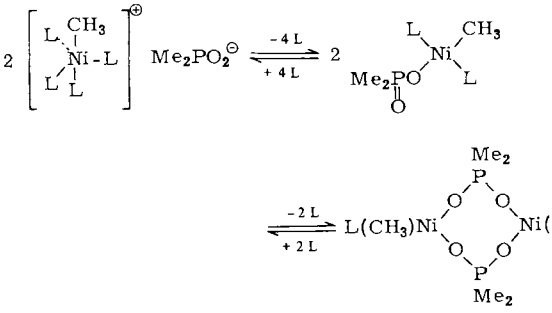
$$d^{n+2}: (M)^{\ominus} \xrightarrow{+CH_3^{\oplus}} (M)\text{—}CH_3 \quad (B)$$

Oxidative addition

2. Square Planar Complexes

2.1. Mononuclear Complexes

The anionic alkylation of bis(phosphane)nickel dihalides by organoalkali metal, Grignard, or organoaluminum compounds is the usual method for the preparation of alkylnickel phosphane complexes[23]. Methyllithium affords methyl and dimethylnickel complexes according to eq. (13) in high yields of both steps[21].

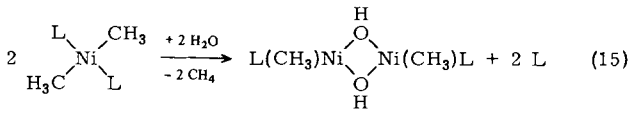


(13)

L = PMe_3
X = OH, OCH_3, OC_6H_5, $OSiMe_3$, SMe, O_2CCH_3, F, etc.

The stepwise alkylation corresponds to a two-step protolytic cleavage of the $NiCH_3$ functions. Alcohols or water cleave only one of the NiC bonds, while the other reacts only with strong mineral acids, liberating methane[21]. The high reactivity of a *trans* dialkyl arrangement indicates the *trans* influence of alkyl ligands. The stability of monomethylnickel compounds in (oxygen-free) aqueous solution can be compared with methylmercury compounds[24]. Square-planar Ni^{II} compounds are 16-electron complexes and can add a further ligand, adopting a trigonal-bipyramidal geometry (see Section 3). However, according to eq. (14) they can also release phosphane ligands. Both reactions are responsible for a fast ligand exchange which is conveniently observed by dynamic spectroscopic methods[19,22].

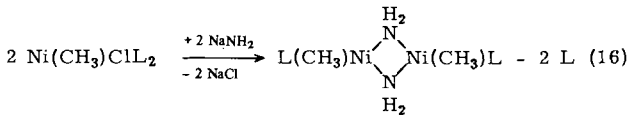
The mononuclear neutral methylnickel dimethylphosphinate can only be detected in a solution from which the ligand-rich and the dinuclear complex are actually isolated [eq. (14)].



(14)

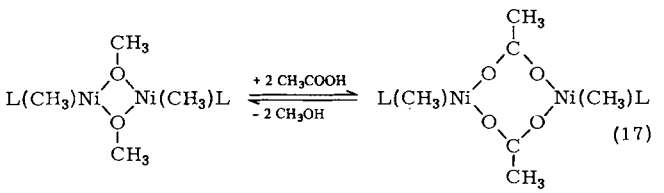
The dinuclear dimethylphosphinate complex is cleaved by phosphane in nonpolar medium to give the mononuclear complex; in a polar medium providing efficient anion solvation the pentacoordinate cation is formed.

2.2. Dinuclear Complexes in *cis* and *trans* Forms



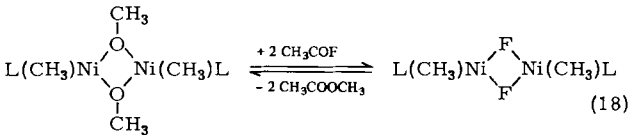
Three types of reaction can be used for a synthesis of dinuclear methylnickel compounds[25,26]:

a) Protolytic fission of dimethylnickel compounds, *e.g.*



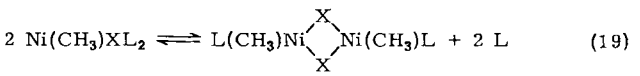
(15)

b) Exchange of halide in methylnickel halides, *e. g.*



(16)

c) Exchange of anion bridges in equilibria, *e. g.*

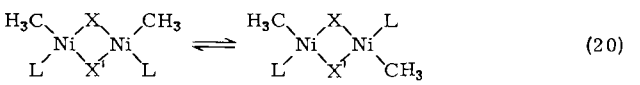


(17)

d) Transesterification, *e. g.*

(18)

An investigation of a large number of methylnickel compounds[25-28] participating in equilibrium (19)

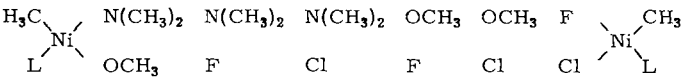


(19)

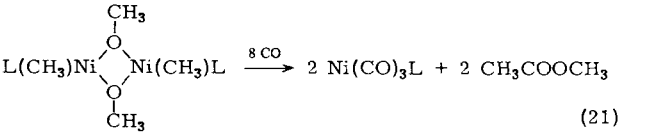
has resulted in a sequence of anions which show an increasing tendency to form anion-bridged complexes.

$X^{\ominus} = Cl^{\ominus} < O_2CCH_3^{\ominus}$, $O_2PMe_2^{\ominus} < OPh^{\ominus}$, $SPh^{\ominus} < OR^{\ominus}$, $SR^{\ominus}$, $OSiMe_3^{\ominus} < F^{\ominus} < OH^{\ominus} < NH_2^{\ominus} < NMe_2^{\ominus}$

The square-planar coordination of the nickel centers allows for *cis* and *trans* isomers. In particular the dinuclear compounds containing a four-membered ring system are found to occur as *cis* and *trans* forms in equilibria[29].



(20)

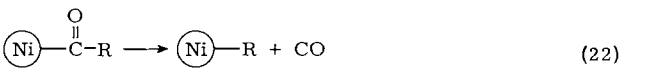


cis-(X = X', X ≠ X) *trans*-(X = X')

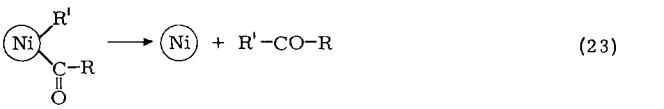
Methyl(trimethylphosphane)nickel amide dimer crystallizes in the *trans*-form. Upon dissolution in pyridine ($\varepsilon = 12.3$) at 30 °C it isomerizes within a few hours to give an equilibrium concentration of the *cis*-isomer (36%). In toluene this equilibrium reaches only 20% of the *cis*-isomer. In a number of solvents the molar fraction of the polar *cis*-form in equilibria is roughly proportional to the dielectric constants suggesting a kind of linear free energy relation[30].

Dinuclear methylnickel compounds containing different bridging ligands (X ≠ X') are only known as *cis*-isomers. Moreover, the bridging ligand with the lowest tendency towards bridge formation occupies the position opposite to both methyl groups:

Simple olefins like ethene or propene have little influence on the position of equilibria (19). In spite of numerous possibilities of coordination at the nickel no olefin insertion into Ni—CH_3 bonds is observed. In contrast all dinuclear methylnickel compounds react with carbon monoxide already at low temperatures[31]. One finds products of reductive elimination reactions according to eq. (21) rather than methyl or acetylnickel compounds.

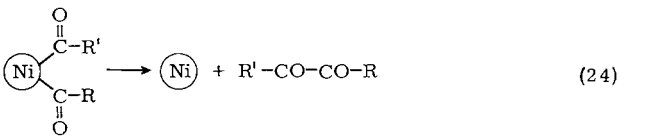


(21)



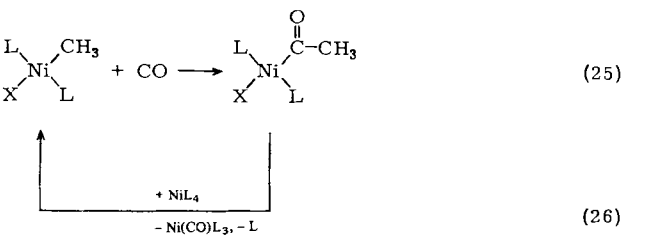
On the other hand the insertion reaction of CO into Ni—C bonds could be conveniently investigated in mononuclear methylnickel halides.

2.3. Acetylnickel Compounds



Equilibria involving carbonylation and decarbonylation reactions of organoplatinum and palladium complexes have been known for a long time through the work of *Chatt et al.*[32]. Until a few years ago, stable acylnickel complexes had only been isolated in a few exceptional cases[33]. More success had usually been prevented by either a dominant decarbonylation (22) or by C—C coupling reactions, (23) and (24), at the nickel center[34].

(22)



(23)

(24)

Carbonylation of trimethylphosphane methylnickel halides at normal pressure according to eq. (25) yields stable acetylnickel complexes[35].

(25)

(26)

Acetylnickel halides adopt a *trans*-configuration and display intermolecular exchange of ligands in solution, and thus closely resemble the corresponding methylnickel halides. The *trans* square-planar structure of acetylbis(trimethylphosphane)nickel chloride has been confirmed by a single crystal X-ray structural analysis (Fig. 1)[36].

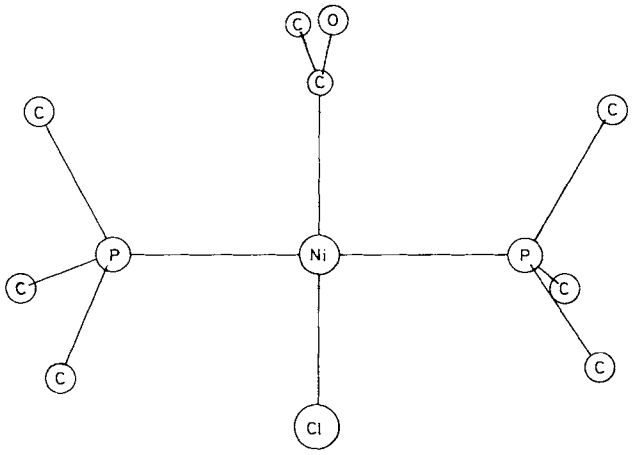


Fig. 1. Structure of *trans*-$Ni(COCH_3)Cl(PMe_3)_2$ (cf. [36]).

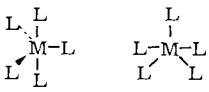
The ketone type carbonyl group points out of the nickel coordination plane at right angles. The Ni—C distance is 10 pm shorter than in methylnickel complexes of similar structures[37] and reflects some strengthening by π-interaction. The C—C bond is longer than in ketones, indicating an easy mobilization of the CO fragment. The preparative decarbonylation is achieved using CO-acceptor complexes like tetrakis(trimethylphosphane)nickel(0) according to eq. (26).

Acylnickel compounds are particularly interesting because of their crucial position in catalytic cycles of the following kind: a) oxidative addition to the nickel(0) complex; b) CO insertion into the Ni—C bond; c) reductive elimination leading back to the nickel(0) state. In this connection, the reaction of acyl halides with Ni^0 complexes has been repeatedly investigated. In most cases decarbonylation products had been obtained[38]. These results are now understood as there is always a competing reaction according to eq. (26) which is relatively fast. A cationic acylation of nickel(0) complexes can only succeed if oxidative addition according to eq. (27) is faster than both competing reactions: decarbonylation according to eq. (26) and the quarternization of the trialkylphosphane according to eq. (28) giving acylphosphonium salts[35].

$$NiL_4 + RCOX \rightarrow Ni(COR)XL_2 + 2L \quad (27)$$

$$RCOX + PMe_3 \rightarrow [RCOPMe_3]^{\oplus}X^{\ominus} \quad (28)$$

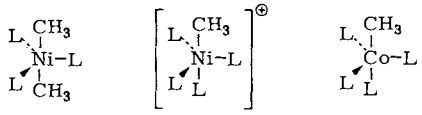


Although there is some additional acylation of the nickel(0) complex by the acylphosphonium salt, this reaction is so slow that the overall processes is dominated by the decarbonylation reaction according to eq. (26). Yet another competing reaction is C—C linkage *via* attack of acyl halide at the acylnickel function with its changed polarity. This reaction according to eq. (29) will start only at elevated temperatures.

$$Ni(COCH_3)ClL_2 + CH_3COCl \rightarrow NiCl_2L_2 + CH_3COCOCH_3 \quad (29)$$

Meanwhile, further syntheses of acylnickel compounds have been reported[39], the conditions being such as to allow for an undisturbed reaction according to eq. (27). This route includes a successful synthesis of benzoyl and phenylnickel halides[40].

3. Trigonal-Bipyramidal Complexes



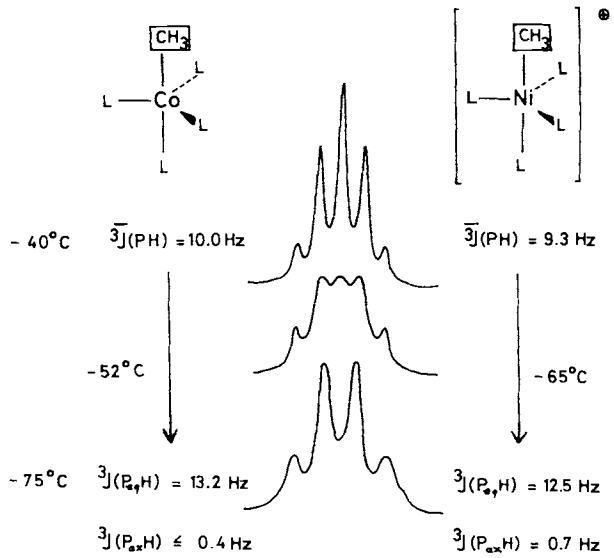
Pentacoordinate molecules or complexes in their ground states adopt either a trigonal-bipyramidal or a square-pyramidal geometry, the differences in energy being small[41] particularly in complexes with five identical ligands.

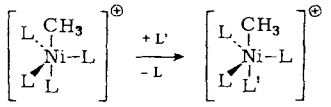
$M(d^8) = Ni^{II}, CO^{I}, Fe^{0}$

A typical feature of these molecules is a dynamic behavior involving an intramolecular change of positions of substituents or ligands, respectively, by a pseudorotation process (Berry mechanism, turnstile mechanism)[42].

18-electron species of methylnickel compounds can be reversibly obtained by addition of trimethylphosphane to coordinatively unsaturated complexes [see eq. (14), reverse reaction]. In contrast, there exists only one methylcobalt(I) complex, $CoCH_3L_4$ (18 electrons), out of a number of isoelectronic species.

In the ground state the methyl groups of dimethyltris(trimethylphosphane)nickel occupy axial positions; intermolecular ligand exchange is activated more easily than pseudorotation[21]. The pseudorotation process can be observed by spectroscopy with the methylnickel cation; only at the





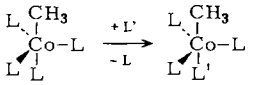


Fig. 2. Temperature dependent ^{1}H-NMR spectra of isosteric methyl compounds $CoCH_3L_4$ (in toluene) and $[NiCH_3L_4]^{\oplus}$ (in CH_2Cl_2), L = PMe_3, due to pseudorotation.

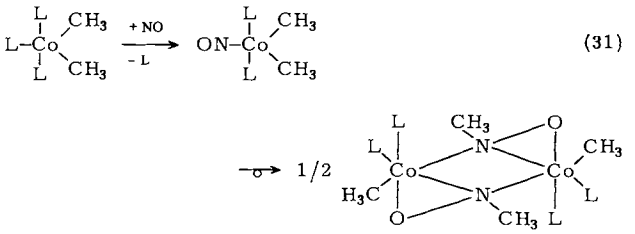


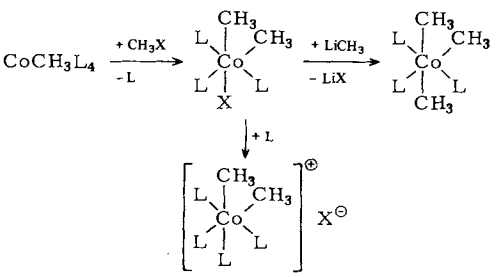
stage of rapid motion is this superimposed by intermolecular exchange[43]. The neutral isoelectronic species, $CoCH_3L_4$, finally shows only pseudorotation in the temperature range recorded[44]. In spite of differing charge on the complexes[45], both intramolecular movements have the same activation energy (50—55 kJ/mol) which proves the validity of the concept of isosteric species for this type of complex.

The *trans* influence of the axial methyl group causes all entering ligands [L′ = CO or $P(OCH_3)_3$] to regioselectively occupy the second axial position; a second substitution reaction becomes significantly more difficult for $L' = P(OCH_3)_3$.

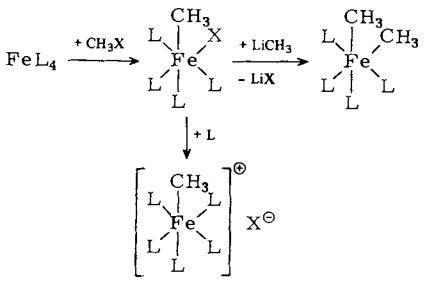
(30a)

(30b)

In contrast to the 18-electron complex $Ni(CH_3)_2L_3$ the 17-electron compound $Co(CH_3)_2L_3$[46] adopts a *cis* configuration. The equatorial positions of the two methyl groups are suggested by the reactions with acids which unspecifically remove one or both methyl groups and also by the equatorial position of the NO ligand in a diamagnetic nitrosyl derivative.



(31)



Subsequent rearrangement *via* insertion of NO into one of the Co—C bonds followed by dimerization leads to an octahedral Co^{III} complex containing bridging nitrosomethane ligands [eq. (31)].

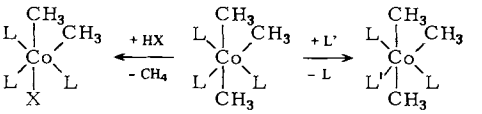
4. Octahedral Complexes

While octahedral nickel(IV) complexes containing phosphane ligands remain unknown to date, a large number of examples have been described for cobalt(III) and iron(II). If these complexes only contain unidentate ligands, the preferred arrangement of neutral and anionic ligands of the metal(d^6) center is recognized.

Oxidative addition of methyl halide to metal(d^8) systems proceeds analogously for cobalt(I)[44,47,48] and iron(0)[49].

(32a)

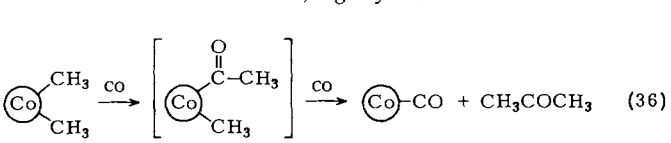
(32b)



Neutral methylcobalt(III) complexes have a meridianal configuration. Unlike *mer*-hydridocobalt(III) complexes [eq. (33)], a reductive elimination of *cis*-fixed methyl groups according to eq. (34) does not occur.

(33)

L′ = PPh_3



(34)

L = PMe_3

(35)

X = Cl, Br; L′ = $P(OMe)_3$

The reactions of trimethylcobalt complexes according to eq. (35) are similarly regiospecific like those of dimethylnickel [eq. (13)] and of the isosteric complexes $[Ni(CH_3)L_4]^{\oplus}$ and $Co(CH_3)L_4$ [eq. (30a, b)]. The cleavage by protic acids proceeds in the C—C axis of the molecule, the substituting neutral ligand enters a position *trans* to the unique methyl group. In isosteric complexes $[Co(CH_3)_2L_4]^{\oplus}$ and $Fe(CH_3)_2L_4$ disubstitution with neutral ligands is again found[12] to occur in both positions *trans* to the methyl groups. In this case both methyl groups experience *trans* influences of equal neutral ligands prior to, as well as after, the disubstitution, while in all methylcobalt complexes of eq. (35) there are methyl groups with a different degree of polarization of the Co—C bonds. This should favor an elimination on ethane. However, in all methylcobalt complexes containing more than one methylcobalt function[46,48] a spontaneous reductive elimination only occurs after transformation, *e.g.* by CO insertion.

(36)

(37)

As soon as a CO insertion into one of the Co—C bonds has occurred, acetone is formed according to eq. (36)—presumably from an acetyl(methyl)cobalt species. No such intermediates can be trapped in a normal pressure carbonylation reaction according to eq. (37).

5. Hydridophosphane Complexes

The first phosphane-substituted analogues of the familiar carbonyl hydrides, $FeH_2(CO)_4$, $CoH(CO)_4$, and of the iso-

electronic $Ni(CO)_4$, were the phosphorus trihalide complexes[50]. The low oxidation states of the three metals formally arising from strongly acidic M—H functions (-II, -I, 0) led to the assumption that σ-donating ligands like the trialkylphosphanes would not prove satisfactory by themselves. This is not so, however, as has been shown by the preparation of trimethylphosphane complexes NiL_4[51], $CoHL_4$[47,51], and FeH_2L_4[51-54] ($L = PMe_3$) which are more stable thermally than their carbonyl and trifluorophosphane counterparts.

Unlike NiL_4, which has a tetrahedral NiP_4 skeleton, the isoelectronic hydride complexes are called pseudotetrahedral, because the hydrogen residing on the metal needs little space and moves around a slightly distorted tetrahedral MP_4 skeleton (tetrahedral-edge-traverse mechanism[55-59]).

This concept can be extended to cationic complexes $[NiHL_4]^{\oplus}$ (18 electrons)[60] and $[CoHL_4]^{\oplus}$ (17 electrons)[44] ($L = PMe_3$). The IR spectra of all hydride complexes display broad ν(MH) bands with a bathochromic shift when compared with complexes of strongly π-accepting ligands.

In parallel fashion, the acidity of the metal hydride function decreases: $CoH[P(OMe)_3]_4$ can still be deprotonated using potassium hydride[55], while the trimethylphosphane complexes $CoHL_4$ and FeH_2L_4 resist attack by strong base[51].

6. Tetrahedral Complexes ML_4

Metal(d^8) configuration: Depending upon the nature of the monodentate ligands, bis(phosphane)nickel(II) halides adopt a square-planar (diamagnetic) or a tetrahedral (paramagnetic) configuration. For some compounds transitions between the two classes are induced by simply varying the environment (solvation, crystal lattice)[61]. The interesting question of the magnetic properties of a tetrakis(trimethylphosphane)nickel dication is still open, because in equilibria with the preferred $[NiL_5]^{2\oplus}$ ($L = PMe_3$)[62] it could not be fully characterized. On the other hand, the isoelectronic cation $[CoL_4]^{\oplus}$ is likely to be tetrahedral because of its magnetic moment, while a diamagnetic cation $[CoL_5]^{\oplus}$ cannot be prepared with trimethylphosphane ligands only[63]. (For a survey see Table 1.)

There is some evidence for the paramagnetic nature of the neutral molecule in this series, FeL_4[53,64], which has been proved to exist in an equilibrium of an intramolecular oxidative addition (see Section 8) by an indirect method. The 18-electron compound FeL_5 also could not be obtained, while phosphite complexes of an analogous composition are known[52,54,65].

Metal(d^9) configuration: Solutions of methyltetrakis(trimethylphosphane)nickel(II) tetraphenylborate evolve ethane and methane on exposure to diffuse daylight. According to eq. (38), a salt of the tetrakis(trimethylphosphane)nickel(I) cation[66] is formed.

$$[NiCH_3L_4]^{\oplus}[BPh_4]^{\ominus} \xrightarrow{h\nu} [NiL_4]^{\oplus}[BPh_4]^{\ominus} + C_2H_6 + CH_4 + \cdots \quad (38)$$

$$NiL_4 + NiCl_2L_2 + 2L + 2NaX \rightleftharpoons 2[NiL_4]^{\oplus}X^{\ominus} + 2NaCl \quad (39)$$

$L = PMe_3$, $X = BPh_4$, BF_4, PF_6

In contrast to the known nickel(I) complexes $NiXL'_3$ [$L' = P(C_6H_5)_3$, X = halide][67], a trimethylphosphane complex of this stoichiometry cannot be obtained. Only after precipitating the halide ligands is a cationic nickel(I) complex formed in an oxidation reduction equilibrium (39).

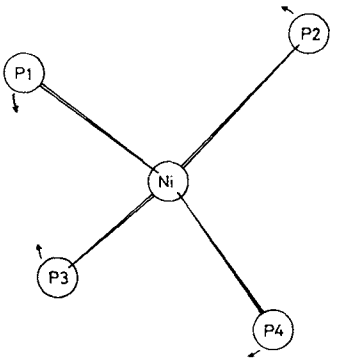


Fig. 3. Distortion of the NiP_4 tetrahedron in the cation $Ni(PMe_3)_4^{\oplus}$ (P1NiP3 104.6(1)°, P2NiP4 119.9(1)°).

In the crystal lattice (Fig. 3) the PNiP angles of the cation $[Ni(PMe_3)_4]^{\oplus}$ differ only slightly from the ideal tetrahedral geometry of the NiP_4 skeleton and do not give any indication of a Jahn-Teller distortion which can be expected in a d^9 configuration of metal valence electrons. The ESR spectrum (77 K) consists of only one isotropic line ($g = 2.12$).

More favorable conditions for relaxation in the isosteric $Co(PMe_3)_4$ result in a well-resolved hyperfine structure of the ESR spectrum (4 K, toluene glass)[68] containing two sets of eight lines ($I_{Co} = 7/2$).

Table 1. Range of existence of tetrahedral trimethylphosphane complexes ($L = PMe_3$). [Species in brackets have not yet been isolated.]

Electrons	16	17	18	16	17	18	16	17	18
M(d^8)	FeL_4		$[FeL_5]$	$CoL_4^{\oplus}$		$[CoL_5^{\oplus}]$	$NiL_4^{2\oplus}$		$NiL_5^{2\oplus}$
M(d^9)		$[FeL_4^{\oplus}]$			CoL_4			$NiL_4^{\oplus}$	
M(d^{10})	$[FeL_3^{2\ominus}]$		$[FeL_4^{2\ominus}]$	$[CoL_5^{\oplus}]$		$CoL_4^{\ominus}$	$[NiL_3]$		NiL_4

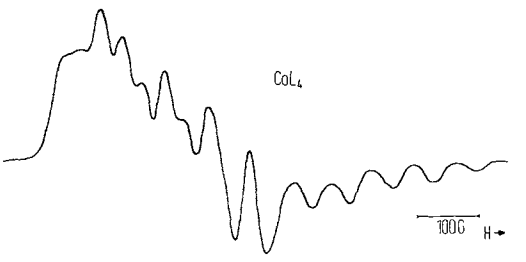

Fig. 4. ESR spectrum of $Co(PMe_3)_4$ (toluene glass, 4 K).

In the ground state $Co(PMe_3)_4$ therefore adopts an axial symmetry, as has been elucidated for $Co(CO)_4$ in low temperature matrices[69].

Reduction of the system $CoCl_2$/4 Me_3P/THF with magnesium in a sort of Grignard reaction under argon (not under nitrogen, see Section 10) affords tetrakis(trimethylphosphane)cobalt(0) in high yield[44].

$$CoCl_2 \xrightarrow[-MgCl_2]{+4\,L,\,Mg} CoL_4$$

$$CoL_4 \xrightarrow{PhN=NPh} Co(PhN{=}NPh)L_2 \quad (40)$$

$$CoL_4 \xrightarrow{CO} [L_2Co(CO)_2]_2 \quad (41)$$

$$CoL_4 \xrightarrow{3/2\,I_2} CoIL_3 + Me_3PI_2 \quad (42)$$

$$CoL_4 \xrightarrow{NO} Co(NO)L_3 \quad (43)$$

In substitution reactions, the paramagnetic valence state of $Co(PMe_3)_4$ can be preserved [eq. (40)] or lost by dimerization [eq. (41)] or through an incoming three-electron ligand such as NO [eq. (43)]. Under carefully adjusted reaction conditions halogen oxidizes the metal complex and the liberated phosphane ligand (42). The magnetic properties of cobalt(I) halides[63] ($\mu_{eff}/\mu_B = 3.0$—3.2) suggest a C_{3v} symmetry in the $CoXP_3$ skeleton, which is also favored with other phosphane ligands[70].

L = PMe_3
X = Cl, Br, I, O_2CCH_3

Surprisingly a methylcobalt compound of comparable composition does not exist[44].

$$CoClL_3 \xrightarrow[-LiCl]{+LiCH_3} 3/4\,CoCH_3L_4 + 1/4\,Co + \cdots \quad (44)$$

In an attempted synthesis according to eq. (44) cobalt metal is deposited until enough phosphane ligands become available for the formation of the 18-electron compound $CoCH_3L_4$.

In a sequence of tetrahedral trimethylphosphane complexes ML_4, the influence of increasing electron density is recognized by means of infrared spectroscopy from the bands of the coordinated trimethylphosphane.

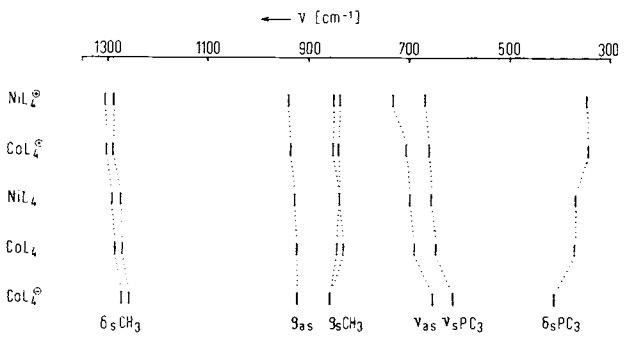

Fig. 5. Sequence of increasing electron density in tetrahedral complexes $M(PMe_3)_4$ derived from given IR bands.

In Figure 5 all bands are listed which have been observed within the given limits except for the low intensity metal phosphorus stretching modes (ν(M—P) = 300—250 cm^{-1}). According to *Goubeau et al.*[71] at least the PC_3 stretching mode is regarded as a reliable indicator of electronic changes in the trimethylphosphane ligand. Furthermore all other bands in the sequence (as we go from top to bottom in Fig. 5) are shifted in a characteristic way as a consequence of increasing induction of negative charge from the complex center into the P—C—H bonding system. We cannot decide whether only the skeleton of σ-bonds is affected or whether there are additional π-components between metal and phosphorus atoms, which could well be larger than estimates obtained from phosphane-carbonyl complexes[72]. Unexpectedly the properties of the complexes listed in Figure 5 did not result in a parallel sequence of increasing dissociation of trimethylphosphane ligands.

Metal(d^{10}) configuration: The neutral molecules NiL_4[51,60] and CoL_4[44] can be sublimed *in vacuo*[73], and even the alkali metal cobaltates $MCoL_4$ (M = Li, Na, K) under the same conditions (80 °C, 0.1 torr) do not release more phosphane ligands than the other compounds in Figure 5. The thermal stability of anionic complexes is worth mentioning because at the cobaltate stage a clear limit of loading charge on tetrahedral trimethylphosphane complexes is reached[47] [eq. (45)].

$$CoL_4 + M + x\,OR_2 \rightleftharpoons M^{\oplus}CoL_4^{\ominus} \cdot x\,OR_2 \quad (45)$$

L = PMe_3, M = Li, Na, K OR_2 = THF; $x = 0.5$
$OR_2 = OEt_2$; $x = 1$

According to eq. (45) yellow to orange solids are obtained which display interesting thermochromic and solvatochromic effects: In the low temperature limit, the ethereal solutions become orange and diamagnetic. At 20 °C and with poor solvation of cations, *e.g.* in pentane, brown coloration by CoL_4 and turbidity of the solution is seen to arise from finely dispersed alkali metal. Upon chilling, these solutions display the ESR signal of CoL_4 (Fig. 4).

Three variables favor the formation of alkali metal cobaltates:

a) Lowering the temperature;

b) increasing concentrations of diethyl ether or—more efficiently—THF;

c) an increasing reduction potential of alkali metals: Li < Na < K.

Thus the anion $CoL_4^{\ominus}$ rates among the strongest known soluble reducing agents. Benzophenone or naphthalene are readily transformed into radical anions at −30 °C. Butadiene and isoprene are efficiently polymerized. However, there is no clear distinction as to which is the active species: the cobaltate anion or the finely dispersed alkali metal.

Alkali metal cobaltates are strong bases and very reactive nucleophiles. Reactions with organic or inorganic electrophiles and even simple protonation reactions proceed according to the scheme of an oxidative addition[47].

7. Oxidative Addition Reactions

Metal(d^{10}) configuration: Oxidative additions to tetrakis(trimethylphosphane)nickel(0) are successfully carried out according to eq. (46) in polar medium only.

Under the conditions of oxidative substitution reactions according to eq. (47), the methylnickel intermediate is attacked faster by the electrophile than it is generated[60].

The stronger nucleophile cobaltate attacks methyl halides even at −70 °C. The first product of the reaction according

$$NiL_4 + CH_3I \xrightarrow[CH_3CN,\ 20\,^\circ C]{} NiCH_3L_4^{\oplus}I^{\ominus} \quad (46)$$

$$NiL_4 + CH_3I \xrightarrow[OEt_2,\ 20\,^\circ C]{} [Ni(CH_3)IL_2] + 2\ L \quad (47)$$

$$[Ni(CH_3)IL_2] \xrightarrow{L,\ CH_3I} NiI_2L_3 + C_2H_6$$

to eq. (48), $CoCH_3L_4$, undergoes a subsequent oxidative substitution reaction at slightly higher temperatures. Both steps can be conducted separately; chloromethane is best suited for the preparation of $CoCH_3L_4$.

$$CoL_4^{\ominus} \xrightarrow[-X^{\ominus}]{+CH_3X} CoCH_3L_4 \xrightarrow[-L]{+CH_3X} Co(CH_3)_2XL_3 \quad (48)$$

X = Cl, Br, I X = Br, I

$$CoL_4^{\ominus} + CH_3X \longrightarrow \{CoL_4 + CH_3X^{\ominus}_{\bullet}\} \xrightarrow[-X^{\ominus}]{} CoCH_3L_4 \quad (48a)$$

$$CH_3X^{\ominus}_{\bullet} \longrightarrow {}^{\bullet}CH_3 + X^{\ominus}$$

$$^{\bullet}CH_3 \xrightarrow{CoL_4} CH_4 + L_3Co\overset{CH_2}{\underset{PMe_2}{|}} \quad (48b)$$

The high reduction potential of the cobaltate (2.6—3 V[47]) suggests a radical chain mechanism according to eq. (48a, b). Furthermore, the products in the first step strongly depend on temperature and solvent: In the more stable solvent cage of ether molecules at low temperatures a methyl radical is trapped by CoL_4 as soon as it is formed [eq. (48a)]. For pentane at 20 °C, eq. (48b) designates the reaction mode: the "hot" methyl radical abstracts hydrogen from a trimethylphosphane ligand, yielding a three-membered metallacycle of cobalt(I)[75].

With aromatic halides such as chlorobenzene hydrogen abstraction dominates. In an analogous reaction and even under favorable conditions phenyltetrakis(trimethylphosphane)cobalt is formed only in minor quantities.

Metal(d^9) configuration: We find one of the few examples of oxidative addition reactions at paramagnetic complex centers[76] in the chemistry of tetrakis(trimethylphosphane)cobalt(0) which is also a strong nucleophile.

$$CoL_4 \xrightarrow{CH_3I} [CoCH_3L_4^{\oplus}I^{\ominus}] \xrightarrow{CoL_4} CoCH_3L_4 + CoIL_3 + L \quad (49)$$

$$CoL_4 \xrightarrow{HCl} CoHL_4^{\oplus}Cl^{\ominus} \xrightarrow{CoL_4} CoHL_4 + CoClL_3 + L \quad (50)$$

Reacting iodomethane even at low temperatures in ether gives a green solid, presumably $CoCH_3L_4^{\oplus}I^{\ominus}$, which is rapidly reduced by further Co^0 complex yielding Co^I products in an overall 2:1 stoichiometry. The steps of reaction (49) cannot be clearly separated, as the activation energy of this alkylation must be high. However, after protonation according to eq. (50) the corresponding hydridocobalt(II) salt is isolated and can be separately reduced by CoL_4.

8. Reactions at the Coordinated Ligand

When applied to 1,1-dihalides like CH_2Cl_2, the 2:1 stoichiometry of oxidative additions to Co^0 complexes formally results in a (chloromethyl)cobalt compound according to eq. (52a). This species appears to be less stable than the analogous (methoxymethyl)cobalt compound which is obtained according to eq. (51)[47].

$$CoL_4^{\ominus} + CH_3OCH_2Cl \xrightarrow[-Cl^{\ominus}]{} \begin{matrix} L & CH_2OCH_3 \\ & | \\ & Co-L \\ L & | \\ & L \end{matrix} \quad (51)$$

$$2\ CoL_4 + CH_2Cl_2 \longrightarrow \left[\begin{matrix} L & CH_2Cl \\ & | \\ & Co-L \\ L & | \\ & L \end{matrix}\right] + CoClL_3 + L \quad (52a)$$

$$[Co(CH_2Cl)L_4] \longrightarrow [Co(CH_2PMe_3)ClL_3] \quad (52b)$$

$$CoClL_3 + Me_3P{=}CH_2 \longrightarrow \quad (52c)$$

$$\longrightarrow 1/2\ Co(CH_2PMe_3)_2Cl_2 + 1/2\ CoL_4 + L$$

$$3\ CoL_4 + 2\ CH_2Cl_2 \longrightarrow Co(CH_2PMe_3)_2Cl_2 + 2\ CoClL_3 + 4\ L \quad (52)$$

By attack of a phosphane according to eq. (52a, b) the carbenoid moiety is converted into a coordinated phosphorane[77]. In a similar reaction, Fischer-type carbene complexes take up phosphane to form phosphorane complexes[78].

Phosphoranecobalt(I) complexes undergo a dismutation reaction according to eq. (52b, c), which is also observed in an attempted direct synthesis according to eq. (52c). Finally, this reaction gives a bisphosphoranecobalt(II) complex together with CoL_4, thereby explaining the remarkable 3:2 stoichiometry of the overall reaction which is observed exactly by all the 1,1-dihalides investigated[77].

$$Co(CH_2PMe_3)_2Cl_2 + 4\ L \xrightarrow{Na} Me_3P{=}CH_2 + L_3Co\overset{CH_2}{\underset{PMe_2}{|}} + \cdots \quad (53)$$

Phosphoranes are liberated by reductive disintegration of their cobalt complexes, but reasonable yields are only achieved by supplying phosphane ligands for the low-valent cobalt at the same time [eq. (53)]. In the absence of this addition, the phosphorane is converted into a phosphane ligand. This type of conversion is exemplified by reaction of nickel, which is significant because of the mild conditions in a low temperature matrix[79].

$$Ni\ atoms + 4Me_3P \quad CH_2 \rightarrow Ni(PMe_3)_4 + \cdots \quad (54)$$

It has not been possible to elucidate the formation of the three-membered metallacycle according to eq. (53) which could either occur by decomposition of a phosphorane ligand or by proton abstraction from a trimethylphosphane ligand. There is only one rational synthesis for this compound which proceeds by deprotonation of free phosphane according to *Peterson*[15], followed by reaction with Co^I halide according to eq. (55)[16].

$$Me_2PCH_2Li + CoClL_3 \xrightarrow[-LiCl]{} L_3Co\overset{CH_2}{\underset{PMe_2}{|}} \quad (55)$$

A proton abstraction from the coordinated phosphane has been attempted according to eq. (56); however, it was found unable to compete with the reaction at the cobalt center.

$$Me_3CLi + CoClL_3 \xrightarrow[-LiCl]{} L_4CoH + Me_2C{-}CH_2 + Co + \cdots \quad (56)$$

Thus it was all the more surprising that trimethylphosphane at the iron(0) center undergoes smooth and reversible C—H cleavage.

$$FeL_4 \rightleftharpoons \begin{array}{c} L \quad H \quad CH_2 \\ \diagdown \; | \; \diagup \\ Fe \\ \diagup \; | \; \diagdown \\ L \quad L \quad PMe_2 \end{array} \quad (57)$$

Equilibrium (57) is essentially shifted to the side of the hydridoiron(II) complex. However, derivatives of the iron(0) isomer can be obtained directly under suitable conditions[80,81]. C—H cleavage is exclusively intramolecular. In a mixture with perdeuterated complex H/D exchange fails to occur, thus excluding any dinuclear species containing hydride or CH_2PMe_2 bridges.

Equilibrium (57) is a key reaction for the C—H cleavage of activated aliphatic hydrocarbons at metal centers[82-84]. Unfortunately we still do not know the decisive factor promoting this reaction[85]. Steric considerations and the structure of $Fe(CO)_4$[64] support a paramagnetic and slightly distorted molecule FeL_4. The high electron density facilitates oxidative addition type reactions, to which class equilibrium (57) belongs. On the other hand, there are electron-rich compounds like NiL_4 and $CoL_4^{\ominus}$(d^{10}) which have the same composition but do not show any tendency to undergo a similar addition of the coordinated ligand. Even the paramagnetic valence state of CoL_4 does not give rise to a reaction which could yield the known diamagnetic products[51,75] of eq. (58). Likewise, a reverse reaction according to eq. (58) could not be enforced so far.

$$2\ CoL_4 \not\rightleftharpoons CoHL_4 + L_3Co\begin{array}{c} CH_2 \\ | \\ PMe_2 \end{array} \quad (58)$$

$$CoL_4^{\oplus} \not\rightleftharpoons \left[\begin{array}{c} H \quad CH_2 \\ \diagdown \; | \; \diagup \\ L_3Co \\ \diagup \; | \; \diagdown \\ \quad PMe_2 \end{array}\right]^{\oplus} \quad (59)$$

The cation $CoL_4^{\ominus}$ which is isoelectronic with FeL_4 does not exist in an equilibrium with a hydridocobalt(III) complex in the sense of eq. (59).

So far there is only one example of a C—H fission reaction at a cobalt center, *i.e.* of dinitrogen cobaltates (see Section 10).

9. Monoolefincobalt Complexes

Simple olefins like ethene or propene do not form stable complexes of cobalt in its usual oxidation states[86]. Only on stepwise increase of electron density does the cobalt center become attractive for these π-accepting ligands[87,88].

In the cobalt(I) state coordination of ethene is still feeble and is detected only at low temperatures. On slightly increasing the electron density, *e.g.* on going to the methylcobalt(I) compound according to eq. (60), stable olefin complexes are formed. Reduction to the cobalt(0) state has the same effect.

$$\begin{array}{lllll} d^7 & CoCl_2L_2 \overset{C_2H_4}{\rightleftharpoons\!\!\!/} & CoCl_2(C_2H_4)L_2 & & \\ & \downarrow 1/2\ Mg,\ L & & & \\ d^8 & CoClL_3 \overset{C_2H_4}{\rightleftharpoons} & CoCl(C_2H_4)L_3 & \xrightarrow[-LiCl]{+LiCH_3} & CoCH_3(C_2H_4)L_3 \quad (60) \\ & \downarrow 1/2\ Mg & & & CoH(C_2H_4)L_3 \\ d^9 & [CoL_3] \xrightarrow{C_2H_4} & Co(C_2H_4)L_3 & & \quad (61) \\ & & \downarrow K & \nearrow H^{\oplus} & \\ d^{10} & & Co(C_2H_4)L_3^{\ominus}\ K^{\oplus} & & \quad (62) \end{array}$$

Tris(trimethylphosphane)olefincobalt(0) complexes are monomeric and paramagnetic ($\mu_{eff}/\mu_B = 1.85$); they can be sublimed *in vacuo* with some decomposition. Like CoL_4 they give well structured ESR spectra (toluene glass) which as a rule contain three sets of eight lines (Fig. 6) due to a low molecular symmetry[87].

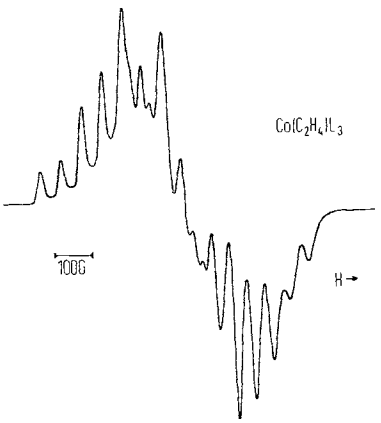

Fig. 6. ESR spectrum of $Co(C_2H_4)(PMe_3)_3$ (toluene glass, 77 K).

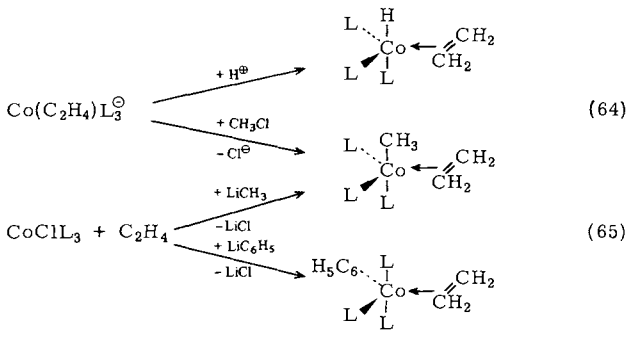
Reduction of olefincobalt(0) complexes on the surface of alkali metals in ether solvents proceeds to completion (as distinct from pentane[89]) according to eq. (63).

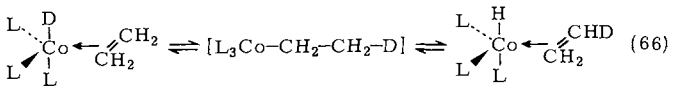


$$Co(C{-}C)L_3 + M \xrightarrow{OR_2} M^{\oplus}Co(C\quad C)L_3^{\ominus} \cdot x\,OR_2 \quad (63)$$

C–C = C_2H_4, C_3H_6, cyclopentene
M = Na, K, Rb, Cs; $OR_2 = O(C_2H_5)_2$, THF; $x = 0.5$—1

The olefincobaltates are orange solids which contain the usual small number of ether molecules for the solvation of alkali metal ions. The thermochromic and solvatochromic effects are less spectacular than with the tetrakis(trimethylphosphane)cobaltates.

Again reactions with electrophiles are of the oxidative addition type. According to eq. (64) they yield a new type of olefincobalt(I) complexes[90] which are also obtained in complementary fashion by anionic alkylation or arylation according to eq. (65)[91].



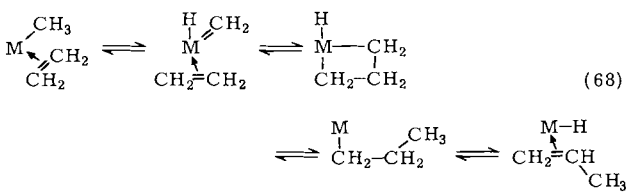
Spectroscopic investigations of these diamagnetic and readily soluble compounds demonstrate a trigonal-bipyramidal ground state configuration in which the σ-bonded ligand and the freely rotating olefin occupy adjacent positions: axial/equatorial and equatorial/equatorial, respectively. The

(64)

(65)

complexes synthesized according to eq. (64) are model compounds for investigations of the insertion step of homogeneous catalysis. The complexes possess all postulated[92] prerequisites: a σ-bound and a π-bound ligand at angles of 90° and 120°, respectively, at the cobalt atom. Furthermore the propeller type rotation of the olefin and the motions of all ligands in the sense of a pseudorotation provide virtually any orientation suitable for the insertion process. Actually this has been verified solely for the hydrido(olefin)cobalt complexes.

(66)



Reaction of the ethenecobaltate with $D^{\oplus}$ according to eq. (64) through equilibrium (66) causes the deuterium to be distributed approximately statistically over five positions: one at the cobalt and four in the ethene. Moreover, this result demonstrates that catalytic reaction of an 18-electron compound is not impaired by the stabilizing effect of the trimethylphosphane ligands[93].

In contrast, the homologous methylcobalt complexes exhibit surprising thermal stability. We would expect insertion into the Co—C bond to be essentially nonreversible because the reverse reaction, which requires *ca.* 75 kJ/mol for the C—C cleavage, cannot compete with the β-elimination needing only about 14 kJ/mol[94]. We therefore expect a reaction sequence according to eq. (67), leading to the hydrido(propene)cobalt complex.

$$CoCH_3(C_2H_4)L_3 \not\rightleftharpoons Co(C_3H_7)L_3 \rightleftharpoons CoH(CH_2{=}CHCH_3)L_3 \qquad (67)$$

This complex can be obtained by a protonation corresponding to eq. (64), but is not formed in reaction (67); nor can it be detected under the conditions necessary for thermolysis of the methylcobalt compound[95].

An olefin insertion into $Co(d^6)$—CH_3 bonds has recently been demonstrated[96]. In view of the high activation energy for this step we still have to consider alternative models, for instance the Green-Rooney mechanism[97] involving metallacycles:

(68)

Numerous examples of olefin insertions into metal-carbene functions have been described[98-100]. Hence an sp^2-carbon attached to a metal could be more prone to insertion than the sp^3-carbon of the methylmetal function.

This idea is contradicted by the properties of a complex $CoC_6H_5(C_2H_4)(PMe_3)_3$ (Fig. 7) which has been recently prepared[91].

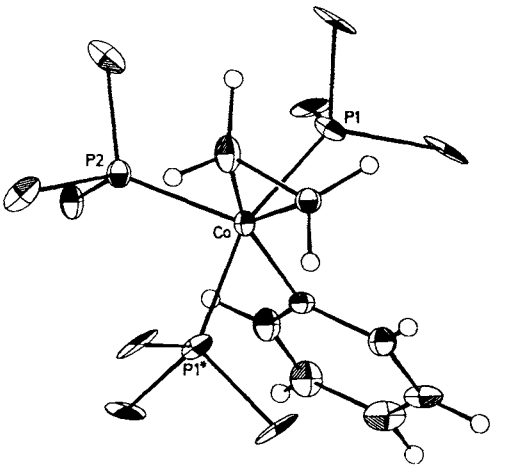


Fig. 7. Structure of $Co(C_6H_5)(C_2H_4)(PMe_3)_3$. Co atom, phenyl group, and C atoms of ethene lie in the equatorial plane.

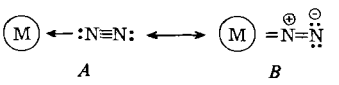


Although in the crystal the cobalt atom and all carbon atoms which are required for the insertion lie in one plane, no insertion product (styrene) can be found in the smooth high yield decomposition reaction in solution according to eq. (69).

$$CoC_6H_5(C_2H_4)L_3 \xrightarrow[\text{Toluene}]{40\,^{\circ}C} Co(C_2H_4)L_3 + 1/2\,C_6H_5{-}C_6H_5 \qquad (69)$$

Further investigations are needed in order to establish all the requirements for this important reaction step in homogeneous catalysis. Last but not least, this includes syntheses of further model compounds and investigations of their reactivity.

10. Dinitrogen Complexes

The high reduction potential of the trimethylphosphane cobaltates should suffice to reduce the dinitrogen molecule, provided a reduced moiety can be stabilized as a product. Today dinitrogen complexes of transition metals are known for almost all Group III to VIII elements[101]. Compared with the dinitrogen molecule (d(NN) = 110 pm), their bond lengths are generally only slightly elongated (d(NN) = 110—113 pm), and only in exceptional cases is there a considerable increase (d(NN) = 135 pm[102]) which may be correlated with the degree of reduction of the N_2 unit. Electron-rich metal centers provide just one of several conditions for stable dinitrogen complexes *A*. Polarization of the N_2 ligand by the metal in the sense of a limiting formula *B*, which is recognized by a strong IR absorption (ν_{NN}), can be enhanced by placing an electron-rich metal center at one end and a polarizing cation at the opposite end of the NN axis.

A *B*

As has been known for ten years[103] the ν_{NN} frequency falls drastically on going from the Co^{I} state over to dinitrogencobaltates.

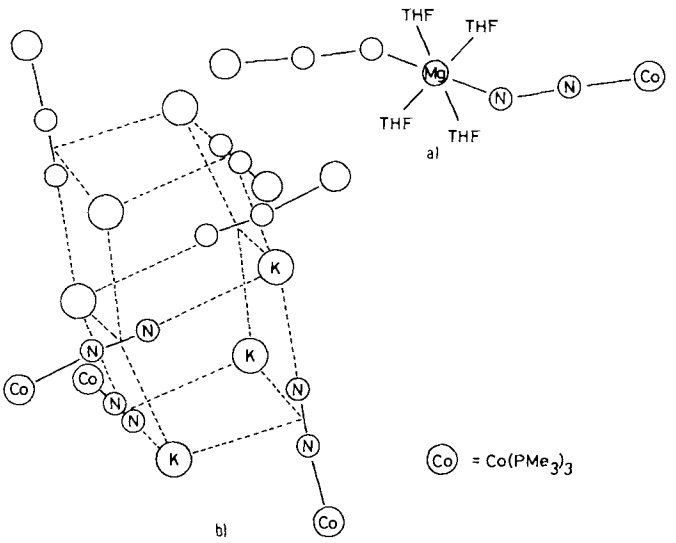
$CoH(N_2)L_3$ $\quad \nu_{NN} = 2060\ cm^{-1}$ (benzene)

$[CoN_2L_3]^{\ominus}Na^{\oplus}$ $\quad \nu_{NN} = 1875\ cm^{-1}$ (tetrahydrofuran)

$L' = P(C_2H_5)_2C_6H_5$

This observation remained unexplained until recently.

The preparation and structural characterization (Fig. 8) of dinitrogentris(trimethylphosphane)cobaltates containing electropositive main group elements as counterions ($K^{\oplus}$, $Mg(THF)_4^{2\oplus}$)[104-106] have provided a better understanding of the role of the cations: While four tetrahydrofuran donors surround the counterion in the magnesium cobaltate, the potassium cobaltate with its remarkable association of a $(KN_2)_6$ cluster core (Fig. 8) interacts with ether donors only in the



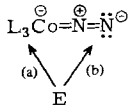


Fig. 8. Structures of dinitrogen cobaltates: a) $L_3Co(N_2)Mg(THF)_4(N_2)CoL_3$ and b) $[K.Co(N_2)L_3]_6$ ($L = PMe_3$).

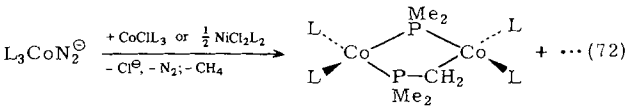
second coordination sphere even in solution[106], because the interactions between potassium and coordinated dinitrogen dominate along the NN axis as well as perpendicular thereto. In both structures the NN bond lengths (116–118 pm) in the cobaltate ion suggest the following representative limiting formula of an ambidentate anion:

Electrophiles E may attack at two points: (a) at the cobaltate center and (b) at the terminal nitrogen. Both reactions have been accomplished. As an oxidative addition of ethyl iodide or benzyl bromide route (a) leads to complete loss of dinitrogen, yielding organocobalt(I) complexes[106] according to eq. (70 a, b).



$$L_3CoN_2^{\ominus} + C_2H_5I \xrightarrow[-I^{\ominus}]{} CoH(C_2H_4)L_3 \qquad (70a)$$

$$L_3CoN_2^{\ominus} + C_6H_5CH_2Br \xrightarrow[-Br^{\ominus}]{} Co(\eta^3\text{-}CH_2C_6H_5)L_3 \qquad (70b)$$

$$L_3CoN_2^{\ominus} + ClSnMe_3 \xrightarrow[-Cl^{\ominus}]{} L_3Co{-}N{\equiv}N{-}SnMe_3 \qquad (71)$$

Route (b) is more interesting because it affords substituted cobalt diazenides (N in a formal oxidation state −I) with reagents such as trimethylchlorosilane or trimethyltin chloride according to eq. (71). However, an extensive reduction of the N_2 unit has not been achieved so far[40].

Oxidations of dinitrogen cobaltates by cobalt(I) or nickel(II) halide complexes according to eq. (72) take an unexpected turn.

Loss of dinitrogen and (formally) methane affords a remarkably stable and weakly paramagnetic dinuclear compound containing a μ-dimethylphosphide and a μ-dimethylphosphanemethanide moiety[107]. As demonstrated by X-ray diffraction (Fig. 9) the last-mentioned ligand contains a PC double bond (171 pm), and an sp^2-CH_2 function is bound to one of the cobalt atoms at a PCCo angle of 88°. The structural subunit $CoPMe_2CH_2Co$ may therefore be described as a *P*-metalated methylenephosphorane which, upon coordination and in contrast to all known phosphorane-metal complexes[108], does not change its ylide function into an sp^3-C atom. In accord with the normal behavior of phosphorane complexes, there is no CO insertion into this particular Co—C bond as became evident from the synthesis of a carbonyl derivative, $L(CO)_2Co(PMe_2)(PMe_2CH_2)Co(CO)_2L$. CO usually undergoes fast insertion into all Co—C-σ bonds[107].

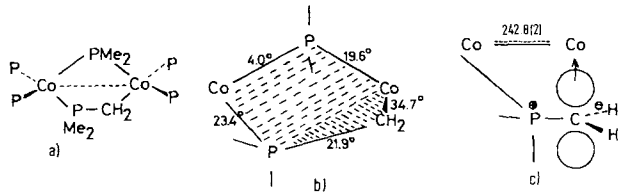


Fig. 9. Structure of $L_2Co(PMe_2)(CH_2PMe_2)CoL_2$ ($L = PMe_3$). a) Geometry around the C atoms; b) dihedral angles of the heterocycle; c) interpretation of bonding in the $Co(CH_2PMe_2)Co$ subunit.

Reaction according to eq. (72) illustrates the role of C—H and P—C bond cleavage under the influence of electron-rich metal centers. In homogeneous catalysis it provides a model for the deactivation of catalysts containing alkylphosphanes.

11. Outlook

The elementary steps of many important processes in homogeneous catalysis have still not been elucidated. Syntheses of simple model compounds therefore provide valuable insights, especially if they simulate complex entities which are thought to serve as switching points in catalytic cycles. In spite of a strongly stabilizing effect of monodentate alkylphosphane ligands, which is largely independent of the electron density at the metal center, the model character of the compounds is not lost: Even 18-electron complexes undergo elementary steps such as the formal insertion of an olefin

into a metal-hydride function unassisted by a cocatalyst. Further model reactions can be easily designed on the basis of the concept of isosteric compounds. However, the real challenge always lies in the synthesis of the model compounds.

Particular interest attaches to the trialkylphosphane cobaltates because their reduction potential equals that of the most electropositive elements. Their pronounced readiness to undergo oxidative additions suggests an approach to C—H and C—C bond cleavage reactions. Furthermore, the synthetic potential of these compounds is not in the least exhausted.

Extensive reduction of dinitrogen in the metalate-counterion matrix may be regarded as a first step in the synthesis of organonitrogen compounds which might possibly be brought about catalytically.

The organometallic and coordination chemistry of the three "foundry metals", nickel, cobalt, and iron, will continue to command a lively interest, both academic and practical.

A sincere word of acknowledgment is directed firstly to my co-workers, Dr. H. H. Karsch, Dr. R. Hammer, J. Wenninger, and J. Gross, who have advanced the present work through their enthusiasm, perseverance, and skill, to my colleagues in the laboratory, and to the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Homogenkatalyse") and the Fonds der Chemischen Industrie for generous financial support.

Thermal Degradation of Polymers to Polymeric Carbon—An Approach to the Synthesis of New Materials[**]

By Erich Fitzer[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

One hundred years ago, *Edison* succeeded in preparing carbon fibers for his incandescent lamp bulb by thermal decomposition of natural polymeric fibers. Ten years ago, progress reports about "Novel Forms of Carbon" predicted outstanding properties and promising new applications for the carbonization products of synthetic polymers. Research and development in this field have been promoted by the problems of conventional technology (shortages of raw material and energy, pollution problems). Polymeric carbon materials—prepared by thermal degradation of synthetic polymers—exhibit a special ribbon-like microstructure. They will provide the chemist with many challenges.

1. Introduction

The thermal degradation of polymeric, organic natural substances, which is one of the oldest technologies of mankind, results in residues with high carbon content. They have a porous structure and low strength, because the cellular structure of the natural precursor material is preserved after carbonization. Moreover, the fibrilous structure of fibrous natural precursor materials is also found in the carbon residues. The mass loss due to elimination of volatile by-products during pyrolysis causes additional porosity and, above all, isotropic shrinkage. Only low carbon yields (<30%) are obtained if no special chemical pretreatment of the precursor is performed before the carbonization.

An essential condition for making carbon fibers from polymers is carbonization as a solid without softening or melting. This was realized in case of the carbon fiber in *Edison*'s incandescent light bulbs and also in case of the first high strength carbon fibers produced from rayon in the 1960's[1,2]. The revolutionary increase of strength and stiffness of the carbon fibers in the last ten years has not been accomplished merely by chemical means, *i.e.* by using fully synthetic polymer fibers, but by way of morphological changes in the initially formed porous carbon material. These morphological changes can be induced by hot stretching or hot working, at temperatures above 2600 °C (cf.[3]), as in the hot working of glasses or metals.

The hot working of carbon requires similar techniques to the hot formation of metals, the drawing of molten glass, or methods of shaping for thermoplastics, but at much higher temperatures. In the wake of this success of hot-stretched carbon fibers not only were prospects for the applications of carbon fibers discussed, but chemical research was also started on the pyrolysis mechanism of polymers[4]. It was expected that the properties important for the technical appli-

[**] Based on a lecture presented at the GDCh General Meeting at Berlin on September 12, 1979.

cation can be improved by using suitable synthetic polymers instead of rayon as precursor material.

The chemist may be surprised that a material with improved properties should result on decomposition and destruction of the polymeric structure. It is therefore appropriate to consider the outstanding properties of carbon. Pure carbon is resistant to attack by weather, water, fungicides, and bacteria. It is also resistant to almost all organic solvents and compounds, to salt solutions, alkalis, and acids. Furthermore, it is not inflammable and oxidizes only slowly in air above 500 °C. Combustion can be accomplished in very hot flames. Carbon resists deformation at temperatures up to more than 2000 °C, it shows an outstanding creeping strength, it is not susceptible to aging, is non-polluting, and above all it is absolutely biocompatible, *i.e.* suitable for implantation in human medicine.

However, of decisive importance for the usefulness of carbon as material are its mechanical properties, and above all its strength. It was therefore appropriate to check which structural prerequisites of the polymer must be fulfilled in order to achieve by pyrolysis a carbon residue with maximum possible strength combined with tolerable fracture behavior despite the absence of plastic deformability. Table 1 provides a survey.

after thermal degradation. This product became known as "glassy carbon" or "vitreous carbon". The difficult process of thermal degradation, and the impossibility of producing objects with a thickness of more than 5 mm, limit the applicability of glassy carbon.

During the last ten years we have also discovered how to modify thermoplastic polymers in respect to the shape-retaining thermal degradation after the shaping into thermosetting polymers by a "stabilization" treatment. It is possible to produce in a simplified process carbon fibers with an anisotropic tensile strength up to 4000 MN/m^2 (400 kg/mm^2) (type II) and a Young's modulus of about 400 GN/m^2 (40×10^3 kg/mm^2) (type I) from synthetic fibers, and above all from polacrylonitrile (PAN). The resulting fibers are suitable as reinforcing material for organic polymers. The prices of such high quality products are not only one tenth of those of other reinforcing fibers[6], but also of the first carbon fibers[7-9].

A promising recent development are the all-carbon composites, where carbon fibers are embedded in a carbon matrix. One example of an application is the surgical replacement of damaged joints. This underlines the fact that these special carbon materials have numerous, rather than just a few potential applications[10].

Table 1. Tensile strength of polymeric carbon, depending on starting material, stabilization, and annealing. PAN = polyacrylonitrile; MA = methyl acrylate.

Starting material	Stabilization treatment	Annealing	Carbon yield [%]	Tensile strength [MN/mm^2]	Ref.
Polyvinyl alcohol	Air oxidation 200 °C	up to 2500 °C	*ca.* 20	500	[48]

Control under non-clean room conditions		1000 °C		1950	
		1400 °C		1300	
		2500 °C		1500	

There exists one special type of carbon material which is formed by the pyrolysis of polymers and which is superior in its mechanical properties on account of its special ribbon-like structure (cf. Fig. 1a and 2). This form of carbon is therefore called "polymeric carbon". Glassy carbon, which is mentioned in the following, and the high strength carbon fibers number among the polymeric carbons.

Since about 1960 it has been known that some synthetic thermosetting polymers, *e.g.* polyfurfuryl alcohol[5], can result in extremely hard and impermeable carbon residues with an isotropic bending strength up to 150 MN/m^2 (15 kg/mm^2)

2. The Microstructure of "Polymeric Carbon"

Figure 1 shows the well-known modifications of carbon: On the upper left we see graphite, a modification stable under normal conditions; the high pressure modification diamond is seen on the bottom left. The pyrolysis residue suitable for technical applications shows none of these lattice orders. It has been known since the 1930's from X-ray diffraction measurements that coke and other carbon residues, formerly called amorphous carbon, actually exhibit a two-dimensional order similar to that in graphite layers. From the

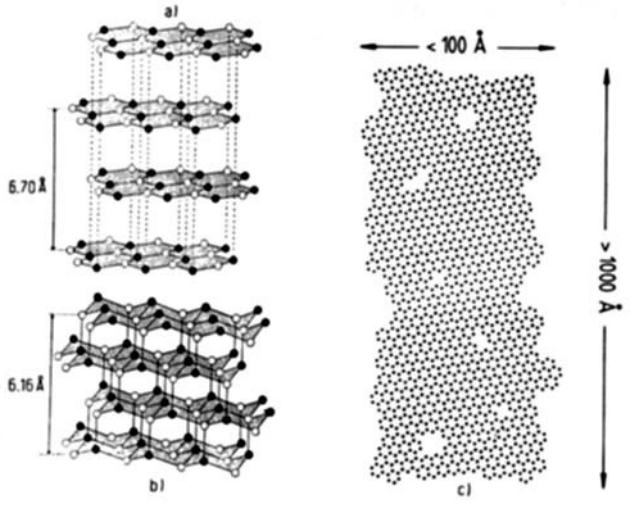

Fig. 1. Structures of elemental carbon: a) Graphite (C/C distance 1.41 Å, C/C bond energy 430 kJ/mol); b) diamond (C/C distance 1.54 Å, C/C bond energy 350 kJ/mol); c) polymeric carbon (especially glassy carbon, C/C distance about 1.42 Å).

broadening of the diffraction profile areas of only a few nm^2 could be concluded. *Braun*[11] showed in 1978 by careful structural analysis of glassy carbon produced from polyfurfuryl alcohol, that bigger average areas of coherent dispersion (apparent $\bar{L}_a$ data) up to 10 nm can be proved by extensive correction of the (10)-interferences with respect to distortion effects.

Today it is known from adsorption measurements (see *e.g.*[12]), and above all from high-resolution transmission electron microscopy (compare [13]), that glassy carbon shows a ribbon- or plate-like structure indicated on the right-hand side of Figure 1. Some of these ribbons can be stacked one upon the other to form plate-like structures which are distinct from a graphitic structure. Figure 2[14] shows the cross-linking between the layers, which corresponds almost to the coiling of chain polymers.

Fig. 2. a) Structural model, b) transmission electron micrograph of glassy carbon produced from polyfurfuryl alcohol as a typical example for isotropic polymeric carbon (see [14]).

No concept has yet been developed for an exact description of this special arrangement of the carbon atoms. Comparison with the structure of polymers seems to be the most suitable, except that polymeric carbon does not consist of chain- or ladder polymers but of planar macromolecules. These polyaromatic layers can be arranged differently and can be cross-linked. Therefore the term "polymeric carbon" is suggested for this carbon with plate- or ribbon-like structure, which is obtained after the pyrolysis of polymers. *Jenkins*[15] introduced the term "polymeric carbon" for the same products, but only in view of the nature of the precursor materials and not of the structure of the pyrolysis residue.

Attempts to establish the presence of tetrahedral structural units, expected for sp^3-hybridization, in polymeric carbon by X-ray methods have remained unsuccessful. *Braun*[16] observed an accumulation in the distribution of the radial interatomic distances at 1.42 Å for the products obtained at all stages of the thermal degradation of polyfurfuryl alcohol, but not at 1.54 Å. This result does not rule out the existence of a partial sp^3-hybridization, for example in interlamellar bonds, at the edges of the layers, or at defects.

The formation and the growth of ribbons of polymeric carbon during thermal degradation has been studied thoroughly for polyfurfuryl alcohol (Fig. 3).

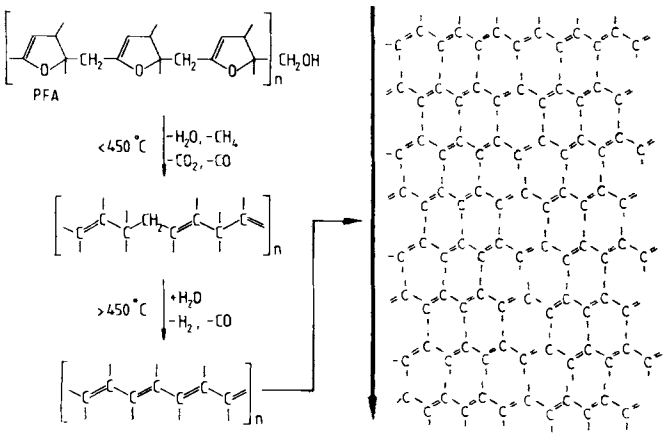

Fig. 3. Intermediate products formed during thermal degradation of polyfurfuryl alcohol (PFA) [17] and direction of growth (thick arrow) of the polymeric carbon ribbons formed by the fixed C/C chains [14].

The furan ring is cleaved at temperatures above 350 °C with concomitant loss of H_2O, CH_4, CO, and CO_2. The methylene linkages are dehydrogenated and fixed contiguous C/C chains with conjugated double bonds result. They are able to cross-link to give two-dimensional polymeric plates (Fig. 3 right) at temperatures above 500 °C[17].

X-ray studies[14] seem to show that the longitudinal growth of the ribbons is controlled by the longitudinal growth of the fixed chains. This shows that the structure of polymeric carbon can be influenced by the chemical composition and the structure of the primary polymer as well as by the process control during the thermal degradation.

The accessibility of the slot-shaped micropores between the layer packings was established by *Kalka*[12] in adsorption measurements with gases. The typical precursor materials for glassy carbon, such as phenolic resins and polyfurfuryl alcohol, give similar results regarding pore sizes, with a maximum at degradation temperatures of about 700 °C, as shown in Figure 4[18] for *p*-polyphenylenes. The pores are clearly seen to shrink with increasing degradation temperature. Contraction perpendicular to the ribbons of polymeric carbon thus can be delayed by a chemical modification of the polymer. For instance, Figure 4b demonstrates the effect of

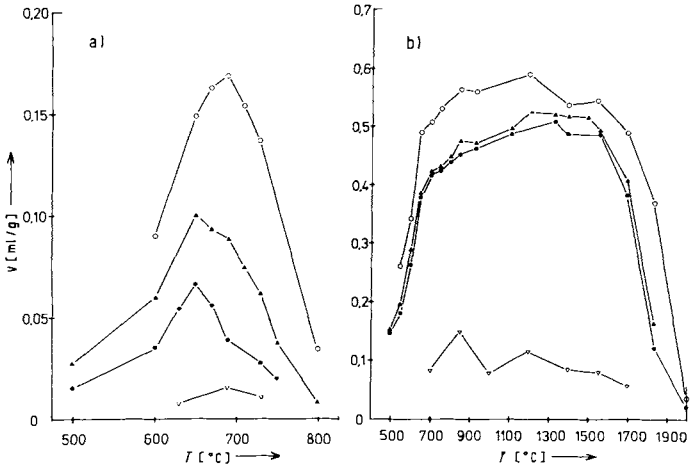

Fig. 4. Volume of micropores V of polymeric carbon produced from: a) p-polyphenylene and b) chlorinated p-polyphenylene as a function of the heat treatment temperature T, measured with: ○, nitrogen; ▲, isobutane; ●, neopentane; ▽, α-pinene. p_{rel} (partial pressure of gas used/total pressure) = 0.25.

chlorination of the polymer prior to pyrolysis. The thermal loss of hydrogen is assisted by dehydrohalogenation occurring in a temperature range insufficient for the growth of carbon ribbons with only few defects. Oxygen (introduced *via* the monomer or *via* the polymer by oxidation) acts similarly. The change in density with degradation temperature clearly reveals the influence of oxygen on the structure of carbon[19]. Stabilization of the slot-shaped pores is of importance for the application of polymeric carbons as catalyst supports or as molecular sieves.

Taking the structure of glassy carbon as a basis and considering that the mass loss of 40 to 50% during thermal degradation causes a linear shrinkage of up to 25%, it can be estimated what internal stresses are set up in this pyrolysis residue. This is the reason for the hardness of glassy carbon, not the tetrahedral structural units as was previously assumed. However, the numerous internal slots limit its ultimate strength: glassy carbon is extremely brittle; nevertheless its bending strength can equal that of the best ultrafine grained types of polygranular graphites (Fig. 5).

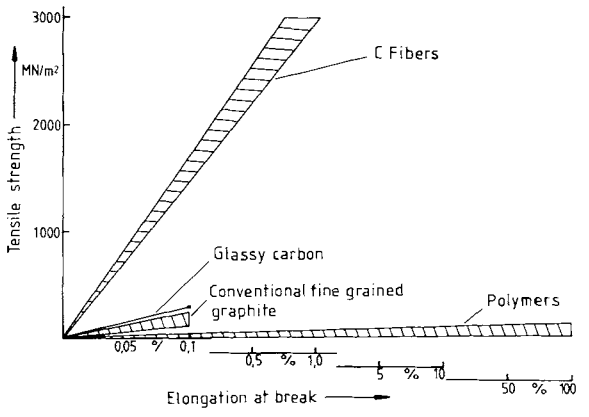

Fig. 5. Deformation behavior up to breaking of isotropic polymeric carbon (glassy carbon) and anisotropic polymeric carbon (carbon fibers), of the primary polymers, and of high quality fine grained graphite.

The stress and fracture properties are greatly improved if the polymeric carbon sheets can be given a preferred orientation. This has been achieved for the high tensile strength carbon fibers, to which a preferred orientation parallel to the fiber axis has been imparted (Fig. 5).

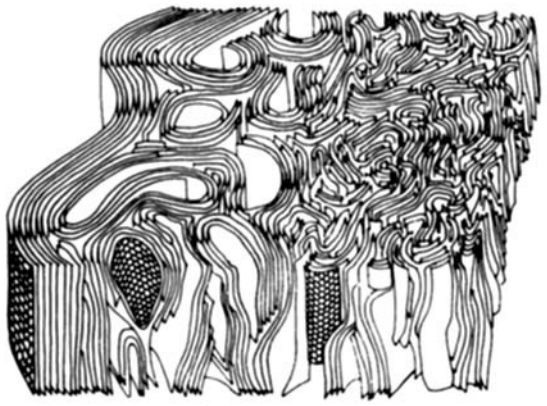

Fig. 6. Structural model of high strength carbon fibers from polyacrylonitrile, designed on the basis of transmission electron microscope studies [13].

Figure 6 shows a structural model of high tensile carbon fibers, designed by *Bennett* and *Johnson*[13] on the basis of transmission electron microscopy studies. Unlike the first high modulus fibers, which were produced by stretch graphitization, present-day efforts are focused—despite maximal orientation of the polymeric backbones parallel to the fiber axis—on maintaining cross-linking perpendicular to the fiber axis in order to ensure transversal, compressive, and torsional strength[9].

3. Pyrolysis of Thermosetting Polymers to Give Polymeric Carbon

The special structure of the carbon layers is achieved largely by chemical modification of the primary polymer. The first structural prerequisite for the formation of polymeric carbon is the non-meltability of the primary polymer; this means that no intermediate liquid phase may occur during thermal degradation. Moreover, it should be possible to impart the final shape desired for the polymeric carbon to the primary polymers.

Chemically, it is essential that the molecular structure should result in a high carbon yield; hence polymers containing aromatic or polyaromatic compounds are the best starting materials[20]. The liberation of volatile low-molecular carbon compounds should be prevented by appropriate chemical composition and cross-linking of the primary polymer. Only ligands should be released, and under ideal circumstances only hydrogen in case of polyannelated hydrocarbons.

Phenolic resins are suitable primary substances because they contain benzene rings joined by methylene groups and the degree of cross-linking can be controlled over a wide range by way of the formaldehyde content and the amount of catalyst. The coke residue is about 60 to 65%, corresponding to a carbon yield of about 85%[17].

Figure 7 shows the mass loss of two polymers during thermal degradation and the amount and the nature of the volatile by-products, from which the mechanism of degradation

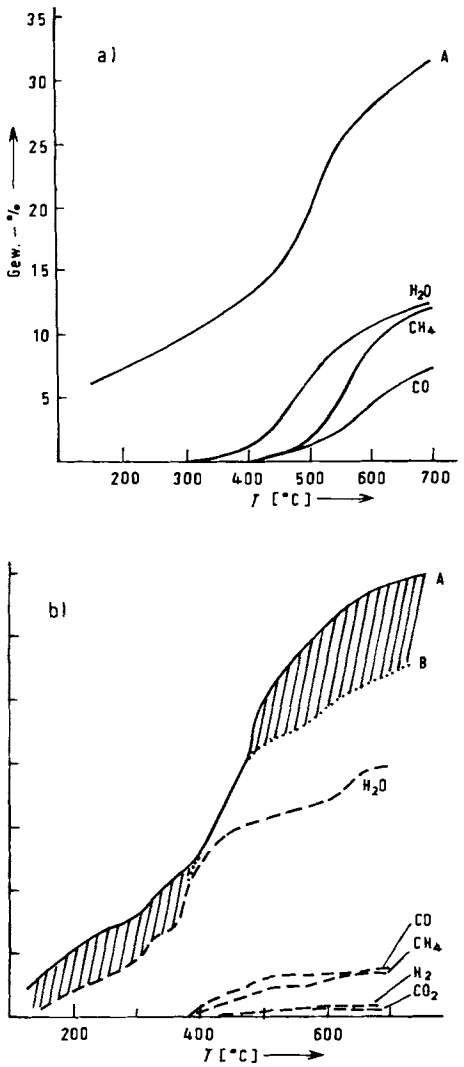

Fig. 7. Thermal degradation of phenolic resins: a) sufficiently cross-linked resin with a phenol : formaldehyde ratio of 2:3; b) insufficiently cross-linked commercial phenolic resin with greater proportion of formaldehyde. A, total mass loss; B, summary of the volatile products; hatched: low molecular substances.

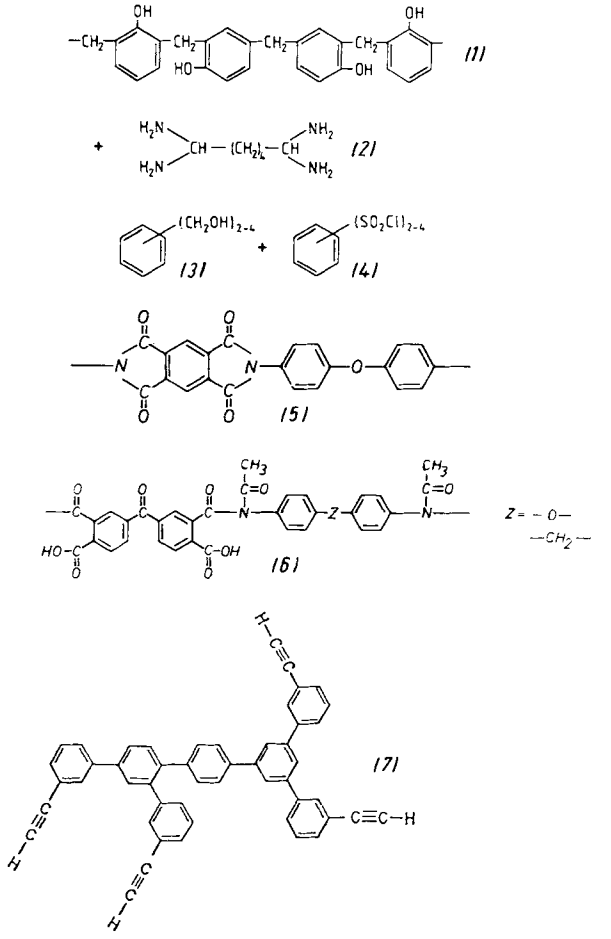

Fig. 8. Phenolic resins, polyimides, and polyphenylenes as thermosetting polymers suitable for the production of polymeric carbon [21, 22].

can be concluded. Figure 7a shows the behavior of a resin with a phenol : formaldehyde ratio of 2:3. The behavior of a resin with a higher proportion of formaldehyde is shown in Figure 7b. The additional mass loss resulting from insufficient cross-linking is seen. The transport of the volatile byproducts is strongly hindered by the microporous structure of the residue. That is why the speed of the condensation and cleavage reactions are of such great importance. With regard to the absence of cracks in the polymeric carbon product the novolacs with 1,1,6,6-hexanetetramine *(2)* as hardener and sulfonyl chlorides *(4)* as catalysts have proved of value (Fig. 8)[21].

Typical ladder polymers such as the polyimides are also very suitable precursors for polymeric carbon. They combine the advantage of high carbon residues resulting from their preformed aromatic rings and their relatively large monomeric units with a degree of prior three-dimensional order over relatively large molecular regions with respect to the formation of the ribbons of polymeric carbon. Therefore preformed ladder polymers show a smaller shrinkage than other polymers. Since the isotropy of shrinkage is also weakened, it becomes possible to produce *e.g.* impermeable polymeric carbon foils from the condensation product of pyromellitic anhydride and 4,4-oxydianiline (H-foil, Dupont) [*(5)* in Fig. 8][22].

p-Polyphenylene is a precursor polymer with ideal chemical and structural groups; it consists solely of benzene rings and is one of the few linear polymers with a complete orientation of the macromolecules. Figure 9 shows its degradation mechanism[23]. Carbon yields up to more than 90% are achieved. The defects in the polymeric carbon sheets, detected by IR-spectroscopic analysis of the C—H bond content, anneal completely at temperatures above 700 °C. Sterically hindering aromatic groups are eliminated simultaneously. The measurements provide an indication of the kind of orientation mechanism operating during the formation of the polymeric carbon ribbons. Additional information is gained from ESR measurements[24], which reveal a second temperature range between 1000 and 1400 °C, where sterically hindering C—C bonds are ruptured. The only disadvantage of *p*-polyphenylene is the difficulty encountered in its shaping by pressing and sintering. The chemist can adopt one of two approaches to avoid this problem: one starts from a thermosetting resin consisting of polyphenylene units with lateral chains of acetylene [see *(7)* in Fig. 8, HA 43 resin, a test product of Hercules Inc.]. This resin proved to be very good as a precursor for polymeric carbon, and particu-

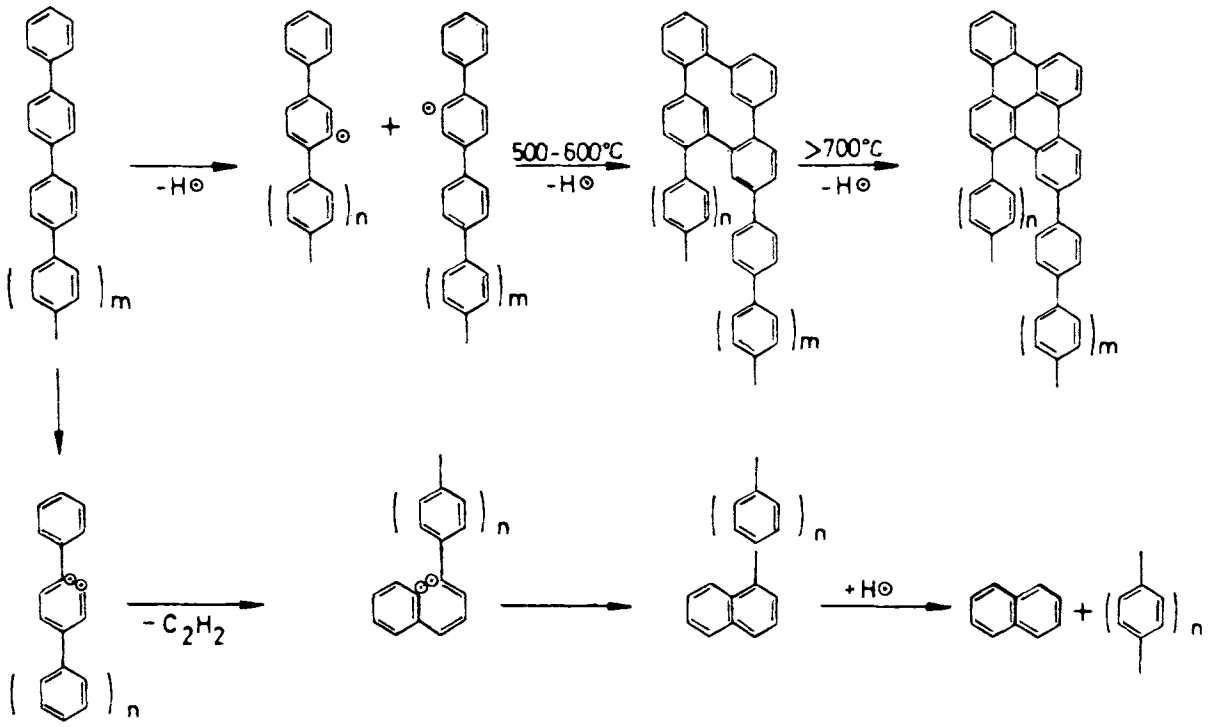

Fig. 9. Thermal degradation of *p*-polyphenylene [23].

larly as matrix precursor in C/C composites. However, production of the resin is difficult and it is not commercially available. The second possibility is to use isomeric polyphenylenes, which are accessible by anionic polymerization of biphenyl. These isomeric mixtures are meltable and can be considered as synthetic pitches. Figure 10 shows structural

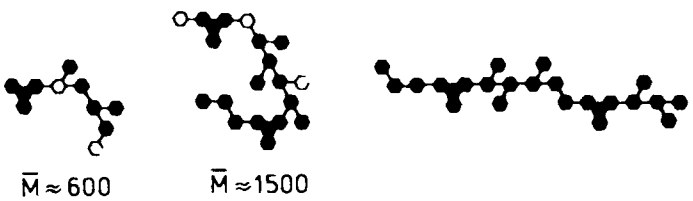

Fig. 10. Structural models of fractions from isomeric polyphenylenes [25]. From left to right: soluble in petroleum ether; soluble in quinoline; insoluble in quinoline. Solid rings, arenes; open rings and chains: aliphatics.

models of some fractions[25]. The solubility or meltability is mainly caused by the aliphatic structural parts. Meltable primary polymers require stabilization before pyrolysis (see Section 4) and have a lower carbon yield.

4. Stabilization of Thermoplastic Polymers for Production of Polymeric Carbon

Meltable primary polymers are unsuitable for the production of polymeric carbon for two reasons: the shape of the polymer is lost and pyrolysis leads to graphitizable residues rather than the metastable, but thermally and chemically stable polymeric carbon (cf. [26]).

Nevertheless, such meltable polymers can be transformed into suitable precursor polymers by a stabilization treatment, involving, *e.g.*, dehydrogenation, cross-linking, cyclization, and aromatization.

A well-studied example is stabilization of polyacenaphthylene *(9)* by hydrogenation and cross-linking with sulfur[27].

Acenaphthylene *(8)*, a component of coal tar pitch, polymerizes thermally at temperatures above 200 °C to polyacenaphthylene *(9)*. Thermal degradation (Fig. 11) *via* the dimer

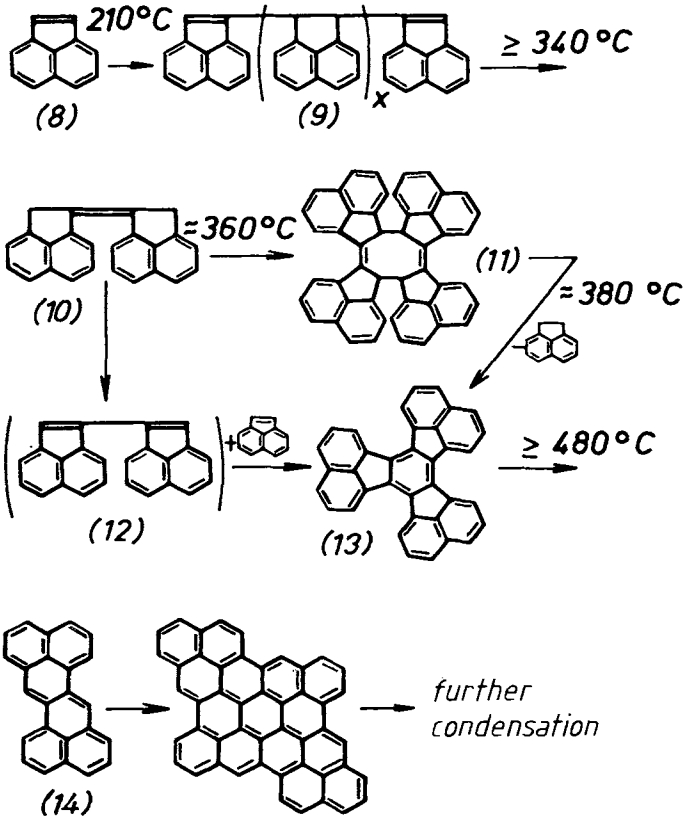

Fig. 11. Formation and degradation of polyacenaphthylene *(9) via* fluorocyclene *(11)*, decacyclene *(13)*, and zethrene *(14)* [27].

(10) leads to polyarenes such as the fluorocyclenes *(11)* and above all to the stable planar decacyclene *(13)*. Tar-like substances which act as a matrix for the formation of a mesophase are formed.

Addition of up to 10% of sulfur relative to the hydrogen content of the monomers leads to a dehydrogenation with formation of H_2S. This increases the carbon yield, but leaves the formation of the mesophase and hence the graphitizibility unaffected. Further addition of sulfur, however, leads to primary cross-linking by formation of polysulfide bonds, as seen from dehydrogenation and formation of H_2S at high temperatures. These residues do not melt, the carbon yield increases to 50%, and the product is a completely isotropic glass-like carbon.

The stabilization process used for the production of anisotropic polymeric carbon plays a key role in the manufacture of fibers from polyacrylonitrile (PAN). On the one hand, cyclization of the polymer with a continuous C/C chain to a ladder polymer takes place, and on the other hand a dehydrogenation to arenes is achieved. There are hundreds of literature references to the cyclization mechanism because of its connection with thermal yellowing of textile PAN fibers. "Black orlon" fiber, a preliminary stage in the production of carbon fibers from PAN, is subjected to mechanical stretching or at least mechanical maintenance of the textile stretching in addition to the oxidizing cyclization in order to keep the preferred orientation of the PAN macromolecules parallel with the fiber axis, also in the case of the ladder polymers which cannot be changed in their steric position thermally or mechanically.

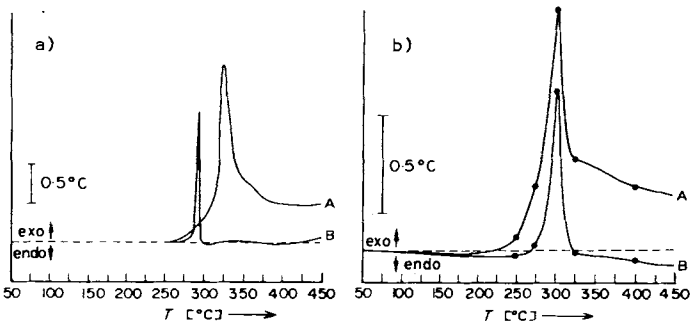

Fig. 12. Differential thermal analysis curves of commercial PAN fibers in air (A) and nitrogen (B) (heating rate 10 °C/min). a) Dry spun homopolymeric acrylonitrile (DRALON T); b) wet spun copolymeric acrylonitrile (DOLAN, 6% methyl acrylate).

First of all we studied the mechanism of the cyclization in an oxidizing atmosphere and the interpretation of the shrinkage during the stabilization treatment. A comparison of the results of differential thermal analysis (DTA) for homopolymeric acrylonitrile in Figure 12a shows an oxidation to precede the exothermic cyclization reaction and another one to follow. Moreover, the cyclization is slowed down by oxygen. This delay is eliminated in copolymeric acrylonitrile, but the sequence of reactions is the same as above[28].

A careful analytical study of the volatile products eliminated during cyclization[29] permits calculation of the stoichiometry and thus provides information about the overall reaction. Figure 13 shows that in the case of homopolymeric acrylonitrile dehydrogenations of the contiguous C/C chains

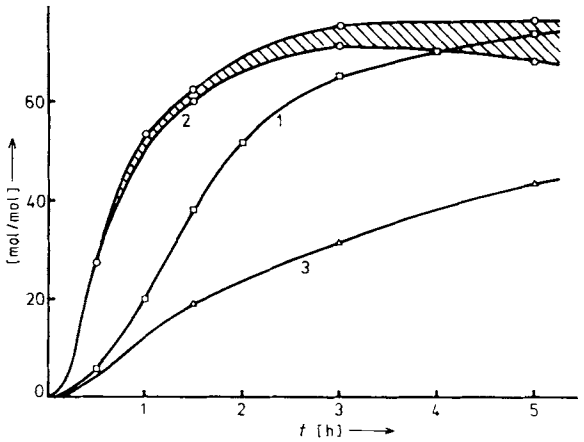

Fig. 13. Course of stabilization of homopolymeric acrylonitrile depending upon the oxidation temperature (t). 1, Cyclization (formation of heterocyclic compounds from nitrile groups); 2, dehydrogenation, based on the monomer units; 3, oxygen taken up by the ladder polymer per monomer unit [29].

(curve 1) precede the cyclization reaction (curve 2). Subsequent oxidation (curve 3) is undesirable, for it lowers the carbon yield and increases the number of defects.

A hypothetical mechanism describing shrinkage during stabilization could be derived from these analytic studies. Furthermore, the chemical effects of mechanical treatment undertaken to prevent cyclization shrinkage can be explained by these studies.

Contrary to the view often expressed in the literature that the stabilization shrinkage is merely an entropy effect, the analytical results mentioned above indicate that chemical effects must also play a part in shrinkage. Dehydrogenation of the carbon chain leads to conjugated double bonds and thus to planar molecular structures. If the tacticity of the chain changes, a kink appears on formation of the bonding angle of 120°; however, if the fiber is stretched during this dehydrogenation reaction, the chain rotates around the single bond at the location of the change in tacticity and no shortening occurs. The previously atactically oriented nitrile groups adopt the same orientation (as a consequence of the formation of the bonding angle of 120°). A molecular struc-

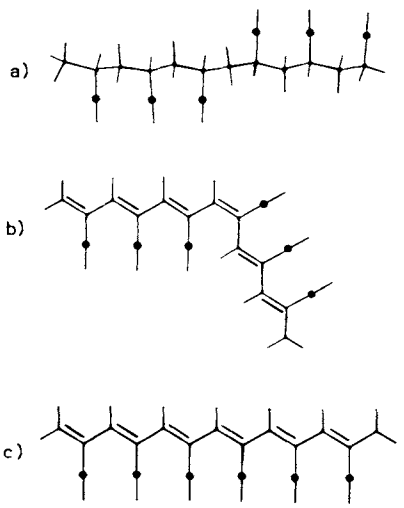

Fig. 14. Structural model a) of atactic polyacrylonitrile; b) of the bending of the molecule chain after the formation of a planar structure with conjugated double bonds; c) of the turning of the atactic lateral groups into a continuous *cis* configuration during stretching [30].

ture with continuous *cis*-configuration thus results, as shown in Figure 14. The subsequent cyclization which can take place only with isotactic sequences is facilitated by the stretching[30].

There has been no lack of attempts to accelerate the cyclization; the diffusion of oxygen through the ladder polymer layer determines the rate of oxidation. An increase in temperature above 250 °C is ruled out by the danger of overheating the fiber during the exothermal reaction and hence thermal decomposition prior to completion of stabilization. Lewis acids in combination with nitrobenzene as oxidizing agent proved to be the best catalysts; a mixture of nitrobenzene and *p*-nitrophenol accelerates stabilization similarly to Lewis acids. The fibers must be swollen in dimethylformamide (DMF) in order to effectively introduce the stabilization catalysts into the fiber. This swelling effect appears to promote the preferred orientation in the polymer in a similar way to mechanical methods, *e.g.* stretching[31]. The copolymer and dyeing additives always present in PAN fibers may also have a catalyzing influence (cf.[32]).

The general trend in the production of high quality carbon fibers seems to be directed less to the development of special polymers particularly suitable for a technically facile stabilization process than to the adaptation of the technical stabilization conditions to cheap polymer fibers on the market as mass produced textile articles.

A knowledge of the stabilization and degradation mechanism also permits continuous production of hollow fibers of polymeric carbon on a laboratory scale (Fig. 15)[33]. Technical and medical applications are expected for these fibers.

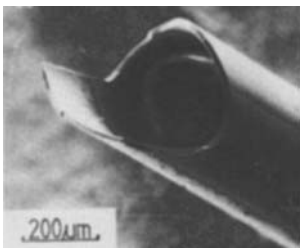

Fig. 15. Hollow fiber of polymeric carbon, produced continuously on a laboratory scale from wet spun hollow PAN fibers containing 6% of methyl acrylate [33].

5. Biocompatibility of Polymeric Carbon

The biocompatibility of smooth carbon surfaces with blood, muscle, and bone tissue has been known for many years. Isotropic polymeric carbon competes as solid material with pyrocarbon as coating material for prosthetic applications in human medicine. Pyrocarbon is deposited on substrates by chemical vapor deposition (CVD).

Figure 16[34] summarizes routine and experimental applications of polymeric carbon in human medicine. Particular mention should be made of the well-established use of glassy carbon in aorta valves.

Anisotropic polymeric carbon is unbeatable as a replacement of tendons and ligaments. The first experiments were carried out at Cardiff[35]. In animal experiments, *e.g.*, knee ligaments were removed and replaced by tows of carbon fibers (Fig. 17a)[36]. Three months later a new, functioning ligament tissue had been formed around the implanted carbon fibers (Fig. 17b). The new ligament including the implant has a greater strength than the original ligament. The elasticity can be increased by stranding the carbon fibers to form tapes. A histological section (Fig. 17c) shows that the new tissue around the carbon fibers contains only few giant cells; this means only slight scarring. The carbon fibers are not chemically decomposed. It appears that residues from mechanically degraded fibers are deposited in the lymphatic nodes.

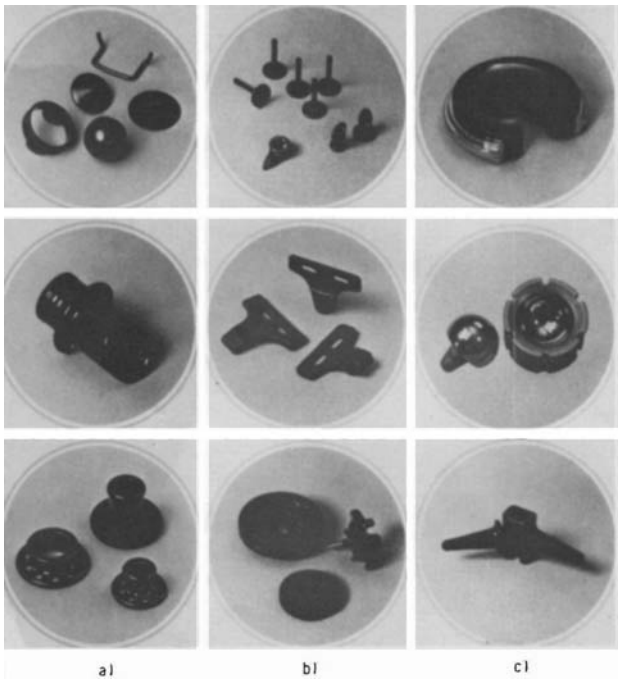

Fig. 16. Present applications of carbon in human medicine. a) Parts made of pyrocarbon/glassy carbon (from top to bottom): Heart valve components, left ventricular apex outlet, percutaneous leads. b) Parts made of pyrocarbon/glassy carbon (from top to bottom): otological prostheses, dental implants, blood pump components. c) Parts made of pyrocarbon (from top to bottom): replacement parts for knee, hip, and finger joints [34].

A recent publication in the Indian press states that such ligament replacing operations have been carried out successfully on about 50 racehorses[37].

Fibers of polymeric carbon can be woven like textile fibers, also with glass fibers to form a hybrid fabric or with organic high modulus fibers. Such fabrics are used mainly in industry, but experiments are being carried out to test their medical potential. Animal experiments performed at Ulm have concentrated on the replacement of abdominal walls by carbon fiber fabrics. A new abdominal wall was found to grow into the implant or around the fabric[38].

6. Chemical Adhesion of Carbon Fibers in a Polymer Matrix

The main and surely revolutionary application of polymeric carbon is its use as reinforcing fiber in composites. The preferred orientation of the carbon ribbons in the marginal zones of the fiber parallel with the surface is the reason

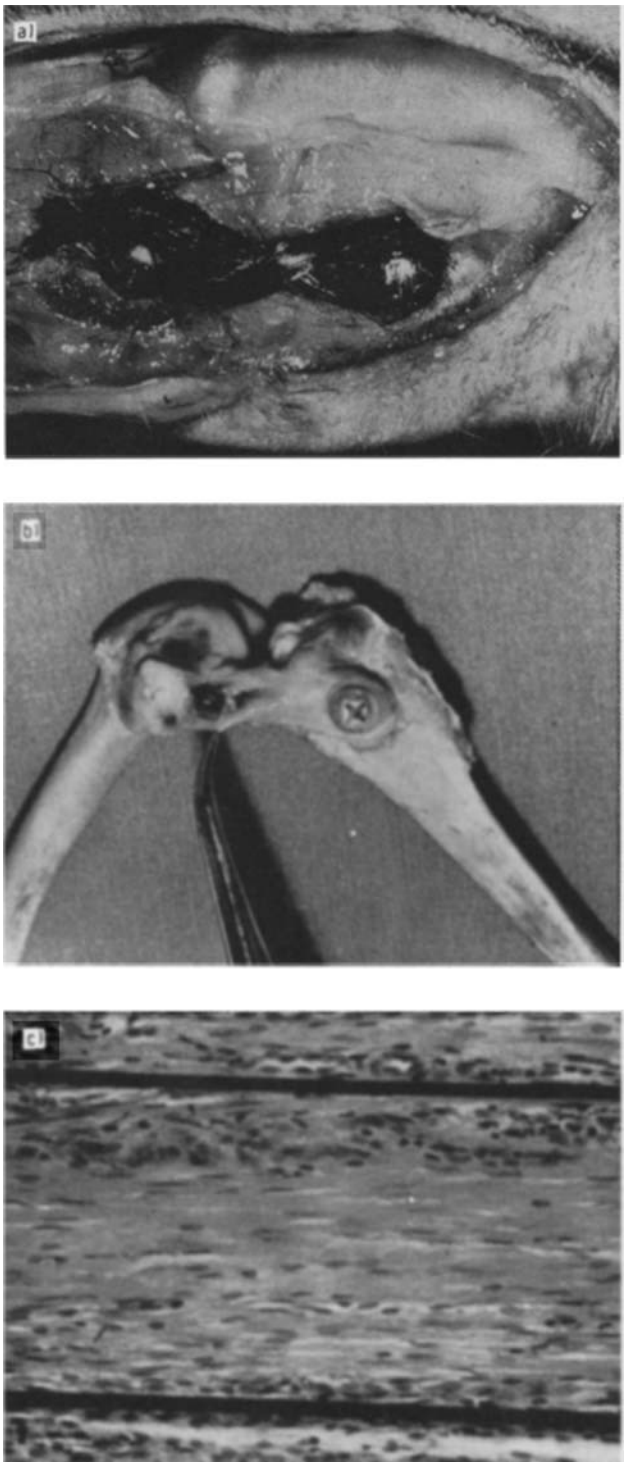

Fig. 17. a) Replacement of a knee ligament by carbon fibers in an animal experiment. b) Reformation of ligament around the implant three months later. c) Histological section through the tissue of the grown ligaments [36].

for the strength of the fiber, and also for chemical inertness of the surface and poor adhesion to the matrix. This precludes the desired transfer of stress between the two components of the composite, resulting in poor shear strength which in turn can cause failures by delamination.

Empirical work aimed at achieving mechanical linking by coating of the fibers with whiskers or by roughening of the fiber surfaces was unsuccessful. Only an oxidizing after-treatment of the fiber surface improves the adhesion behavior.

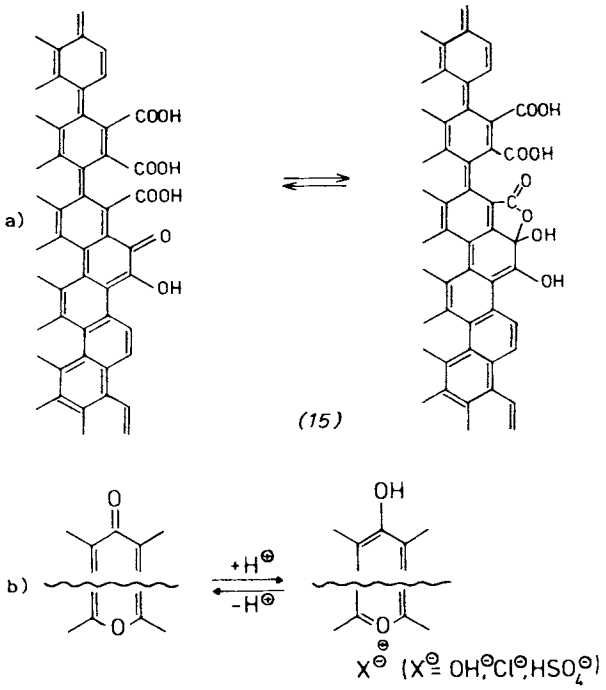

Fig. 18. Presumed structure of a) acidic and b) basic surface groups on carbon (activated carbon fibers) [39, 39a].

The surface groups on the fibers formed by anodic or by wet oxidation react with the matrix components; they can be of an acidic or a basic nature (Fig. 18)[39]. Wet oxidation in boiling nitric acid led to a controlled increase of acid groups; the reinforcing effect in composites with a phenolic resin matrix, measured by the utilization of the fiber strength in the composite, is directly proportional to the concentration of the acid surface groups. Ether groups and ester groups are formed between the phenolic resin matrix and the surface groups[40]. The adhesion aspects are perhaps even more important if epoxy resins are used as matrix. It was shown in an extensive study[41] that prolonged wet oxidation not only improves the adhesion after curing but the reactivity of the carbon fibers can already be measured by wetting experiments. The prepolymer without hardener shows poor wetting, while a diamine hardener wets very well. Therefore the hardener initiates wetting in a mixture of prepolymer and hardener, and acts as an adhesion promotor between the fibers and the prepolymer (Fig. 19).

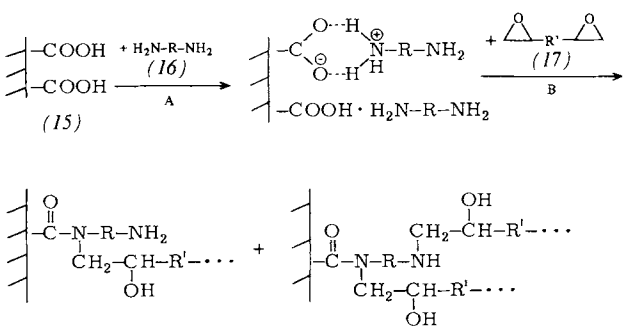

Fig. 19. Reaction steps for the adhesion of hardener *(16)* and prepolymer *(17)* to the surfaces of carbon fibers activated by wet oxidation with nitric acid [compare *(15)* in Fig. 18] [41]. Step A, linkage between fiber and hardener; step B: linkage between hardener and prepolymer at the fiber surface.

7. Applications of Carbon Fiber Reinforced Polymers and of All-Carbon Composites

Now that the adhesion problem between fibers and the polymer has been solved, reinforcement of conventional curable polymers by polymeric carbon fibers can be expected to become the commonest application, *e.g.* the reinforcement of epoxy, polyester, or phenolic resins, and ultimately perhaps the reinforcement of thermoplastic polymers too. The volume fraction and the geometrical arrangement of the carbon fibers will then determine the properties of the composite materials. As a rule, a two-dimensional reinforcement with up to 60 vol % of endless carbon fibers is used.

Expectedly, these materials are widely used in the aerospace industry. Today there is no supersonic aircraft containing less than 15% of such structural materials, and their utilization in other aircraft is already being tested[42].

The American automotive industry is presently considering the possibility of incorporating 50 to 100 kg carbon materials per car[43]. A large-scale technical application of polymeric carbon depends on the costs; the original costs of up to 1000 DM per kg carbon fibers were prohibitive. Today the prices are about 100 DM/kg. A further reduction of 50% seems likely in the near future. This will be of the same order of magnitude as the cost of high quality reinforcing glass fibers; the carbon fibers are superior, however, because of their much higher Young's modulus and their far lower density.

Finally, an application of polymeric carbon without organic polymers may be mentioned, *viz.* all-carbon composites. Such materials contain at least 50 vol% of carbon fibers in a matrix of pure carbon. The matrix may also consist of polymeric carbon formed by thermal degradation of, *e.g.*, a polyphenylene or a phenolic resin or a polyimide. We have also succeeded in producing a carbon matrix oriented parallel to the fiber starting from cheap meltable arene mixtures. They contribute to the mechanical properties of the composite in a similar way as the fibers (Fig. 20)[45].

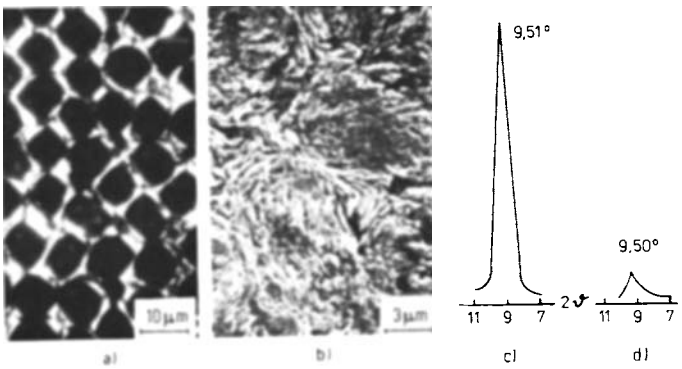

Fig. 20. Orientation of the carbon matrix in all-carbon composites: a) Cross-section, photographed with polarized light; b) cross-section scanning electron micrograph; c) X-ray diffraction, parallel and d) perpendicular to the fiber direction [45].

Carbon fiber reinforced composites are interesting also in medicine as bone plates. The healing of bone fractures can be facilitated by a direct fixing of the broken bone parts using bone plates. However, the metal plates usually employed can induce degeneration of the bone. The detrimental alteration or catabolism of the bone is caused by the difference in the Young's modulus of the bone and the plate, by which a stress gradient across the bone is built up. The disadvantages of metal plates can be avoided by use of carbon fiber reinforced composites. Figure 21 shows bone plates of carbon fiber reinforced epoxy resin, whose surfaces have been sputtered with carbon, and plates of all-carbon composites[44].

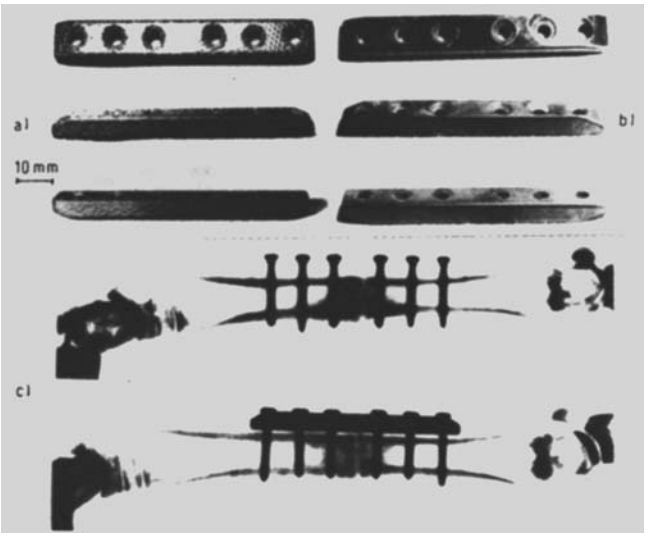

Fig. 21. a) Bone plates made of all-carbon composites; b) bone plates of carbon fiber reinforced epoxy resin with a carbon surface produced by sputtering; c) X-ray photograph of animal bones broken and fixed with bone plates after a healing time of eight weeks [44].

The plates have been tested in preliminary animal experiments and an improvement in the healing process over that with steel plates was found. This success justifies further work on this application.

All-carbon composites have also found technical application in the two-dimensional reinforcement of aircraft brakes, and in the three-dimensional reinforcement of ablation shields, mainly in rocketry. The greatest reinforcing effect in the fiber direction is naturally reached for unidirectionally reinforced composites [material strengths more than 1000 MN/m^2, high temperature strengths up to more than 2000 °C (Fig. 22)]; but three-dimensionally reinforced, *i.e.*,

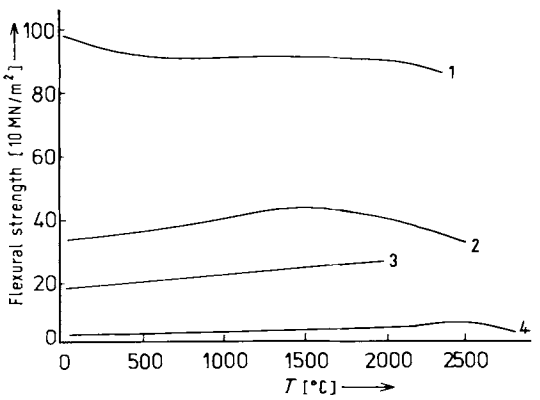

Fig. 22. Short-time flexural strengths at temperatures up to 2500 °C of: 1) uni-directionally and 2) three-dimensionally reinforced all-carbon composites compared with 3) pyrolitic graphite and 4) fine grained graphite ATJ [46].

practically isotropic, all-carbon composites achieve strengths of about 350 MN/m^2 in all directions up to more than 2000 °C. The strength of these composites exceeds not only that of conventional fine grained graphite and of glassy carbon but also that of light metals, ceramics, and glasses. A three-dimensionally reinforced all-carbon composite does not exhibit a real brittle fracture behavior at room temperature, but behaves like a pseudoplastic material. Stress maxima on initial loading are absorbed by microcracks within the macrostructure[46].

The new materials are not only suitable for modern high temperature applications in the aerospace industry. In the Federal Republic of Germany some research programs have been sponsored in order to develop hip joint replacements of all-carbon material. They are superior to the conventional steel replacements (which corrode and work loose) on account of their excellent biocompatibility, the possibility of cement-free implantation, and above all the controllability of the mechanical properties. It is possible with composites to effectively imitate the stress behavior of bone (Fig. 23)[44,46,47]. However, routine application to human medicine is still a long way off. The present medical experiments have been carried out mainly with dogs.

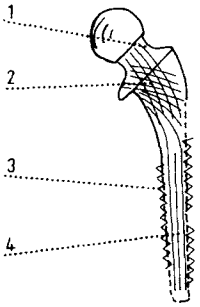

Fig. 23. Suggested approaches to imitation of the femur structure with all-carbon composites; 1-D, 2-D, 3-D stand for uni-, two-, and three-dimensional reinforcement [46].

The possibility of optimum tailoring of the polymeric carbon, depending on the application conditions, will ensure a promising future for these materials.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Amorphous Silver Silicates, Storage Elements with Low Switching Field Strength[**]

By *Martin Jansen* and *Hans Herbert Käs*[*]

Like many other silver-rich oxides, the silver silicates $Ag_6Si_2O_7(I)$[1a], $Ag_6Si_2O_7(II)$[1b], and $Ag_{10}Si_4O_{19}$[1c] studied thus far also have characteristic silver substructures[2]. In spite of the valence shell of Ag^{1+} generally being regarded as closed, apparently there are attractive interactions between such particles which lead, in part, to shorter Ag···Ag distances than in metallic silver; as a rule, the silver arrays correspond to sections from the face-centered cubic structure of elemental silver. To check whether these particular structural features are associated also with particular physical properties, we have investigated the electrical behavior of—in the first instance amorphous (glassy)—silver(I) silicates.

After an electrical forming process, silver(I) silicate glasses exhibit a bistable switching behavior and are thus suitable for digital information storage. Besides having the well-known advantages of amorphous storage systems, silver silicate storage elements are distinguished by having a very low external switching field strength of the order of 10 V/mm. This property makes them of particular interest regarding their practical applications.

The switching behavior is produced by a forming process. The sample is subjected to a burst of alternating current ($f = 50$ Hz), whose amplitude is determined by the forming resistance R_F and whose duration t_F is controlled with an electronic time switch[3]. To illustrate the switching behavior a typical current-voltage curve is reproduced in Figure 1. After the forming process the material has a high resistance. On increasing the voltage, one initially observes ohmic and subsequently voltage-dependent resistance (VDR) behavior until, at Point A on the characteristic curve, a jump occurs into the low-resistance ("ON") part of the curve (Point B). If the voltage is now reduced, the material remains low-resistant. Reversible re-switching to Point D of the high-resistance ("OFF") state follows as soon as Point C in the low-resistance part of the curve is reached.

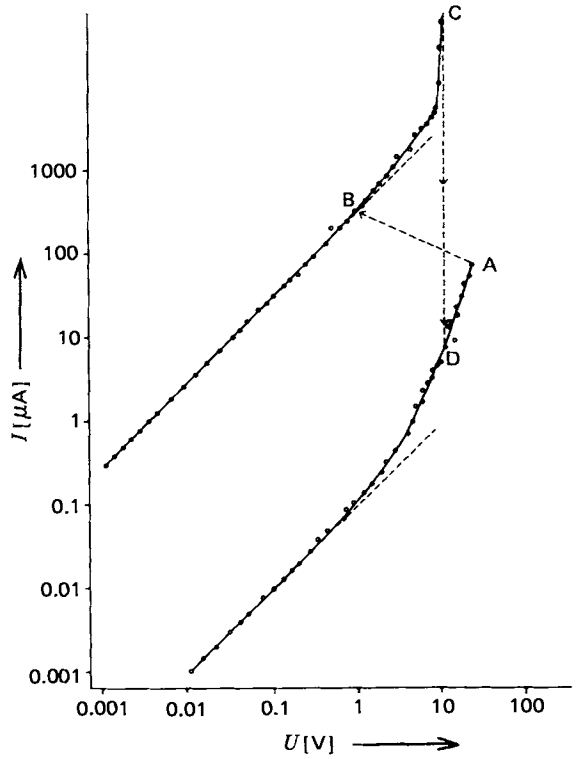

Fig. 1. Current-voltage curve of a formed silver silicate storage element (sample thickness 0.4 mm, Ag/Si = 4, $R_F = 1$ MΩ, $t_F = 0.5$ s).

To investigate the switching behavior the samples were switched with single square-wave pulses of duration t_R and amplitude U_s at a protective resistance R_s and the current and voltage logged on a storage oscilloscope. The switching characteristics depend on the composition of the glasses (Ag/Si ratio), the forming conditions (R_F, t_F) and the switching parameters (t_s, U_s, R_s). Samples with an Ag/Si ratio of 4 formed with $R_F = 1$ MΩ and $t_F = 0.5$ s proved to have the best switching characteristics.

The mechanism of the switching processes is still unclear in detail. Presumably "silver clusters" are of importance, as have been detected in crystalline silver(I) silicates by X-ray diffraction methods[1a,2], and which very likely are also present in the glasses investigated. Such silver-rich zones along with silver-deficient regions were also discussed in explaining the comparable switching behavior of silver metaphosphate glasses[4]. Since the storage state set at any given time remains the same without holding current, structural changes must take place during the switching process. Therefore a comparison of the structures of the material in the two switching states (ON/OFF) would appear to prove especially informative; a relevant series of investigations are presently under way.

Experimental

For preparation of the glasses very finely ground (agate ball mill) mixtures of Ag_2O (Merck) and SiO_2 (L-quartz, Rie-

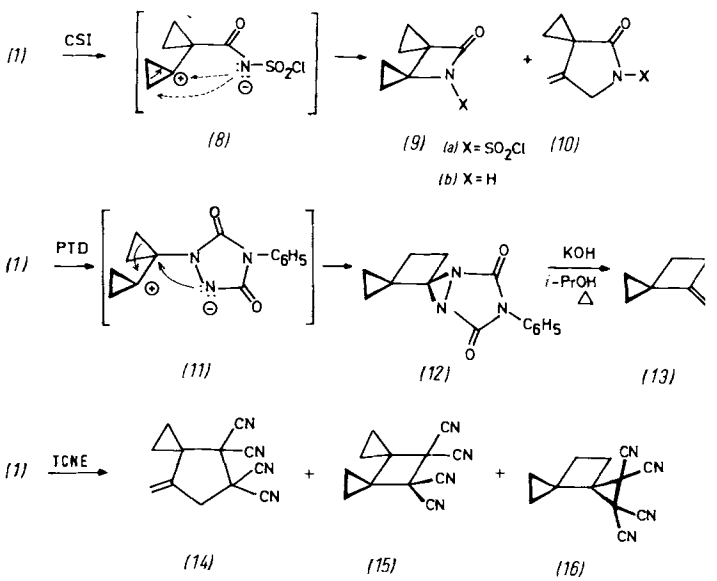
Three Variants of the [2+2]-Cycloaddition of Bicyclopropylidene[**]



By *Walter Weber, Ihsan Erden,* and *Armin de Meijere*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

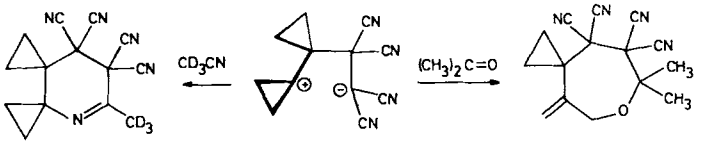
Bicyclopropylidene *(1)*, whose [2+2]- and [2+4]-cycloadditions to conjugated dienes were reported in an earlier communication[1], has recently been shown to be relatively easily accessible[2] and can be used as a synthon for the preparation of compounds which contain the bicyclopropyl group as part of a dispiro system. We have now found that *(1)* does not react with electron-rich olefins, yet undergoes very smooth cycloadditions with a series of electron-deficient double-bond systems.

Thus, reaction of *(1)* with trichloroethylene affords the trichlorodispiro compound *(2)* (see Table 1), while reaction with acrylonitrile furnishes the cyano derivative *(3)* in more than 90% yield after 2 h at 180 °C. Presumably, the addition

Chlorosulfonyl isocyanate (CSI)[5], however, which is well-known for its [2+2]-cycloadditions to olefins, gives only small amounts (15%) of the β-lactam *(9a)* on reaction with

(1) CSI → *(8)* → *(9)* (a) X=SO_2Cl, (b) X=H + *(10)*

(1) PTD → *(11)* → *(12)* KOH, *i*-PrOH, Δ → *(13)*



(1) TCNE → *(14)* + *(15)* + *(16)*

[*] Prof. Dr. A. de Meijere, Dipl.-Chem. W. Weber, Dr. I. Erden

[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Hoechst AG.

(1) at −78 to +20 °C; the main product (85%) is the γ-lactam *(10a)* (see Table 1). This finding is best explained in terms of an intermediary 1,4-zwitterion *(8)*, which cyclizes predominantly with a concomitant cyclopropyl-to-allyl opening of its cationic end group. 4-Phenyl-1,2,4-triazoline-3,5-dione[6] (PTD) also reacts rapidly with *(1)* at 0 °C, surprisingly enough, however, in a mode completely different from that of CSI: the diaziridine derivative *(12)* was the sole product isolated (83%). In this case, the cyclization of the intermediate *(11)* apparently takes place only after or concomitantly with a cyclopropylmethyl—cyclobutyl ring enlargement. Alkaline hydrolysis of *(12)* does not give the expected diaziridine, but cleaves off the whole urazole moiety and forms the spiro[2.3]hexan-4-one *(13)*[7].

(1) reacts with tetracyanoethylene (TCNE) in benzene only in the absence of oxygen; nevertheless, with this reagent all three types of cycloaddition were realized, as demonstrated by the products *(14)* (56%), *(15)* (22%) and *(16)* (22%) isolated. The 1,4-zwitterion *(18)* apparently formed in this reaction can be trapped with CD_3CN to give *(17)*[8], which

(17) *(18)* *(19)*

contains a dispiro system with a six-membered ring and an unrearranged bicyclopropyl group; with acetone, on the other hand, the trapping product *(19)* containing a seven-membered ring was formed. *Noyori et al.*[9], however, maintain that formation of a 1,4-zwitterionic intermediate in the cycloaddition of TCNE to a methylenecyclopropane is unlikely, taking into account the very small solvent effect on the reaction rate.

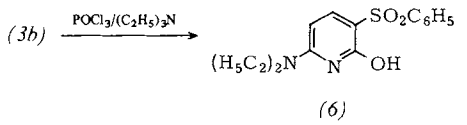
Aminopyridines

By *Werner Jünemann, Hans-Joachim Opgenorth*, and *Horst Scheuermann*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday



A versatile method for the synthesis of substituted pyridines consists in the condensation of 1,3-dicarbonyl compounds with acetic acid amides whose methylene group is additionally activated by an electron-withdrawing substituent[1]. The pyridines prepared in this way contain, besides this substituent in the 3-position, also one or more hydroxy groups in the 2-, 4- and/or 6-position, usually together with further substituents in the 4- or 5-position. We report here on the preparation of 4,5-unsubstituted pyridinediols *(3)* from propiolic ester *(1)*, and on the synthesis of the novel 3-phenylsulfonylpyridinediols *(3b)* and -triols *(8)* and their transformation into the corresponding chloro- and aminopyridines.

(1) *(2)* *(3)* *(5)* *(4)*

(a), R^1 = CN; *(b)*, R^1 = $SO_2C_6H_5$

On reaction of ethyl propiolate *(1)* with cyano- *(2a)* or phenylsulfonylacetamide *(2b)* in methanolic sodium methoxide solution at 60 °C one obtains 3-substituted 2,6-pyridinediols *(3)*. The hydroxy groups can be replaced by chlorine by reaction with $POCl_3$ at 140 °C in the presence of tertiary amines. Triethylamine proved to be a particularly suitable base in the case of *(3a)*→*(4a)* (Method A), while *(3b)* could be converted only with *s*-collidine into the dichloro compound *(4b)* (Method B). Reaction of *(3b)* with $POCl_3$/triethylamine gives the aminopyridinol *(6)*.

(6)

Replacement of the chlorine atoms in *(4)* to give the diaminopyridine *(5)* was achieved in the presence of excess amine above 100 °C. At lower temperatures one obtains only a mixture of isomeric monoamino compounds, whose isolation was not attempted.

Reaction of diethyl malonate *(7)* with phenylsulfonylacetamide *(2b)* analogously affords the triamino compound *(10)* *via* the pyridinetriol *(8)* and the trichloro derivative *(9)* (Method B). The pyridines so prepared are listed in Tables 1 and 2.

[a] TMS internal, δ values. [b] In KBr, $\tilde{\nu}$ in cm^{-1}.

Procedure

(3): A suspension of *(2)* (1 mol) in CH_3OH (190 ml) is treated, firstly with a solution of $NaOCH_3$ (54 g, 1 mol) in CH_3OH (160 ml) and then dropwise with 84 g (1 mol) of *(1)*. After heating under reflux for 1 h [in the case of *(3b)*] or 3 h [in the case of *(3a)*], the mixture is cooled, filtered, and the residue dissolved in warm water. The precipitate of *(3)* obtained on acidification with HCl is filtered off, washed with water, and dried.

(4a), Method A: A mixture of *(3a)* (136 g, 1 mol) with $POCl_3$ (160 ml) is treated dropwise below 95 °C with 227 ml of triethylamine. After 10 hour's stirring at 140 °C the mixture is poured into ice-water; the precipitate is filtered off and dried. The crude product (150 g; Cl: 38.8%) is purified by extraction with cyclohexane in a Soxhlet apparatus; yield 132 g (76%), m.p. 124—126 °C (119—121 °C[2]).

(4b), Method B: A suspension of *(3b)* (251 g, 1 mol) in $POCl_3$ (400 ml) is treated dropwise with 50 ml of *s*-collidine and the mixture stirred for 2 h at 120 °C and then for 5 h at 150 °C. After cooling, the mixture is poured into ice-water; the precipitate is washed with water, dried in air, and recrystallized from isobutyl alcohol; yield 147 g (51%), m.p. 149—151 °C.

(5b): (4b) (28.8 g, 0.1 mol) is transferred portionwise to 72.6 g (0.6 mol) of β-phenylethylamine at 110–120 °C. After 4.5 hours' stirring at 145 °C the mixture is treated with 42 ml of dimethylformamide with subsequent cooling. The resulting solution is added dropwise to a mixture of 33 ml conc. HCl and 830 ml H_2O, and the crystals which precipitate are filtered off under suction and washed with H_2O, dried, and recrystallized from isobutyl alcohol; yield 37 g (81%), m.p. 118 °C.

(8): A mixture of a 30% solution of $NaOCH_3$ in CH_3OH (180 g, 1 mol), *(7)* (80 g, 0.5 mol), ethanol (800 ml) and *(2b)* (99.5 g, 0.5 mol) is heated in an autoclave at 110—120 °C for 10 h. The crystals are filtered off, dissolved in hot water, precipitated with conc. HCl, filtered off, washed with water, and dried; yield 95 g (36%), m.p. 256 °C (dec.).

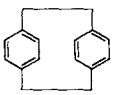
Cyclophanes as Diene Components in Diels-Alder Reactions[1]

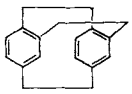
By *Aboul Fetouh Murad, Jürgen Kleinschroth,* and *Henning Hopf*[*]

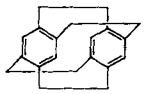
Dedicated to Professor Virgil Boekelheide on the occasion of his 60th birthday

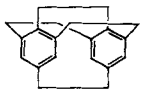
Non-annelated arenes normally do not undergo cycloaddition reactions; for example, they do not participate as diene components in Diels-Alder reactions. To overcome this lack of reactivity, which reflects the "aromatic character"[2] of these hydrocarbons, the overall reaction must be activated. This may be accomplished, from the side of the dienophile by using a particularly reactive reagent at elevated temperatures and/or Lewis acid catalysis[3], as well as from the diene side by the incorporation of bridging structural elements in the arenes[3,4].

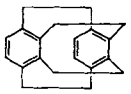
In the present communication, the first comparative study on the chemical behavior of [2_n]cyclophanes, it is shown that the tendency of benzenoid arenes to cycloadd can be enhanced to such an extent by bridging that it begins to equal











[*] Prof. Dr. H. Hopf, Dipl.-Chem. J. Kleinschroth, A. F. Murad, M. Sc., Institut für Organische Chemie der Universität Am Hubland, D-8700 Würzburg (Germany)

Present address: Institut für Organische Chemie der Technischen Universität, Schleinitzstrasse, D-3300 Braunschweig (Germany)

that of polyolefins: formally such molecules behave like cyclohexatriene derivatives.

In order to determine their diene activity the phanes *(1)*—*(5)* were allowed to react in benzene (internal standard) with dienophiles *(6)*—*(11)* which differ considerably in their reactivity (Table 1).

Table 1. Diels-Alder additions [5] with multiply bridged cyclophanes in benzene. NR: no reaction.

Dienophile \ Diene	 *(1)*	 *(2)*	 *(3)*	 *(4)*	 *(5)*
4-Phenyl-1,2,4-triazolin-3,5-dione *(6)*	20 °C, 138 h, 99% (1:2 adduct)	20 °C, 3 h, 79% (1:1 adduct); 20 °C, 24 h, 65% (1:2 adduct)	20 °C, 3 min, 100%	20 °C, 24 h, NR	20 °C, 24 h, NR
Tetracyanoethylene *(7)*	100 °C, 15 h, π-complex; 165 °C (in toluene), 13 h, NR	20 °C, 20 h, 59% (1:1 adduct) + 26% π-complex		20 °C, 20 h, π-complex	100 °C, 15 h, π-complex
Maleic anhydride *(8)*	180 °C (in toluene), 37 h, NR	100 °C, 10 h, 53% (1:1 adduct)		100 °C, 16 h, NR	100 °C, 17 h, NR
Dicyanoacetylene *(9)*	120 °C, 32% (1:1-) + 39% (1:2 adduct); 170 °C, 72% (1:2 adduct) [6]	20 °C, 14 d, 78% (1:1 adduct); 81 °C, 24 h, 30% (1:2 adduct)			
Dimethyl acetylenedicarboxylate *(10)*	NR at elevated temp. [7]	170 °C, 1 h, 61% (1:1 adduct) [7]			170 °C, 1 h, NR
Dimethyl maleate *(11)*	165 °C, 13 h, NR	100 °C, 10 h, NR			

As can be seen from the reaction of phanes *(1)*, *(2)* and *(3)* with dienophile *(6)*, the additivity is directly proportional to the degree of bridging, providing the phane contains at least one pair of *para*-hydrogen atoms. That the isomers *(4)* and *(5)*, which presumably hardly differ from *(3)* in their strain energy, do not cycloadd under comparable conditions is understandable if one remembers that the dienophile must attack the phanes from the "outside" and the substituents on the carbon atoms of the benzene rings are reoriented inwardly during the change from sp^2 to sp^3 hybridization. As long as the substituents are hydrogen atoms—as in *(1)* to *(3)*—there is ample room in the center of the molecule. In the case of *(4)* or *(5)* (and probably also in the case of still more highly bridged phanes), however, the bulky methylene groups of the bridges would not only have to be moved inwardly but also be strongly compressed towards each other. Evidently both molecules cannot fulfil these requirements.

With dienophiles less reactive than 4-*N*-phenyl-1,2,4-triazoline-3,5-dione *(6)* hydrocarbons *(1)*—*(5)* (Table 1) behave similarly; the cyclophane *(2)* forms the 1:1 adduct[7] even with dimethyl acetylenedicarboxylate *(10)* (which is *ca.* 10^6 times less reactive than *(6)*[8]). The limiting reactivity is reached with dimethyl maleate *(11)* (which is *ca.* 70 times less reactive than *(10)*[9]). With tetracyanoethylene *(7)*, only *(2)* could be converted into a (thermolabile) adduct, in all other cases π-complexes are formed, which decompose to the educts on heating.

That the high diene reactivity of *(1)*—*(3)* is not due to the activating effect of the alkyl substituents is shown by control experiments with the respective "halves" of these molecules: neither *p*-xylene, 1,2,4-trimethylbenzene nor durene nor any other polymethylated benzene reacts with *(6)* within 52 d at room temperature.

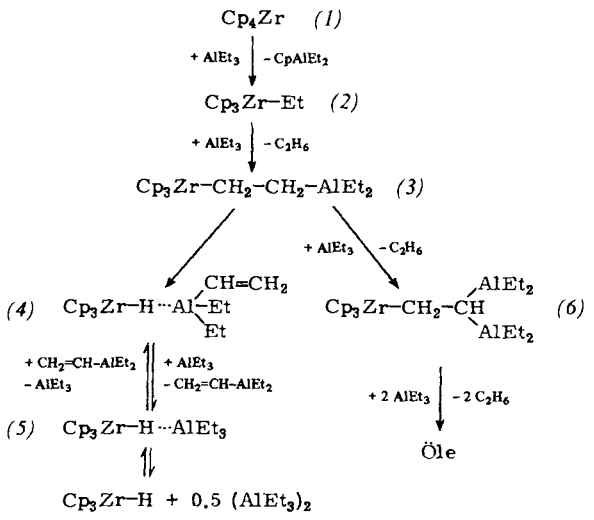
"Living Polymers" on Polymerization with Extremely Productive Ziegler Catalysts



By *Hansjörg Sinn, Walter Kaminsky, Hans-Jürgen Vollmer,* and *Rüdiger Woldt*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The term "living polymers" was first applied by *Bier*[1] to the polymerization of α-olefins with Ziegler catalysts: He found that the polymerization can be interrupted for several hours after removal or consumption of monomer without diminishing the activity of the catalyst on renewed addition of monomer.

Such persistent activity is only possible if inactivation of the catalyst by side reactions involving hydrogen transfer is suppressed. The side reactions are therefore of special interest in connection with Ziegler catalysis[2]. On attempting to synthesize (see Experimental) the compound *(3)*, presumably formed as intermediate in the ethylene polymerization, we obtained a crystalline substance, which according to an X-ray structure analysis[3] was the zirconium hydride complex *(5)* (Fig. 1). The complex *(5)* can also be prepared directly from tris(cyclopentadienyl)zirconium and triethylaluminum.

Both halogen-free bis(cyclopentadienyl)zirconium compounds as well as the tris(cyclopentadienyl)zirconium compound *(5)* are, together with organoaluminum compounds, extremely long-lived catalysts for the polymerization of ethylene[4]. Longer-chain α-olefins can inhibit the ethylene polymerization—as distinguished from analogous titanium systems, which, *e.g.*, enable smooth ethylene-propene copolymerizations[5].

The polymerization activity is particularly enhanced by addition of water. We have therefore synthesized from trialkylaluminum and water the alkyl aluminoxanes, presumably formed in various degrees of oligomerization, and used them as organoaluminum components. The productivity increases with the cryoscopically determined degrees of oligomerization of 10 to 16 (checked in the titanium system with methyl aluminoxane *(7)*[6], see Table 1).

$$n\,Al(CH_3)_3 + n\,H_2O \rightarrow \text{-}[Al(CH_3)\text{—}O]_n\text{-} + 2n\,CH_4$$
(7)

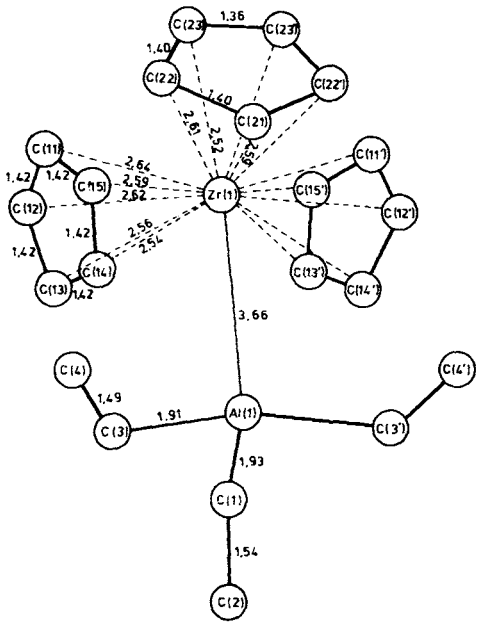

Fig. 1. Crystal structure of the zirconium-aluminum complex *(5)*. Distances in Å.

Table 1. Polymerization of ethylene with 1.34×10^4 mol/l bis(cyclopentadienyl)-dimethyltitanium(IV) and methylaluminoxane *(7)* of various degrees of condensation in 300 ml toluene at 20 °C.

Polyethylene yield [g]	$\bar{M}_n$	*(7)*, *n*	*t* [h]
2	—	2	20
51	360000	5	2
62.1	120000	>10	2

With the system bis(cyclopentadienyl)dimethylzirconium and methyl aluminoxane *(7)*, productivities (g polyethylene per g Zr) of over 10^8 were found. At concentrations of *(7)* between 1.5×10^{-2} and 3×10^{-3} mol Al/l and $Cp_2Zr(CH_3)_2$ concentrations $< 10^{-6}$ mol/l the reaction is sufficiently slow that diffusion no longer plays a decisive role and the reaction rate depends linearly on the zirconium concentration. In this concentration range productivities (g polyethylene per g Zr and 2 h) of around 10^7 were found (Table 2). The changeover time (interval between two insertion steps) is consequently smaller than 0.3 ms and thus comparable to the changover time of the fastest enzymes[7].

The molecular weights, which can be relatively easily varied by choice of temperature, are 10^6 to 10^3 at 0—100 °C[4]. Even under the assumption that each zirconium atom is part of an active center it follows that at least 10000 polymer molecules are formed at productivities of 10^8.

Table 2. Polymerization of ethylene with bis(cyclopentadienyl)dimethylzirconium and methylaluminooxane *(7)* ($n \approx 12$) in 330 ml toluene; ethylene pressure 8 bar, 1 l autoclave.

[a] Extrapolated value. [b] $n \approx 14$. [c] Blank. [d] Corrected with blank.

If ethylene is again added to a system interrupted by withdrawal of monomer and in which the catalyst, though homogeneous in itself has been made heterogeneous by precipitated polyethylene, the polymerization resumes at a rate proportionate with the zirconium concentration and the polyethylene granules begin to swell.

Remarkably, a relatively large excess of organoaluminum component *(7)* is necessary. Preliminary kinetic investigations show that the reaction rate depends linearly on the zirconium concentration and quadratically on the aluminoxane concentration. This is consistent with our concept that a molecule of the organozirconium compound diffuses into an associate of aluminoxanes and forms the catalytically active center. No decomposition reactions take place. Hydrogen transfer leads to formation of zirconium hydrides [cf. *(5)*], from which the alkyl compounds and thus the reactive centers are formed by addition of olefin.

Experimental

(5): A stirred suspension of *(1)* (35 g, 0.1 mol) in *n*-heptane (300 ml) is treated at 40 °C with 70 ml (0.51 mol) triethylaluminum. After *ca.* 15 min the solution is homogeneous, and subsequently white [*(5)*] and dark-red [*(6)*] crystals precipitate with concomitant evolution of ethane. After 3 d the mixture is warmed to 60 °C and filtered. The residue (white crystals) is completely dissolved in toluene at 80 °C, cooled to 0 °C, and recrystallized twice; 40% yield of analytically pure *(5)*.

Polymerization: Toluene (330 ml) is transferred to a 1 l glass autoclave fitted with a thermostat and previously baked out and purged with argon. After warming to 70 °C, oligomeric methylaluminoxane (300 mg, 5.1 mmol Al) is added, the mixture stirred for 3 minutes and then treated with $(C_5H_5)_2Zr(CH_3)_2$ (3.33×10^{-8} mol) in toluene; after a further 3 minutes ethylene is introduced at a pressure of 8 bar. Approximately 120 s later white polyethylene precipitates out. After 1 h the catalyst is destroyed, by addition of methanol, since the polyethylene can no longer be stirred. The polyethylene is filtered off, washed several times with methanol and dried; yield 19.0 g, average molecular weight (viscometric) 166000.

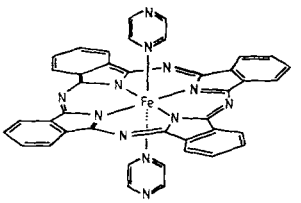
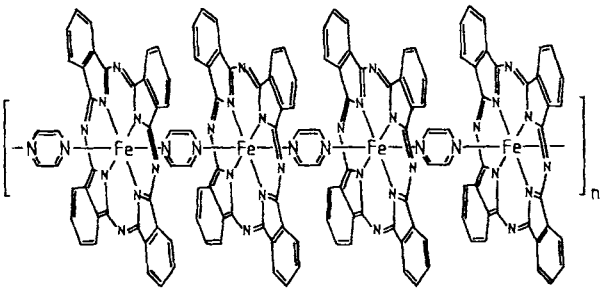
Phthalocyaninatoiron with Pyrazine as a Bidentate Bridging Ligand[**]



By *Otto Schneider* and *Michael Hanack*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday



We recently described a new type of one-dimensional conductor consisting of square-planar metal complexes which are linked bisaxially *via* linear bidentate ligands with one or two crossed longitudinal π-systems to form linear polymeric chains[1a]. The square-planar metal complexes may be metal-phthalocyanines (PcM)[1a,c], metal-hemiporphyrazines (HpM)[1c], or metal-tetraphenylporphines (TPPM)[1d]. Linkage with $:C{\equiv}C:^{2\ominus}$ as a bidentate bridging ligand affords polymeric $[PcM(C{\equiv}C)]_n$ or $[HpM(C{\equiv}C)]_n$ which are predicted by EHMO calculations to have pronounced electrical conductivity[1b].

Monomeric octahedral metal-phthalocyanines with bisaxial alkyne substituents $PcM(C{\equiv}CR)_2$ (R = H, CH_3, C_6H_5, *t*Bu; M = Si, Ge, Sn), $HpGe(C{\equiv}CR)_2$ (R = H, C_6H_5, *t*Bu), and $TPPGe(C{\equiv}CR)_2$ (R = C_6H_5, *t*Bu) have recently been described[1c-e], as have some of the polymers $[PcM(C{\equiv}C)]_n$[1f].

We now report the preparation of phthalocyaninatobis(pyrazine)iron(II) *(1)* and the first successful attempts to synthesize a polymeric metal-phthalocyanine having pyrazine as bridging ligand.

(1)

(2)

Monomeric octahedral $PcFeL_2$ compounds with L = pyridine[2], imidazole and piperidine (pip)[3a], and benzyl[4] and tolyl isocyanide[3b] have been synthesized and the structure is known in the case of bis(4-methylpyridine)phthalocyaninatoiron(II)[5]. The $PcFeL_2$ compounds[3] could be obtained by reaction of solid PcFe[6] in the β-modification (β-PcFe) with the dissolved ligand.

The analogous reaction of β-PcFe with an excess of pyrazine (pyz) (molar ratio 1:5) in boiling chlorobenzene leads

not to the monomer *(1)* but immediately to polymeric blue phthalocyaninato(μ-pyrazine)iron(II) *(2)*. Compound *(2)* is also formed when chlorobenzene is co-distilled with pyrazine on pure β-PcFe.

It proved more difficult to synthesize the violet compound $PcFe(pyz)_2$ *(1)*. However, this can be accomplished by reacting β-PcFe with molten pyrazine for 24 h and then rapidly removing the excess of pyrazine with methanol. Platelet-shaped single crystals of *(1)*, which appear violet by reflected light, can also be obtained by ligand exchange from $PcFe(pip)_2$[3a] dissolved in $CHCl_3$ with a large excess of pyrazine after addition of light petroleum (b.p. 60—90 °C) over a period of one week.

Attempted purification of *(1)* by extraction with chlorobenzene also gave *(2)* with loss of pyrazine. After extraction with $CDCl_3$ the pyrazine liberated from *(1)* can be detected by a sharp singlet at 8.6 ppm in the ^{1}H-NMR spectrum.

The compounds *(1)* and *(2)* are stable to air and moisture; they have been identified by elemental and thermogravimetric analysis. Thermogravimetric studies show *(1)* to be less stable than *(2)*: both pyrazine ligands of *(1)* are eliminated in a single step between 150 and 240 °C. Compound *(2)* undergoes the loss of mass expected for elimination of one pyrazine moiety between 240 and 290 °C[7]. The residue in each case is β-PcFe.

The mass spectra of *(1)* and *(2)* show only $PcFe^{\oplus}$ as the ion of highest mass. The IR and FIR of samples of *(2)* obtained by different routes are identical and contain far fewer bands than the spectra of *(1)* (Table 1).

Table 1. Physical data of phthalocyaninatobis(pyrazine)iron(II) *(1)* and phthalocyaninato(μ-pyrazine)iron(II) *(2)*.

[a] In a 1 M solution of pyrazine in 1-chloronaphthalene. [b] In 1-chloronaphthalene, log ε calculated for $[PcFe(pyz)]_1$. [c] Apparent extinction, 1% of *(1)* or *(2)* in $BaSO_4$ rel. to $BaSO_4$ as std. white. [d] Polyethylene disk. [e] and [f] Fe N_{Pc} stretching and N_{Pc} Fe N_{Pc} deformation mode after [5]. [g] Polycrystalline material, measured at 3 kbar pressure. [h] Prepared in chlorobenzene. [i] Prepared in $CHCl_3$.

The UV/VIS spectrum of *(1)* in a 1 M solution of pyrazine in 1-chloronaphthalene expectedly resembles that of phthalocyaninatobis(pyridine)iron(II) in the wavelength of the absorption maxima and in the extinction coefficients[8]. In contrast, the electronic spectrum of *(2)* in 1-chloronaphthalene, 1,2,4-trichlorobenzene, and benzene exhibits new intense bands at 714, 723, and 788 nm (Table 1), while the intense band of monomeric octahedral phthalocyaninatoiron(II) derivatives around 650 nm is no longer observed.

Reflection spectra of *(2)* recorded with a 1% finely ground mixture in $BaSO_4$ relative to $BaSO_4$ as a standard white show an apparent extinction in the long wave region at 770 nm which is observed neither for *(1)* nor for β-PcFe. The formation of the polymer *(2)* from *(1)* can be followed qualitatively in the electronic excitation spectrum in benzene as solvent. At room temperature the UV spectrum of *(2)* is still observed even in the presence of a 10^6-fold excess of pyrazine; partial regeneration of *(1)* is observed at higher temperature.

We conclude from the results of elemental analysis and the molar ration of PcFe:pyrazine (1:1) determined by thermogravimetry that *(2)* is oligomeric or polymeric; the degree of polymerization is still unknown.

The conductivities of *(2)* measured with polycrystalline samples at 3 kbar are up to 10^6 times higher than for *(1)* (Table 1). This is also indicative of pronounced electron delocalization over the pyrazine bridges[9] in *(2)*. Preliminary doping experiments with iodine in *(2)* indicate a significant increase in conductivity.

General procedure:

(1): Pyrazine (30 mmol) is fused under N_2. After addition of β-PcFe (1 mmol) with stirring the reaction mixture is kept at 80—100 °C for 24 h. The cooled melt is crushed, digested with methanol, and filtered immediately; the violet residue is washed repeatedly with methanol and dried at 80 °C (yield 90%).

(2), Route A: Compound *(1)* (1.4 mmol) is extracted in a Soxhlet apparatus under N_2 for 3 h with anhydrous chlorobenzene (50 ml). The extraction solution is initially blue-green but becomes colorless after a few minutes. The blue residue in the extraction vessel is washed with light petroleum (b.p. 60—90 °C), filtered, and dried at 80 °C (yield 84%).—*Route B:* β-PcFe (2 mmol) is slurried in anhydrous chlorobenzene (180 ml) and boiled under reflux with pyrazine (10 mmol) for 24 h. The blue residue is treated as in route A (yield 86%).

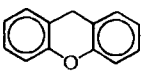
Department of Chemistry, Shiraz University
Shiraz (Iran)



[**] Work at Syracuse was supported by the National Science Foundation, that at Shiraz by the Iranian Ministry of Higher Education.

sent a properly structured model compound for *(1)* it was reasonably concluded that the oxocarbanion derived from *(1)*, *i.e.* *(2)*, may be regarded as a 10π-arene.

Recent findings in our own laboratories[2], however, appeared to cast some doubt on the inference of an aromatically stabilized ion *(2)* insofar as *(3)*, the substance previously employed as an acidity standard[1], was shown to produce a decidedly paratropic anion and, hence, one which might reasonably be regarded as being antiaromatically delocalized[2].

(1) *(2)*

Ph–CH_2–Ph ⟶ Ph–$\overset{\ominus}{C}$H–Ph

(3) *(4)* *(5)*

In view of this controversial situation we decided to check whether *(2)*, the anion of *(1)*, is aromatically delocalized or not. To this end, *(1)* was allowed to react with potassium amide in liquid NH_3 at *ca.* $-30\,^{\circ}C$ in an NMR tube to give *(2)*[3] [(^{1}H-NMR, 60 MHz, NH_3, $\approx 34\,^{\circ}C$): $\delta = 6$—7 (8H, m), 5.6 (1H, t, H-11, $J = 11$ Hz), 4.0 (2H, d, H-10, H-12, $J = 11$ Hz); (^{13}C-NMR, 20 MHz, NH_3, $\approx 30\,^{\circ}C$, TMS): $\delta = 87.92$ (C-10, C-12), 115.62 (C-11), 124.3, 126.15, 128.10, 133.87, 145.50, 157.2]. The ^{1}H-NMR data of *(2)* are consistent with the presence of an unusual π-system—and not with a diatropic 10π- or 18π-system. Especially remarkable in this connection is the *upfield* shift of the signals of all benzenoid protons on transformation of *(1)* into *(2)* (Fig. 1); the signals of

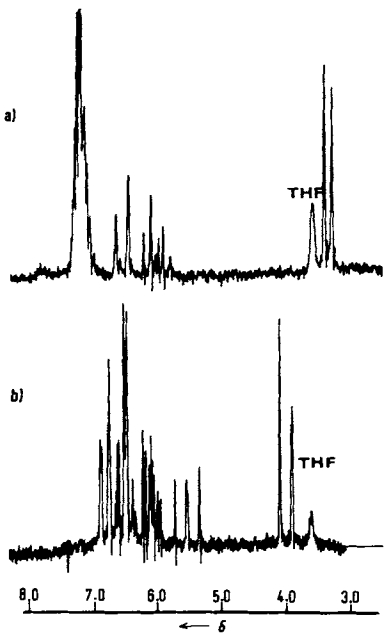


Fig. 1. 60 MHz ^{1}H-NMR spectrum of a) 10*H*-dibenz[*b*,*g*]oxocin *(1)* and b) the dibenz[*b*,*g*]oxocinide ion *(2)* at *ca.* 34 °C in liquid ammonia containing some tetrahydrofuran (< 1%, internal standard) as solvent.

the latter come into the same region as that occupied by the corresponding "benzenoid" resonances in the spectrum of a properly structured acyclic model without the central ring, *e.g.* of the diphenylmethanide ion *(5)* ($\delta = 5.6$—6.8)[2]. Further, the downfield shift of H-10, H-12 (*ca.* 0.6 ppm) on transformation of *(1)* into *(2)* may rationally be attributed simply to rehybridization insofar as a similar shift (*ca.* 0.4 ppm) is also observed for the benzylic proton of the anion *(5)* generated from diphenylmethane *(4)*[2]. This viewpoint is also supported by the close similarity of the ^{13}C-NMR signals of the "benzylic" C-atoms in the anions *(2)* ($\delta = 87.92$) and *(5)* ($\delta = 81.33$).

From the NMR findings it thus follows that the oxocarbanion *(2)* must largely be regarded as a conventional system, *i.e.* one in which the negative charge is primarily localized in the allylic moiety of the eight-membered ring. In conclusion, it is interesting to briefly note that while *(2)* somehow fails to realize its "$(4n+2)\pi$" potential ($n = 2$ or 4) for "aromatic" delocalization, the oxocarbanion derived from xanthene[2] readily realizes its "$4n\pi$" potential ($n = 2$ or 4) by yielding to what may best be described as "antiaromatic" delocalization. This interesting paradox undoubtedly arises from the controlling influence of skeletal (σ-frame) factors which are such as to impose a flat or nearly flat frame to the heterocycle in the xanthenide ion, and a heavily buckled one to that of *(2)*[4].

[3] The ^{1}H-NMR spectrum of *(2)* (Fig. 1b) shows no qualitative or quantitative deterioration upon prolonged (11 h) exposure to ambient temperature. Subsequent water quench of *(2)* produced *(1)* quantitatively.

[4] Besides being supported by simple inspection of a "Dreiding" molecular model the notion of a heavily buckled eight-membered unit in *(2)* receives added confirmation from the magnitudes of key C–H coupling constants $J_{(C\text{-}10)\ H} = 154$ Hz and $J_{(C\text{-}11)\ H} = 156$ Hz, which are inconsistently high for a planar eight-membered ring [5].

4-Sulfobenzyl, a New Carboxy Protecting Group[**]

By *Arnulf Hubbuch, Roland Bindewald, Josef Föhles, Vinod Kumar Naithani*, and *Helmut Zahn*[*]

A cardinal problem in peptide synthesis is the sparing solubility of larger, protected peptide fragments[1]. A solubilizing, polar protecting group[2–5] provides a way out from this preparative bottle-neck. We report here on the combination of the solubilizing sulfo-function[2,5,6] with the benzyl group, a type of protecting group very frequently employed in peptide synthesis[7].

For incorporation of the 4-sulfobenzyl group in amino acids the reagent chosen was sodium 4-(bromomethyl)benzenesulfonate ("4-sulfobenzyl bromide") *(4)*, which should permit preparation of the corresponding ester- and ether-functions. Starting from benzylamine *(1)*, compound *(4)* is

BR	7.59 (d)	7.38 (d)	4.69 (s)	—
OR' [b]	7.61 (d)	7.35 (d)	5.1—5.2 (s)	—

[a] As zwitterion. [b] R = *e.g.* Ala-, Leu-.

The preparation of *N*-protected amino acid 4-sulfobenzyl esters was accomplished by alkylation of cesium-[7] or dicyclohexylammonium salts of *N*-benzyloxycarbonyl- (Z-) or *N*-*tert*-butyloxycarbonyl- (Boc) protected amino acids with the sodium salt *(4)*. The 4-sulfobenzyl group can be incorporated in peptides in yields equally as good as in amino acids:

Z-Leu-Val-Leu-OH + *(4)* →
Z-Leu-Val-Leu-$OCH_2C_6H_4SO_3Na(p)$
(5a), 80% yield

A characteristic feature of the amino acid 4-sulfobenzyl ester is its zwitterionic structure:

$H_3\overset{\oplus}{N}$—CHR—CO—O—$CH_2C_6H_4\overset{\ominus}{S}O_3(p)$ *(5)*

It facilitates purification by recrystallization and/or "filtration" on a mixed-bed exchanger. The multistep synthesis of the protected hydrophobic hexapeptide Z-Leu-Ala-Leu-Leu-Val-Leu-OH with the new ester protection strategy demonstrates the advantages of this protecting function in peptide synthesis. As in the case of cysteic peptides[2,6] the sulfo group considerably increases the solubility in polar solvents: the methyl ester of the above mentioned hexapeptide is insoluble in methanol and dimethylformamide; in contrast the 4-sulfobenzyl ester could be purified on Sephadex LH 20 with methanol.

Incorporation of the sulfo function in the benzyl group considerably increases the stability of the benzyl ester bond towards acids. The selective deblocking of Z-protected peptide-4-sulfobenzyl esters is far less problematical than in the case of unsubstituted benzyl esters (cf. Table 2).

4-Sulfobenzyl esters can be readily cleaved by catalytic hydrogenation or alkaline hydrolysis. The simple synthesis, high acid-stability, and solubilizing properties make the new protective function an attractive alternative to the benzyl- and *p*-nitrobenzyl groups. Moreover, the directed application of 4-sulfobenzyl esters, for example in combination with cationic protecting groups[4,10] or basic amino acids (histidine, arginine), ensures effective purification of protected peptide fragments by ion-exchange chromatography.

Table 2. Properties of amino acid 4-sulfobenzyl esters *(5)*.

a) Cleavage
catalytic hydrogenation: Pd/H_2
alkaline hydrolysis: $NaOH/H_2O$/dioxane
b) Stability towards acids

	benzyl-	4-sulfobenzyl- ester	4-nitrobenzyl-
Trifluoroacetic acid/17 h	12%	0.2%	—
2.5 N HBr/AcOH/24 h	100%	20%	10%

Procedure

(2): *(1)* (100 ml, 915 mmol) was added dropwise to 100 ml of ice-cooled concentrated sulfuric acid. The reaction mixture was then allowed to warm to room temperature and treated with 300 ml 30% oleum, whereupon the temperature increased to about 80 °C. After cooling the mixture was poured into ice-water and the resulting precipitate filtered off, washed with water, methanol and ether, and finally dried over P_2O_5. The yield of crude *(2)* was 92.8 g (54%). The crude product can be purified by recrystallization from water; decomposition above 300 °C.

(3) (cf. [9]): A suspension of *(2)* (18.72 g, 100 mmol) in 500 ml of a 0.04 M solution of sodium acetate was adjusted to pH 3.3 with acetic acid and treated dropwise at 40 °C (bath temperature) with a solution of sodium nitrite (6.9 g, 100 mmol) in 30 ml water. After 1 hour's stirring at the same temperature the solution was evaporated down, the residue taken up in water, transferred onto a cationic exchanger IRC-50 (Amberlite), and the eluate freeze-dried. This was dissolved in methanol, treated with ether, and the precipitate filtered off and dried; yield 20.4 g (97%) *(3)*.

(4): 10.5 g (50 mmol) of *(3)* was treated at room temperature with 110 ml 40% hydrogen bromide in acetic acid and the mixture stirred for 48 h. The residue obtained on evaporation was taken up in methanol, treated with ether, and the precipitate filtered off and dried over P_2O_5; yield 12.9 g (95%) *(4)*.

L-Leucyl-4-sulfobenzyl ester (5b): A mixture of Boc-L-Leu-DCHA (DCHA = dicyclohexylammonium) (4.1 g, 10 mmol) and *(4)* (4 g, 15.3 mmol) in 30 ml anhydrous dimethylformamide was stirred for 24 h at room temperature. After removal of dicyclohexylammonium bromide by filtration and of solvent by evaporation, the resulting residue was stirred for 30 min in trifluoroacetic acid. After evaporation in a vacuum the colorless solid was digested with 50 ml ether and filtered. The crude product was dissolved in 50 ml 5% acetic acid, warmed briefly to 50 °C, cooled, filtered and washed with 5% acetic acid. Recrystallization from water/methanol (2:1 v/v) afforded 1.3 g *(5b)* (m.p. 249 °C; $[\alpha]_D^{20} = -5.8$, $c = 30\%$ AcOH). The combined mother liquors were evaporated down to *ca.* 50 ml and transferred to a mixed-bed exchanger (Dowex 50 WX 8, Dowex 44, NH_4OAc form). A further 1.1 g of *(5b)* was isolated from the freeze-dried eluate; overall yield 80%.—Corresponding esters of L-phenylalanine, L-alanine and benzyloxycarbonyl-L-arginine were prepared analogously.—The products *(2)*—*(4)* and *(5b)* were characterized by ^{1}H-NMR spectroscopy and elemental analysis.

Rigid Phenyl-Group Conformation in Complexes[**]

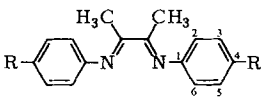
By *Heindirk tom Dieck, Horst Bruder, Kurt Hellfeldt*, and *Dieter Leibfritz* and *Martin Feigel*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Chelate ligands of the diazadiene type, R—N=C(R′)—C(R′)=N—R (dad), especially when complexed with iron, have acclaimed special interest as directive ligands for homogeneous catalytic reactions. Thus, *e.g.*, the dimerization of butadiene or isoprene can be accomplished with $(dad)_2Fe$[1], the product distribution between six- and eight-membered ring compounds depending on the size and conformation of the groups R. 2,2′-Bipyridyl and 2-pyridinealdimines coordinated to iron also give interesting catalytic systems[2]. With complexes $(dad)Fe(NO)_2$ *(1)* we found not only the known dimerization of isoprene to 1,4- and 2,4-dimethyl-4-vinyl-1-cyclohexene *(2)*[3] but, depending upon R,R′, also polymerization at room temperature, predominantly to 3,4-polyisoprene[4] (Table 1).

(2) *(3)*

(1a), R = C_6H_5; *(1b)*, R = i-C_3H_7

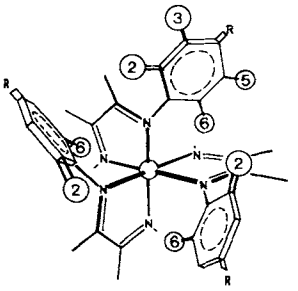


To obtain information about the stereochemical conditions in the coordination sphere of the iron, we have also investigated the complexation of bulky dad-ligands in the tris-chelate complex ion $[(dad)_3Fe]^{2+}$, known previously only with R = *n*-alkyl[5]. Such ions, however, can also be synthesized with secondary alkyl substituents (*e.g.* R = isopropyl, cyclohexyl)[1], while tertiary alkyl groups hinder *cis*- or *trans*-arrangements of two dad-ligands at the octahedrally coordinated metal, as at the trigonal-bipyramidal arrangement. The typical reactions of $(dad)_2Fe$ (reversible addition of CO to give $(dad)_2FeCO$, irreversible addition of $(CN)_2$ to give $(dad)_2Fe(CN)_2$) fail in the case of R = *tert*-butyl.

Table 1. Reactions of $(dad)Fe(NO)_2$ *(1)* with isoprene; ratio Fe:Al: isoprene: tetrahydrofuran = 1:1:150:150.

	T [°C]	*t* [h]	Conversion [%]	Products *(2)* : *(3)* : Polymer
(1) [a]	120	20	40	62 : 19 : 19
(1a)	80	20	30	65 : 7 : 28
(1b) [b]	25	24	100	0 : 0 : 100

[a] No $AlEt_3$ added. [b] The mixture solidified despite the amount of tetrahydrofuran.



Surprisingly, however, tris-chelates can also be prepared with the, supposedly bulky, phenyl derivatives, *e.g.* with *(4a)* and *(4b)*. With tetracarbonyliron iodide as starting compound one obtains the tris-chelates as iodides *(5a)* and *(5b)*, respectively. The rigid conformation of these close-packed compounds is reflected in a unique pattern of the ^{1}H-NMR signals of the aromatic protons.

(4a) → $(dad)_3FeI_2$ *(5a)*
(4b) → $(dad)_3FeI_2$ *(5b)*

(4a), R = H; *(4b)*, R = OCH_3

Figure 1 shows only the region of the aromatic protons of the 270-MHz ^{1}H-NMR spectrum of *(5b)*. The *o*-hydrogen atoms H-2 and H-6 are non-equivalent, as are also the *m*-H atoms H-3 and H-5. H-6 shows a distinct upfield shift, while H_2 shows an exceptional one. With the tabulated parameters for the shielding caused by ring currents[6] and with known structural data of other dad-complexes[7], a maximum upfield shift of H-2 of about $\Delta\delta = 2.5$ ppm can be calculated for a torsional angle θ of the phenyl groups of *ca.* 60° and otherwise ideal octahedral coordination; this value is in satisfactory agreement with the observed values ($\Delta\delta$ for *(5a)* 3.0, for *(5b)* 2.8 ppm). For the remaining protons, especially H-6, on the other hand, the calculation gives no change. The upfield shift of H-6 *must* therefore be caused by the anisotropic

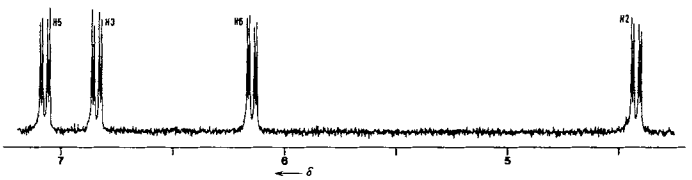


Fig. 1. 270-MHz ^{1}H-NMR spectrum of *(5b)* in CD_3CN (phenyl proton region). For the sake of clarity only three of the six *N*-substituents are shown in the structural diagram.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (special program "homogeneous catalysis") and BASF AG. We are grateful to Prof. *Gütlich* and his co-workers for measuring the Mössbauer spectra.

[***] Present address: BASF AG, D-6700 Ludwigshafen (Germany).

shielding of the 4π electron system of the dad ligand and/or by the 6π electron system of the Fe-dad chelate ring. The mean torsional angle of 60° calculated for the position of H-2 relative to a neighboring phenyl group does in fact give a position for H-6 directly above a neighboring chelate ring (see Fig. 1). The remaining assignments are easily made by double resonance experiments.

An explanation of the unusual chemical shifts in terms of paramagnetic effects can be ruled out. As expected, in the ^{13}C-NMR spectrum[8] a signal is observed for each ring C-atom, but without any unusual shifts. The Mössbauer data of the solid compounds show typical values for low-spin complexes[8,9]. At 80 °C the exchange of H-2/6 and H-3/5 is detectable by means of saturation transfer. All these findings demonstrate the unusual packing density of the six *N*-substituents and at the same time underscore the influence of a single dad ligand on the remaining coordination sites of an octahedral complex.

Procedure

(1): $Fe(CO)_2(NO)_2$ reacts with a *ca.* 0.5 M solution of the relevant dad in toluene at room temperature to give almost quantitative yields of *(1)* as glistening green crystals, which appear brown in transmitted light.

(5): A mixture of $Fe(CO)_4I_2$ and the corresponding dad (molar ratio 1:3) in acetonitrile is stirred for 20 h at 40 °C. The deep-blue-violet crystals, obtained in quantitative yield, are stable to air.

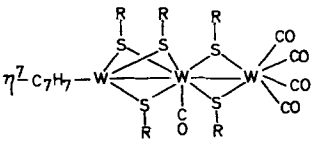
Unusually Bridged Tungsten Complexes with $W(ER)_2W(ER)_3W$ Skeleton (E = S or Se; R = C_2H_5, *n*-C_4H_9, or C_6H_5)



By *Luise R. Krauth-Siegel, Wolfgang Schulze,* and *Manfred L. Ziegler*[*]

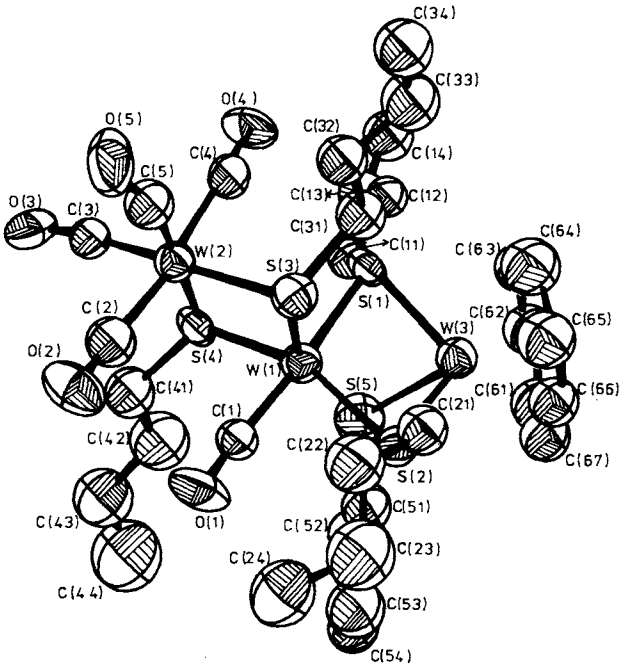
Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Reaction of the thiolates $Pb(SR)_2$ or the selenol $HSeC_6H_5$ with η^7-$C_7H_7W(CO)_2I$ gives, *inter alia,* the dinuclear *(1)* and the trinuclear coordination compounds *(2)* or their analogues *(3)* and *(4)* with SePh in place of SR. Compounds of type *(1)* correspond on the basis of their spectroscopic data to the molybdenum complexes η^7-$C_7H_7Mo(ER)_3Mo(CO)_3$[1a], of which those with E = S and R = *n*Bu, *t*Bu have been characterized by X-ray methods[1b]. Compounds of type *(2)* are novel "noncyclic trinuclear clusters". The analogous complexes *(2)* and *(4)* were characterized[2] by elemental analysis and by their IR and ^{1}H-NMR spectra. The last mentioned spectra show the C_7H_7 ring to be η^7 bonded and that five different SC_2H_5 groups are present in the case of *(2a)*. The unusual molecular structure could be determined by X-ray analysis of *(2b)*.

(1a), R = C_2H_5
(1b), R = *n*-C_4H_9
(3), SeC_6H_5 statt SR

(2a), R = C_2H_5
(2b), R = *n*-C_4H_9
(4), SeC_6H_5 statt SR

In the trinuclear tungsten complex *(2b)* the W atoms which are not in a linear arrangement are doubly and triply bridged by *n*BuS (Fig. 1). Such a combination of bridges has not previously been observed.



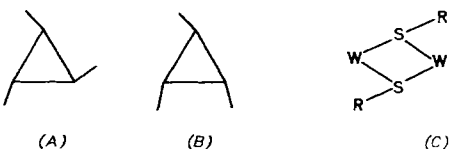


Fig. 1. Crystal structure of the $W(ER)_2W(ER)_3W$ complex *(2b)*.

The W—W distances, the WSW and SWS interior angles[4], and the 18-electron rule call for metal-to-metal bonds between neighboring W atoms. Thus the central W atom is eightfold coordinated and the two outer ones sevenfold coordinated. In the $W(SR)_3W$ moiety of *(2b)* the *n*-butylthio

(A) *(B)* *(C)*

[*] Prof. Dr. M. L. Ziegler, Dipl.-Chem. L. R. Krauth-Siegel, Dipl.-Chem. W. Schulze
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)

groups are arranged in the same way as in *(A)* while the $W(SR)_2W$ moiety has the *anti* configuration *(C)*. We have detected only the arrangement *(B)* in previously examined dinuclear species *(1)* and their Mo homologues[1b,5].

Procedure

η^7-$C_7H_7W(CO)_2I$ (1 mmol) and $Pb(SR)_2$ (0.6 mmol) are stirred together in anhydrous CH_2Cl_2 (30 ml) under N_2 at room temperature for 20 h. The green reaction solution turns red-brown with precipitation of PbI_2. The concentrated filtrate is chromatographed on a silica gel column (0.05—0.2, CH_2Cl_2). The fastest migrating red-brown zone contains compounds *(1)* and *(2)* which are separated by preparative TLC (silica gel, CH_2Cl_2/cyclohexane 1:2, double development). *(2)* (brown) migrates in front of *(1)* (yellow). The fractions are dissolved out of the layer material with CH_2Cl_2 and precipitated at $-70\,^\circ C$ from pentane. Compound *(1b)* forms red-brown crystals (m.p. $>270\,^\circ C$, yield 31%) and *(2b)* forms black-green crystals (m.p. 110 °C (dec.), yield 37%).

The seleno complex *(4)* is obtained by stirring (3 h, 20 °C) of a suspension of η^7-$C_7H_7W(CO)_2I$ (1 mmol) in triethylamine (1.2 mmol), $HSeC_6H_5$ (1.2 mmol), and CH_2Cl_2 (30 ml) under argon. In addition to *(4)* this affords the dinuclear complexes *(3)* and $(CO)_4W(\mu\text{-SePh})_2W(CO)_4$ and the mononuclear complex η^7-$C_7H_7W(CO)_2SePh$; the products can be separated by column chromatography (silica gel) in several steps (CH_2Cl_2, acetone) and TLC (silica gel, CH_2Cl_2/*n*-pentane 1:1). Yield 2.2 mg of *(4)*, m.p. 140 °C (dec.).

OH Clusters with Homodromic Circular Arrangement of Hydrogen Bonds

By *Wolfram Saenger* and *Klaus Lindner*[*]

The general significance of circular hydrogen bonds[1] for the structure of water and the structure of the hydration sheaths of macromolecules[2] was underscored in a recent article. Three kinds of circular H bonds were distinguished, depending upon whether the interactions between OH groups act in the same sense *(homodromic)*, in an opposing sense *(antidromic)*, or in irregular fashion *(heterodromic)* (Fig. 1). As discussed in reference[1], rings and "infinite" chains with homodromic H bonds are stabilized by the cooperative effect[3]; as a consequence of this effect, an OH group which is already an H bond donor/acceptor exhibits enhanced acceptor/donor properties.

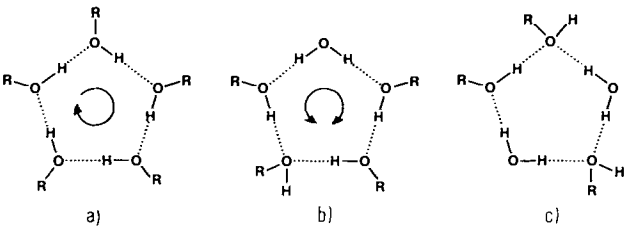

Fig. 1. Three types of circular H bonds: a) having the same sense (homodromic); b) opposing sense (antidromic); c) not having any particular direction (heterodromic) [1].

In a subsequent discussion[4] it was mentioned that, by virtue of its special topography, the water molecule must favor a circular arrangement of H bonds, and the contribution of the cooperative effect therefore appears questionable. However, on the other hand, quantum chemical calculations[4b,5] show (i) that cooperativity leads to a considerable gain in energy and (ii) that rings with homodromic H bonds possess considerably smaller dipole moments than other cyclic and catenary structures. Two further rings with homodromic H bonds will now be considered which support these results.

While the previous study[1] was based on a neutron diffraction analysis of α-cyclodextrin hexahydrate (modification *A*), a detailed and well refined ($R=3.7\%$ for 4500 data) X-ray structure analysis is now available for a second modification (*B*) of α-CD · $6H_2O$ which exhibits a different molecular packing and hence differing H bonds in the crystal lattice from modification *A*. The unit cell contains a total of four $C_{36}H_{60}O_{30}\cdot 6H_2O$ [*i.e.* $(C_6H_{10}O_5)_6\cdot 6H_2O$] units, which are stabilized by $4\times(18+12)=120$ O H···O H bonds. Since all the H atoms except one on water molecule W(5) (see Fig. 2 for nomenclature) could be localized, the H bonds are unequivocally defined. Figure 2 shows a small section from the crystal structure. Primary (O(6)—H) and secondary (O(2)—H; O(3)—H) hydroxy groups of the cyclodextrins are

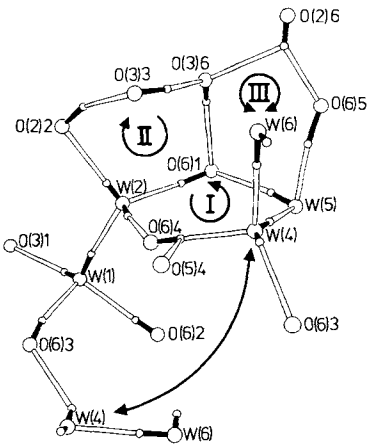

Fig. 2. The OH cluster in α-CD · $6H_2O$ (modification *B*). The rings with homodromic H bonds are designated I and II; the arrows show the directions of the O H···O bonds. Ring III having antidromic H bonds contains a bifurcated H bond emanating from O(2)6 H. An "infinite" chain of homodromic H bonds shown by a double arrow from water molecule W(4) to the symmetrically equivalent W(4) goes through the crystal lattice. Water molecules are indicated by W(1) to W(6), and hydroxy groups of α-cyclodextrins by O(2)*n*, O(3)*n*, O(6)*n*, where *n* (= 1 to 6) is the number of glucose units in the α-CD molecule. O(5)4 refers to the ring O atom in glucose unit No. 4. O═o=O H bond, o⊃O=H···O bond.

shown, which together with the water molecules W(1), W(2), W(4), W(5), W(6) form a H-bond stabilized cluster. This is a component of a homodromic chain structure W(4) H···O(6)3 –H···W(1)– H··· *etc.*, which continues infinitely through the crystal lattice and reveals the influence of the cooperative effect.

The actual OH cluster is formed by two "five-membered" rings (I and II) with homodromic H bonds. The two rings share the O(6)1 –H···W(2) interaction and must therefore run in a mutually opposing sense, as indicated by the arrows. A particular feature is ring III, which contains a bifurcated H bond emanating from O(2)6– –H. This initiates two chains of H bridges, which meet at the O(6)1 atom. Thus while in the previously described rings with antidromic H bonds (cf. Fig. 1b) opposing chains emanated from a water molecule, an H atom is to be regarded as origin in the present case.

The O···O distances of the H bonds systems shown in Figure 2 lie in the "normal" region of 2.67 to 2.97 Å. The H···O distances lie between 1.87 and 2.13 Å and are thus significantly shorter than the sum of the van der Waals distances for H and O (2.6 Å)[6]. The bifurcated bridge is unsymmetrical: H···O(6)5 is 2.00 Å and H···O(3)6 is 2.41 Å. These data are consistent with the results of neutron diffraction analyses[3a].

The angle in a regular pentagon is 108°, and the sum of the angles is therefore 540°. The O···O···O angles in rings I and II lie between 96 and 118° and between 89 and 112°, respectively; however, the sum of the angles only approaches the ideal value in ring I (533°); that in ring II (495°) shows considerable deviation and thus reveals puckering. The coordination tetrahedra around the water molecules W(2), W(4), and W(5) are well formed with O···O···O angles of 84 to 125° while the angles around W(1) range between 82 and 157°. Viewed overall, these geometric data meet expectations more closely than those for modification *A*[1] in which one of the water molecules shows trigonal-planar coordination.

The present cluster structure of circular homodromic H bonds clearly shows that the cooperative effect has a decisive influence on the formation and direction of the H bonds. If this effect were inoperative then an almost random distribution of H bonds would be present such as is found neither in modification *A*[1] nor in modification B. Thus not only the topological effects discussed in ref.[4a] come into play on assembly of water molecules themselves or with hydroxy groups, but cooperativity makes a decisive contribution to stabilization of the aggregates[4b]. Rings with five or six O atoms are formed preferentially. This has mainly topological reasons, since the corresponding endocyclic O···O···O angles lie between 100 and 120 °C and thus correspond to the orientation of the H atoms and the orbitals of the hydroxy groups. Smaller and larger rings would require less favorable geometries and tend to rearrange to the preferred rings.

A Very Crowded Molecule: X-Ray Crystallographic Analysis of Bis(2,4,6-tri-*tert*-butylphenyl)phosphinic Chloride[**]

By *Masaaki Yoshifuji, Ichiro Shima, Naoki Inamoto, Ken Hirotsu,* and *Taiichi Higuchi*[*]

We have recently synthesized the highly substituted title compound *(1)* from 2,4,6-tri-*tert*-butylphenyllithium and phosphorus oxide trichloride[1]. In *(1)*, two very bulky 2,4,6-tri-*tert*-butylphenyl groups are attached to the same phosphorus atom. An X-ray structure analysis of *(1)*[2] was undertaken in order to investigate the large steric congestion expected around the phosphorus atom. As can be seen from Figure 1 and Table 1, the two benzene rings assume unusual distorted boat forms; each "boat" is almost an image of the other.

(1)

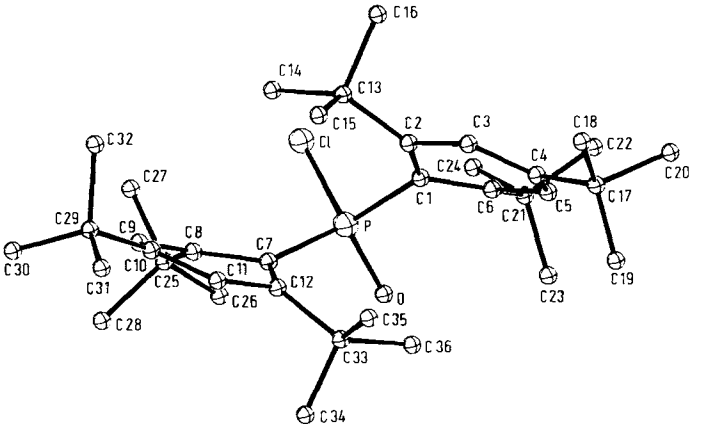

Fig. 1. Molecular structure of *(1)* in the crystal. Bond angles:
C(1) C(2) C(13) = 130.4°, C(3) C(2) C(13) = 112.0°,
C(1) C(6) C(21) = 129.0°, C(5) C(6) C(21) = 112.3°,
C(7) C(8) C(25) = 127.8°, C(9) C(8) C(25) = 115.0°,
C(7) C(12) C(33) = 125.1°, C(11) C(12) C(33) = 116.1°.

The interplanar angles of 17.8° between planes 1 and 2 and of 19.1° between planes 4 and 5 are even larger than the corresponding average values of 13.7° in [2.2]paracyclophane diolefin[4] and of 16.8° in [7]paracyclophane-3-carboxylic acid[5]. Moreover, the exocyclic bonds C(1) P and C(7)—P form angles of 10.9° and 9.1° to the planes 2 and 5, respectively, while planes 3 and 6 are bent at angles of 9.8° and 10.8°, respectively, to the planes 1 and 4. In the case of the *tert*-butyl groups, C(13) is situated 0.21 Å above the plane defined by C(1), C(2), and C(3); in addition, C(21),

Table 1. Deviations of atoms from mean planes, interplanar angles, and intramolecular short contacts in *(1)*.

Plane	Atoms defining plane	Deviations [Å]
1	C(2), C(3), C(5), C(6)	C(2), 0.02; C(3), −0.02; C(5), 0.02; C(6), −0.02; C(1), 0.22; C(4), 0.12; C(13), −0.40; C(21), −0.42; P, 1.12
2	C(1), C(2), C(6)	P, 0.35
3	C(3), C(4), C(5)	C(17), −0.11
4	C(8), C(9), C(11), C(12)	C(8), −0.01; C(9), 0.01; C(11), −0.01; C(12), 0.01; C(7), 0.25; C(10), 0.14; C(25), −0.52; C(33), −0.52; P, 1.13
5	C(7), C(8), C(12)	P, 0.30
6	C(9), C(10), C(11)	C(29), −0.09

Interplanar angles between

1 and 2 = 17.8°;	1 and 3 = 9.8°;	4 and 5 = 19.1°;	4 and 6 = 10.8°

Intramolecular short contacts [Å]

Cl/C(14) = 3.16;	Cl/C(24) = 3.28;	Cl/C(25) = 3.33;	Cl/C(26) = 3.30;
Cl/C(27) = 3.22;	O/C(23) = 3.01;	O/C(24) = 3.06;	O/C(36) = 3.03;
C(1)/C(36) = 3.22;	C(7)/C(14) = 3.24		

C(25), and C(33) deviate by 0.08, 0.21, and 0.31 Å, respectively, from the corresponding planes. The angle C(1)—C(2)—C(13) is opened to a value of 130.4° with a consequent compression of the angle C(3)—C(2)—C(13) to 112.0°. Similar deformations were found for the exocyclic bond angles at positions C(6), C(8), and C(12). The intramolecular distances given in Table 1 are 0.4—0.5 Å shorter than the expected van der Waals distances ($CH_3/C_{aromatic}$ = 3.7, CH_3/Cl = 3.8, and CH_3/O = 3.4 Å). These short contacts are indicative of the high strain within the molecule *(1)* and lead to the remarkable boat forms of the two benzene rings and to the deformation of the bond angles[6]. To our knowledge this is the first example where non-bridged benzene rings prefer a boat form because of strong intramolecular repulsion.

α-D-Glucuronides of 1-(*N*-Alkyl-*N*-nitrosoamino)alkyl Alcohols[**]

By *Horst Braun* and *Manfred Wiessler*[*]

1-(*N*-Alkyl-*N*-nitrosoamino)alkyl alcohols are now designated as proximate carcinogens of *N*-nitrosodialkylamines[1]. It is known that xenobiotics are hydroxylated in the organism and after conjugation with glucuronic acids are excreted *via* the kidney as β-*O*-glucuronides. This process is regarded as detoxification, but there are indications that glucuronides may also be transport forms of highly reactive proximate or ultimate carcinogens[2]. Since their release, due to pH or content of β-glucuronidase, can be organ-specific, the *O*-glucuronides of α-hydroxylated *N*-nitrosodialkylamines might be responsible for their pronounced organotropic action[3]. We now report the first synthesis of the title compounds, *i.e.* the glucuronides of α-hydroxylated *N*-nitrosodialkylamines.

Since stable α-hydroxylated *N*-nitrosodialkylamines are still unknown, while the corresponding α-chlorinated compounds have been reported[4], only an inverse Königs-Knorr reaction[5] was feasible; the nature of the linkage (α or β) should depend upon the glucuronic acid employed. We used methyl 2,3,4-tri-*O*-acetyl-D-glucuronate *(2)*[6], which exists in the α form[7].

Reaction of *(1b)*[4] with *(2)* at 0 °C in the presence of a molar amount of $BF_3 \cdot Et_2O$ and with addition of pyridine[8] gave the α-D-glucuronide *(3a)* in 20% yield (see Table 1) after work-up and chromatography on silica gel (CH_2Cl_2/ether/hexane, 10:7:5). Compounds *(3b)* and *(3c)* are obtained analogously. The coupling constants of 1-*H* and 2-*H* show the compounds *(3)* to belong to the α-series. All attempts to prepare *(3d)*, *(3e)*, or *(3f)* under the same conditions have been unsuccessful[9].

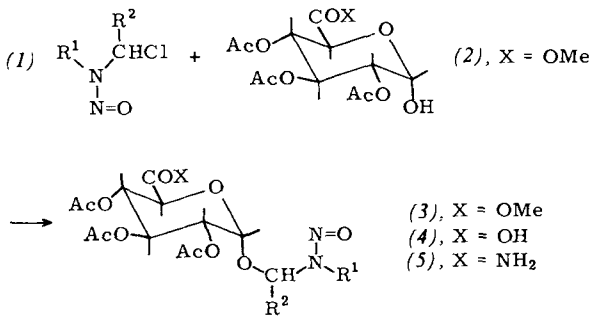

Table 1. Selected properties of products of types *(3)*, *(4)*, and *(5)*. *d*: $R^1 = CH_3$, R^2 = H; *e*: $R^1 = C_2H_5$, $R^2 = CH_3$; *f*: R^1—R^2 = $(CH_2)_3$ [a].

[*] Priv.-Doz. Dr. M. Wiessler, H. Braun
Institut für Toxicologie und Chemotherapie,
Deutsches Krebsforschungszentrum
Im Neuenheimer Feld 280, D-6900 Heidelberg (Germany)

[**] We wish to thank *G. Riethmüller*, Max-Planck-Institut für medizinische Forschung Heidelberg, for performing numerous analyses.

Since the same yields were obtained with pyridine alone as base (without addition of $BF_3 \cdot Et_2O$) we replaced the pyridine by a cross-linked polyvinylpyridine[10]; the reaction was accelerated without any loss of selectivity.

Hydrolysis with 10% methanolic KOH and chromatography on Dowex 50 WX (50—100 mesh, H^+ form/H_2O) led to the glucuronic acids *(4a)*, *(4b)*, and *(4c)* (see Table 1). The ^{1}H-NMR data again confirm that the compounds belong to the α-series.

That the acids *(4)* do not undergo any change under the acidic conditions of ion exchange was demonstrated in the following way: Reaction of *(3a)* with NH_3/CH_3OH gave the same amide *(5a)* (m.p. 128 °C) as was obtained on treatment of the glucuronic acid *(4a)* with an ethereal solution of diazomethane and subsequently with NH_3/CH_3OH.

A Cubane-Type Sn_4N_3O Cage[1]

By *Michael Veith* and *Holger Lange*[*]

Having already synthesized the oligomeric "iminostannylenes" *(1)* and *(2)*[2] we have now succeeded in incorporating both tin(II) and nitrogen atoms as well as an oxygen atom into such cage molecules. As shown by the reaction scheme

it is surprisingly only the open cage *(1)*, and not the closed cage *(2)*, which can be transformed by incomplete hydrolysis into the oxa derivative *(3)*. The cubane-type structure of *(3)* is revealed by the ^{1}H-NMR spectrum (Table 1), which shows only one signal for the three *tert*-butyl groups. Proof of this structure is provided by the quantitative reaction of *(3)* with trimethylaluminum to form the Lewis acid-base adduct *(4)*, whose X-ray structure characterization showed it to crystallize isotypically to *(2)*[2] (Table 1).

Table 1. Physical data and lattice constants of the compounds *(3)* and *(4)*; those of compound *(2)* are also given for the sake of comparison [2].

[8] Cf. *M. Kühn, A. v. Wartburg*, Helv. Chim. Acta *51*, 1631 (1968).
[9] The same behavior is observed on reaction of *(1a)* to *(1f)* with 2,3,4,6-tetra-*O*-acetyl-β-D-glucose. Once again, only the glucosides corresponding to *(3a)*, *(3b)*, and *(3c)* could be isolated, which likewise belong to the α series. In contrast, the more nucleophilic 3,4-dichlorothiophenolate reacts with *(1a)* to *(1f)* to give the thioethers in yields of 50 to 60%.

Institut für Anorganische Chemie der Technischen Universität
Pockelsstrasse 4, D-3300 Braunschweig (Germany)

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/0505-401 $ 02.50/0*

atom of *(2)* is replaced by an oxygen then the tertiary carbon atom must be replaced by a Group 3 element (by a boron atom for true isosteric character[3]) in order to preserve the electron balance.

The smooth reaction *(3)*→*(4)* shows that the oxygen atom still exhibits Lewis basicity in spite of threefold coordination in the polycycle *(3)* (cf. also [4]); the reason for this reactivity possibly lies in the close proximity of four lone pairs owing to bonding to three Sn^{II} atoms. On addition of the acid $AlMe_3$ one of the electron pairs is coordinated, thus reducing the electronic interaction; the O atom becomes tetracoordinate.

Under conditions of thermolysis (200 °C), the cage *(4)* affords the cage *(2)*; the expected fragment ($SnOAlMe_3$) has not yet been intercepted.

The new compounds *(3)* and *(4)* are intermediate members in the series of cubane-type cages $(SnX)_4$ (X = N or O) of *(1)* and *(2)*[2] on the one hand and the cation $Sn_4O_3OH^+$ in $Sn_{21}Cl_{16}(OH)_{14}O_6$ on the other[5]. Owing to the *tert*-butyl groups on the nitrogen atoms, compound *(3)* differs from related SnNO polycycles of lower symmetry and with weaker steric shielding[6] by being soluble in nonpolar solvents.

Procedure

H_2O (0.049 ml, 2.7 mmol) in *tert*-butylamine (5 ml) is slowly added dropwise to *(1)*[2] (7.0 g, 10.9 mmol) in *tert*-butylamine (50 ml). The light yellow solution turns orange and a precipitate appears. After refluxing for 1.5 h the reaction mixture is filtered, *tert*-butylamine is distilled off, and the residue is crystallized from anhydrous benzene. On repeated recrystallization, orange crystals of *(3)* first grow which can thus be separated from *(1)*; yield 2.5 g (44%).

$AlMe_3$ (0.2 ml, 2.1 mmol) is added to *(3)* (1 g, 1.4 mmol) in benzene (10 ml). On concentration, 0.88 g (81%) of the adduct *(4)* crystallizes.

Synthesis of Organotrimetal Polymers Using Trimetal Vapor-Fluid Matrix Techniques[**]

By *Colin G. Francis, Helmut X. Huber,* and *Geoffrey A. Ozin*[*]

Supported trimetallic particle catalysts have been shown to exhibit certain advantages over their respective bimetallic counterparts, noteworthy features being enhanced stability towards segregation, sintering, and poisoning in hydrocarbon reforming processes[1]. These trimetallic compositions are usually prepared by salt impregnation techniques[2] although an attractive alternative would be to attach well-defined, organometallic clusters such as $FeRuOs_2H_2(CO)_{13}$[3] to functionalized polymers or oxide supports in a manner similar to that currently being developed for bimetallic catalyst systems[4]. However, as far as we are aware, neither polymer-anchored, three-component mononuclear nor trimetallic cluster systems have been reported previously in the open literature, although a number of two-component and bimetallic cluster analogues are known[5]. We wish to report that "organotrimetal polymers" containing three different mononuclear metal sites can be readily generated by the metal vapor-fluid matrix technique[6, 10, 11].

The fluid polymer chosen for this feasibility study was a poly(methylphenylsiloxane), Dow Corning DC510. This fluid was originally shown to react with the metal vapors of Ti, V, Cr, Mo, and W (in a metal vapor rotatory reactor) to give a liquid bisarene-organometallic polymer[9], as shown in Scheme 1.

Scheme 1.

We subsequently demonstrated[6, 10, 11] that the metal vapor-liquid polymer encounters that occur in such a reactor system (where one envisages both microscopic and macroscopic mobility in the polymer film) can be adequately simulated in a thin, static film experiment.

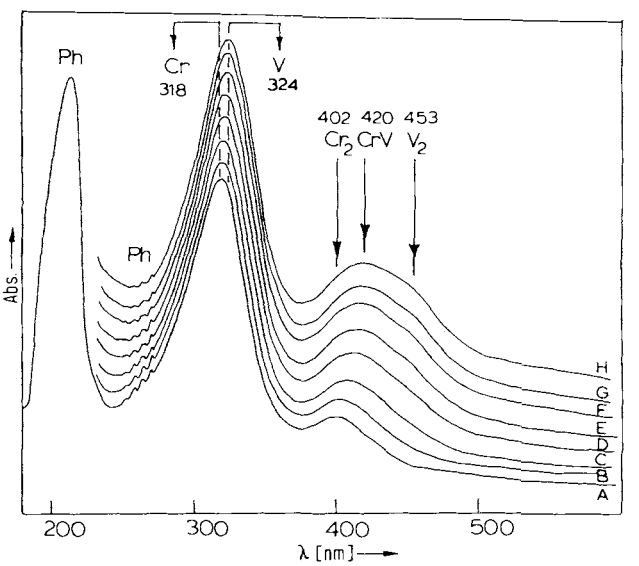

Fig. 1. UV/VIS spectra of the products of (A) a Cr vapor deposition into a thin, static film (*ca.* 10^{-6} m) of DC510 poly(methylphenylsiloxane) at 250 K, followed by (B H) roughly equal increments of V vapor. The spectra initially show the growth of polymer-attached bis(arene)chromium and polymer-stabilized dichromium, which is followed by the appearance of polymer-attached bis(arene)vanadium and polymer-stabilized divanadium and chromium-vanadium (see [10, 11]).

[**] We would like to acknowledge the financial assistance of the National Research Council of Canada, Imperial Oil, the Connaught Foundation, Erindale College and the Lash Miller Chemical Laboratories. The assistance of Dr. *D. McIntosh* with the curve fitting computer analysis is greatly appreciated.

A useful probe of the extent and site of metal attachment is an intense UV metal-to-ligand charge transfer absorption associated with the polymer-anchored bis(arene)metal complex. Thus the Cr, V, and Ti/DC510 systems show MLCT absorptions at 318, 324, and 355 nm, respectively[6, 10, 11].

In a continuing effort to establish the general applicability of the multimetal vapor-liquid polymer technique, we will present initially data for the Cr/V/DC510 system followed by those for the Cr/V/Ti/DC510 system. The initial deposition of Cr into DC510 at 250 K is shown in Figure 1A, and is seen to display the MLCT band of polymer-supported bis(arene)chromium at 318 nm as well as polymer-stabilized dichromium at 402 nm.

Subsequent depositions of V into the DC510 at 250 K, close to the saturation loading, are depicted in Figures 1B—1H and show a small spectral shift of the original 318 nm band to 324 nm, corresponding to the growth of the polymer-anchored bis(arene)vanadium complex[10]. Concomitant with this growth in the MLCT region is the broadening and shifting of the polymer-stabilized dichromium band at 402 nm to eventually yield a structured band with maxima at 402, 420, and 453 nm, the latter being associated with the previously identified divanadium absorption. The new absorption, at energies intermediate between those of Cr_2 and V_2 absorptions, can be ascribed to the polymer-stabilized, bimetallic cluster CrV.

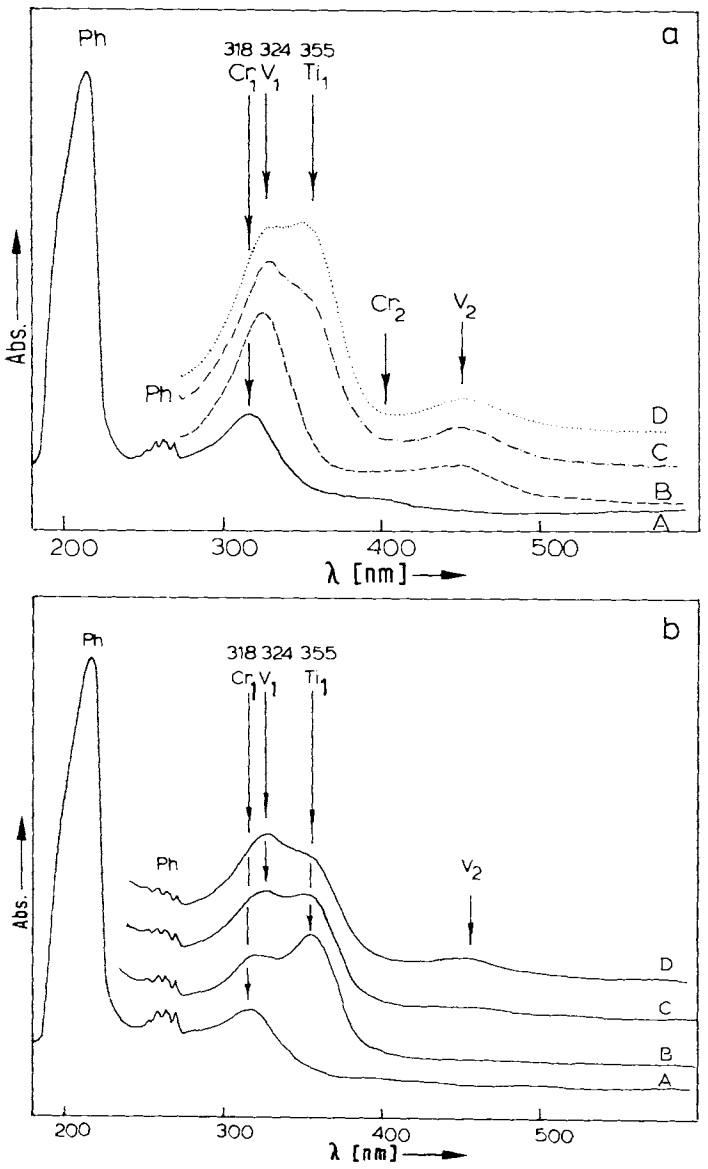

Fig. 2. UV/VIS spectra of a thin static film of DC510 held on a quartz optical window at 250 K following deposition of a) Cr (A), V (B), Ti (C, D) [10, 11] and b) Cr (A), Ti (B), V (C, D), in increments of approximately 2×10^{-6} gm.

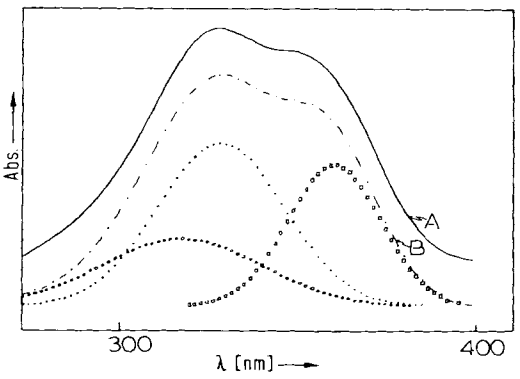
Two kinds of experiment demonstrate the feasibility of extending the above methods to trimetallic systems. By working at least a factor of three below the saturation loading of the phenyl groups for each of the metals employed, one can turn to Figures 2a and 2b which illustrate the progress of sequentially depositing Cr/V/Ti or Cr/Ti/V respectively into a thin film of DC510 adhering to a quartz optical window maintained at 250 K. On depositing approximately 2×10^{-6} gm of chromium into the DC510, one observes the appearance of the characteristic 318 nm absorption of polymer-anchored bis(arene)chromium (Figure 2a: A) together with a small amount of the polymer-stabilized dichromium species as seen by the weak band at 402 nm[10, 11]. Deposition of a roughly equal increment of vanadium causes further growth of the MLCT absorption assigned to bis(arene)chromium but with the noticeable and anticipated red shift of the peak maximum to 324 nm (Figure 2a: B), the wavelength of anchored bis(arene)vanadium[10, 11]. Concurrently with the production of mononuclear vanadium sites, one observes the growth of some polymer-stabilized, divanadium sites indicated by the weak absorption around 453 nm[10]. Deposition of roughly equal increments of titanium into the polymer film (Figure 2a: C and D) causes additional growth in the MLCT region but with a new peak at 355 nm, depicting the generation of polymer-attached bis(arene)titanium[10, 11].

In an attempt to obtain clearer spectroscopic resolution of the bis(arene)chromium and vanadium sites, similar trimetal vapor depositions were conducted but using the deposition order Cr/Ti/V. An illustrative spectral trace is shown in Figure 2b. Following the sequential Cr/Ti depositions (Figure 2b: B), the coexistence of bis(arene)chromium and titanium on the polymer is easily discerned by the MLCT bands at 318 and 355 nm respectively[10, 11]. Further deposition of V clearly defines the continued growth in the MLCT region but with a new maximum at 324 nm (Figure 2c: C and D).

In order to resolve the existence of three absorption maxima within the envelope of Figure 2b: D, the observed spectrum was subjected to a computer curve-fitting procedure (Fig. 3)[12]. Three maxima were obtained with peak positions



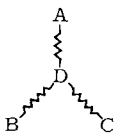


Fig. 3. A triple-Gaussian computer fit of the MLCT absorptions of polymer-anchored bis(arene)chromium, -vanadium, and -titanium. A, observed spectrum (see Fig. 2b, D); B, computer curve fitted spectrum.

corresponding to those for the MLCT absorptions of the individual bis(arene)metal complexes on the polymer.

Experimental

The method essentially involves the deposition of the three chosen metals into a thin, viscous film of a functionalized liquid polymer at close to room temperature. The creation of the distinct, polymer-anchored metal sites is conveniently monitored by means of UV-visible spectroscopy of the fluid sample adhering to a quartz optical window attached to the second stage of a Displex closed-cycle helium refrigeration system. The vacuum furnace employed for these trimetal vapor experiments has not been previously described but is a straightforward modification of the arrangement used for our earlier bimetal vapor work[7]. The device consisted of a water-cooled, four-electrode-flange assembly (illustrated below) having a triangular electrode configuration of live terminals (A, B, C) around a central ground terminal (D). The three different evaporation sources were connected radially (A—D, B—D, C—D) and heated directly and independently by passage of AC. The rate of deposition of the metals was monitored by three *in situ* quartz crystal microbalances[8] aligned behind each metal vapor source. Radiation shields were appropriately positioned between the evaporation sources, liquid polymer sample, and quartz crystals. The geometrical correction factor for this trimetal deposition configuration was determined by replacing the sample window by a fourth mass monitor, thereby permitting a calibration of the forward-to-backward flux for each metal. Chromium metal was vaporized from a tantalum Knudsen cell (wall thickness 0.010″, orifice diameter 0.020″) while vanadium and titanium metal depositions were achieved from thin (0.015″) filaments of the metal. All metals were better than 99.95% as supplied by A. D. McKay, New York.

Distribution of Terminal and Bridging CO-Groups in an Anionic Carbonylmetal Cluster as a Result of Ion-Pair Formation. Crystal and Molecular Structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$[**]

By *Hans-Norbert Adams, Giuseppe Fachinetti,* and *Joachim Strähle*[*]

The interaction between highly acidic countercations and carbonyl groups of mononuclear carbonylmetalates in solvents of relatively poor coordinating ability has already been demonstrated[1], and examples are also known of interactions of this sort in the solid state[2]. The increased reactivity of mononuclear carbonyl metalates towards alkyl halides[3a] and molecular oxygen[3b] has been interpreted on this basis. Anionic carbonylmetalates, however, have not been studied under "acidic" conditions (*i.e.* in weakly coordinating solvents and with countercations of very high charge density), so comparable cation-anion interactions could previously not be observed[4].

We have now succeeded in preparing single crystals of diisopropyl ether solvated $LiCo_3(CO)_{10}$, as product of the reac-

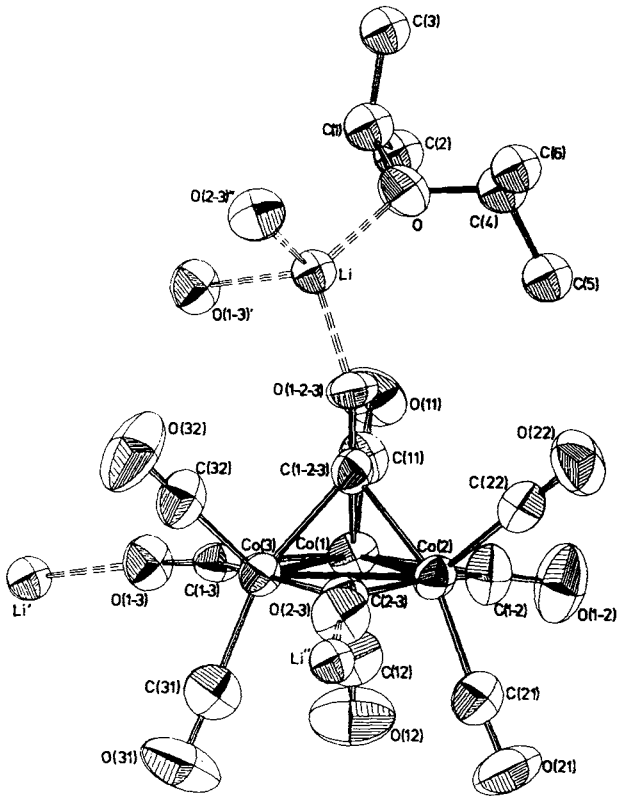

Fig. 1. Molecular structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$. Some important distances [Å] are: Co(1) Co(2) 2.489(1), Co(1) Co(3) 2.472(1), Co(2) Co(3) 2.462(1); average Co C(terminal) 1.800; average C O(terminal) 1.123; average Co C(bridging) 1.956; C(1-2) O(1-2) 1.137(8); C(1-3) O(1-3) 1.164(7); C(2-3) O(2-3) 1.164(7); average Co C(1-2-3) 2.013; C(1-2-3) O(1-2-3) 1.190(7).

tion of $LiCo(CO)_4$ with $Co_4(CO)_{12}$[5]. The molecular structure of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$ *(1)* has been solved by X-ray diffraction methods[6]. It consists of the ions $[Co_3(CO)_{10}]^-$ and Li^+. The cations are approximately tetrahedrally surrounded by one ether oxygen (1.910(12) Å) and by three carbonyl oxygens [one μ_3-CO, 1.859(10) Å, and two μ-CO, Li–O(2-3) 1.989(10), Li–O(1-3) 2.049(10) Å] of three different cluster units.

The three cobalt atoms form an almost regular triangle, forming the base of a tetrahedron having the face-bridging carbon, C(1-2-3), at an apex. The interatomic distances and angles of the Co_3C cluster are comparable with those found in other cluster compounds of the oxymethylidyne type[7].

The IR spectrum of *(1)* as Nujol mull shows strong absorptions around 1800 cm^{-1}, in agreement with the presence of edge-bridging carbonyl groups as established by the X-ray structure analysis. This contrasts with the weak carbonyl absorption observed at 1865 cm^{-1} in ether solution[5]. These observations can be rationalized in terms of small amounts of clusters with edge-bridging carbonyl groups in solvent-dependent equilibria with clusters containing terminal carbonyl groups only. Addition of tetrahydrofuran (1—3 vol-%) to a $n\text{-}Bu_2O$ solution of *(1)*, before decomposition takes place[5], considerably decreases the intensity of the 1865 cm^{-1} band and modifies the spectral pattern associated with the face-bridging carbonyl group at about 1580 cm^{-1}, while the terminal carbonyl stretching region around 2000 cm^{-1} remains essentially unchanged: under these conditions the acidity of Li^+ supposedly is decreased through coordination to the more basic tetrahydrofuran. In the solid state the acidity of Li^+ is greatly enhanced, thus promoting the structural change to the form containing the edge-bridging carbonyl groups.

Our investigations show that dramatic structural changes can occur in an anionic carbonyl cluster by apparently small changes of the acid-base properties of the system.

Experimental

Analytically pure $LiCo_3(CO)_{10}\cdot Et_2O$ (1.3 g) was dissolved in diisopropyl ether (20 ml) and the resulting solution was concentrated to about 5 ml under reduced pressure. On addition of *n*-hexane (100 ml) and filtration, the mother liquor slowly yielded 0.5 g of $LiCo_3(CO)_{10}\cdot i\text{-}Pr_2O$ as black crystals. All of the operations must be carried out under purified argon.

Triple-Decker Sandwich Complexes of 4d and 5d Metals with *cyclo*-Triphosphorus as μ,η^3-Ligand: Structural and Magnetic Properties

By *Claudio Bianchini, Massimo Di Vaira, Andrea Meli,* and *Luigi Sacconi*[*]

The recent synthesis of mononuclear and dinuclear 3d metal complexes containing the *cyclo*-triphosphorus (η^3-P_3) group as a ligand[1] prompted us to attempt the synthesis of the corresponding compounds of the 4d and 5d metals. On reaction of white phosphorus (P_4) with $[Rh(C_2H_4)_2Cl]_2$ *(1)* or $Ir(PPh_3)_2(CO)Cl$ in the presence of 1,1,1-tris(diphenylphosphinomethyl)ethane (triphos) we obtained the mononuclear complexes [(triphos)M(η^3-P_3)] with M = Rh *(2)* and M = Ir *(3)*, respectively[2]. These compounds react with *(1)* and cobalt(II) or nickel(II) tetrafluoborates in the presence of triphos (and, where appropriate, of $NaBPh_4$) yielding the dinuclear compounds

[(triphos)Rh-μ-(η^3-P_3)Co(triphos)]$(BPh_4)_2\cdot 2(CH_3)_2CO$ *(4)*
[(triphos)Rh-μ-(η^3-P_3)Ni(triphos)]$(BF_4)_2\cdot C_4H_8O$ *(5)*
[(triphos)Ir-μ-(η^3-P_3)Co(triphos)]$(BF_4)_2\cdot CH_2Cl_2$ *(6)*
[(triphos)Rh-μ-(η^3-P_3)Rh(triphos)]$BPh_4\cdot(CH_3)_2CO$ *(7)*

whose cations have a triple-decker sandwich structure with *cyclo*-triphosphorus acting as central bridge-forming *trihapto ligand*. The salts *(4)*, *(5)* and *(6)* behave as 1:2 electrolytes, whereas *(7)* is a 1:1 electrolyte. They are all air-stable in the solid state, but rather unstable in solution. Compounds *(4)* and *(6)* are paramagnetic with a magnetic moment corresponding to a doublet ground state. Compound *(7)* is essentially diamagnetic at room temperature, whereas *(5)* has a magnetic moment slightly dependent on the nature of the counterion and of the solvent in the lattice, decreasing from values of 1.3—1.6 μ_B at room temperature to *ca.* 0.7 μ_B at 100 K. The magnetic behavior of *(5)* and *(7)* differs considerably from that of the previously described complexes with 32 valence electrons, which have a magnetic moment corresponding to two unpaired electrons[1]. This difference in the magnetic properties may be traced to structural differences between the compounds[3]: the η^3-P_3 bridge in *(5)* is shifted from the line joining the two metal atoms (cf. Fig. 1) in such

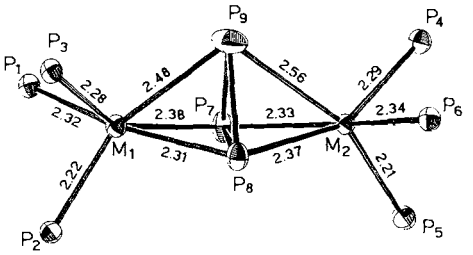

Fig. 1. Structure of the dication of *(5)*. Bond lengths in the η^3-P_3 ligand of the triple-decker complex: P7 P8 = 2.31, P7,8 P9 = 2.15 Å. Each metal site, M, has 50% Rh and 50% Ni (or 50% Co, in compound *(4)*) occupancy.—Bond lengths in complex *(4)*: M P_n = 2.21—2.22 (n = 1—6), 2.29—2.32 (n = 7—9); P_n P_m = 2.19—2.20 (n = 7, 8; m = 8, 9).

[*] Prof. Dr. L. Sacconi, Dr. C. Bianchini, Dr. M. Di Vaira, Dr. A. Meli
Istituto di Chimica Generale e Inorganica dell'Università,
Laboratorio CNR,
Via J. Nardi 39, I-50132 Firenze (Italy)

a way that the approximate C_3 symmetry existing in the structure of *(4)* as well as in those of all the analogous complexes previously investigated[1] is lost. As a consequence of this distortion the degeneracy of the highest-occupied 6e orbital[1] is lifted and a spin singlet, rather than triplet, ground state is attained. The residual paramagnetism of compound *(5)* may include a temperature independent (TIP) contribution but there may also be a contribution from partial occupation of the higher triplet state.

