Reaction Paths on Multidimensional Energy Hypersurfaces[**]

By Klaus Müller[*]

Theoretical investigation of a chemical reaction requires detailed knowledge of the potential energy of the molecular system. As a first step in such a study, minimum-energy reaction paths have to be mapped on a generally multidimensional molecular potential surface. Even at this stage problems are encountered that have only recently been solved satisfactorily. The difficulties involved and various ways to handle them are discussed in connection with a two-parametric model potential. Three chemical reactions examined illustrate the usefulness of such theoretical investigations as well as their current limitations.

1. Introduction

A chemical reaction is conveniently discussed in terms of a reaction energy profile covering aspects of mechanism, structure, and energy[1]. Figure 1 shows such a profile for the simplest case, the one-step transformation of a reactant to a product. According to *Eyring* and *Polanyi*[2], we imagine the molecular system to go from the energy minimum of the reactant state *via* a transition state (a saddle point corresponding to an energy maximum along the reaction path) to the energy minimum of the product state. The reaction coordinate includes all the structural changes that characterize the chemical transformation. Figure 1 is a one-dimensional representation of an inherently multidimensional problem. In most cases, therefore, the reaction coordinate is extremely complex and can hardly be given in analytical terms. As regards the energy, we are primarily concerned with the free enthalpy, which, however, is related to the potential energy of the molecular system by a sequence of well-defined logical steps[3]. A more or less satisfactory potential energy can be obtained by means of theoretical models, *e.g.*, quantum-chemical computational procedures. In principal, there are no restrictions on a theoretical study. The potential energy of a molecular system can be evaluated at any point along the reaction path. By contrast, the experimental situation is less

straightforward. The transition state as well as the region around it are generally not amenable to direct experimental observation. Instead, we have to resort to recording the properties and behavior of the molecular system in its initial and final states and to measuring the progress of transformation from reactant to product in order to guess probable events in the gray area of a chemical reaction (cf. Figure 1).

Nevertheless, various techniques are nowadays available that provide experimental access to this gray area. Some of them are summarized in Figure 2. First of all, there are classical kinetic experiments, such as the determination of activation parameters[4], the measurement of kinetic isotope effects[5], and extensive structure reactivity correlations[6]. All of these, individually or combined, can provide insight into the nature of a transition state. More recently, a variety of mass spectrometric and ion cyclotron resonance (ICR) spectroscopic methods[7,8] have become available, by which detailed kinetic studies can be performed in the gas phase, thus giving information about more or less isolated molecular systems. Such experiments often produce valuable starting points for theoretical investigations. Of particular interest are collision experiments with crossed molecular beams[7,9-11], consisting of neutral and/or charged particles, and their combination with chemiluminescence studies[12]. In connection with suitable model calculations, they may provide information about the behavior of the molecular system in the transition state region. However, the reliable interpretation of such experiments is still limited to rather small molecular systems containing not more than about two to five atoms. Hence, these techniques continue to be part of chemical physics rather than of physical chemistry. Furthermore, there are spectroscopic methods, especially infrared and microwave spectroscopy[13,14], by which information about potential energy profiles can be obtained for hindered intramolecular motions. Finally, we direct attention to the structure correlation method, developed by *Bürgi* and *Dunitz*[15,16] some years ago and since applied successfully[17-22], by which insights into the qualitative course of a reaction path may be gained by correlating crystal structure data of carefully chosen molecular systems. With this short summary we wish to emphasize that theory has no exclusive rights in dealing with the gray area of a chemical reaction; rather, it serves as an important auxiliary tool in promoting experimental access to this region.

As an illustration for the combined use of theoretical, spectroscopic, and crystallographic information, we discuss the inversion-rotation motion of the amino group in enam-

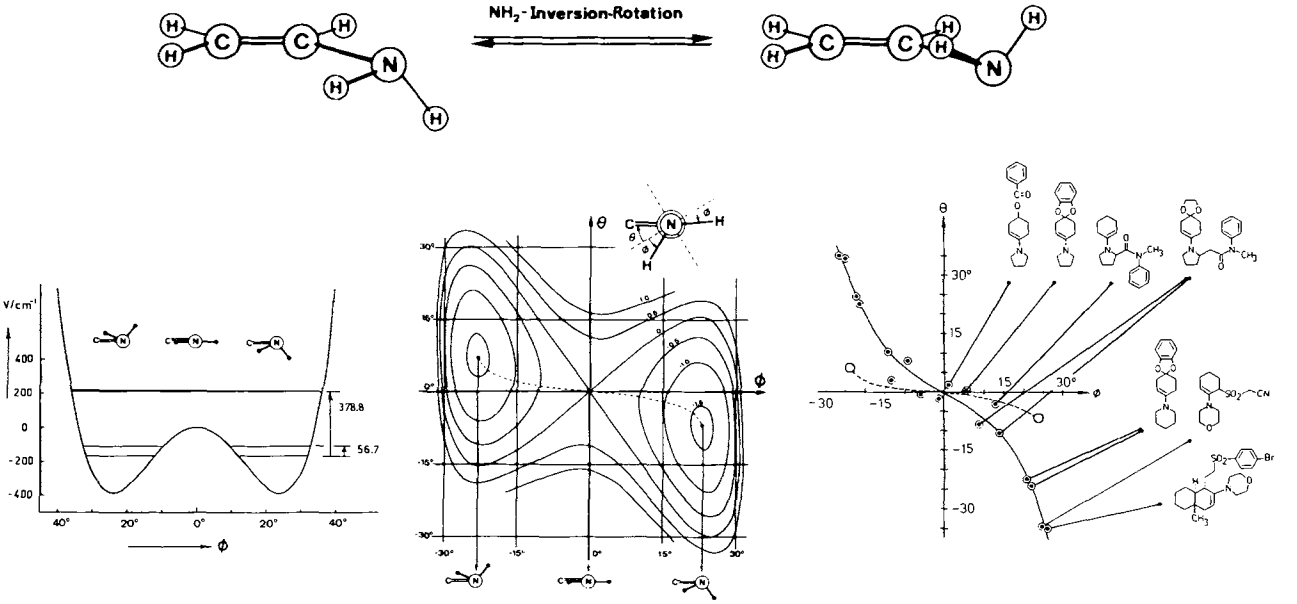

Fig. 3. The inversion-rotation motion of the amino group in enamines as an example for the combined use of theoretical and experimental methods for the elucidation of preferred reaction paths. Middle: Calculated double-minimum potential for a coupled inversion-rotation motion in vinylamine [23]. ines (Figure 3). The theoretical treatment of this process in the unsubstituted vinylamine[23] produced a double-minimum potential with a planar transition state. The position of the two energy minima, lying clearly off the axes of pure NH_2 inversion and rotation, respectively, indicates a pronounced coupling between inversion and rotation of the amino group. These results, as well as further refinements by means of complete and partial structure optimizations, established the basis for an application of the recently proposed method of flexible models for intramolecular motion[24]. With this method a quantitative interpretation of the microwave spectroscopic data of vinylamine[25] was achieved, providing an energy profile for the fully relaxed inversion-rotation motion of the amino group[26]. In an independent effort by *Eschenmoser et al.* and *Dunitz et al.*[21], a number of crystalline enamine derivatives were synthesized and examined by X-ray diffraction. For each enamine derivative, the amount of pyramidality at the nitrogen atom as well as the degree of torsion around the CN single bond were determined from the structural data. Correlation of these parameters in an inversion-rotation diagram produced a set of points that can be taken to represent valley points on a common potential surface describing the intramolecular motion of the amino group in a generalized aliphatic enamine. The so-derived reaction path provides a particularly clear documentation of the coupling between inversion and rotation of the amino group, being of the same type as that evidenced for unsubstituted vinylamine by theoretical and spectroscopic means.

2. Calculation of Reaction Paths

The theoretical treatment of a chemical reaction requires detailed knowledge of the potential energy of a molecular system in terms of all internal degrees of freedom. This prerequisite is independent of whether a static description of the reaction is pursued, *e.g.*, by localizing a minimum-energy reaction path (thick curve in Fig. 4), or whether a dynamic treatment of reactivity is attempted, *e.g.*, by computing numerous classical trajectories (thin curve in Fig. 4), along which the molecular system oscillates back and forth over the reaction valley. However, the call for detailed knowledge of the molecular energy function is faced with two problems. The first arises from the fact that, in general, the potential energy of a molecular system is a function of a large number of parameters and thus does not lend itself to a graphic representation. A two-parameter energy function can be visualized as a three-dimensional relief or mapped by a two-dimensional contour diagram. Accordingly, a multiparametric energy function can be taken as an energy hypersurface in multidimensional space; nevertheless it evades visualization. This does not seem to be a severe problem at first. After all, computers may be run without imagination. However, an intuitive insight into the shape of such a potential surface is often of considerable help (see *e.g.* Section 2.2). For the sake of clarity, our discussions will be based on a two-parameter model potential, whose contour diagram is shown in Figure 4; it contains three energy minima and two saddle points. The results that are obtained here are easily transferred to multidimensional energy hypersurfaces. The second problem arises from the fact that the molecular energy function is usually not analytically available but has to be defined numerically point by point. This, too, does not look like a severe hindrance; in principle, a grid of points could be spanned in the domain of a reaction path. With sufficient resolution this would come close to a knowledge of the analytical form of the energy function. However, such a procedure is

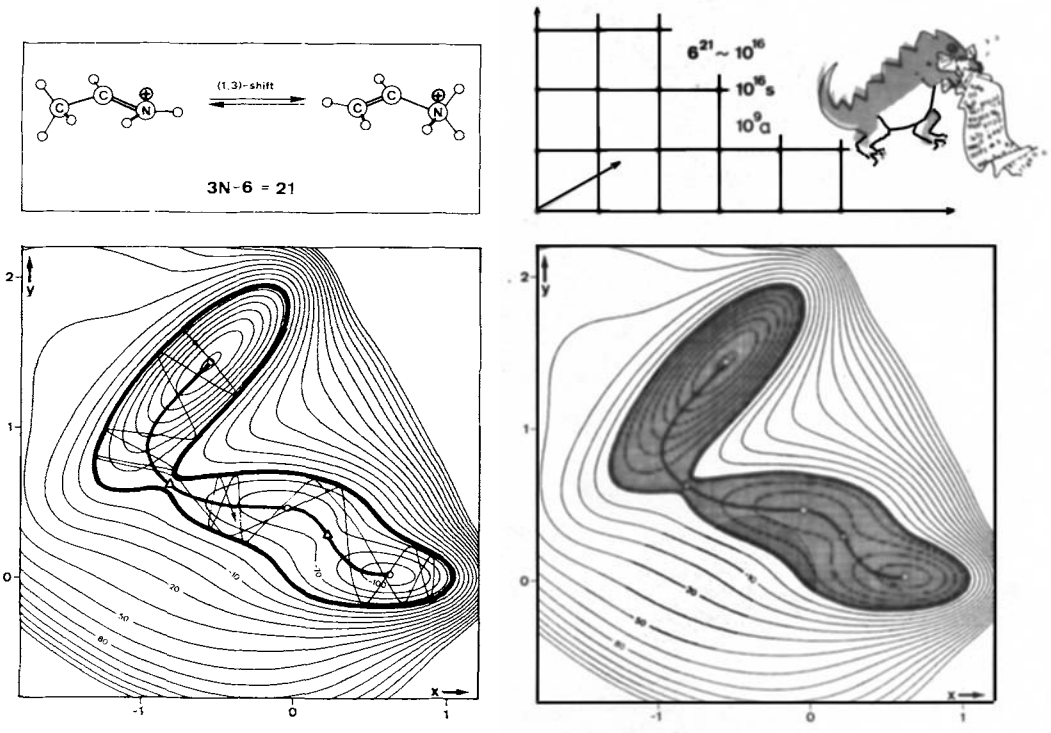

Fig. 4. Two-parametric model potential with three minima (circles) and two saddle points (△) [45]. Left: The minimum-energy reaction path (thick line) shows the course of the reaction valley. The dynamics of a reactive system with specified initial conditions may be described, for example, by means of a classical trajectory (schematically shown by a thin line). Right: An exhaustive examination of the reaction region on a multidimensional potential surface by scanning a grid of points is impracticable for lack of time.

ill-advised. Consider, for example, the case of a hydrogen shift in protonated vinylamine (Figure 4). This molecular system consists of only nine atoms, but has 21 internal degrees of freedom. Let us suppose, as a first step, we want to span a coarse grid with only six points for each degree of freedom. As can be seen from Figure 4, such a grid would not provide sufficient resolution in the case of the two-parameter model potential. Yet, for 21 degrees of freedom, $6^{21} \sim 10^{16}$ points would have to be evaluated. Even if each energy calculation took only one second—still a visionary situation!—our preliminary study would require 10^{16} seconds or roughly 10^9 years. Had we started with the dinosaurs, we would still be calculating. Thus, the bullheaded approach, spanning a grid of points, is out of the question. A theoretical investigation of a chemical reaction therefore concentrates, first of all, on the minimum-energy reaction path in order to locate the reaction valley on the multidimensional potential surface. For this purpose we need special numerical techniques that determine such reaction paths more or less directly, *i.e.*, circumvent the above mentioned "dinosaur-like" problem.

2.1. The Minimum-energy Reaction Path

According to work by *Fukui*[27-29], *Morokuma*[30], and *Basilevsky*[31], a minimum-energy reaction path is nowadays identified as that orthogonal trajectory which connects two energy minima *via* a common saddle point; it is composed of the two steepest-descent paths that emerge from a saddle point in both directions along the principal axis of negative curvature and enter the two adjacent energy minima, each along the principal axis of least curvature. From a physical point of view, it may be considered as a relaxation path, albeit imaginary, along which the molecular system glides from a high-energy saddle point down to either of the two minima, with continuous dissipation of energy, but almost infinitely slow motion (Fig. 5). Strictly speaking, this interpretation holds only if the potential surface is defined in terms of mass-weighted Cartesian coordinates, as commonly used in normal coordinate analyses of molecular vibrations.

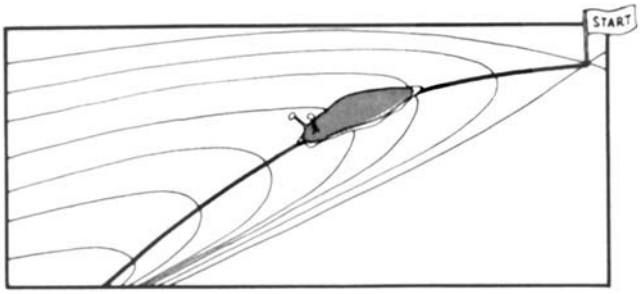

Fig. 5. The minimum-energy reaction path corresponds to an imaginary relaxation path of steepest descent, along which the molecular system glides with almost infinitely slow motion from a saddle point to an adjacent minimum.

2.2. Methods for the Calculation of the Minimum-energy Reaction Path

If the energy function is not analytically available but has to be evaluated point by point, the localization of such reaction paths is beset with difficulties. For a proper assessment of the problems involved it is appropriate to review the most important currently available methods for the calculation of reaction paths. This will be done with reference to the two-parameter model potential.

The traditional and by far most frequently used method consists in choosing a suitable structural parameter as a reaction coordinate[32-34], along which the reaction is driven. This choice is often quite difficult. For selected values of this parameter, the energy of the molecular system is minimized with respect to all remaining structural parameters. This procedure, which will be referred to as the reaction coordinate method, looks quite simple, to be sure, but it is full of pitfalls. Let us apply it to the two-parameter model potential, starting at the minimum A with x as the reaction coordinate (Fig. 6).

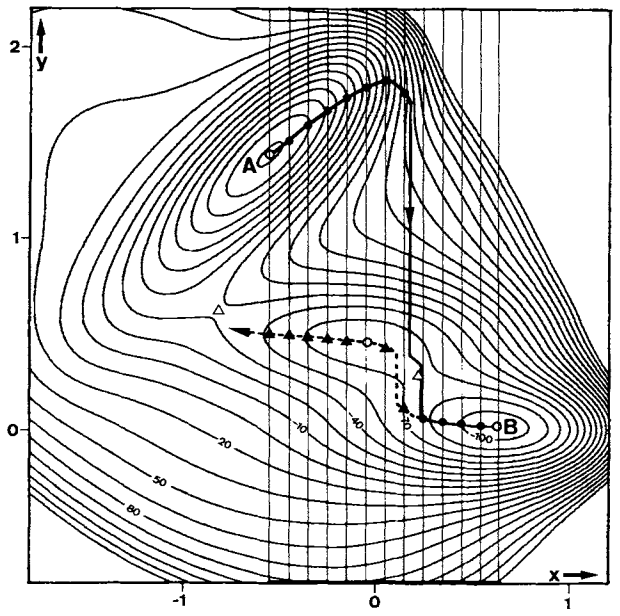

Fig. 6. Application of the reaction coordinate method to the two-parametric model potential.

We obtain a reaction path that starts out in a wrong direction, climbing up the valley wall, until it reaches a point from which it suddenly jumps into the true reaction valley, without ever having passed through the saddle point. After a short travel along the valley bottom, our path takes another discontinuous jump before getting to the destination point B. Using the same reaction coordinate, but this time going in the opposite direction, starting out from minimum B, a completely different reaction path is obtained. It is again discontinuous. Moreover, it does not reach the target minimum A for the limiting value of the x parameter. Instead, it remains in the middle of the energy surface. Such failures of the seemingly simple reaction coordinate method have often been documented and commented on in the more recent literature[33,35-39]: apart from the fact that this method does not provide true minimum-energy paths, it should not be used in cases of doubt.

Likewise, the proposal[39] of using an equipotential curve as a reaction coordinate, instead of an individual structural parameter, does not solve the problems satisfactorily (Fig. 7). This procedure, referred to as the reference coordinate method, first of all requires a suitable equipotential curve, *i.e.*, one

that passes through the regions of two minima as well as a saddle point between. Furthermore, a relatively expensive contour-following algorithm is needed. Advancing step by step along such an equipotential curve, while simultaneously minimizing the energy orthogonal to it, we generate a set of valley points which, in simple cases, trace approximately a minimum-energy reaction path. However, in more complicated cases this procedure may lead to nonsensical results, as shown by its application to the two-parameter model potential. Starting from the energy minimum A (Fig. 7) the series

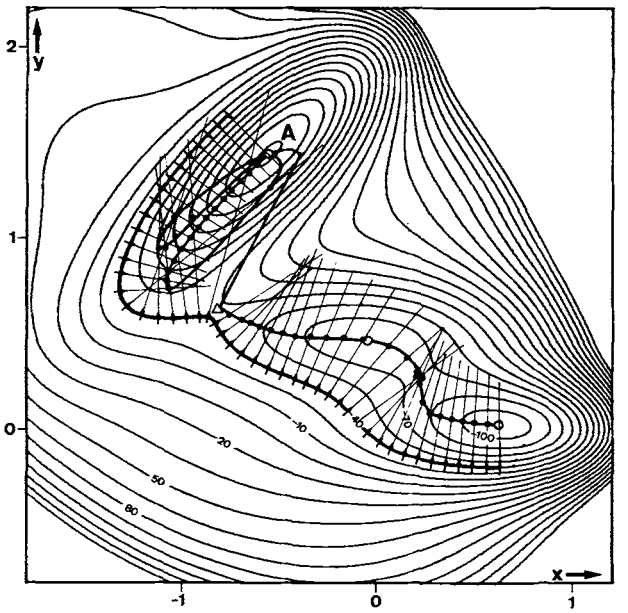

Fig. 7. Application of the reference coordinate method [39] to the two-parametric model potential.

of valley points describes a reaction path that at first heads for the saddle point, correctly following the valley bottom, but, stopping short of it, falls back into the start minimum, performs another unproductive loop, winds up on the valley wall, and jumps abruptly into the saddle point region. It is only from this point on that it leads to the target minimum more or less along the valley bottom.

A rigorous determination of minimum-energy reaction paths requires primarily the localization of saddle points and subsequently the calculation of gradient paths, *i.e.*, steepest-descent paths starting from the saddle points. In comparison to the localization of energy minima (or maxima), which can be effected by various standard function optimization procedures[40], the search for a saddle point is by far more difficult. During the past few years some methods have been developed for this purpose[35,38,41-44].

One group of methods is based on the fact that saddle points, like minima and maxima, belong to the so-called stationary points on an energy hypersurface, *i.e.*, points where the slope vanishes in all directions. Thus, the procedure consists in minimizing the absolute value of the energy gradient (gradient norm) in order to find a stationary point between the start and end minima. That indeed a saddle point has been found must be verified subsequently by calculating the principal axes of curvature at this point. These methods are quite powerful if the energy gradient is obtained directly (*i.e.*, not by taking finite differences), as can be done with several current quantum-chemical procedures. Nevertheless, gradient norm minimization methods have their drawbacks. A first problem lies in the uncertainty that convergence to a stationary point produces a saddle point. As an illustration consider Figure 8, which shows the gradient norm of the two-parameter model potential by means of a contour diagram. The five zero-minima of the gradient norm (full circles), corresponding to minima and saddle points on the energy surface (see Fig. 4), are easily seen. Starting from point 2 in Figure 8, minimization of the gradient norm leads to a zero-minimum that corresponds to a saddle point on the energy surface. On the other hand, starting from point 3, such a minimization converges only to an intermediate energy minimum.

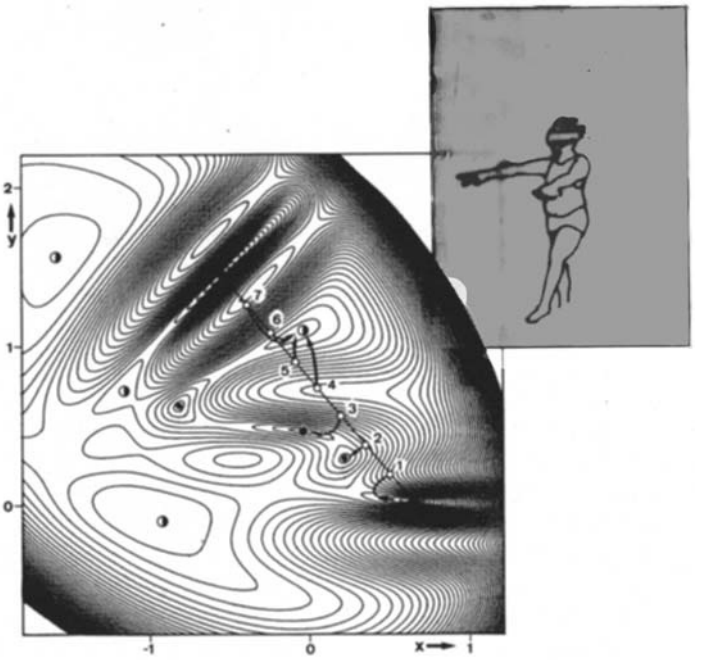

Fig. 8. Contour diagram of the gradient norm of the two-parametric model potential. Zero-minima and secondary minima are marked by filled and half-filled circles, respectively. The open circles 1—7 indicate possible starting points for a saddle point localization by means of gradient norm minimization.

To avoid this uncertainty, a modified procedure has been proposed[42], in which principal axes of curvature are repeatedly evaluated. With this additional, if costly, information convergence can be directed away from energy minima and maxima and guided into regions of possible saddle points. Of course, one has to pay for the assurance of proper convergence. A second problem arises from the fact that a gradient norm may contain not only zero-minima but also secondary minima. For example, the gradient norm of our two-parameter model potential exhibits a total of four secondary minima (half-filled circles) in addition to the five zero-minima. There happens to be a deep secondary minimum just where one might expect to find a saddle point, *i.e.*, in the linearly interpolated region between start and end minima. Wherever we start minimizing the gradient norm in this region, *e.g.* at points 4—7, we are likely to fall into this secondary minimum, which does not correspond to a stationary point on the energy surface but to a flat region on a long crest. Such secondary minima considerably impede the

search for saddle points. Thus, for a straightforward application of gradient norm minimization procedures, the approximate position of a saddle point should be known in advance. However, it is just in this respect that the already mentioned difficulties of visualizing features of multidimensional energy hypersurfaces become most serious. We find ourselves blindfolded, as it were, and chemical intuition is not always a safe guide (Fig. 8).

The so-called X-method[43] is an alternative way to locate saddle points. It is based on the mathematical property that a three-dimensional hyperbolic paraboloid (Fig. 9) contains two straight contour lines that intersect at the saddle point. Thus,

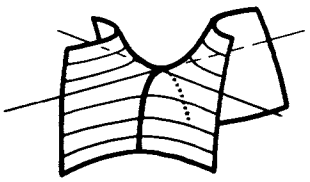

Fig. 9. The hyperbolic paraboloid with two straight contour lines through the saddle point.

for a two-parametric potential function, the procedure consists in a search for those points where an "X", *i. e.* two intersecting lines of constant energy, can be optimally fitted to the potentional surface. In the n-parametric case, an n-dimensional double cone of constant energy has to be embedded into the energy hypersurface, requiring $n+(n-1)+\frac{1}{2}n(n-1)$ parameters to specify its location, shape, and orientation. Hence, with increasing complexity of the energy function, the X-method soon becomes very expensive. To our knowledge, it has only been used once in connection with a 2-parameter potential.

Halgren and *Lipscomb*[38] proposed another procedure, the so-called synchronous transit method. Its basic search strategy may be clarified by considering a network consisting of linearly and quadratically interpolated transit paths between a start and an end minimum and surfaces of constant path coordinates (nonconcentric circles in the 2-dimensional case, as shown in Figure 10, or hyperspheres in the multidimensional case). The localization of a saddle point is effected by

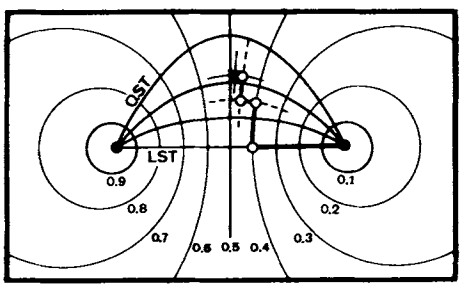

Fig. 10. The search strategy of the synchronous transit method [38] in the two-dimensional case: energy optimizations are performed alternately along linearly and quadratically interpolated transit paths (LST and QST) and along lines of constant path coordinates (nonconcentric circles).

alternately searching for energy maxima along transit paths and energy minima on surfaces of constant path coordinates until a point is reached which represents both an energy maximum along a transit path and an energy minimum on a surface of constant path coordinate. This simple strategy is not without problems, however, as can be shown by application to the two-parameter model potential (Fig. 11). Starting from minimum A, we would first get to maximum B on the

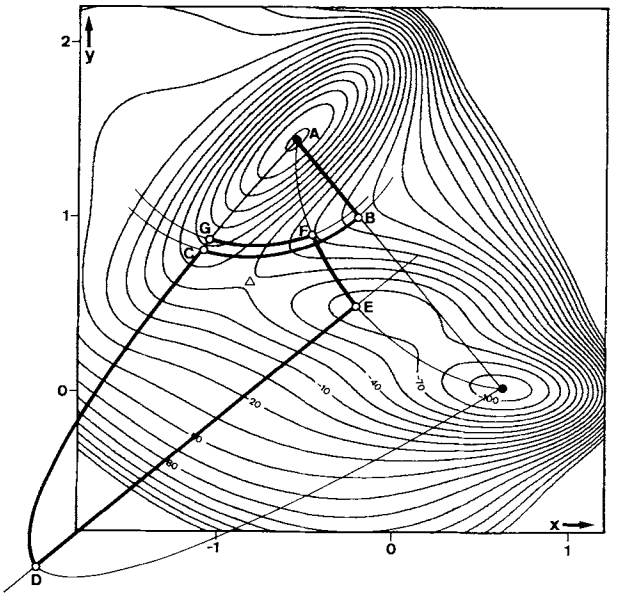

Fig. 11. Application of the synchronous transit method to the two-parametric model potential: failure of the simple search strategy.

linearly interpolated transit path. From there the line of constant path coordinate leads us to minimum C. On the quadratically interpolated transit path through C, we find maximum D. From there we get to E with constant path coordinate, to F on a quadratically interpolated transit path, and so on. Instead of converging into the saddle-point region in due time, this search strategy keeps us beating about the bush. Various additional strategies[44] have been developed to cope with such problems. One, for example, would consist in taking A and E as new starting points (Fig. 12), assuring prompt convergence to the saddle point. The synchronous transit

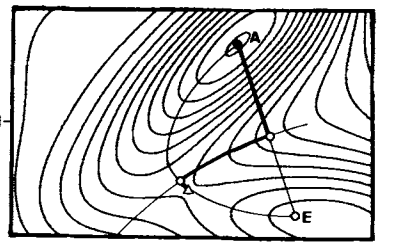

Fig. 12. Application of the synchronous transit method to the two-parametric model potential: successful localization of a saddle point by reapplication of the method to points A and E of Figure 11.

method thus seems to be a powerful tool, especially since no previous knowledge about the approximate position of a saddle point is required.

Recently, a new procedure[45] has been developed which is also characterized by a remarkably simple search strategy. It makes use of the fact that, given a high-energy point on the gradient path along the valley bottom, it is in principle always possible to generate a new point of lower energy, lying on the same gradient path, by minimizing the energy on a hypersphere (or circle in the 2-dimensional case) centered at the higher point. First of all, this helps us to gain a method

for the approximate calculation of minimum energy reaction paths. Provided the initial point is a saddle point, this procedure allows us to descend to an adjacent minimum step by step by generating one path point after another (Fig. 13). With a sufficiently small search radius a set of path points is

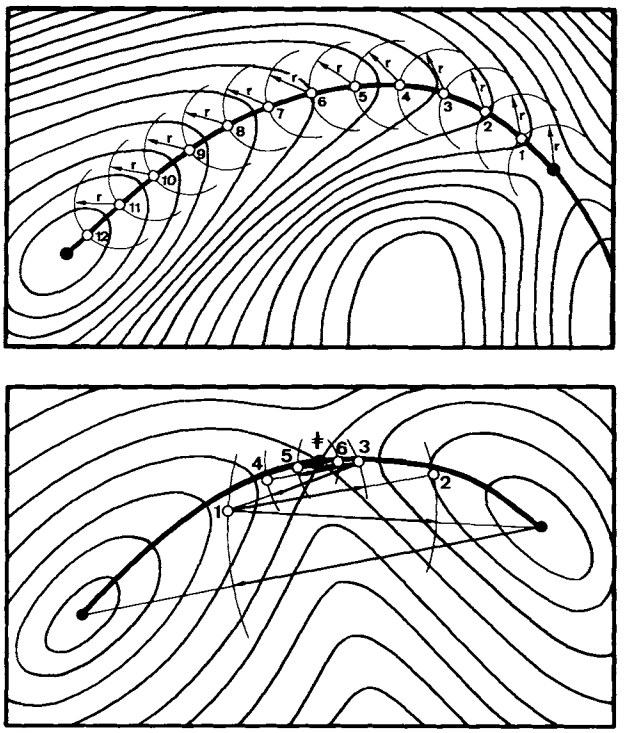

Fig. 13. Localization of valley points by energy minimizations on circles (two-dimensional case) or hyperspheres (multidimensional case) [45]. Top: Calculation of an approximate minimum-energy reaction path by generating a series of descending path points. Bottom: Localization of a saddle point by generating a series of ascending valley points.

obtained that represents a good approximation to the true gradient path. The strategy for the localization of a saddle point now consists in minimizing the energy on suitable hyperspheres between start and end minima so as to generate a series of valley points of increasing energy, which close in on a saddle point from opposite sides. At first sight, a strategy based on ascending valley points seems to be inconsistent with the underlying principle of generating descending path points. However, the crucial point, and one where the new procedure differs basically from the synchronous transit method, is that the search region on the hypersphere and the corresponding center are always on opposite sides of a saddle point. This generally ensures that hypersphere and hypersurface penetrate each other in a way suitable for the generation of descending path points. This strategy depends on a simple energy/distance analysis which, at each round, selects the highest of the growing set of valley points as center of a new hypersphere and directs the search region towards the more distant of the two neighboring points. The typical performance of this localization method may be illustrated by means of the two-parameter model potential (Fig. 14). Beginning with A and B as start and end minima and arbitrarily choosing A as center of the first hypersphere, the saddle point is successfully localized after a series of thirteen valley points. Those generated in the early stages, *i.e.*, with relatively large search radii, may deviate strongly from the minimum energy

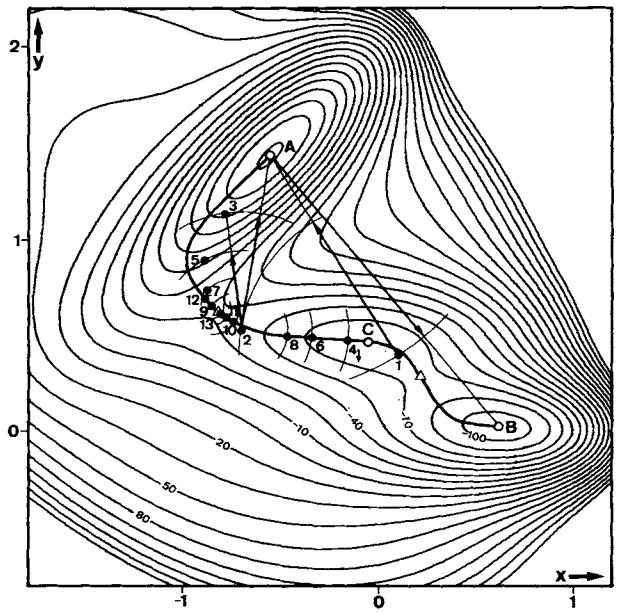

Fig. 14. Localization of a saddle point on the two-parametric model potential surface by means of ascending valley points.

reaction path, whereas those obtained at later stages, *i.e.*, with smaller search radii, represent better path points. Thus, the numerical effort produces not only the saddle point itself but also, as a bonus, a set of valley points which provides at least a rough guide to the course of the reaction path. In our example, the energy/distance analysis properly diagnoses the fourth valley point as one that lies within the region of an intermediate minimum. This is an important piece of information. It initiates the search for another saddle point, which is easily found by first locating the exact position of minimum C and then applying the saddle point localization procedure to the region between B and C. More accurate minimum-energy reaction paths can now be obtained using the technique of descending path points. This is shown in Figure 15 for the two-parameter model potential. The search radii have been

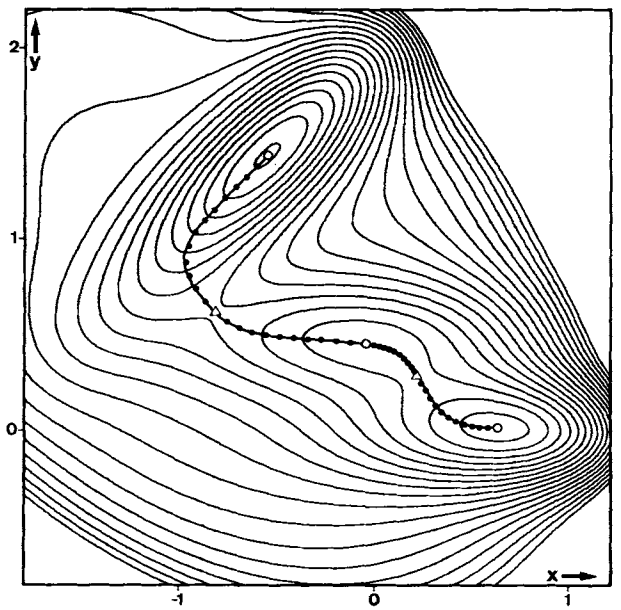

Fig. 15. Approximate minimum-energy reaction path for the two-parametric model potential by means of descending path points.

set to $^1/_{11}$ of corresponding distances between saddle points and adjacent minima, ensuring at least ten path points for each descent path.

To conclude, we mention yet another recently proposed method for the calculation of minimum-energy reaction paths[46]. It is of questionable value, but warrants a comment because it is based on the apparently plausible assumption that, along the valley bottom, one of the principal axes of curvature always lies parallel to the energy gradient. As can be shown mathematically[29], this assumption is generally not valid along a minimum energy reaction path, *i.e.*, the steepest-descent path from a saddle point. However, a procedure that rests on such an assumption may still produce useful reaction paths. Again, an application to the two-parameter model potential brings the problems to the fore (Fig. 16). In those regions where the minimum-energy path (marked by open circles) shows little curvature, *e.g.*, between points C and D, a reaction path (marked by a series of dots) is obtained which approximately follows the gradient path. However, it exhibits a distinct tendency to swing more than the gradient path whenever the valley is curved. In the region between D and A this property even causes it to climb up the valley wall—a result which is incompatible with the concept of a minimum-energy reaction path, whatever its definition.

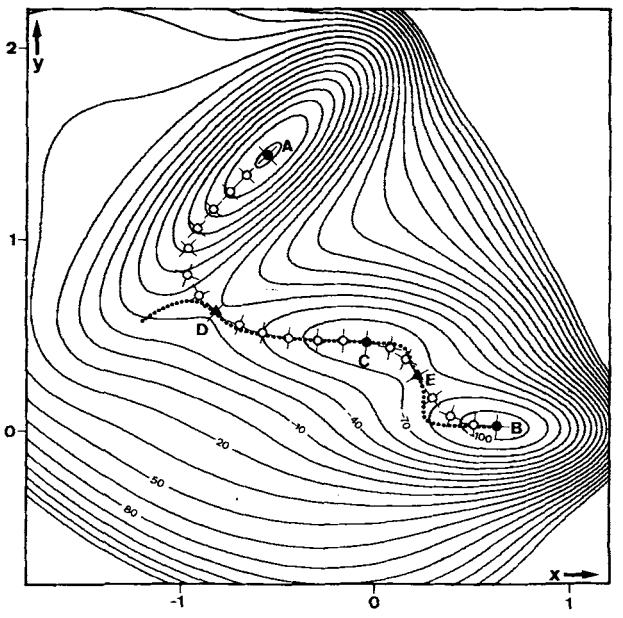

Fig. 16. Principal axes of curvature at points (circles) along the minimum-energy reaction path for the two-parametric model potential. Points at which one of the principal axes of curvature lies parallel to the energy gradient are marked by dots.

3. Examples

Having discussed fundamental difficulties in calculating reaction paths on multidimensional energy hypersurfaces, it is time to illustrate the localization of saddle points and of minimum-energy reaction paths by means of some chemically relevant examples. We shall concentrate mainly on the new methods based on ascending and descending valley points. The potential surfaces are defined within the framework of the nonempirical PRDDO SCF procedure[47].

3.1. Isomerization of Hydrogen Isocyanide to Hydrogen Cyanide

The first example concerns the transformation of hydrogen isocyanide into hydrogen cyanide. This reaction is of both chemical and theoretical interest[30,41,48]. In contrast to the long-known hydrogen cyanide, evidence for the existence of its isomer CNH came only during the sixties, when HCN or CH_3N_3 were photolyzed in an argon matrix at 4 K and 14 K[49]. It was not until 1975/76 that several independent research groups[50-52], using special laboratory techniques,

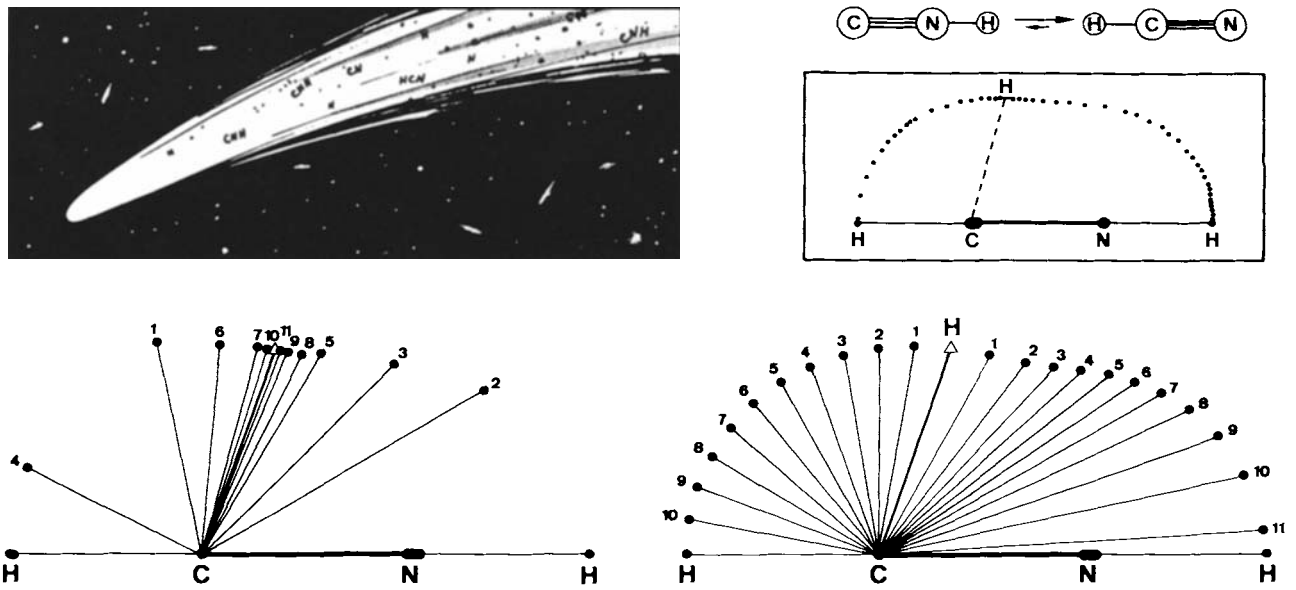

Fig. 17. In the laboratory hydrogen isocyanide CNH can be observed only under special conditions. Its existence in the interstellar space is spectroscopically well documented. The localization of the saddle point and the calculation of the minimum-energy reaction path for the transformation CNH⇄HCN using ascending and descending valley points [45] (bottom) and gradient procedures [30] (top) are shown by means of superimposed molecular structures.

managed to produce CNH in the gas phase in steady-state concentrations sufficient for a spectroscopic characterization of this labile species. Nevertheless, considerable amounts of both hydrogen cyanide and hydrogen isocyanide are present in the interstellar space. Thus, CNH has been detected spectroscopically in various galactic sources, in dark nebulae, and in comets[52-55] (Fig. 17).

The potential energy of this molecular system depends on three structural parameters. Such an energy function is already too complex to be plotted as a contour diagram and, as a hypersurface in 4-dimensional space, it cannot be visualized. Therefore, the results for the rearrangement CNH⇄HCN[45] are presented in Figure 17 by means of superimposed molecular structures, each corresponding to a point on the 4-dimensional potential surface. Apart from the start and end minima CNH and HCN, respectively, we note eleven ascending valley points which lead to the successful localization of the saddle point (lower part of Fig. 17). Clearly, this set of valley points alone provides a qualitatively correct representation of the minimum-energy reaction path. For comparison, the two gradient paths calculated more accurately by means of, respectively, ten and eleven descending path points are also shown in Figure 17. According to the theoretical model of this rearrangement, the hydrogen atom migrates on nearly circular paths around the nitrogen and carbon atoms, but in between, moves more or less parallel to the CN bond axis, thus exhibiting a marked tendency to keep optimum bonding distances as long as possible. Figure 17 also shows the results of an *ab initio* SCF study by *Morokuma et al.*[30], who first localized the saddle point by gradient norm minimization and subsequently calculated the minimum-energy reaction path by repeated gradient evaluations. The results obtained by means of ascending and descending valley points are in full harmony with those based on gradient procedures.

3.2. S_N2 Reaction of the Hydride Ion and Methane

As a second example we consider the S_N2 reaction involving hydride ion and methane. This reaction is prototypical of nucleophilic substitutions at a saturated carbon atom and has frequently been examined theoretically in recent years[56-62], *e.g.*, by *Morokuma et al.*[30] using gradient methods in connection with a standard *ab initio* SCF procedure. It served as a test case for the new methods based on ascending and descending valley points[45]. If we assume that the threefold symmetry of the molecular system is conserved throughout the reaction, the potential energy depends on four structural

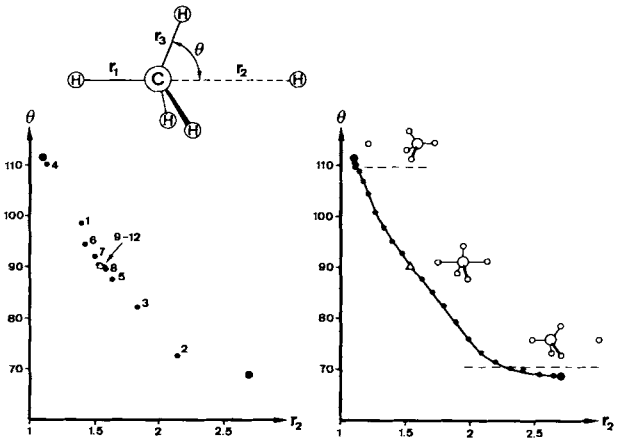

Fig. 18. The localization of the saddle point and the calculation of the minimum-energy reaction path for the S_N2 reaction involving $H^{\ominus}$ and CH_4 by means of ascending and descending valley points [45].

parameters (Fig. 18). To show the computational results we make use of a parametric representation, concentrating on the dependence of the angle, θ, of the CH_3 pyramid upon the distance, r_2, between the entering hydride ion and the central carbon atom. The symmetrically lying saddle point of trigonal bipyramidal structure, which can also be determined directly by partial geometry optimization, is correctly localized after a series of twelve ascending valley points. Again, these valley points provide a satisfactory picture of the minimum-energy reaction path. Indeed, little is gained by a more quantitative calculation of this path using eleven descending path points. This path suggests a slow but continuous opening of the CH_3 pyramid during the approach of the nucleophile $H^{\ominus}$, comparable perhaps to the smooth opening of an umbrella (Fig. 19). It is in good qualitative agreement with the gradient path obtained by *Morokuma et al.*[30]. Moreover, it is consistent with ideas about such a reaction path, as derived

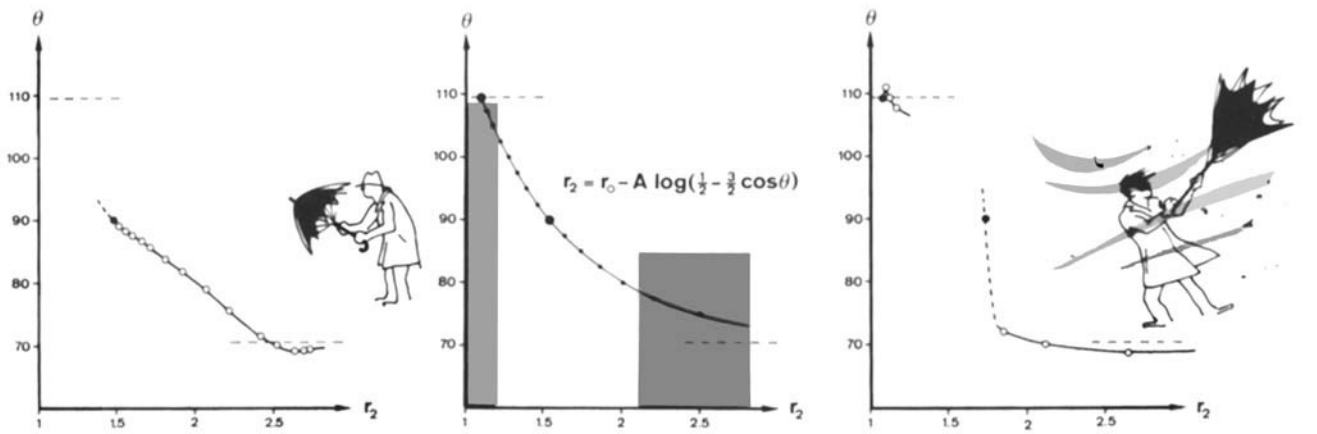

Fig. 19. Reaction paths for the S_N2 reaction involving $H^{\ominus}$ and CH_4. Left: Minimum-energy reaction path using gradient procedures in connection with a standard *ab initio* SCF model [30]. Middle: Idealized reaction path as derived by correlation of X-ray structural data of five-coordinated cadmium complexes [15, 17] and normalized to the molecular system $CH_5^{\ominus}$. Right: Reaction path obtained within the framework of an *ab initio* SCF model using the reaction coordinate method with r_2 as reaction coordinate [59].

by *Bürgi*[15] on the basis of X-ray structural data of five-coordinated cadmium complexes using the structure correlation method. On the other hand, it sharply contrasts with earlier results[59] obtained within the framework of an admittedly sound quantum-chemical procedure, but using the reaction coordinate method with the distance r_2 as reaction coordinate. This seems a natural choice for a substitution reaction, but the method produces a reaction path along which the CH_3 umbrella undergoes virtually no change for a long time and then, suddenly, at a critical value of r_2, shows one of those unfortunate discontinuitites (Fig. 19) for which, no doubt, the reaction coordinate method is to be blamed rather than the underlying quantum-chemical procedure.

3.3. The Computational Effort

Thus far, little attention has been given to an important aspect, the computational effort. In fact, it is not easy to give *valid comments on the costs of a particular method*, particularly since the computational effort depends not only on the localization procedure used but also on the complexity of the energy hypersurface, on the availability of suitable starting points for a saddle point localization, on the desired density of path points for the description of a gradient path, and, last but not least, on the numerical accuracy required for the calculation of molecular structures. Nevertheless, a few comments are in order to caution against an overoptimistic view of current possibilities in a theoretical treatment of chemically relevant problems.

For a number of quantum-chemical procedures, especially semiempirical methods, the energy gradient can be evaluated directly in connection with an energy calculation at only moderate additional expense[41]. Here, gradient procedures are the methods of choice for the localization of saddle points and minimum-energy reaction paths. A simultaneous calculation of the energy and the energy gradient is also feasible by standard *ab initio* SCF procedures. However, this is a much more expensive undertaking than the calculation of the energy alone[30,41]. Thus, it is also for economy that the use of gradient methods for the localization of a saddle point requires an *a priori* knowledge of its approximate position. In principle, there are two ways to get at this information. The first consists in localizing a saddle point within the framework of a less expensive semiempirical method as a starting point for the more expensive *ab initio* procedure. This technique runs the risk that different theoretical models may disagree in their predictions concerning the position of a saddle point. The second consists in narrowing down the saddle point region using a search strategy without gradients. Such a procedure will generally be more expensive, but it allows us to remain within one and the same theoretical model. For various quantum-chemical methods direct evaluation of the gradient is not feasible or is unduly expensive. In these cases, search strategies such as the synchronous transit method or the procedure based on ascending valley points may be of considerable value. Regardless of which localization method is applied, when used in connection with nonempirical calculations, the computational effort soon becomes prohibitive with increasing structural complexity of the molecular system.

The computational effort required by the new methods using ascending and descending valley points has been investigated by a series of systematically selected test cases[45]. The results are summarized in Figure 20. The number of energy

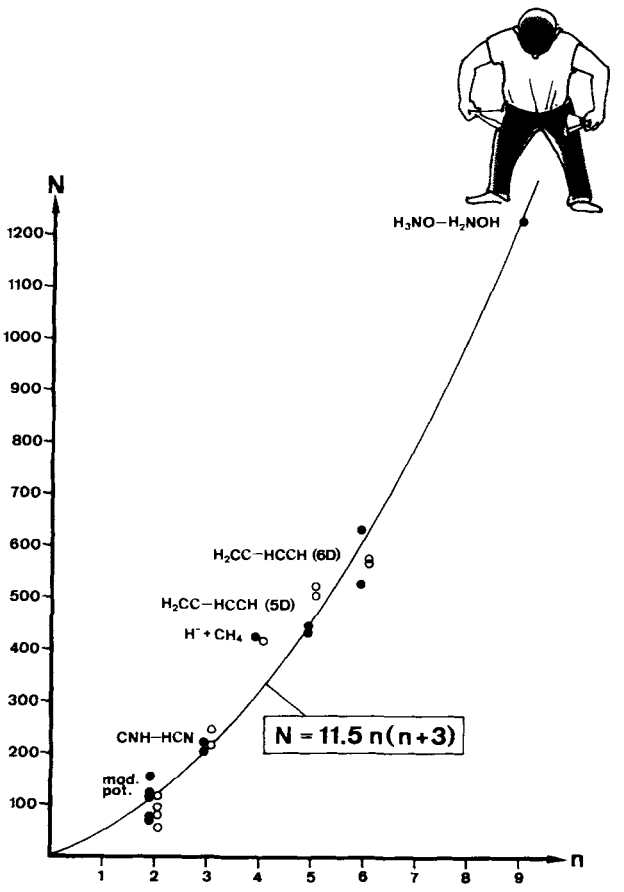

Fig. 20. The number (N) of energy evaluations required for the localization of a saddle point (filled circles, 0.005 A, 0.5°) and a minimum-energy reaction path (open circles, 0.002 A, 0.2°) by means of ascending and descending valley points, respectively, increases with growing dimensionality ($n+1$) of the potential surface (mod. pot. = 2-parameter model potential).

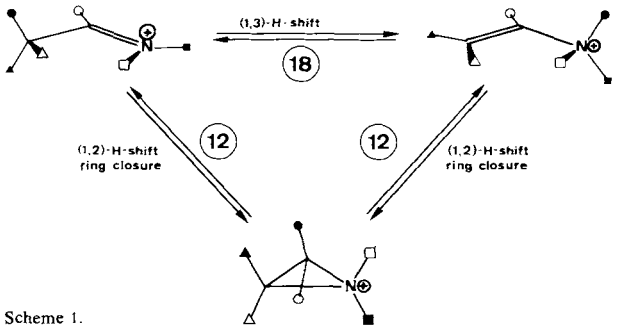

evaluations required for the localization of a saddle point as well as for the calculation of a gradient path increases more or less quadratically with the dimension of the energy hypersurface. Unfortunately, the proportionality factor is rather large. Of course, the computational effort could be reduced at the expense of numerical accuracy; but, as before, a more expeditious localization of a saddle point can be achieved only if its approximate location is known in advance. On the other hand, a definite advantage of the new method (and of the synchronous transit method) is that no prior information regarding the position or the nature of a saddle point is required for its localization; but we have to pay for this.

3.4. Transformation of Vinylammonium into Ethylideneammonium Ion

Finally, we return to the transformation of the vinylammonium ion into the ethylideneammonium ion, already mentioned in Figure 4. This reaction has been studied within the PRDDO SCF approximation in connection with theoretical[23] and experimental[63] work on enamines[64]. It is easily recognized by an experienced chemist as a [1,3] sigmatropic hydrogen or proton shift. Biased by current views

about such reactions[65-67], he is prepared to accept, in principle, two possible modes for the migrating proton, *viz.*, a suprafacial, thermally forbidden process (with a large activation energy) and an antarafacial, thermally allowed process (with a smaller activation energy). However, we recall that the molecular system $C_2H_6N^{\oplus}$ has 21 internal degrees of freedom. As a matter of fact, 18 different reaction paths are formally possible just for the one-step transformation because of permutational symmetries in the reactant and product systems (Scheme 1). In addition, two-step as well as multistep

Scheme 1.

processes have to be considered. For example, a [1,2] hydrogen shift with concomitant ring closure may lead from the ethylideneammonium to the aziridinium ion, which can then rearrange to the vinylammonium ion *via* ring opening and another [1,2] hydrogen shift. Again the permutational symmetry permits twelve different reaction paths for each of the two individual steps. Thus, a sigmatropic rearrangement that looks fairly innocuous at first sight turns out to be extremely complex. According to Figure 20, the rigorous localization of a saddle point on a 21-parameter energy hypersurface by means of ascending valley points is expected to require about 6000 energy calculations. With an average of 15 seconds per energy value[64], this amounts to roughly 90000 seconds or one full day of computer time. Such an undertaking is dangerous for budgetary reasons (Fig. 20), particularly if several saddle points are to be found on this hypersurface. The necessity for a structural simplification led to a number of preliminary studies which helped to differentiate between twelve essential and nine non-essential structural parameters, among them five bond distances to hydrogen atoms. Saddle points and minimum-energy reaction paths were then localized on the simplified 12-parameter potential surface by means of ascending and descending valley points, respectively. The results are summarized in the reaction scheme of Figure 21.

Given the energy minima of the vinylammonium, aziridinium, and ethylideneammonium ions as starting points, a total of seven saddle points were found, in addition to those for internal rotations of the methyl and the ammonium group, respectively; all associated minimum-energy reaction paths were calculated, and two high-energy intermediates were detected. Of the eighteen conceivable possibilities for a one-step transformation of the vinylammonium into the ethylideneammonium ion, only two have survived: a suprafacial and an antarafacial [1,3] sigmatropic hydrogen shift. The remaining reaction modes are linked with these by prior internal rotations of the CH_3 group in the ethylideneammonium ion or of the $NH_3^{\oplus}$ group in the vinylammonium ion. Both [1,3] sigmatropic shifts involve very high energy barriers. There are also two independent paths with considerably reduced barriers leading from the ethylideneammonium ion to the two enantiomeric β-aminoethyl cation intermediates, which are separated by a small conformational energy barrier of about 0.5 kcal/mol. In spite of repeated efforts, no saddle point has been found in the region between the aziridinium and the vinylammonium ion. Likewise, attempts to localize saddle points between the high-lying β-aminoethyl cation and the vinylammonium ion have been unsuccessful. Only one other reaction path has been detected, leading from one of the two intermediates up to the saddle point of the one-step suprafacial [1,3] hydrogen shift; the two saddle points are of roughly equal energy.

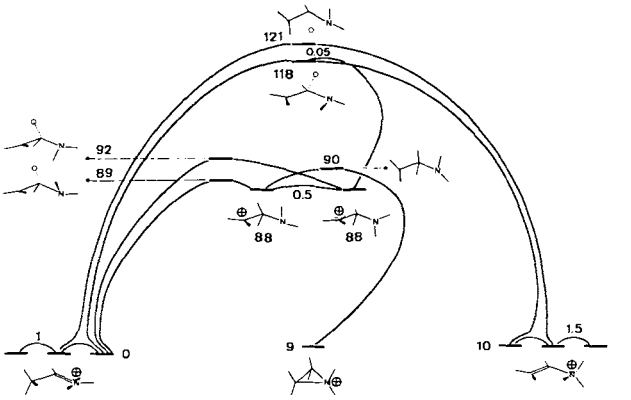

Fig. 21. Reaction scheme involving the vinylammonium, aziridinium, and ethylideneammonium ions, as obtained by localization of saddle points using ascending valley points on a simplified 12-parametric potential surface defined within the PRDDO SCF approximation [64].

In an independent mass spectrometric study, *Williams* and *Hvistendahl*[68] investigated the gas-phase chemistry of $C_2H_6N^{\oplus}$ ions. Based on the analysis of fragmentation products from different isotopically labeled ion precursors and the determination of appearance potentials for various ions, they proposed the approximate reaction scheme shown in Figure 22 (the relevant parts are specifically marked). Of course, the theoretical model can produce a much more detailed description than any currently available experimental technique. Nevertheless, the two reaction schemes agree remarkably well in all their essential features. The vinylammonium and the aziridinium ions are both found to be less

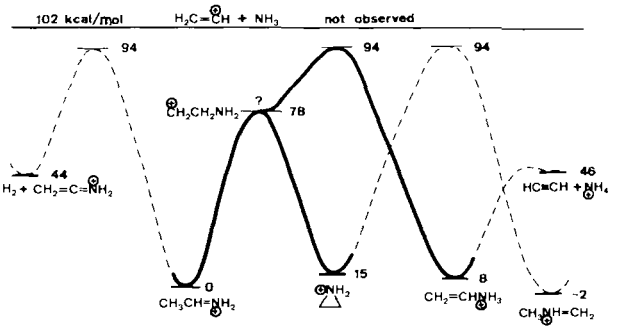

Fig. 22. Approximate reaction scheme for the gas-phase chemistry of $C_2H_6N^{\oplus}$ ions based on mass spectrometric evidence [68].

stable by about 10 kcal/mol[23] than the ethylideneammonium ion. A reaction path leads from the ethylideneammonium to the aziridinium ion, but there is no path with comparable energy barrier from the aziridinium to the vinylammonium ion. The latter can be reached only *via* a much higher barrier, possibly involving the β-aminoethyl cation as a transient intermediate, which has not yet been well characterized experimentally. The calculated energy barriers are consistently too high by about 10—20 kcal/mol. This systematic overestimation is due not so much to the reduction from 21 to 12 internal degrees of freedom but rather to shortcomings of the underlying quantum-chemical procedure, *viz.*, the neglect of electronic correlation effects.

Beyond the mere reaction scheme, the theoretical model provides for each reaction path a detailed description of the cooperation between individual degrees of freedom. This is shown in Figure 23 for the suprafacial [1,3] sigmatropic hydrogen shift. The minimum-energy reaction path is here approximated by sets of, respectively, twelve and thirteen descending path points and is displayed by means of superimposed molecular structures in four different projections. A naive consideration of this reaction might suggest that the hatched hydrogen atom migrates along a more or less straight line from the nitrogen atom (vinylammonium ion) to the terminal carbon atom (ethylideneammonium ion), with two more hydrogen atoms moving so as to planarize the amino group and to pyramidalize the methylene group. Not at all! The theoretical model offers a reaction path that is considerably more intricate. First of all, the $NH_3^{\oplus}$ group in the vinylammonium ion is rotated about the NC bond axis until the predestined hydrogen atom makes an HNCC torsion angle of approximately 90°. From this favorable starting position, the hydrogen atom glides parallel to the NC bond axis, keeping as close as possible to the bonding region. During this process the amino group remains pyramidal, with its conformation virtually unchanged so as to provide optimum partial bonding to the migrating proton. Before the hydrogen atom reaches the central carbon atom, the molecular system crosses the saddle point (atomic positions at the saddle point are marked with arrows in Figure 23). While the hydrogen atom passes over the central carbon atom, the methine proton is temporarily forced out of the CCN plane. The hydrogen atom then glides parallel to the CC bond axis towards the terminal carbon atom. It is only at this stage that the pyramidal amino group is gradually transformed into the planar imminium group and the methylene group starts to pyramidalize, always adjusting its conformation so as to provide optimum partial bonding to the incoming hydrogen atom. Finally, after completion of the intact ethylideneammonium structure, the CH_3 group is rotated about the CC bond axis until its equilibrium position is reached. The process described here is considerably more complicated than is generally assumed to be the case for a suprafacial [1,3] sigmatropic hydrogen shift[65-67]. However, with all its structural complexity it stands much closer to chemical intuition than, for example, a process in which a hydrogen atom is shifted along a more or less straight line over the molecule.

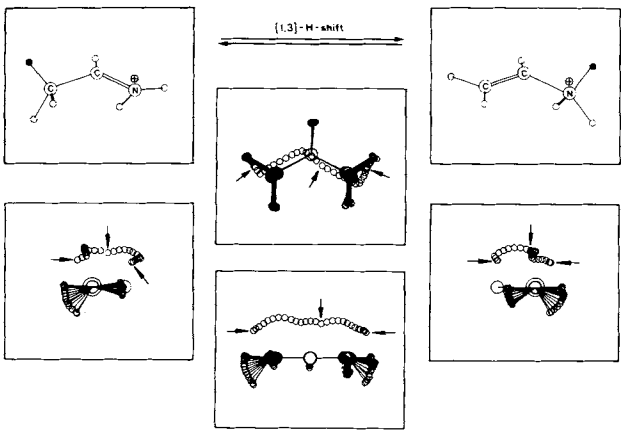

Fig. 23. Minimum-energy reaction path for the suprafacial [1,3] sigmatropic hydrogen shift in protonated vinylamine as shown by means of superimposed molecular structures in four different projections: top view onto the CCN plane (middle top), side view in the CCN plane (middle bottom), view along the CC bond axis (bottom left), view along the NC bond axis (bottom right). Start, end, and saddle point positions of the migrating hydrogen atom are indicated by arrows.

With this example, we emphasize the benefit to be gained from rigorous localization of saddle points as well as from the calculation of gradient paths on multidimensional energy hypersurfaces. With the advent of improved localization methods and more powerful quantum-chemical procedures, such studies will become more and more feasible in the future. A thorough examination of carefully chosen prototype reactions by means of appropriate theoretical models will provide valuable contributions to our understanding of chemical reactivity.

I am particularly grateful to my co-authors who are cited in the bibliography. Financial support by the Swiss National Science Foundation and by Hoffmann-La Roche & Co. (Basel) is gratefully acknowledged.

New analytical methods (17)

Chromatographic Resolution of Racemates

By Gottfried Blaschke[*]

A number of racemates can be resolved into optically pure enantiomers by chromatography on optically active adsorbents. Synthetic polymers with optically active amide, amino acid, and crown ether groups, natural products such as starch and cellulose, and also microcrystalline triacetylcellulose are suitable for this purpose. Racemates can also be resolved by gas chromatography on optically active stationary phases.

1. Introduction

Racemates are usually resolved by fractional recrystallization of diastereomeric salts. However, this conventional method is often laborious, involves high losses, is essentially restricted to carboxylic acids and amines, and does not always yield optically pure samples. One well-known textbook of stereochemistry makes the following comments[1a]: "Racemate separation still remains an art. This is why some of the resolutions described in the literature are difficult to reproduce, and also why a highly skilled experimentalist may get further, *i. e.* obtain higher optical purity or a better yield than a previous author!" Attempts have therefore been made to develop other methods for the resolution of racemic mixtures[1b]. Accordingly, racemic alcohols have been converted with optically active isocyanates into diastereomeric carbamates[2] and racemic amines with optically active lactones into diastereomeric amides [3] and then separated on alumina

or on silica gel. However, these resolutions too require the presence of specific functional groups in the enantiomers, and are inconvenient because of the need to prepare and then to hydrolyze the diastereomers.

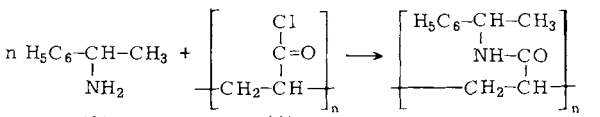
The present review is concerned with the direct chromatographic method, *i.e.* with the resolution of racemates on optically active adsorbents. Diastereomeric complexes are formed by reversible adsorption, and their different stabilities result in different rates of elution of the two enantiomers. A separation is thus possible.

Although many research groups have sought suitable optically active adsorbents for the chromatographic resolution of racemates since *Willstätter*[4], until recently the numerous attempts at separations, described in some 400 publications[5] and several reviews[6-8], have only been successful in exceptional cases. One known example is the resolution of Tröger's base *(1)* which, because of its sensitivity to acids, is otherwise not resolvable. In the chromatography of *(1)* on (+)-lactose hydrate as an optically active adsorbent, *Prelog* and *Wieland*[9] enriched the enantiomers in the initial and the final fraction and separated the excess of enantiomers by fractional crystallization. However, from 6 g of the racemate eluted with 18 liters of petroleum ether on 2.7 kg of adsorbent, they obtained only 150 mg of (+)- and (−)-*(1)*.

(1)

(2)

Similarly, *Lüttringhaus et al.*[10] resolved the cyclic disulfide *(2)* into the enantiomers by repeated chromatography on a 6.5 m-long column packed with partially acetylated cellulose, followed by fractional crystallization. Chromatographic enrichments of enantiomers have also been accomplished on starch[7], cellulose, and many synthetic adsorbents such as polymer-bound L-ephedrine or polymer-bound L-amino acids[11]. In 1970 *Losse et al.*[6] described the state of the chromatographic resolution of racemates as follows: "The survey shows that reliably reproducible separation effects can now be demonstrated on many asymmetric carriers and phases... Nonetheless, it may by expected that in the foreseeable future this separation principle, by further development of the carrier substances and the methodology, can be transformed into an economical preparative process". In the case of many racemates this expectation has since been fulfilled.



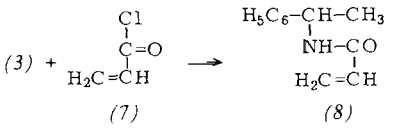
2. Polymerizates of Optically Active Acrylamides and Methacrylamides

2.1. Search for New Adsorbents with the Use of Doubly-Labeled Racemates

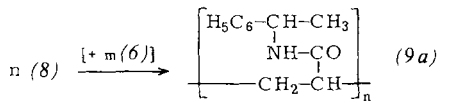
A systematic search for better adsorbents is made more difficult by the material and time expenditure on the preparation of large quantities of the column material and the performance and evaluation of the chromatographic experiments. Moreover, optically active impurities from the column material frequently simulate a separation.

Enantiomer-specifically doubly-labeled racemates[12] have proved very successful in the search for new adsorbents. As in the majority of earlier experiments, mandelic acid was at first used as a test racemate for efficiency of the column resolution, one enantiomer being labeled with ^3H and the other with ^{14}C. The weight or the concentration of one enantiomer is accordingly proportional to the ^3H and that of the other to the ^{14}C activity. The experiment is performed with about 1 mg of the racemate, requiring only about 5 g of adsorbent. Since neither the impurities from the solvent nor any optically active impurities interfere with the radioactivity measurements, double-labeling makes it possible to determine the resolving power of new adsorbents rapidly and reliably.

Synthetic chromatographic adsorbents had previously always been prepared by polymer-analogous reactions of optically active monomers with reactive polymers. The new adsorbents were also at first synthesized by reacting optically active amines, such as 1-phenylethylamine *(3)*, with cross-linked polyacrylic acid chloride *(4)* [cross-linking agent: ethylene diacrylate *(6)*][13].



(3) *(4)* *(5)*



(6)

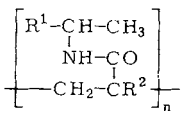
Adsorbents such as the polyamide *(5)* also do not separate racemic mandelic acid to a significant extent[13,14]. Only on some basic polyesters[13] could a low degree of enrichment be established in the initial and final fractions, as on cellulose and starch, and even this slight resolving action was restricted to carboxylic acids[13,14]. Chromatographic resolution of racemates on adsorbents prepared by polymer-analogous reactions is accordingly an exception rather than the rule.

(7) *(8)*

(9a)

The resolving power of polymeric adsorbents is extremely dependent on the method of synthesis. Thus, the polyamide *(9a)*, obtained by radical copolymerization of acrylamide *(8)* with the cross-linking agent ethylene diacrylate *(6)*, in contrast to the polymer-analogously prepared adsorbent *(5)* having the same composition, separates both racemic mandelic acid and racemic mandelamide[15]. *(8)* can be obtained in a high yield by the reaction of (*S*)-1-phenylethylamine *(3)* with acrylic acid chloride *(7)*. The resolving power of such polymers is strongly influenced by the polymerization conditions and emulsifier and by the concentration of solvent and cross-linking agent. Optimization was achieved by systematic variation of the polymerization parameters and testing the polymers by chromatography with doubly-labeled mandelic acid[15].

Radical suspension polymerization gives the adsorbents in practically quantitative yields as snow-white bead polymerizates that swell in benzene, toluene, or chloroform to give transparent gels and enable high flow velocities in the chromatographic column. Because of the cross-linking the adsorbents are insoluble and mechanically stable, can be dried and swelled again, and can be used for chromatography as often as desired without losing their resolving power.



The resolution of mandelic acid and mandelamide on some of these polyamides is summarized in Table 1 (phenylethyl- and cyclohexylethylamine derivatives[16, 17]) and Table 2 (amino acid esters[18]). The efficiency of the resolution is expressed by the optical yield[14]. This was calculated from the optical purity p_i [Eq. (1)] and the mass m_i of each chromatographic fraction in accordance with Eq. (2).

$$p_i = \text{optical purity} = \frac{\text{specific rotation of the enantiomer mixture}}{\text{specific rotation of the pure enantiomer}} \times 100\,[\%] \quad (1)$$

$$\text{optical yield} = \frac{\sum (p_i m_i)}{\sum m_i}\,[\%] \quad (2)$$

If the entire eluate of a chromatographic experiment is collected in the form of a levorotatory fraction and a dextrorotatory fraction, the average of the optical purities of these two fractions is the optical yield. For this reason it is also described as the "average activation Ā"[19] or as the "percentage activation calculated over all chromatographic fractions"[20].

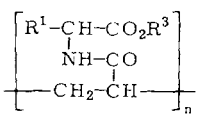


Table 1. Resolving power of polyacrylic and polymethacrylic amides of optically active phenylethyl- and cyclohexylethylamine derivatives of type *(9a)*—*(9f)* [16, 17], crosslinked with ethylene diacrylate *(6)* [Column length: 11—28 cm; solvent system: benzene/dioxane mixtures].

(9a)-*(9f)*

Polymer	R^1	R^2	Optical yield [%] Mandelic acid	Mandelamide
(9a)	C_6H_5	H	28	35
(9b)	C_6H_5	CH_3	8.0	81
(9c)	*c*-C_6H_{11}	H	12	35
(9d)	*c*-C_6H_{11}	CH_3	58	92
(9e)	1-Naphthyl	CH_3	0.0	97
(9f)	*p*-I C_6H_4	H	0.0	0.0

Table 2. Resolving power of polyacrylamides of optically active aminoacid esters of type *(9g)*—*(9m)* [18], cross-linked with ethylene diacrylate *(6)* [Column length: 17—34 cm; solvent system: benzene/dioxane mixtures].

(9g)-*(9m)*

Polymer	R^1	R^2	Optical yield [%] Mandelic acid	Mandelamide
(9g)	CH_3	C_2H_5	14	18
(9h)	*c*-$C_6H_{11}CH_2$	C_2H_5	31	59
(9i)	C_6H_5	C_2H_5	46	34
(9j)	$C_6H_5CH_2$	C_2H_5	51	96
(9k)	*p*-$HOC_6H_4CH_2$	C_2H_5	0	0
(9l)	*p*-$CH_3CO_2C_6H_4CH_2$	C_2H_5	21	42
(9m)	$C_6H_5CH_2$	*t*-C_4H_9	89	80

With a few exceptions, short columns of polymerizates *(9)* resolve both mandelic acid and mandelamide to a considerable extent (Fig. 1). Replacement of benzene, the toxic component of the solvent system, by toluene leads in all the cases tested to practically the same results[22].

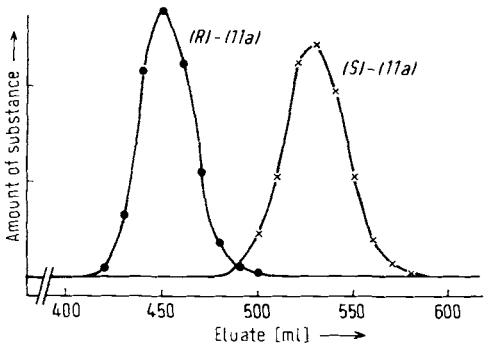

Fig. 1. Chromatographic resolution of 0.1 mg of doubly-labeled racemic mandelamide *(11a)* on 9.0 g of *(9j)* [column: 23 × 1.7 cm; solvent system: toluene/dioxane (95:5)]. The total amount of the substance applied to the column is recovered.

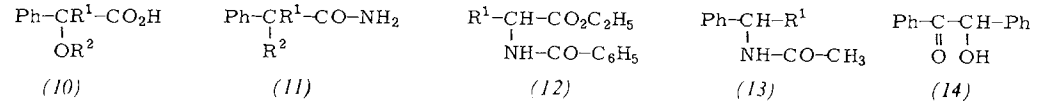
As can be seen from Tables 1 and 2, even small differences in the structure of the optically active group exert an effect on the outcome of the resolution. Moreover, substitution of the polymer chain changes the stereoselectivity of the adsorption. Whereas, for example, the polyacrylamide *(9a)* retains (*S*)-mandelic acid and (*R*)-mandelamide more strongly, on the polymethacrylamide *(9b)*, with otherwise similar structure and configuration, the other enantiomer is adsorbed in preference[16]. This observation as well as the complete absence of a resolving action of polyamides, such as *(5)*, prepared from reactive polymers excludes the interaction of *individual* optically active residues of the adsorbent with the enantiomers as the cause of the resolution. More likely, the resolution proceeds because of different fitting of the enantiomers into asymmetric cavities in the polymer chain. In the radical polymerization of the acrylamides and methacrylamides with bulky substituents it is supposed that ordered regions with a helix structure are produced. Within the helix is the polymer chain with the adsorptively active amide groups; the optically active substituents point outward. Asymmetric cavities are formed between them, and substances are attracted by hydrogen bonding. The different degrees of fit determine the average residence times of the enantiomers in the adsorbent's cavities.

As expected, when the configuration of the optically active residues on the adsorbent is changed, the configuration of the more strongly bound enantiomer also changes, the results being otherwise the same[15].

2.2. Preparative Resolution of Racemic Model Compounds

Table 3 gives a small selection of preparative resolution experiments on the polyacrylamides *(9a)*, *(9c)*, and *(9j)* and also on the polymethacrylamides *(9b)* and *(9d)*[17, 21]. *(9a, b)* can be readily prepared from (*S*)-1-phenylethylamine (*S*)-*(3)*, *(9c, d)* from (*S*)-1-cyclohexylethylamine and *(9j)* from (*S*)-phenylalanine. The standard solvent used in the chromatographic experiments was benzene. If the substance was eluted too slowly, the more polar benzene/dioxane mixtures were used, if too fast, the less polar benzene/cyclohexane



mixtures. Also in these preparative separations replacement of the benzene by toluene did not change the results. According to blank tests, the eluate of the cross-linked polyamides contained no residues; the experiments were thus evaluated by weighing the evaporation residues and measuring the rotation values. Since the resolving power of the columns remained unchanged after repeated use, the preparative resolutions were performed on the same column packings with 150—300 mg of the non-labeled racemates, with layer heights of 16—65 cm. As expected, the resolution proved to be better on the longer columns [experiments with racemates *(13a, b)*].

Tables 1 and 2 and so far not investigated on a preparative scale are particularly suitable.

Complete resolution is achieved by repeated chromatography on one and the same adsorbent. To check the efficiency of the resolution the eluate is pumped through the cell of a polarimeter and a differential refractometer and then back into the column. For example after four runs through a column of polyamide *(9j)*, mandelamide *(11a)* is resolved completely and without losses[22].

So far it has only been possible to obtain optically pure *(13b)* by chromatographic resolution of the racemate. Previous attempts to synthesize this optically active amide *via*

Table 3. Optical yields of preparative resolution experiments with compounds of type *(10)*—*(14)* on adsorbents *(9j)* and *(9a—d)* (for explanations see text).

(10) *(11)* *(12)* *(13)* *(14)*

(12a)	*p*-$HOC_6H_4CH_2$		25	27	33	39	81
(12b)	3-Indolyl-CH_2		29	8.6	20	54	64
(13a)	CH_3		35	26	36 [b] 57 [c]	29	33
(13b)	$CH(CH_3)_2$		6.4	24	44 [d] 58 [e]	22	34
(14)			7.3	0.6	22	10	22

[a] Not determined. Column length [cm]: [b] 43, [c] 116, [d] 39, [e] 107. [f] The discrepancy from the values in Tables 1 and 2 is explained by different solvent system, column length and amount of racemate.

All the compounds in Table 3 can form hydrogen bridges with the amide groups of the optically active adsorbents and can usually be resolved to a considerable extent by chromatography. An example is the resolution of the ethyl ester of *N*-benzoyltyrosine *(12a)* on polymethacrylamide *(9d)* (Fig. 2). Replacement of the benzene in the solvent system by toluene slightly improves the resolution[22].

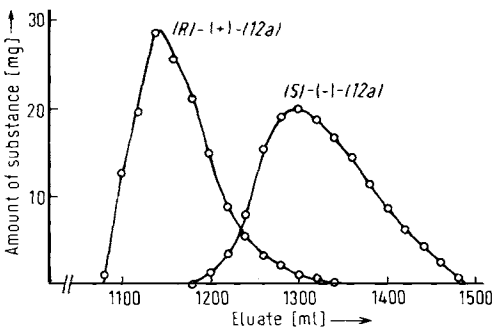

Fig. 2. Chromatographic resolution of 302 mg of racemic *N*-benzoyltyrosine ethyl ester *(12a)* on 65 g of *(9d)* [column: 65 × 2.5 cm; solvent system: benzene/dioxane (80:20)].

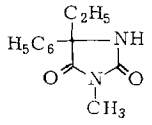
In experiments with new racemates it is impossible to predict on which adsorbent they will be resolved best. It may be that for some racemates adsorbents other than those listed in conventional resolution of the racemic amine *(13b)* (with NH_2 instead of $NHCOOH_3$) have been unsuccessful[23]. A dextrorotatory sample of unknown optical purity was finally obtained from an optically active carboxylic acid[23a]. Chromatography of *(13b)* on adsorbent *(9b)* yielded in the initial and final fractions preparations with much higher rotation values, which did not increase when the chromatography of the samples was repeated, thus confirming the optical purity[21]. The resolving action of optically active polyamides remains largely unchanged with higher column loadings. Even with a weight ratio of the adsorbent *(9b)* to the racemate *(13b)* such as 40:1, 12% of the (+)-enantiomer was still obtained in optically pure form[23b].



2.3. Preparative Resolution of Racemic Pharmaceuticals

In the case of pharmaceuticals the enantiomers usually differ not only in their physiological action but also in their undesirable side effects. The polyamides of type *(9)* have been developed with the particular aim of resolving such racemates. The polyamides resolve chiral drugs with amide and imide structures, whose enantiomers can only be synthesized with difficulty (if at all) by conventional methods.

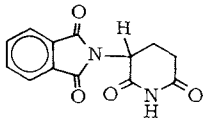


Table 4 demonstrates the extreme differences in the resolving action of those adsorbents in the case of two drugs. Whereas the polyamides *(9j)* and *(9a—d)* resolve racemic

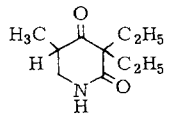
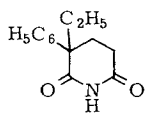
mandelamide *(11a)* almost equally well, the racemic antiepileptic agent mephenytoin *(15)* (Mesantoin®) is resolved well on *(9j)* and poorly on *(9d)*. Conversely, thalidomide *(16)* (Contergan®) is hardly separated into its enantiomers on *(9j)* but completely on *(9d)*.

Table 4. Optical yields of preparative resolution experiments with mephenytoin *(15)* and thalidomide *(16)* on adsorbents *(9j)* and *(9a–d)*. (For explanations see text.)

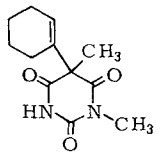


(15)



(16)

Racemate	Optical yield [%] of experiment on				
	(9j)	*(9a)*	*(9b)*	*(9c)*	*(9d)*
(15)	55	9.8	34	21	0.6
(16)	3.8	7.2	42	1.5	100



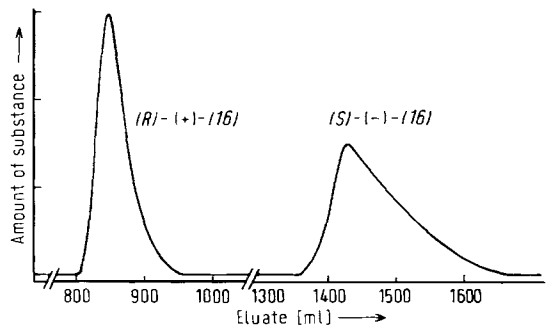
Hitherto it has only been possible to obtain the hypnotic agent methyprylone *(17)* (Noludar®) in optically active form by performing 400 crystallizations (20 kg of initial material), with a yield of less than 0.05%[24]. By means of chromatography on the cyclohexyl polymers *(9c)* and *(9d)*, *(17)* can be resolved partially with optical yields of around 35%.

(17)

(18)

(19)

The hypnotic agents glutethimide *(18)* (Doriden®) and hexobarbital *(19)* (Evipan®) are also resolved to a considerable extent. (+)- and (−)-*(15)* and (+)-*(19)* have both been isolated in optically pure form by repeated chromatography[17]. Of the racemates so far chromatographed on polyamides, thalidomide *(16)* is separated best (Fig. 3)[17,26].



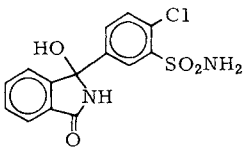


Fig. 3. Chromatographic resolution of 52 mg of racemic thalidomide *(16)* on 65 g of *(9d)* [column: 80 × 2.3 cm; solvent system: benzene/dioxane (80:20)].

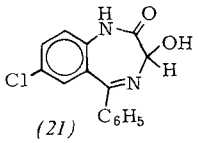


Formerly, the enantiomers of this substance, used at one time as a racemate, were only accessible by synthesis from a costly optically active precursor—a laborious process[25]. Even on a preparative scale it is much simpler to use chromatographic resolution. Although the peaks broaden as the column loading increases, up to 500 mg of racemic *(16)* can be resolved on the same column with 65 g of *(9d)*. In this run a substance-free fraction amounting to at least 120 ml is left between the eluates of dextro- and levorotatory forms. The column packing can be used as often as desired.

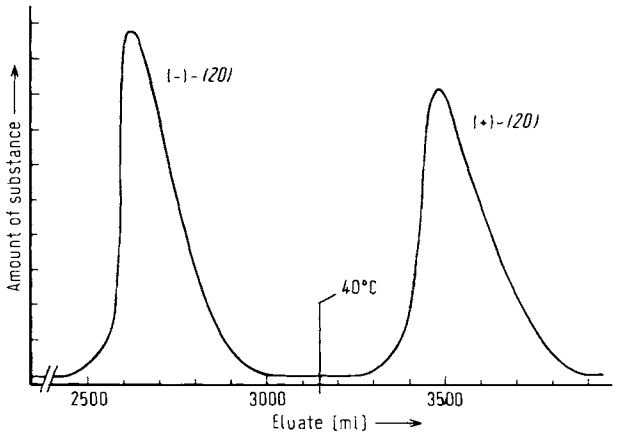
Since on the same column small quantities of the substance can also be separated without losses, the optical purity can be determined analytically by means of chromatography. Synthetic optically active thalidomide has been chromatographed on *(9d)*. The ratio of the enantiomers and thus the degree of racemization could be determined exactly by spectrophotometric assay of the two eluate fractions[17].

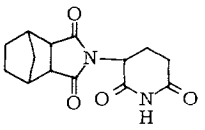
The chromatographically isolated thalidomide enantiomers have been investigated for teratogenic action[26]. On intraperitoneal administration to mice and rats only (*S*)-(−)-thalidomide displayed teratogenic properties; under the experimental conditions used, (*R*)-(+)-thalidomide did not cause any malformations even at the highest doses.

(20)

(21)

The diuretic chlorthalidone *(20)* (Hygroton®) is completely resolved on the polyacrylamide *(9j)*[22]. In the experiment shown in Figure 4 the column temperature was raised to 40 °C after the elution of (−)-chlorthalidone; this increased the elution rate of the (+)-enantiomer, *i. e.* the time required for the resolution was shortened.





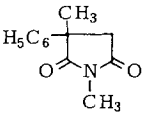


Fig. 4. Chromatographic resolution of 530 mg of racemic chlorthalidone *(20)* on 250 g of *(9j)* [column: 76 × 3.2 cm; solvent system: toluene/dioxane (1:1); pressure 1.2 bar].

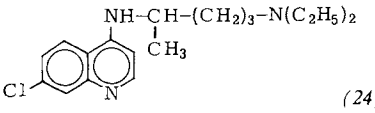
The two enantiomers were thus obtained in optically pure form for the first time. However, they racemize very readily in an alkaline solution[22]. The psychopharmaceutical oxazepam *(21)* (Adumbran®) can also be resolved completely by chromatography on polyamide *(9j)*[22], but the enantiomers racemize under the catalytic influence of a glass surface. They must therefore be collected and evaporated in plastic vessels. Compounds that racemize so readily can only be separated into their enantiomers by chromatography.

Other drugs, such as the potential hypnotic biglumide *(22)*[27], have also been separated on polyamides[17]. Both



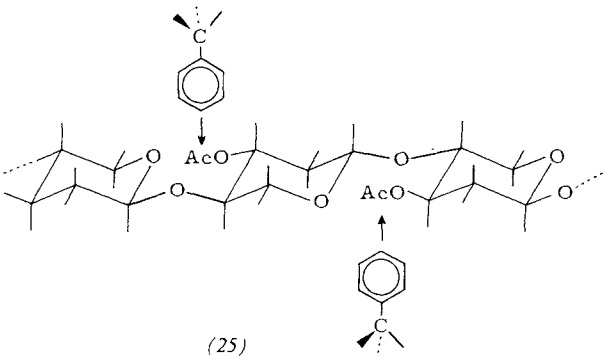
(22)

(23)

enantiomers have been isolated from *(22)*[22]. Compounds with *N*-alkylated imide groups, such as mesuximide *(23)* (Petinutin®), that are unable to form hydrogen bridges with the adsorbent, are eluted with the solvent front and are only slightly resolved[17].

(24)

By means of chromatographic resolution it was possible to test the rotation values for optically active chloroquine *(24)*[29]. As an important antimalarial agent (Resochin®), *(24)* had previously been separated *via* diastereomeric salts into samples considered to be enantiomers, with $[\alpha]_D$ values of $+12.3$ and $-13.2°$[28]. Since these preparations did not differ in their antimalarial action and toxicity, chloroquine has become the textbook example of a drug whose enantiomers, contrary to experience, exhibit the same undesirable and desirable pharmacological effects. By chromatography on polyamide *(9j)*, however, a chloroquine sample with a much higher specific rotation is obtained[29]. The optical purity of the earlier preparations was accordingly only some 10%. Optically pure (+)-chloroquine, which became available by synthetic methods too[29], is more effective against malaria[30,31] and is also less toxic[31] than the racemate.



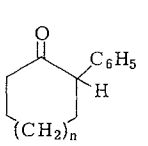
3. Microcrystalline Cellulose Triacetate

3.1. Principle of the Resolution

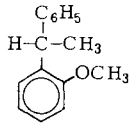
Microcrystalline cellulose triacetate [cf. *(25)*], introduced by *Hesse* and *Hagel*[32], is an optically active adsorbent that in many cases allows an astonishingly good resolution to be achieved. *Lüttringhaus*[10] had extensively investigated racemate resolutions on a partially acetylated cellulose, "cellulose 2½-acetate", but generally had observed only low degrees of enrichment. These cellulose esters were prepared in a homogeneous solution and then precipitated, the original crystalline structure of the cellulose being broken down.

Cellulose can also be acetylated heterogeneously in a suspension in benzene, the fiber structure with crystalline areas then remaining unchanged. The lamellar arrangement in the manner of a crystalline lattice acts as a two-dimensional molecular sieve, making possible the inclusion of foreign molecules. These are held between two layers in an environment which is asymmetric owing to the sterically fixed ester groups of the cellulose triacetate reaching into the cavities. Since the chromatographic resolution of racemates is based on the different degrees of fit into these cavities, *Hesse* called this process inclusion chromatography.

A phenyl group bearing as few substituents as possible in the vicinity of the chirality center is particularly advantageous for the resolution; this group fits especially well into the gaps between the pyran rings of the cellulose fiber and is thus the anchoring group. The racemate to be separated thus needs no functional group for the absorption on the chiral matrix.

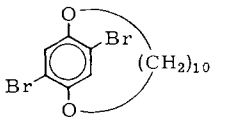


(25)



By dissolution and reprecipitation of the microcrystalline cellulose triacetate the crystalline regions are destroyed and the resolving power is almost completely lost. The different resolving capacities of microcrystalline and amorphous cellulose triacetate are similar to those found for the synthetic polyamides. Here too, uniform arrangements of the optically active residues enabling resolutions were formed only in the polymerization step of optically active monomers.

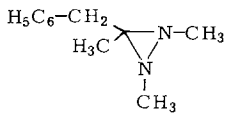
3.2. Resolution of Model Compounds



The standard solvent system for chromatography on microcrystalline cellulose triacetate is 95% ethanol, in which the absorbent swells well but is only sparingly soluble. *Hesse* and *Hagel* have chromatographed many racemates on a 40-cm column. Under these conditions the following compounds were completely resolved: Tröger's base *(1)*, 1,2-dithia-4,5:6,7-dibenzocyclooctadiene *(2)*[33], 2-phenylcyclohexanone *(26a)*, 2-phenylcycloheptanone *(26b)*, 2-(1-phenylethyl)anisole *(27)*, and 2,5-dibromo-*O,O'*-decamethylenehydroquinone *(28)*[32].

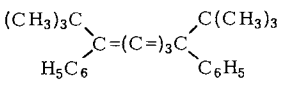
(26a), n = 1
(26b), n = 2

(27)



(28)

Other racemates, however, were resolved incompletely or even poorly. Thus, *m*- and *p*-substituents and carboxyl groups impair the separation. *Hesse*[34] evaluated the applicability of microcrystalline cellulose triacetate as follows: "Even with inclusion chromatography on cellulose esters, complete racemate resolution still remains a matter of luck. A measurable activation of chiral compounds, however, is nearly always obtained".

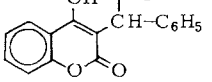


In the author's research group, *Markgraf*[22] chromatographed many racemates only partly resolved on polyamides for comparison with the resolutions on microcrystalline cellulose triacetate. Mostly, racemates with an unsubstituted aromatic group in the direct vicinity of the chirality center

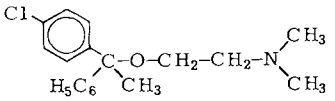
were selected, in accord with previous results the optimal prerequisite for resolution on the triacetate. The 85-cm cellulose triacetate column resolved these racemates with very variable optical yields, sometimes with more success and sometimes with less than the polyamides, but never completely. Thus, the tyrosine derivative *(12a)* extensively separated on the polyamide *(9d)*, was not separated at all on the triacetate, while benzoin *(14)* and benzoin acetate [*(14)*, $OCOCH_3$ in place of OH] were separated better than on polyamides.

Microcrystalline cellulose triacetate has moreover been used for the chromatographic resolution of compounds which easily racemize.

(29)

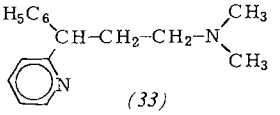


(30)



Mannschreck et al.[35] resolved chiral diaziridines such as *(29)* by repeated chromatography on a short column; *Bertsch* and *Jochims*[36] resolved the chiral pentatetraene *(30)* on a cooled column.

3.3. Separation of Drugs and their Synthetic Precursors



The suitability of microcrystalline cellulose triacetate for the chromatographic separation of enantiomeric drugs has also been investigated by *Markgraf*[22] on some examples. The adsorbent is not suitable for the resolution of thalidomide *(16)*, chlorthalidone *(20)*, oxazepam *(21)*, and chloroquine *(24)*. Other drugs, such as the anticoagulants phenprocoumon *(31a)* (Marcumar®) and warfarin *(31b)* or the antihistamines chlorphenoxamine *(32)*(Systral®) and pheniramine *(33)* (Avil®), are also eluted in fractions displaying no measurable optical activity, although they satisfy the precondition of having an unsubstituted phenyl group at the chirality center.

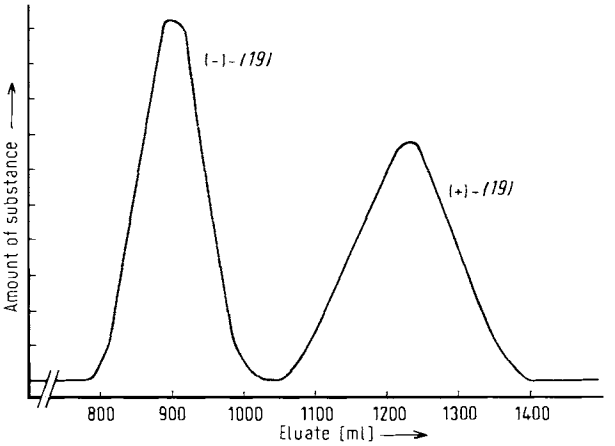
(31a), R = CH_3
(31b), R = $COCH_3$

(32)

(33)

Glutethide *(18)*, mephenytoin *(15)*, and mesuximide *(23)* are, however, resolved to a considerable extent. A slight effect is observed with the chromatography of methyprylone *(17)*, which does not contain a phenyl group. Surprisingly good results are obtained with the chromatography of *N*-methylated barbiturates on cellulose triacetate. According to *Knabe et al.*[37], these barbiturates are accessible from optically active precursors; the enantiomers frequently exhibit very different pharmacological activity.

Hexobarbital *(19)* (Fig. 5) and the *N*-methylated barbiturates *(34a, b, d—f)* were separated completely on microcrystalline cellulose triacetate, *(34c, g)* only partially, and *(34h, i)* not at all (see Table 5). In the case of *(34h)* the difference in size between the ethyl and the propyl group is presumably insufficient, in the case of *(34i)* the chirality center in the side chain is too far away from the adsorptively active imide group in the heterocycle. As shown by the good separation of some aliphatically substituted barbiturates, however, a phenyl group is not absolutely necessary for resolution.



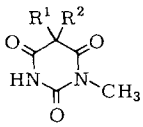


Fig. 5. Chromatographic resolution of racemic hexobarbital *(19)* on cellulose triacetate [column: 85 × 2.5 cm; solvent system: ethanol/water (95:5); pressure 1.2 bar].

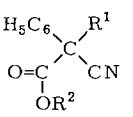
Table 5. Preparative resolution experiments with chiral barbiturates on cellulose triacetate [column: 85 × 2.5 cm; solvent: 95-% ethanol]. For some experiments separation and resolution factors are given in addition to the optical yields.

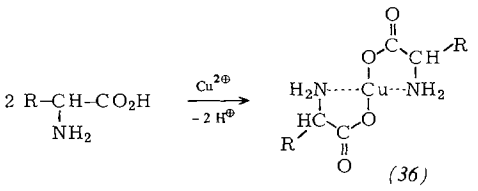


(34a-i)

Racemate	R^1	R^2	Optical yield	Separation factor [a]	Resolution factor [b]
(34a)	Phenyl	CH_3	100		
(34b)	Phenyl	C_2H_5	100	2.3	2.3
(34c)	Phenyl	C_3H_7	48		
(19)	1-Cyclohexenyl	CH_3	100	1.7	1.5
(34d)	1-Cyclohexenyl	C_2H_5	100	2.0	1.7
(34e)	Cyclohexyl	CH_3	100	1.9	1.5
(34f)	Cyclohexyl	C_2H_5	100	2.4	1.7
(34g)	1-Cyclopentenyl	C_2H_5	68		
(34h)	*n*-Propyl	C_2H_5	0		
(34i) [c]	Vinyl	$CH(CH_3)\ C_3H_7$	0		

[a] α = (retention volume of less mobile component minus total dead volume)/(retention volume of more mobile component minus total dead volume).
[b] $R_S = 2$ (retention volume of the less mobile component minus that of more mobile component)/(sum of bandwiths of two peaks).
[c] NH instead of NCH_3.

The cyanoacetic acid esters *(35a—c)*, precursors in the synthesis of chiral barbiturates[37], are also resolved on cellulose triacetate[22]. However, the resolution deteriorates with increasing chain length of the group R^1. For the methyl compound *(35a)* the elution curves of the two enantiomers are far apart. They touch for the ethyl compound *(35b)* and overlap for the butyl compound *(35c)*. The carboxylic acid *(35d)*, however, is not resolved.



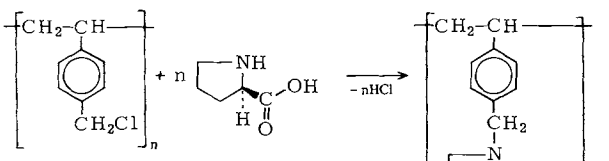
(35a), $R^1 = CH_3$, $R^2 = CH_3$; *(35b)*, $R^1 = C_2H_5$, $R^2 = CH_3$
(35c), $R^1 = C_4H_9$, $R^2 = CH_3$; *(35d)*, $R^1 = CH_3$, $R^2 = H$

With cellulose triacetate too, therefore, as with the polyamides, the outcome of the resolution cannot be reliably deduced from the structure of the enantiomers to be separated.

4. Ligand Chromatography

4.1. Separation Principle

Amino acids in aqueous solution form with Cu^{2+} ions complexes of the structure *(36)*. In these chelates the central atom is bonded to two amino-acid molecules.

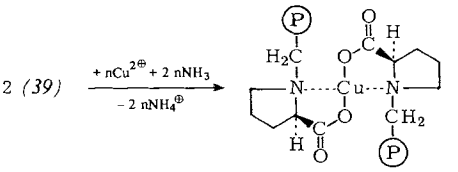


(36)

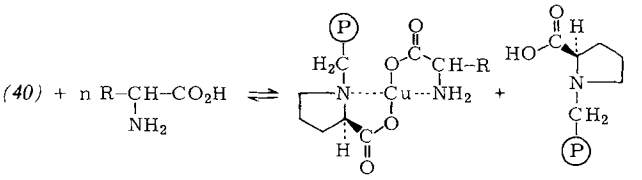
In ligand chromatography as a method of racemate resolution, an optically active ligand is bonded covalently to an insoluble carrier. After charging this adsorbent with Cu^{2+} ions, the racemate to be resolved is chromatographed. The enantiomers then form diastereomeric complexes with the Cu^{2+} ions and the adsorbent. The differences in complex stability enable chromatographic resolution.

4.2. Performance and Application of Ligand Chromatography

Ligand chromatography particularly has been developed by *Davankov* and his group[38] for the resolution of racemic α-amino acids. A very suitable adsorbent is polymer-bound L-proline; on the one hand it enables good resolution and on the other it practically does not racemize under the conditions of the chromatography, with the result that these adsorbents can be used repeatedly. Polymer-bound L-proline *(39)* is prepared by reacting cross-linked chloromethylated polystyrene *(37)* with L-proline *(38)*[39] or, preferably, with L-proline ethyl ester and subsequent hydrolysis of the ester group[40].



(37) *(38)*



(39)

The light-brown sample *(39)* is washed with ammoniacal copper(II) nitrate solution, whereby it assumes a dark-blue color indicating that the chelate complex *(40)* has been formed between two neighboring polymer-bound proline residues *via* the Cu^{2+} ion. The 2:1 ratio of the amino acid residues to the Cu^{2+} ions has been demonstrated by titration and elementary analysis[40].

After charging with Cu^{2+} ions the adsorbent is ready for use in the resolution experiment. The column packed with the adsorbent is connected to a short column with copper-free adsorbent *(39)* to bind washed-out Cu^{2+} ions. In the chromatography of a racemic α-amino acid on *(40)* each amino acid molecule displaces one of the polymer-bound proline ligands to form the mixed complex *(41)* between the polymer-bound L-proline and the amino acid.

(40)

(41) *(39)*

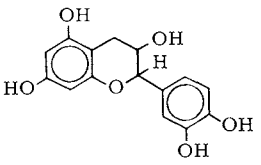
The two complexes of structure *(41)* with the D- and L-amino acid differ in energy content by up to 825 cal/mol[41]. This difference affects the equilibrium between free and complexed amino acids. The complex *(41)* which contains the L-amino acid is usually less stable, so that the L-amino acid is eluted more rapidly.

Racemic proline can be resolved especially well on the proline polymer *(40)*. The differences in the energy content of the diastereomers are in this case so large that L-proline is already eluted with water and D-proline only with ammonia. In this process ammonia displaces D-proline from the complex *(41)*. Both enantiomers are obtained completely and in an optically pure form by evaporation of the eluates. The resolving capacity is remarkably high. 0.5 g of racemic proline can be completely separated on 12 g of *(40)*[39]. In order to regenerate the column it is only necessary to wash out the excess ammonia with water.

Many other amino acids can be partially or completely resolved into enantiomers on *(40)*[41]. The results of some resolutions on *(40)* are given in Table 6. The separation factor, defined as the ratio of the net retention volumes of the two enantiomers, is given as a measure of the resolution.

Table 6. Resolution factors in the chromatography of some racemic amino acids on *(40)* [41] [solvent: 0.3 M NH_4OH].

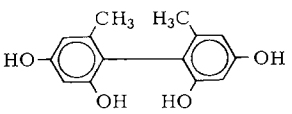
Racemate	Separation factor	Racemate	Separation factor
Norvaline	1.40	Phenylalanine	1.63
Norleucine	1.54	Tyrosine	2.46
Proline	4.00	Methionine	1.04
Hydroxyproline	3.85		



Some other amino acids, such as L-hydroxyproline[42], L-*allo*-hydroxyproline[43], and acetidinecarboxylic acid[41] have also been covalently bound to polystyrene. These adsorbents separate enantiomers, but, like Ni^{2+} complexes[44], generally

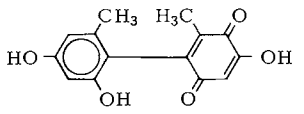
to a much lower extent than the Cu^{2+} complex of polymer-bound L-proline. *(40)* also resolves racemates belonging to other classes of compounds, such as diamines, hydroxyamines, and hydroxy acids, at least partly into enantiomers[45].

Thus, by means of ligand chromatography some compounds can be separated very well indeed, the high loading capacity of the adsorbent being particularly advantageous. However, the method is restricted to compounds with amino and/or carboxyl groups that can also be resolved conventionally *via* diastereomeric salts.

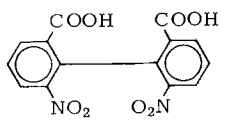


5. Cellulose and Starch

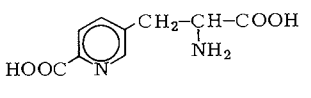
In paper chromatography, the resolution of racemates on the optically active cellulose of the paper has occasionally been observed. Thus, catechol and epicatechol *(42)* are resolved into their enantiomers. This separation can also be used for preparative purposes[46]. Additionally, separations of racemic amino acids[47] and alkaloids[48] by paper chromatography have also been described. However, chromatographic racemate resolution on cellulose requires structural elements such as several neighboring hydroxy groups (*Dalgliesh*'s "three point rule"[47]). The differences in the R_F-values are usually insufficient to obtain preparative amounts of the enantiomers on cellulose columns.



(42)



Starch has been particularly used by *Krebs* and *Musso* for the chromatographic resolution of racemates. *Krebs et al.*[7,49] have observed enrichment of the enantiomers of inorganic complexes, hydrophilic camphoric acids, diphenic acids, and amino acids on starch columns. *Musso et al.*[50] have reported on the separation of biphenyl derivatives such as *(43)* and *(44)*. This research group recently succeeded in a complete resolution of 6,6′-dinitrodiphenic acid *(45)*, the alanine derivative *(46)* and its *N*-oxide, and polar orcine derivatives by optimizing the solvent and the temperature. The solvents were aqueous or aqueous-methanolic buffer solutions[51].



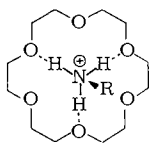
(43)

(44)

(45)

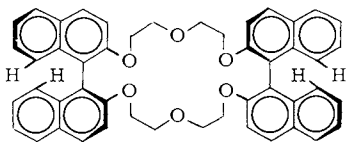
(46)

According to the results hitherto obtained, cellulose seems to be particularly suitable for certain amino acids and starch for polar biphenyl derivatives. Their range of application is thus rather limited. A further disadvantage is the low capacity of these adsorbents.



6. Other Optically Active Adsorbents for Liquid Chromatography

The adsorbents discussed in this section have been developed specifically for liquid-chromatographic resolution of racemates belonging to certain substance classes, but, the usually good resolution is obtained at the expense of a narrowly restricted field of application.



6.1. Chiral Crown Ethers

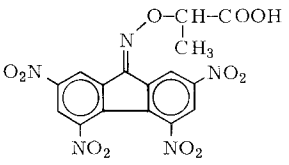
Crown ethers such as *(47)* form complexes not only with alkali metal ions and alkaline earth metal ions but also with salts of primary alkylamines. In these complexes the hydrogen atoms of the ammonium group are hydrogen bonded to the oxygens of the crown ether.

Optically active crown ethers such as the chiral binaphthyl derivative *(48)* have been developed and utilized for racemate resolution particularly by *Cram* and his co-workers[52]. Binaphthyl derivatives of this type have stable configurations since the rotation around the binaphthyl axis is sterically hindered.

(47)

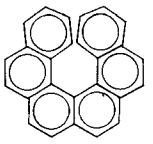
(48)

Alkylammonium ions of structure R NH_3^+ with a chiral group R are drawn into the asymmetric cavity of the crown ether *(48)* and thus form diastereomeric complexes having various degrees of stability. Such suitably substituted ammonium salts can thus be separated by multiple distribution between an aqueous phase and the solution of *(48)* in a solvent immiscible with water[53].



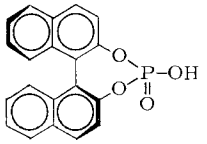
Covalent bonding of optically active crown ethers on cross-linked polystyrene yields optically active adsorbents suitable for the chromatographic racemate resolution of primary alkylammonium ions. With an adsorbent of this kind high-pressure liquid chromatography can be used to resolve several α-amino acids and their methyl esters as perchlorates into enantiomers, the separation factors reaching extremely high values of around 20[54]. With a few exceptions the sequence of the optical forms eluted could be determined in advance using molecule models.

Salts of *p*-hydroxyphenylglycine, phenylalanine, tyrosine, and tryptophan esters have been resolved completely on silica gel substituted with a derivative of the crown ether *(48)* with separation factors of up to 6.4, while salts of 1-phenylethylamine and valine methyl ester have been partly resolved on this adsorbent[55]. These "tailor-made" adsorbents are very well suited for such separations, but the chirality center must be directly adjacent to the ammonium group. Only then do the size differences of the groups at the chirality center come into full play. Unfortunately, such adsorbents are very difficult to prepare.

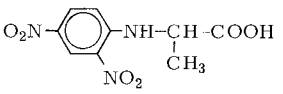


The scope of optically active crown ethers may be extended with macrotricyclic ligands to chiral carboxylic acids whose K^+, Cs^+, and Rb^+ salts also exhibit enantiomer-selective complexation[56].

6.2. Resolution *via* Chiral Charge-Transfer Complexes



Optically active charge-transfer reagents such as 2-(2,4,5,7-tetranitro-9-fluorenylideneaminooxy)propionic acid *(49)* ("TAPA") form with chiral arenes such as hexahelicene *(50)* crystalline diastereomeric charge-transfer complexes resolvable by fractional crystallization. Their different stabilities can be utilized for chromatographic separation and racemate resolution of such helicenes. *Gil-Av et al.*[57] first linked optically active *(49)* and similar charge-transfer acceptors to silica gel by adsorption and then resolved helicenes with solvents in which *(49)* is completely insoluble. Resolutions of this kind can also be performed with silica gel to which *(49)* has been bonded covalently *via* the carboxylic group[58]. Not only are racemic helicenes resolved into the enantiomers on such columns, but also mixtures of helicenes are also separated into their components. Since the separation of different helicenes is easier than resolution of the helicene racemates, groups of signals are observed in the chromatogram; each group is split into the two signals of the enantiomers. The (+)-helicene is always bonded more strongly to *R*-(−)-*(49)*. The optically active binaphthyl derivative *(51)*[58] and the dinitrophenyl derivative *(52)*[59] are also suitable charge-transfer acceptors for resolutions. However, resolutions of this type seem to be restricted to helicenes.

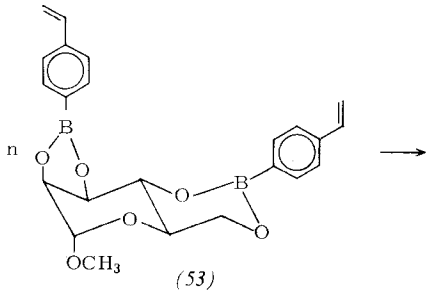


(49)

(50)

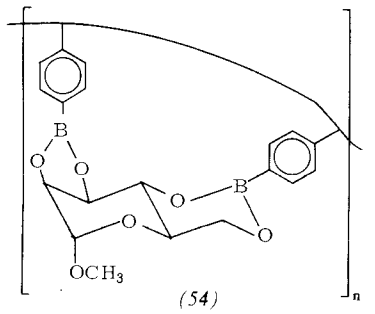
(51)

(52)



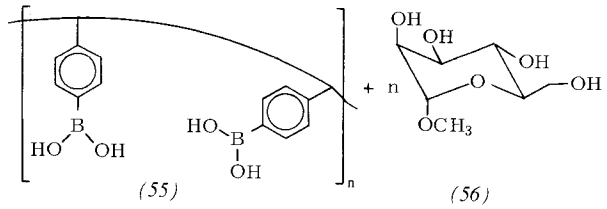
6.3. Optically Active Ion-Exchangers

Chromatographic resolutions of racemic acids and bases have also been attempted on optically active ion-exchangers. Basic ion-exchangers with ephedrine, brucine, and 1-phenylethylamine groups resolve racemic mandelic acid only very poorly[13,14,60]. Pectic acid from sunflowers as well as alginic and polygalacturonic acids have been proposed for the resolution of racemic bases[61]. Ion-exchangers based on Sephadex are also suitable for the enrichment of enantiomers[6,8].



6.4. Polymeric Boronic Acid Derivatives

An interesting possibility for racemate resolution is referred to in a paper by *Wulff et al.*[62]. "Imprinted" silica gels have already been known for some time; these are obtained by precipitation of silica gel from the solution of an optically active compound and its subsequent extraction. In this way asymmetric "prints" of the compound are left behind in the gel particles. This asymmetric imprinting enables the material to adsorb stereoselectively molecules having a similar structure, molecules of the original configuration being bound more strongly. However, so far the resolving powers of such gels have been much too low for practical use[63].



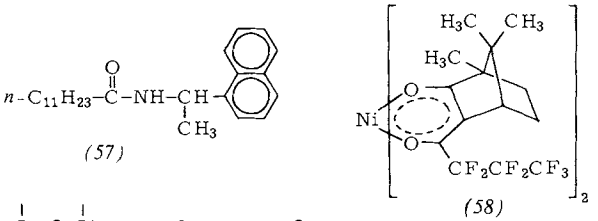
Wulff has obtained such cavitites in the polymeric boronic acid *(55)* by copolymerization of the optically active ester *(53)* with a very high proportion of cross-linked agent to *(54)* and subsequent hydrolytic cleavage of the optically active matrix *(56)*.

(53)

(54)

(55) *(56)*

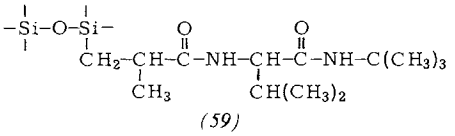
The asymmetric structure of this boronic acid is extensively stabilized by the high degree of cross-linking. From a solution of racemic methyl-α-mannopyranoside *(56)*, the acid *(55)* takes up in preference the enantiomer originally polymerized-in. In this process the enantiomers are not bound adsorptively but in a reversal of the reaction *(54)* → *(55)* + *(56)* as intermediate boronic esters *(54)*. In suitable solvents an equilibrium is set up between esterified and free *(56)*, and thus almost complete resolution of racemic methyl α-mannopyranoside is possible at very low flow rate on the column. Such experiments have also been performed, with a similar result, on 4-nitrophenyl-α-mannopyranoside.



Because of the similarity between the resolution process and partial steps of enzymatic processes, these separation materials are also known as enzyme-analogue polymers.

7. Resolution of Racemates by Gas Chromatography

Gas chromatography on optically active stationary phases is also suitable for resolving racemates. It is used on the ana-



lytical scale for the determination of configurations and optical purity. Since these gas-chromatographic resolutions, developed in particular by *Gil-Av, Lochmüller,* and *Bayer,* have already been reviewed[64], only some new results will be listed here as examples.

Chiral amides such as *N*-trifluoroacetamides, *N*-trifluoroacetylamino acid esters, and α-methyl- and α-phenylcarboxylic acid amides are resolved on (*S*)-*N*-[1-(1-naphthyl)-ethyl]dodecanamide *(57)*[65] and oxiranes on nickel(II) bis(3-heptafluorobutyryl-(1*R*)-camphorate *(58)*[66] as the stationary phase.

(57)

(58)

(59)

Polysiloxanes with covalently bonded L-valine moieties are particularly suitable for the resolution of chiral amides. An example is the L-valine-*tert*-butylamide derivative *(59)* known as Chirasil-Val[67].

Thus, a 20-m long capillary column with *(59)* as the stationary phase separates many *N*-(and also *O*- and *S*-)pentafluoropropionyl derivatives of amino acid isopropyl esters as well as drugs and their metabolites completely into enantiomers[67].

Mixtures of substances can also be analyzed, since such stationary phases at the same time separate mixtures into their components. Good resolutions on *(59)* seem to be largely restricted to amides, since the stereoselective adsorption requires hydrogen bonding between the amide groups of the enantiomers and amide groups of the stationary phase. The resolution deteriorates in the case of racemic *N*-alkylated amides.

8. Outlook

Within a short time chromatographic resolution of racemates has matured into an efficient process, often permitting enantiomers to be obtained for the first time, and there is little doubt that its future development will be equally swift[68]. One particular aim should be the development of adsorbents for racemates not resolvable by conventional means and of adsorbents having a wide range of application.

Thanks are due to Dr. W. Backmann, Dr. F. Donow, Dr. H. P. Kraft, H. Markgraf, Dr. J. Peter, Dr. A. Schwanghart, and Dr. D. Thieme for the results cited from our own working group. We are greatly indebted to Prof. Dr. J. Knabe, University of Saarland, Saarbrücken for suggesting the chromatography of chiral barbiturates and for numerous samples, and to the Deutsche Forschungsgemeinschaft, the Ministerium für Jugend, Familie und Gesundheit, and the Fonds der Chemischen Industrie for supporting the work.

Determination of Morphological Properties of Swellable Solids by Size Exclusion Chromatography[**]

By István Halász and Peter Vogtel[*]

Many technically interesting porous solids, *e.g.* ion exchangers or adsorbents for catalysis, are swellable polymers, *i.e.* the pore structure depends on the solvent medium. A method based on exclusion chromatography, permits determination of the pore size and pore size distribution in the swollen state.—Size exclusion chromatography, also referred to as gel permeation, gel filtration, or molecular sieve chromatography, is a widely employed method for the separation of dissolved substances—mostly polymer mixtures—according to their molecular size. Porous solids are used as stationary phase. Conversely, pore sizes and other structural data can be determined by exclusion chromatography. This application requires a series of standards (polymer samples) of known molecular weight. As a simple and rapid method, it has already proven valuable for such determinations in the case of rigid solids; in the case of swellable solids, this constitutes the sole method by which the pore structure can be characterized: classical methods require dry samples.

1. Introduction

Rigid solids (*e.g.* silica gels, aluminas) are distinguished by the fact that their pore structure does not depend upon the surrounding medium (gas, liquid). The pore structure of non-rigid solids (*e.g.* polystyrene-divinylbenzene copolymers, polyacrylamides, dextrans), on the other hand, is a function of the swelling medium employed.

Organic gels can be obtained by homogeneous or heterogeneous polymerization[1-3]. In the former case a pore structure is formed only when the three-dimensional cross-linked chains in the dry non-porous material become solvated, *i.e.* an expanded mesh structure is formed only in the swollen state. The mean mesh size can be controlled by the cross-linking component. The porosity of the particles, *i.e.* the ratio of pore volume to particle volume, increases with decreasing amount of cross-linking component; at the same time, however, the mechanical stability decreases. In all cases, homogeneously cross-linked copolymers are microporous on swelling (pore diameters $\phi < 20$ Å).

In the case of heterogeneous polymerization an inert substance is added to the mixture of mono- and difunctional components. During the production process a phase separation takes place leading to copolymers which also contain pores in the unswollen state (permanent porosity). These "semi-rigid" gels are macroporous (pore diameters $\phi > 20$ Å). In addition, a further increase in porosity can also occur on swelling.

The structural data of rigid porous solids—such as specific surface area O_{sp}, pore volume V_p, and pore volume distribution (pore diameter distribution)—can be determined by classical procedures (BET method, nitrogen capillary condensation, and mercury porosimetry; see *e.g.*[4]). For gels exclusively displaying swelling porosity, the classical methods are obviously unsuitable. Though they can of course be used in the case of semi-rigid materials, the results have only limited information value.

[*] Prof. Dr. I. Halász, Dr. P. Vogtel
Angewandte Physikalische Chemie der Universität
D-6600 Saarbrücken (Germany)

[**] Part of the Ph. D. Thesis by *P. Vogtel*, Universität Saarbrücken 1977.

Measurements by the classical methods require special preparation of the polymer samples, including conversion from the swollen state into the dry state, thus influencing the results obtained[5]. Moreover, in the case of exclusively macroporous semi-rigid polymers the pore structure is a function of the swelling agent employed. Finally, the micropores additionally formed on swelling cannot be determined.

The morphological properties of rigid inorganic solids can be conveniently determined by a recently described exclusion chromatography (EC) method[6–8]. The new EC method is simple and fast, leading to results in satisfactory agreement with those of the classical methods, despite the different and disputable boundary conditions.

This review will show that the exclusion method is also suitable for the characterization of swellable solids. The new method is the only one available so far for the investigation of swollen gels, *i.e.* the state in which the material is used in practice. Here the classical methods fail, for they require dry samples.

2. Exclusion Chromatography—Description of the Method[*]

The principles and boundary conditions of the EC method for determination of the structural data of porous solids have already been described in detail elsewhere[7]. The basic model concepts of the method will therefore be presented only briefly here.

When a solvent is passed through a column packed with a porous carrier, axial transport of the eluent takes place exclusively in the interstitial volume V_i. The eluent in the pore volume V_p of the carrier is exchanged only by diffusion between V_p and V_i. For all sample substances, it must be established that they are not adsorbed by the carrier. (This has been shown, for example, for silica gel as solid phase, dichloromethane as eluent, and polystyrene or benzene as sample[7].) Under these conditions the same applies for the samples on the column as for the molecules of the eluent: they flow through the interstitial volume of the column and can diffuse into and out of the pores.

The next condition to be fulfilled is that all sample molecules fully utilize the volume available to them for diffusion, *i.e.* that a concentration equilibrium is established between the "phase" in the pore volume and the phase in the interstitial volume. For samples with small molecules (*e.g.* benzene) the whole pore volume in the column is then—as for the eluent—accessible, *i.e.* this sample is eluted with the greatest possible elution volume.

$$V_{e,max} = V_i + V_p \quad (1)$$

As the molecular size of the sample material increases the smaller pores are not accessible, *i.e.* the elution volume decreases. Finally, for the largest sample molecules the whole pore volume is inaccessible, and for the elution volume we have:

$$V_{e,min} = V_i \quad (2)$$

The measuring procedure for the determination of the total pore volume in the column follows from equations (1) and (2):

$$V_p = V_{e,max} - V_{e,min} \quad (3)$$

If the column is emptied on completion of all the measurements and the mass of the carrier is determined, then the specific pore volume $V_{p,s}$ (referred to one gram of solid) can also be calculated.

The elution volumes (V_e) of the remaining samples lie, according to the above mentioned, between $V_{e,max}$ and $V_{e,min}$. If the sample molecule is assigned an exclusion value (ϕ) then a plot of V_e against ϕ corresponds to the residual sum of the pore volume frequency. The exclusion value ϕ_i [Å] thus describes the diameter of the smallest pores which are accessible for a molecule having a molecular weight M_i. Obviously, all pores with diameters greater than ϕ_i are then likewise accessible. The exclusion values of the samples employed are listed in Table 1. In the case of polystyrene (PS) samples the relationship

$$\phi\ [\text{Å}] = 0.62\ M^{0.59} \quad (4)$$

Table 1. Pore diameter ϕ assigned to standard (sample molecule). (PS = polystyrene; the number indicates the molecular weight.)

Sample	ϕ [Å]	Sample	ϕ [Å]
Benzene	7.4	PS 10000	140
Ethylbenzene	8.5	PS 20800	215
Butylbenzene	10.9	PS 36000	297
Hexylbenzene	13.4	PS 111000	576
Octylbenzene	15.9	PS 200000	815
Dodecylbenzene	20.8	PS 498000	1400
Pentadecylbenzene	24.4	PS 867000	1930
PS 600	26.7	PS 2610000	3700
PS 2100	55.9	PS 3700000	4530
PS 4000	81.6		

was assumed[7]; in the case of the alkylbenzoyl samples the ϕ values correspond to the length of the extended chains[8]. From the residual sum of the pore volume frequency a mean pore diameter of ϕ_{50} can be assumed for 50% accessible pore volume.

Assuming homogeneous, cylindrical and continuous pores, the specific surface area O_{sp} of the solid can be calculated from the specific pore volume $V_{p,s}$ [cm³/g] and the mean pore diameter ϕ_{50} [Å]:

$$O_{sp}\ [\text{m}^2/\text{g}] = 0.04 \times \frac{V_{p,s}\ [\text{cm}^3/\text{g}]}{\phi_{50}\ [\text{Å}]} \quad (5)$$

[*] List of symbols:

M ($\bar{M}_w$)	molecular weight (weight-averaged molecular weight of polymer)
O_{sp}	specific surface area
ϕ	pore diameter (assuming the pores to be cylindrical); also the exclusion value of a polymer standard
ϕ_{50}	mean pore diameter (for 50% accessible pore volume)
V_e	chromatographic elution volume of a test sample
$V_{e,max}$	maximum elution volume in calibration series (elution volume of the standard with the lowest molecular weight)
$V_{e,min}$	minimum elution volume in a calibration series (elution volume of the standard with the highest molecular weight)
V_p	pore volume; volume of eluent that has penetrated the pores
$V_{p,s}$	specific pore volume: pore volume per gram of the solid
V_i	interstitial volume

3. Experimental

The measurements were carried out on a simple apparatus for liquid chromatography[7]. The units comprised a pump (Type M 6000, Waters Associates, Milford, Mass. USA); a sample loop injector (Rheodyne Type 7120; Kontron Technik GmbH, Eching bei München, Germany), a UV detector (254 nm) of our own construction, and a differential diffractometer (Type R 401, Waters).

With this apparatus the pore structure of the following polystyrene-divinylbenzene copolymers was investigated:

1. Bio beads SX 12 (BioRad, Richmond, Calif., USA),
2. Styragel 60, 100, 500, and 1000 (Waters),
3. PSDVB B1 to B4 (Farbenforschung Lewatit, Bayer AG, Leverkusen, Germany).

The first five copolymers are commercially available and are well-known stationary phases for exclusion chromatography. The first material is homogeneously cross-linked, the Styragels are heterogeneously cross-linked. The samples B1 and B4 were kindly supplied by the manufacturer. The average particle diameter of these materials is between 10 and 60 μm. As sample substances we used polystyrenes of various degrees of polymerization and narrow range of molecular weight distribution as well as various alkylbenzenes (Merck-Schuchart, Hohenbrunn bei München, Germany). The eluent employed was dichloromethane. The samples were dissolved in the eluent (*ca.* 10 mg/g); *ca.* 1 μg of sample per gram of solid in the column was used.

To avoid any misunderstanding it must be pointed out once again that the standard substances employed as samples were linear polystyrenes dissolved in dichloromethane; the swellable solids, however, were copolymers of styrene and divinylbenzene.

Stainless steel tubes with a nominal internal diameter of 4 mm were used for the columns. The column length (between 30 and 100 cm) was so chosen that at least 300 theoretical plates[9] were obtained for benzene as sample. The columns were packed by a modified balanced-density method[7]. For a 100-cm column, *ca.* 4 g of copolymer was pre-swollen in 30 ml dichloromethane for *ca.* 12 h (CH_2Cl_2 has a greater density than the copolymer!). Before packing the column a further 14 ml of CH_2Cl_2 and 40 ml of tetrahydrofuran were added. The suspension was stirred, transferred to the packing vessel covered with a layer of 40 ml THF to prevent mixing and then with CH_2Cl_2. Dichloromethane was used as pressure liquid. Packing was carried out a flow rate of *ca.* 3 ml/min. The columns for the measurements were also operated with CH_2Cl_2, but also proved to be stable on changing the solvent. All measurements were carried out at room temperature and a flow rate of 1 ml/min. (A detailed account of the evaluation of SEC measurements for the determination of structural data is given in [7,8].)

4. Results and Discussion

Figure 1 shows semilogarithmic plots of the elution volume of a sample as a function of the molecular weight M for five polystyrene-divinylbenzene copolymers. These plots can be regarded as graphical representations of the measuring procedure. The further the curves are shifted to higher molecular weights the greater is the mean pore diameter ϕ_{50} of the solid. The difference in elution volume between the samples with the smallest and those with the largest molecular weight corresponds to the pore volume V_p in the column [see eq. (3)].

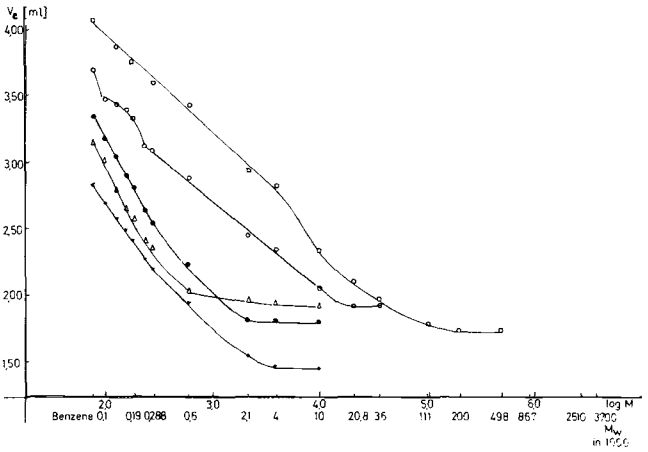

Fig. 1. Elution volumes V_e of the standard substance on five commercial polystyrene-divinylbenzene copolymers. Eluent: dichloromethane; flow rate: 1 ml/min. Standard substances: see Table 1. Solids (copolymers): + BioBeads SX 12; △, ●, ○, □ Styragel 60, 100, 500, 1000.

The integral pore distribution curves are reproduced in Figure 2. The measurements from Figure 1 were so recalculated that the portion of the accessible pore volume V_p is plotted on the ordinate and the exclusion value ϕ (pore diameter) of the sample on the abscissa. From this plot the mean pore diameter ϕ_{50} can be taken for 50% accessibility of the pore volume; the steeper a curve is, the narrower is the corresponding pore distribution. Figure 2 shows that the

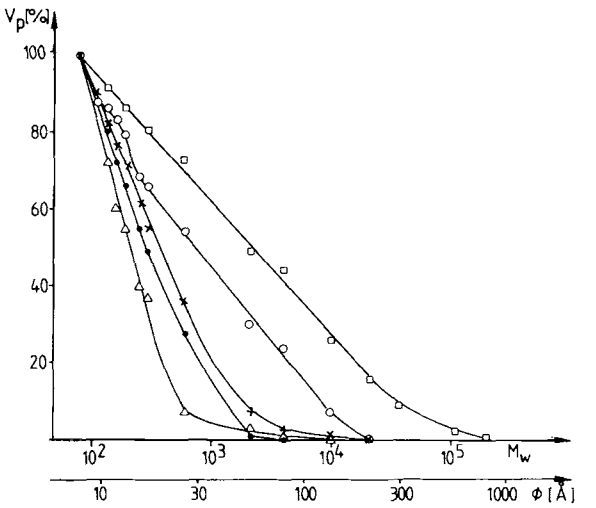

Fig. 2. Sum of residues distribution of the pore diameters (integral distribution curve) for the five copolymers in Fig. 1 (for explanation see text).

samples measured cover the whole range of pore sizes of interest between 10 and 1000 Å. It should be pointed out that—as a result of standardization—no information can be gained from Figure 2 about the absolute size of the pore volume. From the specific pore volume $V_{p,s}$ and the mean pore diameter ϕ_{50}, the surface area of the swollen copolymer in the column can be estimated according to equation (5). Decisive for the use of swellable copolymers is the magnitude of the surface area or pore volume referred to the volume of the

swollen gel. The data in Table 2 are referred to the volume and not the mass of the solid; a knowledge of the packing density makes possible the calculation of these quantities.

Table 2. Pore volumes V_p, mean pore diameters ϕ_{50} and surface areas O referred to the volume of the swollen gel of some swellable copolymers.

Material	V_p [cm³/cm³]	ϕ_{50} [Å]	O [m²/cm³]	Packing density [g/cm³]
SX 12	0.27	17.5	620	0.38
Sty 60	0.35	22.0	636	0.33
Sty 100	0.28	24.0	466	0.31
Sty 500	0.33	29.0	455	0.25
Sty 1000	0.53	53.0	400	—

In Figure 3 the elution volume is plotted as a function of the molecular weight of the sample for four heterogeneously cross-linked PSDVB copolymers manufactured by Bayer AG (Farbenforschung Lewatit). The integral pore distributions derived from these according to the EC method (unbroken line) and according to classical mercury porosimetry (broken line) are shown in Figure 4. The most important data can be taken from Table 3.

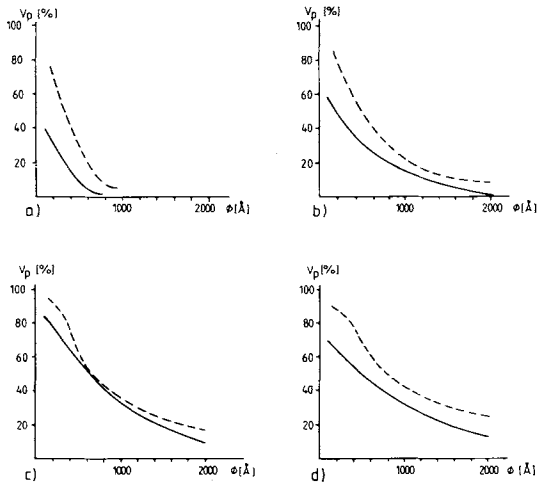

Fig. 4. Sum of residues distribution of the pore diameter (integral distribution curve) according to the EC method (—) and according to the mercury porosimetry method (---) (measurements by the manufacturer). a)—d) PSDVB copolymers B1—B4.

is found to be smaller and the pore volume per grain of solid larger than in the mercury porosimetry measurements. Further, in Table 3 it is shown for sample B1 how strongly the

Table 3. Pore volumes and mean pore diameters ϕ_{50}. The pore volume was calculated from apparent and true density.

Material	Manufacturers data			EC measurements		
	Total pore volume [cm³/g]	Hg-pore volume [cm³/g]	ϕ_{50} [Å]	V_p [cm³/cm³]	$V_{p,s}$ [cm³/g]	ϕ_{50} [Å]
B1 [a]	0.626	0.478	250	0.40	2.50	60
[b]	0.077	0.078	(880)			
B2 [c]	0.881	0.753	260	0.40	2.66	150
B3 [c]	1.211	1.153	270	0.35	2.15	630
B4 [c]	1.639	1.496	210	0.31	2.40	510

[a] Prepared with methanol. [b] Swollen in THF, then THF removed. [c] Dried.

The different results afforded by the two methods are not surprising, since the classical measurements were carried out on dry material and the EC measurements on swollen material. In the EC method the swollen porosity (micropores) is also measured. Thus it would appear reasonable that in the chromatographic measurements the mean pore diameter ϕ_{50} data determined by classical methods can depend on the preparation of the sample prior to carrying out the measurements.

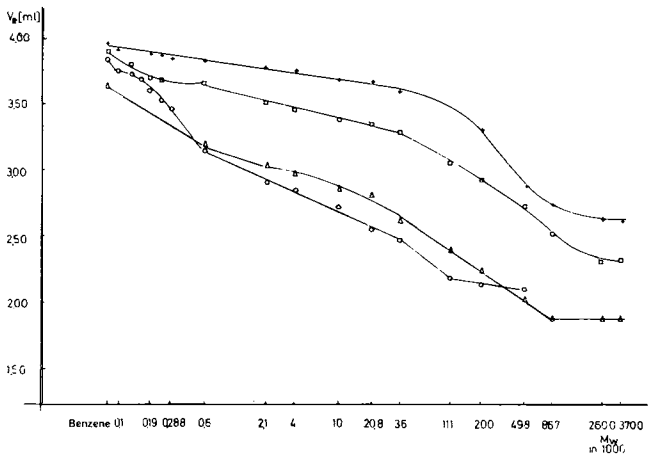

Fig. 3. Elution volumes V_e of the standard substance on four polystyrene-divinylbenzene copolymers from Bayer, Leverkusen. ○, △, □ + PSDVB-copolymers B1—B4. For conditions see Fig. 1.

5. Summary

An exclusion chromatographic method can be used for determination of the structural data of swellable solids. Pore volume, pore distribution, and surface area of swollen materials are measured by this method and reproduce the conditions prevalent in the solids as they are used. This is illustrated by polystyrene-divinylbenzene copolymers of different porosity and having different mean pore diameters. It is suggested that the pore volume and surface area be referred to in terms of the volume of the swollen material, as is usual in catalysis.

When suitable combinations of sample material and eluent are found, it should also be possible to investigate solids which are swollen in different solvents.

We thank the Deutsche Forschungsgemeinschaft for financial support of this work. We are especially indebted to Dr. P. M. Lange and Dr. A. Meyer, Farbenforschung Lewatit, Bayer AG, Leverkusen for supplying some copolymers and the data for these compounds.

A Model of Hydrogen-Bonded Liquids

By Werner A. P. Luck[*]

Dedicated to Professor Gustav Kortüm on the occasion of his 75th birthday

The orientation defect model can be used for quantitative estimates and for understanding the properties of H-bonded liquids, such as water and alcohol. The defect concentrations can be determined by vibrational spectroscopy, and the applicability of the approximation procedure derives from considering H-bonds as chemical equilibria. Possible extensions of the simple model are critically discussed.

1. Introduction

1.1. Statement of Problem

A model has recently been described for nonpolar liquids with spherically symmetrical van der Waals forces[1]. Whether attraction or repulsion prevails is determined by the intermolecular distance. This model[1] would remain incomplete if it were not possible to formulate extensions accounting for dipolar forces with attractive *or* repulsive effects depending upon the orientation of the molecule.

Orientation-dependent interactions of this kind are especially pronounced between protons of acidic groups (*e.g.* OH, NH) and lone pairs in H-bonds. The properties of H-bonded liquids are determined by two partition functions, *viz.* of the distances and of the angles; they cannot yet be described exactly. In view of the importance of just such liquids in biochemistry, colloid chemistry, and large areas of chemical technology, it appears pointless to wait for an exact solution of this problem. For the chemist, too, a bird in the hand in generally worth two in the bush. Having a particularly high concentration of strong H-bonds, water is particularly suitable for a simplifying approximation. On the basis of the model for water on the one hand and nonpolar liquids[1] on the other, a wide scale of liquids can be envisaged taking account of the relative contribution of H-bonds (hydrophilic/hydrophobic balance = HHB). Yet more parameters would have to be considered for metallic and ionic melts.

1.2. Hydrogen Bonds

The intermolecular pair potential of nonpolar molecules can be characterized approximately by their critical temperature T_c[1]. The T_c of nonpolar substances is approximately proportional to the square root of the molecular weight or the sum of the number of electrons Z_e (Fig. 1). H-bonds increase T_c. On the other hand, the relation $T_c(C_nH_{2n+1}OH) \approx T_c(C_{n+4}H_{2(n+5)})$ is found to apply for $n \geq 2$. The effect of an alcoholic OH group thus corresponds

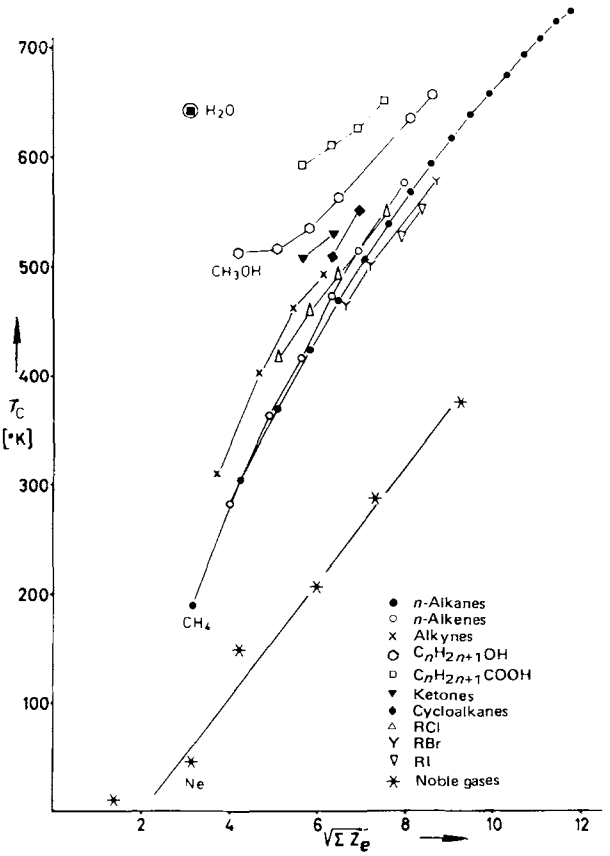

Fig. 1. Critical temperature as a function of the root of the sum of the numbers of electrons Z_e of all the atoms of a molecule. T_c is raised by the presence of H-bonds in carboxylic acids, alcohols, and H_2O.

approximately to the dispersive interaction of $-(CH_2)_3CH_3$ in *n*-paraffins.

Table 1 shows the contributions of H-bonds and dispersive interactions for water; data for CH_4 are also listed for comparison.

Table 1. Intermolecular interactions in H_2O (values in kcal/mol).

		H_2O	CH_4
(a) Sublimation energy	ΔU_s	11.6	2.2
(b) Difference in internal energies	$U(\text{liq.}, T_c) - U(\text{solid}, T_m)$	10.2	2
(c) Dimer dispersion energy (calc. according to [2])	$W((H_2O)_2)$	1.8	
(d) Ice H-bond energy (from (a) and (c))	$2\Delta H_H \approx \Delta U_s - 2W((H_2O)_2)$	8	
(e) H-bond energy per H-bond	ΔH_H	4	

The energy of 4 kcal/mol estimated for a linear H-bond in ice [Table 1, (e)] from the calculated dispersion energy 2 W agrees with the H-bond energy of 3.7 and 4 kcal/mol determined by spectroscopy in liquid H_2O and CH_3OH, respectively[3,4].

H-bonds differ from normal nonpolar van der Waals interactions by a deeper potential energy minimum and by their angular dependence. The potential-distance function for the optimum H-bond angle of $\beta = 0$ (cf. geometry in Fig. 2a) resembles the Morse curve for a covalent bond[5-7], while it corresponds to the encounter between two H atoms of equal spin in the case of pure repulsion (orientations in Fig. 2e and 2f)[8-10].

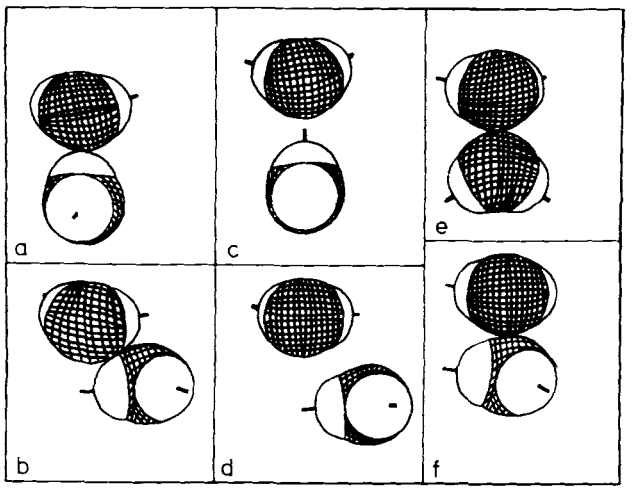

Fig. 2. Orientations of H_2O dimers: a) maximum H-bond interaction for angle $\beta = 0$; b) cyclic dimer, two H-bonds with unfavorable angles β; c) position a with greater intermolecular distance and hence very slight H-bond interaction; d) position b with greater separation and very slight H-bond interaction; e) repulsive orientation of the lone pairs; f) repulsive orientation of the lone pairs.

For $\beta = 0$ (Fig. 2a) a saturation phenomenon is observed. Thus, H-bonds can be regarded as secondary valence effects whose action depends upon the molar concentration of OH groups and of lone pairs.

The c(OH) values listed in Table 2 explain the anomalous values of $T_c(CH_3OH) = 512.5$ K and $T_c(H_2O) = 674.35$ K. Extrapolation of the boiling and melting points of hydrides of type XH_2 to the number of electrons or the molecular weight of H_2O would suggest that water should melt at -90 °C and boil at about -80 °C[11]. The H-bonds cause a drastic rise in the two transition temperatures and thus permit life on our planet.

Table 2. Concentration [mol/l] of OH groups and lone pairs (θ) in water and alcohols at 20 °C.

	H_2O	CH_3OH	C_2H_5OH	n-C_3H_7OH	n-C_4H_9OH
c (OH)	111	24.7	17.1	13.4	10.9
c (θ)	111	49.4	34.2	26.8	21.8

The secondary valence character of H bonds leads in the case of water to a "loose tetrahedral structure of coordination number 4 owing to the charge distribution" as underscored by *Kortüm*[12,13] as a pioneer in the field. This structure is completely different from that of nonpolar liquids, which approach closest packing and coordination numbers of $Z = 12$ between nearest neighbors. Preference for certain spatial directions by H-bonds[14,15] is of fundamental importance for the specificity of higher-order biochemical structures[16].

1.3. Determination of H-Bonds

Apart from higher intermolecular energies detectable by calorimetry, H-bonds lead to anomalously large changes in the frequencies of OH and NH stretching modes and their IR extinction coefficients. This applies particularly to overtones[17-19]. Dilute solutions of H-bonding compounds such as CH_3OH in inert solvents such as CCl_4 exhibit sharp bands (cf. Fig. 3, band at 7122 cm^{-1}) which are due to the so-called "free" OH groups, *i.e.* those not involved in H-bonds[17]. In concentrated solutions, such a band is replaced by a broad band system (cf. Fig. 3, between 7100 and 5600 cm^{-1}, together with some CH bands around 5900 cm^{-1}). This broad overtone induced by OH groups participating in H-bonds differs only slightly in area $\int \varepsilon d\nu$ from the sharp overtone band for the "free" OH groups[20] but significantly in its half-width $\Delta\nu_{1/2}$, and therefore[21,22] in the height of the maximum ε_{max}.

The content O_F of H-bond defect sites can be quantitatively determined from the relative height ε_{max} of the overtone band of the "free" OH groups[*].

$$c_F/c = \varepsilon_c/\varepsilon_0 = O_F; \quad c_B/c = (1 - O_F)$$

or from $\int \varepsilon_c d\nu / \int \varepsilon_0 d\nu$

ε_0 = extinction coefficient for band maximum at concentration c;
ε_0 = extinction coefficient for band maximum at infinite dilution

Methods of calculating chemical equilibria have been successfully applied to c_F and c_B in numerous studies. Equilibrium constants of the association equilibria determined in this way number among the most accurate known in physical chemistry. Thus, for example, H-bonds of lactams with *cis* amide groups have been interpreted quantitatively in the entire solubility range in CCl_4 of 3×10^{-3} to 5 mol/l with the same, and hence true, dimerization equilibrium constant without activity coefficients[14].

The widely differing concentration dependence of O_F for different substances can be interpreted in terms of the angular dependence of H-bonds[14,15]. In solution, the H-bond

[*] Direct quantitative determination of c_B from the H-bond band gives greater errors because of overlap with other bands (OH, CH, or combinations thereof [4]).

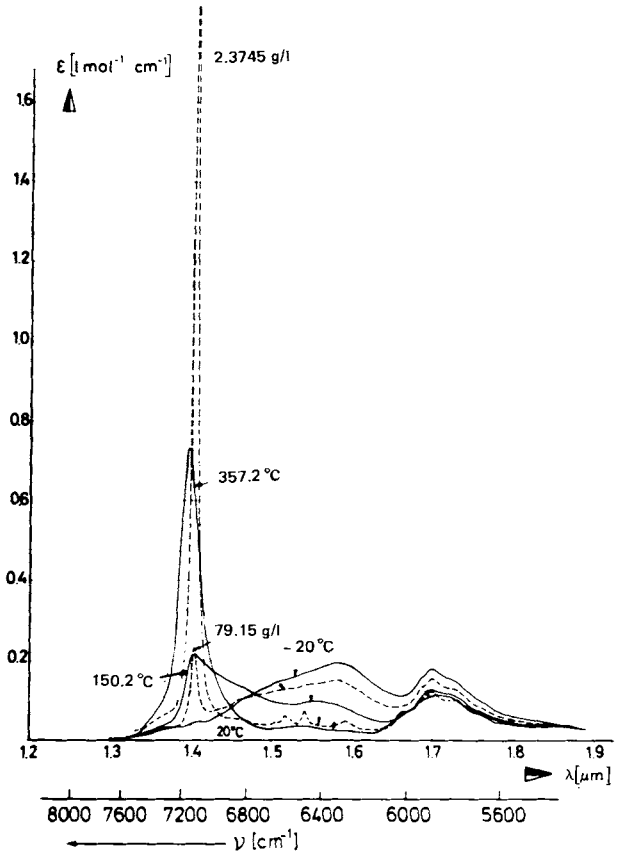

Fig. 3. IR overtone spectra of methanol. Dashed lines: solutions in CCl_4 at 20 °C. Solid lines: liquid at saturation conditions.

angles and lengths essentially have values corresponding to the potential minimum, justifying a treatment as chemical equilibrium between open and closed H-bonds and neglect of intermediate states.—Cyclic aggregates are particularly stable. As a rule, the H-bond angle β is zero in six-membered aggregates (not including protons)—this applies to cyclic dimers of lactams and carboxylic acids, cyclic trimers of oximes and the six-membered H_2O ring in ice[14,15]. If more than two molecules are required in aggregates with $\beta = 0$, then coupled equilibria of various aggregation states will occur[14,15].

H-bonds lead to drastic changes in the intensities of IR fundamental bands[18], in contrast to those of the overtones[3,23-26]. Hence O_F can be determined much less satisfactorily from fundamental modes of liquids exhibiting band broadening; in some cases this can only be done on the basis of considerable experience. This has often been neglected in discussions of the overtone method.

Summary: The content of H-bonds and of their defect sites O_F can be quantitatively determined in solution by IR overtone spectroscopy and treated as chemical equilibria. The resulting equilibrium constants number among the most accurate known.

2. The Model and Its Testing

2.1. Simple H-Bond Defect Model for Liquids

IR overtone spectra of pure liquid alcohols closely resemble those of solutions (cf. Fig. 3). In particular, they also show the band characteristic of "free" OH groups at elevated temperatures[23-26]. Owing to modified environmental conditions (2nd approximation perturbations) this band has a somewhat greater half-width than in solution. According to the rules of spectroscopy[21,22], however, the relation $\varepsilon_{max} \times \Delta\nu_{1/2} = \text{const.}$ still holds. Moreover, $\int \varepsilon d\nu$ is relatively independent of environment for the overtones[20]. The content of "free" OH or NH groups can be determined for pure liquids and for solutions from $\int \varepsilon d\nu$ or, knowing $\varepsilon_{max,0}$, from ε_{max}[3,23-26]. ($\varepsilon_{max,0}$ = extinction coefficient of band for "free" XH groups; it can be determined at elevated temperature[25].)

The overtone spectra of water are very similar to those of alcohols. At elevated temperatures, an identical relatively sharp band appears which is assigned to the "free" OH groups. In the case of H_2O and D_2O, splitting of the stretching band into ν_1 and ν_3 as a result of OH and OD coupling[91,92] also has to be considered. This task is facilitated by the fact that only ν_1 is Raman active and the IR intensity of ν_1 is much lower than that of ν_3, particularly in the overtone range. The difficulties created by two proximate stretching vibrations ν_1 and ν_2 disappear in the case of the monodeuterated HOD spectrum (Fig. 4). Measurements up to 400 °C showed $\nu_{max,0}$ of the "free" OH group in HOD to lie at 7168 cm^{-1}[19,25]. The temperature dependence of O_F agrees for four different H_2O bands, two bands of D_2O, and the first HOD overtone band[3,23,25]. Interference by band overlapping is largely avoided by our method of determining O_F in the frequency range of the narrow band of "free" OH groups. *Schiöberg* was able to show by hitherto unpublished measurements that ΔH_H has a value of -4.1 ± 0.1 kcal/mol both for concentrated alcohol solutions and for the pure alcohol, confirming the validity of the highly successful solution method for pure liquids. The H-bond energy -3.7 kcal/mol of liquid HOD could be established by two different spectroscopic methods: 1) by the overtone band of "free" OH groups[3] or 2) by the band of simultaneous excitation of OH and OD vibrations in two neighboring H-bonded molecules[4].

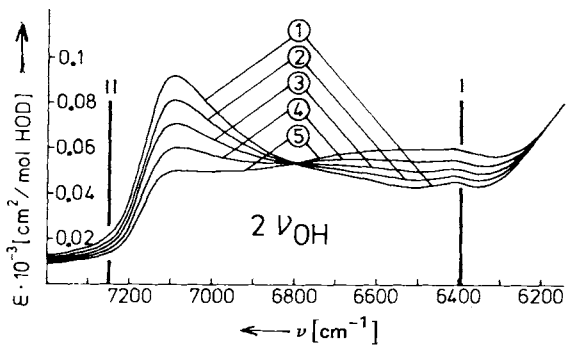

Fig. 4. IR overtone spectra of liquid HOD at various temperatures (HOD in D_2O. D_2O compensated): ① 90 °C; ② 70 °C; ③ 50 °C; ④ 30 °C; ⑤ 10 °C. I: maximum of ice band; II: maximum of vapor band.

Figure 5 shows the O_F values, *i.e.* the fraction of open H-bonds or the so-called orientation defects, for H_2O, CH_3OH, and C_2H_5OH[23,26]. The data pertaining to the alcohols are also obtained by extrapolation of the solution spectra[20]. The analogy with the alcohol spectra also supports the values for water. Close to T_c, strong density gradients[23,24] widen the limits of error. The values given for water in Figure 5 were therefore checked by computer analysis of the spectra[25]. In

order to eliminate the fundamental ambiguity[27] of this analysis, spectra of ice and spectra recorded at supercritical temperatures were chosen as basis. In this way residual H-bonds are found at T_c.

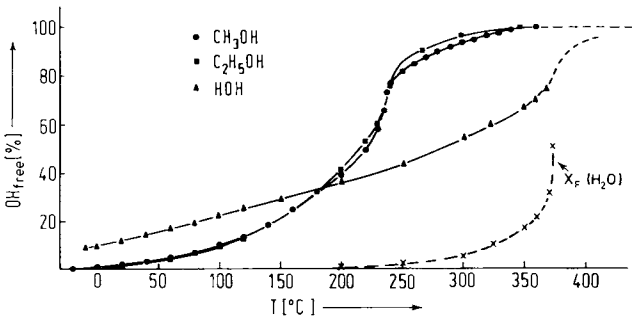

Fig. 5. Fraction of non-H-bonded OH groups in the saturated liquid phase of H_2O, CH_3OH, and C_2H_5OH. Hole defect fraction x_f for H_2O.

According to Figure 5, the fraction of open H-bonds at the melting point T_m is relatively small, and in any case much smaller than assumed in older theories of liquids. Differences between H_2O and the alcohols have the following causes: 1) The concentration of lone pairs θ in alcohols is equal to twice the concentration of OH groups; even for $c(OH_{free})=0$, we find $c(\theta_{free})=c$ [c = concentration of alcohol], whereas for H_2O $c(OH_{free})$ is always equal to $c(\theta_{free})$; 2) the concentration of OH varies; 3) alcohols form branched chain associates whereas H_2O forms an H-bond network with enhanced cooperativity (cf. Section 10.1 in ref. [1]).

On the basis of the existence of "free" OH groups quantitatively demonstrable with high accuracy by the infrared overtones, we have tentatively developed an orientation defect model for H-bonded liquids with the O_F values given in Figure 5. The description of liquids by this simple model is based on the successful description of H-bonds in solution as chemical equilibria. There are two kinds of OH groups in our model: those participating in H-bonds and the "free" OH groups regarded as defects. The following arguments should illustrate the starting point:

1) A description of the bonds with $\Delta H_H > RT$ as a chemical equilibrium between open and closed H-bonds has proved its value in numerous studies.

2) The isosbestic point occurring in all overtone spectra of water (at 6800 cm^{-1}, cf. Fig. 4) is a sensitive indicator that H_2O association can be treated as a simple equilibrium between two OH groups A and B with different stretching vibrations. The frequency range and comparison with spectra of alcohols and their solutions support the formulation of this equilibrium as

$$OH_{free} + \theta_{free} \rightleftharpoons OH_{H\text{-}bond} \quad (1)$$

The isosbestic point becomes unsharp only above 150 °C[19,20,23-25]—this may indicate that smaller aggregates appear at higher temperature and possible inductive effects (cooperative effects involving H-bonds) become less important.

3) The results of our overtone analyses in the range of −70 to 420 °C were confirmed between 0 and 90 °C by difference spectroscopy by *Worley* and *Klotz*[93] and, more recently, by *Paquette* and *Joliceur*[94]. In addition, the somewhat difficult analysis of the fundamental vibrations (IR and Raman spectra) led to agreement[95,96] with our overtone results.

4) It can be assumed from the variation of density with temperature up to 200 °C and from X-ray diffraction experiments[28] that, up to 200 °C, the orientational partition function plays a more important role than the partitioning of the distances. The angular distribution has a relatively sharp minimum for $\beta=0$[14,15]. Recent computer simulations have shown (cf. Section 3.2) that most molecules oscillate about $\beta=0$ in liquid water at low temperature. Replacement of the angular partition functions by the approximation of a two-step function thus appears permissible, especially when it is assumed that the H bonded state observed with the broad H-bond band may be described by angle oscillations around the mean value $\beta=0$.

5) Matrix spectra of H_2O and alcohols in solid Ar or N_2 exhibit only few discrete H-bond bands and no "continuum"; this shows that certain H-bond structures are strongly preferred[29,32].

6) Dielectric relaxation time measurements demonstrate the preponderance of a single relaxation mechanism in liquid water (and suggestions of a second, less pronounced one)[33], indicating the predominant role of two OH states. – Intermediate states between the extremes of closed and open H-bonds admittedly have greater weight in neat liquids than in solutions (greater band half-widths), but they can apparently be neglected to a first approximation because $\Delta H_H > RT$. The practical chemical significance of the liquids considered in this progress report preclude our waiting for a precise knowledge of the partition functions.

The fraction of hole defects x_F in water, methanol, and ethanol formally calculated for $T<0.9\,T_c$ from densities[34,35] according to $x_F=\rho_D/(\rho_L+\rho_V)$ is small in comparison with that of H-bond defects O_F (cf. lower right-hand curve for H_2O in Fig. 5). On a reduced temperature scale T/T_c, the hole defect concentration of water is only slightly lower than that of nonpolar substances (cf. Fig. 2 in ref. [1]). $O_F \gg x_F$ illustrates just how dependent the properties of H-bonded substances should be upon orientation defects.

The fictive occurrence of hole defects in water can be interpreted with the aid of monomeric H_2O molecules in which the random accumulation of thermal energy has led to the breaking of all H-bonds. Such "monomers" should have high vapor pressures, and therefore "evaporate", because their dispersion energy is so small relative to kT. Monomeric fractions greater than 1% should by recognizable from a suggested rotational structure of IR bands. In accord with the estimate of Figure 5, this was not observed for liquid water, in contrast to water vapor. Older theories[36,37] predict values of 65%[36] and 47%[37] (cf. ref. [38]) for O_F at 0 °C. Both spectroscopic studies and a comparative study of the heat of fusion ΔH_m were able to discredit these predictions. Models of water with significant monomer concentrations at room temperature cannot be justified.

2.2. Model for the Properties of H-Bonded Liquids

A simplified model[38-41] can be derived for water (Fig. 6; valid up to about 180 °C) from the results of IR overtone spectroscopy and careful studies of fundamental vibrations:

H-bonds lead to a "liquified ice" structure with coordination numbers of about 4 (cf. the average coordination number of 4.4 from X-ray data[42]). H-bond defects O_F are not distributed entirely randomly (Fig. 6, center) and tend towards closest packing similar to that of nonpolar liquids[1].

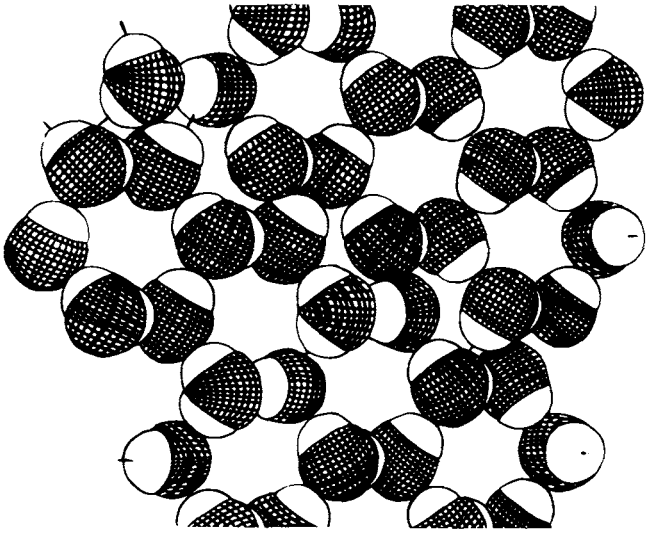

Fig. 6. Idealized two-dimensional model of water. H-bonds of the kind found in ice are assumed to be accompanied by "H-bond defects" with closer packing.

It is the task of models—in a situation that has not been completely elucidated—to describe known and predict unknown properties of substances. As demonstrated by the model underlying the "ideal gas law", stipulating such unreasonable things as force-free, point molecules, models can be sufficiently informative for practical purposes even if they are merely simplifying approximations.

Our simple liquid model which neglects partition functions of angles and distances because the two could not yet be separated will have to prove its worth by quantitative prediction of the properties of materials. After the successes of the hole defect model of nonpolar liquids[1], we shall now test an orientation defect model for H-bonded liquids in which the fraction O_F of H bonds is opened as a result of the random distribution of thermal energy.

2.2.1. Heat of Fusion

When ice melts, the value of O_F changes, increasing by *ca.* 10%. The high heat of fusion of $\Delta H_m = 1.43$ kcal/mol is essentially attributable to the relatively high contribution of H-bond energy: 0.1×7.4 kcal/mol $= 0.74$ kcal/mol (7.4 kcal/mol: H-bond energy per mole of H_2O). If we adopt $\Delta H_m(H_2S) = 0.57$ kcal/mol as a measure for the normal melting process of non-polar substances, and bear in mind that the number of intermolecular degrees of freedom increases on breaking of H-bonds (cf. [1]), then the value of $\Delta H_m(H_2O)$ accords with the prodiction of Figure 5, but contradicts previous theories[36,37]. ΔH_m of the alcohols is lower than the heat of fusion of ice and only slightly higher than for homologous *n*-alkanes (Table 3) in spite of higher molecular weight—*i. e.* greater dispersion forces.

In accord with Figure 1, it can be assumed that the interaction of an OH group which is not due to hydrogen bonding will be greater than that of a CH_2 group. Thus it follows from the spectroscopic findings (Fig. 5) that the contribution of H-bonds to ΔH_m of the alcohols is low.

Table 3. Heat of fusion of alcohols and paraffins.

	C_2H_6	CH_3OH	*n*-C_3H_8	C_2H_5OH	*n*-C_4H_{10}	C_3H_7OH
ΔH_m [kcal/mol]	0.67	0.77	0.84	1.11	1.11	1.24

2.2.2. Heat Content under Saturation Conditions

As in the model of nonpolar or only weakly polar substances[1], we initially consider saturation conditions for the sake of simplicity. Figure 7 shows the enthalpy and internal energy for water as a liquid (H_L, U_L) and as a vapor (H_V, U_V); the zero point is the energy content of the liquid at the melting temperature T_m in equilibrium with ice.

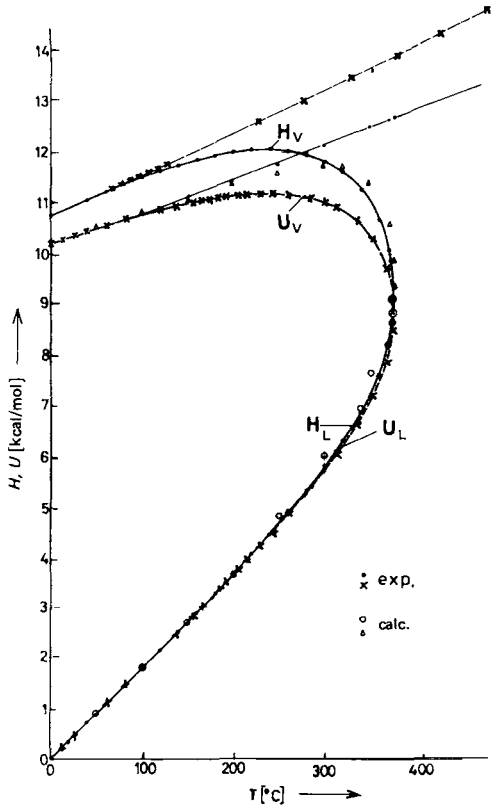

Fig. 7. Heat content of water in liquid/vapor equilibrium (H_L, U_L for liquid; H_V, U_V for vapor), comparison of experimental and calculated values [eqs (2), (4), (6)] (straight lines correspond to ideal gas state).

a) The Liquid State

The energy content of liquid water is made up, according to our simple model, of the following components:

1) Heat content of intramolecular degrees of freedom, obtainable from the specific heat (molar heat capacity) C_V^0 of the ideal gas;
2) the energy required for breaking H bonds $[O_F(T) - O_F(T_m)] \cdot 2\Delta H_H$;
3) heat content of the intermolecular degrees of freedom[1] $(2 + O_F) \times R(T - T_m)$;
4) correction of C_V^0 for loss of translation energy in the liquid phase: $-3R(T - T_m)/2$.

To facilitate comparison with Figure 7, all four terms have been corrected to the chosen zero point at T_m. They are combined in eq. (2).

$$U_L = \int_{T_m}^{T} C_V^0 dT + 2\Delta H_H \cdot [O_F(T) - O_F(T_m)] + \\ + (2 + O_F) \cdot R(T - T_m) - R(T - T_m)3/2 \quad (2)$$

The third summand represents the correction of the intermolecular degrees of freedom. Its contribution to the molar heat was approximated as $C_W = ZR/2$[1,43] (one degree of freedom is attributed to each nearest neighbor with coordination number Z). For our model of water we choose:

$$Z = (1 - O_F)4/2 + O_F 6/2 = 2 + O_F \quad (3)$$

where $Z = 4$ for the ordered regions and $Z'' = 6$ (3 to neighbors with H bonds + 3 for the "free" OH group) for regions with "free" OH groups. We adopt the spectroscopic value of -3.7 kcal/mol for ΔH_H[3,4,25].

The simply derived equation (2), containing only experimentally determinable quantities such as O_F and ΔH_H and no fitted constant, represents the experimental data surprisingly well. Slight deviations at elevated temperatures could be attributed to the hole defects which also occur when the temperature is raised—they are not accounted for in eq. (2). A quantitative correction of these small deviations appears to have little point since the coordination numbers of the sites with "free" OH groups at low T values (existence of larger aggregates with terminal OH groups) would have to be chosen differently from those for high T values (smaller aggregates).

b) The Vapor State

Without any correction for a real gas, the energy of the vapor would be made up of the intramolecular degrees of freedom (first term, eq. (4)) and the heat of evaporation at T_m; this second term can be calculated from the energy of sublimation ΔU_s and the heat of fusion ΔH_m:

$$U_V' = \int_{T_m}^{T} C_V^0 dT + \Delta U_s - \Delta H_m \quad (4)$$

(cf. the straight line shown in Fig. 7, which is a tangent of the experimental curve at T_m).

A real gas correction can first be attempted as with nonpolar substances. 1) At higher vapor densities, intermolecular interaction energies have to be subtracted which can be estimated[1] from the pair potential W and half the coordination number ($12 x_F$ according to the hole defect model[1]). For water that would be

$$W \cdot 4/2 = \Delta U_s - 2\Delta H_H; \quad W = 2.1 \text{ kcal/mol} \quad (5)$$

2) At higher vapor densities an intermolecular component of magnitude $12 RT x_F/2$ has to be added to to the molar heat[1]; however, a loss of translation energy of $3 RT x_F/2$ has to be subtracted in the case of association.

$$U_V = U_V' - 6 W \cdot x_F + \left(\frac{12-3}{2}\right) RT \cdot x_F \quad (6)$$

According to Figure 7, formula (6) gives too small a correction (cf. Table 4); this indicates residual H bonding in the vapor state.

Table 4. Difference between the U_V values calculated by eq. (6) and the experimental values—indication of residual H-bonds?

T [°C]	200	300	350	370
"$\Delta H_{H,V}$" [kcal/mol]	0.23	0.7	1.0	1.1
Vapor pressure P_s [atm]	15.85	87.62	168.01	214.69

A quantitative experimental test of the estimations of H-bonds in the vapor (Table 4) has yet to be performed. It would appear very difficult because of rotational structures[44] and the considerable effort required[22]. The order of magnitude of "$\Delta H_{H,V}$" (Table 4) is in agreement with Figure 5.

2.2.3. Heat of Evaporation

The difference between eq. (2) and (6) corresponds to the energy required for evaporation into the ideal gas state at $V = \text{const.}$, L_V''. The final equation (7) contains the following four terms:

1) Energy for breaking of H-bonds;
2) energy for compensation of dispersion energy $2W$ of the "free" OH groups O_F;
3) heat content liberated on annihilation of intermolecular degrees of freedom in the ideal gas;
4) energy for re-excitation of translation (rotation retained as libration in the liquid, cf. spectroscopy of libration bands[30]).

$$L_V'' = \Delta U_s(1 - O_F) + 2W \cdot O_F - (2 + O_F)RT + RT(1 - x_F) \cdot (3/2) \quad (7a)$$

After rearrangement with $\Delta U_s = 2\Delta H_H + 2W$ (cf. (5))

$$L_V'' = \Delta U_s - 2\Delta H_H \cdot O_F - (2 + O_F)RT + RT(1 - x_F) \cdot (3/2) \quad (7)$$

Instead of L_V'' (ideal gas state) the energy of evaporation L_V (real vapor state) is measured and tabulated. The difference (W_{real}) follows from Section 2.2.2 and more readily from the difference between the straight lines corresponding to eq. (4) or the tangent in Figure 7 and the curve of the experimental H_V values in Figure 7.

As shown by Figure 8, the calculated values of $L_V = L_V'' - W_{real}$ are in good agreement with the data obtained from experiments. Calculation of L_V'' by the model for nonpolar liquids[1] from the hole defects x_F calculated from the densities (Fig. 5) gives only slightly poorer agreement (Fig. 8) than the use of formula (7a). The value of $L_V(0\,\text{K}) = 13.7$ kcal/mol $= L_V^0$ extrapolated for T/T_c gives, by proven methods[1], for water: $Z'f = (3/4)L_V^0/RT_c = 14.1$, *i.e.* a value resembling those for nonpolar substances. The reason is to be found in the (accidently) similar size of $\Delta U_s = 11.6$ kcal/mol; $(12/2) \cdot W = 12.6$ kcal/mol; $(12/2) \cdot (3/2) \cdot RT_c = 11.57$ kcal/mol. Thus in the reduced T/T_c diagram, the anomalous properties of water are not so striking as the greatly increased value of T_c.

For alcohols, L_V can also be calculated from the spectroscopically determined O_F values[39] (cf. Fig. 8). Unfortunately, there are no experimental data available for high temperatures.

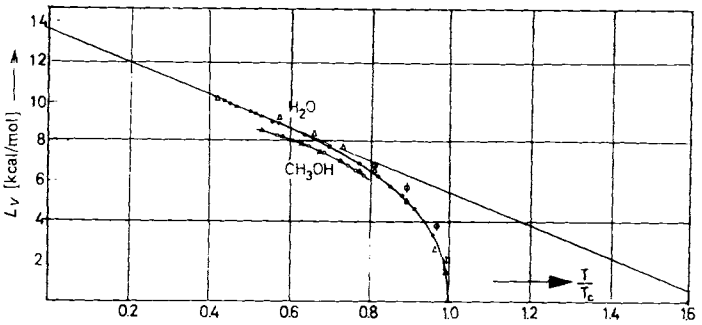

Fig. 8. Heat of evaporation L_V of water and methanol under saturation conditions; ●, ○ experimental; ▲, △ calculated from O_F and eq. (6); ◇ calculated from the hole model and x_F.

2.2.4. Specific Heat

As a differential quantity, the molar heat is a particularly sensitive touchstone for our model. C_σ at the liquid/vapor saturation line (Fig. 7) can be readily represented by the simple two-state model without any modification. The H-bonds induce high values of the heat of evaporation and of the the molar heats of water and the alcohols. Owing to the high relative contributions of H-bonds to the overall forces this has a particularly pronounced effect in the values referred to 1 gram (Table 5).

Table 5. Specific heat capacity c_p and enthalpy of evaporation of selected liquids at 20 °C.

	H_2O	CH_3OH	C_2H_5OH		*n*-Pentane	CH_3COCH_3	Benzene
c_p [cal/g]	0.999	0.57	0.56		0.542	0.51	0.416
ΔH_p [cal/g]	585	287	240		91.4	131	131
	$CHCl_3$	CS_2	CCl_4	HCl	$CHBr_3$		
c_p [cal/g]	0.22	0.237	0.202	0.190	0.128		
ΔH_p [cal/g]	63	89.14	53.8	—	38.28		

As "mobile thermostats", mammals profit from the high heat capacity of water and the high enthalpy of evaporation per unit mass.

The molar heat C_σ of water can be obtained directly by differentiation of eq. (2). The four summands then represent:

1) Intramolecular degrees of freedom;
2) energy required to break H-bonds per degree;
3) increase in heat content of intermolecular degrees of freedom;
4) thawing of translation at defect sites.

Above 200 °C, the fourth term of C_σ has to be increased to account for the hole defects which we could neglect in eq. (2). Neglect of this effect in C_σ would result in a greater error near T_c owing to the differential quotient dx_F/dT giving the energy required for hole defect production per degree (5th term in eq. (8)). Thus, for C_σ we write:

$$C_\sigma = C_V^0 + \frac{dO_F}{dT}[2\Delta H_H + RT] + \\ + (2+O_F)R\bar{A}\frac{3}{2}R(1-x_F) + \frac{dx_F}{dT}\frac{3}{2}RT \qquad (8)$$

The differential quotients dO_F/dT and dx_F/dT are determined from Figure 5. As shown by Figure 9, eq. (8)—again without any adjusted constant—provides a good representation of the experimental values. The second term for the H-bonds in eq. (8) makes a contribution of 50% at room temperature—and explains the anomalously high molar heat of water (cf. Table 5).

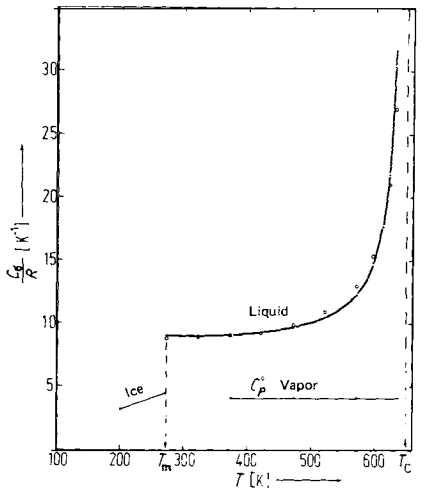

Fig. 9. Molar heat capacity C_σ of liquid water along the saturation line: ●, experimental; ○ calculated according to eq. (8).

The experimental molar heats show a steep maximum for T_c and critical pressure[34,35], the temperature at which it occurs being highly pressure dependent. The maximum corresponds to the point of inflection of O_F at T_c in Figure 5. In semiquantitative experiments we gained convincing evidence that the temperature of the point of inversion of O_F shifts in the same way as the maximum value of the molar heat when the pressure changes. The large pressure gradients[24] in the vicinity of T_c and the start of corrosion of the sapphire window of the IR cell above T_c widen the limits of error of such experiments.

The shift of the point of inversion of O_F with pressure—and thus also of the maximum value of the molar heat—is due to changes of concentration in the H-bond equilibrium. Increase in pressure, and related increases in density and concentration, lower O_F at T=const. and *vice versa*. Spectroscopic studies showed the following O_F values to be similar at temperatures T and densities ρ:

H_2O[3]: $O_F(T_c, 2\rho_c) \approx O_F(325\,°C, \text{saturation})$
$O_F(420\,°C, 2\rho_c) \approx O_F(350\,°C, \text{saturation})$
CH_3OH[24]: $O_F(360\,°C, \rho_c) \approx O_F(310\,°C, \rho_c/2) \approx O_F(230\,°C, \rho_c/4)$

This demonstrates how properties can be determined outside the saturation state.

2.2.5. Density

The anomalously high density of water and its unusual maximum at 4 °C can be readily interpreted with the aid of our model. On breaking of H-bonds, the local structure of coordination number 4 collapses (cf. Fig. 6), leading to higher densities with increasing T. This is opposed by the normal drop in density with increasing temperature as a result of the greater thermal vibration volume. The density of water can be described by the sum of the contributions to the partial molar volumes for OH groups participating in H-bonds (V_b) and for the "free" OH groups (V_F)[39]:

$$1/\rho = V = (1 - O_F)\, V_b + O_F\, V_F \qquad (9)$$

Values somewhat smaller than the data for ice can be used for V_b and its dependence upon T. V_F cannot be determined by spectroscopy, and its values have to be adapted in eq. (9)[39]. Thus, unlike the properties mentioned so far, the density is not a sensitive touchstone for our model. If V_F is fitted for two temperatures, then eq. (9) provides a quantitative description of ρ up to $T = 330$ °C. Additional hole defects have to be considered in eq. (9) at higher temperatures.

2.2.6. Surface Tension and Surface Energy

a) Water

Both the surface tension σ and the surface energy U_σ of water and alcohols can be derived from our simple model. It should initially be noted that the apparently very high surface tension of water $\sigma = 72$ erg/cm^2 (dyn/cm) is not so much a consequence of particularly strong intermolecular forces (as is often assumed) but rather a "consequence" of the unit based on 1 cm^2, which is otherwise most unusual. A discussion of structure again requires conversion to molar units[1,45-47]: $\sigma_M = N_A^{1/3} V^{2/3} \sigma$ (N_A, Avogadro's constant; V, molar volume). The molar surface tension σ_M of water is hardly greater than that of most other liquids (Fig. 10); the high value of σ is due to the large number of H_2O molecules per cm^2. The slightly greater value of σ_M for water, as compared with that for alcohols, is a true indication of its strong molecular interactions.

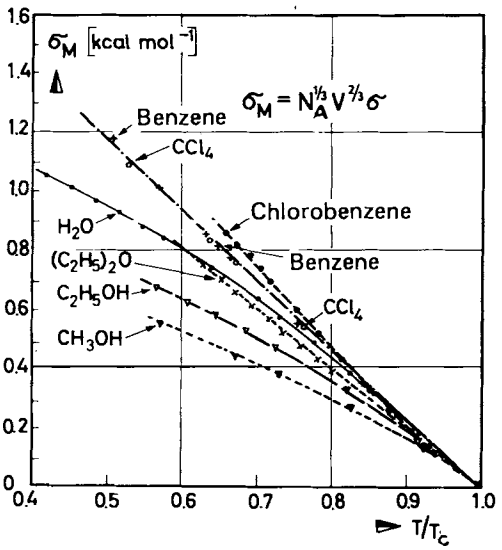

Fig. 10. Molar surface energy: σ_M (energy required to bring 1 mol of molecules to the surface).

Being work measured under isothermal condition, σ and σ_M afford the surface enthalpy by way of the Gibbs-Helmholtz equation:

$$H_\sigma = \sigma_M - T\partial\sigma_M/\partial T \qquad (10)$$

H_σ for liquids differs only slightly from the surface energy U_σ. In contrast to the situation in nonpolar substances, the two quantities are temperature dependent for compounds forming hydrogen bonds (cf. Fig. 11; U_σ calculated from σ values of *Ramsay* and *Shields*[48]; according to [49] for HF, and from our own measurements for alcohols at $T/T_c < 0.65$[45]).

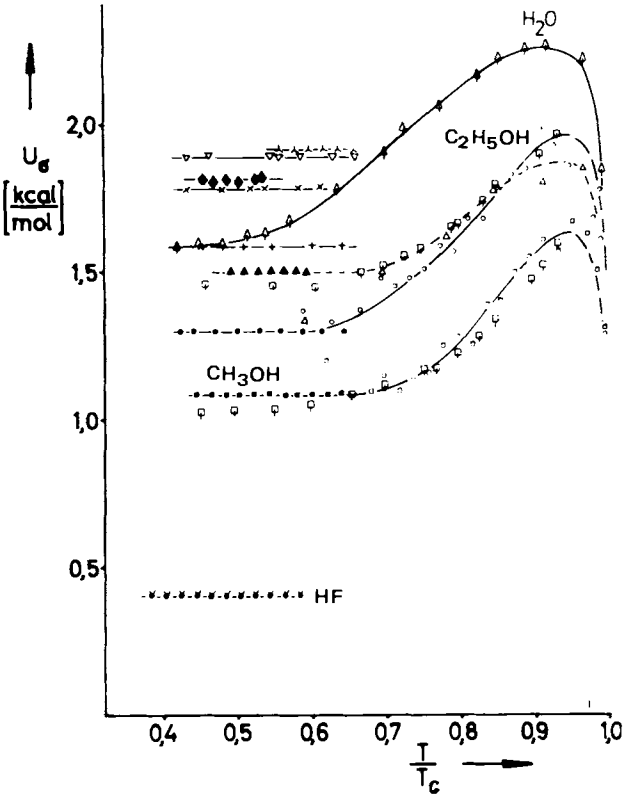

Fig. 11. Surface energy U_σ for H-bonding liquids. Values for alcohols are shown by our own measurements to be independent of T at low temperature, as for nonpolar substances. ⊓ calculated from O_F and eqs (11), (14)

According to the principle of least constraint, mainly "free" OH groups should be brought to the surface when the surface area of water is increased. On breaking "1 mole of pairwise interactions W" there result "2 moles of surface". Thence,

$$U_\sigma = W \cdot Z/2 \cdot 1/2 = 2.1 \cdot 3/4 \text{ kcal/mol} = 1.57 \text{ kcal/mol} \qquad (11)$$

(where $W = 2.1$ kcal/mol, cf. eq. (5), and the coordination number $Z = 3$ between layers of "free" OH groups).

The value of $U_\sigma(H_2O) = 1.58$ kcal/mol determined experimentally at low temperature is in accord therewith. The increase of U_σ with T can be interpreted in terms of the raising of the coordination number of "free" OH groups in smaller aggregates or by model considerations[39]. The maximum for $U_\sigma = 2.22$ kcal/mol corresponds to a coordination number of $Z = 4$ according to eq. (11).

b) Alcohols

The energetically weakest point in alcohols is found in the hydrophobic units associated with the dispersion energy W_d. In the model of chain-like associates (Fig. 12), the coordination number is 6 in the interior of the liquid and 4 at its surface, thus

$$\lim_{T\to 0} U_\sigma = W_d(6/2 - 4/2) = W_d \qquad (12)$$

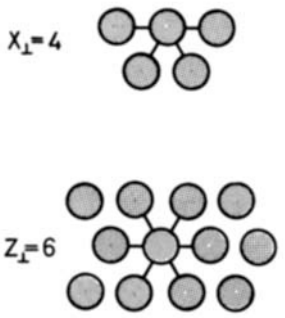

Fig. 12. Model arrangement of alcohol chains perpendicular to OH...OH axis. $Z=6$ for liquid, $Z=4$ at surface.

As for nonpolar substances $\lim_{T\to 0} U_\sigma$ should be independent of T. Since no pertinent experimental data were available, we obtained confirmation of this prediction by performing measurements of our own (difference capillary method)[15,45] (Fig. 11)[*].

$\lim_{T\to 0} U_\sigma(CH_3OH) = 1.08$ kcal/mol $= W_d$ corresponds roughly to the pair potential $W_d = 1.03$ kcal/mol calculated from the limiting value of the heat of evaporation of CH_4 for $T = 0$ K. On resolving the energy of sublimation ΔU_s of the alcohols into H-bond energy ΔH_H and dispersion energy of hydrophobic groups and W of the OH group: $\Delta U_s = \Delta H_H + W_d \cdot (6/2) + W$, then $\Delta U_s(CH_3OH) = 10.7$ kcal/mol and $\Delta H_H = 4$ kcal/mol lead to $W(CH_3OH) = 3.6$ kcal/mol. Taking this value and $\Delta U_s(C_2H_5OH) = 12$ kcal/mol, we calculate $W_d(C_2H_5OH) = 1.47$ kcal/mol—a value which agrees well with $U_\sigma(C_2H_5OH) = 1.3$ kcal/mol for low temperature to within the limits of error[**].

The approximation expression[1] $U_\sigma = 2.85\ RT_c \cdot (3/2)$ applies for nonpolar substances. This expression is also found at low T to apply to alcohols $C_nH_{2n+1}OH$ with $n \geq 2$ if the value of T_c for the n-alkane having the same number of carbon atoms is inserted into the equation[10,45]. The maximum of U_σ at higher temperatures follows from our model with

$$U_\sigma = [(1 - O_F)\Delta H_H + W_d \cdot (6/2) + O_F W] - [(1 - O_{F_0})\Delta H_H + W_d \cdot (4/2) + O_{F_0} W \cdot (2/3)] \qquad (13)$$

The first term in square brackets would be the interaction in the bulk of the liquid, and the second one the interaction at the surface. The coordination numbers are smaller by a factor of $2/3$ at the surface (cf. Fig. 12). As an approximation, we equate the fraction of H-bond defects O_{F_0} at the surface with that of the "free" OH groups in the bulk O_F, and thus obtain from eq. (13) the equation

$$U_\sigma = W_d + O_F W/3 \qquad (14)$$

Eq. (14) satisfactorily reproduces the experimentally observed temperature dependence of U_σ for alcohols (Fig. 11); for $T \to 0$ it assumes the form of eq. (12) because $O_F \to 0$ then applies.

2.2.7. Dielectric Constant

The anomalously high dielectric constant (DC) of water and its drop to the value 7 at T_c has already been explained by *Hasted et al.*[33,50] with the aid of a two-state model closely resembling our own. The values of O_F estimated from the heat of evaporation agree well with those determined experimentally by IR spectroscopy (Fig. 5) up to $T = 250\,^\circ$C; at higher temperatures, deviations result owing to the assumption $O_F(T_c) = 1$, which we had also made in earlier work. In the range $250\,^\circ\text{C} < T < T_c$, the calculated DC values are greater than the experimental values; they could be improved with the experimental O_F values (Fig. 5). Increases in pressure above saturation conditions raise the value of the DC[51], in keeping with our spectroscopic observation that O_F decreases in accord with the H-bond equilibrium[3] under such conditions as a result of the increase in concentration. The DC of ethanol also falls to the value of 2.4[52] at T_c, and, according to Figure 5, should be interpretable with a similar model. The temperature dependence of the magnetic susceptibility[53] or the δ values of NMR signals[54] can likewise be interpreted by the O_F values of Figure 5[41].

2.2.8. Viscosity, Gel Formation, and Cluster Model

Even dynamic quantities such as viscosity and gel formation can be understood, in principle, with the aid of our simple model. Owing to their angular dependence, H-bonds are cooperative[*]. In the vicinity of the defects, the H-bond angles will differ from their optimum values and the energy required to generate further defects will therefore be lower than in ordered regions. It is consequently assumed that owing to this cooperative interaction (cf. Section 10.1 in [1]), the H-bond defects—especially in the network of water—are not randomly distributed but tend to accumulate locally. In the highly idealized limiting case, this leads to a cluster model[3,37] in which ordered regions are separated by zones of H-bond defects. On the basis of Figure 5 and the idealized two-state model, the number N of molecules linked by H-bonds—the size of the cluster—can be estimated[3,15] (cf. upper curve with left-hand scale in Fig. 13).

Substances which undergo only slight interaction with water will preferentially accumulate in these perturbed zones comprising H-bond defects[55,56]. There results a model for solubility[55,56]. The solubility of small molecules dissolved in water by the action of dispersion forces can be arranged according to critical temperature[97] by means of the hole defect model[1]. The relaxation time of 10^{-11} s measured dielectrically for water is regarded as the lifetime of the H-bonds[33].

[*] In this way our model demonstrated its value by predicting *unknown* properties.

[**] The loose network of difunctional water H-bonds is not present here and W for the alcoholic OH groups is therefore higher than the value for HOH.

[*] There may also be a cooperative interaction resulting from charge shifts induced by H-bonds. However, this will hardly change in water up to about 180 °C.

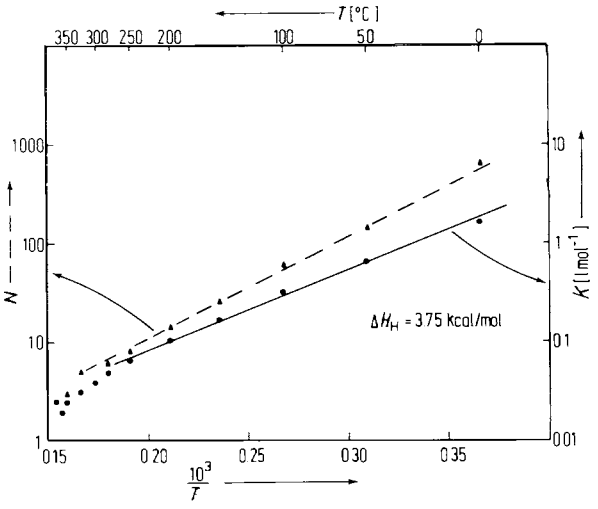

Fig. 13. Upper curve and left-hand scale: mean number N of H_2O molecules linked by H-bonds in water (at saturation, highly idealized model).—Lower curve and right-hand scale: equilibrium constant K of water association.

Perturbed zones will disappear and new ones will be formed on this time scale, leading to what have been called flickering clusters. Larger dissolved molecules will interfere with this mobile mechanism. The anomalous property of gel formation by water on addition of small amounts of foreign matter (*e.g.* 1:1000) thus becomes understandable (cf. the formation of so-called polywater, a gel arising on contamination of water[56]).

The activation energy of the viscosity[42,57] of water (4.8 kcal/mol) or of self-diffusion[57,58] (4.6 kcal/mol) would correspond roughly to the bond energy of an H-bond, *i.e.* the H-bond energy of the water molecules at the perturbed zones. Viscosity and diffusion mechanisms can therefore be envisaged as occurring primarily at the perturbed molecules, at the weak points of the structure.

2.2.9. X-Ray Data

X-ray and neutron diffraction experiments on water in the temperature range of 4 to 200 °C reveal residual "ordered" structures having dimensions of 9 to 4 Å (Table 6)[28,59].

Table 6. Mean radii r of "ordered" regions around a H_2O reference molecule.

T [°C]	4	25	75	200
r [Å] from diffraction data	9	8	6.5	4
r [Å] from O_F values	10.5	9	6.5	4

The radii r of regions with a certain degree of long-range order calculated from distance distribution curves of the diffraction data are in accord with our data regarding the number N of molecules linked by H-bonds (Fig. 13). As early as 1936, *Kortüm*[13] drew attention to ordered regions of 18 to 20 Å in water—*i.e.* containing about 1000 molecules—apparent from X-ray line width measurements by *Scherrer*[60]. On the basis of X-ray diffraction data for alcohols, *Prietzschk*[61] deduced strong association to "chains of considerable length"; according to our IR result of $O_F \approx 1\%$, the $(ROH)_n$ chains should comprise about 100 molecules at room temperature.

2.2.10. Solutions

IR overtone spectra also provide a starting point for a systematic view of aqueous solutions[38,40–42] or even of complicated aqueous systems as in biological cells[10,62] or in membranes[63]. We shall consider just one example: To a first approximation the overtone spectra of water change on addition of electrolyte solutions in the same way as on altering the temperature[10,38,40,64]. The salt series, arranged in the order of the corresponding "structure temperature" T_{str} exhibited by pure water at the same defect content O_F, corresponds to the Hofmeister or lyotropic series of colloid chemistry, which has thus now been identified as a series of modification of the structure of water[38,64]. There are salts in this series whose T_{str} is higher than the solution temperature T_S—so-called structure breakers with O_F (solution, T_S) $> O_F(H_2O, T_S)$—and salts whose T_{str} is lower than T_S—so-called structure makers with O_F (solution, T_S) $< O_F(H_2O, T_S)$. Both groups can also be characterized by NMR spectroscopy (chemical shift, relaxation time)[65]. The first group can exert "salting-in" effects for organic partners, whereas the structure-consolidating ions have a "salting-out" effect, owing to the reduced value of O_F; this is exploited in dyeing and in detergents. The consolidating influence of salts having $T_{str} < T_S$ on the structure of water could be readily appreciated as due to orientation of water dipoles in an ionic field[66], whereas no explanation could be found for the action of the large group of structure breakers.

The frequency shift $\Delta\nu$ of the spectra of water in crystalline hydrates is smaller for most anions than for ice[10,67–70]. Application of the so-called Badger-Bauer rule[18], according to which $\Delta\nu$ is a measure of H-bond energy ΔH_H, to ions as well, raises the question[10,67] whether the field action of numerous anions on OH groups is smaller than that of the lone pairs of the OH groups themselves or similar. The position of the lone pairs close to the "surface" of molecules may cause small distances to OH groups and therefore strong Coulomb interactions. The description of electrolyte solutions could be modified in this respect[67]. The limited solubility of most salts, in spite of their high energy of hydration ΔH_{hyd} would be plausible if H_{hyd} were provided only by a relatively large number of H_2O molecules[67]. Beside ions exerting a hydrolytic action, the ions of strong acids and bases whose spectra show $\Delta\nu$ values greater than that of ice must be treated as exceptions. Their greater solubilities and the tremendous importance of the pH value in chemistry could be attributed by our spectroscopic method to particularly pronounced perturbation of the structure of water as a result of stronger H-bonds than in pure water (for details of aqueous solutions: cf. [10,38,40]; see particularly[97,98]).

2.2.11. H-Bond Energy

In accordance with our two-state model, whose ability to account for many anomalous properties of liquids has been demonstrated in this article, H-bonds in liquids can be described as simple equilibria provided that the temperature is not too high[3].

$$OH_{free} + \theta_{free} \rightleftharpoons OH_{bonded} \tag{15}$$

In the case of water, we have

$$[\theta_{free}] = [OH_{free}] = O_F\, c(OH) \tag{16}$$

$$K = \frac{[OH_{bonded}]}{[OH_{free}]\,[\theta_{free}]} = \frac{(1 - O_F)}{O_F^2\, c(OH)} \tag{17}$$

From $\ln K = f(1/T)$ (cf. lower curve and right-hand scale in Fig. 13) the H-bond energy is found to be $\Delta H_H = -3.4 \pm 0.1$ kcal/mol, in good agreement with the value calculated from an intermolecular (OH + OD) combined frequency of HOD[4]. The literature contains occasional smaller values, during the calculation of which the erroneous assumption of $OH_{free} \rightleftharpoons OH_{bonded}$ was made, neglecting the lone pairs θ_{free}[*]. Eq. (15) and (17) are valid for $T < 250\,^{\circ}C$, a temperature at which $\ln N = f(1/T)$ shows a discontinuity (Fig. 13); smaller aggregates can no longer be neglected at $T > 250\,^{\circ}C$. Of course, they cannot be described by Eq. (15) and (17).

In the case of alcohols, Eq. (16) and (17) are replaced by

$$[\theta_{free}] = [OH_{free}] + c(OH) = (O_F + 1)\,c(OH) \tag{18}$$

$$K = \frac{(1 - O_F)}{(O_F^2 + O_F)\,c(OH)} \tag{19}$$

Up to about 200 °C, $\ln K$ is also a linear function of $1/T$ for alcohols[3]. The successful application of eqs (15) through (19) confirms the utility of the fundamental model.

Summary: The anomalous properties of water and of alcohols and their temperature dependence can be interpreted surprisingly well with the simple two-state model of an equilibrium between open and closed H-bonds.

NB: A model is a simplified system which can describe and predict properties although it may be removed from (frequently unknown) reality (cf. the model underlying the "ideal gas equation"). In the hole model of liquids[1], a model hole may stand for the sum of several real holes which are each smaller than a molecule. In the two-state model of water, the two states could consist of rapid oscillations about certain orientation angles β or molecular distances r, whose mean values lie at $\beta = 0$ and r_{min}, on the one hand, and at very large angles or distances, on the other. The IR overtone spectra show that these mean values (and thus also the mean H-bond energies and the frequencies of the corresponding band maxima) vary only slightly with temperature. Modest increases in the band half-widths with increasing temperature indicate slight increases in the amplitudes of oscillation. It is an advantage of the IR overtone method that the band half-widths contain information about the partition functions of these oscillations. Their accurate analysis is made difficult by the existence of the two parameters β and r. It requires more detailed studies of the—theoretically known—relationships[15, 18] between β, r, and $\Delta\nu$.

3. Improvement of the Simple Model of Water

3.1. The IR Method

Starting from the radial partition functions of diffraction methods, modern research into liquids seeks to acquire an insight into distance and orientation partition functions. The success of our approximation model (with the calculational approach of chemical equilibria) may be a borderline case owing to the relatively high total interaction of water, amounting to 11.6 kcal/mol (cf. standard enthalpies of formation of triethylamine at −11.6 kcal/mol or of ethylene oxide at −12.2 kcal/mol). Nor can details of the overtone spectra be explained by superposition of two bands due to open and closed H-bonds[25]. This requires a third intermediate band whose frequency shift $\Delta\nu$ relative to the band of the "free" OH groups is only 40% of the $\Delta\nu$ value of the ice band. A shift $\Delta\nu$ of 40% of the optimal linear H-bond band has so far been observed: 1) at low concentrations of alcoholic solutions[18]; 2) at low concentrations in the matrix spectra of H_2O and also of alcohols in solid Ar or N_2[18, 29, 32]. Since dipole moment minima occur in the same concentration range[71–75] which were interpreted by analogy with the arrangement in Figure 2b in terms of cyclic dimers, this third band of liquid water and the other two experiments can best be rationalized by assuming configurations with unfavorable H-bond angles. Spectroscopically, only 40% of the energy of a linear H-bond per OH group would correspond to this third state of water with unfavorable H-bond angles of around 100°, *i.e.* for the energy per aggregate with two participating OH groups there would result 80% of the energy of a linear H-bond. Quantum mechanical studies by *Clementi*[5] also ascribed 80% of the energy of a linear dimer to a cyclic dimer. From the trimer upwards, the total energy of cyclic associates is greater, at 12.27 kcal/mol, than that of the linear ones (10.67 kcal/mol).

It should also be noted that the O...O distances become smaller for unfavorable H-bond angles and the dispersive interaction will thus increase relative to linear H-bonds (according to Stuart-Briegleb models, the interaction energy would be *ca.* −3.2 instead of −2.2 kcal/mol for dimers with 7% smaller distances and dispersion forces of $1/r^6$). This increase in energy of 1 kcal/mol may become even greater in condensed phases such as liquids or matrices as a result of increased coordination numbers. The energy difference between H-bonds in the two-state model and such third states with unfavorable angles is thus reduced by an increase in dispersion energy. This would account for the efficacy of our model in the estimation of energetic properties.

Evaluation of computerized band analysis combined with the angular dependence of the frequency shift $\Delta\nu$ of H-bonds and the temperature-dependent half-widths permits estimation of the angular distributions. The area under the curves of Figure 14 corresponds to the percentage angular contributions. In addition, particularly for $T \geq 200\,^{\circ}C$, distance distributions would have to be considered; evidence exists for their influence on the IR frequencies[76–79]. Above 200 °C not only orientation defects (O_F according to Figs. 2b, e, f), but also "distance defects" (Figs. 2c, d) make a significant contribution to the intensity of the band of the "free" OH groups.

Theoretical approaches for the accurate evaluation of IR or Raman bands for partition functions analogous to Figure 14 are being developed[80, 81]. Their application to H-bond bands incurs problems, *e.g.* due to Fermi resonance or to intermolecular coupling with one-quantum excitations of neighboring molecules[4].

In principle, the band shapes of IR and Raman bands and their half-widths contain information about the partition functions of angles and distances and their dynamics. Until methods become available for separating these superposed

[*] A straight line is also obtained for $\ln K = \ln([OH]_{bonded}/[OH_{free}]) = f(1/T)$ since the logarithms of all concentrations are a linear function of $1/T$. The $1/T$ linearity fails to reveal any error in the equilibrium expression!

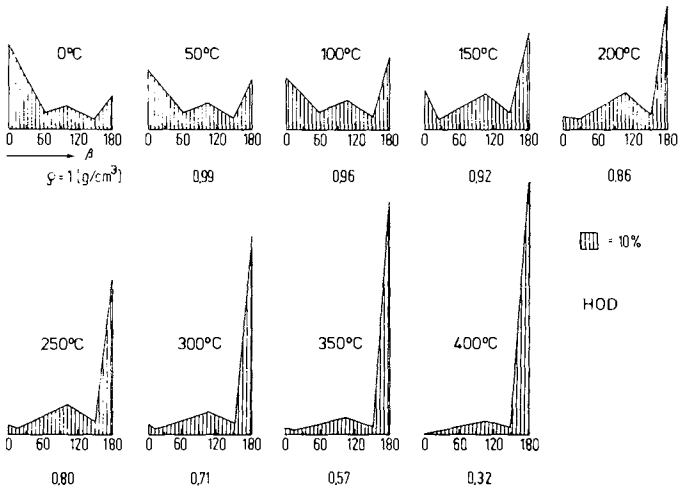

Fig. 14. Estimate of the H-bond defects O_F in water (saturation conditions). At $T<200\,^{\circ}C$ assignment of defects to H-bond angles β; around $\beta=180°$, contributions of "free" OH groups.

functions, use of our model based on mean values appears justified.

3.2. Computer Simulations of Liquids

Computer simulations of the structure of water[82–90] likewise satisfactorily reproduce properties. However, in this approach the potential of the water molecules is "fitted" to the properties. The neon-like dispersion potential used is certainly much too small (cf. in Fig. 1 Ne with CH_4, which is rather H_2O-like); in the range of distances of interest for H-bonds, crucial importance attaches to a "switch potential" which has no physical significance. No contradictions exist between the results of the computer model and those of the model derived from vibrational spectra if the respective nomenclatures are observed. The earlier statement by *Stillinger* and *Rahman*[85] that their calculations would rule out a two-state model of water argues in terms of coordination numbers. Thus it does *not* refer to the model of two different OH groups adopted by us, but rather to different kinds of molecules[*]. The calculated angular distribution[89] between the axis of an OH group and the axes of neighboring lone pairs (Fig. 15) is of interest. The sharpness of the angle partition function around $\beta=0$ accords with our model. A film of a computer simulation by *Geiger*[90] shows most of the molecules to oscillate about $\beta=0$, with rotations being comparatively rare. The second maximum around 100° in Figure 15 arises from the calculation, which simultaneously affords the position of the two OH groups of a H_2O molecule.

The computer model also leads to the conclusion that there is an "unambiguous division of pairs into 'hydrogen bonded' and 'non-hydrogen bonded'"[84] and, for the non-H-bonded states, to the statement that "these entities persist longer than H_2O molecules' vibrational periods"[83].

This corresponds to the observation made with HOD overtone spectra[4] that on increase in temperature the extinction increases in the range of non- or weakly H-bonded OH groups (7200—6800 cm^{-1}) and decreases in the range of bonded OH groups (6800—6200 cm^{-1}) (cf. Fig. 4). The isosbestic point appearing below 150 °C in the overtone spectra of H_2O, HOD, and D_2O supports the approximation of the two-state model. Our experience shows that it is not due to a simple equilibrium between two states but rather to the reluctance of the third state to change in this temperature region.

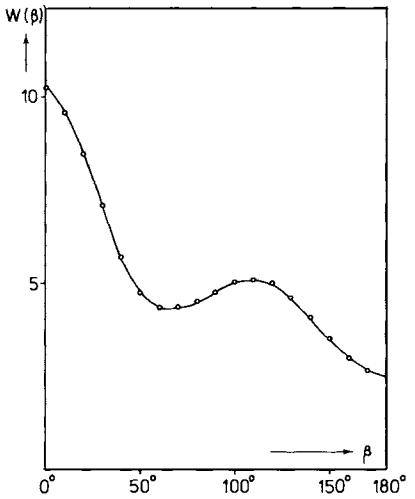

Fig. 15. Probability $W(\beta)$ of the occurrence of the H-bond angle β in water at 32 °C according to computer simulations [89].

The radial partition function calculated from the computer model also indicates residual "ordered" structures up to 7.5 Å from a reference molecule; nearly all the 216 molecules considered exhibit pairwise interaction of at least 3.3 kcal/mol[89]. 216 molecules are fewer than are predicted by the spectra to be linked by H-bonds at room temperature.

Summary: Extensions of the two-state to a three-state model are possible according to vibrational spectra. The spectra also contain information about the angular and distance distribution. In the future we shall learn more about these partition functions. However, the effort involved will probably increase out of proportion to the gain in knowledge.

I am indebted to my teacher Professor G. Kortüm for introducing me to quantitative spectroscopy, which provided an entry to a new field of study in my own contributions reported in this survey. Thanks are also due to my co-workers A. Behrens, C. Buanam-Om, W. Ditter, H. Kleeberg, B. Mann, D. Schiöberg, and O. Schrems for their contributions to our findings.

List of symbols

T_c:	critical temperature
T_m:	melting point
U:	internal energy
H:	enthalpy
ΔU_s:	sublimation energy
ΔH_H:	H-bond energy per H-bond
W:	dispersive interaction energy
W_d:	dispersion energy between hydrophobic moieties of alcohols
U_σ:	surface energy
U_V:	internal energy of saturated vapor
U_L:	internal energy of liquid
H_V:	enthalpy of saturated vapor
H_L:	enthalpy of liquid

[*] I am indebted to Dr. *Stillinger* for clarifying discussions and conformation of this conclusion.

L_V:	heat of evaporation at constant volume
L_V^*:	heat of evaporation into the ideal gas state
C_σ:	molar heat (molar heat capacity) on the liquid/vapor saturation line
C_V^0:	molar heat of ideal gas at V = const.
C_P^0:	molar heat of ideal gas at P = const.
C_W:	molar heat attributable to intermolecular degrees of freedom
σ_M:	surface tension per mole
σ:	surface tension per cm^2
R:	molar gas constant
P:	pressure
V:	molar volume
K_c:	equilibrium constant of H-bond formation
c:	molar concentration
c_F:	concentration of OH groups not participating in H-bonds ("free OH groups")
c_B:	concentration of H-bonds
O_F:	fraction of "free" OH groups
θ:	lone pairs of electrons
θ_F:	lone pairs not participating in H-bonds
N:	number of molecules linked by H-bonds
N_A:	Avogadro's number
Z:	coordination number of nearest neighbors
Z_e:	number of electrons
x_F:	fraction of hole defects
β:	H-bond angle ($\beta = 0$ for linear H-bonds)
ε:	molar extinction coefficient
ε_{max}:	extinction coefficient for band maximum
$\varepsilon_{max,0}$:	extinction coefficient for band maximum extrapolated to $c = 0$
ν:	frequency, wave number
$\Delta\nu_{1/2}$:	half-width

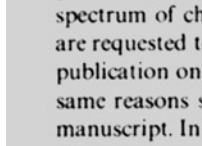
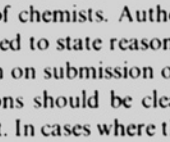
COMMUNICATIONS



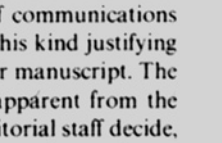
Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis of CH_2-Bridged [4*n*+2]Annulenes by a Building-Block Approach

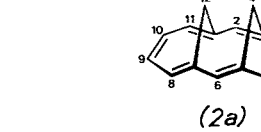


By *Emanuel Vogel, Hans M. Deger, Johannes Sombroek, Jürgen Palm, Arwed Wagner*, and *Johann Lex*[*]

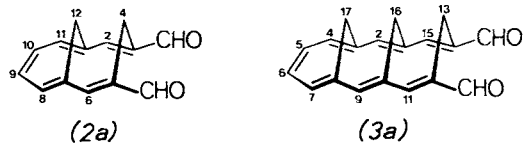
Dedicated to Professor Wolfgang Lüttke on the occasion of his 60th birthday



Since the synthesis of the 10π Hückel aromatic compounds 1,6-methano-, 1,6-oxido-, and 1,6-imino[10]annulene[1], we have been concerned with preparative entries to homologous series of bridged [4*n*+2]annulenes with an acene perimeter. With a view to gaining a deeper insight into the Hückel rule, our interest was focused on series in which the members with two and more bridges possess the *syn*- or *all-syn* configuration[2] geometrically favorable for the occurrence of aromatic character. The development of such [4*n*+2]annulene series requires new strategies, for conventional procedures hardly provide a chance of going beyond bridged [14]annulenes[2]. In our current synthetic considerations cycloheptatriene-1,6-dicarbaldehyde *(1)*[3] and the homologous α,ω-dialdehydes *(2)*, *(3)*, and *(4)* constitute the key intermediates.

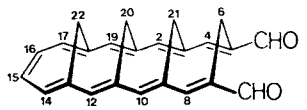


(1)



(2)

syn-Isomer
(3)



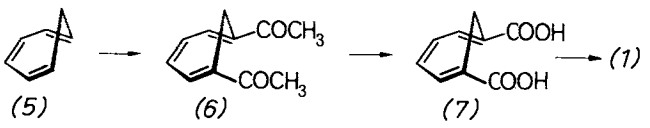
syn,syn-Isomer
(4)

(2a)

(3a)

(4a)

After the dialdehyde *(2)*[4] obtained from 1*H*-3,8-methanocyclopropa[10]annulene had proved to be the *syn* conformer *(2a)*, there was good reason to assume that *(3)* and *(4)* also exist in the *syn* conformation [*(3a)* and *(4a)* respectively]. Arguing from this premise, synthesis of the potentially aromatic 1,6-methano[10]annulene homologues with 14, 18, and 22π electrons and the construction of series of [4*n*+3]annulenylium ions, [4*n*+3]annulenones, [4*n*+1]annulenyl anions and other annulene compounds corresponding to the hydrocarbon series is essentially a question of experimental effort and the ability of the pertinent molecules to exist.



We have now found that the homologous α,ω-dialdehydes *(2)*, *(3)*, and *(4)* having the desired *syn* conformation—and thus most likely many of the [4*n*+2]annulenes and their derivatives listed above—can be obtained by a building-block approach starting from *(1)*.

1) Cycloheptatriene-1,6-dicarbaldehyde (1): The need for a rational synthesis of the previously somewhat inaccessible dialdehyde *(1)*[3] suggested attempts to transform the industrially available compound cycloheptatriene *(5)* by acylation[5] into *(1)* or suitable precursors. A productive entry to *(1)* has now been opened by acetylation of *(5)*.

On treatment with acetyl chloride/zinc chloride in glacial acetic acid/dichloromethane (−30 °C; 4 h), cycloheptatriene *(5)* afforded 1-acetylcycloheptatriene as major product (b.p.

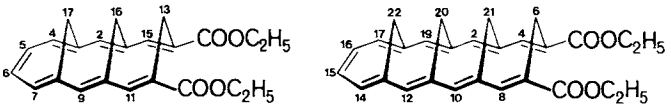
42 44 °C/0.1 torr; yield 45—50%). Introduction of the second acetyl group required isolation of the monoacetyl compound and its treatment with the more aggressive acetylation system acetyl chloride/aluminum chloride in boiling dichloromethane (2 h). There was formed the expected 1,6-diacetylcycloheptatriene *(6)* [b.p. 123—125 °C/0.5 torr, light yellow crystals of m.p. 44—45 °C (pentane), yield 50%; ^{1}H-NMR ($CDCl_3$): $\delta = 2.4$ (s, 6H, $2CH_3$), 3.0 (s, 2H, H-7), 7.0 (AA'BB' system, 4H, H-2, 3, 4, 5); UV (cyclohexane): $\lambda_{max} = 232$ nm ($\varepsilon = 22000$), 309 (5500)]. Haloform reaction (sodium hydroxide/bromine in water/dioxane) degrades *(6)* to the cycloheptatriene-1,6-dicarboxylic acid *(7)*[6] (yield 66%). The dicarboxylic acid→dialdehyde conversion can be accomplished *via* diester and diol, but it was found preferable to prepare the diacyl dichloride from the acid by reaction with thionyl chloride (pyridine catalyzed; 55 °C) and to reduce it with lithium tri-*tert*-butoxyhydridoaluminate in tetrahydrofuran (−70 °C, yield 61%). Compound *(1)* can be prepared in 100g-quantities with comparative ease by this "cycloheptatriene route".

2) Homologization sequence: Carbonyl olefination with the bifunctional Wittig-Horner reagent *(8)* appeared to have potential as the crucial first step in the homologization of *(1)* to *(2a)*. We obtained the heretofore unknown compound *(8)* alongside other products by Michaelis-Arbuzov reaction of diethyl α,α'-dibromoglutarate (*meso* and *rac* form) with triethyl phosphite (8 h; 60 °C). Compound *(8)* can be isolated in sufficient purity for synthetic purposes (*ca.* 95%[7]) by distillation (2×) over a 30-cm Vigreux column [b.p. 185—195 °C/10^{-5} torr; yield 31%; GC/MS: $m/e = 460$ (M^+, < 1%)]. Since the ^{31}P-NMR spectrum of *(8)* exhibits two close peaks, it would appear that *(8)* is likewise a mixture of stereoisomers. On reaction with sodium hydride compound *(8)* affords the bisphosphonate dicarbanion which, on dissolution in benzene, is ready for use in olefination reactions.



(1) (8) (9) (2a)

The utility of *(8)* was demonstrated by reaction with *(1)* in the molar ratio of 1.1:1 in dichloromethane/benzene (reflux, 3 h). Although ring closures with bifunctional olefination reagents are frequently unsatisfactory[8], the present reaction furnished *(9)* in yields of 48—54% after chromatography of the reaction product on silica gel (ether/pentane, 1:1)[9]. In order to transform *(9)* into *(2a)*, the diester first had to be reduced to the diol (diisobutylaluminum hydride in benzene; room temperature; m.p. 130—131 °C; yield 74%) and the diol oxidized (2,3-dichloro-5,6-dicyanobenzoquinone in dioxane; room temperature; yield 85%).

The three-step sequence considered is just as suitable for converting *(2)* into the next-higher homolog *(3)*; no significant modifications of the reaction conditions are necessary [yields of the various steps are 58%, 71%, and 75%, respectively; see Table 1 concerning the properties of *(3)*]. X-Ray structure analysis[10] and chemical transformations confirm the presence of the expected *syn* conformer *(3a)* in the crystal and in solution.

Table 1. Physical data of the α,ω-polyenedialdehydes *(2a)*, *(3a)*, and *(4a)* and the corresponding diethyl esters *(9)*, *(10)*, and *(11)*.

(10) (11)

(2a), m.p. = 215—216 °C (dec.) (chloroform/ether); yellow crystals; UV (dioxane): $\lambda_{max} = 288$ nm ($\varepsilon = 59300$), 369 (4550); IR (KBr): 1662 cm^{-1} (C=O); ^{1}H-NMR (CD_2Cl_2): $\delta = 0.64$ and 4.18 (AX system, $J = 12.5$ Hz, 2H, H-12), 3.33 and 4.92 (AX system, $J = 16.5$ Hz, 2H, H-4), 7.17 (s, 2H, H-2, 6), 6.78—7.30 (AA'XX' system, 4H, H-8, 9, 10, 11), 9.37 (s, 2H, 2CHO)

(3a), m.p. = 264—267 °C (dec.) (dichloromethane); carmine red needles: UV (dioxane): $\lambda_{max} = 326$ nm ($\varepsilon = 80900$), 334 (81600), 409 (5300); IR (CsI): 1668 cm^{-1} (C=O); ^{1}H-NMR ($C_2D_2Cl_4$): $\delta = -0.22$ and 3.27 (AX system, $J = 13.2$ Hz, 2H, H-17), 3.43 and 4.37 (AX system, $J = 15.3$ Hz, 2H, H-16), 3.53 and 4.85 (AX system, $J = 16.2$ Hz, 2H, H-13), 6.75—7.22 (AA'XX' system with 2 s, 8H, H-2, 4, 5, 6, 7, 9, 11, 15), 9.22 (s, 2H, 2 CHO)

(4a), dec. > 300 °C (dichloromethane); red-violet needles; UV (dioxane): $\lambda_{max} = 251$ nm ($\varepsilon = 28100$), 363 (119000), 463 (sh, 8800); IR (CsI): 1680 cm^{-1} (C=O); ^{1}H-NMR ($C_2D_2Cl_4$): $\delta = -0.64$ and 2.59 (AX system, $J = 13.5$ Hz, 2H, H-22), 2.78 and 3.50 (AX system, $J = 16.4$ Hz, 2H, H-20), 3.43 and 4.88 (AX system, $J = 16.8$ Hz, 2H, H-6), 3.93 and 4.60 (AX system, $J = 15.2$ Hz, 2H, H-21), 6.74 (s, 2H, H-2, 10), 6.83 (s, 2H, H-12, 19), 7.18 (s, 2H, H-4, 8), 7.27 (deg. AA'XX' system, 4H, H-14, 15, 16, 17), 9.27 (s, 2H, 2 CHO)

(9), m.p. = 75—76 °C (hexane); light yellow needles; UV (dioxane): $\lambda_{max} = 278$ nm ($\varepsilon = 42100$), 358 (5000); IR (KBr): 1696 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta = 0.30$ and 4.00 (AX system, $J = 12.1$ Hz, 2H, H-12), 3.75 and 4.93 (AX system, $J = 16.3$ Hz, 2H, H-4), 6.70—7.12 (AA'XX' system, 4H, H-8, 9, 10, 11), 7.63 (s, 2H, H-2, 6), 1.32 and 4.25 (t and q, 10H, $2\ C_2H_5$)

(10), m.p. = 162—163 °C (methanol); orange-red needles; UV (dioxane): $\lambda_{max} = 317$ nm ($\varepsilon = 81200$), 339 (sh, 68900), 397 (5650); IR (CsI): 1695 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta = -0.36$ and 3.17 (AX system, $J = 12.9$ Hz, 2H, H-17), 3.35 and 4.22 (AX system, $J = 15.9$ Hz, 2H, H-16), 3.94 and 4.97 (AX system, $J = 16.5$ Hz, 2H, H-13), 6.92 (s, 2H, H-2, 9), 7.20—6.78 (AA'XX' system, 4H, H-4, 5, 6, 7), 7.45 (s, 2H, H-11, 15), 1.29 and 4.22 (t and q, 10H, $2\ C_2H_5$)

(11), m.p. = 168—169 °C (methanol); red needles; UV (dioxane): $\lambda_{max} = 247$ ($\varepsilon = 27000$), 356 (116000), 424 (8400); IR (CsI): 1710 cm^{-1} (C=O); ^{1}H-NMR ($CDCl_3$): $\delta = -0.80$ and 2.50 (AX system, $J = 13.2$ Hz, 2H, H-22), 2.71 and 3.43 (AX system, $J = 16.2$ Hz, 2H, H-20), 3.77 and 4.49 (AX system, $J = 15.4$ Hz, 2H, H-21), 3.99 and 5.00 (AX system, $J = 16.9$ Hz, 2H, H-6), 6.63 (s, 2H, H-2, 10), 7.11 (s, 2H, H-12, 19), 7.20 (deg. AA'XX' system, 4H, H-14, 15, 16, 17), 7.37 (s, 2H, H-4, 8), 1.28 and 4.21 (t and q, 10H, $2\ C_2H_5$)

A second repetition of the homologization process leads from *(3)* to *(4)*. However, the yield of ring closure fell to 22—24%, probably as a result of (i) poorer steric fit between the aldehyde functions of *(3)* and the Wittig-Horner reagent *(8)* as compared with *(1)* and *(2)* and (ii) the need to work at relatively high dilution owing to the lower solubility of *(3)*. The reduction and oxidation steps are again straightforward.

According to the X-ray structure analysis[11] performed by *J. Lex*, compound *(4)* likewise adopts the *syn* conformation *(4a)*. As can be deduced from spectroscopic comparisons, this conformation most likely also applies to the compound in solution. The edge profile of the molecule (Fig. 1) provides more detailed information about the three-dimensional structure of *(4a)* and especially about the significant curva-

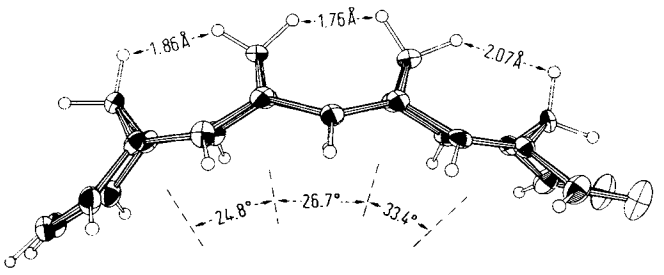


Fig. 1. Edge profile of *(4a)*.

ture of the polyene system which does not appear to greatly affect conjugation.

3) Annulene formation: The general reaction scheme envisaged for transformation of α,ω-polyenedialdehydes *(1)* and *(2a)—(4a)* into the corresponding bridged [4*n*+2]annulenes —and into numerous substitution products not obtainable from the annulenes themselves—is illustrated in the case of the syntheses of *syn*-1,6:8,13-bismethano[14]annulene[4] and *syn,syn*-1,6:8,17:10,15-trismethano[18]annulene[12]. It comprises the following steps (which can be carried out as a one-pot process in specific cases): 1) introduction of the two missing C atoms as C_1 units (these may be linked together by an S atom[4]) by carbonyl olefination with formation of a polyene having (4*n*+2)π electrons; 2) ring closure of the polyene by a thermally allowed disrotatory (4*n*+2)π electrocyclic process, favored by the molecular geometry, which gives a dihydroannulene; and 3) generation of the annulene by β-elimination of an auxiliary substituent introduced on olefination or by (*in situ*) dehydrogenation. The attractiveness of this scheme lies in the range of variation of the initial olefination step, and, methodologically, in the synthetic utilization of hitherto poorly known electrocyclic processes with (4*n*+2) π electrons (*n*>1)[13]. Regarding the synthesis of bridged [4*n*+3]annulenylium ions, [4*n*+3]annulenones, aza[4*n*+2]annulenes, *etc.*, it appears reasonable to look to the chemistry of the synthon phthaldialdehyde.

Generation and Direct Observation of the Xanthenide Anion; a Stable 4*n* π-System[**]

By *A. G. Anastassiou* and *H. S. Kasmai*[*]

A major, yet largely unrealized, goal in the area of nonbenzenoid aromatics is the direct observation and possible classification of potentially delocalizable π-systems incorporating a carbanionic center as well as one or more π-excessive heteroatomic units. Particularly challenging of course in this connection is the case of medium-sized, *i. e.* 6-membered, systems associated with a formal count of 4*n* π-electrons, insofar as a number of serious attempts at generating them have led, thus far, to rapid ring-contractive reorganization[1] [for typical example see reaction (a)] believed to be indicative of intrinsic *antiaromatic* instability resulting from the active participation of *all* properly directed lone pairs (homo- as well as heteroatomic) into delocalization[1].

$Ph-\overset{\ominus}{C}H-Ph$ *(6)*

Bearing in mind that the most reliable spectroscopic manifestation of antiaromaticity consistently has been the development of paratropic character, we decided to undertake the generation and direct examination, by NMR, of the carbanion of xanthene *(4)*[2], a molecule which is structurally incapable of undergoing skeletal reorganization without undue expenditure of energy resulting primarily from disruption of benzenoid resonance.

The oxygen-containing carbanion *(5)* was generated upon exposure of xanthene, *(4)*, to potassium amide in liquid ammonia at −30 °C. The NMR data [*(5)*: 60-MHz ^{1}H-NMR (NH_3, *ca.* 34 °C): δ = 3.08 (1H, s, H-9), 4.9—5.4 (6H, m, H-1, 2, 4), 5.78 (2H, dt, H-3, J = 7.0, 6.0, 2.0 Hz); 20-MHz ^{13}C-NMR (NH_3, *ca.* 30 °C, TMS), δ = 68.92 (d, C-9, J_{CH} = 156 Hz), 109.40 (d, J_{CH} = 161 Hz), 118.84 (d, J_{CH} = 153 Hz), 112.32 (d, J_{CH} = 154 Hz), 126.44 (d, J_{CH} = 153 Hz), 143.04 (s, C-9a), 152.37 (s, C-4a)] reveal some interesting features among which the most informative about the nature of the molecule's π system is, no doubt, the dramatic upfield shifts one observes in the ^{1}H-NMR spectrum on passing from *(4)* to *(5)* (Fig. 1). The signals of the "benzenoid" protons of the anion no longer appear in the "aromatic" region of the spectrum but rather in a portion (δ = 5—6) normally reserved for the protons of conventional olefins. Useful insight into the possible cause of this shift may readily be gained upon comparison of the NMR spectra (in NH_3, at *ca.* 34 °C) of *(5)* and *(6)* (diphenylmethanide ion as model compound): the carbanionic center in *(5)* absorbs at substantially higher field (δ = 68.92) than it does in *(6)* (δ = 81.33), and also the major

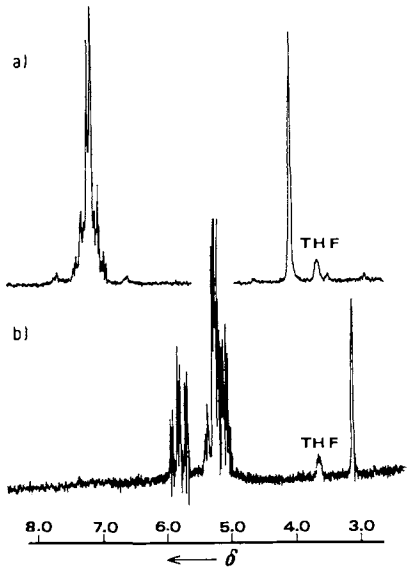

Fig. 1. 60-MHz ^{1}H-NMR spectrum of a) xanthene *(4)* and b) the xanthenide ion *(5)* at *ca.* 34 °C in liquid ammonia containing some THF (<1%; internal standard) as solvent.

group of "benzenoid" protons [6H in *(5)* and 8H in *(6)*] absorbs at a substantially higher field in *(5)* ($\delta = 5.1$) than it does in *(6)* ($\delta = 6.8$). Since the ^{13}C-NMR information convincingly establishes that the carbanionic center of *(5)* retains a significantly larger fraction of the negative charge than its counterpart in *(6)*, it follows that the upfield shift of the signals of the "benzenoid" protons observed on passing from *(6)* to *(5)* cannot be rationally dismissed as an "electron density" effect but may be logically attributed chiefly to the *presence of a paramagnetic ring current.*

The spectra described here would appear to indicate that anion *(5)* is a rather rare example of a remarkably stable[3] species with antiaromatically delocalized π-electrons, *i.e.* paratropic, $4n$-electron π-excessive.

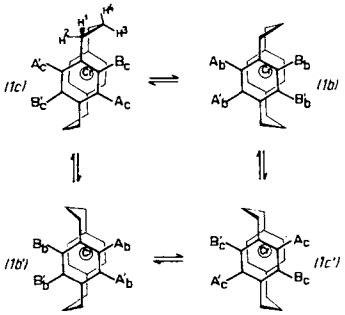
Structural Investigations on (η^{12}-[3.3]Paracyclophane)chromium(0) and Its Cation in (η^{12}-[3.3]Paracyclophane)chromium(I) Triiodide[**]

By *Reinhard Benn, Norman E. Blank, Matthias W. Haenel, Jochen Klein, Ali R. Koray, Klaus Weidenhammer,* and *Manfred L. Ziegler*[*]

(η^{12}-[3.3]Paracyclophane)chromium(0) *(1)* was obtained by cocondensation of [3.3]paracyclophane and chromium in a metal evaporator[1]. We report here on the structural investigation of *(1)* by dynamic ^{1}H-NMR spectroscopy and on the X-ray structure analysis of (η^{12}-[3.3]paracyclophane) chromium(I) triiodide *(3)*.



(1) *(2)*, X = PF_6 *(3)*, X = I_3

According to the ^{1}H-NMR spectrum (270 MHz, *ca.* 1% solution in [D_8]toluene) at −70 °C, *(1)* is present in the chair conformation *(1c)* and boat conformation *(1b)* in the ratio 1:1. Accordingly, two AA'BB' systems or, disregarding the long range couplings ($^4J_{HH}$ and $^5J_{HH} \leq 1.5$ Hz), two AB systems are observed between $\delta = 3.6$ and 4.0 for the upfield phenylene proton signals of the [3.3]paracyclophane ligand (cf. Table 1 and Fig. 1). The assignment of the signals to *(1c)* and *(1b)* follows from the coupling constants J_{AB}[2]. The chemical shifts of the methyl protons of the chair and boat form are apparently not resolved: we assign the absorption at $\delta = 2.63$ (8H) to the "equatorial" benzyl protons H^1 of the chair and boat forms[3]; for the "axial" benzyl protons H^2 and the non-benzylic methylene protons H^3/H^4, multiplets are observed in each case around $\delta \approx 1.2$ (8H) and $\delta \approx 2.0$ (16H) (Table 1, Scheme 1). At higher temperatures the two AB systems degenerate to a singlet at $\delta = 3.76$ (8H, 60 °C); between −90 °C and −30 °C the chemical shifts are linearly dependent upon the temperature (Fig. 1). Accordingly, the signals of the benzyl protons H^1 and H^2 coalesce and at 60 °C they coincide with the signal of H^3/H^4 at $\delta = 1.93$ (halfwidth = 5.4 Hz, 12H). A line shape analysis[4] based on the dynamic behavior of the phenylene protons with four exchanging AB systems neglecting direct chair-chair and boat-boat rearrangements (Scheme 1) gave for the flipflop process between chair *(1c)* and boat *(1b)* forms the activation parameters $E_a = 11.68 \pm 0.22$ (48.9 ± 0.9) kcal/mol (kJ/mol), $\Delta H^{\neq} = 11.20 \pm 0.22$ (46.9 ± 0.9) kcal/mol (kJ/mol) and

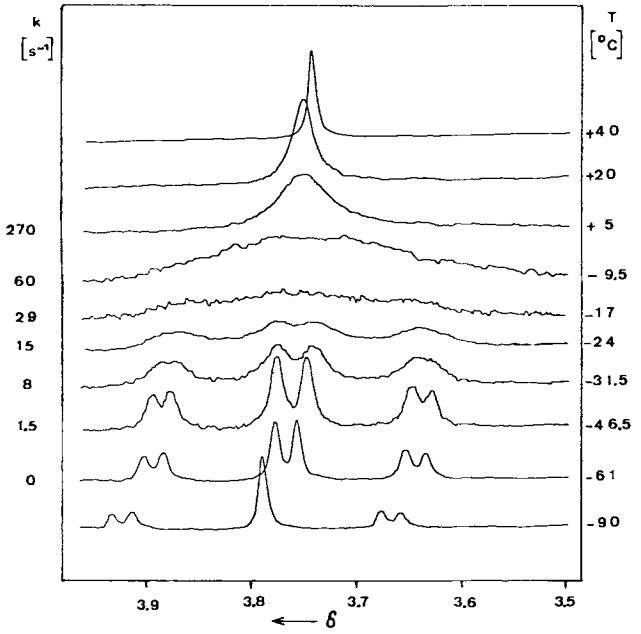

Fig. 1. ^{1}H-NMR spectra (270 MHz, [D$_8$]toluene) of the phenylene protons of *(1)* at various temperatures; values *k* are the calculated exchange rates (cf. Scheme 1).

$\Delta S^{\neq} = -7.7 \pm 0.9$ (-32.2 ± 3.8) cal K^{-1} mol^{-1} (J K^{-1} mol^{-1}).

For comparison the temperature-dependent ^{1}H-NMR spectra of [3.3]paracyclophane were re-examined. Contrary to *Anet* and *Brown*[5a,6], we found the ratio of conformers to be the same as in the case of *(1)*, *i.e. ca.* 1:1[6] [^{1}H-NMR (270 MHz, [D$_8$]toluene, -70 °C) boat: AB system with $\delta_A = 6.62$, $\delta_B = 6.48$, $^4J_{AB} = 1.5$ Hz; chair: AB system with $\delta_A = 6.59$, $\delta_B = 6.50$, $^3J_{AB} = 8.0$ Hz]. However, the line shape analysis[4] of the temperature-dependent ^{1}H-NMR spectra is impaired by the crystallizing out of the chair conformer below -50 °C[6]. Hence, only approximate values can be obtained for E_a and $\Delta H^{\neq}$ of the chair-boat rearrangement of [3.3]paracyclophane which are about 2 kcal/mol (8.4 kJ/mol) smaller than for the rearrangement in the case of *(1)*[7]. The structure of the cation in *(3)* was investigated X-ray crystallographically[1,8]. In the crystal, compound *(3)*, like [3.3]paracyclophane[5b], is present exclusively in the chair conformation. In the cation, the benzene rings, in contrast to the free ligands, are eclipsed. The transannular distances [C(1)···C(4′) = 307.1(17) pm, C(2)···C(5′) = C(3)···C(6′) = 322.2(17) pm], and thus also the boat-shaped deformation of the benzene rings, are somewhat smaller in the cation than in the ligand[8]. The average chromium-carbon distances are 210(1) and 213(1) pm [C(1), C(4) and C(2), C(3), C(5), C(6), respectively] and thus are comparable with those in dibenzenechromium(0) (214 pm)[9a] and dibenzenechromium(I) iodide (213 pm)[9b]. The shortest distance between the central iodine atom of the linear and symmetric triiodide ion [I···I = 291.3(1) pm] and the C(2), C(3), C(5), C(6) (Fig. 2) plane of the benzene ring is 373 pm[8].

Stable 4-Imino-1,2-oxazetidines from *N*-Neopentylidene-*tert*-butylamine *N*-Oxide and Isocyanides

By *Dietrich Moderhack* and *Michael Lorke*[*]

Syntheses of four-membered rings from isocyanides and 1,3-dipoles with internal octet stabilization after the manner of a [3 + 1]cycloaddition are still rare[1]. Although nitrones do react with isocyanides after prior activation with strong Lewis acids such as boron trifluoride[2], the ensuing reaction has so far merely yielded unstable 4-imino-1,2-oxazetidines[3]: alkyl substituents in position 2 with hydrogen attached to the α-C atom promote isomerization to Schiff bases of α-amino acid amides[3]. Stable crystalline products *(3)* have now been obtained, as the very first stable compounds of this type to be isolated[4], on reaction of the nitrone *N*-neopentylidene-*tert*-butylamine *N*-oxide *(1)*.

Cpd. [a]	R	M.p. [°C]	Yield [%]	IR $\nu_{C=N}$ [cm^{-1}]
(3a)	c-C_6H_{11}	68	67	1758, 1748
(3b)	$CH_2C_6H_5$	48	47	1757
(3c)	C_6H_5	85	25	1735

[a] Correct CHN analyses. [b] Recorded in KBr.

The chemistry of the new heterocycles *(3)* is dominated by reactions involving O–N bond cleavage: these are, on the one hand, the thermally initiated [2+2]cycloreversion typical of 1,2-oxazetidines[5] (here giving isocyanate and azomethine)—heating of *(3a)* with 1,2,3,4-tetrahydroisoquinoline as trapping reagent gives the urea *(4)*, m.p. 122—123 °C, in 90% yield—and, on the other, the proton-catalyzed rearrangement to derivatives of α-amino acids—for example, the action of dilute mineral acid on *(3a)* gives the amide *(5)*, m.p. 135—136 °C, in 94% yield together with acetone.

In their mass-spectrometric fragmentation patterns, which strongly support structure *(3)*, the oxazetidines differ from analogous four-membered ring systems (3-imino-1,2-diazetidines, -1-azetines, -azetidines)[1] primarily in the absence of any elimination of isocyanide *(2)*, as is also observed with 2-iminooxetanes[6]; [2+2]cycloelimination (of isocyanate and azomethine or nitrosoalkane and ketenimine) predominates.

Procedure

A mixture of cyclohexyl isocyanide *(2a)* (1.09 g, 10 mmol) and triethylamine (1.01 g, 10 mmol) in CH_2Cl_2 (10 ml) is added within 2 min to a rigorously stirred solution of *(1)*[7] (1.57 g, 10 mmol) and $BF_3 \cdot OEt_2$ (1.35 g, 9.5 mmol) in anhydrous dichloromethane (20 ml) at −40 °C. The reaction mixture is immediately poured into a saturated solution of $NaHCO_3$ (50 ml) and extracted repeatedly with CH_2Cl_2. 2,3-Di-*tert*-butyl-4-cyclohexylimino-1,2-oxazetidine *(3a)* crystallizes after drying (Na_2SO_4) and removal of solvent; yield after recrystallization from acetone/methanol/water: 1.78 g (67%).—^{1}H-NMR ($CDCl_3$): δ = 1.03 (s, 3 CH_3), 1.10 (s, 3 CH_3), 1.1—1.9 (m, 5 CH_2), 3.46 (m, CH), 3.83 (s, CH).—MS (70 eV; 80 °C): M^+ (5%), $[M-C_6H_{10}]^+$ (7%), $[M-C_4H_9NO]^+$ (16%), $[(CH_3)_2C{=}CHC{\equiv}NC_6H_{11}]^+$ (9%), $[M-C_6H_{11}NCO]^+$ (5%), $[(CH_3)_2C{=}N{=}CHC(CH_3)_3]^+$ (11%), $[(CH_3)_3CCH_2C{\equiv}N]^+$ (27%), $[(CH_3)_2C{=}CHC{\equiv}NH]^+$ (37%), $[C_4H_9]^+$ (100%)[8].

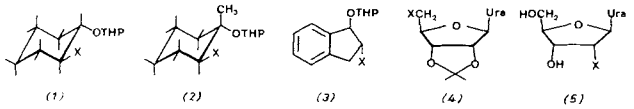
Chromium(II)-catalyzed Electrochemical Dehalogenation of β-Hydroxyhalides—Convenient Entry to Deoxynucleosides[1]

By *Josef Wellmann* and *Eberhard Steckhan*[*]

Deoxynucleosides are often prepared from halo-deoxy compounds by catalytic hydrogenation or by reduction with tributyltin hydride. However, the purity of the products and the selectivity of the reduction are not always satisfactory. We have now found that the products formed by chromium(II)-catalyzed electrochemical reduction[2] (indirect electrolysis) can be isolated in high purity and in excellent yield.

In the dehalogenation of β-hydroxyhalides with chromium(II) reagents it is of decisive importance to suppress elimination leading to the olefin. As *Barton et al.* have shown with steroid derivatives[3], this can be achieved with the aid of butanethiol as H-donor if the mild reducing agent chromium(II) acetate in dimethyl sulfoxide is used and the substrates are tertiary bromides or iodides.



The method failed, however, in the dehalogenation of simple test substrates such as 2-bromocyclohexanol, 2-bromo-1-methylcyclohexanol and 2-bromo-1-indanol with chromium(II) acetate in dimethyl sulfoxide or dimethylformamide (DMF), or with chromium(II) chloride in DMF. Besides the desired alcohols, considerable amounts of olefins were formed; and even with threefold amounts of chromium(II) chloride in DMF only 25%, 30%, and 90% conversions, respectively, could be achieved.

To enforce complete conversion and to increase the selectivity of the reaction we used a strong chromium(II) reducing agent and protected the hydroxy groups in the substrates. Reduction of tetrahydropyranyl ethers *(1a)*—*(3a)* (Table 1) with the very reactive ethylenediamine complex of chromium(II) perchlorate in DMF in the presence of butanethiol led to complete conversion and practically quantitative yields. These results are independent of whether an excess of the reagent is used (molecular ratio of substrate : reagent 1 : 2, Method 1) or whether the chromium(II) complex is electrochemically regenerated in the reactor (Method 2, indirect electrolysis). In the indirect electrolysis, however, only catalytic amounts of reagent are needed; hence, not only is there a saving in costs but also the separation of the products from large amounts of inorganic salts is circumvented. Moreover, handling of the reagent is made easier, since the air-insensitive chromium(III) salt can be used.

[d] Total yield after isolation *via* three steps followed by recrystallization: 1) incorporation of the ethoxyethyl ether protecting group in *(5a)* with vinyl ethyl ether; 2) reduction; 3) cleavage of protecting group from *(5b)* with HOAc (5%).

As typical example for the synthesis of 5′- and 2′-deoxynucleosides, 2′,3′-*O*-isopropylidene-5′-deoxy-5′-iodouridine *(4a)* and 2′-deoxy-2′-bromouridine *(5a)* (protected as the 3′-5′-di-*O*-ethoxyethyl ether) were dehalogenated by indirect electrolysis (Method 2) under the conditions optimized for THP ethers *(1a)—(3a)*. The yield for the reduction step is practically quantitative. From *(5a)* a crude yield of 95% *(5b)* is obtained in three steps (see Table 1); however, only 60% crystalline *(5b)* was isolated.

Experimental

A catholyte of 10 ml DMF, 0.25 ml ethylenediamine, 0.5 ml butanethiol and 1 ml of 0.4 M aqueous solution of chromium(II) perchlorate ($\hat{=}$ 0.4 mmol Cr^{2+}) is transferred to a divided electrolytic cell (Electrolytic vessel EA 876, Metrohm) thermostated at 15 °C and furnished with a 5 mm-thick cathode of glassy carbon (2 cm^2 surface area), a Cd/Hg reference electrode[4] and a platinum mesh anode. A cylindrical glass tube sealed by a G3 glass frit can be used as anode compartment. The anode compartment and the salt bridge of the reference electrode are filled with a 0.2 M solution of $LiClO_4$ in DMF. Electrolysis is carried out at −0.9 V *vs.* Cd/Hg reference electrode. The current density is *ca.* 5 mA/cm^2. After addition of 1.8 mmol of the protected halodeoxynucleoside the current density increases to *ca.* 30 mA/cm^2. The conversion is monitored by thin-layer chromatographic analysis on silica gel F_{254}-plates (Merck) with acetone/benzene/water (60:35:5) as eluent. Conversion of substrate is complete after consumption of 3.2 mF. For workup the catholyte is adjusted to pH = 5 with 10^{-2} M $HClO_4$, extracted with chloroform (5 × 10 ml) and the combined extracts are washed with water (2 × 5 ml). The organic layer is then dried over Na_2SO_4 and the solvent removed in a rotary evaporator.

Intramolecular Cycloadditions of Carbonyl Ylides[**]

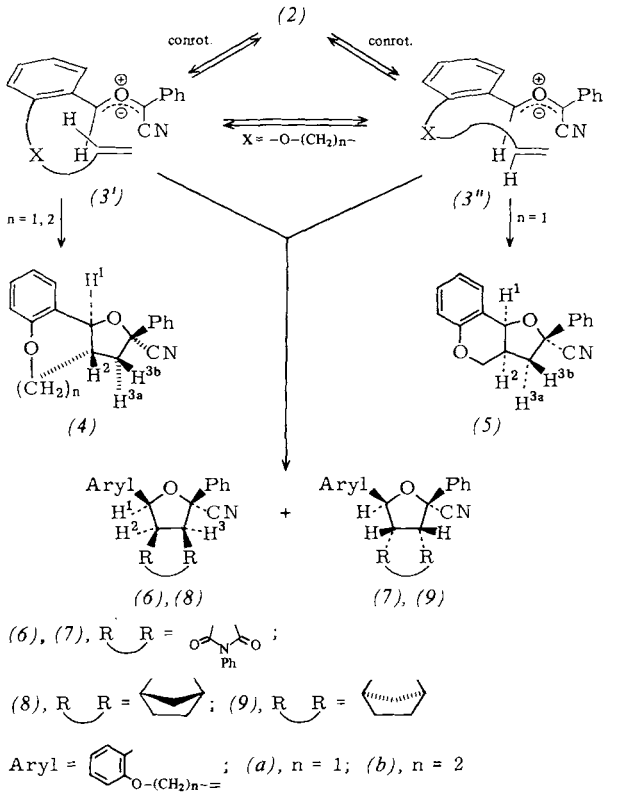
By *Wolfgang Eberbach, Jürgen Brokatzky*, and *Hans Fritz*[*]

The scope of 1,3-dipolar cycloaddition reactions for the stereoselective synthesis of heterocyclic systems has been extended considerably by the intramolecular approach[1]. However, to our knowledge, no such examples have been reported so far with the use of carbonyl ylides as dipoles[2]—except for the special case of the cyclization of 2-oxapentadienyl dipoles to 2,3-dihydrofurans[3]. We have investigated this type of reaction with two derivatives of a model system and report here on intramolecular trapping of the carbonyl ylides *(3a)* and *(3b)* and on their relative reactivity in the presence of external dipolarophiles.

(1)

(a), n = 1; *(b)*, n = 2 *(2)*

As educts we used the trisubstituted oxiranes *(2a)* and *(2b)*, which were obtained sterically pure by Darzens condensation of the alkenyl ethers *(1)*, the latter in turn being readily accessible from salicylaldehyde [*(2a)*: m.p. 52 °C (methanol); UV (ethanol): λ_{max} (ε) = 282 (4200), 274 (3860, sh), 234 (12400, sh), 217 nm (19200, sh); ^{1}H-NMR ($CDCl_3$): δ = 4.44 (oxirane-H); *(2b)*: m.p. 38—39 °C (methanol); UV (ethanol); λ_{max} (ε) = 282 (4260), 274 (3760, sh), 231 (11900, sh), 217 nm (19850, sh); ^{1}H-NMR ($CDCl_3$): δ = 4.41 (oxirane-H)][4].



On heating in bromobenzene or isooctane, the ene-oxirane *(2a)* slowly isomerized above *ca.* 170 °C[5] to the intramolecular cycloadducts *(4a)* and *(5)*, which were isolated as a crystalline 2:1 mixture after thin-layer chromatography [yield after 9 h at 175 °C (40% conversion) 75%][6]. Under the same conditions the homologue *(2b)* gave only the *trans*-diastereomer *(4b)* (yield 66% at 30% conversion)[6].

Evidence for the ring fusion as indicated in *(4)* and *(5)*[4] is provided principally by the NMR coupling constants between H^1 and H^2 (Table 1), which are consistent with the dihedral angles of *ca.* 180° in *(4)* and 40° in *(5)*.

The formation of *(4)* and *(5)* is most likely initiated by a conrotatory opening of the oxirane ring[7] to carbonyl ylides of type *(3)*. Depending on the conformation of the alkenyloxy group, addition to the C=C-group then leads to the *trans*- *(4)* or to the *cis*-annelated ring system *(5)*. Consideration of models shows—in agreement with the preferred and

exclusive formation, respectively, of *trans*-products—that the transition state *via (3')* leading to *(4)* is energetically more favorable than that *via (3")* to *(5)*. However, despite the entropic advantage of intramolecularity, this cycloaddition step is not especially favored, either electronically or sterically, as shown by the following experiments: 1) With *N*-phenylmaleimide, which externally is a particularly powerful dipolarophile owing to the electron deficient C=C-bond[8], *(2a)* and *(2b)* react almost quantitatively even at 120 °C, giving in each case a *ca.* 3:1 mixture of the bimolecular adducts *(6a)/(7a)* and *(6b)/(7b)*, respectively [14 h, yields *ca.* 90%, ^{1}H-NMR data in Table 1; *(6a)* was isolated pure by fractional crystallization from methanol (m.p. 169 °C[4])]; *i.e.* the oxirane ring apparently is opened already at a temperature which is too low for the formation of *(4)* and/or *(5)*[9]. 2) The reaction of *(2a)* and *(2b)* with norbornene as electron-rich dipolarophile is also more rapid than the intramolecular addition: Whereas *(2a)* or *(2b)* upon heating with a fivefold excess of norbornene (in bromobenzene, 180 °C, 12 h, *ca.* 90% conversion) gave rise to the formation of *(4)/(5)* as well as *(8)/(9)* [1.5:1 for *(2a)*, 3:1 for *(2b)*], the reaction carried out in norbornene as solvent afforded *(8)* and *(9)* as the sole products (ratio 3:1; yield of isolated mixtures 50—60%; ^{1}H-NMR data in Table 1). Our investigations have shown that carbonyl ylides are indeed capable of undergoing intramolecular cycloadditions with a C=C-bond. By modifying the educts (*e.g.* incorporating electron-withdrawing groups in the ene unit) the activation barrier of this reaction might be lowered considerably.

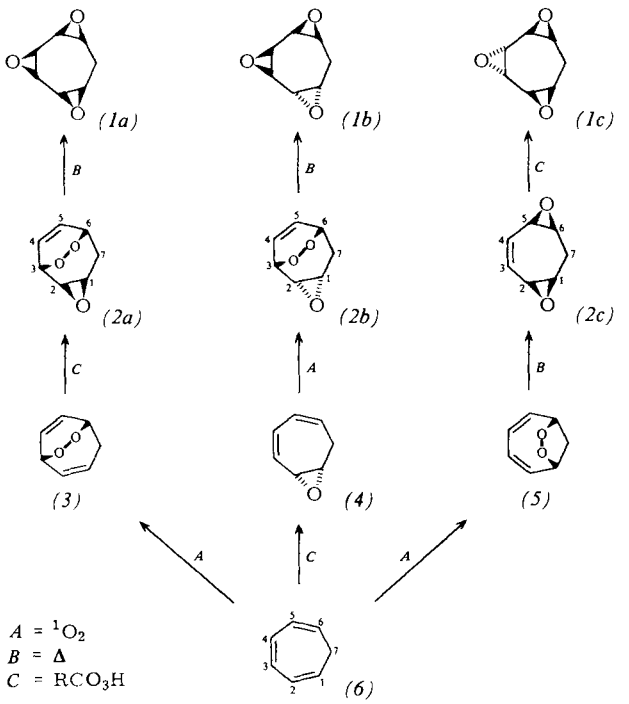
Stereospecific Syntheses of Cycloheptatriene Trioxides[**]



By *Waldemar Adam* and *Metin Balci*[*]

Three stereoisomers are possible for the trioxides of 1,3,5-cycloheptatriene, namely the *syn,syn- (1a)*, the *syn,anti- (1b)*, and the *anti,anti* structures *(1c)*. The thermal or photochemical formation of *syn*-dioxides from endoperoxides, which are readily available through singlet oxygenation of conjugated dienes, should serve as a convenient and effective synthetic approach for the stereospecific design of such complex molecules[1]. Scheme 1 illustrates how 1,3,5-cycloheptatriene *(6)* can be transformed into each one of the trioxides *(1a—c)* by judicious choice of the sequence of singlet oxygenation (step *A*), endoperoxide-dioxide rearrangement (step *B*), and peracid epoxidation (step *C*). To the best of our knowledge, such permutation of these reaction steps has not been utilized before for the stereospecific synthesis of polyoxides.

syn,syn-Trioxide (1a) (sequence A, C, B): Treatment of the [2+4]-endoperoxide *(3)*, readily obtained by singlet oxygenation of *(6)*[2], with *m*-chloroperbenzoic acid in CH_2Cl_2 at 40 °C afforded the *syn*-oxide *(2a)* as the major product (35% yield); it was isolated by chromatography (silica gel/CH_2Cl_2) as colorless plates, m.p. 101—103 °C (n-C_5H_{12}/CH_2Cl_2). Inspection of Dreiding models of the [2+4]-endoperoxides suggests that peracid approach is least encumbered from the *syn* side of the C_3 bridge.

Table 1. ^{1}H-NMR data of compounds *(1a—c)* and *(2a—c)* (TMS standard).

(1a) ($CDCl_3$): δ = 1.7—2.1 (m, 1 H, *endo*-H^7), 2.4—2.8 (m, 1 H, *exo*-H^7), 2.9—3.6 (m, 6 H)
(1b) ($CDCl_3$): δ = 1.6—2.0 (m, 1 H, *endo*-H^7), 2.4—3.4 (m, 7 H)
(1c) (CCl_4): δ = 0.7—1.25 (m, 1 H, *endo*-H^7), 2.45—3.25 (m, 7 H)
(2a) ($CDCl_3$): δ = 2.06 (ddd, 1 H, *endo*-H^7), 2.7 (dd, 1 H, *exo*-H^7), 3.1 (t, 1 H, H^1), 3.35 (t, 1 H, H^2), 4.5—4.8 (m, 1 H, H^6), 4.8—5.1 (m, 1 H, H^3), 6.3—6.8 (m, 2 H, $H^{4,5}$); J_{12} = 4.0, J_{23} = 4.3, $J_{67(exo)}$ = 3.6, $J_{17(endo)}$ = 5.5, $J_{67(endo)}$ = 3.4, J_{77} = 16.7, $J_{17(exo)} \approx 0$ Hz
(2b) ($CDCl_3$): δ = 2.2—2.4 (m, 2 H, H^7), 3.0—3.4 (m, 2 H, $H^{1,2}$), 4.2—4.5 (m, 1 H, H^6), 4.8—5.2 (m, 1 H, H^3), 5.8—6.4 (m, 2 H, $H^{4,5}$)
(2c) (CCl_4): δ = 1.0—1.4 (m, 1 H, *endo*-H^7), 2.3—2.8 (m, 1 H, *exo*-H^7), 3.0—3.3 (m, 4 H, $H^{1,2,5,6}$), 5.65 (s, 2 H, $H^{3,4}$)

Table 2. ^{13}C-NMR data of the isomeric cycloheptatriene trioxide *(1a—c)*.

Trioxide [a]	δ values ($CDCl_3$) [b]						
	C^1	C^2	C^3	C^4	C^5	C^6	C^7
(1a)	52.61	53.11	50.56	50.56	53.11	52.61	28.19
(1b)	1.39	53.19	50.35	50.39	52.83	50.70	27.36
(1c)	51.86	52.29	50.61	50.61	52.29	51.86	32.25

[a] We are grateful to Dr. *Obenauf* (JEOL Company, New Jersey) for the spectra of *(1a)* and *(1b)* and to Dr. *D. Scheutzow* (Würzburg, Germany) for that of *(1c)*; [b] The numbering of the C atoms is based on cycloheptatriene *(6)*.

On heating (190 °C in toluene, 1 h, sealed tube), *(2a)* rearranges to *(1a)* in 32% yield, colorless plates, m.p. 159—162 °C (m.p. 165 °C[3]). This trioxide isomer *(1a)*, the only one of the three possible isomers hitherto isolated, purified, and characterized (X-ray analysis), was prepared by *Prinzbach* and *Rücker*[3] *via* a classical sequence starting from cycloheptatriene oxide. Its ^{13}C-NMR spectrum shows four distinct carbon resonances, which can only be reconciled with a symmetrical structure.

syn,anti-Trioxide (1b) (sequence *C, A, B*): Photo-oxygenation of cycloheptatriene oxide *(4)*, readily available by peracetic acid epoxidation of *(6)*[4], in CCl_4 at 0 °C with tetraphenylporphyrin as sensitizer (see ref. [2a]) gave the endoperoxide *(2b)* in 68% yield after chromatography (silica gel/CH_2Cl_2) as colorless needles, m.p. 125—127 °C. On heating (190 °C in toluene, 1 h, sealed tube), *(2b)* gave *(1b)* in 44% yield after chromatography (silica gel/1:1 $CHCl_3$/*n*-C_5H_{12}) as colorless plates, m.p. 66—67 °C (1:2 CH_2Cl_2/ether). The ^{13}C-NMR spectrum reveals seven distinct carbon atoms, which is only consistent with the unsymmetrical structure *(1b)*.

anti,anti-Trioxide (1c) (sequence *A, B, C*): The [2+6]-endoperoxide *(5)*, obtained alongside *(3)* on photo-oxygenation of *(6)*[2a], served as starting point for the preparation of *(1c)*. On thermolysis, but more conveniently on photolysis at λ = 350 nm in benzene, the *syn*-dioxide *(2c)* was obtained in 57% yield after chromatography (silica gel/$CHCl_3$), colorless needles, m.p. 55—56 °C (2:1 *n*-hexane/ether). Inspection of Dreiding models suggested that peracid epoxidation should take place preferentially *anti* to the existing epoxide rings because *syn* approach appears to be blocked by the *endo*-methylenic hydrogen. Indeed, after treatment of *(2c)* with *m*-chloroperbenzoic acid (CH_2Cl_2, 3 d) *(1c)* was isolated in 31% yield as colorless plates, m.p. 100—102 °C (1:2 CH_2Cl_2/*n*-C_5H_{12}). The ^{13}C-NMR spectrum reveals four distinct carbon resonances, as expected for the symmetrical structure *(1c)*.

Cyclopropanimines by Photolysis of Pyrazolinimines; Thermal Reaction of an Excited State[**]

By *Helmut Quast, Andreas Fuss,* and *Alfred Heublein*[*]

Photochemical elimination of nitrogen from 1,4-dialkyltetrazolines *(1a)—(1c)* yields diaziridinones *(2a)*, diaziridinimines *(2b)*, *(3b)*, and aziridinimines *(3c)*, while elimination from *(1d)* gives carbodiimides and sulfur[1]. Matrix photolysis of the tetrazolinimines *(1b)* at 80 K has been shown by ESR spectroscopy to generate triplet trisiminomethanes *(4)*[2].

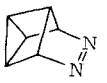
[a] Cf. [8]. [b] Only identified by ^{1}H-NMR spectroscopy.

Depending on the reaction conditions, methylenecyclopropanes or trimethylenemethanes and their consecutive products are obtained on photolysis of 4-alkylidene-1-pyrazolines[3] such as *(5c)*[4a,b]. In contrast, the pyrazolinone *(5a)* *resisted* photochemical conversion into *(6a)*[4c]. We have now prepared the cyclopropanimines *(6e)*—*(6g)* by irradiation of the pyrazolinimines *(5e)*—*(5g)* at elevated temperature.

The reactants *(5e)*—*(5g)* were obtained by prolonged heating of the pyrazolinone *(5a)*[4a,c] with the relevant primary alkylamine without solvent in an autoclave in the presence of a molecular sieve and an acidic SiO_2/Al_2O_3 catalyst (BASF catalyst D10-10)[5] [*(5e)*, 90 h, 110 °C, yield 53%; *(5f)*, 114 h, 150 °C, yield 85%; *(5g)*, 95 h, 150 °C, yield 70% (Table 1)].

The fluorescence of *(5e)*—*(5g)* indicated the necessity of modifying the conventional photolysis conditions for efficient loss of nitrogen[6]. Irradiation of *(5f)* in [D_6]benzene at 90 °C with light of wavelength exceeding 340 nm[7] produces 68% of cyclopropanimine *(6f)* within 2 h. The cyclopropanimine structure of the principal product *(6f)* is deduced from its IR and ^{1}H-NMR spectrum (Table 1) and its fast, quantitative decomposition to 2,2-dimethylpropyl isocyanide *(8)* and 2,3-dimethylbutene *(9)* on irradiation of the photolysis product in [D_6]benzene *without* filter (2 h, 5 °C). The smooth photochemical cleavage into isocyanide and alkene under these conditions is typical of cyclopropanimines, as we have demonstrated with an authentic cyclopropanimine, *viz.* 2-*tert*-butylcyclopropylidene-*tert*-butylamine[8].

(a), X = O; *(c)*, X = CR_2; *(e)*, X = N–CH_3;
(f), X = N–CH_2–$C(CH_3)_3$; *(g)*, X = N–cC_6H_{11}



The second photolysis product could be identified as pyrazolidinimine *(7f)* by comparison with an authentic sample prepared from the pyrazolidinone *(7a)*[4a,c] and 2,2-dimethylpropylamine. Moreover, the decomposition products of *(6f)*, *i.e.* the isocyanide *(8)* and the alkene *(9)*, were also detectable in small amounts (Table 2).

The rate and course of photolysis of *(5f)* are surprisingly dependent upon the temperature, but hardly dependent upon solvent in all cases examined so far (Table 2). The much greater amount of *(7f)* formed in [D_{12}]cyclohexane, as compared with [D_6]benzene, suggests H abstraction from the solvent; however, the reason may also lie in formation of degradation products eluding detection by ^{1}H-NMR spectroscopy (polymers?), since the mass balance was only 80—90% after prolonged irradiation. The situation may resemble that encountered with the tetracyclic azo compound *(10)*: S_1 *(10)* gives $(CH)_6$ isomers by thermally activated nitrogen elimination while T_1 *(10)* rearranges to 1,2-diaza-2,4,6,8-cyclooctatetraene regardless of temperature and solvent[9]. Compounds *(5e)* and *(5g)* behave similarly to *(5f)*.

Table 2. Product ratio and mass balance (determined by ^{1}H-NMR spectroscopy (90 MHz)) on photolysis of pyrazolinimine *(5f)* in [D_6]benzene and [D_{12}]cyclohexane at 5 and 90 °C.

Short-Path Pyrolysis: Silabenzene[**]

By *Bahman Solouki, Pavel Rosmus, Hans Bock,* and *Günther Maier*[*]

Photoelectron spectroscopy has proved to be of immense value as a probe in flow systems for the analysis and optimization of gas phase reactions[1,2]. Thus it is possible to determine the decomposition temperature[3a], to improve the yield[3b], and to characterize the products[3c] of a pyrolysis reaction in a single experiment. However, unstable species with a mean lifetime below about 1 s can only be observed[4] if the distance between the heating and measuring zones [some 30 cm on use of an external furnace[2]] is drastically reduced (Fig. 1).

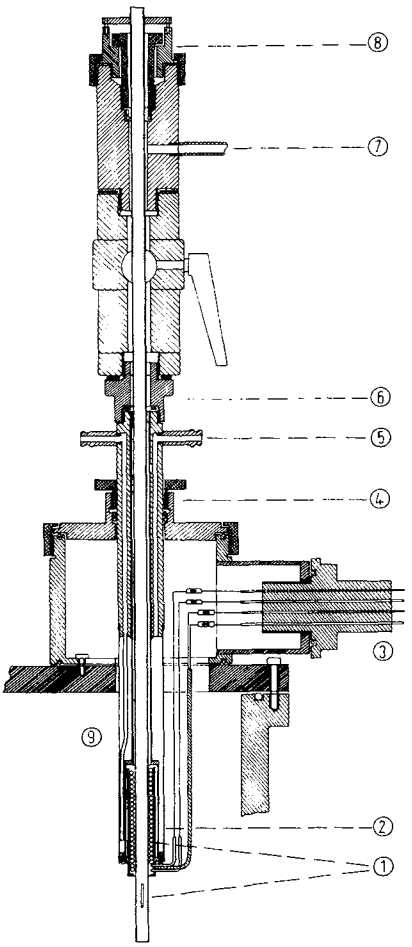

Fig. 1. Newly developed short-path pyrolysis set-up for a Perkin Elmer PS 16 PE spectrometer, designed by *B. Solouki* and built in the mechanical workshops of the Universities of Frankfurt and Mainz. Key: ① furnace of variable length with a high-output miniature heating element (stainless steel jacket, nickel-chromium core) at variable distance above the entry slit of analyzer; ② water cooling jacket for removal of furnace heat (max. temp. 1300 K); ③ current leads (up to 4 A/30 V) for furnace and thermoelement; ④ locking nut for sliding furnace with separate sliding internal tube; ⑤ supply and removal of water; ⑥ centering device; ⑦ vacuum pump connection with stopcock for change of inner tube; ⑧ adjusting device for inner tube; ⑨ PES target chamber. Overall height of apparatus 0.5 m.

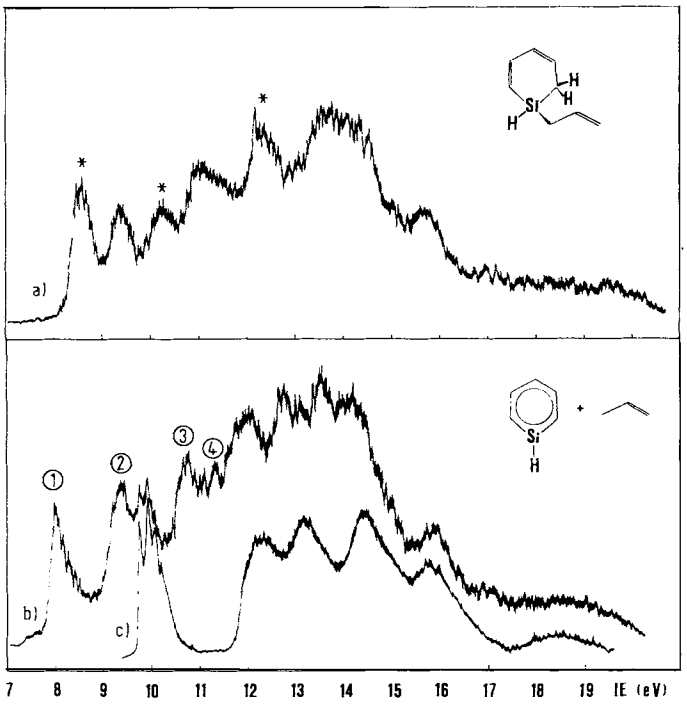
During development of the short-path pyrolysis set-up (Fig. 1), a special difficulty encountered was the accommodation of the furnace and the cooling zone in the existing cylindrical jacket of only 7 mm internal diameter. It was first used for elimination of propene[5] from the 1-allyl-1-sila-2,4-cyclohexadiene derivatives *(1a)* and *(1b)* to form silatoluene *(2a)*[6a,b] and silabenzene *(2b)*[6c] (see Fig. 2).



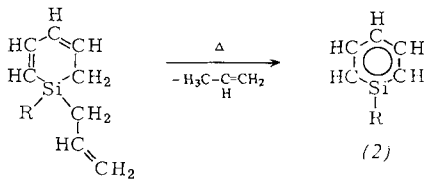


Fig. 2. He(I) PE spectra of (a) 1-alkyl-1-sila-2,4-cyclohexadiene *(1b)*, (b) of the pyrolysis mixture at 1000 K furnace temperature, and (c) of propene. Disappearing reactant bands are marked by an asterisk; the spectrum of the pyrolysis mixture (b) is assigned to silabenzene *(2b)* on the basis of a Koopmans' correlation $IE_n/-\varepsilon_j^{SCF}$ ① $\tilde{X}(^2B_1)$; ② $\tilde{A}(^2A_2)$; ③ $\tilde{B}(^2B_2)$; ④ $\tilde{C}(^2B_1)$.

Assignment of the short-path pyrolysis PE spectrum to silabenzene *(2b)* is supported by SCF calculations[7] and can be explained with the aid of perturbation arguments[8]: in the series of heterobenzene derivatives $(HC)_5X$, the perturbation X = SiH corresponds roughly to that of X = Sb, and, therefore, π-ionization energies $IE_1 \approx 8.2$, $IE_2 \approx 9.2$, and $IE_4 \approx 11.5$

(1) *(2)*

(a), R = CH_3; *(b)*, R = H

eV are expected—in satisfactory agreement with the experimental values of 8.0, 9.3, and 11.3 eV, respectively. The additional methyl-perturbation for silatoluene[6a], which lowers IE_1 to 7.7 eV and leaves IE_2 almost unchanged at 9.2 eV, is in full accord with prediction, as is the UV spectrum recorded in an argon matrix (see ref. [6c]) which is expected to correspond in its features to that of unperturbed benzene[9].

Silabenzene[**]

By *Günther Maier, Gerhard Mihm,* and *Hans Peter Reisenauer*[*]

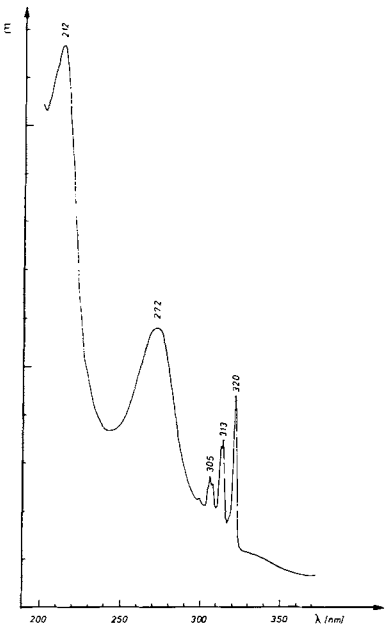
If it is true that silabenzene is characterized by a considerable delocalization energy[1a] and previous attempts at its synthesis[2] were merely thwarted by the pronounced reactivity of the polar C=Si double bond, then the molecule should be isolable in a matrix at low temperature. We now report the experimental realization of this concept[3,4].

Starting from 1,1-dichloro-1-sila-2,4-cyclohexadiene *(2a)*[5a,b] [accessible in 25% yield by copyrolysis of the dimer of cyclopentadiene *(1)* with hexachlorodisilane[5c] at 540 °C (together with 5—10% of *(3a)*[1b])], reduction with $LiAlH_4$ in ether at room temperature afforded the dihydro derivative *(2b)*[5c,d] (80%; b.p. 97 °C). Reaction of *(2b)* with phosphorus pentachloride[6] in carbon tetrachloride at 0 °C leads to the monofunctionalized silacyclohexadiene *(2c)* (55%; b.p. 62 °C/40 torr)[7]. Treatment with sodium acetate (ether, 12 h, 20 °C) affords the monoacetate *(2d)* (80%; b.p. 50 °C/0.3 torr) while treatment with allylmagnesium bromide (ether, 90 min reflux) gives the even more promising[4,8] silabenzene precursor *(2e)* (75%; b.p. 90 °C/75 torr)[9].

(1) *(2)* *(3)*

(a), X = Y = Cl; *(b)*, X = Y = H; *(c)*, X = H, Y = Cl; *(d)*, X = H, Y = O–CO–CH_3; *(e)*, X = H, Y = CH_2–CH=CH_2

Apart from the molecular peaks, the mass spectra of *(2d)* and *(2e)* show an intense signal at the mass number of silabenzene ($m/e=94$). If *(2e)* is pyrolyzed immediately in front of the inlet of the mass spectrometer, characteristic changes are seen in the spectrum. At 500 °C the mass peaks at $m/e=136$ [*(2e)*], 95 [*(2e)*-allyl], and 94 [*(4)*] diminish, and that at 42 (propene) increases in intensity. This suggests that the desired elimination of propene starts under these conditions.



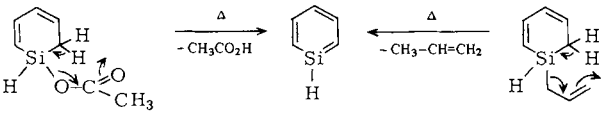


Fig. 1. UV spectrum of silabenzene *(4)* in argon at 10 K [pyrolysis of *(2d)* or *(2e)*; extinction coefficients cannot be given for methodological reasons].

With this in mind we subjected *(2d)* and *(2e)* to flash pyrolysis[10] and condensed the products with argon onto a window at 10 K. The UV spectrum of the pyrolyzate has the habit expected for a π-perturbed benzene. The three bands at $\lambda=212$, 272, and 320 nm fit into the series of bathochromic shifts observed[2,11] with other donor-substituted heterobenzenes. The absorptions are no longer visible after even brief irradiation[12].

(2d) *(4)* *(2e)*

Monitoring of the thermolysis of *(2e)* by IR spectroscopy is no less instructive. The IR spectrum of the matrix-isolated products exhibits bands at $\tilde{\nu}=418$, 566, 598, 886, 1259, 1353, 1500, 1526, and 2217 cm^{-1}, in addition to the characteristic bands of propene. We assign them to silabenzene *(4)* because they disappear both on irradiation in argon at 10 K[12] and on thawing of the matrix[13]. The Si—H stretching vibration of *(4)* lies at 2217 cm^{-1}, *i.e.* between that of a hydrogen atom attached to an sp^3-hybridized silicon atom [*(2b)* and *(2e)*: 2140 cm^{-1}] and that calculated for silaethene (2480 cm^{-1})[14].

These observations, together with the results of PE studies[3], show that ester pyrolysis of *(2d)* and the retro-ene cleavage of *(2e)* lead to the long-sought silabenzene *(4)*. This molecule is stable in an argon matrix at extremely low temperature.

Crystal Structure of 2-Lithio-2-methyl-1,3-dithiane · Tetramethylethylenediamine

By *René Amstutz, Dieter Seebach, Paul Seiler, Bernd Schweizer*, and *Jack D. Dunitz*[*]

The paucity of reliable information on the structure of α-heterosubstituted organolithium compounds contrasts with the wealth of experience concerning their reactivity[1]. From experiments with 4,6-disubstituted derivatives, structure *(1)* with equatorial lithium has been proposed[2a] for lithiodithianes[3]. This proposal is consistent with an n(C)-σ*(S–C) hyperconjugative interaction[2b] (anomeric effect). We now report that crystal structure analysis of the *N,N,N',N'*-tetramethylethylenediamine (TMEDA) complex of 2-lithio-2-methyl-1,3-dithiane[4] leads to a *dimeric*[5a] structure *(2)* in which pairs of dithiane molecules are doubly bridged by Li atoms in equatorial positions.

(1) *(2)* *(3)*

Crystalline *(2)* was obtained by allowing a solution of 2-methyl-1,3-dithiane and TMEDA (each 3.7×10^{-2} molar) in hexane/cyclohexane (1:1), to which an equivalent amount of butyllithium (1.6 molar in hexane) had been added at −30 °C, to stand for several days at −20 °C. A single crystal was coated with tetradecane as adhesive and inserted into a 0.3-mm diameter capillary. All operations were carried out under nitrogen. X-ray measurements (3406 independent reflections) were made at −150 °C. The analysis (R = 0.028, with isotropic hydrogens, other atoms anisotropic) leads to the structure shown in Figure 1; Table 1 gives bond lengths and angles.

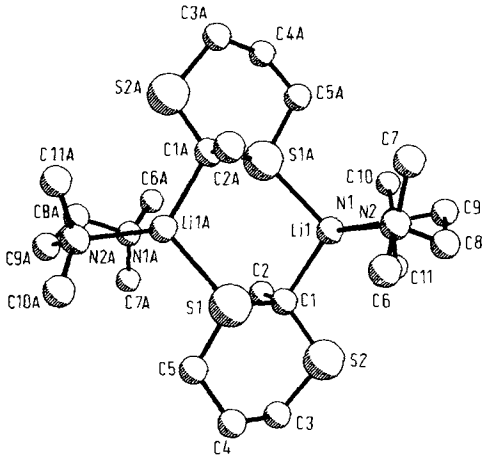

Fig. 1. Structure of the dimer *(2)* with H-atoms excluded (PLUTO program, Cambridge Crystallographic Data Centre); see Table 1.

Table 1. Structural data for complex *(2)*. Bond lengths [pm, σ ≤ 0.5 pm], bond angles [deg, σ ≤ 0.1°]. Space group $P2_1/n$; Z = 2, a = 976.0, b = 1379.6, c = 1109.7 pm; β = 88.64°. The measurements were carried out with an automated Enraf-Nonius CAD4 diffractometer equipped with a graphite monochrometer ($Mo_{K\alpha}$ radiation) and a cooling device.

The centrosymmetric dimer can be concisely described as having a *trans-trans*-perhydroanthracene type skeleton with spiro junctions at the Li atoms. The dimensions of the dithiane rings and of the five-membered chelate rings are similar to those in non-metalated dithianes[4] and TMEDA-Li derivatives[5b], respectively. The new feature is the central six-membered ring. The difference of 33 pm between the Li···C and Li···S distances is practically the same as the difference between the covalent single-bond radii of carbon and sulfur (27 pm). Furthermore, the Li–C and Li–S vectors both lie in tetrahedral directions with respect to the two

atoms[6]. This lithium atom thus interacts about equally strongly with the carbanionoid carbon of the one ring and a sulfur of the other so that it is hardly possible to decide between the alternative descriptions of the complex as a dimer of the C–Li monomer *(1)* or of the S–Li monomer *(3)*. Although the equatorial position of the lithium in this type of compound has been interpreted as a consequence of the anomeric effect[2], the structure of the complex shows that steric factors are probably at least as important. Since the methyl group is the smallest of the three substituents on the dithiane ring, it can be expected to adopt the axial position[7]. This type of structure may well be preserved in THF solutions of lithiodithianes where the oxygen atoms of the solvent molecules can take over the role of the TMEDA nitrogen atoms.

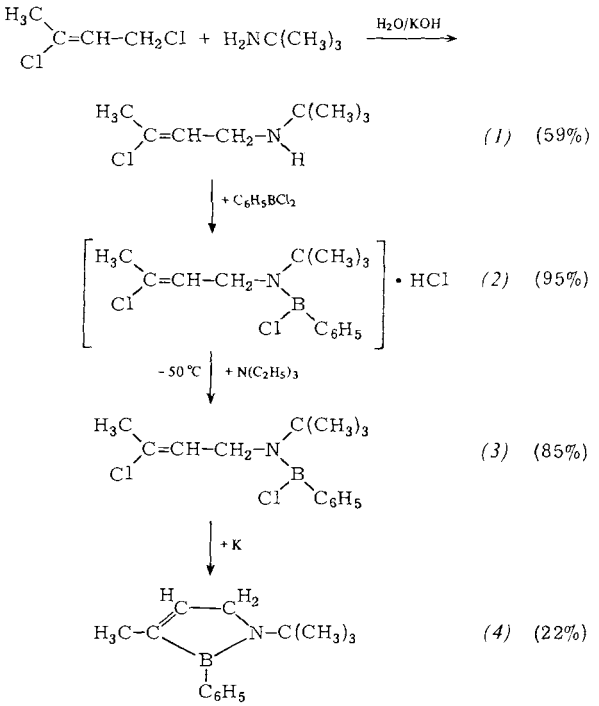
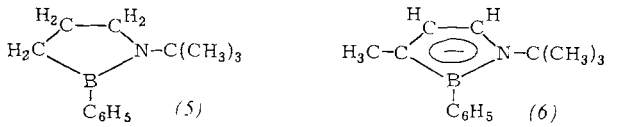
Preparation of 1-*tert*-Butyl-3-methyl-2-phenyl-Δ^3-1,2-azaboroline and Utilization of Its Anion as a Complex Ligand Analogous to Cyclopentadienyl



By *Joachim Schulze* and *Günter Schmid*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

1,2-Azaborolines derive from cyclopentadiene by replacement of a C=C moiety by a BN group. We have now synthesized the first 1,2-azaboroline, the title compound *(4)*.

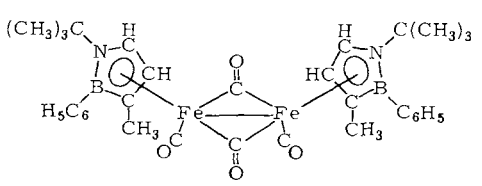


Reaction of 1,3-dichloro-2-butene with *tert*-butylamine leads to *(1)*, b.p. 61—63 °C/15—20 torr, which affords the aminoborane *(3)*, b.p. 103 °C/1 torr, *via* the hydrochloride *(2)* with phenylboron dichloride in light petroleum. In boiling dioxane, *(3)* can be dehalogenated and cyclized to 1,2-azaboroline in 22% yield by potassium. One reason for the relatively low yield is the reaction of *(4)* with potassium to give a solid product which is still being investigated. Moreover, it is not known how large the *trans* component is of 1,3-dichlorobutene[1] and of *(1)*, *(2)*, and *(3)*. Compound *(4)* is a colorless liquid of b.p. 52—53 °C/1 torr; it is soluble in inert organic solvents but somewhat sensitive to moisture.

In addition to the molecular peak at $m/e = 213$, the mass spectrum of *(4)* contains readily characterizable fragments formed by ligand elimination: $m/e = 198$ $(M-CH_3)^+$, 156 $(M-C(CH_3)_3)^+$, 136 $(M-C_6H_5)^+$. The C=C stretching mode appears at 1610 cm^{-1} in the IR spectrum and is thus

(1) (59%) *(2)* (95%) *(3)* (85%) *(4)* (22%)

shifted by 60 cm^{-1} towards longer wavelengths relative to that in the open-chain aminoborane *(3)*. The ^{1}H-NMR spectrum of *(4)* (int. TMS in $CDCl_3$) shows five signals in the intensity ratio 9:3:2:1:5 at $\delta = 1.20$ (s, $C(CH_3)_3$), 1.61 (m, CH_3), 3.84 (m, CH_2), 6.55 (m, CH), and 7.22 (br. s, C_6H_5). The ^{11}B-NMR signal lies at $\delta = 41$ (ext. $BF_3 \cdot O(C_2H_5)_2$). Transition from the unsaturated *(4)* to the saturated *(5)*[2] ($\delta = 46$) is accompanied by a significant downfield shift. The boron atom in *(4)* is better shielded by the stronger delocalization of the π-electrons.



(5) *(6)*

Attempts to prepare an alkali metal salt of the anion *(6)* derived from *(4)* have so far remained unsuccessful. In contrast, the utilization of *(6)* as ligand in complex *(7)* succeeded. Compound *(7)* is formed in analogy to the known cyclopentadienyl complex $[(C_5H_5)Fe(CO)_2]_2$[3] from $Fe(CO)_5$ and *(4)*. The ν(CO) frequencies of *(7)* in solution essentially correspond in number and intensity to those of the dissolved cyclopentadienyl complex: 2000 sh (2054 w)[4], 1980 vs (2005 vs), 1938 s (1958 vs), 1758 vs (1786 s) cm^{-1} (in CH_2Cl_2 and $CHCl_3$); ^{1}H-NMR: five signals in the intensity ratio 9:3:1:1:5 at $\delta = 1.35$ (s, $C(CH_3)_3$), 1.90 (s, CH_3), 4.90 (br. s, CH), 5.45 (d, CH), 7.35—7.70 (m, C_6H_5); ^{11}B-NMR (int. TMS in [D$_8$]THF) $\delta = 22 \pm 1$. A strong upfield shift of the ^{11}B signal expectedly attends the transition from *(4)* to the complex-bonded species *(6)*.

The X-ray structure analysis of *cis-(7)* shows that *(6)* is η^5-bonded, as expected[5].

The crude product appears to contain the *trans* compound too.

(7)

[*] Prof. Dr. G. Schmid, Dipl.-Chem. J. Schulze
Fachbereich Chemie der Universität Essen—GHS
Universitätsstrasse 5—7, D-4300 Essen 1 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0101-0054 $ 02.50/0

Procedure

(4): $CH_3(Cl)C{=}CH{-}CH_2Cl$ (12.5 g, 0.1 mol) is added dropwise to an ice-cooled solution of *tert*-butylamine (37.0 g, 0.5 mol). After reaction for 1 h at the boiling point, a solution of KOH (16.8 g, 0.3 mol) in H_2O (100 ml) is added slowly to the cooled mixture. The organic phase is separated off, the aqueous phase is extracted three times with ether, and the organic phases are dried over $CaCl_2$. Compound *(1)* (9.5 g, 59%) distills over at 61—63 °C/15—20 torr. All further operations are carried out under N_2 in anhydrous solvents. Compound *(1)* (9.4 g, 58.2 mmol) is dissolved in light petroleum (50 ml) and added dropwise at −30 °C to a solution of $C_6H_5BCl_2$ (9.3 g, 58.6 mmol) in light petroleum (400 ml). Stirring is continued for 1 h and the product *(2)* (17.7 g, 95%) is filtered off. Compound *(2)* is added to light petroleum (500 ml); a solution of $N(C_2H_5)_3$ (5.92 g, 58.6 mmol) in light petroleum is then added dropwise at −50 °C. After reaction for 12 h at room temperature, the mixture is heated to boiling for 1 h, filtered, and the filtrate subjected to fractional distillation; 13.2 g (85%) of *(3)* are obtained at 103 °C (1 torr). Compound *(3)* (36.5 g, 128.6 mmol; prepared in several batches) is dissolved in dioxane *(1l)* and treated with pieces of potassium (8.0 g, 204.4 mmol). The mixture is refluxed for 1 h, and the cooled solution filtered and fractionally distilled to give 6.0 g of *(4)* (22%)[6].

(7): Compound *(4)* (0.8 g, 3.75 mmol) is dissolved in $Fe(CO)_5$ (20 ml) and heated to boiling for 10 h. All volatile components are removed *in vacuo* and the residue is washed with ether (10 ml). It is then taken up in tetrahydrofuran, filtered, evaporated down to 5 ml and light petroleum is slowly added. Compound *(7)* precipitates as reddish-brown crystallites. Precipitation is brought to completion by cooling to 0 °C. The precipitate is separated, recrystallized from CH_2Cl_2, and dried *in vacuo*; yield 0.72 g (56%), dec. above 150 °C.

Synthesis and Properties of the First Organosilyl-Gallium Compounds[**]

By *Lutz Rösch* and *Heinrich Neumann*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Tris(trimethylsilyl) derivatives are known for all Group IIIB metals except gallium, for which not a single organosilyl compound has yet been reported. We have now succeeded in synthesizing lithium tetrakis(trimethylsilyl)gallate and tris(trimethylsilyl)gallium.

Lithium tetrakis(trimethylsilyl)gallate *(1)* coordinated with diethyl ether arises formally according to eq. (a) at room temperature.

$$5\,Li + 4\,Me_3SiCl + Ga \xrightarrow[-4\,LiCl]{Hg/Et_2O;\ 14d} \underset{(1)\cdot x\,Et_2O}{Li[Ga(SiMe_3)_4]\cdot x\,Et_2O} \qquad (a)$$

Heating fails to accelerate reaction, as has been observed on preparation of the analogous aluminum compound[1]; decomposition occurs instead. $(1)\cdot x\,Et_2O$ dissolves in diethyl ether and on removal of this solvent it is recovered as a colorless compound, contaminated with small amounts of LiCl, and pyrophoric in air. On vacuum sublimation, $(1)\cdot x\,Et_2O$ undergoes partial decomposition to a colorless, pentane-insoluble fraction and a yellow, pentane-soluble compound. The former product is shown by elemental analysis and spectroscopy to be $(1)\cdot 3\,Et_2O$; it closely resembles the analogous aluminum compound in its properties[1].

Cooling of the pentane solution precipitates yellow needles which ignite spontaneously on exposure to air. They contain gallium as the sole metal and afford trimethylsilane on treatment with hydrogen chloride. The ^{1}H-NMR spectrum consists of just one signal close to that of TMS. These observations indicate that solvate-free tris(trimethyl)gallium *(2)* is liberated from $(1)\cdot x\,Et_2O$ on sublimation. Elemental analysis and the mass spectrum, which exhibits the molecular ion with the calculated isotopic satellites and the signals of the expected fragmentation products, confirm the composition. In the range of expectation for Ga–Si stretching vibrations, the Raman spectrum contains two bands at 312 cm^{-1} ($\nu_s GaSi_3$) and 349 cm^{-1} ($\nu_{as} GaSi_3$); of these two bands only that at higher wavenumber also appears in the IR spectrum. This confirms the planar structure of the $GaSi_3$ group, as expected for a monomeric molecule. In this respect, *(2)* resembles the higher homologue tris(trimethylsilyl)indium, which shows a comparable vibrational spectrum[2], more closely than solvate-free tris(trimethylsilyl)aluminium, whose spectra suggest formation of associates[3].

Thermal decomposition (50 °C) gives, besides gallium, hexamethyldisilane as major product; no evidence was obtained for loss of dimethylsilanediyl, as is observed with trimethylsilylaluminum compounds[4]. Attempts to prepare *(2)* from gallium and bis(trimethylsilyl)mercury were unsuccessful. In contrast, good yields of the desired product are obtained according to eq. (b).

$$GaCl_3 + 6\,Li + 3\,Me_3SiCl \xrightarrow[-6\,LiCl]{THF;\ -10\,°C} \underset{(2)\cdot THF}{Ga(SiMe_3)\cdot THF} \qquad (b)$$

The adduct with tetrahydrofuran (THF) loses solvent on vacuum sublimation. The analogous reaction in diethyl ether does not give *(2)*.

Procedure

All operations are to be performed under argon and with exclusion of air and moisture.

(1)·3 Et_2O and *(2):* Short pieces of lithium wire (3.5 g), gallium (7 g), and mercury (1.5 ml) are heated with stirring for 1 h in diethyl ether (25 ml). After addition of diethyl ether (175 ml) and chlorotrimethylsilane (50 ml), the mixture is stirred at room temperature for 14 d. It is then filtered over a glass frit and the volatile components are removed at room temperature under oil-pump vacuum. The resulting colorless

Institut für Anorganische und Analytische Chemie der Technischen Universität
Strasse des 17. Juni 135, D-1000 Berlin 12 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

powder contains *(1)*·2—3 Et_2O and small amounts of LiCl (crude yield 17 g). The product is purified by sublimation at 40 °C/10^{-5} torr. A yellowish substance collects on the cold finger; it is washed with pentane until the washings are colorless. The residue is dried under oil-pump vacuum and consists of *(1)*·Et_2O; yield *ca.* 3 g, m.p. 50 °C (dec.). The yellow washings are concentrated and cooled to −78 °C. Long yellow needles of *(2)* precipitate; yield 7 g, m.p. 52 °C (dec.).

Direct synthesis of *(2)*: Small pieces of lithium wire (1.2 g) are added at −20 °C to sublimed $GaCl_3$ (5 g) dissolved in pre-cooled THF (150 ml). After dropwise addition of chlorotrimethylsilane (22 ml) with cooling, the mixture is stirred at −20 °C for 2 h and *ca.* 8 h (until disappearance of the lithium) at −10 °C. The solution is decanted off, and the volatile components removed at oil-pump vacuum. Sublimation at 50 °C/10^{-5} torr gives 4.3 g of *(2)* (yield 65%). Any gallate that has also sublimed over can be removed by recrystallization from pentane.

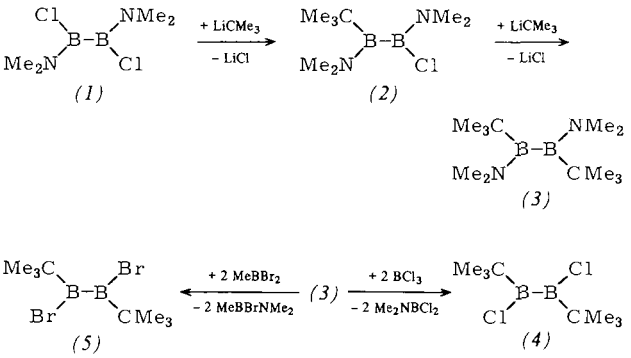
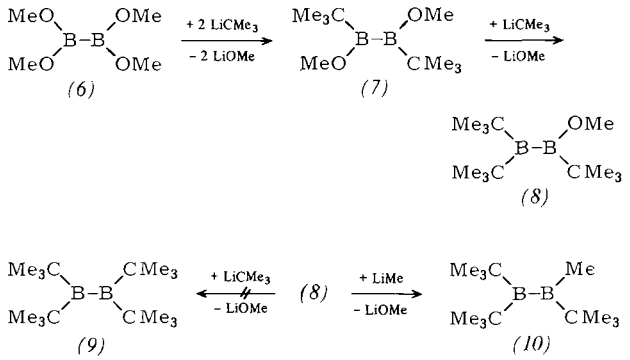
Stabilization of Diborane(4) Derivatives by *tert*-Butyl Groups: The First Tetraalkyldiborane(4)



By *Werner Biffar, Heinrich Nöth,* and *Hans Pommerening*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Increasing electronic shielding of boron in diborane(4) derivatives hinders their characteristic decomposition to BX_3 and polyboron compounds and thereby enhances their thermal stability. This is illustrated by the series $B_2Cl_4 < B_2F_4 < B_2(OR)_4 \ll B_2(NR_2)_4$. Consistent with this observation is the finding that the methyldiboranes(4) $B_2Me_{4-n}X_n$ become increasingly more unstable the greater the number of methyl groups and the weaker the π-back bonding by the group X: B_2Me_4 is unknown[1], $B_2Me_2Cl_2$[2] decomposes above −20 °C, $B_2Me_2(NMe_2)_2$[3] above 150 °C, and $B_2(NMe_2)_4$[4] survives heating for several hours at 200 °C. R_2N groups not only raise the electron density at boron by way of BN (pp)π bonds, but also hinder nucleophilic attack at that site by steric effects. This suggests that diborane(4) derivatives may be stabilized with regard to disproportionation by the highly bulky *tert*-butyl group.



tert-Butyllithium reacts with dichlorobis(dimethylamino)-diborane(4) *(1)* to give di-*tert*-butylbis(dimethylamino)diborane(4) *(3)* *via* *tert*-butylchlorobis(dimethylamino)diborane(4) *(2)*. Treatment of *(3)* with PCl_3 or BCl_3 gives the dichloride *(4)*. $MeBBr_2$ is particularly well suited for synthesis of the dibromide *(5)*. In contrast, attempts to transform *(3)* into di-*tert*-butyldifluorodiborane(4) by reaction with BF_3 were unsuccessful. Only $(Me_2NBF_2)_2$, Me_3CBF_2, and $(Me_3C)_2BF$ were isolated.

Further alkylation of *(4)* or *(5)* with $LiCMe_3$ proceeds in an unclear manner: nucleophilic attack by CMe_3^- leads not

only to alkylation but also to B B bond cleavage and to isomerization of the *tert*-butyl groups. In order to avoid the latter reaction we attempted the preparation of higher alkylated diborane(4) derivatives starting from the less acidic $B_2(OMe)_4$ *(6)*[5].

(6) reacts with $LiCMe_3$ *via* di-*tert*-butyldimethoxydiborane(4) *(7)* to give tri-*tert*-butylmethoxydiborane(4) *(8)*. Attempted conversion of *(8)* by $LiCMe_3$ into tetra-*tert*-butyldiborane(4) *(9)* failed[6]. Under forcing conditions (1 day, 80 °C) B B cleavage occurred to give, *inter alia*, $B(CMe_3)_3$[7].

However, the less bulky $LiCH_3$ reacts with compound *(8)* to form tri-*tert*-butylmethyldiborane(4) *(10)*, the first tetraalkyldiborane(4). Likewise, $LiSiMe_3$ reacts with *(8)* to give $(Me_3C)_2B$ $BCMe_3(SiMe_3)$ *(11)*, the first silylborane which is not resonance stabilized.

The thermal stability of *tert*-butyldiboranes(4) greatly exceeds that of the comparable methyl- and ethyldiboranes(4). This suggests that diboranes(4) decompose *via* intermolecu-

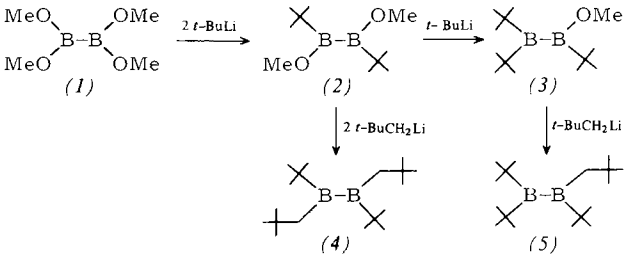
lar processes subject to steric hindrance by the bulky *tert*-butyl groups. The dichloride *(4)* decomposes more readily than *(5)*[8], while the tetraalkyl compounds *(10)* are thermally stable up to at least 50 °C, and the oxygen-stable silyl derivative *(11)* up to at least 80 °C.

Table 1 lists some characteristic data of *tert*-butyldiboranes(4). $\delta(^{11}B) = 126.9$ for the B atom in the B*B*CSi group of *(11)* is the greatest downfield shift yet observed for tervalent boron; it is only 102.0 for B*B*C_2.



Procedure

(3): A 1.57 M solution of $LiCMe_3$ in pentane (40 ml) is slowly added dropwise to a stirred solution of *(1)*[9] (5.7 g, 31 mmol). The reaction mixture is refluxed for two days, and LiCl is filtered off. Fractional distillation affords *(3)* (6.21 g, 88%) as a colorless liquid showing little sensitivity to moisture.

(10): A solution of *(8)* (1.71 g) in ether (10 ml) is cooled to −30 °C, and a 0.685 M solution of LiMe in ether (22.3 ml) is then added dropwise with stirring. The reaction mixture is warmed to room temperature and stirred for 6 h. After filtration, the ether is removed *in vacuo*; *(10)* (0.48 g, 30%) is isolated as an oxidation-sensitive liquid at b.p. 41 °C/10^{-2} torr.

Reaction of tetramethoxydiborane(4) *(1)* with two or three equivalents of *tert*-butyllithium at room temperature leads to *(2)* and *(3)*, the first diboranes(4) which contain both alkyl

and alkoxy groups. We were unable to produce tetra-*tert*-butyldiborane(4) from *(3)* and *tert*-butyllithium, either by recourse to reaction times of several days or at higher reaction temperature (50 °C). We obtained, however 1,2-di-*tert*-butyl-1,2-dineopentyldiborane(4) *(4)* and tri-*tert*-butylneopentyldiborane(4) *(5)* from neopentyllithium and *(2)* and *(3)*.

[a] δ-values, internal TMS, all peaks are singlets. [b] 9H. [c] 18H. [d] *d*-values rel. to external $BF_3 \cdot OEt_2$.

Some of the properties of the new compounds are shown in Table 1. The structure of the diboranes(4) *(2)*—*(5)* follows from the NMR data, that of *(4)* and *(5)* also from their mass spectra.

The ^{11}B-chemical shifts of *(4)* and *(5)*, *i.e.* 103 and 104 ppm, lie in the range predicted for tetramethyldiborane(4) by extrapolation[5].

The tetraalkyldiboranes(4) *(4)* and *(5)* are thermally persistent up to *ca.* 90 and *ca.* 100 °C, respectively; at 120 °C in *o*-dichlorobenzene/[D_8]toluene, *(5)* decomposes with cleavage of the B—B bond with a half-life of *ca.* 30 min into products of unknown structure.

The diboranes *(4)* and *(5)* also exhibit unusual chemical persistence: they do not react at room temperature with methanol, ammonia, hydrazine, or pyridine; the sterically well shielded *(5)* is even persistent towards oxygen.

On reduction at a cathode or with potassium, the B–B bond of *(4)* and *(5)* is readily cleaved; even at −70 °C, we could not detect the expected radical anions *(6)*, which are isoelectronic with the radical cations of correspondingly substituted ethylenes, by ESR spectroscopy. On reduction in the presence of 4-*tert*-butylpyridine, *(4)* and *(5)* give the same persistent radical which we assign structure *(7)* on the basis of its ESR coupling constants ($a^B = 2.2$ G, $a^N = 6.0$ G, $a^H = 4.4$ G for 2H and $a^C = 19.6$ G for 1C). Apparently, the

Persistent Tetraalkyldiboranes(4)[**]

By *Kaspar Schlüter* and *Armin Berndt*[*]

The only diboranes(4)[1] known so far are those in which each boron atom possesses at least one substituent with a lone pair of electrons which contributes to resonance stabilization by donation to the boron[2–4].

We have now synthesized the first tetraalkyldiboranes(4). They owe their persistence to shielding of the boron atoms by bulky groups.

radical anions *(6)* rapidly decompose to anions and radicals. The latter are trapped with pyridine to give the *N*-(dialkylboryl)pyridinyl radical *(7)*[6].

The ready reductive cleavage of tetraalkyldiboranes(4) may explain why previous attempted syntheses carried out under reducing conditions[8,9] were unsuccessful.

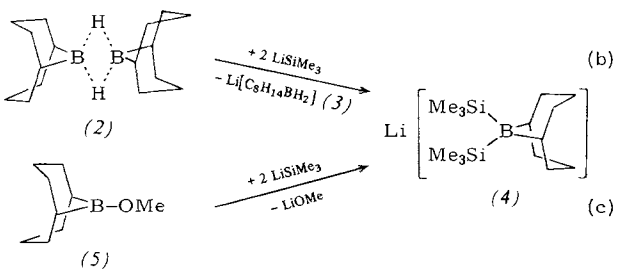
Tetrakis(trimethylsilyl)borate and Other Trimethylsilylborates



By *Werner Biffar* and *Heinrich Nöth*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

The assumption that tri-*tert*-butylborane cannot be isolated for steric reasons proved to be erroneous[1]. The Si-homologue tris(trimethylsilyl)borane should therefore also be isolable since the steric effect of the Me_3C group is greater than that of the Me_3Si group. So far, however, only silylboranes with electron-rich boron atoms[2] are known, apart from $Cl_3Si—BCl_2$[3] and $(Me_3C)_2B—BCMe_3(SiMe_3)$[4].

Our attempts to prepare $B(SiMe_3)_3$ from $LiSiMe_3$ and BX_3 did not lead to silylboranes, but instead to silylborates. No substitution occurs at the boron atom if the borane derivative BX_3 contains poor leaving groups (hydride, alkyl) or the boron atom is subject to strong steric or electronic shielding. In the latter case addition is also suppressed, *e.g.* when $LiSiMe_3$ acts upon 9-*tert*-butyl-9-BBN[5], whereas in the former case the reaction stops at the adduct stage *(1)*, as shown by quantitative reactions in hexane at 0 °C.

$$R_3B + LiSiMe_3 \longrightarrow Li[R_3B{-}SiMe_3] \quad (a)$$
$$R = CH_3,\ C_2H_5 \qquad (1)$$

(2) (b) (4) (c) (5)

LiSiMe$_3$ cleaves the hydride bridges of dimeric 9-BBN *(2)* asymmetrically[6], resulting in a 1:1 mixture of lithium dihydrido-9-boratabicyclononane *(3)* and lithium bis(trimethylsilyl)-9-boratabicyclononane *(4)*, as demonstrated by a 1:2:1 triplet and a singlet in the ^{11}B-NMR spectrum. While LiSiMe$_3$ reacts in a very unclear manner with MeS-9-BBN, MeO-9-BBN *(5)* reacts smoothly to give *(4)*. In neither case could the silylborane Me_3Si-9-BBN be detected. In general, methyl esters of alkylboric acids give trimethylsilylborates in hexane according to reaction (d). These reactions are accompanied, however, by alkyl group transfers, hydridoborate formation, and disproportionation. Thus the 2:1 reaction of LiSiMe$_3$ with Me_2BOMe gives, for example BMe_3 and $Li[(Me_3Si)_3BMe]$ in addition to $Li[(Me_3Si)_2BMe_2]$ as the major product.

$$R_{3-n}B(OMe)_n + (n+1)LiSiMe_3 \rightarrow n\,LiOMe + Li[R_{3-n}B(SiMe_3)_{n+1}] \quad (d)$$

Increasing Me_3Si substitution obstructs borate formation for steric reasons. Nevertheless, silylation of $B(OMe)_3$ according to reaction (e) surprisingly leads to lithium tetrakis(trimethylsilyl)borate *(6)* as a microcrystalline powder soluble in pentane and benzene. Even a substoichiometric amount of LiSiMe$_3$ fails to give $B(SiMe_3)_3$ since it apparently reacts faster with LiSiMe$_3$ than $B(OMe)_3$ and the intermediates $(MeO)_2BSiMe_3$ and $MeOB(SiMe_3)_2$.

$$4\,LiSiMe_3 + B(OMe)_3 \rightarrow 3\,LiOMe + \underset{(6)}{Li[B(SiMe_3)_4]} \quad (e)$$

LiSiMe$_3$ accordingly provides a strongly nucleophilic $SiMe_3$ anion in hexane. The formation tendency of trimethylsilylborates thus far exceeds that of *tert*-butylborates. Trimethylsilylboranes therefore appear to be stronger Lewis acids than their *tert*-butyl analogs. This is due mainly to steric reasons as shown by the non-existence of $Li[B(CMe_3)_4]$[1]. However, if the steric conditions hinder borate formation, as in the $(Me_3C)_2B—BOMe(CMe)_3$/LiSiMe$_3$ system then silylboranes are also capable of existence[4].

Trimethylsilylborates show an increasing Si—B coupling constant and upfield shift of the ^{11}B-NMR signal as the extent of Si-substitution increases. The sign of the coupling constant $^1J(^{11}B^{29}Si)$ is negative. Characteristic NMR data are listed in Table 1. *(6)* contains 36 magnetically equivalent protons whose ^{1}H-NMR signal is split into a quartet by coupling with the ^{11}B nucleus.

Table 1. Some NMR spectroscopic data of trimethylsilylborates (standard: $BF_3 \cdot OEt_2$) [a].

	$\delta(^{11}B)$	$^1J(^{11}B^{29}Si)$ [Hz]	Solvent	M.p. [°C]
$Li[Me_3BSiMe_3]$	−28.5	−74	C_6D_6	127
$Li[Me_2B(SiMe_3)_2]$	−36.1	−61	Hexane	—
$Li[MeB(SiMe_3)_3]$	−45.3	−53	C_6D_6	81
$Li[B(SiMe_3)_4]$ [b] *(6)*	−53.4	−48	C_6D_6	81
(4)	−25.0	−65	THF	—

[a] ^{1}H- and ^{13}C-NMR data correspond to the constitution of these borates. [b] A single ^{1}H-NMR signal was found for *(6)* at $\delta(^1H) = +0.09$, which is split by coupling with ^{11}B to form a 1:1:1:1 quartet, $^3J(^{11}B^1H) = 1$ Hz.

Procedure

(6): $B(OMe)_3$ (10 mmol) in 10 ml *n*-hexane is slowly added dropwise to a stirred solution of LiSiMe$_3$ (40 mmol) in *n*-hexane (64 ml) at −70 °C. After warming to room temperature, the precipitate is separated and the filtrate evaporated down to half its volume. The product crystallizes at −78 °C. Re-

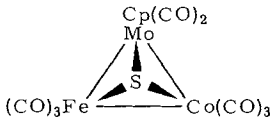
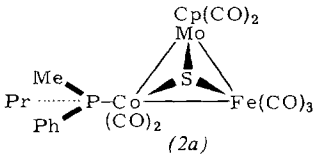
The First Optically Active Cluster: Resolution of Enantiomers and Absolute Configuration of $SFeCoMoCp(CO)_8$[**]

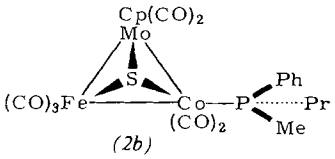


By *Felix Richter* and *Heinrich Vahrenkamp*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday



Tetrahedrane-type chiral molecules with four different corner atoms have not been known for long. Having synthesized such transition metal clusters[1], we have now resolved *(1)* into the pure enantiomers *(1a)* and *(1b)*.



(1a)

(1b)

(2a)

(2b)

The optically active phosphane (*R*)-PMePrPh[2] was introduced into *(1)* as ligand to facilitate resolution. The resulting diastereomers *(2a)* and *(2b)* could be separated by crystallization. The phosphane was subsequently trapped as phosphonium salt by methyl iodide under CO pressure, leaving pure *(1a)* and *(1b)*.

The IR spectra of *(2a)* and *(2b)* cannot be distinguished in the CO stretching region[3]. The ^{1}H-NMR signals of the phosphane ligands recorded in benzene are also identical, whereas the signal of the cyclopentadienyl ligand appears at $\delta = 4.72$ for *(2a)* but at $\delta = 4.71$ for *(2b)*: The molar rotations $[\Phi]_D$ are $-14700 \pm 400°$ for *(2a)* and $10050 \pm 300°$ for *(2b)*. The optical data of *(1a)* are shown in Figure 1.

[*] Prof. Dr. H. Vahrenkamp, Dipl.-Chem. F. Richter
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie and the University Computing Center at Freiburg. We are grateful to Prof. Ullrich, Biochemisches Institut der Universität Freiburg, for the optical measurements.

Crystal-structure analysis of *(2b)*[4] provided a means of determining the absolute configuration of *(1a)* and *(1b)*. The configuration of the cluster could then be deduced from the

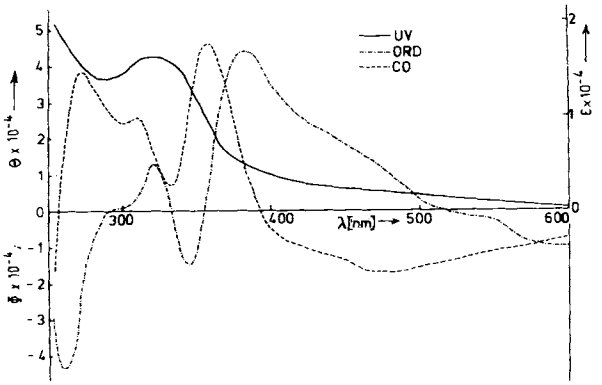


Figure 1. UV, ORD, and CD spectra of optically pure *(1a)*.

known configuration of the phosphane. The structural parameters of *(2b)*[5] should also apply to the clusters *(1)* and *(2a)*.

Like the phosphane, the enantiomers of *(1)* have an optical purity of about 98—100%. This was deduced from the NMR spectrum of the product mixture resulting on renewed reaction of isolated *(1a)* with the (*R*)-phosphane; it consisted almost exclusively of *(2a)*. Thus it was also established that elimination of phosphane from *(2)* is not accompanied by inversion or partial racemization.

The relatively facile synthesis and enantiomeric resolution and the thermal and configurational stability of the cluster *(1)* up to *ca.* 100 °C predestinate it for numerous reactions. The ready accessibility of the metal atoms resulting from the large number of substitutable CO ligands raises considerable hopes regarding optical induction in catalyses and inorganic syntheses.

Procedure

(2a) and *(2b)* can be obtained by known methods[6] from *(1)*[1] and (*R*)-PMePrPh[2]. Recrystallization twice from *n*-hexane affords the less soluble *(2b)* (m.p. 133 °C) in about 40% yield and the more soluble *(2a)* (m.p. 119 °C) in about 65% yield. The phosphane is removed by stirring the pure diastereomer *(2a)* or *(2b)* (120 mg, 0.18 mmol) in cyclohexane (30 ml) with methyl iodide (5 ml) for one week under CO pressure (60 atm). After filtration, the solution is chromatographed with pentane/benzene (2:1) over a 1.5 cm × 20 cm silica gel column. The first red fraction gives 65—75 mg (on average 73%) of *(1a)* or *(1b)* after recrystallization from *n*-hexane; m.p. 105 °C.

Tetrathiafulvalenoparacyclophanes[1]

By *Heinz A. Staab, Joachim Ippen, Chu Tao-pen, Claus Krieger,* and *Barbara Starker*[*]

Owing to its "metallic conductivity"[2] the crystalline 1:1 molecular complex of tetrathiafulvalene (TTF) and tetracyanoquinodimethane (TCNQ) is one of the most interesting organic electron donor-acceptor compounds. Other than in the usual crystal lattices of strong donor-acceptor complexes, in which the donor and acceptor molecules alternate within a stack, in the TTF-TCNQ crystal the components form separate stacks[3]. Whether the special conducting properties are connected with this difference in molecular structure cannot be established experimentally owing to the lack of other crystal modifications of the same complex. Since it appeared *a priori* very unlikely that the crystal structure of the TTF-TCNQ complex is optimal with respect to the electrical conductivity we tried to effect other TTF-TCNQ arrays in the crystal lattice by changing the molecular architecture. For example crystallization in alternating donor-acceptor stacking should be enforced if TTF and TCNQ are bonded to each other cyclophane-like as in *(1)* ($n=3$ or 4). Donor-acceptor cyclophanes with TCNQ as acceptor component have already been synthesized[4]. For the incorporation of TTF in cyclophane structures, however, a novel reaction sequence had to be developed. As example we describe here the synthesis of the parent compounds of *(1)*, namely [3]tetrathiafulvaleno[3]paracyclophane *(2)* and [4]tetrathiafulvaleno[4]paracyclophane *(3)*.

For the synthesis of *(2)*, 4,4'-(*p*-phenylene)dibutyryl chloride *(4)*[5] (prepared by reaction of the corresponding dicarboxylic acid[6] with thionyl chloride, 2 h, 90 °C; 83% yield) was converted *via* the bis(diazoketone) (obtained on reaction with diazomethane in ether) into the bis(chloroketone) *(5)*[5] (m.p. 70—71 °C; 51% yield) (sodium chloride, hydrochloric acid, methanol)[7]. Reaction of *(5)* with potassium *O*-isopropyldithiocarbonate (acetone, 30 minutes' reflux) afforded the corresponding bis(*O*-isopropyldithiocarbonate) *(6)*[5] (m.p. 63—64 °C; 89% yield). Subsequent cyclization (70% perchloric acid, chloroform/ether, 1:1)[8] furnished the bis(1,3-dithiol-2-one) *(7)*, which on reaction with phosphorus(v) sulfide (xylene, 2.5 h, 140 °C) gave the bis(1,3-dithiol-2-thione) *(8)*[5] [m.p. 99—100 °C; 10% yield based on *(6)*].

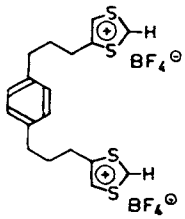
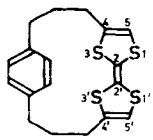
(5), X = Cl
(6), X = S-CS-OiPr



(7), X = O
(8), X = S
(9), X = SMeI$^{\ominus}$



Methylation of *(8)* (methyl iodide in nitromethane, 2.5 h, 70 °C) to give the bis(sulfonium iodide) *(9)* followed by hydride reduction (sodium tetrahydridoborate, tetrahydrofuran/methanol, −78 °C) afforded the bis(methylthio) derivative *(10)*[5] in 91% yield. Reaction of *(10)* with tetrafluoroboric acid in acetic anhydride gave the bis(1,3-dithiolium tetrafluoroborate) *(11)*, which on treatment with triethylamine in acetonitrile in a variation of the TTF synthesis by *Wudl et al.*[9] in dilute solution underwent intramolecular cyclization. The two possible structural isomers *(2)* and *(12)* are formed in a ratio of about 1:1 (^{1}H-NMR). The isomer *(2)* could be obtained pure from the isomeric mixture by repeated recrystallization from cyclohexane.

(10)

(11)

(12)

The product (yellow prisms, m.p. 180—182 °C)[5] was shown by its mass spectra and ^{1}H-NMR spectra[10a] to have the [3]tetrathiafulvaleno[3]paracyclophane structure. Differentiation between the two possible structural isomers *(2)* and *(12)* was accomplished by X-ray structure analysis, which was consistent with the isomer *(2)*[10a]. Figure 1a shows that the electron-rich central double bond of the TTF group is centered almost above the middle of the benzene ring (deviations: $L=7.5$, $M=10.4$ pm). The long axis of the TTF group and the *para*-axis of the benzene ring are twisted by an angle of 15° to each other. The transannular distance of 373 pm, however, is surprisingly large (Fig. 1b). This arises from the fact that the TTF group in *(2)* deviates considerably from planarity owing to ring strain: the S(1A) C(5A) C(4A) S(3A) and S(1B) C(5B) C(4B) S(3B) planes form angles of 28 and 33°, respectively, with the mean plane through the four S-atoms; the S(1A) C(2A) S(3A) and S(1B) C(2B) S(3B) planes are also bent at a slight angle (*ca.* 4°) to the C(2A) C(2B) double bond, and exhibit a mutual twisting of 7° about this bond. The benzene ring is slightly boat-shaped with the bridgehead atoms C(9) and C(12), unlike in normal paracyclophane structures, bending *outwards* from the C(10) C(11) C(13) C(14) plane (the planes C(11) C(12) C(13) and C(14) C(9) C(10) each form an angle of 2° to this basal plane); the exocyclic bonds on C(9) and C(12) are bent outwards by a further 4° (Fig. 1c).

Owing to the unusual ring strain effects in *(2)*, interest was aroused in its higher homolog, for which a more strictly parallel arrangement of donor and acceptor with on average shorter transannular distance was expected. *(3)* was synthesized analogously to *(2)*. Starting from 5,5'-(*p*-phenylene)divaleric acid[11], the bis(chloroketone) *(13)*[5] (m.p. 86—87 °C, 53% yield) was obtained *via* the bis(diazoketone) generated by reaction of the dicarboxylic chloride with diazomethane. *(13)* was then converted into the bis(*O*-isopropyl dithiocarbonate) *(14)*[5] (m.p. 114—115 °C; 75% yield). Subsequent cyclization with perchloric acid gave the bis(1,3-dithiol-2-one) *(15)*[5] (m.p. 86—88 °C; 78% yield), which on reaction with phosphorus(v) sulfide afforded the bis(1,3-dithiol-2-thione) *(16)*[5] (m.p. 104—105 °C; 59% yield). Methylation of *(16)* to *(17)* followed by hydride reduction furnished the

(18)

The mass spectra and ^{1}H-NMR spectra of the product (yellow prisms, m.p. 157—158 °C)[5] are consistent with the [4]tetrathiafulvaleno[4]paracyclophane structure[10b]. However, differentiation between the structural isomers *(3)* and *(8)* was possible only by means of an X-ray structure analysis[10b]. Surprisingly, the main product of the cyclization is not *(3)* but the isomer *(18)*. In *(18)* the benzene ring is displaced sideways to the TTF group and forms an angle of 63.5° with the plane of the TTF central double bond. In contrast to *(2)*, in *(18)* the central part of the TTF group [S(1A)—C(2A)—S(3A)/S(1B)—C(2B)—S(3B)] is coplanar, yet here also the planes defined by S(1A)—S(3A)—C(4A)—C(5A) and S(1B)—S(3B)—C(4B)—C(5B) are each at an angle of about 22° to this plane.

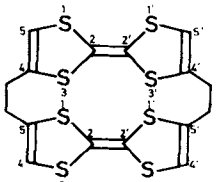
[2.2]- and [3.3]Tetrathiafulvalenophanes[1]



By *Joachim Ippen, Chu Tao-pen, Barbara Starker, Dieter Schweitzer*, and *Heinz A. Staab*[*]

In order to systematically vary the crystal lattice in charge transfer systems which could be of interest as electrical semiconductors or conductors by changing the molecular architecture[1], we synthesized [2.2]- and [3.3]tetrathiafulvalenophanes ("TTF-phanes"). For these compounds the following structural and stereo-isomers are possible: 1) "paracyclophane-like" compounds with diagonal 4',4'- and 5,5-linkage, which may exist as an achiral stereoisomer with approximately parallel TTF "axes" and all corresponding C- and S-atoms of the two TTF groups [*(1)* and *(3)*, respectively] in the eclipsed position as well as a chiral stereoisomer with crossed TTF axes which formally is derived from *(1)* and *(3)*, respectively, by 180° rotation of one of the TTF units about the axis through the C-4'/C-5 points of linkage; 2) "metacyclophane-like" compounds with 4,5- and 4',5'-linkage [*(2)* and *(4)*, respectively], whose TTF groups, as in the metacyclophanes, could be in a step-like *anti*-conformation and—less likely—in a *syn*-arrangement; 3) finally, TTF-phanes in which one TTF group is linked metacyclophane-like, the other paracyclophane-like (4,5-/4',4'-linkage). In the synthetic method employed by us, in which the central C=C double bonds of the TTF groups were formed in the last step[1], in principle, all the structural and stereo-isomers could be formed. Although only a few of them have so far been isolated in pure form and unequivocally characterized, we should like to report some preliminary results even at this stage since representatives of this type of compounds in combination with tetracyanoquinodimethane (TCNQ) show interesting properties.

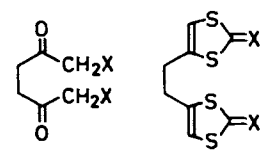
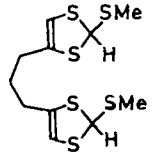
(2)



(3)

(4)

For the synthesis of the [2.2]tetrathiafulvalenophanes *(1)/(2)*, 1,6-bisdiazo-2,5-hexanedione was converted, in analogy to the method given in [2], into 1,6-dichloro-2,5-hexanedione *(5)*[3] (m.p. 87—88 °C; 23%), which on reaction with potassium *O*-isopropyldithiocarbonate (acetone, 20 °C, 3 h) gave the bis(*O*-isopropyldithiocarbonate) *(6)*[3] (m.p. 82—83 °C; 84%). Cyclization of *(6)* with conc. sulfuric acid afforded 4,4′-ethylenedi(1,3-dithiol-2-one) *(7)*[3] (m.p. 135—136 °C; 87%). On boiling with phosphorus(v) sulfide (xylene, 6 h, 140 °C), *(7)* was converted into the bis(thione) *(8)*[3] (m.p. 172—174 °C; 80%). *(8)* was methylated with methyl iodide



(5), X = Cl
(6), X = S-CS-OiPr

(7), X = O
(8), X = S

(9)

(10)

(nitromethane, 2.5 h, 50 °C) and the crude product was reduced with sodium tetrahydridoborate (tetrahydrofuran/methanol, −78 °C; overall yield 27—40%) to the bis(methylthio) derivative *(9)*[3]. Analogously to the synthesis of tetrathiafulvalenoparacyclophane, the bis(thiolium ion) was then prepared from *(9)* by reaction with tetrafluoroboric acid in acetic anhydride. On dropwise addition of its solution in acetonitrile to a solution of triethylamine in acetonitrile under argon the bis(thiolium ion) underwent dimerization and cyclization to [2.2]tetrathiafulvalenophane.

After removal of oligomeric and polymeric reaction products, fractional crystallization from carbon disulfide afforded *(2)*[3] as yellow, cubic crystals (dec. >210 °C) in 10—15% yield. Besides *(2)*, an isomer [presumably *(1)*] could also be enriched, but not completely purified. The mass spectra essentially agree with those of *(2)*[4].

The structure of *(2)* is confirmed by X-ray structure analysis[4]. The molecule has the step-like *anti*-conformation. As in the case of [3]tetrathiafulvaleno[3]paracyclophane[1] the TTF units deviate considerably from a planar arrangement: The S(1)···C(5)···C(4)···S(3) planes in all five-membered rings of *(2)* are bent at an angle of 20° to the planes through the four sulfur atoms and central double bond of the two TTF units.

The [3.3]tetrathiafulvalenophanes *(3)/(4)* were synthesized analogously to *(1)/(2)* *via* the homologs of *(5)*[2], *(6)*[3] (m.p. 98—100 °C; 74%), *(7)*[3] (63—64 °C; 93%) and *(8)*[3] (m.p. 101—102 °C; 52%). Methylation of the bis(dithiolthione) analogous to *(8)* with methyl iodide in nitromethane and subsequent reduction of the almost quantitatively formed methylation product with sodium tetrahydridoborate (tetrahydrofuran/methanol, −78 °C) afforded 4,4′-trimethylenedi(2-methylthio-1,3-dithiol) *(10)*[3] (yellow oil; 77%). Like *(9)*, *(10)* can undergo dimerizing cyclization. Oligomers and polymers can be removed by extraction with carbon disulfide. After evaporating *in vacuo* (9% yield) the extract consisted essentially of one isomer[6], which, however, has not yet been obtained free from isomers.

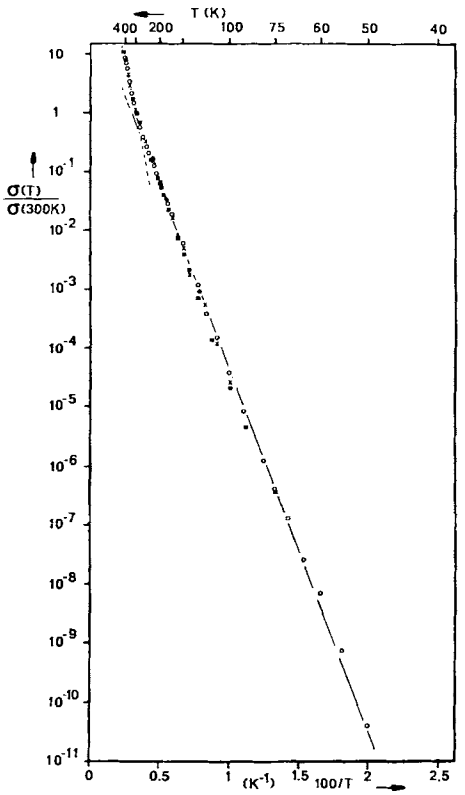


Fig. 1. Conductivities $\sigma(T)/\sigma(300\ K)$ of four single crystals of the 1:4 complex of [3.3]tetrathiafulvalenophane and TCNQ as a function of temperature. σ (300 K) of the four single crystals ▪ 5×10^{-3}, * 5.3×10^{-3}, ▲ 6×10^{-3}, ○ 7.5×10^{-3} [Ω cm]$^{-1}$.

Treatment of the [3.3]tetrathiafulvalenophane obtained with tetracyanoquinodimethane (TCNQ) in carbon disulfide/acetonitrile (room temperature, under argon, exclusion of light) afforded black-needles of a complex, which, according to elemental analysis, has the composition [3.3]tetrathiafulvalenophane/TCNQ = 1:4. The following crystallographic data were determined on a single crystal (0.4 × 0.1 × 0.08 mm) of this complex[5]: triclinic, space group $P\bar{1}$, $a=780$, $b=1393$, $c=2873$ pm, $\alpha=92.9$, $\beta=88.9$ and $\gamma=91.9°$; $\rho_{calc}=1.39\ g\cdot cm^{-3}$; a structure elucidation has not yet been completed. Conductivity measurements (4-contact measurements) on single crystals of this complex showed conductivities between 5×10^{-3} and 10^{-2} $[\Omega\ cm]^{-1}$ along the long axis of the needles at 300 K. Figure 1 shows for four different single crystals the excellent reproducibility of the conductivities measured and their temperature-dependence. Between 40 and 400 K, σ varies by more than ten orders of magnitude. Pellets of the complex (diameter 2.5 mm, thickness 0.5—1.0 mm) show a conductivity very similar to that of the single crystals at room temperature, with $\sigma=6\times10^{-3}$ $[\Omega\ cm]^{-1}$.

6-Fulveneselone[**]

By *Reinhard Schulz* and *Armin Schweig*[*]

Dedicated to Professor Hans Kuhn on the occasion of his 60th birthday

On heating, cycloalkeno-1,2,3-selenadiazoles are converted into cycloalkynes[1]. 1,2,3-Selenadiazole *(1)*[2] can be transformed photochemically[3] (in matrix) and thermally[4] (in the gas phase) into the reactive selenoketene *(2)*. We have now been able to generate for the first time the highly reactive 6-fulveneselone *(4)* from 1,2,3-benzoselenadiazole *(3)*[6] in the gas phase by variable temperature photoelectron spectroscopy and flash vacuum thermolysis (VTPES[5a] and FVT[5b], respectively).

The decomposition reactions A and B take place in the reactor of the spectrometer at *ca.* 5×10^{-2} mbar between *ca.* 450 °C (start of reaction) and *ca.* 700 °C (completion of reaction). In the temperature range investigated acetylene in reaction A is always formed together with *(2)*, while at

800 °C it is the sole product. Dehydrobenzene is not observed in reaction B, even at 800 °C. From these experiments it cannot be decided whether acetylene is formed by direct fragmentation of *(1)* or *via (2)*, or in both ways concurrently. Figure 1 shows the PE spectra of the reactants *(1)* and *(3)* as well as those of the products *(2)* and acetylene and of *(4)*.

The PE spectra of *(1)* to *(4)* very closely resemble those of the corresponding sulfur compounds (1,2,3-thiadiazole[7a], thioketene[7b], 1,2,3-benzothiadiazole[7c] and 6-fulvenethione[7d], respectively). A comparison of the respective PE spectra and of the HeI and HeII spectra[8] provided a basis for the identification of *(2)* and *(4)* and for the following

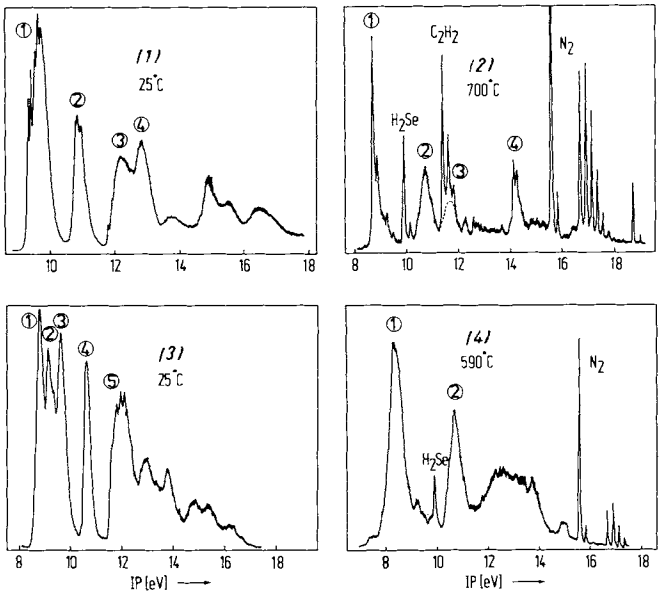

Fig. 1. HeI photoelectron spectra of 1,2,3-selenadiazole *(1)*, selenoketene *(2)* (band ③ is superposed by the $^2\Pi_u$ band of acetylene), 1,2,3-benzoselenadiazole *(3)*, and 6-fulveneselone *(4)*.

band assignments (band positions in eV): *(1)* ① 9.69 $^2A''(\pi)$, $^2A'(\sigma_N)$, ② 10.88 $^2A''(\pi)$, ③ 12.25 $^2A'(\sigma)$, ④ 12.88 $^2A'(\sigma)$; *(2)* ① 8.72 (1300 cm^{-1}) $^2B_1(\pi)$, ② 10.75 $^2B_2(\pi)$, ③ *ca.* 11.6 $^2B_1(\pi)$, ④ 14.15 (950 cm^{-1}) $^2A_1(\sigma)$; *(3)* ① 8.83 $^2A''(\pi)$, ② 9.16 $^2A'(\sigma_N)$, ③ 9.65 $^2A''(\pi)$, ④ 10.66 $^2A''(\pi)$, ⑤ 11.99 $^2A'(\sigma)$ and *(4)* ① 8.34 $^2B_1(\pi)$, $^2A_2(\pi)$, ② 10.76 $^2B_2(\pi)$. Further evidence for the identity of *(4)* can be obtained from Figure 2.

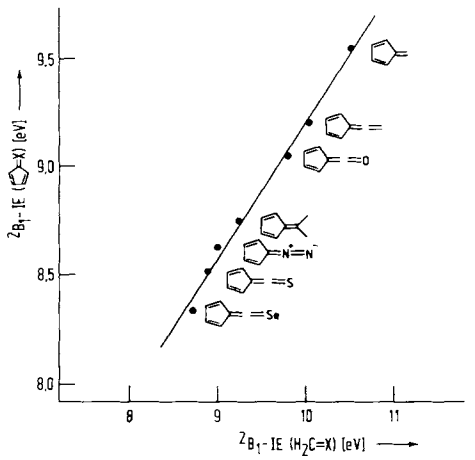

Fig. 2. $^2B_1$ ionization energies (*IE*) of fulvene-like molecules as a function of the $^2B_1$ ionization energy of the respective $H_2C{=}X$ system [fitted line: *IE* (fulvene analog) $= 2.93 \pm 0.25$ eV $+ 0.63 \pm 0.03$ *IE*($H_2C{=}X$); for the LCMO model cf. *E. Heilbronner, H.-D. Martin*, Chem. Ber. *106*, 3376 (1973)]. The measured ionization energy of *(4)* and the value expected from this expression are in good agreement.

6-Fulveneselone *(4)* can be briefly observed as a red deposit on the cold-finger (−196 °C) of a FVT apparatus (600 °C/5×10^{-3} mbar). On growth of a thicker layer, *(4)* reacts spontaneously (explosively) to give a brown polymer. Under conditions which facilitate trapping of *(2)* with dimethylamine[4] no identifiable trapping product of *(4)* could be obtained[9].

μ-Alkylthio- and μ-Arylthio-μ-chlorodicarbonylbis(tri-*tert*-butylphosphane)dirhodium: Dinuclear Rhodium Complexes with Different Bridging Ligands[**]

By *Herbert Schumann, Guy Cielusek,* and *Joachim Pickardt*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Carbonylrhodium complexes having sulfur bridges can be readily prepared in good yield by reaction of tetracarbonyldi-μ-chlorodirhodium with alkali metal thiolates[1]. Both chlorine bridges are always replaced by sulfur bridges, irrespective of the ratio of the reactants; the latter bridges are more stable towards bridge-breaking nucleophilic ligands[2]. Complexes having one chlorine and one sulfur bridge have so far only been suggested[3] or assumed[4] on the basis of IR spectroscopy as intermediates in exchange reactions.

We have now found that such complexes *(3)* are formed as stable yellow crystals on cleavage of the complex dicarbonyldi-μ-chlorobis(tri-*tert*-butylphosphane)dirhodium *(1)* by alkyl- and aryl-trimethylsilylsulfanes *(2)*.

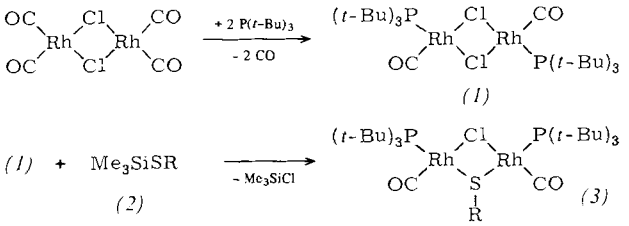

Table 1. NMR spectroscopic data of complexes *(3)* (δ values, ^{1}H-NMR: TMS int.; ^{31}P-NMR: 85% H_3PO_4 ext.; *J* in Hz).

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft.

X-Ray structure analysis (Fig. 1) of the *tert*-butylthio derivative *(3c)* shows that each phosphane ligand is bonded to rhodium in *trans* position relative to the sulfur atom. Thus *(3c)* has a *cis* configuration. Transformation of the *trans* configuration of *(1)* into the *cis* configuration of *(3c)* is attributable to the steric influence of the *tert*-butyl group on the sulfur. We had already deduced from IR and NMR data that such a transformation occurs for steric reasons in corresponding reactions of *(1)* with trimethylsilyldi-*tert*-butylphosphane[5].

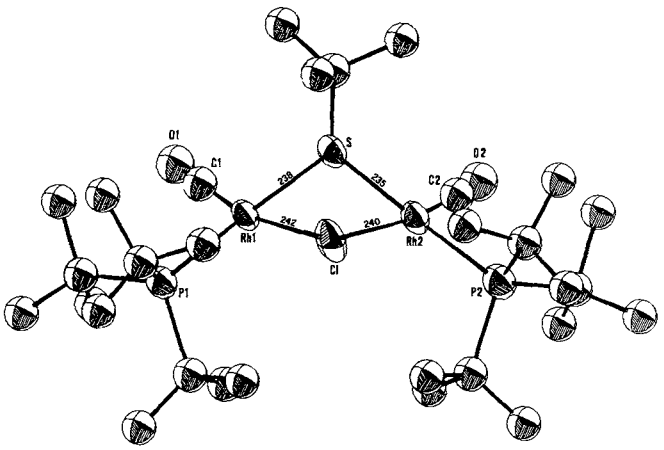

Fig. 1. Structure of $P(t\text{-}Bu)_3(CO)Rh(\mu\text{-}Cl)(\mu\text{-}S\text{-}t\text{-}Bu)Rh(CO)P(t\text{-}Bu)_3$ *(3c)*. Crystal data: orthorhombic, space group Pbca, $Z=8$; $a=2735.6(8)$, $b=1771.1(5)$, $c=1534.7(5)$ pm, $V=7.424\times10^9$ pm^3, $\rho_{calc.}=1.62$, $\rho_{exp.}=1.5$ g/cm^3; 1509 independent reflections: Syntex $P2_1$ four-circle diffractometer, $R_1=0.065$.

In the IR spectrum of *(3c)* (Nujol suspension), the equal-intensity νCO bands of the two *cis* carbonyl groups are observed at 1963 and 1954 cm^{-1}. Field desorption mass spectrometry gives the molecular ion $m/e=790$ as strongest peak. A sharp singlet at $\delta=2.08$ in the ^{1}H-NMR spectrum (benzene, rel. to int. TMS) is assigned to the protons of the *S-tert*-butyl group, and a doublet at $\delta=1.41$ with $^3J(HP)=11.7$ Hz to those of the tri-*tert*-butylphosphane ligands. The proton-decoupled ^{31}P-NMR spectrum contains a doublet at $\delta=89.4$ (C_6D_6, rel. to 85% H_3PO_4) with $^1J(PRh)=142$ Hz for the two equivalent phosphorus atoms. While the NMR spectra of *(3a)* and *(3b)* exhibit only slightly different parameters, the ^{31}P-NMR spectra of *(3d)*, *(3e)*, and *(3f)* show a second doublet of almost half intensity at the same chemical shift but with slightly different coupling constant (Table 1), suggesting two isomers with axial and equatorial substituents R[3].

Complexes *(3)* are excellent hydrogenation, decarbonylation, and isomerization catalysts. They prove highly active in conversion of 1-decen-3-ol into the ketone, in hydrogenation of cyclohexene, in decarbonylation of benzaldehyde, and in isomerization of allylbenzene and allyl alcohols. Thus 1-octen-3-ol could be isomerized almost quantitatively into 3-octanone in the presence of *(3b)*[6].

Procedure

All operations were performed under argon in oxygen- and water-free solvents. Tri-*tert*-butylphosphane (300 mg, 1.48 mmol) is added to tetracarbonyldi-μ-chlorodirhodium (300 mg, 0.77 mmol) in pentane (10 ml). After evolution of CO a clear solution is obtained which is stirred for 5 h at room temperature. *(2c)* (125 mg, 0.77 mmol) is then added slowly, and a yellow precipitate of *(3c)* appears immediately which is collected on a glass frit. A further crop of *(3c)* crys-

tallizes from the mother liquor within 48 h; yield 340 mg (56%), dec. 90 °C.

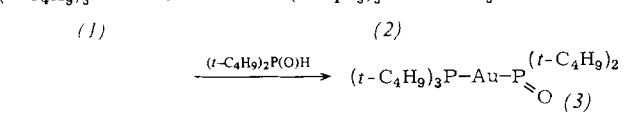
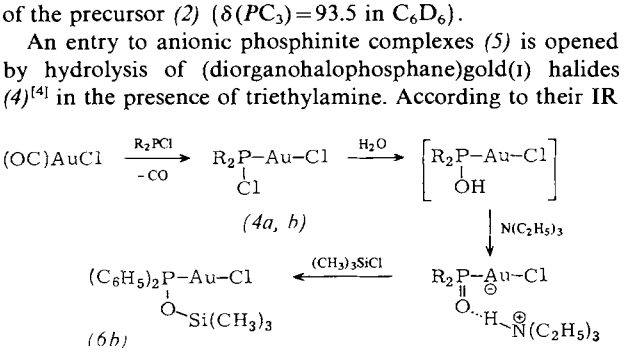
Synthesis and Reactions of Diorganophosphinite Complexes of Gold



By *Hubert Schmidbaur* and *Aref A. M. Aly*[*]

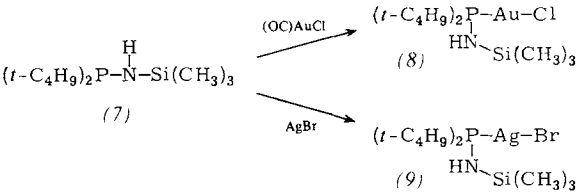
Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

The complexing properties of diorganophosphinite ions $[R_2(O)P:]^{\ominus}$ and the reactions of these species in complexes have hardly been examined, although the excellent donor properties of phosphorus are but little impaired by the oxygen atom[1]. The O atom is frequently also coordinated as well as the P atom, leading to bridge formation[2], and thus gold(I) dialkylphosphinites $[R_2(O)PAu]_3$[3], e.g., form trimers having a nine-membered ring.



We have now discovered further specific modes of reaction of the diorganophosphinite group in gold complexes.

Methylation of (phosphane)gold(I) chloride *(1)*[4] to give *(2)* and its subsequent reaction with $(t\text{-}C_4H_9)_2P(O)H$ by several hours' refluxing in benzene readily affords (phosphane)gold(I) phosphinite *(3)* in high yield.



Compound *(3)* forms air- and moisture-stable crystals shown by DTA not to decompose at their melting point (356 °C). The linear PAuP structure unit leads to a high coupling constant of $J(PP) = 308$ Hz in the ^{31}P-NMR spectrum ($\delta(PC_3) = 93.3$, $\delta(PO) = 124.1$, AX, in C_6D_6). In the IR spectrum $\nu(P{=}O) = 1090$ cm^{-1} reveals an uncoordinated PO function. The observation of a PAuC coupling ($^2J(PAuC) = 89$ Hz) was possible in the ^{13}C-NMR spectrum of the precursor *(2)* ($\delta(PC_3) = 93.5$ in C_6D_6).

An entry to anionic phosphinite complexes *(5)* is opened by hydrolysis of (diorganohalophosphane)gold(I) halides *(4)*[4] in the presence of triethylamine. According to their IR spectra, the thermally stable, salt-like products *(5)* contain hydrogen bonds in the solid state and in solution. In the ^{1}H-NMR spectrum ($CDCl_3$), $\delta(CH_3P)$ is shifted upfield by 0.65 ppm on going from *(4a)* to *(5a)* while $J(PH)$ remains unchanged. Conservation of the AuCl group is established by IR absorption bands at 301/310 *(4a)* and 312/320 cm^{-1} *(5a)*.—Compound *(4)*, R = t-C_4H_9, does not hydrolyze.

(a), R = CH_3; *(b)*, R = C_6H_5

Several hours' refluxing with $(CH_3)_3SiCl$ in benzene transforms the complex *(5b)* into the siloxyphosphane complex *(6b)*. Compound *(6b)* is thermally stable; its IR absorption at 1020 cm^{-1} indicates the presence of a POSi bridge; $\nu(AuCl) = 330/335$ cm^{-1}.

The analogous silylaminophosphane complex *(8)* and the silver derivative *(9)* are directly accessible from (OC)AuCl and AgBr, respectively, and the ligand *(7)*[5] in benzene. The sharp IR bands at 3260 and 3340 cm^{-1} observed for *(8)* and *(9)* rule out hydrogen bonding. Table 1 lists selected physical data of the compounds synthesized.

Table 1. Some physical data of the compounds synthesized. Coupling constants J in Hz.

(9), m.p. 192 °C; yield 70%; ^{31}P-NMR: $\delta = 69$ ($^1J(^{109}Ag^{31}P) = 686.6$)

Procedure

(2): Compound *(1)* (0.85 g, 2 mmol) is metalated in diethyl ether at −50 °C with a slight excess of CH_3Li. After warming to room temperature, the reaction mixture is stirred for 15 h and hydrolyzed at −50 °C. *(2)* is obtained from the ethereal phase.

(4): On addition of an equimolar amount of R_2PCl, benzene solutions of (OC)AuCl immediately evolve CO; pure *(4)* can be isolated in quantitative yield from the reaction solution.

(5a, b): Solutions of *(4a)* in acetone/CH_2Cl_2 or of *(4b)* in acetone/dioxane are treated with $(C_2H_5)_3N$ and the product carefully hydrolyzed with a stoichiometric amount of H_2O. Compound *(5a)* is formed as an oil which can be crystallized from $CHCl_3$/pentane, while *(5b)* precipitates in crystalline form.