Procedure

Synthesis of *(4)*: A solution of *(2)* (410 mg, 0.50 mmol) in 40 ml of CH_2Cl_2 was added under nitrogen at room temperature to a mixture of $Co(BF_4)_2 \cdot 6H_2O$ (170 mg, 0.50 mmol) in 15 ml of ethanol and of the triphos ligand (320 mg, 0.50 mmol) in 20 ml of CH_2Cl_2. A solution of $NaBPh_4$ (350 mg, 1 mmol) in 10 ml of ethanol was then added. After concentration of the resulting solution brown crystals were obtained, which were recrystallized from acetone/ethanol. Yield 80%.

(5): A solution of *(2)* (410 mg, 0.50 mmol) in 80 ml of THF was added under nitrogen at room temperature to a mixture of $Ni(BF_4)_2 \cdot 6H_2O$ (170 mg, 0.50 mmol) in 30 ml of ethanol and of the triphos ligand (320 mg, 0.50 mmol) in 10 ml of THF. The resulting mixture was concentrated to 40 ml under vacuum. After standing overnight dark red crystals had separated. Yield 60%.

(6): Prepared by the same procedure as *(4)* except for substitution of compound *(3)* (450 mg, 0.50 mmol) for *(2)*. The reddish brown crystals were recrystallized from dichloromethane/ethanol. Yield 80%.

(7): Prepared by the same procedure as *(4)* except for substitution of *(1)* or $[Rh(CO)_2Cl]_2$ (0.30 mmol) for the cobalt salt; triphos (0.60 mmol), $NaBPh_4$ (0.50 mmol) in 30 ml of ethanol. Orange-red crystals; yield 70%.

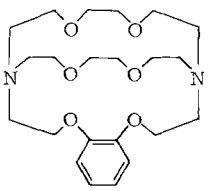
Calcium Isotope Separation on an Exchange Resin Having Cryptand Anchor Groups[**]



By *Klaus G. Heumann* and *Hans-Peter Schiefer*[*]

The stable heavy calcium isotopes ^{46}Ca and ^{48}Ca are of interest primarily for labeling purposes in medical research[1]. In 1977 a French research team reported the enrichment of ^{235}U by crown ethers[2]; *Jepson* and *DeWitt* were able to enrich ^{44}Ca relative to ^{40}Ca with the aid of dibenzo[18]crown-6[3]. Since some of the cryptands are known to form strong complexes with alkaline earth metals[4], we have examined calcium isotope separation on an exchange resin containing the cryptand $[2_B.2.2]$ as anchor group.

Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

[***] Present address: Centre de Recherches sur les Macromolecules, F-67083 Strasbourg (France).

$[2_B.2.2]$ 

The experiments were performed in a thermostated column of 60 cm length and 1.2 cm i.d. packed with 19 g of exchanger resin ("$[2_B.2.2]$ polymer", E. Merck). In each run 40 mg of calcium of natural isotopic composition was applied to the column as $CaCl_2$ dissolved in 1 ml of $CH_3OH/CHCl_3/H_2O$ (70:30 v/v + 1.65 vol% H_2O) and eluted at −21, 0, and 20 °C with this solvent system (*ca.* 0.5 ml/min). The calcium content of the eluate fractions was determined by flame atomic absorption spectrometry and the $^{44}Ca/^{40}Ca$ and the $^{48}Ca/^{40}Ca$ isotope ratio determined by thermionic mass spectrometry[5].

In the case of the isotope exchange reaction between $^{48}Ca^{2+}$ and $^{40}Ca^{2+}$ we find (L = solution; R = resin monomer unit):

$$R\ [2_B.2.2, {}^{48}Ca]^{2+} + {}^{40}Ca_L^{2+} \rightleftharpoons R\ [2_B.2.2, {}^{40}Ca]^{2+} + {}^{48}Ca_L^{2+} \quad (1)$$

The equilibrium constant K_c corresponds to the elementary separation factor $\alpha = 1 + \varepsilon$.

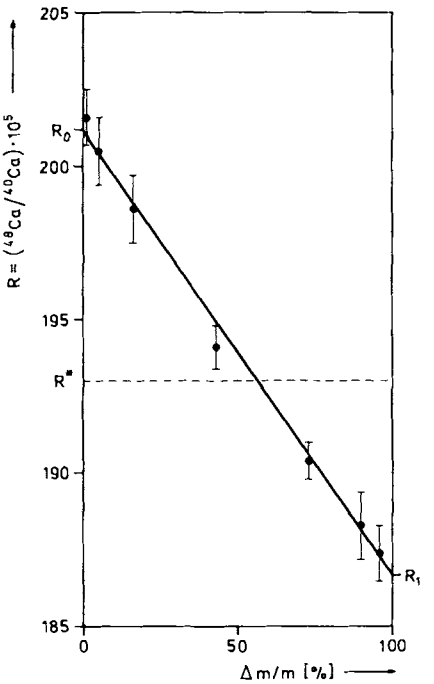

Fig. 1. Calcium isotope separation as function of the eluted amount of substance $\Delta m/m$ at 20 °C. R^* = initial isotopic ratio, R_0 and R_1 = extrapolated isotope ratio at $\Delta m/m = 0$ or 1.

Figure 1 shows the dependence of the isotopic ratio $R = {}^{48}Ca/{}^{40}Ca$ upon the amount of substance eluted $\Delta m/m$ at 20 °C. The relationship between R and $\Delta m/m$ is linear at all the temperatures investigated; unlike comparable isotope exchange reactions[7] the isotope separation increases with increasing temperature (Table 1).

In the first fractions eluted, R is higher than the initial isotopic ratio R^*, and lower in the final fractions. We therefore have an enrichment of the heavier relative to the lighter calcium isotopes in the solution. The direction of this isotopic enrichment is in accord with that of other cation exchanger/aqueous solution systems[6].

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0505-406 $ 02.50/0

Table 1. Isotope separation effects in column chromatography with "[2$_B$.2.2] polymer" as function of temperature. γ (maximum separation efficiency of column) $= (R_0/R_1) - 1$; ε (isotope separation effect) $= \alpha - 1$.

T [°C]	$\gamma(^{44}Ca/^{40}Ca)$	$\gamma(^{48}Ca/^{40}Ca)$	$\varepsilon(^{44}Ca/^{40}Ca)$	$\varepsilon(^{48}Ca/^{40}Ca)$
−21	1.5×10^{-2}	2.5×10^{-2}	0.26×10^{-2}	0.45×10^{-2}
0	2.6×10^{-2}	4.9×10^{-2}	0.42×10^{-2}	0.77×10^{-2}
20	4.4×10^{-2}	7.9×10^{-2}	0.57×10^{-2}	1.04×10^{-2}

Table 1 contains the ε values determined by an approximation method commonly employed in isotope chemistry[8]. They are in good agreement with the values determined in a static experiment at 20 °C [$\varepsilon(^{44}Ca/^{40}Ca) = 0.55 \times 10^{-2}$ and $\varepsilon(^{48}Ca/^{40}Ca) = 1.21 \times 10^{-2}$].

The value of ε determined at 20 °C is by far the greatest known calcium isotope separation effect in an equilibrium step on an ion exchanger; the ε values obtained on sulfonic acid resin exchangers are up to two orders of magnitude smaller[9]. Only the isotopic separation reported for $^{44}Ca/^{40}Ca$ in an extraction system with a crown ether (*i.e.* $\varepsilon = 0.4 \times 10^{-2}$) is comparable[3]. On average $\varepsilon(^{48}Ca/^{40}Ca)$ is greater than $\varepsilon(^{44}Ca/^{40}Ca)$ by a factor of 1.8 (Table 1). This corresponds to the ratio of the relative mass difference (8/48):(4/44) = 1.83. If the logarithm of the K_c values [eq. (1)] is plotted against the reciprocal absolute temperature, then all the values lie on a van't Hoff reaction isobar whose slope gives $\Delta H(^{44}Ca/^{40}Ca) = 46$ J/mol and $\Delta H(^{48}Ca/^{40}Ca) = 87$ J/mol. The few ΔH values known so far for isotope exchange reactions on cation or anion exchangers in aqueous systems are smaller: $\Delta H(^{7}Li/^{6}Li) = -9.6$ J/mol[7b]; $\Delta H(^{37}Cl/^{35}Cl) = -5.4$ J/mol[7a].

The separation results demonstrate for the first time that the chemical pre-enrichment of heavy calcium isotopes can be realized in amounts of interest on a technical scale. For example, use of the above mentioned solvent mixture in the elution makes isolation of the enriched material a practicable proposition; the linearity between isotope separation and amount of substance eluted (Fig. 1) enables isolation of larger amounts of enriched isotope.

In a preliminary experiment, we have been able to isolate 30 mg of calcium in which ^{48}Ca was enriched by 3.3% at 0 °C from 210 mg of calcium having a natural isotope abundance[10].

Acetaldehyde as Main Product of the Oxidation of Ethylene Oxide on a Silver Catalyst[**]

By *Günther Prauser, Guillermo Fischer*, and *Kurt Dialer*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

In the direct oxidation of ethylene to ethylene oxide on silver catalysts acetaldehyde is formed at most in traces. In the absence of oxygen or with substoichiometric amounts of oxygen, however, ethylene oxide also partially reacts on silver to give acetaldehyde[1,2]; thus, *e.g.*, for complete conversion of ethylene oxide at 200 °C without oxygen in the gas phase a product ratio of $CH_3CHO : C_2H_4 : CO_2 = 3 : 1 : 1.2$ was found[2]. In the presence of an excess of oxygen at 200–320 °C, on the other hand, only the total oxidation of ethylene oxide to CO_2 and H_2O has been observed[1,3].

We have studied the kinetics of the oxidation of ethylene oxide in a continuously circulating reactor between 190 and 300 °C with the aim of determining separately the undesired combustion of ethylene oxide in the direct oxidation of ethylene, and thus to be able to formulate a model for the overall reaction. To our amazement we found that acetaldehyde is formed as main product with a selectivity of up to 70% on an unmodified silver catalyst[4], even in the presence of a very large excess of oxygen (molar ratio $O_2 : C_2H_4O$ up to 50:1). In addition, CO_2 and H_2O were formed together with further by-products, of which acetic acid and crotonaldehyde were identified.

As example, Figure 1 shows a plot of the yields of acetaldehyde (Y_{AcH}) and carbon dioxide (Y_{CO_2}), as well as the yield of the remaining by-products (Y_{BP}) calculated from ($C_{EO} - Y_{AcH} - Y_{CO_2}$), over the modified residence time τ^* (where C_{EO} = ethylene oxide conversion). In this series of experiments the reaction temperature was 270 °C.

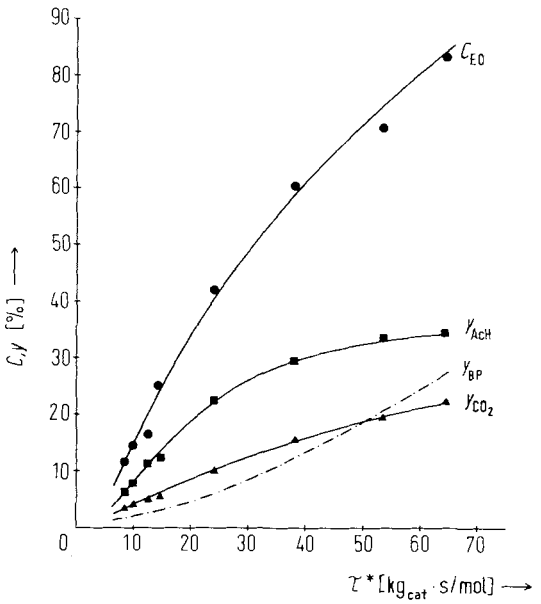

Fig. 1. Dependence of the ethylene oxide conversion (C_{EO}) and the product yields (Y) on the modified residence time τ^*. $T_R = 270$ °C, $p_R = 1.3$ bar, $x^a_{EO} = 0.0223$, $x^a_{O_2} = 0.20$, rest He.

[**] This work was supported by the Max-Buchner-Forschungsstiftung.

The selectivity referred to carbon dioxide $S_{CO_2} = Y_{CO_2}/C_{EO}$ for temperatures $\leq 270\,^{\circ}C$ over a wide range of residence time is about 27%, independent of the conversion C_{EO} and of the concentration of the ethylene oxide feed. In contrast, the selectivity of the acetaldehyde $S_{AcH} = Y_{AcH}/C_{EO}$ decreases with increasing reaction temperature, increasing residence time, and increasing ethylene oxide conversion. From this behavior it can be concluded that the isomerization of the ethylene oxide runs parallel to its total oxidation and that acetaldehyde undergoes very little, if any, further combustion to CO_2 and H_2O at $T_R \leq 270\,^{\circ}C$, but reacts in a secondary reaction, predominantly to give acetic acid.

As investigations on the carrier and on mixtures of carrier and silver catalyst ($A_{spec} = 0.92\ m^2/g$) at a dilution ratio of 5:1 have shown, under the chosen reaction conditions an isomerization of ethylene oxide on the carrier material α-Al_2O_3 ($A_{spec} = 0.06\ m^2/g$) can be ruled out. Similarly, an isomerization in the gas phase during recirculation in the reactor can also be considered as unlikely. Acetaldehyde was also the main product obtained in a simple flow-through tubular reactor, even at *ca.* 300 °C and brief contact times[5].

The observed isomerization is apparently limited to unmodified silver catalysts; for example it does not take place on barium-containing catalysts[4]. Moreover, it is decisive that the ethylene oxide is re-purified by passage over silver at *ca.* 50 °C before being fed into the reactor, whereby the removal of halogen compounds would appear to play an important role.

In parallel investigations on the partial oxidation of ethylene to ethylene oxide on the same catalyst only traces of acetaldehyde were found. It can therefore be assumed that ethylene, and most likely also halogen compounds, block the sites on the surface of the catalyst where ethylene oxide isomerizes. Experience gained with oxygen-free systems would suggest the assumption of silver sites which are not covered by oxygen. Presumably, such sites are met with on unmodified silver catalysts even at high oxygen concentrations.

The demonstrated influence of ethylene on the isomerization of ethylene oxide clearly indicates that the isolated kinetic investigation of a heterogeneous catalytic partial reaction—in this case the oxidation of ethylene oxide—can lead to false conclusions regarding the relevance of this partial reaction for the overall reaction.

New Aspects of the Reaction of Difluorosulfur Imides with Fluorine[**]

By *Ingo Stahl, Rüdiger Mews*, and *Oskar Glemser*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

In fluorination reactions the product composition often depends very strongly on the reaction conditions. Thus difluorosulfur imides react with fluorine in metal autoclaves[1] (catalysis by metal fluorides) according to

$$RN{=}SF_2 + F_2 \longrightarrow RN(F){-}SF_2{-}NR{-}NR(F){-}SF_5 + \cdots$$
$$\xrightarrow{CsF} RN(F){-}SF_5 + \cdots$$

$R = CF_3, C_2F_5$

In pyrex vessels, on the other hand, reaction takes place at room temperature only on irradiation with UV light:

$$\underset{(1)}{F_5C_2N{=}SF_2} + F_2 \xrightarrow{h\nu} \underset{(2)}{\{F_5C_2NSF_3^{\oplus}\}} \rightarrow \underset{(3)}{F_5C_2N{=}SF_4} \rightarrow \underset{(4)}{F_5C_2N(F){-}SF_5}$$

$$\downarrow$$

$$\underset{(5)}{F_5C_2N{=}SF_2{-}NC_2F_5} \rightarrow \underset{(6)}{F_5C_2N(F){-}SF_4{-}NC_2F_5}$$

In this case, the simultaneous occurrence of *(3)* and *(5)* is observed IR spectroscopically—from which it can be concluded that a common intermediate (such as *(2)*) is formed. These primary products are slowly further fluorinated. If, however, the irradiation is interrupted at the correct time one obtains maximum yields of 30% of *(3)*, which is only difficultly accessible *via* alternative routes.

Addition of a further molecule of F_2 to the SN double bond of *(3)* affords the well-known[1] *N*-fluoramine *(4)*. The fluorination sequence *(1)*→*(3)*→*(4)* corresponds to that of $O{=}SF_2$ *via* $O{=}SF_4$ to $FO{-}SF_5$[2].

With the reaction step *(5)*→*(6)* it was possible for the first time to convert a tetracoordinated sulfur(VI) compound into a hexacoordinated one by F_2-addition. This addition leads stereospecifically to *trans-(6)*. An analogous reaction in the SO system to give bishypofluorites $FO{-}SF_4{-}OF$ is unknown.

Pentacoordinated tetrafluorosulfur imides such as *(3)* are of special interest on account of their stereochemistry[3]; owing to their reactivity (similar to that of $O{=}SF_4$) they should also be useful as synthetic building blocks. The hexacoordinated *N*-fluoramines *(4)* and *(6)*, on the other hand, are chemically very resistant, *e.g.* they are not attacked by water at room temperature.

Experimental

A mixture of *(1)* (100 torr) and F_2 (100—400 torr) in a 2 l pyrex flask is irradiated with a Hg high-pressure lamp (Philips 500 W; distance ≈1 cm). The duration of irradiation is dependent upon the amount of F_2, the desired products, and

^{19}F-NMR data (δ values, coupling constants in Hz) and boiling points of the compounds *(3)*, *(4)* and *(6)*.

BOOK REVIEWS

Polarography of Molecules of Biological Significance. Edited by *W. F. Smyth.* Academic Press, New York 1979. xix, 326 pages, bound, $ 47.50.

In ten chapters, written by twelve authors, this book deals with the more recent developments in polarographic (voltammetric) techniques in the field of biological analysis, with particular emphasis on the period since about 1965. Two introductory chapters serve as a brief outline of the principles and rudiments of general and special working techniques, and indicate how the best possible method can be selected. Brief reference is made to the possible applications of computer-assisted electrochemical analysis, where substantial improvements have taken place on the instrumental side. The main part of the book is devoted to applications in pharmacy, pharmacology, medical research, and in environmental research. The bibliography lists sometimes very diverse processes for the determination of a wide variety of medically, pharmacologically, or environmentally toxicologically interesting compounds, the arrangement of the references being designed for easy orientation. The greatest attention is given to the determination of drugs and their metabolites.

The book provides the analyst familiar with electrochemical working methods with a great deal of inspiration and would be difficult to beat as a reference for rapid orientation on more recent work.

Gerhard Eisenbrand [NB 503 IE]

Foundations of Molecular Pharmacology, Vol. 1 and 2. By *J. B. Stenlake.* The Athlone Press, London 1979. xi, 936 pages, bound, £ 36.00 (Vol. 1). xii, 318 pages, bound, £ 18.50 (Vol. 2).

The first of the two volumes of this work concentrates on the physical and chemical properties of medical substances, pharmaceutical additives, and cell components. As the author explains in the introduction, the contents originate from lectures and courses for students of pharmaceutical and medical chemistry. Essentially, the subject is organic chemistry, presented in a systematic arrangement, with brief references to the relationships with biology and medicine. The descriptions of biologically important reaction prerequisites, structural characteristics, and biochemical reaction pathways are particularly valuable. After some general sections on the types of chemical bonds, on radicals, and on other rudiments of chemistry, all the essential classes of organic compounds are dealt with in 21 chapters, ranging from alkanes through alcohols, acids, phenols, amines and amino acids to carbohydrates, vitamins, and heterocyclics of special biological significance (pyridines, purines, and nucleic acids).

The work provides a compressed and detailed summary of biologically and medically important compounds and compound classes that can serve as a textbook and course book for students of pharmaceutical chemistry. For the organic chemist it can also act as a source of rapid information in the field of medicinal chemistry. In this sense the subtitle "Medicinal and Pharmaceutical Chemistry" is in fact more appropriate than the main title.

For pharmacologists, especially those concerned with the basics of the interactions between chemical substances and biological substrates, the second volume, subtitled "The Chemical Basis of Drug Action" is a suitable textbook and source of information. The pharmaceutical chemist will find here information on substance-receptor interactions, on biochemical bonding, on the biological significance of stereochemistry and on the fundamentals of pharmacokinetics and drug metabolism.

The value of the book lies in the fact that it offers the newcomer to the field of drug research, particularly the pharmaceutical chemist, a comprehensive and systematic compendium of knowledge clarified further by many schemes, tables, and figures. The advanced student can rapidly extract information on less familiar fields. A comprehensive bibliography is provided for going further into the subject. The book will prove a valuable aid in the teaching of pharmaceutical chemistry.

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Trivialnamenkartei. 6th supplementary instalment. 1024 additional cards. Verlag Chemie, Weinheim 1979. DM 268.00.

Angewandte Klebtechnik. By *G. Fauner* and *W. Endlich.* Carl Hanser Verlag, München 1979. 227 pp., bound, DM 68.00.—ISBN 3-446-12767-4

Annual Reports on Fermentation Processes, Vol. 3. Edited by *D. Perlman.* Academic Press, New York 1979. xiv, 346 pp., sewed, $ 22.00.—ISBN 0-12-040303-X

Huminstoffe. By *W. Ziechmann.* Verlag Chemie, Weinheim 1980. xi, 408 pp., sewed, DM 95.00.—ISBN 3-527-25839-6

Phase Transfer Catalysis. By *E. V. Dehmlow* and *S. S. Dehmlow.* Verlag Chemie, Weinheim 1980. xi, 316 pp., bound, DM 138.00.—ISBN 3-527-25820-5

Molybdenum Chemistry of Biological Significance. Edited by *W. E. Newton* and *S. Otsuka.* Pergamon Press, New York 1980. x, 425 pp., bound, $ 39.50.—ISBN 0-306-40352-8

Electronic Structure and Magnetism of Inorganic Compounds, Vol. 6. Senior Reporter: *P. Day.* The Chemical Society, London 1980. x, 313 pp., bound, DM 132.30.—ISBN 0-85186-610-7.—A volume of the series "Specialist Periodical Reports"

General and Synthetic Methods, Vol. 3. Senior Reporter: *G. Pattenden.* The Chemical Society, London 1980. xiv, 382 pp., bound, DM 156.80.—ISBN 0-85186-730-8.—A volume of the series "Specialist Periodical Reports"

Carbohydrate Chemistry, Vol. 11. Senior Reporter: *J. S. Brimacombe.* The Chemical Society, London 1979. xv, 546 pp., bound, DM 191.10.—ISBN 0-85186-102-4.—A volume of the series "Specialist Periodical Reports"

Dynamics of Synergetic Systems. Edited by *H. Haken.* Springer-Verlag, Berlin 1980. v, 271 pp., bound, DM 68.00.—ISBN 3-540-09918-2

Chemistry for the Engineering and Applied Sciences. By *W. Steedman, R. B. Snadden,* and *I. H. Anderson.* Pergamon Press, Oxford 1980. viii, 449 pp., sewn, $ 17.95.—ISBN 0-08-022852-6

Topics in Current Physics. Theory of Chemisorption. Edited by *J. R. Smith.* Springer-Verlag, Berlin 1980. xi, 240 pp., bound, DM 58.00.—ISBN 3-540-09891-7

Advances in Heterocyclic Chemistry. Vol. 25. Edited by *A. R. Katritzky* and *A. J. Boulton.* Academic Press, New York 1979. vi, 397 pp., bound, $ 41.00.—ISBN 0-12-020625-0

Reactive Intermediates, Vol. 1. Edited by *R. A. Abramovitch.* Plenum Press, New York 1980. xiii, 522 pp., bound, $ 49.50.—ISBN 0-306-40220-3

Advances in Chemical Physics, Vol. XL. Edited by *I. Prigogine* and *St. A. Rice.* John Wiley & Sons, New York 1979. 504 pp., bound, £ 27.55.—ISBN 0-471-03884-9

Synthetic Aspects of Biologically Active Cyclic Peptides. Gramicidin S and Tyrocidines. By *N. Izumiya, T. Kato, H. Aoyagi, M. Waki,* and *M. Kondo.* Kodansha Ltd., Tokio 1979/Halsted Press, New York 1979. xii, 166 pp., bound, £ 18.25.—ISBN 0-470-26863-8

Springer Series in Chemical Physics. Vol. 9. Secondary Ion Mass Spectrometry SIMS II. Edited by *A. Benninghoven, C. A. Evans, Jr., R. A. Powell, R. Shimizu,* and *H. A. Storms.* Springer-Verlag, Berlin 1979. xiii, 298 pp., bound, DM 58.00.—ISBN 3-540-09843-7

Organic Reaction Mechanisms. By *A. C. Knipe* and *W. E. Watts.* John Wiley & Sons, Chichester 1980. 719 pp., bound, £ 50.00.—ISBN 0-471-27613-8

Biochemie. By *K. Jungermann* and *H. Möhler.* Springer-Verlag, Berlin 1980. xii, 733 pp., bound, DM 98.00.—ISBN 3-540-09302-8

Biochemie. Übungen und Prüfungsfragen. By *K. Jungermann* and *H. Möhler.* Springer-Verlag, Berlin 1980. xi, 229 pp., sewn, DM 19.80.—ISBN 3-540-09300-1

Physiologische Chemie. By *G. Löffler, P. E. Petrides, L. Weiss,* and *H. A. Harper.* Springer-Verlag, Berlin 1979. xvi, 940 pp., bound, DM 98.00.—ISBN 3-540-09332-X

Angewandte chemische Thermodynamik und Thermoanalytik. Edited by *E. Marti, H. R. Oswald,* and *H. G. Wiedemann,* Birkhäuser Verlag, Basel 1979. viii, 385 pp., bound, DM 79.00.—ISBN 3-7643-1142-8

The Kinetic and Mechanistic Evaluation of NMR Spectra

New analytical methods (18)

By Gerhard Binsch and Horst Kessler[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In addition to the static parameters of the chemical shifts and coupling constants, which serve as a source of knowledge for molecular structure and stereochemistry, an NMR spectrum can frequently furnish dynamic quantities characterizing relaxation and exchange phenomena. The information about nuclear switching processes has proved to be particularly useful in practice for the detection of internal molecular motions and for the estimation or determination of the corresponding energy barriers. A plethora of studies of this nature has in the past been performed on simple proton spectra. Methodological developments of recent years have led to a significant reduction of the effort required for the quantitative dynamic evaluation of NMR spectra arising from complex spin systems or involving other nuclei. In many cases it has, moreover, become possible to extract detailed mechanistic information inaccessible by other means. The practical execution of such analyses will be explained and illustrated by a selected number of applications.

1. Introduction

For spectroscopic investigations in the ultraviolet, visible and infrared domains only thermal light sources had been available until quite recently. In contrast, coherent electromagnetic radiation has been employed in magnetic resonance from the very outset. This peculiarity offers the unique possibility of quantitative studies of dynamic processes at the molecular level, notwithstanding the fact that the measurements themselves are performed on samples in thermodynamic equilibrium. The coherence of the radiation imposes a phase relationship on the quantum-mechanical state functions of the microscopic subsystems, giving rise to a macroscopic observable by constructive interference. On the other hand, the random motions of the molecules in fluids and gases tend to reestablish the statistical phase distribution. The spectroscopy devoted to this interplay is referred to as dynamic spectroscopy[1], to distinguish it from the conventional kind in which one is only concerned with the quantum statics of the relevant energy levels and the transition probabilities between them. For most applications it is appropriate to differentiate further between relaxation and exchange processes in regard to the physical origins of the observed effects. The terminology of "dynamic NMR" or "DNMR" spectroscopy suggested 12 years ago[2] has come to be generally adopted, especially for the study of exchange phenom-

ena, and has recently been canonized by the title of a monograph[3].

The potential of DNMR spectroscopy for chemical applications was recognized at an early date[4-8] and has subsequently been exploited so frequently that the typical phenomena of exchange broadening and coalescence of NMR lines are nowadays familiar to every chemist. Already at the qualitative level the method can be very useful in practice. As a reminder we cite the proof of fluxionality for molecules such as bullvalene. In the simplest and frequently encountered case of two equally intense singlets merging in a single broad band on increase of the exchange rate it is, furthermore, trivially easy to perform a quantitative analysis applicable to the singular temperature T_c of the coalescence point. One only needs the chemical shift difference Δ of the singlets in frequency units. On conversion to the rate constant k of the exchange by means of the formula $k = 2^{-1/2}\pi\Delta$ and substitution of k and T_c into the Eyring equation one obtains the free energy of activation $\Delta G_c^{\ddagger}$ of the underlying chemical process at the coalescence temperature with a typical accuracy of 0.2 kcal mol^{-1}. A graphical procedure[9] may be used for the corresponding analysis involving two singlets of unequal intensity. Even when one is dealing with a binary exchange problem involving first-order multiplets, for which a coalescence "point" can naturally no longer be defined, the mechanical application of the cited formula to the vaguely specifiable "temperature of maximum broadening" permits the estimation of a $\Delta G^{\ddagger}$ value that deviates from the true value by not more than 1 kcal mol^{-1}. Another very convenient method for determining a rate constant, which furthermore has the advantage of remaining valid in more complicated cases and which does not even require the knowledge of a chemical shift difference, is based on measurements of the incipient line broadening. After subtraction of the natural linewidth the resulting number (in Hz) yields the k value directly on multiplication by π.

Some 10 years ago we wrote a couple of review articles[2,10] on the applications of DNMR spectroscopy to conformational interconversions, atomic inversions, ring reversals and valence isomerizations, for which the overwhelming majority of the free energies of activation had been calculated or estimated in one of these simple ways. Much of the dynamic information in the most recent literature[3,11-14] still stems from elementary methods of analysis. With the latest advances in methodology it is now feasible, however, to treat complex systems quantitatively on a routine basis, and thus to obtain detailed mechanistic information frequently not accessible from simple systems. In this article we propose to present these developments to a chemical readership and to subject the time-honored and still widely used methods to a critical scrutiny from a modern vantage point.

An explicit bandshape analysis is advisable especially if there are several nuclei in different magnetic environments participating in the exchange, if the spectra exhibit strong spin coupling or if one is dealing with some subtle mechanistic issue. With certain provisos this already applies to the simple binary exchange problems alluded to above if it is desired to determine rate constants at a series of temperatures in order to dissect the free energies of activation into their enthalpic and entropic components $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. The theory of exchange-broadened NMR spectra is highly developed in a formal as well as computational sense, but is not our primary concern in this article. We merely cite some recent expositions[15-17] and confine ourselves to the explanation of those concepts indispensable also for the practitioner. The emphasis of the subsequent discussion will be on the general analysis techniques and the applications of the numerical methods. It will be unavoidable, however, to devote some space to the discussion of those specific experimental and computational aspects through whose frequent neglect in the past DNMR spectroscopy has acquired the reputation of being a quantitatively unreliable technique. For the selection of examples we have preferentially taken recourse to results from our own laboratories.

2. Exchange Types and Spin Systems

DNMR spectroscopy is equally suited for the study of intermolecular as well as intramolecular chemical processes in which a magnetic nucleus exchanges its position with another of the same kind or migrates into a new magnetic environment. Even in the latter case it is still appropriate to speak of an "exchange". As mentioned in the Introduction, DNMR measurements are performed on macroscopic samples in thermodynamic equilibrium. The maintenance of the equilibrium is evidently only guaranteed if there is a concurrent countermigration of a nucleus of the same species from another molecule or from another isomer of the same molecule. Although similar NMR investigations can in principle also be performed on systems suffering a macroscopic change during measurement, the required generalization of the theory has been worked out only very recently[18] and applications[18] have not yet progressed very far.

Intermolecular chemical processes amenable to a DNMR investigation include proton jumps between acidic molecules of the same or of different kinds, ligand exchanges involving inorganic complexes or organometallic compounds, the dissociation of covalent compounds into ions or the reverse process of ion recombination, and those exchange processes of particular importance for biochemistry in which a small substrate molecule or an inorganic ion is in equilibrium between its free form in aqueous solution and its protein-bound state.

Far more frequently still, DNMR spectroscopy has been applied to the problem of the internal mobility of molecules, on which we shall therefore focus our main attention in the following discussion. If the elementary step only leads to a permutation of the nuclear sites, the corresponding chemical process is called a topomerization[19]. The same spectral type is also realized for enantiomerizations, provided that the compounds are investigated in achiral solvents, as is usually the case. Such enantiomerizations become detectable through the presence of prochiral groups (*e.g.* $-CX_2Y$) in the molecule, since the elementary act exchanges the diastereotopic positions of the nuclei X[20]. In diastereomerizations and constitutional isomerizations, on the other hand, each spin is transported to a new magnetic environment. A single spin thus suffices for the identification of the latter exchange type. A consistent exploitation of this differentiability of molecular processes with due regard to symmetry considerations has, for instance, permitted the mechanistic distinction be-

tween inversion and rotation for *syn-anti* isomerizations of imines[21].

It may of course also happen that inter- and intramolecular exchange processes proceed simultaneously[22].

2.1. Computer Programs

The complete bandshape analysis of an exchange-broadened NMR spectrum is not practicable economically without a computer, although a desk calculator will do for the simplest cases. Pertinent computer programs exist in large numbers (at least 50). One has to distinguish between two basic types:

— The NMR computer programs for spectral synthesis—commonly, albeit somewhat inappropriately, called simulation—only produce a theoretical trial spectrum from given spectral parameters (chemical shifts, coupling constants, natural linewidths, populations, exchange rate constants) on the basis of the specified model (exchange type, spin system, permutational mechanism), usually in the form of a computer-drawn tracing. It is then the task of the user to modify the parameters by trial and error until a visual comparison of the newly synthesized curve shows satisfactory agreement with the experimental spectrum.

— With the analysis programs proper, on the other hand, the optimum fit is calculated internally by an iterative process. Their applicability requires, of course, that in addition to the starting parameters the experimental spectrum itself is supplied to the computer in a suitable fashion. Hand digitization is easily possible for strongly exchange-broadened spectra, but in the presence of comparatively sharp lines becomes not only tedious but, above all, too inaccurate. Some kind of automated procedure is in any case to be preferred. A convenient method, for example, consists in copying the raw spectral data, initially recorded to a magnetic disk as commonly practiced, to a magnetic tape which can then serve as an input medium for a large and efficient number cruncher. Regrettably, many laboratories are at present still lacking the necessary equipment.

Most computer programs had originally been designed for special exchange types and simple spin systems and are now principally of historical interest only, since their tasks can also be performed by general programs. There are about a dozen synthesis programs of the latter type. Although the majority of them has not been published, some have been distributed on a personal basis; from acknowledgments and footnotes in relevant papers published in the last decade it can be gleaned that this must have been the case especially for the versions developed by *M. Saunders* (Yale University) and *G. M. Whitesides* (Massachusetts Institute of Technology). Two published synthesis programs for the intramolecular exchange of coupled spin systems[23,24] are available from the organization of the Quantum Chemistry Program Exchange at Indiana University (Bloomington, Indiana 47401, USA).

The latter versions are now also rendered obsolete by recent developments. The analysis program DNMR5[25] emerged from a systematic comparison study[26] of a variety of minimization algorithms and is characterized by high efficiency and absolute stability of the iteration procedure; in other words, divergence is logically impossible by design. This program is also capable of utilizing raw spectral data taken directly from the spectrometer and of performing a complete error analysis on the results. The analysis of exchange-broadened NMR spectra has thereby been automated to a large extent. The modular program structure enables the nonspecialist user to adapt the program by the simple redimensioning of arrays or the incorporation of mechanistic constraints to those intramolecular exchange problems which have not been provided for as standard features.

There is no difference in the computational treatment between intra- and intermolecular exchange if spin coupling is absent from the spectra or if the fine structure has been eliminated by decoupling. This is no longer true, however, for coupled spin systems. Although the theory has long been known also for the general intermolecular case and minor discrepancies in the original formulations have recently been eradicated[17,27], it appears that corresponding computer programs have so far been written only for special exchange types. In this area the potential user might therefore still find himself confronted with the necessity of having to invest some programming work of his own.

2.2. Exchange between Singlets

The simplest case is realized if the exchanging nuclei or groups of nuclei give rise to two singlets of equal or unequal intensity in the NMR spectrum below a certain temperature. From a purely computational standpoint the analysis of the spectra covering the entire temperature range of exchange-broadening presents no difficulty even if the singlets exhibit different natural linewidths. An iterative calculation using the DNMR5 program consumes only a fraction of a second per spectrum on a modern computer, starting for example from 10000 spectral points automatically recorded on a spectrometer and transmitted to a computing facility. That does not answer the question, however, which of the parameters can or should be determined iteratively, and also does not provide any guarantee for the quality of the dynamic results. We shall return to these problems later.

For n exchanging singlets there can be up to $n(n-1)/2$ independent first-order or pseudo-first-order rate constants k_{ij}. The corresponding constants k_{ji} of the reverse reactions are fixed by the relative populations p of the molecular species through the relationships $p_i k_{ij} = p_j k_{ji}$. (Note that in some programs the term "population" is used in a different, purely computational sense for the specification of the number of nuclei per magnetic environment. In the presence of experimental artifacts, such as differential nuclear Overhauser effects in ^{13}C-DNMR spectroscopy, these computational quantities have moreover to be chosen such as to reproduce the actually observed signal intensities.) The full kinetic complexity is indeed occasionally observed in intermolecular exchange, but is atypical for the intramolecular case. The chemical constraints customarily admit of only few possibilities and the DNMR spectra can then lead to valuable mechanistic conclusions. In the extreme case there remains only a single possibility whose mechanism is known beforehand.

A fascinating and frequently investigated example is provided by bullvalene *(1)*, in which a sequence of Cope rearrangements ultimately renders all nuclei of the same species equivalent. Only the $\{^1H\}$-noise-decoupled ^{13}C-PFT-NMR

spectra[28-30] are of interest in the present context. At low temperature one observes four singlets, for which one expects the idealized intensity ratios of 3:3:3:1 in the absence of differential nuclear Overhauser and/or longitudinal relaxation effects. Dynamic spectra for two separate temperature ranges are shown in Figures 1 and 2[29]. In the intermediate region

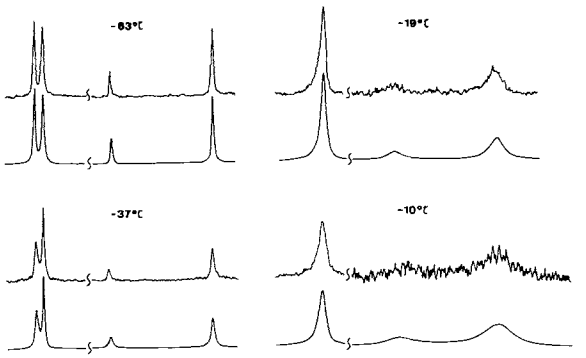

Fig. 1. Observed and computed ^{13}C-DNMR spectra of bullvalene *(1)* at slow exchange [29].

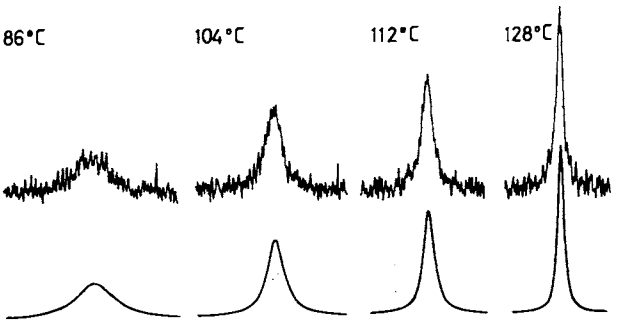
the spectra are so broad that they remain buried in the noise even on accumulation of 6000 transients[29]. By extending the acquisition period to 24 hours or more *Oth et al.*[30] succeeded, however, in obtaining spectra of superb quality also in this domain.



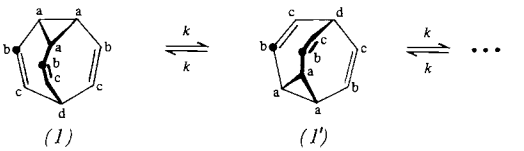


Fig. 2. Observed and computed ^{13}C-DNMR spectra of bullvalene *(1)* at fast exchange [29].

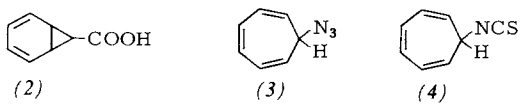
For the calculations one needs the exchange matrix $\mathbf{X}$[15,31], which in the present case of a constitutional topomerization[19] can be written as a product $\mathbf{X}=k\mathbf{Q}$ of a single rate constant k pertinent to the elementary chemical step *(1)*→*(1')*, and a statistical matrix $\mathbf{Q}$. A foolproof method consists in first figuring the off-diagonal elements column-wise. An element q_{ij} represents the probability that a jump out of site j of formula *(1)* ends up in site i of formula *(1')*. Finally the column sums are entered with a negative sign in the diagonal positions. Figure 3 shows the result for the idealized intensity ratios. The indicated procedure pertains to the theoretical standard formulation[15] of exchange-broadened NMR spectra. The nonexpert should be aware that some computer programs are based on classical precursors of the general quantum mechanical theory[32,33] and require instead the transpose $\mathbf{Q}^T$. We also mention that in the iterative program DNMR5[25] only symmetric $\mathbf{X}$ matrices are used internally. They are automatically generated from the unsymmetric standard form of the input by means of a similarity transformation[34]; with this trick the numerical computations can be speeded up considerably[34].

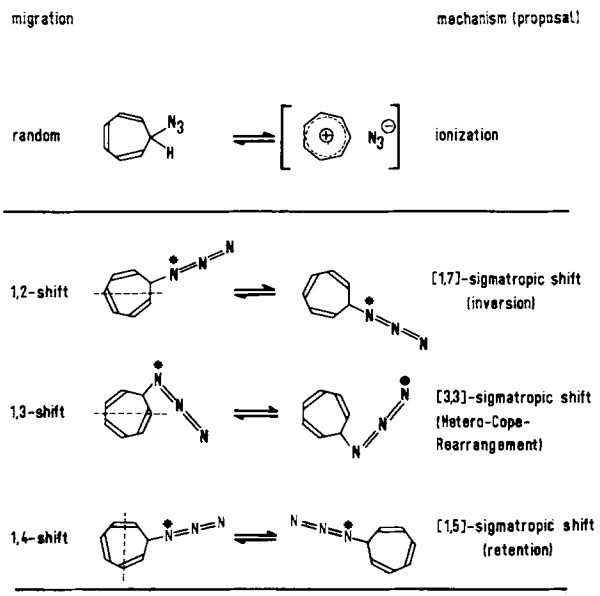
	a	b	c	d
a	−1	0	$\frac{2}{3}$	1
b	0	$-\frac{1}{3}$	$\frac{1}{3}$	0
c	$\frac{2}{3}$	$\frac{1}{3}$	−1	0
d	$\frac{1}{3}$	0	0	−1

Fig. 3. Statistical $\mathbf{Q}$ matrix for bullvalene *(1)* in the standard formulation.



A quantitative bandshape analysis requires in addition that the signal assignments be known. The correct assignment may on first sight not be obvious for the closely spaced singlets of the olefinic ^{13}C nuclei at low fields (Fig. 1), but the missing piece of information is immediately supplied by the spectrum at −37 °C. A straightforward perturbation-theoretical argument leads to the conclusion that the effect of the off-diagonal $\mathbf{X}$ matrix elements can be neglected as long as the lines have not yet started to run together.

The diagonal elements X_{ii} then play the role of an effective transverse relaxation time T_2^{eff}, which according to theory[15] appears as $-1/T_2^{\text{eff}}$ on the diagonal and is related to the linewidth W by the formula $T_2^{\text{eff}}=(\pi W)^{-1}$. Inspection of the $\mathbf{Q}$ matrix (Fig. 3) reveals that the exchange contribution to the incipient broadening of the b signal is smaller by a factor of 3 than for the other singlets. Alternatively, it becomes clear also on examination of the structural formulas that except for two of the three olefinic carbons in the positions b of *(1)* all nuclei change places in the course of a single Cope rearrangement. In other words, with each rearrangement only 1/3 of the b spins depart from their sites, which manifests itself in a diminished broadening of the nonoverlapping b signal. The correct assignment can thus be established already on a qualitative basis. After subtraction of the natural linewidths the effect can be analyzed quantitatively as well, to a good approximation[30]. Of even greater importance in practice is the reverse application of this simple criterion to problems where the assignments are known from other arguments, but the exchange mechanism remains to be ascertained. In Section 5 we shall discuss the further techniques of saturation transfer and 2D spectroscopy, which in the case of exchanging singlets are also suited for obtaining mechanistic information without the necessity of an explicit bandshape calculation.



Selective line broadenings are of great practical importance also in a somewhat different context. In binary isomerizations M⇌N it may happen that the population p_N is insufficient for the direct NMR-spectroscopic detection of species N at low temperature, but still large enough to influence the lines of the major species M dynamically. The selective broadenings or sharpenings of the M lines as a function of temperature can then yield information about the nature of

the N form. With this elegant technique *Günther et al.*, for example, succeeded in adducing indirect evidence for bicyclic valence isomers of substituted cycloheptatrienes[35,36] and azepines[37]; for instance, the existence of the Buchner acid *(2)*, having remained elusive for decades, could in this way be established experimentally[35].

(2) *(3)* *(4)*

Tropylium azide *(3)* provides a pertinent example of an exchange for which the mechanism was not known beforehand. This case was discovered in the course of a systematic DNMR investigation of reversible dissociation processes[38-43] and was studied by dynamic ^1H, ^{13}C and ^{15}N spectroscopy and by the saturation transfer method[43]. In the polar solvent SO_2, *(3)* is found to be almost completely ionized at 203 K. On addition of $CDCl_3$ the covalent form can be detected as well. The ^{13}C-DNMR spectra of Figure 4 are in agreement with theoretical curves calculated on the basis of an azide migration proceeding through the symmetric ion pair. Dynamic effects can still be observed in less polar solvents such as CD_3CN, but the ionic species is no longer detectable and the DNMR spectra are at variance with a random azide migration. In contrast, the migration of the thiocyanate residue in tropylium isothiocyanate *(4)* remains statistical even in

Scheme 1.

Quantitative bandshape analyses were performed for the ^{13}C spectra of *(3)* and the ^1H spectra of $[^2H_6]$-*(3)* (Fig. 5); both agree in that for solutions in CD_3CN the selective 1,2-, 1,3- and 1,4-shifts participate to the extent of 30%, 60% and 10%, respectively, whereas there is no noticeable contribution from the intermolecular exchange through ions. In less

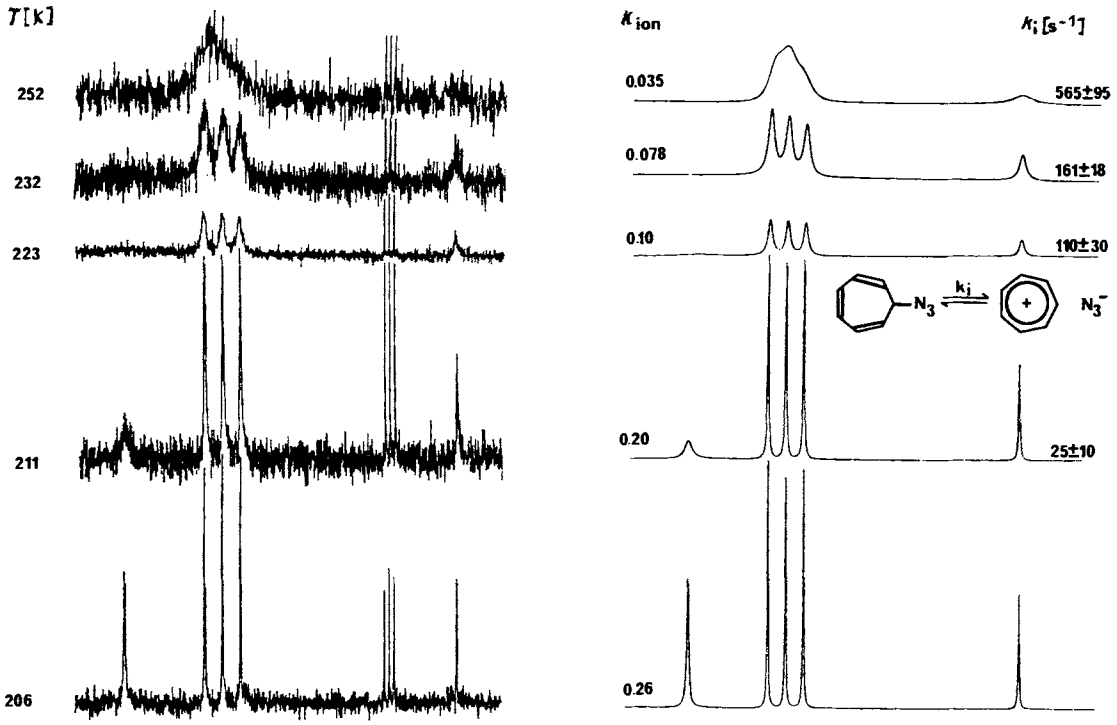


Fig. 4. Observed and computed ^{13}C-DNMR spectra of tropylium azide *(3)* in $SO_2/CDCl_3$ (4:5).

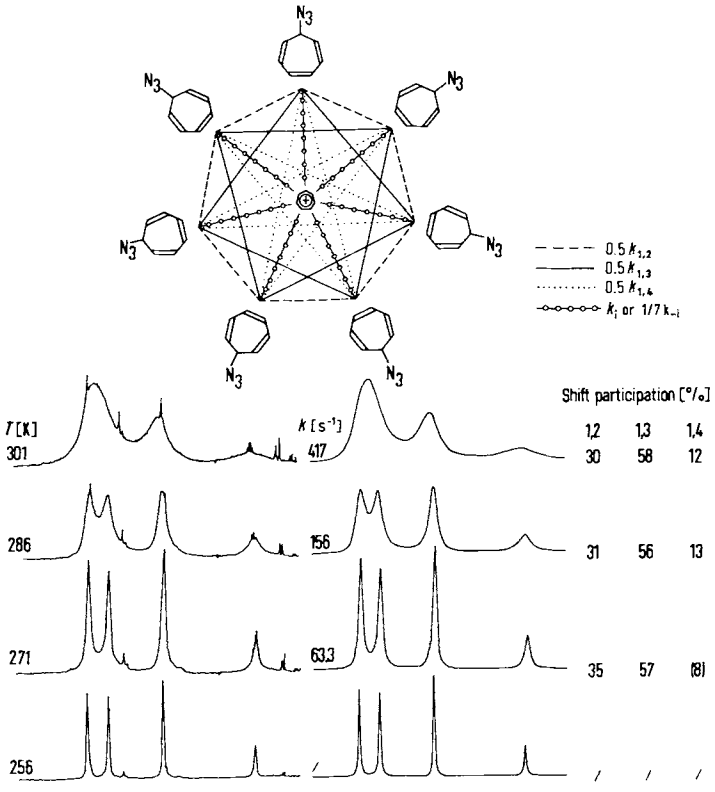
$CS_2/CDCl_3$ solution, where again only the covalent form can be observed[42]. A preferred 7→2 migration (1,3-shift) in *(3)* is proved by saturation transfer experiments at carefully selected temperatures (cf. Section 5). Calculations reveal, however, that none of the pure alternative mechanisms of Scheme 1 is compatible with the observed bandshapes. The exchange matrix must hence be formulated as a linear combination $\mathbf{X} = \sum_i k_i \mathbf{Q}_i$.

polar solvents ($CDCl_3$, THF) the percentage of the 1,3-shift increases still further at the expense of the other possibilities of migration. As a consequence of an isotope effect the isotopomers of $[^2H_6]$-*(3)* are no longer strictly isoenergetic and this has to be taken into account when setting up the **Q** matrices for $[^2H_6]$-*(3)*. As is the case for all mechanistic studies of this kind, DNMR spectroscopy can yield information only about permutational mechanisms; the "chemical" mecha-

nisms also listed in Scheme 1 are therefore to be regarded merely as palpable suggestions.



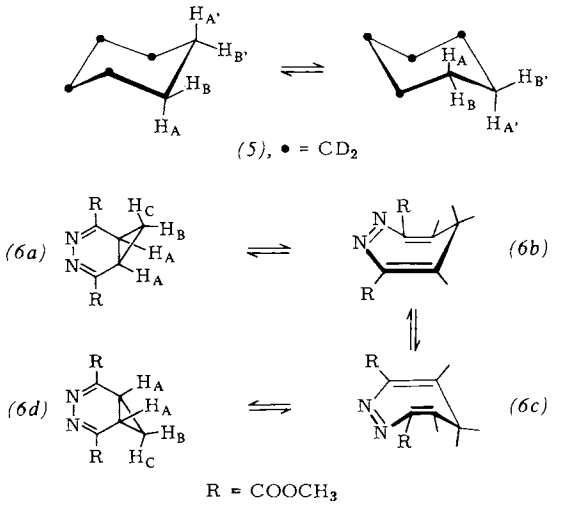


Fig. 5. Isomerization graph for tropylium azide *(3)* and observed and computed 270-MHz ^{1}H-DNMR spectra of $[^2H_6]$-*(3)* in CD_3CN.

2.3. Binary Exchange of Coupled Spin Systems

Spin-Spin coupling causes a quantum-mechanical mixing of the nuclear spin product functions and it is therefore no longer possible to assign a certain line in the spectrum to a single nucleus in the molecule. In the present context the kinetic process must always be formulated as an exchange between "nuclear configurations". If this is done correctly at input time for a computer calculation, the user need no longer concern himself with the details of the **X** matrices required for the general quantum-mechanical theory[15,32,33]; in programs of sufficient generality[23 25] the rate constants are automatically put into their correct locations by the computational algorithm.

The prototype is the mutual exchange AB⇌BA, and is represented by numerous examples in the literature. The remarks made at the beginning of Section 2.2 apply to this case accordingly.

Two slightly more complicated cases of mutual exchange are shown in Figures 6 and 7. In the first we are dealing with the well-known ring reversal of cyclohexane, exemplified by the $^1H\{^2H\}$-DNMR (type AA'BB'⇌BB'AA') spectra of the octadeuterio derivative *(5)*[44], in the second with the successive valence isomerizations and ring reversals of the diazanorcaradiene *(6)*[45,46].

Because of their high energy content the monocyclic forms *(6b)* and *(6c)* do not appear directly in the spectra and the dynamic effects therefore arise from an overall topomerization. It can be seen (Fig. 7) that the A spins are only indirectly involved in the $A_2BC⇌A_2CB$ exchange by virtue of their couplings to the B and C nuclei and that the relevant signals undergo very slight changes throughout the entire temperature range. At first sight it might thus appear as if the A spins merely represent a superfluous complication, which could for instance be chemically removed by specific deuteration, in which case the $^1H\{^2H\}$-spectra would collapse to a singlet on fast exchange. But apart from the fact that there is really no need for such a simplification from the point of view of computational expense, it will become apparent from arguments to be presented later that the presence of such "supernumerary" spins in the system can be distinctly advantageous (cf. Section 4.3).

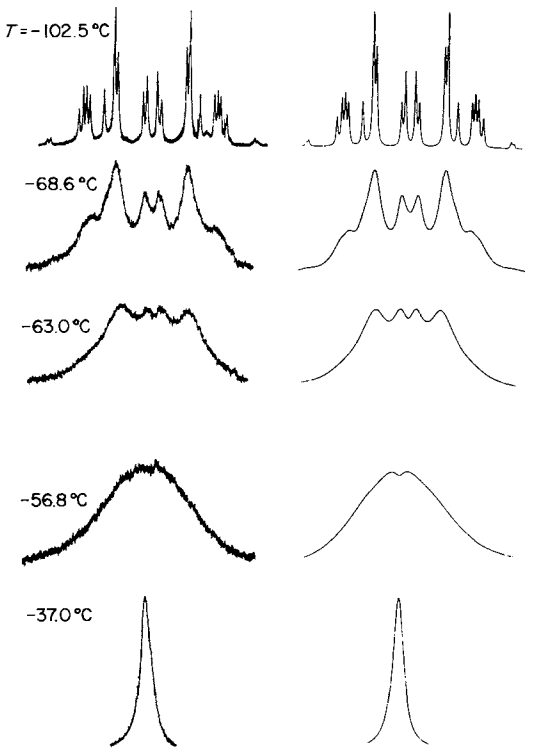

Fig. 6. Observed and computed $^1H\{^2H\}$-DNMR spectra of the octadeuteriocyclohexene *(5)*.

By studying nonmutual exchange processes one not only obtains the kinetic parameters, but in addition the thermodynamic quantities for the equilibria involved. The potential of

(7)

the ABC⇌DEF type for chemical applications has recently been subjected to a systematic scrutiny[44,47]. The nitrogen inversion in the aziridine derivative *(7)* may serve as an example.

At room temperature and below, one observes the superposed, but easily distinguishable static spectra of the separate diastereomers (Fig. 8), of which the *trans* form predominates. In the range from −40.3 to 23.2 °C the temperature dependence of the equilibrium constant could be determined directly by comparison with synthesized spectra. A further data point can be obtained by extrapolation from the averaged spectrum at 158.9 °C (Fig. 9). Since the latter still exhibits fine structure, characterized by three chemical shifts and

three coupling constants, there exists the possibility of checking this extrapolation for internal consistency in six different ways. Some of the dynamic spectra are displayed in Figure 10; the nature of these DNMR spectra is such as to permit the determination of an activation entropy for an atomic inversion with high precision (cf. Sections 4.2 and 4.3). It is encouraging that this number can be understood quantitatively on the basis of the principles of statistical thermodynamics[47].

A more complicated situation is encountered in the homotropylidene derivative *(8)*[48]. Chemically speaking, we are dealing with an overall topomerization, again passing through a sequence of valence isomerizations and ring reversals (Fig. 11), but if one neglects the small cross-ring cou-

(8)

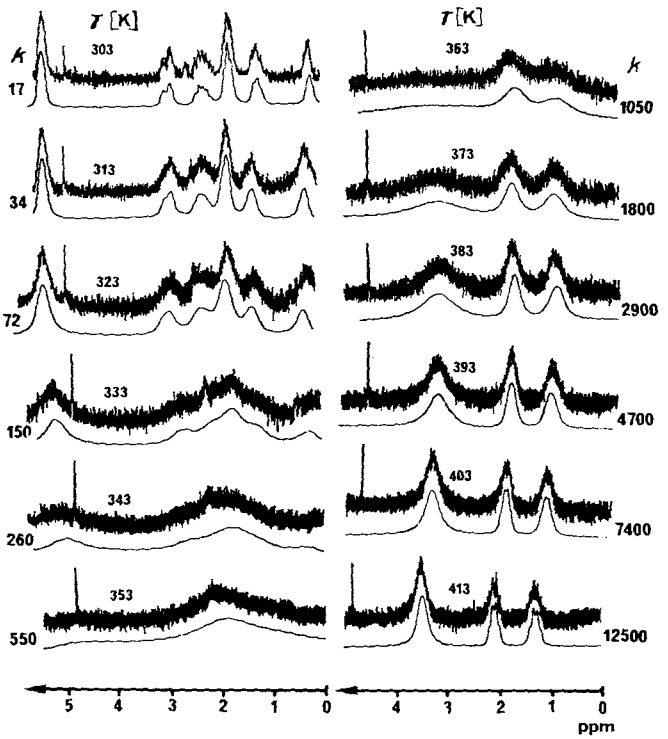

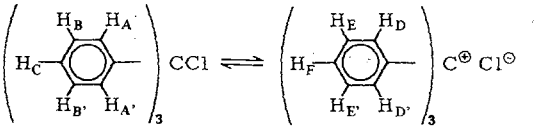

Fig. 12. Observed and computed ^{1}H-DNMR spectra of the homotropylidene *(8)*.

plings the case can be treated computationally as an $A_2BC \rightleftharpoons D_2EF$ nonmutual exchange between two chemically different, albeit of course equally populated nuclear configurations. Dynamic spectra are reproduced in Figure 12. A comparison of the activation parameters with those of analogously substituted derivatives led to conclusions concerning the nature of the transition state of the Cope rearrangement[48].

A very complex example of a quantitatively analyzed binary exchange is provided by the ionization of trityl chloride *(9)* in $SO_2/CDCl_2$[49]. Although the covalent and ionic forms

(9)

are connected *via* an intermolecular process, the theoretical DNMR spectra of the type AA'BB'C$\rightleftharpoons$DD'EE'F (Fig. 13)

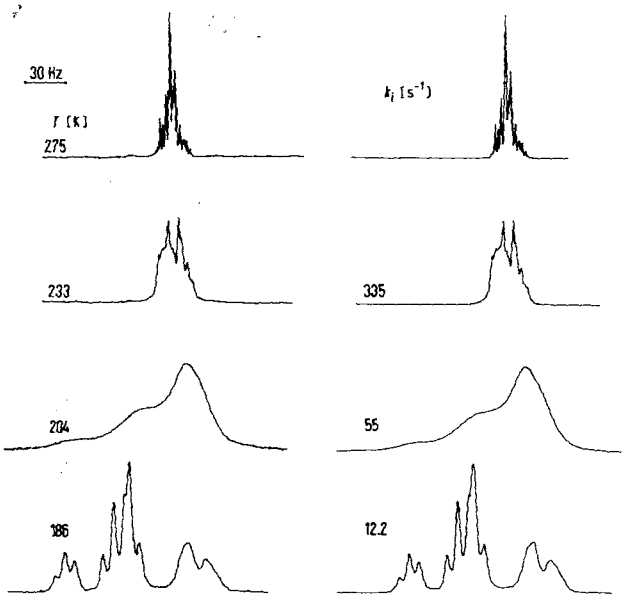

Fig. 13. Observed and computed ^{1}H-DNMR spectra of trityl chloride *(9)* in $SO_2/CDCl_2$ (10:1).

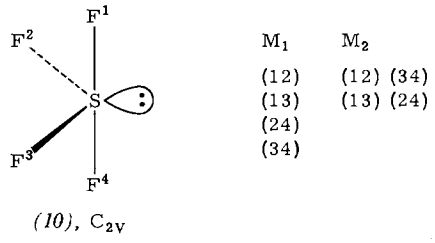

could be calculated[49] using a redimensioned standard program[24], since the aromatic protons show no spin coupling to the departing chloride ligand. Even an iterative determination of the exchange rate constant would still be perfectly feasible. It is true, however, that the complexity is now so high that it becomes quite tedious to determine the numerous static parameters and their temperature dependence from the slow-exchange spectra if one has to rely on conventional techniques. With the recently reported[50-52] automated analysis procedure for complex static spectra this obstacle has now disappeared as well.

2.4. Multiple Exchange of Coupled Spin Systems

As was the case for exchanging singlets, the most intriguing examples are also found in the realm of coupled systems if the chemical constraints are loose enough to permit the exchange between more than two nuclear configurations, at

least in principle. For n spins of the same kind there can be as many as $(n!-1)$ different topomerizations and/or enantiomerizations; the number of exchange possibilities increases further if diastereomers and/or constitutional isomers are involved. This does not mean, however, that all these possibilities necessarily give rise to different DNMR spectra. The number of differentiable processes, for the designation of which there unfortunately exists a bewildering variety of nomenclature suggestions, is often drastically curtailed by molecular symmetry. Before embarking on a bandshape analysis it is therefore first necessary to ascertain the fundamental exchange possibilities with regard to number, nature and degeneracy. The complexity may easily exceed the bounds of chemical intuition and it then becomes unavoidable to resort to group-theoretical techniques. A voluminous formalistic literature has been accumulating on this subject in recent years, but its exposition would go beyond the limits of the present review. We can do no more than cite a few review articles[53-55], in which the aspects relevant to DNMR spectroscopy are treated in some detail. Corresponding applications experienced a sudden upsurge at the beginning of the past decade especially in inorganic chemistry[3,56,57].

The pseudorotation in the repeatedly studied sulfur tetrafluoride, which could finally be clarified by *Whitesides et al.*[58] by the investigation of a carefully purified sample, is transparent enough so as not to require an elaborate group-theoretical machinery and may therefore serve as an illustration of the principles. At low temperature one observes a ^{19}F-NMR spectrum of the type A_2B_2 (or A_2X_2), in agreement with the theoretically expected C_{2v} structure *(10)*. By inspection one finds that of the $4!=24$ permutations (including the identity) of the ^{19}F nuclei there only remain the two differentiable mechanisms M_1 and M_2 of degeneracy 4 and 2, respec-

tively (Scheme 2). The exchange of the axial and equatorial ligands proceeds sequentially in M_1 and concertedly in M_2.

A careful examination of the curves in Figure 15, synthesized on the basis of the permutational schemes shown, reveals that M_2 matches the experimental DNMR spectra of Figure 14 more closely than M_1. This result is in agreement with a process known as Berry pseudorotation, but would equally well be compatible with any other chemical mechanism giving rise to the same nuclear permutations. It cannot be overlooked, however, that the differences between the two sets of theoretical spectra are exceedingly subtle. In fact, when the spectra were recorded at "normal" field strengths, an unambiguous distinction could no longer be made at all. *Whitesides et al.*[58] were forced to reduce the field strength of the spectrometers used in this study to about 10% of their nominal value. This casts an interesting spotlight on the rampant misconception regarding the *universality* of the advantages to be expected from the high-field spectrometers which are becoming so popular these days.

The same difficulty of not being able to differentiate convincingly between alternative mechanisms with the conventional procedure of spectral synthesis has frequently arisen in other studies of this kind and provided the motivation for a further development of the methodology[25,26]. The molecule 1,4-dinitrosopiperazine *(11)* served as a test case[59]. At room temperature one records the superposed spectra of two diastereomeric forms in equilibrium: the AA'BB' pattern of *(11a)* and the two four-proton singlets C_4 and D_4 of *(11b)*. At elevated temperature one observes the onset of internal rotations about the N—N bonds of the *N*-nitroso groups. In calculating the dynamic spectra it has to be remembered that the two singlets also require a full quantum-mechanical treatment, since their equivalence is destroyed in the course of the diastereomerizations. The problem was formulated theoretically as an exchange between four nuclear configurations involving three independent rate parameters, according to the mechanisms of Scheme 3. In the iterative analysis, starting from 10200 raw spectral points fed to the computer, the parameters k_{II} and k_{III} converged to zero. That is to say, the mechanistic conclusion emerged here as a *result* from the analysis. The preprocessed experimental DNMR spectrum at 130 °C reproduced in Figure 16, which was computer-generated from the raw data by smoothing and reduction to 999 points as a preparation for analysis, and the calculated curve plotted on top of it furthermore illustrate the degree of agreement between theory and experiment that can be achieved with this automated procedure. The new technique is clearly the method of choice especially in those cases where the contribution of a "pure" mechanism in a mixture of several mechanisms needs to be determined quantitatively.

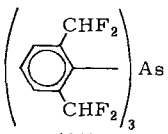
	II	$AA'BB' \rightleftharpoons BB'AA'$
Scheme 3.	III	$C_4 \rightleftharpoons D_4$



We briefly sketch an enticing application of this technique to the problem of correlated motions in triaryl derivatives of the type Ar_3XY, where Y stands for a ligand of conical symmetry or a free electron pair[60]. A restricted internal rotation in trimesityl derivatives of phosphorus and arsenic had already been detected by DNMR spectroscopy in 1969[61]. More recently, the mechanism of this dynamic process has been extensively investigated especially by *Mislow et al.* The theoretical and experimental results communicated in about 20 lengthy papers[62] are overwhelmingly in favor of the chiral (C_3) propeller conformation *(12)* in solution and of the operation of the so-called two-ring flip mechanism, whose transition state is indicated schematically in *(13)*. Surprisingly enough, an iterative DNMR analysis of a single model type with three structurally identical aryl groups can furnish the conclusive proof. The synthesis of the conceived model compounds has recently been successful in four cases[60]; here we

show the spectra of the arsenic derivative *(14)*. The ^{19}F sensor nuclei serve the double purpose of responding to the "edge interchange"[62b] e *as well as* the "helicity reversal"[62b] h, *provided* that the molecule assumes a chiral C_3 equilibrium conformation in solution. That this is indeed the case follows immediately, and rigorously, from the ^{19}F-NMR spectrum at $-91.7\,^{\circ}C$ (Fig. 17). The large chemical shift differences and

M_7	e^3h	1	[DCBA]$_3$	1 AB type [a]

[a] The parameters of this AB spectrum differ from those of the other AB types.

the cleanly separated signals of ^{19}F subspectra of the two ABX systems simultaneously confirm the working hypothesis underlying this project, namely that the ^{19}F nucleus is really the only sensor spin suitable for a successful study of this kind. The chemical constraints permit seven differentiable mechanisms for this $[ABXCDY]_3$ spin system[63], whose nature and consequences are collected in Table 1, where the XY nuclei have been suppressed for simplicity and the (anyway unobservable) long-range couplings disregarded. It can be seen that the high-temperature spectrum of Figure 17 already eliminates all pure mechanisms with the exception of M_5 and M_6. The latter can now be distinguished on the basis of the DNMR spectra, formulated theoretically[60] as an exchange between four ABX-type nuclear configurations with two independent rate parameters. Note, however, that there is still a choice between two alternative relative assignments of the chemical shifts, about which nothing is known initially. This decision can also be left to the computer. The iterative calculation with one of these assignments results in an acceptable fit to the dynamic spectra, but leads to a linear

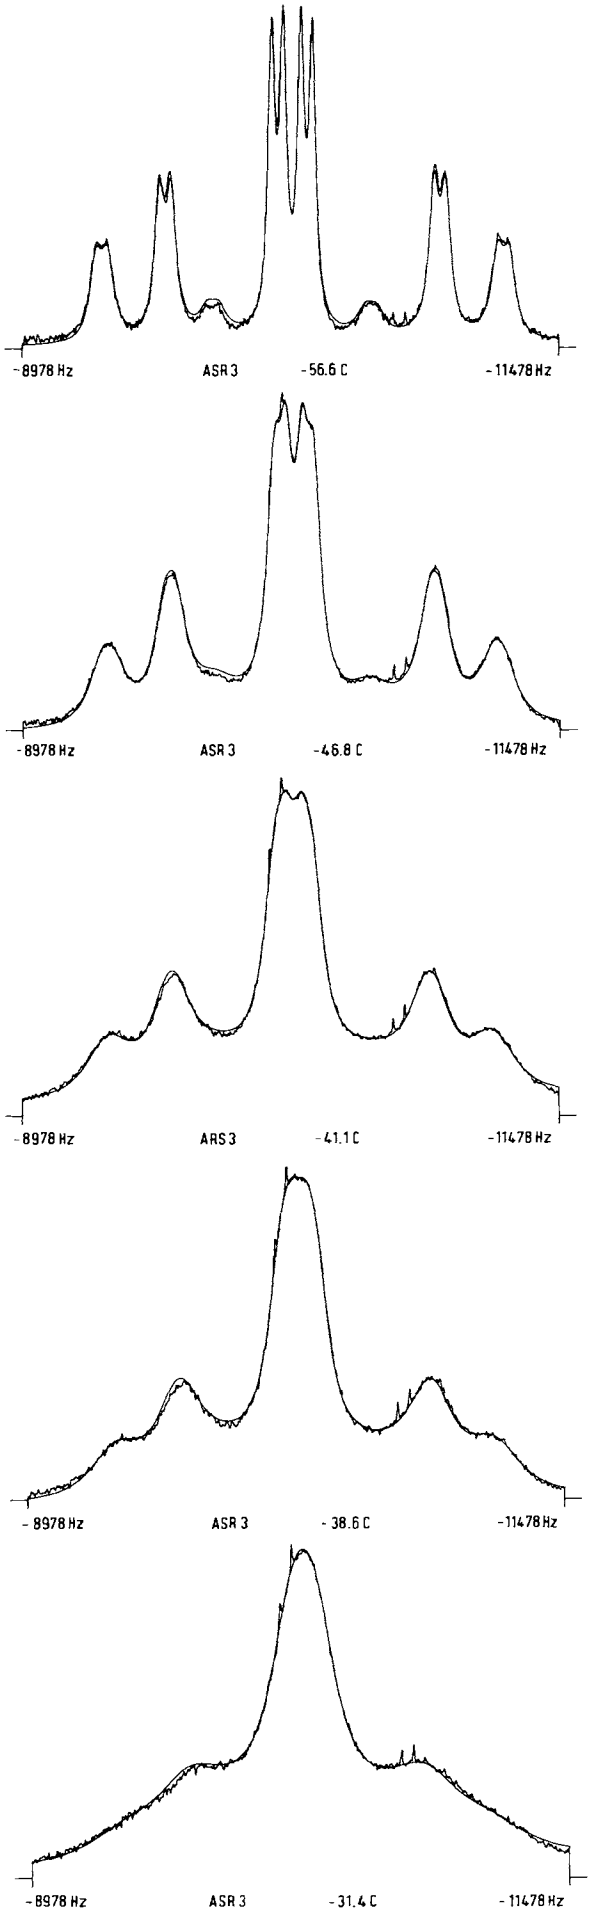

Fig. 18. ^{19}F-DNMR spectra of the triphenylarsane derivative *(14)* and superposed computed spectra (see right-hand column).

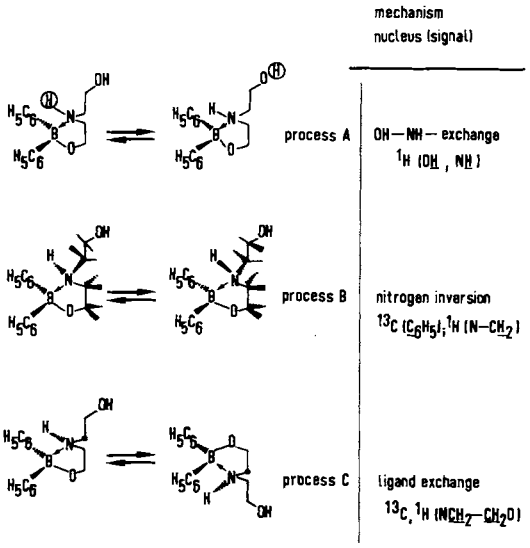
combination of M_5 and M_6 in which one of the rate constants decreases drastically with increasing temperature. This physically nonsensical result can only mean that the incorrect assignment was chosen. With the other assignment one obtains the fits shown in Figure 18 and the results listed in Table 2. This completes the proof of mechanism M_5.

Table 2. Iteratively calculated rate constants for the processes M_5 and M_6 of *(14)* and their standard deviations.

Temperature [°C]	k_5 [s^{-1}]	k_6 [s^{-1}]
−56.6	161.3 ± 4.1	5.1 ± 3.3
−46.8	415.8 ± 5.6	0.9 ± 4.7
−41.1	654.6 ± 5.9	0.7 ± 4.3
−38.6	805.3 ± 8.0	0.8 ± 5.2
−31.4	1366 ± 13	0.6 ± 6.5

Finally, we mention the interesting possibility of mechanistic DNMR studies in nematic phases. In the hypothetical case of cyclobutadiene, for example, a singlet would be observed in the ^1H- (or $^{13}C\{^1H\}$-) spectrum in isotropic solution even if the valence topomerization *(15a)* ⇌ *(15b)* were slow on the NMR time scale, but this would not be the case in a liquid crystal solvent. The technique has already been

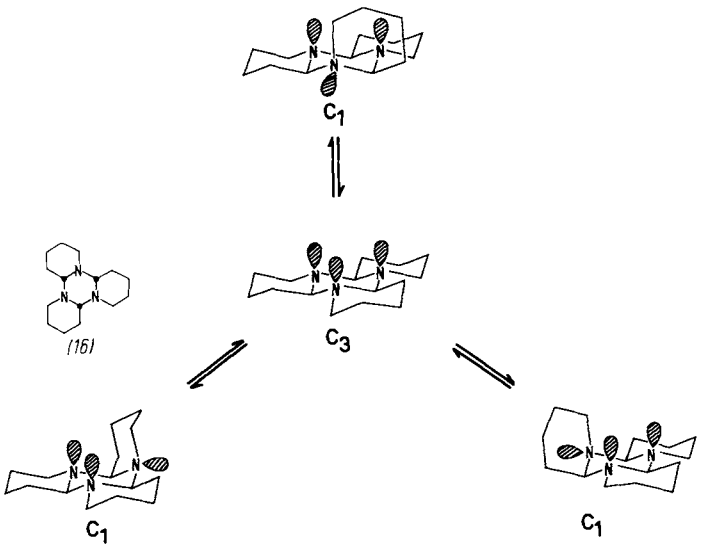
(15a) *(15b)*



applied[64] to the bond-shift process in cyclooctatetraene, previously studied by way of the ^{13}C satellite DNMR spectra[65,66] and on substituted cyclooctatetraenes[67-69]. General computer programs are presently being developed[70] and one may look forward to exciting applications in the future.

3. Choice of Sensor Nucleus

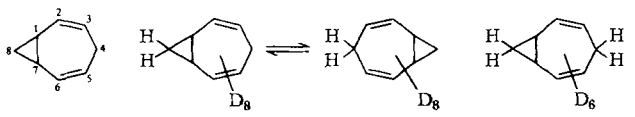
There is no choice at all if the molecule contains only one kind of magnetically active nucleus or if for theoretical or practical reasons (*e.g.* spin > 1) only one kind is suited for a DNMR study. For example, dynamic processes in metal carbonyls can frequently be studied only by ^{13}C-DNMR spectroscopy[13,71].



In other cases the mechanistic details of a specific process may manifest themselves more clearly by the judicious choice of a sensor nucleus. In the example of the tropylium azide already alluded to in Section 2.2 we have focused attention on the seven-membered ring. The preferred 1,3-shift in nonpolar solvents may be interpreted (Scheme 1) as a [3,3]-sigmatropic rearrangement (hetero Cope rearrangement) in which the terminal nitrogen atoms of the azide ligand are interchanged as well. In the ^{15}N-NMR spectrum of an isotopically enriched sample one indeed observes the exchange in the expected temperature range; unfortunately, a quantitative analysis was prevented by the low signal-to-noise ratio of the exchange-broadened ^{15}N-DNMR spectra[43,72].

In the presence of several processes proceeding concurrently one occasionally succeeds in differentiating them by appropriately choosing the sensor nucleus. We have recently investigated a case in which three different processes occur in the temperature interval from −50 to +50 °C[22] (Scheme 4).

Scheme 4.



In the situation most frequently encountered in practice, however, several magnetically active nuclear species respond to one and the same chemical process. Practical aspects such as NMR sensitivity, magnitude of the shift differences and complexity of the spin system then determine the choice. Owing to its superior sensitivity the proton will often be preferred, since it yields an acceptable signal-to-noise ratio even in the highly exchange-broadened region. Exceptions are indicated if the shift differences in the static spectra are too small to permit a quantitative bandshape analysis or if the spin system is too complex even on the basis of present criteria. A pertinent example is *cis*-decalin, for which one observes a sharp singlet in the ^1H-NMR spectrum down to −120 °C, whereas the expected dynamic behavior is easily detectable in the ^{19}F spectrum of 2,2-difluoro-*cis*-decalin[73] or in the ^{13}C spectrum of the parent compound[74]. Similarly, the ^1H-NMR spectrum of tripiperidein *(16)* is too complex (strongly coupled 9-spin system) and too poorly resolved even at 270 MHz, whereas the ^{13}C-NMR spectra establish at once that only the asymmetric C_1 form is populated at low temperature. The dynamics of the molecule (Scheme 5)

Scheme 5.

could be studied without difficulty by means of the three-site exchanges in the ^{13}C-DNMR spectra[75].

The advantages and disadvantages of the various nuclear species and/or spin systems can be demonstrated with the homotropylidene *(17)*. An exact bandshape calculation for the exchanging 10-proton system is at present not feasible. *Günther et al.* have therefore decided to investigate the octadeuterio derivative *(18)* (AB⇌CD exchange with unequal populations owing to the isotope effect in the $^1H\{^2H\}$-DNMR spectrum)[76]. A later analysis[77] of the hexadeuterio derivative *(19)* (AB⇌CD exchange with equal populations) fully corroborated their results.

(17) *(18a)* *(18b)* *(19)*

At this point the question arises as to how much the barrier in the parent compound is changed by a secondary kinetic deuterium isotope effect. The kinetic evaluation of the ^{13}C-DNMR spectra of *(17)* indeed yielded slightly different ΔH^+ and ΔS^+ values[78] and thus provided the motivation for a subsequent reinvestigation of *(17)* by ^{1}H-NMR spectroscopy at 270 MHz. Because of the very large chemical shift differences in the high-field ^{1}H spectrum it is now a good approximation to neglect the couplings to the protons 2-H and 6-H and the small cross-ring couplings[79], so that the exchange can be treated computationally as an $ABC_2 \rightleftharpoons DEF_2$ system[80]. The results are in agreement with the ^{13}C-DNMR (Table 3). The error situation is still marginal, but the internal consistency of the values of Table 3 does suggest the presence of a detectable isotope effect[80].

Table 3. Activation parameters of homotropylidene and its deuterated derivatives.

Cpd.	Method	ΔH^+ [kcal mol^{-1}]	ΔS^+ [cal mol^{-1} K^{-1}]	ΔG^+_{298} [kcal mol^{-1}]
(17)	$^{13}C\{^1H\}$-DNMR	12.34 ± 0.09	−5.9 ± 0.6	14.10 ± 0.09

(19)	270-MHz ^{1}H-DNMR	11.86 ± 0.11	−7.8 ± 0.4	14.184 ± 0.009

4. Experimental and Computational Aspects

The determination of a free energy of activation makes quite modest demands on the accuracy of a rate constant and consequently on the quality of the experimental DNMR spectra and on the validity of the approximations employed in their dynamic evaluation. The reason for this insensitivity resides in the fact that k enters logarithmically into the calculation of a ΔG^+ value by means of the Eyring equation, which for the convenience of the experimentalist shall be reproduced with the currently valid numerical constants:

$$\Delta G^+ \text{[kcal mol}^{-1}\text{]} = 1.9872\,T\,(23.7600 + \ln T - \ln k).$$

Even a temperature error of 3 K can readily be tolerated; the aforementioned (cf. Section 1) typical precision of ±0.2 kcal mol^{-1} remains untouched. The situation changes abruptly, however, as soon as the temperature dependence of k is to be evaluated quantitatively as well[15]. Reliable ΔH^+ and ΔS^+ values, and in particular activation entropies *explicable in a chemically meaningful fashion,* may realistically be expected only if careful attention is paid to the various aspects to be detailed in the following Sections.

4.1. Instrumental Problems

The temperature problem presents itself in three facets: constancy, uniformity and measurement. A convincing instrumental solution (±0.01 K even at −170 °C!) has been reported at least once[81], but is unfortunately not available commercially. With sufficient care the difficulties can, however, be largely overcome with most spectrometers in current use, at least for the temperature range from about −100 to +150 °C. Such care is mandatory, to be sure! If one is not willing to inform oneself about the possibilities of error and to invest the minimum expenditure of effort, it is preferable to abstain altogether from any attempt at evaluating the temperature dependence of k quantitatively; expecially with regard to activation entropies the pertinent literature is already burdened with such a heavy load of ballast that we can easily do without more of the same.

The temperature dial readings of commercial control units cannot be trusted; even a single calibration is by no means sufficient. This is not the place to enter into technical details of the numerous suggested and/or practiced methods and their advantages and disadvantages. We merely indicate the two procedures presumably employed most commonly. In the first method the sample tube is substituted by an open tube partially filled with a suitable solvent (if possible the same that was used in dissolving the compound to be investigated) and containing a thermocouple immersed to the height of the receiver coil; after allowing for adequate equilibration the temperature is recorded before and after performing a DNMR measurement. Alternatively, one may use an "NMR thermometer liquid" (*e.g.* CH_3OH or $HOCH_2CH_2OH$ for ^{1}H-DNMR) which shows a temperature-dependent chemical shift difference for the DNMR sensor nucleus, either also contained in a replacement tube or preferably in a sealed capillary added to the sample solution. A careful recalibration has recently been performed for the ethylene glycol curve[82], making elegant use of the sharply defined and almost instantly regulatable clearing point of liquid crystals. NMR thermometers have also been suggested for other sensor nuclei; the relevant literature can be traced back from a paper published not long ago[83].

In recording the spectra by the CW technique, as commonly practiced in the past, attention has to be paid to the bandshape distortions caused by saturation effects and finite sweep rates; happily, these experimental difficulties have vanished with the FT technique now used almost universally. There has been no change, of course, in the requirement of aiming for a field homogeneity that is as high as possible. It also should not be overlooked that the FT technique has created new problems. The baseline artifacts and signal distortions caused by pulse breakthrough and nonlinear phase

effects are much more serious and also more difficult to avoid for strongly exchange-broadened DNMR spectra than for static spectra consisting of sharp lines; they certainly deserve the careful attention of the experimentalist and may even require modifications of the commercial system software. It hardly needs to be stressed that the most sophisticated band-shape calculation becomes illusory if the quality of the experimental DNMR spectra falls below an acceptable standard. If the spectra are to be evaluated by visual comparison with synthesized DNMR spectra it is therefore good policy to insist from the outset that they be recorded in a sufficiently large format (at least 30 × 30 cm appears to be a normal requirement).

4.2. Static NMR Parameters and Thermodynamic Quantities

A dynamic bandshape calculation requires that the chemical shifts and coupling constants be known at the respective temperature. Using modern programs[25] the static parameters can be determined iteratively as long as the DNMR spectra still exhibit sufficient fine structure. A decision concerning this point may be made on the basis of the correlation coefficients produced by the program. In general, however, one will have to rely on extrapolations. A fit to a linear function of the temperature has been perfectly adequate in virtually all cases studied so far. If the barriers are not too small, the required information can be obtained by static analysis of the spectra in a temperature range below the onset of appreciable exchange broadening[84]. The latest developments[50, 52] have drastically reduced the effort of such analyses for complicated spectra. The reliability of the extrapolations is expected to increase with the temperature range in which static analyses are feasible. In favorable cases[44,47], where the exchange takes place between *chemically* distinct nuclear configurations resulting in averaged spectra still exhibiting fine structure (Fig. 12), the validity of the extrapolations can be subjected to detailed cross-checks.

It may of course also happen that a temperature trend is not detectable within the limits of experimental error or that it makes such a small *percentage* contribution to the crucial frequency differences that it becomes safe to work with constant numbers in a bandshape calculation. This is indeed the normal situation for coupling constants and is, *with the exception of the proton,* often realized for the chemical shift parameters of other sensor nuclei as well. Furthermore, it is clear that only a possible temperature trend of the chemical shift *differences* of the exchanging spins is of interest in the present context; an absolute shift, *e.g.* with respect to an internal reference, is of no relevance for the dynamic analysis. In modern programs[25] this feature is taken into account by the introduction of an additional parameter specifying the spectral origin.

Analogous low-temperature measurements are required if one is dealing with isomerizations or with the intermolecular exchange between chemically different molecules, except that it is now necessary to determine in addition the temperature dependence of the populations. An iterative calculation is to be preferred over a simple integration also for this purpose, even if (and especially if) there are only singlets. The analysis according to van't Hoff yields the ΔH^0 and ΔS^0 values of the equilibria, from which the populations at other temperatures can be back-calculated. An additional data point can be extracted from the exchange-averaged spectrum. In the presence of large chemical shift differences Δ between the species and in the absence of an appreciable temperature dependence of the static parameters, the precision of such a number can be quite high even for singlets[78,85], but decreases hyperbolically with Δ according to the laws of error propagation. As already mentioned in Section 2.3 in connection with the aziridine example *(7)*, fine structure in the spectrum in the fast-exchange limit then offers the possibility of improving the situation by taking the weighted average of several alternatives. This remark also applies to the case of trityl chloride[49] (Fig. 13).

4.3. Natural Line Widths

A generally vastly underestimated problem in connection with the quantitative evaluation of DNMR spectra as a function of temperature is raised by the natural width W_0 of the lines. In conjunction with the aspects to be discussed subsequently, it embodies the principal cause for the overwhelming percentage of worthless $\Delta S^{\neq}$ values in the literature. A statistical analysis[15] demonstrates that for obtaining reliable activation enthalpies and entropies a large temperature interval is a necessary *but not sufficient* requirement. Of decisive importance are almost exclusively only the data in the two extremes of the range, and it is here that the DNMR spectra are least sensitive to the exchange rate. As already pointed out in the Introduction and again in the discussion of bullvalene (Section 2.2), exchanging singlets show up as broadened Lorentzian lines in these regions. Since the natural width is dominated by field inhomogeneity broadening in the absence of special effects, it appears plausible to extract it from an internal reference signal at the respective temperature and subtract it from the exchange-broadened lines or use it as a constant in an explicit bandshape calculation. If field inhomogeneity is no longer dominant, that is to say if there are genuine transverse relaxation effects or unresolved residual splittings, the natural line widths can be extrapolated into the dynamic region from measurements at temperatures below or above detectable exchange broadening[86]. These procedures are indeed perfectly satisfactory for the determination of a free energy of activation even if the exchanging lines are, say, only three times as broad as the standard; a k error of 20%, caused by experimental imperfections, by approximations in the calculations or indirectly by a temperature error, is of absolutely no consequence for the calculation of a $\Delta G^{\neq}$ value from a chemical standpoint. Experience shows, however, and a statistical analysis proves it, that such an error in k in most cases totally prevents the determination of an activation entropy that can be *meaningfully interpreted chemically*[44,46,47].

For exchanging singlets or an AB$\rightleftharpoons$BA exchange no remedy is to be expected for these difficulties from an iterative bandshape analysis either. Because of virtually complete correlation it is clearly impossible to determine k and W_0 separately[87]. A rule of thumb for the nonexpert is to refrain from using a DNMR rate constant for the analysis of its temperature dependence if it stems from an A$\rightleftharpoons$X or AB$\rightleftharpoons$BA DNMR spectrum in which the line widths were less than

about 6 W_0. But this already restricts the available temperature range so severely for the chemical shift differences typical for ^{1}H-DNMR spectroscopy that it is preferable to abstain from any attempt at dissecting a $\Delta G^{\neq}$ value for $\Delta < 50$ Hz if the spin system is too simple.

Of the currently known procedures for avoiding these difficulties we shall discuss the nonstationary methods in Section 5; two further techniques are to be mentioned in the present context. For very large chemical shift differences, as they are typically encountered for many nuclei with the exception of the proton, it is possible to cover such a large temperature interval even when observing the cited rule of thumb that reliable results are to be expected in principle, provided that the sensitivity suffices for spectra of good quality and that other complications are absent. That this expectation could in the past often not be realized for ^{13}C-DNMR spectroscopy becomes depressingly apparent on inspection of the tables in a recently published survey[12]. Another technique exploits the advantages of spin systems of *sufficient* complexity. Whereas the field inhomogeneity affects all lines equally, the exchange may lead to *differential* line broadenings even in the extremes of the temperature range as a consequence of quantum-mechanical mixing, provided of course that fine structure can be observed in both regimes. This condition can be satisfied by the presence of "supernumerary" spins as in *(6)* (Fig. 7) or by chemically different nuclear configurations like in *(7)* (Fig. 10). A distinction of these differential effects from W_0 is already feasible by means of the conventional method of spectral synthesis, but is more profitably carried out using the iterative procedures that have recently become available[25,26], since in this way one automatically also obtains the objective error information required for an unbiased calculation of $\Delta H^{\neq}$ and $\Delta S^{\neq}$. If for lack of the proper equipment one still needs to resort to the synthetic evaluation, it is necessary to determine in each case the upper and lower bounds of the rate constant that lead to unequivocally ascertainable disagreements with the experimental spectrum. In this way one obtains realistic estimates of the rate errors that are required for the calculations to be discussed in the following section.

4.4. Activation Parameters

The quantitative evaluation of the temperature dependence of the rate constants can be performed according to the Arrhenius or Eyring equations. Owing to its lack of easy explicability in chemical terms it is fitting that the former alternative is on the retreat in the modern literature. The popular graphical evaluation is to be rejected for the same reason, as are all numerical procedures in which the statistical weights of the data points cannot be taken into account. For, even if the errors in k and T were the same over the entire range, the laws of error propagation would then demand that they be different for the functions $\ln(k/T)$ and $(1/T)$ of the linearized treatment. In reality, however, the errors in k are normally much higher at the extremes of the temperature range than around the coalescence point. Even the most frequently used standard computer programs for weighted adjustment are not fully appropriate to the DNMR situation, since they only allow for the variances of the dependent variable in the linearized treatment; the errors of the independent variable $(1/T)$ should also enter into the calculation. The correct formalism was first given by *Deming*[88], but is surprisingly still unknown even to many specialists. A typical calculation of this kind for a simple exchange problem, carried out with the program ACTPAR[89], is reproduced graphically in Figure 19.

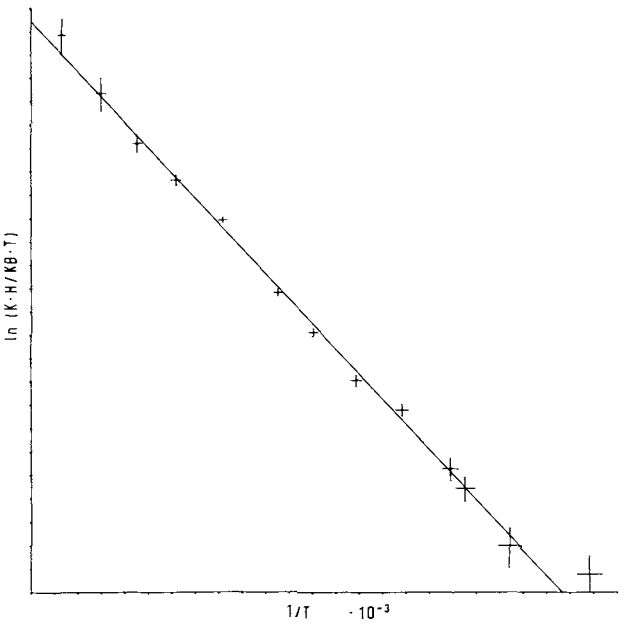

Fig. 19. Graphical Representation of a typical ACTPAR calculation of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the exchange of two singlets.

The neglect of elementary principles of statistics has, *inter alia,* often led to an underestimation of the *purely statistical* errors in $\Delta H^{\neq}$ and $\Delta S^{\neq}$, not infrequently by more than an order of magnitude[90]. On the other hand, it is commonly found that the errors in $\Delta G^{\neq}$ back-calculated from those of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ have been *overestimated.* It is almost invariably overlooked that the covariance $\mathrm{cov}(\Delta H^{\neq}, \Delta S^{\neq})$ plays a decisive role. The correct formula reads

$$\sigma^2(\Delta G^{\neq}) = \sigma^2(\Delta H^{\neq}) + T^2\sigma^2(\Delta S^{\neq}) - 2T\rho(\Delta H^{\neq}, \Delta S^{\neq})\sigma(\Delta H^{\neq})\sigma(\Delta S^{\neq}),$$

and since the correlation coefficient $\rho(\Delta H^{\neq}, \Delta S^{\neq})$ can here be equated to 1 without further ado, in simplified form

$$\sigma^2(\Delta G^{\neq}) \approx \sigma^2(\Delta H^{\neq}) + T^2\sigma^2(\Delta S^{\neq}) - 2T\sigma(\Delta H^{\neq})\sigma(\Delta S^{\neq})$$

or

$$\sigma(\Delta G^{\neq}) \approx |\sigma(\Delta H^{\neq}) - T\sigma(\Delta S^{\neq})|$$

5. Nonstationary Methods

We have already emphasized that the distinction between exchange broadening and natural line width in the extremes of slow and fast exchange is rendered particularly difficult for singlets. It is gratifying that the nonstationary methods of magnetization transfer offer an alternative especially suited for such simple spectra. They permit the determination of a rate constant in the temperature region below the onset of noticeable line broadening.

The method of saturation transfer goes back to classic papers of *Forsén* and *Hoffman*[91] and is usually applied to CW spectra in the experimental version of *Anet* and *Bourn*[92]. Irradiation at the resonance frequency of *one* of the nuclei causes the occupation numbers of the respective energy levels to become equalized. The signals of the other nuclei involved in the exchange thus experience a time-varying intensity change, provided the effect is not extinguished by rapid relaxation. It is of course also possible to monitor the time variation of the signal intensities by means of the FT technique[12,93,94], which is the method of choice especially for ^{13}C-NMR spectra[12,93].

Modern pulse spectrometers allow an even more sensitive version of this experiment. The level populations are inverted by a selective 180° pulse, followed by a delay time τ and a nonselective 90° observing pulse; the evaluation of the signal intensities as a function of τ then yields the desired dynamic information[95-97]. The generation of a selective 180° pulse is a little tricky, but by exploiting the latest techniques[98] it is possible to replace it by m identical $180°/m$ pulses[99] whose separation τ determines the pulse frequency.

Not unexpectedly, these techniques are also subject to a multitude of error sources, about whose influence on the determination of activation parameters systematic experience is at present still largely lacking. Their great practical value for qualitative mechanistic studies has, however, already been established beyond doubt. For tropylium azide *(3)* it was possible, for instance, to prove the preferred 1,3-shifts in relatively nonpolar solvents by saturation transfer experiments at carefully selected temperatures[43,100] (cf. Section 2.2). Recently, it has also been shown[101] that qualitative information of this kind can elegantly be obtained by two-dimensional NMR spectroscopy.

We mention in passing that quantitative DNMR analyses of isomerizations can often be supplemented by classical chemical equilibration studies at sufficiently low temperatures (about 100 K below the coalescence temperature). A discussion of the extensive literature on this topic, however, does not fall within the purview of the present essay.

6. Conclusion and Perspectives

In the arsenal of methods at the disposal of the experimentalist DNMR spectroscopy has long been firmly entrenched as a convenient diagnostic for the detection of molecular rate processes. The quantitative determination of a free energy of activation is routinely possible as well and often calls for less effort than commonly supposed. An estimate of the coalescence temperature or the measurement of an incipient line broadening is in many cases all that is required.

The possibility of exploiting DNMR spectroscopy for the elucidation of reaction mechanisms has been fully appreciated only during the last decade. One may no doubt anticipate further interesting applications in the future.

Although DNMR spectroscopy is also suited for a quantitative determination of activation enthalpies and entropies, experience shows that activation entropies of an accuracy indispensable for a meaningful chemical interpretation are no longer obtained routinely. The number of careful studies has increased in recent years, but still constitutes a small percentage of the total body of investigations. If one limits oneself to those in which a detailed interpretation based on the principles of statistical thermodynamics has been seriously attempted, their number shrinks considerably further. Recent methodological developments and the accumulated experience about sources of error lead to the conclusion, however, that DNMR spectroscopy can be perfected to the point where it becomes a precision method also for activation entropies. This opens up broad avenues for future applications. After a sufficient amount of reliable material has been gathered, it might well turn out that activation entropies are sometimes easier to interpret theoretically than the corresponding energy quantities and that they yield novel information about dynamic properties of transition states inaccessible by direct observation. The first indications of such a possibility have been obtained. One thing is certain already: the tools of classical chemical kinetics, to whose application to mechanistic problems of organic chemistry *Rolf Huisgen* has contributed so brilliantly, have been supplemented and materially amplified by DNMR spectroscopy.

We owe a great debt of gratitude to our coworkers named in the cited publications. Financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

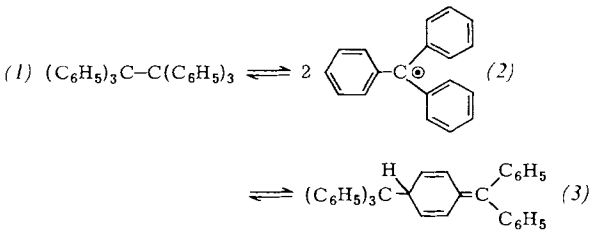
Towards an Understanding of the Carbon-Carbon Bond

By Christoph Rüchardt and Hans-Dieter Beckhaus[*]

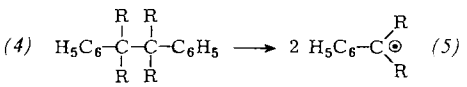


Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In this essay, the classical question of "the influence of the number and kind of substituents on the strength of the C—C bond", is pursued with the modern tools of contemporary physical organic chemistry. Based on the work of *Karl Ziegler,* the products and kinetics of thermolysis of a large number of highly branched aliphatic hydrocarbons and phenyl- or cyano-substituted derivatives were investigated. For each class of compounds, a linear relationship was found between the free enthalpy of activation of the homolytic cleavage of the weakest C—C bond and the strain energy in the ground state. These relationships permitted a *quantitative* separation of steric and electronic effects on the cleavage of C—C bonds. The influence of the size of the substituent groups on bond angles, bond lengths, and the conformational behavior of model compounds was studied by means of experimental structure determinations and force field calculations. C—C bond lengths up to 164 pm, bond angles at tetracoordinate carbon as large as 126°, and unusual eclipsed and *gauche* preferred conformations were found.

1. Introduction

In the last 35 years, the study of organic reaction mechanisms has experienced a golden age which has led not only to the development of new experimental methods and theoretical models but also to elucidation of the mechanisms of most organic reactions and to the discovery of many new ones. *Rolf Huisgen* is one of the scientists who has made authoritative contributions to this development.

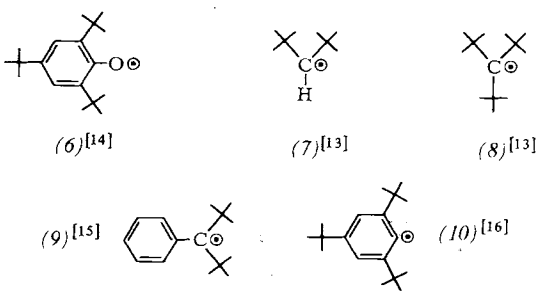


In 1949, *Karl Ziegler* wrote a paper on trivalent carbon[1] starting from the question: "Why is the central C—C bond in the Gomberg hydrocarbon hexaphenylethane *(1)*[2] so weak that the hydrocarbon spontaneously decomposes in solution to give a measurable equilibrium concentration of triphenylmethyl radicals *(2)*?"

Ziegler determined the rates of thermolysis of a series of hydrocarbons *(4)* as well as other compounds, and established that their thermal stability follows the series

$$R = CH_3 > C_2H_5 > C_3H_7 > C_4H_9$$

i.e. their stability decreases rapidly with the size of R[1].



Consequently, the instability of hexaphenylethane *(1)* could no longer be attributed solely to the *electronic stabilization* of the resulting triphenylmethyl radicals *(2)* as had been previously believed. The *"steric acceleration"* of thermolysis, established by studies on *(4)*, also had to be accepted in the case of *(1)*. The fact that the Gomberg hydrocarbon is now known to be the α,*p*-dimer *(3)* which is less crowded than the α,α-dimer *(1)*[3,4], does not, in principle, alter *Ziegler*'s argument. The key point is that all the repulsive forces between atoms and groups of atoms in *(1)*, *(3)*, or *(4)* decrease during the dissociation process as the central C—C bond becomes longer and as the bond angles at the central tetracoordinate carbon atoms increase[5].

On the basis of simple kinetic experiments and considerations of skeletal models, *Ziegler* postulated[1] the principle of "steric acceleration"[6] long before the definition of precise stereochemical concepts such as back strain[6,7], front strain[6-8], steric substituent constants[9], or conformational analysis[10]. Moreover, the modern methods of precise structural analysis were not available at that time.

Meanwhile, steric effects have been firmly established in many reactions[6,11,12]; in particular, many examples of the influence of bulky groups on the persistence of radicals have been recognized[13]. For example, the *tert*-butyl groups in radicals *(6)*—*(10)* hinder their dimerization, because the repulsive van der Waals forces give rise to large activation energies for recombination.

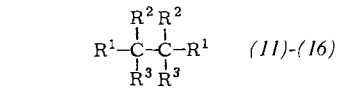
Because the interpretation of the effects discussed so far is still only qualitative, the question of different bond strengths

[*] Prof. Dr. Ch. Rüchardt, Dr. H.-D. Beckhaus
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/0606-0429 $ 02.50/0*

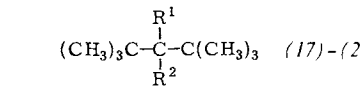
in branched and substituted alkanes is just as real today as it has ever been. The effects are so large that they demand a quantitative interpretation; for example, there is a difference of 76 kcal mol^{-1} between the bond dissociation enthalpy in ethane[17a-c] and that of the Gomberg dimer *(3)*[17d]! Ethane decomposes to methyl radicals with $\tau_{1/2}=1$ h only at 690 °C; in contrast, *(3)* dissociates at the same rate at 0 °C.

$$CH_3{-}CH_3 \xrightarrow{690\,^{\circ}C} 2\,CH_3^{\bullet} \qquad H_D = 88 \text{ kcal mol}^{-1}\text{[17a-c]}$$



$$(3) \xrightarrow{0\,^{\circ}C} 2(C_6H_5)_3C^{\bullet} \quad H_D \approx 12 \text{ kcal mol}^{-1}\text{[17d]}$$

On extrapolation, the two dissociation reactions are seen to differ in their rates by a factor of about 10^{30}. Hardly any other chemical reaction is more drastically influenced by substituents than carbon-carbon bond cleavage.



2. Synthesis and Thermolysis of Highly Branched Hydrocarbons

At the beginning of our work 10 years ago[18], the region between these two extremes of thermal stability had been

Table 1. Thermal stability and strain enthalpy H_{sp} [a] of the hydrocarbons of types *(11)—(16)* and *(17)—(21)*.

[a] $H_{sp}=\Delta H_f^{\circ}(\text{gas})-\Delta H_f^{N}$. Unless otherwise noted, the enthalpy of formation, ΔH_f°(gas) was calculated with the force field MM2 [22] (computer program STRAIN 65 [27a]). The specific reference value ΔH_f^{N} was calculated from group increments [40]. Incremental corrections [22] for free rotation around C—C bonds were added for *(13a—c)*, *(14b—f, h, i)* and *(17)*. [b] Gas phase. [c] Assumed value (see [25] and [26]). [d] ΔH_f°(gas) was calculated with the Allinger force field, supplemented with the phenyl parameters, SET B, of *Mislow* [31] (see [26]). [e] Values for the compounds *(15d, e)* without chlorine substituents. [f] Value determined from heat of combustion measurements (see [26]). [g] A C—*tert*-butyl bond is broken during thermolysis. When there are several equivalent bonds, the kinetic data are statistically corrected.

barely explored, with the exception of the results of *Ziegler*[1] and a few complementary investigations[17d, 19a, b]. Work was subsequently published on the decomposition of phenyl-substituted alkanes[19c, d] and on the kinetics of pyrolysis of simple alkanes in the gas phase[17a-c, 20]. Since then, we have synthesized a great number of highly branched hydrocarbons whose thermal stabilities lie between the two extremes discussed above (see Table 1). In the main, classical dimerization methods such as the Wurtz synthesis and related techniques were used; of course, the yields decrease to a few percent for the highly branched representatives and the isolation of these compounds in gram quantities was therefore extremely laborious. Gas chromatography was an indispensable aid for purity control and occasionally also for isolation. Stepwise syntheses of the compounds in Table 1 were successful in only a few cases. Preparation of the cyclohexyl-substituted ethanes *(13b—e)* and *(14k, m)* was accomplished by high pressure hydrogenation of the corresponding phenyl derivatives.

We divide the symmetrical ethane derivatives which we have studied into two classes designated as the C_t—C_t series *(13), (15)* or the C_q—C_q series *(14), (16)* according to whether the two central C atoms are tertiary or quaternary.

C_t–C_t $\qquad$ C_q–C_q

In addition, a few highly branched unsymmetrical alkanes were prepared and thermolyzed. In the C_q—C_q- and C_t—C_t series, both the alkanes [*(13)* and *(14)*] and the phenyl derivatives [*(15)* and *(16)*] were studied (see Table 1).

The products of thermolysis of a large number of typical representatives were quantitatively determined by gas chromatography[23, 25, 27, 30, 34, 38, 39]. In all cases the major, and usually the only, decomposition pathway was homolytic cleavage of the central C—C bond or of the most substituted C—C bond in the other kinds of molecules *(17)—(21)*.

The kinetics of thermolysis were studied under N_2 using ampoule techniques, and were generally followed by gas chromatographic determination of the decrease in concentration of the starting material. A thermostat utilizing molten tin as the bath liquid was developed for the high temperature measurements. A few kinetic measurements were conducted with other methods, such as radical scavenging techniques with chloranil[1] or other radical traps. In general, aromatic hydrocarbons such as ethylbenzene, toluene, or mesitylene served as solvents; occasionally, decalin or *n*-alkanes with added scavenger such as mercaptan was used. Induced decomposition is recognizable under the specific reaction conditions, *e.g.* by strongly negative entropies of activation, and was not a serious drawback[29] under the conditions of measurement chosen by us.

The results of the kinetic measurements are given in Table 1. The Eyring activation parameters are recorded because the rates of reaction can only be compared at equivalent temperatures and because the actual reaction temperatures are very different. In most cases, the activation parameters were calculated from rate constants measured over a 50-degree temperature range. The temperatures at which $\tau_{1/2} = 1$ h are also listed, in order to permit an easy comparison of the thermal stability of these hydrocarbons.

Application of the Exner test showed that, at least within a series of comparable compounds, isokinetic and even isoentropic relationships exist; a discussion of the relationship between structure and activity in terms of the precisely determined free enthalpies of activation, $\Delta G^{\neq}$, or in terms of the linearly related temperatures for $\tau_{1/2} = 1$ h is therefore permissible[23, 26, 37].

A qualitative examination of the kinetic results in Table 1 supports the findings of *Ziegler*[1]: the thermal stability of the central C—C bond in substituted ethanes is decreased not just by radical-stabilizing α-phenyl substituents, but also especially by increasing size of the groups in the alkyl side chain. This steric acceleration of the homolytic bond dissociation is especially clear in the thermolysis of 3,4-di-*tert*-butyl-2,2,5,5-tetramethylhexane ("tetra-*tert*-butylethane"), *(13f)*[27], which dissociates into ordinary secondary radicals with no special stabilization[43]. The C—C bond of *(13f)* is cleaved at approximately the same rate as the O—O bond in di-*tert*-butyl peroxide ($\Delta H^{\neq} = 37$ kcal mol^{-1}, $\Delta S^{\neq} = 12$ cal mol^{-1} K^{-1} in cyclohexane)[42].

The discovery that the cyclohexyl-substituted compounds *(13d, e)*[25] have $\tau_{1/2} = 1$ h at almost the same temperature as the corresponding phenyl-substituted compounds *(15d, e)*[26], in spite of the fact that the latter decompose into radicals of the benzyl type, points to the same conclusion. Finally, it is striking that the diastereomers *(13d, e)*[22], *(15d, e)*[26], or *(15f, g)*[32, 33] are remarkably different in stability. Since thermolysis of the diastereomeric hydrocarbons gives the same radicals, the heat of formation of the diastereomeric hydrocarbons themselves must be very different. This is apparently the case when the ethane moiety is substituted on both C atoms with *tert*-butyl groups.

Finally, the finding[11, 12, 23, 26, 28, 29] that the rates of thermolysis of the four symmetrical compound types *(13)—(16)* all give good correlations with the steric substituent constants E_s^c or $\mathscr{S}_f$[9d] indicates that, within each series, the different ground state strain of the hydrocarbons is the factor which determines the reactivity.

2.1. Thermal Stability and Strain Enthalpy

We calculated the ground state strain enthalpies, H_{sp}, for the hydrocarbons *(11)—(21)* (see Table 1) in order to be able to *quantitatively* analyze the steric acceleration of the decomposition of these compounds. By definition, H_{sp} corresponds to the difference between the standard enthalpy of formation in the gas phase, ΔH_f^0(gas), and a strain-free "normal heat of formation", ΔH_f^N. The latter is calculated from group increments[40]. We calculated the heat of formation of the hydrocarbons with empirical force field techniques[44], which also give agreement with structural data (see below).

Since the available force fields are not parameterized for highly strained compounds[44], their suitability for such compounds must be tested by comparison with experimental data. This was accomplished by comparison of calculated structural data with the results of X-ray analyses (see Section 3). In addition, we determined the heat of formation from

experimental thermochemical data, *i.e.* heats of combustion, heats of fusion, and heats of sublimation[25-27], for a few of the most highly strained compounds. Their strain enthalpies, H_{sp}, based on the experimentally determined heats of formation of the most highly strained compounds, tetra-*tert*-butylethane *(13f)* (exp. $H_{sp} = 57 \pm 4$ kcal mol^{-1})[45] and 3,4-dimethyl-3,4-dicyclohexylhexane *(14m)* (exp. $H_{sp} = 35 \pm 0.5$ kcal mol^{-1})[30] are in excellent agreement with the values calculated with *Allinger*'s force field MM2[22] (see Table 1). Because the other force fields did not give the same uniformly high precision of agreement, we used the MM2 values for the alkanes *(13)*, *(14)*, and *(17)—(21)* in Table 1. However, since this force field[22] is not yet parameterized for aromatic hydrocarbons, we used the older force field of *Allinger* (71)[44,46] with the phenyl parameters (SET B) of *Andose* and *Mislow*[31] for the phenyl-substituted compounds in Table 1. This choice of force field was fully justified by the structural data (see Section 3).

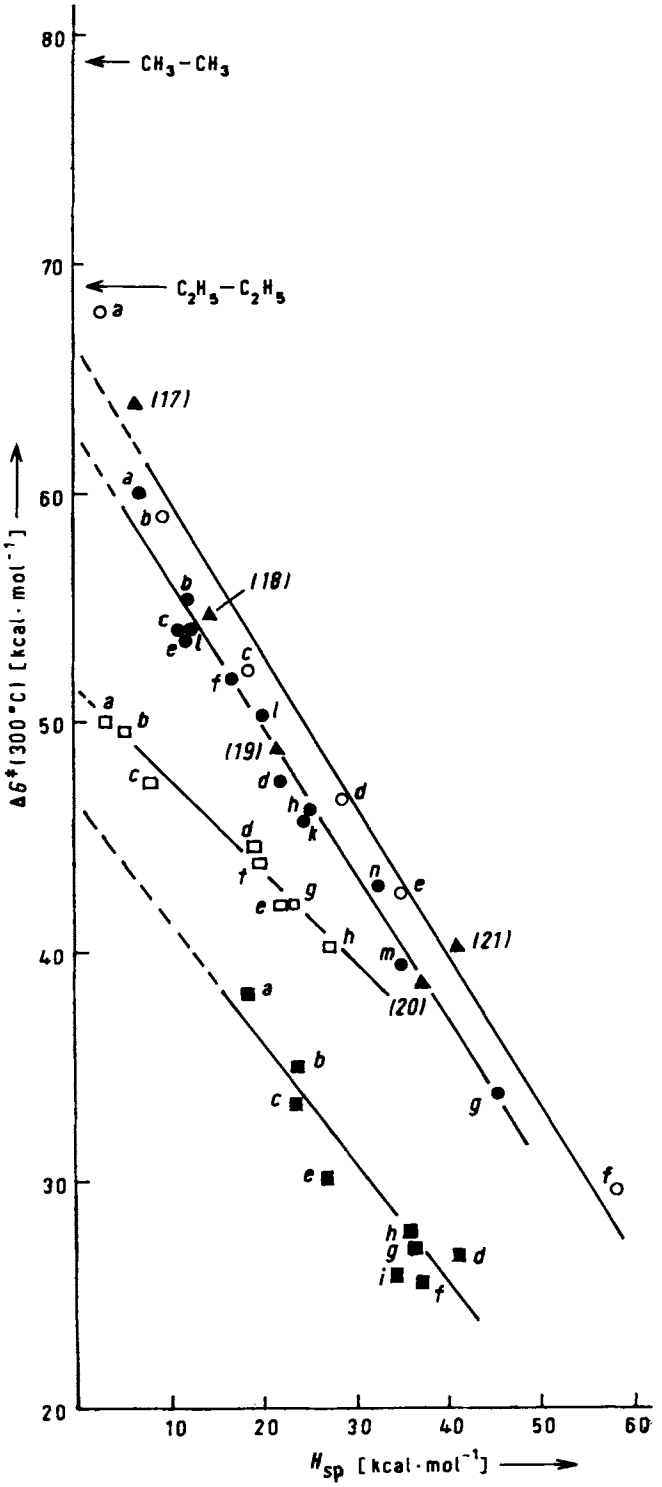

Fig. 1. Correlation between the free enthalpy of activation, $\Delta G^{\ddagger}$ (300 °C), of the thermolysis and the strain enthalpy, $H_{sp} = \Delta H_f^{\circ}(\text{gas}) - \Delta H_f^{N}$ [40], for the hydrocarbons *(13)—(21)* (see Table 1).
The correlation lines yield the following equations:

○ *(13a—f)*: $\Delta G^{\ddagger} = 66.5\ (\pm 1.6) - 0.67\ (\pm 0.05)\ H_{sp}$ kcal mol^{-1}
● *(14a—h)*: $\Delta G^{\ddagger} = 62.4\ (\pm 0.7) - 0.64\ (\pm 0.03)\ H_{sp}$ kcal mol^{-1}
□ *(15a—h)*: $\Delta G^{\ddagger} = 51.4\ (\pm 0.4) - 0.40\ (\pm 0.02)\ H_{sp}$ kcal mol^{-1}
■ *(16a—i)*: $\Delta G^{\ddagger} = 46.2\ (\pm 2.4) - 0.52\ (\pm 0.07)\ H_{sp}$ kcal mol^{-1}
▲ *(17)—(21)*
(Standard deviation in parentheses.)

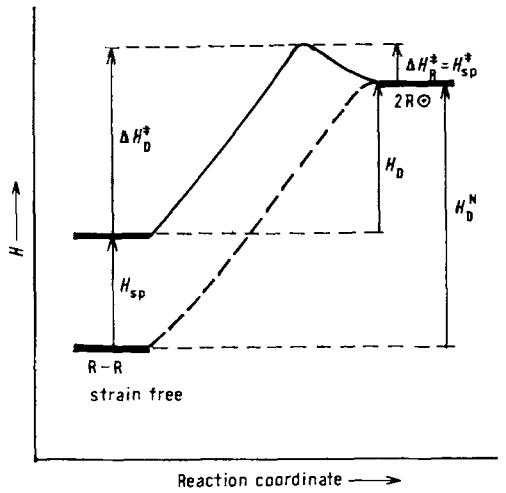
Can a relationship be established between the strain enthalpies of the hydrocarbons and their thermal stabilities? If $\Delta G^{\ddagger}$ (300 °C) for the thermolysis of *(13)—(16)* is plotted against the strain, H_{sp}, a far-reaching linear correlation with astoundingly little scatter obtains for each of the four types of compounds. The slopes of the calculated correlation lines permit conclusions about the sensitivity of the rate of decomposition of a class of compounds to increasing strain in the ground state. The displacements between the lines point to the influence of radical stabilizing substituents on the transition state of the reaction[47].

The correlation lines of the C_t—C_t series *(13)* and the C_q—C_q series *(14)* possess almost the same slope, but differ in intercept by about 4 kcal mol^{-1}. This difference was not established previously, when computational results from the Engler-Schleyer force field were used[37]. Experimental data verify that this older force field leads to excessively high strain enthalpies in the C_q—C_q series[30]. Since *(13)* gives secondary radicals and *(14)* gives tertiary radicals, the small difference in intercepts is now in agreement with the expectation[5,43] of different bond strengths at tertiary and quaternary C atoms. On the other hand, it is seen from Figure 1 that the linear correlations for *(13)* and *(14)* break down for very small strain energies; extrapolation to the intercepts is therefore somewhat questionable. The points for *(13a)* and *(14a)* lie clearly above the correlation lines. However, in contrast to the others, these points are literature values determined in the gas phase.

The trend to a higher stability than is understandable solely in terms of the strain energy is particularly apparent when ethane *(11)* and butane *(12)* are included in the picture. The high stability of their C—C bonds has not yet been satisfactorily explained: weak electronic stabilization of the resulting methyl and ethyl radicals is hardly or only partly responsible. There may be a special stabilization of the hydrocarbon ground state in these cases[5,11,12,43,48]. These minor deviations cast no doubt on the overall correlation which certainly does not have to be strictly linear in any case. Further conclusions can therefore be drawn: the intercepts of $\Delta G^{\ddagger} = 63$ or 66 kcal mol^{-1}, correspond to bond dissociation enthalpies, $H_D = 71.6$ [C_q—C_q alkanes *(14)*] or 74.6 kcal mol^{-1} [C_t—C_t alkanes *(13)*] for the unstrained prototypes, in full accord with expectation[49]. It is particularly impressive that the thermolysis data for the alkanes *(17)—(21)* are generally in line with the correlations in Figure 1. In these cases, the free enthalpies of activation for the thermolyses must be statistically corrected for the number of equivalent bonds and the

bond types must be taken into account [C_q—C_q: *(19)*, *(21)*; C_q—C_t: *(18)*, *(20)*; C_q—C_s: *(17)*] (s = secondary).

It is particularly interesting that the correlations for C_t—C_t and for C_q—C_q alkanes both show a slope of about 0.65. An increase in the ground state strain is therefore only about 65% effective in decreasing the activation enthalpy of C—C cleavage. Approximately 35% residual strain must remain in the transition state of the thermolysis. It is interesting that this rule holds, apparently independently of the total strain in the compound. According to the principle of microscopic reversibility, the recombination of two alkyl radicals must experience a strain in the transition state which corresponds to about 35% of the strain in the dimer. Assuming that the alkyl radicals are unstrained, or at most much less strained than their dimers[27,28], one obtains the reaction coordinate diagram shown in Figure 2.



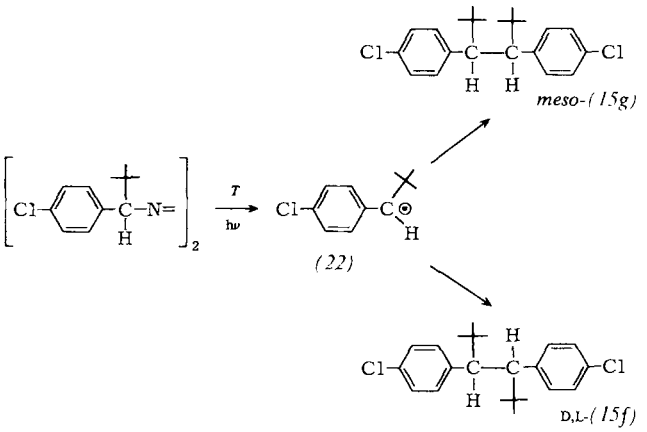


Fig. 2. Reaction coordinate for thermal C—C cleavage.

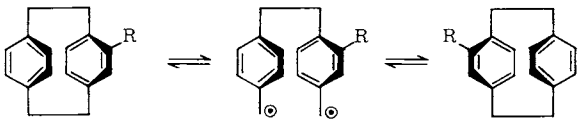
The bond dissociation enthalpy H_D^N of the unstrained compound, the strain enthalpy, H_{sp}, as well as the $\Delta H_D^{\ddagger}$ are accessible through experiment or calculation. By subtraction, one obtains $\Delta H_R^{\ddagger}$, the activation enthalpy for recombination of the radicals and H_D, the thermodynamic bond enthalpy. $\Delta H_R^{\ddagger}$ is diminished, of course, when a residual strain ultimately appears in the radicals themselves[27,28].

In contrast to small alkyl radicals whose recombination rates are diffusion controlled[32,50], hindered radicals have to overcome an activation barrier to dimerization. This is in agreement with the observed lack of dimerization of the hindered radicals *(6)*—*(10)*. Experiments to measure the recombination rates of selected radicals of moderate size by ESR spectroscopy are in progress[51]. For an independent test of this question, the diastereomeric pairs *(13d, e)*, *(15d, e)*, and *(15f, g)* are suitable; their different rates of thermolysis are explained by their different strain enthalpies. According to Figure 2, one anticipates that the formation of the *meso*- and D,L-diastereomers by radical recombination proceeds over different activation barriers. Therefore, the diastereomers should not be formed in 1:1 ratio, as is usually the case with the recombination of smaller radicals. The finding that the dimerization of 1-*p*-chlorophenylneopentyl radicals *(22)* proceeds diastereoselectively to give the more stable D,L-dimer *(15f)*, in preference to *(15g)*, appears to be in agreement with an activation barrier to dimerization of the radicals[32].

However, the product ratio, *(15f)*:*(15g)* = 1.66 was found to be independent of the temperature between −30 and +140 °C[33]. Therefore, in this case it cannot be that the differences in the rates of dimerization are caused by differences in strain enthalpy of the diastereomers. The significance of this diastereoselectivity must be examined with other models[52].

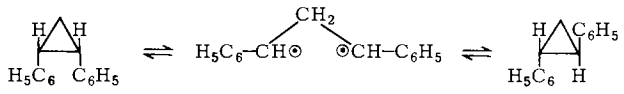


2.2. Influence of Phenyl Substituents

The correlation lines for the phenyl-substituted compounds *(15)* and *(16)* in Figure 1 resemble those for the alkanes *(13)* and *(14)* in several respects. In particular, the correlation lines for *(15)* (C_t—C_t series) and *(16)* (C_q—C_q series) again differ in their intercepts by about 4 kcal mol^{-1}. However, their slopes (0.40 and 0.52 respectively) are significantly smaller than the slopes for the alkanes *(13)* and *(14)* (0.67 and 0.64). The fact that the thermolyses of *(15)* and *(16)* give resonance-stabilized α-substituted benzyl radicals certainly plays an important role. This is also the reason that the correlation lines for the phenyl substituted compounds *(15)* and *(16)* in Figure 1 lie further down than the lines for the aliphatic compounds *(13)* and *(14)*. $\Delta G^{\ddagger}$ is decreased by that part of the resonance energy of the resulting radicals which is set free at the transition state. This resonance energy can be estimated from Figure 1. According to the above arguments, one can be certain that the transition state lies at the energy level of the resulting radicals only in the case of the thermolysis of unstrained hydrocarbons (see Fig. 2). For the dissociation of strained hydrocarbons, the transition state should be reached before the dissociation is complete (see Fig. 2); therefore, the full benzyl resonance cannot be effective in stabilizing the transition state. In order to estimate the benzylic resonance, we therefore compare the intercepts ($H_{sp} = 0$) of the correlation lines of the phenyl-substituted and the corresponding alkane compounds. For the C_t—C_t series [*(13)* and *(15)*], the difference is $\Delta\Delta G_0^{\ddagger} = 15.1$ (±1.7) kcal mol^{-1} and for the C_q—C_q series [*(14)* and *(16)*] $\Delta\Delta G_0^{\ddagger} = 16.2$ (±2.5) kcal mol^{-1}. To be sure, it should be noted that two different force fields were used for the alkanes *(13)* and *(14)* and for the phenyl derivatives *(15)* and *(16)*; the discrepancies caused by this are certainly not large, because the use

of the Engler-Schleyer[53] force field for *(13)* gave[26] a difference in intercepts [*(13)*:*(15)*] of 16 kcal mol^{-1}. Thus, the resonance energy per benzyl radical is *ca.* 8 kcal mol^{-1}, in good agreement with the most recent literature value of 10 ± 2 kcal mol^{-1}[54]. The qualitative estimation of the thermal stability of hydrocarbons in terms of radical stabilization and ground state strain, as intended by *Ziegler*, has thus been put on a *quantitative* basis.

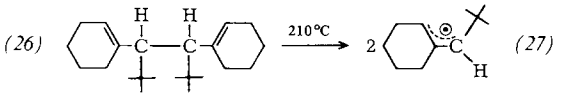
In addition, the smaller slopes of the correlations for the phenyl derivatives are probably explained by the resonance energies of the radicals resulting from the thermolysis. As the strain in the hydrocarbon increases, the transition state of the thermolysis is reached sooner on the reaction coordinate (see Fig. 2), *i.e.* the bond breaking is not complete and the delocalization energy of the benzyl radicals is therefore only partially released. The separation between the correlation lines for the aliphatic and the phenyl substituted derivatives should, therefore, decrease in the region of high strain H_{sp}, as observed. It is not yet known why the effect is smaller in the C_q—C_q series than in the C_t—C_t series. A conclusion will only be possible when the strain enthalpies of the phenyl-substituted compounds have been calculated with the force field MM2 and this force field has been tested in this series against experimental, thermochemical data.



The results described here concerning the demarcation of steric and electronic effects have provided a substantially deeper insight into the laws concerning C—C bond cleavages and have stimulated a study of the reverse reaction, namely the recombination of radicals to give strained hydrocarbons. However, the results also have empirical significance for the prediction of the thermal stability of hydrocarbons. By means of simple force field calculations, these predictions are possible from Figure 1 with considerable precision. The finding that the rates of thermolysis of the unsymmetrical compounds *(17)*—*(21)* corresponds to expectation is especially important. In this regard, it is interesting to see that homolytic cleavage reactions associated with the release of ring strain, but not with the release of F-strain[8], as in our examples, are apparently also in qualitative agreement with the correlations of Figure 1. Thus, the rate of racemization of (−)-methyl [2.2]paracyclophane-4-carboxylate, (−)-*(23)*, which is formulated as a homolysis-recombination reaction ($\Delta G^{\neq} \approx 38$ kcal mol^{-1}; H_{sp} 31.3 kcal mol^{-1})[55] lies on the correlation line for the class of compounds of type *(15)* in Figure 1.

(−)-*(23)* R = $COOCH_3$ (+)-*(23)*

The same applies to the rate of *cis-trans* isomerization of 1,2-diphenylcyclopropane *(24)* [$\Delta G^{\neq}$ (300 °C) = 38.4 kcal mol^{-1}][56] or the rate of racemization of the optically active *trans* compound *(25)* [$\Delta G^{\neq}$ (300 °C) = 40.2 kcal mol^{-1}][57], if 27 kcal mol^{-1}[58] is used as the value for the ring strain.



The activation energies for the ring opening of cyclopropane [$\Delta G^{\neq}$ (300 °C) = 56.4 kcal mol^{-1}][59], methylcyclopropane [$\Delta G^{\neq}$ (300 °C) = 54.5 kcal mol^{-1}][60] and 1,2-dialkylcyclopropanes [$\Delta G^{\neq}$ (300 °C) = 53—54 kcal mol^{-1}][61] correlate less satisfactorily, but still lie in the expected region of Figure 1 for 27 kcal mol^{-1} ring strain[58]. In addition, the homolytic ring opening of cyclobutane with 26 kcal mol^{-1} strain enthalpy[58] [$\Delta G^{\neq}$ (300 °C) = 56 kcal mol^{-1}][62] and methylcyclobutane [$\Delta G^{\neq}$ (300 °C) ≈ 55 kcal mol^{-1}][63] lie in the expected region of Figure 1.

(24) *(25)*

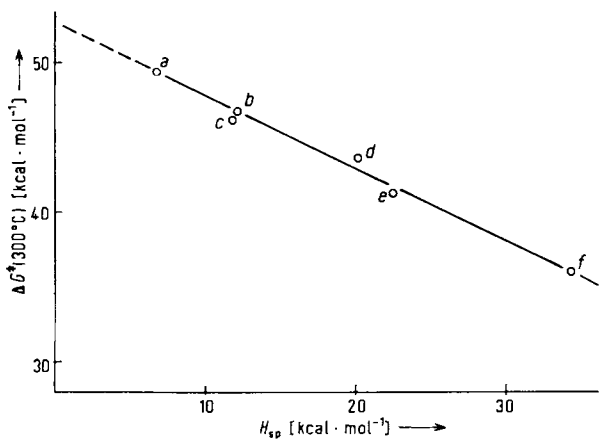
2.3. Further Substituent Effects

Using the methods described in this paper for the hydrocarbons, it should be possible to clarify the question of the stabilizing effect of substituents other than the phenyl group on a neighboring radical center and to clarify the associated question of the thermal stability of the corresponding substituted alkanes. Preliminary experiments with the first α-vinyl substituted compound, *meso*-3,4-di-(1-cyclohexenyl)-2,2,5,5-tetramethylhexane *(26)*[64] showed that the allyl resonance of the radicals *(27)* produced in the thermolysis once again lowers the thermal stability ($\tau_{1/2} = 1$ h at 210 °C)[64].

(26) *(27)*

The further exploration of this class of compounds is of particular interest because they are, in principle, suitable for Cope rearrangement. Can these two reaction possibilities be distinguished from each other?

More kinetic data are available in the tetraalkylated succinodinitrile series *(28)*[65] (see Table 2). Since strain enthalpies for these nitriles have not yet been measured experimentally, and also cannot yet be calculated with the force fields available[44], the strain enthalpy H_{sp} calculated for the corresponding hydrocarbon (CH_3 instead of CN) with the force field MM2[22] is listed for each compound in Table 2. Figure 3



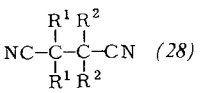


Fig. 3. Relationship between the free enthalpy of activation $\Delta G^{\neq}$ (300 °C) for the thermolysis of tetraalkyl-substituted succinonitriles *(28)* from Table 2 and the strain enthalpies H_{sp} of the hydrocarbons $CH_3CR^1R^2$–$CR^1R^2CH_3$, as calculated with the force field MM2 [22].

shows that an excellent linear correlation between the stability and the strain enthalpies again obtains; the correlation obeys the equation

$$\Delta G^{\neq}(300\,^{\circ}C) = 52.5\ (\pm 0.5) - 0.48\ (\pm 0.03)\ H_{sp}$$

The difference between the intercept of this line (52.5 kcal mol^{-1}) and that for the C_q—C_q alkanes *(14)* in Figure 1 (62.6 kcal mol^{-1}) is once again attributable to the resonance energy of the α-cyanoalkyl radicals. With the reservation that the strain enthalpies H_{sp} of the succinonitriles are only known by modeling, a resonance stabilization of α-cyanoalkyl radicals of 5 kcal mol^{-1} results, in unexpectedly good agreement with literature values which lie between 5 and 7 kcal mol^{-1}[66,67].

Table 2. Thermal stability of tetraalkylated succinonitriles *(28)* [65].

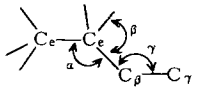
[a] Strain enthalpy of the corresponding hydrocarbons (with CH_3 in place of CN) calculated with force field MM2; see Table 1, footnote [a].

Further refinement of these conclusions by thermochemical measurements will show whether the techniques developed here are generally suited to the quantitative interpretation and prediction of the thermal stability of other substituted hydrocarbon frameworks and to the estimation of resonance energies of α-substituted alkyl radicals.

3. Structure and Strain of Highly Branched Hydrocarbons



It was to be anticipated that strain enthalpies as high as 57 kcal mol^{-1}, as were found for compounds in Table 1, would also have consequences for the structures of these compounds. How do the reduced bond dissociation enthalpies influence the bond lengths? How do the hydrocarbons accommodate the steric pressures by angle deformation? What are the consequences for conformational analysis? To answer these questions the X-ray structure analyses of typical members of the C_t—C_t series [*(13c)*[24], *(13d, e)*[25], *(15d, e)*[68]] and the C_q—C_q series [*(14m)*[30] and *(16i)*[69]] were carried out by *H. J. Lindner* and by *W. Littke*; the applicability to the solution state was justified by NMR investigations[25]. The structural data for these ethanes, together with the structures described in the literature and determined by electron diffraction in the gas phase for *(13a)*[70] and *(14a)*[70], are found in Table 3. The experimentally determined structural data are set alongside the values calculated with the force field MM2. This comparison must show whether the results of these computational techniques also give trustworthy predictions for those structures which lie outside the limited region of parametrization of the actual force field with simple test compounds[44]. The use of the MM2 force field[22] for highly branched alkanes is justified by the precise agreement between experiment and calculation in Table 3, as well as by the comparison of experimental heats of formation with calculated values[71], as discussed above. The less reliable results of calculations with the older Allinger force field[31,44,45] which must be employed for the diphenylethanes *(15)* and *(16)*, give at least the correct trends of the structural deformations evoked by the strain [cf. *(15d, e)* and *(16i)* in Table 3).

The data in Table 3 and further data show that the strain engendered in the hydrocarbons by the steric pressure of the substituents is distributed over several internal coordinates and does not just lead to a stretching of the central C—C bond; rather, neighboring bonds are lengthened and particularly marked angle deformations result. Analysis of all the structural parameters for the hydrocarbons *(13)*—*(21)*, which are accessible through the force field calculations, permit the recognition of two general rules for the relationship between strain and structure:

1) Deformation of bond angles and lengths occur mainly at the C atoms of the weakest, *i.e.* the most highly substituted bond (C_e), and less distinctly at the immediately adjacent atoms (C_β).
2) Highly branched alkanes preferentially yield to the strong van der Waals repulsions between non-bonded groups by expansion of the CCC angles and simultaneous reduction of HCH or HCC angles at the same center. Bond stretching only appears as a secondary effect.

Rule 2 is understandable in terms of the smaller force constants for angle deformation than for bond stretching. From rule 2 it also follows that a marked expansion of CCC angles is possible only at secondary (C_s) and tertiary (C_t) centers because the increase of an angle at a quaternary carbon atom

would be tied to the simultaneous compression of another CCC angle.

3.1. Bond Angles and Bond Lengths

In order to facilitate an overview, the *largest* CCC angles α at the central bonds which are cleaved in the thermolysis of the hydrocarbons listed in Table 1 are indicated as *filled symbols* in Figure 4. With two exceptions *(14g, n)*, α at quaternary C atoms (●) is only slightly expanded to 112—114°. At tertiary C atoms (■), a mildly strained representative such as 2,3-dimethylbutane *(13a)* (H_{sp} = 2.7 kcal mol^{-1}) already has α = 114°. With increasing strain, α at the tetracoordinate C atom of the C_t—C_t series, increases to 120° and above [cf. *(13f)* and *(15d, e)*]. The largest angle deformation, α = 125°, is found at a secondary C atom (▲) in di-*tert*-butylmethane *(17)*, in spite of the relatively low strain enthalpy (H_{sp} = 7 kcal mol^{-1}) of this compound.

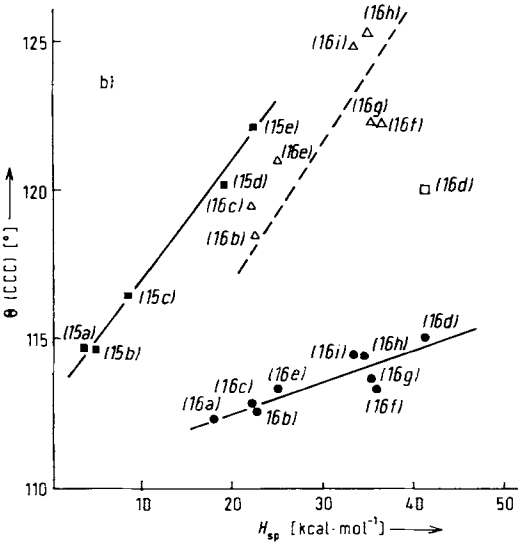

Fig. 4. CCC bond angles a) in the alkanes *(13)*, *(14)*, and *(17)* (calculated values from the force field MM2 [22]) and b) in the diphenylethanes *(15)* and *(16)* (calculated values from the force field of *Allinger-Mislow* [31, 46]) plotted against their strain enthalpy H_{sp} (see Table 1). Filled symbols: large angle α at a central C_e atom; open symbols: angle β at a neighboring C_β atom. ● angle at a quaternary C atom; ■, □ angle at a tertiary C atom; ▲, △ angle at a secondary C atom. The angle β corresponds to the angle γ in Table 3.

A similar picture emerges for the estimated angles β at the β-C atom to the central bond, shown in Figure 4 as *open symbols*. They are also consistently most strongly expanded in the case of secondary or tertiary C_β atoms. In some cases, C_β is unusually broadened; in the neopentyl side chain in *(14h)* ($H_{sp}=25.3$ kcal mol^{-1}), $\beta=126.5°$. Whether this considerable deformation from the tetrahedral angle of 109° is a consequence of a rehybridization of the C-atom or whether bent bonds[72] occur cannot be decided at the present time[73].

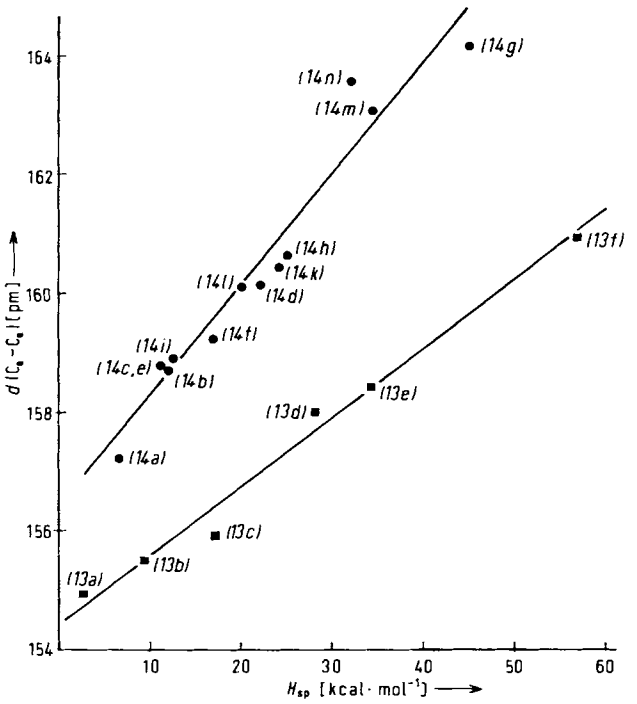

Fig. 5. C—C bond lengths for the central bonds in the alkanes *(13)* and *(14)* plotted against the strain calculated with force field MM2 [22]. ■ C_t—C_t series *(13)*; ● C_q—C_q series *(14)*.

The molecules yield to ground state strain not only through angle deformation, but also through bond stretching. This is recognizable in Figure 5, in which the length of the central, weak C—C bond in *(13)* and *(14)* is plotted against the strain enthalpy H_{sp}. The C_q—C_q alkanes *(14)* (●) have distinctly longer bonds than the C_t—C_t alkanes *(13)* (■). Because angle deformations are hardly possible in the C_q—C_q series, the central C—C bond is more strongly stretched with increasing strain than in the C_t—C_t series. This is expressed in the different slopes for the two lines shown in Figure 5. The extreme bond length in *(14m)* (163.0 pm)[30] and *(14g)* (164.1 pm) are among the longest C—C single bonds known in noncyclic hydrocarbon frameworks[74]. The C_q—C_q and C_t—C_t series of the 1,2-diphenylethanes[35,68,69] show a relationship between H_{sp}, bond angles, and bond lengths which is qualitatively similar to those in Figures 4 and 5.

3.2. Conformations

The broadening of the bond angles has consequences for the conformations of highly substituted ethanes. As a rule, one finds staggered conformations about the ethane bond with 60° torsion angles[75] as the energy minima. A Newman projection of the ethane bond (see Fig. 6) shows that an increase in the bond angle R^1—C—R^2 also leads to a considerable change in the torsion angle. This can have a great effect on conformational equilibria[76].

In the C_q—C_q series [*(14)* and *(16)*], even the strained members of the series show only small changes in the C_e—C_e—C_β and the C_β—C_e—C_β angle (see Fig. 4)[28,35]. Therefore, this series also shows normal staggered conformations with torsion angles between 40 and 80°. The rotamers with the largest side chains in the *anti* position possess energies similar to those with the residues in the *gauche* position, with the exception of the extreme case of *(14g)*[28] which only occurs in the *anti* conformation. *meso*- and D,L-diastereomers are likewise comparable in energy ($\Delta\Delta H<2$ kcal mol^{-1}).

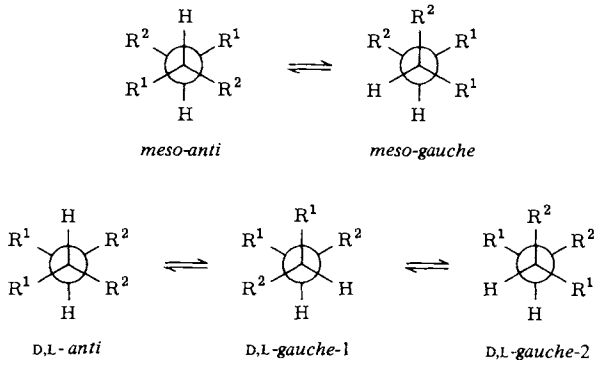

Fig. 6. Alternating conformations at the ethane bond in *(13)* and *(15)*.

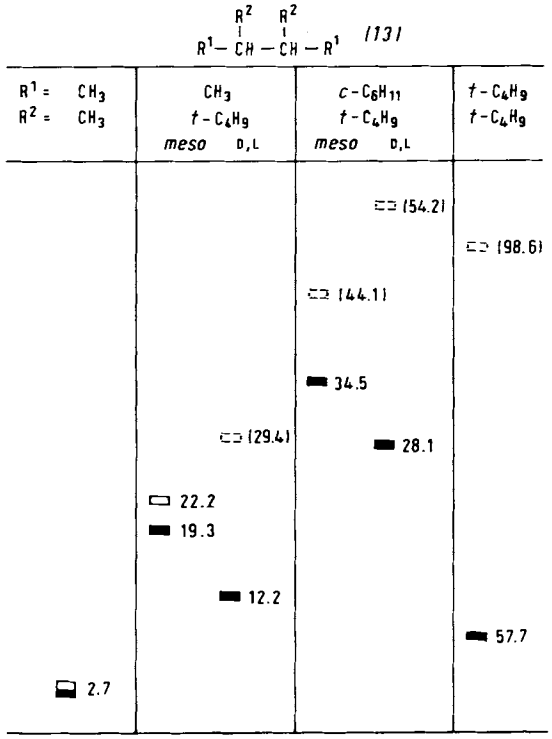
The conformational situation in the series of the C_t—C_t alkanes *(13)* is completely different. There exist alternating $(FB)_3$ conformations[77] with the H atoms in the *anti*- or *gauche* positions. For a *meso* configuration ($R^1\neq R^2$), there are two rotamers: *meso-anti* and *meso-gauche*. For the D,L-configurations, there are one *anti*- and two *gauche* conformations (see Fig. 6). With normal torsion angles, one would expect from experience that the *anti* rotamers are the most stable, because they show only *two* skew interactions and not *three*, as do the *gauche* conformations. In addition, one usually ascribes a higher stability to the *meso* form because the two largest groups (R^1 or R^2) are in an *anti* disposition. These customary predictions are turned completely upside down in the C_t—C_t series *(13)*.

1) All tetraalkylethanes *(13)* prefer the *gauche* over the *anti* arrangement. The energy difference between these two conformations is only 0.1 kcal mol^{-1}[78] for 2,3-dimethylbutane *(13a)*, but grows dramatically with increasing size of the groups, as shown schematically in Figure 7.
2) When different configurations exist (*i.e.* $R^1\neq R^2$), the D,L form is more stable than the *meso* form.

These two unexpected findings follow directly from the *expansion of the geminal angle* R^1—C_e—R^2 in the C_t—C_t alkanes (see Fig. 4). NMR and EFF analysis of the conformations of the extreme member of the series, 3,4-di-*tert*-butyl-2,2,5,5-tetramethylhexane *(13f)* shows this quite clearly[27]:

The strong increase of the angle between the geminal *tert*-butyl groups in the *anti* conformation leads to a drastic increase in strain because of the decreasing distance between



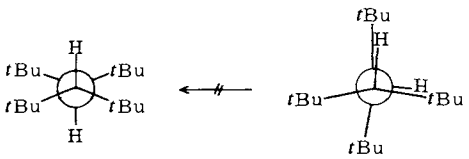


Fig. 7. Strain enthalpies for the C_t—C_t alkanes *(13)* in their various conformations (see Fig. 6) according to calculations with the force field MM2 [22]. ■ H, R^2 *gauche*, □ H *anti*. (Energy levels of rotamers printed as dashed lines are not minima, but are transition states for bond rotation.)

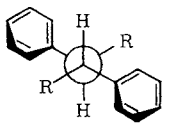
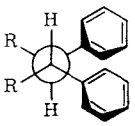
the vicinal *tert*-butyl groups. As a result, the *anti* conformation is a saddle point on the energy surface[27b]: The energy of the *anti* conformation lies higher than the transition state for the thermolysis of *(13f)*. For *(13f)*, there are only strongly



anti-(13f) FBE$_2$-*(13f)*

distorted *gauche*-like minima, in which the *tert*-butyl groups are at the maximum distance from each other. Two of these groups can avoid each other in the "steric hole" caused by the vicinal H atoms. The result is a nearly eclipsed FBE_2 conformation[77].



Similar conformations were found[25] by X-ray analysis for the two diastereomers *meso*- and D,L-3,4-dicyclohexyl-2,2,5,5-tetramethylhexane *(13d, e)*. The higher stability of the D,L diastereomer ($\Delta\Delta H_f^0 = 7.8$ kcal mol^{-1}) results because both the *tert*-butyl groups (R^2 = *tert*-butyl) in the *gauche*-1-conformation of the D,L compound can occupy the sterically preferred position opposite to the vicinal H atom (see Fig. 6). In the *gauche* rotamer of the *meso* form, this is possible for only one of the large *tert*-butyl groups and for the smaller cyclohexyl residue. In addition, tetracyclohexylethane *(13c)* exists exclusively in the *gauche* conformation[24], while both *gauche*- and *anti* conformations are populated[78] for 2,3-dimethylbutane *(13a)*. Apparently then, the rules indicated above are roughly valid even for ethanes *(13)* bearing small groups. Even the torsion angles $\Delta\Theta(RC_eC_eH)$ for these compounds are smaller than 60°.

Finally, it can be deduced that non-alternating conformations[77] can be expected as energy minima only for tetrasubstituted ethanes with unusually large geminal bond angles, *i.e.* when there are large repulsions between the geminal groups, or when the geminal angles are especially small as in dicyclopropyl[80].

The effects of various strong repulsions between geminal groups on conformational equilibria can also be studied in the 1,2-dialkyl-1,2-diphenylethanes *(15)*. The energies calculated with the Allinger-Mislow force field[31,46] for conformers of several compounds of type *(15)* are displayed in Figure 8 for the *meso*- and D,L configurations.

meso-(15)-anti

D,L-*(15)-anti*

The diphenylalkanes *(15)* with primary and secondary alkyl groups R *(15a—c)* behave "normally", *i.e.* they prefer the *anti* conformation. The flat disc shape of the phenyl ring and the associated small steric demand is responsible for this difference from the tetraalkylethanes *(13)*: methyl, ethyl, or isopropyl groups R can arrange themselves over the plane of a *geminally* oriented phenyl group and thereby produce little repulsion. The D,L-*(15)-anti* conformation is additionally favored because of the "stacking"[79] of the two *vicinal* rings. As a result, there is no expansion of the geminal bond angles in the *anti*-conformations of these compounds and the torsion

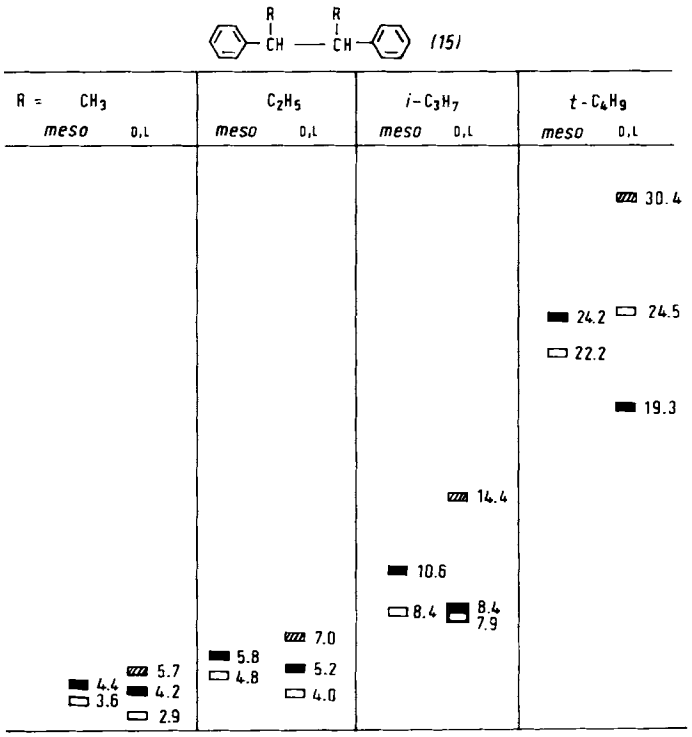


Fig. 8. Strain enthalpies H_{sp} [kcal mol^{-1}] for various conformations of the dialkyldiphenylethanes *(15)* (see Fig. 6) according to calculations with the Allinger-Mislow force field [31, 46]. ■ H, R *gauche*; ▨ H, Ph *gauche*; □ H *anti*.

angles are also normal at *ca.* 60°. The usual rules for the relative stability of the conformations *(anti > gauche)* remain valid.

Even *meso*-2,2,5,5-tetramethyl-3,4-diphenylhexane *(15e)* strongly prefers the *meso-anti* conformation over the *meso-gauche* orientation. In the *anti* conformation the bulky vicinal *tert*-butyl groups achieve the maximum separation, while in the *meso-gauche* arrangement (see Fig. 6, $R^1 = C_6H_5$, $R^2 = tert$-butyl) only one *tert*-butyl group can occupy the favorable position *gauche* to an H atom and even this must be purchased at the expense of a direct *gauche* interaction with the vicinal *tert*-butyl group. The situation is otherwise in *(15d)*: as a result of the geminal repulsion between the *tert*-butyl group and the phenyl ring the repulsion between the vicinal *tert*-butyl groups is increased. Thus, torsion around the central bond leading to the *gauche*-1 conformation (see Fig. 6, $R^1 = C_6H_5$, $R^2 = tert$-butyl) is associated with a decrease in energy. The vicinal *tert*-butyl groups reach an *anti* orientation and both take up the sterically preferred position *gauche* to a vicinal H atom.

The study of the structures of highly branched hydrocarbons has shown that increasing strain is preferentially countered by an increase in the geminal bond angle and that this, in turn, is often the source of a change in the relative stabilities of the rotamers. When expansion of the geminal angles is prohibited, or is possible only in small measure, as in the C_q—C_q series [*(14)* and *(16)*], then a marked bond stretching, particularly of the central C—C bond, is observed as the ground state strain increases.

4. Outlook

The results communicated in this essay confirm that *quantitative* investigations are rewarding and ultimately lead to novel qualitative information. The simple relationships found to exist between stability, strain, and structure are a fitting illustration. These results could not have been achieved without the availability of new experimental methods and theoretical models. The challenge remains to transfer these relationships, established for simple model hydrocarbons, to other classes of compounds. To this end, further refinement of the methodology will be necessary, particularly with regard to the development of suitable force fields.

We thank those co-workers who have participated in this work, Dr. G. Hellmann, Dipl.-Chem. G. Kratt, Dr. R. Winiker, Dipl.-Chem. S. Weiner, Dipl.-Chem. W. Barbe, Mrs. J. Geiselmann, Mrs. K. Lay, for their experimental effort, for continuing critical discussion, and for considerable stimulation. Thanks are also due to Prof. H. J. Lindner, Dr. W. Littke, Prof. H. Fritz for their close cooperation in the work on structural problems. We are indebted to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Dr. Otto Röhm Memorial Foundation for financial support, and the Computer Center of the University of Freiburg for generous allocation of computer time.

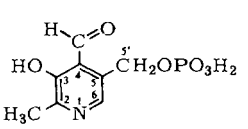
The Role of Pyridoxal Phosphate in the Catalysis of Glycogen Phosphorylases

By Ernst J. M. Helmreich and Helmut W. Klein[*]

Dedicated to Professor Otto H. Wieland on the occasion of his 60th birthday

Glycogen phosphorylases catalyze the degradation of glycogen by phosphate (or arsenate) to glucose 1-phosphate (or glucose + arsenate). All glycogen phosphorylases that have been studied so far contain pyridoxal 5'-phosphate, a vitamin B_6-derivative, as cofactor. Removal of the cofactor results in an inactive apoenzyme. However, reduction of the azomethine bond linking pyridoxal phosphate to an ε-aminolysyl side chain of the enzyme with $NaBH_4$ does not inactivate glycogen phosphorylase. If therefore the cofactor should be involved in catalysis in glycogen phosphorylase it must function differently from all other classical pyridoxal phosphate dependent enzymes, for these are inactivated by reduction. ^{31}P-NMR spectroscopy has revealed that the 5'-phosphate group of pyridoxal phosphate is present in catalytically active forms of glycogen phosphorylases as dianion in a hydrophobic environment shielded from aqueous solvent. Covalent and/or allosteric *activation* of muscle glycogen phosphorylases is accompanied by a transition of the monoprotonated form to the dianionic form of the phosphate group of the cofactor. We now report on such ionization changes in unregulated *active* potato- and *E. coli* maltodextrin phosphorylases on binding of glucose and oligosaccharides and following catalytic turnover, *i. e.* arsenolysis of α-1,4-glycosidic bonds. (Like glycogen phosphorylases, maltodextrin phosphorylases belong to the class of α-glucan phosphorylases.) The results of experiments carried out by our group together with recent findings on the three dimensional structure of crystalline muscle glycogen phosphorylases indicate a participation of the dianionic phosphate group as proton acceptor for the glucosyl transfer to and from the glucosyl acceptor. Although other interpretations are not excluded, at present little doubt remains that in the case of glycogen phosphorylases the dianionic phosphate group of the cofactor functions in catalysis.

1. Introduction



1.1. Properties of Phosphorylase

Glycogen is a highly branched animal reserve carbohydrate made up of α-1,4-D-glucose residues. Glycogen phosphorylases [EC 2.4.1.1] catalyze the phosphorolytic cleavage and formation of α-1,4-glycosidic bonds of glycogen starting from the nonreducing end of the polysaccharide:

$$(\text{Glycogen})_n + P_i \rightleftharpoons (\text{Glycogen})_{n-1} + \text{Glucose 1-phosphate} \quad (1)$$

P_i = inorganic phosphate

The reaction is reversible *in vitro* ($K_{eq} = [P_i]/[\text{glucose 1-phosphate}] = 3.6$ at pH 6.8). In the living cell, however, phosphorylases catalyze glycogen degradation, because of the high concentration of P_i and the relatively small concentration of glucose 1-phosphate (P_i : glucose 1-phosphate = 300 : 1)[1]. All

(1)

glycogen phosphorylases so far studied contain covalently bound pyridoxal 5'-phosphate *(1)*, a derivative of vitamin B_6. Pyridoxal phosphate is linked *via* its aldehyde group with the ε-amino group of a lysine moiety in the phosphorylase. On reduction of this azomethine bond with sodium borohydride the cofactor is irreversibly bound to the enzyme, but as has been shown by *E. H. Fischer et al.*, its activity is retained[2]. Hence, glycogen phosphorylases differ from the "classical" pyridoxal phosphate dependent enzymes which are inactivated by reduction.

1.2. Structure

Phosphorylases from rabbit skeletal muscle, potato and *E. coli* (with which we obtained the data reported here) are dimeric molecules made up of identical subunits. The molecular weight of the subunit of muscle phosphorylase is 97412 as determined by sequence analysis (the polypeptide chain contains 841 amino acids)[3–5]. The molecular weight of the subunit of potato tuber phosphorylase is reported as 103000[6,7], that of the subunit of *E. coli* phosphorylase 81000 and thus considerably smaller than the others[8]. Rabbit skeletal muscle phosphorylase exists in a phosphorylated form (phosphorylase *a*) and an unphosphorylated form (phosphorylase *b*). In both forms subunits may form tetramers. The enzymatically active forms are however the dimeric phosphorylases *a* active without AMP and the dimeric phosphorylases *b* active only in the presence of AMP[9]. Tetramers and monomers are inactive[23 25] or according to others partially active[18,26]. Formation of tetramers is facilitated by low temperature, Mg^{2+}, Ca^{2+}, F^- and other ions,

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/0606-0411 $ 02.50/0*

the presence of the allosteric effector, AMP and of the substrates, P_i and glucose 1-phosphate[10 14]. Tetrameric phosphorylases dissociate to dimers in the presence of glucose, glycogen, caffeine and α-1,4-glucans (hepta- and pentaamyloses)[19 22]. The dimer-tetramer equilibrium of phosphorylase *a* is mainly dependent on ionic strength and the nature of ions, on pH and temperature ($-\Delta H = 60$ kcal/mol)[15 18]. Phosphorylase *a* is tetrameric even at fairly low concentrations and at elevated temperatures. Phosphorylase *b* forms tetramers only at high concentrations, low temperatures and in the presence of AMP[9].

The dimensions of dimeric phosphorylase were estimated by electron microscopy as about $110 \times 65 \times 55$ Å. This agrees with small angle X-ray diffraction curves which gave dimensions of $110 \times 60 \times 55$ Å for an ellipsoidal body. More detailed information became available with the progress of X-ray crystal structure analysis[27-32]. Rabbit muscle phosphorylases *a* and *b* crystallize isomorphously in the presence of glucose or inosinic acid (IMP) respectively in the space group $P4_32_12$ with the unit cell dimensions $a = 128$ Å and $c = 116$ Å[29,30]. These crystals contain a monomer per asymmetric unit. A dimer is formed through the interactions of two monomers across a twofold crystallographic axis of symmetry. The arrangement of the monomers in this space group precludes tetrameric crystals. A detailed and complete interpretation of the electron density maps was only possible after the complete amino acid ("primary structure") sequence of rabbit skeletal muscle phosphorylase was determined by *Titani et al.*[3 5]. The chemical information helped to identify the various parts of the polypeptide chain and to determine the spatial arrangement and structure. Especially the assignment of the ε-aminolysyl-Schiff base with pyridoxal phosphate to position 679 in the enzyme permitted exact location of the cofactor in phosphorylase[27,28]. The polypeptide chain is built to about 50% as α-helix and to about 30% as β-sheet.

The phosphorylase monomer can be divided into three domains: An N-terminal domain with about 320, a central domain with 160 and a C-terminal domain with 360 amino acids. The three domains are arranged in such a manner that the centers form the corners of an equilateral triangle. The contact surfaces of the monomers in the dimeric structure are formed by the N-terminal domains which interdigitate across the axis of symmetry and establish extensive contacts among the subunits[28-30]. Previous investigations of *Madsen et al.* had already shown that two cysteine side chains (108 and 142) are in or near the contact region, for carboxamidomethylation of these cysteins results in dissociation to monomers and inactivation. The remaining SH-groups become accessible to iodoacetamide only after irreversible denaturation of the protein[33-35]. Acylation with succinic-anhydride inactivates phosphorylase *b* and *a*. Inactivation is partly due to dissociation in inactive monomers[36][*].

1.3. Regulation

The pioneering work of *G. T.* and *C. F. Cori* (see [37]) established that glycogen phosphorylase of rabbit skeletal muscle can exist in two forms, *b* and *a*, of which the former is only active in the presence of 5′-AMP.

E. G. Krebs and *E. H. Fischer* subsequently elucidated the interconversion of both forms[38] (see also [39,40]). Phosphorylase *b* is transformed to *a* by phosphorylation of a seryl residue (serine-14) per subunit catalyzed by phosphorylase-kinase [EC 2.7.1.38], ATP and Mg^{2+}. Phosphorylase *a*, which is active without AMP, is dephosphorylated by an enzyme activity described first by *P. J. Keller* and *G. T. Cori*[41], which later proved to be a phosphorylase-phosphatase [EC 3.1.3.17][42]. Phosphorylase was the first enzyme whose activity was shown to be regulated both allosterically and by covalent modification. Phosphorylase *b′*, a tryptic degradation product of phosphorylase *b*, lacks the N-terminal sequence which is phosphorylated in the $b \rightarrow a$ transition. Phosphorylase *b′* can still be activated by AMP indicating that the site of phosphorylation differs from the site for AMP activation[43-45]. This is supported by recent ^{31}P-NMR measurements with native and succinylated phosphorylase *a* at different pH values: this work showed in agreement with recent results from X-ray crystallography that the thiophosphates (phosphates) of AMP-S, (AMP) and of the thiophosphoseryl-(phosphoseryl-) residues act cooperatively but on different sites of phosphorylase[36] (cf. Fig. 4).

Glycogen phosphorylases in muscle and liver are key enzymes whose activities are modulated in a very sophisticated manner in order to adjust them to the needs of cellular metabolism. They can be classed with the α-glucan phosphorylases. The α-glucan phosphorylases of plants and of procaryotes, however, are neither allosterically nor covalently controlled[6,46-48]. Glycogen phosphorylase from yeast is covalently, but not allosterically regulated[49]. Covalent modification ($b \leftrightarrow a$ interconversion) of phosphorylases is controlled by an enzyme cascade consisting of at least five separate enzymes each of which is again interconvertible, and of specific inhibitory proteins and modulator proteins for some of the enzymes. This has the advantage of large rate amplification and control at multiple sites in the cascade by different cellular messengers (Ca^{2+}, cAMP). *Philip Cohen* has contributed much in the last years to further our understanding of the phosphorylase kinase system, which has a key role in the regulation of the phosphorylase cascade[50]. The regulation of the phosphorylase interconversion cascade including hormonal regulation has been extensively reviewed in recent years[1,40,50-54].

2. Pyridoxal Phosphate in α-Glucan Phosphorylases

Baranowski, Illingworth, Brown, and *Cori*[55,56] reported in 1957, and *Kent, Krebs,* and *Fischer* in 1958[57], the presence of pyridoxal phosphate in rabbit skeletal muscle phosphorylase *a* in a stoichiometry of one mol per mol of subunit. Since then pyridoxal phosphate has been found, *inter alia,* in α-glucan phosphorylases from muscles of cat, rat, mouse, dogfish, man, frog, lobster and insects, in liver and brain, in yeast, potato tuber, corn, *Physarum polycephalum, Escherichia coli* and *Klebsiella pneumoniae*[1,6-8,24,37,46,49,53,58,59,102,157-163].

Muscle contains phosphorylase—and hence pyridoxal phosphate—in relatively high concentrations (3×10^{-6} M; about 30 mg per 100 ml of intercellular fluid); since muscle

[*] For the three dimensional structure of phosphorylase *a* and the related functions see *R. J. Fletterick, N. B. Madsen,* Ann. Rev. Biochem., in press.

tissue makes up about 40% of the body mass, more pyridoxal phosphate is present in muscle phosphorylase than in all other pyridoxal phosphate dependent enzymes together. This explains why vitamin B_6 deficiency causes a drastic decline in muscle phosphorylase activity[60,61].

A theory providing for the first time a comprehensive interpretation of the diverse pyridoxal phosphate dependent reactions was proposed by *Braunstein* and *Shemyakin*[62]. Independently, and at about the same time, a similar but more detailed proposal was published by *Metzler, Ikawa,* and *Snell*[63]. From *Snell*'s model studies of the non-enzymic reactions, a minimal structure, the 3-hydroxypyridine-4-carbaldehyde was derived. In the course of catalysis the formyl group forms a Schiffs base with the amino acid substrate which is stabilized by chelation with a metal ion. According to *Braunstein*[64] and *Snell*[65], all pyridoxal phosphate dependent reactions are explained by the special properties of the enzyme bound aldimine-ketimine intermediates [see Fig. 1].

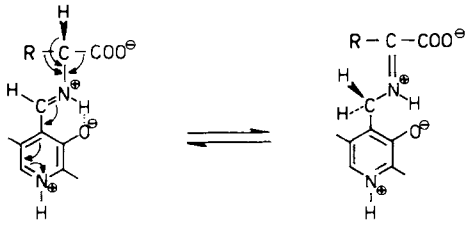

Fig. 1. Tautomerism in protonated Schiff bases of α-amino acids and derivatives of 3-hydroxypyridine-4-carbaldehyde. The arrows point to possible elimination steps.

The participation of an aldimine in catalysis is not restricted to pyridoxal phosphate dependent enzymes. In some enzymes, the formyl group of pyridoxal phosphate is substituted by a carbonyl group; in histidine decarboxylases from *Lactobacillus* and *Micrococcus* an N-terminal pyruvoyl-phenylalanyl residue carries out the function of the enzyme bound pyridoxal phosphate ε-aminolysyl residue[66]. In aldolases[67] and transaldolases[68], acetoacetate-decarboxylase[69], δ-aminolevulinic acid[70] and 2-keto-3-deoxy-L-arabinose dehydratase[71], a carbonyl group of the substrate forms an imine with an ε-aminolysyl side chain. The pivotal role of the Schiff base in catalysis is supported by inactivation following reduction with $NaBH_4$: the enzyme loses catalytic activity. However, one class of pyridoxal phosphate dependent enzymes, the α-glucan phosphorylases, is a remarkable exception. *Snell*[65] wrote: "Phosphorylase, the most plentiful pyridoxal phosphate dependent enzyme of mammals does not act *via* a Schiff base mechanism as shown by the fact that the borohydride reduced enzymes still show activity" (for reviews see [64,65]).

2.1. Chemical Structure of Pyridoxal Phosphate bound to Phosphorylase

C. F. Cori et al. first separated pyridoxal phosphate from crystalline rabbit skeletal muscle glycogen phosphorylases *a, b* and *b'* with $(NH_4)_2SO_4$ at pH 3—4, and obtained inactive crystalline pyridoxal phosphate-free apoenzymes[56]. Incidentally, *Otto Warburg* had already (1938) separated flavin-adenine-dinucleotide (FAD) in a similar manner from a flavin dependent dehydrogenase, the so called "gelbe Atmungsferment"[72]. A high yield of active holoenzyme on reconstitution of apoenzyme with pyridoxal phosphate is however only obtained with the procedure of *Fischer, Shaltiel,* and *Hedrick*[73-75]. According to this procedure, the structure of the phosphorylase *b* protein is first reversibly "deformed" with imidazole citrate.

The exposed Schiff base of pyridoxal phosphate can then be attacked stereospecifically with L-cysteine with formation of a thiazolidine. The cofactor can be removed under mild conditions at pH = 6.4 and 0 °C in about 35 min. This meth-

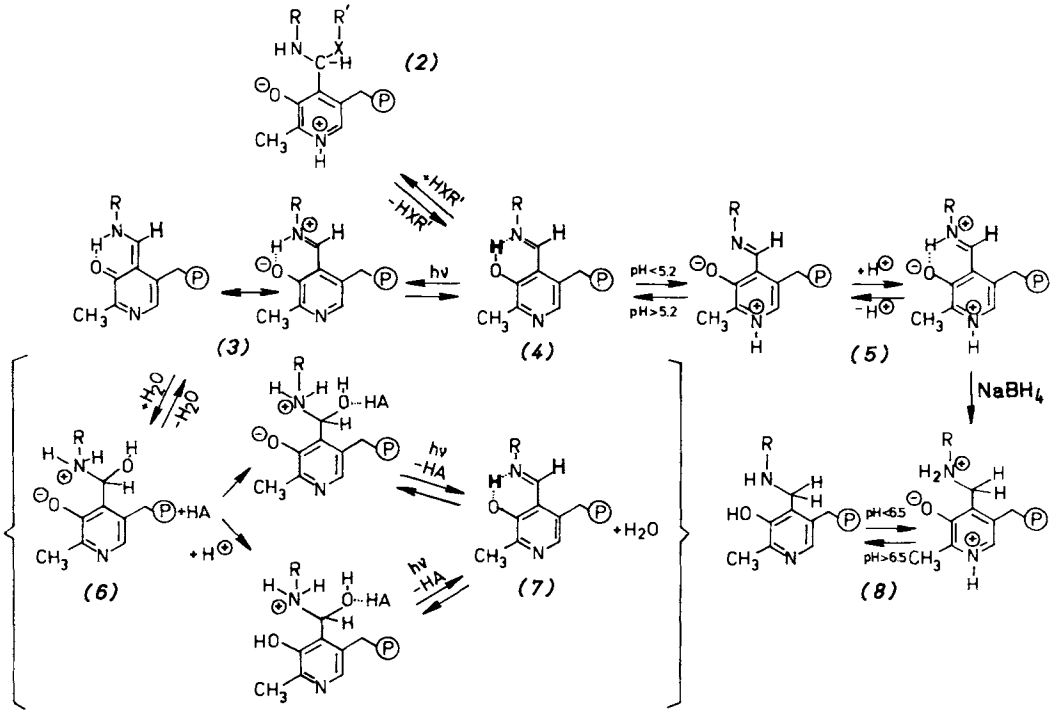

Fig. 2. Structures of phosphorylase bound pyridoxal phosphate (reproduced from [76]). *(2)—(8)*, see text.

od made possible the replacement of the natural cofactor pyridoxal phosphate by chemically modified analogues and the extensive study of the properties of the reconstituted phosphorylase derivatives.

Views on the binding mode of the cofactor to the phosphorylase protein were controversial until recently (see Fig. 2[76]). *Graves et al.*[77], *Shaltiel* and *Cortijo*[78,79] (see also [80,81]) assumed that the catalytically active form is a pyridoxal phosphate Schiff base *(4)*, which absorbs at 333 nm and forms tautomers *(3)*. However, according to *Kent et al.*[57] pyridoxal phosphate is bound in phosphorylase as a substituted aldimine *(2)* with the participation of an unknown nucleophilic group XR'. If this group were a hydroxyl group (*e.g.* of water), one would have an aminomethanol derivative, as was suggested by *Honikel* and *Madsen*[82]. Perturbations of the enzyme structure, for example by acidification, high concentrations of NaCl, exposure to cold, bring the cofactor in contact with the solvent. If the solvent is aqueous, an absorption at 415 nm arises which is characteristic for a Schiff base [*(3)* and *(5)*]. Only now, can the exposed azomethine linkage in *(5)* be reduced with $NaBH_4$[2] (see also [13,83,84]). In contrast, *Honikel* and *Madsen*[82] have proposed that the aminomethanols *(6)* lose water on photochemical excitation and form Schiff bases *(7)*. The different positions of the chelating protons of the hydroxyl group (bold print) in the structures *(4)* and *(7)* are due to different energy potentials[76,82,85]. The spectral properties are summarized in Table 1[76]. They emphasize how difficult it is to assign unequivocally the "abnormal" absorption at 333 nm of phosphorylase-bound pyridoxal phosphate by comparing it with the absorptions of Schiff bases of this cofactor and *n*-butylamine. For example, the 333 nm absorption can either be assigned to the phenolic form *(4)* or to the phenolates *(2)* and *(6)*. Although by comparison with the 3-*O*-methyl analogue of pyridoxal phosphate *(10)* (see Table 2) one can eliminate the phenolate form, but one cannot distinguish by UV spectroscopy alone between the sp^2 and sp^3 hybrids of the phenolic forms. For example, the sp^3 phenolic form of reduced phosphorylase has an absorption (290 nm) like the sp^2 phenolic form of the phosphorylase-bonded 3-*O*-methylpyridoxal phosphate *(10)* (297 nm). However, an unequivocal assignment was possible by comparing the NMR spectra of the proton at the C-atom bonded to the C-4 of pyridoxal phosphate with the UV-spectra: We found that the chemical shifts of the proton resonance of the Schiff base derivatives in dimethyl sulfoxide (DMSO) and D_2O were the same ($\delta = 8.9$). This shows that the phenolic forms of 3-*O*-methylpyridoxal phosphate, pyridoxal phosphate and pyridoxal can all form Schiff bases. The hypsochromic shift (333 nm→295 nm) of the 3-*O*-methylpyridoxal phosphate Schiff base is worth noting. This shift became apparent on comparing UV spectra in DMSO of the Schiff bases with *n*-butylamine and the phenolic forms of 3-*O*-methylpyridoxalphosphate on the one side and pyridoxal-P on the other. To sum up: These experiments prove the chemical structure of pyridoxal phosphate in muscle phosphorylase as a typical Schiff base in the phenolic form and support the assignment of *Johnson et al.*[77] and *Shaltiel* and *Cortijo*[78,79] who have argued that protonation of the 3-phenoxide group of a Schiff base in a hydrophobic environment is responsible for the unusual shift of the UV absorption (415 nm→333 nm) to shorter wavelength and for the fluorescence properties of pyridoxal phosphate bound to phosphorylase.

2.2. The Location of Pyridoxal Phosphate

The location of the catalytic center of phosphorylase was likewise in doubt until recently. The first X-ray structure analyses suggested that the active center of muscle phosphorylase is located in the N-terminal domain near the regulatory AMP-site. A location of the active center at or near the subunit contacts and the regulatory domain was attractive, because allosteric activity control is propagated *via* subunit interactions. Moreover, this location would have offered an explanation for our findings that phosphorylase monomers are inactive[25]. With the improvement in the resolution of the X-ray diffraction patterns down to 3 Å and finally to 2.5 Å[86,27] a second binding domain was found, where a second (weaker) binding site for the allosteric effector 5'-AMP and binding sites for glucose 1-phosphate, P_i and glucose, a competitive inhibitor for glucose 1-phosphate are located. Moreover, at higher resolution, pyridoxal phosphate could now be located: It was found in close proximity to the other sites in the second binding domain in the central core of the subunit.

Table 1. UV absorption maxima of pyridoxal phosphate derivatives (reproduced from [76]). The measurements were carried out in aqueous solutions, except where stated otherwise.

Cofactor	Reagents for the cofactor and products

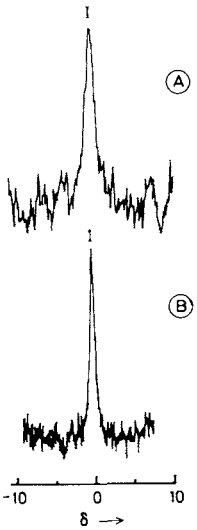
[a] pH = 5—7. [b] In dioxane/water. [c] In dimethyl sulfoxide. [d] No solvent and pH data.

The active center of muscle phosphorylase is located at the bottom of a deep narrow crevasse near the center of the subunit where the three structural domains meet.

In this context, results of a recent ^{31}P-NMR study carried out by our group with succinylated rabbit skeletal muscle glycogen phosphorylases *b* and *a* are worth reporting, because they demonstrate quite impressively how NMR spectroscopy of the enzyme in solution can help to support or correct structural assignments made by X-ray diffraction methods. In this particular case, ^{31}P-NMR studies helped to clarify the location of pyridoxal phosphate in muscle phosphorylase[36]: We have compared the ionization of the phosphate group of pyridoxal phosphate in native and succinylated, partially dissociated (monomer:dimer ratio = 40:60) rabbit muscle phosphorylases *b* and *a* (Fig. 4[36]). It may be



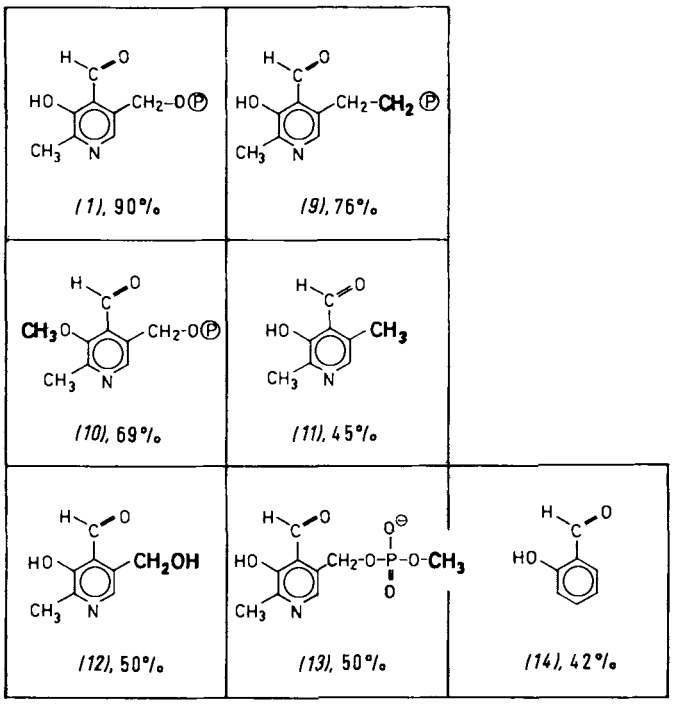


Fig. 3. ^{31}P-NMR spectra (72.86 MHz) of pyridoxal phosphate in (A) native rabbit skeletal muscle phosphorylase *b* and in (B) succinylated muscle phosphorylase *b*. (A) pH = 7.1, form I; (B) pH = 7.23, form I (reproduced from [36]).

noted that in the succinylated, partly dissociated enzyme the phosphate resonance of pyridoxal phosphate is at $\delta = -0.37$, and hence at the same location as the resonance of the protonated form I of the cofactor phosphate in the "inactive" conformation of native phosphorylase *b* ($\delta = -0.31$). At pH = 7.2, at which the experiment was performed, one would have anticipated more than 90% of the pyridoxal phosphate as dianion if dissociation to monomers had established contact of the cofactor with the aqueous solvent. This would have been expected if the active center were indeed situated on the contact-surfaces of the subunits in the dimer, as was originally assumed. But the results of our ^{31}P-NMR studies are only compatible with a location of the cofactor in a protected area in the monomer which is shielded from the solvent.

2.3. Catalytically Functional Groups of Pyridoxal Phosphate

Resolution of phosphorylase from pyridoxal phosphate results in dissociation of apophosphorylase into monomers. Crystalline apophosphorylase *b* is nearly completely monomeric at 35 °C[87] (see also [88,9]). This raised the question whether pyridoxal phosphate functions as a structural ligand in glycogen phosphorylase and whether it is required to stabilize the quaternary structure which is a prerequisite for activity and regulation. We have excluded this possibility[89]: Table 2 demonstrates convincingly that the chemical structure of the cofactor which is required for dimer formation

Table 2. Activity induction by aldehydes (reproduced from [89]). Substituents in bold type represent essential modications. The numbers signify the catalytic activity of a "dimer" of a native monomer and a monomer of apophosphorylase + aldehyde.

differs from the structure required for catalytic activity: In the experiments in Table 2, 50% activity implies that a monomeric subunit which carries a pyridoxal phosphate analogue which is *inactive* in the dimeric holoenzyme nevertheless can fully *elicit activity* on dimerization in a subunit carrying the original pyridoxal phosphate cofactor.

Many chemical analogues of pyridoxal phosphate[90-93] were tested for binding and reactivation of apophosphorylase. The results in Table 3 exclude, with exception of the nitrogen atom and the 5′-phosphate group, all other functional groups of pyridoxal phosphate for a role in catalysis of α-1,4-glucan phosphorylases (see also [53]). The nitrogen atom of the pyridine ring is however an anchor point like the formyl group; for example, if it is quaternated by a methyl group (No. 19), the cofactor can no longer bind to the apoenzyme[92]. The *N*-oxide analogue of the partially active 3-*O*-methylpyridoxal phosphate is bound, albeit weakly, but the reconstituted enzyme is inactive[94]. But participation of the nitrogen atom (pK = 8.7[95]) in catalysis seems unlikely. This view receives some support from the observations that drastic changes in the basicity of this group, for example by introduction of fluorine in position 6 or methylation of the 3-OH group still yield pyridoxal phosphate derivatives which form active phosphorylases[92,96]. This leaves the 5′-phosphate group of the cofactor: A direct participation of the phosphate group of pyridoxal phosphate as a reactant in phosphorolysis was already excluded by *Illingworth et al.*; there is no P_i-glucose 1-phosphate exchange with the 5′-phosphate group of the cofactor[88] (see also [37,56]). However, all modifications of the 5′-position of the cofactor yield inactive phosphorylases, when a) the 5′-phosphate group is miss-

ing, b) the phosphate is replaced by another acidic group with a different pK, c) the sterical conformation of the 5′-phosphate has been altered, or d) the second protonatable group of the phosphate residue is blocked, as for example in the pyridoxal phosphate monomethyl ester *(13)* synthesized by us[94,97].

Graves et al.[98] made the remarkable observation that rabbit muscle phosphorylase *b* containing pyridoxal *(12)* has a few percent of the enzymic activity of the native enzyme in synthesis (and degradation) of glycogen when incubated in high phosphate concentrations (50 mM). The activity of pyridoxal phosphorylase *b* when compared with native pyridoxalphosphate phosphorylase *b* is about 6% with phosphate, 8% with phosphite and fluorophosphate and 3% with arsenate. All phosphate analogues which elicit activity have nearly identical tetrahedral structures. Thiophosphate, bicarbonate and pyrophosphate are strong inhibitors, sulfate and nitrate weak inhibitors. Pyrophosphate is bound stoichiometrically one mol per subunit, and blocks the binding site for phosphate, phosphite, fluorophosphate and glucose 1-phosphate. All anions which activate phosphorylase *b* reconstituted with pyridoxal seem to bind to the site normally occupied by the 5′-phosphate group of the natural cofactor. This assumption by *Parrish et al.*[98] is supported by experiments carried out by our group which demonstrated that high concentrations (100 mmol/l) of phosphate fail to activate phosphorylase reconstituted with pyridoxal phosphate monomethyl ester *(13)*, presumably because the inactive phosphoric acid ester blocks the phosphate site necessary for catalysis[98a]. Since fluorophosphate and phosphate bind equally tight to the enzyme, *Parrish et al.*[98] assumed that these phosphates are bound as dianions FPO_3^{2-} and $HOPO_3^{2-}$, respectively. This interpretation is in line with our ^{31}P-NMR measurements, which showed that the 5′-phosphate group of pyridoxal phosphate in native, enzymatically active phosphorylases is in the dianionic form[99,100,101][*].

2.4. The Role of Pyridoxal Phosphate in Allosteric Regulation

Monod et al.[103] classified phosphorylase *b* as an allosterically regulated enzyme of the "K" type which is either in the inactive T- or in the active R-conformation. The positive allosteric effector, 5′-AMP binds to the R-form. *Helmreich* and *Cori*[104] could demonstrate, with crystalline rabbit skeletal muscle phosphorylase *b* positively cooperative and reciprocal homo- and heterotropic interactions between substrates and AMP and thus found an explanation for the obligatory requirement of 5′-AMP for the activity of muscle phosphorylase *b*. In the meantime, several other nucleotides and nucleotide analogues have been tested as allosteric activators of phosphorylase *b*[105–108].

AMP and IMP generate different enzyme conformers which crystallize in different space groups. As a matter of fact, it was the IMP-phosphorylase *b* complex which permitted the successful exploration of its three dimensional structure by X-ray diffraction. Phosphorylase *b* forms tetragonal crystals in the presence of 2 mM IMP with a single subunit in the asymmetric unit[29]. The positive regulatory effector binding sites are all in the amino terminal part of the poly-

[*] The partial activation (8%) of the pyridoxal enzyme with fluorophosphate, which has a much lower pK value ($pK_{II}=4.8$) than phosphate ($pK_{II}=7.2$), is puzzling and needs to be explained, because the pK_{II} of fluorophosphate is too low to allow for a function as proton acceptor at a pH range where muscle phosphorylase is active. In that context, one should recall that the pH-activity-peak of yeast phosphorylase is at pH 5.8 [102]. Muscle phosphorylases have their maximal activities, dependent on buffer and conditions at around pH 6.2 [17].

peptide chain, whereas the catalytic sites are located in another ("heavy") segment (HS) of the chain. Both domains are loosely connected *via* a segment which is readily accessible to proteolytic enzymes. The molecular details of the conformational transitions resulting from the interactions of muscle phosphorylase *b* with the physiological activator, 5′-AMP, have not yet been worked out, but rapid progress may be anticipated in the near future once the structures of different conformers can be compared in the crystalline state (X-ray diffraction) and in solution (NMR-spectroscopy)[36] (see also [109, 110]).

In this context, allosteric regulation is of interest only insofar as the study of a possible structural role of pyridoxal phosphate in the regulation of muscle glycogen phosphorylases led one of us *(E. H.)* to consider a catalytic role for the cofactor. Some time ago, we studied[9, 10] the allosteric transitions of inactive apophosphorylase *b* and of the pyridoxal *(12)* and 5′-deoxypyridoxal *(11)* phosphorylase derivatives on binding of AMP. We could show that the inactive phosphorylase derivatives containing a cofactor without the 5′-phosphate group are still capable of binding 5′-AMP in a highly cooperative manner. These findings could be repeated more recently with nearly identical results by *Feldmann* using a new rate dialysis method and the inactive pyridoxal phosphate monomethyl ester *(13)* of phosphorylase *b* where the 5′-phosphate group of the cofactor is no longer protonatable at $pK = 6.2$[111]. Although these phosphorylase derivatives with or without a monoanionic 5′-phosphate group of the cofactor are not catalytically active, they nevertheless are allosterically regulated and still bind AMP positively cooperative with a Hill coefficient of about 2.0. Moreover these phosphorylase *b* derivatives sediment in the analytical ultracentrifuge like active, native pyridoxal phosphate containing phosphorylase *b*, whereas, apophosphorylase *b* sediments mainly as monomer[10, 97, 112]. Tritium-hydrogen exchange was used by *Weisshaar* and *Palm*[113, 114] in the Würzburg laboratory to compare the structures of the different phosphorylase derivatives. This approach is based on the observations of *Hvidt* and *Nielsen*[115] that different conformers of one and the same protein can be distinguished by the numbers and the rates of the exchanging hydrogens. The Tritium-hydrogen exchange rates of the pyridoxal phosphate monomethyl ester *(13)* reconstituted phosphorylase *b* derivative were very similar to those of the native phosphorylase *b*. It thus appears that this analogue is bound to apophosphorylase in a manner quite analogous to the natural cofactor pyridoxal phosphate[113, 114]. We could show, therefore, that at least in these special cases the 5′-phosphate group of the cofactor is not obligatorily required for the expression of allosteric control properties of oligomeric phosphorylases from mammalian muscle. Tritium-hydrogen exchange revealed that pyridoxal phosphate monomethyl ester *(13)* traps protons on binding to apophosphorylase as effectively as the natural cofactor which forms an active holoenzyme[113, 114]. Nevertheless, the enzymes containing a cofactor analogue with a modified 5′-phosphate group or lacking the 5′-phosphate are inactive. This provoked one of us [*E. H.*] already in 1968 to propose an additional, catalytic role for the 5′-phosphate group of pyridoxal phosphate[9]: "If one wishes to consider an additional role for the prosthetic group of phosphorylase, attention obviously centers on the 5′-phosphate, since the phosphate group is apparently essential for catalytic activity, whereas its role with respect to the allosteric properties of the enzyme protein is permissive." However, the observation of the phosphate of pyridoxal phosphate in its natural environment was made possible only once a superconducting wide-bore NMR-spectrometer with high resolving power allowed measurement in the Fourier-transform mode of the ^{31}P resonance of pyridoxal phosphate in the enzyme in solution.

2.5. Ionization Changes of the Phosphate Group of Pyridoxal Phosphate on Transition from Inactive to Active Phosphorylase

Feldmann and *Hull*[99] have shown by ^{31}P-NMR that 5′-AMP in cooperation with an anionic substrate triggers the deprotonation of the 5′-phosphate group of pyridoxal phosphate bound to rabbit skeletal muscle phosphorylase *b* (Fig. 4[99]). The weaker effect of AMP alone (without anionic substrate) is explained by the allosteric properties of phosphorylase *b*: The substrate strengthens the binding of the activator to muscle phosphorylase *b*, as was shown by *Helmreich* and *Cori*[104]. The activation constant (K_a) for 5′-AMP and phosphorylase *b* is 3×10^{-4}—5×10^{-4} M without and 4×10^{-5}—10×10^{-5} M with anionic substrate. Arsenate can replace phosphate. The tightening of the AMP-phosphorylase complex by arsenate shifts the ^{31}P-NMR signal of pyridoxal phosphate by about $\delta = -0.2$ to -3.6. A good separation of the ^{31}P-NMR signals of AMP and pyridoxal phosphate was achieved by substituting AMP by AMP-S, whose signal is shifted by about 40 ppm to lower field. Fortunately, AMP-S is even a more effective allosteric activator of phosphorylase *b* than AMP[116, 117]. On tightening the binding of the nucleotide, AMP-S to phosphorylase *b*, pyridoxal phosphate is

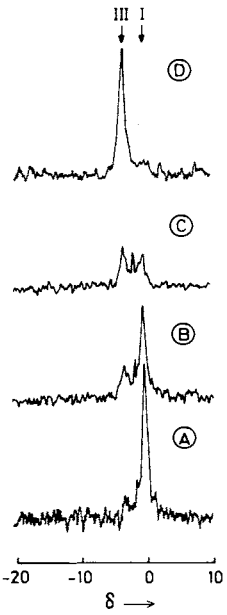

Fig. 4. Influence of AMP-S (adenosine 5′-monothiophosphate) on the ^{31}P-NMR spectrum (72.86 MHz) of pyridoxal phosphate in (D) native and (A—C) succinylated rabbit skeletal muscle phosphorylase *b* (reproduced from [36]). (A) no AMP-S, no arsenate, pH = 7.12; (B) 0.7 mM AMP-S, pH = 7.05; (C) 0.7 mM AMP-S and 30 mM arsenate, pH = 7.29; (D) 1.5 mM AMP-S and 36 mM arsenate, pH = 7.1; the resonance in (B) and (C) between forms I and III is most likely due to a phosphate containing impurity.

present almost exclusively as form III, the dianionic form ($\Delta\nu = 60$ Hz). K_d ($= k_{-1}/k_1$) is about 1×10^{-4} M for the AMP-S phosphorylase *b* complex with arsenate. These data are in good agreement with published values of K_a for AMP and phosphorylase *b* with phosphate or arsenate[104]. The ^{31}P-NMR signal of pyridoxal phosphate bound to phosphorylase *b* in the inactive state, *i.e.* in the absence of ligands, was assigned to form I, the protonated form. Addition of AMP or AMP-S in the presence of saturating concentrations of arsenate triggers the transition to the active conformation. This transition is accompanied by the transition of form I to form III of the cofactor phosphate.

Form I, inactive Form III, active

The chemical shift is compatible with the formation of the dianionic form III of the pyridoxal phosphate Schiff base. One can form with phosphorylase *b* kinase, Mg^{2+} and ATP-γ-S an active phosphorylase *a* derivative containing thiophosphoserine residues. The ^{31}P-NMR spectrum of this active phosphorylase *a* derivative recorded at pH = 7.7 was identical regarding chemical shift and linewidth ($\Delta\nu = 60$ Hz) with the phosphorylase *b*—AMP-S complex with 50 mM arsenate; the resonances were predominantly form III and a minor portion was form I resonance (Fig. 5A[99]). Binding of AMP-S (1 AMP-S per site) results in the transition of the residual form I into form III (Fig. 5B). One should recall here that muscle phosphorylase *a* is active without AMP whereas phosphorylase *b* is active only with AMP. Recently, we have repeated these experiments with partly dissociated succinylated phosphorylase *b* (Fig. 6[36]). As was expected transition of the inactive, protonated form I to the active, dianionic form III on binding of the nucleotide (AMP-S) is incomplete in the case of succinylated phosphorylase *b* and about one half as much form III is formed as in the case of native phosphorylase *b*. The transition from the inactive form I to the dianionic form III is likewise hindered in the case of succinylated phosphorylase *a*[36].

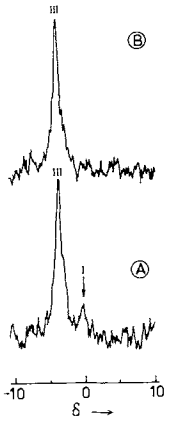

Fig. 5. ^{31}P-NMR spectra of pyridoxal-P (PLP) in native rabbit skeletal muscle phosphorylase *a* (reproduced from [99]). (A) no AMP-S; (B) 0.35 mM AMP-S, pH = 7.7.

The ^{31}P-NMR studies of *Feldmann* and *Hull*[99] with the regulated rabbit skeletal muscle phosphorylases *b* and *a* have shown that the transition from an inactive to an active conformation is accompanied by deprotonation of the cofactor phosphate. Another way to interpret these ionization changes implies that in aqueous solvent, the transition from form I to form III results in a lowering of the pK value of the phosphate group by at least three units. This shift to the acidic side is about equal to a change in free energy of about 3.9 kcal/mol, which is about the free energy required for formation and cleavage of α-glycosidic bonds or for hydrolysis of glucose 1-phosphate. Although this ionization change is compatible with a catalytic function of the phosphate group of pyridoxal phosphate in α-glucan phosphorylases, these experiments do not give us any information on how the phosphate dianion might participate in catalysis. But recent ^{31}P-NMR studies with the non-regulated *E. coli*[100] and potato[101] phosphorylases which we discuss now, have considerably extended our views on the catalytic role of the cofactor phosphate.

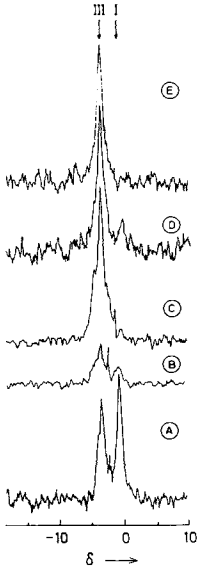

Fig. 6. ^{31}P-NMR spectroscopically observed differences in the ionization of pyridoxal phosphate in succinylated (A, B) and native (C—E) rabbit skeletal muscle phosphorylase *a* (after [36]). (A) residual activity 12%; pH = 7.35; (B) as in A, but with 1.17 mM AMP-S (3 mol/mol of monomer); (C) pH = 6.5; (D) pH = 7.67; (E) as in D, but with 0.35 mM AMP-S (1.3 mol/mol of monomer).

2.6 How Does the Phosphate Group of Pyridoxal Phosphate function in Catalysis?

The crystallographers have until now studied exclusively "inactive" conformers of the well-characterized crystalline rabbit skeletal muscle phosphorylases *b* and *a*[28,27]. We have recently initiated ^{31}P-NMR studies with phosphorylases whose activity is neither allosterically nor covalently controlled. These enzymes can be obtained in a pure state and crystallized and in the large quantities needed for NMR work[8,100,101]. The ^{31}P-NMR spectrum of native potato phosphorylase has a resonance line at $\delta = -4.5$ with a linewidth of $\Delta\nu = 35$ Hz (Fig. 7A[101]). Taking into account that potato- and muscle-phosphorylase have comparable molecular weights (103000 and 97412 respectively[4,6,7]), the linewidth of the pyridoxal phosphate signal of the potato phosphorylase ($\Delta\nu = 35$ Hz) is much narrower than the linewidth of the

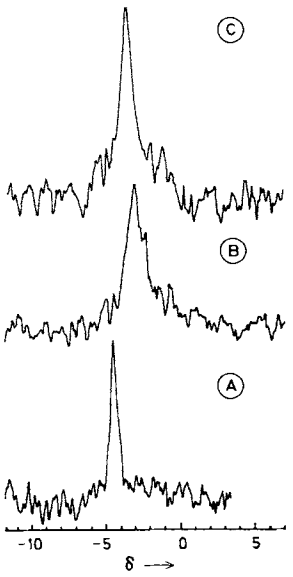

Fig. 7. ^{31}P-NMR spectra (72.86 MHz) of pyridoxal phosphate in potato-phosphorylase. In all experiments the pH was 6.5. (A) without ligands; (B) 90 mM glucose; (C) 90 mM glucose and 100 mM arsenate (after [101]).

phosphorus of the cofactor bound to muscle phosphorylase (35 Hz). One might speculate that the sharper resonance line results from a greater mobility of the 5′-phosphate group around the C—O bond. A comparably narrow linewidth ($\Delta\nu = 35$ Hz) was also observed with the *E. coli* maltodextrin phosphorylase, which has however a smaller molecular weight (83000 per subunit)[8]. The ^{31}P-NMR signal of potato phosphorylase was pH independent in the pH range 6.3 to 7.8. This indicates that the binding site is protected and shielded from the aqueous solvent. In analogy, with muscle phosphorylase we assign the signal at $\delta = -4.5$ to the dianionic form of the 5′-phosphate group. The corresponding signal of the muscle enzyme appears at $\delta = -3.76$ (Fig. 6C and 6D). This shift could be due to a distortion of the O—P—O angle resulting from electrostatic interactions with the protein and/or reflecting differences in the hydrophobic environment of the cofactor[118-120]. We will discuss that later. The substrate analogue, arsenate, but likewise other divalent anions which are not substrates, such as for example sulfate and methylphosphonate shift the ^{31}P-NMR signal of the cofactor on binding to potato phosphorylase to higher field in a small but reproducible and concentration dependent manner. In the presence of 30 mM arsenate, the signal is exchange-broadened with a linewidth of 50 Hz at $\delta = -3.98$. At saturating (60 mM) arsenate concentration, the signal is sharpened with a linewidth of 40 Hz and shifted upfield to $\delta = -3.75$[101]. At present, we cannot offer a mechanistic explanation for this effect of substrate and non-substrate/anions, except to speculate that high concentrations of arsenate may mobilize the 5′-phosphate group of the cofactor[99].

Of special interest are ionization changes of the 5′-phosphate group of the cofactor in potato phosphorylase on binding of glucose and oligosaccharides with or without arsenate. Glucose binds to rabbit skeletal muscle phosphorylase *a* either free or esterified with phosphate to the α-D-glucose 1-phosphate site[121]. Since glucose is also a competitive inhibitor with α-D-glucose 1-phosphate and potato phosphorylase, we have assumed that glucose binds likewise to the glucose 1-phosphate site in potato phosphorylase. The elucidation of the three dimensional structure of muscle phosphorylase *a* down to 2.5 Å resolution has allowed location of the anionic substrate sites of P_i, arsenate, glucose 1-phosphate and of the inhibitor glucose in the active center.

Substrates and inhibitor bind less than a few Å away from the 5′-phosphate of pyridoxal phosphate[27, 28, 86]. We admit however that the assumption that the structure of the catalytic centers in the muscle phosphorylases and the non-regulated potato and *E. coli* maltodextrin phosphorylases is nearly identical is at present only supported by sequence homologies of the pyridoxal phosphate sites in these enzymes (see Table 4 and [8]). The final proof requires comparative studies of the three dimensional structures of these enzymes by X-ray diffraction. Such efforts are presently being made[121a]. Experiments with glucose are also of interest, for rabbit skeletal muscle phosphorylase *a*, whose three dimensional structure is known in detail, has been studied by X-ray diffraction as glucose complex in the tetragonal, "T" (inactive) conformation[122]. Addition of 90 mM glucose shifts the ^{31}P-NMR signal of pyridoxal phosphate bound to potato phosphorylase upfield from $\delta = -4.5$ to $\delta = -3.0$. The signal is considerably broadened (see Fig. 7A and 7B)[101]. In contrast to muscle phosphorylase *A*, there is no evidence for glucose-induced conformational changes in potato phosphorylase. We have therefore neglected this possibility and interpret the upfield shift as indicating a drastic change in the pK of the 5′-phosphate group of the cofactor. With 90 mM glucose and 100 mM arsenate we observe a downfield shift ($\delta = -3.45$) and sharpening of the resonance line ($\Delta\nu = 65$ Hz; Fig. 7C). On the basis of the titration curve of the ^{31}P-NMR signal of a model Schiff base of pyridoxal phosphate and ε-amino caproic acid in aqueous solution (cf. Fig. 11) one could alternatively interpret that to mean that arsenate mobilizes and partially deprotonates the phosphate group of the cofactor protonated by glucose. It should be noted that in the presence of glucose (in contrast to its absence), deprotonation or shift in pK are specific. Neither sulfate nor methylphosphonate are effective. Sulfate, $pK_{II} = 1.9$, and methylphosphonate, $pK_{II} = 7.8$, do not function as substrates, but the latter is a competitive inhibitor for inorganic phosphate.

In the active, pyridoxal 5′-deoxymethylenephosphonate *(9)* containing rabbit skeletal muscle phosphorylase *a*, the situation is more difficult to interpret, because glucose induces a conformational transition which is reported by a partial

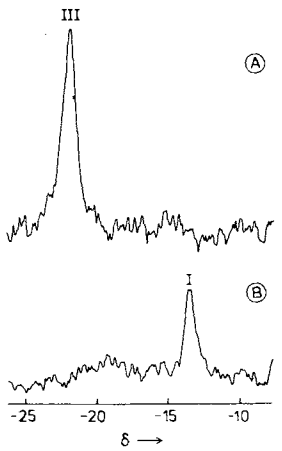

Fig. 8. ^{31}P-NMR spectra of pyridoxal 5′-deoxymethylenephosphonate *(9)* in rabbit skeletal muscle phosphorylase *a*. (A) pH = 7.07; no glucose; (B) as in A, but with 100 mM glucose (after [36]).

shift of the cofactor phosphate from the "active" dianionic form III (R-conformation) to the "inactive" protonated form I (T-conformation) (cf. Fig. 8[36,121]). As was expected, this allosteric transition is not observed with potato phosphorylase. However, both phosphorylases -the regulated skeletal muscle and the unregulated potato phosphorylase—have in common that in the presence of glucose the dianionic forms III of the phosphate of the cofactor are in rapid exchange with a mobile unknown form[*]. This is an interesting observation which needs to be studied in more detail.

Additional information was obtained with *E. coli* maltodextrin phosphorylase. The 5'-phosphate group of the cofactor can be titrated in this phosphorylase in the absence of substrates or substrate analogues in a pH dependent manner like a model Schiff base[100]. This is in striking contrast to the behavior of potato- and muscle phosphorylases. In fact, as we shall show later (cf. Fig. 11), the *E. coli* maltodextrin phosphorylase behaves in the absence of substrates like the "typical" pyridoxal phosphate dependent *E. coli* D-serine dehydratase[123]. However, if glucose is bound one also observes with *E. coli* phosphorylase the characteristic upfield shift, indicating that the 5'-phosphate group of the cofactor is protonated and becomes pH independent (Fig. 9A and 9B). In

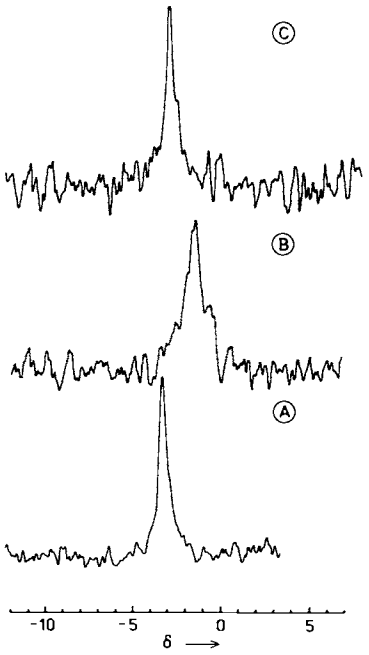

Fig. 9. ^{31}P-NMR spectra (72.86 MHz) of pyridoxal phosphate in *E. coli* maltodextrin phosphorylase. (A) pH = 6.92, no ligands; note that only without ligands and under these conditions the chemical shift is pH dependent (see Fig. 11). (B) pH = 6.59, 100 mM glucose; (C) pH = 7.05, 50 mM glucose and 100 mM arsenate (*H. W. Klein*, unpublished experiments).

the presence of arsenate and glucose, the ^{31}P-NMR spectra of the *E. coli* maltodextrin and the potato phosphorylases are at least qualitatively similar. Both spectra are indicative of an equilibrium between monoprotonated and dianionic forms (cf. Fig. 7C and 9C). But most important the ionization equilibria are now pH-independent also in the case of maltodextrin phosphorylase from *E. coli* in the range of pH 6.1—7.4 and in the range of 75—100% enzymatic activity[*].

α-Glucan phosphorylases, in contrast to sucrose phosphorylase, require an oligosaccharide as primer[124,125] (but see also [126,127]). Mammalian phosphorylases prefer α-1,6 branched α-1,4-polysaccharides, glycogen and amylopectin. Maltodextrin phosphorylases from *E. coli* and *Klebsiella pneumoniae* prefer maltodextrin and amylose[8,37,46,47]. Potato phosphorylase has no preference for branched or unbranched polysaccharides[6,7]. X-ray structure analyses[27-30,86] have shown an oligosaccharide binding site which is 33 Å—25 Å distant from the catalytic center of muscle phosphorylases *b* and *a*. *Kasvinsky et al.*[128] have therefore named this site the glycogen storage site, which is thought to be responsible for binding phosphorylase to glycogen in the living cell[129-131]. Since the glycogen storage site is located in muscle phosphorylases in the regulatory domain distant from the catalytic center, the participation of this site in glycogen activation which results in formation of active dimers and in heterotropic cooperativity with other substrate binding sites and the allosteric AMP activator site is plausible, whereas its participation in catalysis is unlikely, even when the presence of oligosaccharides or glycogen in the catalytic center has not yet been reported. *Kasvinsky et al.*[128] have recently presented a kinetic model which postulates that the glycogen storage site must be occupied before heptaamylose (or glycogen) can bind to the active center. Incidentally, a kind of "compulsory order of addition"for glycogen was invoked by *Michaelides* and *Helmreich* to explain the protection of muscle phosphorylase by the polysaccharide against inhibition by anti-phosphorylase Fab-fragments[132,133]. If glucose is replaced by heptaamylose, which has a much higher affinity to potato phosphorylase than glucose, one finds already with 1 mM

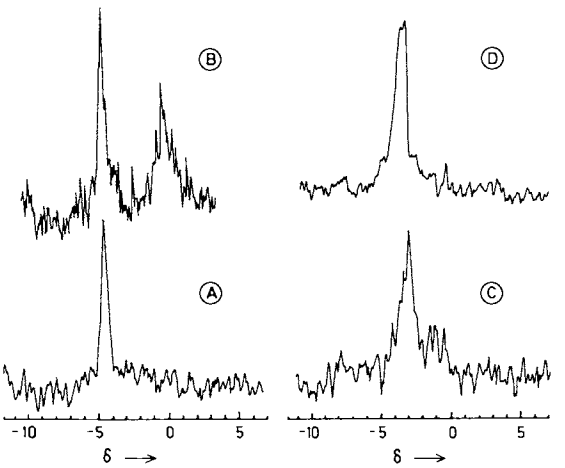

Fig. 10. ^{31}P-NMR spectra (72.86 MHz) of pyridoxal phosphate in potato phosphorylase. (A) no substrates; (B) 1 mM heptaamylose, (C) 15 mM heptaamylose; (D) 15 mM heptaamylose and 100 mM arsenate; all measurements at pH = 6.5 (after [101]).

[*] We have assigned the forms I and III in active pyridoxal 5'-deoxymethylenephosphonate *(9)* reconstituted phosphorylase *a* by analogy with the 5'-phosphate of pyridoxal phosphate *(1)* in native rabbit muscle phosphorylase *a*. On titration of a model Schiff base of *(1)* and ε-aminohexanoic acid in aqueous solvent (Fig. 11), the signals of the dianionic and the monoprotonated forms shift and in the opposite direction and less strongly than in the case of *(9)* in phosphorylase *a*. These differences warrant further investigation, because they point to a different geometry of the 5'-deoxymethylenephosphonate group of the cofactor in active muscle phosphorylase. Moreover, these results are of general interest regarding how the geometry of the phosphate group of the cofactor in the enzyme influences the chemical shifts.

[*] The pH activity profile of *E. coli* maltodextrin phosphorylase is dependent on the nature of the buffer and the direction of the reaction (synthesis or degradation). The information applies to synthesis in [4-(2-hydroxyethyl)piperazine]ethanesulfonic acid (HEPES) buffer.

heptamylose (1 mM = 1/90 of the glucose concentration) at pH = 6.5 together with the original signal a new signal which is shifted upfield by about 4 ppm (Fig. 10B)[101]). Linewidth and resolution show that both forms do not exchange or very slowly exchange. The broadened signal at higher field is, however, in exchange with a signal, which at higher oligosaccharide (15 mM heptaamylose) concentrations becomes the dominant signal (Fig. 10C). This resonance at $\delta = -3$ corresponds to the chemical shift induced by 90 mM glucose (Fig. 7B). 100 mM arsenate and 15 mM heptaamylose result in arsenolysis of the glycosidic bonds and in the formation of glucose and arsenate. Accordingly, a spectrum is obtained which resembles the spectrum in the presence of glucose and arsenate (cf. Fig. 7C and 10D).

We could demonstrate by ^{31}P-NMR spectroscopy that glucose in *E. coli* maltodextrin phosphorylase and glucose and oligosaccharide in potato phosphorylase change the p*K* of the 5′-phosphate group of pyridoxal phosphate. The pK changes may be interpreted as indicating protonation of the 5′-phosphate. Furthermore, we could show with potato phosphorylase that protonation is dependent on the oligosaccharide concentration. Control experiments carried out up to now, support the view that this effect is specific: Replacing glucose or oligosaccharide by 2-deoxy-D-glucose or D-glucal did not result in protonation. These findings and the finding that cyclodextrins which are bound and which are competitive inhibitors of potato phosphorylase with respect to glycogen and oligosaccharides but not substrates are ineffective, would seem to argue against "induced fit", *i. e.* structural rearrangements at the active site as the principal reasons for the ionization changes[134,135]. In the catalytic reaction with heptaamylose and arsenate or in the simulated reaction with the products glucose and arsenate, a rapid equilibrium between protonated and dianionic forms of the 5′-phosphate group of the cofactor is established (cf. Fig. 7 and 10). However, if one intends to interpret the protonation changes of the 5′-phosphate group of pyridoxal phosphate as proton-transfer in catalysis, one needs to know what role the 5′-phosphate group of the cofactor plays in catalysis by "classical" pyridoxal phosphate dependent enzymes.

2.7. Comparative ^{31}P-NMR Studies with Typical Pyridoxal Phosphate Dependent Enzymes

Martinez-Carrion[136] has recorded the ^{31}P-NMR spectrum of pyridoxal phosphate bound to aspartate aminotransferase from pig-heart cytosol (EC 2.6.1.1). The spectra were evaluated by comparison with unbound pyridoxal phosphate and interpreted to indicate that in the enzyme and in contrast to unbound pyridoxal phosphate the phosphate group of the bound cofactor is salt-bridged to a cationic amino acid residue at the catalytic site and inaccessible to aqueous solvent. This could explain the high stability of the coenzyme-apoenzyme complex compared with coenzyme-enzyme complexes lacking the 5′-phosphate group. Binding of substrates and substrate analogues did not change the ^{31}P-NMR signal; this would appear to rule out a catalytic role for the 5′-phosphate group of pyridoxal phosphate in this enzyme, which was postulated by *Furbish et al.*[137]. In aspartate aminotransferase the 5′-phosphate group is only an anchor point. The same applies to D-serine dehydratase of *E. coli* (EC 4.2.1.14) which is also a "classical" pyridoxal phosphate dependent enzyme. It was recently studied by *Schnackerz et al.*[123]. The ^{31}P-NMR resonance of pyridoxal phosphate bound to D-serine dehydratase in contrast to the cofactor bound to aspartate aminotransferase is pH dependent and behaves like an ε-aminohexanoic acid pyridoxal phosphate Schiff base in aqueous solution (see Fig. 11[100,123]). Binding of the substrate ana-

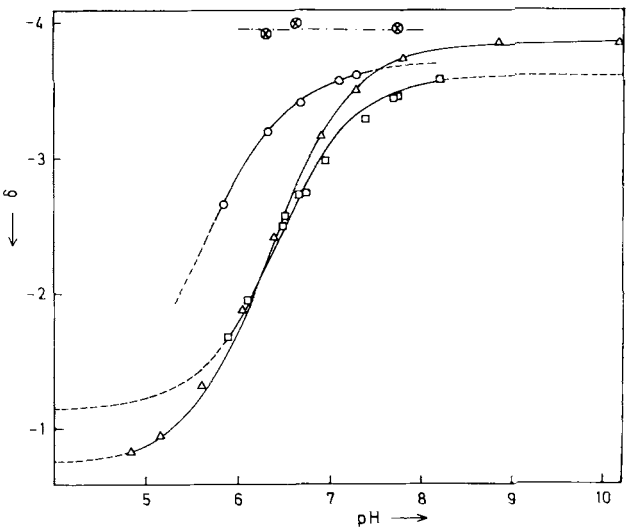

Fig. 11. Comparison of ^{31}P-NMR titration curves. ○—○: pyridoxal phosphate in *E. coli* maltodextrin phosphorylase; △—△: ε-amino hexanoic acid-pyridoxal phosphate Schiff base; □—□: pyridoxal phosphate in D-serine dehydratase; ⊗—⊗: pyridoxal phosphate in D-serine dehydratase with 25 mM isoserine (see [100, 123]).

logue isoserine shifts the ^{31}P-NMR signal downfield. It was thus assumed that the formation of the transaldimination complex required for catalysis is facilitated by immobilization of the 5′-phosphate group. When an azomethine complex between substrate and the formyl group of the pyridoxal phosphate bound to enzyme is formed, the dianionic 5′-phosphate group of the cofactor forms by electrostatic interactions a salt bridge with a cationic (arginyl) residue and removes the phosphate from the aqueous solvent. The phosphorus resonance becomes pH independent in the pH-stability range of the enzyme. Hence, also in D-serine dehydratase, the phosphate group of the cofactor serves only as a structural anchor point which helps to position and stabilize the transaldimination complex. In this respect, the role of the phosphate of the cofactor in D-serine dehydratase and in *E. coli* maltodextrin phosphorylase is different.