Activation and Sulfur-Atom Transfer Reaction of Cluster-Bonded S_2^{2-}-Bridge Ligands: Synthesis of the New Cluster $[Mo_3^{IV}S_4(CN)_9]^{5-}$ from $[Mo_3^{IV}S(S_2)_6]^{2-}$ and CN^-

By *Achim Müller* and *Uta Reinsch*[*]

Reactions of complex- or cluster-bonded activated ligands are of topical interest in view of their bio-inorganic and catalytic relevance. Very little is known about reactions of S_2^{2-} ligands. Especially interesting is the fact that "labile sulfur" is removed from the Mo-containing enzyme xanthine-oxidase on addition of CN^-, resulting in deactivation of the enzyme function and formation of NCS^-[1]; the following reaction types have been postulated[1b]:

$$Mo^m\text{—}(S_2^{2-}) + CN^- \rightarrow Mo^m\text{—}(S^{2-}) + SCN^- \quad (I)$$

(atom transfer without reduction of the Mo center)

and

$$Mo^m\text{—}(S^{2-}) + CN^- \rightarrow Mo^{m-2} + SCN^- \quad (II)$$

(atom transfer with reduction of the Mo center)[2]

We report here on the first model reaction of type I: In H_2O, $[Mo_3S(S_2)_6]^{2-}$ *(1)*[3] undergoes nucleophilic attack by CN^- at the three S_2^{2-} bridge ligands, which cleave with quantitative formation of the new cluster[4] $[Mo_3S_4(CN)_9]^{5-}$ *(2)*. On addition of ethanol to the aqueous solution, dark-green crystalline $K_5[Mo_3S_4(CN)_9]\cdot n\,KCN\cdot m\,H_2O$ *(3)* is precipitated, which is diamagnetic and extremely soluble in water. The salt $K_5[Mo_3S_4(CN)_9]\cdot 3\,KCN\cdot 4\,H_2O$ *(4)* was characterized, not only by elemental analysis, TG and magnetic measurements, and IR, UV/VIS, and ESCA spectra, but also by a complete crystal structure analysis[5].

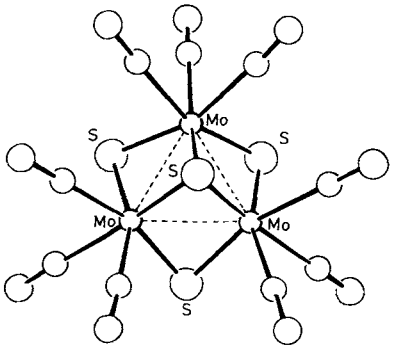

Fig. 1. Structure of the anion *(2)* in crystals of *(4)*.

[*] Prof. Dr. A. Müller, Dipl.-Chem. U. Reinsch
Fakultät für Chemie der Universität
Universitätsstrasse, D-4800 Bielefeld 1 (Germany)

In the IR spectrum (solid, Nujol) the bands of greatest intensity (with exception of the H_2O bands) lie at 2118 [ν_{as}(CN· –E)], 367 and 337 cm^{-1} [ν(MoSMo)]; the bands in the ν(CN) region indicate high symmetry of the anion *(2)* (ideal symmetry C_{3v}; site symmetry, however, C_s). In the trinuclear cluster (Mo—Mo 2.773 Å) each Mo atom is surrounded by a distorted octahedral array of three CN^- groups and three S atoms (Fig. 1). The central $\{Mo_3S_4\}$-skeleton may be regarded as an incomplete, distorted cube[6] (comparable with the $\{Fe_3MoS_4\}$-cage in the model system of nitrogenase[7]), in which the incorporation of a $FeSR^+$ would be interesting.

From the vibration frequencies and SS distances of *(1)* it follows that the S_2^{2-} bridges in the educt are activated for attack (low population of the π_v^* level through reduced electron density) by nucleophiles such as CN^-[3,8]. Remarkably, the oxidation number of the molybdenum is not altered by an atom transfer of *neutral sulfur* from S_2^{2-} (experimental evidence for the presence of a S_2^{2-} ligand and not S_2 has frequently been discussed![8]).

A reaction of Type II, with reduction of the molybdenum, was first observed in the synthesis of $[(CN)_6MoS\text{-}Mo(CN)_6]^{6-}$[9]. The mechanism of the "formal exchange" of each of the three terminal S_2^{2-} ligands by three CN^- in the conversion into *(2)* is still unclear. During the reaction, the coordination of the Mo center changes (octahedral → pseudotetrahedral) and consequently a different number of d-functions is available for bonding in the Mo_3-unit of product and reactant [*(2)*: d_{xy}, d_{xz}, d_{yz}; MOs: $(1a_1)^2(1e)^4$, $2a_1$, $(2e)^*$, $(3e)^*$, $(1a_2)^*$.—*(1)*: $d_{x^2-y^2}$, d_{z^2}; MOs: $(1a_1)^2(1e)^4$, $(a_2)^*$, $(2e)^*$]. As a result of the different density in the MO state in the Mo_3-cluster, the LUMO a_2 in *(1)* is strongly antibonding, while the corresponding MO $2a_1$ in *(2)* is weakly bonding. This explains the different influence of the Mo_3 units on the optical, electrochemical and chemical properties of *(1)* and *(2)*. Thus, in contrast to *(1)*, compound *(2)* should undergo reversible reduction.

Experimental

On addition of KCN (5 g) to an aqueous suspension (20 ml) of $(NH_4)_2[Mo_3S_{13}]$[3] (0.5 g), a deep-green solution of $[Mo_3S_4(CN)_9]^{5-}$ is obtained. (The isolation of solid *(3)* and separation of the "by-product" KSCN and excess KCN is complicated owing to high solubility.) After 1 h, the mixture is filtered and ethanol is added to the filtrate until clouding occurs (precipitation of a colorless substance). After filtration of the precipitate the process is repeated. The filtrate is then treated with 2—5 ml ethanol, and no more turbidity should occur. After several hours have elapsed, the precipitated needle-shaped, dark-green crystals of *(3)* are washed with ethanol, ether, and *n*-pentane and dried over P_4O_{10} (yield *ca.* 70%).

Nucleophilic Elimination-Cycloaddition of α,ω-Alkanediyl Bis(triflates), a Novel Method for the Synthesis of Metallacycles with Reactive Metal-Carbon σ Bonds[1]

By *Ekkehard Lindner* and *Hans-Jürgen Eberle*[*]

Dedicated to Professor Gerhard Fritz on the occasion of his 60th birthday

Heterocycles with metal-carbon σ bonds have recently been the subject of numerous detailed investigations, since they play an important role as intermediates in transition metal catalyzed reactions[2] and in organic syntheses[3]. In the search for new general methods for the synthesis of such compounds having aliphatic ring systems of various sizes we have examined the reaction of dianionic manganese complexes[4] $[(OC)_4Mn(PR_2O)]^{2-}$ with alkane derivatives containing the carbenium ion-stabilizing trifluoromethanesulfonate moiety ("triflate") in the α,ω-position as favorable leaving group.

At 20 °C the variously nucleophilic centers of $[(OC)_4Mn(PPh_2O)]^{2-}$ attack the terminals of the hydrocarbon chain almost simultaneously with elimination of $CF_3SO_3^-$. This pseudosynchronous mechanism hinders β-hydrogen elimination. Owing to the chelate effect, the colorless metallacycles *(1)* are thermally stable; they sublime in a high vacuum and are soluble in all the common organic solvents. They were characterized by complete elemental analysis, IR, mass spectra (Table 1), and ^{1}H-NMR spectra [*e.g. (1a)*, C_6D_6 rel. to TMS: $\delta = 1.04$ (td; $J = 6.4$ Hz, Mn—CH_2—CH_2; $J = 2.1$ Hz, P—Mn—CH_2), 1.92 (m; CH_2—CH_2—CH_2), 3.79 (dt; $J = 15.3$ Hz, P—O—CH_2; $J = 4.7$ Hz, O—CH_2—CH_2)]; *(1a)* was additionally characterized by an X-ray crystal structure analysis[5].

The six-membered ring of *(1a)* has a distorted chair shape with dihedral angles of 130.6 and 164.2°. The Mn3···C4 distance is markedly greater than the sum of the single bond radii. Substantial widening of the tetrahedral angle is indicative of a highly strained ring. The deviation of C6 from the plane formed by C4, C5, O1, P2 effects slight distortion of the tetrahedral angle. The *trans* CO-ligands are bent inwards to the heterocycle (C10···Mn3···C8 164.9(2)°).

The MnC σ bond is extremely reactive. Thus the action of liquid SO_2 or CO on *(1b)* and *(1c)* leads *via* an insertion reaction to the expanded, colorless heterocycles *(2b)* and *(2c)* which are soluble only in polar solvents (cf. Table 1).

We have thus demonstrated the first instance of CO insertion in the M···C bond of a metallacycloalkane.

Experimental

The heterocycle *(1)* is obtained by dropwise addition of a solution of $Na_2[(OC)_4Mn(PPh_2O)]$ (1 mmol) in dimethyl

[*] Prof. Dr. E. Lindner, Dipl.-Chem. H.-J. Eberle
Institut für Anorganische Chemie der Universität
Auf der Morgenstelle 18, D-7400 Tübingen 1 (Germany)

ether (DME) (50 ml) to a solution of ZCH_2-X-CH_2Z (1 mmol) in DME (30 ml) at 20 °C. After 1 h the solvent is removed in a high vacuum and the residue is extracted with *n*-heptane at 40 °C. After filtration (D3), the *n*-heptane is removed and *(1)* is sublimed at *ca.* 100 °C in a high vacuum. Yield 15—56%.

(1b) (0.5 mmol) is allowed to react in 30 ml of liquid SO_2 for 1 h at −60 °C. After removal of SO_2, *(2b)* is obtained in quantitative yield.

A solution of *(1c)* (0.5 mmol) in *n*-heptane (15 ml) is transferred to an autoclave and subjected to a CO pressure of 300 bar at 80 °C. After 16 h, analytically pure *(2c)* crystallizes from the solution in 80% yield.

Lithium Nitride Halides—New Solid Electrolytes with High Li^+ Ion Conductivity

By *Peter Hartwig, Werner Weppner, Winfried Wichelhaus,* and *Albrecht Rabenau*[*]

Dedicated to Professor Harry Hahn on the occasion of his 65th birthday

Hahn et al.[1] have examined the existence of ternary lithium-nitrogen-halogen compounds on the quasibinary Li_3N-LiX cut (X = Cl, Br, I) of the Gibbs phase triangle Li-N-X. For $Li_9N_2Cl_3$, the LiCl-richer phase of the two lithium nitride chlorides, an antifluorite structure was found in which 10% of the lithium sites are vacant while the anionic partial lattice is almost completely occupied by N and Cl. In order to underscore the cationic underoccupation of the antifluorite phase, we choose the designation $Li_{1.8}N_{0.4}Cl_{0.6}$.

On interchanging the anionic and the cationic lattices, an analogy is seen to exist with a series of known solid oxygen and fluorine ion conductors, *e.g.* ZrO_2 doped with 20 mol-% of CaO.

Coordination		
Cubic	Tetrahedral	
$Zr_{0.8}Ca_{0.2}$	$O_{1.8}\square_{0.2}$	Fluorite type O^{2-} ion conductor
$N_{0.4}Cl_{0.6}$	$Li_{1.8}\square_{0.2}$	Antifluorite type Li^+ ion conductor

[**] Present address: Jenaer Glaswerk Schott & Gen., D-6500 Mainz, Germany.

In neither case does the fluorite structure occur with the ideal composition ZrO_2 and "$Li_2N_{0.5}Cl_{0.5}$".

These structural properties prompted us to characterize lithium nitride chloride with respect to ionic conductivity[2] and thermodynamic properties. The studies were extended to other lithium nitride halides for purposes of comparison. We found all the compounds listed in Table 1 to have a high lithium ion conductivity and negligible electronic conduction.

Table 1. Activation energy E_A (products of ionic conductivity and absolute temperature), decomposition potentials U_{dec}, and free energy of formation ΔG_f^0 of the lithium nitride halides from the elements in their standard states [a]. $Li_{6.67}N_{1.98}I$ and $Li_{9.27}N_{2.76}I$ are different stoichiometries of the same phase. LT = low temperature modification, HT = high temperature modification.

	E_A [eV]	U_{dec} [V]	ΔG_f^0 [kJ/gAtom]	T [°C]
$Li_{1.8}N_{0.4}Cl_{0.6}$	0.49	2.52	−185	101
$Li_{11}N_3Cl_2$	0.83	1.86	−154	332
Li_6NBr_3	0.46	>1.30		176
$Li_{13}N_4Br$ (LT)	0.73	1.32		146
$Li_{13}N_4Br$ (HT)	0.47	0.66		300
Li_5NI_2 (LT)	0.50	1.96	−138	98
Li_5NI_2 (HT)	0.44	1.63	−124	287
$Li_{6.67}N_{1.89}I$	0.55	0.92	− 90	313
$Li_{9.27}N_{2.76}I$	0.80	0.92		316

[a] The energies of formation of the binary lithium halides were taken from standard tabulations [5].

The logarithms of the product of the conductivities (obtained by AC measurements) and the absolute temperature are plotted as a function of the reciprocal temperature in Figure 1. The relation obeys an Arrhenius law for the diffusion constant of the ions.

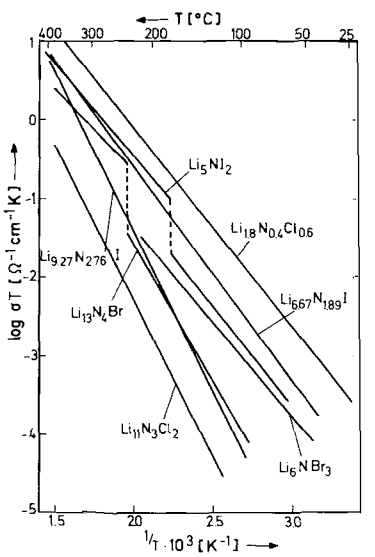

Fig. 1. Temperature dependence of the product of electrical conductivity and absolute temperature of the lithium nitride halides.

It is seen that the conductivity of the antifluorite phase $Li_{1.8}N_{0.4}Cl_{0.6}$ is greatest over the entire temperature range; at the same time, the activation energy of 0.49 eV is comparatively low. The discontinuities in the conductivities of $Li_{13}N_4Br$[3] and Li_5NI_2 are attributed to kinetically strongly inhibited phase transitions which are confirmed by calorimetric measurements. The Li_3N-richer phase of the two lithium nitride iodides is the only compound to exhibit a relatively wide phase width, extending at least from $Li_{6.67}N_{1.89}I$ to $Li_{9.27}N_{2.76}I$ ($Li_3N:LiI = 1.89$ to 2.76). The ionic conductivity increases by several orders of magnitude with increasing

LiI content in the lower temperature range, while the activation energy falls from 0.80 to 0.53 eV. The pre-exponential factor of the Arrhenius equation $\sigma T = A \exp(-E_A/kT)$ remains approximately constant, *i.e.* the jump frequency is independent of the composition.

Transfer experiments were undertaken with lithium to establish that the electrolytic current is indeed due to lithium ions. EMF measurements on lithium concentration cells with $Li_{1.8}N_{0.4}Cl_{0.6}$ as electrolyte and Li and Li_xTiS_2 as electrodes also confirmed practically pure ionic conduction.

All the ternary compounds lying on the quasibinary cuts Li_3N-LiX are thermodynamically stable towards pure lithium, which can therefore be used as anode in electrolytic cells. Moreover, all lithium nitride halides decompose only at low lithium activities. This leads to high decomposition potentials, *e.g.* more than 2.5 V for $Li_{1.8}N_{0.4}Cl_{0.6}$ at 100 °C (cf. Table 1). The high thermodynamic stability permits use of thin low-resistance layers, *e.g.* in printed circuits.

The free energy of formation of lithium nitride halides from the elements can be calculated from the decomposition potentials given a knowledge of the ternary phase diagrams Li-N-X. Applying the experimental result that all ternary compounds are in equilibrium with nitrogen and no other chlorides and iodides occur, the values listed in Table 1 were obtained. Measurement of the specific heat of $Li_{1.8}N_{0.4}Cl_{0.6}$ gave the standard enthalpy as $H^0(298\,K) - H^0(0\,K) = 9.57$ kJ/mol.

Experimental

The lithium nitride chlorides were produced by annealing tablets pressed from a mixture of finely ground Li_3N[4] and LiCl [Fluka AG] for 48 hours at 450 °C under N_2; the lithium nitride bromides and iodides were prepared analogously by annealing at 300 °C or by 3 hours' fusion of the binary compounds in tungsten vessels. The conductivity was determined by AC measurements over the frequency range of 1 Hz to 150 kHz. The frequency dependence could be analyzed by way of Debye equivalent circuits. The electronic partial conductivities were determined with DC by blocking the ion flux with molybdenum electrodes.

BOOK REVIEWS

Strained Organic Molecules. By *A. Greenberg* and *J. F. Liebman.* Organic Chemistry. A Series of Monographs. Vol. 38. Academic Press, New York 1978. xi, 406 pages. Bound, $ 41.50.

This is a long-awaited book. There has been no monograph on this subject since *A. von Baeyer* coined the term "strain" for angle deformations relative to the tetrahedral arrangement at carbon. The volume and the variety of the material collected is overwhelming; the huge number of strained compounds being scarcely conceivable.

In accordance with the authors' claim of aiming somewhere between a textbook for advanced students and a monograph focused on a special field, one would expect a clear taxonomy of strained compounds from thermodynamic and kinetic points of view, and portrayal (with examples) of the types, causes, and chemical consequences of strain.

To be perfectly honest, the book does not live up to all these expectations. For example, thermodynamic and kinetic stability are not discussed until the penultimate chapter, though the lability of many strained compounds is referred to much earlier. Stability and instability are discussed in terms of thermochemical concepts—and it is clear that conformational enthalpy differences have been ignored—yet one becomes suspicious, if the dissociation enthalpy $CH_4 \rightarrow CH_3^{\bullet} + H^{\bullet}$ is used as a basis and hence methane would have 19 kcal/mol of strain. The unsolved problem of the *mean* bond enthalpy of a C–H bond is dealt with by reference to the difference in the bond energy (dissociation energy) in methane and toluene. Not all readers will agree with a choice of bond and group increments according to which ethylene and tetrafuoroethylene become strained compounds. Also, one has to get accustomed to the conclusion that conjugative destabilization of anti-aromatic annulenes amounts to strain.

The report about the tranformations of strained carbocycles under the influence of transition metals is undoubtedly of great interest. Other current topics touching upon our concepts of bonding and reactivity in general are only indicated: the slow isomerization of prismane in solution may be a forbidden reaction according to the Woodward-Hoffmann rules, but the substance itself is explosive; cyclopropene has a short and thus stable double bond, but it is highly strained and reactive as a dienophile; the influence of fluorine substituents on stability and lability; lithium as a "strain-reducing" substituent on a carbon atom; and the significance of steric hindrance for the properties of strained compounds. The importance of quantum-chemical results is not always clearly recognizable. A sentence such as "Calculational evidence supporting the intermediacy of ..." (p. 287) is unlikely to find undivided agreement.

While the book hardly offers a modern treatment of "The present state of strain theory"[*], it contains what is promised in the title—a comprehensive catalog of strained and labile organic compounds.

Reinhart Keese [NB 485 IE]

Luminescence Spectroscopy. Edited by *M. D. Lumb.* Academic Press, New York 1978. ix, 375 pp., bound, $ 49.75.

The book consists of five independent contributions: 1) Inorganic Luminescence (*G. F. Imbush,* 92 pp.), 2) Organic Luminescence (*M. D. Lumb,* 56 pp.), 3) Luminescence Instrumentation (*T. D. S. Hamilton, I. H. Munroe, G. Walker,* 90 pp.), 4) Magnetic Effects in Organic Molecular Spectroscopy (*N. E. Geacintov, C. E. Swenberg,* 60 pp.), 5) Magneto-optical Investigations of Recombination Radiation in Inorganic Crystals (*B. C. Cavenett,* 70 pp.).

[*] *W. Hückel,* Fortschr. Chem., Phys., Phys. Chem. *19* (4), 1 (1927).

In his foreword, the editor writes: "The subject of luminescence spectroscopy has in recent years been divided into the two specific areas of organic luminescence and inorganic luminescence. This monograph attempts to merge these two areas within the common ground of experimental physics. ...The aim of this monograph is to provide sufficient theoretical and experimental groundwork for experimental physicists, chemists, or biologists entering this field for the first time to grasp the essentials of luminescence spectroscopy". In terms of these claims, the book must regarded as a failure. The authors of contributions 1, 2, 4, and 5 have made not the slightest attempt to present organic and inorganic luminescence as areas of the same discipline. There is no coordination between contributions 1 and 5 and between 2 and 4. In the following, I shall restrict my comments to contributions 2, 3, and 4, which correspond to my own field of study.

The second contribution reads like an unsuccessful precis of the book "Photophysics of Aromatic Molecules", by *J. B. Birks*. It contains numerous inaccuracies and errors. Only one example will be mentioned: the structural formula of azulene (p. 117) contains a *six*-membered ring and a five-membered ring, and in the text (p. 115) only the five-membered ring is mentioned as a special feature of azulene. I consider this contribution to be completely superfluous because the very same topic has already been treated far better by other authors.

The third contribution comes closest to fulfilling the aims of the book. However, the presentation is probably insufficiently detailed for the real newcomer. This section can be recommended to the more advanced worker on the strength of its good survey of experimental methods and the sound discussion of possible sources of error in luminescence studies.

The fourth contribution is a revised version of the article "Exciton Interactions in Organic Solids" in "Organic Molecular Photophysics" (Editor: *J. B. Birks*). It is concerned with the influence of an external magnetic field on pairwise interaction of triplet excitons in molecular crystals and is a good introduction to this special field.

Bernhard Nickel [NB 488 IE]

Organic Liquids: Structure, Dynamics, and Chemical Properties. Editors: *A. D. Buckingham, E. Lippert,* and *S. Bratos.* John Wiley & Sons, London 1978, 352 pp., bound, £ 18.00.

This book contains the 20 lectures presented at the Euchem conference of the same name. They are concerned with the methodology and results of techniques for the study of liquids (scattering experiments, flash spectroscopy, other dynamic methods, computer simulations, dielectric and thermodynamic properties, *etc.*).

The contributions provide a good survey of research into liquids, which is becoming increasingly topical. Up till now, physical chemistry had rather neglected the liquid state, which is actually the most important phase for most chemists. Regrettably, only few research groups have set themselves the task of providing chemists with information of value in practice. In the present book, such aims remain in the background (the article by *Reichardt* about solvent scales is an exception). Much more effort is devoted to the study of complicated partition functions of liquids which are of relatively little practical help to most chemists. While nobody will deny physical chemistry the right to conduct research for its own sake, it should not be forgotton that chemists need approximate models of the liquid phase for their work.

W. A. P. Luck [NB 491 IE]

Recent Books

The following books have been received by the editor. Detailed reviews will not be published in all cases because of the limited space available under this heading in the journal. All the publications listed are available through Buchhandlung Chemie, Boschstrasse 12, D-6940 Weinheim (Germany).

Chemisorption of Gases on Metals. By *F. C. Tompkins.* Academic Press, London 1978. xii, 370 pp., bound, £ 16.80.

A plethora of new methods has led to a vigorous development in studies on the interaction between gases and metal surfaces during the past decade. A glance at the bibliographies given in some publications could even create the impression that the field was non-existent just a few years ago, which is of course incorrect.

One of the past-masters of this discipline, *F. C. Tompkins,* has made a laudable attempt to survey the entire field, including modern developments, in a terse monograph—with mixed success. Non-uniform presentation of theoretical principles and experimental aspects is a disturbing feature of this work. (In this respect, *Wedler*'s book is certainly more suitable for newcomers.) The references hardly go beyond 1974, *i. e.* the very latest developments are not included. The choice of examples is sometimes rather unfortunate, and errors are also to be found. On the other hand, the historical development of various concepts receives fitting treatment and a comprehensive overview of the field is actually given. However, in view of the other monographs available in this field, the book cannot be unreservedly recommended.

Raw Material–Polymer Interrelationships — Today and Tomorrow[**]

By Klaus Weissermel[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Against the background of increasing demand and limited availability of fossil, non-regenerative fuel reserves and resources, ways are indicated of ensuring future supplies of raw materials and energy. The ambivalence of petroleum, natural gas, and coal in the energy and chemical sectors is demonstrated and opportunities for the gradual separation of their dual function are indicated. Taking into account the time factor, the necessary restructuring processes are analyzed critically with respect to their impact on the raw material–polymer relationship.

1. Fossil Organic Raw Materials: Combustion or Upgrading?

In no other branch of industry is the interrelationship between fossil energy sources and organic raw materials as intimate as in the chemical industry, for more than 90% of the energy and raw materials consumed throughout the world are based on petroleum, natural gas, and coal.

There are signs that the two most important chemical feedstocks—petroleum and natural gas—will already be threatened with exhaustion in the medium term and coal in the long term, unless it is possible for their dual function as sources of energy and raw materials to be gradually disengaged in good time and ultimately eliminated.

The switchover from coal, the most common fossil source of energy, to petroleum and natural gas was only possible because the latter have hitherto been available on world markets at prices well below their value as energy and upgraded product and because they are easier to transport, utilize, and upgrade. In the wake of this economic development, a far-reaching process of restructuring has taken place throughout the world in the last thirty years, as shown in Figure 1.

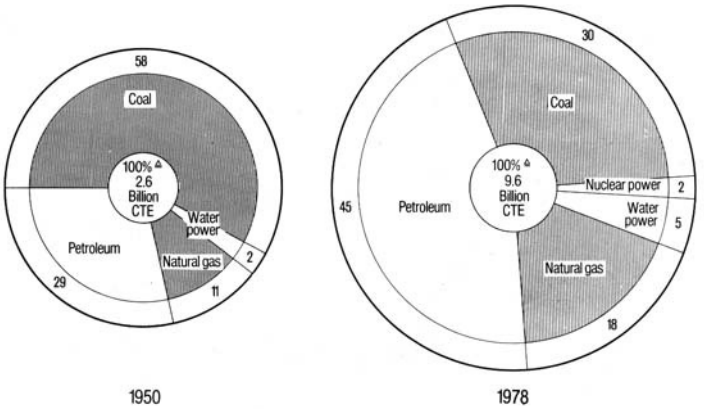

Fig. 1. Primary global energy consumption in 1950 and in 1978.

As a result of rapid economic growth, particularly in the highly developed countries, world consumption of primary energy has changed considerably, not only in terms of quantity, but also in the proportions of the individual fossil energy sources used. Especially affected by this development is petroleum, which now bears by far the chief burden of the energy supply. In comparison with its geological age of around 500 million years, we are in the process of consuming this valuable, non-regenerative raw material "in a matter of seconds".

In spite of geological limitations, political restrictions, and economic factors related to its availability, the consumption of petroleum is at present continuing to rise and inevitably this has greatly increased the supply risks and the dependence of many countries on imports. On a national and a regional level, however, it is possible to ascertain important differences in the energy consumption structure (cf. Fig. 2).

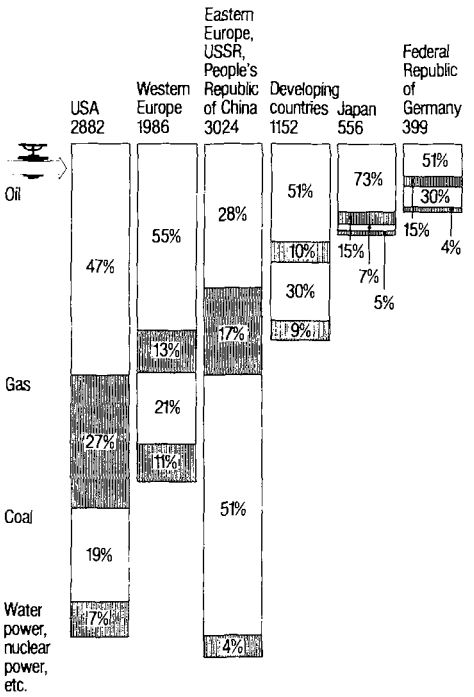

Fig. 2. Regional annual energy consumption for 1978 (in million CTE).

According to Figure 2, Eastern Europe, the USSR, and China have been largely spared the repercussions of the oil crisis, since it is in these regions that the greatest equilibrium in consumption exists between the individual sources of energy. At the same time, this diagram shows clearly the tremendous efforts that are required in order to direct patterns of consumption, especially in the Western industrialized countries, into new channels. It must be assumed that the introduction of a new energy system or the changeover to a new raw material basis will, according to past experience with coal, petroleum, as well as with nuclear energy, take at least 20 to 30 years from the time of its availability on a technical scale to the attainment of a large market share.

Up to the turn of the millenium we shall thus only be able to avail ourselves of those energy sources and raw materials, the recovery of which has already reached an advanced technological stage, which are economically and ecologically acceptable, and which can be reliably controlled. From this it follows that we must be clear as to the possible alternatives for future supply of energy and raw material and that regulative perspectives must determine the rules of action. Long-term strategies cannot be derived from short-term demand considerations.

The widespread crisis of acceptance that we are at present experiencing in the utilization and urgently needed development of nuclear energy is a typical example of the fact that we are not prepared, or not yet prepared, to initiate developments affecting the period beyond the year 2000. This is by no means based on a factually substantiatable assessment of the technological consequences, but is marked by an irrational fear of technology. Uncertain, and in some cases contradictory statements on the exhaustion of fossil reserves and its effect on the existence of human life is an additional factor that has hampered orientation. It is in fact frequently overlooked that there is a considerable difference between reserves and resources of fossil sources of energy. By definition, reserves are proven supplies of fossil materials that are recoverable under modern production conditions. Resources are geologically probable deposits which will be recoverable at considerably greater expense at some time in the future. They include the reserves. As a result of technological progress, the boundaries between reserves and resources will continuously shift. Nevertheless the recoverable proportion amounting to some 3200 billion CTE is still far below the estimated world deposits of fossil energy sources of 12000 billion CTE[1]. If the energy potential provided by nuclear energy and the so-called inexhaustible energy sources are included in the considerations, it should be sufficient for any growth rate.

The safeguarding of energy and raw material supplies in the long-term is thus less a question of resources, but is concentrating more and more on making them available in good time. Scarcity thus has many causes—we should on no account underestimate the time factor. Recent experience, in particular, has shown that changes often take place more rapidly than the development of alternative means of combating them.

The modern power industry has only been in existence for three generations. If it is not to end in an impasse in the fourth and fifth generation, we must break with the present pattern of energy consumption, as shown in Figure 3[2].

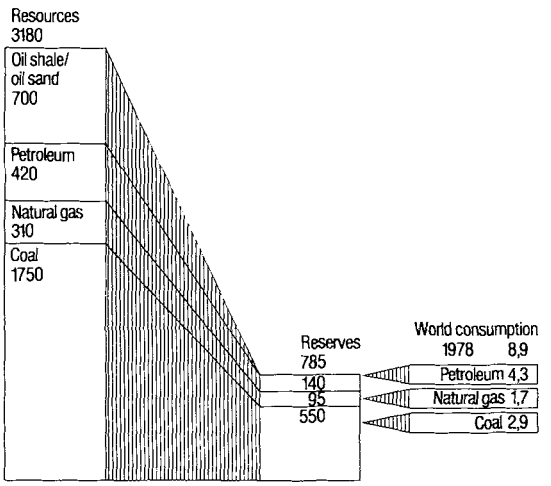

Fig. 3. Recoverable fossil fuels from reserves and resources (billion CTE).

Although the recoverable coal deposits are four times, and probably even five times as large as those of petroleum, this diagram illustrates the crass discrepancy between reserves and consumption. At the same time, Figure 3 makes it possible to estimate how long the predatory exploitation of natural resources can continue. If consumption were to remain unchanged, petroleum resources would only last a period of decades and coal would be exhausted in a few centuries. The problems are intensified still further if we bear in mind the future growth in energy demand.

At all events we require more energy, particularly if we are to preserve the environment and utilize sparingly the valuable, non-regenerative natural products. However how much does this "more" imply? Past experience has shown that there can be a wide gap between estimates and reality and that nothing is as constant as the changes that occur in the data used in forecasts and estimates of demand. Nevertheless it appears to me possible to make a qualitative statement as to the trend.

The main difficulty lies in predicting the energy and raw material demand per head of the world's population. This leads us to the crucial issue: for how many people when and in which region do we expect what demand? Figure 4 illustrates the problems of forecasting. It provides information on the current *per capita* consumption of primary energy and the breakdown by countries and regions[3].

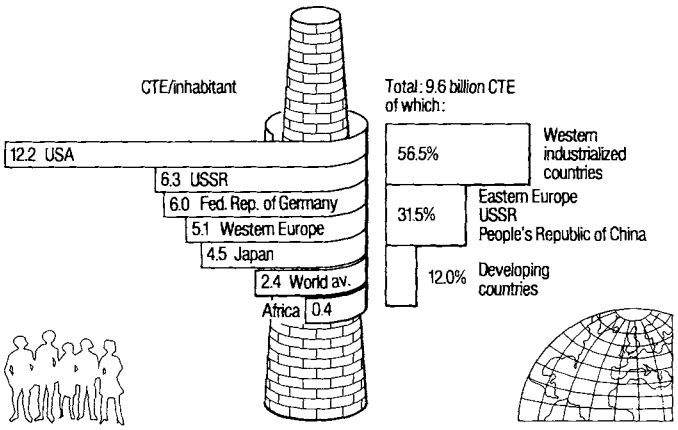

Fig. 4. World consumption of primary energy in 1978. (5.1 CTE/inhabitant for Western Europe includes the Federal Republic of Germany.)

Currently some 4 billion people have to be supplied with energy and raw materials; at the turn of the millenium the number will have reached 6 billion and in 50 years the 8 billion will probably have been reached or exceeded[4].

Advancing industrialization, in particular in the developing countries, inevitably leads to a continuing rise in the consumption of primary energy. It can be assumed, however, that economic growth will in future proceed more slowly in the industrialized countries and be accompanied by a more gradual rise in energy consumption. This is based on the assumption that there is still considerable scope for reducing energy utilization, especially in the non-industrial area.

According to studies carried out by *Keyfitz*[5], an increase in primary energy consumption from 2 CTE to 3—5 CTE per person per year is to be anticipated during the next 50 years. This would then mean a total annual consumption of 24—40 billion CTE compared to 9.6 billion CTE in 1978. Although these figures may appear excessive, energy consumption must nevertheless be expected to at least double within a few decades. However, the attempt to present the estimated development of primary energy demand and supply, broken down by energy sources, is worthy of consideration[6].

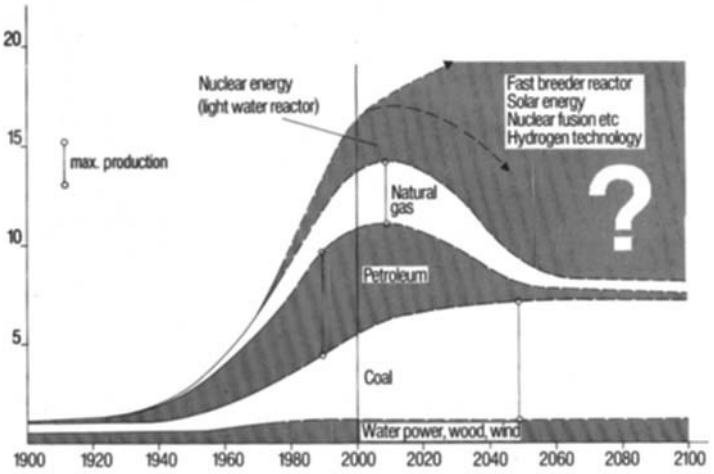

Fig. 5. Development of the world consumption of primary energy (billion CTE).

Figure 5 is intended to show that the further we are removed from the year 2000, the more difficult it is to make a tangible statement as to the proportionate usage of conventional sources of energy and those still to be developed. In my view, however, it is important to observe that the extent to which the fossil resources will last beyond the year 2000 is also decisively influenced by scientific and technical progress, *i. e.* by our ability to open up new sources of energy and develop their utilization to technical maturity at an early stage.

Although a greater degree of probability can be attached to forecasts of the development of primary energy demand in the eighties and nineties, the energy supply trend can by no means be regarded as satisfactory. Figure 5 makes plain that we shall probably have to abandon any hopes in the short-term of being able to make any lasting changes in the pattern of energy consumption. It could be rated a success if oil consumption were to be further reduced during this period. Nevertheless, petroleum will continue in the year 2000 to be the largest single source of energy.

This statement finds confirmation in a recently published study by Deutsche Shell AG on the development of demand for primary energy and the pattern of consumption in the Federal Republic of Germany up to the year 2000[7]. For the sake of completeness, it is presented here in the form of a graph (Fig. 6), which requires no further comment.

Stretching the use of all fossil, non-regenerative energy sources over a longer period remains of vital importance. If rapidly expanded, both at national and global level, the utilization of nuclear energy could already contribute to this objective in the medium-term. After thirty years of development, this source of energy has reached industrial maturity; from the environmental pollution aspect it is preferable to coal and petroleum and is economically superior to energy production from fossil sources[8]. At present it offers the only alternative source of energy that can replace petroleum and

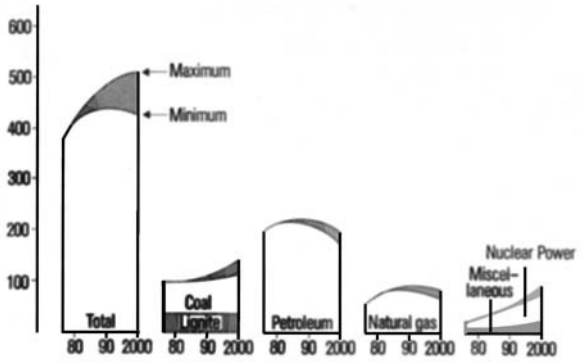

Fig. 6. Predicted primary energy and energy sources in the Federal Republic of Germany between 1978 and 2000 (million CTE).

natural gas on a scale that would be quantitatively significant.

Coal, too, in the form of its conversion products, will have to make a greater contribution towards meeting the demand for energy. In view of its limited availability, natural gas should, however, be largely reserved for processing by the chemical industry.—Unfortunately, even in the medium term this aim would appear scarcely achievable, even though for energy policy reasons the use of natural gas in electric power stations is probably on the decline *vis-à-vis* hard coal.

The development in demand forecast for the period beyond the year 2000 underlines the urgency of the need to separate the interrelationship between energy and raw materials. It requires a radical restructuring and not simply a corrective adjustment. Above all it calls for courage and an awareness of the need for change. A power industry based both on hydrogen and electricity—utilizing inexhaustible sources of energy—would be a worthwhile although distant aim, in order that the fossil reserves will long remain available for applications yielding a higher net product and for instances where there is no alternative source of supply. The future doubtless lies in an integrated energy set-up, utilizing all sources of energy—and in particular in a partnership between coal and nuclear energy.

2. Safeguarding Raw Materials through Structural Changes

Compared to the world consumption of petroleum amounting to 3 billion tonnes in 1978, the share of petroleum-based raw materials for the chemical industry of the order of 5—6% appears to be insignificant.

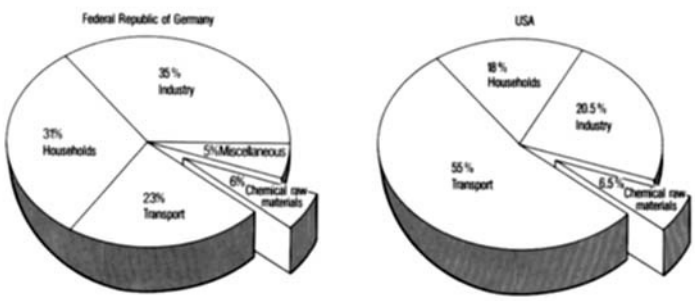

Fig. 7. Petroleum consumption by sectors (Federal Republic of Germany 1976 [9], USA 1975 [10]).

The data (cf. Fig. 7) can easily give rise to misinterpretation, since they do not reveal the true dependence of the chemical industry on petroleum. This dependence only becomes clear on considering the fact that the primary chemicals of organic chemistry are based almost entirely on petrochemicals. This development, which initially commenced in the USA and became established in Europe at the start of the fifties, had two main causes: on the one hand, the petroleum and natural gas fractions, in the main crude naphtha, ethane, propane, and LP gas, which were favored by the chemical industry, were available cheaply in increasing quantities and accelerated the development of pyrolysis processes for the production of the most important olefinic and aromatic building blocks for the chemical industry. On the other hand, new processes were discovered for the polymerization of olefins and the production of monomers on an olefin basis. Both developments were closely linked to one another by a large number of reciprocal relationships and feedbacks and gradually initiated the replacement of acetylene as the starting material for the classical monomers.

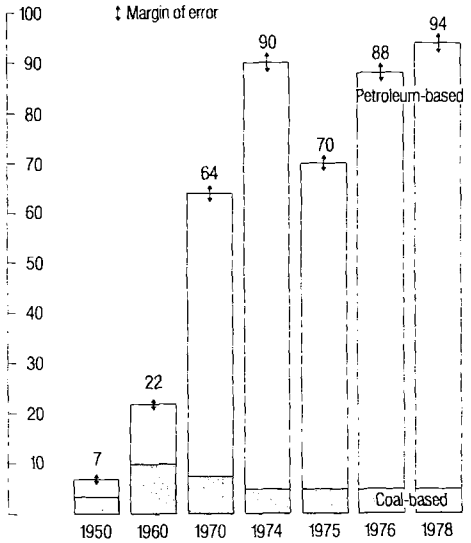

Fig. 8. World production of organic primary chemicals in millions of tonnes (without Eastern Europe, the USSR, and the People's Republic of China).

Figure 8 shows the development in the last three decades and underlines the importance of petroleum-based products in the chemical industry and the extent to which they are used. Only 5% of the primary chemicals are at present still based on coal.

The dependence of the organic speciality products and polymer products on specific petroleum or natural gas fractions that are limited in quantity is evident, particularly since it must be assumed that as intermediates for many branches of industry both will continue to grow at an above-average rate.

There are several possibilities of safeguarding energy supplies; for safeguarding supplies of organic raw materials it may be many times more difficult to replace petroleum. The upgrading of petroleum must always take priority over combustion, since hydrogen-containing carbon compounds are not necessary for energy production, whereas for upgrading processes they are essential and are already present in petroleum in the desired C/H ratio.

The logical consequences as regards the competitiveness of an alternative chemical feedstock are thus indicated. It is not only a function of the cost price of the basic product, but includes the upgrading, finishing, and capital costs involved in the manufacture of primary chemicals.

Under present economic conditions and the latest state of conversion technology, coal cannot compete with petroleum as a chemical feedstock. Exceptions to this are the polycyclic ring systems which, however, are not significant from the volume aspect. Following the establishment of a coal producing and processing infrastructure adapted to meet the increased demand, coal is, however, doubtless able in the medium term to contribute to a marked easing of the pressure on petroleum and natural gas in the form of coal gasification and coal liquefaction products for the heating fuel and motor fuel sector.

Although exploitation of oil shale and oil sand deposits has been initiated it is proving to be more difficult from the technological and the ecological standpoint than at first expected, and will have no appreciable impact on raw material supplies in this century.

The much discussed possibilities of producing raw materials from regenerative natural products are in my view highly overrated. They will not make any decisive global contribution to the supply of primary chemicals but will be confined to a few products at regional level. The upgrading of natural products and the processing of their waste materials will be of prime importance. This is a sphere of activity that opens up future-oriented opportunities for the biotechnology field at present at the development stage.

All factors considered realistically, the chemical industry is still far removed from a "post-petroleum economy". It will begin by way of a more intimate interrelationship between petroleum and coal, while taking into account the possibilities of upgrading that are specific to both raw materials. From the present viewpoint, the following developments and priorities are emerging:

2.1. Optimizing the Upgrading of Crude Oil

A marked rise in the degree of crude oil upgrading for the purposes of the chemical industry would appear possible and urgently necessary within the coming decade.

A prerequisite of this change is a restructuring into petrochemical refineries of refineries which in Western Europe are primarily operated on conventional lines; this will permit the naphtha yield to be increased from 23 to a maximum of 60%. This measure permits the specific crude oil demand for petrochemical primary chemicals to be reduced to one-third (cf. Fig. 9)[11]. However, this reorientation of the refinery structure, such as is practised in the USA, necessitates additional capital expenditure.

In addition to the increased yield of primary chemicals, the petrochemical refinery enjoys the additional advantage over the conventional refinery that its production structure enables it to be extensively adapted to the chemical industry's requirements for different primary chemicals. The increase in yield outlined is attained by operating crackers with naphtha and gas oil and furthermore by the use of plants for converting heavy mineral oil fractions into lighter fractions and also by resorting increasingly to heavy oil for the production by partial oxidation of synthesis gases rich in hydrogen. The flow diagram of Figure 10 illustrates the main process characteristics for the optimum utilization of crude oil as a chemical raw material[12].

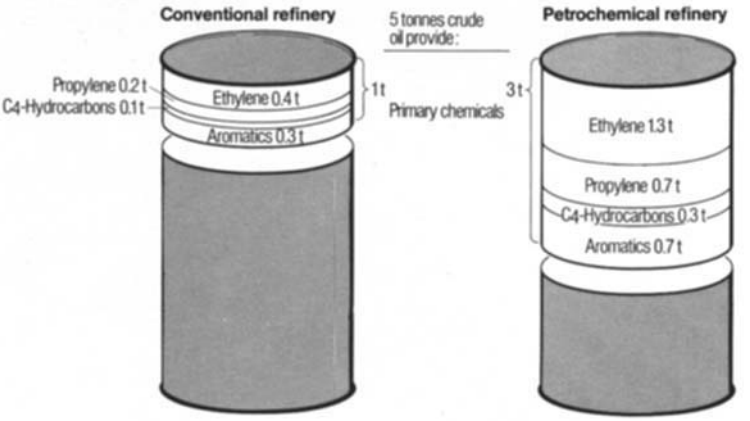

Fig. 9. Primary chemicals from petroleum: influence of the refinery structure [11].

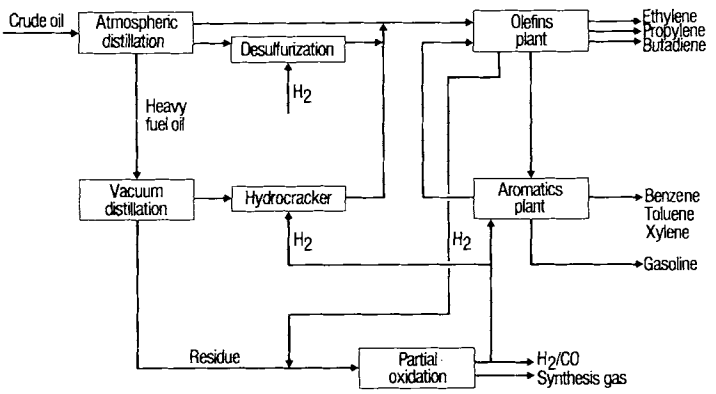

Fig. 10. Flow diagram of a petrochemical refinery.

2.2. Optimization of Crude Oil Production

Exploration and production techniques are being continuously developed to more advanced stages. It is foreseeable that they will increasingly extend to offshore areas and regions that are difficult to exploit. This requires considerable effort in the technical field and a high capital commitment. Of equal importance is the field of drilling and petroleum auxiliaries for secondary and tertiary production. By means of suitable chemical additives that have different tasks to fulfil, the objective of raising exploitation of the deposits from 25—30% to 40—50% and more is already aimed at in the medium term.

2.3. Expansion of Coal Upgrading

As crude oil becomes scarcer and more expensive, increasing importance will attach to the symbiosis of petroleum and coal as a basis for chemical feedstocks.

The production of primary chemicals from coal is fundamentally possible and is based on processes developed during the twenties and thirties in Germany and also employed on a large industrial scale in that country during the Second World War. Conversion of the coal takes place using two methods, one entirely different from the other.

In the Fischer-Tropsch synthesis, it is first necessary to convert the coal into synthesis gas, *i. e.* into carbon monoxide and hydrogen, which in the presence of suitable catalysts is in turn converted into aliphatic hydrocarbons of different structures and chain lengths.

Hydrogenation of coal by means of the Bergius/Pier method or extraction by hydrogenation in the Pott/Broche or IG/Uhde processes are based on the addition of hydrogen to the coal, effecting a partial cleavage and a consequent liquefaction. This process, which does not require the total degradation of the coal, is mainly suited for hydrocarbon fractions with a high aromatics content. The thermal efficiency is higher than in the Fischer-Tropsch synthesis[13].

Up to 1945, 12 hydrogenation plants and 9 Fischer-Tropsch plants were in operation in Germany. The average capacity of the hydrogenation plants was 400000 tonnes per annum, that of the synthesis plants using the Fischer-Tropsch process was below 100000 tonnes per annum. In the fifties, a consortium consisting of Ruhrchemie and Lurgi concluded an agreement with the South African firm of Sasol for the erection of a Fischer-Tropsch plant (Arge process). This plant in South Africa draws upon readily workable coal reserves and today represents the world's only industrial-scale Fischer-Tropsch unit (fixed bed reactor) with an annual capacity of 270000 tonnes of coal chemicals[14]. Coal chemicals are understood to mean the total of all gaseous, liquid, and solid hydrocarbons. A second plant employing the Synthol process of Kellogg (fluidized dust reactor) is shortly to come into operation with a capacity of 2 million tonnes per annum. A further plant of the same size is at the planning stage.

Although the technology of coal gasification and liquefaction has since been developed further[15], and synthesis gas chemistry would also appear capable of additional development, the upgrading potential of coal remains far below that of petroleum.

From the aspect of regulative perspectives that are not only determined by the economic, geological, and political availability, but also by the technological availability, it seems to me that, as mentioned earlier, coal upgrading should pre-eminently be directed towards meeting the expected shortage in supply and easing the pressure on liquid secondary energy sources (naphtha, motor fuel, heating fuel).

The entry to coal upgrading will preferably be by way of coal gasification and the latter must thus be given top priority. The process to be used must be determined by the nature of the coal available and the intended application of the gasification products. In every process, the coal consumption for maintaining the required temperature level of the coal gasification could be reduced by introducing process heat from high-temperature nuclear reactors[16]. The decisive advantage of this future-oriented technology lies in the fact that coal is only used as a raw material, whereby under optimum conditions a coal utilization efficiency of 0.8 and higher appears attainable. An appreciable reduction in coal consumption is a desirable objective, not only to stretch the coal resources over a longer period, but also to counter the rising concentration of carbon dioxide in the atmosphere and the possible climatic changes associated therewith. This could in general become a limiting factor[17].

Because of its low calorific value and high carbon monoxide content, synthesis gas cannot, however, replace natural gas in domestic heating. In the industrial sector there are only limited substitution opportunities for lean gas in energy production. Further processing into synthetic natural gas (SNG) or coal gasification by hydrogenation are possible alternatives that should be given priority in future development activities.

The classical method of carbon monoxide hydrogenation using the Fischer-Tropsch synthesis is extremely capital-intensive and only acceptable in cases where the cost price of the coal used for the production of gasoline and other hydrocarbon fractions is highly favorable. It requires at least 4 tonnes of hard coal for each tonne of coal chemicals.

The Mobil Oil process[18], in which synthesis gas is first converted into methanol, appears to be more promising, even though it has not yet been tested on an industrial scale. The methanol is converted in the presence of zeolite-containing catalysts with concomitant dehydration *via* dimethyl ether into hydrocarbons with a high aromatics content. If one assumes a specific coal consumption of 1.3—1.5 tonnes of hard coal, a total coal consumption of about 3.4 tonnes can be calculated for the production of 1 tonne of coal chemicals.

The production of C_2—C_4 olefins from methanol with high selectivity likewise appears possible with modified catalysts. However, as long as petroleum fractions are still burnt, the production of hydrocarbons and olefins from synthesis gas not only represents a devious route involving a higher expenditure of energy, raw materials, and capital, but its conversion technology is also much more complicated. The unfavorable thermal efficiency is, however, an incentive to bypass the olefin stage for a number of oxygen-containing products during the transition from petroleum to coal.

Special opportunities exist for those synthesis gas derivatives in which carbon monoxide is wholly or partly present in the final product. The process chain of coal–synthesis gas–methanol–acetic acid derivatives is a typical example that is already capable of computation.

Although in view of the present cost-price ratio, the use of lignite instead of methane in the production of synthesis gas still involves appreciable cost increases, it is already superior to naphtha and can be almost compared with the use of heavy petroleum fractions for gasification.

The conversion of heavy and light petroleum fractions through cracking by hydrogenation also offers an alternative to light fuel oil for the domestic sector. As the shortages continue, the further development of coal liquefaction in two directions must ultimately be considered: First, low-sulfur and low-ash fuels for power stations and industrial heating could be produced from coal by slight hydrogenation and extraction by hydrogenation. On the other hand, the route of catalytic high-pressure hydrogenation of coal results in a coal oil with a higher hydrogen content which could be converted into gasoline, naphtha, and primary chemicals in a refinery designed for the production of coal chemicals[19]. In the development of the individual process sequences and upgrading stages it will be possible to build on the extensive experience gained in the processing of petroleum.

The advantages of direct conversion of coal into liquefied coal products are partly offset by the disadvantages, in particular, of a high hydrogen consumption and complex technol-

ogy. This circumstance could be allowed for by using a practical combination of coal extraction by hydrogenation and coal gasification for the production of hydrogen and synthesis gas. According to our present knowledge, the specific coal consumption for the production of 1 tonne of coal chemicals by direct hydrogenation of coal is 3.6 tonnes of hard coal[20]. Of this, 1 tonne alone is used for energy production and 1.36 tonnes for producing the hydrogen required.

The direction pursued in coal upgrading and in coal chemistry and their development potential in comparison to petroleum are thus indicated. The former is directed at the substitution of petroleum-based energy sources for the domestic, industrial, and transport sectors, the latter at the much more elaborate techniques for the production of specific organic primary chemicals. This is illustrated in Figure 11[21].

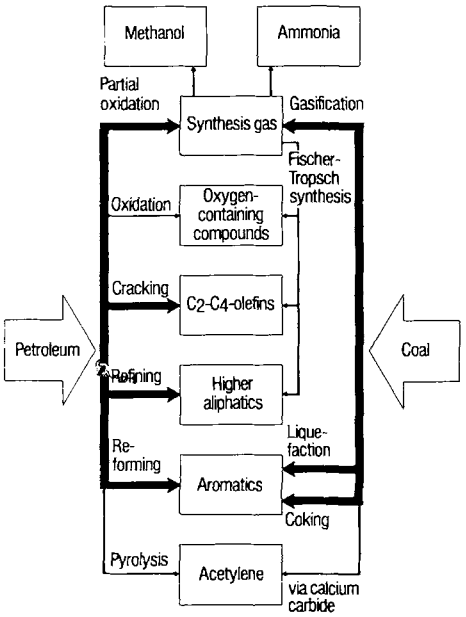

Fig. 11. Upgrading of petroleum and coal.

If the possibilities of substitution are realistically assessed, the transition to new supply patterns which result from the symbiosis of petroleum and coal will be gradual and partially overlap. It is not possible within the scope of this paper to deal with the economic conditions which differ greatly from region to region.

Changes in the pattern and availability of raw materials based on petroleum and coal, as they are to be expected in the medium and long term, are not without an influence on the intertwined system of starting products and intermediates of the chemical industry. These are problems that can be solved if they are recognized and tackled in good time. In view of the high state of development of the chemical industry, rising raw material and energy costs can only to a limited extent still be absorbed by savings in consumption. These costs will in future have a lasting influence on the price structure of all chemical products and, depending on the situation, will also cause processes to be changed.

3. Is Resubstitution of Plastics Foreseeable?

The increase in the price of raw materials will undoubtedly make itself felt most of all in respect of the products with the least number of upgrading stages. A large number of polymers are involved. This raises the question of resubstitution by alternative methods of inorganic or organic origin such as glass, wood and metal, since the introduction of a new material is normally undertaken for reasons of price. Under the pressure of costs, non-utilized properties of materials are not appreciated. The regulating mechanism in the resubstitution of plastics is, however, not determined by the price-property relationship of the raw material alone, but by the final cost of the finished products. The extent of a possible substitution thus depends on several cost factors which result among other things from the processing, shaping, and finishing operations. From the present-day viewpoint, no substantial resubstitution is to be expected, since the cost advantages of plastics products with regard to capital expenditure and labor and energy costs predominate in comparison with finished goods made from natural products.

The multiplicity of properties and combinations of properties have thrown open large markets and opened up new fields of application for plastics, synthetic resins, elastomers, and man-made fibers. In their range of applications they are far superior to all natural products. This explains the steep world-wide increase in the consumption of polymers (cf. Fig. 12).

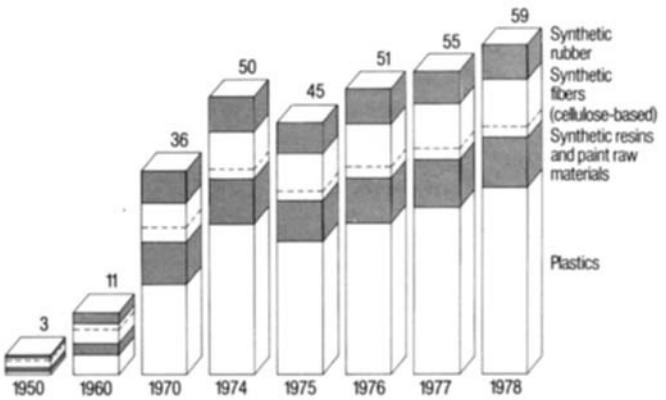

Fig. 12. World consumption of organic polymers between 1950 and 1978 in million of tonnes (without Eastern Europe, the USSR and the People's Republic of China).

In the area of thermoplastics the situation is marked by the commodity resins, namely the polyolefins (HDPE, LDPE, PP), polyvinyl chloride (PVC), and polystyrene (PS and EPS). If one traces the development of the consumption of commodity resins back to 1970, it is evident that pronounced shifts have taken place in the proportions accounted for by the individual types of plastic (cf. Fig. 13).

This development is an expression of the fact that the incentive to substitute commodity resins for one another is determined to a great extent also by the relationship between price and properties, providing that the processability and shaping characteristics are equal. The possibilities of varying the property profiles had considerably extended the application spectrum of plastics and thus facilitated their interchangeability. This trend will continue and is a mark of the dynamism of the market and of creativity.

Fundamentally new commodity resins are not to be expected. Further development of these classes of plastics by

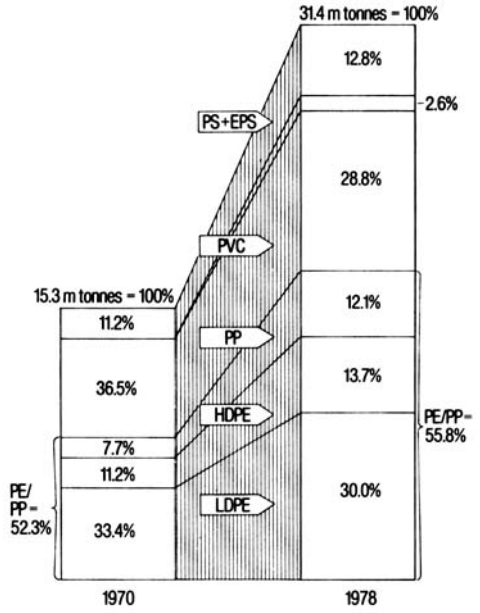

Fig. 13. Development of the world consumption of commodity resins 1970 and 1978 (without Eastern Europe, the USSR and the People's Republic of China).

specific combination and variation of the mechanical and physical properties, tailored to the respective application, will be of primary importance. It is difficult to predict the changes that may occur in the consumption pattern. In most cases, the price-cost gap referred to earlier on will be decisive in the large fields of application.

Commodity resins are appropriately complemented by a large number of high-quality engineering plastics. They are gaining increasing importance as polymer materials and are marked by a high development potential. Narrow limits are placed on their possible substitution for one another, since very specific property combinations are called for in polymer materials, which for reasons of safety and serviceability do not permit any compromise.

On the other hand, the substitution of metals such as zinc, aluminum, copper, and iron by polymer materials will continue, especially in the housing sector and in vehicle and machinery production. This process of substitution was triggered off by the higher energy consumption of metal production (cf. Fig. 14) and processing[22,23].

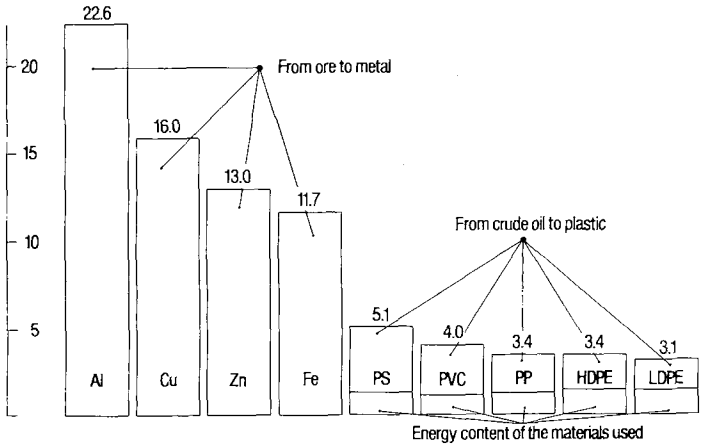

Fig. 14. Consumption of materials and energy (CTE/m³).

Designs of plastic moldings that take into account the properties of the material result in savings in finishing and assembly costs as compared to mass-produced metal parts. These savings are also reflected in the processing costs, particularly the labor costs. In the face of rising energy costs there is an economic incentive to increase the substitution of polymer materials for conventional materials. This is demonstrated with the aid of three examples in Figure 15[24].

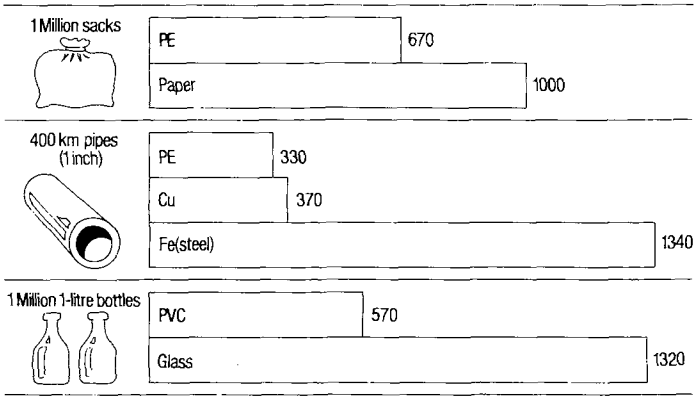

Fig. 15. Finished products and energy consumption (CTE).

Hand in hand with the production of more and more sophisticated products, reinforced thermoplastics and thermosets will continue to gain ground as materials of construction. Since the development of an injection molding process for thermosetting molding compounds and the surmounting of other processing problems, the substitution of thermoplastics for thermosets is no longer of such prime importance. Moreover, in their range of properties they differ markedly from the thermoplastic materials.

For reasons of raw material and energy saving, the applications for highly filled plastics, *i. e.* combinations of polymers with inorganic fillers, will be extended. This applies also to plastics foams, especially those based on polystyrene and polyurethane. They are being increasingly used for thermal insulation in the housing sector and in the form of structural foam as materials for lightweight constructions. In the wide and versatile field of packaging, the process of substitution in favor of plastics film based on petrochemicals is making further progress. This applies mainly to polypropylene due to its low price, its high dimensional stability under heat, and its low permeability to water vapor.

The incentive to re-use plastics and recover waste will be stimulated in respect of all types of plastics. Several technically and economically feasible methods are emerging both for re-use and the indirect utilization of plastics waste by pyrolysis or hydrolysis to obtain low molecular weight hydrocarbon compounds. The potential for innovation is by no means exhausted. I have merely cited examples in order to underline the statement that the polymer field will continue to gain in scope and importance.

Temporary bottlenecks in the supply of raw materials can never be excluded. The great variability of plastics is a characteristic of this area of production which has already proved in the past that it can rapidly adjust itself to changed raw material situations.

4. Summary

Let us return to the starting point of our reflections about raw material-polymer interrelationships—present and future. What final conclusions can be drawn?

Under no circumstances may we continue in the future in the way we started. It would then no longer be possible to safeguard supplies of energy and raw materials even in the medium term. We must therefore follow new paths that will result in radical changes of a structural nature. Above all, we must not lose any time if we are to win the race against tomorrow's problems.

It is my hope that something can be accomplished by determination and not just by necessity,
it is my wish that an awareness of the essentials can accomplish much,
it is my belief that intelligence and prudent restraint can accomplish everything.

I wish to thank Dr. F. Kluge and Dr. W. Scheibitz for their assistance with the content and graphic presentation of the diagrams.

Chemistry and Function of Human Plasma Proteins

By Hans-Gerhard Schwick and Heinz Haupt[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Human blood plasma contains a large number of proteins. New analytical and preparative techniques have so far permitted the isolation of more than one hundred such proteins; about ninety percent of these were first characterized in the last 30 years. The plasma proteins include components of the clotting and complement systems as well as proteinase inhibitors, immunoglobulins, lipoproteins, and carrier proteins. The biological function of some of the plasma proteins is not yet known. Deficiency of one or more plasma proteins usually causes serious health disorders, the best known example being hemophilia. Several biologically active proteins can be gained from blood plasma; these proteins—for example the blood clotting factors—are of great prophylactic and therapeutic importance and allow a better exploitation of the valuable plasma than can be obtained by means of transfusion.

1. Introduction

30 years ago *H. E. Schultze*[1] published a report on "Die Plasmaeiweisskörper im Blickfeld des Chemikers". At that time, approximately ten proteins had been purified from human blood plasma and had been well characterized by physicochemical techniques. The number of proteins isolated from human blood plasma now amounts to more than 100. Their identification and purification were made possible, mainly in the last 15 years, by the development of new analytical and preparative techniques; the great diversity of the plasma proteins was revealed in particular by immunological detection methods and many human plasma proteins were then soon purified by preparative chromatographic methods (see Table 1).

There are three main reasons for the fractionation and purification of plasma proteins:

1) the isolation of protein preparations with prophylactic and therapeutic properties from human blood plasma;
2) the utilization of pure proteins for obtaining plasma protein antisera which are nowadays indispensible reagents for clinical diagnoses; and
3) the utilization of pure proteins in structural analyses, *e.g.* determination of amino acid sequences and X-ray structure analyses in order to elucidate the functions of these proteins at a molecular level.

[*] Prof. Dr. H. G. Schwick, H. Haupt
Behringwerke AG, D-3550 Marburg/Lahn (Germany)

Table 1. A century of plasma protein fractionation. Analytical and preparative techniques which have had a major influence on the preparation of highly purified plasma proteins.

Year	Method	Approx. number of highly purified plasma proteins
1880	Mineral salt precipitation	1
1890		2
	Euglobulin precipitation	
1900		2
1910	Electrodialysis	2
	Alcohol precipitation

1980		100

Whereas at the time of *Schultze*'s publication no complete amino acid sequence analyses of human plasma proteins were known, the entire sequences of some and partial sequences of many of these proteins have now been established (Table 2).

Table 2. Amino acid sequence analyses of human plasma proteins.

1. Plasma proteins, for which complete or almost complete sequences have been determined:	*2. Plasma proteins, for which detailed partial sequences, amino terminal sequences, and sequences of the active center have been determined:*
Prealbumin	Transferrin
Albumin	Ceruloplasmin
α_1-Acid glycoprotein	Complement-component C1q
Haptoglobin: α_1^S-, α_1^F-, α_2-, β-chain	Complement-component C1r
Apolipoproteins A-I, A-II, C-I, C-II, C-III	Complement-component C1s
Fibrinogen; α-, β-, γ-chain	Retinol-binding protein
β_2-Microglobulin	β_2-Glycoprotein I
C3a-Anaphylatoxin	9.5S α_1-Glycoprotein
C5a-Anaphylatoxin	Prothrombin
C-reactive protein	α_1-Antitrypsin
IgG; γ-chain	α_1-Antichymotrypsin
IgA; α-chain	Plasminogen and plasmin
IgM; μ-chain	Hemopexin
IgE; ε-chain	Factor XIII
κ-chain	Secretory component
λ-chain	
J-chain	

As there is so much information available concerning the chemistry and function of plasma proteins, this review cannot be complete. We shall concentrate on reporting more recent findings and otherwise refer to comprehensive reviews.

2. Classification of the Plasma Proteins

2.1. Definition of the Plasma Proteins

Putnam[2b] recently compiled a list of criteria which characterize the true plasma proteins (Table 3).

Table 3. Criteria for classification as a true plasma protein [2b].

1. Presence in the plasma (after the neonatal period)
2. Synthesis in liver or RES system rather than in specialized tissues
3. Primary function (including transport function) mediated in the vascular system rather than in a target organ
4. Protein actively secreted into blood rather than by leakage through tissue damage
5. Protein concentration highest in blood of all body fluids
6. Appreciable half-life in plasma rather than just a short transit time
7. Protein may exhibit genetic polymorphism or variant forms but polymorphism not due to tissue of origin, as with some isozymes
8. Protein not derived by catabolic proteolytic cleavage in plasma (as Fab or Fc) but may be proteolytic cleavage product of physiological pathways such as complement or coagulation

These criteria are fulfilled, for example, by proteins which are components of multienzyme systems (such as the clotting or complement systems), by immunoglobulins, lipoproteins, proteinase inhibitors, and carrier proteins. In addition, human plasma contains a large number of proteins which cannot be assigned to any of these systems or groups and whose functions are still not known.

This definition of the plasma proteins thus excludes hormones, enzymes originating in the tissues, erythrocyte proteins, and numerous proteins which only circulate temporarily in the blood plasma under physiological or pathophysiological conditions without exercising any function. The latter were termed "passenger proteins" by *Putnam*[2b].

2.2. Concentration of the Plasma Proteins

There are enormous differences between the normal mean concentrations of the plasma proteins. This is shown particularly well in a diagram by *Putnam*[2b] which we have modified somewhat and completed by adding proteins which have been recently described (Fig. 1).

In this diagram the normal mean concentrations of 63 plasma proteins are plotted on the logarithmic scale as functions of their electrophoretic mobility (u).

Proteins which belong to the same system or group are denoted by the same color. The large differences between the concentrations of proteins within a system or group should be noted. The range extends from 4 g per 100 ml plasma for albumin to 5 μg per 100 ml plasma for IgE (immunoglobulin E). The concentration of most plasma proteins is less than 100 mg/100 ml. This means that the few plasma proteins which are found in quantities of more than 100 mg/100 ml already account for about 90% of the protein content of human plasma; the remainder of approximately 10% contains more then 100 plasma proteins. It is thus understandable that great difficulties are encountered when purifying trace proteins (1 to 10 mg/100 ml) from human plasma; many trace and ultra-trace proteins (up to 1 mg/100 ml) with important physiological functions are certainly still not known today.

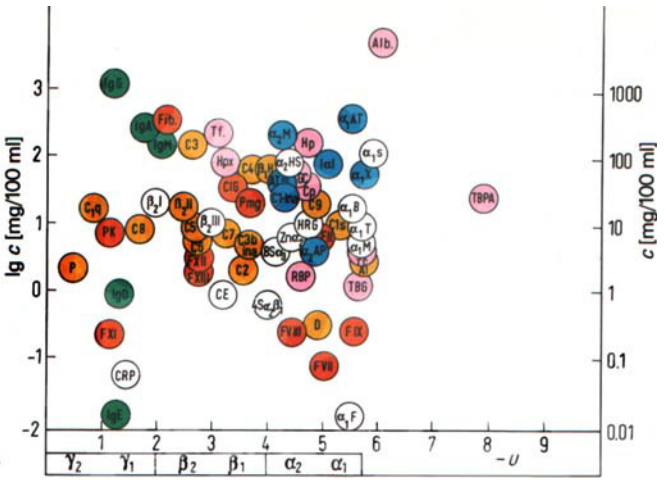

Fig. 1. Distribution diagram (without lipoproteins) of human plasma proteins (modified according to [2b]). Red: blood clotting system; Fib. = fibrinogen, CIG = cold-insoluble globulin (fibronectin); PK = prekallikrein, Pmg = plasminogen, F = factor in F II, F VII, F VIII, F IX, F XI, F XII, F XIII. Pink: carrier proteins; Alb. = albumin, Tf. = transferrin, Hp = haptoglobin, Hpx = hemopexin, GC = Gc globulin, Cp = ceruloplasmin, TBPA = prealbumin, TC = transcortin, RBP = retinol-binding protein, TBG = thyroxine-binding globulin. Yellow: complement system; proteins C1q, C1s, C2, C3, C4, C5, C6, C7, C8, C9, β_1H; AI = anaphylatoxin inactivator. ber of proteins in plasma is age-dependent[3,4]. In the case of newly born infants and in early childhood, the concentrations of a series of plasma proteins (including components of the complement and clotting systems and the immunoglobulins) are lower than those of adults. In the case of older individuals there may also be an increase or decrease in the concentrations of certain plasma proteins under normal physiological conditions[5–7]. Finally, the concentrations of several proteins in human plasma are sex-dependent: for example women have higher mean values for immunoglobulin M (IgM), α_2-macroglobulin, and apolipoprotein A[8].

3. Plasma Protein Systems and Groups

3.1. The Clotting System

Like the complement system, the blood clotting system is a very complex multienzyme system. Both systems involve activation and cascade reactions, which lead to intermediate products or new components.

Excluding the inhibitors, 14 protein components are involved in blood clotting. Most of them have been highly purified and physicochemically well characterized within the last few years (see Table 4)[9–12]. They differ considerably in their molecular weights, electrophoretic mobilities, and plasma concentrations. Apart from fibrinogen, plasminogen, and fibronectin, all clotting proteins are trace or ultra-trace proteins.

The blood clotting factors can be functionally classified into enzymes (factors II, IX, X, XI, XII, prekallikrein, and plasminogen), accessory factors (factors III, V, and VIII,

Table 4. Blood clotting factors: nomenclature and properties.

Factor	Conventional name	Molecular weight	u_{rel} [a]	c [mg/100 ml] [b]
Factor I	Fibrinogen	340000	β	200—450
Factor II	Prothrombin	72000	α_1	5—10
Factor III	Tissue factor			
Factor IV	Calcium ions			
Factor V	Proaccelerin	250000—300000	β	
Factor VII	Proconvertin	56000	α	*ca.* 0.1
Factor VIII	Antihemophilic globulin	*ca.* 2×10^6	β	*ca.* 0.1—1
Factor IX	Christmas factor	57000—70000	α_1	0.1—0.7
Factor X	Stuart factor	60000	α_1	
Factor XI	Plasma-thromboplastin-antecedent (PTA)	160000—210000	γ	*ca.* 0.6
Factor XII	Hageman factor	80000	β	1.5—4.7
Factor XIII	Fibrin stabilizing factor	340000	β	1.0—4.0
	Prekallikrein	80000—127000	γ	4—5
	HMW kininogen (high molecular weight kininogen)	120000	α	6
	Plasminogen	87000	β	10—15
	Fibronectin	440000	β	25—40

[a] Relative electrophoretic mobility, pH 8.6; see also Fig. 1. [b] Normal mean concentration in plasma.

The ultra-trace protein IgE which belongs to the immunoglobulins was, for example, only discovered because it occurred in the serum of a very small number of patients suffering from multiple myeloma in concentrations which were increased 50000 fold.

The present state of our knowledge of the diversity and concentrations of the plasma proteins has been strongly affected by the development of qualitative and quantitative immunological techniques. Very soon after the introduction of electrophoresis and immunological plasma protein determination, it was found that the concentration of a large number of proteins in plasma is age-dependent[3,4]. In the case of newly born infants and in early childhood, the concentrations of a series of plasma proteins (including components of the complement and clotting systems and the immunoglobulins) are lower than those of adults. In the case of older individuals there may also be an increase or decrease in the concentrations of certain plasma proteins under normal physiological conditions[5–7]. Finally, the concentrations of several proteins in human plasma are sex-dependent: for example women have higher mean values for immunoglobulin M (IgM), α_2-macroglobulin, and apolipoprotein A[8].

high molecular weight kininogen, and fibronectin), catalysts (phospholipid, Ca^{2+} ions), substrates (fibrinogen), and proteinase inhibitors.

It is impossible to describe the entire physiology of clotting in detail here, however prothrombin activation will be used as an example to show how well the protein chemistry of the reactions of the blood clotting system is now understood. The upper part of Figure 2[13] schematically demonstrates the fixation of prothrombin to a phospholipid vesicle; this is brought about *via* the Ca^{2+} binding sites in the amino terminal of the prothrombin molecule. It has been shown that the

clotting factors in the wound are also concentrated and activated according to this reaction principle.

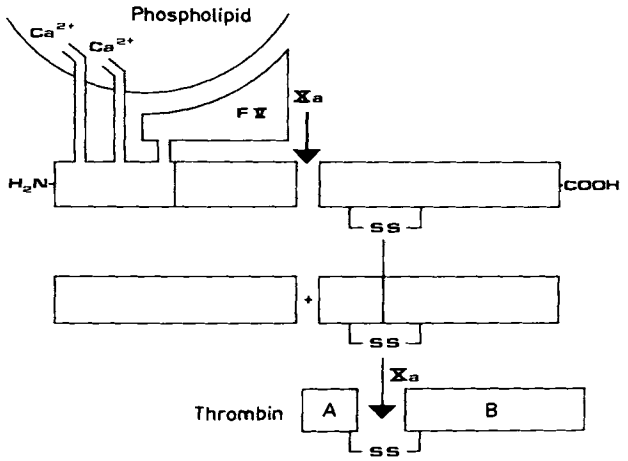

Fig. 2. Activation of prothrombin by factor Xa, catalyzed by Ca^{2+} and phospholipid (modified according to [13]). For details see text.

It is also evident from Figure 2 that thrombin is liberated from prothrombin by two successive peptide cleavages which are catalyzed by factor Xa. In the absence of factor V this activation proceeds very slowly, in the presence of factor V the reaction is accelerated a thousand-fold, *i.e.* factor V has an accessory function. Factor V apparently binds to the prothrombin molecule and the phospholipid and brings the two molecules so close together that charge transfer is possible, resulting in cleavage of the peptide bond by factor Xa. The prothrombin-activator complex is thus only formed to promote the activation of prothrombin. Even after the first cleavage of prothrombin by factor Xa the residual molecule is already separated from the activation complex. The resulting cleavage product does not contain any γ-carboxyglutamic acid residues and thus no longer differs in this respect from other serine esterases.

As regards the proteins involved in the clotting system, we will merely mention a protein which was already isolated more then 30 years ago[14], the function of which, however, was recognized only recently; this protein, which is insoluble in the cold, has now been called fibronectin[15]. It is a glycoprotein (molecular weight 440000) consisting of two subunits linked by disulfide bridges[16]. Fibronectin has an affinity for collagen, fibrin, heparin, and the cell surface[15, 17]. During the last phase of blood clotting it is cross-linked with itself and fibrin by factor XIII. The cross-linking with fibrin favors adhesion of fibroblasts to the fibrin matrix, this is an important prerequisite for the colonization of these cells in the wounded area, for their survival and collagen synthesis[18].

3.2. The Complement System

The importance of the complement system in plasma lies in its "complementation"—hence the name—of humoral and cellular immunity. Disregarding the inhibitors or inacti-

vators, 17 proteins belong to this system (see Table 5)[19–22]. Although most complement components are trace proteins, all of them have been isolated and physicochemically characterized. They differ, like the proteins of the blood clotting system, in their molecular weights and electrophoretic mobilities. Their subunit composition has been extensively investigated. As far as is known, all complement components are glycoproteins.

From the chemical point of view the protein C1q is one of the most unusual proteins of the complement system and of the entire human blood plasma, for it resembles collagen. C1q (molecular weight approximately 400000) consists of 18 polypeptide chains (6A, 6B, and 6C) each containing approximately 200 amino acids. Amino acid sequence analyses have shown that the three types of chains are similar and that each possesses a region of about 80 amino acids close to the N terminal with typically collagen-like sequences[23]. The triplet Gly-X-Y, which repeats itself in this region, often contains hydroxyproline or hydroxylysine in position Y. Similarly to collagen and the basal membrane, glucosylgalactosyl groups are bound to the hydroxy groups of this hydroxylysine; these groups account for about 2/3 of the total carbohydrate content (9.8%) of the C1q molecule.

The complement system can functionally follow one of two pathways[19,20]. The first or classical pathway is activated by type IgG or IgM complexes. The proteins involved can be divided into several functional units or complexes: the unit with recognition properties (C1q, C1r, C1s), the activation unit (C2, C3, C4) and the membrane attack complex which is finally responsible for membrane lysis (C5, C6, C7, C8 and C9). The alternative pathway or properdine pathway is activated by aggregated IgA and by naturally occurring polysaccharides and lipopolysaccharides. Six proteins are involved in this pathway, one of them (C3) also participates in the classical pathway. The unit with recognition properties is here formed together with the initiating factor from the components, C3, B and D, whilst the complex consisting of C3b, B, D and P (=properdin) shows activation properties and

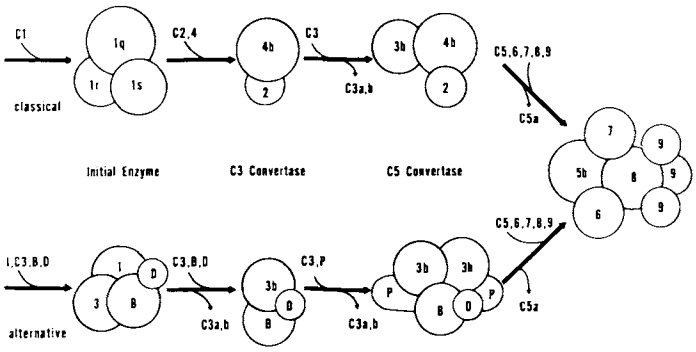

Fig. 3. Schematic representation of complement activation [20]. The circles symbolize different protein molecules. For details see text.

activation peptides (C3a and C5a) cause, for example, the liberation of histamine from mast cells, chemotactic attraction of polymorphonuclear leucocytes and contraction of smooth muscle.

3.3. The Proteinase Inhibitors

Whereas in the two preceding sections protein systems have been described in which the components react with one another, the proteinase inhibitors represent a group of human plasma proteins with similar functions. The proteinase inhibitors are closely connected with the blood clotting and complement systems. The inhibitors act in the cascade-like system of activating steps and are responsible for the regulation or inactivation of the activated enzymes. The special importance of the proteinase inhibitors lies in the fact that they maintain the equilibria of *several* multienzyme systems. This means, certain proteinase inhibitors are acting with a given priority in two or more multienzyme systems.

Eight proteinase inhibitors are so far known, seven of them have been purified and well characterized chemically (Table 6)[27,28].

Table 6. Properties of the proteinase inhibitors of human plasma.

	Inhibitors	Molecular weight	c [mg/100 ml] [a]	u_{rel} [b]	Carbohydrate [wt.-%]
α_1AT	α_1-Antitrypsin	54000	290.0	α_1	12.2
α_1X	α_1-Antichymotrypsin	69000	48.7	α_1	24.6

acts on C5—C9 in an analogous fashion to the C5-convertase complex of the classical pathway (Fig. 3).

The biological consequences of activation of the complement system are:

1) irreversible structural and functional modification of biological membranes and subsequent cell death[24–26] and
2) activation of special cell functions triggered by the reaction products of complement components[19]. Two such

When compared with the proteins of the systems so far discussed, the concentrations of the proteinase inhibitors in human plasma are relatively high. They differ greatly in their molecular weights and, on the basis of their electrophoretic mobilities, they are all α-globulins. α_1-Antitrypsin, α_1-antichymotrypsin, antithrombin III, C1 inactivator, and α_2-antiplasmin each consist of a single polypeptide chain. α_2-Macroglobulin has a tetrameric structure[29,30]; the subunits (molecular weight 185000) are similar or identical. Two di-

sulfide dimers are held together by non-covalent bonds and form the native α_2-macroglobulin. One molecule of α_2-macroglobulin binds two zinc atoms[31]. The subunit structure of the inter-α-trypsin inhibitor is still unknown.

All proteinase inhibitors are glycoproteins. Little is yet known about their chemical composition. According to amino acid sequence analyses of the N-terminals of α_1-antitrypsin and α_1-antichymotrypsin, there is no sequence homology between their first amino acid residues. There is, however, a strong structural correlation of the two proteins between residues 33—45 of α_1-antitrypsin and residues 16—27 of α_1-antichymotrypsin[32,33]. There is no homology with the N-terminal moiety of antithrombin III. It is, however, remarkable that the unusual terminal arginine is found in both α_1-antichymotrypsin and inter-α-trypsin inhibitor.

All proteinase inhibitors with the exception of α_1-antichymotrypsin exhibit a wide spectrum of activities, *i.e.* they can neutralize several proteolytic enzymes (Table 7)[28].

inhibitor for each protease present in the plasma. Information about the real physiological function of an inhibitor cannot, however, be derived from its activity spectrum; this can only be achieved by determining the molar concentrations of the inhibitors and their relative affinities for the proteolytic enzymes in question.

The proteinase inhibitors can be classified into inhibitors of proenzyme activation, blood clotting, fibrinolysis, kinin liberation, and of endogenous and other proteases (cf. Table 8). In clinical diagnoses the inhibitors can be determined by functional and immunological methods.

3.4. The Immunoglobulins

The immunoglobulins represent a group of five proteins which have, in addition to functional similarity and structural homology, a common site of synthesis. Of all the plasma

Table 7. Spectrum of the action of proteinase inhibitors (see Table 6) of human plasma. + = strong, possibly stoichiometric inhibition, ? = not determined.

Proteinase Name	Function	Inhibitors α_1AT	α_1X	IαI	ATIII	C1-ina	α_2M	α_2AP
Factor IIa	clotting	–	–	–	+	–	+	+

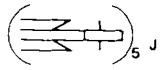
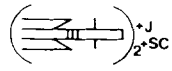
Papain	metabolism	–	–	?	?	?	+	?
Bromelin	metabolism	–	–	?	?	?	+	?
Ficin	metabolism	–	–	?	?	?	+	?





This is apparently a general feature of the inhibitory action and also of the specificity of proteinases. Most of them are serine proteinases. α_1-Antitrypsin, for example, thus inhibits a large number of enzymes regardless of their origin. A further consequence of this fact is that there is more than one

proteins the immunoglobulins have been investigated physicochemically and also functionally in the most detail. Since there are good review articles dealing with the immunoglobulins[34–37] we have only listed a few of their physicochemical properties (Table 9)[38].

Table 8. Physiological functions of some proteinase inhibitors of human plasma.

Inhibitor	Function	Pathology
C1 Inactivator	Activation and control of: blood clotting, fibrinolysis kallikrein, and complement	Hereditary angioneurotic edema: permeability disorders as a result of a deficiency or functional inactivity of the inhibitor
Antithrombin III	Local limitation of clotting	Hereditary antithrombin III deficiency: thromboembolic disorders
α_2-Macroglobulin	Local limitation of clotting	Consumption of antithrombin III: hypercoagulability
α_2-Macroglobulin	Limitation of fibrinolysis to pathological substrates	Consumption of α-macroglobulin during fibrinolytic therapy
C1 Inactivator	Limitation of fibrinolysis to pathological substrates	
α_1-Antitrypsin	Limitation of fibrinolysis to pathological substrates	
α_2-Macroglobulin	Control of infections and inflammations; prevention of autodigestive processes and side reactions in the clotting system	Hereditary α-antitrypsin deficiency: pulmonary emphysema
α_1-Antitrypsin	Control of infections and inflammations; prevention of autodigestive processes and side reactions in the clotting system	Local consumption of the inhibitors in: acute inflammations, infections of the nasal mucous membrane, rheumatic arthritis in the synovial fluid, in burns, leukemia, endotoxin shock
Inter-α-trypsin inhibitor	Control of infections and inflammations; prevention of autodigestive processes and side reactions in the clotting system	
α_2-Antiplasmin	Control of fibrinolysis	Hereditary α_2-antiplasmin deficiency: strong bleeding tendencies, hemarthrosis

3.5. The Lipoproteins

The lipoproteins will be briefly described as the final example of the protein groups. Intensive studies on plasma lipoproteins have contributed considerably to the understanding of lipid metabolism and the diseases connected with it[39-41]. The lipoproteins are complex macromolecules whose lipid moieties are linked to the protein components by non-covalent bonds. The lipoproteins also have a small carbohydrate content. They are classified into four groups according to their physical characteristics and their chemical composition. Each of these groups can be further divided into subclasses by means of ultracentrifugation or gel filtration, the subclasses are however still heterogeneous with respect to their compositions and sizes (see Table 10).

Table 11. Distribution of polypeptide chains (apolipoproteins) within the lipoprotein classes. + = Detected in traces, − = not detected.

Apo-lipoprotein	Chylomicrons	VLDL	LDL	HDL
	[% of the apolipoprotein fraction]			
A-I	+	+	−	65—70
A-II	+	+	−	25—50
B	5—20?	40 [a]	>95	−
C-I	15	10 [a]	+	1—3
C-II	15	10 [a]	+	1—3
C-III	45	30 [a]	+	5—10
D [b]	−	+	−	+
E	+	[c]	−	+
F	−	−	+	[d]

[a] Varies within the VLDL subspecies, denser VLDL contain more B in relation to C. [b] Is also described as the "thin line protein" and Apo A-III. [c] Integral component of the apolipoprotein fraction of the VLDL. [d] Integral component of the apolipoprotein fraction of the HDL.

Table 10. Properties of the lipoproteins of human plasma. VLDL, LDL, and HDL indicate lipoproteins with very low, low, or high densities, respectively.

	Chylomicrons	VLDL	LDL	HDL
Density	0.95	0.95—1.006	1.006—1.063	1.063—1.210
Molecular weight		8×10^6—35×10^6	2×10^6—4×10^6	175000-360000
Diameter [Å]	750—10000	300—800	215—220	
Triglycerides [%]	80—95	60	10	5
Cholesterol [%]	5	12	50	20
Phospholipid [%]	3	18	15	25
Protein [%]	1—2	10	25	50

A series of proteins (apolipoproteins) is known to be involved in different concentrations in the construction of the lipoprotein classes (Table 11)[39]. Whereas the polypeptides A-I and A-II are found mainly in the HDL (high density lipoproteins), protein B is preferentially found in the LDL and VLDL (low and very low density lipoproteins respectively)[41a].

According to latest investigations[41], type A and B polypeptides have a "core" protein character and act as nuclei in the formation of all lipoprotein complexes apart from the chylomicrons. It is not known whether the Type C polypeptides have a corresponding function.

As the C proteins are readily transferred between the HDL and VLDL, it is not likely that they are tightly bound to the

core proteins A or B. Furthermore the stoichiometric ratio C-I:C-II:C-III is not the same in the HDL and VLDL. It can thus be concluded that at least one of the C peptides exchanges between these two lipoprotein classes. The peptide C-II has, in addition to lipid transport, another physiological function—it is a potent activator of the enzyme lipoprotein lipase.

4. Proteins with Known Functions (Carrier Proteins)

In this section proteins will be discussed which cannot be assigned to a protein system but whose function is known. This function is usually the transport or binding of substances in blood serum. The proteins can bring these substances to their sites of action or they prevent the body from losing important metabolic products or other compounds; they can, however, also remove metabolic products and thus have a detoxifying function. They do not carry out these functions in a systemic process as do the clotting or complement proteins, but act individually. In some cases, for example an inborn deficiency of one of these transport proteins, another protein can take over the function of the one that is lacking.

Some proteins with carrier functions are listed in Table 12.

Prealbumin[46] is a plasma protein with considerable biological importance; it transports a hormone and a vitamin. Whereas thyroxine is directly bound to the prealbumin molecule, retinol (vitamin A alcohol) is indirectly bound to prealbumin *via* its specific carrier protein—the retinol-binding protein[47]. Formation of this very loosely bound protein-protein complex prevents fast excretion of the relatively low molecular weight retinol-binding protein by the kidneys.

Scientists at the Laboratoire de Christallographie, CNRS, in Paris and the Laboratory of Molecular Biophysics in Oxford have performed structural studies in collaboration with our group on prealbumin at a resolution of 2.5 Å. According to these investigations, prealbumin consists of four identical subunits which are held together by non-covalent bonds. The subunits form a canal in the middle of the molecule which contains the two binding sites for thyroxine[48,49]. The complete complex of prealbumin and retinol-binding protein can bind one molecule of thyroxine and one of retinol.

Thyroxine-binding globulin[50]: the structure of this globulin which is found in serum in traces is also now well known. Its secondary and tertiary structures have been investigated by circular dichroism and fluorescence spectroscopy. The relaxation time shows that thyroxine-binding globulin is a compact, symmetrical molecule in which one half of the amino acid residues form α-helices and the other half β-pleated sheets. The molecule has only one polypeptide chain and is a

Table 12. Properties of the carrier proteins of human plasma.

Protein	Biological function	Molecular weight	c [mg/100 ml] [a]
Prealbumin	Binding of thyroxine and retinol binding protein	54980	25
Albumin	Transport of ions, pigments, *etc.*, osmotic function	66000	3500—5500
Transcortin	Binding and transport of cortisol	55700	4
Thyroxine binding globulin	Binding of thyroxine	54000	1—2
Retinol binding protein	Binding of retinol	21000	4.5
Gc-Globulin	Binding of vitamin D_3	50800	40
Transcobalamine I	Binding of vitamin B_{12}	60000	?
Transcobalamine II	Binding and transport of vitamin B_{12}	53900	Traces
Ceruloplasmin	Binding of copper; oxidase	132000	35
Transferrin	Binding and transport of iron	76500	295
Hemopexin	Binding of hemin	57000	80
Haptoglobin	Binding of hemoglobin	100000 (Typ 1-1)	170—235

[a] Normal mean concentration in serum.

The carrier proteins are synthesized at different sites; they differ in their molecular weights, and their concentrations in human serum range from 1 to over 1000 mg/ml (albumin). Of all the plasma proteins albumin has the most diverse binding properties. It is impossible to mention all the endogenous or exogenous substances which are transported by albumin. It should be mentioned here that the technique of electrophoresis provided the most important contribution in the discovery of the carrier proteins and in the recognition of the prime importance of albumin as a vehicle protein. The name of *Hans Bennhold*[42] is closely associated with these early studies.

The most important carrier proteins will be briefly dealt with in the following.

Albumin: a great deal of progress has been made as regards the elucidation of the biosynthesis of albumin, its structure and binding sites[43,44]. Bilirubin, for example, is bound with high affinity to the lysine residue at position 240[45].

glycoprotein. It is very stable in the alkaline range up to pH = 10.5, below pH = 5.0 it very readily loses its hormone-binding properties in an irreversible fashion[51,52].

Gc-globulin[53]: the group specific component discovered by *Hirschfeld*[54]—now called Gc-globulin—was recently shown to be identical with transcalciferin, a plasma carrier protein which transports vitamin D. Gc-globulin has a binding site for vitamin D_3 and its 25-hydroxyderivative, it may also transport other vitamin D metabolites[55,56].

Transcobalamin I and II[57-59]: at the present time, not very much is known about the structure and composition of the vitamin B_{12}-binding proteins. This is certainly closely connected with their very low concentrations in human serum. They can be chromatographically separated into two fractions—transcobalamin I and II. Transcobalamin I is a glycoprotein with a carbohydrate content of 33%, transcobalamin II is a pure polypeptide. The two proteins differ from each other immunologically. Transcobalamin II is apparently of

greater physiological importance than transcobalamin I; it is responsible for the transfer of vitamin B_{12} to tissue cells.

Hemopexin[60,61] is a heme-binding serum protein; it is a single-chain glycoprotein with a carbohydrate content of approximately 22%. It binds equimolar quantities of porphyrins and metallo-porphyrins and prevents the body from losing iron.

Haptoglobin[62], the hemoglobin-binding protein of the serum, exhibits genetic polymorphism. Haptoglobin from homozygote Hp 1-1 individuals only gives one band on molecular-sieve electrophoresis; haptoglobin of homozygote type Hp 2-2 and heterozygote type Hp 2-1 is, however, composed of a series of polymorphous proteins with increasing molecular weights[63,64]. Haptoglobin is composed of light (α) and heavy (β) chains. The heavy β chain (molecular weight 40000) is common to all types and contains the carbohydrate moiety. There are three forms of the lighter α chain—α_1F, α_1S, and α_2 chains (molecular weights 8900, 8900, and 16000 respectively). The α_2 chain is supposed to have originated from the α_1 chain by gene duplication. The complete amino acid sequence analyses of all the α chains are known. There is an evolutionary similarity between the α_2 chain of haptoglobin and the L chains of the immunoglobulins[65]. An α chain-like segment has also been found in the α_1-acid glycoprotein[66].

Transferrin[67,68] has, as a metal-binding protein, a true carrier function. It shows structural homology with lactoferrin and ovotransferrin in its N-terminal amino acid sequence[69]. Transferrin possesses two binding sites for iron which, contrary to earlier assumptions, show small but significant differences and can be identified by isoelectric focussing[70,71]. The mechanism of iron release at the reticulocytes has been well studied[72,73].

Ceruloplasmin[74] is not a true carrier protein, but possesses ferroxidase activity. It contains one peptide chain and six copper atoms which are bound differently[75,76]. Part of a 20000 dalton ceruloplasmin fragment has a structure similar to that of plant plastocyanins and bacterial azurines[77].

5. Human Plasma Proteins with Unknown Functions

Several α- and β-glycoproteins from human plasma have been purified and well characterized physicochemically without anything being known about their functions (Table 13).

Some more recent results concerning these proteins will be given in the following; the majority of these proteins were first purified and described by our laboratory.

The structure of the *α_1-acid glycoprotein*[78], which is found in human serum in relatively high concentrations, has been well studied thanks to the excellent work of *K. Schmid et al.*[79-81]. It consists of a single polypeptide chain whose asparagine residues in positions 15, 38, 54, 75 and 85 are *N*-glycosidically linked to polysaccharide units. Its carbohydrate content is almost 40%. There is a certain similarity between the amino acid sequences of α_1-acidic glycoprotein and the immunoglobulins. It is assumed that α_1-acidic glycoprotein originated from the same stem as the immunoglobulins but before the primitive L chain arose[80]. In connection with this fact it is interesting that α_1-acid glycoprotein is not only synthesized in the liver but also in lymphocytes, granulocytes, and monocytes[82]. α_1-Acidic glycoprotein binds several steroids and basic drugs such as aprenolol and imipramine[83] and exhibits striking inhibitory properties in platelet aggregation[84].

Table 13. Properties of human plasma proteins with unknown functions.

Protein	Molecular weight	Carbohydrate [wt.-%]	I.P. [a]	c [mg/100 ml] [b]
α_1-Acid glycoprotein	41000	37.9	2.7	90
α_1T-glycoprotein	60000	13.7		8
α_1B-glycoprotein	50000	13.3	4.4—4.6	22
9.5S-α_1-glycoprotein	308000	12.8	5.0	5.5
α_1-Microglobulin	26700	20		5.4
Zn-α_2-glycoprotein	41000	18.2	3.8	5
α_2HS-glycoprotein	49000	13.4	4.1	60
Histidine-rich 3,8S-α_2-glycoprotein	58500	14.3	5.6—6.5	9
Leucine-rich 3,1S-α_2-glycoprotein	49600	23	3.8—4.1	2.1
8S-α_3-glycoprotein	220000	31.4	4.2—4.6	4
4S-$\alpha_2\beta_1$-glycoprotein	60000	27.7	4.0	0.02
β_2-Microglobulin	11800	0	5.56	0.15
β_2-Glycoprotein I	40000	18.8	5.4—6.25	20
β_2-Glycoprotein III	35000	10	5.1—5.8	10
C-reactive protein	110000—140000	0		<0.1

[a] Isoelectric point. [b] Normal mean concentration in plasma.

Whereas there is no recent data for the *α_1T-*[85] and *α_1B-glycoproteins*[86], it has been shown that the *9.5Sα_1-glycoprotein*[87,88] is identical with the P component of human plasma and must be assigned to the "pentagonal structure" found on electron microscopical examination of organs with amyloid deposits[89]. The 9.5Sα_1-glycoprotein is also identical with the C1t protein described by *Painter et al.* which was erroneously considered to be a fourth subcomponent of the C1 complex of the complement system[90]. In reactions with galactans, the 9.5S-α_1-glycoprotein has lectin-like properties[91]. On the basis of the sequence analysis of the first 30 amino acids, there is extensive homology between the 9.5Sα_1-glycoprotein and the C-reactive protein[92,93].

There are no recent findings concerning the physiological functions of the *Zn-α_2-*[94], *8S α_3-*[95], *4S $\alpha_2\beta_1$-*[96] and leucine-rich *3.1S α_2-glycoproteins*[97]. 3.1S α_2-Glycoprotein was first discovered by us three years ago and is distinguished by the fact that about every fifth one of its amino acids is leucine.

According to more recent studies, *α_2-HS-glycoprotein*[98] is a component of bone matrix; it is supposed to have opsonizing properties (*i.e.* causes increased phagocytosis) and its level decreases in the serum of patients after major surgical operations[99,100].

According to *Morgan*, the histidine-rich *3.8S α_2-glycoprotein*[101] binds hemin, other organic compounds and some divalent metal ions[102,103]. It is, however, still not certain whether these properties are of physiological significance.

α_1-Microglobulin[104,105] is a glycoprotein and was first isolated from the urine of patients suffering from tubular proteinuria by a Swedish group of workers. It is also present in the serum and urine of healthy individuals. *Takagi et al.*[106] have recently examined its distribution in tissues. It is localized on the surface of T and B lymphocytes and is apparently synthesized there. It still has to be resolved whether α_1-microglobulin is identical with the α_1-microglycoprotein isolated by *Seon* and *Pressman*[107] from the urine of patients suffering from cancer.

Since the discovery of *β_2-microglobulin* more than ten years ago by *Berggård* and *Bearn*[108], many reports have been published about this protein. Here attention will therefore only be drawn to its structural and evolutionary relationship to the immunoglobulins, to its identification as a membrane protein and to the fact that it is a component of the histocompatibility antigens[109].

β_2-Glycoprotein I was already known in 1961[110]. It is a carbohydrate-rich, polymorphous glycoprotein which can be easily crystallized[111]. We were later able to find a family who suffered from an hereditary deficiency of β_2-glycoprotein I but without any recognizable ill effects[112]. On gel diffusion according to *Ouchterlony*, this protein is directly precipitated by dextran sulfate and heparin and transports heparin on agar gel electrophoresis[113]. *Burstein* and *Legmann*[114] have recently discovered that the precipitation of tryglyceride-rich lipoproteins with anionic detergents only succeeds in the presence of β_2-glycoprotein I. In connection with this, attention is drawn to a recent publication by *Polz et al.*[115] according to which β_2-glycoprotein is supposed to be an integral component of the very low density lipoproteins (VLDL). It is perhaps involved in triglyceride metabolism.

β_2-Glycoprotein III was also first described several years ago by our laboratory[116]; even now nothing more substantial is known about its physiological importance. *Chase* and *Prochaska*[117] showed by means of immunofluorescence that in several diseases it is deposited in the kidney where it is apparently associated with immunocomplexes.

The *C-reactive protein* is an example of the "acute phase reactants" whose serum levels rise rapidly in the acute phase of particularly inflammatory diseases. The C-reactive protein does not contain any carbohydrate; its amino acid sequence is known. It consists of five identical subunits (molecular weight 21 500) which are each composed of 187 amino acids[118]. According to electron microscopical studies, these subunits are assembled in the form of a ring so that a pentagonal structure[93] similar to that of the 9.5S-α_1-glycoprotein can be seen. The true physiological function of the C-reactive protein is still unknown despite these precise structural and chemical findings and although it has been found to perform a series of biological activities (such as immunoprecipitation[119] and -agglutination[120], complement activation[121,122], acceleration of phagocytosis[123,124], and inhibition of thrombocyte aggregation[125]).

6. Genetic Modifications in Human Plasma Proteins

All plasma proteins are genetically controlled. During the course of evolution the genes responsible for the synthesis of these proteins have been changed so much by mutations that the structures and activities of the proteins now differ considerably[126,127]. In human plasma proteins genetic defects must be distinguished from polymorphism. In the first case the structure of the proteins is modified with loss of the original biological activity or the proteins are completely lacking (*i.e.* they are not synthesized). In the case of loss of activity these proteins can still be detected by immunological techniques.

In the case of polymorphism, a change in the primary structure gives rise to separate phenotypes, the biological activity is not affected.

Hereditary deficiencies of more than 30 human plasma proteins are known. The lack or defective synthesis of these proteins is usually closely associated with a more or less serious disease (Table 14).

Table 14. Genetic deficiencies in human plasma proteins.

Protein	Clinical condition
α_1-Antitrypsin	Pulmonary emphysema; neonatal hepatitis
α_1-Lipoprotein	Tangiers disease; enlarged yellow tonsils; hepatosplenomegaly; lymphadenopathy
C1-Inactivator	Angioneurotic edema
Ceruloplasmin	Wilson's disease; actue hemolytic anemia
Transferrin	Hypochromic anemia
Transcobalamine II	Neonatal megaloblastic anemia, growth disorders, repeated infections
β-Lipoprotein	Steatorrhea, neuromuscular disorders
C1q	Hypogammaglobulinemia?
C1r	Kidney and skin disorders
C3, C5, C3b INA	Impaired bactericidal activity
IgG, IgA, IgM	Antibody-deficient diseases
Fibrinogen	Abnormal bleeding tendencies
Prothrombin	
Proaccelerin	
Proconvertin	
Antihemophilic globulin	
Christmas factor	
Stuart factor	
Fibrin-stabilizing factor	
Prekallikrein	
α_2-Antiplasmin	
Albumin	Healthy
Thyroxine-binding globulin	
Haptoglobin	
β-Glycoprotein I	
C2, C6, C7	

The plasma proteins which exhibit genetic polymorphism are compiled in Table 15. The phenotypes can be detected by electrophoretic or immunological techniques or, as in the case of cholinesterase, by enzymatic methods. In several cases it is known that polymorphism is due to the exchange of single amino acids or entire polypeptide chains.

Table 15. Human proteins with genetic variants or genetic polymorphism.

Protein	Variants
Albumin	So far 20 variants
α_1-Antitrypsin	Pi-system, so far 25 known alleles
α_1-Acid glycoprotein	Types FF, FS, SS
α_2-Macroglobulin	Xm-system
Gc-Globulin	Gc1-1, Gc2-1, Gc2-2 and rare variants
Ceruloplasmin	CpA, CpB, CpC, CpNH, CpBpt, CpTh
Haptoglobin	Hp1-1, Hp2-1, Hp2-2 and rare variants
Cholinesterase	So far 10 phenotypes
Transferrin	So far 20 variants
β-Lipoprotein	Ag-system, Lp(a)- and Ld-system
C3-Proactivator	Bf FF, Bf FS, Bf SS and others
C2-component	Types $C2^1$ and $C2^{2\text{-}1}$
C3-component	So far 16 variants
C4 component	So far 8 phenotypes
C6 component	Types A, B, AB and rare variants
Fibrinogen	Fibrinogen Baltimore, fibrinogen Detroit
IgG	Gm-allotypes of γ-chains
IgA	Am-allotypes of α-chains
IgM	Mm-allotypes of μ-chains

If the numerous polymorphisms of enzymes and other genetic characteristics of man are added to the genetic polymorphism of the plasma proteins, it is clear that each indi-

vidual has a unique combination of proteins and enzymes, *i. e.* is characterized by his pattern of polymorphism in the same way as by a fingerprint[128].

7. Function of Carbohydrates in Human Plasma Proteins

The majority of the human plasma proteins are glycoproteins, only a few such as albumin, the retinol-binding protein, or the C-reactive protein are free of carbohydrate.

Glycoproteins in the broadest sense of the word are proteins which contain carbohydrates as prosthetic groups. The carbohydrates which have so far been found in human glycoproteins are *N*-acetyl-D-glucosamine, *N*-acetyl-D-galactosamine, D-galactose, D-mannose, D-glucose, L-fucose, *N*-acetylneuraminic acid, and D-xylose.

The chemistry of the carbohydrates of the serum glycoproteins obeys the following rules: only asparagine, threonine, and serine—in rare cases also hydroxylysine—are linked to the oligosaccharide units. The oligosaccharides can be structurally divided into alkali-stable chains which are *N*-glycosidically bonded to asparagine or alkali-labile chains which are *O*-glycosidically bonded to serine or threonine. *N*-Acetyl-D-glucosamine always participates in the *N*-glycosidic bonds and only *N*-acetyl-D-galactosamine participates in the *O*-glycosidic bonds. In extremely rare cases, as is found in the C1q protein, a glucosyl-galactosyl disaccharide is *O*-glycosidically linked to hydroxylysine.

Of all the functions[129–131] performed by the carbohydrates of the glycoproteins, that of recognition is the most important. Positive recognition will be explained using ceruloplasmin as an example. As long as the terminal neuraminic acid molecule is still bound to ceruloplasmin it is not recognized by the parenchymal liver cells. After cleavage of this molecule however (asialoglycoprotein), the galactose residues exposed are immediately recognized by a lectin-like protein in the liver cell membrane and the protein is very quickly eliminated from the circulation[132]. An example of negative recognition is provided by the masking or covering of antigen determinants or of larger areas on the membrane surface[133].

Lectins are very important for the characterization and determination of glycoproteins. Lectins[134] are proteins or glycoproteins which, in a manner analogous to that of antibodies, react specifically with carbohydrates but they do not have an antibody structure. They are found in plants, invertebrates and vertebrates, and their property of recognizing specific carbohydrate structures is a valuable aid in the study and isolation of glycoproteins. We were recently able to show in collaboration with *Uhlenbruck* that some serum glycoproteins have lectin-like properties[91].

8. Clinical Importance of Plasma Proteins

8.1. Diagnoses

Many diseases are accompanied by changes in the plasma protein levels. The quantitative determination of one or more plasma proteins is thus of importance for diagnosing and monitoring the course of these diseases. In the first stages of this development the technique of electrophoresis[135–137] was most important but the plasma proteins are now mostly determined quantitatively by immunological methods[138,139]. The necessary precipitating antisera are chiefly obtained by immunizing animals with highly purified plasma proteins. More then 80 proteins can now be determined by these techniques.

8.2. Prophylaxis and Therapy

Since proteins with prophylactic and therapeutic actions were first obtained from human blood plasma, more than 20 protein preparations have been developed (Table 16).

Table 16. Prophylactically and therapeutically active "drugs" obtained from human plasma.

Year	Plasma protein	Indication
1942	Gammaglobulin (immunoglobulin)	Antibody deficiency
1942	Albumin	Volume substitute, plasma expander
1947	Fibrinogen	Fibrinogen-deficiency
1947	Antihemophilic globulin (AHG)	Hemophilia A
1948	Stabilized serum conserve	Volume substitute, plasma expander
1960	Cryoprecipitate (fibrinogen and AHG)	Fibrinogen deficiency and hemophilia A
1962	Intravenously administrable gamma globulin	Antibody deficiency
1965	Specific immunoglobulins	Antibody deficiency
1966	Anti-rhesus-D immunoglobulin	Hindrance of rhesus erythroblastosis
1968	Prothrombin concentrate	Prothrombin and factor-VII deficiency, hemophilia B
1969	Factor-IX concentrate	Hemophilia B
1969	IgA concentrate	Antibody deficiency
1969	IgM concentrate	Antibody deficiency
1969	Serum cholinesterase	In anesthesia with atypical cholinesterases
1970	Transferrin	Inborn deficiencies
1972	Fibrin-stabilizing factor (F XIII)	Deficiencies, wound-healing disorders
1973	C1 inactivator	Angioneurotic edema
1976	Plasminogen	Fibrinolysis therapy (in clinical trial)
1977	Antithrombin III	Deficiencies (high risk of thrombosis) (in clinical trial)
1979	Thyroxine-binding globulin	Hyperthyreosis (in clinical trial)

The immunoglobulins and albumin were the first proteins to be developed in this way. Blood clotting factors and several other biologically active proteins soon became available to hospitals for prophylactic or therapeutic use. Improved fractionation techniques and new findings concerning blood plasma proteins will certainly enable still more proteins from human blood to be developed as "drugs". In this way the limited quantities of blood plasma available can be better and more effectively utilized than is possible with blood plasma transfusion.

New Technologies for the Filmless Manufacture of Printing Forms[**]

By Hansjörg W. Vollmann[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

The economic reproduction of graphic information was first made possible in the western world by *Gutenberg*'s invention of movable type. In the printing methods of that time, mechanical transfer processes played the major role, while chemical processes were of secondary importance. When *Alois Senefelder* invented planographic printing (lithoprinting) at the end of the 18th century he called the new process "chemical printing". Since then, chemistry has attained great importance in the production of printing forms: Thus the manufacture of surface (litho-) printing forms with light required temporary storage materials and image reproduction processes based on chemical reactions. Since the advent of electronic processing of information, however, several former temporary storage media have become obsolete; newer, more sensitive image reproduction processes are increasingly making less use of chemical principles than of the electrical properties of materials.

1. Introduction

Printing, originally an art and later a craft, has today become a commercial process of great importance. In this paper we shall deal with some of the scientific aspects of printing.

1.1. Printing Processes

The four main commercial printing processes[1-4] are letterpress printing, gravure printing, planographic or offset printing, and screen printing. The various processes essentially differ from one another in the nature of the printing form or surface. The underlying principles of each of the processes are illustrated in Figure 1.

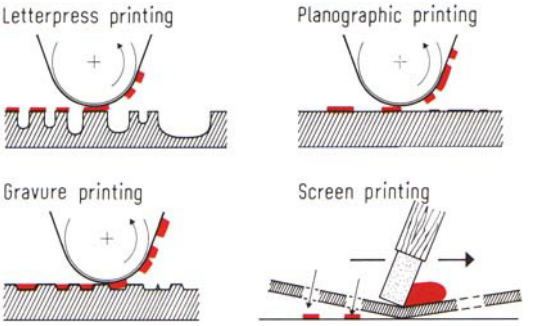

Fig. 1. Principles of the four main printing processes.

Whereas in letterpress printing, ink is transferred from raised areas of a printing form onto the material to be printed, in gravure printing the situation is exactly the converse: here the image areas of the printing form are recessed and a relatively low viscosity gravure ink is transferred from the recesses or cells of the printing form onto the material to be printed, for example paper.

In planographic or offset printing[5,6], the process with which we shall be primarily concerned here, the printing

[**] Based on a GDCh lecture delivered at the Achema 1979 on June 20, 1979 in Frankfurt/Main.

form is without appreciable relief or depression, *i.e.* the image differentiation takes place virtually in one plane, and is effected physicochemically[7] by means of oleophilic and oleophobic areas on the printing form. The oleophobic areas consist of the decoated (ink-repelling) surfaces of the carrier material, usually aluminum, whilst the oleophilic, *i.e.* ink-receptive, areas normally consist of an organic resin coating.

In screen printing[8], the ink is forced through a stencil-like printing form, for example through the meshes of a screen—hence the name of the process.

Each of the above processes has its particular fields of application.

1.1.1. Economic Aspects

Figure 2 shows the forecast development of the three major printing processes up to 1990, both on a worldwide basis and for the Federal Republic of Germany: In 1980, planographic printing will overtake letterpress printing in the Federal Republic of Germany, and in 1984 will similarly overtake it world-wide. Letterpress printing, which in 1972 still accounted for a market share of 60%, will have dropped to 30% by 1990, whilst the market share for planographic printing will, over the same period, have risen from 25% to 50%.

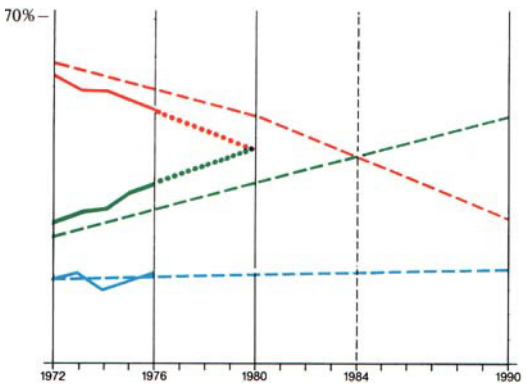

Fig. 2. Economic development of the major printing processes (excluding screen printing). Red: letterpress printing. Green: planographic or offset printing. Blue: gravure printing. ----: anticipated world-wide development; —— actual development in the Federal Republic of Germany; ····: anticipated development in the Federal Republic of Germany.

This forecast[9] is based on predictable trends of technological development. However, because of rapid changes in the graphic arts industry during the past few years no accurate statistics are available on a worldwide basis. If, for example, some revolutionary method made it possible to manufacture gravure printing forms much more cheaply, then the statistics could shift substantially in favor of gravure printing. At the present time, over 72% of all U.S. newspaper titles are already being printed by the planographic process[10a]; however, since those newspapers with the widest circulation are still being printed by the letterpress process, only 37% of the total newspaper output is accounted for by planographic printing.

1.1.2. Production of Printing Forms by means of Light Energy

In planographic printing, the production of printing forms by means of light energy has decades of tradition behind it, and is quite uncomplicated. It utilizes the change in solubility of a light-sensitive coating on exposure to light in order to produce an image-wise differentiation.

Photopolymer (wash-out) plates, which are produced photomechanically, are also of outstanding importance in letterpress printing, because of their compatibility with photocomposing[11–14]. However, owing to the degree of relief necessary in such plates, substantially higher energy is required for photohardening than in the case of planographic printing plates.

The term "photomechanical" is applied to all reproduction processes which are based on photochemical reactions and entail both photographic and etching type processes.

1.1.3. Areas of Application of the Various Printing Processes

Letterpress printing is used in particular for black-and-white printing, for example in the printing of newspapers and simple books. It is the oldest of the printing processes and, as already mentioned, still enjoys world-wide dominance. However, planographic printing is steadily attracting more attention because it gives prints of better quality, especially in color work, and allows simple and more rapid production of the printing form.

Gravure printing gives prints of particularly high quality. However, its rate of development and scope of application has so far been thwarted by the cost of producing the printing cylinder. Screen printing is a special type of printing, used for example in textile printing, in the advertising sector and, more recently, also in the field of electronics. In Germany, its share of the reprographic market is about 3% (see Fig. 3).

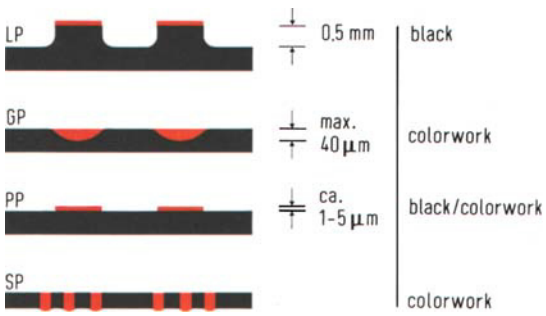

Fig. 3. Comparison of the four main printing processes. LP = letterpress printing (44%), GP = gravure printing (17%), PP = planographic printing (36%); SP = screen printing (estimated 3%). The figures refer to the market share in the Federal Republic of Germany (1977) [10b].

1.2. Photomechanical Production of Offset Printing Forms

Let us once again particularly compare the printing forms required for letterpress printing, gravure printing and offset printing. Whilst with a letterpress printing form a substantial relief, namely of about 0.5 mm, must be produced, and whilst considerable amounts of material, namely up to about 40 µm, must be etched from the surface of a gravure printing cylinder, the coatings constituting the image areas on a planographic printing form are only up to a few µm thick (Fig. 3). If we turn to the photochemical process or the etching

process, we see that undoubtedly the material which has to be converted or transferred to achieve image differentiation is least in the case of the photomechanical production of a planographic printing form.

Depending on whether the areas of a printing plate which have been exposed to light are more soluble or less soluble than initially, the system concerned is referred to as positive or negative, respectively. The process of producing a planographic printing form (*negative* system) is shown in Figure 4.

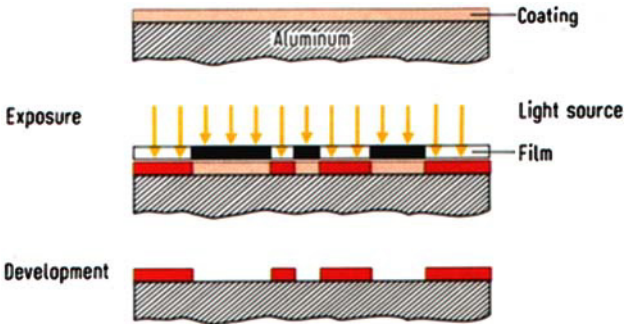

Fig. 4. Photomechanical manufacture of an offset printing form (negative plate).

A film original, generally a silver halide film negative, is placed on a printing plate consisting of an aluminum sheet, which is about 0.1—0.5 mm thick, and an organic light-sensitive coating, which is from less than 1 to 5 μm thick. The assembly of plate and negative is then held in contact by vacuum in a copying frame and exposed to the light of a metal halide-doped mercury vapor lamp, usually of 5 kW input power. After a typical exposure time of about 20 seconds to 1 minute, the coating is hardened, *i. e.* chemically cross-linked, in the exposed areas. After removing the non-cross-linked areas by means of a developer, the printing form is ready to use.

Positive planographic printing plates, on the other hand, are based on a chemical principle in which hydrophobic compounds, contained in a resin matrix of limited solubility in alkali, are converted photolytically to more hydrophilic compounds. The exposed areas of the coating are thus made accessible to the action of an aqueous alkaline developer, and are dissolved out. The image areas which remain on the aluminum carrier consist of chemically unchanged original coating material and correspond directly to the mask through which the exposure was carried out. These image areas transfer the ink during the printing process.

In both cases, the film is an intermediate "master" which has first to be produced from the actual original; this intermediate "master" is necessary for the conventional technique just described, but can be dispensed with in the filmless production of printing forms.

1.3. Filmless Production of Printing Forms

In small offset printing and duplicating, the production of printing forms without using a silver halide film as an intermediate master has long been known, and has proven its value over the years[15]. Examples which may be mentioned are the silver salt diffusion process and transfer process, photodirect films and electrophotographic films. These processes have proven successful for paper sizes of up to about DIN A2 and will retain their importance in the forseeable future.

On the other hand, the filmless production of planographic printing forms for medium and large paper sizes and for runs of up to about 100000 prints or even more, is novel[16–18]. It is a pioneer technology which essentially was first introduced to the public at the DRUPA printing and paper exhibition in Düsseldorf in 1977, and which is rapidly gaining favor, above all, but not exclusively, in newspaper printing.

This new technology was made feasible by the interdisciplinary co-operation of chemists, physicists, engineers and electronics experts.

Before dealing with the technology in more detail, we will first discuss the basic chemistry of the light-sensitive layers of some of the currently used planographic plates.

2. Printing Plates with Photochemically Active Coatings

The chemistry of a light-sensitive layer must be such that the absorption of the coating matches the emission of the light source if optimum energy utilization is to be achieved. As is shown in Figure 5, the sensitivity maxima of conventional light-sensitive systems are to be found in the near UV range or the short wavelength end of the visible range; an example of a light source which is particularly suitable for this sensitivity range is a gallium iodide-doped mercury vapor lamp[19], the emission spectrum of which is also shown in Figure 5. High power mercury vapor lamps have substantially superceded the previously used carbon arc lamps and xenon high pressure lamps.

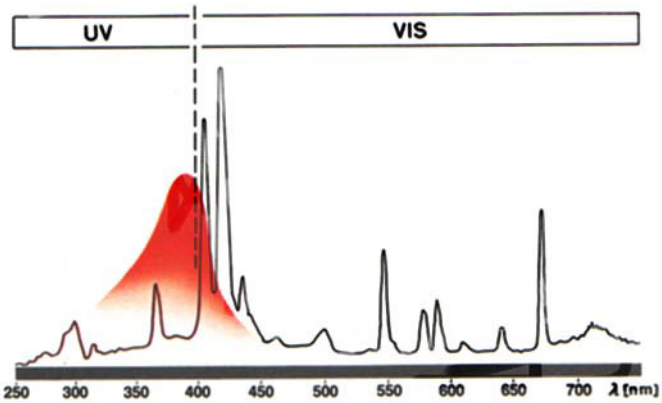

Fig. 5. Spectral sensitivity of an offset plate (red) and emission of a Ga-doped Hg high-pressure lamp.

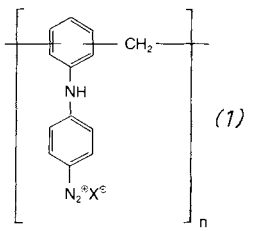
From a chemical point of view, there is a great variety of possible ways of producing photoactive systems for reprographic applications. Correspondingly, such systems are well documented in the literature[20–25]. In practice, however, only a relatively small number of such chemical systems have found acceptance.

2.1. Positive Systems

Positively acting light-sensitive coatings are based virtually exclusively on "naphthoquinone diazides" (2-diazo-1(2*H*)-

naphthalinone derivatives)[26,27], which are mostly used in combination with phenolic resins. However, even today research work[28] is still being carried out on these light-sensitive compounds—30 years after their introduction.

Of the other positive lithographic systems which have been proposed, none has hitherto been able to gain a share of the market.



2.2. Negative Systems

Essentially four chemical principles are employed for negative photosensitive coatings which are to have a good shelf life.

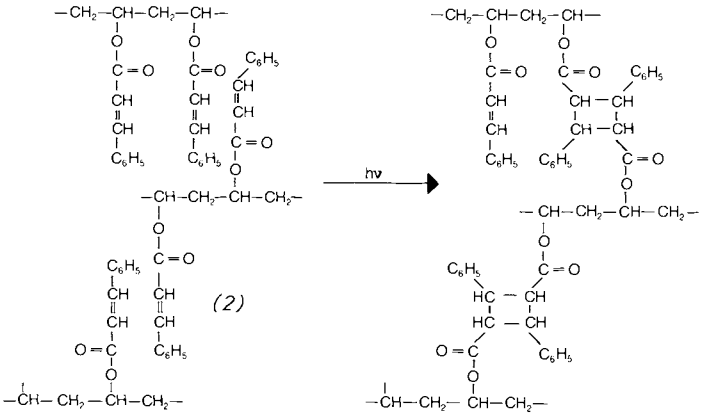
2.2.1. Diazonium Salts and Azides

The oldest and even today the most widely used system employs diazo resins which are obtained by acid condensation of diphenylamine-4-diazonium (*p*-anilinophenyldiazonium) salts with formaldehyde[20,24,29].

The structure of these oligomeric "tanning diazo compounds" is shown in idealized form in Formula *(1)*. Suitable as anion $X^{\ominus}$ is, *e.g.* $1/2\ ZnCl_2^{\ominus}$; other suitable inorganic and organic anions $X^{\ominus}$ are to be found in the literature[30,31].

(1)

These soluble, and in most cases even water-soluble, polyfunctional diazonium salts lose their salt character as a consequence of nitrogen elimination on exposure to light. They become water-insoluble, and are at the same time able to crosslink the polymer matrix surrounding them. This well-proven principle forms the basis of most negative diazo planographic plates.



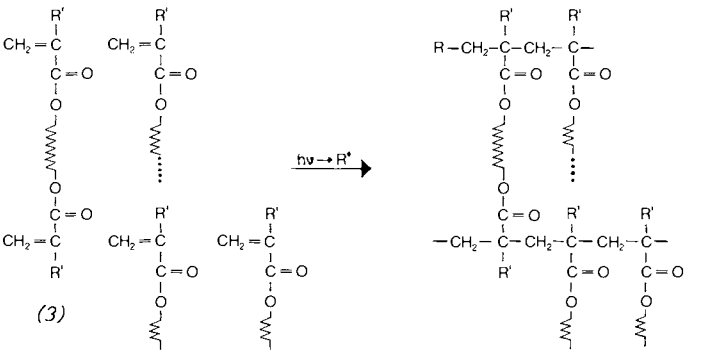
Light-sensitive coatings based on arylazides[20,22,23] are also employed. Arylazides can be spectrally sensitized.

Other systems which have attained considerable importance are coatings based on the principle of photodimerization[20,22,23] and on photoinitiated free radical polymerization[20–23].

2.2.2. Crosslinking by Photodimerization

The photodimerization of cinnamic acid derivatives is an example of the first of the crosslinking principles mentioned, in which the crosslinking of two molecules is brought about, *inter alia,* by light-induced cycloaddition of the activated double bonds to different kinds of cyclobutane structures[32]. For reprography, this chemistry is only of interest if a polymer chain carries many groups of this type. A typical example is the polyvinyl cinnamate shown in *(2)*.

A remarkable property of cinnamates is that they can be sensitized to light of relatively long wavelengths, up to about 500 nm[32], by triplet energy transfer; in the case of cinnamylidene derivatives, it is even possible to extend the sensitivity



(2)

range beyond this wavelength[33]. It is true that spectral singlet sensitization of diazonium salts is feasible in solution[34,35], but it has hitherto not been possible to exploit this in practice for increasing the sensitivity in solid reprographic coatings; indeed for some fundamental reasons this is unlikely to be realized.

2.2.3. Photopolymerizing Systems

The additional and desirable increase in the light sensitivity of the systems hitherto discussed is limited so long as at best only one new linkage between two molecules can be produced per quantum of light.

This restriction also applies to photopolymerization in its narrower sense[36], where one photon is required per growth step, but not to photoinitiated polymerization, where light is merely required to activate an initiator. In industry, this latter process is generally also referred to as photopolymerization[37]; in the following text the term photopolymerization is to be understood only in this sense of photoinduced polymerization. The principle is illustrated for the example of acrylic acid derivatives *(3)*. Theoretically, one quantum of light can convert a large number of monomer molecules into high molecular weight polymers. However, termination reactions and the presence of inhibitors, especially atmospheric oxygen dissolved in the polymerizing layer, impose natural limits in such polymerizations.

(3)

As is shown for the example of reaction *(3)* it is however possible on this basis to devise planographic photopolymer plates which have somewhat higher light sensitivity than diazo layers or layers based on dimerizing compounds if suitable measures are taken to repress further diffusion of oxygen

into the layer during exposure. This can be achieved, for example, by applying an overcoat, of low permeability to oxygen, over the photopolymer coating[38].

2.3. Light Sensitivity

The sensitivity to light of even the best of these systems is, however, too low for them to be considered as ideal materials for the filmless production of planographic printing forms.

At the present time, the most sensitive formulations, based on diazo resins such as *(1)* or cinnamates such as *(2)*, require an energy of 5—10 mJ/cm^2 (50—100 J/m^2) for photohardening. This makes it possible to devise direct imaging systems without a film as intermediate master, but only when using very powerful light sources.

There are good reasons for employing such systems. On the one hand, all customers would like to have high-sensitivity materials, on the other they are used to daylight conditions, or at best to yellow safelight when processing the plates, *i.e.* when producing planographic printing forms. A change-over to darkroom conditions would be a major disadvantage to the user and incidentally, not least of all, also to the manufacturers of presensitized planographic printing plates, since these are currently produced under filtered light resembling daylight. "Presensitizing" means, in technical terms, the application of a light-sensitive coating.

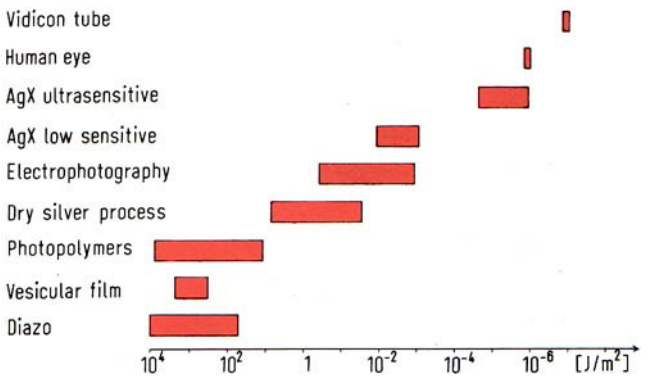


Fig. 6. Energy requirements of light-sensitive systems. (The photoactive layer of vesicular film consists of diazonium salts in a resin matrix. Bubbles of nitrogen liberated in the exposed areas give rise to opacity.)

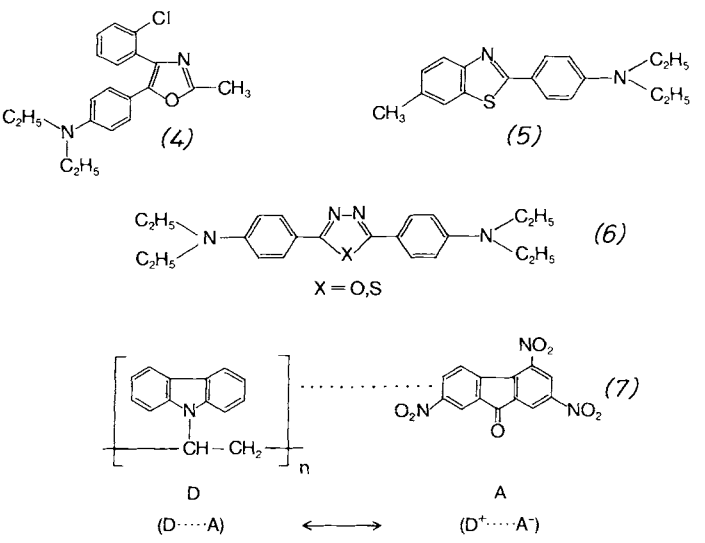
A comparison of light-sensitive systems (see Fig. 6) shows that these highly sensitive photochemical systems are to be encountered at the lower end of the series, and their ranges partly overlap, whilst the silver halide film materials are to be found at the upper end of the series. This comparison encompasses different imaging mechanisms. However, quantitative comparison is subject to certain restrictions, since the read-out mechanism (physiological and electrical effects, and differences in optical density, conductivity and solubility) is, in practice, effected by a variety of methods.

3. Production of Printing Forms by Electrophotographic Processes



The electrophotographic materials shown in the middle of the series are ideal for the filmless production of printing forms, since their light sensitivity ranges from a few 100 to 1000 times greater than that of the diazo systems and photopolymer systems hitherto known. In order to be able to work with such photoconductive coatings under relatively bright darkroom illumination, materials whose exposure energies lie in the middle to upper range of the band shown in Figure 6 are preferred.

Suitable photoconductors for electrophotography have insulating properties in the dark and prevent the dissipation of charges applied by means of a corona discharge. The term corona discharge means a type of discharge which occurs at sharp edges, points or wires under atmospheric pressure at high voltage.

On exposure to light, the electrical conductivity of the photoconductors increases substantially. The charges are dissipated in the exposed areas and a latent charge image is formed. This can be rendered visible by means of colored liquids or powders, referred to as toners. Further details in this sector can be found in the standard work by *R. M. Schaffert*[39].

3.1. Photoconducting Systems

In the industrial filmless manufacture of printing forms, both inorganic and organic photoconductors[40-42] are used. The inorganic compounds include cadmium sulfide and zinc oxide. Examples of organic compounds which show photoconductivity, to a degree industrially utilizable in electrophotography, include various heterocyclic compounds, such as oxazoles, benzothiazoles, oxadiazoles and thiadiazoles[43]; *(4)*—*(6)* are examples. Certain charge transfer complexes are even more light-sensitive, but are not used in planographic printing plates. In these complexes, an ionic component is present even in the ground state, and becomes more pronounced as a result of photoexcitation. An extensively investigated example is the donor-acceptor complex *(7)* of polyvinylcarbazole and 2,4,7-trinitrofluorenone. Planographic printing forms can be readily produced electrophotographically by using organic photoconductors[44].

3.2. Manufacture of Printing Forms

The photoconductive coating on an aluminum carrier is negatively charged, as shown in Figure 7. On imagewise exposure, the charges on the areas exposed to light disappear, whilst those on the unexposed areas remain. Toner particles of the opposite charge—in the present instance positively charged particles—are attracted to the charge image areas

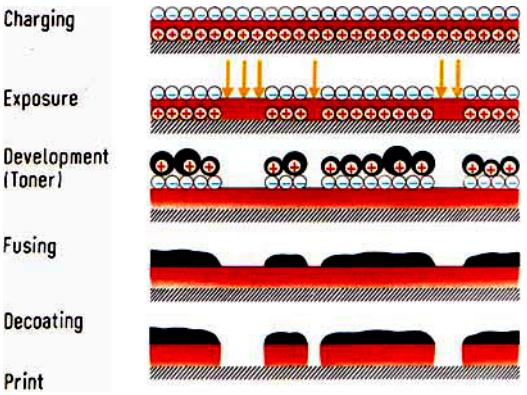


Fig. 7. Electrophotographic process for producing an offset printing form.

thus produced and are subsequently fixed to the surface of the coating by a heat treatment. The areas not protected by the toner stencil are removed by dissolving them in a decoating solution, so that in these areas the carrier surface is bared. After this treatment, the printing form is ready for the press and its application does not differ from that of a conventionally produced printing form.

4. Materials and Processing Lines for the Electrophotographic Manufacture of Printing Forms

Whilst electrophotographic printing plates based on zinc oxide have long been known[45] and are still being used industrially at the present time, for example as "Chemco-Newsplate"[15], an electrophotographic printing plate working on a different principle, namely the KC-crystal plate[9,46], was introduced at the IMPRINTA trade fair in Düsseldorf in February 1979; the heart of this plate is an inorganic cadmium sulfide photoconductor[47,48], as shown in idealized form in Figure 8. The cadmium sulfide, in a thickness of only

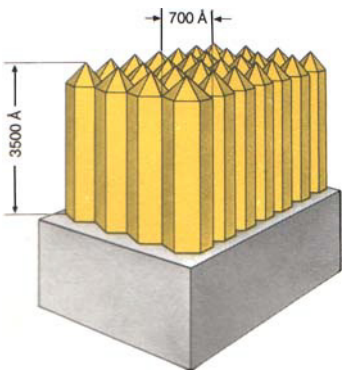

Fig. 8. Photoconductive cadmium sulfide crystals of the KC plate.

0.35 μm, is applied by cathode sputtering onto a metallic carrier. It grows onto the carrier in the form of very regular crystals. The crystal coating of this plate is then—exactly as described earlier for the case of an organic photoconductor—charged, exposed, developed with a special liquid toner and baked. In a further process step the unprotected cadmium sulfide coating must be rendered hydrophilic in the non-image areas before the plate can be used for printing; this is achieved by a chemical oxidation step. This novel printing plate, which has not yet found industrial acceptance and is very expensive, counts amongst the most sensitive of the electrophotographic systems known hitherto.

4.1. Methods of Exposure

The industrial processes for the electrophotographic filmless production of printing forms, explained below, in part use different exposure systems. Basically, there are two possibilities:

The first possibility is overall exposure in which the entire photosensitive coating is simultaneously exposed to light energy. Figure 9 (left) shows a copying process by transmitted light, on a 1:1 scale. Of course it is also possible, as,

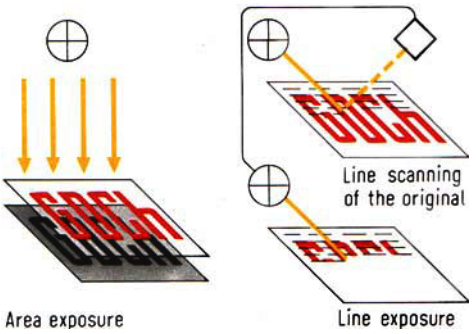

Fig. 9. Methods of exposure.

for example, in an episcope, to employ reflected light for copying or to magnify or reduce the original optically. When using an episcope, more light is lost in the reflecting rays during the copying process than when using a diascopic process, and therefore particularly light-sensitive printing plates are needed.

The alternative to overall exposure is line exposure, where it is possible to use the signals, received from an illuminated original, to control a second, independent light source. It is only the latter which transfers the information onto a light-sensitive coating.

4.2. Processing Lines

An automatic camera designed for newspaper production and already employed by many newspapers, namely the EA 692 Elfasol camera[49], employs an overall exposure system. Figure 10 illustrates the largely automated, photomechanical filmless production of a planographic printing form.

The operator introduces the original, in the present case the paste-up, into the copyholder and starts the machine. An electrophotographic plate is automatically taken from a plate stack, positioned in the exposure table, exposed, then treated

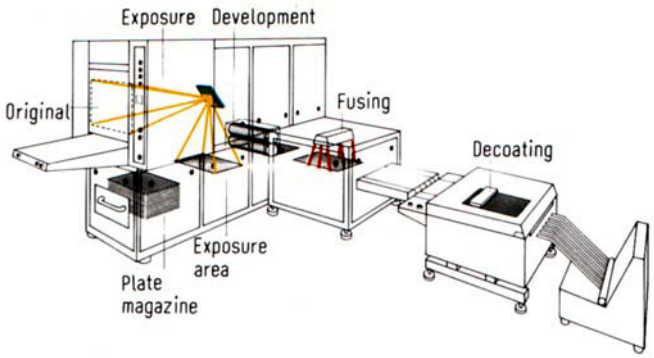

Fig. 10. Elfasol unit EA 692.

with toner, fixed by heating, stripped and placed, ready-to-print, on a stack. The first plate leaves the machine after four minutes and subsequent plates at intervals of one minute. In contrast, the exposure time alone of a conventionally processed planographic printing plate is up to one minute, with a total production time of 8—12 minutes[49], including the production of a silver halide film. In addition to the resulting reduction in labor costs, electrophotographic printing plates offer a cost saving due to film not being needed, and considerable time saving, which is particularly important in newspaper production.

A similar system—Pyrofax[15,17]—works on a somewhat modified principle (Fig. 11). The electrostatic charge image of an original, produced episcopically and by overall exposure on an electrophotographic zinc oxide film, is developed with a toner. A silicone rubber mat, the "transmat", takes the toner image from the film. In a separate, manual step the image is then transferred, in a fusion station, onto an uncoated planographic printing plate, and is burned into the latter. The procedure is not fully automatic. At the present time there are about 100 Pyrofax installations throughout the world.

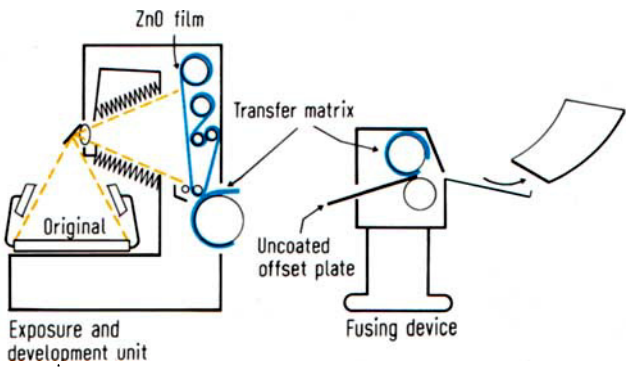

Fig. 11. Pyrofax system.

In the EPS system[50], in contrast to the above process, the toner image is transferred from a zinc oxide photoconductor coating directly onto the printing plate which is coated with a non-photoconductive resin. After the toner has been fused, the resin coating is removed from the non-image areas by dissolution in a decoating solution.

The printing plates with a cadmium sulfide photoconductive coating[47,48], already mentioned, are exposed by a modified slit exposure process, which can be regarded as an intermediate stage between pure overall exposure and line exposure.

In the apparatus used for exposure of the plate, namely the KC-Camera-Platemaker (Fig. 12), the image of the original is optically transferred, a strip at a time, onto a cadmium sulfide crystal plate by means of transmitted light or reflected light.

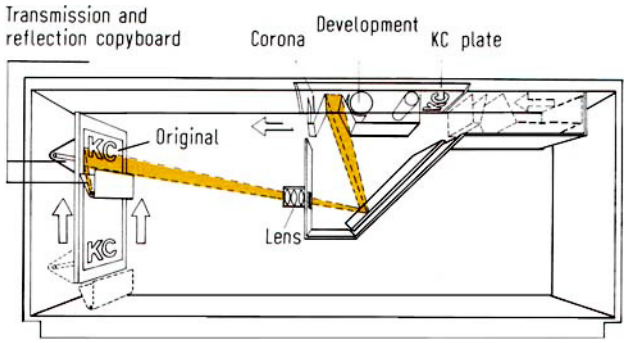

Fig. 12. Exposure device KC camera plate maker.

Table 1 once again compares the various systems. In the KC system and the Chemco-system[15], in contrast to conventional planographic printing forms and to the remaining systems, the function of the non-image areas is not fulfilled by the surface of the carrier but by the photoconductive coating which has been made hydrophilic.

Table 1. Comparison of electrophotographic printing plate systems.

System	KC	Chemco	Pyrofax	EPS	Elfasol
Photoconductor	CdS	ZnO	ZnO	ZnO	organic
Binder in photoconductive coating	−	+	+	+	+
Toner	liquid	liquid	dry	dry	dry
Image differentiation	hydrophilation	hydrophilation	transfer	transfer and decoating	decoating
Printing layer	toner and photoconductive coating	toner and photoconductive coating	toner	toner and resin coating	toner and photoconductive coating

5. Lasers as Sources of Modulatable Radiation

In recent times, line-imaging, which has long been known and extensively used, particularly in television technology—has found increasing application. The reason for its increasing use in reprography is the development of lasers of sufficient stability, which can also be employed on a production scale.

Laser light[51] has various properties, which predestine it for use in reprography: first, in contrast to light from conventional sources which radiate in all directions, it is emitted in one direction only, possesses good parallelity and is mono-

chromatic; second, it has a high energy density, can be modulated and responds to control signals with virtually no delay. Even making optimistic assumptions in favor of the most powerful currently available doped gas discharge lamps, the energy densities achievable with these in the 300—450 nm region are lower by at least a factor of 1000 than the energy density of an argon ion laser with 2—3 W UV output power, such as is used industrially in printing form production.

Because of their high energy density and also because of the position of their emission lines in the ultraviolet and visible region, argon ion lasers, in particular, are used in reprography (Fig. 13). This is true both for the exposure of conventional printing plates and of electrophotographic printing plates[52]. Figure 13 also shows the principal emission lines of the krypton ion laser, which for many conventional systems would be an even better choice. Unfortunately its stability, *i.e.* the life of the laser tube, is at present still inadequate when compared with the stability of the argon ion laser.

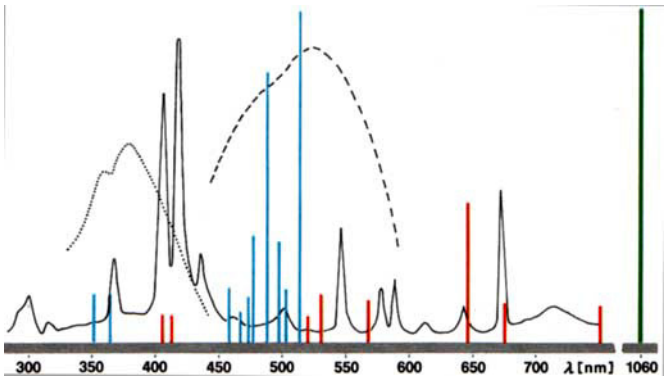

Fig. 13. Spectral sensitivity of different types of printing plates and principal emission of various radiation sources; —: Ga-doped Hg high-pressure lamp; ·····: diazo laser printing plate; ----: electrophotographic laser printing plate; blue: argon ion laser; red: Krypton ion laser; green: yttrium-aluminum-garnet (YAG) laser.

The height of the argon and krypton laser lines shown in Figure 13 indicates their relative intensity under specific operating conditions. The emission spectrum of a gallium-doped mercury high pressure lamp, the intensity of the yttrium aluminum garnet (YAG) laser line and the curves of the spectral sensitivities of the two types of printing plate are based on different, arbitrarily chosen scales.

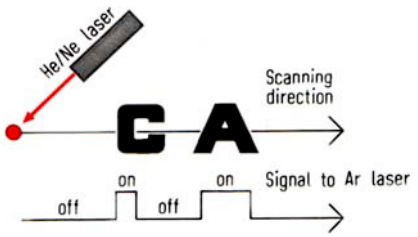

Fig. 14. Laser scanning mode.

The principle of how an image is sensed and built up linewise with the aid of lasers is shown in Figure 14. The light beam of a helium-neon laser, which emits with comparatively low power at 633 nm, scans the original which is to be reproduced. The light is reflected at the non-image areas whilst it is absorbed at the image areas. The local image information thus becomes a time sequence of light/dark information, which can be converted into electrical signals. These control another laser, for example a high-output argon ion laser, which is used to expose the light-sensitive material.

6. Lasers in Printing Form Production

6.1. The Laserite System

Industrially, this principle is put into operation in, for example, the Laserite system[53,54] (Fig. 15). The beams of the helium-neon read laser and of the argon ion write laser are combined, and again separated, in this equipment with the aid of dichroic mirrors. The linewise deflection of the light is effected by a pyramidal mirror which rotates at about 5000 revolutions per minute and travels, on a carriage, over the original and the plate. By superposing line scanning and forward travel of the optics on the carriage, the whole surface is scanned. The beams of the read laser which are deflected by the pyramidal mirror pass through the optics, and through the dichroic mirror—which transmits the red light of the He/Ne laser—onto the original, where they are absorbed by the image areas and reflected by the nonimage areas. This produces a sequence of light/dark information, which is picked up by a glass fiber optics bundle and fed to a photomultiplier. The latter converts the optical signals into electrical signals and passes them, as control pulses, to the modulator of the argon ion write laser. Thus, the sequence of light/dark information from the original is imprinted on the light beam of the write laser. This light now travels by the same optical path as the light of the read laser, *via* the pyramidal mirror and the optics, to the dichroic mirror, where it is reflected onto the plate.

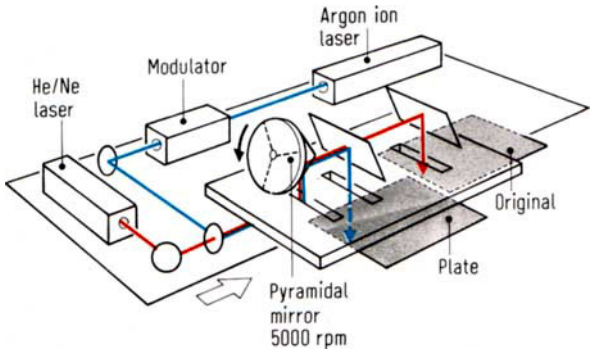

Fig. 15. Laserite system, schematic.

Using a high-energy argon ion laser it is possible, in such imaging units, to expose highly light-sensitive diazo plates or photopolymer plates with an energy of 5—10 mJ/cm^2 (50—100 J/m^2). Alternatively, using a substantially weaker—and correspondingly less expensive and more robust—argon ion laser, electrophotographic printing plates can be exposed with an energy of 10^{-2} to several 10^{-3} mJ/cm^2 (10^{-1}—10^{-2} J/m^2), *i.e.* with an energy expenditure which is less by about a factor of 1000[55]. In Laserite installations it is possible, during the relatively short and hence hectic produc-

tion state of a newspaper just before starting the press, to automatically produce one ready-to-print newspaper printing form about every minute.

6.2. The LogEscan System

The LogEscan system[15,56] also employs laser radiation in the filmless production of planographic printing forms. However, it operates on a different principle (Fig. 16):

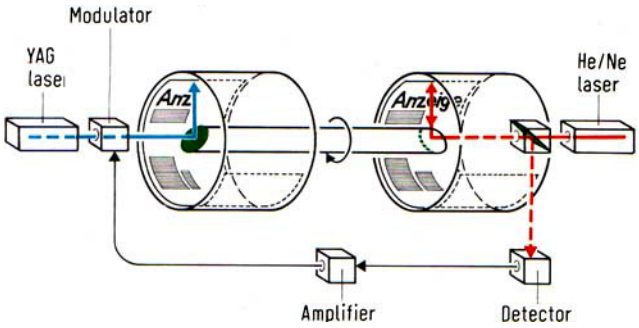

Fig. 16. LogEscan system, schematic.

The apparatus consists of two stationary, transparent drums, of which the drum shown on the right in Figure 16 is fed with the original whilst the other carries a black transfer film[57]—referred to as a "laser mask"—in contact with an uncoated aluminum plate. The "laser mask" consists of a film which is essentially coated with nitrocellulose and carbon black. A rotating He/Ne laser beam in the axis of one drum scans the original and controls, *via* the modulator, the write laser beam running in the other drum. This beam originates from a neodymium-doped YAG laser, which emits in the infrared. Where the beam of the YAG laser strikes the black transfer film, an oleophilic composition which accepts printing ink is thermally transferred onto the uncoated aluminum plate. After a fusing step, the planographic printing form is ready for use in the press. The transferred resin composition leaves transparent areas on the transfer film, which accordingly has simultaneously been converted into a negative image and can be used for the conventional production of additional plates, or for archive storage.

6.3. Use of Lasers for the Production of Printing Forms for Letterpress and Gravure Printing

There has been no lack of attempts at filmless production of printing forms for letterpress printing and gravure printing using imaging equipment which employs lasers. Whilst the LGS process[15,58] for the production of letterpress printing plates, which was developed at the beginning of the 1970's, did not prove right for the market, the Crosfield system[59], introduced in 1979, may be able to reduce the production costs of gravure printing cylinders (Fig. 17): A 0.75 mm-thick plastic tube is first shrunk onto a metal cylinder which is then rotated rapidly in the imaging unit, and, in one and the same process step is first turned by means of a diamond until exactly circular in shape and immediately afterwards "engraved" image-wise by means of a modulated CO_2 laser beam. This produces a groove of variable depth, running spirally round the cylinder, in the plastic; in the printing process, the groove takes up the printing ink and transfers it onto the paper.

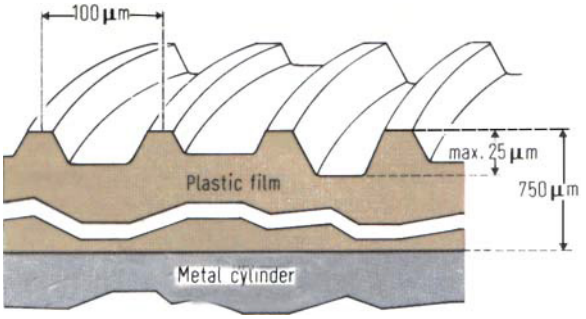

Fig. 17. Gravure cylinder manufactured by means of a laser beam.

7. Long-distance Transmission and Data Compression

The processes which have just been described show the diverse ways in which laser radiation can be employed in the production of printing forms if the image information is to be scanned directly from the original without an intermediate film. However, as already described, this can also be achieved with overall exposure of electrophotographic printing plates. Accordingly, the exposure equipment fitted with lasers would be nothing more than an expensive camera if the system employed were not to offer additional capabilities.

A factor of vital importance is that the high energy density of the laser radiation permits linewise exposure of reprographic coatings. The light/dark information, converted for this purpose, can easily be transmitted as an electrical signal from one location to another, so that image sensing—*i. e.* reading—and image reproduction—*i. e.* writing—can take place at separate locations.

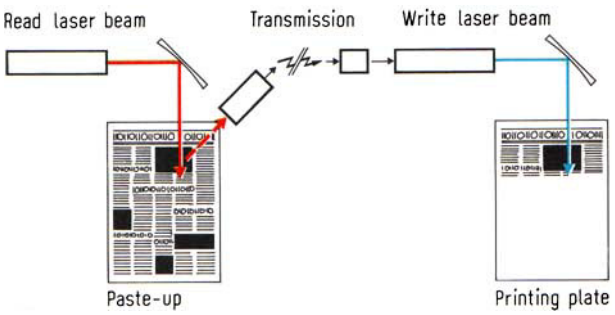

Fig. 18. Fascimile transmission, schematic.

Figure 18 illustrates the principle: The read beam scans the image which is to be reproduced; the electrical information ultimately obtained from this scanning is transmitted *via* a conventional communication channel to the location where the write laser exposes light-sensitive material, either synchronously or after intermediate storage of the data. Depending on the energy of the write laser, electrophotographic or highly sensitive conventional planographic printing plates can be exposed in this way, thereby surpassing the previous state of the art which only allowed exposure of highly sensitive silver halide film materials.

The frequency required for the transmission follows from the information density, the speed of travel of the scanning spot, its size and the line spacing. Normally, the frequency is of the order of 5 megahertz, so that transmission channels similar to those for television are needed.

In principle, the analog image signal produced from the converted light/dark information could be transmitted amplitude-modulated or frequency-modulated (Fig. 19)[60].

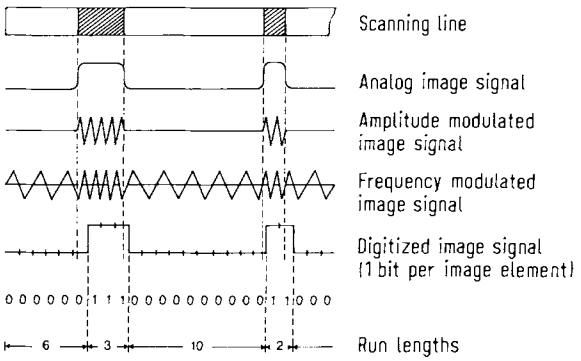

Fig. 19. Types of signals.

Because of the short transmission times needed in the newspaper industry, with its particular production sequence—one page should as rule require not longer than one minute for transmission—a digitized signal instead of the analog signal is transmitted if a video channel is not available. This has the advantage that data compression becomes possible. The extent of the information to be processed is thereby reduced; for example, all that is transmitted is that the first white signal is six units long, the first black signal is three units long, and so on. It is only this data compression which ensures rapid yet nevertheless economical long-distance transmission. Digitization results in strictly rectangular signals; these at the same time make it possible to modulate the write laser unambiguously, *i.e.* to direct the beam onto the information carrier which is to be imaged, or to deflect it. Furthermore, threshold value suppression becomes possible, in that, for example, up to a certain optical density gray shades are not accepted as signals. By this method, the contrast of the copy on the printing form can be made higher than the contrast in the original.

8. Electronics on the Advance

This cooperation of reprography and electronics produces a variety of possibilities. Thus, filmless printing form production in the newspaper sector is being greatly assisted by rapid development in the field of electronic information processing systems. The individual stages have, even today, already been mapped out[61,62].

At the present time (Table 2) the text is generally fed out from the phototype setter as galley proofs in the form of photopaper prints (pulls). Photographs are brought to the form required for the "print original" by means of a line scanner. For example, the images are screened, the tonal values are corrected, and changes in format are effected.

The text columns and the screened positive prints (pulls) are assembled, in accordance with the layout, to produce the paste-up of a page, which then serves as the original, either in a camera (overall exposure) or in a laser unit (line exposure), for the direct production of a printing form.

At the present time it is also already possible (Table 2) to produce the makeup of the text electronically and to obtain the text portion of a complete newspaper page, set ready-to-print, from the phototype setter. By inserting the screened positive prints of the pictures, the paste-up can then be quickly completed and used to produce the printing form in a camera or a laser unit.

The next stage of development of filmless printing form production will dispense with feed-out of text matter in a material form (Table 2). The text information will be fed into the central processing unit, where it will be stored. Pictorial information—which, particularly for colored reproduction, requires a higher store capacity—is supplied by a scanner in the form of a screened positive image and, correctly positioned, is fed, on an otherwise empty original sheet into a

laser unit for producing the printing form. On exposure of the printing plate, the beam of the write laser is directly controlled by the central processing unit in those areas which are to contain text information. When, on the other hand, the write laser beam reaches an area where a picture is to be imaged onto the plate, the modulation of the write laser is taken over by signals which are read off a paste-up. The information on the newspaper page is thus only collated on the printing form, and is not already collated on the paste-up. This form of newspaper production is likely, for economic reasons, to be ultimately the most advantageous in many cases.

Fully integrated picture scanning and text scanning by electronic methods (Table 2 and Figure 20) furthermore means an additional simplification, which, however, at the present time cannot yet be achieved at commercially justifiable expense.

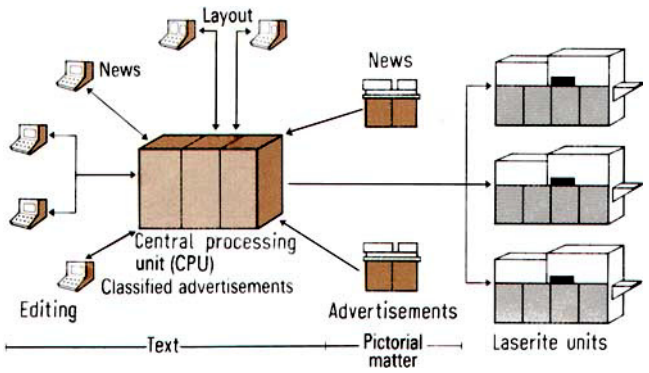

Fig. 20. Combination of full page pagination and direct plate making.

Not only do the individual editors write their contributions *via* terminals into the store of the central processing unit, where previously received and stored news and advertisements are deposited, but the processed pictures are also fed into this store. The makeup is then produced fully electronically by rearrangement of the information which has thus been stored. After approval of this non-material makeup on the screen, the entire page is directly written by laser imaging units onto printing plates.

This approach could most easily be realized in the case of the production of newspaper printing forms, because the format always remains the same, the number of pictures to be reproduced is small and is mainly black-and-white, and the print quality is of a relatively simple standard.

Where, however, four-color work of high quality, and in large amounts, is to be electronically processed and stored, store capacities which are a hundred or a thousand times greater than those for text areas of the same size would be needed. Even this already appears technically feasible at the present time, especially if it is borne in mind that store capacity will in future become progressively less expensive. Of course, stores of the conventional type will not be able to grow indefinitely, since the storage density and the read-out mechanism will not permit this. In the problem of economical storage of colored pictures, we at present come up against the limits of data processing.

9. Outlook

The innovatory leap forward which electronics have triggered will, within a forseeable time, force numerous traditional reprographic processes to give way to novel electronic methods[63]. This demands rethinking not only by the user of such complex systems but also by the chemical industry, regarding the role it plays in the processing of optical information. Even more versatility and flexibility will be expected of those newly entering this field of research—attributes which are not only equatable with personal endeavor but which are to a large extent dependent upon internal and external motivation. *Bunsen*'s dictum "Ein Chemiker, der kein Physiker ist, ist gar nichts"[64] aptly underscores the situation regarding those engaged in research in the sector of reprography, not forgetting that electronics and engineering also belong to this interdisciplinary field of activity.

Discussion with colleagues have prompted the submission of this paper for publication; valuable information accruing from such discussions have greatly helped in its planning and composition. Special thanks are due to Dr. G. Buhr and Dr. W. Frass for their enthusiastic assistance with the drafting of the manuscript and the diagrams.

On the Symbolic Language of the Chemist

By Rudolf Hoppe[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Körper und Stimme verleiht die Schrift dem stummen Gedanken;
Durch der Jahrhunderte Strom trägt ihn das redende Blatt.
(Friedrich von Schiller)

1. Introduction

In a stroke of genius, *Jöns Jacob Berzelius* created the formula language of chemistry still in use today. Few changes have been made to that language in the intervening 160 years. New methods and materials, entirely different concepts and modern theories have meanwhile drastically modified our discipline. Has its formula language become outmoded? Can it be altered? Is it still capable, particularly in the case of inorganic solid state chemistry, of describing what we know, believe to know, or want to know?

Unlike the other exact sciences, chemistry utilizes not only mathematical symbols but its own formulae, *e.g.* C_6H_6 or NaCl, which can be combined in equations (*e.g.*: $2KInO_2 + Na_2O = 2NaInO_2 + K_2O$[1]). Such formulae and equations qualitatively and quantitatively encode experience, often in facile manner. Moreover, they stimulate the expert to undertake new experiments if everyday experience (*e.g.*: noble gases are inert[2]) is combined with a portion of critical doubt (SnF_4, SbF_5, TeF_6, IF_7, Xe/F?[3]) and suitably formulated (here: $Xe + F_2 = XeF_2$[4]).

As *Homo sapiens*, and hence *ξῶον πολιτικόν*, we differ from other anthropoids, and possibly even from other hominoids, by our ability to transmit not only feelings and moods but also experience, knowledge, and cognition in a well-defined phonetic language to other members of our species. However, it is only the written word, an early discovery in some cultures and a late one in others, in many cases simply copied, which permits flow of essentially error-free information between past and future. Since language was (at least formerly) subject to spatial and temporal limitations, in times of tempestuous cultural development the written word became a new tool also of the enquiring mind.

Unlike language *per se*, the written word can, as a huge clamp, hold together entities which would otherwise fall apart all too readily (*e.g.* such a gigantic empire as China with so many different languages, dialects, and ethnic groups). It is the written word which enables someone "in the know" to communicate intellectual activities (and other matters) from one generation to the next with hitherto unknown accuracy. There are of course various kinds of writing. Pictograms (Figs. 1 and 2) are important precursors of

any kind of script intended to transmit as much information as possible to as many people as possible (see also Fig. 3).

Fig. 1. Offer to barter. The cross means crossed hands, no weapons, gesture for trading/bartering. Offer (right): bison, otter, and weasel skins; wanted (left): gun and 30 beaver skins. Based on *G. Mallery*, Annu. Rep. Bureau Ethnol. (Washington) Vol. *4* (1882/83), Vol. *10* (1888/89).

Based on: The Graphic Art of the Eskimos, Annu. Rep. Board Regents Smithsonian Inst. 1895. Hoffmann, Washington 1897.

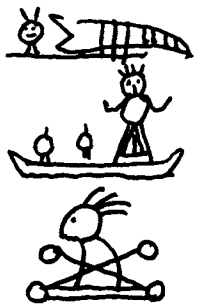

Fig. 3. From Walam Olum of the Delaware Indians dating form pre-European times. Cf. *H. Jensen:* Die Schrift in Vergangenheit und Gegenwart. Verlag der Wissenschaften, Berlin 1958. [Aid to memory for the following text: "The great fish, the many, they ate some, the moon-woman with the boat, she helped come! She came, she came, helped all, Nanabusch (God of awakening life) is the grandfather of all, the grandfather of the creatures, the grandfather of mankind, the grandfather of the tortoise tribe" (totem animal of the Delaware: tortoise).]

The example from the notebook of an East Frisian messenger woman unable to read and write (Fig. 4) nevertheless shows that there are simple possibilities of storing information in such a way that it is, sometimes intentionally, incomprehensible to most people (except herself in this case). This also applies, *e.g.*, to hobo signs (cf. Fig. 5) and modern coded texts of political intelligence departments[5].

The symbols used by alchemists undoubtedly number among those methods of recording experience such that it is accessible only to the initiated. It is quite conceivable—as reported—that the same author used different signs depending upon whether he wished to inform just his own circle of associates or friends or also his "competitors". Formerly inexplicable differences in chemical behavior (*e.g.* of tin when it is comparatively pure or contains relatively large amounts of lead) were indicated by different names (*i.e.* al quasḍīr or al kal'ī)[6] ("kalaitic lead").

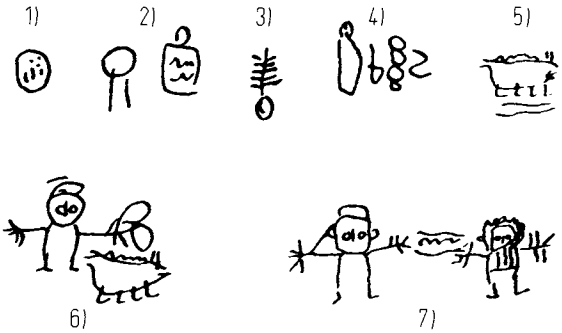

Fig. 4. From the notebook of an East Frisian messenger woman. Cf. Kosmos, Handweiser für Naturfreunde, 1914, p. 225. [Meaning: 1) rice; 2) slate and sponge; 3) leeks; 4) wine; 5) bacon, pork, lard; 6) a man should come to slaughter a pig and bring two additional pigs' bladders; 7) hand over letter from village smith to his lover in the town.]

[Content: imprisoned (under a roof, thrice questioned), for highway robbery, at night, help requested, quickly (don't run around, but straight here and take me under your protection(?).]

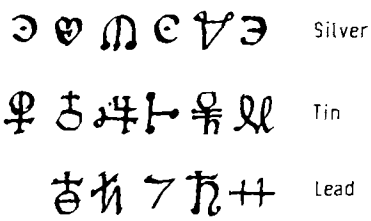

Fig. 6. Examples of alchemical symbols (Ag, Sn, Pb).

The advent of the balance, and thus of the principle of quantitative measurement in chemistry, compelled investigators to symbolically express the composition of substances "additively" according to analytical findings. The proposals of *Hassenfratz* and of *Adet*, and also of *Dalton*[7] were too arbitrary and cumbersome. Moreover, *Dalton*'s "formulae" (*e.g.* the highly modern formulation of CO_2 as ⊕○⊕) appeared to overtax the printer's art.

It is to the everlasting credit of *Berzelius*[8] that he laid the foundation stone of present day chemical formulation in 1813. He proposed that the elements should be represented by *one* (typical nonmetals) or *two* Roman characters—*e.g.* S, Sb, Se, Si, Sm, Sn, Sr—of which the first, upper case one is the first letter of the scientific name, and the second, lower-case one provides supplementary information. If several atoms of the same kind are present in a molecule, the composition was initially indicated by superscripts—*e.g.* CH^4. *Berzelius* also introduced shorthand forms (*e.g.* Cy for cyanide or A for acetate) strongly suggestive of modern practice, and

denoted oxygen, which he considered so very important from his atomic weight determinations by analysis of oxides, by dots (*e.g.* S̈ instead of SO^2). This did not help his contemporaries to immediately appreciate the inestimable advantages of his system.

This way of describing something new by combination of individual characters is strongly reminiscent of the creation of various signs of Chinese script (Fig. 7). Duplication, *e.g.* ClCl for the chlorine molecule as against Cl for the atom, leads to something so entirely different as does the doubling of the old Chinese sign for woman 女 to give that for quarrel 奸 (modern form: 女女).

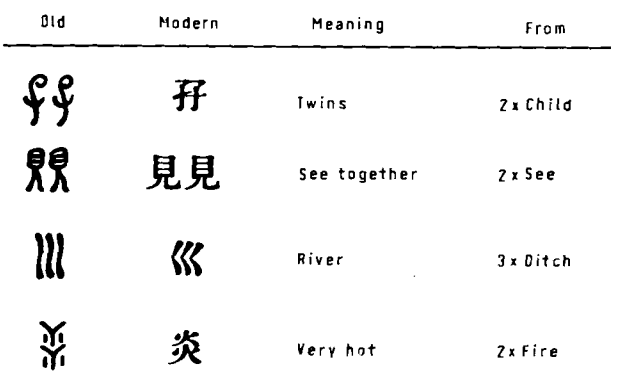

Fig. 7. Examples of Chinese characters.

After the known corrections had been made to *Berzelius'* original notation, we now write SO_2 and $K_3[Fe(CN)_6]$, *etc.*, his formulae have decisively influenced chemistry ever since. *Kekulé*'s benzene formula[9] and the discovery of the "asymmetric carbon atom"[10] introduced pronounced steric aspects which were subsequently also introduced into inorganic chemistry by *Werner*[11]. Since then, structural formulae supplement molecular or empirical formulae according to *Berzelius*.

Nevertheless, the wealth of information about the structure of chemical compounds and their reactions available from a simple molecular formula such as β-$C_{10}H_7SO_3H$ or $C_6H_{12}O_6$ is enormous and largely accessible even to the novice!

2. Problems of Inorganic Solid State Chemistry

To this day, the conceptual world of many chemists is to some extent colored by the overwhelming endorsement of *Berzelius'* sign language in connection with the dispute with *Berthollet* concerning the composition of chemical compounds. Contrary to the opinion of *Dalton* and *Berzelius*, *Berthollet* had maintained that the laws of constant and multiple proportions—*i.e.* the prerequisites for the representation of analytical results by simple formulae such as Cu_2O and CuO—do not always apply.

Today we know just how right he was. Even simple metal oxides can "only just" (*e.g.* Fe_2O_3) or "hardly" (Nb_2O_5) be characterized by these simplifying formulae, as demonstrated by the classical example of "FeO"[12]. In $NbO_{2.500-\delta}$, the value of δ *may be*, but *is not necessarily* distinct from zero, and the extent of maximum deviation also differs in the various modifications, of which 25 are known to date[13]; *e.g.* $0 \leq \delta \leq 0.011$ in H-Nb_2O_5[14]. Other oxides, which like "PbO_2" may be of great industrial importance, are known as materials but have not (yet) been prepared as "pure substances" or even as single crystals having a composition corresponding to the formula[15].

Inorganic solid state chemistry is a decidedly *young* science. It was only about 1930 that X-ray structures were first undertaken in conjunction with preparative work on the production of new substances in chemical laboratories like those of *E. Zintl* and *W. Klemm*; modern methods of structural solution employing single crystals have only been used during the past twenty years or so. Yet solid-state chemistry proper starts from a knowledge of crystal structure.