3. Interpretation and Synopsis

H. Neurath, E. H. Fischer et al. have recently summarized the evidence which supports a role of pyridoxal phosphate in the catalysis by α-1,4-glucan phosphorylases[4].

1) The amino acid sequence of the binding site of pyridoxal phosphate in muscle-[3 5], yeast-[49], potato-[138] and *E. coli* maltodextrin phosphorylase[8] has been highly conserved during evolution from procaryotes to eucaryotes (see Table 4[8]). This is in contrast to the N-terminal sequence which is phosphorylated and which is responsible for covalent and allosteric control. For example, the phosphory-

lated sequence of yeast phosphorylase[49] differs from the corresponding sequence of rabbit skeletal muscle phosphorylase. Moreover, the N-terminal sequences of rabbit skeletal muscle phosphorylase, of the plant phosphorylases, for example potato phosphorylase and of the bacterial maltodextrin phosphorylases differ from each other, although to a different degree[3, 4, 5, 48].

Up to now, phosphorylation and/or allosteric activation of plant and bacterial phosphorylases has not been reported.

2) The localization of the catalytic center in the three dimensional structure of skeletal muscle phosphorylases brought the pyridoxal phosphate site into close proximity of the sites for the two anionic substrates, phosphate (arsenate) and glucose 1-phosphate to which also glucose, a competitive inhibitor for glucose 1-phosphate, is bound. The van der Waals radii of the oxygen atoms of the phosphate group of pyridoxal phosphate and of the hydroxyl groups of the glucose moiety overlap, which makes a participation of the phosphate group of pyridoxal phosphate in catalysis feasible on structural grounds.
3) Our ^{31}P-NMR studies have shown that changes in the ionization of the phosphate group of pyridoxal phosphate signal the transition from inactive to active muscle phosphorylases *b* and *a*.

We now report on more recent ^{31}P-NMR investigations with the unregulated *E. coli* maltodextrin and potato phosphorylases which have shown that in the unregulated, *active* phosphorylases, as in the allosterically or covalently *activated* muscle phosphorylases, the phosphate group of pyridoxal phosphate is present as dianion. This explains our previous observation that phosphorylase derivatives containing a monoanionic pyridoxal 5′-phosphate monomethyl ester analogue are inactive in the pH range of catalysis[53] and as well the experiments of *Parrish et al.*[98] on partial reactivation of apophosphorylase with pyridoxal and phosphate. These findings taken as a whole support a role of the phosphate group of pyridoxal phosphate as a dianion in the catalysis of α-glucan phosphorylases.

A model for the participation of the phosphate group of pyridoxal phosphate in catalysis should consider the sucrose phosphorylase reaction [cf. [124, 139]]: Sucrose phosphorylase from *Pseudomonas saccharophilae* [EC 2.4.1.7] catalyzes the phosphorolysis of sucrose with retention of the α-configuration at the C-atom of glucose 1-phosphate:

Saccharose + $P_i \rightleftharpoons$ glucose 1-phosphate + fructose;

This reaction proceeds *via* a glucosyl-enzyme intermediate[124]. There is no report available that pyridoxal phosphate functions as a cofactor in sucrose phosphorylase. However, in contrast to α-glucan phosphorylases, sucrose phosphorylase neither requires a poly- or oligosaccharide as primer nor does it catalyze glucosyl transfer to poly- or oligosaccharides as acceptors. These differences between disaccharide and oligosaccharide phosphorylases make it attractive to speculate that pyridoxal phosphate with its 5′-phosphate group is required for the catalysis of α-glucan phosphorylases, because it has an essential function in glucosyl transfer from and to the oligo- or polysaccharide acceptors. If one considers for example that it is energetically more expensive to position and align for catalysis an oligo- or polysaccharide than a disaccharide in a narrow hydrophobic site, one could rationalize the need for a phosphate dianion instead of a monoanionic amino acid side chain in order to make catalysis effective in α-glucan phosphorylases. A requirement for a dianion would also be in line with the extremely hydrophobic environment of the catalytic site in glycogen phosphorylases pointed out first by *Shaltiel* et al.[78-81]. One would expect a hydrophobic environment to favor phosphorolysis over hydrolysis. The unusually strong hydrophobicity of the environment of the substituted pyridine ring system in phosphorylase can be deduced from the unusual spectral properties of the phosphorylase bound cofactor[76, 81]. However, UV and fluorescence studies cannot report on the environment of the 5′-phosphate group of pyridoxal phosphate in α-glucan phosphorylases. In order to obtain this information we have carried out ^{31}P-NMR experiments.

Protonation of the 5′-phosphate group of pyridoxal phosphate in the non-regulated α-glucan phosphorylases on binding of glucose and oligosaccharides may be interpreted as an increase of the p*K* value reporting increased hydrophobicity. One should recall that the catalytic site in *E. coli* maltodextrinphosphorylase becomes inaccessible to the aqueous medium on binding of glucose (see Fig. 9 and 11). An increased apparent p*K* value of the phosphate group of pyridoxal phosphate on changing the solvent from water to dioxane-water mixtures was noted by us before[97].

Consideration of the phosphate dianion of pyridoxalphosphate in *active* and *activated* forms of glycogen phosphorylases as proton acceptor in catalysis is more an additional rather than an alternative interpretation. It is so to speak, only the other side of the coin: We have presented evidence for a protonation-deprotonation equilibrium with participation of the 5′-phosphate of pyridoxal phosphate after the reaction reached equilibrium (see Fig. 7, 9, and 10). The ion-

ization equilibrium is pH independent in the range of pH = 6.1 to pH = 7.4 and in the range of 75 to 100% enzymatic activity. *Bender et al.*[164] obtained a 2500 fold rate acceleration of the hydrolysis of *endo*-5-[4′,(5′)-imidazolyl]bicyclo[2.2.1]hept-*endo*-2-yl cinnamate by addition of benzoate anions (0.5 M) in an aprotic solvent (H_2O:dioxane = 1:4 (mol/mol)). The rate acceleration was explained by deprotonation of the imidazole group by the benzoate anion followed by proton uptake by the imidazolyl group. Accordingly, a participation of the phosphate dianion of pyridoxal phosphate as a base and proton acceptor in catalysis is comprehensible. As acid, a glutamic acid residue might be considered which has been localized by *Sprang* and *Fletterick* by X-ray structure analysis at 2.5 Å resolution besides a histidine adjacent to the glucosyl residue of glucose 1-phosphate in the catalytic center of muscle phosphorylase *a*[27].

^{31}P-NMR spectra obtained with potato phosphorylase in the presence of arsenate and heptaamylose and arsenate and glucose resemble each other, at least qualitatively. This is to be expected since glucose 1-arsenate formed on arsenolysis of α-1,4-glycosidic bonds spontaneously decomposes to glucose and arsenate[141]. Judging from the chemical shift one estimates at equilibrium a 1:1 ratio of monoprotonated and dianionic forms of the 5′-phosphate group of pyridoxal phosphate. However these results raise an obvious question; namely, how can glucose and arsenate give the same chemical shift as glucose arising from heptaamylose and arsenate? Glucose, although it binds to the glucose 1-phosphate site which is in close proximity to the 5′-phosphate of pyridoxal phosphate, does not participate in catalysis. On the other hand, poly- and oligosaccharides, which are catalytically cleaved by arsenolysis forming glucose, bind to another, nonoverlapping site[27,28]. This dilemma is readily resolved when one postulates a transfer site which can either be filled with the "substrate glucosyl" of glucose 1-phosphate on the way to the poly- or oligosaccharide acceptor or with the "product glucosyl" before leaving the enzyme. The glucose, which is "sensed" by the phosphate of the cofactor, is bound to the common transfer site and would represent a "glucosyl analogue", which, however, in contrast to the "energized glucosyl" arising from glucose 1-phosphate cannot form a glucosyl-enzyme intermediate. This hypothesis seems worth testing:

The proton transfer during catalytic glucosyl transfer might be too fast to measure on the NMR time scale in the normal temperature range[143]. However, one might try to distinguish and compare the protonation-deprotonation state of the phosphate group of the cofactor after catalytic glucosyl transfer (see Fig. 7, 9, 10) and in the presence of cyclodextrin and glucose 1-phosphate when a glucosyl-enzyme intermediate might be formed. In the latter case, glucosyl transfer does not take place since the acceptor is missing. This experiment requires either a glucose 1-phosphate analogue which can form a glucosyl intermediate but which does not interfere with the ^{31}P-NMR detection of pyridoxal phosphate or a suitable "glucosyl transition state analogue". In addition, ^{13}C-NMR spectroscopy might have to be employed. Another but equally attractive approach would be to look for a glucosyl enzyme intermediate (see Fig. 12).

Gold and *Osber*[142] have searched without success for reversible cleavage of the phosphate-ester bond in ^{18}O-labeled glucose 1-phosphate with muscle phosphorylase. Such cleavage would have been anticipated when a ternary complex of phosphorylase, glucosyl residue and phosphate is formed with an enzyme bound orthophosphate, which can rotate freely. *Kokesh* and *Kakuda*[135] repeated this experiment with potato phosphorylase, which in contrast to muscle phosphorylase binds cyclodextrins which are competitive inhibitors with starch and glycogen, but which do not function as acceptors for glucosyl residues. Potato phosphorylase was indeed found to catalyze in the presence of cyclodextrin and glucose 1-phosphate labeled with ^{18}O in the ester position (like the glucose 1-phosphate in the experiment of *Gold* and *Osber*[142]) exchange between the ester oxygen of glucose 1-phosphate and the peripheral oxygens of the phosphate at a rate comparable with the rate of starch synthesis[135]:

Phosphorylase · glucose 1-phosphate · cyclodextrin ⇌
Phosphorylase · glucosyl · P_i · cyclodextrin

This experiment does not tell us the type of bond which links the glucosyl intermediate to potato phosphorylase. It is equally compatible with a covalently bound glucose or a bound glucose cation. The kinetic studies of *Firsov et al.*[144] (but see also [145]) with muscle phosphorylase *b* would seem to argue for a covalent intermediate, because no secondary isotope effect was found with C-1[^{3}H] and C-1[^{2}H] labeled glucose 1-phosphate, respectively. If a glucosyl cation were bound reversibly to the enzyme, a measurable secondary isotope effect would have been expected[144]. *Doudoroff*[139] had postulated a covalent glucosyl intermediate in the case of sucrose phosphorylase which was subsequently isolated by *De-Toma* and *Abeles*[146] and shown to be a β-glycosidically linked glucose, as to be expected in a double displacement reaction with retention of configuration (see Fig. 12[147]). We are making efforts to verify the existence of a covalent glucosyl intermediate in potato phosphorylase. For this purpose, the enzyme was incubated with α-cyclodextrin and ^{14}C-uniformly labeled glucose 1-phosphate[165]. The radioactive protein was subsequently separated from substrates by sepharose G 25 chromatography, denaturated with 5% trichloroacetic acid and exhaustively washed until radioactivity was no

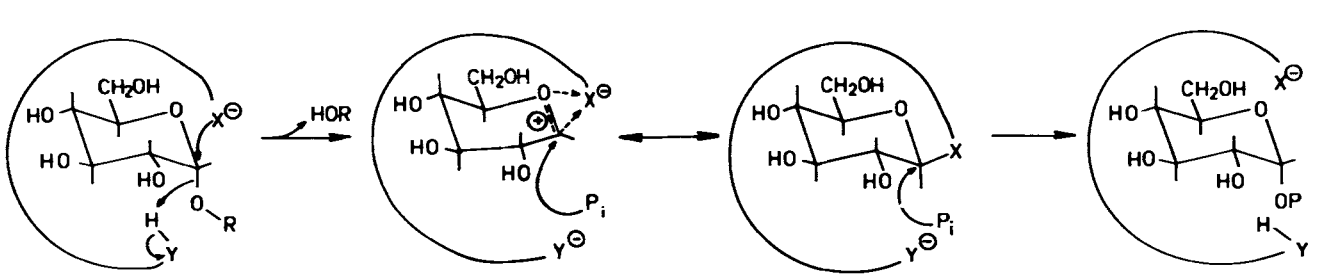

Fig. 12. Glucosyl enzyme intermediate, schematic. X: electron donor, nucleophile; HY: proton donor, electrophile; R: $(glucosyl)_n$; P_i: phosphate (after [147]).

longer detectable in the wash fluids. After chymotryptic digestion and electrophoretic separation ^{14}C-labeled peptides were found. No radioactivity in the peptides was found in control incubations of potato phosphorylase with ^{14}C-glucose or ^{14}C-glucose 6-phosphate or with ^{14}C-glucose 1-phosphate without α-cyclodextrin. Of course, unspecific binding can only be safely ruled out when the chemical structure of enzyme bound glucose has been elucidated and the glucose-enzyme intermediate located within the catalytic center.

Needless to say, the proposal that the dianionic phosphate group of pyridoxal phosphate functions as proton acceptor in the catalysis of α-glucan phosphorylases, although it is compatible with our ^{31}P-NMR data represents only one possibility. In fact, a role of the dianionic phosphate group of pyridoxal phosphate as a nucleophile has recently been proposed by *L. N. Johnson et al.*[140]. This proposal is the outcome of building models based on crystallographic data obtained with muscle phosphorylase *b* at 3 Å resolution. But whatever the answer may be, little doubt remains that the phosphate group of pyridoxal phosphate plays an obligatory role as dianion in the catalysis of α-glucan phosphorylases. It is to be hoped that further advances make it possible in the not too distant future to formulate a precise chemical mechanism of phosphorylase catalysis with the participation of the 5′-phosphate group of pyridoxal phosphate. It should then be possible to decide whether our prediction was correct that "nature may have found it advantageous to utilize in the case of glycogen phosphorylases protonatable groups of a vitamin rather than those of amino acid side chains to facilitate catalysis"[97].

Aside from the persons mentioned in our publications, the following colleagues at the University of Würzburg have greatly helped us in work on the role of pyridoxalphosphate in α-glucan phosphorylases: Priv.-Doz. Dr. Knut Feldmann, Professor Dieter Palm, Dr. George R. Philips, Dr. Klaus Schnackerz, Dr. Emil Schiltz and Dr. Manfred Bühner. We are grateful to Professors Louise N. Johnson, Oxford, Niels B. Madsen and Richard J. Fletterick, Edmonton, Donald J. Graves, Ames, Sh. Shaltiel and A. Kupfer, Rehovot, Henri Buc, Paris and T. Fukui, Osaka for making information available prior to publication. We are especially indebted to Dr. William H. Hull, Karlsruhe, Professor Edmond H. Fischer, Seattle, and Professor Esmond E. Snell, Austin, for criticism and valuable suggestions. Our work was supported in part by the Deutsche Forschungsgemeinschaft, by the Volkswagen foundation and by the Fonds der Chemischen Industrie.

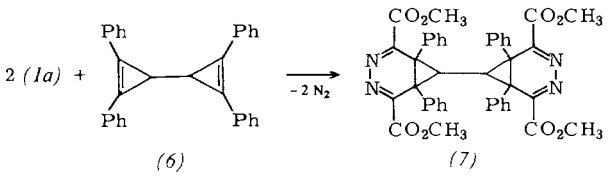
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

One-Pot Synthesis of Substituted Semibullvalenes

By *Dörte Paske, Richard Ringshandl, Ingeborg Sellner, Heinz Sichert,* and *Jürgen Sauer*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Ever since the first synthesis of a molecule having a "fluxional" structure was reported by *Doering* and *Roth*[1], these compounds have been the subject of numerous investigations[2]. We report here on a one-pot reaction for the synthesis of 2,4,6,8-tetra-substituted semibullvalenes *(5)* which proceeds *via* the diazasnoutenes *(4)*.



(1a-c) *(2)* *syn-(3a-c)* *anti-(3a-c)* *(5a-c)* *(4a-c)*

(a), R = CO_2CH_3; *(b)*, R = C_6H_5; *(c)*, R = CH_3

The high reactivity of 1,2,4,5-tetrazines in the addition to cyclopropenes makes 3,4-diazanorcaradienes of type *(3)* a readily accessible class of compounds[3]. We have been able to improve the yield of the synthesis of *(2)*[4] so that it is obtainable on a gram scale.

Semibullvalenes *(5)* are formed and can be isolated on allowing *(2)* to react with symmetrical tetrazines *(1)*. In the reaction of *(1b)* and *(1c)*, the diazanorcaradienes *(3)* can be detected by NMR spectroscopy; only on warming are they converted into the semibullvalenes *(5b)* and *(5c)*, respectively. Whether or not an equilibrium *syn-(3)* $\rightleftharpoons$ *anti-(3)* is involved is still uncertain. We have not been able to detect *(3a)* in the reaction of *(1a)* with *(2)*; apparently the intramolecular addition to give *(4a)* proceeds very rapidly. In no case could criteria be obtained evidencing measurable concentrations of *(4)*, since *(4)*, favored by the two *anti* cyclopropane rings, rapidly loses N_2 and forms *(5)* (cf. [2a]).

Attempts to carry out the analogous reaction with the cyclopropene derivative *(6)*[5] have failed so far. Even on using the dilution principle with *(1a)* we only obtained the 1:2 adduct *(7)*.

(6) *(7)*

The semibullvalenes *(5)* obtained by us already show the time-averaged spectra at room temperature with ^{1}H-NMR signals for the methyl protons between $\delta = 1$—2, for the ring protons between $\delta = 3.7$–4.8. The analogous ^{13}C-NMR average signals appear at $\delta = 15$ for the methyl C-atoms, at $\delta = 60$ for C-4/C-8 and at $\delta = 89$—94 for C-1, C-3, C-5, C-7 (see Table 1).

Relation between Orbital Character and Reaction Product in the Reaction of Benzvalene and Homobenzvalene with Thiophenol[**]

By *Manfred Christl, Reinhard Lang, Rainer Herbert,* and *Gertrud Freitag*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Both olefins[1] as well as bicyclo[1.1.0]butanes[2] add thiols in radical chain reactions. In order to check which function is the more active partner for the thiol we treated benzvalene *(1)* and homobenzvalene *(8)*, which contain both these functions, with thiophenol. After 24 h at 20 °C the 1:2 mixture of *(1)* and thiophenol furnished four products: 3-phenylthiotricyclo[3.1.0.0^{2,6}]hexane *(2)*, *exo*- and *endo*-4-phenylthiobicyclo[3.1.0]hex-2-ene *(6)* (6:1), and 2-*exo*,5-*endo*-bis(phenylthio)bicyclo[2.1.1]hexane *(3)*. The constitution and the stereochemistry of these products follow from the NMR spectra (Table 1).

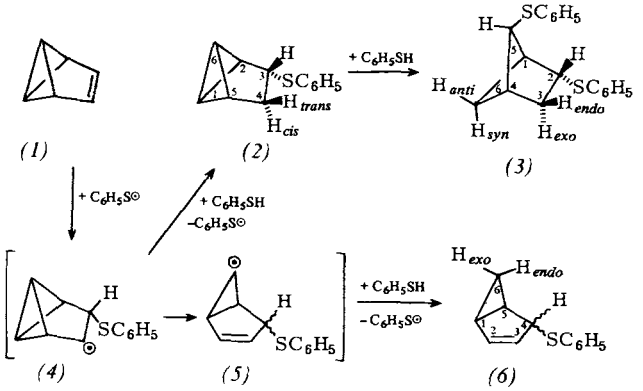

Table 1. NMR data of the new compounds (in $CDCl_3$, δ values, J in Hz).

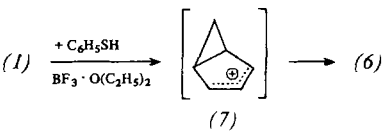
(2): ^{1}H-NMR: 1.22 (dd, 4-H$_{cis}$, $J_{3,4}=3.1$, $J_{4,4}=11.7$), 1.83 (dd, 4-H$_{trans}$, $J_{3,4}=8.2$), 1.86—1.96 (m, 1-H, 5-H, 6-H), 2.19 (m, 2-H), 3.31 (dd, 3-H), 6.88—7.48 (m, C_6H_5); ^{13}C-NMR: 3.4 (d, C-1), 5.8 (d, C-6), 32.9 (d, C-5), 35.5 (t, C-4), 39.3 (d, C-2), 46.3 (d, C-3); C_6H_5: 125.4 (d), 128.6 (d), 129.3 (d), 137.5 (s)



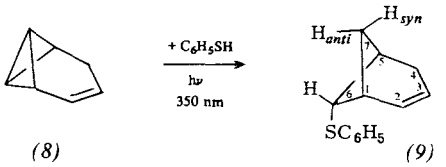
(3): ^{1}H-NMR: 1.42—1.66 (m, 6-H$_{anti}$, 3-H$_{exo}$), 1.58 (d, 6-H$_{syn}$, $J_{6,6}=7.6$), 2.50 (dd, 3-H$_{endo}$, $J_{2,3}=8.2$, $J_{3,3}=12.2$), 2.74 (m, 1-H, 4-H), 3.53 (q, 5-H, $J_{1,5}=J_{3\,exo,5}=J_{4,5}=2.4$), 3.96 (m, 2-H), 6.95—7.45 (m, C_6H_5)

exo-(6): ^{1}H-NMR [a]: −0.10 (q, 6-H$_{endo}$, $J_{1,6}=J_{5,6}=J_{6,6}=3.9$), 0.69 (dt, 6-H$_{exo}$, $J_{1,6}=J_{5,6}=7.6$), 1.40—2.10 (m, 1-H, 5-H), 4.00 (m, 4-H), 5.44 (m, 3-H, $J_{2,3}=5.5$), 6.10 (m, 2-H); C_6H_5: 7.15—7.50 (m, 3H) and 7.50—7.85 (m, 2H); ^{13}C-NMR: 19.5 (t, C-6), 23.4 (d) and 23.8 (d) (C-1 and C-5), 54.3 (d, C-4), 126.7 (d, C-3), 137.4 (d, C-2); C_6H_5: 126.3 (d), 128.5 (d), 131.2 (d), 135.1 (s)

(9): ^{1}H-NMR: 1.53 (d, 7-H$_{syn}$, $J_{7,7}=8.2$), 2.00 (dt, 7-H$_{anti}$, $J_{1,7}=J_{5,7}=5.4$), 2.15 and 2.75 (br. AB-System, 4-H$_{endo}$ and 4-H$_{exo}$, $J_{4,4}=18.3$), 2.65—2.90 (m, 1-H, 5-H), 3.76 (t, 6-H, $J_{1,6}=J_{5,6}=5.2$), 5.69 (m) and 6.08 (m) (2-H, 3-H, $J_{2,3}=9.0$), 6.90—7.50 (m, C_6H_5)

[a] In C_6D_6.

Mechanistic studies suggest a radical chain reaction in which the phenylthio radical, formed from thiophenol by oxidation with atmospheric oxygen, adds to the double bond in *(1)*. There are two routes open to the resulting radical *(4)*: hydrogen abstraction from thiophenol leads to *(2)*; preceding bond reorganization, in the sense of a cyclopropylmethyl-homoallyl radical rearrangement[3,4] to *(5)*, affords *(6)*. The addition of thiophenol to the central bicyclo[1.1.0]butane bond of *(2)* with formation of *(3)* follows known paths[2]; however, it proceeds considerably slower than the formation of *(2)* (see below).



(6) could also be formed *via* the cation *(7)*[5]. We have enforced this ionic route by addition of boron trifluoride-ether and obtained pure *(6)*, b.p. 60—80 °C (bath)/0.01 torr, in 82% yield. Labeling experiments, however, rule out this route in the absence of boron trifluoride-ether.

Owing to the difference in molecularity the competing steps starting from the intermediate *(4)* require the dependence of the ratio *(2)*:*(6)* on the thiophenol concentration. This was indeed found:

Reaction of 6.40 mmol *(1)* and 27.2 mmol thiophenol in 13 ml ether for 20 min at 20 °C afforded 92% of a 96:4 mixture of *(2)* and *(6)*, b.p. 60 °C/0.01 torr. In contrast, on dropwise addition of 6.44 mmol of thiophenol in 50 ml ether over 7 h to 6.40 mmol of *(1)* in 13 ml ether, a 83% yield of a mixture of *(2)* and *(6)* in the ratio 12:88 was isolated.

As observed in the case of other tricyclo[3.1.0.0^{2,6}]hexane derivatives[6], UV irradiation also considerably promotes thiophenol addition to *(2)*. On irradiation of a mixture of 2.56 mmol *(1)* and 45.4 mmol of thiophenol in 5 ml ether for 18 h with 350-nm light we obtained 87% *(3)* as colorless crystals, m.p. 54—55 °C.

Homobenzvalene *(8)* reacts only slowly with thiophenol at room temperature. In contrast, on irradiation with 350-nm light the addition is complete within 2 h, giving 6-*endo*-phenylthiobicyclo[3.1.1]hept-2-ene *(9)* in 73% yield without formation of isomers. Together with results quoted in the literature, the structure, as confirmed by the ^{1}H-NMR spectrum (Table 1), and the reaction conditions suggest the radical

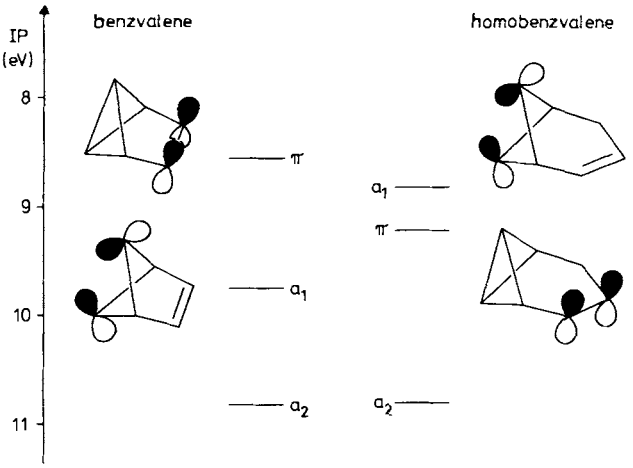


Fig. 1. Ionization potentials and orbitals of benzvalene *(1)* and homobenzvalene *(8)* according to [8].

chain reaction already accepted in the case of other bicyclo[1.1.0]butanes[2].

Why does the phenylthio radical attack benzvalene *(1)* at the double bond but homobenzvalene *(8)* at the bicyclo[1.1.0]butane system? Since thio radicals have electrophilic character[7], the interaction with the HOMO of the substrate may play the decisive role in the transition state of the addition. As shown by the ionization potentials determined by photoelectron spectroscopy and assigned on the basis of MINDO/3 calculations[8], the HOMO in *(1)* is located in the double bond, in *(8)*, however, in the central bond of the bicyclo[1.1.0]butane system (Fig. 1).

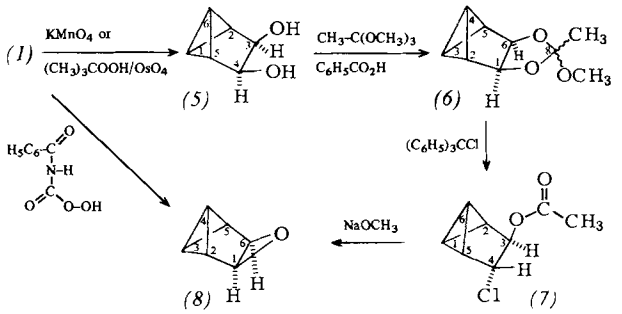
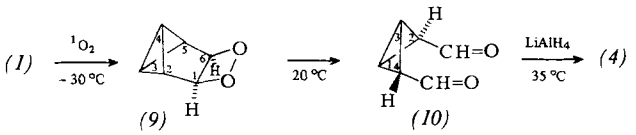
Oxidation Reactions of Benzvalene: Ozonolysis, *cis*-Hydroxylation, Epoxidation, and Singlet Oxygen Addition[**]

By *Hartmut Leininger* and *Manfred Christl*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



Ready accessibility and high reactivity predestine benzvalene *(1)* as a useful starting material for many bicyclo[1.1.0]butane derivatives and other small-ring polycycles[1,2]. By reaction of *(1)* with classical oxidizing agents, we have prepared some interesting synthetic building blocks containing the bicyclo[1.1.0]butane moiety.



[*] Prof. Dr. M. Christl, Dipl.-Chem. H. Leininger

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

In our first investigation of the ozonolysis of *(1)* we surprisingly obtained the cyclobutane derivative *(4)* on reduction of the polymeric ozonide with $LiAlH_4$[3]. We have now found that the desired bicyclo[1.1.0]butane-2,4-*endo,endo*-dimethanol *(3)* is formed in 52% yield in tetrahydrofuran at $-30\,^{\circ}C$ if six equivalents of $LiAlH_4$ are used. If only three equivalents are employed, one obtains a 1:3 mixture of *(2)* and *(3)* which is separable by distillation. Reaction of *(2)* at $-30\,^{\circ}C$ and of *(3)* at $35\,^{\circ}C$ with $LiAlH_4$ in ether affords *(3)* and *(4)*, respectively, thus proving that *(4)* is formed *via* the alkoxides of *(2)* and *(3)*. The unexpected hydrogenation of a σ-bond in the reaction *(3)*→*(4)* is probably favored by the high p-character of the orbitals whose electrons form the (C-1)—(C-3) bond in *(3)*, and by the oxygen function, which may complex an Al—H species, so that H-transfer can take place intramolecularly.

The *cis*-hydroxylation of *(1)* in ether to give tricyclo[3.1.0.$0^{2,6}$]hexane-3,4-diol *(5)* can be performed under standard conditions with potassium permanganate or, with a better yield of 54%, with *tert*-butyl hydroperoxide/OsO_4 using the method of *Sharpless et al.*[4]. A new method[5] enabled us to convert *(5) via (6)* (two isomers in the ratio 7:3, 70% yield) and *(7)* (56%) into 7-oxatetracyclo[4.1.0.$0^{2,4}$.$0^{3,5}$]heptane *(8)*. Reaction of peracetic acid or *m*-chlorobenzoic acid with *(1)* does not give any *(8)*, even if trapping of the liberated acid is supposedly taken care of by a base or a buffer. On the other hand, the new epoxidizing agent benzoylperoxycarbaminic acid[6], which affords benzamide and carbon dioxide, leads to *(8)* in 54% yield.

As an olefin having a high energy HOMO[7], *(1)* also smoothly takes up singlet oxygen. On bubbling oxygen through an ethereal solution of *(1)* and tetraphenylporphine exposed to a sodium vapor lamp at $-30\,^{\circ}C$, *(1)* completely disappears within two days. The ^{1}H-NMR spectrum of the solution then shows, besides the CHO signal of *(10)* at $\delta = 9.15$, an intense broad singlet at $\delta = 5.20$, which could arise from 1-H and 6-H in the dioxetane *(9)*[8]. Further signals are superposed by ether bands. At room temperature, the singlet disappears within 6 h with concomitant growth of the band at $\delta = 9.15$, thus indicating the expected transformation[8] of *(9)* into *(10)*. After addition of C_6D_6 and removal of the ether, the ^{1}H-NMR spectrum showed all the signals of *(10)* (Table 1) gradually diminishing in intensity, besides slowly growing broad bands. The coupling constant $J_{1,2}$ (3.6 Hz) is of similar magnitude to that in *(3)* (4.0 Hz) and characteristic for the *exo* arrangement of 2-H, 4-H[9] in these compounds. The line separation of 1.5 Hz in the CHO-doublet of *(10)* resembles the value of 2.4 Hz in 1,3-*cis*-cyclobuta-

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0606-458 $ 02.50/0

nedicarboxaldehyde[10]. On treatment with $LiAlH_4$ in ether at 35 °C, *(10)* is reduced to *(4)*.

(7), b.p. 45—50 °C (bath)/0.01 torr; ^{1}H-NMR: 2.06 (s, CH_3), 2.38 and 2.46 (in each case br. s, 1-H, 6-H, 2-H, 5-H), 3.84 (br. s, 4-H), 4.86 (br. s, 3-H); ^{13}C-NMR: 6.0 and 7.2 (in each case d 220.6 Hz, C-1, C-6), 20.9 (q, 129.4 Hz, CH_3), 35.6 (d 172.8 Hz, C-2), 39.7 (d 173.6 Hz, C-5), 65.0 (d 160.3 Hz, C-4), 85.2 (d 161.0 Hz, C-3), 170.4 (s, C=O)

(8), b.p. 40—60 °C (bath)/14 torr; ^{1}H-NMR: 2.19 (dt, 4-H, $J_{3,4} = 8.1$ Hz, $J_{2,4} = 2.6$ Hz), 2.33 (m, 2-H, 5-H), 2.98 (dt, 3-H, $J_{2,3} = 1.1$ Hz), 3.26 (s, 1-H, 6-H); ^{13}C-NMR: −1.1 (d 221.8 Hz, C-4), 26.5 (d 214.7 Hz, C-3), 37.0 (d 170.6 Hz, C-2, C-5), 56.9 (d 189.0 Hz, C-1, C-6)

(10), IR (ether): 1720 cm^{-1} (C=O); ^{1}H-NMR: 1.48 (t, 1-H, 3-H, $J_{1,2} = 3.6$ Hz), 2.81 (m, 2-H, 4-H), 9.15 (br. d, CH=O, line sepn. 2.4 Hz)

[a] *(6a)*: major amount isomer; *(6b)*: minor amount isomer.

The structures of *(2)*, *(3)*, *(5)*—*(8)*, and *(10)* are confirmed by NMR spectra (Table 1). Two phenomena warrant special comment: The value of 197.3 Hz for the direct CH coupling of C-1, C-3 in *(3)* is relatively small, but by comparison with known data[11] can possibly be explained in terms of the dihedral angle being enlarged by the two *endo* substituents. In *(8)* there is a large difference of 27.6 ppm between the chemical shifts of C-3 and C-4, indicating that the epoxide ring exerts a similar anisotropic effect as the cyclopropane[11,12] and aziridine[2] rings.

(3) and *(10)* are the first bicyclo[1.1.0]butanes containing no substituents other than two functional groups in the *endo* positions.

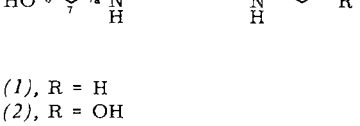
Indole Pigments from the Fruiting Bodies of the Slime Mold *Arcyria denudata*[**]

By *Wolfgang Steglich, Bert Steffan, Lothar Kopanski,* and *Gerd Eckhardt*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Slime molds constitute a class of very primitive organisms of uncertain systematic position which can be assigned neither to the plant nor the animal kingdom[1]. Their delicate fruiting bodies (Sporangia) often have bright colors, the chemical nature of which still remains virtually unknown[2].



From 2 g of the red fruiting bodies of *Arcyria denudata* (L.) Wettstein, we obtained a red methanolic extract, which was separated by chromatography on Sephadex LH-20 (eluent methanol) into three red and two yellow main fractions (see Table 1).

Table 1. Pigments from *Arcyria denudata*, purified by re-chromatography. Empirical formulas were determined by high-resolution mass spectrometry [a].

		R_f [b]	Color	Yield [%]	M.p. [°C]
Arcyriarubin B	*(1)*	0.33	red	0.4	154—155
Arcyriarubin C	*(2)* [c]	0.21	red	1.5	205—206
Arcyriaflavin B	*(3)*	0.33	pale yellow [d]	0.05	350
Arcyriaflavin C	*(4)*	0.21	pale yellow [d]	0.05	350
Arcyroxepin A	*(5)* [c]	0.42	red [e]	0.3	268—270

[a] *(1)*, $C_{20}H_{13}N_3O_3$; *(2)*, $C_{20}H_{13}N_3O_4$; *(3)*, $C_{20}H_{11}N_3O_3$; *(4)*, $C_{20}H_{11}N_3O_4$; *(5)*, $C_{20}H_{11}N_3O_3$. [b] Silica gel TLC plates, Merck 60 F_{254} (eluent: benzene/ethyl formate/formic acid 10:5:3). [c] Correct elemental analyses obtained. [d] Strong bright yellow fluorescence at 366 nm. [e] Reversible color change to violet over NH_3 vapor.

In its ^{1}H- and ^{13}C-NMR spectrum (Table 2) arcyriarubin C shows only half of the full set of signals and must therefore have a symmetrical structure. According to the IR bands at 1755 and 1705 cm^{-1} a maleimide moiety is present; this is confirmed by the ^{13}C-NMR signals at δ = 175.3 and 129.2[3]. From the splitting and position of the arene signals, and from the NH protons (coupled with 2-H) at $\delta = 10.42$ in the ^{1}H-NMR spectrum, it follows that the maleimide is substituted by two (5- or 6-hydroxy)indol-3-yl groups. The ^{13}C-NMR spectrum would favor *(2)*: the position of the C-7 signal at $\delta = 97.7$ can be reconciled only with the OH group being in a 6-position[4].

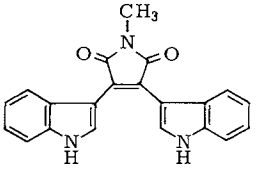
[a] 90-MHz; δ values, TMS (int.). [b] The signals marked with an asterisk are broadened by coalescence; assignment of the signals of coupled spectra by selective decoupling and increment calculation.



Arcyriarubin B has the structure and composition *(1)*, in agreement with all the spectroscopic data.

Like *(2)*, arcyriaflavin C is composed of two identical moieties. The absence of the 2,2' H-signals and the unusual downfield position of the 4,4' H-signal at δ = 8.93 are consistent only with structure *(4)*. The structure is confirmed by the transformation of *(2)* into *(4)*, which already occurs on gentle warming in conc. sulfuric acid. Arcyriaflavin B *(3)* has only one OH group, and an additional downfield signal is consequently observed in the ^{1}H-NMR spectrum at δ = 9.15.

Especially interesting is the third red pigment, $C_{20}H_{11}N_3O_3$, which shows a reversible color-change to violet on TLC plates over NH_3 vapor. According to the IR spectrum it contains the maleimide system and has a symmetrical structure. The absorption spectrum strongly resembles that of the reference compound *(6)*, which is readily accessible in 60% yield by condensation of indolylmagnesium iodide with 1-methyl-3,4-dibromomaleimide in benzene at 25 °C in the presence of a small amount of hexamethylphosphoric triamide[5]. In the 400-MHz ^{1}H-NMR spectrum of the pigment, three protons of the benzene ring are clearly recognizable [δ = 7.18 ("t", J = 8 Hz); 7.32 (br, "d", 8 Hz); 7.38 ("d", 8 Hz), while the shape and position of the fourth depends very strongly on the measuring conditions[6]. Since the indole NH-protons give rise to one singlet at δ = 9.82 and no signal is observed for the 2,2' H, the third oxygen atom can only link the two indole rings; hence the pigment called by us arcyroxepin A must have the formula *(5)*.

(5)

(6)

The arcyriaflavins are structurally related to staurosporin, an antibiotic and antihypertensive which has recently been isolated from *Streptomyces staurosporeus*[7]. In the platelet diffusion test, *(1)*, *(2)* and *(5)* exhibit medium inhibiting action against *Bacillus brevis* and *B. subtilis*[8].

Sequence Analysis of Ergochrome-Biosynthesis by Competitive Incorporation[**]

By *Burchard Franck, Gerhard Bringmann,* and *Georg Flohr*[*]

Information about alternative intermediates is of cardinal importance for an understanding of natural product biosyntheses and for the development of biomimetic syntheses. By means of competitive incorporation[1] we have been able to detect alternative intermediates in the biosynthesis of mycotoxins of the ergochrome type[2], *e.g.* of secalonic acid D *(5)*, and to assign them to an informative sequence.

Ergochromes are formed by oxidative ring opening[2,3] of the anthraquinone emodin *(1)*, a key building block in the

biosynthesis of natural products[4]. In this reaction a hydroxy group has to be removed from C-6 and an additional one incorporated at C-4. Thus besides emodin *(1)*, the natural anthraquinones chrysophanol *(2)*, islandicin *(3)*, and catenarin *(4)*, whose hydroxy group arrangements resemble fully or partly that of a half-molecule of *(5)* (see box), are also of interest as intermediates in biosynthesis.

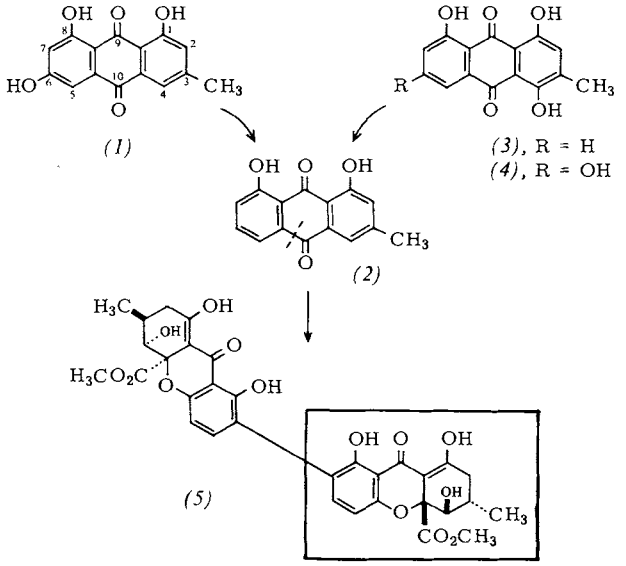

Table 1. Competitive incorporation of the radioactive anthraquinones *(1)*–*(4)* in secalonic acid D *(5)* by *Penicillium oxalicum* [a].

Expt.	Anthraquinone	Spec. incorp. [b] [%]	a/b
1	a) [U-^{14}C]emodin *(1)*	0.432	1.03
	b) [U-^{3}H]emodin *(1)*	0.418	
2	a) [U-^{14}C]chrysophanol *(2)*	3.42	3.56
	b) [U-^{3}H]emodin *(1)*	0.96	
3	a) [U-^{14}C]islandicin *(3)*	0.163	0.301
	b) [U-^{3}H]emodin *(1)*	0.541	
4	a) [U-^{14}C]catenarin *(4)*	0.008	0.022
	b) [U-^{3}H]emodin *(1)*	0.37	

[a] ATCC 10476. [b] Specific radioactivity of the isolated secalonic acid D *(5)* divided by that of the fed anthraquinone and by the number of anthraquinone molecules which can be incorporated in *(5)* × 100.

For the competitive incorporation, pairs composed of biosynthetically prepared uniformly labeled [U-^{3}H]emodin *(1)* and one of the [U-^{14}C]anthraquinones *(1)* to *(4)*[5] were fed to the mold *Penicillium oxalicum*[6]. After isolation and purification to constant radioactivity, the $^{3}H/^{14}C$ ratio in *(5)* was determined in a scintillation counter (Table 1).

As experiment 1 shows, [U-^{3}H]emodin loses only 3% or less of its tritium radioactivity (predominantly located in the methyl group) during conversion into *(5)* by the mold. It is therefore suitable as reference compound for competitive incorporation reactions. From the incorporation values (ratio a/b) referred to emodin *(1)* of the other experiments it significantly follows, irrespective of deviations of the enzyme activity of various components, that chrysophanol *(2)* (Experiment 2) is incorporated into *(5)* 3.6 times better than *(1)* and 11.8 times better than *(3)* (Experiment 3). In contrast, *(4)* can be ruled out as a biosynthetic precursor[7].

From these findings it can be concluded that emodin *(1)* and islandicin *(3)* are converted into the ergochromes, *e.g. (5)*, *via* chrysophanol *(2)*. The hydroxy group on C-4 is thus incorporated after oxidative ring opening which precedes the dimerization[3,8]. The preferred suitability of *(2)* for preparatively useful biomimetic ring-opening reactions is already well known[9].

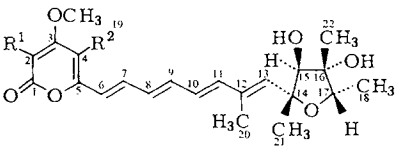
Citreoviridins from *Aspergillus terreus*[**]

By *Burchard Franck* and *Henning-Peter Gehrken*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday



The potent neurotoxic mycotoxin citreoviridin *(1a)* is responsible for the epidemic-like occurrence of *cardiac beriberi*[1] in East Asia. Its acute toxicity, comparable to that of the aflatoxins, is caused by inhibition of the mitochondrial ATP synthetases[2]. *(1a)* was previously found in moldy rice and in *Penicillium citreoviride* and related *Penicillium* species[3]. We isolated citreoviridin *(1a)* and further previously unknown derivatives of similar structure from the mold *Aspergillus terreus*, one of the commonest organisms occurring in soil, on various types of grain and sugar-containing nutrients and which is used biotechnologically[4]. It deserves special mention that the occurrence of citreoviridin, which belongs to the most dangerous mycotoxins, is not restricted to East Asian mold fungi, and that the citreoviridin production by strains of *Aspergillus terreus* is extremely high—up to 2% of the dried mycelium. This made possible a thorough biogenetic analysis of the mycotoxin.

On closer examination of *Aspergillus terreus* for active substances, we discovered in the case of 5 of 13 strains[5] brilliant yellow metabolites showing typical polyene UV/VIS spectra. The main metabolite (deep-yellow needles, m.p. 109–110 °C, from MeOH, $\lambda_{max} = 237, 287, 295, 388$ nm) proved to be identical to citreoviridin *(1a)*[6]; in addition we found

[**] Metabolites of Fungi, Part 31.—Part 30: *B. Franck, G. Bringmann, G. Flohr*, Angew. Chem. *92*, 483 (1980); Angew. Chem. Int. Ed. Engl. *19*, 460 (1980).

small amounts of five very similar metabolites. We therefore give the citreoviridin *(1a)* the suffix "A" and the other components in order of their R_s values (1.44, 1.35, 1.24, 0.72, 0.62; ethyl acetate on TLC strips SI F-Riedel de Haen) referred to *(1a)* = 1.00 as B, C, D, E, and F. The components C and D could be assigned the structures *(1b)* and *(1c)* from spectroscopic data. Fragments formed in the mass spectrometer by cleavage of the C-5/C-6 bond indicated that *(1a)*, *(1b)*, and *(1c)* differ only by methyl groups on C-2 and C-4. Accordingly, only the signals of C-2 and C-4 showed significant differences in the ^{13}C-NMR spectra ([D$_6$]acetone).

[a, b] These assignments can be interchanged.

The structure of citreoviridin A *(1a)* suggests a biosynthesis from nine acetate moieties *via* acetyl- and malonylcoenzyme A and the C_{18} polyketide *(3)*, and its *C*-methylation at four positions (C-4, C-12, C-14, C-16). This is consistent with previous incorporation experiments[3b] with acetate and methionine, in which, however, only few positions of incorporation could be determined by chemical degradation because of labeling with ^{14}C. Application of [1-^{13}C]- and [2-^{13}C]acetate (90% ^{13}C-enrichment; 200 mg/100 ml nutrient) to *Aspergillus terreus* (CBS 503.65)[4] gave isotopomeric citreoviridins A *(1a)*. Their unusually high incorporation of 17.6 and 25.7%, respectively[7], enabled accurate determination of ^{13}C-positions by ^{13}C-NMR spectra (Table 1). It follows from the spectra that all odd C-atoms (×) of polyketide chain *(3)* of *(1a)* originate from the carboxy groups of the acetate building block and the even C-atoms (●) of *(3)* from the methyl groups. The C-atoms of the methoxy and of the C-methyl groups, like the unlabeled C-atoms of the C_{18} chain, showed no significant signals consistent with their origin from the C_1 pool of the organism.

As an advanced intermediate of the citreoviridin biosynthesis from acetate moieties, attention was directed to oleic acid. It contains as many C-atoms as the polyketide *(3)* and is a key building block[8] for the biosynthesis of many polydehydrocarboxylic acids[9]. The radioactivity of citreoviridin *(1a)* isolated after the feeding of *Aspergillus terreus* with [1-^{14}C]oleic acid corresponded to a small incorporation of only 0.00093%. $KMnO_4$-oxidation of this citreoviridin *(1a)* afforded a cumalic acid derivative *(2)*, which contained only 36% of the radioactivity to be expected on direct incorporation. The low incorporation of the [1-C^{14}]oleic acid might therefore be best explained in terms of a degradation to ^{14}C-acetate.

Procedure

Isolation of *(1a)*: 200 surface cultures of *Aspergillus terreus* (CBS 503.65) on 350 ml batches of Czapek-Dox nutrient[11] in 1 l Erlenmayer flasks, which were grown for 21 d at 26 °C, gave 750 g of freeze-dried mycelium. This was washed consecutively, five times with 3.5 l petroleum ether (126 g residue) and acetone (65.2 g residue). The acetone residue was taken up in ethyl acetate, the insoluble material removed by filtration and the filtrate chromatographed several times with ethyl acetate on columns of silica gel (Merck, particle size 0.063—0.2 mm). The residue obtained on evaporation of the combined eluates was recrystallized from methanol; yield 15.1 g (2.01% of the dry mycelium) *(1a)*, m.p. 108—110 °C.

[7] The incorporation was determined mass spectrometrically. For calculation of the ^{13}C enrichment in the labeled positions of the citreoviridin *(1a)* obtained after feeding [1-^{13}C]- and [2-^{13}C]acetate, the intensities of their ^{13}C-NMR signals are divided by the corresponding intensities of unlabeled *(1a)*. The reduced intensities I_r thus obtained are multiplied by the quotients $\bar{A}_m/\bar{I}_r$ ($\bar{A}_m$ = mass spectrometrically determined, average ^{13}C enrichment at the labeled positions in multiples of the natural ^{13}C abundance).

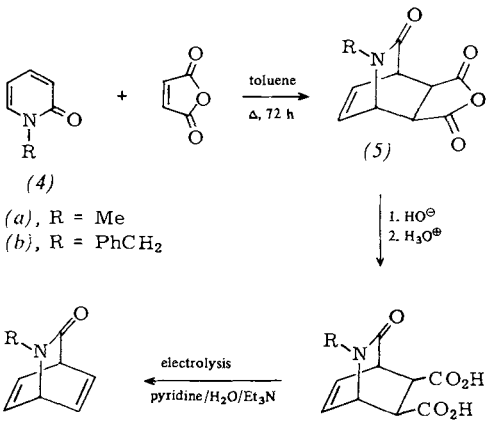
2-Azabarrelenone and 3-Methoxy-2-azabarrelene[**]

By *Rudolf Gompper* and *Axel Schmidt*[*]

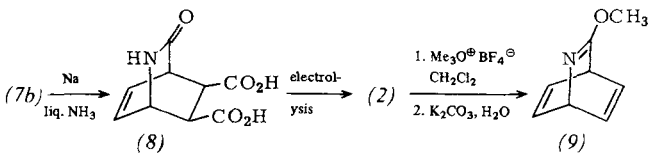


Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Barrelene is to be classed among the antibicycloaromatic compounds[1]. In the case of the anions of the barrelenone *(1)*[2a] and other bicyclo[2.2.2]octenones the antibicycloaromaticity or antihomoaromaticity has its effect on the polarity of the enol systems and hence on the course of methylation in accordance with the allopolarization principle[2b] (*O- vs. C*-methylation). Besides *(1)* and methylenebarrelene[2c], 2-azabarrelenone *(2)* is a further interesting species for the study of homoallylic interactions. Moreover, *(2)* can be used as starting material for the synthesis of the hitherto unknown 2-azabarrelenes (cf. [3]). According to STO-3G calculations, 2-azabarrelene *(3)* and barrelene have similar stabilities[4]; 2-methoxycarbonyl-2-azabicyclo[2.2.2]octa-5,7-diene already decomposes at room temperature[5].

(1) *(2)* *(3)*

C,N-Substituted derivatives of *(2)* have been prepared by reaction of *N*-substituted α-pyridones with dehydrobenzene[6a] or acetylenedicarboxylates[6b]. For the synthesis of *(2)* and *C*-unsubstituted derivatives of *(2)* we have used the 2-aza-3-oxobicyclo[2.2.2]octa-7-ene-5,6-dicarboxylic acids *(7)* as starting compounds; *(7b)* (yield 97%, m.p. 170 °C) (see Table 1) was obtained analogously to *(7a)*[7] from *(4b)* and maleic anhydride *via* the anhydride *(5b)* (yield 31%, m.p. 161 °C (from ethyl acetate)). The electrolytic bisdecarboxylation (cf. [2a,c,8]) of *(7)* affords the 2-azabicyclo[2.2.2]octa-5,7-dien-3-ones *(6)* (see Table 1) in yields of up to 45% (the yields vary owing to the difficulty in accurately reproducing the experimental conditions).



(4) *(5)* *(6)* *(7)*

(a), R = Me
(b), R = $PhCH_2$

The IR carbonyl bands of *(6a)* and *(6b)* (1673 and 1670 cm^{-1}, respectively ($CDCl_3$)) appear at higher wave numbers than is found in the case of the tetrahydro derivatives of *(6)* (1658 (CCl_4) and 1645 cm^{-1} ($CHCl_3$)[9a]); this can be attributed to a relatively large contribution of the polar resonance structure (cf. also 7-azabicyclo[4.2.2]deca-2,4,9-trien-8-one: $\nu_{C=O}$ 1667 cm^{-1}[9b]). Also in agreement with this assumption is the position of the N—CH_3 signal at $\delta = 2.83$ in the ^{1}H-NMR spectrum of *(6a)*; for comparison: the N—CH_3 signals of 1-methyl-4-(*p*-methoxyphenyl)-2-azabicyclo-[2.2.2]octane and 1-methyl-2-azabicyclo[2.2.2]octan-6-ol appear at $\delta = 3.02$[9c] and 3.06[9d], respectively.

The benzyl group of *(7b)* can be cleaved with sodium in liquid ammonia to give the dicarboxylic acid *(8)* (yield 88%, m.p. 176 °C, from water) (see Table 1). Electrolysis of *(8)* affords the desired 2-azabicyclo[2.2.2]octa-5,7-dien-3-one (2-azabarrelenone) *(2)* in moderate yield (6—8%, colorless fine crystals, m.p. 151 °C (sublimation at 80 °C/0.01 mbar)) (see Table 1)—the reaction solution was evaporated down in a vacuum, the brown-red semi-solid residue digested several times with ethyl acetate, the resulting solution evaporated in a vacuum and the residue chromatographed with chloroform/ethyl acetate (1:1) on silica gel; the middle fraction gave, after removal of the solvent by distillation, colorless crystals in a yellowish oil, which could be removed with CCl_4 (see Table 1).

(7b) *(8)* *(2)* *(9)*

Table 1. Some physical data of the compounds *(2)*, *(6a)*, *(6b)*, *(7b)*, *(8)*, and *(9)*.

(2): IR ($CHCl_3$): 3445, 2993, 1685 (C=O), 1623 cm^{-1} (C=C); ^{1}H-NMR ($CDCl_3$): $\delta = 4.10$—4.60 (m; 1H, H-4), 4.83—5.32 (m; 1H, H-1), 6.63—7.22 (m; 4H, H-5, 6, 7, 8), 7.47—8.75 (m; 1H, NH); ^{13}C-NMR ($CDCl_3$): $\delta = 177.19$ (C-3), 137.12 and 136.72 (C-5, 6, 7, 8), 54.31 (C-4), 52.82 (C-1); MS (70 eV, 100 °C): $m/e = 121$ (1%, M^+), 78 (100%, M − HNCO), 43 (18%, $M - C_6H_6$))

(6a): colorless leaflets, m.p. 58 °C (from ether/pentane), b.p. 100 °C/0.1 mbar (bulb tube); IR (KBr): 1650, 1582 cm^{-1}; IR ($CDCl_3$): 1673 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta = 2.83$ (s; 3H, CH_3), 4.36 (mc; 1H, H-4), 4.83 (mc; 1H, H-1), 6.83 (mc; 4H, H-5, 6, 7, 8); ^{13}C-NMR ($CDCl_3$): $\delta = 172.89$ (C-3), 136.53 and 135.42 (C-5, 6, 7, 8), 59.83 (C-4), 54.22 (C-1), 33.33 (CH_3)

(6b): colorless, broad needles, m.p. 56 °C (from ether/pentane), b.p. 150 °C/0.1 mbar (bulb tube); IR (KBr): 1675, 1658 cm^{-1}; IR ($CDCl_3$): 1670 cm^{-1} (C=O)

(7b) IR (KBr): 1730, 1625 cm^{-1}; ^{1}H-NMR ([D_6]DMSO): $\delta = 3.26$ (mc; 2H, H-5, 6), 3.60 (mc; 1H, H-4), 4.0—4.8 (m; 3H (H-1, CH_2), 6.46 (mc; 2H, H-7, 8), 7.33 (mc; 5H, aromatic-H, 12.26 (mc; 2H, CO_2H)

(8): ^{1}H-NMR ([D_6]DMSO): $\delta = 3.26$ (m; 3H, H-4, 5, 6), 4.30 (mc; 1H, H-1), 6.40 (mc; 2H, H-7, 8), 8.13 (mc; 1H, NH), 10.26 (mc; 2H, CO_2H)

(9): IR (film): 1656, 1625 cm^{-1}; IR ($CHCl_3$): 1647 (C=N), 1615 cm^{-1} (C=C); ^{1}H-NMR ($CDCl_3$): $\delta = 3.62$ (s; 3H, OCH_3), 4.33—4.73 (m; 1H, H-4), 5.53—5.90 (m; 1H, H-1), 6.43—6.97 (m; 4H, H-5, 6, 7, 8); ^{13}C-NMR ($CDCl_3$): $\delta = 181.61$ (C-3), 140.57 and 134.88 (C-5, 6, 7, 8), 63.46 (C-4), 55.40 (OCH_3), 49.95 (C-1); MS (70 eV): $m/e = 135$ (48%, M^+), 134 (81%, M − H), 105 (71%, $M - CH_2O$), 104 (67%, $M - CH_3O$), 78 (100%, $M - CH_3OCN$), 57 (14%, $M - C_6H_6$))

The conversion of *(2)* into 3-methoxy-2-azabicyclo-[2.2.2]octa-2,5,7-triene (3-methoxy-2-azabarrelene) *(9)* (yield 75%, colorless oil with a pleasant eucalyptus-like aromatic odor, b.p. 80 °C/0.01 mbar) (see Table 1) was achieved by reaction with trimethyloxonium tetrafluoroborate according to known methods (cf.[9b]). *(9)* slowly decomposes at room temperature; however, the decomposition is minimal during distillation (80 °C). *(9)* is thermally less stable than *(6a)*; this can be ascribed to an antiaromatic effect.

Brominations with *N*-Bromosuccinimide: Solvent and Selectivity[**]

By *Werner Offermann* and *Fritz Vögtle*[*]

We have found that brominations with *N*-bromosuccinimide (NBS) lead all the more selectively to the benzyl bromide derivative the lower the refractive index of the solvent. Since the reactivity-selectivity principle[2] would appear valid one can select a solvent as reactive as necessary and as selective as possible. In the traditional solvent tetrachloromethane[3] the selectivity is very low. Very "selective solvents" such as methyl formate direct bromine into the ring of electron-rich arenes; this can be exploited preparatively for the bromination of benzo[15]crown-5.

By ^{1}H-NMR integrative evaluation of competitive experiments[1] we have determined the selectivity κ for NBS bromination in eleven solvents (Table 1).

$$\kappa = k_1/k_2 \quad (1)$$

$$\text{Aryl-CH}_3 \xrightarrow{k_1} \text{Aryl-CH}_2\text{Br} \xrightarrow{k_2} \text{Aryl-CHBr}_2 \quad (2)$$

Model substrates were *p-tert*-butyltoluene, 4-methylbiphenyl (*p*-phenyltoluene), and *p*-nitrotoluene; the solvents were chosen on the basis of two criteria: dielectric constant less than 10, so as to avoid ring bromination, availability from the standpoint of preparative use.

The selectivities κ determined at the boiling points were corrected[4] *via* the isoselective temperature[2] to 20 °C. From these values and the σ^+ constants of the toluene substituents (NO_2, Ph, *t*Bu) the following structure-selectivity (σ^+/κ) relationships (3) to (9) (valid at 20 °C) could be estimated.

methyl formate:	$\log\kappa = 1.57 - 0.47\,\sigma^+$	(3)
methyl acetate:	$\log\kappa = 1.52 - 0.48\,\sigma^+$	(4)
dichloromethane:	$\log\kappa = 1.41 - 0.57\,\sigma^+$	(5)
trichloromethane:	$\log\kappa = 1.38 - 0.62\,\sigma^+$	(6)
tetrachloromethane[1]:	$\log\kappa = 1.09 - 0.62\,\sigma^+$	(7)
benzene:	$\log\kappa = 1.38 - 0.69\,\sigma^+$	(8)
carbon disulfide:	$\log\kappa = 1.04 - 0.71\,\sigma^+$	(9)

Table 1. Selectivity κ and maximum yield Y_{max} for NBS bromination of three substrated toluenes in eleven solvents; at the boiling points (above), and corrected to 20 °C (below).

[**] NBS bromination selectivity Part 6. This work was supported by the Fonds der Chemischen Industrie. We thank Dipl.-Chem. *B. Jansen* for carrying out the experiments with benzo[15]crown-5. Part 5: [1].

E_T[5e] and δ[5f,6] the refractive index n and its functions yield the best correlations, saving the tetrachloromethane values. With $(1-1/n^2)$, the solvent-dependent term of an energy parameter[5c], one obtains the relationships (10) to (12) (valid at 20 °C):

p-tert-butyltoluene:	$\log\kappa = 0.315 + 2.50/n^2 \; (r^2 = 0.76)$	(10)
4-methylbiphenyl:	$\log\kappa = 0.392 + 2.32/n^2 \; (r^2 = 0.94)$	(11)
p-nitrotoluene:	$\log\kappa = -0.972 + 3.93/n^2 \; (r^2 = 0.98)$	(12)

Figure 1 illustrates the exceptional behavior of tetrachloromethane. Though the selectivity in specially purified tetrachloromethane (Table 1) is higher, even these values do not fit into the relations *(10)* to *(12)*.

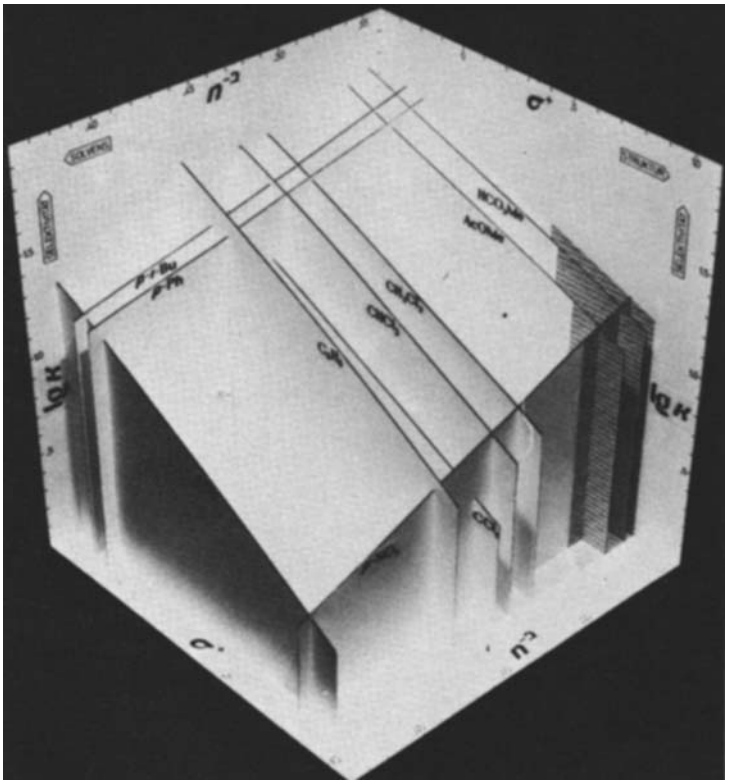

Fig. 1. Influence of solvent and substrate on the selectivity (at 20 °C).

Thus, the most promising solvents for NBS brominations would appear to be methyl formate and dichloromethane, which combine two properties promoting selectivity: low refractive index and low reaction temperature[4]. In certain cases the yields can be doubled with these solvents[7]. In methyl formate very weakly reactive substrates are no longer converted to the predicted extent Y_{max}[1], even by an excess of NBS (Fig. 1). On increasing the refractive index stepwise the solvent is adapted to inert substrates. The "ideal" solvent just meets the "reactivity requirements" of the substrate. This accommodation is all the more important since unreactive substrates obeying the inverse reactivity-selectivity principle also react unselectively[1].

Table 2. Ring bromination of benzo[15]crown-5 by NBS at the boiling points.

Solvent	Catalyst [mol $AlCl_3$/mol educt]	Yield [%]
CCl_4	—	57 [8]
CCl_4	1	85
HCO_2Me	—	80
HCO_2Me	1	63
HCO_2Me	2	59

In NBS brominations of electron rich substrates "selective" media promote formation of ring-brominated products. Thus the ring bromination of benzo[15]crown-5[8] can be improved (Table 2).

In bromine solvate complex, methyl formate acts like a Lewis acid on bromine. This type of solvation also increases the selectivity in radical reactions. In contrast, in chlorinations the selectivity increases in basic medium[9].

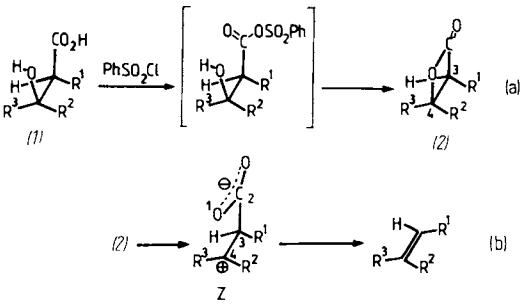
Thermal Decarboxylation of β-Lactones: Steric Hindrance of Mesomerism as Indication of a Zwitterionic Intermediate

By *Johann Mulzer, Matthias Zippel*, and *Gisela Brüntrup*[*]



Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The thermal decarboxylation of β-lactones (2-oxetanones) has repeatedly been employed in the stereospecific synthesis of olefins[1]. The reaction belongs to the rare type of [2+2]-cycloreversions proceeding with retention of configuration and is thus of special interest from the mechanistic viewpoint[2]. It was unclear so far whether the reaction proceeds in a concerted manner or *via* an intermediate (Z). We report here on kinetic experiments giving clear evidence for the participation of Z.

The β-lactones *(2)* (see Table 1) were prepared in a conventional way[1d,e,h] from the 3-hydroxycarboxylic acids *(1)* [eq. (a)]; remarkably, the *threo* acids always gave the *trans*-lactone, the *erythro* acids the *cis*-lactone.

The kinetics of the decarboxylation of *(2)* was monitored by ^{1}H-NMR spectroscopy. Particularly informative from the mechanistic point of view is the comparison of the rate constants of analogously substituted *cis*- and *trans*-β-lactone isomers (Table 1). For a concerted process one would expect *k (cis)* to be greater than *k (trans)* since the substituents move

contrast, fully benefits from the anisyl resonance stabilization. Hence Q is especially large.

That, despite the acyclic intermediate Z, the decarboxylation proceeds with retention of configuration is astonishing, but easily explainable. Z can be regarded as a heterotetramethylene; therefore we may expect in Z similarly high rotation barriers as those which have been calculated[4] and experimentally confirmed[5] for 1,4-butanediyls, the parent all-carbon systems.

Table 1. Reaction rate constants for the thermal decarboxylation of *(2)* in 1,2-dichlorobenzene [a].

Lactone	R^1	R^2	R^3	Config.	$k \times 10^5$ [s^{-1}] (bei [°C])	$Q = k$ *(trans-2)*/ k *(cis-2)* [b]
(2a)	*t*-Bu	Ph	H	*cis*	1.14 (140.0)	250
(2b)	*t*-Bu	H	Ph	*trans*	4.36 (100.0)	
(2c)	Ph	*t*-Bu	H	*cis*	1.42 (140.0)	2.7
(2d)	Ph	H	*t*-Bu	*trans*	3.76 (140.0)	
(2e)	CH_3	Ph	H	*cis*	68.6 (140.0)	26
(2f)	CH_3	H	Ph	*trans*	32.5 (100.0)	
(2g)	*t*-Bu	2,6-$Cl_2C_6H_3$	H	*cis*	0.391 (175.0)	390
(2h)	*t*-Bu	H	2,6-$Cl_2C_6H_3$	*trans*	3.40 (140.0)	
(2i)	*t*-Bu	4-$CH_3OC_6H_4$	H	*cis*	9.80 (100.0)	1100
(2j)	*t*-Bu	H	4-$CH_3OC_6H_4$	*trans*	37.3 (50.0)	

[a] All β-lactones *(2)* (yield 82—93%) were characterized spectroscopically and by elemental analysis. As examples the IR and ^{1}H-NMR data ($CDCl_3$, TMS, 60 MHz) of *(2a—d)* are given: *(2a)*: m.p. 88—89 °C; IR (KBr): 1810 (C=O), 1130 (C—O) cm^{-1}; ^{1}H-NMR: $\delta = 0.85$ (s, 9H, *t*Bu), 3.90 (d, $J = 6.5$ Hz, 1H, C*H*—*t*Bu), 5.70 (d, $J = 6.5$ Hz, 1H, C*H*—O), 7.42 (s, 5H, phenyl-H); *(2b)*: m.p. 38—39 °C; IR (KBr): 1835 (C=O), 1115 (C—O) cm^{-1}; ^{1}H-NMR: $\delta = 1.13$ (s, 9H, *t*Bu), 3.38 (d, $J = 4$ Hz, 1H, C*H*tBu), 5.35 (d, $J = 4$ Hz, 1H, C*H*—O), 7.42 (s, 5H, phenyl-H); *(2c)*: m.p. 86.5—87 °C; IR (KBr): 1810 (C=O), 1110 (C—O) cm^{-1}; ^{1}H-NMR: $\delta = 0.80$ (s, 9H, *t*Bu), AB-system ($\delta_A = 4.33$, $\delta_B = 4.96$, $J = 7$ Hz), 7.18 (s, 5H, phenyl-H); *(2d)*: m.p. 39.0—39.5 °C; IR (neat): 1820 (C=O), 1120 (C—O) cm^{-1}; ^{1}H-NMR: $\delta = 1.05$ (s, 9H, *t*Bu), AB-system ($\delta_A = 4.25$, $\delta_B = 4.52$, $J_{AB} = 4$ Hz), 7.30 (s, 5H, phenyl-H). [b] For comparison of the *cis-trans* reactivities at different temperatures the k (*cis*-2) value was in each case extrapolated with the aid of the activation parameters to the lower temperature of the k (*trans*-2) value.

apart from one another on going from the β-lactone to the olefin and, thus, the strain relief in the *cis* compound should be greater than in the *trans* isomer. However, as shown in Table 1, the *trans*-lactone generally decarboxylates far more quickly. This is consistent not with a synchronous mechanism, but rather with a reaction *via* Z [eq. (b)].

A decisive factor is the stabilization of the unsaturated center at C-4 of Z. In *(2b)* the 4-phenyl group can rotate in the plane of the resulting sp^2 carbon atom. In *(2a)* it cannot, because it is forced into a twisted conformation by the bulky 3-*tert*-butyl substituent. The result is a rate quotient (Q) (k *(2b)*/k *(2a)*) of 250! On the other hand, in the case of *(2c)*/*(2d)*, where only a weakly stabilizing *tert*-butyl group is present at C-4, Q is *ca.* 10^2 smaller. Similarly, a comparison of the rate constants of the four isomers *(2a)—(2d)* also clearly indicates the participation of Z: *(2b)*, whose Z has by far the most effective C-4 stabilization, decomposes 100 to 350 times more rapidly than *(2a)*, *(2c)* and *(2d)*, which differ only slightly in their reactivity.

A high value for Q in the thermolysis of *cis-trans* isomeric lactones is thus inevitably connected with the presence of a highly twisted 4-aryl group in Z. This is again confirmed by the pairs *(2e)*/*(2f)* ($R^1 = CH_3$, therefore only slight twisting) and *(2g)*/*(2h)* (bulky groups at C-3 and C-4), therefore strong twisting): compared to the pair *(2a)*/*(2b)*, Q decreases by a factor of 10 and increases by a factor of 1.6, respectively.

Is Z a zwitterion or a diradical? A Hammett diagram for the aryl analogues of *(2b)* clearly answers this question in favor of the zwitterion (*p*-substituents: NO_2, CN, Cl, CH_3OCH_3, σ^+ correlation[3], $\rho = -3.4$ with $r = 0.992$). The last pair *(2i)*/*(2j)* in Table 1 may be seen as a summary of the results we have presented so far: in *(2i)* the aryl group of Z is twisted; the carbenium center at C-4 profits very little from the +M effect of the *p*-CH_3O substituent. The Z of *(2i)*, by

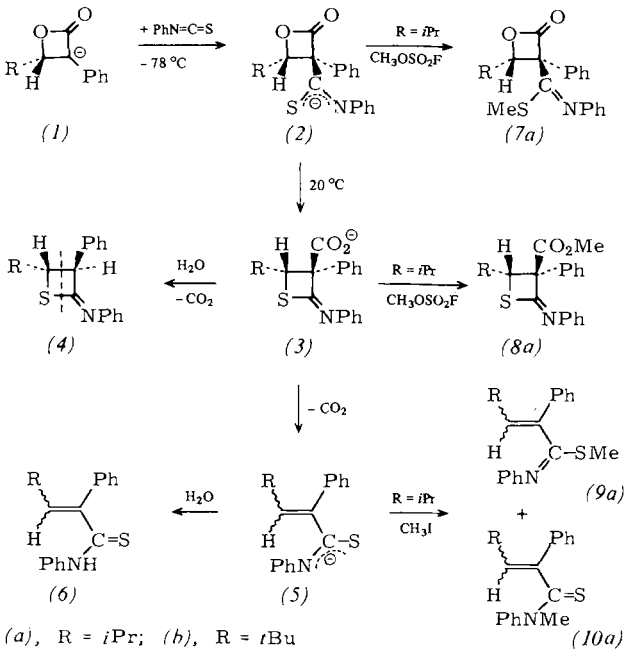
2-Thietanimines from α-Deprotonated β-Lactones and Phenyl Isothiocyanate—A Novel Four-Membered Ring/Four-Membered Ring Recyclization

By *Johann Mulzer* and *Thomas Kerkmann*[*]



Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

2-Thietanimines are a rare class of substances for which only two examples have so far been described[1]. We have

[*] Dr. J. Mulzer, T. Kerkmann
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0606-466 $ 02.50/0

now found a novel entry to this class of compounds. If β-lactones (2-oxetanones) are deprotonated with lithium diisopropylamide (LDA) and the resulting anion *(1)*[2] is allowed to react with phenyl isothiocyanate one obtains after hydrolysis the *N*-phenylthietanimine *(4)*[3] and the thioamide *(6)*, which can be separated by TLC. Thus, in the overall reaction CO_2 is exchanged for PhNCS. In the case of the isopropyl derivatives, the anionic intermediates *(2)*, *(3)* and *(5)* can be trapped by methylation.

to the isopropyl group; hence, 3,3,4-trisubstituted compounds *(4)* can also be prepared in sterically pure form, *e.g. c*-4-isopropyl-3-methyl-*r*-3-phenyl-2-thietan-*N*-phenylimine.

When heated to 120 °C *(4a)* completely rearranges to *(6a)*; in contrast to β-lactones, *(4)* does not yield an olefin on thermolysis.

Procedure

4-Isopropyl-3-phenyl-2-oxetanone (500 mg, 2.63 mmol) is deprotonated in anhydrous THF (2 ml) at −78 °C with 2.63 mmol of LDA. After 10 min the solution is treated with 2.63 mmol of phenyl isothiocyanate, allowed to warm up for 30 min and, after addition of water, extracted with ether. The crude product mixture consists of *(4a)* and *(6a)* (70:30) and is separated by TLC on silica gel with pentane/ether (95:5); yield 305 mg (41%) *(4a)* and 270 mg (36%) *(6a)*. Analogously 405 mg (52%) *(4b)* and 310 mg (40%) *(6b)* were obtained from the appropriate educts.

Trapping experiments: (2a): Immediately after addition of the phenyl isothiocyanate the mixture is treated at −78 °C with 1.25 mol. equiv. of methyl fluorosulfate; yield after workup with H_2O/Et_2O, 185 mg (21%) *(7a).—(3a):* After addition of the phenyl isothiocyanate the mixture is allowed to warm up for 10 min and is then treated with 1.25 mol. equiv. of methyl fluorosulfate; hydrolytic workup yields 280 mg (32%) *(8a).—(5a):* The same procedure is used as in the preparation of *(4a)/(6a)* except that methyl iodide is added in the molar ratio 1:8. Usual workup affords 880 mg (56%) of a mixture of *(9a)* and *(10a)* (63:37).

The key step of this remarkable synthesis is the four-membered ring recyclization *(2)*→*(3)*, which proceeds—as the structure of the trapping product shows[4]—with inversion at C-4, at least in the case of the isopropyl derivatives. Equally surprising is the ring opening *(3)*→*(5)*, which corresponds to a fragmentation.

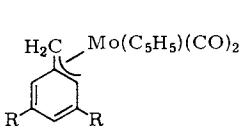
(4a) can be smoothly deprotonated with LDA at −78 °C in tetrahydrofuran, and reacted with methyl iodide; as in the reaction *(1)*→*(2)*, the electrophile attacks at the position *trans*

[1] *V. Bertolasi, G. Gilli*, Acta Crystallogr. *B 34*, 3403 (1978); *A. Dondoni, A. Battaglia, P. Giorgianni, G. Gilli, M. Sacerdoti*, J. Chem. Soc. Chem. Commun. *1977*, 43.

[2] *J. Mulzer, Th. Kerkmann*, J. Am. Chem. Soc., in press.

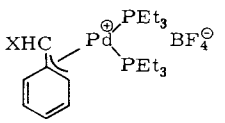
[3] The *trans* configuration of *(4a)* and *(4b)* follows from the ^{1}H-NMR coupling constant $J_{3,4}$ = 4.5 Hz; the same value was found in the case of *trans*-3,4-di-

substituted β-lactones. That compounds *(4)* are thietanimines and not the isomeric β-thiolactams [attack at nitrogen in the reaction step *(2)*→*(3)*] follows from the mass spectra of *(4)*. The indicated fragmentation leads to a signal $m/e = 193$ (Ph—CH=C=NPh); no signals appears at $m/e = 134$ (Ph—CH=C=S). The IR band at *ca.* 1660 cm^{-1} is also characteristic (cf. [1]).



[4] Assignment of the configuration of *(7a)* and *(8a)* is supported by the anisotropy of the isopropyl-CH_3 in the ^{1}H-NMR spectrum (cf. Table 1); this would indicate a vicinal phenyl group *cis* to the isopropyl group. In *(4a)* these groups are *trans*; no anisotropy is observed.

(1,2,5,6-η-1,5-Cyclooctadiene)-(1,2,7-η-7-methylbenzyl)(7,8-η-styrene)rhodium(I)—Antarafacial Fluctuation of the Benzyl Ligand and Temperature-Dependent Coordination of Styrene



By *Hans-Otto Stühler*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

Fluctuating η^3-benzyl ligands represent an unusual type of coordination in transition metal compounds. Since the discovery of this type of bonding in (η^3-benzyl)(η^5-cyclopentadienyl)dicarbonylmolybdenum[1], NMR spectroscopic investigations on complexes *(1)* and *(2)*, for example, have shown that the fluctuation of the benzyl ligand proceeds through all four positions (side and edge combinations) α-δ (Fig. 1)[2,3], thus requiring both supra- and antarafacial rearrangements.

(1)

(2), X = H
(2a), X = D

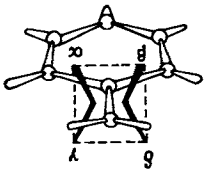


Fig. 1. Positions of possible coordination to η^3-benzyl ligands.

On the NMR time-scale this leads to equivalence, both of the two benzyl protons as well as of the *ortho* protons of the benzyl ligand. At low temperature the metal atom can be fixed in one of the four positions. In the case of *(2a)* it was shown[3] that the fluctuation of the benzyl ligand is to be understood in the sense of the known η^3,η^1,η^3-allyl rearrangement[4].

We have now synthesized and investigated the rhodium compound *(3)* (see Procedure). The ^{1}H-NMR spectroscopic findings indicate that a temperature-dependent equilibrium exists between *(3a)*, *(3b)*, and *(3c)* in solution, and that the benzyl ligand fluctuates above −40 °C (Fig. 2).

At room temperature the ^{1}H-NMR spectrum ([D_{10}]diethyl ether) shows the signals of free styrene. On cooling, the signals of the vinylic protons are strongly shifted upfield until at −50 °C they overlap the signals of the olefinic protons of the coordinated cyclooctadiene at $\delta \approx 3.90$, *i.e.* coordination of the styrene *via* the exocyclic double bond increases with decreasing temperature. The η^3-bonded part of the benzyl ligand gives rise to three signals at room temperature: a sharp

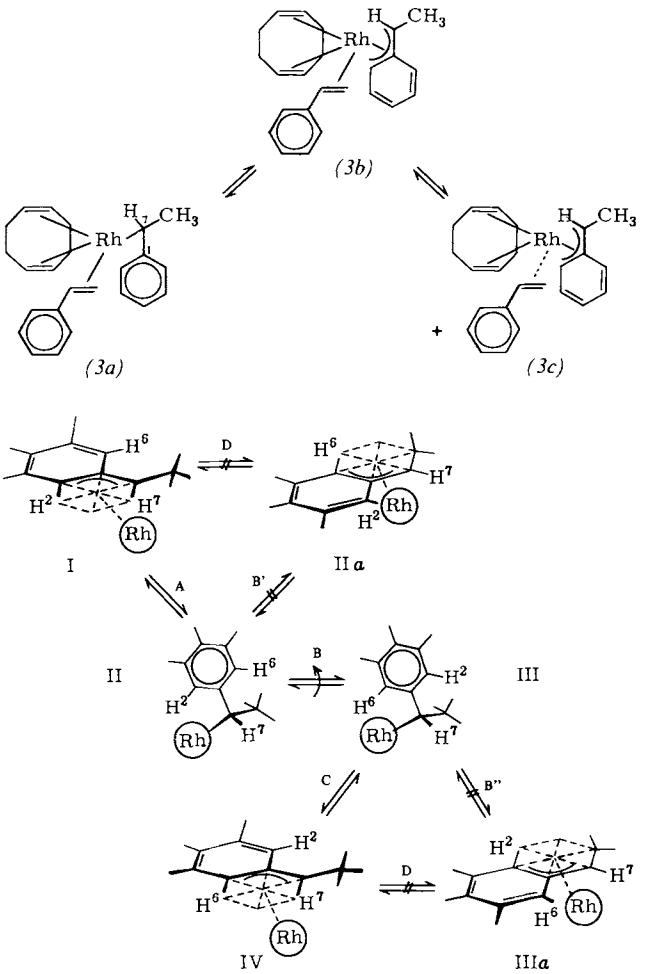

Fig. 2. Mechanism of fluctuation of the η^3-7-methylbenzyl ligand.

doublet of a *syn*-methyl group[5] at δ = 1.50, the quartet of an *anti* proton at δ = 2.20, and a broad signal (δ = 5.80) of the two *ortho* protons. On warming to +50 °C this signal becomes sharper; on cooling it broadens and almost disappears into the background at −30 °C. At the same time, it is shifted downfield; the signals of the methyl group and of the *anti* proton H^7 are correspondingly shifted upfield. Both signals, however, remain sharp from +50 to −70 °C; despite the rapid rearrangement of the benzyl ligand, which leads to equivalence of the two *ortho* protons, the *steric environment at the benzyl carbon does not alter.* This requires existence in the transition state[3] of the short-lived σ-alkyl compound II, from which IV is formed after rotation about the C^1—C^7 axis through 180° (to III) (reaction sequence A, B, C in Fig. 2). The overall reaction is an antarafacial rearrangement, *i.e.* the two *ortho* protons H^2 and H^6 change places relative to the substituent on C-7.

An antarafacial rearrangement by rotation of the η^3-benzyl group through 180°, on the other hand, would give the enantiomorphic form of I, but would not lead to exchange of the *ortho* protons H^2 and H^6. Suprafacial shifts[6] (reaction paths A,B′; C,B″; D = [1,5]-shift) lead to the *anti*-isomers IIa and IIIa, which however are not observed. The steric reasons for this may be the same as those which led exclusively to formation of the *syn*-isomers in the complexes (diene)Rh(subst. allyl)[5].

At low temperature the fluctuation comes to a standstill. At −40 °C two broad signals of the non-equivalent *ortho* protons are observed at δ = 7.0 and 6.2; the first of these sig-

[*] Dr. H.-O. Stühler

der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

nals disappears under the signals of the aromatic protons at $-50\,^{\circ}C$, the last only at *ca.* $-100\,^{\circ}C$. This can be interpreted in the sense of a successive transition from *(3b)* to *(3a)*. The presence of the η^1-bonded benzyl ligand in the low-temperature form *(3a)* can be regarded as a further indication that the fluctuation of the η^3-benzyl ligand takes place at higher temperature *via* this σ-form. The signals of the rigid cyclooctadiene ligand also show temperature-dependent changes.—*(3a)* and *(3c)* formally contain 16 valence electrons. In the case of complexes of the type (diene)Rh(allyl) several such systems are known[5, 7].

A selective antarafacial rearrangement of an η^3-benzyl ligand has to our knowledge hitherto not been reported. This rearrangement at the same time proves that an η^1-bonded benzyl moiety must be present in its transition state.

Procedure

All operations must be carried out under an inert gas. A solution of styrene (3 ml) in ether (10 ml) is added to a solution of di-μ-chlorobis(1,5-cyclooctadiene)dirhodium[8] (0.98 g, 2 mmol) in ether (20 ml) at $-78\,^{\circ}C$ and the stirred mixture treated with a Grignard solution prepared from 0.19 g (8 mmol) Mg and 1 ml i-C_3H_7Br. The mixture is allowed to warm within 3 h to $0\,^{\circ}C$ and the solvent and excess ligand are then removed in a high vacuum. After elution with 200 ml of pentane and filtration on Al_2O_3 (7% H_2O) (frit and receiver cooled to $-78\,^{\circ}C$), analytically pure orange-red *(3)* crystallizes at $-78\,^{\circ}C$; yield 1.498 g (3.75 mmol; 89%), m.p. $-9\,^{\circ}C$.

[**] Liquid Chromatography on Triacetylcellulose, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie. The samples of (±)-*(1)* and (−)-*(1)* were provided by Professor Dr. *K. H. Büchel* and Dr. *G. Jäger*, Bayer AG, Leverkusen, who have also kindly checked the manuscript. We are grateful to Dr. *M. Holík* and Dipl.-Phys. *R. Küspert*, Regensburg, for helpful suggestions.—Part 1: [1a]. Part 2: [1b].

As far as the measurement of P by chromatography is concerned, conversion of the enantiomers to diastereoisomers by a reagent and subsequent analysis on an *achiral* sorbent represent an established procedure. It relies on the absence of racemization and on a knowledge of P of the reagent[2]. Chromatography on an *optically active* stationary phase does not need a standard for P and is therefore one of the few *absolute*[2] methods. In this respect, gas chromatography has advanced considerably, *i.e.* baseline separations of enantiomers have been achieved in many cases. The areas under their peaks permit the direct calculation of P. Gas chromatography usually requires elevated temperatures, whereas liquid chromatography (LC) can be performed at room temperature, thus reducing the rates of possible decompositions or racemizations. However, this technique has not been widely used for P determinations, mainly because enantiomers frequently give overlapped or even fused peaks[1a, 3]. Therefore, a method applicable *in spite of peak overlap or fusion* (Fig. 1a), would clearly extend the analytical possibilities.

$$P = \frac{\varepsilon b \int \alpha \, dv}{[\alpha] l \int A \, dv} = \frac{\int \alpha \, dv}{C_+ \int A \, dv} \qquad (1)$$

In eq. (1)[4] v is the actual eluate volume, $\alpha(v)$ the angle of rotation and $A(v)$ the absorbance (see *e.g.* Fig. 1). The factor[4] $C_+ = \alpha_+ / A_+$ relates the rotation angle and absorbance of the predominant, dextrorotatory enantiomer. If this enantiomer appears at higher v, the eluate *cannot contain a relevant amount of the less abundant enantiomer* in the Δv region of Fig. 1. Therefore, in this region, α equals α_+ and A equals

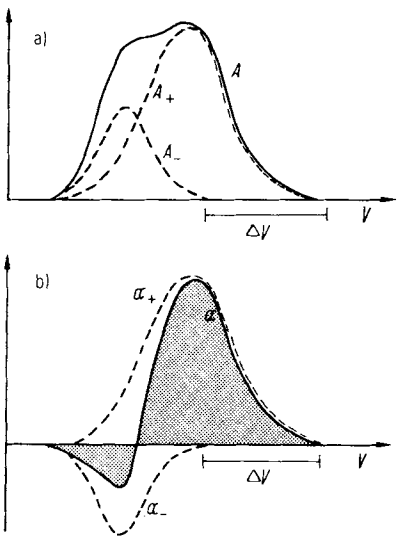

Fig. 1. Schematic chromatograms a) $A(v)$ and b) $\alpha(v)$ for a mixture of enantiomers (+ prevailing) after passage through an optically active sorbent. v: Actual volume of eluate. Δv: Region of v, where the eluate does not contain a relevant amount of the less abundant enantiomer. A: Absorbance of eluate. A_+ and A_-: Absorbances of the enantiomers ($A_+ + A_- = A$). α: Rotation angle of eluate. α_+ and α_-: Rotation angles of the enantiomers ($\alpha_+ + \alpha_- = \alpha$). The derivation [4] of eq. (1) does not depend upon the particular shapes (e.g. symmetry) of the component peaks (-----) chosen for demonstration.

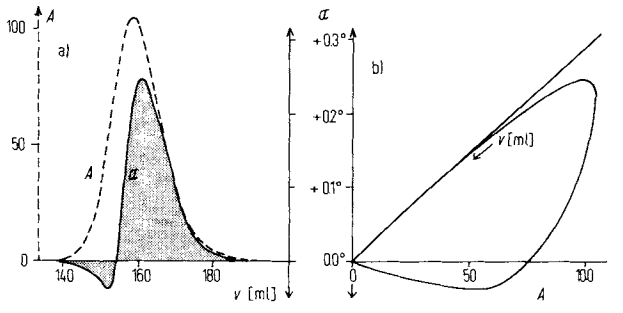
A_+, *i.e.* $\alpha_+ / A_+ = C_+$ can be measured from a plot of α *versus* A (cf. Fig. 2b) by determining its slope at high volumes. $\int \alpha \, dv$, consisting of a positive and a negative area, and $\int A \, dv$ are also accessible, *e.g.* by the cut-and-weigh procedure, from the same experiment. In a preliminary test, LC (Fig. 2) of (+)-1-phenylethanol ($P = 52\%$, calculated from the specific rotation) resulted in $P = 54\%$ *via* eq. (1).



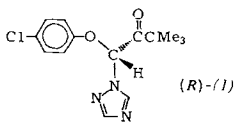


Fig. 2. a) Chromatograms $A(v)$ and $\alpha(v)$ and b) diagram $\alpha(A)$ of (+)-1-phenylethanol ($P = 52\%$) in ethanol/H_2O (96:4) after passage (flow rate 3.1 ml/min) through a column of triacetylcellulose. v: Actual volume of eluate; injection at $v = 0$. A: Absorbance at 254 nm, measured in "units" *i.e.* mV; α: Rotation angle at 365 nm. The straight line in b) has a slope of $C_+ = 0.0031°$/unit. We have used microcrystalline, swollen triacetylcellulose [1, 3b, 5] (particle sizes 0.03 to 0.06 mm, column 30 cm × 2.5 cm). Further details are: Eluent ethanol/water (96:4); temperature 22 °C; pressure ~11 bar; flow rate 2.1 ml/min, except for Fig. 2. The eluate was passed through one compartment (path length 2.0 mm, volume 0.08 ml) of the photometer double-cell, then through the polarimeter cell (path length 100 mm, volume 1 ml), and back through the photometer, in order to simulate the simultaneity of the detections which seems to be important for the measurement of C_+ (or C_-). A x-y recorder was used for the diagrams $\alpha(A)$, a two-pen recorder for $A(v)$ and $\alpha(v)$.

Our procedure was checked by 25 mg samples[6] of (−)-*(1)* (Table 1), the P-values of which were known (for experimental details see legend of Fig. 2; flow rate 2.1 ml/min). The 67.6% sample gave recordings very similar to Figure 2. For all measurements, $C_- = 0.0045$ to $0.0051°$/unit in the linear $\alpha(A)$ region. The agreement (Table 1) between the initial P-values and the ones obtained *via* eq. (1) is satisfactory. The determination of errors must be deferred until more results are available.

Further support for our method is derived from samples of (+)- and (−)-1,2-diphenylcyclopropane, separated[5] by LC on triacetylcellulose. Application of eq. (1) yields $P = 86\%$ and 100%, respectively. As the overlap of the (+)- and (−)-peaks is weak, the areas under the $\alpha(v)$ curve must represent good approximations for the relative concentrations. As expected, the results $P = 84\%$ and 100% are close to the above findings[5].

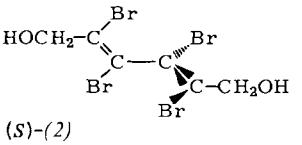

Table 1. Enantiomeric purity P of (−)-*(1)* samples.

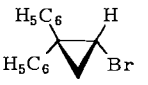
	P [%] [a]	P [%] [b]
 (*R*)-*(1)*	4.9	6
	10.1	10
	48.9	49
	67.6	68
	88.3	87



[a] Weighed amounts of (±)-*(1)*, Triadimefon (Bayleton®, Bayer AG), and of a sample of (−)-*(1)* were mixed. For the latter, $P = 99.8\%$ had been measured using calorimetry [7] by Dr. *H. Doerr*, Bayer AG, Leverkusen. The error of the above initial P-values is estimated to amount to ±0.2%. [b] For these mixtures, P was determined *via* eq. (1) (see text).

As a first application we have analyzed a sample of (−)-*(2)*, obtained by LC on triacetylcellulose ($[\alpha]_{589}^{20} = -29°$, 2.48 mg/ml, acetone; m.p. 99—100 °C), in order to obtain the hitherto unknown specific rotation of the pure enantiomer. Similarly to Figure 2 and to the diagrams of (−)-*(1)*, the $A(v)$ curve showed no sign of a splitting, *i.e.* the peaks of (+)- and (−)-*(2)* were fused. Application of eq. (1), using a 35 mg sample[6], resulted in $P = 29\%$, which means $[\alpha]_{589}^{20} = -100°$ for pure (−)-*(2)*. From this figure, the unknown P of an earlier preparation[8] of (−)-*(2)* *via* crystallization of diastereoisomers has now been calculated to 14%.

As application of our method to an enantioselective synthesis, we investigated 6 mg[6] (−)-*(3)* ($[\alpha]_{365}^{31} = -584°$, 1.07 mg/ml, ethanol), which were likewise obtained by LC on triacetylcellulose. We found $P = 71\%$, *i.e.* $[\alpha]_{365}^{31} = -826°$ for pure (−)-(*R*)-*(3)*, from which the unknown optical yields of (+)- and (−)-*(3)* samples[9] obtained cathodically (in presence of alkaloids) can be calculated.

(*S*)-*(2)*

(*R*)-*(3)*

The present determination of P depends neither upon the symmetry of each peak nor upon equal widths of the peaks. It does, however, depend upon *some* separation by the sorbent (generating an $\alpha(v)$ detection), though a separation yielding a *split* $A(v)$ chromatogram is not needed. Our method may be improved by avoiding manual area determination. Finally, eq. (7)[4] suggests the calculation of $[\alpha]$, the specific rotation of a pure enantiomer, from the measurement of C_+ (or C_-) by using *exclusively* the racemate. A preliminary trial showed that this suggestion is realistic.

[4] If a mixture contains n_+ and n_- moles of the enantiomers ($n_+ > n_-$), P is given [2] by

$$P \equiv (n_+ - n_-)/(n_+ + n_-) = \int (c_+ - c_-)\,dv / \int (c_+ + c_-)\,dv \qquad (2)$$

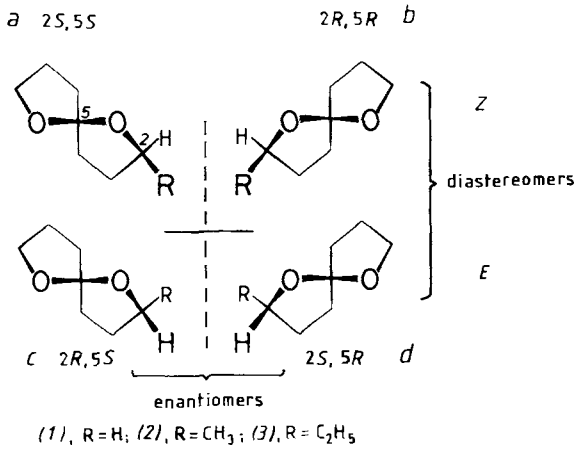
where n_+ and n_- have been replaced by $\int c_+\,dv$ and $\int c_-\,dv$, respectively, *i.e.* the injected n_+ moles are distributed (actual concentration c_+) in the eluate volume v. The absorbances A_+ and A_- (Fig. 1a) are expressed by Beer's law, the rotation angles α_+ and α_- (Fig. 1b) by Biot's law:

$$\varepsilon b c_+ = A_+ \qquad (3)$$
$$\varepsilon b c_- = A_-$$
$$\varepsilon b (c_+ + c_-) = A_+ + A_- \equiv A \qquad (4)$$

$$+[\alpha] l c_+ = \alpha_+ \qquad (5)$$
$$-[\alpha] l c_- = \alpha_-$$
$$[\alpha] l (c_+ - c_-) = \alpha_+ + \alpha \equiv \alpha \qquad (6)$$

$A(v)$ and $\alpha(v)$ represent chromatograms (*e.g.* Fig. 1) of passage through an optically active sorbent, whereby partial separation of the enantiomers, *i.e.* overlap or fusion of their peaks, has occurred. Introduction of eq. (4) and (6) transforms eq. (2) into eq. (1); then

$$C_+ \equiv [\alpha] l \varepsilon^{-1} b^{-1} \qquad (7)$$



Using eq. (3) and (5) we get $C_+ = \alpha_+ / A_+$.

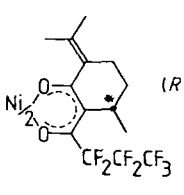
Quantitative Separation of the Enantiomeric Pairs of the Pheromone 2-Ethyl-1,6-dioxaspiro[4.4]nonane by Complexation Chromatography on an Optically Active Metal Complex[**]

By *Bernhard Koppenhoefer, Klaus Hintzer, Roland Weber,* and *Volker Schurig*[*]



Spiroketals are widespread in Nature, yet little is known about their chiroptical properties. 2-Ethyl-1,6-dioxaspiro[4.4]nonane (Chalcogran) *(3)*, the main component in the aggregation pheromone of the forest pest *Pityogenes chalcographus (L.)* ("Kupferstecher"), has recently been identified and synthesized[1]. *(3)* contains two asymmetric centers; therefore, four configurational isomers can exist.

(1), R = H; *(2)*, R = CH_3; *(3)*, R = C_2H_5

The influence of the stereochemistry of chiral pheromones on their biological activity has been demonstrated[2]. A method for the quantitative determination of the stereochemical composition of naturally occurring (and biologically active) spiroketals is of interest with regard to the directed application of synthetic attractants in biological field trials, the investigation of the biosynthesis from chiral precursors, and the search for genetic relationships between species and genuses.

So far, only the gas chromatographic separation of the racemic *Z*- and *E*-diastereomers of *(3)* has been described[1a], but not their further separation into the enantiomeric pairs. The quantitative analytical separation of the four configurational isomers of *(3)* has now been accomplished by complexation gas chromatography, exploiting the diastereo- and enantiospecific coordinative interaction of *(3)* with the optically active metal chelate nickel(II) bis(6-heptafluorobutyryl)-(*R*)-pulegonate (*R*)-*(4)*.

(*R*) - *(4)*

[**] Based on a lecture delivered at the conference "Chiral Structures" on May 23, 1979, in Milly la Forêt (France) *(V. S.)*. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Haarmann and Reimer, Holzminden (Germany), for generously supplying us with a sample of (*R*)-pulegone.

The novel optically active stationary phase (*R*)-*(4)* combines the advantage of considerable enantiomeric differentiation with short retention times and is thus suited for the enantiomeric resolution of substrates which are volatile only at elevated temperatures. By means of a nickel capillary column coated with a solution of (*R*)-*(4)* in squalane (0.09 m), the unsubstituted spiroketal *(1)* (also known as oxetone) can be resolved into the antipodes within 150 min at 50 °C. Following proof of the configurational stability of the spiro carbon atom of *(1)* during the separation by the occurrence of sharply separated peaks, we synthesized the homologs *(2)* and *(3)* (Chalcogran) according to procedures given in the literature[1a,c] and chromatographed the spectroscopically characterized compounds on 0.12 m (*R*)-*(4)* in squalane (Fig. 1, above).

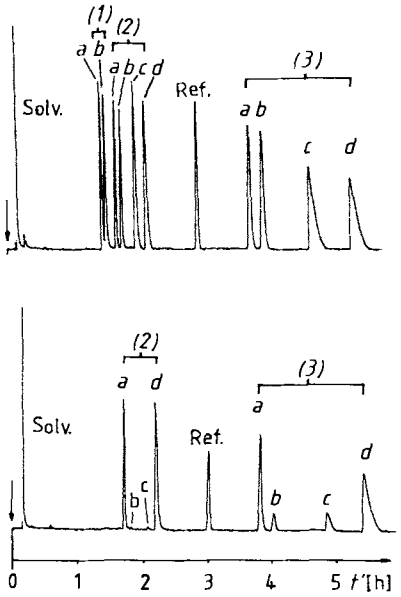

Fig. 1. Separation of enantiomers and diastereomers of chiral spiroketals by complexation chromatography on (*R*)-*(4)* (0.12 m in squalane) at 60 °C. Top: Separation of the racemic enantiomeric pairs *(1a, b)*, $\alpha = 1.04$; *(2a, b)*, $\alpha = 1.05$; *(2c, d)*, $\alpha = 1.09$; *(3a, b)*, $\alpha = 1.06$; *(3c, d)*, $\alpha = 1.15$. Bottom: Analysis of enantiomer-enriched (2*S*,5*R*/*S*)-*(2)* and (2*S*,5*R*/*S*)-*(3)*. Reference standard: *n*-decane; solvent: ethyl acetate; column: 100 m × 0.5 mm nickel capillary, carrier gas: 2.8 ml/min N_2; split 1:50.

As follows from Figure 1 the *Z*- and *E*-diastereomers of *(2)* and *(3)*, which are present in different concentrations, are each resolved into two enantiomeric pairs (*a, b* and *c, d*). The separation of the four configurational isomers was confirmed by the identity of the mass spectra for all four peak eluates *(a—d)* and their agreement with authentic *(2)*, and *(3)*, respectively[3].

Enantiomer-enriched Chalcogran (2*S*,5*R*/*S*)-*(3)* was obtained from (*S*)-1,2-epoxybutane (enantiomeric excess 69 ± 0.5%[4]), which was prepared racemization-free from technical (*R*)-2-amino-1-butanol (ee 69 ± 0.5%[5]) *via* the trimethylammonium hydroxide by Hofmann elimination; (2*S*,5*R*/*S*)-*(2)* was synthesized from (*S*)-epoxypropane[4] (ee 96.4 ± 0.2%[4]) according to the method of *Mori et al.*[1c]. The chromatogram is shown in Figure 1.

The appearance of pairwise unequal peak areas ($a/b = d/c$) in Figure 1 proves the separation into two enantiomeric pairs. Furthermore, the enantiomeric excess determined by integration for (2*S*)-configurated *(3)* (69 ± 0.5%) and *(2)* (96.3 ± 0.2%) confirms the racemization-free synthesis[1c]. The two (2*S*)-configurated isomers of *(2)* and of *(3)* both exhibit the weakest and the strongest coordinative interaction

with *(R)-(4)*. It follows therefore that the chiral discrimination of the enantiomeric pairs (*a*, *b* and *c*, *d*) is determined by the absolute configuration at the chiral spiro center C-5. Assuming[1b] that the *E* isomers of *(2)* and *(3)* undergo the stronger interaction with *(R)-(4)* on steric grounds, the assignment of the peaks can be given as follows: $a = 2S,5S$, $b = 2R,5R$, $c = 2R,5S$ and $d = 2S,5R$. The splitting patterns of *(2)* and *(3)* on *(R)-(4)* are identical (Fig. 1, bottom). Therefore, a rule developed earlier[4] for homologous oxiranes for correlation of the absolute configuration with the retention behavior on an optically active metal complex is also valid for spiroketals and can thus be used for determining the configuration at C-2.

To our knowledge this is the first direct gas chromatographic resolution of enantiomers of a chiral pheromone. Complexation chromatography surpasses other methods[6], since purification and derivatization are unnecessary and only a small sample size is required.

Stereoselectivity was not considered an aim at this juncture, since *Corey*[4a] had already described a markedly higher

A Novel Entry to Brefeldin A[**]

By *Yetkin Köksal, Peter Raddatz*, and *Ekkehard Winterfeldt*[*]

In order to exploit the synthetic potential of 4-oxo-2-cyclopentenyl acetate *(1)* for the synthesis of *trans*-disubstituted cyclopentanones by successive Michael addition [*(1)*→*(2)*] we chose as synthesis target the macrolide antibiotic brefeldin *(3)*[2], previously isolated from *Penicillium Brefeldianum*. *(3)* displays antifungal and cytostatic activity. Its structure and composition were first elucidated in 1964[3]; a few total syntheses and special reactions of this lactone have already been described[4].

Since *(1)* is available as optically active compound[5], in principle, an enantioselective synthesis of *(3)*, which hitherto could only be achieved *via* a tedious route involving numer-

[**] Cyclopentenones, Part 3. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. *A. von Wartburg* and Dr. *H. Hauth*, Sandoz AG, Basel (Switzerland) for supplying us with natural brefeldin A.—Parts 1 and 2, see [1a] and [1b].

rate of formation of the lactone derivative with a natural configuration on C-15, so it appeared possible to exploit this effect for the separation of the epimers. For completion of the other chains the mixture of the aldehydes *(12a)* and *(12b)* is first prepared by reduction of *(11a)* and *(11b)* with $LiAlH_4$ followed by reoxidation; subsequent Wittig olefination affords the unsaturated esters *(13)*.

We removed the silyl ether groups in *(13)* with fluoride ions to give a mixture of the alcohols *(14)*, without separation of the epimers. The hydroxy acids obtained on hydrolysis could be cyclized with α-chloro-*N*-methylpyridinium iodide according to the method of *Mukaiyama*[9] to give a mixture of the lactones *(15)*, which is converted by cleavage of thioketal into the ketones *(16)* (see Table 1).

Also in our lactonization technique, no differences attributable to alternative configurations at C-15 could be observed; however, we could confirm the high stereospecificity of the reduction of the oxo group on C-4 in *(16)* described by *Bartlett*[4c].

On reduction with $NaBH_4$ (−78 °C), the mixture of the C-15 epimeric ketones *(16)* furnished only two easily separable alcohols, namely *(17a)* and *(17b)*, of which *(17a)* could be resolved with $TiCl_4$ into sterically pure brefeldin A *(3)*, whose IR, NMR and mass spectra as well as TLC behavior were identical with those of an authentic sample of the natural product.

Experimental

(6a): A solution of 5-chloro-1-iodo-1-pentane (6.5 g, 28 mmol) in anhydrous ether (80 ml) was added at −78 °C to a solution of 1.6 N butyllithium (17.5 ml, 28 mmol) in hexane and the mixture stirred for 1 h at −78 °C. A mixture of copper(I) 1-pentyn-1-ide (3.67 g, 28 mmol) and tris(dimethylamino)phosphane (9.2 g, 56 mmol) in anhydrous ether (50 ml) was prepared in a separate flask and stirred for 0.5 h at room temperature (yellow-brown solution). This mixture was then poured slowly at −78 °C into the solution of the organolithium reagent and the resulting mixture stirred for a further 0.5 h and then treated with a solution of *(4)* (7 mmol) in anhydrous ether (40 ml). After 1 h the reaction mixture was poured into 0.5 N HCl, extracted with ether, washed with 2 N HCl and saturated $NaHCO_3$ solution, dried over $MgSO_4$ and, after removal of the ether, chromatographed on silica gel (ether/petroleum ether 7:4); yield 2 g (76%).

(6b) was prepared analogously; yield 1.55 g (75%).

(15a) + *(15b)*: A solution of the seco acid mixture *(14a)* + *(14b)*, H instead of C_2H_5, in anhydrous acetonitrile was treated with 250 mg (2.5 mmol) of triethylamine and then syringed into a refluxing solution of α-chloro-N-methylpyridinium iodide (400 mg, 1.5 mmol) in acetonitrile. The mixture was allowed to boil for 1 h, the solvent removed *in vacuo*, and the residue taken up in ether, washed with 2 N HCl and saturated NaCl solution, dried over $MgSO_4$ and chromatographed after removal of solvent with ether/petroleum ether (7:4); yield 63 mg (68%).

(16a) + *(16b)*: A solution of $AgNO_3$ (70 mg, 0.4 mmol) and *N*-chlorosuccinimide (70 mg, 0.5 mmol) in acetonitrile (2 ml, 20% H_2O) was treated with 6 drops of lutidine and the mixture immediately poured into a solution of the mixture of *(15a)* + *(15b)* (16 mg, 0.035 mmol) in acetonitrile (1 ml). After 1.5 minute's stirring at room temperature a saturated solution of $NaHSO_3$ and NaCl was added and the reaction mixture extracted with CH_2Cl_2. The organic phase was washed with 2 N HCl and saturated $NaHCO_3$ solution, dried over $MgSO_4$ and, after removal of the solvent in a vacuum, chromatographed on silica gel (ether); yield 11 mg (83%).

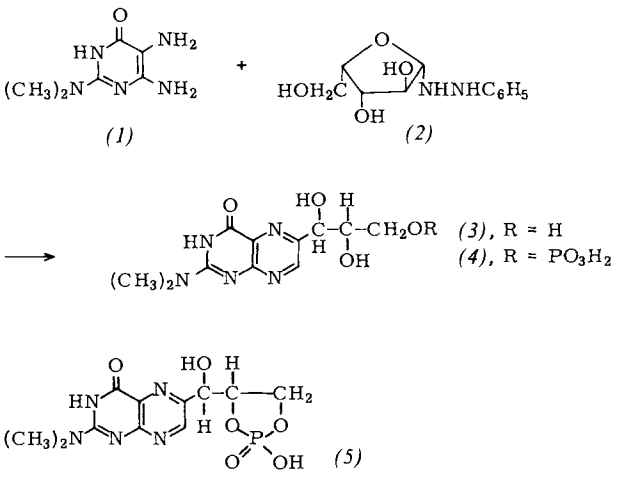
Euglenapterin—An Unusual New Natural Pteridine Derivative from *Euglena gracilis*



By *Manfred Böhme, Wolfgang Pfleiderer, Erich F. Elstner,* and *Wilhelm J. Richter*[*]

The phytoflagellate *Euglena gracilis* shows both animal and plant metabolic characteristics. During studies on the constituents[1] of this organism, three components showing

yellowish fluorescence were obtained after treatment of the natural material with MnO_2 in acetic acid solution; they were regarded as possible unconjugated pteridines. However, since none of these products could be identified by chromatographic or spectroscopic methods as one of the natural pterins we have re-investigated them. First of all, the component showing the greatest migration on chromatography on cellulose with *n*-propanol/1% ammonia (2/1) ($R_f = 0.48$) was enriched chromatographically and then purified by HPLC on RP-8 carrier material.

The field desorption mass spectrum (FD-MS) of the isolated material gave a $M^{\oplus\ominus}/MH^{\oplus}$ double signal ($m/e = 281/282$) corresponding to the molecular formula $C_{11}H_{15}N_5O_4$, which was confirmed by the high resolution electron impact mass spectrum (EI-MS) of the tetrakis(trimethylsilyl) derivative obtained by reaction with bis(trimethylsilyl)acetamide in pyridine at 60 °C ($M^{\oplus\ominus}$ at $m/e = 569$, $C_{23}H_{47}N_5O_4Si_4$). The possible structure of a 2-dimethylamino-6-trihydroxypropyl-4-oxo-3,4-dihydropteridine could be deduced from the presence of four silylatable (acidic) H atoms, the characteristic mass spectrometric fragments, and UV spectra of the various forms of the molecule, which show a slight bathochromic shift relative to the pterins. This structure could be confirmed, and the stereochemistry of the trihydroxypropyl side chain established, by chemical synthesis of all four stereoisomers from 5,6-diamino-2-dimethylamino-4-oxo-3,4-dihydroxypyrimidine *(1)* and the phenylhydrazones of D- and L-arabinose and D- and L-xylose *(2)* by conventional methods of pterin chemistry[2].

(1) *(2)* *(3)*, R = H; *(4)*, R = PO_3H_2 *(5)*

Comparison of the CD spectra of the four synthetic products with that of the natural material reveals the side chain to have the L-*threo* configuration *(3)*, and that a structural analogy exists with ciliapterin which was isolated from *Tetrahymen pyriformis*[3].

Once the constitution of euglenapterin *(3)* had been established, the structures of the other two yellow-fluorescing constituents, which had already been recognized as phosphates[1], could be assigned as the 3′-phosphate *(4)* (FD-MS: $MH^{\oplus}$ at $m/e = 362$; EI-MS after trimethylsilylation: $M^{\oplus\ominus}$ of the expected pentakis(trimethylsilyl) derivative at $m/e = 721$ and characteristic fragmentation) and as the 2′,3′-cyclophosphate *(5)* (FD-MS: $MH^{\oplus}$ at $m/e = 344$, $MNa^{\oplus}$ at $m/e = 366$; EI-MS after trimethylsilylation: $M^{\oplus\ominus}$ of the tris(trimethylsilyl) derivative at $m/e = 559$). Phosphorylation of *(3)* with $POCl_3$ in trimethyl phosphate by the Yoshikawa method[4], which preferentially attacks the primary OH function, leads to good yields of *(4)* or *(5)*, depending upon the conditions of work-up. Both substances (isolated as barium salts) are chromatographically and spectrometrically identical with the natural products.

Euglenapterin is thus the first example of a novel natural type of pterin. It remains to be seen whether the structural modification of the 2-amino group of the pterin system[5] is of general biological and physiological relevance.

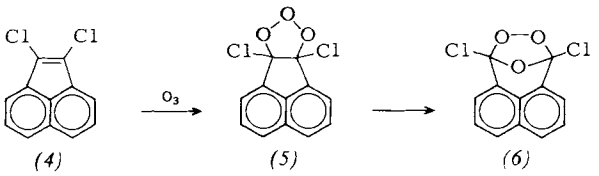
Ozonolysis of 1,2-Dichloroacenaphthylene

By *Helmut Seltzer, Siegmar Gäb*, and *Friedhelm Korte*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In the ozonolysis of olefins, monomeric normal ozonides (1,2,4-trioxolanes) are obtained if the cycloaddition of the carbonyl oxide ($>C=\overset{\oplus}{O}-O^{\ominus}$) to the carbonyl compound can successfully compete with other stabilizing reactions. The activity of the carbonyl function and the lifetime of the carbonyl oxide play a decisive role[1]. If both groups are in one molecule, then intramolecular cycloaddition is preferred, particularly if the two groups cannot be removed far from each other spatially after the cycloreversion of the primary ozonide (1,2,3-trioxolane). In agreement with this, the chlorine-containing ozonides *(1)*, *(2)*, and *(3)* are formed in high yields from the corresponding chloroolefins[2], while the ozonization of *trans*-2,3-dichloro-2-butene affords only small amounts of products ascribable to a 3,5-dichloro-1,2,4-trioxolane[3].



(1) *(2)* *(3)*

The formation of a monomeric ozonide should also be favored on steric grounds in the case of 1,2-dichloroacenaphthylene *(4)*. When *(4)* is ozonized at 0 °C in inert solvents, two stable O_3-addition compounds can be isolated from the reaction mixture by chromatography on silica gel. On the basis of analytical data the structures *(5)* and *(6)* are proposed for the colorless crystalline substances[4].

(4) (5) (6)

According to molecular weight (268, cryoscopically in benzene) and spectroscopic data, compound *(6)* (1,4-dichloro-1,4-epoxy-1*H*,4*H*-naphtho[1,8-*de*][1,2]dioxepin) is a monomeric ozonide. The EI mass spectrum shows the molecular ion with characteristic isotope distribution for two Cl atoms at $m/e = 268$. In the IR spectrum bands appear at 1040 and 1090 cm^{-1}, which are typical for the C—O stretching vibrations of 1,2,4-trioxolanes[5]. The total of seven ^{13}C-NMR signals between $\delta = 120.42$ and 133.40 ([D_6]acetone, TMS) is consistent with the molecule having a symmetrical structure.

The ^{13}C-NMR spectrum of *(5)* shows the same number of lines between $\delta = 116.39$ and 136.97 ($CDCl_3$, TMS). The observed upfield shift of the trioxolane carbon in *(5)* ($\delta = 116.39$) compared with in *(6)* ($\delta = 120.42$) is analogously found with trioxolane protons in the primary and normal ozonides of *cis*- and *trans*-alkenes[6]. Both the molecular weight (266, cryoscopically in benzene) and the FD mass spectrum ($m/e = 268$, 2 Cl, M^+) of *(5)* indicate a monomeric ozonide.

For further differentiation between primary ozonide and normal ozonide, either the larger thermal stability of *(6)*, or the difference in behavior of *(5)* and *(6)* towards tetracyanoethylene (TCNE) can be consulted[7]. While *(5)* is no longer detectable after a short while in the presence of TCNE, *(6)* remains unchanged[8]. The reaction sequence *(5)*→*(6)* (TLC detection) under the conditions of ozonolysis is important for the assignment.

The ozonide *(6)* decomposes slowly under our reaction conditions into 1,8-naphthalenedicarboxylic anhydride[9], which, after ozonolysis of *(4)*, can be isolated from the reaction mixture in over 70% yield.

Procedure

A solution of *(4)* (2.2 g) in dichloromethane (150 ml) is treated at 0 °C with ozone until the yellow color disappears. After distillation of the solvent in a vacuum the colorless, crystalline residue is separated by column chromatography at −7 °C on silica gel (eluent: *n*-hexane/benzene 1:1). The purity of the fractions is monitored by thin-layer chromatography (TLC plates Kieselgel 60, Merck; eluent: *n*-hexane/benzene 1:1; on spraying with diphenylamine the spots of *(5)*, $R_f = 0.27$, and *(6)*, $R_f = 0.51$, turn dark grey. One obtains 180 mg (6.7%) of *(5)* and 260 mg (9.7%) of *(6)*.

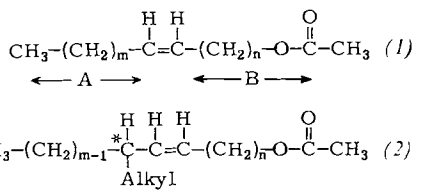
[8] The finding that *(6)* is formed on ozonolysis of *(4)* in the presence of TCNE, but not in the reaction of *(5)* with TCNE can be explained in terms of different reaction paths.

[9] 2,3,4,6-Tetrachlorobicyclo[3.2.1]oct-3-ene-2,7-dicarboxylic anhydride (m.p. 198—200 °C) is formed in good yields on photolysis ($\lambda > 290$ nm) of the stable ozonide *(1)* in CCl_4.



Differentiation between Chiral Pheromone Analogues by Chemoreceptors[**]

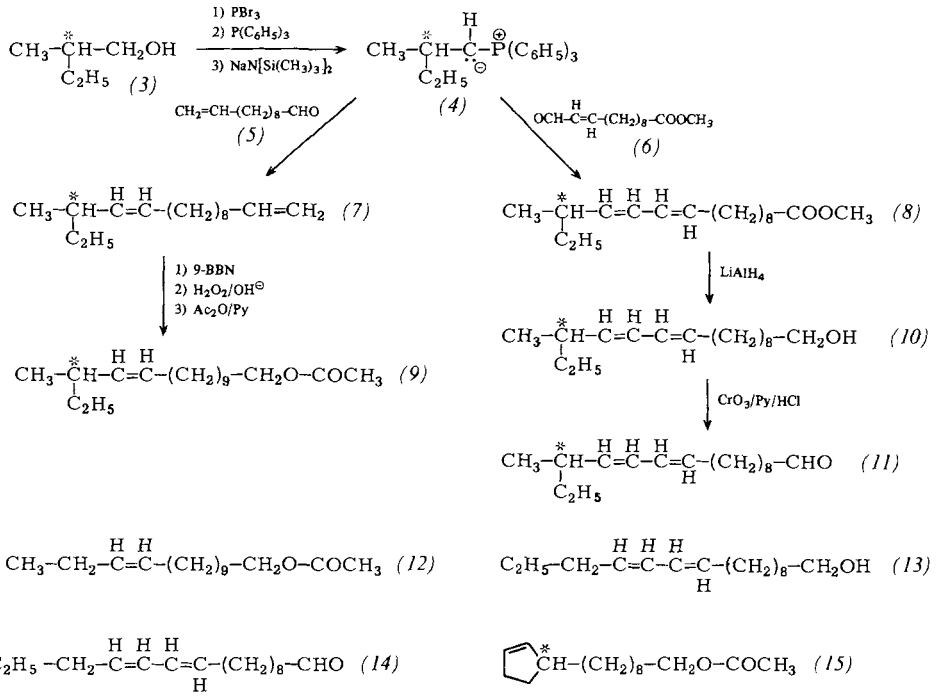
By *Hans Jürgen Bestmann, Hans Ludwig Hirsch, Hans Platz, Marlies Rheinwald,* and *Otto Vostrowsky*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

On the basis of structure-activity studies on pheromones and their analogues[1], we recently proposed a dynamic model for the interaction between pheromone molecule and the receptor region on the dendritic membrane of the sensilla of Lepidoptera[2]: the signal molecule is considered to be flexibly incorporated into the entire receptor region[3].

Presumably the receptor region contains several chirality elements, and the sections of the multiply prochiral pheromone molecule [*e.g.* A or B in *(1)*] will only fit into one of the two enantiotopic sides of the respective prochirality centers. This means that the signal molecule is incorporated in a definite conformation. Changes in the receptor region are also to be expected during this process. If these model concepts are correct, then receptors showing a maximum response to achiral pheromone molecules of type *(1)* should be able to distinguish between the enantiomers of chiral pheromone analogues *(2)* because additional diastereoisomeric interactions occur and only one of the two enantiomers can extensively adopt the conformation of section A of the signal molecule as required by the receptor region.

(1)



(2)

We have prepared the optically active pheromone analogues *(9)*, *(10)*, and *(11)* in order to test this postulate.

The synthon for the chiral moiety was 2-methyl-1-butanol *(3)*, whose (*S*)-(−)-enantiomer is commercially available. Attempts to obtain the (*R*)-(+) antipode by conventional resolution of (*R,S*)-*(3)* were unsuccessful. However, we were able to resolve racemic 2-methylbutyric acid with (−)-α-phenylethylamine to give the (*R*)-(−) enantiomer ($[\alpha]_D^{20} = -15.70°$ (100%), 90% optical purity). Its reduction to (*R*)-(+)-*(3)* with $LiAlH_4$ can be accomplished without racemization ($[\alpha]_D^{20} = 4.060°$ (100%), 90% optical purity). The enantiomers of *(3)* are transformed into the bromides and thence,

			(R)-(−)-*(11)*	3

We have included the enantiomers synthesized by *Chapman et al.*[9] and the racemate of *(15)* in our measurements. In contrast to *(9)*, compound *(15)* is not free to adopt any conformation in part A of the molecule because it is fixed by the ring. In *(15)* the chirality center is located in part B.

The relative EAG activities listed in Table 2 show that the receptors are able to distinguish between the enantiomers in all cases. In the case of *Ostrinia* and *Agyrotaenia*, which use the same pheromone molecule although they belong to different families, *(R)*-*(9)* is one hundred times as effective as the (*S*) enantiomer. The enantiomers of *(15)* are also distinguished by the two species (factor of 10—30). The activity of the racemate lies between those of the enantiomers in all cases examined by the present statistical method[1b]. In a behavioral test the racemate of *(15)* was more effective than the antipodes for *Agyrotaenia velutinana*[9], but not in the EAG test.

Table 2 also shows that the activities of the mobile *(R)*-*(9)* and of the rigid *(S)*-*(15)* differ by a factor of 30 and 100, respectively, in the two species. Compared with the species-specific pheromone the activity of *(R)*-*(9)* is diminished only tenfold, but that of *(S)*-*(15)* 300- or 1000-fold.

Bombyx mori also distinguishes between the (*R*)- and the (*S*)-form of *(10)* and *(11)*. However, the (*S*)-enantiomer is only three times as active as the (*R*)-form, and the racemate lies between the two.

All these results support the above ideas concerning the dynamics of the interaction between pheromone molecule

and chiral acceptor region. We consider it remarkable that the position of the additional side chain (circled) at the asymmetric C atom in the preferred enantiomers is the same. This applies to all the species examined so far, even when they belong to different families.

Intercalation Complexes of Metallocenes in Iron Oxide Chloride[**]

By *Hartwig Schäfer-Stahl* and *Raimund Abele*[*]

Iron oxide chloride (FeOCl) can accommodate guest atoms or molecules in its interlayer regions which are held together only by van der Waals forces. Amines[1], aromatic heterocycles[2], and alkali metals[3] may reduce some of the Fe^{3+} centers on inclusion. These inclusion compounds are of interest because of their semiconductor and superconductor properties and their catalytic behavior.

We prepared inclusion complexes from FeOCl and metallocenes in order to gain information about possible redox interactions.

As the host component we used violet-red FeOCl crystals (sieve fraction between 0.025 and 0.1 mm) which were obtained from Fe_2O_3 and $FeCl_3$ by annealing at 350—300 °C. Intercalation of the metallocenes can be accomplished between 20 and 110 °C in glyme under N_2, or directly from the gas phase in the case of $(C_5H_5)_2Fe$ and $(C_5H_5)_2Co$. The reaction was stopped on disappearance of the original FeOCl reflections in the Debye diagram. At higher temperatures other phases are formed; FeOCl reacts with the metallocenes of the alkaline earth metals and with $(C_5H_5)_2Mn$ and $(C_5H_5)_2V$ below room temperature with partial formation of $(C_5H_5)_2Fe$ and solvent-containing intercalation compounds[4].

The host crystal accommodates one guest molecule per five to seven formula units of FeOCl, *i.e.* (given two FeOCl units per unit cell) one guest molecule for about three unit cells. The expansion of the *b* axis (791.7 pm in FeOCl[5]) was about 518 pm in all cases. That is somewhat smaller than twice the van der Waals radius of the metallocenes for which 680 pm has been reported along the fivefold axis, and 560 pm perpendicular thereto. It could be demonstrated in the case of intercalation of $[C_5(CH_3)_5]_2Fe$ in FeOCl[7] that the planes of the intercalated rings are parallel to the *b* axis and project a little into the planes of the host lattice[8] with all the intermediate layers being occupied. Intercalation of the metallocenes in FeOCl is illustrated schematically in Figure 1. A similar situation has already been assumed in the intercalation compounds of metallocenes in dichalcogenides[6].

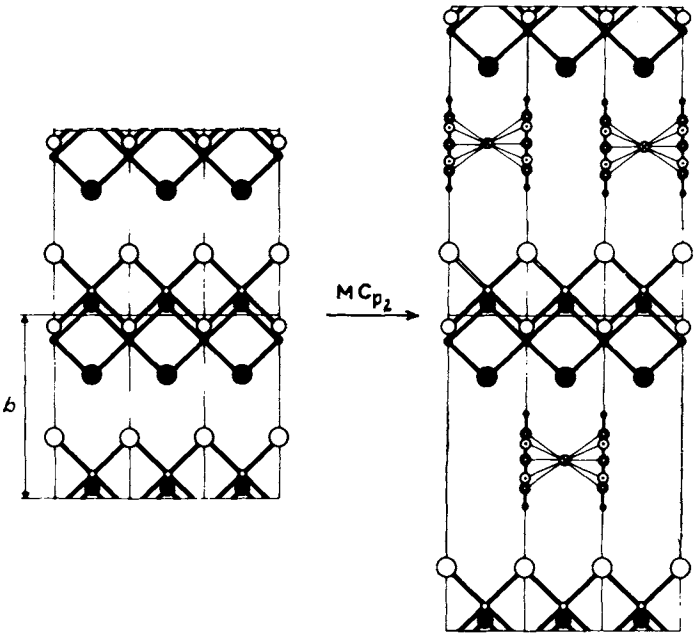

Fig. 1. Inclusion of metallocenes in FeOCl, schematic. • Fe^{3+}, $z=1/2$; • O^{2-}, $z=1/2$; ● Cl$^-$, $z=1/2$; ○ Fe^{3+}, $z=0$; ○ O^{2-}, $z=0$; ○ Cl$^-$, $z=0$; ⊗ M^{2+}, ○ C, • H.

The Mössbauer spectra of the intercalation complexes show a doublet. The quadrupole splitting is somewhat smaller than for FeOCl (Table 1). It must be concluded from the almost unchanged chemical shift that the high-spin Fe^{3+} state of the host lattice is retained on inclusion, *i.e.* that no reduction to Fe^{2+} occurs.

Table 1. Production and characterization of FeOCl intercalation complexes.

	Reaction conditions t [d]/T [°C]/solvent	b [pm]	Mössbauer parameters δFe	ΔE^Q [mm/s]
$NiCp_2 \cdot 6.6\,FeOCl$	8/ 20/Glyme	1310	0.49	0.69
$CoCp_2 \cdot 5.5\,FeOCl$	8/ 20/Glyme	1310	0.50	0.67
$FeCp_2 \cdot 6.3\,FeOCl$	8/ 20/Glyme	1310	0.48$_5$	0.64
$FeCp_2 \cdot 7.5\,FeOCl$	5/110/(Vacuum)	1310	0.49	0.66
$FeCp_2 \cdot 6.4\,FeOCl$	5/ 80/Glyme	1310	0.49	0.68
$CrCp_2 \cdot 7.1\,FeOCl$	8/ 20/Glyme	1310	0.49	0.69
FeOCl	30/350—300/(Vacuum)	792	0.41	0.92

Interestingly, the typical Mössbauer absorptions (quadrupole splitting $\Delta E^Q = 2.37$ mm/s) of ferrocene have completely disappeared in $FeCp \cdot 6\,FeOCl$. The transformation of ferrocene into the ferrocene cation is established by the appearance of the Mössbauer absorption band of the guest molecule, which is masked in the room temperature spectrum, as a singlet of chemical shift $\delta = 0.49$ mm/s at 4 K (alongside the 6-line system of the completely magnetically ordered iron

centers of the host lattice). This corresponds to the singlet of $FeCp_2^+Cl^-$[9].

The observation that ferrocene is oxidized to the $FeCp^+$ ion on intercalation while the host lattice remains unchanged and shows only high-spin Fe^{3+} centers compellingly demonstrates that the intercalation compound must contain "free" electrons; we therefore propose the formulation $[Fe(C_5H_5)_2]^+ \cdot [6\,FeOCl] \cdot e$. The conductivity of the crystals is accordingly about 10^4 times greater than that of FeOCl. A compressed powder sample shows a conductivity of 10^{-3} $\Omega^{-1}\,cm^{-1}$ at room temperature, which lies in a region corresponding to typical semiconducting materials (*e.g.* doped germanium)[10].

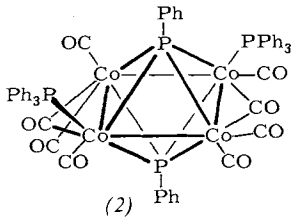
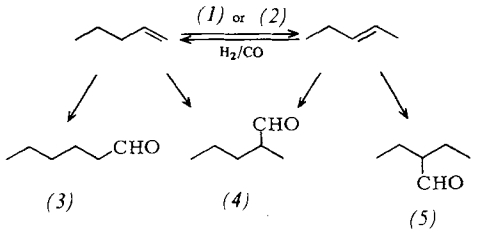
Dumesic*, Physika *99B*, 128 (1980), have meanwhile reported the inclusion of $CoCp_2$, $Fe[C_5(CH_3)_4C_2H_5]_2$, and $FeCp_2$ in FeOCl from toluene at 80—100 °C. However, the resulting intercalation compounds do not exhibit an enhanced conductivity. Other physical data also indicate that these phases differ from those which we have obtained at room temperature.



Catalysis of Hydroformylation by $Co_4(CO)_{8-x}(\mu_2\text{-}CO)_2(PPh_3)_x(\mu_4\text{-}PPh)_2$, $x = 0$ or 2: Clusters as Catalysts[**]

By *Charles U. Pittman, Jr., Gary M. Wilemon, W. Dean Wilson*, and *Robert C. Ryan*[*]

Soluble transition metal cluster compounds have recently attracted a great deal of interest as, *inter alia*, homogeneous catalysts, and as models for catalysis at metal surfaces[1-3]. A key problem is the tendency of clusters to fragment under the reaction conditions into homonuclear moieties[2-4]. So far there has been no definitive evidence demonstrating conclusively that a cluster actually serves as the active catalyst. To synthesize non-fragmenting clusters we have advocated the use of elements of the first transition series that are bound both by metal-metal bonds and by stable, nonfluxional bridging ligands[1,2,5]. We report here on hydroformylation of 1- and 2-pentene in the presence of cobalt clusters *(1)* and *(2)*, where the effect of added phosphanes on selectivity and rate of this reaction appears to rule out fragmentation of the clusters to catalytically active homonuclear fragments.



(1)

(2)

Cluster *(1)* was prepared by a known route[6] and converted by refluxing in toluene/PPh_3 into *(2)*, which could be isolated by chromatography on neutral Al_2O_3 and elution with deoxygenated hexane and hexane/toluene. The structures of *(1)* and *(2)* were established by elemental analysis, IR spectroscopy, and single crystal X-ray structural determinations[7]. Hydroformylations of 1- and 2-pentene to aldehydes were catalyzed in high yields and under mild conditions (120–150 C, 17—100 bar, CO/H_2 1:1); aldehydes were the major products. Some representative results are given in Table 1.

After completion of hydroformylation the cluster *(1)* could be recovered in high yield (95%). High pressure liquid chromatography (HPLC) was used to show that the concentration of *(1)* did not decrease within the limits of detection (*ca.* 0.5%) during reactions at 145 °C and 68.9 bar. No other metal-containing complexes could be detected by HPLC or TLC. The selectivity, *i.e.* the ratio of normal (*(3)*) to branched aldehydes (*(4)* + *(5)*), in the reaction of 1-pentene increased from 1.5 (31.3 bar) to 3.8 (80.0 bar) at 130 °C and from 2.5 (30.3 bar) to 4.7 (75 bar) at 110 °C, similarly as observed for $Co_2(CO)_6(PR_3)_2$-catalyzed hydroformylations where the active species is $HCo(CO)_3(PR_3)$[8]. Addition of PPh_3 to *(1)* decreases the rate (entries 5—7, Table 1). The selectivity increases from 1.4 to 2.9 (150 °C, 41.4 bar) upon the addition of two moles of PPh_3 per mol of *(1)* and to 3.6 on addition of four moles of PPh_3 per mol of *(1)*. The isomerization *(1)* ⇄ *(2)* competes with hydroformylation, both in the presence and in the absence of PPh_3.

Several key points were noted. First, very little alcohol is formed (≤5%) on hydroformylation of 1-pentene with *(1)* and PPh_3 at 150 °C and 34.5—48.3 bar, even with long reaction times. In contrast, in the $Co_2(CO)_8$-catalyzed hydroformylation the addition of PPh_3 (or $P(n\text{Bu})_3$) leads to high yields of alcohols[9]. $Co_2(CO)_8$ fragments under these conditions to $HCo(CO)_3PPh_3$[4b]. Accordingly, in the presence of PPh_3, *(1)* cannot fragment to $HCo(CO)_3PPh_3$. Secondly, only *(1)* was isolated or detected (TLC, HPLC) in hydroformyla-

[a] Phosphane refers to the phosphane added to the catalyst solution. The number in brackets indicates the number of moles of phosphane per mol of *(1)* or *(2)*. All chelating phosphanes $Ph_2P(CH_2)_xPPh_2$ were used in the ratio 1 mol per mol of *(1)* [*i. e.* P: *(1)* = 2:1]. [b] Pressure range refers to initial and final pressures (± 5%) at the reaction temperature. Those entries with one pressure were done under constant pressure during the entire reaction. [c] Yields are based on pentene consumed. Major products: hexanal *(3)*, 2-methylpentanal *(4)* and 2-ethylbutanal *(5)*. The amounts of pentane formed were ≤2% in all cases. [d] Selectivity = *(3)*/(*(4)* + *(5)*).

tions conducted with a fourfold excess of PPh_3. This behavior contrasts with that of $Co_2(CO)_8$-catalyzed reactions where only $[Co(CO)_3PPh_3]_2$ could be isolated when PPh_3 was the added ligand. Thus, cluster *(1)* could not have fragmented to $HCo(CO)_4$ or $HCo(CO)_3PPh_3$ during the hydroformylation. Thirdly, the selectivity increased from 2.9 to 3.8 and the rate decreased (entries 6 and 8, Table 1) when PPh_3 was replaced by $Ph_2PCH_2CH_2PPh_2$ as the ligand. This response of selectivity and rate is just the opposite of that observed for $Co_2(CO)_8$ when PPh_3 was replaced by $Ph_2PCH_2CH_2PPh_2$: there was a decrease in selectivity (from 1.9 to 1.3) and an increase in rate[9]. Taken together, these results show that *(1)* does not fragment to mononuclear species.

Despite the effect of PPh_3 on selectivity and rate, when *(2)* was used as the catalyst, only *(1)* could be recovered at the end of sample reactions. Use of HPLC demonstrated that under hydroformylation conditions (145 °C, 68.9 bar) *(2)* was rapidly converted into $Co_4(CO)_7(\mu_2\text{-}CO)_2(PPh_3)(\mu_4\text{-}PC_6H_5)_2$ and then into *(1)*.

(6)

Since both *(1)* and *(2)* contain two stable PPh bridges, they cannot easily dissociate to mononuclear species. If such dissociation did occur, it is difficult to imagine how such fragments would be able to reassemble into *(1)* at 100—150 °C and 30—100 bar CO/H_2. Our results do not rule out possible fragmentation to *(6)* during the reaction, although the reconversion of *(6)* to *(1)* would require loss of two CO ligands.

Extreme ^{13}C-NMR Data as Information on Organometal Radicals[**]

By *Frank H. Köhler, Karl-Heinz Doll*, and *Wolfram Prössdorf*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

The problem of numerous radicals failing to give any ESR spectra has been resolved step by step in recent years, particularly regarding organometal radicals: at first by paramagnetic ^{1}H- and later by ^{13}C-NMR spectroscopy (cf. earlier communications in this series). Unfortunately, however, the applicability of ^{13}C-NMR spectroscopy was hitherto greatly restricted. Signals broader than *ca.* 500 Hz are routinely regarded as unobservable; the not very satisfactory results obtained by *Kreilick et al.*[1] with a spectrometer of special construction confirmed this view.

We have now obtained ^{13}C-NMR spectra of the partially substituted nickelocenes *(1)*—*(7)*[2], whose individual signals have halfwidths >5000 Hz (signal groups > 20000 Hz) and cover a range of >2200 ppm. A typical example is shown in Figure 1. Nickelocenes, for which we had predicted very broad signals[3], are a special test case for the extension to other types of compounds, since here very narrow and very

[**] NMR spectroscopy of paramagnetic complexes, Part 21.—Part 20: *F. H. Köhler*, Z. Naturforsch. *B 35*, 187 (1980).

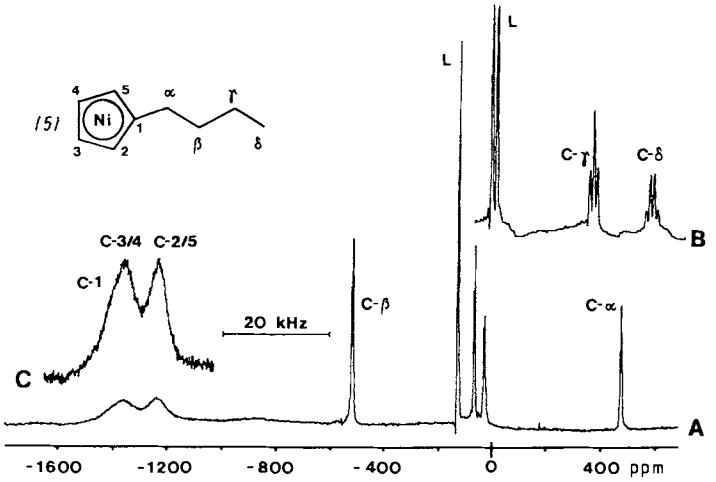

Fig. 1. ^{13}C-NMR spectrum of $(n\mathrm{BuC_5H_4})_2$Ni *(5)* in C_6H_6 at 77 °C. A) Overview; B) C-1 to C-5 amplified; L solvent, C_α and C_β expanded.

broad signals occur close to each other at the same time. As Figures 1B and 1C show, the spectrum of $(n\mathrm{BuC_5H_4})_2$Ni provides information on C-H coupling[4] and the symmetry of the five-membered ring. The poorly developed shoulder for C-1 is clearly recognizable in the spectrum of $(t\mathrm{BuC_5H_4})_2$Ni *(6)* (Fig. 2). This spectrum also provides the long sought[5]

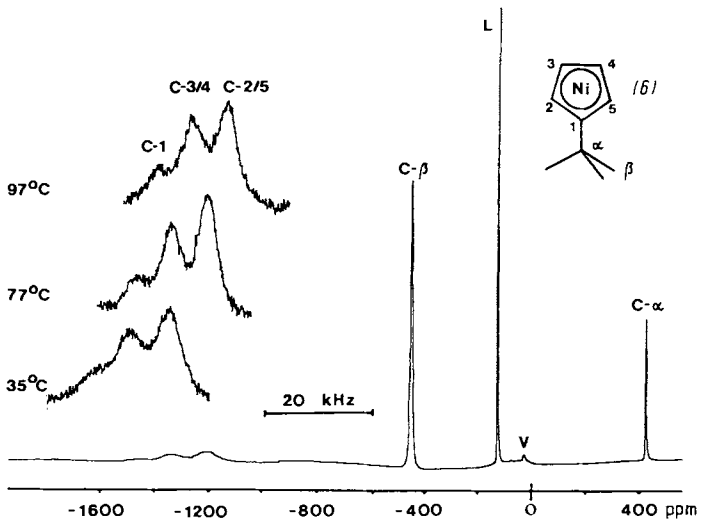

Fig. 2. ^{13}C-NMR spectra of $(t\mathrm{BuC_5H_4})_2$Ni *(6)* in C_6D_6 at 35, 77 and 97 °C; C-1 to C-5 amplified; V = impurity.

evidence for strong temperature dependence of the shifts and halfwidths.

The ^{13}C-NMR data of the nickelocenes investigated are collected in Table 1.

According to these data the nickelocenes *(1)—(6)* are radicals, which, with two unpaired electrons, shift in particular the signals of the five-membered ring C-atoms to an extreme, characteristic region. The number and position of the signals afford proof of structure just as easily as in the case of diamagnetic molecules.

Surprisingly, the C-1 signal in the compounds $(\mathrm{RC_5H_4})_2$Ni *[(3)—(6)]* is shifted further than the rest of the five-membered ring signals. In analogy to cobaltocenes[5b] the opposite was to be expected. It can be concluded, therefore, that the unpaired electrons in both metallocenes are in e_{1g} orbitals[7a], but slight perturbation of the degeneration (by substitution with R) leads to e_{1g}^+ and e_{1g}^-[7b], each of which give opposite signal splittings. In substituted cobaltocenes apparently the

[d] Proposed assignment (cf. Text).

one, in substituted nickelocenes the other orbital determines the transfer of unpaired electrons to the ligand. Hence, the assignment of C-3/4 and C-2/5 (cf. Table 1) should also be opposite to that in cobaltocenes[8].

We have checked the accuracy with which such ^{13}C-NMR spectra are obtainable with perdeuterated nickelocene. Table 1 shows the very small difference of 8 ppm between the signals of *(1)* and *(2)*, which to our knowledge is, nevertheless, the largest ^{13}C-NMR isotope shift observed so far. This value falls neatly in line with our findings on other metallocenes[9].

N-Isocyanoiminotriphenylphosphorane: Synthesis, Coordination Chemistry, and Reactions at the Metal[**]

By *Bernd Weinberger* and *Wolf Peter Fehlhammer*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

Isodiazomethane ($CNNH_2$) cannot be obtained as a pure substance owing to its ready decomposition[1]; it can however

[*] Prof. Dr. W. P. Fehlhammer, Dipl.-Chem. B. Weinberger
Institut für Anorganische Chemie der Universität Erlangen-Nürnberg
Egerlandstrasse 1, D-8520 Erlangen (Germany)

[**] Metal complexes of functional isocyanides. Part 4. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 3: [2].

be stabilized by coordination to a metal. Unfortunately, $CNN[Si(CH_3)_3]_2$, the precursor for the synthesis of $Cr(CO)_5CNNH_2$[2] is not easily accessible[3].

In search of a suitable "form of storage" of isodiazomethane we have now been able to prepare *N*-isocyanoiminotriphenylphosphane *(1)*[4] according to

$$HCO\quad NHNH_2 + 2PPh_3 + 2CCl_4 + 2NEt_3 \rightarrow \rightarrow CNNPPh_3 + 2HCCl_3 + 2[NEt_3H]Cl + OPPh_3$$

(1)

The surprising stability (dec. pt. 159—160 °C) of this functional *N*-isocyanide is apparently due to the masking of the primary amine function.

Apart from synthetic route and IR spectrum [(KBr): 2067 w (ν(CN)), 1117 s, 1009 sh (ν(P=N)) cm^{-1}] it is particularly its strong tendency to form complexes, which proves *(1)* to be an isocyanide. Thus, the stable[5] complexes *(2a—c)* and *(3)* are formed smoothly from tetrahydrofuran or bromo derivatives and *(1)*, respectively. No more problems arise in the syntheses of *(4)* and *(5)* by, respectively, addition of *(1)* to

$M(CO)_5CNNPPh_3$ *(2a—c)*, M = Cr, Mo, W

$Mn(\eta\text{-}C_5H_5)(CO)_2CNNPPh_3$ *(3)*

$PdI_2[CNNPPh_3]_2$ *(4)*

$[PtCl(CNNPPh_3)(PPh_3)_2][BF_4]$ *(5)*

PdI_2 and cleavage of the bridge in $[PtCl(PPh_3)_2]_2[BF_4]_2$. Complex formation is accompanied by an increase Δν(CN) in the ν(CN) frequency, which in the case of *N*-isocyanides reaches values up to 130 cm^{-1} (Pt^{II} complexes)[6]. In view of the high Δν(CN) values found here, and the low-lying CO bands of the pentacarbonylmetal moiety [*(2a)*: KBr: 2055 s [A_1], 1924 vs [E] cm^{-1}] *(1)* is primarily a donor ligand, *i.e.* bonding in metal complexes of *(1)* is perhaps best described by the resonance formula

$$L_n\overset{\ominus}{M} \leftarrow C\equiv\overset{\oplus}{N}\text{—}\overset{\ominus}{N}\text{—}\overset{\oplus}{P}Ph_3$$

As expected, the iminophosphorane bond in *(2)* can be cleaved hydrolytically under conditions leaving the rest of the molecule untouched. The isodiazomethane complexes *(6)*[2] formed in >70% yield according to

$$(2) + H_2O \xrightarrow{H^{\oplus}} M(CO)_5C\equiv N\text{—}NH_2 + OPPh_3$$

(6)

are stable enough to be sublimed after chromatographic separation from phosphane oxide.

(2) reacts with aldehydes and ketones in a Wittig-type reaction to give complexes *(7)* with *N*-isocyanoiminoalkane ligands

$$(2) + RR'C{=}O \xrightarrow{H^{+}} M(CO)_5C\quad N\quad N\quad CRR' + OPPh_3$$

(7)

e.g. R = R′ = CH_3; R = C_6H_5, R′ = H

In this way, a class of compounds becomes readily accessible in metal complexes, of which only one representative—$CNN{=}C(CH_3)C_6H_4\text{-}p\text{-}OCH_3$—has so far been characterized in free form[7].

There is definitely more synthetic potential in pentacarbonylmetal(6A) complexes of *(1)* as shown by the acid-catalyzed isomerization to the complex cyanamide *(8)*, which is complete in 2—3 d at room temperature[8]. This reaction proceeds particularly smoothly and quantitatively in the presence of palladium(II) compounds in a CO atmosphere.

$$(2) \xrightarrow{H^{\oplus}} M(CO)_5N\equiv C\text{—}N\text{—}PPh_3 \quad (8)$$

Procedures

All solvents and reagents must be anhydrous and, where necessary, saturated with N_2.

(1): A suspension of PPh_3 (157.4 g, 0.6 mol) in CH_2Cl_2 (600 ml) is treated with 50.6 g (0.5 mol) of NEt_3 and 15.3 g (0.25 mol) of formylhydrazine and heated to 50—60 °C. CCl_4 (77.0 g, 0.5 mol) is added dropwise to the mixture, which is kept at 50—60 °C for 4—5 h. After removal of the volatile components at room temperature, the residue is dried in a high vacuum, pulverized, stirred in 200 ml ethanol/water (1:1.5), filtered, and recrystallized from hot ethanol; yield 31.7 g (42%) *(1)* as orange-brown crystals.

(2c): A solution of $W(CO)_6$ (1.76 g, 5 mmol) in tetrahydrofuran (100 ml) is irradiated until ≈110 ml of CO have evolved. The solution is then cooled to −30 °C, mixed with 1.39 g (4.6 mmol) of *(1)*, stirred for 2 h at −30 °C, and for 1 h at 0 °C. After removal of the solvent (0 °C, high vacuum) and sublimation of $W(CO)_6$, the residue is extracted with 6 × 50 ml boiling petroleum ether (40—60 °C), the extract filtered rapidly through filter-cellulose, concentrated to *ca.* 1/3 of its volume and transferred to a refrigerator. Pale yellow *(2c)* crystallizes out; yield 2.91 g (93%).

(7), M = W, R = R′ = CH_3: Dry HCl gas is passed into a solution of *(2c)* (0.63 g, 1 mmol) in acetone (30 ml) for *ca.* 1/2 min. The solution is stirred for 2 h, the solvent removed, and the mixture chromatographed on silica gel with CH_2Cl_2/*n*-hexane (4:1). After evaporation of the solvent 0.20 g of a pale yellow solid (50%, m.p. 86.5 °C) are left behind.

B_8S_{16}—An "Inorganic Porphine"[**]

By *Bernt Krebs* and *Hans-Ulrich Hürter*[*]

The preparation and characterization of boron sulfides is difficult. The only compound to have been unequivocally identified in the solid state is B_2S_3, which has a polymeric structure made up of B_3S_3 six-membered rings and B_2S_2 four-membered rings[1]. The existence of $B_{12}S$, B_4S, BS, and B_2S_5[2] as defined phases has not yet been confirmed. The

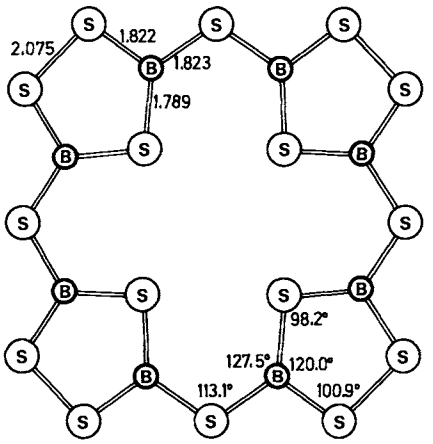
[*] Prof. Dr. B. Krebs, Dipl.-Chem. H.-U. Hürter
Anorganisch-chemisches Institut der Universität
Gievenbecker Weg 9, D-4400 Münster (Germany)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and the Fonds der Chemischen Industrie.

only evidence for a species of composition BS_2 has so far come from mass spectrometry and thermal analysis[2, 3].

During our studies on binary and ternary boron sulfides[1, 4a, b] we have now obtained a new boron disulfide of molecular formula B_8S_{16} by two different routes. Rapid heating of a B_2S_3/S mixture (molar ratio 1:1.5) to *ca.* 300 °C at *ca.* 10^{-4} bar in a sealed quartz glass tube[4c], which has been graphitized or protected by a boron nitride coating, in a two-zone furnace with a sharp temperature profile (300/100 °C) leads to deposition of a crystalline product within a narrow region in the colder zone of the reaction tube. The colorless needles are up to 2 mm long, extremely sensitive to hydrolysis, and decompose above 115 °C in a sealed vessel under normal pressure (N_2).

The compound [elemental analysis B:S = 1:2.01(2)] forms monoclinic crystals (space group $P2_1/c$), $a = 12.158(3)$, $b = 4.089(1)$, $c = 21.961(4)$ Å, $\beta = 107.65(3)°$, $Z = 16$ BS_2, $V = 1040.4$ Å^3, $\rho_{calc} = 1.913$, $\rho_{exp} = 1.90(2)$ g cm^{-3}. As shown by the complete X-ray structure analysis (1349 diffractometer data, $R = 5.5\%$), solid boron disulfide is made up of discrete exactly planar B_8S_{16} molecules whose porphine type skeleton contains four 1,2,4,3,5-trithiadiborolane rings linked by sulfur bridges. Figure 1 shows the molecular structure with distances and angles averaged over chemically equivalent bonding parameters. Within the limits of experimental accuracy the molecule has D_{4h} symmetry (exact symmetry in the crystal is C_i). The average B—S bond length (1.811 Å)



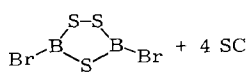


Fig. 1. B_8S_{16} molecule with bond lengths [Å] and bond angles ($\sigma = 0.003$ Å and 0.1°, respectively).

corresponds approximately to that in B_2S_3 (1.808 Å[1]) and once again, in agreement with the planarity of the molecule, is indicative of strong (p-p)π interactions. The significant difference between the two types of B—S bond lengths in the five-membered rings (Fig. 1) provides the first confirmation of the differing π bond orders estimated by CNDO calculations on trithiadiborolanes[5]. The similarity of the structural characteristics to those of dimethyl- and dichloro-1,2,4,3,5-trithiadiborolane in the gas phase[6] demonstrates the remarkable, substituent-independent constancy of the bonding in the stable five-membered ring.

A second synthetic route leading to B_8S_{16} was found in the thiolysis of the halogenated trithiadiborolanes described by *Schmidt* and *Siebert*[7]. Thus reaction of 3,5-dibromo-1,2,4,3,5-trithiadiborolane with trithiocarbonic acid as an H_2S generator[8] in dilute CS_2 solution according to

affords the porphine-like B_8S_{16} in *ca.* 6% yield along with polymeric $(B_2S_4)_x$ chains made up of S-linked B_2S_3 five-membered rings[9]. Cyclization can be promoted in the reaction mixture by addition of d^8 or d^9-transition metal compounds; the geometry of the B_8S_{16} molecule permits formation of interesting transition metal complexes having square-planar coordination of the tetradentate ligand (transannular S···S distance in B_8S_{16}: 4.667 Å).

In addition to other fragmentation products, the mass spectrum shows $B_2S_3^+$ as fragment of maximum intensity. The Raman spectrum contains bands at 942, 935, 883, 861, 835, 590, 530, 518, 462, 439 (vs), 344, 328 cm^{-1} in the region of stretching vibrations.

Hexakis(dimethylamino)cyclohexaborane, a Boron(I) Compound without Electron Deficiency

By *Heinrich Nöth* and *Hans Pommerening*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The molecular structures of boron(I) compounds in the solid state are characterized by B_n-polyhedral frameworks: B_4Cl_4 a tetrahedron *(1a)*[1a], B_8Cl_8 a square antiprism[1b], $(BCl)_{10}(CH)_2$ and $B_{12}H_{12}^{2-}$ an icosahedron[1c, d]. Surprisingly, however, in solution B_4Cl_4 shows a ^{11}B-NMR signal at $\delta = 85$ relative to $BF_3 \cdot OEt_2$[2a], which would contradict a *closo* structure, yet support presence of threefold coordinated boron (the same applies for B_4Br_4[2b]). According to *Williams*[3] B_4Cl_4 could therefore adopt the four-membered ring structure *(1b)* in solution. If this assumption is supported by further findings, then a polyhedral ring rearrangement

(1a) *(1b)*

would be demonstrated for the first time in the realm of boron chemistry[4]. Apparently, neither the energy difference between the two structural isomers is particularly large, nor the

[*] Prof. Dr. H. Nöth, Dr. H. Pommerening
Institut für Anorganische Chemie der Universität
Meiserstr. 1, D-8000 München 2 (Germany)

activation energy to bring about the rearrangement. Weak BCl π-bonds could contribute to the stabilization of *cyclo*-B_4Cl_4 *(1b)*. Thus dimethylamino groups, which are capable of stronger π-interactions with boron, should promote the monocyclic isomer. *Urry et al.*[5] assumed that the product of the dimethylaminolysis of B_4Cl_4 has a ring structure, since bands typical for the B_4 tetrahedron are not present in the IR spectrum; however, unequivocal characterization of the presumed $B_4[N(CH_3)_2]_4$ is still lacking.

Dehalogenation of (dialkylamino)boron chlorides with Na/K alloy leads to products with B—B bonds[6a], of which the first four members of the series $B_n[N(CH_3)_2]_{n+2}$ ($n=2$—5) have been completely characterized; there is evidence for the formation of higher members[6b].

We have now found that orange-red prisms, m.p. 163 °C (dec.), slowly crystallize from the distillation residues of the dehalogenation of $[(CH_3)_2N]_2BCl$. In [D_8]toluene solution they show a single ^{11}B-NMR signal at $\delta=65$. Likewise only one ^{1}H-NMR and one ^{13}C-NMR signal ($\delta=2.87$ and 46.65, respectively) could be observed. The mass spectrum shows a characteristic isotopic pattern for six B atoms at $m/e=330$. These findings are consistent with the composition $B_6[N(CH_3)_2]_6$ with boron of coordination number 3, since the resonance of the $(CH_3)_2NB(B)_2$ groups of $B_3[N(CH_3)_2]_5$ and $B_4[N(CH_3)_2]_6$ lie in the same $\delta(^{11}B)$ region (50—60)[6b]. The cyclic structure of the new compound was confirmed by X-ray structure analysis.

cyclo-$B_6[N(CH_3)_2]_6$ crystallizes monoclinically (space group C2[7]), $a=951.9(9)$, $b=1747.9(11)$, $c=713.8(4)$ pm, $\beta=108.77(6)°$, $Z=2$, $\rho_{calc}=0.974$ g cm^{-3}. Figure 1 shows the ORTEP plot of a molecule which has the symmetry of point group C_2 in the solid state but according to the NMR spectra, must however have a higher symmetry (D_{3d}?) in solution.

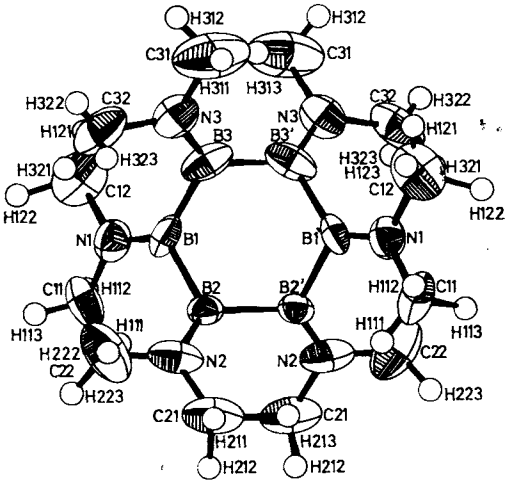

Fig. 1. Molecular structure of hexakis(dimethylamino)cyclohexaborane in the crystal. Selected bond distances [pm]: B1B2 170.4(13), B1B3 177.8(9), B3B3' 167.6(10), B1N1 139.7(5), B2N2 139.0(7), B3N3 140.7(7); bond angles [°]: B2B1B3 112.2(6), B1B2B2' 109.2(5), B1B3B3' 111.1 (5), B2B1N1 121.8(7), B3B1N1 124.9(7), B1B2N2 124.0(5), B2'B2N2 125.9(5), B1B3N3 123.1(5), B3'B3N3 124.5(5). The angle between the planes through B1B2B3 and B2B2'B3B3' is 57.6°; the C_2NB planes are twisted at an angle of *ca.* 65° to the NBB_2 planes.

All B and N atoms are planar coordinated. The twisting of the C_2NB planes w.r.t. the NBB_2 planes (Fig. 1) permits strong, though not optimum BN(pp)π bonding. The average BN distance of 140 pm is correspondingly longer than the shortest known BN distances (136 pm) in monoaminoboranes. The mean value of the unequal B—B bond distances in the solid state corresponds to that found in other six-membered ring systems containing B—B bonds (170 pm)[8].

The B_6 ring has a chair confirmation. Hence, as a consequence of the relatively strong BN(pp)π bonding, $B_6[N(CH_3)_3]_6$ also does not show any structural characteristics of an electron-deficient compound in the solid state. Structurally, the cyclohexaborane derivative resembles the radialenes[9a], particularly the isoelectronic $C_6(CHCH_3)_6$, whose C_6 ring is likewise not planar but shows a chair conformation[9b]. A more detailed comparison of the two isosteric systems will afford valuable information about the molecular states of the new boron compound. This opens an entry to further derivatives, since R_2N groups can easily be substituted.

Procedure

8.2 g of the distillation residue, obtained on preparation of $B_2[N(CH_3)_2]_4$ by reaction of 87.6 g of $ClB[N(CH_3)_2]_2$ with 25.6 g of Na/K alloy (1:3) in 350 ml hexane, was redistilled to remove $B_3[N(CH_3)_2]_5$ and $B_4[N(CH_3)_2]_6$[6b]. From the brown viscous oily residue *ca.* 30 mg of dark orange crystals separated out over four months; after decanting and washing with cold pentane, the crystals melt at 163—165 °C.

Boron Trifluoride: Crystal Structure of a Metastable Phase[**]

By *Dietrich Mootz* and *Michael Steffen*[*]

The trigonal-planar molecular structure of boron trifluoride and the B—F bond length of 1.31 Å were determined directly by spectroscopic and electron diffraction measurements in the gas phase[1]. We report here on the determination of the crystal structure of this simple compound.

[*] Prof. Dr. D. Mootz, Dipl.-Chem. M. Steffen
Institut für Anorganische Chemie und Strukturchemie der Universität
Universitätsstr. 1, D-4000 Düsseldorf (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

The growth of a single crystal in a sealed glass capillary on a diffractomer was achieved by slow cooling in a stream of cold gas to $-131\,^{\circ}C$ (m.p. $-127.1\,^{\circ}C$). All X-ray diffraction measurements were also carried out at this temperature. They were consistent with the monoclinic space group $P2_1/c$, giving the lattice constants $a = 4.779$, $b = 14.00$, $c = 7.430$ Å, $\beta = 107.60^{\circ}$ and eight molecules of BF_3 in the unit cell[2].

The molecules are planar; the B—F bond lengths (uncorrected for thermal motion) and the FBF angles vary between 1.26 and 1.31 Å (mean value 1.287 Å) and between 118 and 122°, respectively. Taking into consideration B...F contacts between 2.68 and 2.71 Å, the boron atoms have trigonal-bipyramidal coordination (Fig. 1).

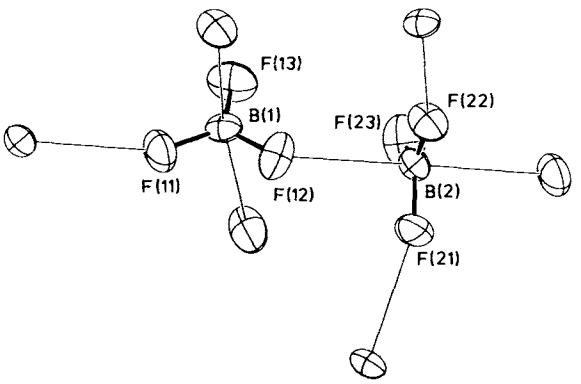

Fig. 1. The two independent BF_3 molecules with intermolecular B...F contacts (ORTEP diagram).

Each molecule is linked *via* such contacts with a total of four molecules of the other independent kind into a three-dimensional array. Linked molecules are always almost vertical to each other, since the two independent molecules are oriented almost vertical and parallel to the b axis. In each independent molecule one fluorine atom does not participate in this linking.

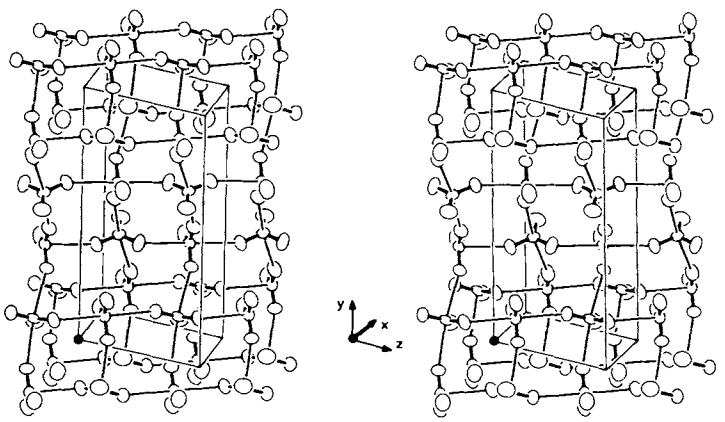

Fig. 2. Stereoscopic ORTEP diagram of the crystal structure of BF_3.

Thus, the crystal structure fundamentally differs from that of the other trihalides of boron with parallel orientation of only two molecules in a hexagonal unit cell[3]. This, and in particular marked interactions of eight molecules per unit cell in boron trifluoride, could already be concluded from IR and Raman crystal spectra[4,5]. The same cell content also results from single crystal X-ray photographs at $-173\,^{\circ}C$[5]; however, with similar latter constants the crystal system is described as triclinic. With X-ray powder measurements (Guinier-Simon technique) we could observe an enantiotropic phase change at $-147\,^{\circ}C$. The crystal structure given here is that of a yet another, metastable phase.

The $(Ph_4C_4GeMe)Fe(CO)_3$ Cation: Synthesis, Structure, and Bonding[**]

By *Peter Jutzi, Alfons Karl,* and *Peter Hofmann*[*]

Dedicated to Professor Helmut Behrens on the occasion of his 65th birthday

Tricarbonyl(η^4-cyclopentadiene)iron *(1)* can be transformed into tricarbonyl(η^5-cyclopentadienyl)iron cation *(2)* by elimination of hydride[1]. We have now also succeeded in eliminating the anionic ligand X from the germanium-containing complexes *(3a)* and *(3b)*[2]: quantitative removal of the hydride ion from *(3a)* can be accomplished by reaction with Ph_3CBF_4 in CH_2Cl_2, and that of the chloride ion from *(3b)* by treatment with $AgBF_4$ or $AgSbF_6$ in liquid SO_2. The resulting yellow salts *(4a)* and *(4b)* are amorphous to X-rays, very sensitive to hydrolysis, and thermolabile. On heating, preferably in a vacuum, they afford the fluorine compound

(3c) together with BF_3 or SbF_5. Conductivity measurements in CH_3NO_2 confirm that *(4a)* and *(4b)* are 1:1 electrolytes.

(3a—c), R = C_6H_5, X = H, Cl, F; *(3d)*, R = H, X = F
(4a, b), R = C_6H_5, anion = $BF_4^{\ominus}$ or $SbF_6^{\ominus}$; *(4c)*, R = H

Interestingly, the cation in the salts *(4a)* and *(4b)* is not to be regarded as an η^5-germacyclopentadienyl complex—by analogy with *(2)*—but as an η^4-diene complex in which the positive charge is localized mainly at the germanium atom. The proposed structure follows from a comparison of the spectroscopic data of *(4a, b)* and *(3a—c)*. Table 1 contains the principal data for *(3c)* and *(4b)*.

Table 1. Selected physical data of *(3c)* and *(4b)*.

(3c): ^{1}H-NMR (CS_2, CH_2Cl_2 int.): $\delta = 1.18$ (d, CH_3, $J = 5.1$ Hz); $^{13}C\{^1H\}$-NMR (CD_2Cl_2): $\delta = -1.2$ (d, CH_3, $J = 11.8$ Hz), 75.0 (d, C-2, 5, $J = 14.7$ Hz), 110.8 (C-3, 4), 211.1 (d, CO, $J = 52$ Hz); IR (cyclohexane: νCO = 2044, 1985 cm^{-1}; ^{57}Fe-Mössbauer spectrum: $\delta = +0.325$ mm/s rel. to $Na_2[Fe(CN)_5NO]\cdot H_2O$, $\Delta E^Q = 1.484$ mm/s
(4b): ^{1}H-NMR (CD_3NO_2): $\delta = 2.01$ (CH_3); $^{13}C\{^1H\}$-NMR (CD_3NO_2): $\delta = 0.58$ (CH_3), 82.8 (C-2, 5), 112.3 (C-3, 4), 209.2 (CO); IR (CH_3NO_2): νCO = 2049, 1989 cm^{-1}; ^{57}Fe-Mössbauer spectrum: $\delta = +0.355$ mm/s, $\Delta E^Q = 1.528$ mm/s; ^{121}Sb-Mössbauer spectrum: $\delta = +10.92$ mm/s rel. to SbIn, $\Delta E^Q < 3$ mm/s

While *(1)* and *(2)* differ significantly in their ^{13}C-NMR, ^{57}Fe Mössbauer, and νCO IR data, this is not the case for *(3)* and *(4)*. As demonstrated by the ^{13}C-NMR data of the ring carbon atoms, the CO frequencies in the IR spectra, and the ^{57}Fe Mössbauer data, the electronic conditions are very similar in the tricarbonyl(diene)iron units of the complexes *(3)* and *(4)*. The downfield shift of the ^{1}H- and ^{13}C-NMR signals of the methyl groups on going from *(3)* to *(4)* likewise constitutes indirect evidence for the positive charge on the germanium atom; the relatively slight effect suggests shielding by the $Fe(CO)_3$ unit of coordination or solvent molecules to three-coordinate germanium.

The similarity in bonding and in the $Fe(CO)_3$ coordination in the cation of the salts *(4a, b)* and in the diene complexes *(3a—c)* is confirmed by MO model calculations[3] on *(3d)*, *(4c)*, and *(2)*. A perturbation treatment of the interactions between the $Fe(CO)_3$ fragment and its valence orbitals[4] with the relevant orbitals of the pertinent organic ligand leads to a clear comparative description. The typical picture of a butadiene- or cyclopentadiene-$Fe(CO)_3$ complex[5] results for *(3d)* with strong bending of the ring center not bonded to iron, as known for analogous molecules[6]. The calculations on the cation *(4c)* show that incorporation of the electropositive Ge atom into the cyclic ligand leads to a kind of bonding far more similar to that in tricarbonyl(diene)iron complexes and thus in *(3a—d)* than to that in *(2)*. The changes occurring in the π system of the cyclopentadienyl ligand on replacement of a CH by a $GeCH_3$ group are shown in Figure 1.

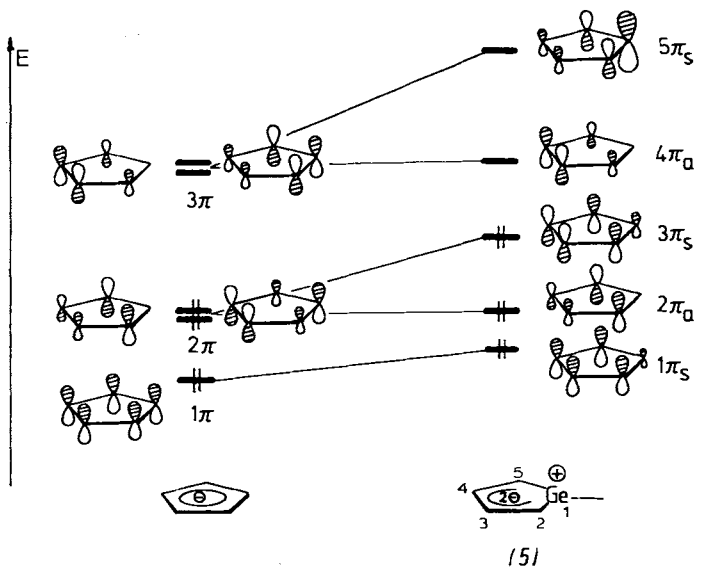

Fig. 1. Bonding in cyclopentadienide and 1-methylgermacyclopentadienide ion [resonance formula *(5)*].

The destabilization of the orbitals $1\pi_s$, $3\pi_s$, and $5\pi_s$ compared to those in the C_5H_5 parent conserves the butadiene character of the cyclic ligand, even for cations of type *(4)*. The small orbital coefficients at Ge in the $1\pi_s$ and $3\pi_s$ MOs lead to more pronounced localization of the positive charge on the electropositive ring atom, which is predicted by the rules of perturbation theory to play a significant role in the wave function only in the highest π orbital $5\pi_s$. The model calculations require that the $Fe(CO)_3$ unit be shifted from the center of the ring[7] towards the C^3—C^4 bond and that the $GeCH_3$ group be bent upwards by about 10°[7]. In terms of resonance theory, the butadienoid character of the $C_4H_4GeCH_3^{\ominus}$ ligand and the positive charge on the germanium could be expressed as participation of the resonance formula *(5)* in the ground state.

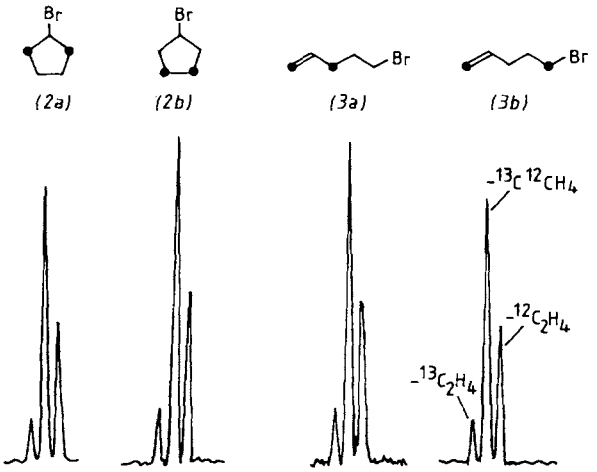
rearrangements involving reorganization of the C-skeleton, *(1a)* ⇄ *(1b)*, have not yet been demonstrated.

(1)

(1a) *(1b)*

We have now studied this possibility experimentally in the gas phase. Dissociative ionization (electron impact MS at 70 eV and at 12 eV) of doubly ^{13}C labeled isotopomeric precursors, the bromocyclopentanes *(2a)* and *(2b)* and the acyclic 5-bromo-1-pentenes *(3a)* and *(3b)*, led to $C_5H_9^+$ ions. The unimolecular elimination of ethylene from these $[M-Br]^+$ ions (whose lifetime was $\approx 10^{-5}$ s), was followed by the MIKES method[2] (Fig. 1).



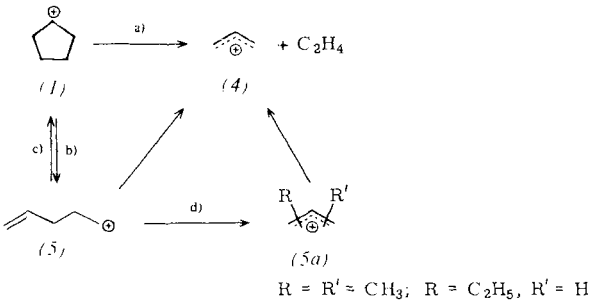


Fig. 1. Unimolecular ethylene elimination from the $[M-Br]^+$ ions of *(2a)*, *(2b)*, *(3a)*, and *(3b)*. (●) Indicates a ^{13}C-labeled center.

Table 1. $^{13}C/^{12}C$-Isotope distribution [%] on ethylene elimination from the $[M-Br]^+$ ions of *(2a)*, *(2b)*, *(3a)*, and *(3b)*. The data were obtained from the areas of the peaks shown in Figure 1.

Ethylene	Precursor				Calculated
	(2a)	*(2b)*	*(3a)*	*(3b)*	for C-equilibration
$^{13}C_2H_4$	10.4	9.9	10.4	9.8	10
$^{13}C^{12}CH_4$	59.0	59.7	61.6	58.8	60
$^{12}C_2H_4$	30.6	30.4	28.0	31.4	30

The data in Table 1 are convincing: $C_5H_9^+$ ions from both cyclic and acyclic precursors undergo statistical carbon scrambling before C_2H_4 is eliminated. These results are not consistent with a number of mechanistic models which have been discussed in the literature[1b,3], *e.g.*, a) cycloreversion,

(1)→*(4)*, b) two stage decomposition of *(1)* *via* *(5)*, c) head/tail cyclization, *(1)* ⇄ *(5)*, followed by ethylene elimination, or d) hydride shift along the C_5 chain, *(5)*→*(5a)* before heterolysis to *(4)*.

We now propose an alternative mechanism which is consistent with all available evidence. This is shown in Figure 2, which summarizes reaction profiles obtained from MINDO/3 calculations; all minima and transition states are geometry-optimized. Figure 2 indicates that carbon scrambling in the cyclopentyl carbon *(1)* can, in principle, proceed either *via* the bisected cyclobutylcarbinyl cation *(6)* or *via* the non-classical, pyramidal cation *(7)*[4]. The transition states, TS_1 and TS_2, for both these rearrangements lie well below TS_3, which represents our proposed transition state for ethylene elimination from *(7)*. In contrast, ethylene elimination from *(6)* or from acyclic $C_5H_9^+$ ions are less likely energetically. Of all the paths we have investigated by calculation, the most favorable involves pyramidal *(7)*, which thus serves both as the carbon scrambling intermediate and as the species from which ethylene elimination can take place. Electronic reorganization in *(7)* leads to transition state *(8)* which can be regarded as a partially opened cyclopropyl cation "solvated" by interaction with C_2H_4[5].

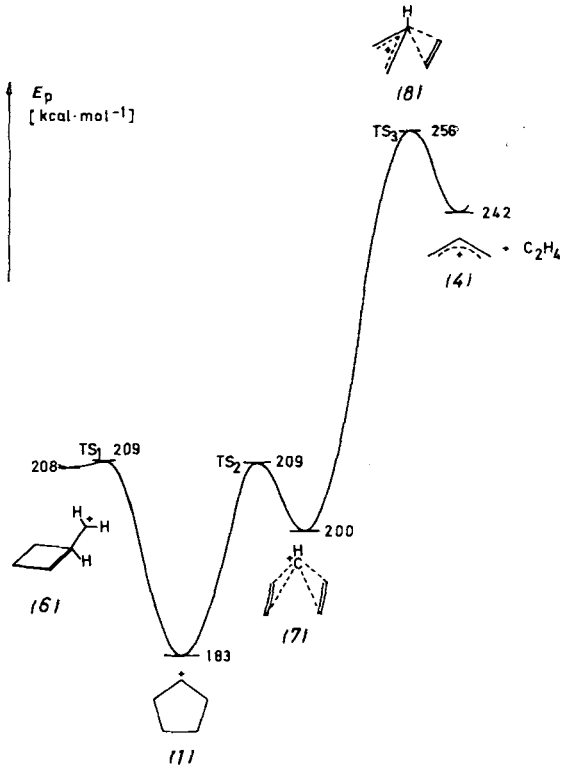

Fig. 2. MINDO/3 reaction profiles for the C-equilibration in the cyclopentyl cation *(1)* and for the reaction $C_5H_9^+ \rightarrow C_5H_7^+ + C_2H_4$.

It seems unlikely that acyclic pentyl cations *(5)* are involved in any of the reaction processes (ionization, Br^--loss, C-equilibration, or ethylene elimination)[3]; such primary carbocations are not expected to be minima on the potential energy surface. Instead, rearrangements concerted with ion formation should take place. Hydride shifts would lead to acyclic allyl cations which would split off ethylene only with difficulty energetically. The experimental observation that the $[M-Br]^+$ ion from *(3)* also undergoes complete carbon scrambling is consistent with the assumption that *(1)* [or *(6)*] rather than *(5)*, is the first intermediate, formed by π-electron participation during the ionization process[6]. *(1)* or *(6)*

© Verlag Chemie, GmbH, 6940 Weinheim, 1980
0570-0833/80/0606-486 $ 02.50/0

would then react further according to the scheme in Figure 2.

Does the equilibration, *(1a)*⇌*(1b)*, also take place in condensed phases? This question cannot be answered as yet. In SbF_5—SO_2ClF solution, the ^{13}C-NMR chemical shift of *(1b)* is 10 Hz upfield and of *(1a)* 4 Hz downfield from the normal cyclopentyl cation ^{13}C-NMR chemical shift. This means that the interconversion *(1a)*⇌*(1b)* could easily be detected experimentally. However, experiments at −20 °C or at lower temperatures indicated no such scrambling; the barrier must thus be greater than about 16 kcal mol^{-1}, in general agreement with the theoretical results. If complications with ion decomposition can be overcome, experiments at higher temperatures may provide additional information.

(7) is one of the simplest representatives of an increasingly populated class of pyramidal carbocations formally comprised of a CH^+ "cap" interacting with various four electron systems[4]. At the *ab initio* theoretical level, *(7)* is also found to be an energy minimum, but lying higher than the classical

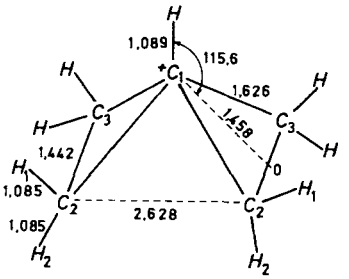

Fig. 3. *Ab initio* geometry of *(7)* calculated with the STO-3G basis set: C_{2v} symmetry; ∢ $H_1C_2O = 119.9$, ∢ $H_2C_2O = 119.7$, ∢ $H_1C_2OC_1 = 260.9$, ∢ $H_2C_2OC_1 = 105.4°$ (o is the midpoint of C_2C_3).

cyclopentyl cation *(1)* by 45.4 kcal mol^{-1} (STO-3G basis set optimized) or 30.8 kcal mol^{-1} (4-31G//STO-3G). The calculated STO-3G geometry is indicated in Figure 3.

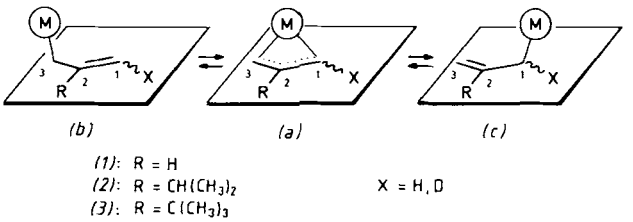
[5] The process *(7)*→*(8)*→*(4)* + C_2H_4 is closely related to the elimination of H_2 from $C_3H_7^+$. A transition state for the latter involving a similar partially opened cyclopropyl cation "solvated" by H_2, has been postulated on the basis of MINDO/3 calculations: *H. Schwarz, W. Franke, J. Chandrasekhar, P. v. R. Schleyer*, Tetrahedron *35*, 1969 (1979).



[6] Following *Baldwin*'s rules, the process, *(3)*‡ → *(6)* + Br$^{\cdot}$, should be favored over the alternative, *(3)*‡ → *(1)* + Br: *J. E. Baldwin*, J. Chem. Soc. Chem. Commun. *1976*, 734.

Allylic Compounds of Magnesium, Lithium, and Potassium: σ- or π-Structures?[**]

By *Manfred Schlosser* and *Manfred Stähle*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Hitherto, organic compounds of alkali and alkaline-earth metals have only rarely been obtained in crystalline form, and even then required mostly complexation with an unusual ligand such as tetramethylethylenediamine[1]. Owing to a lack of X-ray structure data, the question of the bonding between metal and the carbon skeleton in, say, allyllithium remains open. Even if they could reliably provide the desired accuracy of 1—3 kcal/mol, quantum chemical calculations[2a] will continue to be unrealistic as long as they assume "naked" rather than peripherally solvated metals[2b]. Nor has NMR spectroscopy provided unequivocal information about the bonding involved. Magnetic equivalence of the two terminal sites of allyllithium[3] is equally compatible with a ground state having mirror symmetry (π-structure *(1a)*, X = H, η^3-allyl ligand) as with fast, reversible transition between two identical and asymmetric metallomers (σ-structures *(1b)* and *(1c)*, X = H, η^1-allyl ligand). Nevertheless, the degree of uncertainty can be reduced: for instance, if the ^1H- and ^{13}C-NMR spectra of 2-isopropylallylpotassium *((2)*, X = H)[4] fails to show diastereotopism of the methyl groups even at −155 °C then the activation barrier for the oscillation of the metal cannot exceed 4 kcal/mol, provided that such a motion takes place at all.

We hoped to gain clearer insight by use of the isotopic perturbation technique developed by *Saunders et al.*[5] to distinguish between "classical" and "non-classical" carbocations. Owing to the lower zero point energy of the CD, as compared to the CH bond[6], the heavy hydrogen isotope should show a significantly greater preference than the light one for an olefinic carbon atom if it has a choice between such an atom and a saturated one. Thus, on introduction of deuterium into one of the allylic termini the proportion of metallomer *(b)* should increase at the expense of *(c)* if they are present in equilibrium (dynamic isotope effect). Independently of the exchange rate, separate signals should appear for the two terminal carbon nuclei, to the right and the left of the original signal. In the case of a symmetrical structure *(a)*, on the other hand, the deuterium would merely lead to a slight, isotope-specific upfield shift (static isotope effect).

We have recorded the ^{13}C-NMR spectra of some deuterium-free and mono-deuterated allyl-metal compounds *((1)—(3)*, X = H and D, Table 1 and Figures 1 and 2), obtained by metalation of propene, [3-^{2}H]propene[7a], 2,3-dimethyl-1-butene, 2-([^{2}H]methyl)-3-methyl-1-butene[7a], 2,3,3-trimethyl-1-butene, and 2-([^{2}H]methyl)-3,3-dimethyl-1-butene[7a] with

[a] The absolute chemical shifts may vary by up to 0.5 ppm from sample to sample since they are temperature- and, in particular, concentration-dependent. The chemical shift difference between two neighboring signals is reproducible with a reliability of at least 0.05 ppm. [b] Owing to the possible effect of solvent on the Schlenk equilibrium (cf. *Stucky et al.*, J. Am. Chem. Soc. *92*, 1150 (1970)) the spectra of the diethyl ether solutions of the organomagnesium compounds were also measured; the chemical shifts were almost identical [$\delta(C^3)=58.7$ and 57.7, $\delta(C^2)=148.2$ and 148.3, $\delta(C^1)=58.7$ and 59.1 for the deuterium-free and the monodeuterated compound]. [c] At −35 °C (in diethyl ether) the individual signals are farther apart [$\delta(C^3)=57.5$, $\delta(C^2)=147.9$, $\delta(C^1)=59.2$] and overlap only slightly. [d] Leads to splitting of the $\delta(C^1)$ signal to a 1:1:1 triplet ($J=21$—23 Hz). [e] Accurate determination was impossible since the triplet of the deuterated carbon atom is not cleanly split.

trimethylsilylmethylpotassium[7b] and, where appropriate, by subsequent treatment with lithium bromide or magnesium dibromide. Allylmagnesium bromide *(1)*-MgBr is accordingly seen to have a *monohapto* structure ("σ-compound") in tetrahydrofuran and diethyl ether. The signal of the deuterated and hence split (1:1:1 triplet) carbon atom C^1 and that of its next-but-one neighbor C^3 are distinctly separated. The difference of *ca.* 1.9 ppm [$\delta(C^1)-\delta(C^3)$; +0.4 ppm for the static isotope effect] reveals an equilibrium distribution of *(1b)*-MgBr : *(1c)*-MgBr (at 24 °C) between 51:49 and 52:48[8]. In the lithium compounds *(1)*-Li and *(3)*-Li, however, deuteration gives rise to only a slight downfield shift (0.1 ppm).

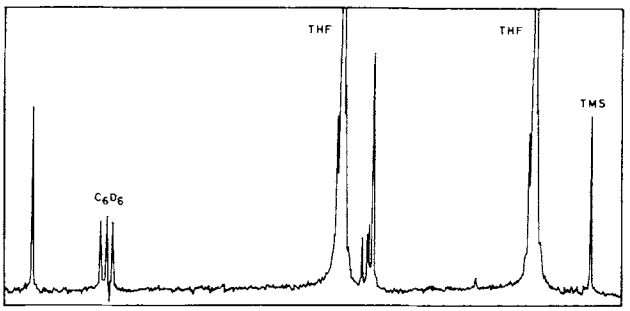

Fig. 1. ^{13}C-NMR spectrum of terminally monodeuterated allylmagnesium bromide in THF at 24 °C. The differences relative to the spectra of allyllithium and -potassium are not very large, they only become noticeable on stretching the spectra (Fig. 2).

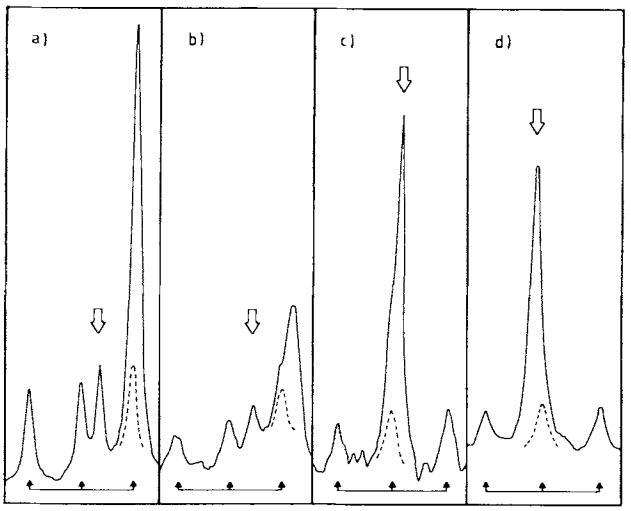

Fig. 2. ^{13}C-NMR spectra of a) [1-^{2}H]magnesium bromide contaminated with a small amount of allylmagnesium bromide (broad arrow!) at +24 °C; b) at −35 °C; c) and d) [1-^{2}H]allyllithium and potassium in THF at +24 °C. The position of the 1:1:1 triplet assigned to the deuterated carbon atom is shown in all cases by a three-pronged rake, and masked parts of signals are indicated by broken lines.

Table 2. ^{13}C-NMR data of allyl, crotyl, and prenyl-magnesium bromide, lithium, and -potassium (*(1)*, *(4)*, and *(5)*) in tetrahydrofuran solution at 25 or −40 °C [a]: chemical shifts (rel. to TMS) [b—d].

[a] The samples of *exo*-2-butenylpotassium and of prenyllithium and -potassium must be kept below −40 °C since they are otherwise unstable. [b] Crotyl = 2-butenyl; prenyl = 3-methyl-2-butenyl. [c] Where two series of numbers are given for a crotyl derivative *(4)*, the upper values apply to the *endo(cis)* isomer and the lower ones for the *exo(trans)* isomer; the upper value in the $\delta(CH_3)$ column of prenyl derivatives *(5)* refers to the *endo(cis)* and the lower one to the *exo(trans)* methyl group. [d] The $\delta(C^3)$ and the $\delta(C^1)$ values are informative; the other signals (in italics) are given only for the sake of completeness. [e] The chemical shifts of the hydrocarbons propene, 2-butene, and 3-methyl-2-butene are given for comparison; the single methyl group is always referred to as C^1. [f] Mixed signals arising by fast and reversible transition between two mirror-image structures; for "frozen" structures we would expect approximately 92 and 22 for the $\delta(C^3)$ and $\delta(C^1)$ values of allylmagnesium bromide and 57 and 45 for those of allyllithium. [g] Not recognizable at 25 °C since probably excessively broadened by coalescence; on cooling (to −30 °C) two separate signals appear at 18 and 26 ppm (the latter is masked by THF) and a mixed signal appears at 22 ppm on warming. [h] Data for crotyllithium: *J. P. C. M. van Dongen, H. W. D. van Dijkman, M. J. A. de Bie*, Rec. Trav. Chim. Pays-Bas *93*, 29 (1974). [i] Masked by signals of the usual solvent THF ($\delta=68$ and 26), visible in dimethyl ether ($\delta=59$).

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/0606-488 $ 02.50/0*

Hence we conclude that allyllithium possesses a non-symmetrical π-structure with similar, but not identical C^1Li and C^3Li bond lengths. Asymmetrically distorted π-complexes of transition metals are already known[9]. In contrast, allylpotassium *(1)*-K, 2-isopropylallylpotassium *(2)*-K, and 2-*tert*-butylallylpotassium *(3)*-K apparently form (closely or perfectly) symmetrical "π-complexes" in tetrahydrofuran and in diethyl ether[10] as a result of an essentially regular *trihapto* interaction between metal and allyl moiety. The signal of the deuterated carbon atom is shifted upfield by 0.2 ppm relative to the other terminal site.

We then examined whether the conclusions drawn for the allyl series also apply to the homologous crotyl- and prenylmetal compounds. This is confirmed by the chemical shifts (Table 2). The spectra of the magnesium compounds resemble those of the corresponding hydrocarbons (*(4)* and *(5)*, M = MgBr and H). Thus, as already assumed by *Roberts et al.*[11] on the basis of the ^{1}H-NMR spectra, σ-structures with the metal attached to the primary carbon atom have to be attributed to all allylic Grignard compounds. The relative upfield shift of the $\delta(C^3)$ signal indeed suggests a certain accumulation of electron density at the substituted end of the allylic moiety. Moreover, a polarizing interaction between metal and double bond (a kind of partial valence) may also be considered. The downfield shift of the $\delta(C^2)$ signal would be compatible with such an effect. Conversely, on the basis of the NMR data, crotyl and prenyl-potassium [*(4)*-K and *(5)*-K] belong to the essentially symmetrical π-structures. The large atomic radius of the metal favors the η^3-bonding state in two respects: potassium readily spans the allylic ligand from one end to the other and the gain in energy on addition of a further solvent molecule (cf. [2b]) would be smaller than in the case of lithium or magnesium[12]. The lithium compounds *(4)*-Li and *(5)*-Li are regarded as unequally distorted π-complexes, with the bond to the secondary or tertiary carbon atom appearing to become longer and weaker with increasing degree of substitution. While allyllithium itself presumably exhibits only slight asymmetry, prenyllithium probably occupies a position intermediate between the η^1 and η^3 bond types.

(1): R = R' = H
(4): R = H, R' = CH_3 (*endo*); R = CH_3, R' = H (*exo*)
(5): R = R' = CH_3

More detailed structural knowledge should provide a better understanding of the regioselectivity of allylmetal reactions and thus permit their directed modification. However, it should not be overlooked that large energy differences are not to be expected between σ- and π-allyl compounds of alkali and alkaline earth metals. *Structural changes immediately prior to reaction* can consequently not be ruled out *a priori*.

[10] The spectra of 2-*tert*-butylallyllithium and -potassium recorded in diethyl ether (DEE) or tetrahydrofuran (THF) are almost identical. The insufficient solubility of allylpotassium in pure DEE precludes such a comparison for this compound. In a 1:1 mixture of DEE/THF close pairs of peaks are found at the same positions where single lines occur in pure THF (δ = 144 and 53). This doubling could be due to aggregate formation (coexistence of dimers and monomers or boat-like and chair-like dimers?).

The First "Small Ring" in Fluorometalates: $Ba_6F_4(F_4AlF_{2/2})_4$ = "$Ba_3Al_2F_{12}$"

By *Rainer Domesle* and *Rudolf Hoppe*[*]

In contrast to many "cation-rich" oxometalates, not one of the hundreds of known fluorometalates possesses a polynuclear anion (such as $Na_{10}[Co_4O_9]$[1a]) or cyclic anion (such as $K_4[Ag_4O_4]$[1b]).

The number of hexafluorometalates such as $Na[Rh^VF_6]$[2a], $K_2[Ni^{IV}F_6]$[2b], or $Cs_2K[Ag^{III}F_6]$[2c] is especially large. A naturally occurring example of such fluorides of aluminum is $Na_3[AlF_6]$, cryolite. In place of the octahedral structural unit AlF_6, octahedra are linked to form an *infinite chain* in the fluorine-poorer compounds such as $Tl_2[AlF_5] = Tl_2[AlF_{4/1}F_{2/2}]$[3a], to form a *two-dimensional sheet* in $K[AlF_4] = K[AlF_{2/1}F_{4/2}]$[3b], and to form a *three-dimensional skeleton* in others such as $Cs[AgF_3] = Cs[AgF_{6/2}]$[3c]; $Cs[AlF_4] = Cs_3[(F_2AlF_{2/2}F_{2/2})_3]$ represents a remarkable special case having a "one-dimensional three-stranded chain" of three mutually *cis*-linked octahedra[3d].

What is the structure of $Ba_3Al_2F_{12}$? Is it a simple analogue of cryolite conforming to $Ba_3[AlF_6]_2$? Does the "counterpolarizing" action of Ba^{2+} lead to structural peculiarities, as for instance in $Ba_2ZnF_6 = Ba_2F_2[ZnF_{2/1}F_{4/2}]$[4]?

We have obtained the low-temperature form α-$Ba_3Al_2F_{12}$ for the first time from the flux (650 °C) as lustrous, colorless,

[*] Prof. Dr. R. Hoppe, Dr. R. Domesle
Institut für Anorganische und Analytische Chemie der Universität
Heinrich-Buff-Ring 58, D-6300 Giessen (Germany)

transparent, multi-faceted single crystals. Contrary to earlier claims[5], powder data show α-$Ba_3Al_2F_{12}$ to form orthorhombic crystals in Pnnm-D_{2h}^{12} with $a = 10.18_7$, $b = 9.86_9$, $c = 9.50_2$ Å, $Z = 4$, $\rho_{calc} = 4.82$ and $\rho_{exp} = 4.79$ g cm^{-3}.

As shown by structural elucidation [four-circle diffractometer PW 1100, $Mo_{K\alpha}$, 1958 I_0 (*hkl*); $R = 7.2_9$, and $R_w = 5.6_7\%$]—cf. motifs of mutual assignment in Table 1—there are no "isolated" [AlF_6] octahedra present. Surprisingly, this is the first case of a fluorometalate containing a tetrameric structural unit according to $Ba_6F_4[(F_{4/1}AlF_{2/2})]_4$, a "ring" such as has only been encountered previously in a few neutral molecules $(MF_5)_4$ with M = Mo, Ru, *etc.*[6]. In those cases ring formation was discussed as an effect of the d orbitals[7]. We consider it remarkable that they can play no role in the present case.

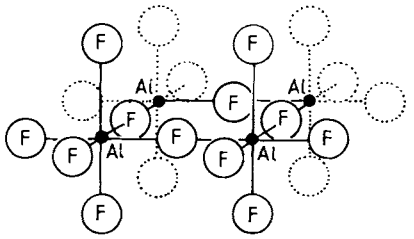

Fig. 1. The $[(F_4AlF_{2/2})_4]^{8-}$ "ring".

Four Al atoms situated in a plane form an almost square (edge length 3.50_1 and 3.54_2 Å) rectangle. Two of the four bridging F atoms lie in the same plane but are slightly displaced towards the center of the ring; the other two are not only displaced outwards but also in a manner slightly suggestive of a "chair" conformation. Four further terminal F atoms complete the octahedra around each Al. The coordination number of Ba is 10—11; however, naive counting proves difficult for Ba(2) and Ba(3) (cf. Table 1). The "rings" are in a space-saving arrangement (Fig. 2).

The Madelung part of the lattice energy (MAPLE[8]) for $Ba_3Al_2F_{12}$ (5141 kcal/mol) is in good agreement ($\Delta = 0.7\%$) with the sum of the MAPLE values of the binary fluorides (5179 kcal/mol). It remains to be investigated whether, and if so to what extent, paramagnetic ions of transition metals can be incorporated into the ring in place of Al^{3+}.

nents on going to the corresponding compounds of elements of Groups V and IV[1]. Heteropolar interactions are also characteristic of the alkali and alkaline earth metal salts of acids with complex anions (*e.g.* sulfates, phosphates, *etc.*), and yet there is a lack of systematic studies on compounds with complex anions with analogous metallic bonding components. We have now synthesized the compounds $Sr_3Si_2As_4$ *(1)* and $Sr_3Ge_2As_4$ *(2)* which have a metallic luster but appear red by transmitted light when viewed as thin layers; complete X-ray structure analysis on single crystals[2] showed them to contain networks of infinite chains which are to be interpreted in this way (Figs. 1 and 2).

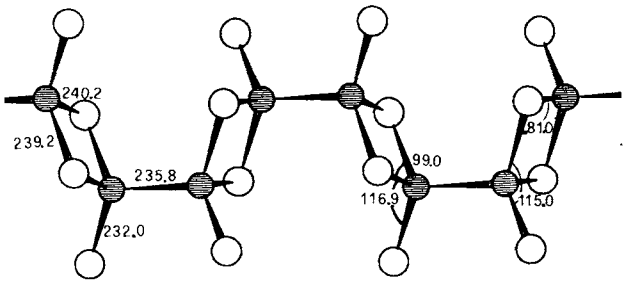

Fig. 1. $[Si_2As_4^{6-}]_n$ anion in $Sr_3Si_2As_4$ *(1)*: ⊜ Si, ○ ≙ As.

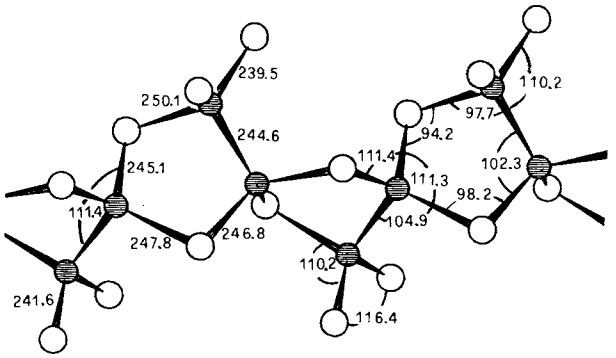

Fig. 2. $[Ge_2As_4^{6-}]_n$ anion in $Sr_3Ge_2As_4$ *(2)*: ⊜ Ge, ○ ≙ As.

In the two novel compounds *(1)* and *(2)* the Si and Ge atoms are surrounded tetrahedrally by three As atoms and one neighbor of the same kind. Thus As_3Si—$SiAs_3$ and As_3Ge—$GeAs_3$ units arise, which, in the case of the silicon compound, are linked by shared edges (cf. Fig. 1) to form one-dimensionally infinite chains. In contrast, the As_3Ge—$GeAs_3$ units in the germanium compound are joined together in such a way that all three As atoms of a $GeAs_3$ group form bridges while only one As atom of the other $GeAs_3$ group contributes to the network; two As atoms are still terminal (Fig. 2). In both cases, chain anions result which are shown by their composition and the coordination of their components (Zintl-Klemm concept[1]) to require description as $(Si_2As_4^{6-})_n$ and $(Ge_2As_4^{6-})_n$. The six negative charges are compensated by three Sr^{2+} ions.

Our results clearly show that transition from salts with complex anions to ternary intermetallic compounds leads to transitions in bonding similar to those demonstrated previously for numerous binary compounds[1].

Experimental

Stoichiometric amounts of the elements are heated to 1150 °C under argon in a corundum crucible in an evacuated quartz bomb kept at that temperature for 1 h, and then cooled at a rate of *ca.* 100 °C per hour. Crystalline platelets can be broken out of the homogeneous reguli.

Catalytic Graphite-Intercalation with Alkali Metals in Solution[**]

By *Hans-Friedrich Klein, Joachim Gross,* and *Jürgen O. Besenhard*[*]

Liquid or evaporated alkali metals A form stoichiometric lamellar intercalation compounds AC_x with graphite or graphite-like samples of carbon. These compounds differ in the number n of carbon planes between two layer vacancies occupied by A (compounds of the n-th stage) and in the occupation of the interlayer vacancies.

When A = K, Rb, Cs, then $x = 8$, 24, 36, 48, 60 for compounds AC_x of the 1st to 5th stage[1a], whereas other compositions were found for A = Li, Na, *e.g.* LiC_6 and LiC_{12} for the 1st and 2nd stage[1b].

The formation of AC_x can also be accomplished in metallic reducing solutions, *e.g.* of A in liquid ammonia[2a], by alkali metal salts of organic radical anions such as naphthalenesodium in ethers[2b], and by electrochemical reduction of graphite in aprotic solutions of $A^{\oplus}$ salts[2c].

However, these procedures require strongly polar solvents which solvate $A^{\oplus}$ and lead to ternary compounds $A(solv)_yC_x$ which are generally extremely labile.

Solvate-free alkali metal intercalation compounds have so far only been accessible from the elements at elevated temperature, with intercalation usually being performed in high vacuum from the vapor phase[3].

We have now found a catalytic method of generating non-solvated compounds KC_8, RbC_8, and CsC_8 from graphite[4] in an apolar medium, at room temperature, and in short reaction times [reaction (1)].

$$\text{A + flake graphite} \xrightarrow[\text{pentane, 25°C}]{\text{[catalyst]}} AC_8 \qquad (1)$$
$$A = K, Rb, Cs$$

The catalysts used are monoolefintris(trialkylphosphane)cobalt(0) complexes which are reversibly reduced in an apolar medium. A reduced form of the catalyst A[Co(olefin)$(PR_3)_3]_2$[5] transports the alkali metal through the hydrocarbon solution to the graphite where the cobalt(0) complex is regenerated (Fig. 1). R is preferably methyl.

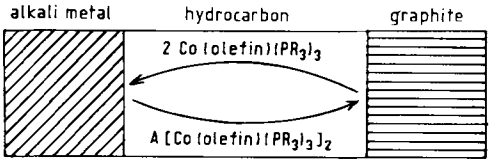

Fig. 1. Catalytic intercalation of graphite (A = K, Rb, Cs).

[**] This work was supported by the Fonds der Chemischen Industrie.

In polar solvents ternary compounds $A(solv)_yC_x$ are expectedly formed according to eq. (1); this also provides the first one-step entry to such compounds solvated with arenes[6a]. Thus, reaction of HOPG (highly oriented pyrolytic graphite) with excess potassium (10% $Co(C_2H_4)(PMe_3)_3$ in benzene, 8 d, 25 °C) gave the C_6H_6-solvated compounds of the 1st and 2nd stage, for which the compositions $K(C_6H_6)_yC_{24}$ and $K(C_6H_6)_yC_{48}$ and basal spacings of 930 and 1260 pm, respectively, are given[6b]. For the 2nd stage, however, we found a basal spacing of only 1245 pm[7]. Although the composition and X-ray diffraction data of the nonsolvated and the solvated alkali metal-graphite compounds correspond to those reported in the literature, some of the properties of the catalytically generated species are modified:

On rigorous exclusion of air, KC_8 forms lustrous golden flakes. They swell on contact with benzene, turning black. "High-temperature" KC_8 has been described as inert towards this arene[6a]. During the synthesis of KC_{24} we observed that a small portion of the graphite flakes adopts a golden sheen immediately after dissolution of the potassium, while the major part appears unchanged.

Only after prolonged reaction times (10% $Co(C_2H_4)(PMe_3)_3$ in pentane, 5 d, 25 °C) are all the flakes uniformly dark blue and have the same basal spacing. Equation (2) describes the overall reaction. The cobalt complex also catalyzes equilibration between phases of different degrees of intercalation.

$$K + \boxed{C_x} \xrightarrow[\text{pentane, 1 d, 25 °C}]{\text{[catalyst]}} \boxed{KC_8} \xrightarrow[\text{pentane, 4 d, 25 °C}]{\text{[catalyst]}} \boxed{KC_{24}} \qquad (2)$$

The reaction mechanism was confirmed by X-ray powder diagrams for nonsolvated K, Rb, and Cs compounds: After short reaction times only the compounds of the 1st stage (AC_8) were generally observed along with unchanged graphite. On prolonged reaction times compounds of higher stages could be prepared with appropriate quantities of potassium.

Thus, intercalation according to reaction (1) is kinetically controlled. Nucleation of the AC_x phases appears to be the rate determining step. In contrast, electrochemical intercalation is thermodynamically controlled, *i.e.* the reaction proceeds starting from graphite *via* higher stages to the 1st stage as the final product[2c].

The unusual reactivity of catalytically generated KC_8 is probably attributable to disorder effects. In general, solid state reactions performed at room temperature lead to less ordered, and hence frequently more "active" products than high temperature reactions.

Catalytic intercalation in solution permits the first transformation of highly oriented carbon fibers into good electrical conductors by conversion into KC_8[8].

Preliminary experiments have shown that solution intercalation of alkali metals can also be accomplished with metal chalcogenides having layer structures (MoS_2, WS_2). Catalytic reductions with Li are also feasible. Thus gray antimony (1.7 g, 1% $Co(C_5H_8)(PMe_3)_3$ in tetrahydrofuran (10 ml), 48 h, 25 °C) quantitatively yields the cubic low-temperature phase β-Li_3Sb. The potential of these highly reducing solutions is estimated at 2.5—3 V.

Nonstoichiometric Alkali Metal Titanium Sulfides with Channel Structure

By *Robert Schöllhorn, Wolfgang Schramm,* and *Dieter Fenske*[*]

The reduction of binary transition metal chalcogenides M_yX_z in alkali metal halide melts represents a suitable technique for the preparation of ternary chalcogenides $A_xM_yX_z$ (A = alkali metal, M = transition metal, X = S, Se, Te)[1]. In a study on the Ti/S system we observed the formation of the ternary sulfide $K_{0.3}Ti_3S_4$, which crystallizes in a structure type not described so far for the alkali metal titanium sulfides. Reduction of TiS_2 in a KCl melt at 1300 K with potassium metal (TiS_2:K = 1:1.7) leads to formation of a solid phase consisting of gray, needle-shaped crystals with a metallic luster; analytical data correspond to a ratio K/Ti/S = 0.3/3/4. Direct reduction of TiS_2 with K in titanium vessels at 1300 K yields the same compound, which, however, is contaminated by additional phases. Guinier powder diagrams and Weissenberg single crystal photographs showed $K_{0.3}Ti_3S_4$ to be hexagonal ($a = 950.5$, $c = 341.4$ pm, $Z = 2$). The structure was determined from automatic diffractometer data (MoK_α, 590 symmetry independent reflections, space group $P6_3/m(C_{6h}^2)$. There are two different sulfur positions in the unit cell; Ti and S(2) atoms occupy the position 6 h, whereas the S(1) atoms occupy the positions 2(c) (for positional parameters see Table 1). With Ti and S parameters only the structure model gave an agreement factor of $R = 0.081$. In a subsequent difference Fourier synthesis maxima could be detected on the positions 2a (0, 0, 1/4) and 2b (0, 0, 0). With the assumption of a statistical distribution of K^+ on these positions R showed a minimum at 0.30(5) K/Ti_3S_4; the agreement factor was $R = 0.065$.

Table 1. Positional parameters of Ti and S atoms in $K_{0.3}Ti_3S_4$.

	x	y	z
Ti	0.4867(2)	0.3546(2)	1/4
S(1)	1/3	2/3	1/4
S(2)	0.6928(3)	0.6437(3)	1/4

The structure can be described in terms of distorted TiS_6 octahedra joining common faces and edges to form a three-dimensional framework which is characterized by wide channels parallel to the hexagonal c axis which are incompletely occupied by potassium atoms (Fig. 1). The Ti atoms are displaced from the center of the TiS_6 octahedra so that

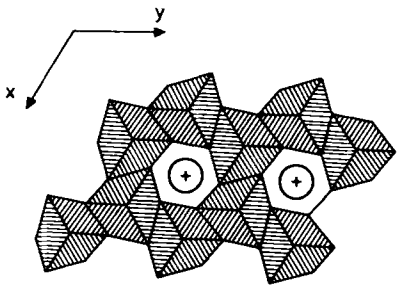

Fig. 1. Scheme of $K_{0.3}Ti_3S_4$ structure (cross section perpendicular to channel axis; circles indicate positions of $K^{\oplus}$ ions).

metal-metal zig-zag chains are formed; the Ti—Ti distance of 315.2(3) pm is close to that in titanium metal. The S(1) atoms are surrounded by six Ti atoms at the corners of a trigonal prism, while the S(2) atoms form the "channel wall" and have strongly asymmetric environment. Similarly to $Tl_xTi_6Se_8$[2], $A_xNb_3S_4$ and $A_xNb_3Se_4$[3] the ternary sulfide $K_{0.3}Ti_3S_4$ can thus be considered as a partially filled up structural version of the Nb_3Se_4 type[4].

Chalcogenides with channel type structure (*e.g.* Nb_3S_4, Mo_6S_8) have recently been shown by us to undergo reversible topotactic redox reactions at ambient temperature by electron/ion transfer[3, 5]. Like layered structures[6] they are of interest regarding their application as reversible electrodes in high density batteries. We found that the ternary titanium sulfide phase described here contains highly mobile $K^{\oplus}$ ions and is able to react in a similar way according to:

$$Ti_3S_4 + x\,e^{\ominus} + x\,A^{\oplus} \rightleftarrows A_x^{\oplus}[Ti_3S_4]^{x\ominus} \qquad (1)$$

Anodic oxidation of polycrystalline $K_{0.3}Ti_3S_4$ electrodes in $K^{\oplus}/H_2O$ electrolyte yields Ti_3S_4, while on cathodic reduction $K_{1/3}Ti_3S_4$ is obtained at the upper phase limit. The reduction of Ti_3S_4 in organic $Li^{\oplus}$/propylene carbonate electrolyte results in the reversible formation of $Li_{0.8}Ti_3S_4$; the steps appearing in the potential/charge transfer curve (Fig. 2) indicate the existence of intermediate phases. As a consequence of the rigid host lattice matrix changes in the lattice parameters with x are very small.

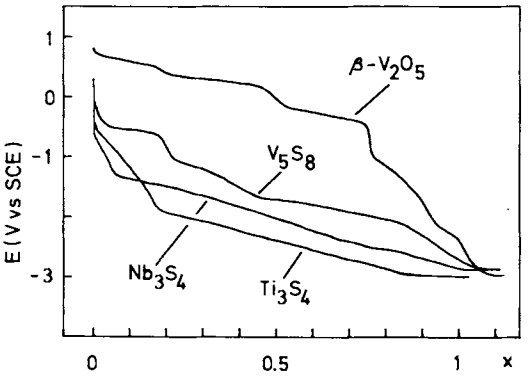

Fig. 2. Potential/charge transfer curves for topotactic cathodic reduction of Ti_3S_4, Nb_3S_4, V_5S_8 and β-V_2O_5 in 1 M $Li^{\oplus}$/propylene carbonate at 298 K; charge transfer $x = e^{\ominus}$/unit formula.