This is probably connected with the notable absence, or inadequate treatment, in most textbooks of facts peculiar to compounds whose characteristic properties are associated with the solid state: compounds made up of molecules such as benzene can usually be prepared in very different ways. The products of varying quality can be subsequently purified, however, and the final samples are all "identical" within the present limits of analytical accuracy.

In the case of solids, however, the formula (*e.g.* CsOH) primarily represents the "compound *per se*", almost in the sense of an idea of *Plato*. Again, one can attempt to prepare samples of "CsOH" by entirely different methods (*e.g.* dehydration of $CsOH \cdot H_2O$, reaction of metallic Cs or of Cs_2O with the properly calculated amount of H_2O, reaction of Cs_2O_2 with H_2). The procedure adopted also plays a role (Cs_2O_2 can be heated in a current of H_2 or annealed in sealed Ag tubes under H_2, reacting in the latter case only with H_2 that has diffused through the wall, and thus undergone further purification[16]). Subsequent purification is hardly possible. Not even samples obtained by the same synthetic pathway are necessarily "identical" (*e.g.* because of differences in quality of the starting material Cs_2O or Cs_2O_2). Recent findings with KCo_2O_4[17] have shown that practically every single crystal belongs to one of two superstructures, and yet exhibits a further individual "super-superstructure"[18].

Only in the light of modern studies with high-resolution electron microscopes did the incredible complexity of the structure of individual single crystals became evident, as regards structural defects and hence composition (cf. Fig. 8)[19]. Thus it becomes understandable that many a simple compound generally considered to be known is still awaiting preparation. Sb_2O_5, known as a metal oxide since the publication of the "*Triumphwagen des Antimonii*"[20], has only recently been prepared pure by *Jansen*[21]; he also obtained the first sample of "pure" As_2O_5[22]. Not only could the structure be elucidated with the aid of previously unavailable single crystals, but, even more remarkably, there are striking differences in behavior: thus according to former reports[23] As_2O_5 melts with decomposition at 330 °C, whereas *Jansen*'s samples melt without decomposing at 760 °C.

Long known as a titration product of KOH with H_3PO_4 in solution, K_3PO_4 was only recently prepared in the pure anhydrous state in our laboratory[24]; the industrial product Na_3PO_4 has likewise only recently been prepared as single crystals[25]; no "pure" samples of the powder have yet been obtained.

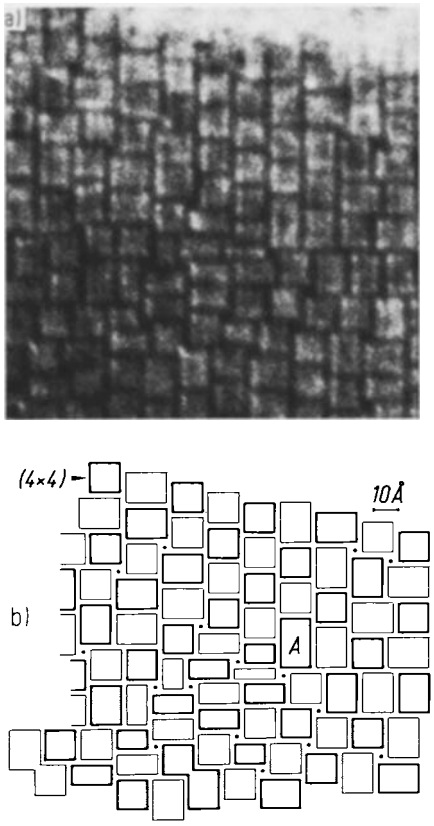

Fig. 8. a) Transmission electron micrograph shows disorder in a WO_3-containing preparation of niobium pentoxide deposited at 780 °C from the gas phase; incorporation of WO_3 leads to $O/\sum M = 2.53$ (M = Nb, W).—b) As shown by the interpretation of the transmission electron micrograph both the linkage and the size of the structural units ["block" consisting of $(n \times m)$ M O octahedra] are irregular. Unusual block sizes, such as the (6×4)-block (A) with $O/M = 2.584$ and the neighboring (5×2) block with $O/M = 2.381$ are characteristic of the metastable preparation. Worthy of note are the unusual edge linking in the (4×5)-blocks and the (4×4)-blocks which are to be regarded as a typical structural unit of the N-Nb_2O_5 modification.

Only few methods—*e.g.* chemical transport, zone melting, recrystallization from the flux—are presently available which permit subsequent purification of typical solids in special cases. This difficult problem still requires experimental solution.

3. Shortcomings of the Berzelius Notation

After just a few semesters of study, any chemistry student can appreciate the wealth of information about structure, symmetry, spectra, chemical behavior, and reaction pathways of "smaller" molecules, which is transmitted by the simple Berzelius notation, and the extent to which the properties of such molecular compounds are established thereby.

A formula such as NaCl, CdS, or CuI reveals neither the thermodynamically stable crystal structure nor whether (and if so how many) other modifications occur and what their structural characteristics may be. It may even claim to give false information, a fact which has received far too little attention. CuS, the characteristic sulfide of copper in group analysis, is certainly not to be formulated as $Cu^{2+}S^{2-}$ but according to $Cu^{2+}Cu_2^{1+}(S_2)^{2-}S^{2-}$, in every respect a "mixed-valence" sulfide[26].

In the case of nonmetallic elements such as P_4[27], S_8, S_{12}[28], and Cl_2, a certain amount of structural information is provided by the formula, but none is forthcoming in the case of metals such as Fe or Mn. One must *know* what transformations occur on heating α-iron, and while the hypothesis that all metals melt from the cubic space-centered form[29], provided they can exist in this form, provides an "explanation" why δ-Fe (like α-Fe) forms cubic space-centered crystals, there is still no real understanding in this matter or with regard to the structural capers of α- and β-manganese[30].

4. Chemical Nomenclature of Solid State Compounds

International rules for the notation of chemical names and formulae are indispensable for coding and for the compilation of thesauri. They are a welcome aid in the standardization of curricula for the teaching of beginners. They hinder progress if instead of $K_2[PtCl_6]$ (or more consistently: $[PtCl_6]K_2$) the formula $KCl_3(Pt_{1/2})$ is not permitted: the first, and, even more so, the second formulation emphasizes that a complex is present with Pt^{4+} as the central ion and Cl as ligand. It is almost irrelevant whether electroneutrality is achieved by K^+ or any other ion, *e.g.* Cs^+: the chemical behavior will be modified at most by the difference in solubility. However, neither formulation says why K^+ has a coordination number (C.N.) of 12 towards Cl^- instead of 6 as in KCl. The reason can be deduced (cf. Section 8) from the notation $KCl_3(Pt_{1/2}) = KCl_{12/4}(Pt_{1/2}) = ClK_{4/12}Pt_{1/6}$ with C.N. 5 for Cl^-.

Why do we write Al_2O_3? In memory of Daltonian concepts which are fundamentally inapplicable here? Why do we convey to the beginner the impression that NaCl is a compound made up of molecules like HCl? Why don't we write $Al_{0.4}O_{0.6}$? Or $AlO_{3/2}$? Or $OAl_{2/3}$? Why not Al_6O_9?

Chemistry is an empirical science. Without one's own experience and that of others it is impossible to pursue the study of chemistry. Experience, however, particularly when it is encoded in formulae and equations, can resemble a chitin shell, and the stronger it becomes the more difficult it will be to shed in order to permit further growth, *i.e.* to recognize and experience something new for what it is. But it is precisely this ability which the young science of solid-state chemistry constantly needs, particularly from the most experienced chemists. More than elsewhere, it is necessary not only to look for what is new but to question what is known (or more precisely: what is believed to be known). To this end it is useful to shock oneself and, where possible, others too by use of new notations, *e.g.* $ClPt_{1/6}K_{4/12}$.

We shall therefore not adhere to canonical formula and nomenclature rules such as those laid down by IUPAC.

5. The Notation of *Niggli*

Many have tried to adapt Berzelius formulae to solids. A particularly impressive and comprehensible notation is that proposed by *Niggli*. He was the first[31] to write $SiO_{4/2}$ instead of SiO_2 and thereby discovered what is termed the *motif of functionality*, and sometimes *motif of mutual adjunction* in what follows. He employed his notation only descriptively. Perhaps *Niggli* himself, like so many others who were less

gifted, fell to the enchantment of structural elucidation as a result of the fascinating aspects and results of X-ray structure analysis.

6. Motif of Coordination

All of the (*ca.* 20) known crystalline forms of SiO_2 except stishovite[32] exhibit Si^{4+} in a tetrahedral environment of $4O^{2-}$. We designate SiO_4 as the motif of coordination (Mo.C.) of Si^{4+}, and OSi_2 analogously as the Mo.C. of O^{2-} in SiO_2.

The corresponding motifs for stishovite are SiO_6 and OSi_3 respectively. We find the same Mo.C. in SiP_2O_7[33]. This becomes understandable when we employ the unconventional formulation $SiO_6(POP)$, ascribe the bridging O-entity a special status, and require that all "terminal" O-entities of the P_2O_7 groups be equivalent towards Si. A series of questions arises, *e.g.* whether or when SiO_5 also plays a role instead of the Mo.C. SiO_4 on glass formation, or which oxides of silicon $SiO_n(Y)$ with suitably chosen Y (in place of POP) permit the case of $n=5$ and thus possibly the hitherto unknown C.N. of 5 for Si towards O? Does this Mo.C. possibly even occur in SiO_2 itself? Table 1 lists possible data for such a hypothetical form of SiO_2, and Figure 9 shows the proposed structure.

Table 1. Coordination number 5 in $SiO_2=Si(O1)_{3/3}(O2)_{2/2}$, a hypothetical form (cf. Fig. 9) with $a=b=3.043$, $c=3.220$ Å, $\gamma=120°$.

Madelung part of lattice energy (MAPLE) in kcal/mol			
	$Si(O1)_{3/3}(O2)_{2/2}$	α-Quartz	β-Quartz
Si^{4+}	2277.6	2219	2209
$O(1)^{2-}$	688.8	710 × 2	703 × 2
$O(2)^{2-}$	643.7		
Σ	3610	3639	3615

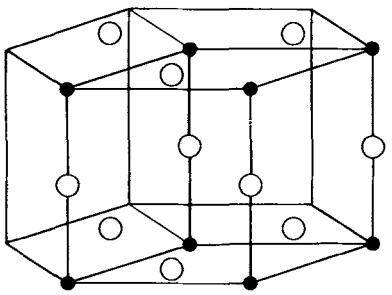

Fig. 9. Hypothetical form of SiO_2 with C.N. 5 for Si towards O (cf. Table 1). Si^{4+}: 0, 0, 0; $(O1)^{2-}$: 2/3, 1/3, 0; $(O2)^{2-}$: 0, 0, 1/2.

The search for the Mo.C. SiO_3, *e.g.* in the form of a "carbonate-analogous" silicate also belongs to this genus of questions.

Thus formulated, compounds appearing inconspicuous in the classical notation often offer stimulating starting points for new studies. $Mn(IO_3)_2$ and $Fe(IO_3)_3$ having the isoelectronic ions Mn^{2+} and Fe^{3+} appear to be "harmless" iodates. On formulation as $MnO_6(I_2)$ and $FeO_9(I_3)$, it is immediately seen that $FeO_6(IO)_3$ appears far more likely than $FeO_9(I_3)$ owing to preference of C.N. 6 by Fe^{3+} towards O^{2-}, and that the different O^{2-} of the IO_3 groups act nonequivalently towards Fe^{3+}, as confirmed by the structure determination[34]; hence pecularities are possible in the physical behavior of $Fe(IO_3)_3$.

In view of the variety of known forms of Al_2O_3, the question arises whether AlO_6 is always the Mo.C. as in corundum.

7. Motifs of Functionality

The motifs of coordination (Mo.C.) in inorganic chemistry are almost invariably "fictive" quantities. Even in "island silicates" such as Mg_2SiO_4 there are no truely "isolated" SiO_4 groups—rather they are linked *via* shared Mg^{2+} (the ionic charges are given as indicators of oxidation states or sums thereof) to form three-dimensional networks. In the following we shall call formulations such as $SiO_{4/2}$ motifs of functionality (Mo.F.). In the case of our example, the formulation means that all O in the forms of SiO_2 (except stishovite) bridge two $2Si^{4+}$ each. Owing to the expected C.N. of 4 (valid for all oxosilicates known so far) the Mo.F. in, *e.g.*, Na_2SiO_3 is surely $Si(O1)_{2/1}(O2)_{2/2}$.

The simpler the composition of a solid, the less informative is the Mo.F. The same Mo.F. of $ClNa_{6/6}$ applies to NaCl as to NiAs ($NiAs_{6/6}$) although the two structures are entirely different. In contrast, if functional differences of chemically equivalent particles are to be expected in binary compounds, then such differences are soon recognized in the Mo.F.

For a variety of reasons, partly because of its relatively high melting point, SnF_4[35] is not expected to have a molecular structure but instead the C.N. of Sn^{4+} for F^- is expected to be 6. This leads directly to $Sn(F1)_{4/2}(F2)_{2/1}$ as the Mo.F. of Sn^{4+}; the (F1) are seen to act as bridges according to $(F1)Sn_{2/4}$ and the (F2) are terminal.

In silicates such as Na_2SiO_3 or $MgSiO_3$, $Si(O1)_{2/1}(O2)_{2/2}$ is expected as Mo.F. of Si^{4+}; bridges and terminal anions are again present.

8. Motifs of Mutual Adjunction

Only the motifs of mutual adjunction (Mo.A.) clearly reveal structural details or peculiarities.

It has so far remained unanswered what reasons are actually responsible for the way in which a given motif of functionality (Mo.F.) is crystallographically solved in a real case.

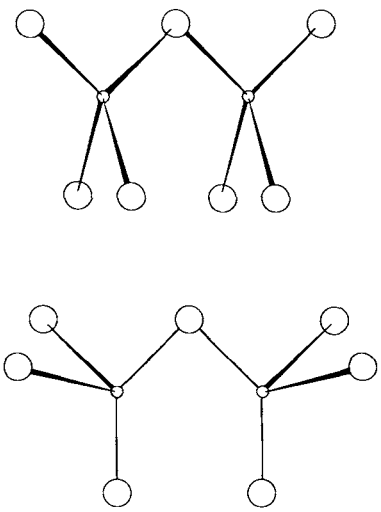

Fig. 10. Conformations of the Cr_2O_7 group in $Sr[Cr_2O_7]$.

One must bear in mind that many simple concepts, even though frequently substantiated, need not always apply.

For example, not all the groups $[Cr_2O_7]$ have to have the same conformation in the crystal of a dichromate like $K_2[Cr_2O_7]$; *e.g.* in $Sr[Cr_2O_7]$ it has been shown[36] that the conformations given in Figure 10 occur in the ratio of 1:1.

Thus the crystallographic description of mutual adjunction for a given Mo.F. can vary widely even for related compounds. For example, according to the occupation of different point sites in Na_2SiO_3[37] corresponding to $Na_2Si(O1)_{2/1}(O2)_{2/2}$, the starting situation is completely different from that of $MgSiO_3$ in which, according to (Mg1)(Mg2)(Si1)(Si2)(O1)...(O6)[38], a far more complicated crystallographic situation prevails. The Mo.A. of these two "metasilicates" are given in Table 2.

Table 2. Motifs of mutual adjunction in Na_2SiO_3 and $MgSiO_3$.

a) $Na_2Si(O1)_{2/1}(O2)_{2/2}$

C.N.	4	3	3	

e) Diopside, $CaMgSi_2(O1)_2(O2)_2(O3)_2$; distances [Å] are given in addition to the Mo.A.

	2(O1)	2(O2)	2(O3)	C.N.	E.C.N. [a]
Ca	2/1 2.44	2/1 2.34	2/1 2.52 (2/1 2.87)	6 (+2)	6.7
Mg	2/1 2.07, 2/1 2.12	2/1 2.11		6	6.0
2 Si	1/1 1.54	1/1 1.59	1/1 1.64, 1/1 1.76!	4	3.6!
C.N.	4	3	3 (+1)		

[a] E.C.N. = effective coordination number (ECoN: *R. Hoppe*, Z. Kristallogr., in press).

Hence, in the case of $MgSiO_3$, it follows for the formulation of $MgSiO_{2/2}O_{2/1}$ (Table 2c) either that the coordination number of the terminal O^{2-} is smaller than that of the bridging moieties or that it is two units greater at C.N. 4 as against C.N. 2 (for bridging O^{2-})—experience shows both alternatives to be unlikely. It is thus appreciated why the equality of Mo.F. and Mo.A. found for Na_2SiO_3 does not hold for $MgSiO_3$, with the terminal O^{2-} being present in two different forms. It is not clear, however, why two crystallographically distinct Mg positions are necessary. The differences between these positions become more obvious in derivatives such as diopside ($MgCaSi_2O_6$)[39], although it can be reasonably doubted whether Ca^{2+} can be assigned C.N. 8 towards O^{2-} in the case of diopside (cf. Table 2e); we shall refrain from discussing such misgivings in this article.

Of interest in this context is $BaSiO_3$[40] for which the Mo.A. (cf. Table 3) show that the functionally equivalent terminal O^{2-} are now also equal with regard to their C.N. towards all cations. Owing to the formal agreement in composition with $MgSiO_3$, this requires that the C.N. of Ba^{2+} is now 7 instead of 6.

Table 3. Motifs of mutual adjunction in $BaSiO_3 = BaSi(O1)(O2)(O3)$.

	(O1)	(O2)	(O3)	C.N.
Si	2/2	1/1	1/1	4
Ba	1/1	3/3	3/3	7
C.N.	3	4	4	

Not only do the Mo.A. quickly provide a simple and readily understood description of relatively complicated crystallochemical situations; what is even more important, they promote new syntheses and provide some indication of their probable chances of success. Let us consider two examples:

8.1. Oxoniccolates(II) of Alkali Metals

Numerous attempts to prepare oxoniccolates(III) such as $KNiO_2$[41] have so far proved unsuccessful; the products obtained could not be identified. On the basis of preparative considerations we first attempted the synthesis of Li_2NiO_2, and were successful[42]. Table 4 lists the Mo.A. and shows that C.N. 4 for Li^+ must necessarily lead to C.N. 4 for Ni^{2+}, a value otherwise not encountered in oxides, if it is assumed that a maximum of six cations can be assigned to O^{2-}. This assumption has been frequently confirmed, even though isolated exceptions are found, *e.g.* in $K_6[Fe_2O_6]$[43] and $K_6[Mn_2O_6]$[44], two oxides with discrete anions having a structure analogous to Al_2Cl_6. Table 5 shows that, under these premisses, "isolated" structural units $^0_\infty[NiO_{2/1}]$ may occur in $K_2[NiO_2]$ if K^+ is allowed to have C.N. 5 instead of the expected value of 6.

Table 4. Motifs of mutual adjunction in Li_2NiO_2.

	O	C.N.
Li	4/4	4
Ni	4/2	4
C.N.	6	

Table 5. Motifs of mutual adjunction in K_2NiO_2.

	O	C.N.
K	5/5	5
Ni	2/1	2
C.N.	6	

In the experimentally difficult synthesis we first consciously exploited the "wall reaction" (Ni tubes), otherwise regarded as the bane of solid state reactions, in order to rule out partial oxidation by residual traces of O_2. Structural analysis[45] revealed a "filled" molecular structure of XeF_2 type[46], *i.e.* a structure isotypic with $K_2[HgO_2]$[47] and the presence of linear CO_2-analogous dumbbells with a surprisingly short distance $d(Ni\text{--}O) = 1.68$ Å (knight's move relationship between Ni and Hg in the Periodic Table!).

The related highly interesting question of the crystal structure of Na_2NiO_2[48] was only recently answered, and then for only one of the two modifications: α-Na_2NiO_2 exists as a further variant of the Li_2NiO_2 principle ($PdCl_{4/2}$-analogous chains $^1_\infty[NiO_{4/2}]$)[49], with one of the two O^{2-} showing C.N. 7 towards the cations (cf. Table 6). Surprisingly, therefore, the premise for the "understanding" of the occurrence of C.N. 2 of Ni towards O in K_2NiO_2 is not fulfilled. Despite considerable effort, the crystal structure of β-Na_2NiO_2 is still unknown.

8.2. Oxocobaltates(II) of Alkali Metals

It came as a surprise when we found that the first oxoferrate(II), $Na_4[FeO_3]$, again obtained by "reaction with the wall" (the Fe inlet of the tube), unexpectedly exhibited carbonate-analogous discrete groups $[FeO_3]$[50]. Table 7a shows why the unusually low C.N. of 3 towards O^{2-} occurs for Fe^{2+}. Viewed in this light, the tremendous effort involved in the syntheses of alkali metal oxocobaltates(II) as single crystals appeared well worthwhile. The synthesis was successful and we also found CO_3^{2-}-analogous "anions" in $Na_4[CoO_3]$[51] (cf. Table 7b). If such experiments give other

oxides, as sometimes happens, such as $Na_{10}Co_4O_9$, the simplest possible Mo.A. (Table 8a) shows that either not all O^{2-} or not all Na^+ are coordinationally equivalent if Co^{2+} is assumed to have C.N. 3 towards O^{2-} as in $Na_4[CoO_3]$. Structural elucidation[52] revealed that a compromise is reached between the two limiting cases. We have just obtained another oligooxometalate, *viz.* the first tetraaluminate $Na_{14}[Al_4O_{13}]$[53] (cf. Table 9). In this connection, mention should also be made of the "island oxometalates" $Na_5[FeO_4]$[54], $Na_5[NiO_4]$[55], and the recently prepared intermediate member $Na_5[CoO_4]$[56] (cf. Table 10).

9. Motifs of Mutual Linkage (Knotting)

α-Ga_2O_3 is isotypic with corundum. In discussing the structure of possible other forms of gallium oxide it appears justifiable to query whether Ga^{3+} has C.N. 4 towards O^{2-} in Ga_2O_3, as is present in oxogallates such as $KGaO_2$[57]. A possible Mo.A. would be, *e.g.* $GaO_{3/3}O_{1/2}$. However, this would imply that part of O^{2-} serve as a bridge between two Ga^{3+} which is highly unlikely in view of the structure of α-Ga_2O_3. While such oxides are indeed known, *e.g.* $Na_8Ga_2O_7$[58], the bridging position of O^{2-} in the Cr_2O_7-analogous group Ga_2O_7 is enforced by the numerous Na^+ partners of this "cation-rich oxide"[59]. Accomplishment of C.N. 4 in Ga_2O_3 is possible only when Ga^{3+} partly retains C.N. 6 of the corundum type, or a least adopts C.N. 5.

Let us consider the argumentation for the simplest possible such case with only two kinds of Ga particles of different coordination in the ratio (Ga1):(Ga2) = 1:1 (in the case of the ratio 1:3 our discussion would lead to the spinel type). Corresponding to the Mo.A.

$$(Ga1)(O1)_{(4-x)/4}(O2)_{x/3}, \quad (Ga2)\ldots$$

there are five distinct possibilities ($x = 0, 1, \ldots 4$) for (Ga1), of which we rule out that with $x = 0$: given a tetrahedral environment of (Ga1) then $(Ga1)(O1)_{4/4}$ leads either to layers consisting only of (Ga1) and (O1) strictly isolated from the (Ga2) part of the structure, or to the ZnS type for this part of the structure which would then no longer have room for (Ga2) and its O fraction. Conversely, for $x = 0$ the formulation $(Ga2)(O2)_{6/3}$ would apply to (Ga2), again leading to "strictly isolated" layers as in CdI_2 or to three-dimensional linkage *e.g.* of rutile type leaving no room for (Ga1) and its O fraction.

Among the other possibilities, which can be analogously assessed on the basis of the Mo.A., that with $x = 3$ is realized in β-Ga_2O_3:

$$(Ga1)(O1)_{1/4}(O2)_{3/3}, \ (Ga2)(O1)_{3/4}(O3)_{3/3}$$

$(Ga2)(O1)_{3/4}(O3)_{2/2}$ would lead to C.N. 5 for (Ga2); however, we have definitively excluded the possibility of such bridges as in $Na_8Ga_2O_7$.

These Mo.A. imply that (O1) necessarily links (Ga1) and (Ga2) together. By analogy, (O2) and (O3) may also be expected to link both kinds of Ga entities. This expectation finds expression in the *motif of knotting* (Mo.K.)

$$(Ga1)(O1)_{1/4}(O2)_{2/3}(O3)_{1/3}, \ (Ga2)(O1)_{3/4}(O2)_{1/3}(O3)_{2/3}$$

or in greater detail

$$(Ga1)(O1)_{1/(1+3)}(O2)_{2/(2+1)}(O3)_{1/(1+2)},$$
$$(Ga2)(O1)_{3/(1+3)}(O2)_{1/(2+1)}(O3)_{2/(1+2)}$$

where, *e.g.* $(Ga1)(O1)_{1/(1+3)}\ldots$ means that (Ga1) has one (O1) as neighbor which in turn links one (Ga1) and three (Ga2) together. The Mo.A. is seen in Table 11.

It is the Mo.K. which can predict in specific cases whether a given Mo.A. is geometrically realistic.

Table 11. Motifs of mutual adjunction in β-Ga_2O_3.

	(O1)	(O2)	(O3)	C.N.
(Ga1)	1/1	2/2	1/1	4
(Ga2)	3/3	1/1	2/3	6
C.N.	4	3	3	

At the present state of knowledge we cannot say why the formulation

$(Ga1)(O1)_{2/(2+2)}(O2)_{1/(1+2)}(O3)_{1/(1+2)}$,
$(Ga2)(O1)_{2/(2+2)}(O2)_{2/(1+2)}(O3)_{2/(1+2)}$

has not yet been found or cannot be realized.

10. A Critical Incidental Remark

Sections 6 to 9 introduced four concepts, of which the Mo.C. does not correspond entirely to the conventional coordination number. In practice, any statement about the number of "bonding partners", *e.g.* for SiO_5, is very difficult to divorce from the question of their geometric arrangement. In view of the difficult "real" aspects of a more general discussion of crystal structures, even of simple compounds, we have not mentioned this before. However, the very mention of the existence of an unknown form of SiO_2 (according to $SiO_{2/2}O_{3/3}$) underlines the close relationship between the Mo.C. and the Mo.A. The Mo.K. permits consideration of the fundamental likelihood of the structures found if one is not merely content to accept them at face value. The price to be paid for the relative ease with which the Mo.F. can frequently (but by no means always) be given is that they often fail to provide definite indication of specific structural characteristics.

It might therefore be suspected that these concepts are essentially formal in nature. That is not the case, as we shall see on considering an appropriate example.

Before proceding further, however, the reader is reminded that the concept of atomic, ionic, or "covalent" radius is over 50 years old. Since the early days of structure determinations, however, it has been known that an additivity of radii or volumes[60] does not strictly apply, even for alkali metal halides. This is underscored by the structure of $ZrCl_4$[61] (cf. Table 12). Just how differently chemically equivalent entities may act within the same compound is demonstrated by the example of UF_3[62] (Fig. 11 and 12).

Our example is taken from the chemistry of thorium and embraces the fluorides $KNaThF_6$[63], $(NH_4)_3ThF_7$[64], $(NH_4)_4ThF_8$[65], K_5ThF_9[66], and $K_7Th_6F_{31}$[67] (which actually belongs at the beginning of the series of increasing F:Th ratio). The Mo.A. are given in Tables 13—17.

Table 12. Concerning the structure of $ZrCl_4$ [61].

$ZrCl_4 = Zr(Cl1)_{2/1}(Cl2)_{4/2}$
d(Zr Cl) = 2.42 Å; thus it follows for an octahedron:
d(Cl Cl) = 3.41 Å; hence:
$R(Cl^-) \leq 1.70$ Å (according to *Shannon* [92]: 1.81 Å)

For the shortest distances d_k, it holds that:

d_k[(Cl1) (Cl1)] = 3.30 Å; → R(Cl1) = 1.65 Å
d_k[(Cl1) (Cl2)] = 3.49 Å; → R(Cl2) = 1.84 Å
d_k[(Cl2) (Cl2)] = 3.55 Å; → R(Cl2) = 1.78 Å

Yielding:

a) R(Cl1) < R(Cl2)

For the Zr Cl distances:

d_k[Zr (Cl1)] = 2.50 Å
d_k[Zr (Cl2)] = 2.31 Å

b) R(Cl1) > R(Cl2)

a) contradicts b)

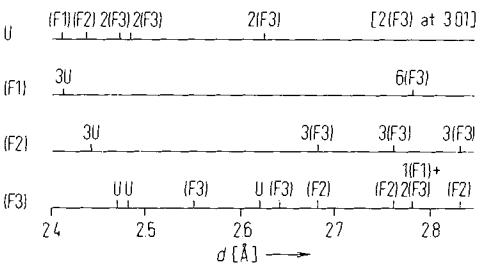

Fig. 11. Interatomic distances in UF_3.

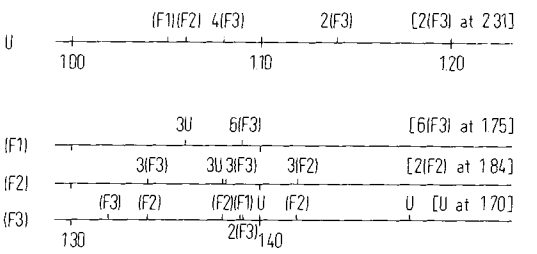

Fig. 12. Reduced distances in UF_3.

$$d(U-F)_{red} = d(U-F) \cdot \frac{R(U^{3+})}{R(U^{3+}) + R(F^-)}$$

$$d(F-U)_{red} = d(F-U) \cdot \frac{R(F^-)}{R(U^{3+}) + R(F^-)}$$

In spite of the relatively small quotients F: Th = 6, Th^{4+} undoubtedly has C.N. 9 towards F^- in $KNaThF_6$. The Mo.A. lead to C.N. 4 towards the cations for all F^-. Th^{4+} has the same C.N. of 9 in $(NH_4)_3ThF_7$; however the two NH_4 show distinctly different coordination; such differences also apply to the C.N. of F^- which for $(NH_4)_4ThF_8$ (also with C.N. 8 for Th^{4+}) are again somewhat better balanced. Unexpectedly, the fluorine-richest member K_5ThF_9 exhibits only C.N. 8 for Th^{4+} and "without any compelling necessity" 4+1+1 K^+ are assigned to (F7).

Even more surprising is the C.N. 8 for Th^{4+} also in the fluorine-poorest compound $K_7Th_6F_{31}$ (F: Th = 5.17) and the unexplained failure of (F6) to contribute to the C.N. of Th^{4+} or of K^+ in spite of the "dearth of fluorine"; as in solid solutions of CaF_2 and fluorides MF_3, and in BiF_3[68], it is present as "lone ion".

In view of these inexplicable contradictions for comparable fluorides of very simple composition, it can hardly be expected that theory will soon dispel the darkness of the reasons which determine crystal structure. It might be thought that the structure analyses of these thorium fluorides are not of compatible accuracy. In such cases, calculations of the Madelung part of the lattice energy (MAPLE)[69] permit scrutenization without the need for new experiments. We have calculated the MAPLE values and thence, by subtraction (with NH_4F as N^+F^- since the H positions of $(NH_4)_3ThF_7$ and $(NH_4)_4ThF_8$ are still unknown), *e.g.* according to MAPLE($KNaThF_6$) − MAPLE(KF) − MAPLE(NaF), obtained MAPLE(ThF_4). Now while the crystal structure of ThF_4 itself is still unknown, the agreement between the values of MAPLE(ThF_4) is so good that the available structure determinations should be of comparable quality (cf. Table 18).

Table 18. Madelung part of lattice energy (MAPLE) of ThF_4 [kcal/mol].

	MAPLE (ThF_4)

11. Motifs of Spatial Arrangement

The varying size of various entities raises questions that have not yet been considered. The example of the series NiO(d(Ni—O) = 1.98 Å), Li_2NiO_2 (1.84 Å), and K_2NiO_2 (1.68 Å)—cf. Section 8.1—shows how large changes in distances (and thus of "radii") can be on changing coordination numbers, and therefore how difficult it is to build up structural arguments on the basis of radii—whatever kind they may be (unless nothing better were available: "A poor estimate is better than none at all").

We shall therefore only apply such arguments "implicitly" in this paper.

These questions, still largely uninvestigated, will first be illustrated by one example and then will undergo the most detailed treatment presently possible in the case of another example.

11.1. Cs_2PbO_3

Whether strictly cubic[70], which appears questionable, or not[71], $BaPbO_3$ undoubtedly belongs to the perovskite family[72]. The parent type (ReO_3 type, cf. Fig. 13) is characterized by the motif $^3_\infty[PbO_{6/3}]$ and exhibits *one* large vacancy per Pb^{4+} which can be occupied by correspondingly large cations, Ba^{2+} in this case. In the case of Cs_2PbO_3[73], the presence of *two* such large cations can lead either to a layer structure $^2_\infty[PbO_{6/3}]$, which we know to be most unlikely and hardly possible geometrically, or to a drastic change of the C.N. of Pb^{4+}. The latter occurs. Formation of $PdCl_2$-type chains is found according to $^1_\infty[PbO_{4/2}O_{1/1}]$, where an additional O per Pb *alternately* (electrostatically "favorably") enlarges their environment to a tetragonal pyramid (cf. Fig. 14a).

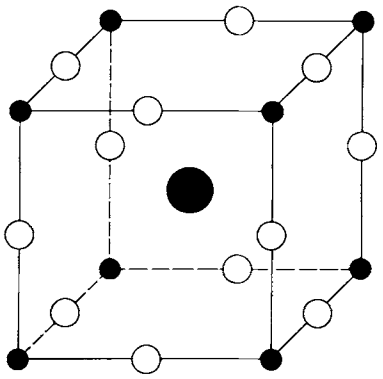

Fig. 13. ReO_3 type (•:Re^{6+}, ○:O^{2-}) with the "large" vacancy (●) occupied in representatives of the perovskite type.

This principle not only solves these structural difficulties but also extends to thiotitanates(IV) such as Cs_2TiS_3[74] (Fig. 14b).

11.2. Ba_2HgS_3

It has long been known that HgS dissolves in solutions of alkali metal sulfides and, *e.g.* after precipitation as metacinnabarite can be transformed by repeated "cooking" into cinnabar as the more stable form. In contrast to thiozincates like Ba_2ZnS_3[75] or thiocadmates like $BaCdS_2$[76], thiomercurates long remained uninvestigated. After earlier attempts[77], we again turned our attention to the preparation and study of such materials and obtained first $A_6[HgX_4]$ with A = K, Rb, Cs and X = S, Se[78] and more recently barium thiomercurates, *viz.* Ba_2HgS_3[79] and $BaHgS_2$[80], and elucidated their structure.

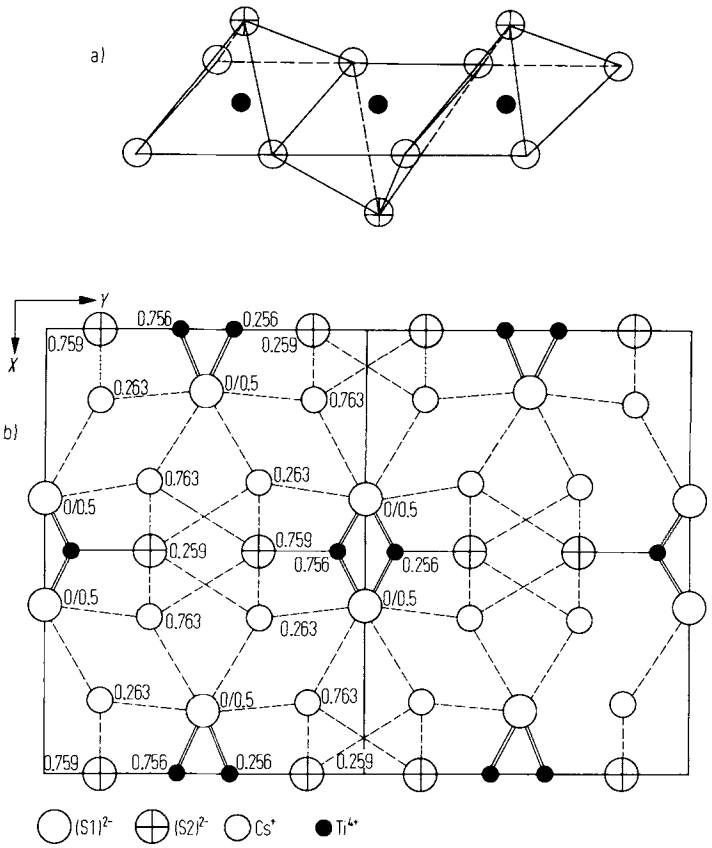

Fig. 14. Crystal structure of Cs_2TiS_3 (Cs_2PbO_3 type). a) Motif of the chain. b) Projection onto [001], heights in z/c.

Owing the possibility of comparison with Ba_2ZnS_3 we select Ba_2HgS_3 as example here.

Preliminary note: All the concepts introduced so far will be employed in the following disussion. An attempt will be made to show how the motifs of structural arrangement "necessarily" result on applying assumptions soundly based on experience. Opportunity will be taken to show where decisive switching or branching points are to be found.

1st Assumption: The structural situation is represented by the notation (Ba1)(Ba2)Hg(Si)(S2)(S3), simpler [*e.g.* $Ba_2Hg(S1)(S2)(S3)$] or more complicated forms [*e.g.* $(Ba1)_2(Ba2)_2(Hg1)(Hg2)(S1)_2(S2)_2(S3)(S4)$] are excluded.

2nd Assumption: The C.N. of Hg^{2+} towards S^{2-} is 4 and the Mo.C. is a tetrahedron. Reasoning: HgS is known to exist in two modifications, in which C.N. of Hg is 2 and 4, respectively. Since $BaHgS_3$ is a comparatively sulfur-rich compound this assumption appears plausible.

3rd Assumption: All S^{2-} have C.N. 6 towards the cations. Reasoning: In accord with $Ba_2S_3(Hg)$ a BaS derivative is almost present; BaS has an NaCl structure.

4th Assumption: The Mo.C. of S^{2-} is a (distorted) octahedron, not a trigonal prism. This rules out (cf. Table 19) nu-

merous other possibilities. Reasoning: It is "less common" for an anion to be surrounded by six cations in the form of a trigonal prism.

Table 19. Possible combinations of the coordination polyhedra octahedron (O) and trigonal prism (TP) around sulfur in Ba_2HgS_3.

(S1)	(S2)	(S3)
O	O	O
TP	O	O
O	TP	O
O	O	TP
TP	TP	O
TP	O	TP
O	TP	TP
TP	TP	TP

5th Assumption: C.N. (Ba1) should be equal to C.N. (Ba2). Simplicity is the sole justification for this assumption. It is also satisfied for $BaHgS_2$.

1st Conclusion: As shown by Table 20 there are a total of 90 possibilities for the corresponding Mo.A.

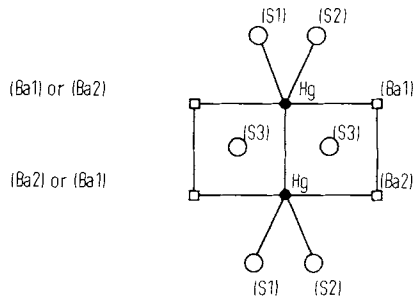

Fig. 15. Double group $(Ba1)_2(Ba2)_2Hg_2(S1)_2(S2)_2(S3)_2$.

4th Conclusion: Owing to $Hg(S3)_{2/2}$ and $(S3)Hg_{2/2}$, only a double group (Fig. 15) or a one-dimensional chain of octahedra (Fig. 16) can be present.

5th Conclusion: The double group in Figure 15 already has the composition Ba_2HgS_3 and no further Ba is available for constructing the undoubtedly three-dimensional network. It therefore offers no possibility of a reasonable arrangement (cf. Fig. 17).

Table 20. Motifs of mutual adjunction in Ba_2HgS_3.

	(S1)			(S2)						(S3)				
	a	b	c	a	b	c	d	e	f	a	b	c	d	e
(Ba1) [a]	5/5	4/4	3/3	5/5	4/4	3/3	2/2	1/1	0/0	4/4	3/3	2/2	1/1	0/0
(Ba2) [a]	0/0	1/1	2/2	0/0	1/1	2/2	3/3	4/4	5/5	0/0	1/1	2/2	3/3	4/4
Hg	1/1	1/1	1/1	1/1	1/1	1/1	1/1	1/1	1/1	2/2	2/2	2/2	2/2	2/2
C.N.	6	6	6	6	6	6	6	6	6	6	6	6	6	6

[a] The combinations (Ba1) 0/0, 1/1, 2/2 and (Ba2) 5/5, 4/4, 3/3 only mean renumbering of Ba.

2nd Conclusion: Of the motif of coordination of (Ba1) is $(Ba1)(S1)_m(S2)_n(S3)_p$, then there follows $(Ba2)(S1)_{5-m}(S2)_{5-n}(S3)_{4-p}$.

6th Assumption: m, n, p $\neq 0$. Reasoning: It is plausible that for a sulfide with the $\sum$ cation: $\sum$ anion ratio of 1, each S^{2-} will have at least one of each kind of cation as neighbor. The example of the thorium fluorides (Section 10) shows how uncertain this conclusion is.

3rd Conclusion: Accordingly, C.N. (Ba1) = C.N. (Ba2) = 7.

There remain only the possibilities given in Table 21. Of these, (a) is identical with (e) [simultaneous renumbering of (Ba1) and (Ba2) and of (S1) and (S2)].

Table 21. Remaining motifs of mutual adjunction for Ba in Ba_2HgS_3; C.N. (Ba1) = C.N.(Ba2) = 7.

	(Ba1):			(Ba2):		
	(S1)	(S2)	(S3)	(S1)	(S2)	(S3)
(a)	4/4	2/2	1/1	1/1	3/3	3/3
(b)	4/4	1/1	2/2	1/1	4/4	2/2
(c)	3/3	3/3	1/1	2/2	2/2	3/3
(d)	3/3	2/2	2/2	2/2	3/3	3/3
(e)	3/3	1/1	3/3	2/2	4/4	1/1

7th Assumption: In the approximately octahedral coordination polyhedron around (S3) the two Hg occupy *cis* positions.

Reasoning: Both modifications of HgS show HgSHg valence angles of about 100°. In contrast to the S—Ba bond, the Hg—S bond has more covalent character.

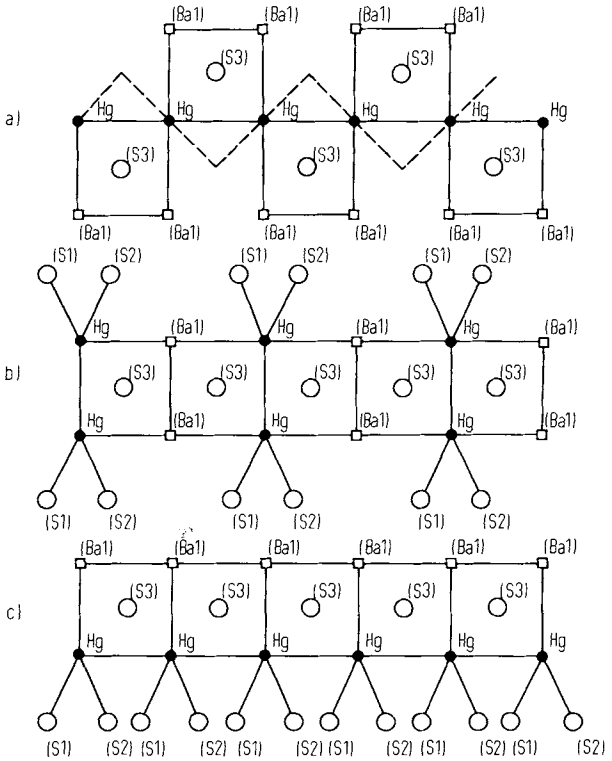

Fig. 16. Possible chains of octahedra as structural unit of Ba_2HgS_3.

Observation: As immediately seen with a model, a chain of the kind shown in Figure 16a or 16b cannot lead to a three-

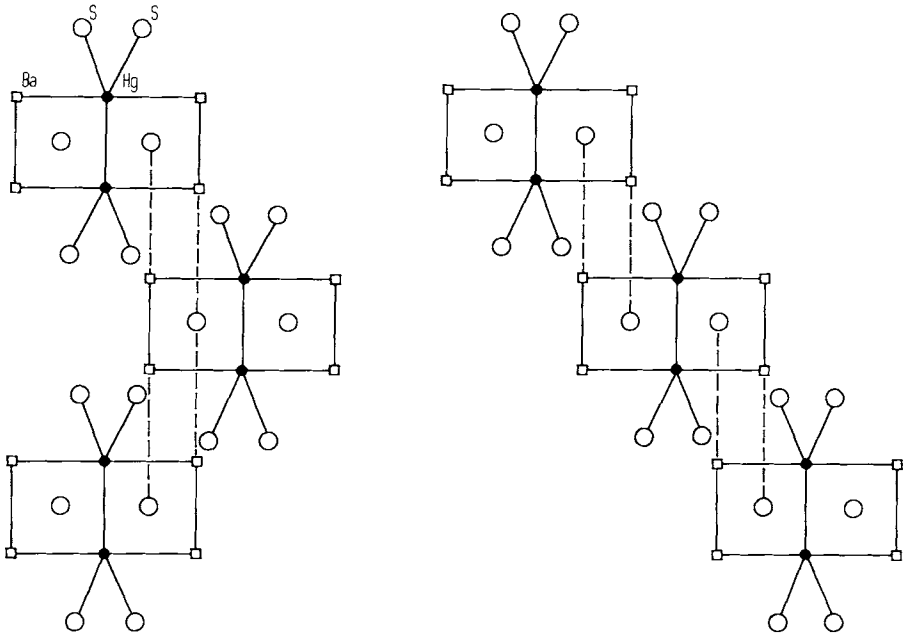

Fig. 17. Attempts to stack the unit $(Ba1)_2(Ba2)_2Hg(S1)_2(S2)_2(S3)_2$ (topological relationships).

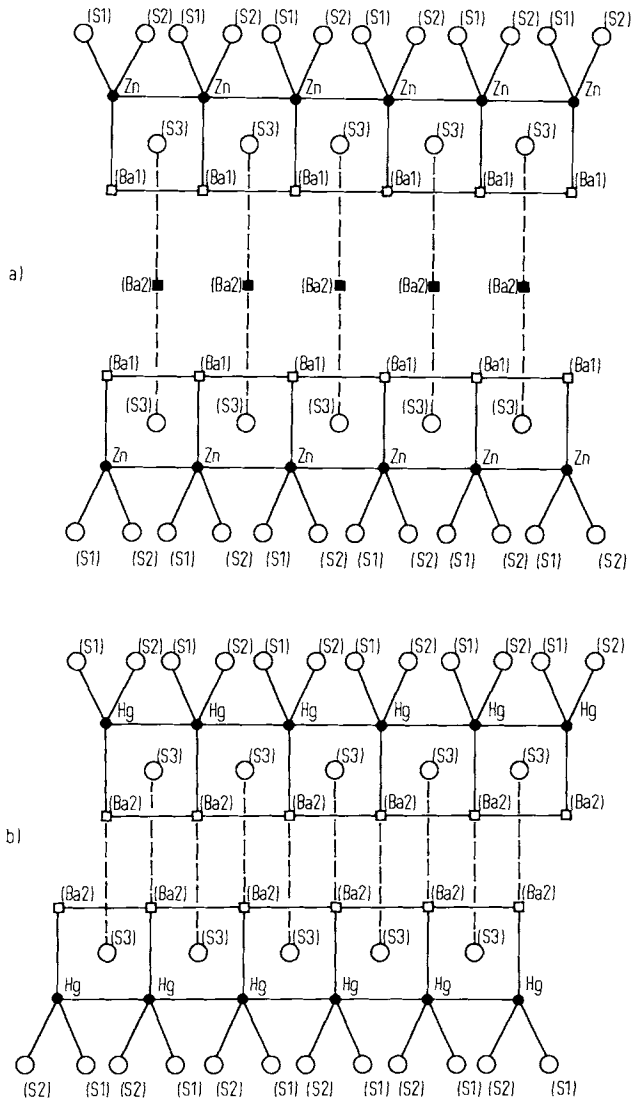

Fig. 18. a) Double chain in Ba_2ZnS_3. b) Double chain in Ba_2HgS_3.

dimensional network since (S1) and (S2) of such chains will be subject to hindrance.

6th Conclusion: There accordingly remain only the two possibilities corresponding to Figure 18:

a) either the Ba entities expanding the coordination polyhedron around (S3) to a distorted octahedron are *equivalent*—and thus necessarily distinct from the Ba present in the chain which contribute to the base of the octahedron (this case is encountered in Ba_2ZnS_3, cf. Fig. 18a)

b) or they are *nonequivalent*—then one will be necessarily identical with that present in the chain and stacking of the chain as shown in Figure 18b must occur (this is the case with Ba_2HgS_3).

Incidental comment: All the assumptions listed, which are plausible if not necessarily valid, lead to a *structural predisposition.* That one alternative is encountered in Ba_2ZnS_3 and the other in Ba_2HgS_3 depends, at our present state of knowledge, on the ratio of ionic radii [in this case $R(M_a^{2+})/R(M_b^{2+})$ where M_a = Ba and M_b = Zn, Hg] (cf. Table 22 which contains further examples).

Table 22. Ionic radii (in Å according to [92]) and ratios of ionic radii of compounds crystallizing in the Ba_2HgS_3 and Ba_2ZnS_3 types.

A_2BX_3	A	B	X	A/B	A/X	B/X	Ref.
Ba_2HgS_3	1.38	0.96	1.84	1.43	0.75	0.52	[79]
Ba_2CdS_3	1.38	0.78	1.76	1.76	0.75	0.52	[76]
K_2AgI_3	1.46	0.79	2.20	1.84	0.65	0.35	[89]
$(NH_4)_2AgI_3$	1.46	0.76	2.20	1.84	0.65	0.35	[89]
Rb_2AgI_3	1.56	0.79	2.20	1.97	0.65	0.35	[89]
Ba_2ZnS_3	1.38	0.78	1.84	2.30	0.75	0.32	[75]
K_2CuCl_3	1.46	0.57	1.81	2.56	0.80	0.30	[90]
$(NH_4)_2CuBr_3$	1.46	0.57	1.96	2.56	0.74	0.29	[91]
Cs_2AgCl_3	1.67	0.79	1.81	2.10	0.92	0.43	[90]
Cs_2AgI_3	1.67	0.79	2.20	2.10	0.75	0.36	[90]

7th Conclusion: The spatial arrangement derived so far is shown as a projection in Figure 19a and in perspective in Figure 19b. It necessarily follows: If the Ba entity located in

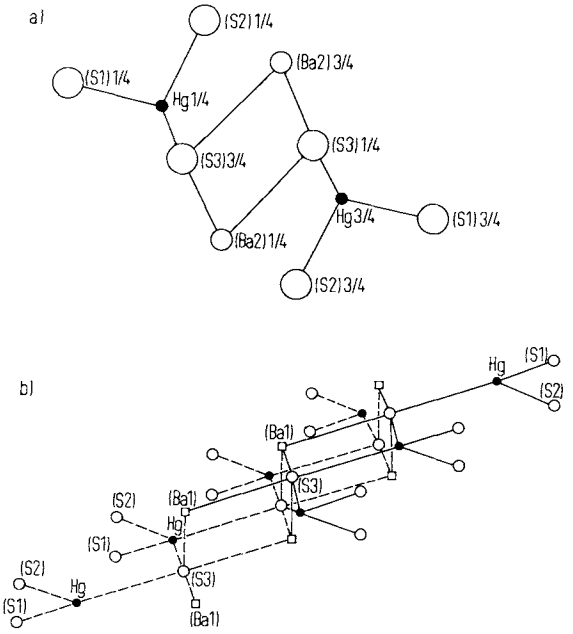

Fig. 19. a) Projection of double chain of Ba_2HgS_3 along [010]. b) $(Ba)_1Hg(S1)_1(S2)_1(S3)_1$, shown in perspective.

the "chain" is designated as (Ba2) then (Ba1) must complete the "octahedron" around (S3) which therefore contains one (S3) and two (S1) from the double chain as ligands. Since the double chain with the additional two (Ba1) expanding the octahedron by (S3) already has the composition $(Ba1)_2(Ba2)_2Hg_2(S1)_1(S2)_2(S3)_2$, completion of the coordination polyhedron around (Ba1) can only occur by joining of such supplemented double chains. Since (S3) does not contribute to completion of the coordination polyhedron around Ba, only (S1) and (S2) can serve this purpose, necessarily to equal extents. Thus the crystal structure of Ba_2HgS_3 shown as projection in Figure 20 is logically established. It corresponds to the alternative (a) in Table 21—the structure of Ba_2ZnS_3 corresponds to alternative (d).

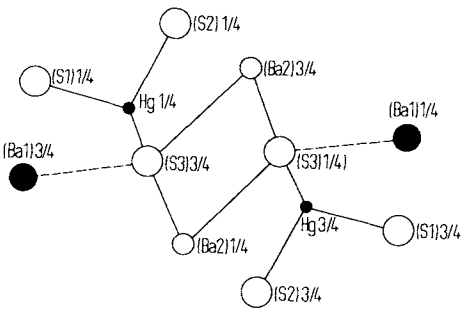

Fig. 20. Ba_2HgS_3: Enlargement of the coordination polyhedron around (S3) by (Ba1), heights in y/b.

Supplementing the coordination polyhedron by (Ba1) can then only take place as shown in Figure 21, thus establishing the structure of Ba_2HgS_3.

Summary: On the basis of seven plausible but not absolutely necessarily valid assumptions, the variety of possible motifs of coordination, functionality, adjuncture, and knotting can be restricted such that a structural predisposition is established, branching into two alternatives: this leads on the

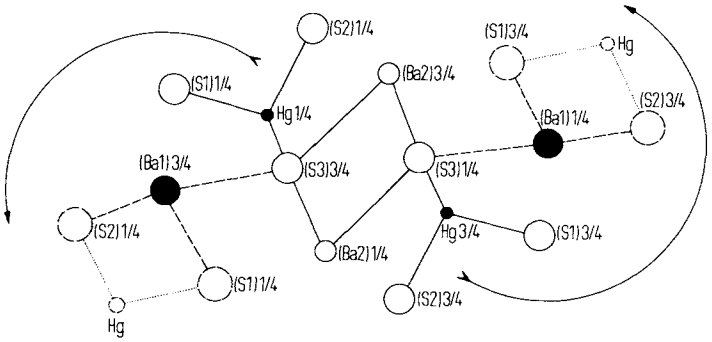

Fig. 21. Ba_2HgS_3: Enlargement of the coordination polyhedron by (Ba1), heights g/b.

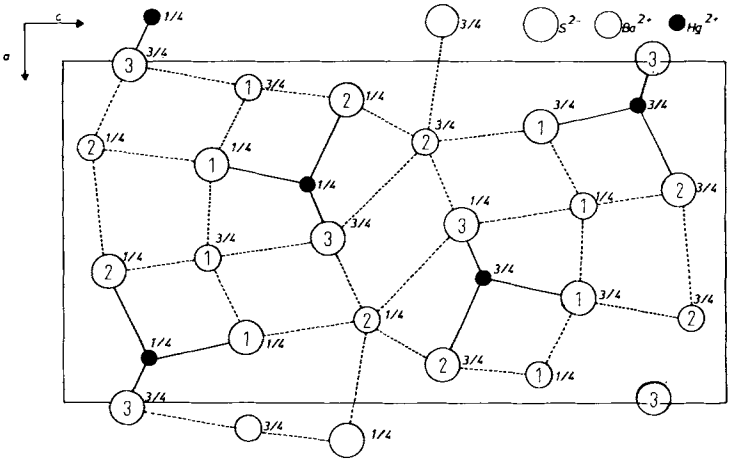

Fig. 22. Crystal structure of Ba_2HgS_3, projection along [010].

one hand, as already shown in detail, to the motif of structural arrangement of the Ba_2HgS_3 type, and on the other hand, not shown here, with similar logic to that of the Ba_2ZnS_3 type. In both cases the principal axis of the "capped trigonal prisms" around (Ba1) and (Ba2) are mutually perpendicular. The situation is different in $SrZnO_2$[81], $BaCdO_2$[82], $BaCdS_2$[76], and $BaHgS_2$[80], where the axes are all parallel.

12. Closing Comments

1) The conclusions presented in Section 11.2 for Ba_2HgS_3 still lead to an almost infinite range of variants having the same fundamental topology. The gap separating this situation and the real crystal structure with given space group and occupied sites appears unbridgeable. Even for the simplest composition it is incredibly difficult to enumerate the possibilities open—as demonstrated by *Hahn*[83] for tetrahedral structures.
2) The avoidance of any direct reference to radii is intentional. It does not mean (cf. [73]) that the author underestimates their influence.
3) The overall result remains unsatisfactory. The general situation is even less clear than these attempts at a systematic discussion of $Ba_2HgS_3/(Ba_2ZnS_3)$ would indicate. In particular, crystal structures such as that of C_6H_6, CCl_4, *etc.* reveal our almost breathtaking inability to imbue structural knowledge with understanding. The example of $Cs_3Ta_5O_{14}$[84], an oxotantalate(v), which we discovered

and elucidated structurally during a search for $CsTaO_3$, which is still unknown in contrast to $LiTaO_3$[85], $NaTaO_3$[86], $KTaO_3$[87], and $RbTaO_3$[88] may serve to illustrate the (still almost hopeless) position of the preparative solid-state chemist.

When will the new *Berzelius* arrive?

Table 23. Motifs of mutual adjunction in $Cs_3Ta_5O_{14}$ = (Cs1)(Cs2)(Cs3)(Ta1)(Ta2)(Ta3)(Ta4)$_2$(O1)...(O6)(O7)$_2$...(O10)$_2$.

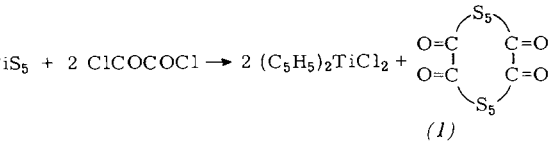
COMMUNICATIONS



Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Synthesis and Crystal Structure Analysis of Decathiacyclotetradecane-6,7,13,14-tetraone, $S_{10}(CO)_4$[**]

By *Herbert W. Roesky, Hamid Zamankhan, Jan Willem Bats,* and *Hartmut Fuess*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

So far the structures of the following sulfur homocyclic systems have been reported: S_6, S_7, S_8, S_{10}, S_{12}, and S_{20}[1]; some of them are stable for any length of time only at low temperature. They should be stabilized by incorporation of heteroatoms into the ring systems—numerous cases of such stabilization are known from sulfur-nitrogen chemistry[2]—and novel systems should thus become accessible. For example, on condensation of Cp_2TiS_5[3] with oxalyl chloride in carbon disulfide we obtained a fourteen-membered ring, *viz.* the title compound *(1)*, for the first time.

(1)

Precession photographs of crystals of *(1)* revealed monoclinic symmetry, space group $P2_1/n$, $Z=4$, $a=781.2(2)$, $b=727.3(2)$, $c=1257.0(7)$ pm, $\beta=91.33(4)°$, $V=714.0\times10^6$ pm^3. Using an automatic Syntex $P2_1$ diffractometer ($Mo_{K\alpha}$ radiation), 2194 reflections (942 non-equivalent ones) were recorded. The standard reflections, recorded at intervals of 50 reflections, indicated considerable radiation damage and resulting intensity losses of between 30 and 60%. After corresponding correction of the data ($\mu=1.48$ mm^{-1}) and solution of the structure with the Multan program (positions of C and O by Fourier syntheses), refinement led to $R(F)=0.104$ and $R_w(F)=0.065$.

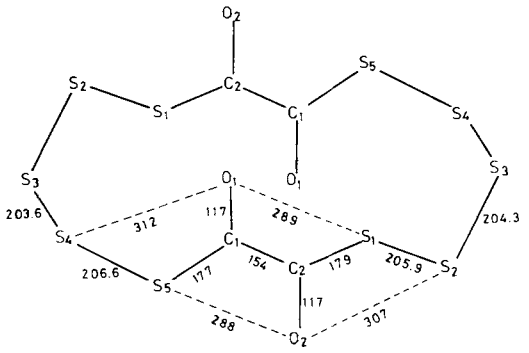


Fig. 1. Molecular shape and interatomic distances [pm] of $S_{10}(CO)_4$ in crystal (standard deviations: S—S, 0.5; S—C, S—O, C—O, 1.0; C—C, 2 pm).

The conformation of the heterocyclic tetraone *(1)* corresponds to expectation. The mean value of the SS bond lengths of 205.1 pm is comparable with that for S_{12} (205.3 pm)[4a]. The SS bonds adjacent to the long SS bonds are shortened, as in S_7O[4b], by bond interaction (the shortest one is located next to the longest SS bond, and the latter in turn next to the shortest SC bond, cf. Fig. 1). The torsional angle between the planes S1–C2–O2–C1 and S5–C1–O1–C2 is 15°. The compound is not volatile without decomposition; only fragments are observed in the mass spectrum of *(1)*. On the basis of our results we assume that the readily soluble species $S_5(CO)_2$ occurs as "monomeric" intermediate during the formation of *(1)*.

Experimental

Oxalyl chloride (1.5 g, 11.8 mmol) is added at room temperature to a suspension of Cp_2TiS_5[3] (4 g, 11.8 mmol) in CS_2 (250 ml) under a nitrogen atmosphere. On heating under reflux for 5 h, the color of the solution changes from dark violet to yellow, and red Cp_2TiCl_2 precipitates. After filtration, evaporation, and repetition of these separation steps, the yellow product *(1)* crystallizes on cooling to $-20\,^{\circ}C$; yield 1.2 g (48%), dec. 110 °C.

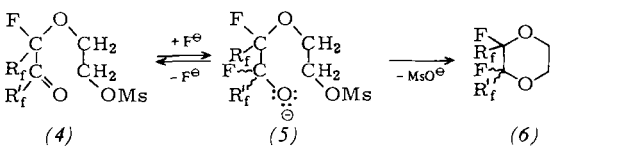
1,4-Dioxanes with Four Fluorine and/or Trifluoromethyl Substituents on C^2 and C^3 from Vicinal Perfluorodicarbonyl Compounds[**]

By *Werner Schwertfeger* and *Günter Siegemund*[*]



Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

So far, two reactions have been reported in the literature for the preparation of 1,4-dioxanes perfluorinated at C^2 and C^3. Thus, 2,2,3,3-tetrafluoro-1,4-dioxane *(6a)* was obtained in *ca.* 3% yield on catalytic hydrogenation of the difficultly accessible perfluoro-2,3-dihydro-1,4-dioxane[1]. In contrast, reaction of perfluoropinacol and 1,4-dioxane affords 2,2,3,3-tetrakis(trifluoromethyl)-1,4-dioxane in quantitative yield[2].

In the search for general synthetic routes for the preparation of fluorinated 1,4-dioxanes *(6)* we found that these ethers are formed on reaction of perfluorinated vicinal dicarbonyl compounds *(1)* with ethylene dimesylate *(3)* (mesyl = methanesulfonyl) and potassium fluoride and/or cesium fluoride in the molar ratio 1:1:2.

(1) *(2)* *(3)*

(4) *(5)* *(6)*

(a), $R_f = R'_f = F$; *(b)*, $R_f = F$, $R'_f = CF_3$ or $R_f = CF_3$, $R'_f = F$; *(c)*, $R_f = R'_f = CF_3$

Scheme 1. Proposed reaction mechanism. The simultaneous addition of two fluoride ions to *(1)* has not been considered.

From hexafluorobiacetyl *(1c)*[3] the diastereomeric 1,4-dioxanes *(6c)* are obtained in the ratio 10:1. Hitherto, the mixture could not be separated, either by distillation or by preparative gas-chromatography. The proposed reaction mechanism (Scheme 1) suggests that the sterically more favorable *trans* product is the main component.

Experimental

The dry alkali-metal fluoride and dried solvent are transferred to a previously dried flask fitted with a mechanical stirrer, thermometer, and reflux condenser. After addition of *(1)* and *(3)*, the mixture is slowly warmed to the reaction temperature. The reaction mixture is steam distilled and the organic phase recovered is dried over sodium sulfate and distilled.

(6a) 0.5 mol *(1a)*[4], 0.5 mol *(3)*, 1.1 mol KF, 0.05 mol CsF, 500 ml diethylene glycol dimethyl ether; 8 h at 85 °C, 14% yield, b.p. 119—121 °C/750 torr. ^{1}H-NMR[5]: $\delta = 4.20$ (s); ^{19}F-NMR[5]: $\delta = -93.73$ (s).

(6b): 0.25 mol *(1b)*[6] (as dimer), 0.25 mol *(3)*, 0.75 mol KF, 200 ml tetraethyleneglycol dimethyl ether; 24 h at 110 °C, 4.4% yield, b.p. 74.5—76.5 °C/100 torr. ^{1}H-NMR[5]: $\delta = 3.25$—4.80 (m); ^{19}F-NMR[5]: $\delta = -81.27$ (m, 3F, CF_3), -85.46 (dm, $J_{gem} = 156$ Hz, 1F, CF_2), -87.37 (dm, $J_{gem} = 156$ Hz, 1F, CF_2), -139.26 (m, 1F, CF).

(6c): 0.3 mol *(1c)*[3], 0.3 mol *(3)*, 0.625 mol CsF, 200 ml tetraethylene glycol dimethyl ether; 14 h at 100—105 °C, 46% yield, b.p. 75—90 °C/100 torr. ^{1}H-NMR[5]: $\delta = 3.65$—4.75 (m); ^{19}F-NMR[5] "α-form": $\delta = -79.76$ (m, CF_3), -125.35 (m, CF); "β-form": $\delta = -79.98$ (m, CF_3), -133.37 (m, CF); intensity ratio of signals at -125.35 and $-133.37 \approx 1:10$.

A Selective Pathway from Methanol to Ethylene and Propene[**]

By *Friedrich August Wunder* and *Ernst Ingo Leupold*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Increasing scarcity of crude oil compels us to look for alternative entries to the feedstocks of the chemical industry.

Apart from hydrogenation of coal and the Fischer-Tropsch synthesis[1] increasing attention is being focused on

[**] This work was supported by the Federal German Ministry of Research and Technology (grant designation: 01 VM 399-ZK/NT/NTS 2036).

the catalytic synthesis of ethylene and propene from methanol[2] which is readily accessible, in principle, from all carbonaceous raw materials[3]. Most of the known catalysts[4] transform methanol into a wide range of products with a considerable proportion of higher aliphatic and aromatic hydrocarbons[5].

$$n\ CH_3OH \xrightarrow{cat.} \text{Hydrocarbons} + n\ H_2O \qquad (a)$$

More selective catalysts are accessible by doping zeolites with lanthanoids[6].

Use of manganese-doped aluminosilicates[7] has now given a surprisingly narrow product spectrum with a high proportion of ethylene and propene.

For instance, if a methanol/water mixture (30 vol. % water) is passed at 400 °C and normal pressure over a mixture of chabasite and erionite whose exchangeable cations have been replaced by manganese, then only C_1 to C_4 hydrocarbons are formed. The conversion is over 90%. After condensation of the water of reaction, the gas compositions given in Table 1 are obtained.

Table 1. Composition of the gas obtained [eg. (a)] after condensation of the water of reaction.

Products	Amount [vol. %]	
Ethylene	37.1	66.3 C_2- to C_4-olefins
Propene	26.5	
Butenes	2.7	
Methane	12.6	21.8 C_1- to C_4-alkanes
Ethane	1.3	
Propane	6.6	
Butanes	1.3	
C_5- and higher hydrocarbons	<0.1	
Aromatics	<0.1	
CO	0.5	
H_2	5.2	
H_2O	≈2	
Dimethyl ether	4.7	

Dimethyl ether can be recycled as an intermediate[8]. Table 2 shows the selectivities in this case.

Table 2. Selectivity of reaction (a) on recycling of dimethyl ether. The selectivity refers to the gaseous products.

Products	Selectivity [%]	
Ethylene	36.3	80.3 C_2- to C_4-olefins
Propene	38.8	
Butenes	5.2	
C_1- to C_4-alkanes	19.5	

The high concentration of the C_2 to C_4 olefins in the reaction gas suggests a future industrial exploitation of this reaction. The relatively narrow product spectrum facilitates distillative work-up. Thus the procedure opens a route to these important feedstocks of industrial synthesis which is independent of the availability of individual raw materials.

Addition of Alkanethiols to Diketene

By *Ulrich Hertenstein*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

The course taken by an acid-catalyzed addition of alkanethiols to diketene *(1)* could not be predicted from the reactions known so far.

Thermal and base-catalyzed additions of thiols to diketene *(1)* give thioesters *(2)*[1]; on irradiation or in the presence of azodiisobutyronitrile (AIBN), however, β-(alkylthiomethyl)-β-propiolactones *(3)* are formed[2]. This addition proceeds in anti-Markownikoff fashion.

In the same way, thiols add to vinyl esters. This reaction is subject to both radical-[3] and acid catalysis[4].

In contrast, the likewise acid-catalyzed addition of thiophenol to diketene[5] proceeds according to the Markownikoff rule to give β-phenylthiocrotonic acid *(4)*.

We found that alkanethiols undergo anti-Markownikoff H_2SO_4-catalyzed addition to diketene *(1)*. The adducts *(3)* were isolated and identified by ^{1}H-NMR spectroscopy (Table 1).

$$RSH + (1) \xrightarrow{H_2SO_4/Et_2O} (3)$$

(5d)	n-C_4H_9	83—93/0.001	1720	1600	50

Procedure

(3): Diketene *(1)* (0.5 mol) is added between 0 and 3 °C to a solution of thiol (0.5 mol) in anhydrous ether (200 ml) cooled to 0 °C. Concentrated H_2SO_4 (49.0 g, 0.5 mol) is then added dropwise between 0 and 5 °C to the cooled (ice/salt) reaction mixture. Stirring is continued for 2 h at room temperature, the two phases are separated, the organic phase washed with water, dried over Na_2SO_4 and distilled.

(5): The procedure is as above but without work-up. After addition of alcohol (2 mol), the ether is distilled off. The mixture is heated to 70 °C for 1.5 h, poured on to 1 l of crushed ice, extracted with ethyl acetate, dried over Na_2SO_4, and distilled.

Direct Synthesis of the Perfluoroalkanesulfinates of Iron(II), Cobalt(II), and Nickel(II): SO_2-Assisted Addition of Alkyl Halides to Transition Metals

By *Konrad von Werner* and *Hermann Blank*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Typical transition metals normally react with alkyl halides only when they have been transformed into a particularly energetic state by physical (metal atom technique[1]) or chemical methods (reduction of metal salts[2]).

We have now found that commercial grade iron, cobalt, and nickel powder react under mild conditions with 1-iodoperfluoroalkanes *(1)* in the presence of sulfur dioxide and strongly polar aprotic solvents (dimethylformamide, dimethyl sulfoxide, hexamethylphosphoric triamide). Use of DMF gave products shown by elemental analysis, IR data, and magnetic moments to be cationic di-μ-iododimetal(II) complexes *(2)* (see Table 1).

$$2\ M + 2\ R{-}I + 2\ SO_2 \xrightarrow[20\,^\circ C]{DMF}$$
(1)

$$\left[(Me_2N{-}CH{=}O)_4M\begin{smallmatrix}I\\I\end{smallmatrix}M(O{=}HC{-}NMe_2)_4\right]^{2\oplus}\ \left[RSO_2^{\ominus}\right]_2$$
(2)

M = Fe, Co, Ni; R = $CF_3(CF_2)_n$, n = 1-9

Table 1. Characteristic data of some complexes *(2)*, R = n-C_6F_{13}.

	M	IR (Nujol) [cm^{-1}] $\nu(CF)+\nu_{as}(SO_2)$	IR (Nujol) [cm^{-1}] $\nu_s(SO_2)$	Magn. moment [BM] exp.	Magn. moment [BM] calc. [a]	Color	Dec. [°C]	Yield [%]
(2a)	Fe	1241 s, 1203 s, 1174 w, 1148 s, 1130 w	1018 m	4.88	4.90	ocher-yellow	>42	88
(2b)	Co	1240 s, 1204 s, 1172 w, 1147 s, 1127 w	1018 m-s	3.65	3.87	violet	>47	67
(2c)	Ni	1241 s, 1205 s, 1168 w, 1147 s	1018 m-s, 1005 sh	—	2.83	green	>45	43

[a] "Spin only" values.

The complexes *(2)* can be isolated as paramagnetic crystals which are highly sensitive to oxidation and moisture. The IR spectra indicate the DMF ligands to be coordinated *via* oxygen ($\nu(C{=}O) = 1645\ cm^{-1}$) and the very weakly nucleophilic RSO_2 groups to be present only as counterions. In their chemical behavior, the complexes *(2)* resemble the structurally analogous compounds of type $[L_2MCl_2ML_2][CF_3SO_2]_2$ (M = Fe, Ni; L = bpy, phen) described by *Lindner et al.*[3].

On warming in DMF solution, *(2)* already decomposes at 40 °C into $M(DMF)_4(I)_2$ and $[M(DMF)_6][RSO_2]_2$. Nor is SO_2 liberated at higher temperatures.

No reaction occurred with very finely divided metal powders after prolonged exposure to air. In these cases, a dense oxide layer was expectedly found on the metal surface by ESCA.

Activation of the metal by chemisorption of SO_2 as a $(M{\rightarrow}SO_2)$-adduct is assumed to occur during formation of *(2)*. This is supported (i) by the slow reaction of the metals with *(1)* in DMF only above 100 °C in the absence of SO_2,

[*] Dr. K. von Werner, H. Blank
Werk Gendorf, Hoechst Aktiengesellschaft
D-6230 Frankfurt am Main 80 (Germany)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0202-0128 $ 02.50/0

and (ii) by the absence of any shift of the ^{19}F-NMR signal of the terminal CF_2I group of *(1)* in DMF solution after saturation with SO_2, ruling out activation of *(1)*. Complexes *(2)* are most probably formed by oxidative addition of *(1)* to an initially formed $M^0(SO_2)$ complex, to give a solvated (RMI) species and insertion of SO_2 into the M—C bond.

The postulated insertion reaction of SO_2 into a perfluoroalkyl-transition metal bond appears unusual[4]. However, it could be accomplished with the model compound *(3)*[5] which can be readily transformed by SO_2 and DMF into *(2a)*.

$$\underset{(3)}{cis\text{-}(CO)_4Fe(C_6F_{13})I} + SO_2 \xrightarrow[-4CO]{DMF,\ 20\,^\circ C} \underset{90\%\ \text{yield}}{(2a)}$$

The synthesis of sulfinato complexes is not limited to *(1)* but is also possible with other halides. The products are sometimes highly labile and could not all be characterized. The following reaction series was found for M=Fe: $C_6F_{13}I$ > CH_2=CH—CH_2Br > C_6H_5—CH_2Cl > $C_6F_{13}Br$ > $C_6F_{13}CH_2CH_2I$ > $C_8H_{17}I$.

The compound C_6H_5-NSO also reacts at 20 °C with Fe and *(1)*, albeit slower than SO_2. The resulting $[C_6H_5\text{--}N\text{--}S(=O)R]^{\ominus}$ anion was detected by methylation with CH_3I[6] to give *N*-methyl-*N*-phenylperfluoroalkanesulfinamides.

Procedure

(All operations performed under dry N_2)!

(2a): $C_6F_{13}I$ (231.9 g, 0.52 mol) is added dropwise to a stirred suspension of Fe powder[7] (27.9 g, 0.5 mol) in DMF (750 ml) over 3 h with simultaneous introduction of SO_2 (64 g, 1.0 mol). The mixture is kept below 25 °C, and first turns green and then yellowish-brown. After stirring for 48 h, it is filtered and as much DMF removed as is possible at 0.1 torr and a maximum temperature of 30 °C. The distillate contains *ca.* 5 g of $C_6F_{13}H$. The residue is cooled to −20 °C for several days; the crystal slurry is filtered under suction and the crystals dried *in vacuo* (yield 378 g). *(2b, c)* can be prepared similarly.

Pyrrolizidines by Rearrangement of β-Lactams

By *Friedrich Cavagna, Adolf Linkies, Hartmut Pietsch*, and *Dieter Reuschling*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

During attempts to synthesize compounds with thienamycin-like structure we obtained the racemic 6-(2-iodoethyl)-7-oxo-1-azabicyclo[3.2.0]heptane-2,2-dicarboxylic acid diethyl ester *(1)*, which on reaction with acids or bases surprisingly undergoes rearrangement with ring expansion. Thus, on treatment with glacial acetic acid, *(1)* is slowly, with trifluoroacetic acid rapidly, converted into the pyrrolizidium salt *(2)*. On reaction with bases such as sodium methoxide or sodium cyanide in methanol, *(1)* undergoes transesterification, giving the pyrrolizidine *(3)*.

The intramolecular reaction of *(1)* with bases can be explained in terms of the increased reactivity of the nitrogen by the annelated five-membered ring and the consequently enforced perturbation of the amide mesomerism[1]. The spatial proximity of the two reactive groups leads to additional entropic promotion of the reaction. No racemization occurs, either in the acidic or in the basic conversion, *i.e.* the steric arrangement at C-5 and C-6 of *(1)* remains intact at C-7a and C-1, respectively, of *(2)* and *(3)*.

This reaction opens an entry to 1,5-disubstituted pyrrolizidines. On hydrolysis with KOH, *(3)* is decarboxylated to the sterically homogeneous 1,5-pyrrolizidinedicarboxylic acid *(4)*. The configuration at C-5, however, is still unclear.

The rearrangements have been established by the ^{1}H-NMR spectra (270 MHz, INDOR technique). Diagnostically decisive for the structures are the parameters of H-3 [*(2)* (in D_2O): ^2J=11.0 Hz, δ=3.82, ^3J=0 and 6.5 Hz, δ=3.18, ^3J=7.2 and 9.0 Hz; *(3)* (in [D_6]-DMSO): ^2J=−11.0 Hz, δ=3.01, ^3J=2.2 and 10.1 Hz, δ=2.80, ^3J=7.2 and 11.0 Hz] and H-7a; instead of J_{cis}(H-5, H-6)=5.5 Hz in *(1)* we find in *(3)* J(H-1, H-7a)=9 Hz. In contrast to the β-lactam spec-

trum, the pyrolizidine spectra are strongly pH-dependent. In acid medium the spectrum of *(3)* is almost identical to that of *(2)*. In *(3)* the signals of H-7a appear at higher field ($\delta = 3.68$), in *(2)* at lower field ($\delta = 4.20$), than the signals of H-5 in *(1)* ($\delta = 4.03$). The anisochronism of the aminomethylene protons (H-3) becomes greater on protonation of the nitrogen atom.

Also the ^{13}C-NMR spectra allow an unequivocal assignment to the two structural types (Table 1).

Experimental

(2): A solution of *(1)* (10 g, 24 mmol) in CH_3CO_2H (50 ml) and CF_3CO_2H is stirred for 45 minutes. After removal of solvent *in vacuo*, the residue is stirred in ethyl acetate until it becomes completely crystalline. Yield 6.2 g (60%), m.p. 126 °C (acetone).

(3): A mixture of *(1)* (10 g, 24 mmol) and NaCN (2.8 g, 54 mmol) in methanol (50 ml) is heated to boiling for 12 h. After evaporating down, the reaction product is isolated by passage through silica gel (ethyl acetate/hexane 1/2; $R_f = 0.36$) and distilled; b.p. 120 °C/0.05 torr; yield 4.2 g (62%). With $NaOCH_3$ instead of NaCN (6 days at room temperature), *(3)* is obtained in 95% yield.

(4): To a solution of *(3)* (16.5 g, 61.3 mmol) in methanol (20 ml) is added 100 ml of methanolic KOH and the mixture heated at 60 °C for 12 h. After dilution with 400 ml methanol the mixture is treated dropwise with 200 ml 70% $HClO_4$, filtered and the filtrate evaporated down; the residue, dissolved in 10 ml H_2O, crystallizes out on addition of acetone. Yield 8.5 g (64%); m.p. above 290 °C, dark coloration.

Syntheses with Cyanogen—A Simple Route to 4,5-Dichloroimidazoles

By *Dieter Günther* and *Dieter Bosse*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Bromine and iodine derivatives of imidazoles not substituted on nitrogen can be prepared easily and in good yields by halogenation[1]. The corresponding chlorine derivatives, on the other hand, are virtually unknown. Thus imidazole reacts with bromine in chloroform or ether to give 2,4,5-tribromoimidazole[2,3], while chlorination with elemental chlorine affords 2,2,4,5-tetrachloro-2*H*-imidazole[4]. Some imidazoles can be converted into the 4,5-Dichloroderivatives by reaction with *N*-chlorosuccinimide[5] or sodium hypochlorite[6].

We have now found that 4,5-dichloro-2-phenylimidazole *(1a)* ($R = C_6H_5$) is formed in good yields on reaction of benzaldehyde with cyanogen and hydrogen chloride in diethyl ether. The sole by-product formed in the reaction is oxamide, which is only sparingly soluble in most common solvents and can easily be separated.

To illustrate the scope of this reaction we report here on the reaction of some aliphatic, aromatic, and heteroaromatic

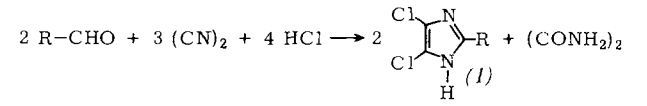

Table 1. Synthesis of 2-substituted 4,5-dichloroimidazoles *(1)*.

	R [a]	Solvent [b]	Yield [%]	M.p. [°C]
(1a)	C_6H_5	DME	67	165
(1b)	*p*-Cl C_6H_4	DEE	71	176
(1c)	*m*-$C_6H_5OC_6H_4$	DEE	72	175
(1d)	*p*-O_2N C_6H_4	Dioxane	46	235
(1e)	2-Benzo[*b*]furyl	Dioxane	70	195
(1f)	2-Thienyl	DEE	36	216
(1g)	$(CH_3)_3C$	Dioxane	45	236

[a] The composition and structure of the compounds are also confirmed by ^{1}H- and/or ^{13}C-NMR, IR and mass spectra. [b] DME = dimethoxyethane. DEE = diethyl ether.

aldehydes with cyanogen and hydrogen chloride (see Table 1). Aromatic aldehydes and aliphatic aldehydes with a tertiary α-C atom afford compounds *(1)* in good yields. In the case of enolizable aliphatic aldehydes and basic heteroaromatic aldehydes side reactions such as catalyzed aldol reactions and salt formation drastically reduce the yields. The 2-aryl-4,5-dichloroimidazoles *(1)* are crystalline, stable substances having the properties of weak acids. Only treatment with concentrated mineral acids leads to formation of salts, which completely hydrolyze on dilution.

While reaction of *(1)* with dimethyl sulfate or methyl iodide under phase-transfer catalysis conditions (NaOH/toluene) led smoothly to the 1-methyl derivatives *(2)*, attempted acylations with acid chlorides or isocyanates were unsuccessful. The salt *(4)*, formed on reaction with sodium methoxide, however, could be acylated to *(5)* in the usual way (see Table 2).

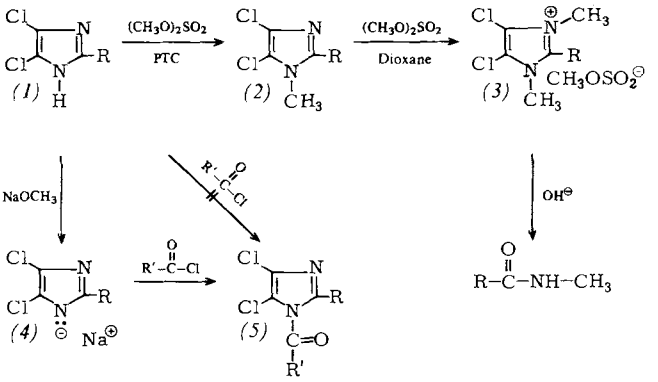

Table 2. Synthesis of derivatives of the 4,5-dichloroimidazoles *(1)*.

Functionalization of α-Methylene Ketones

By *Jürgen Sander* and *Karl Clauss*[*]

Dedicated to Professor Rolf Sammett on the occasion of his 60th birthday

Chlorosulfonyl isocyanate (CSI) and fluorosulfonyl isocyanate (FSI) are well-investigated, highly reactive compounds[1]. α-Methylene ketones *(1)* can be transformed by CSI into β-oxonitriles[2]. On reaction with FSI, α-methylene ketones *(1)* form *N*-fluorosulfonyl-β-oxocarboxamides *(2)*, which cyclize to 1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxides *(3)*[3].

We have now found that the products *(3)* react with phosphorus pentachloride to give 4-chloro-1,2,3-oxathiazine 2,2-dioxides *(4)* which in turn undergo a novel reaction with nucleophiles NuH *via* ring opening and SO_3 elimination to form β-substituted acrylonitriles *(5)* and/or *(6)*. Suitable choice of reaction conditions largely suppresses or avoids formation of substitution products *(7)*.

Table 1 lists examples for steps *(3)*→*(4)* and *(4)*→*(5)* and/or *(6)*.

Procedure

(4): A mixture of *(3)*[3] (0.50 mol), CCl_4 (400 ml), and PCl_5 (0.53 mol) is heated and stirred until a solution arises and evolution of HCl ceases. After cooling, the solvent and phosphorus oxide chloride are removed by vacuum distillation. The residue *(4)* is purified by vacuum distillation in a thin-layer evaporator or by crystallization from diisopropyl ether.

(5) and/or *(6):* A solution of *(4)* (30 mmol) in CH_2Cl_2 (25 ml) is added dropwise at 20 °C to a solution of NuH (30 mmol) in CH_2Cl_2 (50 ml) and triethylamine (90 mmol) [in the case of *(j)—(l)*] or triethylamine (60 mmol) and 4-dimethylaminopyridine (30 mmol) [in the case of *(a)—(i)*]. After 12 hours' stirring at room temperature, the organic phase is washed with water and dried over sodium sulfate. The solvent is evaporated *in vacuo* and the residue chromatographed on a silica gel column (70—230 mesh, cyclohexane : ethyl acetate, 1:1). The products *(5)* and/or *(6)* are distilled or recrystallized from diisopropyl ether or acetonitrile.

Synthesis and Structure of 3-Chloro-4-hydroxy- and 3,4-epoxyphospholane 1-Oxides

By *Friedrich Cavagna, Utz-Hellmuth Felcht,* and *Erich F. Paulus*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

1-Alkyl(alkoxy,aryl)-3-phospholene 1-oxides *(1)* add cleanly at the C=C double bond with hypochlorous acid formed *in situ* from chlorine and water to give 1-alkyl(alkoxy,aryl)-3-chloro-4-hydroxyphospholane 1-oxides *(2)* (Table 1), which, apart from the derivative with $R^1 = C_6H_5$, R^2, $R^3 = CH_3$[1a], were hitherto unknown. Alkaline cleavage of the chlorohydrins *(2)* affords the 3,4-epoxyphospholane 1-oxides *(3)* (Table 1) in almost quantitative yield and is thus

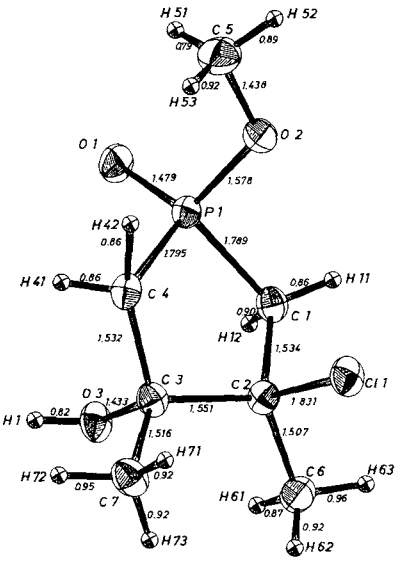

Fig. 1. ORTEP diagram of the molecular structure of (1*SR*, 3*SR*, 4*RS*)-3-chloro-4-hydroxy-3,4-dimethyl-1-methoxyphospholane 1-oxide *(2f$_1$)* in the crystal. Standard deviations Cl C, P O: 0.002 Å, O C, C C: 0.003 Å, C H: 0.02 Å.

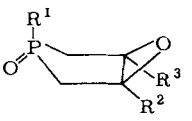
superior to previously known syntheses of such compounds[1b,2].

If during the chlorination of *(1)* in aqueous solution the pH is kept between 3 and 7 (see Experimental) then a maximum yield of the chlorohydrins *(2)* is obtained without formation of *(4)* being observed.



The arrangement of the substituents on C-3 and C-4 relative to the P=O group in the chlorohydrins *(2)* is decisive for the position of the epoxide ring in the epoxides *(3)*. Hence, an X-ray structure analysis was carried out on *(2f$_1$)*[3]. As shown in Figure 1 the hydroxy- and oxo groups are situated on the same side of the ring plane.

Diastereomeric mixtures of *(2)* lead also to diastereomeric mixtures of *(3)*, whereas use of the individual diastereomers [*(2d$_1$), (2d$_2$), (2f$_1$), (2f$_2$)*] affords in each case only one isomer of *(3)*[4]. In the case of *(3a)* the isomers could be separated by preparative layer chromatography[5]. Basically, two configurational isomers (A and B) are conceivable[6].

Isomer A

Isomer B

The structural assignment of the two pairs of isomers *(3a$_1$)/(3a$_2$)* and *(3d$_1$)/(3d$_2$)* must however still remain open[7], whereas in the case of the epoxides *(3f$_1$)/(3f$_2$)* an assignment of conformation is possible by X-ray structure analysis of *(2f$_1$)*; *(2f$_1$)* ought to afford *(3f$_1$)* as isomer A, while *(2f$_2$)* ought to give *(3f$_2$)* as isomer B[6].

Experimental

(2): Chlorine (0.5 mol) is passed into a stirred solution of *(1)* (0.5 mol) in water (180 ml) at 20—25 °C with external cooling and with simultaneous dropwise addition of a solution of sodium carbonate (0.25 mol) in water (100 ml) such that the pH of the mixture is kept between 3 and 7. The mixture is then neutralized, water removed at 40 °C/1.6 × 10^{-2} bar, and the residue stirred with 100 ml CH_2Cl_2. Filtration followed by removal of solvent at 30 °C/1.0 × 10^{-2} bar affords *(2)* as colorless crystals.

(3)[8]: A solution of sodium hydroxide (0.5 mol) in water (50 ml) is added dropwise to a stirred and externally cooled solution of *(2)* (0.5 mol) in water 150 ml. After 15 min the mixture is neutralized and worked-up as in the case of *(2)*. Thin-layer chromatographically homogeneous *(3)* is obtained as a colorless oil or crystals.

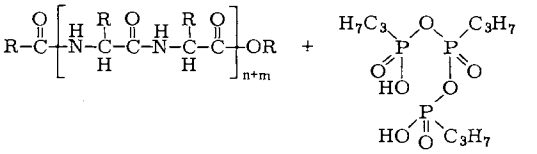
[8] *(2)* does not need to be isolated in the synthesis of *(3)* from *(1)*.

New Peptide Synthesis



By *Hans Wissmann* and *Hanss-Jerg Kleiner*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

We wish to report on a novel peptide synthesis using alkylphosphonic anhydrides such as *(1)* as condensation agents. In contrast to the analogous phosphorus compounds used previously[1], the alkylphosphonic anhydrides have the following advantages: simple preparation, long shelf-stability at room temperature, very good solubility in all solvents employed in peptide synthesis, little tendency to racemization.

(1)

One advantage over the convenient and stable dicyclohexylcarbodiimide lies in the fact that no difficultly soluble secondary products of the new condensation agent occur; the resulting alkylphosphonic acid derivative is also soluble in water. Moreover, the well-known allergenicity of dicyclohexylcarbodiimide should not be forgotten[2].

With regard to the yield and degree of racemization the new method has so far proven just as good as, and in certain cases superior to, the improved dicyclohexylcarbodiimide technique (see Table 1). Of the alkylphosphonic anhydrides it would seem that propylphosphonic anhydride[3] is especially suitable owing to its favorable solubility properties and also because of its ready accessibility from commercially available starting materials. The alkylphosphonic anhydrides can be prepared by well-established methods[4]. Thermal dehydration of the alkylphosphonic acids also leads to the anhydrides[5] in good yields. Propylphosphonic anhydride is up to more than 50-wt.% soluble in dichloromethane, dioxane, tetrahydrofuran, and dimethylformamide. The lipophilicity of the alkylphosphonic anhydrides increases with increasing length of the alkyl chain. While crystalline methylphosphonic anhydride shows satisfactory solubility only in dimethylformamide and dimethyl sulfoxide, the non-crystalline higher homologs are also soluble in much less polar solvents. Thus, *n*-hexylphosphonic anhydride is even soluble in *n*-hexane.

[*] Dr. H. Wissmann, Dr. H.-J. Kleiner
Hoechst Aktiengesellschaft
D-6230 Frankfurt am Main 80 (Germany)

According to experimental observations made thus far, propylphosphonic anhydride is at least a "trimer". During the course of peptide synthesis anhydride bonds are opened, yielding alkylpyrophosphonic acid groups. Further cleavage apparently proceeds very slowly under the conditions of peptide synthesis. For peptide synthesis, the reagent is best used in twofold excess with respect to the reactive anhydride bonds. Moreover, the excess of alkylphosphonic anhydride has a good solvating action. During the synthesis, free acid groups are buffered with a tertiary base, *e.g. N*-ethylmorpholine. The components used in the peptide synthesis should be adequately cooled (0—5 °C) during mixing; as a rule the reaction time amounts to 24 h at room temperature (see Experimental).

[a] $c=2$.

Table 1 shows the results comparable with those cited in the literature and the, in part, considerably improved yields. The racemization model peptide described by *Anderson et al.*[8] was isolated in good yield and in higher optical purity. No DL-peptide could be obtained on recrystallization from ethanol.

Experimental

Propylphosphonic anhydride: Distilled water (85 g) is added dropwise with stirring to 760 g (588 ml) of *n*-propylphosphonic dichloride. At first the temperature rapidly increases to 40 °C. The water is then so added that the temperature remains constant. Complete addition of the water requires about 2.5 h. At the same time hydrogen chloride escapes *via* a highly-efficient condenser. After addition of water is complete a tube of calcium chloride is attached to the condenser and stirring is continued for 1 h, then 3 h at 80 °C/17 torr, and 3 h at 80 °C/5 torr. There remains 500 g of propylphosphonic anhydride (100%); b.p. 200 °C/0.3 torr, chlorine content < 0.1%. The colorless, water-clear, syrupy anhydride can be distilled in a high vacuum, but is also sufficiently pure for use in peptide synthesis without distillation. A 50% solution of the anhydride can be stored in a brown bottle for several months.

Peptide synthesis: *N*-Ethylmorpholine (60 ml) is added at 0 °C to a solution or suspension of 0.1 mol each of amino component (*e.g.* amino acid or peptide ester hydrochloride) and carboxyl component (*e.g.* benzyloxycarbonylamino acid or -peptide) in dimethylformamide. A 50 wt-% solution (88 g) of propylphosphonic anhydride in dichloromethane is then added with stirring to the cooled (0—20 °C) mixture. After one hours' further stirring the mixture is allowed to stand at room temperature for 24 h before the solvent is removed by distillation in a vacuum at or just above room temperature. For isolation of the peptide derivative the reaction product is digested with saturated sodium hydrogen carbonate solution, filtered and the product washed thoroughly with water and 10% citric acid solution or taken up in ethyl acetate and washed several times with water, sodium hydrogen carbonate solution and 5% potassium hydrogen sulfate. Finally, the ethyl acetate solution is dried over magnesium sulfate and the peptide derivative isolated by concentration of the solution and precipitation with ether or petroleum ether.

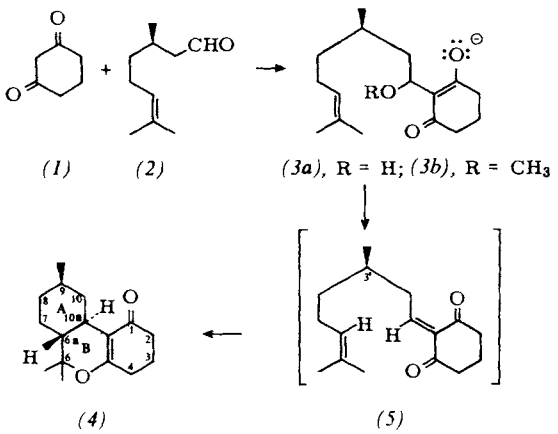
Stereocontrolled Intramolecular Diels-Alder Reaction of Heterodienes; Studies on the Synthesis of Cannabinoids[**]

By *Lutz-F. Tietze, Günter von Kiedrowski, Klaus Harms, William Clegg,* and *George Sheldrick*[*]

In recent years the intramolecular Diels-Alder reaction of 1,3-dienes has been most successfully applied to the stereoselective synthesis of natural products[1]. To our knowledge, however, the heteroanalogous variant[2] using α,β-unsaturated carbonyl compounds has not yet been described, although the intermolecular reaction has long been used in the preparation of dihydropyran derivatives[3].



We now wish to describe the synthesis of the tricyclic dihydropyran *(4)*, in which a 100% stereocontrolled intramolecular Diels-Alder reaction of the intermediate α,β-unsaturated ketone *(5)* can be assumed as key step. Having the (*R*)-configuration at C-6a and *trans* linkage of rings A and B, compound *(4)* corresponds to the parent skeleton of tetrahydrocannabinol[4].

Tammannstrasse 2, D-3400 Göttingen (Germany)
Prof. Dr. G. Sheldrick, Dr. W. Clegg, K. Harms
Anorganisch-chemisches Institut der Universität
Tammannstrasse 4, D-3400 Göttingen (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. We wish to thank Prof. Dr. *D. Leibfritz* and Dr. *M. Feigl*, Universität Bremen, for recording the 360-MHz ^{1}H-NMR spectrum and the Dragoco Company, Holzminden, for supplying citronellal.

In order to synthesize *(4)*, 1,3-cyclohexanedione *(1)* was transformed by sodium methoxide into the enolate and treated as such with (*R*)-citronellal *(2)* ($[\alpha]_D^{20} = 14.9°$ ($c = 1$, $CHCl_3$)) according to the method of *Polansky et al.*[5].

Initial formation of the enolate *(3a)* can be assumed; it does not react further under these conditions. Formation of a methyl ether *(3b)* as is observed in similar systems[5] could not be detected by NMR spectroscopy. Acid work-up led, after chromatography on silica gel, distillation, and recrystallization, to a 33% yield of *(4)* (m.p. 90 °C, $[\alpha]_D^{20} = 291.5°$ ($c = 1$, $CHCl_3$)).

(1) *(2)* *(3a)*, R = H; *(3b)*, R = CH_3

(4) *(5)*

Isolation of the ketone *(5)* was impossible. This accords with an estimate of the energies of the LUMO and the HOMO of the heterodiene and the dienophile, which suggests the occurrence of a fast reaction corresponding to a Diels-Alder reaction with inverse electron demand[6].

In addition to *(4)*, condensation products of citronellal *(2)* could also be isolated. However, no diastereomers of *(4)* were detected. It can thus be deduced that complete control by the chiral center of the reactant citronellal *(2)* is operative in the transition state of cycloaddition of *(5)*. Owing to the *trans* linkage of the rings A and B in *(4)*, it must also be assumed that the *exo* transition state is energetically more favorable than the *endo* transition state[7]. Thus molecular models show that minimum steric interaction is to be expected in the *exo* transition state with pseudo-chair-shaped arrangement of the carbon chain and pseudo-equatorial orientation of the methyl group on C-3'.

The structure and configuration of *(4)* were established by analysis of a 360-MHz ^{1}H-NMR spectrum[8] and by X-ray structure analysis[9] (Fig. 1).

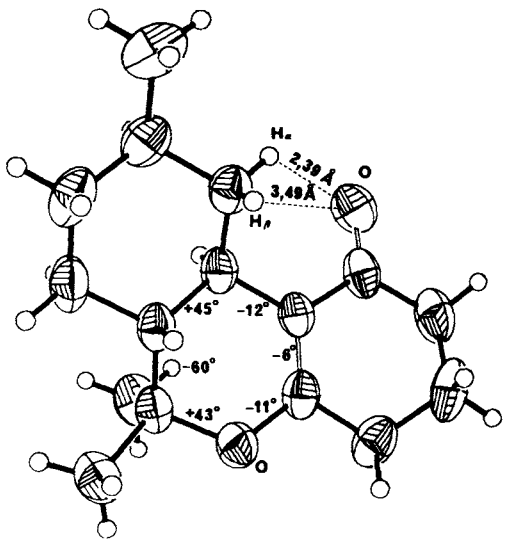

Fig. 1. Structure of compound *(4)* with thermal ellipsoids (50% probability) for C and O. *(4)* crystallizes in the monoclinic space group $P2_1/n$, $a = 11.907(3)$, $b = 8.094(2)$, $c = 14.868(5)$ Å, $\beta = 90.03(5)°$, $V = 1432.9$ Å^3, $Z = 4$, $\rho_{calc.} = 1.152$ g cm^{-3}, $\mu = 0.7$ cm^{-1} ($Mo_{K\alpha}$). Structure solved from diffractometer data by direct methods, refinement (C and O anisotropic, H isotropic, fixed C H bond lengths) gave $R = 0.063$ for 1487 reflections with $F > 4\sigma(F)$. The torsion angles in ring B and the distances from the carbonyl oxygen to 10α-H and 10β-H are shown.

Procedure

(4): A solution of *(1)* (2.00 g, 17.9 mmol) and freshly prepared sodium methoxide (997 mg, 17.9 mmol) in anhydrous methanol (70 ml) was added dropwise over 30 min at 0 °C to (*R*)-citronellal *(2)* (10 ml, 8.59 g, 50.5 mmol) in anhydrous methanol (70 ml). The mixture was then stirred for 1 h at 20 °C, evaporated down *in vacuo*, and the residue extracted with dichloromethane (30 ml) to remove excess *(2)*. The remaining slime (sodium salt) was shaken with dichloromethane (150 ml) and 1 N HCl, the organic phase washed with water, dried, and after evaporation of the solvent chromatographed on silica gel (light petroleum/ether (1:1)). Bulb-to-bulb distillation (150 °C) of the major fraction ($R_F = 0.40$) and recrystallization from diisopropyl ether/light petroleum gave 1.47 g (33%) of colorless platelets.

(3*R,S*)-3,4-Dicarboxy-3-hydroxybutyl Coenzyme A, an Inhibitor of the Citrate Synthase Reaction

By *Hermann Eggerer, Walter Giesemann,* and *Horst Aigner*[*]

The enzyme citrate synthase of the tricarboxylic acid cycle catalyzes the formation of citrate and coenzyme A from acetyl CoA and oxalacetate[1]. It also catalyzes the hydrolysis of (3*S*)-citryl CoA to the products and the cleavage of (3*S*)-citryl CoA to the reactants of the overall reaction[2], as well as the methyl-activation of acetyl CoA[3]. However, the question whether (3*S*)-citryl CoA is formed as genuine intermediate on the synthase, as has been demonstrated for the enzyme citrate lyase[4], is still unclear. Also unclear is the nature of the active centers of the identical subunits of the dimeric enzyme[5].

In order to contribute to the solution of these ambiguities, we have synthesized the title compound *(5)* as an intermediate analog suitable for enzymological and crystallographic investigations. In *(5)* the carbonyl group of citryl CoA attached to sulfur is replaced by a methylene group, so that besides chemical stability also high affinity to the enzyme can be expected.

The alkylating agent (*RS*)-2-(2-bromomethyl)-2-hydroxybutane required for formation of the alkyl thioether *(5)* was obtained from (*R,S*)-*S*-citryl-*N*-octanoylcysteamine *(1)*[6] by reduction with $NaBH_4$ to (*R,S*)-2-hydroxy-2-(2-hydroxyethyl)butanedioic acid *(2)*, esterification, and subsequent bromination. Reaction of *(3)* with coenzyme A afforded the dimethyl ester *(4)*, which on mild alkaline hydrolysis gave *(5)*. The structure of the compounds *(2)*—*(5)* is confirmed by elemental analysis and by spectroscopic and chromatographic data.

(4), $R^1 = CH_2SCoA$, $R^2 = CH_3$
(5), $R^1 = CH_2SCoA$, $R^2 = H$

Simple alkylthio CoA compounds[7], *inter alia* the ethylthio-CoA first described[8] after completion of our work, have been prepared in order to check the influence of the substituents in *(5)* on the interaction with the enzyme. Further alkyl thioethers analogous to acetyl CoA have recently been reported[9].

According to kinetic measurements *(5)* is a strong noncompetitive inhibitor of the overall reaction between acetyl CoA and oxalacetate and a strong competitive inhibitor of the cleavage and hydrolysis of (3*S*)-citryl CoA. An X-ray structure analysis of the complex of *(5)* with the monoclinic form of the citrate synthase[5] is in progress[10].

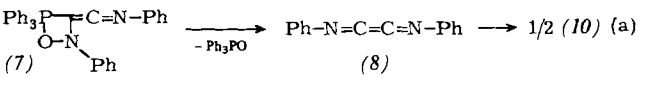
Tetrakis(phenylimino)cyclobutane (Tetrameric Phenyl Isocyanide)

By *Hans Jürgen Bestmann, Günter Schmid,* and *Eberhard Wilhelm*[*]

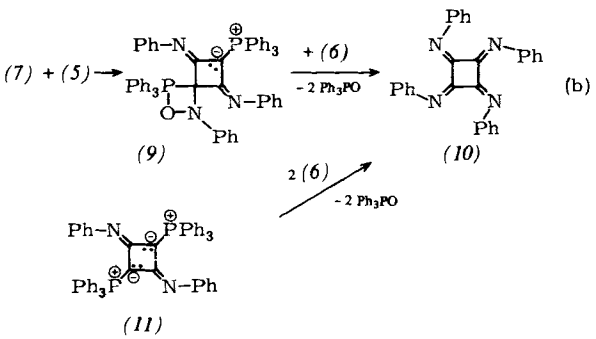
Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

All previous attempts to prepare cyclobutanetetraone *(1)* (tetrameric carbon monoxide) have so far failed; only its tetrahydrate could be isolated[1]. *Hünig et al.* succeeded in synthesizing the bis- and tetrakis-imino compounds *(2)* and *(3)*[2], while *Seitz et al.* have reported the preparation of the tetrahydrazones *(4)*[3].



(1) *(2)* *(3)* *(4)*

We have now found a simple entry to tetrakis(phenylimino)cyclobutane *(10)* (tetrameric phenyl isocyanide). Reaction of equimolar amounts of (phenyliminovinylidene)triphenylphosphorane *(5)*[4] and nitrosobenzene *(6)* in benzene at room temperature affords red-violet crystals of *(10)*, m.p. 181 °C, in 53% yield.



(5) *(6)*

We propose two possible reaction paths (a and b), but as yet we are unable to distinguish between the pair of them. Path a: *(5)* and *(6)* unite to form the cyclic phosphorane *(7)*, which on elimination of triphenylphosphane oxide is converted into the "dimeric isocyanide" *(8)*. *(8)* dimerizes to

(7) *(8)* (a)

(9) *(10)* (b)

(11)

[*] Prof. Dr. H. J. Bestmann, Dr. G. Schmid, Dr. E. Wilhelm
Institut für Organische Chemie der Universität Erlangen-Nürnberg

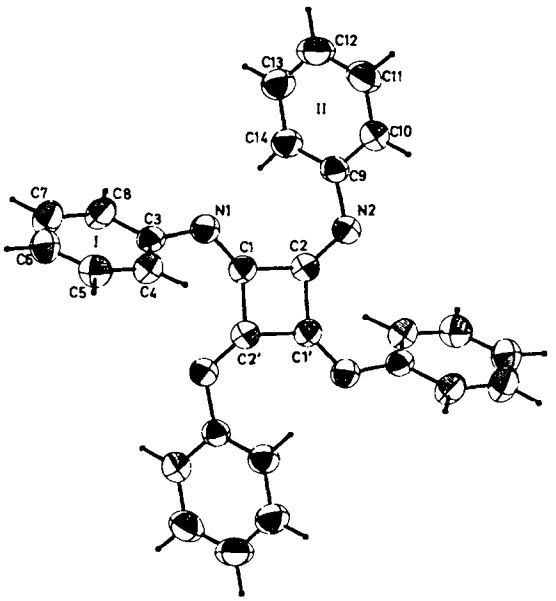
(10). Path b: *(7)* undergoes cycloaddition with *(5)* to give *(9)*, which on reaction with *(6)* loses phosphane oxide with formation of *(10)*. We could also prepare *(10)* by reaction of the "dimer" of *(5)*, namely *(11)*[5], with *(6)*.

X-ray structure analysis provides proof of the structure of *(10)* (cf. Fig. 1). Several geometric isomers of *(10)* are possible having variously arranged phenyl groups. However, only the isomer with substituents oriented in the same direction crystallizes[6]. From the bond lengths, the exocyclic bonds can be regarded as pure C=N double bonds; other than in *(3)*, there is no double bond component in the ring[8]. N2 deviates by +21.3 pm, N1 by only +4.7 pm, from the plane of the four-membered ring; the phenyl C-atoms C9 and C3, on the other hand, deviate by +29.6 and −14.9 pm, respectively, from the plane of the ring. The sum of the angles at C1 is 360°, and at C2 358.4°. The two phenyl groups are inclined to the plane of the four-membered ring; the phenyl ring I at 59°, and phenyl ring II at 46°.



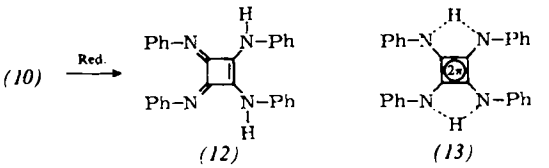


Fig. 1. Molecular structure of *(10)* in the crystal [6, 7]. Selected bond lengths [pm] and angles [°]: C1 C2 150.5, C2 C1' 150.6, C1 N1 127.0, C2 N2 127.7, N1 C3 141.6, N2 C9 141.7; C2' C1 C2 90, C1 C2 C1' 90, C2' C1 N1 131.4, C1' C2 N2 138.3, C2 C1 N1 138.6, C1 C2 N2 130.1, C1 N1 C3 122.0, C2 N2 C9 120.4.

The ^{13}C-NMR spectrum (in CD_3NO_2, TMS internal) of *(10)* shows five signals [δ = 148.18 (C=N), 130.02, 129.42, 124.50, 121.41 (arom. C)], which appear as sharp lines at 70 °C but considerably broaden on cooling. A splitting could not be achieved below 0 °C owing to sparing solubility. We attribute the temperature-dependence to a to-and-fro vibration of the phenyl groups.— In the EI mass spectrum a stepwise fragmentation of phenyl isocyanide is observed [*m/e* = 412 (M^+), 309 ($M^+ - 103$), 206 ($M^+ - 206$), 103].— UV (CH_2Cl_2): $\lambda_1 = 244$ ($\varepsilon = 3.1 \times 10^4$), $\lambda_2 = 433$ nm (1.7×10^4).

Compound *(10)* proves to be a strong oxidizing agent; for example it oxidizes hydroquinone to quinone and primary alcohols to the corresponding aldehydes. *(10)* is thereby reduced to *(12)*. Reaction of *(10)* with phenylhydrazine also leads *via* elimination of nitrogen to *(12)* (yellow crystals, m.p. 100 °C). *(12)* is the first squaric acid amidine in which the four N atoms are not ring members[2]. IR and Raman spectra[9] are consistent with the amidine structure *(12)* in the crystal. *(12)* forms intra- and intermolecular hydrogen bridges; its ^{13}C-NMR is therefore solvent-dependent. In $CDCl_3$ a spectrum very rich in lines is obtained, indicating the presence of several geometric isomers and tautomeric forms. In nitromethane, however, only five signals are observed (δ = 153.83, 145.53, 129.93, 124.37, 121.63) (TMS internal). This finding indicates the equivalence of all four C···N C_6H_5 units, as would arise by complete delocalization of the NH protons by intra- or intermolecular hydrogen bonding. Formula *(13)* represents one possibility.

The phenylamino groups in *(12)* can be replaced by phenylhydrazine. In contrast to the extremely stable *(12)* the reaction products, so far unobtainable in pure form, undergo autoxidation and form structural analogues of *(3)* and *(4)*.

β-Azolyl-α,α-dicarbonyl Compounds

By *Thomas Maier* and *Hilmar Mildenberger*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

1,2,4-Triazole *(2)* and pyrazole *(4)* add with surprising ease to α,β-unsaturated α,α-dicarbonyl compounds *(1)*. Spontaneous, weakly exothermal reaction affords the hitherto unknown stable β-azolyl-α,α-dicarbonyl compounds *(3)* and *(5)* which precipitate from the reaction mixture in generally quantitative yield and high purity. A basic catalyst such as triethylamine is of advantage. The "heteroderivatives" *(6)* and *(7)* are accessible in similar manner.

Tetrachlorovinylcarbene from Tetrachlorocyclopropene; Facile Synthesis of Vinylcyclopropanes[**]

By *Walter Weber* and *Armin de Meijere*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

The Diels-Alder reactivity of tetrachlorocyclopropene *(1)* with 1,3-dienes is sufficiently well known[1]. However, apparently no investigations have hitherto been carried out to check whether *(1)* is also capable of undergoing cycloadditions with monoolefins analogously to the highly fluorinated and chlorinated ethylenes[2]. We report here on a series of such experiments and their unexpected results.

Table 1. Compounds *(3)* and *(5)*, as well as *(6)* and *(7)*, synthesized. Correct elemental analyses and appropriate NMR spectra were obtained for all compounds [a].

	R^1	R^2	R^3	Solvent	*(3)* M.p. [°C]	*(5)* M.p. [°C]

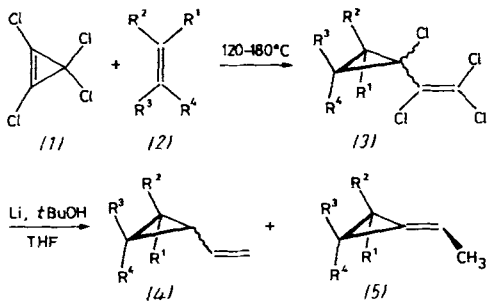
[a] ^{1}H-NMR ($CDCl_3$): *(3a)*: δ = 8.15 (s, 1 H, triazole 5-H), 7.95 (s, 1 H, triazole 3-H), 4.9 (ddd, J = 10 and 10 and 4 Hz; 1 H, CH-β), 4.05 (d, J = 10 Hz, 1 H, CH-α), 3.8 (s, 3 H, OCH_3), 3.55 (s, 3 H, OCH_3), 2.5—1.35 (m, 2 H, CH_2), 1.35—0.75 (m, 5 H, C_2H_5). *(5a)*: δ = 7.55—7.4 (m, 2 H, pyrazole 3- and 5-H), 6.15 (t, J = 2.3 Hz, 1 H, pyrazole 4-H), 4.8 (ddd, J = 10 and 10 and 4 Hz, 1 H, CH-β), 4.1 (d, J = 10 Hz, 1 H, CH-α), 3.75 (s, 1 H, OCH_3), 3.5 (s, 1 H, OCH_3), 2.4—1.4 (m, 2 H, CH_2), 1.35—0.75 (m, 5 H, C_2H_5). *(3g)*: δ = 8.05 (s, 1 H, triazole 5-H), 7.9 (s, 1 H, triazole 3-H), 7.35 (mc, 5 H, aromatic H), 6.1 (d, J = 11.5 Hz, 1 H, CH-β), 5.25 (d, J = 11.5 Hz, 1 H, CH-α), 2.2 (s, 3 H, CH_3), 2.0 (s, 3 H, CH_3). *(5g)*: δ = 7.5—7.2 (m, 7 H, aromatic H and pyrazole 3- and 5-H), 6.15 (t, J = 2.3 Hz, 1 H, pyrazole 4-H), 6.0 (d, J = 10.5 Hz, 1 H, CH-β), 5.25 (d, J = 10.5 Hz, 1 H, CH-α), 2.2 (s, 3 H, CH_3), 2.0 (s, 3 H, CH_3).

Alcohols should be avoided as solvents for addition of *(2)* to α,β-unsaturated diketones such as *(1g)* because an acyl group can be eliminated under mild conditions.

Numerous triazole derivatives *(3)* and *(6)*, expecially *(3c)* and *(3g)*, have excellent fungicidal activity towards various mildews, while the pyrazole derivatives *(5)* and *(7)* are ineffective.



The imidazole derivatives corresponding to compounds *(3)* and *(5)* can be isolated as sparingly soluble components from the reaction mixtures but decompose upon dissolution in the solvents examined. Thus the half-life of a 6% (2%) solution of *(3g)*, imidazolyl in place of triazolyl, in chloroform is 7 min (40 min); the equilibrium lies 70% (90%) on the side of the reactants.

Procedure

(3c): A mixture of *(1c)* (74.4 g, 0.3 mol), 1,2,4-triazole *(2)* (20.7 g, 0.3 mol), triethylamine (40 ml), and ethanol (20 ml) is stirred for 20 h at room temperature. Crystallization occurs on scratching with a glass rod. The crystals are filtered off, washed with diisopropyl ether, and dried; yield 82 g, m.p. 79—82 °C. The concentrated mother liquor affords a further crop of 8.2 g, m.p. 79 °C. Overall yield: 90.2 g (95%).

Received: November 23, 1979 [Z 384 IE]
German version: Angew. Chem. 92, 128 (1980)

The first indication that *(1)* is capable of reacting with a monoolefin was provided by its reaction with bicyclopropylidene at 80 °C, in which it behaves formally as trichlorocyclopropenylium chloride to give a product of electrophilic addition[3]. Normal olefins *(2)*, however, were only attacked at 150—180 °C, and then in a completely different fashion. Thus, reaction of 2,3-dimethyl-2-butene *(2a)* with *(1)* for 12 h at 180 °C afforded 1-chloro-2,2,3,3-tetramethyl-

[a] Reductive dehalogenation not investigated. [b] A further product was isolated but could not be unequivocally characterized. [c] For reasons still unclear only *(5e)* could be isolated. [d] The free vinylcyclopropanecarboxylic acids are formed from *tert*-butyl esters by acid-catalyzed elimination of isobutylene.

1-(trichlorovinyl)cyclopropane *(3a)* in 82% yield. Numerous examples show that this is a generalizable type of reaction (see Table 1). The method is also suitable for the preparation of substituted 2-(trichlorovinyl)cyclopropanecarboxylates and carboxylic acids[4] which are of interest as potential components in pyrethroid insecticides[5] [see Table 1, *(3p)*—*(3t)*]. The ^1H- and ^{13}C-NMR spectroscopic assignment of configuration was confirmed by an X-ray structure analysis[6] on *(Z)-(3q)*.

The ^1H-NMR spectra of the esters of *(3q)* show double signals at room temperature for most kinds of protons, which coalesce at higher temperatures (+40 to +90 °C in the case of the (*Z*)- and (*E*)-configurated methyl and benzyl esters). This phenomenon is indicative of an equilibrium between two conformers with an unusually high torsional barrier for vinylcyclopropanes[7]; from the coalescence temperatures, $\Delta G^{\neq}$ values of 77 kJ/mol and 74 kJ/mol, respectively, could be estimated for the (*E*)- and (*Z*)-configurated esters.

The finding that the configuration of the olefin moiety is retained in all adducts of *cis*- *(2d)* and *trans*-2-butene and of *cis*- *(2g)* and *trans*-3-hexene *(2h)* suggests that a vinylcarbene intermediate is first formed from *(1)*[8]; the high efficiency with which this intermediate can be intercepted intermolecularly to give vinylcyclopropanes[9] is most surprising. The formation of the by-product 1,1,2,3,3-pentachloropropene, which was found in varying relative amounts (2—20%) in almost all reactions of *(1)*, can also be explained in terms of intermediary tetrachlorovinylcarbene. Further conclusive evidence for the occurrence of this carbene is the observation that *(1)*, like dichlorocarbene[10], forms C—H insertion products with saturated hydrocarbons. Thus, reaction of *(1)* with *n*-hexane at 180 °C afforded the isomeric tetrachloroolefins *(6)*, *(7)*, and *(8)*[4] (yield 23%, ratio 14:43:43) and with adamantane the bridgehead derivative *(9)*[4] (28%) and the 1,3-bisadduct (5%). Whether tetrachlorovinylcarbene is formed by simple ring opening of *(1)*, or ionically[3] *via* the pentachlorocyclopropyl- and the pentachloroallyl anion, is still unknown.

The thermal addition of *(1)* to olefins *(2)* provides a generally useful method for the synthesis of chloro(trichlorovinyl)cyclopropanes *(3)*[4] and also of vinylcyclopropanes *(4)*[4], since the derivatives *(3)* can be conveniently dehalogenated (see Table 1). With lithium/*tert*-butyl alcohol in tetrahydrofuran, ethylidenecyclopropanes *(5)*[4] are formed as by-products, which, however, can also be converted into the vinylcyclopropanes *(4)* without isolation with potassium *tert*-butoxide. In this way *(4a)* and *(4k)* were isolated in total yields of 67 and 63%, respectively, from *(3a)* and *(3k)*.

Experimental

(3): A mixture of *(2)* and *(1)* (molar ratio 1:1) in a sealed, thick-walled glass ampule (dimensions according to amount of mixture, wall thickness 2.5 mm) and protected by a 2-mm thick steel cylinder is heated in a hot-air oven (see Table 1). The viscous reaction mixture, which is usually black, is taken up in a minimum of dichloromethane; *(3)* is purified by short-path distillation *in vacuo*. Where appropriate, stereoisomers are isolated by preparative gas chromatography.

(4) and *(5):* A mixture of *(3)* (4 mmol) in anhydrous tetrahydrofuran, finely divided lithium (100 mmol), *tert*-butyl alcohol (50 mmol) and water (4 mmol) is allowed to boil under reflux for 3 h. The mixture is then poured into 100 ml H_2O and extracted with pentane (3 × 50 ml). The organic phase is washed with saturated sodium chloride solution (5 × 50 ml), dried over sodium sulfate and concentrated to *ca.* 3—5 ml on a 30-cm packed column. *(4)* and *(5)* are isolated from the residue by gas chromatography (see Table 1).

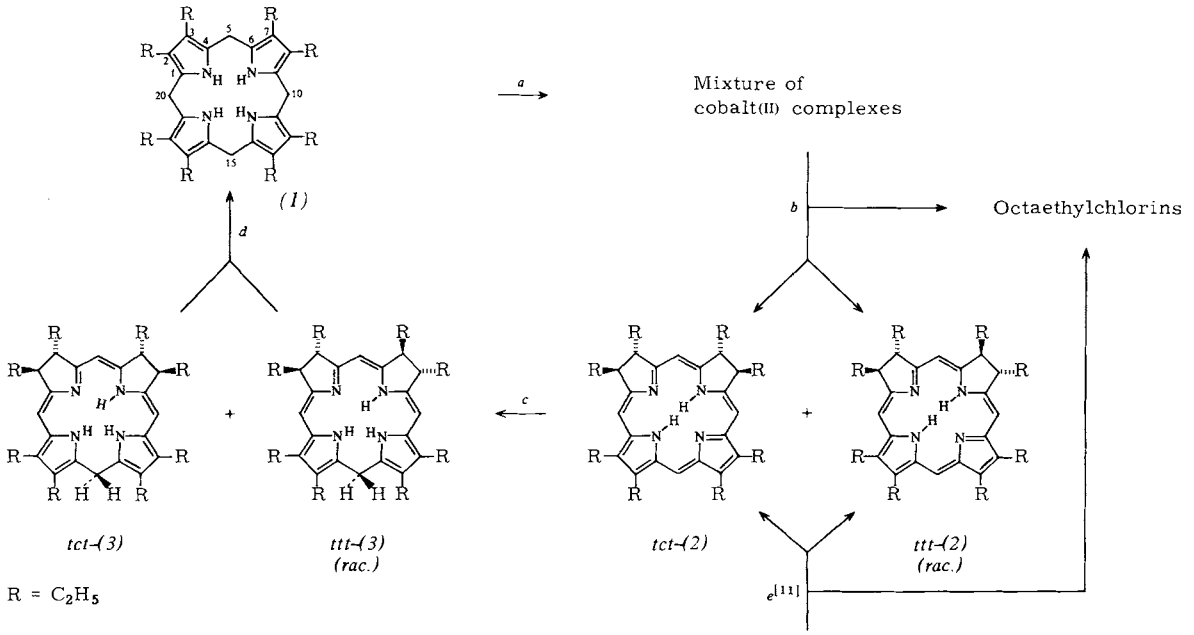
Mutual Interconversion of the Chromophoric Systems of Porphyrinogen and Isobacteriochlorin[**]



By *Christof Angst, Masahiro Kajiwara, Engelbert Zass*, and *Albert Eschenmoser*[*]

Recently raised questions concerning the origin and ancestral forms of the corrin structure[1] as well as present knowledge of vitamin B_{12} biosynthesis[2] demand an extension of our understanding of the anaerobic chemistry of hexahydroporphyrins. In this and the following publication[3] we report experimental results concerning the position and establishment of equilibria between hydroporphinoid ligands with pyrroloid and corrinoid chromophores (see Scheme 1) as well as the dependence of such equilibria upon metal ions.

Scheme 1

Heating highly diluted solutions of octaethylporphyrinogen *(1)*[4] in xylene and in the presence of $CoCl_2$, acetic acid, and triethylamine in a sealed tube (exclusion of light) under the best possible exclusion of oxygen[5] leads to a mixture of hydroporphinoid cobalt(II) complexes. According to VIS spectroscopic analysis[6], this mixture consists predominantly of chlorin- and isobacteriochlorin complexes in about equal proportions (see Scheme 2). Decomplexation by trifluoroacetic acid at room temperature produced, besides 19% *trans*- and 10% *cis*-octaethylchlorin[8], a mixture of diastereomeric octaethyl-isobacteriochlorins (recognized by UV/VIS and ^{1}H-NMR spectra) in *ca.* 30% yield. The main components of this latter mixture were the diastereomers *ttt-(2)* and *tct-(2)* (*ca.* 60%) in a ratio of about 2:1. Column chroma-

[a] If the designations "*ttt*" or "*tct*" are absent then the NMR signals of the two isomers are identical. [b] The UV/VIS spectrum shows additional weak bands of about 1 mol-% *(2)*; cf. the spectrum of *(10)* in [7]. The assignment of NMR-signals of *(2)* and *(3)* to *ttt* and *tct* respectively is derived from the relative intensities of the singlet/double doublet signal pair originating from the H_2C-15 in the ^{1}H-NMR of a (1:2)-mixture of *ttt/tct-(3)*.

ttt-isomer are homotopic and appear in the spectrum as a singlet (δ = 3.79), while those of the *tct*-isomer are diastereotopic and give rise to a clearly discernible AB-system (δ = 3.51 and 4.07, J_{AB} = 8 Hz). The ^{1}H- and ^{13}C-NMR spectra of both components show the presence of a twofold simple and an alternating axis of symmetry, respectively. This symmetry argument does not exclude the structures *ctc* and *ccc*; however, these are ruled out by the results of *Inhoffen et al.*[11a], who observed *trans*-octaethylchlorin as the exclusive autoxidation product of their "octaethylisobacteriochlorin"[13].

Tautomerization of the binary mixture of dipyrroloid hexahydroporphyrins *ttt/tct-(3)* in pyridine/acetic acid 1:1 at 60 °C for 40 hours under exclusion of oxygen led, after strict anaerobic work-up, to a product consisting of more than 98% octaethylporphyrinogen *(1)* according to the ^{1}H-NMR spectrum. From one such experiment, we have preparatively isolated in good yield the highly oxygen-sensitive product *(1)* in crystalline, spectroscopically pure form.

Our results show that the equilibrium between the tetrapyrroloid chromophore of 5,10,15,20,21,23-hexahydroporphyrins ("porphyrinogens") and the hemicorrinoid-dipyrroloid structure of the tautomeric 2,3,7,8,15,23-hexahydroporphyrins can lie on the side of the porphyrinogen[14] and that metal ions reverse the trend of this equilibrium. The earlier observation of *Eisner*[11b] and *Shul'ga et al.*[15] on the formation of isobacteriochlorins (among other products) in the tetramerization of 2-(dimethylaminomethyl)pyrroles by Grignard reagents bears an important relationship to the porphyrinogen → isobacteriochlorin interconversion[16] described here.

[8] The chlorin mixture, only sparingly soluble in ether/methanol, was isolated by crystallization and separated into homogeneous diastereomers by HPLC (neutral alumina, pentane/dimethoxyethane/triethylamine 1000:30:15, no exclusion of oxygen). These diastereomers were identified by comparison of the UV/VIS, ^{1}H/^{13}C-NMR, MS, and IR spectra with those of reference material prepared according to [11a].

[9] Neutral alumina, pentane/dimethoxyethane/triethylamine 2000:30:15.

[10] The less soluble *tct*-isomer can be enriched by repeated crystallizations of the *ttt/tct*-mixture from ether/methanol; the corresponding nickel(II) complexes are easily separable by HPLC (results of *J. E. Johansen* with material prepared according to [11a], cf. [3]).

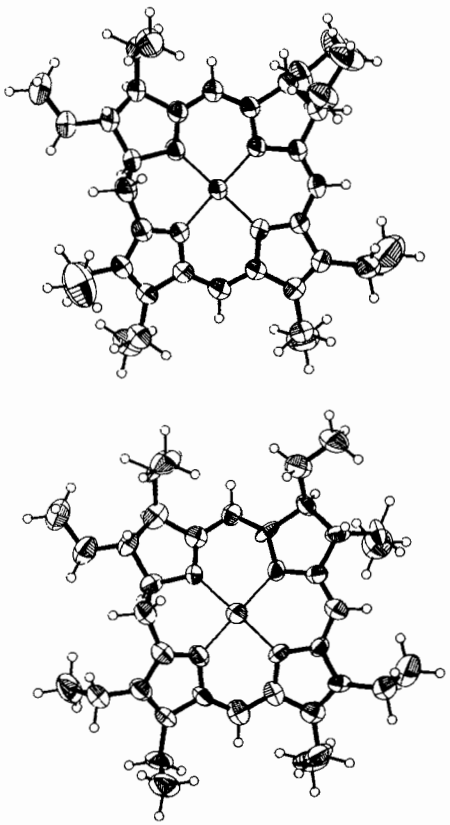
[**] The Chemistry of Hexahydroporphyrins, Part 2. This work was supported by the Swiss National Science Foundation. *Ch. K.* gratefully acknowledges financial support by the Austrian National Science Foundation (project no. 3763) and the Austrian Academy of Sciences.—Part 1: [1].

sion of oxygen leads to a different pattern of reactions than the analogous treatment of porphyrinogen *(1)* in the presence of cobalt(II) salts[1]. The major reaction products formed at high dilution are diastereomeric nickel(II) complexes *(2)* of a previously unknown hemicorrinoid-pyrromethenic ligand system, octaethyl-1,2,3,7,8,20-hexahydroporphyrin, which is a protomer of octaethyl-porphyrinogen (yields up to 90%, see Scheme 1). If the reaction is conducted at higher concentrations of starting material (10^{-3} instead of 10^{-4} M), the product contains about 45% each of *(2)* and of a fraction of (diastereomeric) nickel(II) isobacteriochlorinates *(3)*, in addition to small amounts of nickel(II) chlorinates (*ca.* 5%) and traces of nickel(II) octaethylbacteriochlorinates (*ca.* 1%)[2] (Scheme 1). After removal of side products by column chromatography, mixtures of the stereoisomeric nickel(II) hexahydroporphyrinates can be separated into the crystalline major components *tttt-(2)* and *ttct-(2)* by HPLC[3]. On dehydrogenation with DDQ in hexane/ether, the faster moving (HPLC) isomer *ttct-(2)* gives crystalline nickel(II) isobacteriochlorinate *tct-(3)*, the configurational assignment of which can be deduced from the results reported in [1]. In contrast to the free ligands *(4)* the corresponding mixture of nickel(II) complexes *ttt/tct-(3)* (cf. [1,4b]) is easily separable by HPLC. The faster moving nickel(II) complex has the configuration *tct*[5] and is identical with the dehydrogenation product of *ttct-(2)* (HPLC, ^{1}H-NMR, UV/VIS, MS).

Scheme 1. For experimental details, see [6]. *(1)→(2):* 1.0 *(1)* (*ca.* 10^{-4} M), 7.3 $Ni(OAc)_2 \cdot 4H_2O$ in *p*-xylene, 2 vol.-% $AcOH/(CH_3CH_2)_3N$ (4:1), 140 °C in evacuated tube, 15—21 h; cf. [2].—*(2)→(3):* *ttct-(2)* in hexane, DDQ in diethyl ether, *ca.* −10 °C, reaction followed by UV/VIS [yield 60% *tct-(3)* plus 20% starting material and 6% chlorinate].—*(4)→(3):* 1.0 *ttt/tct-(3)* (3:2) [4b, 1], 3.7 $Ni(OAc)_2 \cdot 4H_2O$, in ethanol, 70 °C, evacuated tube (yield 96%), HPLC separation [3] of *ttt-(3)* and *tct-(3)*.

X-ray structural analyses of *tttt-(2)* and *ttct-(2)* carried out in the Graz laboratory (Fig. 1) confirm the constitution deduced from spectroscopic data[7] and provide the complete configurational assignment for both isomers[8]. In addition, they reveal the remarkable phenomenon of a conformational coupling between rings A and B (presumably *via* the coordinated nickel(II) ion). Both ethyl groups at ring B of the *tttt*-isomer are in a quasi-diaxial conformation. If ring A were not conformationally coupled with ring B, the ring B ethyl groups of *tttt-(2)* would be expected to prefer a quasi-diequatorial conformation, or otherwise the ring B ethyl groups of the *ttct*-isomer would show up in a quasi-diaxial conformation[9].



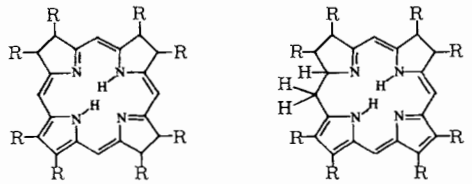


Fig. 1. ORTEP drawings of molecules *tttt-(2)* (top) and *ttct-(2)* (bottom). *tttt-(2):* triclinic, $P\bar{1}$, $a = 11.485$, $b = 11.702$, $c = 13.376$ Å, $\alpha = 72.06$, $\beta = 76.92$, $\gamma = 73.28°$, $Z = 2$, $d_x = 1.23$ g cm^{-3}; 4234 reflections refined, $R = 0.08$; *ttct-(2):* triclinic, $P\bar{1}$, $a = 11.853$, $b = 12.856$, $c = 13.021$ Å, $\alpha = 118.81$, $\beta = 98.5$, $\gamma = 100.44°$, $Z = 2$, $d_x = 1.21$ g cm^{-3}; 4869 reflections refined, $R = 0.058$. A complete description of the crystal structure analyses will be published separately (*Ch. Kratky*, Mh. Chem., in press).

On repeating the classical experiments of *Eisner*[4a] on the reduction of iron(III) octaethylchlorinate to hydroporphyrins with sodium and isopentyl alcohol, the ^{1}H-NMR spectrum of the product showed clearly[6] that the reported "hexahydro derivative" is not of structural type *(5)* (cf. Scheme 2) as had previously been assumed[4a], but a mixture of four diastereomeric hexahydroporphyrins of the structural type *(6)*[10].

Scheme 2 *(5)* R = C_2H_5 *(6)*

The chemical conversion of the porphyrinogen-structure [cf. *(1)*] *via* a tautomerization-complexation-disproportionation pathway leads preferentially, as does the reduction of porphyrins[4, 11], to those chromophoric systems found in biologically active hydroporphinoid cofactors. The particular ease with which the isobacteriochlorin-chromophore forms chemically[11] on the tetrahydroporphyrin oxidation level is of special interest in relation to the recent discovery of sirohydrochlorin[12]. On the other hand, the ligand system of 1,2,3,7,8,20-hexahydroporphyrin which seems to be a thermodynamically and kinetically favored type of structure, is not known to occur in nature, and the ligand system of natural corrinoids still has to be shown to form by transformation of porphyrinogens *via* simple tautomerization and complexation processes.

Table 1. Spectroscopic data of compounds *tttt-(2)*, *ttct-(2)*, *ttt-(3)* and *tct-(3)*. For experimental details, see [6]. *ttct*: methylene group C-20 at C-1 and R at C-2 in *trans* position, *etc.*

ttct-(2): dark green cubes (contains 3% *tct-(3)*, HPLC [3]).—UV/VIS (hexane, green): λ_{max} = 264 (log ε = 4.24), 300 (4.18), 370 sh (4.18), 381 (4.43), 407 sh (4.16), 440 (4.10), 465 sh (3.76), 550 sh (3.65), 591 (4.15), 642 nm (4.54).—MS: *m/e* = 596 (100%, M^+, ^{58}Ni) + isotope peaks, 581 (4%, $M^+ - CH_3$), *etc.*—^{1}H-NMR ($CDCl_3$): δ = 0.8—2.0 (32 H/8 CH_3 + 4 CH_2), 2.15—2.75 (10 H/4 CH_2 + H_2C-20), 4.12 (m/HC-1?), 5.13 (s/HC-5), 5.69 (s/HC-10), 6.68 (s/HC-15).—^{13}C-NMR ($CDCl_3$): δ = 11.28/11.38/12.65 (3 q/4 CH_3), 15.82 (q/4 CH_3), 17.21/17.67/17.99/18.06 (4 t/4 CH_2), 25.90/28.27/28.55/28.65 (4 t/4 CH_2), 36.31 (t/C-20), 47.73/50.01/51.65/55.73 (4 d/4 CH), 69.74 (d/C-1), 92.33/93.14 (2 d/C-5, 10), 113.46 (d/C-15), 126.53/130.01/130.65/133.83/136.22/143.29/149.13/152.62/157.97/167.07/167.37 (11 s/11 C)

[2] The percentages of Ni^{II} isobacteriochlorinates, -bacteriochlorinates, and -chlorinates were determined by UV/VIS spectroscopy after chromatographic separation from *(2)*. Characterization of the main fraction of Ni^{II} 7,8,17,18-tetrahydroporphyrinate (= Ni^{II} bacteriochlorinate) (after separation by column chromatography (silica gel, hexane/benzene/triethylamine 140:20:3.2) and HPLC separation [3] in 3 fractions, *ca.* 6:3:1): UV/VIS (pentane/triethylamine, 1000:1): λ_{max} = 743 (ε relative = 100), 707 (12), 680 (6), 508 (4), 520 (4), 390 (74), 327 nm (48); MS: *m/e* = 597 (19%), 596 (44), 595 (43), 594 (100, M^+), 592 (28). A UV/VIS controlled experiment (before HPLC) with 2-chloro-5,6-dicyano-1,4-quinone led within seconds to the spectrum of a Ni^{II} chlorinate and within minutes to that of a Ni^{II} porphyrinate.

[3] Stationary phase: Merck alumina T, 12 μm; mobile phase: pentane/triethylamine 1000:1; see *E. Walter, J. Schreiber, E. Zass, A. Eschenmoser*, Helv. Chim. Acta *62*, 899 (1979).

[5] *tct-(4)* [1, 4] was enriched by up to 97% by 11 recrystallizations from ether/methanol and converted into the nickel(II) complex, which was shown by UV/VIS spectrum and HPLC [3] to be identical with the faster moving isomer of *(3)*.

[6] *Ch. Angst*, Diss. ETH Zürich (planned for 1980).

[7] Cf. *P. Naab, R. Lattmann, Ch. Angst, A. Eschenmoser*, Angew. Chem. *92*, 143 (1980); Angew. Chem. Int. Ed. Engl. *19*, 143 (1980).

[8] The diastereomers *tttt-(2)* and *ttct-(2)* are presumably the thermodynamically most stable of the 16 possible isomers (cf. [9]). A third isomer (?) (about 1%) was detected during HPLC of the isomer mixture *(2)* resulting from the reaction *(1)* → *(2)*.

[9] According to preliminary experiments, *tttt-(2)* can be epimerized to *ttct-(2)* to an extent greater than 50%; the latter isomer hardly reacts under the same conditions (potassium *tert*-butoxide in THF, RT).

[10] A non-crystalline fraction of *Eisner*'s "hexahydroporphyrin", prepared according to [4a] with a modified work-up and isolated by HPLC (silica gel, hexane/triethylamine/dimethoxyethane 200:1:1) in 20% yield, showed the following data: MS and FD-MS: M^+ at 540 (100%); UV/VIS (hexane): λ_{max} = 340 sh (ε relative = 1.10), 355 (1.43), 374 (1.21), 444 (0.15), 486 sh (0.27), 520 (0.51), 553 (0.68), 630 (0.21), 667 nm sh (0.17); ^{1}H-NMR (360 MHz, $CDCl_3$): three signal groups of vinylic protons at 4.75/5.30/6.55 ppm with four signals each (unchanged by decoupling), corresponding to four diastereomers. The UV/VIS spectrum after incorporation of Ni^{II} ($Ni(OAc)_2$ in ethanol, 60 °C) corresponded very closely to the spectrum of pure *ttct-(2)* (cf. Table 1).

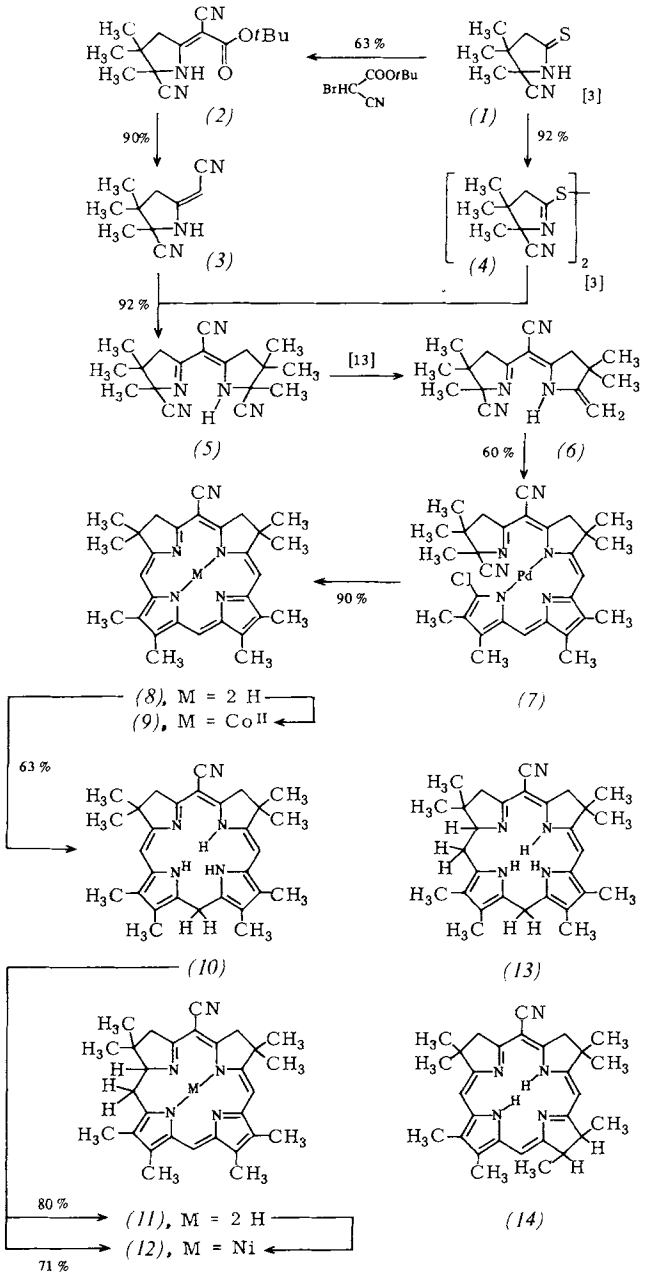
Synthesis and Transformations of 5-Cyano-2,2,8,8,12,13,17,18-octamethylisobacteriochlorin[**]



By *Paul Naab, René Lattmann, Christof Angst,* and *Albert Eschenmoser*[*]

The title compound *(8)*, possessing C_{2v} symmetry, is one of the model substrates in our studies on the anaerobic chemistry of hexahydroporphyrins. We describe here the synthesis and transformations of *(8)*, which are of relevance to the two preceding communications[1a, b].

The preparation of *(8)* (Scheme 1) follows the concept of the *de novo* synthesis of isobacteriochlorins recently published together with *Battersby et al.*[1c]. The condensation of the hemicorrinoid A/B-component *(6)* with 5,5'-dichloro-3,3',4,4'-tetramethylpyrromethene[2] to give *(7)*, requiring the template effect of palladium(II)[1d], and the cyclization of the intermediate zinc(II) 19,20-*seco*-isobacteriochlorinate to *(8)* proceed in this series in good yields. The preparation of the new compound *(6)* starts from the thiolactam *(1)*[3], using previously established procedures for corrin syntheses[3, 4]. Both C,C-bond formation steps in this sequence [*(1)* → *(2)* and *(3)* + *(4)* → *(5)*] are accomplished *via* the sulfide contraction method. Direct C,C-bond formation *via* intermolecular iminoester condensations[5] is sterically hindered in this series[6].

Scheme 1 [11]. *(1)→(2):* 1.0 *(1)* [3] + 1.5 *tert*-butyl bromocyanoacetate + 1.2 DBU [12] in CH_2Cl_2, RT (removal of elemental S with Hg).—*(2)→(3):* a) CF_3COOH, 0 °C; b) melting the carboxylic acid, 180 °C.—*(3)→(5):* 1.0 *(3)* + 1.0 DBU [15] + 1.0 *(4)* [3] in DMF, RT; then $(C_2H_5O)_3P$ in xylene, 130 °C.—*(5)→(6):* K-salt of *(5)* in toluene/acetonitrile (15:1), 80 °C [13].—*(6)→(7):* 1.0 *(6)* + 1.4 $Pd(OAc)_2$ + 2.65 DBU + 1.6 5,5'-dichloro-3,3',4,4'-tetramethyl-pyrromethene [2] in CH_3CN, 80 °C, HV, sealed tube.—*(7)→(8):* a) 10 KCN in CH_3OH/CH_2Cl_2, RT, then + 20 $Zn(OAc)_2 \cdot 2H_2O$; b) 4 *t*-BuOK in *t*-BuOH, 140 °C, HV, sealed tube, then CF_3COOH under N_2.—*(8)→(9):* 5 $Co(OAc)_2 \cdot 4H_2O$ in $CH_3OH/CHCl_3$ (1:1), 60 °C, HV, sealed tube (work-up with benzene/H_2O under N_2).—*(8)→(10):* 3 times Pt/C by weight (5%), H_2, in $CH_3COOC_2H_5$, RT.—*(10)→(11):* in HCOOH (degassed), HV, sealed tube, 70 °C, 50 h.—*(10)→(12):* *ca.* 7 $Ni(OAc)_2 \cdot 4H_2O$ in benzene + 1 Vol.-% $CH_3COOH/(CH_3CH_2)_3N$ (4:1), 100 °C, HV, sealed tube.—*(11)→(12):* *ca.* 5 $Ni(OAc)_2 \cdot 4H_2O$, in $CH_3OH/CHCl_3$ (1:1), 60 °C, HV, sealed tube.—*(10)→(8)+(13):* 110 °C in xylene + 4 Vol.-% pyridine/HCOOH (1:1.3), 110 °C, HV, sealed tube.

The symmetry of the substitution pattern in *(8)* facilitates the study of the transformations of the isobacteriochlorin chromophore. The extremely oxygen-sensitive[7] hexahydroporphyrin *(10)*, for example, produced from *(8)* by catalytic hydrogenation with platinum in ethyl acetate, is a crystalline compound with a symmetrical dipyrroloid constitution easily recognizable by the NMR spectra (cf. Table 1). We originally assumed that the monopyrroloid ligand system *(14)*, a tautomer of *(10)*, might be fixed by complexation with suitable metal ions. This could not be confirmed experimentally. Under reaction conditions sufficiently vigorous for the incorporation of metal ions such as nickel(II) and zinc(II), complexes of the isomeric hemicorrinoid-pyrromethenic chromophore *(11)* are formed instead. The free ligand *(11)* can be isolated in crystalline form by acidolysis of the zinc complex[8]. Remarkably, *(11)* is also formed in good yield by heating *(10)* in formic acid in the absence of metal ions. The thermodynamic and kinetic lability of the hemicorrinoid-dipyrroloid structure also manifests itself in the fact that *(10)* disproportionates to a mixture of *(8)* (52%) and *(13)* (39%)[9] on heating with pyridine/formic acid (1:1.3) in xylene at 110 °C with exclusion of air[10]. This lability can be rationalized by regarding the conjugative destabilization between all three (NH)-lone pairs in *(10)*.

Table 1. Spectroscopic data of compounds *(8)*—*(11)* [11].

(8): violet needles from CH_2Cl_2/hexane, m.p. >250 °C.—UV/VIS (CH_2Cl_2): λ_{max} = 363 sh (log ε = 4.90), 369 (4.95), 380 (4.71), 402 (5.21), 483 (4.03), 508 (4.09), 541 (3.82), 585 (4.25), 629 nm (4.63).—MS: *m/e* = 453 (6%), 452 (33), 451 (100, *M'*). *etc.*—^{1}H-NMR ($CDCl_3$): δ = 1.78 (s/4CH_3), 1.86 (broad s/2NH), 2.92/3.01 (2s/2CH_3 each), 4.25 (s/2CH_2), 7.68 (s/2CH), 8.70 (s/1CH)

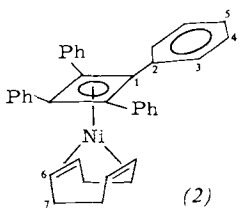
Tetraphenylcyclobutadienecycloalkenenickel(0) Complexes

By *Heinz Hoberg* and *Christian Fröhlich*[*]

Unstable tetraphenylcyclobutadiene can be fixed both to nickel(II)[1] as well as to nickel(0)[2]. Bis(tetraphenylcyclobutadiene)nickel(0), with its 18-electron configuration, formally corresponds to bis(1,5-cyclooctadiene)nickel(0) and bis(cyclooctatetraene)nickel(0)[3].

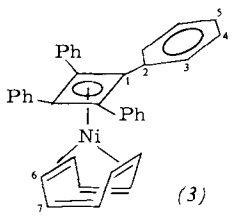
We have found that also mono(tetraphenylcyclobutadiene)nickel(0) compounds are accessible if the chelate effect of 1,5-cyclooctadiene (COD) or cyclooctatetraene (COT) is utilized for the stabilization. Thus, reaction of (tetraphenylcyclobutadiene)nickel bromide *(1)* with sodium[4] in ether in the presence of COD or COT affords the new complexes *(2)* and *(3)*, respectively.

$$\underset{(1)}{[(C_6H_5)_4C_4]NiBr_2} + 2\,Na + COD \rightarrow \underset{(2),\ 66\%}{[(C_6H_5)_4C_4]Ni(COD)} + 2\,NaBr$$



$$\underset{(1)}{[(C_6H_5)_4C_4]NiBr_2} + 2\,Na + COT \rightarrow \underset{(3),\ 77\%}{[(C_6H_5)_4C_4]Ni(COT)} + 2\,NaBr$$

(2) and *(3)* crystallize in the form of green prisms and are soluble in benzene, toluene, or tetrahydrofuran, giving intensely green solutions. In chlorinated hydrocarbons such as chloroform they gradually undergo decomposition. Both compounds are diamagnetic, astonishingly thermostable, and melt with decomposition at 220 and 260 °C, respectively.

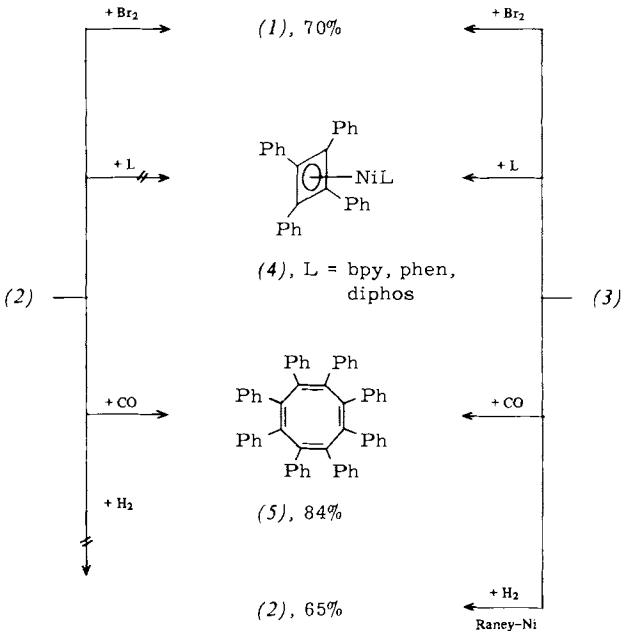


The mass spectra of *(2)* and *(3)* show, besides the respective molecular ions at $m/e = 552$ and 518, the characteristic fragmentation $m/e = 414$ ($[(C_6H_5)_4C_4]Ni$). The cryoscopically determined relative molecular masses of 515 for *(2)* and 532 for *(3)* in benzene afford proof of their monomeric structures. In the IR spectra (KBr) the aromatic absorptions are accompanied by a characteristic band in the C—C region (1620 cm^{-1}) only in the case of *(3)*. The ^1H-NMR spectrum (C_6D_6) of *(2)* shows, in addition to the signals of the aliphatic protons ($\delta = 2.3$, m, 8H), the signals of the vinyl protons which are shifted upfield by complexation ($\delta = 3.70$, broad, 4H). COT in *(3)*, like COD in *(2)*, functions as η^4-ligand ($\delta = 5.75$, s, 4H; $\delta = 3.69$, s, 4H).

The ^{13}C-NMR spectra[5] (Table 1) of *(2)* and *(3)* each contain only seven signals and thus suggest a η^4-coordination of the tetraphenylcyclobutadiene.

Table 1. ^{13}C-NMR spectra (25.2 MHz, Varian-XL-100A-15) of *(2)* and *(3)* in [D_8]tetrahydrofuran at 34 °C referred to TMS.

(2)



(3)

	C-1	C-2	C-3, 4		C-5	C-6	C-7
(2)	88.02	135.77	128.75	128.64	126.35	93.22	32.39
(3)	90.63	135.38	128.87	128.84	127.01	98.07	135.14
Mult.	s	s	d	d	d	d	*(2)*: t; *(3)*: d

The UV spectra of *(2)* and *(3)* (tetrahydrofuran) are identical in the region 240 to 500 nm. The band at 295 nm ($\lg \varepsilon = 4.6$) is assigned to the cyclobutadiene groups[6].

Reaction of *(2)* and *(3)* with bromine in dichloromethane at −20 °C does not lead to bromination of the cyclobutadiene ring[7], but to formation of *(1)*. COT in *(3)* reacts with 2,2′-bipyridine (bpy), 1,10-phenanthroline (phen), and ethylenebis(diphenylphosphano) (diphos) (toluene, 80 °C, 48 h) to give tetraphenylcyclobutadiene(ligand)-nickel complexes *(4)* in 86, 83, and 76% yields, respectively. *(2)* does not react with these N- and P-donors.

Also on reaction with carbon monoxide (toluene, 1 atm) it is clear that COD in *(2)* is more firmly complexed than COT in *(3)*. Thus, even at 20 °C, 1 mol of *(3)* takes up to 4 mol of CO with displacement of both ligands, while such an uptake

Scheme 1. Reactions of *(2)* and *(3)*. The compounds *(4)* were characterized by elemental analysis, and by IR and mass spectra.

requires 50 °C in the case of *(2)*. Tetraphenylcyclobutadiene affords octaphenylcyclooctatetraene *(5)*.

(2) and *(3)* are inert towards molecular hydrogen at 20 °C/1 atm in tetrahydrofuran. *(3)* reacts with hydrogen to give *(2)* only on addition of Raney nickel (see Scheme 1).

Experimental

A mixture of *(1)* (10.4 g, 18.1 mmol), cycloalkene (10 ml, *ca.* 90 mmol) and sodium (833 mg, 36.2 mmol; spherules, ⌀ *ca.* 1 mm) in 200 ml diethyl ether is vigorously stirred at −50 °C. The suspension gradually turns dark green[8]. After three days the precipitate is filtered off on a cooled frit (−50 °C), washed with cold diethyl ether (2 × 50 ml), dried in a high vacuum at 20 °C, and finally taken up in 500 ml toluene. After removal of insoluble NaBr by filtration the filtrate is evaporated down to *ca.* 50 ml; addition of about 100 ml diethyl ether leads to precipitation of both *(2)* (6.2 g, 66%) as well as *(3)* (7.2 g, 77%) in microcrystalline, analytically pure form. *(2)* and *(3)* can be recrystallized from toluene : diethyl ether (1:1).

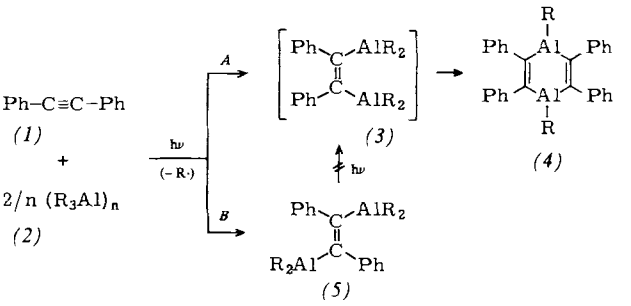
Photochemically Induced 1,2-Bis(dialkylalumination) of Diphenylacetylene

By *Heinz Hoberg* and *Fernando Aznar*[*]



Trialkylaluminum/alkali metal[1] and dialkylaluminum halide/alkali metal[2] add to disubstituted alkynes, especially diphenylacetylene, in a dark reaction to give respectively *cis*- and *trans*-bis(alumino)alkenes, from which 1,4-dialuminacyclohexadienes *(4)* can be prepared[3,4].

We have now found that a 1,2-bis(dialkylalumination) of diphenylacetylene *(1)* with trialkylaluminum *(2)* is also possible photochemically in the absence of donors; it leads to 1,2-bis(aluminum compounds) *(4)* and *(5)*. The yield is highly dependent upon the nature of R and the temperature.

After 48 hours' irradiation at 25 °C triethylaluminum *(2a)* affords mainly the six-membered ring compound *(4a)*, which can be isolated as the crystalline bis-THF adduct (32%) (THF = tetrahydrofuran). At 60 °C, on the other hand, *(2a)* also reacts to give *(5)* (*ca.* 49%), which can be isolated as the bis-THF adduct in 30% yield.

The difference in the course of reaction (route A or B) can be attributed to the degree of association (*n*) of the trialkylaluminum compounds *(2)*[5]. Trimethylaluminum is only slightly reactive under the given conditions [yield of *(4)* and/or *(5)* < 1%].

[*] Prof. Dr. H. Hoberg, Dr. F. Aznar
Max-Planck-Institut für Kohlenforschung
Postfach 011325, D-4330 Mülheim-Ruhr 1 (Germany)

We assume that *(1)* reacts photochemically with dimeric trialkylaluminum compounds *(2)* with *cis*-1,2-addition *via (3)* to give *(4)*, while the monomeric trialkylaluminum compounds *(2)* afford mainly the *trans*-1,2-addition products *(5)* (Table 1). It should be mentioned that *(5)* cannot be isomerized photochemically to the *cis*-form *(3)* or its secondary products *(4)* in the absence of donors (Et_2O, THF)[4].

Table 1. Yield (GC) of *cis*- and *trans*-stilbene after irradiation of *(1)* and R_3Al *(2)* (molar ratio 1:2, 48 h) and hydrolysis [a]. *cis*-Stilbene is formed from *(4)*, *trans*-stilbene from *(5)*.

	R	*n*	Stilbene [Yield] *cis* [%]	*trans* [%]	*T* [°C]
(2a)	C_2H_5	2	4	2	0
(2a)	C_2H_5	2	52	14	25
(2a)	C_2H_5	2	4	49	60
(2b)	*i*-C_3H_7	≈1	8	40	25
(2c)	*i*-C_4H_9	≈1	3	7	0
(2c)	*i*-C_4H_9	≈1	12	43	25
(2d)	*t*-C_4H_9	≈1	11	42	25

[a] For determination of the yields a solution of *(1)* and *(2)* was irradiated (see Experimental), hydrolyzed with 0.1 N H_2SO_4, and extracted with diethyl ether. The ethereal phase was evaporated down and the residue chromatographically analyzed.

On irradiation in the presence of *(1)* the ethyl groups in *(2a)* are eliminated in the form of C_2H_4, C_2H_6, C_4H_{10}, and H_2.

Experimental

(4a)·2THF: A solution of *(1)* (12.0 g, 67.4 mmol) and *(2a)* (15.4 g, 19.2 ml, 134.8 mmol) in toluene (200 ml) is irradiated with a Philips HPK 125 lamp for 48 h at 25 °C in a quartz-glass immersion apparatus. All but *ca.* 80 ml of the toluene is then removed by evaporation and the remaining solution treated with 15 ml THF and cooled to 0 °C. After six days the crystals are filtered; yield 6.6 g (32%). Melting point and IR spectrum agree with those given in Ref.[3].

(5b)·2THF: For the preparation of *(4a)* a solution of *(1)* (8.93 g, 50.16 mmol) and *(2b)* (19.84 g, 24.8 ml, 100.4 mmol) in 200 ml of toluene is irradiated for 48 h. The toluene is then evaporated down to *ca.* 50 ml; after addition of 15 ml THF and 100 ml hexane the solution is cooled to 0 °C. After six days the crystals are filtered; yield 8.0 g (26%). Melting point and IR spectrum are identical with those given in Ref. [2].

Heterogeneously Catalyzed Gas-Phase Bromination of Trifluoromethane[1]

By *Hans Bock, Jan Mintzer, Jörg Wittmann,* and *Jürgen Russow*[*]

Dedicated to Professor Rolf Sammet on the occasion of his 60th birthday

Owing to its suitability as a highly effective fire-extinguishing medium in automatic extinguishing installations for the protection of valuable goods[2], considerable interest attaches to a facile preparation of trifluorobromomethane. One possible pathway is the gas phase bromination of trifluoromethane:

$$F_3CH + Br_2 \rightarrow F_3CBr + HBr \quad (1)$$

Useful yields of *ca.* 70% are obtained in the thermal reaction only above about 600 °C[3,4] (cf. Table 1); however, undesired side-products are formed at such high temperatures and corrosion problems also occur. Experiments with catalysts[5] have so far failed to give improved yields at lower temperatures.

Optimization of the heterogeneously catalyzed gas-phase bromination (1) was accomplished in three steps:

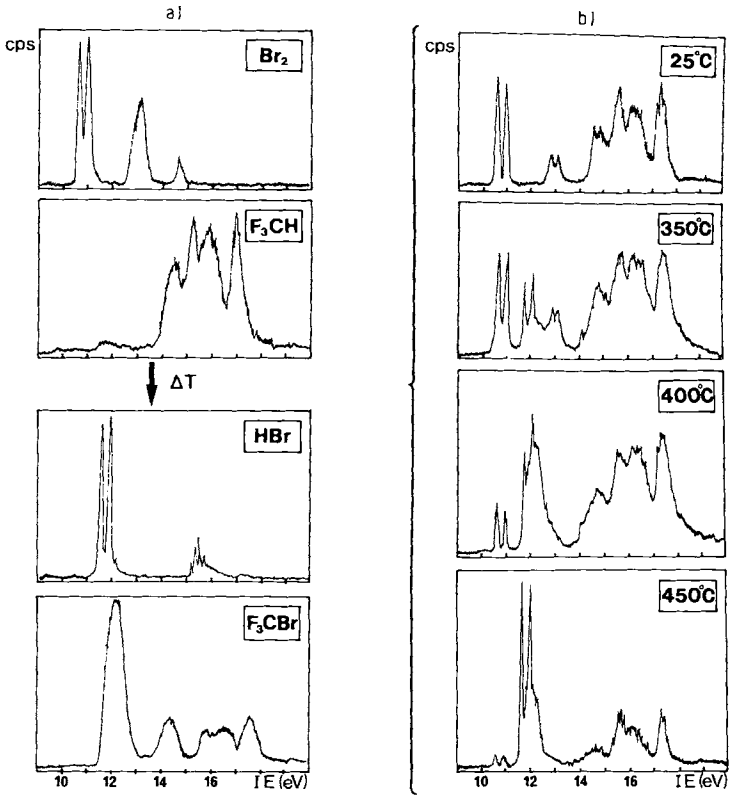

Fig. 1. a) PE spectra of reactants Br_2 and F_3CH and the products HBr and F_3CBr. The bands are seen not to overlap completely. The two double needles assigned to spin/orbit coupled states each of $Br_2^{\oplus}$ and $HBr^{\bullet\oplus}$ [6] are particularly suitable for gas analysis. b) Bromination of F_3CH over a $CuCl_2$/active charcoal catalyst as function of temperature: The 1:1 mixture (25 °C) reacts above 350 °C. The Br_2 double peak at 10.6/10.9 eV disappears and that of HBr appears at 11.7/12.0 eV. At the same time, the first F_3CH band at 14.8 eV is replaced by the second one of F_3CBr at 14.3 eV.

[*] Prof. Dr. H. Bock, Dipl.-Chem. J. Mintzer, Dipl.-Chem. J. Wittmann

Niederurseler Hang, D-6000 Frankfurt am Main 50 (Germany)
Dr. J. Russow
Hoechst Aktiengesellschaft
D-6230 Frankfurt am Main 80 (Germany)

1) On the basis of the partly published[6] and not completely overlapping photoelectron spectra of the reactants F_3CH and Br_2 and those of the products F_3CBr and HBr (Fig. 1a), a gas-analytical technique could be worked out for mixtures of any composition[7], which permits continuous monitoring of all components of the four-component system.

2) The catalyst screening—fast and with small sample quantities [7,8]—was by PE spectroscopy (Fig. 1b): determining at what temperature the same result is obtained as in the thermal reaction (*e.g.* in a tube packed with quartz rings, see Table 1). The gas-analytical approach chosen also proved advantageous, in that fluorination of oxide support material such as SiO_2 and γ-Al_2O_3 occurring mainly at high temperature can be recognized from the appearance of the characteristic ionization bands of H_2O (12.6 eV), CO_2 (13.8 eV), and/or CO (14.0 eV)[6].

3) Conversion and yield under reaction conditions optimized by PE spectroscopy are determined at atmospheric pressure on a preparative scale by conventional analysis: after passage through the heated catalyst compartment the excess of Br_2 is condensed out of the gas mixture; the bromine balance (% conversion) is established by addition of the bromine to cyclohexene. HBr is subsequently absorbed in 1 N NaOH; back titration gives the yield (%). The F_3CH/F_3CBr ratio in the residual gas is determined by gas chromatography.

Table 1. Yield of F_3CH bromination according to Eq. (1) as function of catalyst, furnace temperature T, and contact time $t_{contact}$.

Catalyst	T [°C]	$t_{contact}$ [s] [a]	Yield [%]
Quartz rings	450	19	51
	500	10	66
	600	14	68
	600	6	72
Activated charcoal	450	12	52
$CuCl_2$/activated charcoal	450	4	56
	450	12	59
$FeCl_3$/activated charcoal	450	15	66
KBr/activated charcoal	450	15	51
$FeCl_3$/KBr/activated charcoal [b]	450	12	71

[a] Conventionally defined as 1/[l gas/time·l catalyst]. [b] See procedure.

Table 1 shows that the thermal gas-phase bromination in a tube packed with quartz rings at 600 °C affords yields up to 72% depending upon the contact time; prolonged residence times promote decomposition reactions. Activated charcoal is ineffective, but is suitable as an inert carrier under the reaction conditions. Metal salts such as $CuCl_2$ and $FeCl_3$ catalyze the reaction, while KBr acts as a promoter.

Procedure

$FeCl_3$/KBr/C catalyst: HCl is passed over activated charcoal (30 g; Alfa 88765/28 mesh) at 150 °C for 1 h. After cooling in a stream of HCl, the substrate is impregnated with anhydrous $FeCl_3$ (5.6 g; corresponding to about 6% Fe on the carrier) and KBr (0.6 g) in CH_3OH (0.6 g). After stripping off the solvent *in vacuo* in a rotatory evaporator, the material is fluorinated in a stream of F_3CH (1/2 h at 30 °C, 1 h at 280 °C, 2 h at 300 °C, 3 h at 350 °C, and finally 5 h at 450 °C). It is important that the temperature be raised very slowly between 280 and 320 °C owing to transformation of $FeCl_3$ (m.p. 304 °C) into FeF_3 (m.p. 1030 °C).

BOOK REVIEWS

Ullmanns Encyklopädie der technischen Chemie [Ullmann's Encyclopedia of Industrial Chemistry]. Editorial board *E. Bartholomé, E. Biekert, H. Hellman, H. Ley* (deceased), *W. M. Weigert* (deceased), and *E. Weise*. Volume 17: Milchsäure to Petrolkoks. Verlag Chemie, Weinheim 1979. 4th edition, xv, 733 pages, bound, DM 425.00.

The individual volumes of Ullmann's fourth edition[*] are appearing with admirable regularity. A scan through this particular volume confirms that Ullmann is a genuine encyclopedia, going beyond the specific realm of industrial chemistry to deal with the necessary foundations and to include related fields. Individual overlapping entries treat special areas, such as the "oxidation" entry in the present volume, which describes in summary the oxidation processes for the preparation of organic intermediates; the many references to other entries for further information on certain processes are particularly valuable. To name some of the volume's entries taken from the sphere of inorganic chemistry, we have molecular sieves (10 pages), molybdenum (28 pages), sodium (87 pages), nickel (64 pages), and niobium (12 pages), including their compounds and alloys (especially important compounds such as sodium chloride and sodium hydroxide have their own entries), nitrides (7 pages), oxide ceramics (15 pages), and peroxo compounds (38 pages). From organic chemistry there are lactic acid (7 pages), naphthalene and derivatives (50 pages), aliphatic (10 pages) and aromatic (6 pages) nitriles, nitroso compounds (7 pages), aliphatic (10 pages) and aromatic (34 pages) nitro compounds, optically active compounds (7 pages), oxalic acid (8 pages), and peroxides and peroxy acids (30 pages). From the sphere of dye chemistry we can quote naphthalimide dyes (6 pages), naphthoquinone and benzoquinone dyes (5 pages), nitro and nitroso dyes (9 pages), and optical brighteners (15 pages), and from the sphere of pharmacology anesthetics (7 pages), nucleic acids and their derivatives (6 pages), and parasitoses (8 pages). Interested in fossil fuels? There are 14 pages on oil sands, 14 on oil shale, 5 on petroleum coke, and 20 on motor fuels; this last entry is restricted to gasoline, as diesel and turbine fuels are discussed under fuel oils. In addition, the following application-oriented entries should be mentioned: perfumes (5 pages), furs (9 pages), nitrocellulose (12 pages), and in particular paper, subdivided into fibrous raw materials (46 pages) and manufacture (59 pages).

The present volume is the equal of its predecessors in quality of presentation and material. This is undoubtedly due in essence to the editors' efforts in finding competent authors for the wide range of topics and then in coordinating their contributions.

Ulfert Onken [NB 497 IE]

The Chemical Applications of Transmission Electron Microscopy. *J. R. Fryer.* Academic Press, London 1979. x, 286 pages, 126 figures, 4 tables, bound, $ 38.00.