The ternary phases TlV_5S_8 and β-$Cu_{0.5}V_2O_5$, both of which are characterized by channel type structures[7], revealed a topotactic redox behavior basically similar to that of $K_xTi_3S_4$. The lattice channels in these compounds are occupied by Tl and Cu atoms, respectively, which according to our results are mobile at ambient temperature. Oxidation of TlV_5S_8 results in the formation of V_5S_8 (residual Tl content corresponding to $Tl_{0.07}V_5S_8$) with the monoclinic lattice parameters $a = 1139.9$ pm, $b = 664.5$ pm, $c = 1129.3$ pm, $\beta = 91.49°$. On cathodic reduction in aqueous or organic electrolytes V_5S_8 may take up reversibly mono- and bivalent cations with an ionic radius up to *ca.* 140 pm; for $Li^{\oplus}$/propylene carbonate a maximum degree of reduction corresponding to $Li_1V_5S_8$ was observed (Fig. 2).

On anodic oxidation of β-$Cu_{0.5}V_2O_5$ a binary metastable phase β-V_2O_5 is obtained after a transfer of $1.0\,e^{\ominus}$/$Cu_{0.5}V_2O_5$; the upper phase limit on cathodic reduction of V_2O_5 in $Cu^{2\oplus}/H_2O$ electrolyte is equivalent to $Cu_{0.65}V_2O_5$. For $Li_xV_2O_5$ phases, which can be prepared, *e.g.*, from $Li^{\oplus}$/propylene carbonate, the maximum guest ion content corresponds to $Li_{1.1}V_2O_5$ (Fig. 2). In contrast to $A_xM_3X_4$ phases the vanadium sulfide and oxide phases show clear changes in lattice parameters with the guest cation content. This reflects a higher flexibility of the host lattice matrix due to lower symmetry and less dense lattice framework.

Polymer-Polymer Miscibility. By *O. Olabishi, L. M. Robeson,* and *M. T. Shaw.* Academic Press, New York 1979. xii, 370 pp., bound, $ 42.50.

In the last decade, polymer mixtures have been studied with increasing interest. In the literature one finds two lines of research; on the one hand there exist numerous papers supplying more or less detailed experimental information, and on the other, theoreticians have tried to develop molecular models for such systems.

This book gives an excellent survey of both approaches. Starting from first principles the authors give an extensive review of recent developments of classic statistical thermodynamic considerations about the subject. The physical meaning of the parameters introduced in the various molecular models is discussed thoroughly.

With respect to the experimental data in the literature the authors first critically review the methods for determining the state of the mixture. Miscible (co-)polymer blends reported so far are conveniently listed together with some comments about the result. For immiscible polymer pairs the reader is referred to other publications.

As is well known, most polymer pairs are partially miscible. A lot of research is being carried out nowadays in the enhancement of polymer miscibility. The authors discuss several methods that can be used for this purpose.

The aim of most work in polymer mixtures is to obtain a significant diversification of physical properties. In this book a broad field of physical properties of miscible polymer and copolymer mixtures is treated in relation to theoretical models and experimental findings. Some industrial applications, including two phase systems, are given to illustrate the commercial importance of 'versatile' polymer blends.

Summarizing one may conclude that this book offers the academic polymer specialist an up-to-date guide for necessary future investigations, while industrial researchers will find practical possibilities of miscible polymer systems. In addition it will serve as an excellent source-book.

The Principle of Minimum Chemical Distance (PMCD)[***]

By Clemens Jochum, Johann Gasteiger, and Ivar Ugi[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

The principle of minimum chemical distance (PMCD) allows one to formulate the isoprene rule, the conversion of tetrahydrodicyclopentadiene into adamantane, five syntheses of colchicine, and the syntheses of C_{16}-hexaquinacene, morphine and strychnine as optimization problems which can be solved by computers in less than a second. The principle of minimum chemical distance is based on an algebraic theory of constitutional chemistry. The PMCD, a corollary to the well known principle of minimum structure change, is a quantitative heuristic rule which serves as the foundation of the computer-assisted combinatorial solution of a great variety of chemical problems, particularly in substructure analysis, the study of reaction mechanisms, and the design of syntheses.

1. Introduction

Since the introduction of the concept of chemical constitution around the middle of the last century, chemists have relied on the assumption that chemical reactions proceed generally with minimum structural change in the participating molecules. This heuristic rule has been used with great success in the solution of many problems in organic chemistry, and it has gradually acquired the status of a principle, namely the *principle of minimum structure change* (*Hückel*[1a], *Wheland*[1b]). *Hine*[2] has recently discussed the relation between the principle of minimum structure change and various other heuristic rules and principles which have been postulated for chemical reactions. The first of such principles to be formulated was the Rice-Teller principle[3], which led to the principle of least nuclear motion, and the principle of least change in electronic configuration. The Schuler principle[4] and the Woodward-Hoffmann rules[5] should also be mentioned in this context. Neither the principle of minimum structure change nor any one of the latter principles has been stated in a quantitative form in which it may directly serve as the basis for combinatorial algorithms and computer programs by which some expected minimum can be found.

The topic of this article is the *principle of minimum chemical distance* (PMCD) and its applications. It is a heuristic principle which is a corollary to the principle of minimum structure change. In contrast to the latter, it is directly usable in the computer assisted solution of a great variety of chemical problems.

[***] Abbreviations: PMCD = principle of minimum chemical distance; *EM* = ensemble of molecules; *FIEM* = family of isomeric *EM*.

 © *Verlag Chemie, GmbH, 6940 Weinheim, 1980* *0570-0833/80/0707-0495 $ 02.50/0*

The following example may serve as an introductory illustration for potential applications of the PMCD. A recently published synthesis[6] of C_{16}-hexaquinacene *(2)* involves the conversion of *(1)* as follows:

(1) *(2)*

The structural changes which lead from *(1)* to *(2)* appear to be rather deep-seated and complex. However, an efficient scheme for the overall conversion of *(1)* into *(2)* was found in extremely little computation time (0.03 s, Cyber 175) by a computer program which is based on the principle of minimum chemical distance. It involves the breaking of the bold-faced bonds in *(1a)* and the linking of the bold-faced bonds in *(2a)*. It corresponds to an atom onto atom mapping as shown by the indexing of *(1a)* and *(2a)*. It is interesting to note that the bonds which were actually broken and made in the published synthesis of *(2)* from *(1)* coincide precisely with the bonds indicated in *(1a)* and *(2a)*.

(1a) *(2a)*

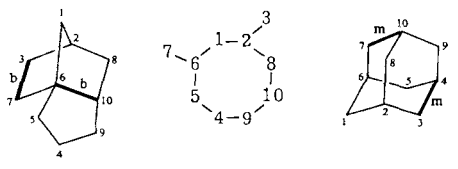
2. The Principle of Minimum Chemical Distance (PMCD)

In 1973 a mathematical model of the logical structure of families of isomeric ensembles of molecules *(FIEM)*, an algebraic theory of constitutional chemistry, was published[7]. According to this theory the isomeric ensembles of molecules *(EM)* which can be formed from a collection of n atoms are representable as points in $\mathbb{R}^{n^2}$, an n^2-dimensional euclidean space. According to this theory the number of valence electrons that are redistributed during a real or conceivable chemical reaction corresponds to a distance between the points representing the isomeric *EM*s which participate in the reaction from the educts to the products. The term *chemical distance* has been introduced for the number of valence electrons which must be shifted in order to interconvert isomeric *EM*[*] under a given atom onto atom mapping. The chemical distance between two isomeric *EM*s is a quantitative measure for the chemical relatedness of molecular systems. This permits the formulation of the principle of minimum structure change in quantitative terms as the *principle of minimum chemical distance* (PMCD):

Most chemical reactions proceed along a pathway of minimum chemical distance, i. e. with a redistribution of a minimum number of valence electrons.

The translation of the principle of minimum structure change into PMCD is quite obvious. Since a reaction pathway of minimum chemical distance corresponds to a reaction in which a minimum number of valence electrons is being redistributed, it is also a reaction pathway with minimum breaking and making of bonds, as well as minimum involvement of free valence electrons. Thus it proceeds with minimum structure change.

The term "minimum chemical distance" is used in this article instead of "minimum number of redistributed valence electrons", in order to remind the reader of the fact that the chemistry of a family of isomeric ensembles of molecules *(FIEM)* is of a metric nature. We also wish to call attention to the fact that we really exploit the metric properties of the representation spaces of *FIEM* in our computer programs for finding an atom onto atom mapping for isomeric *EM*s with minimum chemical distance[8,9].



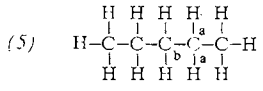
3. Scope of the Principle

The scope of the PMCD is the interconversion of ensembles of molecules regardless of whether or not this interconversion is actually possible or only conceivable. We have investigated three major types of applications of the PMCD: substructure matching, the elucidation of reaction mechanisms, and the evaluation of syntheses.

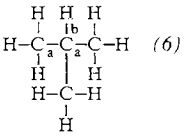
3.1. Substructures

Any atom by atom matching of two isomeric ensembles of molecules has a characteristic chemical distance. In a matching with minimum chemical distance we have maximum coincidence of substructures. Therefore the PMCD may be used to correlate substructures: The chemical similarity of two isomeric ensembles of molecules in terms of common substructures is obtained by an atom onto atom mapping under the aspect of minimum chemical distance.

The PMCD leads to a well-defined procedure for finding substructures which are common to a pair of ensembles of molecules. The corresponding search procedure detects the ensemble structures, which can be generated by breaking a minimum number of bonds in one, or both ensembles (largest set of largest substructures).

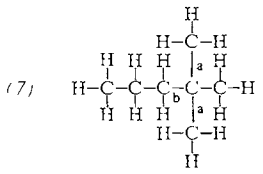


(3) *(4)*

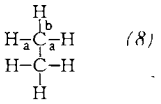


[*] A factor of two which stems from the algebra of BE- and R-matrices and was part of the original definition [7] has been omitted for simplicity.

Intuitively, a six-membered ring might be seen as the largest substructure common to molecules *(3)* and *(4)*. According to the PMCD the conversion of *(3)* into *(4)* can be achieved by breaking ("b") and making ("m") the bonds indicated. This corresponds to an atom onto atom mapping as shown by the indexing of structures *(3)* and *(4)*. As can be seen from this result, *(3)* and *(4)* have a disubstituted eight-membered ring as largest common substructure.

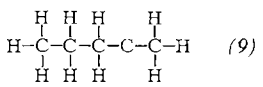


Note that our approach which looks for the *largest set of largest substructures* might give results which are different from those obtained with other substructure search procedures which perceive only the *largest common substructures*.

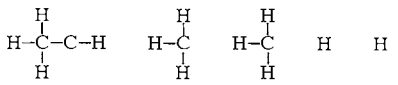


(5)

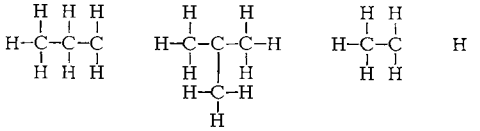
(6)



(7)



(8)



Obviously, the largest substructure which is common to the two ensembles {*(5)*, *(6)*} and {*(7)*, *(8)*} is *(9)*; the complementary substructures of *(9)* are shown underneath. The interconversion of {*(5)*, *(6)*} and {*(7)*, *(8)*} with preservation of these substructures requires the breaking of the bonds labeled by "a"; the chemical distance for this conversion is eight. In the ensemble of substructures 25 bonds are retained.

(9)

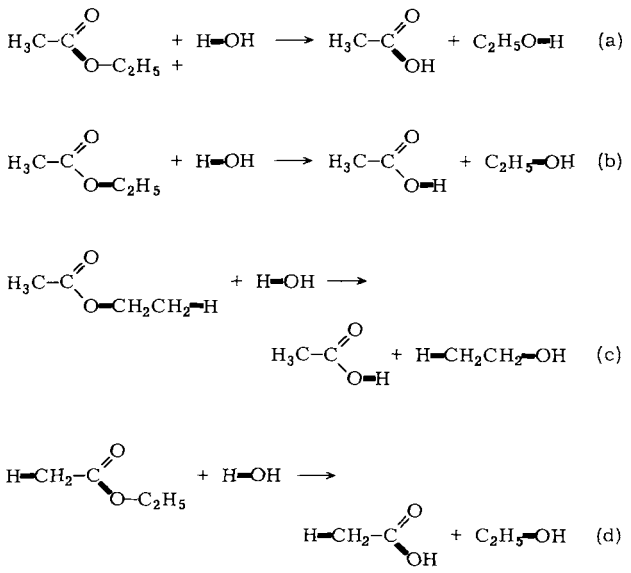
Our procedure yields the following four substructures: The correlation is obtained by breaking the bonds with label "b". The chemical distance between *(5)* and *(6)*, and *(7)* and *(8)* is four; 27 bonds are retained. This example illustrates that in

the correlation of substructures the search for the largest one may be chemically less meaningful than the search for the largest set of largest substructures which leads to a maximum overall coincidence.

3.2. Chemical Reactions

The correlation of the atoms in the educts and products of a reaction often depends on the reaction mechanism. Conversely, conclusions about the mechanism can be drawn if one knows for each atom in the products the corresponding atom in the educts. This is the working basis for any elucidation of reaction mechanisms by isotopic labeling. In essence our present computer program labels all atoms involved and finds a correlation of labelings which corresponds to a minimum chemical distance.

In the elucidation of reaction mechanisms the minimum chemical distance is a measure of the minimum mechanistic complexity of the reactions: the minimum chemical distance is twice the minimum number of arrows which are needed for describing the reaction by an "electron shifting pattern". For a given overall reaction there may be several mechanistic pathways which correspond to the same minimum chemical distance.



Chemical reactions are generally sequences of elementary steps. They are here treated as a single overall process. The chemical distance they cover is given by the overall displacement of electrons. The number of valence electrons which may have participated in the individual mechanistic steps of the reaction may be larger than is seen in the chemical change which determines the chemical distance.

With increasing complexity of reactions, *i.e.* with an increase in the number of elementary steps, the chance is enhanced that the reaction proceeds with an overall displacement of more valence electrons than the minimum number required. However, even then the number of valence electrons shifted deviates only slightly from the minimum chemical distance. This is always the case when a reaction mechanism involves the intermediate formation of a bond which is broken again in a later step and vice versa, or when an intermediate redox process occurs, which is later followed by a reverse process. Catalytic reactions proceeding through intermediates are typical representatives of such reactions whose actual pathways are "longer" than the minimum chemical distance. The reason for the preference of certain longer pathways is that they avoid some high energy barriers which sometimes obstruct the shortest pathway. Even in such cases investigation of the minimum chemical distance leads to valuable insights, for "mechanistic detours" tend to be as short as possible. The correlation of educts and products from the aspect of minimum chemical distance indicates the least changes which must be accomplished in the overall process.

The hydrolysis of ethyl acetate may serve as a simple illustration. For this reaction the four schemes (a)—(d) are conceivable.

The minimum chemical distance of four corresponds to two of the known mechanistic types of ester hydrolysis, *i.e.* O-acyl (a) and O-alkyl cleavage (b). Reaction path (c) involves the intermediacy of ethylene and (d) that of ketene. In both cases the chemical distance is six. Reactions corresponding to path (c) and (d) are conceivable but do not occur in simple cases.

Thus, determination of the minimum chemical distance and the corresponding bond shifting processes affords a good starting point for studying the mechanism of the reaction. It should be noted that the sum of the chemical distances of the individual mechanistic steps of path (a) is larger than the overall chemical distance: The hydrolysis of ethyl acetate proceeds *via* a tetracoordinated intermediate which is formed by attack of the nucleophile on the carbonyl-carbon. The

carbonyl double bond is later restored by elimination of the leaving group. In this way the direct O-acyl cleavage is generally avoided. Further, on acid catalysis an O—H bond is formed which is broken again later.

3.3. Multistep Syntheses

The PMCD is not only applicable to chemical reactions but also to sequences of reactions. Hence, PMCD provides guidance in the design of multistep syntheses.

Under given conditions the mechanistic pathways for chemical reactions are determined by the educts and products, whereas in synthesis the pathways for the conversion of given starting materials into the desired synthetic target are chosen by the chemist. In the design of syntheses, the principle of minimum structure change, which we apply in the form of the PMCD, cannot only be used in the selection of synthetic pathways with a given beginning and end, but it is also potentially useful in the choice of starting materials for a given synthetic target. It helps, *inter alia,* to avoid wasteful use of starting materials.

With very few exceptions, the great multistep syntheses of natural products would appear to have been designed according to the principle of minimum structure change. Syntheses which follow this principle have some natural appeal (cf. Section 5.3).

In a multistep synthesis the conversion of given starting materials into the synthetic target is achieved with minimum structural change, if the synthesis proceeds with an overall displacement of a minimum number of valence electrons. Thus it is desirable to find pathways of minimum structure change, because in these pathways only those bonds participate whose opening and closing is absolutely necessary. The choice of such pathways generally leads to a minimum number of synthetic steps.

Often a synthesis not only requires the operations and materials which are directly needed, but also the protection and deprotection of functional groups which might otherwise undergo undesirable reactions. Obviously the group protection techniques increase the number of synthetic operations to be performed and the amount of material being used. This is reflected by an increase in the chemical distance. However, we wish to emphasize that minimum chemical distance is just one criterion for the evaluation of syntheses. A synthesis along a pathway of minimum chemical distance may not necessarily be feasible, or best in yield. Sometimes a pathway with a moderate detour may be more effective in practice.

4. Solution of the Minimization Problem

In this section we briefly discuss the logic of the approach (cf. [8], for details see [10]). Every chemical reaction can be regarded as an isomerization of an ensemble of molecules *(EM)*. The conversion of an $EM(\mathbf{B})$ at the beginning of a reaction or sequence of reactions into an $EM(\mathbf{E})$, which contains the synthetic target, may be represented by a transformation $\mathbf{B} \rightarrow \mathbf{E}$ of the corresponding BE-matrices $\mathbf{B} = (b_{ij})$ and $\mathbf{E} = (e_{ij})$ by the addition of an R-matrix $\mathbf{R} = (r_{ij})$[*] according to

$$\mathbf{B} + \mathbf{R} = \mathbf{E} \tag{e}$$

The BE-matrices **B** and **E** of the ensembles $EM(\mathbf{B})$ and $EM(\mathbf{E})$ which contain the same collection of n atoms are symmetric $n \times n$ matrices, whose rows and columns are assigned to the atoms in the isomeric *EM*; the i-th row and the i-th column both represent the core of the i-th atom A_i. The entries b_{ij}, and e_{ij} $(i \neq j)$ respectively, are the formal orders of the covalent bonds between the atoms A_i and A_j and the entries b_{ii}, e_{ii} are the numbers of the valence electrons of the atoms A_i.

The n rows/columns of an $n \times n$ BE-matrix may be assigned to the n atoms of an *EM* in n! different ways. Thus a given $EM(\mathbf{B})$ is representable by up to n! distinct BE-matrices, which are interconvertible by row/column permutation. Therefore any two BE-matrices **B** and **B'** represent the same $EM(\mathbf{B})$, if **B** is transformed into **B'** according to:

$$\mathbf{B}' = \mathbf{P} \cdot \mathbf{B} \cdot \mathbf{P}^t \tag{f}$$

Here $\mathbf{P} = (p_{ij})$ is an $n \times n$ permutation matrix, and $\mathbf{P}^t$ its transposed matrix. Since each permutation can also be expressed by a mapping which reorders the numbers 1,..., n, equation (f) can also be written as:

$$b'_{ij} = b_{\pi(i)\,\pi(j)} =: \pi(\mathbf{B}) \qquad i,j = 1,\ldots,n \tag{f'}$$

$$\text{with} \quad \pi: \{1,\ldots,n\} \rightarrow \{1,\ldots,n\}$$

The n^2 entries in a BE matrix can be regarded as coordinates in a n^2-dimensional euclidean space ($\mathbb{R}^{n^2}$). The matrices **B** and **E** correspond to a pair of points in $\mathbb{R}^{n^2}$. The function

$$D(\mathbf{E},\mathbf{B}) = \frac{1}{2}\sum_{i,j}|e_{ij} - b_{ij}| = \frac{1}{2}\sum_{i,j}|r_{ij}| \tag{g}$$

[*] The abbreviation BE-matrix was chosen to point out that it describes *b*onds and *e*lectrons in molecules as well as the *b*eginning and *e*nd of a reaction.

corresponds to the "city block distance" between the points in $\mathbb{R}^{n^2}$ which represent **E** and **B**. We call $D(\mathbf{E},\mathbf{B})$ the *chemical distance* between $EM(\mathbf{E})$ and $EM(\mathbf{B})$, since it has a direct chemical meaning: It is the number of valence electrons which are displaced in the reaction $EM(\mathbf{B}) \rightarrow EM(\mathbf{E})$. In contrast, the euclidean distance

$$d(\mathbf{E},\mathbf{B}) = \sqrt{\sum_{ij}(e_{ij}-b_{ij})^2} \qquad (h)$$

has no direct chemical meaning. However, as a metric of $\mathbb{R}^{n^2}$ the euclidean distance is topologically equivalent to the chemical distance, because

$$\frac{1}{2}d(\mathbf{E},\mathbf{B}) \leq D(\mathbf{E},\mathbf{B}) \leq \frac{1}{2}n^2 \cdot d(\mathbf{E},\mathbf{B}) \qquad (i)$$

The BE-matrices **B** and **E** correspond to an arbitrarily fixed indexing of the atoms in $EM(\mathbf{B})$ and in $EM(\mathbf{E})$. If the indexing of the atoms in $EM(\mathbf{E})$ is maintained while the indexing of the atoms in $EM(\mathbf{B})$ is permuted according to eq. (f), the chemical distance

$$D(\mathbf{E},\mathbf{PBP}^t) = \frac{1}{2}\sum_{ij}|e_{ij}-b_{p(i),p(j)}| = F(\mathbf{P}) \qquad (j)$$

is a function of the permutation **P** acting on the row/column indices of **B**. The minimum $F(\mathbf{P}) = \text{min!}$ is a measure of the inherent chemical dissimilarity of the isomeric *EM*. Since the function $F(\mathbf{P})$ can only be minimized by trial and error, some other way must be found to correlate the atoms in pairs of isomeric *EM* according to their minimum chemical distance.

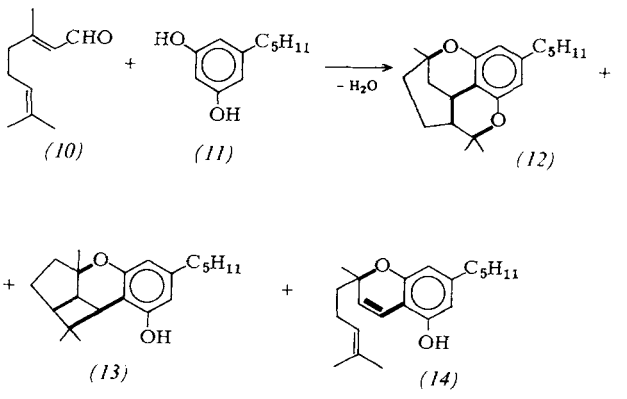
In operations research quadratic assignment algorithms[11, 12] are used which can be modified to find the maximum of the scalar product

$$G(\mathbf{P}) = \sum_{i,j} e_{ij} \cdot b_{p(i),p(j)} = \text{max!} \qquad (k)$$

It can be shown that the maximization of $G(\mathbf{P})$ is equivalent to the minimization of the euclidean distance $d(\mathbf{B},\mathbf{E})$ between **B** and **E**. It can further be shown that the solutions for the maximum of eq. (k) include all solutions for the minimum of eq. (j). Thus the minimization problem of eq. (j) for the chemical distance can be solved by maximizing eq. (k). These quadratic assignment algorithms[12-14] to maximize eq. (k) are based on the construction and searching of a decision tree. Each node of the decision tree consists of a number of already fixed assignments. Nodes and branches starting from a certain node indicate additional fixed assignments. Since there are n! different assignments possible the whole decision tree has n! different branches which differ in at least one node. The algorithm now detects the necessary and sufficient criteria for pruning branches and leading to an optimum solution.

At each node a lower bound is determined for solutions which all have certain fixed assignments determining this node. In addition, an optimum solution for this node, *i.e.* an optimum solution with respect to these certain fixed assignments is determined. If this solution is better than a previously found solution, it is stored and considered as an upper bound to all possible solutions. If a lower bound of a certain node is higher than the upper bound (of all solutions), the nodes starting from this node do not have to be treated since they cannot contain an optimum solution and all branches starting from this node can be pruned. These algorithms are often called branch-and-bound algorithms since they determine bounds to and among branches of a decision tree.

5. Applications of the Principle

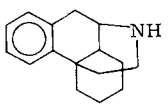


The preceding parts of this article demonstrate that the PMCD is universal in nature and can be applied to the solution of many substantially different types of problems. In this section, its usefulness, scope, and limitations will be illustrated.

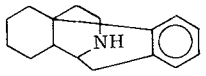
5.1. Correlation of Substructures

The correlation of substructures by the PMCD does not only differ from other methods of substructure correlations by leading to the largest set of largest substructures but also by providing a direct atom onto atom mapping.

The terpenes are a class of natural products with an unusually high degree of structural variety. Here, the isoprene rule is a powerful principle of order. The validity of the isoprene rule and deviations from it can be checked by a substructure analysis of the terpenes according to the PMCD. Had our program existed before the discovery of the isoprene rule, this rule would have been found as follows: The occurrence of C_5-subunits can be recognized from the empirical formulas of the terpenes. Starting with combinations of all conceivable C_5-subunits the PMCD would have led to isoprene as the universally occurring substructure. For the individual terpenes as well as the whole set of the known terpenes isoprene would have been found as "precursor". Furthermore, this approach matches the isoprene units with the terpene atom by atom. Thus this atom to atom matching shows how the isoprene subunits have been incorporated into the terpene structure. The recognition of isoprene subunits in the structures of natural products by PMCD is not confined to compounds where the skeleton consists only of isoprene units but it may also be extended to molecules with other skeletal subunits.

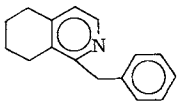


The condensation of citral *(10)* with olivetol *(11)* yields three products: the tetracycle *(12)*, cannabicyclol *(13)*, and cannabichromene *(14)*, which differ significantly in molecular structure[15].



(10) *(11)* *(12)* *(13)* *(14)*

The analysis of the educts and products of this reaction by the PMCD program shows in detail the incorporation of the starting materials into the products and the placement of the isoprene subunits. The bonds in bold face are made during the reactions. The chemical distance from olivetol *(11)* and citral *(10)* to both the skeletons of *(12)* and *(13)* is eight, to the skeleton of *(14)* it is six.



A further example of the application of the PMCD is the correlation of 1-benzyl-5,6,7,8-tetrahydroisoquinoline *(15)* and morphinan *(16)*. The structure of morphinan can be drawn in different ways—*e.g.* as *(16a)* or *(16b)*—with implicit emphasis of various kinds of substructures, each suggesting some synthetic approach.

(16a)

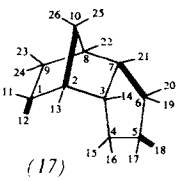
(16b)

(15)

It is customary to represent the structure of morphinan by formulas of type *(16a)* which emphasizes the relation to its degradation product phenanthrene. It must have been the recognition of the structural relation between 1-benzyl-5,6,7,8-tetrahydroisoquinoline *(15)* and morphinan in its form *(16b)* that led *Grewe et al.* to the design of their morphinan synthesis[16]. This important correlation of substructures was also found by the PMCD program. The chemical distance between the skeletons of *(15)* and *(16)* is only two, demonstating the close relationship between them.

5.2. Elucidation of Reaction Mechanisms

The preparation of adamantane required laborious multistep syntheses until *Schleyer*'s discovery of the conversion of the readily available tetrahydrodicyclopentadiene *(17)* into adamantane *(18)*. This conversion proceeds directly from tetrahydrodicyclopentadiene to adamantane through a sequence of carbonium ions without any directly observable intermediates, although a multistep sequence of rearrangements must undoubtedly be involved. The mechanism of this rearrangement presents an intriguing and not yet completely solved problem.



Whitlock[17] proposed a network of conceivable pathways, which consists of 1—2 shifts only. One of the pathways was selected by *Schleyer*[18] as the likeliest one by molecular mechanics calculations.

PMCD provides new insights into this process. Beginning with an arbitrary indexing of tetrahydrodicyclopentadiene *(17)*, we find an indexing of adamantane *(18)* which corresponds to a minimum chemical distance of eight. In comparison, the sum of the chemical distances of the individual

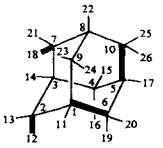


Table 1: Minimum chemical distance between the carbonium ions of tetrahydrodicyclopentadiene *(17)* and adamantane *(18)* [numbered according to *(17a)* and *(18a)*, respectively].

Reaction No.	Carbonium ions in *(17a)*	Carbonium ions in *(18a)*	Disconnected H-Atoms in *(17a)*	Disconnected H-Atoms in *(18a)*	Chemical Distance	Broken Bonds in *(17a)*	Made Bonds in *(18a)*

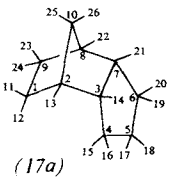
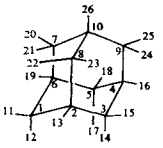
4	4	1	15	12	6	1–9 3–7 6–20	3–4 6–7 9–24
5	5	1	17	12	6	1–12 2–10 6–7	2–3 4–9 7–20
6	10	1	26	12	8	1–9 3–7 4–16 6–20	3–4 5–17 7–10 8–23
7	1	10	12	26	8	1–11 2–10 5–18 6–7	2–3 5–17 7–20 8–10
8	2	10	13	26	8	3–4 5–18 8–10 9–24	1–11 4–9 5–6 8–23
9	3	10	14	26	8	1–12 2–10 5–18 6–7	1–2 5–6 8–23 9–24
10	4	10	16	26	8	1–9 3–7 4–15 6–20	1–6 5–17 8–23 9–10
11	5	10	18	26	8	3–4 5–17 8–10 9–24	3–15 5–17 6–7 8–10
12	10	10	26	26	10	1–11 1–12 2–10 5–18 6–7	2–3 3–15 5–18 7–20 8–10

steps of the pathways suggested by *Schleyer*[18] is twenty. If the reaction proceeded from hydrocarbon to hydrocarbon the bonds indicated in bold face in *(17)* would be broken, and those in *(18)* would be made. The numbering of the atoms in *(18)* indicates their origin in *(17)*.



(17)



(18)

We are investigating whether the overall change in bonds corresponding to the PMCD can be broken down into mechanistically reasonable steps. In order to obtain a gross classification of the pathways we compared the minimum chemical distance of the 12 pathways which lead from one of the six isomeric carbonium ions of *(17)* to one of the two carbonium ions of adamantane *(18)* (cf. Table 1).

(17a)

(18a)

In all examples the atoms in *(17)* are indexed as in *(17a)*, and the atoms in *(18)* as in *(18a)*, in order to have a reference for the bonds broken and made. Interconversion of the hydrocarbons requires the involvement of two more bonds than the interconversion of the carbonium ions.

Thus a minimum chemical distance of six can be expected for the carbonium ions. This minimum is only found for the pairs in rows 1, 4 and 5. It is noteworthy, that all pathways with a minimum chemical distance of six lead from a secondary carbonium ion of *(17)* to a secondary carbonium ion of *(18)*. In each one of these cases the secondary carbonium ion center in *(18)* corresponds to an initially tertiary carbon atom in *(17)*.

5.3. The Study of Chemical Syntheses

Synthetic strategies involve the ability "to look ahead" from the target molecule to the starting materials along the reverse pathways[19,20]. In general this looking ahead covers only parts of synthetic pathways, and only a few most ingenious syntheses seemed to have been designed with a complete "look ahead" from the target to the starting materials.

With the PMCD we have a tool in our hands which allows us to find the largest set of largest substructures in a pair of isomeric *EM*s. In synthetic planning these two ensembles comprise, on the one hand, the target and its coproducts, and on the other, a set of starting materials taken from a list of all available compounds. The selection of an appropriate collec-

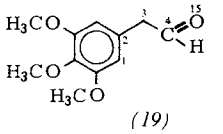
tion of starting materials from the list involves the comparison of various combinations of starting materials. Any eligible combination of molecules in the list must contain substructures whose union covers the target. The remaining substructures in the starting materials must yield a combination of feasible coproducts. With this concept, synthetic design consists of two parts: first, the selection of a suitable collection of starting materials and coproducts, and secondly a search for optimum synthetic pathways from the starting materials to the target (and its coproducts).

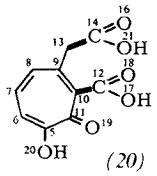
In order to explore the performance and merits of the PMCD program for this latter part of synthetic design with a complete "look ahead", we applied the program to the target and its coproducts together with the known starting materials of various published syntheses. We now consider the pathways which begin with the same ensemble of starting materials *EM*(**B**) and end with the same target ensemble *EM*(**E**) containing the target compound and its products. Generally there are many conceivable pathways for the synthesis of a target ensemble *EM*(**E**) from a given ensemble of starting materials *EM*(**B**). Besides the compounds involved, the bonds which are broken and made as well as the sequence of these changes are characteristic for individual synthetic pathways.

In a multistep synthesis each step has its characteristic chemical distance, and the sum of these distances is a typical feature of a given multistep synthesis. An electron shifting pattern with a characteristic chemical distance may be associated with the overall changes in valence electron distribution which take place in the synthesis. In such a pattern intermediate changes which cancel out in the net results are neglected, *e.g.* bonds which are made and broken in protecting group techniques. Obviously the sum of the chemical distances of the individual steps of a synthesis may be larger than the overall chemical distance, and this in turn may be larger than the minimum chemical distance between *EM*(**B**) and *EM*(**E**).



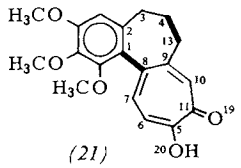
We conjecture that in the design of syntheses the best synthetic routes from a given *EM*(**B**) to *EM*(**E**) will be found among those for which the characteristic overall chemical distance is equal, or close, to the minimum chemical distance. This is illustrated by the following examples in which some published syntheses or their essential parts are analyzed by minimization of chemical distance. We deliberately chose sequences of synthetic reactions corresponding to complex chemical changes which are not immediately obvious.

Because of its interesting pharmacological properties and its unusual structure, colchicine *(21)* has attracted much attention from synthetic chemists. Of the numerous syntheses we chose five; they all involve rather complex chemical changes. Within each of these syntheses a sequence of steps was selected which reflects the essential concept of the whole synthesis. For none of the investigated sequences of reactions can one tell off-hand the pattern according to which the precursors are incorporated into the target molecule.

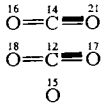


In the syntheses of natural products the construction of the molecular framework is the main task. Therefore and because changes in the placement of hydrogen atoms take place easily and can be treated separately, only bonds between nonhydrogen atoms were taken into account to determine the minimum chemical distance.

In the following synthetic schemes the bonds broken and made are shown in boldface.

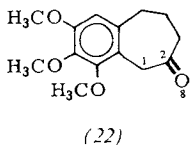


The synthesis by *Scott et al.*[21] is probably the one in which the mapping pattern of incorporation of the two starting materials in desacetamidocolchicine *(21)* is easiest to guess.

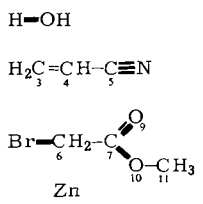


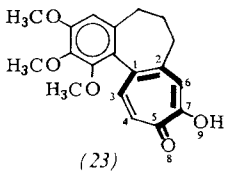
(19)

(20)



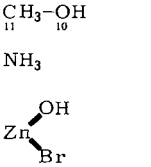
(21)



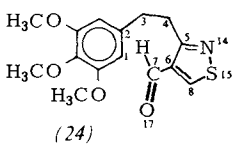


With the PMCD program we obtain the minimum chemical distance and a substructure matching for the conversion of *(19)* and *(20)* into *(21)* + O + 2 CO_2, which corresponds to the overall breaking and making of bonds in the actual synthesis. The brevity and elegance of the synthesis is reflected in the rather low value of the minimum chemical distance of eight.

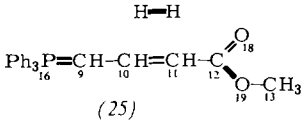
The conversion of *(22)*, acrylonitrile and methyl bromacetate into *(23)* is the centerpiece of the synthesis of *van Tamelen et al.*[22]. For this we find a minimum chemical distance of 18 and an overall scheme of bond breaking and making which agrees with the published synthesis. The higher value for the minimum chemical distance in this synthesis relative to the synthesis of *Scott et al.* is a consequence of the small size of the substructures which are combined, as well as of the bond shifting in a multiple bond system.



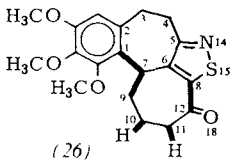
(22)



(23)

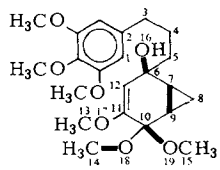


In the colchicine synthesis of *Woodward et al.*[23] the overall changes in the construction of the molecular framework [*(24)* + *(25)* → *(26)*] are also achieved with the minimum chemical distance (= 14)[*].

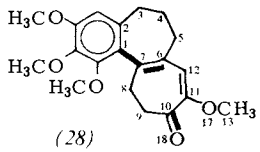


[*] In this synthesis the participation of some hydrogen atoms must be taken into consideration.

(24)

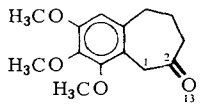


(25)

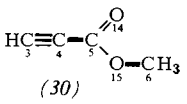


(26)

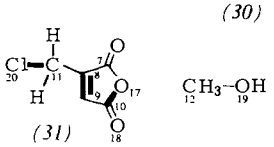
The main feature of the colchicine synthesis of *Evans et al.*[24] [*(27)*→*(28)*] is a deep-seated rearrangement of the bond system. Thus it may be surprising that the PMCD program found precisely the scheme of bond breaking and making which underlies this conversion. The minimum chemical distance for the conversion *(27)*→*(28)* is eight.



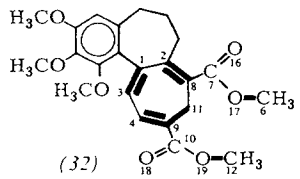
(27)



(28)



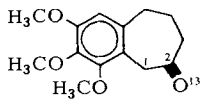
The colchicine synthesis of *Eschenmoser et al.*[25] demonstrates that in synthesis planning the PMCD is not a rule without exceptions. The essential overall changes in this synthesis correspond to the breaking and making of bonds according to the scheme below [*(29)* + *(30)* + *(31)* + *(32)*] and has a chemical distance of 20.



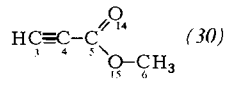
(29)

(30)

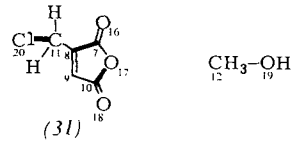
(31)



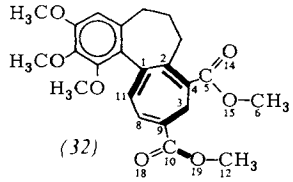
(32)



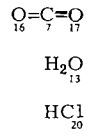
For the same conversion our program finds a minimum chemical distance of 14 for the following bond breaking and making scheme.



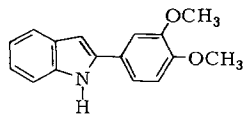
In the formulation of the PMCD we carefully avoided the categoric requirement that the results of each and any sequence of reactions must be achieved through a pathway of minimum chemical distance. A reaction or a sequence of reactions must not necessarily proceed with the displacement of a minimum number of valence electrons. It may well be possible that for a given chemical conversion a pathway with a higher chemical distance than the minimum is more favorable than one with the minimum chemical distance.



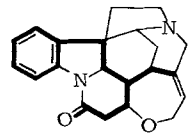
(29)



(30)

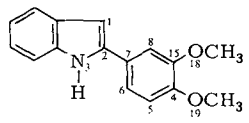


(31)

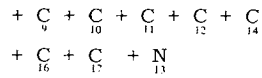


(32)

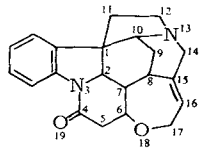
Strychnine! For its molecular size it is the most complex structure known. These words characterize well the total synthesis of strychnine by *Woodward et al.*[26] as one of the milestones in organic synthesis. One of the ingenious features in this synthesis is the use of veratrol derivative *(33)* as a starting material and its incorporation into the target *(34)* (bold face).



(33)



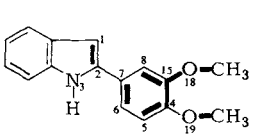
(34)



We considered the complex synthetic problem of strychnine as a suitable test case for studying the scope and limitations of the PMCD program.

First we wanted to see how the program would use the veratrol derivative *(33)* as a starting material for strychnine. For

(33)



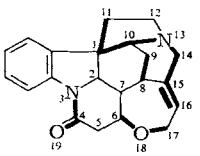
(34)

+ 2 CH_3

this, *(33)* was augmented by seven carbon atoms and a nitrogen atom to yield an *EM* which has the same set of non-hydrogen atoms as strychnine. Two optimal matchings were obtained. One of them corresponds to the incorporation of *(33)* into strychnine by *Woodward et al.*

The other matching is only different by coincidence of carbon atom C-15 in *(33)* and C-9 (instead of C-15) in strychnine. This result could hardly have been achieved by any one of the customary substructure search programs. In the customary approach to substructure search either the entire structure of *(33)* or a heuristically defined substructure (*e.g.* indolyl or dimethoxyphenyl) would be compared with strychnine. The heuristic definition of substructures must be chosen, because the set of all substructures is prohibitively large [there are up to 19! substructures in *(33)*]. In our approach we search for the largest set of largest substructures by selectively breaking bonds during the matching process with the chemical distance as a guideline. Thus, it is not surprising that with the PMCD program a benzene ring is matched with a chain of six carbon atoms.

In *Woodward*'s synthesis, in addition to *(33)*, two C_2-units (acetylene and ethyl glyoxylate), a C_1-unit, and a C_2N-unit (from formaldehyde and cyanide) were used for the construction of the strychnine skeleton. As a second part of our study we therefore investigated the matching of *(33)* and these buildings blocks onto strychnine. Several matchings corresponding to the minimum chemical distance were found, including also the pattern of *Woodward*'s synthesis. In formula *(34a)* the bonds which are made during the synthesis are indicated by bold face lines.



(33)

$+ \overset{11}{C}-\overset{12}{C}-\overset{13}{N}$

$+ \overset{9}{C}-\overset{10}{C}$

$+ \overset{16}{C}\equiv\overset{17}{C}$

$+ \overset{14}{C}$

(34a)

$+ 2\ CH_3$

This result is particularly noteworthy because of the very large number of synthetic steps which are needed to reach strychnine. This example illustrates the "look-ahead" capabilities of this program. It also shows that the PMCD program can be used to minimize those parts of starting materials which are not built into the target but enter the unwanted coproducts.

The atom by atom matchings and "electron shifting" patterns of multistep syntheses are obtained by minimization of the chemical distance with complete neglect of the stereochemical aspect. It should, however, be noted that any efficient synthetic pathway which also accounts for the stereochemistry should belong to the set of pathways with minimum chemical distance. The examples which we have analyzed confirm this.

6. Conclusion

The PMCD is a principle which is widely applicable in chemistry. Because many general rules which reflect chemical experience, *e.g.* the rule of "minimum structure change", are closely related or equivalent to the PMCD most chemists who learn about it, feel that, intuitively, they have already known the principle. Thus it should be pointed out again that the chemical distance is a quantitative measure of the "efficiency" of chemical reactions which has evolved from an algebraic theory of constitutional chemistry.

The reason for the long delay in its formulation lies in the fact that, despite the conceptual simplicity of the PMCD, its application is practically impossible without an algorithm which permits one to overcome the combinatorial barriers. By the minimum chemical distance program which is described here, it has become possible to apply the PMCD and explore its scope and limitations. Many applications are foreseeable for the PMCD program as a tool in its own right. The real importance of the PMCD program lies, however, in its future uses as a subunit of modular computer programs. Predictably, the computer-assisted design of syntheses, and the elucidation of reaction mechanisms will make increasing use of the PMCD program.

In the future, the development of computer programs for the solution of chemical problems will be characterized by efforts to consider all conceivable solutions. On the other hand, to avoid a "combinatorial explosion", heuristic rules and principles free of arbitrariness have to be developed to select optimum solutions. The large number of alternatives has compelled one, up to now, to disregard many conceivable solutions more or less arbitrarily by rejecting entire categories of solutions or by limiting oneself on empirical information, only. The search for non-arbitrary selection rules and measures of chemical relatedness and their algorithmic treatment will be of decisive importance for progress in that field.

The PMCD is a quantitative heuristic rule and a step in that direction.

High-Resolution Transmission Electron Microscopy Re-examined as a Tool in Solid State Chemistry

By Reginald Gruehn and Wilhelm Mertin[*]

Transmission electron microscopy (TEM) can be used with crystalline solids to obtain direct images of small structural groups comprising a few coordination polyhedra with resolution nearly down to atomic scale ("lattice imaging"). More exact knowledge of the conditions required for direct imaging, as well as improvements in the instruments themselves, have now made it possible to examine very small defect regions (microdomains), faults in the stacking sequence of structural groups or atom layers (planar or Wadsley defects), and isolated defects in narrowly delimited areas that may actually be below the dimensions of the unit cell. The structural principle of the very smallest ordered regions can even be determined when X-ray structure analysis proves unable to do this. "Block structures" are particularly suitable as models for the testing and further development of the high-resolution method; the detection of three-dimensional, two-dimensional, and one-dimensional defects has been studied on such structures.

1. Introduction

A great deal of information is currently available on the structure of solids, and particularly in the case of the crystalline solids the number of known crystal structures is almost beyond computation. The positional parameters of individual atoms, ions, or structural groups (complex ions, molecules, "clusters") in crystalline substances can be determined, most commonly by diffraction methods, and primarily by X-ray structure analysis supplemented by neutron and electron diffraction. However, these diffraction techniques are at their most effective[1] only when a sufficiently large number of adjacent structural elements (unit cells) are ordered, *i.e.* when some structural principle imposes a periodic recurrence over a large region of the solid material (Section 3.7). When this condition is largely satisfied, as is the case with many crystalline materials, then it can be considered that single crystal X-ray diffraction is the most powerful method of structural investigation available to date.

X-Ray structure analysis requires a crystalline region with a uniform structure, *e.g.* with a size of about 1000 Å in all directions; it follows that the picture of the crystal structure obtained is one that has been "averaged" over a large number of unit cells.

Detailed information about structural irregularities in narrowly delimited regions cannot be obtained by such methods, or only at the cost of a great amount of labor, since it is difficult for the X-ray beam to "see" disordered departures from the periodicity. Defects the size of a unit cell, or even ones extending over no more than a few atoms, could be detected until recently only by indirect physical measurements. In particularly favorable cases (as in the metals W, Pt, and Au) point defects could be made directly visible by field ion microscopy (*E. W. Müller* 1956)[2-4].

The direct imaging of structural defects[*] found wider application after *Wadsley*, together with *Allpress* and *Sanders* in 1967, had succeeded[6] in examining thin, suitably oriented crystal fragments by transmission electron microscopy. Since that time, direct imaging has enriched the repertoire of techniques available to solid state chemists, mineralogists, and crystallographers.

In the meantime, the examination of solids at a resolution of about 3—4 Å has been achieved in several laboratories[7–13]. In special cases, in which the objective was to develop the technique rather than to obtain the information itself (*e.g.* with Au[14], Si[15], or Ge[16]), even higher resolutions (1—2 Å) have been reached; this is quite possible in principle, but generally requires special specimen-preparation techniques.

2. Trends of Development in the Last 15 Years

2.1. Previous Developments

Whereas ordinary electron microscopy in the transmission mode (transmission electron microscopy, TEM[**]) goes back to *E. Ruska* (1932)[17], since about 1965 it has been complemented and to some extent displaced by scanning electron microscopy (SEM)[18]. The scanning methods, in combination with an analytical evaluation of the emitted X-rays, are not limited to the investigation of surface structures; scanning-transmission methods (STEM) can achieve still more, even yielding information about the bulk of the object under examination. In one new field of application, the investigation of the atomic structure in crystalline solids by high-resolution direct lattice imaging, transmission electron microscopy is however preferred to any other method, even to the STEM combination.

A first decisive step along this path had already been taken by *Menter* (Cambridge), who around 1956 studied the copper and platinum phthalocyanines using a Siemens-Elmiscope 1. The large structural elements of these solid compounds produce conditions favorable to the imaging of the lattice plane separations of 10.3 and 12.0 Å. With foresight, *Menter* wrote about this: "It is suggested that this method may be extended to the study of crystals of even smaller lattice dimensions than the phthalocyanines, making possible the direct study of imperfections in a wide range of materials in relation to properties known to be affected by them such as strength, plastic flow and fracture"[19]. In this case it was also significant that the crystals investigated were stable to the electron beam. In general, organic molecular compounds cannot withstand the beam irradiation at the highest magnifications; however, new impetus resulted from work on high-melting inorganic crystals.

2.2. Block Structures as a Springboard

A whole decade passed after *Menter*'s original success before investigations on Nb_2O_5 and Nb_2O_5-rich ternary oxides led to a major methodological step forward. This development was favored by the two-dimensionally extended unit cells with large structural elements ("blocks") of Nb–O octahedra (Fig. 1), which constitute an unusually variable structural principle (Fig. 2) in systems such as NbO_2–Nb_2O_5 and TiO_2–Nb_2O_5, and also in the Nb_2O_5-rich portions of the systems Nb_2O_5–WO_3 and Nb_2O_5–NbO_2F[20–22].

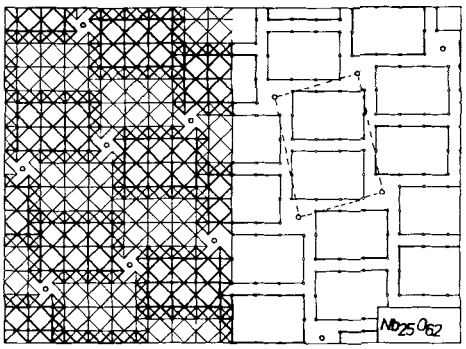

Fig. 1. Ideal structure of $Nb_{25}O_{62}$ as an example of a block structure [20]. The niobium is surrounded octahedrally by oxygens. The niobium atoms in tetrahedral positions between the blocks are indicated by circles. The left-hand side of the figure shows the idealized octahedra, which can be regarded as square-base bipyramids. The direction of view is from an apex down onto the basal plane, so that in projection the apexes appear to be at the points of intersection of the base diagonals. Within the blocks the octahedra are interconnected *via* the apexes in all directions; where the blocks abut against one another, the octahedra are linked with each other along edges. The outlines of the blocks are shown more clearly on the right; for the interconnection of the [3 × 4] blocks, see Figs. 2a and 2b. The different "heights" of the blocks in the direction of the short b-axis (perpendicular to the plane of the figure) are indicated by lines of different thickness; the unit cell is shown by broken lines.

For our knowledge of these concepts we are indebted to X-ray structure investigations, especially those carried out by *Wadsley et al.*[20,23]. More closely related structures can be grouped into "families" or "series", whose members differ in the extent of the blocks (mostly in the longitudinal direction, see Fig. 1), depending on the number n of octahedral layers involved. Together with the size of the blocks, there is also a stepwise change in the chemical composition of the phases (anion/cation ratio), with two-phase regions between them. As shown by the example of some phases in the Nb_2O_5–WO_3 system (Table 1), this concept seems to allow neither for "in-

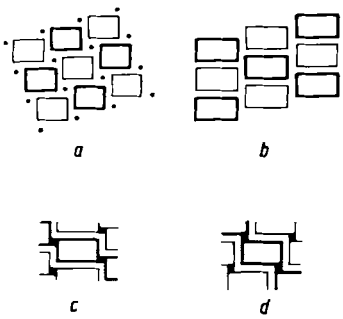

Fig. 2. Modes of interconnection of block structures [21]. a) The blocks are surrounded on all sides by (4/4) tetrahedral sites, *e.g.* $W_{4/4}Nb_{12}O_{33}$; b) the blocks are interconnected exclusively *via* the edges (both short edges), *e.g.* $MgNb_{14}O_{35}F_2$; c) detail of the connection *via* the short edges (see b); d) interconnection as in b and c, but *via* the longer edges (not known up to now in structurally uniform crystals).

[*] The term "Wadsley intergrowth defects" was coined by *Andersson* [5] in memory of *A. D. Wadsley* (1918—1969) (Section 4.3).

[**] The term electron microscopy was first used by *E. Brüche* [16a].

Table 1. Structural principle of some structurally related ternary oxides of the Nb_2O_5–WO_3 system. In the $M_{4n+1}O_{11n}$ series the block sizes of neighboring structures differ by one octahedral layer (n is an integer). The blocks are interconnected on all sides *via* tetrahedral sites ($W_{4/4}$) (see Fig. 2a). The block sizes correspond to the number of coordination polyhedra.

n	$Nb_2O_5:WO_3$	Structural principle [20]	Block size	$O/\sum M$ (M = Nb, W)
3	6:1	$W_{4/4}Nb_{12}O_{33}$	[4 × 3]	2.538
4	7:3	$W_{4/4}Nb_{14}W_2O_{44}$	[4 × 4]	2.589
5	8:5	$W_{4/4}Nb_{16}W_4O_{55}$	[4 × 5]	2.619

termediate phases" nor for phase widths. It was therefore at first surprising to find a further ternary oxide of composition $Nb_2O_5:WO_3 = 13:4$ *between* the 6:1 and the 7:3 phases of this system[24]. In other systems one can even find as many as four additional intermediate phases between the members of the $M_{3n+1}X_{8n-2}$ series ($7 \leq n \leq 11$ with M = Nb and X = O, F)

2.3. On the Road to Atomic-Scale Resolution

Like *Menter*[19], *Wadsley*'s working group first used a one-dimensional[29] imaging technique, *i.e.* the lattice planes of only *one* crystallographic direction were portrayed by selecting the corresponding diffraction spots. Lattice plane separations of *e.g.* 21, 14, and even 10.5 Å could be distinguished, but with the EM 200 electron microscope and side-entry goniometer used, a resolution better than 8—10 Å could not be achieved; in large measure this was due to the use of a goniometer (Section 3.6), which however, one cannot do without. Soon afterward *Allpress*[20] reported a two-dimensional technique, which yields information simultaneously about lattice planes in various crystallographic directions. In this case the diffractogram is not composed of the diffraction spots of only *one* direction, *e.g.* the h00 or 00l spots (direction of incidence along the b-axis) as in the one-dimensional case, but of h0l spots, which also increases the number of

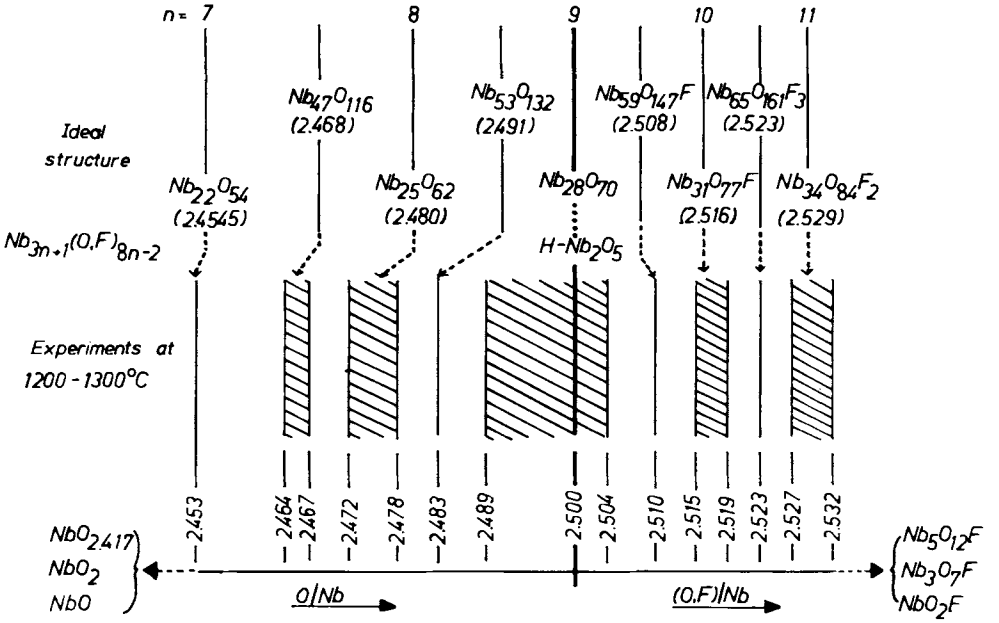

Fig. 3. The NbO_2–Nb_2O_5 and Nb_2O_5–NbO_2F systems at high temperatures [22]. In the representation of the Nb_2O_5-rich partial systems, not to scale, $Nb_{12}O_{29}$ has been omitted as a member of the $Nb_{3n}O_{8n-3}$ ($n = 4$) series. Note the very small but definite differences between the experimentally determined compositions and the ideal structures.

(Fig. 3)[25-27]. As shown by an X-ray structure analysis rendered highly elaborate because of the large unit cells[28], the 13:4 intermediate phase contains the structural elements of the two adjacent phases in a periodic arrangement thus consisting of alternating rows ("layers", see Section 4.3) of blocks with sizes of [4 × 3] and [4 × 4].

This first discovery, that blocks of different sizes can be combined coherently ("intergrowth"[23]) into a new structure ("hybrid phase"[21]), may—like the existence of additional intermediate phases, the then structurally inexplicable phase widths, the observed deviations of the narrow phases from the composition of their ideal structure (Fig. 3), and the joint discussion of the details of these questions at Münster[5]—have inspired *Wadsley* and *Allpress* and *Sanders* in 1967[6] to begin applying transmission electron microscopy to this field. At the same time they gave impetus to the development of a new investigation method.

spots that contribute to forming the picture (Section 3.5). Gradually, greater experience led to increasing confidence that this did not involve any "artefacts" but that the true characteristics of the crystal structure in question were being portrayed. It was recognized that one could come close to a direct lattice imaging (1:1 representation) of the crystal structure projected onto a plane, and this has been confirmed both theoretically[1] and by computer simulation[30,31].

Improved resolution soon led to further advances in the lattice imaging of crystal structures; several teams were especially successful as the result of using electron microscopes with top-entry goniometer stages[8,9,32]. As early as 1971, *Iijima*[32], a member of *Cowley*'s team, led the field in resolution capability (*ca.* 3 Å). The advances made in as little as five years are illustrated in Figure 4 on the example of WO_3, whose structure, analogous to that of ReO_3 (apex-connected W-O octahedra), is shown in Figure 4c in projection along a

diagonal of an octahedron. Edge connections between the coordination octahedra can appear if there is a slight oxygen deficiency (reduction), corresponding to some composition that may be denoted by WO_{3-x}; the edge-connected octahedra are arranged in planes of a determined crystallographic direction (shear planes, see Fig. 4c). When the oxygen deficit

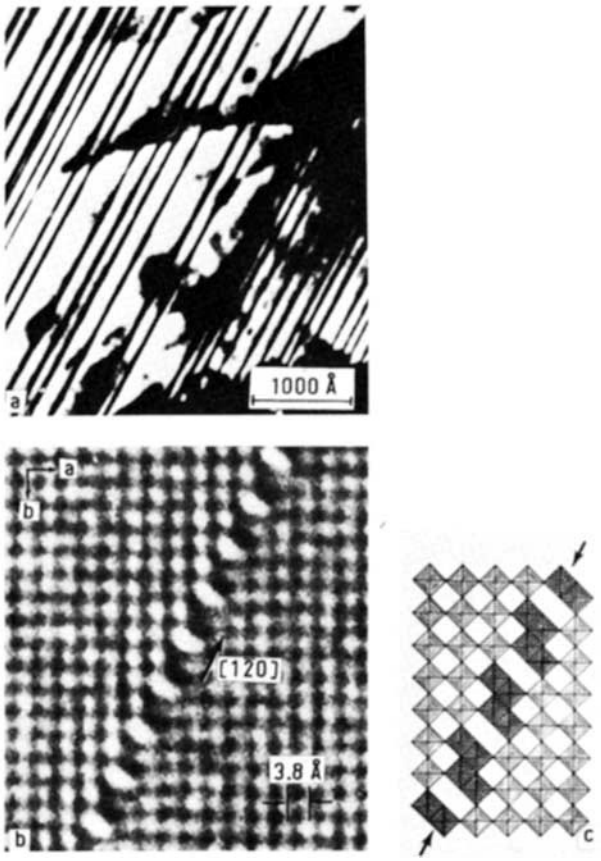

Fig. 4. Transmission electron micrographs of partially reduced tungsten trioxide (WO_{3-x}) with so-called planar defects. a) "One-dimensional" photograph [33] with nonperiodic shear planes in the [1$\bar{2}$0] direction; b) high-resolution "two-dimensional" image [34]; the centers of the W–O octahedra are recognizable, as are characteristic features of the octahedral interconnection (cf. c) along a [1$\bar{2}$0] shear plane; c) idealized model of the structure of WO_3 with apex-interconnected W–O octahedra. A [1$\bar{2}$0] shear plane is indicated, with characteristic edge interconnection of the octahedra.

x is small, the shear planes may fail to form a periodic sequence (cf. Section 4.3); when the sequence is periodic, they constitute an important structural element of many crystal structures, *e.g.* the block structures (Fig. 1). As shown by Figure 4a, nonperiodic shear planes can even be shown up by one-dimensional imaging[33], but in this case their structure cannot be made out. High-resolution two-dimensional images (Fig. 4b) reveal the individual coordination polyhedra (*i.e.* their most strongly scattering W centers) with their respective connections[34].

3. Foundations of Transmission Electron Microscopy

3.1. Structural Principles of the Microscope

The design of the microscope column is in principle similar in all transmission electron microscopes (Fig. 5). At the top there is an electron gun, and beneath this the anode, the condenser system (two lenses), and the objective lens with the specimen chamber. Underneath the objective lens there

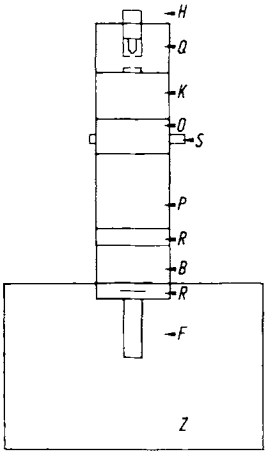

Fig. 5. Schematic sketch of a transmission electron microscope with a side-entry goniometer. H = high voltage input, Q = electron gun (see Fig. 6), K = condenser system, O = objective lens with specimen chamber (see Fig. 7), S = specimen airlock of the goniometer, P = projector system, R = recording camera (35 mm film), B = observation chamber with fluorescent screen, R = sheet film or plate camera, F = television camera, Z = electronics, pumps, *etc.*

is a projector system comprising three or four lenses, which project the image formed by the objective lens onto a fluorescent screen situated at the bottom of the column for direct observation. Modern electron microscopes have special magnetic lenses[35]. In most instruments the images can be recorded on 35 mm, sheet film, or photographic plates, and it is also possible to mount a television camera or a 70 mm cine camera as an attachment. The space comprising the electron gun, the interior of the microscope column, the specimen chamber, and the observation chamber with its fluorescent screen and plate camera must be under high vacuum. In most instruments the high-voltage generator, the control electronics, and the vacuum pumps are housed in a desk console below the column itself.

3.2. Electron Generation

In order to produce electrons as coherent as possible and to achieve a sufficient light intensity for observation and photography, several types of electron gun have been developed. In TEM the electrons are usually produced by incandescent emission from a hairpin cathode (tungsten wire about 0.1 mm thick) surrounded by a metal cap (Wehnelt cylinder) to control the electron emission; this cap is maintained at a slightly negative potential (*ca.* -100 V) (Fig. 6). The tip of the hot filament, bent into the shape of a hairpin, is situated opposite the aperture in the Wehnelt cylinder.

Apart from the simple hairpin cathode, variously shaped point cathodes have been proposed, which up to now have been used mostly for scanning electron microscopy. For example, some pointed cathodes have hairpins with the smallest possible radius of curvature, while in others the bent portion is drawn to a point[35]. Greater brightness can be attained by using LaB_6 cathodes[36], but these are more difficult to make than hairpin cathodes. Likewise, for some years

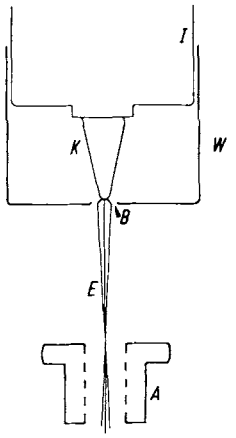

Fig. 6. Sketch of an electron gun. I = Insulator with high-voltage input, K = hairpin cathode, W = Wehnelt cylinder, B = Wehnelt aperture, E = electron beam, A = anode.

field emission electron sources have been available for routine use. These produce more coherent electron beams and give a high beam directionality, but their emission surface area is very small[37]; they are thus particularly suitable for scanning transmission electron microscopy (STEM) or for surface imaging (SEM). All these electron sources of special design may become particularly significant in high resolution transmission electron microscopy.

3.3. The Operating Principle of the Microscope

The electrons emitted from the tip of the hairpin cathode are accelerated toward the anode. Accelerating voltages of up to about 100 kV can be applied in most of the usual commercial electron microscopes. The wavelength of the accelerated electrons can be calculated from de Broglie's equation[35] (Table 2). The wavelengths of the electron beam is considerably shorter than that of the X-ray beams commonly used for the investigation of crystal structures (*e.g.* $Cu_{K\alpha} = 1.5418$ Å).

Table 2. Wavelengths of accelerated electrons.

U [kV]	80	100	120	200	500	1000
λ [Å]	0.041_7	0.037_6	0.033_5	0.025_1	0.014_2	0.008_7

The accelerated electrons oriented close to the optical axis pass through the anode, which has an aperture in the beam direction, into the condenser system (Fig. 6). This system can be used to adjust the beam diameter and the convergence of the beam incident on the specimen.

The specimen is imaged by the objective lens (Fig. 7), which is thus the most important lens of the electron microscope; its properties essentially determine the performance of the instrument. The position of the lens function exerted by the coils of the objective lens lies between the pole-pieces of the lens coils, so that the space available for the specimen between the pole-pieces is determined by the coil and pole-piece geometry. On the one hand, the separation of the pole-pieces should be as large as possible to enable the necessary mechanical devices to fit in; for example, there must be room for the specimen holder, diaphragm screens, and a cold trap, while for the investigations described here it should also be possible to raise or tilt the specimen by means of a goniometer. On the other hand, the separation of the pole-pieces should be as small as possible to reduce lens aberrations (particularly spherical aberration).

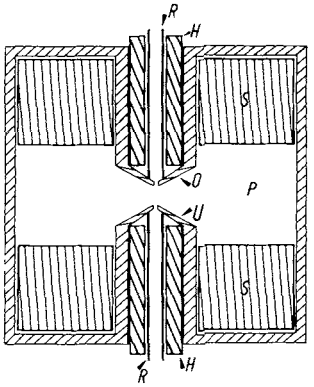

Fig. 7. Sketch of the objective lens. R = evacuated inner tube of the microscope column, H = auxiliary coils, S = main coils, O = upper pole-piece, U = lower pole-piece, P = specimen chamber.

After the objective lens the electrons pass into the projector system, which comprises the diffraction lens, one or more intermediate lenses, and one or more projector lenses. This enables one to vary the image magnification or to switch from the imaging to the diffraction mode (see Fig. 8), by varying the lens currents and so the focal lengths of the lenses, or by switching the lenses on and off. Since the electrons follow spiral paths when passing through the magnetic fields of the lenses[35], the image is rotated with respect to the specimen itself, the axis of rotation coinciding with the optical axis. The amount of rotation depends upon the setting of the lenses of the magnification system.

3.4. Crystallographic Adjustment of the Specimen

The orientation of crystalline specimens can be identified from the diffraction pattern of the crystal; this is done using the method of selected area diffraction[38,39] (Section 3.5). If the instrument is fitted with a goniometer, the orientation of the crystal can be changed until the desired diffraction pattern has been obtained. The electron beam is then perpendicular to the desired plane of the reciprocal lattice of the crystal (Sections 3.6 and 3.9). With a eucentric goniometer the image of the crystal can be kept within the diffraction diaphragm during the tilting or rotation.

3.5. Selected Area Diffraction

At low magnifications (*e.g.* × 20000) the specimen is moved about until an image of a seemingly suitable area of the crystal to be examined by diffraction is obtained. This image is brought within the aperture of the diffraction diaphragm visible on the fluorescent screen, this aperture having previously been centered in the middle of the field of view. The diffraction diaphragm is arranged in the microscope column in such a way that it lies in the image plane of the objective lens and can also be imaged sharply by the dif-

fraction lens (Fig. 8). With a sharply imaged diffraction diaphragm, the image of the crystal is focused in the plane of the diaphragm, *i.e.* both the diaphragm and the crystal are sharply imaged on the observation screen. The microscope is then switched into the diffraction mode. This type of diffraction is known as selected area diffraction[38,39].

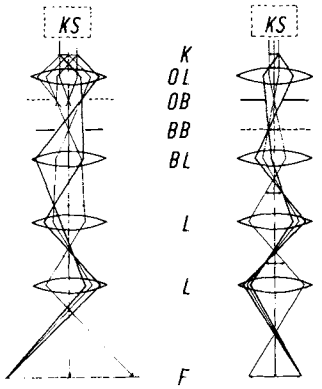

Fig. 8. Simplified ray diagram of the electron microscope. Left: Selected area diffraction, right: imaging mode. KS = condenser system, K = crystalline specimen, OL = objective lens, OB = objective aperture, BB = diffraction aperture, BL = diffraction lens, L = other lenses in the projector system, F = film plane.

Since the wavelength of the electrons is very short, the diffraction angles θ are small, up to about 3°. This can be seen directly from the Bragg equation:

$$n \cdot \lambda = 2d \sin\theta$$

(n = diffraction order, λ = wavelength, d = lattice plane separation, θ = angle between the lattice plane and the diffracted beams). The crystals must be very thin in the transmission direction (phase object, see Section 3.6)[1,7]. Under these conditions the number of structural units available to diffract the beam is small, and for this reason the diffraction maxima in this direction are not very sharp. The diffraction spots are in this direction elongated into so-called spikes. When the electron beam makes a right angle with a plane of the reciprocal lattice of a crystal, the situation is as shown in Figure 9. Although no spot lies with its mid-point exactly on the surface of the Ewald sphere, *i.e.* though the Bragg condition is not exactly satisfied for any of the points, very many of the rodlet-shaped spots intersect or touch the sphere. This is the starting point for later high resolution imaging (Section 3.6).

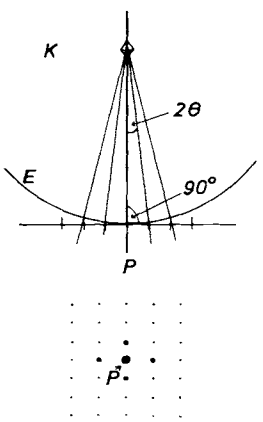

Fig. 9. Sectional view through the Ewald sphere and multibeam pattern. Top: production of a beam pattern [39]; crystal orientation required for high-resolution work. Bottom: schematic view of the corresponding diffraction pattern. K = crystal, E = Ewald sphere, P = primary beam, θ = glancing angle.

The diffraction pattern of an object is sharply imaged by the objective lens at its back focal plane[35]. In this plane there is also the perforated diaphragm known as the objective diaphragm (Fig. 8). In the diffraction mode, the diffraction lens is so adjusted that it forms a sharp image of what appears at the back focal plane of the objective lens. This image is projected onto the observation screen, or onto photographic film, by the intermediate and projector lenses further down. The diffraction pattern of a correctly oriented crystal, obtained here on account of the pointed (rod-shaped) intensity distribution of the spot intensity from a fixed crystal (Fig. 9), looks like a Buerger precession diagram made with X-rays. The spot intensities in themselves are of no direct use, but in regard to the spot separations and the angles between spot series the pattern can be evaluated like a precession pattern[39,40]:

$$a^* = \frac{A}{\lambda \cdot L}$$

(a^* is the separation between two spots in the reciprocal lattice, A the separation between two points on the film, and L the camera length, *i.e.* the apparent distance between the crystal and the film). With orthogonal crystal systems this yields the lattice plane separation r in the real lattice, $r = 1/a^*$[41]. With oblique-angled crystal systems the calculation is more complicated[40]. In contrast to the case of a precession camera, with an electron microscope it is easy to vary the camera length, and with it the scale of the image, within wide limits. The camera length can be calibrated for various settings of the instrument with the aid of a known substance.

3.6. High Resolution Lattice Imaging[1,7]

The orientation of the crystal with respect to the electron beam must be set accurately to within about 0.1—0.2°, since otherwise the image will show contrast variations and distortion. When the crystal has been oriented (Section 3.4), a correctly centered objective aperture in the back focal plane of the objective lens is used to pick out the number of diffraction spots required to contribute to the image.

Spots too far out from the primary beam, such as those admitted by too large an aperture, will be affected by additional phase alterations because of lens aberrations and will produce contrast errors and spurious detail in the image. All these factors affect the resolving power of the instrument. A decision must therefore be made concerning which spots may sensibly be allowed to contribute to the image, *i.e.* what size of objective aperture should be selected (*e.g.* about 50 μm for one of the block structures mentioned).

Spots that lie far out from the primary beam are produced by lattice planes whose mutual separation is very small. The smallest distance between two points on the object that can be resolved with an electron microscope can be evaluated from the following relationship[1]:

$$\Delta x \approx 0.6 \cdot C_s^{1/4} \cdot \lambda^{3/4}$$

(Δx = smallest resolvable separation, C_s = error constant of spherical aberration).

When, after the spots have been selected, the instrument is switched over to the image mode, the projector system will produce the "normal" image generated by the objective lens approximately in the plane of the diffraction aperture (Fig. 8). It is advisable to focus the image sharply, making the Fresnel fringes at a crystal edge or at a hole in the supporting film (Section 3.8) disappear completely, or making the supporting film (carbon film) appear with the least possible contrast. To allow the best possible correction of the astigmatism of the instrument, the primary magnification must be increased to at least 400000—500000. The contrast of high resolution images is especially sensitive to the influence of astigmatism, which therefore has to be corrected extremely thoroughly. To achieve this, we have found it very useful to inspect a part of the image using CCTV. The focus is then adjusted in the smallest possible steps. With a certain degree of underfocus (500—1000 Å), the correct image contrast is set to its clearest level[1, 7, 35]; this approximately compensates for phase changes of the electron waves occasioned by lens aberrations. It is recommended to take a picture for each focusing step, and pick out the best image later. The part of the crystal that is to be imaged at very high magnification must be very thin in the beam direction to constitute an effective phase object (*ca.* 100 Å; the edges of crystal flake fragments are suitable)[1, 7]. Under these conditions it is permissible to correlate contrast phenomena of the image directly with structural elements of the crystal.

The exposure time should not exceed 2—4 s, mainly because otherwise mechanical instabilities of the instrument will lead to blurring of the image. It can be difficult to obtain sufficiently intense illumination at very high magnifications, since in order not to allow too great a beam divergence ($<0.05°$)[1], an aperture size of about 100 μm should be chosen in the second condenser lens. The total observation time of a crystal can run to hours. Thus, it is important to maintain a good vacuum in the electron microscope, so as to decrease the deposition of organic impurities onto the sample (contrast reduction).

Our own TEM photographs reproduced in this article were taken using an EM 400 Philips electron microscope with an HMG high resolution side-entry goniometer; the accelerating voltage was 120 kV. For this instrument, in which the vacuum was very good (ion getter pump), a largely vibration-free mounting position was chosen.

3.7. Comparison between X-Ray and Electron-Microscopic Methods

The fundamental difference between these two methods of structure determination[1] is that since X-rays cannot be sufficiently affected to produce any lens-like effect, one cannot use "X-ray optical" methods to obtain an image from the diffraction pattern carrying phase information. Instead, the intensities of the diffraction phenomena must be measured for later computer generation of an image, and the phase information is lost during this process. The intensity is usually determined only at selected points that can be described by integral indices. X-Rays are less strongly scattered than electrons, and thus only relatively large crystals (mosaic crystals) are suitable for X-ray studies. As a result, the intensities obtained are averaged out and permit no conclusions about individual defect sites[1].

In contrast, in the electron microscope, after diffraction at the crystal, the beam can proceed without interruption, *i.e.* with all the pertinent phase relationships, so that an image of the crystal structure can be obtained. Which features are seen depends on the resolution and on the crystal structure itself (Section 3.10). The image is formed not only on the basis of the intensities of individual spots in the diffraction pattern, but rather of all the diffraction information from such electrons as pass through the selected objective aperture (structure determination by electron diffraction)[42, 43].

3.8. Specimen Preparation

The crystalline substances are placed on support grids (diameter 2 or 3 mm), usually copper grids covered with a perforated film of carbon (Fig. 10). The perforated film also serves to conduct away electrons. The preparation conditions for such perforated films (see *e.g.*[44]) are difficult to reproduce, and therefore we use our own method. The part of the crystal to be examined should be positioned over one of the holes in the film, so as to minimize loss of contrast due to an image background.

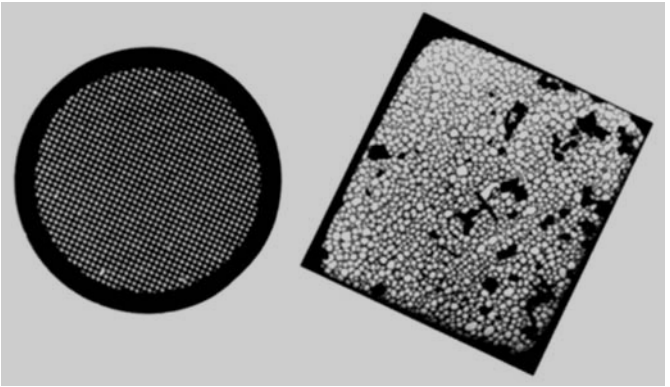

Fig. 10. Support grids. Left: copper grid (3 mm diameter); right: an individual mesh of this grid (about 0.04×0.04 mm^2) with perforated carbon film and crystals.

To obtain the thinnest possible crystal edges (Section 3.6), the specimen is first carefully crushed in a mortar, suspended in a liquid (chloroform, alcohol, water), and some of it is taken up onto a support grid. Even a dry crystalline powder can often be made to stick in sufficient quantity to the film.

During the comminution of the specimen care should be taken to avoid producing structural alterations such as may occur on milling in a mechanical mill[45]. In the investigations discussed here (Section 4) it was observed that the type of the defects present depended on the conditions of the chemical preparation (*e.g.* crystal growth from the vapor phase). By varying the preparation conditions, apart from severely disordered crystals it was also possible to obtain crystals free from a particular type of defect or ones that had only very low concentrations of structural defects. This provided confirmation that our way of comminuting the specimen, and also the irradiation in the microscope, did not generate any recognizable structural changes.

In special cases it is also possible to obtain regions of the preparations thin enough for direct imaging in other ways, *e.g.* by chemical etching or by polishing and ion-etching of the specimens[46].

The work on specimen preparation can be made negligible or at least reduced if the crystalline solid is in the form of a film, though it should be confirmed in each individual case whether the findings obtained with thin films can be extended to compact crystals[13].

3.9. Mounting the Specimen in the Microscope

The support grid is fitted into a specimen holder and inserted into the electron microscope. In instruments without a goniometer the positioning of the specimen is in principle mechanically more stable than with an arrangement in a goniometer. Consequently, up to now the highest resolutions had been attained in microscopes without goniometers[14 16]; however, such instruments have the decisive drawback that the inclination of the specimen with respect to the electron beam cannot be alterated. Thus, in this way one can only examine accurately pre-oriented crystal regions (*e.g.* [14 16]), or those crystal fragments that happen to be correctly oriented by pure chance[47,48].

Where a goniometer is needed, a choice has to be made between the top-entry and the side-entry types. The top-entry systems are mechanically quite stable, but up to now have not been available as eucentric goniometers. The support grid, fitted into a small specimen holder, is introduced from the top into the objective lens segment and is finally situated between the pole-pieces of the lens[13].

The side-entry goniometers currently available on the market are designed as uniaxial eucentric goniometers, *i.e.* the specimen holder is moved perpendicular to the longitudinal direction until the rotation axis of the goniometer passes through the specimen region that is to be observed. Thus, they are convenient to manipulate. The support grid is arranged at the leading end of a rod-shaped specimen holder; an electric motor is coupled to the other end in the case of the double-tilt or rotation and tilt holders. The holders are pushed into the microscope column through a generally pre-evacuated airlock; they are about 30 cm long, and are sealed and supported near the middle by an O-ring. Because of this type of bearing and their length, these holders are very sensitive to mechanical vibrations.

3.10. Specimen Requirements

The specimen-preparation techniques usual up to now (Section 3.8) for substances due to be examined in the electron microscope at very high resolutions have required that the material should not be sensitive to moisture, since crystal areas thin enough to be suitable for imaging could otherwise undergo rapid attack. The crystals should also be stable to electron irradiation within the microscope. There should be no unwanted phase transformations or other changes in the crystal structure; likewise, the crystals should not melt, vaporize, or decompose. For materials that are sensitive to air or moisture, *in situ* observation can offer advantages[13,49].

Thus, the high-resolution technique (lattice imaging) is particularly promising for structure investigation when the three-dimensional structure of the substance to be investigated can easily be projected onto a plane, so that the contrast will be as high as possible, *i.e.* the structural features will be clearly perceptible. It is advantageous if the beam can be directed along one of the short axes; a very small repeat period of *e.g.* about 4 Å (corresponding to one layer of polyhedra in the oxides we investigated) is particularly useful. Problems due to overlapping in projection of structural information from different parts of the unit cells are then minimal. Under these conditions, for example, structural defects can most easily be recognized when they extend through the entire depth of the crystal specimen in the direction of the beam.

4. A Broad Field of Application: Structural Defects

4.1. General Review

The direction of investigations carried out by the high-resolution technique has been decisively influenced[50 52] by questions relating to the structure of "nonstoichiometric" compounds[53]. Both this term and similar admittedly not very apt designations[50,52,53] indicate that the observed composition of the solid, *e.g.* the anion/cation ratio, cannot be described in terms of small whole numbers. In particular, variable compositions (phase widths) such as those in Nb_2O_5-rich systems (Fig. 3), that can be described neither in terms of a simple, periodically recurring unit cell nor by a statistical population of lattice planes, have given impetus to the electron-microscopic investigation of nonperiodic "deviations" from the matrix structure (structural defects) (Section 2.2).

The structural defects observed by electron microscopy show a very wide variation. In principle, the possibilities of the generation of different structural defects are especially numerous when the matrix structure is already highly variable, as *e.g.* in the case of "block structures"[20,21], "bronzes"[10,51,54,55], variants of the WO_3[34,51] and rutile[9,51] structures, and in many silicates[56,57]. Regions with different structures can then be connected to one another coherently, *i.e.* without undue deformation of their coordination polyhedra; this possibility extends even to a combination of the structural principle of "bronzes" with the WO_3 structure[10,51,55]. However, in the following sections, we shall only be able to deal with the situation relating to block structures. In block structures, bronzes, and WO_3 variants the variability and the coherence of the modes of interconnection depend upon the predominant presence of apex-to-apex and edge-to-edge connections of the coordination octahedra and in rutile variants also upon their additional connections by faces. Structural defects with noncoherent arrangement of their structural elements are also known[8].

Essentially, the observable structural defects (Section 3.10) are "extended" defects, among which three-dimensional, two-dimensional (planar), and one-dimensional defects may be distinguished[52]. The most important three-dimensional defects are the microdomains (Section 4.2); furthermore, nonperiodic clusters or defect clusters also play some part. In general, the microdomains are small regions within a crystalline matrix that possess their own (periodic) structure; if this conforms with the structure of one of the neighboring phases

in the system, then one can speak of a "microheterogeneity", especially when the homogeneous regions are large in comparison. Some authors also consider smaller *ordered* regions within an *unordered* matrix to be microdomains[58].

In general, the structural defects mentioned also differ in chemical composition (anion/cation ratio) from the surrounding part of the crystal; less frequently one observes defects that do not differ in composition, *e.g.* microdomains of a different modification, stacking faults, twin planes, and antiphase boundaries[50,51]. The anion/cation ratio in narrowly delimited defect zones of block structures can often be inferred from the structure observed in the electron microscope[48,59], especially when the structural elements of the disturbed region (*e.g.* the coordination polyhedra and their mode of interconnection) are well known from X-ray studies of the undisturbed matrix or of another related structure and it is assumed that a "fully populated" crystal structure is present. Isolated point defects, which cannot be detected by TEM, cannot be taken into account by this procedure. Notwithstanding their designation as "extended defects", the very small size of the microdomains and other defect zones, which in many cases cannot even be approached by selected area diffraction (Section 3.5), has up till now frustrated the direct determination of their composition by chemical analysis.

4.2. Microheterogeneities, Microdomains

In investigations of the phase relationships in a multicomponent system, the answer to whether a given specimen should still be regarded as homogeneous or already as heterogeneous is influenced not only by structural similarity but also, and in particular, by the particle sizes of the secondary phases to be detected. Thus, the Guinier method, which can be used for high-sensitivity X-ray investigations of polycrystalline or powdered specimens, is the *less* sensitive, the greater the similarity between the diffraction patterns. In other words, the closer is the structural relationship between the phases[22], the less accurate will be the localization of the phase boundary compositions in a multicomponent system. For example, in the TiO_2–Nb_2O_5 system, as little as 1% of the compound $(Ti,Nb)O_{2.33}$ can be detected in rutile, while the relative detection sensitivity for $(Ti,Nb)O_{2.483}$ side by side with $(Ti,Nb)O_{2.489}$ is only 17%, or an order of magnitude smaller, since the diffraction patterns of these two phases only differ in some very weak lines. X-Ray confirmation of phase purity is called into question when the particles or uniform regions of the secondary phase to be detected are too small for this method ("microheterogeneities"), as can be brought about *e.g.* by segregation. In the X-ray investigation of "single crystals" (mosaic crystals) it should be borne in mind that an apparently well ordered matrix structure may show a dispersion of coherently included regions ("microdomains") of one or more neighboring phases without any such structural defects being detectable by X-rays (Section 3.7).

Microheterogeneities can often be detected by electron microscopy in specimens that appear to be uniform to X-rays (Guinier method). Thus, in Guinier-pure $(Ti,Nb)O_{2.483}$, whose structural principle can be described in terms of the different composition $TiNb_{52}O_{132}$ (similar to $Nb_{53}O_{132}$; Fig. 3), *Allpress*[60] found microdomains of the lower neighboring phase $TiNb_{24}O_{62}$ and of the previously unknown compound $Ti_2Nb_{76}O_{194}$ ($TiNb_{38}O_{97}$). However, the electron-microscopically observed inhomogeneity of a substance such as $(Ti,Nb)O_{2.483}$ seems to us insufficient to classify the system as a two-phase one. For example, in this case if one were to ascribe to the pure phase a composition above $(Ti,Nb)O_{2.483}$, it would be difficult to see why the composition $(Ti,Nb)O_{2.485}$ is already heterogeneous to X-rays, as shown by the presence of the higher neighboring phase $(Ti,Nb)O_{2.489}$ with the H-Nb_2O_5 structure. The analogous situation in the NbO_2–Nb_2O_5 system (Fig. 3) lends support to the considerations concerning the demarcation of the phases present[22]. Since segregation during the cooling of the specimens can be excluded on account of the observed sluggishness of the reactions in these oxides, it seems here that equilibrium is not fully established within the solid material. This is also supported by observations in the Nb_2O_5–WO_3 system[61], where, in one and the same crystal fragment, regions of both the

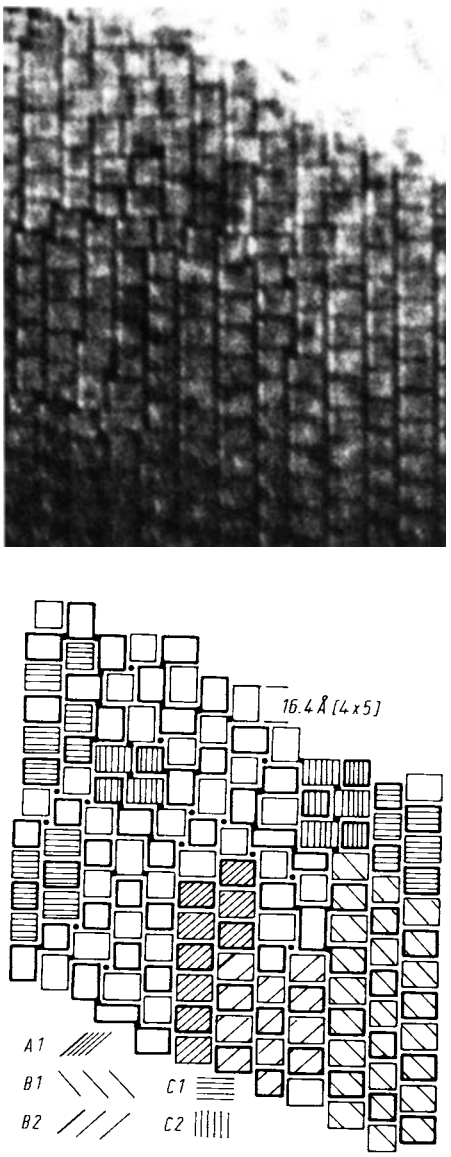

Fig. 11. a) Transmission electron micrograph and b) interpretation of a severely defective crystal region. Specimen composition $Nb_2O_5:WO_3 \approx 6:1$, deposition temperature 780 °C. Microdomains of five structure variations (Table 3) are indicated. Of the possible edge connections, only the unusual type of connection along the longer block edges is marked (as in Fig. 2d).

lower and the higher neighboring phases have been detected by electron microscopy.

It should be noted that microdomains of the compound $Ti_2Nb_{76}O_{194}$ can be formed before the final state has been reached. This compound was not observed in the stable

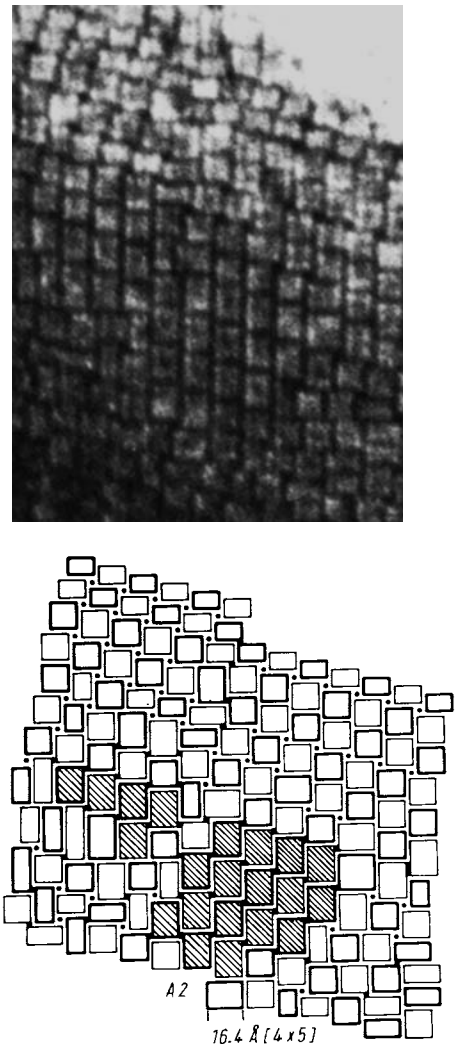

Fig. 12. a) Transmission electron micrograph and b) interpretation of a second crystal region of the same specimen as in Fig. 11. The unusual connection along the longer edges of the [4 × 5] blocks is marked.

TiO_2–Nb_2O_5 system, and is possibly metastable. There is a close structural relationship between the $TiNb_{52}O_{132}$ matrix and the microdomains of $Ti_2Nb_{76}O_{194}$. $TiNb_{52}O_{132}$ can be regarded as a 1:1 hybrid phase[21] of the structures $TiNb_{24}O_{62}$ and $Nb_{28}O_{70}$ (H–Nb_2O_5), and $Ti_2Nb_{76}O_{194}$ as a 2:1 hybrid phase with the same structural elements. Thus, the connection principle of the structural elements is the same in both structures.

Microdomains differing fundamentally from the matrix in the connection principle and in the size of the structural elements (blocks) have recently been discovered in the Nb_2O_5–WO_3 system, in crystals of the approximate composition $Nb_2O_5:WO_3 \approx 6:1$[62]. The 6:1-specimens crystallizing under conditions close to equilibrium possess a uniform structure of (3 × 4) blocks interconnected as shown in Figure 2a[20], but if

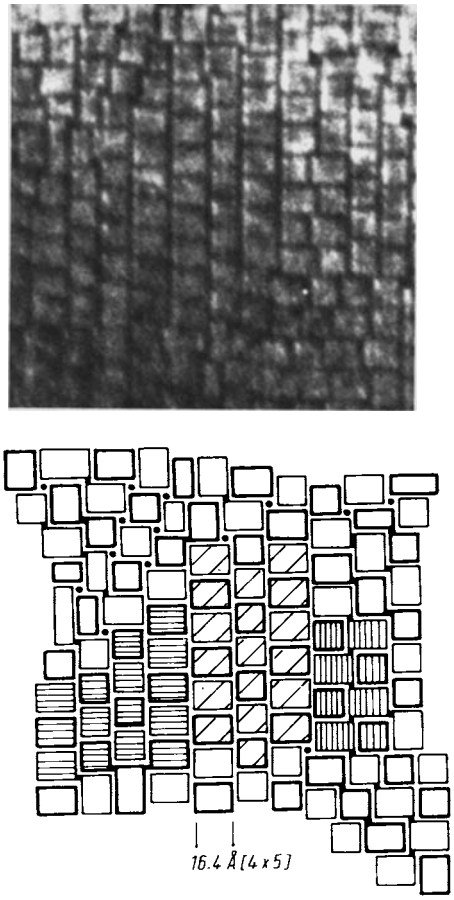

Fig. 13. a) Transmission electron micrograph and b) interpretation of a third crystal region of the specimen of Fig. 11. Microdomains of C1 and C2 (with zipper-like connections), and of B2, are clearly visible. In addition, as in Fig. 12, one can see individual blocks of dissimilar sizes (*e.g.* [3 × 6]) and with unusual types of interconnection (*e.g.* top right), see Section 4.4.

the crystals are deposited from the vapor phase by a chemical transport reaction[63] at a relatively low temperature of about 780 °C, their structure is severely disturbed. As shown in Figures 11—13, numerous microdomains of various structures can be detected even in a *single* crystal fragment[62].

Table 3. Structure of the microdomains in Figs. 11—13. The blocks are connected along the shorter (s) or longer (l) block edges (see Figs. 2c or d); monoclinic sequence of block rows = (m); orthorhombic = (o).

Region	Composition	O/$\sum$M (M = Nb, W)	Size and connection of the blocks
A1	$W_2Nb_{18}O_{51}$	2.55	[4 × 5] (s, m)
A2	$W_2Nb_{18}O_{51}$	2.55	[4 × 5] (l, m)
B1	$W_4Nb_{52}O_{142}$	2.536	[4 × 4] + 2 [4 × 5] (s, m)
B2	$W_4Nb_{52}O_{142}$	2.536	[4 × 4] + 2 [4 × 5] (s, o)
C1	$W_2Nb_{34}O_{91}$	2.528	[4 × 4] + [4 × 5] (s)
C2	$W_2Nb_{34}O_{91}$	2.528	[4 × 4] + [4 × 5] (l)

The edge interconnections are of particular interest; these hold the blocks together in a way never before observed in the Nb_2O_5–WO_3 system (Fig. 2b—d) and the blocks themselves have a size of [4 × 5] octahedra previously unknown for this type of connection. It is also unexpected to find the connections *via* the longer edges of the blocks (Fig. 2d) in re-

gions A2 and C2. Table 3 summarizes the unusual structures observed in the form of microdomains (for calculation of the compositions, see[48,59]). No macroscopically uniform specimens with any of the structures mentioned have yet been prepared. There is no doubt that nonequilibrium processes played a part at the relatively lower temperature at which these crystals were grown from the vapor phase.

4.3. Planar Defects, Wadsley Defects

As X-ray structure investigations have shown[64,65], particular structural elements, the shear planes, are characteristic[50] of regular series of closely adjacent and structurally related Hägg-Magnéli phases[22] (*e.g.* Fig. 3, Table 1 and the systems MoO_2–MoO_3, WO_2–WO_3, Ti_2O_3–TiO_2, V_2O_3–VO_2 *etc.*[64-67]. These can be described as planes in which the coordination octahedra are particularly closely connected to one another (along their edges or faces) (Fig. 4c); thus, the less dense "matrix" structure (*e.g.* of ReO_3 or rutile type) appears to be periodically divided into "layers" or "blocks". The separation of the connecting planes from one another can vary stepwise (structure-related series, *e.g.* Table 1), as also can their crystallographic direction. Both these features have been confirmed by electron microscopy[9,51,61].

If the composition of a crystal is very close to that of the matrix structure (*e.g.* WO_3 with ReO_3-like configuration in Fig. 4), the mutual separation of the "shear planes" is too great for an ordered distribution. Thus, sufficiently separated (see Fig. 4a)[33,34] shear planes should be regarded as nonperiodic structural defects, which become increasingly like the structural elements of ordered crystal structures (Hägg-Magnéli phases) as the separation decreases and they come closer together. This consideration is particularly applicable to systems or structurally related series that are limited at the upper end by a phase with the matrix structure (WO_3, TiO_2, VO_2); it fails, for example, in Nb_2O_5-rich systems where the connection planes (Fig. 1) of the block structures run perpendicular to one another. In this case a transition to what could be considered as a matrix structure, represented by the ReO_3 (or NbO_2F or WO_3) extraneous to the system, and an extensive "dilution" of the shear planes consequent upon this, cannot be achieved by chemical means (ReO_3), because "foreign" structures occur on approach to the limiting composition (NbO_2F, WO_3). In such materials it seems more meaningful to regard "blocks" or "rows of blocks" as the structural units. Both can occur nonperiodically as structural defects, since they can be included coherently in the structure matrix (for isolated blocks as structural defects, see Section 4.4).

Rows of blocks with irregular block sizes, known as Wadsley defects (Section 1), have been detected in many electron-microscopic investigations[5,60,61,68] as structural defects in block structures; Figure 14 shows a micrograph of a specimen of $W_3Nb_{14}O_{44}$ with two different block rows[62], one of $[4\times3]$ blocks, like those in the compound $WNb_{12}O_{33}$, and one of $[4\times6]$ blocks; up to now, no compound $W_7Nb_{18}O_{66}$ built up uniformly from this type of blocks has been re-

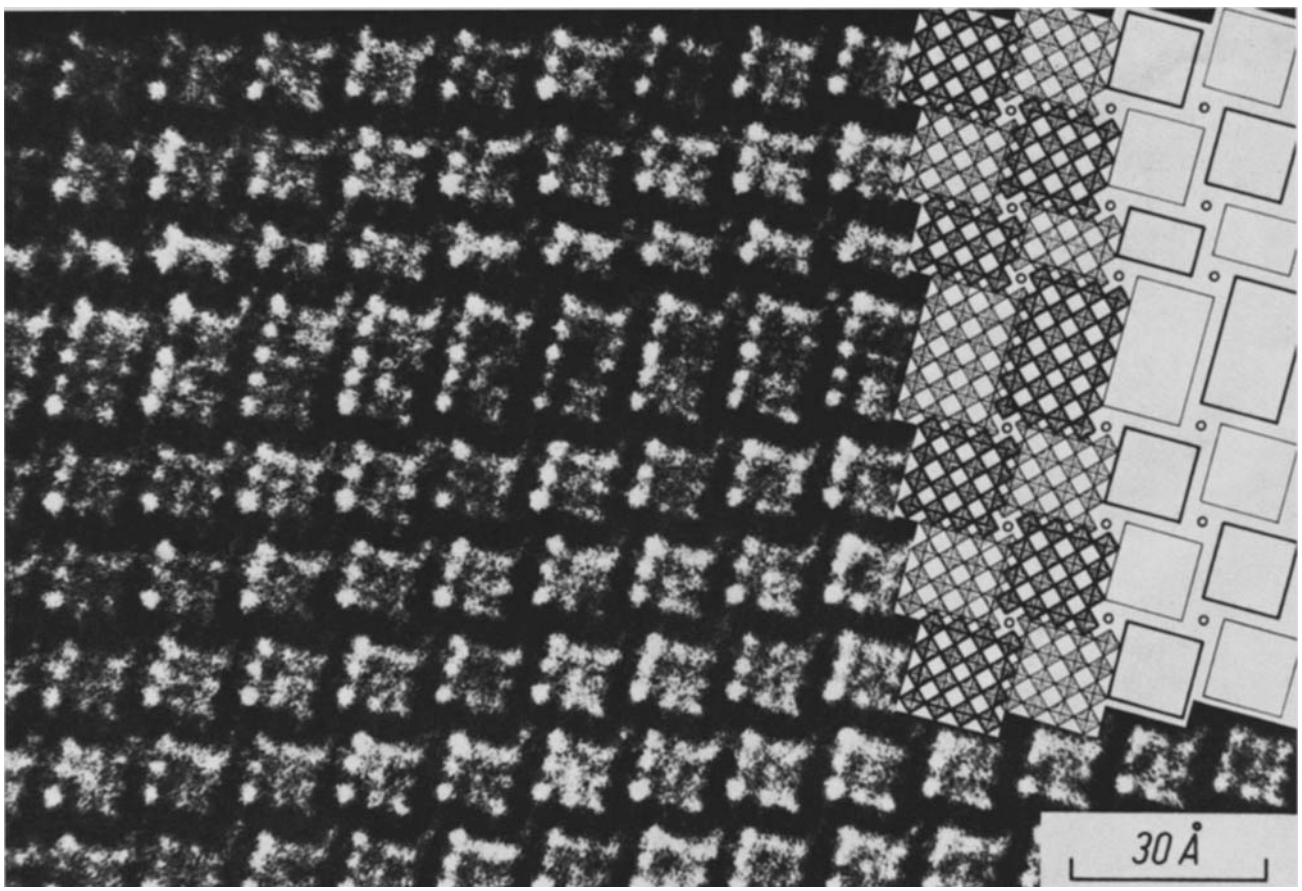

Fig. 14. Transmission electron micrograph of a specimen of $W_3Nb_{14}O_{44}$ with Wadsley defects. The manner of inerpretation is given (see Figs. 1 and 2a). The bright spots correspond to holes (perovskite holes) in the octahedra blocks, lying in the beam direction.

ported. The WO_3-deficit due to the [4 × 3] blocks (reduction of the $O/\sum M$ ratio) is overcompensated by the [4 × 6] blocks, so that the ratio $O/\sum M$ of the defect region amounts to 2.605, whereas for the matrix $W_3Nb_{14}O_{44}$ the $O/\sum M$ ratio is only 2.588[62]. If their compositions compensate partially or completely, the Wadsley defects can be healed by annealing[61]. Under these conditions the nonperiodically ordered shear planes (*e.g.* in WO_{3-x}) will attempt to achieve some degree of order, but they cannot disappear without a change in the overall composition of the specimen.

The block rows that can be seen in projection in an electron microscope image are three-dimensional "layers". Their layer thickness perpendicular to the viewing direction is determined by the size of the blocks; the total extent of a structural defect depends on the number of block rows that it comprises, *i.e.* for the two rows in Figure 14 together it amounts to about 30 Å. On account of their three-dimensional extension, these structural defects can scarcely be referred to as "planar defects", and we thus prefer the term Wadsley defects. As can be seen from the octahedron model (Fig. 4c), the individual shear planes, *e.g.* in a WO_3 matrix, also have an extension in space, and for this reason they cannot strictly be regarded as two-dimensional defects.

If several block rows with various types of blocks are *ordered* one after another, then it is difficult to decide whether such a region is a (large) Wadsley defect or a (small) microdomain (but with its own, new structure); we speak of a microdomain (Section 4.2) when two or more block rows are ordered in sequence[62]. The term "extended defect" is, however, appropriate in all the cases mentioned. It is not yet known for the materials in question how many periodically ordered layers are needed, before one can speak of a phase in the thermodynamic sense.

The occurrence of shear planes and Wadsley defects is not limited to structures made up predominantly of coordination octahedra. The large group of silicates offers an example of the usefulness of these concepts with structures comprising tetrahedral structural units[69].

4.4. From Macroscopic to Narrowly Delimited Defects

Crystals deposited from the vapor phase[48,62] by chemical transport[63] and examined by scanning electron microscopy[*] in many cases showed irregularities or "macroscopic" structural defects that take the form of channels or tubes running through the crystal in the growth direction[70,71]. An ex-

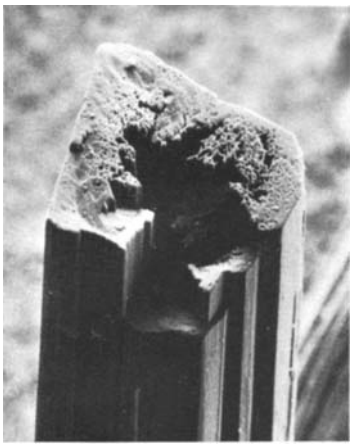

Fig. 15. Scanning electron micrograph of a $W_5Nb_{16}O_{55}$ crystal with tube-like cavities in the growth direction. Diameter of the needle-shaped crystal about 0.1 mm.

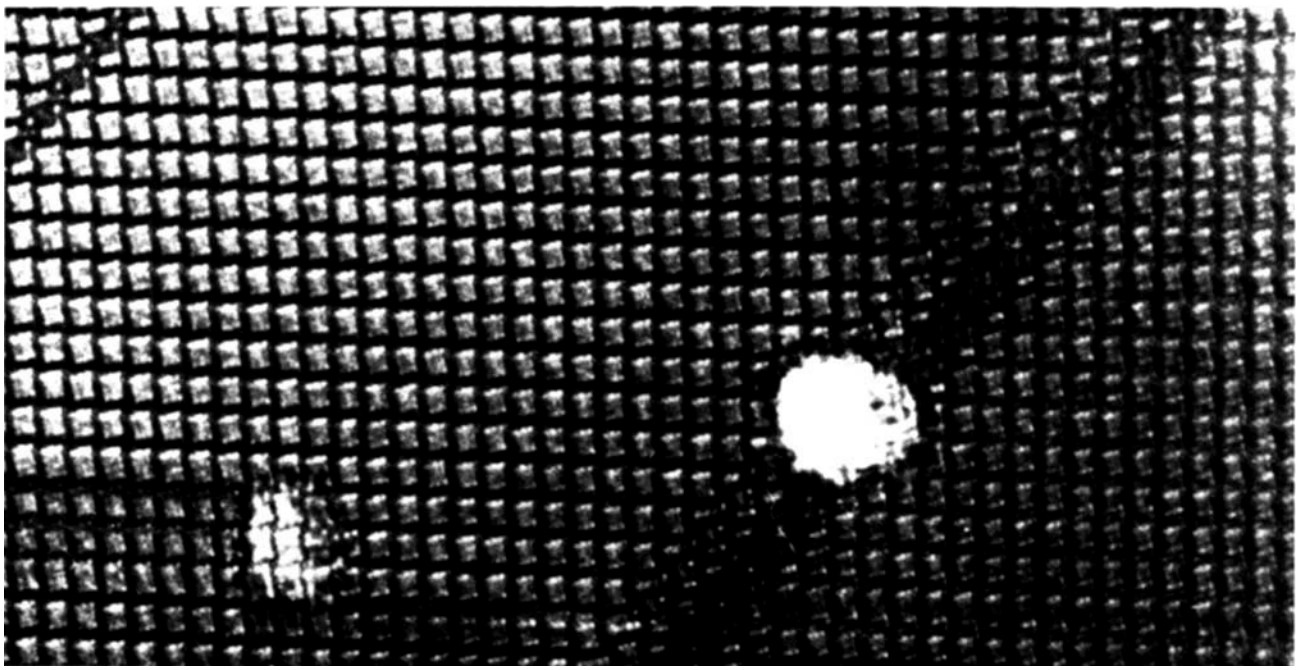

Fig. 16. Transmission electron micrograph of a fragment of the crystal in Fig. 15. The direction of the transmitted beam is along the short crystallographic axis (the growth direction). In a matrix of [4 × 5] blocks, in addition to other structural defects, two tubes can be seen in cross section (diameter about 50—60 Å), which do not pass completely through. The dark diagonal "bands" are defects in the b-direction (Section 6).

[*] The photographs were prepared at the Radiation Center of Giessen University.

ample of this can be seen in Figure 15, which shows a single crystal of the ternary oxide $Nb_2O_5:WO_3 = 8:5$[71]. Fragments of this preparation were examined by high-resolution transmission electron microscopy[72] in order to obtain comparative data on the "building-in" of structural defects during the longitudinal growth of such acicular or rod-shaped crystals. Apart from larger tube apertures, not reproduced here, one can observe defects of this type down to the order of magnitude of the unit cell (Fig. 16). The extremely small tube apertures recognizable in this case, whose size is *e.g.* below that of the Wadsley defects, could be regarded as "narrowly delimited" defects. The observations suggest that the processes involved in the formation and the "building-in" of the tube apertures and structural defects are evidently not different from each other in principle so far as the block structures in question are concerned. The situation may be different with crystals such as MoO_3 that grow in the form of flat plates, which in a few cases also have "holes" (about 1000 Å in diameter)[13].

Narrowly delimited defects of various types are found predominantly in specimens prepared under nonequilibrium conditions. Thus, deposition by chemical transport at relatively low temperatures gives particularly strongly defective crystals, *e.g.* in the Fe_2O_3–Nb_2O_5[47] or Nb_2O_5–WO_3[48,62] systems. As Figures 11—13 show, very few Wadsley defects (Section 4.3) occur at the deposition temperature of 780 °C selected in this case; apart from various microdomains (Section 4.2), there are some *individual* blocks that differ from their surroundings in size and mode of interconnection as well as in their anion/cation ratio[48,59], and that can be regarded as narrowly delimited structural defects like certain unusual types of interconnections.

Whether interconnections recognized from crystal structure determinations (Fig. 2a—c) are present or whether unusual types of interconnections are involved (*e.g.* Fig. 2d) is a question to be settled from the way the blocks are positioned with respect to one another and from the contrast phenomena observed. In this way sporadically occurring particular types of interconnection and "gaps" in the network of polyhedra can be inferred even when the limits of resolution of the electron microscope have been reached[48].

Figure 17 shows a severely defective region of a crystal of composition $Nb_2O_5:WO_3 \approx 7:3$ (deposition temperature 800 °C); an unusual connection around a bright spot can be seen within the circled area. Figure 18 shows the block arrangement in the form of a diagram, but no further attempt is made to interpret the interconnection in this region. If it is borne in mind that an arrangement comprising several terminal O-particles (octahedron apexes) is improbable[48], one arrives at an arrangement of the R1-type gap (tunnel) (for the nomenclature, see [48]) in Figure 19, which also illustrates a variety of other gaps; with the resolution attainable at present, it is not yet possible to decide between the two possibilities given for the S-type gaps[48]. Except for the R-type gaps, which constitute a structural element of the compound $NaNb_{13}O_{33}$[73], all the gaps known up to now have been found exclusively as structural defects. In this case the designation "narrowly delimited defect" may be the most appropriate one on account of their unusually small extension in the plane of observation.

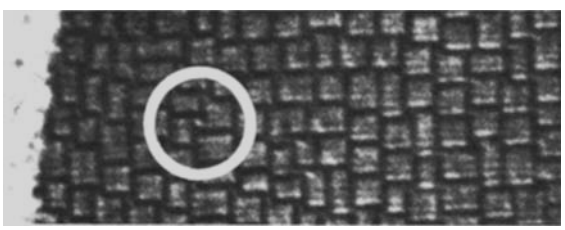

Fig. 17. Transmission electron micrograph of a specimen of $W_3Nb_{14}O_{44}$ with a narrowly delimited defect (circled). The bright spot indicates an interstice (see Figs. 18 and 19).

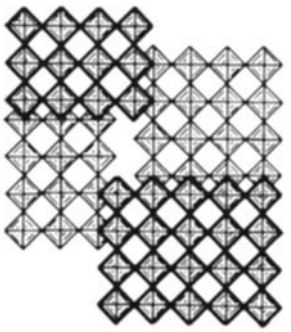

Fig. 18. Interpretation of the narrowly delimited defect of Fig. 17. The arrangement of the blocks can be inferred from the transmission electron micrograph and from crystallographic data. The situation at the center of the connection is left open (see text).

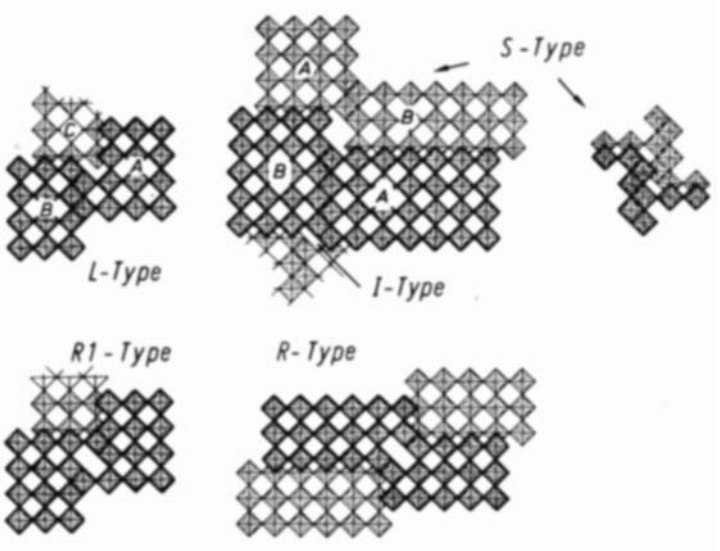

Fig. 19. Models of some narrowly delimited defects. The blocks include "gaps" because of unusual types of interconnection (see text). A, B, C denote blocks whose $O/\sum M$ values have to be evaluated in different ways.

5. Determination of the Crystal Structure

In favorable cases high-resolution transmission electron microscopy makes it possible to ascertain the crystal structure directly in exceptionally small specimens, though the determination of accurate positional parameters still remains the province of X-ray methods[42]. In addition to the information obtained by selected area diffraction, electron microscopy yields transmission micrographs showing a projection of the crystal structure in the selected favorable direction (see

Section 3.10). Fundamentally, the image can also be used to elucidate the structure, at least in regard to the principle of the latter, but to avoid faulty interpretations, it is indispensable to possess certain knowledge of the expected image contrast (Section 6). Furthermore, the reliability of the interpretation of an electron-microscopic picture is increased if one knows what images are produced by related well-known structures at high resolution; in general this is true of the works mentioned here. Investigations in the silicate field[57,74]—at first without any such comparison material—give an impression of the potential of this method. A clear example of an electron-microscopic structural picture is the micrograph of beryl (Fig. 20)[74], whose crystal structure has long been known from X-ray investigations.

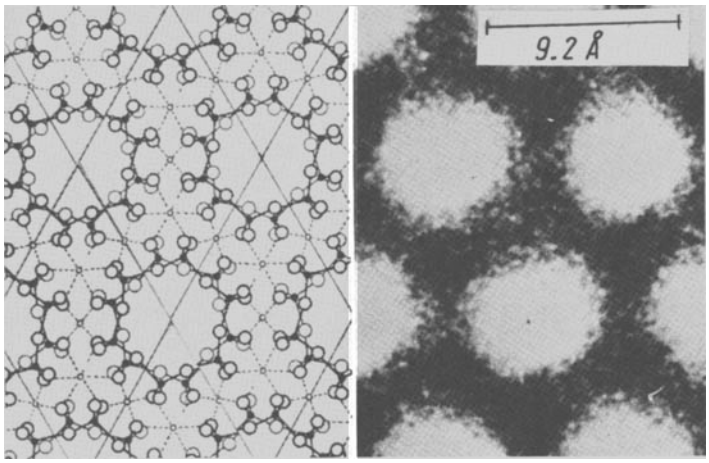

Fig. 20. Right: transmission electron micrograph of beryl [74]. The line of sight along the hexagonal c-axis makes the structural principle easy to recognize (rings of SiO_4 tetrahedra). Left: the ideal structure of beryl ($Al_2Be_3Si_6O_{18}$), drawn to the same scale.

As has been recognized for a long time (Section 2.2), the electron microscope is useful for the clarification of structures when it is difficult or impossible to apply other diffraction methods for the following reasons:

a) When the unit cells are particularly large, *e.g.* with superlattices or the hybrid phases mentioned in Section 2.2[21], in the case of stacking variants such as barium ferrites[75] or hexagonal polytypes of perovskite-related structures[76,77].
b) With structures that cannot be prepared as uniform crystals, *i.e.* that only exist in very small regions. This applies particularly to the structure determinations in microdomains, which sometimes cover only a few unit cells (see Section 4.2).

Furthermore, a transmission electron micrograph such as Figure 20 can very quickly yield an impression of the structural principle and thereby provide valuable indications for a detailed X-ray structural study.

In general, the factors a) and b) will both apply in the case of electron-microscopic investigations; this is true, for example, in the examination of Nb_2O_5-rich systems comprising block structures. The new structural variations recognizable in Figures 11—13, which up to now have only ever been detected in very small regions (microdomains, see Section 4.2), are for the most part hybrid phases (B1, B2, C1, C2 in Table 3); further structural variations in the Nb_2O_5–WO_2 system are known[62,78] or are at present being investigated[72]. An example from the TiO_2–Nb_2O_5 system[60] was mentioned in Section 4.2.

Metastable solids often cannot be obtained in the form of well crystallized specimens (or only with great difficulty), or are available only in exceptionally small amounts; this is also evident from the observations of microdomains mentioned earlier. Electron microscope studies can also achieve progress in this case (b); examples are a new metastable modification of $FeNbO_4$[79] or the oxidation products of $Nb_{12}O_{29}$ and other phases between $Nb_{12}O_{29}$ and Nb_2O_5[80,81].

6. Future Prospects

In this research review the applications of high-resolution transmission electron microscopy have been discussed taking as examples niobium oxides and niobium-oxide-containing systems; the method has also been used with other solids (*e.g.* [9,10,12,13,33,34,54–57,74–77]). Block structures have provided the impetus for this direction of work (Section 2.2), and they are also extremely suitable models for the study of structural defects and for the testing and further development of investigation methods, since they can be irradiated along their short crystallographic axis (Section 3.10).

In the interpretation of the results it was first assumed that, like the surrounding undistorted structure, the structural defects imaged continue with uninterrupted periodicity through the crystal *in the direction of the transmitted beam.* However, it has since been found that this is not an invariable rule—the observable "defects in the b-direction" (*e.g.* in Fig. 16), *i.e.* in the direction of irradiation[82] and *Ijima*'s point defects[83] cannot be discussed in detail here. Deviations in the occupation of the tetrahedral sites (likewise lying in the beam direction) (Figs. 1 and 2a), such as those first investigated more closely in $GeNb_{18}O_{47}$[84], are of special interest, since the differences between the compositions of the ideal and real structures shown in Figure 3 may possibly be elucidated with their help[21,51]. Particular attention should be paid in further work to the arrangement of defects in the beam direction.

In the investigations discussed here we have avoided mistaking for real observations any artefacts that may have been produced during the preparation process, during irradiation of the specimen (Section 3.8) or spuriously simulated by contrast effects. Further technical developments and systematic work, which will answer the following questions also for materials other than those investigated by us, seem to us to be urgently necessary:

1) Does the mechanical or other specimen pretreatment or comminution give rise to structural defects? (On the subject of mechanical-chemical reactions, see [45]).
2) How can one reduce the radiation load or how can one exclude the possibility of changes in the specimen's structure due to the electron beam? (On the production of point defects, see [13,83].)

Other points that still require discussion are how the influence of lens aberrations can be reduced and the correct in-

terpretation of contrast relationships. The lens aberration that can be influenced by the user is astigmatism. In the usual commercial instruments the basic astigmatism may be too great to allow high-resolution work, since the fine adjustment of the focus becomes meaningless under these circumstances.

Other desirable technical developments relate to the mechanical stability, *e.g.* the suppression of specimen "creep" during the time of the observation. The necessary stability of the high voltage ($\Delta E/E$) is improved when one changes, for example, from a 100 kV to a (technically much more complicated) 1000 kV microscope[11]; the radiation load of the specimen is not increased here in the same proportion. Organic molecular compounds are very sensitive to such irradiation[85]. Chlorinated copper phthalocyanine has proved to be a relatively stable model substance[86].

Niobium oxides and oxide fluorides, and also other particularly stable compounds with suitable structures known from X-ray structure analysis, have in the last ten years been used by physicists as model substances in order to perfect the theory of computer simulation of electron microscopic images. Computer methods are now in use that portray the crystal as being built up of layers (the multislice method[87]), and that make it possible to calculate the intensity relationships in a high-resolution microscope on the basis of the dynamical theory of electron diffraction (the dynamical n-beam multislice method)[30,31,88-90]. The effects of defocusing, spherical and chromatic aberration, the size of the objective aperture, *etc.* can all be taken into account. It is particularly important that model calculations can even be applied to structural defects, to the occupation of interstitial lattice points, and so on. Only by such model calculations can one interpret complicated contrast relationships in electron micrographs with a sufficient degree of reliability. Such parallel computer investigations are the more necessary, the more accurately are the real structures to be examined.

Our own investigations using the new method would not have been possible without enthusiastic co-workers; particular thanks must go to Dr. H. Brunner, Dipl.-Chem. G. Heurung, Dr. H. Hibst, and Dipl.-Chem. B. Meyer. We are indebted to Frau H. Geiss and to Herr M. Zahrt for technical assistance. Our work was generously supported by the Fonds der Chemischen Industrie and by the Deutsche Forschungsgemeinschaft.

Alkali Metal-Transition Metal π-Complexes[**]

By Klaus Jonas and Carl Krüger[*]

In this progress report a new principle is described for the synthesis of multimetal π-complexes with hitherto unknown structural features. The nickel(0)-olefin complexes 1,5,9-cyclododecatrienenickel(0) and bis(1,5-cyclooctadiene)nickel(0) react unexpectedly with main-group metals, in particular alkali metals, their hydrides, and organometallic compounds, to give nickel-ligand species with a surplus charge. These species endeavor to transfer the excess charge onto π-ligands such as olefins or dinitrogen. Multimetal complexes with electron rich transition metal π-ligand units can, in addition, be prepared from metallocenes, alkali metals, and unsaturated compounds. The syntheses, structures, and reactions of this new class of substances will be summarized.

1. Introduction

The main group metals—especially those of the first to third groups of the periodic table—their hydrides and organometallic compounds play an important role in the syntheses of organo-transition metal compounds. Their reactions with transition metal salts open the way for the preparation of low-valent transition metal complexes and permit the syntheses of well-defined hydrido- and organo-transition metal complexes as well as the construction of active catalytic systems such as the Ziegler catalysts[1].

Whereas electropositive main-group metals M_M[*], for example alkali metals, magnesium, or aluminum, reduce transition metal salts M_TX_n (eq. (a) to (c))[2-4], their organo-compounds M_MR_n or hydrides M_MH_n act primarily as sources of groups R or H atoms.

$$3\,CrCl_3 + 2\,Al \xrightarrow{6\,C_6H_6,\ 13\,AlCl_3} 3\,[(C_6H_6)_2Cr]AlCl_4(AlCl_3)_4 \qquad (a)$$

(1)

Examples of products from this double displacement reaction are organo-transition metal complexes with M_T—C σ-bonds such as *(4)*[5] and π-complexes like ferrocene *(5)*[6] and bis(π-allyl)nickel *(6)*[7]. From reduction of the transition metal come such compounds as the nickel(0) olefin complexes[8] $(CDT)Ni^0$ *(7)* or $(COD)_2Ni^0$ *(8)*.

In 1952 *Gilman et al.*[9] reported that poorly soluble methyl-copper, prepared as in eq. (e), dissolves in diethyl ether in the presence of methyl lithium (eq. (f)). Lithium dimethylcuprate *(9)* is formed showing that the tendency of main-group organo metallic compounds and hydrides to combine with their corresponding alkali metal derivatives to give metalates (atecomplexes) such as $Li[AlH_4]$ or $Li[B(C_6H_5)_4]$ [known from the early work of *Wanklyn*[10] and *Hein et al.*[11] together with the systematic investigations by *Wittig et al.*[12] and *Schlesinger et al.*[13]] is also found for a transition metal alkyl compound.

As in the synthesis of *(9)* and analogous cuprates[14,15], the first step in the numerous other syntheses of transition metal

$$CuI + LiCH_3 \rightarrow CuCH_3 + LiI \quad (e)$$

$$CuCH_3 + LiCH_3 \rightarrow Li[Cu(CH_3)_2] \quad (f)$$

(9)

metalates is a double displacement reaction, in particular between transition metal halides and organo-alkali metal compounds. The addition of mM_AR to M_TR_n leading to the metalate can be considered as a separate step. This usually takes place on the intact M_TR_n species so that starting from M_TX_n a metalate of the form *(10)* results[15-17].

$$M_TX_n + (m+n)M_AR \rightarrow (M_A)_m[M_TR_{n+m}] + nM_AX$$

(10)

This is also true for the f-element metalate complexes that have been described so far[18]. Representative examples of *(10)* are the cuprates[14,19] such as *(9)*, which are gaining increasing importance in organic chemical syntheses, the transition metal alkynyl complexes $(M_A)_m[M_T(C{\equiv}C{-}R)_{m+n}]$ thoroughly investigated by *Nast*[20], the Hein chromium complexes[21] $Li_3[Cr(C_6H_5)_6]$ and $Na_2[Cr(C_6H_5)_5]$ as well as $Li_2[Ni(CH_3)_4]$[22] and $Li_2[W(CH_3)_8]$[5].

2. From the "Nickel Effect" to Isolable Organo-Alkali Metal-Nickel(0) π-Complexes

Transition metals are characteristic in their ability to interact with the π-systems of unsaturated hydrocarbons or their residues. The first example of a system of this type was an ethylene-platinum compound; it was first prepared by *Zeise*, who over 150 years ago obtained the salt $K[PtCl_3(C_2H_4)]H_2O$[23], which was named after him, from $PtCl_4$, KCl and ethanol. Transition metal metalates containing π-ligands and bearing only organic ligands at the M_T atom, such as $[Li(TMEDA)_2]^{\oplus}[CH_3{-}Ni(C_2H_4)_2]^{\ominus}$ *(16a)*, on the other hand, have only become known in recent years. We have reported these in brief[24,25].

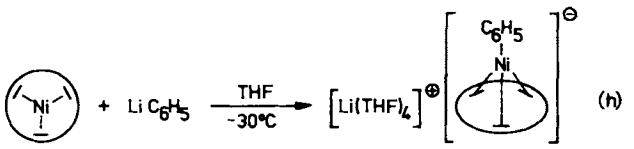
The starting point of our investigations were studies on the mechanism of the "nickel effect"[26] discovered by *Ziegler* and *Holzkamp*. These studies were based on a comprehensive nickel chemistry developed, in particular, by *Wilke et al.*[27]. It was found that aluminum alkyl compounds not only react with salt-like nickel compounds by double displacement reactions as in eq. (d), but can also interact with nickel(0)[28,29]. The original observation by *Ziegler* and *Holzkamp* that the „Aufbau" reaction[30] of $Al(C_2H_5)_3$ with ethylene is transformed into dimerization of ethylene by addition of traces of nickel salts ("nickel effect")[26] depends on both of these factors, while the observation[28,29] that particular nickel(0)-olefin complexes such as *(7)* or *(8)* or tris(ethylene)nickel(0) *(11)*[31] are extremely effective catalysts for the alkyl exchange of higher molecular weight aluminum-alkyl compounds with olefins, for example eq. (g), depends on the latter.

$$Al(n\text{-}C_4H_9)_3 + 3\,C_2H_4 \xrightarrow[0\,^{\circ}C]{(C_2H_4)_3Ni^0\ (11)} Al(C_2H_5)_3 + 3\,C_4H_8 \quad (g)$$

The nickel(0)-catalyzed transalkylation [eq. (g)] very probably proceeds within a complex where the aluminum alkyl compound and the olefin are bound to nickel and a multicenter bond $R_2Al{-}R{-}Ni^0$ exists between R_3Al and nickel(0). Stereochemical observations and model considerations agree with this supposition[29].

This fundamental view of the "nickel effect" is supported by the fact that compounds could be obtained from reactions of nickel(0)-olefin complexes with more polar organometallic compounds than R_3Al, *i.e.* with organo-alkali metal compounds. These compounds, particularly those of lithium, form isolable multimetal compounds $(M_AR)_x(n\text{-donor ligand})_yNi^0(\pi\text{-ligand})_z$ with *n*-donor ligands, nickel(0), and olefins or other molecules with multiple bonds (π-ligands) in which up to three M_AR units per nickel atom can be bound. In several of these compounds multicenter bonding of the type $M_A{-}R{-}Ni^0$ has been demonstrated by X-ray structural analyses (see Section 4).

3. Salt-Like M_AR-, M_AH-, and M_APR_2-Nickel(0) π-Complexes

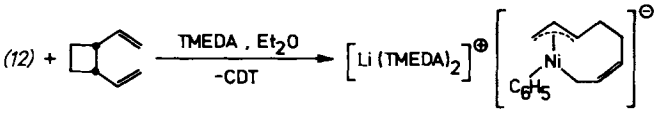


Both in the solid state[32,33] and in solution[34], organolithium compounds can, depending on the nature of R and on the solvation ability (n-donor strength)[35] of the solvent, be associated or exist as monomeric solvated ion pairs. Dissociation into freely moving ions plays but a minor role in solutions to which strong n-donors such as tetrahydrofuran (THF) or *N,N,N',N'*-tetramethylethylenediamine (TMEDA) have been added in order to stabilize the cations. Stabilization of the carbanion, on the other hand, is much better in promoting an ionic dissociation, which can be attained—as *Hein et al.*[11] were able to show, through conductivity measurements, for example on $Li_2[ZnR_4]$ and $Li[AlR_4]$—with main-group metal organometallic Lewis acids (here ZnR_2 and AlR_3, respectively).

3.1. Carbanion Complexes of Nickel(0)

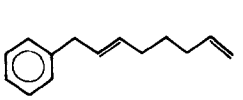
We have found[24, 25, 36] that certain nickel(0)-olefin complexes or nickel(0) complex fragments with π-ligands can heterolytically cleave the Li—C bond in simple organolithium compounds provided that the lithium ion can be sufficiently stabilized with n-donors.

Thus the dark red coordinatively unsaturated $(CDT)Ni^0$ *(7)*, for example, reacts smoothly with phenyl lithium in THF to give the yellow 1:1 adduct *(12)*.



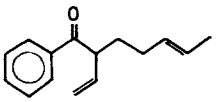
In *(12)* four THF molecules are bonded to the lithium cation, and the phenyl anion, acting as a two electron ligand, fills the fourth coordination site on nickel—as is known for phosphanes and phosphites[27]—to give the cyclododecatriene(phenyl)nickel(0) anion.

(h)



(7) *(12)*

(12) reacts with *cis*-divinylcyclobutane with the loss of the CDT-ligand and opening of the cyclobutane ring to give *(13)*[37]. In *(13)* the C_8H_{12} chain is bonded to nickel as a π-allyl group at one end and as a σ-allyl group at the other, as is observed for $(C_6H_{11})_3PNiC_8H_{12}$[38].



(13)

(13) reacts with carbon monoxide with transfer of a phenyl group or a benzoyl group, formed by CO insertion, to the C_8H_{12} chain on the nickel atom. The main products resulting from protonation are *(14)* and *(15)*[37].

(14)

(15)

The simplest nickel(0) π-ligand carbanion complexes *(16)* can be prepared from $(CDT)Ni^0$ *(7)* or $(COD)_2Ni^0$ *(8)*, organolithium compounds, TMEDA, and ethylene in diethyl ether (Et_2O)[24].

$$(CDT)Ni^0 + 1\,LiR + 2\,C_2H_4 + 2\,TMEDA \xrightarrow{Et_2O}$$

(7)

$$[Li(TMEDA)_2]^{\oplus}[R{-}Ni(C_2H_4)_2]^{\ominus} + CDT$$

(16)

(16a), R = CH_3; *(16b)*, R = C_2H_5; *(16c)*, R = *n*-C_4H_9; *(16d)*, R = C_6H_5

The ionic nature of *(16)* has been demonstrated by conductivity measurements and an X-ray structure analysis of *(16a)*. The complex salts *(16)* have about a 10^3 times higher specific conductivity than organolithium compounds (0.25 M in THF at −30 °C) and their conductivity corresponds to that of lithium perchlorate in THF solution.

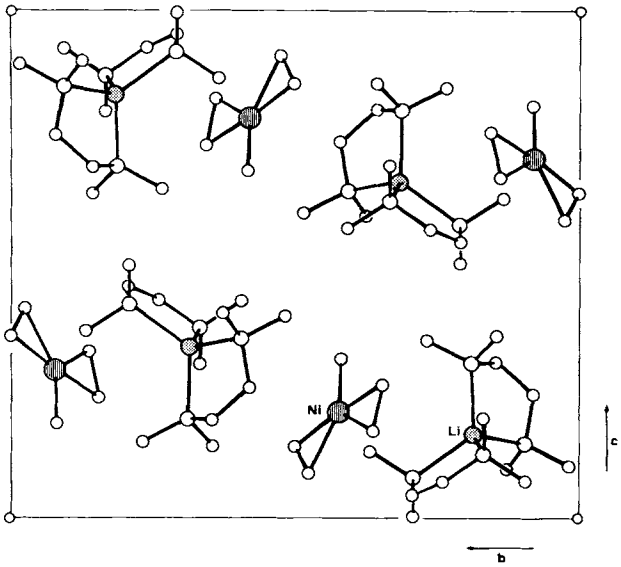


Fig. 1. Packing diagram of $[Li(TMEDA)_2]^{\oplus}[CH_3Ni(C_2H_4)_2]^{\ominus}$ *(16a)*, projected along −*a*.

The packing diagram of *(16a)* (Fig. 1) shows that the separated ions are arranged in a linear fashion. Each lithium cation, tetrahedrally coordinated by two TMEDA ligands, lies equidistant between two planar bis(ethylene)methylnickel anions. The relatively short C=C distances (1.36, 1.38 Å) of the complexed ethylene molecules indicate only a weak interaction with the metal; the Ni—C σ-bond at 1.91 Å is nevertheless exceptionally short[39].

Both ethylene molecules in *(16)* can be displaced by CO or cyclooctatetraene, while only one ethylene molecule is displaced with nitriles such as C_6H_5CN or CH_3CN at −30 °C. As a result, new complexes, *e.g. (17)*, can be isolated, in which an anionic phenyl group, an ethylene, and a benzonitrile are bonded to nickel.

$$(16d) + 1\,C_6H_5CN \xrightarrow[-TMEDA,\ -C_2H_4]{Et_2O}$$

$$Li(TMEDA)C_6H_5Ni(C_2H_4)(C_6H_5CN)$$

(17)

The carbanion ligands in *(16)* can be abstracted by several main-group organometallic Lewis acids, *e.g.* $Al(C_2H_5)_3$. Thus from *(16b)* and $Al(C_2H_5)_3$ in the presence of COD one obtains $(COD)_2Ni^0$ *(8)* and TMEDA-complexed lithium tetraethylaluminate *(18)* in high yields.

$$[Li(TMEDA)_2]^{\oplus}[C_2H_5{-}Ni(C_2H_4)_2]^{\ominus} + 1\,Al(C_2H_5)_3 + 2\,COD \rightarrow$$

(16b) (i)

$$(COD)_2Ni^0 + [Li(TMEDA)_2]^{\oplus}[Al(C_2H_5)_4]^{\ominus} + 2\,C_2H_4$$

(8) *(18)*

3.2. The Hydride Ion $H^{\ominus}$ as a Bridge between two Nickel Atoms

The reverse of reaction (i) using a hydridoaluminate, *i.e.* with $M_A[AlR_mH_{4-m}]$, results in hydride transfer onto the nickel atom, and can be used for the synthesis of novel alkali metal hydride-containing nickel olefin complexes[40]. Where-

as (CDT)Ni^0 *(7)* reacts with Na[Al(C_2H_5)$_3$H] or Li[AlH_4] to give the complex anions [(CDT)Ni—H—AlR_3]$^\ominus$ or [(CDT)Ni—H—AlH_3]$^\ominus$, in which the hydride ion bridges the nickel and aluminum atoms, the reaction with tris(ethylene)nickel(0) *(11)* results in complete hydride transfer to the nickel atom, and a complex salt is formed containing two nickel atoms in the anion, *e.g. (19).*

$$2(C_2H_4)_3Ni^0 + Li[Al(i\text{-}C_4H_9)_2H_2] \xrightarrow{2\,TMEDA}$$

(11)

$$[Li(TMEDA)_2]^\oplus[(C_2H_4)_2Ni—H—Ni(C_2H_4)_2]^\ominus + Al(C_2H_5)(i\text{-}C_4H_9)_2 + C_2H_4$$

(19)

The two nickel atoms in *(19)* are probably trigonally-planar coordinated [as in the carbanion-containing complex salts *(16)*] and the two parts of the anion are bound *via* a linear or bent two-electron three-center Ni—H—Ni bond (Fig. 2).

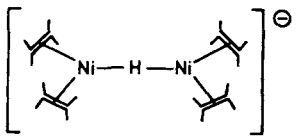

Fig. 2. Proposed structure for the bimetallic anion of [Li(TMEDA)$_2$]$^\oplus$[(C_2H_4)$_2$Ni—H—Ni(C_2H_4)$_2$]$^\ominus$ *(19)*.

3.3. The $R_2P^\ominus$ Anion as a Bridge between two Nickel Coordination Centers

Lithium diorganophosphides[41] have two available σ-donating electron pairs and can form complexes of type *(20)* or *(21)* with either one or two bis(ethylene)nickel(0) units, respectively[42,43].

$$\xrightarrow{LiPR_2}$$

$$+ (COD)_2Ni(0)\ (8),\ + 2\ C_2H_4,\ + 3\ THF \downarrow - 2\ COD$$

$$(THF)_3LiR_2PNi(C_2H_4)_2 \quad (20)$$

$$+ (COD)_2Ni(0)\ (8),\ + 2\ C_2H_4,\ + THF \downarrow - 2\ COD$$

$$[Li(THF)_4]^\oplus[(C_2H_4)_2Ni(PR_2)Ni(C_2H_4)_2]^\ominus \quad (21)$$

R = C_6H_{11}

The dinuclear complex *(21)* is a stronger electrolyte than *(20)*, since both electron pairs of the phosphorus atom in *(21)* are involved in bonding to the two (C_2H_4)$_2$Ni units, and none is available to interact with the lithium ion. Figure 3 shows the structure of *(21)* as determined by an X-ray analysis[44].

Each nickel atom is trigonally-planar coordinated and the coordination planes make an angle of 95° with each other; the Ni—P—Ni angle is 105.7°. The Ni—Ni distance of 3.57 Å indicates that a metal-metal interaction is unlikely. The different Ni—C(olefin) distances suggest there might be some steric interaction in the coordination planes of the nickel atoms. The bridging phosphorus atom is approximately tetrahedrally coordinated.

There are no preferred intermolecular contacts to be seen in the packing diagram of *(21)*, and the lithium to phosphorus and ethylene distances lie well into the region of an ionic interaction (Li—P = 7.88 Å, Li—C = 5.54—6.00 Å). Here there is an indication of an—albeit very weak—ion pair interaction between a main group metal and a π-bonded olefin.

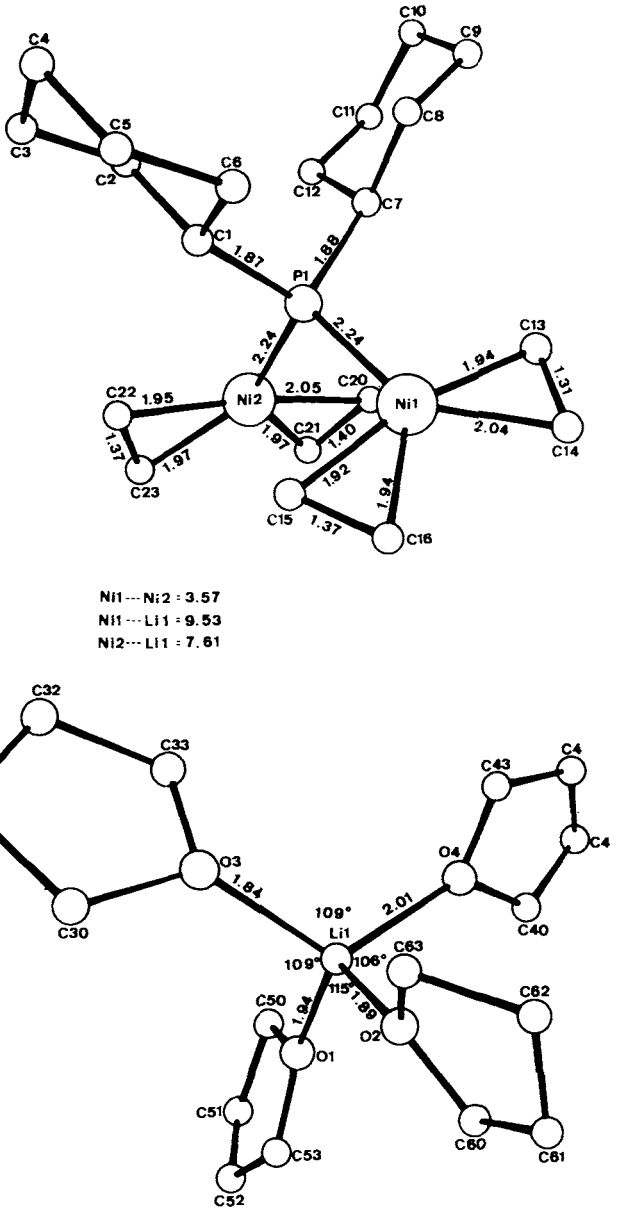

Fig. 3. Structure of [Li(THF)$_4$]$^\oplus$[(C_2H_4)$_2$Ni(PR_2)Ni(C_2H_4)$_2$]$^\ominus$, R = C_6H_{11} *(21)*.

Reaction of *(20)* with excess butadiene at room temperature gives exclusively polybutadiene. This suggests that *(20)*, like pure $LiPR_2$[43], initiates a fast anionic polymerization, which is unaffected by nickel. *(21)* reacts somewhat differently with butadiene. In addition to polybutadiene (*ca.* 50%) typical oligomerization products from nickel(0)-catalyzed reactions[27] such as C_8H_8 (COD, vinylcyclohexene, and divinylcyclobutane) and CDT are also formed. The product distribution obtained with *(21)* can be explained in terms of the interplay of known catalytic systems if one considers the following simplified dissociation equilibria:

$$\underset{I}{[Ni—PR_2—Ni]^\ominus} \rightleftarrows \underset{II}{[Ni]} + \underset{III}{[NiPR_2]^\ominus} \rightleftarrows 2\underset{II}{[Ni]} + \underset{IV}{[PR_2]^\ominus}$$

Acting as ligand-modified nickel(0) catalysts, I and possibly also III, effect the formation of C_8 products. II catalyzes the

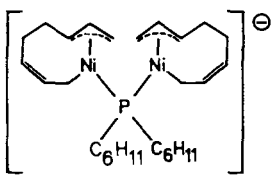
cyclotrimerization (CDT formation), while IV and probably III are the polymerization catalysts.

The ionic complex *(22)*, formed by the reaction of *(21)* with butadiene at low temperature, is interesting in connection with the catalytic effect of I. It may well be an intermediate in the cyclodimerization of butadiene by *(21)*.

$$(21) + 4\,C_4H_6 \xrightarrow[-4\,C_2H_4]{} [Li(THF)_4]^{\oplus}[(C_6H_{11})_2P(NiC_8H_{12})_2]^{\ominus}$$

(22)

In *(22)* two butadiene molecules have linked on each nickel atom to give a C_8H_{12} chain, and according to the ^{13}C-NMR spectrum[46] the chains are bonded to the metal *via* π-allyl and σ-allyl attachments as in *(13)*[37] and $(C_6H_{11})_3PNiC_8H_{12}$[38] (see Fig. 4).



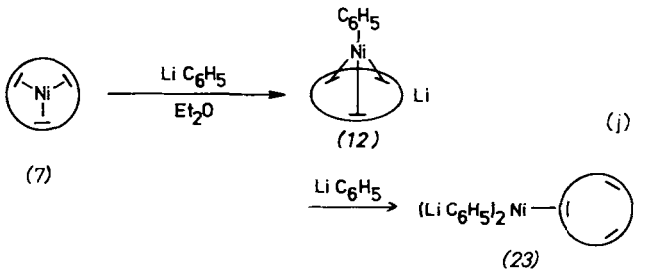


Fig. 4. Proposed structure for the anion of $[Li(THF)_4]^{\oplus}[(C_6H_{11})_2PNi(C_8H_{12})_2]^{\ominus}$ *(22)* (schematic).

4. Complex Formation between Unsaturated Molecules and the Bis(phenylalkali metal)nickel(0) Unit

4.1. Syntheses of Bis(phenylalkali metal)nickel(0) π-Complexes

If $(CDT)Ni^0$ *(7)* is reacted with phenyl lithium in the molar ratio of 1:2 in ether at 0 °C [eq. (j)] one obtains a yellow-red solution of $[(LiC_6H_5)_2(Et_2O)_y]Ni(CDT)$ *(23a)*. $[(LiC_6H_5)_2(THF)_4]Ni(CDT)$ *(23b)* or $[(LiC_6H_5)_2(TMEDA)_2]Ni(CDT)$ *(23c)* crystallizes[36] out of this solution at low temperatures after addition of THF or TMEDA. Similarly, $(COD)_2Ni^0$ *(8)* reacts with LiC_6H_5 (molar ratio 1:2) with the loss of a COD ligand to give *(24)*[*]. Crystals of *(24a)* or *(24b)* can be isolated after addition of THF or TMEDA, respectively[36].

(23) (j)

$$(COD)_2Ni^0 + 2\,LiC_6H_5 \xrightarrow[-COD]{THF} [(LiC_6H_5)_2(THF)_4]Ni(COD)$$

(8) *(24a)*

$$(8) + 2\,LiC_6H_5 \xrightarrow[-COD]{Et_2O,\ TMEDA} [(LiC_6H_5)_2(TMEDA)_2]Ni(COD)$$

(24b)

[*] *(24)* is likewise formed from *(8)* and $LiPb(C_6H_5)_3$ [47].

According to the ^{13}C-NMR[46] spectrum, the cyclododecatriene ligand in *(23)* is only coordinated to the nickel atom *via* one double bond; this is in contrast to what is seen in complexes *(7)* and *(12)*. The CDT ligand can be displaced by other molecules containing multiple bonds such as alkenes, alkynes, arenes, ketones, or nitriles. In this way, new bis(phenyllithium)nickel(0) π-complexes can be prepared, eq. (k); examples are given in Table 1.

$$(LiC_6H_5)_2Ni(CDT) + \pi\text{-Ligand} \xrightarrow{\text{n-Donor ligand}}$$

(23)

$$[(LiC_6H_5)_2(\text{n-Donor ligand})_x]Ni(\pi\text{-Ligand}) + CDT \qquad (k)$$

Table 1. Bis(phenyllithium)nickel(0) π-complexes obtained according to eq. (k).

π-Ligand	Complex	
Ethylene	$[(LiC_6H_5)_2Et_2O]NiC_2H_4$	*(25)*
Norbornene	$[(LiC_6H_5)_2Et_2O]NiC_7H_{10}$	*(26)*
3-Hexyne	$\{[(LiC_6H_5)_2(THF)_3]Ni\}_2C_2H_5C{-}CC_2H_5$	*(27)*
Naphthalene	$[(LiC_6H_5)_2(THF)_x]NiC_{10}H_8$	*(28)*
Phenanthrene	$[(LiC_6H_5)_2(THF)_4]NiC_{14}H_{10}$	*(29)*
Benzophenone	$[(LiC_6H_5)_2(THF)_3]Ni(C_6H_5)_2CO$	*(30)*
Acetonitrile	$[(LiC_6H_5)_2(THF)_3]NiCH_3CN$	*(31)*

The synthesis of pure bis(diethyl ether)ethylenebis(phenylsodium)nickel *(32)*[48] can be performed in ether by treating $(CDT)Ni^0$ *(7)* with a salt-free mixture of NaC_6H_5/LiC_6H_5 (Na:Li = 2—4:1) in the molar ratio $(NaC_6H_5 + LiC_6H_5):Ni^0 = 2:1$ in the presence of ethylene. The phenyllithium-containing nickel complex *(25)* remains in solution, and the complex *(32)* precipitates as an orange-red powder.

$$(CDT)Ni^0 + 2(m\,NaC_6H_5 + n\,LiC_6H_5) \xrightarrow[-CDT]{C_2H_4,\ Et_2O}$$

(7)

$$m[(NaC_6H_5)_2(Et_2O)_2]NiC_2H_4 + n \qquad (25)$$

(32)

$m:n = 2—4:1;\ m+n=1$

$[(NaC_6H_5)_2(THF)_{2.5}]NiC_2H_4$ *(32a)* $\qquad$ $[(NaC_6H_5)_2(DME)_2]NiC_2H_4$ *(32b)*

Exchange of the coordinated ether molecules in *(32)* by THF or dimethoxyethane (DME) gives the crystalline complexes *(32a)* or *(32b)*.

In the complexes *(23)*—*(32)*, containing two M_AR groups per nickel atom, there are no more than two n-donor atoms in the form of diethyl ether, tetrahydrofuran, dimethoxyethane, or *N,N,N',N'*-tetramethylethylenediamine bonded to each alkali metal atom. This is different from what is observed in the salt-like complexes $(M_AR)[Ni(C_2H_4)_2]$ and $(M_AH)[Ni(C_2H_4)_2]_2$ (Section 3). This observation together with their 10^2—10^3 times lower specific conductivity than $(M_AR)[Ni(C_2H_4)_2]$ (0.25 M in THF at −30 °C) indicate that ionic structures are unlikely for compounds *(23)*—*(32)*. Probably several of the free coordination sites on the lithium atoms, *i.e.* those not occupied by n-donors, are involved in multicenter or ion-pair interaction. The structures of *(32a)* and *(29)* are described in the next section.

4.2. Structures of Ethylenebis(phenylsodium)nickel(0) and Phenanthrenebis(phenyllithium)nickel(0)

We have characterized several of the bis(phenylalkalimetal)nickel(0) π-complexes by X-ray structure analyses. The results show surprising structural features which will be described for the compounds *(32a)*[49] and *(29)*.

(A) Ni---‖ (B) O, Na

The dimeric ethylenebis(phenylsodium)nickel compound *(32a)* (Fig. 5) contains two trigonal-planar $Ph_2Ni(C_2H_4)$ units A, in which Ni^0 is surrounded by two σ-bonded phenyl groups and one π-bonded ethylene molecule.

Four $Na(THF)_x$ units B ($x=1$, 2) are bound in different ways to these subunits. Two of these B groups ($x=1$) bridge the A groups and form a Ni_2Na_2 four-membered ring (Ni—Na = 2.883(1) Å). Comparable structural units are known in $Na_2Fe(CO)_4(dioxane)_{1.5}$[50] and disodium pentaphenylchromate[51]. In the first, for example, two $[Fe(CO)_4]^{2-}$ groups are linked by two sodium bridges to give a dimeric cluster (Fe—Na = 3.086 Å).

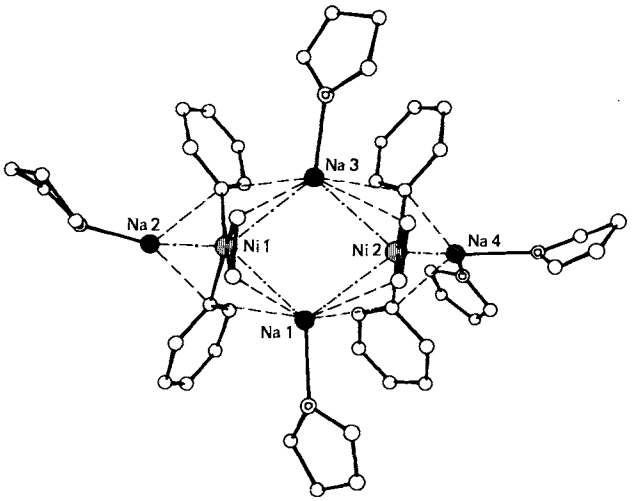

Fig. 5. The molecular structure of $\{[(NaC_6H_5)_2(THF)_{2.5}]NiC_2H_4\}_2$ *(32a)*.

Each of the two remaining B groups interacts with a different A group. The corresponding Ni—Na distances are longer and unequal. Their difference (Ni1—Na2 = 3.037 Å; Ni2—Na4 = 2.926 Å) can be explained as a consequence of the different occupations of the free coordination sites about the sodium atoms: whereas Na4 has two THF molecules bonded to it, Na2 has only one (as do Na1 and Na3). Consideration of the packing of the molecules in the unit cell provides an explanation. It is possible to ascribe a weak bond between Na2 of one molecule and a coordinated ethylene in a neighboring molecule. The molecules are therefore arranged in a one-dimensional polymeric fashion in the crystal lattice (see Fig. 6). The sodium atom Na2 sits on the opposite side of the ethylene molecule from nickel. Hence the electron density on ethylene might be high.

Semi-empirical MO calculations support this view. The arrangement of sodium atoms and phenyl groups in unit A suggest similar ion-pair interactions here (Fig. 5 and 6). In-

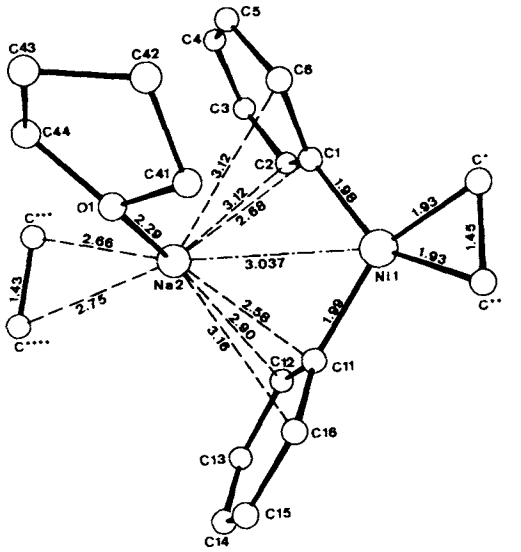

Fig. 6. Section from the polymeric molecular structure of *(32a)*.

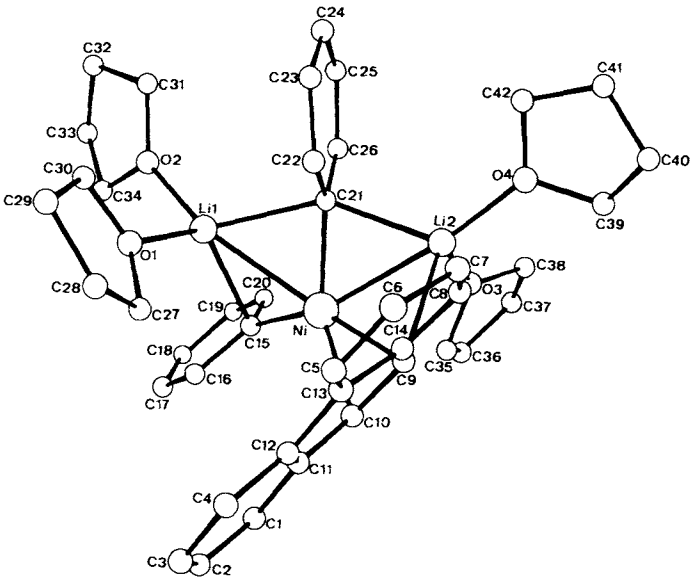
teractions of this kind are known from structural analyses of both aryl- and alkyl-alkali metal compounds[33].

Bonding features found in *(32a)* can be seen again in the structure of *(29)* (Fig. 7).

Here a trigonally-planar coordinated nickel atom is surrounded by two σ-bonded phenyl groups (Ni—C15 = 1.950(4) Å, Ni—C21 = 1.963(4) Å) and a π-bonded phenanthrene molecule which, as expected[52], is bound *via* the 9,10-positions with its molecular plane lying almost perpendicular to the coordination plane of the nickel atom. The C9—C10 distance is lengthened from 1.341(7) Å, in free phenanthrene, to 1.445(6) Å; the Ni—C distances are



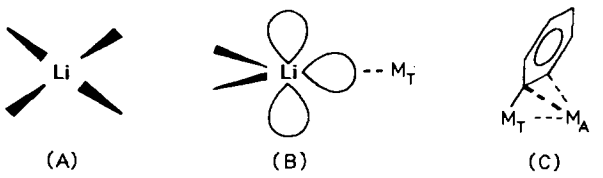


Fig. 7. Molecular structure of $[(LiC_6H_5)_2(THF)_4]NiC_{14}H_{10}$ *(29)*.

1.989(4) and 1.977(5) Å. The fact that Ni—C9 is longer than Ni—C10 can be explained in terms of the additional interaction of C9 with Li2. There is also an ion-pair interaction between one of the phenyl groups and both of the lithium atoms through C21. Such an interaction has also been observed in analogous cobalt compounds[53a] and in nickel dinitrogen complexes (see Section 6).

The second phenyl group on nickel and the phenanthrene molecule are, on the other hand, only adjacent to Li1. The

two out of four coordination sites on lithium in *(29)* and sodium in *(32a)* that are not occupied by tetrahydrofuran are preferentially directed towards the α-carbon atoms of the phenyl groups bonded to nickel. Although this geometry results in relatively short Li—Ni or Na—Ni distances, the question as to whether a direct alkali metal-nickel bond exists must remain open[79b]. The observed interaction of the alkali metal with delocalized π-systems could, in the case of a tetrahedral arrangement of ligands (sp^3) (A), be purely electrostatic in nature. If however, the alkali metal, especially lithium, is trigonally-planar coordinated (sp^2), one of the coordination sites being occupied by a transition metal (B), then there is an unoccupied p-orbital perpendicular to the coordination plane which is available to interact with delocalized π-systems.

Both interactions mentioned lead to a novel, unsymmetrical three-center arrangement (C), in which the charge flow takes place *via* bonds of different symmetry.

5. NMR-Data for Complexed Ethylene in Trigonal-Planar Nickel(0) Ethylene Complexes

The position of the ^{1}H- and ^{13}C-NMR signals (C=C—H) of olefins bonded to metals depends on, among other factors, the electron density at the double bond. Shifts of the signals to higher field on coordination of the olefin are usually observed when the π-back bonding contribution from the metal is greater than the σ-bonding contribution from the olefin

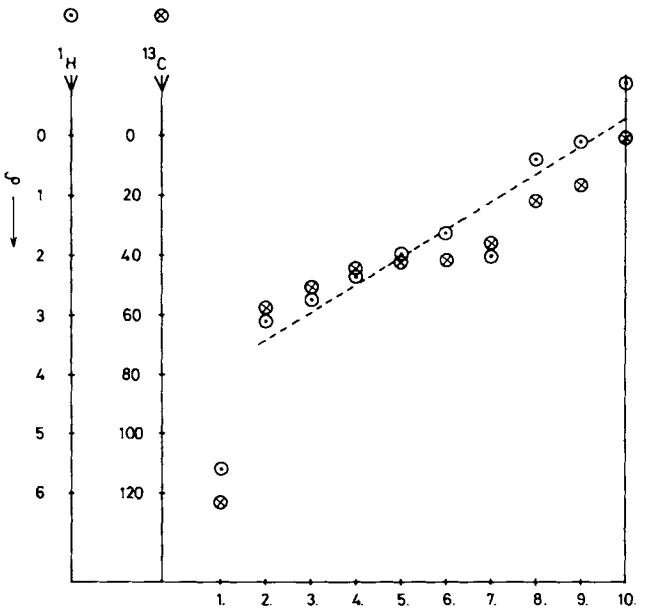

Fig. 8. ^{1}H- and ^{13}C-NMR data for free ethylene and ethylene bonded in trigonal-planar nickel(0)-ethylene complexes. 1, C_2H_4; 2, $(C_2H_4)_3Ni$ *(11)*; 3, $(C_6H_{11})_3PNi(C_2H_4)_2$ [45]; 4, $Li^{\oplus}[(C_6H_{11})_2P\{Ni(C_2H_4)_2\}_2]^{\ominus}$ *(21)*; 5, $Na^{\oplus}[(C_2H_4)_2Ni—H—Ni(C_2H_4)_2]^{\ominus}$ [cf. *(19)*]; 6, $Li^{\oplus}[C_2H_5—Ni(C_2H_4)_2]^{\ominus}$ *(16b)*; 7, $[(C_6H_{11})_3P]_2NiC_2H_4$; 8, $(NaC_6H_5)_2NiC_2H_4$ *(32)*; 9, $(LiC_6H_5)_2NiC_2H_4$ *(25)*; 10, $(LiC_2H_5)_2NiC_2H_4$ [65].

to the metal[54]. For several metal olefin cations only small upfield shifts or even downfield shifts are seen. Here a significant bonding contribution results from a charge flow from the olefin into an unoccupied metal orbital[55].

Figure 8 shows that for tris(ethylene)nickel(0) *(11)* (no. 2) the ^{1}H- and ^{13}C-NMR signals of the complexed ethylene molecules appear at a higher field than those in the free molecule (no. 1) ($\Delta\delta$-^{1}H ≈ 2.5, $\Delta\delta$-^{13}C ≈ 60). If one of the coordinated ethylenes is replaced by phosphane, phosphide, hydride, or $R^{\ominus}$ giving the complexes nos. 3—6, containing only 2 C_2H_4 per Ni, then an even stronger high-field shift is observed. The corresponding ^{1}H-NMR signals of the complexes nos. 8—10, those with only 1 C_2H_4 per Ni but now containing 2 M_AR per Ni, lie at only a slightly lower or even higher field (no. 10) than the signal of the internal standard tetramethylsilane! High-field shifts of the olefin signals on complexation with a zero-valent transition metal of this order are unusual. They indicate that the bis(organoalkali metal)nickel(0) unit is exceptionally electron rich and ideally suited for π-back bonding into the unoccupied orbitals of unsaturated molecules.

6. Dinitrogen Bonded Side-on to Nickel

The question whether dinitrogen can be bonded side-on to a metal atom M (Fig. 9c and d) has been the focus of interest ever since the instigation of intensive efforts to accomplish *in vitro* N_2 activation in a metal complex[56-58]. The recent findings by *Chatt et al.*[59] that dinitrogen end-on bonded (Fig. 9a) to molybdenum(0)-phosphane units, *e.g. (3)*, can be protonated by sulfuric acid and reduced to ammonia do not totally rule out a side-on fixation of dinitrogen during enzymatic N_2 activation. In fact, it might well be relevant[60] that some biological systems (nitrogenase) are able to reduce not only dinitrogen, $N_3^{\ominus}$, N_2O, CH_3NC, and RCN but also acetylene (C_2D_2 in H_2O and C_2H_2 in D_2O give *cis*-dideuteroethylene).

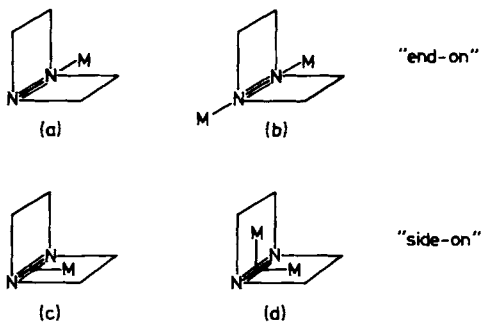

Fig. 9. Possible bonding modes of a N_2 molecule onto metal atoms.

Our nickel complexes *(33)*[62,63] and *(35)*[64] are the only[*] dinitrogen metal complexes with dinitrogen bonded side-on to a transition metal to have been structurally characterized by X-ray methods so far.

Stable dinitrogen transition metal complexes with end-on bonded N_2 molecules often contain transition metals in low oxidation states or activated by good donor ligands (*e.g.* $C_6H_5(CH_3)_2P$ in *(3)* or $(C_6H_{11})_3P$ in $[(C_6H_{11})_3P]_2Ni—N{\equiv}N—Ni[P(C_6H_{11})_3]_2$[66]). From this and

[*] In the X-ray analysis of $RhCl(N_2)[P(C_3H_7)_3]_2$ [61] a statistical disorder (Cl, N_2) about an inversion center was interpreted as a side-on bonded dinitrogen molecule.

spectroscopic data one is led to conclude that the stability of the M_T—N bond in most mononuclear dinitrogen transition metal complexes and the related destabilization of the N≡N triple bond mainly results from good d_π-p_π* back bonding[59,67]. This together with the NMR data for $[(LiC_2H_5)_2Et_2O]NiC_2H_4$[65] and $[(LiC_6H_5)_2Et_2O]NiC_2H_4$ *(25)* (see Fig. 8) led us to investigate the reactivity of organo-alkali metal-nickel(0) systems towards molecular nitrogen.

An ethereal solution of phenyllithium and (CDT)Ni^0 *(7)* in the molar ratio 3:1 absorbs molecular nitrogen (1 bar) at 0 °C. 1 N_2 is bound per 2 Ni. At the end of the reaction (after 1—2 h, corresponding to an absorption of *ca.* 280 Nml N_2 per 25 mmol of starting material *(7)*) some of the nickel N_2-complex *(33)* precipitates out as a yellow powder. Further *(33)* crystallizes out of solution within several weeks after addition of pentane (total yield *ca.* 50%). The ether content in *(33)* varies; generally there are 2—3 Et_2O per 6 LiC_6H_5.

$$4\,(CDT)Ni^0 + 12\,LiC_6H_5 + 2\,N_2 \xrightarrow[Et_2O]{0\,^\circ C} \underset{(33)}{\{[(LiC_6H_5)_3(Et_2O)_{1\ldots1.5}Ni]_2N_2\}_2} + 4\,CDT$$
(7)

In view of the formation of the adducts *(12)* and *(23)* from phenyllithium and (CDT)Ni^0 *(7)* and the structural data for *(33)*[63], the formation of *(33)* can be interpreted as follows:

$$\underset{(7)}{(CDT)Ni^0} + 1\,LiC_6H_5 \rightarrow \underset{(12)}{LiC_6H_5Ni(CDT)} \qquad (h)$$

$$(12) + 1\,LiC_6H_5 \rightarrow \underset{(23)}{(LiC_6H_5)_2Ni(CDT)} \qquad (j)$$

$$2\,(23) + 2\,LiC_6H_5 + 1\,N_2 \xrightarrow[-2CDT]{} [(LiC_6H_5)_3Ni]_2N_2 \qquad (33a)$$

$$2\,(33a) \xrightarrow{Et_2O} (33)$$

The 1:1 adduct *(12)*, formed from *(7)* and LiC_6H_5, reacts with further LiC_6H_5 to give *(23)*. The CDT ligand in this molecule is bonded to nickel by only one double bond and can be displaced by N_2 in the presence of LiC_6H_5. A formal $[(LiC_6H_5)_3Ni]_2N_2$ unit *(33a)* is formed when each N_2 molecule bonds to two nickel atoms; the crystalline final product *(33)* is a dimer.

Active solutions, which contain methyllithium or a mixture of NaC_6H_5/LiC_6H_5 in addition to (CDT)Ni^0 *(7)*, also take up 1 N_2 per 2 Ni at 0 °C[62,64]. With NaC_6H_5/LiC_6H_5 as the organo-alkali metallic component one obtains, among other products, the poorly soluble compound *(34)*. In this compound too there is 1 N_2 per 2 Ni, and approximately 3 M_AR per Ni. Eq. (l) is a typical reaction.

$$6\,(NaC_6H_5/LiC_6H_5) + 2\,(CDT)Ni^0 + 1\,N_2 \xrightarrow[Et_2O]{0\,^\circ C} \underset{(34)}{[(NaC_6H_5)_{2.44}(LiC_6H_5)_{0.67}(Et_2O)_{2.8}Ni]_2N_2} + 2\,CDT \qquad (l)$$

A further mixture of products crystallizes from the filtrate at 0 °C. This contains the nickel(0)-N_2 complex *(35)*, in which ethoxide groups resulting from ether cleavage are incorporated[64].

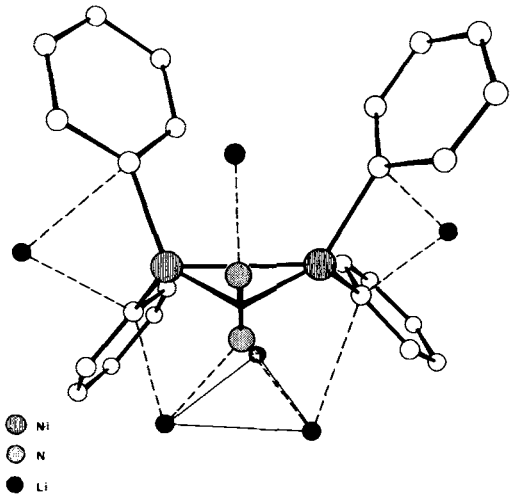

Fig. 10. Important structural features of a "half" of molecule *(33)*, *i.e.* a $[(LiC_6H_5)_3Ni]_2N_2$ unit *(33a)*. The two phenyl groups bonded to the Li_3-ring are not shown.

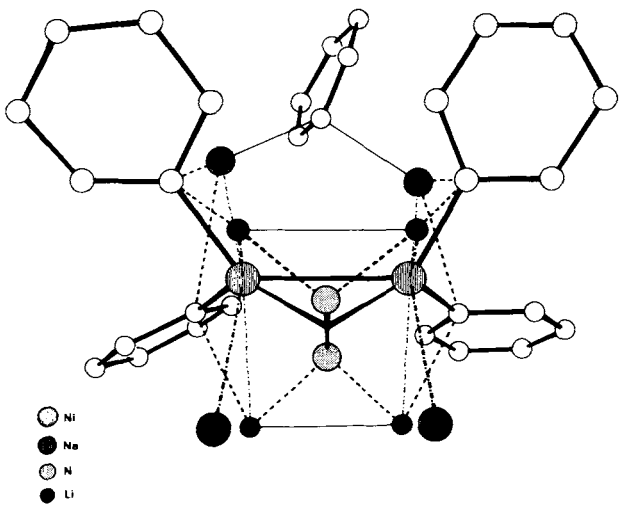

Fig. 11. Important structural features of a "half" of $\{C_6H_5(NaEt_2O)_2[(C_6H_5)_2Ni]_2N_2NaLi_6(OEt)_4Et_2O\}_2$, *(35)*.

$$\underset{(35)}{\{C_6H_5[NaEt_2O]_2[(C_6H_5)_2Ni]_2N_2NaLi_6(OEt)_4Et_2O\}_2}$$

Both N_2 complexes *(33)* and *(35)* show structural features similar to those already described for the related olefin complex *(32a)* (cf. Fig. 5 and 6). Their important structural subunits are reproduced in Figures 10 and 11. Two dinitrogen-bridged trigonal-planar diphenylnickel units form the central part of both molecules, and are so arranged as to allow a weak Ni—Ni bond. Comparable bridging arrangements are known for π-bonded alkynes[68] and azo compounds[69]. In the structures both bonds of σ-character and π-type, back bonding interactions between nickel and dinitrogen can be seen. Excess negative charge on dinitrogen is removed in the following two ways. Firstly, there is an end-on interaction between the lone pairs and the cationic lithium atoms. In *(33)* the chemical environment at each end of the N_2 molecule is different. At one end, the lone pair interacts with just one lithium ion, while at the other the lone pair is involved in a two-electron four-center bond with a Li_3 ring[70]. The sec-

ond apical position of the trigonal bipyramid defined using the Li_3 ring as the equatorial plane is occupied by a phenyl carbanion (not shown in Figure 10), so that overall a four-electron five-center bond arises. The bonding features are similar though somewhat simpler in *(35)*. In this case we observe similar two-electron three-center bonds to lithium at both ends of dinitrogen. Secondly, the system is stabilized by ion-pair interactions between lithium and dinitrogen on the opposite side of the dinitrogen molecule from nickel (cf. the analogous interactions in Fig. 6). The total effect of all interactions is to make the N≡N bond much weaker than in free N_2, and this manifests itself in the greatly enlarged N—N distances (1.34—1.36 Å) which lie within the range of those observed for single and double bonds.

The complexed dinitrogen in *(33)* can be displaced by carbon monoxide or ethylene. *(33)* reacts with ethylene in THF to give, in addition to the calculated amount of N_2, the nickel-ethylene complex *(25)*, free LiC_6H_5, and Et_2O. On hydrolysis of *(33)* in THF some of the dinitrogen (found 30—38%) is converted into ammonia, and the rest is liberated as N_2 gas. Hydrogen is not evolved.

$$3/2\ \{[(LiC_6H_5)_3(Et_2O)_{1.5}Ni]_2N_2\}_2 \xrightarrow[-78\ \text{to}\ 20\ ^\circ C]{\text{THF, } H_2O} 2NH_3 + 2N_2 + \cdots \quad \text{(m)}$$

(33)

The dinitrogen that is reduced according to eq. (m) can be found in the molecular structure of *(33)*; this is explained in Figure 12.

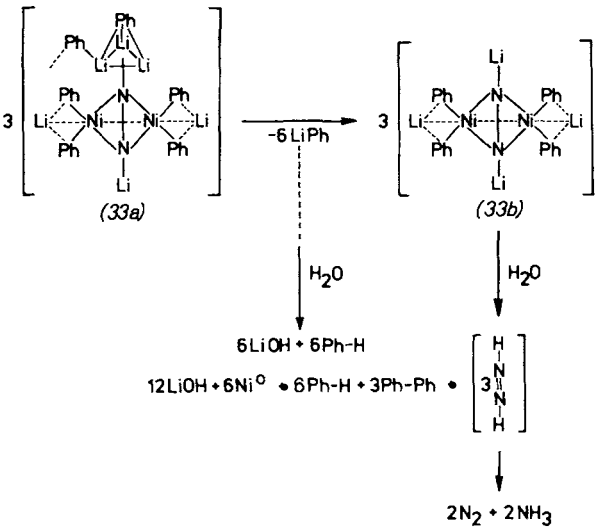

Fig. 12. Hydrolysis of $[(LiC_6H_5)_3Ni]_2N_2$ units *(33a)* and the conversion of side-on bonded dinitrogen into ammonia.

Of the four lithium atoms bonded to the nitrogen, the three in the Li_3 ring are additionally bonded to phenyl groups. *(33a)* is converted into *(33b)* after loss of two LiC_6H_5 molecules from the $Li_3(C_6H_5)_2$ group. In *(33b)* the two lithium atoms bonded to dinitrogen interact solely with nitrogen. A conceivable exchange of these Li atoms by $H^\oplus$ with concomitant transfer of two electrons from the side-on bonded $[Ni(C_6H_5)_2Li]$ units to nitrogen would lead to biphenyl and diimine. The latter could form N_2 and NH_3 in analogy with the N_2H_2 disproportionation[71] on low-valent titanium atoms.

The reaction scheme (Fig. 12) does not, of course, describe the exact mechanism for the hydrolysis of *(33a)* or *(33)*. It merely gives the total stoichiometry and shows that the yields of ammonia and biphenyl are equivalent. The reduction equivalents for the conversion of dinitrogen into ammonia are supplied by the carbanionic phenyl groups bonded to nickel. The nickel atoms, which are present after the hydrolysis as nickel(0), *i.e.* elemental nickel, just direct the electron flow from $C_6H_5^\ominus$ to N_2. Bearing this in mind, the hydrolysis reaction of *(33)* differs from that of the N_2 reductions which *Chatt et al.*[59] and *Bercaw et al.*[72] have described for Mo, W, or Zr with end-on bonded dinitrogen: Reduction and protonation of the N_2 ligand in this case results in oxidation of the transition metal.

7. Dilithium-Nickel-Olefin Complexes

7.1. Syntheses and Structures

In the reactions of nickel(0) olefin complexes with organoalkali metal compounds, alkali metal hydrides and alkali metal diorganophosphites, it was seen in Sections 3 to 6 that the charge on the alkali-metal atoms is transferred onto nickel atoms and π-ligands bonded to them *via* C, H or P atoms. The syntheses, structures, and NMR data[46,73] of compounds described in this section show that the charge on the alkali metal atom can also be transferred directly onto nickel(0) π-ligand systems.

The dilithium-nickel-olefin complexes *(36)* and *(37)* which result from the lithiation of $(CDT)Ni^0$ *(7)* or $(COD)_2Ni^0$ *(8)*[74] are examples of a new class of d-element compounds, in which alkali metals, acting as one-electron ligands, together with olefins are bonded to transition metal atoms.

$$(CDT)Ni^0 + 2Li + 2TMEDA \xrightarrow[0\ ^\circ C]{THF} [Li(TMEDA)]_2Ni(CDT)$$

(7) *(36)*

$$(COD)_2Ni^0 + 2Li \xrightarrow[-30\ \text{to}\ 0\ ^\circ C]{THF} [Li(THF)_2]_2Ni(COD)_2 \quad \text{(n)}$$

(8) *(37)*

The conversion of *(7)* into *(36)* with lithium can be attributed to the tendency of the coordinatively unsaturated 16e complex $(CDT)Ni^0$ *(7)* to attain the noble gas configuration; the two requisite electrons are supplied by the lithium atoms.

Nickel also has a noble-gas configuration in *(37)*. *(37)* is a fluxional molecule (Fig. 13). The low temperature ^{1}H-NMR spectrum of *(37)* shows four signals of equal intensity for the olefin protons; one, at $\delta = 5.4$, can be attributed to the protons of an uncomplexed double bond. At room temperature, however, only one signal for the olefin protons is seen which remains unaltered on the addition of COD (the signals of free COD are also unperturbed). The observed signal equivalencing depends, therefore, on an intramolecular exchange process involving the free double bond (identifiable in the IR spectrum, $\nu_{C=C} = 1655\ cm^{-1}$ (THF at 0 °C)). The fluxional process of the pentacoordinate complex cannot be satisfactorily described by a Berry pseudo-rotation or turnstile rotation[75,76] alone. The structure and the rearrangement mechanism, schematically represented in Figure 13, are in accord with the NMR and IR data.

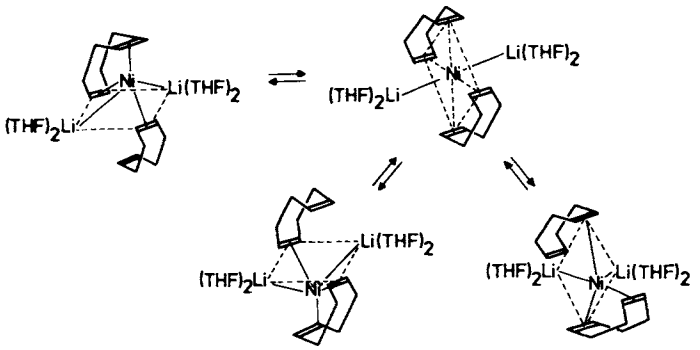

Fig. 13. The fluxional process in $[Li(THF)_2]_2Ni(COD)_2$ *(37)* (schematic).

The coordination geometry of the nickel atom is possibly tetragonal-pyramidal with the lithium atoms residing in *trans* positions. Breaking and remaking of the nickel-olefin bonds occur simultaneously with retention of the noble-gas configuration around nickel. Merely the slightest displacement at the nickel atom, *i.e.* a change in the Li—Ni—Li angle, is all that is required for this process.

The two cyclooctadiene ligands in *(37)* can be displaced by monoolefins or dienes, and new dilithium-nickel-olefin complexes are formed containing tetra- or pentacoordinate nickel atoms (see Table 2)[74, 77, 78].

$$[Li(THF)_2]_2Ni(COD)_2 + z\,\text{Olefin} \xrightarrow[-4\,THF]{2\,y\text{n-Donor ligand}} \underset{(37)}{} \qquad (o)$$

$$[Li(n\text{-Donor ligand})_y]_2Ni(\text{Olefin})_z + 2\,COD$$

Table 2. Dilithium-nickel-olefin complexes.

Olefin	Complex	
CDT	$[Li(TMEDA)]_2Ni(CDT)$	*(36)*
COD	$[Li(THF)_2]_2Ni(COD)_2$	*(37)*
N,N,N',N'-Tetramethyl-2-butene-1,4-diamine	$Li_2Ni[(CH_3)_2NCH_2CHCHCH_2N(CH_3)_2]_3$	*(38)*
N,N-Dimethyl-allylamine	$Li_2Ni[(CH_3)_2NCH_2CHCH_2]_4$	*(39)*
Ethylene	$[Li(TMEDA)]_2Ni(C_2H_4)_3$	*(40)*
Ethylene	$[Li_2(TMEDA)_{1.5}]Ni(C_2H_4)_2$	*(41)*
Norbornene	$[Li(TMEDA)]_2Ni(C_7H_{10})_2$	*(42)*
Norbornadiene	$[Li(TMEDA)]_2Ni(C_7H_8)_2$	*(43)*
Butadiene	$[Li(THF)]_2Ni(C_4H_6)_3$	*(44)*
Dimethyl butadiene	$[Li(TMEDA)]_2Ni(C_6H_{10})_2$	*(45)*
Styrene	$[Li(TMEDA)]_2Ni(C_6H_5CHCH_2)_2$	*(46)*
trans-Stilbene	$[Li(THF)_2]_2Ni(C_6H_5CHCHC_6H_5)_3$	*(47)*

Dilithium-nickel-olefin complexes are best classified as non-salt-like compounds. There are valid arguments for this: None of the compounds in Table 2 contains more than three n-donor atoms per lithium atom, most of them have only two; four n-donor atoms are required to stabilize a cationic, tetrahedrally coordinated lithium atom. Olefin ligands, particularly those with doubly alkyl-substituted double bonds (CDT, COD), are only relatively weak π-acceptors and are thus poorly suited to stabilize a doubly negatively charged nickel anion. Even carbon monoxide, a typical π-acceptor ligand, is unable to do this[*]. The complexes *(36)*, *(37)*, and *(38)* are soluble in benzene, toluene, and perceptibly so in pentane, and show only a slight conductivity in THF. The cryoscopic molecular weight determination of *(36)* in benzene gives the expected value. Finally, semi-empirical molecular orbital calculations[79b] on model compounds suggest that a completely salt-like structure for these compounds is unlikely.

We assume therefore that during the reductive addition of lithium to *(7)* and *(8)* to give *(36)* and *(37)*, respectively, an electron rich Li_2Ni skeleton is formed which remains intact during the olefin exchange reaction [eq. (o)], and in which the lithium atoms are connected to the nickel atom by covalent, strongly polarized metal-metal bonds ($Li^{\delta\oplus}$—$Ni^{\delta\ominus}$).

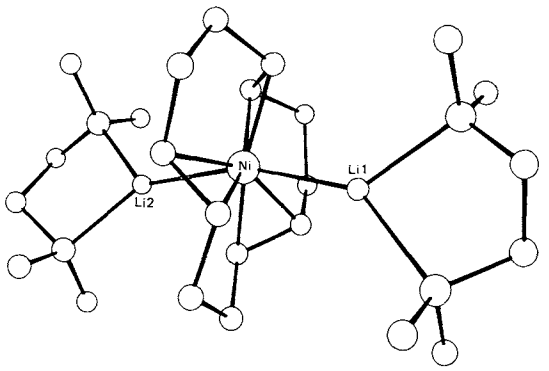

Fig. 14. Molecular structure of $[Li(TMEDA)]_2Ni(CDT)$ *(36)*.

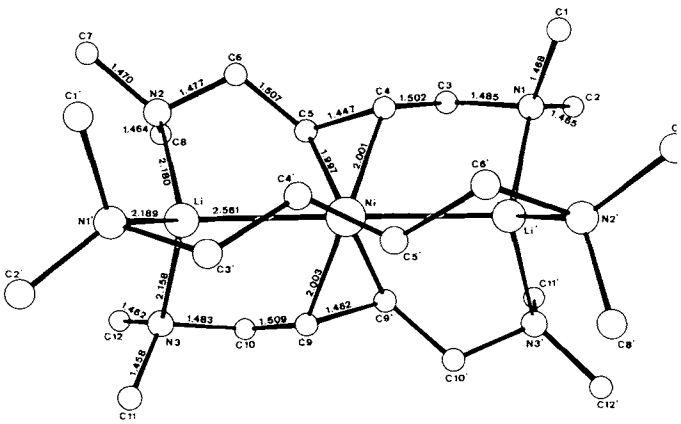

Fig. 15. Molecular structure of $Li_2Ni[(CH_3)_2NCH_2CHCHCH_2N(CH_3)_2]_3$ *(38)*.

Characteristic features of this class of compounds can be seen in the structures of *(36)* and *(38)* (Fig. 14 and 15)[79a]. Nickel has, in both cases, a trigonal-bipyramidal coordination geometry, the mid-points of the double bonds occupy equatorial positions and the lithium atoms sit at the vertices. A comparison of the two structures accentuates lithium's different coordination abilities; in *(38)* lithium adopts a tetrahedral sp^3-coordination geometry with a direct metal-metal bonding interaction with nickel (Ni—Li = 2.561 Å), while in *(36)* lithium is trigonally-planar coordinated (sp^2) (Ni—Li = 2.39 Å). As was described in Section 4.2, this latter arrangement allows interaction between the unoccupied p-orbital on lithium and the π-orbitals of the olefins bonded to nickel. In order to optimize this bonding the linear Li—Ni—Li skeleton seen in *(38)* distorts in *(36)* in such a way (∢ Li—Ni—Li = 162.2°) as to give the best overlap between the olefin and the lithium orbitals. The shorter Li—Ni distance in *(36)* may indicate a higher Ni—Li (p-d) π-back bonding than in *(38)*, and the greatly lengthened C—C bonds in *(38)*

[*] The tricarbonylnickelate dianion $[Ni(CO)_3]^{2\ominus}$ is as yet unknown.

(mean 1.452(9) Å) together with the related changes in angles are also characteristic of strong bonds between olefins and nickel.

The Ni—Li distances (2.381 Å) are extremely short in the square-planar, centrosymmetric 16e complex *(42)* (Fig. 16).

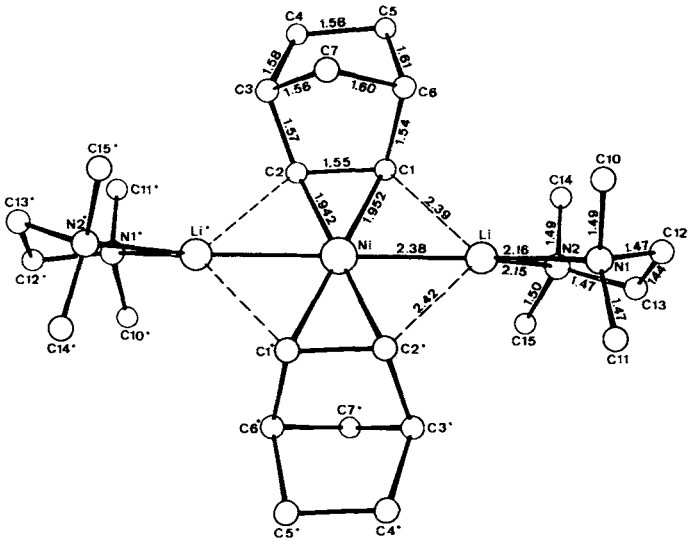

Fig. 16. Molecular structure of $[Li(TMEDA)]_2Ni(norbornene)_2$ *(42)*.

Here again the planes of the trigonally-planar coordinated lithium atoms are so oriented that optimal bonding to both olefinic carbon atoms of the norbornene ligands can be achieved. Short Li—C distances result, and there is a consid-

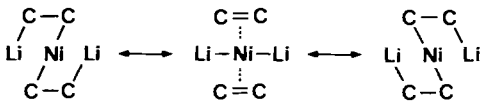

Fig. 17. Resonance structures for the central part of *(42)*.

erable lengthening of the olefinic double bonds (mean 1.551 Å). This molecular geometry may be formulated in terms of the mesomeric system shown in Figure 17.

7.2. Dilithium-Nickel-Olefin Complexes, a New Form of Soluble and Reactive Lithium

7.2.1. Nickel(0)-Olefin Complexes from Dilithium-Nickel-Olefin Complexes

An important criterion for the reactivity of dissolved alkali metals is their ability to reduce. In order to examine the dilithium-nickel-olefin complexes in this regard, we have reacted them with oxidants of different electron affinities.

The dilithium-nickel-olefin complexes *(36)* and *(37)* are converted into the nickel(0)-olefin complexes *(7)* and *(8)*[74], respectively, by relatively strong oxidants such as iodine or cyclooctatetraene (COT) and by observing the molar ratios given below.

$$[Li(TMEDA)]_2Ni(CDT) + 1\,COT \rightarrow \underset{(36)}{} \underset{(7)}{(CDT)Ni^0} + Li_2(COT) + 2\,TMEDA$$

$$[Li(THF)_2]_2Ni(COD)_2 + 1\,I_2 \rightarrow \underset{(37)}{} \underset{(8)}{(COD)_2Ni^0} + 2\,LiI + 4\,THF$$

When weaker oxidants such as aromatic hydrocarbons are used, it is possible to see that the reductive ability of the Li_2Ni unit depends in a characteristic way on the electron affinity of the complexed olefins. The reductive ability can thus be set by the choice of the olefin ligands[78,80] [see eq. (p) to (s)].

$$[Li(THF)_2]_2Ni(COD)_2 + 2\,Biphenyl \xrightarrow{THF} \underset{(37)}{} \underset{(8)}{(COD)_2Ni^0} + 2\,Li[Biphenyl] \quad (p)$$

$$[Li(THF)_2]_2Ni(COD)_2 + 2\,Naphthalene \xrightarrow{THF} \underset{(37)}{} \underset{(8)}{(COD)_2Ni^0} + 2\,Li[Naphthalene] \quad (q)$$

$$[Li(TMEDA)]_2Ni(C_2H_4)_3 + 2\,Naphthalene \xleftarrow{THF} \underset{(40)}{} \underset{(11)}{(C_2H_4)_3Ni^0} + 2\,Li[Naphthalene] \quad (r)$$

$$[Li(TMEDA)]_2Ni(C_2H_4)_3 + 2\,Anthracene \rightarrow \underset{(40)}{} \underset{(11)}{(C_2H_4)_3Ni^0} + 2\,Li[Anthracene] \quad (s)$$

Thus biphenyl is able to delithiate *(37)* in THF at low temperatures. According to the ^{1}H-NMR and ESR spectra the dark-green reaction solution contains *(8)* and biphenyllithium. *(8)* can also be isolated from the reaction solution of *(37)* and naphthalene. If olefins with greater electron affinities than COD are bonded to the Li_2Ni unit, such as ethylene molecules (*e.g.* in *(40)*), then the electron affinity of naphthalene is not sufficient to effect oxidation, and anthracene with its higher electron affinity must be used.

Several dilithium-nickel-olefin complexes are listed in Table 3 together with the arenes whose electron affinities are just sufficient for their oxidation.

Table 3. The oxidation of dilithium nickel olefin complexes by arenes.

$[Li(TMEDA)]_2Ni(CDT)$	*(36)*	Oxidized by biphenyl
$[Li(THF)_2]_2Ni(COD)_2$	*(37)*	
$[Li(TMEDA)]_2Ni(C_2H_4)_3$	*(40)*	Oxidized by anthracene,
$[Li_2(TMEDA)_{1.5}]Ni(C_2H_4)_2$	*(41)*	but not oxidized by biphe-
$[Li(TMEDA)]_2Ni(C_7H_{10})_2$	*(42)*	nyl or naphthalene
$[Li(TMEDA)]_2Ni(C_7H_8)_2$	*(43)*	
$[Li(THF)]_2Ni(C_4H_6)_3$	*(44)*	
$Li_2Ni[(CH_3)_2NCH_2CHCHCH_2N(CH_3)_2]_3$	*(38)*	Oxidized by perylene

The rule that the reductive ability of the Li_2Ni unit increases with decreasing electron affinity of the olefin ligands, fulfilled by complexes *(36)*—*(44)*, is not obeyed by *(38)*, although the electron affinity of the ligand *N,N,N',N'*-tetramethyl-2-butene-1,4-diamine is comparable with those of CDT and COD. This can be explained in terms of the chelating ef-

fect of the unsaturated diamine which, by coordinating to the nickel and both the lithium atoms, greatly stabilizes the Li_2Ni unit (cf. Figure 15).

7.2.2. The Nickel(0)-Induced Synthesis of Ethyllithium from Lithium, Hydrogen, and Ethylene

If dilithiumbis(cyclooctadiene)nickel *(37)* is reacted with molecular hydrogen (1 bar) in THF at $-60\,^{\circ}C$, the light yellow, almost insoluble, powdery *(48)* is formed after take-up of 1 H_2 and loss of 0.5 COD per Li_2Ni.

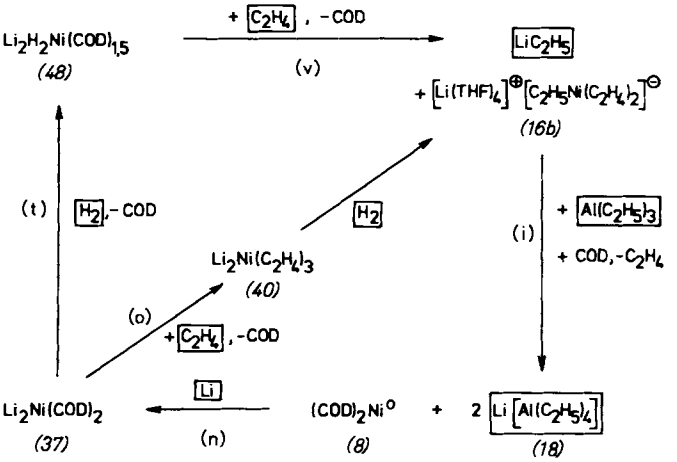
$$[Li(THF)_2]_2Ni(COD)_2 + 1\,H_2 \xrightarrow[-COD]{THF,\ -60\,^{\circ}C} \underset{(48)}{Li_2H_2(THF)_xNi(COD)_{1.5}} \quad (t)$$
(37)

The molecular structure of *(48)* is unknown at present as its insolubility precludes adequate spectroscopic characterization. From its chemical properties, it can be inferred that the lithium and hydrogen atoms in *(48)* behave as two particularly reactive lithium hydride molecules[25,77,81].

(48) dissolves in tetrahydrofuran in the presence of organometallic Lewis acids (*e.g.* $Al(C_2H_5)_3$) and COD. The complex-bonded Li and H atoms are released and are transferred as lithium hydride onto $Al(C_2H_5)_3$; the hydridoaluminate $Li[Al(C_2H_5)_3H]$ [isolated as *(49)*] and $(COD)_2Ni^0$ *(8)* are formed in high yields.

$$\underset{(48)}{Li_2H_2(THF)_xNi(COD)_{1.5}} + 2\,Al(C_2H_5)_3 + 0.5\,COD \xrightarrow[-30\,^{\circ}C]{THF} \underset{(8)}{(COD)_2Ni^0} + 2\,Li[Al(C_2H_5)_3H] \quad (u)$$

$$Li[Al(C_2H_5)_3H] \xrightarrow{TMEDA} \underset{(49)}{[Li(TMEDA)_2]^{\oplus}[Al(C_2H_5)_3H]^{\ominus}}$$



If one includes the lithiation of *(8)* to give *(37)* [eq. (n)], then equations (n), (t), and (u) describe a nickel(0)-induced stoichiometric synthesis of $Li[Al(C_2H_5)_3H]$ from lithium, hydrogen, and $Al(C_2H_5)_3$ which only requires very mild conditions.

$$2\,Li + 1\,H_2 + 2\,Al(C_2H_5)_3 \xrightarrow{Ni^0} 2\,Li[Al(C_2H_5)_3H]$$

A nickel(0)-catalyzed synthesis of the hydridoaluminate is not possible using *(8)*, lithium, and $Al(C_2H_5)_3$ because hydrogen does not bond to *(37)* in the presence of $Al(C_2H_5)_3$. Of course, the $(COD)_2Ni^0$ formed in equation (u) can be relithiated, *etc.* Thus it is possible to synthesize $Li[Al(C_2H_5)_3H]$ in a stepwise fashion (pseudo-catalytically).

Pure lithium hydride made from Li and H_2 does not add to C=C double bonds[82a]. The complexed "lithium hydride" in *(48)* is much more reactive. It is able to hydrolithiate C=C double bonds even at low temperatures, and the speed of addition depends on the structure of the olefin, as is the case for hydroalumination[82b].

The double bonds on the COD ligands in *(48)* are doubly substituted by alkyl groups. *(48)* is stable at room temperature; the addition of LiH to the complexed COD ligands is thus not observed. *(48)* dissolves slowly in THF with propylene below $-20\,^{\circ}C$. Probably propyllithium is formed; ethylene reacts with *(48)* to give ethyl lithium[25,77,81]. Following this reaction sequence the synthesis of alkyllithium compounds from lithium hydride and olefins, which *Ziegler* failed to accomplish in 1952[82a], can be achieved.

(48) reacts with ethylene at a satisfactory rate even at $-60\,^{\circ}C$ [eq. (v)]; the clear reaction solution contains *(16b)* and free ethyllithium. *(16b)* and $Li(C_2H_5)$ react with $Al(C_2H_5)_3$ and COD to give $Li[Al(C_2H_5)_4]$ *(18)* and $(COD)_2Ni^0$ *(8)*. The lithiation of *(8)* leads back to *(37)* [eq. (n)]. There is a second route from *(37)* to *(16b)* and LiC_2H_5 other than *via (48)* [eq. (t)], and that is by displacing the COD in *(37)* by ethylene [eq. (o)] to give *(40)* and then reacting this with hydrogen.

8. Olefin-Transition Metal and Alkali Metal-Olefin-Transition Metal Complexes from Metallocenes by Reductive C_5H_5-Abstraction

After it was found that nickel(0)-olefin complexes react with lithium to give dilithium-nickel-olefin complexes, we became interested in preparing alkali metal-olefin-transition metal complexes with other transition metals besides nickel. The number of other transition metal-olefin complexes for which alkali metalation might be possible is, however, limited, and their formation often requires a considerable experimental effort (co-condensation[83] of M_T atoms and olefins) so we sought a new way of preparing them.

Metallocenes $(\pi\text{-}C_5H_5)_2M_T$ are known for all 3d-elements except titanium. They can be synthesized from the corresponding halides and alkali metal- or alkaline-earth metal-cyclopentadienides in high yields [cf. *(5)* in Section 1]. Their reactions can be divided into two large groups. In one group the five-membered ring ligands remain attached to the transition metal. Among these are the thoroughly investigated substitution reactions of ferrocene *(5)*[84], such as Friedel-Crafts acylation, sulfonation, mercuration, or metalation[85] with organolithium compounds.

$$(\pi\text{-}C_5H_5)_2Fe \xrightarrow[-RH]{LiR} (\pi\text{-}C_5H_5)(\pi\text{-}C_5H_4Li)Fe \xrightarrow[-RH]{LiR} \pi\text{-}C_5H_4Li)_2Fe$$
(5)

Reactions belonging to the second group include those where the C_5H_5 ligands are displaced by other ligands, *e.g.* two-

electron ligands like CO, PR_3, PF_3, or RNC. Ring ligand displacement reactions[86] are less characteristic for metallocenes, since the breaking of the C_5H_5—M_T bond generally requires somewhat severe conditions. The 18-electron complex ferrocene *(5)* is particularly stable in this regard.

Since 1957 it has been known[87] that several metallocenes react with alkali metals to give alkali metal cyclopentadienides and transition metals, for example as in eq. (w).

$$(\pi\text{-}C_5H_5)_2Fe + 2Li \rightarrow 2LiC_5H_5 + Fe \qquad (w)$$
(5)

Remarkably, it has been overlooked that reactions of this type open a convenient route for the preparation of "naked" transition metals which should be well suited for the synthesis of low-valent transition metal organometallic complexes.

Our investigations on the $(\pi\text{-}C_5H_5)_2M_T$/alkali metal systems with M_T = Ni, Co, Fe[88-91] show that transition metal precipitation according to equation (w) is actually absent if the metallocenes are treated with alkali metals in the presence of molecules capable of functioning as π-ligands, *e.g.* olefins.

$$(\pi\text{-}C_5H_5)_2M_T \xrightarrow[-M_AC_5H_5]{M_A,\ Olefin} (M_A)_x(\pi\text{-}C_5H_5)M_T(Olefin)_z$$

$$\xrightarrow[-M_AC_5H_5]{M_A,\ Olefin} (Olefin)_zM_T \xrightarrow{M_A} (M_A)_xM_T(Olefin)_z$$

M_T = Ni, Co, Fe; M_A = Li, Na, K

After loss of the C_5H_5 ligands as $M_AC_5H_5$ from the transition metal, alkali metal-free or alkali metal-containing olefin-transition metal complexes are formed even at low temperatures (in yields of greater than 65% in THF, for example). These complexes contain one or two M_A atoms per M_T. In addition, by a particular choice of the molar ratio of reactants, of the reaction conditions, and of the transition metal, it is possible to remove one or both of the C_5H_5 ligands from the M_T atom; hence this method[92] can be used to prepare a variety of new transition metal-olefin complexes.

8.1. The Nickelocene/Lithium/Olefin System

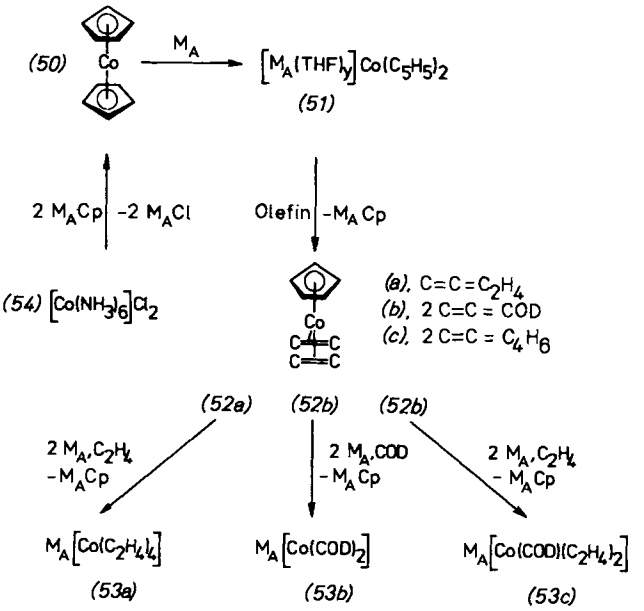
$[Li(THF)_2]_2Ni(COD)_2$ *(37)* (see Section 7) can be prepared from nickelocene, cyclooctadiene, and lithium.

$$Cp_2Ni \xrightarrow[-2LiCp]{2Li,\ 2COD} \underset{(8)}{(COD)_2Ni^0} \xrightarrow[THF]{2Li} \underset{(37)}{[Li(THF)_2]_2Ni(COD)_2}$$

Cp = C_5H_5

Both C_5H_5 ligands can be removed from nickelocene using either the two lithium atoms complexed in *(37)* or lithium metal.

$$Cp_2Ni + \underset{(37)}{[Li(THF)_2]_2Ni(COD)_2} + 2COD \xrightarrow[-THF]{} \underset{(8)}{2(COD)_2Ni^0} + 2LiCp$$



8.2. Cobalt-Olefin and Alkali Metal-Cobalt-Olefin Complexes from Cobaltocene

The removal of both C_5H_5 ligands from cobaltocene by alkali metals and the addition of an M_A atom to the Co atom proceeds *via* reduction of Co^{II} (d^7) in the 19e complex cobaltocene *(50)* to give Co^{-I} (d^{10}) in the $M_A[Co(C\equiv C)_4]$ complexes *(53)* (18e); three alkali metals are required for this process:

$$\underset{(53)}{Cp_2Co} + 4C\equiv C + 3M_A \xrightarrow[-60\text{ to }0\,^\circ C]{THF} M_A[Co(C\equiv C)_4] + \underset{(50)}{2M_ACp}$$

C ≡ C = Ethylene or 1/2COD; M_A = Li, Na, K

In the formation of the alkali metal-cobalt-olefin complexes *(53)* (yields 70–90%), alkali metal-containing and alkali metal-free intermediates are formed and these can be isolated[89,93].

In the absence of olefins, cobaltocene *(50)* reacts with an excess of lithium in THF at −30 °C to give *(51)* where the addition of just one Li atom has occurred. *(51)* crystallizes out of solution at −78 °C. It still contains both C_5H_5 ligands. Loss of the first C_5H_5-ring as $M_AC_5H_5$ only occurs when olefins are added, and even at temperatures as low as −30 to 0 °C complexes of the type *(52)* are formed. COD and butadiene give the exceptionally thermally stabile complexes *(52b)* and *(52c)* which have until now been prepared under more severe reaction conditions[94]:

$$Co_2(CO)_8 \xrightarrow[60\,^\circ C]{Cp-H} CpCo(CO)_2 \xrightarrow[130\,^\circ C]{COD} \underset{(52b)}{CpCo(COD)}$$

$$\underset{(50)}{Cp_2Co} \xrightarrow[130\,^\circ C]{C_4H_6} \underset{(52c)}{CpCoC_4H_6}$$

The more thermally labile $(\pi\text{-}C_5H_5)$Co(olefin) complexes like (η^5-cyclopentadienyl)bis(ethylene)cobalt *(52a)* cannot be prepared by conventional methods. We initially prepared

(52a) from *(51)* and ethylene[89], but we have also synthesized it directly from cobaltocene *(50)*[93].

$$[Li(THF)_n]CoCp_2 + 2C_2H_4 \xrightarrow{Et_2O} CpCo(C_2H_4)_2 + LiCp$$

(51) *(52a)*

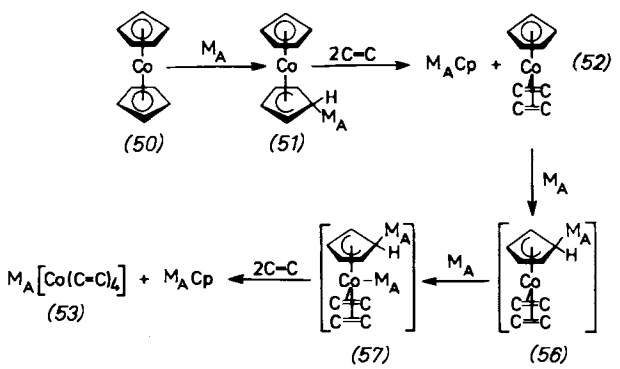
$$Cp_2Co + 1K + 2C_2H_4 \xrightarrow[-20\text{ to }0\,^\circ C]{Et_2O} CpCo(C_2H_4)_2 + KCp$$

(50) *(52a)*

(52a) is stable at room temperature and can be prepared on a 50-g scale in yields of *ca.* 80%; the easy displacement of the ethylene ligands makes a variety of reactions possible[89,93,95].

If the complexes *(52)* are again treated with alkali metals (Li, Na, K) in the presence of olefins, the second C_5H_5 ligand is lost from cobalt, and the alkali metal-cobalt-olefin complexes *(53)* and corresponding alkali metal cyclopentadienides are formed in high yields. Reaction of the latter with $[Co(NH_3)_6]Cl_2$ regenerates cobaltocene *(50)*[96].

All in all, the C_5H_5 group fulfills the important role of a support ligand. It is transferred first to and then from cobalt, and without it even the synthesis of the C_5H_5-free cobalt complexes *(53)* would not have been possible. If one reduces cobalt(II) chloride with sodium in THF/pyridine/COD[97], for example, one obtains (η^4-1,5-cyclooctadiene)(η^3-cyclooctenyl)cobalt *(54)*, which can also be prepared electrolytically[98] from cobalt(II) acetylacetonate and COD or by reduction of cobalt(II) acetylacetonate and COD with R_2AlH[99] or from $M_A[Co(COD)_2]$ *(53b)* and methanol[92]. *(54)* does not react with alkali metals (Li, Na) to give *(53b)* but gives a dialkali metal cobalt complex *(55)*, *e.g.* the crystalline $[Li(TMEDA)]_2Co(C_8H_{13})(COD)$[92,100].



$$(\pi\text{-}C_5H_5)_2Co \xrightarrow[THF]{M_A,\ COD} M_A[Co(COD)_2]$$

(50) *(53b)*

$$M_A[Co(COD)_2] \xrightarrow{CH_3OH,\ -\ M_AOCH_3} CoCl_2 \xrightarrow[THF,\ Pyridine]{M_A,\ COD} (C_8H_{13})(COD)Co \xrightarrow{M_A} (M_A)_2Co(C_8H_{13})(COD)$$

(54) *(55)*

The different reaction course when using cobaltocene *(50)* as the cobalt(II) compound and the special advantage of the C_5H_5 ligand over and above typical anions like halides arise from the fact that metallocenes, are substantially more soluble in THF for example, and that both C_5H_5 ligands can be successively lost very easily from the transition metal even at

low temperatures. The latter seems to be the determining factor in the synthesis of the new cobalt olefin complexes *(52a)* and *(53a—c)*.

Several possibilities for the attack of a M_A atom on cobaltocene *(50)* might be envisaged. An electron could be transferred from a M_A atom onto *(50)*, resulting in the complex salt $[M_A]^\oplus[(C_5H_5)_2Co]^\ominus$. Polarographic investigations on $[(C_5H_5)_2Co]^\oplus[PF_6]^\ominus$, for example, have demonstrated[101,102] the existence of the cobaltocene anion, which is isoelectronic with nickelocene. If, on the other hand, the alkali metal—in particular lithium, which is the one most inclined to bond covalently—were to bond to *(50)*, it could add either to the ligands or to the metal. If the addition were to the ligands, as is the case for the isobutyronitrile radical ($^\ominus C(CH_3)_2CN$)[103], then *(50)* would be converted into *(51)* (see Scheme). In *(51)* the $M_AC_5H_5$ ring could be either diene-fashion bonded to cobalt, η^4, or allyl-fashion, η^3, as in the allyl group of $(\pi\text{-}C_5H_5)CoC_3H_5MgBr(THF)_2$[104]. Loss of the alkali metal cyclopentadienide and complexation of two olefinic double bonds give the 18e complex *(52)*. A second alkali metal could then form the 17e complex *(56)* with *(52)* or, alternatively, attach itself to the cobalt (radical center on the ligands), or even the formation of a $[C_5H_5Co(C{\cdots}C)_2]$ anion could be imagined[*]. In all cases, the addition of a second alkali metal would lead to *(57)*, which after loss of $M_AC_5H_5$ and addition of two olefinic double-bonds, would give the stabile 18e complex *(53)*.

The alkali metal-cobalt-olefin complexes $M_A[Co(C{\cdots}C)_4]$ *(53)*, in contrast to the dilithium-nickel-olefin complexes of Section 7, but like $M_A[Co(CO)_4]$[105], are inclined to dissociate into ions. Their specific conductivities in 0.25 M THF solution (−30 °C) are approximately $10^{-3}\ \Omega^{-1}\ cm^{-1}$. These are comparable with the values obtained for the salt-like nickel complexes $[Li(TMEDA)_2]^\oplus[R{-}Ni(C_2H_4)_2]^\ominus$ *(16)*. The observation that the cobalt complexes *(53)* can be prepared not only with lithium but also with sodium and potassium is also in agreement with the electrolytic character of these complexes. The number of n-donor atoms that are bound to an M_A atom in the crystalline complexes *(53)* can vary by large amounts; the number depends on the type of the M_A atom, the type of olefin ligands as well as the type of n-donor ligand itself. The temperature at which the particular cobalt complex in question crystallizes out of solution, and the pressure and temperature of drying the crystal will also affect this number. Thus $Li[Co(COD)_2]$ *(53b)* crystallizes with two THF or three DME molecules[88], of which certainly only two are bonded to the lithium ion. Hence a salt-like structure can be assumed for $[Li(DME)_2]^\oplus[Co(COD)_2]^\ominus \cdot DME$ *(53b)*, for crystalline $[Li(TMEDA)_2]^\oplus[Co(C_2H_4)_4]^\ominus$ *(53a)* and for $[Li(TMEDA)_2]^\oplus[Co(COD)(C_2H_4)_2]^\ominus$ *(53c)*.

If the C···C double bonds are able to move freely around the cobalt atom in *(53a)* the undisturbed $[Co(C{\cdots}C)_4]$ anion, which is not bonded by an ion pair bond to the M_A cation, will be tetrahedral. This is the most stable ligand arrangement for tetracoordinated d^{10} transition metal olefin complexes according to MO calculations[106] on the hypothetical $(C_2H_4)_4Ni^0$. Figure 18 shows a proposed structure for the tetrakis(ethylene)cobalt anion which is in accord with the ^{13}C-NMR spectrum[46] of *(53a)*.

[*] We were recently able to isolate the complexes $[Li(THF)_4]^\oplus[C_5H_5Co(COD)]^\ominus$ and $[K(THF)_2]^\oplus[C_5H_5Co(COD)]^\ominus$ at low temperatures [93].

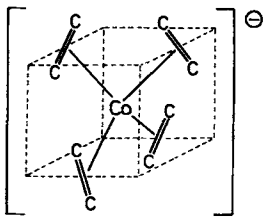


Fig. 18. Proposed structure for the $[Co(C_2H_4)_4]^{\ominus}$ anion *(53a)* (schematic).

In the presence of free ethylene the ^{13}C-NMR spectrum of $K[Co(C_2H_4)_4]$ *(53a)* shows two signals for the complexed ethylene molecules ($\delta = 55.5$ and 37.5) in $[D_8]$-THF at $-70\,^{\circ}C$. On warming the solution these signals broaden, and at room temperature only a broad signal at $\delta = 47$ appears. At all temperatures, the signal for free ethylene remains sharp and fixed. The broadening and coalescence of the ethylene signals can be traced back to a rotation of the ethylene ligands about the ethylene-cobalt bond.

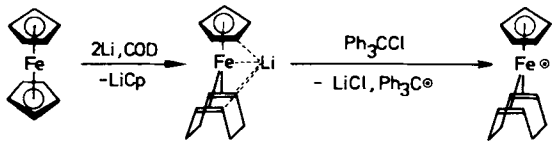
The four ethylene ligands in *(53a)* or the two COD ligands in *(53b)* can be displaced by CO or butadiene even at low temperatures[88,89]. The diphosphane $(CH_2)_2[P(C_6H_{11})_2]_2$ reacts with *(53a)* at $0\,^{\circ}C$ with loss of only two ethylene ligands to give *(59)*[93]. These compounds ($M_A = Li$, K) react with molecular hydrogen to give novel alkali metal-phosphane-hydrido-cobalt complexes *(60)*, in which $2\,H_2$ are bonded per M_ACo.

$$M_A[Co(C{=}C)_4] + 2\,C_4H_6 \rightarrow M_A[Co(C_4H_6)_2] + 4\,C{=}C$$
(53a–c) *(58)*

$$M_A[Co(C_2H_4)_4] + (CH_2)_2(PR_2)_2 \xrightarrow[-2\,C_2H_4]{} M_A[(CH_2)_2(PR_2)_2Co(C_2H_4)_2]$$
(53a) *(59)*

$$(59) + 4\,H_2 \xrightarrow[-30\,^{\circ}C]{THF} M_A[(CH_2)_2(PR_2)_2CoH_4] + 2\,C_2H_6$$
(60)

$R = C_6H_{11}$



As in the anion of *(58)*, the butadiene ligands in $R_3Sn{-}Co(C_4H_6)_2$ ($R = CH_3$, C_6H_5) and $Zn[Co(C_4H_6)_2]_2$ bonded to the cobalt atom are not linked together. These three complexes are formed in high yields from *(58)* and R_3SnCl or $ZnCl_2$, and like *(58)* itself, are stable at room temperature[93].

$$2\,(58) + ZnCl_2 \xrightarrow[-2\,M_ACl]{} (C_4H_6)_2Co{-}Zn{-}Co(C_4H_6)_2$$

8.3. Iron-Olefin and Alkali Metal-Iron-Olefin Complexes from Ferrocene

As with cobaltocene *(50)*, one or both C_5H_5 ligands in ferrocene *(5)* can be displaced by olefins and alkali metals[43,90-92].