The present monograph treats the principles of image formation and image contrast in an electron microscope, microscope attachments, specimen preparation, high-resolution microscopy, and phase contrast, as well as the study of surface phenomena, crystal structures, and precipitates from solutions. The fascinating possibility of an *in-situ* observation of a chemical reaction in an electron microscope is considered in the last of the eight chapters. The book gives a good balance between theory and empiricism, the current state of the art in high-resolution microscopy being emphasized in preference to the physical principles of electron optics. The examples have been taken mainly from the author's own work. It is rather unfortunate that the technical details are explained predominantly for the example of the Siemens apparatus used in Glasgow, especially as Siemens no longer produce electron microscopes.

On the subject of high resolution, supplementary information would be desirable in a new edition, such as data on structural features that favor the use of this method and a more extensive discussion of the studies on oxides, in which the most recently published, higher-resolution pictures are taken into consideration. The table of the graphite compounds requires revision: it contains many printing errors and does not correspond to the current state of the art.

It was the author's intention that the bibliography should provide information on the work of other authors on subjects treated in less detail here. To achieve this aim revision is necessary to include further authors, such as *S. Andersson* and *L. Kihlborg*.

Finally, it should be emphasized that the book is a handy and practically-oriented summary with emphasis on providing a really useful introduction to the field, up to now not easily available to those who wanted to familiarize themselves with the methods of transmission electron miscroscopy.

Treatise on Analytical Chemistry. Part I: Theory and Practice. Edited by *I. M. Kolthoff et al.* John Wiley & Sons, New York 1979. 2nd edit., xxviii, 881 pages, bound, $ 78.50.

If the first edition of the present monograph was a boon to the teacher, practical chemist, and student alike, then the first volume of the second edition is a still more valuable addition to basic analytical literature.

The publishers invited expert authors to write on general and fundamental problems. The 14 chapters, arranged in four sections, contain excellent discussions of the rudiments of analytical chemistry in general (2 chapters), methodology (4 chapters), the relationship of general chemistry and analytical chemistry (5 chapters), and above all solution equilibria (3 chapters).

Kolthoff's scientific background and his love of the already classical direction of analytical chemistry come across clearly in the first chapter. One could wish for a more comprehensive account of the physical aspects of modern methods involving the interactions of elementary particles (use of electron and ion beams). This is not to say that anything else should be omitted, but rather that some expansion of this kind, perhaps with philosophical reflections, would emphasize the interdisciplinary nature of analytical chemistry still more strongly.

In comparison with the excellent methodological section—and here the chapters on "Sampling", "Precision", and "Standards" deserve particular praise—the contribution on "Education" loses a little. The editors have succeeded very well, however, in incorporating general and physicochemical aspects, such as the structural considerations relating to the process of dissolution.

In summary, it must be said that the work is of a high standard as regards the description of general data and methods of working; it can only be hoped that the same standard will be maintained in the subsequent volumes. The acquisition of this work is a must for every institution concerned with analytical chemistry, since it is practically compulsory reading for any budding analyst.

Hanns Malissa [NB 492 IE]

Recent Books

Electrophilic Reagents—Recent Developments and Their Preparative Application

By Franz Effenberger[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The most widely known electrophilic agents are protic acids and compounds with an electron-sextet partial structure. Recent research has aimed at the development of new electrophilic reagents, with greater reactivity on the one hand and higher selectivity on the other, which would largely obviate the addition of Lewis acids (Friedel-Crafts catalysts), and also allow control of the isomer ratio in reactions with ambivalent substrates. Compounds with "super-leaving groups", such as trifluoromethanesulfonate and fluorosulfate, have been demonstrated as most advantageous in this respect since they are sufficiently polarized or dissociated for reactions to take place even in the absence of Friedel-Crafts catalysts. Heterocycles such as pyridones or imidazole are likewise suitable leaving groups; they are employed for their high selectivity, and also because they allow working under non-aqueous conditions.

1. Introduction

The terms "electrophile" and "electrophilic reagent" were introduced into organic chemistry by *C. K. Ingold*[1a]; his definitions, given in a comprehensive review[1b] and in his standard work "Structure and Mechanism in Organic Chemistry"[1c], are still valid today:

> "Reagents which act by acquiring electrons, or share in electrons which previously belonged to a foreign molecule will be called electrophilic reagents, or sometimes electrophiles."

Ingold distinguishes here between electrophiles which actually take over the electrons from another molecule (oxidants in the true sense), and those which form covalent bonds and thence place only a partial demand on the substrate electrons. This definition smoothly accommodates both protic acids and compounds with an electron-sextet structure which coordinate with lone electron pairs of other molecules in an electrophilic manner.

[*] Prof. Dr. F. Effenberger
Institut für Organische Chemie der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

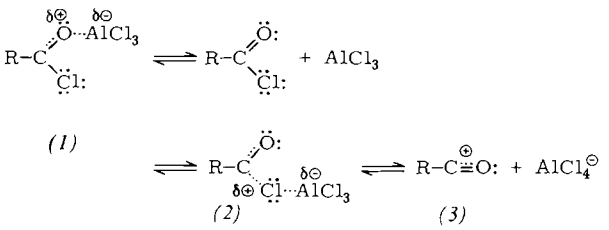
The basic principle underlying the interaction between acid/base, acceptor/donor, and electrophile/nucleophile has been a controversial issue for a long time, and has led to frequent attempts at an optimum systematization or classification[2]. *Ingold* had already recognized clearly, though, that a formal (electric) charge is not prerequisite for the electrophilicity of a certain species; rather, the actual electrophilic moiety may be formed *in situ* in the reactant mixture.

In electrophilic bond formation, the bonding electrons must by definition stem from the substrate. Thus only compounds with lone pairs or π-electrons are as a rule susceptible to electrophilic attack; electrophilic reactions of σ bonds remain exceptional for energetic reasons[3]. Alcohols and amines, as compounds with lone electron pairs, consequently number among the most important substrates for electrophiles, *e.g.* in alkylation or acylation. Usually, these reactions are considered under the aspect of the nucleophile; because of the considerable influence of the electrophilic partner, however, recent developments in this field will be discussed here too.

The most frequently employed reactions of unsaturated compounds are the electrophilic substitution of arenes and hetarenes, the electrophilic addition to alkenes and alkynes, respectively, and their substitution; in this context, enols and

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0303-151 $ 02.50/0

enol derivatives (enol ethers, acylates, and silyl enol ethers) as well as enamines must be considered as specially substituted olefins.

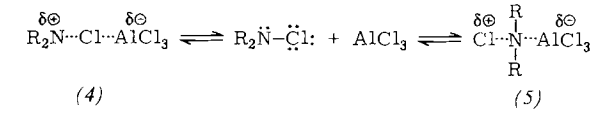


The quest for new electrophiles has been directed primarily towards greater reactivity and higher selectivity; such reagents should render the addition of equimolar amounts of Friedel-Crafts catalysts superfluous, and allow at least some control of the isomer distribution in reactions with ambivalent substrates (*e.g.* substituted aromatics or enols).

A decisive factor for both the generation and the reaction potential of an electrophile is whether the reagent is dissociated into anion and cation (as the actual electrophilic species), or whether a more or less polarized bond is cleaved in the desired direction only under the influence of the co-reactant:

$$E-A \leftrightarrow E^{\delta\oplus} \blacktriangleleft A^{\delta\ominus} \rightleftharpoons E^{\oplus}\,A^{\ominus} \rightleftharpoons E^{\oplus} + A^{\ominus}$$

In the absence of a suitable substrate, bond polarization is determined primarily by the electronegativity difference between E and A; the extent of bond cleavage mainly depends on the stability of the ions $E^{\oplus}$ and $A^{\ominus}$ in a given solvent, as long as the system provides the necessary energy for dissociation.



The described bond polarization or cleavage of a reagent E–A is frequently catalyzed by electron acceptors (Brønsted or Lewis acids) which in this context are generally designated summarily as Friedel-Crafts catalysts. The mode of interaction of these electron acceptors is not the same, though, for the various potential electrophiles—as, for example, in Friedel-Crafts alkylation and acylation; a general classification with respect to their catalytic effectiveness is therefore not feasible. A compound with lone pairs at different atoms, for example, can be attacked by the catalyst at each of the nucleophilic sites; this in turn may lead to the formation of different electrophiles, rendering predictions as to the actual reagent rather difficult. The presence of both oxonium complexes *(1)* and acylium ions *(3)*, for instance, has been established for Friedel-Crafts acylation with acyl chlorides and $AlCl_3$[4a,b]. Additionally, the acyl halide suffers halogen exchange—proven by isotopic labeling—which also can be rationalized only *via* the intermediate *(2)* and an equilibrium with the acylium ion *(3)*[4c].

(1) *(2)* *(3)*

From kinetic experiments, it has been deduced that a further intermediate is involved in the formation of *(3)* in which the carbonyl oxygen is likewise complexed by $AlCl_3$[4d]. All three potential electrophiles [*(1), (2), (3)*] now can act as the effective acylating agent in Friedel-Crafts acylation.

Another striking example is the amination with chloroamines in the presence of Friedel-Crafts catalysts. Attack of the Lewis acid at a lone pair of the chlorine atom produces an aminating agent *(4)*, whereas attack at the nitrogen lone pair results in the formation of a chlorinating agent *(5)*[5].

(4) *(5)*

This problematical situation in electrophilic reactions with Friedel-Crafts catalysts has been dealt with comprehensively in several reviews[6]. In the development of new, both more reactive and selective electrophiles, attempts have been made to eliminate the difficulties inherent in the application of Lewis acids, and, by introducing better leaving groups, to achieve sufficient polarization or dissociation of the reagents E—A *per se*. The present review will focus attention primarily on these aspects.

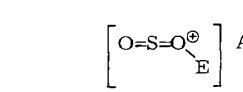
2. Importance of the Leaving Group for Electrophile Formation

A decisive factor for the reactivity of an electrophile is the degree of its polarization or dissociation. Numerical values for the leaving tendency of different groups have been derived mainly from the kinetics of nucleophilic substitution at a saturated carbon atom. For estimating relative reactivities of electrophiles with different leaving groups, solvolysis probably represents the best model; here, the dissociation step is rate-determining and, consequently, the influence of the leaving group on the reaction rate far greater than in S_N2 substitution[7]. For some of the more common leaving groups, relative rates in S_N1 reactions are given below (relative to bromide):

Leaving group $Z^{\ominus}$:	$CF_3SO_3^{\ominus}$	p-CH_3—C_6H_4—$SO_3^{\ominus}$	$Br^{\ominus}$
k_Z/k_{Br}:	5×10^8	5×10^3	1
Leaving group $Z^{\ominus}$:	$Cl^{\ominus}$	p-O_2N—C_6H_4—$COO^{\ominus}$	
k_Z/k_{Br}:	2.5×10^{-2}	2×10^{-6}	

Yet even in S_N1 reactions, the influence of the leaving group on the reaction rate depends to some extent on the stability of the carbenium ion formed upon dissociation, diminishing with increasing cation stability[7]. If dissociation of E–A, as stated above, is in fact determined principally by the stability of the ions $E^{\oplus}$ and $A^{\ominus}$, then, for any given electrophile $E^{\oplus}$, the stability of $A^{\ominus}$ alone should determine its leaving tendency; in this case, the pK_a of the conjugate acid could provide a quantitative measure. Good correlation indeed exists between leaving tendency and conjugate acid strength in many cases, even though pK_a values are defined for H–A bond dissociation while in S_N1-type solvolyses >C–A bonds are cleaved heterolytically. Within the halide series, for instance, the leaving tendencies parallel the pK_a values of the hydrohalic acids (I > Br > Cl > F).

For the solvolysis of sulfonates, with C–O bond cleavage, a good correlation has been established between the leaving tendency of the sulfonate anion, $XSO_3^{\ominus}$, and the acid strength of XSO_3H (X = CF_3, F, C_6F_5, p-CH_3—C_6H_4)[8].



According to a recent investigation, acid strength and leaving tendency are loosely correlated even for very strong acids[9]. The rates of solvolysis of methyl trifluoromethanesulfonate (= methyl triflate), fluorosulfate, and perchlorate, for instance, are graduated comparably in the three solvent media water, methanol, and acetonitrile ($CF_3SO_3CH_3$ >

$FSO_3CH_3 > ClO_4CH_3$); the differences, though, are fairly small. Conductometric determinations in aprotic media and in CH_3COOH, on the other hand, give similar acidities for perchloric and trifluoromethanesulfonic acid, and a somewhat lower value for fluorosulfuric acid[10].

The exceptionally high leaving tendency of the trifluoromethanesulfonate ("triflate") ion has been attributed to specific electronic interaction of the CF_3 group in the dissociation step[11]. However, the paramount importance of triflate as leaving group is due to the extraordinary thermal stability and resistance towards oxidative and reductive degradation of both triflate ion and the free acid. In a recent summary of preparative applications of trifluoromethanesulfonic acid and its derivatives, *Howells* and *McCown* have particularly stressed this point[12].

Since the quantitative data on the leaving tendency of various moieties Z have all been derived from the solvolysis of C—Z bonds, they are not directly applicable to "hetero-electrophiles" (O, N, halogen electrophiles). For this, the other types of bonds involved in heterolysis, the changed bond polarization due to the altered electronegativity differences, and the disparate cation stabilization must all be taken into account. Nevertheless, the correlations between reactivity and stability of the leaving group, established for carbon electrophiles, have been applied successfully also in the development of new hetero-electrophiles.

A fundamental problem which so far has thwarted satisfactory quantification is the solvent effect in reactions with electrophiles. In the case of nucleophiles, reactivity is affected by solvent and gegenion in a well defined manner[13]. In contrast to these generally stable particles, most cationic electrophiles are stable and detectable only in superacid systems[13,14]; their high reactivity additionally limits the choice of organic reaction media to haloalkanes, nitriles, sulfones, and the like. Even so, most electrophiles do not undergo regular solvation; rather, they form definite 1:1 adducts with the solvent which constitute the actual electrophilic species. Thus, upon reaction in acetonitrile, nitrilium salts are produced[9,15], and in haloalkanes halonium derivatives[16]; even in SO_2, addition compounds of the following type are observed[14a,16].

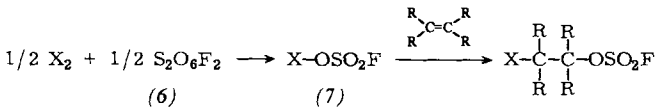
This, of course, severely affects the reactivity of the electrophiles. Nitronium salts, for instance, in inert solvents such as dichloroethane or sulfolane are weaker nitrating agents—despite their established ionic structure $[NO_2^{\oplus}]Z^{\ominus}$—than the normal mixtures of HNO_3 and H_2SO_4[17] since in the less nucleophilic acid mixture electrophile/solvent interaction is much less pronounced. Some information about the influence of solvation on carbenium ions has been obtained from a comparison of the relative stabilities of cations in the gas phase and in solution[18].

3. Halogen Electrophiles[19]

Apart from perchloryl fluoride, which is utilized for introducing the ClO_3 group into aromatics[20], the only halogen electrophiles of practical interest are the monovalent cations $I^{\oplus}$, $Br^{\oplus}$, $Cl^{\oplus}$, and $F^{\oplus}$. So far, however, they have not been observed directly either in solution or in the solid state[21a]; attempts at their generation, usually in superacid systems, always afforded only $X_2^{\oplus}$ and $X_3^{\oplus}$ species[21b]. The stability of these poly-ions increases, as expected, in the order $F < Cl < Br < I$, and with the number of halogen atoms incorporated, *i.e.* from $X_2^{\oplus}$ to $X_3^{\oplus}$[22]. Several of these polyhalo cations have been isolated in the solid state[23], yet nothing has been reported about their use as electrophilic halogenating agents.

Preferentially, therefore, reagents of the type $Z^{\delta\ominus} \blacktriangleright X^{\delta\oplus}$ are employed in electrophilic halogenation where the crucial bond is polarized in the requisite direction by linking the halogen to a more electronegative element (O, N, or another halogen), and Z at the same time is a good leaving group. These conditions are met, *inter alia*, by interhalogen compounds, halogen nitrates, fluorosulfates, and trifluoromethanesulfonates, by the hypohalites and some organic *N*-halo derivatives, as well as by carbon-halogen compounds with a $C \blacktriangleright X$ bond polarized sufficiently by electron withdrawing substituents.

With interhalogen compounds themselves only iodination and bromination of activated arenes such as phenols and aromatic amines is possible[24]. Mixtures of $SbCl_5$ and Br_2 or I_2 in which interhalogens are also assumed to be present as reactive species allow the substitution of less reactive aromatics too, for instance *meta*-bromination of nitrobenzene in 65% yield[25].



Halogen nitrates are prepared either from the anhydrides of the constituent acids[26] or, as pyridine complexes, with silver nitrate in pyridine directly from the halogens[27a]. The positivation of the halogen atoms in these reagents has been ascertained from spectroscopic results[28] as well as from their reaction behavior[26]: for example, their addition to double bonds proceeds both regioselectively and—*via* halonium intermediates—stereospecifically to give the *trans* adduct[27b].

$$Cl_2O + N_2O_5 \xrightarrow{0\,^{\circ}C} 2\,Cl{-}ONO_2$$

$$X_2 + AgNO_3 \xrightarrow[\text{Pyridine}]{CHCl_3} [X \cdot 2\,\text{Pyridine}]^{\oplus}NO_3^{\ominus} + AgX$$

$X = Br, I$

Halogen fluorosulfates *(7)* are usually prepared from the halogens with peroxodisulfonyl difluoride *(6)*[29,30]; their facile addition to olefins has been investigated extensively and is supposed to proceed *via* an electrophilic mechanism.

(6) *(7)*

X = F, Cl, Br; R = H, F, Cl

Recent investigations have confirmed the exceptional halogenating potential of halogen triflates *(8)*. Iodine triflate *(8a)*, for instance, though known for some time[31], has only recently been employed in iodination reactions.

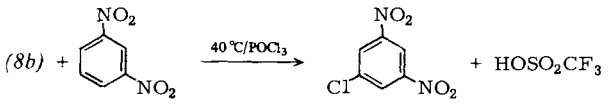
$$6\,CF_3SO_3H + I_2 + 3\,S_2O_6F_2 \xrightarrow[-6\,HSO_3F]{} 2\,I(OSO_2CF_3)_3$$

(6)

$$\xrightarrow[140\,^\circ C]{+2\,I_2} 6\,I{-}OSO_2CF_3$$

(8a)

Chlorine triflate *(8b)* was synthesized almost simultaneously by two independent pathways[32,33].

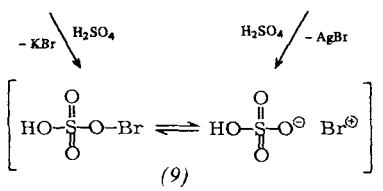


$$CF_3SO_3H + ClF \xrightarrow[-HF]{-111\text{ to }-78\,^\circ C} Cl{-}OSO_2CF_3$$

(8b)

$$\xrightleftharpoons{-80\text{ to }-40\,^\circ C} 1/2\,Cl_2O + 1/2\,(CF_3SO_2)_2O$$

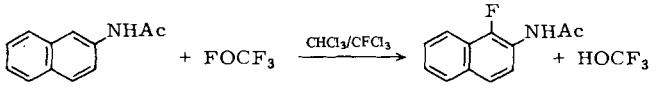
Not unexpectedly, *(8b)* is an extremely powerful electrophile and chlorinates even *m*-dinitrobenzene in good yield[33]. Since the trifluoromethanesulfonic acid liberated in the course of the reaction is converted back into trifluoromethanesulfonic anhydride by the solvent $POCl_3$, only 20 mol-% need be employed[33].



$$Cl_2O + (CF_3SO_2)_2O \rightleftharpoons 2\ (8b)$$

$$2\,CF_3SO_2OH + POCl_3 \longrightarrow (CF_3SO_2)_2O + Cl_2P(=O)OH + HCl$$

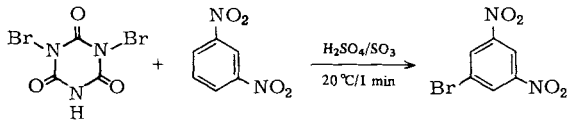
Bromine[34] and iodine triflate *(8a)*[35], prepared *in situ* from silver triflate and bromine or iodine, respectively, have also been successfully employed for the halogenation of deactivated arenes[34]. The findings with other halogen sulfonates[34] have led to the conclusion that for brominations in sulfuric acid, bromine hydrogen sulfate *(9)* is the reactive species, both in the presence of silver sulfate[36a] and with potassium peroxodisulfate[34].



$$1/2\,K_2S_2O_8 + Br_2 \qquad 1/2\,Ag_2SO_4 + Br_2$$

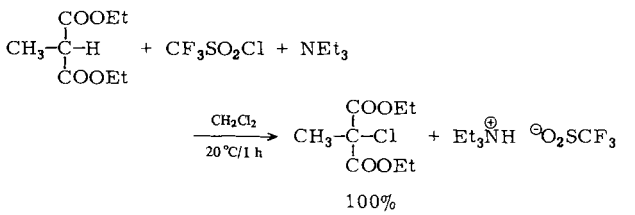
(9)

Cesium fluoroxysulfate, obtained from cesium sulfate and fluorine, is both a powerful oxidant and fluorinating agent[36b].



Among the hypohalites, which have long been used as main source of electrophilic halogen, fluoroxytrifluoromethane *(10)* has gained increasing importance[37a], particularly for the introduction of fluorine into the steroid skeleton. Reaction with both π- and σ-bonds[37b] most probably proceeds *via* an electrophilic mechanism.

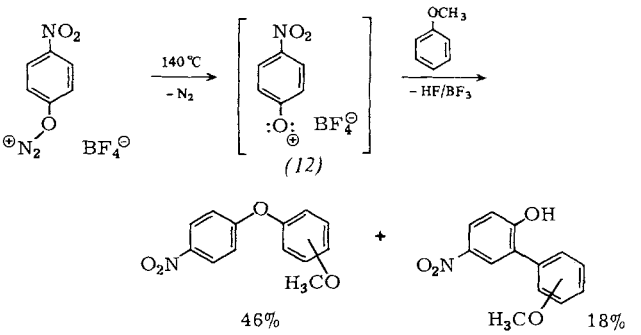
(10) > 50%



The XeF_6-graphite occlusion compound $C_{19}\cdot XeF_6$ which is more stable and thence easier to handle than the usually employed XeF_2[19b], has been applied specially for the fluorination of polycyclic arenes[38].

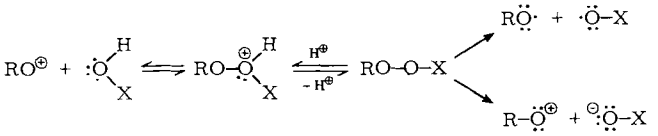
The halogen in the widely used *N*-halo derivatives can react either as radical or as electrophile[19b], depending on the further substituents at the nitrogen. With the extremely reactive *N,N*-dibromocyanuric acid *(11)*, for example, even strongly deactivated arenes are brominated in 15% oleum in good yield[39a], protonated *(11)* most likely being the reactive species[39b].

(11) 86%



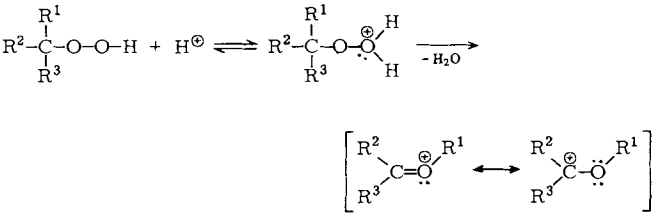
A very mild reagent for the chlorination of CH-acidic substrates is trifluoromethanesulfonyl chloride; it gives much better yields than *N*-chlorosuccinimide[40].

100%



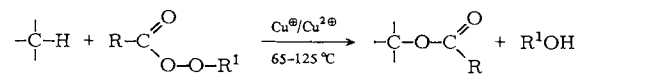
4. Oxygen Electrophiles

The oxygen electrophiles mainly used are compounds $RO^{\delta\oplus} \blacktriangleleft Z^{\delta\ominus}$ (R = H, organic group), with a sufficiently polarized O—Z bond and a good leaving group; because of the high electronegativity of oxygen itself, this must be either fluorine, another oxygen moiety, or a positively charged function ($-N_2^{\oplus}$, $-S^{\oplus}R_2$). The aryloxylium ion *(12)* so far is the only cationic oxygen electrophile $R-\ddot{O}^{\oplus}$ for which there is definite proof[41].



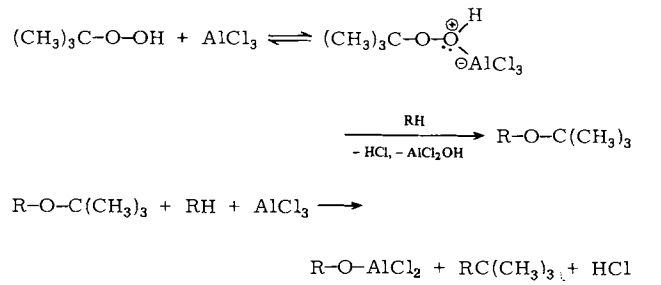
(12)

In practice, oxygen electrophiles are obtained mainly from hydrogen peroxide and its derivatives (peroxides, hydroperoxides, peroxo acids, peroxycarboxylic acids)[42]. Preferentially, peroxy functions are cleaved homolytically; a polar cleavage of the fairly weak O—O bond can be achieved, though, in polar solvents, also by substituents which are able to stabilize charges, and under the influence of proton or Lewis acids which polarize the O—O bond and, at the same time, generate better leaving groups[43].



In generating oxygen electrophiles from peroxy precursors, heterolysis of the O–R bond may occur besides O–O bond cleavage[44]. Much more frequent and detrimental, however, is the rearrangement of the primarily formed cations into the well-stabilized carbenium ions[44].

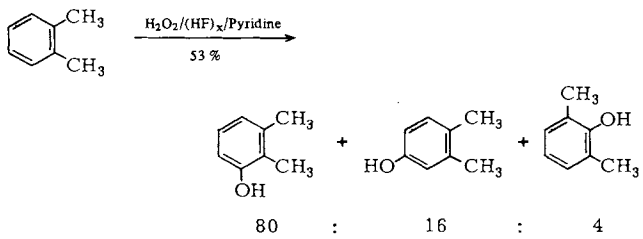
Since in aryloxylium ions, *e.g. (12)*, analogous rearrangements are not possible, their existence could be demonstrated unequivocally by follow-up reactions[41].



Acoxylation with peroxides is carried out with addition of transition metal ions; the reaction is employed regularly, and proceeds *via* radical intermediates[45].

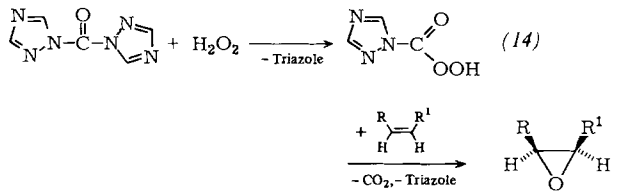
R^1 = *t*Bu, ArylCO,...

An electrophilic mechanism, on the other hand, is assumed—on the basis of reactivity gradation and isomer distribution—for the reactions of the more electrophilic diaryl- and bis(arylsulfonyl) peroxides with nucleophilic arenes[46].



In the electrophilic hydroxylation of aromatics, the main problems are secondary (poly)hydroxylation—due to the enhanced reactivity of the hydroxyarenes formed—and oxidative processes which lead to a wide spectrum of products[47]. Polyhydroxylation can be avoided by using *tert*-butylperoxy isopropyl carbonate[48] or *tert*-butyl hydroperoxide[49] in the presence of Friedel-Crafts catalysts; in this case, the primary product, aryl *tert*-butyl ether, is transformed into the aryloxyaluminum dichloride *(13)* and thus deactivated.

R = Aryl *(13)*



Electrophilic hydroxylation with peroxycarboxylic acids has gained increasing importance[42], especially since the ready accessibility of various peracids allows variation of the electrophilic potential within wide limits[50]. The yields in arene hydroxylation can be improved by addition of BF_3[51]; addition of $AlCl_3$ or $SbCl_5$, on the other hand, only favors the formation of oxidation products[47]. So far, inorganic peracids have found little use for arene hydroxylation—probably because of their instability in non-aqueous media. One example is the hydroxylation of alkyl- and hydroxybenzenes with peroxomonophosphoric acid; the high percentage of *ortho*-substitution products has led to the assumption of a cyclic transition state for this reaction[52].

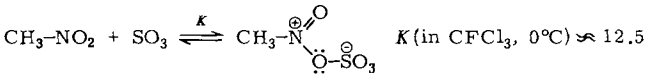
Attempts within the past few years to utilize hydrogen peroxide itself as source of electrophilic oxygen were highly successful, and have made arene hydroxylation now possible on an industrial scale. Good yields of mono-hydroxylation products are thus obtained with highly concentrated hydrogen peroxide in the presence of $AlCl_3$[53] or strong acids[54] since in this case secondary reactions of the newly formed phenols are largely suppressed by protonation or complexation. The mixtures H_2O_2/HF[55a,b] and $H_2O_2/(HF)_x$/pyridine[55c] have proven exceptionally advantageous in this respect.

Surprisingly, poly-hydroxylation is also largely suppressed by the addition of CO_2[55a]. With H_2O_2/urea adducts and $AlCl_3$, arenes can likewise be hydroxylated in good yields[56].

Reaction of concentrated hydrogen peroxide with isocyanates[57a] or carbonyldiazolides[57b] affords peroxycarbamidic acids *(14)* which can serve as source of electrophilic oxygen in absolutely neutral medium, *e.g.* for the epoxidation of acid-labile olefins.

Hypofluoric acid HOF is one of the few oxygen electrophiles not derived from hydrogen peroxide. Other than HOCl, it yields only phenols in the reaction with arenes and no halogen derivatives. It has been supposed[58] that the electrophilicity of HOF is significantly enhanced by formation of the adduct *(15)* since with H_2O_2/HF no hydroxylation occurs under these conditions.

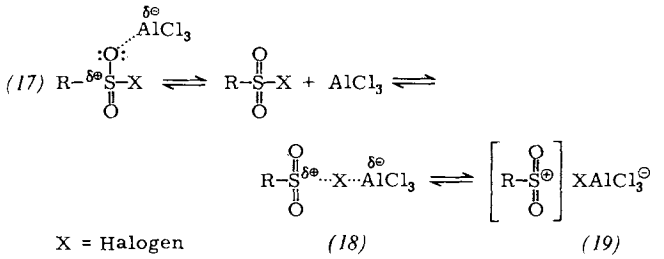
(15)



R = aryl

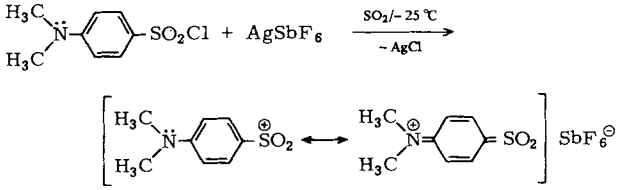
5. Sulfur Electrophiles

Among the reactions with electrophilic sulfur derivatives, sulfonation, sulfonylation, and likewise sulfenylation are of great importance; reactions with sulfurous acid derived electrophiles, on the other hand, have attracted much less attention[59].



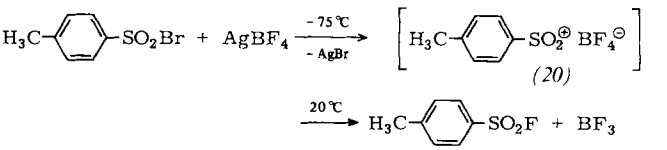
5.1. Sulfonation and Sulfonylation

Sulfonation is carried out prevalently with sulfuric acid of varying concentration—aqueous, concentrated, or SO_3-containing; SO_3-content and acid strength strongly affect both the formation of the electrophile and its reaction behavior[60]. With higher SO_3 concentration, for instance, more pyrosulfuric acids are formed ($H_2S_2O_7$, $H_2S_4O_{13}$) whose enhanced sulfonating potential is rationalized in terms of the higher leaving tendency of the respective larger anions[60b]. Adducts of SO_3 and cyclic ethers, pyridine, or tertiary amines are employed as selective sulfonating agents[61]. An addition complex *(16)* is present, too, in equilibrium in the sulfonation with SO_3 in nitromethane or nitrobenzene; though less reactive, *(16)* is significantly more selective than free SO_3 in haloalkane media[62].



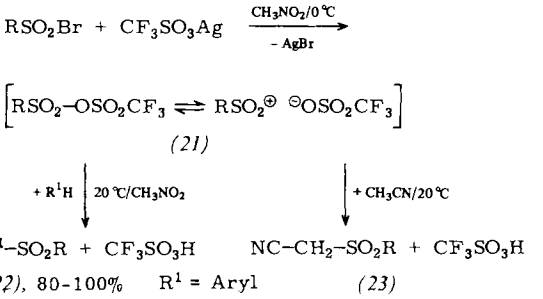
(16)

Sulfonylations are usually carried out with sulfonyl halides in the presence of Friedel-Crafts catalysts; as active electrophile in this case, either the oxygen- or the halogen-complexed intermediates, *(17)* or *(18)*, respectively, or the sulfonylium salts *(19)* are to be considered.

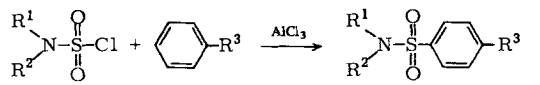


X = Halogen *(18)* *(19)*

Oxygen-addition products *(17)* result from the action of antimony pentahalides upon alkyl- and arylsulfonyl halides which bear no strong donor substituents[63a,b]; if the positive charge is sufficiently stabilized, *e.g.* by dialkylamino or alkoxy groups, sulfonylium salts *(19)* are formed[63b,c].

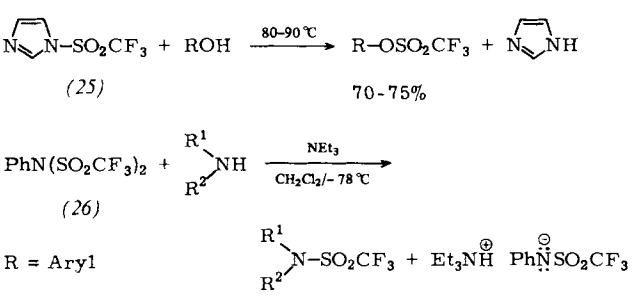


Klages et al.[64] who first investigated the reaction of toluenesulfonyl halides with silver perchlorate and tetrafluoroborate had already recognized the ionic nature of the powerful sulfonylating agents formed at low temperature with silver halide precipitation. Isolation of these sulfonylium salts



is not possible, though, since they decompose at slightly higher temperatures. The electrophilic potential of the *p*-toluenesulfonylium ion in *(20)*, for instance, is sufficient to strip off one fluoride from the gegenion $BF_4^{\ominus}$[64b].

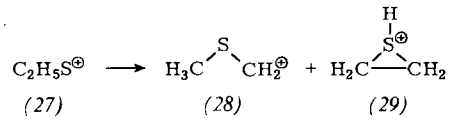
In preparing new sulfonylating agents from aliphatic and aromatic sulfonyl bromides and silver triflate, the considerable stability of the triflate ion could be utilized to great advantage: The mixed anhydrides *(21)* can thus be obtained in neat form; their exceptional electrophilic potential allows, for instance, arylsulfone *(22)* formation in very good yields already at room temperature without addition of any Friedel-Crafts catalyst[65]. If preparation of the anhydrides *(21)* is attempted in acetonitrile as solvent, the cyanomethyl sulfones *(23)* are formed.



The way in which the relative reactivities in aryl sulfonylation depend on the rest R in the sulfonyl moiety indicate the dissociated form of *(21)* as the reactive species. The aliphatic anhydrides *(21)*, R = alkyl, are thermally labile; their rate of decomposition increases with increasing stability of the alkyl cations generated upon SO_2 expulsion ($CH_3^{\oplus} < C_2H_5^{\oplus} < (CH_3)_2CH^{\oplus}$)[65a].

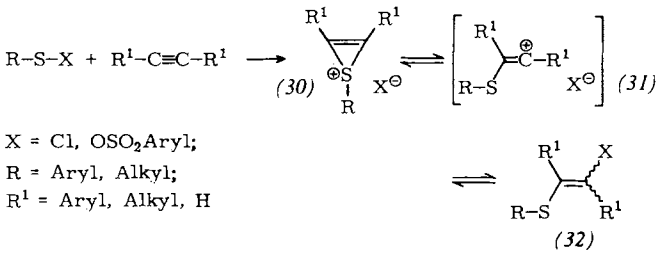
(24) 50-100%

R^1, R^2 = C_2H_5, $-(CH_2)_5-$; R^3 = H, CH_3, Cl



With the dialkylsulfamoyl chlorides *(24)*, *N,N*-dialkylsulfamoyl groups may be introduced into the *p*-position of mono-substituted arenes[66]. For the sulfonylation of OH- and NH-functions, both *N*-trifluoromethylsulfonylimidazolide *(25)*[67] and phenyl-*N,N*-bis(trifluoromethylsulfonyl)amide *(26)*[68] are very mild and highly selective reagents.

R = Aryl

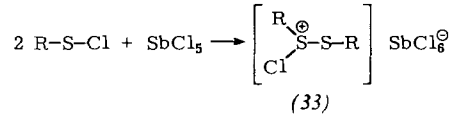


5.2. Sulfenylation

A comprehensive review of sulfenylium ions and other sulfenylating agents has appeared in 1976[69]; therefore, only work of the last few years will be commented upon here. Despite many efforts, free sulfenylium ions could so far not be detected in solution; once formed, they immediately stabilize by interaction or co-ordination with the solvent. In the gas phase, sulfenylium ions very rapidly rearrange into more stable species (*e.g.* the ethanesulfenylium ion *(27)* into *(28)* and *(29)*[70]). In general, electrophilic sulfenylating agents are generated from sulfenyl halides with Friedel-Crafts catalysts or *via* substitution of the halogen by a better leaving group[69].

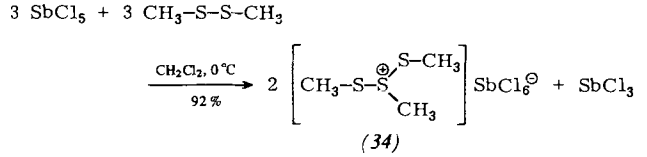
(27) *(28)* *(29)*

The electrophilic addition of sulfenic acid derivatives to olefins[71] and acetylenes[72] has been investigated most extensively. Thiirenium salts *(30)* could be isolated from the reactions with acetylenes, partly in crystalline form. In solution, an equilibrium exists between these salts and the vinyl cations *(31)* and vinyl sulfides *(32)*; this equilibrium is the more shifted towards the side of the vinyl sulfides *(32)* the more nucleophilic the anion $X^{\ominus}$[72].



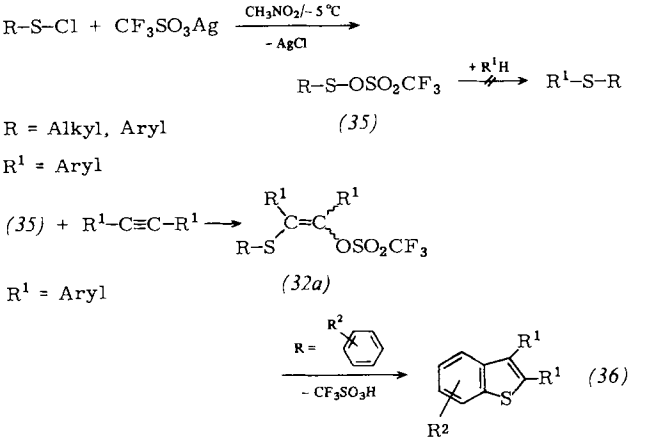
(30) *(31)*

X = Cl, OSO_2Aryl;
R = Aryl, Alkyl;
R^1 = Aryl, Alkyl, H



(32)

No free sulfenylium ions could be detected either in these reactions; rather, the attack of Lewis acids upon sulfenyl chlorides leads to the addition compounds *(33)* which then react as actual electrophilic species with the alkyne[72].



(33)

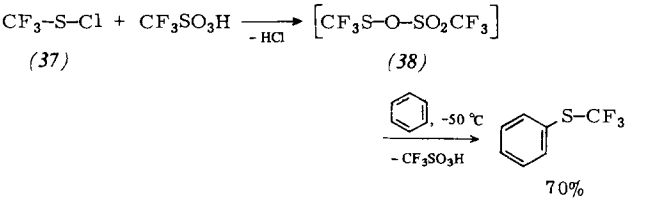
The sulfonium salts *(34)*, easily accessible from disulfides and antimony pentachloride, are excellent sulfenylating reagents[73].

(34)

The electrophilicity of the sulfenylating agents *(35)*, obtained from sulfenyl chlorides and silver triflate[74], does not suffice for arene sulfenylation; they add smoothly, though, to acetylenes. Due to the presence of the good triflate leaving group, the vinyl sulfides *(32a)* thus formed are subject to facile dissociation into vinyl cations; in the case of R = aryl, benzothiophenes *(36)* are formed in good yield by rearrangement of these vinyl cations[74].

(35)

R = Alkyl, Aryl
R^1 = Aryl



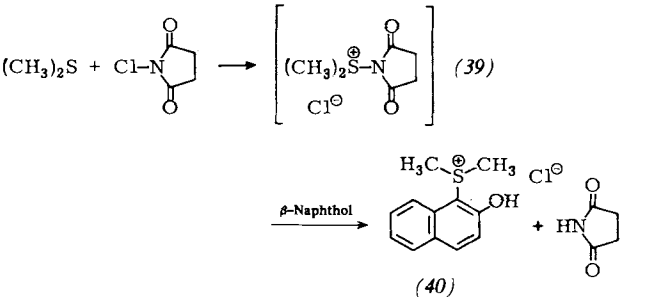
(32a)

R^1 = Aryl

(36)

An analogous benzothiophene formation upon heating arylsulfenic trinitrobenzenesulfonic anhydride with acetylenes had already been observed in earlier work[75].

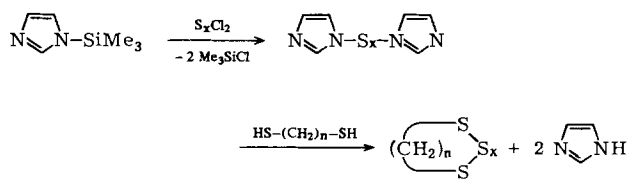
The CF_3S function can be introduced directly into arenes and hetarenes with trifluoromethanesulfenyl chloride *(37)* in the presence of trifluoromethanesulfonic acid, for which the sulfenic sulfonic anhydride *(38)* formed intermediately is assumed as effective electrophile[76].



(37) *(38)*

70%

Iron[77] and silica gel[78] have proven exceptionally good catalysts for electrophilic aromatic substitution with sulfenyl halides.



Salts of the type *(39)*[79], prepared from sulfides with chlorine[80] or from sulfoxides with mineral acids, allow electrophilic introduction of the R_2S moiety into arenes with formation of sulfonium salts such as *(40)*[69,81].

(39)

(40)

Electrophilic sulfurization has recently been carried out by utilizing the imidazolide procedure[82].

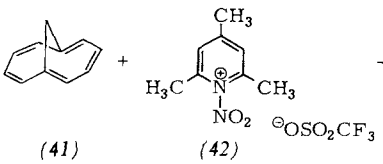
A mixture of $Pb(SCN)_2$ and $SbCl_5$ in CCl_4 permits introduction of the thiocyanato function into alkyl- and halobenzenes, probably *via* $(SCN^{\oplus}SbCl_6^{\ominus})$ as reactive species[83].

6. Nitrogen Electrophiles

Organic derivatives are known of practically all oxidation states of the N atom. Among the reactions with nitrogen electrophiles, though, only nitration, amination, nitrosation, and diazonium coupling reactions are of practical significance. Our discussion will be focused primarily on nitration and amination since, as far as diazonium salts as electrophiles are concerned, no fundamentally new aspects have appeared in recent years, and since, on the other hand, conditions for nitrosation are fairly similar to those for nitration.

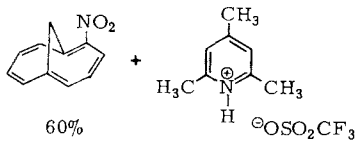
6.1. Nitration and Nitrosation

Aromatic nitration is of great technical and scientific consequence and has therefore been investigated very thoroughly; the relevant earlier literature is adequately covered in some recent summaries[84–87].



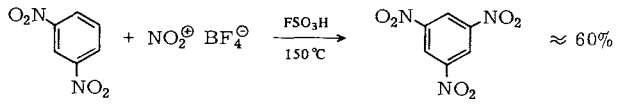
Replacement of the sulfuric acid in the usual nitration mixtures, made up of nitric acid and sulfuric acid of varying concentration, has a marked effect on the product spectrum in aromatic nitration. Thus trifluoromethanesulfonic acid[88a] and HF[88b] have both proven most advantageous for directing anthraquinone nitration into the 1-position. With combinations of nitric acid and either an arylsulfonic or phosphoric acid[89], a significantly higher *o/p*-ratio results on toluene nitration.

Since the use of HNO_3/H_2SO_4 mixtures is ecologically rather problematical, considerable efforts are being made to either curtail their use or, better, to completely replace them by other nitrating agents. Use of dichloromethane as solvent for nitrations with HNO_3/H_2SO_4 mixtures not only gives higher yields, *e.g.* in the reaction with equimolar amounts of nitric acid, since much less oxidation and sulfonation products are formed, but also permits recovery of sulfuric acid from the reaction mixture[90].



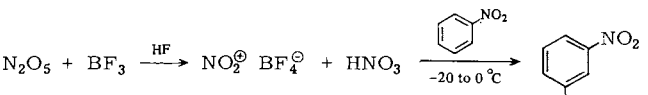
Nitryl salts were introduced by *Olah* and *Kuhn*[87,91] into preparative organic chemistry as effective nitrating reagents; they also allow nitration under non-aqueous conditions which is especially advantageous in the case of solvolysis- or oxidation-prone substrates.

Salts of the nitryl ion $NO_2^{\oplus}$ with complex perfluoro anions (*e.g.* $BF_4^{\ominus}$, $PF_6^{\ominus}$, $SbF_6^{\ominus}$, $SeF_5^{\ominus}$, $IF_6^{\ominus}$) have been known for some time; their spectral properties have recently been critically evaluated[92]. In addition, nitryl triflate[17,93] as well as the respective hydrate[94] and also nitryl hydrogen sulfate[90] have been synthesized in recent years. The reactivity of these various nitryl salts in organic solvents critically depends on both solubility and the extent of ion/solvent interaction[17].



Just as in the case of the well-known reactions with *N*-nitropyridinium salts[95,96], highly interesting results may still be expected[87] from the adducts of nitryl salts with donor molecules (alcohols, ethers, sulfides), namely with respect to special selectivity in nitration. With the 1:1-addition compound *(42)* of nitryl triflate and collidine[97], which is readily soluble in dichloromethane, acid-labile substrates such as 1,6-methano[10]annulene *(41)* can be selectively nitrated in good yield[98].

(41) *(42)*

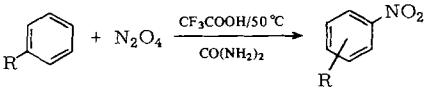


Nitryl tetrafluoroborate in fluorosulfuric acid represents an exceptionally reactive nitrating species which converts *m*-dinitrobenzene into trinitrobenzene in relatively high yield[99].

Nitration with nitryl halides in the presence of Friedel-Crafts catalysts[87], though possible in principle, so far has gained no practical significance. On the one hand, the nitrogen-halogen bond is not polarized unequivocally because of the comparable electronegativities of N and the halogens, and on the other, attack of the catalyst at an oxygen atom of the nitro group can render the nitryl halide a potential halogenating species.

Among the oxides of nitrogen, both dinitrogen tetroxide and dinitrogen pentoxide can be employed for nitration reactions; nitrations with N_2O_5 are well known and have been investigated extensively[87]. Nitryl salts are generated from N_2O_5 by the action of protic or Lewis acids, which then react as described above; if HF is used as solvent, or the pyridinium/polyhydrogen fluoride mixture[4] which is experimentally easier to handle, an effective electrophile of especially high nitrating potential is obtained.

> 90%



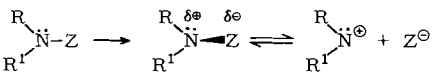
Sensitive substrates are nitrated preferentially in organic solvents[100], *e.g.* CCl_4, where N_2O_5 apparently reacts in the undissociated form.

Dinitrogen tetroxide, which as a rule dissociates into two NO_2 radicals, can also be cleaved heterolytically under the influence of Lewis acids. Since a potential nitrating and nitrosating agent are generated simultaneously, this has no great practical importance[87,101].

$$N_2O_4 + 3\,H_2SO_4 \rightleftharpoons NO_2^{\oplus} + NO^{\oplus} + H_3O^{\oplus} + 3\,HSO_4^{\ominus}$$
$$3\,N_2O_4 + 8\,BF_3 \rightarrow 3\,NO_2^{\oplus}\,BF_4^{\ominus} + 3\,NO^{\oplus}BF_4^{\ominus} + B_2O_3$$

Use of N_2O_4 as nitrating species is limited to some special cases, for instance the nitration of arylthallium compounds; toluene thus can be nitrated prevalently in *para*-position in

an overall yield of 98% (*o/m/p*-ratio 11:2:87)[102]. High yields are likewise achieved for N_2O_4 nitration in the presence of palladium salt catalysts[103], in trifluoroacetic acid with addition of at least a molar amount of urea—in this case without any Pd salts—[103], and in the case of reactive arenes even without added urea[104]. In all these N_2O_4 reactions, effective trapping of the nitrous acid seems to be the decisive factor.

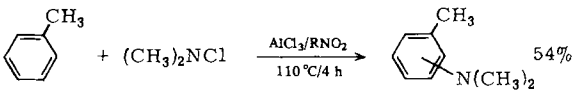


R	Yield [%]	Ratio of isomers *o* : *m* : *p*
H	99	
CH_3	76	55 : 2 : 43
Cl	100	36 : — : 64

In the presence of Lewis acids, *e.g.* Nafion-H (a perfluorosulfonic resin) or BF_3, alkyl nitrates and 1-cyano-1-methylethyl nitrate ("acetone cyanohydrin nitrate") are mild, non-oxidating nitrating reagents[105]. Titanium(IV) nitrate, employed for arene nitration in CCl_4, might, because of its low substrate selectivity, gain some preparative interest for the nitration of deactivated arenes and hetarenes[106].

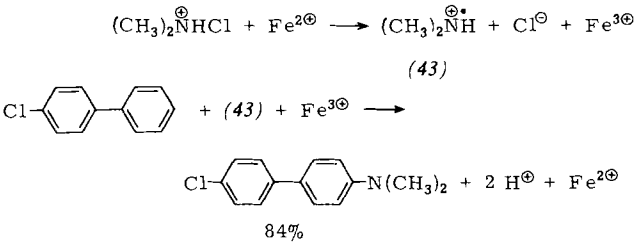
The practical importance of nitrosation is much less than that of nitration. Since the weak electrophilicity of the nitrosating reagents is coupled with a relatively high oxidation potential, only strongly activated arenes such as phenols or aminobenzenes can be nitrosated successfully. The preparative aspects of nitrosation with the more common reagents have been summarized recently[84]. Nitrosyl salts[91b]—readily prepared and easy to handle—likewise are only weakly electrophilic, yet strongly oxidizing[107]; they are widely employed for the nitrosation of amines, alcohols, and anionic species[91b,107]. However, their electrophilic potential is not sufficient for rection with scarcely activated aromatic substrates.

6.2. Amination[108]



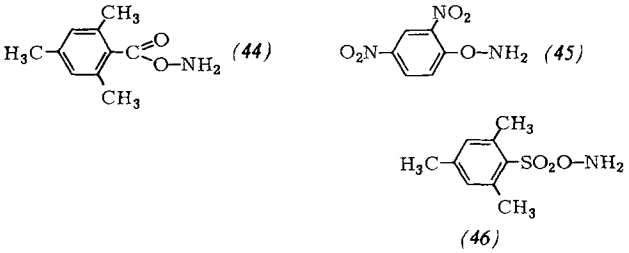
By introducing a good leaving group Z, ammonia and amines can be converted into electrophilic aminating agents. For all H_2N–Z derivatives reported so far, only N–Z bond polarization may be assumed; there are no indications for the existence of free $NH_2^{\oplus}$[109]. Investigations by *Gassman et al.* on the occurrence and chemical behavior of nitrenium ions $RR^1N^{\oplus}$ (R, R^1 = alkyl, aryl) have shown that these ions are much less stable than the structurally analogous carbenium ions[109]. The effect of the leaving group on heterolysis of the N–Z bond displays the same graduation as in carbenium ion formation[110]. Because of their high electronegativity, halogen and oxygen functions are mainly incorporated as leaving groups Z.

R, R^1 = H, Alkyl, Aryl



The long-known electrophilic introduction of amino groups with haloamines has been reviewed in considerable detail[108,111]. Satisfactory yields of amination products are generally obtained only with relatively strong nucleophiles (*e.g.* amines, alcohols), indicating a S_N2 character of these reactions[112]. With weakly nucleophilic substrates such as arenes, one observes competing electrophilic amination, amination *via* radical intermediates, and halogenation[111]. The isomer distribution for the amination of toluene with chlorodimethylamine, under the conditions given in the scheme below, points towards an electrophilic mechanism (R = CH_3, n-C_3H_7, $C(CH_3)_3$, C_6H_5).

Reaction of anisole with chlorodimethylamine under comparable conditions, on the other hand, exclusively affords chlorinated products (67% yield)[113].

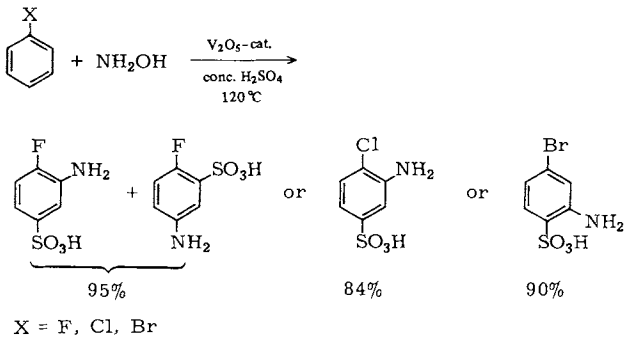


o:*m*:*p* = 7:15:32

The amination of arenes with chloroamines in highly acidic medium and in the presence of redox catalysts ($Fe^{2\oplus}$, $Ti^{3\oplus}$) is of great preparative value because of the good yields and high selectivities obtained[114]. Amino radical cations *(43)*, which have some electrophilic character, are the reactive species in this case[114]; the only isomers formed are the 4,4′-disubstituted biphenyls.

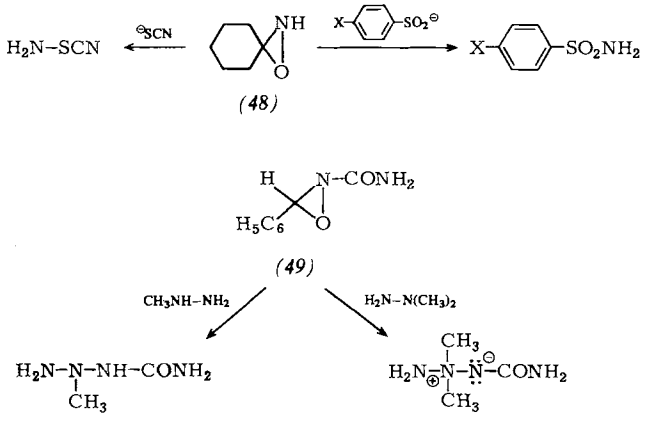
Far more important for electrophilic aminations than the haloamines are hydroxylamine derivatives. For this, however, the hydroxylamine OH function must first be converted into a good leaving group (as in the case of the alcohols in the carbon compound domain). Hydroxylamine-*O*-sulfonic acid[115] was the first and, for quite some time, the only such derivative whose manifold reactions with nucleophiles were investigated extensively[108]. Because of their higher reactivity, due to the presence of a better leaving group, the reagents *(44)*, *(45)*, and *(46)*[116,117] are now mainly used in practice.

The instability of some of these aminating agents is a great drawback. For instance, *(46)* is highly explosive[118]; all attempts to prepare the triflate derivative *(47)* *via* the hydroxyl-



amine thallium salt have likewise failed[119]. This instability of the hydroxylamine derivatives could be due to an α-elimination to give nitrene and follow-up reactions.

$$H_2N{-}O{-}Tl + Cl{-}SO_2CF_3 \xrightarrow[-TlCl]{-40\,^\circ C} [H_2N{-}OSO_2CF_3] \xrightarrow{?} [\ddot{N}H] \rightarrow \cdots$$



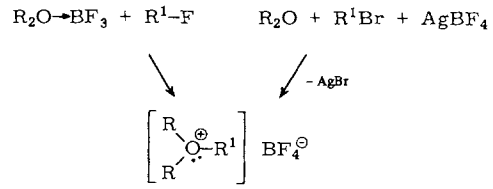
(47)

If α-elimination is prevented by suitable *N*-substituents, stable compounds result, *e.g.* the bis(trimethylsilyl) derivatives[120] of *(44)* and *(46)* and a *N,N*-diacyl derivative of *(47)*[121]. Nothing is known, though, about the usefulness of these compounds as aminating agents[121]. Besides nitrogen- and sulfur-containing substrates, carbanions have also been aminated with *N,N*-dialkyl derivatives of *(46)*[117].

Amination of haloarenes with acidic solutions of hydroxylamine according to the Turski method gives good yields[123]; however, the product distribution is strongly dependent on the halogen substituent. No radical intermediates could be detected in this process[122].

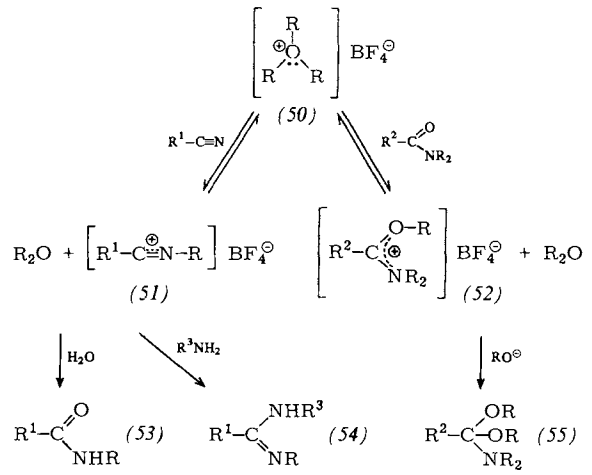
The oxaziridines *(48)* and *N*-carbamoyloxaziridines *(49)*, prepared *via* electrophilic amination processes, are themselves aminating agents which can be used for transferring amino or ureido functions respectively[108].

7. Alkylating Agents[6b, 124]



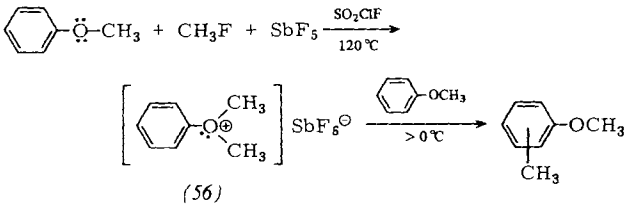
The electrophilic introduction of alkyl groups into organic compounds, under formation of a new C—C, C—O, C—N, or C—S bond, is preparatively of the utmost importance, but has also played a decisive role in the development of mechanistic concepts: carbocations were first postulated as intermediates in organic reactions for this type of reactions—with all the ensuing consequences.

The various alkylating reagents differ primarily in the degree of positivation of the reactive carbon center. In principle, this covers the whole range from mere bond polarization to the formation of free carbenium ions, influenced, as many investigations have shown, by the stability of the cation formed, by the leaving tendency of Z, and by the solvent medium[125].



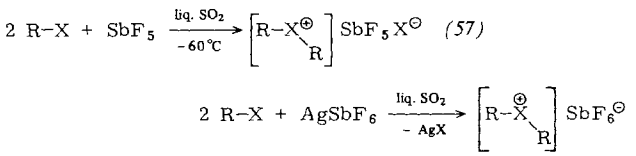
The electrophilicity of a given alkylating agent goes up, of course, with increasing positivation of the carbon center. Thus, alkyl halides react with strong nucleophiles—such as anions, amines, and alcohols—even in non-dissociated form; the reaction with weakly nucleophilic substrates (arenes, olefins, σ-bonds), on the other hand, requires the addition of Friedel-Crafts catalysts. In the following, our attention will be directed primarily to those alkylating reagents with good leaving groups which were developed within the last few years in the course of the investigation of onium structures[91b] and have found a broad preparative application.

Among the onium compounds, the trialkyloxonium salts discovered by *Meerwein et al.*[126] have long been known as excellent alkylating agents. They are prepared from alkyl halides with BF_3, SbF_5, or $SbCl_5$ in ethereal solution[127].



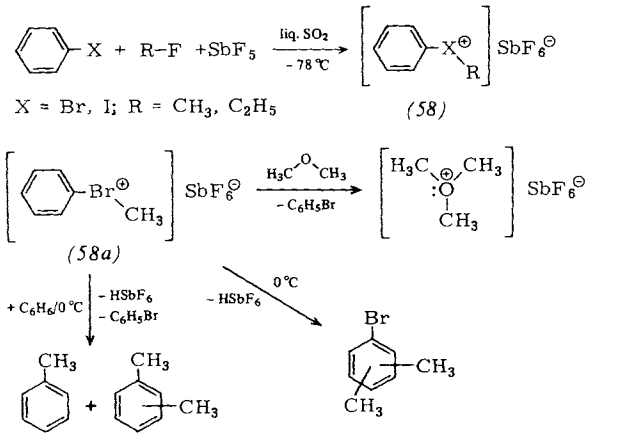
Although their electrophilic potential is not sufficient for alkylation of normal arenes, reactions are possible already with substrates which have such slight nucleophilic character as azulenes, nitriles, and carboxamides[126a].

The salts *(51)* and *(52)*, formed from nitriles and amides, respectively, and in equilibrium with the oxonium precursors *(50)*, are themselves alkylating agents. However, their addition to nucleophiles (water, amines, alcohols) affords *N*-alkyl amides *(53)*, amidines *(54)* and amide acetals *(55)*.



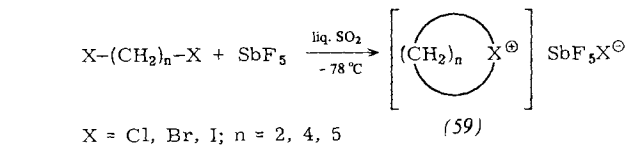
Dialkylaryloxonium salts *(56)*, accessible by alkylation of aryl alkyl ethers, have a higher alkylating potential than the trialkyl analogues and can be employed for arene alkylation[128].

(56)



Triaryloxonium salts may be obtained in $<2\%$ yield from diaryl ethers and benzenediazonium salts; since they are practically inert towards nucleophiles, they are of no consequence as arylating agents[129].

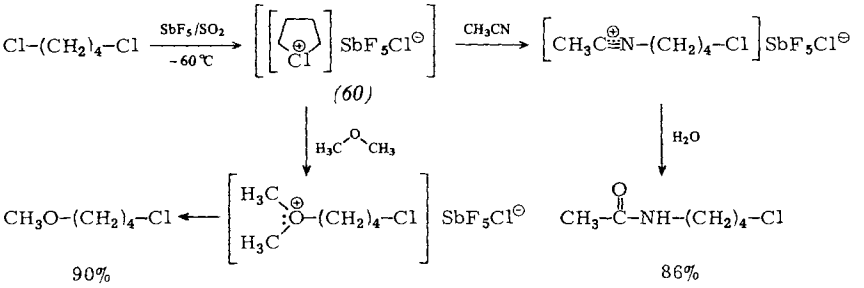
The alkylhalonium compounds *(57)*, recently prepared by *Olah* and *DeMember*, can be used as highly reactive alkylating agents in the same manner as the oxonium salts[130, 131].



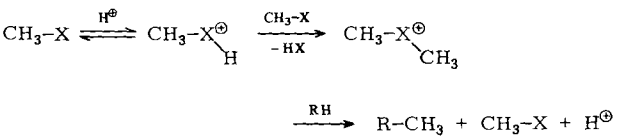
X = Cl, Br, I; R = CH_3, C_2H_5, $(CH_3)_2CH$

Alkylarylhalonium salts *(58)* are accessible analogously from halobenzenes[132] and are likewise used as powerful alkylating agents[130, 132].

(58a)



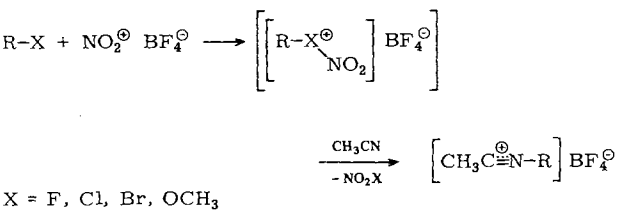
The cyclic halonium ions *(59)*, postulated as intermediates in the electrophilic addition of halogens to olefins for a long time, could now be isolated under like conditions as the open-chain analogues as well as directly from the halogenation of olefins[130, 133].



X = Cl, Br, I; n = 2, 4, 5 *(59)*

These cyclic halonium derivatives, *e.g. (60)*, have also proven to be effective alkylating agents[133].

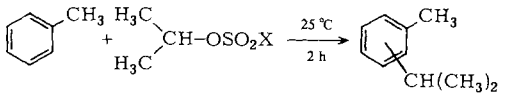
From our present knowledge about halonium salts, many Friedel-Crafts alkylations with primary and partly also with secondary alkyl halides now are assumed to proceed *via* dialkylhalonium ions; they have definitely been established as intermediates in proton-catalyzed alkylations[134].



(60)

X = Cl, Br, I; R = Aryl

Onium complexes are formed from alkyl halides and ethers also with other strong electrophiles, such as nitryl[135a] or nitrosyl[135b] salts; they react as powerful alkylating agents.

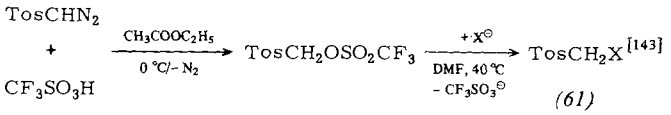


X = F, Cl, Br, OCH_3

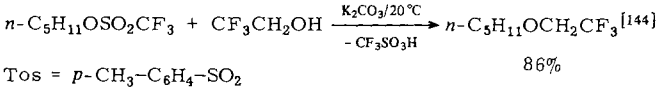
Apart from these efforts to improve the reactivity, chemists have also endeavored to suppress secondary alkylation and isomerization in the Friedel-Crafts alkylation of arenes as far as possible; attempts with heterogeneous catalysts ($AlCl_3$ on graphite[136] or Nafion-H[137]) have met with at least partial success. Solvents such as nitroalkanes where the effectiveness of the catalyst is attenuated by complexation likewise improve the selectivity and curb isomerization[138].

Arene alkylation with secondary or tertiary carbenium ions in the gas phase gives a product spectrum comparable with that obtained for reactions of strong alkylating agents in a weakly solvating medium[139].

Among the new alkylating reagents, alkyl triflates[12] command special interest, due not only to the good leaving properties of the triflate ion but, as outlined above, also because of the high stability of both the trifluoromethanesulfonic acid and its alkyl esters. The instability of alkyl perchlorates[141], in contrast, renders them unsuitable as practical alkylating agents even though most can be prepared in high yield[140], and in spite of the good leaving group $ClO_4^{\ominus}$.



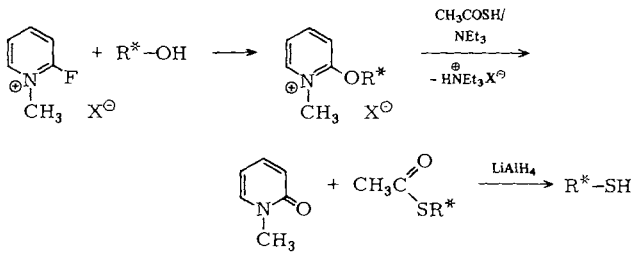
Isopropyl triflates and fluorosulfates allow the non-catalyzed alkylation of arenes such as benzene and toluene in good yield; the esters of primary alcohols, on the other hand, still require Friedel-Crafts catalysts[142].



≈ 50%

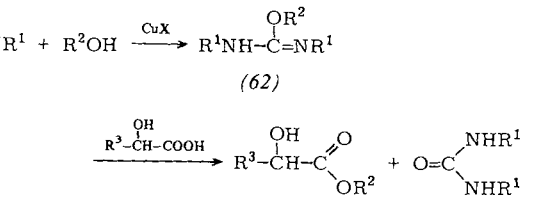
X	*o*	: *m*	: *p*
F	44.3	17.7	38.0
CF_3	46.5	19.1	34.4

In the alkylation of anions[143] and of highly acidic alcohols[144], good yields could likewise be obtained only with alkyl triflates; for example, 96, 82, 79, and 76% of *(61)* were obtained with X = Cl, I, N_3, and SCN, respectively. In contrast, elimination and rearrangements are observed to a large extent under the rather more severe reaction conditions required for the usual alkylating agents such as tosylates.



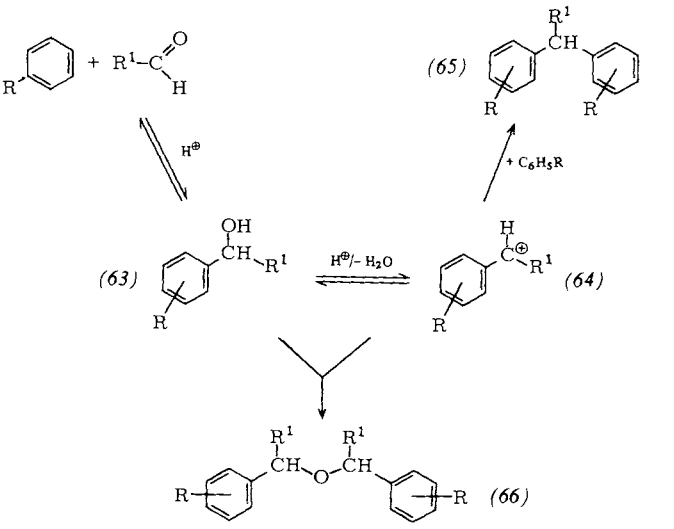
(61)

Tos = *p*-CH_3–C_6H_4–SO_2

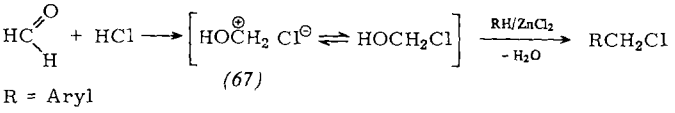


Generation and unequivocal proof of the existence of the extremely unstable vinyl cations was also achieved only by solvolysis of the respective triflates[145]. Deactivated arenes (*e.g.* halobenzenes) have already been alkenylated with vinyl cations without added Friedel-Crafts catalyst although their preparative application is still in its preliminary stages[146].

Heterocyclic moieties sometimes have proven to be advantageous leaving groups in alkylation processes. Thiols, for instance, can be prepared smoothly by reaction of thiolacetic acid with 2-alkoxy-*N*-methylpyridinium salts *(61)* and subsequent hydrogenolysis; optically active alcohols show Walden inversion in this reaction[147].

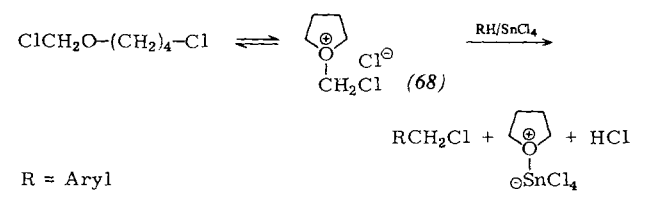


Pyridine itself has also been employed as leaving group in alkylation reactions[148], as have ureas. With *O*-alkylisoureas *(62)*, for instance, obtained by addition of alcohols R^2OH to carbodiimides, the alkylation of carboxylic and phosphoric acids, of thiols, amines and alcohols can be carried out under very mild conditions[149]. These reactions proceed with good yields and high selectivity, and thence are especially applicable in natural product synthesis.

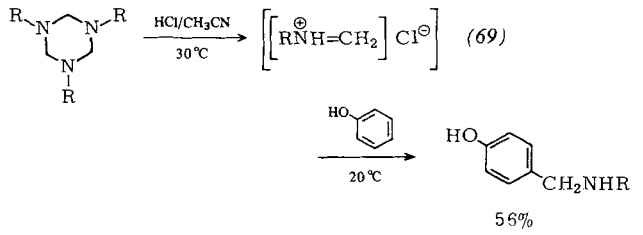


The term hydroxyalkylation denotes reactions of aldehydes and ketones with nucleophilic arenes[124]. These reactions frequently are complicated by secondary processes since, under the conditions employed, the hydroxyalkyl products *(63)* are readily converted into the carbocations *(64)*; once formed, these immediately react either with the nucleophilic substrate still present to give *(65)*, or with the primary products *(63)* to give *(66)*. Both of these secondary products for their part can again be alkylated by unreacted carbonyl compound.

(62)

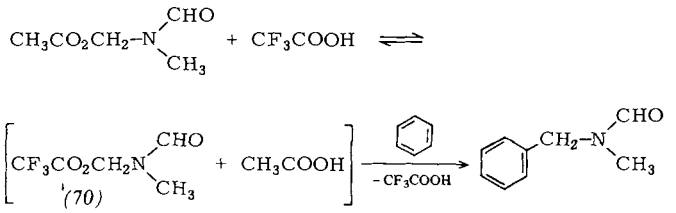


These reactions are of great technical significance in the synthesis of resins (*e.g.* phenol/formaldehyde, urea/formaldehyde). Undesirable secondary reactions can be circumvented by the use of hydrohalic acids which trap the carbenium ions, as soon as they are set free, in the form of haloalkyl derivatives (haloalkylation)[24]. Direct chloromethylation with formaldehyde/HCl[150], in which the carcinogenic hydroxymethyl cation *(67)* is considered as the attacking species, is preparatively very important.



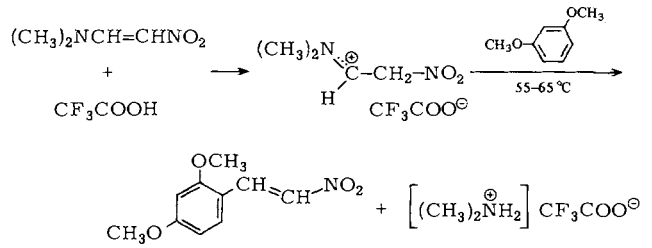
R = Aryl

Instead of formaldehyde/HCl, α-halo ethers may be applied; they likewise have been shown to be carcinogenic. Efforts to replace chloromethylation, especially in technical processes, by less precarious procedures so far have met only with limited success. In one variant, less volatile reagents such as *(68)* are employed[151]; in another, the iminium deri-



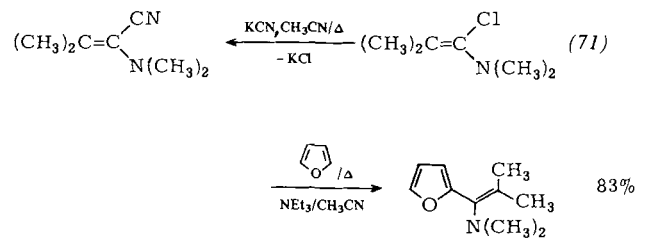
R = Aryl

vatives *(69)* of the parent carbonyl compounds are utilized as electrophiles[152]. This reaction results in aminoalkylation, and has successfully been applied to carbanions (Mannich reaction), heteroatom-H bonds, electron-rich π-systems (enol ethers, enamines, ynamines), and reactive arenes and hetarenes (*e. g.* phenols or furans[153]).



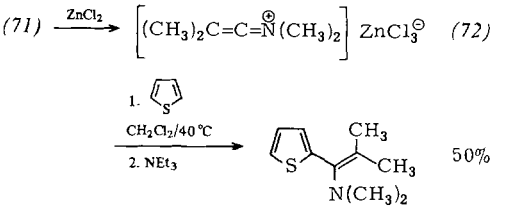
(69)

Aminoalkylation of less reactive arenes requires amino reagents such as *(70)* where the electrophilic potential is enhanced by both electron-withdrawing N-substituents and by a good leaving group as gegenion ($ClO_4^\ominus$, $BF_4^\ominus$, $CF_3COO^\ominus$)[154,155].



(70)

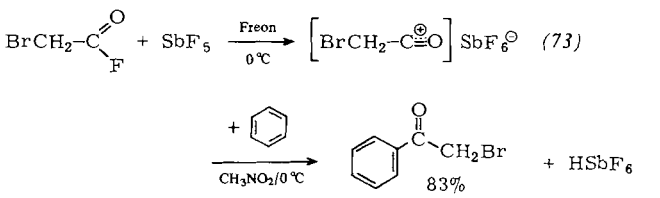
The nitro-olefination of indenes and electron-rich arenes such as resorcinol dimethyl ether actually is an aminoalkylation too; dimethylamine is immediately eliminated in the process, though, and the more favorable conjugated system developed[156].



Reaction of nucleophiles with α-halo enamines *(71)* likewise represents a variant of aminoalkylation[157].

(71)

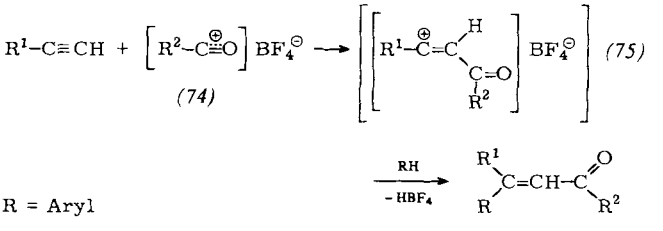
With less nucleophilic aromatic substrates, ketene-iminium chlorides, formed in a predissociation step, are assumed as reactive species. The primary formation of such a salt *(72)* has been established for the reactions with thiophene and anisole whose lower reactivity requires addition of a Lewis acid[157].



(72)

8. Acylating Agents

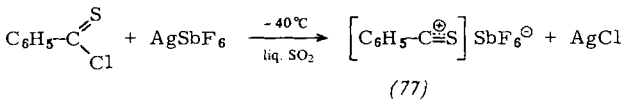
In electrophilic acylation, carboxylic acid derivatives are made to react with hetero- or carbon-nucleophiles, usually with substitution of a hydrogen atom[158]; in this review, the accent is placed on new, highly reactive acylating reagents for aromatic substrates.



For arene acylation, the electrophilicity of regular acyl derivatives—esters, halides, anhydrides—has to be enhanced, as a rule by addition of a Friedel-Crafts catalyst (proton or Lewis acid)[6a,159]. The actual attacking electrophile in these catalyzed processes is not known with certainty; as outlined in the introduction, equilibria have been established for these systems in which both oxonium species *(1)* and acylium ions *(3)* are present[4b,160].

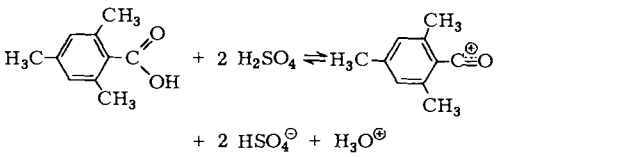
Since Friedel-Crafts acylation normally requires at least equimolar amounts of Lewis acid for acceptable yields, interest has recently been concentrated on truly catalytic processes. Thus, several groups almost simultaneously reported the catalytic effectiveness of traces of Fe salts (≤1 mol-%)[161]. On the basis of our present knowledge of the structure of acylating reagents, it was an obvious step to also try isolated salts of acylium ions *(3)*. An acylium salt was characterized for the first time by *Seel*[162]; the general modes of preparation and especially the preparative applicability of acylium salts have been investigated extensively by *Olah et al.*[159,160,163]. As a rule, these hygroscopic salts, *e.g. (73)*, are treated with a large excess of aromatic substrate in nitromethane solution.

(73)



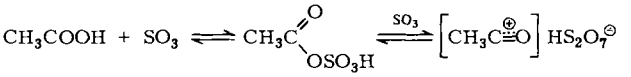
So far, this method of arene acylation has been utilized only sparingly—despite the very good yields of phenone products obtained in most cases. With olefinic[164] and acetylenic substrates[165], however, acylium salts undoubtedly have their advantages compared with the usual acylation reagents. Acylation at low temperature of alkynes with acylium tetrafluoroborates *(74)*, for instance, in the presence of arenes yields the α,β-unsaturated ketones *(76)*[165], *via* reaction of

(74) *(75)* *(76)*

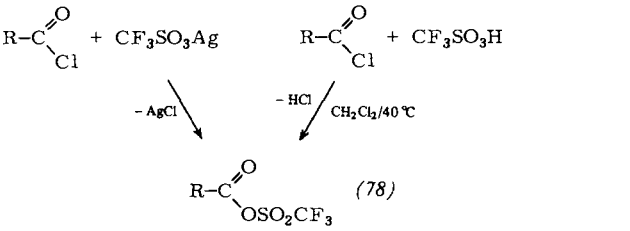


the primarily formed vinyl cations *(75)* with the aromatic substrate.

Thioacylium salts *(77)* are easily prepared[166a]; apparently, they are more stable than the O-analogues[166b].

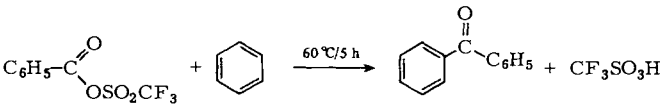


(77)

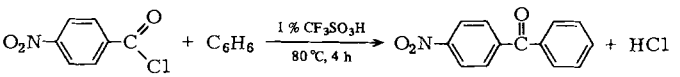


From the observed freezing point depression, it was deduced fairly early that acylium ions are generated by the action of strong mineral acids on carboxylic acids, esters, or anhydrides[167]. This acylium ion formation is particularly pronounced with 2,6-disubstituted benzoic acids.

If carboxylic anhydrides or SO_3-containing sulfuric acid are employed, primary formation of mixed anhydrides is assumed which then dissociate into acylium ions under the influence of a second molecule of SO_3[160,168].



Even diacylium salts of substituted terephthalic acids could thus be obtained and made to react with several nucleophiles[169]. Spectroscopic investigations have shown the presence of mixed anhydrides between carboxylic and very strong inorganic acids in equilibrium with acylium ions and protonated species[160,170]. The reaction of acyl chlorides with silver triflate, and also that of acyl chlorides with trifluoromethanesulfonic acid in inert solvents, gives good yields of carboxylic trifluoromethanesulfonic anhydrides *(78)* in pure form[171].

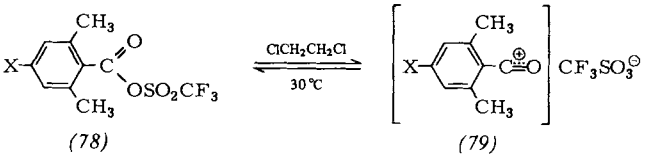


The anhydrides *(78)* can likewise be prepared by reaction of *S*-methyl thiolcarboxylic esters with methyl triflate (with dimethyl sulfide elimination)[172a] or by dehydration of a 1:1-mixture of trifluoroacetic and trifluoromethanesulfonic acid with P_2O_5[172b].

From the high leaving tendency of the triflate ion, the anhydrides *(78)* could be expected to be good acylating agents. This was fully confirmed: their acylation potential is greater than that of all known reagents. With other carboxylic sulfonic anhydrides, for instance, xylenes show no reaction after 24 h at 100 °C[173]; in contrast, the even less reactive benzene is smoothly acylated upon warming with *(78a)* without addition of any Friedel-Crafts catalyst[171]. The trifluoromethanesulfonic acid liberated in the course of the reaction can be recovered quantitatively as barium salt.

(78a) 90%

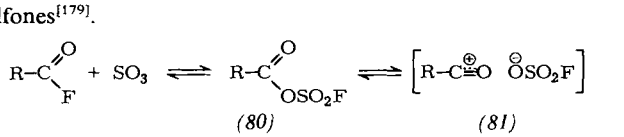
Since the anhydrides *(78)*, on the other hand, are accessible also directly from the acyl chlorides and trifluoromethanesulfonic acid, a way was open for the development of a catalytic arene acylation. The general procedure, worked out along these lines, is specially suited for substrates that otherwise give undesirable side-reactions with the usual Friedel-Crafts catalysts (*e.g.* nitro compounds)[174].



82%

The exceptional position of trifluoromethanesulfonic acid in this respect is exemplified strikingly if one compares the yields for the acylation of *p*-xylene with benzoyl chloride under addition of one 1% each of various strong acids[174]. Heterogeneous acid catalysis for Friedel-Crafts acylation with Nafion-H has recently also been reported[175].

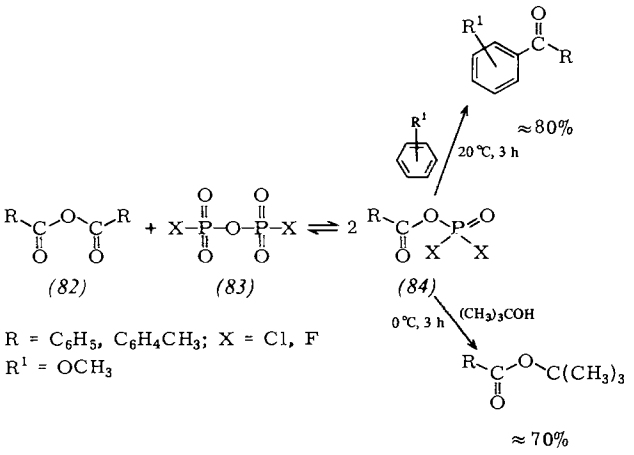
Acid:	CF_3SO_3H	FSO_3H	*p*-H_3C C_6H_4	SO_3H
Ketone yield [%]:	82	20	31	
Acid:	conc. H_2SO_4	$HClO_4$	CF_3COOH	$HPOF_2$
Ketone yield [%]:	28	14	21	4



The extent to which the anhydrides *(78)* are dissociated in inert solvents, *e.g.* dichloroethane, depends in the expected manner on steric and electronic factors in the acyl moiety; the equilibrium concentration of the acylium ions *(79)* correlates fairly well with *Brown*'s σ^+-constants for the substituents X[176], and thus with former results on the relative stability of benzoyl cations[177].

(78) *(79)*

X	X= OCH_3	CH_3	H	Cl	NO_2
Eq. conc. of *(79)* [%]	= 87	66	45	33	10

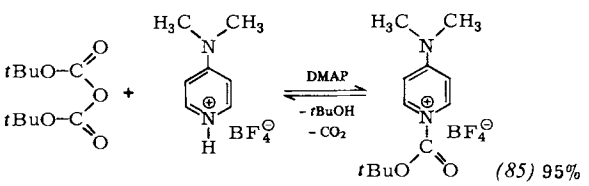


Mixed anhydrides could also be prepared from carboxylic acids and other strong inorganic acids; however, they exhibited no special potential for the acylation of arenes. The carboxylic fluorosulfuric anhydrides *(80)*, for instance, were synthesized by insertion of SO_3 into the C–F bond of acyl fluorides[178,179]. In solution, the anhydrides *(80)* are dissociated into acylium ions *(81)* and fluorosulfate anions[179]; upon reaction with arenes, though, only moderate yields of ketones are obtained, the main side-products being diaryl sulfones[179].

(80) *(81)*

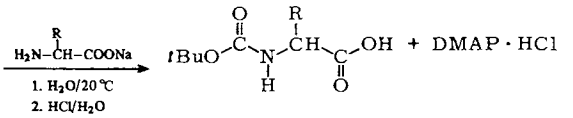
R	= C_6H_5	*p*-CH_3 C_6H_4	*p*-Cl C_6H_4
Yield of *(80)* [%]	= 70	50	50

The anions of dihalophosphoric acids are likewise good leaving groups[180] but, with few exceptions[181], have not yet been applied in organic preparative practice. Recently, carboxylic dihalophosphoric anhydrides *(84)* were prepared in good yield from the anhydrides of the constituent acids, *(82)* and *(83)*. Upon investigation of their reaction behavior[182], they were found to display an exceptional acylation potential which, for example, allows arene acylation under mild conditions without addition of Friedel-Crafts catalysts, and also the esterification of tertiary alcohols in good yield.



(82) *(83)* *(84)*

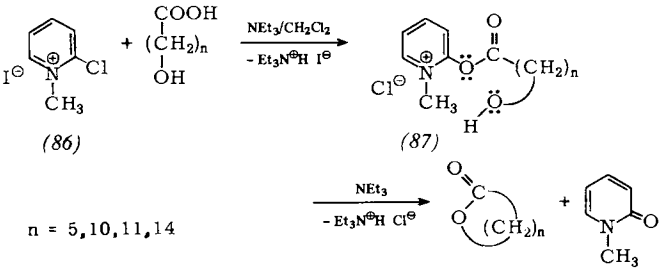
R = C_6H_5, $C_6H_4CH_3$; X = Cl, F
R^1 = OCH_3



The anhydrides *(84a)*, X = Cl, are also formed as intermediates in the reaction of carboxylic acids with $POCl_3$[182], as already postulated by *Th. Wieland*[183]. Carboxylic perchloric anhydrides, which can be prepared in good yield from acyl chlorides and silver perchlorate, are explosive and therefore unsuitable as practical acylating reagents[184].

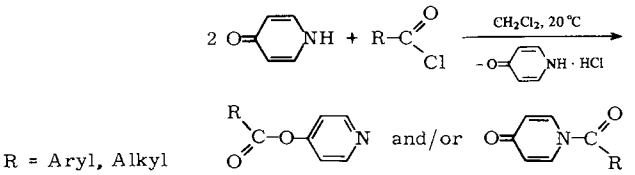
Acylium ions are certainly the reactive species in many normal Friedel-Crafts acylations and also frequently in reactions of the mixed anhydrides of carboxylic and strong inorganic acids described above; it has been doubted[160], though, whether they are sufficiently electrophilic to react with σ-bonds. Protonated acylium ions have therefore been postulated as the effective electrophile in superacid systems[160]; recent calculations have provided additional strong evidence for their existence[185].

The interest of preparative chemists is naturally focused on acylating agents which react both very selectively *and* under mild conditions. Out of the multitude of investigations on reagents for the acylation of OH, NH, and SH functions, we shall discuss primarily those in which heterocyclic moieties are employed as leaving groups. The acylazolides developed by *Staab*'s group[186] are among the most versatile reagents of this type.



(85) 95%

In recent years, the importance also of pyridines and pyridones as leaving groups has grown steadily. Acylation with anhydrides or acyl chlorides in the presence of pyridine has been known for a long time; however, the acceleration of acylation on use of 4-dimethylaminopyridine (DMAP) instead of pyridine was not recognized until comparatively late[187]. The best yields in this procedure are obtained with carboxylic anhydrides and catalytic amounts of DMAP in aprotic and slightly polar solvents; thus, a 96% yield of *N-tert*-butoxycarbonyl amino acid is obtained in the reaction shown below. Pyridinium salts *(85)*, in equilibrium with the reactants, are considered as the reactive electrophiles. Sometimes it is better to employ isolated pyridinium salts, preferentially with anions of low nucleophilicity, in aqueous medium as acylating agents[188]. L-Proline, for instance, can thus be transformed into *N*-butoxycarbonyl L-proline in 96% yield.



The reagents, prepared by *Mukaiyama et al.* from the *N*-alkyl-2-halopyridinium salts *(86)* and carboxylic acids, *e.g. (87)*, allow reaction under very mild conditions[189]; apart from acylated alcohols, thiols, and amines, difficultly accessible lactones could likewise be obtained in good yield by this method[189].

(86) *(87)*

n = 5,10,11,14

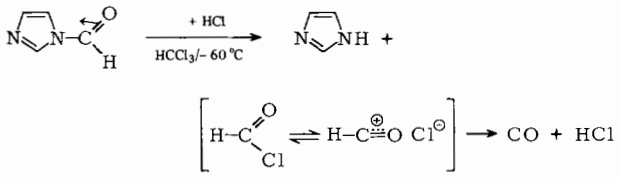
Upon acylation of 4-pyridones, acyloxypyridines *(88)* and/or *N*-acylpyridones *(89)* are formed in good yields, respectively, *via N*- or *O*-reaction[190].

R = Aryl, Alkyl

(88) *(89)*

Acylation with these nonionic acylpyridones, *(88)* and *(89)*[190], as well as with the 2-acyloxypyridines[191], can be carried out in inert solvents under neutral or weakly acidic conditions. In solution, *(88)* and *(89)* are in equilibrium at room temperature; its position strongly depends on the nature of the acyl moiety[190, 192], and in the case of the 2-pyridone is shifted more to the *O*-acyl side[191, 193].

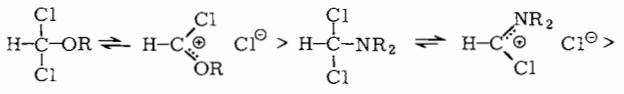
Pentafluorophenyl acetate has recently been reported as a highly selective agent for the acetylation of amino alcohols[194].



9. Formylating and Carboxylating Reagents

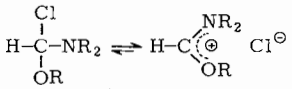
Formylation and carboxylation differ from the principally comparable acylation reactions mainly in generation, stability, and reactivity of the requisite electrophiles. For instance, the formyl derivatives required for a Friedel-Crafts formylation are unstable even at room temperature. Interaction be-

tween Friedel-Crafts catalysts and carbonic acid derivatives, the appropriate electrophiles for carboxylation, appears even more complex than for the carboxylic acid derivatives. Furthermore, the electrophilic potential of carboxylating agents is lowered substantially, relative to that of acylating reagents, by the mesomeric influence of yet another heteroatom (O, N).



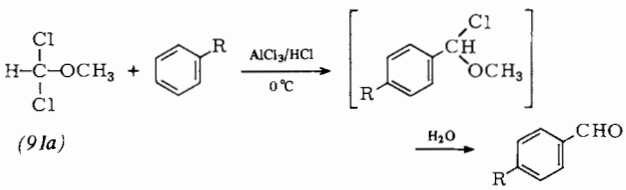
9.1. Formylation[195]

The facile decarbonylation of an intermediate formyl cation *(90)* makes formylations with formyl derivatives problematical; this decomposition reaction is probably also responsible for the instability of formyl chloride and formic anhydride[196].

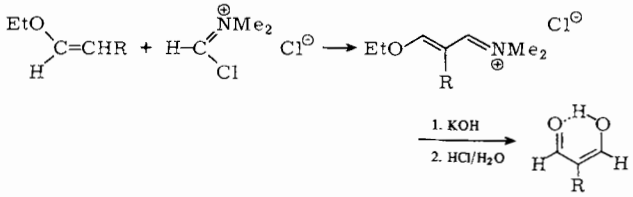


(90)

With formyl reagents where the oxygen atom is suitably substituted or replaced by a nitrogen function, CO elimination can be avoided[197,198]. *(91)*, *(92)*, and *(93)*, for instance, meet these requirements; their definite graduation of reactivity can be derived straightforwardly from the general substituent effects.

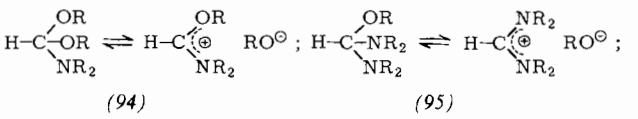


(91) *(92)*



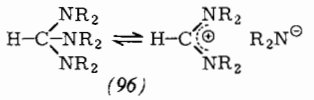
(93)

The stability of the cations generated upon dissociation increases markedly from *(91)* to *(93)*; of course their formylation potential declines concomitantly[197,199]. The non-dissociated α,α-dichlorodimethyl ether *(91a)*, for example, allows formylation even of non- or slightly-activated arenes in the presence of a Friedel-Crafts catalyst; thus, benzene is formylated in 37% yield, and toluene even in 80% yield[200].



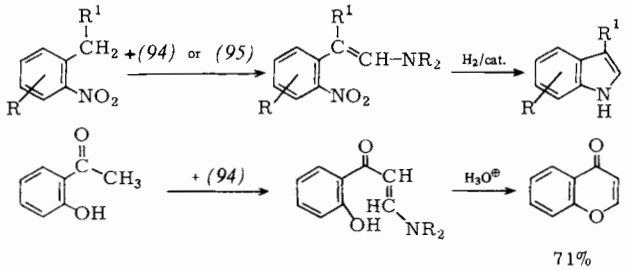
(91a)

The α,α-dichlorotrialkylamines *(92)* (chloromethyliminium chlorides), which are fully dissociated, can be used as formylating agents without Friedel-Crafts catalysis, though only for the more reactive arenes[195,201]. They are also employed in the Vilsmeyer-Haack-Arnold formylation of activated olefins (enol ethers and acetates, enamines); this reaction is of great consequence since it makes polycarboxy compounds accessible, *e.g.* malondialdehyde[202], which constitute important synthetic building blocks.



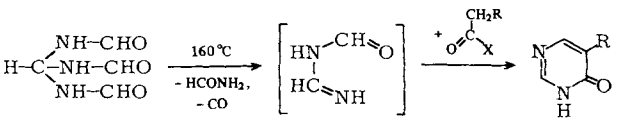
The graduated reactivity of the various formylating agents, accessible from dimethylformamide and, *inter alia,* phosgene, phosphorus oxide chloride, dimethyl sulfate, and mineral acids, has been the subject of a comprehensive investigation[203]. The (expected) reactivity difference between compounds of type *(92)* and *(93)* was shown to depend not only on the stability of the carbenium ion, but also on the nature of the anion[203]. In the formylation of *N,N*-dimethylaniline, the unequal reactivity of some carboxamide complexes of type *(92)* had already been recognized before[204].

Orthoformic acid derivatives have found general interest as formylating agents only since the monoamide diesters *(94)*, diamide esters *(95)*, and triamides *(96)* have become available[205]; their autodissociation (as indicated above) could be demonstrated by conductivity measurements[206].



(94) *(95)*

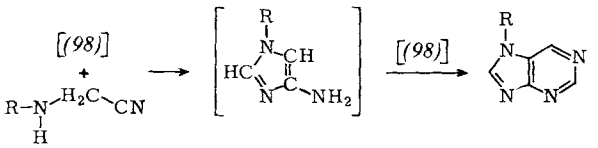
(96)



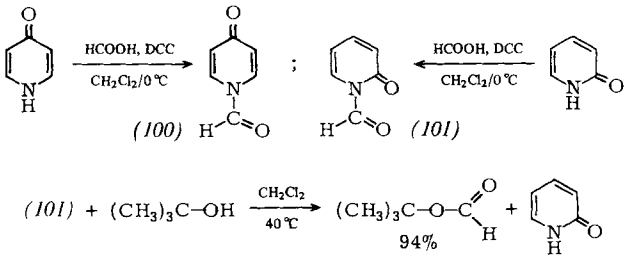
Reactivity decreases markedly in the order *(96)* > *(95)* > *(94)*. This can be rationalized (i) in terms of the degree of dissociation (which in turn is determined by the stability of the ions generated) and (ii) in terms of the different base strength of compounds *(94)*—*(96)*. Higher base strength of the orthoamide derivatives or of the anions $RO^{\ominus}$ and $R_2N^{\ominus}$, respectively, promotes the formation of anions from the CH-acidic substrate which is to be formylated, and hence favors electrophilic attack.

Owing to their low electrophilicity, the orthoamide derivatives listed above are generally unsuitable for the formylation of arenes; they are especially effective formylating agents, though, for CH-acidic substrates[205,207]. Of the respective manifold applications, only a general indene synthesis[208] and a simple preparation of chromone[209] need be mentioned specifically. Sensitive substrates may be formylated in a straightforward manner with *tert*-butoxy-bis(dimethylamino)methane [*"Bredereck's* reagent", see *(95)*][210].

71%



N,N',N''-Methylidinetriformamide *(97)*[211], *s*-triazine, and formamidine acetals [see *(95)*] all represent important formylating agents in the field of heterocyclic synthesis since they at the same time incorporate the amidine component for a subsequent ring closure. For instance, *N*-formyl formamidine *(98)*[212] which is liberated from *(97)* upon heating reacts with carbonyl substrates[213a] or nitriles[213b] smoothly and in good yields to give 5-substituted pyrimidines *(99)*.

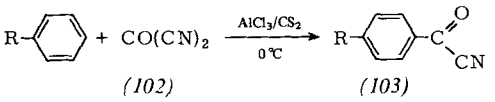


(97) *(98)* *(99)*

R = $COOR^1$, CN, $CONH_2$; X = OR^1, NH_2

This synthetic principle permits facile and efficient purine syntheses[214a], starting from aminoacetonitrile and proceeding *via* a 4-aminoimidazole with subsequent annelation of the pyrimidine ring[214b] (R = CH_3, C_2H_5, C_6H_5; yield 43, 46, 70%, respectively).

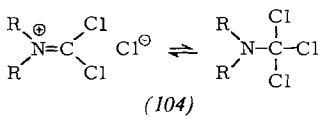
The *N*-formyl pyridones *(100)* and *(101)*, easily accessible from formic acid and dicyclohexylcarbodiimide (DCC), are excellent formylating agents for amines, alcohols, and thiols[215].



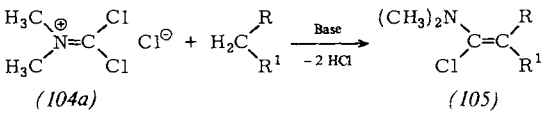
(100) *(101)*

(101) also allows a highly selective formylation of a mixture of primary, secondary, and tertiary alcohols, the tertiary substrates reacting least well, the primary ones best[215]. Even tertiary alcohols which are sterically severely hindered, such as 17α-hydroxyprogesterone, can be transformed into formates with *(101)* in dichloromethane at 40 °C[215]. Above 40 °C, *(101)* also shows a considerable extent of decarbonylation.

9.2. Carboxylation[6b, 159]



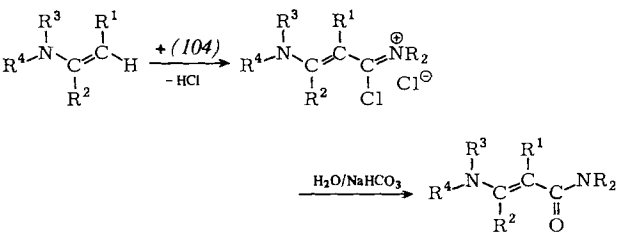
The general aspects of Friedel-Crafts acylation of course apply also to carboxylation; as in the case of the formylation reaction, though, there are no carbonic acid derivatives which might be used as generally applicable reagents[216]. For acylations, halides are nearly always employed in practice; the corresponding haloformates, however, decarboxylate under the action of Friedel-Crafts catalysts[217], and then act as alkylating agents. With the dihalide phosgene, aroyl chlorides are formed from arenes in the presence of Friedel-Crafts catalysts; as a rule, though, these are further converted into aromatic ketones under the reaction conditions. With carbonyl dicyanide *(102)* in place of phosgene, this secondary reaction is avoided[218], and aroyl cyanides *(103)* are obtained in good yield; the drawback of the procedure is that *(102)* is not as easily accessible as $COCl_2$[218].



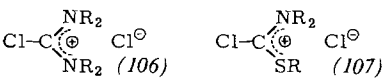
(102) *(103)*

R	= H	CH_3	Cl
Yield [%]	= 71	79	16

The more reactive dichloromethyleneiminium chlorides *(104)* (phosgeneiminium salts) constitute far better carboxylating agents[219]; they are specially suited for the carboxylation of CH-acidic substrates which are thus converted into α-chloroenamines *(105)*[219,220].



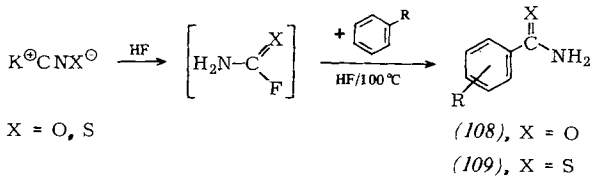
(104)



(104a) *(105)*

R	= CN	CN	COOEt
R^1	= CN	COOEt	$Ph_3P^{\oplus}$
Yield [%]	= 77	85	62

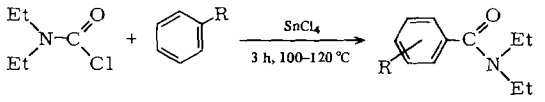
Enamines[221] and enol ethers[219] can likewise be carboxylated in good yield with these phosgeneiminium salts. However, their electrophilic potential in general is not sufficient for carboxamidation of arenes, except in the case of highly activated substrates such as *N,N*-dimethylaniline or resorcinol dimethyl ether[219].



On replacement of one Cl atom in the phosgeneiminium salts *(104)* by another hetero substituent, they still remain potential carboxylating agents; since the higher +*M* effect of these substituents diminishes their reactivity, however, chloro formamidinium salts *(106)*[222a] and also the sulfur compounds *(107)*[222b] are of little significance as carboxylating agents.

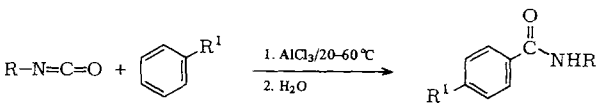
(106) *(107)*

The carboxamidation of arenes (Gattermann amide synthesis) presents some preparative problems since the unstable carbamidic chloride is difficult to handle. This disadvantage can be avoided by using KOCN in HF[223]; under these conditions, the carbamoyl fluoride formed *in situ* immediately reacts with the aromatic substrate to give the benzamides *(108)*. Potassium rhodanide may analogously be employed for the synthesis of *thio*amides *(109)*[223].



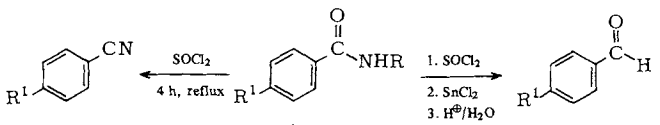
X = O, S

(108), X = O
(109), X = S



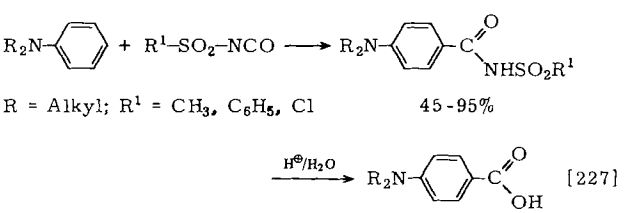
R	= H	CH_3	Cl
Yield of *(108)* [%]	= 63	70	9

Carboxamidation of alkyl arenes with *N,N*-diethylcarbamoyl chloride is less complicated and gives better yields[224].



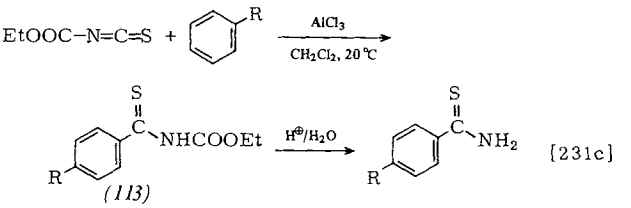
R = Alkyl 69-93% (≥80% *p*-Isomer)

Arene carboxylation with isocyanates and isothiocyanates has proven exceptionally advantageous. *Leuckart* had already obtained *N*-substituted amides *(110)* from the reaction of aromatic isocyanates with activated arenes in the presence of $AlCl_3$[225]. This facile synthesis for aromatic carboxamides was later extended also to less activated aromatic substrates and aliphatic isocyanates[226a].



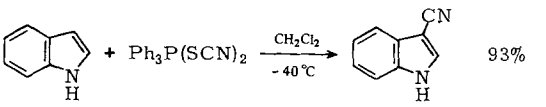
R^1 = Alkyl, Halogen, Alkoxy *(110)* 65-100%

Use of aliphatic isocyanates is preparatively advantageous since the *N*-alkyl amides *(110a)*, R = alkyl, offer the possibility of further chemical conversion; upon warming with thionyl chloride, for instance, they are transformed into the nitriles *(111)*, and, *via* the imidoyl chlorides, with Sn(II) chloride into the aldehydes *(112)*[226b].



(111), 90-100% *(110a)* *(112)*
R^1 = F, 83%

With the more reactive sulfonyl isocyanates, *Seefelder*[227] and *Graf*[228] succeeded in carboxamidating electron-rich arenes (dialkylanilines, resorcinol dimethyl ether) and hetarenes (pyrrole, thiophene, indene, carbazole) in good yields even without addition of Friedel-Crafts catalysts[229,230].



R = Alkyl; R^1 = CH_3, C_6H_5, Cl 45-95% [227]

Isothiocyanates can similarly be reacted with arenes, though in the presence of $AlCl_3$, to *N*-substituted thioamides *(113)*[231].

R	= H	CH_3	*t*-Bu	CH_3O	Cl
Yield of *(113)* [%]	= 52	63	41	90	29

By the use of cyanogen halides or alkyl cyanates, a direct electrophilic introduction of the CN function is possible with highly nucleophilic groups (OH, SH, NH); only poor yields are obtained with aromatic substrates[232]. Good yields of cyanation products are achieved with triphenylphosphane/dirhodane in the case of reactive hetarenes (indene, pyrrole)[233].

10. Concluding Remarks

I have tried in this contribution to delineate the general trends in the development of new electrophilic species and, at the same time, to show up the preparative advantages and the applicability of these novel reagents.

The "super-leaving groups", known from carbenium ion chemistry (*e.g.* triflate and fluorosulfate), are doubtless of crucial importance in this context. Since their paramount importance in solvolysis reactions had already been recognized in the sixties, it is indeed surprising that their specific properties were not utilized until so much later for the development of new, highly effective electrophiles.

A second trend noted in recent years is towards more and more selective electrophiles. To this end, heterocyclic moieties in particular have been employed as leaving groups; in many instances, this also allows working under neutral and/or aprotic conditions. At the same time, it has been recognized more and more clearly that the interaction of charged electrophiles with solvents containing lone pairs (*e.g.* nitriles, tertiary amines, ethers, thioethers, nitro and halo compounds) constitutes a decisive factor; reactivity and selectivity of the electrophile can thus be varied in a controlled fashion.

Electrophilic metalation, phosphorylation, and silylation have deliberately been excluded from this account, since the alternative mechanistic routes which would have to be discussed for these reactions lie outside the scope of this review.

My sincere thanks go to my dedicated co-workers, both former and present, who have collaborated in the work cited here. Generous support of our investigations by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

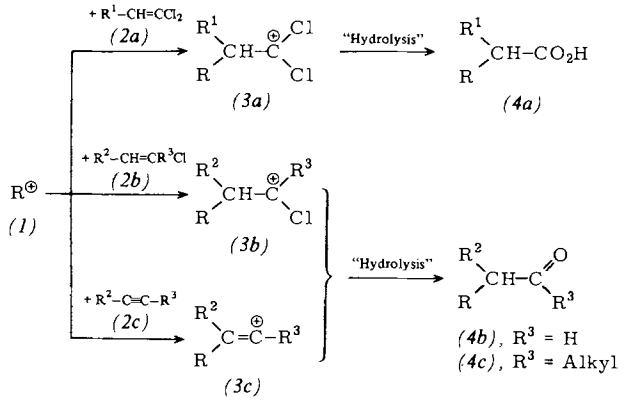
Coupling of Solvolysis and C—C Linkage: A Promising Synthetic Route to Functionalized Carboxylic Acids, Aldehydes, and Ketones

By Kaspar Bott[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Numerous additions of carbocations to chloroolefins or acetylenes can be coupled with a solvolysis step when performed in a suitable acid; the products are variously substituted carboxylic acids, aldehydes, and ketones. Factors determining the success of these syntheses are the stability of the intermediate carbocations and suppression of the competing addition of protons to the unsaturated reaction component. Under the conditions of the Tscherniac-Einhorn reaction, amidomethylation of chloroolefins and acetylenes, *i.e.* the introduction of acylaminomethyl groups, is shown not to involve a trigonal α-chloro carbocation or a linear vinyl cation, but instead to proceed *via* a cyclic oxazinium ion intermediate.



1. Introduction

Many syntheses in organic chemistry are possible only if C—C linkage is followed by an energetically favored step, such as salt formation. Typical examples of this strategy are the carbonylation of aromatic hydrocarbons according to *Gattermann-Koch*[1] and ester condensation according to *Claisen*[2].

In the following we shall survey those reactions in which the formation of an intermediate *(3a–c)* from the carbocation *(1)* and the unsaturated component *(2a–c)* is forcibly coupled with the energetically particularly favorable hydrolysis to

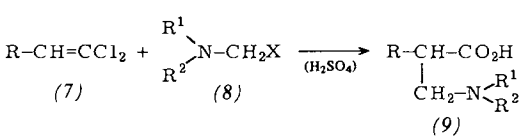
give carboxylic acids *(4a)*, aldehydes *(4b)*, and ketones *(4c)*. Thus, subsequent elimination of *(1)* from the intermediate *(3)* is practically impossible.

As will be shown for a particular example (Section 2.3) the production of carbonyl compounds *(4a-c)* according to the given synthetic scheme has the decisive advantage that the adduct ions *(3a-c)* can be generated under much milder reaction conditions than is otherwise possible.

In the preferred reaction medium, *viz.* sulfuric acid, the synthetic step leading to *(3)* must compete with addition of a proton to the olefin *(2a,b)* or to the acetylene *(2c)*. For instance, chloroacetic acid *(6)* thus arises from trichloroethylene *(5)*:



Carboxylic acids *(4a)*, aldehydes *(4b)*, and ketones *(4c)* can only be obtained in good yields if such competing saponifications can be forced into the background.

2. Synthesis of Carboxylic Acids

2.1. β-Acylamino Carboxylic Acids

The reaction named after *Tscherniac* and *Einhorn* permits the introduction of an acylaminomethyl group ("amidomethyl group") into an aromatic ring[3] or into an activated methylene group[4]. Since these syntheses normally take place in strong sulfuric acid, it was to be expected that suitable amidomethyl cations [from *(8)*] would react with the 1,1-dichloroolefins *(7)* to form *N*-acylated β-amino carboxylic acids.

According to available studies[5-7] (cf. Table 1) the weakly basic dichloroalkenes *(7)* require particularly electron-poor amidomethyl cations as reagents. In the choice of the amidomethylation agent *(8)* the phthalimido, maleimido, trichloroacetamido, and trifluoroacetamido group have proved of advantage as amide component, whereas not only the usual anionic substituents such as chlorine or hydroxyl, but also the carboxamide components R^1R^2N—, represent possible choices for X. A further possibility for generation of amidomethyl cations consists in dissolving the carboxamide R^1R^2NH and (oligomeric) formaldehyde in sulfuric acid prior to addition of the olefin *(7)*.

Table 1. β-Acylamino carboxylic acids *(9)* from 1,1-dichloroolefins *(7)* and amidomethylating reagents *(8)*.

Phthaloyl =  ; Maleoyl = 

	R	R₁ R²	X	Yield of *(9)* [%] [a]
(9a)	Cl	Phthaloyl	OH	94
(9b)	Cl	Cl_4-Phthaloyl	OH	92

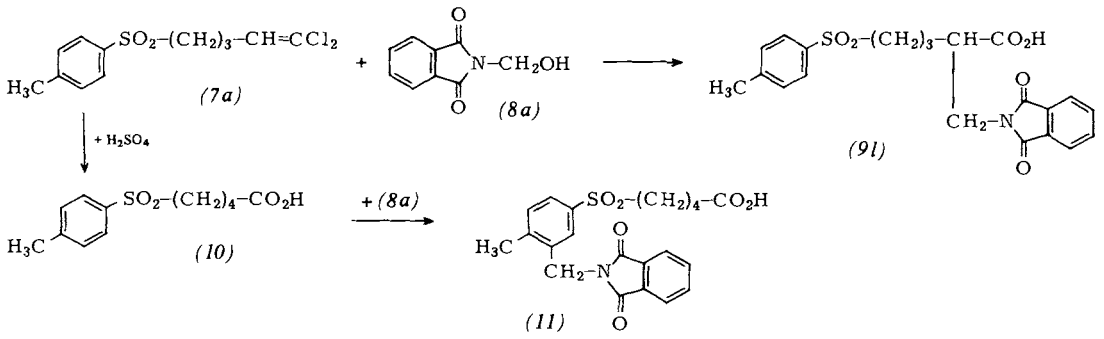
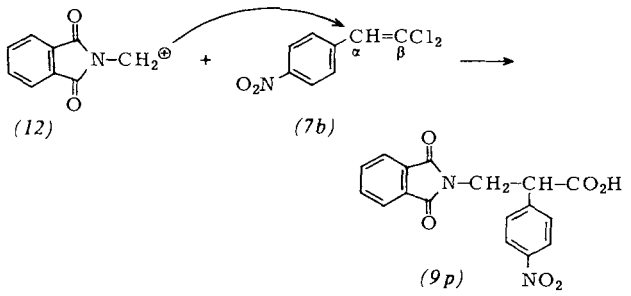
(9o)	Phthalimido-$(CH_2)_3$	Phthaloyl	OH	95
(9p)	p-$NO_2C_6H_4$	Phthaloyl	OH	92



[a] The yields are based on the reactant used in substoichiometric amounts.
[b] Amidomethylation with trioxane + trichloroacetamide.

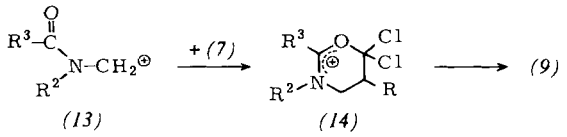
The 1,1-dichloroolefins *(7)* and chloroolefins *(46)* used in the synthesis of β-(acylamino) carbaldehydes exhibit a clear gradation of reactivity towards the electrophilic reagent *(8)*, which is manifested in the differing reaction temperatures. The temperature for reaction of vinyl chloride[8] is 0 to 5 °C, that for 1,1-dichloroethylene and its alkyl derivatives 5 to 15 °C, that for 1,2-dichloroethylene 30 to 35 °C, that for trichloroethylene and 1,1-dichloro-2-(*p*-nitrophenyl)ethylene is 40 to 50 °C, and finally that for 2-bromo-1,1-dichloroethylene is 50 to 60 °C.

Tscherniac-Einhorn syntheses with the 1,1-dichloroalkenes *(7)* are carried out in 95% sulfuric acid, and prove highly productive on use of *N*-(hydroxymethyl)phthalimide *(8a)* and its tetrachloro derivative. Comparison of the data listed in Table 1 shows that the yield always drops considerably upon incorporation of a trichloro- or a trifluoroacetamidomethyl group.



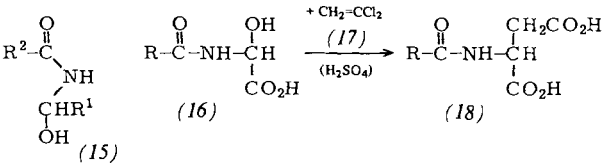
Preparation of *N*-acylated β-alanines in which R, as in *(9i)* and *(9j)*, is an arylalkyl group requires that the aryl group be protected against amidomethylation by a strongly electron-withdrawing substituent.

For the same reason, it is necessary to avoid an excess of *N*-(hydroxymethyl)phthalimide *(8a)* on preparation of 2-(phthalimidomethyl)-5-(*p*-toluenesulfonyl)valeric acid *(9l)*. If 1,1-dichloro-5-(toluenesulfonyl)-1-pentene *(7a)* is first allowed to react only with sulfuric acid at room temperature and the component *(8a)* is added on completion of "acidolysis", then the carboxylic acid *(11)* isomeric with *(9l)* results as



final product. The structure of *(9l)* follows unequivocally from the ^{1}H-NMR-spectrum.

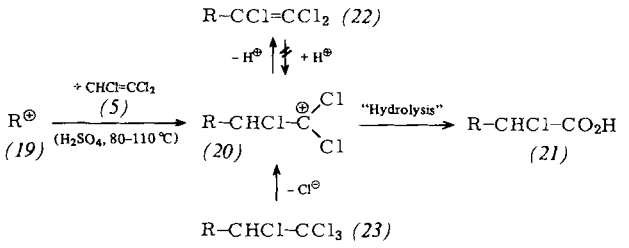
The last example listed in Table 1, *viz.* 2-(*p*-nitrophenyl)-3-phthalimidopropionic acid *(9p)* is of interest because, in its formation, the "positive end" of the phthalimidomethyl cation *(12)* does not attack the β-position, as might have been expected, but only the α-C atom of the styrene skeleton of *(7b)*.



Evidence is available showing that the addition of the amidomethyl cation *(13)* to the dichloroolefins *(7)* does not proceed *via* an open-chain dichloro carbocation [such as *(3a)*] but can profit from concerted formation of a low-energy oxazinium intermediate *(14)*. Thus "true" carbocations react with trichloroethylene *(5)* (Section 2.3) in sulfuric acid only

at 80 to 110 °C whereas amidomethylation of the same olefin occurs under much milder conditions. As considered in more detail later (Section 3.1), the stereoisomeric cycloadducts can be isolated in high purity on treatment of the cation *(12)* with *cis/trans* isomeric olefins in chlorohydrocarbon solvents.

2.2. *N*-Acylaspartic Acids



The use of amidomethylation agents *(15)* bearing an aliphatic group R^1 in the synthesis of β-amido carboxylic acids is subject to limitations because the substances *(15)* as aldehyde derivatives normally have a very short lifetime in sulfuric acid. In contrast, α-(acylamino)glycolic acids *(16)* (*N*-acyl-α-hydroxyglycines), accessible from glyoxylic acid (carboxylated formaldehyde), have a stability comparable with that of *N*-hydroxymethylcarboxamides *(8)*, X = OH, in concentrated mineral acids.

1,1-Dichloroethylene *(17)* is the only chloroolefin component tried so far in reactions of compounds *(16)* and butyl α-hydroxyhippurate[9,10]. The *N*-protected aspartic acids *(18)*, R = ethoxy or *n*-butoxy or phenyl, were obtained in yields of 47 to 87%, at reaction temperatures between 0 and 20 °C.

2.3. α-Chloro Carboxylic Acids

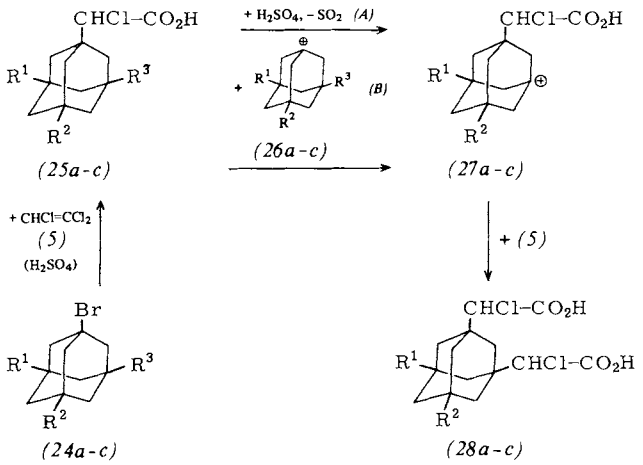
The addition of carbocations to 1,1-dichloroethylene *(17)* in sulfuric acid has already been surveyed in detail[11]. Application of this reaction proceeding under mild conditions (5 to 10 °C) to the less basic compound trichloroethylene *(5)* requires that the temperature be raised to 80 to 110 °C[12,13]. Under such drastic conditions the only substances that can react with *(5)* to give the α-chloro carboxylic acids *(21)* are those in which olefin formation from the intermediate carbocation *(19)* is strongly suppressed or completely ruled out.

In this context, it is of interest whether the products *(22)* and *(23)* resulting from the classical Prins reaction of an alkyl chloride RCl and *(5)* can be transformed into a substituted chloroacetic acid *(21)* *via* a common intermediate *(20)*. With the aid of readily accessible model substances it could be demonstrated[13] that 1,1,1,2-tetrachloro-3-(*p*-nitrophenyl)propane [*(23)*, R = *p*-nitrobenzyl] is hydrolyzed only slowly (25% conversion after 5 h) to α-chloro-*p*-nitrohydrocinnamic acid even at 115 °C, whereas 1,1,2-trichloro-3-(*p*-nitrophenyl)-1-propene [*(22)*, R = *p*-nitrobenzyl] and trichloro(2-norbornyl)ethylene [*(22)*, R = 2-norbornyl] are

largely oxidized by sulfuric acid. However, the trichloroolefins *(22)* were isolated in some cases as by-product of carboxylic acid synthesis from *(19)* and *(5)*.

2.3.1. Introduction of the Chloroacetic Acid Group into the Adamantane System[12,13]

Reaction of trichloroethylene *(5)* with the bromoadamantanes *(24a–c)*, which serve as precursors of 1-adamantyl cations *(26a–c)*, does not stop at α-chloro-1-adamantaneacetic acids *(25a–c)*. The greater part of *(25a–c)* reacts once again after hydride abstraction from the bridgehead position with *(5)* to give α,α′-dichloro-1,3-adamantanediacetic acids *(28a–c)* (see Table 2). The extent to which *(28a–c)* are formed expectedly depends upon the reaction temperature, the sulfuric acid concentration, and the degree of bridgehead substitution.



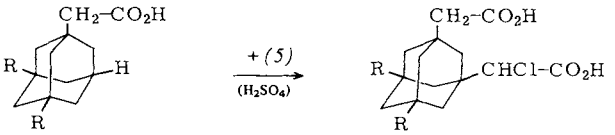


Table 2. Production of α-chloro-1-adamantaneacetic acids *(25)* and α,α′-dichloro-1,3-adamantanediacetic acids *(28)* from 1-bromoadamantanes *(24)* and trichloroethylene *(5)* in 90% sulfuric acid at 100 to 105 °C [a].

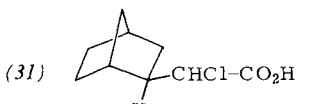
	R_1	R_2	R_3	Yields [%]	
(24a)	H	H	H	*(25a)* 15	*(28a)* 65
(24b)	CH_3	H	H	*(25b)* 26	*(28b)* 55
(24c)	CH_3	CH_3	H	*(25c)* 28	*(28c)* 37
(24d)	CH_3	CH_3	Br	—	*(28c)* 88
(24e)	CH_3	CH_3	CH_3	*(25e)* 94	—

[a] The yields of *(25a–c)* and *(28a–c)* are based on the amounts of *(24a–c)* used. The amount that is lost as (methylated) adamantane by addition of hydride to *(26a–c)* is disregarded.

The intermediate carbocations *(27a–c)* are generated from *(25a–c)* both by oxidation with sulfuric acid (path *A*) and by hydride transfer to *(26a–c)* (path *B*). Remarkably, the transformation of the 1-adamantyl cations *(26)* into 2-adamantanones observed by *Geluk* and *Schlatmann*[14,15] fails to take place in the presence of trichloroethylene.

In order to isolate the synthetic products *(25)* and *(28)*, their methyl esters are separated by fractional distillation. These esters arise as mixtures of the *meso* forms with the diastereomeric pairs of antipodes; the highly viscous oils do not show any particular tendency to crystallize. 1,3-Dibromo-5,7-dimethyladamantane *(24d)* and 1-bromo-3,5,7-trimethyladamantane *(24e)* may be regarded as ideal model substances for selective syntheses because they react with *(5)* to give high yields of α,α′-dichloro-5,7-dimethyl-1,3-adamantanediacetic acid *(28c)* and α-chloro-3,5,7-trimethyl-1-adamantaneacetic acid *(25e)*, respectively. If the 1-adamantaneacetic acids *(29a)* and *(29b)* are allowed to react with trichloroethylene *(5)* in 95% sulfuric acid, then only one chloroacetic acid group is introduced at the (unsubstituted) bridge-

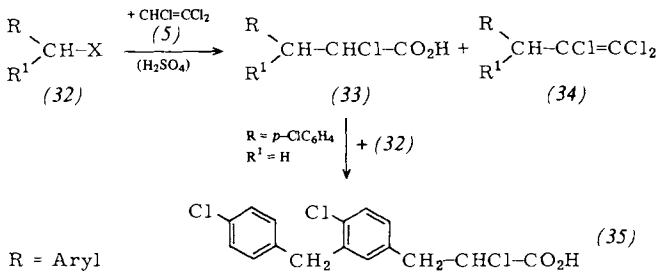


(29) *(a)*, R = H; *(b)*, R = CH_3 *(30)*

head position; the dicarboxylic acids *(30a)* and *(30b)* are formed highly selectively in yields of 85–86% based on the degree of conversion. The abstraction of hydrogen as hydride ion which precedes addition of trichloroethylene is relatively slow. Preparation of the 3-(carboxymethyl)-α-chloro-1-adamantaneacetic acids *(30a)* and *(30b)* requires temperatures between 105 and 115 °C. In order to perform the reaction under normal pressure, compound *(5)* must therefore be diluted with perchlorobutadiene since it boils at 87 °C. Formation of side products is minimized by keeping the conversion of *(29)* below 80%.

2.3.2. α-Chloro-2-*exo*-norbornaneacetic Acid

Another carbocation in the cycloaliphatic series which possesses considerable stability is the 2-norbornyl cation. Hence, α-chloro-2-*exo*-norbornaneacetic acid *(31)* can easily be synthesized from norbornene or norborneol and trichloroethylene (yield 66%).



Proof of structure was obtained by dehalogenating the mixture of the two diastereomeric pairs of antipodes *(31)* with zinc. The anilide of the resulting *exo*-norbornaneacetic acid was identical with an authentic sample[16].

On introduction of a methyl group, the 2-norbornyl cation loses its ability to add to trichloroethylene. An alkyl substituent apparently facilitates formation of an olefinic double bond which undergoes secondary reactions such as oxidation, polymerization, or sulfonation.

2.3.3. α-Chlorohydrocinnamic Acids[13,17]

The preparation of α-chlorohydrocinnamic acids *(33)* from benzyl alcohols or their esters *(32)* and trichloroethylene *(5)* in sulfuric acid requires the presence of strongly electronegative substituents on the benzene ring. Otherwise, the initially formed carboxylic acids *(33)* undergo nuclear alkylation; this leads mainly to substances of higher molecular weight such as *(35)*.

It can be unequivocally demonstrated in the case of the reaction of *p*-chlorobenzyl alcohol *(32)*, R = *p*-chlorophenyl,

$R^1 = H$, X = OH, with *(5)* that the initial alkylation step leading to *(35)* is followed by further substitutions. This is the reason why no distillable products can be isolated even after esterification with methanol.

In the pentachlorobenzyl cation *(37)*, on the other hand, all the positions of the benzene ring could be blocked by substituents. For this reason, the pentachlorobenzyl half ester *(36)* of disulfuric acid, readily accessible by oxidation of pentachlorotoluene with sulfur trioxide, reacts without the complications mentioned with trichloroethylene *(5)* to give 3-(pentachlorophenyl)-2-chloropropionic acid *(38)*[18].

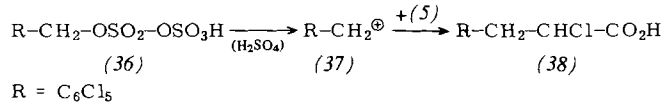


Table 3 surveys those substituents which can protect the benzene ring in compounds of type *(33)* from electrophilic attack and thus favor addition of phenylcarbenium ions to trichloroethylene *(5)*.

Table 3. Synthesis of α-chlorohydrocinnamic acids *(33)* from *(32)* and trichloroethylene *(5)*.

$RR^1CHX + CHCl{=}CCl_2 \rightarrow RR^1CH\ CHCl\ CO_2H$

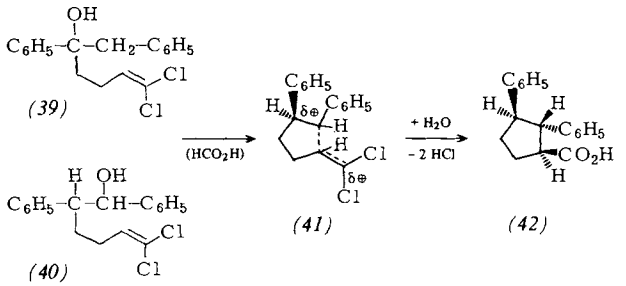
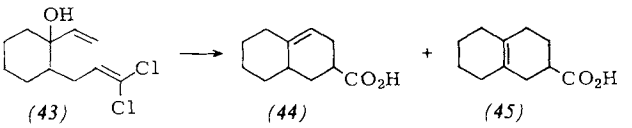
(33j)	*m*-O_2N C_6H_4	*m*-O_2N C_6H_4	Cl	71 [b]



[a] Obtained as methyl ester. [b] Determined after conversion into the cinnamic acid derivative. [c] Isolated as methyl *p*-benzenesulfonylcinnamate. [d] A considerable amount of the product is destroyed by decarboxylation. [e] 51% of higher molecular carboxylic acids are also formed.

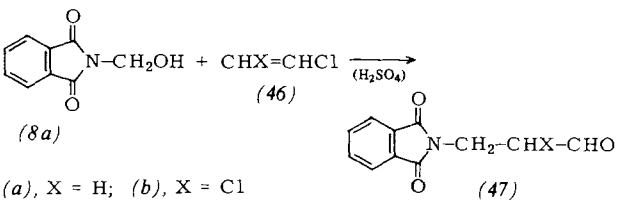
Apart from hydrocinnamic acids *(33)*, this synthesis also yields trichloroethylene derivatives *(34)*, isolable in yields between 2 and 6%.



With regard to the production of α-chloro-β-arylhydrocinnamic acids such as *(33i)* and *(33j)*, the synthesis of carboxylic acids with trichloroethylene complements the Meerwein reaction[19], which can only be employed when $R^1 = H$. The preparative utility of these syntheses is underscored by the possibility of obtaining cinnamic acids in high yields by treating α-chloro-hydrocinnamic acids *(33)* with sodium hydroxide.

2.4. Cycloalkanecarboxylic Acids

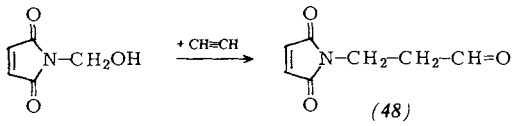
Production of cycloalkanecarboxylic acids by intramolecular addition of a carbocation to a dichlorovinyl terminal group occupies a special place[20]. If five- or six-membered rings are to be constructed, C—C linkage is successful in formic acid as reaction medium. Refluxing a solution of the isomeric deoxybenzoins *(39)* or *(40)* in formic acid gives *trans,trans*-2,3-diphenyl-1-cyclopentanecarboxylic acid *(42)* (yield *ca.* 50%), regardless of which starting material is used.



The result indicates that the carbocations formed initially from the alcohols *(39)* and *(40)* are in mutual equilibrium and that in the case of the energetically less favorable secondary carbocation [from *(40)*] the transition state *(41)* of the cyclization step has a lower energy content. In the same way, the allyl alcohol *(43)* can be transformed into a mixture of the double-bond isomeric octalincarboxylic acids *(44)* and *(45)* (overall yield 40%) while the likewise feasible ring closure to give cyclobutane fails to occur.

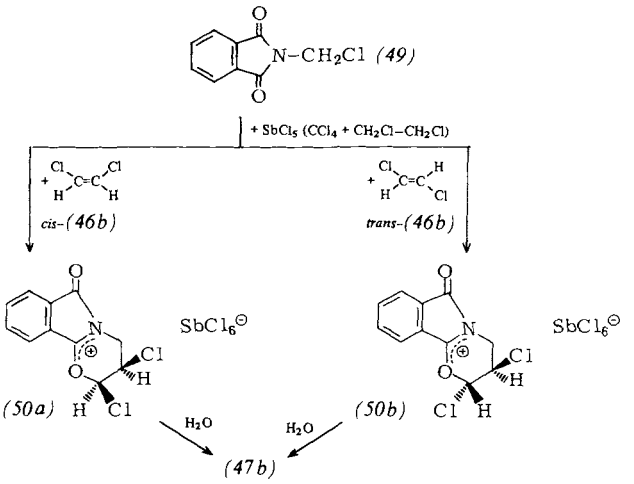
3. Synthesis of Aldehydes and Ketones

3.1. β-Acylamino Carbaldehydes and β-Acylamino Ketones



The reaction of vinyl chloride *(46a)* and *cis*- or *trans*-1,2-dichloroethylene *(46b)* with *N*-(hydroxymethyl)phthalimide *(8a)* in 90 to 96% H_2SO_4 provides a facile entry to 3-phthalimidopropionaldehydes *(47a)* and *(47b)* (yield 83 and 53%, respectively)[7,21].

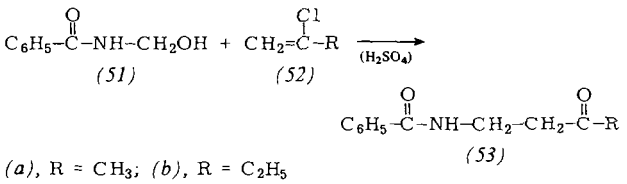
Use of acetylene in place of *(46a)* proves just as successful. Reaction goes to completion within a few minutes at 5 to 10 °C under normal pressure, as can be seen from the cessation of acetylene take-up.



3-Maleimidopropionaldehyde *(48)* synthesized in the same way from *N*-(hydroxymethyl)maleimide and acetylene cannot be isolated in the pure state owing to its pronounced tendency to polymerize; however, titration of the crude product

against hydroxylammonium chloride solution shows the yield of aldehyde to be 80%.

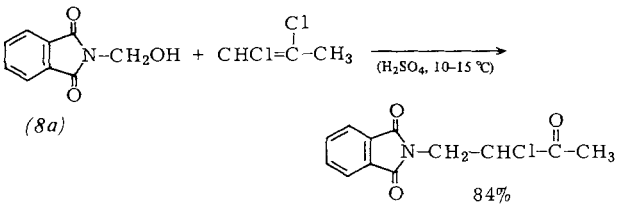
(48)



It is unlikely that the action of *N*-(hydroxymethyl)carboxamides on acetylene in sulfuric acid affords "free" vinyl cations which would be easily recognizable from their rearrangement products (cf. Section 3.2). Instead, as in the case of chloroolefins *(7)* and *(46)*, synchronous formation of a cyclic intermediate can be assumed. Such a reaction course can easily be detected by treating an equimolar mixture of antimony pentachloride and *N*-(chloromethyl)phthalimide *(49)* with the pure isomers of 1,2-dichloroethylene *(46b)* in chlorohydrocarbons. The expected cycloadducts *(50a)* and *(50b)* can be isolated as crystalline hexachloroantimonates[7].

The NMR spectra of the two dihydrooxazinium hexachloroantimonates reveal that *(50a)* and *(50b)* each contain at most 10% of the other isomer. Water rapidly transforms the isolated salts into the 2-chloro-3-phthalimidopropionaldehyde *(47b)*.

The proposed synchronous mechanism for the generation of the intermediate from a chloroolefin or acetylene and an amidomethyl cation suggests a low-energy transition state according to the Woodward-Hoffmann rule[22]. Further support for one-step construction of the dihydrooxazine comes from stereochemical results obtained by *R. R. Schmidt*[23] on amidomethylation of olefins more strongly basic than *(7)* and *(46)*.

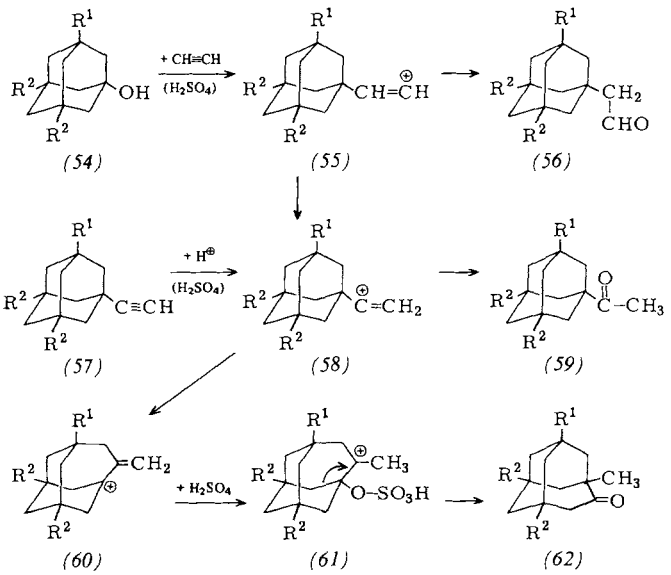


Replacement of the α-hydrogen by an alkyl group in the vinyl chloride *(46a)* affords the considerably more acid-sensitive 2-chloro-1-alkenes *(52)*. Consequently, it is not surprising that 2-chloro-1-propene *(52a)* is merely saponified to acetone by a solution of *N*-(hydroxymethyl)phthalimide *(8a)* in 80 to 90% sulfuric acid. At the same time, *(8a)* affords *N*-(chloromethyl)phthalimide *(49)*. Only on use of the more readily ionizing amidomethylation agent *N*-(hydroxymethyl)benzamide *(51)* is it possible to prepare the desired *N*-(3-oxobutyl)benzamide *(53a)* (yield 51%) and *N*-(3-oxopentyl)benzamide *(53b)* from *(52a)* and *(52b)*, respectively.

(51) (52) (53)

(a), R = CH_3; (b), R = C_2H_5

The introduction of a second chlorine atom into the vinyl group of *(52a)* markedly decreases the reactivity of the corresponding olefin towards strong acids. Thus 1,2-dichloro-1-propene is still capable of reacting with *N*-(hydroxymethyl)phthalimide *(8a)* to form *N*-(2-chloro-3-oxobutyl)phthalimide (84% yield), even though 95% sulfuric acid is used as the reaction medium.



(8a)

3.2. Aldehydes and Ketones Belonging to the Adamantane Series

In 90 to 95% sulfuric acid, 1-adamantanol *(54a)* and its bridgehead methyl derivatives *(54b,c)* already react at 4 to 7 °C within just a few minutes with an equimolar amount of acetylene[24,25]. Subsequent hydrolysis affords 1-adamantaneacetaldehydes *(56a–c)*, 1-adamantyl methyl ketones *(59a–c)*, and homoadmantan-2-ones in overall yields between 88 and 95%. The following product composition is found for 1-adamantanol *(54a)*: 72% *(56a)*, 3% *(59a)*, and 25% *(62a)*.

Hydride exchange between the 1-adamantyl cations and the adamantaneacetaldehydes *(56a)* or *(56b)* with free bridgehead sites, giving mainly 1,3-adamantanediacetaldehydes and (methylated) adamantanes, can be avoided by

(54) (55) (56) (57) (58) (59) (60) (61) (62)

(a), $R^1 = R^2 = H$; (b), $R^1 = H$, $R^2 = CH_3$; (c), $R^1 = R^2 = CH_3$

Table 4. Relative yields of 1-adamantyl methyl ketones *(59)* and homoadamantan-2-ones *(62)*.

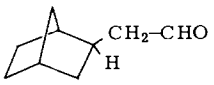
Reactants	$R^1 = R^2$	Relative yields	
		(59) [%]	*(62)* [%]
(54a) + C_2H_2	H	*(59a)* 11	*(62a)* 89
(54c) + C_2H_2	CH_3	*(59c)* 29	*(62c)* 71
(57a)	H	*(59a)* 31	*(62a)* 69
(57c)	CH_3	*(59c)* 48	*(62c)* 52

dropwise addition of solutions of the adamantanols *(54a)* and *(54b)* to sulfuric acid in an acetylene atmosphere.

Separation of the products *(56)*, *(59)*, and *(62)*, on a preparative scale can be accomplished by chemical means, *i. e.* by exploiting their significant gradation of reactivity [*(56)* > *(59)* > *(62)*] towards carbonyl reagents for selective precipitation of the semicarbazones[26].

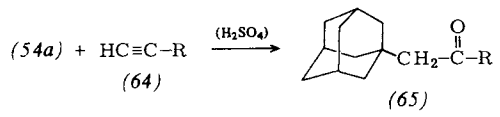
As shown by the scheme, the adamantols *(54)* and acetylene initially form 2-(1-adamantyl)vinyl cations *(55)* which are then largely converted into the adamantaneacetaldehydes *(56)*. This stabilization step presumably proceeds *via* an enol sulfuric acid half ester[27,28]. A small proportion of *(55)* rearranges to the lower-energy 1-(1-adamantyl)vinyl cations *(58)* which can be generated directly by protonation of the adamantylacetylenes *(57)*. Cations *(58)* react to a lesser extent to give the adamantyl methyl ketones *(59)*; the principal reaction is transition to the "trigonal" carbocation *(60)* (see Table 4). This process is associated with a considerable gain in energy although no overlap of the spatially fixed π-bonding orbitals with the vacant orbital of the carbenium carbon atom is possible in *(60)*. The intermediacy of *(61)* can be assumed in the formation of the homoadamantan-2-one *(62)* from *(60)*.

Acidolysis of 1-adamantylacetylenes *(57a)* and *(57c)* in 90% sulfuric acid expectedly gives only the adamantyl methyl ketones *(59)* and the homoadamantanones *(62)*[26]. Table 4 shows that the molar ratio of the ketones *(59)* and *(62)* depends both upon the way in which they are generated and upon the number of bridgehead methyl groups.



As shown by a study of the "detailed mechanism" of the reaction between 1-adamantol *(54a)* and acetylene[27,28], the proportion of 1-adamantaneacetaldehyde *(56a)* falls drastically in favor of homoadamantanone *(62a)* if the sulfuric acid concentration is lowered from 98 to 85% (Table 5). Use of boron trifluoride/ether complex as reaction medium even raises the absolute yield of *(62a)* to 60%.

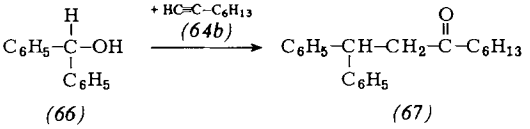
Table 5. Relative yields of the reaction of 1-adamantol *(54a)* with acetylene at various concentrations of sulfuric acid.



H_2SO_4 conc. [wt.-%]	Relative yields	
	(56a) [%]	*(62a)* [%]
98	89.1	10.9
92.5	71.2	28.8
90	66.0	34.0
87.6	60.0	40.0
85.5	57.0	43.0

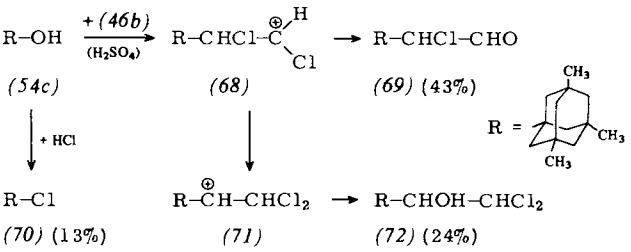
Independently of the synthesis of the aldehyde *(56a)* and the ketone *(62a)* described above, the initially formed species *(56a)* is slowly transformed into 1-adamantyl methyl ketone *(59a)* in sulfuric acid without traversing a vinyl cation stage. Thus *Sasaki et al.*[29] demonstrated 1-adamantyl methyl ketone *(59a)* as the only product of the reaction between acetylene and 1-bromoadamantane *(24a)* which requires considerably longer reaction times than *(54a)*. The ketone can be obtained in 80% yield by this method[28].

Reactions of 1,3-adamantanediols with acetylene in sulfuric acid are complicated and have not been studied in detail. The synthesis of 2-*exo*-norbornaneacetaldehyde *(63)* (yield 19%) from norbornene and acetylene warrants mention as an example of reaction of a secondary carbocation in the cycloaliphatic series[25].



(63) 

On application of the addition reactions of carbocations to substituted acetylenes it was found that the expected ketones *(65a)* and *(65b)* are obtained in 40 to 43% yield from 1-pentyne *(64a)* or 1-octyne *(64b)* and 1-adamantol *(54a)*, while analogous preparation of 1,1-diphenyl-3-nonanone *(67)* from *(64b)* and benzohydrol *(66)* is far less productive (yield 23%).



(a), R = n-C_3H_7; *(b)*, R = n-C_6H_{13}

The highly reactive phenylacetylene is mainly saponified to acetophenone under the conditions of this synthesis.

The scope of the above ketone syntheses from alkyl- and arylacetylenes is limited above all by the fact that protonation of the alkyne often plays a predominant role. In contrast, rearrangements of the secondary vinyl cations functioning as intermediates recede into the background.

An example of the production of an α-chlorocarbaldehyde is seen in the well-studied reaction of 3,5,7-trimethyl-1-adamantol *(54c)* with 1,2-dichloroethylene *(46b)*[21]. The initially formed α-chloro carbocation *(68)* can be stabilized in two ways. It can either hydrolyze directly to α-chloro-1-adamantaneacetaldehyde *(69)* or form 1-(1-adamantyl)-2,2-dichloroethanol *(72)* *via* the rearranged cation *(71)*. In addition, a small part of the reactant *(54c)* is transformed by liberated hydrogen chloride into the inert 1-chloroadamantane *(70)*. The yields given in the formula scheme are calculated from gas chromatographic analysis of the distilled reaction products.

Intramolecular additions of carbocations to a C—C triple bond or to a chlorovinyl group provide a pathway to cycloalkanones and cycloalkyl ketones. Such syntheses proceeding *via* ring closure which have already been reviewed[30,31] do not generally require a strongly acidic medium but can instead be performed in formic acid or trifluoroethanol.

4. Conclusion

The methods considered in this review for the synthesis of carboxylic acids, aldehydes, and ketones are not only of preparative importance but also permit a further insight into the chemical behavior of carbocations. Thus the first generation of a "primary" vinyl cation [*(55a)*] devoid of stabilizing substituents was accomplished by addition of the 1-adamantyl cation to acetylene and the reaction of this cation monitored. On the other hand, it has been found that the reactions of amidomethyl cations with chloroolefins in sulfuric acid do not involve a carbocation but an oxazonium ion as intermediate. These results could prove valuable for the planning of new syntheses. The availability of the starting materials should also encourage the exploitation of these reactions.

Synthesis of Intermediates by Rhodium-Catalyzed Hydroformylation

By Hardo Siegel and Walter Himmele[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The reaction of olefins with carbon monoxide and hydrogen to give aldehydes is referred to as hydroformylation (oxo reaction). As catalyst for this reaction rhodium is about three to four orders of magnitude more active than the more commonly employed cobalt. With special rhodium compounds, *e.g.* di-μ-chlorobis(η-1,5-cyclooctadiene)dirhodium $[RhCl(C_8H_{12})]_2$, in the presence of chiral phosphanes, even asymmetric hydroformylations can be achieved; however, the enantiomeric purity of the products (20–30%) is not high enough for industrial-scale syntheses.

1. Introduction

The hydroformylation or oxo reaction first carried out by *Roelen* in 1938 has developed into an industrially important process for the production of aldehydes and alcohols from olefins, carbon monoxide and hydrogen[1]. The world production of hydroformylation- and secondary-products, the main ones being *n*-butanol and 2-ethylhexanol, is at present *ca.* 4.5 million t/a.

Advances made in the area of homogeneous catalysis in the last ten years, mainly through the introduction of tailor-made metal complexes, have opened up new possibilities for the synthesis of higher-purity intermediates by high-pressure and catalytic methods. One example, which is also of interest in the industrial sector, is rhodium-catalyzed hydroformylation. Since rhodium is 10^3 to 10^4 times more active than cobalt, the reaction parameters pressure and temperature can

[*] Dr. H. Siegel, Dr. W. Himmele
Hauptlaboratorium der BASF Aktiengesellschaft
D-6700 Ludwigshafen

be widely varied, thus allowing better control of the selectivity. Olefins are transformed, usually in high yields, into aldehydes, which in turn can be converted by well-known industrially employed methods into alcohols, amines, or acids and find use in C—C coupling reactions such as condensations, Mannich, Wittig, and Grignard reactions, or ethynylations.

2. Selectivity of Hydroformylation with Rhodium Catalysts—Arylalkenes

In the catalytic hydroformylation of olefins with rhodium complexes the formyl group can, in principle, be inserted at each C-atom of the double bond.

$$RCH{=}CHR' \xrightarrow[\text{Rh cat.}]{CO/H_2} RCH(CHO)-CH_2R' + RCH_2-CH(CHO)R'$$

Important for the selectivity are the steric and electronic properties of the substituents R and R', the choice of reaction conditions such as temperature and pressure, special complex ligands, and the ratio of carbon monoxide to hydrogen. In addition side reactions such as isomerization and hydrogenation, which occur in every hydroformylation, can also influence the selectivity.

On hydroformylation with rhodium catalysts (100–700 bar, 70–150 °C) with or without complex ligands on the rhodium (molar ratio $<5:1$), the formyl group is generally incorporated at the electron-poorest C-atom if the electronic properties of the substituents at the double bond are decisive. If, however, the steric factors dominate, then the formyl group enters at that C-atom of the double bond least shielded by substituents.

(1) (2)

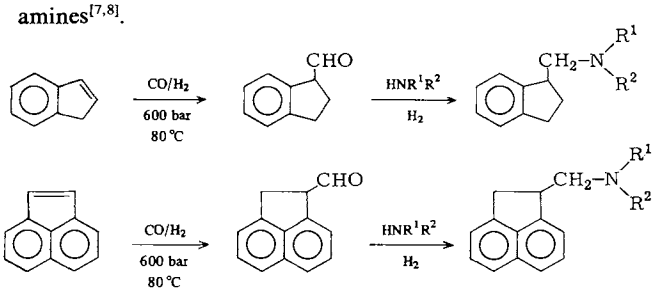
Table 1. Incorporation of the formyl group in the positions a, b, c of the olefins (1) and (2) (in %).

	(1)			(2)		
T[°C]	a	b	c	a	b	c
70	0	48	52	95	5	0
80	3	45	52	90	10	0
100	11	37	52	50	45	5
130	41	24	35	40	50	10

600 bar $CO/H_2 = 1:1$, 20 ppm Rh as $[RhCl(1,5\text{-cyclooctadiene})]_2$.

Temperature has a marked influence on the selectivity. This is immediately evident, *e.g.*, in the hydroformylation of eugenol *(1)* and isoeugenol *(2)*[2] (Table 1).

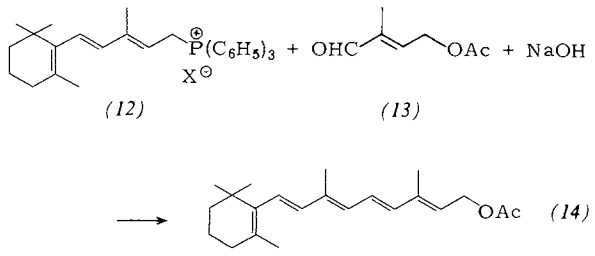
3. Intermediates for the Synthesis of Pharmacologically Active Compounds



A few classes of substances which are of interest for the synthesis of pharmacologically active amines are readily accessible by hydroformylation with rhodium catalysts[3,4]. Thus, the 2-aryloxypropanals *(3)* obtained from aryl vinyl ethers *(4)* are used for the synthesis of (aryloxypropyl)amines *(5)*; 3-arylbutanals *(6)*, prepared from 2-arylalkenes *(7)*, are intermediates for the synthesis of 3-arylbutylamines *(8)*, and

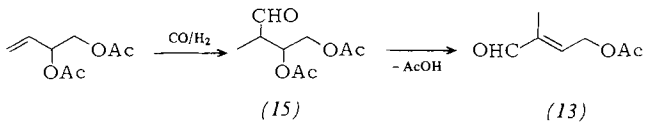
2-arylpropanals *(9)*, obtained from 1-arylalkenes *(10)*, are precursors for the synthesis of β-phenylpropylamines *(11)*.

In order to achieve a high selectivity in the hydroformylation, the reaction is carried out in all cases at 600–700 bar CO/H_2 and $<100\,°C$ with rhodium concentrations in the ppm range.



Modified β-phenylethylamines with interesting hypotensive properties are obtained by hydroformylation of indene[5] or acenaphthalene[6] in the presence of rhodium catalysts and subsequent reaction of the resulting aldehydes with amines[7,8].

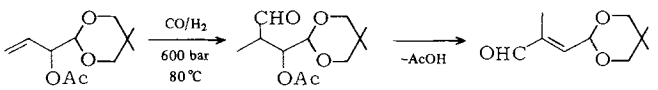
4. Intermediates for Vitamin and Terpene Chemistry



4.1. Unsaturated Aldehydes from 2-Alkenyl Acetates

In the process used at BASF for the industrial synthesis of vitamin A the ylide of a C_{15}-phosphonium salt is allowed to react with a C_5-aldehyde[9]. A phosphonium salt[11] *(12)*, prepared by reaction of vinyl β-ionol[10] and triphenylphosphane in the presence of an acid, serves as C_{15}-moiety and *trans*-3-formyl-2-butenyl acetate *(13)* as C_5-moiety. The synthesis, in presence of a base, leads directly to the vitamin A acetate *(14)*.

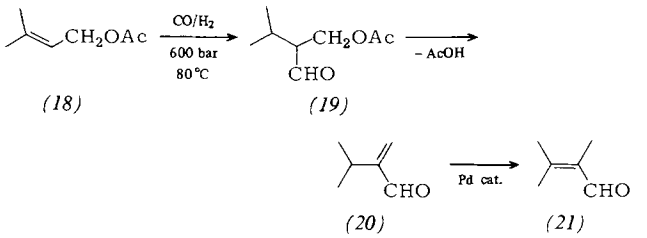
(12) (13) (14)



The unsaturated aldehyde *(13)* can be prepared *via* hydroformylation of 1-vinylethylene diacetate in the presence of a rhodium catalyst.

(15) (13)

High pressure and low temperature favor formation of the branched aldehyde *(15)*. At 80 °C and 600 bar CO/H_2 selectivities of up to *ca.* 80% can be achieved. The acetoxy group in the β-position to the formyl group is readily removed as acetic acid to give pure *trans-(13)*[12,13]. This synthesis of α,β-unsaturated aldehydes by hydroformylation of 2-alkenyl acetates and subsequent elimination of acetic acid can also be used for the production of further intermediates which are of interest in terpene chemistry.

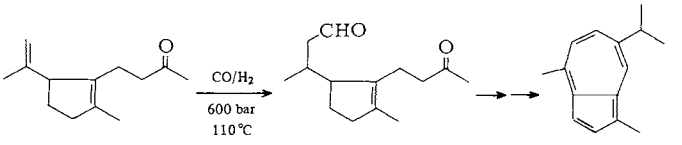


trans-2-Methyl-3-(5,5-dimethyl-1,3-dioxan-2-yl)acrylaldehyde *(17)*, an important intermediate for the synthesis of carotinoids[14], can be obtained in the same way from the acetal *(16)*.

(16) (17)

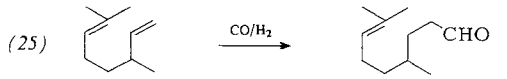
Reaction of *(17)* with the ylide of the C_{15}-phosphonium salt *(12)* and subsequent hydrolysis affords easy access to retinal (vitamin A aldehyde).

Hydroformylation of the 3-methyl-2-butenyl acetate *(18)* leads in high yields to 2-formyl-3-methylbutyl acetate *(19)*, elimination of acetic acid from *(19)* to α-isopropylacrylaldehyde *(20)*. This is isomerized in the presence of palladium catalysts to trimethylacrylaldehyde *(21)*, an important intermediate for the synthesis of irones[15].



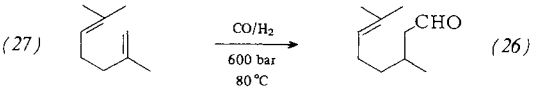
(18) (19) (20) (21)

4.2. Unsaturated Aldehydes by Hydroformylation of Non-Conjugated Diolefins



A further possibility for the synthesis of unsaturated aldehydes consists in the selective hydroformylation of non-conjugated diolefins. Here, steric factors play a decisive role regarding the degree of hydroformylation of the double bonds.

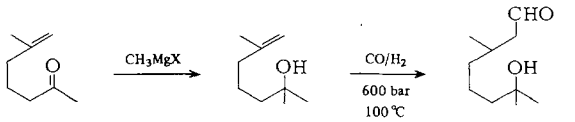
The ketone *(22)*[16] accessible from linalool is selectively hydroformylated at the isopropenyl group. An intramolecular ring closure of the resulting ketoaldehyde *(23)* followed by further reaction steps affords guaiazulene *(24)*[17].



(22) (23) (24)

In citronellene *(25)* the formyl group is almost exclusively incorporated terminally (at 600 bar, 70 °C, with rhodium catalysts) owing to steric hindrance by the two methyl groups[18].

(25)

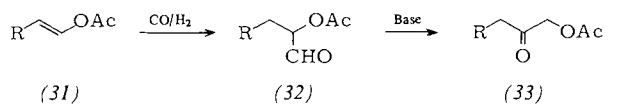


Synthesis of the industrially important citronellal *(26)* from 2,6-dimethyl-1,5-heptadiene *(27)*[19] proceeds in a similar fashion.

(27) (26)

4.3. Synthesis of Hydroxycitronellal

An industrial process for production of the important odorant hydroxycitronellal *(28)* consists in hydroformylation of the 2,6-dimethyl-6-hepten-2-ol *(30)*[20] obtainable from 6-methyl-6-hepten-2-one *(29)* *via* a Grignard reaction.



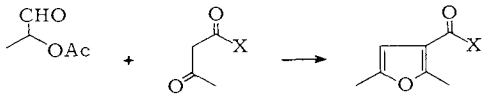
(29) (30) (28)

5. Intermediates for the Synthesis of Heterocycles

5.1. Furancarboxylic Acid Derivatives from 1-Alkenyl Acetates

In the hydroformylation of 1-alkenyl acetates *(31)*, which are readily accessible by formation of the enol acetate from the corresponding aldehydes, the formyl group is incorporated with a selectivity of >90% at the α-position to the acetoxy group [*(32)*] at 600 bar and *ca.* 110 °C.

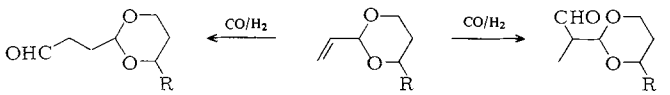
In the presence of weak bases, *(32)* readily undergoes a type of Lobry-de-Bruyn-van-Ekenstein rearrangement to give the ketoacetate *(33)*[21].



(31) (32) (33)

Hydroformylation of vinyl acetate affords 2-formylethyl acetate *(34)* in high yields. This ester, and also other 2-formylalkyl acetates, are important intermediates for a novel one-step synthesis of furancarboxylic acid derivatives.

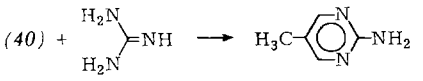
Reaction of *(34)* with acetoacetamides *(35)* or acetoacetates *(37)* leads in high yields to the 2,5-dimethyl-3-furancarboxamides *(36)* or the corresponding esters *(38)*, respectively[22,23].



Furancarboxylic acid derivatives are of great industrial importance in seed disinfection[24] and in wood preservation[25].

(34) *(35)*, X = NR_2 *(37)*, X = OR *(36)*, X = NR_2 *(38)*, X = OR

5.2. Pyrimidines *via* Methylmalonaldehyde Monoacetals

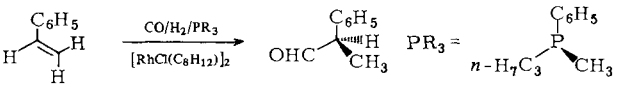


Depending on the reaction conditions hydroformylation of the cyclic acetals of acrylaldehyde *(39)* leads either to the methylmalonaldehyde monoacetals *(40)* or succinaldehyde monoacetals *(41)*.

(41) *(39)* *(40)*

When the reaction is carried out at 600 bar CO/H_2 and 80 °C in the absence of complexing agents, *(41)* and *(40)* are obtained in the ratio 25:75[26]. At 20 bar CO/H_2 and 140 °C in the presence of more than a fiftyfold excess of triphenylphosphane (referred to rhodium) the reaction product contains 70% *(41)* and 30% *(40)*. Compound *(41)* is a possible intermediate for the synthesis of 1,4-butanediol[27].

5-Methyl-2-pyrimidinylamine *(42)*, which is used as starting material for the synthesis of sulfonamides, can be readily prepared by reaction of the methylmalonaldehyde monoacetal *(40)* with guanidine.



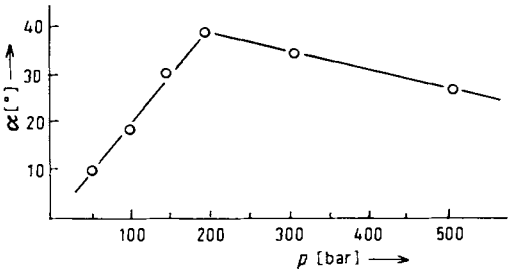
(42)

6. Asymmetric Hydroformylation with Chiral Rhodium Complexes

Horner was the first to point out that an asymmetric hydrogen transfer should be possible[29] by reaction of an optically active phosphane as ligand with one of the rhodium complexes previously found by *Wilkinson et al.*[28] to be effective catalysts in hydrogenation. Following the subsequent independent confirmation of this prediction by *Knowles* and *Sabacky*[30] and by *Horner et al.*[31], Monsanto started using this novel synthetic method on an industrial scale. *Knowles et al.* developed a method for the preparation of L-dopa by asymmetric hydrogenation of an appropriately substituted α-(*N*-acylamino)cinnamic acid[32].

Reaction of styrene *(43)* with carbon monoxide and hydrogen in the presence of *(S)*-(+)methyl(phenyl)-*n*-propylphosphane, *(S)*-*(44)*[33], and rhodium complex catalyst affords optically active (*R*)-(−)-phenylpropanol *(R)*-*(45)*[34].

(43) *(R)*-(−)-*(45)* *(S)*-(+)-*(44)*



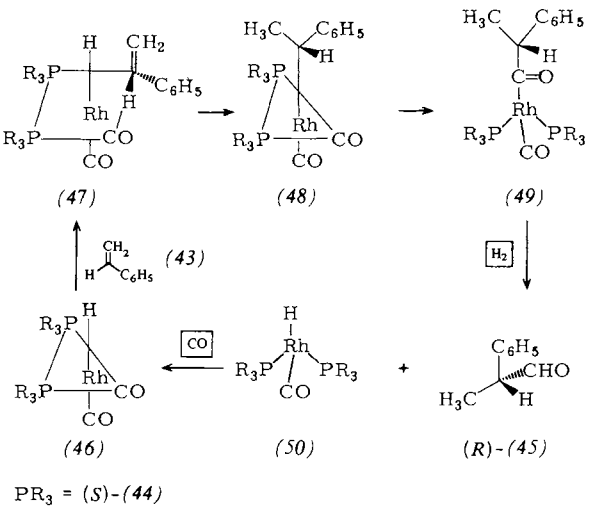


Fig. 1. Dependence of optical induction on pressure in the hydroformylation of styrene *(43)* to *(R)*-(−)-2-phenylpropanol *(R)*-*(45)* with di-μ-chlorobis(η-1,5-cyclooctadiene)dirhodium and *(S)*-(+)-methyl(phenyl)-*n*-propylphosphane *(S)*-*(44)*.

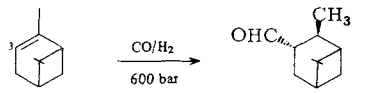
As shown in Figure 1 a noticeable enantioselective synthesis can be observed at 500 bar CO/H_2—a proof that carbon monoxide does not completely displace the chiral phosphane from the carbonylrhodium complex, even at high pressure. In order to establish its absolute configuration, the prepared (−)-2-phenylpropanol *(45)* was oxidized by various methods to 2-phenylpropionic acid. In each case this had *R*-configuration; accordingly, *(45)* is likewise *R*-configurated. This enantionselective synthesis can best be explained in terms of the mechanism proposed by *Wilkinson et al.*[35] for the hydroformylation of olefins with $HRhCO(PPh_3)_3$ or $HRh(CO)_2(PPh_3)_2$.

(47) *(48)* *(49)* *(43)* *(46)* *(50)* *(R)*-*(45)*

PR_3 = *(S)*-*(44)*

Similarly to an enzyme, the chiral catalyst *(46)* can differentiate between the enantiotopic sides of the prochiral olefin. In the case of *(S)*-(+)-*(44)* as ligand PR_3 of the coordinative unsaturated complex *(46)*, styrene *(43)* preferably adds at the side unshielded by the phenyl group. A Rh-π-complex *(47)* is formed and is rapidly converted into a complex *(48)* containing a Rh-alkyl bond. The absolute configuration of the 2-

phenylpropanal is thus established, since CO is inserted in the *cis* position [*(48)*→*(49)*]. The rate determining step of the reaction is cleavage of the acylrhodium complex *(49)* by hydrogen: *(R)*-(−)-*(45)* and the tetrahedral hydrido complex *(50)* are formed, which after uptake of CO to give the complex *(46)* can further add styrene.

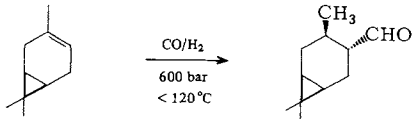


A mechanism involving replacement of one of the two chiral phosphane groups by a carbonyl group in the reaction *(46)*→*(50)* leads to the same result.

With *(S)*-phosphanes, the *(R)*-aldehyde is formed. It is immediately apparent that the arrangement of the groups in the chiral 2-phenylpropanol *(45)* pre-images to a certain extent the groups in the chiral phosphane. With *(S)*-(+)-*(44)* or the corresponding isopropyl compound as complex ligand the enantiomeric purity of the products is *ca.* 20% and 30%, respectively.

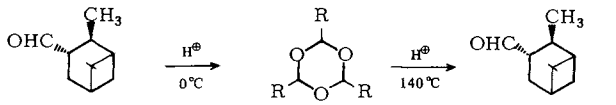
The asymmetric hydroformylation of prochiral olefins has so far found no use in industry. One reason for this is the low enantiomeric purity—also observed by other authors[36–39]—of the products obtained from the substrates hitherto examined. Hence, this method is at the moment considered impracticable for the industrial production of optically active intermediates which could be used for optical resolution or asymmetric syntheses.

7. Optically Active Intermediates *via* Hydroformylation of Unsaturated Chiral Natural Products



(−)-α-Pinene *(51)*, which is available in large amounts from the cluster pine *(Pinus Pinaster* Sol.), is hydroformylated with rhodium catalysts in a diastereoselective synthesis to (+)-3-pinanecarbaldehyde *(52)*[45]. (+)-α-Pinene from the Aleppo pine (*Pinus Pinaster* Mill.) affords (−)-3-pinanecarbaldehyde[40].

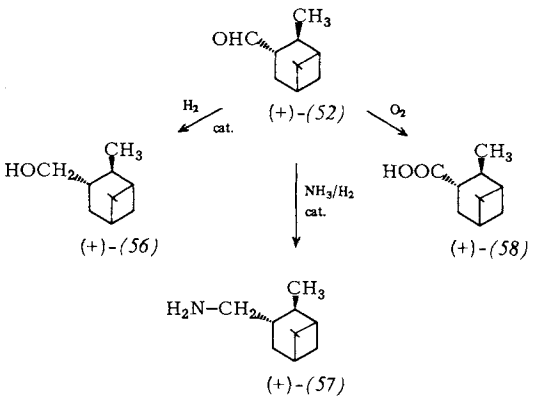
(−)-*(51)* (+)-*(52)*



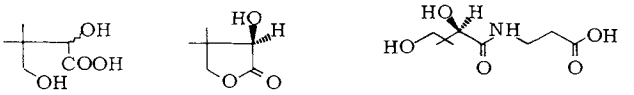
The formation of the reaction products can be explained by the fact that the intermediary alkylrhodium complex evades as far as possible steric hindrance by the isopropylidene bridge and the methyl group. The least hindered position is the equatorial one on the carbon atom 3 of the α-pinene *(51)*. The *cis* addition of CO and H_2 then forces the methyl and formyl group likewise to take up an equatorial position in the 3-pinanecarbaldehyde *(52)*. Depending on the reaction conditions the selectivities are up to 85%. The most important by-products are isomeric aldehydes, which are derived from the β-pinene formed during the reaction by isomerization of the double bond. In the analogous hydroformylation of (+)-3-carene, (+)-*(53)*, the reaction proceeds with a selectivity of only 60–65% to the (+)-2-caranecarbaldehyde (+)-*(54)*[41] owing to comparably little steric hindrance by the isopropylidene bridge.

The enantiomeric purity of the (−)- or (+)-3-pinanecarbaldehyde *(52)* corresponds to that of the α-pinene employed (70–85%). Enantiomerically pure 3-pinanecarbaldehyde is obtained by acid-catalyzed trimerization in the presence of

(+)-*(53)* (+)-*(54)*



solvents[42]; only one enantiomer is thereby preferentially trimerized to the crystalline compound *(55)*. This is isolated and then cleaved again in the presence of acids to 3-pinanecarbaldehyde.



enantiomeric purity 70–85% *(55)* enantiomeric purity ≈100%

R = (+)-3Pinanyl

The optically active pinanecarbaldehydes are very stable against racemization. They can be hydrogenated, aminohydrogenated, or oxidized with retention of configuration by the usual industrial methods.

(+)-3-Pinanylmethanol *(56)*, (+)-3-(pinanylmethyl)amine *(57)*, and (+)-3-pinanecarboxylic acid *(58)* are configurationally stable, optically active intermediates which can be used for enantiomerization and asymmetric syntheses. For example, the amine (+)-*(57)* forms very easily separable diastereomeric salts with DL-pantoic acid *(59)*.

(59) *(60)* *(61)*

Thus, D-(−)-pantolactone *(60)*, a precursos of D-pantothenic acid *(61)*, is obtained in 90% yield and in very high enantiomeric purity[43,44].

8. Outlook

The rhodium-catalyzed hydroformylation of special olefins for the production of aldehydes is a versatile method for unconventional solutions of problematic syntheses in the fine chemicals industry. The possibilities of this method range from simple aliphatic aldehydes to chiral compounds. A dis-

advantage, however, is that not all of the necessary starting olefins are avilable on an industrial scale and that, with higher concentrations of catalyst, the expensive and relatively scarce rhodium must be recycled. However, in spite of these problems still further new syntheses with rhodium-catalyzed hydroformylation intermediates are to be expected in the future.

We thank all our colleagues and co-workers for their most invaluable teamwork and assistance, and Dr. Hohenschutz, Dr. Pape, and Prof. Dr. Reif for their kind support of this work.

3-Phenylpropylamines, A New Class of Systemic Fungicides

By Walter Himmele and Ernst-Heinrich Pommer[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The biological activity of 3-phenylpropylamines is not exclusively determined by their structure. It could be demonstrated that the fungicidal activity of partially hydrogenated compounds of this class of substances is also substantially influenced by the conformation. An optimization of the conformational criteria—illustrated by many examples, yet constituting only a small number of those actually examined—afforded compounds with excellent properties, *e.g.* *N*-[3-(4-*tert*-butyl-1-cyclohexenyl)-2-methylpropyl]-*cis*-2,6-dimethylmorpholine.

1. Introduction: Importance of Fungicides for Crop Growth

Amines such as *N*-tridecyl-2,6-dimethylmorpholine *(Tridemorph)* and *N*-cyclododecyl-2,6-dimethylmorpholine *(Dodemorph)* are active in crops against special types of fungi. Also other 2,6-dimethylmorpholines with suitable substituents on nitrogen and on the heterocycle have very good fungicidal properties, especially toward powdery mildew[1].

Today in intensive crop cultivation, besides a well-balanced fertilization, directed plant protection measures are of importance. First of all, the emphasis for assuring and improving crop yields lay in the area of weed-control. But in the last 10–15 years, besides seed desinfection, the use of fungicides in combatting foot rot and leaf and ear diseases has been recognized as an important factor as well. In 1971 in the fight against mildew in barley a breakthrough was made by the introduction of the systemic fungicide Tridemorph; depending upon the type of disease a 10% or substantially greater increase in produce could be achieved. This fungicide is also very active toward wheat mildew, but we have observed in the case of some wheat species and under unfavorable application conditions that the tolerance of the plant is unsatisfactory. The search for new biologically active substances without this shortcoming, and at the same time which are active against other important plant pathogenic fungi, *e.g.* wheat rust fungi, formed the starting point for the work described in this paper.

The most important parasites which cause leaf diseases in crops are the powdery mildew fungi from the species Erysiphe and the rust fungi from the species Puccinia. It is estimated that alone in Europe a crop cultivation area of more than six million hectares is endangered. For economic reasons the farmer would like to use the smallest possible amounts of plant protection substances and therefore he prefers fungicides having a broad activity spectrum, thus making the use of specifically active products unnecessary. The activity of the conventional fungicides, *e.g.* dithiocarbamates, is restricted because essentially they protect the plant surface only through direct contact with the fungi spores. Such fungicides are directly exposed to rain, air, wind, light *etc.* and cannot give protection to many parts of a plant during rapid growth. From a systemic fungicide however, one expects the following properties:

1. easy uptake through leaves and roots, independent of the plant type;
2. rapid transport and rapid distribution throughout the entire plant, independent of whether one year old or ligneous plants (trees) are involved;
3. broad spectrum of fungicidal activity;
4. well tolerated, even after attaining the fungitoxic concentration in the plant tissue; persisting activity also after "dilution" of the fungicide by new growth;
5. degradation of the biologically active fungicide to harmless metabolites within a definite time period between the last application and harvest.

The fungicidally active 3-phenylpropylamines so far investigated showed systemic properties. Representatives from the species of powdery mildew fungi and of grain rust fungi were chosen since our aim was to find biologically active substances exhibiting the above mentioned range of activity. Wheat, barley and oats were chosen as the cultivated plants.

The compounds mentioned in this article were synthesized by the usual preparative methods. Stereoisomers could be separated using laboratory columns with forty to eighty plates. Assignment of configuration was achieved by means of ^{1}H- and ^{13}C-NMR spectroscopy[*].

2. 3-Phenylpropylamines with Optimized Fungicidal Activity

2.1. Discovery of this Class of Compounds

Instead of morpholine derivatives (tetrahydro-1,4-oxazines), derivatives of other cyclic amines can be used for the investigation. The fungicidal activities of 2,6-dimethylmorpholines[1,2] and of 3,5-dimethyl-4-piperidones[3,4], in both cases with the same substituent on the nitrogen, are about the

same. In the following investigations, both classes of compounds are examined.

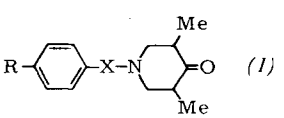
Aryloxyalkylamines[1a], in which the nitrogen is part of a morpholine ring, are also satisfactorily effective against barley mildew, though their activity against wheat mildew is not strong enough. In many cases also the tolerence in wheat does not meet with market requirements.

2.2. Significance of the Alkylene Chain for Fungicidal Activity

3,5-Dimethyl-4-piperidones[2b] with a suitable arylalkyl substituent on the nitrogen atom show fungicidal activity against wheat mildew, barley mildew and brown rust of wheat[3,4]. The phytotoxicity of this class of compounds is relatively low.

Table 1. Dependence of the fungicidal activity on the alkylene chain between the aromatic ring and the heterocycle. BM = barley mildew, WM = wheat mildew, CRO = crown rust of oats. See text for concentration of the active compound and the biological assessment.

(1)



Cpd.	R	X	BM	WM	CRO

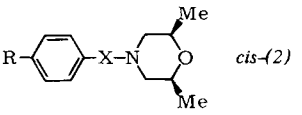
(1b)	H	CHMe CH_2	2		
(1c)	H	CH_2 CHMe	2	2	5
(1d)	OCH_3	CHMe CH_2	2	0	
(1e)	H	CHMe CH_2 CH_2	2	0	5

The biologically active solution is prepared by dissolving the substance in acetone, adding a wetting agent and diluting with water. The concentration of the substance is 0.05 weight percent (Tables 1–13).

The fungicidal activities listed in the tables are assessed as follows: 0 = complete destruction of fungi, graded to 5 = no significant attack against the fungi. A = trace, B = intermediate and C = intense damage to the leaves; no remark = no crop damage.

A clear dependence of the activity on the size of the alkylene chain can be seen for the compounds listed in Table 1. The activity against barley mildew increases with increasing length of the chain between the aromatic ring and the cycloamine. The benzyl derivative *(1a)* has no activity against mildew fungi. A clearly defined activity is seen in compounds such as *(1b)*–*(1d)* which have a β-phenylethyl moiety attached to the nitrogen.

Table 2. Dependence of the fungicidal activity on the alkylene chain between the aromatic ring and the heterocycle. BM = barley mildew, WM = wheat mildew, CRO = crown rust of oats.



(1)

Cpd.	R	X	BM	WM	CRO

(1e)	H	CHMe CH_2 CH_2	2	0	5
(1g)	H	CHMe CH_2 CHMe CH_2	0	5	5
(1h)	H	CH_2 CH_2 CHEt CH_2	0C	3	5
(1i)	H	CHMe CH_2 CHEt CH_2	2	3A	5A
(1j)	H	$(CH_2)_3$ CHMe CH_2	0	5	

3-Phenylpropylamines[4–9] are found to be quite active against both mildew species (see Table 2). While *(1f)*, with an unsubstituted chain, has relatively good activity against barley mildew, it shows only moderate activity against wheat mildew. The activity level changes if the trimethylene chain is substituted. Thus, compound *(1e)*, which has a methyl group α to the phenyl group, has a very good activity against wheat mildew. Generally, a good activity against barley mildew but a strongly reduced activity against wheat mildew is observed if the chain is lengthened to 4–5 carbon atoms and at the same time substituted with lower alkyl groups.

Table 3. Dependence of fungicidal activity on the alkylene chain between the aromatic ring and the heterocycle. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.

cis-(2)

Cpd.	R	X	BM	WM	BRW

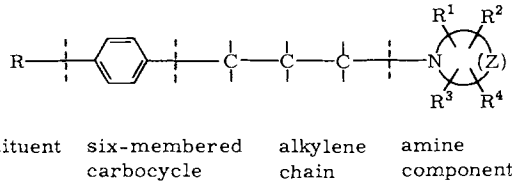
cis-(2b)	H	$(CH_2)_2$ CHEt $(CH_2)_2$	0	0	5
cis-(2c)	H	CHMe CH_2 CHMe CH_2	0	5	5

The same structure-activity relation holds true for *cis*-2,6-dimethylmorpholines in which the nitrogen atom is substituted by an arylalkyl moiety. An alkylene chain with more than three members appears to decrease the activity against wheat mildew and brown rust of wheat (Table 3).

An optimization of the activity against crop-damaging fungi for the compounds discussed here is obtained by a chain containing three (substituted) methylene groups. These results motivated continuation of our work based on the model shown in Figure 1.



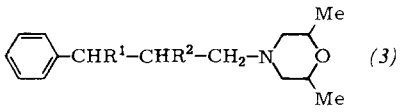


Fig. 1. Molecular model for illustrating the working hypothesis.

The substitution pattern of the alkylene chain is important for the activity. A methyl group α to the nitrogen usually causes a decrease in the activity against barley mildew while the activity against brown rust of wheat is almost completely lost [see *(1l)*, Table 6]. Introduction of methyl groups in the corresponding β-phenylethylamine derivatives [see *(1c)*] also results in a strong decrease in activity. Hence, the effect of alkyl groups attached to the middle carbon atom and at the γ-carbon atom of the chain was primarily studied.

Compounds of type *(3)*, which are alkyl-substituted at the middle carbon atom and/or at the γ-carbon atom of the trimethylene chain, generally have a low activity level (Table

Table 4. Dependence of fungicidal activity on the alkylene chain between the aromatic ring and the heterocycle. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.

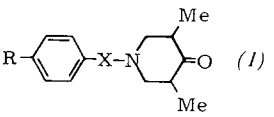
cis-(2e)	*t*-Bu	O CHMe CH_2	3	3	3
cis-(2f)	*c*-Hex	O CHMe CH_2	0		

[a] Crown rust of oats.

The extent to which the activity is changed on replacing a carbon atom by a heteroatom in the alkylene chain can be deduced from Table 5.

If the carbon atom α to the aromatic ring is replaced by an oxygen atom, the fungicidal activity decreases. The same effect is observed on replacement of this atom by a methylamino group. The comparison *(1e)/(1k)*, however, is not exact since the chain is differently substituted; the same holds true for a comparison of *(3b)* (mixture of stereoisomers; see Table 4) and *cis-(2d)*.



2.3. Influence of the Substituents of the Aromatic Ring on the Fungicidal Activity

A marked increase in the activity can be achieved by *para*-substitution of the aromatic ring.

Table 6 shows that an isopropyl group in the *para* position of the phenyl group increases the activity. A *tert*-butyl group in the same position causes an even clearer increase in the activity. This holds true for barley and wheat mildew as well as for brown rust of wheat.

Introduction of a methyl group in the trimethylene chain and at the same time *para*-substitution of the aromatic ring leads to a very good level of fungicidal activity over the entire spectrum (see Table 7). A decisive increase in the fungicidal activity, and with it the breakthrough for utilization in wheat cultures, was brought about by an introduction of a methyl group at the middle carbon of the trimethylene chain.

Table 6. Change in fungicidal activity on simultaneous variation of the substituents on the aromatic ring and of the position of the methyl group in the trimethylene chain. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.

(1e)	H	CHMe CH_2 CH_2	2	0	5 [a]
(1n)	*i*-Pr	CHMe CH_2 CH_2	0A	3	3
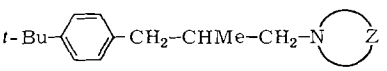
(1o)	*t*-Bu	CHMe CH_2 CH_2	0A	2	2
(1p)	*i*-Pr	CH_2 CHMe CH_2	0	0	0
(1q)	*t*-Bu	CH_2 CHMe CH_2	0	0	0

[a] Crown rust of oats.



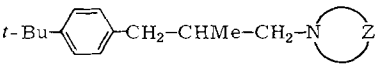
At the test concentrations chosen here (0.05 wt-%), the isopropyl group as substituent on the aromatic ring leads to the same activity as the *tert*-butyl group. If more dilute solutions are used, the *tert*-butyl compound *(1q)* is clearly more active than the corresponding isopropyl compound *(1p)*.

2.4. Significance of the Cycloamine Component for the Fungicidal Activity

As can be seen from Table 7, from the point of view of composition and structure the 3-(*p-tert*-butylphenyl)-2-methylpropyl group is the "optimum arylalkyl residue". Cycloamines with this group substituted on the nitrogen generally show a very good activity against barley mildew, wheat mildew and brown rust of wheat.

The differences in activity of the cycloamine derivatives *(4)* examined (Table 8), which were used here in concentrations of 0.05 weight-%, first become noticeable at low concentrations. In general, piperidine derivatives such as *(4b)* show very good activities. The C-4 atom of the piperidine ring can also be replaced by a heteroatom such as oxygen

Table 8. Dependence of the fungicidal activity on variation of the "optimally substituted arylalkyl moiety" on the cycloamine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.



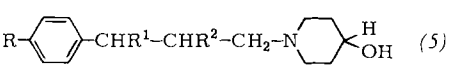
(4)

Cpd.	Z	BM	WM	BRW
(4a)	$(CH_2)_4$	0	0	0
(4b) [a]	$(CH_2)_5$	0	0	0
(4c)	$(CH_2)_6$	0	0	0
(4d)	$(CH_2)_2$ O $(CH_2)_2$	0	0	0
(4e)	$(CH_2)_2$ NMe $(CH_2)_2$	0	0	0
(4f)	CH_2 CHMe S CHMe CH_2	0	0	0

[a] Fenpropidin.

[*(4d)*], sulfur [*(4f)*] or nitrogen [*(4e)*]. A particularly good activity is obtained by methyl group substitution in the 3- and 5-position of the six-membered amine ring [see *e.g.* *(4f)*] (see also Tables 12 and 13).

Table 9. Dependence of the fungicidal activity on variation of the "optimally substituted arylalkyl moiety" on the cycloamine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.



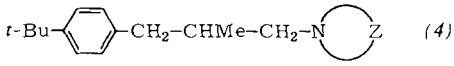
(4)

Cpd.	Z	BM	WM	BRW
(4g)	CH_2 $CH(CH_2OH)$ $(CH_2)_3$	0	0	0
(4h)	$(CH_2)_2$ CHOAc $(CH_2)_2$	0	0	0
(4i)	CH_2 CHMe $(CH_2)_3$	0	0	0
(4j)	CH_2 CHMe CH_2 CHMe CH_2	0	0	0
(4k)	CH_2 $C(Me)_2$ $(CH_2)_3$	0	0	0
(4l)		0	0	0

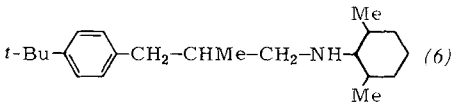
Table 9 shows that there is just as little decrease in activity on substitution of the six-membered amine ring with alkyl groups or hydroxymethyl groups as on benzoannelation.

The dependence of the fungicidal activity on the substitution has also been examined in the case of the six-membered ring amine 4-hydroxypiperidine, whose polarity is completely different from that of the cycloamines used previously (Table 10). The dependence was found to be the same in the case of the piperidones (Table 7). The "optimum arylalkyl residue" proves to be the best also in compounds *(5)*.

Table 10. Dependence of the fungicidal activity on the arylalkyl moiety substituted on the nitrogen atom of 4-hydroxypiperidine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.



(5)



Cpd.	R	R^1	R^2	BM	WM	BRW
(5a)	*i*-Pr	Me	H	0	2	5
(5a) · HCl				3	2	5
(5b)	*t*-Bu	Me	H	0	2	5
(5b) · HCl				0	2	5
(5c)	*i*-Pr	H	Me	0	2	5
(5c) · HCl				0	2	2
(5d)	*t*-Bu	H	Me	0	0	0
(5d) · HCl				0	0	0

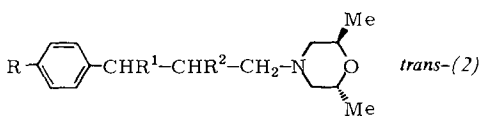
While slight deviations from the optimum composition and structure in all the variations studied (Tables 7 and 10) initially decrease the activity against brown rust of wheat, further modification of the otherwise promising type of compounds bearing six-membered cycloamines can lead to a completely different behavior (Table 11).

Table 11. Dependence of the fungicidal activity on variation of the "optimally substituted arylalkyl moiety" on the cycloamine or amine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.

(4)

(6)

Cpd.	Z	BM	WM	BRW
(4m)	CH_2 $C(Me)_2$ CH_2 CHMe CH_2	0	3	0
(4n)	CHMe CH_2 CHMe $(CH_2)_2$	0	3	0
(4o)	CHMe $(CH_2)_2$ CHMe CH_2	3		0
(4p)		0	5	0
(6)	see above	0	3	0



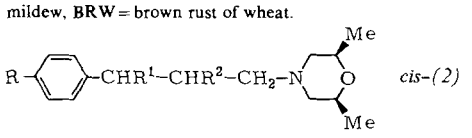
Although the activity against brown rust of wheat is retained on alkyl substitution of such a cycloamine (cf. Table 8), the activity against wheat mildew is decreased to a very low level.

3. Significance of the Configuration for the Fungicidal Activity

3.1. Influence of the Configurational Features of the Cycloamine Component

The specificity of the activity against fungi, which is brought about by configurational features of the cycloamine component, can be seen in Tables 12 and 13.

Table 12. Dependence of the fungicidal activity on the arylalkyl moiety on the nitrogen atom of *trans*-2,6-dimethylmorpholine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.



trans-(2)

Cpd.	R	R^1	R^2	BM	WM	BRW
trans-(2g)	*i*-Pr	Me	H	3	2	5
trans-(2g) · HCl				3	2	5
trans-(2h)	*t*-Bu	Me	H	2	0	5
trans-(2h) · HCl				0	0	5
trans-(2i)	*i*-Pr	H	Me	0	0	3
trans-(2i) · HCl				0	0	0
trans-(2j)	*t*-Bu	H	Me	0	0	0
trans-(2j) · HCl				0	0	0

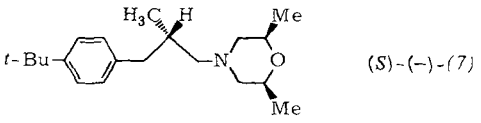
Compounds *cis-(2g)* to *cis-(2j)* have a much more favorable activity than their *trans* analogues. Here also it is quite evident that small deviations from the optimum structure

Table 13. Dependence of the fungicidal activity on the arylalkyl moiety on the nitrogen atom of *cis*-2,6-dimethylmorpholine. BM = barley mildew, WM = wheat mildew, BRW = brown rust of wheat.

cis-(2)

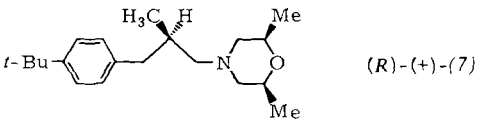
Cpd.	R	R^1	R^2	BM	WM	BRW
cis-(2g)	*i*-Pr	Me	H	0	0	5
cis-(2g) · HCl				0	0	3
cis-(2h)	*t*-Bu	Me	H	0	0	3
cis-(2h) · HCl				0	0	3
cis-(2i)	*i*-Pr	H	Me	0	0	0
cis-(2i) · HCl				0	0	0
cis-(2j)	*t*-Bu	H	Me	0	0	0
cis-(2j) · HCl				0	0	0

and configuration cause a decrease in the activity towards brown rust of wheat. Generally, for a decrease in activity against wheat mildew, more drastic deviations from these optimal conditions are necessary.



Since the *cis*-2,6-dimethylmorpholine derivative *cis-(2j)* has far better fungicidal properties than *trans-(2j)*, conversion of the *trans*-derivative into the *cis*-derivative was investigated. This isomerization can be accomplished using palladium catalysts at elevated temperatures[10]. The two stereoisomeric forms can be separated without difficulty by fractionation, thus making it possible to use the more effective isomer *cis-(2j)* in a purity of more than 98%.

N-[3-(*p-tert*-Butylphenyl)-2-methylpropyl]-*cis*-2,6-dimethylmorpholine [*cis-(2j)*], which was chosen for further development, has a favorable LD_{50}; for rats (p.o.) it is 3515 mg/kg. From experience so far, 500–750 g substance per hectare is enough to keep the crop free of mildew and rust for at least three to four weeks[2].



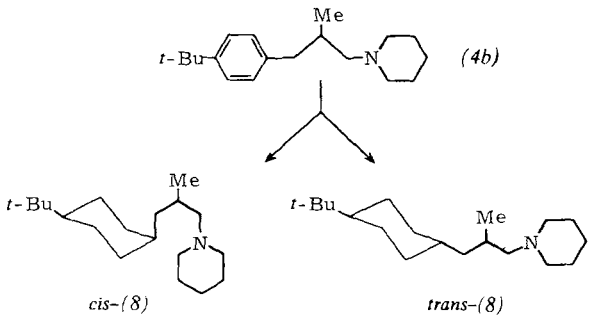
3.2. Influence of the Chiral Center in the 2-Methyltrimethylene Chain

A chiral center exists at the middle of the trimethylene chain owing to the presence of the methyl substituent. Separation of the two enantiomeric forms of the compound *cis-(2j)* was achieved by the classical method using camphorsulfonic acid[11]. A distinct difference in the activity of the two enantiomers (−)-*(7)* and (+)-*(7)* against crop damaging fungi was observed (Table 14).

Table 14. The difference in activity of the enantiomers with different arrangement at the chiral center in the 2-methyltrimethylene chain.

(S)-(−)-*(7)*

(R)-(+)-*(7)*



Cpd.	*c* [%]	Wheat mildew	Brown rust of wheat
(S)-(−)-*(7)*	0.012	0	0
	0.006	0	0
	0.003	0	0
(R)-(+)-*(7)*	0.012	0	2
	0.006	2	3
	0.003	3	3
Control	—	4	4

Whereas the (−)-enantiomer is very active against both wheat mildew and brown rust of wheat, the (+)-enantiomer displays only moderate activity against wheat mildew and is practically inactive against brown rust of wheat.

An X-ray structure analysis[*] of the hydrochloride of the levorotatory form showed it to be the *(S)*-enantiomer [*(S)*-(−)-*(7)* · HCl].

3.3. Configurational Features which Influence the Fungicidal Activity of 3-(4-*Tert*-Butylcyclohexyl)-2-methylpropylamine Derivatives

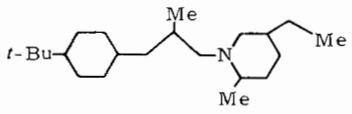
When 3-(*p-tert*-butylphenyl)-2-methylpropylamine, in which the nitrogen atom is part of a cycloamine, is catalytically hydrogenated to the cyclohexane derivative, two isomers are obtained which differ in their stereochemistry at the C-1 and C-4 positions of the cyclohexane ring[12].

(4b)

cis-(8) *trans-(8)*

Tests carried out against crop fungi (see Table 15) clearly showed that the 1,4-*trans* product has the stronger activity.

Table 15. The difference in activity of the two stereoisomers of perhydrogenated Fenpropidin.



Cpd.	*c* [%]	Wheat mildew	Brown rust of wheat
cis-(8)	0.025	0	3
	0.012	0	3
	0.006		3
	0.003	0	3
	0.0015	0	4
	0.00075	1	5
trans-(8)	0.003	0	0
	0.0015	0	3
	0.00075	0	4

Although the *cis-(8)* and *trans-(8)* derivatives show very little difference in activity toward wheat mildew, only the *trans*-form exhibits very good activity against brown rust of wheat. Other amine derivatives behave in a similar fashion.

If 5-ethyl-2-methylpiperidine is chosen as amine component of the perhydrogenated compound [*(9)*], three fractions

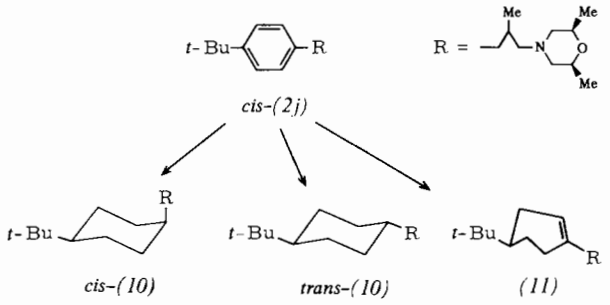
[*] We thank Dr. *E. Hädicke*, BASF/Ammonia Laboratory, for the X-ray structural analysis.

can be obtained by distillation. The lowest boiling fraction I is inactive against wheat mildew and brown rust of wheat. Fraction II shows a good activity against wheat mildew but no activity against brown rust of wheat. The highest boiling fraction III is very active against both fungi.

(9)

3.4. Fungicidal Activity of *N*-[3-(4-*tert*-butyl-1-cyclohexenyl)-2-methylpropyl]-*cis*-2,6-dimethylmorpholine *(11)*

If cycloamines of type *(10)*, bearing a 3-(4-*tert*-butylcyclohexyl)-2-methylpropyl residue on the nitrogen are prepared by hydrogenation of the aromatic precursers and if the hydrogenation is interrupted when about half of the starting material has disappeared, the product contains besides starting material and the two cyclohexane compounds yet another 1-cyclohexenyl derivative. By several fractionations it is possible to enrich the cyclohexenyl derivative, *e.g. (11)*, to more than 85% (see Fig. 2).



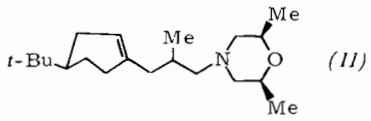


Fig. 2. Partial hydrogenation of *cis-(2j)* to *(11)*.

Table 16. Fungicidal activity of the cyclohexenyl derivative *(11)*.

(11)

Wheat mildew *c* [%]		Brown rust of wheat *c* [%]	
0.025	0B	0.025	0
0.012	0	0.012	0
0.006	0	0.006	0
Systemic activity against wheat mildew			
0.003	0/2 [a]		
0.0015	2/3 [a]		

[a] Mildew attack on untreated fresh foliage.

As shown in Table 16, the activity of compound *(11)* against wheat mildew and brown rust of wheat can be designated as very good. Compound *(11)* has a substantially better activity than the 1,4-*cis*-cyclohexane compound *cis-(10)*.

The conformation of *(11)* is similar to that of the educt *cis-(2j)* and to that of the very active 1,4-*trans*-cyclohexane compound *trans-(10)*. It would seem that the conformation of this class of compound plays a very important role regarding the fungicidal activity.

4. Conclusion

It has been shown in this article that the fungicidal activity of 3-phenylpropylamines is primarily determined by the conformation of the molecule. If a molecule contains several chiral centers it is also worth while making an optimization with regard to the configurational features. The effort spent in doing this is amply rewarded in the form of a better fungicidal activity and thus in a lowering of the amount of fungicide required. The productivity is improved to the same extent by this small amount of substance as by a larger amount of the stereoisomeric mixture. The crop culture is far less burdened on using a substance having an optimum molecular structure.

Developments in the Field of Inorganic Pigments[**]

By Knut Bittler and Werner Ostertag[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The specific properties of inorganic pigments result from an interplay of solid-state properties, particle size, and particle shape. However, phenomena occurring at the pigment interfaces also have implications for the use of the pigment. The interrelations for individual classes of pigments are indicated, and two selected examples, namely transparent colored pigments and magnetic pigments, are subsequently discussed with particular attention being paid to industrial developments.

1. Introduction

Inorganic pigments have been known for a very long time. They are found in prehistoric cave drawings, for example the drawings in the Pech-Merle caves in the South of France.

Fig. 1. a) Detail from a cave drawing in Pech-Merle (France). b) Antique Grecian vase, from the 5th century BC.

Figure 1a shows a detail from these cave drawings, believed to be about 17000 years old.

Another example of the use of inorganic colored pigments is to be found in antique pottery, such as the antique Grecian vase in Figure 1b which dates from the 5th century BC.

An appreciation of the artistic value of the pigments was soon followed by an appreciation of their commercial importance, and in this respect inorganic pigments have meanwhile lost none of their attractiveness. Today, with world sales running at about 10 billion DM per annum they are an important economic factor.

The beginnings of the pigment industry date back to the 18th century when colored pigments such as Berlin blue, $Fe[Fe_2(CN)_6]_3$, cobalt blue, $CoAl_2O_4$, Scheele's green, $Cu(AsO_2)_2 \cdot Cu(OH)_2$, and chrome yellow, $PbCrO_4$, were discovered and produced on a large scale.

The real commercial upswing, however, only occurred in the present century thanks to more modern means of production and more refined methods of scientific investigation. New applications were also discovered.

Nowadays, pigments are classified under the following headings:

Colorants; magnetic pigments; rustproofing pigments; and fillers.

Pigments are small solid particles roughly within the size range from 0.1 to 1 μm[*], and of greatly varying shape. They furthermore have a narrow particle size distribution and conform to a number of stability criteria, such as heat resistance, insolubility in solvents and binders, fastness to weathering, and stability to ultraviolet light.

The specific properties of a pigment, which determine its use as a colorant, magnetic pigment, rustproofing pigment or filler, essentially result from the interplay of the solid state properties, particle size, and particle morphology of the pigment. In addition, there are numerous phase boundary phenomena occurring between the pigment and the binder.

Typical solid state properties, *i. e.* properties resulting from the chemical composition and structure of the solid, include the color, the refractive index, and the magnetic order.

Pigment properties which are determined by, or affected by, the particle size and particle shape include the hue, the light scattering and the magnetic coercive field strength.

Phase boundary phenomena occurring between the pigment and the binder in the main play a part in the dispersibility of a pigment and the stability of the dispersion, but also in other specific effects, which will be referred to later. Pigments are always employed in dispersed form, because only in this form do the properties other than purely solids properties of the pigments come into play. At the same time, dispersions are technically easy to apply.

2. Properties of Pigment Categories

2.1. Colorants

Colorants are classified into white pigments and colored pigments[**].

White pigments show no absorption in the visible range; colored pigments absorb certain wavelengths of visible light. The reasons for the color reside in the molecule itself or in

[*] Dr. Knut Bittler, Dr. Werner Ostertag
BASF Aktiengesellschaft, Hauptlaboratorium
D-6700 Ludwigshafen (Germany)

[**] Based on a plenary lecture read at the General Meeting of the GDCh at Berlin on September 12, 1979.

[*] The size range is not precisely defined: there are pigments of 0.01 μm particle size and also pigments of 10 μm particle size.

[**] In this classification, black pigments are regarded as colored pigments.

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0303-0190 $ 02.50/0 Angew. Chem. Int. Ed. Engl. 19, 190-196 (1980)

the type of lattice. Various absorption mechanisms may be involved[1].

The following are some characteristic examples: The color of yellow lead chromate $PbCrO_4$ is attributable to charge transfer in the chromate anion. This electronic transition from oxygen to chromium is caused by the blue region of visible light.

The color of the blue cobalt aluminum spinel $CoAl_2O_4$ is due to the ligand field of the O^{2-} tetrahedra of the spinel lattice. This ligand field splits the originally equivalent d-levels of the Co^{2+} and permits electron transitions between the split energy levels as a result of light absorption in the visible range.

In the case of the red pigment Cd(SeS), the color is caused by the absorption of light of short wavelengths, which triggers electron transitions between the valency band and the conduction band of the solid.

Finally, the color of pigments can also be due to the presence of different valencies of one and the same element in the lattice, and to non-stoichiometric compositions. Examples are black iron oxide Fe_3O_4, and molybdenum blue MoO_{3-x}, a non-stoichiometric molybdenum oxide.

Whilst the color of a colored pigment is due to the light absorption *per se,* the shape of the absorption spectrum is responsible for the purity of hue.

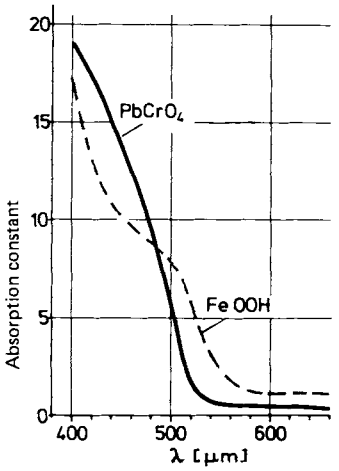

Fig. 2. Absorption spectra of chrome yellow, $PbCrO_4$, and yellow iron oxide, FeOOH, in the 400–660 µm range [2].

Figure 2 shows the absorption spectra of chrome yellow and yellow iron oxide[2]. The sharper, *i.e.* the steeper, the absorption edge, and the fewer additional absorption bands present in the visible range, the purer the hue of a colorant. The sharper rise in absorption in the case of chrome yellow is responsible for its exceptional brilliance. In the case of yellow iron oxide, the absorption curve is overall not so steep and therefore the color is distinctly duller.

Color and purity of hue are, however, not the only requirements which a colorant has to meet; it must also possess good tinctorial strength[*] and hiding power.

[*] In practice, the tinctorial strength is determined as the relative tinctorial strength according to DIN 53254 and DIN 55943; it results from the particular absorption characteristics *and* scattering characteristics of the pigment in question.

The hiding power of a colorant depends primarily on the light scattering which occurs at the pigment particles in the dispersion. This phenomenon is shown diagrammatically in Figure 3.

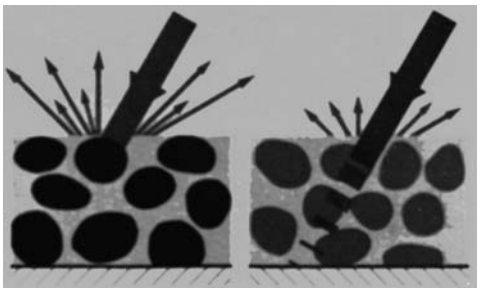

Fig. 3. Diagrammatic representation of light scattering at pigment particles in a dispersion; particles of high refractive index on the left; particles of low refractive index on the right. The gray background represents the binder.

The light scattering is seen to be more pronounced, the greater the difference in refractive indices of the pigment and the binder.

However, the scattering power also depends on the particle size of the pigment; this dependence is shown in Figure 4 for a rutile dispersion in oil[3].

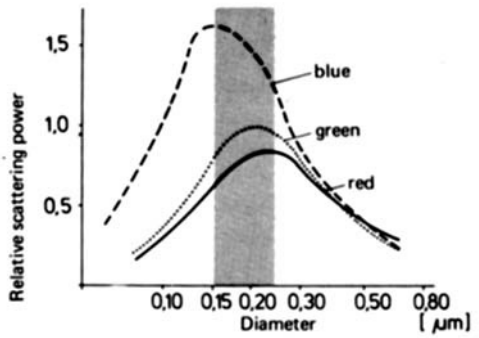

Fig. 4. Dependence of the relative scattering power of a rutile/oil dispersion on the type of light and the particle size [3].

It will be seen that optimum light scattering requires a very specific particle size for each wavelength. For the white pigment TiO_2, the particle sizes corresponding to this optimum are in the range from 0.15 to 0.25 µm. This is because, for TiO_2, the scattering maxima for the wavelengths of white light lie in this range.

2.2. Magnetic Pigments

The most important requirement for a magnetic pigment is ferromagnetism or ferrimagnetism. As is well known, this magnetism depends on the crystalline state of the material and is due to the parallel orientation of the spin moments of greater or lesser domains of the crystal lattice.

Examples of ferromagnetic materials are iron and CrO_2, and examples of ferrimagnetic materials are certain iron oxides, *e.g.* γ-Fe_2O_3, or ferrites, *e.g.* $CoFe_2O_4$. Both categories of materials are equally suitable for the production of magnetic pigments.

The first field of use for magnetic pigments was in sound-recording tapes. At the present time, magnetic tapes are used extensively not only in the entertainments industry but in information and data processing. Figure 5 shows, in a greatly simplified form, the principle of magnetic recording[4]. The magnetic tape is led past the gap of a horseshoe-shaped iron or ferrite core, which is wound with a coil and referred to as the magnetic head. The information to be stored is first converted into an electrical alternating voltage. This alternating voltage is used to generate, *via* the coil and the iron or ferrite core, a magnetic leakage field at the gap. This leakage field orients the initially random magnetic domains of the pigment coating on the tape. This orientation is retained after the magnetization, *i. e.* after leaving the leakage field.

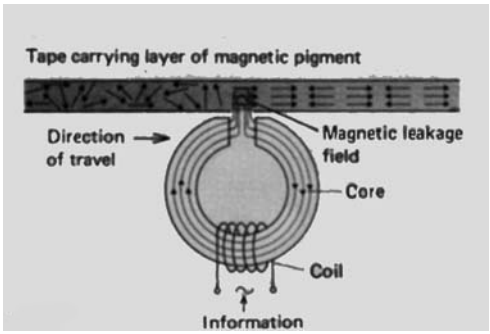

Fig. 5. Principle of magnetic recording. The arrows represent the magnetic domains of the pigment coating. The core may be iron or ferrite.

The intensity and durability of the magnetic recording is essentially dependent on three parameters: the Curie temperature, the residual induction, and the coercive field strength. The Curie temperature indicates the temperature at which the pigment loses its magnetization due to thermal motion of the spins, and becomes paramagnetic. Hence, for practical applications the Curie temperature should be as high as possible. The residual induction and coercive field strength are characteristic parameters of the magnetization behavior of a pigment. The magnetization behavior is represented in the form of a hysteresis loop (Fig. 6a). The residual induction M_r is the magnetization which remains after magnetically saturating the pigment by means of the external magnetic field (M_s = saturation magnetization) and then switching off the field. The coercive field strength H_c of a pigment is the magnetic field needed in order completely to demagnetize the magnetic pigment again. The coercive field strength can also be regarded as a measure of the ability of the pigment to resist demagnetization, *i. e.* a measure of its ability to retain information once accepted. The hysteresis curve has a characteristic appearance for each pigment.

In general, pigments of high residual induction are desirable, since they exhibit powerful recording signals and hence permit production of very thin magnetic coatings. On the other hand, the coercive field strength must not be too low or too high. If it is too low, the tape can be demagnetized too easily, and loses its information. If it is too high, the tape can no longer be erased.

However, the residual induction and coercive field strength of a magnetic tape are not merely characteristics of the particular solid-state material used. The shape of the pigment particles also greatly influences the magnetic tape characteristics. This effect was recognized at an early stage, and it was found that acicular particles give higher coercive field strengths than compact particles. Moreover, acicular pigment particles also prove advantageous in other respects. This is because, the pigment particles in the flowing dispersion can be oriented parallel to the tape surface and tape direction by means of a permanent magnet. This orientation widens the hysteresis curve and thus further increases the coercive field strength and produces a not insubstantial gain in residual induction[5] (see Fig. 6b).

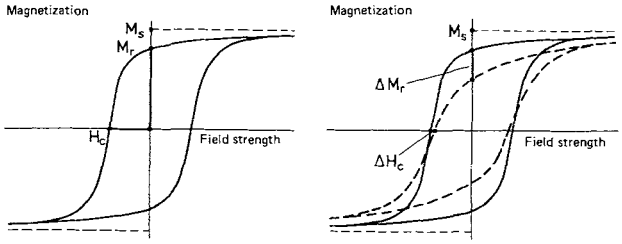

Fig. 6. a) Magnetization behavior of a magnetic pigment. Ordinate: Magnetization of the pigment. Abscissa: Field strength of an externally applied magnetic field. M_s = saturation magnetization, M_r = residual induction, H_c = coercive field strength. b) Effect of the orientation of acicular pigment particles. Broken curve without orientation; solid curve with orientation. ΔM_r = gain in residual induction, ΔH_c = gain in coercive field strength.

2.3. Rustproofing Pigments

The effect of a rustproofing pigment is attributable to diverse physical and chemical phenomena occurring at the surface of the pigment particle. The physical protective action may be illustrated with reference to micaceous iron ore, which is a rustproofing pigment[6] (Fig. 7).

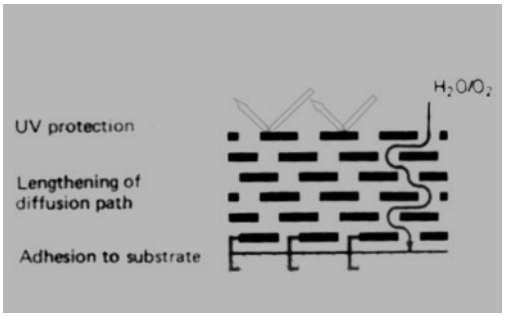

Fig. 7. Diagrammatic representation of physical rustproofing action illustrated for micaceous iron ore [6].

The black bars in the figure represent the flake-like micaceous iron ore particles. The binder — indicated in gray — is

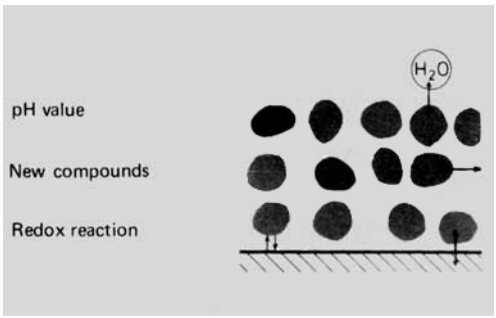

Fig. 8. Diagrammatic representation of chemical rustproofing action.

located between the particles. It is found in practice that pigmented finishes show better adhesion to the substrate than non-pigmented finishes. This adhesion is symbolized by brackets. In addition, the overlapping flakes form a kind of labyrinth for any penetrating air and moisture, and thus lengthen their diffusion path to the surface to be protected.

Further protection results from the fact that the pigment screens the organic binder against UV rays, both by absorption and by reflection.

As is shown diagrammatically in Figure 8, the chemical protective action of pigments is based on chemical interactions in the interfacial region between the pigment and the substrate, the pigment and the binder, and the pigment and any moisture which has penetrated. For example, redox reactions occur, new protective compounds are formed or a certain pH results in the vicinity of the pigment particles.

In the case of red lead it is known[7] that the redox reaction between tetravalent lead and the iron substrate results in the formation of insoluble protective layers containing Pb^{2+} and Fe^{3+} ions. In addition, the reaction of the red lead with the fatty acids of the binder leads to the formation of "lead soaps", which also act as a protective film. Hydrolysis finally gives $Pb(OH)_2$, which produces a basic pH in the vicinity of the particles and hence additionally retards corrosion.

It follows from what has been said above that the ideal rustproofing pigment must perform a large number of functions. The problem of rusting would in principle be solved if it were possible to produce coatings which cannot be damaged mechanically, adhere firmly, and are impermeable to water and to air. However, this has not hitherto proved possible. Hence, pigments remain the best solution to the problem of corrosion.

2.4. Fillers[*]

Fillers serve as diluents, for extending and improving pigment dispersions[8]. For example, fillers can be used to adjust the flow characteristics of finishes and dispersions, and to improve their processability. Moreover, the hardness, and adhesion to the substrate, of a pigment dispersion can also often be optimized by adding fillers. Fillers can also be used to render surfaces hydrophilic or hydrophobic. In some cases, fillers are used in order to fix dyes. Well-known fillers include pyrogenic silica, SiO_2, and Blanc fixe, $BaSO_4$.

3. Recent Developments

3.1. Transparent Colored Pigments

The relatively recent field of transparent colored pigments has become commercially interesting in the last 10 years, because they make possible particular optical effects. Figure 9a shows a photograph covered with two lacquer film strips pigmented with iron oxide. Both strips contain the same amount of iron oxide and are of equal thickness. Nevertheless, the left-hand strip is opaque and the right-hand strip transparent. The phenomenon is readily explained when the particle size of the particular pigments is considered. The opaque dispersion layer has a particle size of about 0.5 μm whilst the particles in the transparent layer are substantially smaller.

The hiding power of a pigmented lacquer film depends — as indicated in Section 2.1 — on the particle size of the pigment used. The larger particles show high light scattering and hence good hiding power. On the other hand, the substantially smaller particles have largely lost the ability to scatter light; the corresponding lacquer film is transparent. However, the light absorption, and hence the color, persists also in the case of the small particles. As a result, interesting effects can be achieved with transparent pigments. For example, it is possible to pigment articles without masking and hence losing the structure of the substrate. This effect is shown in Figure 9b on three samples of wood treated with transparent pigment dispersions.

What pigments are suitable for transparent lacquers and glazes? In principle, all colored pigments, provided their process of manufacture allows them to be obtained in a sufficiently finely divided form.

Table 1. Transparent inorganic colorants.

FeOOH	Iron oxide yellow
Fe_2O_3	Iron oxide red
$Cr_4O_3(OH)_6$	Hydrated chromium oxide green
Cr_2O_3/SiO_2	Chromium oxide green
$CoAl_2O_4$	Cobalt blue

Table 1 shows compounds with which it has hitherto proved possible to produce transparent colorations. Essentially, they are transition metal oxides.

Of these pigments, it is especially the iron oxide pigments which are commercially important. The reasons include their good pigmenting power and the ability of iron oxide to absorb UV radiation and hence to protect the organic dispersants against rapid degradation. Among the transparent iron oxides, iron oxide red, which is particularly heat-stable, has found the widest use. Transparent iron oxide red pigments are manufactured industrially by two processes, a wet chemical precipitation process and a pyrolytic process.

The precipitation process[9] involves three steps:

$$\text{Precipitation } Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2$$
$$\text{Oxidation } Fe(OH)_2 + \text{air} \rightarrow FeOOH$$
$$\text{Dehydration } FeOOH \rightarrow Fe_2O_3$$

Pigments prepared by this method have the typical acicular appearance shown in Figure 10a. The average particle size is about 0.1 μm. Due to the method of preparation, iron oxide pigments obtained by precipitation are difficult to disperse. The user must frequently subject the finely divided oxide, which tends to agglomerate, to a very lengthy deagglomeration treatment because the optical effect of agglomerates is similar to that of larger particles, *i. e.* agglomerates reduce the transparency.

[*] The classification of fillers and pigments overlapped for a long time. According to the definition in a German standards specification (DIN 55943) and an international standards specification (ISO standard 3262), white powders with refractive indices greater than 1.7 are regarded as pigments and those with refractive indices of less than 1.7 as fillers.

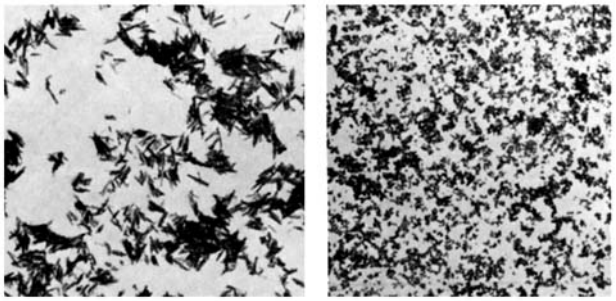

Fig. 9. a) Photograph with two lacquer strips pigmented with iron oxide (the amounts of iron oxide and the thickness of the lacquer film being the same for both strips). The left-hand lacquer film is opaque and the right-hand strip transparent. b) Samples of wood treated with various transparent pigment dispersions.

A more easily dispersible finely divided pigment is obtained by the pyrolytic process[10]:

$$Fe(CO)_5 + air \xrightarrow{600\,^{\circ}C} Fe_2O_3 + CO_2$$

The essential point in this process is to avoid sintering. The particles of pyrogenic iron oxide red pigments are smaller by about a factor of ten than the particles of the products obtained by precipitation. This can be seen very clearly in the electron micrographs in Figure 10. In contrast to the acicular precipitated product, the pyrolytically produced particles have a round shape.

a) b)

Fig. 10. Electron micrographs of transparent iron oxide red pigments. a) Pigment obtained by the wet precipitation process. 15 mm in the figure correspond to 1 μm. b) Pigment obtained by the pyrolytic process.

Table 2 compares further properties of the pyrolysis product with the corresponding properties of the precipitated product. The very finely divided nature of the pyrolysis product manifests itself in its larger specific surface area and in a more yellowish hue. The smaller particles give better transparency but as a result a lower tinctorial strength. A factor particularly important in practice is the excellent dispersibility of the pyrolytically prepared pigment, as shown by the short dispersing time needed to develop the full depth of color.

Table 2. Comparison of some properties of transparent Fe_2O_3 pigments.

Product	Surface area, BET method [m^2/g]	Hue	Relative tinctorial strength [%]	Dispersing time [min]
Pyrolysis product	160	yellowish red	85	5
Precipitation product	100	red	100	40

Transparent iron oxides are in the main used in high-grade metallic-effect finishes in the automotive industry. Other fields of use are in tinting wood, in printing of packaging materials, and in coloring plastics and leather.

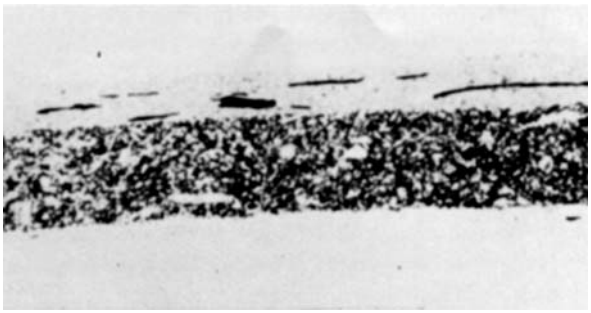

Fig. 11. Microscopic section through a metallic-effect finish. Bottom: primer layer. Top: pigmented finish containing aluminum flakes: 12.5 mm correspond to 25 μm.

Figure 11 shows a microscopic section through a metallic-effect finish. The lacquer layer, pigmented with transparent iron oxide red, lies on top of the dark primer layer. This lacquer layer additionally contains aluminum flakes, about 10–50 μm in size, which in the electron micrograph appear as thin black lines in the lacquer layer. These aluminum flakes act as miniature mirrors and produce the well-known metallic effect. They also allow the surface of the automobile to show a pronounced light-dark visual effect (cf. Fig. 12a). Such light-dark effects can only be achieved with particularly finely divided pigments.

Fig. 12. a) Light-dark effect in metal-effect finishes. b) Light-dark effect as a function of the particle size of the pigment used. Left: lacquer film strip containing high-hiding pigment (larger particles); right: lacquer film strip containing transparent pigment (very small particles); between these: two lacquer film strips containing semi-transparent pigments.

This effect is demonstrated for a slightly curved aluminum foil in Figure 12b. Four different lacquer film strips are applied to this foil; one containing a high-hiding pigment is shown on the extreme left, followed by two containing semi-transparent pigments and, finally, one containing a transparent pigment on the extreme right. The light-dark change in brightness is very pronounced only in the case of the right-hand strip. In the case of the semi-transparent strips the change in brightness is just still discernible, while in the case of the high-hiding film the brightness differences have disappeared.

3.2. Advances in Magnetic Pigments

The very rapid development of radio, television, and not least electronic data processing is ultimately attributable to magnetic pigments. This development started in the early 1930's and resulted from the cooperation between AEG and the Ludwigshafen Research Department of what was at that time IG Farben.

Subsequently, four important types of pigment have come to the forefront. Table 3 shows their characteristic parameters[11].

Table 3. Types of magnetic pigment and some of their characteristic data. Curie temperature, coercive field strength (H_c), saturation magnetization (M_s), and residual induction (M_r). The values (average values) shown apply to acicular pigments.

Pigment	Curie temp. [°C]	H_c [Oe]	M_s [gauss cm³/g]	M_r
γ-Fe_2O_3	600	340	76	60
CrO_2	120	570	100	75
$Co_xFe_{3-x}O_4$ [a]	580	630	90	70
Fe (Co, Ni) [b]	800	1000	217	160

[a] Average values for a pigment containing 10% of cobalt. [b] The magnetic values apply to an iron pigment.

The classical product among these pigments is γ-Fe_2O_3. The manufacture of acicular γ-Fe_2O_3 pigments requires a complicated multi-stage process leading *via* iron oxide hydrate, FeOOH, and magnetite, Fe_3O_4[5,12]. The key product is FeOOH which is easily obtained in an acicular form and to which the shape of the pigment ultimately obtained is attributable.

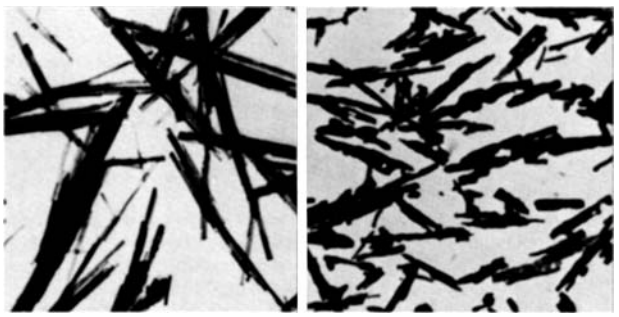

Fig. 13. Electron micrographs of iron oxide pigments. a) an FeOOH pigment; b) the γ-Fe_2O_3 pigment prepared therefrom. 16 mm in the figure correspond to 1 μm.

Figure 13a shows an electron micrograph of FeOOH needles. The needles shown in Figure 13b are the γ-Fe_2O_3 pigment prepared from the FeOOH needles. It will be seen that whilst the acicular shape suffers considerably as a result of the intermediate conversion stages, it is nevertheless basically retained, and this is the vital factor.

The particular advantage of γ-Fe_2O_3 pigments resides in their chemical stability and heat stability, and in the low temperature-dependence of the magnetic properties. The magnetic properties of γ-Fe_2O_3 shown in Table 3 allow γ-Fe_2O_3 pigments to be used for all applications, for example computer tapes, video tapes, and radio tapes. Hence, it is not surprising that this pigment enjoyed a monopoly position for a long time. However, in the mid-1960's miniaturization in the audio and video industry started and the age of the cassette began.

In order to achieve the desired playing time of several hours in small handy cassettes it is necessary for space reasons to make better use of the tapes in these cassettes, *i. e.* to write more closely on the tapes. The high recording density of the cassette tapes is nowadays achieved, *inter alia*, by a drastic reduction in the speed at which the tape is led past the recording head or playback head. The high recording densities required for this technology can, however, not be achieved with conventional γ-Fe_2O_3 pigments without sacrificing some quality; pigments with higher coercive field strengths are required.

As may be seen from Table 3, the other three pigments show the requisite higher coercive field strengths.

Chromium dioxide pigment was first introduced in the early 1970's. Chromium dioxide is chemically metastable; it contains tetravalent chromium. Nevertheless, it can be handled industrially since it releases substantial amounts of oxygen only at elevated temperatures.

Chromium dioxide magnetic pigments can be prepared by two methods[13]:

$$CrO_3 \rightarrow CrO_2 + 0.5\ O_2$$
$$CrO_3 + Cr_2O_3 \rightarrow 3\,CrO_2$$

Both reactions must be carried out under hydrothermal conditions.

Fig. 14. Electron micrograph of a CrO_2 pigment. 14 mm in the figure corresponds to 1 μm.

Figure 14 shows an electron micrograph of a chromium dioxide pigment. The extreme uniformity of the particles is discernible; they are essentially single crystals.

A conspicuous feature is the low Curie temperature of CrO_2, which is about 120 °C. However, this has not proved of disadvantage in practice. On the contrary, a particularly interesting use for CrO_2 pigments results from this very prop-

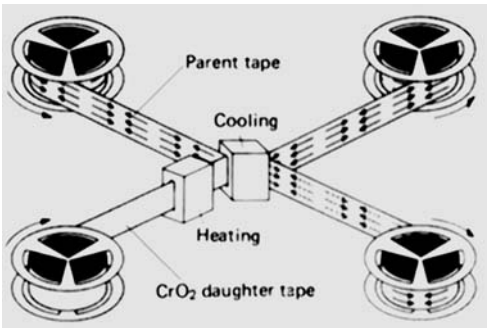

Fig. 15. Diagram illustrating thermoremanent copying.

erty: the low Curie temperature of CrO_2 and the substantial stability of the magnetization up to the Curie temperature make thermoremanent copying feasible. This process, which is only feasible with chromium dioxide pigments, is illustrated in greatly simplified form in Figure 15.

The parent (or mother) tape corresponds to a printing plate, carrying information in mirror image form. The parent tape is brought into intimate contact with the daughter (or slave) tape, which has been heated to just above the Curie temperature. On cooling, the magnetic domains of the pigment of the daughter tape undergo orientation corresponding to the parent tape, and pick up the information of the latter.

In audio cassettes and video cassettes, however, chromium dioxide soon encountered competition from cobalt-modified iron oxides, which show magnetic properties similar to those of CrO_2. It has been known since about the mid-1950's that the coercive field strength of Fe_3O_4 pigments is greatly increased by modifying the pigments with cobalt[14]. Originally, the modification was effected by replacing part of the Fe^{2+} in the octahedral lattice positions in the magnetite randomly by Co^{2+} so that the modification extends over the entire lattice.

With this type of modification, however, the heat stability of the magnetic recording diminishes considerably with increasing cobalt content. Hence, the magnetic tapes produced with such modified iron oxide pigments did not prove satisfactory.

A breakthrough was only achieved when a different type of modification was used, namely surface modification[15]. The principle in shown in Figure 16.

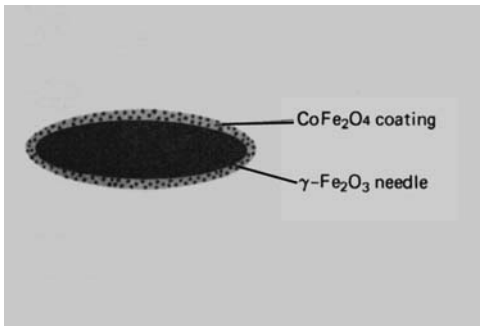

Fig. 16. Principle of surface modification.

In this process, a coating of, say, cobalt ferrite is applied, *e.g.*, to acicular γ-Fe_2O_3 pigments. In this way, the advantages of both types of pigment are exploited: the γ-Fe_2O_3 core gives heat-stable magnetic properties while the Co-containing coating at the same time confers a high coercive field strength upon the pigment.

The ultimate objective of magnetic pigment research has always been to obtain suitable metallic pigments, since metals have attractive magnetic properties. The fact that metal pigments have not long been in use is due to the difficulty of preparing stable, elongate—preferably acicular—metallic pigment particles. Only very recently has this been achieved.

The preferred element for the production of metallic pigments is iron, mainly because of its residual induction.

However, the preparation of metallic iron pigments[16] yields pyrophoric particles, which raises substantial problems. Not only must the particles be protected against oxidation during the manufacturing process; it is also necessary, in particular, to ensure that the pigment subsequently remains stable in the tape.

Looking at the magnetic properties of metallic pigments (Table 3), it is clear that they are the pigments of the future. However, how rapidly metallic pigment tapes will be able to gain a foothold in magnetic recording technology, and how wide their use will be, depends not least on the equipment manufacturers and on the success of their endeavors to modify the equipment to give optimum results with such pigments.

The tape manufacturers have already offered the first metallic pigment tapes to the public—for the first time in 1978 at the "Consumers Electronic Show" in Chicago, and more recently at the 1979 Radio Exhibition in Berlin.

4. Future Prospects

The present-day importance of inorganic pigments is attributable, to a not insignificant degree, to the constantly refined methods of investigation and preparative techniques available in the field of solid-state compounds. The likely future advances in the physics and chemistry of surfaces and solids may therefore be expected also to lead to new fields of use, and to maintain the momentum of the inorganic pigment sector.

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.

Ultratrace Analysis: Determination of Cr, Fe, and Co in the ppb and ppt Range for Checking the Preparation of High-Purity Niobium[**]

By *Werner G. Faix, Viliam Krivan,* and *Klaus Schulze*[*]

Interest in high-purity niobium has increased tremendously in recent years owing to its scientifically and technologically important properties and its possible application in nuclear and superconductor technology, fusion research, and other fields[1]. Many interesting properties of niobium can be influenced by mere trace of impurities[2]. Hence, the development of highly efficient methods for preparation and analysis are of decisive importance.

We have now been able for the first time to prepare extremely pure niobium and to carry out a reliable analytical characterization. The contents of the elements investigated Cr, Fe, Co, Ta and W lie in the ppb to ppt range. Other highly purified high-melting metals of this type are unknown.

The research group in Stuttgart has developed a three-step purification method. 1. Commercially available pure niobium is subjected to refining electrolysis in a ternary alkali-metal fluoride melt containing Nb^{4+} at $T=750\,^{\circ}C$ with simultaneous cathodic separation as single crystals. 2. The single crystals are purified by zone refining in an ultravacuum according to the "floating-zone method". 3. Immediately after zone refining, the samples are heated in the same apparatus by direct current to temperatures slightly below the melting point of niobium, decarburized in a stream of oxygen at $p_{O_2}=10^{-6}$ mbar, and finally annealed for 48 h until a pressure of 10^{-10} mbar is reached.

Of interest in assessing the purification method are: i) the content of major impurities Ta and W, which can be determined by instrumental neutron activation analysis, and ii) the content of a few other trace elements such as Cr, Fe, and Co, whose overall concentration is relatively high so that contamination can even take place during the purification process.

Since the detection limits and accuracy in non-activation methods are essentially determined by the blank values it appeared more meaningful to us to use neutron activation analysis, which offers unique advantages with respect to the blank[3]. The research group at Ulm has worked out the following analytical procedure: Sample and standard are activated by prolonged irradiation in a medium or high-flux reactor (in our case: 42 days' irradiation in the FR-2 at the Nuclear Research Center in Karlsruhe, with a thermal neutron flux of 8×10^{13} n cm^{-2} s^{-1}). After irradiation and surface decontamination of the niobium sample, 2 mg each of Cr, Fe and Co are added as carriers and the sample dissolved in HF/HNO_3. The matrix and major impurities, and the radionuclides formed from them are separated (based on work given in[4]) on a strongly basic anion exchanger (Dowex 1, X4, 50/100 mesh) in fluoride form. The eluate (50 ml 2N HF) after this separation contains the indicator radionuclides (IRN) of the investigated elements ^{51}Cr, ^{59}Fe, and ^{60}Co and can be used for their quantitative determination by gamma-ray spectroscopy. For specific separation of the IRN (based on work given in[5]) the sample solution is transferred in hydrochloric acid medium (*ca.* 8 N) onto a strongly basic anion exchanger in chloride form and eluted with HCl of different concentrations (50 ml 8 N HCl→Cr; 50 ml 4N HCl→Co; 50 ml 0.1N HCl/0.1% N_2H_4→Fe). The fractions containing each of the elements are then counted using a 3 × 3″ NaI well-type detector in an 11 cm-thick shielding of low-activity lead.

For a sample weight of *ca.* 100 mg, detection limits down to 10 ppt for Cr, 1.5 ppb for Fe and 4.0 ppt for Co can be achieved.

Using this analysis technique, the concentrations of Cr, Fe, and Co in several high-purity niobium samples were determined. The results for these elements as well as for Ta and W (determined by instrumental neutron activation analysis) are given in Table 1.

Table 1. Contents of Cr, Fe, Co, Ta and W determined in niobium (for the description of samples and purification methods see text).

Element	Sample		
	Nb-WCT [a]	R-Nb-1 [b]	R-Nb-2 [b]
Cr	1.7 ± 0.5 ppb	3.6–16.7 ppb	10 – 24.7 ppt
Fe	15.5 ± 3.0 ppb	0.6– 1.8 ppm	2 – 6.6 ppb
Co	53.9 ± 2.0 ppt	0.2– 1.6 ppb	4 – 19.0 ppt
Ta	163 ppm	0.1– 6.0 ppm	0.1– 6.0 ppm
W	7.5 ppm	2 –60 ppb	2 –100 ppb

[a] Averages from three determinations with average deviations.
[b] Content ranges of five separately purified samples.

As starting material for the high-purity niobium samples we used Nb-WCT (Teledyne Wah Chang, Albany, Oregon [USA]), which was remelted under vacuum in an electron beam furnace. The lower melting metals Cr, Fe, Co evapo-

rate with high vapor pressure at $T > 2500\,^{\circ}C$, thus accounting for their low content; the high melting impurities Ta and W, on the other hand, remain in the niobium. The samples R-Nb-1 were electrolyzed; the major impurities Ta and W are thus removed, but metals such as Cr, Fe, and Co are apparently involved by contamination. The samples R-Nb-2 were additionally zone refined and annealed, which leads to a marked decrease in the Cr, Fe, and Co content.

The niobium thus obtained can be additionally characterized by its specific electrical resistivity of ϱ (4.2 K) $= 6 \times 10^{-10}\ \Omega$ cm in the normal state; the total content of non-metals is about 100 ppb. These findings show that niobium of particularly high purity and structural perfection can be prepared by the above method. The analytical method developed here for the determination of Cr, Fe, and Co is characterized by its extremely high sensitivity and freedom from error regarding contamination and losses.

Synthesis of Monosubstituted (*S*)-Oxiranes in High Optical Purity

By *Ulrich Schmidt, Jörg Talbiersky, Frank Bartkowiak,* and *Jochen Wild*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Epoxides are cleaved regioselectively and stereoselectively by nucleophiles. Optically active epoxides are therefore useful building blocks for the synthesis of complicated chiral natural products. We have found that the optically active 2,2-dimethyl-1,3-dioxolan-4-ylmethyl *p*-toluenesulfonate (2,3-isopropylideneglycerol 1-tosylate) *(1)* reacts stereoselectively with alkylmetal compounds to give the dioxolanes *(2)*, in which the toluenesulfonyloxy group of *(1)* is replaced by an alkyl group. (*S*)-*(2)* gives oxiranes *(5)* of high optical purity having the *S* configuration.

The reactant (*R*)-*(1)* is readily accessible on a 100 g-scale from diisopropylidenemannitol, whose preparation[1] could be improved. The 1,2-butanediol derivative *(2a)* obtained from *(1)* and methyllithium/copper(I) iodide was transformed by treatment with hydrogen bromide/glacial acetic acid[2] into a mixture of bromoalkyl acetates *(3a)/(4a)*, from which 1,2-epoxybutane *(5a)* resulted by elimination. The rotatory power of *(5a)* agreed with the value reported[3]

Scheme 1. (*R*)-*(1)*→(*S*)-*(2a)*, variant *A*: CH_3Li/CuI; (*R*)-*(1)*→(*S*)-*(2b)*: variant *A*: n-C_4H_9Li/CuI; variant *B*: $(n\text{-}C_4H_9)_2Mg/Li_2CuCl_4$; *C*: CH_3COOH/HBr [2]; *D*: n-$C_5H_{11}OH/n$-$C_5H_{11}OK$ [2].

for optically pure (*S*)-*(5a)*. Optically pure (*S*)-1,2-epoxyheptane *(5b)* is produced analogously[4]. Variant *B*[5] gave a higher yield (67%) in step *(1)*→*(2b)* than did variant *A* (43%) (Scheme 1).

Procedure

Diisopropylidenemannitol: Anhydrous zinc chloride (544 g, not fused) is dissolved in acetone (2800 ml). The solution is allowed to stand for 3 d over a 3-Å molecular sieve (200 ml), D-mannitol (340 g) is added, and the mixture is stirred for 2 h at room temperature, whereupon the mannitol dissolves. After filtering off the molecular sieve, the mixture is rapidly stirred into a solution of potassium carbonate (680 g) in water (700 ml) covered with ether (2000 ml). After 30 min, zinc carbonate is decanted off and the precipitate washed with ether/acetone (1:1). The combined organic phases are evaporated down *in vacuo* and the residue recrystallized from water; yield 470 g of moist crude product of sufficient purity for further work.

(R)-(1): Diisopropylidenemannitol is cleaved according to ref.[6] with sodium periodate and the resulting aldehyde reduced directly with $NaBH_4$. The optically active isopropylideneglycerol which—contrary to the statement in ref.[6]—can be distilled without racemization (b. p. 33 °C/0.1 torr; $\alpha_D^{20} = +15.59°$ (neat), is treated with *p*-toluenesulfonyl chloride to give *(R)-(1)*; m. p. of crude product: 20–25 °C.

(S)-(5a): A solution of *(1)* (7.25 g) in ether (35 ml) is added at −35 °C to a solution prepared from CuI (6.79 g) in ether (15 ml) and CH_3Li (71.3 mmol) in ether (40 ml) according to ref.[7]. The mixture is warmed to 0 °C within 1 h and stirring continued for 12 h. After hydrolysis with saturated NH_4Cl solution, it is extracted several times with ether, and the ethereal solution is dried and distilled; yield 2.31 g (70%), *(2a)*, $\alpha_D^{25} = +19.2°$ ($c = 0.8$ g/100 ml, methanol).—HBr/glacial acetic acid (saturated) (11.6 g) is added dropwise to *(2a)* (2.12 g) at 0 °C within 5 min. After 30 min the mixture is diluted with H_2O (100 ml), neutralized with Na_2CO_3, and extracted repeatedly with ether and the ethereal phase distilled; yield 2.6 g (82%) of *(3a)/(4a)*, b. p. 72 °C/16 torr.—Elimination according to ref.[2] in *n*-pentanol with potassium pentyl oxide afforded 0.93 g of (*S*)-*(5a)*, yield 96%, $\alpha_D^{16} = -12.25°$ ($c = 6$ g/100 ml, dioxane); ref.[3]: $\alpha_D^{16} = -12.4°$.

Rearrangement of Cyclopropyl Ketone Oximes to 5,6-Dihydro-4*H*-1,2-oxazines

By *C. N. Rentzea*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Cyclopropyl 4-methylstyryl ketone oxime *(2a)*, R = *p*-tolyl, was obtained by reaction of the *trans*-ketone *(1a)*[1] with $NH_2OH \cdot HCl$ in ethanol at 40 °C as a *Z/E* mixture[2]; m. p. 118 °C, yield 14% and m. p. 135 °C, yield 57%, respectively. Both the ketone *(1a)* and the oxime *(2a)* led, under more drastic conditions[3] (8 h reflux in ethanol; *(1a)* or *(2a)*: $NH_2OH \cdot HCl = 1:1.5$), to the same *trans*-3-(4-methylstyryl)-5,6-dihydro-4*H*-1,2-oxazine *(5a)*[2] in 41% yield. Further examples are to be found in Table 1.

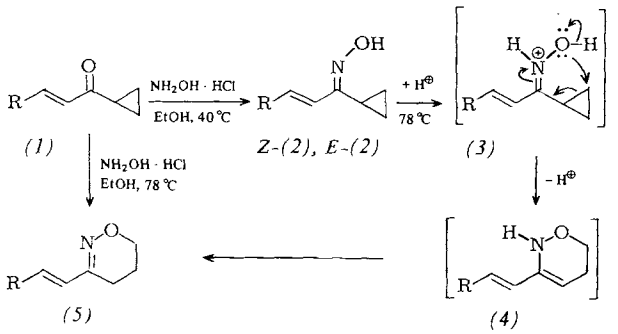

Table 1. Physical data of the compounds *(5a-k)*[2] obtained from the ketones *(1a-k)*[1]. IR in KBr, ^{1}H-NMR in $CDCl_3$, TMS as internal standard.

(5a), m. p. 199 °C (from acetone); IR: 1545, 1225, 960, 800 cm^{-1}; ^{1}H-NMR: $\delta = 2.06-2.2$ (m, 2H), 2.33 (s, 3H), 2.84–2.95 (t, 2H), 4.0–4.11 (t, 2H), 6.77–6.86 (d, 1H), 7.11–7.2 (d, 2H), 7.31–7.42 (d, 1H), 7.37–7.46 (d, 2H); ^{13}C-NMR ($CDCl_3$): $\delta = 143.63$, 139.42, 136.58, 133.50, 129.63 (×2), 127.36 (×2), 115.07, 62.71, 28.45, 21.28, 16.96

(5b), R = C_6H_5; m. p. 164 °C (from acetone); yield 42%; ^{1}H-NMR: $\delta = 2.0-2.36$ (m, 2H), 2.83–3.1 (t, 2H), 4.0–4.25 (t, 2H), 6.8–7.02 (d, 1H), 7.3–7.7 (m, 6H)

(5c), R = 4-$(C_6H_5)C_6H_4$; m. p. 196 °C (from acetonitrile); yield 45%; ^{1}H-NMR: $\delta = 1.88-2.33$ (m, 2H), 2.55–2.96 (t, 2H), 3.70–4.10 (t, 2H), 6.52–6.38 (d, 1H), 7.05–7.55 (m, 10H)

(5d), R = 1-$C_{10}H_7$; m. p. 153 °C (from acetic acid); yield 41%; IR: 1540, 1225, 962, 778 cm^{-1}; ^{1}H-NMR: $\delta = 2.13-2.26$ (m, 2H), 3.0–3.08 (t, 2H), 4.08–4.17 (t, 2H), 7.42–7.57 (m, 4H), 7.62–7.75 (d, 1H), 7.77–7.91 (m, 3H), 8.06–8.15 (d, 1H)

(5e), R = 4-ClC_6H_4; m. p. 171 °C (from acetone); yield 30%; IR: 1540, 1232, 960, 805 cm^{-1}; ^{1}H-NMR: $\delta = 1.95-2.4$ (m, 2H), 2.73–3.1 (t, 2H), 3.88–4.25 (t, 2H), 6.55–6.9 (d, 1H), 7.10–7.50 (m, 5H)

(5f), R = 4-BrC_6H_4; m. p. 192 °C (from acetone); yield 40%; IR: 1542, 1230, 963, 802 cm^{-1}; ^{1}H-NMR: $\delta = 2.0-2.42$ (m, 2H), 2.75–3.1 (t, 2H), 3.84–4.18 (t, 2H), 6.48–6.82 (d, 1H), 7.10–7.45 (m, 5H)

(5g), R = 2,4-$Cl_2C_6H_3$; m. p. 150 °C (from acetone); yield 40%; IR: 1550, 1220, 960, 810 cm^{-1}; ^{1}H-NMR: $\delta = 1.95-2.5$ (m, 2H), 2.80–3.20 (t, 2H), 3.9–4.35 (t, 2H), 6.9–7.48 (m, 4H), 7.55–7.85 (d, 1H)

(5h), R = 3,4-$Cl_2C_6H_3$; m. p. 175 °C (from acetonitrile); yield 47%; ^{1}H-NMR: $\delta = 2.0-2.58$ (m, 2H), 2.81–3.18 (t, 2H), 3.98–4.38 (t, 2H), 6.62–7.0 (d, 1H), 7.22–7.76 (m, 4H)

(5i), R = 4-$(F_3C)C_6H_4$; m. p. 196 °C (from acetone); yield 47%; ^{1}H-NMR: $\delta = 1.86-2.35$ (m, 2H), 2.54–2.96 (t, 2H), 3.7–4.16 (t, 2H), 6.51–6.9 (d, 1H), 7.12–7.52 (d, 5H)

(5j), R = 4-$(O_2N)C_6H_4$; m. p. 216 °C (from acetic acid); yield 40%; IR: 1532, 1340, 975, 833 cm^{-1}; ^{1}H-NMR: $\delta = 2.0-2.48$ (m, 2H), 2.7–3.1 (t, 2H), 3.84–4.2 (t, 2H), 6.52–6.92 (d, 1H), 7.19–7.4 (d, 1H), 7.5–7.6 (d, 2H), 7.88–8.15 (d, 2H)

(5k), R = 4-$(CH_3O)C_6H_4$; m. p. 169 °C (from acetone) yield 29%; ^{1}H-NMR: $\delta = 1.95-2.45$ (m, 2H), 2.7–3.12 (t, 2H), 3.78 (s, 3H), 3.85–4.28 (t, 2H), 6.76–7.64 (m, 6H)

Like the Cloke rearrangement[4] of *(6)* to *(7)*, this novel rearrangement of cyclopropyl ketone oxime *(2)* to oxazines *(5)* appears to involve protonation of the nitrogen atom.

The cyclization of *(3)* to *(4)* is probably an example of 6-*endo-tet* ring closure rarely observed so far.

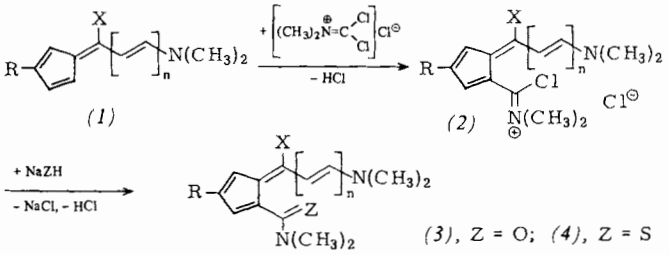
Synthesis of Carbocyclic and Heterocyclic π-Electron Systems with Pentafulvenoid Chloroformamidinium Chlorides

By *Klaus Hafner* and *Hans-Peter Krimmer*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

In 1960, *Eilingsfeld, Seefelder*, and *Weidinger*[1] first reported the preparation and reactions of "carbamide chlorides" (chloroformamidinium chlorides) which have proved



[*] Dr. C. N. Rentzea
BASF-Aktiengesellschaft, Hauptlaboratorium
D-6700 Ludwigshafen (Germany)

[*] Prof. Dr. K. Hafner, Dipl.-Ing. H.-P. Krimmer
Institut für Organische Chemie der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

their value as reactive synthons in the past two decades[2]. We have now found a facile method for the preparation of pentafulvenoid chloroformamidinium chlorides, which permit surprisingly easy syntheses of interesting carbo- and heterocyclic π-electron systems.

By analogy with the formylation of dialkylaminofulvenes of type *(1)*[3], their reaction with dichloromethylene(dimethyl)ammonium chloride[2] gives the cyclically vinylogous chloroformamidinium chlorides *(2)* (yellow hygroscopic crystals; yield 50–70%), which display pronounced reactivity towards numerous nucleophilic partners. Structural proof comes, *inter alia*, from their hydrolysis or reaction with sodium hydrogen sulfide to give amides of carboxylic and thiocarboxylic acids *(3)* and *(4)* (yellow crystals; yield 35–90%).

The 1,4- and 1,6-bifunctional fulvenes *(2)* react with suitable nucleophiles *via* cyclization thus *(2d)* reacts with ammonia to give 5-*tert*-butyl-1,3-bis(dimethylamino)-2-azapentalene *(5)*[4] in 31% yield (blue-violet needles), while 6-*tert*-butyl-1,4-bis(dimethylamino)-2*H*-cyclopenta[*d*]pyridazine *(6)* (dark green needles, yield 51%) is formed with hydrazine. The reaction of *(2d)* with sodium cyclopentadienide and its *tert*-butyl derivative gives the 4,8-bis(dimethylamino)-*s*-indacenes *(7a)* and *(7b)* (green and golden yellow platelets with metallic sheen; 30 and 38% yield, respectively) as heat- and

	R	X	*n*
a	H	H	0

c	H	$(CH_3)_2N$	0
d	$(CH_3)_3C$	$(CH_3)_2N$	0
e	H	H	1

air-stable derivatives of the parent compound so far detected only in solution at low temperature[5].

Like *(2d)*, compound *(2e)* also reacts with ammonia to give the stable 4-(dimethylamino)-5-azaazulene *(8)* (blood red platelets; yield 54%)[6].

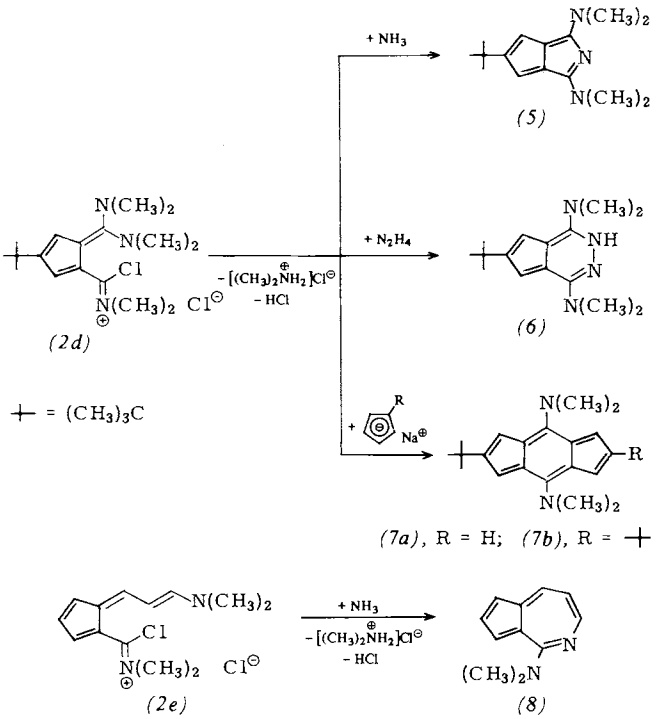

Table 1 lists physical data of some new compounds.

Table 1. Selected physical data of compounds *(2a)*, *(3a–d)*, *(4a)*, *(5)*, *(6)*, *(7a)*, *(7b)*, and *(8)*.

0570-0833/80/0303-0200 $ 02.50/0

Procedure

(2d): A suspension of dichloromethylene(dimethyl)ammonium chloride in CH_2Cl_2 (20 ml) is added dropwise to a stirred solution of *(1d)*[7] (2.2 g, 20 mmol) and triethylamine (2.0 g, 20 mmol) in CH_2Cl_2 (100 ml) at 0 °C. The mixture is then refluxed for 2 h. After cooling to room temperature the solution can be used directly for preparation of *(5)*, *(6)*, and *(7)*. Compound *(2d)* can be isolated as perchlorate.

(5): A slow stream of dry ammonia is passed into the solution of *(2d)* at 0 °C for 30 min. After 2 h, saturated aqueous NH_4Cl solution (200 ml) is added and the mixture extracted with CH_2Cl_2 (3 × 50 ml). On removal of the solvent the residue is chromatographed on Al_2O_3 B IV with ethyl acetate; 770 mg (31%) of *(5)* is isolated from the first violet zone.

(6): Anhydrous hydrazine (320 mg, 10 mmol) is added at room temperature to a solution of *(2d)* and the mixture refluxed for 2 h and worked up as *(5)*. The first green zone gives 1.33 g (51%) of *(6)*.

(7a) and *(7b):* A 2.69 M solution of sodium cyclopentadienide (3.7 ml, 10 mmol) in tetrahydrofuran is added dropwise to a solution of *(2d)*. After refluxing for 2 h the product is worked up as *(5)*. Yield 880 mg (30%) *(7a)*. Compound *(7b)* is obtained analogously with sodium *tert*-butylcyclopentadienide.

(8): A suspension of dichloromethylene(dimethyl)ammonium chloride (1.6 g, 10 mmol) in CH_2Cl_2 (20 ml) is added dropwise to a stirred solution of *(1e)*[3] (1.5 g, 10 mmol) and triethylamine (2.0 g, 20 mmol) in CH_2Cl_2 (100 ml) at 0 °C under N_2. After stirring for 2 h at 0 °C, dry ammonia is passed into the mixture for 30 min and the product is worked up as *(5)*; eluent: hexane/ether (4:1). The first red zone affords 930 mg (54%) of *(8)*.

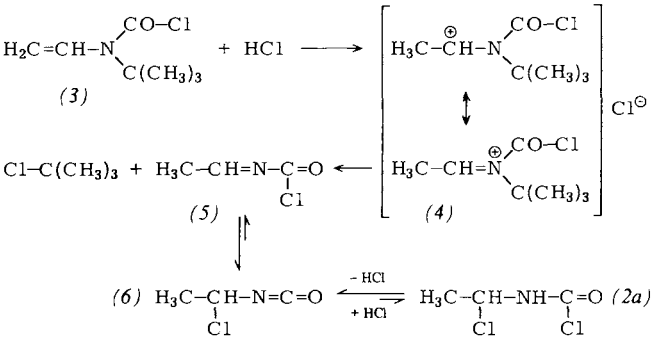
Synthesis of α-Haloalkylcarbamoyl Halides

By *Karl-Heinz König, Christian Reitel,* and *Karl-Heinz Feuerherd*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Ever since vinyl isocyanate[1] was first synthesized there have been repeated reports on the polymerizability of α,β-unsaturated isocyanates and their sensitivity to moisture, acids, and bases[2]. Since these compounds are readily accessible on an industrial scale[3] we have been engaged in a detailed examination of their chemical properties.

We have found that α,β-unsaturated isocyanates *(1)* can react with hydrogen halides at low temperature without polymerization to give α-haloalkylcarbamoyl halides in very good yields (Method A; Table 1)[4]. Remarkably, some of these compounds can be stored for several weeks with cooling.



(1a-n) *(2a-n)*

Table 1. Overview of the α-haloalkylcarbamoyl halides *(2)*.

[*] Dr. K.-H. König [+], Dr. Ch. Reitel, Dr. K.-H. Feuerherd
BASF Aktiengesellschaft, Hauptlaboratorium, WHW
D-6700 Ludwigshafen (Germany)
[+] Author to whom correspondence should be addressed.

Moreover, we have found a further entry to *(2)* (Method B) which avoids dealing with isocyanates *(1)*. Hydrogen chloride is allowed to react with *N*-(1-alkenyl)-*N*-alkylcarbamoyl chlorides[5] of type *(3)*. Thus, for example, *N-tert*-butyl-*N*-vinylcarbamoyl chloride *(3)* reacts with hydrogen chloride at 0 °C with elimination of *tert*-butyl chloride to give α-chloroethylcarbamoyl chloride *(2a)*[6].

That the reaction involves attack by hydrogen chloride at the vinyl group with intermediary formation of *(4)* follows from the observation that *N-tert*-buyl-*N*-chloromethylcarbamoyl chloride is not cleaved. The driving force would appear to lie in the cleavage of *tert*-butyl chloride with intermediary formation of *N*-ethylidenechloroformamide *(5)*, which should be present in equilibrium[7] with α-chloroethyl isocyanate *(6)*. Both *(5)* as well as *(6)* can form the end product *(2a)* with hydrogen chloride.

On storage at room temperature some of the solid derivatives *(2)* eventually lose hydrogen chloride and begin to liquefy without any appreciable amount of polymeric products being formed. Other than in the case of the well-known alkylcarbamoyl chlorides, the equilibrium between *(2a)* and *(6)* already lies well on the side of *(6)* at room temperature. The form *(5)*, already postulated in the case of α-chlorobenzyl isocyanates[7c], could be detected in small amounts in equilibrium with *(6)* by IR spectroscopy.

The new α-haloalkylcarbamoyl halides *(2)* and α-haloalkyl isocyanates *(6)* are highly reactive bifunctional synthetic building blocks. Their structure was confirmed by IR and NMR spectroscopy.

Procedure[4a,6]

(2a), Method A: A mixture of *(1a)* (69 g, 1 mol) and CCl_4 (400 ml) is treated with 73 g (2 mol) of hydrogen chloride at −20 °C. After an additional 15 minutes' stirring the crystalline product is filtered off under N_2; yield 137 g *(2a)* (96%); m. p. 21 °C (dec.); ^{1}H-NMR (CCl_4): $\delta = 1.8$ (3H, d), 5.8 (1H, q), 7.5 (1H, broad).

(2a), Method B: *(3)* (161.5 g, 1 mol) is treated with 75 g (2.05 mol) of hydrogen chloride within 1 h at 0 °C. The mixture is stirred for a further 15 minutes, excess hydrogen chloride is removed by passage of N_2, *tert*-butyl chloride is drawn off at reduced pressure, and the residue is crystallized from CCl_4; yield 135 g *(2a)* (95%); m. p. 20–21 °C (dec.).

Cycloadditions of Diazoalkanes to 1-Alkenes

By *Rolf Huisgen, Johannes Koszinowski, Akihiro Ohta,* and *Reinhard Schiffer*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The successful MO perturbation treatment of the reactivity and regioselectivity of concerted cycloadditions bestows special importance on simple models. Disregarding angularly strained cycloalkenes and bicycloalkenes, very little has been reported about 1,3-dipolar cycloadditions of diazoalkanes to non-conjugated alkenes; the reasons are the slow rate of reaction and the sensitivity of the adducts. The report that 4-substituted pyrazolines are formed on reaction of diazomethane and 1-alkenes[1] is incorrect.

(1), R = H
(2), R = C_4H_9
(3), R = $CH_2C_6H_5$
(4), R = C_4H_9
(5), R = $CH_2C_6H_5$

Azzarello[2] obtained *ca.* 10% crude pyrazoline on passing ethylene into an ethereal solution of diazomethane. We allowed ethylene to react (at a pressure of 50 at) with 0.29 M diazomethane in ether for 24 h at 20 °C in a glass vessel in an autoclave; after removal of ether, GC analysis (anisole as standard) showed 95% 1-pyrazoline *(1)*. This method provides the best access to *(1)*, which can be obtained in pure form on subsequent distillation[3].

1-Hexene reacts ninety times slower than ethylene with diazomethane at 25 °C[4]. A solution of diazomethane (0.63 M) in 1-hexene turned colorless after 24 days at 5 °C and yielded after distillation 50% *(2)*; the area ratio of the downfield and upfield multiplets in the ^{1}H-NMR spectrum approaches 3:11, whereas the isomeric 4-butyl-1-pyrazoline would require 4:10. On treatment with hydrochloric acid, *(2)* was tautomerized to the 2-pyrazolines *(4)* and *(6)*, which were dehydrogenated by sulfur at 175 °C to give 3-butylpyrazole *(12)* in 85% yield. *(12)* was identified by its ^{1}H-NMR spectrum (Table 1) and by permanganate oxidation to 3-pyrazolecarboxylic acid.

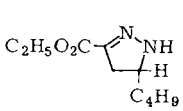
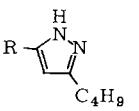
A 0.90 M solution of diazomethane in allylbenzene afforded 91% *(3)* within four days at 5 °C. The diastereotopy of the α-benzyl protons and the ratio of the ring protons in the ^{1}H-NMR spectrum (Table 1) confirm substitution in position 3. On treatment with hydrogen chloride in $CHCl_3$, *(3)* is converted into the hydrochlorides of the 2-pyrazolines *(5)* and *(7)*; in *(5)* the benzyl protons are isochronous, in *(7)* anisochronous.

(6), R = C_4H_9
(7), R = $CH_2C_6H_5$

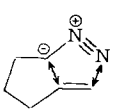


(8), R = $CH_2C_6H_5$
(9), R = CH_3



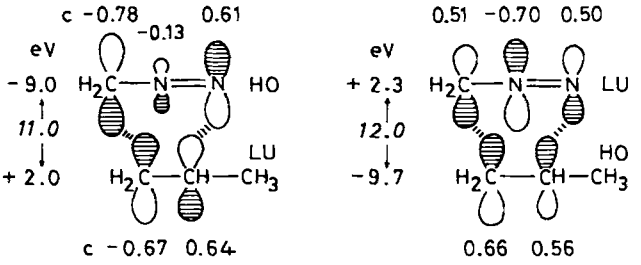
(10)

In the reaction with allylbenzene *ca.* 10% of the structurally isomeric cycloadduct could have eluded detection—in the reaction with 1-hexene even more. On the other hand, the fully resolved ^{1}H-NMR spectrum of the adduct *(8)* from 2-diazopropane and allylbenzene (red solution decolorized after 4 h at 5 °C) guaranteed freedom from isomers within more narrow limits. The anisochronism of the protons of the 5-methyl groups, of the methylene protons at C-4, and of the α-benzyl protons (Table 1) confirms the 3-position of the benzyl. The hydrochloride of the 2-pyrazoline *(10)* obtained in quantitative yield on treatment of *(8)* with HCl shows the expected symmetry by exhibiting singlets in the NMR spectrum.



2-Diazopropane was condensed onto propene; decolorization occurred after 3 h at 5 °C. The trimethyl-1-pyrazoline *(9)* could not be completely separated from the acetone azine; the latter arose from the competing decomposition of 2-diazopropane. The NMR spectrum unequivocally confirmed the structure *(9)*.

(11)



(12), R = H
(13), R = $CO_2C_2H_5$

(14)

The same direction of addition is observed in the case of ethyl diazoacetate. After 30 days' heating with 1-hexene at 70 °C the oily 2-pyrazoline *(11)* could be isolated in 56% yield and was aromatized with chloranil to *(13)*; the structure and composition was confirmed by the NMR spectrum and by oxidation to 3,5-pyrazoledicarboxylic acid.

As in many concerted cycloadditions the orientation rules are not rigid. The intramolecular reaction in *(14)* (as those producing larger rings) is effected in the opposite direction[5] compared with the above examples; the electronically "normal" addition would lead to a strained ring in the case of *(14)*.

Scheme 1

Scheme 1 contains atomic orbital coefficients calculated by CNDO/2 as well as values for HOMO and LUMO energies which are based on ionization potentials and electron affinities[6]. The MO perturbation treatment of the frontier orbital interaction of diazomethane and propene shows that the formation of 3-methyl-1-pyrazoline is slightly favored. The switchover from 3- to 4-substitution is presumably in the region of the enol ethers (and alkoxyacetylenes) for diazomethane and diazoacetic acid ester[7]. In the case of ethyl diazoacetate, which cycloadds to enamines[7] and ynamines[8] to give 4-aminopyrazolines and pyrazoles, respectively, the bidirectionality has been established more convincingly than in the case of diazomethane.

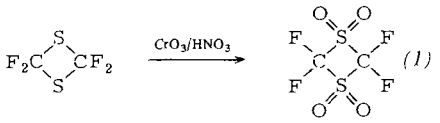
Perfluoro- and Perchlorodisulfenes[**]

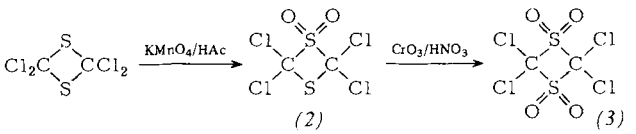


By *Rolf Seelinger* and *Wolfgang Sundermeyer*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

While 1,3-dithietane 1,1,3,3-tetraoxide ("disulfene"), first synthesized by dehydrohalogenation of mesyl chloride with

[*] Prof. Dr. W. Sundermeyer, Dipl.-Chem. R. Seelinger
Anorganisch-chemisches Institut der Universität
Im Neuenheimer Feld 270, D-6900 Heidelberg 1 (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



trimethylamine, has long been known[1], all attempts to prepare the corresponding prefluoro compound *(1)*, as the smallest perfluorinated cyclic disulfone, have so far failed[2]. Following unsuccessful attempts to electrofluorinate disulfene[3] we have now been able to prepare 2,2,4,4-tetrafluoro-1,3-dithietane 1,1,3,3-tetraoxide *(1)* by reaction of tetrafluoro-1,3-thietane with excess chromium trioxide in boiling fuming nitric acid.

(1)

The white crystalline oxidation product (m. p. 134 °C, subl.) isolable by sublimation has a peculiar moldy smell. The unusually high symmetry of the molecule *(1)* (planar ring, F and O atoms each in a plane vertical to each other and to the ring plane) was determined by X-ray structure analysis[4] and explained the high vapor pressure. Elemental analysis, mass spectrum ($m/e = 228$, M^+, 5%), ^{19}F-NMR (singlet at $\delta = 95.9$ rel. $CFCl_3$ int.), and IR data (1401 vs, 1255 vs, 1201 vs, 1174 vs, 853 vs, 718 vs, 522 vs, 510 m, and 482 cm^{-1} s) confirm the structure and composition of the compound, which is sensitive to hydrolysis and is soluble in tetrachloromethane, glacial acetic acid and acetonitrile. As by-product in the synthesis of *(1)* we also obtained 2,2,4,4-tetrafluoro-1,3-dithietane 1,1-dioxide[2].

The analogous reaction of tetrachloro-1,3-dithietane (dimeric thiophosgene) using this method fails, owing to rapid hydrolysis; however, the reaction with potassium permanganate in glacial acetic acid affords white crystalline 2,2,4,4-tetrachloro-1,3-dithietane 1,1-dioxide *(2)* (m. p. 89.5 °C) in 60% yield, which is likewise sublimable and can be recrystallized from petroleum ether.

(2) *(3)*

Above 120 °C, the 1,1-dioxide *(2)* [X-ray structure[4]; IR: 1372 vs (sulfone group), 1180 vs, 873 m, 820 vs, 696 vs, 558 vs, 535 vs, 398 m, and 355 cm^{-1} m] loses tetrachloroethylene. On prolonged standing, formation of a small amount of the isomeric 1,3-dioxide can be detected (mass spectrum; IR band at 1255 cm^{-1}), which, however, could not yet be isolated in pure form. The non-halogenated 1,3-dithietane 1,3-dioxide is well known[5].

(2) is soluble in fuming nitric acid, in which it reacts with CrO_3 to give the 2,2,4,4-tetrachloro-1,3-dithietane 1,1,3,3-tetraoxide *(3)*, a white, crystalline (from petroleum ether), readily sublimable substance (m. p. 200 °C, b. p. 215 °C). The structure of the perchloro compound is also confirmed by the IR spectrum (1383 vs, 1156 vs, 1050 m, 712 vs, 710 s, 569 vs, 480 vs, 404 m, and 333 cm^{-1} s) and X-ray structure analysis[4]. On oxidation of tetrabromo-1,3-dithietane[6] with $KMnO_4$ in glacial acetic acid we obtained the 1,1-dioxide homologous to *(2)* in 45% yield [IR: 1370 vs, 1162 vs, 740 m, 676 s, 550 s and 500 cm^{-1} s]; 2,2-dibromo-4-oxo-1,3-dithietane[6] and CBr_4 occur as impurities. — *(4)* can be further oxidized, analogously to *(2)*→*(3)*, to the already well-known 2,2,4,4-tetrabromo-1,3-diethietane 1,1,3,3-tetraoxide[1].

Procedure

(1): $(F_2CS)_2$ (8.3 g) is added dropwise within 2 h to a stirred solution of dry CrO_3 (15 g) in fuming HNO_3 (40 ml) (reflux condenser: −15 °C). After one hour's refluxing, the solution is evaporated down in a high vacuum. *(1)* is separated from the residue by sublimation and purified; yield 15%.

(2): Pulverized $(Cl_2CS)_2$ (11.4 g) is added portionwise to a solution of $KMnO_4$ (15.8 g) in glacial acetic acid (80 ml) such that the reaction temperature does not exceed 40 °C. After one hour's stirring at room temperature, the mixture is poured onto ice and the precipitate recrystallized from petroleum ether; yield 60%.

(3): (2) (6.5 g) is added within 1.5 h to a stirred solution of CrO_3 (10 g) in fuming HNO_3 (50 ml). Stirring is continued for a further 1 h and the temperature not allowed to exceed 40 °C. The reaction solution is then poured onto ice and the precipitate is recrystallized from petroleum ether; yield 27%.

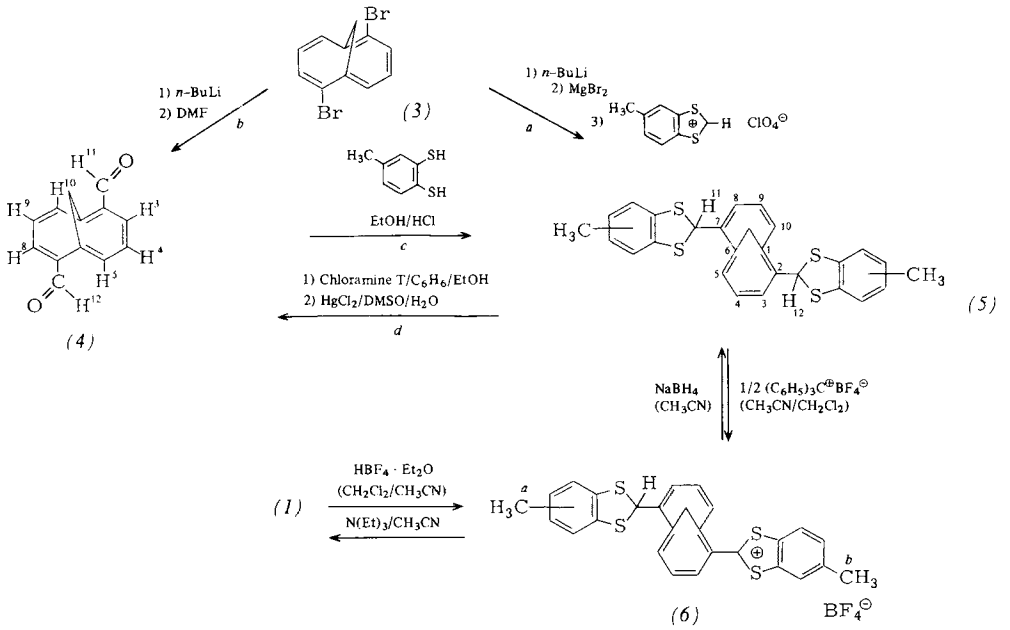
Synthesis of a Homologous Tetrathiafulvalene with Central Bicyclo[4.4.1]undeca-1(10),3,5,8-tetraene-2,7-diylidene Group[**]

By *Richard Neidlein* and *Hartmut Zeiner*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

We now report the synthesis of dimethyl-2,2′-bicyclo[4.4.1]undeca-1(10),3,5,8-tetraene-2,7-diylidenedi(1,3-benzodithiol) *(1)*. This compound contains structural units of a tetrathiafulvalene and a quinodimethane and is of interest as a potential donor component. Although the dione *(2)*[1] derived from the central bicycle is stable and to be regarded as a quinone on the basis of its physicochemical properties[1], it does not open a preparative entry to *(1)*.



(1) *(2)*

Such an entry is provided by the key compound *(5)* which we have prepared by two pathways (see Scheme 1).

Reaction a: (3) was transformed by *n*-butyllithium into the dilithium compound (anhydrous Et_2O, −20 to 0 °C, N_2) according to *Vogel et al.*[1-3]; metal exchange with anhydrous $MgBr_2$ then affords the bifunctional Grignard compound. Reaction with freshly prepared 5-methyl-1,3-dithiolium perchlorate[4] at 0 °C, followed by 1 hour's stirring at room temperature, addition of NH_4Cl, and chromatography on silica gel (CH_2Cl_2) gives the pale yellow *(5)* as a mixture of diastereomers.

Reactions b and c: The dialdehyde *(4)* was obtained from *(3)* by metalation with *n*-butyllithium (anhydrous ether, −20

Scheme 1

to 0 °C, N_2) and subsequent reaction with an excess of dimethyl-formamide (DMF). Thioacetalization of *(4)* with 4-methyl-1,2-benzenedithiol in HCl-saturated ethanol (0 °C, 45 min) led to *(5)* in 72% yield.

Reaction d: Subsequent thioacetal cleavage of *(5)* with Chloramine T and $HgCl_2$[5] gave almost pure *(4)* in 78% yield. Abstraction of a hydride ion from *(5)* with triphenylmethyl tetrafluoroborate (2 h, 60 °C, 12 h, room temperature) furnished the monocation *(6)* which could be transformed into *(1)* by elimination of a proton with triethylamine in CH_2Cl_2/CH_3CN. Compound *(1)* forms brick-red crystallites which can be stored for about one day but are air- and acid-sensitive; addition of $HBF_4 \cdot Et_2O$ to *(1)* regenerates the monocation *(6)*. Reduction with $NaBH_4$ in CH_3CN transforms *(6)* into *(5)*.

Structural proof of *(1)* was accomplished by spectroscopic methods (cf. Table 1); the reaction *(1)*→*(6)* also shows that *(1)* contains the molecular skeleton of *(6)*. The ^{1}H-NMR spectrum of *(1)* clearly indicates that de-aromatization of the 1,6-methanocyclodecapentaene group occurs on deprotonation of *(6)*. The question whether *(1)* has C_2 symmetry and thus exists as an enantiomeric pair and not as a mixture of diastereomers cannot be answered with absolute certainty, although some supporting evidence is available (^{1}H-NMR, TLC). Thus the protons of the two CH_3 groups appear as a singlet ($\delta = 2.30$, 6H); however, diastereotopic CH_3 groups can also exhibit accidental isochronism, or differences in chemical shifts may avoid detection at the measurement frequency.

Table 1. Selected physical properties of compounds *(4)*, *(5)*, and *(6)*.

(1): m. p. 166–168 °C; yield 95% based on *(6)*; ^{1}H-NMR (90 MHz, $CDCl_3$): $\delta = 1.29$ (s, 2H, CH_2), 2.30 (s, 6H, CH_3), 6.0–6.36, 6.87–7.21 (2 m, 12H, 2 identical ABC systems for 6 olefinic H, 2 ABX systems for 6 aromatic H); UV (CH_2Cl_2): $\lambda_{max} = 234$ nm ($\varepsilon = 43495$), 271 (21345, sh), 316 (9263, sh), 494 (17720); MS (70 eV): $m/e = 472$ (63%, M^+)

(4): m. p. 107 °C; yield 48% (based on *(3)*); ^{1}H-NMR (90 MHz, $CDCl_3$): $\delta = -0.13$ (s, 2H, CH_2), 7.30–8.60 (m, 6H, $H_3 - H_{10}$; simple ABC system: 8.56 (d, 2H, H_3, H_8, $J_{3,4} = J_{8,9} = 8.6$ Hz), 7.74 (d, 2H, H_5, H_{10}, $J_{4,5} = J_{9,10} = 9.1$ Hz), 7.40 (t, 2H, H_4, H_9 because $J_{3,4} \approx J_{4,5}$), 10.15 (s, 2H, H_{11}, H_{12}); UV (CH_3CN): $\lambda_{max} = 202$ nm ($\varepsilon = 18376$), 222 (15390), 268 (28138), 352 (13093), 400 (5283, sh), 408 (5053, sh), 424 (3675, sh); MS (70 eV): $m/e = 198$ (46%, M^+); IR (KBr): 2730 cm^{-1} (w, C H-aldehydic proton), 1670 (C=O)

(5): m. p. 77–79 °C (dec.); yield 60% (path *a*); ^{1}H-NMR (90 MHz, $CDCl_3$): $\delta = -0.5$ (s, 2H, CH_2), 2.26 (s, 3H) and 2.28 (s, 3H) for diastereotopic CH_3, 6.83 (s, 2H, H-11, H-12), 6.89–7.84 (m, 12H: 2 identical ABC systems of annulene-H and ABC systems of the benzo-aromatic H); UV (CH_2Cl_2): $\lambda_{max} = 234$ nm ($\varepsilon = 42902$), 268 (58313), 318 (14578), 330 (13747, sh); (CH_3CN): $\lambda_{max} = 231$ nm (44645), 265 (61269), 315 (14486), 327 (13774, sh); MS (70 eV): $m/e = 474$ (26%, M^+)

(6): m. p. 212 °C (dec.); yield 82%; ^{1}H-NMR (90 MHz, CD_3CN): $\delta = 0.01$ (B part: H_{anti}) [6], 0.09 (A part of AB system: H_{syn}; 2H, $J_{AB} = 10.7$ Hz, A part as triplet owing to long range coupling doublet of doublets $J \approx 1$ Hz, CH_2), 2.23, 2.28 (2s, 3H, CH_3-a), 2.63 (s, 3H, CH_3-b), 6.90 (s, 1H), 6.94–8.45 (m, 12 aromatic H); UV (CH_3CN): $\lambda_{max} = 207$ ($\varepsilon = 36089$), 237 (29389), 264 (20690 sh), 324 (7053), 430 (7523, sh); (CH_2Cl_2): $\lambda_{max} = 233$ (38635), 250 (33734, sh), 320 (7496, sh), 340 (6631, sh), 453 (7352, sh), 521 (9659); IR (KBr): 1050 cm^{-1} (s, $BF_4^\ominus$)

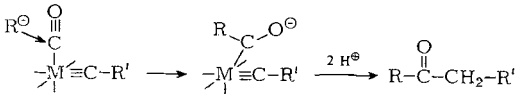
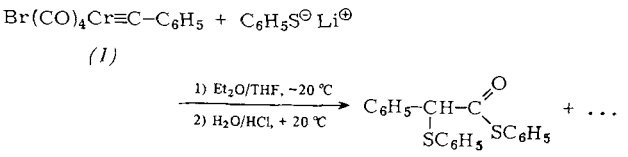
Double Addition of a Nucleophile to Carbyne and Carbonyl C-Atom: *S*-Phenyl 2-Phenyl-2-(phenylthio)thioacetate from *trans*-Bromotetracarbonyl(phenylcarbyne)chromium and Thiophenolate[1]



By *Ernst Otto Fischer* and *Werner Röll*[*]

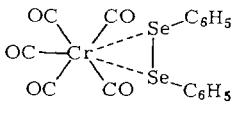
Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday



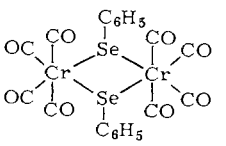
Neutral *trans*-halotetracarbonyl-carbyne complexes react with nucleophiles such as $I^\ominus$[2], Li-cyclopentadienide[3], or

[*] Prof. Dr. E. O. Fischer, Dipl.-Chem. W. Röll
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstrasse 4, D-8046 Garching (Germany)

carbonylmetalate ions[4] with replacement of the halogen ligand. Anions such as $C_6H_5^{\ominus}$, $OH^{\ominus}$, $OR^{\ominus}$, on the other hand, attack the positively polarized C atom of a carbonyl ligand[5]; the next reaction step is probably transfer of the resulting "acylate group" onto the carbyne carbon atom, followed by reductive elimination of the entire organic ligand on protonation by acid:



We have surprisingly obtained the hitherto unknown *S*-phenyl-2-phenyl-2-(phenylthio)thioacetate *(2)* on reaction of *trans*-bromotetracarbonyl(phenylcarbyne)chromium *(1)* with Li-thiophenolate and subsequent protonation with hydrochlorid acid:



(1) *(2)*

This result can be explained in terms of double attack by the thiophenolate ions on a carbonyl and on the carbyne carbon atom and differs from the reaction of *(1)* with $C_6H_5O^{\ominus}$, which affords the expected phenyl phenylacetate in poor yield. The analogous reaction with selenophenolate does not lead to a corresponding ester but, *inter alia,* to (diphenyl diselenide)pentacarbonylchromium *(3)* and di-μ-phenylselenobis(tetracarbonylchromium) *(4)*.

(3)

(4)

The IR spectrum (KBr) of *(2)* exhibits the strong CO band of the thioester at 1690 (vs) cm^{-1} and typical phenyl absorptions (980 s, 750 vs, 725 s, 690 s cm^{-1}). In the ^{1}H-NMR spectrum (CCl_4) one finds a multiplet at $\delta = 7.2$ for the three phenyl groups and a singlet at $\delta = 5.0$ for the methine proton.

In addition to the multiplets of the ring carbon atoms in the range $\delta = 128.38$ to 134.62, the ^{13}C-NMR spectrum ($CDCl_3$) exhibits the two singlets of the α-C atom ($\delta = 63.88$) and the CO groups ($\delta = 195.32$).

Procedure

Methyllithium (10 mmol) is added to thiophenol (1.1 g, 10 mmol) in tetrahydrofuran (25 ml) and the resulting thiophenolate solution is added dropwise at −20 °C to a stirred solution of *(1)* (3.3 g, 10 mmol) in ether (150 ml). After 2 h, the solvent is removed at 20 °C and the brown residue is stirred in ether (100 ml) for 15 min with 4N HCl (25 ml). The ether phase is separated off, deacidified with $NaHCO_3$ solution, dried over Na_2SO_4, and evaporated down. Chromatography of the crude product on silica gel with ether/pentane (1:10) and twofold recrystallization from pentane gives *(2)* as analytically pure colorless needles, m. p. 70 °C. Yield 18%.

Correlation between Radical Reactivities and Copolymerization Parameters[**]

By *Bernd Giese* and *Jürgen Meixner*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Radical copolymerizations are directed by the rates k_{ij} of addition of the polymeric radicals $R_i^{\ominus}$ to the competing monomeric alkenes M_j[1]. *Alfrey* and *Price*[2] described the substituent influence of the alkenes in terms of Q_j and e_j values, which can be determined from the copolymerization parameters r_1 and r_2[1,3] [eq. (a)–(c)]. P_i and e_i values characterize the properties of the radicals.

$$M_1 \rightarrow R_1^{\ominus} \xrightarrow[M_2]{k_{12}} ; \quad r_1 = \frac{k_{11}}{k_{12}}$$

$$M_2 \rightarrow R_2^{\ominus} \xrightarrow[M_1]{k_{21}} ; \quad r_2 = \frac{k_{22}}{k_{21}}$$

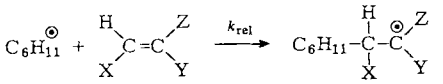
$$k_{ij} = P_i \cdot Q_j \cdot e^{-e_i \cdot e_j} \qquad \text{(a)}$$

$$r_1 = \frac{Q_1}{Q_2} e^{-e_1(e_1 - e_2)} \qquad \text{(b)}$$

$$r_1 \cdot r_2 = e^{-(e_1 - e_2)^2} \qquad \text{(c)}$$

We have now *directly* measured the substituent effect on the rate of addition of the alkyl radical *(1)* to the polymerizable alkenes *(2)*–*(17)* and hence the chain propagation step of the radical copolymerization; the rate constants determined by the "mercury method"[4] are listed in Table 1.

If the experimental values k_{rel} of radical addition are inserted into eq. (a) and P_i and e_i are kept constant, then the *Q,e* scheme can be checked according to eq. (d).



$$\log k_{rel} - \log Q_j = \text{const} - \frac{e_i}{2.303} e_j \qquad \text{(d)}$$

A straight line is indeed obtained on graphical evaluation of eq. (d) (Fig. 1).

The linear relationship between the parameters of copolymerization and the reactivities of the radical *(1)* is surprisingly good (correlation coefficient = 0.95), particularly since the relative rate constants for the mono-, di-, and trisubstituted

(14)	Methylmaleic anhydride			140
(15)	H	Cl	CN	200
(16)	H	$CO_2C_2H_5$	$CO_2C_2H_5$	270
(17)	CN	H	CN	310

[a] The k_{rel} values are the rate constants per vinylic C atom attacked.

alkenes (2)-(17) extend over five orders of magnitude. The slope of the straight line in Figure 1 affords an e_j value of −1.9 for the cyclohexyl radical. Because e parameters characterize the influence of polar effects[1,5], the negative e value once again proves the nucleophilic[6] properties of alkyl radicals.

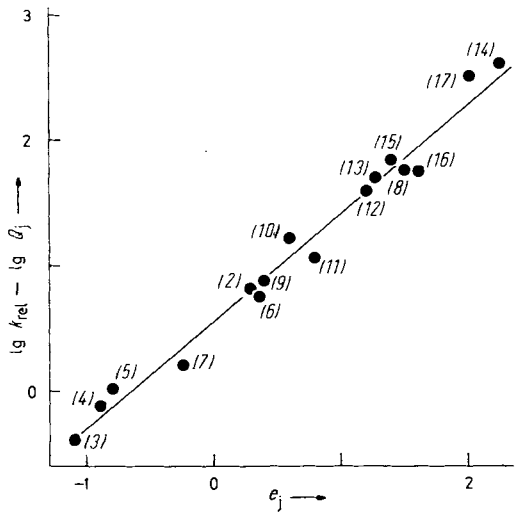

Fig. 1. Correlation between the relative reactivities (log k_{rel}) of the cyclohexyl radical (1) and Q_j, e_j values of the alkenes (2)-(17).

Such reactivity measurements permit a simple determination of the Q_j and e_j values of new alkenes and thus facilitate prediction of optimum conditions for their copolymerization.

Aza[14]annulenes[**]

By *Herbert Röttele* and *Gerhard Schröder*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Monocyclic vinylogs of benzene, furan, and pyrrole containing $(4n+2)$ π electrons have already been well documented[1]. We recently reported on aza[18]annulene[2], the first monocyclic vinylog of pyridine containing $(4n+2)$ π electrons. In this communication we describe the synthesis and some properties of the aromatic and conformationally mobile aza[14]annulene (1).

(1)

(2), R = $COOC_2H_5$
(3), R = COOH
(4), R = CON_3
(5), R = $NH-CONH_2$
(6), R = N_3

Reaction of tricyclo[6.4.0.0^{9,12}]dodeca-2,4,6,10-tetraene[3] with ethyl diazoacetate in the presence of copper powder affords three structurally isomeric monoadducts, of which (2) is the main product[4]. The carboxylic acid (3)[4] is converted by reaction with triethylamine, ethyl chloroformate and aqueous sodium azide into the acid azide (4) (92%). On heating for 3 h in benzene, (4) is converted into the isocyanate (not isolated), which reacts with NH_3 to give the urea derivative (5) (90%). The incompletely characterized N-nitrosourea [obtained by reaction of (5) with N_2O_4 in ether] reacts with lithium azide in methanol to give the 11-azidotetracyclo[6.5.0.0^{9,13}.0^{10,12}]trideca-2,4,6-triene (6), which after column chromatography (SiO_2, pentane/ether = 9:1) is obtained, still in impure form, as a colorless oil [*ca.* 10% (6) based on (5)][5]. The reaction path described here for transformation of an acid azide into an azide has already proven successful in other cases[2,6]. Photolysis of (6) in pentane (*ca.* 10^{-4} M) at −70 °C with a Hg low-pressure lamp affords, dark-violet crystalline aza[14]annulene (1) (≥50%).

The temperature-dependent ^{1}H-NMR spectra of (1) (see Table 1) provide confirmation of structure. The low-temperature ^{1}H-NMR spectrum (−70 °C) provides the following information: the difference between the centroids of the resonance signals of the three inner (Hi) and ten outer protons (Ha) amounts to *ca.* 9.5. (1), like [14]annulene[8], is distinctly diatropic. Both doublets of the two outer protons are caused by the protons (H_α) situated in the α-position to the nitrogen and having non-identical chemical shifts. The coupling constants prove the *cis* arrangement of H_α and H_β; hence the ni-

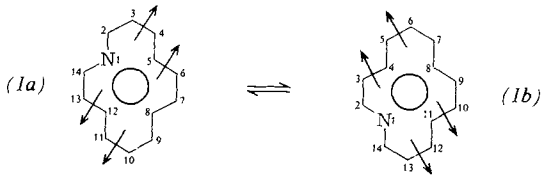
Table 1. Selected physical data of compounds *(1)-(6)*.

(1): m. p. *ca.* 135 °C (dec., from pentane); ^{1}H-NMR (90 MHz, −70 °C, CD_2Cl_2): $\delta = -1.28$ (t, $J = 14.1$ Hz, 1Hi), −1.12 and −0.58 (one t each, $J = 13.7$ Hz, 2Hi), 7.73 (d, d, $J = 6.2$, 8.0 Hz, $1Ha = 1H_\beta$), 7.90–9.10 (m, 7Ha), 9.60 (d, $J = 4.4$ Hz, $1Ha = 1H_\alpha$), 9.69 (d, $J = 6.2$ Hz, $1Ha = 1H_\alpha$); ^{1}H-NMR (90 MHz, 30 °C, CD_2Cl_2): $\delta = -0.51$ (pseudo-t, J ca. 13.0 Hz, 1Hi), 2.0–6.4 (very broad unstructured absorption which hardly rises above the base line, 2Hi + 2Ha), 7.70–8.80 (m, *ca.* 6Ha), 9.55 (d, $J = 5.3$ Hz, $2Ha = 2H_\alpha$); ^{1}H-NMR (90 MHz, 80 °C, [D$_6$]-DMSO) [7]: $\delta = -0.50$ (m, 1Hi), 4.00 (two overlapping br. m., 2Hi + 2Ha), 7.70–8.70 (m, *ca.* 6Ha), 9.47 (d, $J = 5.3$ Hz, $2Ha = 2H_\alpha$); UV (dioxane): $\lambda_{max} = 323$ ($\varepsilon = 76700$), 398 (7200), 420 (sh, 4760), 435 (sh, 3460), 499 (420), 512 (494), 544 (531), 561 (593), 580 (sh, 642), 599 (1685), 620 nm (1760)

(2): colorless oil, ^{1}H-NMR (60 MHz, 35 °C, CCl_4): $\delta = 1.23$ (t, $J = 7$ Hz, 3H), 1.53 (pseudo-s, 1H), 2.27 (m, 2H), 2.58 (m, 2H), 3.60 (m, 2H), 4.09 (q, $J = 7$ Hz, 2H), 5.90 (m, 6H); UV (cyclohexane): $\lambda = 250$ nm (sh, $\varepsilon = 1700$)



(3): m. p. 222 °C (dec.); ^{1}H-NMR (100 MHz, 26 °C, [D$_5$]-pyridine): $\delta = 1.82$ (pseudo-s, 1H), 2.50 (narrow m, 4H), 3.56 (narrow m, 2H), 5.80 (s, 2H), 6.02 (AB system 4H); UV (methanol): $\lambda_{max} = 253$ nm ($\varepsilon = 1600$)

(4): m. p. 91 °C (dec.); ^{1}H-NMR (90 MHz, 28 °C, $CDCl_3$): $\delta = 1.64$ (pseudo-s, 1H), 2.52 (narrow m, 4H), 3.62 (narrow m, 2H), 5.80 (s, 2H), 6.00 (AB system, 4H); UV (dioxane): $\lambda = 258$ nm (sh, $\varepsilon = 1900$)

(5): m. p. 196 °C (dec.); ^{1}H-NMR (90 MHz, 28 °C, $CDCl_3$): $\delta = 2.10$ (d, $J = 3$ Hz, 2H), 2.53 (narrow m, 3H), 3.62 (narrow m, 2H), 4.77 (br. s, 2H, NH_2), 4.93 (br.s, 1H, NH), 5.80 (s, 2H), 6.00 (AB system, 4H); UV (dioxane): $\lambda = 250$ nm (sh, $\varepsilon = 1700$)

(6): colorless oil, ^{1}H-NMR (90 MHz, 28 °C, $CDCl_3$): $\delta = 2.06$ (d, $J = 3$ Hz, 2H), 2.53 (narrow m, 2H), 2.92 (pseudo-s, 1H), 3.60 (narrow m, 2H), 5.80 (s, 2H), 6.0 (AB system, 4H); IR (CCl_4): 2100 cm^{-1}

trogen in the aza[14]annulene *(1)*, like that in the aza[18]annulene[2], occupies an inner position. In the ^{1}H-NMR spectrum of *(1)*, one H_β can be located by double resonance experiments. Its two vicinal protons are *cis* oriented.

(1a) ⇌ *(1b)*

The characteristic temperature-dependent ^{1}H-NMR spectra demonstrate a pairwise mixing of proton resonance signals. The degenerate equilibrium *(1a)*⇌*(1b)* describes the conformational mobility of the aromatic aza[14]annulene *(1)*. The following protons change places pairwise: outer protons (Ha): H-2/H-14, H-3/H-13, H-6/H-10, H-7/H-9; inner (Hi) *and* outer protons (Ha): H-4/H-12, H-5/H-11; only the inner proton H-8 remains unchanged. Particularly striking in the ^{1}H-NMR spectrum at 80 °C are the doublet for the two H_α and the 4H signal resulting around $\delta = 4.00$ by averaging.

^{1}H-NMR Investigations on the Mutarotation of *N*-Acetyl-D-neuraminic Acid[**]

By *Horst Friebolin, Martin Supp, Reinhard Brossmer, Gunda Keilich*, and *Dietmar Ziegler*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Numerous oligosaccharides, glycoproteins, glycolipids, and gangliosides contain *N*-acetyl-D-neuraminic acid (Neu5Ac[1]) with α-ketosidic bonding as terminal sugar. From the optical properties, however, it was deduced that free Neu5Ac is present exclusively in the β-configuration in aqueous solution. It was shown by X-ray structure analysis that Neu5Ac also crystallizes in the β-configuration[2]. The anomer, α-Neu5Ac, could only recently be detected; *Friebolin et al.*[3] showed by ^{1}H-NMR spectroscopy that free Neu5Ac is an anomeric mixture in aqueous solution. In agreement with ^{13}C-NMR measurements[4] 5–8% α-Neu5Ac was found besides 95–92% β-Neu5Ac; accordingly a mutarotation equilibrium should exist for Neu5Ac, as for other sugars.

β-Neu5Ac ⇌ α-Neu5Ac

Moreover, the detection of separate signals for α- and β-Neu5Ac in the NMR spectra points to a slow kinetic process on the NMR time scale. Owing to the unfavorable position of this equilibrium, however, determination of the kinetic data of the mutarotation is impossible, either NMR spectroscopically or polarimetrically.

In investigations on the specificity of neuraminidases we have now succeeded for the first time in demonstrating by means of ^{1}H-NMR spectroscopy that α-Neu5Ac is liberated as primary fragment from a α-ketoside of Neu5Ac[5]. This finding contradicts previously held views[6].

For this experiment we used an incubation solution (0.5 ml) of 20 mM Neu5Acα2→3Galβ1→4Glc (II^{3}Neu5Ac-Lac) in 50 mM Na/K phosphate buffer in D_2O (pD = 5.4) and 800 mU neuraminidase from *Clostridium perfringens*[7]. Hydrolysis was carried out in the spectrometer, and spectra were recorded at various intervals. We specifically observed the region of the signals of the axial and equatorial protons on C-3 (cf.[3]). Initially, we found only the characteristic signals of α-Neu5Ac together with those of the substrate. Then, in the further course of reaction, the additional signals of β-Neu5Ac were observed. This β-Neu5Ac can only be formed by mutarotation from α-Neu5Ac. As long as α-Neu5Ac is still being liberated from the substrate, determination of

quantitative data on the kinetics of the mutarotation is problematic. In our experiment, no more substrate was detectable after 168 min. At this point the concentration of α-Neu5Ac was *ca.* 40%, and that of β-Neu5Ac was *ca.* 60% (Table 1).

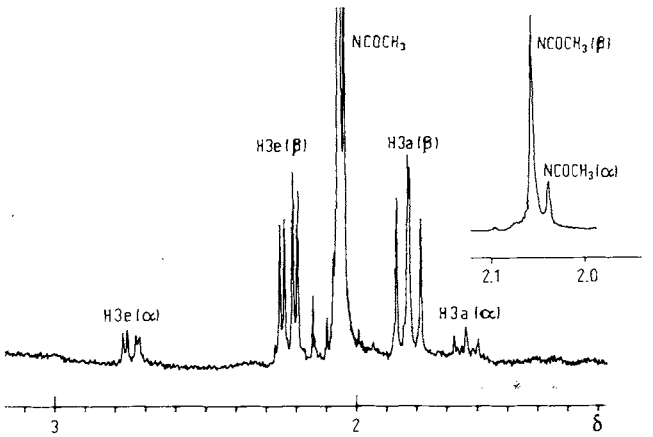

Fig. 1. Part of the 300-MHz ^{1}H-NMR spectrum of the anomeric mixture of α- and β-Neu5Ac, recorded 294 min after beginning the cleavage experiment (see text). Small diagram: Signals of the *N*-acetyl protons. Spectrometer: Bruker Physik WH 300, solvent D_2O, phosphate buffer (pD = 5.4), internal standard δ [$(CH_3)_3SiCD_2CD_2COONa$] = 0, T = 30 °C, number of pulses 830, 8 K data points (duration of measurement *ca.* 15 min).

Table 1. Ratio of the amounts of II^{3}Neu5Ac-Lac (substrate) and α- and β-Neu5Ac determined during the cleavage reaction. Up to t = 138 min the signals of the protons on C-3 and on the *N*-acetyl group were measured, thereafter only the *N*-acetyl signals were integrated. The numerical data are mean values for the time required to record the spectrum (*ca.* 10–20 min).

t [min]	α [%]	β [%]	II^{3}Neu5Ac-Lac [%]
18	43	8	49
58	42	25	33
108	41	41	18
138	38	53	9
168	38	62	<5
194	33	67	
251	23	77	
280	19	81	
294	17	83	
317	17	83	
340	16	84	
368	13	87	
900	8	92	

This ratio deviates so markedly from the equilibrium (8% α-Neu5Ac: 92% β-Neu5Ac) that it is possible for the first time to follow its course. In order to determine the amounts of α- and β-Neu5Ac as a function of time we integrated the well resolved signals of the *N*-acetyl protons of the two anomers (Fig. 1, Table 1).

The following data could be calculated[8] for the mutarotation equilibrium and the kinetics:

$$\alpha\text{-Neu5Ac} \underset{k_\beta}{\overset{k_\alpha}{\rightleftharpoons}} \beta\text{-Neu5Ac}$$

$$K = [\beta]/[\alpha] = 11.5$$

$$\Delta G(\alpha) - \Delta G(\beta) = 6.1 \text{ kJ/mol } (= 1.55 \text{ kcal/mol})$$

$$k_\alpha = 1.3 \times 10^{-4} \text{ s}^{-1};\ k_\beta = 1.1 \times 10^{-5} \text{ s}^{-1}$$

$$t_{0.5} = 80 \pm 10 \text{ min}$$

From these investigations we could show that establishment of the equilibrium of mutarotation of Neu5Ac in 50 mM Na/K phosphate buffer in D_2O (pD = 5.4) is unexpectedly slow (half-life = $t_{0.5}$).

Structural Changes on Oxidation: Flattening of the C_4-Cluster of Tetrahedrane[1]

By *Hans Bock, Bernhard Roth,* and *Günther Maier*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Oxidation or reduction of molecules M generally leads to structural modifications[2] which can be advantageously investigated by ESR spectroscopy of radical ions $M^{\bullet\oplus}$ or $M^{\bullet\ominus}$[1]. In clusters, the number of electrons is most important: in the case of electron-deficient compounds such as boranes or carbaboranes, oxidation effects progressive "encapsulation" *hypho* → *arachno* → *nido* → *closo*[3], whereas in the case of electron-excess compounds cage-opening can occur, *e.g.* S_4N_4 yields the planar dication $S_4N_4^{2\oplus}$[2,3]. Little is known about the oxidation and reduction behavior of clusters with a "balanced" number of electrons such as tetrahedranes $(CX)_4$: the tetrahedral structure of the systems with 12 electrons in the C_4 skeleton corresponds to *Euler*'s formula for convex polyhedra[4]: number of faces = number of edges − number of vertices + 2 = 6 − 4 + 2 = 4. The tetrakis(*tert*-butyl) derivative is formed photochemically from its cyclobutadiene valence isomer with assistance from the "corset effect" of the bulky alkyl groups[5]; the delicate balance of charge distribution is underlined by the possibility of thermal reconversion to starting material at the melting temperature of 135 °C[6].

As a saturated alkane, tetra-*tert*-butyltetrahedrane exhibits the unusually low ionization energy of only 7.50 eV[7] and is therefore oxidized to the radical cation by $AlCl_3/CH_2Cl_2$[1]. The ESR spectrum of $[C_4(C(CH_3)_3)_4]^{\bullet\oplus}$ shows the equidistant signals of the proton 37-tet (Fig. 1).

Heating of tetrahedrane to 140 °C for 1 h in the evacuated ESR capillary and subsequent $AlCl_3/CH_2Cl_2$ oxidation of the resulting tetra-*tert*-butylcyclobutadiene [which is even easier to ionize at IE_1 = 6.35 eV[7]] affords an identical ESR spectrum (Fig. 1).

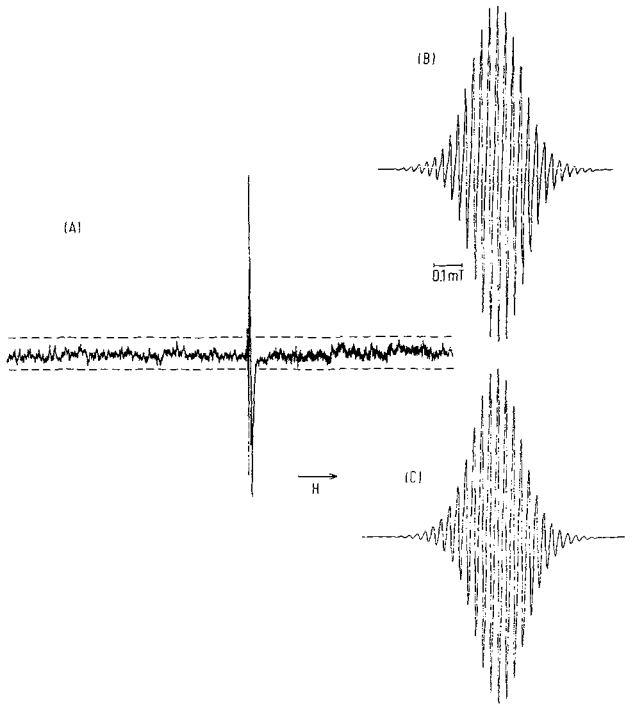
In order to discuss the unexpected result that both valence isomers of $C_4(C(CH_3)_3)_4$ give the same radical on $AlCl_3/CH_2Cl_2$ oxidation, sections are calculated through the energy



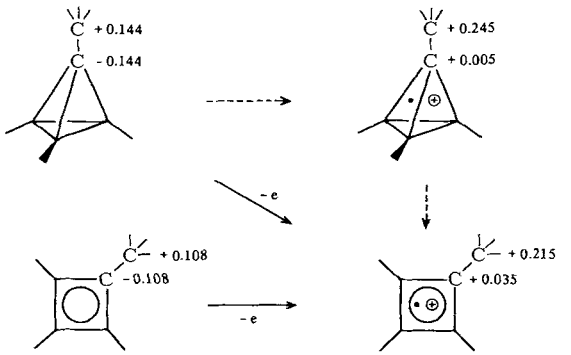


Fig. 1. ESR spectrum of the radical cation generated from tetra-*tert*-butyl tetrahedrane by treatment with $AlCl_3/CH_2Cl_2$, recorded at 180 K: (A) entire range (20 mT, 10 × amplification), in which ^{13}C satellites (1:4, 1.1% natural abundance) cannot be detected within the given intensity range (----); (B) highly resolved center line with simulation; (C) for the 37-tet of the protons the coupling constant amounts to $a_H = 0.027$ mT and the intensity ratio of the outside line: center line = 1:9.075135298. The same ESR spectrum is observed on oxidation of the valence isomeric tetra-*tert*-butylcyclobutadiene; in both cases the radical cation generated is stable up to about 200 K and exhibits a g factor of 2.0024.

hypersurfaces along the isomerization valleys for the sterically unconstrained tetramethyltetrahedrane and its radical cation (Fig. 2).

Spontaneous isomerization of the C_4 cluster on electron removal (Fig. 2) can be explained on the basis of the calculated charge distributions[8].

The positive charge can be better distributed on participation of the cyclobutadiene π-system; greater stabilization of the $M^{\bullet\oplus}$ ground state is also suggested by the ionization energy of 6.35 eV, which is lower than that of tetrahedrane by 1.15 eV[7]. While the neutral C_4 cluster can exist with support from substituents, oxidation leads to its planarization as in the case of $S_4N_4^{2\oplus}$.

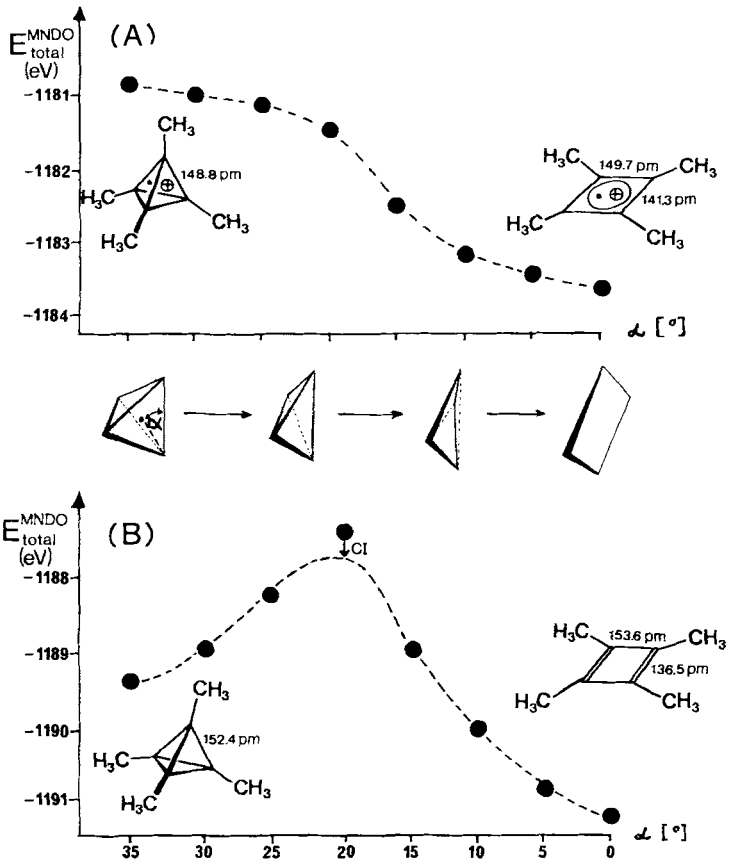

Fig. 2. Tetrahedrane ⇄ cyclobutadiene valence isomerization is advantageously described by an angular coordinate: if α is made smaller then two opposite tetrahedral edges approach each other. Calculation of the individual points along the isomerization section through the hypersurface is performed with open shell (A) and closed shell (B) MNDO [8], with structure optimization in each case, *i.e.* the CC distances and the CCC angles are determined afresh each time. An isomerization barrier of 170 kJ/mol [6] is approximately calculated (without CI) for going from tetramethyltetrahedrane to he energetically more favorable tetramethylcyclobutadiene. However, the radical cation does not lie in a local minimum and the C_4 cluster should therefore undergo spontaneous isomerization on electron removal.

Structure of Tetra-*tert*-butylcyclobutadiene[**]

By *Hermann Irngartinger, Norbert Riegler, Klaus-Dieter Malsch, Klaus-Albert Schneider,* and *Günther Maier*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The results of X-ray structure analysis[1] of tetra-*tert*-butylcyclobutadiene *(1)*[2], the first kinetically stabilized cyclobutadiene having four identical substituents, are surprising: the molecule lies on a crystallographic twofold axis which runs through the center of the two long bonds of the four-membered ring (Fig. 1). Long [1.482(2), 1.484(2) Å] and short bonds [1.464.(2) Å] occur in the ring; although they differ significantly, they do not alternate nearly so pronouncedly as in the derivatives *(2)* (1.344 and 1.600 Å)[3a], *(3)* (1.339 and 1.597 Å)[3b], or *(4)*[3c].

(1) *(2)*, X = S; *(3)*, X = CH_2 *(4)*

The quaternary C-atoms of the *tert*-butyl substituents of *(1)* deviate alternately by 0.37 Å above and below the plane through the ring atoms. The four-membered ring is not planar but possesses a folded conformation with a dihedral angle of 170.2°.

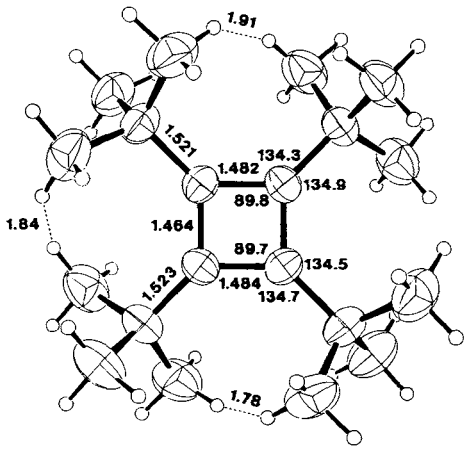

Fig. 1. Selected bond lengths [Å], angles [°], and intramolecular distances [Å] of *(1)* in the crystal, standard deviations 0.002–0.003 Å and 0.1°. The $C(sp^3)$-$C(sp^3)$ bonds have an average length of 1.533 ± 0.004 Å.

The pronounced lengthening of the double bond in *(1)* from a standard value of 1.34 Å to 1.464 Å can be attributed to two reasons: steric interaction between the *tert*-butyl groups imposes a torsional angle of 28.1° on the double bond (Fig. 2), leading to weakening of the bond. Comparison with other twisted double bond compounds shows[4] that this

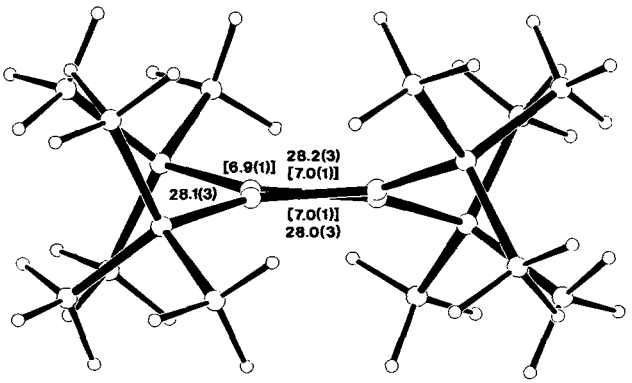

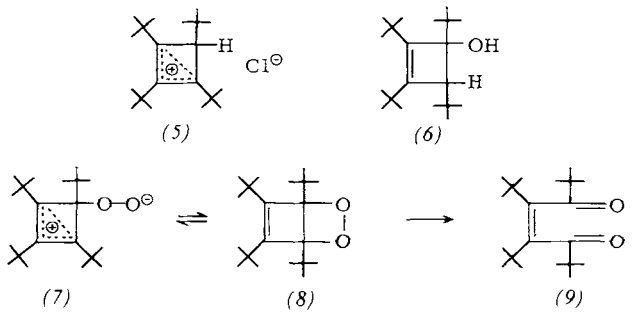

Fig. 2. Side view of *(1)* looking along the twofold axis. The numbers given are torsional angles [°]. The values in square brackets are the torsional angles in the four-membered ring.

alone does not suffice to explain the extent of bond lengthening, particularly since the torsion on the "inside" is only 6.9° owing to fixation in the ring system. Moreover, in spite of the deviation of the substituents from the plane of the four membered ring (Fig. 2), additional repulsive interactions — the H ... H distance in *(1)* is still extremely small at 1.84 Å — lead to further lengthening of the weakened double bond.

The $C(sp^2)$-$C(sp^2)$ single bond in *(1)* is considerably shorter, compared with *(2)*–*(4)*, and lies in the usual range for such bonds in four-membered rings[5]. Thus in *(2)* and *(3)* the single bond is stretched, and in *(1)* the double bond. Almost four-fold symmetry is established in this way for *(1)*.

Such a geometry raises the question of the spin multiplicity of *(1)*. The chemical properties do not permit any decision, since by analogy with tri-*tert*-butylcyclobutadiene[6a] *(1)* shows both basic and "diradical-type" behavior. Addition of hydrogen chloride in dichloromethane affords the homocyclopropenylium salt *(5)*, which reacts with water to give cyclobutenol *(6)* [colorless crystals, m. p. 74 °C; IR (CCl_4): 3650 cm^{-1} (OH); MS: $m/e = 294$ (M^+)]. The same alcohol is also formed without acid catalysis on direct action of water on *(1)*. On the other hand, the cyclobutadiene is very sensitive to oxygen; the primary oxidation product is the dioxetane *(8)*. In a polar medium (CD_2Cl_2) this molecule shows broadening between 0 and 30 °C and coalescence of the ^1H- and ^{13}C-NMR signals of the two kinds of *tert*-butyl groups[6b]. This result suggests that in the temperature interval specified the peroxide bridge in *(8)* migrates around the carbon ring in a kind of merry-go-round rearrangement *via* intermediates of type *(7)*. In a competing process, *(8)* undergoes a slow (half-life *ca.* 2 h at room temperature) irreversible cleavage to the diketone *(9)* [colorless crystals, m. p. 93 °C; IR (CCl_4): 1680 cm^{-1}; MS: $m/e = 308$ (M^+)].

Now that *(1)* has been shown to have a folded structure, which is undoubtedly due to the four bulky substituents and which explains the ready valence isomerization to tetrahe-

RT = room temperature.

drane[2], it nevertheless remains to be examined whether this kind of stabilization [transition from the more energetic D_{4h} to D_{2d} (or D_2) instead of D_{2h} symmetry[7]] might also be significant in other cases too, possibly even in the unsubstituted parent compound.

Enantioselective Synthesis of α-Methylserines[**]

By *Ulrich Schöllkopf, Wolfgang Hartwig*, and *Ulrich Groth*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Optically active synthetic amino acids are gaining increasing importance in research and practice, *e.g.* as enzyme inhibitors or as pharmaceuticals.

We recently reported on the enantioselective synthesis of α-methylamino acids by base-induced alkylation of (3*S*,6*S*)-(+)-2,5-dimethoxy-3,6-dimethyl-3,6-dihydropyrazine *(1)*, which is obtainable by reaction of cyclo(L-Ala-L-Ala) with trimethyloxonium tetrafluoroborate[1]. We have now found that lithiated lactim ethers *(2)* also react with carbonyl compounds *(3)* — in tetrahydrofuran (THF) or (better) dimethoxyethane — with, in some cases very high, induction at C-3 (cf. Table 1). With aldehydes or unsymmetric ketones, a chirality center is also established at C-7 of the product *(4)*. The induction is somewhat lower in this case, being 41–78% (cf. Table 1).

The configuration and degree of induction at C-3 of *(4)* can — if R^1 or R^2 is aryl — be determined ^{1}H-NMR spectroscopically from the signal of the C-6 methyl protons. This appears at relatively high field in the case of the isomer formed in lower yield because the methyl group is situated in the shielding anisotropic region of the aryl group, which might lie π-complex-like over the heterocycle[2]. Accordingly, the carbonyl compound adds to *(2)* preferably in the *trans*-position to the C-6 methyl group, so that an *R*-configuration is induced at C-3 of *(4)*. This also applies in the case of formaldehyde, since (*R*)-(−)-α-methylserine[3] is obtained on hydrolysis of *(4a)*. Acid hydrolysis of the adduct *(4)* leads to α-methylserine esters *(5)*. Their enantiomeric purity at the α-carbon atom corresponds to the asymmetric induction, when optically pure *(1)* is used as starting material[4].

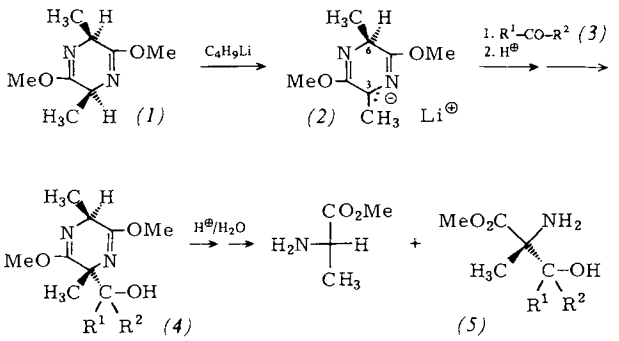

Table 1. Adducts *(4)* synthesized from the metalated lactim ethers *(2)* and carbonyl compounds *(3)*.

[**] Asymmetric syntheses *via* Heterocyclic Intermediates, Part 3. — Part 2: [1].

A retroaldol reaction can occur during the hydrolysis. Thus, *(4c)* readily decomposes to benzophenone and *(1)*, whereas the hydrolysis of *(4a)* or *(4b)* is straightforward. The diastereomers of *(4e)* (separated by HPLC) primarily afford (2*R*,3*R*)-α-methyl-β-phenylserine methyl esters, which decompose *via* retroaldol reaction on distillation[5], while the (2*R*,3*S*)-diastereomer is thermostable[5].

Lactim ethers of type *(1)*, which are differently substituted on C-3 and C-6, also react with carbonyl compounds with high asymmetric induction; *e.g.*, in the reaction of (3*S*)-6-lithio-2,5-dimethoxy-3-(3,4-dimethoxybenzyl)-3-methyl-3,6-dihydropyrazine with acetone it is ≈93%[6].

Procedure

(1)→(4): Butyllithium (11 mmol, 7 ml of a 1.55 N solution in hexane) is added to a solution of *(1)*[7] (1.7 g, 10 mmol) in *ca.* 20 ml of THF or (better) dimethoxyethane at −70 °C. A solution of the carbonyl compound *(3)* (10 mmol) in *ca.* 20 ml THF or dimethoxyethane, precooled to −70 °C, is then added dropwise to the mixture. In the case of formaldehyde a suspension of 20 mmol of paraformaldehyde in 20 ml of THF is added. After stirring for 6–10 h (20 h in the case of *(4a)*) at −70 °C the mixture is treated with 0.66 g of glacial acetic acid in *ca.* 5 ml of THF and the temperature allowed to come to room temperature. After removal of solvent *in vacuo* the residue is shaken with 30 ml of ether and 50 ml of phosphate buffer solution (pH = 7); the aqueous solution is then extracted twice more with 20 ml ether and the combined ether extracts are dried over sodium sulfate. After removal of ether, *(4)* is distilled in a bulb-to-bulb apparatus.

(4b)→(5b): A mixture of *(4b)* (0.23 g, 1 mmol) and 0.13 N HCl (16 ml) is stirred for 15 min at room temperature. After removal of solvent in a vacuum (bath temp. 40 °C) the remaining mixture is covered with a layer of ether (5 ml). The vigorously stirred mixture is then treated with dilute ammonia solution until the pH = 8. The ether phase is saturated with sodium chloride and extracted a further five times with ether. The combined ether extracts are dried over sodium sulfate and, after removal of ether, distilled (slight decomposition); yield 0.11 g (72%) (*R*)-(—)-α,β,β-trimethylserine methyl ester, b. p. 100–110 °C/0.1 torr, enantiomeric purity 71% (determined with Eu(hfc)$_3$), corresponding to an asymmetric induction in the case of *(4b)* of *ca.* 80%. — ^{1}H-NMR ($CDCl_3$): δ = 1.26 and 1.40 (s, $CH_3$9H), 1.49 (s, $NH_2$2H), 3.75 (s, OCH_3, 3H); 8.3 (br., OH); $[\alpha]_D^{20} = -64.1°$ (*c* = 1.1 in ethanol).

Lithium [Bis(trimethylsilyl)methylene]diphenylphosphoranide, a Building Block for the Synthesis of Bis(methylenephosphoranes)[1]

By *Rolf Appel* and *Gerhard Haubrich*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Previous studies have shown that the deprotonation of methylene-bridged bisphosphonium salts *(1)* always takes place at the central C-atom. Either carbodiphosphoranes *(2)* or double ylides *(3)* containing a conjugated P=C–P bond system are obtained[2]. The formation of isomeric bis(methylenephosphoranes) of type *(7)* containing two terminal ylide functions, which are of interest as potential chelating agents, has hitherto not been observed[2].

We have now found that the salt *(5)*, *i.e.* the title compound, which is obtainable from [bis(trimethylsilyl)methyl]diphenylphosphane *(4)* and *n*-butyllithium, permits the synthesis of the novel double ylides *(7a)*–*(7c)*. From the smooth reaction of *(5)* with diiodomethane *(6a)*, 1,2-dibromoethane *(6b)* and dichloro(phenyl)phosphane *(6c)* it can be concluded that the species originally deprotonated at the α-C-atom reacts ambivalently as "Li-phosphoranide" with the difunctional halogen compounds.

Only the reaction with diiodomethane yields *(7a)*; dichloromethane is dehydrochlorinated by *(5)*, while reaction with dibromomethane leads to *(4)* together with three further still unidentified products.

The structure and composition of the double ylides are confirmed by elemental analysis, characteristic fragmentation pattern in the mass spectrum[3], and above all by the po-

NMR spectroscopic data of the bis(methylenephosphoranes)[4]
(7a): $^{31}P\{^1H\}$-NMR: δ = 18.7 (s); ^{1}H-NMR: δ = 0.05 (s, $SiCH_3$), 0.31 (s, $SiCH_3$), 1.20 (t, ^2J(PCH) = 12.0 Hz, CH_2), 7.45 (m, C_6H_5); $^{13}C\{^1H\}$-NMR: δ = 3.0 (d, ^3J(PCSiC) = 1.4 Hz, SiC), 7.1 (pseudo-t, ^3J(PCSiC) + ^5J(PCPCSiC) = 3.6 Hz, SiC), 13.8 (t, J(PC) = 53.6 Hz, CH_2), 128.6 (d, ^3J(PC-3) = 23.8 Hz, C-3), 131.6 (s, C-4), 133.8 (pseudo-dd, ^2J(PC-2) + ^4J(PCPC-2) = 10.2 Hz, C-2), 139.8 (pseudo-dd, J(PC-1) + ^3J(PCPC-1) = 87.4 Hz, C-1).

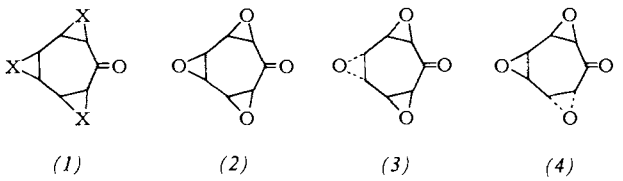
sition—and the coupling pattern in the case of *(7c)*—of the methylenephosphorane signal in the $^{31}P\{^1H\}$-NMR spectrum. The chemical non-equivalence of the *exo*- and *endo*-silyl groups in *(7a)* and the ^{1}H-NMR triplet for the methylene bridge preclude a prototropic carbodiphosphorane structure. We ascribe the surprising stability with regard to a 1,3-proton shift from the methylene bridge to the ylide center to the influence of the silyl substitution.



Procedure

A 15% solution of *n*-butyllithium (125 ml, 200 mmol) in *n*-hexane is added rapidly to a magnetically stirred solution of *(4)*[5] (13.8 g, 40 mmol) in ethylene glycol dimethyl ether (80 ml). After cooling, the suspension is filtered in the absence of moisture and the yellow precipitate is taken up in 200 ml of *n*-hexane and added dropwise within 2 h to a solution of *(6)* (20 mmol) in benzene (100 ml). After *ca.* 12 h the lithium halide that is formed is separated off, the solvent removed in a vacuum, and *(7)* recrystallized from *n*-hexane.—*(7a):* yellow crystals, m. p. 76 °C (dec.), yield 46%. *(7b):* anthracite colored crystals, m. p. 113 °C, yield 61%. *(7c):* minium-colored crystals, m. p. 123–125 °C (dec.), yield 56%.

(1) *(2)* *(3)* *(4)*

The starting compound for *(2)* and *(3)* is the *cis*-diepoxide *(5)*[2], which is readily accessible from tropone. *(5)* preferably exists as the "open" tub configuration and is only difficultly amenable to electrophilic attack at the C=C double bond. Consequently, a direct epoxidation succeeds only to a very limited extent (<5%)[3], even under drastic conditions. On the other hand, *(5)* smoothly adds the components of HOX (X = Br, Cl): with *N*-bromosuccinimide in water/dioxane (1:1, 0 °C) the overall yield is good, but the (β-OH) selectivity is poor. Besides *ca.* 10% dibromide *(9a)* (m. p. 145 °C (dec.), ν_{CO} = 1688 cm^{-1}), 40% and 27%—not optimized—of 6α,7β-*(7a)* and 6β,7α-bromohydrin *(8a)* (oil), respectively, are also formed, *(7a)* as the semiacetal *(6a)* (m. p. 175 °C (dec.)). High α-OH selectivity is attained with *tert*-butyl hypochlorite in water/acetone (1:1, 0 °C): in addition to the 6α,7β-isomer *(7b)*, isolated as *(6b)* (5%, m. p. 185 °C (dec.)), 80–85% of the oily 6β,7α-chlorohydrin *(8b)* (urethane: m. p. 244 °C (dec.)) is obtained, with traces of *(9b)* possibly escaping detection.

Semiketal formation and the open boat conformation also determine the result of the reaction of *(6a)*⇄*(7a)* with 5% methanolic KOH solution (60 °C). Without epoxide formation to give *(2)* being detectable (TLC, ^{1}H-NMR), transannular substitution takes place almost exclusively—*via (11)*—to give *(10)* (84–88%, m. p. 117 °C). However, on using diazabicyclononene (DBN) or -undecene (DBU) in aprotic media (CH_3CN, 60 °C)[4], only the desired "α,α,α"-trioxaketone *(2)* is isolated (provisionally 70–75%; m. p. 245 °C, ν_{CO} = 1731 cm^{-1}; see Table 1).

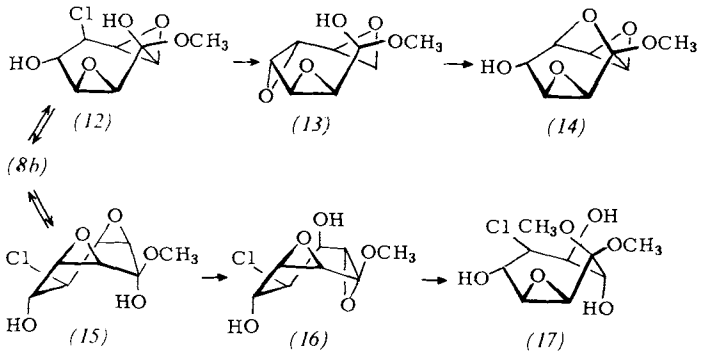
"α,α,α"-, "α,β,α"- and "α,α,β"-Trioxa-tris-σ-homotropone[**]

By *Wolfgang Seppelt, Hans Fritz, Christoph Rücker,* and *Horst Prinzbach*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The tris-σ-homotropones *(1)* (X = CH_2, O, NR) are of interest to us in connection with theoretical and preparative objectives already reported in a previous communication[1]. We have now synthesized the stereoisomeric trioxa-compounds *(2)*–*(4)*.



Semiketal formation, transannular substitution, and, in addition, epoxide migration[5] are the dominant competing processes in the reaction of *(8a)*/*(8b)* with KOH/methanol (1.5 equiv.). Plausible intermediates in the reactions leading to *(14)* (m. p. 144 °C) and *(17)* (m. p. 189 °C), obtained from *(8b)* and isolated in 47 and 42% yield, respectively, are the compounds *(12)* and *(13)* and *(15)* and *(16)*, respectively. In

(10) *(11)* *(2)*

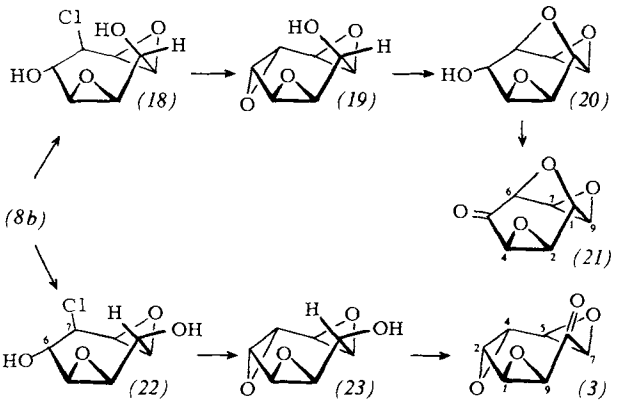
favor of *(13)* is the observation that *(3)* smoothly yields *(14)* under the same conditions. Unexpected—and so far inexplicable—is the behavior towards the bases, which have already been successfully employed in the case of *(6a)*⇄*(7a)*. Thus, even at 0 °C *(8a)*/*(8b)* react with DBN or DBU or KOH/tBuOH or tBuOK/tBuOH almost spontaneously to give a dark polymer. The supposition that the quasi-antiperiplanar arrangement of the X/O pair, as in previous cases[4], is



hindered by electrostatic interactions between halogen atom and epoxide oxygen atom(s), and epoxide formation is rendered relatively difficult, is, in view of the ease of polymerization and the smooth cyclization *(22)*→*(23)*, wholly unsatisfactory.

The complications arising from CO in *(8a)*/*(8b)* are avoidable by the circuitous route *via* the alcohols. On reaction with $NaBH_4$ (ethanol, 0 °C) a *ca.* 1:1 mixture of the diols *(18)* and *(22)* (m. p. 183 and 181 °C, respectively; overall yield provisionally 70%) is obtained from *(8b)*. Treatment of this mixture with 5% KOH/methanol (1.5 equiv., 60 °C, 20 min) affords *(20)* and *(30)* in quantitative yield. A control experiment confirms that *(19)*—prepared from *(3)*—is wholly converted into *(20)* under these conditions. *(20)* (m. p. 135 °C) and *(23)* (m. p. 159 °C) can be separated chromatographically (silica gel, ethyl acetate) and oxidized conventionally (CrO_3/pyridine/CH_2Cl_2) to *(21)* (55–60%, m. p. 150 °C, $\nu_{CO}=1735\ cm^{-1}$; see Table 1) and to the "α,β,α"-trioxaketone *(3)*, respectively (65–70%, m. p. 169, $\nu_{CO}=1728\ cm^{-1}$; see Table 1). The extent to which the reduction of *(8b)* can be more selectively controlled has still to be checked.

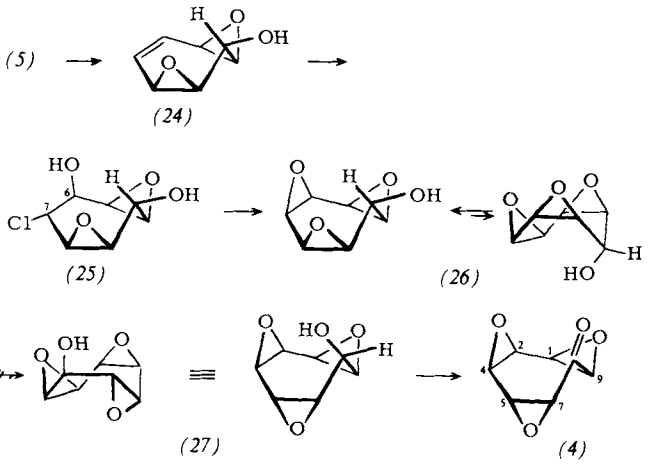


Table 1. ^{1}H- and ^{13}C-NMR data (δ values, *J* [Hz]) of the ketones *(2)*, *(3)*, *(4)*, and *(21)*.

	^{1}H-NMR	^{13}C-NMR
(2)	3.72 (7(9)-H), 3.69 (2(4)-H), 3.61 (1(5)-H); $[J_{1,2}+J_{1,4}]\approx 1$, $J_{1,9}=4.5$	194.9, 55.1, 54.1, 50.5
(3)	3.73 (7(9)-H), 3.53 (2(4)-H), 3.67 (1(5)-H); $[J_{1,2}+J_{1,4}]\approx 1$, $J_{1,9}=4.5$	200.5, 58.0, 54.6, 52.8
(4)	3.75, 3.69, 3.56, 3.52, 3.48, 3.42; *J* = 1.5, 1.7, 2.4, 3.5, 4.8, 4.8	199.6, 58.4, 55.9, 53.7, 52.9, 52.8, 52.2
(21)	4.59 (6-H), 4.27 (1-H), 3.96 (7-H), 3.63 (9-H), 3.62 (4-H), 3.17 (2-H); $J_{1,2}=1$, $J_{2,4}=4.0$, $J_{4,6}=1.5$, $J_{7,9}=3.0$, $J_{1,9}=J_{6,7}=0$	200.6, 79.9, 70.7, 54.1, 52.6, 52.0, 51.5

The "α,α,β"-isomer *(4)* was originally sought *via* an epoxide migration[5] in the α-alcohol *(26)* to give *(27)*. *(26)* is obtained in high yield from *(5)*, since reduction ($NaBH_4$, ethanol, 0 °C, 95% *(24)*, 5% β-alcohol) and addition of HOCl (conditions as in the case of *(5)*; besides 15% dichloride (m. p. 135 °C), 65% 6β,7α-chlorohydrin *(25)* (acetate m. p. 125 °C), possibly traces of 6α,7β-isomer *(22)*) can be carried

out stereoselectively and the subsequent cyclization (5% KOH/methanol, 60 °C, 15 min) is unproblematic (85–90%, m. p. 200 °C)[6]. However, under a large variety of conditions *(26)* does not isomerize to *(27)*. Apparently the transition into the "closed" conformation necessary for this isomerization is energetically unattainable. Hence, *(4)* (m. p. 104 °C, $\nu_{CO}=1727\ cm^{-1}$; see Table 1) was prepared by oxidation (RuO_2, $NaIO_4$, CH_2Cl_2, H_2O, K_2CO_3, 20 °C, 90%) of *(27)*[1] generated *via* an alternative route[7].

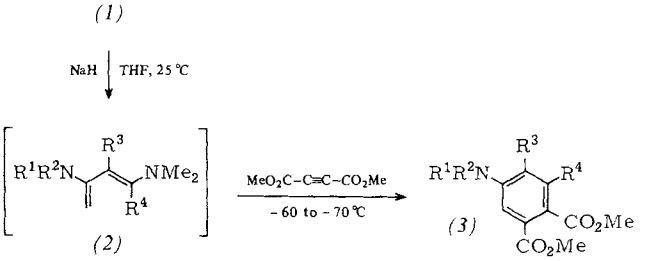
1,3-Bis(dialkylamino)-1,3-butadiene from 1-Methylvinamidinium Salts[**]

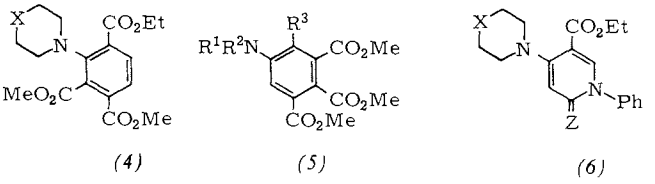
By *Rudolf Gompper* and *Ulrich Heinemann*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Vinamidinium salts [vinylogous amidinium salts, see *(1)*] are able to react as ambifunctional systems with bases and nucleophiles[1,2]. With 2-ethoxy-1,1-dimethoxy-4-(dimethylamino)-1,3-butadiene and 1,1-dimethoxy-2,4-bis(dimethylamino)-1,3-butadiene as examples we have shown that "electron-rich" butadienes can be prepared by deprotonation of the corresponding 1-(dimethoxymethyl)allylium salts with NaH[2]. Independently of us, *Oppolzer et al.*[3] and *Ghosez et al.*[4] have found that 1-aminobutadienes can be obtained from 1-amino-3-methylallylium salts. 1-(Dialkylamino)butadiene derivatives have been formulated as intermediates also in polysubstitutions of olefins and ketones with dimethylformamide/phosphorus oxide chloride[5] and in thio-Claisen rearrangements[6].



Since only relatively few 1-alkylvinamidinium salts such as *(1e,f)* (Table 1)[7,8] have been described, we have prepared a few others *(1a–d)* from β-aminocrotonic esters and dimethylformamidoyl chloride derivative (Table 1).



R^3 = CO_2R, R^4 = H

(1a–d)

fact that besides *(3c,d)* small amounts of *(4c,d)* are found, which derive from [2+2]-cycloadditions. Furthermore, on

reaction of *(1a–c)* with two equivalents of dimethyl acetylenedicarboxylate, the tetracarboxylates *(5)* (Table 1) are also obtained besides *(3)* and *(4)*.

(4) *(5)* *(6)*

If heterocumulenes such as phenyl isocyanate or isothiocyanate are used as trapping reagents for *(2)*, the α-pyridones and α-thiopyridones *(6)*, respectively, can be isolated (Table 1).

The 1,3-bis(dialkylamino)-1,3-butadienes *(2)* are generated by action of sodium hydride on *(1)* (tetrahydrofuran, room temperature). Attempts to isolate them have so far met without success; they are best handled in solution. If, after evolution of hydrogen has ceased, the solution is cooled to −60 to −70 °C and then treated with one equivalent of dimethyl acetylenedicarboxylate, one obtains the phthalates *(3)* (Table 1).

Presumably *(3)* is formed by a [4+2]-cycloaddition involving dipolar intermediates. This is supported, *inter alia*, by the

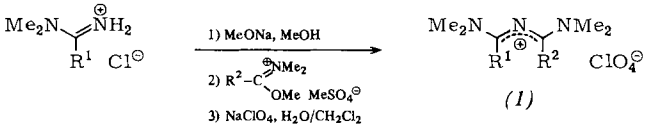
1,3-Bis(dimethylamino)-2-aza-1,3-butadienes from 1-Alkyl-2-azavinamidinium Salts[**]

By *Rudolf Gompper* and *Ulrich Heinemann*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Numerous aspects of the chemistry of 2-aza-1,3-butadienes have been investigated over the past ten years. In connection with investigations on the application of the allopolarization principle[1] to 2-azaallyl anions we found simple methods for the synthesis of 4-(dimethylamino)- and 4,4-bis(methylthio)-2-aza-1,3-butadienes[2]. The conversion of 1-methylvinamidinium salts into 1,3-bis(dialkylamino)-1,3-butadienes[3] now also opens a route to 1,3-bis(dimethylamino)-2-azabutadienes *(2)*.

The 1-alkyl-2-azavinamidinium salts *(1)* required as starting substances (cf. also [4]) can be obtained by reaction of amidines or guanidines[5] with carboxamide/dimethyl sulfate adducts[6] (see Table 1). Reaction of *(1)* with sodium hydride



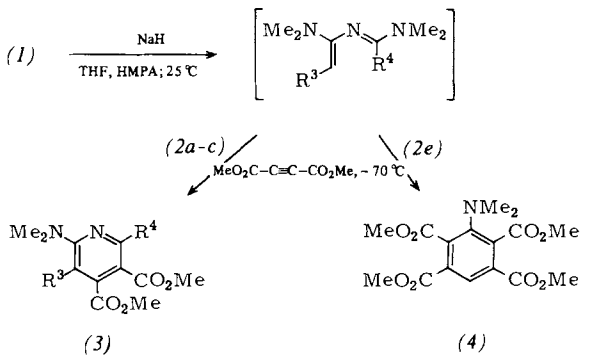


Table 1. 2-Azavinamidinium salts *(1)* and trapping products of the intermediary 1,3-diamino-2-aza-1,3-butadienes *(2)*.

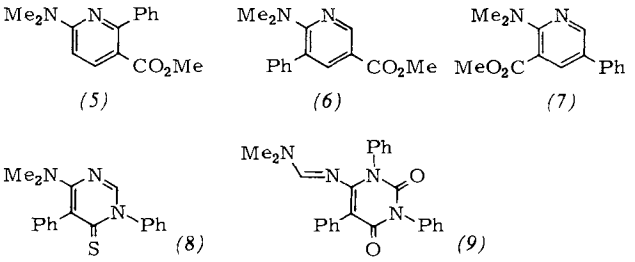
	Product	R^1	R^2	M.p. [°C]	Yield [%]
	(1a)	Me	H	94–95	79
	(1b)	$PhCH_2$	H	129–131	61
	(1c)	Ph	Me	111–112	73
	(1d)	Me	Me	185–187	70
	(1e)	Me_2N	Me	88–89	74
Reaction	Product	R^3	R^4	M.p. [°C]	Yield [%]
(1a)→*(2a)*→*(3a)*		H	H	111–112	16
(1b)→*(2b)*→*(3b)*		Ph	H	113–114	50
(1c)→*(2c)*→*(3c)*		H	Ph	91–92	28
(1e)→*(2e)*→*(4)*				173	12
				173 [7]	



in tetrahydrofuran (THF) or—in the case of *(1b,c)*—hexamethylphosphoric triamide (HMPA) affords the azabutadienes *(2)*, which can be identified by their reactions; so far, they have not been isolated. On addition of dimethyl acetylenedicarboxylate to solutions of *(2a–c)* at −70 °C, the 6-(dimethylamino)-3,4-pyridinedicarboxylates *(3)* are obtained (see Table 1).