If ferrocene is treated with lithium and COD or ethylene in DME at -60 to $-40\,^{\circ}C$, only one C_5H_5 ligand is displaced and one obtains the complex $[Li(DME)](\pi\text{-}C_5H_5)Fe(COD)$ *(61a)* or the analogous ethylene complex. On addition of TMEDA, crystalline $[Li(TMEDA)](\pi\text{-}C_5H_5)Fe(COD)$ *(61b)* or $[Li(TMEDA)](\pi\text{-}C_5H_5Fe(C_2H_4)_2$ *(62)* is obtained.

(5) *(61)* *(63)*

(61) reacts with trityl chloride to give the monomeric, alkali metal-free $(\eta^5$-cyclopentadienyl$)(\eta^4$-1,5-cyclooctadiene)iron *(63)* which, in contrast to the dimeric $[(\pi\text{-}C_5H_5)Fe(CO)_2]_2$[107], contains one unpaired electron. The iron(I) complex *(63)* has a magnetic moment of 2.1 B.M. at room temperature, and the ESR spectrum shows an absorption signal ($g = 2.12 \pm 0.01$) with a peak width at half height of 39 gauss at $-100\,^{\circ}C$ and 106 gauss at $-30\,^{\circ}C$.

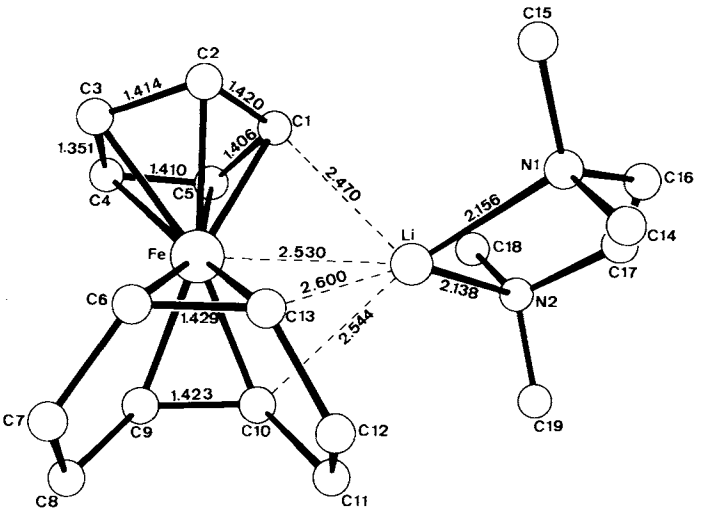


Fig. 19. Molecular structure of $[Li(TMEDA)](\pi\text{-}C_5H_5)Fe(COD)$ *(61b)*.

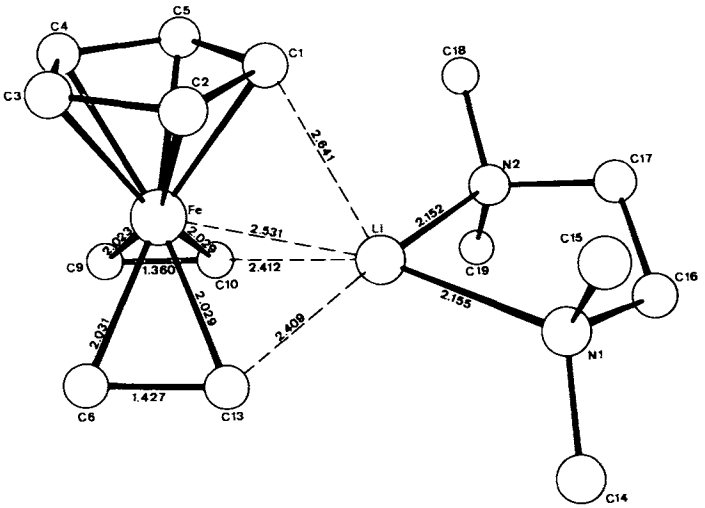

Fig. 20. Molecular structure of $[Li(TMEDA)](\pi\text{-}C_5H_5)Fe(C_2H_4)_2$ *(62)*.

As can be seen from Figures 19 and 20, the metal coordination geometries in the two compounds *(61b)* and *(62)* are very similar, and the organic ligands are arranged around the iron atom as they are around cobalt in the isoelectronic $(\pi\text{-}C_5H_5)Co(COD)$[53b]. The close proximity of the alkali metal,

however, causes changes in the C—C distances in the C_5H_5 ring which are consistent with the formulation of an increased double-bond character in the C—C bond most distant from lithium (C3—C4). In *(61b)* the distance from lithium to C1 of the cyclopentadienyl ring is shorter than to the carbon atoms on the neighboring olefins; in *(62)* the opposite is true. However, the Fe—Li distances are equal (2.531 Å) in both compounds so that a direct metal-metal interaction between the iron atom and the trigonally-planar coordinated lithium atom, in addition to the already mentioned ion-pair bond, might be a structure-determining factor.

The lithium-containing complexes *(61)* and *(62)*[43,90] and, in particular, the iron(I) compound $(\pi\text{-}C_5H_5)Fe(COD)$ *(63)*[108] are suitable starting materials for the synthesis of numerous new organo-iron compounds. Thus from *(61)* and $ZnCl_2$ one obtains the complex *(64)*, where the olefin ligands are bonded to iron, or the corresponding magnesium compound *(65) from (63)* and magnesium. Alkali metals react likewise with *(63)* to give *(61)*.

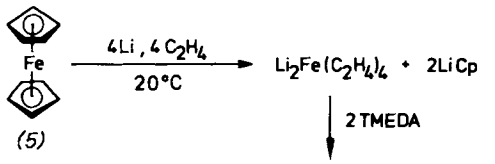
$$2\,Li[(\pi\text{-}C_5H_5)Fe(COD)] + ZnCl_2 \rightarrow Zn[(\pi\text{-}C_5H_5)Fe(COD)]_2 + 2\,LiCl$$
(61) *(64)*

$$2(\pi\text{-}C_5H_5)Fe(COD) + Mg \xrightarrow{THF} [Mg(THF)_6][(\pi\text{-}C_5H_5)Fe(COD)]_2$$
(63) *(65)*

$$(\pi\text{-}C_5H_5)Fe(COD) + M_A \rightarrow M_A[(\pi\text{-}C_5H_5)Fe(COD)]$$
(63) *(61)*

The new iron(II) complexes *(66)* or *(67)* are formed from *(61)*, HX ($(CH_3)_3COH$, CH_3OH, CH_3COOH) and ethylene or benzonitrile. The reaction probably proceeds *via* exchange of Li in *(61)* by H, addition of the Fe—H bond to a double bond on the cyclooctadiene ligand, and subsequent isomerization of the Fe—C_8H_{13} group to give the products. The ethylene or benzonitrile is displaced by carbon monoxide to give *(68)* which is stable at room temperature.

$$Li[(\pi\text{-}C_5H_5)Fe(COD)] + HX + C_2H_4 \xrightarrow[-LiX]{}$$
(61)



$$(\pi\text{-}C_5H_5)(\pi\text{-}C_8H_{13})FeC_2H_4$$
(66)

$$(61) + HX + C_6H_5CN \xrightarrow[-LiX]{} (\pi\text{-}C_5H_5)(\pi\text{-}C_8H_{13})Fe(C_6H_5CN)$$
(67)

$$(\pi\text{-}C_5H_5)(\pi\text{-}C_8H_{13})FeL + CO \xrightarrow[-L]{} (\pi\text{-}C_5H_5)(\pi\text{-}C_8H_{13})FeCO$$
(66) *(68)*

$L = C_2H_4$, C_6H_5CN

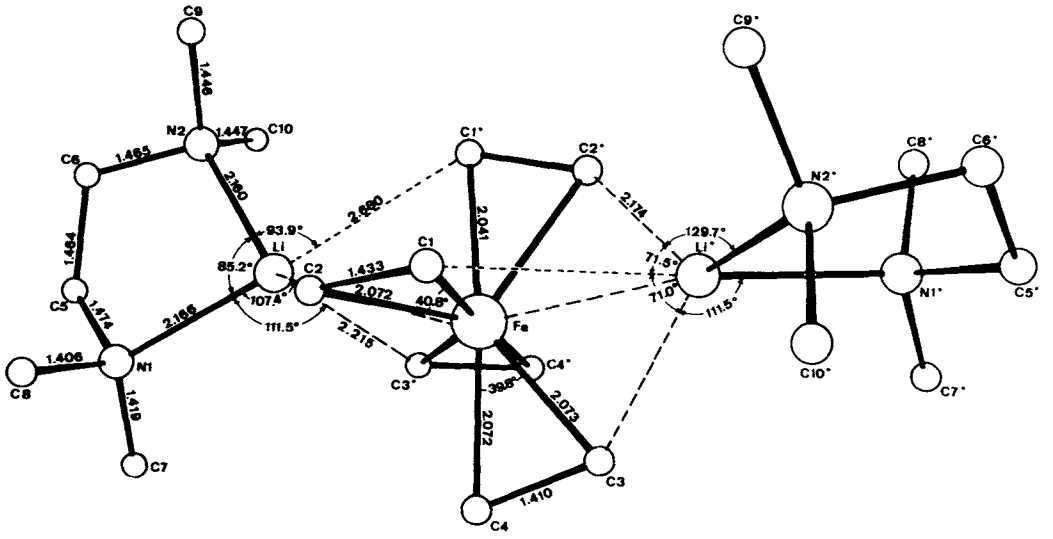
Ferrocene *(5)* reacts with lithium and ethylene in THF at room temperature with the loss of both C_5H_5 ligands from iron to give dilithium-tetrakis(ethylene)iron which can be isolated as crystalline $[Li(TMEDA)]_2Fe(C_2H_4)_4$ *(69)*[43,91,92].

(5)

$[Li(TMEDA)]_2Fe(C_2H_4)_4$ *(69)*

The structure[91] of the 18e complex *(69)* (Fig. 21) is reminiscent of that of the 16e Li_2Ni complex *(42)* (see Fig. 16). In this compound, a crystallographic twofold axis passes through the distorted octahedrally coordinated central iron atom and bisects the C1—C1* vector. There are short contacts between the trigonally-planar coordinated lithium atom and carbon atoms of the coordinated ethylenes (2.17—2.21 Å). Disregarding the iron-lithium bond (Fe—Li = 2.619 Å), the lithium atom appears to be tetrahedrally surrounded by ligands.

(69) takes up four equivalents of CO (1 bar) and four equivalents of C_2H_4 are lost. It reacts with COD at 40—70 °C to



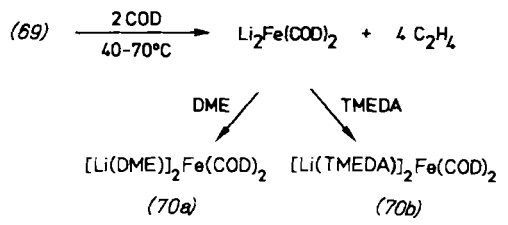


Fig. 21. The molecular structure of $[Li(TMEDA)]_2Fe(C_2H_4)_4$ *(69)*. Fe---Li = 2.619 Å.

give $Li_2Fe(COD)_2$ *(70)*—which can be isolated as crystalline *(70a)* or *(70b)*—whereupon the series of the isoelectronic cyclooctadiene complexes of the Group VIII 3d-elements, namely $(COD)_2Ni$ *(8)*, $M_A[Co(COD)_2]$ *(53b)*, and $Li_2Fe(COD)_2$ *(70)*, is complete.

9. Closing Remarks

The observations described here show that the combination of transition metal π-complexes and main-group metals, their hydrides, or organometallic compounds to give well-defined multimetal compounds is a new and attractive area of organometallic chemistry. The properties of these compounds not only reflect the structures and reactivities of the metal-containing starting components, but show new aspects as well. By pursuing the principles described here, we discovered new methods of synthesis, of which the reductive abstraction of C_5H_5 from metallocenes is particularly worthy of emphasis because of its efficiency and practicability. Examination of the breadth of application of this method for the synthesis of as yet unknown or difficultly prepared organometallic compounds seems to us to be especially worthwhile. Finally, detailed experimental investigations into the electron-density distributions together with model theoretical calculations should be attempted in order to gain a better insight into the bonding in the multimetal compounds described here.

We thank the members of both our groups who participated in obtaining the results presented here for their enthusiastic collaboration. Furthermore, we are indebted to numerous colleagues at the Max-Planck-Institut für Kohlenforschung for many discussions and analytical services. Our special thanks go to the director of the institute, Prof. Dr. Günther Wilke, for valuable discussions and the stimulating furtherance of our work.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Electrochemical Oxidation of Dicarbene Complexes of the Type (Carbene)$_2$MoL(CO)$_3$: Interconversion Among Three Isomers *via* Electrochemical Redox Processes[**]

By *Reuben D. Rieke, Hiroyuki Kojima*, and *Karl Öfele*[*]

Carbenecarbonylmetal complexes constitute a relatively new class of organometallic compounds which are currently the subject of intensive investigation[1]. In 1970 *Öfele* and *Herberhold* reported the preparation of *cis*- and *trans*-dicarbenetetracarbonylmetal complexes[2]. We have been involved in a study of the redox properties of dicarbene metal carbonyl complexes and recently we reported on an unusual electrochemical isomerization without net current flow in the case of *trans*-dicarbenetetracarbonylmetal complexes[3].

We report here on further unusual isomerizations in neutral ligand-substituted dicarbenetricarbonylmolybdenum complexes of the type (imid)$_2$MoL(CO)$_3$ *(1)*: In these systems, we found that interconversion occurs among the three isomers *via* electrochemical redox processes.

imid =  ; *a*, L =  ; *b*, L = PEt_3, *c*, L = PPh_3, *d*, L = 

The compounds *(1a—c)* were synthesized by ligand exchange from (imid)$_2$Mo(py)(CO)$_3$ *(1d)*, which had been prepared photochemically from (imid)$_2$Mo(CO)$_4$ *(2)*, and were identified as the *sym-mer*-isomers by IR and NMR spectra. *sym-mer-(1)* was electrochemically oxidized in dichloromethane and propylene carbonate with tetrabutylammonium perchlorate (TBAP) as supporting electrolyte. Since the complexes *(1)*, except *(1a)*, are very air-sensitive, care was taken to exclude air from the cells. To prevent the possibility of the compounds isomerizing, preparation of the solutions and electrochemical measurements were performed at low temperature.

Cyclic voltammetry of *sym-mer-(1a)* yielded two oxidation waves at the peak potentials $E_p^a = -0.20$ and 0.09 V (*vs.* SCE) in dichloromethane (Fig. 1a). This voltammogram is very similar to that of *trans-(2)*[3]. The amplitude of the first wave is much smaller at room temperature and/or slow scan rates.

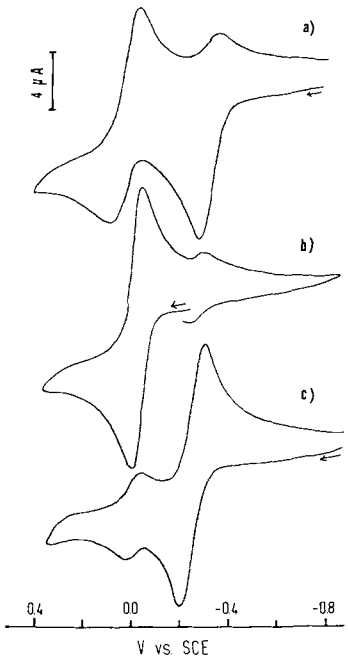

Fig. 1. Cyclic voltammogram of (imid)$_2$Mo(CN-*cyclo*-C_6H_{11})(CO)$_3$ *(1a)* in 0.25 M TBAP/dichloromethane solution at −20 °C; sweep rate 0.20 V/s. a) starting solution; *sym-mer-(1a)*; b) after electrooxidation of the first wave; conversion into *fac-(1a)*; c) after electrooxidation of the second wave, then electroreduction of the third wave; conversion into *asym-mer-(1a)*.

The electrolysis of the intense yellow solution was complete within a few minutes; the amount of current consumed was less than 10% of that required for a one-electron oxidation. The cyclic voltammogram of the resulting pale yellow solution showed that formation of the second wave was roughly reversible (Fig. 1b). This process turned out according to coulometry to correspond to a normal one-electron oxidation. However, on re-reduction a new wave appeared at a cathode potential $E_p^c = -0.27$ V. This suggests that the cation produced in the second wave converts to yet another new species. The neutral complex of this third species was obtained by successive bulk electrooxidation of the second wave and bulk electroreduction of the third wave, and it was characterized by its voltammogram (Fig. 1c).

These two new species corresponding to the waves at $E_p^a = 0.09$ V and $E_p^a = -0.20$ V were isolated after electrolysis by removing TBAP and were identified by NMR and IR

spectra. The methyl protons of the imid ligand (N—CH_3) for the second species showed a single signal at $\delta = 3.42$ (60 MHz, TMS int., in C_6D_6), which was shifted upfield by 0.5 ppm compared to the signal of *sym-mer-(1a)* ($\delta = 3.86$); for comparison: $\delta = 3.98$ for *trans-*, 3.62 for *cis-(2)* (TMS int., [D_6]acetone). The consequent assignment of the second species as *fac-(1a)* is also supported by the similarity of the electrochemical behavior of *(1a)* and *trans-(2)*. In the case of the third species, the methyl protons appear as a doublet with a chemical shift ($\delta = 3.33$, 3.29; TMS int., in C_6D_6) similar to that of *fac-(1a)*. This species can be assigned the structure of the remaining *asym-mer*-isomer.

Additional support for these assignments was provided by the C≡N stretching frequency of the isocyanide ligand in *(1a)*[4]. Both *sym-mer-(1a)* and *fac-(1a)* showed a broad absorption band at about 2080 cm^{-1}, while *asym-mer-(1a)* showed this absorption at about 1980 cm^{-1}. Only the *asym-mer*-isomer has one of the imidazole ligands *trans* to the isocyanide; in the other isomers the isocyanide group has CO ligands *trans* to it. Since the carbene ligand is a poorer π-acceptor than CO, the assignment of the *asym-mer* structure to the third complex is consistent with the lower stretching frequency of the R—N≡C group.

$$2\,[\textit{asym-mer-(1b)}]^{\oplus} \longrightarrow [\textit{asym-mer-(1b)}]^{0} + [\textit{asym-mer-(1b)}]^{2\oplus}$$

$$[\textit{asym-mer-(1b)}]^{0} \longrightarrow [\textit{fac-(1b)}]^{0}$$

$$[\textit{fac-(1b)}]^{0} \longrightarrow \textit{cis-}(\text{imid})_2\text{Mo(CO)}_4 \quad \textit{cis-(2)}$$

$$[\textit{asym-mer-(1b)}]^{2\oplus} \longrightarrow \text{dec.}$$

showed very similar electrochemical behavior to that of the triethylphosphane complex *(1b)*. However, *fac-(1c)* is much less stable than *fac-(1b)* and forms the dicarbene complex *(2)* within a few hours. The pyridine complex *(1d)* decomposes very rapidly, especially in dichloromethane, with a change in color from purple-red to brown; however, it is fairly stable in propylene carbonate at low temperature. Electrochemical studies on this system showed a similar isomerization scheme as in the case of *(1a—c)*, but a much faster rate of formation of the dicarbene complex *(2)* was observed. Table 1 shows the half-wave oxidation potentials of each isomer and the estimated rates of isomerization of the complexes. The oxidation potentials vary considerably; in the case of *(1d)*, *e.g.*, by over 360 mV.

Table 1. Half-wave potentials and approximate isomerization rate of the complex $(imid)_2MoL(CO)_3$ *(1)* [a].

		$E_{1/2}$ [V *vs* SCE] [b]			k_1 [s^{-1}] at −20 °C			Formation of *cis-(2)*
	L	*sym-mer*	*fac*	*asym-mer*	[*sym-mer*]$^{\oplus}$ → [*fac*]$^{\oplus}$	[*fac*]$^{\oplus}$ → [*asym-mer*]$^{\oplus}$	[*asym-mer*]^{0} → [*fac*]^{0}	
(1d)	py [d]	−0.43	−0.08	−0.44	$t_{1/2} = 3$ s at 20 °C	$t_{1/2} = 10$ s	$t_{1/2} \approx 2$—3 min	immediately without py
(1b)	PEt_3	−0.33 [c]	−0.04	−0.34	2×10^{-2}	$> 3 \times 10^{2}$	4×10^{-2}	days
(1a)	CN-*c*-C_6H_{11}	−0.30	+0.05	−0.24	4×10^{-1}	$\sim 10^{-3}$	[e]	not detected
(1c)	PPh_3	−0.24 [c]	+0.01	−0.25	2×10^{-2}	$> 3 \times 10^{2}$	1×10^{-1}	hours

[a] Measurements as in [3] in 0.25 M TBAP/dichloromethane solution at −20 ± 2 °C except where otherwise stated. [b] The values were obtained by averaging the peak potentials of anodic and cathodic waves. [c] These values are approximate because of rapid isomerization. [d] In 10% pyridine solution. [e] Negligibly small.

The electrochemical behavior of the *sym-mer* complexes *(1b—d)* was similar to that of the *sym-mer-(1a)*, but in some cases it was more complex.

The triethylphosphane complex *fac-(1b)* did not give a corresponding wave on re-reduction, but gave the very stable cation [*asym-mer-(1b)*]$^{\oplus}$, even at scan rates of up to 100 V/s and at −20 °C. Its cyclic voltammogram showed another oxidation wave as well as the corresponding oxidation wave to this cation. This new wave turned out to correspond to *fac-(1b)*. It follows, therefore, that [*fac-(1b)*]$^{\oplus}$ is extremely rapidly converted into [*asym-mer-(1b)*]$^{\oplus}$, and that *asym-mer-(1b)* returns to the *fac*-isomer. As well as these isomerization reactions, there are other very slow chemical reactions, *fac-(1b)* slowly forms the dicarbene complex *cis-(2)* (within a few days) in solution. The complex was identified by the cyclic voltammogram and the spectral properties. Presumably, the ligand exchange reaction shown below takes place. The species *(3)* was not detected electrochemically.

$$4\,\underset{\textit{fac-(1b)}}{\textit{fac-}(\text{imid})_2\text{MoL(CO)}_3} \rightarrow 3\,\underset{\textit{cis-(2)}}{\textit{cis-}(\text{imid})_2\text{Mo(CO)}_4} + \underset{\textit{(3)}}{(\text{imid})_2\text{MoL}_4}$$

cis-(2) is also formed in a solution of [*asym-mer-(1b)*]$^{\oplus}$ after a few days at room temperature. This observation is best explained in terms of the following disproportionation of [*asym-mer-(1b)*]$^{\oplus}$. The triphenylphosphane complex *(1c)* showed very similar electrochemical behavior to that of the triethylphosphane complex *(1b)*. However, *fac-(1c)* is much less stable than *fac-(1b)* and forms the dicarbene complex *(2)* within a few hours. The pyridine complex *(1d)* decomposes very rapidly, especially in dichloromethane, with a change in color from purple-red to brown; however, it is fairly stable in propylene carbonate at low temperature. Electrochemical studies on this system showed a similar isomerization scheme as in the case of *(1a—c)*, but a much faster rate of formation of the dicarbene complex *(2)* was observed. Table 1 shows the half-wave oxidation potentials of each isomer and the estimated rates of isomerization of the complexes. The oxidation potentials vary considerably; in the case of *(1d)*, *e.g.*, by over 360 mV.

In some cases, the cations are more stable than that of the dicarbene complex *(2)*[3]. In the isomerization scheme (Fig. 2) the electrochemical redox processes are indicated by thick arrows, while spontaneous or non-spontaneous processes are indicated by thin arrows. There are several unusual features of the isomerization scheme: a) the direct conversion of *sym-mer-(1)* into *asym-mer-(1)* is inhibited, while either conversion of *sym-mer-(1)* into *fac-(1)* or [*fac-(1)*]$^{\oplus}$ into [*asym-mer-(1)*]$^{\oplus}$ can occur, and b) the *fac/asym-mer* conversion proceeds in opposite directions in the neutral and the cation states. These puzzling results suggest that there is a specific

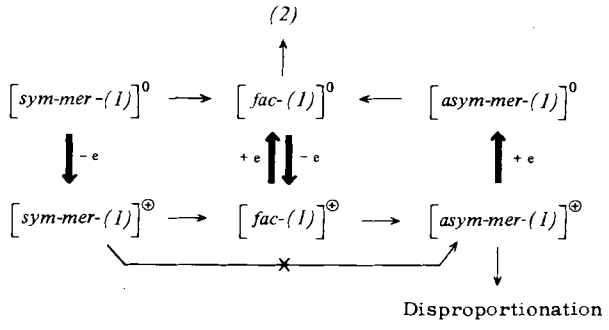

Fig. 2. Isomerization *via* electrochemical redox processes.

mechanism for the isomerization of these systems and that carbene ligands play an unusual and important role. We assume, firstly that dissociation of a CO group takes place at a selective position in an initial stage of the isomerization, and secondly that a substantial change of π-acceptability of the carbene ligand from the neutral to the cation states has to be invoked.

A Phlorizin Polymer as Affinity Gel for Sugar-Binding Proteins[***]

By *Jiann-Trzuo Lin* and *Rolf Kinne*[*]

Phlorizin *(1)*, a β-glycoside found in apple tree roots, was isolated in 1835[1] and synthesized in 1942[2]. Compound *(1)* is known as potent inhibitor of renal and intestinal sugar transport, and is therefore particularly suited for investigations on the properties of the sugar transport system[3]. Owing to the numerous phenolic hydroxyl groups it was possible to cross-link the aglucone moiety while leaving the sugar residue unchanged. As shown below, this polymer san serve as affinity gel for sugar-binding proteins. In contrast to the commonly used affinity gels based on agarose as matrix, both the matrix and the ligand are provided by the same molecule in the phlorizin polymer.

(1)

Phlorizin undergoes cross-linkage with formaldehyde and urea in the presence of acetic acid to give a white polymer. From the glucose content of the polymer[4] a phlorizin content of 3.05% can be estimated, and from the nitrogen content (32.53%) a molar ratio of 1:4:16 is found for phlorizin: urea:formaldehyde. Following the concepts developed for other resins[5], the polymer can be envisaged as composed of phlorizin molecules interconnected by $-CH_2-O-$ and $CH_2-NH-CO-NH-$ chains. The distance between the phlorizin molecules is governed by the amount of formaldehyde and the amount of urea used for synthesis. It has to be large enough to allow free rotation of the sugar moiety and for unrestricted access of the sugar-binding proteins.

In order to test the ability of the polymer to act as affinity gel for sugar-binding proteins the binding capacity for Concanavalin A (ConA) and lentil lectin was first determined. At 22 °C approximately 2×10^{-7} mol ConA and 8×10^{-8} mol lentil lectin were bound per gram of dry polymer. Then purified ConA was applied on a column of phlorizin polymer. In contrast to bovine serum albumin, ConA was adsorbed by the column and could be eluted by D-glucose (Fig. 1a). The polymer was also used to purify ConA from a crude extract of Jack beans. As shown in Figure 1b, most of the proteins present in the extract passed through the column. A small amout of protein was recovered by elution with D-glucose. The composition of this fraction is virtually identical to the composition of commercially available purified ConA (see Fig. 2).

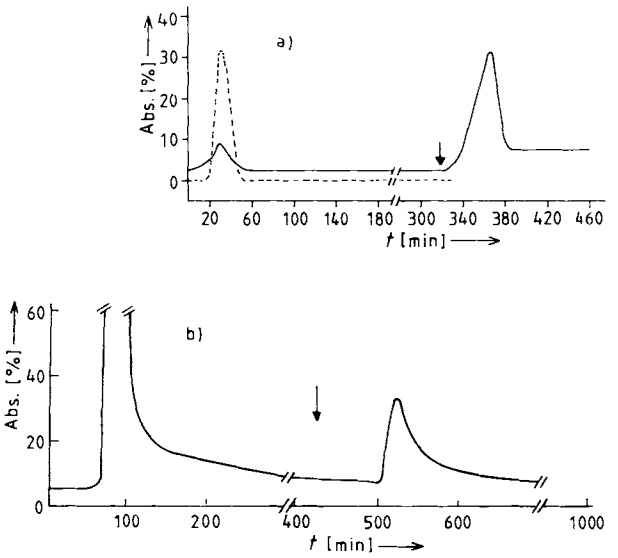

Fig. 1. Affinity chromatography on phlorizin polymer. a) 500 µl of a ConA solution (1.7 mg/ml) (– ·) or 200 µl of bovine serum albumin (4.7 mg/ml) in water were applied onto an affinity column (30 × 0.9 cm). The column was eluted with deionized water, rate 9 ml/h, fraction volume 3 ml. The protein content of the eluate was monitored at 279 nm. Concanavalin A could only be eluted with 0.2 mol/l of D-glucose (arrow). b) 400 µl of crude Jack bean extract in 0.1 M ammonium acetate, pH 7.0, were applied to a column. The proteins adsorbed to the column were eluted with D-glucose (0.5 mol/l), see arrow.

Preliminary experiments with extracts from hog kidney brush border membranes show that the protein fraction adsorbed on the column and eluted by D-glucose exhibits an at least five-fold higher transport activity than the membrane itself. The transport activity was determined after incorporation of the proteins into liposomes. Thus the phlorizin polymer seems to be suitable for the purification of a variety of proteins that show an affinity for D-glucose linked to the matrix by a β-glycosidic bond.

Procedure

Preparation of the polymer: A mixture of phlorizin (2 g), urea (30 g), 37% formaldehyde (65 ml), and acetic acid (1 drop) is stirred for 20–30 min at 120–140 °C. The white mass obtained is broken into small pieces and washed with water/ethanol and then with ethanol in order to remove nonpolymerized material. After drying at 60 °C, 46.2 g of dry polymer was obtained. For further investigations the polymer is ground to a particle size of about 200 mesh and equilibrated

with the appropriate buffer. After transfer to a chromatography column, the polymer was washed with water or buffer solution until no absorption was observed at 256 nm in the eluate. The protein mixture was then applied.

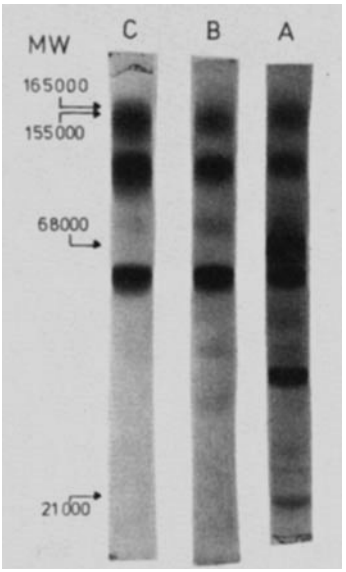

Fig. 2. Protein pattern of the fractions obtained from the crude Jack bean extract (Fig. 1b). A, crude extract; B, fraction eluted by D-glucose; C, commercially available Concanavalin A (Pharmacia, Tübingen). The protein pattern was determined by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulfate (SDS). Polyacrylamide concentration 8%.

Binding of lectins: The binding was determined by incubation of the polymer (10 mg) with increasing concentrations of the lectins (0.13 mg/ml–2.6 mg/ml) in ammonium acetate (0.1 mol/l, pH 6.5) for 2 h at 22 °C. After the incubation, the polymer was sedimented and the protein content of the supernatant was determined. Bovine serum albumin was used as control for unspecific adsorption; this adsorption was negligibly small.

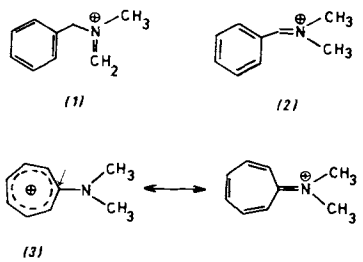
Collision Induced Fragmentation of Alkylideneammonium Ions[**]

By *Hans J. Veith*[*]



Alkylideneammonium ions play a special role in organic synthesis and as natural products (cf. [1a]). We report here on a mass spectrometric method (FD-CA) with which, in addition to their molecular weights, structural details of alkylideneammonium salts can be determined.

Previously, such salts could not be investigated mass spectrometrically since the ionic structure does not remain intact on transfer of the salt into the gas phase (cf. [1b]). With the field desorption (FD) method, however, alkylideneammonium ions can be generated intact in the gas phase from the corresponding salts. While the masses of the cations can thus be determined directly, and the occurrence of cluster ions permits determination of the molecular weights of the salts, no structural details are obtained from the FD-mass spectrum, since the field-desorbed alkylideneammonium ions do not decompose within the mass spectrometric time scale owing to the low excitation energy[2].

A possibility of producing fragmentation is offered by the collisional activation (CA) method. The highly accelerated ions collide inelastically with a neutral target gas, thereby experiencing an excitation separated in space and time from the actual ion-formation process, which leads to fragments of the ions to be investigated (cf. [3]). These fragment ions are generated in the first field-free region of a double-focusing mass spectrometer and recorded with a linked-scan device[4].

The FD-CA mass spectra of the three isomeric alkylideneammonium ions *(1)*—*(3)* (Fig. 1), generated by field desorption from the tetrafluoroborates[5], differ primarily in the intensity ratios of the main fragmentations. The ion *(1)* decomposes, predominantly by heterolysis of the N—C_{benzyl} bond, into a $C_7H_7^{\oplus}$ ion ($m/e = 91$). This charge transfer from the N atom to the aromatic ring is also observed in ion *(2)*, but the formation of the $C_7H_7^{\oplus}$ ions from *(2)* and from *(3)* is associated with a hydrogen migration. Apparently, less energy is required for the elimination of *N*-methylmethyleneamine from *(1)* than in the case of the ions *(2)* and *(3)* since the proportion of competing decompositions in *(2)* and *(3)* increases considerably. In the CA spectrum of *(2)* the $[M^{\oplus} - CH_4]$ ion ($m/e = 118$) reaches *ca.* 60% of the intensity of the $C_7H_7^{\oplus}$ ion and appears as base peak in the spectrum of the ion *(3)*.

The *N,N*-dimethylaminotropylium structure, both in the case of ion *(3)* as well as partially after isomerization of *(2)*, is proven by the occurrence of more intense signals at $m/e = 90$ and 89 in comparison to the CA spectrum of *(1)*. The formation of these ions can be explained in terms of homolysis of the C—N bond and *N,N*-dimethylamine elimination, respectively. As in the case of phenylalkyl-substituted ammonium ions[4] the elimination of 52 mass units ($m/e = 82$) is observed with ions *(1)* and *(2)* and of 26 mass units ($m/e = 108$) with ion *(3)*. Despite the low signal intensity these fragments provide information about the charge localization. Positively charged aromatic systems eliminate one molecule of acetylene, both as is well-known under electron-impact as well as under CA conditions; uncharged benzene rings, on the other hand, directly lose two acetylene molecules in the form of a neutral fragmentation under CA conditions.

(1) *(2)*

(3)

Besides its use in structural analysis, the FD-CA method opens up new entries to comparative studies on gas-phase fragmentations of alkylideneammonium ions, which are gen-

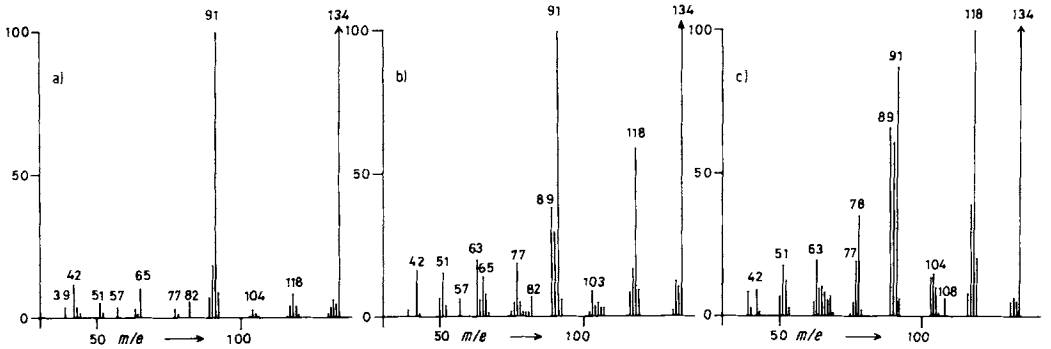

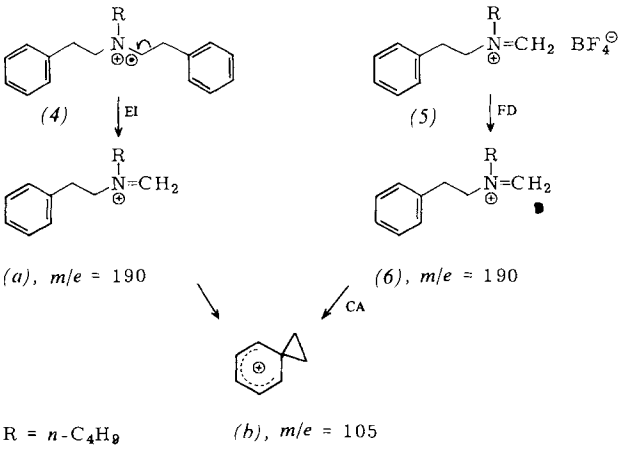

Fig. 1. FD-CA mass spectrum a) of the *N*-benzyl-*N*-methylmethyleneammonium ion *(1)*, b) of the *N,N*-dimethylbenzylideneammonium ion *(2)*, c) of the *N,N*-dimethylaminotropylium ion *(3)*.

Scheme 1. Main fragmentation of the methyleneammonium ion *a* and *(6)*, which was generated by α-cleavage in an electron-impact ionized molecular ion of *(4)* or from the tetrafluoroborate *(5)* under FD-CA conditions.

erated from the molecular ions of alkylamines by α-cleavage after electron impact (EI) excitation or under FD conditions from alkylideneammonium salts.

Under EI conditions α-cleavage of the molecular ion of *N,N*-bis(β-phenylethyl)butylamine *(4)* affords the methyleneammonium ion *a* ($m/e = 190$), which, after homobenzylic heterolysis with loss of *N*-methylenebutylamine, decomposes into the ion *b* ($m/e = 105$) (cf. Scheme 1[6]). This reaction, accompanied by a charge transfer from the N atom to the benzene ring, is likewise the main reaction in the collision-induced decomposition of the ion *(6)* liberated under FD conditions from the salt *(5)*. From the intensities of the $C_7H_7^{\oplus}$ ions ($m/e = 91$) generated from *(4)* and *(6)*, which are consistent within the experimental error, it follows that the $C_7H_7^{\oplus}$ ions recorded in the EI mass spectrum of compound *(4)* are formed by secondary fragmentation from the methyleneammonium ion *a* and not, as would appear at first sight, by cleavage of a benzyl bond in the molecular ion of *(4)*. Further agreement between the EI and the FD-CA spectrum has been established for the propene and butene eliminations ($m/e = 148$ and 134, resp.), well-known in electron-impact mass spectrometry[7] (cf. Table 1).

In contrast to the electron-impact fragmentations, in the CA spectrum of *(6)* signals appear for the elimination of propane ($m/e = 146$), butane ($m/e = 132$), toluene ($m/e = 98$), and ethylbenzene ($m/e = 84$), the more intense signals being recorded for the cleavage of allyl bonds. As D-labeling experiments show, the H atom to be eliminated with the leaving

group for an alkane elimination does not originate from the alkylideneammonium function. On the basis of findings with alkyl-substituted methyleneammonium ions[8], a cycloalkylmethyleneammonium structure is postulated for the ions formed in the alkane elimination. While alkane eliminations under EI conditions are only observed to a small extent—if at all—as secondary fragmentations of alkylamines, they occur as collision-induced main fragmentations in field desorbed alkylideneammonium ions. Furthermore, alkane eliminations are also recorded as collision induced main fragmentation reactions in other "closed shell" ions, *e.g.* in quaternary ammonium ions[4,9a] and in the protonated amines[9b] accessible by chemical ionization.

Base-Catalyzed Conversion of an Equatorial into an Axial Methoxycarbonyl Group Due to a 1,5-Long-Range Substituent Effect[**]

By *Raphael Mechoulam, Naftali Lander, Ilana Tamir, Zvi Ben-Zvi,* and *Yosef Kimmel*[*]

In connection with a structure/activity relationship study we needed the two isomeric diacetates *(4)* and *(5)* of 7-hydroxy-1,2,3,4,5,6-hexahydrocannabinol. They were prepared by catalytic reduction of *O*-acetyl-2,3,4,5-tetrahydrocannabinol-7-oic acid methyl ester *(1a)*[1] to the hexahydro derivatives *(2a)* and *(3a)*, which were separated by chromatography and further reduced by $LiAlH_4$ to the alcohols which on acetylation gave *(4)* and *(5)*[2]. The ethers *(2b)* and *(3b)* were prepared by hydrogenation from *(1b)*[3]. The ether *(2b)* was also prepared from the acetate *(2a)* by standard methods.

(a), R = $COCH_3$; *(b)*, R = CH_3

The esters *(2a)* and *(3a)* were separately boiled for 16 h with dry sodium methoxide in dry benzene, and the products were acetylated. We were surprised to establish that the equatorial ester *(3a)* was converted into the axial ester *(2a)*, while the latter remained unchanged under these conditions. (The stereochemical assignments are based on data given in Table 1.)

Table 1. Selected NMR data of compounds *(2a)*, *(2b)*, *(3a)*, *(3b)*, *(4)*, and *(5)* (δ values, cf. [4—6]) [a].

Pharmacy School, Jerusalem (Israel)

[**] We thank the US National Institute of Drug Abuse for financial support.

Harvey et al.[2] have shown that the methoxycarbonyl group in *(2a)* is axial. We were able to confirm this result and to assign the configuration of C-7 for *(2a)*, *(2b)*, *(3a)*, *(3b)*, *(4)*, and *(5)* on the basis of further NMR data (Table 1). The two protons H-7 are not equivalent in *(4)* and *(5)*.

In contrast to the *O*-acetyl compound *(2a)* (with axial ester group), which does not undergo rearrangement, the corresponding *O*-methyl compound *(2b)* forms the isomer *(3b)* (with equatorial ester group) under the same basic conditions *(vide supra)*; *(3b)* is stable under these conditions. The unusual conversion of the equatorial methoxycarbonyl group in *(3a)* into an axial one in *(2a)* seems to depend on the presence of the potential phenolate ion situated five carbon atoms away from the methoxycarbonyl group.

(6), R = H
(8), R = CH_3

(7) *(9)*

Another cannabinoid reaction likewise influenced by the free phenol group is the dehydrochlorination of 1-chlorohexahydrocannabinol *(6)* by strong bases to give *(7)*[7]. With potassium *tert*-pentyl oxide the yield is essentially quantitative. However, reaction of the ether *(8)* with the same base gives exclusively *(9)*, an isomer of *(7)*.

In contrast to the rich and varied chemistry and physics displayed by *inter*molecular electron donor-acceptor complexes of tetracyanoquinodimethane (TCNQ)[3], the chemistry of *intra*molecular versions of these complexes has only recently begun to develop. These studies by *Misumi et al.*[4] and *Staab et al.*[5], however, have been concerned only with the cyclophane type compounds such as *(3)* and its derivatives. We now report on the intramolecular CT interaction between TCNQ and remote benzene moieties in triptycene type compounds *(7a)* and *(7b)*.

1,4-Dimethyltriptycene *(4a)*[6], on bromination with *N*-bromosuccinimide [$(PhCO)_2O_2$, benzene, reflux 3 h] gave 1,4-bis(bromomethyl)triptycene *(5a)*[7] [colorless plates, m.p. 200—202 °C, 74%] which was cyanated with potassium cyanide in dimethyl sulfoxide [110 °C, 4 h] to the biscyanomethyl derivative *(6a)*[7] [colorless prisms, m.p. 284—286 °C, 60%]. Conversion of *(6a)* into the desired TCNQ type compound *(7a)* could be accomplished according to the well-known Wheland-Martin procedure[8] for TCNQ synthesis, *i.e. (6a)* was treated with sodium methoxide in benzene and dimethyl carbonate under reflux for 3 h and the resulting methanol was distilled off azeotropically with benzene. At room temperature cyanogen bromide was distilled with dry nitrogen into the reaction mixture which was then refluxed for 1 h. Chromatographic workup [Wako gel C-200] with a 1:1 mixture of benzene and hexane afforded *(7a)* as red microcrystals in 5% yield.

(4a), X = Y = H
(4b), X = H, Y = OCH_3
(5a), X = Br, Y = H
(5b), X = Br, Y = OCH_3
(6a), X = CN, Y = H
(6b), X = CN, Y = OCH_3

(7a), Y = H
(7b), Y = OCH_3

The methoxy derivative *(7b)* was prepared as green microcrystals starting from *(4b)*, readily available from 1,4-dimethylanthracene and 3-methoxybenzyne [generated *in situ* from 2-bromo-3-iodoanisole and magnesium].

The structures of *(7a)* and *(7b)* were confirmed primarily by their spectroscopic properties (Table 1). In the ^{1}H-NMR spectra the bridgehead protons appear at very low field [$\delta = 6.84$ for *(7a)* and 6.76 for *(7b)*] due to the close proximity of the cyano groups to these protons.

The electronic spectra of *(7a)* and *(7b)* along with those of TCNQ itself and the cyclophane *(3)* are shown in Figure 1. The new absorption bands of *(7a)* and *(7b)*, not shown by either component alone, are expectedly observed in the visible; at the same time the wavelength of the absorption maximum of *(7b)* is much longer than that of *(7a)* owing to the increased π-basicity of the anisole ring. In sharp contrast to the cyclophane *(3)*[9], these long wavelength absorption maxima

Table 1. Selected physical properties of *(7a)* and *(7b)*.

Cpd.	M.p. [°C] (dec.)	UV/VIS λ_{max} nm (log ε) [a]	^{1}H-NMR (δ-values) [b]
(7a)	>300	409 (4.66) 535 (3.40)	7.56, 7.13 (AA'BB', 8H), 7.34 (s, 2H), 6.84 (s, 2H)
(7b)	>300	411 (4.66) 584 (3.02)	7.52, 7.12 (AA'BB', 4H), 7.40 (d, 1H, $J = 8.0$ Hz), 7.34 (s, 2H), 7.14 (d, 1H, $J = 2.5$ Hz), 6.76 (s, 2H), 6.60 (dd, 1H, $J = 8.0$, 2.5 Hz), 3.75 (s, 3H)

[a] In CH_2Cl_2. [b] In CD_2Cl_2 for *(7a)*, in $CDCl_3$ for *(7b)*.

of *(7a)* and *(7b)* are strongly solvent dependent and exhibit a blue shift with increasing polarity of the solvent [*(7a)*: $\lambda_{max} = 535$ nm in CH_2Cl_2; $\lambda_{max} = 505$ nm in CH_3CN; *(7b)*: $\lambda_{max} = 584$ nm in CH_2Cl_2; $\lambda_{max} = 544$ nm in CH_3CN][10]. These observations suggested that the bands observed in the long wavelength region are to be assigned to CT transitions between benzene rings and the remote TCNQ moiety. As can be seen from Figure 1, the apparent CT interaction in *(7a)* is stronger than that of the [2.2]paracyclophane *(3)*[4a].

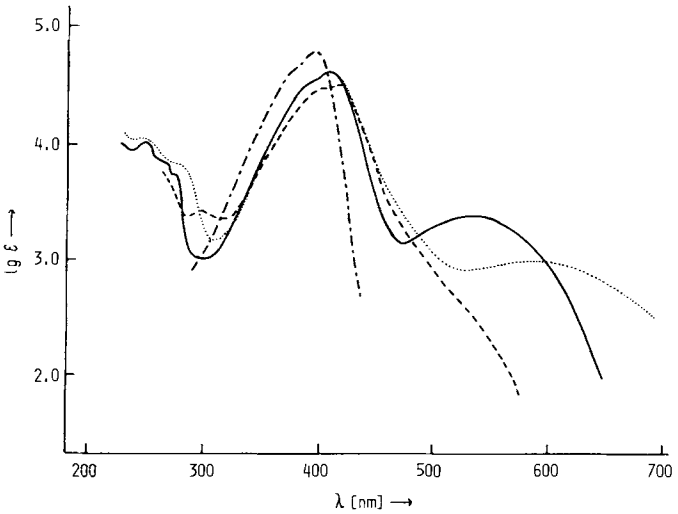

Fig. 1. UV and visible spectra of *(7a)* (—), *(7b)* (···), TCNQ (— · — · —), and *(3)* (– – –) in dichloromethane.

Thus the absorption of *(7a)* at 535 nm is almost eight times stronger than that of *(3)*. These results should provide information about the dependence of the intramolecular CT band on the mutual orientation of the donor and acceptor units.

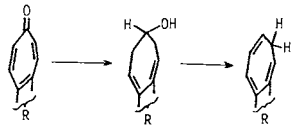
Synthesis and Intramolecular Charge-Transfer Interaction in 1,4-Dihydro-1,4-ethanobenzotropylium Tetrafluoroborate[**]



By *Tomoo Nakazawa, Yoshihide Niimoto, Keiji Kubo,* and *Ichiro Murata*[*]

We have previously reported strong intramolecular charge-transfer (CT) interactions between the tropylium unit and remote benzene rings in *(1)* despite the minimized overlap of the orbital systems of both donor and acceptor[1]. In principle, olefins should conceivably be able to replace the aromatic hydrocarbon moiety as donor. Thus, the title compound *(2a)* seems to be a reasonable candidate for examination of intramolecular remote π-π interaction. This communication describes the synthesis and properties of *(2a)* together with those of the dihydro analog *(2b)* as a reference compound.

(1) *(2a)* *(2b)*

Reduction of the bridged tropone *(3a)*[2] [$NaBH_4$ in aq. CH_3OH, at room temp.] gave the dienol *(4a)*[3], colorless needles, m.p. 90.5—91.5 °C, in 65% yield. Compound *(4a)* was converted into its mesylate [CH_3SO_2Cl and Et_3N in CH_2Cl_2] which (without isolation) was subjected to elimination with 1,5-diazabicyclo[5.4.0]undec-5-ene in CH_2Cl_2 to give the tropylidene *(5a)*[3] in 77% yield. Subsequent hydride abstraction with trityl tetrafluoroborate afforded, in 57% yield, the salt *(2a)*[3] as colorless needles, m.p. 116—117 °C (dec.). The dihydro derivative *(2b)*[3], colorless leaflets, m.p. 130.5 °C (dec.), was prepared in the same manner starting from *(3b)*[2].

(3) *(4)* *(5)*

a, R =  *b*, R = 

The structural assignment of *(2a)* and *(2b)* was based on spectral data (Table 1). As a consequence of the strong interaction in an excited state, *(2a)* exhibits characteristic absorptions, absent from the saturated reference compound *(2b)*[4] (Fig. 1). The spectrum of *(2a)* in acetonitrile exhibits *inter alia* a new absorption maximum at 325 nm which is shifted to 334 nm upon changing the solvent to less polar dichloromethane[5], suggesting a CT interaction between the tropylium ring and the remote ethylene π-system[6].

In order to examine the effect of the electronic interaction on the ground state stability of the tropylium unit we have determined pK_{R^+} and the reduction potentials of *(2a)* and *(2b)* which are also shown in Table 1. The tropylium is con-

[**] This work was supported in part by a Grant-in-Aid for Scientific Research (No. 343007) from the Ministry of Education, Japan. We thank Prof. *S. Ikeda, T. Ozeki* and *K. Yokoi* of this department for measurement of the reduction potentials.

siderably more stable in *(2a)* and *(2b)*, corresponding to the increase in reduction potentials (decrease in electron affinity) when compared with the parent tropylium ion. The remarkably high pK_{R^+} values and reduction potentials of *(2a)* and *(2b)* appear to be due to an electron donating inductive effect of the bridging alkyl group[7]. At first glance, the apparent CT interaction observed in the UV spectrum of *(2a)* would seem to stabilize the tropylium unit. Interestingly, however,

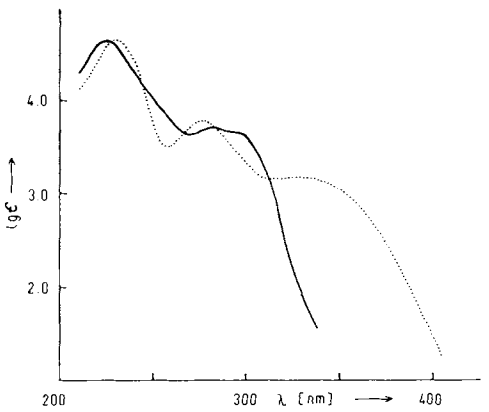

Fig. 1. UV spectra of *(2a)* (····) and *(2b)* (—) in CH_3CN.

the pK_{R^+} value of *(2a)* is found to be less than that of *(2b)*, albeit by only 0.35 pK units. This trend is also reflected in the slight decrease in the reduction potential of *(2a)* as compared with that of *(2b)*[8]. This indicates that the CT interaction between the tropylium ring and the remote ethylene π-system is more favorable in the excited state than in the ground state of *(2a)*.

L-Gulose or D-*gluco*-Hexodialdose from D-Glucurono-6,3-lactone by Controlled Reductions[**]

By *Wilhelm V. Dahlhoff, Peter Idelmann*, and *Roland Köster*[*]

The reduction of *O*-ethylboron-protected -onic and uronic acid lactones with ethyldiboranes(6)[***] is well suited for the preparation of aldoses and dialdoses. In some cases, by incorporating monofunctional *O*-(diethylboryl)-[1a,2] or difunctional *O*-(ethylboranediyl)-[1d] protecting groups, the reactions can also be directed, so that various pure end products become accessible in high yield from the same starting material.

We obtained highly pure L-gulose *(3)* by reduction of the free β-D-glucurono-6,3-lactone *(1)* with ethyl-hydro-boranes(3)[***]. The lactone *(1)* is converted in a single step at ≈50 °C with diethyl-hydro-borane(3) (molar ration ≤1:5) into an *O*-ethylboron-protected α/β-gulofuranose *(2)*, from which the anhydrous solid L-gulose *(3)* can be liberated without loss by treatment with methanol/ethylene glycol (Scheme 1).

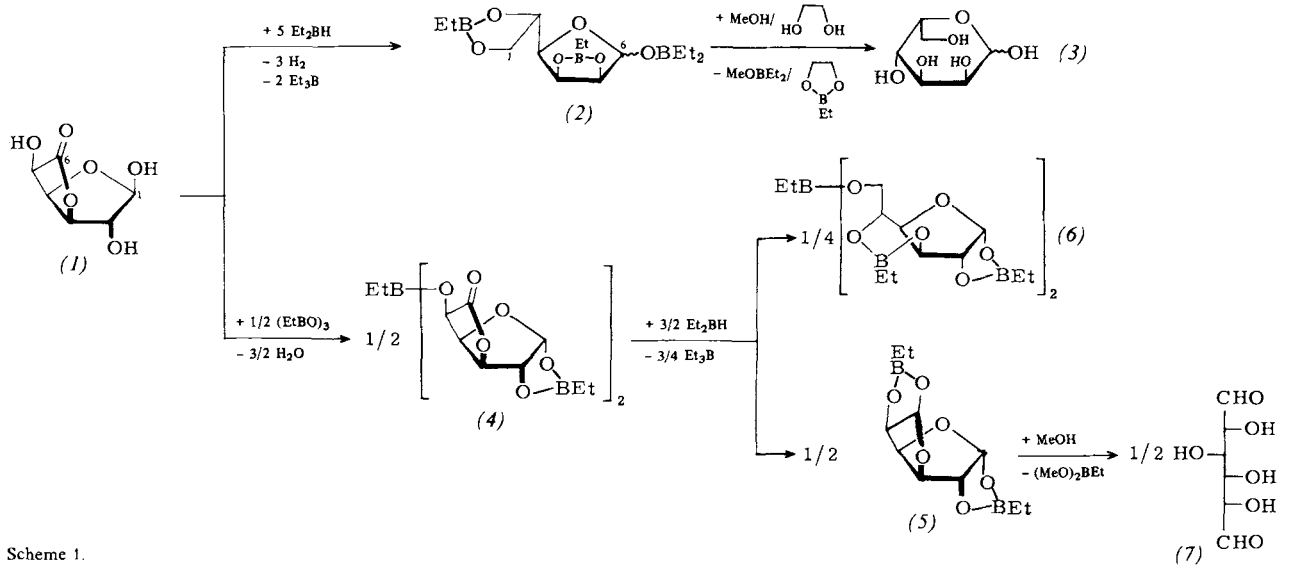
However, if the non-reduced compound *(4)* is initially prepared from *(1)* with the aid of various *O*-(ethylboranediyl) reagents *e.g.* triethylboroxin[1d] or triethylborane/ethyldiboranes(6)[1c] the treatment of the product with ethyldiboranes(6) gives an essentially quantitative yield of an equimolar mixture of ethylboron-protected D-*gluco*-hexodialdose *(5)* and D-glucose *(6)*. Compound *(5)* can easily be separated completely from *(6)* and transformed quantitatively by methanol into pure anhydrous D-*gluco*-hexodialdose *(7)* (Scheme 1).

The chemical analyses [C, H, B values, ethane number[1a], hydride number[1d]] and spectroscopic data [IR, MS, ^{1}H-, ^{13}C-NMR] of *(2)* to *(7)* confirm their composition, structure, and purity.

Hitherto, L-gulose *(3)* was known only as a hydrate syrup; the older method of preparation from *(1)* led to impure *(3)* in *ca.* 10% yield. Likewise, *(7)* was accessible from *(1)* in only moderate yields (≲22%)[3].—With the new *O*-ethylborane method, *(3)*[3,6] and *(7)*[3,4] can be prepared in pure form considerably more simply and in better yields than previously.

Procedure

(2): To a solution of ethyldiboranes(6) (23.4 g, 335 mmol >BH, 14‰ $H^{\ominus}$) in tetrahydrofuran heated to 45 °C is added 11.3 g (64.2 mmol) of *(1)* within 3.5 h from a swivel-mounted side arm. An increase in temperature (to 50—60 °C; exothermic reaction!) is accompanied by evolution of H_2 (≈4.2 Nl). Ethene is passed (≈30 min) into the colorless, clear solution (trapping by excess >BH) at ≈50 °C. On evaporating the solution down at ≤80 °C (bath)/10^{-1} torr, 20.4 g (98%) of *(2)* is obtained as a colorless syrup; $[\alpha]_D^{20} = +24.7$ (c=7.4, $CHCl_3$); ^{1}H-NMR ($CDCl_3$): δ=5.65 ($J_{1,2}$<1 Hz; H^1, β-*(2)*), 5.74 ($J_{1,2}$=5 Hz (H^1, α-*(2)*); α:β≈38:62 (after 1 h).



(3): Methanol (≈100 ml) is added dropwise to 12.9 g (39.8 mmol) of *(2)* with continuous removal of $MeOBEt_2$/MeOH from the mixture by distillation. After subsequent further evaporation at 10^{-1} torr the residue is treated with 15 ml of 1,2-ethanediol and once again evaporated down (≤80 °C (bath)/10^{-3} torr). The boron-free residue is treated with

Scheme 1.

≈ 20 ml ethanol and then distilled at 10^{-3} torr to remove all volatiles. The glassy *(3)* thus obtained (7.2 g, 100%) can be ground to a white powder, which softens at 60—80 °C and gives a clear melt at 80 °C: $[\alpha]_D^{22} = +23.3$ ($c = 1.6$, H_2O); calc. and obs. 2.8% $H^{\oplus}$[1a]. Solid *(3)* can be precipitated from ethanol with diethyl ether.—Hitherto, *(3)* has only been isolated as a syrup: $[\alpha]_D^{23} = +20$ ($c = 13.6$, H_2O)[5]; syrupy *(3)* contains 1.2 mol of H_2O per mol (determination of ethane number[1a]).

(7): Triethylboroxine (10.6 g, 63.1 mmol) is added dropwise to a stirred suspension of *(1)* (10 g, 56.8 mmol) in boiling benzene (150 ml) such that benzene/water can be continuously removed by azeotropic distillation. Finally, all readily volatile materials are removed at 10^{-2} torr. A solution of the syrupy residue [*(4)*] in toluene (50 ml) is then treated with 4.7 g (88.8 mmol ≙ BH) ethyldiboranes(6) (with 18.9‰ $H^{\ominus}$) and the mixture stirred for 24 h. After removal of all readily volatile materials (≤ 105 °C (bath)/10^{-3} torr), distillation of the partially crystalline residue [*(5)*, *(6)*] affords 7.1 g (49%) of *(5)*; b.p. 97 °C/10^{-3} torr, m.p. 85 °C; $[\alpha]_D^{22} = -13.6$ ($c = 7.1$, CCl_4).—After dissolution of *(5)* in 40 ml of heptane and addition of 30 ml of methanol, the $(MeO_2)BEt$/MeOH is azeotropically distilled off during simultaneous dropwise addition of methanol (≈ 150 ml). Concentration at 12 torr affords 4.9 g (49%) of *(7)* as anhydrous syrup, which precipitates as colorless crystals in boiling THF; m.p. 155 °C (dec.); $[\alpha]_D^{22} = +48.4$ ($c = 2.6$, H_2O).—*(7)* could hitherto not be obtained by dehydration of the monohydrate (m.p. < 100 °C); $[\alpha]_D^{22} = +49.9$ (calc.)[3].

Pure D-Gulose from D-Gulono-1,4-lactone[**]

By *Roland Köster, Peter Idelmann*, and *Wilhelm V. Dahlhoff*[*]

Like the carboxylic acid group of the *O*-ethylboron-protected D-glucurono-6,3-lactone[1], the 2,3:5,6-bis-*O*-(ethylboranediyl) derivative *(2)* of D-gulono-1,4-lactone *(1)* can also be partially reduced with ethyldiboranes(6)[***] to the aldehyde stage *(3)*. Removal of the protecting groups from *(3)* by reaction with methanol and then with glycol afforded, for the first time, pure D-gulose *(4)* from *(1)* in quantitative overall yield.

Chemical analyses [C, H, B values; B_C value[2a]; ethane number[2b]; hydride number[2c]] and spectroscopic data [IR, MS, ^1H-, ^{13}C- and ^{11}B-NMR] confirmed the composition and structure of *(2)*, *(3)* and *(4)*. Like *(4)*, *(2)* and *(3)* can also be prepared in pure form.

Previously, D-gulose *(4)* could be obtained from *(1)* or *via (1)* by reduction [*e.g.* with Na-amalgam[3]; $NaBH_4$[4]; disiamylborane[5]] only as aqueous syrup in yields of up to 50%, or contaminated with *(1)* and L-glucitol in yields of at most 80%[4]. On using tetra-*O*-benzoyl-D-gulono-1,4-lactone as starting material no *(4)* could be isolated after reduction with

[**] Organoboron Monosaccharides, Part 7 (Part of a planned dissertation by *P. Idelmann*, Universität Bochum, 1980).—Part 6: [1].

[***] Ethyldiboranes(6) or ethyl-hydro-boranes(3) mentioned in the text and the Et_2BH denoted in the Scheme are actually equilibrium mixtures with the overall composition of "tetraethyldiborane(6)"; cf. *R. Köster* and *P. Binger*, Inorg. Synth. XV, 141 (1974).

disiamyl-hydro-borane *(3)*[5]. The five-step synthesis of *(4)* from D-glucose is also less productive[6].

The efficiency of this new method of synthesizing *(4)* from *(1)* might be attributed to the combined reaction of *O*-ethylboranediyl protecting groups on sp^2-hybridized atoms and the ethyl-hydro-borane[***] reagent. *O*-Ethylboranediyl moieties are more easily removed than the usual difunctional protecting groups. This and the anhydrous working conditions offer additional advantages.

Experimental

(2): Triethylboroxine (43.7 g, 260.1 mmol) is added dropwise within ≈4 h at ≈90 °C (bath) to a solution of *(1)* (58 g, 325.6 mmol) in benzene (150 ml) and benzene/water azeotrope is continuously removed by distillation in a stream of inert gas (11.8 ml H_2O). All volatiles are then removed at 60 °C (bath)/10^{-3} torr. 82.8 g (100%) of white, crystalline *(2)* is obtained in >99% (GC) purity; m.p. 81 °C; $[\alpha]_D^{20} = +119.7$ ($c = 3.9$, CCl_4).

(3): Ethyldiboranes(6) [16.66‰ $H^{\ominus}$] (12.5 g, 208.3 mmol >BH) are added dropwise in 5—10 min to a stirred solution of *(2)* (46.7 g, 183.9 mmol) in toluene (150 ml) at 30—40 °C (cooling bath!). Stirring is continued for 1—2 h at 30—35 °C and ethene is then passed through the solution for 1.5 h. After removal of all volatiles *in vacuo*, 59.6 g (≈100%) of colorless, viscous *(3)* is obtained; $[\alpha]_D^{21} = -29.4$ ($c = 6.8$, CCl_4).

(4): Methanol (150 ml) is added dropwise to a solution of *(3)* (59.9 g, 183.8 mmol) in boiling methanol (50 ml) and at the same time all readily volatile compounds are removed by distillation. After removal of solvent *in vacuo* the residue is treated with 1,2-ethanediol (50 ml) and the mixture stirred for ≈1 h at 75 °C (bath) and finally distilled at 80 °C (bath)/10^{-3} torr. The glycol procedure is repeated. After addition of ethanol (50 ml) the solution is evaporated (10^{-3} torr) to complete dryness, giving 33.2 g (≈100%) of glassy, solid *(4)*, which can be crushed to a highly hygroscopic powder; flow point ≈60 °C, $[\alpha]_D^{22} = -23.2$ ($c = 2.1$, H_2O)[7].

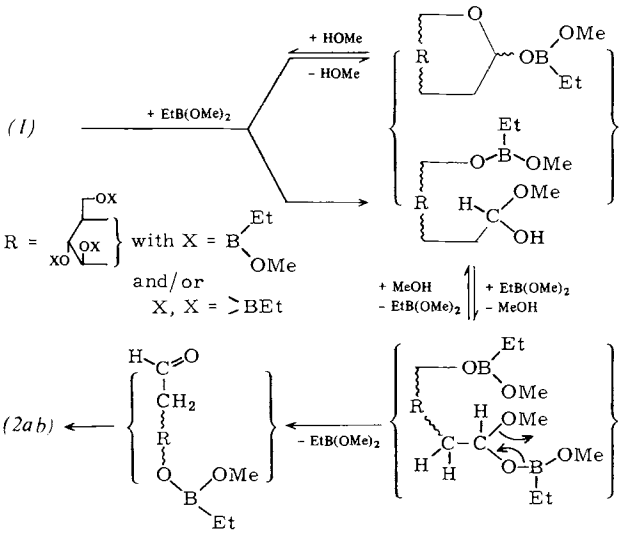
Simple New Method for the Synthesis of 2-Deoxy-*aldehydo*-hexoses[**]

By *Wilhelm V. Dahlhoff* and *Roland Köster*[*]



Open-chain *aldehydo*-hexoses were previously accessible from monosaccharides only *via* particularly reactive intermediates—primarily *via* the dialkyldithioacetals with mercury(II) chloride[1]. We have now discovered a preparatively very simple, novel, and direct route for the synthesis of 2-deoxy-*aldehydo*-hexoses from the free monosaccharides.

2-Deoxy-D-*arabino*-hexose [2-deoxy-D-glucose] *(1)* reacts with ethyl(dimethoxy)borane at room temperature in almost quantitative yield to give a mixture of ≈85% 2-deoxy-3,4:5,6-di-*O*-(ethylboranediyl)-*aldehydo*-D-*arabino*-hexose *(2a)* and ≈15% of the 3,5:4,6-isomer *(2b)*.

Reaction of *(1)* with ethyl(dimethoxy)borane leads initially to acetals of the methyl 2-deoxy-D-*arabino*-hexoside with intra- and intermolecular *O*-ethylboranediyl linkages. On equilibration, ethyl(dimethoxy)borane is already eliminated from these acetals at room temperature with formation of *(2b)*. Complete elimination can be achieved by removal of the borane reagent in a vacuum.

The intermediary open-chain methylacetals can be detected by ^{1}H-NMR spectroscopy by their H^1 and O^1CH_3 signals at $\delta = 4.93$ and 3.45, respectively. The characteristic ^{1}H-NMR signals of *(2ab)* are first observed as a result of elimination of $EtB(OMe)_2$ from C^1-atom during the reaction (see Table 1). No detectable amounts of *(2)* are formed on reaction of *(1)* with triethylboroxine[3] or with 1,2-diethyl-1,2-dipivaloyldiboroxane[2,3]. Thus, ethyl(dimethoxy)borane has a specific directing influence on the reaction.

The mixture *(2ab)*, which is distillable without decomposition *in vacuo*, can be stored for weeks at ≈0 °C. *(2ab)* is thus well suited for syntheses with participation of the free aldehyde function. The isomerism has no influence on most of the reactions. The protective groups can readily be removed with methanol.

Reaction of 2-deoxy-D-*lyxo*-hexose (2-deoxy-D-galactose) *(3)* with ethyl(dimethoxy)borane at room temperature leads

[**] Organoboron Monosaccharides, Part 8.—Part 7: *R. Köster, P. Idelmann, W. V. Dahlhoff*, Angew. Chem. *92*, 553 (1980); Angew. Chem. Int. Ed. Engl. *19*, 547 (1980).

initially to a mixture consisting of at least three isomeric open-chain methyl 2-deoxy-di-*O*-(ethylboranediyl)-D-*lyxo*-hexosides *(4a—c)* and only a small amount (≤10%) of 2-deoxy-di-*O*-(ethylboranediyl)-*aldehydo*-D-*lyxo*-hexoses *(5ab)*. Above ≈100 °C the ^{1}H-NMR signals for *(4a—c)* [δ = 4.9 and 5.1 (H^1), 3.50, 3.46 and 3.43 (O^1CH_3)] disappear.

(5ab) (see Table 1) can be distilled as a colorless, mobile liquid (b.p. 77 °C/10^{-3} torr), which becomes highly viscous at room temperature and finally solidifies as glassy oligomer *(6)*. On heating, *(6)* becomes mobile again and can be distilled *in vacuo* as a mixture of ≥80% 2-deoxy-3,5:4,6-di-*O*-

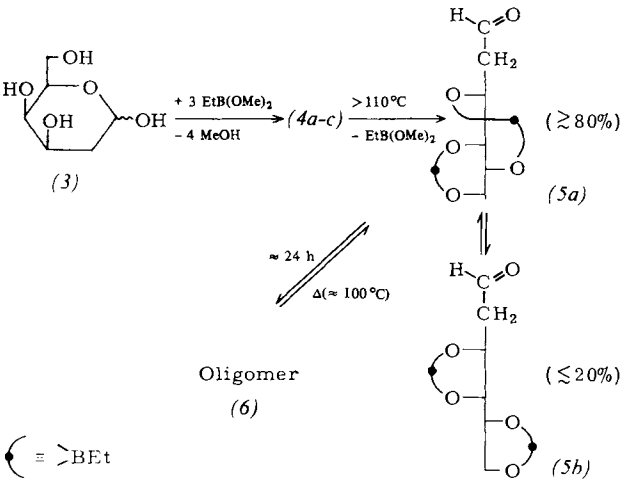

Table 1. Some spectroscopic data of the mixtures *(2ab)* and *(5ab)*.

(2ab): MS (70 eV): $m/e = 240$ ($M^{\oplus}$, B_2, <1%), 196 (B_2, 12), 141 (B_1, 65), 113 (B_1, 30), 99 (B_1, 100), 57 (B_1, 65); ^{1}H-NMR (80 MHz, $CDCl_3$): δ = 9.84 (t, $J_{1,2}$ = 1.8 Hz, H^1), 4.66 (q, $J_{2,3}$ = 6 Hz, $J_{3,4}$ = 6 Hz, H^3), 4.5—3.7 (m, H^4—H^6), 2.72 (dd, $J_{1,2}$ = 1.8 Hz, $J_{2,3}$ = 6 Hz, H^2), 0.9 (m, BC_2H_5); ^{11}B-NMR (neohexane): δ = 34.8 (halfwidth = 200 Hz)

(5ab): MS (70 eV): $m/e = 240$ ($M^{\oplus}$, B_2, <1%), 196 (B_2, 41), 141 (B_1, 27), 112 (B_1, 100), 99 (B_1, 75), 83 (B_1, 32), 57 (B_1, 72); ^{1}H-NMR (80 MHz, C_6D_6): δ = 9.35 (dd, $J_{1,2}$ = 2 Hz, $J_{1,2'}$ = 1.5 Hz, H^1), 4.29 (ddd, $J_{2,3}$ = 8 Hz, $J_{2',3}$ = 6 Hz, $J_{3,4}$ = 2 Hz, H^3), 3.3—3.9 (m, H^4—$H^{6'}$), 2.03 (ddd, $J_{1,2}$ = 2 Hz, $J_{2,3}$ = 8 Hz, $J_{2,2'}$ = −16.5 Hz, H^2), 1.77 (ddd, $J_{1,2}$ = 1.5 Hz, $J_{2',3}$ = 6 Hz, $J_{2,2'}$ = −16.5 Hz, $H^{2'}$), 0.95 (m, C_2H_5); ^{11}B-NMR (neohexane): δ = 31.5 (halfwidth = 200 Hz)

(ethylboranediyl)-*aldehydo*-D-*lyxo*-hexose *(5a)* and ≤20% of, presumably, the 3,4:5,6-isomer *(5b)*. As *O*-ethylboranediyl derivatives of the threitol type[4], *(5a)* and *(5b)*, in contrast to *(2a)* and *(2b)*, are in equilibrium with each other.

Experimental

(2ab): A mixture of *(1)* (5 g, 12.2 mmol) and ethyl(dimethoxy)borane (~25 ml) is heated for ≈2 h at 60—80 °C. The homogeneous mixture is finally evaporated down at 12 torr. Subsequent distillation affords 7.2 g (≈99%) *(2ab)*: b.p. ≈75 °C/10^{-3} torr; $[\alpha]_D^{20} = +14.6$ ($c = 0.7$, $CHCl_3$).

(5ab): A mixture of *(3)* (2.5 g, 15.2 mmol) and ethyl(dimethoxy)borane (10 ml) is stirred for ≈1.5 h at ≈60 °C (bath). After ≈8 min, a homogeneous phase is obtained. Removal of all readily volatile material at 12 to 10^{-3} torr and subsequent distillation of the residue (4.0 g) at 100—110 °C (bath)/10^{-3} torr for 3 h affords 3.3 g (93%) of *(5ab)*; b.p. ≈77 °C/10^{-3} torr; $[\alpha]_D^{22} = +26$ ($c = 0.7$, $CHCl_3$); 0.1 g residue.

Absolute Configuration of the Cancerostatic *S*(−)-Isophosphamide

By *Dorota A. Adamiak, Maria Gdaniec, Krzysztof Pankiewicz,* and *Wojciech J. Stec*[*]

Dedicated to Professor Jan Michalski on the occasion of his 60th birthday

Isophosphamide, 3-(2-chloroethyl)-2-[(2-chloroethyl)amino]-1,3,2-oxazaphosphorinane 2-oxide (Holoxan) *(1)*, has been found to elicit therapeutic response in human breast, ovarian and lung cancer[1]. *(1)* is chiral. In order to study the influence of configuration on the clinical significance[2] and mechanism of action of *(1)* we carried out the stereospecific synthesis of the two enantiomers[3]. In this communication we wish to describe the assignment of the absolute configuration of the levorotatory enantiomer of *(1)*, $[\alpha]_D^{20} = -39.4°$ ($c = 5.0$, MeOH). (−)-*(1)* crystallizes from diethyl ether in the orthorhombic space group $P2_12_12_1$ with $a = 5.144(1)$, $b = 12.655(3)$ and $c = 19.004(4)$ Å; $Z = 4$. The structure was solved by usual methods[4]; in the refinement the coordinates and temperature factors were varied, both for the model (x, y, z) and the enantiomorph ($\bar{x}$, $\bar{y}$, $\bar{z}$) with proper inclusion of anomalous scattering contributions from Cl and P atoms. Final weighted discrepancy indices ($R_w = [\sum w(|F_{obs}| - |F_{cal}|)^2 / \sum w|F_{obs}|^2]^{1/2}$) are 7.9% for (x, y, z) and 7.7% for ($\bar{x}$, $\bar{y}$, $\bar{z}$). On the basis of *Hamilton*'s $\mathcal{R}$-factor ratio test[5], the model (x, y, z) can be excluded at a significance level <0.005. Thus (−)-*(1)* is *S*-configurated[6] (Fig. 1).

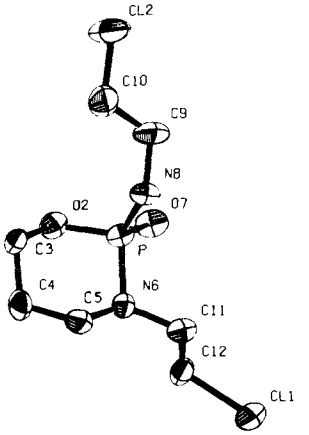

Fig. 1. Molecular structure of *S*(−)-*(1)* (ORTEP plot) showing thermal ellipsoids of the atoms at the 20% probability level.

The six-membered ring has a chair conformation; the substituent O7 is equatorial, while in the racemate structure it is axial[7]. The P—N bonds have partial double bond character; the hybridization of N6 is found to lie between sp^2 and sp^3. The molecules in the crystal are linked *via* only one 2.79 Å-long hydrogen bond between atoms N8 and O7.

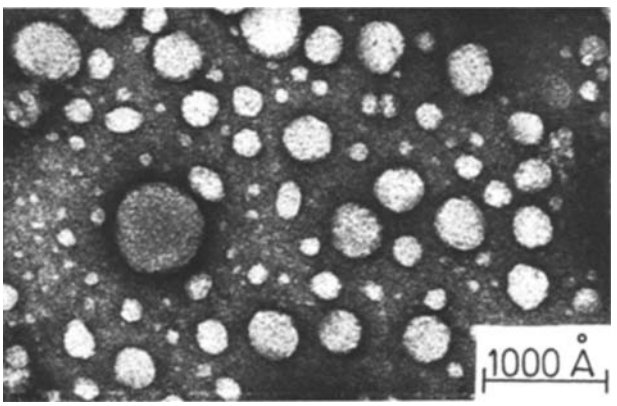
Vesicles with a Monolayer, Redox-Active Membrane

By *Ehrenfried Baumgartner* and *Jürgen-Hinrich Fuhrhop*[*]

The first monolayer membranes made of ammonium amphiphiles with two charged end groups, flexible polymethylene chain, and rigid central unit were recently synthesized by *Kunitake et al.*[1]. These membranes form vesicles only on addition of large amounts of cholesterol. We now report a similar, but much simpler membrane which forms stable vesicles without additives and also contains redox-active terminal groups.

The monomethylbipyridinium ion *(1)* was prepared in 70% yield from bipyridine by reaction with dimethyl sulfate in $CHCl_3$ and treated with *N,N'*-(β-bromoethyl)dicarboxamides *(2a—c)* in *n*-butanol. The tetracations *(3a—c)* were obtained in 60—70% yield. Compound *(3a)* could be isolated as the crystalline tetrachloride; *(3b, c)* are amorphous but chromatographically homogeneous, and their spectroscopic data (quantitative UV, ^{1}H-NMR in CD_3OD, IR) are in accord with the structures given. *(3a)* and *(3b)* are readily soluble in water (≥100 mg/ml) and have not yet been further investigated. *(3c)* was only modestly soluble in water (≤1 mg/ml) and gave milky suspensions from which solids slowly deposited.

Sonification of a suspension containing about 10 mg of *(3c)*/ml at 50 °C (Ultrasonics W 18 SF, frequency 20 kHz, *ca.* 100 watt) gave clear colorless solutions in which hydrophobic dyes such as protoporphyrin dimethyl ester, magnesium protoporphyrin dipotassium salt, and magnesium octaethylporphyrin dissolved at concentrations up to about 10^{-4} M. On chromatography of such solutions, *e.g.* with the dipotassium salt on Sephadex G 25, the red dye migrates as a uniform zone. It does not migrate in alkaline solution without addition of *(3c)*. The colorless solution of *(3c)* was studied by electron microscopy without fractionation after sonification. After staining with uranyl acetate, spherical vesicles having typical diameters of about 100—600 Å could be detected at 40000× magnification.



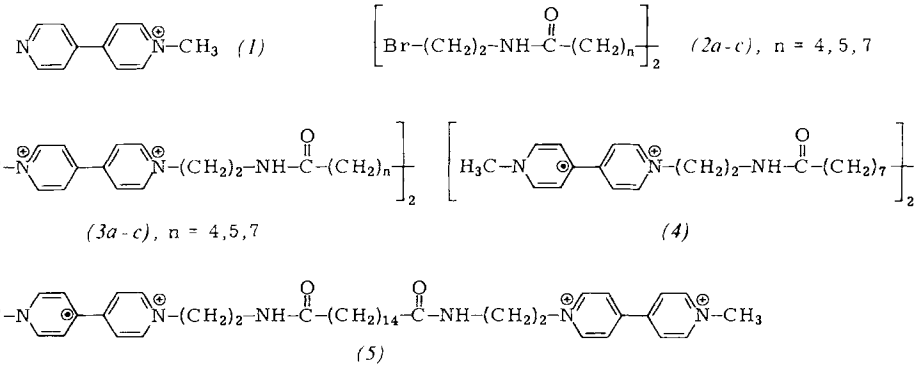


Fig. 1. Electron micrograph of the vesicles (stained with uranyl acetate).

These vesicles are relative large. Comparison with analogous dimolecular membrane particles of lecithin[2] and of synthetic material[3] suggests that the vesicles contain several membranes. The monolayer cholesterol-containing membrane obtained by *Kunitake*, however, forms single-walled vesicles[1]. We could answer this structural question by a simple chemical experiment, *viz.* by reducing an aqueous solution of *(3c)* with sodium dithionite before and after sonification, to give the viologen radical *(4)*.

Since the dithionite ions cannot penetrate the hydrophobic vesicle membrane, only the bipyridinium layer facing the external aqueous medium is reduced. We found that in the case of the clear vesicle solution exactly 50% of the bipyridinium units are reduced [formation of *(5)*], while 100% reduction to *(4)* is observed in the emulsion. Deviations from the expected extinction[4] did not exceed ±5% in several independent experiments. Hence it can be concluded that the vesicles described are single walled, for only 25% reduction of the bipyridinium "heads" would be possible for double-walled vesicles. Attempts to reduce the internal layer of the vesicles by

sonifying the emulsion of *(3c)* in the presence of dithionite have so far failed because the viologen radicals *(4)* decompose under the influence of ultrasonics.

The ^{1}H-NMR spectra of the vesicles of *(3c)* and the ESR spectra of the radical vesicles of *(5)* showed only slight signal broadening compared to those of non-aggregated analogous molecules. We therefore believe that these novel synthetic vesicles are particularly well suited for the study of effects originating from substances dissolved in the membrane. Moreover, electrons and protons can probably be transferred from the aqueous phase *via* the redox-active surface into the hydrophobic interior of the membrane; this effect could be utilized to drive energy-consuming processes.

New Dinuclear Iridium(II) Complexes Arising by Oxidative Addition of I_2 to $[Ir_2(\mu\text{-}StBu)_2(CO)_2L_2]$[**]

By *Jean-Jacques Bonnet, Philippe Kalck,* and *René Poilblanc*[*]

The mechanisms of oxidative addition reactions of small molecules to mononuclear d^8 transition metal complexes are of current interest[1]. In some cases, an observed free radical process[2] has been interpreted in terms of d^7 labile intermediate species. Carrying on our investigations on the reactivity of dinuclear bridged d^8 metal complexes[3,4], we have studied the oxidative addition of halogens. This paper deals with the general preparation of dinuclear iridium(II) complexes by reaction of iridium(I) compounds with iodine. Only very few iridium(II) compounds are known[5].

$$[Ir_2(\mu\text{-}StBu)_2(CO)_2L_2] + I_2 \rightarrow [Ir_2(\mu\text{-}StBu)_2(CO)_2L_2I_2]$$
(1)—(4) *(5)—(8)*

(1) and *(5)*, L = CO; *(2)* and *(6)*, L = $P(OMe)_3$
(3) and *(7)*, L = PMe_2Ph; *(4)* and *(8)*, L = PMe_3

The complexes *(1)—(4)*[6] react readily at room temperature with one mole of iodine to give compounds of types *(5)—(8)*. All these complexes were obtained as crystals in high yield from toluene/hexane solutions. Microanalytical data and molecular weights are consistent with the above quoted molecular formula.

The infrared spectrum of *(5)* (Table 1) exhibits two systems with three ν_{CO} bands each, which suggests the presence of two isomers. Each group of three bands is characteristic of C_{2v} symmetry. Since $[Fe_2(\mu\text{-}SMe)_2(CO)_4(PR_3)_2]$, where the two phosphane ligands are in apical position[7], also gives a pattern of three ν_{CO} bands, it may be concluded that the iodine atoms of *(5)* are in apical position as well, and that the isomerism is due to different relative positions of the *tert*-butyl groups. Comparison with the $^{13}C\{^1H\}$-NMR spectrum of *(1)* shows *(5b)* to be the *syn-endo* isomer while *(5a)* is the *anti* isomer. The same mixture of isomers (*(5a)* ≈ 15% and *(5b)* ≈ 85%) is obtained, irrespective of the conditions of synthesis (*i.e.* low or high temperature, UV irradiation).

The complexes *(2)* and *(3)* give only the *cis-anti* isomers *(6a)* and *(7a)*. However, starting from *(4)*, which was found to be *cis* both in the solid state and in solution[6], two isomers are detected. Slow crystallization at low temperature from toluene/hexane allows the separation of pure *(8a)* (red crystals); *(8b)* is obtained together with small amounts of *(8a)*. The infrared spectrum of *(8a)* contains two ν_{CO} bands; the $^{31}P\{^1H\}$-NMR spectrum shows just one signal, indicative of a symmetric molecule containing two equivalent phosphorus atoms. As no phosphorus-phosphorus coupling was observed, and by analogy with complex *(5)*, we attribute the apical positions to iodine atoms. This situation differs substantially from that of the complex $[Ir_2(\mu\text{-}StBu)_2(CO)_2(PMe_3)_2H_2]$[3] where the two phosphane ligands are in apical position, leading to a large J_{PP} coupling constant. Moreover, the $^{13}C\{^1H\}$-NMR spectrum indicates *(8a)* to have *cis-anti* geometry. Indeed, as shown for *(5a)* and *(5b)*, the shifts of quaternary carbons are characteristic of the *endo* and *exo* positions.

(8a) *(8b)*

The data for isomer *(8b)* (Table 1) are consistent with a *trans-anti* geometry. In order to explain the diamagnetism observed for complexes *(5)—(8)*, a metal-metal bond is required.

A full X-ray structure determination was undertaken on a single crystal of *(7a)*. Its structure (Fig. 1) is reminiscent of that found for *(2)*[3] concerning the relative positions of the various ligands. The metal-metal distance in *(7a)* is 2.703 Å, as against 3.216 Å found for *(2)*.

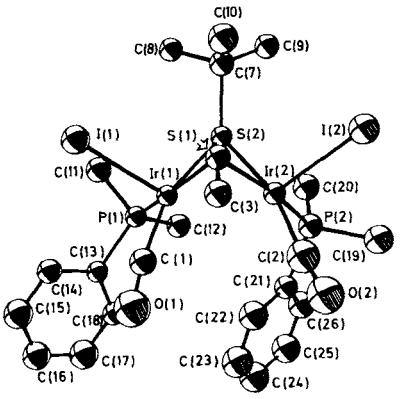

Fig. 1. Crystal structure of compound *(7a)*; isotropic model, $R = 7\%$.

As no interconversion was observed at room temperature between isomers *(8a)* and *(8b)*, the question of the mechanism of the oxidative addition to the *cis*-configurated complex *(4)* is of interest. Indeed the addition of small molecules to rhodium thiolato-bridged dinuclear complexes was found to occur on *a single* metal center[4]. Similarly the addition of H_2 to complexes *(2)—(4)* was rationalized in terms of a mono-addition to only one metal center followed by the migration of one hydrogen atom[3]. Since the addition of galvinoxyl retards the reaction, a radical process could be involved for the addition of iodine.

A Novel Proton-Ordered, Two-Dimensional Cross-linking of Water Molecules in Pyridine Trihydrate

By *Dietrich Mootz* and *Hans-Georg Wussow*[*]

Dedicated to Professor George A. Jeffrey on the occasion of his 65th birthday

Pyridine and water form an addition compound in the solid state, which was hitherto regarded as a dihydrate[1]. By reinvestigation of the melting diagram of pyridine-water and a complete crystal structure determination we have now been able to characterize this compound[2] as a trihydrate, whose structure is determined in an unusual way by hydrogen bonds.

Pyridine trihydrate melts incongruently at $-29.5\,^{\circ}C$ with decomposition into liquid phase and ice. Single crystals obtained from solutions with *ca.* 40 mol-% pyridine show the orthorhombic space group Pbca with eight $C_5H_5N \cdot 3H_2O$ formula units in the unit cell and, at $-50\,^{\circ}C$, the lattice constants $a = 1244.6(3)$, $b = 1783.2(6)$, $c = 679.1(2)$ pm. The structure determination (932 significant reflections, $R = 0.078$) led to ordered positions for all atoms. The water molecules are cross-linked two-dimensionally by five independent hydrogen bonds with O...O distances of 274.7 to 284.0 pm with formation of annelated four-, five-, and six-membered rings in the ratio 1:2:1 (Fig. 1[3]). One proton on each atom O(1) does not participate in this crosslinking, but makes, alternately from both sides of the water layer, a hydrogen bond to the N atom of a pyridine molecule (O...N 279.6 pm). In this way, the pyridine molecules are enclosed between successive water layers at a distance *b*/2.

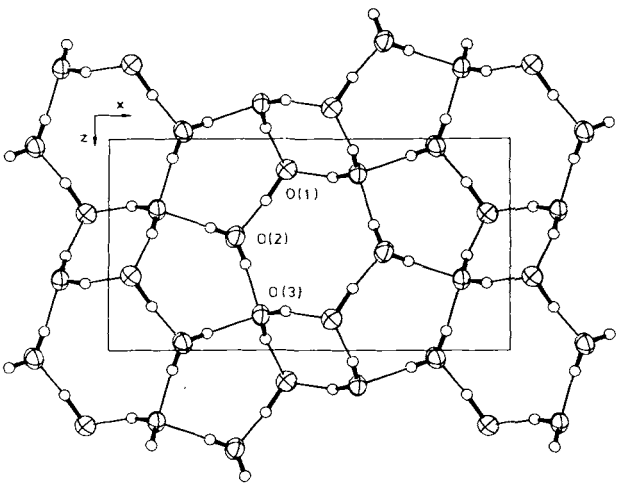

Fig. 1. Two-dimensional cross-linking of the water molecules in pyridine-water (1/3) by hydrogen bonds.

The geometry of the enclosure and the cross-linking of the water molecules are thus fundamentally different from that in the three-dimensional polyhedric clathrate and semicla-

thrate hydrates[4] (*inter alia*, gas hydrates, higher hydrates of alkylamines), even though the rings occurring in the water structures and in limited regions also their annelation are common structural elements.—Two-dimensional water structures have also been observed in the hexahydrates of piperazine[5] and pinacol[6], but in both cases only with five-membered rings, disordered protons and more extensive cross-linking through the difunctional organic molecule.

A New Variant of the Amphoterism of Tin(II) Hydroxide: $Sn(OH)_2$ as Stannio Complex Ligand[**]

By *Wolf-Walther du Mont* and *Brigitte Neudert*[*]

Tin(II) hydroxide is a colorless, highly associated compound of unknown structure[1] which decomposes on dissolution or fusion. Attempts to precipitate tin(II) hydroxide from aqueous solutions do not give $Sn(OH)_2$ but rather basic Sn^{II} derivatives whose compositions only approximate to SnO_2H_2, such as "$3\,SnO \cdot H_2O$". Structural features of such compounds are Sn—O(H)—Sn and Sn—O—Sn bridges, as well as pyramidal SnO_3 and SnO_4 units at tin(II)[1,2]. The amphoterism of "$Sn(OH)_2$" (in aqueous medium: acceptor and donor of OH^-) has long been known. So far there has been no evidence for basic properties of tin(II) hydroxide arising not from OH groups but from the metal itself as a weak Lewis base. If it were possible to involve the 5s-electron pair of tin in coordination with metal acceptors without significantly perturbing the tin-oxygen bridge, then $Sn(OH)_2$ would appear of interest as a non-toxic polymeric carrier material for transition metal catalysts.

We have now prepared the first such complexes in which transition metal acceptors ML_n are indeed fixed to tin(II) hydroxide by coordinative Sn—M bonds. Thus the lone pair at tin, which is frequently stereochemically active in SnO and its derivatives[2a,3], can be utilized for tin-transition metal coordination.

$$M(CO)_5SnCl_2 \cdot THF + 2\,R_3SnOH \rightarrow 2\,R_3SnCl + THF + M(CO)_5Sn(OH)_2 \quad (2)$$

(1a), M = Cr R = C_6H_5
(1b), M = W R = CH_3

Like *Zuckerman*'s synthesis of $Sn(OH)_2$, our preparation of $Sn(OH)_2$ metal complexes utilizes chloride/hydroxide exchange with triphenyl- or trimethyl-tin hydroxide: the $SnCl_2$-metal complexes *(1)* react with R_3SnOH in toluene at room temperature within a few days to form pentacarbonyl(dihydroxystannio)chromium(0) *(2a)* and -tungsten(0) *(2b)* which can be isolated in 50—75% yield as yellow and colorless powders, respectively.

The physical properties of the $Sn(OH)_2$-metal complexes are remarkably similar to those of tin(II) hydroxide: the new compounds *(2)* are not volatile and cannot be melted without decomposition (decomposition above about 150 °C); they are sparingly soluble in water, alcohols, and inert organic solvents. The tin-transition metal coordination is confirmed by well-resolved doublet signals in the ^{119m}Sn Mössbauer spectra (Table 1); the values of the isomer shifts are characteristically lowered relative to those of $Sn(OH)_2$ by withdrawal of 5s electrons into Sn—Cr or Sn—W bonds[4], with the quadrupole splitting being increased.

In contrast to $Sn(OH)_2$, the complexes *(2)* are sufficiently soluble in tetrahydrofuran (THF) to permit recording of NMR spectra. The ^{119}Sn-NMR spectra each show one signal (Table 1); that of *(2b)* is shifted upfield by about 200 ppm relative to that of *(2a)*[5]. THF adducts of the stannio complexes are present in these solutions, as also revealed by the changed CO stretching frequencies. The frequency of the ν(CO) bands of the solid, base-free but associated (by tin-oxygen bridging) $Sn(OH)_2$ metal complexes (Table 1) shows the inorganic polymer $Sn(OH)_2$ to be a ligand with donor/acceptor properties resembling those of conventional phosphane or phosphite ligands.

Table 1. Spectroscopic data of the $Sn(OH)_2$-metal complexes *(2)* [a].

$Sn(OH)_2$ [1]	2.83	2.20	—	3390 (br)	—

[a] The composition of the compounds was confirmed by elemental analysis. [b] δ and Δ values in mm s^{-1}; $BaSnO_3$ as standard [4]. We are grateful to Prof. *J. J. Zuckerman*, University of Oklahoma, Norman, OK. [c] Conc. solution in THF/C_6D_6; Bruker SXP, 33.55 MHz; $(CH_3)_4Sn$ as standard. [d] Nujol suspension between CsI plates, values in cm^{-1}.

Procedure

Compound *(1b)* (1.7 g, 2.9 mmol) and trimethyltin hydroxide (1.2 g, 6.7 mmol) are stirred in toluene (25 ml) and THF (2 ml) for 3 d. After removal of solvent, washing of the residue with toluene and dichloromethane, and drying at 0.1 mbar, compound *(2a)* (0.7 to 1.1 g, 50—75%) is obtained as a colorless powder that does not melt below 200 °C. The compound dissolves in THF to give a yellow solution.

Bis(di-*tert*-butylphosphino)tellurium(II): A Derivative of Phosphinous Anhydride Exhibiting Umpolung[**]

By *Wolf-Walther du Mont*[*]

Formation of phosphane chalcogenides R_3PX (X = O, S, Se, Te) from phosphanes is generally regarded as a P^{III}/P^{V} redox reaction[1]. We have found phosphane tellurides to be exceptions insofar as they behave like kinetically labile tellurium complexes in the presence of an excess of phosphane[2]. All known R_3PTe/PR_3 systems display fast tellurium transfer reactions ("fluxional redox systems") on the ^1H- and ^{31}P-NMR time scale, even at room temperature[2,3] [eq. (1)]. However, if tellurium is correspondingly transferred from tri-*n*-butylphosphane telluride to di-*tert*-butyl(trimethylsilyl)phosphane *(1a)*, then tellurium transfer to silylphosphane is followed immediately by insertion of tellurium into the phosphorus-silicon bond [eq. (2)]. Elemental tellurium reacts similarly, with insertion into the P—Si, P—Ge, and P—Sn bonds of the phosphanes *(1a)*—*(1e)* [eq. (3)].

$$R_3P{=}Te + R'_3P \rightleftharpoons R'_3P{=}Te + R_3P \quad (1)$$

(R, R' = Alkyl, dialkylamino, in some cases aryl)

$$n\mathrm{Bu_3P{=}Te} + \underset{(1a)}{t\mathrm{Bu_2(Me_3Si)P}} \rightleftharpoons \left[t\mathrm{Bu_2P}\begin{matrix}\diagup\!\!=\mathrm{Te}\\ \diagdown\ \ \mathrm{SiMe_3}\end{matrix}\right] + n\mathrm{Bu_3P} \quad (2)$$

$$\downarrow$$

$$t\mathrm{Bu_2P{-}Te{-}SiMe_3}\ \ (2a)$$

$$t\mathrm{Bu_2P{-}EMe_3} + \mathrm{Te} \longrightarrow t\mathrm{Bu_2P{-}Te{-}EMe_3} \quad (3)$$

(1) → *(2a)*, E = Si; *(2b)*, E = Ge; *(2c)*, E = Sn

The silyl-, germyl-, and stannyl-phosphane tellurides $R_2(Me_3E)P{=}Te$ expected as intermediates in the essentially quantitative formation of the new silyl, germyl, and stannyl tellurophosphinites *(2a)*—*(2c)* according to eq. (2) and (3) are not sufficiently long-lived to permit detection in the ^{31}P-NMR spectra of the reaction mixtures[4]. In contrast, the insertion products *(2)* with the new structural unit R_2P—Te—ER_3 have been unequivocally characterized by ^1H-, ^{31}P-, and ^{119}Sn-NMR spectra (Table 1). These compounds cannot be prepared pure because the rapid formation of *(2)* is followed within a few hours by redistribution equilibria [eq. (4)]; hence *(2)* is always accompained by the known bis(trimethylelement)tellurides *(3)* and the new "tellurophosphinous anhydride" *(4)* in the isolated products.

The remarkable formation tendency of *(4)*, the first tellurium compound substituted only with R_2P groups, in equilibrium with *(2)* and *(3)* and the thermal stability (formation of R_4P_2 only on UV irradiation) suggested synthesis according to eq. (5): The product, obtained in 80% yield in toluene, crystallizes from pentane as pale-yellow needles, m.p. 77 °C[5]. Its ^1H- and ^{31}P-NMR spectra confirm the P—Te—P linkage in the monomeric compound (Table 1).

$$2\,(2a\text{—}c) \rightleftharpoons \underset{(3a),\ E=Si}{\underset{(3b),\ E=Ge}{\underset{(3c),\ E=Sn}{(\mathrm{Me_3E})_2\mathrm{Te}}}} + \underset{(4)}{t\mathrm{Bu_2P{-}Te{-}P}t\mathrm{Bu_2}} \quad (4)$$

$$\mathrm{Na_2Te} + 2\,t\mathrm{Bu_2PCl} \rightarrow (4) + 2\,\mathrm{NaCl} \quad (5)$$

The reaction of *(2c)* and *(4)* with protic reagents (water, alcohol) is surprising: The Te—P and Te—Si bonds of *(2a)* are smoothly cleaved, with deposition of tellurium to give not only siloxane derivatives but above all the P—H compound [di-*tert*-butylphosphane, $\delta(P) = 19.4$, $^3J(HP) = 11.4$ Hz]; in contrast, *(4)* undergoes very slow hydrolysis, and the di-*tert*-butylphosphane can likewise be detected by NMR spectroscopy. The polarity of the P—Te bond is very low (phosphorus and tellurium have very similar electronegativities), and is probably even reversed relative to the P—O, P—S, and P—Se bonds. Thus the silylphosphane *(1a)* is not necessarily oxidized on tellurium insertion according to eq. (2), but tellurium formally disproportionates in the course of formation of *(3)* and *(4)* from *(2)*, according to eq. (4)! Moreover, we no longer consider the description of phosphane tellurides $R_3P{=}Te$ as "phosphane complexes of tellurium(0)"[6] to be inappropriate.

Table 1. ^1H-, ^{31}P-, and ^{119}Sn-NMR data of compounds *(2)* and *(4)* [a].

Ring-Strained Carbodiphosphoranes

By *Hubert Schmidbaur, Thomas Costa, Beatrix Milewski-Mahrla,* and *Ulrich Schubert*[*]

"Carbodiphosphoranes" R_3PCPR_3[1] are of importance in chemical synthesis[2] and as complex ligands[3]. Their highly variable molecular structures[4] and bonding[5] are topics of controversial discussion, and are closely connected with the phenomenon of triboluminescence[6].

Structural investigations on carbodiphosphoranes in the gaseous state[7] and in crystals[4] have revealed that the PCP angle can apparently fall to 121° without any great expenditure of energy[4a]. Thus it appeared possible to incorporate the P=C=P structural unit into ring systems although no examples have previously been reported.

Quaternization of methylenebis(diphenylphosphane) *(1)* with the α,ω-dihaloalkanes *(2a—c)* affords the bisphosphonium salts *(3a—c)*[8] which can readily be characterized by elemental analysis and NMR spectroscopy. Mild dehydrohalogenation of these salt precursors with methylenetrimethylphosphorane through double transylidation in tetrahydrofuran or benzene with cooling to 0—10 °C gives deep yellow solutions from which the three carbodiphosphoranes *(4a—c)* can be isolated, some of them in good yields.

(a): n = 2, *(b)*: n = 3, *(c)*: n = 4

Scheme 1

Synthesis according to Scheme 1 gives the six-membered ring *(4b)* as the sole product only for $n=3$. In the case of $n=4$, side reactions occur with skeletal rearrangement[2b,9]; however, the seven-membered ring *(4c)* can be isolated pure in *ca.* 30% yield, m.p. 127 °C (dec.). Compound *(4c)* forms yellow crystals which, unlike *(4b)*, are readily soluble in organic solvents. In the ^{13}C-NMR spectrum the C atom of the double ylide function appears at $\delta=-3.4$ as a triplet with $^1J(PC)=75.7$ Hz (in C_6D_6 rel. to TMS as int. std. at 25 °C); $\delta(CH_2)=24.0$ (s) and 35.2 (AXX') can be unequivocally assigned for the other ring carbon atoms, as can the resonance signals of the four equivalent phenyl groups. In the $^{31}P\{^1H\}$-NMR spectrum the presence of a singlet proves the equivalence of the phosphorus atoms ($\delta=-1.68$ rel. to H_3PO_4 as ext. std.). The ^1H-NMR spectrum contains only complex multiplet signals which are hardly simplified in a $\{^{31}P\}$ experiment. Mass spectrum (70 eV): $m/e=438$ (M^+). IR spectrum: $\nu(P{=}C{=}P)=1270$ and 1300 cm^{-1}.

In contrast to *(4c)*, *(4b)* shows considerable thermal lability and already decomposes at 35 °C. The mass spectrum also suggests a monomeric structure [$m/e=423$ (M^+-1)], although the poor solubility initially appeared rather puzzling. The structure was therefore elucidated by X-ray diffraction[10], and revealed an extremely unusual helical arrangement of the monomeric units in the hexagonal single crystals. Figure 1 shows one of the heterocycles in which C-5 is disordered after the fashion of a chair-boat conformation. The screw-like packing of the molecules is seen in Figure 2. Both levo- and dextro-rotatory helix packings are found in the crystalline conglomerate (space groups $P6_5$ and $P6_1$).

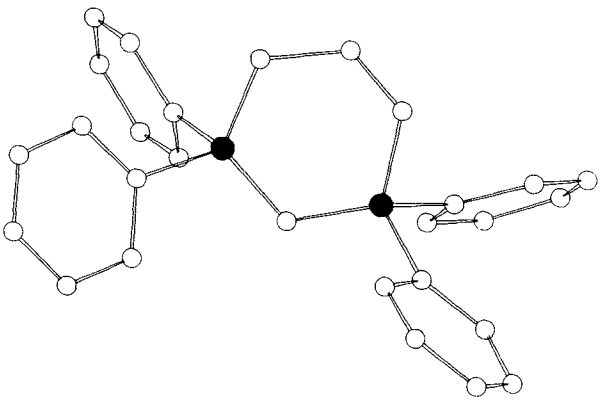

Fig. 1. Molecular structure of $(C_6H_5)_2P\text{-}C{=}P(C_6H_5)_2(CH_2)_3$ *(4b)*. The alternative position of the disordered atom C-5 has been omitted; it corresponds to a chair/boat relationship. Atomic parameters are available from the authors on request.

The P=C=P structural unit has the smallest known carbodiphosphorane angle of 117° but also equal P=C distances which lie in the expected range at 164.5 and 165.3 pm. It can be deduced from the decomposition of *(4b)* that the limit of strain of angle deformation is exceeded at ≤120°. The structure is best described by formulation as

(4b)

Compound *(4a)* is therefore expectedly even less stable and decomposes within a few hours at 20 °C. The very poorly soluble compound has so far only been characterized by means of its ^1H- and ^{31}P-NMR spectra [$\delta(P)=-22.45$ (s); $\delta(CH_2)=2.73$ ("d"), $(C_6H_5)=7.1—8.0$ (m)], mass spectrum, elemental analysis, and derivatization[11].

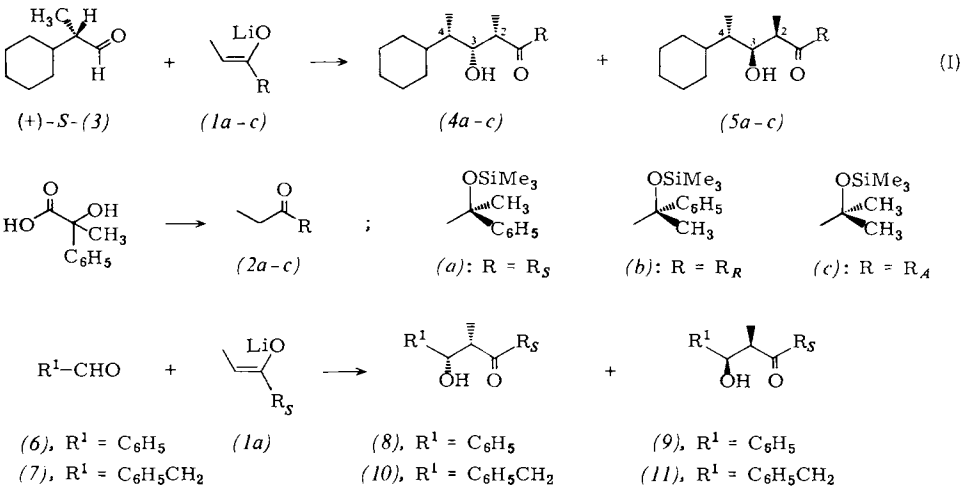
Ph(Me$_3$Si)C=P—Cl, the First *P*-Halofunctionalized Methylenephosphane[**]

By *Rolf Appel* and *Axel Westerhaus*[*]

A few examples of acyclic phosphorus(III) compounds with coordination number 2 have recently been reported in the literature[1]. The stability of these C=P-compounds, being other than expected according to the double bond rule, was previously attributed to shielding by the bulky substituents on the carbon (*t*-Bu[1a], $SiMe_3$[2]) or phosphorus atom[1b]. That this assumption only partly applies is evidenced by the surprisingly easy preparation of the *P*-chloromethylenephosphanes *(2)*, which was accomplished by dehydrohalogenation of the α-CH acidic primary dichlorophosphanes *(1)* with tertiary amines (B).

(1) *(2)*

	R	R'	B
(a)	H	H	$N(C_2H_4)_3N$
(b)	Ph	Ph	NEt_3
(c)	Ph	$SiMe_3$	$N(C_2H_4)_3N/NEt_3$



Of the new methylenephosphanes, only *(2c)* has hitherto been isolated in analytically pure form.

Chloro[phenyl(trimethylsilyl)methylene]phosphane *(2c)* is a yellow-green, distillable substance, which can be stored unchanged for several weeks in a refrigerator. Besides the correct elemental analysis and the mass spectrometrically and cryoscopically determined relative molecular mass for *(2c)*, the ^{31}P- and ^{13}C-NMR spectra unequivocally characterize the compound—and *(2a)* and *(2b)*—as methylenephosphane[3].

With *(2a)*—*(2c)* we now have ready access to valuable synthetic building blocks which can be exploited for derivatiza-

Scheme 1

tion at the phosphorus atom, and in the case of *(2c)* for incorporation of the P≡C triple bond by thermal elimination of trimethylchlorosilane[4].

Procedure

Chlorophenyl(trimethylsilyl)methane (72.4 g, 360 mmol) is converted with Mg (10.0 g, 400 mmol) in diethyl ether (200 ml) into the Grignard compound, which is then added dropwise slowly to an ice-cooled solution of PCl_3 (49 g, 360 mmol) in ether (150 ml). $MgCl_2$ is removed by filtration and the filtrate is evaporated down under vacuum. Fractional distillation of the residue furnishes 52.7 g (55%) of *(1c)*, b.p. 53 °C/10^{-3} torr [$^{31}P\{^1H\}$-NMR (C_6D_6): δ = 189].

A solution of *(1c)* (15.0 g, 57 mmol) in ether (200 ml) is treated with 25.3 g (220 mmol) of 1,4-diazabicyclo[2.2.2]octane and the mixture is stirred for 12 h at room temperature. The insoluble material is filtered off and washed with ether. The combined filtrates are then evaporated down under vacuum and the amine hydrochloride which precipitates is removed by filtration. After removal of solvent the residue is treated with *n*-pentane, filtered and the filtrate evaporated down and distilled: yield 7.1 g (54%) of *(2c)*, b.p. 51 °C/10^{-3} torr.

Highly Stereoselective Aldol Condensation Using an Enantioselective Chiral Enolate[**]

By *Satoru Masamune, Sk. Asrof Ali, David L. Snitman*, and *David S. Garvey*[*]

The concept of the diastereomeric transition state is well documented[1]. Thus, in a kinetically controlled reaction which leads to the formation of new chiral centers, certain pairs of optically active substrates react to form one diastereoisomer predominantly, whereas other combinations result in inferior stereoselection. We have observed this phenomenon in an aldol condensation (Eq. 1) and have consequently developed a chiral enolate reagent which is highly enantioselective and synthetically useful. A recent report by *Heathcock et al.*[2] concerning this subject has prompted us to summarize our independent findings in preliminary form[3].

Table 1. Aldol condensation of aldehyde *(3)* with lithium enolate *(1)*.

	Aldehyde *(3)* [a]	Enolate	Structures [b] of products *(4)* and *(5)*	Combined Yields [%]	Ratio of *(4)* to *(5)*
1	(+)-*S*	*(1a)*	*(4a)*, *(5a)*	75	1:8
2	(+)-*S*	*(1b)*	*(4b)*, *(5b)*	72	1.5:1
3	(−)-*R*	*(1a)*	*(4d)*, *(5d)* [c]	75	1.5:1
4	(−)-*R*	*(1b)*	*(4e)*, *(5e)* [d]	78	1:8

[a] Prepared from optically pure 2-cyclohexylpropionic acid $LiAlH_4$ reduction and Collin's oxidation [(+)-*S*: $[\alpha]_D^{25} = +19.3$ (*c* = 1.185 C_2H_5OH); (−)-*R*: $[\alpha]_D^{25} = -18.6$ (*c* = 2.055 C_2H_5OH)] *via* methylation. (+)-*S*- and (−)-*R*-*(3)* had $[\alpha]_D^{25} = +62.8$ (*c* = 1.545 CH_2Cl_2) and −63.1 (*c* = 0.950 CH_2Cl_2), respectively. [b] The stereochemistry of the aldol products is based on the conversion of *(4)* and *(5)* through acid hydrolysis and oxidation into the corresponding 4-cyclohexyl-3-hydroxy-2-methylpentanoic acids which were compared with those obtained from 4-phenyl-3-hydroxy-2-methylpentanoic acids of known stereochemistry. [c] *(4d)*, *(5d)*: enantiomers of *(4b)*, *(5b)*. [d] *(4e)*, *(5e)*: enantiomers of *(4a)*, *(5a)*.

Initial exploratory work in this area involved the use of chiral lithium enolates *(1a)* and *(1b)* derived from *S*- and *R*-atrolactic acids, respectively. Thus, treatment of the acids[4] with 3.3 equivalents of ethyllithium provided a 65% yield of the corresponding ethyl ketones, which were in turn silylated to yield *(2a)* and *(2b)* (Scheme 1)[5]. The aldol condensation was then carried out in the usual way: after dropwise addition of aldehyde *(3)*[6] to a THF solution (−78 °C) of enolate *(1)*, generated from *(2)* with lithium diisopropylamide, the reaction mixture was stirred for 25 min and quenched with aqueous ammonium chloride for workup. The structures and yields of products *(4)* and *(5)* in each reaction are summarized in Table 1.

Two pairs (Table 1, entries 1 and 4) provided a significant stereoselection of 1:8 in sharp contrast with that (1.5:1) observed in the other cases (entries 2 and 3). Thus, only a certain pair of chiral substrates produces predominantly one of the four possible stereoisomers in an aldol condensation.

The stereochemical course of the above reaction requires some analysis. While the *Z*- or *E*-stereochemistry [only *Z* shown in *(1)*] of the enolate has been shown to be directly

correlated with the *syn*- and *anti*-2,3 stereochemistry[7] of the products *(4)* and *(5)*[8], the 3,4-stereochemistry appears to depend on two factors, (a) the selectivity inherent in the reacting aldehyde commonly referred to as Cram/anti-Cram selectivity[9] and (b) the enantioselectivity arising from the chirality present in the enolate. These two selectivities were evaluated separately.

The reaction of (+)-*(3)* with the achiral reagent *(1c)* utilized earlier by *Heathcock et al.*[8c] provided a 27:73 mixture of *(4c)* and *(5c)*, showing that the selectivity inherent in aldehyde *(3)* approximates a ratio of 1:3[10]. Also, achiral aldehydes *(6)* and *(7)* were condensed with *(1a)* to afford products *(8)* and *(9)* (1:3.5 ratio in 80% yield) and *(10)* and *(11)* (1:6 in 75% yield), respectively[12]. Hence the enantioselectivity of *(1a)* can be estimated to be about 1:5. Therefore, enhanced stereoselection is only achieved when these two factors are acting in concert (entries 1 and 4).

The above results encouraged us to seek a more enantioselective chiral reagent. After investigating a variety of enolates, it was found that the hexahydro derivative *(12a)* of *(1a)*[13] demonstrated a significant increase in stereoselection (*ca.* 15:1) in the aldol condensation with phenylacetaldehyde, as compared with *(1a)*. Also, the high degree of enantioselectivity of *(12a)* or *(12b)* can counteract the normally small Cram/anti-Cram selectivity of aldehydes to the extent that *either the 3,4-anti or the 3,4-syn*[7] *aldol adduct* can now be obtained as the predominant product.

A clear demonstration of this fact is the stereoselective synthesis of both Prelog-Djerassi and *iso*-Prelog-Djerassi lactonic acid [*(13)* and *(14)*, respectively][11].

Scheme 2

As shown in Scheme 2, aldehyde *(15)*[14] was condensed with *(12a)* in THF at −78 °C to yield a mixture of *(16a)* and *(17a)* in a ratio of 15:1. Conversion of *(16a)* into (+)-*(13)* was accomplished *via* a three-step sequence[15]. In a similar fashion, the *iso*-acid *(14)* could also be obtained as the major product. Condensation of *(15)* and *(12b)* provided *(16b)* and *(17b)* in a ratio of 1:10. Thus, this new, readily available reagent can be used to control the 3,4 stereochemistry of aldol products with high diastereoselection, an achievement which has not been realized before.

[4] *S:* $[\alpha]_D^{25} = +36.5$ ($c = 1.525$, C_2H_5OH); *R:* $[\alpha]_D^{25} = -36.7$ ($c = 2.932$, C_2H_5OH). The reported specific rotations of the *S*- and *R*-acids are $[\alpha]_D^{10.5} = +37.7$ ($c = 3.500$, C_2H_5OH) and $[\alpha]_D^{13.8} = -37.7$ ($c = 3.354$, C_2H_5OH), respectively: *A. McKenzie, G. W. Clough,* J. Chem. Soc. *97*, 1016 (1910).

[5] Prepared by *T. Sato. (2a):* $[\alpha]_D^{25} = -125.9$ ($c = 1.290$, CH_2Cl_2); *(2b):* $[\alpha]_D^{25} = +125.5$ ($c = 1.535$, CH_2Cl_2). Both were optically pure to the limit of detection by NMR using $Eu(hfbc)_3$.

[6] *D. J. Cram, F. D. Greene,* J. Am. Chem. Soc. *75*, 6005 (1953), describe the preparation of *(3)* of unspecified optical purity.

[7] The usage of *"threo"* and *"erythro"* is often confusing. In this communication, the main chain is drawn in the zig-zag fashion, and two substituents on the same side are designed *"syn"*, and those which are not, *"anti"*.

[8] For recent examples, see for instance: a) *S. Masamune, S. Mori, D. E. Van Horn, D. W. Brooks,* Tetrahedron Lett. *1979*, 1665; *M. Hirama, S. Masamune, ibid. 1979*, 2229; b) *R. W. Hoffmann, H. J. Zeiss,* Angew. Chem. *91*, 329 (1979); Angew. Chem. Int. Ed. Engl. *18*, 306 (1979); c) *C. T. Buse, C. H. Heathcock,* J. Am. Chem. Soc. *99*, 8109 (1977).

[9] This problem has been discussed in the past in terms of several different conformations of the α-substituent (Cram, Cornforth, Krabatsos and Felkin rules). See reference [1].

[10] Somewhat surprisingly, aldehyde *(3)* prefers the "anti-Cram" approach of enolates (cf. Table 1). For an earlier example, see reference [11].

[11] *M. Hirama, D. S. Garvey, L. D.-L. Lu, S. Masamune,* Tetrahedron Lett. *1979*, 3937.

[12] Although all of compounds *(8)*—*(11)* are *syn*-2,3 stereoisomers [7], the absolute configurations of these chiral centers have not been unambiguously established.

[13] The corresponding ethyl ketones were obtained from *R*- and *S*-hexahydroatrolactic acid ($[\alpha]_D^{25} = -15.9$ ($c = 1.240$, C_2H_5OH) and $[\alpha]_D^{25} = +16.3$ ($c = 1.690$, C_2H_5OH), respectively) in the same manner as for *(2a)*.

[14] Aldehyde *(15)* was prepared from the optically pure monomethyl ester of *meso*-2,4-dimethylglutaric acid, $[\alpha]_D^{25} = -4.61$ ($c = 7.050$, $CHCl_3$).

[15] The lactonic acids *(13)* and *(14)* were formed from their corresponding aldol products by: a) lactonization with trifluoroacetic acid/methanol/dichloromethane, b) reduction with $Zn(BH_4)_2$, and c) oxidation with Jones' reagent.

Outer Sphere Electron Transfer Reactions: A Novel Linear Relationship between the Selectivity and the Normal Potential of the Reducing Agent

By *Hans-Michael Huck* and *Karl Wieghardt*[*]

In the simplest mechanism of electron transfer (ET) between two transition metal complexes (the outer-sphere mechanism) the reactants form an encounter complex in a preceding equilibrium. In the rate-determining step, the electron is transferred through the intact first coordination spheres of the two complexes; the resulting complex then decomposes to the products[1]:

$$[Ox] + [Red] \overset{K_0}{\rightleftharpoons} \{[Ox][Red]\}$$

Encounter complex

$$\downarrow k_{et}$$

$$\{[Ox^-][Red^+]\} \xrightarrow{Fast} \text{Products}$$

Successor complex

Equation (a) can then be derived for this scheme:

$$\text{rate} = \frac{k_{et} \cdot K_0 [Ox][Red]}{1 + K_0 [Red]} \qquad (a)$$

[*] Prof. Dr. K. Wieghardt, Dipl.-Chem. H. M. Huck
Institut für Anorganische Chemie der Universität
Callinstrasse 9, D-3000 Hannover 1 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0707-0558 $ 02.50/0

For the one-electron reduction of the inert complexes $[Co(NH_3)_6]^{3+}$ and $[Co(NH_3)_5OH_2]^{3+}$ by the aqua complexes of Sm^{II}[2], Yb^{II}[3], U^{III}[4], Eu^{II}[5], Cr^{II}[6], V^{II}[6], and by $[Ru(NH_3)_6]^{2+}$[7] as well as by $[Cr(bpy)_3]^{2+}$[6a], eq. (a) simplifies to eq. (b) because $K_0[Red] \ll 1$.

$$\text{rate} = k[Ox][Red]; \quad k = k_{et} \cdot K_0 \tag{b}$$

Since K_0 is generally unknown, it is impossible to make any statement about the reactivity ($\log k_{et}$) of the encounter complexes.

The structures of the cations $[Co(NH_3)_6]^{3+}$ (Ox1) and $[Co(NH_3)_5OH_2]^{3+}$ (Ox2) differ only slightly; however, Ox2 is the stronger reducing agent. It therefore appears plausible to assume that for a given reducing agent y from the above series the formation constant K_0 of the encounter complexes {[Ox1],y} and {[Ox2],y} must be of the same magnitude (under otherwise identical reaction conditions). It is therefore reasonable to calculate the difference of the logarithms of the rate constants of reduction [eq. (c)].

$$\log(k_{et}^{Ox2,y} \cdot K_0) - \log(k_{et}^{Ox1,y} \cdot K_0) = \log k_{et}^{Ox2,y} - \log k_{et}^{Ox1,y} \tag{c}$$

This difference then describes the difference in reactivity between the complexes {[Ox1],y} and {[Ox2],y}; it is called the selectivity[8].

The selectivity is found to show a linear correlation with the normal potential of the reducing agent y: the more strongly reducing the action of the reducing agent, the smaller is the observed selectivity (Fig. 1):

$$\log k_{et}^{Ox2,y} - \log k_{et}^{Ox1,y} = (1.3 \pm 0.1)\, E_0^y + (2.3 \pm 0.1) \tag{d}$$

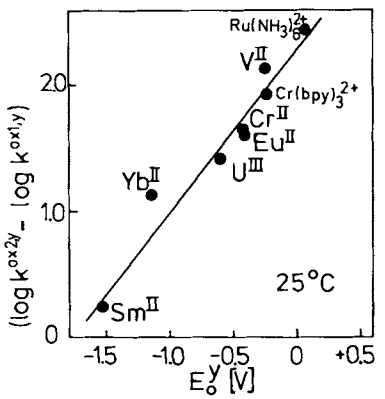

Fig. 1. Difference in the logarithms of the rate constants of reduction k [$M^{-1}s^{-1}$] of $[Co(NH_3)_6]^{3+}$ (Ox1) and of $[Co(NH_3)_5OH_2]^{3+}$ (Ox2) on reduction with the aqua ions of Sm^{II}, Eu^{II}, Yb^{II}, U^{III}, Cr^{II}, V^{II}, and by $[Ru(NH_3)_6]^{2+}$ as well as by $[Cr(bpy)_3]^{2+}$ as a function of the normal potential, E_0^y, of the reducing agent y.

The existence of a relationship such as eq. (d) appears all the more remarkable in view of the fact that the reactivities within the encounter complexes {[Ox1],y1}, {[Ox1],y2}, {[Ox1],y3}, ... *etc.* are *not* a simple function of the reduction potential of the reducing agents y1, y2, y3... For example, the outer-sphere reduction of [Ox1] and [Ox2] with $Ru(NH_3)_6^{2+}$ is about three orders of magnitude *faster* than the corresponding reaction with the stronger reducing agent $[Cr(OH_2)_6]^{2+}$. Thus the reactivity-selectivity principle[8] is not fulfilled in this case for outer-sphere ET reactions between transition metal complexes.

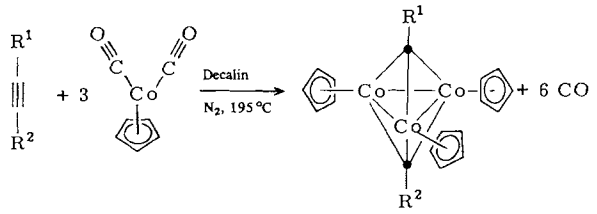
Biscarbyne Clusters by Alkyne Cleavage: A General Reaction[**]



By *John R. Fritch* and *K. Peter C. Vollhardt*[*]

Surface carbyne species have recently been implicated in the H/D exchange of polymethylcycloalkanes mediated by cobalt films[1a], the isomerization of saturated hydrocarbons on iridium catalysts[1b], the interaction of acetylene and ethylene with platinum, nickel, and rhodium single crystals[1c], and the hydrogenation of carbon monoxide (Fischer-Tropsch reaction) on heterogeneous systems[1d]. We describe a *general* synthesis and preliminary physical and chemical properties of biscarbyne clusters prepared by a conceptually most simple route, the direct cleavage of alkynes. Biscarbyne clusters, particularly those derived from multiple cleavage of oligoynes, have excellent potential as, *e.g.*, suitable substrates on which to study surface-homogeneous cluster analogies[2].

We[3] have found that $(\eta^5\text{-}C_5H_5)Co(CO)_2$, which ordinarily functions as a mediator of alkyne oligomerizations to furnish catalytic and stoichiometric products (*e.g.* benzenes, and complexed cyclopentadienones and cyclobutadienes)[4] assembles a trinuclear $[(\eta^5\text{-}C_5H_5)Co]_3$ cluster which inserts into alkyne functions with remarkable ease. Thus, when a solution of diphenylacetylene and $(\eta^5\text{-}C_5H_5)Co(CO)_2$ (3 equiv.) in decalin is slowly added (syringe pump) to boiling and nitrogen flushed decalin over 24 h only 9% of the ordinarily expected cyclopentadienyl(tetraphenylcyclobutadiene)cobalt[5] is isolated on alumina chromatography. The major product (72%) is the biscarbyne cluster *(1)* (see Table 1).

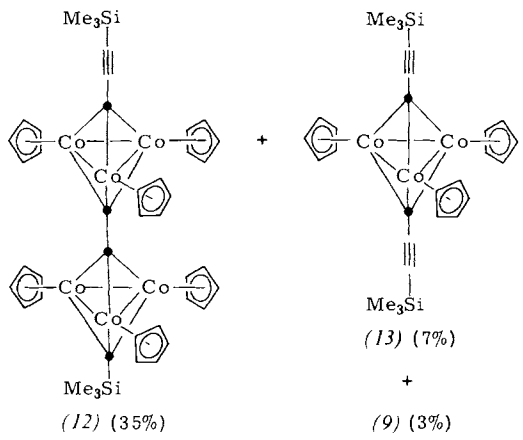
Sloan Foundation, 1976—1980, and a Camille and Henry Dreyfus Teacher-Scholar, 1978—1983; *J. R. F.* is the recipient of a Regents' Predoctoral Fellowship (1977) and a Gulf Oil Fellowship (1978).

(1), $R^1 = R^2 = C_6H_5$ (72%)
(2), $R^1 = R^2 = n\text{-}C_4H_9$ (56%)
(3), $R^1 = R^2 = CO_2CH_3$ (16%)
(4), $R^1 = Si(CH_3)_3$, $R^1 = H$ (32%)

The clusters *(2)*—*(4)* may be isolated in similar fashion. This finding is important in view of the lack of generality of the many reactions of transition metals with organic substrates. In the cleavage of trimethylsilylated alkynes, traces of



other clusters are observed which are derived from acetylide coupling and decoupling, hydrolysis, and dimerization processes. For example, complete analysis of all chromatographable products from the conversion of bis(trimethylsilyl)butadiyne *(5)* with $(\eta^5\text{-}C_5H_5)Co(CO)_2$ (molar ratio 1:6) reveals seven clusters [*(4)* and *(6)*—*(11)*]! It should be noted that the "multiple decker" sandwich *(7)* is formed despite the considerable steric crowding. Compounds *(4)* and *(9)* most likely arise *via* metathesis of *(5)* to trimethylsilylacetylene and bis(trimethylsilyl)hexatriyne (or their equivalents) in the coordination sphere of cobalt. A control experiment showed that *(7)* is an unlikely source of *(4)* *via* cleavage of the carbido bridge under the reaction conditions. Ketone *(8)* may be thought of as a hydrolysis product of *(6)* and cluster *(10)* is derived from *(6)* by protodesilylation under the reaction conditions *(vide infra)*. The formation of *(11)* points to the presence of 1,4-bis(trimethylsilyl)-1,3-butenyne in the reaction mixture, possibly derived by dimerization of trimethylsilylacetylene[6].

A similar array of products is obtained in the analogous reaction of bis(trimethylsilyl)hexatriyne, but again the major components of the reaction mixture are the singly inserted *(13)*, and the "multiple deckers" *(9)* and *(12)* (Table 1).

Treatment of *(6)* with 1% KOH/EtOH gave quantitative monodesilylation to the unstable terminal acetylene *(14)* (Table 1), whereas the action of $n\text{-}Bu_4N^{\oplus}F^{\ominus}$ in hot THF led to complete desilylation to the unsilylated analogue of *(6)*, compound *(15)* (Table 1).

The parent biscarbyne *(16)* is accessible from *(4)* by protodesilylation $C_6H_5CH_2N(CH_3)_3^{\oplus}F^{\ominus}$ (DMSO, 105 °C, 6 h, 87% yield) (Table 1). Remarkably, instant H/D exchange at the carbyne carbon is observed when *(4)* or *(16)* are exposed to CF_3CO_2D/C_6D_6 (1:1, 25 °C, deep green solution) in an NMR tube under conditions which lead to neither deutero-

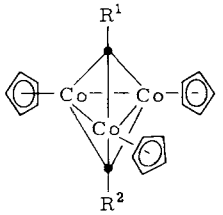
(12): red-bronze flakes, dec. p. 393 °C; *m/e* 962 ($M^{\oplus}$, 44%), 773 ($M - Cp_2Co$, 21), 189 (100); ^{1}H-NMR ($CDCl_3$): $\delta = 4.68$ (s, 15H), 4.62 (s, 15H), 0.92 (s, 9H), 0.53 (s, 9H); IR (KBr): $\nu_{C\equiv C}$ 2069 cm^{-1}



(13): purple crystals, m.p. 161.5—165 °C; *m/e* 590 ($M^{\oplus}$, 37%), 189 (100); ^{1}H-NMR (C_6D_6): $\delta = 4.38$ (s, 15H), 0.48 (s, 18H); IR ($CHCl_3$): $\nu_{C\equiv C}$ 2061 cm^{-1}

(14): purple flakes, dec. p. 102—116 °C; *m/e* 494 ($M^{\oplus}$, 32%), 189 (100); ^{1}H-NMR (C_6D_6): $\delta = 6.78$ (s, 1H), 4.45 (s, 15H), 0.79 (s, 9H); IR ($CHCl_3$): ν_{CCH} 3300 cm^{-1}, $\nu_{C\equiv C}$ 2024 cm^{-1}

(15): purple prisms, dec. p. 25 °C; *m/e* 422 ($M^{\oplus}$, 45%), 271 (17), 189 (100); ^{1}H-NMR (C_6D_6): $\delta = 18.68$ (s, 1H), 6.72 (s, 1H), 4.43 (s, 15H); IR ($CHCl_3$): ν_{CCH} 3295 cm^{-1}, $\nu_{C\equiv C}$ 2020 cm^{-1}

(16): purple crystals, sublimation 160 °C/10^{-3} torr; dec. p. 380—390 °C; *m/e* 398 ($M^{\oplus}$, 64%), 370 (42), 247 (45), 189 (100), 124 (10); ^{1}H-NMR (C_6D_6): $\delta = 18.37$ (s, 2H), 4.38 (s, 15H)

desilylation nor deuterium in corporation into the cyclopentadienyl ligands (1 h)[7]. In contrast, cluster *(1)* is inert to alcoholic HCl, but reacts with hot CF_3SO_3H to furnish benzene and toluene. On the other hand, when *(4)* is exposed to *n*-BuLi/TMEDA (THF, 25 °C, 30 min) followed by D_2O work-up unchanged *(4)* is isolated.

(14), R^1 = C≡CH, R^2 = $SiMe_3$
(15), R^1 = C≡CH, R^2 = H
(16), R^1 = R^2 = H

To test for the potential of carbyne exchange, *(1)* was heated in boiling decalin with excess (molar ratio 1:4) of di-*p*-tolylacetylene[8] for 39 d. Only traces of 1,2-diphenyl-3,4-ditolyl- and tetratolylcyclobutadiene(cyclopentadienyl)cobalt were recovered, in addition to diphenylacetylene (21%), starting cluster *(1)* (74%), and ditolylacetylene (74%). Biscarbynes may act as, or be precursors of, catalytically active species. Heating *(4)* with 1-heptene in a stainless steel bomb to 200 °C for 36 h in the presence of CO (*ca.* 27 bar) and H_2 (*ca.* 55 bar) gave 1-octanal, 1-octanol, 2-methylheptanal, and 2-methylheptanol with respective turnovers of 30, 6.8, 15.4, and 5.0 per equivalent of cobalt. Starting *(4)* was completely consumed.

The unusual spectral data of the reported biscarbynes are compiled in Table 1. They reveal the profoundly deshielding effect and the strong electron donor ability of the cluster unit[9].

Gold(I)-Gold(I) Interactions. Tetrameric Gold(I) Dithioacetate

By *Olivo Piovesana* and *Pier Francesco Zanazzi*[*]

The electronic factors responsible for the geometries and stabilities of multinuclear d^{10} systems[1] are still not completely understood, particularly from the standpoint of the

[*] Prof. O. Piovesana [+]
Università di Perugia, Dipartimento di Chimica
Via Elce di Sotto 10, I-06100 Perugia (Italy)

[+] Author to whom correspondence should be addressed.

degree of stabilization afforded by the interactions between the d^{10} centers (with formally closed shells)[2].

Unlike copper(I), which forms clusters with 2 to 8 metal atoms[2c], gold(I) appears to form relatively few multinuclear systems[3] in which metal atom distances are short enough to suggest some M—M bonding, and, with one possible exception[4] *(vide infra)*, all such structurally determined compounds involve either dinuclear units or mononuclear linear molecules forming polymeric gold chains or layers[3].

Here we report the facile synthesis of the air-stable gold(I) dithioacetate, which appears to be the first dithiocarboxylic acid derivative of gold, along with preliminary information on its X-ray structure. This consists of discrete tetranuclear units, $Au_4(CH_3CSS)_4$, with direct gold-gold interactions.

In the tetrameric molecule (Fig. 1) the four gold atoms are at the vertices of a rhomb. The four bridging ligands are alternately above and below the plane of the metal cluster. The molecule has approximate D_2 symmetry. The four equivalent Au—Au distances average 3.01 Å; the unique Au(2)—Au(4) distance is 3.29 Å. At an Au—Au distance of 3.01 Å, compared with those in the metal, 2.884 Å[5], and in the periphery of unbridged cluster compounds such as $[Au_6(PPh_3)_6]^{2+}$, 3.02 Å[6a], and $Au_{11}I_3[P(p\text{-}FC_6H_4)_3]_7$, 2.98 Å[6b], the metal-metal interactions are most likely to be attractive. Actually, recent MO calculations on these cluster compounds have indicated that there is a significant bonding between the peripheral gold atoms[7a]. The Au—S bond distances are normal and average 2.30 Å. The S—Au—Au and S—Au—S

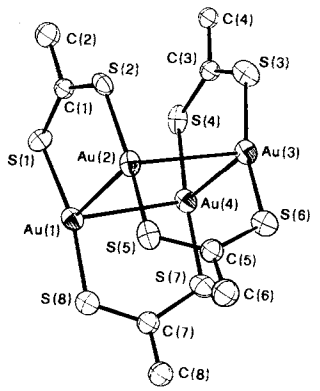

Fig. 1. Molecular structure of $Au_4(CH_3CSS)_4$ in the crystal. Space group $P\bar{1}$, $a=12.200(5)$, $b=9.728(3)$, $c=8.876(3)$ Å, $\alpha=95.32(2)°$, $\beta=110.71(3)°$, $\gamma=92.67(2)°$, $Z=2$, $\rho_{calc}=3.914$ g cm^{-3}. The intensities were measured in the $\theta-2\theta$ scan mode using monochromated Mo-K_α radiation, on a Philips PW1100 single crystal diffractometer. 3347 independent reflections were collected ($3°<\theta<25°$) of which 1828, having $I<3\sigma(I)$, were considered observed and used in the analysis. The structure was solved by direct methods and refined by a full-matrix least-squares approach (SHELX-76 program), anisotropically for the Au and S atoms, to $R=0.10$. Principal bond parameters are: Au(1)—Au(2), 2.989(3); Au(1)—Au(4), 3.003(3); Au(2)—Au(3), 3.020(3); Au(3)—Au(4), 3.022(3); Au(1)—S(1), 2.30(1); Au(1)—S(8), 2.29(1); Au(2)—S(2), 2.31(1); Au(2)—S(5), 2.32(1); Au(3)—S(3), 2.26(1); Au(3)—S(6), 2.30(1); Au(4)—S(4), 2.30(1); Au(4)—S(7), 2.30(1) Å; Au(2)—Au(1)—Au(4), 66.6(1); Au(2)—Au(3)—Au(4), 66.1(1); Au(1)—Au(2)—Au(3), 113.8(1); Au(1)—Au(4)—Au(3), 113.3(1)°.

mean angles are 94 and 193°, respectively. The deviation from linearity in the S—Au—S coordination is determined by a dihedral angle of about 16° between the planes of the ligands on opposite sides of the metal cluster.

The unstable, colorless chloro(piperidine)gold(I) is the only compound in which Au_4 units have been located[5]. Here, the unbridged, linearly co-ordinated gold atoms form a loose square cluster with an Au—Au mean distance of 3.30 Å. Whether M—M bonding interaction does or does not occur in this compound is not clearly understood[5].

The geometry of the Au_4 units and the M—M interactions in the title compound are attributable to both steric and electronic factors. Thus, interligand S—S and methyl-methyl repulsion would be severe with two alternate pairs of eclipsed ligands and interplanar separations of about 3 Å. On the other hand, there seems little to account for the deviations from linearity in the gold-sulfur coordination except some residual mutual repulsion of the ligands.

Electronic factors seem to be related to the ability of the dithioacetato ligand system to encourage d-s orbital mixing[7] on gold and to dissipate antibonding density from the plane of the cluster through its delocalized π virtual orbitals.

In a simplified bonding picture, empty ($d_{z^2}+\lambda s$) gold hybrid orbitals (directed along the S—Au—S axes) are available for the sulfur donation and filled ($d_{z^2}-\lambda s$) orbitals interact in the plane of the metal cluster. Because of the nondirectional character of the latter orbitals, the gold-gold interactions and the π interactions with the ligand system are angularly independent. The gold atoms, therefore, can move with respect to each other without sacrifice of orbital overlap and do it in order to minimize interligand repulsion.

The four in-plane hybrid atomic orbitals give rise to four cluster MOs, (one bonding, two nonbonding and one antibonding), with eight electrons and an overall antibonding effect. The extent of attractive interactions between the gold atoms should depend, therefore, on the capability of the delocalized π virtual orbitals of the tetrakis(dithiocarboxylato) framework to relieve antibonding density from the plane of the cluster.

It may be noted that d-s orbital mixing on gold and π acceptance by ligands from it have been recently found to be negligible in a large variety of mononuclear, linear gold(I) complexes[8].

Experimental

The red $Au_4(CH_3CSS)_4$ compound was prepared by heterogeneous reaction of $NaAuCl_4\cdot 2H_2O$ (1 g, 2.51 mmol) with CH_3CSSH (1 g, 10.87 mmol) in diethyl ether (50 cm^3). After the mixture stood for *ca.* 20 h at room temperature, it was filtered. The solid was recrystallized from carbon disulfide; yield *ca.* 30%, based on original gold.

Are α-Oxothioacyl Chlorides Formed in the Reaction of Methyl Ketones with Thionyl Chloride?[**]

By *Gunadi Adiwidjaja, Horst Günther,* and *Jürgen Voss*[*]

Oka and *Hara*[2] recently reported that they had prepared α-oxothioacyl chlorides *(2)* from methyl ketones *(1)* as well as from the α-chlorosulfenyl chlorides *(3)* formed in the same reaction. Proof of the structure of *(2)* was based merely on rather uninformative ^{1}H-NMR spectra, a C=S band at 1230 cm^{-1} (arising, however, from thionyl chloride) and a peak at $m/e = 184$ in the mass spectrum of the product mixture obtained from acetophenone *(1b)*, and its subsequent reaction to give the α-oxothioamide *(5b)*.—With exception of the oxamide derivative $R_2N—CO—CS—Cl$[3], compounds of type *(2)* have so far not been described in the literature and their existence is highly questionable (cf. [4]). We obtained other results, both on exact repetition as well as on slight modification of the procedure given in [2] (see Scheme 1).

Scheme 1.

Table 1. Primary and secondary products of the reaction of methyl ketones *(1)* with thionyl chloride.

[a] *(4a)*, *(4b)*, *(5)* and *(6)* gave correct elemental analyses. *(3c)*, *(3d)*, *(4c)*, and *(4d)* were not characterized; the mixtures obtained from *(1c)* and from *(1d)* on reaction with thionyl chloride were allowed to react directly with nucleophiles. [b] Determined NMR spectroscopically. [c] Referred to *(3a)*: [*(3a)* + *(4a)*] gave 85% *(5a)*. [d] From [*(3)* + *(4)*], referred to *(1)*. [e] M.p. (literature) 84–85 °C [2]. [f] From 1,4-diacetylbenzene. [g] From acetone. [h] From 1,3,5-triacetylbenzene. [i] λ_{max} (isooctane) = 392 (log ε = 1.68), 309 (225), 260 (3.39) s, 220 (3.94) nm; ν(CO) = 1705 cm^{-1}. [k] λ_{max} (isooctane) = 398 (log ε = 1.97), 338 (2.39), 251 (4.17), 218 (3.54) s; ν(CO) = 1665 cm^{-1}. [l] Referred to *(5a)*.

That a mixture of *(3)* and the trisulfane *(4)* is formed on reaction of *(1)* with thionyl chloride in pyridine follows from the spectroscopic data (Table 1), and especially from the ^{13}C-NMR spectra. *(4a)*, which crystallizes from the crude product at −20 °C in yields of up to 25%, was characterized, *inter alia*, by X-ray structure analysis (Fig. 1). *(4b)* could be isolated by column chromatography (SiO_2, CH_2Cl_2/CCl_4 (1:1), 5% yield).

Both the mixture [*(3)* + *(4)*] as well as pure *(4)* afford α-oxothioamides *(5)* almost quantitatively on reaction with dimethylamine. This reaction can also be carried out with other secondary aliphatic or araliphatic amines and *tert*-butylamine.

Reaction with methanol in the presence of bases affords the previously unknown α-oxothionic esters *(6)* (see Table 1), which represent a further type of esters containing adjacent C=O- and C=S-groups. In contrast to the blue α-thioxo esters R—CS—CO—OR, which tend to dimerize[5], the orange-colored isomers *(6)* are stable.

Surprisingly, we also obtained 85% 1,4-benzenebis(*N,N*-dimethyl-α-oxothioacetamide) *(5e)* from 1,4-diacetylbenzene, and even from the very complex mixtures which are formed on reaction of $SOCl_2$ with acetone or 1,3,5-triacetylbenzene we were able to isolate 5% *N,N,N',N'*-tetramethylmesoxaldithioamide *(5f)*[6] and 3% of the tristhioamide *(5g)*, respectively, in analytically pure form by column chromatography (see Table 1).—2,4,6-Tri-*tert*-butylacetophenone, on the other hand, does not give the corresponding thioamide.

The α-oxothioamides *(5)* can be sulfurized with the dimeric phosphane sulfide *(9)*[7] in good yields to the red to green-

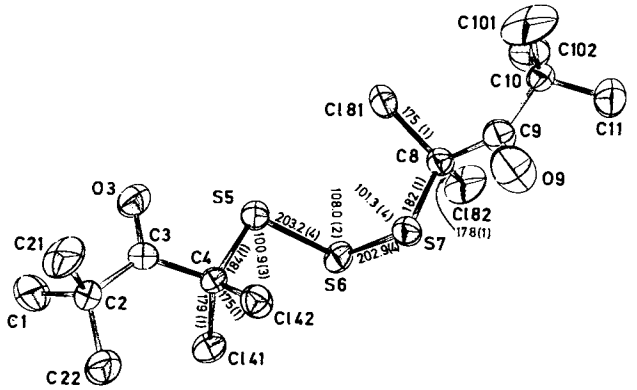
[**] Activated Thiocarboxylic Esters, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft (Project Vo 180/5) and the Fonds der Chemischen Industrie. We thank Chemischen Werken Hüls for supplying us with 1,3,5-triacetylbenzene.—Part 6: [1].

ish black α-thioxothioamides *(10)*, a class of substances of which only one example has hitherto been reported[8].

The mixture of *(3)* and *(4)*, which is also readily accessible in larger quantities, is thus a valuable starting material for products which presumably would be formed from the still unknown *(2)*.



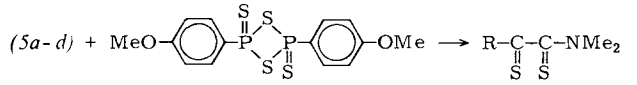


Fig. 1. Molecular structure of the trisulfane *(4a)* in the crystal (ORTEP diagram); vibration ellipsoids with 30% probability. – Space group $P2_12_12_1$, $a = 2655.6$, $b = 1173.5$, $c = 629.1 \pm 0.1$ pm, $Z = 4$, $\rho = 1.48$ g cm^{-3}. The intensities of the reflections were measured with an automated single crystal diffractometer Syntex P_{2_1} ($Cu_{K\alpha}$ radiation) and corrected in the usual way. The crystal structure was determined on the basis of 1584 symmetric independent structure amplitudes by the direct method using the computer program MULTAN and refined to $R = 6.8\%$ ($R_w = 6.1\%$).

On heating (distillation) [*(3)* + *(4)*] one obtains acyl chlorides *(7)* and *(8b)*, but not the pure α-chlorosulfenyl chlorides *(3)*, and under no circumstances *(2)*[2]. Recent reports of *Pizey* and *Symeonides*[9], in which only pivaloyl chloride *(7a)*, *i.e.* the thermolysis product of [*(3a)* + *(4a)*], could be obtained on reaction of pinacolone with thionyl chloride, are to

(9) *(10a-d)*

be seen in this light. The surprisingly uniform thermolysis, however, is preparatively not without interest, for it leads practically in one step from methyl ketones to acyl chlorides in acceptable yields.

Experimental

(5a): A solution of *(4a)* (4.32 g, 10 mmol) in ether (50 ml) is added dropwise at −80 °C to a stirred solution of $(CH_3)_2NH$ (4.5 g, 100 mmol) in ether (50 ml). After warming to room temperature, the reaction mixture is poured into 500 ml of water, neutralized with dil. HCl, the ether removed, the aqueous phase extracted with $CHCl_3$, the organic phases washed with water, dried with Na_2SO_4 and evaporated to dryness. Recrystallization of the residue from hexane affords pale yellow crystals of *(5a)*.—*(5b—d)* are synthesized analogously from [*(3)* + *(4)*].

(6a): The mixture [*(3a)* + *(4a)*] obtained from *(1a)* (5 g, 50 mmol) is dissolved in 100 ml methanol and treated dropwise with stirring at 0 °C with 27.7 ml (20.2 g = 200 mmol) of triethylamine. The mixture is diluted with 300 ml water, neutralized with dil. HCl, extracted with ether, washed with water, dried with Na_2SO_4 and evaporated down. The residue is dissolved in $CHCl_3$, filtered over a layer of SiO_2, and distilled in a vacuum; *(6a)* is an orange-yellow oil.

(10a): A solution of *(5a)* (5 g, 28.9 mmol) in toluene (60 ml) is treated with 6.5 g (15.9 mmol) of *(9)* and the mixture heated under reflux for 3 h. After cooling, the mixture is poured into 500 ml water, extracted with ether (3 × 150 ml), the combined ether phases washed twice with water, dried with Na_2SO_4, and evaporated down. The red, crystalline residue is dissolved in $CHCl_3$ and filtered over a layer of SiO_2. *(10a)* forms luminous carmine-red crystals.

Distillation of [*(3a)* + *(4a)*] at normal pressure affords *(7a)* in 50% yield [based on *(1a)*].—[*(3b)* + *(4b)*] gives a mixture of *(7b)* (36% yield) and *(8b)* (15% yield).

Acylated Ketenimines and Allenes from Oxazol-5(4*H*)-ones and Furan-2(3*H*)-ones[**]

By *Hans-Michael Berstermann, Raymond Harder, Hans-Wilhelm Winter*, and *Curt Wentrup*[*]

Flash vacuum pyrolysis of 4-substituted isoxazol-5(4*H*)-ones results in the elimination of CO_2 and formation of acetylenes, isocyanides, or related compounds[1]. Oxazol-5(2*H*)-ones thermally extrude CO_2 with formation of nitrile ylides[2a], whereas both CO_2- and CO-elimination from oxazol-5(4*H*)-ones is known[2b]. We now report that oxazol-5(4*H*)-ones *(1)* and *(3)* and furan-2(3*H*)-ones *(5)* extrude CO only. The reaction of *(5)* constitutes a useful synthesis of propadienyl ketones *(6)*.

(1) *(2)*

(a), $R^1 = R^2 = C_6H_5$; *(b)*, $R^1 = p\text{-}CH_3C_6H_4$, $R^2 = C_6H_5$; *(c)*, $R^1 = C_6H_5$, $R^2 = H$

The oxazol-5(4*H*)-ones *(1)* were prepared by standard methods[3] and subjected to flash pyrolysis[4] at 500—900 °C/*ca.* 10^{-4} torr. Over this temperature range, the only products,

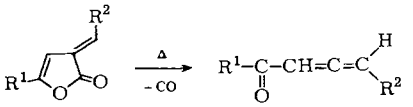
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie and abstracted in part from the diploma thesis of *H.-M. Berstermann*, Marburg 1979, and the doctoral thesis of *R. Harder*, Lausanne 1976.

formed virtually quantitatively (95—99% at 600 °C), were the *N*-alkylideneamides *(2)*.

This simple reaction offers certain advantages over the normal procedure for the preparation of aroylated imines *(2)*. For example, *(2b)* was prepared for the purpose of comparison in 20% yield from *p*-toluyl chloride and benzophenone imine; the latter is obtained in 80% yield from phenylmagnesium bromide and benzonitrile.

An analogous CO extrusion from the azlactones *(3)* would give rise to the ketenimines *(4)*. Indirect evidence for the formation of *(4a)* was obtained previously by pyrolysis of *(3a)*[5]. We have now secured direct IR spectroscopic evidence for the formation of *(4)* by pyrolysis of *(3)* at 600 °C/*ca.* 10^{-4}



(3) *(4)*

(a), R = C_6H_5; *(b)*, R = CH_3

torr in an apparatus equipped with a 10-cm quartz pyrolysis tube and collecting the products on a turnable KBr disc cooled to *ca.* −196 °C. On infrared monitoring of the pyrolyses of *(3a)* and *(3b)*, sharp absorptions ascribed to *(4)* were observed at 2019 cm^{-1}, the region typical[6] for ketenimines.

The above results prompted an examination of the pyrolysis of 3-arylmethylidenefuran-2(3*H*)-ones *(5)* which, by analogy, should yield the propadienyl ketones *(6)*. The compounds *(5)* (see Table) are easily prepared by condensation of the appropriate 5-substituted furan-2(3*H*)-one with aromatic aldehydes[7], and were shown by ^{1}H-NMR spectroscopy to exist in the *E*-form[8]. The compounds *(5)* were pyrolyzed at 700 °C/*ca.* 10^{-4} torr, the products isolated on a cold

(5) *(6)*

finger cooled with liquid N_2, and then purified by layer chromatography on SiO_2. The allenes *(6)* were characterized by their IR absorptions (see Table 1), ^{1}H-NMR and mass spectra, and by ^{13}C-NMR resonances near $\delta = 215$ ppm (=C=), and near $\delta = 190$ (CO). All the allenes *(6)* are unstable at room temperature, the furoylallenes *(6c)* and *(6f)* so much so that they could not be isolated in substance.

Compound *(6a)* was the only member of this series previously known; it had been obtained[9] together with an isomeric alkyne. In our work, no evidence (IR spectroscopy) has been obtained for the production of alkynes isomeric with *(6a—f)*. This, together with the sensitivity of compounds *(6)*, testifies to the mildness of flash vacuum pyrolysis as a preparative method.

Experimental

(2b): *(1b)* [m.p. 135 °C] was prepared in 69% yield from benzilic acid and *p*-tolunitrile adapting the method reported[3] for *(1a)*. The pyrolysis of *(1b)* (250 mg) at 600 °C/10^{-4} torr (25 × 2 cm quartz pyrolysis tube) gave 200 mg (95%) of *(2b)*, m.p. 152 °C after recrystallization from EtOH. ^{1}H-NMR (CCl_4): $\delta = 2.4$ (s, 3H), 7.1 (d, $J = 8$ Hz, 2H), 7.2—7.6 (m, 10H), 7.7 (d, $J = 8$ Hz, 2H) ppm; IR (KBr): 1660 (C=O), 1630 (C=N) cm^{-1}.

(6): *(5a)* (500 mg) was pyrolyzed at 700 °C/10^{-4} torr by sublimation from a flask held at 145—150 °C. The pyrolyzate was collected on a cold finger at −196 °C, rapidly dissolved in $CHCl_3$, and chromatographed on a 20 cm SiO_2 plate (0.5 mm thickness), eluting with toluene. The compound having $R_f \approx 0.1$ was extracted with acetone and identified as *(6a)* (see Table 1).—*(6b, d, e)* were prepared in a similar manner and isolated by layer chromatography; *(6c, f)* dimerized under these conditions.

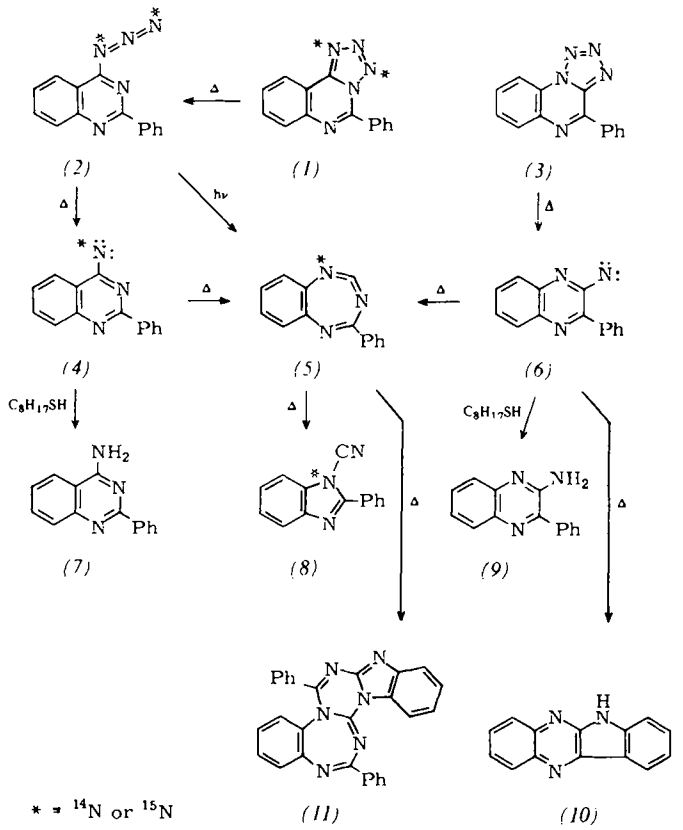
Cyclic Carbodiimides in Nitrene Rearrangements[**]



By *Curt Wentrup, Célestin Thétaz, Enrico Tagliaferri, Hans Jörg Lindner, Brigitte Kitschke, Hans-Wilhelm Winter,* and *Hans Peter Reisenauer*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

In the course of our studies on the rearrangements of heterocyclic nitrenes it became necessary to postulate cyclic carbodiimides as key intermediates in some reactions[2]. However, no such intermediate had ever been directly observed. We now wish to report conclusive chemical evidence as well as the direct spectroscopic observation of a cyclic carbodiimide in reactions of this type.

The tetrazolo[1.5-*c*]quinazoline *(1)* exists exclusively as a tetrazole in the solid state[3], but sublimation of *(1)* at 100 °C/10^{-4} torr and subsequent condensation of the vapor on a KBr disc at −196 °C afforded the azide *(2)*, characterized by intense IR absorptions at 2150, 2120, 1620, 1570, and 1370 cm^{-1}. The solid azide was transformed back into the tetrazole *(1)* on warming to *ca.* −40 °C. It can thus be asserted that a gas-phase thermolysis of *(1)* will give initially the azide *(2)*[4].

Flash vacuum thermolysis of *(1)* at temperatures above 300 °C/10^{-3} torr gave 2-phenylbenzimidazole-1-carbonitrile *(8)* in quantitative yield[5]. The same product was obtained in 92% yield together with 8% of indolo[2,3-*b*]quinoxaline[5] *(10)* by thermolysis of tetrazolo[1,5-*a*]quinoxaline *(3)* at 380 °C/10^{-3} torr. In the case of *(3)*, only weak bands due to the corresponding azide were observable by IR spectroscopy at −196 °C, following thermolyses near the temperature where the reaction *(3)*→*(8)* takes place (300–400 °C).

Ring contraction to *(8)* also occurred by thermolysis of either *(1)* or *(3)* in benzene solution in a sealed tube at 160–180 °C (59 and 88%, respectively). In addition, the solution thermolyses of *(1)* and *(3)* in various solvents always afforded a yellow dimer in variable yield (*e.g.* 57% from *(1)* in cyclohexane at 180 °C for 72 h; 25% from *(3)* in mesitylene at 165 °C for 240 h). The infrared, ^{13}C-NMR, and mass spectra of the dimers obtained from *(1)* and *(3)* were identical, and the structure *(11)*, possessing the novel imidazo[1,2-*a*][1,3,5]triazino[6,5-*a*][1,3,5]triazepine ring system, was determined by X-ray crystallography[6]. The solution thermolyses also afforded the amines *(7)* and *(9)*, respectively, which are the products expected from hydrogen abstraction by the triplet ground state nitrenes *(4)* and *(6)*. The best yields of amines were obtained by decomposition of *(1)* and *(3)* in a 1:1 mixture of octanethiol and mesitylene at 150 °C for 16 h, giving 10% of *(7)*, and 20% of *(9)*, respectively. It was established that no *(9)* was formed from *(1)*, and no *(7)* from *(3)*. An interconversion of the nitrenes *(4)* and *(6)* is therefore excluded.

When *(1)* was labeled with ^{15}N (90 atom-% ^{15}N[3]), a subsequent flash vacuum thermolysis gave *(8) labeled exclusively in the ring*, as shown by hydrolysis to 1-[^{15}N]-2-phenylbenzimidazole. A direct ring contraction *(4)*→*(8)* is therefore excluded[7].

Since *(1)* did not give any *(9)* or *(10)*, the reaction *(4)*→*(6)*→*(8)* is also excluded. The only reasonable precursor for *(8)* and *(11)* is therefore the cyclic carbodiimide *(5)*. When starting from the quinoxaline *(3)*, a direct ring contraction *(6)*→*(8)* cannot be excluded, but since the same dimer *(11)* is obtained, the nitrene *(6)* must isomerize at least in part to *(5)*. The presence of the triazepine ring in *(11)* indicates that this is a rearrangement product of an initially formed carbodiimide dimer.

Proof for the formation of the cyclic carbodiimide *(5)* was obtained by photolysis of the azide *(2)*, matrix-isolated in Ar

at 10 K [$\lambda > 375$ nm]. The azide absorptions disappeared rapidly, and were replaced by intense carbodiimide absorptions at 2010 and 1610 cm^{-1}. The carbodiimide was stable at 10 K, but the bands disappeared irreversibly on warming of the matrix.

The ring expansion of other arylnitrenes and -carbenes has been described elsewhere[2, 8]. However, this is the first time that a common intermediate—the seven-membered ring carbodiimide *(5)*—has been shown to be involved in the gas phase, in solution, and in a matrix.

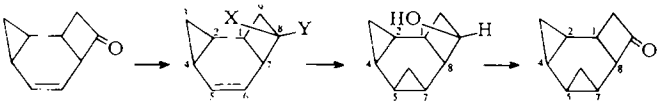
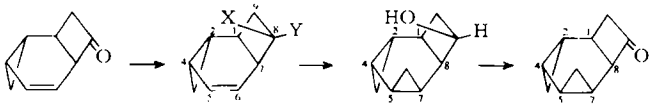
cis-/trans-Tris-[2.1.1]-σ-homobenzenes; Synthesis and Stereochemistry of $[_\sigma 2 + _\sigma 2 + _\sigma 2]$-Cycloreversions[**]



By *Horst Prinzbach, Hans-Peter Schal, Dieter Hunkler*, and *Hans Fritz*[*]

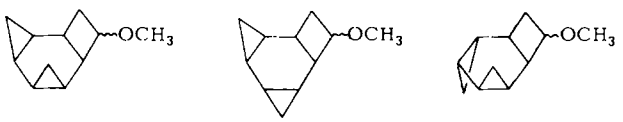
Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday



The *cis-/trans*-isomers of tris-[1.1.1]-σ-homobenzenes differ in their tendency to undergo $[_\sigma 2 + _\sigma 2 + _\sigma 2]$ cycloreversions. This—preparatively exploitable—differentiation is determined stereoelectronically and should increasingly alter in favor of the *trans* compounds in transition states with more than nine ring members. Thus, for the tris-[2.1.1]-, tris-[2.2.1]- and tris-[2.2.2]-skeletons[1] it could be expected, with overall increasing activation barriers, that the *trans*-compounds also increasingly undergo $[_\sigma 2 + _\sigma 2 + _\sigma 2]$ cycloreversions[2]. However, it was questionable whether "trishomoaromatic" stabilization in the stereoisomeric ten-, eleven-, and twelve-membered transition states would be sufficient to favor the "internal" cycloreversion process over the "external" competing reactions.

For our initial thermolysis studies on tris-[2.1.1] systems we synthesized the *cis-/trans*-isomeric tris-[2.1.1]-ketones *(5)* and *(10)* from the bis-[2.1]-ketones *(1)* and *(6)*[3], respectively. The CO function in *(1)* and *(6)* should sterically facilitate homologization and retard the Cope reaction typical for the corresponding 1,4,7-cyclodecatriene in the expected thermolysis products *(12)* and *(14)*. The ketone *(5)* is also of interest as potential precursor for the still unknown *cis*-tris-[1.1.1] skeletal unit.

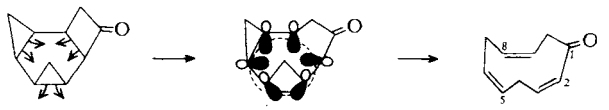
The cyclopropanation of *(1)* and *(6)* meets with the usual difficulties[4]. Satisfactory—though not always completely reproducible—results could only be achieved after reduction to the respective *endo*-alcohols *(2)* and *(7)*. Reaction of *(1)* with $NaBH_4$ or diisobutylaluminum hydride (DIBAH) afforded *(2)* and *(3)* in the ratio 6:1 and 10:1, respectively (total yield



(1) *(2)*, X = OH, Y = H; *(3)*, X = H, Y = OH *(4)* *(5)*

(6) *(7)*, X = OH, Y = H; *(8)*, X = H, Y = OH *(9)* *(10)*

of 94% in each case). Almost pure *(7)* [< 5% *(8)*, total *ca.* 90%] was obtained on reaction of *(6)* with $NaBH_4$. On subjecting *(2)* to a modified Conia procedure[5], a mixture of alcohols and their methyl ethers is obtained in *ca.* 50—60% yield which have to be separated by preparative layer chromatography (CH_2Cl_2/SiO_2). The main product (40%) is the *endo*-[2.1.1]-alcohol *(4)*; the methyl ethers *(4a)* and *(4b)* could also be identified. *(7)* is cyclopropanated in comparable yield (50—60%) on the side of the OH-group to give *(9)* and the side product *(4c)*. After oxidation with pyridinium chlorochromate (CH_2Cl_2, 20 °C), the colorless oily ketones *(5)* and *(10)* (^{1}H-NMR data, see Table 1) are each obtained in *ca.* 60% yield.



(4a) *(4b)* *(4c)*

The *cis*-ketone *(5)* is stable in CCl_4 solution up to *ca.* 120 °C; at higher temperatures ($t_{1/2}$(150 °C) = 40 min) it is converted quantitatively (TLC, GC, ^{1}H-NMR) into the conformationally flexible *Z,Z,Z*-2,5,8-cyclodecatrien-1-one *(12)*. This uniform behavior is also observed on gas phase pyrolysis (350 °C; quartz tube)[6] (no products such as ketenes or cyclooctatriene[2] resulting from the cleavage of "external" bonds). Calculations based on kinetic data measured (^{1}H-NMR) between 135 and 160 °C in degassed samples and evaluated according to the first order rate law gave the parameters $E_a = 140 \pm 2$ kJ mol^{-1} ($\log A = 13.8$) and $\Delta H^{\neq} = 137 \pm 2$ kJ mol^{-1} ($\Delta S^{\neq} = 8 \pm 3$ JK^{-1})[7]. The unifor-

(5) (11) (12)

mity and ease of the conversion *(5)*→*(12)* leave no doubt of a cooperative orbital involvement [*(11)*]; the difference in the kinetic data compared to those estimated for the *cis*-tris-[1.1.1] skeletal moiety ($E_a = 100$—126 kJ·mol^{-1})[8a] reflects not only the reduced H/H transannular strain in the educt but also the lower bent-bond character of the four-membered ring.

(10) is kinetically very much more stable than *(5)*: in solution (CCl_4) there is still no recognizable change (^{1}H-NMR) after 2 h at 200 °C. At 300 °C (gas phase) and 50% conversion (GC/MS and ^{1}H-NMR analysis), *Z,E,E*-trienone *(14)* and *(12)* (88% and 5%, respectively) are formed, together with at least two further trace components which do not occur in the thermolysis of *(5)*[9]. At 350 °C and 75% conversion the ratio *(14)*:*(12)* changes to 77:8 (it is still unclear whether *(14)* isomerizes to *(12)*). Since the two remaining 2,5,8-cyclodecatrien-1-ones arising from "forbidden" routes should be more

(10) (13) (14)

stable than *(14)* opening of one bond disrotatorily and of two bonds conrotatorily in *(10)* is most likely exclusive rather than only highly selective. The *Z,E,E*-configuration of *(14)*, which is unusual in ten-membered rings, leads to high steric strain and conformational hindrance (see Table 1). That 5-H/9-H shows a high chemical shift (Table 1) in spite of mutual compression, may be due to anisotropic influences, as are evident in the conformation formulated here. Under these steric conditions the "trishomoaromatic" transition state *(13)* (C-2/C-4 disrotatory, C-1/C8 and C-5/C7 conrotatory) has preference. For this variant of the "symmetry allowed" $[_\omega 2 + _\sigma 2 + _\sigma 2]$ cycloreversion a very efficient overlapping between the six potential sp^2 centers can actually be seen in the model—although later on the reaction coordinate than in the case of *(5)*→*(12)*. *(10)* isomerizes more readily than the *trans*-tris-[1.1.1] skeletal moiety studied by *de Meijere et al.*[8b]; this observation is in agreement with the prediction based on a concerted process. However, the threefold disrotation formulated for *(10)*[8] and other *trans*-tris-[1.1.1] skeletal units[10] is questionable. Together with *(5)*→*(12)*, the transformation *(10)*→*(14)* can be regarded as a particularly impressive example for the preference of cooperative processes in tris-σ-homobenzene skeletons. This preference goes so far that even cyclobutane rings participate in trishomoconjugated systems[11]. Hence the ketones *(5)* and *(10)* or their derivatives, *e.g.* the alcohols *(4)* and *(9)* are potential precursors (σ route) for the hitherto undetectable ten-membered trishomotropylium ions.

Ligand-Property Control in the Nickel(0)/Butadiene/P-Ligand Catalytic System: Dominance of "Steric" Factors in the Control of Oligomer Distribution[**]

By *Paul Heimbach, Joachim Kluth, Hartmut Schenkluhn,* and *Bruno Weimann*[*]

The control of isomeric distribution in the cyclooligomerization of butadiene on nickel-ligand catalysts can be attributed to several mutually independent ligand-association processes[1]. This finding permits the study of the control of individual association processes by ligand properties and hence comparison of the results obtained with various model complexes. We illustrate such an analysis in the present report of control of the degree of oligomerization (details of the control of cyclodimer distribution will be found in [2]).

Table 1. Experimental data on ligand-property control in the nickel(0)/P-ligand/butadiene (1:1:170) catalytic system, $[Ni]_0 = 34$ mmol/l (40 mmol/l at $-78\,^{\circ}C$); $T = 60\,^{\circ}C$, $t = 48$ h, butadiene conversion >95%; see [1a] for experimental procedure. *c*-DIM = cyclodimer, *c*-TRIM = cyclotrimer; $Z = 100 \times c\text{-TRIM}/(c\text{-DIM} + c\text{-TRIM})$.

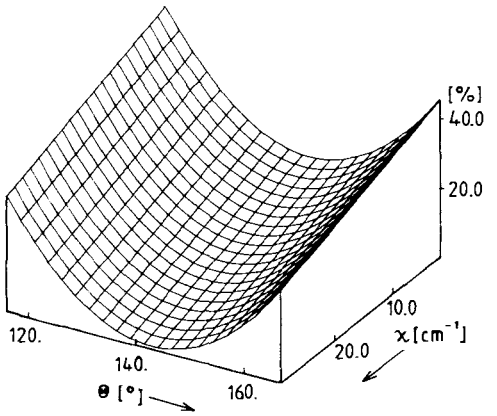
[a] Remainder: unknown and open-chain butadiene oligomers. [b] Tol = tolyl. [c] Biph = biphenylyl.

In order to obtain quantitative information about the (ligand-property dependent) control of the degree of oligomerization (see Table 1) at constant $[L]_0/[Ni]_0$ ratio of unity, the amount of trimer was examined by multilinear regression analysis[3]. The ligand properties were characterized by the "steric" parameter θ and the "electronic" parameter χ[4]. Figure 1 reproduces the correlation found. Each ligand $L_i(\theta_i, \chi_i)$ is characterized by a point in the xy plane; the amount of trimer Z is plotted in the z direction. According to this analysis the influence of the "steric" parameter θ predominates:



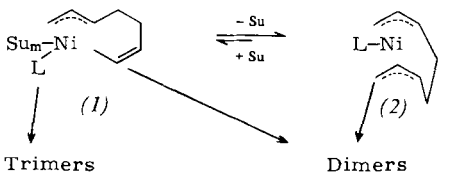


Fig. 1. Surface representation of the amount of cyclododecatriene in the butadiene cyclooligomers as function of "electronic" χ and "steric" θ ligand parameters

$$Z_{calc} = 946.8 - 0.67\,\chi - 12.968\,\theta + 0.454 \cdot 10^{-1}\,\theta^2$$

$S = 5.47$; $MR = 0.9606$; σ (estimated) = 4.5; extent of control 25% "electronic", 75% "steric".

75% of the overall control induced by the chosen P-ligands is "steric" in character. Thus both small and large cone angles θ of the P-ligands favor cyclotrimerization of butadiene.

According to studies on ligand concentration control maps of 11 representative P-ligands[1,5], an octadienediyl(ligand)nickel(II) complex is responsible for control of the degree of oligomerization at a $[L]_0/[Ni]_0$ ratio of unity at constant nickel concentration of 34 mmol/l. Depending upon the ligand, the π,σ-bisallyl form *(1)* (L = tricyclohexylphosphane[6a]) or the π,π-bisallyl form *(2)* (L = triphenylphosphane[6b], tri(2-biphenylyl) phosphite[6c]) is preferentially formed. Only the π,σ form can associate with a further substrate molecule and react to form butadiene trimers.

Su = Butadiene, L = P–Ligand, m = 0 or 1

Increasing donor character (decreasing χ value) or bulkiness of the P-ligand ($\theta > 150°$) favors formation of *(1)*. Thus trimer formation should increase with such ligands. Moreover, it should also be considered that for steric reasons association of the substrate to form *(1)* is all the easier the smaller the cone angle of the P-ligand ($\theta < 140°$); association should be more difficult at large angles.

There are accordingly two opposing effects to be expected for the control of the degree of cyclooligomerization, in agreement with the minimum found in the proportion of steric control. The electronic ligand effect, however, is uniform and probably essentially reflects the $\pi,\sigma/\pi,\pi$-equilibrium of the precursor complexes (thermodynamic selectivity).

Ligand-Property Control in the Nickel(0)/Butadiene/P-Ligand Catalytic System: "Electronic" Factors in the Control of Cyclodimer Distribution[**]

By *Paul Heimbach, Joachim Kluth, Hartmut Schenkluhn*, and *Bruno Weimann*[*]

In the cyclooligomerization of butadiene on nickel-ligand catalysts the ligand-property control of the degree of oligomerization at a $[L]_0/[Ni]_0$ ratio of unity is primarily of a "steric" nature and can be interpreted by corresponding association processes[1]. We now report an analysis of the ligand-property control of cyclodimer distribution.

Under the conditions given in Table 1 the dimers vinylcyclohexene (VCH) and 1,5-cyclooctadiene (COD) predominate; Figure 1 shows the result of multilinear regression analysis[2]. (For a definition of the "electronic" and "steric" parameters χ and θ, see [1,3].) A purely "electronic" effect is found for the amount of COD in the control region

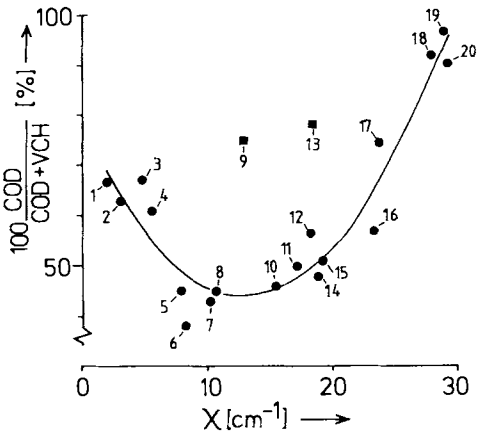

Fig. 1. Dimer distribution in the cyclooligomerization of butadiene on nickel-ligand catalysts as function of the "electronic" ligand parameter χ. (See Table 1 for numbers of experiments.)

$Z_{calc} = 79.3 - 5.43\,\chi + 0.206\,\chi^2$ (without nos. 9 and 13)

$S = 5.41$; $MR = 0.9589$; σ (estimated) $= 4.0$; extent of control: 100% "electronic" (*S*, *MR*, σ, see [1]).

Table 1. Experimental data on ligand-property control in the system nickel(0)/P-ligand/butadiene = 1:1:170, $[Ni]_0 = 34$ mmol/l, $T = 60$ °C, $t = 48$ h, butadiene conversion >95%; see [5] for experimental procedure. VCH = vinylcyclohexene, COD = 1,5-cyclooctadiene; $Z = 100 \times COD/(VCH + COD)$. The cyclodimer divinylcyclobutane, which is likewise formed, rearranges during the catalytic process to COD and VCH and can no longer be detected after 48 h[5]. The values in parentheses were not considered in the regression analysis.

[**] Control of Metal-Catalyzed Reactions, Part 11.—Part 10: [1].

given. The correlative relation can be represented by a simple parabola (the ligands PPh_3 and PPh_2OPh are exceptions).

Octadienediyl(ligand)nickel(II) complexes are assumed as crucial catalytic intermediates for the control of the dimer distribution (see [1,4]). As expected, the pronounced steric influence of the P-ligands found in trimer formation is no longer operative in the control of dimer formation. If the ratio of cyclodimers COD and VCH were determined solely by the $\pi,\sigma/\pi,\pi$-equilibrium of the complexes *(1)* and *(2)* (thermo-

dynamic selectivity[5]), then a similar picture would result for the contribution of electronic control as for control of the degree of oligomerization (see [1]). While increasing donor character of the P-ligands (decreasing χ value) uniformly favors formation of trimers, the amount of COD in the dimeric products goes through a pronounced minimum. Hence the $\pi,\sigma/\pi,\pi$-equilibration is insufficient to explain the relationship found: a further opposing independent effect must also be considered.

Such an effect would be a ligand-induced relative activation or inhibition of the product-forming reaction step to give the dimers (kinetic selectivity[5]). In that case, the overall reaction rate of dimer formation $(\bar{v}_{max})_{DIM}$ should correlate with the corresponding product selectivity owing to the relative activation or inhibition. We therefore plotted $\log((\bar{v}_{max})_{DIM}/[Ni]_0)$[6] *versus* the product selectivity

Su = Butadiene, L = P–Ligand, m = 0 or 1

($\kappa = \log(\text{COD/VCH})$) at $[L]_0/[Ni]_0 = 1$ (Fig. 2) for a series of representative P-ligands. Remarkably, a linear relationship is found.

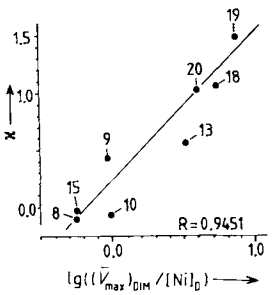

Fig. 2. Reactivity-selectivity diagram for the cyclodimers in cyclooligomerization of butadiene on nickel-ligand catalysts. (See Table 1 for numbers of experiments.)

Judging by the kinetic results (positive slope of the correlation lines in the reactivity/selectivity diagram[7]) the ligand control under discussion can be orbital-controlled. Further evidence for FMO control is seen in the nickel catalyzed cyclodimerization of piperylene to four-membered ring derivatives (symmetry-controlled metalla-ring closures)[8] and in the nickel-catalyzed 2:1 cooligomerization of butadiene with perturbed monoenes[9], in which the regiospecificity is determined *via* the electronic requirements in the LUMO of the cosubstrate (coefficient control).

$P_4(N\text{-}i\text{-}C_3H_7)_6$, a P_4X_6 Molecule with and without Adamantane Structure[**]

By *Otto J. Scherer, Kurt Andres, Carl Krüger, Yi-Hung Tsay,* and *Gotthelf Wolmerhäuser*[*]

Replacement of the edges of a P_4 tetrahedron by bridging groups X (O, NCH_3, *etc.*) formally affords P_4X_6 molecules which, without exception, have the adamantane-type structure[1]. The structural alternative of a P_4 rectangle doubly bridged on its short sides and singly bridged on its long sides has now been realized for the first time in the multidentate cage molecule *(2)* ("double decker"), whose design principle corresponds to that of a cryptand[2]. *(2)* was synthesized[3] by thermolysis of the diazadiphosphetidine *(1)*:

The novel tricyclic compound *(2)* forms colorless crystals which are readily soluble in benzene, ether, and dichloromethane, but sparingly soluble in pentane[4]. The ^{1}H-NMR spectrum shows the two groups of signals in the area ratio 2:1 expected for a symmetric structure [CD_2Cl_2, TMS int.; $\delta CH_3 = 1.19$ (d), $^3J(HCCH) = 6.8$ Hz (bridge), $\delta CH_3 = 1.20$ (d), $^3J(HCCH) = 6.4$ Hz (four-membered ring), $\delta CH =$ 3.82—4.22 (m)]. The singlet occurring at $\delta = 145.8$ in the $^{31}P\{^1H\}$-NMR spectrum (CD_2Cl_2, 85% H_3PO_4 ext.) is shifted downfield compared to *cis*-configurated diazadiphosphetidine derivatives (*P*-alkyl or NR_2 substituents)[5]. Compound *(2)* has a crystallographic center of symmetry (Fig. 1). The P atoms and the N atoms N1, N*1, N2, N*2 form rectangles perpendicular to each other with edges of length 2.58(1) and 3.13(1) Å (P-rectangle) and 2.23(1) and 3.07(2) Å (N-rectangle), respectively. The two $P_2(NR)_2$ four-membered rings are almost planar[6].

If *(2)* is heated in a sealed tube for several days at 156—158 °C (dry cupboard), it is converted quantitatively into the

BOOK REVIEWS

Chemische Struktur und biologische Aktivität von Wirkstoffen. Methoden der Quantitativen Struktur-Wirkung-Analyse. By *J. K. Seydel* and *K.-J. Schaper*. Verlag Chemie, Weinheim 1979. xi, 359 pages, bound, DM 118.00.

The book justifies the claim, formulated in the preface, of being an introduction to methods and possibilities in the complex field of quantitative structure-activity analysis.

A number of books professing a similar aim have appeared in the last few years, but this is the first work of this type in German and it has several advantages over its English-language predecessors. The whole subject is treated very comprehensively. The material includes an accurate description of experimental physicochemical and biological determinations,
explanatory definitions of the parameters used, with a collection of constants for more than 700 substituents in the Appendix,
an account of the historical development of the fundamental theories,
the derivation of the most important semiquantitative processes (Topliss scheme, *Darvas'* simplex method, *Bustard's* Fibonacci process),
explanations of the most common methods with statements of theoretical principles (Hansch analysis, Free-Wilson process); these are made particularly clear by numerous figures and examples,
a short outline of more recent processes (cluster, discriminants, and factor analysis, pattern recognition), with valuable hints on the formulation of appropriate computer programs,
and finally, many published examples of structure-activity relationships.

The advantages and disadvantages of the described techniques, and also their limitations, are looked at critically, in welcome contrast to the euphoria often encountered in American publications.

Study of the comprehensive review of published quantitative structure-activity analyses, which has been drawn up with remarkable industry, is greatly facilitated by the tabular presentation arranged by biological effects.

The book contains one of the most comprehensive literature collections for this field; moreover, in contrast to previous compilations, the European literature has been duly taken into account.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0707-0572 $ 02.50/0

The following critical observations may be made: In view of the confused mass of abbreviations already used in the technical literature, the introduction of new abbreviations (*e.g.* QSWB = *Q*uantitative *S*truktur-*W*irkung-*B*eziehung, for QSAR = *Q*uantitative *S*tructure *A*ctivity *R*elationship) is regrettable. The balance between the chapters does not always appear appropriate and the relevance of the described procedures for the drug chemist engaged in syntheses does not always appear to be correctly evaluated. This may be due to the fact that the book also gives an account of the relevant investigations of the Institut für Experimentelle Biologie und Medizin at Borstel, where both authors are working.

In order to promote the practical use of this book and its employment as a valuable reference work, the subject index, at the moment comprising only seven pages, should be made uniform (*e.g.* not all abbreviations are included) and substantially expanded (*e.g.* the classes of substance investigated are of interest to the chemist; so far only benzylpyridinium ions, carboxylic acid hydrazides, phenylguanines, sulfonamides, and sulfonylureas are mentioned).

The book can be recommended as required reading and/or an interesting work to all those active in the complex interdisciplinary field of research on active principles—whether drugs or plant-protection agents.

Eike Möller [NB 511 IE]

Radiotracers in Agricultural Chemistry. By *M. F. L'Annunziata.* Academic Press, New York 1979. 536 pages, bound, $ 62.00.

The special value of this book lies in its capacity as a textbook and practical manual giving both students and practical workers primarily an introduction to a broad working domain ranging from nuclear radiation and isotope decay to scintillator techniques. No more than a good third of the contents relates to problems of agricultural chemistry and to their solution by the application of radioactive-isotope techniques; two-thirds of the processes and data given could also be in a laboratory manual for radioactive procedures. To this extent, the title is unfortunately somewhat misleading.

The up-to-date nature of the literature references attached to each section must be emphasized. If, therefore, in spite of the comprehensive account given, the reader feels the need for further information, the way toward more intensive study is clearly indicated.

In the section on special problems and techniques of agricultural chemistry the emphasis is on the isolation and localization of a radioactively labeled element or its compounds. The main part—studies on soils, plants, and animals—is of somewhat smaller extent but is supplemented by about 250 literature references largely of fairly recent date. In spite of its restricted compass, the third part, which deals with autoradiography, is packed with information and contains a teaching experiment to be followed by the reader.

The Appendix (about 20% of the book) contains, *inter alia,* decay data for the most common radionuclides and references to statistical criteria of the measurement processes and to dangers, procedures for characterizing labeled substances, permissible limiting concentrations of radionuclides, and regulations for the latter's discharge into water or soil.

The author's aim, to write a classroom laboratory manual on radiotracer techniques in agricultural chemistry, has undoubtedly been achieved, but cannot be deduced from the title of the book. For the experienced practical laboratory worker many common techniques, such as Soxhlet extraction, are perhaps explained in too much detail. Surprisingly enough, the standard German-language work (*Linser* and *Kaindl:* Isotope in der Landwirtschaft) does not appear to the author to be worth mentioning.

Albert Wünsch [NB 512 IE]

German-Jewish Pioneers in Science 1900—1933. By *D. Nachmansohn.* Springer-Verlag, Berlin 1979. xx, 388 pages, bound, DM 60.00.

When in 1933 more than a thousand scientists of Jewish origin had to escape from Germany, the country lost within a few years the leading position that it had formerly been able to claim in many disciplines. This applies particularly to atomic physics, chemistry, and biochemistry, the three fields to which *David Nachmansohn* confines himself when he investigates the contribution of German Jews to modern natural science on the basis of the biographies of some important German-Jewish scientists.

An introductory chapter is devoted to the emancipation of the German Jews in the 19th century. Physics is dealt with next. Here among the Jews who had been in important positions prior to 1933, apart from *Einstein* who is deliberately excluded, one may mention in particular *Max Born, James Franck* and *Gustav Hertz,* other examples are *Otto Stern, Lise Meitner,* and *Wolfgang Pauli,* who are considered only briefly. This chapter includes little that cannot be found in the exhaustive accounts by *Armin Hermann* (Die Jahrhundertwissenschaft (1977); Die neue Physik (1979)); its real importance is that it shows how unimportant for the German scientists of the 'twenties' was the question of racial origin. It was—and this is *Nachmansohn*'s thesis—the cooperation between the Jewish and the non-Jewish scientists, almost unmarred by anti-Semitic resentment, that led to the brilliant triumphs of physics during that period.

As a biochemist, the author (who was forced to emigrate to the United States *via* France in 1933) is particularly well acquainted with the history of his own field. Chemistry and biochemistry in the early 20th century are treated exhaustively, the book being devoted mainly to the work of the Kaiser Wilhelm Institute in Berlin-Dahlem. This chapter, which with 176 pages makes up almost half the book, will prove of the greatest value for the chemist interested in the more recent history of his subject, on the one hand because of the profound knowledge of the field by the author who was an associate of *Otto Meyerhof* in Berlin until 1933, and on the other hand because of his many personal reminiscences of the scientists about whom he writes.

At the center of his considerations are the biographies of *Haber, Willstätter, Warburg, Meyerhof, Neuberg,* and *Embden.* Another, shorter chapter is devoted to representatives of the younger generation, born around 1900, who were generally only at the beginning of their careers when they were forced to emigrate: *Krebs, Ochoa, Schoenheimer,* and *Chain. Nachmansohn* has particularly studied the question of the attitude of German scientists of Jewish origin towards Judaism, and demonstrates clearly that in most cases their origin had played a minor role: they thought and felt as Germans and had substantially departed from the religious tradition of Judaism; they had often become Christians. Only the anti-Semitism of the 'twenties' and the nazi persecution made many of them turn back to Zionism, but even then Germany remained their home from which they could part only with difficulty.

What is particularly remarkable is the author's championship of the German scientists who did not emigrate in 1933. Just as he understands *Fritz Haber*'s participation in the production of poison gas in the first World War, he also defends

Werner Heisenberg against the reproach that he should have emigrated or have resisted instead of remaining in Germany and cooperating in the construction of an atomic reactor. The art of not judging human and political behavior from the point of view of the present but of understanding it in the context of its own time, which *Nachmansohn* always attempts, is an outstanding example of objective historical scholarship.

The book is directed at a wide readership, and the scientific background necessary for understanding it is explained with much didactic skill. It would be highly desirable for a German translation to appear in the near future. Many inadvertent errors could thus easily be eliminated. Most regrettably, there is no name index and only a few names appear in the subject index. More factual errors are contained particularly in the chapter on atomic physics: *Rathenau* was murdered not in July 1922 but on 24th June 1922 (p. 19). The planetary model of the atom was not a contradiction of classical Newtonian mechanics, but of Maxwell's electrodynamics (p. 35). *Johann Jakob Balmer* was not Swedish but Swiss (p. 36). *Otto Stern*'s birthplace is called Sorau (not Sohrau) and is not in Upper Silesia but in Niederlausitz (p. 39). *Sommerfeld*'s first name was not *Arthur* but *Arnold* (p. 43). *Einstein* did not die in 1956 but in 1955 (p. 78). *Strassmann* did not receive the Nobel prize (p. 136).

Physicochemical Principles and Applications of Supercritical Fluid Chromatography (SFC)

New analytical methods (19)

By Ulrich van Wasen, Issam Swaid, and Gerhard M. Schneider[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

In supercritical fluid chromatography (SFC) compressed gases in the region of their critical temperature are used as mobile phases. SFC has important advantages over gas chromatography (GC) for the separation of low-volatile or thermally unstable substances. Like high pressure liquid chromatography (HPLC) and gel chromatography, it is used for various special applications and preparative separations, *e.g.* in the petroleum industry and in the separation of oligomers. SFC is of great interest in fundamental research on fluid extraction and for the determination of the physicochemical properties of fluid systems. In this contribution the most important physicochemical, methodological, and instrumental principles of SFC are summarized; characteristic physicochemical applications are the determination of capacity ratios, partition coefficients, partial molar volumes, interaction second virial coefficients, and diffusion coefficients.

1. Introduction

Supercritical fluid chromatography (SFC) uses compressed gases in the critical temperature range as mobile phases. This relatively new chromatographic technique supplements well-known techniques such as gas chromatography (GC) and high pressure liquid chromatography (HPLC), and makes possible, *e.g.*, the analytical and preparative separation of thermally unstable and/or low-volatile compounds.

Klesper, Corwin, and *Turner*[1] are considered to be the discoverers of this technique: in 1962 they proposed the use of supercritical chlorofluoromethanes for the separation of some derivatives of porphyrins. Further development and extension of the method, however, were slower than might have been expected, considering its advantages. The reason for this delay could be, *inter alia*

- the rapid development of other methods, especially HPLC, on which the efforts of analytical chemists and instrument manufacturers were concentrated,
- the special operational parameters, widely unexplored and unfamiliar to chemists, as well as the technical difficulties and the high cost of SFC equipment which are, however, comparable with those of modern HPLC, as well as
- the advanced physicochemical knowledge that is necessary for an understanding of the theoretical and experimental principles of SFC.

In the mean time, SFC has found a place among chromatographic techniques, as may be seen from the increasing number of publications in this field, *e.g.* on applications in preparative separation, in the petroleum industry, and for the determination of physicochemical properties. This development was assisted by the astonishing progress of fluid extraction where supercritical gases are already used as extractants on an industrial scale.

In this contribution a survey is given in order to draw the attention of potential users to this interesting and promising method of separation.

As long ago as 1966/67, *Sie et al.*[2 5] described the use of compressed gases in chromatography. These important fundamental investigations overlap with SFC in the modern definition. The same holds for two reviews by *Giddings et al.*[6]. An interesting survey was given by *Vigdergauz* and *Semkin*[7] (see also [8,90]). In 1972 *Doran*[9] discussed the application of SFC to routine analysis. In 1973 *Bartmann* treated several aspects of this field in his thesis[10], where problems of separation theory were also considered (see also [11]). The reviews by *Gouw* and *Jentoft*[12 14] found great interest; they consider all the problems relevant to SFC (especially influence of operational parameters, apparatus, applications, *etc.*). A summary of SFC applications in practice, especially in the petroleum industry, was published in 1979 by *Snyder* and *Saunders*[15]. In 1978 *Klesper*[16] treated the most important operational parameters of SFC especially with respect to the separation of polymers. A patent has already been granted in the field of SFC[103].

Numerous citations concerning the physicochemical principles of fluid extraction that are also of interest for SFC[*] are given in some reviews[17 20].

2. Solubilities and Transport Properties in Supercritical Phases

Extensive theoretical and experimental studies have shown that highly compressed supercritical gases are able to dissolve large amounts of low-volatile substances. This pronounced solvent power is of considerable practical interest, *e.g.* in fluid extraction of caffeine (from coffee), nicotine (from tobacco), hops, spices, drugs, *etc.* A survey was provided by the Symposium on "Extraction with Supercritical Gases" held on June 5 and 6, 1978, at Essen (for contributions, see [21,22]). Three sessions at the 6th AIRAPT International High Pressure Conference, July 25—29, 1977, Boulder, Colorado, USA, and the 157th Meeting of the Electrochemical Society, May 11—16, 1980, St. Louis, Mississippi, USA, had the same main topic. (For a detailed discussion of all relevant problems see [17 25].) In this article only the most important physicochemical properties of supercritical solutions and solvents of interest for SFC are briefly reviewed.

2.1. Physicochemical Properties of Supercritical Gases

The physicochemical properties of supercritical gases will be considered for the case of carbon dioxide, which is especially important for fluid extraction and SFC. Figure 1a shows some characteristic pressure(p)–density(ρ) isotherms[26] plotted with the use of reduced variables. The compressibility κ_T

$$\kappa_T \equiv -\frac{1}{V}\cdot\left(\frac{\partial V}{\partial p}\right)_T = \frac{1}{\rho}\cdot\left(\frac{\partial \rho}{\partial p}\right)_T \qquad (1)$$

is especially large just above the critical temperature T_c (*e.g.* in the dotted region of Fig. 1a); at the critical point CP, κ_T tends to infinity. Hence a slight increase in pressure in this region causes a considerable increase in density. Since the solvent power for low-volatile substances is essentially correlated with the density (see below), this behavior is of fundamental importance for SFC, too.

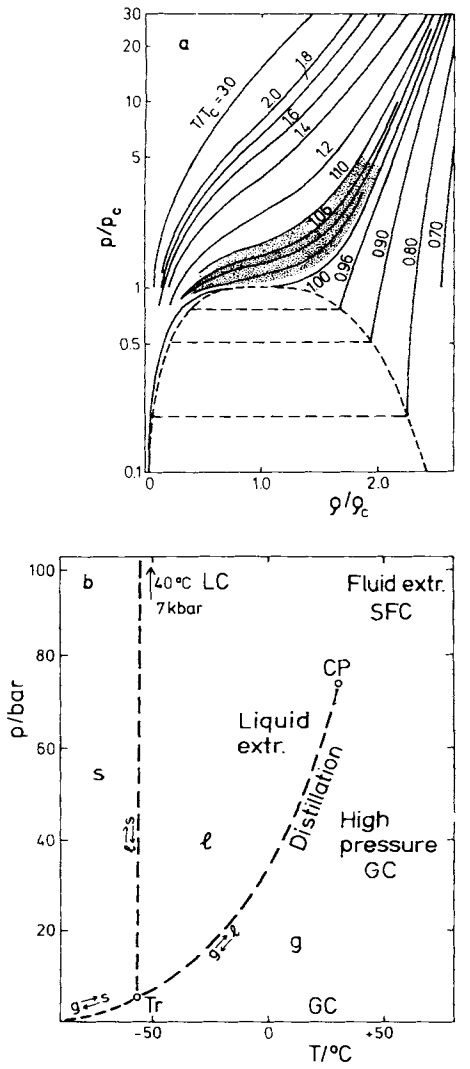

Fig. 1. Physicochemical properties of pure carbon dioxide a) $p(\rho)$ isotherms and b) $p(T)$ phase diagram (according to [26]); p = pressure, T = temperature, ρ = density, CP = critical point, p_c = critical pressure, T_c = critical temperature, ρ_c = critical density, Tr = triple point (here gls), g = gas, l = liquid, s = solid.

Figure 1b shows the $p(T)$ projection of the phase diagram of pure carbon dioxide. Here the vapor pressure curve (g⇄l) separates liquid (l) and gaseous (g) states. In Figure 1b the regions are also marked where different methods of separation (*e.g.* distillation, extraction, GC, high pressure GC, fluid extraction, SFC) can be used. The sublimation pressure

[*] For a search in the literature it might be helpful to know that the key words for SFC in the Chemical Abstracts are: chromatography, high pressure; —, supercritical; —, petroleum separation; gas chromatography, high pressure; —, supercritical; —, hyperpressure; —, dense gas; —, petroleum separation and (unfortunately) others too.

curve (g⇄s) and the melting pressure curve (l⇄s) are of no interest with regard to SFC.

Since substances are approximately in a corresponding state at their critical points, very similar reduced $p(\rho)$ diagrams as in Figure 1a are also found for other substances that can be used as extractants in fluid extraction or as mobile phases in SFC. Some of them are compiled in Table 1 (more detailed tables are found in [12, 14, 16, 47].)

Table 1. Physicochemical properties of some compounds that can be used as supercritical solvents in fluid extraction and/or mobile phases in SFC (b.p. boiling temperature at 1 atm; T_c = critical temperature; p_c = critical pressure; ρ_c = critical density; critical data of NH_3 and N_2O, and all b.p. values taken from [101], all other data from [100]; for similar compilations see [20, 16]; 1 atm = 1.013 bar).

Compound	B.p. [°C]	T_c [°C]	p_c [atm]	ρ_c [g·cm^{-3}]
CO_2	− 78.5 [a]	31.04	72.85	0.468
NH_3	− 33.35	132.4	112.5	0.235
H_2O	100.00	374.15	218.3	0.315
N_2O	− 88.56	36.5	71.7	0.45
Ethane	− 88.63	32.28	48.16	0.203
Ethene	− 103.7	9.21	49.66	0.218
Propane	− 42.1	96.67	41.94	0.217
Pentane	36.1	196.5	33.25	0.237
Chlorotrifluoromethane	− 81.2	28.9	38.7	0.579

[a] Sublimation.

For an understanding of a dynamic method of separation, such as SFC, transport properties are also important. Since in SFC the mobile phase consists of a pure supercritical gas or highly dilute solutions of the substances to be separated, it should be sufficient in most cases to discuss the transport properties of the pure supercritical gas (for details, see *e.g.*[25]). In the following only the viscosity η and the self-diffusion coefficient D_{11} will be briefly considered; characteristic values are given in Figures 2 and 16 (see [11]).

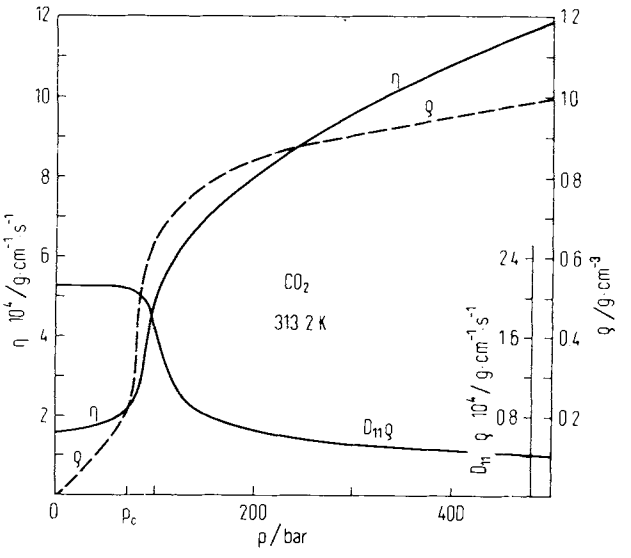

Fig. 2. Density ρ, viscosity η, and $D_{11}\cdot\rho$ of pure carbon dioxide as a function of pressure p at 40 °C (according to data from [11]); D_{11} = self-diffusion coefficient.

According to Figure 2, the viscosity of CO_2 at 40 °C (that is *ca.* 9 K above the critical temperature) remains approximately constant with increasing pressure up to the critical pressure (*i.e.*, *ca.* 70 bar) and increases significantly only at still higher pressures. Correspondingly, the product $D_{11}\times\rho$[89] is approximately constant up to the critical pressure (as predicted from the simplest approach of the kinetic theory of gases) and declines at higher pressures only. In the pressure range between p_c and *ca.* 200 bar the self-diffusion coefficients lie between 10^{-3} and 10^{-4} cm$^2\cdot$s^{-1}. It should be mentioned here that only semiquantitative information concerning diffusion processes in the mobile phase can be obtained from self-diffusion coefficients: in fact the binary diffusion coefficient D_{1i}, which can also be determined from SFC experiments, has to be considered (see Section 5.4).

Table 2. Orders of magnitude of some important physicochemical properties of supercritical fluid phases in comparison with characteristic data for liquids and dilute gases under standard conditions (NTP) (for similar compilations, see [20, 16]).

	Gas (NTP)	Supercritical fluid phase	Liquid
Density ρ [g·cm^{-3}]	10^{-3}	0.3	1
Diffusion coefficient D [cm$^2\cdot$s^{-1}]	10^{-1}	10^{-3}—10^{-4}	$<10^{-5}$
Viscosity η [g·cm$^{-1}\cdot$s^{-1}]	10^{-4}	10^{-4}—10^{-3}	10^{-2}

Table 2 compares the orders of magnitude of some important physicochemical properties of supercritical fluid solvents with characteristic values for liquids and gases (for a similar compilation see, *e.g.*, *Klesper*[16]). With respect to density (and therefore solvent power) a supercritical phase resembles a liquid more closely than a gas, whereas its viscosity is more similar to that of a NTP gas; consequently it also has a large thermal conductivity. The self-diffusion coefficients are smaller than in a NTP gas by about two to three orders of magnitude; they are, however, greater than in a normal liquid by a factor of at least 10^2. This is advantageous for the rate of equilibration and of mass transfer, as compared with liquid-liquid extraction.

2.2. Phase Equilibria in Fluid Mixtures

Of interest for SFC are highly compressed fluid mixtures of CO_2 or similar gases that can be used as mobile phases (see Table 1) predominantly with low-volatile organic compounds. The complicated phase equilibria of such mixtures have been investigated up to the critical region and at much higher pressures (*e.g.* several kbar)[17, 20, 23, 24]. For SFC applications it is an advantage that (in contrast to fluid extraction) very dilute solutions are normally present in the supercritical fluid phase. Thus it is sufficient to discuss dilute binary solutions of the substances to be separated in the extractive gas (*e.g.* CO_2), interactions between the molecules of the solutes being more or less negligible.

The different types of phase behavior of such fluid binary systems can be understood at least qualitatively from the shape of the critical curves[17, 20]. A schematic survey is given in Figure 3.

The type that is schematically represented in Figures 3a, 3c, and 3e is often found for binary mixtures of CO_2 with organic substances of medium size and polarity (*e.g.* for CO_2 + decane[27]). In Figure 3a the two-phase region liquid-gas (lg) is limited to increasing pressures by the critical curve liquid-gas; beyond the critical curve both substances 1 and 2 are miscible in all proportions. At much lower temperatures

phase separation into two liquid phases (ll) is additionally assumed; this region is normally less important for SFC experiments.

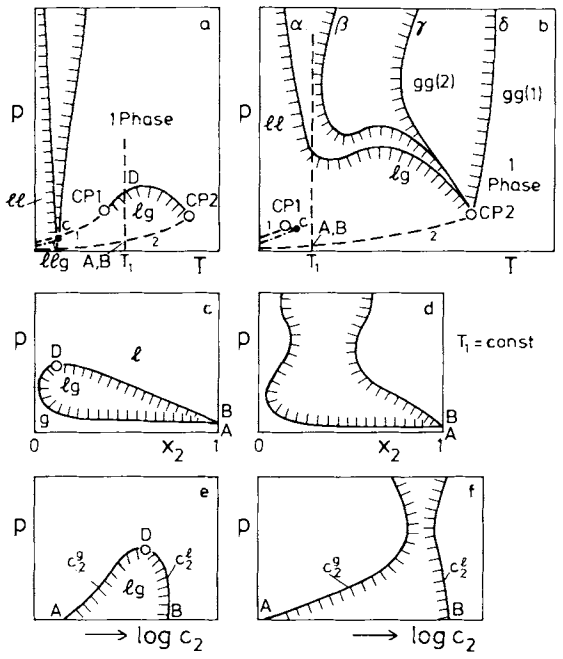

Fig. 3. Phase behavior of fluid binary systems at high pressures (schematic). a) and b) $p(T)$ projection of the phase diagram. (——) = critical curve, (- - - -) = vapor pressure curve, (— · — · —) = three-phase line llg, CP = critical point of pure component, C = critical endpoint; c) and d) $p(x_2)$ isotherm at $T = \text{const} = T_1$; e) and f) $p(\log c_2)$ isotherm at $T = \text{const} = T_1$. In b), d), f) the critical temperature of component 2 is higher and the mutual miscibility with the high-volatile component 1 lower than in a), c), d). For A, B, D see text.

Figure 3c shows a schematic $p(x)$ section for $T = \text{const} = T_1$. The lower branch between point A and the maximum D corresponds to the solubility of the low-volatile component 2 in the supercritical gas 1 whereas the upper branch between B and D represents the solubility of the supercritical gas 1 in the low-volatile liquid 2; point D is the binary critical point at the given temperature. For the pure component 2 it holds that $x_2^g = 1$ (at point A) and $x_2^l = 1$ (at point B); the densities of the gaseous and liquid phases in equilibrium, however, differ extremely, the difference being all the greater the lower the vapor pressure and hence the volatility of the pure component 2.

As a more adequate measure of composition, the concentration (here in $g \cdot cm^{-3}$) was therefore chosen instead of the mole fraction x in Figure 3e, whose abscissa is logarithmic. Here point B corresponds to the concentration of pure component 2 in the liquid phase and point A to that in the gaseous phase. On adding substance 1, c_2^g increases and c_2^l decreases with increasing pressure; at the critical point D c_2^g equals c_2^l. Figure 4 shows such a $p(\log c_2)$ isotherm for CO_2 (component 1) + decane (component 2) at 37.8 °C according to measurements by *Reamer* and *Sage*[27]. Whereas point B corresponds to a density of about 0.73 $g \cdot cm^{-3}$ and is situated somewhat below $c_2^l = 10^0$ $g \cdot cm^{-3}$, a concentration of $c_2^g \approx 3 \times 10^{-5}$ $g \cdot cm^{-3}$ for point A can be estimated from the vapor pressure of pure decane of about 0.005 bar and with the assumption of an ideal gaseous phase. The binary critical point D for the given temperature is at $p \approx 80$ bar and $c_2 \approx 8.2 \times 10^{-3}$ $g \cdot cm^{-3}$. The addition of CO_2 to pure decane thus increases the decane concentration in the gaseous phase up to point D by more than two orders of magnitude; at higher pressures decane and CO_2 are even completely miscible in all proportions.

In Figure 3b, 3d, and 3f the phase behavior is represented for binary mixtures of a high-volatile substance 1 with a substance 2 having a higher critical temperature and being less miscible with substance 1 than has been assumed in Figures 3a, 3c, and 3e. With decreasing mutual miscibility the branch of the critical curve that corresponds to liquid-liquid immiscibility (ll) in Figure 3a is shifted to higher temperatures. A superposition of the critical phenomena liquid-liquid (ll) and liquid-gas (lg) (types α and β) occurs and finally a phase behavior of type γ or δ is found; in the literature the two last types are attributed to gas-gas equilibria of the second and first kind respectively (for details see [17, 20, 23, 24]). It should additionally be mentioned that all types of phase behavior in fluid binary mixtures such as are shown in Figures 3a and 3b can be calculated in good agreement with experimental data (references are given in [28, 30, 20]).

In Figures 3d and 3f a pressure-composition isotherm is represented for case β in Figure 3b at a temperature T_1 that is situated above the critical temperature of pure component 1 (or more exactly above the temperature of the critical end point C[18]) but below the temperature minimum on the critical $p(T)$ curve in Figure 3b. In Figure 3d the right-hand branch corresponds to the solubility of 1 in 2 and the left-hand branch to that of 2 in 1; here the points A ($x_2^g = 1$) and B ($x_2^l = 1$) again coincide. A phase behavior of this type should be characteristic for typical applications of fluid extraction and SFC.

The corresponding $p(\log c_2)$ isotherm in Figure 3f is of fundamental and decisive importance. Corresponding to the very low vapor pressure of component 2, point A is situated at a very small c_2 value that increases greatly with increasing pressure (by addition of component 1). For the case shown, however, no complete mutual miscibility of the two components is obtained but the miscibility gap becomes larger again after running through a minimum width; complete mutual miscibility would only be possible at a temperature above the temperature minimum on the critical $p(T)$ curve in Figure 3b.

The relevant orders of magnitude are demonstrated in Figure 4 where the $p(\log c_2)$ isotherm at 40 °C (that is *ca.* 9 K above the critical temperature of pure CO_2) is shown for the system CO_2 (component 1) + squalane (component 2) according to measurements of *Liphard*[31] (squalane = 2,6,10,15,19,23-hexamethyltetracosane). In keeping with the density of liquid squalane of about 0.81 $g \cdot cm^{-3}$, point B is again situated somewhat below $c_2^l \approx 10^0$ $g \cdot cm^{-3}$ as was also the case for decane. Corresponding to the very low vapor pressure of squalane of only about 3×10^{-10} bar, however, point A is shifted to the very small concentration of $c_2^g \approx 5 \times 10^{-12}$ $g \cdot cm^{-3}$. Addition of CO_2 up to a pressure of 400 bar increases this concentration by about 10 orders of magnitude but without leading to complete mutual miscibility—as already mentioned above.

This increase in c_2^g is much greater than that calculated thermodynamically from the elevation of vapor pressure under the influence of the pressure of an inert gas (Poynting ef-

fect); besides, this gas is normally assumed to be insoluble in the liquid, an assumption that is only valid at vanishing inert gas pressure. This enormous increase demonstrates the specific interaction between substance 2 and the supercritical

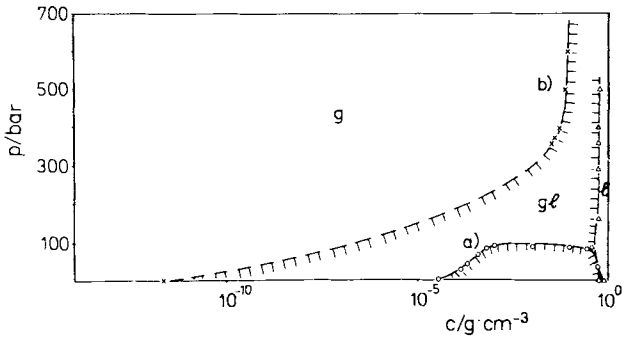

Fig. 4. $p(_{10}\log c_2)$ isotherm for a) CO_2 (component 1) + decane (component 2) at 37.8 °C (according to [27]) and b) CO_2 (component 1) + 2,6,10,15,19,23-hexamethyltetracosane (squalane; component 2) at 40 °C (according to [31]).

solvent 1, and represents the essential effect in fluid extraction and SFC. This effect has been studied by several groups[18, 20, 30, 32]. Often plots of $\log c_2^s$ *versus* density ρ at constant temperature give fairly good straight lines. In relation to SFC, this effect can also be deduced from experiments of *Stahl* and co-workers[32, 33] on the selective dissolution of low-volatile substances (especially drugs) by supercritical solvents (especially CO_2 and N_2O) and are thus related to chromatographic techniques (for a compilation, see [20, 32, 33]).

3. Apparatus

The apparatus required for SFC is similar to that for HPLC. Special features of SFC include the generation and control of the pressure, especially because of the large and highly variable compressibility of the mobile phase near the critical point and of the pressure-dependent viscosity. Until now, no fluid chromatographs are commercially available. Among the numerous chromatographs described in the literature, only those of *Karayannis et al.*[34], *Bartmann*[35, 36], *Jentoft* and *Gouw*[37], *Klesper* and *Hartmann*[38, 39], as well as the equipment of *van Wasen*[40] are mentioned (for a review, see *e.g.*[13]).

Figure 5 schematically shows the apparatus of *van Wasen*[40], which was modified by *Swaid*[41] for the measurement of diffusion coefficients (see Section 5.4). This apparatus allows fluid- as well as liquid-chromatographic investigations between room temperature and 250 °C and at pressures up to 200 bar. Detection of the eluted samples is by a UV detector. The column exit pressure can be held constant at pressures up to 200 bar by means of a special regulator.

Control of pressure and flow rate: An electrically driven duplex diaphragm pump (MP) is used to compress the mobile phase. The residual pulsations are damped by a buffer volume (P) located in an air-bath (Th_1) ($T \gg T_c$). A PI-regulator is used for pressure control. The signal of the pressure transducer (DD) at the end of the column is used to adjust the stroke of one piston of the pump, while the other piston is adjusted manually. The regulator can be connected to a programmer. The flow rate is regulated by a thermostated expansion valve (DM in Th_3) located after the detector at the end of the column; it consists of a two stage pressure reducer and a constant flow resistance (R). The pressure after the second stage is manually adjustable between 0 and 1.5 bar. The flow rate is measured by a soap bubble flowmeter (SSM) and controlled by a thermoconductivity flowmeter (SM).

The method proposed by *Klesper* and *Hartmann*[62] for control of the pressure and flow rate seems technically more complicated (for other methods of regulation of these parameters, see [13, 37, 48]).

Measurement and control of temperature: In SFC the requirements for the thermostat are very restrictive (high precision, good stability, wide temperature regime) because the experiments have to be conducted near the critical point of the mobile phase. The column of the apparatus shown in Figure 5[40] is located in a well insulated air-bath (TH_2); louvers and fans ensure temperature uniformity throughout the bath, the temperature of which is regulated using a Pt-100 sensor. The temperature of the bath is controlled by a

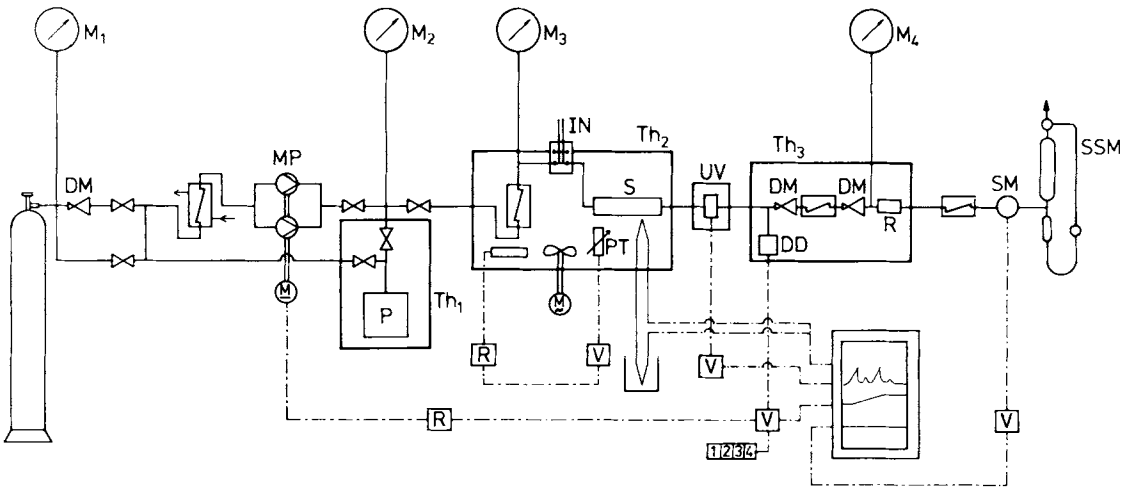

Fig. 5. Fluid chromatograph according to *van Wasen* [40] and *Swaid et al.* [41]; for comments see text. DD = pressure transducer, DM = expansion unit, IN = sample introduction, $M_{1\ldots3}$ = manometer, MP = diaphragm pump, P = buffer volume, PT = Pt-sensor, R = flow resistance, R = regulator, S = column, SM = thermoconductivity flowmeter, SSM = soap bubble flowmeter, $Th_{1\ldots3}$ = airbath, UV = UV detector, V = amplifier, 1 2 3 4 = A/D converter.

five-junction Fe-Constantan thermopile and measured by a calibrated Hg-thermometer. The mobile phase is brought to the bath temperature by passage through a tube filled with copper turnings.

Sample introduction: At low pressures (<100 bar) it is possible to inject the sample using a syringe through a septum, as is common with gas chromatographs. For pressure up to *ca.* 300 bar HPLC-introduction systems with sample loops are suitable. The most flexible introduction method, which allows the sample size to be varied, is the use of an HPLC injection system. Such an injection system was used in the apparatus shown in Figure 5. Samples of *ca.* 2 μl solution of the substance under test in CCl_4 (concentration *ca.* 3 $mg \cdot cm^{-3}$) were injected for the determination of the k_i values (see Section 5.1); 0.6 μl of the pure liquid substance were used for the determination of D_{1i} values (see Section 5.4).

Stationary phase: Adsorbents, chemically bonded phases, and molecular sieves are all used in SFC. Since the pressure drop across the column depends mainly on the geometry and the surface properties of the stationary phase, the particle size and its distribution depend on the problem to be treated. Although in many separation problems a high pressure drop is necessary to increase the efficiency of the column (see *e.g.*[16]), this is not generally the case in the determination of physicochemical properties with SFC. The conventional coated stationary phases used in GC are unsuitable for fluid chromatographic investigations, because the liquid film is easily dissolved by the supercritical mobile phase[10, 13]. Chemically bonded phases have proved to be more suitable. Adsorbents (silica gel, alumina, or molecular sieves) are generally used when the mobile phase has a relatively high critical temperature (for more specific details, see [40]).

Mobile phase: While the selectivity in GC depends on the stationary phase, in SFC and HPLC it is determined mostly by the mobile phase. The substances listed in Table 1 are used most frequently as mobile phases in SFC. Cyclohexane, benzene, ethyl acetate, tetrahydrofuran, isopropyl alcohol, and diisopropyl ether are also recommended. On the other hand, the use of halogenated alkanes, branched alkanes, ketones, and acetonitrile is limited by their thermal instability (see [47]). H_2O and NH_3 might also be used for some specific applications. The investigations carried out with the apparatus shown in Figure 5 used CO_2 and ethane as mobile phases.

Detectors: The UV detector is particularly important in SFC because most substances used as mobile phases are transparent in the UV region, while most of the medium- and high-molecular compounds usually investigated contain one or more chromophores. The investigations carried out with the apparatus shown in Figure 5 were performed using an UV detector with fixed wavelengths ($\lambda = 243$, 280 nm) and a two-beam optical system with a modified high pressure cell[40]. A UV detector developed for HPLC was also used for determination of D_{1i}; it has the following advantages: The cell has a small dead volume (8 μl) and laminar flow conditions can easily be maintained[41]. The detector cells were also thermostated to the temperatures of the mobile phase (for improvements of UV detectors in SFC, see [37, 42]).

Flame ionization detectors have been used on several occasions, but difficulties are encountered because the mobile phase must be expanded before detection (see [10, 35, 36, 43, 44, 99]). Differential refractometers attract increasing interest[47], particularly since they are more universally applicable; on the other hand, technical problems associated with the mechanical strength of the cell and the stability of the baseline must be solved. Adsorption[45, 46], scintillation[42], and thermoconductivity detectors[10] have also been used in SFC. Mass spectrometry is being used more and more widely for analysis and characterization of fractions[53].

Fraction collector: For a description and an account of the mode of operation of fraction collectors, see reference[37].

4. Analytical and Preparative Applications

Since the analytical and preparative applications have been comprehensively discussed in surveys by other authors[9, 12-16], only the most important operational parameters will be briefly described and some selected examples discussed.

4.1. Operational Parameters

The fundamental condition for the application of SFC is an adequate solubility of the substances to be investigated in the mobile phase. The most important parameters are therefore those which influence this solubility.

Pressure and temperature programs: In SFC experiments, pressures between two and three times the critical pressure and temperatures of 5 to *ca.* 40 K above the critical temperature of the mobile phase are employed. If the molecular weights of the components in the sample are distributed over a wide range (*e.g.* an oligomeric sample), then these components exhibit very different solubilities in the supercritical mobile phase. In such a case, depending upon the column conditions the components of a sample elute either incompletely (leaving the practically insoluble part on the column), or all together with a poor resolution at sufficiently high pressure and suitable temperature (regarding the pressure dependence of the height equivalent to a theoretical plate, see [2, 10]). Therefore pressure variation is essential during elution in order to obtain higher resolution and efficiency. This can be achieved by a pressure program which, for technical reasons, normally consists in a linear pressure increase with time[10, 16]. Because of the shape of the isotherms (see Fig. 1a), a large density change takes place in the region near the point of inflection and at temperatures just above the critical temperature of the mobile phase. This undesired effect can be reduced by operation at higher temperatures, as one can easily see from the form of the $p(\rho)$ isotherms at higher temperatures (Fig. 1a). Recent systematic investigations by *Klesper* and *Hartmann*[16, 39, 62], as well as by *Nieman* and *Rogers*[59], show that a slow or moderate increase in pressure with time is important for a satisfactory resolution. The best resolution possible, however, is obviously attained by a combination of pressure and temperature programs[39]. These results support the view that a continuous and gradual increase of the dissolving power of the mobile phase is important for higher resolution and that the pressure and the temperature programs should operate appropriately to this end. Particularly important is an understanding of the influence of temperature on the solubility in supercritical gases, especially at

relatively low and high pressures (in Fig. 1a these are the regions on the lower left and on the upper right).

Flow rate: The resolution is not strongly influenced by the flow rate. As a first approximation, one can assume that the thermodynamic equilibrium between the mobile and the stationary phase depends on the local values of pressure and temperature. The rate of approach to equilibrium, however, does depend on the flow rate, and low flow rates therefore improve the resolution somewhat. Furthermore, the dependence of the HETP values on the flow rate decreases with decreasing particle diameter of the stationary phase[3]. For the dependence of the HETP values on the flow rate, see [49].

Moderators: Moderators are known to increase resolution and efficiency in HPLC as well as in SFC. For example, admixture of small amounts of low-molecular alcohols such as methanol[62,96] and isopropyl alcohol[4,55,59] to a pure mobile phase (*e.g.* pentane) leads to a considerable improvement of the resolution in the separation of styrene oligomers. Whether this behavior should be attributed to the increase of the solubility in the mobile phase[102] or to a modification of the surface of the stationary phase by the moderator (see [10]) is not yet clear.

The influence of the variation in polarity of the mobile as well as of the stationary phase was systematically investigated by *Sie* and *Rijnders*[97]; they showed that an increase in the polarity of the mobile phase favors a separation of the components according to their molecular weights, while increasing polarity of the stationary phase promotes separation with respect to functional groups (so-called type separation).

4.2. Selected Examples

In the following the discussion of the operational parameters in Section 4.1 will be illustrated by selected examples.

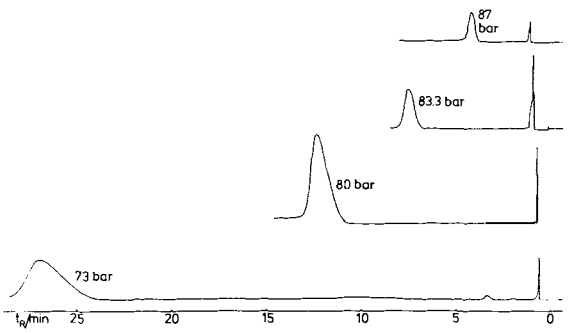

Fig. 6. Retention times t_R of hexadecane at 40 °C and several CO_2 pressures (according to [51]; see [19]). Mobile phase: 0.5 $dm^3 \cdot min^{-1}$ (NTP); stationary phase: Carbowax 400/Porasil C; column: length 2 m, internal diameter 1.4 mm; sample size: 0.2 µl.

Figure 6 demonstrates the effect of increasing the pressure of the mobile phase (here CO_2 at 40 °C, that is *ca.* 9 K above the critical temperature) on the retention time t_R of a test substance (here hexadecane) on a chemically bonded stationary phase (here Carbowax 400 on Porasil C) according to measurements by *van Wasen*[51]. At 73 bar, the peak maximum appears after *ca.* 27 min ($=t_R$); the small peak at about 3 min ($=t_0$) corresponds to an inert substance (here air). The measurements were effected with a modified flame ionization detector. With increasing pressure, t_R decreases drastically and at 87 bar it is reduced to just a few minutes.

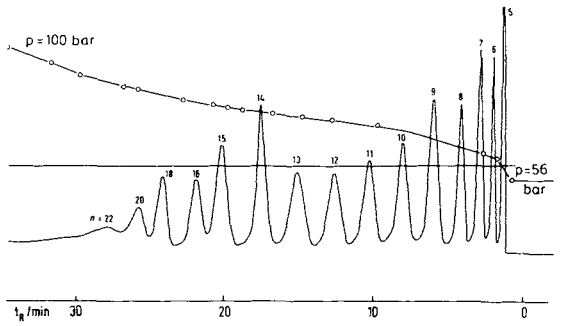

Fig. 7. SFC separation of *n*-alkanes on aluminum oxide with CO_2 at 40 °C (according to [10, 36]). Mobile phase: 1.0 $dm^3 \cdot min^{-1}$ (NTP); column: length 3 m, internal diameter 2 mm. The initial pressure of 56 bar is increased up to *ca.* 100 bar during the separation according to the pressure program given. The horizontal line gives the temperature (here 40 °C).

Figure 7 shows the separation of the *n*-alkanes from *n*-pentane to *n*-docosane also with CO_2 at 40 °C on aluminum oxide according to measurements by *Bartmann*[10,36]; here again a flame ionization detector was used. Additionally, a pressure program was used, *i.e.* the pressure increases monotonously with time by analogy with the use of a temperature program in normal GC (for details see Sections 3 and 4.1).

It is particularly remarkable that an adsorbent was used in the separation shown in Figure 7. Similar experiments using a chemically bonded stationary phase (*e.g.* Carbowax 400 on Porasil C) show a completely analogous behavior[10,36]. It follows from these findings that, in contrast to GC, the specific influence of the stationary phase is relatively small in SFC and that selectivity (as in HPLC) depends mainly on the mobile phase. Knowledge about the physicochemical state of the stationary phase in such investigations is extremely scarce, *e.g.* whether the fundamental step is a partition or an adsorption process.

An example of the separation of cyclic hydrocarbons is shown in Figure 8[10,36]. The effects are analogous to those shown in Figure 7, in spite of the fact that a chemically bonded stationary phase (Carbowax 400 on Porasil C) was used instead of an adsorbent (as in Fig. 7). During the last few years other authors have intensively studied analytical separations of hydrocarbons, especially with respect to problems in the petroleum industry (see Section 4.3).

Figure 9 shows an interesting example of a preparative separation from a paper by *Klesper* and *Hartmann*[16]. With a supercritical mobile phase consisting of 95% pentane and 5% methanol the oligomers of polystyrene up to $n=40$ are completely separated. Here the use of a moderator (5% methanol) added to the mobile phase (here pentane) in order to modify

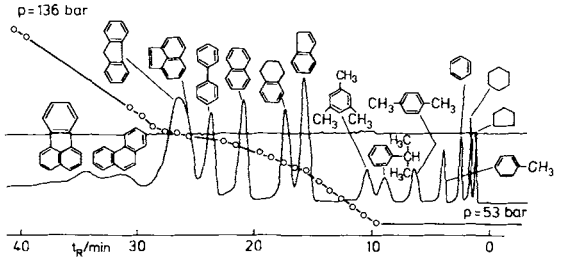

Fig. 8. SFC separation of some cyclic hydrocarbons on Carbowax 400/Porasil C with CO_2 at 40 °C (according to [10, 36]). Mobile phase: 1.0 $dm^3 \cdot min^{-1}$ (NTP); column: length 3 m, internal diameter 1.7 mm. The initial pressure of 53 bar is increased up to *ca.* 136 bar during the separation according to the pressure program given. The horizontal line gives the temperature (here 40 °C).

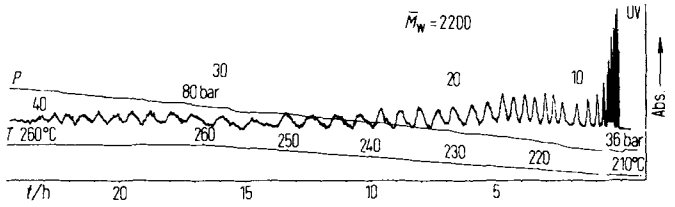

Fig. 9. SFC separation of the oligomers of styrene (up to 40 units) according to *Klesper et al.*[10,62] with combined pressure and temperature programs. Mobile phase: 95% pentane + 5% methanol, 4.2 $cm^3 \cdot min^{-1}$; stationary phase: Porasil A; column: length 6 m, internal diameter 3 mm.

its solvent properties, and a combined pressure and temperature program, are of considerable interest. Up to now few details are available regarding the joint operation of these parameters.

4.3. Literature

In the following some applications taken from the literature are cited in order to demonstrate the wide scope of SFC which is far from exhausted; especially promising preparative applications are still in an initial phase.

Up to now SFC has been applied to alkanes[10,11,36,40,54], arenes (especially polyarenes)[13,36,42,56,57], alkyl bromides[34,37], di-*n*-alkyl phthalates[50], siloxanes[58,59], polymers (especially polystyrene)[38,39,60-66], automotive exhaust gases[42,53], sulfur compounds in cigarette smoke[67], petroleum products (especially high-boiling fractions, residues, crudes)[14,15,68-70], organometal complexes, acetylacetonates, salicylaldoximes, and thenoyltrifluoroacetonates[34,37,71-73,98], as well as substances of interest for biochemistry[6].

5. Physicochemical Applications

Chromatographic experiments may afford many important physicochemical data that are often difficult to obtain by other methods, *e.g.* capacity ratios, virial coefficients, thermodynamic properties of solutions (partial molar enthalpies of solution or vaporization, activity coefficients, excess properties, *etc.*), complexation equilibrium constants, thermodynamic properties of adsorption (adsorption isotherms, enthalpies of adsorption, surface areas, *etc.*), kinetic data (*e.g.* rate constants) and diffusion coefficients (for reviews see, *e.g.*, [74-76]). Up to now the application of SFC to this field is still in its infancy. Nevertheless, very interesting physicochemical data of highly compressed fluid mixtures and pure substances can be deduced from SFC experiments.

5.1. Capacity Ratios and Partition Coefficients

The most important property in the theory of chromatographic separation processes is the capacity ratio k_i of a component i under test, given by

$$k_i \equiv \frac{c_i^{stat}}{c_i^{mob}} \cdot \frac{V^{stat}}{V^{mob}} = K_i \cdot \frac{V^{stat}}{V^{mob}} \tag{2}$$

Here c_i^{stat} and c_i^{mob} are the concentrations of component i in the stationary (stat) and the mobile (mob) phase and V^{stat} and V^{mob} the total volume of the stationary and the mobile phase in the column, respectively. V^{stat}/V^{mob} is characteristic for a given column and, to a first approximation, can be assumed constant and pressure independent. In most cases, however, the partition coefficient $K_i \equiv c_i^{stat}/c_i^{mob}$ strongly depends on the operational parameters (see Section 4.1).

Normally the capacity ratio k_i can be determined relatively easily and accurately from SFC experiments since it is related to the (total) retention time t_{Ri} of a substance i and to the retention time t_0 of an inert substance, according to

$$k_i = (t_{Ri} - t_0)/t_0 \tag{3}$$

Thus it depends linearly on t_{Ri}. Since according to equation (2) k_i is proportional to the partition coefficient K_i, equations (2) and (3) allow the calculation of thermodynamic properties (see Sections 5.3 to 5.5). Unfortunately reliable values for K_i are usually unobtainable, because V^{stat}/V^{mob} often cannot be defined exactly or can only be determined with large errors.

Here the pressure dependence of k_i is of primary interest. According to the chromatographic method different relations are found that will be shortly discussed in the following.

For liquid-liquid chromatography (LC) it can be deduced from the thermodynamics of mixtures that relation (4) holds[10,35,52]

$$\left(\frac{\partial \ln k_i}{\partial p}\right)_T = \frac{V_i^{E,\infty mob} - V_i^{E,\infty stat}}{R \cdot T} \tag{4}$$

where $V_i^{E,\infty mob}$ and $V_i^{E,\infty stat}$ are the partial molar excess volumes of component i at infinite dilution in the mobile and stationary liquid phase respectively.

At relatively low pressures, where second virial coefficients are sufficient to describe the deviations of the mobile phase from ideal behavior[2,7,54,77,78], the corresponding equation for gas-liquid partition chromatography (GC) is given by

$$\left(\frac{\partial \ln k_i}{\partial p}\right)_T = \frac{2B_{1i} - V_i^{\infty stat}}{R \cdot T} \tag{5}$$

Here B_{1i} is the interaction second virial coefficient of the mobile gas 1 and the component i under test and $V_i^{\infty stat}$ the partial molar volume of substance i in the stationary phase at infinite dilution. Thus B_{1i} data can be determined from $\ln k_i$ values as a function of pressure (see Section 5.3).

For the ranges of pressure normally relevant in SFC experiments neither a description with excess properties (as in LC) nor with virial coefficients (as in GC) will be adequate. The present discussion follows a treatment proposed by *van Wasen*[40]. In partition chromatography, eq. (2) holds for the capacity ratio k_i. For adsorption chromatography this relation can be modified to give

$$k_i = \frac{\Gamma_i}{c_i^{mob}} \cdot \frac{A_s}{V^{mob}} \tag{6}$$

where Γ_i is the surface concentration of component i and A_s the surface area of the stationary phase. This relation can be transformed to become completely analogous to eq. (2). Since pressure and temperature change neither A_s nor V^{mob}

significantly, all changes in k_i are caused by variations in the partition coefficient K_i or in Γ_i/c_i^{mob}.

In order to describe the pressure dependence of k_i thermodynamically *van Wasen* used a model originally developed by *Everett*[79] for adsorption from solutions. Here the adsorption process is assumed to be equivalent to a "chemical" equilibrium reaction according to

$$1^{mob} + \frac{1}{r} i^{stat} \rightleftarrows 1^{stat} + \frac{1}{r} i^{mob}$$

The parameter r takes into account the different spatial requirements of the molecules 1 and i on the surface of the stationary phase and is given by $r = a_i/a_1$ where a_1 and a_i are the partial molar surface areas of component 1 and i respectively. The result of a detailed treatment is

$$\left(\frac{\partial \ln k_i}{\partial p}\right)_T = \frac{V_i^{\infty,mob} - (a_i/a_1) \cdot V_{m1}^{*mob}}{R \cdot T} - \kappa_1^* \qquad (7)$$

Here $V_i^{\infty,mob}$ is the partial molar volume of component i at infinite dilution in the mobile phase, V_{m1}^{*mob} the molar volume of the pure mobile phase 1, and κ_1^* the compressibility of the pure mobile phase 1 according to equation (1). To a first approximation, one can use $r \approx (V_{mi}^{*s}/V_{m1}^{*s})^{2/3}$ for spherical molecules and $r \approx V_{mi}^{*s}/V_{m1}^{*s}$ for chain molecules (s = solid). For a corresponding relation giving the density dependence of k_i, see [40].

Figures 10 to 13 exemplify the influence of temperature and pressure, as well as of the stationary and the mobile phases, on the capacity ratio k_i of a sample i.

Figure 10 shows results for naphthalene and fluorene (component i) on deactivated silica gel (Reversed Phase, Perisorb RP-8) as stationary phase using carbon dioxide as mobile phase according to measurements by *van Wasen*[40]. Figure 10a shows $\log k_i$ for naphthalene plotted *versus* the carbon dioxide pressure p at 35, 40, and 50 °C, *i.e. ca.* 4, 9, and 19 K above the critical temperature of pure carbon dioxide. The S-shaped curves found are typical for such experiments in the supercritical region, whereas the shape at low pressures is represented in Figure 15. The pressure dependence is found to be very large: between 20 and 120 bar, k_i changes by nearly three orders of magnitude. The temperature dependence is especially interesting. The isotherms intersect at about 60 bar; at lower pressures k_i declines and at higher pressures it rises with increasing temperature, corresponding respectively to an increase or a decrease of c_i^{mob} relative to c_i^{stat}. This difference in temperature dependence can be explained from the fact that for $p \rightarrow 0$ $k_i \sim (p_i^* \cdot \lim_{x_i \rightarrow 0} f_i^{stat})^{-1}$ (where p_i^* and f_i are the vapor pressure and the activity coefficient of component i respectively; see Section 5.3). Since p_i^* (and consequently c_i^{mob}) increases with increasing temperature, k_i decreases, the temperature dependence of $\lim_{x_i \rightarrow 0} f_i^{stat}$ being normally negligible in comparison with that of p_i^*. At high pressures, however, it is no longer the vapor pressure of component i but rather the density of the supercritical solvent that is decisive for the solvent power of the mobile phase, and k_i increases with increasing temperature since the density of the mobile phase decreases with increasing temperature at constant pressure and thus c_i^{mob} declines.

The fact that the temperature dependence at higher pressures is really a density effect is demonstrated by Figure 10b

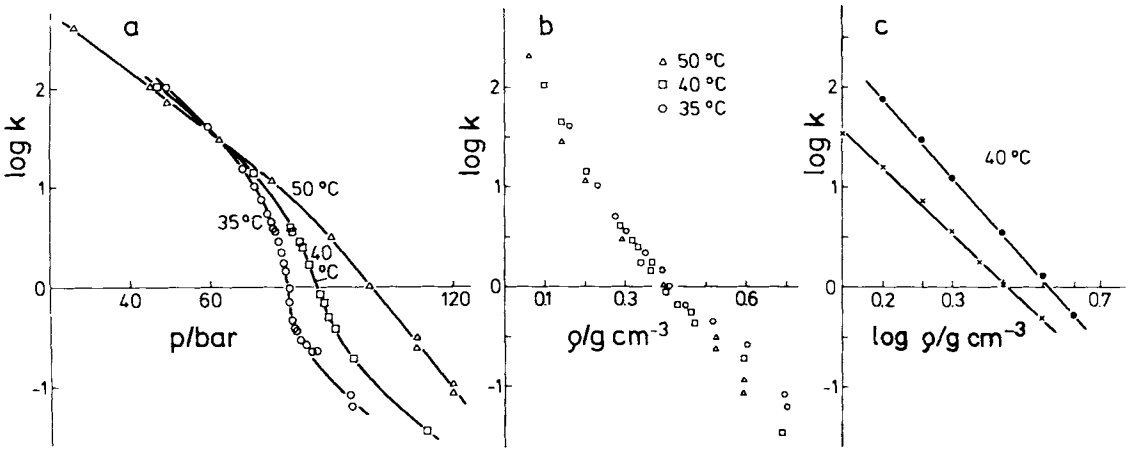

Fig. 10. Capacity ratio k as a function of pressure and temperature. $_{10}\log k$ of naphthalene on deactivated silica gel (Reversed Phase, Perisorb RP-8) at 35, 40, and 50 °C with CO_2 as mobile phase as a function of a) pressure p, b) density ρ, and c) $_{10}\log\rho$ (naphthalene (×), fluorene (•)) (according to [40]).

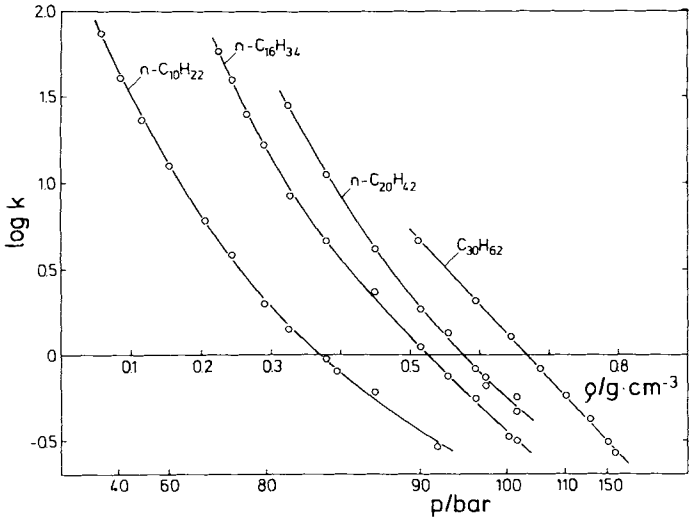

Fig. 11. Capacity ratio k for four samples. $_{10}\log k$ of decane, hexadecane, eicosane, and squalane (2,6,10,15,19,23-hexamethyltetracosane) on Carbowax 400/Porasil C (100—120 mesh) at 40 °C with CO_2 as mobile phase (0.5 $dm^3 \cdot min^{-1}$ (NTP)) as a function of density ρ and pressure p (according to [51]). Column: length 2 m, internal diameter 1.4 mm.

where $\log k_i$ is plotted against the density of pure carbon dioxide. In this diagram all isotherms coincide more or less within the limits of experimental accuracy. The plots are no longer S-shaped but only slightly curved. According to Figure 10c the curves can be further linearized by plotting $\log k_i$ *versus* $\log \rho$. Thus Figure 10 demonstrates that in the near-critical region the density of a given supercritical gas dominates its solvent power.

In Figure 11, $\log k_i$ is plotted *versus* pressure p and density ρ for decane, hexadecane, eicosane, and squalane (2,6,10,15,19,23-hexamethyltetracosane) as samples i and on Carbowax 400 (chemically bonded on Porasil C) according to measurements by *van Wasen*[51] (see Figures 10a and b). For all substances i, only slightly curved $\log k_i(\rho)$ isotherms are found that are essentially parallel. Such curves should greatly facilitate the planning of pressure programs for analytical or preparative separations.

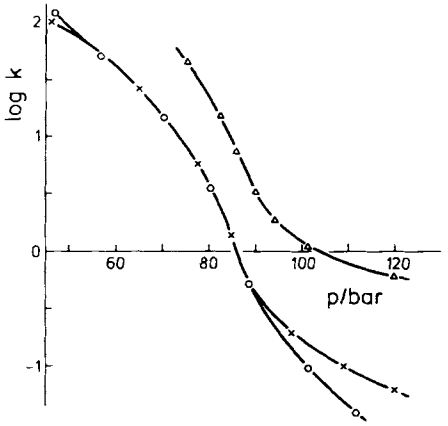

Fig. 12. Capacity ratio k for three stationary phases. $_{10}\log k$ of naphthalene on silica gel, 14 $m^2 \cdot g^{-1}$ (×), deactivated silica gel (Reversed Phase, Perisorb RP-8) (○) and silica gel, 500 $m^2 \cdot g^{-1}$ (△) at 40 °C with CO_2 as mobile phase as a function of pressure p (according to [40]).

Figure 12 shows the influence of the stationary phase. Here $\log k_i$ for naphthalene with CO_2 at 40 °C as mobile phase is plotted against pressure for three different stationary phases according to measurements by *van Wasen*[40]. For comparable surface areas the specific characteristics of the surfaces (here silica gel, 14 $m^2 \cdot g^{-1}$, or deactivated silica gel (Reversed Phase, Perisorb RP-8) with a similar surface area) have only a slight influence whereas the drastic increase in the surface area of the silica gel to 500 $m^2 \cdot g^{-1}$ is important. Corresponding to the larger A_s value, the curve is shifted to higher values of $\log k_i$; the shift, however, is smaller than would correspond to the relative increase in surface area. Thus it can again be deduced from Figure 12 that in SFC the selectivity depends primarily on the mobile phase.

Figure 13 demonstrates the influence of the mobile phase[40]. Here $\log k_i$ of naphthalene on deactivated silica gel (Reversed Phase, Perisorb RP-8) at 40 °C is plotted *versus* the density ρ (Figure 13a), *versus* the reciprocal of the molar volume $1/V_m$ (Figure 13b), which is proportional to the particle density, as well as *versus* the reduced density ρ/ρ_c (Figure 13c) for both carbon dioxide and ethane as mobile phases. The smaller capacity ratios for ethane in Figure 13a are caused by smaller Γ_i/c_i^{mob} values probably because of higher concentrations in the mobile phase ethane at the same density (here in $g \cdot cm^{-3}$). As shown in Figure 13b the distance between the curves $\log k_i(p)$ at equal values of the reciprocal molar volume (or of the particle density) becomes smaller, but the solubility in ethane remains higher. Plotting the data against reduced density (Figure 13c) changes the sequence of the curves because of the considerably smaller critical density of ethane (see Table 1).

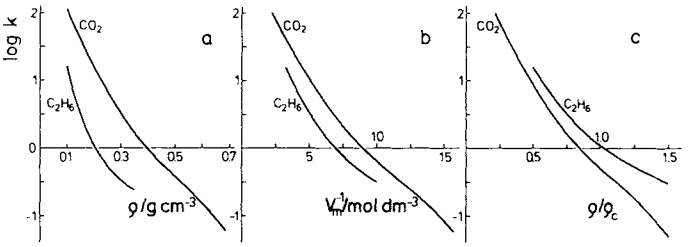

Fig. 13. Capacity ratio k for two mobile phases. $_{10}\log k$ of naphthalene on deactivated silica gel (Reversed Phase, Perisorb RP-8) at 40 °C for carbon dioxide and ethane as mobile phase respectively as a function of a) density ρ, b) reciprocal molar volume $1/V_m$, and c) reduced density ρ/ρ_c (according to [40]).

5.2. Partial Molar Volumes

Partial molar volumes in compressed fluid mixtures are difficult to determine experimentally, *e. g.* from very accurate pVT data of mixtures and of the pure components; it is even more difficult to determine the partial molar volume V_i^{∞} of a solute i at very low concentrations, *e. g.* at infinite dilution. SFC offers an elegant possibility of obtaining such experimental V_i^{∞} values; they can be deduced directly from the slopes of $\log k_i(p)$ isotherms according to equation (7).

An especially interesting application is the determination of V_i^{∞} at the critical point of the pure solvent 1; here values running to negative as well as to positive infinity are predicted by theory. In Figure 14 V_i^{∞} values of naphthalene and fluorene in CO_2 are shown that were determined by *van Wasen*[40, 80] from SFC experiments. Approaching the critical

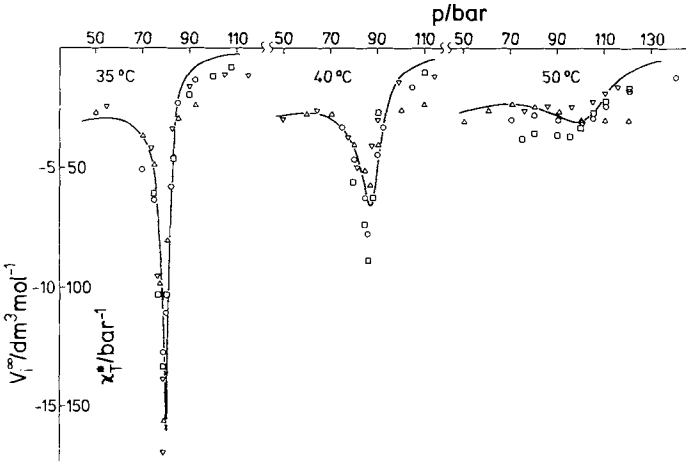

Fig. 14. Partial molar volumes V_i^{∞} (at infinite dilution) of naphthalene and fluorene in supercritical CO_2 from SFC experiments (according to [40, 80]). (▽) and (△) naphthalene, stationary phase Perisorb A and Perisorb RP-8 respectively; (□) and (○) fluorene, stationary phase Perisorb A and Perisorb RP-8, respectively; — isothermal compressibility κ_T^* of pure CO_2 (see Text).

point of pure CO_2, increasingly negative V_i^{∞} values are found; thus the experiments suggest a limiting value of V_i^{∞} tending to negative infinity. It follows from Figure 14 that, in agreement with eq. (7), no influence of the stationary phase

used in the SFC experiments can be observed. Added to this is the fact that, within the limits of experimental error, the V_i^{∞} values of the two test substances do not differ. The proportionality between V_i^{∞} and the isothermal compressibility κ_T^* of the pure solvent (here CO_2) predicted theoretically is also confirmed.

5.3. Virial Coefficients

According to equation (5) interaction second virial coefficients B_{1i} between the supercritical solvent and the solute i can be determined from the slopes of the $\log k_i(p)$ isotherms. In order to remain within the assumptions made in the derivation, the slope has to be determined at low pressures or best as the limiting slope of the curves for vanishing pressure. B_{1i} values of several systems have been determined by SFC since the mid-1960's (see [2,7,54,77,78]). Interaction second virial coefficients are of fundamental interest, *e.g.* for corrections in the determination of thermodynamic data from vapor-liquid equilibria or for theoretical predictions concerning the interaction between unlike particles.

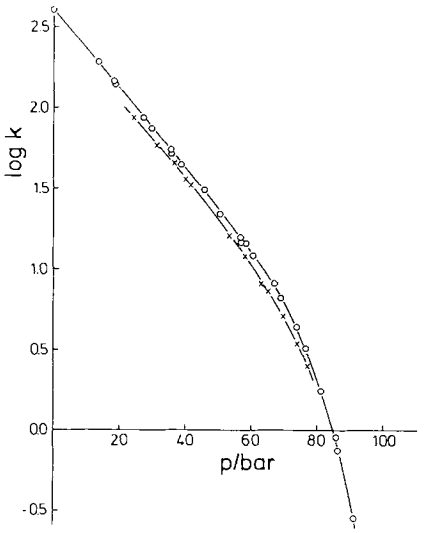

Fig. 15. Interaction second virial coefficients B_{1i} from SFC experiments with CO_2 (component 1). $_{10}\log k$ for decane (component i) on Carbowax/Porasil C (100—120 mesh) (○) and on oxydipropionitrile (OPN)/Porasil C (80—100 mesh) (×) at 40 °C with CO_2 as mobile phase (according to [51]); column: length 2 m, internal diameter 1.4 mm; flow rate of CO_2 0.5 $dm^3 \cdot min^{-1}$ (NTP). B_{1i} results from the limiting slope for $p \rightarrow 0$ (see text).

Remarkably, according to eq. (5) the slope of a $\log k_i(p)$ isotherm at sufficiently low pressures depends on the component i, the mobile phase 1, and the temperature T only and not on the stationary phase. This is also demonstrated in Figure 15 where $\log k_i$ of decane (component i) for Carbowax 400 and oxydipropionitrile (OPN) both on Porasil C with CO_2 (component 1) as mobile phase are presented according to measurements by *van Wasen*[51]. As expected, the curves exhibit the same slopes (within experimental accuracy) at low pressures. Using $V_i^{\infty stat} \approx V_{mi}^{*1}$, it follows from the limiting slope for $p \rightarrow 0$ that $B_{1i} = -635\ cm^3 \cdot mol^{-1}$ for decane and CO_2 at 40 °C; for measurements of this kind the experimental errors are about ±10%.

In contrast to the limiting slopes, the limiting values of $\log k_i$ for $p \rightarrow 0$, however, depend on the choice of the stationary phase since here k_i is proportional to $(p_i^* \cdot \lim_{x_i \rightarrow 0} f_i^{stat})^{-1}$. Thus limiting values of the activity coefficients can be calculated from the extrapolated k_i values. With increasing pressures, the $\log k_i(p)$ isotherms turn off to lower values in a characteristic manner and show the typical S-shaped curvature mentioned above (see Fig. 10a, 12).

5.4. Diffusion Coefficients

In 1960 *Giddings* and *Seager*[81], *Boheman* and *Purnell*[82], and some other groups independently developed methods for the determination of diffusion coefficients in gas mixtures by chromatographic techniques. Since then, numerous papers have been published in this field (for reviews, see [83,84,74]). Additionally, an important modification of this technique, the "peak arrest" method, has also been developed[91,92].

During such investigations *Balenoviç*, *Myers*, and *Giddings*[85] determined diffusion coefficients in compressed gases; the technique has also been extended to liquid systems[93,94]. *van Wasen*[40,86], *Swaid* and *Schneider*[41,87], and *Feist*[88] improved this technique and determined the diffusion coefficients of some organic substances in supercritical carbon dioxide at pressures up to 160 bar. Such data are of interest for mass transfer processes in SFC and fluid extraction (also on an industrial scale).

In this method the concentration profile of the eluted solute is measured at the exit of the empty column (characteristic dimensions: length *ca.* 100 m, internal diameter *ca.* 0.2 to 0.5 mm). For negligible interactions with the inner wall of the column and for $D_{eff}/\bar{U} \cdot L \leq 0.01$ an approximately symmetrical Gaussian profile is found and the variance in length units is given by

$$\sigma_i^2(z) = 2 \cdot D_{eff} \cdot t_{Ri} \tag{8}$$

For laminar flow in the column the effective diffusion coefficient D_{eff} is given by

$$D_{eff} = D_{1i} + \frac{r_0^2 \cdot \bar{U}^2}{48\, D_{1i}} \tag{9}$$

Here $\bar{U}$ is the mean linear velocity of the mobile phase, L and r_0 are the length and the inner radius of the empty column respectively, and t_{Ri} is the retention time. From the variance $\sigma_i^2(z)$ of the concentration profile, D_{eff} and then D_{1i} can be determined (see [41,87]).

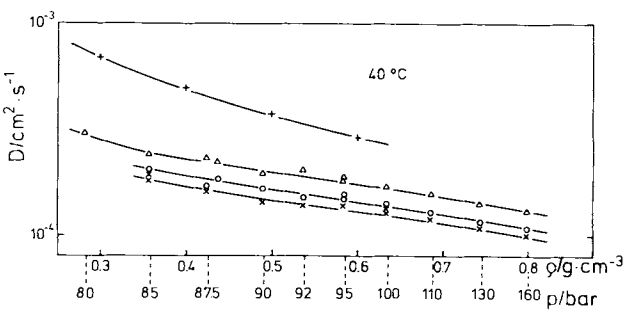

Fig. 16. Binary diffusion coefficients D_{1i} from SFC experiments with CO_2 (component 1). D_{1i} (logarithmic scale) for benzene (△), *n*-propylbenzene (○) and 1,3,5-trimethylbenzene (×) in CO_2 as a function of density ρ (according to [41, 87]); for comparison, the self-diffusion coefficient D_{11} of pure CO_2 (+) at 42 °C is plotted according to measurements of *Robb* and *Drickamer* [89].

In Figure 16 $\log D_{1i}$ for benzene, *n*-propylbenzene, and 1,3,5-trimethylbenzene in CO_2 at 40 °C is plotted against density ρ, according to measurements by *Swaid*[41, 87]; for comparison the self-diffusion coefficients D_{11} of CO_2[89] are also given. All D_{1i} values are situated between 10^{-3} and 10^{-4} $cm^2 \cdot s^{-1}$. Thus they are smaller than those of gases at normal pressure by about two or three orders of magnitude; they are, however, greater than in normal liquids by a factor of about 10^2 and are situated below the self-diffusion coefficients of pure CO_2 by one order of magnitude only. It is remarkable that *n*-propylbenzene diffuses faster in supercritical CO_2 than the isomeric 1,3,5-trimethylbenzene. Experiments for naphthalene, phenol, and caffeine gave similar results[88]. These last measurements demonstrated, however, that for even higher-molecular substances increasing interaction with the inner walls of the columns can limit the application of the method.

5.5. Miscellaneous

SFC has already been applied to the determination of molecular weight distributions, *e.g.* for polystyrenes[61] (see Figure 9). An important application of SFC could also become the study of adsorption phenomena on solid surfaces at high pressures from supercritical media[95].

6. Outlook

At present, supercritical fluid chromatography (SFC) is in a state of rapid development. Compared with gas chromatography (GC), it has important experimental advantages especially in the separation of substances with extremely low volatility or thermal stability. Like HPLC and gel chromatography, SFC is also used for special applications, *e.g.* in the petroleum industry or in the separation of oligomers. Additionally, SFC is of great interest for fundamental research concerning fluid extraction or the determination of physicochemical properties of fluid systems. These items alone indicate that the importance of SFC will increase in the future, particularly since commercial HPLC equipment should easily be modified for use in SFC.

Up to now advances in SFC have been made mainly by physicochemists or analytical chemists with physicochemical interests. For the future, studies in the following fields would appear desirable:

1) Fundamental research into the physicochemical properties of fluid pure substances and mixtures at elevated pressures (*e.g.* thermal and caloric equation of state, phase behavior, transport properties, correlation and calculation of physicochemical data).
2) Systematic investigations concerning the mobile phase (*e.g.* use of substances other than CO_2 and of mixtures, as well as choice and dosage of moderators).
3) Systematic investigations concerning the stationary phase (*e.g.* improvement of chemically bonded phases and quantitative physicochemical description of the elementary steps of separation).
4) Development of separation theory in this field (*e.g.* quantitative description of HETP, optimization of operational parameters; see [10, 11, 16]).
5) Improvement of apparatus (*e.g.* with respect to electronic control, use of density programs instead of pressure and/or temperature programs hitherto applied as well as of gradient programs for the dosing of moderators, improvement of detectors and of the experimental technique in preparative applications).

In view the significant progress made in fluid extraction (also on an industrial scale) during the last years, rapid developments may be expected in SFC in the near future.

Our own investigations reported in the present review were started in the late 1960's at the Institute of Physical Chemistry and Electrochemistry of the University of Karlsruhe. The authors are indebted to Professor E. U. Franck for his help and valuable suggestions during that time. Financial support by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Valence Changes at High Pressure in Systems Containing Lanthanoids

By A. Jayaraman[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

Pressure-induced valence change in samarium sulfide SmS is reminiscent of alchemy, for when the electronic transition has taken place, the originally dull looking substance glitters like gold. Although it is not the realization of the alchemist's dream in the true sense, the material in the new state exhibits extraordinarily interesting behavior. As a novel feature, the valence state of the samarium fluctuates between two electronic configurations at a very fast rate. The physical properties of systems containing lanthanoids can be profoundly altered by manipulating the valence state by pressure or by chemical substitution. These phenomena will be described and discussed in the present article.

1. Introduction

I intend reviewing in this paper a topic which is of great interest not only to solid state physics but also to solid state chemistry. In rare earth systems involving Ce, Sm, Eu, Yb, and Tm a change in the valence state of the lanthanoid ion can be induced by high pressure, temperature or by chemical substitution[1]. Usually, the change is from a lower to a higher valence state. The reason for this electronic transition lies in the small energy difference between the $4f^n$ and $4f^{n-1}$ electronic configurations. The valence transition usually

[*] Prof. Dr. A. Jayaraman
Bell Laboratories
Murray Hill, New Jersey 07974 (USA)

leads not to an integral valence but to an intermediate valence state. Materials of this kind generally exhibit extremely interesting properties.

The lanthanoids are predominantly trivalent due to their $4f^n 5d^1 6s^2$ outer electronic structure. On going from cerium to lutetium the inner 4f shell acquires its full complement of 14 electrons, while the number of valence electrons remains constant at 3 (4f-electrons are well localized and do not contribute to bonding). Therefore trivalency dominates the series. However, in accord with Hund's rule, near the half period and towards the end of the lanthanoid series the 5d-electron drops into the 4f-shell, giving a stable half-filled and a fully filled 4f-shell in the case of europium and ytterbium, respectively. Consequently the divalent state is a stable state for these elements. Samarium simulates Eu, and thulium simulates Yb in this respect, and are therefore also stable in the divalent state. The outer electronic structures of these divalent rate earth elements are shown along with that of Ce in Table 1.

Table 1. Outer electron configuration and potential valence state of selected lanthanoids.

Element	II	III	IV
Ce	[a]	$4f^1 5d^1 6s^2$,	$4f^0 5d^2 6s^2$
Sm	$4f^6 5d^0 6s^2$,	$4f^5 5d^1 6s^2$,	[a]
Eu	$4f^7 5d^0 6s^2$	$4f^6 5d^1 6s^2$,	[a]
Tm	$4f^{13} 5d^0 6s^2$,	$4f^{12} 5d^1 6s^2$,	[a]
Yb	$4f^{14} 5d^0 6s^2$,	$4f^{13} 5d^1 6s^2$,	[a]

[a] Non-existent.

The divalent state of Sm, Eu, Tm, and Yb should become unstable under high pressure. This can be foreseen from the fact that they have smaller ionic radii in their trivalent state and hence high pressure would favor the higher valence state. Recent high-pressure experiments on a series of lanthanoid compounds[1-3], in particular the monochalcogenides Sm, Eu, Tm, and Yb, have demonstrated the occurrence of such transformations. Moreover, not only pressure can effect this transition but also chemical substitution. A vast amount of literature has accumulated on this subject in recent years and the field of valence changes continues to be of great interest, both experimentally and theoretically[4].

The most interesting feature concerning valence transition is that the valence change is not integral but has an intermediate value. For instance in SmS, a classic substance in this regard, the valence of the high pressure phase obtained at 7 kbar is 2.7. The intermediate valence state has been variously referred to as "homogeneously mixed valence state", "fluctuating valence state", or "interconfiguration fluctuation". We will discuss the anomalous properties of this phase below.

2. Valence Change in Cerium

Historically a first-order transition in cerium at about 7 kbar was first reported in 1927[5]. Subsequent studies[6,7] established that the phase transition discovered by *Bridgman* is associated with a change in the valence state in metallic cerium, from trivalent towards the tetravalent state: this was concluded primarily from the fact that the face centered cubic *(fcc)* structure of cerium is retained while the volume decreases by about 12%. Subsequent pressure/temperature studies established the phase diagram[8] reproduced in Figure 1. The unique features of this the phase diagram are the termination of the so-called γ to α cerium phase boundary at a critical point and the shallow minimum in the melting curve. Critical termination of a phase boundary is common for vapor/liquid systems but uncommon for a solid phase boundary. The existence of a critical point for a solid-solid transition, first demonstrated in the case of cerium, would appear to characterize substances undergoing an isostructural transition. As in the case of a liquid/vapor equilibrium, there is no symmetry restriction upon a continuous transition, and hence critical points appear natural for isostructural transitions.

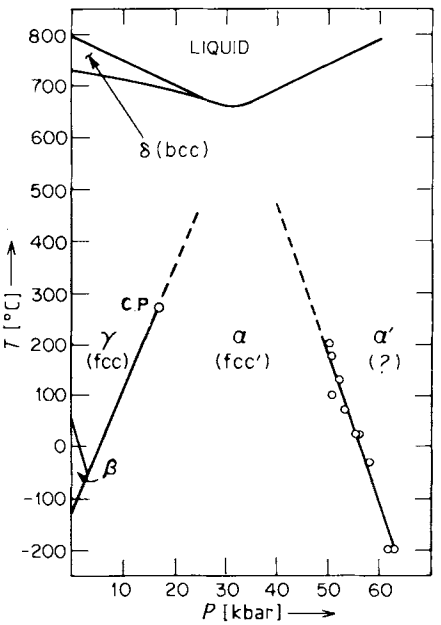

Fig. 1. Phase diagram of cerium. CP is the critical point for the γ- to α-cerium transition. β-Ce is dhcp.

The anomalous fusion behavior of cerium is again connected with valence change; the turnover in the fusion curve stems from a continuous valence change in *fcc*-cerium in the supercritical region. So far, α-cerium remains the only substance that exhibits a broad fusion curve minimum. At a pressure near 55 kbar and at room temperature, cerium is believed to undergo another isostructural transition, associated with a further change in valence towards the quadrivalent state.

3. Valence Change in Samarium Monochalcogenides

The lanthanoids and chalcogens form one-to-one compounds which all crystallize in the NaCl-type structure. A plot of their lattice parameter against atomic number is shown in Figure 2. The Sm, Eu, and Yb monochalcogenides have anomalously large lattice parameters, in the otherwise smoothly decreasing series of values. These anomalous values reflect the larger size of the divalent cation. While the compounds of the divalent metals are semiconductors, those of the trivalent ones are metallic. There is a very simple rea-

son for this: when the lanthanoid ion is divalent there is exact charge compensation and no electron is available for conduction (for instance, SmS in the ionic representation is $Sm^{2+}S^{2-}$ and the two valence electrons of Sm are taken up by the sulfur).

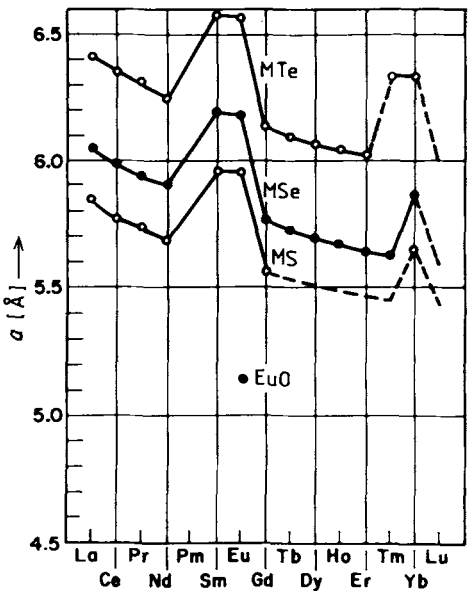

Fig. 2. Lattice parameter of lanthanoid monochalcogenides. The M^{II} monochalcogenides have anomalously large lattice parameters. Eu in EuO is divalent.

In the monochalcogenides of trivalent lanthanoids (for instance $Gd^{3+}S^{2-}+1e$) however, one electron per molecule is available for conduction (*ca.* 10^{22} electrons per cm^3). When a monochalcogenide of a divalent lanthanoid, such as SmS, is subjected to pressure it transforms according to

$$Sm^{2+}S^{2-} \rightarrow Sm^{3+}S^{2-} + 1e$$

A semiconductor-to-metallic transition results, and approximately 10^{22} electrons per cm^3 are released from the localized 4f state into the conducting 5d state. This valence change and 4f electron delocalization occur in SmS near 7000 bar. It is a spectacular phase transition reminiscent of alchemy, for the initially dull black substance suddenly glitters like gold when the transition pressure is exceeded. The material returns to its original state when the pressure is released, exhibiting a large hysteresis characteristic of a first-order transition.

The electrical conductivity of SmS abruptly increases at the transition pressure, as would be expected for a semiconductor-to-metallic transition. The resistance *vs* pressure behavior of samarium monochalcogenides is shown in Figure 3. In the case of SmSe and SmTe the semiconductor-to-metallic transition due to the valence change occurs continuously, as reflected in the ten orders of magnitude decrease in the resistivity over the 1–60 kbar region.

X-ray studies show that the NaCl-type structure is retained while the lattice contracts, resulting in a substantial change in volume. When the 4f electron is promoted to the 5d state, the outer-electronic structure of the samarium ion experiences an additional attractive force from the now unscreened nuclear change. This considerably reduces the ionic radius, and has been called an "electronic collapse", in which the crystal structure does not change but the lattice parameter simply decreases. Consequently, the compressibilities of these compounds are anomalous (see Fig. 4). The pressure-volume relationships clearly confirm the continuous nature of the valence transition in SmSe and SmTe, and a first-order phase transition in SmS.

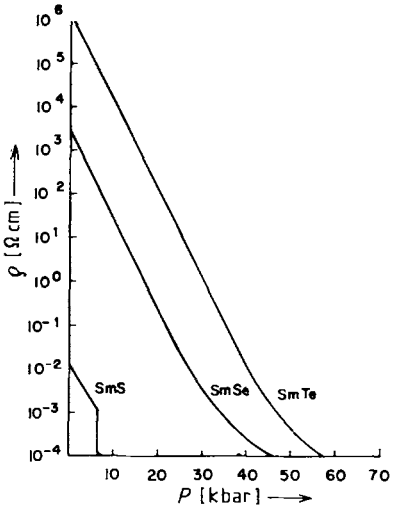

Fig. 3. Resistance *vs.* pressure data for samarium monochalcogenides. SmS undergoes a first-order transition due to valence change.

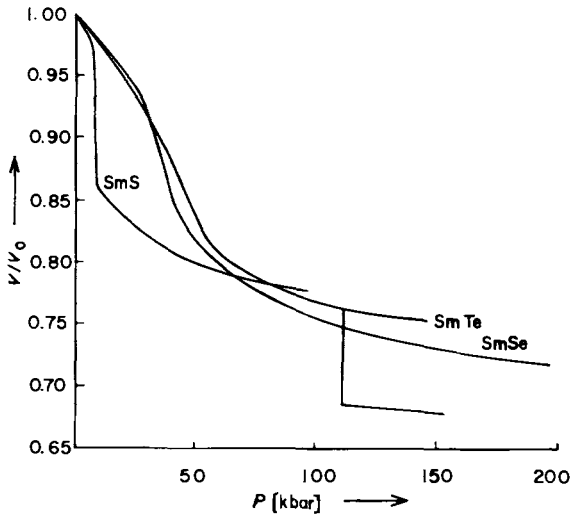

Fig. 4. Pressure-volume relationship for samarium monochalcogenides. The abrupt change in SmS is due to valence change (isostructural transition) and the abrupt change in volume for SmTe near 110 kbar is due to NaCl-CsCl transition.

It is also remarkable that the color of SmSe and SmTe turns bright copperish and metallic purple respectively. In fact, the sequence of color changes resulting from the increase in the electron concentration can be vividly seen with the latter two substances in a diamond anvil cell, which permits optical observation on the samples while they are subjected to high pressure. That the color should change with electron concentration is connected with what is known as the "plasma edge" associated with systems containing free electrons. The bright reflectivity of metals has its origin in this effect and since valence change induces the metallic state, the observed changes are to be expected. The charac-

teristic colors of the metallic chalcogenides are, however, connected with what is known as the interband contribution to the dielectric constant. Thus the change in color under pressure constitutes visible evidence of the valence transition in these divalent rare earth monochalcogenides.

It has been shown that the phase transition in SmS can also be induced by substituting a trivalent lanthanoid ion such as Gd^{III} for Sm^{II}[1,9]. The lattice parameter behavior for the substituted system $Sm_{1-x}Gd_xS$ is shown in Fig. 5. The lattice parameter varies smoothly up to $x=0.15$ and then abruptly decreases at higher gadolinium concentrations. The substance appears black up to the critical concentration, and then turns gold-like. Apparently an internal lattice pressure on Sm^{2+} arises on substitution, because the Gd^{3+} ion is much smaller than Sm^{2+}; this forces the Sm^{2+} to change its valence state.

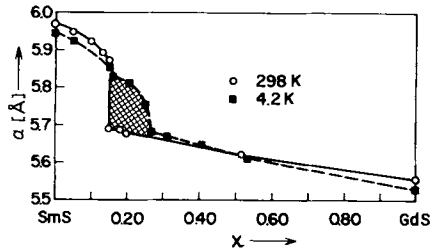

Fig. 5. Lattice parameter of $Sm_{1-x}Gd_xS$ as a function of x. The shaded region represents the composition range where the metallic phase would transform to a black phase on lowering the temperature, due to relocalization of the 4f-electron.

Thus chemical substitution can stabilize the high pressure phase at atmospheric pressure, which greatly facilitates its study. Such substitutions have been attempted for the whole lanthanoid ("Ln") series[9,10] and very interesting results have been reported for the $Sm_{1-x}Ln_x^{3+}S$ systems.

4. Intermediate Valence

As noted in Section 1, the most interesting aspect of the valence change is that an intermediate valence state is established. The lattice parameter of the collapsed SmS is found to be 5.68 Å. If the samarium had collapsed fully to the trivalent state, its lattice parameter would have decreased to 5.62 Å; this can be calculated from the known ionic radii of Sm^{3+} and S^{2-}. Thus one is led to conclude from the intermediate lattice parameter that the samarium ions have not changed their valence all the way to the Sm^{3+} state. However, the intermediate lattice parameter in itself is not sufficient proof for the intermediate valence state, for the following reason. It is possible to have in the collapsed metallic phase of SmS a mixture of Sm^{3+} and Sm^{2+} ions distributed randomly in the lattice and still observe an intermediate lattice parameter. According to *Vegard*'s law, in systems which are completely miscible with each other the lattice parameters can adopt any value intermediate between those of the pure compounds. However, confirmation that our system is not a statistically frozen mixture of Sm^{2+} and Sm^{3+} ions comes from the magnetic susceptibility behavior of the high pressure metallic phase[11] (Fig. 6). The Sm^{3+} ion should carry a local magnetic moment (angular momentum quantum number $I=5/2$) which means that one can expect strong diver-

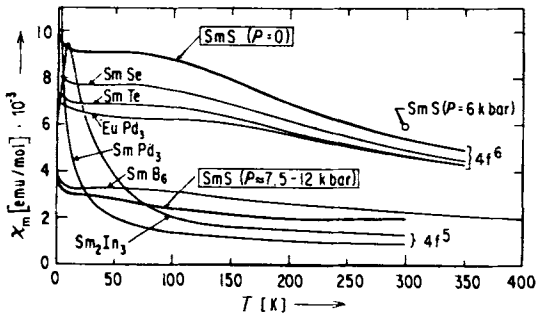

Fig. 6. Magnetic susceptibility of the high-pressure metallic phase of SmS. Other substances containing Sm^{3+} are shown for comparison. SmB_6 also exhibits behavior similar to the metallic phase of SmS. The insulating SmS phase ($P=0$) exhibits van Vleck paramagnetism.

gence in magnetic susceptibility and even magnetic ordering at low temperatures. The data in Figure 6 show neither of these to apply; in fact the susceptibility at lower temperatures is found to remain constant with temperature. This behavior is not consistent with the presence of Sm^{3+} ions, but corresponds to an intermediate valence state in which an electron fluctuates very rapidly between two electronic configurations, namely $4f^5 5d^1$ and $4f^6 5d^0$; the former is magnetic and the latter is not. Because of this rapid fluctuation the electron does not stay in the magnetically active state for sufficient length of time to contribute to the magnetic susceptibility.

In a quantum mechanical sense[12] the fluctuating valence means that the wave function of the electron is a mixture of functions having f- and d-character; the f- and d-states are hybridized:

$$\Psi = a\Psi_f + b\Psi_d$$

where a and b give the proportion of f- and d-character. The electronic band structure of such a state of affairs is represented schematically in Figure 7.

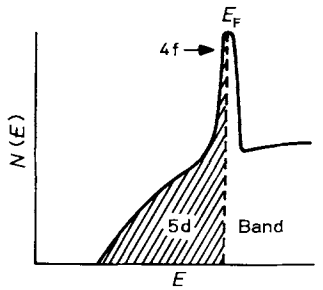

Fig. 7. In the intermediate valence phase of SmS, the Fermi level E_F is pinned at the 4f-level; the electron has both f and d character.

The Fermi level E_f is pinned to the 4f-states, and the wave function near the peak of $N(E)$ is a linear combination of f- and d-type wave functions. This picture of homogeneously mixed valence state derives support from many experimental studies on the high pressure metallic phase by X-ray photoelectron spectroscopy[13], and Mössbauer spectroscopy[14], and from measurements of transport properties[15], magnetic properties[16], bulk modulus[17], and low temperature specific heat[18]. The Debye-Waller factors for the X-ray reflections of the intermediate valence phase of SmS[19] and neutron scattering[20] studies seem to indicate that the time scale of

the fluctuation is around 10^{-12} s. The whole lattice "breathes" in unison, with the average size of the samarium ion at the lattice point corresponding to a valence of 2.7+. The picture of hybridization mentioned above may appear to be inconsistent with fluctuations between two electronic configurations, but it must be remembered these are merely two different ways of looking at the intermediate valence state.

Valence changes have also been found in the ytterbium monochalcogenides and in EuO[2]. In the Eu and Yb monochalcogenides the 4f—5d separation is far larger than for SmS and hence higher pressures are needed. These compounds are thus much more stable in the divalent state; this is to be expected because the Hund's rule stability conditions are met for Eu^{II} and Yb^{II}. The pressure-volume relationships, which provide the strongest evidence for valence change in these systems, are shown for Yb and Eu monochalcogenides in Figures 8 and 9.

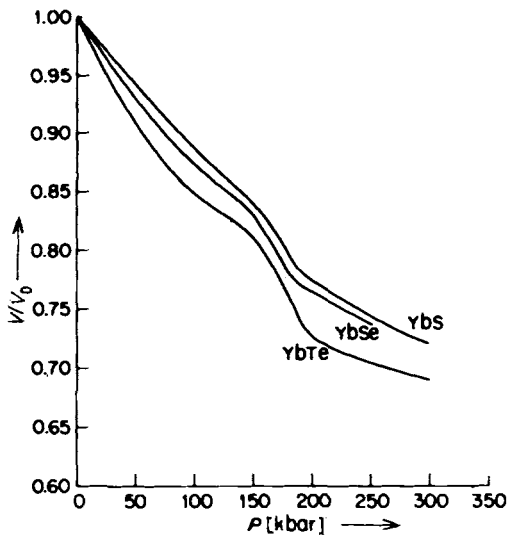

Fig. 8. Pressure-volume behavior of ytterbium monochalcogenides. The anomalies are due to valence changes.

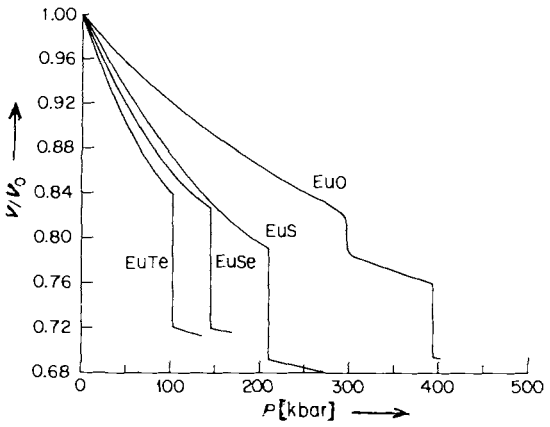

Fig. 9. Pressure-volume relationship for europium monochalcogenides. The abrupt changes in EuTe, EuSe, and EuS are due to NaCl-CsCl transition. EuO exhibits both a valence change (near 300 kbar) and NaCl-CsCl transition (near 400 kbar).

All the Yb monochalcogenides undergo a valence change which is believed to occur continuously with pressure. The color of the substance shows spectacular changes to metallic gold, copperish, and deep purple in YbS, YbSe, and YbTe respectively, which is again strong evidence for the valence change. In the case of Eu monochalcogenides, there is a competing phase transition from NaCl-type to CsCl structure. The discontinuities in Figure 9 for the Eu chalcogenides are due to the latter transition, except in the case of EuO. Only in the case of EuO does the valence change precede the NaCl-CsCl transition; this follows from the appearance of two volume discontinuities, the first of which is an isostructural transition. The homologous compounds should also exhibit the valence change at very high pressure.

5. Other Systems

Another samarium-containing system which also exhibits a valence change at high pressure will now be discussed. This compound is not as simple as the chalcogenides and has the formula Sm_4Bi_3[21]. It crystallizes in the so-called *anti*-Th_3P_4 structure, since the less electronegative samarium occupies the P sites and the more electronegative bismuth the Th sites. However, it still has a cubic structure and is easy to study by X-ray diffraction under high pressure. Charge compensation according to $3\,Sm^{2+} + 1\,Sm^{3+} + 3\,Bi^{3-}$ provides a reasonably accurate description of the compound, as confirmed by the plot of the lattice parameter[5] shown in Figure 10. The lattice constants of Sm_4Bi_3, Eu_4Bi_3, and Yb_4Bi_3 are anomalously large compared to those of the trivalent lanthanoids. In the latter the extra electron becomes a conduction electron. Thus the compounds in which the lanthanoid tends towards the divalent state are found to be semimetals with overlapping

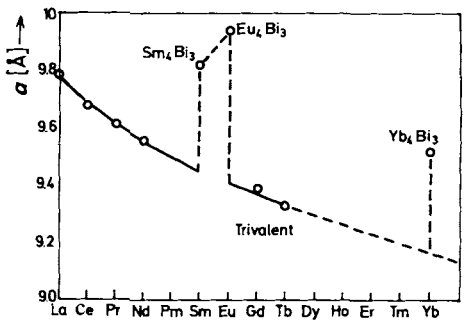

Fig. 10. Lattice parameters for the Ln_4Bi_3-type compounds. The anomalies at Ln = Sm, Eu, and Yb reflect the partial divalent nature of the lanthanoid ions.

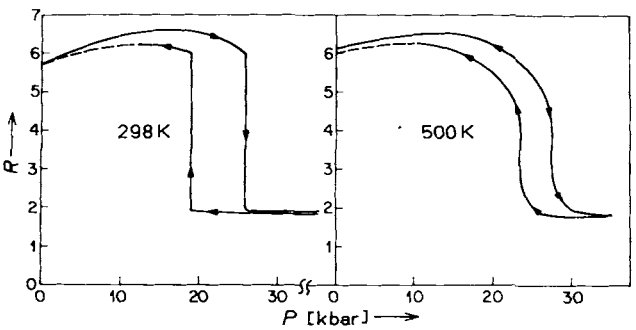

Fig. 11. Resistance (arbitrary units) *vs.* pressure data for Sm_4Bi_3. The abrupt decrease is due to the valence transition near 27 kbar. At 500 K the resistance anomaly becomes rounded. This is due to critical termination of the phase boundary at about 800 K.

valence and conduction bands. When high pressure is applied, the divalent ions may be expected to change to the higher valence state. The first of this group of compounds to be studied is Sm_4Bi_3 which shows the valence transition at about 27 kbar. Figure 11 shows the resulting sharp decrease in electrical resistivity. In Figure 12 the lattice parameter is shown as a function of pressure. An isostructural transition takes place at precisely 27 kbar with an abrupt decrease in the lattice parameter, showing the valence transition in Sm_4Bi_3 to be of first order.

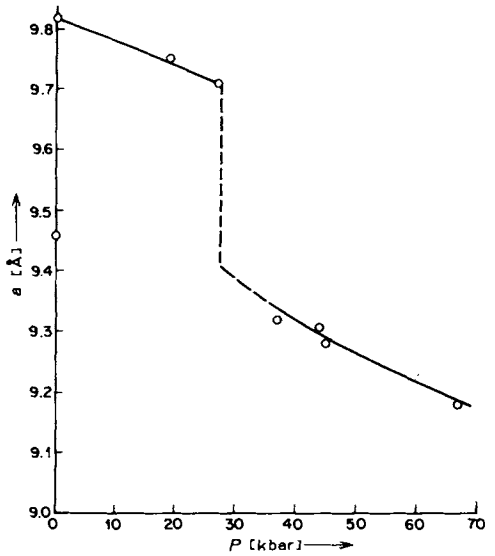

Fig. 12. Lattice parameter change under pressure for Sm_4Bi_3. The first-order valence transition is marked by an abrupt volume decrease without change of structure (isostructural transition).

The phase diagram for Sm_4Bi_3 is shown in Figure 13. Interest again centers on the critical termination of the phase boundary connected with the isostructural transition. The phase boundary in the low temperature region is connected with another subtle transition in Sm_4Bi_3, the origin of which is not clear at present.

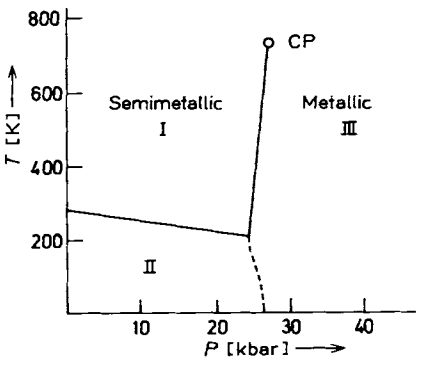

Fig. 13. Pressure/temperature diagram of Sm_4Bi_3. The I-II phase change is seen as a striking resistance decrease. The dotted line has been arbitrarily drawn as representing the II-III phase change.

Pressure studies on cerium-based systems are of much current interest, for pressure can change the valence state of cerium from Ce^{III} to Ce^{IV}, through an intermediate state[4]. There seem to be three distinct types of behavior in these systems: (i) In the trivalent state cerium carries a local magnetic moment and hence exhibits magnetic order at low temperatures; (ii) in the strongly mixed valence state the magnetism is quenched by fluctuations; and (iii) in the quadrivalent state the 4f-level is far removed from the d-band, so that it is unoccupied and the system becomes a d-band metal which may exhibit superconductivity at low temperatures[22]. Thus merely by varying the pressure we can change the system all the way from magnetism to superconductivity through an intermediate state of mixed valence. This has already been demonstrated for cerium metal.

6. Concluding Remarks

The subject of valence instabilities is at present an active field of research both from the theoretical and from the experimental point of view. Many different models and ways of looking at the so-called homogeneously mixed valence phases have been proposed, but there is still no unified picture valid for all of them. For instance, SmB_6 appears to have a hybridization gap, whereas it is not clear if SmS has a similar gap. TmSe is another system which seems to stand on a different footing. More experiments are necessary if we are to understand the homogeneously mixed valence state at the microscopic level. Homogeneously mixed valence states may have analogies in narrow d-band situations and further developments in this area are expected.

Among the potential applications of the novel state, the most obvious lies in the exploitation of the metal-semiconductor transition. Another promising application utilizes the sharp change in optical reflectivity accompanying the transition. However, such applications must await the solution of problems associated mainly with hysteresis.

From the chemical point of view, it has been suggested that the homogeneously mixed valent materials might be excellent catalysts. This most interesting aspect may turn out to be one of the most fruitful applications of fluctuating valence materials. Valency and valence changes are chemical concepts which still hold surprises in store.

I wish to thank Professor Manuel Cardona for critically reading the manuscript and the Alexander von Humboldt Foundation for the U.S. Senior Scientist award, during the term of which this paper was written at the Max-Planck-Institut für Festkörperforschung, Stuttgart.

Liquid Metals and Liquid Semiconductors[**]

By Friedrich Hensel[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

Numerous liquid systems have electrical properties which resemble those of crystalline and amorphous semiconductors. The existence of "semiconducting" behavior in these liquids is mostly related to a continuous transition from a metallic to a "semiconducting" state when a thermodynamic variable such as temperature, density or concentration is changed. Changes in the nature of the chemical interaction and the associated changes in the structure of the liquid are of fundamental importance for the transition to a "semiconducting" state. This will be demonstrated for the ionic liquid CsAu, for covalent liquid selenium, and for expanded liquid metals.

1. Introduction

The discovery of noncrystalline semiconducting materials and the application of such "amorphous semiconductors" for technical purposes have stimulated an increasing interest in the electrical and physicochemical properties of electronically conducting liquids during the past 15 years. According to a proposal by *Joffe* and *Regel*[1] two classes of such liquids can be distinguished: "liquid metals" and "liquid semiconductors". At present the line of distinction between the two classes is arbitrary since generally accepted theoretical or experimental criteria are still lacking. It has become established practice to call those liquids which have electrical conductivities σ larger than 2000 $ohm^{-1}\,cm^{-1}$ metallic, since the mean free paths of the electrons calculated from σ within the framework of the free electron model[2,3] are mostly larger than the mean interatomic distance. Liquids with conductivities σ smaller than 300 $ohm^{-1}\,cm^{-1}$ are called "semiconducting"[4] because they exhibit some properties which are typical for solid crystalline and amorphous semiconductors, *e.g.* a positive temperature dependence of σ characterized by the presence of an activation energy.

The difficulty in precisely defining the boundaries between the two types of conduction is essentially related to the existence of a continuous transition from semiconducting to metallic behavior which is observed in most semiconducting liquids on changing a thermodynamic variable such as temperature, density, or composition. Conversely, it is always possible, at least in principle, to transform any metallic liquid into a semiconducting or insulating state by expansion to very low densities or by alloying with a nonmetal. Hence, a comprehensive theoretical description of semiconducting liquid systems must include not only the properties of the semiconducting range, but must also account for the properties during the course of the metal-nonmetal transformation, *i.e.* it must include a description of the electrical properties of those liquids which lie at the borderline between typical metals and typical semiconductors. Accordingly, the most appropriate experiments for the investigation of electronically conducting liquids are those which not only extend to the semiconducting and the metallic state but also embrace the transition range between the two. In Table 1 a list of groups

Table 1. List of selected liquid systems in which a metal-nonmetal transition can be induced.

Group	System	Inducing physical effect
1	Semiconducting alloys (Mg_3Bi_2, Li_3Bi, CsAu, *etc.*)	change of concentration
2	Metal-salt mixtures (Cs—CsCl, Bi—$BiCl_3$, *etc.*)	change of concentration
3	Alloys of metals with S, Se, Te (Tl_2Te, In_2Se_3, Ga_2Te_3, *etc.*)	change of concentration
4	Se, Te and their mixtures (Se_xTe_{1-x})	change of chemical structure by an increase of temperature and pressure
5	Metals (Hg, Cs, Rb, K, *etc.*)	expansion to low densities at high temperature

of liquids is assembled for which semiconducting properties and a metal-nonmetal transition have been observed.

Changes in the chemical interaction and the associated structural changes of the liquid are of fundamental importance for the transition from metallic to semiconducting behavior. The best evidence for this is provided by the semiconducting liquid alloys (Table 1, Group 1). Although *e.g.* molten Li, Cs, Mg, Au, Bi, Pb and Sb are very good metallic conductors, their liquid mixtures have a relatively low conductivity at the stoichiometric compositions Li_3Bi, Li_4Pb, Mg_3Bi_2, Cs_3Sb and CsAu. At the same time the temperature dependence of the conductivity is positive. In this article, interest is focussed on the role of charge transfer in these systems, *i.e.* whether the chemical interaction is essentially ionic, as in salts. If this is the case the metal-nonmetal transition in this group would be similar to the transition observed in metal-molten salt mixtures (Table 1, Group 2), whose properties have been extensively studied by *Bredig*[5,6] and about which there are recent detailed reviews by *Nachtrieb*[7] and *Warren*[8]. We shall therefore exclude from further consideration these metal-molten salt systems as also the alloys of metals with the nonmetallic elements S, Se and Te which are listed as Group 3 in Table 1. The properties of the latter systems have also been reviewed recently[8-10]. In many respects they behave similarly to the alloys with two metallic constituents (Table 1, Group 1); here also, the conductivity has a minimum at the stoichiometric composition.

The chemical interactions in the systems mentioned above vary widely from essentially ionic to predominantly covalent depending on the differences in electronegativity of the constituent atoms, whereas in the pure liquid elemental semiconductors S, Se and Te the chemical interaction is purely covalent with a small contribution of van-der-Waals-interaction. The electronic and structural properties of selenium are especially interesting when considered over a larger temperature and pressure range. Near the melting point the properties of liquid selenium are consistent with the assumption that it consists of long polymeric chains containing up to 10^5 atoms[11,12]. However, the average chain length, the local liquid structure and the coordination number can change with increasing temperature and pressure. This continuous change in molecular structure is accompanied by a significant modification of the electronic structure: At high temperatures and pressures a continuous transformation into a liquid with conductivities approaching those in the metallic range is observed[13].

In addition to the transitions between metallic and predominantly ionic or purely covalent interaction, which will be discussed in the present article in detail for liquid CsAu and selenium, metal-nonmetal transitions in expanded fluid metals like Hg, Cs or Rb are of great theoretical and technical interest (Table 1, Group 5). Such a transition occurs in any metal at very high temperatures due to thermal expansion of the liquid to low densities[14]. As in the other systems this transition from metal to nonmetal implies that the nature of the chemical or interatomic interaction changes. A knowledge of the physicochemical mechanism of the transition is of fundamental importance, since the thermodynamic properties, as *e.g.* the free energy, the equation of state, or the specific heat of the system are determined by the interatomic interaction. This is especially important in view of the possible technical applications of liquid metals at high temperatures. In this case thermodynamic data are needed; a theoretical prediction and treatment of such data is desirable.

2. Liquid Ionic Alloys

In some liquid binary alloys of metallic constituents the conductivity passes through a minimum at well defined stoichiometric compositions. The most extensively studied system is the Cs-Au system, whose electrical conductivity σ in the concentration range between 0 and 60 atom-% Au at 600 °C is plotted in Figure 1. σ changes by almost four orders

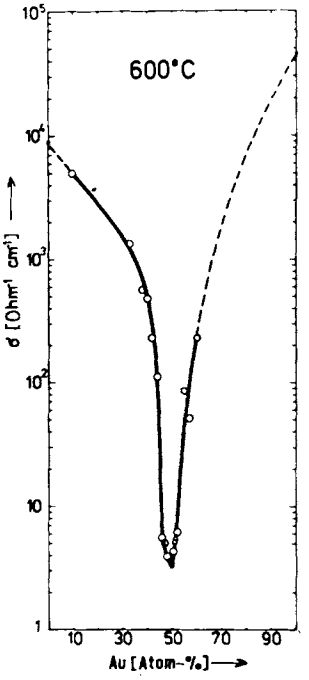

Fig. 1. Electrical conductivity σ of liquid Cs-Au mixtures as a function of the gold content at 600 °C.

of magnitude and has a pronounced minimum of 3 ohm^{-1} cm^{-1} at the stoichiometric composition CsAu. This value is of the same order of magnitude as the conductivities of molten salts; *e.g.* σ of CsCl at the melting point is about 1 ohm^{-1} cm^{-1}.

The transition to nonmetallic behavior is accompanied by a change in the temperature dependence of σ[15,16]. In Figure 2 the logarithm of the conductivity is plotted versus the reciprocal temperature. At a concentration of 44 atom-% Au, corresponding to a conductivity of about 100 ohm^{-1} cm^{-1}, the temperature dependence changes from negative to positive. The corresponding apparent activation energy E_A of the conductivity calculated according to the relationship

$$\sigma = \sigma_0 \exp(-E_A/RT) \qquad (1)$$

approaches a maximum of about 20 KJ/mol at the stoichiometric composition. It is not possible, however, to decide whether E_A is the activation energy of the diffusive motion of the ions Cs^+ and Au^- or that of thermally activated electrons, since eq. (1) is valid for both conduction mechanisms. Measurements of the optical absorption are required. Analogously to crystalline semiconductors there also exists for non-

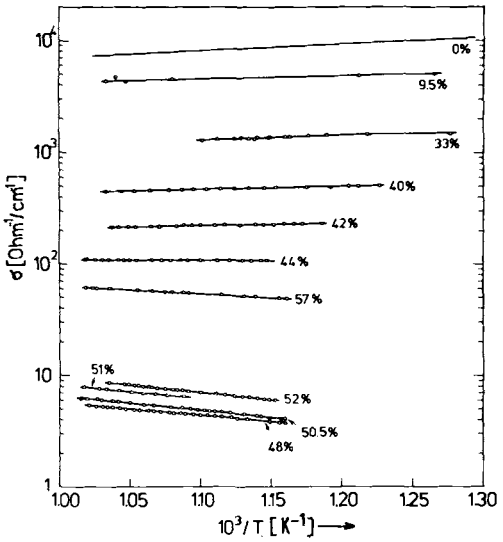

Fig. 2. Electrical conductivity σ of liquid Cs-Au mixtures as a function of the reciprocal temperature at different Au-concentrations in atom-%.

crystalline semiconducting systems a correlation between E_A for thermally activated electrons and the distance between valence- and conduction-band as derived from the optical absorption edge. However, in disordered systems—including liquids—the absorption edges are far from sharp, because there are always a few allowed states for an electron in energy ranges which are forbidden in the corresponding crystalline arrangement[4]. A schematic representation of this situation is given in Figure 3. The singularities in the electronic

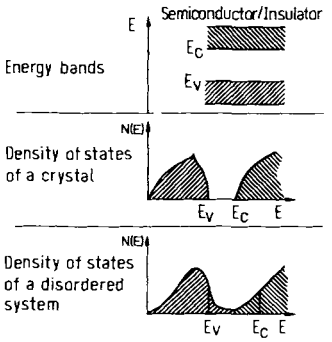

Fig. 3. A schematic representation of the energy bands and the density of states $N(E)$ as a function of the energy E of a crystalline semiconductor or insulator and a corresponding disordered semiconducting system. E_c = bottom of the conduction band, E_v = top of the valence band.

density of states $N(E)$ at the band edges are smeared out. The energy gap in the crystal [$N(E)=0$] is replaced by a minimum in $N(E)$. Figure 4 shows new results for the optical absorption edges of CsAu in the solid as well as in the liquid state[17]. The spectral dependence of the absorption coefficient $K(\omega)$ for solid CsAu (from 25 °C to 560 °C; CsAu melts at 590 °C[18]) and for liquid CsAu (626 °C) is shown as a function of the photon energy. The absorption edges of the solid phase exhibit the expected red shift which is usually observed for crystalline semiconductors or ionic insulators with increasing temperature[19]. On melting, there is an abrupt change in the position of the absorption edge of about 0.7 to 0.8 eV. The lower part of Figure 4 shows the temperature de-

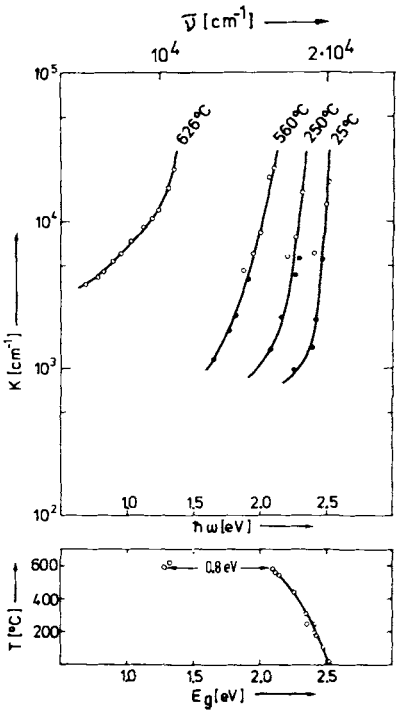

Fig. 4. Top: Optical absorption of a 100 μm-thick sample of solid or liquid CsAu as a function of the photon energy. Bottom: the temperature dependence of the position of the absorption edge. The arrow indicates the abrupt change of the position of the edge at the melting point (590 °C).

pendence of the position of the optical gap which corresponds roughly to the gap between valence- and conduction-band. It is a plot of the photon energy corresponding to $K=10^4$ cm^{-1} as a function of the temperature. There is a striking quantitative similarity between the behavior of CsAu and that of molten salts, as is demonstrated in Figure 5, where measurements of the absorption edges as a function

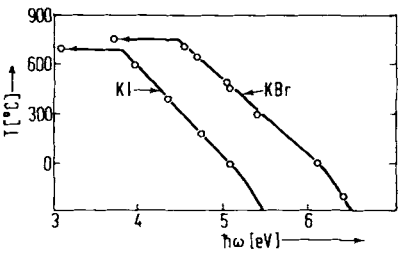

Fig. 5. Position of the absorption edge of 1 mm-thick samples of salt in the solid and liquid state. The abrupt change of the position takes place at the melting point.

of temperature are reproduced for solid and molten KI and KBr[20]. The experimental points correspond to the highest energy of light transmitted through a 0.1 cm-thick layer of the molten salt sample. The similarity between the data for CsAu and those for the molten salts is consistent with the assumption of predominantly ionic bonds in solid and liquid CsAu.

Comparison of the measured optical energy gap between valence- and conduction-band in liquid CsAu of 1.3 eV with the activation energy E_A measured for the electrical conductivity σ leads directly to the conclusion that σ is determined by ionic conduction. For a crystalline or noncrystalline intrinsic semiconductor the optical energy gap should be about

twice the activation energy for thermally activated electrons; *i.e.* one would expect an E_A-value of about 63 KJ/mol. In contrast to this the measured value of $E_A = 20$ KJ/mol is of the same order of magnitude as that observed for ion migration in salts[21]. Direct experimental evidence that liquid CsAu is entirely ionic like fully ionized salts stems from an electromigration experiment[22,23]. When electrolyzed, liquid CsAu conforms to Faraday's law. Within experimental error, one Cs^+ and one Au^- are transported to the relevant electrodes per elementary charge. Measurements of the absolute thermoelectric power also show that the contribution of electrons to the electrical transport in the liquid Cs-Au system near the stoichiometric composition is negligibly small.

Our knowledge about the electrical properties of the solid stoichiometric compound CsAu is quite poor compared to what we know about molten CsAu. The phase diagram[18] shows the existence of a congruent melting phase with a narrow range of homogeneity. It melts at 590 °C and is known to crystallize with the CsCl structure with a lattice constant of 4.263 Å[24]. The corresponding calculated molar volume of 46.63 cm^3 is 42% smaller than the volume obtained by simply adding the atomic volumes of Cs and Au. The optical energy gap at 25 °C (Fig. 4) is 2.6 eV[17,25]. On the basis of electrical conductivity σ and thermoelectric power[26,27] measurements it can be deduced that solid CsAu is always an extrinsic n-type semiconductor. Since the measured conductivity σ is always relatively large (ranging from 5 to 100 $ohm^{-1}\ cm^{-1}$) and not well reproducible, and since its temperature dependence is slightly negative (like in metals), it is suggested that a broad impurity band is formed by excess cesium which may eventually overlap with the conduction band. NMR measurements[24] show that the excess Cs is atomically dispersed in the CsAu.

Several band structure calculations have been performed for CsAu[27-29]; the results compare well with photoemission valence-band data[27,30], and they confirm the essential ionic character of the bonds in CsAu. Further support for this ionicity stems from recent Mößbauer[31] and ESCA spectroscopic measurements[32]. However, with an energy gap of 2.6 eV (at 25 °C) between conduction- and valence-band, CsAu belongs to those compounds which lie on the borderline between electronic semiconductors and ionic insulators. Consequently, CsAu shows features of both (*i.e.* electronic and ionic conductivity), as is clearly demonstrated by the behavior of the electrical conductivity at the melting point (Fig. 6). The marked change in σ on melting indicates that the electrical transport mechanism in liquid CsAu is different from that in solid CsAu. Other semiconducting substances show, in contrast to the decrease in conductivity of CsAu, a more or less large increase in σ on melting. For these semiconductors two groups must be distinguished. In the first group (Ge, Si, InSb *etc.*) the coordination number and the nature of the chemical interaction change drastically on melting. The melt becomes a metallic conductor, *i.e.* a semiconductor-metal transition accompanies the solid-liquid phase transition[33]. In the second group (Se, In_2Se_3, Ga_2Te_3 *etc.*) the coordination number changes only slightly in the melt and the short-range order of the solid persists to a large extent, *i.e.* at the melting point a transition from a solid to a liquid semiconductor occurs. In these systems the short-range order is changed only at very high temperatures and a continuous transition to metallic behavior occurs (see Section 3).

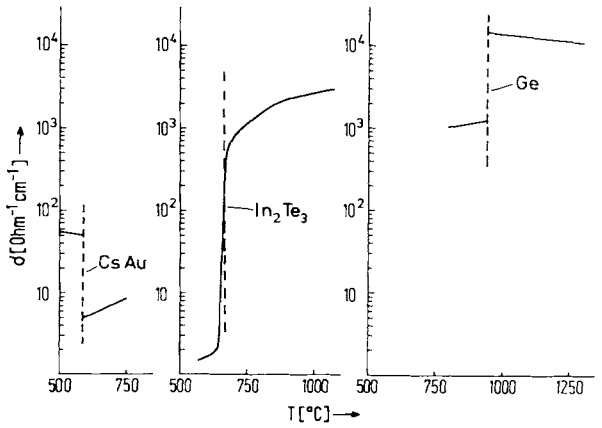

Fig. 6. Comparison of the behavior of the electrical conductivity of semiconductors at the melting point: CsAu, In_2Te_3 and Ge.

It is evident from the results presented above that CsAu does not belong to one of these two groups. It is possible for semiconductors with essentially ionic bonds and energy gaps of between 2.5 eV and 3 eV at room temperature that the solid-liquid phase transition coincides with a transition from a solid electronic semiconductor to a liquid ionic conductor. CsAu is the first example for which such a transition has been observed.

The concentration dependence of the conductivity σ in the liquid Cs-Au system (Fig. 1 and 2) establishes the occurrence of a transition from metallic to nonmetallic behavior. At σ-minimum for the stoichiometric composition CsAu the electrical transport is determined by the diffusive motion of Cs^+ and Au^-. Therefore, it seems reasonable to assume that bound states associated with the formation of Cs^+Au^- ionic assemblies remove electrons from the conduction band of cesium if the concentration is changed between pure Cs and

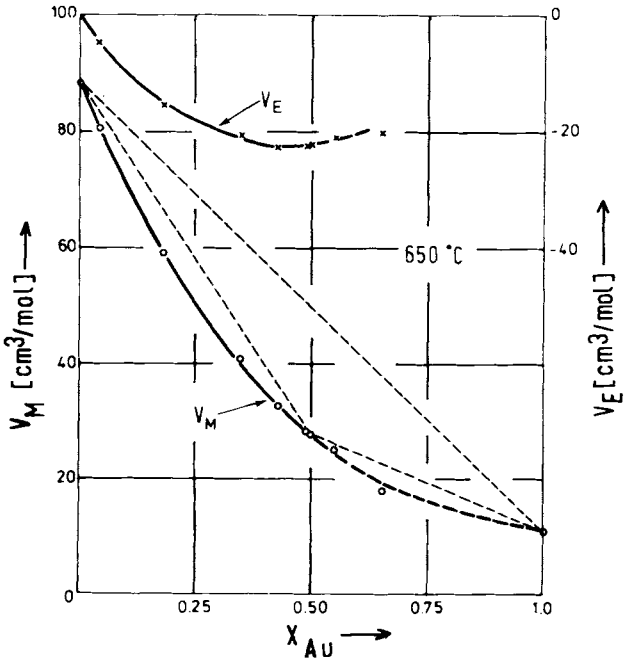

Fig. 7. Molar volume of the mixture V_M and excess volume V_E of liquid Cs-Au mixtures as a function of the mol fraction of gold.

CsAu; *i.e.* the liquid alloys over the whole concentration range—including the metallic range—are assumed to be binary mixtures of Cs^+ and Au^- and the excess metal Cs or Au. Direct evidence for the validity of this assumption comes from very recent measurements of the concentration dependence of the molar volume of the mixtures[34,35] and of the radial distribution function[35,36].

Figure 7 shows the data compiled by *Kempf* and *Schmutzler*[34] for the volume of the mixture $V_M(x)$ as a function of the mole fraction x together with those of the excess volumes V_E.

$$V_E = V_M(x) - (1-x)\,V_M(0) + x\,V_M(1) \tag{2a}$$

V_E has a broad minimum in the vicinity of the stoichiometric composition CsAu. Its unusually large negative value is comparable with the strong contraction observed on formation of CsI or CsBr from their pure constituents. Assuming that the packing fraction in the stoichiometric CsAu melt is about the same as that in molten cesium halides, *Kempf* and *Schmutzler*[34] estimated from the V_M and the well known ionic radius of Cs^+ (1.65 Å) the value $r_{Au^-} = 1.8$ Å for the Au^- ion. The resulting value for the average nearest-neighbor distance of 3.45 Å is in surprisingly good agreement with that of 3.55 Å obtained from the measured total pair distribution function[35]. Figure 8 shows the pair distribution function $g(R)$

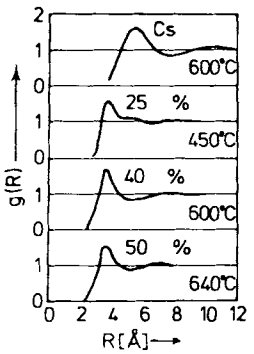

Fig. 8. Pair distribution function $g(R)$ of liquid Cs and liquid Cs-Au mixtures at different concentrations. The numbers labeled at the curves are the concentrations of Au in atom-%.

for different liquid Cs-Au mixtures which were obtained from neutron diffraction data and which are reproduced from a paper by *Martin et al.*[35]. In view of the hypothesis that an Au^- ion is formed even in very dilute solutions of Au in Cs it is especially interesting that for a Au-concentration of only 25 atom-% a first maximum is observed at 3.55 Å. At this concentration the conductivity is still higher than 10^3 ohm^{-1} cm^{-1} and in the metallic range. This is a clear indication that Cs^+ and Au^- are formed even in the diluted solutions. The attractive forces between the unlike charges and the repulsive forces between the like charges lead to short-range ordering like that which occurs in molten salts. Such ordering in dilute solutions is convincingly demonstrated by an analysis of the concentration dependence of the volume of the mixtures[34]. Figure 9 shows the partial molar volumes of Cs and Au, *i.e.*

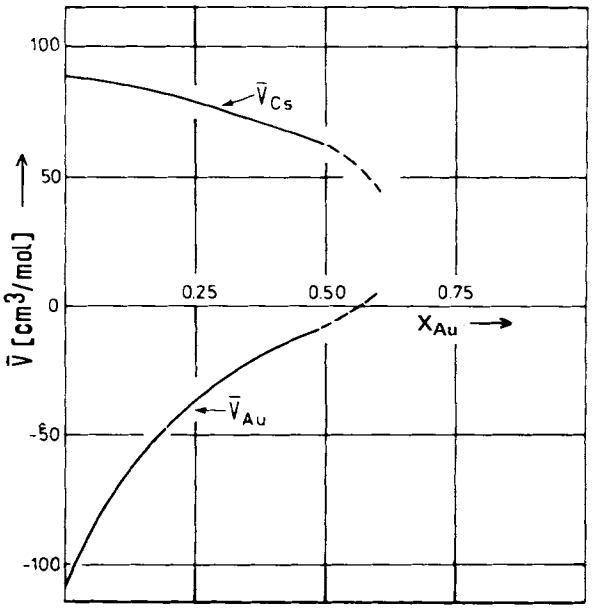

Fig. 9. Partial molar volumes $\bar{V}_{Cs}$ and $\bar{V}_{Au}$ as a function of the mol fraction of gold.

$$\bar{V}_{Cs} = V_M(x) - x\left(\frac{\partial V_M(x)}{\partial x}\right)$$

$$\bar{V}_{Au} = V_M(x) - (1-x)\left(\frac{\partial V_M(x)}{\partial x}\right) \tag{2b}$$

as a function of the mole fraction x of gold. For dilute solutions in the metallic range (*i.e.* $x<0.3$ and $\sigma>10^3$ ohm^{-1} cm^{-1}) $\bar{V}_{Cs}$ is nearly independent of the concentration and close to the value of pure liquid Cs[37], whereas $\bar{V}_{Au}$ tends to large negative values approaching -107 cm^3/mol for $x \to 0$.

The data available at present establish that liquid CsAu at the stoichiometric composition has the properties of a liquid salt. The metal-nonmetal transition in this system can be described as in the case of solutions of metals in their salts (*e.g.* Cs in CsCl[38]), *i.e.* as a solution of Cs or Au in CsAu. The concentration dependence of the electrical conductivity (Fig. 1) and of the magnetic susceptibility (Fig. 10) can be satisfactorily explained within the framework of this model[39]. The gram susceptibility shows a deep diamagnetic minimum at the stoichiometric composition CsAu. The temperature dependence near the minimum is relatively small and negative[39]. Since this is once again consistent with the assumption of predominantly ionic bonding in liquid CsAu, *Freyland* and *Steinleitner*[40], using their experimental results, and taking for the Cs^+ ion the value -36×10^{-6} cm^3 mol^{-1}[41],

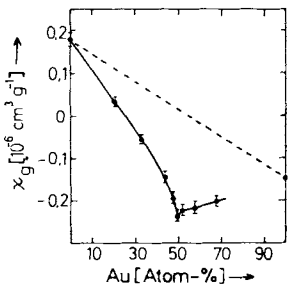

Fig. 10. Magnetic gram susceptibility, χ_g, of liquid Cs-Au mixtures as a function of the gold content.

calculated the molar diamagnetic susceptibility of the Au^- ion as -48×10^{-6} cm^3 mol^{-1}. This value is in surprisingly good agreement with the value of -50×10^{-6} cm^3 mol^{-1} obtained by extrapolation of the values for the isoelectronic sequence Bi^{+3}, Pb^{2+}, Tl^+, Au^-[41].

There is relatively little direct experimental information about the properties of the other alkali metal-gold systems. Solid LiAu and RbAu compounds crystallize, like CsAu, in the CsCl structure, whereas the structures of NaAu and KAu are complex and have not been well explored[18]. Recent experimental results for the conductivity of the liquid MAu-systems (M = alkali metal) at the stoichiometric composition are shown in Figure 11 as a function of temperature[42]. The

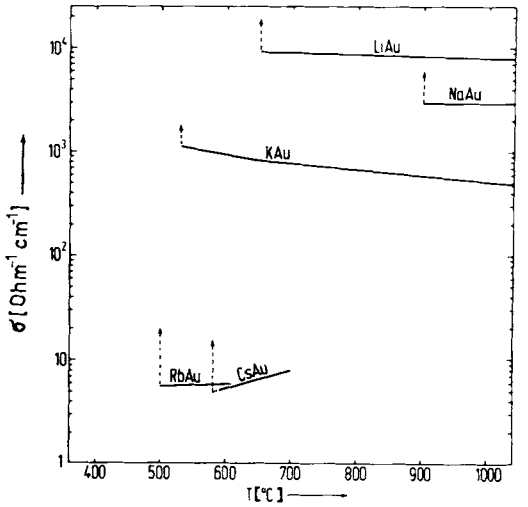

Fig. 11. Electrical conductivity σ of liquid MAu-compounds (M = alkali metal) as a function of temperature. The arrows indicate the melting temperature.

arrows indicate the melting temperature of the different compounds. The conductivities extend from values typical for ionic melts (about 5 ohm^{-1} cm^{-1}) to values for metallic melts (about 10^3 to 10^4 ohm^{-1} cm^{-1}). From the similarity of the conductivity of CsAu and RbAu it can be concluded that liquid RbAu is also an ionic conductor. In contrast to RbAu, liquid LiAu is a metallic conductor. On the other hand, the conductivity of liquid NaAu is only 3000 ohm^{-1} cm^{-1}, which represents a lower limit for metallic conductors. Liquid KAu seems to be a borderline case with properties between metallic and semiconducting behavior.

The results indicate that the transition from an ionic semiconductor to a metal lies between RbAu and NaAu. This observation is consistent with band structure calculations for the solid compounds CsAu, RbAu and LiAu[27]. The calculations show that CsAu and RbAu are semiconductors, while LiAu is a metal. The most interesting aspect of the calculation, however, is that the valence charge is centered essentially around the gold atom in all compounds. Thus LiAu is also mainly ionic despite the fact that it is a metallic and surely electronic conductor. The few data available at present demonstrate the importance of the ratio of the sizes of cations and anions. The transition from an ionic semiconductor to a metal occurs in parallel with a relatively large decrease in the size of the alkali metal atoms.

The behavior of the alkali metal-gold systems (with the exception of CsAu and perhaps RbAu) is similar to that of the well explored liquid semiconductors Li_3Bi[43-45], Mg_3Bi_2[46-49] and Li_4Pb[50-52]. Measurements of the thermodynamic properties[43,48-51] and of the liquid structure[52] indicate that the melt has an essentially ionic structure, whereas the electrical transport properties are dominated by the contribution of electrons[43,45-47]. The different behavior of CsAu, with respect to its electrical data, is essentially due to the larger energy gap between valence band and conduction band which leads to a negligibly small contribution of the electrons to the conductivity compared with the contribution of the ions, which are highly mobile in the liquid state.

3. Liquid Elemental Semiconductors

The influence of chemical interaction on the electronic structure of molten semiconductors becomes especially apparent when their behavior is studied over a wide range of temperature (cf. Fig. 6). The predominantly ionic molten CsAu retains its nonmetallic character over a wide range of temperatures. In contrast, it is characteristic of covalent semiconductors that they can be converted into an essentially metallic state by a sufficiently large increase in the temperature. It is demonstrated in Figure 6 that semiconductors such as Ge or In_2Te_3 become metallic immediately on melting while a large number of substances such as *e.g.* In_2Se_3 or Se are continuously transformed into a metallic state when the temperature is raised. The covalent structure is gradually broken down with increasing temperature, so the bonding electrons become delocalized and form an almost free "electron gas". The following treatment of the interrelation between the change in chemical structure and the semiconductor-metal transition will be mainly concerned with selenium.

The tendency of the selenium atom to bond in two-fold coordination favors formation of long helical chains (trigonal crystalline Se) or of Se_8-rings (monoclinic crystalline Se). It was long assumed that liquid selenium near its melting point also consists of a mixture of Se_8-rings and long chains[53]. However, recent investigations[54] cast doubt on the previously determined concentration of Se_8-rings[55]. In any case, the physical properties of liquid selenium—*e.g.* the unusually high viscosity of 25 poise at the melting point[56,33]—are mainly influenced by the polymeric chains. *Keezer* and *Bailey*[12] determined an average chain length of 10^5—10^6 atoms. Structural investigations by X-ray and neutron diffraction confirm the two-fold coordination in the melt[57,58]. The distance between nearest-neighbor atoms (2.38 Å)[59] is the same as in crystalline trigonal selenium. The structure of liquid selenium is, however, strongly dependent on temperature. The average chain length must decrease very rapidly with increasing temperature. For example, there is a marked decrease in the viscosity, which is only 1 cP at the normal boiling point (684.9 °C)—a value of the same order of magnitude as that of other liquids. The strong influence of temperature on the structure of liquid selenium must be accompanied by modification of its electronic structure and related electrical properties. However, an estimation of the average degree of polymerization in liquid selenium—using experimental data of the viscosity, the magnetic susceptibility and electron spin resonance[60]—shows that even at 1000 °C (the melting temperature is 217 °C) more than 90% of the atoms are still two-

fold coordinated. Since the semiconducting properties of the liquid essentially result from this twofold coordination of neighboring atoms, it is necessary to extend measurements for investigating the influence of changes in the short range order on the electronic properties to very high temperatures. The electrical conductivity[13,61,62], the absolute thermoelectric power[63,64] and the nuclear magnetic resonance[65] of liquid selenium have been measured up to supercritical temperatures and pressures. The critical pressure $p_c = 380$ bar and the critical temperature $T_c = 1590\,^{\circ}C$ have been determined[61]. Figure 12 shows the electrical conductivity σ of selenium at two pressures together with conductivity isobars of liquid tellurium[66] and of a selenium-tellurium mixture containing 50 atom-% of each component[67]. At relatively low temperatures σ markedly increases with increasing temperature, as one would expect for a semiconductor. For temperatures higher than about 1300 °C the selenium isobars flatten off and, close to the critical temperature, reach maxima with strongly pressure dependent conductivity values of almost metallic order of magnitude. In the direct vicinity of the critical point, where relatively small changes in pressure and temperature can lead to large changes in density, σ drops very rapidly with increasing temperature to values smaller than 0.1 $ohm^{-1}\,cm^{-1}$. In this region selenium can be assumed to consist mainly of Se_2 and a small amount of atomic Se. This assumption is supported by measurements of the magnetic susceptibility[68], by extrapolation of the known composition of selenium vapor at low temperatures[70], and by comparison with the optical data of supercritical sulfur vapor[69].

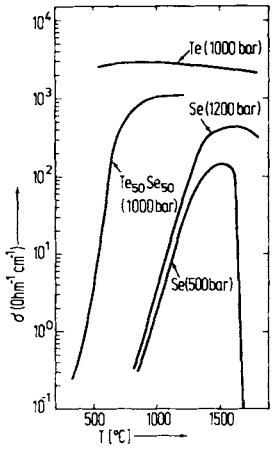

Fig. 12. Electrical conductivity σ of Se, Te and a Se-Te mixture in the molten state as a function of temperature at constant pressures.

It is obvious from Figure 12 that the conductivity isobar for the Se-Te system is very similar to the isobars for pure selenium; but the maximum is located at a lower temperature. In contrast, pure tellurium has a flat maximum with σ-values in the metallic range. There exists a direct correlation between the levels and the positions of the maxima and the bond strengths of the covalently bonded atoms in the chains which decreases in the sequence Se-Se, Se-Te[71], Te-Te. This tendency is also reflected in the structural properties of these systems[72-75]. For tellurium at the melting point an average first coordination number of three is obtained from the area under the first peak of the radial distribution function $g(R)$. This value would appear to increase rapidly with increasing temperature[73,76]. In contrast, the coordination number of selenium remains two, even up to temperatures higher than 1000 °C[74,75]. Although these numbers cannot be definitely identified with the number of bonds between an atom and its neighbor they do, however, indicate that the disorder in liquid Te is greater than in liquid Se.

The strongest indication that the transition from semiconducting to nearly metallic behavior is accompanied by a change in the local coordination number can be obtained from measurements of the thermodynamic properties. Figures 13 and 14 show the behavior of the isobaric thermal expansion coefficient α_p derived from pVT data[77,78,64] and the adiabatic compressibility β_s which was recently determined by *Yao et al.*[79] from sonic measurements. A minimum in α_p with negative values and a maximum in β_s is observed for the Se-Te mixture in the temperature range in which the conductivity σ approaches a maximum with values nearly as high as in the case of metals. Figure 13 demonstrates again the very different behavior of tellurium, which becomes metallic just above the melting point, and selenium, which tends to a metallic state at temperatures above 1300 °C. The α_p-curves have different slopes, and negative values of α_p are only observed for Te in the supercooled melt (the melting temperature is 449.5 °C). The temperature dependence of α_p of selenium fits into this picture. Figure 15[78] shows a plot of the volume of both sulfur and selenium at a fixed reduced pressure $p/p_c = 3$ as a function of the reduced temperature T/T_c. The sulfur isobar shows the behavior of normal molecu-

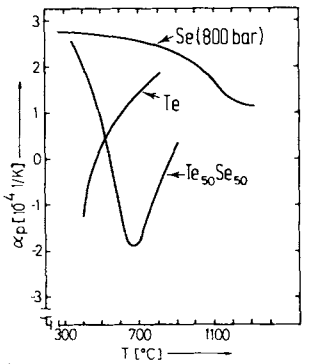

Fig. 13. Isobaric thermal expansion coefficient α_p of liquid Se, Te and $Te_{50}Se_{50}$ as a function of temperature; $\alpha_p = \frac{1}{V}\left(\frac{\partial V}{\partial T}\right)_p$.

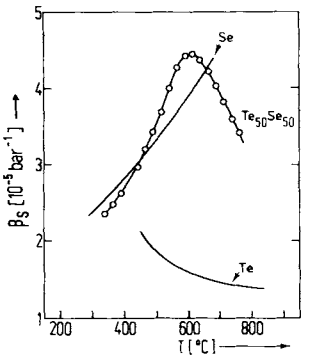

Fig. 14. Adiabatic compressibility β_s of liquid Se, Te and $Te_{50}Se_{50}$ as a function of temperature.

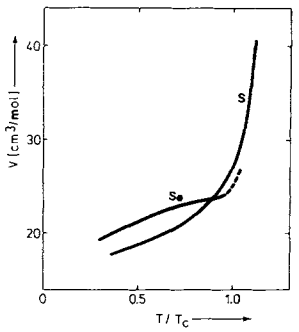

Fig. 15. Volume V of sulfur and selenium at constant supercritical reduced pressure $p/p_c = 3$ as a function of the reduced temperature T/T_c.

lar fluids with a continuous increase in volume as the critical temperature is approached, whereas the curve of selenium flattens out at a reduced temperature of about 0.8 and starts rising again in the vicinity of the critical point T_c. A plausible explanation for the anomalous minimum or maximum in α_p or β_s seems to be that the packing becomes denser with increasing temperature leading to a higher density despite the competing normal thermal expansion. The latter behavior can be compared with the abrupt metal-nonmetal transition of covalent semiconductors with diamond structure (Ge, Si and InSb) on melting, which is accompanied by an increase in the coordination number and a corresponding decrease in volume. For Se and Se-Te mixtures this metal-nonmetal transition is smeared out over a wide range of temperatures. Figure 16 gives a schematic illustration of the behavior of the volume as a function of temperature.

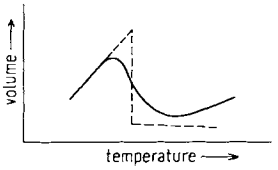

Fig. 16. Schematic illustration of the temperature dependence of the volume of a system for which the metal-nonmetal transition coincides with the liquid-solid phase transition (---, *e.g.* Ge), and for a system with a continuous transition spread over a wide temperature range (—, *e.g.* Se).

A model for the semiconductor-metal transition in liquid selenium has recently been proposed by *Warren* and *Dupree*[65]. It is mainly based on structural data, a critical analysis of the NMR data and on the assumption that the electronic structure of semiconducting polymeric selenium can be derived from the band structure of crystalline trigonal selenium. Of the six valence electrons of the selenium atom ($4s^2 4p^4$) the two 4s electrons are about 4—5 eV lower in energy than the lowest 4p-electrons and are unimportant for the electrical transport properties. Two 4p electrons form bonds to the two neighbors while the other two occupy a non-bonding state. In the condensed state (solid or liquid) the highest occupied valence band is formed by the nonbonding states (n.b.) while the empty antibonding σ^*(p) states form the conduction band (cf. Fig. 17a). The number of polymeric selenium molecules, and hence the number of neutral chain ends with unpaired electrons (C_1^0-centers), increases with increasing temperature. However, it cannot be ruled out that,

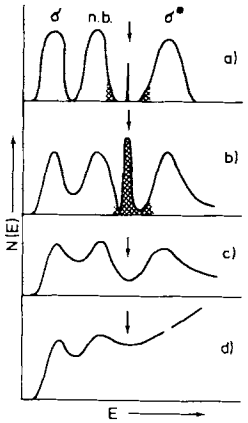

Fig. 17. Electronic structure of liquid selenium under different conditions (see text).

in liquid Se, a chain end C_1^0 reacts with the lone pair electrons of a Se-atom in an appropriate configuration to give a neutral threefold center (C_3^0-center). The existence of such stable defects has been proposed for amorphous selenium by *Mott* and *Street*[80] and by *Kastner, Adler* and *Fritsche*[81]. Calculations[82] show that the C_1^0- and C_3^0-centers lie close together in energy with a slightly lower value for C_1^0. The neutral centers introduce a narrow band of defect states in the middle between valence and conduction band (indicated by the arrows in Fig. 17) which increases with increasing temperature at the expense of the valence and conduction bands[82]. It can be expected that all bands become broader with decreasing lengths of the polymeric chains. From the behavior of the magnetic susceptibility it can be concluded[65] that the width of the band of defect states is smaller than $kT = 0.16$ eV up to 1550 °C and 400 bar. An additional increase in pressure results in a delocalization of the states between valence and conduction band (Fig. 17c). Finally, at still higher pressures the band becomes essentially metallic, similar to that of liquid Te (Fig. 17d). The validity of this model has been confirmed qualitatively by recent measurements of the optical reflectivity of liquid selenium[83] at temperatures up to 1400 °C and pressures up to 1500 bar. The characteristic features of the spectrum change only slightly with increasing temperature as long as the pressure is smaller than 500 bar, whereas application of higher pressures at temperatures above 1300 °C leads to a rapid change in the shape of the spectrum. Under high pressure it becomes very similar to that of liquid tellurium[84].

At high temperatures and slightly increased pressure the electrical, optical and structural properties of liquid selenium resemble those of liquid tellurium at its melting point. In contrast, the electrical properties of sulfur are completely different from those of selenium and tellurium over the whole liquid range. Near its melting point, sulfur is an insulator with a conductivity smaller than 10^{-12} ohm^{-1} cm^{-1}[85]. This is consistent with the large optical energy gap which can be derived from the data shown in Figure 18. It shows the absorption spectra[86] of liquid sulfur in the photon energy range from 0.5—3.5 eV (1 eV ≙ 8065.46 cm^{-1}) at temperatures between 140 °C and 1000 °C and pressures slightly higher than the vapor pressure. A continuous red shift of the edge is observed with increasing temperature. A precise analysis of the data shows that the polymerization of liquid sulfur

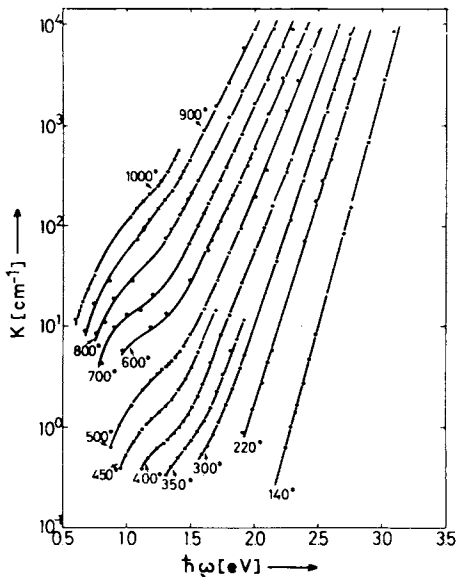

Fig. 18. Absorption spectrum of liquid sulfur as a function of temperature (in °C) at equilibrium pressure (1 eV ≙ 8065.46 cm^{-1}).

at 160 °C[87] does not affect the red shift. This result is qualitatively consistent with the fact that the number of first neighbors and their separation are virtually unchanged by the polymerization. This leads to nearly the same energy levels for both structures. However, new absorption shoulders appear in the infrared region at energies of about 1.3 eV and increase very rapidly with increasing temperatures above the polymerization temperature. From a comparison of the intensities of these absorption bands with measurements of the magnetic susceptibility[88] and of the ESR-signal[89,90] as a function of temperature it has been concluded that the absorption at 1.3 eV derives from the chains which possess unpaired electron spin states at the chain ends[86]. This conclusion is also in agreement with theoretical results obtained on the basis of the CNDO-S model[91]. Except from the appearance of the low energy band, the form of the optical absorption edge of sulfur—especially at K-values higher than 10^4 cm^{-1}—is essentially determined by a series of overlapping absorption bands which can be assigned to different species

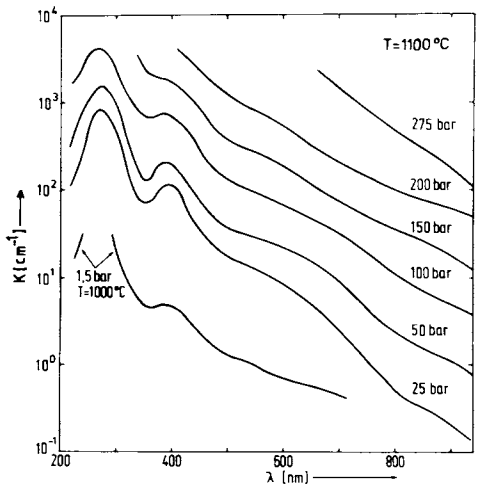

Fig. 19. Absorption spectrum of fluid sulfur at the constant supercritical temperature of 1100 °C as a function of pressure.

of sulfur, such as S_8, S_2, S_3, S_4 and probably S_6 or others[86,92,93]. Several studies on the composition of dilute sulfur vapor using different methods have established the existence of these species, and their concentration has been measured as a function of pressure and temperature[92-96]. An efficient experimental approach for explaining the spectral behavior of liquid sulfur is therefore provided by a comparison with the spectrum of the vapor, especially above the critical temperature where the density can be continuously changed over a wide range by variation of pressure. Figure 19[93] shows the behavior of the absorption coefficient as a function of the wavelength at a supercritical temperature of 1100 °C. (The critical data of sulfur are: $p_c = 205$ bar, $T_c = 1040$ °C and $\rho_c = 0.6$ g/cm^3.) A strong increase in the intensity of the S_3-band at 400 nm and of the S_4-band at 520 nm is observed with increasing pressure or density (Fig. 19). This is a clear indication that at high temperatures, liquid sulfur contains different small highly absorbing molecules besides the diradical chains detected by absorption bands at 1.3 eV[92,86,93]. Due to the logarithmic scale in Figure 19 the bands are partly smeared out to shoulders.

Recent measurements of the electrical conductivity σ of liquid sulfur over a wide range of temperature have shown that the free-radical chain-ends of the polymeric molecules give rise to carriers which determine σ[97]. Figure 20 shows a

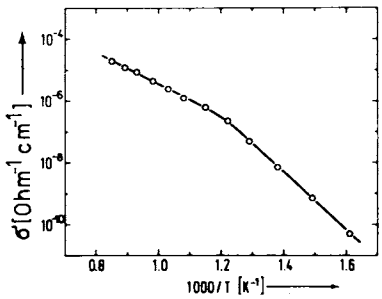

Fig. 20. Electrical conductivity σ of liquid sulfur as a function of the reciprocal temperature.

plot of the logarithm of the conductivity as a function of the reciprocal temperature [cf. eq. (1)]. The dominant feature is the relatively sharp change in the slope of the curve at about 550 °C, corresponding to activation energies of $E_A = 1.05$ eV for $T > 550$ °C and $E_A = 1.9$ eV for $T < 550$ °C. A comparison of the activation energies of the conductivity σ with the optical absorption band at 1.3 eV and the temperature dependence of the ESR signal of the free-radical chain-ends led *Edeling et al.*[97] to the conclusion that the chain-ends give rise to charge carriers which determine the form of the temperature dependence of σ in Figure 20. The inevitable presence of a very small number N_x of monovalent impurities X in liquid sulfur[98] influences the polymerization equilibrium[60]. There are two types of chain-ends. The chains are terminated by either a S—X bond or an unpaired spin[60]. The concentration of free-radical chain-ends N^* is nearly independent of X, but the average chain length decreases with increasing N_x. Under such circumstances, liquid sulfur behaves like a doped semiconductor with $(N^* + N_x)$ available defect levels and N^* acceptors[97]. The activation energy of the conductivity of such a semiconductor changes by a factor of 2 at a well defined temperature which is determined by the concentration N_x[99].

4. Metals at High Temperatures

The possible application of liquid metals at high temperatures as working fluids for technical purposes has been extensively discussed in recent years. This discussion is stimulated by the fact that liquid metals have a favorable combination of physical properties such as, *e.g.*, high latent heat of vaporization, high thermal conductivity, and high-temperature liquid range. In spite of this technological interest many fundamental physicochemical properties such as pVT-data, critical data, or specific heats, are not known with sufficient accuracy for most liquid metals at high temperatures. Reliable theoretical calculations of such data are still lacking. Experimental data relevant to properties like equation of state and critical data have to be determined at very high temperatures and relatively high pressures; the liquid range of metals extends to very high temperatures (Fig. 21). Only the critical data for Hg[100,101], Cs[102,103], Rb[103], K[104] and Na[105] have been measured with static experimental methods. *Fucke* and *Seydel*[106] have recently determined the values for Mo in a transient experiment with exploding wires.

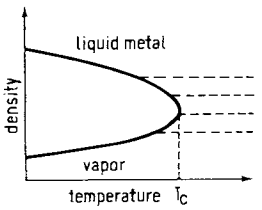

Fig. 21. Schematic illustration of the liquid-vapour equilibrium of a metal. Critical data of some metals (T_c, p_c): Hg 1490 °C, 1530 bar; Cs 1740 °C, 115 bar; Rb 1820 °C, 130 bar; K 1950 °C, 155 bar; Na 2230 °C, 250 bar; Mo 14000 °C, 5700 bar.

The main difficulty in the theoretical calculation of the properties of liquid metals, especially thermodynamic data, is the absence of an adequate interatomic-potential function for the entire liquid range. Regardless of the way in which the interatomic forces in a metal are described they must reflect the screening of the ionic charges by the electron gas and must therefore be always implicit functions of the electron density, *i.e.* of the metal density. In addition it is well known that a transition from metallic to nonmetallic, mostly semiconducting, state occurs also in a pure liquid metal, if it is continuously expanded to a low density fluid by increasing the temperature at a pressure higher than the critical pressure (*i.e.* avoiding evaporation)[14]. The transition to a nonmetallic state implies that the nature of the chemical interaction or of the interatomic forces changes; *i.e.* the description of the forces of interaction in a liquid metal must take into consideration the changes in density. This is in contrast to non-conducting liquids like argon, for which to a first approximation the thermodynamic data are usually described by reference to a single pair-potential over the whole density range from the dilute gas to the liquid.

Since the electrical properties of expanded metals in the transition range to nonmetallic behavior have already been reviewed in detail[14] we shall restrict ourselves here to only a few basic problems, *e.g.*: where in the phase diagram (Fig. 21) does the metal-nonmetal transition occur? Does a "law of corresponding states" exist for metals? How does the transition affect the thermodynamic properties and the liquid structure?

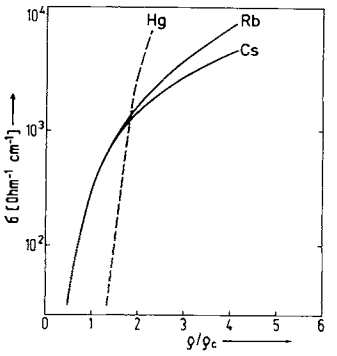

Fig. 22. Electrical conductivity σ of Hg, Cs and Rb at the supercritical, constant reduced temperature $T/T_c = 1.05$ as a function of the reduced density ρ/ρ_c.

Most measurements over a wide range of temperature—mostly up to supercritical temperatures—have been performed on the metals Hg, Cs and Rb. This is simply because these metals have the lowest critical temperatures. For Hg, extensive experimental data are available, including the electrical conductivity[100,101,107,108], the thermoelectric power[109], the Hall effect[110], the optical absorption[111] and reflection[112,113], the velocity of sound[114], the specific heat[115], the nuclear magnetic resonance[116] and the pVT-data[100,101,108]. Less data are known for the more corrosive alkali metals Cs and Rb. Up to now, the electrical conductivity[117,103,118], the thermoelectric power[117,118], the magnetic susceptibility[119,120] and the pVT-data[118,103] have been measured. The radial distribution function and thus the structure factor of Rb have recently been measured by means of neutron scattering experiments[103,120,121].

Figure 22 gives a comparison of the behavior of the conductivity of Hg[108], Cs and Rb[103] in the form of a plot of the conductivity as a function of the reduced density ρ/ρ_c at constant reduced temperature T/T_c. There is a striking difference between the two alkali metals and mercury. This is because Hg shows the characteristics of a liquid semiconductor at densities ρ smaller than 9 g/cm^3 (*i.e.* in the liquid state, $\rho_c = 5.3$ g/cm^3)[14]. The existence of an activation energy derived from eq. (1) has recently been proven for densities smaller than 9 g/cm^3[108].

By way of contrast, it is apparent from Figure 22 that the density dependence of the conductivity of Cs and Rb is very similar. The curves become identical at densities smaller than $2\rho_c$. At the density $2\rho_c$, the electron mean free path calculated with the free electron model[2] becomes equal to the mean interatomic distance. At the same time, the temperature dependence of the conductivity changes in sign from negative to positive[103]. The value of the conductivity at the critical point is about 300 ohm^{-1} cm^{-1} for both metals. This value is very close to the minimum metallic conductivity defined by *Mott* in numerous theoretical papers[122,4]. On the basis of this argument one can conclude that the metal-nonmetal transition in liquid alkali metals (a similar value of σ is observed for potassium at the critical point) coincides with the liquid-vapor phase transition.

Since the thermodynamic properties, like the electrical conductivity, are mainly determined by the density of the electron gas[2] a similar behavior of the pVT-data of Cs and

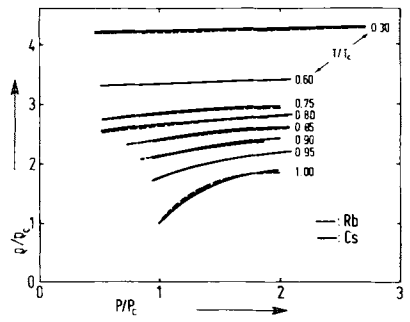

Fig. 23. Reduced diagram of the pVT data of Cs and Rb. Reduced density ρ/ρ_c as a function of the reduced pressure p/p_c at various reduced temperatures T/T_c. The isotherms for Cs and Rb at $T/T_c=0.6$ and 0.95 are indistinguishable.

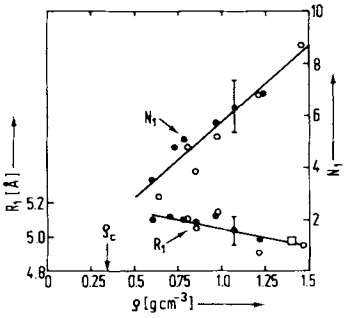

Fig. 25. Average number N_1 and mean distance R_1 of next neighbors in liquid Rb as a function of the density ρ.

Rb can be expected to occur in corresponding regions of the phase diagram according to Figure 22. This suggestion is supported by the plot in Figure 23[103]. Both metals have the same compressibility factor $z_c=p_c V_c/(RT_c)=0.22$ which is markedly different from the value $z_c=0.385$ for mercury, which is already nonmetallic at the critical point. The theoretical reasoning of this observation should lead to a "law of corresponding states" for groups of similar metals. The existence of such a law would be of considerable importance with regard to possible technical applications of liquid metals at high temperatures. In this connection a knowledge of the structure and of the isochoric thermal pressure coefficient $\gamma_v=(\partial p/\partial T)_v$ of the metals over a wide range of temperatures is of special interest. It is well known that at the melting point both quantities can be reasonably modelled[124,125] in a first approximation by hard spheres[126]. However, it must be emphasized that in a metal the diameters of the spheres will vary not only with temperature but also with density, due to the simultaneous variation in the number density of the free electrons. Figure 24 shows new measurements of the static structure factor $S(Q)$ for liquid rubidium[103,121,120,123] obtained by neutron scattering experiments. $S(Q)$ is directly related to the pair distribution function, $g(R)$, which is the probability of finding two particles of the liquid at a distance of R from each other. $g(R)$ depends only on R (see Fig. 24). The density dependence of $g(R)$ mainly reflects a linear decrease of the number of nearest neighbors, N_1, (Fig. 25) as calculated from the first peak of $g(R)$ using the formula given in the legend of Figure 24. In contrast to N_1, the nearest neighbor distance R_1, defined by the first maximum of $g(R)$, is almost constant (Fig. 25). A similar behavior is observed for the inert gases Ar and Ne[127]. From this similarity it can be assumed that the application of the hard sphere model, which provides an appropriate description of the liquid metal structure at the melting point, can be extended over a wide range of densities. A comparison between the measured structure factor $S(Q)$ and that calculated with the hard sphere model[126] is given in Figure 26. Allowing a decrease

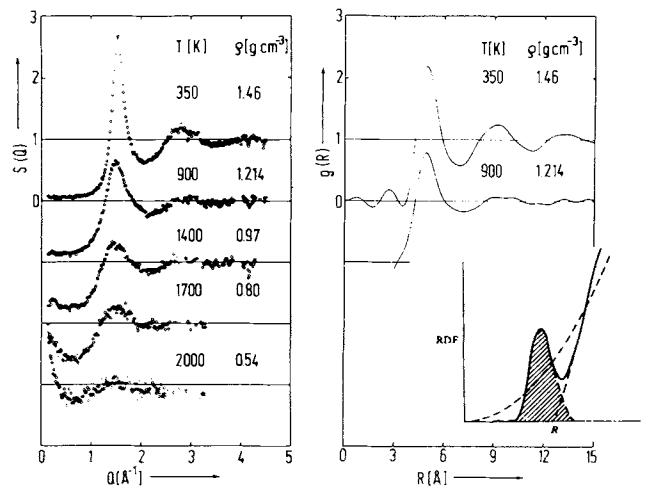

Fig. 24. Left: Static structure factor $S(Q)$ of liquid Rb as a function of temperature and density. The pair distribution function $g(R)$ (right, top) is derived from $S(Q)$ using

$$g(R)=[1+1/(2\pi n R)]\int_0^\infty [S(Q)-1)\,Q\cdot\sin(QR)]\,dQ$$

The average number of nearest neighbors is derived using $\mathrm{RDF}=4\pi R^2 g(R)$ (right, bottom)

$$N_1=2\times 4\pi\times n\int_0^{R_1} g(R)R^2\,dR$$

R_1 = position of the first peak in $G(R)$.

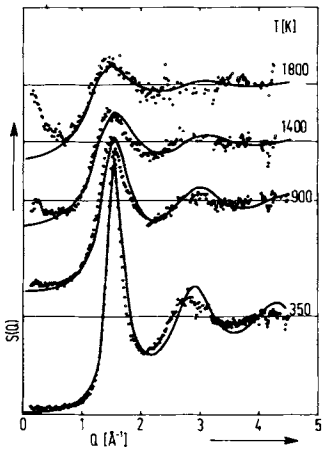

Fig. 26. Comparison between measured static structure factors $S(Q)$ (points) and those calculated with the hard sphere model (curve).

of the hard sphere diameter from 4.4 Å to 4 Å over the density range covered by the measurement yields a qualitatively satisfactory fit for $Q>0.1$ Å^{-1} over a surprisingly large density and temperature range. This observation has led to a number of attempts[103,118,130] to describe the pVT-data of liquid metals by a van-der-Waals type of theory[128]. The underlying idea is that the liquid consists of hard spheres immersed in a uniform potential which provides the cohesion that the hard-sphere system otherwise lacks. This description

is especially plausible for liquid metals, the cohesion energy of which can be attributed to the uniformly distributed gas of conduction electrons rather than to short range forces between neighboring particles. With these assumptions the pressure is given by:

$$p = p_0 - \left(\frac{\partial U}{\partial V}\right)_T = \gamma_v T - \left(\frac{\partial U}{\partial V}\right)_T \tag{3}$$

where p_0 is the hard-sphere pressure, $\gamma_v = (\partial p/\partial T)_v$ is the isochoric thermal pressure coefficient and U is the internal energy of the liquid. Figure 27 shows the γ_v-values of Rb de-

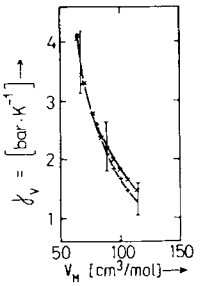

Fig. 27. Isochoric thermal pressure coefficient $\gamma_v = (\partial p/\partial T)_v$ of liquid Rb as a function of the molar volume. (×) experimental points, (+) calculated with the hard sphere model.

rived from experimental pVT-data. They are in good agreement, within experimental error, with those calculated with the hard-sphere model. The experimentally determined internal pressure $(\partial U/\partial V)_T$ is indeed to a first approximation

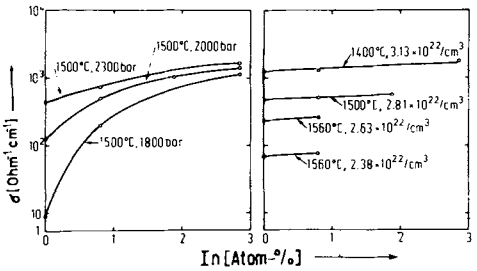

Fig. 28. Comparison of the concentration dependence of the electrical conductivity σ of dilute indium amalgams at constant pressure (left) and at constant number-density (right).

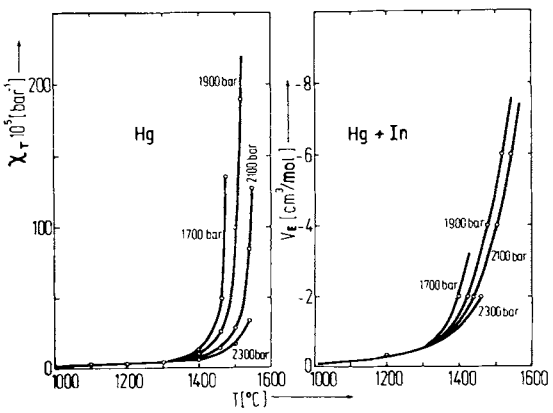

Fig. 29. Isothermal compressibility χ_T of pure Hg and excess volume V_E of In in Hg (Hg with 2.8 atom-% In) as a function of temperature at constant pressure.

only volume dependent[109, 118]. Its density dependence between the melting point density and about twice the critical density $2\rho_c$ is essentially determined by the existence of the electron gas[103]. For densities smaller than $2\rho_c$, also the electrical conductivity deviates from free-electron behavior. The experimentally observed simple dependence of the terms in eq. (3) on the volume V and temperature T is consistent with the existence of a "law of corresponding states" for the group of alkali metals.

The (divalent) metal mercury shows "semiconducting" behavior with respect to several properties at densities lower than 9 g/cm^3[14] (see Fig. 22). In this range, for example, the conductivity σ has an activation energy, and addition of a small concentration of excess electrons at constant pressure leads to marked enhancement of σ[129]. However, it has recently been demonstrated that these increases in σ have nothing to do with the "semiconducting" character of the electronic structure of Hg but are caused by the liquid and expanded state of mercury[130, 131], as is apparent from Figures 28 and 29. Figure 28 shows the effect of a few atomic percent (trivalent) indium at different constant pressures (left-hand side) or at constant number densities (right-hand side). It is obvious that the enhancement of the conductivity at constant pressure is caused by a corresponding volume contraction on alloying with In. Such a large contraction is generally observed in solvents having a very high compressibility on addition of small amounts of a solute, whose molecules exercise strong attractive forces on the molecules of the solvent[132]. The relationship between the compressibility χ_T of pure mercury and the excess volume of mixing V_E of In in Hg is demonstrated in Figure 29. Both χ_T and V_E rise quite sharply at temperatures higher than 1400 °C, *i. e.* as the density falls below the metal-nonmetal transition density of 9 g/cm^3. The transition implies a change in the nature of the interatomic interaction, and therefore anomalous behavior of the thermal properties—*e. g.* of χ_T—may generally be connected with the transition range in the electronic structure characteristic for metallic systems. It must be pointed out, however, that the transition range from a well defined liquid metal of high density to a gaseous dielectric of low density extends over a wide density range. First measurements of the dielectric behavior of gaseous Hg for densities smaller than 3.5 g/cm^3 (*i. e.* for conductivities smaller than 10^{-2} ohm^{-1} cm^{-1}) by *Hefner*[113] show a drastic increase in the refractive

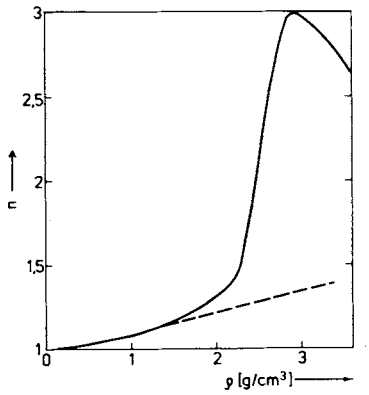

Fig. 30. Refractive index n of mercury vapour at $\lambda = 2$ μm as a function of the mercury density ρ at $T = 1530$ °C. The dotted line gives n calculated according to *Clausius-Mosotti*.

index n for densities larger than 2 g/cm^3 (Fig. 30). For comparison, Figure 30 includes a graph of the behavior of n calculated according to the Clausius-Mosotti relationship using the constant polarizability of the isolated Hg-atom. A striking upward deviation of about a factor of 2.5 from Clausius-Mosotti behavior is observed within a relatively small density range. A rapid decrease in the ionization energy[113] is expected to occur in this range due to the far-reaching polarization-forces between the neutral Hg-atoms and the ions and electrons of the slightly ionized (at 1530 °C) mercury. At the relatively low density of 3 g/cm^3 ($\rho_c = 5.3$ g/cm^3) and a temperature of 1530 °C the character of the optical properties of Hg-vapor changes abruptly within a very small and experimentally undetectable density range. This change is indicated in Figure 30 by the onset of an inflection in the refractive index curve. According to its optical data, mercury vapor above $\rho = 3$ g/cm^3 has all the properties of a solution of small metallic clusters in a solvent of a high dielectric constant. The a.c. conductivity has a maximum in the infrared spectral range which increases rapidly with increasing density[133]. In contrast, the d.c. conductivity is smaller than 10^{-1} ohm^{-1} cm^{-1} and nonmetallic. The abrupt formation of stable metal-clusters in the dense gaseous phase and particularly the mechanism of their formation and the investigation of the chemical interactions leading to their stabilization are of current interest in connection with metal-cluster complexes[134].

The Influence of Density and Temperature on the Properties of Pure Molten Salts

By Klaus Tödheide[*]

Dedicated to Prof. Dr. E. U. Franck at the occasion of his 60th birthday

Molten salts differ from most other types of liquids because of their high charge carrier density, which is responsible for a number of their extraordinary properties such as high ionic conductivity. Experimental and theoretical investigations during the past few years have provided information on the static and dynamic microscopic structures of this class of liquids and their relationship with the macroscopic properties. A consistent, albeit incomplete picture of the behavior of molten salts over wide ranges of temperature and density is now available including the transition from an insulator to an ionic conductor which a salt undergoes when it is compressed from vapor-like to liquid-like densities.

1. Introduction

Molten salts have been the subject of experimental and theoretical investigation for many decades. A quantitative knowledge of the equilibrium and transport properties of pure salts and of salt mixtures was necessary for the development and improvement of technical processes based on molten salts and for searching for new applications. Since the statistical treatment of liquids was not sufficiently advanced to correlate the experimental data and to interpret the results in terms of the properties of the microscopic constituents, semiempirical models were developed for this purpose[1]. The information accumulated up to about 1965 is presented in a number of books[2–5] and review articles[6–13]. Most of the data collected is contained in a handbook[14].

It is remarkable that up to that time the properties of molten salts were measured and discussed either at a fixed temperature or as a function of temperature at constant (normal) pressure. Since the density changes with temperature at constant pressure the measured temperature dependencies always included a density dependence which was neglected in the interpretation of the experimental results. The influence of density on the properties of molten salts, however, can be very important, as is demonstrated by an extreme example: liquid potassium chloride is a good ionic conductor, whereas the vapor in equilibrium with it contains nothing but uncharged particles such as molecules and associates of molecules and consequently behaves as an insulator. A transition from an insulator to an ionic conductor must therefore occur

as the density is raised at constant temperature from low values to those typical for liquid phases.

To facilitate the interpretation of experimental data a clear separation of the temperature effects from those of density or volume is desirable. The separation is straight forward in the theoretical treatment of liquids by statistical or computer simulation methods, because volume and temperature can be chosen as independent variables. Experimentally it can be achieved by high-pressure investigations in combination with PVT data over the pertinent pressure and temperature ranges.

The aim of this article is to report on the progress which has been made during the past few years in the investigation of the equilibrium and transport properties and of the ionization behavior of molten salts as a function of temperature and density. Wherever possible, the results of statistical mechanical calculations, computer simulations, and experiments will be compared with one another.

2. Equilibrium Properties

2.1. Introductory Remarks

The macroscopic properties and structure of molten salts, like those of other liquids, can in principle be calculated from the properties of their microscopic constituents and the intermolecular forces, if the trajectories of all particles are followed as a function of time. The least complicated salts for such a procedure are those which are completely dissociated into monatomic ions with spherical symmetry like *e. g.* the alkali metal halides. In this case the Hamiltonian $\mathcal{H}$ of the system does not contain contributions from internal degrees of freedom and the total potential energy U_N depends only on the coordinates of the particles but not on their relative orientations:

$$\mathcal{H} = \sum_{i=1}^{N} (1/2m)|\vec{p}_i(t)|^2 + U_N(\vec{r}_1(t), \ldots, \vec{r}_N(t)) \tag{1}$$

The microscopic state of an isolated system of N such particles with mass m is completely determined by fixing the coordinate vectors $\vec{r}_i$ and the momentum vectors $\vec{p}_i$ for all particles. The time evolution of the system is described by the coupled first order differential equations (Hamilton)

$$\dot{\vec{r}}_i = \frac{\partial \mathcal{H}}{\partial \vec{p}_i}; \quad \dot{\vec{p}}_i = -\frac{\partial \mathcal{H}}{\partial \vec{r}_i}; \quad (i = 1, 2, \ldots, N) \tag{2}$$

or by the coupled second order differential equations (Newton)

$$\dot{\vec{p}}_i = m\ddot{\vec{r}}_i = -\frac{\partial \mathcal{H}}{\partial \vec{r}_i} = -\frac{\partial U_N(\vec{r}^N)}{\partial \vec{r}_i} \tag{3}$$

The potential energy can in principle be determined by solving the Schrödinger equation for all nuclei and electrons in the Born-Oppenheimer approximation[15].

However, for particle numbers of the order of 10^{23} neither the calculation of U_N nor the solution of the differential equations (2) or (3) is feasible. In order to circumvent this difficulty two different approaches have been attempted:

1. Statistical mechanics is used to calculate the macroscopic properties as far as possible by purely analytical methods as averages of microscopic properties weighted by the appropriate distribution functions[16].

2. Computer simulations are used to perform the averaging procedure numerically for systems containing 10^2 to 10^3 particles. In order to avoid the influence of the boundary of the system, which plays a very important role in the case of such small systems, periodical boundary conditions are introduced[17, 18]. The molecular dynamic method (MD) solves the equations of motion (3) and calculates time averages. The Monte Carlo method (MC) evaluates ensemble averages by producing the microstates of the system by a random number method. The probability for the microstate to be counted in the averaging procedure is chosen to be proportional to the corresponding Boltzmann factor.

The most comprehensive probability information about a system of N particles of the kind described previously is given by a distribution function $P^{(N)}(\vec{r}^N, \vec{p}^N, t)$ called probability density. Multiplied by the volume element of phase space $d\vec{r}^N d\vec{p}^N$ it yields the normalized probability of finding the system at a given time t in a microscopic state in which each of the particles $i = 1, \ldots, N$ has the coordinate vector $\vec{r}_i$ and the momentum vector $\vec{p}_i$. Because of the large number of particles this function is of no practical use. On the other hand, it contains more information than necessary for the calculation of macroscopic properties. It is thus useful to define distribution functions of lower order which are derived from $P^{(N)}$ by integrating over the coordinates and momenta of a fraction of the particles at the expense of some information being lost. At equilibrium all these distribution functions are independent of time.

2.2. Radial Distribution Function

The pair distribution function

$$f_0^{(2)}(\vec{r}_1, \vec{r}_2) = \frac{N!}{(N-2)!} \int\int P^{(N)}(\vec{r}^N, \vec{p}^N)\, d\vec{r}^{(N-2)} d\vec{p}^N \tag{4}$$

is obtained from the N particle equilibrium distribution function by integrating over all momentum vectors and $N-2$ coordinate vectors and by introducing a combinatorial factor which accounts for the indistinguishability of the particles. This function, divided by the square of the average number density $\rho = N/V$, yields

$$g_0^{(2)}(\vec{r}_1, \vec{r}_2) = f_0^{(2)}(\vec{r}_1, \vec{r}_2)/\rho^2 \tag{5}$$

For an isotropic fluid this function only depends on the distance between the two particles and is called the radial distribution function $g(r)$

$$g_0^{(2)}(\vec{r}_1, \vec{r}_2) = g(|\vec{r}_1 - \vec{r}_2|) = g(r) \tag{6}$$

The radial distribution function plays an important role in the treatment of equilibrium properties of liquids:

1. It gives the ratio of the local to the average density

$$g(r) = \rho(r)/\rho \tag{7}$$

and is therefore related to the number of particles $dN(r)$ in a spherical shell of thickness dr at a distance r from a reference particle

$$dN(r) = \rho g(r)\, 4\pi r^2\, dr \tag{8}$$

It is thus readily obtainable from computer simulations.

2. The radial distribution function can be determined from scattering experiments, *e.g.* X-ray diffraction or elastic neutron scattering.

3. Statistical mechanics demonstrates that the radial distribution function is related to the compressibility of the system by

$$\rho k T \kappa_T = 1 + 4\pi\rho \int_0^\infty [g(r) - 1] r^2\, dr \tag{9}$$

If the total potential energy can be written as the sum of effective pair potentials

$$U_N(\vec{r}^N) = \frac{1}{2} \sum_{i=1}^{N} \sum_{j \neq i} u_{ij}(r) \tag{10}$$

simple relations hold between the radial distribution function and the internal energy U and the pressure P of the system

$$U = \frac{3}{2} N k T + 2\pi N \rho \int_0^\infty u(r) g(r) r^2\, dr \tag{11}$$

$$P = \rho k T - \frac{2}{3}\pi\rho^2 \int_0^\infty \frac{du(r)}{dr} g(r) r^3\, dr \tag{12}$$

For calculation of the thermodynamic properties of the system it suffices then to know the effective pair potential and the radial distribution function as a function of temperature and density.

The utility of effective pair potentials for molten alkali metal halides has been discussed extensively by *Woodcock*[19] and by *Sangster* and *Dixon*[20]. If the difference in ionic sizes is not too large the Born-Mayer-Huggins potential

$$u_{ij}(r) = \frac{z_i z_j e^2}{4\pi\varepsilon_0 r} + B_{ij} \exp(-A_{ij} r) - C_{ij} r^{-6} - D_{ij} r^{-8} \tag{13}$$

has proven to be useful, although improvements are desirable in some cases. It does not contain a term which accounts for the polarizability of the ions. $z_i e$ is the charge of an ion. The parameters A, B, C, and D can be determined from the properties of the corresponding crystalline salts[20–23].

For molten salts two complications arise as compared with simple liquids (*e.g.* argon):

1. Since ions with positive and negative charge are present in the melt at least three different partial radial distribution functions $g_{++}(r)$, $g_{+-}(r)$, and $g_{--}(r)$ are needed for the description of even the simplest molten salts.

2. The Coulomb term in the pair potential [eq. (13)] which stems from the charge of the ions is long-ranged compared to the other terms and therefore complicates the statistical treatment as well as the computer simulations.

2.2.1. Experimental Determination of Radial Distribution Functions

The arrangement of particles in melts, like their positions in crystals, can be extracted from diffraction patterns. Elastic neutron scattering is particularly well suited for the determination of radial distribution functions in molten salts. Since neutrons are scattered from nuclei the positions of the nuclei are directly reflected by the distribution of the scattered intensity. In addition the scattering behavior of a melt may be varied drastically by isotopic substitution without changing the structure of the melt.

From the intensity scattered into a scattering angle 2θ one obtains, after application of corrections for background, multiple, and incoherent scattering and suitable normalization, a scattering function $I(Q)$ which is related to the partial structure factors $S_{\alpha\beta}(Q)$ ($\alpha, \beta = +, -$) of a binary system[24–26] by

$$I(Q) = N[x_+ f_+^2 S_{++}(Q) + x_- f_-^2 S_{--}(Q) + f_+ f_- S_{+-}(Q)] \tag{14}$$

where $Q = (4\pi/\lambda)\sin\theta$; λ is the wavelength of the neutrons, f_α is the average scattering length and x_α the mole fraction of the ions of type α. The partial structure factors are connected with the partial radial distribution functions through a Fourier transformation:

$$S_{\alpha\beta}(Q) = \delta_{\alpha\beta} + \frac{8\pi x_\alpha x_\beta \rho}{x_\alpha + x_\beta} \int_0^\infty [g_{\alpha\beta}(r) - 1] \frac{\sin Q r}{Q \cdot r} r^2\, dr \tag{15}$$

where $\delta_{\alpha\beta}$ is the Kronecker symbol. If an isotopic substitution is carried out for the anions in the melt, f_- in eq. (14) is changed but the $S_{\alpha\beta}$ remain unaltered. Thus the three partial structure factors of a binary melt can be derived from the elastic neutron scattering patterns of three different, suitably chosen isotopic mixtures. From the structure factors the partial radial distribution functions are calculated by inverting eq. (15).

A favorable candidate for an isotopic substitution is chlorine, because the coherent scattering lengths of ^{35}Cl and ^{37}Cl differ by almost a factor of five.

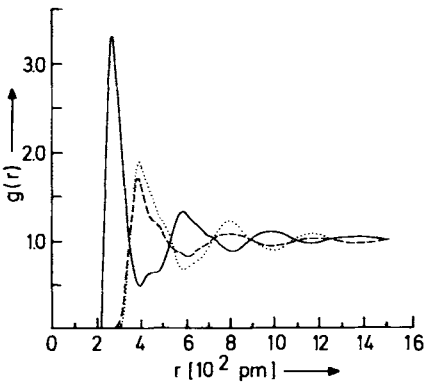

Fig. 1. Partial radial distribution functions in molten sodium chloride at 875 °C from measurements by *Edwards et al.* [29]:
———— g_{NaCl}; - - - - - - - - - - - - g_{NaNa}; · · · · · · · · · · · · · g_{ClCl}.

Measurements have been made so far on CuCl[27] KCl and CsCl[28], NaCl[29], RbCl[30], AgCl[31], and on $BaCl_2$[32]. Figure 1 shows as example the partial radial distribution functions

in molten NaCl at 875 °C and 1 atm, from which the following conclusions can be drawn:

1. The strong maximum in g_{NaCl} at 260 pm indicates that the particles are mainly surrounded by particles of opposite charge, as would be expected for an ionic melt.

2. The Na—Cl distance at the first maximum is considerably shorter than in the crystal (276 pm), although the volume increase upon melting is about 25 percent.

3. The nearest neighbor coordination number which is given by the area under the first peak of g_{NaCl} is 5.8 ± 0.1. This number is only slightly smaller than the number of nearest neighbors in the NaCl crystal.

4. g_{NaNa} and g_{ClCl} do not differ greatly. In cases where the ionic radii approach each other, *e.g.* for RbCl, g_{++} and g_{--} almost coincide.

5. The maxima of g_{NaNa} and g_{ClCl} fall on the minima of g_{NaCl} and vice versa, indicating a strong tendency towards charge compensation which is almost complete above a distance of 500 pm.

6. The number of next nearest neighbors (equal charge) is 13.0 ± 0.5.

7. The shortest distance between Na and Cl is 220 pm, between Na and Na 270 pm, and between Cl and Cl 300 pm.

8. Since g_{NaNa} and g_{ClCl} attain values different from zero at distances below that of the first minimum in g_{NaCl} a non-negligeable fraction of equally charged ions penetrates into the first coordination shell.

9. The structure of the partial radial distribution functions extends to distances above 1 nm, whereas the average radial distribution function

$$g_m(r) = (1/2)[g_{+-}(r) + 1/2(g_{++}(r) + g_{--}(r))]$$

which can be obtained from a single scattering experiment does not exhibit any structure beyond 500 pm.

The results for the other alkali metal halides show the same qualitative features. Deviations reported for KCl and CsCl[28] are most probably due to experimental errors[29].

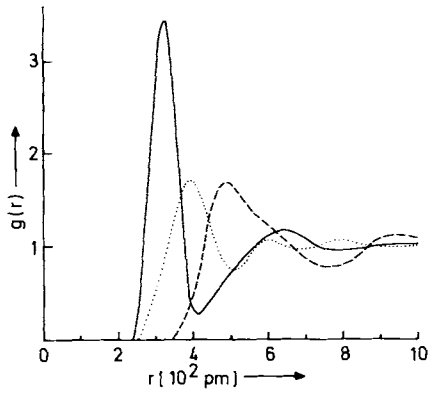

Fig. 2. Partial radial distribution functions in barium chloride at 1025 °C from measurements by *Edwards et al.* [32]:
——— g_{BaCl}; - - - - - - - - - - g_{BaBa}; ····· g_{ClCl}.

The partial radial distribution functions of $BaCl_2$[32] are shown in Figure 2. The most obvious changes with respect to the alkali metal halides are:

1. g_{BaBa} and g_{ClCl} strongly differ from each other. This is partly due to the charge difference. The comparative absence of structure in g_{ClCl} with respect to g_{BaBa} is probably linked with the higher mobility of the Cl^- ions in the melt.

2. There is substantial penetration of the chloride ions into their first coordination shell.

Elastic neutron scattering experiments on molten salts have not yet been performed at elevated pressures. Thus the influence of density on the radial distribution functions has not been established experimentally.

2.2.2. Calculation of Radial Distribution Functions by Computer Simulation

The calculation of the partial radial distribution functions can be achieved by both Monte Carlo and molecular dynamics methods. For the simulation it is necessary to split the Coulomb term in the effective pair potential into parts and to perform the Ewald summation[21,23] in order to obtain sufficiently accurate results. The major part of the results obtained so far[20,33] are for the alkali metal halides. It turns out that the Born-Mayer-Huggins potential [eq. (13)] with the constants taken from *Fumi* and *Tosi*[22,23] is superior to other effective pair potentials used for the simulations. The calculated radial distribution functions agree with the measured ones in all essential features mentioned in the preceding paragraph. The calculated first maximum of g_{+-} is usually slightly higher and is found to appear at a distance which is about 10 pm shorter than that derived from experiments. The calculations also give a slightly smaller number of nearest neighbors. This is shown for NaCl as example in Figure 3, where measurements by *Edwards et al.*[29] are compared with calculations by *Lewis et al.*[34]. The figure also demonstrates that for this salt there is no noticeable influence on the calculated radial distribution functions when the polarizability of the ions is taken into consideration by introducing a shell model[75]. For salts with a larger difference in the ionic radii (*e.g.* NaI) the influence of the polarizability starts to become evident[20]. It mainly affects g_{++}, the first peak of which is shifted towards smaller distances.

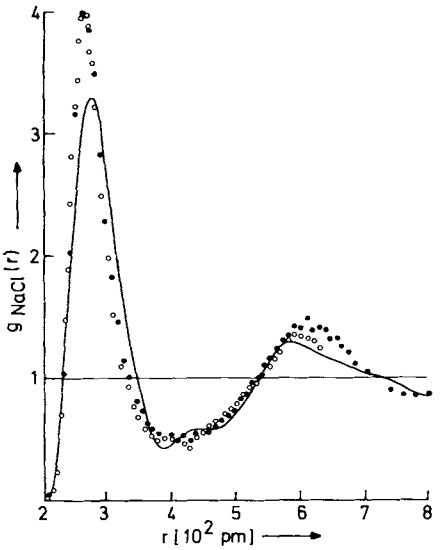

Fig. 3. Partial radial distribution function g_{NaCl} in molten sodium chloride after *Sangster* and *Dixon* [20]:
——————— measurements [29] at 1148 K;
●●●●●●●●●●●● MC calculations [34] at 1073 K;
○○○○○○○○○○○○ MD calculations accounting for the polarizabilities of the ions [75] at 1427 K.

Radial distribution functions for the alkaline earth metal halides were calculated by *Rahman et al.*[35] (BeF_2) and by *de Leeuw*[36,37] (CaF_2, $SrCl_2$). A direct comparison with experimental results is not possible, but the partial radial distribution functions calculated for $SrCl_2$ and those measured for $BaCl_2$[32] (Fig. 2) show the same characteristic features.

van Wechem[38] carried out calculations for KNO_3 assuming a disk-like shape for the nitrate ion with a radius of 230 pm and three different point charge distributions. As was expected the calculated angle-dependent distribution functions vary strongly when the charge distribution is changed. Comparison with experiment is not yet possible.

The influence of density on the radial distribution function is demonstrated in Figure 4, where the Monte Carlo results for KCl[39] are shown. Here g_{++} and g_{--} coincide within the limits of error. The characteristic quantities of the functions plotted in Figures 4a through 4c are collected in Table 1.

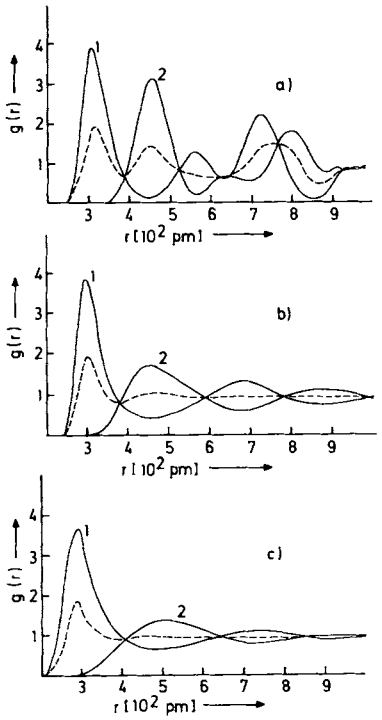

Fig. 4. Partial radial distribution functions in potassium chloride after *Woodcock* and *Singer* [39]: a) solid KCl, b) and c) molten KCl (temperatures and molar volumes, see Table 1). 1: g_{KCl}; 2: $g_{KK}=g_{ClCl}$; -------- $g_m=\frac{1}{2}g_{KCl}+g_{KK}$.

creases and the distance of closest approach d_{++} decreases markedly. An increase in the volume of the melt by a factor of two (Fig. 4, b→c) again shortens the distance r_{+-}^{max} and simultaneously diminishes the coordination number. This indicates that at the limit of very low density r_{+-}^{max} must approach as its limiting value the equilibrium distance of K and Cl in the isolated KCl molecule (267 pm) and that the coordination number n_{+-} approaches unity. Because of the higher temperature, and thus higher kinetic energy of the ions, d_{+-} decreases considerably.

This and other examples demonstrate that computer simulations offer an opportunity of calculating the structures of molten salts with spherical ions to a degree of accuracy comparable with that of experimental determinations. Furthermore, they enable calculations also in those regions of temperature and density which are inaccessible in experiments.

2.2.3. Calculation of Radial Distribution Functions by Statistical Mechanics

The analytical calculation of radial distribution functions for dense fluids from the pair potential is a difficult task. The Born-Green integrodifferential equation which links these two functions also contains the three-particle distribution function as a further unknown. For solution of the problem it is necessary to make assumptions concerning the radial distribution function or its relation to the three-particle distribution function (*e.g.* Percus-Yevick[40]). This leads to new equations relating $g(r)$ to $u(r)$ which in some cases can be solved exactly for simple potentials such as the hard sphere potential. For more realistic potentials, however, only approximate solutions can be made. Perturbation methods appear to be most successful[41]. For simple liquids (argon), systems of hard or soft spheres with temperature- and density-dependent diameters have been used as reference systems for perturbation calculations. An obvious choice as reference system for molten salts is a system of charged hard spheres. Monte Carlo simulations by *Larsen*[42] for the restrictive primitive model, in which the oppositely charged spheres have the same diameter, have shown that this system meets most of the requirements as a reference system for molten salts. The attempts made at calculating the radial distribution functions of a reference system consisting of charged spheres have been reviewed by *Gillan*[43] and *Parrinello* and *Tosi*[25]. So far, only approximative solutions of the problem are available: the mean spherical approximation (MSA)[44-46]

Table 1. Characteristic quantities for the radial distribution functions of potassium chloride shown in Fig. 4 from Monte Carlo calculations [39].

Fig.	T/K	V/cm³ mol⁻¹	Phase	d_{+-}/pm	r_{+-}^{max}/pm	r_{+-}^{min}/pm	n_{+-}	d_{++}/pm	r_{++}^{max}/pm	r_{++}^{min}/pm	n_{++}
4a	1045	41.48	solid	234	307	445	6.0	318	454	570	12.2
4b	1045	48.80	liquid	233	296	455	5.5	298	438	675	15.6
4c	2874	97.60	liquid	211	289	515	3.9	254	513	735	10.1

Upon melting (Fig. 4, a→b) the first peak in g_{+-} is shifted towards smaller distances, although the volume increases by about twenty percent. The peak is broadened and the number of nearest neighbors slightly decreases. The distance of closest approach d_{+-} remains constant. For the next nearest neighbors the distance of the first peak shortens, n_{++} in-

and the self-consistent Ornstein-Zernike approximation (SCOZA)[47,48]. Both approximations give the essential features of the radial distribution functions of the system as calculated by Monte Carlo simulation, but also show some deficiencies. The MSA, for example, gives an unphysical result in the form of negative values for $g_{+-}(r)$ at small values of r.

A purely analytical solution for a reference system on which perturbation calculations could be based for ionic melts with more realistic pair potentials has not yet been found.

2.3. Thermodynamic Properties

2.3.1. Statistical Mechanical Calculation

The calculation of the thermodynamic properties and of an equation of state for simple molten salts is in principle feasible using the methods described in Section 2.2.3. The necessary approximations, however, cause some deficiencies. The MSA leads to inconsistent results. Pressures calculated from eq. (9) differ substantially from those calculated from eq. (12). The SCOZA avoids such inconsistency by introducing four adjustable parameters, but this may lead to negative pressures under conditions where the system should be stable[49]. Because of these difficulties it is not yet possible to obtain useful thermodynamic data by purely analytical methods.

2.3.2. Computer Simulations

The development of computer simulations intended for the calculation of thermodynamic data for molten salts has been reviewed by several authors[20, 33, 50]. The majority of the calculations were carried out for alkali metal halides for temperature and volume conditions which correspond to normal pressure. The Born-Mayer-Huggins potential (13) generally affords the best agreement with experimental data. In most cases the results are not markedly improved when the polarizability of the ions is taken into account. Table 2 shows a comparison of Monte Carlo results with experimental data for KCl at its normal melting point. The excellent agreement for the molar heat capacity at constant pressure is probably fortuitous. The calculations for the internal energy are relatively accurate. As can be seen from the Table, the deviations for the properties listed generally fall outside the experimental error limits. The deviation for the pressure evaluated from the virial is exceptionally large. As *Schäfer* and *Klemm*[54] have pointed out, the virial fluctuates considerably because of the long-ranged pair potential. In order to improve the pressure calculations the statistical errors have to be reduced by enlarging the volume of the system. At constant density this requires a considerable increase in the number of particles and thus an extension of computer time.

Computer simulations offer the opportunity of analyzing the contributions of different parts of the pair potential to the magnitude of the macroscopic properties of a system. For KCl at 1045 K and a molar volume of 48.80 $cm^3\ mol^{-1}$, *Woodcock* and *Singer* calculated the following contributions (in $kJ\ mol^{-1}$) to the total potential energy of -655.5 kJ mol^{-1}: Coulomb term -724.4; repulsion K^+—K^+: 1.9; repulsion Cl^-—Cl^-: 2.6; repulsion K^+—Cl^-: 91.5; r^{-6} term: -23.7; r^{-8} term: -3.4. If the r^{-8} term, which contributes only 0.5% to the potential energy were neglected, the volume would be increased by about 5%.

In addition to the large number of simulations at normal pressure there are a few calculations for high pressures. The results of the high-pressure studies will be compared with experimental data in the next section.

Table 2. Monte Carlo results of *Woodcock* and *Singer* [39] and experimental data (cf. Ref.) for molten potassium chloride at 1045 K and 48.80 $cm^3 \cdot mol^{-1}$.

	MC	Exp.	Deviation [%]	Ref.
U/kJ mol^{-1}	−629.4	−625.5	− 0.6	[51]
P/bar	670	1.01	—	[52]
$10^6\ \kappa_T$/bar^{-1}	30.6	36.5	−16.2	[53]
$10^4\ \alpha_P$/K^{-1}	3.04	3.82	−20.4	[52]
β_V/bar K^{-1}	9.93	10.5	− 5.4	[52, 53]
C_P/$JK^{-1}\ mol^{-1}$	67.3	66.9	0.6	[51]
C_V/$JK^{-1}\ mol^{-1}$	51.7	46.9	10.2	[52]

2.3.3. Experimental Results

Thermodynamic data for molten salts at elevated pressures have exclusively been derived from *PVT* measurements which were made for the alkali metal nitrates[55-57], silver nitrate[55], some organic salts[58-60], bismuth trichloride[61], and potassium chloride[62] using various experimental techniques. At temperatures not too high above the melting temperature the density isotherms can be excellently represented by the Tait equation[64]:

$$[\rho(P)-\rho(P_0)]/\rho(P)=A\ln[(B+P)/(B+P_0)] \tag{16}$$

Here P_0 is a reference pressure (usually 1 bar), A and B are constants. The Tait equation has also been successfully used for fitting the density isotherms of other classes of liquids[65], although it gives an "unphysical" result in the limiting case of infinitely high pressure. For molten KCl the Tait equation was made an equation of state by allowing A and B to be functions of temperature. With

$$A(T)=A_0+A_1(T-T_F) \tag{17}$$

$$B(T)=B_0+B_1(T-T_F)+B_2(T-T_F)^2 \tag{18}$$

and the values for the constants given in Table 3 it is possible to fit the experimental *PVT* data for molten KCl up to 1325 K and 6 kbar with a standard deviation of 0.04%, which is one order of magnitude smaller than the experimental error (0.41%) at the highest pressure.

Table 3. Constants for the Tait equation of state with temperature dependent parameters A and B according to eqs. (16) to (18).

Constant	Value
T_F	1043.5 K
A_0	0.093619
A_1	$7.2495\times10^{-5}\ K^{-1}$
B_0	2750.5 bar
B_1	-3.8324 bar K^{-1}
B_2	3.4383×10^{-3} bar K^{-2}

The high accuracy of the *PVT* data and its analytical representation enables the calculation of other thermodynamic properties such as thermal expansion coefficient, compressibility, and internal pressure as functions of pressure and temperature for molten KCl as typical example of an ionic melt. Free energies, entropies, enthalpies, and molar heat capacities may be calculated for high pressures from their values at ordinary pressure using the well-known thermodynamic relations.

In Figure 5 the compressibility of KCl is plotted as a function of pressure for various constant temperatures. At low pressures the compressibility is substantially smaller than that of normal molecular liquids, but it becomes about the same at high pressures, thus indicating that the individual differences in the pair potentials become less important at high pressures where the compressibility is almost exclusively influenced by the repulsion forces determined by the size and shape of the particles.

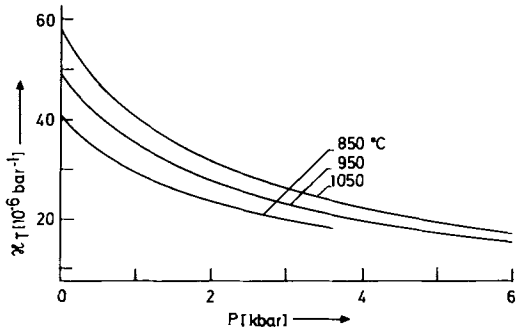

Fig. 5. Compressibility of molten potassium chloride [63].

The internal pressure of KCl at the melting point is 8.8 kbar. For molten alkali metal nitrates values of around 10 kbar were found[66], whereas the internal pressure for many simple molecular liquids lies between 2.5 and 3.5 kbar. From *PVT* measurements on molten tetraalkylammonium tetraalkylborate salts and their corresponding isoelectronic hydrocarbon-analogues it follows that the internal pressure of the salts is always higher by a factor of about 1.5 than that of the corresponding hydrocarbon[59]. For KCl, the internal pressure plotted as a function of molar volume exhibits a broad maximum which lies around 50 cm^3 mol^{-1}. It falls off slowly on the low density side of the maximum but it decreases rather steeply on the high density side. The latter feature was not found in the computer simulations[39]. From this and other observations it may be concluded that the repulsion term in the effective pair potential [eq. (13)] is too soft.

Figure 6 shows the molar heat capacity C_P of KCl at constant pressure. The values at normal pressure were calculated

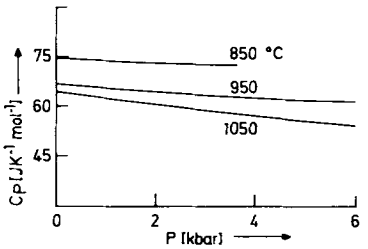

Fig. 6. Molar heat capacity of molten potassium chloride [63].

from velocity of sound measurements by *Bockris* and *Richards*[53]. C_P decreases with increasing pressure and temperature. A negative temperature dependence of C_P is unusual but was also found for $NaNO_3$ and KNO_3[67], for water[68], and for mercury[69]. The computer simulations for KCl[39] show the same trend. C_V also decreases when the temperature is raised.

The experimental results for KCl lend themselves for a comparison with computer simulation studies over broad temperature and density ranges. Table 4 shows a comparison of the *PVT* data with the best computed data. The difference between the measured densities and the values calculated by *Woodcock* and *Singer*[39], who applied the Monte Carlo method together with the Born-Mayer-Huggins potential is up to 2%. This corresponds to a pressure difference of about 850 bar. Monte Carlo calculations by *Larsen et al.*[70] show a deviation of about 4% in density. Other calculations[71–74], the results of which are not shown in the Table, deviate by as much as 15 percent in density. It appears that the Monte Carlo method used in combination with the Born-Mayer-Huggins pair potential yields results which are closer to the experimental values than those of other simulations and that the results for the thermodynamic properties in general are not improved when the polarizability of the ions is taken into account. Table 5 shows a comparison of calculated and measured values for some derived quantities. The trends in varia-

tion of the macroscopic properties thermal expansion coefficient, compressibility, thermal pressure coefficient and molar heat capacity with temperature and pressure are reproduced correctly by the simulations, but, in general, the deviations from the experimental values are larger than the experimental limits of error. The comparison thus leads to the conclusion that computer simulations do not produce results with an accuracy equal to that of careful experimental studies, even for the favorable case of a salt with spherical ions under conditions that are difficult from an experimental point of view.

Since PVT measurements on molten salts at high pressures are complicated and time consuming, it is highly desirable to have an empirical equation of state which can be used to estimate PVT data with an accuracy high enough to enable the evaluation and interpretation of other measurements. For this purpose the following equation proved to be very useful.

$$\rho(P,T)=\rho(P_0,T)/\{1-0.1\ln[1+10P\cdot\varkappa_T(P_0,T)]\} \tag{19}$$

It can be derived from eq. (16) by setting $A=0.1$ and $B(T)=0.1\,\varkappa_T^{-1}(P_0,T)$, where $\varkappa_T$ is the compressibility at normal pressure. Eq. (19) fits the measured densities of molten salts, including organic molten salts, with an accuracy of better than one percent in the pressure range up to 5 kbar. It can be assumed that it also enables the calculation of unknown PVT data with the same accuracy and that in this respect it is superior to the computer simulations.

3. Transport Properties

3.1. Statistical Treatment, Computer Simulations and Inelastic Neutron Scattering

For the statistical treatment of transport properties time-dependent distribution functions are needed which describe the dynamic behavior of the system. If the total potential energy of the system can be written as a sum of pair interactions it suffices to know the one- and two-particle functions in order to calculate macroscopic transport properties such as *e.g.* viscosity or thermal conductivity. An integrodifferential equation can be derived which contains both unknown distribution functions. In order to solve the equation, additional assumptions have to be made which can only be valid for limited ranges of the state variables. For dense, fluid phases *Rice* and *Alnatt* (cf. [28]) derived equations which enable the calculation of the transport coefficients from molecular parameters and from distribution functions. They split the pair potential into a repulsion term, which is represented by the hard sphere potential, and a soft attraction term, and then calculated the influences on the transport properties of the two parts of the potential independently. The transport coefficients calculated with the Rice-Alnatt equations deviate considerably from experimental values, even for simple liquids[28]. *Cafky* and *Babb*[76] calculated the transport coefficients of compressed gases using the Rice-Alnatt formalism. They obtained unphysical results, *e.g.* negative viscosities, when approaching liquid-like densities. Molecular dynamics calculations by *Smedley* and *Woodcock* on liquid argon and molten KCl demonstrated that cross-correlations of the forces originating from the repulsive and the attractive part of the potential are not negligible in either case and that thus one of the basic assumptions of the Rice-Alnatt theory is invalid[77].

While it is presently impossible to calculate a two-particle time-dependent distribution function by purely analytical methods or to link it with macroscopic transport properties in such a way as to give sufficiently accurate results, it is possible to establish relations between time-dependent distribution functions and physical properties of a substance which may be determined experimentally. Similarly to elastic neutron scattering, inelastic scattering enables the evaluation of a structure factor $S(\vec{Q},\omega)$ which not only depends on the transfer of momentum but also on the energy transfer $\hbar\omega$ during the scattering process. A two-particle correlation function $G(\vec{r},t)$ can be derived from the structure factor by double Fourier transformation. It is called the van Hove correlation function and measures the probability of finding a particle at $\vec{r}$ at a time t, when a particle is at $\vec{r}=0$ at $t=0$. At $t=0$ it is linked with the radial distribution function by the simple relation

$$G(\vec{r},0)=\delta(r)+\rho g(r)=G^s(\vec{r},0)+G^d(\vec{r},0) \tag{20}$$

in which the first term G^s describes the autocorrelation of single particles and the second term the cross-correlations between different particles. G^s can be obtained separately from the incoherent part of the neutron scattering.

For molten salts, three different functions $G_{\alpha\beta}(\vec{r},t)$ (α, $\beta=+,-$) are again needed for a complete description, which can only be evaluated from isotopic substitution experiments. Up to now, two inelastic neutron scattering experiments have been carried out for molten salts[78,79], both without isotopic substitution. *Price* and *Copley*[78] measured $S(\vec{Q},\omega)$ for RbBr, for which the scattering properties of the two nuclei are such that the experiment yields information on the density fluctuations in the melt. Both the scattering experiment as well as molecular dynamics calculations for this system[80] show that the density fluctuations are strongly attenuated and that they die off in very much the same way as in non-ionic systems. The limited Q-range and the limited accuracy of the experiments did not allow a calculation of $G(\vec{r},t)$. The second experiment was performed on KBr with the aim of gaining some information on charge fluctuations at high frequencies. Unfortunately, the accuracy of the experiment was insufficient for sound conclusions to be drawn.

Relations between macroscopic transport coefficients and (different) time-correlation functions of the equilibrium system can be established under the assumption that a perturbation caused by an external force is a linear function of the perturbing force and that the system responds to the perturbation in such a way as if it were generated by fluctuations in the equilibrium system (linear response theory). For the self-diffusion coefficient a relation (cf. [25])

$$D=\frac{kT}{m}\int_0^\infty Z(t)\,dt \tag{21}$$

to the normalized velocity autocorrelation function

$$Z(t)=\langle\vec{v}_i(t)\cdot\vec{v}_i(0)\rangle/\langle\vec{v}_i^2(0)\rangle \tag{22}$$

is derived in this way. The symbol $\langle\,\rangle$ denotes averaging over all the ions present as well as over different time origins.

For the specific electrical conductivity (dc) of a salt of type MX (alkali metal halides) one obtains

$$\sigma = \frac{\rho e^2}{\mu} \int_0^\infty J(t)\,\mathrm{d}t \tag{23}$$

where μ is the reduced mass of the two ions and

$$J(t) = \langle \vec{j}(t) \cdot \vec{j}(0) \rangle / \langle \vec{j}^2(0) \rangle \tag{24}$$

is the normalized autocorrelation function of the electric current

$$\vec{j}(t) = \sum_{i=1}^{N} z_i \vec{v}_i(t) \tag{25}$$

In eq. (25) the summation has to be carried out over all particles. $J(t)$ thus contains cross-correlation terms of the velocities of different particles. It can be shown that these terms are responsible for deviations from the Nernst-Einstein relation which are frequently found in the case of molten salts. For a model system of a molten salt in which the only difference between the two types of ions is the sign of their charge, this deviation may be expressed by Δ in

$$\sigma = \frac{\rho e^2}{kT}(D_+ + D_-)(1-\Delta) \tag{26}$$

Figure 7 shows the normalized autocorrelation functions of the velocity and electrical current from molecular dynamics calculations by *Hansen* and *McDonald*[80,81] for such a simple model system. The correlation functions become negative after a characteristic time interval. This means that, on average, after collisions with their neighbors the ions move in the opposite direction after this time has elapsed. For times longer than this, the correlation is lost completely. Figure 7 also shows the difference between the two functions from which $\Delta = 0.19$ is derived, a value which is almost identical with the experimental value for NaCl (0.18). *Ciccotti et al.*[83] carried out molecular dynamics calculations of transport properties using the more realistic pair potential from eq. (13). Table 6 shows their results for self-diffusion coefficients, specific conductivities, and viscosities and the good agreement with experimental data, especially for conductivity and viscosity.

Owing to the extraordinary long computing times necessary for calculation of the transport coefficients of molten salts, no temperature and density dependencies have been calculated as yet.

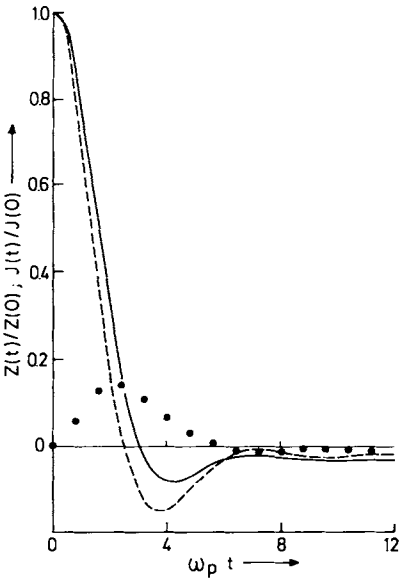

Fig. 7. Normalized autocorrelation functions of velocity (——) and of electric current (--------) and the difference between them (•••••) as function of time [81, 82]; $\omega_p^2 = 4\pi\rho e^2/m$.

3.2. Experimental Studies

For early measurements of the diffusion coefficients[84,85] and viscosities[86–88] of molten alkali metal nitrates at elevated pressures gases have been used as pressure transmitting media. During the measurements the gases dissolved in the molten salt and thus changed its properties considerably. The measured pressure dependencies of the transport coefficients depend on the type of gas and thus tell us very little about the pure salt.

Cleaver and *Herdlicka*[89] measured the interdiffusion coefficient of silver ions in molten alkali metal nitrates up to 1 kbar using a chronopotentiometric technique. The activation volume for the diffusion of silver ions increases from 5.6 cm^3 mol^{-1} in $NaNO_3$ to 13.7 cm^3 mol^{-1} in $CsNO_3$ and is thus always slightly greater than the activation volume of the molar conductivity of the respective pure solvent (cf. Table 8). It was thus concluded that the first coordination shell of the silver ions in the nitrates changes with size and polarizing power of the cations of the solvent.

The transport property of molten salts which has been studied most extensively at high pressures is the electrical conductivity. The specific conductivity of a molten salt may be written in the form

$$\sigma = \sum_i \rho_i |z_i| e \mu_i \tag{27}$$

Table 6. Comparison of transport coefficients from MD calculations [83] with experimental data [14].

Salt		T [K]	V [cm^3 mol^{-1}]	D_+ [10^{-5} cm^2 s^{-1}]	D_- [10^{-5} cm^2 s^{-1}]	σ [Ω^{-1} cm^{-1}]	η [10^{-3} kg m^{-1} s^{-1}]

	exp.			6.6	5.8	1.81	0.90

The summation is carried out over all types of ions i. The mobilities μ_i are not independent of each other. With $\rho_i = \nu_i \alpha \rho_0 = \nu_i \alpha N_A / V_m$, where ν_i is a stoichiometric coefficient, ρ_0 the number density of the molecules when the salt is completely undissociated, α the degree of ionization, N_A Avogadro's number, and V_m the molar volume, one obtains

$$\sigma = \sum_i \nu_i |z_i| e N_A \alpha \mu_i / V_m \tag{28}$$

From this equation it follows that the conductivity may be influenced by temperature and pressure in three ways by changing:

1. the molar volume,
2. the mobilities of the ions,
3. the degree of ionization.

In order to separate these three effects it is useful to study first of all those salts for which $\alpha = 1$, that is, which are completely dissociated into ions. This does not mean that the oppositely charged ions are greatly separated in space as in the case of dilute solutions. Here the absence of a peculiarity in the first peak of the partial radial distribution function g_{+-} at small values of r that correspond to the equilibrium distance of the ions in an isolated molecule could be used as a criterion for complete ionization. The conductivity of such salts has been studied extensively, among them the alkali metal halides[90-93], nitrates[94-99], other oxoanion salts[99-100], and a few organic salts[101,102]. Figure 8 shows as example the

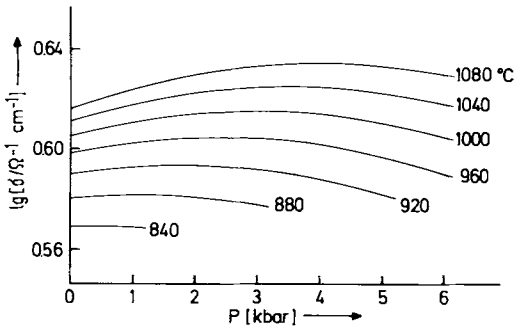

Fig. 8. Specific conductivity of molten sodium chloride [92].

specific conductivity of molten sodium chloride as a function of pressure up to 6 kbar for temperatures up to 1080 °C. At the lowest temperatures the conductivity decreases monotonously with increasing pressure. At higher temperatures it goes through a maximum which, with increasing temperature, becomes more pronounced and is shifted towards higher pressures. This behavior is caused by a superposition of the first and second of the three effects mentioned above. At lower temperature, where the density is high and the compressibility low, the pressure influence on the mobilities determines the pressure dependence of the conductivity over the whole pressure range. At high temperatures, where initially the density is lower and the compressibility higher, the influence on the molar volume is dominating, but at sufficiently high pressures the influence on the mobilities finally becomes the predominant one. Figure 9 shows the influence of the ionic sizes on the pressure dependence of the specific conductivity. Exchange of the anion in the series of sodium salts has only a small effect; the maximum is slightly shifted towards lower pressures with increasing size of the anion. In contrast, exchange of the cation in the sequence of chlorides strongly alters the pressure dependence of the conductivity. KCl still exhibits a slight maximum at the temperature chosen in Figure 9, whereas the conductivities of RbCl and CsCl fall monotonously over the whole pressure range. At still

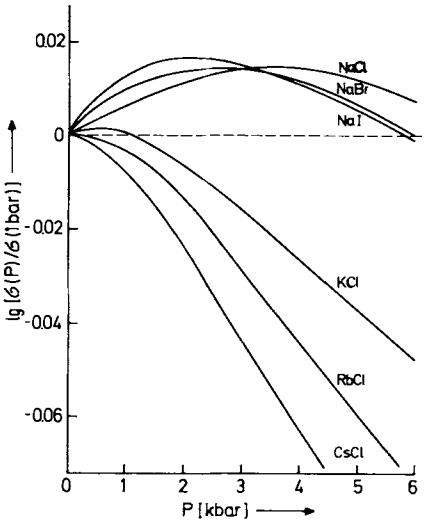

Fig. 9. Influence of the ionic sizes on the pressure dependence of the specific conductivity of molten alkali metal halides at 1040 °C [92].

higher temperatures, where measurements are not yet available, the conductivities of these salts would also show a maximum at intermediate pressures. Maxima in the conductivities when plotted against pressure were not found for the nitrates and other salts of oxoacids. These salts could only be studied over narrow temperature ranges because they start to decompose at relatively low temperatures (exception: lithium salts).

Whether the explanation given for the appearance of the maximum of the specific conductivity is correct or not can be proven by a discussion of the molar conductivity Λ, which is calculated from the specific conductivity by multiplication with the corresponding molar volume

$$\Lambda = \sigma \cdot V_m = \sum_i \nu_i |z_i| e N_A \alpha \mu_i \tag{29}$$

If $\alpha = 1$, the pressure dependence of this quantity should reflect the pressure dependence of the ionic mobility alone. Figure 10 shows the molar conductivity of NaCl as example. In fact, the maximum disappeared and the mobilities decrease monotonously over the whole pressure range.

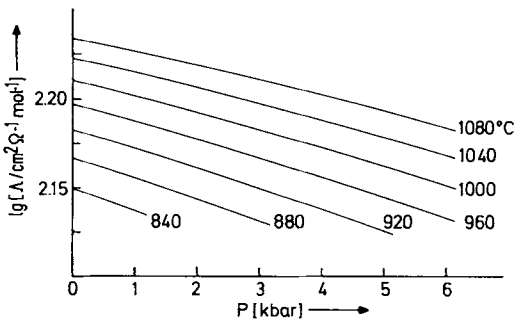

Fig. 10. Molar conductivity of molten sodium chloride [92].

Pressure and temperature dependencies of the conductivity may conveniently be expressed by the activation volume ΔV_Λ and the isobaric and isochoric activation energies, $(E_\Lambda)_P$ and $(E_\Lambda)_V$, respectively, which are defined as

$$\Delta V_\Lambda = -RT(\partial \ln \Lambda/\partial P)_T$$
$$(E_\Lambda)_P = -R(\partial \ln \Lambda/\partial(1/T))_P \quad (30)$$
$$(E_\Lambda)_V = -R(\partial \ln \Lambda/\partial(1/T))_V$$

As can be seen from the slopes of the isotherms in Figure 10, ΔV_Λ decreases with increasing temperature and is not completely independent of pressure. The activation energies increase with increasing pressure.

Table 7. Activation volume and energies for molten alkali metal halides at 1000 °C and 5 kbar [92].

	ΔV_Λ [cm³ mol⁻¹]			$(E_\Lambda)_P$ [kJ mol⁻¹]			$(E_\Lambda)_V$ [kJ mol⁻¹]		
	Cl	Br	I	Cl	Br	I	Cl	Br	I

K	4.8	5.9	6.9	17.0	18.2	17.8	9.6	6.7	6.3
Rb	6.0	6.4	7.4	18.6	18.6	18.7	7.5	5.5	6.2
Cs	7.0	8.6	8.7	19.2	19.4	19.3	7.4	7.3	7.7

The activation parameters evaluated for the alkali metal halides at 1000 °C and 5 kbar are collected in Table 7. The activation volume increases with increasing ionic size. The influence of the anion is much weaker than that of the cation. The activation energies are not strongly dependent on the ionic sizes except for the lithium salts. A similar picture is obtained for the alkali metal nitrates, the activation parameters of which are listed in Table 8. Lithium nitrate has a very small activation volume and a markedly higher isochoric activation energy than the other nitrates. This is due to the small size of the lithium ions (ionic radius: 60 pm) which allows for considerable shorter distances between the oppositely charged ions, thus leading to stronger Coulombic attrac-

Table 8. Activation volume and energies for molten alkali metal nitrates at 400 °C and 1 bar [96].

[a] At 450 °C.

tions. The last column in Table 8 gives the ratio of the isochoric to isobaric activation energy which measures the fraction of the isobaric energy of a particular melt not needed for a volume increase. For other series of completely ionized salts one finds, with a few explainable exceptions, the same dependence of the activation parameters on the ionic sizes. Thus a good estimate of the temperature and pressure dependencies of the molar conductivity seems to be feasible also for those salts for which measurements have not yet been made.

For all the salts studied so far which do not tend to form glasses, the activation volume is about 10% of the molar volume or less, whereas in solid ionic conductors (except superionic conductors) it reaches about 50% of the molar volume. If this difference were due to the volume increase upon melting, which creates the opportunity for voids of the size of the ions to be formed in the melt by thermal density fluctuations, it should be likely that a change in the charge transport mechanism is observed at very high densities, where the voids become too small to accomodate the ions. To check this, the conductivity of KCl was measured up to pressures of 50 kbar and temperatures of 1500 °C in a belt-type high-pressure apparatus[103]. Figure 11 shows the result of this investigation. The slopes of the conductivity isotherms change only slightly. There is no indication of a drastic change in the conduction mechanism, although the highest densities reached are higher than the density of crystalline KCl under normal conditions.

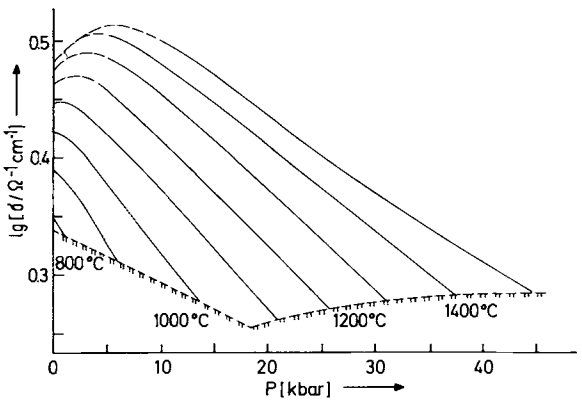

Fig. 11. Specific conductivity of molten potassium chloride up to pressures of 50 kbar [103].

Earlier measurements on the alkali metal nitrates[98] up to 50 kbar showed a change in the activation volume of the conductivity to half its low-pressure value within a pressure interval of about 5 kbar. The change was found around 20 kbar for $NaNO_3$, around 14 kbar for KNO_3 and around 9 kbar for $RbNO_3$. For $LiNO_3$ it was not observed in the pressure range covered by the experiments. The behavior found for the nitrates is most probably due to a change in the rotational motion of the nitrate ion when the density is raised.

From conductivity measurements on the lithium halides up to 1 kbar by *Cleaver et al.*[91] and to 6 kbar by *Ransford et al.*[93] it follows that for these salts not only the specific conductivity but also the molar conductivity goes through a maximum as a function of pressure, as is shown in Figure 12 for LiBr. This behavior is probably due to the high polarizing power of the lithium ions which leads to a particularly strong interaction between the lithium ion and one of the anions in its first coordination shell. When the density is increased the average distance of all the other nearest neighbors from the lithium ion decreases and this reduces the effect mentioned and makes the lithium ion more mobile. A similar effect has been found in alkali metal halide crystals which were doped with the respective lithium salt. In these crystals the lithium ion is not positioned exactly at its lattice site but is slightly shifted towards one of its neighboring anions. Upon compression of the crystal its equilibrium position moves towards the lattice site and the lithium ion simultaneously becomes more mobile[104, 105]. This observation de-

monstrates the limitation of the concept of splitting the influence of pressure on the molar conductivity into two parts, one due to a change in the ionization equilibrium and the

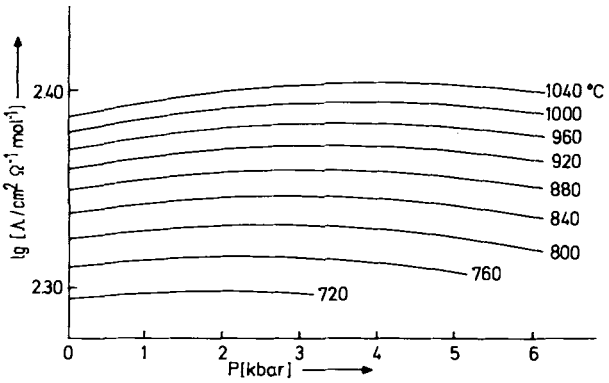

Fig. 12. Molar conductivity of molten lithium bromide [93].

other due to a change of the mobility. The model used to explain the increase of the molar conductivity of the lithium halides can be interpreted as an increase of the mobility as well as a change in the ionization equilibrium.

4. The Transition from an Insulator to an Ionic Conductor

As has been mentioned in the introduction, a salt undergoes a transition from an insulator to an ionic conductor when the density is changed from low to high values. The transition is a consequence of the increasing dissociation of the salt molecules into ions. At low temperatures the transition is discontinuous when the saturation density of the vapor is reached and the salt condenses. At supercritical temperatures, however, the transition is totally continuous. Measurements of the specific conductivity and of PVT data in this region can yield information about the ionization equilibrium as a function of density, especially at which densities the transition occurs. The most suitable salts for such an investigation are the alkali metal halides. Unfortunately, their critical temperatures are estimated to lie around 3000 K[106], too high for static high-pressure experiments. The alkali metal nitrates and other oxoanion salts start to decompose at temperatures well below their critical temperature. The first measurements in the supercritical temperature range of a molten salt have therefore been carried out on bismuth trichloride[61,107], which has a critical temperature of 905 °C and which is a reasonably good ionic conductor at its ordinary melting point ($\sigma = 0.4\ \Omega^{-1}\ cm^{-1}$). The result of this difficult experimental investigation is shown in Figure 13, where the specific conductivity of $BiCl_3$ is plotted as a function of temperature up to 1200 °C at several constant pressures up to 4 kbar. The conductivity changes by six orders of magnitude in the range covered by the measurements. Such a strong variation cannot be accounted for by the mobility effect discussed in the preceding Section. Figure 13 shows that the conductivity is extremely temperature- and pressure-dependent in the vicinity of the critical point (CP), where the density changes rapidly. The molar conductivity can be calculated from the specific conductivity and the molar volume[61] which has been measured over the same temperature and pressure ranges. It increases by five orders of magnitude when the density increases by about a factor of twenty at constant temperature, goes through a maximum and finally decreases again, since at sufficiently high densities the salt is completely ionized and the density influence on the mobility alone determines the behavior of the molar conductivity. In this range the activation volume (3.5 $cm^3\ mol^{-1}$) and the isobaric activation energy (10.9 kJ mol^{-1}) have values which are typical for completely ionized salts, whereas at low densities the isobaric activation energy can be as high as 50 kJ mol^{-1} and the activation volume has strongly negative values.

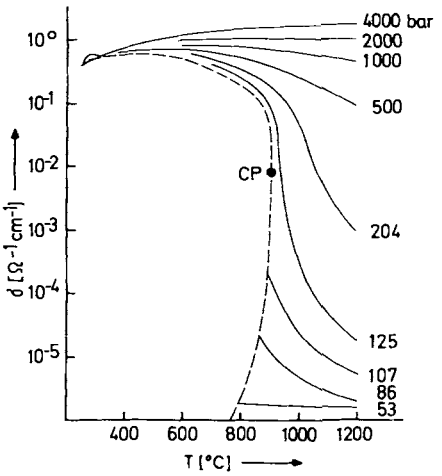

Fig. 13. Specific conductivity of bismuth trichloride in the supercritical temperature range [107].

With the reasonable assumption that the dissociation reaction is

$$2\,BiCl_3 \rightleftarrows BiCl_2^+ + BiCl_4^-$$

and with an estimate of the ionic mobilities, the degree of ionization of the salt can be estimated using eq. (29). The result is shown in Figure 14, where the degree of ionization is

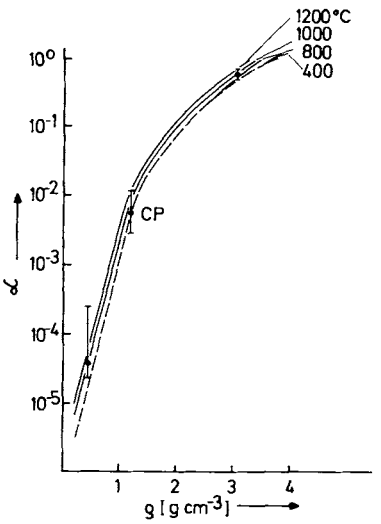

Fig. 14. Degree of dissociation of bismuth trichloride [107].

plotted as a function of density together with the respective error bars caused by the uncertainty of the mobilities. At the highest densities the degree of ionization reaches the value one, whereas at a density of 0.2 g cm^{-3} it is about 10^{-5}. The strong variation of the ionization equilibrium in favor of the ions with rising density is a consequence of the large volume shrinkage due to the dissociation reaction. The ions formed cause an electrostriction effect on the remaining molecules which are forced into the solvation shells of the ions. At constant density the degree of ionization increases only slightly with rising temperature. At the critical point (CP) only one percent of the $BiCl_3$ molecules are ionized. Bismuth trichloride is thus an essentially molecular liquid at its critical point.

The result obtained for bismuth trichloride raises the question, how the dissociation equilibrium is changed with density and at which density complete ionization ($\alpha = 1$) is reached for other salts which are either better or poorer conductors at normal pressure. As has already been mentioned no information is available for the alkali halides. However, *Buback* and *Franck* measured the electrical conductivity[108] and the density[109] of molten NH_4Cl, which may be regarded as a pseudo alkali metal halide. This salt, when heated under pressures higher than about 50 bar, melts to form an ionic melt. Its conductivity was measured along the saturation line up to 30 K below its critical temperature of 1155 K. The conductivity increases monotonously up to that temperature, contrary to that found in the case of $BiCl_3$ (Fig. 13) and other molten salts[110-112]. NH_4Cl thus appears to be an essentially ionic liquid at its critical point.

The molten mercury(II) halides are poor conductors at their normal melting points (cf. Table 9) indicating that only a small fraction of the molecules is dissociated into ions. Their conductivities were measured as a function of pressure[113-115]. They strongly increase with increasing pressure, *e.g.* by two and a half orders of magnitude in the case of $HgBr_2$ in the pressure range up to 6 kbar. The molar conductivity goes through a maximum when plotted as a function of density, like in the case of $BiCl_3$. At the point of maximum conductivity these salts are also almost completely ionized, and at still higher densities the mobility effects governs the density dependence of the molar conductivity. The maximum is found for HgI_2 at 9.5 kbar[116]. The density dependence of the molar conductivity enables an estimate of the density at which a salt is completely ionized. This density devided by the critical density is listed in Table 9 for various salts.

A behavior similar to that just discussed for the mercuric halides is also observed for a number of other molten salts which are not completely ionized at ordinary pressure, among them AlI_3, GaI_3, InI_3, BiI_3 and CdI_2 whose conductivities were measured by *Cleaver et al.*[117] up to 1 kbar. It may be suspected, therefore, that many other substances whose molecules consist of at least two different atoms with appreciably different electronegativities and which are not or only slightly ionized at ordinary conditions approach the completely ionized state as the density is increased to sufficiently high values. In fact, measurements of the conductivity of pure water up to 1000 °C and 100 kbar by *Holzapfel* and *Franck*[118] demonstrated that the ionic product of water under these conditions, where the density is about 1.6 g cm^{-3}, is by about twelve orders of magnitude higher than for liquid water under normal conditions. More than 0.1% of the H_2O molecules are ionized under the conditions quoted. Shock wave measurements[119] have shown that water reaches complete ionization at about 1.92 g cm^{-3}. Conductivity measurements on ammonia[120] indicated that this substance approaches complete ionization at a density of about 1.7 g cm^{-3}.

The examples just mentioned show that there is no qualitative difference in the ionization behavior of substances which are very dissimilar under normal conditions of pressure and temperature, *e.g.* NH_4Cl and water or typical molten salts and polar liquids. The values listed in Table 9, however, also demonstrate that much higher reduced densities and thus very high pressures are needed in order to force pure polar liquids into a completely ionized state, whereas typical molten salts may be completely ionized at densities considerably lower than their normal liquid density, which corresponds to a reduced density of about three.

Table 9. Dissociation behavior of molten salts and polar liquids: order of magnitude of the specific conductivity at normal pressure (column 2) and reduced density $\rho_r = \rho/\rho_c$ at which ionization is complete (column 3).

5. Outlook

It is obvious that progress in the investigation of the static and dynamic properties of molten salts and their temperature and density dependencies has been rather rapid during the last few years. The computer simulation techniques have proven to be excellent mediators between theoretical and experimental studies, because they yield "exact" values for simple model systems which provide a means of testing the quality of approximations in the theoretical treatment of such systems, and, on the other hand, allow conclusions to be drawn about the applicability of effective pair potentials for more realistic ionic systems by comparing the results with experimental values. It can be assumed that the methods developed for simple molten salts will be improved and supplemented in such a way that they can also be used for more complicated molten salts and their mixtures in order to elucidate the relations between their microscopic structure and their macroscopic properties. In view of current developments regarding the use of such molten salts, not only for traditional applications but also on a large scale for batteries and fuel cells, for coal gasification and desulphurization, for scrubbing of stack gases, and for heat storage, this would constitute a great success in this field of chemistry.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Unusually Rapid *cis-trans* Isomerization of a Tetrasilylated Ethylene: Generation of Free Radicals During the Rotation[1]

By *Hideki Sakurai, Hiromi Tobita, Mitsuo Kira,* and *Yasuhiro Nakadaira*[*]

In a previous paper, we described the preparation and some properties of tetrakis(trimethylsilyl)ethylene *(1)* and related compounds including anion and cation radicals of *(1)*[2]. In this paper, we report the fast *cis-trans* isomerization of tetrasilylated ethylenes *(4)* and generation of free radicals during rotation around the double bond.

Scheme 1

(*Z*)-1,2-Bis[dimethyl(phenyl)silyl]-1,2-bis(trimethylsilyl)-ethylene (*Z*)-*(4)* was prepared according to Scheme 1 from 1,1,2,2-tetramethyl-3,4-bis(trimethylsilyl)-1,2-disila-3-cyclobutene *(2)*[3]. The reaction mixture contains almost only (*Z*)-isomer (NMR); however, after 3 h (the minimum time to separate and purify each isomer by TLC at room temperature) the ratio of (*Z*)-*(4)* to (*E*)-*(4)* was 90:10. Each isomer isomerizes to the same 60:40 (*Z*)/(*E*) mixture within 3 days at room temperature.

$$(Z)\text{-}(4) \underset{k'}{\overset{k}{\rightleftharpoons}} (E)\text{-}(4)$$

The rate constants of isomerization, k and k', were determined at 68 °C to be 3.7×10^{-4} s^{-1} and 5.6×10^{-4} s^{-1}, respectively. The activation energy is 30 kcal·mol^{-1}. The remarkably low activation energy is an indication that the olefin is very crowded.

Interestingly, *cis-trans* isomerization also takes place photochemically. Irradiation of either (*Z*)-*(4)* or (*E*)-*(4)* with a 500-W high-pressure mercury lamp for 45 min at room temperature resulted in equilibration with (*Z*)/(*E*) = 40:60. The photochemical equilibrium constant is different from the thermal one, for reasons which are still unclear.

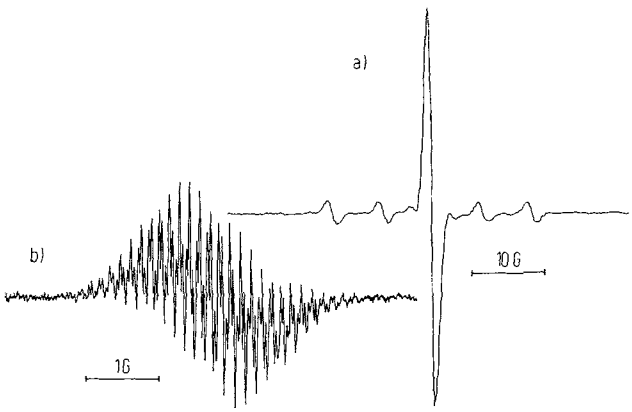

Fig. 1. ESR spectrum of *(5)*: a) Full spectrum; b) expanded spectrum of the central line.

The parent compound in the series, *viz. (1)*, shows very interesting phenomena related to the very facile isomerization of *(4)*. Thus, when *(1)* was heated neat or in decalin at about 150 °C, a strong ESR signal of the persistent radical *(5)* appeared (Fig. 1). The spectral parameters agree well with those reported previously for *(5)* by *Griller* and *Ingold*[4] (values in parentheses): $a^{29}_{Si} = 13.58$ (13.71) G, $a^{29}_{Si} = 27.75$ (27.59) G, $a_{^{13}C} = 4.8$ (4.88) G, $a_H = 1.4$ (1.35) G.

$$(Me_3Si)_2C{=}C(SiMe_3)_2 \rightleftharpoons (Me_3Si)_2\overset{\odot}{C}\text{–}\overset{\odot}{C}(SiMe_3)_2$$
(1)

$$(Me_3Si)_2\overset{\odot}{C}\text{–}\overset{\odot}{C}(SiMe_3)_2 \xrightarrow{RH} (Me_3Si)_2CH\text{–}\overset{\odot}{C}(SiMe_3)_2$$
(5)

Apparently *(1)* can abstract hydrogen during the rotation.

Synthesis and Rearrangement of Azulenesulfonium Salts

By *Manfred Müller, Siegmar Braun,* and *Klaus Hafner*[*]

Dedicated to Professor Rolf Huisgen on the occasion of his 60th birthday

Rearrangement reactions of azulenes with retention of the bicyclic system have hardly been studied so far; just a few thermally induced or acid-catalyzed isomerizations of 1-alkyl-, 1-aryl-, and 1-acylazulenes to the corresponding 2-substituted azulenes are known[1]. We have now found that *S,S*-dimethyl-4-azulenylmethylsulfonium salts of type *(3)* not only provide a facile entry to numerous 4-functionalized azulene derivatives, but also undergo a mechanistically and preparatively interesting rearrangement.

Compound *(3)* (blue platelets) can be prepared by reaction of sodium (6,8-dimethyl-4-azulenyl)methanide *(1)*[2] with dimethyldisulfane to give 6,8-dimethyl-4-(methylthiomethyl) azulene *(2)* (blue crystals) followed by methylation of *(2)*. On reaction with nucleophiles (dimethylamine, aqueous sodium acetate, sodium azide, lithium chloride or bromide), compound *(3)*—a potential umpolung product of *(1)*—affords the hitherto inaccessible compounds *(4a—e)* (blue crystals or oils, see Table 1). Reaction of *(3)* with triphenylphosphane gives the phosphonium salt *(4f)* (blue crystals) which is capable of undergoing Wittig reactions with aldehydes[3] (see Table 1).

Contrary to initial expectations, deprotonation of *(3)* with sodium methoxide (in methanol, room temperature) fails to yield the resonance-stabilized sulfonium ylide *(5a)*. Instead, a fast, and for non-benzenoid, cyclically conjugated π-electron systems previously unknown, [2.3]sigmatropic rearrangement of *(5b)*—which is presumably in equilibrium with *(5a)*—with loss of the 10π-electron system apparently takes place, giving a 78% yield of the readily isolable, stable 6,8-dimethyl-4-methylene-3a,4-dihydroazulene derivative *(6)* (yellow crystals), along with 10% of the isomeric 4,6,8-trimethyl-

azulene derivative *(7)* (blue needles). The structure of *(6)* was established primarily by analysis of the ^{1}H-coupled ^{13}C-NMR spectrum. Formation of compound *(6)* corresponds to that of the methylenecyclohexadiene intermediates detected in the Sommelet-Hauser rearrangement of *o,o'*-disubstituted benzyl-dimethylsulfonium and -trimethylammonium salts[4].

Unlike these intermediates, *(6)* does not undergo thermal rearrangement; however, acid-catalyzed rearrangement (1% $HClO_4$ in CH_3OH) regenerates the azulene system to give 4,6,8-trimethyl-1-(methylthiomethyl)azulene *(8)* (blue needles).

Physical data of the new compounds are compiled in Table 1.

Dimerization of Propylene with Catalysts Exhibiting Activities Like Highly-Active Enzymes

By *Borislav Bogdanović, Bernd Spliethoff,* and *Günther Wilke*[*]

In 1963 we discovered soluble catalysts which dimerize ethylene and propylene with high activity, even at $-20\,^{\circ}C$ at normal pressure[1]. As catalysts we have employed, *inter alia,* π-allylnickel halides in combination with Lewis acids such as $EtAlCl_2$. The dimerization of propylene can be controlled within wide limits by addition of phosphanes having different electronic and, especially, steric properties, so that dimers of various structures can be prepared at will[1]. The olefin dimerizations were performed in CH_2Cl_2 or C_6H_5Cl. We have quoted the activity of the catalysts in the dimerization of propylene at normal pressure and $-20\,^{\circ}C$ for 3—6 kg product/(g Ni·h).

In later experiments we established that the previously found, but nevertheless considerable activity was apparently exclusively determined by the reaction conditions such as stirring, cooling, and gas feed, even though relatively small amounts of catalyst were employed. As we have now found, the activity is in fact about one thousand times higher. The experiments for determining such high activities were performed as follows:

100 ml of C_6H_5Cl, 350 g (8.33 mol) of 99.8% propylene, and 0.6 g (4.72 mmol) of $EtAlCl_2$ are mixed at temperatures between -45 and $-75\,^{\circ}C$). The relatively large amount of $EtAlCl_2$ should ensure that traces of impurities are trapped (under the conditions given, $EtAlCl_2$ does not react with propylene). The vigorously stirred mixture is then treated with a solution of 0.0023 g (5 μmol) of π-$C_3H_5NiBrP(C_6H_{11})_3$ in 1 ml C_6H_5Cl (prepared by multiple dilution of aliquot amounts). A strongly exothermic reaction immediately sets in, so intensive cooling is necessary to keep the temperature of the reaction mixture constant. After 30 min the reaction is terminated by passage of gaseous NH_3, excess propylene (250—300 g) is bubbled off, and the product worked up. Table 1 lists the results of experiments at various temperatures.

Table 1. Catalytic dimerization of propylene.

T [°C]	g Product/(5 μmol cat. × 30 min)	kg Product/(g Ni·h)	mol C_3H_6/(mol Ni·h)	Turnover number/s [a]
−75	22	152	209524	60
−65	47	324	447619	130
−55	84	580	800000	230

[a] Turnover number = reaction steps at the active center; here: molecules of propylene/atom Ni (approx. values).

As expected, in the temperature range quoted the amount of product/30 min doubles on increasing the temperature by 10 °C. The composition of the products is practically independent of the temperature, in contrast to catalysts in which

[**] Activity = amount of reacted substrate/(catalyst unit × unit time).

$(t\text{-}C_4H_9)P(i\text{-}C_3H_7)_2$ was employed as steering ligand[2]. In the present case we obtained, besides 10—15% of higher olefins, dimers of the following composition: 18% 4-methyl-1-pentene, 1–3% *cis*-4-methyl-2-pentene, 76% 2,3-dimethyl-1-butene, 4% 2-methyl-1-pentene, as well as traces of other isomers.

The values in Table 1 already show that the activity of the catalyst is higher by a factor of about 100 even at −55 °C than previously quoted for −20 °C. Assuming a doubling of the activity/10 °C, gives an activity of *ca.* 6000—7000 kg product/(g Ni·h) and hence the factor 1000. For a comparison with enzyme activities, appropriate experiments had to be performed at 25 °C. As experiments under pressure have shown[1b], at this temperature the catalysts are fully active, though a determination of the actual activity under pressure can be achieved only with considerable effort, owing to the limitations of the apparatus. Calculation as above gives a value of *ca.* 150×10^3 kg/(g Ni·h) and a turnover number/s of *ca.* 60000; the corresponding data for enzymes[3] are: hexokinase 100, catalase 80000, carboanhydrase 600000.

The activity of the catalyst diminishes at higher conversions, probably because of traces of impurities; nevertheless, in one experiment at −45 °C we have achieved turnover numbers of 10^6 mol propylene/mol of catalyst; on terminating the reaction the activity had fallen to about 10% of the activity during the first 30 min.

If, under otherwise identical conditions, propylene is allowed to react with a catalyst not containing phosphane, the activity is only *ca.* 1/15 of that quoted above, *i.e.* the phosphane not only exerts steering properties but also effects considerable activation. Generally, however, this catalysis would also appear to be a further example of the phenomenon already observed several times, *i.e.* that the product selectivity increases with increasing catalyst activity[4]. To our knowledge the systems described here are the most active synthetic homogeneous catalysts known to date.

Solubility of Nonvolatile Biochemical Substances in Compressed Carbon Dioxide[**]

By *Ziad Alwani*[*]

Industrial methods have recently been developed for the extraction of natural products with supercritical or fluid solvents at pressures of up to *ca.* 400 bar (cf. [1]). As examples might be mentioned the decaffeination of coffee, the production of hop extract, and the extraction of spices. In the construction of chemical plant for high-pressure extraction, a knowledge of parameters such as, *inter alia,* extraction rate and solubility data, is of paramount importance.

[*] Dr. Z. Alwani
Lehrstuhl für Physikalische Chemie II der Universität Bochum
Present address: Thyssen-Maschinenbau GmbH
D-5810 Witten-Annen (Germany)

[**] Based on a lecture delivered at the GDCh-Hauptversammlung in Berlin, September 12, 1979.

We have investigated the solubility of difficultly volatile biochemical substances in compressed fluid solvents using as example the model substance α-tocopheryl acetate (vitamin E acetate) in CO_2. For the measurements, a newly developed optoelectrical method[2] was used which enabled experimental determination of relatively low solubilities (for older methods see [3]).

From the clouding points of a mixture measured at various pressures and temperatures a family of $p(T)$ mixing curves was constructed for each mixture examined. The curves in Figure 1 are continuous between 20 and 50 °C and do not show any discontinuity in the neighborhood of the critical temperature of CO_2 (*ca.* 31 °C). This would indicate a continuous transition between the liquid-liquid and liquid-gas phase equilibria (for an explanation of these phenomena see [4, 5, 8]).

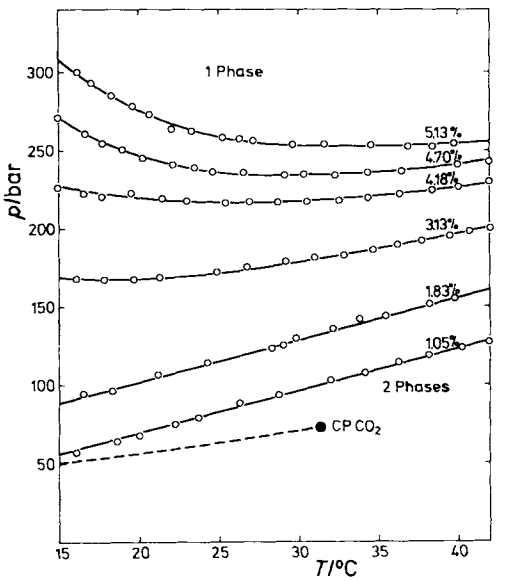

Fig. 1. $p(T)$ Curves for α-tocopheryl acetate in CO_2 at several constant concentrations [wt-%]. CP = critical point.

From the $p(T)$ curves (Fig. 1) the solubilities were determined as a function of pressure at a given temperature; sim-

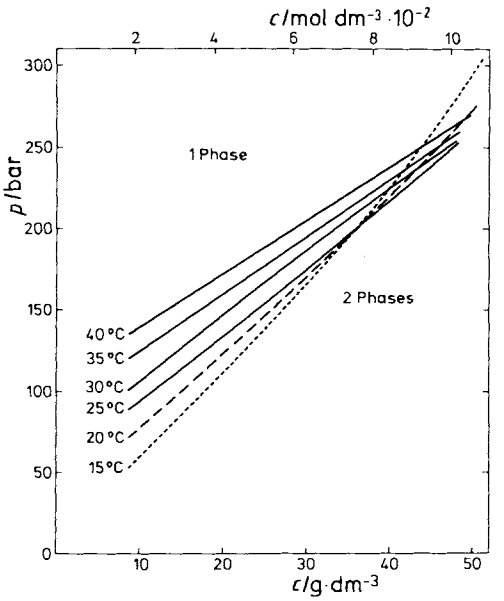

Fig. 2. $c(p)$ Curves for α-tocopheryl acetate in CO_2 at several constant temperatures.

plified additivity of the volumes of the pure substances was assumed (from the densities of CO_2[10]). According to Figure 2 the solubility increases monotonously with increasing pressure and reaches a value of *ca.* 40 $g \cdot dm^{-3}$ at 250 bar. The slopes of the curves differ only slightly above and below the critical temperature of CO_2. However, at temperatures below the critical point of CO_2, some of the curves intersect at a concentration of *ca.* 35 $g \cdot dm^{-3}$ and a pressure of *ca.* 180 bar. The systems squalane + CO_2[5] and caffeine + CO_2[9] behave similarly.

Figure 3 shows the solubility of α-tocopheryl acetate as a function of temperature at constant pressure. At constant pressures below 200 bar the solubility decreases with increasing temperature; a maximum solubility occurs at pressures above 200 bar. These curves are also continuous, *e.g.* also in the neighborhood of the critical point of CO_2.