Reaction of *(2e)* with dimethyl acetylenedicarboxylate surprisingly leads—*via* a [2+2]-cycloadduct—to the aminobenzenetetracarboxylates *(4)*.

(2a), $R^3 = R^4 = H$; *(2b)*, $R^3 = Ph$, $R^4 = H$;
(2c), $R^3 = H$, $R^4 = Ph$; *(2e)*, $R^3 = H$, $R^4 = NMe_2$

On reaction of *(2c)* with methyl propiolate, the pyridinecarboxylate *(5)* is obtained (yield 12%, m. p. 46–48 °C). The corresponding reaction of *(2b)* yields, besides the 6-dimethylamino-3-pyridine-carboxylates *(6)* ([4+2]-cycloaddition), the 2-(dimethylamino)-derivative *(7)* ([2+2]-cycloaddition) (yields 29 and 14%, m. p. 66 °C and b. p. 230 °C/0.01 mbar, respectively).

Reaction of *(2b)* with phenyl isothiocyanate leads to the expected pyrimidinethione *(8)* (yield 36%, m. p. 203–204 °C), whereas reaction with phenyl isocyanate, however, gives the aminouracil derivative *(9)* (yield 30%, m. p. 254–255 °C). A 1,3,5-triazocinedione structure for *(9)*, also likely on the basis of its ^{1}H-NMR spectrum ($\delta = 2.49$, s, 6H), could be ruled out because acid hydrolysis of *(9)* leads to the well-known triphenylbarbituric acid[8].

Enhancement of 1,2-Asymmetric Induction on C—C Linkage by Use of Chiral 2-Butenylboronic Esters[**]

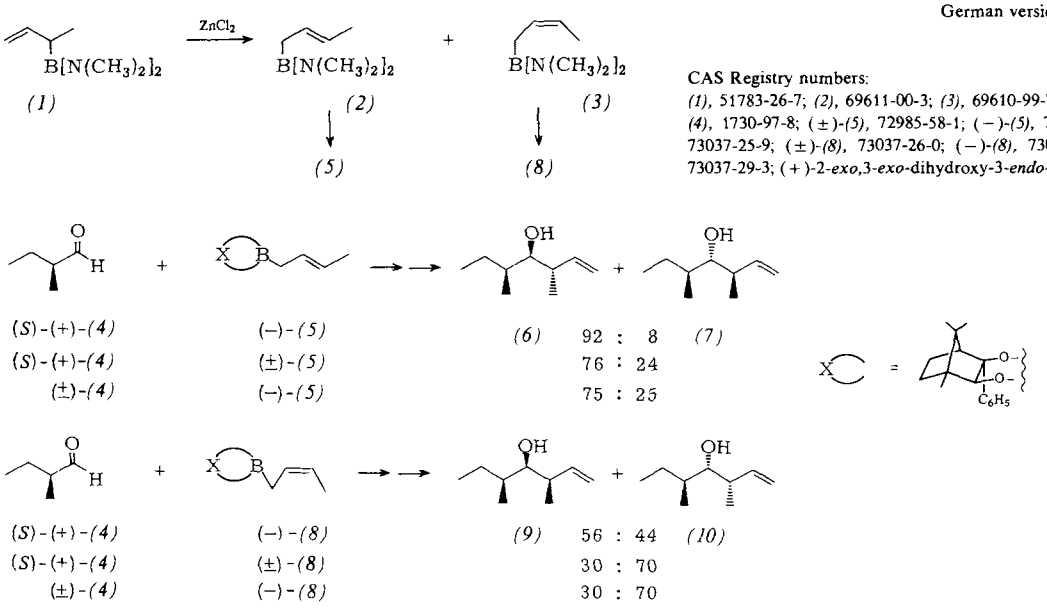
By *Reinhard W. Hoffmann* and *Hans-Joachim Zeiss*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The formation of β-methylalkanols by aldol-type C—C linkage is of cardinal importance in the synthesis of macrolides and related structures[1]. This raises the problem of 1,2-asymmetric induction associated with the Cram rule[2]:

The diastereoselectivities achieved so far lie mainly in the range of 0.8–4:1[3]. These results should be open to improvement by use of a chiral reagent instead of an achiral one in the reaction with the optically active aldehyde normally used[4]. We have therefore examined the effect of modifying the chirality[5] on the reaction of 2-methylbutyraldehyde *(4)* with 2-butenylboronic esters[6].

1-Methylallylboronic bis(dimethylamide) *(1)* was isomerized[7] by heating with 10 wt. % of $ZnCl_2$ at 150 °C for 80 h, giving a 7:3 mixture of 2-butenylboronic bis(dimethylamides) *(2)* (b. p. 98.3 °C/100 torr) and *(3)* (b. p. 101 °C/100 torr). After separation over a 1-m spinning band column, compounds *(2)* and *(3)* were transformed quantitatively into the chiral reagents (−)-*(5)* and (−)-*(8)* by treatment with (+)-2-*exo*,3-*exo*-dihydroxy-3-*endo*-phenylbornane[5]. The reaction of racemic 2-methylbutyraldehde *(4)* with the (*E*)-butenylboronic ester *(5)* afforded (as in ref.[5]) the two isomers *(6)* and *(7)* of 3,5-dimethyl-1-hepten-4-ol in 95% yield; the ratio of the isomers was determined by gas chromatography. Both isomers must have a *threo* configuration with respect to C-3/C-4[6]. Assignment of the relative configuration of C-4/C-5 was accomplished, after hydrogenation of the double bond, on the basis of the ^{13}C-NMR spectra since the hydrogenation product of *(7)* shows a symmetry plane. The *erythro* products *(9)* and *(10)* arising from *(4)* and *(8)* were determined and assigned in corresponding manner.



Reaction of racemic *(5)* with the (*S*)-(+)-aldehyde *(4)*[8] gave the isomeric alcohols in the ratio of 3:1, with the "Cram" product *(6)* predominating. On use of chiral *(5)*, the diastereoselectivity rose to *ca.* 11:1 because the tendency towards preferential formation of the Cram product and the tendency of the reagent to form an alcohol with (*R*) configuration at C-4[5] now cooperate. This result demonstrates the enhancement of diastereoselectivity which can be effected by a chiral reagent. It can be deduced from the diastereomeric ratio of 3:1 found for the reaction of the racemic aldehyde with the chiral reagent *(5)* that the (*R*)-(−)-aldehyde yields the enantiomers of *(6)* and *(7)* in the ratio of 1.4:1 because the Cram preference and chiral control by the reagent now oppose each other.

On reaction of the racemic (*Z*)-2-butenylboronic ester *(8)* with the (*S*)-(+)-aldehyde *(4)*, the anti-Cram product *(10)* predominated in the ratio 2.3:1. Although the amount of *(9)* could be increased by the chiral ragent *(8)*, it was not possible to overcompensate the anti-Cram preference. On the other hand, the anti-Cram preference and chiral control should again reinforce each other in the reaction of (*R*)-(−)-2-methylbutyraldehyde with *(8)*. Indeed, the data obtained for the reaction of racemic *(4)* with chiral *(8)* indicate a corresponding selectivity of 20:1! It can be seen that the selectivity could so far only be adequately enhanced in favor of one out of two possible diastereomers.

The anti-Cram preference in the reaction of *(8)* with *(4)* is also remarkable: such preference has so far only been observed in the addition of (*Z*)-enol borinates[3d], but not in that of lithium (*Z*)-enolates[3a]. This could be a result of the more compact cyclic transition states encountered with the boron reagents[10]; molecular models show that the anti-Cram transition state is less hindered in the case of *(8)*, and the Cram transition state less hindered in the case of *(5)*.

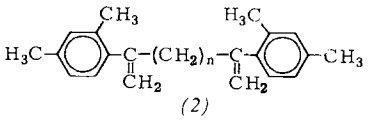
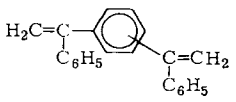
1,3-Bis(1-lithio-3-methyl-1-phenylpentyl)benzene, an Organodilithium Compound Soluble in Aromatic Hydrocarbons[**]

By *Günther Schulz* and *Hartwig Höcker*[*]



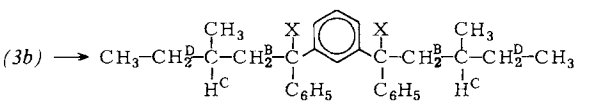
Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Some vinyl compounds, such as 1,1-diphenylethylene[1], α-isopropenylnaphthalene, and 1-isopropenyl-2,4-dimethylbenzene[2] cannot be anionically homopolymerized. On electron transfer from alkali metals (in polar solvents, *e.g.* tetrahydrofuran) they form monomeric radical anions, which combine to give dimeric dianions.



In the presence of electron transfer agents the corresponding divinyl compounds undergo polycombination reactions, which—depending on the structure of the divinyl compound—can proceed either exclusively inter- or inter- and intramolecularly. Some of the polyanions thus obtained are suitable as initiators for anionic polymerization (*e.g.* of styrene and butadiene). The divinyl compounds *(1)* and *(2)* tend to undergo side-reactions (*e.g.* proton abstraction)[4a], while *(3a)* and *(3b)* give uniform products[3]. Particularly noteworthy is the high tendency of *(3b)* to undergo cyclodimerization in the presence of electron transfer agents[5], which leads to the tetraanion.

(1)



(2)

(3a), p-
(3b), m-

The reaction of anionically non-homopolymerizable divinyl compounds with butyllithium should lead to organodilithium compounds. If these dissolve in apolar solvents (benzene, toluene) they offer the possibility of initiating the anionic bifunctional 1,4-polymerization of 1,3-dienes. Since all previously known organodilithium compounds are scarcely soluble in such solvents owing to association, either polar substances such as ethers or amines have to be added, or they must be treated with small amounts of monomer (diene) to give oligomers (seeding technique). Disadvantages are the higher 1,2-content of the polymers and the heterogeneity of the initiator[6].

The compounds *(1)* and *(2)* react only to a negligibly small extent within 24 h even with excess *sec*-BuLi in toluene or benzene at 65 °C. *(3a)* is preferably monolithiated by BuLi. Reaction of *(3b)* with *sec*-BuLi (molar ratio 1:2) in toluene at room temperature, however, leads within 2 h quantitatively to the diadduct *(4)*, which is protonated to 1,3-bis(3-methyl-1-phenylpentyl)benzene *(5)*[4].

(4), X = Li; *(5)*, X = H^A; *(6)*, X = COOH

The starting compound *(3b)* can no longer be detected in the gas- and gel-chromatograms of *(5)*; on the basis of the gel chromatogram, higher adducts are ruled out. The IR spectrum shows no absorption at 900 cm^{-1} characteristic for the double bonds in *(3b)*. Proof of the structure is provided by the ^{1}H-NMR spectrum [δ = 7.11 and 7.00 (14 aromatic H), 3.94 (t, 2H^A, J_{AB} = 7 Hz), 1.8 (broad, 4H^B), 1.2 (m, 2 H^C + 4 H^D), 0.6–1.0 (m, 12 H, CH_3)] and the mass spectrum (70 eV) [*m/e* = 398 (M^+), 327 ($M^+ - C_5H_{11}$), 179 ($327 - C_5H_{11} - C_6H_5$)]. In addition, the fragment with *m/e* = 257 is formed by McLafferty rearrangement and elimination of isopentene.

The initially formed dilithium compound *(4)* is soluble in benzene and toluene up to a concentration of 0.1 mol/l. Clouding of the solution does not occur, even after 10 weeks' storage in a refrigerator.

The bifunctionality of the initiator *(4)* was checked by chemical methods on 0.1 M solutions in toluene.

1. Double titration by the method of *Gilman*[7] gave 95% of the calculated content of active organolithium groups.

2. The product obtained on reaction with solid CO_2 was isolated by extraction with aqueous NaOH. The IR spectrum of the carboxylic acid obtained on acidification is consistent with the expected structure *(6)*; the ^{1}H-NMR spectrum confirms the presence of a dicarboxylic acid quantitatively: δ = 0.3–1.6 (18 methyl-, methylene-, methine-H), 2.26 (4H^B), 7.15 (14 aromatic H), 12.07 (2 carboxylic H).

3. The dilithium compound *(4)* is suitable as bifunctional initiator for the anionic 1,4-polymerization of 1,3-butadiene and for the preparation of block copolymers (*e.g.* with styrene) of type ABA[8].

Procedure

To 40 ml of toluene or benzene, previously boiled for several days over potassium in an argon atmosphere, is added a small amount of *sec*-BuLi and the solution distilled directly into a reaction vessel containing 1.412 g (0.005 mol) *(3b)*. When *(3b)* (at 20 °C) has dissolved, a 1 M solution of *sec*-BuLi (10.0 ml) is added to the mixture. After one hour's standing at 20 °C the 0.1 M solution of the dilithium compound is ready for use; it can be stored for several weeks at −20 °C.

$(AsPh_4)_2[W_2NCl_{10}]$, a μ-Nitrido Complex Containing Tungsten(V) and Tungsten(VI)

By *Frank Weller, Wolfgang Liebelt,* and *Kurt Dehnicke*[*]

The only dinuclear μ-nitrido complexes of transition metals hitherto reported in the literature were those of ruthenium(IV)[1,2] and of osmium(IV)[1,3]. We have found during attempts to synthesize the previously described $AsPh_4[WNCl_4]$ complex[4] in acetonitrile that dark brown single crystals of the composition $(AsPh_4)_2[W_2NCl_{10}]$ *(1)* are formed in a slow side reaction. As follows from elemental analysis, IR spectrum and a crystal structure determination[5], *(1)* is the first dinuclear μ-nitrido complex of tungsten containing two tungsten atoms in different oxidation states.

In the anion of *(1)* (Fig. 1) the WNW bridge is linear. The centrosymmetric space group $P2_1/n$ precludes any definite decision between a symmetric or asymmetric position of the N atom between the W atoms since disorder of the crystal might create the impression that the former applies. Under this assumption the refinement affords the two WN distances of 165.7 and 207.2 pm. Also in agreement with this is the IR spectrum, in which two WN stretching vibrations are observed at 1015 and 944 cm^{-1}.

A comparison with the WN bond lengths of the tetrameric $[WNCl_3 \cdot POCl_3]_4 \cdot 2POCl_3$[6] *(2)*, linked *via* stretched W≡N—W bridges, shows that also the long WN bond in *(1)* profits from a $d_\pi p_\pi$ overlapping. This multiple bonding also manifests itself in the *eclipsed* position of the four equatorial Cl atoms: The W atoms utilize the two d orbitals d_{xz} and d_{yz} at right angles to each other for bond strengthening. As a result of the sterically demanding WN multiple bonds the equatorial Cl atoms are shifted outwards a little (on average 7 pm), along the WNW axis. The W...W distance of 372.9 pm in *(1)* is markedly shorter than in *(2)* (386.0 pm)[6], corresponding to a Jahn-Teller stabilization of the tungsten(V). An analogous W...W distance of 372.8 pm was found in the complex $(HNMe_3)_2[W_4O_8Cl_8(OH_2)_4] \cdot 2H_2O$, in which tungsten(V) and tungsten(VI) are likewise coupled *via* linear WOW bridges[7].

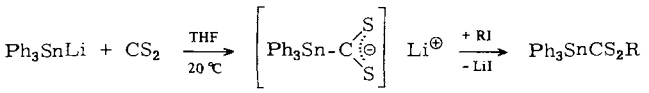
Nucleophilic Addition of Triphenylstannyllithium to Carbon Disulfide

By *Paul-Reiner Bolz, Udo Kunze,* and *Werner Winter*[*]

Triorganoelement anions of Group IVb elements, R_3El^- (R = Ph, Me; El = Si, Ge, Sn, Pb), are strong nucleophiles and therefore should react readily with electrophilic heteroallenes such as CO_2, COS, CS_2, R'NCO, and R'NCS according to



to give element-functional ligand systems which can be stabilized with Lewis acids ($X^\oplus$). Almost all such attempts have hitherto failed, since formation of the stable di-element compounds, $R_3El—ElR_3$, with reduction of the heteroallene predominates[1]. On the other hand, the reactions of carbonylmetalate ions[2] and diorganophosphides[3] with carbon disulfide (and other heteroallenes) demonstrate that the proposed reaction route is fundamentally possible.

[+] Author to whom correspondence should be addressed.
[++] X-ray structure analysis.

We have now been able to show that a nucleophilic addition takes place on reaction of triphenylstannyllithium with carbon disulfide. The initial product *(1)* can be trapped by alkylation with methyl or ethyl iodide in tetrahydrofuran (THF).

(1) *(2a)*, R = Me; *(2b)*, R = Et

After separation by column chromatography, the products *(2a)* and *(2b)* can be crystallized from petroleum ether as air-stable violet needles of m. p. 128–129 °C and 47–48 °C, respectively, with the given composition.

With aryl halides such as iodobenzene or *p*-bromotoluene, however, no substitution products could be detected, but only bis(triphenyltin) sulfide in small amounts. Attempted nucleophilic addition of trimethylstannyllithium also failed; apparently stabilization of the electron-rich initial product by mesomerizable groups attached to tin is essential.

Table 1. Spectroscopic data of the substitution products *(2a)* and *(2b)*.

Method	*(2a)*	*(2b)*

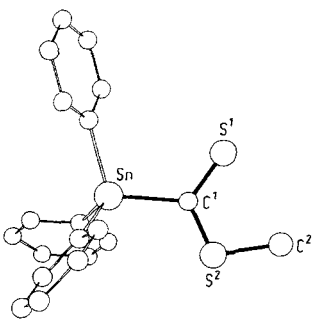
UV ($CHCl_3$) λ_{max} [nm] (ε)	313 (5070), 532 (126)	314 (5000)

[a] 70 eV, direct inlet. [b] Molecular mass, calc. 441.3, exp. 439 (osmometric in benzene).

It cannot be definitely decided from the spectroscopic data (Table 1) whether the stannyl-substituted dithioformate (*A*) or the isomeric dithiocarboxylate complex (*B*) is formed.

Dithiocarboxylates of the structural type (*B*) are indeed known[4] (not of course, for R = Me, Et), but they differ very little from the substitution products *A* in their physical properties. Therefore an X-ray structure analysis of *(2a)* was carried out[5], which confirmed the structural type *A*.



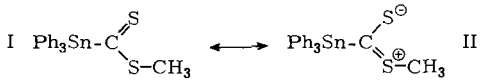


Fig. 1. Molecular structure of *(2a)*; Sn—C^1 = 214 ± 0.8, C^1—S^1 = 164 ± 2, C^1—S^2 = 162 ± 2, C^2—S^2 = 184 ± 4 pm; angles around C^1: 120 ± 1°, C^1—S^2—C^2 = 106 ± 1.5° [5].

Crystallographically, *(2a)* has a tetraphenyltin structure exhibiting "ordered disorder"[6] in which the phenyl groups with a population factor of 0.25 are replaced by methylthiothiocarbonyl ligands. An outstanding feature of this completely planar structural unit[7] is that the S—C^1 bonds are, within the limits of error, of equal length, thus suggesting participation of the mesomeric resonance hybrid II:

Procedure

Double the stoichiometric amount of CS_2 is added dropwise to a stirred solution of Ph_3SnLi[8] (16 mmol) in THF (50 ml), whereupon the solution becomes warm and turns reddish-brown in color. After cooling, MeI or EtI is added in excess. Column chromatographic separation (silica gel, THF) of the violet solution affords a red fraction and a dark brown fraction. After removal of solvent and double recrystallization from petroleum ether the red fraction gives pure *(2a)* (yield 60%) and *(2b)* (yield *ca.* 5%), respectively.

Photooxidation of the Ligands of Bis(*o*-semiquinonediimine)nickel(II) and -platinum(II)[**]

By *Arnd Vogler* and *Horst Kunkely*[*]

All the photoredox reactions of transition metal complexes examined so far involve direct participation of the metal[1]. We now report a photoreaction in which the ligands are oxidized while the oxidation state of the metal remains unchanged.

o-Hydroquinones and *o*-quinones[2], as well as *o*-phenylenediamine and *o*-quinonediimine[3] form transition metal complexes which can undergo mutual interconversion by several reversible one-electron redox reactions *via* stable semiquinone and semiquinonediimine species, respectively. The complexes $M[o\text{-}C_6H_4(NH_2)]_2^z$ having M = Ni, Pd, and Pt then occur with charges $z = -2, +1, 0, -1$, and -2[3]. The end members with $z = +2$ and -2 contain the ligands *o*-qui-

[*] Prof. Dr. A. Vogler, Dr. H. Kunkely

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

nonediimine o-$C_6H_4(NH)_2$ and o-phenylenediamide o-$C_6H_4(NH)_2^{2-}$. The most stable members of these redox series are the uncharged diamagnetic and deep-blue complexes $M[o\text{-}C_6H_4(NH)_2]_2$ having two mutually coupled o-semiquinonediimine ligands. One-electron oxidation of the neutral complexes leads to the cations $M[o\text{-}C_6H_4(NH)_2]_2^+$, with loss of one ligand electron. This can be deduced, *inter alia*, from the fact that the potentials of the oxidation are almost independent of the metal and the unpaired electron of the cations is localized on the ligands[3]. We observed that this ligand oxidation also occurs as a photochemical reaction. The complexes of Ni and Pt were studied in detail.

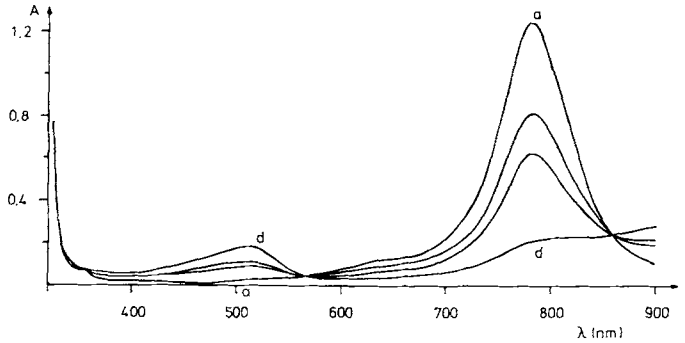

Fig. 1. Change in the absorption spectrum during the photolysis of $Ni[o\text{-}C_6H_4(NH_2)]_2$ (2.29×10^{-5} mol/l) in $CHCl_3$ in a 1-cm cell. Excitation with light of $\lambda > 330$ nm; duration of irradiation: a = 0, d = 3 min.

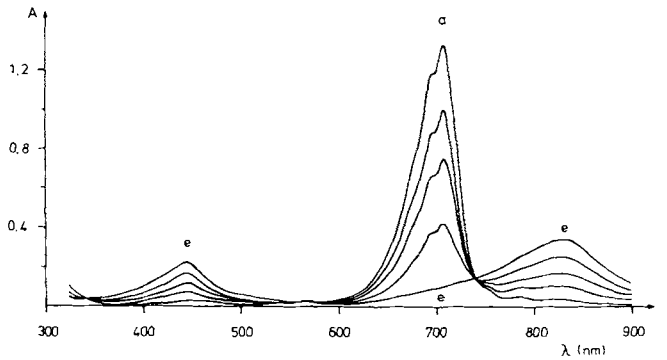

Fig. 2. Change in the absorption spectrum during the photolysis of $Pt[o\text{-}C_6H_4(NH)_2]_2$ (1.37×10^{-5} mol/l) in $CHCl_3$ in a 1-cm cell. Excitation with light of $\lambda > 330$ nm; duration of irradiation a = 0, e = 4 min.

Irradiation of the complexes $M[o\text{-}C_6H_4(NH)_2]_2$ (M = Ni and Pt) dissolved in $CHCl_3$ with light of wavelength $\lambda < 350$ nm led, with decoloration of the blue solutions in a smooth reaction (Figures 1 and 2), to formation of the cations $M[o\text{-}C_6H_4(NH)_2]_2^+$ which could once again be reduced completely to the neutral complexes (*e.g.* with $NaBH_4$). The solvent $CHCl_3$ serves as electron scavenger[4] during the photooxidation. The quantum yields were $\phi = 0.28$ (Ni) and 0.33 (Pt) on excitation at $\lambda = 313$ nm.

It is assumed that the photooxidation is initiated by an excited intraligand state since the excitation wavelength ($\lambda < 350$ nm) is independent of the metal. It is remarkable that light absorption by the intense long-wave bands (Fig. 1 and 2), which are also assigned to intraligand transitions, did not lead to a photoreaction.

Oxidation of Isatins to Isatoic Anhydrides and 2,3-Dioxo-1,4-benzoxazines

By *Gernot Reissenweber* and *Dietrich Mangold*[*]

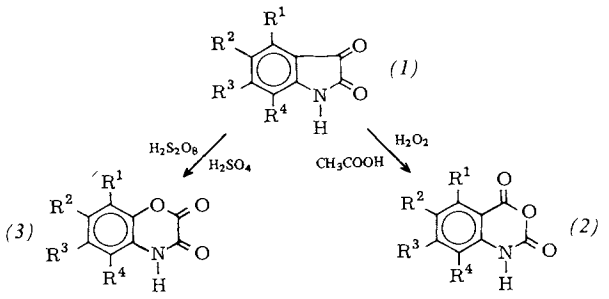
Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Isatoic anhydrides[1], which are of interest as intermediates for the synthesis of numerous heterocycles, can be obtained by oxidation of isatins with chromium trioxide in glacial acetic acid or acetic anhydride[2]. With the aim of using a less toxic oxidizing agent than chromium trioxide we have further investigated the Baeyer-Villiger oxidation of isatins, for it is well known that *N*-phenyl-substituted isatins can be converted by peracids into the corresponding isatoic anhydrides[3].

In a Baeyer-Villiger oxidation of isatins *(1)* two reaction products are possible on attack of peroxide at C^3: Rearrangement of the initially formed Criegee adduct yields isatoic anhydride *(2) via* route *a* and the isomeric 2,3-dioxo-1,4-benzoxazines *(3) via* route *b*.

Depending upon the reaction conditions and the oxidizing agent we have been able to carry out a regioselective synthesis of isatoic anhydrides *(2)* or 2,3-dioxo-1,4-benzoxazines *(3)* from *(1)*; Table 1 shows some examples.

On addition of an equimolar amount or slight excess of 30% aqueous hydrogen peroxide to a suspension of isatin in glacial acetic acid at 25–35 °C, a slightly exothermic reaction ensues after a short period of time; the suspension goes into solution and after a few minutes the isatoic anhydride *(2)* begins to precipitate from the warm solution. As a rule the compounds *(2)* are free of isomers.



The reaction is accelerated by catalytic amounts of sulfuric acid, phosphoric acid, or *p*-toluenesulfonic acid. Use of formic acid as solvent or use of larger amounts of sulfuric acid leads to lower overall yields of *(2)*, and the crude product is contaminated with varying amounts of *(3)*.

In contrast, the oxidation of isatins *(1)* with potassium peroxodisulfate in sulfuric acid at room temperature or below affords 2,3-dioxo-1,4-benzoxazines *(3)* in high yields in

an exothermic reaction. Isatoic anhydrides do not occur as by-products.

Some of the compounds prepared, *e.g. (3c)* and *(3d)*, are very sensitive to hydrolysis even in weakly acid solution at room temperature, so that mixtures of benzoxazine *(3)* and *N*-(2-hydroxyphenyl)oxamidic acid *(4)* are sometimes obtained on work-up.

Compared with the synthesis of 2,3-dioxo-1,4-benzoxazines *(3)* from *o*-aminophenols and oxalyl chloride[4], the synthesis from isatins *(1)* offers advantages, particularly for the directed synthesis of derivatives substituted at the benzene ring. Thus, for example, preparation of the *o*-aminophenols required for the synthesis of *(3b)* or *(3c)* is tedious and not without difficulty, whereas the corresponding isatins are readily accessible[5].

The isomers *(2)* and *(3)* can be easily and unequivocally distinguished by mass spectrometry.

Procedure[6]

(2): A suspension of *(1)* (1 mol) in glacial acetic acid (*ca.* 1000 ml) and conc. sulfuric acid (5 ml) is heated to *ca.* 30 °C. It is then treated dropwise within 20 min with 1.1 mol hydrogen peroxide as a 30% aqueous solution and the reaction temperature kept at 60–70 °C by gentle cooling. After 2 hours' stirring and cooling to room temperature the precipitate is filtered off and washed with water.

(3): 1 mol of *(1)* is added to a solution of $K_2S_2O_8$ (1–1.5 mol) in *ca.* 1000 ml 85–95% sulfuric acid at 0 to 10 °C. After stirring for a few minutes the solution is poured onto ice. The precipitate is filtered off and washed with water.

Influence of Isomerism of Alkanes on the Thermodynamic Properties of Cyclohexane/Alkane Mixtures

By *Andreas Heintz, Rüdiger N. Lichtenthaler,* and *Klaus Schäfer*[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

The various chemical structures of isomeric hydrocarbons also lead to differences in thermodynamic behavior of the pure isomers and of their mixtures with other compounds. Owing to the industrial importance of such mixtures in isolation procedures, a knowledge of the so-called excess quantities ΔZ_M is important. For binary mixtures it holds that:

$$\Delta Z_M = Z_M - x_1 Z_1 - x_2 Z_2 \qquad (1)$$

The quantity Z may be, *e.g.* the enthalpy H, the entropy S, the free energy G, or the volume V. ΔZ_M represents the difference between Z in the mixture (subscript M) and the contributions of the pure components 1 and 2; x_1 and x_2 are the mole fractions.

As examples of our studies, Figure 1 shows the experimentally determined molar enthalpies of mixing ΔH_M for mixtures of cyclohexane (*c*-C_6) with *n*-octane (*n*-C_8), 2,2,4-trimethylpentane (*i*-C_8), *n*-hexadecane (*n*-C_{16}), and 2,2,4,4,6,8,8-heptamethylnonane (*i*-C_{16}).

Physikalisch-Chemisches Institut der Universität
Im Neuenheimer Feld 253, D-6900 Heidelberg (Germany)

The data were obtained with an isothermal flow calorimeter which has been described on a previous occasion[1]. Figure 2 shows experimental results for the equimolar entropy

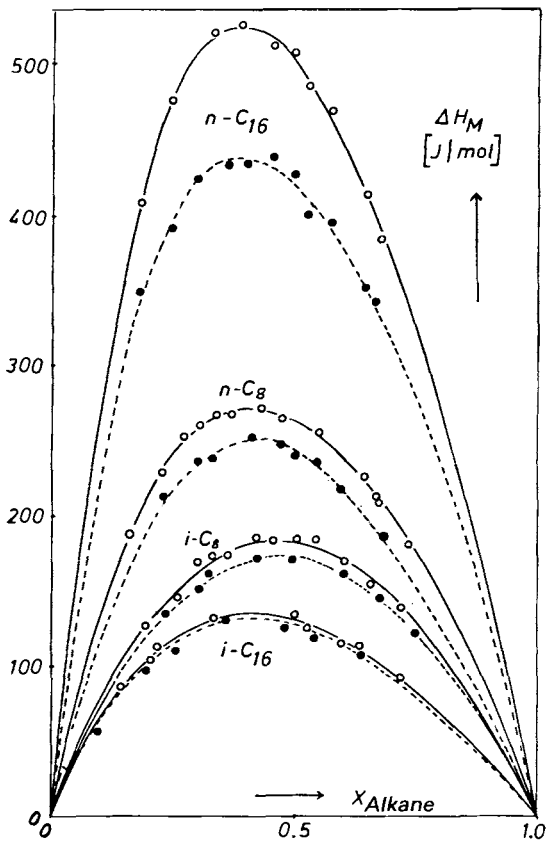

Fig. 1. Experimental molar enthalpies of mixing ΔH_M for mixtures of cyclohexane with isomeric alkanes as a function of the mole fraction x_{alkane} at 298.15 K/1 bar (—○) and 313.15 K/1 bar (---●).

of mixing ΔS_M of various isomeric alkanes + c-C_6 as a function of the number of carbon atoms n. These data were obtained from measurements of the vapor pressure of the mixtures with a recently described vapor pressure apparatus[2], from which ΔG_M was initially determined. The entropy of mixing ΔS_M could then be calculated with the aid of the calorimetrically determined ΔH_M values.

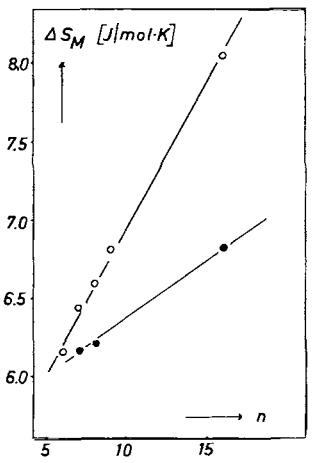

Fig. 2. Experimental equimolar entropies of mixing ΔS_M for mixtures of cyclohexane with isomeric alkanes at 298.15 K as a function of the number of carbon atoms n. ○ points for n-alkanes, ● points for branched alkanes (i-C_7=2,2-dimethylpentane; i-C_8, i-C_{16}, see text).

It is seen that ΔH_M and ΔS_M are considerably higher for the n-alkane/c-C_6 systems than ΔH_M and ΔS_M for the systems with branched isomers. It is seen from Figure 1 that ΔH_M decreases significantly with increasing temperature, which is not the case with the branched isomers. Theoretical rationalization of this difference in behavior is not only of interest from the standpoint of molecular physics but is also important in practice in order to predict the excess quantities over large ranges of temperature and pressure.

A theory suitable for treating mixtures of molecules of different sizes is that of *Flory et al.*[3]. This theory employs experimental quantities of state of the pure components and requires for calculation of the excess quantities just a single adjustable parameter X_{12} which contains the difference between the segmental intermolecular interaction parameters η_{ij} of identical and different molecules of the mixture. It holds that

$$X_{12} \triangleq (\eta_{11} + \eta_{22} - 2\eta_{12}) \qquad (2)$$

Adjustment of the theoretical expression for ΔH_M to the experimental data leads to widely differing X_{12} values for mixtures of the isomers with c-C_6; *e.g.* $X_{12}(i\text{-}C_{16} + c\text{-}C_6) = 5.1$ J cm^{-3} and $X_{12}(n\text{-}C_{16} + c\text{-}C_6) = 16.5$ J cm^{-3} at 298.15 K. Moreover, the temperature dependence of ΔH_M in the n-alkane/c-C_6 mixtures cannot be described with a constant value of X_{12}; instead, lower X_{12} values are required at higher temperature. For example $X_{12}(n\text{-}C_{16} + c\text{-}C_6) = 16.5$ J cm^{-3} at 298.15 K and 14.1 J cm^{-3} at 313.15 K. This does not agree with the simple Flory theory which stipulates that X_{12} should be constant as a molecular parameter. Nor can the large differences in X_{12} of the isomeric pairs be explained by the differing numbers of CH_3, CH_2, and CH group increments since the differences in interaction energy are slight[4]. Experimental results obtained on depolarized Rayleigh light scattering showed that some degree of close range order exists in the pure n-alkanes, probably sterically favored partial parallel orientations of molecular chain segments which are also energetically stabilized[5].

On mixing with a globular molecule such as c-C_6 these ordered structures are destroyed, depending upon the mixing ratio; this is associated with an endothermic contribution to ΔH_M. Thus ΔH_M is considerably greater for n-alkanes than for branched isomers which have practically no such ordered structures. This also explains the higher ΔS_M values of n-alkane/c-C_6 mixtures since the entropy of the pure n-alkane is smaller than for the corresponding branched isomer owing to the ordered structure.

Application of a theory of rotational transformation of simple molecules[6] to chain segments permits derivation of expressions for a orientation-dependent component of the segmental interaction energies so that an effectively temperature dependent component must also be considered in addition to the expression valid for η (n-alkane) in eq. (2). It then follows[1]:

$$X_{12} = X_{12}^{\infty} \cdot T/(T - T_0) \quad (T > T_0) \qquad (3)$$

X_{12}^{∞} is the value of X_{12} when T approaches infinity; the second factor in eq. (3) is temperature dependent and includes the "orientational component" of X_{12}. T_0 has the formal significance of a transition temperature for orientation of the chain segments. T_0 and X_{12}^{∞} in eq. (3) can be determined from the temperature dependence of X_{12}. X_{12}^{∞} has an approximately constant value of 3.5 J cm^{-3} for n-alkane/c-C_6 mixtures, while T_0 lies about 10–30 K below the melting point of the particular n-alkane. In fact, transition phenom-

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0303-0224 $ 02.50/0

ena have already been observed for alkanes in the solid state[7].

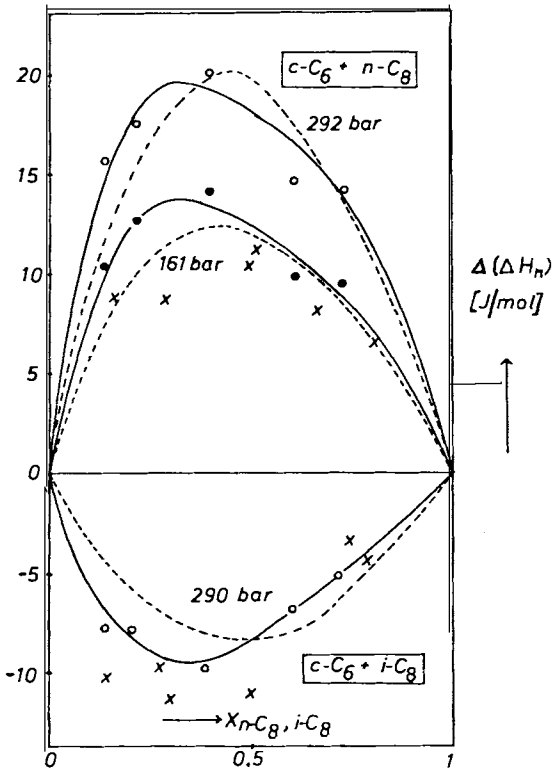

Fig. 3. Pressure dependence of enthalpy of mixing $\Delta(\Delta H_M)$ for n-C_8 + cyclohexane and i-C_8 + cyclohexane at 298.15 K. (—○) calorimetric data, × indirect data obtained from ΔV_M. --- curves calculated with adjusted X_{12} values.

In order to study the temperature dependence of the ordered structures, ΔH_M of several alkane/c-C_6 mixtures at high pressure was determined in a modified flow calorimeter. A recent report[8] concerns this apparatus. Figure 3 shows

$$\Delta(\Delta H_M) = \Delta H_M \text{ (high pressure)} - \Delta H_M \text{ (1 bar)}$$

for n-C_8 + c-C_6 and i-C_8 + c-C_6. In addition to directly determined calorimetric experimental values, indirectly determined ones are also given, which were obtained from measurements of the excess volume ΔV_M and its temperature dependence according to the following thermodynamic identity:

$$\Delta(\Delta H_M) = (\Delta V_M - T \cdot [\Delta(\Delta V_M)/\Delta T])\Delta p \qquad (4)$$

The excess volumes were established from density measurements of the mixtures and the pure components by a proven new method[9]. The broken curves in Figure 3 have been calculated with adjusted X_{12} values. For i-C_8, X_{12} remains pressure-constant (7.2 J cm^{-3}), while for the n-C_8 mixture X_{12} increases from 9.7 J cm^{-3} at 1 bar to 10.7 J cm^{-3} at 290 bar. According to eq. (3), an increase of X_{12} means an increase in T_0 with pressure. This is to be expected since T_0 is shown in ref.[6] to be proportional to the energy required to bring about the transition. This energy is all the greater, the higher the pressure (*i.e.* the density) since steric and energetic hindrance of the transition are all the greater at higher density.

The extended Flory theory thus permits a consistent description of the excess quantities for mixtures of isomeric alkanes with cyclohexane. They provide not only an accurate picture of the systems under study in terms of molecular physics but also allow prediction of excess quantities in other ranges of temperature and pressure.

Complex Stabilization of 3-Oxopropadienylidene (C_3O) with Pentacarbonylchromium(0)[**]

By *Heinz Berke* and *Peter Härter*[*]

A facile entry to metal complexes containing carbene-analogous cumulene ligands is possible *via* propiolic acid derivatives[1]. We have now been able to synthesize pentacarbonyl(3-oxopropadienylidene)chromium(0) *(1)*.

On using the method of *Connor et al.*[2] with pentacarbonyliodochromate and the silver acetylide derivative of sodium propiolate as starting substances, presumably a π-complex is initially formed (IR spectroscopic detection), which we did not isolate but allowed to react further with thiophosgene. Chromatographic separation of the product mixture afforded *(1)* in *ca.* 35% yield. Losses on purification due to the high volatility of this black-violet compound (dec. pt. 32 °C), which is stable for some time in the crystalline and pure state at room temperature, can hardly be avoided. The structure of *(1)* follows from spectroscopic findings and chemical characterization.

In the IR spectrum (solution in n-hexane) the absorptions of the carbonyl ligands correspond to C_{4v} symmetry [2074 w (A_1), 1977 s (E), 1971 cm^{-1} m (A_1)]. A further band at 2028 cm^{-1} (s) is assigned to the vibration in the complex *(1)* which is equivalent to the ν_1 vibration of free C_3O[3], appearing, as expected, at a lower wavelength. In the gas phase, two absorptions of weak intensity are observed [2005 m (A_1), 2001 cm^{-1} s (E)]. No band, which could be assigned to the ν_2-vibration of the C_3O ligand, has been observed so far. Even in investigations on free C_3O[3] and on carbonylmethyl compounds[4] no such band has ever been found.

The ^{13}C-NMR data of *(1)* are listed in Table 1.

Fakultät für Chemie der Universität
Postfach 5560, D-7750 Konstanz (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by Research Facilities of the Universität Konstanz.

Table 1. Chemical shifts in the ^{13}C-NMR spectrum of *(1)* at −40 °C in diethyl ether rel. to TMS.

	CO_{cis}	CO_{trans}	C-1	C-2	C-3
δ	212.8	224.0	440.6	—	389.9

The value of δCO_{cis} and δCO_{trans}, as well as their difference, are normal for a pentacarbonylchromium compound[5]. The tentative assignment of the two extreme resonances to C-1 and C-3 is supported by the charge distribution obtained for C_3O in *(1)* from MO calculations by the extended Hückel method[6].

The mass spectrum of *(1)* shows the successive fragmentation of three CO groups (m/e=244 $[M^+]$, 216 $[M-CO]^+$, 188 $[M-2\ CO]^+$, 160 $[M-3\,CO]^+$). A further fragmentation path is indicated by the appearance of $Cr(CO)_6^+ = [M-C_2]^+$ and its CO-fragmentation series. The intensity of the pure organic fragment ion m/e=76 $[C_5O]^+$ depends on the temperature of the ion source; it successively loses carbon atoms.

In *n*-hexane solution, *(1)* undergoes detectable decomposition with decoloration, even at 0 °C. The metal-containing product $Cr(CO)_6$ is apparently formed by loss of a C_2 fragment, from which highly unsaturated organic species (acetylenic and cumulenic IR bands) can be formed *via* well-known reaction steps[7].

Oxidation of *(1)* by the method of *Casey et al.*[8] and methanolysis leads to dimethyl malonate (GC/MS analysis).

$$(CO)_5CrC_3O \xrightarrow{DMSO} [C_3O_2] \xrightarrow{MeOH} CH_2(CO_2Me)_2$$

Our findings show that C_3O, a "cumulog"[9] of the CO molecule is stable as ligand. The complex *(1)* can thus be included in the series of coordination compounds in which particles otherwise detectable only in low-temperature matrices are considerably stabilized.

Procedure

$[n\mathrm{Bu_4N}][(CO)_5CrI]$ (1.4 g, 2.5 mmol) is dissolved in CH_2Cl_2 (90 ml) and ether (10 ml) at −60 °C. $AgBF_4$ (700 mg) is added and the mixture allowed to warm to −20 °C. AgC≡C—CO_2Na (for preparation see below) is added in slight excess and the mixture homogenized in an ultrasonic bath with cooling to *ca.* −30 °C. After 1 hour's stirring at −10 °C, 0.5 ml of thiophosgene is added, whereupon the color of the mixture turns violet. At substantially shorter reaction times a mixture is obtained containing the thiophosgene complex $(CO)_5Cr(Cl_2CS)$, which cannot be separated on work-up. After filtration over kieselguhr the solvent is removed below −10 °C. The residue is taken up in *n*-pentane and chromatographed on silica gel (l=20 cm) at −50 to −60 °C. The eluate of the deep-violet zone is evaporated down at −20 °C. For further purification the residue is sublimed onto a cold finger (−20 °C) at 0 °C. Yield: 220 mg of *(1)* (36%).

AgC≡C–CO_2Na is prepared by a combination of the two procedures by *Bayer*[10a] and *Wille et al.*[10b] from the Na-salt of the propiolic acid in sodium carbonate solution by addition of $AgNO_3$. The acetylide separates out as a yellow precipitate. The precipitate is filtered off and washed several times with water, ethanol, and ether. Since the acetylide is sensitive to light, and readily detonates on aging, it cannot be stored.

First Fixation of the Unstable Species Sulfur Monoxide in a Cluster: Synthesis and Structure of $Fe_3(CO)_9(S)SO$

By *László Markó, Bernadett Markó-Monostory, Thomas Madach*, and *Heinrich Vahrenkamp*[*]

It has long been known that acidification of aqueous solutions containing tetracarbonylferrate and sulfite leads to polynuclear iron carbonyl sulfides $Fe_3(CO)_9S_2$ *(1)* and $Fe_2(CO)_6S_2$[1]. The course of this complex reaction has not yet been elucidated; however, it may be assumed that $Fe(CO)_4H_2$ is involved as a strong reducing agent. In addition to the products mentioned, we have now also found a more strongly polar compound *(2)* which can be prepared in good yield from $Fe_3(CO)_{11}H^-$, which in turn arises on partial oxidation of $Fe(CO)_4^{2-}$.

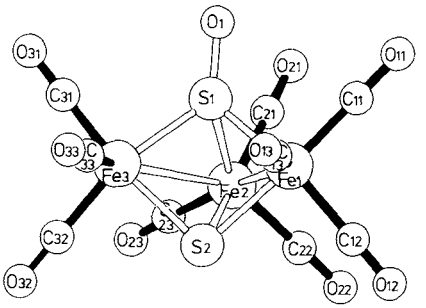

Fig. 1. Molecular structure of complex *(2)* in the crystal.

Albertstrasse 21, D-7800 Freiburg (Germany)

2035 s, 2026 m, 2017 w, 1992 cm^{-1} w, br) closely resembles that of *(1)* shifted to higher wave numbers by 7–20 cm^{-1}. Moreover, *(2)* shows a strong band at 1107 cm^{-1} (in KBr) which can be assigned to the SO stretching vibration.

The structure of *(2)* was determined by X-ray methods[2] (cf. Fig. 1); this provided the first proof of the existence of an SO ligand[3]. The S—O bond length is 147 pm and corresponds to that in free SO (148 pm)[4a] and many other S=O double bonds[4b]. The Fe—S bonds to the SO group are significantly shorter than those to the S atom, probably due to the radius contraction of the sulfur by the electronegative oxygen. This shift of the SO group towards the center of the molecule leads to an S···S contact of only 272 pm, which is considerably shorter than the sum of the van der Waals radii (2×185 pm). In analogy with some complexes of the $Fe_2(CO)_6(\mu_2\text{-}X)_2$ type[5], a partially bonding S—S interaction must therefore be assumed in this case.

The fact that *(2)*, like *(1)*[6], contains an open triangle of iron atoms, *i.e.* only two metal-metal bonds, leads to the conclusion that the SO molecule is a 4-electron ligand like the S atom. This is also supported by the close relationship observed between the structures of *(1)* and *(2)*.

The extensive similarity between the two complexes also justifies our viewing *(2)* as the product of addition of a Lewis-acid O atom to *(1)*, with only minor modification of the bonding in the skeleton of *(1)*. The sufficient basicity of a μ_3-bonded sulfur atom in M_3S cluster units has already been detected: the 16-electron fragment $Cr(CO)_5$ can be added[8] to the $SFeCo_2(CO)_9$ cluster[7], again with hardly any structural change. Complex *(2)* can also be regarded as an intermediate of reduction of sulfite to sulfide by iron carbonyl hydrides [$Fe_3(CO)_{11}H_2$ is a less powerful reducing agent than $Fe(CO)_4H_2$!].

In contrast to its formation, the bonding and the structure of *(2)* are not unusual. This suggests that further SO clusters might be accessible.

Procedure

First H_2O_2 (16.7 mmol; 1.7 ml of a 30% aqueous solution) and then $Na_2SO_3 \cdot 7H_2O$ (7.5 g, 30 mmol; dissolved in water (20 ml)) are added to a solution obtained by basic reaction of $Fe(CO)_5$ (4.9 g, 25 mmol) and NaOH (4.0 g, 100 mmol) in H_2O/CH_3OH (1:2) (30 ml). After 10 min, the reaction mixture is acidified with dilute hydrochloric acid, the dark precipitate filtered off, washed with water, and chromatographed in benzene on a silica gel column. Elution with hexane gives *(1)* (24% yield) and with benzene gives *(2)* (yield 10%). *(2)* can be recrystallized from toluene (+25/−78 °C), affording 0.28 g (0.56 mmol; 6.7%) of dark red-brown, air-stable crystals. The compound decomposes without melting at 125–128 °C.

Direct Photolysis of Uranium Hexafluoride as a Preparatively Utilizable Endothermic Reaction[**]

By *Frank S. Becker* and *Eberhard Jacob*[*]

For the laser isotope separation of uranium the photodissociation of UF_6 by an infrared multiphoton process or by a combination of infrared and ultraviolet irradiation is considered to be one of the most promising approaches. In connection with such experiments it is important to know to what extent the photodissociation is possible without the use of a scavenger and what part the fluorine can play in the following reactions.

It is well known that the photodissociation of UF_6 is feasible in the presence of scavengers (H_2, CO, SO_2)[1]. Photodissociation of pure UF_6 by UV light in an argon matrix at 10 K is small[2a] and at 27 K impossible[2b]. Experiments with α rays[3a] electron-beams[3b] and UV light[1c,3c] at room temperature yielded only very small quantities.

On use of a suitable experimental set-up, we were able to dissociate by UV light about 50 g of UF_6 in the gas phase at room temperature according to

$$2\,UF_6 \xrightarrow[39\,h]{h\nu} 2[UF_5]_s + F_2 \qquad (1)$$

nearly quantitatively (98.8%) into β-UF_5 and ultrapure F_2. This endothermic photoreaction ($+132 \pm 19$ kJ/mol[4]) is accompanied by a transformation of photon energy into chemical energy. The energy balance of usual photoreactions is exothermic, because the always endothermic photoexcitation is more than compensated by the exothermic character of the following reactions[5].

A series of photolysis experiments showed a strong influence of the reaction cell geometry on the final attainable dissociation yield of the UF_6. Special care has to be taken to avoid deposition of UF_5 on the irradiation window. In addition to a vertical window position the presence of F_2 proves to be useful, because the photofluorination of UF_5[5a] hinders the formation of a deposit on the window. At constant UF_6 pressure (solid state UF_6) the increasing F_2 pressure brings the reaction to equilibrium. Nevertheless, a nearly complete UF_6 dissociation according to eq. (1) can be attained by creating suitable UV-shaded regions where the produced UF_5 can be irreversibly deposited. From time to time, the F_2 formed should be partially withdrawn (cf. Fig. 1). A fast production of UF_5 is indicated by a dense white fog, which should be convected into the shaded regions to obtain high yields.

A simplified kinetic consideration shows that the polymerization of the UF_5 molecules should be the rate determining step of reaction (1)[3c,6]. These kinetic conditions make possible the thermodynamically unexpected endothermic reaction.

The direct photodissociation of UF_6 is a more effective way of preparing β-UF_5 than the photoinduced UF_6 reduction with CO[1b] which was described only a short time ago (optimum amount of UF_5: 5 g per experiment). The attained yields of the direct dissociation are higher, compared with the photoreduction[1], because only in the presence of fluo-

[**] Chemistry of Uranium Fluorides and Oxide Fluorides, Part 3. We wish to thank Prof. *K. L. Kompa*, Garching, and Prof. *F. Seel*, Saarbrücken, for helpful comments. Part 2: *E. Jacob*, Z. Anorg. All. Chem. *400*, 45 (1973).

rine is free entrance of the UV light into the reaction cell effected. In addition, the direct dissociation of UF_6 is a method for the preparation of small amounts (1–2 bar l per experiment) of ultrapure fluorine[7, 8].

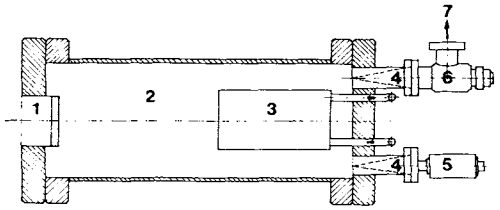

Fig. 1. Photoreactor: 1, sapphire window of I. D. 44 mm in NW 100 CF flange (Odelga-Physik D-7441 Aich); 2, nipple NW 100 CF (Balzers Hochvakuum, D-6200 Wiesbaden); 3, cold finger (∅ 55 × 100 mm) in NW 100 CF flange; 4, dust filter (porous stainless steel cone); 5, pressure transducer (0–1000 mbar, Bell and Howell); 6, NW 16 CF valve (Balzers);, 7, to vacuum line. — All components consisted of stainless steel and the flanges were copper sealed and He leak controlled. UV-light source: 1000 W mercury super high pressure lamp (Osram HBO 1000 or Philips CS 1000) with quartz condensor for parallell light beam, 100 mm water filter for IR elimination. The irradiation was performed in horizontal position.

In principle, the direct photodissociation of UF_6 hints at the possibility of performing the laser isotope separation without a scavenger. On the other hand, it is of fundamental interest to learn to what extent the unspecific reaction

$$UF_6 + F \rightarrow UF_5 + F_2$$

would compensate the isotopically selective dissociation of UF_6 already accomplished.

Procedure

The photodissociation is performed in the reactor depicted in Figure 1. After evacuation down to 10^{-5} mbar, the cold finger is filled with liquid N_2 and UF_6 (47.668 g, 135.4 mmol) is frozen into the reactor. Afterwards the cold finger is warmed up to 1–2 degrees below room temperature by means of a thermostat. The UF_6 pressure during the irradiation lies between 120 and 180 mbar. The progress of the photolysis can be monitored by the pressure rise caused by F_2 production. After 17 h the F_2 production comes to a standstill. The cold finger is filled with liquid N_2 again and the nondissociated UF_6 is frozen out. The F_2 is collected in a 63 K cold trap[8b], leaving about 30–40 mbar. After warming up the cold finger the photolysis is continued, and the fluorine withdrawal is repeated after 6 and 16 h respectively. After a total irradiation time of 39 h at 25 °C, 98.8% of the UF_6 has decomposed. After pumping off the remaining F_2, the reactor is opened in a glovebox. It is possible to remove 43.6 g (130.9 mmol) of a powdery light-green deposit from the walls. X-ray analysis shows the existence of β-UF_5[9a]. Chemical analysis of the UF_5 is accomplished by fluorination to UF_6 with IF_7 while monitoring the weight[9b]. A PVT measurement of the gas collected with the 15 K cryopump ("cryo-Töplerpump")[2b] gave 1641 mbar l of mass-spectroscopically pure fluorine. According to (1) 0.5 mole F_2 is produced per mole of dissociated UF_6.

BOOK REVIEWS

Kirk-Othmer: Encyclopedia of Chemical Technology. Editorial board: *H. F. Mark, D. F. Othmer, C. G. Overberger,* and *G. T. Seaborg.* John Wiley & Sons, New York 1979, 3rd Edition. Vol. 5: Castor Oil to Chlorosulfuric Acid. xxv, bound, £ 60; Vol. 6: Chocolate and Cocoa to Copper. xxiii, 869 pp., bound, £ 60.

The fifth and sixth volume of the new edition of Kirk-Othmer[*] are now available. The principal contributions to Volume 5 are: Catalysis (55 pp.); Cellulose and cellulose derivatives (90 pp.); Ceramics (80 pp.); Chemotherapeutics (100 pp.); and Chlorocarbons (180 pp.). In volume 6 the greatest space is devoted to: Coal and coal conversion processes (90 pp.); Coatings (95 pp.); Cobalt and cobalt compounds (40 pp.); Colors (80 pp.), and Complex compounds (40 pp.).

As in the previous volumes, the individual chapters are scientifically impeccable and lucidly written. Production and work-up processes are almost always accompanied by clear flowcharts and important technical details are backed up by drawings or photographs. The properties of the products, specifications, and analytical methods are given adequate treatment, as are environmental and safety aspects. Econom-

[*] Angew. Chem. Int. Ed. Engl. *18*, 704 (1979)

 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0303-0228 $ 02.50/0

ic data pertaining to the processes are also invariably instructive.

The balance between the various chapters does not always seem to be maintained. Pharmaceutical and medical topics occupy more space than would be expected from the title of the work. For example, it could be asked whether the section on chemotherapeutics deserves more space than that on coal and coal conversion processes. Articles on computers or even contact lenses (each 20 pp.) do not strictly belong in a handbook of chemical technology.

It is also noticeable that recent European process developments are frequently missing. For instance, there is no mention of the process for manufacturing carbon tetrachloride from chlorinated residues (high pressure chlorolysis) in the article about chlorocarbons. No account is given on recent advances in the coking and fluidized bed combustion of coal. In this respect, the American authors could perhaps do a little more to present an international picture.

R. Steiner [NB 490 IE]

Synthetische Arzneimittel (Synthetic Drugs). *S. Ebel.* Verlag Chemie, Weinheim 1979. x, 631 pages, bound, DM 98.00.

In this textbook and handbook the chapters are arranged according to pharmacological indications. Within each chapter there is a brief introduction, followed by sections on synthesis, stability, biotransformation, and finally examples of analyses.

The concise introductions omit details and concentrate on essentials, taking into account the more recent developments and modern views on the action mechanism. Throughout, they are so useful and pleasant to read that it is easy to overlook the few instances of over-informal phrasing (*e.g.* "chlordiazepoxide and diazepam hold an almost scary proportion of the market", p. 225).

The lucid presentation of basic chemical structures and variable groups has been achieved excellently by means of the two-tone printing; the same is true of the use of color to emphasize the metabolically newly formed groups.

It is also gratifying that in the case of drugs with several designations the page number is given in the index after every name, thus saving one the trouble of searching for the "right" name. The errors—including printing errors—are limited in number and should be easy to correct later. Thus, the hypoglycemic action of sulfonamides had already been discovered in 1942 (p. 466); some cardiac agents with a calcium antagonistic action (Nifedipine, Segontin, Verapamil) are more than just coronary dilators (p 444/5); azole antimycotics do not act as histidine synthesis inhibitors, but affect steroid synthesis (p. 572).

Although the book is striking in its wealth of material on drug metabolism, it lacks a chapter that would actually appear indispensable for such a textbook, namely one dealing with the principles of the biotransformations (hydrolysis, oxidation, *etc.*); such a section would make it easier for the student to recognize the salient points amidst the plethora of data. In addition, "the feel for the success of a chemical synthesis" (see cover notes) would definitely be better demonstrated if the formula section were curtailed in favor of a few explanations.

It may well be that the aims of a textbook (clear presentation of the basics, critical delimitation of outdated and modern preparations) and a handbook (comprehensive collection of data) are difficult to combine in a single work of this size. The reviewer read this very consistent and fluent book with pleasure, and is of the opinion that it tends rather toward being a handbook; however, it deserves to be given greater recognition as a textbook too.

Hans Joachim Kabbe [NB 495 IE]

Molecular and Crystal Structure Models. *A. Walton.* Ellis Horwood Ltd., Chichester/John Wiley and Sons, London 1978. 201 pages, bound, £ 9.00.

Anne Walton has written the first book of consumer information for professional model users. It is *the* reference work for the teacher wishing to illustrate his lectures with molecular models.

The book rightly foregoes a comprehensive philosophical and didactic discussion of the subject, which can be found elsewhere, and instead describes a good 80 (!) commercially available molecular and crystal structure model systems with a high degree of accuracy often with the aid of photographs. It gives the scale, the available parts, the technical characteristics, the preferred fields of application and more besides. No prices are quoted, only the phrases "cheap", "fairly cheap", "rather expensive", and "expensive". The reader will find space-filling models for molecules (12 systems) and crystals (26), ball-and-stick models (25), skeleton models (10), orbital models (5), such for macromolecules and dynamic models. Further chapters provide a guide for making these models oneself and introduce molecular pictures ("planar models"). The appendix lists manufacturers and suppliers.

One could wish for a separate classified bibliography. Because of its encyclopedic nature, only regular supplements and revisions will preserve the undisputed value of this book in the future. A critical comparative evaluation of similar models would be a worthwhile feature. And to extend the train of thought logically, when will a competent team get together to recommend one or two model systems most suitable for the private user? The germs for the crystallization of this idea are already there (*e.g. K. Beyermann:* Molekülmodelle. Verlag Chemie, Weinheim 1979).

Werner Offermann, Fritz Vögtle [NB 498 IE]

Radicals. *D. C. Nonhebel, J. M. Tedder,* and *J. C. Walton.* Cambridge University Press, Cambridge 1979. 200 pages, bound, £ 5.50.

Since in most textbooks the chemistry of radicals is only touched upon, the present pocket-size book clearly fills a gap. In 17 chapters the authors discuss the theme in an introductory qualitative way, but with up-to-date information that covers the full scope of the field. There are subsections on physicochemical methods (ESR, CIDNP) and chemical-engineering aspects (combustion, oxidation, polymerization), on organic reaction mechanisms, on modern preparative methods, and even on the significance of radicals in biological systems. The only addition that the reviewer would like to have seen is a chapter on bond dissociation energies.

Particular praise is due for the highly appropriate way in which the authors have selected their material from the wide range of possibilities, the careful restriction to qualitative application of theory, the sensible selection of modern examples, and the clear style and careful classification. No book can be more highly recommended as an introduction to the field. The most important recent reviews and monographs are cited and point the way to a deeper understanding of radical chemistry. Original references are not given.

Christoph Rüchardt [NB 493 IE]

Organofluorine Chemicals and Their Industrial Applications. Edited by *R. E. Banks*. John Wiley & Sons, London 1979. 255 pages, bound, £ 17.50.

Since its discovery in 1886, fluorine, that most aggressive and reactive element, has made slow but persistent penetration into industry. Fluorine products are nowadays encountered daily in all spheres of life, *e.g.* as the active principles in pharmaceutical preparations, as heat-resistant and chemically resistant materials, as blood, artery, and bone substitute materials, inhalation anesthetics, aerosol propellants, surfactants, *etc.*

The present book contains twelve chapters written by experts active in the study of organofluorine chemistry and its industrial significance.

The subject matter is presented lucidly, and the many references make it possible to go deeper into the field. The book should be within the reach of all chemists concerned with fluorine chemistry in industry, research, or teaching, and can be recommended without any reservations.

Alois Haas [NB 496 IE]

The Chemistry of Silica. Solubility, Polymerization, Colloid and Surface Properties, and Biochemistry. *R. K. Iler*. John Wiley and Sons, Chichester 1979. xxiv. 886 pages, bound, £ 39.50.

Iler's monograph on "The Colloid Chemistry of Silica and Silicates", published in 1955 was in its time extremely useful and informative. It is now the author's aim, at the end of his professional career in industry, to bring out a second edition of this book, giving a picture of the latest situation. However, so much that is new in this field has since been published that a limitation became necessary; the chapters on insoluble silicates, clay minerals and silicic esters had to be left out. Even so, the scope of the work has increased severalfold.

The author concentrates first of all on the occurrence of silica, the dissolution and precipitation equilibria of silicic acids, and on the water-soluble silicates. Much space is given to the treatment of condensation equilibria and to the formation of the industrially important silica sols and gels. Colloid-chemical processes, especially coagulation and flocculation, are discussed in detail. Control of the pore structure of silica gel is described, as is the manufacture and application of finely divided, precipitated or pyrogenically prepared SiO_2. In the description of surface chemistry special reference is made to the OH groups on the SiO_2 surface, their esterification, and other methods of hydrophobization, and also the adsorption behavior with respect to inorganic ions and polymer molecules. The last chapter is on silica in biochemistry, in which context the toxicology of SiO_2, silicic acid derivatives, and Si compounds is considered. The present state of knowledge about the causes and chemotherapy of silicosis is given in detail.

This is a book by a practical man for practical men. It contains a wealth of information. The number of literature sources quoted runs to more than 3200, though some of them are obviously cited in several chapters and are then numbered again. The citations include many references to patents. On the other hand, it is remarkable that in a monograph on silica there is no discussion of the nature and the peculiarities of the siloxane bond; accordingly its hydrophobic character, for example, is introduced without comment.

The work will undoubtedly become an indispensable aid to all those involved with silica and silicic acids. The contents justify the high price. The reader might often wish that the results from the quoted papers had been presented in greater detail, but this could not have been done in a single volume. Even as things are, it was only possible to compress the test into one volume because a relatively fine print was used. This unfortunately means that the reader is soon fatigued—at least this was the effect on the reviewer.

Viroids: A Class of Subviral Pathogens

By Hans J. Gross and Detlev Riesner[*]

Infectious RNA molecules lacking a protein coat have recently been shown to be the cause of several diseases in higher plants. These molecules, termed viroids, have been characterized as circular chains composed of about 360 nucleotide residues. They therefore comprise a class of infectious pathogens even smaller than viruses or bacteriophages. As a result of work on viroids it is now possible for the first time to give a complete description of the structure of a eukaryotic pathogen. Viroids possess structural and dynamic properties which have not as yet been observed with other nucleic acids. This article summarizes and discusses the results of predominantly biochemical and physicochemical studies on viroids.

1. Introduction

Viroids are a new and independent class of pathogens which are distinguished from viruses and bacteriophages by the absence of a protein coat and by their unusually small size (Fig. 1). They are of considerable practical importance since they are the cause of disease in several economically important crops. In addition, the infectious and pathogenic properties of this group of RNA molecules of hitherto unknown structure make them interesting objects for molecular biological research.

Viroids occur in particular in tropical and subtropical climatic zones, and are also found in greenhouse plants in temperate and cold zones. They can attack potato[1,2], citrus fruit[3,4], chrysanthemum[5–7], cucumber plants[8], coconut palms[9,10], hops[11], the ornamental plant *Columnea erythropae*[12] and the avocado tree[13]. In 1971—72 groups of researchers in America[1,4], Canada[2] and Germany[3], looking for the causes of these plant diseases found that the infectious agents were unencapsidated (lacking a protein coat) ribonucleic acids of an unexpectedly small size.

It had been known since the early 1960's that free nucleic acids could be infectious and cause plant diseases. The existence of a new type of pathogen termed viroid (=virus-like)[1], was first established in 1971—72 when it became clear that the agents producing the diseases mentioned above were extremely small. The name viroid was based on the observation that the symptons of an infection, which occurred

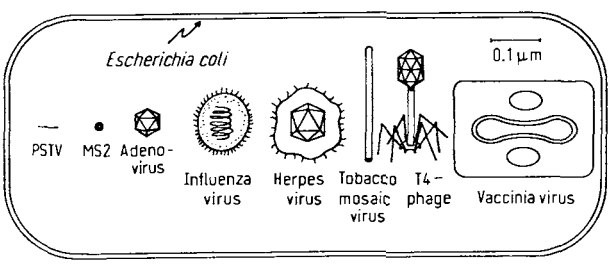

Fig. 1. Comparison of the size of "potato spindle tuber viroid" (PSTV) with viruses and the bacterium *Escherichia coli*.

after an incubation period of weeks or months (or in some cases even years) closely resembled those produced by well known plant viruses. These include inhibition of growth and warping or yellowing of the leaves; the fruit of the infected plant can also be affected, *e. g.* yellow cucumbers or spindle-like potatoes.

The propagation of viroids seems to occur chiefly *via* tools used by man in pruning, cultivation and harvesting, but it also seems quite likely that the infection can be transmitted without human intervention, for example *via* pollen at fertilization.

Certain plants in developing countries are particularly prone to viroid infection. In the Philippines, whole groves of coconut palms have been eradicated by the Cadang-Cadang viroid. It is at present not possible to treat diseased plants, and therefore the only remedy is to limit the propagation of the viroid by appropriate measures and to obtain fresh seed from viroid-free plants.

So far, viroids have only been found in plants, but the fact that other pathogens such as viruses, bacteria and mycoplasma are widely distributed suggests that viroids or viroid-like agents may also occur in man and other animals.

As a result of work on viroids, it is now possible for the first time to collect detailed information about the chemical and physical structure of a pathogenic agent of eukaryotic origin. This should provide an important basis for investigating the replication and pathogenic action of these agents.

This article is concerned chiefly with structural studies which are now to a large extent concluded. Ideas about replication and pathogenesis are very much in their infancy and these are discussed briefly at the end of the article. Readers who are interested in biological or microbiological aspects are referred to specialized reviews[1-14].

2. Biochemical Characterization

Four groups of researchers, namely *T. O. Diener,* Beltsville, USA[1], *R. P. Singh,* Fredericton, Canada[2], *H. L. Sänger,* Giessen[3] and *J. S. Semancik,* Riverside, USA[4], independently discovered that viroids were small, infectious unencapsidated ribonucleic acids.

Certain unusual features which distinguished viroids from other pathogens suggested that a different type of agent was involved; in contrast to many viruses and bacteriophages they were highly sensitive to RNA degrading enzymes (RNases), but were unusually resistant to the effects of organic solvents. These observations suggested that they were composed of RNA with a very simple structure. Animals injected with viroid preparations did not develop antibodies to viroid specific proteins which may have been presumed to be present. It was also noted that viroids were very mobile in an electric field but not in a centrifugal field, from which it was concluded that they have an exceptionally low molecular weight.

The development of a successful procedure for isolating viroids from diseased plants found in the potato field or groves of citrus fruit or coco palms was a long and tedious process. A necessary initial step was to find appropriate test plants which could be cultivated in large numbers in greenhouses, and which would also show clear symptoms of viroid infection as rapidly as possible. Early attempts to isolate for example the citrus exocortis viroid were dependent on young citrus shoots which only showed symptoms several months after infection. It soon became clear that the young tomato plant was a more amenable host, developing symptoms after only a few weeks under optimum conditions. The tomato had another very helpful characteristic which was that most viroids known at the time replicated on it and produced symptoms similar to those shown in Figure 2a.

Fig. 2. a) Symptoms of viroid-infection. Healthy tomato plant (left), diseased (right). b) Test of infectivity on tomato plants. The characteristic smaller size of the plants in the middle shows that the fractions used for infection contained viroid. From back to front increasing concentrations were used for infection. (We are indebted to Prof. *Sänger,* Giessen, for the figure.)

The same general scheme is employed for isolating all viroids[14,15]. Leaf material is homogenized, extracted with phenol, and the nucleic acids remaining in the aqueous phase are precipitated with ethanol. Repeated precipitation and extraction steps are used to free the precipitate (which contains the infectious material) from large nucleic acids and also from polysaccharides whose presence complicates the purification a great deal. Repeated preparative polyacrylamide gel electrophoresis finally yields a nucleic acid which is infectious, and which is absent from similar preparations derived from healthy plants.

In developing a purification procedure, the biological infectivity of the fractions containing viroid must be established at each stage; this means that the analysis of each fractionation step involves infecting whole series of plants and examining them after several weeks for symptoms of disease.

Such a test series is shown in Figure 2b, which illustrates a variation in infectivity resembling a chromatographic elution profile. In the standard preparations which have now been developed, the occurrence of a specific band in polyacrylamide gel electrophoresis can be used to diagnose the presence of a viroid. However, despite these developments, the purification is still very tedious, and the yield is extremely small. As a rough guide, about 0.1 mg of pure viroid can be obtained from 5000 diseased plants. Thus, biochemical and physicochemical investigations of the structure have to be carried out with the smallest possible quantity of substance.

Many investigations, especially sequencing, require radioactively labeled viroids or viroid fragments. Several fundamental difficulties had to be overcome in order to obtain these. It is of course in principle possible to label viroids *in vivo* with radioactive ^{32}P[16], but because of their slow replication, and time consuming isolation, one obtains material whose specific activity is far too low for detailed structural investigations.

Radioactively labeled 5-iodocytosine can be produced *in vitro* by chemical labeling. This method has occasionally been used with viroids[17-19], but is of limited applicability since only fragments containing cytosine are labeled. The only generally applicable method at present available for viroids is to label them enzymatically with ^{32}P *in vitro*[21-23]. The method involves transferring the γ-[^{32}P] phosphate group from γ-[^{32}P]-ATP to the free 5′-hydroxy group of nucleic acids or fragments derived from them by 5′-polynucleotide kinase from phage T_4 infected *E-coli* cells. However, the procedure is not without its own practical difficulties: *(i)* γ-[^{32}P]-ATP of high purity and specific activity has to be regularly synthesized in the laboratory, *(ii)* 5′-polynucleotide kinase from phage T_4 infected bacteria must be isolated absolutely free from ribonucleases, *(iii)* the short half-life of ^{32}P imposes a continual pressure for rapid work, and *(iv)* viroid preparations have to be as pure as possible, since there is a risk that contaminating nucleic acids would be preferentially labeled *in vitro*.

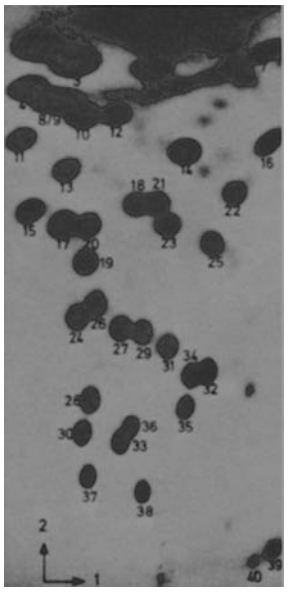

Fig. 3. Fingerprint of the oligonucleotides of PSTV after cleavage with RNase T_1. PSTV was hydrolyzed by RNase T_1, and the 3′-terminal phosphate residues of the oligonucleotides produced were removed with phosphatase. After inactivation of the phosphatase the oligonucleotides were radioactively labeled *in vitro* with [γ-^{32}P]-ATP and 5′-polynucleotide-kinase and separated in two dimensions; 1st dimension: electrophoresis at pH = 3.5/5000 V on cellulose acetate [67]; 2nd dimension: homochromatography on thin layers of DEAE-cellulose [68]. The labeled oligonucleotides were made visible by autoradiography (cf. also Section 4.1). B indicates the position of the blue dye xylene cyanol after an optimum running time.

A sample of viroid can be characterized very precisely by cleavage with specific ribonucleases and labeling the oligonucleotides produced at the 5′ end with [^{32}P]-phosphate. When the oligonucleotide mixture produced is subjected to two dimensional chromatography and analyzed by autoradiography, a characteristic "fingerprint" of the viroid is produced (Fig. 3) which can provide the clearest evidence for the purity of the viroid preparation[21]; only a few percent of RNA impurity from the host produces many other oligonucleotides which can readily be detected from the occurrence of additional dark spots in the autoradiogram. Fingerprints can be used to identify different viroids unambiguously, and were important in initially establishing that viroids associated with different plant diseases had different nucleotide sequences[17,21].

3. Physical Properties

3.1. Molecular Weight

Estimates had been made on the size of viroids long before methods for isolating them had been fully established. These estimates were obtained by comparing the rates of sedimentation in sucrose gradients and R_f-values in gel electrophoresis with the behavior of ribonucleic acids of known molecular weight[1,3,4,24]. The position of the viroid band was found using the rather time-consuming and inconvenient infectivity tests described earlier. These estimates depended chiefly on comparing the mobilities of viroids with those of other nucleic acids, and a condition for obtaining reliable estimates of molecular weight is that comparisons should be made between species whose structures are similar; false values would be obtained if for example the behavior of a spherical and a rod-like molecule were compared. The shape of the viroid molecule was not known, and in an attempt to overcome this problem to some extent, comparisons were made between nucleic acids which had all been converted into the random coil configuration in the hope that they would also have similar structures[25]. However, it later became apparent that even the random coil form of the viroid had a structure different from that of other nucleic acids. It is not surprising therefore that estimates of the molecular weight in the literature ranged from 25000 to 130000. But despite this variation, these values did establish quite clearly that these pathogens were about an order of magnitude smaller than the nucleic acid components of the smallest phages, and that based on their size they constituted a new group of molecular pathogenic agents. Inactivation of viroids by UV light or ionizing radiation gave a target size which indicated a molecular weight of about 100000[26].

When pure viroids became available, the molecular weight could be determined, using the analytical ultracentrifuge, from the concentration distribution measured by the optical absorption[15]. The sedimentation-diffusion equilibrium

method yields estimates of molecular weight which are independent of any assumptions about the shape of the molecule. These studies gave values for the molecular weight of between 110000 and 127000 for different viroids; the viroid responsible for the potato spindle tuber disease (PSTV), which is discussed in detail below, was shown to have a molecular weight of 127000 ± 5000.

3.2. Molecular Shape

The shape of nucleic acids of the size of viroids can be studied by high resolution electron microscopy. In such pictures, viroids appear uniformly as rod-like molecules[15,27]; in the preparative procedure used for the sample shown in Figure 4a the average length was about 370 Å and the width 20 Å.

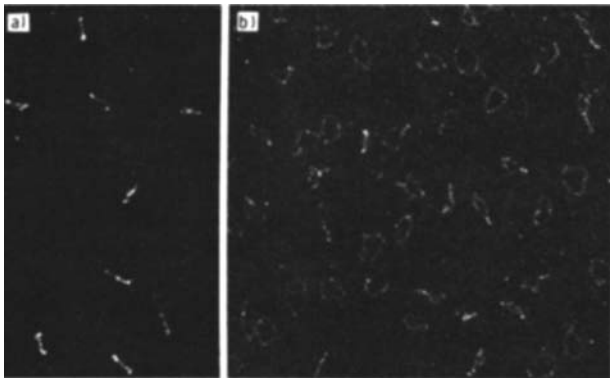

Fig. 4. Electron micrographs of viroids. a) In the native state: viroids were spread at room temperature with benzyldimethylalkylammonium chloride, stained with uranyl acetate, and observed in dark-field illumination ("alkyl", $C_{12}/C_{16} = 60/40$); b) in the denatured or partially denatured state: viroids were spread at 70 °C in the presence of urea. Enlargement 92500 times.

Since under certain circumstances the results obtained from electron microscopy can be influenced by artefacts arising in the preparation of the sample, the shape was also examined by investigating the hydrodynamic properties of viroids under physiological conditions[15]. By determining the molecular weight and sedimentation coefficient independently, an axial ratio of 20:1 was estimated—a value in good agreement with the electron microscope results.

3.3. Ring Structure of the Nucleotide Chain

Section 5 describes in detail how the formation of Watson-Crick base pairs leads to a well defined structure for viroids. Anticipating this discussion somewhat, we note here that the characteristic double helical structure produced by strands running in opposite senses can be formed either between two separate chains or by folding a single chain back on itself. In order to investigate the structure of a nucleotide chain in the denatured state, the base pairs are disrupted by urea, by formamide or by elevated temperatures, and the resulting structure is sometimes fixed with formaldehyde. The molecular weights of viroids in the native and denatured states were the same, indicating that they are composed of a single nucleotide chain.

When highly purified samples of viroid were denatured and examined by electron microscopy, the pictures showed the nucleotide chains to be almost exclusively circular[15] (Fig. 4b); since under the conditions used to prepare the samples all base pairs should have been dissociated, this suggests that the structure was a covalently closed ring. This conclusion was clearly confirmed by chemical methods[15]. It was not possible to transfer ^{32}P to the native viroid using the 5′-transphosphorylation reaction discussed in Section 2, showing that the viroid lacked a 5′ terminus. Similarly, treatment with periodate followed by reduction with $B^3H_4^-$ did not lead to the incorporation of radioactivity into the viroid, showing that it lacked a 3′ terminus with associated vicinal 2′- and 3′-OH groups which would have been susceptible to oxidation. The finding that viroids have a covalently closed ring structure, meanwhile amply confirmed by electron microscope studies in other laboratories and with other species of viroid[20,28], was a surprising development, since they are the first example of a naturally occurring covalently closed RNA ring. Ring structures had previously only been found in DNA, and these were of much higher molecular weight. Circular RNA molecules of various sizes have recently also been found in the cytoplasm of eukaryotic cells[29], but conclusions about their structures presently depend solely on electron microscope pictures.

Samples of viroid also contain, in addition to circular molecules, some linear chains in a proportion which depends on the method used in the preparation[15,28]. However, it was shown that linear chains can arise very readily from Mg^{2+}-catalyzed cleavage of the rings, and that the linear viroids produced show little or no infectivity[30]. It is not yet known to what extent linear viroids occur natively in the infected plant cells, possibly as an intermediate stage in the production of the mature viroid[30,31].

4. Nucleotide Sequence of PSTV

The first complete primary structure of a viroid, the cause of the potato tuber spindle disease, was established in 1978[23]. This achievement may appear relatively straightforward compared with the work which elucidated the sequence of the bacteriophage MS 2[32] which has about 3600 ribonucleotide residues. But, as has already been pointed out, it is not possible to label the viroid *in vivo* with ^{32}P, unlike the situation for phage MS 2; in addition, the quantities of viroid RNA available were exceedingly small. The chemical methods of DNA sequencing which have recently been developed into routine procedures[33] could not be used, since in the case of viroids it is not yet possible to enzymatically generate complete copies of complementary DNA with defined starting points. A relatively new and untried procedure had to be used to obtain the sequence based only on ^{32}P labeling *in vitro* (see Section 2).

4.1. Total Hydrolysis with Specific Ribonucleases

Figure 3 illustrates a fingerprint of PSTV obtained after complete hydrolysis with ribonuclease T_1, which cleaves on the 3′ side of guanosine. A different characteristic fingerprint is obtained if pancreatic ribonuclease is used for cleavage[21]. The 40 oligonucleotides from the RNase T_1-digest, each labeled at the 5′ terminus with ^{32}P (Fig. 3), and the corresponding 32 oligonucleotides from the pancreatic digest,

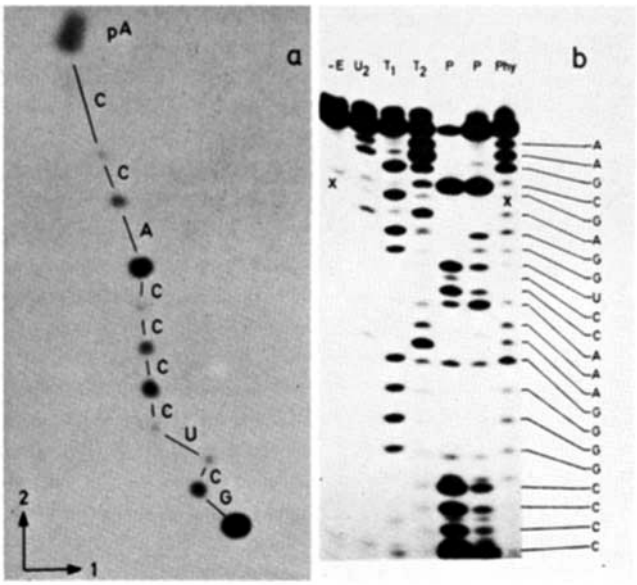

Fig. 5. Sequence analysis of 5′-^{32}P-labeled RNA-fragments. a) The fragment No. 37 from the RNase-T_1-fingerprint of PSTV (Fig. 3) was cleaved with nuclease P_1 [34] under limiting conditions, so as to obtain a mixture of fragments, all of which are labeled at the 5′-terminal and differ in chain length. After two-dimensional separation (electrophoresis/homochromatography) and autoradiography the sequence of the nucleotides may be directly read off from the differences in mobility of neighbored oligonucleotides (in 5′-3′-direction top to bottom) [35]. b) The PSTV-fragment No. 69 (cf. Fig. 7) was distributed in eight aliquots. These were digested under limiting conditions with the RNases U_2, T_1, T_2, pancreatic RNase (P), and Phy I in order to localize subsequently the adenosines, guanosines, pyrimidines, and cytidines by polyacrylamide-electrophoresis and autoradiography [36, 37]. The nucleotide sequence may be directly read off (in 5′-3′-direction bottom to top) from the autoradiogram. X indicates the position of the blue dye xylene cyanol after optimal running time. The hydrolysis with P was carried out twice in order to meet optimum conditions.

were all eluted separately from the fingerprint chromatograms. The 5′ terminal nucleotide residue of each was identified by total hydrolysis with nuclease P_1[34]; this produces 5′-mononucleotides, but only that from the 5′ terminus is labeled with ^{32}P. The terminal residues were identified by autoradiography of thin layer chromatograms run together with authentic samples of the nucleotide. The nucleotide sequence of a 5′-[^{32}P]-labeled oligonucleotide was determined by partial cleavage with nuclease P_1. Ideally, the conditions for this partial hydrolysis should be so arranged that only a single phosphodiester bond is cleaved at a random position for most of the oligonucleotides present, and a small proportion should not be attacked at all. The mixture of products is separated by two dimensional electrophoresis and chromatography, and the chromatogram examined autoradiographically. The electrophoretic mobility in the first dimension depends on the base composition, whereas the chromatographic mobility in the second dimension is approximately inversely proportional to the chain length of the oligonucleotide, so that the largest oligonucleotide has the lowest mobility. The resulting autoradiogram shows a specific pattern of partial hydrolysis resulting from the loss of one or more nucleotides from the 3′ end (Fig. 5a); the nucleotide sequence can simply be read from this pattern from the angle and separation between the successive spots.

4.2. Partial Hydrolysis

The oligonucleotides obtained from the pancreatic and RNase T_1 cleavages now have to be ordered into the complete sequence. For a normal linear RNA, this could involve enzymatically labeling the 5′ or 3′ ends with ^{32}P and using various procedures to establish the structure progressively from the two termini. A different method had to be adopted with circular viroid RNA. Samples of a few micrograms of PSTV were partially cleaved under various conditions with different enzymes so as to produce as many long PSTV fragments as possible. The conditions used were essentially: low temperature and/or low concentrations of RNase, or high salt concentrations which stabilize the secondary structure of the viroid. The mixture containing such long fragments was subjected to two-dimensional polyacrylamide gel electrophoresis after labeling the 5′ ends with [^{32}P]-phosphate; Fig-

Fig. 6. Separation of long 5′-^{32}P-labeled PSTV oligonucleotides. After partial hydrolysis of PSTV with nuclease from *S. aureus* the oligonucleotides produced were labeled enzymatically and separated by two-dimensional polyacrylamide gel electrophoresis. 1st dimension: 10% polyacrylamide, pH = 3.5; 2nd dimension: 20% polyacrylamide, pH = 8.3 [69, 70]. The oligonucleotides were made visible by autoradiography, cut out, and isolated by electrophoretic elution.

ure 6 shows a typical autoradiogram. The appropriate small portions of the gel were cut out, and after electrophoretic elution about 50—70 long 5′-labeled fragments could be obtained in a pure state. The nucleotide sequence of these fragments, which contained between 20 and 100 residues, was determined using recently developed electrophoretic procedures[36, 37]. An aliquot of each fragment was treated with the guanosine specific RNase T_1 under limiting conditions. Visible spots in the autoradiogram are only produced by those decomposition products from the original RNA fragment which have a [^{32}P]-labeled 5′ end and a guanosine at the 3′ end. The number of such sub-fragments produced corresponds to the number of guanosine residues present in the original RNA fragment, and the length of these sub-fragments depends on the distance of the guanosine from the 5′-[^{32}P]-phosphate. The electrophoretic separation of this hydrolyzate in 0.35 mm polyacrylamide layers yields a pattern of bands from which the ordering of guanosines in a sequence can be read off (Fig. 5b). Other aliquots of the RNA fragment were treated similarly with RNase U_2 or pancreatic RNase, in order to locate the adenosine and pyrimidine residues in the sequence. Uridine and cytidine were distinguished by using RNase Phy I from *Physarum polycepha-*

lum[38] or the endonucleases from *Staphylococcus aureus* and from *Neurospora crassa*[39]. The position of the nucleotide reference frame was obtained using RNase T_2, which can cleave any phosphodiester band.

4.3. Overlapping Fragments and the Complete Sequence

Since the fragments which had been sequenced were obtained by partial cleavage using enzymes of different base specifities, they often overlapped the same section of the viroid sequence. The segments shown in Figure 7 comprise a large proportion of the fragments sequenced. The partial sequences can be combined using these overlapping regions to yield the complete sequence of the PST viroid (outside circle in Fig. 7). Since these overlaps cover the entire circular viroid chain, this analysis of the sequence firmly establishes the ring structure of the PST viroid.

5. Structure in Solution

5.1. Structural Hierarchy of Nucleic Acids

The nucleotide sequence, or primary structure, is the lowest step of a hierarchy which includes secondary and tertiary structures as higher levels of structural organization. The type of structural hierarchy involved depends on the nature of the macromolecule, since structures are stabilized by various kinds of interactions and are subject to different steric restrictions (for protein structure cf. [40]). The important element in the secondary structure of nucleic acids is the Watson-Crick double helix, in which the bases adenine and uracil (or thymine in DNA) are linked by two hydrogen bonds, and guanine and cytosine by three hydrogen bonds. Base pairing between guanosine and uracil can also occur in double helices formed between strands whose sequences are not fully complementary. The secondary structure of a nucleic acid denotes the complete two dimensional scheme of all possible base pairs formed either between two separated strands, or by simple folding back of a single strand. Base pairs formed between single stranded regions which are remote from one another and whose immediate neighborhood is already highly structured, do not form part of the secondary structure. For example, Figure 8a illustrates a typical secondary structure; the additional base pairs shown in Figure 8b (assuming that sterically they could be formed at all) would not comprise part of the secondary structure.

The secondary structure is therefore a theoretical model which describes the state of lowest free energy, and which

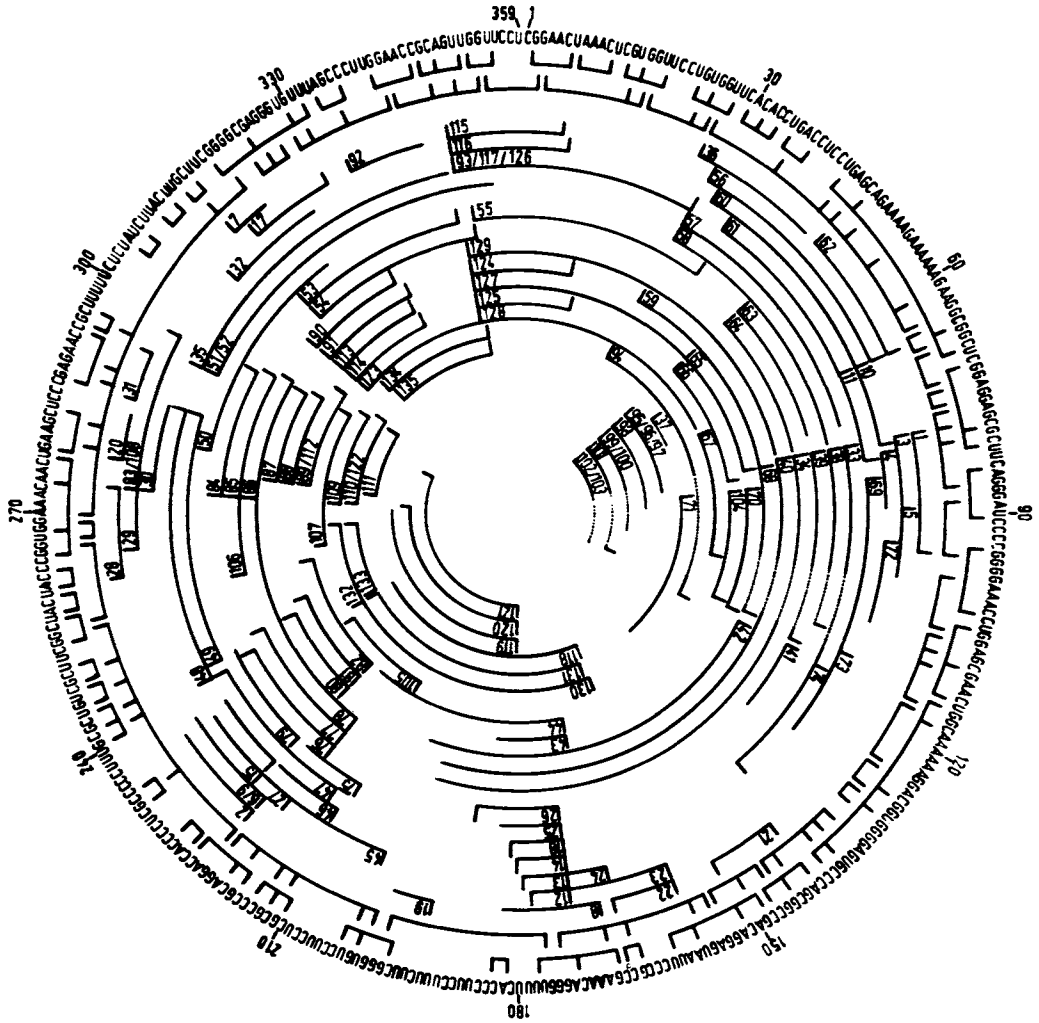

Fig. 7. Primary structure of PSTV. The nucleotides were numbered clockwise from 1 to 359. The brackets in the two outer circles indicate the products of total hydrolysis with RNase A and RNase T_1, respectively. The numbered segments in the inner rings indicate long PSTV-fragments, the nucleotide sequence of which was worked out. From a combination of this information the complete circular primary structure of PSTV was obtained.

only takes normal AU, GC and GU base pairs into account.

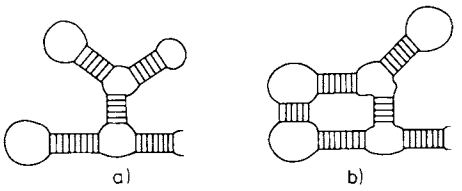

Fig. 8. Examples of the secondary structure of nucleic acids. a) nucleic acid with secondary structure only, b) nucleic acid with secondary and tertiary structure.

In general, the tertiary structure is considered to be the three dimensional configuration of a macromolecule, and thus every nucleic acid necessarily possesses a tertiary structure. However, we would like to use a more restricted definition of tertiary structure, and consider it to be those structural features resulting from interactions which are not a part of the secondary structure. The folding of the clover leaf structural model of transfer RNA into the compact tertiary structure revealed by X-ray crystallography is a familiar example[41, 42]. Chemical or physical investigations simultaneously probe the combined secondary and tertiary aspects of structure.

5.2. Secondary Structure of PSTV

Two stages are involved in finding the secondary structure which is most stable energetically: firstly, models with a higher degree of base pairing are constructed, and then the differences in free energy between each of these models and the fully unpaired state is calculated. The first step can be approached systematically using a computerized graphical procedure[43] with minor modifications for dealing with circular structures[44]. This involves representing all possible intramolecular helices in the form of a matrix, and designing complete structures based on these helices. The highest number of base pairs is the criterion for favorable structures in the first approximate stage, but studies with 10—20% fewer base pairs are also brought into consideration in the second quantitative stage in which free energies are calculated.

In order to calculate the free energy difference between the desired secondary structure model and the fully unpaired state, the former is considered to arise from the latter as the product of a multistage process of known elementary steps whose contributions to the overall free energy are then summed. The elementary steps with their associated thermodynamic parameters are known from many studies on oligonucleotides; they are depicted in Table 1.

Table 1. Stability parameters of ribonucleic acids. The values for the equilibrium constants, reaction enthalpies, and reaction entropies can be found in the literature [45]. The growth parameters of base pairing (see 1) not only depend upon the type of base pair to be formed but also upon the type of the preceding base pair. Loop formation (see 2) depends upon the factor γ, which describes the probability of pairing of bases which are within a favorable distance, and upon the loop weighting function $\rho(p+1)$ which describes the probability of approaching the favorable distance and includes the geometry of the loop. I_{tot} = total number of nucleotides of the molecule

1) Base pairing

s_{GG}, s_{GA}, s_{AA} (CC, CU, UU) experimental

2) Loop formation

a) hairpin loop

$p<13$: experimental, Monte-Carlo-calculations

$p \geq 13$: $\rho(p+1) = 0.319 \cdot p^{-3/2}$

b) internal loops

$r \leq 8$: experimental

$r > 8$: $\rho_i = \rho(r+1)$

c) bulge loops

$t \leq 8$: experimental

$t > 8$: $\rho_b = \rho(t+1)$

3) Base pairing in circles

$$K = \gamma \frac{\rho(p+1) \cdot \rho(q+1)}{\rho(I_{tot})} \cdot s^{n-1}$$

The secondary structure shown in Figure 9 is by far the most favored structure energetically for the PST viroid[23, 44]; trivial shifts in the regions of small helices and large loops are possible but thermodynamically unlikely[44]. Branched structures such as those shown in Figure 8 lead to at least 30 fewer base pairs, and about a 50% less favorable free energy. At low temperatures, the structure most favored thermodynamically is that with the largest possible number of base pairs. At the conclusion of the sequencing work, a model was described[23], based on maximizing the number of base pairs and taking into account the accessibility of single stranded regions to enzymes and chemical reagents (cf. Fig. 10); this model is almost identical to the thermodynamically optimized model.

5.3. Experiments on the Secondary and Tertiary Structures of PSTV

A variety of chemical, physical and enzymatic methods which have been used successfully to investigate the structures of other nucleic acids were adapted with minor modifi-

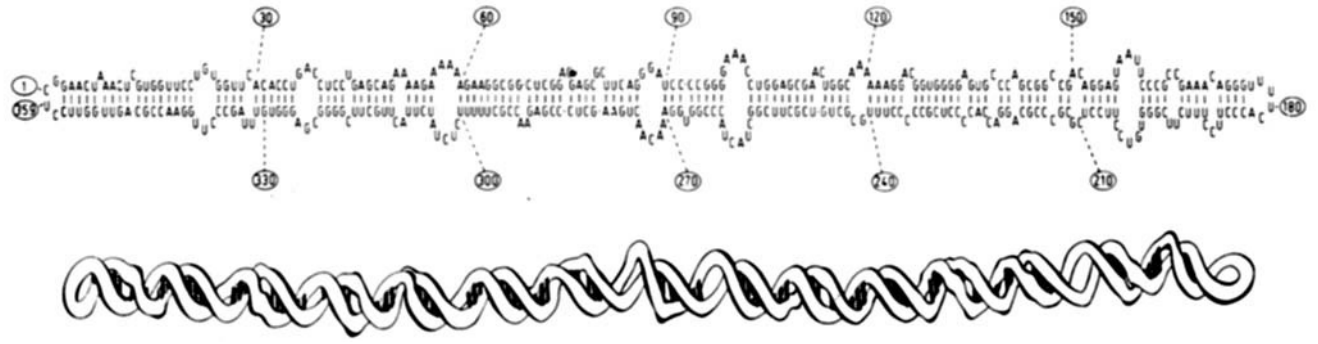

Fig. 9. Structure of PSTV. Base pairing scheme (top), three dimensional representation (bottom).

cations for studying viroids. They are not described in detail here, but the salient points are shown schematically in Figure 10. Further information about the structure is provided by thermodynamic and kinetic methods which are described in Section 6. NMR measurements have also been carried out, but, owing to the low resolution of the spectra, these were merely able to establish that there was a high degree of base pairing, and could not provide more detailed information[49].

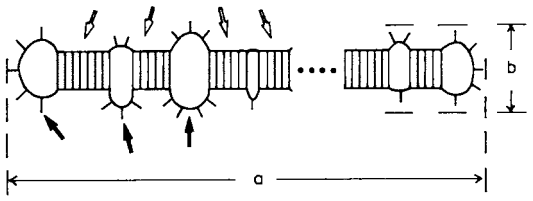

Fig. 10. Structural probes for viroids. ⇦⇨: accessibility of double helices for dye binding [44, 46] and double-strand specific nucleases [47]; in PSTV, however, the double helices are not cleaved by the double-strand specific RNase III because of their low number of base pairs [47]. ←: accessibility of unpaired regions for enzymatic digestion [23], chemical modification of cytidine to uridine with bisulfite [22, 23], and oligonucleotide binding [48]. *a*: length in the electron micrograph [15, 25]; *a/b*: axial ratio from the independent determination of the molecular weight and the sedimentation coefficient [15].

Of the methods outlined in Figure 10, those concerned with oligonucleotide binding ought to be described more fully, since a modification of commonly used methods was developed especially for studying viroids[48]. It was found that specific transfer RNAs were a particularly suitable form of oligonucleotide for such studies; these form base pairs between the anticodon triplet and a complementary triplet of another transfer RNA[50], or a corresponding sequence in a single stranded region of another nucleic acid. The principal advantage of using transfer RNAs is that the binding constant for this interaction lies between 10^5 and 10^6 M^{-1}, about two to three orders of magnitude stronger than simple tri- or tetra-nucleotides. In some cases the binding was followed spectroscopically, otherwise hydrodynamic methods were used. This approach was used to probe the accessibility of various single stranded regions in the viroid to binding of specific tRNAs. The results, which are shown schematically in Figure 10a, indicated that binding was found experimentally in those cases when it would have been expected from the model of the secondary structure.

The results of the structural experiments on the geometry of the molecule (revealed by electron microscopy and hydrodynamic studies), and on the accessibility of double stranded regions to dye binding, and of single stranded regions to chemical modification, enzymatic cleavage and oligonucleotide binding, can all be summarized very simply: the PST viroid does not possess additional elements of tertiary structure which would modify the shape or restrict the accessibility from what would be predicted by the model of the secondary structure. Thus, this model can be used directly as the basis of a three dimensional representation of the molecule (Figure 9b). The overall impression is approximately that of a section of double helix; the internal single stranded regions are irregularities in the structure which endow the molecule with a degree of flexibility, as well as being regions which could possibly interact with other RNA-species, as the tRNA binding experiments show.

The fact that the structure of the PST-viroid is completely characterized by interactions in the secondary structure is not the rule, but very much an exception among ribonucleic acids. Transfer RNA, messenger RNA, ribosomal RNA and single stranded viral RNA all possess pronounced and partially globular tertiary structures, which are not at all characterized by a scheme of two-dimensional base pairing. It ought also to be admitted that it is the very absence of additional elements of tertiary structure which has enabled much of the structural work on viroids to reach firm conclusions, and in particular to make an exhaustive thermodynamic and kinetic treatment of PSTV (see Section 6) at all feasible, despite its relatively high molecular weight of 120000.

The culmination of the structural description of a species is normally considered to be a crystallographic analysis, which can define the complete set of atomic coordinates. At the moment this is not feasible for viroids owing to lack of material. Detailed information about the conformations of internal single stranded regions could only come from single crystal studies; analysis of fibers would hardly be able to reveal new aspects of their structure. Since, according to our present view of viroid structure, the single-stranded regions are flexible in solution, it may well prove to be the case that they appear unsharp in the X-ray picture. It is therefore by no means certain that the enormous effort involved in attempting to obtain this information would be worthwhile.

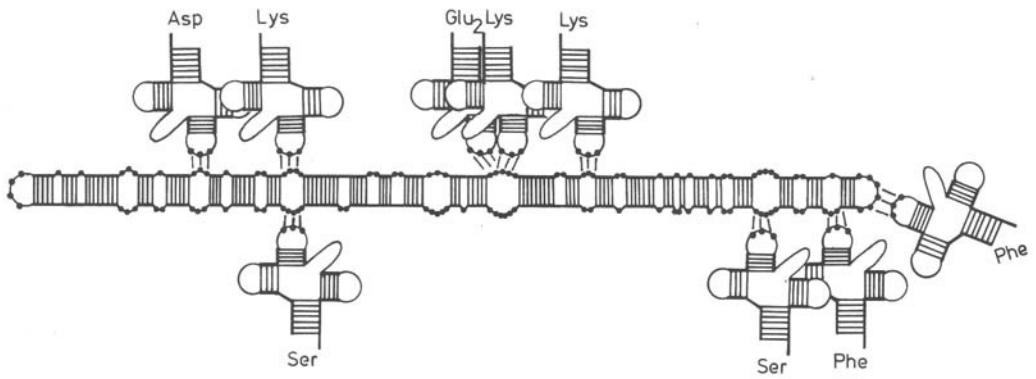

Fig. 10a. Binding of specific tRNAs to unpaired regions of PSTV. For all tRNAs depicted, binding has been demonstrated experimentally. For two other species no binding could be detected; there is also no sequence in one of the unpaired regions of PSTV, which is complementary to the anticodons of the non-binding species [48]. The anticodon-regions of $tRNA_2^{Glu}$, $tRNA^{Lys}$ and $tRNA^{Phe}$ contain odd nucleotides, the optical absorption or fluorescence of which changes characteristically due to the binding to the viroid and was used for a direct optical titration.

6. Structural Dynamics

The characteristics of the structural transitions undergone by nucleic acids are dependent on and can be inferred from the participating structures themselves. Also, it should not be thought that even *in vivo* nucleic acids have fixed, rigid structures, but rather that they can be functionally active in various conformations.

6.1. Denaturation Curves

A nucleic acid can be denatured by increasing the temperature which converts the double helical state into coiled single strands. This transition can readily be monitored from the increase in absorbance at 260 nm, and the associated curve is termed the optical denaturation curve, or less precisely but more colloquially the melting curve. Such curves have been obtained for various viroids[15,49,51-54], and Figure 11 illustrates the curve for PSTV together with those for t-RNA[55] and double stranded viral RNA[56]. Denaturation curves are characterized by two parameters: the mid-point temperature (T_m) at which half of the total hypochromic effect has been reached, and the transition width ($\Delta T_{1/2}$) which is the temperature interval between the half lengths on the denaturation curve, which resembles a Gaussian distribution. The close connection between structure and structural transitions is evident on comparing the three curves. Without going into the quantitative treatment of cooperative transitions in biopolymers (cf. [55,57,58]), the following general conclusions can be drawn from the theory as regards transitions in nucleic acids. In single stranded nucleic acids such as, *inter alia*, t-RNA and 5S-RNA, several short double helical segments of low enthalpy (cf. Fig. 8) denature independently, leading to an overlapping of several broad transition curves. In contrast to this behavior, in homogeneous double stranded nucleic acids, a large number of neighboring base pairs denature in a highly cooperative process; the enthalpies of many base pairs are assimilated into a single step, and, in accord with the van't Hoff relationship, this produces a sharp transition over a very narrow range of temperature.

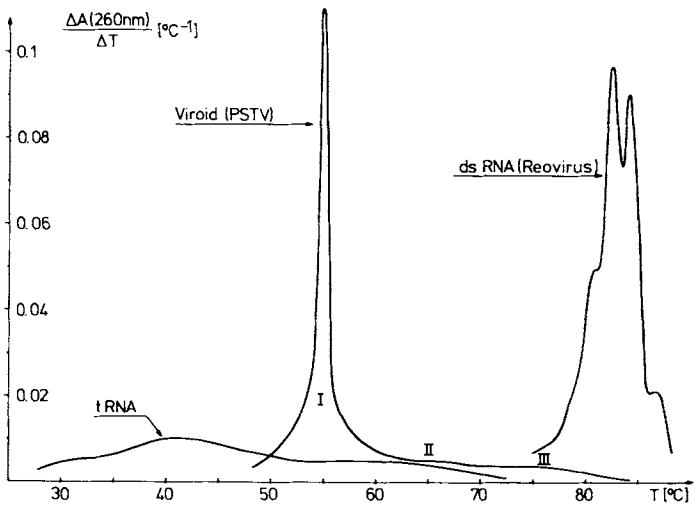

Fig. 11. Optical denaturation curves of PSTV [54], tRNA [55] and double-stranded (ds) RNA from Reovirus [56]. The curves are presented in the differentiated form as commonly used today. Multistep transitions are easily recognizable because of the appearance of several peaks. The interpretation of part II and III in the curve of PSTV as well-resolved transitions follows from detailed kinetic experiments [54]. Buffer conditions: pH = 7 and 0.02 M Na^+.

Viroids unite two thermodynamic properties which appear to be at variance according to the ideas described above: the transition occurs at low temperature in a region characteristic of single stranded nucleic acids, but the cooperativity of the transition is as high as that of homogeneous double strands. Similar denaturation curves are obtained from calorimetric measurements, in which the additional heat capacity ΔC_p is measured[59]. The time-dependence of the denaturation, obtained from relaxation measurements after a temperature jump, shows that 80–90% of the process occurs in a single-step reaction, emphasizing the high degree of cooperativity of the transition[52,54]. The denaturation curves of all other viroids investigated show the same behavior qualitatively, although the actual values of T_m and $\Delta T_{1/2}$ for each viroid do deviate from one another by respectively a few degrees and a few tenths of a degree[53].

Initial calculations, made at a time when the sequence of the PST viroid was not known, were able to explain these properties from a general model of the secondary structure[53]. This model was not based on a particular viroid sequence, but incorporated much of the known experimental data such as: T_m, $\Delta T_{1/2}$, the size and circularity of the molecule, as well as its G:C content and the calorimetrically determined reaction enthalpy *etc.* Optical denaturation curves for various models were calculated using the known stability parameters for ribonucleic acids (Table 1) and compared with those obtained experimentally. Good agreement was obtained for one model in which short double helices (four to seven base pairs) alternating with small unpaired regions (two to six bases) were arranged in a linear unbranched structure. Such a general model is in complete agreement with the specific model for PSTV.

6.2. Mechanism of Denaturation

The properties of the structural transition were subsequently interpreted in terms of both the general model and the specific structure of PSTV[44,54]. Further analysis of the results showed that two additional transitions (designated II and III in Fig. 11) could be observed after the principal highly cooperative transition had occurred. This indicates that small regions of the viroid are still base paired after dissociation of the major part of its structure. Despite the small hypochromic effect associated with these transitions, kinetic measurements were able to reveal the number of base pairs in the double helical arms, the size of the unpaired loops and the G:C content.

These stable regions have a feature which is unusual in nucleic acids. Thermodynamic[54], enzymatic[44] and electron microscopic studies[44] indicate that they are not a part of the native structure, but are formed during the highly cooperative major transition. The structures of these newly formed looped regions in the viroid are collected in Table 2; there is good agreement between the expected and observed parameters characterizing these base paired regions, and furthermore there are no other areas within the native structure which would have led to comparable agreement.

The mechanism of denaturation of PSTV modified to incorporate these newly formed stable regions is shown in Figure 12. The overall structure dissociates in a highly coopera-

tive process in which three new stable loops are formed (see also Table 2). The structures shown in the dashed box are kinetic intermediates which are not present in significant concentrations at equilibrium. The sequence of steps which produces these intermediate states must therefore be a theoretical model which is in agreement with the experimental results, especially with those obtained from kinetic studies. All of the stable areas are formed according to the same general principle (see arrows in Fig. 12). A section which is already

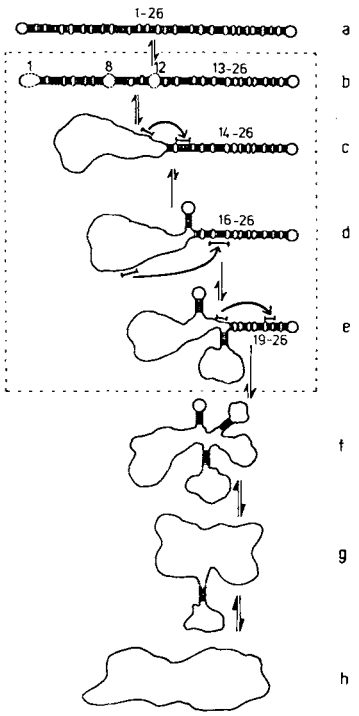

Fig. 12. Denaturation of PSTV. The numbers 1—26 indicate the 26 double helices of the native structure. The states in the dashed box (b—e) are kinetic intermediates. The transitions a→f, f→g, and g→h correlate with part I, II, and III of the denaturation curve in Figure 11.

denatured can form one of the stable structures by pairing with a section which is itself only in a partially base-paired state. The left half of the molecule has a strongly destabilizing influence on the right half, and induces a kind of long distance cooperativity; thus, a high degree of cooperativity in the transition can be examined by this special mechanism without having to postulate any other kind of interaction than the familiar one between nearest neighbors (Table 1). The mechanism can also be depicted in a simple $\Delta G^0(T)$ diagram (Fig. 13). Neglecting the stable arms, the transition temperatures would be calculated to be T_1 and T_2 for a two step dissociation of the native structure. However, from a temperature of T_I ($< T_1$), the branched structure is most stable, and this then dissociates stepwise at the experimentally determined temperatures of T_{II} and T_{III}. The half-opened linear structure does not occur in measurable concentrations at any temperature.

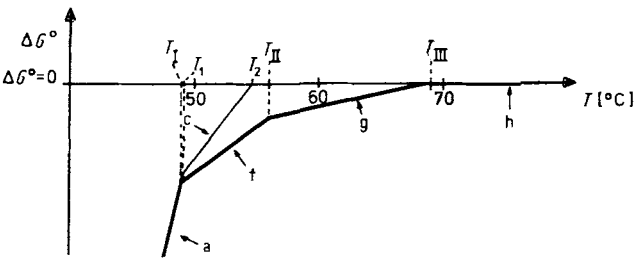

Fig. 13. $\Delta G^0(T)$-diagram of the conformations of PSTV. The difference from the totally denaturated state was calculated. The bold line belongs to the thermodynamically most stable states. T_I, T_{II}, and T_{III} are the mid-point temperatures of the three transitions (cf. Fig. 11 and 12). The thin line between T_1 and T_2 belongs to a hypothetical state which would exist if mere dissociation without new formation of stable hairpins were possible.

The dynamics of the structural transitions of viroids are characterized by two mechanistic features which have not previously been observed in any other nucleic acid. The unusually high cooperativity is attributable to the formation of stable loops, and the principal structural transition is not a simple process of denaturing base pairs, but the result of competition between a linear and a branched structure.

7. Structure and Function

Viroids are distinguished from other ribonucleic acids by a combination of three mutually dependent features: circularity, an unusual secondary structure, and the dynamics of a highly cooperative structural transition.

Table 2. Comparison of calculated (calc.) and observed (obs.) properties of the stable hairpins of PSTV [54]. The calculations were carried out for 1 M NaCl. Under these conditions complications which arise from the polyelectrolyte properties of nucleic acids may be avoided. The observed values were extrapolated to 1 M NaCl [54].

	T_m [°C]		G:C content [%]		Loop size		Base pairs	
	calc.	obs.	calc.	obs.	calc.	obs.	calc.	obs.
79 87 CGCUUCAGG 14 GCGAGGUCC 110 102	91	89–94	67	77±5	14	20±10	9	2×7–11
127 135 CGGUGGGGA 24 GCGCCCCUU 168 160	95		75		24		9	
227 236 CCCUCGCCCC 82 GGGAGCGGGG 328 319	105	102	90	90±5	82	>40	10	10

The question arises to what extent the structure determined for PSTV is applicable to other viroids. In the case of tRNA it was necessary to establish several structures before the clover leaf model was widely accepted. However, with viroids we are in a completely different situation. By comparing the thermodynamic properties of different viroids[53,54], it can be concluded that they are all constructed according to the same general principle (Figures 9a and 9b). Calculations on circular RNA molecules of the same size and base composition as viroids but with random sequences showed that such viroid analogs formed 20—30 fewer base pairs than PSTV, and exhibited a lower thermal stability and markedly reduced cooperativity[44]. Figure 14 illustrates the simulated denaturation curve of such a random sequence; the reduced cooperativity is particularly noteworthy. Comparative mechanistic studies on viroids[44,54] have shown that the principle of the denaturation scheme in Figure 12, which incorporates the formation of branched structures as an essential element, is common to all other viroids investigated. The chance of this mode of denaturation being realized in a random sequence is very small. These specific properties must therefore be encoded in the particular nucleotide sequence of each viroid, and there are only a limited number of sequences which would produce molecules with such properties. Unlike tRNA, it is possible even when the structure of only a single viroid is known (Figure 9) to draw firm and definite conclusions about the structures of other viroids.

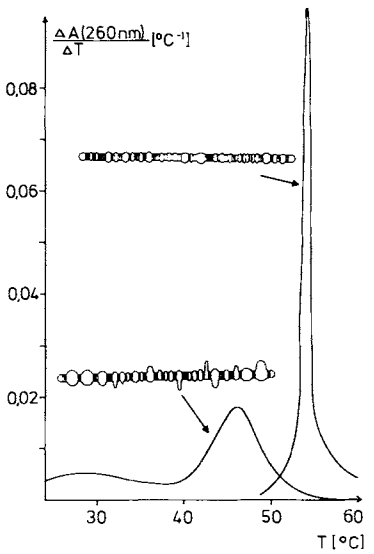

Fig. 14. Thermodynamic comparison of PSTV with a viroid-analogous random sequence. The curve of the viroid-analogous sequence (bottom) was calculated first for 1 M ionic strength and then extrapolated to the conditions of the experimental curve of PSTV (top).

It has not yet proved possible to ascribe specific biological roles to the very unusual structure and dynamic properties which viroids exhibit; at present we can only conjecture about the relationship between structure and function. In the rest of this section we discuss a few selected aspects of the functional consequences of the structure of viroids, but do not attempt to give a comprehensive account of the many, and to some extent contradictory hypotheses which have been proposed.

The significance of the ring structure is clear from the finding that viroids in a circular conformation are several orders of magnitude more infectious than the linear molecules (see Section 3); the circular structure would certainly offer a high degree of protection from exonucleases which degrade nucleic acid chains from the ends.

The linear or stretched out structure of the native viroid, composed of alternating sections of short helices and single stranded regions, can most reasonably be interpreted as a fine compromise between maximal structural stability and functional flexibility. It follows from this that the native structure is still completely intact just below the transition temperature, and that the complete transition is achieved much more readily than in a completely homogeneous double-stranded RNA. Similar alternations between double helices and unpaired regions have also been found in the initiation regions for the replication of phage DNA[60], although they are appreciably shorter than in viroids. It is altogether unclear whether the unusual dynamics of the structural transition are important in the replication of the viroid; the identity of the host enzymes which participate in the replication is not yet known, nor has it proved possible to replicate viroids specifically in a cell free system. However, it seems certain that host RNA- or DNA-polymerases are involved, since the viroid RNA is too small to contain sufficient information for the synthesis of its own specific polymerase. Inhibition experiments have provided evidence that the DNA dependent RNA polymerase II is involved either directly or indirectly in viroid replication[61]. This enzyme is responsible for the synthesis of messenger-RNA in uninfected plants; the fact that it is localized in the cell nucleus can be linked to the early finding that viroids are found in fractions enriched in nuclei[3,62]. It is by no means clear whether the complementary strand to the viroid is present in the form of DNA or RNA, nor indeed whether viroid sequences are a part of the genome of healthy plants or are introduced into the cell *de novo* on infection. The literature contains evidence claiming to support each of the incompatible proposals[63]; some of these results are unconvincing either because impure material was used or because they neglected to take the unusual structure of viroids into account. The finding that sequences complementary to viroids occur in the form of RNA only in infected plants has now been established by several recent studies, but the complementary RNA has not been further characterized as regards size or function.

Various intensive searches have also been instigated for proteins which could be coded for by the viroid. It could be supposed theoretically that the PST viroid could code for peptide chains up to a total length of 283 amino acids[23] but such peptides have not yet been identified experimentally. The idea that viroids do code for proteins or peptides must certainly be considered as a possibility, but there is a good deal of support for the view that they do not carry the information for proteins but merely code for their own structures.

8. Outlook

Studies on viroids have revealed a novel structural principle which produces a natural nucleic acid with unusual features. For the first time, the structure of a eukaryotic pathogenic agent has been elucidated, which appears to code only for its own molecular structure and not for its own proteins.

Since the principles underlying the structure of viroids now appear to be established, this should provide a firm basis for other kinds of investigations into these extraordinary species.

The replication and pathogenic action of viroids do not readily accord with conventional ideas, and it is therefore to be expected that much of the work in the immediate future will be devoted to these problems. It might reasonably be hoped that such work would not only illuminate the mode of action of viroids, but also lead to a better understanding of some more fundamental aspects of molecular biology.

More emphasis will also be laid on applied aspects of the subject, which are of major importance in agriculture and horticulture; other plant diseases may also be recognized as being of viroid origin. At present it is not possible to protect plants against viroids, but knowledge of the structure and progress in understanding the function and mode of action of these agents should enable specific inhibitors to be developed.

Viroids are also of considerable interest in medicine, since it has often been suggested that viroid-like pathogens are also active in man and other animals. The best investigated examples of the many suggestions put forward are scrapie in sheep, and the Kuru disease and the Jacob-Creutzfeldt syndrome in man. These three conditions are degenerative disorders of the central nervous system, which have been attributed to "slow-virus" infections, but the agents responsible for them have never been identified. From the many and partly contradictory results, it can at least be concluded that entities of sub-viral size are responsible[64–66]. The possibility that viroids are involved will increasingly have to be considered, but only the future will show whether the action of viroids is restricted to plants or whether similar agents also exist in man and other animals.

Our own results which are discussed in this article arose from close cooperation with Prof. H. L. Sänger (Giessen). Also involved in this were our co-workers H. Alberty, Dr. H. Domdey, Dr. K. Henco, Dr. P. Jank, J. Langowski, Dr. Ch. Lossow, Dr. M. Raba, U. Rokohl, and U. Wild. This work was generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Photochemical Rearrangements and Fragmentations of Benzene Derivatives and Annelated Arenes

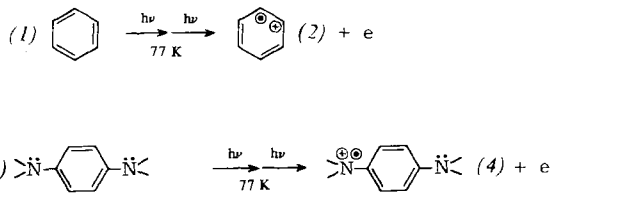
By Gerd Kaupp[*]

In this article the numerous intramolecular reactions of electronically excited benzene derivatives, which in many instances are only mentioned in original papers, are systematically analyzed and arranged according to reaction types. All known reaction types can be classified, and subdivided into reactions of the benzene ring (ionization, ring opening, ring alteration), reactions with participation of side chains (α-, β-, γ-cleavage, homolysis, heterolysis), reactions of substituents with side chains (cyclization, dealkylation, cleavage of protective groups), and reactions of side chains with the aromatic ring (substitution, addition, dearomatization, cyclization). The selectivity of the energetically feasible competing reactions is primarily determined by geometric factors. Applications of the empirical effects are numerous and varied in preparative organic chemistry. Many of the reactions under discussion are already utilized industrially (*e.g.* in photochromism, UV stabilization, photography, information storage, printing, coating and polymer technology, and pharmacy).

1. Introduction

The field of aromatic photochemistry has been unusually widely investigated. All benzene derivatives absorb light in readily accessible wavelength regions. A large portion of the many reaction types can as yet only be extracted from original publications. That excited molecules must choose between these reaction types as well as luminescence and chemically unproductive deactivations, is in most cases a consequence of high energy excesses after the absorption of light. The plethora of available reference material calls for a classification. Present theoretical concepts are obviously able to systematize only a part of the intramolecular photochemistry of aromatic compounds[1], and even then there is the risk that a sub-group of so called "forbidden reactions"[1] will not be adequately represented by examples. Therefore, another didactic approach would seem to be indicated: Arrangement of the entire material according to reaction types enables a comprehensive treatise of all practically important aspects. As this will immediately reveal the common features of or differences between the various types, which may be used for extrapolative purposes, consideration is given at the same time to the interest in advanced theoretical concepts and questions related to practical applications in syntheses (*e.g.* planning, improvement in yields, more complete product distribution, choice of protective groups, asymmetric syntheses and reactive intermediates), in chemical technology (*e.g.* photochromes, absorbers, initiators, polymer and phototechnology, printing, photoconductors), in ecology (*e.g.* degradation of insecticides and herbicides, energy storage), and in biology and pharmacy (*e.g.* vitamin B_2 and B_c, alkaloids, tumor inhibitors).

Photochemical syntheses are particularly valuable, if one can achieve high selectivities for the desired reactions. A directed synthesis is possible by suitable choice of reaction conditions (*e.g.* reaction medium, concentration, temperature, pressure, light intensity, wavelength, sensitization) and by structural variations of the substrates. Steric factors and cage effects are more important here than in thermochemistry, where energetic effects usually dominate. This treatise considers only as many typical examples of any single reaction type as appears necessary for the characterization of the specific requirements (best possible yield) and variability (indication of synthetic scope). Some further examples are accessible from the literature. The photoreactions of styrenes and stilbenes[2] are not dealt with here, unless their aromatic rings undergo direct chemical change.

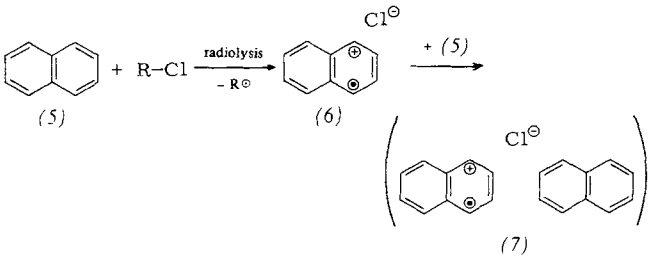


2. Reactions of the Benzene Ring

2.1. Ionization

Perhaps the most simple photoreaction of arenes is the splitting off of an electron to produce radical cations. Benzene *(1)* [first ionization potential (IP) in the gas phase: 9.25

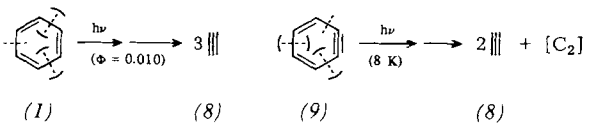
[*] Prof. Dr. G. Kaupp
Chemisches Laboratorium der Universität
Albertstrasse 21, D-7800 Freiburg (Germany)



eV] is ionized upon absorption of vacuum UV-, x-, γ-rays, electrons (cf. photoelectron and mass spectroscopy) or of two photons (*via* its triplet; $\lambda = 253.7$ nm) at 77 K. If adsorbed on SiO_2 at 77 K *(1)* may form *(2)*, as detected by its ESR spectrum (7 lines, $a_H = 4.5$ gauss)[3]. Even easier is the biphotonic ionization of *(3)* to give the cation *(4)* (*Wurster*'s Blue) and electrons, which are trapped in holes of 3-methylpentane at 77 K within 1 ns. The VIS/NIR spectra of *(4)* and the immobile electron are measurable for several minutes, *i.e.* the system constitutes a storage system for light energy. The luminescent recombination of *(4)* and e may be stimulated photochemically, thermally, or electrically. Furthermore, the system also constitutes an electric conductor with high dark resistance[4].

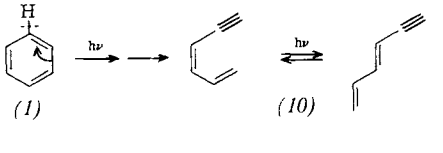
In boric acid glasses the IPs of annelated arenes are about 2.3 eV lower than in the gas phase. The electrons are captured by protons (formation of H_2). Even at room temperature one obtains the colored radical cations after absorption of two photons using normal light intensities or the IP may be already surpassed by the absorption of one photon (*e.g.* $\lambda = 235$—245 nm in the case of anthracene). Thus, the radical cations of naphthalene, pyrene, anthracene, 3,4-benzopyrene, perylene, and tetracene could be measured[5].

With laser sources, biphotonic ionizations are possible in solutions at room temperature. In this case the ionization mechanisms of *e.g. (3)*, pyrene, and perylene are different in polar and non-polar solvents[6].

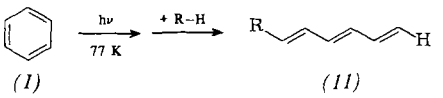


The ionization of arenes and annelated arenes [*e.g. (5)*] may also be sensitized at 77 K by alkyl chlorides (*e.g. n*-BuCl/2-methylbutane = 1:1)[7], when γ- (^{60}Co)[7,8] or x-rays ($Cu_{K\alpha}$)[9] are employed. γ-Radiolysis at 77 K served for the measurement of UV/VIS/NIR spectra of numerous radical cations, which combine with the neutral arenes to give dimer radical cations *(7)*, even on raising the temperature only very slightly[7,8,10].

2.2. Ring Opening Reactions



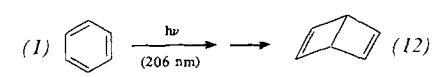
2.2.1. [2+2+2]-Cycloreversion



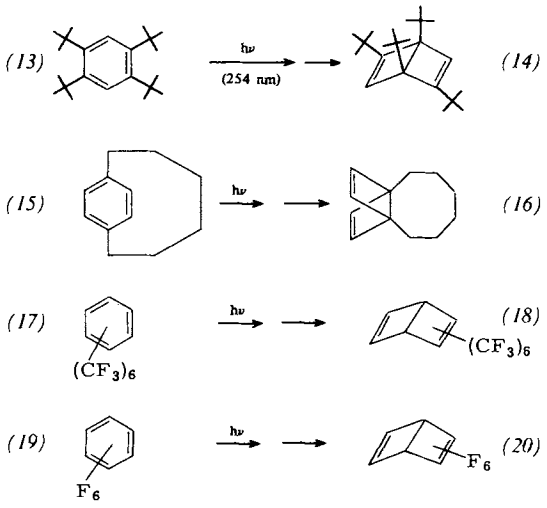
The tendency of the benzene ring to cleave into three acetylene fragments, which is the reverse of a known photochemical benzene synthesis[11], appears to be less pronounced than in some six-membered heterocycles[12]. Nevertheless, it could be shown that *(8)* is formed as a primary product on photolysis of gaseous *(1)* with unfiltered light from a low pressure mercury arc[13]. However, this reaction proceeds with little specificity, for there is competition from several primary and secondary photolyses. Already at 8 K, dehydrobenzene *(9)* photolyses slowly to *(8)* and C_2[14].

2.2.2. Ring-Chain Isomerization

The ring opening of benzene with 1,3-H-shift in the gas phase leads to the stereoisomeric 1,3-hexadien-5-ynes *(10)*[15]. This may be compared with the preparatively useful photolyses of furans (oxazoles) to give oxoketenes (oxoketeneimines)[16]. However, it is not yet clear, whether *(10)* is formed in part *via* fulvene [*(35)* in Section 2.3.3]. The photolysis of benzene *(1)* in glasses at 77 K is striking. One obtains rather sharply structured UV-spectra ($\lambda_{max} = 255$, 264, 275 nm), which point to the formation of substituted 1,3,5-hexatrienes *(11)* *via* ring opening and solvent addition[17]. Thus, low temperature photolyses in glassy media may be severely disturbed by traces of benzene.

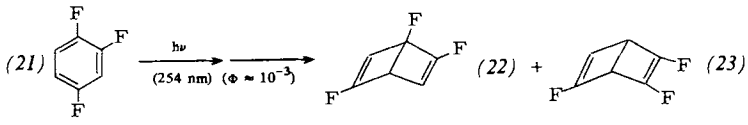


2.3. Ring Alterations

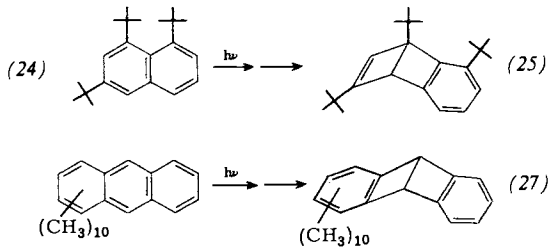


Photochemical ring isomerizations transform benzene (or its derivatives) into Dewar benzenes, benzvalenes, fulvenes, and rearranged benzene derivatives. The product ratios are strongly dependent on the experimental conditions[18]. Owing to photochemical and thermal lability it is not always possible to isolate all of these products.

2.3.1. Dewar Benzenes

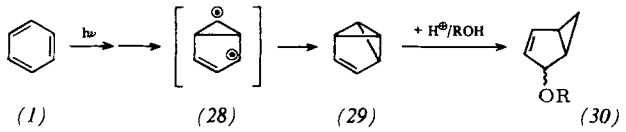


Benzene *(1)* is converted into Dewar benzene *(12)* apparently only upon short wavelength irradiation in solution[15a,19].

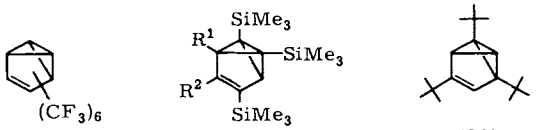


Fewer difficulties are encountered with the alkyl-derivatives [*(13)*→*(14)*[20]; *(15)*→*(16)*[21]], trifluoromethyl-derivatives [*(17)*→*(18)*[22]], and fluoro-derivatives [*(19)*→*(20)*[23]]. In some cases remarkable selectivities are observed [*(21)*→*(22)* + *(23)*, but not 1,2,4-trifluorobicyclo[2.2.0]hexa-

2,5-diene][24], and the corresponding reactions can be achieved with substituted naphthalenes [*(24)*[25]] and anthracenes [*(26)*[26]]. The same reaction type has also been well investigated in the case of pyridine and pyridine derivatives[27].



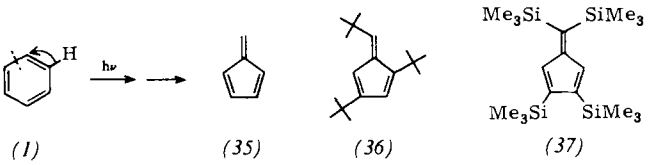
The highly energetic Dewar benzenes have been used for thermal and photochemical transformations.



2.3.2. Benzvalenes

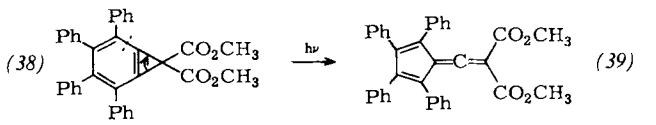
Even long wavelength excitation of liquid or dissolved benzene *(1)* leads to formation of benzvalene *(29)*[28], which may be isolated by vapor phase chromatography. A diradical "prebenzvalene" or "prefulvene" *(28)* is assumed to be an intermediate in this reaction[18]. The addition of water, alco-

hols, and acetic acid to *(29)* to give the bicycles *(30)*[29] can be catalyzed with acids. The substituted benzvalenes *(31)*[30], *(32)*[31], *(33)*[31], and *(34)*[32] are also obtainable from the corresponding benzene derivatives.



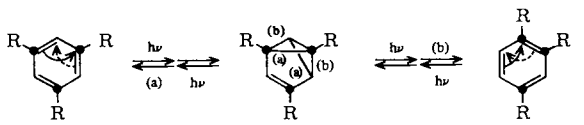
(31) *(32)*, R^1 = H, R^2 = $SiMe_3$
(33), R^1 = $SiMe_3$, R^2 = H

(34)



2.3.3. Fulvenes

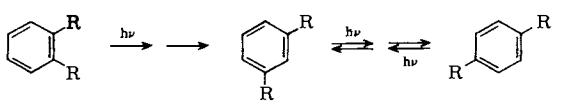
The photolysis of benzene in solution or in the gas phase leads *via* ring contraction and H-migration to fulvene *(35)*, which can be isolated by vapor phase chromatography[15a].



(1) *(35)* *(36)* *(37)*

However, it is still not possible to definitely decide whether *(35)* is a primary product of benzene photolysis [*e.g.* formation *via* prefulvene *(28)*[18]], as benzvalene *(29)* gives benzene and fulvene with rather high quantum yields upon photolysis. The isolation of the fulvenes is often rendered difficult by their tendency to polymerize. *(36)*[32] and *(37)*[31] have been characterized. A productive synthesis of highly substituted, stable fulveneallenes such as *(39)* (66%) has been reported[33].

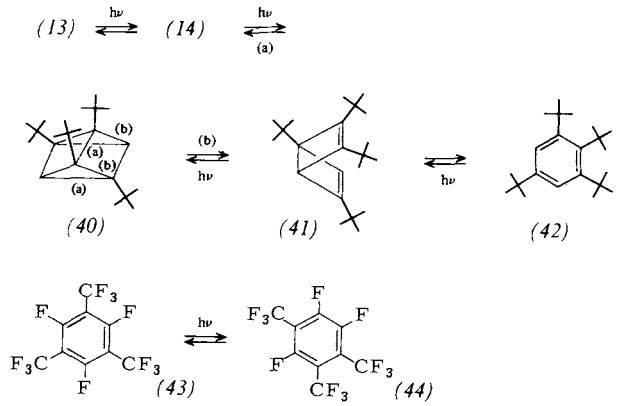
2.3.4. Shifts of Ring Carbons



Suitably substituted benzvalenes (Section 2.3.2) and prismanes, which are photochemically formed from Dewar benzenes[2] (Section 2.3.1), may react further to either of two different benzene derivatives. These reactions lead to a rearrangement of the ring carbons, which stay linked to their substituents (apparent 1,2- and duplicated 1,2-substituent migration). Thus, 1,3,5-trideuterio-[34], 1,3,5-trimethyl-[35], and 1,3,5-tri-*tert*-butylbenzene[36] form almost uncontaminated photoequilibria with their 1,2,4-isomers *via* benzvalenes [Eq. (a)].

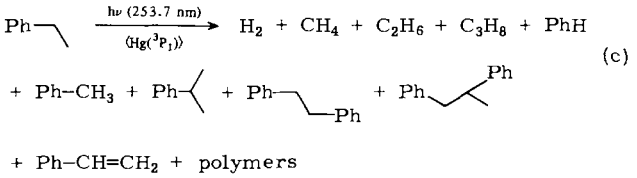
(a)

R = D, CH_3, $C(CH_3)_3$



Correspondingly, *o*-xylene[37] and *o*-di-*tert*-butylbenzene[38] form at first the *meta*- and then the *para*-isomers, presumably again *via* benzvalenes [Eq. (b)]:

(b)

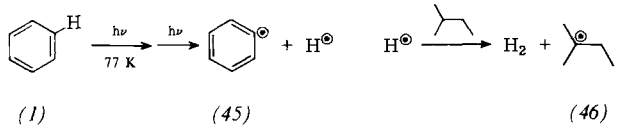


R = CH_3, $C(CH_3)_3$

In the case of benzene derivatives, which photochemically form Dewar benzenes but not benzvalenes, such isomerizations should proceed *via* prismanes. Examples are *(13)*[20] and *(43)*[39].

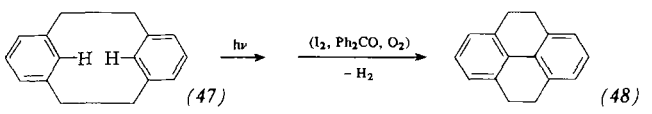
3. Reactions with Participation of Side Chains

Upon photolysis, the side chains of substituted arenes may be cleaved or rearranged or may react with the benzene ring. Homolyses, heterolyses, and cyclization reactions may occur. As a rule these primary photoprocesses are followed by consecutive thermal reactions as in the case of ethylbenzene [Eq. (c)][40] or in the photodegradation and photo-crosslinking of



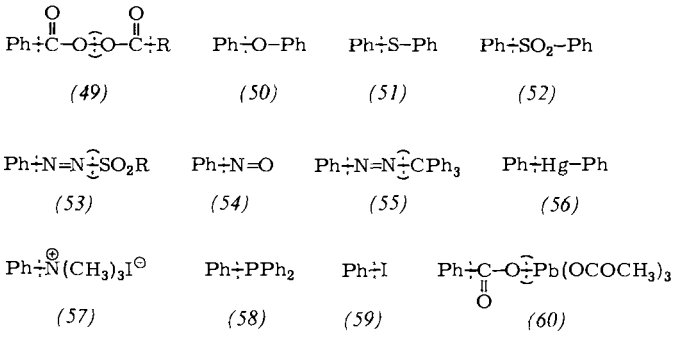
(c)

polystyrene[41] *via* radicals, which can be detected by ESR spectroscopy at 77 K[42]. Nevertheless, it is still possible to present a lucid classification according to reaction types.

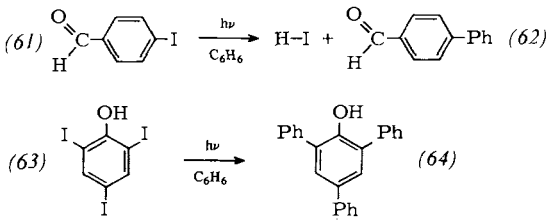


3.1. α-Cleavage

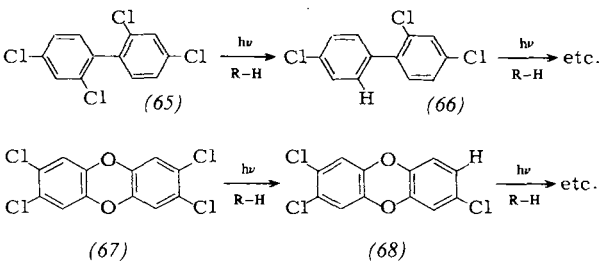
3.1.1. Homolysis into Aryl Radicals



The biphotonic irradiation of (hexadeuterio-) benzene *(1)* at 77 K (λ = 230—260 nm) leads to the (pentadeuterio-) phenyl radical *(45)*, which has been detected by ESR spectroscopy[43]. The hydrogen atom generated simultaneously reacts with isopentane to give H_2 and the radical *(46)*[43]. The formation of biphenyl, which has been observed several times

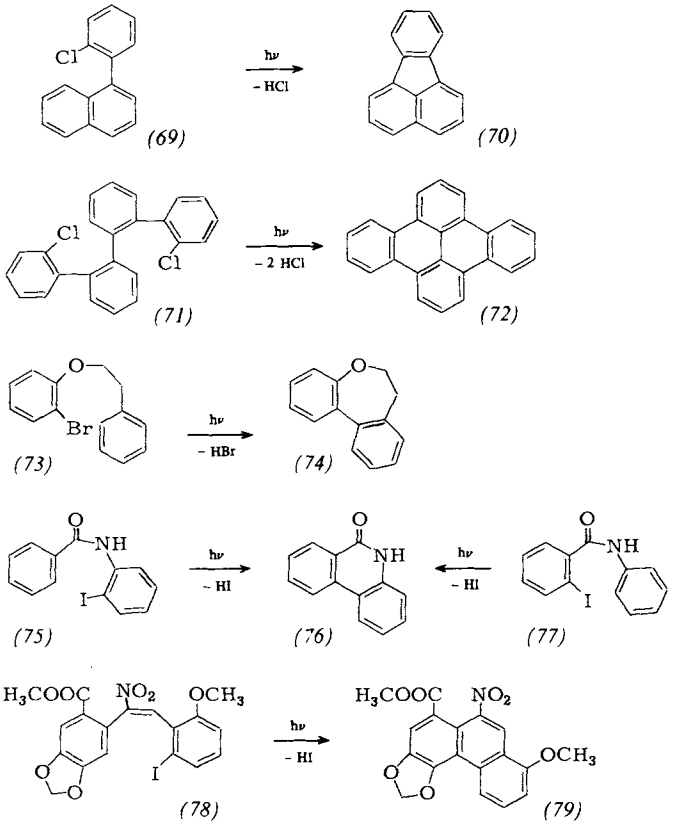


upon irradiation of gaseous and dissolved benzene[44], would also suggest the formation of *(45)*, which either dimerizes or else combines with benzene with the intervention of an oxidizing agent to form biphenyl. This is similar to the transannular dehydrogenation of *(47)* to give *(48)*, a reaction which proceeds with or without oxidizing agents[45].

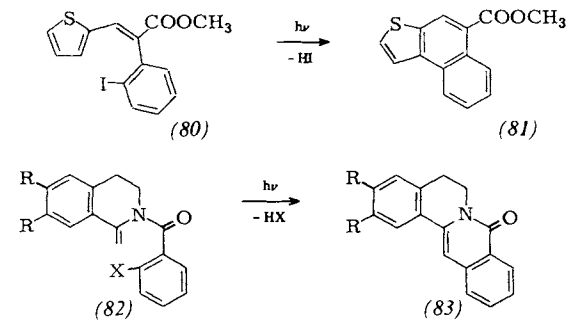


Phenyl radicals *(45)* are formed in small amounts on photolysis of ethylbenzene[40]. They occur in larger amounts upon photolysis of *e.g.* benzoyl peroxides *(49)*[46], diphenyl ether *(50)* (photo-Fries rearrangement, see Section 4.1.2)[47], diphenyl sulfide *(51)*[48], diphenyl sulfone *(52)*[49], phenyldiazosulfones *(53)*[50], nitrosobenzene *(54)*[51], alkylazobenzenes [*e.g.* *(55)*[52]], numerous phenyl-metal compounds [*e.g.* *(56)*[53]], phenylammonium salts *(57)*[54], triphenylphosphane *(58)*[55], halobenzenes [*e.g.* *(59)*[56]], and lead(IV) benzoates *(60)*[57].

These photocleavages into radicals are of considerable importance in view of the increasing demands for initiators[58] for photografting and photo-crosslinking (coatings, printing plates, microelectronics, photoengraving, *etc.*)[59]. In all cases phenylation takes place following photocleavage (*e.g.* formation of biphenyl with benzene). The major application of this reaction is in the directed synthesis of more complicated compounds such as *(62)* (90%)[60] or *(64)*[56]. The phenyl radicals are able to react with solvents by accepting chlorine (*e.g.* CCl_4), bromine (*e.g.* $CHBr_3$) or hydrogen atoms (*e.g.* cyclohexane) or they may react with trivalent boron, phosphorus,

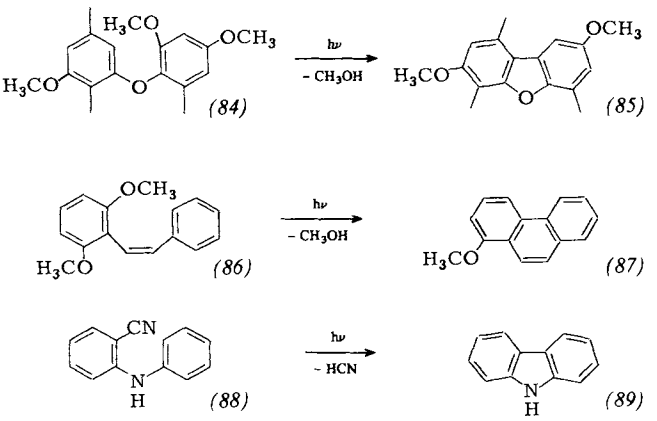


and arsenic compounds to give phenyl-element compounds[56]. The photochemical homolysis of the aryl-chlorine bonds of bioactive compounds such as polychlorobiphenyls [*e.g.* *(65)*[61]] or TCDD *(67)*[62] is of considerable importance in environmental chemistry. Usually one obtains an increasing detoxification *via* consecutive dechlorination. In nature, the aryl radicals formed may also be trapped by oxygen to give oxygen-containing decomposition products.

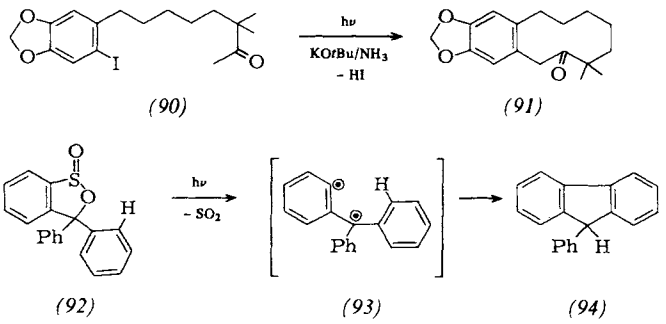


3.1.2. Substituting Cyclizations

As in the case of intermolecular phenylations [see *(62), (64)*] it can be assumed that the variable intramolecular syntheses (substituting photocyclizations of aryl halides) of *(70)* (72%)[63], *(72)* (87%)[64], *(74)* (35%)[65], *(76)* [48% from *(75)*, 18% from *(77)*][66] and of the tumor inhibitor aristolochioic acid (methyl ester) *(79)* (54%)[67] are initiated by a homolysis of the Ar—X bonds[56].

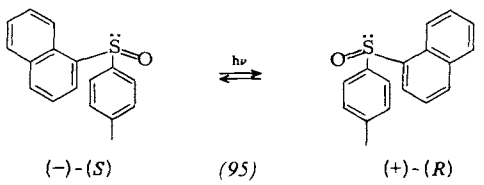


Numerous applications for alkaloid syntheses have already been reported[68]. The aryl radicals first formed can also be trapped by the C—H bonds of heterocycles [see *(80)*][69] or C=C double bonds [see *(82)*][70].

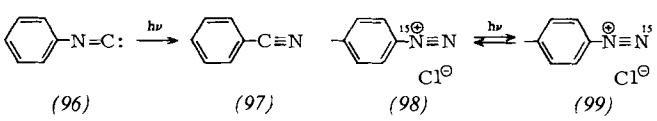


R = OCH_3; X = F, Cl, Br, OCH_3, $OCOCH_3$, SCH_3, NO_2

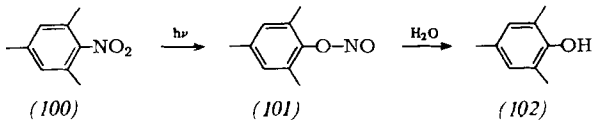
It is not certain whether the homolysis mechanism applies here and in the substituting cyclizations with loss of methanol [*(84)* (35%)[71], *(86)* (90%)[72]] or hydrogen cyanide [*(88)*[73]], or whether there is first cyclization followed by elimination.



Intramolecular nucleophilic photosubstitutions [*e.g.* to give 35% *(91)*[74]] and the complicated elimination followed by cyclization of *(92)* to give *(94)* (42%)[75] also belong to this section.

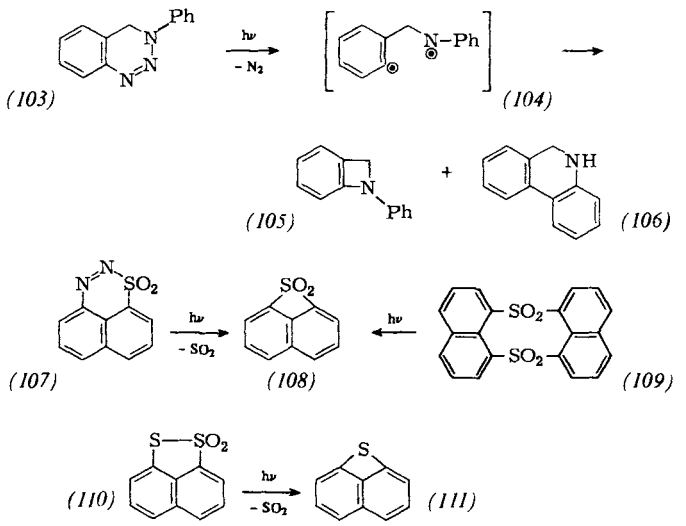


3.1.3. Reversal of Substituents

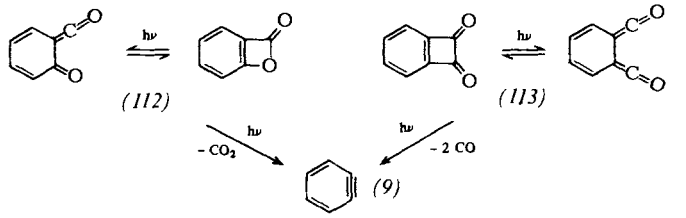


The original α-bonds have to be cleaved when the linking sites of substituents are interchanged. However, the photoracemization of diaryl sulfoxides such as *(95)* could also be explained by assuming inverting vibrations of the pyramidal sulfur[76].

More clear cut are the isomerizations of phenyl isocyanide *(96)* (gas phase)[77], (labeled) diazonium salts *(98)* / *(99)*[78],

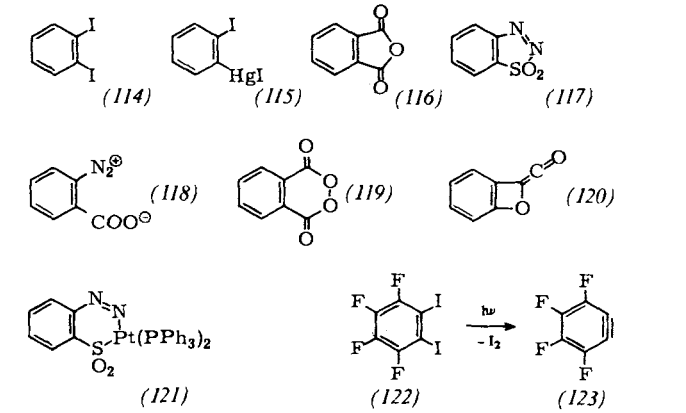


and nitroarenes such as *(100)*[79] [cf. Smiles rearrangement, *e.g. (530)* in Section 4.1.2].



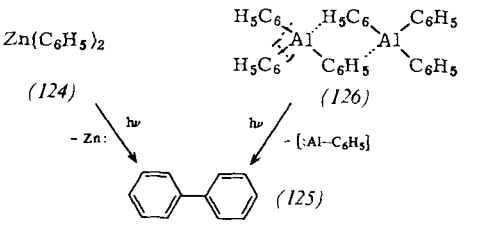
3.1.4. Ring Contraction

Homolytic α-cleavages with ring contraction by elimination deserve interest. Thus, the reactions of *(103)*[80], *(107)*[81], *(109)*[81], and *(110)*[82] yield the unusual *o*- or *peri*-coupled heterocyclic four-membered rings *(105)* (50%), *(108)* (25%; 20%) and *(111)* (97%).

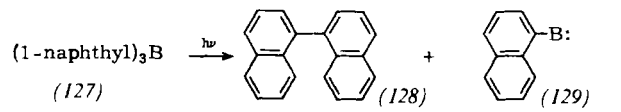


3.1.5. Formation of Dehydrobenzenes

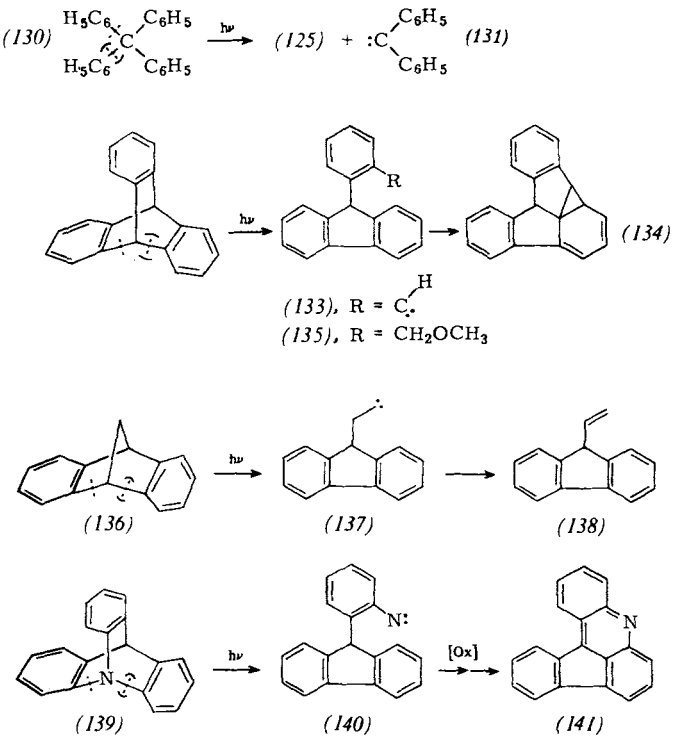
On cleavage of two *ortho* bonds on a benzene ring, one obtains dehydrobenzene *(9)*, which dimerizes or trimerizes to give bi- or triphenylene and which may also be trapped by 1,3-dienes to give Diels-Alder adducts. The reactions of *(112)*



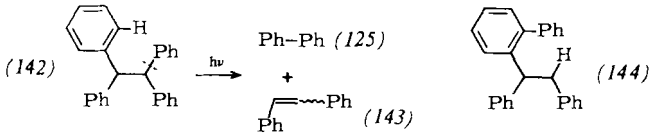
and *(113)* proceed at temperatures as low as 8 K[14]. Further starting materials for *(9)* are *(114)*[83], *(115)*[84], *(116)* (also in the plasma of glow discharges)[85], *(117)*[86], *(118)*[87], *(119)*[14,84], *(120)*[88], and *(121)*[89]. Substituted dehydrobenzenes such as *(123)*[90] are also obtainable.



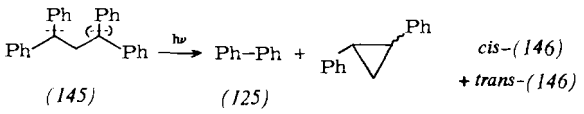
3.1.6. Formation of Biphenyls



If two or more phenyl groups are linked to one atom, two α-cleavages can lead to the elimination of biphenyl *(125)* and reduction of the central atom without liberation of phenyl

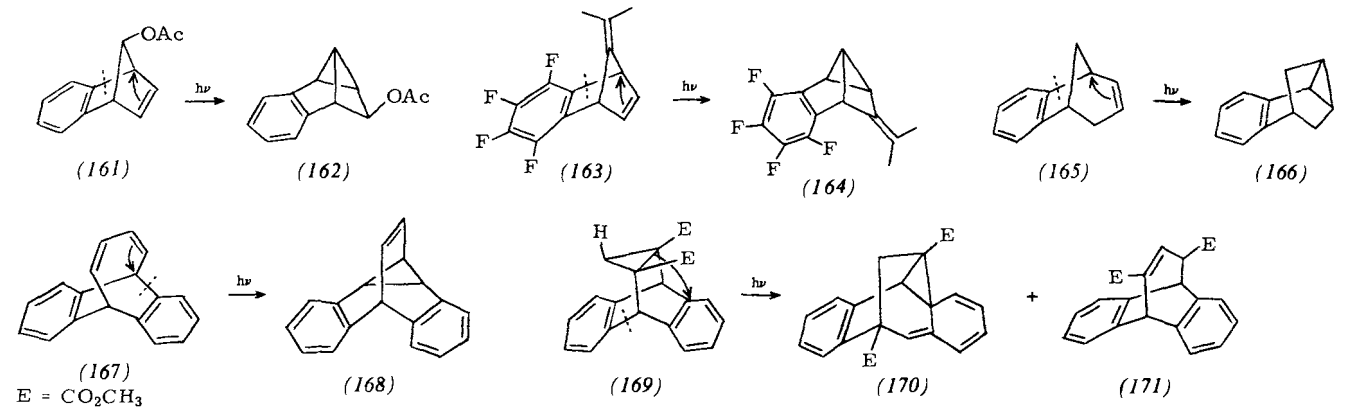


radicals (cf. Section 3.1.1). This reaction path is preferred by diphenylzinc *(124)*[91], dimeric triphenylaluminum *(126)*[92], and tri-1-naphthylborane *(127)*[93].

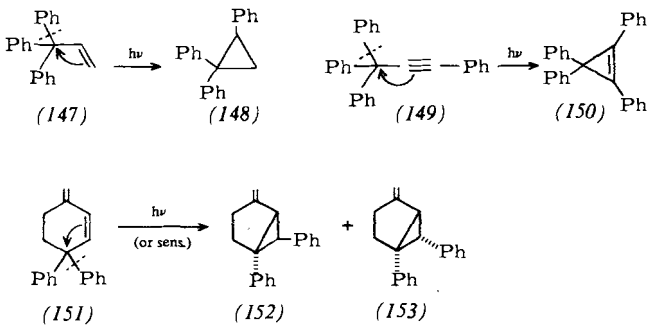


Tetraphenylmethane *(130)*[94], triptycene *(132)*[95], dibenzonorbornadiene *(136)*[96], and azatriptycene *(139)*[97] react completely analogously. Two benzene rings combine, producing carbenes [*(131), (133), (137)*] and presumably the nitrene *(140)*, which can be transformed or trapped in different ways[98]. Thus, the methyl ether *(135)* is formed from *(132)* in methanol.

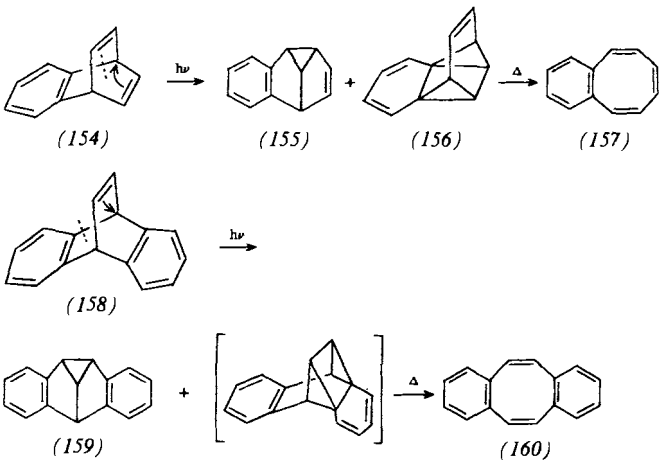
Even two phenyl groups, which are linked to different carbon atoms, may be eliminated intramolecularly. From *(142)* one obtains *(125)* and *(143)* together with *(144)*[99] (this biphenyl derivative is formed by intramolecular substitution).



Correspondingly, the homologous compound *(145)* decomposes into biphenyl *(125)* and *(146)*[100].

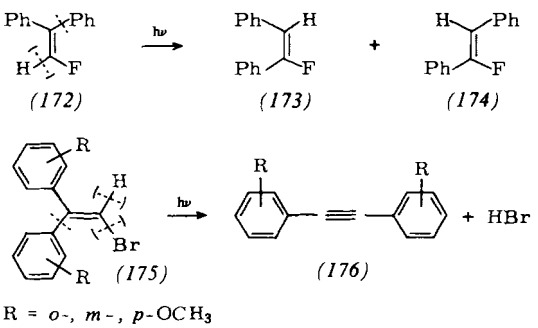


3.1.7. Di-π-methane Rearrangement



α-Cleavages of aryl-C-bonds with 1,2-shift to an adjacent double bond have been termed "di-π-methane rearrangements"[101]. Numerous rearrangements of acyclic [*e.g.* *(147)*[102], *(149)*[103]], monocyclic [*e.g.* *(151)*][104], and bicyclic compounds are known (for further 1,2- and 1,4-phenyl shifts see [2]).

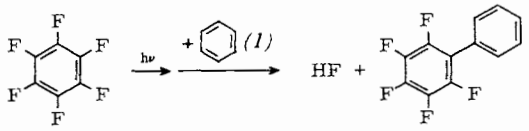
In the case of benzo- *(154)*[101] and dibenzobarrelene *(158)*[101] the ratio of di-π-methane rearrangement and intramolecular [2+2]-cycloaddition upon direct and sensitized excitation[105] (cf. Section 4.3.4) has been carefully studied.



Numerous variations in ring size have been realized. Thus, *(162)* (stereospecific, 85%)[106], *(164)* (94%)[107], *(166)* (94%)[108], *(168)* (84%)[109], and *(170)*[110] have been obtained. In competition with the di-π-methane rearrangement in *(169)*, a 1,2-shift produces *(171)*[110] (for further side reactions see [98a,b]).

3.1.8. 1,2-Shifts along Double Bonds

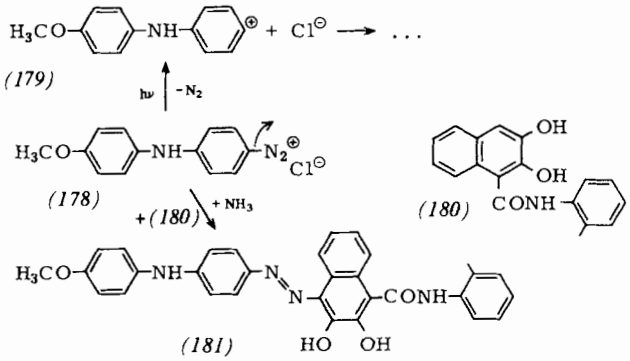
After absorption of light a phenyl group and the hydrogen atom in 2-monosubstituted 1,1-diphenyl-1-alkenes may migrate in opposite directions. Thus, *(172)* gives the isomers *(173)* (28%) and *(174)* (23%)[111]. Also in the photoelimination of HBr from *(175)*[112] [see *(36)* in [2]] at least one aryl group has to migrate along the double bond.



3.1.9. Heterolysis

It is not possible to draw a sharp borderline between homolytic and heterolytic α-cleavages; some of the reactions discussed in Sections 3.1.1 through 3.1.8 might proceed heterolytically or *via* zwitterionic intermediates.

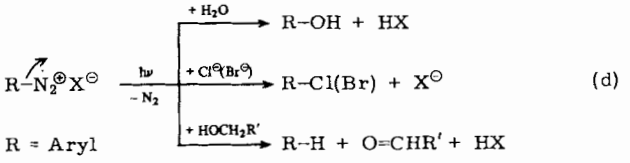
In the photolysis of hexafluorobenzene *(19)* there exist striking peculiarities, even though the products correspond



to those of formally related radical reactions [*e.g.* the synthesis of *(177)*][113]. However, a homolysis of the aryl-F bond is excluded for energetic reasons. The reaction is considerably

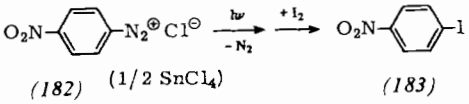
(19) *(177)*

enhanced by addition of minor quantities of acetonitrile, methanol, or trifluoroacetic acid[113]. Whether or not this might indicate a photoheterolysis (to give aryl cation and $F^{\ominus}$) has not yet been investigated.



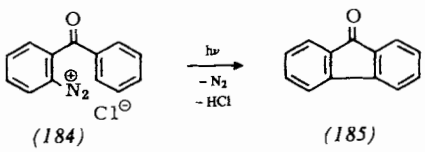
Nitrogen eliminations from aryldiazonium salts are by necessity heterolytic. The photochemical version of this process has practical impact in diazotype-copying (*e.g.* Ozalid® process)[59, 114]. Thus, *p*-aminobenzenediazonium salts [*e.g.* Variamine Blue B salt *(178)*] are mixed with phenols [*e.g. (180)*] in acidic foils. They are irradiated through the pattern to be copied with high-pressure mercury arcs and thus selectively decomposed. Exposure to ammonia then causes azo-coupling in the unirradiated regions, forming the blue dye *(181)* and thus producing a positive image.

(179) *(178)* *(180)* *(181)*



Copying rates of 30 patterns per second and developing times of 90 seconds have been achieved[114a].

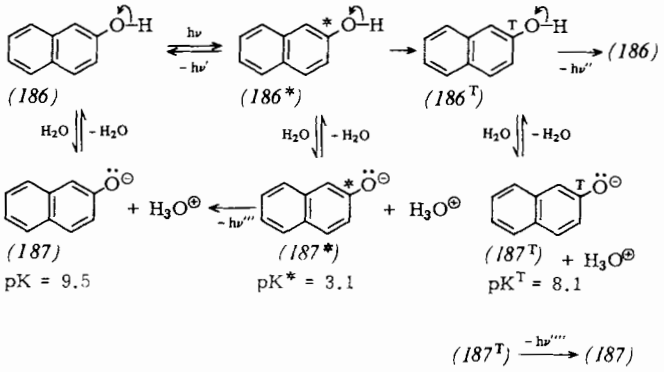
In solution the photodecomposition of diazonium salts may be used for the formation of phenols[115, 116], aryl halides[116], or other benzene derivatives (in alcohols perhaps *via* free radicals, following electron transfer from $X^{\ominus}$)[117, 118]. The yields are frequently higher than in the corresponding thermal processes.



(d)

The preparative possibilities are well represented by the syntheses of *(183)* (92%)[118] and *(185)* (40%)[119].

(182) *(183)*

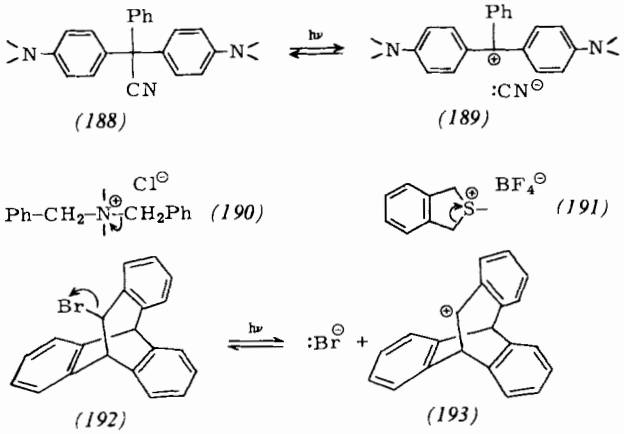


(184) *(185)*

3.2. β-Cleavage

The photolysis of substituted benzene derivatives may lead to cleavage not only of α- but also of β-bonds. Again this occurs either hetero- or homolytically. It is not always clearly distinguishable which of the mechanisms occurs, and it is to be expected that solvent effects will influence the polarity of β-cleavages.

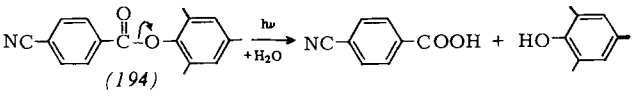
3.2.1. Heterolyses



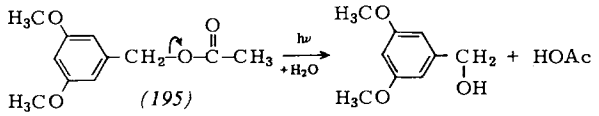
The acid/base reactions of electronically excited phenols [*e.g. (186)*][120] undoubtedly proceed heterolytically. These de- and re-protonations are adiabatic reactions (as in the analogous acid/base reactions of anilines, acridines, *etc.*). Thus, one obtains the fluorescing or phosphorescing anions, respectively, from the strong acids *(186*)* (singlet) or *(186^T)* (triplet)[120].

(186) *(186*)* *(186^T)* *(187)* *(187*)* *(187^T)*

pK = 9.5 pK* = 3.1 pK^T = 8.1

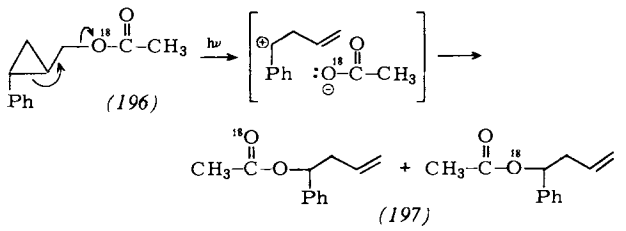


In polar solvents, leucomalachite green cyanide *(188)*[121] and further leuco cyanides may reversibly photolyze into ions. The photoreaction of *(188)* has been used in actinometry [quantum yield for the formation of *(189)*: $\Phi = 1.0$][121b]. In polar solvents benzylammonium- *(190)*[122] and benzylsulfonium salts [*e.g. (191)*][123] and the bromohomotriptycene *(192)*[124] undergo photoheterolysis. There is also little doubt,



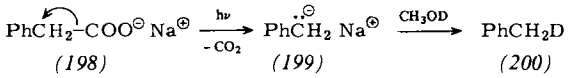
(188) *(189)* *(190)* *(191)* *(192)* *(193)*

that the photohydrolyses (-solvolyses) of aryl benzoates [*e.g. (194)*][125], benzylic esters [*e.g. (195)*][126], and the isomerization of labeled *(196)* to the isotopomers *(197)* in the ratio 1:1[127] have to be included here (see also Section 3.2.14).