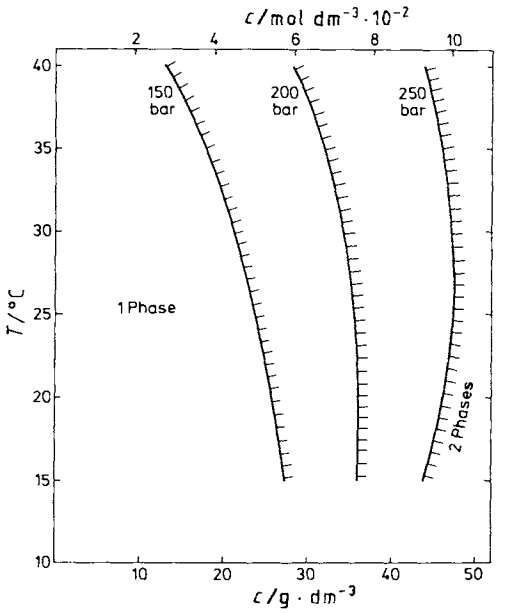

Fig. 3. $c(T)$ Curves for α-tocopheryl acetate in CO_2 at several constant pressures.

The most important findings can be summarized as follows: i) The solubility of α-tocopheryl acetate increases with increasing pressure, both in liquid as well as in supercritical CO_2. ii) Contrary to some data quoted in the literature[6, 7], the solubility of α-tocopheryl acetate changes relatively slightly when the solvent (here CO_2) is heated from subcritical to supercritical temperatures at constant pressure.—These results can be extrapolated to other nonvolatile substances and fluid solvents.

Dianion and Tetraanion of [2₄]Paracyclophanetetraene—New Unusual Perimeter Systems[**]

By *Walter Huber, Klaus Müllen,* and *Olof Wennerström*[*]

The current question regarding external or internal aromaticity in polycyclic compounds like porphyrins[1] and their ions is in effect a question of whether perimeter structures with resonance stabilization can exist, and *via* which conjugation route[2]. We have found that the dianion *(2)* and the tetraanion *(3)* of [2₄]paracyclophanetetraene *(1)*[3], exhibit unusual spectroscopic properties and are novel macrocycles in which such a peripheral conjugation is present.

As electrochemical reduction of *(1)* shows, the molecule reversibly takes up two electrons at low potential[3]. On reduction with metal in a sealed NMR tube (lithium, 0.05 M solutions of *(1)* in [D_8]-tetrahydrofuran, −80 °C) a diamagnetic species is formed, which on the basis of its ^1H- and ^{13}C-NMR spectra and trapping experiments *(vide infra)* is identified as dianion *(2)* and which on prolonged contact with metal forms a new product, the tetraanion *(3)*. Both ions are stable in the absence of air, even above +60 °C.

(1) *(2)* *(3)*

Observation of the dianion, however, is possible only in the absence of the intermediary radical anions [$(1)^{\ominus}$[4], $(2)^{\ominus}$] and therefore necessitates careful monitoring of the reduction by recording the ESR and NMR spectra.

It is possible at each stage of the reduction to recover the neutral compound *(1)* as sole product by reoxidation with oxygen. Reaction of *(2)* and *(3)* with methanol affords, respectively, diprotonated and multiprotonated[5] products in which olefinic double bonds are hydrogenated.

The neutral compound *(1)* shows chemical shifts typical for aromatic and olefinic protons (see Fig. 1 and Table 1). However, owing to the drastic difference in shifts of the external (H-3) and internal (H-4) protons—both in *(2)* and in *(3)*—one must conclude that a peripheral ring current, and hence a perimeter conjugation, exists. The internal benzene protons in the dianion *(2)* absorb at $\delta = -7.07$ (!). The diamagnetic ring current in *(2)* and the paramagnetic ring cur-

rent in *(3)* evidence the ions as typical 26 $(=4n+2)\pi$- and 28 $(=4n)\pi$-perimeter systems, respectively.

Table 1. ^{1}H- and ^{13}C-chemical shifts (δ-values referred to TMS) and $^1J_{CH}$ coupling constants [Hz] of [2$_4$]paracyclophanetetraene *(1)*, its dianion *(2)*, and its tetraanion *(3)* [a]; [D$_8$]-tetrahydrofuran, $-80\,^\circ$C, ions as lithium salt. The ^{1}H-NMR signals (singlets) were assigned on the basis of the ring current effects and on the exchange-broadenings observed in the spectrum of *(2)* above $-20\,^\circ$C. The assignment of the ^{13}C-NMR signals is based on selective ^{1}H-decoupling experiments.

	Cpd.	H-1 or C-1	C-2	H-3 or C-3	H-4 or C-4	⟨δ⟩
$\delta(^1H)$	*(1)*	6.48		7.37	7.37	
	(2)	9.56		9.26	−7.07	
	(3)	2.09 [b]		4.48 [b]	12.76	
$\delta(^{13}C)$	*(1)*	129.9	136.2	129.3	129.3	131.2
	(2)	108.8	119.8	123.9	116.5	117.3
	(3)	95.9 [b]	133.3	122.4 [b]	121.6	118.3
$^1J_{CH}$	*(1)*	154		158	158	
	(2)	143		147	159	

[a] Determination of the $^1J_{CH}$ coupling constants of *(3)* is hampered by the small signal separation. [b] The assignment possibly has to be interchanged.

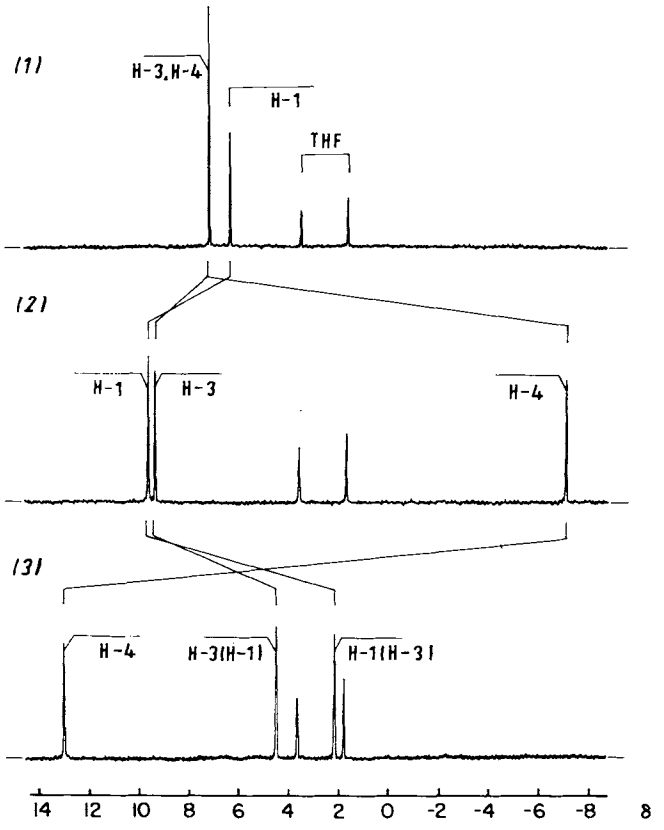

Fig. 1. ^{1}H-NMR spectra (90 MHz) of [2$_4$]paracyclophanetetraene *(1)*, its dianion *(2)*, and its tetraanion *(3)*; [D$_8$]tetrahydrofuran, $-80\,^\circ$C, ions as lithium salt.

Characteristic of the structure of the ions is the mutual approach of the π-bond orders of the formal single and double bonds. This follows from the fact that the very rapid rotation of the benzene fragments about the single bonds in the neutral compound is drastically slowed down on transition to the ions[6].

Particularly surprising from the point of view of bond theory is the fact that a perimeter conjugation extends beyond the benzene units[7]. In view of the poorly understood bonding situation in related polycycles[1,7], the question arises whether this form of conjugation differentiates between the external (C-3) or internal (C-4) loop of the benzene. Closely coupled with the solution of this problem is the knowledge of the charge distribution, which can be investigated experimentally *via* the ^{13}C-chemical shifts and/or the relevant $^1J_{CH}$-coupling constants[8].

On going from *(1)* to the dianion *(2)* the coupling constants $^1J_{CH}$ for the positions 1 and 3 diminish by *ca.* 11 Hz owing to additional π-charging. The analogous coupling constant for position 4, on the other hand, remains practically unchanged and gives no indication of the existence of an excess charge in the inner loop. That the signal of C-4 in *(2)* nevertheless experiences a pronounced upfield shift can be ascribed, in view of the topology of the present system, to the influence of the ring current on the resonance of the carbon nuclei[9]. Thus, it is also not surprising that the upfield shift of the center point of the ^{13}C-NMR signals in the transition from *(1)* to *(2)* is distinctly larger than one would expect on the basis of the usual correlation between π-charge density and chemical shift.

The aforementioned spectroscopic findings prove not only the surprising existence of a peripheral conjugation in the ionic cyclophane systems but also show that the 26 π-perimeter is preferably formed in the dianion with participation of the external loop of the benzene units.

[5] That mainly the dihydro and octahydro product—apart from small amounts of the two constitutionally isomeric tetrahydro systems—are formed in the protonation of *(3)* is readily explained in terms of a series of interchanging protonation and electron transfer. *(3)* is thereby acting as reducing species.
[6] The rotation about the formal single bonds within the macrocycle, which leads to an exchange of the magnetic sites 3 and 4, cannot be frozen in *(1)*, even at $-130\,^\circ$C. While the ^{1}H-NMR spectrum of the dianion *(2)* above $-20\,^\circ$C shows an exchange broadening of the signals of H-3 and H-4 (not of H-1), indicative of the mentioned transformation of conformation, the spectrum of *(3)* shows no evidence of a dynamic process up to $+60\,^\circ$C.

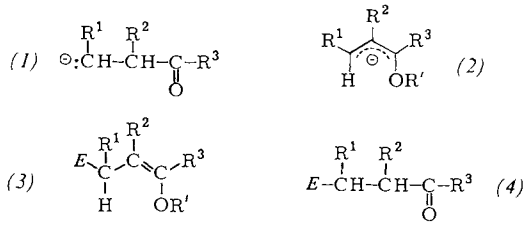
Lithiated Allyl *N,N*-Dialkylcarbamates as Homoenolate Equivalents; Synthesis of Protected 4-Oxoalkanoates[**]



By *Dieter Hoppe, Rudolf Hanko*, and *Alfons Brönneke*[*]

Among the synthetic equivalents of the homoenolate ions *(1)* ("carbonyl-d^3 reagents"[1]), the *O*-substituted 1-hydroxyallyl anions *(2)*[2] offer the most direct preparative solution[3,4]. They are generally attacked ambidoselectively[5] by electrophiles *E* at the γ-position; the resulting enol ethers *(3)*

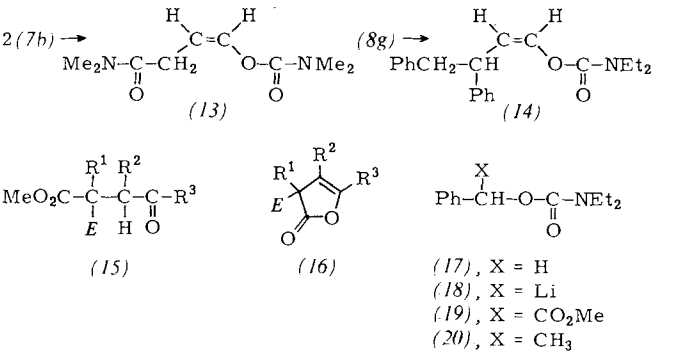
[**] Metalated Nitrogen Derivatives of Carbonic Acid in Organic Synthesis, Part 18.—Part 17: *D. Hoppe, R. Follmann*, Liebigs Ann. Chem., in press.

can be hydrolyzed to the β-substituted carbonyl compounds *(4)*.



In particular, the anions *(2)* of allyl alkyl and of allyl trialkylsilyl ethers (R′ = alkyl, $SiMe_3$, or $SiEt_3$)[2] have previously been employed; however, their utility (in the absence of other electron withdrawing groups) is limited to the derivatives *(2)*, $R^1 = R^3 = H$, owing to insufficient acidity of α- and γ-substituted allyl ethers[2b]. We have now found that the presence of *N,N*-dialkylcarbamoyl groups[6] in the esters *(7)* increases the kinetic acidity of α-protons by chelation to such an extent that alkyl-substituted allyl derivatives such as *(7d)* and *(7f)* (Table 1) can also be deprotonated.

The allyl *N,N*-dialkylcarbamates *(7)*, obtained from the allyl alcohols *(5)* and the acid chlorides *(6)*, were allowed to react at −70 °C in the presence of 3 equivalents of dimethyl carbonate with 2.1 equivalents of lithium diisopropylamide (LDA) and then with an electrophile *EX*. Subsequent work-up of the reaction mixture yielded methyl *Z*-4-carbamoyloxy-3-butenoates *(11)*[7,8] together with (usually) small amounts of the isomers *(12)* (see Table 1).

Intermediates formed in the reaction sequence *(7)*→*(11)* are the allyl anions *(8)* and *(9)*, each of which react with high selectivity[5]. Only the crotyl esters *(7d)* and *N,N*-dimethylcarbamates, *e.g. (7b)*, yield substantial amounts of the α-adducts *(12)* (Table 1), *via* the anions *(10)*. As has been demonstrated with *(7c)*, the bulky *N,N*-diisopropylcarbamoyl groups effects a further increase in regioselectivity.

On metalation in the absence of a trapping agent, *(7b)* undergoes self-condensation[10] to give the butenamide *(13)*[7] (yield 40%), while the anion *(8g)* is stable at −78 °C and can be trapped as enol ester *(14)*[7] (yield 60%) with benzyl bromide.

The method described here offers a versatile entry by a one-pot process to immediate precursors of 4-oxoalkanoates *(15)* and 3-buten-4-olides *(16)*[9]. The approach demonstrated here—the protection of hydroxy groups as carbamates with concomitant enhancement of CH acidity—has also proven valuable in the generation of other α-alkoxycarbanions. For instance, reaction of the benzyl ester *(17)* proceeds *via* the lithium compound to give *(18)*, which we trapped as *(19)*[7] with dimethyl carbonate, and as *(20)*[7] with methyl iodide (yields 74 and 90%, respectively).

Procedure

The ester *(7)* is prepared by reaction of *(5)* with *(6)* (1.05 equiv.) and pyridine (1.6 equiv.) (10 h at 90 °C) under N_2 without solvent, followed by conventional aqueous-acidic and distillative workup.

Methyl Z-4-diethylcarbamoyloxy-2-methyl-3-butenoate (11d): A solution of LDA (10.5 mmol) in tetrahydrofuran (THF)/*n*-hexane (4:1) (40 ml) is treated with 1.35 g (15.0 mmol) of methanol-free dimethyl carbonate under N_2 at −78 °C; *(7a)* (0.79 g, 5.0 mmol) is then injected into the solution over 10 min *via* a CO_2-cooled tube. The mixture is stirred at −78 °C until complete consumption of *(7a)* (TLC check, $t = 1$ h) and then treated with a solution of methyl iodide (0.78 g, 5.5 mmol) in THF (3 ml). After 5 h at −78 °C, stirring is continued for 1 h at −20 °C, the mixture is neutralized with glacial acetic acid (0.90 g, 15.0 mmol) and, after removal of solvent *in vacuo*, subjected to the usual workup (with ether). The crude product is found to contain 5% *(12d)* (^{1}H-NMR: $\delta = 5.8$; 4-H_2). Chromatography on 200 g silica gel (neutral, 40—63 μm, 2.5 bar) with ether/petroleum ether (1:5) affords 0.804 g (70%) *(11d)* with $R_F = 0.50$ (1:1) [*(12d)*: 0.46]; IR (film): 1730 (O—C=O), 1715 (N—C=O), 1665 cm^{-1} (C=C); ^{1}H-NMR (CCl_4): $\delta = 6.98$ (dd, $J_{cis} = 6.5$ Hz, $^4J = 1.0$ Hz; 4-H), 4.75 (dd, $J = 6.5$ and 9 Hz; 3-H), 3.60 (s, OCH_3), 3.3 (m, 5H; NCH_2 and 2-H), 1.25 (d, $J = 7$ Hz, 2-CH_3), 1.2 (m, NCH_2CH_3).

A New Preparation of 4-Aminobutyramide

By *Axel Kleemann, Wolfgang Leuchtenberger, Jürgen Martens*, and *Horst Weigel*[*]

The hydrochloride of 4-aminobutyramide *(3)* (Gabamide) is of considerable interest on account of its psychotropic properties[1]. In connection with our work on the synthesis of derivatives of natural and unnatural amino acids[2], we have now discovered a facile, productive synthesis of *(3)*: Selective hydrogenation of 3-cyanopropionamide *(2)* in the presence of hydrogen chloride affords the hydrochloride *(3)* in 71% yield.

[*] Dr. A. Kleemann, Dr. W. Leuchtenberger, Dr. J. Martens, H. Weigel
Degussa, Fachbereich Forschung Chemie
Postfach 1345, D-6450 Hanau 1 (Germany)

The synthesis of *(2)* by partial hydrolysis of succinonitrile reported in the literature[3] is unsuitable for preparative purposes, owing to the poor yield and complicated workup of the reaction mixture. We therefore sought a more favorable synthesis of *(2)* (see Table 1), and found that hydrogen cyanide cleanly adds to acrylamide *(1)* in dimethylformamide (DMF) in the presence of catalytic amounts of potassium cyanide.

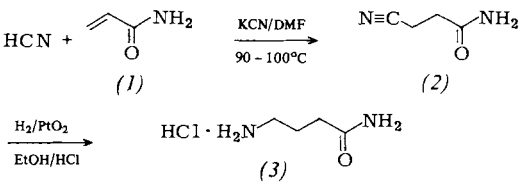

Table 1. ^{1}H-NMR data [a] of compounds *(2)* and *(3)* [b].

(3)	8.25 (s; 3H, γ-NH_3), 7.55 (br. s; 1H, —CO—NH), 6.83 (br. s; 1H, —CO—NH), 2.83 (m; 2H, —CH_2—), 2.22 (m; 2H, —CH_2—), 1.90 (m; 2H, —CH_2—)

[a] 60-MHz spectra in [D_6]-DMSO/$CDCl_3$ with TMS as internal standard; δ values. [b] *(2)* and *(3)* gave correct elemental analyses.

Our synthesis leads directly to a very clean product *(3)* (Table 1); not even the slightest traces (TLC) of butyrolactam are formed under the conditions given in the experimental section[4].

Experimental

(2): A solution of acrylamide *(1)* (71.0 g, 1 mol), dimethylformamide (100 ml), and hydrocyanic acid (27.0 g, 1 mol) is added dropwise over 1—1.5 h to a suspension of potassium cyanide (1.5 g) in dimethylformamide (50 ml) at 90 °C. The reaction is exothermic. The reaction temperature is kept at 90—100 °C. After 30 min at 95 °C, acetic acid (3 ml) is added and the reaction mixture is evaporated down at 20—30 mbar until a residue weighing 140 g is left. Addition of toluene (200 ml) and subsequent cooling to 20 °C furnishes brown crystalline *(2)* (89.1 g, 91%). Recrystallization from ethyl acetate affords pure *(2)* (72.6 g, 74%, m.p. 92—95 °C; lit. value 94 °C[3]).

(3): Compound *(2)* (19.6 g, 0.2 mol) and PtO_2 (1.5 g) are transferred to a 500 ml Hastelloy agitated autoclave containing ethanol (275 ml) and hydrogen chloride (8 g), whereupon *(2)* dissolves. After flushing with nitrogen, the mixture is hydrogenated at a hydrogen pressure of 5 bar. The reaction solution is maintained at 33 ± 3 °C. Hydrogen take-up starts immediately and is complete after 2 h. Compound *(3)* precipitates during hydrogenation. After cooling to 10—15 °C, *(3)* is washed out of the filter cake with hot methanol (100 ml). The methanolic solution of *(3)* is concentrated to 40 ml in a water-pump vacuum and stirred with ethyl acetate (100 ml). Colorless crystalline *(3)* (73%, m.p. 137—139 °C) is obtained at 20 °C.

(6*R*,7*R*)-(−)-7-Hydroxy-3-oxabicyclo[4.3.0]non-1-en-9-one, A Readily Accessible and Highly Versatile Intermediate

By *Klaus Weinges, Herbert von der Eltz,* and *Dao Tran-Viet*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Starting from hexaacetyl dihydrocatalpol *(1)* we obtained the crystalline compound (6*R*,7*R*)-(−)-7-hydroxy-3-oxabicyclo[4.3.0]non-1-en-9-one *(3)*, in two reaction steps without any need for time-consuming separations. The keto enol ether *(3)* is highly reactive and is of interest as an optically active key compound, both for correlative determination of configuration of iridoid monoterpenes, and for the synthesis of natural products, especially prostanoids[1].

The starting compound *(1)* is produced almost quantitatively by acetylation and subsequent catalytic hydrogenation from catalpol, which can be isolated on a 100-g scale from a readily available drug[2]. $LiAlH_4$ reduction in tetrahydrofuran converts *(1) via* a regioselective epoxide cleavage into the amorphous product *(2)* whose constitution is established by analytical and spectroscopic studies on its crystalline heptaacetate (see Table 1). The reaction *(1)*→*(2)* can be applied to all other acetylated epoxy-iridoid glucosides (*e.g.* pentaacetyl unedoside, antirrhinoside and procumbide) and their dihydro derivatives (70—85% yield).

(1) *(2)* *(3)*

G_{Ac} = Tetraacetyl-β-D-gluco-pyranosyl G = β-D-Gluco-pyranosyl

Table 1. Some physical properties of *(2)*-heptaacetate and *(3)*.

(2)-heptaacetate: ^{1}H-NMR (300 MHz, $CDCl_3$): δ = 5.80 (s; 1H, H-1), 5.27—4.80 (m; 6H, H-6, H-10, H-1′ to H-4′), 4.42 (d, ^2J = 12.5 Hz; 1H, H-10), 4.40 (d, ^2J = 12.5 Hz; 1H, H-6′), 4.12 (m; 1H, H-6′), ≈3.76 (m; 1H, H-5′), ≈3.65 (m; 2H, H-3), 2.71 (d, ^3J = 7.5 Hz; 1H, H-9), ≈2.52 (m; 1H, H-5), ≈2.40 (m; 1H, H-7), 2.28 (d, ^2J = 16.0 Hz, 1H, H-7), 2.1—2.0 (7s; 21H, CH_3CO), ≈1.6 (m; 1H, H-4), ≈1.3 (m; 1H, H-4); ^{13}C-NMR (75.46 MHz, $CDCl_3$): δ = 170.66—169.02 (6s; 7 $COCH_3$), 96.01 (d; C-1′), 93.86 (d; C-1), 88.25 (s; C-8), 77.38 (d; C-6), 73.39 (d; C-3′), 72.29 (d; C-5′), 71.42 (d; C-2′), 68.72 (d; C-4′), 65.40 (t; C-10), 62.10 (t; C-6′), 57.59 (t; C-3), 49.22 (d; C-9), 41.70 (t; C-7), 40.26 (d; C-5), 24.17 (t; C-4), 21.18—20.58 (5q; 7 CH_3CO)
(3): ^{1}H-NMR (300 MHz, $CDCl_3$): δ = 7.47 (d, ^4J = 2.4 Hz; 1H, H-2), 4.40 (m, ^2J = 11.4 Hz; 1H, H-4), ≈3.96 (m; 2H, H-4, H-7), 3.03 (s; 1H, OH), 2.64 (m, ^2J = 17.3 Hz; 2H, H-6, H-8), 2.41 (m; 2H, H-5, H-8), 1.52 (m; 1H, H-5); ^{13}C-NMR (22.63 MHz, $CDCl_3$): δ = 200.66 (s; C-9), 150.71 (d; C-2), 115.92 (s; C-1), 74.82 (d; C-7), 67.26 (t; C-4), 47.95 (t; C-8), 42.18 (d; C-6), 25.62 (t; C-5); MS: *m/e* = 154 (M^+, calc. 154.0630, exp. 154.0625); 136 ($C_8H_8O_2$), 110 ($C_6H_6O_2$), 82 (C_5H_6O)

Unlike other glucosides, the iridoid glucosides also undergo cleavage of the glucoside bond on treatment with aqueous sodium periodate solution, thus yielding carboxylic acids as well as the aglycones. Compared to acid-catalyzed glucoside cleavage this method has the advantage that the aglycones can be isolated directly from the weakly alkaline solution after saturation with sodium hydrogen carbonate and do not have to be separated from the glucose. The carbon skeleton of the iridoids is, of course, only retained in this reaction if the cyclopentane ring contains no vicinal hydroxy groups. In periodate cleavage of *(2)*, water is eliminated on saturation of the reaction solution with sodium hydrogen carbonate, thus forming *(3)* instead of the aglycone (see Table 1). The configuration at C-6/7 of *(3)* is determined by that of catalpol and corresponds to the configuration at C-11/12 of prostaglandins, showing their partial synthesis from *(3)* to be possible without resolution of racemates[1].

Procedure

6,8-Dihydroxy-8-(hydroxymethyl)-1-iridanyl 1′-β-D-glucopyranoside[3] *(2)*: Hexaacetyl dihydrocatalpol *(1)* (18.4 g, 30 mmol; m.p. 155—156 °C; $[\alpha]_{589}^{20} = -69.3$ (*c* = 2 g/100 ml $CHCl_3$)) is added portionwise to a suspension of $LiAlH_4$ (7.4 g, 195 mmol) in anhydrous tetrahydrofuran (THF) (1000 ml) and heated under reflux for 4 h. The excess of $LiAlH_4$ is destroyed by addition of ethyl acetate and water. After passage of CO_2, inorganic salts are filtered off and the residue washed several times with water. The THF is removed *in vacuo* at 40 °C bath temperature and the aqueous solution heated with active charcoal (50 g) to 80 °C for 3 h. After decanting from the precipitated charcoal, the solution is treated twice more with active charcoal (2 × 50 g). TLC shows that *(2)* is no longer present in the aqueous solution. The charcoal is filtered off under suction and washed with water until no inorganic salts can be detected. After drying in air, it is extracted several times with 95% ethanol for 10 min at boiling temperature. The combined filtrates are evaporated to dryness *in vacuo*; yield 9.5 g (86%) of colorless amorphous *(2)*; $[\alpha]_{589}^{20} = -77.1$ (*c* = 1.9 g/100 ml CH_3OH).

Heptaacetate of *(2)*: P_4O_{10}-dried *(2)* (1 g) is acetylated with anhydrous pyridine (2.3 ml) and anhydrous acetic anhydride (2.9 ml) for 24 h at 50 °C. The reaction mixture is poured into ice-water and the oil precipitated is rubbed until it turns solid. The solid product is filtered off, washed with ice-water, and recrystallized from ethanol; yield 1.1 g (61%). (The mother liquor contains a hexaacetate in which one tertiary hydroxy group is not acetylated.) M.p. 100—102 °C; $[\alpha]_{589}^{20} = -61.6$ (*c* = 1 g/100 ml $CHCl_3$); $R_F = 0.31$ (mobile phase: benzene/acetone 8:2).

(3): Sodium periodate (15 g, 70 mmol) is added to a solution of *(2)* (5.5 g, 15 mmol) in water (250 ml). The solution is left to stand for 30 min at room temperature with occasional shaking. After addition of sodium hydrogen carbonate (20 g; pH = 8), the inorganic salts are filtered off and washed with water (50 ml). The filtrate is concentrated *in vacuo* at a bath temperature of 35 °C until further inorganic salts begin to precipitate. The colorless solution is extracted with ethyl acetate (5 × 100 ml), and the combined ethyl acetate extracts are dried with sodium sulfate and evaporated to dryness *in vacuo* at 35 °C bath temperature. The oil precipitated crystallizes on scratching; yield 1.8 g (78%) of *(3)*. For analysis the product is dissolved in a very small volume of cold dioxane and carbon tetrachloride is added until the onset of turbidity. Compound *(3)* crystallizes in a refrigerator; m.p. 95—97 °C; $[\alpha]_{589}^{20} = -267$ (*c* = 3 g/100 ml CH_3OH).

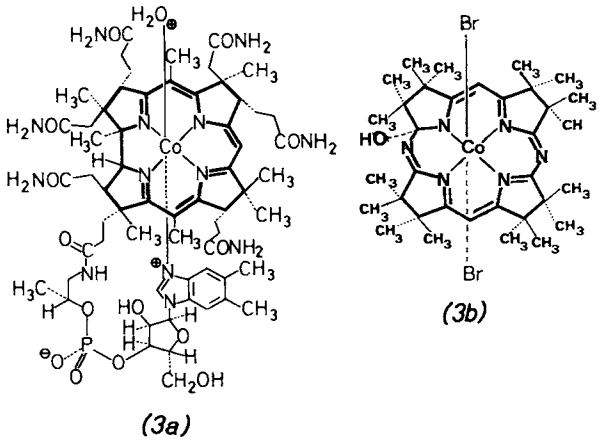
Vitamin B_{12} and a Vitamin B_{12} Model Compound as Catalysts of Reductive Removal of β-Haloethyl Protecting Groups from Acids[**]

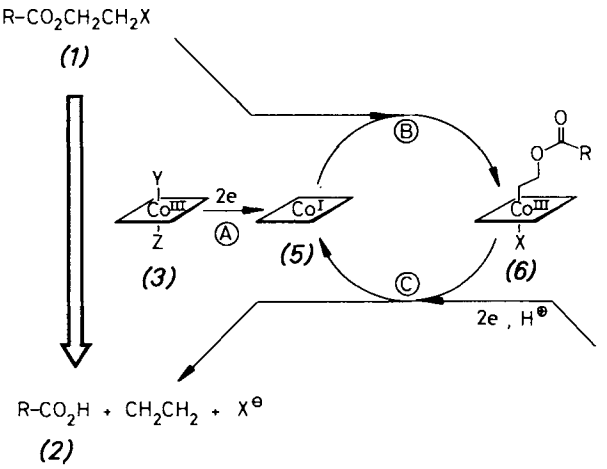
By *Rolf Scheffold* and *Erik Amble*[*]

β-Haloethyl groups are used as protecting groups[2] for carboxylic acids[3a], amines[3b,c], phosphoric acids[3d], alcohols[3e], and also for aldehydes and ketones[3f]. They supplement the range of protecting groups removable by solvolysis, because they are selectively eliminated by reductive elimination according to



$$R{-}O{-}CH_2{-}CH_2{-}X + H^{\oplus} + 2e \rightarrow R{-}OH + CH_2{=}CH_2 + X^{\ominus}$$

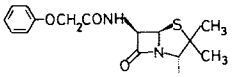
Sources of electrons are metals such as zinc[4a], metal ions in low oxidation states[4b] and their complexes such as the supernucleophilic cobalt(I)-phthalocyanines[3e], and the cathode in direct[4c] or indirect[4d] electrochemical processes. The reactivity of the β-haloethyl groups decreases along the series $-CH_2CBr_3 > -CH_2CCl_3 > -CH_2CH_2I > -CH_2CH_2Br \gg -CH_2CH_2Cl$. No mild and effective elimination procedures were hitherto known[4a] for the β-chloroethyl group, which is the most stable towards bases and nucleophiles.



We have now found that vitamin B_{12} derivatives, *e.g.* aquocobalamin *(3a)*[5] and the readily synthesized vitamin B_{12} model compound dibromo[1-hydroxy-2,2,3,3,7,7,8,8,12,12,13,13,17,17,18,18-hexadecamethyl-10,20-diazaoctahydroporphinato]cobalt(III) *(3b)*[6], catalyze the reductive elimination of β-chloroethyl esters *(1)*, even in amounts of 10^{-3} mol. equiv. [with respect to *(1)*] under extremely mild conditions. Table 1 shows some examples of elimination catalyzed by *(3a)* or *(3b)* according to two procedures: I with zinc dust/ammonium chloride and II electrochemically at a cathode potential of -1.9 to -2.0 V[7]. The reaction conditions are mild enough not to hydrolyze even β-lactam derivatives such as *(1c)*. No reaction occurs in the absence of catalyst.

The mode of action of the catalyst is shown in Scheme 1.

$$\underset{(1)}{R{-}CO_2{-}CH_2{-}CH_2{-}X} + H^{\oplus} + 2e \longrightarrow R{-}CO_2H + CH_2{=}CH_2 + X^{\ominus}$$
$$(2)$$



In step A, the octahedral Co^{III} complexes *(3a)* and *(3b)* are reduced at -1.5 V and at -1.2 V[8] to the catalytically active square-planar green Co^{I} complexes *(5a)* and *(5b)*, respectively. These products react in step B as nucleophiles with *(1)* to form the octahedral red Co^{III}-alkyl complexes *(6a)* and *(6b)*[8,9]. At potentials more negative than -1.7 V[7] these complexes undergo two-electron reduction according to step

Scheme 1

[**] Synthesis and Reactions of Porphinoid Metal Complexes, Part 9. This work was supported by the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (Projekt 2.151-0.78). We are grateful to Dr. *P. Schneider*, CIBA-GEIGY AG, Basel, for supplying penicillin V and its β-haloethyl esters.—Part 8: [1].

C, and decompose to *(2)*, ethylene, and the Co^{I} complex *(5)*. If the potential required for reduction of *(6)* is maintained (electrochemically or by another reducing agent, such as zinc) the reaction continues until the substrate is completely consumed, as shown by appearance of the green color of *(5)*. We therefore call the reductive cleavage of β-haloethyl esters catalyzed by *(3)* the "traffic light reaction", since a color

change from red to green gives the go-ahead for further workup.

Procedure

Route I: β-Chloroethyl *N*-(*p*-tolyl)carbamate *(1d)* (0.53 g, 2.5 mmol), aquocobalamine *(3a)* (50 mg, 0.036 mmol), NH_4Cl (3.0 g, 56 mmol), and zinc dust (0.5 g, 7.6 mmol) [activated by 0.1 N hydrochloric acid and washing with water] in 1:1 ethanol/water (30 ml) were stirred together under argon at room temperature for 15 h. The green suspension was filtered and worked up with CH_2Cl_2: 0.26 g (96%) *p*-toluidine *(4)*, m.p. 41—43 °C.

Route II: Penicillin V β-bromoethyl ester *(1c)* (0.75 g, 1.73 mmol) and *(3a)* (95 mg, 0.07 mmol) were dissolved in 25 ml of electrolyte (0.1 N $LiClO_4$, 0.13 N NH_4ClO_4 in 4:1 ethanol/water) and electrolyzed at a stirred Hg electrode in the cathode compartment of an electrolysis cell at −1.95 V[7] and 1 °C under argon. After 17 h, the reaction solution was diluted with water (50 ml) and worked up with CH_2Cl_2: 0.57 g (95%) penicillin V *(2c)* (identified by TLC and by IR and NMR spectra).

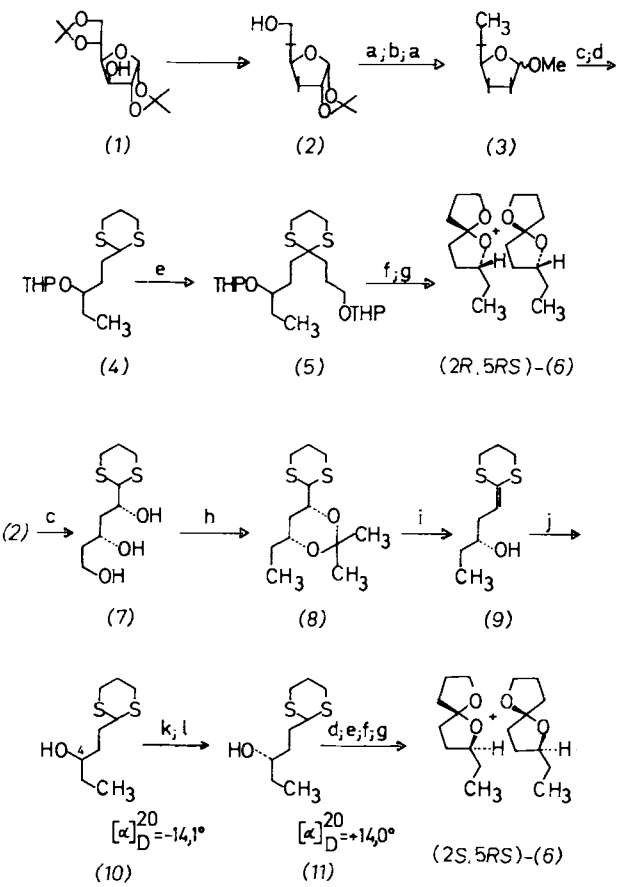
Optically Active Chalcogran (2-Ethyl-1,6-dioxaspiro[4.4]nonane)[**]



By *Hartmut Redlich* and *Wittko Francke*[*]

Chalcogran *(6)* is the aggregation pheromone of the bark beetle *Pityogenes chalcographus* (L.)[1]. Spiroketals of this type play a vital role as volatile chemical messengers in many insect species[2]. Chalcogran occurs as a mixture of diastereomers [(2*R*,5*R*) : (2*R*,5*S*), and (2*S*,5*R*) : (2*S*,5*S*), respectively, about 1:1] in the beetles.

Gas chromatograms of the volatile components of *P. chalcographus* and its sympatrically distributed relative *P. quadridens* (Htg.) cannot be distinguished[3], although the beetles are perfectly able to differentiate between the pheromone bouquets of the individual species under natural conditions. As in other bark beetles[4], a species specificity of this kind may arise from the differing chirality of the principal pheromone.

With the aim of answering this question, we have synthesized optically pure (2*R*,5*RS*)-chalcogran (2*R*,5*RS*)-*(6)* from D-glucose. Carbohydrates are in many respects ideal starting materials for the synthesis of highly pure optically active natural products. For example, use of 1,3-propanedithiol in the reaction of sugars with thiols[5] to give dithioacetals leads, with almost any sugar, to a dithiane compound which can be linked by the Corey-Seebach method[6], and thus to a wealth of readily accessible chiral synthons suitable for the preparation of chiral natural products. We have used this approach for the synthesis of the open-chain, completely protected chalcogran precursor *(5)*.

Starting from D-glucose, the 3,5-dideoxy compound *(2)*[7] and the tetradeoxy compound *(3)* can be synthesized *via* the diisopropylidene compound *(1)* (see Scheme 1). Reaction of

[**] Open-Chain Sugar Dithioacetals as Synthons for Natural Products, Part 1.

(3) with propanedithiol affords the open-chain optically active dithiane alcohol which, as a tetrahydropyranyl (THP) derivative *(4)*, can be linked with THP-protected 3-bromo-1-propanol by the Corey-Seebach method[6] to form the open-chain, blocked (2*R*)-chalcogran precursor *(5)*. Cleavage of the dithiane to give the ketone[8] and removal of the THP protecting groups in an acid medium lead *via* spontaneous cyclization to the desired mixture of diastereomers (2*R*,5*RS*)-*(6)* (see Scheme 1). After purification by gas chromatography, it has an optical rotation of $[\alpha]_D^{20} = +18.4$ ($c = 3.7$ in pentane)[9].

Better yields of (unprotected) *(4)* [*i.e. ca.* 70% *(10)* instead of 30% *(4)*] are obtained by the alternative reaction sequence starting from the dideoxy compound *(2)*. Compound *(2)* can be transformed directly into the open-chain thioacetal *(7)*, which in turn affords the isopropylidene compound *(8)*. Elimination with butyllithium leads to the ketene thioacetal *(9)*[10], which can be hydrogenated to *(10)*[11].

The open-chain alcohols *(10)* having (*R*) configuration at C-4 can be quantitatively converted into the benzoate with (*S*) configuration[12]. After removal of the ester group, comparison of the optical rotations [$[\alpha]_D^{20} = -14.1$ for *(10)* and $+14.0$ for *(11)*] indicates complete inversion at C-4. Compound *(11)* was transformed into (2*S*,5*RS*)-chalcogran by a reaction sequence analogous to that for (unprotected) *(4)* (see Scheme 1).

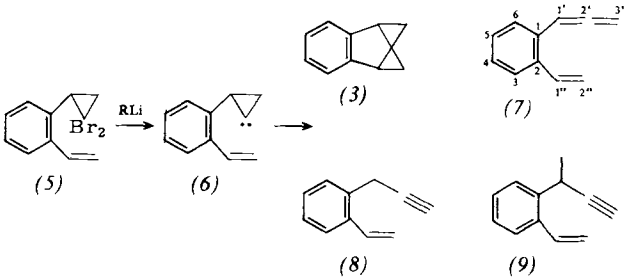
4,5-Benzotricyclo[4.1.0.0^{1,3}]hept-4-ene[**]

By *Udo H. Brinker* and *Joachim Streu*[*]



Intramolecular additions of carbenes to C=C double bonds are often the decisive reaction step in the synthesis of uncommon, highly strained hydrocarbons[1]. Strained polycyclics containing bicyclo[1.1.0]butane[2] and spiropentane units *(1)* ($n = 2, 3$)[3] can be prepared according to this principle. In tricyclo[4.1.0.0^{1,3}]heptane *(2)*[3a,b] there is high angular strain, which is reflected in its thermal behavior[4]. In the hitherto unknown unsaturated hydrocarbons *(3)* and *(4)*[5] for the first time the cyclopropane rings of the spiropentane moiety can interact with the aromatic or olefinic π-electron system.

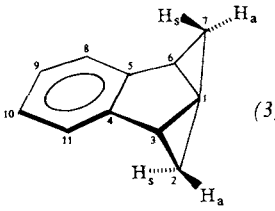
(1) *(2)* *(3)* *(4)*

We report here on a facile synthesis and some properties of 4,5-benzotricyclo[4.1.0.0^{1,3}]hept-4-ene *(3)*, the first representative of this class of hydrocarbons.

Addition of dibromocarbene to *o*-divinylbenzene affords *o*-(2,2-dibromocyclopropyl)styrene *(5)*[6]. Reaction of *(5)* with methyllithium (molar ratio 1:1, ether) at −50 °C leads only to a mixture of the hydrocarbons *(3)* and *(7)* (35:65) in 90–95% yield. The product ratio of *(3)* and *(7)* shows a similar temperature-dependence as that already observed by *Skattebøl* in the reaction of 1,1-dibromo-2-(3-butenyl)cyclopropane with methyllithium[3a,b]. Under otherwise identical conditions, the reaction is more selective with increasing temperature [*(3)* and *(7)* at 25 °C = 15:85]. Assuming that the competing reactions of *(6)*, *i.e.* intramolecular addition of the cyclopropylidene[7] to the vinyl group to give *(3)* and cyclopropylidene-allene rearrangement to give *(7)*, proceed from the same intermediate, this finding would indicate that the temperature-dependence of the ratio of *(3)* and *(7)* is determined by a low isoselective temperature[8]; T_{iso} is estimated at −80 °C.

(5) *(6)* *(3)* *(7)* *(8)* *(9)*

At room temperature the mixture of *(3)* and *(7)* is accompanied by traces of the alkyne *(8)*, which could have been formed by isomerization of the allene *(7)* under the basic conditions employed[9]. In the presence of an excess of methyllithium, *(9)*[10] is formed, probably by methylation of the benzyl anion of *(8)*[9]. Temperatures between −55 and −90 °C favor the formation of *o*-(2-bromocyclopropyl)- and *o*-(2-bromo-2-methylcyclopropyl)styrene(s). These products could be formed by protonation and methylation, respectively, of the intermediate resulting from halogen-metal exchange in *(5)*.



The separation of *(3)* and *(7)* by standard chromatographic methods (LC, TLC, GC, HPLC) is difficult. However, the pure substances can be obtained as follows: After reaction of the mixture of *(3)* and *(7)* with sodamide (3 equivalents) in liquid ammonia, *(3)* can be separated by distillation from any sodium acetylide that is probably formed. Reaction of the mixture with a saturated ethanolic silver nitrate solution enables isolation of *(7)* in pure form. Apparently, only *(3)* reacts to give high-boiling products, from which *(7)* can be separated by distillation (see Table 1)[10].

(3)[10] crystallizes as colorless needles, m.p. 13.5–15.5 °C (pentane), which are sensitive to atmospheric oxygen. Owing to the C_2 symmetry the ^{1}H-NMR spectrum is simple (Table

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Degussa (Frankfurt) for supplying us with chemicals, Dr. *W. Dietrich* for the ^{13}C- and 250 MHz ^{1}H-NMR spectra of the title compound, Dipl.-Chem. *U. Günther* for the analysis of the ^{1}H-NMR spectrum, and Prof. *Klärner* for valuable discussions.

1). The aromatic protons form an AA'BB' system and the three-membered ring protons and ABX system. The detailed analysis of both systems permits exact determination only of the parameters of the aromatic protons. Protons and coupling constants of the ABX system can be assigned on the assumption that the benzylic hydrogen atoms H-3 and H-6 resonate further downfield than H-2_a and H-7_a. Table 1 lists the proton sequence for this assignment.

(3)

Table 1. Some spectral data for compounds *(3)* and *(7)*.

(3), ^{1}H-NMR (C_6D_6, 250 MHz): $\delta = 7.24$ (2H, H-9, 10), 7.03 (2H, H-8, 11), $J_{9,10} = 7.45$ Hz, $J_{8,9} = 7.38$ Hz, $J_{8,10} = 1.42$ Hz, $J_{8,11} = 0.58$ Hz, 1.74 (2H, H-3, 6), 1.66 (2H, H-2_a, 7_a), 1.28 (2H, H-2_s, 7_s), $J_{3,2a} = J_{6,7a} = 6.7$ Hz, $J_{3,2s} = J_{6,7s} = 3.3$ Hz, $J_{2s,2a} = J_{7s,7a} = -4.4$ Hz; ^{13}C-NMR ($CDCl_3$, 22.6 MHz): $\delta = 149.0$ (C-4, 5), 126.0 (C-8, 9, 10, 11), 25.1 (C-3, 6), 19.1 (C-1), 15.7 (C-2, 7); MS (70 eV): $m/e = 143$ (15%, $M^+ + 1$), 142 (100, M^+), 141 (73, $M^+ - 1$), 115 (11), 91 (6); UV (*n*-hexane): $\lambda_{max} = 209$ nm ($\varepsilon = 59\,500$), 230 (8400, sh), 275 (2900), 283 (3200)
(7), ^{1}H-NMR (CCl_4, 60 MHz): $\delta = 5.04$ (d, $J_{1',3'} = 7$ Hz, 2H, H-3'), 5.28 (dd, $J_{2'',E,1''} = 11$ Hz, $J_{2'',E,2'',Z} = 1.5$ Hz, 1H, H-2''*E*), 5.56 (dd, $J_{2'',Z,1''} = 17.5$ Hz, 1H, H-2''*Z*), 6.43 (t, $J_{1',3'} = 7$ Hz, 1H, H-1'), 6.76—7.56 (m, 5H, H-1'', 3, 4, 5, 6); IR (CCl_4): $\nu = 1940$ cm^{-1} (C=C=C); UV (*n*-hexane): $\lambda_{max} = 228$ ($\varepsilon = 38000$), 258 (32000)

The ^{13}C-NMR spectrum shows only five signals, which can be assigned by "off-resonance" decoupling (Table 1). The symmetry of *(3)* is reflected in its IR spectrum, which contains only few bands. The UV bands are shifted bathochromically by about 4—9 and 5—11 nm, respectively, compared to the corresponding bands of model compounds such as 2,3-benzobicyclo[4.1.0]hept-2-ene[11] and 2,3-benzobicyclo[3.1.0]hex-2-ene[11]. *(3)* is only moderately thermostable, its half-life in CCl_4 at 56 °C is *ca.* 40 min. The chemical and thermal properties of *(3)* are currently under intensive investigation.

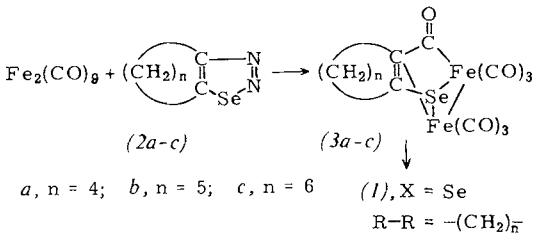
Reactions of Cycloalkeno-1,2,3-selenadiazoles with Transition Metal Carbonyls[**]



By *Keith H. Pannell, Armin J. Mayr, Rodney Hoggard,* and *Roger C. Pettersen*[*]

The stabilization of thioxo- and selenoxoketenes by iron carbonyls has been reported by *Rees et al.*[1] and *Schrauzer et al.*[2]. Using the reaction between the appropriate thia- or selena-diazole and $Fe_2(CO)_9$ they obtained complexes of the general structure *(1)*.

(1), X = S, Se

During a study of the properties of related cycloalkeno-1,2,3-selenadiazoles *(2a—c)*[3] we observed that the reactions of these ligands with $Fe_2(CO)_9$ in hexane at room temperature resulted in the formation of two complexes in good yield. These complexes may be readily separated using an alumina column, such that elution with hexane yields complexes *(1a—c)*, X = Se, while elution with CH_2Cl_2 yields complexes *(3a—c)*. Complexes *(3a—c)* are examples of a new class of complex.

(2a-c) *(3a-c)*

a, n = 4; *b*, n = 5; *c*, n = 6 *(1)*, X = Se
R–R = $-(CH_2)_n-$

An X-ray diffraction analysis of *(3a)* is illustrated in Figure 1. The molecule possesses a selenaferrole ring which is complexed to the second $Fe(CO)_3$ group *via* the selenium and iron atoms, and the double bond.

Upon heating to 60 °C, or upon irradiating with ultraviolet light, the complexes *(3a—c)* readily decarbonylate and rearrange to complexes *(1)*. This observation suggests that these latter complexes are not formed directly. Both *Rees* and *Schrauzer* performed their reactions in polar solvents at elevated temperatures, *i. e.* conditions under which the transformation *(3)*→*(1)* would be extremely rapid. This probably explains their failure to detect *(3)*.

Reactions of the selenadiazoles *(2)* with other metal complexes such as Group VI hexacarbonyls, norbornadienetetra-

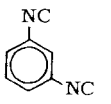
Template Polymerization of Rhodium(I) with Rigid Bent Diisocyanide Ligands[**]



By *Avi Efraty, Irene Feinstein, Lorenz Wackerle*, and *Felix Frolow*[*]

Non-chelating bidentate ligands capable of forming stereochemically rigid bridges between metal nuclei are of special interest in the molecular design of rather unusual coordination polymers. This novel concept is exemplified in the current communication by the molecular design of two-dimensional coordination polymers of rhodium(I) having an unusual shape of a Greek cross with bent arms, and a stacked layers arrangement.

1,3-Diisocyanobenzene, 2,4-diisocyanotoluene and 4,4′-diisocyanodiphenylmethane[1] are rigid bent-bridging ligands capable of separating metal nuclei by approximately 10 and 14 Å, respectively. These ligands undergo a facile reaction with $[Rh(CO)_2Cl]_2$ to afford insoluble green polycrystalline polymers of the type *(1a)*, *(1b)*, and *(2)* in quantitative yields. The new air-stable polymers readily absorb water when exposed to air, and therefore, unless rigorously dried under vacuum these materials are best formulated as $[Rh(Bridge)_2^+Cl^- \cdot xH_2O]_n$ ($x = 0$—8). The IR spectra of these polymers exhibit one strong ν(NC) frequency (2142 ± 3 cm^{-1}) which is characteristic of terminally coordinated isocyanides in a symmetric environment.

The models in Figure 1 simulate the two-dimensional networks formed by template polymerization of tetragonal Rh^I with 1,3-diisocyanobenzene to give *(1a)* and with 4,4′-diisocyanodiphenylmethane to give *(1b)*. The models were con-

(1a)

(2)

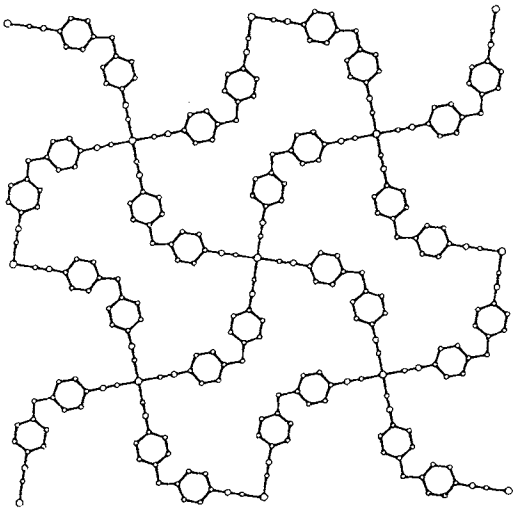

Fig. 1. Two-dimensional models of the polymer network in *(1a)* and *(2)*.

structed using idealized bond angles and distances similar to those reported for certain related complexes[2,3].

Model calculated cell dimensions are $a = 14.47$ Å *(1a)* [and *(1b)*] and $a = 20.26$ Å *(2)*. Inspection of these coplanar models reveals certain unrealistically short inter-bridging distances in *(1a)* (*e.g.* C5$\cdots$C5), as well as some constraint associated with the intra-bridging C2$\cdots$C2 distance in *(2)*. In the case of *(2)*, the constraint is either reduced or removed by the change in relative orientation of the phenylene rings. The established tendency of monomeric cations of type $Rh(CNR)_4^+$ to oligomerize *via* weak $Rh^1\cdots Rh^1$ bonding interaction[2] may suggest the stacking of the two-dimensional models *(1)* and *(2)* in an eclipsed fashion[3].

In the absence of suitable single crystals, powder X-ray diffractometric traces of the new polymers *(1a)*, *(1b)*, and *(2)* were measured. Especially informative results were obtained for *(1b)* and *(2)*. Both polymers have the space group P4; the cell constants are $a = 15.42(6)$, $c = 3.21$ Å and $a = 21.95(8)$, $c = 3.36$ Å, respectively. The powder diffraction data appear to be consistent with the presence of a tetragonal system[4] of rhodium atoms in these polymers. The most intense reflection found in these traces has been assigned to the 110 rhodium-containing planes, whose spacings correspond to the distance of separation of the metal nuclei by the bridging unit (10.91 and 15.49 Å, respectively). Besides other hk0 reflections[4], each trace also contained one reflection which was assigned to the 001 plane. The Rh—Rh distances [*d*(001)] in *(1b)* (3.21 Å) and *(2)* [3.36 Å] are similar to those found in dinuclear cationic complexes of the type $[Rh_2(CNAryl)_8]^{2+}$ (*e.g.*, 3.19[2], 3.21[3] and 3.25 Å[3]), as well as in a related rhodium polymer with colinear 1,4-diisocyanobenzene bridging units (3.31 Å)[5].

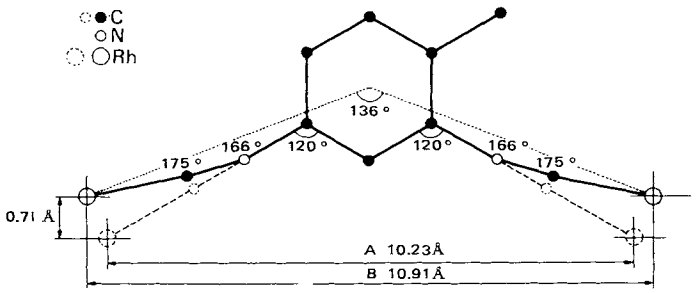

Fig. 2. *d*(110) in the polymer *(1b)*; A: calculated for the model; B: determined experimentally.

The shortcomings associated with the model are resolved in the real polymer *(1b)* by the small increase (≈ 0.68 Å) in the bridge span of 2,4-diisocyanotoluene (see Fig. 2); this corresponds to a ≈ 0.71 Å displacement of the methylphenylene unit towards the 110 plane. In a presumed situation involving the presence of proximity related eclipsed 2,4-diisocyanotoluene units, the inter-bridging distances in the real polymer *(1b)* (*e.g.*, C6$\cdots$C6 ≈ 3.64 Å; $CH_3\cdots CH_3 \approx 4.90$ Å) are estimated to be considerably longer compared with the respective (*e.g.*, ≈ 1.54 and ≈ 2.80 Å) model derived terms. The increase in the bridge span can be rationalized by the non-idealized C—N—C(Rh) and N—C—Rh bond angles (see Fig. 2).—The powder X-ray diffractometric trace of the polymer *(1a)* deviates from the expected pattern of a tetragonal system; interpretation of this trace has not yet been completed.

Experimental

1,3-Diisocyanobenzene (1.06 g, 8.28 mmol) dissolved in CH_2Cl_2 (100 ml) was added dropwise into a stirred solution (CH_2Cl_2, 50 ml) of $[Rh(CO)_2Cl]_2$ (0.4 g, 1.03 mmol) at room temperature. The dark green polycrystalline *(1a)* formed during this reaction in a quantitative yield (based on the Rh reactant), was filtered off, washed with CH_2Cl_2 (5 × 50 ml), and then vacuum dried (80 °C/0.1 torr). The polymers *(1b)* and *(2)* could be prepared utilizing essentially the same procedure. The complete elemental composition data of the new polymers are consistent with their formulation as $[Rh(Bridge)_2^+Cl^-\cdot x H_2O]_n$.

The powder X-ray diffractometric traces were obtained on a Phillips Diffractometer using filtered Cu radiation and a scan speed of 1° (2θ) min^{-1}.

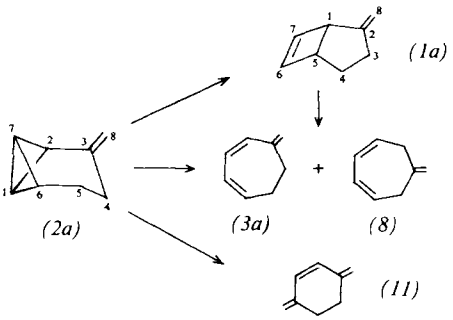
New C_8H_{10} Isomers: 2-Methylenebicyclo[3.2.0]hept-6-ene and 3-Methylenetricyclo[4.1.0.0^{2,7}]heptane—Thermal and Metal-Catalyzed Rearrangements[**]

By *Dieter Hasselmann* and *Klaus Loosen*[*]



Strained small-ring hydrocarbons are of interest owing to their reactivity as well as their spectroscopic and structural properties[1]. The bicyclic isomer *(1b)*[2a] of toluene undergoes thermal isomerization exclusively *via* rupture of the central bond to give 5-methylene-1,3-cyclohexadiene *(3b)*, which should also be accessible from its isomer *(2b)* having a bicyclo[1.1.0]butane structural unit. In contrast, methylenebicycloalkenes *(4)* are observed to undergo both structural isomerization to methylenebicyclo[2.2.*n*]alkenes *(5)* and a degenerate methylenecyclobutane rearrangement[2b,c]. In comparison with this behavior and with the hydrocarbons *(6)* and *(7)* having an endocyclic double bond, the reactions of 2-methylenebicyclo[3.2.0]hept-6-ene *(1a)* and 3-methylenetricyclo[4.1.0.0^{2,7}]heptane *(2a)*, respectively, would appear particularly interesting[3]. We now report on thermal and metal-catalyzed rearrangements of the C_8H_{10} isomers *(1a)* and *(2a)*.

[**] Reorganizations of Strained Methylenecycloalkanes, Part 6. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. *M. Christl*, Universität Würzburg, for communication of unpublished results.—Ref. [2b] is to be regarded as Part 5.

(1a) and *(2a)* were obtained by methylenation of the appropriate ketones[4] with methylenetriphenylphosphorane in dimethyl sulfoxide in 42 and 65% yield of the pure compounds after preparative gas chromatography[5]. Assignment of structure is based on spectroscopic data[5c], hydrogenation (Pd/C) [*(1a)* giving *endo*- and *exo*-2-methylbicyclo[3.2.0]heptane (90:10)[5a,b], and *(2a)* giving *cis*- (24%) and *trans*-1,4-dimethylcyclohexane (72%) and methylcycloheptane (4%)], and their rearrangements.

Thermolysis of *(1a)* in the stationary gas phase leads only to the methylenecycloheptadienes *(3a)* and *(8)*[6a], which are in equilibrium (*(3a)*:*(8)* = 98.8:1.2 at 198.6 °C) under the reaction conditions[6b]. The temperature dependence of the rate of the pressure-independent (0.1–7 mbar) monomolecular cycloreversion of *(1a)* can be described between 163 and 208 °C by the Arrhenius parameters listed in Table 1. In *(1a)* the exocyclic methylene substituent not only effects the expected lowering of activation energy ($\Delta E_a = 7.7$ kcal/mol) relative to the unsubstituted system *(9)*[7a], but also a lowering relative to the certainly more strained compound *(6a)* with endocyclic double bonds[7b] ($\Delta E_a = 1.7$ kcal/mol) (Table 1).

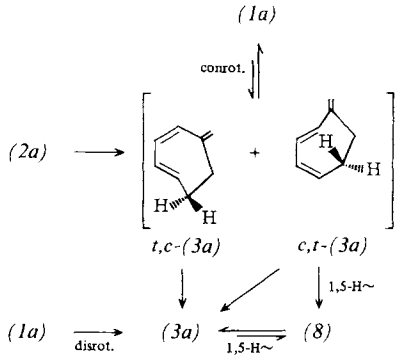

Table 1. Activation parameters.

Cpd.	Phase	E_a [kcal/mol] [a]	log$A$ [s^{-1}]	Ref.

(10)	Solution	37.8	12.8	[9b]

[a] 1 cal = 4.184 J. [b] [D_8]-Toluene/tetramethylethylenediamine. [c] Dimethyl phthalate.

Two reaction pathways must be considered for the rearrangements *(1a)*→*(3a)* + *(8)*: (a) a disrotatory route, forbidden by orbital symmetry, in which rupture of the bridgehead bond in the transition state profits more from formation of the conjugated system than the less flexible species *(6a)*; this leads directly to *(3a)*, which subsequently equilibrates with *(8)* *via* 1,5-hydrogen shift; (b) conrotatory, symmetry-allowed opening of *(1a)* to give *trans,cis*- and/or *cis,trans*-methylenecycloheptadienes [*t,c-(3a)* and *c,t-(3a)*, respectively], which relieve their considerable strain by direct *trans-cis* isomerization, initially giving *(3a)*, and/or by 1,5-hydrogen shift [conformationally preferred *c,t-(3a)*→*(8)*] initially giving *(8)*. Enhanced formation of *(8)* as compared with the equilibrium *(3a)*⇄*(8)* at small conversions of *(1a)* can be taken as experimental evidence for participation of *trans*-cycloheptadienes[8].

Thermolysis of the tricyclic compound *(2a)* in *n*-heptane (123—153 °C) primarily gives only the monocyclic species *(1a)*. Small amounts of *(3a)* and *(8)* are attributable to decomposition of *(1a)*. In the stationary gas phase (123—173 °C), the rate of consumption of *(2a)*, which is pressure independent between 0.1 and 5 mbar, is strictly of first order, but only half as high as in solution. This behavior is describable with Arrhenius parameters (Table 1) which lie in the expected range compared with those of tricycloheptane *(10)*[9b] and tricycloheptene *(7a)*[9b]. However, the product spectrum is more complicated than that obtained in solution. In addition to *(1a)*, more *(3a)* + *(8)* is formed than would be expected under the reaction conditions from the amount of *(1a)* formed; *(3a)* and *(8)* are apparently also formed directly from *(2a)*. For the same conversions of *(2a)*, the product ratio *(1a)*/[*(3a)* + *(8)*] decreases with falling pressure, *e.g.* $p = 5$ mbar→10^{-3} mbar: *(1a)*/[*(3a)* + *(8)*] = 10.0→0.8 (7 h, 154 °C). The rate of consumption of *(2a)* is concomitantly reduced by 15%. Surprisingly, *(11)*[10] appears as an additional product, accounting for up to 8% of the total[11].

In analogy to the thermolysis of other *endo,endo'*-bridged bicyclobutanes[9], the isomerization *(2a)*→*(1a)* can be regarded as a concerted [$_\pi 2_s + _\pi 2_a$]-reaction to give *c,t*- and/or *t,c-(3a)*, which subsequently recyclize to *(1a)*. However, diradical processes involving rupture of the C^2C^7 bond in *(2a)* as the initial step also appear to be energetically attainable (cf. [9b,c]). The pressure-dependent enhanced formation of *(3a)* in the gas phase could be due to reaction branching at the stage of vibrationally excited *c,t*- or *t,c-(3a)* or *(1a)*. Purely thermal formation of *(11)* is less readily understood. In doubly bridged bicyclo[1.1.0]butanes a similar thermal isomerization to transoid 1,3-butadienes has recently been interpreted in terms of a retro-carbene ring opening[12]. However, a reaction pathway *(2a)*→*(11)* with participation of a carbene [rupture of the C^2C^7 and the C^1C^7 bond in *(2a)*] and its insertion into the C^6—H bond should be relatively inaccessible from an energetic viewpoint.

An insight into the behavior of *(2a)* towards transition metals[1c] is provided by the following results: silver(I)-catalyzed rearrangement (benzene, 25 °C) leads *via* α-cleavage[1c] exclusively to *(3a)*. In contrast, on heating with copper(0) in benzene (1.5 h, 110 °C) primarily β-rearrangement[1c] is observed, giving *(11)* (81%) together with *(3a)* (17%) and *(1a)* (2%). This behavior resembles that of benzvalene *(7b)*: reaction with Ag^I gives only benzene, that with Cu^0 only fulvene[13].

^{13}C-NMR Spectroscopic Studies on [^{13}C]methylated Bituminous Coal

By *Matthias W. Haenel, Richard Mynott, Klaus Niemann, Udo-Burckhard Richter,* and *Lothar Schanne*[*]

A prerequisite for the spectroscopic characterization of coal by high-resolution NMR spectroscopy is the preparation of soluble coal derivatives largely retaining the original structure[1]. A mild chemical reaction meeting these requirements is reductive derivatization using the "blue solutions" of solvated electrons formed by potassium at low temperature in oligomeric polyethylene glycol dimethyl ethers[2]. Transfer of these electrons to bituminous coal and subsequent hydrolysis[2a] or reaction with electrophiles such as dimethyl sulfate or methyl iodide[2b] affords reduced or reductively methylated coal derivatives, respectively, having high pyridine solubilities in some cases.

In the coal skeleton, in which aromatic and hydroaromatic moieties are cross-linked by aliphatic chains[3], not only do methylations of acidic structures and Birch-Hückel reductions of arenes occur, but benzylic C—C bonds in diarylethane and diarylmethane structures are also cleaved, as demonstrated by quantitative IR spectroscopy on coal derivatives[2] and cleavage reactions on model compounds[4]. The associated degradation of the coal macromolecules is apparently responsible for the enormous increase in pyridine solubility—*e.g.* from 12 to 75% on reductive methylation of one bituminous coal[2b].

Reductive methylation of a medium volatile bituminous coal from the Ruhr coalfield (see Table 1) with [^{13}C]methyl iodide (90 mol-% ^{13}C) gave a methylated coal derivative whose [^{13}C]labeling and high pyridine solubility (74.4%) permitted an NMR study. As shown by the ^{13}C/^{12}C isotope ratio, determined by mass spectrometry after combustion of a sample to carbon dioxide, 4.4 methyl groups have been incorporated per 100 coal carbon atoms. The ^{13}C-NMR spectrum shows, apart from the [D_5]pyridine signals ($\delta = 149.9$, 135.5, 123.5), strong peaks in the range $\delta = 10$—65, which, in view of the high isotope enrichment, are essentially due only to the incorporated [^{13}C]methyl groups (Fig. 1a, expanded in Fig. 2); this follows from a comparison with the ^{13}C-NMR spectrum of a correspondingly prepared coal derivative having natural isotopic abundance (Fig. 1b).

The spectrum (Fig. 2) provides information about the nature of the methyl groups introduced. The ^{13}C-NMR spectra

Table 1. Composition and normalized empirical formulas of the starting coal and the methylated coal [Westerholt mine, seam "Robert": 23.6% volatile matter, 4.1% ash, 0.7% water, 12% soluble in pyridine].

	Composition [wt-%]					Empirical formula, normalized	Methyl/100 C [b]
	C	H	N	O [a]	S		
Starting coal	84.6	4.6	1.3	4.2	1.4 [c]	$C_{100}H_{64.1}N_{1.3}O_{3.7}S_{0.6}$	$C_{100}H_{64.1}$
[^{13}C]methylated coal	86.1	5.8	2.9	3.1		$C_{100}H_{80.6}N_{2.8}O_{2.6}$	$C_{100}H_{64.1}(CH_3)_{7.5}$ [d]
Methylated coal	85.8	5.5	1.0	4.0		$C_{100}H_{76.1}N_{1.0}O_{3.5}$	$C_{100}H_{64.1}(CH_3)_{5.4}$

[a] Determined directly. [b] From the H/C ratio, assuming that hydrogen is incorporated only by methylation. [c] Including pyrites. [d] By mass spectrometry after combustion to $^{13}CO_2/^{12}CO_2$: 4.4 CH_3 per 100 C atoms.

[8] The borderline case of both rotational nodes should have been reached with *(1a)*; bicyclo[4.2.0]oct-7-ene undergoes conrotatory opening: *J. J. Bloomfield, J. S. McConaghy, Jr.*, Tetrahedron Lett. *1969*, 3719, 3723.

[9] a) *K. B. Wiberg, G. Szeimies*, Tetrahedron Lett. *1967*, 1235; *L. A. Paquette, S. E. Wilson, R. P. Henzel, G. R. Allen, Jr.*, J. Am. Chem. Soc. *94*, 7761 (1972); b) *M. Christl, U. Heinemann, W. Kristof, ibid.* *97*, 2299 (1975); improved data for *(10)* (*M. Christl*, personal communication, Feb. 1980); c) according to *Dewar* and *Kirschner*, there is no contradiction between a diradical intermediate and stereoselective product formation in the rearrangement of bicyclo[1.1.0]butanes: *M. J. S. Dewar, S. Kirschner, ibid.* *97*, 2932 (1975).

[10] a) *R. E. Benson, R. V. Lindsey, Jr.*, J. Am. Chem. Soc. *81*, 4250 (1959); *W. J. Bailey, R. Barclay, Jr., ibid.* *81*, 5393 (1959); b) we synthesized *(11)* in simpler manner by cleavage of its cyclopentadiene adduct [5a, b].

[11] The results were obtained reproducibly without loss of material in two independent thermolysis apparatus; they were unaffected by a conditioning of the thermolysis vessel. *p*-Xylene, the acid-rearrangement product of *(11)*, was not formed. Treatment of *(2a)* with acids in solution at room temperature gave little *(3a)* in addition to considerable polymerization.

[**] Permanent address: Rheinische Braunkohlenwerke AG, D-5000 Köln (Germany).

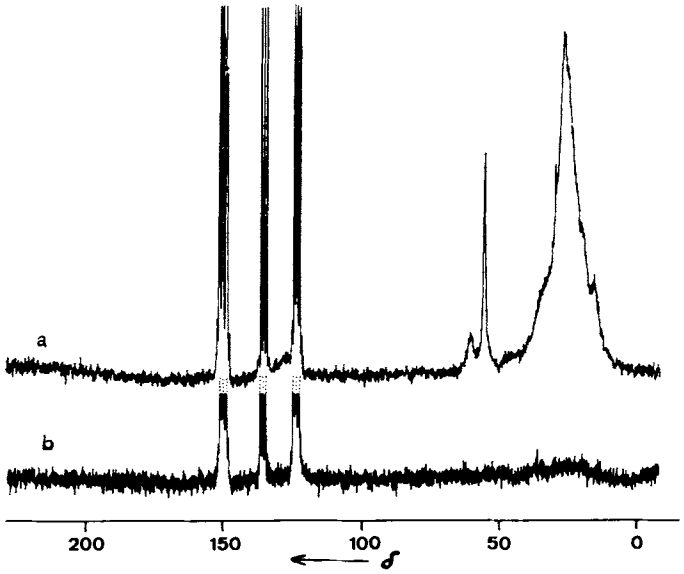

Fig. 1. $^{13}C\{^1H\}$-FT-NMR spectra (25.2 MHz, [D5]pyridine) of (a) [^{13}C]methylated coal and (b) methylated coal.

of reference compounds and ^{13}C-NMR data from our computer index were consulted during spectral analysis. (i) The signal around $\delta = 60.6$ [according to its integral it accounts for 0.12 (3%) of the 4.4 methyl groups/100 C atoms] is assigned to enolic methyl ethers apparently formed by Birch-Hückel reduction and methylation of phenolic structures[5].

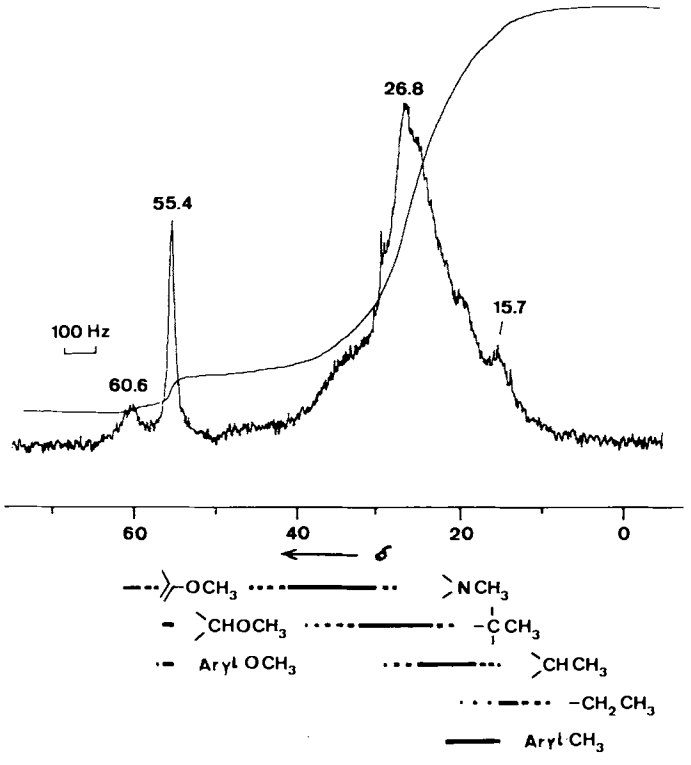

Fig. 2. $^{13}C\{^1H\}$-FT-NMR spectrum (25.2 MHz, [D5]pyridine) of [^{13}C]methylated coal, range between $\delta = 0$ and 60 expanded.

(ii) The signal at $\delta = 55.4$ [0.28 (6%)] corresponds to *sec*-alkyl methyl ethers and, above all, to aromatic methoxy groups. (iii) The shoulder at about $\delta = 35$ is assigned to *N*-methyl groups ($\delta = 29$—40)[6]. Nevertheless, owing to the low nitrogen content of the coal employed, the main absorption between $\delta \approx 10$ and 30 can essentially arise only from *C*-methyl groups, even assuming that all the nitrogen is methylated. (iv) Methyl groups bonded directly to aromatic rings, whose signals are found between $\delta \approx 21.3$ (without *ortho* substituents) aud $\delta \approx 15$ (with two *ortho* substituents), cannot represent the major component because of the low intensity in this region. (v) The center of the signal between $\delta \approx 22$ and 30 shows that most of the methyl groups are bonded to tertiary and quaternary carbon atoms. In particular, the results are consistent with methyl groups attached to tertiary and quaternary *benzylic* carbon atoms[7], such as arise on methylation of C—H acid structures, Birch-Hückel reductive methylation of polycyclic arenes, and on methylation of carbanions formed by cleavage of benzylic C—C bonds[8].

Chemical derivatization with isotopically labeled groups as a spectroscopic probe is an interesting method for investigating complicated substrates such as coal or polymers.

Procedure

Small pieces of potassium (2.7 g, 69 mmol) were added under argon to a stirred mixture of dimethoxyethane (150 ml; freshly distilled from sodium tetraethylaluminate) and polyethylene glycol dimethyl ether[9] (30 ml) at $-30\,^\circ$C. Once the solution had turned deep blue, finely ground coal[10] (2.7 g; see Table 1) was added. After 16 h, methyl iodide or [^{13}C]methyl iodide (90 mol-% ^{13}C, Merck Sharp & Dohme, Canada) (10 g, 70 mmol) was slowly added dropwise. Acidification with 2 N hydrochloric acid (0.5 l), filtration, washing with water, methanol extraction for 24 hours in a Soxhlet apparatus, and drying at 10^{-3} torr gave 2.6 g of coal product which was 74.4% soluble in pyridine (determined by Soxhlet extraction).

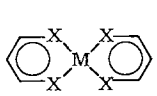
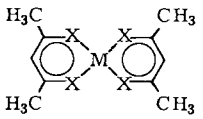
[7] Compare some ^{13}C-chemical shifts (δ) of methyl groups attached to secondary, tertiary, and quaternary benzylic C atoms: ethylbenzene (15.7), 9-methylfluorene (18.2) [7b], 2,3-diphenylbutane (DL + *meso:* 21.0), 1,2-diphenylpropane (21.2), 1,1-diphenylethane (21.9), 1-methyl-1,2,3,4-tetrahydronaphthalene (22.9) [7c], 9,9-dimethylfluorene (27.1) [7b], 2,2-diphenylpropane (30.8), 1,1-dimethyl-1,2,3,4-tetrahydronaphthalene (31.9) [7d]; b) *H. Fritz, T. Winkler, A. M. Braun, C. Decker,* Helv. Chim. Acta *61*, 661 (1978); c) *R. Gretler, E. Askitoğlu, H. Kühne, M. Hesse, ibid. 61*, 1730 (1978); d) *K. S. Seshadri, R. G. Ruberto, D. M. Jewell, H. P. Melone,* Fuel *57*, 111 (1978).

[8] *S*-Methyl groups appear at $\delta = 14 \pm 2$. The absence of a signal in this region and the low sulfur content of the coal (0.6 S/100 C) rule out any significant contribution.



[9] Technical grade polyethylene glycol 400, containing mainly the octamer, was converted into the dimethyl ether. We wish to thank Dr. *W. Eisenbach* for this preparation.

[10] The previously crushed coal, mixed with Dry Ice to render it brittle and provide an inert atmosphere, was ground in a high speed impingement mill and a screening mill (average particle diameter 60 μm), dried at 10^{-3} torr for 3 d, and stored under argon.



Transition-Metal Complexes of Malonaldehyde and Dithiomalonaldehyde

By *Ulrich T. Mueller-Westerhoff* and *Arnold Alscher*[*]

2,4-Pentanedionates *(3)* and 2,4-pentanedithionates *(4)* have been well documented[1]; complexes of the type *(1)* and *(2)*, however, which are derived from malonaldehyde and dithiomalonaldehyde, have so far not been described in the literature[2]. We report here on the complexes *(1)* and *(2)* of the d^8-metals Ni, Pd, and Pt.

(1), X = O, M(mal)$_2$
(2), X = S, M(ptt)$_2$

(3), X = O, M(acac)$_2$
(4), X = S, M(SacSac)$_2$

Of the three malonaldehyde complexes which we attempted to prepare, Pd(mal)$_2$[3] was by far the easiest to obtain. Hydrolysis of 1,1,3,3-tetraethoxypropane (malonaldehyde diacetal) in aqueous HCl, neutralization, and reaction with a suspension of $PdCl_2$ in ether affords the complex in more than 50% yield. Pd(mal)$_2$ was characterized by elemental analysis, mass spectrum ($m/e = 248$, $M_r = 248.5$), UV and NMR spectrum (see Table 1). Ni(mal)$_2$ and Pt(mal)$_2$ could not be prepared in an analogous way.

The Ni-, Pd-, and Pt-complexes of dithiomalonaldehyde are stable, yet reactive, deep-blue compounds. They are synthesized almost analogously[1b,4] to the SacSac complexes *(4)*. Reaction of tetraethoxypropane in anhydrous ethanol with dry HCl and H_2S in the presence of the corresponding metal chloride furnishes the M(ptt)$_2$ complexes *(2)* in varying yields (between 50% for M = Ni and over 80% for M = Pt, after column chromatographic purification on SiO_2 and recrystallization). In all three reactions $C_6H_6S_3$[3,5] is formed as side product, to which, on the basis of its ^{1}H-NMR spectrum, we assign the structure *(5)*; our data, however, are also consistent with the structure *(6)*.

(5) 

 *(6)*

Some physical properties of the complexes of type *(1)* and *(2)* are listed in Table 1. The strong interaction between the metal and the entire ligand in the complex Pt(ptt)$_2$ is manifested in the ^{195}Pt-^{1}H coupling constants: The signal of the α-proton at $\delta = 9.35$ has satellites at ± 52 Hz ($J = 104$ Hz) having one quarter of the intensity of the principal doublet (corresponding to the natural ^{195}Pt abundance of 33.8%); in the triplet at $\delta = 7.40$, the ^{195}Pt-$^1H_\beta$ coupling with $J = 8$ Hz is clearly recognizable. For the ^{13}C-^{195}Pt coupling the reverse order is found. The α-C atoms at $\delta = 155.56$ (rel. TMS) have $J_{C\text{-}Pt} = 40$ Hz, the β-C atoms at $\delta = 133.42$, $J_{C\text{-}Pt} = 137.2$. These data are indicative of strong electron delocalization. Whether or not the ppt-(and SacSac-)complexes are to be regarded as aromatic systems still has to be decided. In the case of the acac complexes there is clear evidence against aromatic character[6].

The dithiomalonaldehyde complexes M(ptt)$_2$ had been synthesized with the aim of obtaining planar, sterically undemanding transition-metal compounds, which can function as electron-donor components in charge-transfer complexes. Donor-acceptor complexes of the long known SacSac derivatives have so far not been described. Pd(ptt)$_2$ and Pt(ptt)$_2$ react with tetracyanobenzoquinodimethane (TCNQ) in acetonitrile to give the 1:1 charge-transfer complexes[3]. Our earlier predictions that such complexes show poor electrical conductivity, even if they form segregated donor and acceptor columns in the crystal, appeared to be borne out by the measurement of the electrical conductivity parallel to the principal axis of the crystal of Pt(ptt)$_2$-TCNQ ($\sigma_{\parallel} = 2 \times 10^{-8}$ Ω^{-1} cm^{-1}). However, the X-ray structure analysis[8] showed that mixed D-A-D-A columns are present in the molecular crystal, and moreover, as can be estimated from the bond lengths of TCNQ, that the charge-transfer must be small.

Equally insulating donor-acceptor complexes of TCNQ should likewise be prepared with the donors Pd(mal)$_2$, Pd(acac)$_2$, Pd(SacSac)$_2$, and Pt(SacSac)$_2$[3]. Reaction of the ptt-complexes with iodine as electron acceptor does not lead to any partially oxidized mixed-valence systems, but exclusively to oxidative addition: for example, reaction of Pt(ptt)$_2$ and iodine in chloroform affords *trans*-Pt(ptt)$_2$I$_2$ (dark red-brown crystals, m.p. 131 °C); Pt(SacSac)$_2$I$_2$ is formed analogously. The corresponding reaction of 2,4-pentanedionates such as Pt(acac)$_2$ is well known[9].

The Question of Bicycloconjugation in Naphtho-Fused 9-Heterobicyclo[4.2.1]nona-2,4,7-trienes as Examined by ^{13}C-NMR Spectroscopy[***]

By *A. G. Anastassiou, H. S. Kasmai,* and *R. Badri*[*]

In previous work directed at assessing the electronic requirements for the development of heteroatom-induced bicycloconjugation it was first demonstrated[1] by use of PE spectroscopy and shortly thereafter confirmed[2] *via* ^{13}C-NMR analysis that of the three unrestricted π-excessive heteroatomic centers (NH, O, S) examined only the first, *i.e.*, NH, is capable of promoting bicycloconjugation in the 9-heterobicyclo[4.2.1]nonatriene molecular environment shown in *(1)*. Further, having prescribed to the notion that what might reasonably be considered a necessary first step for triggering three-center interaction in *(1)* is such symmetry-controlled coupling between the lone pair and the HFMO of the system's $(4n+2)\pi$ segment, *i.e.*, the ethylene bridge, as is required to raise the energy of the former (lone pair) and thus enhance its potential for nonbonded delocalization, we resolved to examine a derivative of *(1)* whose "ethylene"-bridge energetics are so modified as to provide for overall stabilization of nitrogen-bridge lone pair with attendant reduction of its ability to promote bicycloconjugation. Interestingly, replacement of the ethylene moiety in *(1)* with the naphthalene segment of *(2)* appears to satisfy this condition insofar as the highest filled symmetric[3] MO (ψ_4) of the latter is located at a significantly higher energy (ϵ_4 = 8.02 eV)[4] than the *isolated* NH lone pair of the fully saturated analog of *(1a)* [≡ *(6a)*] (ϵ_N = 8.50 eV)[1a].

Synthetically, the general skeleton depicted in *(2)* became available *via* thermally induced cycloaddition between *(1)* and isobenzofuran *(3)* followed by acid-induced dehydration of the resulting primary cycloadducts *(4)*[5], and, when called for, defunctionalization of X, *i.e.*, SO to S, NCN to NH, *etc.* The method of analysis employed in the present study relating to changes in "bridgehead" C—H coupling constants was entirely analogous to that employed earlier with the parent system *(1)*[2].

Examination of the tabulated information reveals the additively estimated magnitude of ΔJ for the key aza-bridged molecule *(2a)*, *i.e.*, $\Delta J(6\rightarrow 7) + \Delta J(6\rightarrow 5) = 7$ Hz to be essentially the same as that actually observed, *i.e.*, $\Delta J(6\rightarrow 2) = 8$ Hz. Within the validity of the ^{13}C-NMR criterion then, the obvious conclusion to be drawn from this observation is that the three-unit p-π system of naphtho-fused azabicycle *(2a)* is *not detectably bicycloconjugated.* While sharply contrasting with the well-documented[1a,2] ability of the parent molecule *(1a)* to partake in bicycloconjugation, the apparent failure of *(2a)* to do so is entirely in keeping with our prediction *(vide supra)* that the ability of the nitrogen lone pair to manifest a p-π effect suitable for the development of three-center delocalization is effectively impaired by the *stabilization* it experiences *via* interaction with the highest-filled *symmetric* MO of the system's $(4n+2)\pi$ segment.

Table 1. ^{13}C-H "bridgehead" coupling constants [Hz] of compounds having 9-heterobicyclo[4.2.1] skeletons and suitably chosen differences between ^1J values.

Further emphasizing the basic differences between structural relatives *(1)* and *(2)* with regard to their ability to sustain bicycloconjugation is the fact that analysis of the ^{13}C-NMR information relating to the oxa counterpart of *(2a), i.e. (2c),* reveals the actual $\Delta J(6\rightarrow 2)=7$ Hz to be significantly greater (*ca.* 200%) than the additive value, $\Delta J(6\rightarrow 7)+\Delta J(6\rightarrow 5)=2$ Hz! (see Table 1). At this early stage, one can tentatively explain the apparent increase in three-center mobility of the oxygen lone pair of *(2c)* (originally located at 9.1 eV)[1c] chiefly on the basis of the destabilization it is expected to experience through interaction with the lower-energy (9.4 or 9.9 eV)[4,6] second highest occupied *symmetric*[3] MO of the naphthalene unit, *i.e.*, ψ_2 in free naphthalene. It is hoped that careful analysis of pertinent PE-spectroscopic information will allow us to further define the contrasting influences brought to play on the nitrogen and oxygen lone pairs by the molecular environment of *(1)* and *(2)*.

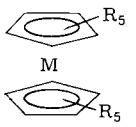
[2] *A. G. Anastassiou, E. Reichmanis,* J. Am. Chem. Soc. *98*, 8267 (1976).

[3] The classification refers to the "long", nontrivial, plane of symmetry which is coincident with the single plane of molecular symmetry in *(2)*.

[4] Extracted from the PE spectrum of hydrocarbon model *(5)*, X = CH_2, kindly recorded for us by Prof. *A. Schweig* at Marburg.

[5] Entirely consistent spectroscopic (IR, ^{1}H-NMR, ^{13}C-NMR, UV, MS) and combustion (C, H, X) data were obtained for all new compounds prepared. The following "final product" melting points were recorded: 199—200 °C for *(2a)*, 241—242 °C for *(2b)*, 195—196 °C for *(2d)*, 238—239 °C for *(2d)*, 249—250 °C for *(2e)*, 239—240 °C for *(2f)*.

[6] While these two values are believed to correspond to ψ_3 and ψ_2 of the naphthalene segment of *(2)* it is not possible to offer a specific assignment without recourse to suitable calculation, insofar as it is not known whether the well-documented ordering in free naphthalene, *i.e.*, ψ_3(A) and ψ_2(S), is carried over unchanged to the naphthalene moiety of *(2)*. The possibility of a reversal in the ordering of unperturbed naphthalene MOs is certainly not to be dismissed since ψ_2(S), being associated with substantially larger (*ca.* × 2.5) HMO eigenvectors at key positions 2 and 3 than is ψ_3(A), ought to be proportionately more perturbed (destabilized) by the annulation process leading to *(5)*, X = CH_2.



Permethylated Electron-Excess Metallocenes[**]

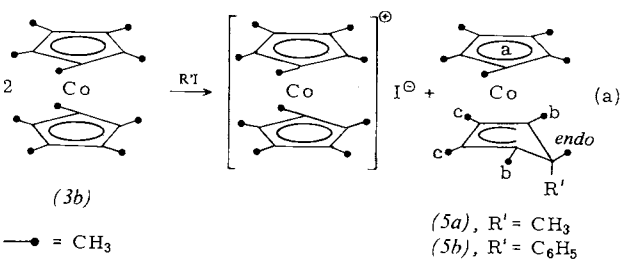
By *Ulrich Koelle* and *Fouad Khouzami*[*]

The exhaustive methylation of aromatic ligands can drastically change the properties of corresponding π-complexes[1]. An example from the metallocene series is provided by decamethylmanganocene *(1b)*, which unlike *(1a)* not only has a magnetically anomalous ground state in solution, but can also be reversibly oxidized and reduced[2]. We now report the first synthesis and reactions of the permethylated electron-excess metallocenes *(3b)* and *(4b)*.

Syntheses: The preparation of decamethylcobaltocene *(3b)* can be accomplished with $C_5(CH_3)_5$-Li in tetrahydrofuran (THF)/ether (12 h reflux) if an ether adduct, *e.g.* Co(DME)Br_2 (DME = dimethoxyethane) is employed instead of the usual hexaamminecobalt(II) chloride[3], and the neutral complex is oxidized *in situ* with $FeCl_3$ to $(3b)^+$,

R \ M	Mn	Fe	Co	Ni
H	*(1a)*	*(2a)*	*(3a)*	*(4a)*
CH_3	*(1b)*	*(2b)*	*(3b)*	*(4b)*

which can be precipitated from water as hexafluorophosphate [yield 85%, $\delta(^1H)=1.82$ (CD_3COCD_3)]. The paramagnetic neutral compound *(3b)* was obtained as black crystals by reaction of the salt with K/Hg in THF and sublimation [yield 82%, m.p. 300 °C, $\delta(^1H)=40$, $\Delta\nu=60$ Hz]. The green nickel complex *(4b)* could be isolated under the same conditions without intermediate oxidation and reduction[4] [yield 90%, m.p. 290 °C, $\delta(^1H)=237$, $\Delta\nu=615$ Hz].



Redox potentials: Table 1 shows the redox potentials for the first oxidation of the metallocenes *(2)—(4)* and for the second oxidation of *(4b)* (cyclic voltammetry, dichloromethane, *vs.* SCE). The cathodic shift by the ten methyl groups increases from Fe to Ni, reflecting the greater ligand contribution to the e_{1g} orbital in *(3)* and *(4)*[5]. In contrast to *(4a)*[6], *(4b)* also undergoes an electrochemically reversible second oxidation [$(4b)^{+/2+}$]. Mild oxidizing agents such as C_2Cl_6 oxidize *(4b)* to $(4b)^+$, whereas stronger oxidants such as Br_2/CH_2Cl_2 or atmospheric oxygen in acid aqueous solution give the diamagnetic [$\delta(^1H)=2.20$ (CF_3COOH)] dication $(4b)^{2+}$ in the form of stable salts as the first π-complex of nickel(IV). *(4a)* does not form a dication.

Table 1. Redox potentials of metallocenes and permethylmetallocenes in dichloromethane (V rel. to SCE).

M		$M(C_5H_5)_2$		$M[C_5(CH_3)_5]_2$	Δ [a]
Fe	*(2a)*	+0.49	*(2b)*	−0.08	0.57
Co	*(3a)*	−0.86	*(3b)*	−1.48	0.62
Ni	*(4a)*	+0.07	*(4b)*	−0.73	0.80
$Ni^{+/2+}$		≃ +0.9		+0.37	≃0.53

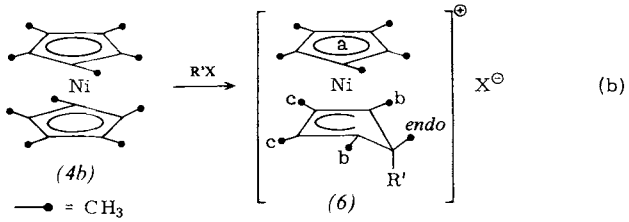
[a] Difference between the potentials in columns 3 and 5.

Reaction of (3b) with electrophiles: Like *(3a)*, decamethylcobaltocene *(3b)* reacts with alkyl and aryl halides R′X *via* oxidative addition[7] [eq. (a)], thus demonstrating that this reaction can also take place at substituted positions of a π-ligand. Concomitant with the more strongly negative potential for the reduction of the cation, *(3b)* is considerably more reactive than *(3a)*. Thus weak electrophiles, which are inert towards *(3a)*, will also react. For example, CH_3I which reacts only slowly (2 h, 80 °C)[8] with cobaltocene *(3a)* gives *(5a)*

(3b)

—● = CH_3

(5a), R′ = CH_3
(5b), R′ = C_6H_5



from *(3b)* within 1 h, and C_6H_5I which is totally inert towards *(3a)* yields *(5b)* from *(3b)* within 6 h at 20 °C. The

[**] This work was support by the Deutsche Forschungsgemeinschaft.

structures of the complexes *(5)* follow from their ^{1}H-NMR (Table 2) and mass spectra, and from elemental analysis. The yields of reaction (a) are *ca.* 90%.

Reaction of (4b) with electrophiles: Decamethylnickelocene *(4b)* is the first neutral 20-electron complex to which electrophiles can be added [eq. (b)]. The reaction yields the novel cyclopentadiene(cyclopentadienyl)nickel cations $(6)^+$ as green salts stable to air and water. For example, in contrast to *(4a)*[9], *(4b)* is protonated (CF_3COOH, pentane/water) to give the *exo*-addition product $(6a)^+$, which can be precipitated from water.

The variety of electrophilic substrates which can be reacted with *(4b)* demonstrate that, apart from the simple electrophilic addition (*e.g.* with CF_3COOH and $CF_3SO_3CH_3$), electron transfer to form $(4b)^+$ and radicals $R'^{\odot}$, with subsequent radical addition to $(4b)^+$, is a mechanistic possibility in the case of nonpolar electrophiles (*e.g.* CCl_4). Such radical additions are known in the case of the isoelectronic compound *(3a)*[10].

Structural evidence for the cations $(6)^+$ comes from the ^{1}H-NMR absorptions, which show a similar pattern for all the compounds (Table 2). In particular, the similar shifts of the *endo*-methyl signals of *(6a—c)* suggests *exo*-addition of R′ in all cases.

Table 2. ^{1}H-NMR data of the addition products *(5)* ($CDCl_3$) and $(6)^+$ (CD_3NO_2) (δ, int. TMS).

M	R′	R′X	Cpd.	CH_3-a	CH_3-b [a]	CH_3-c	CH_3-*endo*	R′-*exo*
Co	CH_3	CH_3I	*(5a)*	1.70	0.71	1.90	1.28	0.24
Co	C_6H_5	C_6H_5I	*(5b)*	1.72	0.77	1.95	1.25	
Ni	H	CF_3COOH	$(6a)^+$ [b]	1.75	1.28	2.25 (d)	1.35 (d)	
Ni	CH_3	$CF_3SO_3CH_3$	$(6b)^+$	1.76	1.33	2.24	1.42	0.75
Ni	$C_6H_5CH_2$	$C_6H_5CH_2Br$	$(6c)^+$	1.67	1.32	1.66	1.63	2.51 (CH_2)
Ni	CCl_3	CCl_4	$(6d)^+$	1.83	1.52	2.26	2.12	
Ni	C_6H_5CO	C_6H_5COCl	$(6e)^+$	1.75	1.33	2.02	1.84	

[a] The assignment of the absorptions to CH_3-c and CH_3-b in $(6a)^+X^-$ is established by the allylic coupling of CH_3-b with H_{exo}. Assignment in the other compounds was made analogously. [b] $^4J_{CH_3\text{-}b,H_{exo}} = 3$ Hz, $^3J_{CH_3\text{-}endo,H_{exo}} = 8$ Hz.

Conformational Analysis of 1-Phenylethyl Substituents in Metal Complexes and Their Importance for Asymmetric Catalysis[**]

By *Henri Brunner, Giuseppe Agrifoglio, Ivan Bernal*, and *Michael W. Creswick*[*]

The phenyl moieties of the $P(C_6H_5)_2$ groups in metal complexes of chelate phosphanes adopt axial/equatorial positions, in which they are almost perpendicular to each other[2]. In asymmetric catalysis, these phenyl orientations transmit the chiral information from the chelate backbone of the optically active phosphanes to the adjacent coordination positions of the metal atom at which the catalysis takes place[2]. In this study, we demonstrate the controlled influence of coordination positions in metal complexes by means of optically active 1-phenylethyl substituents at chelate rings.

In the reaction of $C_5H_5Mo(CO)_3Cl$ with optically active (*S*)-amidines HNR—CR′=NR*, $C_5H_5(CO)_2Mo$-amidinato complexes are formed which differ only in the configuration at the Mo atom. For $R = CH_2C_6H_5$, $R' = C_6H_5$, $R^* = CH(CH_3)(C_6H_5)$ the diastereoisomers *(1A)* and *(1B)* can be obtained optically pure by fractional crystallization. After equilibration with respect to the Mo configuration at 70 °C in acetone, a diastereoisomer ratio *(1A)*/*(1B)* = 70:30 is obtained. A single crystal X-ray structure analysis was carried out on the thermodynamically more stable isomer *(1A)* (Fig. 1).

The plane of the phenyl group R′ at the C atom of the chelate ring is approximately perpendicular to that of the chelate. The orientation of the substituents R and R* at the N

[**] Part 66 of the Series "Optically Active Transition Metal Complexes". This work was supported by Deutsche Forschungsgemeinschaft, Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen, as well as by the US National Science Foundation and the R. A. Welch Foundation.—Part 65: [1].

atoms is determined by the tendency of the C—H bonds of both substituents to lie in the ligand plane. Both phenyl rings point up towards the C_5H_5 ring while the methyl group of the (*S*)-1-phenylethyl substituent and a hydrogen atom of the benzyl substituent point down towards the CO ligands. Exactly the same conformation of (*S*)-1-phenylethyl was shown by X-ray structure analysis to occur in the thioacetamidato complex $C_5H_5(CO)_2MoSC(R')N(R^*)$[3] and in four other thioamidato complexes[4]. Like *(1A)*, these complexes are without exception the *A*-diastereomers favored at equilibrium. With the thioamidato complex $R' = 1\text{-}C_{10}H_7$, $R^* = CH(CH_3)(C_6H_5)$, for the first time, an X-ray structure analysis could be carried out of one of the *B*-diastereoisomers[4]. The following conformation of the (*S*)-1-phenylethyl moiety was found: C—H bond in the ligand plane, methyl group up towards the C_5H_5 ring, and phenyl ring down towards one of the two CO ligands, as indicated for *(1B)*.

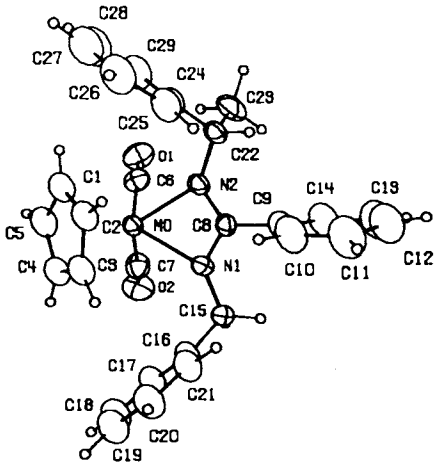

Fig. 1. ORTEP diagram of *(1A)*. Orange rhombs, space group P1, $Z=2$, $a=9.796(9)$, $b=11.875(4)$, $c=11.885(3)$ Å, $\alpha=88.27(2)$, $\beta=67.42(5)$, $\gamma=83.71(2)°$; $V=1268.21$ Å^3; $\rho_{calc}=1.400$, $\rho_{exp}=1.389$ g·cm^{-3}. From 3907 measured reflections ($Mo_{K\alpha}$ radiation, $\lambda=0.71073$ Å) 3575 with $I>2\sigma(I)$ were used for refinement of the structure; $R=3.77$, $R_w=3.82\%$, $w=1/\sigma^2(F)$]. The absolute configuration was determined by the Bijvoet method, using 12 strong reflections. The sequence $C_5H_5 > NCH(CH_3)(C_6H_5) > NCH_2C_6H_5$ defines the absolute configuration of Mo as (*R*) and the overall configuration of *(1A)* as (*R,S*). The unit cell contains two independent almost identical molecules I and II. Bond lengths, bond angles and dihedral angles for I: Mo—N1 2.175(7), Mo—N2 2.199(6), N1—C8 1.300(11), N2—C8 1.295(11), C15—N1 1.448(14), C22—N2 1.448(12) Å; N1—Mo—N2 59.2(2), N1—C8—N2 112.8(8), Mo—N1—C8 94.4(5), Mo—N2—C8 93.4(5), Mo—N1—C15 138.2(5), Mo—N2—C22 140.6(5)°; Cp—Ph(C16—C21) 58.8, Cp—Ph(C24—C29) 62.6, Cp—(ligand plane) 142.8, ligand plane—Ph(C16—C21) 89.3, ligand plane—Ph(C24—C29) 80.5°.

These results can be interpreted in the following way: the conformation-determining effect for the orientation of a (*S*)-1-phenylethyl substituent is the coplanar arrangement of the C—H bond of the asymmetric center with the C—R′ bond of the chelate ring. In addition, the weak attraction between the phenyl substituent of the asymmetric center R* and the MC_5H_5 group (the β-phenyl effect) as well as the weak repulsion between the alkyl group of the asymmetric center R* and the MC_5H_5 group are effective.

In [D_6]acetone, the C_5H_5 signals of diastereoisomers *(1A)* and *(1B)* lie at $\delta=4.73$ and 5.39, while those of the corresponding diastereoisomers *(2A)* and *(2B)*, with R = isopropyl instead of benzyl, appear at 5.11 and 5.77. These chemical shift differences are the result of a high field shift of the C_5H_5 signals in all the compounds, in which there is a MC_5H_5/phenyl interaction. This high field shift arises because the C_5H_5 protons lie within the inner anisotropy region of the phenyl ring. Such a shift or β-phenyl effect, observed twice for *(1A)*, once for *(1B)* and *(2A)*, and not at all for *(2B)*, characterizes the ^{1}H-NMR spectra of 46 $C_5H_5(CO)_2Mo$-amidinato and -thioamidato complexes[5,6]. It proves that the conformations determined by X-ray structure analyses are not only the result of crystal effects but also persist in solution as the favored conformations.

In the equilibrium $A \leftrightarrows B$ the isomers *A* are always present in higher concentrations than the isomers B. In the first place this is due to the attraction C_6H_5/MC_5H_5 which is possible for the (*R*)-configuration at the Mo atom in *(1A)* but not for the (*S*)-Mo configuration in *(1B)*. This β-phenyl effect, however, does not explain the trend in the equilibrium values $A:B = 70:30$, 87:13, 97:3 if in the amidinato complexes *(1)* the alkyl group at the asymmetric center R* varies in the series methyl, ethyl, *i*-propyl. For this it is necessary to assume an increasing repulsion alkyl/MC_5H_5 with increasing size of alkyl in R* according to a destabilization of *B*. If besides H, there are two different alkyl groups at the asymmetric center R*, the energy differences between the diastereomers *A* and *B* are only small. The diastereoisomer ratios $A:B$ lie between 50:50 and 60:40, with the bigger alkyl group probably pointing towards the C_5H_5 ligand in *A*.

The arrangement of a 1-phenylethyl substituent with respect to the ligand plane (shown as *A* or *B*) depends on the configuration at the Mo atom and is valid only for complexes carrying a large substituent at the neighboring C atom of the chelate ring. As the equilibrium ratios $A:B = 74:26$, 78:22, and 87:13 for the thioamidato complexes $C_5H_5(CO)_2MoSC(R')N(R^*)$ show, the effects increase along the series $R' = CH_3$, C_6H_5, $1\text{-}C_{10}H_7$[5,6]. In contrast, the conformations *A* and *B* are not the preferred conformations of the compounds in which a C—H bond in the chelate is adjacent to the 1-phenylethyl substituent, as in the $C_5H_5(CO)_2Mo$ thioformamidato and pyridinimine complexes[1,5]. This indicates that the conformation-determining effect (C—H of 1-phenylethyl in the ligand plane) can be ascribed to the steric hindrance of the phenyl and the methyl groups in R* with the big substituent R′ at the neighboring C atom. Also, the repulsion alkyl of R*/MC_5H_5 seems to be a steric effect. The attraction C_6H_5 of R*/MC_5H_5, obvious from the strongly negative λ-parameter for phenyl in the Ruch/Ugi model[6], is confirmed in present X-ray structure analysis especially by the orientation of the benzyl group.

The catalytic activity of amidinato complexes is documented[7]. Consequently, the conformational analysis presented above offers a way of controlling stereochemistry at coordination positions adjacent to the chelate ring in amidinato complexes, and similar compounds, by optically active 1-phenylalkyl substituents.

N-Fluoroiminosulfur Tetrafluoride, F—N=SF_4[**]

By *Darryl D. DesMarteau* and *Konrad Seppelt*[*]

Oriented double bonds on sulfur(VI) tetrafluoride systems open new theoretical and structural aspects[1,2]. Here we present the simplest fluorinated sulfur(VI) imide.

$$Cl_2N\text{–}SF_5 \xrightarrow[-\ ClF]{F_2} FClN\text{–}SF_5$$

$$FClN\text{–}SF_5 \xrightarrow{Hg/CF_3COOH} FHN\text{–}SF_5$$

$$FHN\text{–}SF_5 \xrightarrow[-\ HF]{KF} \overset{\cdot\cdot}{F}N{=}SF_4$$

Starting with Cl_2N—SF_5[3], chlorofluoroaminosulfur pentafluoride[4] (b.p. 25.3 °C (extr.)) is prepared first, which in turn is reduced by mercury in trifluoroacetic acid to fluoroaminosulfur pentafluoride[4] (b.p. 25.3 °C (extr.), m.p. −71 °C). From this, HF is eliminated by potassium fluoride, and the title compound F—N=SF_4 is obtained in 85% yield. It is a colorless gas, stable to at least 100 °C (b.p. −13.5 °C, m.p. −99 °C). The elemental composition has been secured by vapor density determination (M_r exp. 142.7, calc. 141.02), and by mass spectroscopy (70 eV, $m/e = 141$ (M_r^+) and fragments). Structural information was obtained by vibrational spectroscopy and ^{19}F-NMR. The IR spectrum (NaCl region) shows absorptions at 1128 (ν_{NS}), 930 (ν_{SF}), 870 (ν_{SF}), 757 (ν_{NF}), and 648 ($\delta_{S\ N}$) cm^{-1}. The spectrum is very similar to that of SOF_4[5] with an additional N—F stretching frequency. The N=S valence vibration occurs at about 100 cm^{-1} lower than expected, a surprising result in view of the rigidity of the molecule. The highly complicated ^{19}F-NMR spectrum could still be simulated as a A_2BCD spin system[6]. The spectrum shows the sulfur to have a trigonal bipyramidal environment, with one equivalent pair and one nonequivalent pair of fluorine atoms. The N—F group certainly occupies an equatorial position, and in analogy to CH_2=SF_4[1] the *N*-fluorine atom will be oriented in the axial plane.

This means that the molecule is rigid, with no change in position of the *N*-fluoro atom being observed. The rigidity of the F—N=SF_4 molecule is in sharp contrast to the nonrigidity of the molecules CH_3—N=SF_4, CF_3—N=SF_4, and O=SF_4[7], but is comparable to the behavior of CH_2=SF_4[1]. Only a Berry pseudorotation of the four *S*-fluorine atoms is possible; however, it cannot be observed because of the remaining nonequivalency of the participating atoms.

It is still not explainable why F—N=SF_4 does not form a dimer with a $(NS)_2$ four-membered ring unit, as is observed in $(Cl\text{—}NSF_4)_2$, which has not yet been observed as a monomer[8].

F—N=SF_4 is a weaker F^- donor than SOF_4[9]. AsF_5 forms an adduct at −78 °C that is completely dissociated at +20 °C. With SbF_5, an explosion occurs at −10 °C. Whether the adduct contains cationic species $N^{+}{\equiv}SF_4$ or $FN{=}\overset{+}{S}F_3$ remains to be seen.

Structure of $[(CO)_5CrNEt_2]BF_4$, a Key Organometallic Compound; Reaction to Give the Carbene Complex $(CO)_5CrC(AsPh_2)NEt_2$[1]

By *Ulrich Schubert, Ernst Otto Fischer*, and *Dieter Wittmann*[*]

Our preparation of carbene complexes by reaction of hexacarbonylchromium, -molybdenum, or -tungsten with nucleophiles and alkylation of the resulting acylmetalates[2]

[*] Prof. Dr. E. O. Fischer, Dr. habil. U. Schubert, Dipl.-Chem. D. Wittmann
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

is not applicable to weak nucleophiles. In such cases, a route proceding *via* the sequence[3,4]

$$Cr(CO)_6 \xrightarrow[2)\ [Et_3O]BF_4]{1)\ LiNEt_2} (CO)_5Cr{=}C(NEt_2)(OEt) \xrightarrow{BF_3}$$

$$[(CO)_5Cr{\equiv}C{-}NEt_2]BF_4 \xrightarrow{Nu^{\ominus}} (CO)_5Cr{=}C(NEt_2)(Nu)$$

(1) *(2)*

i.e. indirect exchange of an alkoxy group for another nucleophilic substituent (Nu), gives the desired product.

The general applicability of step *(1)*→*(2)* has now been confirmed once again, *i.e.* by the successful synthesis of an arsenic-substituted carbene-complex by reaction of *(1)* with potassium diphenylarsenide (Nu = $AsPh_2$). The spectroscopic data of $(CO)_5CrC(AsPh_2)NEt_2$ are given in Table 1.

Table 1. Spectroscopic data of the diphenylarseniocarbene complex *(2)*, Nu = $AsPh_2$.

IR (ν_{CO} region, *n*-pentane NaCl optics): 2055 (m), 1942 (vs), 1936 (vs) cm^{-1}.
MS (CI source, 30 °C): m/e = 449 $[M-2CO]^+$, 421 $[M-3CO]^+$, 393 $[M-4CO]^+$, 313 [carbene]$^+$.
^{1}H-NMR ([D$_6$]-acetone, −30 °C, rel. to CD_3COCD_2H): δ = 7.39 (10H, S; C_6H_5), 4.62 and 3.97 (each 2H, Q; CH_2, *E,Z* isomers), 1.66 and 0.78 (each 3H, T; CH_3, *E,Z*).
^{13}C-NMR ([D$_6$]-acetone, −20 °C, rel. to CD_3COCD_2H): δ = 287.74 ($C_{carbene}$), 225.29 ($C_{CO,trans}$), 218.0 ($C_{CO,cis}$), 142.13, 133.85, 130.03 and 129.54 (C_{phenyl}), 59.69 and 56.69 (CH_2; *E,Z*), 15.11 and 14.21 (CH_3; *E,Z*).

Since the carbene complexes accessible by reaction of *(1)* with nucleophiles are themselves of preparative and theoretical interest (cf. [4,5]), the cationic carbyne complex *(1)* assumes a key role. Carbyne(pentacarbonyl)metal cations $[(CO)_5MCR]^{\oplus}$ (M = Cr, Mo, W) have also been discussed as intermediates in connection with the preparation of carbyne from carbene complexes[6] but so far only those with $R = NR_2'$ have been isolated. Thus, fundamental information about the nature of this class of compounds was expected from the X-ray structure analysis[7] of *(1)*.

The most striking features of the structure of *(1)* (cf. Fig. 1) are the long Cr—$C_{carbyne}$ bond relative to other aminocarbyne complexes of chromium[5a,8] and the large Cr—C_{CO} distance of the CO group *trans* to the carbyne ligand. The Cr—$C_{carbyne}$ bond in *(1)* is the longest observed so far, being 178 pm. Comparison with those of about 168—170 pm in *trans*-halo(tetracarbonyl)aryl or -alkylcarbyne complexes demonstrates the extensive participation of the resonance formula *(B)*.

$$(CO)_5\overset{\oplus}{C}r{\equiv}C{-}NEt_2 \longleftrightarrow (CO)_5Cr{=}C{=}\overset{\oplus}{N}Et_2 \longleftrightarrow (CO)_5Cr{=}\overset{\oplus}{C}{-}NEt_2$$

(A) *(B)* *(C)*

Consequently, the $C_{carbyne}$—N distance of 128 pm also lies in the double bond region. The influence of the resonance formula *(C)* is manifested not only in the reactions of *(1)* but also in the fact that, in spite of the greatest Cr—$C_{carbyne}$ distance in the series of aminocarbyne complexes, the C—N distance in *(1)* corresponds roughly to the value of 126 pm found for *trans*-$Ph_3Sn(CO)_4CrCNEt_2$ (Cr—$C_{carbyne}$ = 174 pm)[8b]. The extreme Cr—C_{CO} distance to the CO group located *trans* to the carbyne ligand finally indicates that the chromium atom also accepts some of the positive charge (resonance formula *(A)*).

The delocalization of the positive charge therefore extends over the entire Cr-C-N unit. Replacement of the amino group by an alkyl or aryl moiety increases the positive charge on the metal atom by eliminating *(B)*, thereby further weakening the Cr—C_{CO} *trans* bond. The corresponding cationic carbyne complexes are consequently destabilized to such an extent that they can no longer be observed or isolated under the usual conditions.

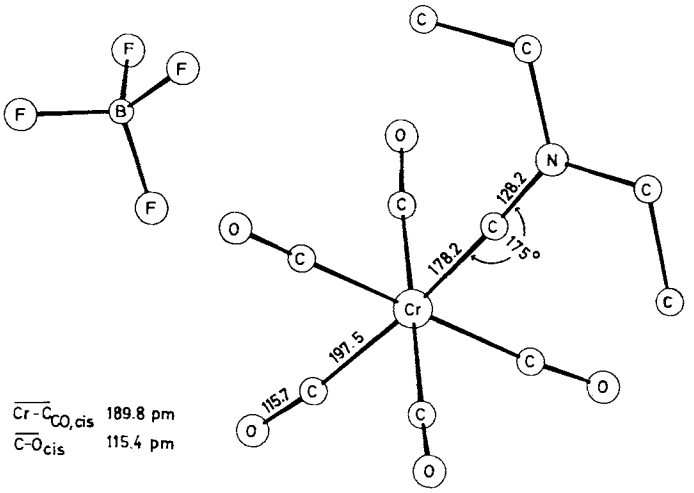

Fig. 1. Crystal structure of *(1)* with selected important distances (pm) and angles. The standard deviations of the distances are 1 pm for Cr—C and 2 pm for C—O and C—N.

Procedure

All operations are performed under N_2 with dried, O_2-free solvents.

A red solution of $KAsPh_2$ [prepared by adding $HAsPh_2$[9] (3 g, 13 mmol) in THF (20 ml) to a suspension of KH (0.53 g, 13 mmol) in THF (10 ml) at −30 °C and allowing the mixture to react at room temperature] is slowly added to a suspension of *(1)* (4.36 h, 12 mmol) in THF (50 ml) at −60 °C. The mixture turns dark brown and *(1)* dissolves on stirring for 30 min. The solvent is stripped off at −30 °C and the residue is extracted with CH_2Cl_2 prior to filtration. The filtrate is concentrated to 10 ml and purified by column chromatography on silica gel at −40 °C with pentane/CH_2Cl_2 (10:1) as eluent. After removal of solvent *(2)*, Nu = $AsPh_2$, is recrystallized from ether/pentane (5:1); yield 0.7 g (12%) of ocher crystals, m.p. 57 °C (dec.).

Molecular and Crystal Structure of β-SeBr[**]

By *Detlef Katryniok* and *Rüdiger Kniep*[*]

Contributions to the structural chemistry of compounds belonging to the class A_2B_2 (A = S, Se; B = F, Cl, Br) have so far come mainly from spectroscopic studies[1]. Most of these electron-rich chalcogen halides are readily accessible and have been known for several decades. We now report the first crystal structure analysis of a representative of this class, *i.e.* β-SeBr; both the structure of the individual molecule and the three-dimensional structure of the crystalline state are considered. A resemblance to a tellurium subiodide[2] is clearly seen.

DTA and powder photographs show the Se-Br system to contain the thermodynamically stable phases α-SeBr and α-$SeBr_4$[3]; both compounds are dimorphous, each with another β-phase which is metastable with regard to the phase diagram. A single crystal of β-SeBr was grown from the melt (SeBr) in a glass capillary (i.d. 0.2 mm) on a diffractometer assembly as described by *Simon et al.*[4] in a temperature gradient of 25 °C → −13 °C; its structure was analyzed at −80 °C[5].

The crystals of β-SeBr contain BrSeSeBr molecules, whose geometry and bonding are shown in Figure 1. The Se-Se distance of 2.241 Å in the molecule is significantly smaller than in the elemental structure (Se_{hex}, 2.373; Se_{mcl}, 2.318 Å[6]), and comparable with the corresponding distance determined by IR spectroscopy in FSeSeF (2.25 Å[1]); the Se—Br bond lengths in β-SeBr correspond to the terminal bond lengths in the cubane-type molecules $(SeBr_4)_4$ of α-$SeBr_4$ (average values 2.368(1) and 2.36(3) Å[3]).

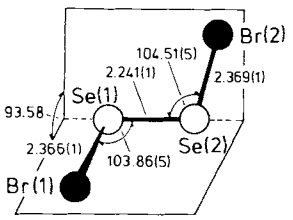

Fig. 1. Se_2Br_2 molecular geometry in β-SeBr (bond lengths [Å], bond angles (dihedral angles) [°]; standard deviations in brackets).

The β-SeBr structure also exhibits some intermolecular Se...Br contacts which are significantly closer than the sum of the van der Waals radii of 3.95 Å[7] (cf. Fig. 2). The shortest interaction of this kind (3.373(1) Å) exists between the Se(2) and Br(1) atoms of two adjacent BrSeSeBr molecules (generated *via* symmetry centers of the structure). Along the short crystallographic *c*-axis, translationally equivalent adjacent molecules exhibit Se(1)...Br(2) contacts of 3.514(1) Å. Each Se(1) atom also has a relatively short distance of 3.773(1) Å to Br(1) atoms of molecules that are adjacent along the *b*-axis.

A certain degree of similarity between the X-ray powder diagrams of β-SeBr and macromolecular β-TeI has already been reported[3]. If the $\left(\begin{smallmatrix}1\\ \infty\end{smallmatrix}\right)$-structural unit[2] extending along the direction of the shortest repeat distance (b = 4.182(2) Å)—a Te chain with alternatingly bridging and terminal I atoms—is regarded as being made up of n covalently bonded ITeTeI units, then a similar sequence of

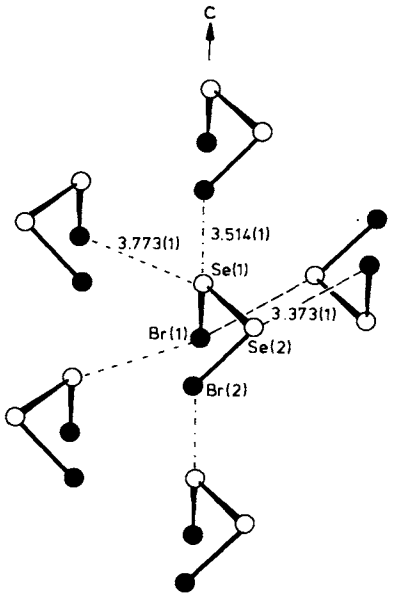

Fig. 2. Intermolecular Se...Br distances <3.95 Å (sum of the van der Waals radii [7]); standard deviations in brackets.

BrSeSeBr molecules[8] is found for β-SeBr along the shortest repeat distance (c = 4.974(2) Å; see also Fig. 2).

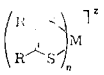
Photolysis of Water Catalyzed by Transition Metal Dithiolenes

By *Rainer Henning, Wilhelm Schlamann*, and *Horst Kisch*[*]

The photochemical cleavage of water permits the conversion of solar energy into the environmentally unobjectional energy source hydrogen[1]. One of the principal prerequisites for this conversion is the availability of a suitable photocatalyst ($\lambda_{max} \approx 400$—800 nm). Since many transition metal complexes absorb in this wavelength region, their photochemical behavior—especially their photoredox reactions—lie at the center of current interest. All the systems so far described as

[*] Priv.-Doz. Dr. R. Kniep, Dr. D. Katryniok
Institut für Anorganische Chemie und Strukturchemie der Universität Universitätsstrasse 1, D-4000 Düsseldorf (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft.

[*] Priv.-Doz. Dr. H. Kisch, Dr. R. Henning, W. Schlamann
Institut für Strahlenchemie im Max-Planck-Institut für Kohlenforschung Stiftstrasse 34—36, D-4330 Mülheim/Ruhr (Germany)

active for photochemical water cleavage in homogeneous solution require either strongly acid conditions[2a] or stoichiometric amounts of a mild reducing agent such as triethanolamine[2b]. We now report the photoreduction of water proceeding in neutral solution in the presence of transition metal dithiolene complexes ($\lambda_{max} \approx 800$ nm)[3].

We irradiated ($\lambda \geq 290$ nm) one of the complexes of Table 1[4] in tetrahydrofuran (THF)/H_2O (11.5:1 v/v), and detected H_2 by gas chromatography of the gas phase; no H_2 is detected on exclusion of light. The first quantitative H_2 determinations[5] were performed with the nickel complex *(1)*: irradiation in THF/H_2O at $\lambda \geq 290$ nm for 185, 350, and 483 h, respectively, generates 46, 100, and 225% of H_2[6], after irradiation for the same time in anhydrous THF, 9, 16, and 77% of H_2 were detected; a simultaneously irradiated blank (THF/H_2O) containing no compound *(1)* yielded traces of hydrogen (*ca.* 0.5%) after 165 h. On irradiation ($\lambda \geq 254$ nm) in a quartz apparatus, H_2 formation is much faster: 141 mg (0.26 mmol) of *(1)* in 200 ml of THF/H_2O (9:1) gives 209 Nml (9.4 mmol) of hydrogen in 22 h.

Table 1. "Transition metal dithiolenes".

	n	M	R	*Z*	
	2	Ni	Ph	0	*(1)*
	2	Pd	Ph	0	*(2)*
	2	Pt	Ph	0	*(3)*
	2	Fe	Ph	0	*(4)*
	2	Co	Ph	0	*(5)*
	3	W	Ph	0	*(6)*
	3	Mo	Ph	0	*(7)*
Cation:	2	Ni	Me	0	*(8)*
Me_4N^+	2	Ni	Ph	−1	*(9)*
Bu_4N^+	2	Ni	Ph	−2	*(10)*
Bu_4N^+	2	Ni	CN	−2	*(11)*
Ph_4P^+	3	W	CN	−2	*(12)*

The fact that even the reaction in anhydrous THF[7] gives some H_2 suggests that part of the H_2 could come from *(1)* and/or the solvent. The former appears highly unlikely since irradiation of *(1)* in CCl_4 fails to produce H_2. In order to elucidate the second possibility, several irradiation runs were performed ($\lambda \geq 290$ nm) in the presence of D_2O and the composition of the gas phase was determined by mass spectrometry[8]. At the same solvent/D_2O ratio (12:1), the following values were found for the HD/D_2 ratio: THF, 13 and CH_3CN, 2.1; the D/H ratio is accordingly about 1 and 2. These results confirm the cleavage of D_2O and H abstraction from the solvent. The formation of hydrogen, though in small amounts, on irradiation of *(1)* in heterogeneous aqueous solution demonstrates that the organic solvent is not an essential component of the system.

The mechanism of this novel photochemical cleavage of water is still unknown. It is uncertain whether electronically excited *(1)* and/or its mono- or dianion, *(9)* and *(10)*, respectively, promote the reaction; since formation of *(10)* was observed in all reactions of *(1)*[9], the last two possibilities cannot be ruled out[10].

Procedure

Depending upon their solubility, up to 0.1 mmol of the "metal dithiolene" is dissolved in 25 ml of a THF/H_2O mixture (11.5:1, v/v). The solution is flushed with argon for *ca.* 30 min in a screw-cap vials with a magnetic stirrer and gas-tight rubber seal; the vials are then closed and irradiated in a merry-go-round apparatus at room temperature in a water bath for 5—7 d with an Hg high pressure lamp (Philips HPK 125 W). GC analysis of the gaseous products was performed on a molecular sieve column (5 Å)[12].

Cyclic Water Cleavage by Visible Light: Drastic Improvement of Yield of H_2 and O_2 with Bifunctional Redox Catalysts[**]

By *John Kiwi, Enrico Borgarello, Ezio Pelizzetti, Mario Visca*, and *Michael Grätzel*[*]

The photoinduced reduction of methylviologen (*N,N'*-dimethylbipyridine dication, MV^{2+}) by a suitable sensitizer, such as $Ru(bpy)_3^{2+}$, can be exploited to achieve cleavage of water into hydrogen and oxygen[1]. The photoredox process is performed in the presence of two redox catalysts, one of which, *i.e.* colloidal platinum, effects reduction of water[2], and the other, *e.g.* RuO_2, oxidation of water[3]:

In order to render the water decomposition by light effective, one has to employ an extremely active platinum catalyst. At moderately high Pt concentrations ($\approx 2 \times 10^{-4}$ M) this has to react with the reduced electron relay (MV^+) in the microsecond time domain. Use of a catalyst system comprising an ultra fine Pt sol protected by a copolymer of styrene and maleic anhydride, and colloidal or macrodispersed RuO_2 gave quantum yields of *ca.* 1.5×10^{-3}. This is 100 times smaller than the H_2-yield obtained with a sacrificial system[4] were EDTA instead of water served as the reductant of $Ru(bpy)_3^{3+}$. Undoubtedly, the decreased quantum yield arises from undesirable cross reactions, in particular the reaction of oxygen with the reducing MV^+. This report describes the performance of a new cofunctional redox catalyst which achieves astonishingly high quantum yields in the water splitting process.

The catalytic material consists again of a combination of Pt and RuO_2. However, in contrast to the previous experiments[1] where individual particles of the two catalysts were suspended in solution, the new preparation contains Pt and RuO_2 codeposited on a common carrier, *i.e.* colloidal TiO_2. A mixed oxide of RuO_2 and TiO_2 was first prepared from a solution of the respective chlorides. The TiO_2 powder produced has a grain size of 1000 to 2000 Å and contains *ca.* 0.1% RuO_2. The TiO_2 is made n-type conducting through doping with Nb. The powder is subsequently charged with finely divided Pt by stirring it in a solution containing a Pt-sol (mean particle diameter 30 Å). Thereby colloidal particles are produced which can act simultaneously as *oxidation and reduction catalysts* (cofunctionality). Results obtained from the photolysis of aqueous solutions containing this catalyst are shown in Table 1. Irradiation of a solution containing $Ru(bpy)_3^{2+}$ (10^{-4} M), MV^{2+} (5×10^{-3} M), and EDTA (5×10^{-2} M) with visible light illustrates the high efficiency of this catalyst with respect to hydrogen generation. In this system no oxygen is produced. Instead of water, EDTA is irreversibly oxidized[2d,4]. One notes that for a given Pt concentration (40 mg/l) the H_2-evolution rate is influenced by the TiO_2 content of the solution. Optimal yields are obtained with a TiO_2 concentration of 50 mg/100 ml. Interestingly, with such a system one obtains a hydrogen generation rate which exceeds that obtained with colloidal platinum alone (particle diameter 30 Å, protected by Carbowax-20 M) by a factor of 4.

Table 1. Evolution of hydrogen from aqueous solutions with various redox catalytic systems under the action of visible light.

Catalyst [a]	Amount (mg/100 ml)	System	pH	ml H_2/l/h
$Pt/TiO_2/RuO_2$	100	$Ru(bpy)_3^{2+}$/	4.7	50
	50	MV^{2+}/EDTA		300
	25			260
	10			250
	5			200
Carbowax/Pt	80			80
$Pt/TiO_2/RuO_2$	50	$Ru(bpy)_3^{2+}$/	4.7	45
		MV^{2+}	3.0	3
			1.0	2
$Pt/TiO_2/RuO_2$	50	H_2O	4.7	0
		$Ru(bpy)_3^{2+}$ [b]		0
		MV^{2+}/EDTA		0

[a] Concentration of platinum 40 mg/l. [b] No illumination.

In the second part of Table 1 are listed results obtained with a cyclic system, *i.e.* in the absence of EDTA. The quantum yield for hydrogen generation is astonishingly high. If one accounts for the fact that EDTA doubles the quantum yield for MV^{2+} reduction, the efficiency of the cyclic system is only a factor of three lower than that of the sacrificial one. This may be further improved by optimization. It is noted from Table 1 that the rate of hydrogen evolution decreases with the solution pH. This is attributed to the decrease in the driving force for water oxidation by $Ru(bpy)_3^{3+}$.

A further important feature of the cyclic system is that the H_2 evolution can be sustained over long irradiation times. Thus after two days of irradiation there was no noticeable decrease in the hydrogen generation rate.

Oxygen production occurs simultaneously with the formation of hydrogen under illumination. Thus in the experiment where 45 ml of H_2 was generated during one hour of photolysis the quantity of O_2 produced was 16 ml. This value is distinctly below the stoichiometric proportion. Presumably part of the O_2 generated in the photolysis is absorbed on the surface of TiO_2 which under our conditions may be more than 100 m^2/l solution.

A series of blank experiments was performed to confirm the above results: There is no H_2 formation in the absence of light. Both the electron relay and sensitizer have to be present to obtain light-induced water decomposition: If the RuO_2,Pt-doped TiO_2 particles are illuminated alone in aqueous suspensions there is neither hydrogen nor oxygen formation. Presumably visible light is inefficient in directly exciting the TiO_2 semiconducting particles which have a band gap of 3 eV. When excited by UV-light TiO_2 can mediate a number of photosynthetic processes[5] and has been claimed to cleave water[6].

The surprisingly high activity of our cofunctional redox catalyst may be rationalized in terms of adsorption of the redox species in solution on the TiO_2 surface. This favors the catalytic processes and eliminates rate limits imposed by three-dimensional diffusion of the reactants. It is feasible that the whole process of water cleavage occurs on a single TiO_2 particle *via* adsorbed species. Whether electronic levels of the TiO_2 participate in this reaction remains to be investigated.

Experimental

For the preparation of the Pt-doped TiO_2/RuO_2 particles a platinum sol with a mean particle diameter of 30 Å was first produced[7]. (100 mg H_2PtCl_6 was dissolved in 250 ml H_2O and subsequently reduced with 35 ml of a 1% solution of citrate. The mixture was heated during *ca.* 4 h at 90 °C and the excess of citrate was removed with an Amberlite ion exchange resin.) To disperse the Pt on TiO_2 it suffices to stir the mixture containing the required amount of TiO_2 for approximately 1 h.

Figure 1 shows results obtained from applying the quasi-elastic light-scattering technique to the particle dispersions. Correlation functions were measured with a Chromatix[8] instrument. The Pt-doped RuO_2/TiO_2 particles show a mean hydrodynamic radius of 470 Å which lies distinctly below the grain size of the powder. Apparently a higher degree of dispersion is achieved in solution.

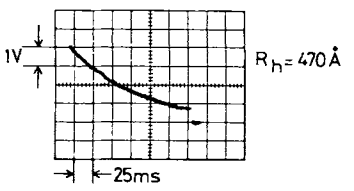

Fig. 1. Correlation function obtained from aqueous solutions of the $Pt/TiO_2/RuO_2$ particles (10 mg/l). Scattering angle $\theta = 4.5°$.

Illuminations were carried out with a XBO 450-W Xe lamp. The IR and UV content of the light was removed by a 16 cm water jacket and a 450 nm cut-off filter. Hydrogen and oxygen were analyzed by gas chromatography. Alternatively O_2 detection was carried out with an END-O-MESS instrument[9].

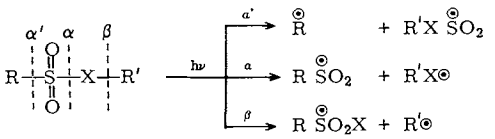
Photochemistry of Sulfonamides and Sulfonylureas: A Contribution to the Problem of Light-Induced Dermatoses

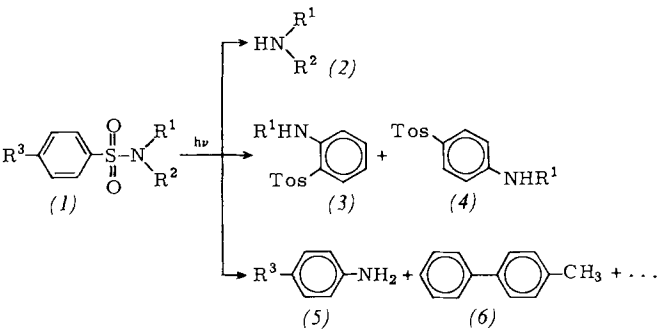
By *Bernd Weiss, Heinz Dürr,* and *Hermann Josef Haas*[*]



Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Sulfonamides and sulfonylureas have acquired great importance as pharmaceuticals, but they can elicit light-induced dermatoses or photosensitization of the human organism as side effect[1]. Surprisingly, the photochemistry of the sulfonamides and sulfonylureas has previously not been studied in very great detail. The compounds are relatively photostable, but give complex product mixtures on prolonged irradiation.

We report here on (i) model studies on the simple sulfonamides *(1a—d)*, (ii) the photochemistry of the chemotherapeutic sulfathiazole *(1e)* and (iii) the photochemistry of the antidiabetics tolbutamide (Rastinon) *(7a)* and carbutamide (Invenol) *(7b)*.



[*] Prof. Dr. H. Dürr, Dr. B. Weiss

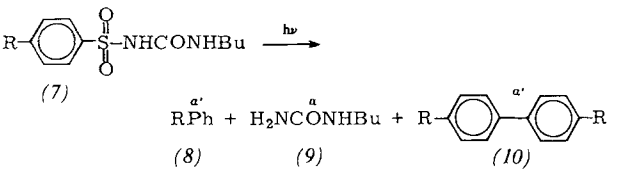
D-6600 Saarbrücken (Germany)
Prof. Dr. H. J. Haas
Fachbereich 3 der Universität Saarbrücken
D-6650 Homburg (Germany)

In principle, the bonds marked in Scheme 1 can be cleaved (α'-, α-, and β-cleavage) on photolysis of sulfonamides and sulfonylureas. The radicals $R'X\overset{\ominus}{S}O_2$, $R\overset{\ominus}{S}O_2$, and $R\overset{\ominus}{S}O_2X$ should eliminate SO_2 and form simple alkyl or aryl radicals, which then stabilize by recombination or by abstraction of hydrogen from the solvent[2].



Scheme 1

The sulfonamides *(1a—e)* were irradiated in a Gräntzel apparatus (Hg low-pressure lamp, 70 W) at room temperature in ether, methanol, or ethanol. Low-boiling components were identified by GC analysis (comparison with authentic samples), solids were separated by column or thin-layer chromatography and identified by comparison with authentic material or spectra (Table 1).

The sulfonylureas tolbutamide (Rastinon) *(7a)* and carbutamide (Invenol) *(7b)* were photolyzed under conditions similar to those in the case of *(1)* (see Table 2). In the photolysis of *(7a)*, both in ether as well as in methanol, toluene *(8a)*, *n*-butylurea *(9)*, and 4,4'-dimethylbiphenyl *(10a)* were formed. In $MeOH/O_2$, however, no toluene or dimethylbiphenyl was obtained thus indicating chemical rather than physical quenching by O_2. Prolonged photolysis (100 h) of *(7b)* in methanol yielded aniline *(8b)*, *n*-butylurea *(9)*, and three products of unknown structure. Thus, a *p*-amino group drastically increases the photochemical stability of the sulfonamides *(1)* as well as the sulfonylureas *(7)*.

In mechanistic studies on *(7a)* we obtained the following results: 1) The excited state is likely to have $n\pi^*$ or $\pi\pi^*$ character. 2) The effectiveness of the photofragmentation of *(7a)* is moderate, *i.e.* the quantum yield is only 0.04 (disappearance of the educt). 3) Sensitization experiments with xanthone ($E_T = 73$ kcal/mol) proceeded negatively, while the findings with $MeOH/O_2$ indicate chemical rather than physical quenching of the excited state. No luminescence is observed with *(7a)* [however, in the case of *(7b)* and *(1e)* fluorescence was observed]. 4) A cage-effect participates in product formation.—All these findings indicate that the photo-

[a] Also three unidentified products.

fragmentation of *(7a, b)* originates from an excited singlet-state. 5) No long-lived intermediates can be detected by the ED- and EDQ technique of *Mauser*[2]. 6) Radical intermediates can be established by ESR spectroscopy (direct methods and spin-trap technique).

cleavage. The products toluene *(8a)* and aniline *(8b)* point to additional α′-cleavage. A direct cleavage of the arylsulfonyl radicals with formation of hydrocarbons is endothermic and therefore fairly unlikely[4].

In spite of the "non-physiological" conditions in the photolysis of *(7)* the following conclusions drawn from the mechanistic findings might be of importance for the problem of photosensitization: The results of the sulfonamide photolysis depend upon the solvent. Since *(7a)* ($\lambda = 222$ nm) absorbs far below 280 nm it should not be directly excited by sunlight. A secondary reaction of the products *(8)—(10)* formed in the photofragmentation could hardly be plausible in the photosensitization caused by *(7a)* [the same applies for *(7b)* and *(1e)*]. The following hypothesis would appear more attractive:

(7a) could absorb UV light directly; the radicals formed would then react with the cell components and give rise to

Scheme 2

The reaction mechanism of the photofragmentation of sulfonamides *(1)* and sulfonylureas *(7)* is outlined in Scheme 2. The key-fragment in the α-cleavage is the radical pair *(13)* + *(14)*, in the α′-cleavage *(11)* + *(12)*.

Summary: 1) The *N*-arylsulfonamides *(1a)* and *(1b)* undergo α-cleavage to *(2a)* and *(2b)*, while the *N*-aroylsulfonamides *(1c)* and *(1d)* preferably undergo α-cleavage to *(2c)* and *(2d)*; in *(1c)* some β-cleavage to ethyl carbamate and *(5c)* is observed as side reaction. The decisive spin state for the photoreaction might have S_1-character. 2) If the nitrogen atom of the sulfonamides *(1a, b, d)* bears a phenyl group, Photo-Fries rearrangement to *(3a, b, d)* + *(4a, b, d)* occurs as main competing reaction. 3) The α-cleavage of the alkylsulfonamides of type *(1)*[3] and of the sulfothiazole *(1e)* proceeds *via* T_1-states; *(1e)* gives aniline by α′-cleavage *via* a S_1-state. 4) The sulfonylureas *(7a, b)* fragment essentially in the sense of a α-

the observed damage. Any SO_2 formed could bring about additional complications. This would amount to a *phototoxic reaction*. Furthermore, *(7a)* could attack at the cell protein directly as hapten. This system would now be light sensitive through a bathochromic shift and could be cleaved to products having a long-term effect, which could be regarded as a *photoallergic process*.

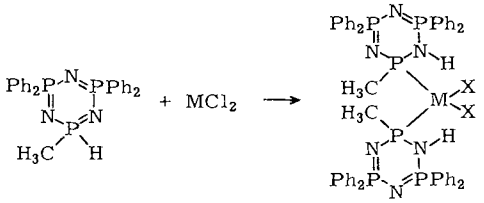
Cyclotri(phosphazene) Complexes with *P*-Coordinated PdX_2 and PtX_2[**]

By *Alfred Schmidpeter, Klaus Blanck, Heinz Hess,* and *Heinz Riffel*[*]



Dedicated to Helmut Behrens on the occasion of his 65th birthday

The chemistry of electropositively substituted cyclotri(phosphazenes) is still in its infancy[1]. Metalated cyclotri(phosphazenes) *(1)*, M = Li[2] and Cu[1][3], have proven to be preparatively useful species despite their being sensitive or even unisolable intermediates. They are tentatively formulated ionically or as *(1a)* with *N*-coordinated metal M.

(1a)   *(1b)*

We report here on derivatives of coordination type *(1b)*, M = Pd and Pt.

The cyclotri(λ^5-phosphazene) *(2)*[4] reacts with the nitrile complexes of $PdCl_2$ and $PtCl_2$ or also directly with $PdCl_2$ and K_2PtCl_4, respectively, to give the crystalline 2:1 complexes *(3)*. The metal displaces the hydrogen at P-2 towards N-1. Thus, in the complex, the otherwise unobservable[4] NH-form prototropic to *(2)* is fixed. In the complexes, chloride can readily be replaced by bromide to give *(3)*, X = Br.

(2) M = Pd, Pt *(3)*, X = Cl

Structure *(3)* is supported by the NMR spectra (Table 1), particularly by the strong and metal-dependent downfield shift of the P-2 signal [in *(2)*: $\delta(^{31}P) = 6.9$] and by the disappearance of the $^1J_{PH}$- and appearance of a $^1J_{PPt}$-coupling. As expected this coupling lies between the regions characteristic for phosphane- and phosphite-complexes, *i.e.* between 3500 and 6200 Hz, respectively. By protonation of N-1, which is more strongly basic than N-5[5], P-4 and P-6 become anisochronic; in pyridine or nitrobenzene as solvent or, partly also in dichloromethane at high concentrations of *(3)*, the exchange of the proton between N-1 and N-3 is rapid enough for them to appear equivalent again (at averaged ^{31}P-shift).

Table 1. NMR and IR spectroscopic data of the complexes *(3)*. *J* in Hz.

M	Pd	Pd	Pt	Pt
X	Cl	Br	Cl	Br
Solvent	CH_2Cl_2	$CHCl_3$	CH_2Cl_2	$C_6H_5NO_2$
$\delta(^{31}P)$ P-6	17.9	18.4	16.8 }	15.1
P-4	13.3	15.2	13.5 }

J_{PNPCH} [c]	0.8	1.0	0.9	1.0
J_{PtPCH}			22.8	
νM—Cl [d]	260		260	
	289		288	

[a] X-part of a $[ABCX_3]_2$ system. [b] L = 14.6: $J_{PCH} = \pm 10.5$, $J_{PPtPCH} = \pm 4.1$ Hz. [c] Estimated from the linewidth of the N-doublet. [d] KBr disk, ν in cm^{-1}.

Since two M—Cl vibration bands are observed for *(3)*, they ought to be *cis*-complexes; however, the ^1H-multiplets of the 2-methyl groups are consistent with this assumption only when M = Pt, whereas in the case of M = Pd they indicate a $^2J_{PPdP}$ coupling, which is too large for a *cis*-arrangement and therefore would suggest an equilibrium with the *trans*-form in solution.

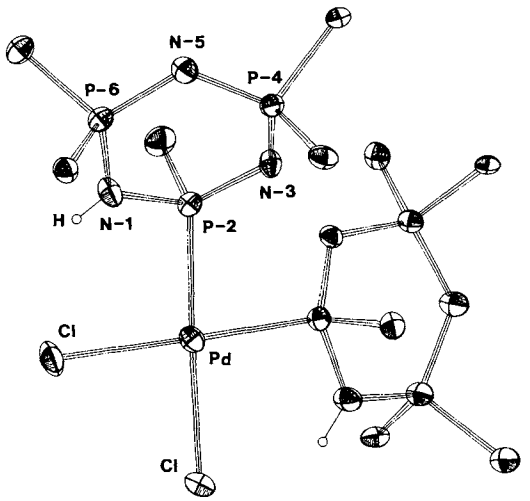

Fig. 1. Molecular structure of the $PdCl_2$ complex *(3)* in the crystal; most important bond lengths [pm], angles at Pd, and internal ring angles (mean values):

Pd—Cl	239.8(1)	Cl—Pd—Cl		89.5(5)°	
Pd—P-2	224.2(1)	P-2—Pd—P-2′		87.4(5)°	
P-2—N-1	170.4(4)	P-2	106.7(2)°	N-1	126.2(3)°
P-6—N-1	165.2(4)	P-4	115.4(2)°	N-3	124.2(2)°
P-6—N-5	157.9(4)	P-6	111.3(2)°	N-5	124.7(2)°

For simplicity only the C atom 1 of the phenyl substituents on P-4 and P-6 is shown.

An X-ray structure analysis[6] of *(3)*, M = Pd, X = Cl, confirms the bonding of the metal to the phosphorus and supports the *cis*-arrangement in the crystal (Fig. 1). The cyclo-

[**] Phosphazenes, Part 72. This work was supported by the Fonds der Chemischen Industrie.—Part 71: *J. Högel, A. Schmidpeter*, Z. Naturforsch. *B 34*, 915 (1979).

phosphazene rings have a distinct boat-conformation and project outwards in opposite directions from the P_2PdCl_2 plane. The endocyclic angle at the Pd-substituted P-2 is unusually small, evidencing its partial P^{III} character. The angle at the neighboring protonated N-1, on the other hand, is slightly wider; the bonds from N-1 to the phosphorus are lengthened considerably[7]. The rest of the PN-bonds, however, are in good agreement with the comparative value of 160 pm for $(Ph_2PN)_3$.

Procedure

(2) (920 mg, 2 mmol) is added to a hot solution of $PdCl_2$ (178 mg, 1 mmol) in CH_3CN (20 ml). *(3)*, M = Pd, X = Cl, separates out as pale-yellow crystals of m.p. 267—268 °C (dec.); yield 1000 mg (92%).

A solution of K_2PtCl_4 (415 mg, 1 mmol) in water (10 ml) is added to a boiling solution of *(2)* (920 mg, 2 mmol) in ethanol (45 ml). The red color immediately disappears, and on evaporation *(3)*, M = Pt, X = Cl, precipitates out; colorless crystals, m.p. 279—281 °C (from anisole); yield 1130 mg (95%).

For Cl/Br exchange a solution of *(3)*, X = Cl in dichloromethane (M = Pd) or hot anisole (M = Pt) is stirred for 10 h with an excess of finely powdered KBr. From the filtered (if necessary concentrated) solution, *(3)*, X = Br, is precipitated by addition of ether; bright yellow (M = Pd) or yellow crystals (M = Pt).

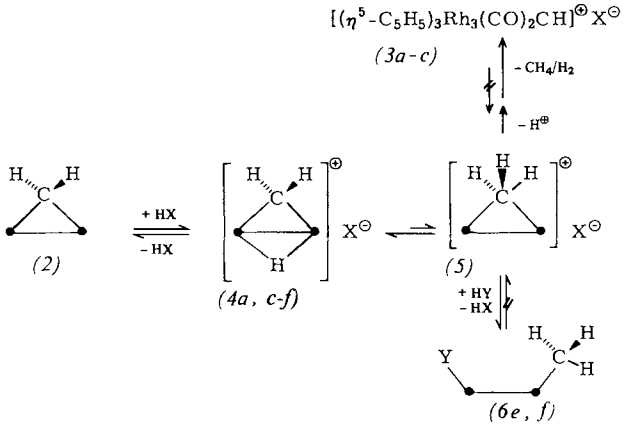
Synthesis of the First Methylidyne-Rhodium Cluster by Proton-Induced H_2/CH_4-Elimination from a μ-Methylene Complex[**]



By *Wolfgang A. Herrmann, Johann Plank, Ernst Guggolz,* and *Manfred L. Ziegler*[*]

While carbene complexes $L_xM{=}CRR'$ represent a well-documented class of compounds, both from the preparative point of view and regarding their reactivity[1], the chemistry of μ-methylene complexes *(1)* has rarely been reported on in the literature apart from occasionally observed intramolecular isomerism phenomena[2]. Stimulated by theoretical considerations[3a] and NMR spectroscopic findings[3b], according to which the complexes *(1)* can be formulated as dimetallacyclopropanes and appear to display a high electron density at the bridgehead carbon, we have investigated the nucleophilic activity of the latter. Here, we report for the very first time on acid-induced reactions of the readily accessible prototypal rhodium compound *(2)* containing an unsubstituted methylene bridge[4].

(1)

Surprisingly enough, HBF_4 reacts with *(2)* in tetrahydrofuran (THF) essentially quantitatively to give the trinuclear, ionic cluster compound *(3a)*, which crystallizes straight away as black, lustrous, air-stable and exceedingly thermally stable needles. The same is true for the completely analogous trifluoroacetate *(3b)* and trifluoromethanesulfate *(3c)*[5].

● = $(\eta^5\text{-}C_5H_5)Rh(CO)$; *(a)*, X = BF_4; *(b)*, X = CF_3COO; *(c)*, X = CF_3SO_3; *(d)*, X = FSO_3; *(e)*, Y = Cl; *(f)*, Y = Br

Although NMR spectra strongly indicated the presence of μ_3-methylidyne functions in the cations of *(3a—c)*, a conclusive assignment of structure proved possible only by means of a single crystal analysis (Fig. 1, Table 1). The cluster ion which electronically meets the EAN rule essentially consists

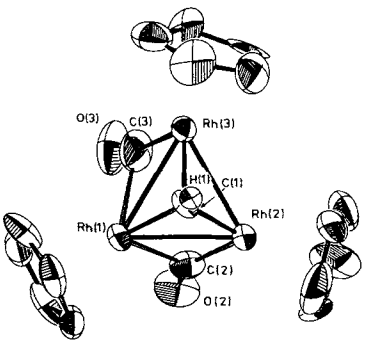


Fig. 1. ORTEP diagram of the cation di-μ_2-carbonyl-μ_3-methylidynecyclotris[(η^5-cyclopentadienyl)rhodium] (3*Rh—Rh*) of *(3b)* in the crystal. The thermal vibration ellipsoids correspond to 50% probability. *(3b)* crystallizes from acetonitrile (−18 °C) in the monoclinic system, space group C_{2h}^5-C2/c, $a = 1772.54(56)$, $b = 1060.67(34)$, $c = 2270.90(74)$ pm, $\beta = 103.895(25)°$; $Z = 8$. 2045 independent non-zero reflections were recorded on a computer-controlled single crystal diffractometer (AED Siemens) (Mo-Kα; $65° \leq 2\theta \leq 4°$) and corrected in the usual way. $R_F = 0.042$.

of an equilateral triangular Rh_3-skeleton symmetrically bridged by the CH group, while the two carbonyl ligands resemble unsymmetrical edge-bridging functionalities. The methylidyne building block of *(3a)* can be recognized in the ^{1}H-NMR spectrum through its extremely deshielded proton (symmetric quartet at $\delta = 16.23$, $^2J_{Rh,H} = 2.6$ Hz) and is confirmed ^{13}C-NMR spectroscopically by a downfield resonance at $\delta = 303.6$[5].

Strikingly, the acid-induced synthesis of the first CH-rhodium compounds *(3a—c)* from the μ-methylene complex *(2)* proceeds *via* H_2- and CH_4-elimination[6], in a curious twist with the formation of stable μ-methyl derivatives which arise from protonation of *Wilkinson*'s $(\mu\text{-}CH_2)_3Ru_2[P(CH_3)_3]_6$[7]. The initial steps of protonation were characterized by the following experiments:

1. The methylene species *(2)* is converted by HBF_4 (CF_3SO_3H or FSO_3H) in prompt and quantitative precipitation reactions in diethyl ether, without evolution of gas, into yellow, rather heat- and moisture-sensitive derivatives, which on the basis of their conductivity, composition (complete elemental analysis) and IR and ^{1}H-NMR spectra[8] were shown to represent the novel ionic carbonyl-bridged protonation products *(4a)*[8], *(4c)* and *(4d)* in the solid state. Methyl groups are not detectable ^{1}H-NMR spectroscopically in solutions of *(4)*: While signals of terminal and bridging CH_3-ligands are absent in the range $\delta = 3 \ldots -7$[3b,7], the symmetric triplets centered around $\delta = -12.91$ or -12.97 in the case of *(4a)*[8] are, on the basis of the chemical shift, the intensity, the multiplicity, and the coupling constants ($^1J_{Rh,H} = 23.0$ Hz) unambiguously diagnosable as signals of Rh—*H*—Rh functions; the signals in the range $\delta = 10 \ldots 6$ can be exclusively assigned to methylene protons[3b,7]. The observed signal-doublings highly likely originate from the equilibria of the diastereomeric forms *cis*-Cp/*trans*-Cp ($K(20\,°C) = 45:55$).

2. Even weakly basic solvents such as THF, dimethyl sulfoxide, or hexamethylphosphoric triamide effect the deprotonation *(4)*→*(2)*. A rapid CH_2/Rh*H* exchange has been proven to occur by labeling experiments; *e.g.*, the complex [D]-*(4d)* precipitated with FSO_3D reacts with CD_3OD/$NaOCH_3$ or else CH_3OD/$NaOCH_3$ yielding the labeled precursor *(2)* (36% D_0, 38% D_1, 26% D_2; MS). Accordingly, reaction of excess [D]-trifluoroacetic acid with *(2)* in THF under otherwise equal conditions leads to the D-labeled methylidyne species [D]-*(3b)* (80 ± 5% D; ^{1}H-NMR). It is thus demonstrated that mechanistically decisive methyl intermediates participate in the synthesis of *(3)*. Besides, this is the only reasonable interpretation which fully accounts for the formation of deuterated methylidyne products *(3)* in the course of subsequent H_2/CH_4(!)-elimination.

3. The kinetics of the reaction [D]-*(4d)*→[D]-*(3d)* shows (NMR investigation) that the synthesis of the trinuclear methylidyne complex proceeds *via* partial deprotonation of the hydrido(methylene) precursor *(4)* and includes unsymmetrically substituted dinuclear complexes of previously unknown constitution.

4. The protonation of *(2)* which starts at the electron-rich metal-metal bond rather than at the bridgehead carbon is consistent with the likewise surprising observation that the μ-carbonyl complex $(\mu\text{-CO})[(\eta^5\text{-}C_5H_5)Rh(CO)]_2$ which is isostructurally[4] and electronically[3a] completely analogous to *(2)*, can be smoothly converted with HBF_4/ether into the readily isolable cation $[(\mu\text{-CO})(\mu\text{-H})\{(\eta^5\text{-}C_5H_5)Rh(CO)\}_2]^+$, which is again reversibly deprotonatable with bases[9].

5. The irreversible shift to the methyl tautomers *(5)*[10] of the equilibrium *(4)* ⇄ *(5)* circumstantially evidenced by labeling experiments and shown by NMR findings to lie practically completely on the side of the hydrido(methylene) compound *(4)*[10], was accomplished with nucleophiles capable of coordination: thus HCl or HBr reacts rapidly with *(4a)* under anhydrous conditions to give the new dinuclear, neutral halogeno(methyl) complexes *(6e)*, Y = Cl, and *(6f)*, Y = Br[11].

These results demonstrate the acid-induced synthesis of the methylidyne cluster *(3)* to be initiated by protonation of the electron-rich metal-metal bond of the μ-methylene complex *(2)* and to proceed *via* tautomeric organometallic hydrido(methylene)/methyl cations. This most simple synthetic approach is also applicable to μ-carbonyl complexes[12].

similar S_4N_3 skeleton is found in 1,7-bis(*p*-tolyl)tetrasulfur trinitrogen chloride[7c].

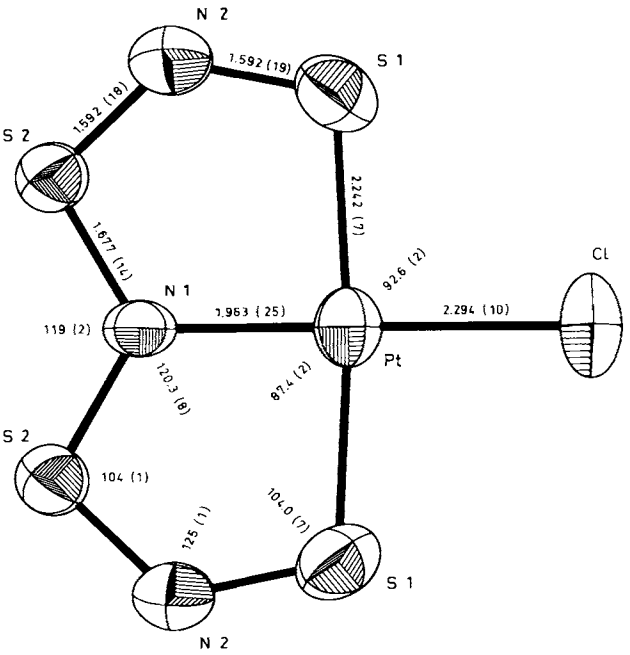

Fig. 1. Molecular structure of $PtCl(S_4N_3)$ in the crystal, with bond lengths [Å] and angles [°].

A Novel SN-Ligand: Structure of $PtCl(S_4N_3)$

By *Helmut Endres* and *Elisabeth Galantai*[*]

As starting compounds for reactions connected with our current studies we require complexes of Ni, Pd, Pt which keep the S_4N_4 molecule as intact as possible. When halides of these metals are allowed to react with S_4N_4, cleavage of the molecule occurs and complexes containing bidentate S_2N_2H- and S_3N-ligands are formed[1,2]. The formation of $(Ph_3P)_2Pt(S_4N_4)$, besides other products, in the reaction of $(Ph_3P)_4Pt^0$ with S_4N_4 has been reported[3]; however, an X-ray structure analysis of this compound has so far not been described. The complex $CuCl(S_4N_4)$ contains Cu—Cl—Cu chains, the Cu atoms of neighboring chains each being bridged by two S_4N_4 molecules[4]. Numerous Lewis acid/Lewis base adducts of S_4N_4 with stronger Lewis acids have been isolated[1].

We investigated the reaction of S_4N_4 with *cis*-$PtCl_2(NCPh)_2$[5], for we assumed that S_4N_4 would readily replace the benzonitrile moiety, known as a good leaving group. If a solution of equimolar amounts of the reactants in toluene is heated under reflux for 5 h, a black powder interspersed with rectangular, deep-violet crystals precipitates on cooling. As the X-ray structure analysis of such a crystal shows (Fig. 1)[6], a novel type of complex is formed, in which a formally singly negatively charged S_4N_3 group is coordinated as planar tridentate ligand to the Pt^{II}. The molecule displays mirror symmetry with N1, Pt, and Cl in the plane of symmetry. All S—N bond lengths have values between those for a single bond and a double bond, the shorter distances of 1.59 Å (N2—S1, N2—S2) corresponding to those in S_4N_4, 1.60—1.63 Å[7a], the longer distances of 1.68 Å (N1—S2) to those in $S_4N_4H_4$, 1.663—1.669 Å[7b]. A geometrically very

The planar complex molecules form stacks along the *a*-axis with the normals of the planes tilted at 48.8° relative to the stacking direction. The projection of two neighboring molecules of a stack onto each other does not reveal any marked intermolecular interactions.

Formally the anionic ligand S_4N_3 is formed by cleavage of a positively charged N-atom from S_4N_4. The Pt^{II} starting complex loses the two benzonitrile ligands and a Cl^-. An indication of the reaction mechanism might be given by the observation that NH_4Cl precipitates in the reflux condenser during the reaction.

The new compound can be obtained in the form of black dendritic crystal aggregates after extraction of the powdery precipitate with toluene; recrystallization, even on slow cooling (2—3 d), does not afford crystals suitable for single crystal studies. The identity of the substance thus isolated with the crystals employed for the structure analysis is proven by elemental analysis and Debye-Scherrer diagrams. The compound dissolves in toluene, acetone *etc.* to give a red solution. It is stable towards air, and does not melt below 250 °C.

Procedure

A mixture of *cis*-$PtCl_2(NCC_6H_5)_2$ (4 mmol) and S_4N_4 (4 mmol) in toluene (*ca.* 100 ml) is heated under reflux for 5 h, whereupon the color of the solution changes from yellow to wine-red. The flask is left in the heating mantle and the solution is allowed to cool down slowly overnight. A powdery black precipitate mixed with deep-violet crystals settles out; this is filtered off and extracted with toluene in a Soxhlet extractor. On cooling the extract, $PtCl(S_4N_3)$ crystallizes out. Evaporation of the reaction solution furnishes a further crop of the compound. Yield *ca.* 10%, m.p. >250 °C. IR (nujol): 1005, 834, 820, 730, 717, 696, 663, 502, 334 cm^{-1}, all bands

MoS_4^{2-} and $MoOS_3^{2-}$ as Structurally Versatile and Biochemically Interesting Ligands in Crystalline Multinuclear Cu- and Fe-Complexes

By *Achim Müller, Hartmut Bögge, Heinz-Gerhard Tölle, Rainer Jostes, Uwe Schimanski*, and *Mechtild Dartmann*[*]

The importance of thiomolybdates and especially of MoS_4^{2-} ions in various biological processes has recently been recognized[1,2]. Thiomolybdates were detected (on the basis of the electronic absorption spectra of the species which we previously investigated in aqueous solution) in the hydrolysis product of nitrogenase (FeMo-protein of *Clostridium pasteurianium*)[1]. Thiomolybdates are most probably formed in the rumen of grazing animals[2] and also appear to be involved in human medicine in disorders of Cu metabolism. MoS_4^{2-} is generally the strongest antagonist of Cu metabolism[2b], and the Cu deficiency caused by high contents of Mo in pasture soils (the interaction in grazing animals takes place both in the rumen and in cell tissues) constitutes a very serious problem for ruminants in some parts of the world[2]. We have now been able to show that thiomolybdates, which together with thiotungstates were introduced by us as ligands in coordination chemistry[3], have a strong tendency to form various types of multinuclear Cu-complexes (reaction already detectable with *ca.* 10^2 ppm of the reactants referred to the amount of solvent!), and that there is also a high tendency for the complex $[Cl_2FeS_2MoS_2]^{2-}$ *(1)* to be formed. *(1)* is interesting, since the complex can serve as precursor for the synthesis of the low-molecular weight FeMo cofactor (FeMo-co)[4]. Because of the Mo/W antagonism[2a], the W-derivatives would also appear to be of interest from the biochemical point of view.

We have now been able to isolate the compounds *(2)*, *(3)*, and *(4)* listed in Table 1 and to characterize them by elemental analysis, ^{57}Fe-Mössbauer, IR and electronic absorption spectra, magnetic measurements, and complete crystal structure analyses (Syntex $P2_1$, $Mo_{K\alpha}$) (cf. Fig. 1, 2 and Table 1).

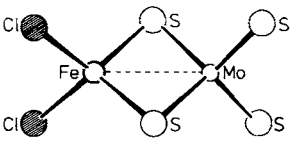

Fig. 1. Molecular structure of $[Cl_2FeMoS_4]^{2-}$ in crystals of *(4)*; Fe...Mo = 2.775 Å (structure of thiometalato complexes: Type I with tetrahedrally coordinated Fe central atom).

In the Cu/Mo multinuclear complexes[5] *((3):* trinuclear complex with trigonal-planar and tetrahedral coordination of Cu; *(2):* with central cubic skeleton; Type IV: with cage structure of two six-membered metal-sulfur rings) the MoS_4^{2-} (and $MoOS_3^{2-}$) ion functions as twofold (in *(3)*) and threefold bridging ligand (in *(2)* and Type IV). Noteworthy is that in *(2)* and Type IV three S atoms of the $MoOS_3^{2-}$ ion are each linked with two different Cu atoms, so that *one thiometalate ion* participates in a total of *six Cu—S bonds.*

Table 1. Multinuclear Mo-complexes and their properties.

Compound and Color	X-Ray Crystallographic Data	Physical Data

[a] Solid state (KBr), cm^{-1}. [b] Dimethylformamide, nm. [c] mm/s (Prof. Dr. *A. Trautwein*, Saarbrücken). [d] The Fe—Mo distance can be determined in spite of the disorder.

The great affinity of Cu cations (strong soft acids) for thiomolybdate ions (strong soft bases) is also clear from the strong tendency to form various (and structurally interesting) types of multinuclear complexes, since their formation depends only on the relative concentrations of the reaction partners (Cu: thiomolybdate: ligand). These facts, and *in vivo* experiments with molybdates, MoS_4^{2-}, sulfur-containing compounds, and Cu salts (also with radioactive Cu and Mo isotopes) on ruminants and rats[2b] indicate a participation of multinuclear thiomolybdato complexes in Cu metabolism.

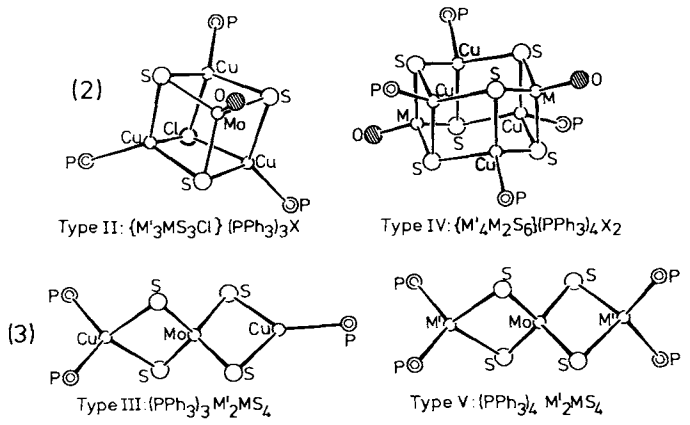

Fig. 2. Molecular structure of the multinuclear Mo complexes (Type II-IV: M' = Cu, Ag; M = Mo, W; X = O, S [5]).

Complexes containing a FeS_2Mo unit as in *(1)* are interesting because the Fe···Mo distance is comparable with that in nitrogenase (2.72 ± 0.03 Å) where the molybdenum is surrounded by three to four sulfur atoms[6]. M···M' distances of this order of magnitude (M' = 3d-metal, M = Mo, W) are found in *(1)* as well as other multinuclear thiometalato complexes containing bidentate thiometalate ligands[7]. These short distances in the four-membered ring systems $M'^{II}S_2M^{VI}$, with a large difference in the *formal* valencies of M and M', are responsible for the particular electronic properties of these systems, which have been studied in detail by us by SCCC extended Hückel calculations on *(1)* and complexes of the type $[M'(MS_4)_2]^{n-}$. These investigations gave the following qualitative results for *(1)*:

Since the Fe-3d level lies at practically the same energy as the nonbonding S-3p level, MoS_4^{2-} acts as a strong σ-donor and because of low-lying unoccupied orbitals, at the same time also as strong π-acceptor. On complex formation the electron density at the Fe center is reduced, at the Mo center it is increased in comparison to the free MoS_4^{2-} (electron delocalization Fe→Mo), and at the terminal S atoms it remains practically unchanged. Fe-Mössbauer data for *(1)* likewise prove the strong Fe→Mo electron delocalization, the tetrahedral coordination of the Fe and, in accord with the μ_{eff} values, the presence of a high-spin complex. The Fe_mS_nMo group of FeMo-co (proof of its presence: analytical composition Mo:Fe:S ≈ 1:8:6 (?)[4] and Mo-EXAFS data[6]) should, on account of the catalytic properties of the cofactor (or of the enzyme), likewise show a strong electron delocalization and easy displaceability of electron density (complexes of the type $[M'(MS_4)_2]^{n-}$ with differing electron population also exist![8]).

From the MO calculation it follows that addition reactions should be possible at the terminal S atoms owing to the high electron density. Hence, in Fe complexes the MoS_4^{2-} ligand should show multidentate and multibridging behavior resembling that in Cu complexes[9a]. It should be possible to use *(1)* as starting substance for the synthesis of a multinuclear Fe—Mo complex, since on the basis of the first finding substitution reactions can also be carried out at the chloro-ligand, and since the metal atoms are not coordinatively saturated (cf. first reports on other multinuclear Fe—Mo—S compounds[9]).

Present investigations would indicate that direct interactions between the three bio-metals Fe, Cu, and Mo (MoS_4^{2-}) are likely in biological processes (besides the well-known antagonistic Fe/Cu and Cu/Mo relationships[2b]).

Procedure

(2) [and *(3)*]: An aqueous solution (100 ml) of 0.23 g Cs_2MoOS_3 [0.21 g $(NH_4)_2MoS_4$] is extracted with a solution of 0.17 g $CuCl_2 \cdot 2H_2O$ and 0.4 g PPh_3 [0.6 g] in 25 ml CH_2Cl_2. The organic phase is separated, filtered, and covered with a mixture of 40 ml *n*-pentane [50 ml] and 20 ml acetone [10 ml]. After 2—3 d, red crystals of *(2)* separate out. Yield *ca.* 0.1 g [0.15 g red platelets of *(3)*].

(4): A filtered solution of 0.2 g $FeCl_2 \cdot 4H_2O$ and 0.4 g $[(C_6H_5CH_2)=(CH_3)_3N]Cl$ in 50 ml CH_3CN is added with stirring to a solution of 1 g $[(C_6H_5)_4P]_2MoS_4$ in 100 ml CH_3CN. The reaction mixture is filtered and treated with 80 ml diethyl ether (analytically pure). *(4)* precipitates as dark-red crystals. Yield: 0.55 g.

[5] Compounds of Type III and V are formed with tetrathio- but not with trithiomolybdate (because of the thiophilic character of, *e.g.* Cu). It is therefore remarkable and also serves as proof for the strong tendency of cage structures II and IV to be formed, that compounds of this type can be isolated with trithio- and also tetrathiometalates [*A. Müller, H. Bögge, U. Schimanski*, J. Chem. Soc. Chem. Commun. *1980*, 91; *A. Müller, H. Bögge, E. Königer-Ahlborn, ibid. 1978*, 739]. However, a compound with a composition corresponding of Type III (with $Cu^+/MoOS_3^{2-}$), but according to preliminary X-ray structure data another structure (Type VI), could be obtained. So far the Cu/Mo compounds of Type IV and V could not be isolated in pure form; however, the corresponding Cu^+/WOS_3^{2-} (Type IV) and Ag^+/MoS_4^{2-} (Type V) species could be isolated.

Handbook of Liquid Crystals. By *H. Kelker* and *R. Hatz.* Verlag Chemie, Weinheim 1980. xviii, 917 pages, bound, DM 420.00.

In recent years the field of liquid crystals has undergone a tempestuous growth, which is still by no means over. The reasons for this particular interest in the research and technology of liquid crystals lie above all in their unique electro-optical properties. Now that liquid-crystal materials with a large meso-phase region and suitable electro-optical parameters have been developed, liquid crystals have found a wide field of application in electronic displays for clocks, calculators, and measuring instruments and will shortly be used in motor vehicle instrumentation as well.

This development has been accompanied by an immense flood of publications, too many even for the expert to take in. In the light of this situation the present book emerges as a valuable aid at exactly the right time. It differs from the monographs that have appeared to date in that it deliberately does not aim at a textbook-like introduction but attempts to cover the field as completely as possible. The emphasis is thus more on the general picture than on details.

One of the authors' special concerns was to cover the literature. With its more than 8000 citations, the book is of great informative value, particularly because the titles of the publications are also included. This part is 266 pages long and constitutes by far the largest section of the book. The literature is practically complete up to and including 1976, and even covers the bulk of the papers that appeared in 1977.

The following aspects have also received closer attention: "Chemical Constitution" (Chapter 2) with a detailed (44-page) Table of Mesogens, "Behavior in Magnetic and Electric Fields" (Chapter 4), "Optical Properties" (divided into optically inactive and optically active meso-phases, Chapters 6 and 7), and finally "Nuclear Magnetic Resonance and Electron Spin Resonance Studies" (Chapter 10, by *C. Schumann*). In contrast to this, Chapter 14 on "Technical Applications" is rather short (24 pages).

Even though in a rapidly advancing field it is fundamentally impossible to give a definitive picture, the two authors have succeeded after years of research in creating a work worthy of regard. The vast wealth of collected material arranged by subject matter in this book never fails to impress. The clear layout greatly facilitates the use of the handbook: at the start of each chapter its list of contents is given once more (even the general index is preceded by a summary!). Increasingly specific subdivision leads the reader step by step to the required specialist field, so that the book is easy to use in spite of its extensive scope. All in all, an extremely valuable work that can be recommended without hesitation.

Gerhard Meier [NB 515 IE]

Metal Complexes in Organic Chemistry. By *R. P. Houghton.* Cambridge University Press, Cambridge 1979; 308 pages, bound, £ 7.50.

The present book gives a survey of metal complexes in organic chemistry. In Chapters 1 (general principles), 2 (effects and applications of complex formation), 3 (metal complexes in addition reactions), and 5 (oxidative addition and insertion) many fields of application are summarized in a synoptic arrangement. Metal-catalyzed polymerization processes have been deliberately excluded. Aside from the comments below it must be borne in mind that the book was written in 1978 and accordingly does not reflect the rapid development of the field. In addition to this, the examples seem to have been selected only from the point of view of the inorganic chemist and the materials chemist.

In Chapter 1 there is no mention of the significance of metals as couplers of π-systems. The wide range of ring closure reactions and H displacements by metalation is not dealt with. In the discussion of the difficulties of separating several effects of complex formation no mention is made of regression analysis. Furthermore, reference should surely have been made in the "General principles" to the different thermodynamic conditions within and outside the complex. In the discussion of the reaction mechanisms one would like to see a good example of the attack on complex-bound π-systems from the metal and from outside the complex.

In the discussion of the effects and applications of complex formation in Chapter 2 it should have been mentioned that the stability of complexes does not always change monotonically as the properties are changed, but can also exhibit minima or maxima. To demonstrate the wide application of metal complexes for purposes of synthesis, reference should have been made *e.g.* to the diethylzinc/Cu variants for the Simmons-Smith reduction and the metathesis reaction.

These critical remarks may serve as an illustration of the difficulties facing an author engaged in writing a book on a rapidly developing field.

Paul Heimbach [NB 514 IE]

Metal and Metalloid Amides. By *M. F. Lappert, P. P. Power, A. R. Sanger,* and *R. C. Srivastava.* John Wiley & Sons, Chichester 1980. 847 pages, bound, £ 50.00.

This compact but highly informative book is the first to present a comprehensive inventory of the field. Up to now the number and the significance of compounds with the ligands NR^1R^2 (and also their oligomers and polymers) have only been the subject of summaries in extract or synoptic form, and complete documentation of the above amides, which have grown tremendously in number of the last 25 years, has been long overdue.

To restrict the scope of the work to reasonable limits, compounds with macrocyclic ligands and amides of the nonmetals have been excluded from the discussion of the element amides, whereas the data on the amides of phosphorus, silicon, and boron and on ionic amides such as $M^+NH_2^-$ have been kept very concise. Three-quarters of the contents (eight chapters) are dedicated to the synthesis, the structure, and the physical properties of the metal amides; in the last quarter typical reactions are discussed over nine chapters. Because of its systematization, it is precisely this section that exhibits the advantages of a comprehensive discussion of all metal and metalloid amides, and will prove particularly useful and stimulating for those engaged in active research. Thus, in addition to inclusion, protolysis, reactions with hydrides, exchange, and dehydrochlorination reactions as well as Lewis base and Lewis acid reactions, there is a discussion of applications such as polymerization catalysis.

The larger, reference-type first part, set out mainly in the form of tables, is divided into chapters on amides of elements in the 1st, 2nd, 3rd, and 4th main groups (except carbon), amides of phosphorus, arsenic, antimony, and bismuth and amides of the transition elements. The sections on amides of elements in the 3rd and 4th main groups and on phosphorus

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0808-0656 $ 02.50/0

amides occupy, corresponding to the importance of these, more than half of the book; a more far-reaching selection would have made it possible to shorten the work by 100—200 pages. Similarly, the structures have not always been reproduced in the most economical manner, as in Fig. 16, page 495, in comparison with Fig. 4, page 248.

However, criticism of the book is unjustified. Rather, the authors deserve thanks and an acknowledgement of their competent description of an important field of molecular chemistry. Points worthy of emphasis are the well-balanced arrangement and the painstaking care that can be perceived even in minor details such as of umlauts. The book finishes with a brief subject index and a 60-page author index covering some 2500 literature citations up to and including 1978. It can be recommended not only to chemists working on amides and to libraries, but also—in spite of its price—to all inorganic and organic chemists and to polymer and structure chemists who want reliable information on a relatively uniform "inter-disciplinary" class of substances.

Hans Bürger [NB 517 IE]

Macromolecules. An Introduction to Polymer Science. Edited by *F. A. Bovey* and *F. H. Winslow.* Academic Press, New York 1979. xiii, 549 pages, bound, $ 39.50.

This is a new textbook compiled from an introductory course for polymer scientists at the Bell Laboratories, Murray Hill, N. J. offering a short but understandable review of the current state of the field.

Following a brief introduction (in which reference is already made to such problems as tacticity and mechanical properties), which also contains a very interesting excursion into the history of polymers, Chapter 2 "Formation of Macromolecules" deals with the most important reactions giving rise to macromolecules. Some important aspects of the reaction kinetics are discussed in each case. The section on copolymerization kinetics deserves special emphasis. Chapter 3 is concerned with the clarification of the structure of polymers by means of physical methods, but here it is assumed that the reader is familiar with the basic principles of IR and NMR spectroscopy. The influence of geometric isomerism on the spectra is explained for some well-chosen examples. At this point the authors also discuss in comprehensible language the problems of chain statistics. Chapter 4 considers the thermodynamics of polymer solutions and methods of molecular-weight determination. The mathematics are restricted to essentials and there are no confusing calculations. Morphological aspects of macromolecules, their physical characteristics such as viscoelasticity, amorphous and crystalline polymers, and transport in polymers are the subjects of Chapters 5 and 6. On the subject of polymer reactions the editors regrettably restrict themselves to degradation and cross-linking. The introduction of functional groups into polymers is not dealt with, but it would be desirable to include a section on this topic in a new edition. The work is rounded off with a chapter on biological macromolecules and their significance. Every chapter contains a collection of well-chosen literature references which provide the reader with rapid entry into the original literature. In a second edition it would be desirable to give the data in SI units.

The book can be recommended to any reader interested in polymer science. It represents a valuable and reasonably priced addition to the reference library of any polymer scientist.

Structure and Function of the Energy-Converting System of Mitochondria

By Gebhard von Jagow and Wolf Dieter Engel[*]

Dedicated to Professor Otto H. Wieland on the occasion of his 60th birthday

The main energy source for all endergonic processes occurring in living organisms is the phosphate bond energy of nucleoside triphosphates, especially adenosine triphosphate (ATP). In aerobic organisms, as for instance in mammals, more than 90% of ATP is formed during the process called oxidative phosphorylation. In this process, similar to that of muscle contraction and nerve excitation, nature works with vectorial processes taking place at a membrane separating distinct spaces from each other. The present article deals with the operation of a set of water-insoluble membrane proteins and enzymes vectorially transporting electrons, protons and other ions, which finally leads to the formation of ATP. This machinery transforming substrate oxidation energy into chemical energy in the form of the phosphoric anhydride bond of ATP operates with a very high efficiency.

The structure and function of the machinery of mitochondrial oxidative phosphorylation are described. It consists of the electron transfer chain, the ATP-synthetase, the adenine nucleotide translocase and the phosphate carrier. The electron transfer chain can be resolved into multiprotein complexes—at three of them energy conversion takes place—and into the electron carriers ubiquinone and cytochrome c. The substrate oxidation energy is converted into the chemical energy of ATP with an electrochemical proton gradient as intermediary form. The energetic aspects of the processes are analyzed by linear irreversible thermodynamics. Great success has been gained during the past few years on the structural characterization of the participating proteins. The function of the various systems is partially elucidated on the molecular level; this concerns especially the mechanism of proton and adenine nucleotide translocation, as well as ATP formation.

1. Introduction

The interaction of the enzymes involved in oxidative phosphorylation is treated on the basis of the chemiosmotic theory[1,2], which may be applied to interpret not only the energy-converting processes in the mitochondrion, but also in bacteria, algae and green plants[3–6]. The theory postulates a proton gradient at the inner mitochondrial membrane as an intermediary form of energy[7]. It should be mentioned, however, that there exists some reservation with respect to the free release of protons. There may exist microspaces at the inner mitochondrial membrane which may prevent such a free proton release[8]. The article will show that the main part of the protons is transported across the membrane by proton pumps.

Recent and former results have gained new meaning by their interpretation with the aid of irreversible thermodynamics[9,10].

The proton/electron stoichiometries that have been under discussion since the development of the chemiosmotic hypothesis 20 years ago[1] are now thoroughly analyzed and agree with the thermodynamic requirements. The number of protons transported across the inner mitochondrial membrane per electron transferred from substrate to oxygen, as well as that of protons consumed per ATP synthesized, are twice as high as reported previously[11,12]. Previous data proved false, since the proton consumption of the phosphate:proton co-transporter was not taken into account.

In the present description of the mitochondrial machinery of energy conversion, particular attention has been paid to the multitude of new results concerning the structure of the participating enzymes, most of which are multiprotein complexes.

2. The Mitochondrion

The machinery for the conversion of substrate oxidation energy into chemical energy in the form of adenosine triphosphate (ATP) is located in the mitochondrion, an organelle of most eukaryotic cells. The mitochondrion possesses two membranes, the outer membrane and the inner membrane (Fig. 1). The outer membrane, which is freely permeable to molecules with molecular weights of up to several thousands[13], encloses the organelle. This membrane is of minor importance for the mechanism of energy conversion; it is therefore not further discussed in this article. The inner mitochondrial membrane, impermeable to most metabolites, is folded into cristae mitochondriales in order to enlarge its surface. This membrane contains the enzymes of oxidative phosphorylation. Furthermore, the inner membrane contains a multitude of proteins which are embedded in the phospholipid bilayer, so-called integral membrane proteins, for instance the acyl-CoA dehydrogenase[14], the α-glycerophosphate dehydrogenase[15], the β-hydroxybutyrate dehydrogenase[16], and the energy-dependent pyridine nucleotide transhydrogenase[17,18,19]. In addition, as it is impermeable to mono- or multivalent ions, the inner membrane contains numerous transport systems[20]. Furnished with all these systems, the inner membrane has an exceptionally high content of proteins (>70%). The lipids of the inner membrane consist almost entirely of phosphatidylcholine, phosphatidylethanolamine and diphosphatidylglycerol. In contrast to most eukaryotic membranes, the inner mitochondrial membrane contains no cholesterol.

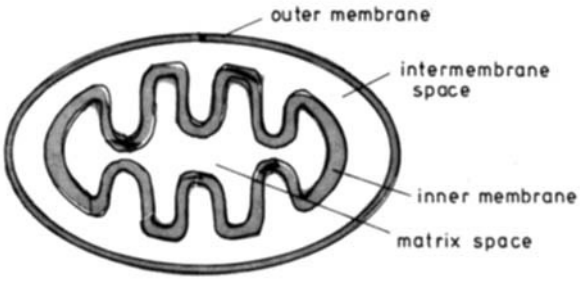

Fig. 1. Schematic diagram of the structure of the mitochondrion.

The two membranes delimit two spaces. The inner membrane surrounds the matrix space, between the two membranes lies the intermembrane space. The outer membrane separates the mitochondrion from the cytosol of the cell. For discussion of the process of energy conversion only the two terms 'matrix space' and 'cytosolic space' will be used here. The localization of the various enzymes, the metabolism, and the metabolic interactions of the mitochondrial compartments have been treated extensively in recent reviews[21,22].

3. The Electron Transfer Chain

In accordance with its structural and functional aspects, the mitochondrial electron transfer chain can be resolved into multiprotein complexes which are linked by the electron carriers ubiquinone and cytochrome c[23,24]. Each complex crosses the phospholipid bilayer[25]. The relatively small mobile ubiquinone molecule, situated in the phospholipid phase, presumably undergoes a transverse movement from one to the other face of the membrane[26]. Cytochrome c, finally, is a peripheral membrane protein located at the cytoplasmic face, where it is probably subject to lateral diffusion and rotational movement[27]. The four complexes of the respiratory chain are traditionally indicated by the roman numerals I—IV.

3.1. Complex I (NADH:Ubiquinone Oxidoreductase)

The NADH:ubiquinone oxidoreductase is the complex of the respiratory chain about which the least information has been gained so far. In contrast to the values of the other three complexes, an unusually high number of 16—18 polypeptides has been reported for complex I (Table 1)[28–30]. This, as well as enzymatically measurable contaminations, indicate that some foreign proteins, for instance the pyridine nucleotide-transhydrogenase[29,31], are present in the complexes isolated so far. As redox centers the complex carries a non-covalently bound flavin mononucleotide (FMN) and various non-heme iron centers (Fig. 2). By means of EPR studies seven different iron-sulfur centers have been identified[32], but the association of some of these centers with complex I is not generally accepted[33]. The exact arrangement of the FMN and the iron-sulfur centers is still unknown. From a content of 1.5 μmoles FMN/g protein for the purest preparation a minimum molecular weight of 670000 can be calculated. This represents a molecular weight about three times larger than that of the minimum units of the other complexes.

Complex I is the entry port for the redox equivalents of NADH, produced mainly in the course of the nutrient oxidation, as given in equation (1) (S = substrate):

$$SH_2 + NAD^{\oplus} \rightarrow S + NADH + H^{\oplus} \quad (1)$$

The electron transfer from NADH to ubiquinone is coupled to a proton translocation across the membrane, as has been shown for mitochondria[34] and submitochondrial particles[35], as well as for complex I incorporated into phospho-

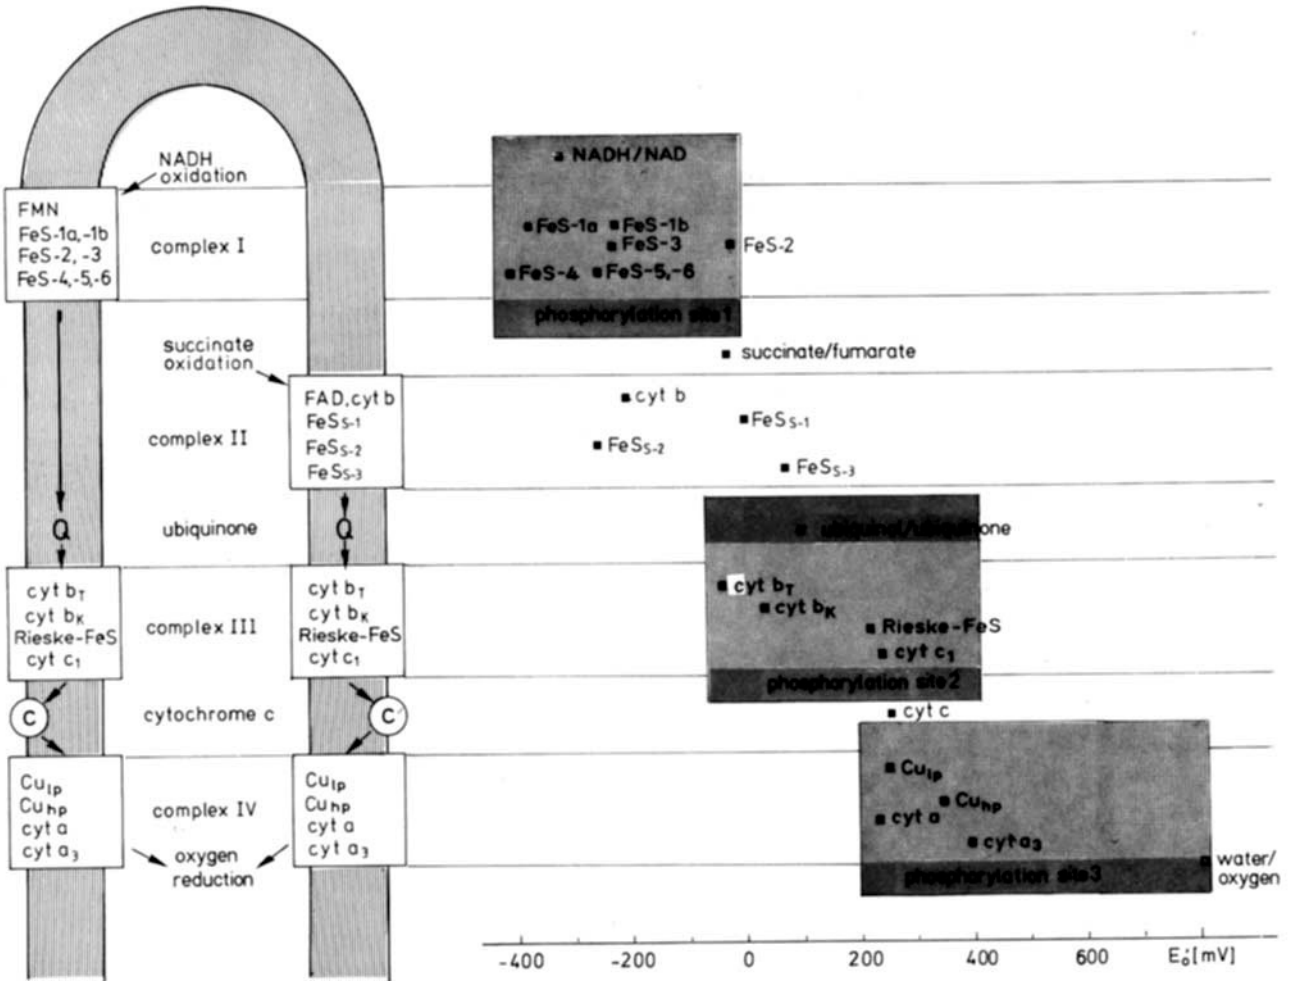

Fig. 2. Schematic representation of the arrangement and electrochemical connection of the four electron-transferring complexes within the inner mitochondrial membrane. On the left side of the membrane the connection between complex I and complexes III and IV is pointed out, on the right side of the membrane the connection between complex II and complexes III and IV. Complexes I and III, as well as complexes II and III are connected by ubiquinone (Q); complexes III and IV are connected by cytochrome c (C). The diagram on the right-hand side of the figure depicts the half-reduction potentials (E_0') of the redox components at pH 7.0. In order to calculate the free energy of the various redox steps the actual redox potentials had to be given, which, of course, depend on the respective energetic state. The deviations, however, generally do not amount to more than 50—100 mV. The subscripts lp and hp denote low and high potential, respectively.

lipid vesicles[36]. The protons are translocated from matrix to cytosolic space with a stoichiometry of $4H^{\oplus}/1$ NADH oxidized, corresponding to $4H^{\oplus}/2e^{\ominus}$ transferred to ubiquinone (Fig. 3)[7]. Hence the enzymatic activity of complex I can be defined by equation (2), where the transported protons are italicized. The function of the two hydrogen atoms taken up in the course of ubiquinone (Q) reduction is discussed in Section 3.4.

$$NADH + H^{\oplus} + Q + 4H^{\oplus}_{in} \rightarrow NAD^{\oplus} + QH_2 + 4H^{\oplus}_{out} \quad (2)$$

The mechanism of the proton translocation at site 1 of energy conservation is not yet elucidated. In the first version of the chemiosmotic theory a hydrogen transport *via* FMN was assumed[1]. This type of mechanism would represent a vectorial hydrogen movement through the membrane connected with a $2H^{\oplus}/2e^{\ominus}$ release upon oxidation of $FMNH_2$. Since now a $4H^{\oplus}/2e^{\ominus}$ stoichiometry seems to be established for site 1, however, another type of mechanism must be involved in proton translocation responsible for the missing two protons or perhaps for all four protons (if FMN is not involved in the process of translocation). Two mechanisms have been suggested so far: i) A ubiquinone radical mechanism, in which a protein-bound ubiquinone would connect iron-sulfur centers FeS-1 and FeS-2[3]; during the uptake of $1e^{\ominus}$ by this ubiquinone from FeS-1, $1H^{\oplus}$ would be taken up from the matrix side, yielding ubisemiquinone $QH^{\odot}$; on oxidation at FeS-2, this $H^{\oplus}$ would be released to the cytosolic side. ii) in contrast to a ubiquinone-mediated proton transfer, a pump mechanism[37] could translocate not only the missing two protons if FMN is involved in proton translocation, but also all four protons, without any further mechanism. Such a proton pump mechanism will be discussed in Section 3.4.

3.2. Complex II (Succinate:Ubiquinone Oxidoreductase)

The second multiprotein complex, transferring redox equivalents onto ubiquinone, is the succinate:ubiquinone oxidoreductase. The smallest possible unit consists of only four protein subunits[38] (Table 1). The redox centers are formed by one covalently bound flavin adenine dinucleotide (FAD), one heme b, and three non-heme iron centers (Fig. 2)[39]. The polypeptide of molecular weight 70000 carries the FAD which is bound to the N-3 of a histidyl residue by its C-8 methyl group[40,41]. The two iron-sulfur centers, FeS_{s-1} and

FeS_{s-2}, which are Fe_2S_2-type centers[42], are also on the largest subunit, whereas the third iron-sulfur center, FeS_{s-3}, which is a Fe_4S_4-type iron-sulfur protein[43], is present in the 27000 subunit[44]. The heme b center can presumably be ascribed to the polypeptide of molecular weight 15000. The minimum molecular weight of complex II amounts to 125000, assuming the presence of one specimen of each polypeptide subunit.

ferred to as succinate dehydrogenase, a term normally used for the whole enzyme as component of the citric acid cycle. The subcomplex cannot transfer electrons from succinate to ubiquinone, but only onto artificial electron acceptors, for instance *N*-methylphenazonium methyl sulfate. The lipophilic subcomplex consists of the two smaller polypeptides; it has been suggested that one of these smaller subunits carries a ubiquinone-binding site[48-51] (see also Section 3.3).

Table 1. Molecular weight, polypeptide and prosthetic group composition of complexes I—V from beef heart mitochondria.

Complex	Molecular weight per min. unit	Number of subunits	Molecular weight of subunits ($\times 10^3$)	Name or assignment of subunits	Content of prosthetic groups [μmol/g]

[a] DCCD = dicyclohexylcarbodiimide.

The sequence of the redox centers in the path of electron flow is only partially understood so far. The function of the heme b center is not yet quite clear either. The measured half-reduction potential of -200 mV[45] is far too negative to indicate an involvement in the path of the electron flow from succinate to ubiquinone. Therefore it has been argued that cytochrome b may be involved in special metabolic pathways, or may possess regulatory functions on the rate of electron flow[46]. The same applies to the FeS_{s-2} center.

Complex II can be dissociated by means of chaotropic agents, for instance $ClO_4^{\ominus}$, into two subcomplexes[47]. The water-soluble part obtained consists of the two large polypeptides (70000 and 27000). Erroneously this part has been re-

The electron flow from succinate to ubiquinone is not connected with a vectorial proton transport, therefore this part of the respiratory chain does not contribute to the process of energy conversion, but it channels reducing equivalents from a reduced substrate (succinate) to Q (ubiquinone), as do other enzymes. The catalytic activity of complex II can therefore be summarized by the simple reaction equation (3):

$$\text{succinate} + Q \rightarrow \text{fumarate} + QH_2 \qquad (3)$$

Complex II is subject to a regulatory mechanism[52]. There exist at least two forms of the enzyme. The inactive form is stabilized by oxaloacetate, which is tightly bound to the com-

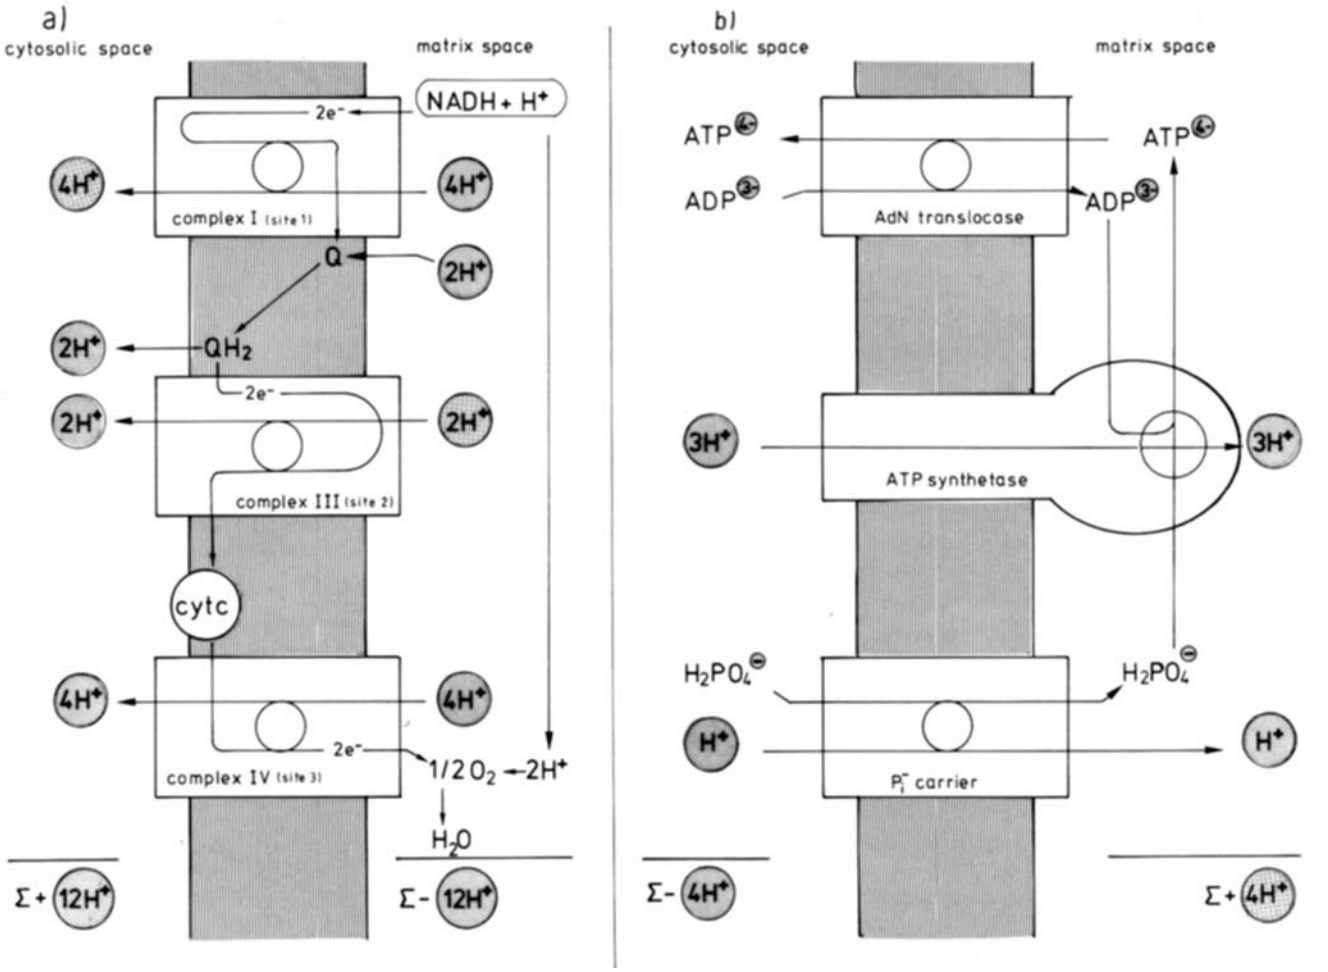

Fig. 3. Schematic representation of the creation and consumption of the proton gradient during oxidative phosphorylation. a) Electrogenic proton movement established by complexes I, III, IV and ubiquinone during transfer of $2e^{\ominus}$ from NADH to oxygen. The shaded area indicates the inner mitochondrial membrane. The complexes are depicted as horizontal rectangles 'plugged' through the membrane; b) Proton back-flow taking place during formation of one molecule of ATP. The charge imbalance of the adenine nucleotide transport is balanced by the positive charge remaining at the cytosolic face during neutral phosphate $H^{\oplus}$ cotransport.

plex in a 1:1 stoichiometry[53,54]. The enzyme can be converted into the active form by incubation with activating ligands, such as some dicarboxylic acids[55], some anions like perchlorate, nitrate, or bromide[56,57], as well as ATP[58], ubiquinol[59], or succinyl-CoA[60]. One striking difference between the active and the inactive form is seen in the half-reduction potential of FAD. It changes from about 0 mV to less than -190 mV when the enzyme is converted from the active into the inactive form. This diminution is explained in terms of a conformational change: the planar oxidized flavin assumes a bent configuration reminiscent of the reduced flavin[52]. No data are available so far for the cytochrome b subunit and the FeS_{s-2} iron-sulfur center, which may show a similar behavior. Complex II is very sensitive to SH-blocking agents; the reactive SH-groups can be protected by substrates and competitive inhibitors[61].

3.3. Ubiquinone

Ubiquinones are derivatives of 2,3-dimethoxy-5-methyl-1,4-benzoquinone, substituted at C-6 with isoprenoid side chains comprising 6—10 isoprene units (Fig. 4). The length of the side chain depends on the species; mammalian ubiquinone, for instance, possesses a side chain of 10 isoprene units[62], whereas that of baker's yeast possesses a side chain of only 6 isoprene units[63]. The highly lipophilic molecules are integral membrane components, occurring in about 10-fold molar excess over complex III[64,65]. In order to visualize the mechanism of ubiquinone action, which is still under discussion, some introductory remarks are necessary.

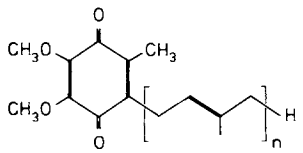

Fig. 4. Oxidized form of ubiquinone (Q); $n = 6$—10. Q-6 is present in some microorganisms, Q-10 in mitochondria of mammals.

Although ubiquinones are very small molecules compared with other redox components (proteins) of the respiratory chain, the length of about 5.5 nm for one fully extended ubiquinone-10 molecule suffices to span a phospholipid bilayer with a diameter of about 6.0 nm (cf. Fig. 5). Two possibilities of orientation seem to exist for ubiquinone in the membrane, *i.e.* either an arrangement perpendicular to the plane of the membrane, or one parallel to the plane of the membrane[66]. A perpendicular orientation would imply that the ubiquinone molecule spans the membrane, its quinone ring ex-

posed to one surface of the membrane. A lateral movement of the molecule would be possible in this case, but a flip-flop of the molecule, bringing the quinone ring from one to the other face of the membrane, would be hindered due to its high activation energy[67]. The second possibility, a planar arrangement in the middle of the membrane at the interface of the two phospholipid layers, would cause an inaccessibility of the ubiquinone molecule for hydrophilic compounds.

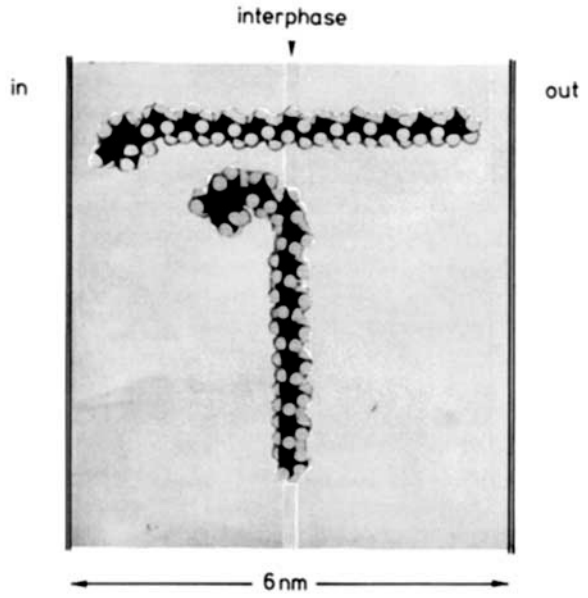

Fig. 5. Hypothetical arrangement of ubiquinone-10 (Q-10) in the inner mitochondrial membrane, demonstrated by the lower ubiquinone molecule. Q-10 is arranged with the main part of its isoprene side chain along the interphase of the phospholipid bilayer of the mitochondrial membrane, but with the head region and the first two isoprene units perpendicular to the plane of the membrane due to a kink of about 90° in the side chain. The respective reaction centers arranged at opposite faces of the membrane are reached by an 'anchor-facilitated flip-flop mechanism' as discussed in the text.

Both conceptions of arrangement are supported as well as questioned by experimental results. In one set of experiments the quinone ring, when placed in the mitochondrial membrane, was found to be inaccessible to hydrophilic compounds such as dithiothreitol, irrespective of the side of attack; in other experiments, ubiquinone was found to be accessible, as demonstrated by the reduction of ferricyanide, trapped in phospholipid vesicles, by external dithionite. In these experiments, the reduction was mediated by both short and long chain ubiquinones[68], but with remarkable kinetic differences depending on the length of the isoprenoid side chains. Thus, ubiquinone-9 catalyzed the reduction of ferricyanide considerably faster than ubiquinone-1, but the activation energy required was much higher for the long-chain than for the short-chain ubiquinone-mediated reaction. An involvement of the double bonds in the reaction was excluded by experiments with ubiquinone-9 analogs carrying a saturated side chain, which behaved similarly to ubiquinone-9[68].

The contradictory results concerning the accessibility of ubiquinone embedded in the membrane for polar reducing agents may be due to a different composition of the membranes under study (*i.e.* mitochondrial membranes having a high content of negatively charged cardiolipin and more than 70% protein content versus phospholipid vesicles consisting of neutral phosphatidylcholine). The different curvatures of the investigated membranes affecting packing of the molecules may also have influenced the results.

A more direct approach in studying the localization of ubiquinone in the membrane has been undertaken by tracing the quenching of a fluorescent probe (12-(9-anthroyl)-stearic acid) penetrating the membrane to a depth of 1.4 nm[69]. The quenching was ascribed to the presence of the ubiquinone ring at this region of the membrane.

The arrangement of the lower molecule in Figure 5 represents our own present view on the orientation of ubiquinone in the membrane. It combines the two types of orientation discussed above. Long-chain ubiquinones are arranged with the main part of the isoprene side chain along the interphase of the phospholipid bilayer, but with the head region plus the first two isoprene units perpendicular to the plane of the membrane. The penetration of the quinone head into the phospholipid layer is made possible by a kink of the side chain between the second and the third isoprene units, as demonstrated by the space-filling model shown in Figure 5. According to this arrangement, the transfer of redox equivalents from one to the other side of the membrane is made possible by a rotation of the head region around the axis of the tail region of ubiquinone situated in the interphase of the membrane. This movement may be defined as an 'anchor-facilitated flip-flop mechanism'.

Ubiquinones with less than three isoprene units probably simply diffuse through the membrane so that a transfer of redox equivalents is established, a process which obviously requires less activation energy than the proposed facilitated flip-flop mechanism. The higher rate of reduction of ferricyanide by long-chain ubiquinones than by short-chain ubiquinones may be due to a definite fixation of the ubiquinone tail in the interphase region, inducing a more successful collision of the ubiquinone head with the appropriate reaction center.

Several mechanisms have been proposed to explain the function of ubiquinone in the respiratory chain. Without any doubt ubiquinone acts as a coenzyme that transfers reducing equivalents from complexes I and II, as well as from several other dehydrogenases to complex III (Figs. 2 and 3).

Many experimental results have led to the postulate that the main part of ubiquinone forms a homogeneous redox pool connecting the individual dehydrogenases with complex III[70,71]. In contrast to this view there is a recent accumulation of experimental findings which indicate that, besides this class of ubiquinone, a second class of ubiquinone exists, namely a protein-bound ubiquinone. Recent results, for instance, suggest that complexes I and III can combine to a single unit transferring electrons from NADH to cytochrome c. Less than three ubiquinone molecules per unit have been shown to suffice for near-maximum activity[72]. Using excess of phospholipids and ubiquinone, a pool behavior of ubiquinone was restored[73], which was explained by frequent dissociation-reaggregation of the complex I-III-unit, rather than by the existence of a ubiquinone pool transporting the redox equivalents between the various complexes. From a kinetic point of view, a redox-connection by the ubiquinone pool seems more probable than the proposed aggregation process, which would need a proper arrangement of huge complexes.

An analogous unit (a kind of 'supercomplex'), consisting of complexes II and III, has been described recently[74].

From recent EPR studies it has been concluded that a ubisemiquinone pair exists with the oxygen-oxygen axis perpendicular to the plane of the membrane[51]. So far, this type of orientation as well as the functioning of semiquinones seem to be unlikely, unless a stabilization of the radical species by a protein moiety takes place. The 15000 subunit of complex II, supposed to be a ubiquinone binding protein, could perhaps play such a role[48].

The involvement of ubiquinone in proton translocation has not yet been fully clarified. As originally proposed[2], it may act as a hydrogen carrier across the membrane (Fig. 6).

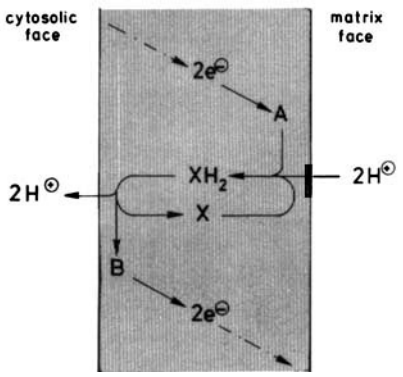

Fig. 6. Schematic diagram of a redox loop mechanism working with a $2H^{\oplus}/2e^{\ominus}$ stoichiometry. The mobile hydrogen-transferring component X accepts at a reaction center A (situated at the matrix side of the membrane) two electrons and two protons from the matrix space; XH_2 donates to the reaction center B (situated at the cytosolic side of the membrane) two electrons and releases two protons into the cytosolic space. In the case of the ubiquinone loop, X = ubiquinone.

During this process, defined as a redox loop mechanism, ubiquinone (X) is reduced at the active center of redox component A on the matrix face. The reduction is accompanied by an uptake of two protons. After ubiquinol (XH_2) migration across the membrane, it is oxidized at the redox center of component B on the cytosolic face, associated with a release of two protons; the two electrons are subsequently transferred onto the next electron acceptor. Judging from chloroplast studies, it seems likely that the proposed mechanism exists in nature[11].

3.4. Complex III (Ubiquinol:Cytochrome c Oxidoreductase

Complex III transfers the redox equivalents from ubiquinol onto cytochrome c. Its smallest possible unit is composed of 8—9 polypeptides (Table 1)[46,75,76]. The two largest polypeptides with molecular weights of 49000 and 47000 are traditionally called 'core proteins'[77]. Although they do not carry redox centers, they probably have a function besides a structural one, as discussed below. The four polypeptides of intermediate molecular weight all possess a redox center. They consist of two cytochromes b with a molecular weight of 30000 each[78,79], the Rieske iron-sulfur protein, a Fe_2S_2-type protein with a molecular weight of 25000[80,81] and, finally, cytochrome c_1 with a molecular weight of 29000[82] (Fig. 2). The remaining two to three polypeptides are small molecules with molecular weights of about 12000, 11000 and 8000, containing no redox centers[76]. The function of the four to five polypeptides without redox centers has not been elucidated so far, although they constitute half of the mass of the complex. The cytochrome b molecules of complex III are coded for on mitochondrial DNA[83], whereas the remaining polypeptides are coded for on nuclear genes[84]. In contrast, the gene of cytochrome b of complex II is found in the nuclear DNA[85].

Adding up the molecular weights of the individual polypeptides and assuming two heme b and one heme c per complex, an apparent molecular weight of 250000 is calculated for the smallest possible unit. However, when the complex is isolated in the presence of mild detergents and studied by gel chromatography and ultracentrifugation, it behaves as a molecule of molecular weight 500000[86]. It has therefore been speculated that this 2×250000 complex (involving four cytochromes b, two iron-sulfur proteins and two cytochromes c_1) represents the functional structure of the complex existing in the mitochondrial membrane[86]. The same quaternary structure also emerged in recent electron micrographic studies obtained from 'two-dimensional crystals' formed by the isolated complex inlayed in a phospholipid bilayer[87]. The molecules of molecular weight 500000 are arranged in an up-and-down manner in the crystal lattice. The gross architecture of the molecule has been derived from final reconstruction of the image-processed ultramicrographs (Fig. 7). A good third of the dimer protrudes above the inner surface and about one quarter above the outer surface of the phospholipid bilayer. The halves of the dimeric complex are in contact with each other within the interior of the phospholipid bilayer. The contact surfaces are probably formed by the four cytochrome b subunits. Thus the possibility arises that the four cytochromes b of the complex III dimer function cooperatively as a tetramer in the process of energy transformation *(vide infra)*.

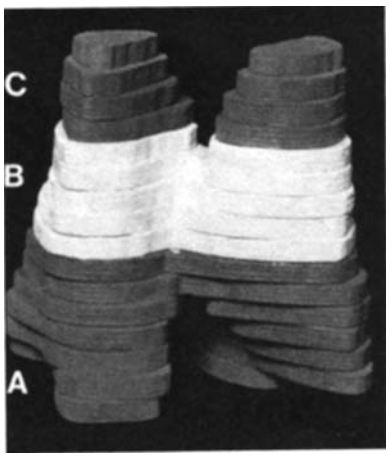

Fig. 7. Model of the gross structure of a single dimer of complex III, with the dimer axis running from top to bottom (by courtesy of *K. R. Leonard* and *H. Weiss*, unpublished). The white region (B) is the part of the complex embedded in the membrane. The upper dark region (C) extends into the cytosol, the lower dark region (A) into the matrix space.

The sequence of the redox components in the path of electron flow is not yet quite clear. The following arrangement is proposed: ubiquinone, two cytochrome b molecules, iron-sulfur protein, cytochrome c_1, cytochrome c[46].

One crucial point giving rise to many questions pertains to the complicated arrangement of the two or four cytochrome b molecules. These molecules show two different absorbance spectra and half-reduction potentials, as well as an intricate kinetic behavior[46,81,88]. From these findings the existence of two different molecular entities has been suggested[89]. However, genetic and DNA sequence studies revealed only one single structural gene coding for cytochrome b of complex III[90,91,92]. In addition, the partial amino acid sequence analysis, including the amino and carboxyl terminals of the peptide, offered no indication of the existence of heterogeneous monomers[79]. In a model published recently, a homodimer was assumed. The functional differences of the cytochrome b molecules have therefore been explained by a cooperative interaction[37].

Complex III accepts the redox equivalents from ubiquinol, which is reduced by complexes I or II and by some other dehydrogenases *(vide supra)*, and transfers them onto cytochrome c. A large difference in the half-reduction potentials occurs between cytochromes b and the iron-sulfur protein; accordingly, this part of the complex was attributed to energy conversion site 2 (Fig. 2).

The electron transfer through complex III is coupled with proton translocation resultung in a $4H^{\oplus}/2e^{\ominus}$ net yield, analogous to the situation existing in complex I (Fig. 3)[7,93]. Thus the overall reaction of complex III can be summarized as:

$$QH_2 + 2\,\text{cyt.}\,c^{3\oplus} + 2H_{in}^{\oplus} \rightarrow Q + 2\,\text{cyt.}\,c^{2\oplus} + 4H_{out}^{\oplus} \qquad (4)$$

The mechanism of the vectorial proton movement is still being studied. As described in Section 3.3, a proton-motive ubiquinone loop could only transport half of the protons. Alternatively, a ubiquinone cycle mechanism has been considered (Fig. 8)[94,95]. It is characterized by a back-flow of one electron (dashed line), thus doubling the $H^{\oplus}/e^{\ominus}$ stoichiometry. The cycle starts with a reduction of ubiquinone by one electron from cytochrome b of complex III, accompanied by an uptake of one $H^{\oplus}$ from the matrix side (Reaction 1). Subsequently the semiquinone radical $QH^{\ominus}$ is reduced by a further electron supplied from an iron-sulfur center of complex I or complex II, accompanied by an uptake of a second $H^{\oplus}$ from the matrix side (Reaction 2). After its migration across the membrane, ubiquinol is reoxidized by complex III, releasing two $H^{\oplus}$ to be cytosolic side. One electron flows to cytochrome b (Reaction 3), where it is required for the reduction of the next ubiquinone molecule. The second electron is fed into the Rieske iron-sulfur protein of complex III, finally reducing cytochrome c (Reaction 4). The mechanism involves two ubiquinone radicals as intermediary states. The occurrence of the radical acting between reactions 3 and 4 is feasible, since it may be stabilized at a common reaction center. However, the radical occurring as product of reaction 1 has to move from complex III to complexes I or II. Due to the low stability of this species, this radical migration is hardly imaginable, if one does not assume a structural association of the two complexes. Therefore, it is worthwhile to deliberate whether additionally, or alternatively, to the proton transfer *via* a ubiquinone loop, protons may be pumped across the membrane by means of a proton translocator. The cytochrome b molecules of complex III suitably act as proton translocator[37,96].

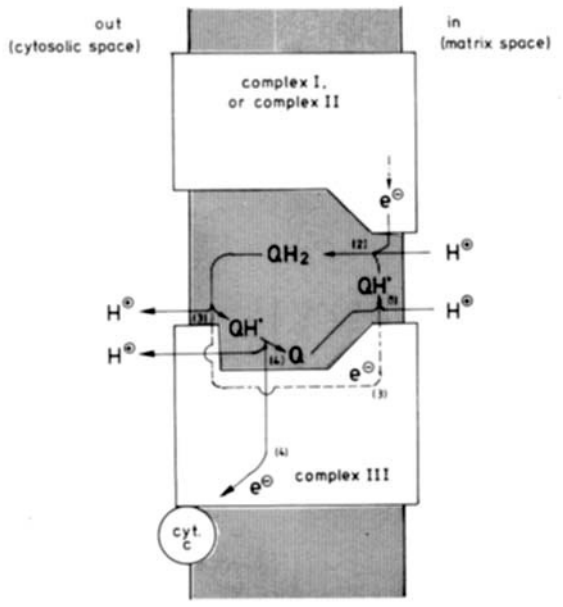

Fig. 8. Hypothetical scheme of the ubiquinone cycle working with a $4H^{\oplus}/2e^{\ominus}$ stoichiometry. The sequence of the reactions and sites of the reaction centers are described in the text.

Cytochrome b undergoes a protonation:deprotonation reaction in dependence of its state of reduction (Fig. 9). From an analysis of published redox titrations[97,98] it has been deduced that at physiological pH the protonation reaction 1 of group R precedes the reduction reaction 2 of the heme center. The cycle consists of a symmetrical sequence, since the oxidation reaction 4 precedes the deprotonation reaction 5. Reactions 3 and 6 represent changes in the conformation of cytochrome b. During reaction 3 the amino acid residue R is transferred from a matrix position, *i. e.* inner position, to a cytosolic, *i. e.* outer position. Reaction 6 represents the return of group R to its original position. It has been calculated that group R has a pK of 6.9 if the heme center is oxidized and a pK >8.5 if the heme center is reduced[37]. According to the symmetric reaction sequence, protonation and deprotonation occur on both sides of the membrane with a pK value of 6.9. At the inner position the change in pK (6.9 to >8.5 due to reduction) stabilizes the protonated state of R during translocation (Reaction 3); at the outer position the change in pK (>8.5 to 6.9 due to oxidation) facilitates the release of $H^{\oplus}$ to the cytosolic face. A reversal of the reaction sequence can be experimentally induced by a high phosphorylation potential ($[ATP]/([ADP]\cdot[P_i])$). The electrons flow in reverse direction in the electron transfer chain in this process, which is driven by a proton gradient built up by the reverse reaction of the ATP synthetase, *i. e.* the ATPase activity (cf. Section 4).

The model presented here of the cytochrome b proton pump implies that the main prerequisite for a redox component, enabling it to act as a proton translocator, is its intrinsic ability to undergo conformational changes in accordance with the redox changes of its metal center. In the case of cytochrome b, the heme center undergoes a change from the ferric to the ferrous state, which is supposed to cause a conformational change that involves a shift of an amino acid residue, R, (*e. g.* histidine). In dependence on the redox state of the heme center, the shifting residue undergoes a pK change

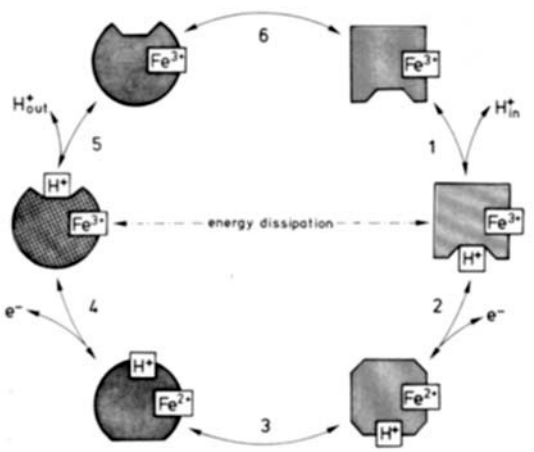

Fig. 9. Hypothetical scheme of the reaction sequence of cytochrome b acting as a proton translocator with a $2H^{\oplus}/2e^{\ominus}$ stoichiometry. The angular conformations indicate group R (which undergoes protonation) as situated on the matrix side; the circular conformations indicate group R (which undergoes deprotonation) as situated on the cytosolic side. Reduction of cytochrome b leads to a change in the pK of group R from 6.9 to about 8.5 as indicated by the closed conformation of the respective proton-binding sites. The dotted arrow indicates the possibility of a non-productive transition, which presumably occurs to only a small extent (see text).

which facilitates the process of proton translocation. An analogous model was proposed for cytochrome oxidase[99] acting as a proton pump.

The shift of the amino acid residue R across probably only a few tenths of a nm would suffice to cover a distance between two proton channels establishing the connection to the matrix and cytosolic faces of the membrane[100]. These proton channels may be formed by an α-helical structure[101] of the proton translocator (cytochrome b) arranged perpendicularly to the plane of the membrane, or, additionally by α-helical structures of adjacent polypeptide subunits, for instance the core proteins. In contrast to a conceivable shift of a group R due to a proton back-flow which may take place at the proton-driven ATP-synthetase[102], the movement of $RH^{\oplus}$ of the proton translocator occurs against a proton gradient and membrane potential, driven by the substrate oxidation energy.

The question arises whether the non-productive transition from $(Cyt\,b^{3}H^{\oplus})_{out}$ to $(Cyt\,b^{3\oplus}H^{\oplus})_{in}$ (indicated by the dotted line in Figure 9) takes place, diminishing the $2H^{\oplus}/2e^{\ominus}$ stoichiometry. It is tempting to speculate that—in analogy to other enzyme-catalyzed systems[103]—a certain unspecificity is always present in a proton translocator to ensure a sufficiently high velocity of the translocation. A decrease in the cytosolic pH under experimental conditions may further increase the amount of this energy dissipation due to an accumulation of $(Cyt\,b^{3\oplus}H^{\oplus})_{out}$. Under physiological conditions the proton translocator may act with an average yield slightly below $2H^{\oplus}/2e^{\ominus}$. In this case we would have to correct our former statement[37] that the $H^{\oplus}/e^{\ominus}$ stoichiometry of such a system is always an integer one. This small extent of energy dissipation inherent in a proton translocator has to be distinguished from the high extent of energy dissipation inherent in the $OH^{\ominus}$-ion translocator of brown adipose tissue, a machinery specifically designed for energy dissipation in the form of heat (see Section 8).

Summarizing, it should be stated that at complex III, *i.e.* at energy conversion site 2, if no ubiquinone-mediated proton transport occurs, two redox proton pumps would have to operate, since one cytochrome b pumps only with a $2H^{\oplus}/2e^{\ominus}$ stoichiometry. The work could be done by the two cytochrome b molecules if they were connected in series. This would be in contrast to our recent model[37].

3.5. Complex IV (Ferrocytochrome c:Oxygen Reductase)

Complex IV, the terminal segment of the respiratory chain, is also known as cytochrome oxidase. Compared to the other complexes, it has been the most intensively investigated regarding structure and function[99, 104, 105]. The multisubunit molecule accepts electrons from ferrocytochrome c and finally transfers them onto oxygen, reducing one molecule of oxygen to two molecules of water (Fig. 2). Details of the mechanism of oxygen activation will not be described here; they are the subject of recent comprehensive reviews[106, 107]. This section will concentrate on structural aspects and on the presumable mechanism of proton transfer in this region of the respiratory chain. The energy conversion site involved in complex IV is traditionally termed site 3.

The smallest possible unit of the complex consists of 12 polypeptides[108] (Table 1). It contains four electron-accepting centers, two copper centers, referred to as $Cu_{low\,potential}$ and $Cu_{high\,potential}$[109] (Fig. 2) and two types of hemes, termed cytochrome a and cytochrome a_3[110]. It has not yet been possible to assign the four redox centers to individual polypeptides, as has been done for complex III (see Section 3.4), owing to the fact that complex IV could not be dissociated into its functional polypeptides under mild conditions; the use of high concentrations of salt and detergent leads to a loss of the redox centers from the apoproteins.

The three largest and most hydrophobic polypeptides are coded for by mitochondrial DNA[111, 112] and translated on mitochondrial ribosomes; the remaining ones are products of cytosolic protein synthesis.

More analogies probably exist between complexes IV and III than has been realized to date. This concerns not only the different systems of protein synthesis for the individual subunits, the mechanisms of assembly of the whole complex, and the mechanism of proton translocation, but also the quaternary structure of the molecule and the possible cooperative function of the heme centers.

The molecular weight of the smallest possible unit of complex IV amounts to 166000, calculated from the heme content (12 μmol/g protein), assuming two heme a/minimum unit. From the sum of the molecular weights of the single subunits, it amounts to 178000. In ultracentrifugal studies the molecule behaves as a dimer.

Complex IV has been crystallized in two different forms. When the protein was isolated in Triton X-100 by negative extraction, it had a higher phospholipid content[113] than when it was prepared in deoxycholate[114]. The Triton preparation forms vesicles containing the complex in a dimeric aggregation state[115], the cholate preparation forms sheets containing the complex in a monomeric state[116]. In both kinds of 'two-dimensional crystals' the monomeric complex reveals the same rough shape of a lopsided 'Y', 11 nm in length (Fig. 10). The domains which form the arms of the Y are 5.5 nm in length. They are arranged on the matrix side of the membrane and are thought to be buried in the phospholipid bi-

layer. The stem of the Y, also 5.5 nm in length, is situated on the cytoplasmic face of the membrane and probably protrudes above the surface.

Fig. 10. Model of the gross structure of the monomeric complex IV. M1 and M2 are the matrix side domains and C is the cytoplasmic domain (by courtesy of *R. Henderson*).

These studies led to the speculation that the dimer (not shown), containing four cytochromes a and four copper centers, represents the functional state of complex IV in the inner mitochondrial membrane[115].

Apart from a knowledge of the gross structure and boundaries of the molecule, however, no precise data exist so far regarding the geometrical arrangement of the individual subunits in the complex. The sequence and function of the four metal centers in the path of electron flow are only partially understood. The half-reduction potentials of cytochrome a and a_3 differ by about 200 mV (Fig. 2)[117]; a much larger potential jump, however, occurs between cytochrome a_3 and oxygen, amounting to about 400 mV.

During the past three years it has been proven that the electron flow from ferrocytochrome c to oxygen is coupled with a vectorial proton transport (Fig. 3)[118]. The data emerged from numerous studies on complex IV incorporated into phospholipid vesicles and from studies on the complex residing in the mitochondrial membrane[119,120]. A $2H^{\oplus}$ $2e^{\ominus}$ stoichiometry was found in the isolated and reconstituted enzyme[99], but the stoichiometry of the process in the biological membrane amounts to $4H^{\oplus}/2e^{\ominus}$[121]. The lower, $2H^{\oplus}/2e^{\ominus}$, stoichiometry found in the vesicle preparation may stem from a merely partial restoration of the pumping device in the artificial system. The overall process catalyzed by cytochrome oxidase can be summarized as follows:

$$2\,\mathrm{cyt.c}^{2\oplus} + \tfrac{1}{2}\mathrm{O_2} + 4H^{\oplus}_{in} + 2\mathrm{H}^{\oplus}_{in} \rightarrow 2\,\mathrm{cyt.c}^{3\oplus} + \mathrm{H_2O} + 4H^{\oplus}_{out} \quad (5)$$

The italicized protons are the transported ones (cf. Fig. 3).

Complex IV is a segment of the electron transfer chain which does not dispose of quinone or other mobile hydrogen carriers. Therefore, in the authors' opinion, the results almost force the conclusion that the proton movement in complex IV is established by means of two proton pumps that may be connected in sequence. Cytochromes a and a_3 may be regarded as likely candidates, since they show a pH-dependence of their half-reduction potentials, like the cytochromes b of complex III[122].

3.6. Cytochrome c

In contrast to most of the other components of the respiratory chain, cytochrome c is a protein that has been structurally and functionally characterized on the molecular level. It differs from the other components in that it is a hydrophilic molecule. It is a peripheral membrane protein that can be extracted without the aid of detergents. Thus it is detached from its location on the outer side of the mitochondrial inner membrane by high ionic strength. It is easily purified by taking advantage of its high isoelectric point[123]. The molecular weight of cytochrome c is about 12000[124]. Characteristically for most c-type cytochromes, protoporphyrin IX is covalently bound to the apoprotein by two thioether bridges formed by the vinyl groups of protoporphyrin IX and two cysteine thiol groups of the protein[125]. The amino acid sequence of cytochrome c is known for more than 50 species[126]. From these data a phylogenetic tree of evolution has been constructed[127]. Moreover, the three-dimensional structure of tuna heart cytochrome c has been established at a 0.2 nm resolution[128]. The heme is held in a hydrophobic crevice by the two thioether bridges formed by Cys-14 and Cys-17 (Fig. 11). The fifth and sixth ligands of the iron, His-18 and Met-80, can be recognized on the right and on the left of the heme

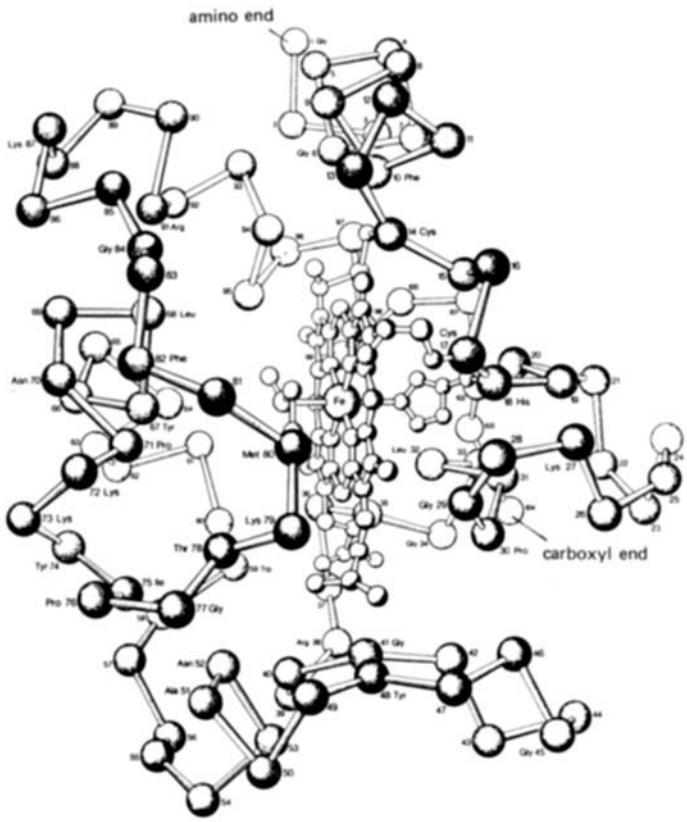

Fig. 11. Skeletal structure of the amino acid α-C atoms of horse cytochrome c (by courtesy of *R. E. Dickerson*).

system, that is exposed to the medium at one edge. The mass of basic amino acid residues (Lys-5, Lys-7, Lys-8, Lys-13, Lys-27, Lys-72, Lys-73, Lys-86, Lys-87) surround the opening of the crevice; this is a general feature in cytochrome c from different sources.

A half-reduction potential (pH-independent at physiological pH range) of about +250 mV has been determined for cytochrome c, indicative of its localization in the respiratory chain between the b-type and a-type cytochromes. Indeed, cytochrome c is reduced by the cytochrome b-containing complex III and oxidized by the cytochrome a-containing complex IV (Fig. 2).

From acetylation studies performed with free cytochrome c and in a state bound to cytochrome c_1 or to complex III, it has been concluded that cytochrome c binds to the cytochrome c_1 subunit of complex III[129, 130]. The binding domain lies in the region of the lysine residues 13, 72, 73, 83, 87 and 88 in the left upper part of cytochrome c (Fig. 11), shown by the fact that these residues were shielded and therefore less accessible to the acetylation reagent. The same binding domain was found for the binding to cytochrome oxidase[131, 132], indicating that cytochrome c does not form a fixed link between complexes III and IV, but moves or turns the opening of its heme crevice to the distinct reaction centers of complexes III and IV.

After establishment of the three-dimensional structure of cytochrome c, it has been suggested that the aromatic amino acid residues Tyr-74, Trp-59 and Tyr-67 are involved in the electron conduction to the iron atom *via* the fourth pyrrole ring[133]. The proposed free radical transfer mechanism had to be rejected, however, when the three-dimensional structure of cytochrome c_{550} from *P. denitrificans* became known[134]. This cytochrome c possesses a Leu-residue instead of Tyr-74, but it is still active with complex III[135]. A further argument against the free radical transfer mechanism—regarded as a kind of electron hopping—consists in the fact that a high energy barrier exists, demanding an activation energy of about 250 kJ/mol[136].

To date, two other mechanisms of electron transfer have drawn attention: i) an outer sphere process[137], and ii) an electron tunneling mechanism[138, 139]. The first mechanism presumes an overlap between the π-orbital system of the heme of cytochrome c at its exposed edge with a prosthetic group of the reductase or oxidase. The distance that can be spanned between the two systems by this mechanism can reach maximally 0.3 nm. The term 'electron tunneling' is used to describe the motion of particles across energy barriers which would be impossible according to classical mechanics, but which is predicted by the quantum theory regarding electrons in their particle wave function. According to a simple description of this process it is possible by electron tunneling to span a maximal distance of 3 nm[138, 139], which is in the same order of magnitude as the distance between the hemes of cytochrome oxidase and cytochrome c[140, 141]. An exclusive tunneling process would show no temperature dependence, which was found, however, above 100 K for the system that has been most investigated in this field, namely the photo-oxidation of cytochrome c in the purple membrane of the sulfur bacterium *Chromatium*.

A more elaborate description of the electron tunneling mechanism, termed 'thermally activated electron tunneling', does involve a temperature dependence[142]. The calculations predict the bridging of a distance of only about 1 nm. The shorter distance does not necessarily represent a disadvantage, since a tunneling distance of 3 nm might include the involvement of various redox centers, whilst the shorter distance of 1 nm may cause an even sharper discrimination between the reaction centers.

4. ATP-Synthetase (Complex V)

Proton-driven ATP-synthetases are found not only in the inner mitochondrial membrane, but also in the cytoplasmic membrane of bacteria and in the thylakoid membrane of chloroplasts. The ATP-synthetases from these different sources are very similar in structure and function[143, 145]. The mitochondrial enzyme is easily split into two multiprotein subunits and at least two additional polypeptide components (Fig. 12).

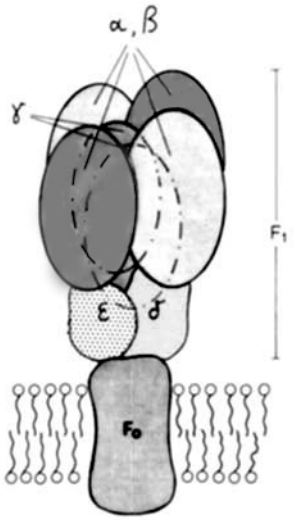

Fig. 12. Subunit composition of the ATP-synthetase. The subunits of F_0 as well as the oligomycin-sensitivity-conferring protein (OSCP) and the coupling factor F_6 are not represented in the drawing.

One of these multiprotein subunits, called coupling factor F_1, is a water-soluble component which has been crystallized recently[146, 147]. It consists of five different polypeptide subunits (α, β, γ, δ, ε). Possibly the stoichiometry is α_2, β_2, γ_2, δ_2, ε_2 (Table 1), but this is still controversial[148-150]. F_1 has the rare property of a cold-lability due to a dissociation occurring at low temperatures[151].

In contrast to F_1, the second multiprotein subunit—called F_0—is an integral membrane component. Presumably it consists of four polypeptide subunits (see Table 1)[152, 153].

In addition to the multiprotein subunits F_1 and F_0, the mitochondrial ATP-synthetase contains two other proteins: the oligomycin-sensitivity-conferring protein (OSCP) with a molecular weight of 19000[154, 155], binding directly to F_1 with a 1:1 stoichiometry[156]; and the coupling factor F_6 (molecular weight 8000)[157], believed to participate in the binding of OSCP—F_1 to F_0[158, 159].

A further protein, the F_1 inhibitor protein, was isolated from bovine heart mitochondria[160]. It can bind to the F_1 part at a low ATP/ADP ratio, apparently inhibiting the ATPase but not the ATP-synthetase reaction[161, 162].

In electron micrographs the ATP synthetase was seen in the form of spheres connected by stalks to the membrane. The spheres, which are oriented towards the matrix space, are attributed to the F_1 part. The stalks should consist of OSCP and F_6, whereas the membrane part is attributed to the F_0 unit[163, 164]. It should be mentioned, however, that the appearance of the electron micrographs has also been ascribed to fixation artefacts.

Certain catalytic activities can be attributed to the individual subunits of the ATP synthetase[144]. The isolated F_1 part, and even F_1 depleted of subunits γ and δ, reveals ATP hydrolytic activity, but has lost the ATP synthetase activity[165]. This finding is in agreement with the postulate, that energy transduction occurs *via* an electrochemical proton gradient across the inner mitochondrial membrane, which cannot be created by a soluble enzyme residing in a uniform phase. The F_0 part forms a proton channel[166]. If the mitochondrial membrane is depleted of F_1, it is no longer able to maintain a proton gradient, but preserves a proton conductivity which is sensitive to dicyclohexylcarbodiimide[167, 168]. This inhibition is due to the covalent binding of dicyclohexylcarbodiimide (DCCD) to a glutamate residue of the smallest subunit of F_0[169].

The coupling factor F_1 has several binding sites for adenine nucleotides[143] which may have different functions in ATP synthesis and regulation. The present description will be restricted to 'tight binding sites' for adenine nucleotides. The non-covalent linkages of ADP and ATP to these sites are stable during dialysis and gel filtration. As has been shown by photo-affinity labeling, the tight binding sites are located on the β-subunits[170–172].

It has been shown in artificial systems that either a pH gradient or an electrical field can drive the flow of protons which is coupled to ATP synthesis[173, 174]. The mechanism by which this proton flow drives ATP synthesis is unknown so far, but several proposals are under discussion[175–177]. One hypothetical reaction scheme for ATP synthesis is described here[178] (Fig. 13). It is based on the assumption that there are

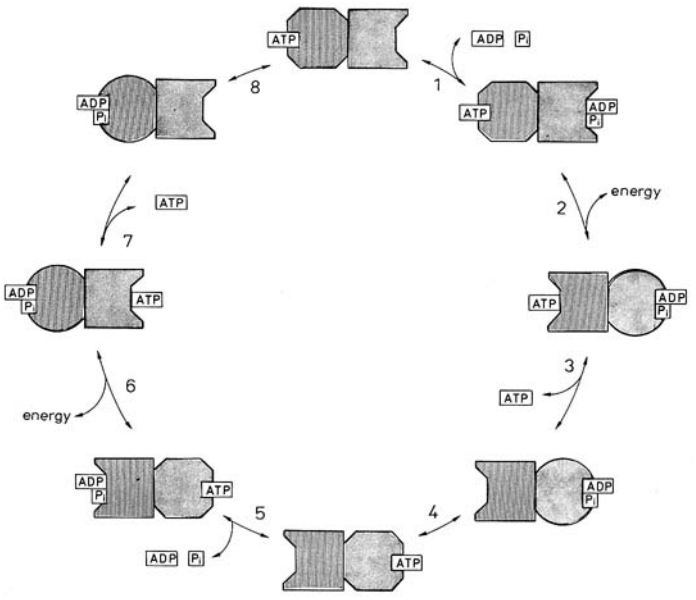

Fig. 13. Modified scheme of the reaction sequence taking place during ATP-synthesis at the two alternating binding sites of the ATP-synthetase (after *P. D. Boyer et al.* [177]). The two binding sites are indicated by different shading.

two identical binding sites for ATP or ADP + P_i on the two β-subunits of one F_1 molecule, with the two binding sites functioning alternatively. As one ATP is bound tightly to the first site, ADP and P_i are bound weakly to the second site (Reaction 1). Then, in an energy-dependent reaction, ADP and P_i are bound tightly, whereas the binding of ATP at the other site is weakened (Reaction 2). It is the weakening of the ATP binding that is thought to be the energy-consuming step, not the formation of the anhydride bond. In the next step, ATP is released (Reaction 3). Finally, the tightly bound ADP and P_i are transformed into ATP (Reaction 4). The second half of the cycle runs in the same sequence, but utilizing the same binding sites in an alternate fashion (Reactions 5 to 8). Contradictory results, indicating more than two binding sites involved in the process of ATP synthesis[143] may be due to the fact that a population of some of the intermediary states may have been 'frozen' and interpreted as different binding sites.

The view that the step with the high energy expenditure is the release of tightly bound ATP and not the formation of the anhydride bond of ATP is assumed also for the Na,K-ATPase[178], for the $Ca^{2\oplus}$-ATPase[179] and for the myosin-ATPase[180].

The action of the ATP synthetase is reversible in that it can also work as an electrogenic proton pump (ATP-driven proton pump)[181, 182, 183]. A $3H^{\oplus}$/ATP stoichiometry now seems to be established for the actual ATP synthetase reaction (Fig. 3) (see Section 9)[7].

5. Adenine Nucleotide Translocase

The adenine nucleotides ADP and ATP have to be transported across the inner mitochondrial membrane, since this membrane is impermeable to the highly charged and bulky molecules $ADP^{3\ominus}$ and $ATP^{4\ominus}$[184, 185, 186]. The transporting enzyme, adenine nucleotide translocase, has a minimum molecular weight of 30000, as shown in sodium dodecyl sulfate gel electrophoresis[187]. In mild detergents used for analytical ultracentrifugal studies, however, the carrier reveals a molecular weight of 60000[188]. Here it is present in a dimeric state of aggregation. Since only one binding site for adenine nucleotides and the specific inhibitors has been found per dimer, which is available for both ADP and ATP[185], it is tempting to speculate that the dimer represents the functional state of the protein in the inner mitochondrial membrane. Partial amino acid sequence analysis has not indicated any heterologies. It has therefore been assumed that the enzyme is a homodimer. The carrier is a highly hydrophobic integral membrane protein, comparable in this respect to the cytochrome b dimer of complex III. Due to its function, a transmembranous arrangement has been presumed[189, 190].

The adenine nucleotides ADP and ATP are translocated across the membrane in a strict 1:1 type of counter-exchange (Fig. 3)[185, 190]. The enzyme is highly specific for ATP and ADP when compared to other nucleotides. AMP is not transported by the enzyme. Specific inhibitors of the carrier exist, *e.g.* the plant toxin atractylate (a diterpenoid derivative)[191], and the bacterial toxin bongkrekate (a polyisoprenoid derivative)[192]. In a model, the mechanism of the transport has been described as a 'gated pore mechanism'[193]. The carrier represents a highly active membrane transport system, con-

stituting about 14% of the whole protein of the inner mitochondrial membrane. The rate of translocation can be compared to that of the phosphate translocase (see Section 6). The adenine nucleotide transport does not seem to limit the supply of the cytosol with the mitochondrially synthesized ATP, *i.e.* the adenine nucleotide carrier may work at a higher rate than the proton-driven ATP synthetase (cf. Fig. 3).

The adenine nucleotide transport is a secondary active transport, consuming energy that is provided in the form of the membrane potential[194]. The transport takes place against a phosphorylation potential ($[ATP]/([ADP]\cdot[P_i])$) that is higher in the cytosol (about 66 kJ) than in the matrix space (about 55 kJ)[195]. The exchange system works asymmetrically in the energized state, *i.e.* the ADP uptake is highly preferred over ATP uptake and vice versa the ATP release is preferred over ADP release[194]. When the membrane potential is collapsed by means of uncouplers, like dinitrophenol, the asymmetry of the transport is abolished, *i.e.* ATP is then taken up at the same rate as ADP, and ADP is released with the same activity as ATP; theoretically, then also a pure ADP:ADP or ATP:ATP counter-exchange can occur.

The influence of the membrane potential on the exchange activities and on the asymmetry due to the electrical nature of the transport process have recently been elucidated in more detail in a reconstituted system consisting of purified carrier protein incorporated into phospholipid vesicles[196, 197].

The interrelation between the electron transfer creating the electrochemical membrane potential, and the three processes consuming the potential (ATP synthesis, adenine nucleotide exchange and phosphate transport), are discussed in Section 7.

6. Phosphate Transport System

Mitochondria possess two carrier systems capable of transporting phosphate across the inner membrane: the dicarboxylate carrier and the phosphate carrier[20, 198, 199]. The dicarboxylate carrier exchanges $HPO_4^{2\ominus}$ against dicarboxylates, *e.g.* succinate or malate. This transport system differs from the phosphate carrier in that it can be inhibited by some non-physiological dicarboxylates like *n*-butyl malonate[198], whereas the phosphate carrier is highly sensitive to SH-blocking reagents[199, 200]. The dicarboxylate carrier does not seem to function as P_i-supplier for ATP synthesis taking place in the matrix space, but rather to be involved in a dicarboxylate uptake by a dicarboxylate : $HPO_4^{2\ominus}$ counter-exchange.

Phosphate is delivered mainly by a specific phosphate carrier, a protein that reveals a molecular weight of about 30000 in sodium dodecyl sulfate electrophoresis when it is labeled by *N*-Ethylmaleimide[201, 202, 203]. This transport system is probably the most active one in the inner mitochondrial membrane[199]. The phosphate uptake is electroneutral[204], following either an $H_2PO_4^{\ominus}/OH^{\ominus}$ counter-exchange or an $H_2PO_4^{\ominus}/H^{\oplus}$ cotransport. For the sake of simplicity, the latter type of exchange will be adhered to in the following. In any case the uptake is governed by the proton gradient existing at the membrane (Fig. 3).

Since the phosphate carrier transports only $H_2PO_4^{\ominus}$ from the cytosolic to the matrix space under physiological conditions, it may be speculated that the ΔpH across the mitochondrial membrane may be affected to a greater extent than expected from the cotransported proton, due to the removal of $H_2PO_4^{\ominus}$ from the dissociation equilibrium of phosphoric acid in the cytosolic phase and due to its enrichment in the matrix phase. This secondary influence on the pH gradient can be neglected, however, since phosphate is formally added as $H_2PO_4^{\ominus}$ to ADP in the matrix space during phosphorylation and released as $H_2PO_4^{\ominus}$ from ATP at the cytosolic space during ATP consumption. As shown in Figure 3, the balance is therefore re-established.

7. Proton and Charge Balance of the Whole Set of Systems Converting Oxidative Energy into Chemical Energy

The transfer of electrons from NADH to oxygen *via* complexes I, III and IV is coupled to an electrogenic translocation of 12 $H^{\oplus}$ across the inner mitochondrial membrane[11, 12, 93, 205–208] (Fig. 3a). For succinate oxidation 8 $H^{\oplus}$ were measured (not shown). Since it has been known for a long time that NADH oxidation approaches a maximum of 3 ATP and succinate oxidation one of 2 ATP, it seems evident that mitochondrial ATP formation needs 4 $H^{\oplus}$ per molecule of ATP synthesized (Fig. 3b).

Electrogenic proton translocation without cotransport of anions generates both a proton gradient (ΔpH) and a membrane potential ($\Delta\Psi$). As the phosphate uptake is electroneutral, only the ΔpH is affected, *i.e.* the corresponding positive charge of the proton transported electrogenically during electron flow remains at the outer face of the membrane. This positive charge is balanced by the electrogenic ADP, ATP counter-exchange (Fig. 3b). Therefore three electrogenic protons remain for the ATP synthesis reaction. This stoichiometry is in general agreement with thermodynamic considerations (see Section 9).

The ATP production of submitochondrial particles is most informative as regards the energy yield induced by a change of side of the individual processes. In submitochondrial particles obtained by ultrasonication of mitochondria, the inner membrane has been inverted (inside out) and a transport of adenine nucleotides and phosphate is no longer necessary for ATP synthesis. In agreement with this consideration, a stoichiometry of 3 $H^{\oplus}$/ATP formed was reported for submitochondrial particles[209, 210]. From these values a stoichiometry of 4 ATP/NADH oxidized is derived, which is calculated from the values of 12 $H^{\oplus}$ translocated per NADH oxidized, and 3 $H^{\oplus}$ consumed per 1 ATP formation.

8. Thermogenesis in Mitochondria of Brown Adipose Tissue

In mammals heat is usually produced by fine random contractions of skeletal muscle, called muscle shivering[211]. However, another possibility exists for heat production, a non-shivering thermogenesis occurring in the mitochondria of the brown adipose tissue[212–214]. The process is unique to new-born mammals (including man), hibernators and cold-adapted small mammals. Brown adipose tissue differs from white adipose tissue in that it contains multilocular triglycer-

ide droplets and possesses an extremely high content of mitochondria[215].

The brown adipose tissue mitochondria dispose of an energy dissipation pathway that is not present in other tissues. It is a reaction that competes with the ATP synthetase for the electrochemical membrane potential $\Delta\tilde{\mu}_{H^{\oplus}}$, built up by the proton-translocating electron flow[212]. The mitochondria respire free fatty acids at a high rate, but produce scarcely any ATP. They possess a 32000 protein which spans the membrane[216]. The protein forms a pore for $H^{\oplus}$ or $OH^{\ominus}$ ions, the permeability of which is regulated by a specific binding of purine nucleotides. Binding of GDP or GTP or, less effectively, that of ADP or ATP, inhibits the $OH^{\ominus}$ ion flow[213,217,218], driven by the membrane potential.

9. The Irreversible Thermodynamic Approach to Energy Coupling in Mitochondria

The analysis of the process of oxidative phosphorylation has received fresh impetus in the past few years by the application of irreversible thermodynamics[9,10,219]. Since an exact treatment within the framework of this theory is too complicated, a linear first order approximation to the nonlinear problem has been developed. The approximation, termed 'linear nonequilibrium thermodynamics', proved to be valuable for a description of the processes under study. Concepts such as 'P/O ratio' (the number of ATP molecules synthesized from ADP and P_i per oxygen atom reduced) or 'respiratory control' have gained a new meaning and interpretation. The respiratory control ratio r is defined as the quotient of the respiration rate which occurs at substrate saturation in the presence of ADP and the respiration rate under the same condition if ADP is lacking. Thus it has been shown that, even at a low respiratory control r, a high degree of coupling, q, can occur. The degree of coupling, which can reach values from 0 (no coupling) to 1, is related to the respiratory control r, in accordance with the following equation:

$$q = 1 - \sqrt{1 - 1/r} \qquad (6)$$

The degree of coupling q is a far better indicator for coupling of oxidation with phosphorylation than the respiratory control r, used previously to describe the quality of preparations of mitochondria.

Of further significance is the finding that the measured P/O values, although they are not equivalent to the mechanistic stoichiometries, can be good approximations of the stoichiometries if they are measured at a high degree of coupling. The application of linear nonequilibrium thermodynamics, however, permits a calculation of phenomenologic stoichiometries, not from the flow ratio (rate of ATP synthesized/rate of oxidation) at state 3, but from the force ratio (free energy of ATP hydrolysis/free energy of substrate oxidation) at state 4 and the degree of coupling. Thus, P/O stoichiometries of 3.0 for NADH oxidation and of 2.1 for succinate oxidation were calculated. Of special interest are the $H^{\oplus}/O$ and the $H^{\oplus}/ATP$ stoichiometries for mitochondria as well as for submitochondrial particles, calculated from the respective force ratios at state 4 and the degree of coupling. Stoichiometries of 11.8 $H^{\oplus}/O$ for NADH oxidation, 8.1 $H^{\oplus}/O$ for succinate oxidation and 3.9 $H^{\oplus}/ATP$ for proton-driven ATP synthesis have been obtained for mitochondria[6]. Due

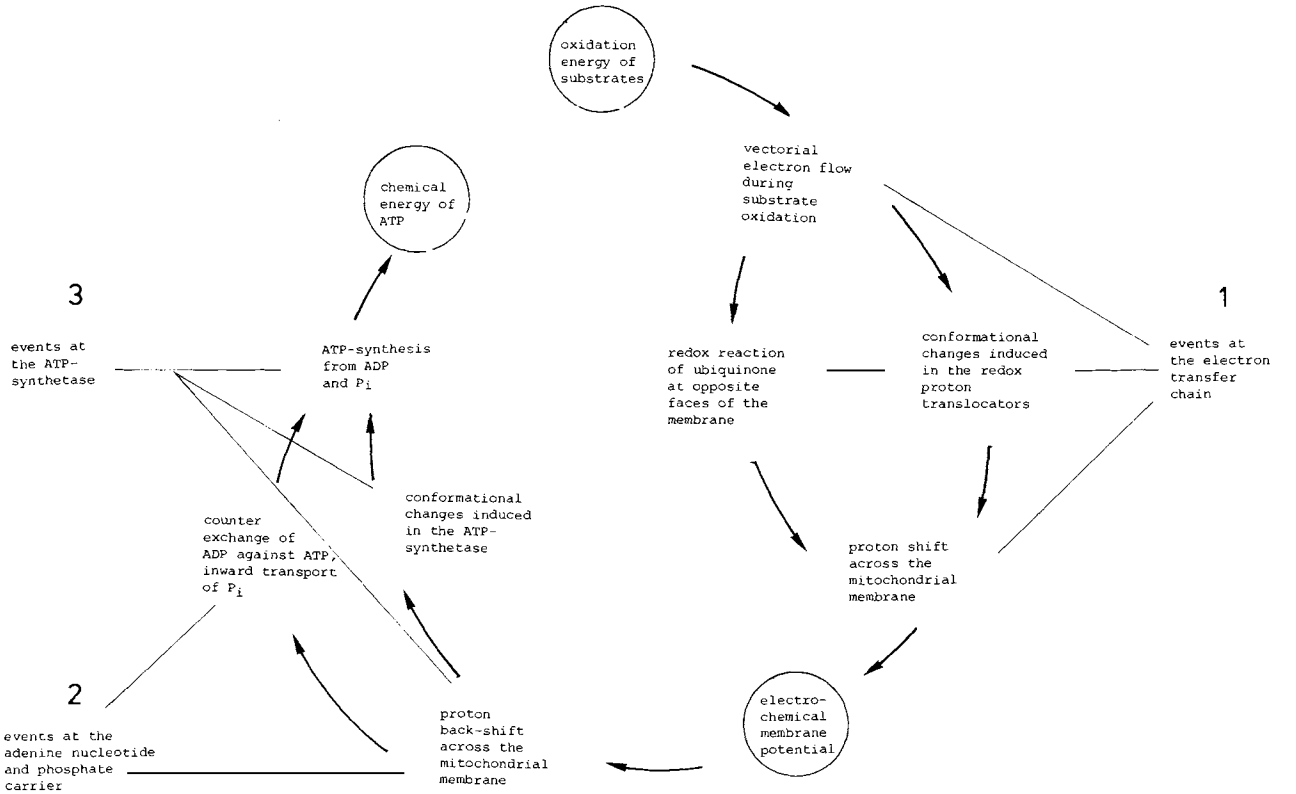

Fig. 14. Sequence of events taking place during mitochondrial oxidative phosphorylation. The three existing forms of energy are encircled. The spiral of events embraces the two probable mechanisms of proton transport: i) The proton pump mechanism. ii) The redox (carrier-mediated) loop mechanism. The latter may occur at energy conversion site 2.

to the fact that no proton motive force is discharged for adenine nucleotide exchange and phosphate transport in submitochondrial particles, P/O stoichiometries of 3.9 for NADH oxidation, 2.7 for succinate oxidation and 2.8 $H^{\oplus}$/ATP for ATP formation were obtained. All these data, calculated on the basis of state 4 force ratio values and the degree of coupling q, are in good agreement with the stoichiometries that were actually measured at state 3 conditions with mitochondria or submitochondrial particles that showed a high degree of coupling.

A very intriguing result reached by the use of irreversible thermodynamics is that a degree of coupling q close to unity is not realized in mitochondria operating *in vivo*, although the efficiency of oxidative phosphorylation, defined as:

$$\eta = \frac{\text{phosphorylation flow} \times \text{phosphorylation potential}}{\text{oxidation flow} \times \text{redox potential}}$$

increases with increasing degree of coupling q. At a degree of coupling close to unity, however, the phosphorylation flow vanishes, which leads to a small output (phosphorylation flow × phosphorylation potential). Maximization of the output with respect to the degree of coupling results in an ideal degree of coupling of about 0.9[9].

10. Summary and Outlook

To sum up the causal relationship of mitochondrial energy conversion, the whole process is depicted in a simple energy flow diagram drawn in the shape of a spiral of events (Fig. 14). The sequence of reactions shows that the proton translocation driven by the redox proton pumps (1) and, vice versa, the ATP formation catalyzed by the ATP synthetase (3), depend on conformational changes taking place at the enzymes. These conformational changes may occur within polypeptides and between individual polypeptides of the respective multiprotein complexes. The scheme, however, does not take into account a direct conformational interaction between the electron-transferring complexes and the ATP-synthetase complex, as proposed extensively in previous models[220]. A ubiquinone-mediated proton transport by aid of a loop mechanism is also considered in the scheme, since it probably takes place at energy conversion site 2 (cf. Section 3.4)[3]. The postulation of a sophisticated reaction mechanism such as the ubiquinone cycle is hardly necessary, however, since probably additionally to the ubiquinone loop a proton pump works at energy conversion site 2.

Two-dimensional crystals have been obtained so far from mitochondrial complexes III[87] and IV[115,116], as well as from bacteriorhodopsin[221,222]. The gross structure of these membrane proteins has been elucidated. Attempts are being made to achieve the high resolution required for analyzing the fine structure of the proteins. The isolation of the residual proteins of oxidative phosphorylation, as well as the determination of the primary structure of these proteins will continue and support the elucidation of the reaction mechanisms on a molecular level.

The authors thank Prof. Dr. M. Klingenberg, Dr. R. Krämer and Dr. W. Wintermeyer for valuable discussions. We are very grateful to Drs. R. E. Dickerson, R. Henderson and K. R. Leonard for permission to include Figs. 7, 10, and 11. The assistance of Dr. M. Stitt in correcting the manuscript is greatly appreciated. Some of the cited studies were aided by grants from the Deutsche Forschungsgesellschaft to G. v. J. and from the Studienstiftung des Deutschen Volkes to W. D. E.

Photophysical and Photochemical Processes in Micellar Systems

By Nicholas J. Turro, Michael Grätzel, and André M. Braun[*]

A fascinating feature inherent to aqueous surfactant solutions is the phenomenon of self-organization: above a certain critical concentration (the critical micelle concentration, CMC) detergent molecules associate spontaneously to build up structural entities of colloidal dimensions called micelles. The architecture of these agglomerates is such that the interior contains the hydrophobic alkyl chain of the amphiphile while the hydrophilic head groups are located at the surface and are in contact with bulk water. In the case of ionic micelles the interface is charged giving rise to an electrical double layer and a potential difference of up to several hundred millivolts between the micellar pseudophase and water. Thus micellar systems are microheterogeneous in character: the electrostatic potential and polarity prevailing in the interior of the aggregate differ from those of the bulk aqueous phase. A particularly attractive aspect of photochemical studies in micellar systems is the possibility of organizing the reactants at a molecular level: by comparison of the data in micelles with similar data in homogeneous solution one can learn about the molecular details of a given reaction and establish which conditions favor one pathway or another. In simple surfactant systems differences in rate and efficiency of a reaction will often be controlled by local electrostatic potentials and the compartmentalization of the reagents within the surfactant aggregates. Through the latter effect the statistics of probe distribution over the micelles becomes important in controlling fast photochemical events. Functional micelles are distinguished by the fact that the surfactant molecule contains a group which itself participates in the photoprocess. These units are unique in that self-assembly often introduces striking cooperative effects.

1. Introduction

The objectives of this article are to review the conventional model of micelles formed by ionic detergents in aqueous solution and to show how photoluminescence methods provide

information on the compositional, structural and dynamic characteristics of such micelles. We demonstrate how photoluminescence and photochemical probes may serve both as valuable sensors of micellar structure and microenvironments and as reporters of solute partitioning. Furthermore, we will show that photophysical and photochemical reactions in micellar systems may differ significantly from analogous reactions in homogeneous solution[1].

2. Luminescence Probes

A *chromophore* is an atom or group of atoms that may be conveniently considered as a unit which *absorbs* visible or ultraviolet light. A *lumophore* is an atom or group of atoms that may be conveniently viewed as a unit which *emits* visible or ultraviolet light. For example, aromatic hydrocarbons behave as lumophores, as do ketone groups. There are two commonly encountered luminescences: *fluorescence* and *phosphorescence*. Fluorescence is generally associated with the emission of light accompanying the transition of excited singlet states to the ground state and phosphorescence is generally associated with the emission of light from the lowest triplet state to the ground state (Fig. 1).

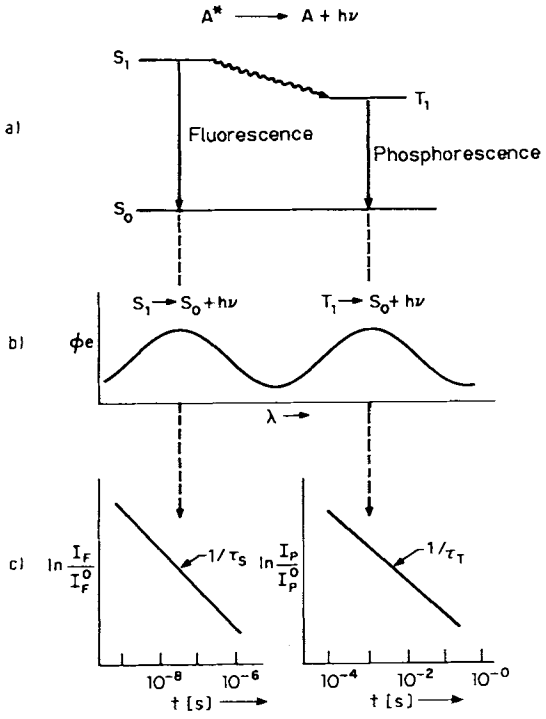

Fig. 1. a) The conventional "three level energy diagram" depicting the luminescent states of an organic molecule. Emission from the excited singlet state (S_1) is termed *fluorescence* whereas emission from the triplet state (T_1) is termed *phosphorescence*. b) Fluorescence bands generally occur at higher energies (shorter λ) than phosphorescence bands. c) Fluorescence decay is usually much shorter lived (τ_S) than phosphorescence decay (τ_T).

A *luminescent probe* is any molecule or group of atoms whose luminescent properties may serve to explore and examine the structural and dynamic features of systems of interest. Thus there exist *fluorescence probes* and *phosphorescence probes*. In order to be effective, a property of a luminescent probe must change and be measurable when the probe is added to the test system. The general idea behind a luminescence probe is that luminescence parameters are sensitive to changes in the microenvironment of the probe and that a luminescence probe in different microenvironments will display experimentally distinct luminescence properties which will characterize uniquely each environment.

2.1. Measurable Properties of Luminescent Probes

The readily measured quantities derived from the emission of lumophores are: (1) Emission spectrum (intensity of emission as a function of wavelength for a fixed absorbed intensity and fixed excitation wavelength). (2) Excitation spectrum (intensity of emission at fixed wavelength as function of absorbed intensity and variable excitation wavelength). (3) Luminescence decay (fall-off of the intensity of the emission spectrum as a function of time after an excitation pulse). (4) Quantum yield of luminescence (the number of photons emitted relative to the number of photons absorbed). (5) Polarization of luminescence (the orientation of the emitted light vector relative to the orientation of the absorbed light vector). (6) Quenching (a decrease in luminescence intensity or increase in decay rate as a function of added solute or changing environment). (7) Sensitization (an increase in luminescence intensity or decrease in decay rate as a function of added solute or changing environment). (8) Energy transfer (electronic excitation transferred from an initially excited lumophore to a second lumophore).

Each of the above quantities has been employed to measure properties of micellar aggregates.

3. Luminescence Probes as Sensors and Reporters of Microenvironments

Luminescence probes may be thought of a "sensors" of microenvironments. The photons emitted by such probes are "reporters" of the local structure in the vicinity of the probe at the time of emission. The emitted photons may be employed to "read back" a *map* of the microenvironment of the probe. In this mode, the probe serves as a *clock* of molecular dynamics of its environment (Fig. 2).

Luminescent probes provide the greatest degree of information for characterization of microenvironments when the probe exhibits a strong and selective affinity for a given environmental site or if, when it is distributed among distinct sites (*e.g.*, micellar environment and bulk aqueous solution), the measurable luminescence properties are distinctly different. For example, if the emission spectrum, the excitation spectrum, the decay time, the quantum yield of emission, the polarization of luminescence, or the quenching (or sensitization) of emission is environment dependent, the luminescence probe can be employed to characterize the environment. The effective use of luminescence probes requires a detailed knowledge of the nature of radiative and radiationless transitions and of the mechanisms of excited state interactions with different environments.

The "structure" examined by a luminescent probe may be of a "local" nature (*i.e.*, the immediate microenvironment of the probe) or of a more "expanded" nature (*i.e.*, the secondary or tertiary environmental characteristics).

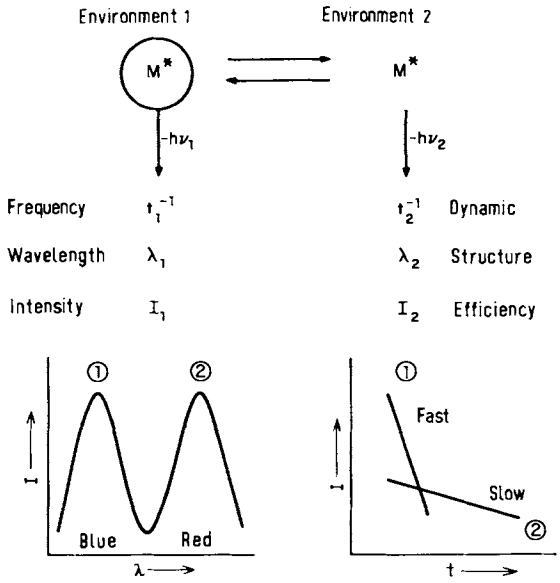

Fig. 2. Schematic representation of a luminescent probe (M*) in two environments. If the luminescence of M* (either fluorescence or phosphorescence) is different in decay time, wavelength, or intensity, a means of gaining information on the structure and dynamics of the probe and/or its environment is available. For example, suppose the emission of M* is "blue" and "fast" in a hydrophobic (say a micellar) environment and is "red" and "slow" in an aqueous environment, then a means of examining the two environments is available.

The measured changes in a luminescent probe have been related to molecular properties of the environment of the probe such as: (1) Polarity; (2) viscosity; (3) diffusion; (4) partitioning between phases; (5) concentration of quenchers; and (6) distance between groups.

The "dynamic range" of luminescence probes spans 13 orders of magnitude! Decay rates of fluorescence commonly range from $10^5\ s^{-1}$ to $10^9\ s^{-1}$ and those of phosphorescence range from $10^{-1}\ s^{-1}$ to $10^3\ s^{-1}$. Since quantum yields of emission of 10^{-3} are readily measured, the effective experimental dynamic range of fluorescence is $10^6\ s^{-1}$ to $10^{12}\ s^{-1}$ and that of phosphorescence is 10^{-1} to $10^6\ s^{-1}$. Thus there is a continuum for a potential dynamic measurement for the range $10^{-1}\ s^{-1}$ to $10^{12}\ s^{-1}$ (Fig. 3).

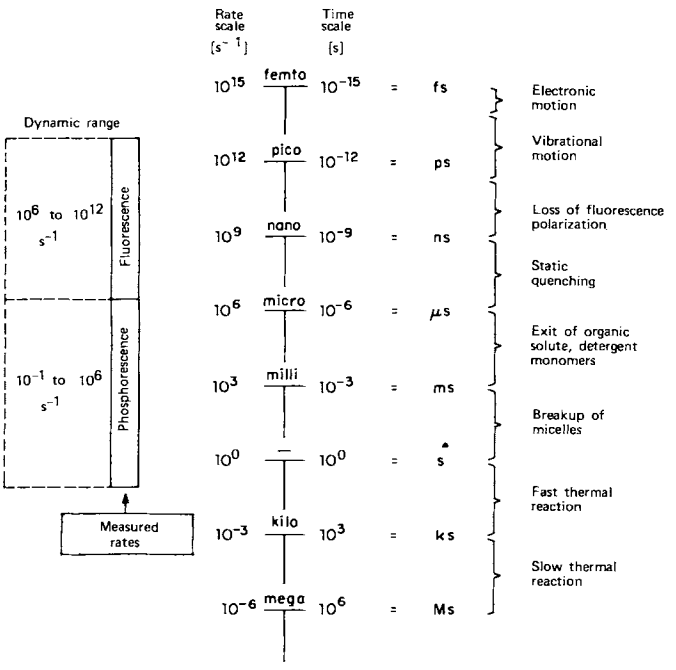

Fig. 3. The "dynamic range" of luminescence probes.

It should be stated that one difficulty must always be considered when interpreting results derived from the use of luminescence probes: the probe of necessity is a "foreign body" in the environment that is being probed. It is therefore crucial to provide independent evidence that the probe does not change the inherent quality of the measured property. For example, in the case of micellar systems, it must be established whether the association of the probe in the system causes a fundamental change in the nature of the "native" micelle. With the recognition that it is usually more desirable to use a direct spectroscopic measurement of some intrinsic property of a system, it is commonly not feasible to do so. If we view the utilization of probes as an exercise in information acquisition and in the strategy of experimental design, luminescence probes and methods may be profitably employed.

3.1. Fluorescence/Phosphorescence Probes

Fluorescence probes are probably the best known of all luminescent probes, and have been employed widely in the study of structure and dynamics of many systems. Fluorescence methods are often outstanding in terms of sensitivity and selectivity for the investigation of chemical and physical dynamic processes that occur on the time scale of 0.1–1000 ns. Processes such as rotational and diffusional motion, solvent reorganization, and energy transfer often occur in this time domain and have been investigated by means of fluorescence probes.

In contrast to the extensive use of fluorescence probes, just a few scattered cases have been reported in which phosphorescence probes were employed to investigate structure or dynamics in fluid solution (see Section 6). This is indeed unfortunate since a wealth of molecular information is potentially available from phosphorescence spectroscopy. The absence of literature on phosphorescence probes does not result from the lack of potential usefulness of such molecules, but more likely resides in the "conventional wisdom" that organic molecules do not phosphoresce in fluid solution or that the observation of phosphorescence in fluid solution requires very special (or exotic) solvents, elaborate purification procedures, and sophisticated, specially designed and ultrasensitive detection equipment. Since nearly all measurements of phosphorescence have been performed in rigid glasses at low temperatures, the general belief has arisen that such conditions are required for the observation of phosphorescence in solution.

"Conventional wisdom" is quite inappropriate for micellar systems. For instance, we shall see that the phosphorescences of simple organic molecules are readily observed in micellar solutions.

Indeed, both fluorescence and phosphorescence may be observed for the same molecule. Since the dynamic range of fluorescence is in the 10^{-11} to 10^{-6} s range and that of phosphorescence is in the 10^{-6} to 10 s range, the combination of fluorescence and phosphorescence probes allows (potentially) scanning of a dynamic range of 10^{13}!

4. Aqueous Solutions of Detergents and Micelles

A surfactant (surface active material) or detergent is a molecule that possesses both polar (or ionic) and nonpolar moieties, *i.e.*, they are "amphiphilic" or "amphiphatic" species[1b]. This property imbues detergents with a sort of molecular schizophrenia and causes aqueous solutions of detergents to exhibit a number of important and unusual properties. A typical detergent structure is RX where R is a straight chain hydrocarbon of 8—18 carbon atoms or some other hydrophobic residue, and X is a hydrophilic group. Depending on the nature of X, detergents may be classified as (a) nonionic, (b) cationic, R^+X^-, or (c) anionic, R^-X^+. Typical examples of ionic detergents are listed in Figure 4. In aqueous

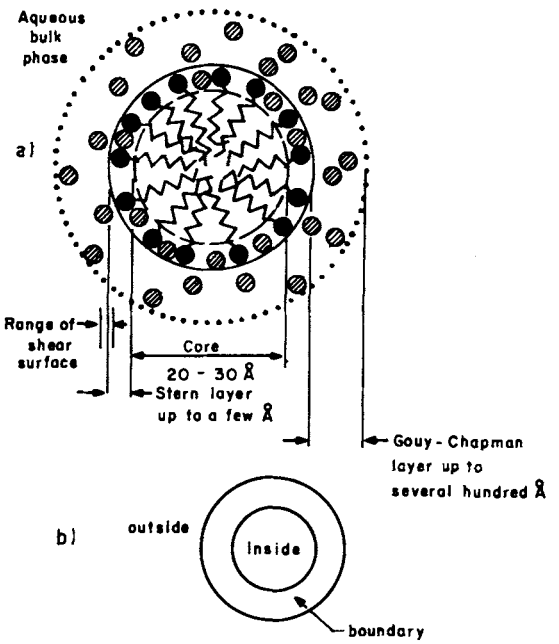

Fig. 4. a) Conventional representation of the micelles formed by an ionic detergent. Although represented as spherical, the instantaneous or even the average shape may be ellipsoid or irregular. The "topological" shape (b) is preserved, however. The "inside" or "core" of the micelle consists of the hydrocarbon "tails" of the detergent molecules. The "boundary" or Stern layer consists of the detergent "head" groups and bound gegenions. The immediate "outside" or Gouy-Chapman region is a diffuse double layer containing unbound gegenions. Typical ionic detergents are n-$C_{12}H_{25}OSO_3^{\ominus}Na^{\oplus}$ (SLS) and n-$C_{16}H_{33}N^{\oplus}(CH_3)_3Br^{\ominus}$ (CTAB) and the corresponding chloride (CTAC).

solutions the polar portion of the detergent is hydrophilic and the nonpolar portion is hydrophobic. The result of these conflicting chemical features is a tendency for cooperative self-association of detergent monomers to form aggregates. For example, the addition of detergent to water often results in formation of solutions that contain association colloids. The term *micelle* refers to such aggregates of colloidal dimensions, and implies a situation in which these aggregates are in a mobile equilibrium with the molecules or ions from which they are formed. It is commonly observed that there is a relatively small range of concentrations below which micelles are absent or present in very low concentrations and above which virtually all the detergent molecules exist as micelles. The "relatively small range of concentrations" defines a *"critical micelle concentration"* or CMC, which may be extracted from an experimental plot of some observable property *versus* detergent concentration.

In aqueous solution detergent molecules (Fig. 4) such as sodium dodecyl sulfate (SLS) or hexadecyl(trimethyl)ammonium bromide (CTAB) form micelles above a certain concentration (strictly speaking over a small range of concentrations), *i.e.* their *critical micelle concentration.* Depending on the temperature, concentration, and other experimental variables, the micelles may be roughly spherical, ellipsoidal, disk-like, or rod shaped (Fig. 5). The charged sulfate or ammonium head groups are directed toward the aqueous phase and the hydrocarbon chains are directed away from the water and the micellar "boundary", which separates the hydrophobic inferior from the bulk aqueous phase. This region is a diffuse double layer (Gouy-Chapman) containing unbound counterions.

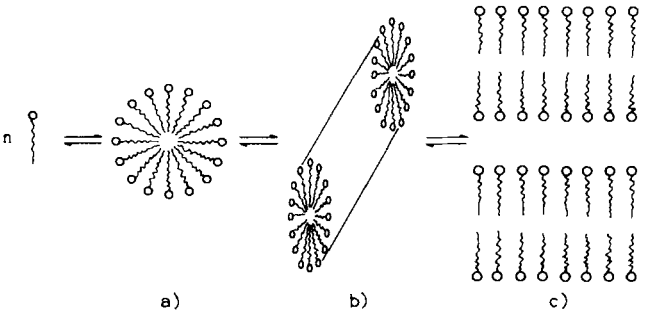

Fig. 5. A schematic representation of the conversion of detergents into (a) "spherical" micelles (recall Fig. 4), (b) "rod-shaped" micelles, and (c) bilayers.

Given this (oversimplified) model, a number of questions, both qualitative and quantitative, arise concerning the structure and dynamics of micellar aggregates. For example, how hydrocarbon-like is the interior, *i.e.*, how viscous, how nonpolar?

Micelles are responsible for many of the practical applications of detergents, such as enhancement of solubility of organic compounds in water and catalysis of organic reactions. Furthermore, in recent years micelles have been proposed as simple model systems for a variety of important "two phase" systems such as monolayers, colloids, proteins, enzymes, and membranes[1f]. Among the primary reasons for the usefulness of micelles as models are: (a) the thermodynamic stability and reproducibility of many micellar systems; (b) the simplicity of the structure of the micelle; (c) the two-phase nature of the micelle; (d) the ionic composition of many micelle surfaces.

For instance, the micelle aqueous interface incorporates features of electrical double layers, and may be typical of other interfacial systems such as membranes. The importance of micelles and mixed micelles in the transport and absorption of lipids as solubilizers in physiological systems has been pointed out[1f]. For example, the mobile monomer-micelle equilibrium may serve as a general model for hydrophobic interactions, a problem of central interest in biology. The most fundamental or topological features of a chemical system are those which are qualitatively preserved over a variety of specific conditions. These topological features are generally definable in terms of structural and dynamic characteristics. It is important to understand and to elucidate the

topological features of a system because it is precisely these features which are generally transferred from a model system to a system of interest.

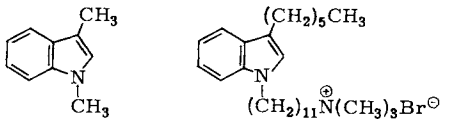
For instance, the topological features of micelles (cf. Fig. 4 and 5) that are of major interest for *structural* comparison with biomolecules (*e.g.*, membranes) include: (a) the fact that a micelle has an inside, an outside, and a boundary; (b) the fact that the inside is hydrophobic, the outside is hydrophilic; (c) the fact that the micellar boundary is fluid (in the sense that it is undulating with time and not rigid) and possesses a finite (although not necessarily fixed) thickness; (d) the fact that the composition of the micelle (aggregation number) is fairly well defined; (e) the fact that molecules may be sequestered and organized in the micelle interior or on (or in) the micellar boundary.

Micelle formation may be viewed as a thermodynamic analogue of a phase separation with the CMC corresponding to a saturation concentration. Of course, the micelles differ from a macrophase separation in that they do not coalesce into a continuous phase at the CMC, but instead they are uniformly distributed in the bulk aqueous phase and form a "pseudophase".

The topological features of micelles that are of major importance for *dynamic* comparisons with biomolecules include: (a) the detailed mechanism of monomer-micelle equilibrium; (b) the influence of experimental variables (temperature, detergent concentration, presence of solutes, *etc.*) on this equilibrium; (c) the detailed mechanism of entrance and exit of solute molecules into and out of a micelle, *i.e.*, the mechanism by which a solute penetrates the barrier.

The actual quantitative rates of steps involved in the monomer equilibrium and of solute movement in and out of a micelle are important for calibration and for the experimental establishment of plausible limits for dynamic processes involving micelles.

5. Location and Orientation of Organic Molecules Solubilized in Micelles



An organic molecule, solubilized in water by addition of detergent, evidently interacts with a micelle in some fashion. The question arises as to the nature of the interaction, as to the location and/or orientation of the solute with respect to the micelle.

For example, a completely non-polar solute (a) may be located, on the average, completely "inside" the hydrophobic core of the micelle, (b) may be absorbed on the surface of the micelle, or (c) may penetrate to a particular depth into the surface layer. An amphiphilic solute may be oriented with its polar portion in the surface layer and its non-polar portion in the hydrophobic core. Each situation possesses possible features with respect to "local" dynamics of the solute (*e.g.*, rotational motion) and "transport" dynamics of the solution (*e.g.*, diffusional motion within the micelle or on the surface, translational motion "inside and outside" of the micelle, *etc.*).

5.1. Functionalized Micelles as Luminescence Probes

Instead of incorporating a "guest" luminescence probe into a "host" micelle, it is possible to synthesize detergents that possess a luminescence probe as an integral part of their structure.

The indole lumophore shows significant solvent sensitivity. For example, 1,3-dimethylindole *(1a)* shows fluorescent maxima at 305 nm and 370 nm in cyclohexane and water, respectively[2]. Its fluorescence lifetime is also strongly solvent dependent (4×10^{-9} s and 16×10^{-9} s in cyclohexane and water, respectively).

(1a) *(1b)*

A survey of 1,3-dialkylindoles indicated that these compounds are associated with micelles from CTAB and CTAC (Fig. 6) but that they tend to remain close to the ionic interface. However, the indole detergent *(1b)* was found to be incorporated in micelles of CTAB and also form its own micelles (Fig. 7). Furthermore, *(1b)* shows a dramatic shift in its fluorescence maximum as it passes through the fluorescence lifetime of *(1b)* in both a micellar environment and in bulk aqueous solution. It is found that: (a) the fluorescence maximum of *(1b)* occurs at ≈ 370 nm in an aqueous environment and at ≈ 350 nm in a micellar environment. (b) The fluorescence lifetime of *(1b)* is $\approx 6 \times 10^{-9}$ s and $\approx 18 \times 10^{-9}$ s in a micellar and in an aqueous environment, respectively.

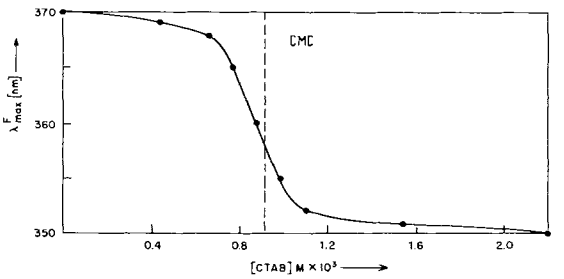


Fig. 6. Fluorescence maximum of *(1b)* as a function of the concentration of detergent *(1b)*. The concentration of *(1b)* is kept constant and the concentration of CTAB is varied. CMC = critical micelle concentration.

Wavelength-correlated single photon counting has been employed to resolve the two emissions of *(1b)* under conditions such that the molecule is partially in a micellar and partially in an aqueous environment (Fig. 8). The relative inten-

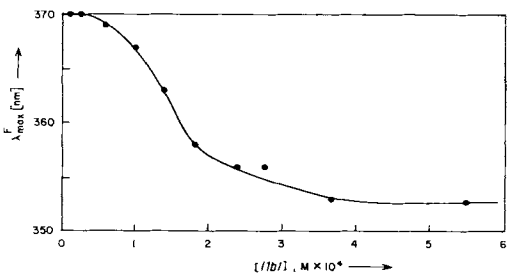

Fig. 7. See Fig. 6; the concentration of *(1b)* alone is varied.

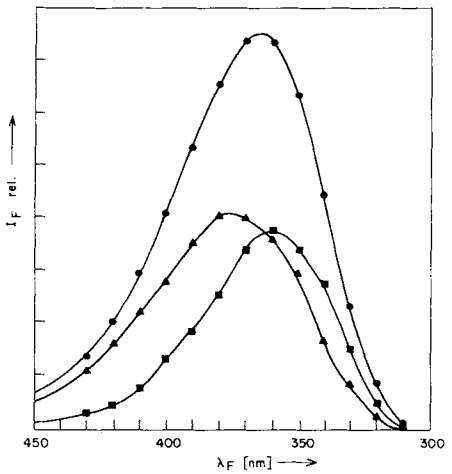

Fig. 8. Time-resolved fluorescence spectra (see Fig. 2) of aqueous *(1b)* at its CMC. ●, total spectrum; ▲, aqueous phase, $\tau_F = 18.0$ ns; ■, micellar, τ_F (micelle) = 6.6 ns.

sities of these emissions correlate qualitatively with the expected proportion of micellized surfactant as the surfactant concentration is increased beyond the CMC.

6. Phosphorescence in Micellar Solutions

An outstanding example of "micellar protection" of an excited molecule is available in the ready observation of phosphorescence from micellar solutions. The main deactivation pathways of organic triplets in homogeneous solutions usually involve quenching by impurities, by "self-quenching", or by triplet-triplet annihilation. At low occupancy numbers, *i.e.*, $\langle S \rangle < 0.1$ (for a definition and discussion of occupancy number, $\langle S \rangle$, see eq. (1), below), triplets may become virtually immune to deactivation, self-quenching, and triplet-triplet annihilation. Furthermore, oxygen molecules, well-known, ubiquitous and powerful triplet quenchers, are solubilized selectively into the micellar environment. For a micelle concentration of 10^{-3} M and an oxygen concentration of $\approx 10^{-4}$ M, $\langle O_2 \rangle = 0.1$, 90% of the micelles will be free of oxygen; thus, triplets which are formed in such micelles will be "protected" from oxygen quenching and display an enhanced phosphorescence. For example, the phosphorescence of 1-bromonaphthalene *(2)* in micelle solution is shown in Fig. 9[3].

"Functionalization" of SDS micelles by "heavy atom" gegenions (Ag^+, Tl^+) allows the observation of phosphorescence of aromatic hydrocarbons such as naphthalene and pyrene[4]. The "heavy atom" serves to enhance the radiative rate of triplets without a comparable enhancement of triplet quenching. The result is an enhanced quantum yield of phosphorescence. Figure 10 shows the emission spectrum of

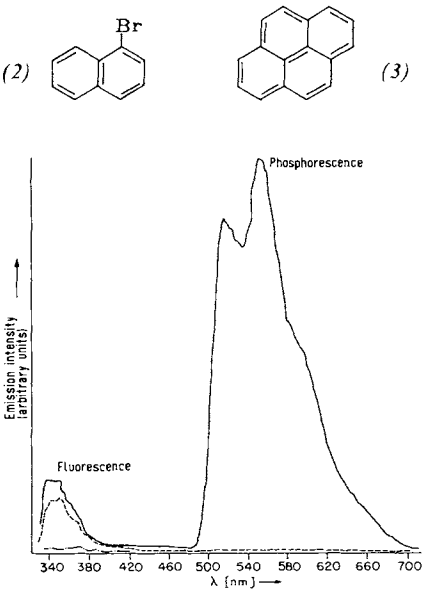

Fig. 9. Phosphorescence spectrum in micellar solution. Total emission of a 10^{-3} M solution of 1-bromonaphthalene *(2)* in aqueous solutions of 0.05 M CTAB. Below the CMC the phosphorescence of *(2)* in aqueous solution is not detectable. —, N_2-bubbled; – – –, aerated; – · – aerated (without CTAB).

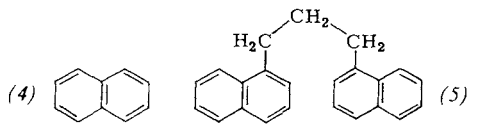
pyrene *(3)* in 5×10^{-2} M AgDS solution. The fluorescence, though normally strong, is here barely visible, the spectrum being dominated by the strong phosphorescence peak with a maximum at 600 nm[4b].

7. Luminescence Probes of Microviscosity

The fluidity of the environment of a probe molecule that is associated with a micelle may differ substantially from that of the bulk aqueous phase. Thus, the "microviscosity" experienced by the probe molecule may be considerably different from the macroscopic viscosity of the micellar solution. Luminescence probes may serve to measure microviscosity since numerous quantities such as the loss of luminescence polarization, the efficiency of excimer formation, and the efficiency of quenching should depend on the magnitude of the microviscosity experienced by the probe.



The depolarization of fluorescence from solubilized probes provides information concerning the probe mobility[5]. In homogeneous solutions the extent of loss of depolarization may be quantitatively related to the macroscopic viscosity of the solvent. Likewise, one can associate the extent of loss of polarization of a micellized probe with the microviscosity experienced by the probe. For the typical micelles formed from SLS and CTAB, the measured microviscosities near room temperature are about 15—30 cP[5]. These values can be compared to the 1—2 cP values of viscosities of typical hydrocarbons and pure water.

Although microviscosities may also be determined by intermolecular excimer formation[6], the analysis for micellar systems requires the use of Poisson statistics[7]. This complication may be circumvented by employing intramolecular excimer formation as a probe of microviscosity. Experimentally, the ratio of intensities of monomer to excimer emission (I_m/I_x) for several diarylalkanes are known to be viscosity dependent in homogeneous solution[8]. Comparison of the value I_m/I_x found in micellar solution with that found in homogeneous solution leads to an evaluation of microscopic viscosity. The values obtained are in good agreement with each other and with the values obtained from fluorescence depolarization. An exception is found in the case of 1,3-diphenylpropane as a probe[8c]. This result is interpreted to result from a different location of the smaller probe relative to the larger probes.

8. Naphthalene Fluorescence as a Luminescence Probe for Solute Partitioning

Depending on the time constant associated with luminescence decay and the exit and entrance rates associated with solute partitioning between micellar and aqueous environment, the luminescence quantities measured may represent an "instantaneous snapshot" or a "time-averaged snapshot" of the solute-micelle system. From the time scales listed in Figure 3 hydrophobic fluorescence probes of micelles will generally fall into the "instantaneous snapshot" category. This means that on the time scale for fluorescence (≈ 1—100 ns), micelles form physically discrete cells among which the solute molecules can distribute themselves. In this limit, excited probe molecules report, *via* their fluorescence, the micellar/aqueous partitioning of ground state probe molecules, *i.e.*, since probe fluorescence is faster than probe exit or entrance rates, emission reflects the initial, ground state distribution.

As discussed above, in order to be of practical use the fluorescence probe must show some measurable difference in micellar and aqueous environment. The absorption characteristics and the spectral distribution of naphthalene fluorescence are not significantly modified upon proceeding from an

aqueous to a micellar environment. However, for dilute ($<10^{-4}$ M) solutions of naphthalene *(4)* the fluorescence lifetime shows clear evidence of a two-component decay for solutions near the CMC of CTAB (Fig. 11)[8a]. The long-lived decay ($\tau_F \approx 35$ ns) is assigned to naphthalene molecules dissolved in the bulk aqueous phase and the short-lived decay ($\tau_F \approx 18$ ns) is assigned to naphthalene molecules associated with micelles. The shortening of the fluorescence lifetime in the latter environment is due to enhanced quenching of naphthalene singlets by $Br^{\ominus}$ gegenions in the Stern layer of CTAB micelles[9].

At higher concentrations of naphthalene ($>10^{-3}$ M) the fluorescence decay characteristics become more complex and the spectral distribution of fluorescence reveals evidence of naphthalene excimer emission (Fig. 12a). The dynamics of excimer formation are related to the viscosity of the medium in which excimer formation occurs. However, for the situation in which excimer formation is fast relative to entrance and exit times, the statistical distribution of solutes among the micelles must be considered in any quantitative treatment[10]. It has been found that Poisson statistics are appropriate for this distribution. Poisson statistics assume that the probability of a solute molecule going into a micelle does not depend on whether the micelle already contains a solute or not.

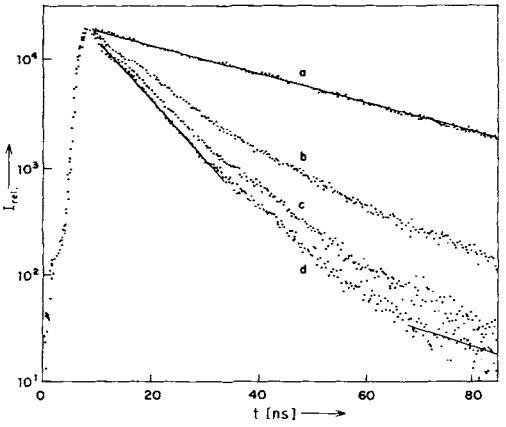


Fig. 11. Time-correlated emission of naphthalene *(4)* (3.9×10^{-3} M) in CTAB; $\lambda = 325$ nm; 20 °C. a) Water (saturated solution), b) 0.02 M CTAB, c) 0.05 M CTAB, d) 0.20 M CTAB.

Poisson statistics lead to a distribution of solutes that is given by

$$P(n) = \frac{\langle S \rangle^n}{n!} \exp(-\langle S \rangle) \qquad (1)$$

where $P(n)$ is the probability of finding a micelle containing n solute molecules and $\langle S \rangle$ is the "mean occupancy number" or the ratio of the bulk concentration of solute molecules to the bulk concentration of micelles. For easy visualization, Poisson statistics for partitioning of solutes in micelles is analogous to the completely random partitioning of "marbles in boxes", under conditions such that the probability that entry of a marble into a given box is independent of the number of marbles already in the box. Realistically, in analyzing micellar dynamics, Poisson statistics will not hold for very large values of $\langle S \rangle$, *i.e.*, the size of the micelle is finite and the inclusion of too many solute molecules will eventually cause gross disturbances of the micellar characteristics.

Table 1. Poisson distribution of solute molecules at various values of $\langle S \rangle$.

$\langle S \rangle$ ⟶	0.1	0.5	1.0	2.0
$P(0)$	0.90	0.61	0.37	0.13

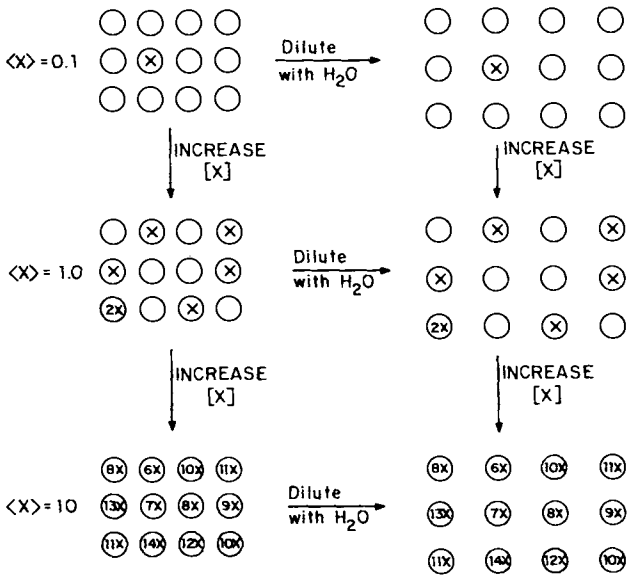

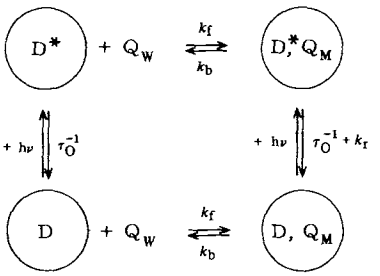

Fig. 13. Schematic representation of dilution (above the CMC) and increasing occupancy number (above the CMC) on solutes in micelles.

Table 1 lists some values of $P(n)$ for various values of $\langle S \rangle$. Notice that when $\langle S \rangle = 0.1$, most of the micelles are "empty" at any given instant, *i.e.*, less than 10% of the micelles contain one or more solute molecules. Even when $\langle S \rangle = 1.0$ (*i.e.*, equal concentration of solute and micelle) 37% of the micelles are empty and 63% will contain two or more solutes.

In Figure 13, an interesting feature of the dilution of micelles is shown. As long as the system is above the CMC, dilution preserves the number of micelles and serves only to separate them in space. This slows down the rate of "collisions" between micelles and the rate of exchange of solutes between micelles. The dilution procedure offers a simple method of distinguishing intramicellar events from intermicellar events.

9. Photoluminescence Quenching. Evaluation of Partition Coefficients, Aggregation Numbers, Entrance and Exit Rates

The use of Poisson statistics to describe the distribution of solute molecules among micellar aggregates allows derivation of relations which allow luminescence quenching to serve as a means for evaluating important micellar parameters[10]. For the commonly encountered case of a hydrophobic luminescence probe (donor D) which is completely micellized (Scheme 1), so that quenching occurs exclusively in the micellar environment, the following general expression for luminescence decay is obtained[10a]:

Scheme 1. Q_W = quencher in bulk aqueous phase; Q_M = quencher in micellar phase, D = probe (donor).

$$I(t)/I(0) = \exp - \{t/\tau + \langle Q \rangle \alpha_r^2 (1 - e^{-(k_r + k_b)t})\} \quad (2)$$

where

$$\tau^{-1} = \tau_0^{-1} + k_Q[Q_W] \quad (3)$$

$$k_Q = \alpha_r k_f; \quad \alpha_r = k_r/(k_r + k_b) \quad (4)$$

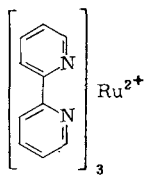
$[Q_W]$ = concentration of quencher in the aqueous phase

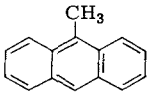
For the case of a completely micellized donor, four limiting situations are (1) the quencher of the luminescent probe is totally micellized (complete "static" quenching only); (2) the quencher is partially micellized (static quenching only); (3) the quencher is totally micellized ("non-static" and "static" quenching); (4) the quencher is partially micellized ("non-static" and "static" quenching). From the derived expressions we find that Case (1) yields information on the mean aggregation number of the micellar aggregates; Case

(2) yields information on the mean aggregation numbers of the micellar aggregates, the quencher binding constant and the entrance rate of the quencher into the aggregate; Case (3) yields information on the rate constant for quenching in micellar aggregates; Case (4) yields, in principle, all the information available from Cases (1—3), although in practice a complex fitting of experimental data may be required.

The mean aggregation number, $\bar{n}$, of micelles may be derived from luminescence quenching measurements when "static" quenching of a completely micellized donor occurs exclusively and when Q is selected to exclusively reside in the micellar phase. From eq. (2) the measured ratio of luminescence from D* in the presence of Q to that in the absence of Q is given by

$$I/I^0 = \exp\{-[Q]/[M]\} \tag{5}$$





where [M] is the micelle concentration and is given by

$$[M] = \frac{[Det] - [free\ monomer]}{\bar{n}} \tag{6}$$

The combination of eqs. (5) and (6) yields

$$(\ln I^0/I) = \frac{[Q]\bar{n}}{[Det] - [free\ monomer]} \tag{7}$$

This expression allows evaluation of the aggregation number and the concentration of free monomer in equilibrium with micelles.

(6)  (7) 

An experimental example[11] which follows eq. (5) is the tris(α,α'-bipyridine)ruthenium(II) *(6)* and Q = 9-methylanthracene *(7)* system with Det = SLS. A plot of $\ln I^0/I$ *versus* [SLS] at fixed concentration of Q yields a straight line as shown in Figure 14. The slope is identified as $\{\bar{n}[Q]\}^{-1}$ and the intercept as $\{[Det] - [free\ monomer]\}$. Since [Q] and [Det] are known, $\bar{n}$ and [free monomer] may be evaluated. The experimental values of $\bar{n} = 60$ and [free monomer] $= 7.5 \times 10^{-3}$ M agree very well with values measured by other methods.

Situations other than those for which the donor is completely micellized have been encountered in the literature. The following general equation for the time evolution of the excited state has been developed[12]:

$$[D^*]_t = [D^*]_0 \exp\left[-\left(k + \frac{k_Q k_f [Q_w]}{k_b + k_Q}\right) t - \frac{K_M k_Q^2 [Q_w]}{(k_b + k_Q)^2}\left(1 - e^{-(k_b + k_Q)t}\right)\right] \tag{8}$$

where k is the specific rate constant of the decay of D* in the absence of quencher.

This equation may be used to evaluate kinetic parameters such as specific rate for entry and exit of the quencher and intramicellar diffusion rates.

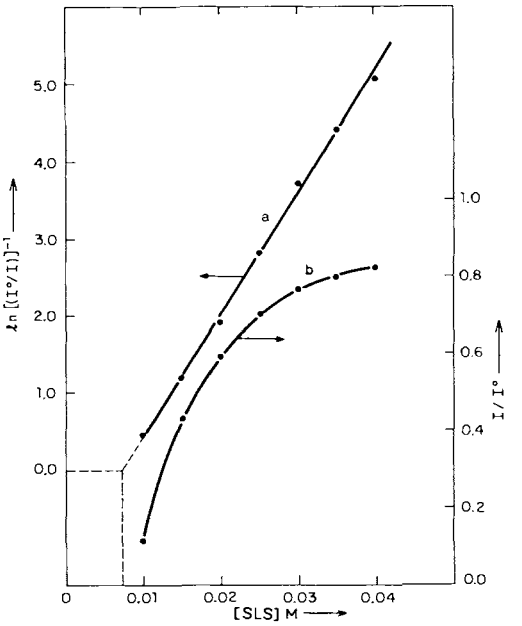


Fig. 14. Dependence on detergent concentration of $Ru(bpy)^{2+}$ *(6)* luminescence, with concentration of 9-methylanthracene quencher (Q) *(7)* fixed at 1.05×10^{-4} M. a) Intensity normalized relative to that in the absence of Q; b) analysis according to eq. (5). Slope $= 157\ M^{-1}$; $\bar{n} = [Q]^{-1} \times \text{slope}^{-1} \simeq 60 \pm 2$; intercept $= 7.5 \times 10^{-3}$ M; CMC $= 8.2 \times 10^{-3}$ M.

An important limiting case is the one for which all the quenching of a strongly micellized probe occurs in the aqueous phase. In this situation the exit of the probe from the micelle may become the rate limiting process for donor decay, *i.e.*, quenching occurs with unit efficiency at sufficiently high (aqueous) quencher concentration. The quenching of triplet 1-bromonaphthalene by NO_2^- ions in SLS solution was found to conform to this case[13]. The kinetics for this situation cannot be deduced from the formulation discussed above, but may be readily derived from standard steady state considerations. The resulting expression allows evaluation of k_b. If k_f can be evaluated, then the equilibrium constant, $K_M = k_f[Q]/k_b$, for partitioning of the quencher between the micelle and the aqueous phase may be evaluated.

Some values of K_M, k_f, and k_b obtained from luminescence quenching are gathered in Table 2.

From eq. (4), the rate constant k_Q, evaluated from experimental data is seen to be a composite of k_r, k_f, and k_b. The rate constant k_r has the characteristics of a pseudo-unimolecular rate constant, *i.e.*, $k_r = k_r'[Q]_M$. In cases for which the quencher carries the same charge as the surface of the micelle, $[Q]_M$ is substantially decreased relative to the bulk concentration of Q; correspondingly, if Q possesses the opposite charge as the surface of the micelle, $[Q]_M$ may be substantially increased relative to the bulk concentration of Q. These two situations lead to micellar "inhibition" of quenching and micellar "catalysis" of quenching.

For example, the quenching efficiency of the fluorescence by $Br^\ominus$ or Eu^{3+} of micellized aromatic hydrocarbons is very dependent on the charge of the micelle[9a]. Thus, $Br^\ominus$ is an effective quencher of the fluorescence of naphthalene *(4)* when the arene is dissolved in cationic (*e.g.*, hexadecyl(trimethyl)ammonium (CTA)) micelles, but $Br^\ominus$ is an ineffective quencher of naphthalene fluorescence when the hydrocarbon is dissolved in anionic micelles (*e.g.*, dodecyl sulfate

Table 2. Partitioning constants K_M, entrance and exit rate constants, k_f and k_b, respectively, for selected molecules in micellar aggregates of CTAB and SLS.

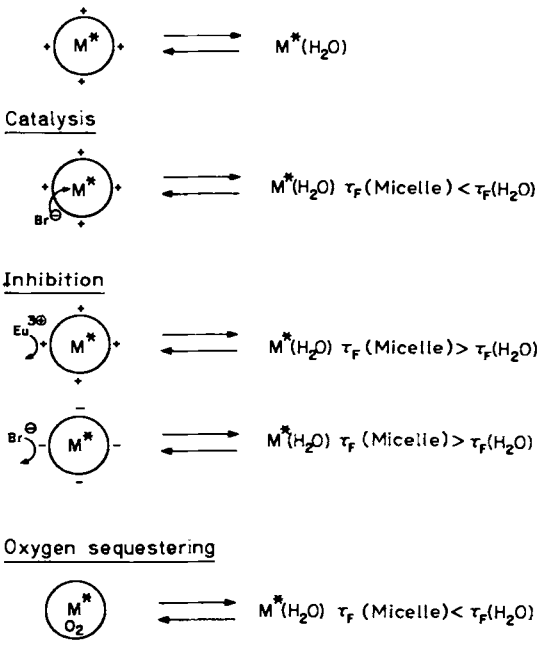

Fig. 15. Schematic representation of the "catalysis" of quenching of naphthalene *(4)* (M*) fluorescence in CTAB and the "inhibition" of naphthalene fluorescence in SLS.

(LS)). Just the opposite is true for quenching of the fluorescence of pyrene *(3)* by Eu^{3+}, even though $k_q > 10^9$ M^{-1} s^{-1} in water. These situations are summarized schematically in Figure 15.

10. Dynamics of Intramicellar Probe Diffusion

10.1. Excimer Formation, Pyrene

Pyrene *(3)* shows a number of photophysical features that make it an attractive fluorophore to probe the microenvironment present in micellar aggregates. The unusually long fluorescence lifetime[14] ($\bar{\tau}_F = 400$ ns) enables one to study the dynamics of its interaction with quenchers partitioning between the aqueous and micellar phase[7, 15]. From these studies, factors influencing the permeability of the lipid/water interface may be deduced[16]. The relative intensity of the vibrational fine structure peaks in the emission spectrum is sensitive to the probe environment (Ham effect[17]), allowing for the determination of the local polarity at the solubilization site[18, 19]. Finally, from the dynamics of excimer formation information may be derived about the microviscosity and dynamics of pyrene motion within the micelle. Only the latter point will be elaborated in more detail now, since the other subjects have been treated exhaustively in two recent reviews[1b, c].

Förster and *Selinger*[20] were the first to compare the relative intensities of monomer and excimer emission in homogeneous solvents and micellar solutions. The fact was recognized that in the latter system the pyrene molecules are compartmentalized through the surfactant aggregates—an effect which favors excimer formation. A simple kinetic model was introduced later by *Pownall* and *Smith*[6] to interpret these phenomena. Failure to take random distribution effects into account resulted in abnormal high viscosity values. Subsequently more advanced theories were developed[10d, 21-23] which take into account the statistics of probe distribution over the micellar aggregates. As the exchange of pyrene molecules between different micelles is much slower than the excimer formation itself, only multiply occupied micelles can contribute to the excimer emission. Their fraction can be calculated from the Poisson distribution function [cf. eq. (1)]. For example, in Figure 16 is shown a fluorescence spectrum of a solution containing 2×10^{-4} M pyrene *(3)* in aqueous so-

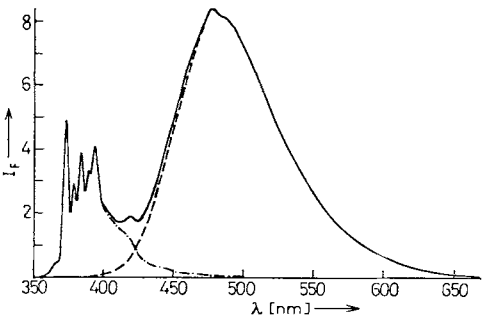

Fig. 16. Fluorescence spectrum of pyrene *(3)* (2×10^{-4} M) in aqueous 5×10^{-3} M CTOES solution. ——, total emission; – – – –, pure excimer emission; – · – · –, pure monomer emission. CTOES = n-$C_{16}H_{33}O(CH_2CH_2O)_3SO_3^{\ominus}Na^{\oplus}$.

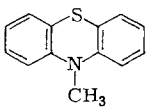


dium 3,6,9-trioxapentacosyl sulfate 5×10^{-3} M (sodium hexadecyltrioxyethylene sulfate, CTOES). Clearly the excimer emission dominates the spectrum, although it would be practically absent in a homogeneous solution at a comparable pyrene concentration.

A quantitative understanding of these phenomena is provided by a recent theoretical treatment[23] that takes into account the statistics of probe distribution and the intramicellar kinetics of the excimer formation. Apart from the CMC, a number of other important parameters were derived from this study, such as the micellar aggregation number ($n = 96$ for CTOES). Even more important is the fact that these studies provide information on the rate of intramicellar probe

diffusion. (The mean encounter time of two pyrene molecules in a CTOES aggregate is $\bar{c} = 110$ ns.)

10.2. Functional Micelles with Reactive Boundaries

Unusual effects are also observed when triplets are incorporated into functional micelles. Consider, for example, the quenching of *N*-methylphenothiazine (MPTH) *(8)* triplets by Ni^{2+} or Co^{2+} ions:

(8)

$$MPTH^T + Ni^{2+}(Co^{2+}) \rightarrow Ni^{2+}(Co^{2+}) + MPTH \quad (9)$$

In homogeneous solution, *i.e.* ethanol/water (1/2, v/v), this reaction occurs at a comparatively slow rate, the rate constants being $k_2(Ni^{2+}) = 7.7 \times 10^6$ and $k_2(Co^{2+}) = 1.4 \times 10^7$ $M^{-1} s^{-1}$, respectively. A drastic increase in the quenching efficiency is observed when *(8)* is solubilized in dodecyl sulfate micelles containing a Ni^{2+} or Co^{2+} counterion atmosphere. The lifetime of $MPTH^T$ is only 100 ns for Ni^{2+} and 50 ns for Co^{2+} counterions, irrespective of the micellar concentration[24]. Thus, through molecular organization one achieves high local quencher concentrations in the interface (3—6 M) even in very dilute solutions. This increases the quenching activity by several orders of magnitude with respect to a homogeneous solvent.

By selecting a different kind of counterion, *i.e.* Ag^+ instead of Co^{2+} or Ni^{2+}, the same effect may be exploited to obtain a drastic increase in the triplet yield and even room temperature phosphorescence. Micelles of silver decyl sulfate (AgDS) form readily above a surfactant concentration of 3×10^{-2} M and incorporate arene molecules such as pyrene *(3)* or naphthalene *(4)* (see Section 6 and Fig. 10).

10.3. Intramicellar Triplet Energy Transfer

The transfer of excitation energy from a triplet donor to a ground state acceptor

$$D^T + A \rightarrow A^T + D \quad (10)$$

proceeds *via* an exchange mechanism which requires close approach of the reactants. Consider the situation where both donor and acceptor are hydrophobic and hence solubilized in the interior of the micelle. Since on the time scale of reaction no intermicellar exchange of A or D molecules can take place, the energy transfer will occur within groups of only a few molecules that are compartmentalized within their host aggregates. As a result, statistical and proximity effects will influence the efficiency and rate of reaction. These have been illustrated for the reversible and irreversible transfer of energy from triplet *N*-methylphenothiazine ($MPTH^T$) to *trans-stilbene* and naphthalene respectively[25]. Both experiments were performed in CTAB micelles. In the $MPTH^T$-stilbene system the transfer is irreversible and occurs at a rate constant $k_q = 1.5 \times 10^7 s^{-1}$ for micelles containing one donor-acceptor pair. Conversely, the reaction between $MPTH^T$ and naphthalene is reversible, the respective rate constants for the forward and backward transfer being $k_q = 2.8 \times 10^6 s^{-1}$ and $k_{-q} = 3.3 \times 10^6 s^{-1}$. Confinement of the reaction space to micellar size induces both a drastic enhancement of the observed transfer rate as well as a reduction of the reaction order from two to one. Interestingly, these effects are predicted from applying diffusion reaction theory to the interaction of a small number of reactants in a small and confined reaction space. In fact, quantitative predictions of the rate constant of deactivation are possible for the three cases where: (1) the excited state quencher is identical with the counterion atmosphere (this case was discussed in Section 10.2); (2) the energy transfer occurs between a pair of reactants within the micelle (present case); and (3) the acceptor and donor are located on the surface of the micelle. These predictions are in excellent agreement with the experimental results[26].

11. Dynamics of Molecular Oxygen in Micellar Solutions

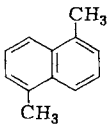
Molecular oxygen is a general and effective quencher of the fluorescence of hydrocarbons. The quenching process is commonly diffusion controlled in homogeneous solution, requiring that quenching within the "solvent cage" occurs with an efficiency close to unity. In two (or multiphase) pseudo-homogeneous aqueous solutions (micelle-containing detergent solutions, solutions containing protein membranes and other macrobiomolecules) the observed efficiency and reactivity of oxygen quenching will depend on the partitioning of molecular oxygen in the various phases, the lifetimes of the excited substrate and the dynamics of entrance, exit, and quenching interaction of the oxygen molecule in an "effective quenching volume" about the substrate. Thus, in extreme situations quenching (1) can be very effective if oxygen molecule and substrate are "pre-complexed" and confined to a small volume in a given phase or (2) can become very inefficient if the substrate and the molecular oxygen are in separate phases and volumes of space and the rate of penetration of oxygen into an "effective quenching volume" is slow compared to the decay rate of the excited substrate.

It has been shown that molecular oxygen readily penetrates the micelle aqueous boundaries[27]. The mechanism of penetration of molecular oxygen across such boundaries is potentially of great significance for important biological processes such as respiration and photodynamic effects.

The "observed" rate constant for quenching of fluorescent probes by molecular oxygen in micellar solutions is generally smaller than that obxerved for the same probes in homogeneous solution[15]. These results have been interpreted in terms of a smaller "effective" concentration of oxygen in the phase or aggregates containing the probe, in terms of a smaller rate constant for quenching interaction or some combination of both factors. The ability of association to "protect" excited probes from oxygen quenching is strikingly demonstrated by the ready observation of phosphorescence from organic molecules in micelle-containing detergent solutions[3,4].

Information on the solubilization, entry and exit of molecular oxygen into and out of micelles produced in detergent solution is potentially available from an investigation of the time-resolved measurement of fluorescence lifetime of a mi-

cellized probe as a function of oxygen pressure and application of eq. (2). A study of the oxygen quenching of 1,5-dimethylnaphthalene *(9)* fluorescence in micelle containing detergent solutions of hexadecyltrimethylammonium bromide (CTAB) and sodium dodecyl sulfate (SLS) allowed an estimation of dynamic and solubility parameter of molecular oxygen in this "two phase" system[28]. The results are summarized in Table 3.



(9)

Table 3. Summary of parameters derived from fluorescence quenching of 1,5-dimethylnaphthalene *(9)* by oxygen in micellar solutions [28].

Parameter	Micelles	
	CTAB	SLS
k_i, entrance rate constant [$M^{-1}\,s^{-1}$]	$1.3 \pm 0.2 \times 10^{10}$	$1.4 \pm 0.2 \times 10^{10}$
k_b, exit rate constant [s^{-1}]	$< 4.6 \pm 0.5 \times 10^{7}$	$< 5.3 \pm 0.7 \times 10^{7}$
τ_m, residence time [s]	$< 2.2 \times 10^{-8}$	$< 1.9 \times 10^{-8}$
k_r, static quenching constant [s^{-1}]	$< 4.6 \pm 0.5 \times 10^{7}$	$< 5.3 \pm 0.7 \times 10^{7}$
α, quenching efficiency	0.89 ± 0.15	0.80 ± 0.17
$K_{eq} \equiv k_i/k_b$, equilibrium constant [M^{-1}]	$2.8 \pm 0.3 \times 10^{2}$	$2.6 \pm 0.4 \times 10^{2}$

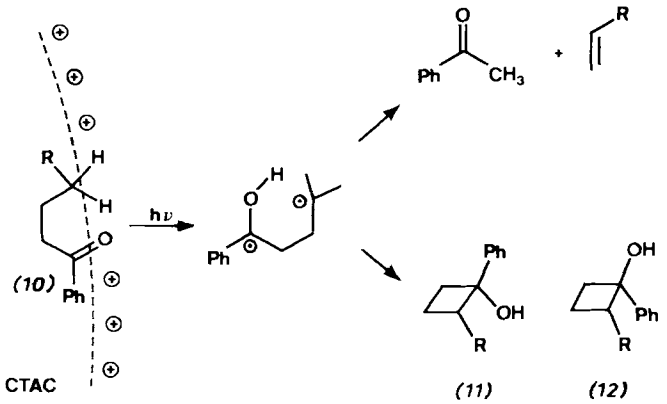
The values of the entrance rate constants 1.3×10^{10} M^{-1} s^{-1} (CTAB) and 1.4×10^{10} M^{-1} s^{-1} (SLS) are comparable with those derived from fluorescence quenching by oxygen in homogeneous fluid solution of low viscosity. Values of 8.3×10^{9} M^{-1} s^{-1} (CTAB) and 9.2×10^{9} M^{-1} s^{-1} (SLS) were reported for the total "bulk" oxygen quenching of pyrene *(3)* monomer fluorescence. The long inherent lifetime of pyrene fluorescence ($\approx$200 ns in CTAB and $\approx$450 ns in SLS, respectively) probably allows oxygen escape from the micelle to be competitive with oxygen quenching; therefore, the observed quenching constant is somewhat lower than that for diffusion of oxygen into the micelle[27].

The value of the rate constant for interaction (quenching) of excited 1,5-dimethylnaphthalene *(9)* is expected to be of the order of that for intramicellar encounter of an oxygen molecule and an excited naphthalene molecule. From the values of the reported microviscosities of CTAB and SLS micelles (39 and 9 cp, respectively), a micelle radius of $\approx$20 Å and an effective radius of the probe of $\approx$3.0 Å, a value of $\approx 1 \times 10^{7}$ to $\approx 5 \times 10^{7}$ s^{-1} is calculated from diffusion theory for the encounter rate[26]. An experimental value of $\approx 10^{7}$ s^{-1} has been evaluated for the intramicellar encounter of two pyrene molecules in an anionic micelle. Finally, a value of $\approx 6 \times 10^{7}$ s^{-1} has been evaluated for the rate of intramolecular excimer formation of 1,3-di-α-naphthylpropane *(5)* in CTAB micelles (see Fig. 12b). All these data suggest micellar interaction rate constants of the order of 10^{7}—10^{8} s^{-1} for the systems studied. Our derived value of $\lesssim 4.6 \times 10^{7}$ s^{-1} or $\lesssim 5.3 \times 10^{7}$ s^{-1} is comparable with literature estimates.

The fact that the efficiency of quenching is close to unity is consistent with results from homogeneous solution where O_2 is found to quench the fluorescence of aromatic hydrocarbons at close to the diffusional limit.

Finally, the limit of K_{eq} of $\approx 3 \times 10^{2}$ M^{-1} implies a higher solubity of O_2 in the micellar phase relative to the aqueous phase (on a molar basis). This result is consistent with the observation that O_2 is generally an order of magnitude more soluble in organic solvents than it is in water. The comparable value of K_{eq} for CTAB and SLS is consistent with a recent investigation of the oxygen quenching of naphthalene fluorescence in aqueous solutions of these two detergents.

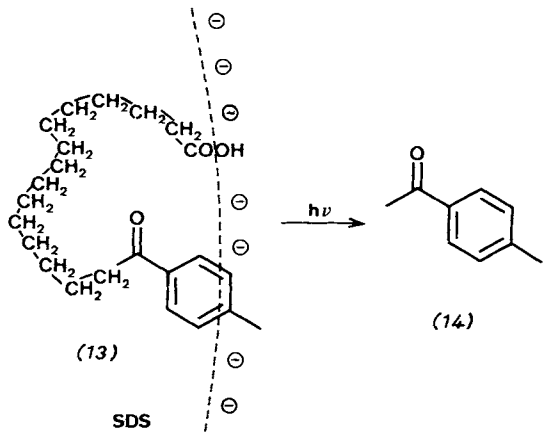
12. Photochemical Reactions in Micellar Systems



12.1. Photoinduced Hydrogen Abstraction Reactions

The triplet n,π* states of carbonyl compounds abstract hydrogen atoms from a variety of substrates including the relatively unactivated hydrogens of a saturated hydrocarbon[1g]. Employing the triplet n,π* state of an aryl ketone as "typical", the rate constant for hydrogen abstraction from a saturated methylene chain is expected to be $\approx 10^{4}$—10^{5} M^{-1} s^{-1}. Upon proceeding from nonpolar to polar solvents the rate constant for hydrogen abstraction occasionally decreases in cases where state "switching" or state "mixing" of n,π* and π,π* states occur. The efficiency of intramolecular hydrogen abstraction (Type II reaction) is enhanced upon proceeding from nonpolar to polar solvents. Thus, it should be possible to employ either hydrogen abstraction reactivity or efficiency measurements to serve as probes of the environment in which hydrogen abstraction occurs. Furthermore, "cage effects" on the type of products produced from intermolecular hydrogen abstraction are expected. Finally, there is a possibility that selective hydrogen abstraction might occur when flexible substrates are incorporated in micelles.

12.2. Intramolecular Hydrogen Abstraction Reactions



The "Type II" reaction of phenyl alkyl ketones is one of the best studied and understood of all organic photoreactions[29]. Both cleavage products (acetophenone and alkene) and cyclization products (cyclobutanols) are observed to occur *via* a primary product diradical. The quantum yield of overall reaction and the ratio of stereoisomeric cyclobutanols are solvent sensitive. Thus, measurement of the quantum yield and of the cyclobutanol ratio serve as monitors of local solvent properties of micelles. Experimentally[30], the quantum yield of Type II reactions of phenyl heptyl ketone (octanophenone) *(10)*, R = *n*-C_4H_9, is $\approx$0.7 in CTAC and the ratio of cyclobutanols *(11)/(12)* is 1.2 (Scheme 2). These values are much closer to those for Type II reaction in *t*-BuOH [$\Phi = 1.0$, *(11)/(12)* = 1.5:1] than those in benzene ($\Phi = 0.33$, *(11)/(12)* = 4.7:1).

These results are consistent with the ketones (or the intermediate diradicals) not being solubilized exclusively in the hydrocarbon core of the micelle. They suggest that the ketone (or the diradical intermediate) must spend at least some time in the polar Stern layer of the micelle. Quenching experiments with Eu^{3+} (a good quencher of the Type II reaction in water) show that no significant amount of probe reacts in the aqueous phase; *i.e.*, Eu^{3+} does not quench the Type II reaction of octanophenone *(10)* in CTAC solutions[30].

Scheme 2.

In another study, a surfactant ketone 16-oxo-16-(*p*-tolyl)hexadecanoic acid *(13)* was incorporated in SLS micelles[31]. The quantum yield of reaction was found to be 0.8 (as against 0.2 in benzene solution). 4-Methylacetophenone *(14)* was the only volatile product detected (Scheme 3).

Scheme 3.

These results can be interpreted to imply that hydrogen abstraction occurs when the fourteen carbon polymethylene chain is mostly bent such that both ends lie near the micellar surface. These results contrast sharply with those found for photolysis of *(13)* in monolayer assemblies made from arachidic acid, in which case the quantum yield for Type II reaction is $\approx 10^{-4}$, *i.e.*, Type II reaction is severely inhibited in the highly organized monolayer environment.

12.3. Intermolecular Hydrogen Abstraction Reactions

Aryl ketones should be capable of abstracting hydrogen atoms from the polymethylene chains of SLS and CTAC. In fact, the phosphorescence of benzophenone is quenched by such detergent molecules[32]. Interestingly, in a fluorinated micelle such as sodium perfluoro-octanoate ($CF_3(CF_2)_6COO^{\ominus}Na^{\oplus}$, SPFO) benzophenone phosphorescence is readily observed[32].

Product studies reveal that hydrogen abstraction occurs in the case of substituted benzophenones[33,34]. Several investigations have explored the selectivity of intermolecular hydrogen abstraction in micelles. For example, surfactant ketones have been photolyzed as "guests" in "host" micelles such as SLS and CTAB. The selectivity of hydrogen abstraction by triplet benzophenone along a detergent chain has been investigated[33], for both anionic and cationic C_{16} detergents. Benzophenone and several of its 4-carboxylate esters were employed as hydrogen abstractors. The general result was that attack occurs relatively non-selectively from positions ≈ 5 through 14, but in some cases a substantial selectivity for attack at 15 is observed (Fig. 17).

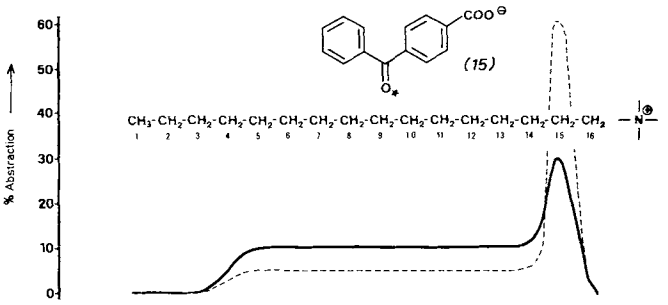


Fig. 17. Positions of hydrogen abstraction from the cationic detergent by the triplet of the 4-benzoylbenzoate anion *(15)*. (—) above CMC; (---) below CMC.

In the case of photolysis of mixed micelles of SLS and the 4-benzoylbenzoate anion *(15)* hydrogen abstraction from the detergent backbone methylene groups occurs and is followed by attachment of the benzophenone moiety to the detergent. Abstraction occurs from over positions 5 to 11 of the chain. The observed non-selectivity of the hydrogen abstraction suggests extensive coiling and folding of the detergent chains[33].

Interestingly, photolysis of 4-(4-benzoylphenyl)butyrate anion in CTAB solutions below the CMC leads to highly selective hydrogen abstraction at C-15 of CTAB. Above the CMC, attack becomes random. The reactions of benzophenones possessing different length chains in the 4-position with CTAB become less selective at C-15 as the chain is lengthened. This result is interpreted in terms of folding of the detergent chain[33].

Photolysis of the benzophenone derivative *(16)* in sodium tetradecanoate micelles results in a different selectivity: hydrogen is abstrated only from positions 5 through 8, with position 7 showing the highest reactivity (Fig. 18). In the case of *(15)*, abstraction from positions 3 through 8 is observed, with position 6 showing the highest reactivity[34].

These studies indicate that a certain selectivity is possible for reactions involving hydrogen abstraction from polyme-

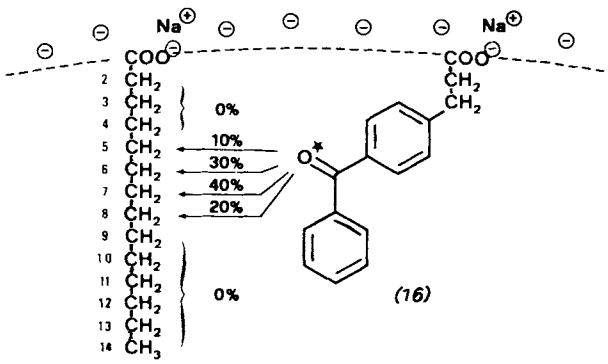

Fig. 18. Positions of hydrogen abstraction from sodium tetradecanoate by the triplet of sodium 2-(4-benzoylphenyl)propionate *(16)*.

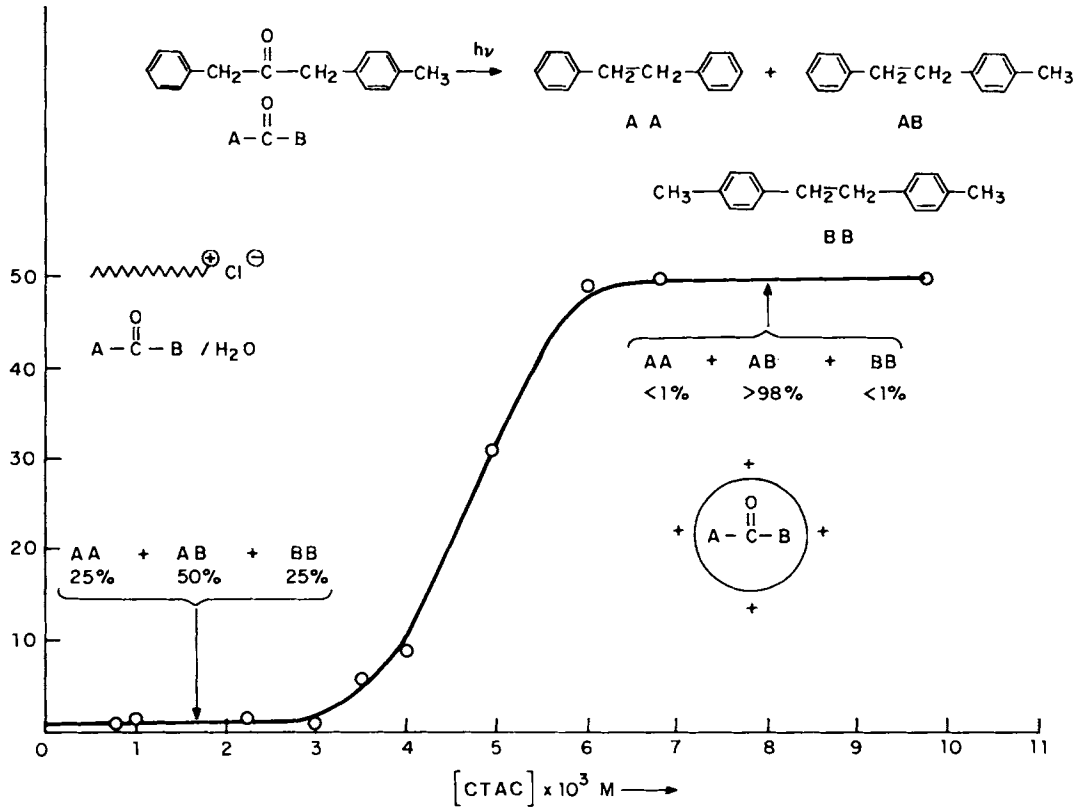

Fig. 20. The yield of recombination products on photodecarbonylation of benzyl *p*-methylbenzyl ketone (type A—CO—B) depends on the concentration of the detergent CTAC and shows a typical CMC profile.

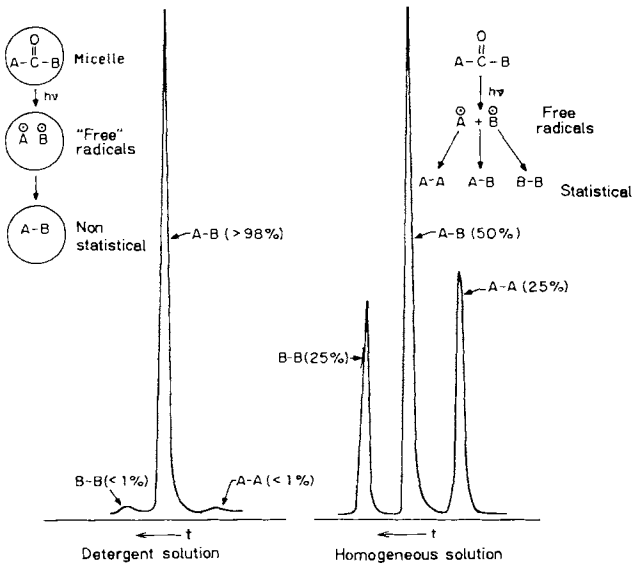
thylene chains of detergents. The results are consistent with considerable folding of the detergent chain and a certain amount of preferential ordering of ketone probes in micelles.

12.4. Photochemical Fragmentation Reactions

A rather obvious application of micellar environments is the enhancement of radical cage reactions of hydrophobic radical pairs relative to homogenous solution. The idea is that if a hydrophobic radical pair is generated in a micelle, the probability of cage reaction between spin correlated radical pairs increases relative to reaction of free radicals without spin correlation.

For example, the photodecarbonylation of unsymmetrical dibenzyl ketones A—CO—B in homogeneous solution occurs *via* a free radical mechanism to produce 1,2-diarylethanes in quantitative yield[35]. The latter products (AA, AB, and BB) are formed in yields of 25, 50, and 25%, precisely the ratio expected for statistical, nonselective coupling of spin-noncorrelated radicals A and B produced by decarbonylation of A—CO—B.

In contrast[36], photolysis of A—CO—B in micelle-containing solutions of CTAC results in selective formation of AB (Fig. 19). The yield of AB relative to (AA + BB) is dra-



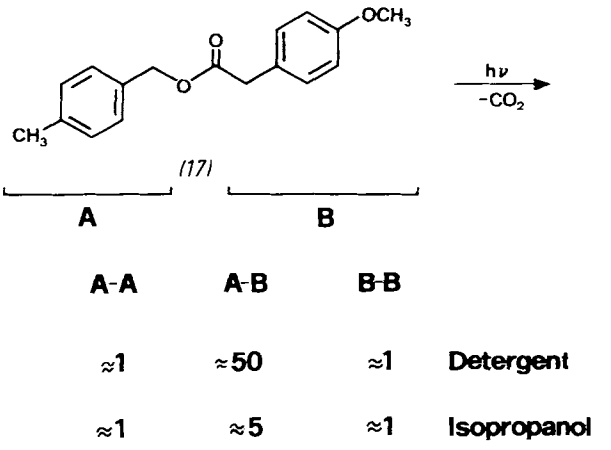


Fig. 19. Schematic representation of GC results of the photodecarbonylation of unsymmetrical dibenzyl ketones A—CO—B in detergent and homogeneous solution.

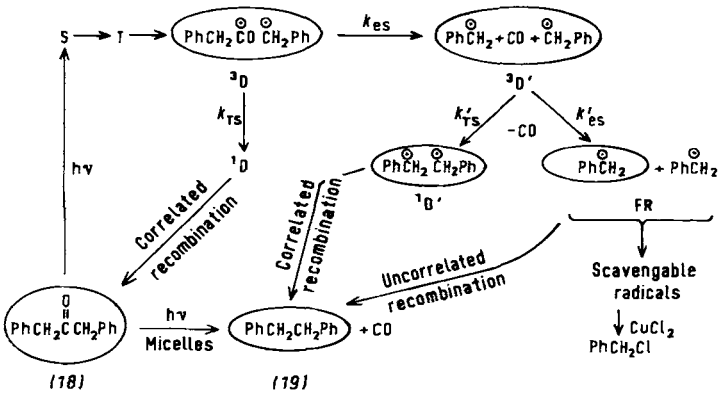
Scheme 4.

matically dependent upon the CTAC concentration and shows a typical CMC profile (Fig. 20).



In analogy to the results with photolysis of dibenzyl ketones, benzyl phenylacetates, *e.g. (17)*, undergo a more regioselective decarboxylation in potassium dodecanoate solutions than that observed in homogeneous solution (*e.g.*, isopropanol, Scheme 4)[37].

12.5. Application of Photofragmentation in Micelles to ^{13}C-Enrichment

The photolysis of dibenzyl ketone *(18)* (Scheme 5; see also Section 12.4) proceeds *via* an initial triplet radical pair (^3D). These radical pairs may be classified in terms of the occurrence of a ^{13}C or a ^{12}C nucleus in the carbonyl group of the radical pair. This classification is informative because CIDNP studies suggest that intersystem crossing of a radical pair such as $PhCH_2\overset{\odot}{C}O\overset{\odot}{C}H_2Ph$ occurs *via* a nuclear hyperfine induced mechanism. Since ^{12}C does not possess a nuclear moment while ^{13}C does, it is expected, from the observation that hyperfine coupling is most effective at the carbonyl center, that radical pairs with a ^{13}CO group will undergo more rapid $^3D' \rightarrow {}^1D'$ intersystem crossing than radical pairs with ^{12}CO. Since $^1D'$ radical pairs can undergo cage reactions (*e.g.*, recombination) but $^3D'$ radical pairs cannot and since $^1D'$ radical pairs are formed enriched in ^{13}C, the cage products will also be enriched in ^{13}C.

In the case of dibenzyl ketone *(18)*, the relevant cage product is dibenzyl ketone *(18)*. Thus, as the photoreaction proceeds the recovered starting material is found[38] to be enriched in ^{13}C! The magnitude of the enrichment is relatively small for homogeneous solutions but increases by over an order of magnitude in micelles (measured by the single stage separation factor). In micelle solution, the quantum yield for photolysis of *(18)* (90% ^{13}CO) is $\approx 30\%$ less than for natural abundance of ^{13}C at the CO carbon. In homogeneous solution, the quantum yield for photolysis is the same for both ^{13}C-enriched and natural abundance materials.

The striking difference in the photochemistry of *(18)* in micellar and homogeneous solutions has been attributed to the reduced dimensionality available to a substrate in a micellar aggregate. This feature provides a "super cage" environment that allows a spin-correlated radical pair to diffuse sufficiently far apart to allow hyperfine interactions to develop effectively, but not so far apart that spin-uncorrelated free radicals result.

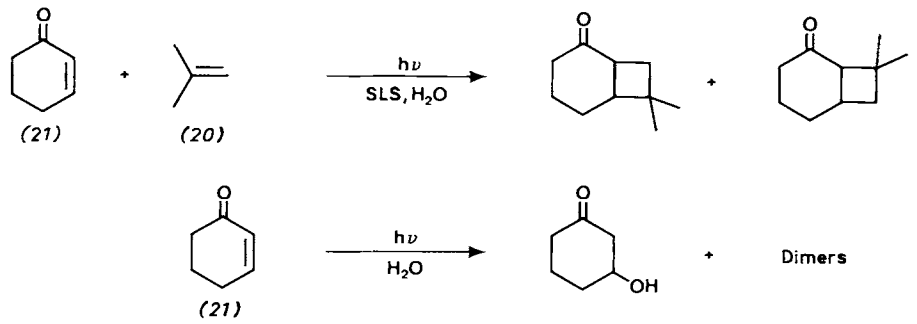
Scheme 5.

These results are consistent with the observation of CIDNP when micellar solutions of *(18)* are irradiated in an NMR spectrometer[38b]. It is interesting to note that the "super solvent cage" of a micelle serves to confer the maximum separation of radical centers of the $PhCH_2\overset{\odot}{C}O$ and $\overset{\odot}{C}H_2Ph$ fragments to a restricted region of space in a manner similar to the way that a chain of atoms separates the radical centers of a diradical.

12.6. Cage Effects and Magnetic Field Effects on Cage Reactions

Photolysis of dibenzyl ketone *(18)* in CTAC (Scheme 5) results in substantial cage decarbonylation to produce a triplet (spin-correlated) geminate radical pair ($Ph\overset{\odot}{C}H_2 + Ph\overset{\odot}{C}H_2$). Some of these radical pairs undergo intersystem crossing and geminate cage recombination to form diphenylethane *(19)*, and some pairs exit the micelle, enter the aqueous phase and eventually return to a micelle to undergo secondary cage recombination. The latter radical pairs are scavengable by Cu^{2+} which resides exclusively in the aqueous phase. Experimentally, it is found that in the presence of Cu^{2+} the yield of *(19)* is reduced by 25% of its value in the absence of Cu^{2+}. This means that a "cage effect" of 25% operates. The absolute quantum yield for this cage effect was found to be 0.06.

If the "cage effect" experiment is repeated in the presence of a laboratory magnetic field ($\gtrsim 200$ gauss) the quantum yield for geminate cage reaction drops to 0.02! This dramatic decrease in geminate recombination is ascribed to a splitting of two of the three triplet levels of the radical pair by the laboratory field. When this happens, only one of the three triplet levels is capable of intersystem crossing to a singlet diradical which can form cage products. The two radical pairs which do not form cage products leave the micelle and are scavenged by Cu^{2+}.

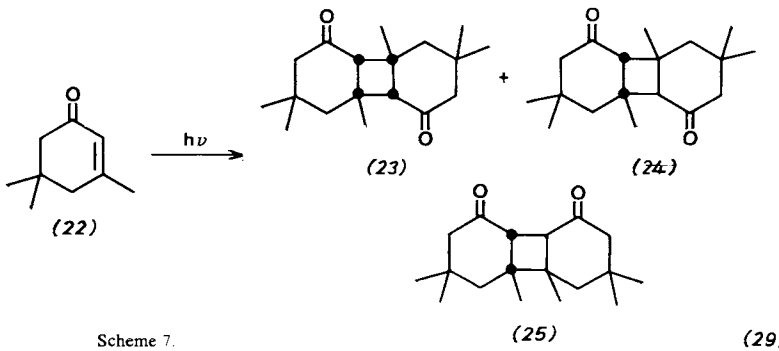


12.7. Photocycloaddition Reactions in Micelles

It is expected that, at comparable substrate concentrations, the quantum efficiency of intermolecular cycloaddition reactions of organic compounds might be higher for micellar solution than for homogeneous solution. This expectation is based on the high local concentrations of a substrate that are achieved by solubilization of the substrate into micellar aggregates. For example, if a solute is completely micellized at a macroscopic concentration of 10^{-4} M, the substrate concentration in the micelle aggregate is $\approx 10^{-1}$ to 10^{-2} M. Thus, rate enhancements of $\approx 10^2$—10^3 over those in homogeneous solution are expected and a cycloaddition reaction which is inefficient in homogeneous solution may be quite efficient in micellar solution.

In addition to simply serving as a means of achieving high local concentrations, photocycloadditions in micelles may also introduce unique features if the micelle is capable of speciate orienting effects.

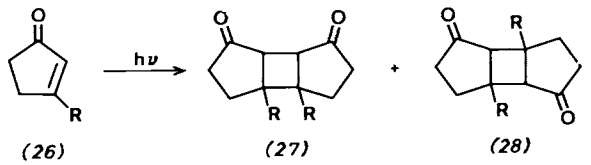
Micellar solutions of SLS saturated with isobutylene *(20)* contain high local concentrations of the alkene within the micellar hydrophobic area. Cycloaddition to cyclohexenone *(21)* (Scheme 6), which is soluble in water and therefore only partially solubilized, becomes more efficient under these



conditions than dimerization of *(21)*, which is a major side reaction in homogeneous solution[39].

(21) (20) (21)

Scheme 6.



The enone *(21)* dissolved in the aqueous phase reacts mainly with the solvent yielding the expected γ-keto alcohol (Scheme 6). The dimerization of isophorone *(22)* (Scheme 7) has been found to be enhanced in micellar systems and microemulsions. In addition, the formation of isomers *(22)*—*(25)* depends strongly on the polarity of the solvent and the dominant phase, respectively[40].

(22) (23) (24) (25)

Scheme 7.

Photoexcitation of 3-alkylcyclopentenones *(26)* in solutions of potassium dodecanoate (KDC, above CMC) results in a greatly increased efficiency of dimerization compared to that which occurs in homogeneous solution such as benzene[41]. Furthermore, the photodimerization in detergent solutions occurs in a highly regiospecific manner; moreover, the relative yield of head-to-head *(27)* to head-to-tail dimer *(28)* is opposite to that observed in homogeneous solutions (Scheme 8).

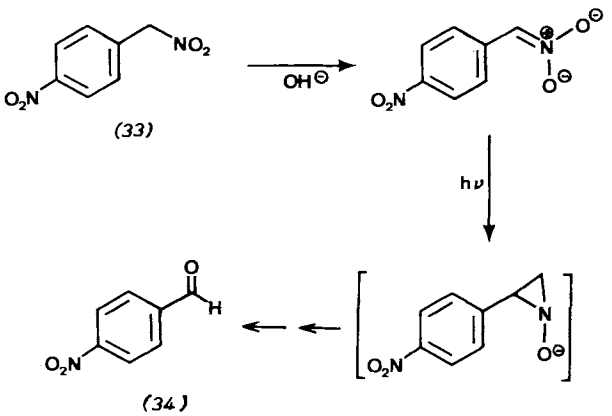
12.8. Photoinduced Substitution of Aromatic Compounds

Ionic detergents are known to alter the rate of thermal reactions of nucleophiles with organic substrates[40a]. Both retardation and acceleration of reaction rates in micelles may be achieved depending on whether the charge of the detergent causes repulsion of attacking nucleophile or causes organization of the attacking nucleophile and substrate.

Such effects have been observed in photoinduced substitution reactions of aromatic compounds[44]. Photoexcitation of aqueous solutions of 4-methoxy-1-nitronaphthalene *(31)* containing CN^- ions results in formation of 4-methoxy-1-naphthalenecarbonitrile *(32)* (Scheme 11). The efficiency of reaction is low even at $[CN^-] = 0.8$ M, *i.e.*, $\Phi \approx 0.002$. When the photoreaction was conducted in the presence of CTAC micelles, a large enhancement in the quantum yield of the

reaction was observed, even at relatively low [CN^-]. The enhancements in quantum yields (at comparable concentrations of CN^-) approached values of 10^3—10^4. In the case of SLS micelles quantum yields of reaction are exceedingly low.

The enhancement factor for reaction in CTAC is much larger than the characteristic rate enhancements commonly observed for micellar effects on ground state substitution reactions, suggesting that some factor other than substrate-nucleophile organization might be important. It was proposed that the polar local environment of excited 1-methoxy-4-nitronaphthalene *(31)* influences the rate constant for substitution. This postulate is supported by the observation of strong solvent dependence of quantum yields for photoinduced aromatic substitution reactions in homogeneous solution.

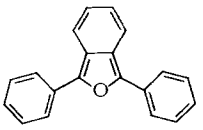


(31) *(32)*

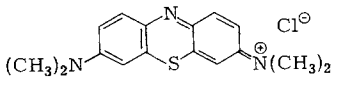
Scheme 11. $\Phi(H_2O)=0.0$, $\Phi(SLS)=0.0$, $\Phi(CTAC)=0.2$.

12.9. Miscellaneous Photoreactions in Micelles

The photorearrangement of 4-nitrophenyl-nitromethane *(33)* into 4-nitrobenzaldehyde *(34)* was found to be much more efficient in a cationic detergent (CTAB) than in basic ethanol/water solution (Scheme 12)[45].



(33) *(34)*



Scheme 12.

The anion of *(33)* is postulated as the key intermediate in this rearrangement. The effects of cationic detergent may be two-fold: (1) an organization effect and (2) a polarity effect. Both of these effects would be expected to enhance the equilibrium concentration of anion and thereby enhance the quantum yield of reaction.

Photosensitized oxidations have been performed in micellar solution[46,47]. Generally, singlet oxygen is the key reactive intermediate in such reactions. In one case, oxidation of 2,5-diphenylisobenzofuran *(35)* in SLS micelles in aqueous

(35)

(36)

solutions of methylene blue *(36)* was investigated. Because methylene blue is a cationic sensitizer and since *(35)* is expected to be totally micellized, it was proposed that singlet oxygen was produced in the aqueous phase and that diffusion to the micelle and penetration of the micelle barrier followed. Once in a micelle containing substrate, attack on the latter by singlet oxygen then led to products of oxidation. Assignment of $^1O_2$ as the reactive species should be made with care when oxidations are performed in aqueous solution because other oxidizing species may also participate.

These results and a later study comparing kinetic studies in H_2O and D_2O are consistent with an "averaging" of the lifetime of singlet oxygen as a result of rapid exit and entrance into the micelle during its lifetime (1×10^{-6} s in H_2O). In turn this conclusion is consistent with a number of investigations of the mobility of ground state oxygen in and out of micelles[48].

13. Synthetic Applications of Photochemistry in Micellar Systems; Practical Considerations

The selective capacity of solubilization of micellar aggregates based on their specific molecular organization opens, in principle, a wide variety of applications in preparative photochemistry. The present technological standard is, however, characterized by the limited capacity of solubilization of the applied surfactant, hence requiring vast volumes of solution to be photolyzed. Other limiting factors are: (1) the reactivity of the surfactant; (2) the restrictive temperature range in which micelles are stable; and (3) the low number of surfactants suitable for an eventually continuous separation of product and surfactant. Consequently, relatively few experiments with micellar solutions used in synthetic or preparative photochemistry have been reported.

Amphiphilic sensitizers[49] and quenchers may be separated from the aqueous phase like ordinary surfactants. For their crystallization upon addition of electrolytes and simultaneous extraction of the photoproducts by organic solvents, alkylsulfonic acid salts have been found to be convenient and practical.

Due to the temperature dependence of the solubility of these surfactants, the geometry of the photochemical reactors to be used should provide a clean separation of the micellar solution from the well. Experiments with immersion-type reactors have shown that the temperature difference between the photolyzed solution and the water-cooled jacket wall may cause the precipitation of the surfactant. In cases where immersion-type reactors have to be used, wells with evacuated outer jackets are recommended.

The use of substrate compounds on a preparative scale does not alter the technique of solubilization. While liquid substances are introduced with minute fluxes into well-agitated solutions of a chosen surfactant (concentration >CMC), solids are first dissolved in a suitable solvent of

high vapor pressure at a concentration as high as possible. A thin film of the substrate will coat the walls of a given flask after evaporating the stirred solution by a stream of inert gas. A solution of the surfactant placed into the flask and kept at high turbulence will solubilize the dispersed compound within hours.

Since aggregation of micellar systems varies with temperature changes, the use of thermostated vessels is highly recommended. Particularly, micelles containing substance solubilized in their hydrophobic core and surfactants with low solubilities tend to deposit insoluble films or to crystallize at the surface of cold spots. Consequently, film reactors providing a separation between the well and the liquid to be photolyzed are highly recommended[50]. For immersion type reactors, a well provided with an evacuated or thermostated outer compartment may prove helpful.

Work-up procedures consist basically of an extraction of the solubilized material by hydrocarbons, chlorinated hydrocarbons, or ethers of low boiling points. The use of special surfactants, such as amphiphilic redox chromophores[51] and sensitizers[49] may require a recyclization of such micelle forming compounds. Simultaneous separation and subsequent isolation of both the solubilized material and the surfactant is achieved by saturating the micellar solution prior to extraction with a salt of high solubility in water but of low solubility in polar organic solvents. While liquid-liquid extraction separates the solubilized compounds from the reaction mixture, the surfactant will precipitate and may be filtered, then purified for re-use by recrystallization from mostly polar organic solvents.

14. Electron Transfer in Transition Metal Ion Micelles

The simplest type of functional surfactant is one where the counterion is a participant in the redox reaction. For example, replacement of the Na^+ ions in sodium dodecyl sulfate (SLS) by Cu^{2+} yields assemblies in which Cu^{2+} ions constitute the counterion atmosphere of the micelle (Fig. 21).

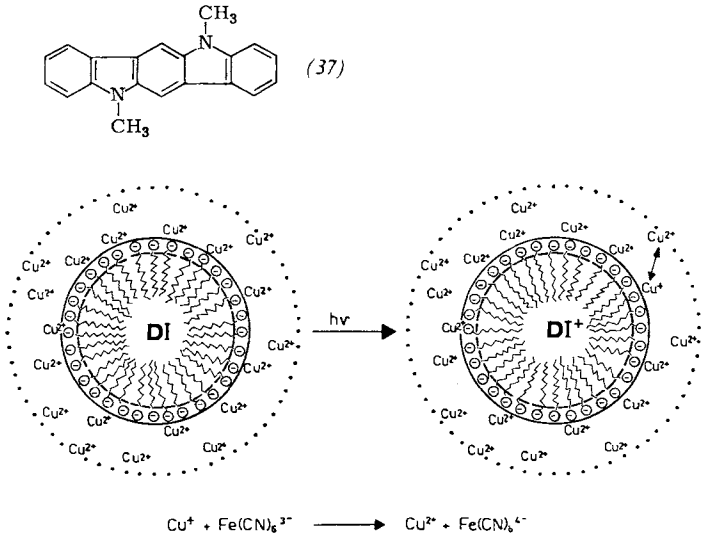


Fig. 21. Schematic representation of a $Cu(LS)_2$ micelle and of a photoinduced electron transfer of compound *(37)* (DI) in such a functional surfactant system.

These may be photoreduced to Cu^+ by suitable donor molecules incorporated in the micellar interior, *e.g.* by *N,N'*-dimethyl-5,11-dihydroindolo[3,2-*b*]carbazole (DI) *(37)*[24]. The absorption spectrum of an aqueous micellar solution of *(37)* is shown in Figure 22.

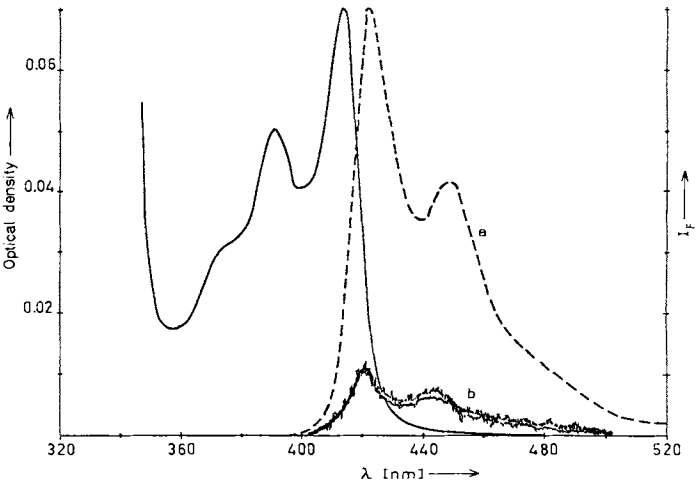

Fig. 22. Absorption and fluorescence spectra of *N,N'*-dimethyl-5,11-dihydroindolo[3,2-*b*]carbazole *(37)* (DI). a) Fluorescence of 3.7×10^{-5} M *(37)* in 0.2 M SLS; b) fluorescence of 5.1×10^{-5} M *(37)* in 0.1 M $Cu(LS)_2$.

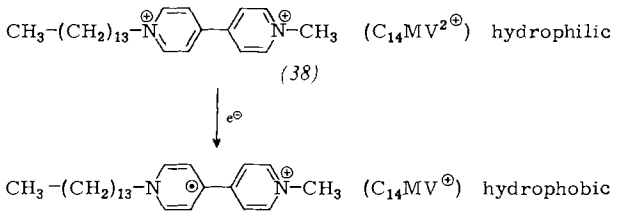
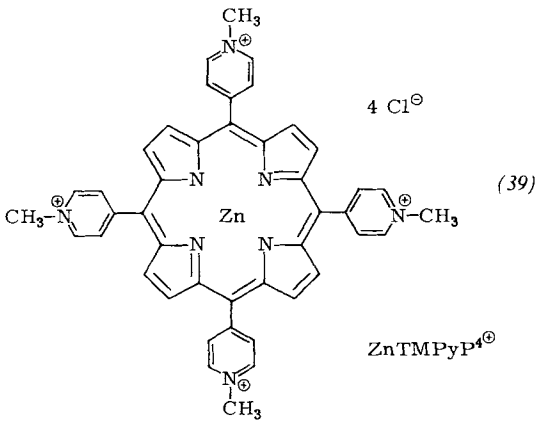


When dissolved in SLS micelles, *(37)* displays an intense fluorescence whose spectrum is also included in Figure 22. The fluorescence lifetime $\bar{\tau}_F$, measured by laser techniques, is 144 ns. Introduction of Cu^{2+} as counterion atmosphere induces a 300-fold decrease in the fluorescence yield and lifetime of *(37)*. The detailed laser analysis of this system showed that in $Cu(LS)_2$ micelles there is an extremely rapid electron transfer from the excited singlet state of *(37)* to the Cu^{2+} ions. This process occurs in less than a nanosecond and hence can compete efficiently with fluorescence and intersystem crossing. This astonishing result must be attributed to a pronounced micellar enhancement of the rate of the transfer reaction. It is of course a consequence of the fact that within such a functional surfactant unit regions with extremely high local concentrations of Cu^{2+} prevail. Theoretical estimates predict the counterion concentration in the micellar Stern layer to be between 3 and 6 M (see Section 10.2.)[52].

The significance of this functional organization becomes evident also when the back reaction of Cu^+ and DI^+ is considered. Previous studies[24,53] have shown that the intramicellar electron transfer from Cu^+ to DI^+, though thermodynamically high favorable, cannot compete kinetically with the escape of the cuprous ion from its native micelle into the aqueous phase. An efficient escape route is provided by the exchange with one of the Cu^{2+} ions present in high local concentration in the Gouy-Chapman layer. According to mere electrostatic arguments, the latter ion is $\exp(-e\psi/kT)$ times more likely to be absorbed on the micellar surface than Cu^+. Once in the aqueous phase, Cu^+ can be used for a second redox process such as the reduction of $Fe(CN)_6^{3-}$. The back reaction of the $Fe(CN)_6^{4-}$ with the oxidized donor, DI^+, is prevented by the negatively charged micellar surface. Hence, such a system is successful in storing light energy originally converted into chemical energy during a photoredox process.



15. Micellar Systems Where the Surfactant Head Group Serves as an Electron Acceptor

15.1. Methylviologen Surfactant Assemblies

The encouraging results obtained with the simple surfactant systems enhanced our efforts to search for more developed molecular organizations suited for the conversion of light into chemical energy. We shall first consider assemblies containing the surfactant derivative of methylviologen as an electron acceptor. A characteristic feature of this species is that the oxidized form $C_{14}MV^{2+}$ has strongly hydrophilic properties while its reduced form is hydrophobic.

Consider now a solution containing $C_{14}MV^{2+}$ as an electron acceptor and the porphyrin derivative *(39)* as the photoactive electron donor. The concentration of $C_{14}MV^{2+}$ is

(39)

maintained below its CMC value, *i.e.* $<10^{-3}$ M. The reduction of the $C_{14}MV^{2+}$ by the triplet state of the porphyrin was studied by laser photolysis technique. Figure 23 shows the behavior of the optical absorption of a solution at 890 and 602 nm. The former is characteristic of the porphyrin triplet state while the latter reflects the production and disappearance of the redox products $ZnTMPyP^{5+}$ and $C_{14}MV^{+}$. Consider first a solution containing only $ZnTMPyP^{4+}$ and $C_{14}MV^{+}$. The reaction

$$ZnTMPyP^{4+} + C_{14}MV^{2+} \xrightarrow{h\nu} C_{14}MV^{+} + ZnTMPyP^{5+} \qquad (11)$$

occurs here reversibly: The decay of the triplet state is accompanied by the formation of redox products which, however, undergo a rapid back reaction (as shown in oscillogram b). In marked contrast to this behavior stand the results obtained in the presence of CTAC micelles. Here the forward electron transfer goes to completion without any subsequent

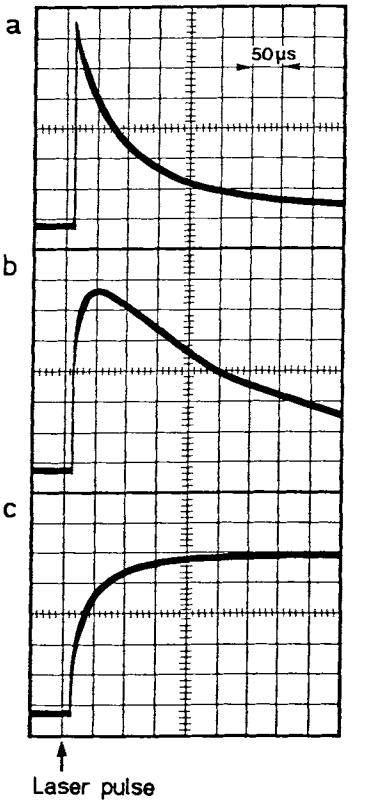


Fig. 23. Light-induced reduction of $C_{14}MV^{2+}$ by the triplet state of $ZnTMPyP^{4+}$. a) Triplet decay, $\lambda = 890$ nm; b) growth and decay of redox products in pure aqueous solution, $\lambda = 602$ nm; c) stabilization of redox products by CTAC micelles, $\lambda = 602$ nm. $[ZnTMPyP^{+}] = 5 \times 10^{-5}$ M, $[C_{14}MV^{2+}] = 10^{-3}$ M, $[CTAC] = 5 \times 10^{-2}$ M.

back reaction. In fact, the signal of $C_{14}MV^{+}$ and $ZnTMPyP^{5+}$ remains stable over many milliseconds. Detailed kinetic analysis shows that the back reaction is retarded by the CTAC micelles by at least a factor of 1000[63].

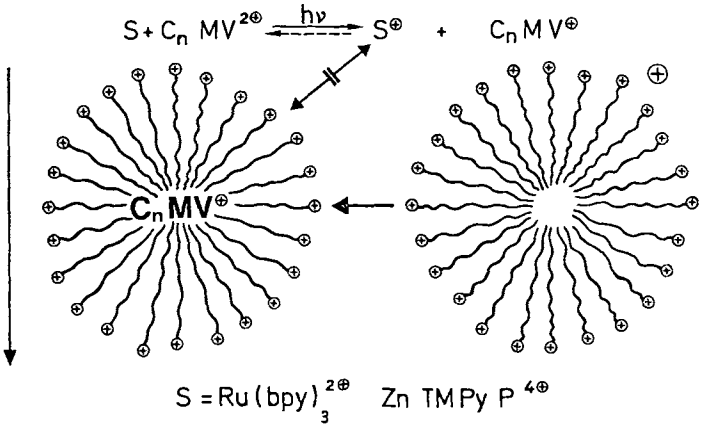

Fig. 24. Principle of charge separation by cationic micelles in the photoinduced reduction of amphiphilic viologen derivatives C_nMV^{2+}, *e.g. (38)*.

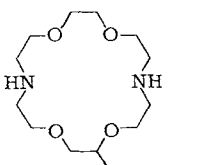
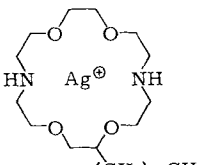
This charge separation effect induced by the micelles is explained schematically in Figure 24. The hydrophilic acceptor is mainly present in the aqueous phase and does not associate with the CTAC micelles. Upon reduction it acquires pronounced hydrophobic character. This leads to rapid solubilization in the cationic surfactant assemblies of CTAC. The

oxidized porphyrin is prevented from approaching the cationic micelles by their repulsive surface chearge. As the ζ-potential of CTAC micelles is about +100 mV the probability of encounter with $ZnTMPyP^{5+}$ is only 2×10^{-9}. This explains the effective micellar inhibition of the back reaction.



The $C_{14}MV^+$ produced in the photoredox reaction may be used to generate hydrogen from water. Recently, very active noble metal catalysts have been developed in our laboratory which can mediate the reaction:

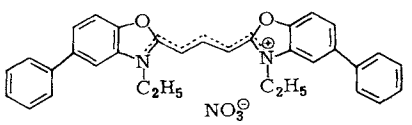
$$2C_{14}MV^+ + 2H_2O \rightarrow 2C_{14}MV^{2+} + H_2 + 2OH^- \quad (12)$$



Continuous illumination of $ZnTMPyP^{4+}$ solutions containing $C_{14}MV^{2+}$, CTAC, and such a Pt catalyst leads to the production of hydrogen. In the initial experiments, EDTA or nicotinamides served as sacrificial donors to replenish the electron in $ZnTMPyP^{5+}$. However, more recently two nonsacrificial photochemical water-cleaving systems based on viologen derivatives have been introduced in our laboratory[64,65].

15.2. Reduction of Silver Ions in Aza-Crown Ether Surfactants

Macrocyclic compounds with a paraffinic chain were first described by *Cinquini et al.*[54]. In aqueous solution they readily form micelles with CMC values ranging between 10^{-5} and 10^{-3} M, depending on the exact nature of the head group and the chain length[55,56]. Crown ether surfactants are particularly suited as electron relays in redox events, since different metal ions covering a wide range of standard potentials may be inserted into the macrocyclic ring. Consider, for example, the crown 2-tetradecyl-1,4,10,13-tetraoxa-7,16-diazacyclooctadecane *(40)*. Compound *(40)* strongly binds Ag^+ ions[57], the complexation constant being about 10^8.



(40)

(41)

We shall now be concerned with the photoinduced reduction of the silver ion derivative *(41)*. This surfactant possesses a CMC value of 3×10^{-4} M. The micellar aggregates formed are relatively large, the molecular weight being 6.3×10^6 as determined by quasielastic light scattering technique. A variety of sensitizers when solubilized in aqueous micellar solutions of *(41)* were shown to be oxidatively bleached, with concomitant formation of Ag^0. Consider, for example, the cyanine dye *(42)*:

(42)

Its fluorescence emission is totally quenched ($\Phi_F < 10^{-6}$) in micellar solutions of *(41)*. On illumination with visible light,

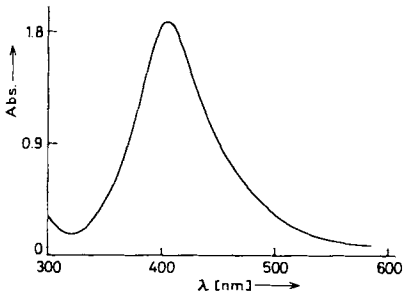


Fig. 25. Absorption spectrum of aza-crown ether *(40)* complexed and stabilized Ag^0 upon photolysis of the cyanine dye *(42)*.

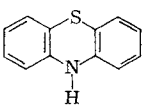
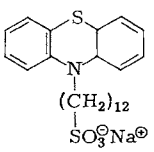


one observes a rapid bleaching of the cyanine and formation of a new stable absorption band with a maximum at $\lambda = 415$ nm (Fig. 25). This spectrum can be attributed to silver atoms stabilized by the macrocyclic ligand. It appears that in our system silver is prevented from aggregation by insertion in the crown ether cavity and hence preserved in the monoatomic state. The speed of Ag^0 formation is so rapid that it cannot be resolved by ns-laser photolysis techniques. Obviously, this effect has to be attributed to the close proximity of photoactive donor and Ag^+ sites on the surface of the micelle. The photoinduced reduction of Ag^+ can be performed with a number of other donor chromophores such as porphyrins, $Ru(bpy)_3^{2+}$, and pyrene. In all those cases no back reaction between oxidized donor and Ag^0 is observed. Apparently, through electrostatic interactions, the donor cation is ejected from the positively charged aggregates before back electron transfer can take place[58]. Once in the aqueous phase, the re-entry of the donor cation into the micelle is prevented by the repulsive surface charge. We conclude that in the photoinduced reduction of Ag^+ to silver atoms the functional macrocyclic surfactant serves three important purposes: high local concentration of the acceptor drastically accelerates the forward rate—and hence the yield— of reaction (13);

$$D^* + A \rightleftharpoons D^+ + A^- \quad (13)$$



the Ag atom is stabilized by the macrocyclic ligand, and finally the back electron transfer is prevented by the microscopic electrostatic barrier provided by the lipid/water interface.

16. Functional Micelles with Attached Redox Chromophores

A significant development in the field of functional surfactants is the design of molecules where the redox chromophore is chemically linked to the hydrocarbon tail of the surfactant. It is expected that these "redox" micelles will play a fundamental role in light energy storing photoreactions. Consider, for example, the photoionization of phenothiazine (PTH) *(43)* which has been studied in anionic mi-

(43)

(44)

$$PTH \xrightarrow{h\nu} PTH^{\oplus\ominus} + e_{aq}^{\ominus} \quad (14)$$

celles[59,60,61]. Process (14) is monophotonic and leads to the formation of cation radicals and hydrated electrons. However, such a system is not suitable for use in the photoproduction of solvated electrons in an energy storing device since the solubility of *(43)* in the anionic micelles is limited ($<2\times10^{-4}$ M) and $PTH^{\oplus\ominus}$ is rapidly deprotonating. This renders the capacity of the system low. This problem is overcome when the functional PTH derivative sodium 12-(10′-phenothiazinyl)dodecylsulfonate *(44)* is used as the light absorbing chromophore. *(44)* micellizes readily at concentrations $>5\times10^{-4}$ M. An interesting cooperative effect was discovered with this redox chromophore[62]: When monomeric solutions of *(44)* are irradiated with low intensity light, no photoionization occurs. In contrast, above the CMC, hydrated electrons and cations are produced monophotonically in high yield. Moreover, the lifetime of the cation is hours to days in such a solution. This effect may be understood in terms of photoejection of electrons from the micellar into the aqueous phase and subsequent stabilization of the radical ions by the charged micelle water interface. The latter acts as a Schottky barrier, preventing the approach of hydrated electrons and parent ions (see Fig. 26).

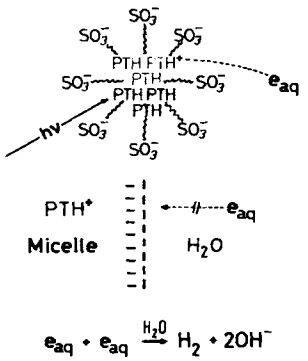


Fig. 26. Schematic illustration of the photoionization and charge separation processes in functional micelles formed by PTH—$SO_3^{\ominus}Na^{\oplus}$ *(44)* above the CMC. Re-entry of the electrons into the micelle is prevented by the potential barrier on its surface.

17. Conclusion

The conventional model of ionic micelles considers them as aggregates which form in aqueous solutions of detergents and that are capable of sequestering organic species. The photophysics of organic molecules that are solubilized by micelles provide information on the composition, structure and dynamics of the micellar environment. In turn, photochemical reactions in micelles display characteristics that distinguish them from comparable reactions in homogeneous solvents.

A number of specific examples of photoluminescence techniques are applicable and useful to probe the nature and behavior of micelles. For example, aggregation numbers, exit and entrance rates of solubilized species, and equilibrium distributions of solutes may be evaluated from photoluminescent probes. Information on structure and dynamics of micelles and the methods and strategy for obtaining this information, should be applicable to the investigation of more complex assemblies of biological interest such as membranes and cells.

The micellar aggregates may influence photophysical and photochemical properties of solutes in interesting ways as a result of the statistics, the restricted space, the local concentration effects, and the polar proximity of head groups and gegenions imposed upon species that are compartmentalized in a micellar aggregate. For example, phosphorescence efficiencies may be increased both by reduction of triplet quenching processes due to statistics and restricted space features of micelles and by the enhancement of phosphorescence rates by heavy atom gegenions. Excimer and exciplex formation may be greatly enhanced by local concentration effects. The lifetime of species produced by electron transfer may be lengthened by association with a micelle and by the stabilization of these highly reactive charged intermediates due to the proximate polar environment, which allows kinetic control of the important electron back transfer reactions. Photolyses which produce organic radical pairs in a micelle create high (0.1 M) local concentrations of organic radical pairs. These concentrations are maintained within the micelle's restricted space for relatively long time periods and allow for selectivity in the reactions of the radical pair. In effect, the micelle serves as a "super cage" for radical pairs and keeps them together in a restricted space for a time orders of magnitude longer than is possible in fluid homogeneous solution. Magnetic isotope and magnetic field effects of radical pairs are amplified in micellar systems.

Finally, the idea of "functionalized micelles", the strategy in which detergents themselves possess photophysically or photochemically active groups which are localized in the hydrophobic portion or in the ionic portion of the micellar structure, has provided novel information and has lead to unusual chemical processes. The extension of these ideas will surely be seen in current and future experimental investigations.

N. J. Turro thanks the National Institutes of Health (Grant CM-25523) for their generous support of this research. Acknowledgment is made to the Swiss National Foundation for supporting the work of M. Grätzel and A. M. Braun under grant No. 4.061.076.04 and 4.101.076.04, respectively. Both are also grateful to Ciba-Geigy Ltd., Basel, Switzerland, for financial and technical aid.

The Structure of Simple Molecular Liquids

By Manfred D. Zeidler[*]

Dedicated to Professor Ernst Ulrich Franck on the occasion of his 60th birthday

Liquid structure is described by the pair-correlation function. If the liquid particles are molecules then the respective correlation function depends on distance and several angular variables; hence, for the sake of simplicity a symmetry-adapted representation must be used. The most important structural parameters of this molecular pair-correlation function can be determined approximately by a combination of several scattering experiments, such as neutron (employing different isotopes), X-ray and electron diffraction. Light scattering, dielectric, and nuclear magnetic relaxation experiments provide further, albeit less direct, access to such determinations. Some results obtained by measurements on chloroform are reported. Theoretical computations of these structural parameters are also discussed.

1. Introduction

The important role of liquids in chemical experiments can hardly be overemphasized, for most chemical reactions are carried out in the liquid phase. Apart from water, organic liquids are primarily used as solvents. The liquids of initial interest in chemistry are those which may be termed molecular liquids as distinct from atomic liquids (liquid rare gases).

Unfortunately, our theoretical understanding of the liquid state, occupying a position intermediate between the well-ordered solids and the disordered gases, is beset with considerable problems. During the last three decades remarkable progress could be made in the case of atomic liquids, whereas molecular liquids still give rise to many difficulties.

This explains why interest still centers on simple molecular liquids, *i.e.* molecules containing less than about ten atoms, exhibiting high symmetry, having no internal flexibility, and obeying the laws of classical statistical mechanics.

The aim of a theory of the liquid state is the calculation of thermodynamic data and of transport coefficients from given intermolecular potentials. The first task is more easily dealt with since we restrict ourselves to equilibrium properties (statistical thermodynamics), whereas transport coefficients have to be calculated within the framework of nonequilibrium statistical mechanics.

In relation to statistical mechanical theories the special importance of structural investigations follows from the fact that an intermediate experimental check can be made in going from the input of the potential to the output of the thermodynamical data: only those theories are acceptable which predict the correct structure.

2. The Intermolecular Potential

Even the input parameters for the theory cause remarkable difficulties. Clearly, the intermolecular potential depends on a whole series of parameters. Figure 1 shows the spatial arrangement of a pair of non-spherical molecules. A molecule-fixed coordinate system is assigned to each partner. In principle it may be chosen arbitrarily. However, it is convenient to

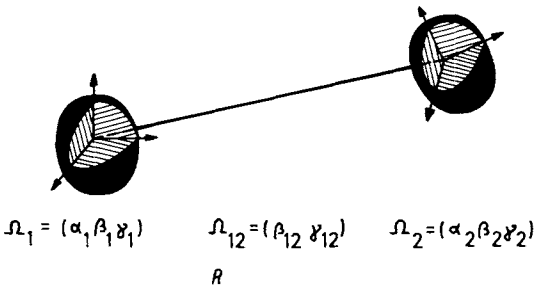

Fig. 1. Coordinates for a pair of non-spherical molecules.

define it in such a way that its axes coincide with the symmetry axes of the molecule. At a later stage the molecular symmetry may then be used to simplify the theoretical relations. As shown in Figure 1, two sets of Eulerian angles are needed to describe the orientation of both molecules in a reference system chosen arbitrarily (each set Ω consists of three angles α, β, γ). Moreover, a degenerate set of Eulerian angles (consisting of the two angles β and γ) is introduced to describe the orientation of the vector joining the molecular centers. An attentive reader will immediately notice that, strictly speaking, three Eulerian angles are redundant. Instead of an arbitrary choice of the reference system we are free to define the molecule-fixed coordinate system of one of the interaction partners as a reference system. However, our feeling for symmetry tells us that such a preference of a particular partner should be avoided. Otherwise, the symmetry inherent in the theoretical relations could be destroyed. Moreover, the arbitrary reference system may, if necessary, be identified with any system defined by the physical operation underlying the measurements. In any case it is clear that the intermolecular potential is a function of six independent parameters, *i.e.*, the distance R and five angles.

The question immediately arises as to how a function of so many variables can best be represented, if at all. This problem is generally associated with orientation dependent quantities: it always arises on going from spherical atoms to mole-

On leave from the Institut für Physikalische Chemie und Elektrochemie der Universität
D-7500 Karlsruhe (Germany)

cules. A brief summing-up of the situation reveals that a tabulated representation is out of the question, since a rather more accurate documentation, *e.g.* using an angular grid of 5° for $0 \leq \beta \leq 180°$ and $0 \leq \alpha, \gamma \leq 360°$, and a radial grid of 0.1 for $0.8 \leq R/\sigma \leq 3$ (where σ is the distance at which the potential is just zero owing to mutual compensation of repulsive and attractive forces) would end up with 10^{10} entries. In theoretical treatises, however, one requires relatively clear and distinct analytical expressions.

To proceed further one introduces symmetry-adapted descriptions, as is usually done when confronted with complex problems. Obviously, the intermolecular potential does not depend on the absolute location of the molecular pair; in other words, it is totally symmetric with respect to infinitesimal rotations of the pair in three-dimensional space. Moreover, if the interaction partners exhibit an intrinsic molecular symmetry, *e.g.* if they are of tetrahedral shape, the intermolecular potential is also totally symmetric under the symmetry operations of these tetrahedrons. Again the symmetry operations involve rotations, but in contrast to the above situation these rotations are finite. However, all finite rotations may be regarded as sums of infinitesimal rotations. Apart from the orientations discussed above, also rotations in three-dimensional space can be described by Eulerian angles, because a rotation transforms a given orientation into a new one. A mathematical formulation of rotations is obtained by the introduction of transformation matrices, which relate the coordinates before and after a rotation. In principle, the coordinates, *i.e.* functions of the Eulerian angles, may be chosen arbitrarily. However, there exists a specially distinguished set of functions, characterized by the fact that the transformation matrix possesses the most simple structure. Those readers who are familiar with the mathematical theory of symmetry, the so-called group theory[1], will recognize that one chooses the basis for the irreducible representation of the continuous three-dimensional rotation group. These basis functions (whose explicit relations to the Eulerian angles are not needed here) may be written as $\Phi_{m_1 m_2}^{(l_1 l_2 l_{12})}(\Omega_1, \Omega_2, \Omega_{12})$. The indices l_i can take all integral values between 0 and ∞, the m_i all integral values from $-l_i$ to $+l_i$. In the construction of these functions the invariance of the potential with respect to the rotations of the molecular pair has already been taken into consideration; therefore, there appear only five instead of eight indices (corresponding to five or eight angles, respectively). A typical property of basis functions of irreducible representations in group theory is their orthogonality; consequently, it is also an important feature of these Φ-functions.

We next define potentials which are weighted with these Φ-functions and which are averaged over all orientations:

$$u_{m_1 m_2}^{(l_1 l_2 l_{12})}(R) = \iiint u(R, \Omega_1, \Omega_2, \Omega_{12}) \Phi_{m_1 m_2}^{(l_1 l_2 l_{12})}(\Omega_1, \Omega_2, \Omega_{12})^* \, d\Omega_1 \, d\Omega_2 \, d\Omega_{12} \quad (1)$$

where * denotes the complex conjugate (Φ may become complex). These quantities will be referred to as *u*-coefficients. Each coefficient, characterized by five indices, depends on the distance *R*, only. Knowledge of all these coefficients allows the reconstruction of the potential according to

$$u(R, \Omega_1, \Omega_2, \Omega_{12}) = \sum_{l_1 l_2 l_{12}} \sum_{m_1 m_2} u_{m_1 m_2}^{(l_1 l_2 l_{12})} \cdot \Phi_{m_1 m_2}^{(l_1 l_2 l_{12})} \quad (2)$$

One might immediately ask how many terms of this expansion are needed. The answer depends on the accuracy which is required for a characterization of the orientation dependence. It is known from group theory that the number of symmetry operations, summed up in definite classes, is equal to the number of irreducible representations in a symmetry group. To describe small differences in orientation, more rotational operations must of course be taken into account than are required in the case of rough differences, *i.e.* the expansion (2) involves more terms in the former case.

So far the above expansion corresponds to a Fourier transformation of the angular space. The more isotropic the potential, the faster the expansion converges. For a totally isotropic potential, only the term $u_{00}^{(000)}$ contributes. One may estimate from an uncertainity relation of the form

$$l_{max} = 2\pi/\Delta\varphi \quad (3)$$

up to which term with index l the expansion has to be considered, allowing an uncertainty $\Delta\varphi$ in the respective angle.

In order to obtain the final number of terms up to a given value l, some symmetry considerations are necessary, with which the vanishing terms can immediately be determined. As mentioned above, the pair potential has to be invariant under symmetry operations, in particular rotations, of both molecules. A suitable choice of the molecule-fixed axes facilitates such considerations. If the molecule possesses a K-fold symmetry axis, this may be chosen as the reference axis for the first Eulerian angle; then the index m (for molecule 1 or 2, respectively) must be an integral multiple of K. Thus, *e.g.*, for a three-fold axis all terms vanish, except those with $m = 0, 3, 6, 9 \ldots$; for rotation axes of infinite order (linear molecules) only terms with $m = 0$ contribute. Similar conditions hold for the second molecule-fixed axis, being orthogonal to the first axis discussed above. In the latter case the possible values of l are influenced. Considering *e.g.* linear molecules with a two-fold symmetry axis perpendicular to the axis of infinite order, l is limited to even numbers. We next consider a molecule possessing a rotation reflection axis. Then, m is determined by the order of the proper rotation axis, whereas the order of the rotation reflection axis determines the possible values of l. An instructive example is the tetrahedron, which exhibits a four-fold rotation reflection axis, coinciding with a proper two-fold axis. In this case both the sum $l + \frac{2m}{4}$ and m itself must be even. Finally, if we are dealing with identical molecules 1 and 2, the result must also be invariant with respect to an interchange of the indices l_1, l_2 and m_1, m_2, apart from the occurrence of a trivial factor $(-1)^{l_1 + l_2}$. Moreover, the possible values l_{12} are always restricted by the condition $|l_1 - l_2| \leq l_{12} \leq l_1 + l_2$; in addition, the sum $l_1 + l_2 + l_3$ must be even. The latter conditions follow from the invariance of the pair potential in the reference system.

These considerations show in which cases an expansion similar to eq. (2) will provide a useful representation of orientation dependent quantities. In any case, the number of data is manageable compared with the astronomically large number of entries in the aforementioned tabulation. An expansion according to eq. (2) was probably first introduced by *Jepsen* and *Friedman*[2], though similar but less general for-

mulations have been discussed in the earlier literature[3-5]. Detailed treatments may be found in references[6-9].

A calculation of u-coefficients is possible on the basis of certain models, one of the most popular and physically reasonable being the atomic model, where atoms are assumed as the interaction centers. This interaction is usually described by an empirical expression of the Lennard-Jones type:

$$u(R) \sim \varepsilon \left[\left(\frac{\sigma}{R}\right)^{\alpha} - \left(\frac{\sigma}{R}\right)^{\beta}\right] \tag{4}$$

where the four parameters ε, σ, α and β are the depth of the potential at its minimum, the distance at which the potential is zero, and the exponents characterizing repulsion and attraction. Frequently used values are $\alpha = 12$ and $\beta = 6$; at least the latter value can be established theoretically. With the above expression one then obtains for the u-coefficients of the molecular potential[9,10]:

$$u_{m_1 m_2}^{(l_1 l_2 l_{12})}(R) \sim \sum_{AB} Y_{m_1 m_2}^{(l_1 l_2)}(\theta_A, \varphi_A, \theta_B, \varphi_B) \times \varepsilon_{AB}\left[\left(\frac{\sigma_{AB}}{R}\right)^{\alpha_{AB}} X^{(l_1 l_2 l_{12})}\left(\alpha_{AB}, \frac{r_A}{R}, \frac{r_B}{r_A}\right) - \left(\frac{\sigma_{AB}}{R}\right)^{\beta_{AB}} X^{(l_1 l_2 l_{12})}\left(\beta_{AB}, \frac{r_A}{R}, \frac{r_B}{r_A}\right)\right] \tag{5}$$

Eq. (5) holds only in the range $R > r_A + r_B$; its application requires knowledge of the polar coordinates r, θ, φ in the molecule-fixed coordinate system. Summation runs over all pair-interactions AB. The functions X and Y are easily calculated; X contains a convergent series.

Obviously, the atom model suffers from the fact that shifts of the electrons due to the formation of chemical bonds are neglected. However, this effect can be accounted for by the addition of electric multipole interactions. This procedure is quite simple, because the multipole expansion is in accordance with the expansion in eq. (2). In particular, in the non-overlapping region the following relation holds[2,11]:

$$u_{m_1 m_2}^{(l_1 l_2 l_1 + l_2)}(R) \sim \frac{M_{l_1} \cdot M_{l_2}}{R^{l_1 + l_2 + 1}} \tag{6}$$

where M_l is the respective multipole moment (M_1 = dipole moment, M_2 = quadrupole moment, M_3 = octupole moment, *etc.*). In a similar way one can account for contributions due to induction and dispersion forces. If the multipole moments of the molecule are known from other sources, the respective calculations are easily performed.

An examination of the input potential on the basis of experimental quantities is only meaningful if the theoretical interrelationship is well established. This is true for the second virial coefficient, which only depends on pair interactions. The explicit relation is:

$$B(T) = 2\pi N_A \left(\frac{1}{8\pi^2}\right)^3 \int\int\int\int [1 - e^{-u(R,\Omega_1,\Omega_2,\Omega_{12})/kT}] R^2 \, dR \, d\Omega_1 \, d\Omega_2 \, d\Omega_{12} \tag{7}$$

On taking into consideration eq. (2) and integrating over all angles the second virial coefficient can be related to the u-coefficients.

3. Description of the Structure

In a solid the constituents are located at definite positions, resulting in a lattice, the structure of which may easily be described. In contrast the particles in a liquid can be arranged almost at random; only at some positions is there a slightly diminished or increased distribution. Consequently, a structural description of the type that is well established for solids is impossible. Instead, one adapts a concept known from statistics, the so-called correlation function. The correlation function yields the probability density of finding a given configuration of h coordinates. The coordinates themselves may consist of radial and orientational coordinates. If the sample consists of N particles, the N-particle correlation function is related to the potential energy *via* the Boltzmann factor:

$$g_N(q^N) \sim e^{-U(q^N)/kT} \tag{8}$$

q stands for the total set of single particle coordinates, and q^N denotes the total set of coordinates of all particles. If now a sub-set consisting of h particles of the total sample is considered, it is convenient to introduce reduced correlation functions

$$g_h(q^h) = \frac{1}{(N-h)!} \int g_N(q^N) \, dq^{N-h} \tag{9}$$

which are obtained by integration over all coordinates of the $(N - h)$ species not included in the sub-set.

In most applications the potential energy in eq. (8) is approximated by a sum over the two-particle potentials discussed in the preceding section. The sum covers all pairs AB, the number of which is quite obviously $(1/2)(N^2 - N)$. This fundamental assumption provides the basis for the so-called pair theory of liquids. At the present stage it is questionable whether extension to higher correlations is worthwhile. Of course, deviations from the pair approximation may occur within the limits of some percent, but these difficulties can be solved in a later refinement.

Clearly, in the pair theory the pair correlation function, *i.e.* the reduced correlation function with $h = 2$, plays an important role. Since we are concerned exclusively with this function, we drop the subscript 2. The relevant coordinates q are the same as discussed above for the pair potential, so we therefore denote the function by $g(R, \Omega_1, \Omega_2, \Omega_{12})$. All features of an orientation dependent quantity, discussed in the preceeding section, prove correct in this case, too. An analogous expansion to that in eq. (2) leads to g-coefficients, which form the basis for a quantitative description of the structure of a liquid[5-7].

4. From the Intermolecular Potential to the Structure

There exists only one reliable method for the calculation of g-coefficients from an input potential: computer simulation[12]. Of the two possible procedures, *i.e.* molecular dynamics and the Monte-Carlo method, the former is often preferred, because apart from equilibrium properties, transport coefficients can also be calculated. The procedure of

molecular dynamics is based on the numerical solution of Newton's equations of motion for a many-particle system (typically 4×3^3 up to 4×6^3 particles are accounted for). At first, the force acting on a particle is determined from the total potential energy, which is represented by a sum over all pair potentials. In the next step, accelerations, velocities, and positions are determined as a function of time, using optimum time increments. In spite of efficient programming and optimizing, especially in calculating the force, typical computer times of several minutes up to several hours are necessary per simulation of a molecular liquid on modern computers. Especially difficult is the calculation of rotational motion, since the relevant equations of motion, expressed by Eulerian angles, involve numerical instabilities. Various alternative treatments have therefore been attempted (for a review of the pertinent literature see [13]). A particularly attractive method has recently been developed by *Ryckaert et al.*[14]. The various atoms of a molecule are first assumed to move independently, *i.e.* they are allowed to undergo an independent translational motion. Thus, the well established computer-simulation procedures developed for atomic liquids can be used. Naturally, the molecules cannot decompose; therefore, one introduces additional constraints which preserve the intrinsic molecular geometry.

Interesting properties, such as the pair correlation function, are then obtained by evaluating the respective time averages. For this purpose one generates *e.g.* 2000 configurations; with a typical time increment of 5×10^{-15} s the course of the system with time is thus monitored over 10 ps. However, the average is only based on each 10th or 20th configuration, *i.e.*, one waits until marked changes have occurred in the system. In order to calculate g-coefficients according to eq. (1) one utilizes the fact that the ratio $g_{m_1m_2}^{(l_1l_2l_{12})}/g_{00}^{(000)}$ represents the angular average of the function $\Phi_{m_1m_2}^{(l_1l_2l_{12})}$ at the distance R (due to $\Phi_{00}^{(000)}=1$). The center-center distances R of all molecular pairs are then calculated for each configuration and likewise the functions $\Phi_{m_1m_1}^{(l_1l_2l_{12})}$ from the Eulerian angles. Then, within a discrete range ΔR, the results for the Φ-functions characterized by identical indices are added. Finally, the total sum over all considered configurations is calculated, and the result normalized in a suitable way. Thus, the sum in each range ΔR must be divided by $4\pi R^2 \Delta R$ in order to obtain the particle density, which on division by the 'macroscopic' number density of particles ρ yields the probability density.

So far, g-coefficients have been determined by the aid of computer simulations for the following model potentials: Two-center hard spheres[15], two-center Lennard-Jones potential neglecting[16,17], or accounting for quadrupolar interaction[18,19], three-center Lennard-Jones potential[20]. These potentials should approximate the behavior of the molecules N_2, F_2, Cl_2, Br_2, CO_2 and CS_2. Figure 2 shows the results obtained by *Singer* for Cl_2[17].

Apart from computer simulations several attempts have been made to find analytical methods for the calculation of g-coefficients, but with very little success. One should require, of course, that such methods are faster and more efficient than computer simulations. For atomic liquids there are well established analytical methods available. One therefore tries to extend such procedures to include molecular systems. The most reasonable way would appear to be *via* per-

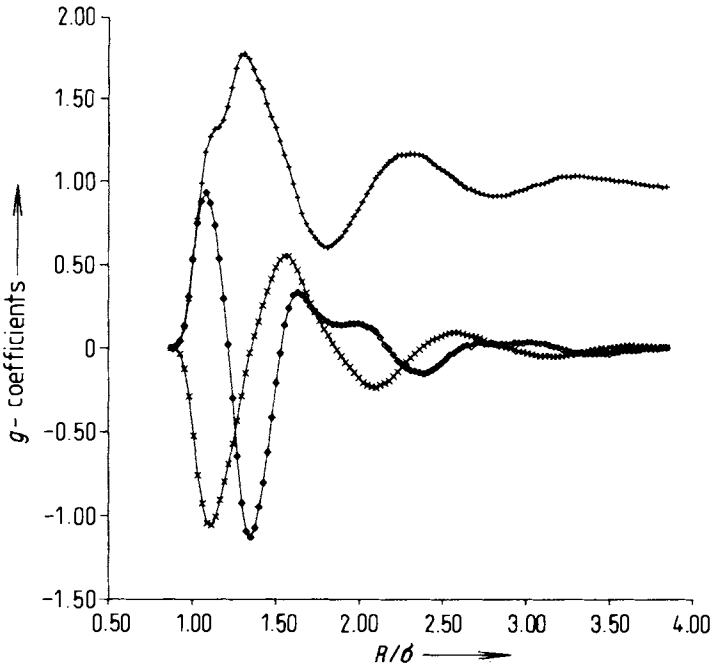

Fig. 2. g-Coefficients of the molecular pair correlation function, calculated by computer simulation. For the calculations a two-center Lennard-Jones potential has been used, $(r_A + r_B)/\sigma = 0.63$ (corresponding to Cl_2). The results are given for the density $\rho = 0.539\ \sigma^{-3}$ and the temperature $T \approx 1.00\ \varepsilon k^{-1}$.
(+—+) $g_{00}^{(000)}$;
(×—×) $\frac{1}{5} g_{00}^{(202)}$;
(◆—◆) $\frac{1}{5} g_{00}^{(220)} - \frac{2}{35} g_{00}^{(222)} + \frac{2}{35} g_{00}^{(224)}$
(after [17]).

turbation theories, in which the properties of the system of interest are developed from the known properties of a reference system. In order to guarantee the theory remaining simple, calculations should be limited to perturbations of the first order or, at most, second order.

For atomic liquids the following procedure has proven successful: A hard sphere liquid is chosen as reference system, the pair correlation function of which is very accurately known, also in its density dependence. Instead of resorting to tables, an empirical, analytical expression may be used which is based on the Percus-Yevick theory[21–23] and which can be empirically fitted to the results of computer simulations[24]. In order to obtain the pair correlation function of a Lennard-Jones liquid one first takes only the repulsive term u_R $(=(\sigma/R)^\alpha)$ of the potential given by eq. (4), since the structure is essentially determined only by this term. Figure 3 shows the exact type of separation; it was first suggested by *Weeks, Chandler,* and *Andersen*[25]. Next the diameter σ_{hs} of the hard spheres chosen as a reference is evaluated. The condition that the areas under the pair correlation functions of both systems (*i.e.* the reference system and the system of interest, the latter characterized by u_R) must be equal, may serve as an objective criterion. *Verlet* and *Weiss*[24] have developed a simple iteration procedure for the determination of this effective diameter. Finally, the resulting pair correlation function of the hard sphere system $g_{hs}(R)$ has to be multiplied by the Boltzmann factor $\exp[-u_R(R)/kT]$. Clearly, the Lennard-Jones system cannot have a discontinuity, in contrast to the hard sphere system, where $g_{hs}(R)$ drops discontinuously to zero at $R = \sigma_{hs}$. Therefore, one has to extra-

polate $g_{hs}(R)$ continuously to values $R<\sigma_{hs}$, before multiplying by the Boltzmann factor. This procedure, however, presents no difficulties[26]. Anyhow, the extrapolation range is small, since the Boltzmann factor itself rapidly approaches zero, due to the marked increase in u_R with decreasing R (see Fig. 3). All the steps of this procedure can easily be perform-

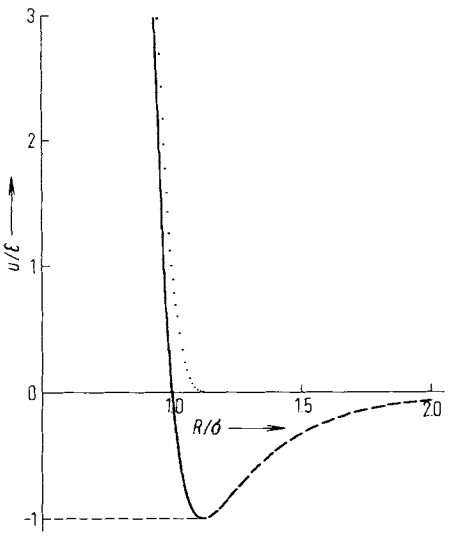

Fig. 3. Lennard-Jones potential (———) and its separation into a repulsive (·····) and attractive (– – – –) contribution; cf. eq. (4) (after [25]).

ed on a programmable pocket calculator[*]; the results can hardly be differentiated from those of a computer simulation. Figure 4 shows such results obtained for a Lennard-

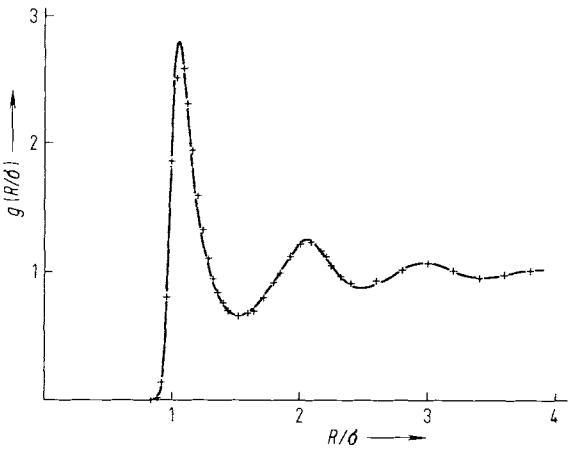

Fig. 4. Pair correlation function for a Lennard-Jones liquid at the temperature 1.273 εk^{-1} and the density 0.85 σ^{-3}. The curve has been calculated by the perturbation method described in the text, the crosses represent the results of a computer simulation [27].

Jones liquid ($\alpha=12$, $\beta=6$) at the density $\rho=0.85\,\sigma^{-3}$ and the temperature $T=1.273\,\varepsilon k^{-1}$; $g_{hs}(R)$ of the corresponding reference system has been calculated using the hard sphere diameter $\sigma_{hs}=1.0026\,\sigma$. For comparison, the results of a computer simulation[27] are also shown.

[*] If desired, a program for the TI-59 pocket calculator can be obtained from the author.

For molecular liquids, there lacks a method of comparable elegance. Previous attempts of similar treatments for molecular liquids should be briefly described (for a detailed summary see [28]). In most cases perturbation theories start from a spherical reference system so as to be able to apply the above procedures, originally developed for atomic systems. However, there is the disadvantage that the anisotropic systems of interest usually deviate too much from the isotropic reference system, so that first and second order pertubation theories may not suffice. In order to define a reference system one can separate $u_{00}^{(000)}$ in eq. (2) from the remaining terms. The respective pertubation theories for the pair correlation function have been treated up to second order[29]. An alternative choice of the reference system is obtained, if one replaces u in eq. (2) by the Boltzmann factor $\exp[-u/kT]=f$. The isotropic term $f_{00}^{(000)}$ can then be used again. One should note that $f_{00}^{(000)}$ does not only depend on $u_{00}^{(000)}$; inspection of eq. (1) shows that all other u-coefficients contribute, too. A reference system characterized by u_{ref} can be defined *via* the relation $f_{00}^{(000)}=\exp[-u_{ref}/kT]$. Pertubation calculations may then be performed in an analogous way[30]. Similarly to the atomic situation, considerations may be restricted to the repulsive term of the potential. With the aid of the corresponding term $f_{00}^{(000)}$ one can define an effective hard sphere potential, which then serves as reference[31]. The next logical step is the transition from spherical to non-spherical reference systems, but the additional numerical efforts are obvious: In order to calculate the final system, the pertubation theory has to be applied twice[32,33].

5. From the Structure to Thermodynamics

A further advantage of the expansion according to eq. (2) follows from the fact that the well known[34–40] statistical mechanical expressions for thermodynamical quantities can be used separately for each term of the expansion. As example the configurational contribution to the internal energy might be mentioned. Direct transfer of the well known relation yields

$$E_{m_1m_2}^{(l_1l_2l_{12})}=\frac{1}{2}N_A\cdot\rho\int_0^\infty u_{m_1m_2}^{(l_1l_2l_{12})}(R)\cdot g_{m_1m_2}^{(l_1l_2l_{12})}(R)\cdot 4\pi R^2\,dR \tag{10}$$

Addition of the various terms then provides the total internal energy. An analogous procedure can be used to calculate the pressure.

In some cases the thermodynamical quantity is determined by one single term of the expansion; in other words, there exist specific selection rules. This is true for expressions of the form

$$G^{(l)}-1\sim\rho\int_0^\infty[g_{00}^{(l10)}(R)-\delta_{l0}]\,4\pi R^2\,dR \tag{11}$$

In particular, $G^{(0)}/(\rho kT)$ is the isothermal compressibility, $G^{(1)}$ is the Kirkwood correlation factor, occurring in the theory of dielectrics[41], and $G^{(2)}$ is the Kerr correlation factor, occurring in the theoretical treatment of light scattering[42].

Normally, in the case of molecular liquids the higher terms of the expansion are of the same importance as the isotropic term in the case of atomic liquids.

6. Experimental Determinations of Structure

6.1. Neutron and X-ray Scattering

As is well known, in structural investigations the interference of waves can be used for measuring the distances between two diffraction centers. This method can be applied successfully, if the wavelength of the radiation is of the same order as that of the spacing. As shown in Figures 2 and 4, intermolecular distances are of the order of 10^{-10} m; thus X-ray and neutron radiation fulfill this condition. (Of course, this holds for intramolecular distances too, which, however, are not of interest here. They cause only additional disturbing interferences.) The wavelength λ of the neutrons depends on their velocity v or their energy E *via* the DeBroglie relation

$$h = \lambda \cdot mv = \lambda \cdot \sqrt{2mE} \tag{12}$$

m is the mass of the neutron. In order to obtain a wavelength of 7×10^{-11} m (which corresponds to the wavelength of the frequently used $Mo_{K\alpha}$ X-rays) the neutrons must have a velocity of 5651 ms^{-1} or an energy of 167 meV. This energy is markedly higher than the thermal energy at room temperature ($kT = 25$ meV at 298 K). These neutrons are therefore referred to as 'hot' neutrons. Consequently, the neutrons leaving a reactor must be accelerated. From a comparison of the velocities of neutrons and X-rays (the latter having the speed of light, *i.e.* 3×10^8 ms^{-1}) it is evident that structural determinations with neutrons are beset with difficulties, because molecular motions in liquids are characterized by velocities of similar magnitude. This ist the reason why one uses neutrons to study dynamic processes. One analyzes the change in energy of the scattered neutrons (inelastic scattering), which is a consequence of the Doppler effect, caused by the motion of the diffraction centers. In structural investigations with neutrons, one is not interested in the dynamics. Therefore, the energy is not recorded, rather one measures the number of scattered neutrons irrespective of their energy. Nevertheless, the energy transfer must be taken into account in the evaluation of the data; this is done by the so-called Placzek correction.

A further essential difference between scattering experiments with X-rays and those with neutrons arises as a result of the different nature of the scattering centers. X-rays are diffracted by the electron clouds, whereas neutrons penetrate as far as the nucleus and then are scattered. There are two consequences: 1) With atoms of the same nuclear charge, the scattering centers for X-rays are all equal, whereas, for neutrons they may behave differently due to the occurrence of different isotopes and also due to the possible existence of a nuclear spin, which can couple with the different spin states of the neutron spin. Unfortunately, different scattering centers partially destroy the interference of the radiation. Hence, the scattered radiation contains both coherent and incoherent contributions. Owing to their different origin, one distinguishes here between isotopic and spin incoherence; only the first effect can be suppressed (by working with isotopically pure samples), while if an isotope exhibits too strong a spin incoherence, its application is probably prohibitive. An important extreme case is the ^1H isotope, the scattering of which is about 98% incoherent *(vide infra)*. 2) The diffraction centers differ markedly in size. A comparison with the wavelengths of the radiations shows that the diffraction centers for X-rays are of comparable magnitude. In contrast, neutrons can be considered as point centers. This implies for the angular distribution of the scattered radiation, that X-rays scatter anisotropically, whereas neutrons scatter isotropically.

Scattering at the free atom is quantitatively described by the so-called scattering length, *i.e.* the range of interaction between the radiation and the center. For both types of radiation it is of the order of 10^{-15} m. Thus, it corresponds to the dimension of a (classical) electron or a nucleus. One distinguishes between coherent and incoherent scattering lengths, the former, denoted by f, are of particular interest for structural investigations. As discussed above in the case of neutrons f is a quantity independent of the angle, whereas in the case of X-rays it is an angular dependent quantity. The neutron scattering lengths of various isotopes (in the bound state) are collected in Table 1[43-45], while the scattering lengths for X-rays are shown in Figure 5[46].

On going from free atoms to atomic liquids the scattered neutron radiation is expected to be anisotropic too, owing to the possible occurrence of interferences. Thus, the angular distribution of the scattered radiation can be measured in order to determine the structure of the liquid. Figure 6 shows a schematic representation of the scattering experiment. The quanta, being generated by a monochromatic source, possess an incident momentum $\hbar\vec{k}_0$ and an incident energy E_0. They penetrate into the cyclindrically shaped sample, which is arranged perpendicular to the plane of the figure, and are scattered. After the scattering process their momentum is $\hbar\vec{k}$ and their energy E. The detector is positioned at the scattering angle 2θ. Instead of the transmission geometry shown in the figure, a reflection geometry is also frequently used in X-ray scattering experiments; the surface of the sample is thereby planar and the vector bisecting the angle between the inci-

Table 1. Scattering Lengths for Neutron Scattering.

Atomic Number	Isotope	Coherent Scattering Length f [a] [10^{-15} m]
1	^1H	−3.74
	^2H	6.67
6	^{12}C	6.65
	^{13}C	6.0
7	^{14}N	9.36
	^{15}N	6.44
8	^{16}O	5.80
	^{17}O	5.78
	^{18}O	6.00
9	^{19}F	5.66

35	^{79}Br	6.78 [d]
	^{81}Br	6.80
53	^{127}I	5.28

[a] In neutron scattering this scattering length for isotopes in the bound state is usually denoted by b. [b] *L. Koester, K. Knopf, W. Waschkowski*, Z. Phys. *A 289*, 399 (1979). [c] *L. Koester, K. Knopf, W. Waschkowski*, Z. Phys. *A 282*, 371 (1977). [d] *L. Koester*, private communication.

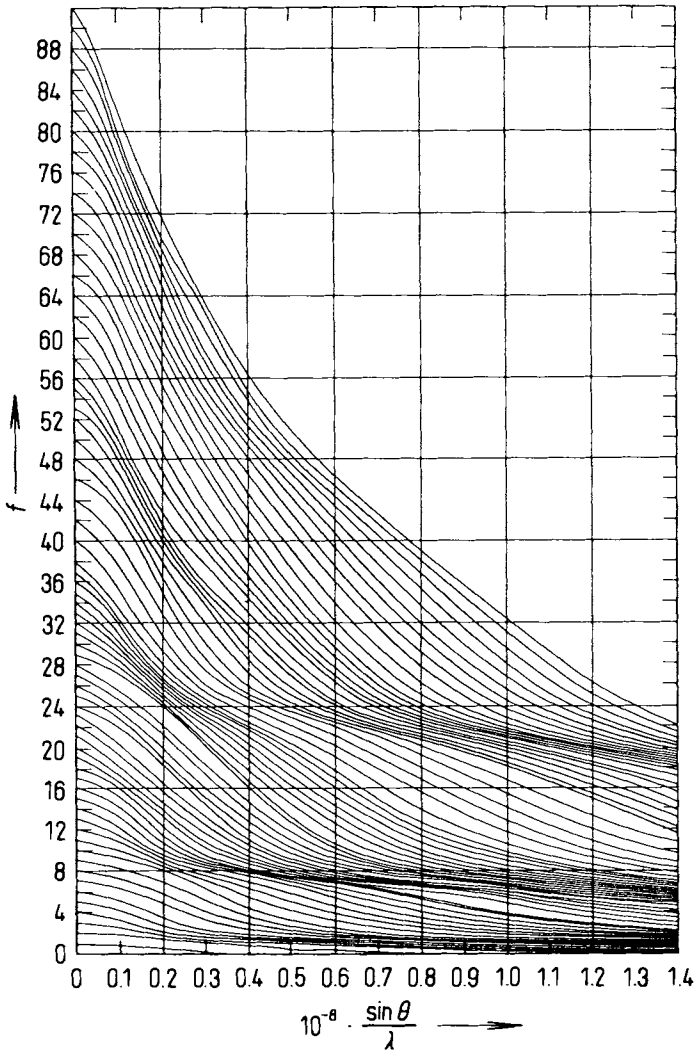

Fig. 5. Scattering lengths f of neutral atoms for X-ray scattering as a function of the scattering angle 2θ, or the wavelength λ, respectively. At $\theta = 0$, f is identical with the atomic number of the element, thus the curves can immediately be assigned to the elements. From reference [46].

dent and the reflected beam is oriented perpendicular to this surface. The corresponding arrangement is realized by synchronous rotations of the source and the detector, or, of the sample and the detector. The cuvette must be constructed in such a way that background scattering is minimal; a suitable cuvette material for neutron scattering is vanadium, for X-ray scattering beryllium. The intensity of the radiation, scattered into a differential angular cone defined by the size

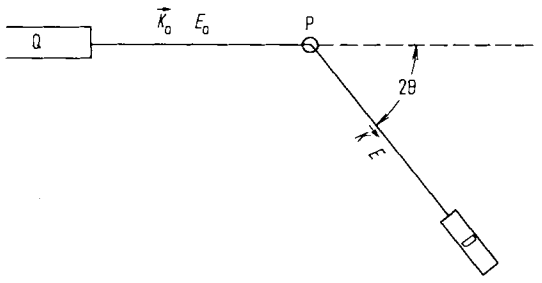

Fig. 6. General arrangement of a scattering experiment. Q: monochromatic radiation source, P: Sample , D: Detector, $\vec{K}_0$: wave vector of the incident beam, $\vec{K}$: wave vector of scattered beam, E_0: energy of the incident beam, E: energy of the scattered radiation, 2θ: scattering angle.

of the detector window, is now measured by moving the detector around the sample. One can save time by using detector banks consisting of several detectors, since the counting processes at the various detectors can be performed simultaneously at different angular positions. Figure 7 shows some results obtained for X-ray and neutron scattering experiments on dichloromethane[47].

If the energy transfer during the scattering process is neglected then the transfer of momentum on elastic scattering is given by

$$\hbar\vec{\kappa} = \hbar\vec{k}_0 - \hbar\vec{k} \tag{13}$$

The magnitude of the transfer of momentum ist obtained likewise, observing simple trigonometric rules, accounting for $k = k_0$ and introducing the DeBroglie relation (12):

$$\kappa = \frac{4\pi}{\lambda_0}\sin\theta \tag{14}$$

In the latter case the transfer of momentum would depend only on the wavelengths of the incident quanta and on the scattering angle. However, as mentioned above, the measur-

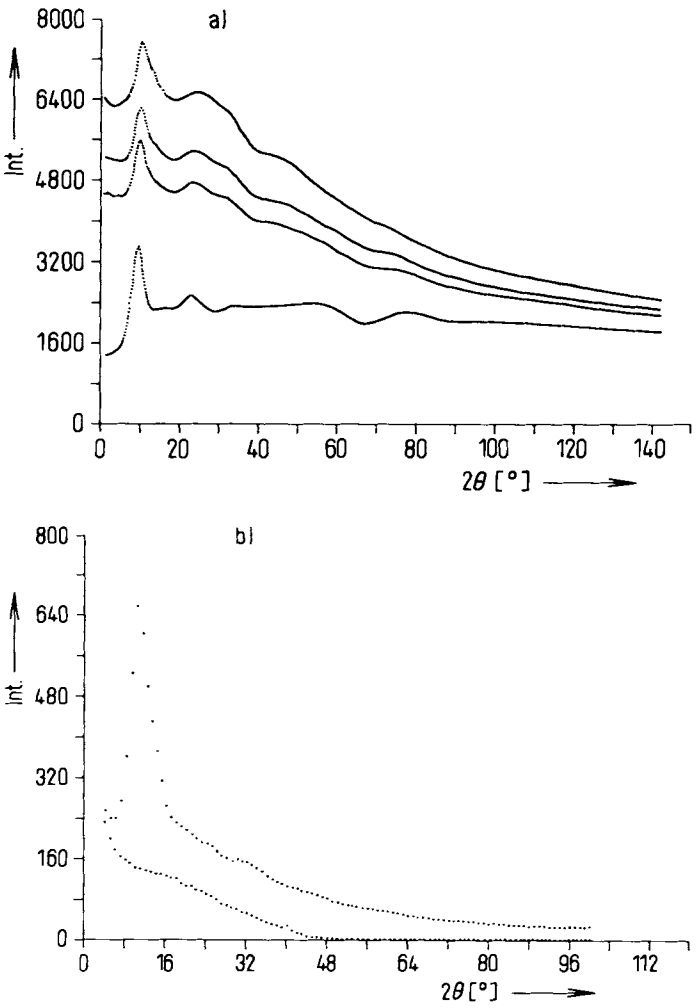

Fig. 7. Results a) for neutron and b) X-ray scattering on dichloromethane. The intensity is represented as a function of the scattering angle. a) The curves from top downwards refer to CH_2Cl_2, a mixture 0.64 CH_2Cl_2/0.36 CD_2Cl_2 (at this mixture composition the mean coherent scattering length of hydrogen vanishes), a mixture 0.5 CH_2Cl_2/0.5 CD_2Cl_2 (in mole fractions), and CD_2Cl_2. The strong intensity decay of the ^1H carrying samples with increasing scattering angle is caused by the inelastic effects, which are taken care of in the Placzek-correction. b) Upper curve: cuvette filled with CH_2Cl_2; lower curve: results for empty beryllium cuvette.

able energy changes in the neutron experiment give rise to the fact that measurements at a given scattering angle do not correspond to observations at a constant κ value. Therefore one has to account for the Placzek correction. With the identity (14) the scattering intensity can be represented as a function of the momentum transfer κ.

The general scattering theory for atomic liquids[43,45,46,48,49] relates this scattering intensity to the pair correlation function, which describes the structure of the liquid. The explicit relation is

$$I_{\mathrm{coh}}(\kappa) \sim f^2 \left\{ 1 + \rho \int_0^{\infty} [g(R) - 1] j_0(\kappa R)\, 4\pi R^2 \, \mathrm{d}R \right\} \tag{15}$$

Obviously, we are only interested in the coherent contribution of the scattered radiation (denoted by the index coh); the incoherent contribution has to be subtracted. It can be calculated from tables for incoherent scattering lengths. The expression in the curly brackets is termed the 'structure factor'; its second term modifies the atomic scattering, expressed by f^2. j_0 is the spherical Bessel function of zero order. The expression within the square brackets stands for the pair correlation function from which its asymptotic value at large R has been subtracted; the continuum contributes only at extremely small angles and cannot be measured, because the incident beam dominates at $2\theta = 0$.

We next consider molecular liquids. Here, one must distinguish between intramolecular and intermolecular contributions, because the scattering centers may belong to the same or to different molecules. Furthermore, there must exist a relation between the orientation dependent molecular pair correlation function $g(R, \Omega_1, \Omega_2, \Omega_{12})$ and the intermolecular coherent scattering intensity. An advantage of the expansion of the molecular pair correlation function (see eq. (2)) is that the relations well established for atomic liquids can be transferred for each single term. Therefore, using eq. (15) one arrives at the result[6,7,50,51]

$$I_{\mathrm{coh}(m_1 m_2)}^{(l_1 l_2 l_{12})} \sim a_{m_1}^{(l_1)}(\kappa)\, a_{m_2}^{(l_2)}(\kappa) \left\{ 1 + \rho \int_0^{\infty} [g_{m_1 m_2}^{(l_1 l_2 l_{12})}(R) - \delta(l, m; 0)] j_{l_{12}}(\kappa R)\, 4\pi R^2 \, \mathrm{d}R \right\} \tag{16}$$

The total scattering intensity is then given by a summation of the individual contributions. An interpretation analogous to eq. (15) shows that $a_m^{(l)}(\kappa)$ can be considered as the scattering length of the molecule. Owing to the comparable magnitudes of the wavelength of the radiation and the molecular size, in the case of neutron scattering $a_m^{(l)}$ is now also angular dependent. The two terms in the curly brackets are the intramolecular and the intermolecular contribution, respectively. Accounting only for the isotropic term $g_{00}^{(000)}$, eq. (16) reduces to eq. (15); only in this case is the Kronecker symbol $\delta(l, m; 0)$ unity, otherwise it vanishes. In order to obtain the molecular scattering length, one has to assume that the atomic scattering lengths do not change on going from the free atom to a molecule. This condition certainly holds in the case of neutron scattering, but it is questionable in the case of X-ray scattering, because X-rays are diffracted at the electron clouds. Thus, only the atomic scattering lengths and the coordinates of the atoms in the molecule-fixed coordinate system are needed to calculate $a_m^{(l)}$.

In order to obtain information on the liquid structure, one tries to determine as many g-coefficients as possible, using eq. (16). Apart from the usual, more or less established corrections for scattering experiments (corrections for background scattering, absorption, multiple scattering, and, in the case of neutrons, Placzek effects) a separation into intra- and intermolecular contributions is required. This separation is based on the fact that the molecular structure does not essentially change on going from the gas to the liquid state. Thus, the structure known from the gaseous phase is introduced to calculate the scattering intensity, which at large scattering angles must agree with the experimental value, since the intermolecular contribution has already vanished in this range. Discrepancies may be accounted for by allowing small changes in the molecular geometry.

The fact that the separated intermolecular coherent scattering intensity consists of a sum over many individual contributions, according to the second term in eq. (16), should not be discouraging. The number of g-coefficients depends on the distinctness of the orientations. The less pronounced they are, the more coefficients vanish. The reductions caused by symmetries have also already been discussed. In addition, the proportionality factors not explicitly written in eq. (16), and in particular the scattering lengths of the molecules, rapidly decrease with increasing indices. For example, it has proven correct that in the case of chloroform (possessing C_{3v} symmetry) the observed intensity is only influenced by four terms. For such a small number of important terms an experimental separation can be performed by an *equal* number of scattering experiments, if the scattering lengths of the molecules are varied from experiment to experiment. One is not, of course, allowed to change the structure of the liquid. There exist two possibilities: 1) application of different radiations (X-rays, neutrons and, recently, also electrons[52]). 2) Use of different isotopes in neutron scattering experiments. In the latter case the coherent scattering lengths of the isotopes should differ markedly. Inspection of Table 1 shows that, especially for organic liquids, there is only a limited number of suitable isotopes: chlorine is ideal, nitrogen is quite useful, carbon, oxygen and bromine cannot be used, fluorine, phosphorus and iodine consist only of one single isotope. ^{1}H presents difficulties owing to the strength of the incoherent contribution and to Placzek effects. This can easily be recognized from Figure 7; the scattering curves exhibit an increasing, monotonous drop to larger angles with increasing ^{1}H content due to inelastic scattering. Nevertheless, we cannot reject the application of this isotope due to the limited number of possibilities. In the case of chloroform successful measurements have recently been carried out with ^{1}H[53]. Obviously, the atomic concentration of the element in the molecule whose isotopes are varied, should be high, *i.e.* the less the scattering lengths of the isotopes differ, the higher should be the concentration. If all these conditions are favorable and the required number of scattering experiments can be performed, the individual contributions to the scattering intensity may be evaluated for each value κ, by solving the resulting system of simultaneous equations. However, eq. (16) shows that by this procedure only those terms can be separated whose scattering pre-factor can be varied independently. For this reason splitting of terms with equal indices l_1 and l_2 but different l_{12} is not possible.

So far, only a few scattering experiments aimed at a determination of g-coefficients have been performed in the liquid phase: water[52], acetonitrile[51], chloroform[53,54], the homologous series of methyl halides (chloride, bromide, iodide)[55] and dichloromethane[47]. Investigations on water have been performed using three different radiations[52,56]. In the author's group the main interest has been focussed on neutron scattering, using different isotopes. The following isotopic substitution experiments have been performed: ^{14}N and ^{15}N in acetonitrile[57,58]; ^{35}Cl and ^{37}Cl as well as ^{1}H and ^{2}H in chloroform[53], ^{1}H and ^{2}H in dichloromethane. In the case of methyl halides the gradual change in properties along the homologeous series has been exploited in order to separate the various contributions according to eq. (16). In all cases X-ray scattering experiments have also been carried out[47,51,55,60]. Obviously, the system most investigated is chloroform, where the results of five independent scattering experiments are available. One can also investigate mixtures of isotopes, as has been done in the case of chloroform[59]. The condition is that the system of simultaneous equations is linearly independent, which is still fulfilled in the case of three mixtures. However, the investigation of an additional mixture is only useful if the isotopes have very different scattering lengths, otherwise the differences between a pure isotope and a mixture are too small. In this context the chlorine isotopes are particularly favorable. In Figure 8 are shown the coefficients $g_{00}^{(000)}$, $g_{00}^{(101)}$, $g_{00}^{(110)}$ and $g_{00}^{(202)}$ determined for chloroform[53]. One should note, that $g_{00}^{(110)}$ still contains contributions due to $g_{00}^{(112)}$, which cannot be separated. Combination of the various experimental results, all of which show statistical deviations in the measured data, leads to the indicated error bars. It should be pointed out that such investigations can only be performed with the aid of a high flux reactor, and still one needs two or three days measuring time per isotope. Our measurements were carried out at the reactor of the Laue-Langevin Institute in Grenoble.

In the following, a qualitative interpretation of these results will be given. The coefficient $g_{00}^{(000)}$ describes the distribution of the molecular centers, or, more correctly, of the origins of the molecule-fixed coordinate systems, which, as discussed above, may be chosen arbitrarily. In the present example the origin is placed in the carbon atom of the chloroform molecule, the z-axis coincides with the three-fold axis pointing in the direction of the C—H bond. $g_{00}^{(000)}$ oscillates around unity. A first maximum is observed in the range of nearest neighbors at 4.5 Å, and a second (very weak) maximum can be recognized at 9 Å. The area under the first maximum, though not well defined, can serve as an estimate of the number of closest neighbors; for chloroform about six other molecules are found around a molecule selected at random. On the right of the first maximum a marked shoulder can be recognized, which is never observed in atomic liquids. The other g-coefficients provide information on orientational correlations. Similarly to $g_{00}^{(000)}$, where values larger than unity describe preferred configurations, positive products $g_{m_1m_2}^{(l_1l_2l_{12})} \cdot \Phi_{m_1m_2}^{(l_1l_2l_{12})}$ for the higher order terms occurring in eq. (2) indicate preferred orientations. (One should note, that only $g_{00}^{(000)}$ oscillates around unity, all other terms oscillate around zero.) Both factors must have the same sign, so that a positive product results. Therefore, knowledge of the sign of the angular function, in particular of the terms $\Phi_{00}^{(l01)}$ with $l=1$

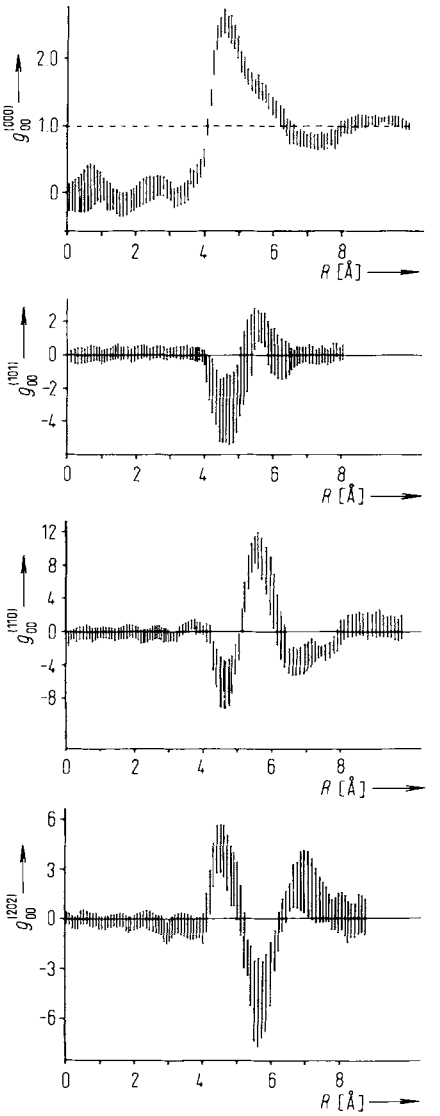

Fig. 8. g-Coefficients of the pair correlation function of chloroform at 298 K (after [53]).

and $l=2$ and $\Phi_{00}^{(l10)}$ with $l=1$, is required. If one denotes the angle between the z-axis and the intermolecular vector joining the molecular centers by β, there exist the simple relations

$$\Phi_{00}^{(101)} \sim -\cos\beta$$
$$\Phi_{00}^{(202)} \sim \tfrac{3}{2}\cos^2\beta - \tfrac{1}{2} \qquad (17)$$

Table 2. Orientational correlations in liquid chloroform, derived from results shown in Figures 8 and 9.

R-range [Å]	Sign of $g^{(101)}$	Sign of $g^{(202)}$	Angular range for β [°] [a]
4—5	−	+	0—55
5—6	+	−	90—125
6—7	?	+	0—55 or 125—180

R-range [Å]	Sign of $g^{(110)}$	Angular range for β [°] [b]
4—5	−	0—90
5—6	+	90—180
6—7	−	0—90

[a] Angle between the C_3-axis of the molecule and the intermolecular center-center vector. [b] Angle between the C_3-axes of two molecules.

which are displayed graphically in Figure 9. Identical expressions can also be derived for $\Phi_{00}^{(llO)}$, but in the latter case β describes the angle between the z-axes of the two molecules. A comparison with Figure 8 yields the results summarized in Table 2. Thus, already on a qualitative basis interest-

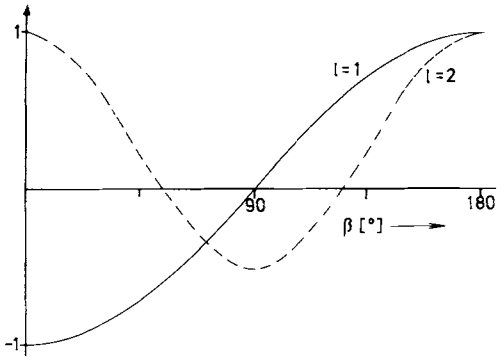

Fig. 9. The angular functions $\Phi_{(1)}^{(l_1l_2l)}$ and $\Phi_{(0)}^{(llO)}$ according to eq. (17) for l=1 and l=2.

ing conclusions may be drawn. For more quantitative interpretations, it is convenient to consider the ratios $g_{m_1m_2}^{(l_1l_2l_{(2)})} / g_{00}^{(000)}$, which represent the angular averages of the Φ-functions at varying distances from the reference molecule (see Section 4).

6.2. Light Scattering, Dielectric Measurements and Nuclear Magnetic Relaxation

Besides the scattering experiments with neutrons and X-rays, whose wavelengths are ideal for structural investigations, some further experimental methods have to be mentioned. However, these methods yield only integral structural quantities according to eq. (11). Here, the momentum transfer may be negligibly small due to too large a wavelength [see eq. (14)], as in the case of light scattering, or, no change of the momentum is experimentally observed, as in the measurements of the dielectric constant and in nuclear magnetic relaxation. A common disadvantage of light scattering and dielectric experiments, as well as X-ray scattering, is the fact that the electron clouds are involved. As a consequence, polarization effects can cause a complex change in the properties, thus affecting the corresponding measurable quantities. These are the dipole moment and the polarizability of the molecules, two properties which with respect to molecular rotations behave like the irreducible representations of the continuous three-dimensional rotation group with l=1 (dipole moment) or l=2 (polarizability). Therefore, it is possible to determine selectively the respective components in the expansion according to eq. (2). This fact can be characterized as an advantage of these methods. In contrast, nuclear magnetic relaxation involves no similar selectivity. In the latter case, and also in light scattering, additional difficulties arise due to molecular motions, as already discussed in the case of neutron scattering.

Light scattering occurs at wavelengths of about 5000 Å. One distinguishes between polarized experiments, where the polarization planes of the incident and the scattered light are parallel, and depolarized experiments. In the latter case the polarization vectors of the incident and the scattered light are perpendicular. The polarized scattering contains an *isotropic* component, caused by the rotationally invariant part of the molecular polarizability α_0. Owing to the spherical symmetry this component cannot depend on the orientation of the molecules, rather it has to be related to the $G^{(0)}$ term[6,42,61,62]:

$$I_{iso} \sim \alpha_0^2 G^{(0)} \tag{18}$$

I is the total scattering intensity, integrated over all frequencies. The *anisotropic* component of the molecular polarizability causes depolarized scattering. The total intensity I_{aniso} is given by an analogous expression, but now depending on $G^{(2)}$[42,62]

$$I_{aniso} \sim (\alpha_\perp - \alpha_\parallel)^2 G^{(2)} \tag{19}$$

if one is limited to molecules with a three-fold or higher symmetry axis. Then $a_\perp$ and $a_\parallel$ are the polarizability components perpendicular and parallel to these axes, respectively. A large number of studies on the total intensity I_{aniso} has been reported in the older literature. However the evaluation of these data is not so simple. A review of the respective difficulties and of the older literature has been given by *Pecora et al.*[63].

In the last few years it has been found that the occurrence of the term $G_{aniso}^{(2)}$ is not only restricted to the total intensity I_{aniso}. *Keyes* and *Kivelson*[64] could show that orientational pair correlations also enter into the frequency spectrum of depolarized light scattering. If the reorientational motions of the molecules in the liquid obey a rotational diffusion equation, the depolarized Raleigh-line possesses the form of a simple Lorentzian, characterized by a width at half height of

$$\Delta\tilde{\nu} = 1/(2\pi c \tau_{LS}) \tag{20}$$

(in wave numbers: cm^{-1}), where c is the speed of light. τ_{LS} is a correlation time describing the molecular reorientation. It is often referred to as the 'collective correlation time', because it involves contributions due to orientational correlations, in contrast to the correlation time τ_S which describes the reorientation of individual molecules. In the limit of a diffusive process τ_{LS} and τ_S are related by

$$\tau_{LS} = \frac{G(2)}{J^{(2)}} \cdot \tau_S \tag{21}$$

The factor $J^{(2)}$ accounts for dynamic correlations between neighboring molecules. For liquids consisting of small molecules and exhibiting no specific interactions such as hydrogen bonding, $J^{(2)}$ should be close to unity. Eq. (21) may then be used to determine $G^{(2)}$. For this purpose, two independent experiments must be performed, determining τ_{LS} from light scattering and τ_S from nuclear magnetic relaxation times or Raman experiments. A series of experimental results for $G^{(2)}$ has been compiled by *Pecora et al.*[63].

The dielectric constant is related to the term $G^{(1)}$ *via* the Kirkwood-Fröhlich equation[41]:

$$\frac{(\varepsilon - \varepsilon^{(\infty)}) \cdot (2\varepsilon + \varepsilon^{(\infty)})}{\varepsilon \cdot (\varepsilon^{(\infty)} + 2)^2} = \frac{1}{9} \cdot \frac{\rho}{\varepsilon_0 kT} \cdot G^{(1)} \mu_0^2 \tag{22}$$

It is not only necessary to know the static value of ε, usually obtained by capacity measurements at frequencies in the MHz region, but one has to determine also the high-frequency limit ε^{∞}, where the contributions to dipole reorientation have vanished, whereas those from molecular vibrations are still negligible. Clearly, it is not an easy matter to find the correct frequency. ε_0 is the permittivity (dielectric constant) of the vacuum, μ_0 is the dipole moment of the free molecule. A series of recent determinations of $G^{(1)}$ over a wide range of densities and temperatures can be found in reference[65].

Finally, the interrelationship between the nuclear magnetic relaxation time T_1[66] and the liquid structure should be mentioned. As already discussed in the case of scattering experiments, the desired information is contained in the intermolecular contribution, which can be separated by isotopic dilution experiments[67]. Owing to the smallness of the intermolecular contribution to the relaxation time of most nuclei, only the relaxation of protons needs further consideration. A disadvantage is the simultaneous dependence on structure and dynamics. A procedure similar to that employed in scattering experiments, *i. e.* an integration over all frequencies in order to eliminate the dynamic effects is impossible, since, owing to technical limitations, the interesting region of frequencies is not accessible (>10 GHz, the highest available NMR frequency for protons is at present 600 MHz). Therefore one is forced to introduce models for molecular motions. In the case of intermolecular relaxation such models become particularly complex, because both translational and rotational motions of the molecules have to be considered. By neglecting a coupling between rotational and translational motions and assuming a purely diffusive behavior, the intermolecular relaxation rate $1/T_1$ can be connected with the g-coefficients[68].

7. Conclusion

In this review of the structure of molecular liquids a consequent concept has been followed: Only such work has been discussed which is based on the total molecular pair correlation function, expressed by g-coefficients. This point of view should be acceptable, for this is a general description, from which partial results can always be deduced. An impressive advantage of the concept of g-coefficients is the simple application of the interconnections known from spherical systems to molecular (non-spherical) systems. Finally, a short account should be given of other methods used to describe the structure of molecular liquids.