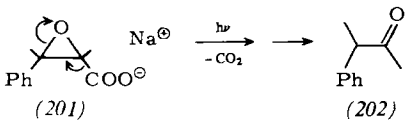


It is possible that even some photo-Fries rearrangements (see Section 4.1.2) proceed *via* ionic intermediates. Benzyl anions *(199)* are obtained on photodecarboxylation of aryl-

(194)



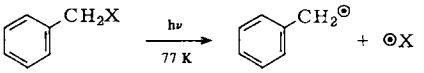
(195)



(196)

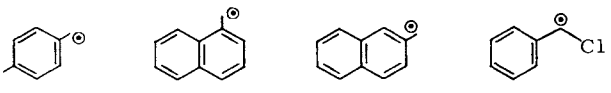
(197)

acetic acid salts *(198)*[128]. The yields of alkylbenzenes [*e.g. (200)*] are almost quantitative[128]. Finally the corresponding reaction of *(201)* proceeds with heterolysis of the oxirane ring[129].



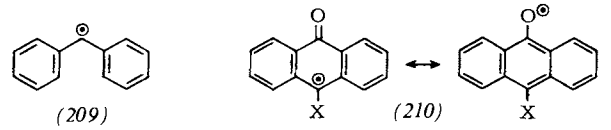
(198) (199) (200)

(201) (202)



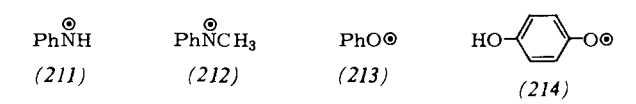
3.2.2. Homolysis into Radicals

Homolytic β-cleavages are apparently very widespread in the photochemistry of substituted arenes. Toluene and toluene derivatives [*e.g. (203)*] form benzyl radicals [*e.g. (204)*], which can be spectroscopically detected at low temperatures[130]. From the large number of examples studied,



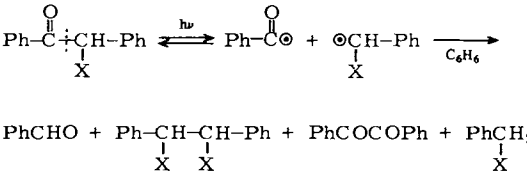
(203) (204)

X = H, Cl, OH, NH_2, CN, COOH, CH_2NH_2, CH_2OH, CH_2CH_2OH



(205) (206) (207) (208)

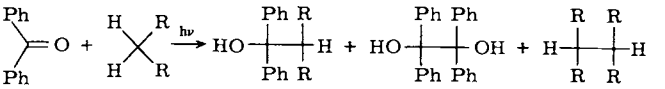
(209) (210)



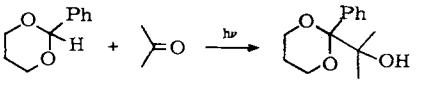
X = H, Cl, Br

(205), (206), (207), (208), (209)[130], and *(210)*[131] [cf. *(611), (612)* in Section 4.2.2] are included here. The hydrogen abstractions in these reactions require the absorption of two photons (electronically excited triplets)[132]. The corresponding photolysis of anilines and phenols generates the radicals *(211), (212)* (from methyl- or dimethylaniline), *(213)*, and *(214)*[130].

(211) (212) (213) (214)

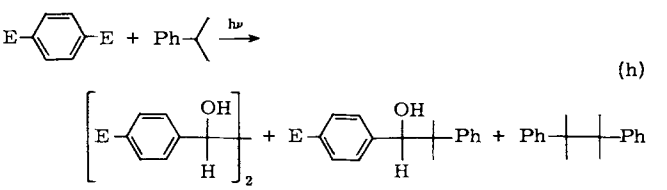


The generation of free radicals by photochemical β-cleavage is of major industrial importance (cf. radicals by α-cleavage in Section 3.1.1). Useful initiators for polymerization and crosslinking[58,59] are found especially among benzoin derivatives. These react in benzene [primarily according to Eq. (e)] to yield the usual, radical-derived products[133].



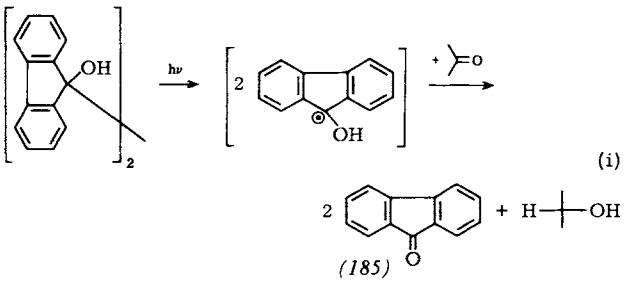
(e)

With these radical initiators (X = H, CH_3, Ph, OR) it is possible to crosslink, for instance, fumaric acid polyesters with styrene. On using 1—3% of initiator, hardening or drying of say 0.1 mm thick films, primings, coatings, and printing inks is achieved within seconds through illumination with high pressure mercury arcs, which provide outputs of 10 kW/m^2. This method is utilized commercially for finishing and coating furniture and automobiles, printing plates, microcircuits, and precision instruments.



The β-cleavages of toluene (-derivatives) upon direct excitation may be compared with ketone or benzoic ester sensitized reactions. As shown in Eqs (f)[134], (g)[135], and (h)[136], H-abstraction affords benzyl radicals, which dimerize or combine with further radicals.

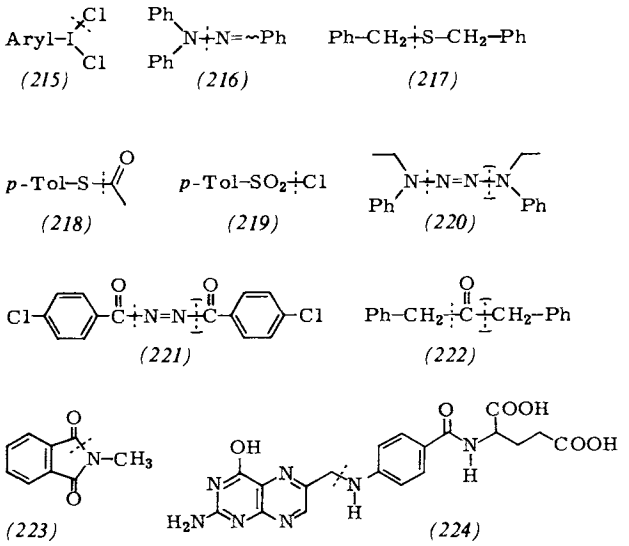
R = *p*-CH_3O-C_6H_4 (f)



(g)

(h)

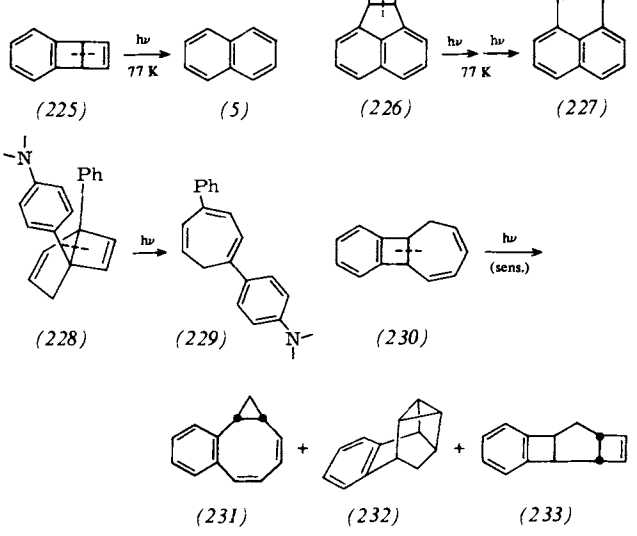
E = CO_2CH_3



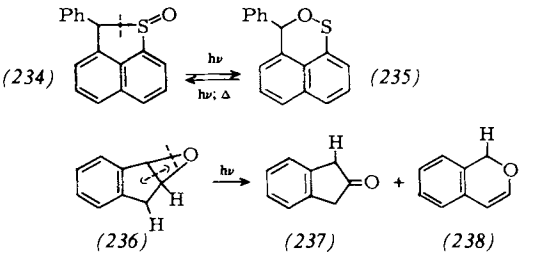
Aryl pinacols cleave at the central bond upon photolysis. The radicals formed can be oxidized by acetone [Eq. (i)][137]. Numerous other β-cleavages are known, the versatility of which can be demonstrated by some selected examples, such as *(215)*[138], *(216)*[139], *(217)*[140], *(218)*[141], *(219)*[142], *(220)*[143], *(221)*[144], *(222)*[145], *(223)*[146]. *(224)* (pteroylglutamic acid,

(i)

(185)



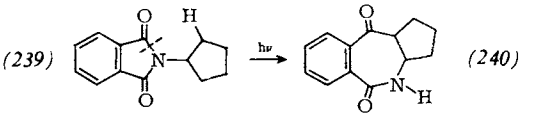
folic acid, vitamin B_c) also undergoes the corresponding photocleavage[147]. The resulting radicals undergo the usual reactions (*e.g.* addition to double bonds or oxidation with O_2, *etc.*).



(215) (216) (217) (218) (219) (220) (221) (222) (223) (224)

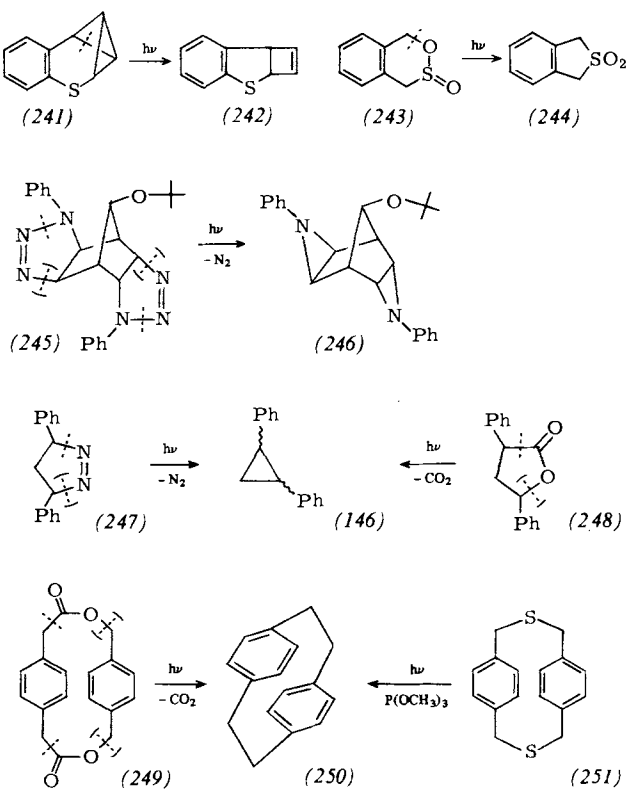
3.2.3. Ring Enlargement

Arenes, which are condensed to carbo- or heterocyclic rings, may undergo β-cleavage followed by ring enlargement *via* widely differing mechanisms. The reaction of *(225)* proceeds at 77 K to give initially electronically excited *(5)* (apparently adiabatic reaction), because product fluorescence [more intense than that of *(225)*] and product phosphorescence were measured[148]. For the formation of *(227)* at 77 K the triplet of *(226)* has to absorb a second photon[149]. *(228)* with *cis*-chromophores[150] undergoes cyclobutene opening without complications[151]. *(230)* rearranges to the ring-enlarged products *(231)* (17%) and *(232)* (17%) [there is also formation of *(233)* (60%)]. *(231)* (80%) predominates upon sensitized excitation[152]. Ring enlargement of *(234)* proceeds



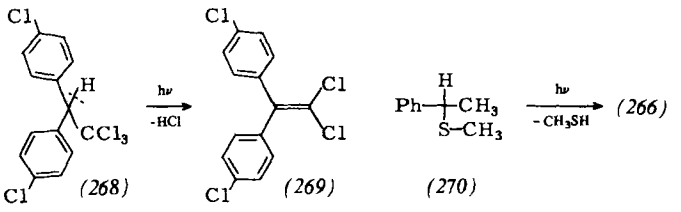
(225) (5) (226) (227) (228) (229) (230) (231) (232) (233)

(234) (235) (236) (237) (238)

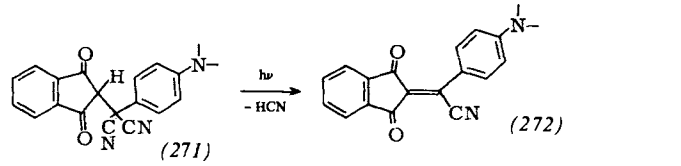


more slowly than photoracemization[153]. The syntheses of *(237)* (42%) and *(238)* (30%)[154] require H-shifts following the β-cleavages. In the reaction of *(239)* to give *(240)* (48%)[155] a C—H-bond adds to the original β-bond.

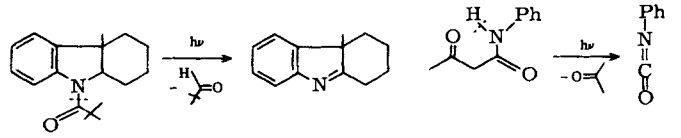
(239) (240)

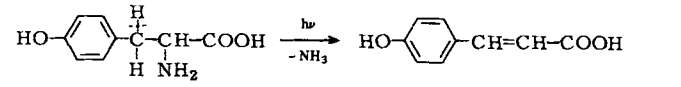


3.2.4. Ring Contraction



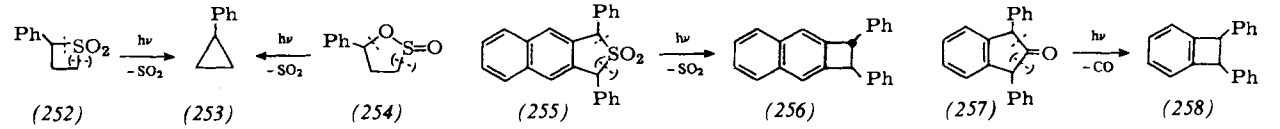
The ring contraction reactions of arenes, which are annelated to carbo- or heterocycles, may lead to isomerizations as in the case of *(241)*[156] and *(243)*[157] or more frequently to

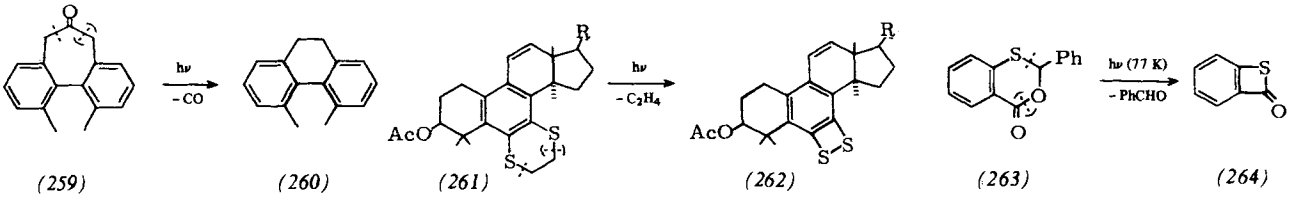


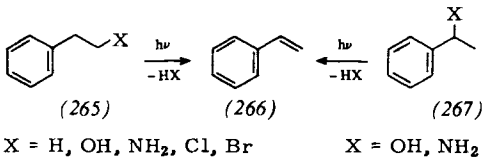


(241) (242) (243) (244) (245) (246) (247) (146) (248) (249) (250) (251)

fragmentations. Cleavable fragments are N_2 [synthesis of aziridines: *e.g. (245)→(246)*[158]; synthesis of cyclopropanes: *e.g. (247)→(146)*[159]], CO_2 [*(248)→(146)* (51%)[133b]; *(249)→(250)* (70%)[160]], sulfur (reductively) [*(251)→(250)* (80%)[161]; metacyclophanes[162]], SO_2 from sulfones and sultones [*(252)→(253)* (95%); *(254)→(253)* (95%)[157]; *(255)→(256)* (75%)[163]], CO [*(257)→(258)* (*trans* 89%, *cis* 11%)[164]; *(259)→(260)* in addition to racemization of *(259)*[165]], ethylene [*(261)→(262)* (91%)[166]], and benzaldehyde [*(263)→(264)*, which forms a dimer above 233 K][167]. Such syntheses are versatile and promise numerous further applications.

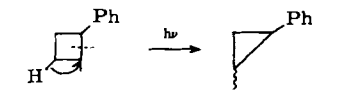


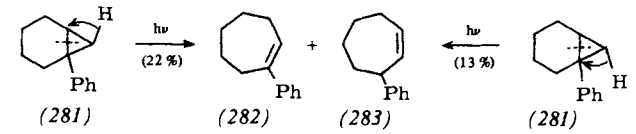




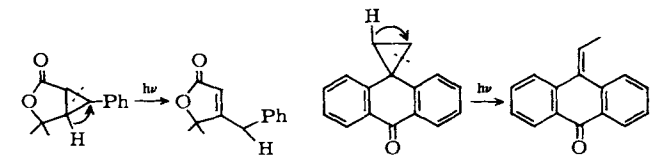
3.2.5. 1,2-Elimination

Photochemical β- and γ-cleavages of benzene derivatives can lead to 1,2-eliminations. Thus, ethylbenzenes with 2- *(265)* or 1-substituted side chains *(267)* form styrene *(266)* upon elimination of HX at 77 K[130]. This reaction type is of ecological importance in the photodegradation of DDT *(268)* (direct and sensitized excitation) to give DDE *(269)*[168]; it is observed with thioethers such as *(270)*[140a, 169], and it is used for the synthesis of merocyanine dyes *(272)*[170] or 3*H*-indoles

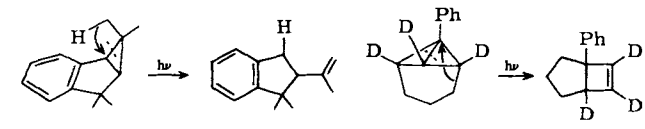




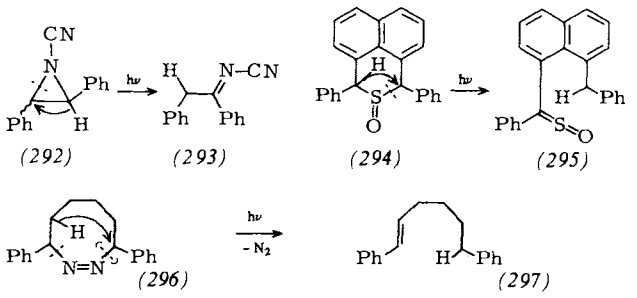
[*e.g. (274)*, 57%] from *N*-acylindolines *(273)*[171]. The elimination of acetone from *(275)*[172] has been termed a "Norrish type II-cleavage" (cf. p. 891 ff. in [101]). The photochemical elimination of NH_3 from tyrosine *(277)*[173] is of biological interest.



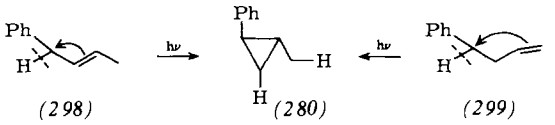
3.2.6. H-(Alkyl-)Migration



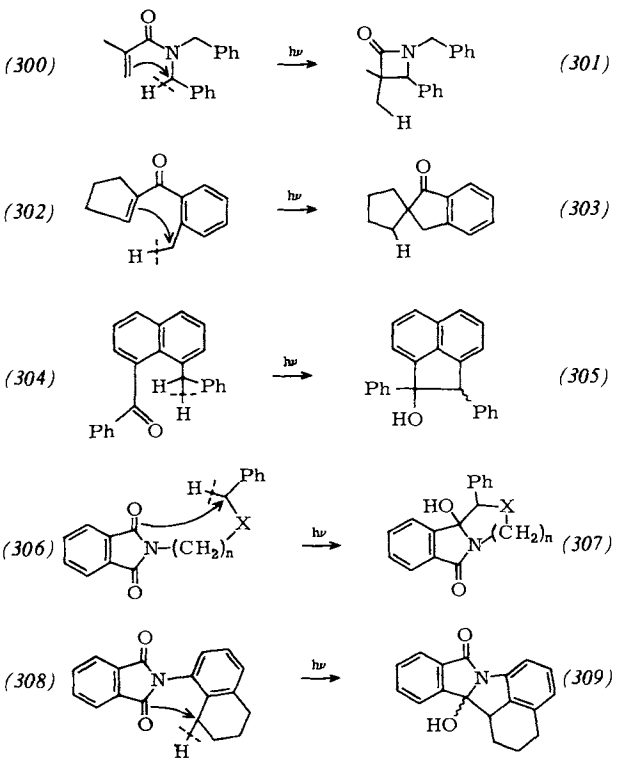
Subsequent to photochemical β-cleavages remote hydrogens may migrate to the centers of the cleavage. Phenylcyclobutane *(279)* undergoes ring contraction to give *(280)* (*cis* and *trans*)[174]. Phenylcyclopropanes such as *(281)*[175] and *(284)*[176] or spirocyclopropanes such as *(286)*[177] undergo ring opening and form a new double bond.



In the case of the homoindene *(288)* a hydrogen atom of the methyl substituent migrates[178], whereas the polycycle *(290)* undergoes an alkyl shift to give *(291)* (50%)[179]. Hydrogen migrations may be observed with aziridines *(292)*[180], sulfoxides *(294)* (>80%)[181], and even in the case of N_2-eliminations from cyclic azo compounds such as *(296)* [65% *(297)*][182].



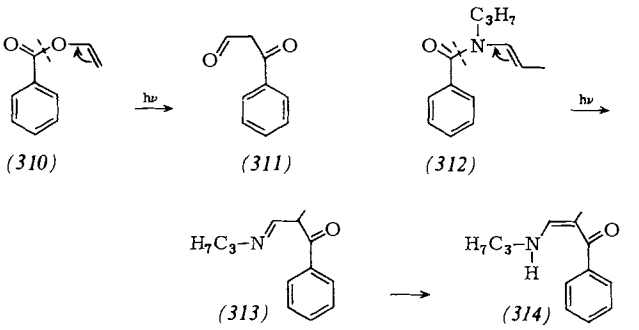
(292) (293) (294) (295) (296) (297)



3.2.7. Addition to Double Bonds

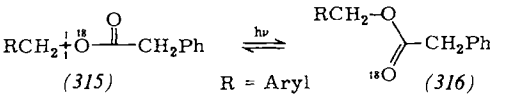
The reversal of the olefin-forming reactions which require hydrogen migration to the benzylic site [Section 3.2.6, *e.g. (281)→(283)*], leads to additions of benzylic C—H-bonds to double bonds. Thus, upon photolysis of *(298)*[183] and *(299)*[184] one obtains the cyclopropane *(280)*. This reaction

(298) (280) (299)



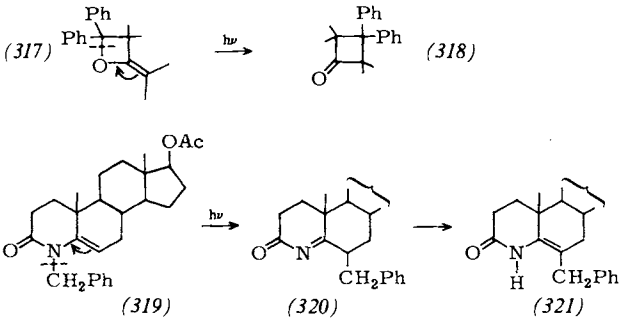
type may also be used for the synthesis of four- [*e.g.* β-lactam *(301)* (84%)][185] and five-membered rings [*(303)* (94%)][186]. From a synthetical point of view the extension of this process to C=O-double bonds of ketones and imides is particularly productive (cf. "Norrish type II cyclizations": p. 798ff. in [101]). Thus, one obtains the alcohols *(305)* (*E*-: 53%; *Z*-: 38%)[187] and the heterocycles *(307)* [X=S: 27%[188]; X=NCH$_2$Ph, $n=1$; 2; 3[189]] and *(309)* (77%)[190].

(300) (301) (302) (303) (304) (305) (306) (307) (308) (309)



3.2.8. 1,3-Shifts

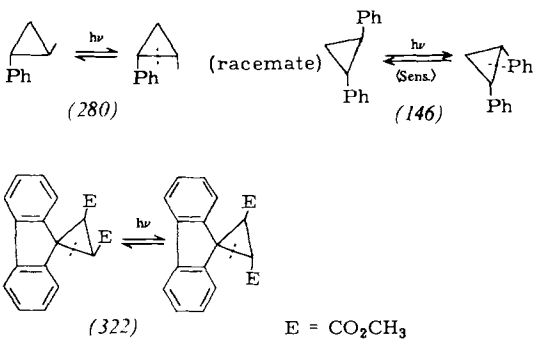
In β-cleavages with a 1,3-shift a benzoyl (or benzyl) group migrates to the opposite end of an allyl system. This happens in the case of photochemical Claisen rearrangements of benzoic acid vinyl esters [*e.g. (310)*][191] and amides [*(312)*][192].



(310) (311) (312) (313) (314)

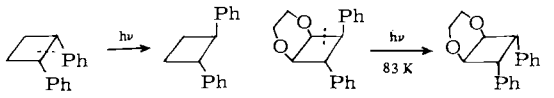
Benzyl (or 1-, 2-naphthylmethyl) groups in esters may also migrate from the ether-oxygen to the carbonyl-oxygen [*(315)→(316)*][128]. Similar rearrangements take place in benzyl enol ethers [*e.g. (317)*][193] and cyclic enamides such as *(319)* [to give 43% *(321)*][194].

(315) R = Aryl (316)



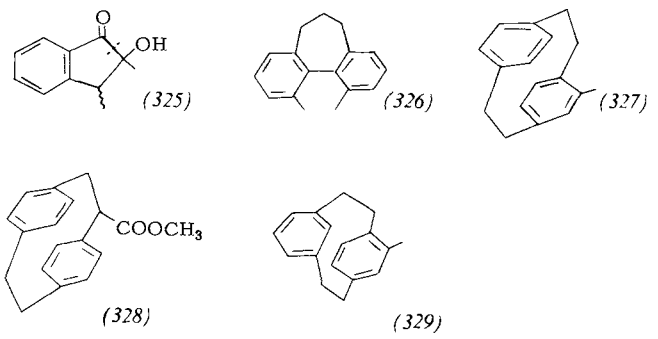
(317) (318) (319) (320) (321)

Phenyl allyl ethers rearrange only partially with 1,3-shift of the phenoxy group when irradiated[195]. Photo-Fries rearrangement to allylphenols predominates (see Section 4.1.2).



3.2.9. Stereoisomerizations

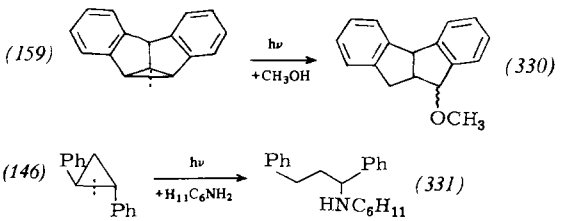
Stereoisomerizations of aryl-substituted small ring cycloalkanes require cleavage and, after (partial) internal rotation, reformation of β-bonds. Thus, *trans- (280)* reacts to give *cis-(280)* in the gas phase (quantum yield $\Phi=0.12$)[196]. The photoequilibrium *cis/trans-(322)* can be established in solution



(280) (racemate) (146) (322) E = CO$_2$CH$_3$

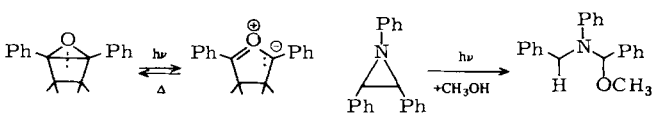
(97–98% *trans*)[197]. In the case of *(146)* the *trans/cis*-isomerization was studied with the chiral sensitizer *N*-[1-(1-naphthyl)ethyl]acetamide. In the photoequilibrium (*cis/trans* = 1.03) the antipode of the *trans*-form (spec. rotation: +28°), whose sensitization is geometrically more difficult[198], prevails. [2+2]-Cycloreversions (Section 3.2.11) compete with the geometric isomerizations of the cyclobutanes *(323)*[199] and *(324)*[150b]. The formation of *cis-(324)* succeeds upon photolysis of the *trans*-isomer even at 83 K, *i. e.* without thermal activation[150b].

(323) *(324)*



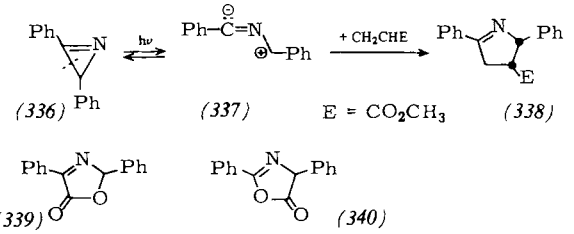
While the *trans/cis*-photoisomerization of *(325)*[200] necessarily requires ring opening, in the case of larger rings this could also proceed *via* conformational change without transient bond breaking. One may mention here the photoracemizations of *(326)*[165] as well as of the cyclophanes *(327)*, *(328)*, and *(329)*[201].

(325) *(326)* *(327)* *(328)* *(329)*



3.2.10. 1,3-Diradicals; Ylides

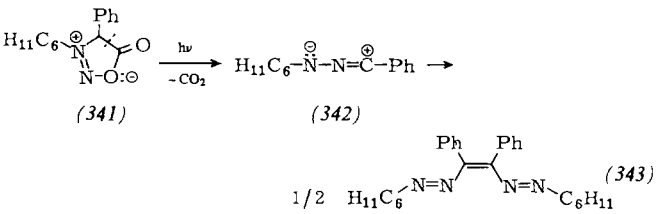
The photolysis of aryl-substituted cyclopropanes leads to β-cleavage. This produces 1,3-diradicals, which may add alcohols, amines, or dienophiles. Thus, dibenzosemibullvalene *(159)* gives *(330)* (*syn*-: 48%; *anti*-: 19%) in methanol[202] and *(146)* reacts in cyclohexylamine to give *(331)* (30%)[203].



(159) *(330)* *(146)* *(331)*

Upon photolysis (λ = 253.7 nm) in benzene or diglyme, *(332)* forms violet solutions, in which the presence of so-called "carbonyl-ylides" *(333)*[204] is surmised. From *(334)* one obtains the solvolyzing product *(335)* (>33%), in competition

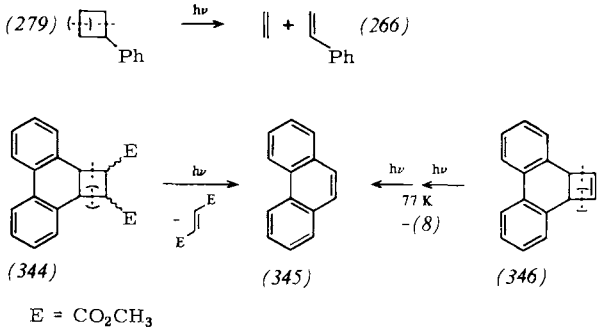
(332) *(333)* *(334)* *(335)*



with fragmentation to phenylcarbene and benzylidene aniline (24%)[205] (cf. Section 3.2.12). The reactive intermediates in the photolysis of phenyl-substituted azirines are conventionally formulated as nitrile ylides [*e.g. (337)*; 77 K: λ_{max} = 344, 244 nm]. From *(336)* and methyl acrylate one obtains *(338)*[206]. *(337)* may add CO_2 to give *(339)* and *(340)* (1:1)[207].

(336) *(337)* E = CO_2CH_3 *(338)*

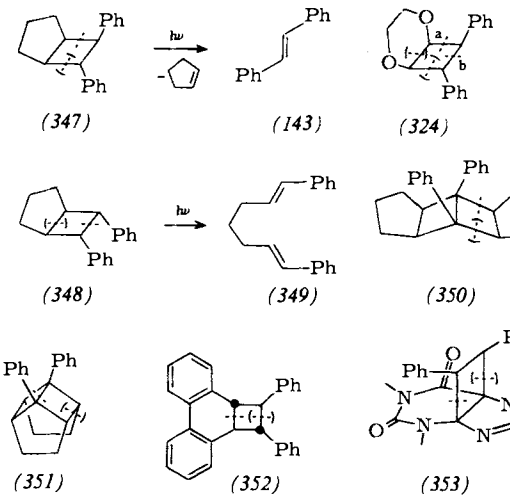
(339) *(340)*



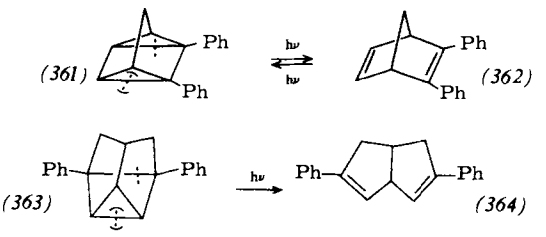
The photodecarboxylation of the phenylsydnone *(341)* yields the nitrile imine *(342)*, which dimerizes to *(343)*[208].

(341) *(342)* *(343)*

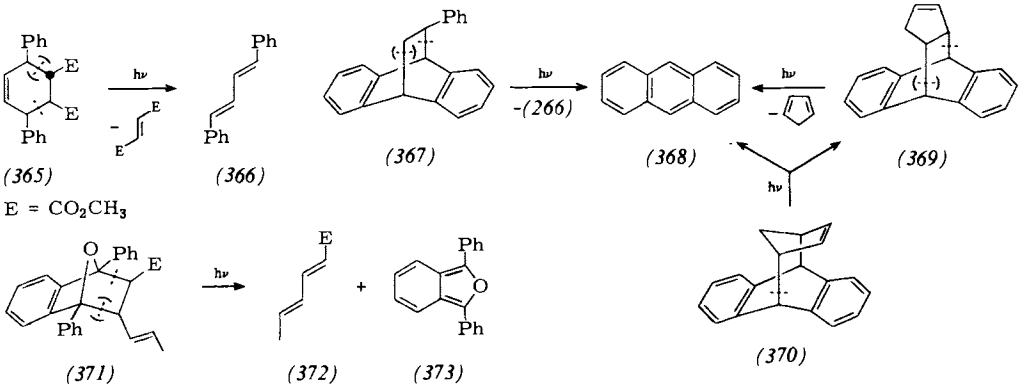
3.2.11. Cycloreversions (Without Carbene Formation)



Numerous examples for photocycloreversions are known in the series of aryl-substituted cyclobutanes, cyclohexenes, *etc.*[150,199,209]. Thus, *(279)* decomposes at 298 K and at 83 K to give ethylene and styrene *(266)*, and *(344)* reacts with high quantum yields (*trans*: Φ = 0.8; *cis*: Φ = 0.4)[210] to give *(345)*.

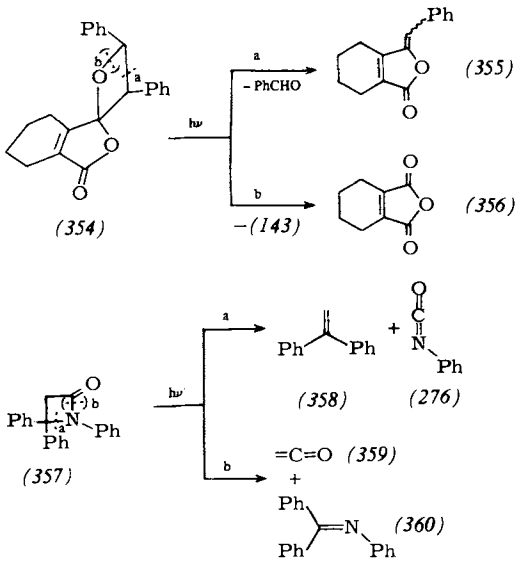


(279) *(266)* *(344)* *(345)* *(346)* *(8)*

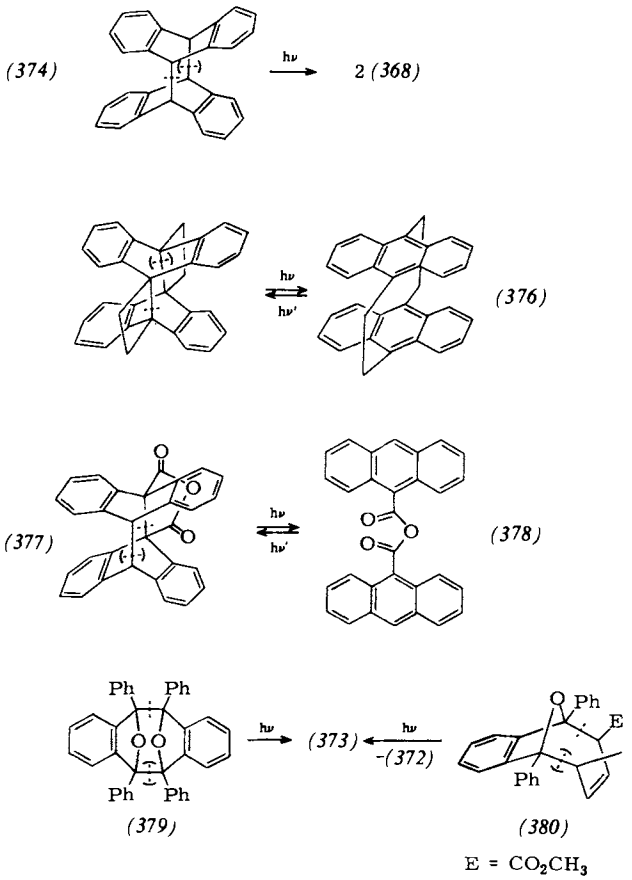


E = CO_2CH_3

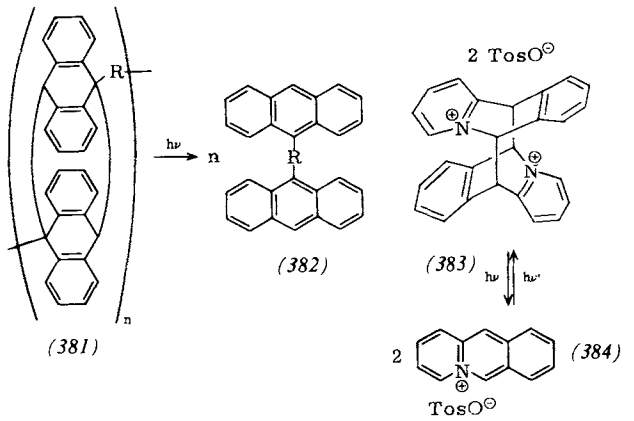
In the case of *(346)* the elimination of acetylene proceeds at 77 K biphotonically *via* the triplet[211]. Orientation selectivities are understandable and predictable on the basis of the *cis*-effect[212], which is inherent in the kinetically[98a] and stereochemically[150b] derived diradical mechanism. The best possible release of steric hindrance in the primary step is decisive, and not the stability of the diradical formed[150]. Thus, *(347)* reacts at 289 K and at 83 K to give *(143)* [in addition to *(348)*][150b], whereas *(348)* forms *(349)*[199]. *(324)* prefers the cleavage *a* [31% *cis-(324)* and 45% *(143)*], but because of the inevitable light absorption by the *anti*-phenyl group 24% of stereoisomeric 1,8-diphenyl-3,6-dioxa-1,7-octadienes (cleavage *b*) are also formed[150b]. *(350)*, *(351)*[199], *(352)*[213a], and *(353)*[213b] photocleave, as expected, only in the indicated



deactivation *via* unproductive ring motions. Photochemical retro-Diels-Alder reactions ([4+2]-type) then succeed at 298 K and 83 K, as do [2+2]-, [4+4]-, [4+6]-, *etc.* reactions. They show no peculiarities, as may be exemplified with *(365)*[199], *(367)*[209b], *(369)*[209b], and *(371)*[209a] (cf. also 40% O_2-abstraction upon short wavelength excitation of 9,10-diphenylanthracene endoperoxide[217]).

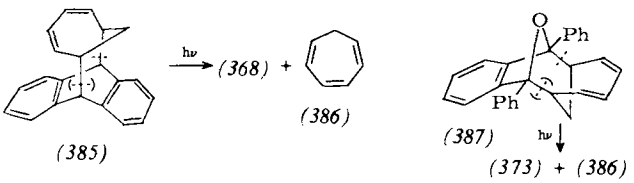


sense. Even spirooxetanes [*e.g. (354)*[214]; *a/b* = 17/83 (λ = 253.7 nm)][215] and β-lactams [*e.g. (357)*; *a/b* = 64/19][216] exhibit pronounced orientation selectivities in their [2+2]-photocycloreversions.



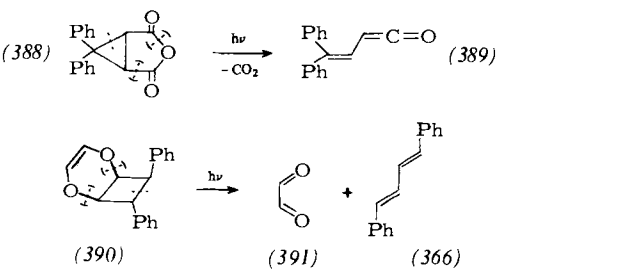
[2+2]-Photocycloreversions can be observed with the polycyclic compounds *(361)* and *(363)*, even at 83 K[98a].

Cyclovinylogous photocycloreversions must be promoted with steric or conformational effects, in order to avoid rapid

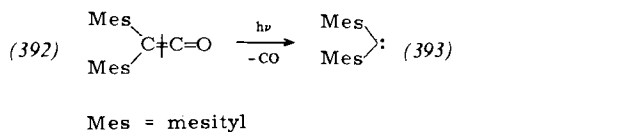


(370) undergoes [4 + 4]-photocycloreversion to *(368)* in addition to the 1,3-shift (allylic rearrangement) to yield *(369)*[209b]. Numerous further [4 + 4]-cleavages are known (reviews:[98a], [218]). Thus, anthracene dimers such as *(374)*[98a, 219], *(375)*[98a], and *(377)*[98a, 218] or rigid (di-)benzocyclooctadienes such as *(379)* and *(380)*[209a] photocleave at 298 K and 83 K, as indicated. These reactions promise practical applications. Thus, photolabile polymers such as *(381)* can be pro-

duced[220] and the system *(383)*⇌*(384)* is possibly suitable for holographic storage of information[221]: Starting with single crystals of the dimer *(383)* one may photoreversibly generate thermostable images or diffraction gratings (over several thousand cycles), which may be read outside their regions of UV-absorption, because of the considerable change in refractive index.

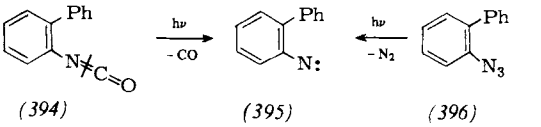


The reactions of *(385)* and *(387)* (298 K or 83 K)[222] are significant examples of [6 + 4]-photocycloreversions.

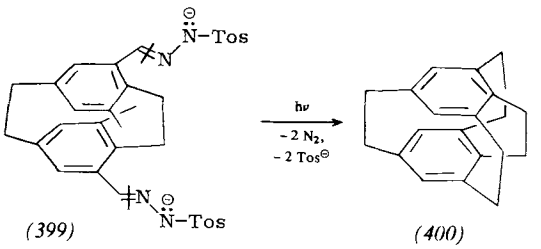


Altogether three bonds are cleaved in the [2 + 2 + 2]- and [4 + 2 + 2]-photocycloreversions of *(388)*[223] and *(390)*[150b], respectively. Further cycloreversions are mentioned in Sections 3.1.5, 3.2.12, 4.2.1, 4.2.3 ([6 + 6]-type), 4.3.4, and 4.3.5 (cycloadditions).

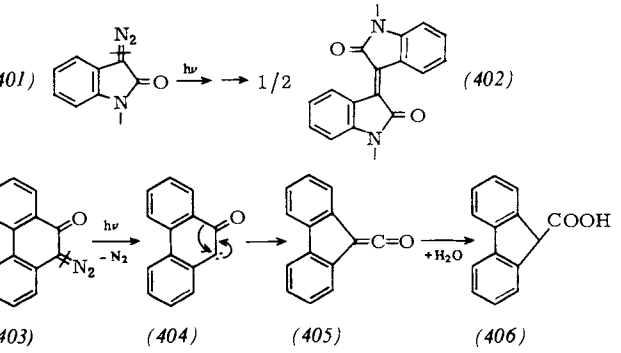
3.2.12. Carbenes, Nitrenes, and Other Low Valent Fragments



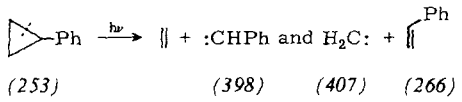
Upon cleavage of double bonds or cycloreversions of usually odd-numbered rings one obtains carbenes, nitrenes, or other low valent fragments such as CO, S, SO, SO_2, N_2, SiR_2. These reactions may be classified either with respect to the number of π-electrons (*i.e.* index 0 for carbenes *etc.*) or with respect to the number of atoms (*i.e.* index 1 for carbenes *etc.*).

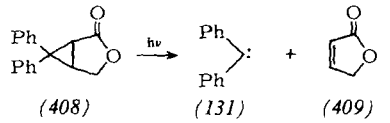


The type [0 + 0] ([1 + 1]) is represented by the cleavages of arylketenes [*(392)*[224]], -isocyanates [*(394)*[225]], -azides [*(396)*[226]], -diazoalkanes [*(397)*[227]], and -tosylhydrazone anions [*(399)*[228]]. The carbenes and nitrenes, thus formed, may undergo the usual dimerizations [*e.g. (393)*[224]], insertions [*e.g. (359)*→carbazole *(89)*[225, 226], *o*-biphenylcarbene → fluorene[229], *(399)*→*(400)*[228]], and additions to double bonds (yielding three-membered rings) or amines (*e.g.* phenylnitrene + NEt_3 → 2-(diethylamino)-3*H*-azepine[230]); upon matrix isolation at 10 K, 1-aza-1,2,4,6-cycloheptatetraene could be detected as an intermediate[230a] (review on the numerous synthetic applications: p. 1158—1282 in [101]).

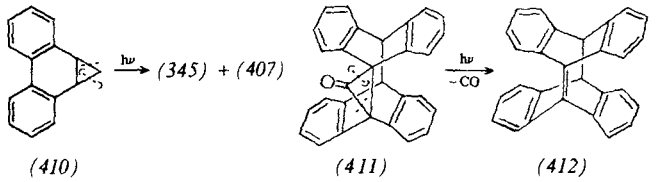


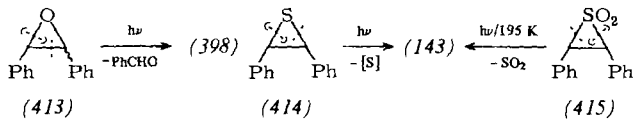
Mes = mesityl



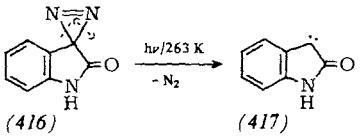


Arylacylcarbenes of suitable constitution may dimerize [*e.g.* dimethylisoindigo *(402)* (11%) from *(401)*][231] or undergo the Wolff rearrangement. From *(403)* one obtains *(406)* *via* the hydrolizable ketene *(405)*[232]. Owing to the solubility of carboxylic acids such as *(406)* in alkaline media, *o*-quinonediazides having long side chains find widespread application for offset printing plates in rotary press printing (Süs reaction)[59, 114c].



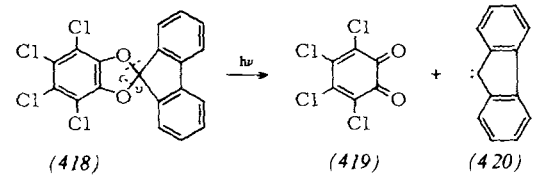


(253) (398) (407) (266)

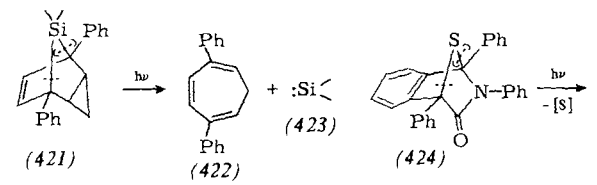


(408) (131) (409)

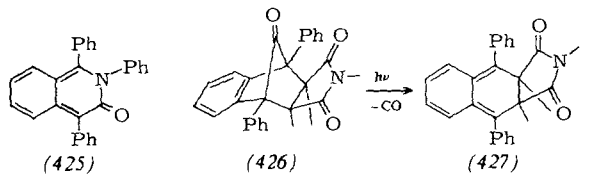
(410) (411) (412)



(413) (414) (415)

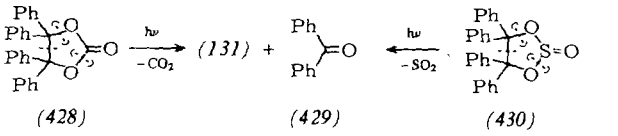


(416) (417)

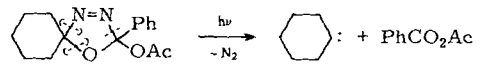


The type [2+0]- ([2+1]-) cycloreversions may be represented by the photolyses of *(253)*[233], *(408)*[223], *(410)*[234], *(411)*[235], *(413)*[236], *(414)*[237], *(415)*[238], and *(416)*[239], which demonstrate the variability and synthetic utility of such cleavages. The [4+0]- ([4+1]-) reactions of *(418)* (30%)[233], *(421)*[240], *(424)* (55%)[241], and *(426)* (80%)[242] are preparatively useful (related examples in Section 4.2.1). The [2+2+0]- ([2+2+1]-) cycloreversions of *(428)*[233], *(430)*[243],

(418) (419) (420)

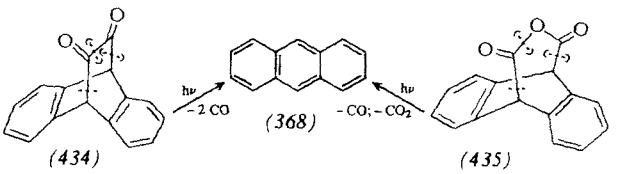


(421) (422) (423) (424)



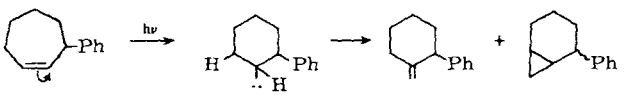
(425) (426) (427)

and *(431)*[159c] are significant in that they provide a new method for the generation of the carbenes *(131)* and *(432)*.



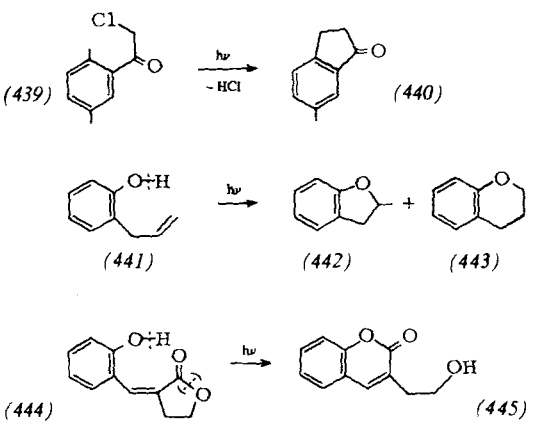
Even higher cyclovinylogous types are realized in the photolyses of *(434)*[244] ([4+0+0] or [4+1+1]) and *(435)*[245] ([4+2+0] or [4+2+1]).

(428) (429) (430)



(431) (432) (433)

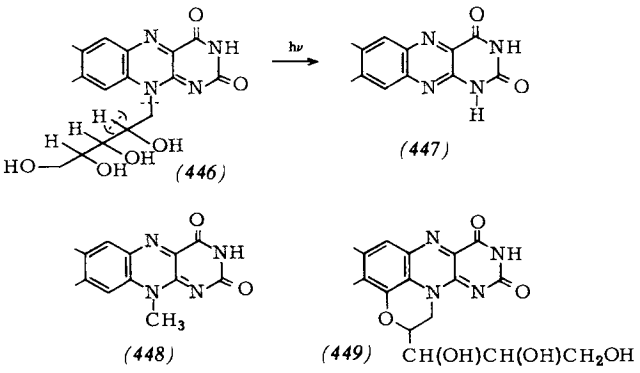
(434) (368) (435)



Further modes of formation of carbenes and nitrenes were described in Section 3.1.6 as α-cleavages. An interesting variant is the β-cleavage of *(283)* (α-cleavage w.r.t. the double bond). C—H-insertion affords the products *(437)* and *(438)*[175].

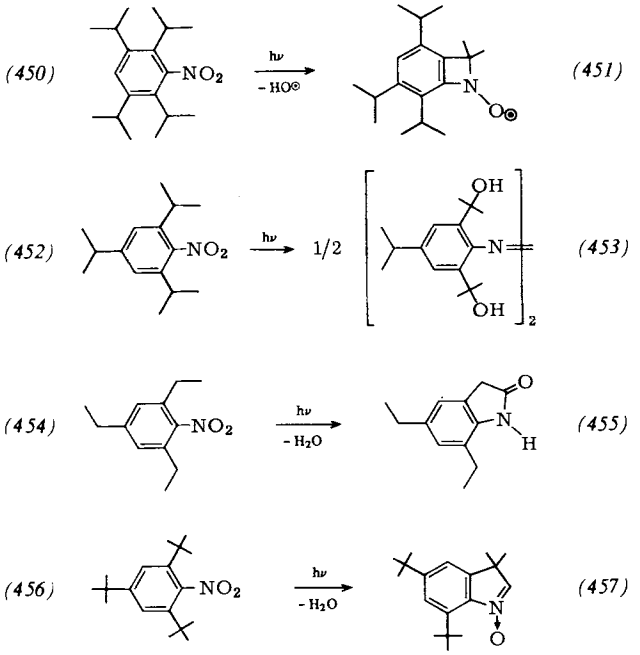
(283) (436) (437) (438)

3.2.13. Reactions of Substituents with Side Chains



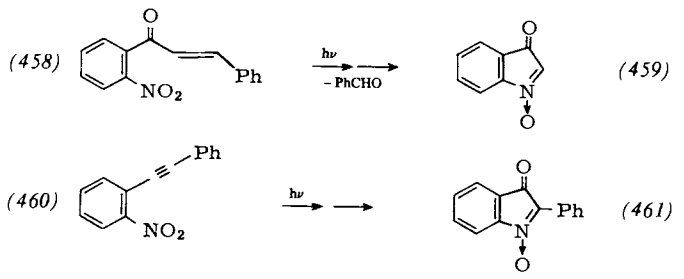
The cyclization with elimination of HCl from *(439)* presumably proceeds *via* an *o*-quinodimethane intermediate[246] (cf. Section 4.2.1). Phenolic OH-groups may add to double bonds of *o*-side chains. *(441)* gives *(442)* (24%) and *(443)* (2%)[247]. The photolysis of *(444)* leads to an intramolecular

(439) (440) (441) (442) (443) (444) (445)



transesterification[248]. Photochemical dealkylations of aminoarenes such as riboflavine (vitamin B_2, previously called lactoflavine) *(446)* to give lumichrome *(447)* (45%)[249] are of considerable importance. In alkaline solution, also lumiflavine *(448)*[249] and presumably *(449)*[250] (cf. Section 4.1.3) are formed. Several further (iso-)alloxazines can undergo corresponding dealkylations[250].

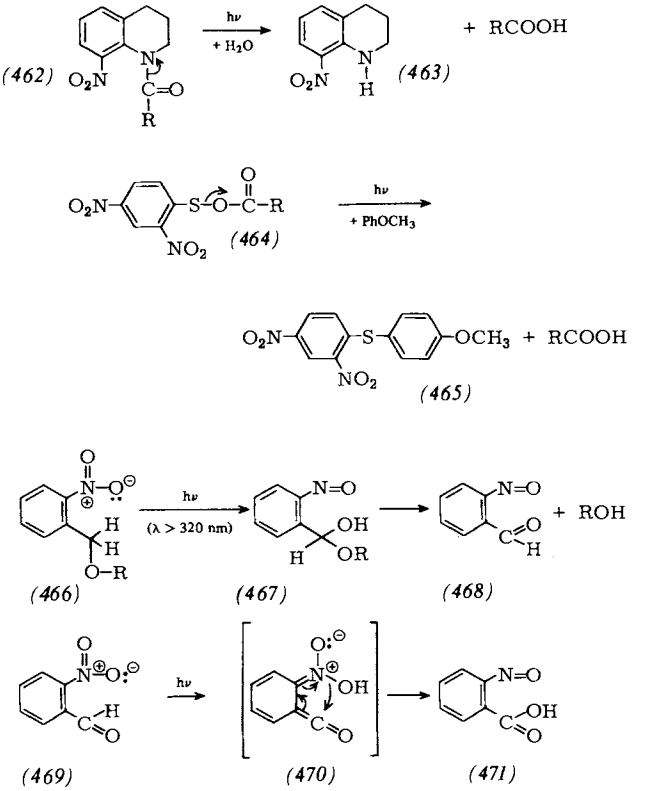
The modes of reaction of nitroarenes with *o*-alkyl substituents depends on the extent of steric hindrance[251]. In the



(446) (447) (448) (449) $CH(OH)CH(OH)CH_2OH$

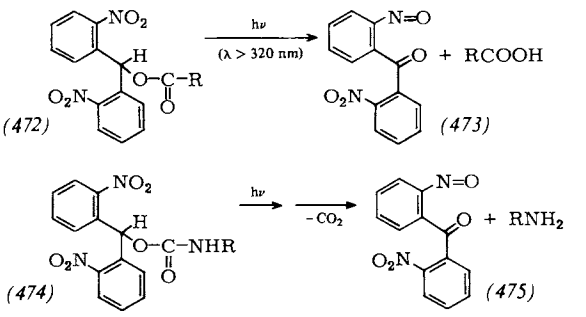
reactions of *(450)* and *(452)* benzylic H-atoms (β-cleavage) participate. However, it is also possible to transfer H-atoms, which are more remote from the benzene ring, to the nitro group, as is shown with the reactions of *(454)* and *(456)*. Un-

(450) (451) (452) (453) (454) (455) (456) (457)



doubtedly, in all these cases complicated multistep reactions are involved, in which *o*-quinoid *aci*-nitrocompounds and or diradicals presumably occur as intermediates (also an *o*-quinomethide oxime intermediate in the case of *(452)*→*(453)*; cf. Section 4.2.1). The synthesis of indoxyl *N*-oxide (indigo synthesis) from *(458)*[252] and of phenylisatogen *(461)* from *(460)*[253] have been long known. These need be mentioned here, even though there are several mechanistic alternatives.

(458) (459) (460) (461)

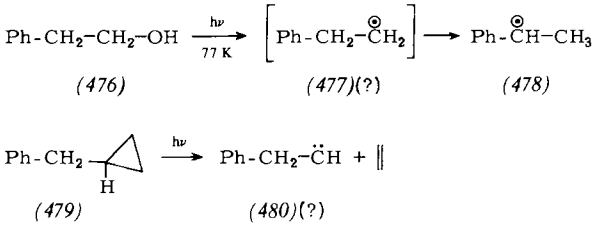


3.2.14. Light-Sensitive Protecting Groups

The principle of β-cleavage of substituted benzenes allows the protection of carboxylic acids, alcohols, and primary or secondary amines followed by mild and almost quantitative regeneration under neutral conditions, which is particularly suited to the requirements of peptide, carbohydrate, and nucleic acid syntheses. Thus, photohydrolyses of amides such as *(462)* (100%)[254] and heterolytic cleavages of the dinitrobenzenesulfenyl esters *(464)* (83–92%)[255] are possible. From the ether *(466)*, the alcohol (*e.g.* D-glucose, 100%) may be liberated photochemically[256]. The semiacetal *(467)* is presum-

(462) (463) (464) (465) (466) (467) (468) (469) (470) (471)

ably formed, in analogy to the transformation of *o*-nitrobenzaldehyde *(469)* into *o*-nitrosobenzoic acid *(471) via (470)*[257], after initial H-transfer to the nitro group (cf. Section 4.2.1) by OH-transfer with rearomatization. *(472)* and *(474)* correspondingly regenerate the carboxylic acids (100%) and amines (70—95%), respectively[258].

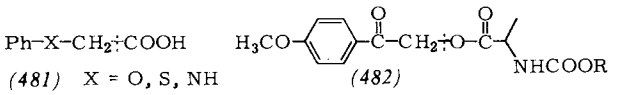


(472) (473) (474) (475)

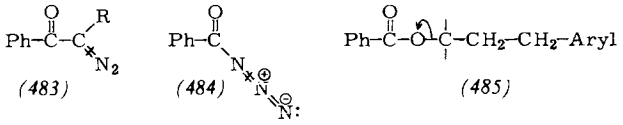
3.3. γ-Cleavage

It is not certain whether the electronic energy which is absorbed by benzene chromophores may cause dissociative vi-

brational excitations in γ-bonds separated by two insulating centers. The spectroscopic detection of *(478)* [in addition to β-cleavages of *(476)* (also formation of styrene) at 77 K][130] still does not prove an intermediate *(477)*. A more complicated mechanism [*e.g. via* styrene *(266)*] could operate, particularly as H-atoms are able to diffuse in ether/isopentane/ethanol-glass (EPA) at 77 K . Ethylene [and perhaps benzylcarbene *(480)*?] is formed from *(479)* besides the products of α- and β-cleavage[259]. Again this, by itself, does not constitute proof of a direct cleavage of two γ-bonds. Rather, ethyl-

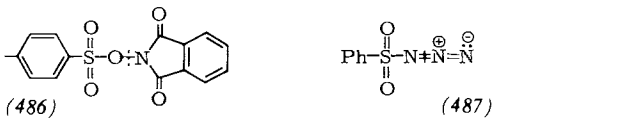


(476) *(477)*(?) *(478)*



(479) *(480)*(?)

ene could well be generated by reactions of alkyl or phenyl radicals (which form simultaneously) with the cyclopropane ring in *(479)*.



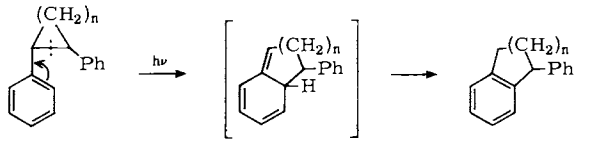
When the benzene chromophore is extended with O-, S-, NH-, C=O-, SO_2-groups, the γ-bonds (w.r.t. the benzene ring) may be cleaved photolytically. However, it is probably more correct to classify these reactions as β-cleavages of ethers (thioethers, amines) [*e.g.* phenoxyacetic acid *(481)*][260] and ketones [*e.g. (482)*[261], *(483)*, *(484)*][262], as α-cleavages of

(481) X = O, S, NH *(482)*

(483) *(484)* *(485)*

(486) *(487)*

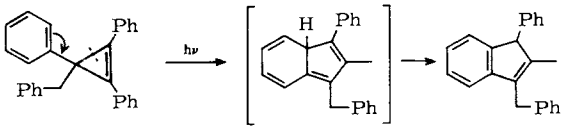
carboxylic esters [*e.g. (485)*][263] and amides [*e.g. (486)*][264], or as fragmentation of sulfonylazides [*e.g. (487)*][265], *etc.*, even though the influence of the arene ring on the absorption and on the secondary reactions (*e.g.* Wolff and Curtius rearrangement in the case of *(483)* and *(484)*, resp.) cannot be dismissed.



4. Reactions at the Benzene Ring

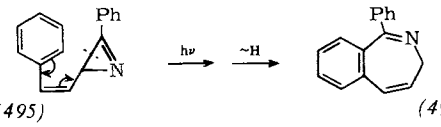
Benzene rings may be altered by participation of side chains leading to substitution, lengthening of the conjugated system, addition, cycloaddition, and cyclization. These processes provide a large number of preparatively and industrially important reactions.

4.1. Substitutions

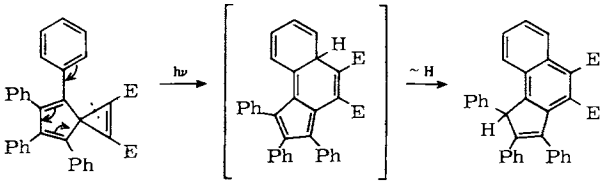


4.1.1. Alkylation with Three- and Four-Membered Rings

Phenylcyclopropanes and phenylcyclobutanes like *(146)* and *(323)* may, *inter alia*, rearrange to cyclic alkylation products such as *(489)*[266] and *(491)*[267] by parallel addition of a ring bond to the benzene ring (also describable as 1,3-alkyl shift) followed by H-shift (cross-addition in Section 4.3.2).



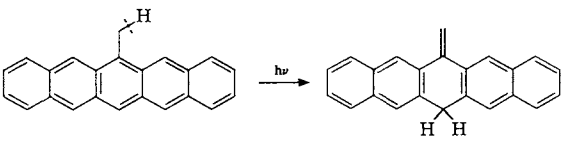
(146), n = 1 *(488)*, n = 1 *(489)*, n = 1
(323), n = 2 *(490)*, n = 2 *(491)*, n = 2



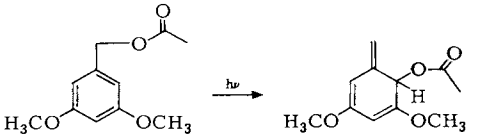
Arylcyclopropenes and -azirines like *(492)*[268], *(495)* [80% *(496)*][269], and *(497)* [40% *(499)*][270] react analogously.

(492) *(493)* *(494)*

(495) *(496)*



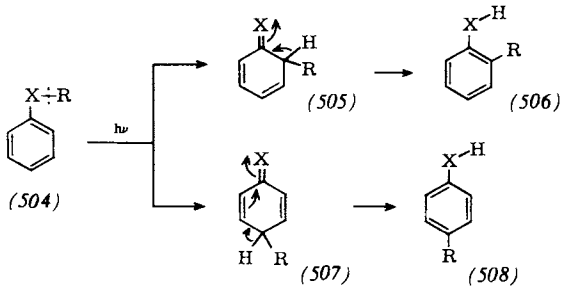
(497) *(498)* *(499)*

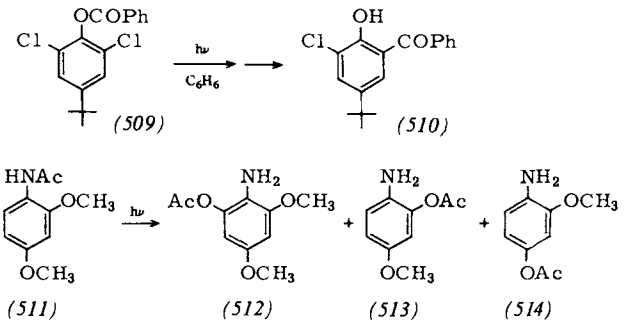


E = CO_2CH_3

4.1.2. Photo-Fries Rearrangement

On photolysis, 6-methylpentacene *(500)* forms the more stable isomer *(501)*[271], while the triene *(503)* (17%)[272] may be formed from *(502)*. These reactions are models for the primary reactions of photo-Fries rearrangements, which usually





(500) *(501)*

(502) *(503)*

proceed further to give the substituted arenes by rapid H-shift. One obtains *o*- and *p*-substituted products by 1,3- and 1,5-migration of R and counter migration of H. The radical migration proceeds primarily within the solvent cage[273]. However, due to cage escape, considerable amounts of inter-

the presence of oxygen[302b]. Also of practical interest are the corresponding rearrangements in polymeric phenyl esters, which are accompanied by chain destruction and yellowing[305].

Table 1. Photo-Fries rearrangements of phenyl esters, *N*-phenylamides and other aryl derivatives *(504)*. Yields referred to converted educt.

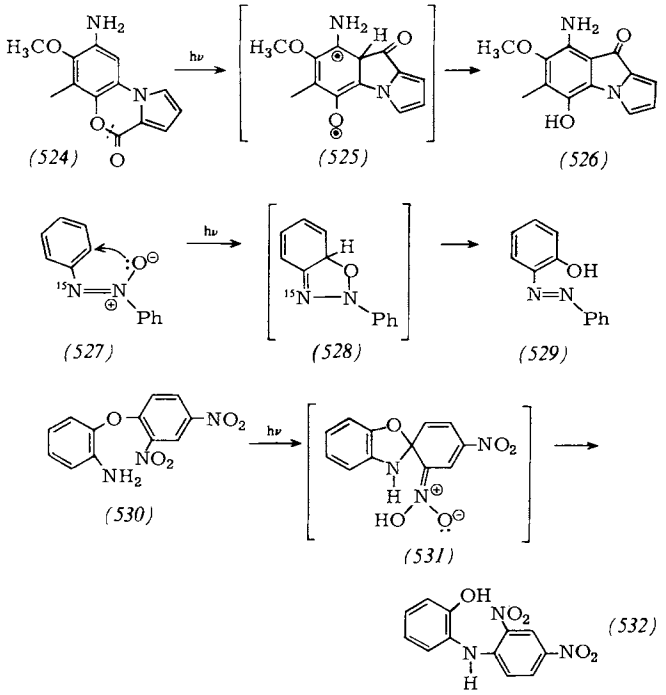
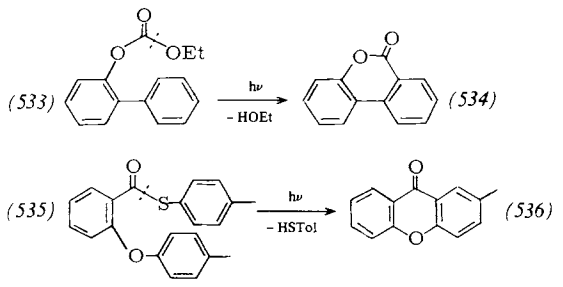
[a] Yield not quoted. [b] *p*-Methyl-*(504)*. [c] Yield referred to total educt. [d] 1-Naphthyl-X-R instead of phenyl-X-R. [e] *p*-Methoxy-*(504)*. [f] Final product is thioxanthone (selenoxanthone), the cyclization product of *(505)* with HCl-elimination. [g] *(505)* has been trapped with 2.2 M 2,3-dimethylbutadiene (37%).



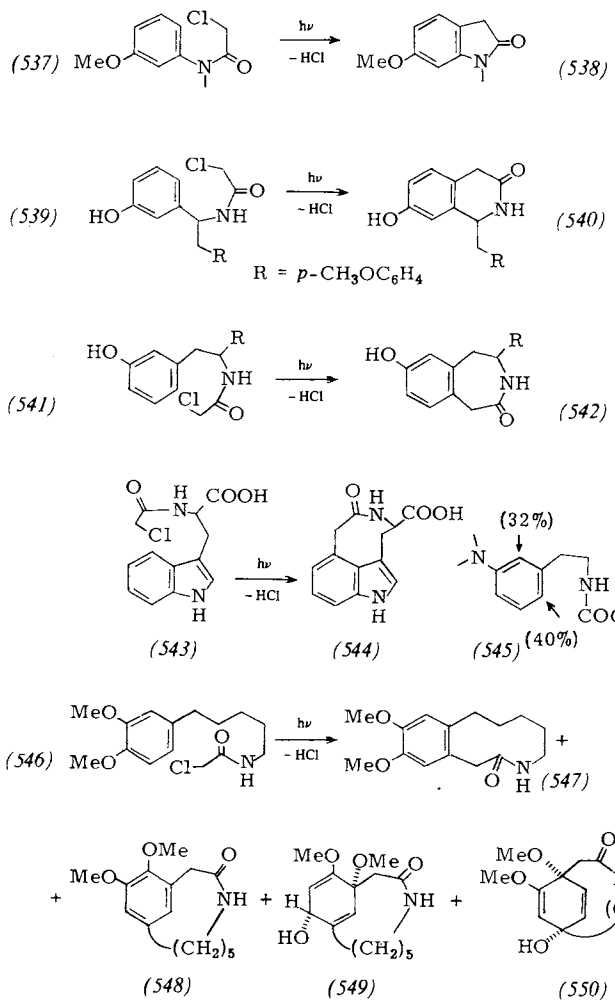
molecular products (Aryl—XH) are found in most cases. Improvements in the yields of rearranged products could be achieved by two-phase photochemistry with phenolic esters on silica gel[274]. In the gas phase one does not always obtain the same products[275] (cf. [195]). Table 1 summarizes the numerous possible variants[276, 277].

In place of hydrogen *o*-Cl, *o*-Br, *o*-I, and *o*-,*p*-methoxy substituents may also be displaced (presumably in the form of $X^{\oplus}$ and HCHO). Thus reactions of *(509)* to give *(510)*[279] and of *(511)* to give *(513)* and *(514)* in addition to *(512)*[300] have been observed.

Photo-Fries rearrangements have also been performed with various substituted arenes (and heterocycles). The synthetic utility may be demonstrated by the selected examples *(515)* [36% *(516)*, two-fold rearrangement][301], *(517)*[302a], *(520)* [$\Phi = 0.082$; 80% *(521)*][303], and *(522)* [32% *(523)*][304]. *(519)* is formed on irradiation of *N*-nitrosodibenzoazepine in



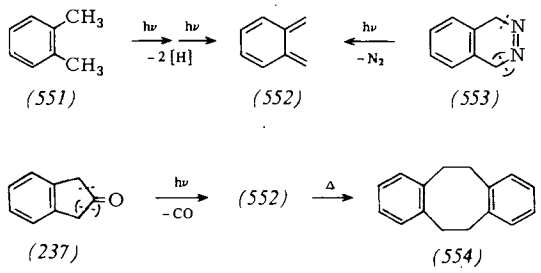
The *meta*-photo-Fries rearrangement of *(524)*[306] is sterically enforced. A close relationship exists between the Fries-, Wallach- (of azoxybenzenes to give *o*-hydroxyazobenzenes) and Smiles-rearrangements (of activated aminophenoxyethers to give arene amino alcohols). Thus, *(527)* rearranges *via (528)* to *(529)*[307] and *(530)* reacts correspondingly *via (531)* to yield *(532*[308].



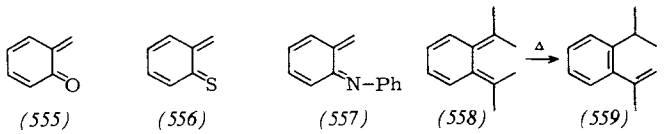
4.1.3. Cyclizing Substitutions

Together with numerous special cases of cyclizing substitutions[309], Friedel-Crafts acylations (cf. the reactions in Section 4.1.2) and alkylations are synthetically useful. Thus, the carbonic ester group in *(533)*[310] and the thiocarbonic ester moiety in *(535)* exhibit acylating action (86%)[311]. Particularly well studied are the productive cyclizing alkylations of

benzene rings possessing chloroacetylamide side chains which frequently lead to pharmacologically interesting lactams. Five-, six-, seven-, eight-membered, and even larger rings may be constructed. The benzene ring should, if possible, contain an activating *m*-hydroxy (*m*-methoxy; *m*-amino) substituent. In the presence of *p*-hydroxy groups, side reactions such as [4+2]-cyclodimerization of the intermediate predominate[312]. Characteristic examples are the syntheses of *(538)* (74%)[313], *(540)* (49%)[314], *(542)* (R=H: 71%, R=COOH: 25%)[315], and *(544)* (40%)[316]. *(545)* cyclosubstitutes in the *o*- (32%) and *p*-positions (40%) w.r.t. the dimethylamino substituent[317]. *(546)* in acetonitrile/water afforded 10% *(547)*, 16% *(548)*, and—by hydroxylation of the intermediary cations—23% *(549)* and 20% *(550)*[318].

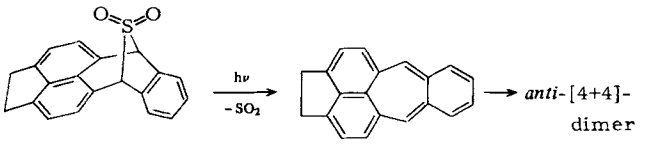


Formally related to these photochemical Friedel-Crafts alkylations are the cyclizations of phenyl enamines, enol ethers, and vinyl ketones in Section 4.4.2. H-migration leads to formation of five-membered rings.



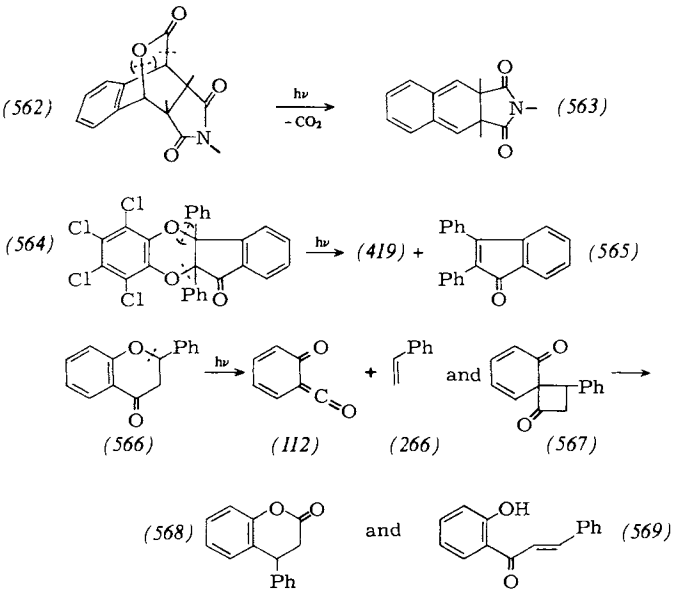
4.2. Formation of Quinodimethanes

4.2.1. *o*-Quinodimethanes (Photochromes, UV-Stabilizers)



On absorption of light, 1,2-disubstituted benzene derivatives may undergo β-cleavage and produce usually very labile *o*-quinodimethanes. Thus, at 77 K two hydrogen atoms are split off from *(551)*[319] or one nitrogen molecule from *(553)*[320]. *(552)*, which dimerizes to give *(554)*, may also be generated by photodecarbonylation of *(237)*[321]. According-

ly, the intermediates *(555)*[322], *(556)*[323], and *(557)*[324], which are potent addition partners (for dienophiles and nucleophiles), or *(558)*, which apparently immediately rearranges[325], may be generated by photodecarbonylation.

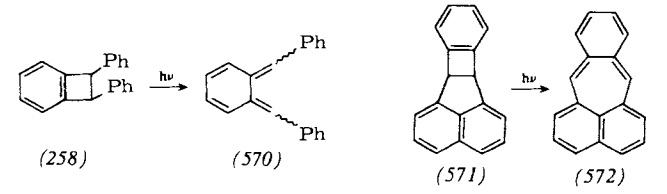


(555) *(556)* *(557)* *(558)* *(559)*

(560) *(561)* *anti*-[4+4]-dimer

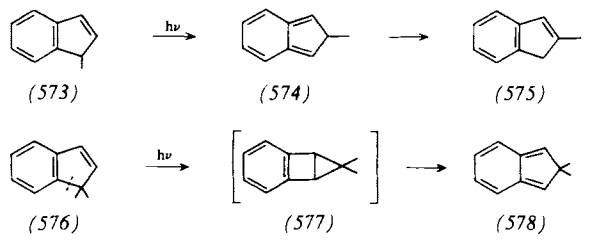
(561) has been formed by photochemical SO_2-elimination[326]. Suitably substituted tetrahydronaphthalenes such as *(562)*[327] or *(564)*[328] undergo photochemical retro-Diels-Alder reactions (cf. Section 3.2.11). The corresponding reaction of *(566)* to give *(112)* proceeds less selectively (4%). There is competing formation of the spirocyclobutane *(567)*, which rearranges to give *(568)* (15%) and *(569)* (20%)[329].

(562) *(563)*



(564) *(419)* + *(565)*

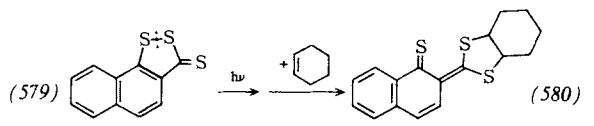
(566) *(112)* *(266)* *(567)*



(568) and *(569)*

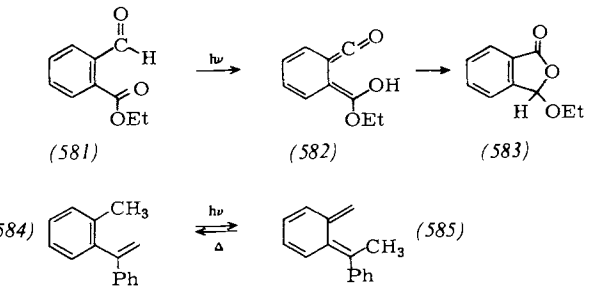
At 77 K numerous benzocyclobutenes undergo (frequently biphotonic) photolytic ring openings to form *o*-quinodimethane derivatives. Typical examples are the reactions of *(258)*[330] and *(571)*[331].

The photoisomerization of substituted indenes like *(573)* proceeds *via* isoindenes *(574)*[332]. It is not clear whether these involve β-cleavages. Thus, 1,1,3-triphenylindene undergoes 1,2-phenyl-migration to yield 1,2,3-triphenylindene[332b],



(258) *(570)* *(571)* *(572)*

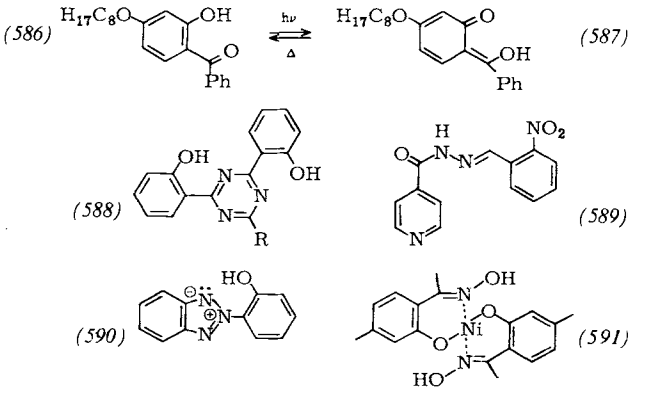
(573) *(574)* *(575)*



(576) *(577)* *(578)*

whereas *(576)* forms *(578)*[332] (*via* α-cleavage), which can be trapped with cyclohexene (cf. Section 3.1.7). Photolysis of *(579)* in cyclohexene gives *(580)*, which does not dimerize[333].

(579) *(580)*

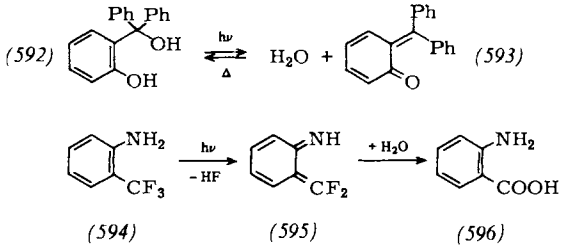


Hydrogen migrations between *o*-substituents are particularly versatile and productive for the generation of *o*-quinoid compounds. If secondary cyclizations, such as in the photolysis of *(581)*[334] are avoided, (see also benzocyclobutenols from *o*-alkylarylketones: p. 799 in [101]) one obtains photochromic systems (deuterium-labeled *(584)* undergoes H/D-exchange)[335].

(581) *(582)* *(583)*

(584) *(585)*

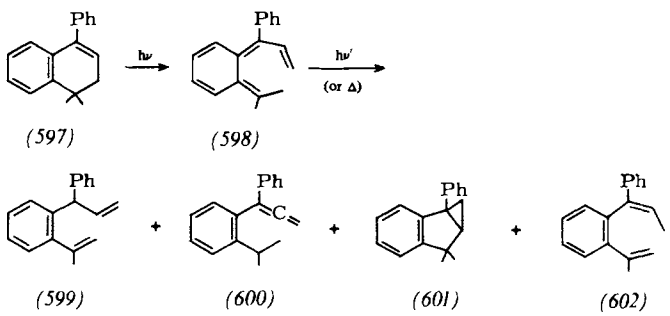
Useful hydrogen donors are methyl, formyl, hydroxyl, amino, and mercapto substituents. Hydrogen acceptors are C—C-double and triple bonds, carbonyl, imino, azo, cyano, nitro, nitroso (cf. Sections 3.2.13 and 3.2.14), sulfoxyl, and sulfonyl groups. The reactions can be used for light protection in the textile and cosmetics industries, because the photoproducts revert to the starting material with release of heat[336]. Among the technically applicable UV-stabilizers are *o*-hydroxybenzophenones such as *(586)*[336,337], *o*-hydroxyphenyltriazines *(588)*[336,338], and compounds such as



(586) *(587)*

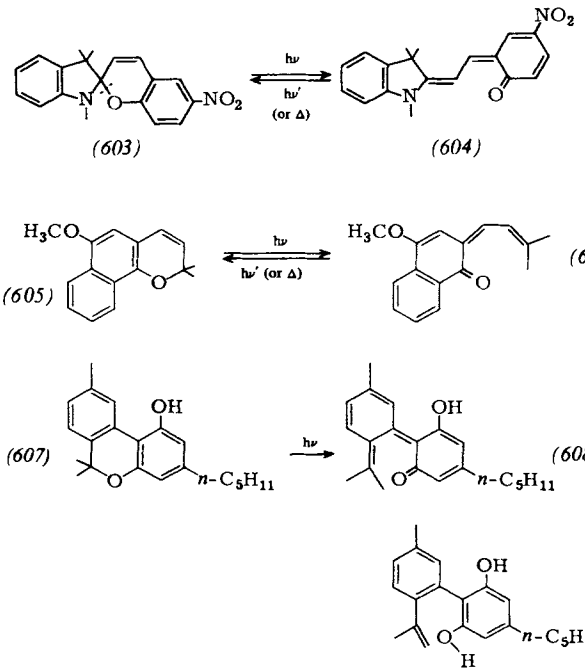
(588) *(589)*

(590) *(591)*



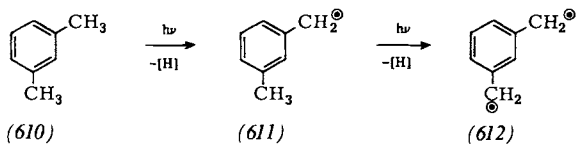
(589)[339], *(590)*[336,340], and *(591)*[336]. Trapping reactions of *o*-quinodimethanes generated by this technique (*e.g.* from *o*-benzylbenzophenone)[341] with dienophiles to produce tetrahydronaphthalenes are of preparative interest.

The reactions of *(592)*[342] and *(594)*[343] are useful 1,4-eliminations.



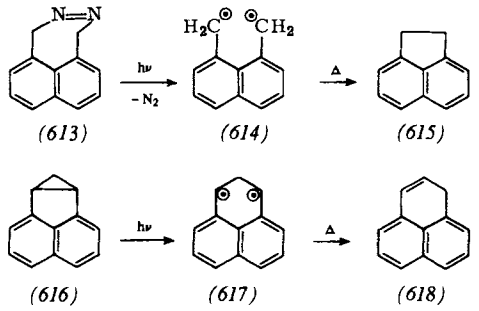
(592) *(593)* *(594)* *(595)* *(596)*

1,2-Dihydronaphthalene derivatives are an important source of conjugated *o*-quinodimethanes. At 92 K *(597)* photolyzes to give *(598)* (λ_{max} = 402 nm), which photochemically or thermally (above 143 K) forms *(599)*, *(600)*, *(601)*, and *(602)*[344]. This ring opening reaction occurs with 2*H*-1-benzopyrans[345], 2*H*-1-benzothiopyrans[346], 2*H*-1-benzothiopyran 1,1-dioxides[347], and 1,2-dihydroquinolines[348]. The photochromic spiropyrans [*e.g. (603)*][349] and spirothiopyrans[346] are particularly important. The photochemically formed merocyanine dyes [*e.g. (604)*] may be bleached with light of longer wavelength. This may be utilized for reusable photochromic films[350]. The ring opening of the plant constituent lapachenol *(605)* leads to the yellow *(606)*, which is quite stable at ambient temperature[345]. Whether or not this is used by plants for regulation purposes, has apparently not been widely investigated. Cannabinol *(607)* reacts photochemically to give cannabinodiol *(609)*[351]. Presumably an intermediate *(608)* occurs.



(597) *(598)* *(599)* *(600)* *(601)* *(602)*

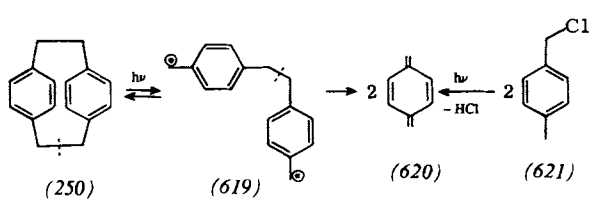
(603) *(604)* *(605)* *(606)* *(607)* *(608)* *(609)*



4.2.2. *m*-Quinodimethanes

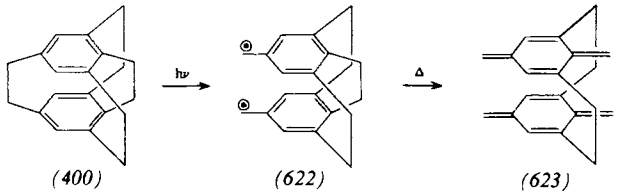
β-cleavage upon irradiation of *m*-xylene *(610)* at 77 K yields the *m*-xylyl radical *(611)* and *m*-quinodimethane *(612)*, which absorbs and fluoresces at shorter wavelengths[319]. Similarly 1,8-naphthoquinodimethanes like *(614)*[352] and *(617)*[353] have to be generated by photochemical β-cleavage at 77 K (N_2-elimination or cyclopropane opening), because of facile thermal rearrangements. Accord-

(610) *(611)* *(612)*



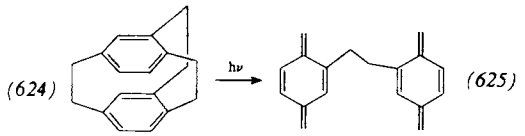
ing to latest ESR measurements *m*- and *peri*-quinodimethanes do not occur in the singlet[353] but in the triplet configuration[354].

(613) *(614)* *(615)* *(616)* *(617)* *(618)*

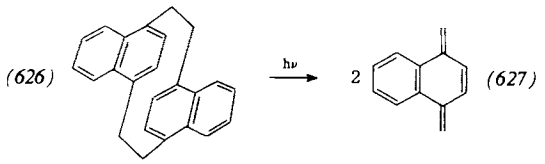


4.2.3. *p*-Quinodimethanes

[2.2]Paracyclophanes can undergo [6 + 6]-photocycloreversions if energy consuming ring motions are mechanically hindered by using highly viscous media[355]. Thus, on short wavelength irradiation (253.7 nm) of *(250)* at 77 K one obtains the UV and fluorescence spectra of the 1,4-diradical *(619)*, which upon thawing to about 90 K forms *(620)*[356]. Irradiation at 83 K immediately produces *(620)*[355], which is

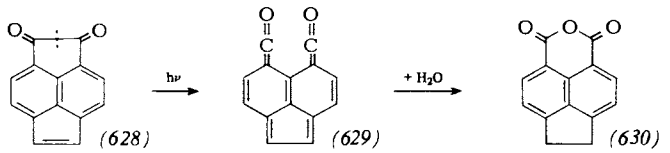


(250) *(619)* *(620)* *(621)*

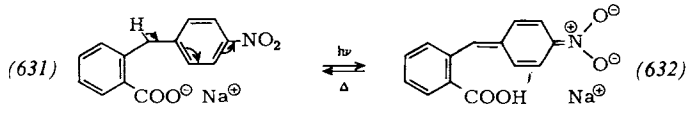


also obtained by HCl-elimination from *(621)*[222]. It is important for the diradical theory, that even *cisoid* representatives like *(622)*, which experience considerable interaction be-

(400) (622) (623)

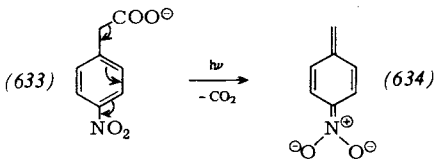


(624) (625)



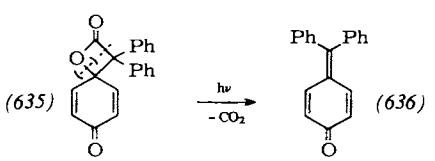
(626) (627)

tween the radical centers, are stable at 77 K or 83 K and form bis-*p*-quinodimethanes such as *(623)* at considerably higher temperatures[356]. Further representatives for [6 + 6]-photocycloreversions are found with *(624)*[222] and *(626)*[355] (at 83 K).

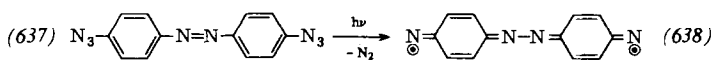


(628) (629) (630)

Only one β-cleavage is required for the formation of *(629)*[357].



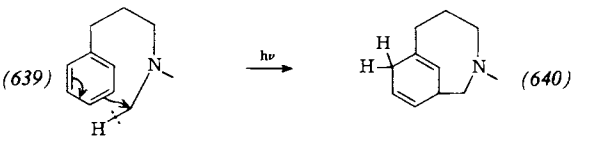
(631) (632)



(633) (634)

The same is true for the (presumably heterolytic) reaction of *(631)* to give the yellow dye *(632)*[358] and for the decarboxylation of *(633)*[359]. The decarboxylation of *(635)*[360] and the photolysis of the diazide *(637)* to generate the triplet *(638)*[361] also belong here.

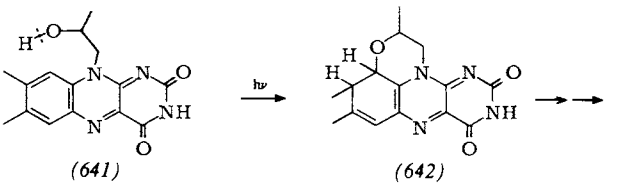
(635) (636)



(637) (638)

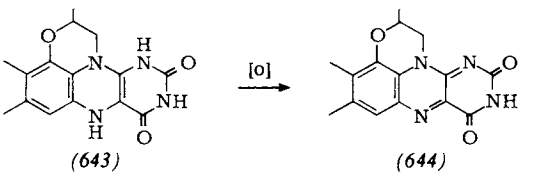
4.3. Additions to the Benzene Ring

Electronically excited benzene rings are readily susceptible to additions. Particularly favorable conditions exist, if R—H or C—C bonds, carbenes, or double bonds in side chains or other benzene rings are geometrically well placed w.r.t. the absorbing chromophore.



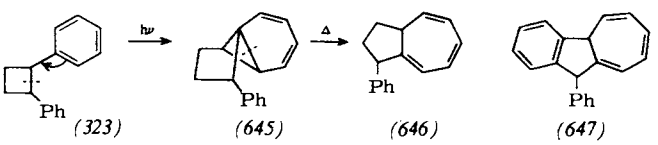
4.3.1. Addition of C—H and O—H Bonds

(639) photocyclizes by 1,4-C—H-addition at the positions 2 and 5 to yield *(640)*[362]. *(641)* undergoes O—H-addition



(639) (640)

(especially in presence of high concentrations of divalent anions: *e.g.* 2 M $SO_4^{2\ominus}$ presumably first giving *(642)*, which is stabilized by H-migration to form *(643)*. Subsequent oxidation (O_2) affords *(644)* (cf. the side product *(449)* from vitamin B_2)[363]. These reaction modes deserve a systematic study, as do also conceivable intramolecular additions of S—H and N—H bonds (the photocyclization of 3-[ω-(anilino)alkoxy]nitrobenzenes[364] involves the nitro group in the addition step; cf. also [309b]).

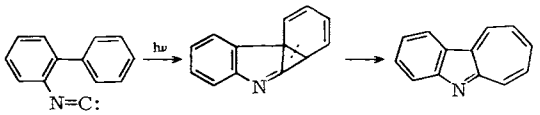


(641) (642)

(643) (644)

4.3.2. Addition of C—C Bonds

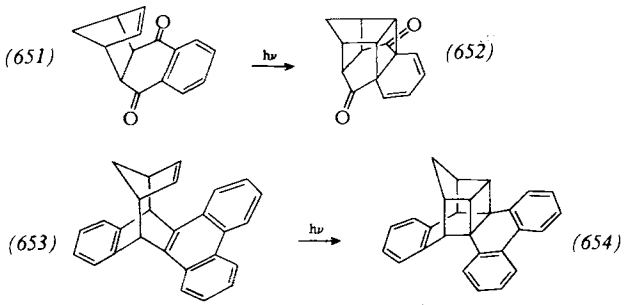
Absorption of light by 1,2-diphenylcyclobutanes leads to cross-addition of the β-bond to a phenyl group (also describable as a 1,2-shift). Thus, *(323)* reacts to give the norcaradiene derivative *(645)*, which in turn isomerizes to *(646)*[267] [basically a 1,2-H-shift in *(645)* might also produce *(491)*].



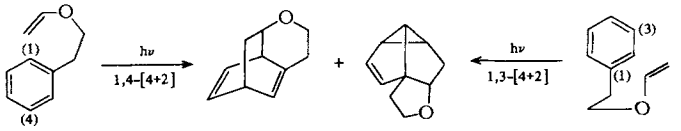
(323) (645) (646) (647)

The same reaction type applies to 1,2,3,4-tetraphenylcyclobutanes[365] and 2,3-diphenylcyclobutenes[366], as shown *e.g.* by the synthesis of *(647)*.

4.3.3. Addition of Carbenes

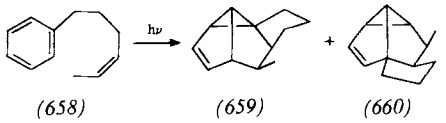


If carbene or nitrene fragments are generated (*e. g.* photochemically) at a favorable distance from the aromatic ring, thermal [2+0]- ([2+1]-) cycloadditions or C—H-insertions follow (cf. Sections 3.1.6 and 3.2.12). *o*-Biphenyl isocyanide *(648)* only undergoes a [2+0]-addition to the adjacent benzene ring upon irradiation. One finally obtains *(650)*[367].

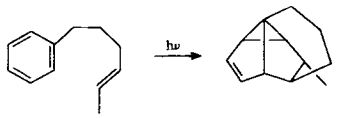


(648) *(649)* *(650)*

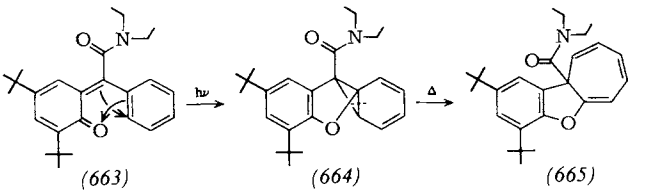
4.3.4. Addition of Double Bonds



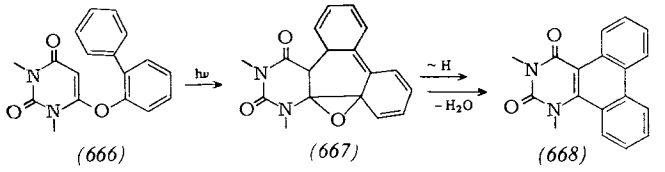
Suitably oriented double bonds in side chains may be added to electronically excited benzene rings. The reactions of *(651)* [80% *(652)*][368a], *(158)* [with subsequent rearrangement to give 75% *(160)*][101] (cf. corresponding syntheses of benzoazepines, benzoxepins[98a,b], and formation of 1-phenylindane from 1,3-diphenylpropene[101]), and *(653)* to *(654)*[368b] have to be classified as [2+2]-additions.



[4+2]-additions may proceed according to the 1,4-, and also to the 1,3-mode, as is the case with *(655)*. One obtains the polycycles *(656)* and *(657)* in the ratio 15:1[369]. *(658)* forms the isomers *(659)* and *(660)*, while *(661)* forms *(662)*[370]. *(663)* cyclizes (cross-addition of the [4+2]-type) to give *(664)* [and thence *(665)*][371], while in *(666)* the double bond adds to the diene system of the biphenyl moiety[372]. A [4+4]-addition has been observed with *(669)*. The highly

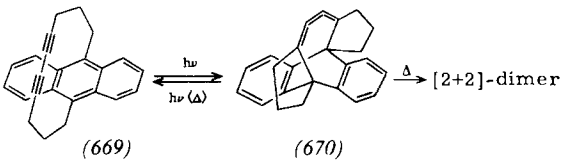


(655) *(656)* *(657)* *(655)*



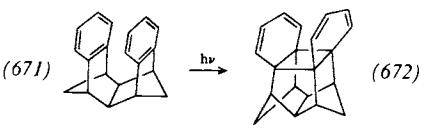
(658) *(659)* *(660)*

(661) *(662)*

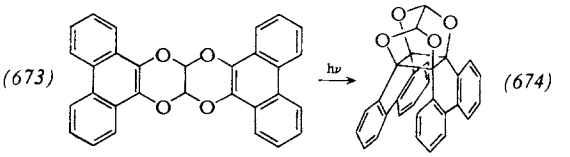


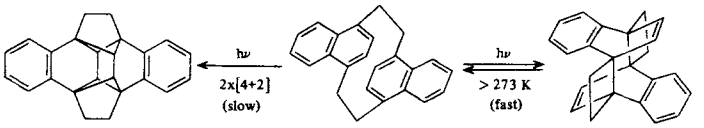
(663) *(664)* *(665)*

(666) *(667)* *(668)*



strained *(670)* could be spectroscopically detected at 77 K. It dimerizes at 293 K to a [4]radialene derivative[373].

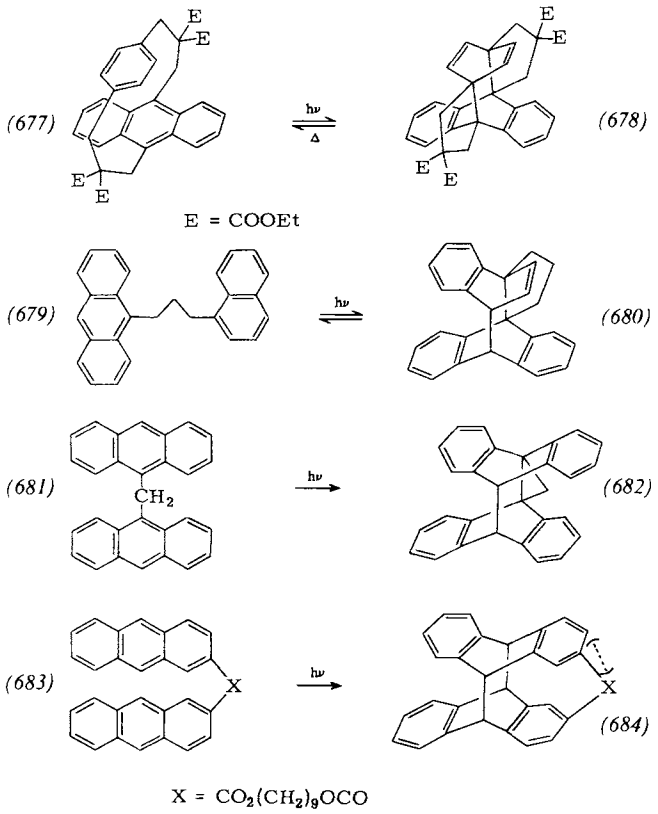


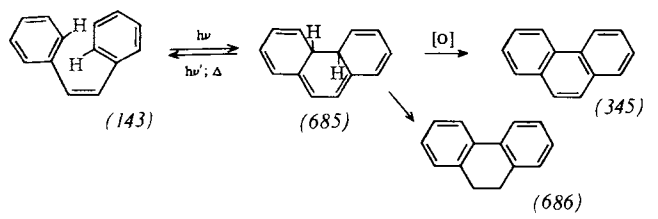


(669) *(670)*

4.3.5. Addition of Benzene Rings

Intramolecular cyclodimerizations of arenes, which are linked together through side chains, are numerous. Thus, [2+2]- [*(672)*[374], *(674)*[375]], [4+2]- [*(675)*[376]], and [4+4]-additions [*(676)*[377]] can be readily accomplished.

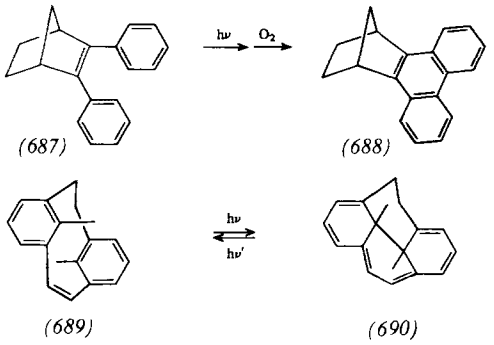




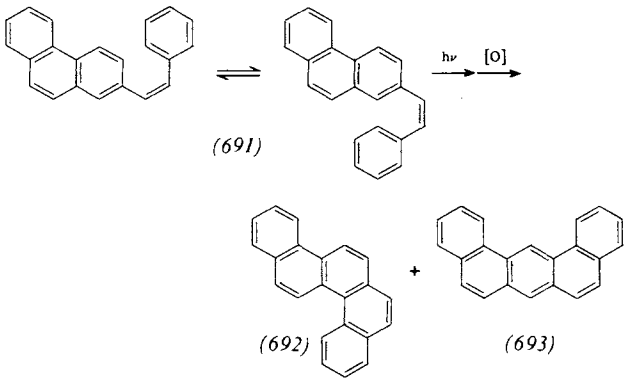
(675) *(626)* *(676)*

Intramolecular [4+4]-photocycloadditions involving anthracene moieties are particularly productive [*e. g.* *(376)*→*(375)*; *(378)*→*(377)*][98a]. *(376)*, which after light absorption must be designated as an excimer, does not react in one step but, according to kinetic analysis, *via* a (diradical) intermediate *(375)* ($\Phi_{forw.}=0.30$; $\Phi_{back}=0.6$; no fluorescence)[98a]. Hence, it is to be assumed, that (diradical) intermediates will be involved also in the further, less favorable examples. The suitability of such [4+4]-cycloadditions with exothermal reformation of the starting material for energy storage purposes has been investigated[218,378]. As typical representatives, the reactions of *(677)*[379], *(679)*[380], *(681)*[218], and *(683)* [to give both isomers *(684)*][381] may be mentioned.

4.4. Cyclizations of Conjugated Systems

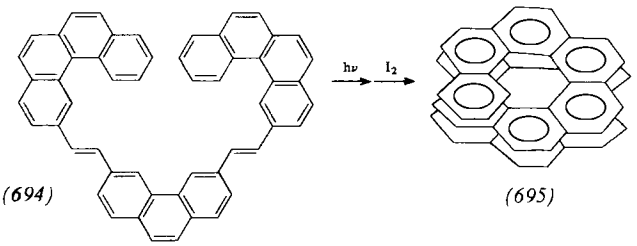


Cyclizations of the type hexatriene ⇌ cyclohexadiene[2] may be performed with *cis*-stilbene *(143)* (in photoequilibrium with *trans*-stilbene) and related conjugated aromatic compounds. Initially, polyenes of the *trans*-4a,4b-dihydrophenanthrene type *(685)* are formed, which usually are thermo- and photolabile[382] and which are irreversibly oxidized by *e.g.* I_2 or O_2 to give phenanthrene (derivatives) *(345)*[383].



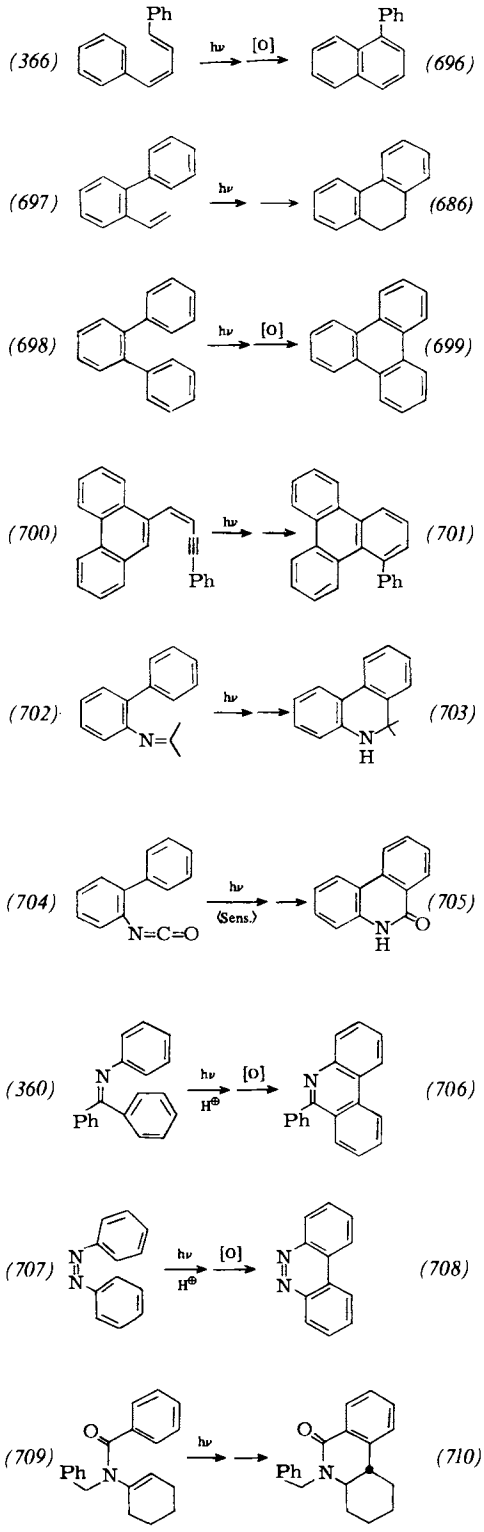
This phenanthrene synthesis fails only occasionally due to isomerization of the intermediate. 9,10-Dihydrophenanthrenes *(686)* are formed primarily under the influence of electron-withdrawing substituents X[150a,384]. Even analogously generated 4b-methyl-4a,4b-dihydrophenanthrenes are readily oxidized by oxygen to give phenanthrene derivatives[385]. The current number of applications also in pharmaceutical and natural product chemistry is impressive[386]. Only a few typical representatives shall be mentioned here. A compilation of the possibilities for structural variation would appear more important.

4.4.1. Six-Membered Ring Formation

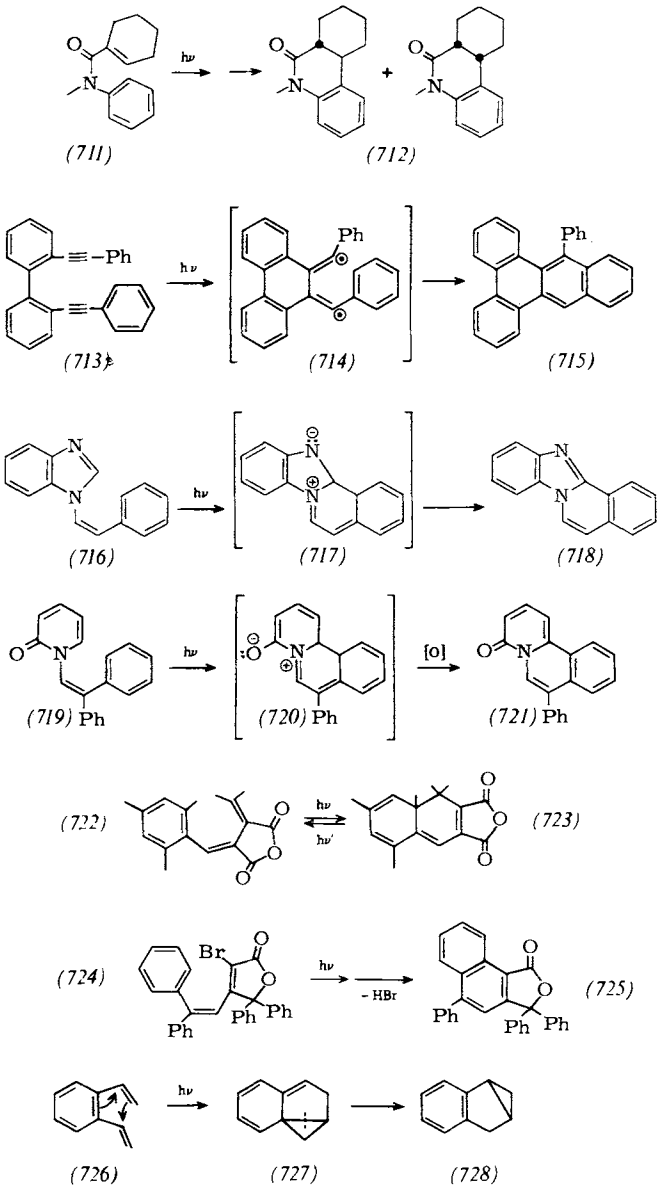


Oxidative cyclizations of fixed *cis*-stilbenes such as *(687)* ($\Phi = 0.43$)[98a] occur with particularly high quantum yields (cf. 1,2-bis(β-naphthyl)cyclopentene[387]). The same is true for the cyclization of *(689)* ($\Phi = 1.0$) to the photolabile ($\Phi' = 0.02$) dihydrophenanthrene derivative *(690)*[388].

Stilbenes whose central double bond is not part of a ring form homogeneous phenanthrenes, if substituted in the 2,2'-, 4,4'- or α,α'-position. Otherwise mixtures of isomers are obtained. Steric effects govern the preferred orientation for the ring closure[389]. Thus, 2-styrylphenanthrene *(691)* affords *(692)* and *(693)* in the ratio 99:1[390].



Numerous helicenes, which occur with right- and left-handed helices, have been synthesized, *e.g.* tridecahelicene *(695)* (52%)[391].

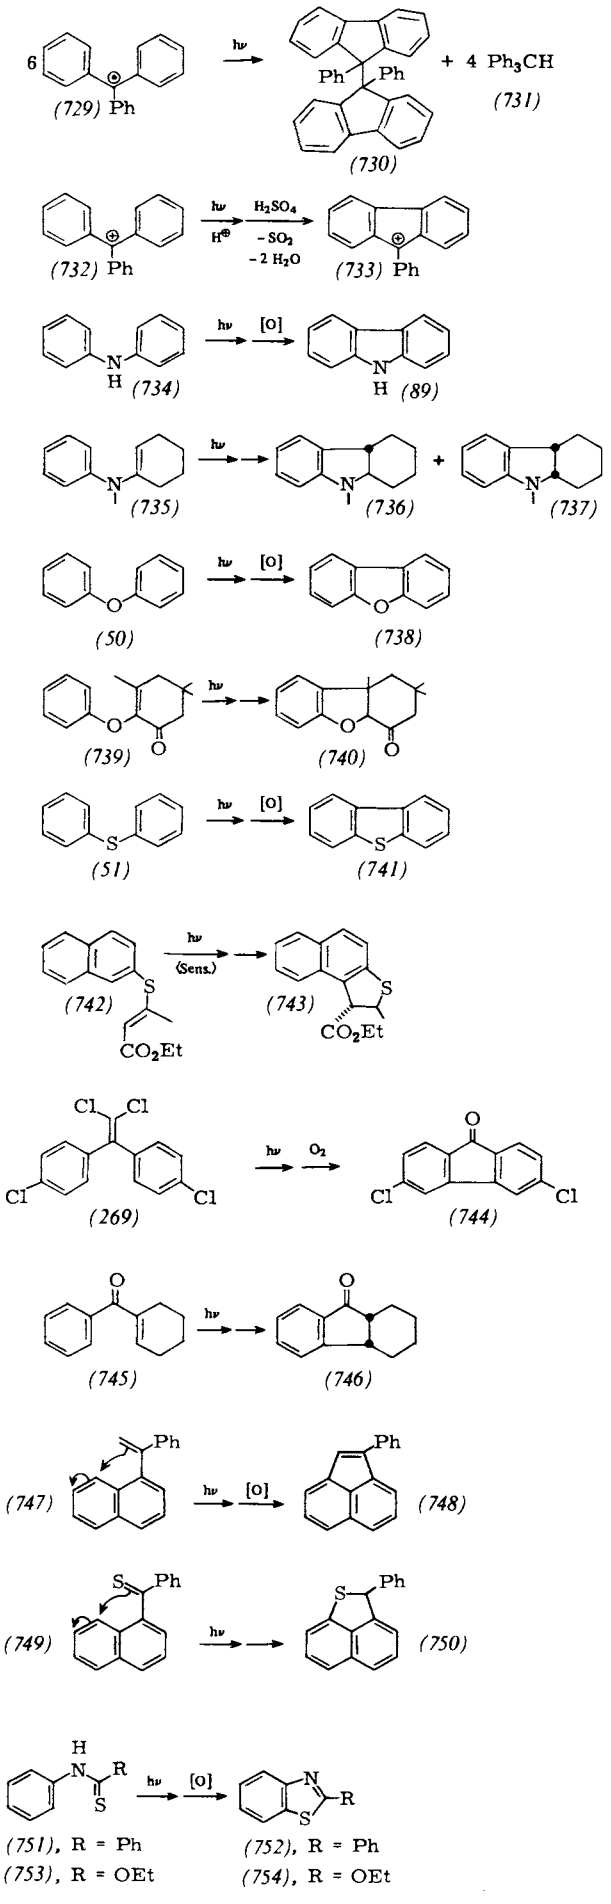


The stilbene unit may be widely varied by removal, addition, or displacement of aryl rings and by modification of the double bond without losing its ability for cyclization. This is shown by the syntheses of *(696)* (50%)[392], *(686)* (100%)[393], *(699)* (88%)[394], *(701)* (6%)[395], *(703)* (66%)[225], *(705)* (70%)[225], *(706)* (46%)[396], *(708)* (45%)[397], *(710)* (35%)[398], and *(712)* (59%)[399].

The special cases with *(i)* a more extended conjugated system *(713)*[400], *(716)*[401] and *(ii)* participation of conjugated acceptor double bonds [*e.g. (719)* (60%)][402], also illustrate the wide variability of this type of reaction.

The photochromic system *(722)/(723)*, which is thermally stable up to 160 °C, contains methyl groups which prevent interfering oxidation of the red *(723)*[403]. On cyclization of *(724)* the naphthalene derivative *(725)* (84%) is formed by HBr-elimination[404] (cf. Section 3.1.2).

As with aliphatic hexatrienes[2] there is the possibility for *o*-divinylbenzenes to undergo the bicyclo[3.1.0]hexene formation. *(726)* reacts to give *(727)*, which then rearranges to give *(728)*[405].



4.4.2. Formation of Five-Membered Rings

When the central double bond in stilbene *(143)* or 1-phenyl-1,3-butadiene is replaced by three-valent carbon [*(729)*[406]; *(732)*[407]], nitrogen [*(734)*[408]; *(735)*[409]], oxygen [*(50)*[410]; *(739)*[411]], sulfur [*(51)*[410]; *(742)*[412]] or by a cross-conjugated double bond [*(269)*][413] or a carbonyl group [*(745)*][186], one obtains photocyclization followed by oxidation or H-migration to give five-membered ring compounds. The yields are usually high and the synthetic possibilities have been widely exploited.

The photodegradation of the DDT-metabolite DDE *(269)*[413] is of considerable ecological importance.

Further cyclizations giving five-membered rings succeed by bridging the *peri*-positions of naphthalene in *(747)*[414] and *(749)*[415], even though this requires the intermediacy of a zwitterion or diradical. It is to be assumed, that these orientations are enforced by conformational effects, as the larger substituent (Ph) avoids proximity to the *peri*-position.

Further variations are possible. For example, *(751)*[416] and *(753)*[417] can be oxidatively cyclized.

5. Outlook

The long and lively development of arene photochemistry has produced a large variety of reaction types. Many of them are of preparative, industrial, biological, pharmaceutical, and ecological importance. No doubt other useful reaction types, which compete with those described in the present report, will be discovered. The classification of the available material chosen here may assist in locating still existing gaps, for it purposely does not concentrate on mechanistic aspects (*e.g.* singlet/triplet, high/low temperature, gas/condensed phase, adiabatic/diabatic) nor on the mere number of presently known examples but, by selection of characteristic examples, contributes to an understanding of the requirements for the most selective (high yield) course of specified reaction types. In conjunction with the exploitation of frequently clearly predictable orientation- and regio-selectivities in the available reaction types, further development in this sector promises new examples of the combined application of several reaction types for the realization of more sophisticated rearrangements [*e.g. (154)→(157); (158)→(160)*; cf. the combination of alkene photochemistry[2] ([2+2]-cycloaddition) and arene photochemistry (β-cleavage) in ref. [418]].

Not only the preparative aspects but also the kinetic/mechanistic aspects of aromatic photochemistry warrant further extensive investigation in order to disclose as many reactivity effects as possible and thereby enable useful extrapolations.

I am indebted to my colleagues who participated in the above studies performed by our research group: R. Dyllick-Brenzinger, H.-W. Grüter, E. Jostkleigrewe, K. Krieger, C. Küchel, K. Rösch, M. Stark, E. Teufel, and I. Zimmermann. Support for this work from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged.

Heterocyclic Analogues of Methylenecyclopropanes

By Gerrit L'abbé[*]

Heterocyclic three-membered rings with an exocyclic double bond merit special interest in view of their ring strain and their fascinating chemistry. Their synthesis, thermal decomposition, ring opening, and cycloaddition reactions will be discussed in this review. α-Lactams, alkylideneaziridines, diaziridinones, and diaziridinimines belong to the best known classes, but the chemistry of alkylideneoxiranes and -thiiranes, α-lactones, α-thiolactones, thiiranimines, and aziridinimines has also been studied to some extent. Two elusive three-membered rings are oxiranimines and thiaziridinimines; the former were postulated as reactive intermediates in the thermal decomposition of α-lactams, whereas the latter were trapped efficiently with double and triple bonds during thermolysis of *N*-sulfonyliminothiatriazolines. In spite of many attempts to prepare thione derivatives of the title compounds, they are still unknown. Included in this review are also some open-chain dipolar species which are isomeric with the heterocyclic three-membered rings.

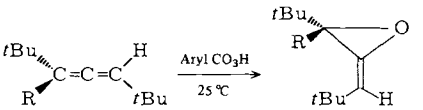
1. Introduction

Oxiranes, thiiranes, and aziridines are strained three-membered heterocycles which are discussed in many textbooks. The introduction of an exocyclic double bond on the ring leads to compounds of type *(1)* which are characterized by even greater ring strain. Hence, special methods for their preparation and isolation have been devised. The best results

(1)

X, Y, Z: carbon or heteroatoms with or without substituents

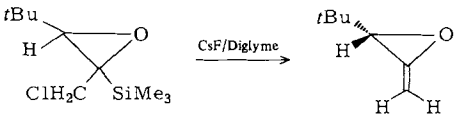
were obtained by the use of bulky substituents (such as *tert*-butyl and adamantyl) whose van der Waals repulsion interactions are opposed to ring-strain forces. Furthermore, bulky groups shield the ring from nucleophilic attack, thus contributing to its kinetic stability and isolation under appropriate basic conditions.



In this review, the synthetic methods leading to the title compounds are surveyed and their interesting chemistry (thermal decomposition, ring opening, cycloadditions) is discussed. Many cycloaddition reactions where the three-membered heterocycles have been postulated as reactive intermediates are also included for comparison. A characteristic feature of *(1)* is the IR stretching vibration of the exocyclic double bond at high wave number. In many cases this will be given with the structure.

2. Alkylidene Derivatives

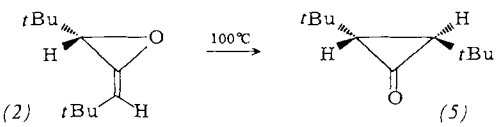
The alkylidene derivatives of oxiranes, thiiranes, and aziridines have all been prepared and were previously generally referred to as allene derivatives in the literature: *i.e.* allene oxides, allene episulfides, and allenimines.



2.1. Alkylideneoxiranes

Two methods have led to the isolation of stable allene oxides: (i) epoxidation of *tert*-butyl-substituted allenes with *m*-chloroperbenzoic acid [eq. (a)][1] and (ii) β-elimination of a suitably substituted epoxysilane [eq. (b)][2]. Compounds *(2)*,

(a)

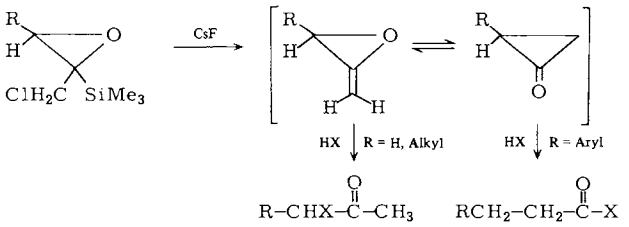


(2), R = H (IR: 1795 cm^{-1})
(3a), R = *t*Bu (IR: 1780 cm^{-1})
(3b), R = Me (IR: 1785 cm^{-1})

(4) (b)

(3), and *(4)* are the only stable alkylideneoxiranes so far known. In all the other cases studied, no allene oxides can be isolated, but products are formed which are derived therefrom[2,3]. Also, other potential routes have been explored but failed to produce stable alkylideneoxiranes[4], and a claimed synthesis of 2-isopropylidene-3,3-dimethyloxirane ("tetramethylallene oxide") was later retracted[5].

Alkylideneoxiranes are the valence isomers of the better known cyclopropanones[6], and, indeed, *(2)* is converted into *(5)* upon heating at 100 °C[1]. This isomerization, however, is



not observed for *(3)* and *(4)*[1,2]. According to *Chan, Ong, et al.*[2] the isomerization of alkylideneoxiranes into cyclopropanones proceeds *via* an oxallyl intermediate and occurs very readily with the elusive aryl substituted derivatives. This was demonstrated by generating the alkylideneoxiranes in the presence of protic nucleophiles (HX = alcohols, phenols,

[*] Prof. Dr. G. L'abbé

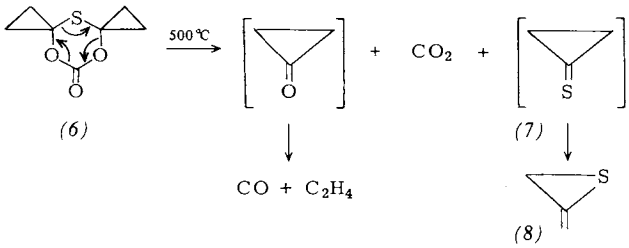
 © Verlag Chemie, GmbH, 6940 Weinheim, 1980 0570-0833/80/0404-0276 $ 02.50/0

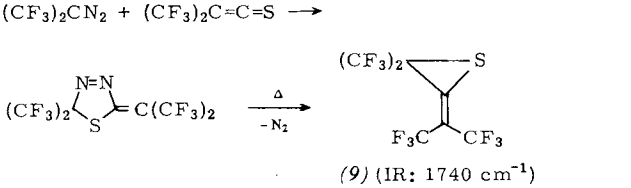
thiols, amines, *etc.*) which resulted in the formation of different products depending on whether R = alkyl or aryl (Scheme 1).

Scheme 1



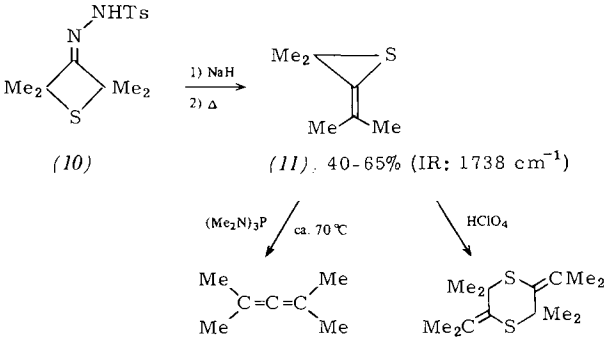
Ring-opening of the stable alkylideneoxirane *(4)* also occurs on nucleophilic attack at the formal sp^3C atom[2]. With boron trifluoride, compound *(3)* undergoes ring-opening isomerization *via* an oxyallyl cation as presumed intermediate[1].

(3)



2.2. Alkylidenethiiranes

The parent compound of this series, methylenethiirane *(8)*, can be generated by flash thermolysis of the cyclic carbonate *(6)* at *ca.* 500 °C[7a]. Its formation is assumed to result from valence isomerization of the elusive cyclopropanethione *(7)*. Although *(8)* only remained stable in solution up to −30 °C, it could be reasonably well purified and characterized by spectral methods[7a]. Flash thermolysis of several other precursors also produced *(8)* which was identified by microwave spectroscopy[7b].

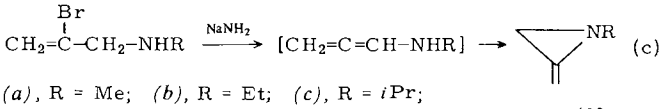


(6) *(7)* *(8)*

Only two substituted derivatives of *(8)* are known as stable substances. Thus, the fully trifluoromethylated derivative *(9)* is obtained from the reaction of the corresponding thioketene with hexafluoro-2-diazopropane, followed by thermolysis of the resulting thiadiazoline[8]. The chemistry of *(9)* is unexplored!

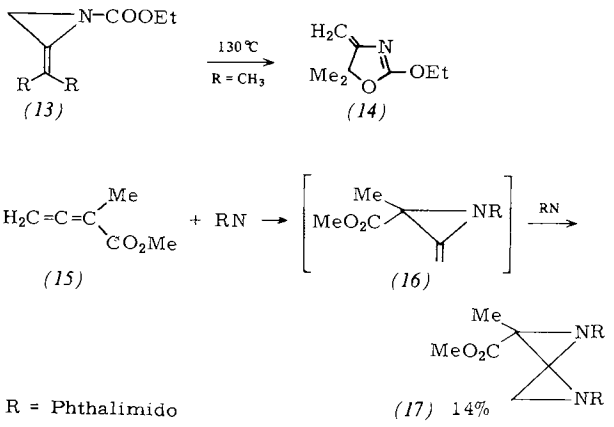
(9) (IR: 1740 cm^{-1})

2-Isopropylidene-1,1-dimethylthiirane ("tetramethylallene episulfide") *(11)* results from thermolysis of the sodium salt of *(10)* at 150 °C *in vacuo*[9]. It undergoes desulfurization upon heating with hexamethylphosphoramide and is dimerized to a 1,4-dithiane under acidic conditions (Scheme 2).



(10) *(11)*, 40-65% (IR: 1738 cm^{-1})

Scheme 2

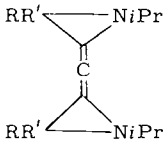


2.3. Alkylideneaziridines

N-Alkyl-substituted alkylideneaziridines *(12)* are readily prepared by dehydrohalogenation of *N*-(2-bromoallyl)alkylamines with sodium amide in liquid ammonia [eq. (c)]; *N*-alkylpropargylamines are formed as side products[10]. This reaction was carried out as long ago as 1951[11], but the correct structure of the reaction products was only established several years later[12,13]. A subsequent mechanistic study revealed the intermediacy of an allenic amine [eq. (c)][14]. Alkyl-substituted derivatives are also prepared by this method[15,16]. The IR stretching frequency of *(12)*, R = Et, lies at 1770 cm^{-1}.

(a), R = Me; *(b)*, R = Et; *(c)*, R = *i*Pr;
(d), R = *t*Bu; *(e)*, R = *c*-C_3H_5; *(f)*, R = $PhCH_2CH_2$ *(12)*

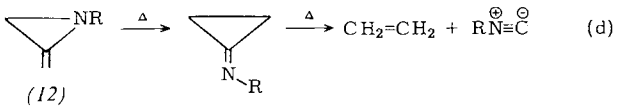
In analogy with the epoxidation reaction mentioned in eq. (a), the addition of nitrenes to allenes can be considered as another potential synthetic route to allenimines. However, the results obtained thus far are not promising. Thus, the esters *(13)*, R = H or CH_3, were only obtained in small amounts



(13) *(14)*

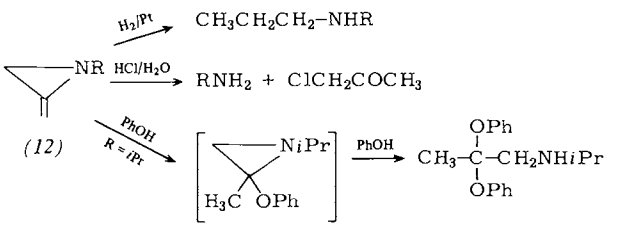
(15) *(16)*

R = Phthalimido *(17)* 14%



(3—8%) from ethoxycarbonylnitrene and allenes[17]. The nitrene was generated by base-catalyzed α-elimination of *N*-(*p*-nitrobenzenesulfonoxy)urethane. In another experiment, *Atkinson* and *Malpass*[18] isolated a strained diazaspiro[2.2]pentane *(17)* by reacting the allene *(15)* with phthalimidonitrene and postulated *(16)* as intermediate.

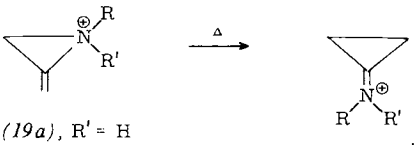
Finally, the reaction of carbon vapor (produced in a carbon arc) with imines is reported to produce a mixture of products in which *(18)* has been characterized by infrared and mass spectroscopy, but not isolated in pure form[19].



(18a), R = Ph, R' = H
(18b), R = R' = Ph

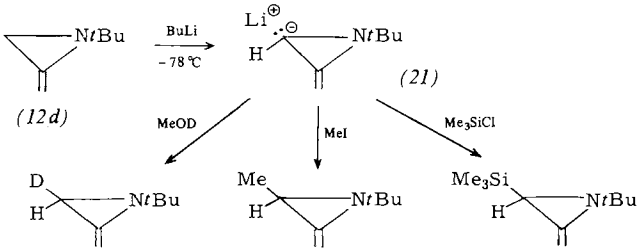
N-Alkylalkylideneaziridines undergo nitrogen inversion much easier than aziridines[20]. Their thermal decomposition proceeds *via* cyclopropanimines to give olefins and isonitriles [eq. (d)][15,21]. In contrast, *(13)* (R = CH_3) is thermolyzed at 130 °C into oxazoline *(14)*[17].

(12) (d)



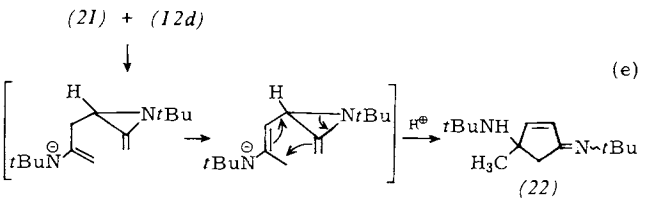
The reactions of *(12)* with hydrogen[11], dilute hydrochloric acid[13], and phenol[22] are summarized in Scheme 3.

Scheme 3



Protonation at nitrogen without ring cleavage was achieved by treatment of *(12a)*, *(12e)*, and *(12f)* with $HFSO_3/SbF_5$ in liquid sulfur dioxide at −78 °C[23a]. Similarly, methylation of *(12)* occurs cleanly with $(CH_3)_2Cl^+SbF_5Cl^-$ under the same conditions. The corresponding methyleneaziridinium ions *(19a)* and *(19b)* exhibit a remarkable thermal stability in the absence of nucleophiles, remaining unchanged, according to ^{1}H-NMR, in $HFSO_3$ solution up to +50 °C. At higher temperature, they rearrange into cyclopropaniminium ions *(20a,b)* analogous to the uncharged species [cf. eq. (d)][23b].

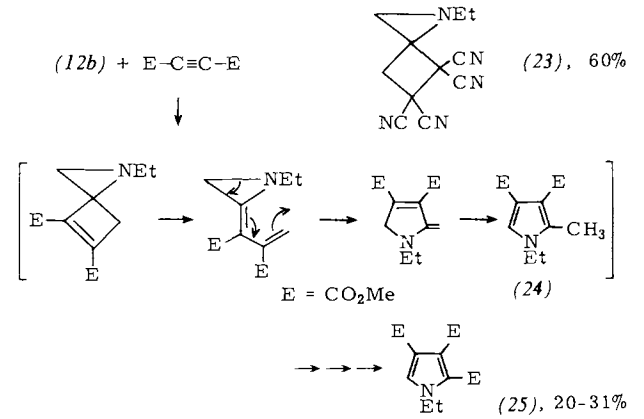
The carbanion *(21)* is generated when *(12d)* is treated with *n*- or *sec*-butyllithium at low temperature[16]. It can be deuterated, methylated and silylated as shown in Scheme 4. Using a silylated product in 12% optical yield, it was demonstrated that the thermal rearrangement into cyclopropanimine [cf. eq. (d)] proceeds stereospecifically, most probably with inversion at the migrating carbon atom[24].



(19a), R' = H
(19b), R' = Me

(20a), R' = H; *(20b)*, R' = Me

Scheme 4

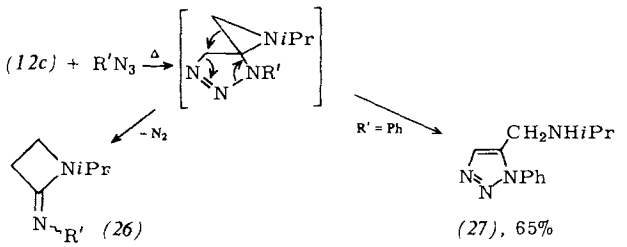


If a cooled solution of the carbanion *(21)* is allowed to warm up to −15 °C, dimerization occurs to give a *E,Z*-mixture of *(22)*. The mechanism formulated by the authors[16] is given in eq. (e).

(e)

(22)

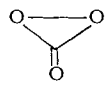
Several cycloaddition reactions on *N*-alkylalkylideneaziridines have been carried out. Thus, *(12b)* reacts with tetracyanoethylene to give the spiro adduct *(23)*, and reaction with dimethyl acetylenedicarboxylate at room temperature is reported to yield *(25)*[25]. The course of this reaction has not been completely elucidated. The authors[25] suggest that the primary stages involve successively [2+2]-cycloaddition, ring opening of the cyclobutene, valence isomerization, and tautomerization to give *(24)*. The pathway leading from *(24)* to *(25)* is not understood.



(23), 60%

(24)

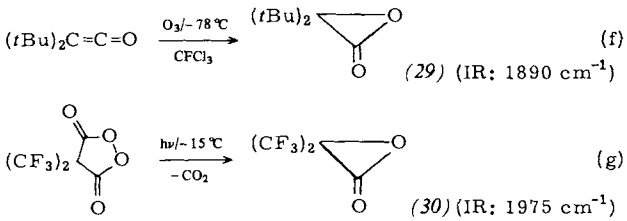
(25), 20-31%



Addition onto the exocyclic C=C bond of *(12c)* also occurs when this compound is allowed to react with organic azides[22]. The spirotriazolines thus formed as intermediates are converted into four-membered ring amidines *(26)* with extrusion of molecular nitrogen. In the case of phenyl azide, the amidine *(26c)* is obtained alongside the triazoline *(27)*.

(26a), R' = Ts, 100%; (26b), R' = CO_2Et, 60%; (26c), R' = Ph, 35%; (26d), R' = CO_2tBu

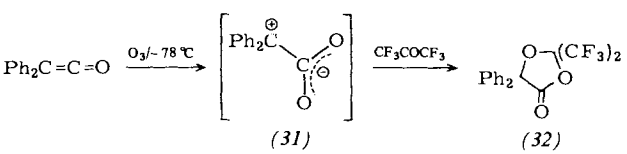
3. Ketone Derivatives



Among the heterocyclic analogues of cyclopropanones to be considered are α-lactones, α-thiolactones, α-lactams, and diaziridinones. Carbon trioxide *(28)* has been detected and analyzed by IR during the photochemical reaction of oxygen atoms with CO_2 molecules at 77 K[26], but it has not been studied chemically.

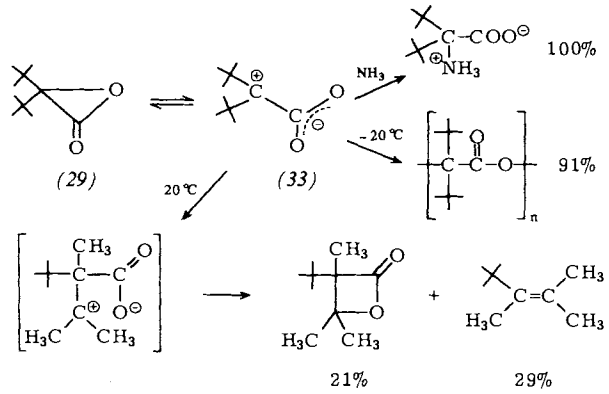
(28) (IR: 2045 cm^{-1})

3.1. α-Lactones (Oxiranones)



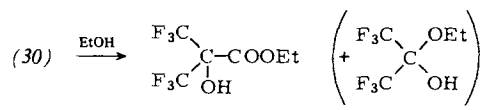
α-Lactones have been postulated as short-lived intermediates in a variety of reactions[27], but their thermal instability precluded any isolation. Only low temperature ozonolysis of di-*tert*-butylketene[28,29] and low temperature photolysis of 1,2-dioxolane-3,5-diones[30] furnished α-lactones [eq. (f), (g)] which were characterized by NMR and IR spectroscopy. The two most stable members of the class are *(29)* and *(30)*, decomposing respectively at −20 °C and at room temperature.

(29) (IR: 1890 cm^{-1}) (f)



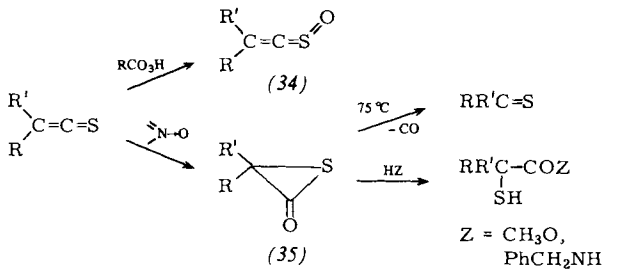
(30) (IR: 1975 cm^{-1}) (g)

In addition to the ozonolysis of di-*tert*-butylketene, *Wheland* and *Bartlett*[28] also investigated the ozonolysis of diphenylketene but could neither isolate nor detect the corresponding α-lactone. However, in the presence of hexafluoroacetone as trapping reagent, cycloadduct *(32)* was obtained in unspecified yield. The authors suggested that diphenylacetolactone is generated in its open-chain form *(31)* since the ring-closed α-lactone *(29)* is unable to undergo cycloaddition under the same conditions. Theoretical support has been gathered for this conjecture[31].



(31) *(32)*

Facile ring-opening of α-lactones to a dipolar species, *e.g. (33)*, accounts for their extreme reactivity (Scheme 5)[28]. They polymerize readily to polyesters and undergo decarbonylations, even at low temperature (hexafluoroacetone/trichlorofluoromethane solvent system).

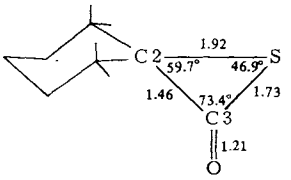


Scheme 5

Bis(trifluoromethyl)acetolactone *(30)* requires a separate comment. The formation of a zwitterion analogous to *(31)* and *(33)* is disfavored for this lactone, with the result that nucleophilic attack occurs exclusively at the carbonyl function[30].

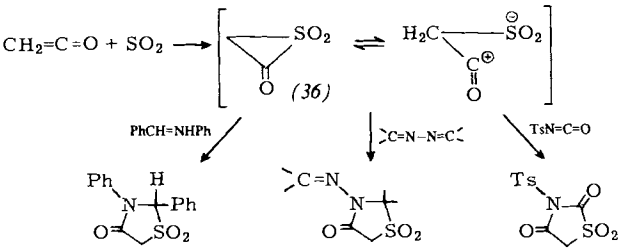
3.2. α-Thiolactones (Thiiranones)

Whereas peroxy acids and hydrogen peroxide oxidize stable thioketenes to thioketene *S*-oxides *(34)*[32], nitrones of the 1-pyrroline 1-oxide type (>N→O) furnish α-thiolactones *(35)*[33]. These compounds are of very recent date; the only reactions reported so far are the thermal decarbonylation and the sp^2C—S bond cleavage with nucleophilic reagents such as methanol and benzylamine (Scheme 6)[33].



(a), R = R' = *t*Bu; *(b)*, R = *t*Bu, R' = *i*Pr; *(c)*, R + R' =

Scheme 6

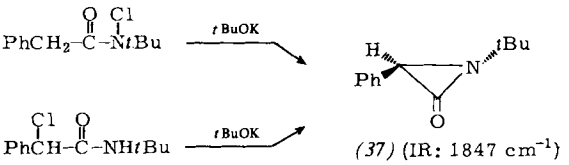


Of importance is the X-ray structure analysis of *(35c)* which shows an unusually large S—C^2 distance (1.92 Å compared with 1.81 Å for the sum of the covalent radii) and short C^2—C^3 and S—C^3 bonds[33], a situation also observed for other three-membered rings [see *(47)*, *(55)*, *(74)*, *(81)*, *(90)*].

The exocyclic C=O bond has a normal length of 1.21 Å. The small bond angle at the sulfur atom (46.9°) is also noteworthy.

(35c) (IR: 1785 cm^{-1})

To our knowledge, α-thiolactones have not been invoked as intermediates in cycloaddition reactions, but the *S,S*-dioxide *(36)* has been reported in this respect[34]. According to the authors, *(36)* is formed *in situ* when ketene is dissolved in liquid SO_2 at −78 °C, and can be trapped with imines, azines, and tosyl isocyanate (Scheme 7). Here, the supposed intermediate *(36)* undergoes sp^2C—S bond cleavage as expected, rather than sp^3C—S bond cleavage. At low temperature, *(36)* seems to have more than a transient existence.

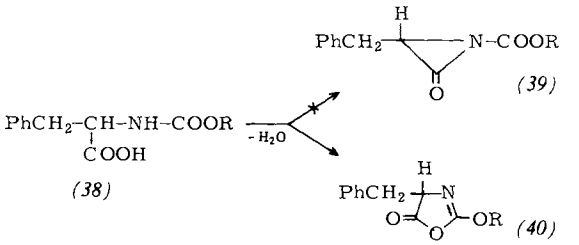


Scheme 7

3.3. α-Lactams (Aziridinones)

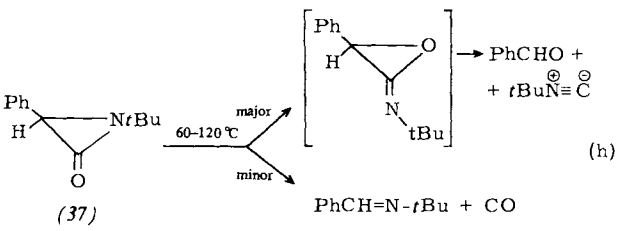
α-Lactams have been invoked as possible intermediates in numerous processes before the first member *(37)* was isolated by *Baumgarten* in 1962[35]. Subsequent work by many research groups established their chemistry and an excellent review exists on the subject to which the reader is referred for more details[36].

Stable α-lactams, having bulky *N*-substituents, are prepared by treatment of *N*-chloroamides or α-chloroamides with potassium *tert*-butoxide (Scheme 8)[35].

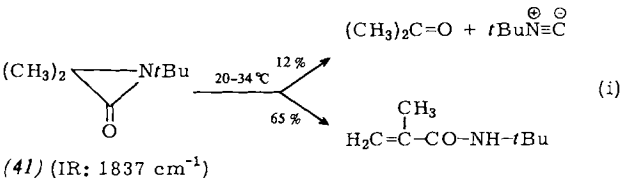


(37) (IR: 1847 cm^{-1})

Scheme 8



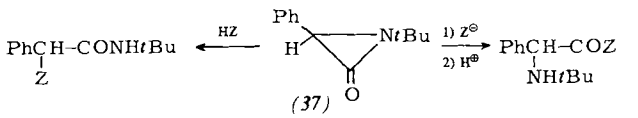
A report by *Miyoshi*[37] that *N*-functionalized α-lactams *(39)* are obtained by cyclodehydration of amino acid derivatives *(38)* proved later to be erroneous[38]; oxazolin-5-ones *(40)* are formed instead of *(39)*.

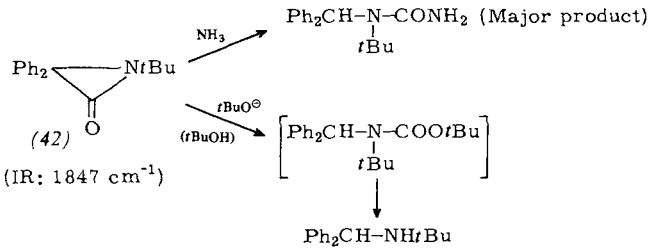


A large number of substituted α-lactams have been synthesized by the methods of Scheme 8[39], and these exhibit a considerable range of stability. For instance, the sterically hindered α-lactams 1,3-di-*tert*-butylaziridinone and 1,3-

diadamantylaziridinone are very stable (decomposition far above 100 °C), while 1-*tert*-butyl-3,3-dimethylaziridinone *(41)* undergoes slow decomposition at room temperature. No derivatives have been isolated in which an aromatic group or an *n*- or *sec*-alkyl substituent is attached to nitrogen.

Thermally, α-lactams fragment into carbonyl compounds and isocyanides, presumably *via* the elusive iminolactones as intermediates [eq. (h)][36]. (*Bott*[40] claimed to have detected an iminolactone during the synthesis of 3-adamantyl-1-*tert*-butylaziridinone, but no structure evidence was given.) If β-hydrogens are present on the α-lactam ring, thermal isomerization into α,β-unsaturated amides is an important competing reaction [eq. (i)]. In contrast, the main products of the photoinduced decomposition of α-lactams are carbon monoxide and the corresponding imines[41]. This pathway only occurs to a minor extent in some thermal degradations [cf. eq. (h)][36].

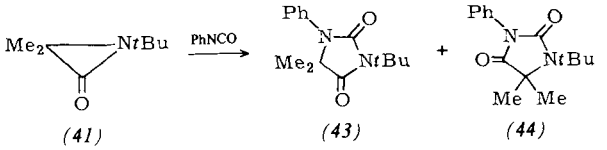




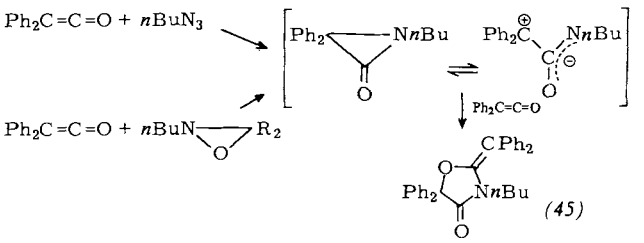
(41) (IR: 1837 cm^{-1})

In general, α-lactams undergo two types of selective ring-opening by nucleophiles (Scheme 9)[36,42]. Reaction with proton-containing nucleophiles, *e.g.* water, alcohols, thiols, amines, and mineral acids (HZ), leads exclusively to amides, corresponding to an sp^3C—N bond rupture. In contrast, reaction of α-lactams with aprotic nucleophiles, *e.g.* alkoxides, $LiAlH_4$, and sulfur ylides (Z^-), yields amino acid derivatives, resulting from sp^2C—N bond scission. The third possible way of opening the ring, namely at the C—C bond, has been observed for *(42)* (Scheme 10)[43].

The two types of ring-opening mentioned in Scheme 9 are also observed in the cycloaddition reaction of *(41)* with phenyl isocyanate[44]; adducts *(43)* and *(44)* are formed in a ratio

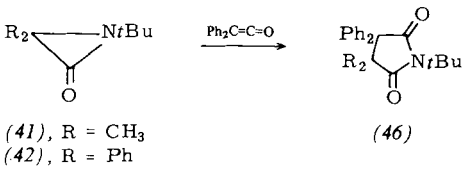


Scheme 9

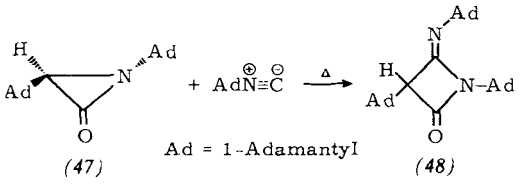


Scheme 10

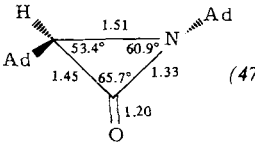
of 7:3. However, when the reaction is carried out with unstable α-lactams generated *in situ* from α-bromoamides in tetrahydrofuran at −50 °C only hydantoins [cf. *(43)*] arising from sp^3C—N bond cleavage are obtained[44].



The pronounced dipolar reactivity of unstable α-lactams may also account for the formation of oxazolidinone *(45)* on reaction of diphenylketene with *n*-butyl azide[45] and oxaziridines[46] (Scheme 11). With the stable α-lactams *(41)* and

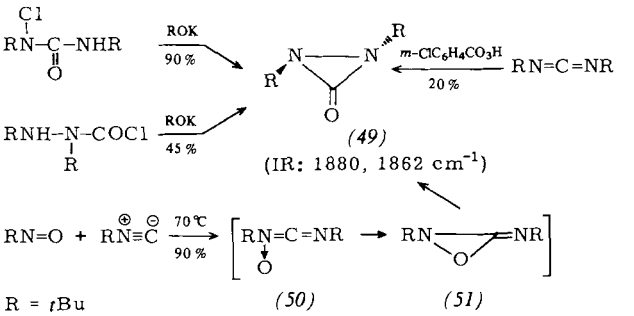


Scheme 11



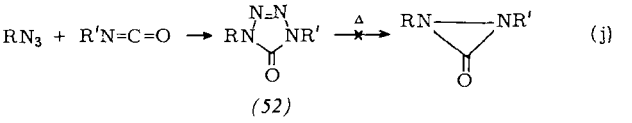
(42), addition occurs across the C=C double bond of diphenylketene to yield succinimides *(46)*[47]. This difference in selectivity between stable and unstable α-lactams may be explained by invoking steric arguments.

The sterically stabilized α-lactam *(47)* reacts with adamantyl isocyanide on warming to yield the β-lactam *(48)* in 71% yield[48]. The latter is also formed along with the corresponding aldehyde and isonitrile when *(47)* is decomposed at 115—160 °C. The weakness of the sp^3C—N bond, which is



broken in this reaction, is apparent from an X-ray crystallographic study (1.51 Å compared with 1.46 Å for a normal C—N bond length)[49]. Furthermore, the substituents attached to nitrogen are not coplanar as they are in amides, inhibiting the π-resonance stabilization which is normally ascribed to amides.

(47) (IR: 1830 cm^{-1})

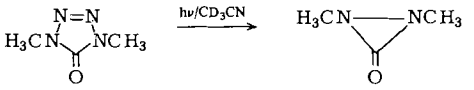


3.4. Diaziridinones

Stable diaziridinones having tertiary alkyl groups attached to both nitrogen atoms are well known. Four of the synthetic methods developed by *Greene* and co-workers are exemplified in Scheme 12 for di-*tert*-butyldiaziridinone *(49)*. They involve: (a) treatment of 1-chloro-1,3-di-*tert*-butylurea with potassium *tert*-butoxide[50]; (b) treatment of 2,3-di-*tert*-butylcarbazoyl chloride with the same reagent[50]; (c) treatment of *tert*-butyl isocyanide with a nitroso compound [a reaction which occurs *via* the intermediacy of the carbodiimide *N*-oxide *(50)* and probably also *via* the oxaziridinimine *(51)*[51]; and (d) treatment of di-*tert*-butylcarbodiimide with a peroxy acid[52].

Scheme 12

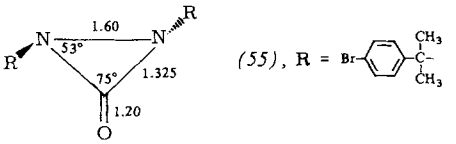
The possibility of generating diaziridinones by thermolysis of 1,4-disubstituted tetrazolinones *(52)* has also been considered. The tetrazolinones were obtained by cycloaddition reactions of organic azides with isocyanates [eq. (j)][53]. They proved, however, to be thermally stable with the exception of 1-alkyl-4-arylsulfonyl derivatives which undergo cycloreversion at 100—120 °C instead of elimination of nitrogen. Cycloreversion also occurs upon electron impact[54].



(j)

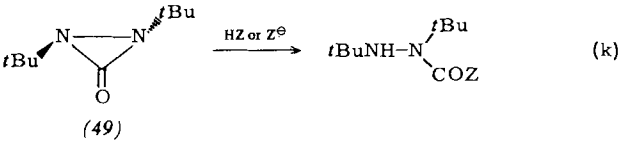
(52)

R = Alkyl, R' = Aryl, Acyl, Alkoxycarbonyl
R = Alkyl, Aryl, R' = Arylsulfonyl



In contrast, photolysis of 1,4-dimethyltetrazolinone *(53)* produces the corresponding diaziridinone *(54)*[55].

An X-ray analysis of *(55)* has been carried out and confirmed the expected *trans* arrangement of the *N*-substit-



(53) (54) (IR: 1882 cm^{-1})

uents[56]. They are situated 56° above and below the plane defined by the ring atoms. Further characteristics of the ring are the unusually long N—N bond (1.60 Å compared with 1.39 Å for the N—N bond in OCH—NH—NH—CHO), the short C—N bonds, and the normal ketone C=O length.

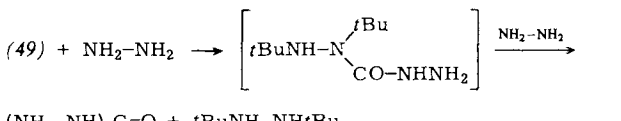
(55), R = Br-C(CH3)2-CH3

Diaziridinones undergo facile sp^2C—N ring opening with acids, but they are rather sluggish towards nucleophilic reagents [eq. (k)][50]. Thus, methanolysis of *(49)* into methyl carbazate occurs much faster under acidic conditions than in the presence of methoxide.

(49) (k)

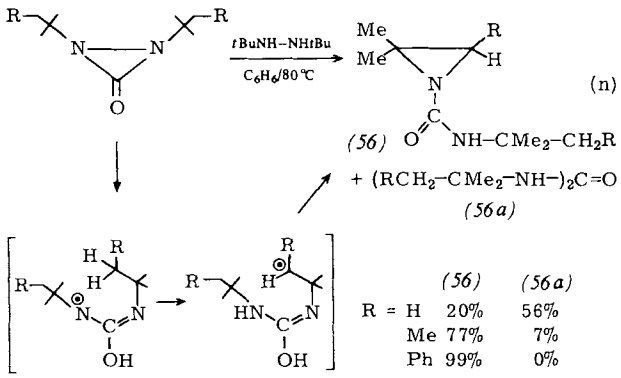
HZ = HCl (dry), $CH_3OH/H^{\oplus}$, C_6H_5COOH, HCOOH, picric acid, $(CH_3)_2CHNH_2$
$Z^{\ominus} = CH_3O^{\ominus}$ (refluxing CH_3OH), $tBuO^{\ominus}$ (refluxing *t*BuOH), $H^{\ominus}$

Whereas 1,3-di-*tert*-butylaziridinone (an α-lactam!) is not reducible electrochemically, *(49)* is cleanly converted into 1,3-di-*tert*-butylurea by electrochemical reduction[57]. Reduction of *(49)* is also achieved with hydrogen on palladium, sodium naphthalenide, *tert*-butyllithium, as well as with a number of other reducing agents summarized in eq. (l)[50].



(49) → *t*BuNH—CO—NH*t*Bu (l)

|2H| = H_2/Pd/C, $PhNHNH_2$ (→ $C_6H_6 + N_2$), RNHNHR (→ RN=NR), EtSH (→ EtSSEt), *t*BuNHOH (→ *t*BuN=O), PhOH, Ph_2CHOH (→ Ph_2C=O)



Hydrazines can react in three different ways; as reducing agents [eq. (l)], as nucleophiles [eq. (m)], or as catalysts of the rearrangement of diaziridinones into aziridinecarboxamides *(56)* by a radical mechanism [eq. (n)][50,58]. From the yields reported in eq. (n) it is evident that the rearrangement is favored by increasing the lability of hydrogen β to nitrogen in the diaziridinone. Furthermore, low hydrazine concentrations favour rearrangement over reduction of diaziridinone.

Tervalent phosphorus compounds, *e.g.* $(EtO)_3P$, effect the deoxygenation of *(49)* to give di-*tert*-butylcarbodiimide and ethyl phosphate [eq. (o)][52]. This reaction proceeds *via* an isocyanate and iminophosphorane; the former was shown to accumulate in the course of the reaction.

(NH2–NH)2C=O + *t*BuNH–NH*t*Bu (m)

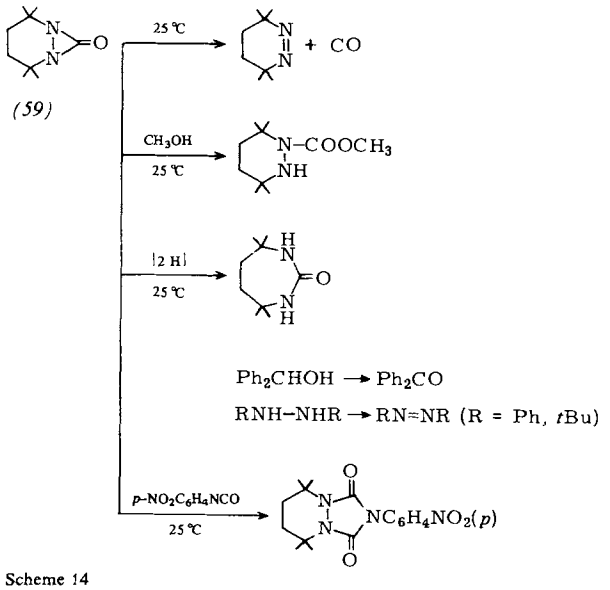
(49) + $(EtO)_3P$ → [*t*BuN=C=O + $(EtO)_3P$=N*t*Bu] → *t*BuN=C=N*t*Bu + $(EtO)_3P$=O (o)

Thermal decomposition of diaziridinones occurs at high temperatures [at 180 °C for *(49)*], resulting in decarbonylation as well as fragmentation into isocyanate and imine. The latter arises from rearrangement of a nitrenoid species[56,59]. Other products are also formed in minor amounts and are accounted for by radical mechanisms.

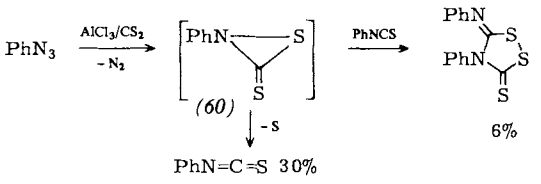
(57)



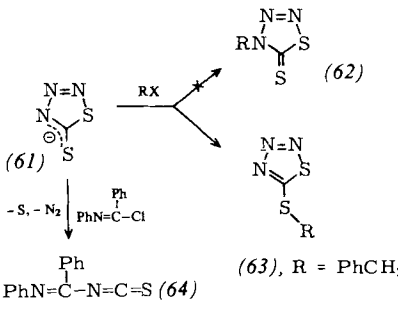
Since the open-chain dipolar form *(57)* of a diaziridinone should be less stable than that of α-lactones or α-lactams[31], cycloaddition reactions involving this intermediate cannot be expected. *Greene et al.*[50–52] stressed the lack of reactivity of di-*tert*-butyldiaziridinone *(49)* towards cyclohexene, cyclo-

Scheme 13

pentadiene, norbornene, maleic anhydride, isocyanides, and phenyl isocyanate. Successful cycloadditions were carried out with diphenylketene, acyl- and sulfonyl isocyanates, and benzonitrile in the presence of boron trifluoride (Scheme 13)[59-61]. In all but one case, *i.e. (58)*, the mode of addition is the result of sp^2C—N bond cleavage, which is also the mode of scission when the three-membered ring is treated with electrophiles and nucleophiles [cf. eq. (k)].



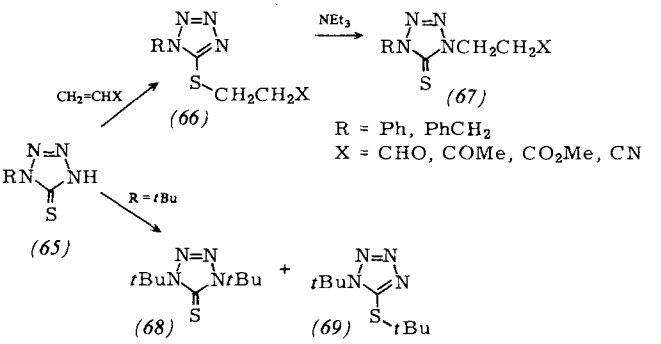
Finally, it is worth mentioning that a *cis*-fused diaziridinone *(59)* has been prepared by dehydrochlorination of the corresponding *N*-chlorourea (yield 14–23%)[61]. This compound undergoes quantitative decarbonylation on standing at room temperature and reacts with nucleophiles, reducing agents, and activated isocyanates much faster than *(49)*, although in a similar manner (Scheme 14).



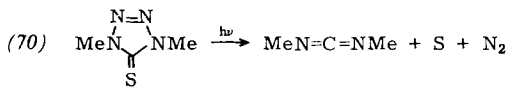
Scheme 14

4. Thioketone Derivatives. There are None!

Borsche[62] first proposed thiaziridinethione *(60)* as a reactive intermediate in the $AlCl_3$ catalyzed decomposition of phenyl azide in CS_2. This intermediate was also postulated for the reactions of oxaziridines with CS_2, giving isothiocyanates in high yields[63]. In both cases, however, no direct evidence for the presence of *(60)* is available and its formation was only assumed in order to rationalize the reaction course.



The possibility that 4-substituted thiatriazolinethiones *(62)* would yield thiaziridinethiones has been considered in our laboratory. However, all attempts to prepare the starting materials were unsuccessful since alkylation and acylation of sodium thiatriazolinethiolate *(61)* (obtained from CS_2 and

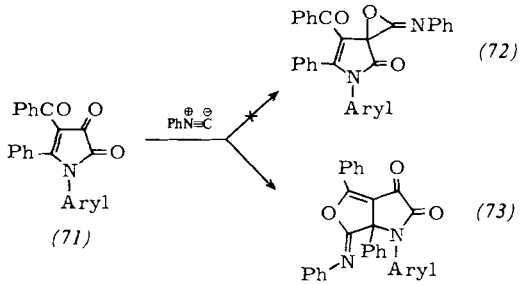


NaN_3)[64] furnished the *S*-substituted derivatives *(63)* in all cases[65]. Treatment of the triethylammonium salt of *(61)* with phenylbenzimidoyl chloride in tetrahydrofuran resulted in elimination of nitrogen and sulfur, and formation of the imidoyl isothiocyanate *(64)*[66].

In contrast with the corresponding ketones, diaziridinethiones cannot be obtained by treatment of thioureas with *tert*-butyl hypochlorite and potassium *tert*-butoxide; instead, desulfurization occurs to yield carbodiimides[66,67].

Thermolysis of 1,4-disubstituted tetrazoline-5-thiones, *e.g. (67)* and *(68)*, also failed to give diaziridinethiones. The starting materials of type *(67)* were prepared by Michael additions of *(65)* (obtained from isothiocyanates and NaN_3)[68] to electron-poor olefins in basic medium[69]. In the absence of base, *S*-substituted derivatives *(66)* are formed which, however, isomerize to *(67)* upon addition of a base[69]. 1,4-Di-*tert*-butyltetrazoline-5-thione *(68)* is prepared from *(65)*, R = *t*Bu, by *tert*-butylation with a mixture of *tert*-butyl alcohol, dicyclohexylcarbodiimide and cuprous chloride as described by *Henry*[70]. Besides *(68)* (65%), the *S*-substituted derivative *(69)* is formed in smaller amount (15%)[66]. The thiones *(67)* and *(68)* remain unchanged when heated at 120—150 °C[66,69], thus resembling the corresponding ketones in their thermal stability[53].

Also photolysis of *(70)* does not produce the three-membered ring but, instead, furnishes a carbodiimide after loss of nitrogen and sulfur[55].



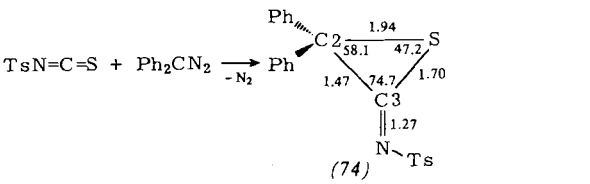
5. Imino Derivatives

In this series, thiiranimines, aziridinimines, and diaziridinimines have been isolated whereas oxiranimines and thiazir-

idinimines have been demonstrated only as elusive intermediates.

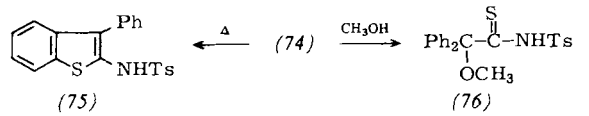
5.1. Oxiranimines

We have previously mentioned that oxiranimines (iminolactones) are postulated as reactive intermediates in the thermal decomposition of α-lactams into carbonyl compounds and isocyanides [eq. (h)]. The reverse reaction was reported by *Ziegler et al.*[71] for the heterocyclic diones *(71)* and phenyl isocyanide at 100 °C, but a careful reinvestigation indicated that *(73)* is formed instead of *(72)*[72].



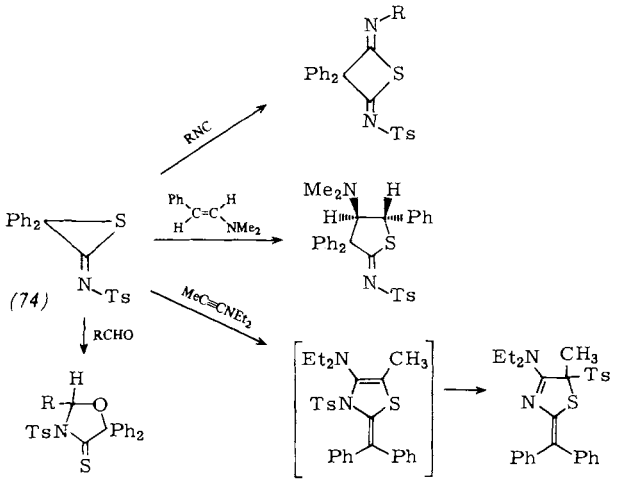
(71) *(72)* *(73)*

Also, the claim[40] that an oxiranimine has been detected as side product (3—5%) during the synthesis of 1-*tert*-butyl-3-adamantylaziridinone should be regarded with much reservation until more evidence is given for its structure.



5.2. Thiiranimines

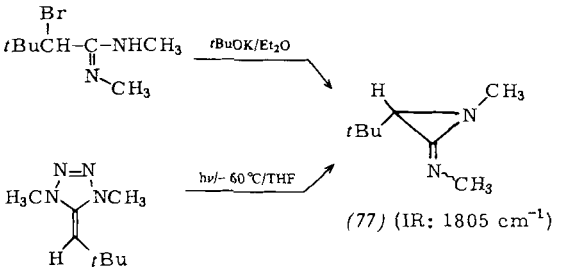
The first member of the class of thiiranimines, *i.e. (74)*, was synthesized in 1978 by reaction of tosyl isothiocyanate with diphenyldiazomethane [eq. (p)][73]. X-Ray analysis revealed the presence of an unusually long C^2—S bond which is broken in chemical reactions. Thus *(74)* isomerizes into benzothiophene *(75)* upon warming, and its reaction with methanol furnishes the thioxosulfonamide *(76)*.



(p)

(74)

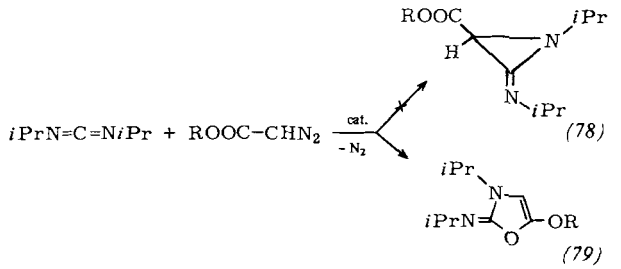
(75) *(76)*



In cycloaddition reactions the C^2—S bond is also cleaved and adducts are formed which involve participation of either the C^2 and S, or the N and S, or the C^2 and N atoms depending on the nature of the co-reagent. The results are summarized in Scheme 15[74,75]. In the case of ynamines, exemplified with *N*-diethylaminopropyne, the primary cycloadduct (addition along the N,S part of the molecule) undergoes a sulfonyl migration from N^3 to C^5 during the reaction.

Scheme 15

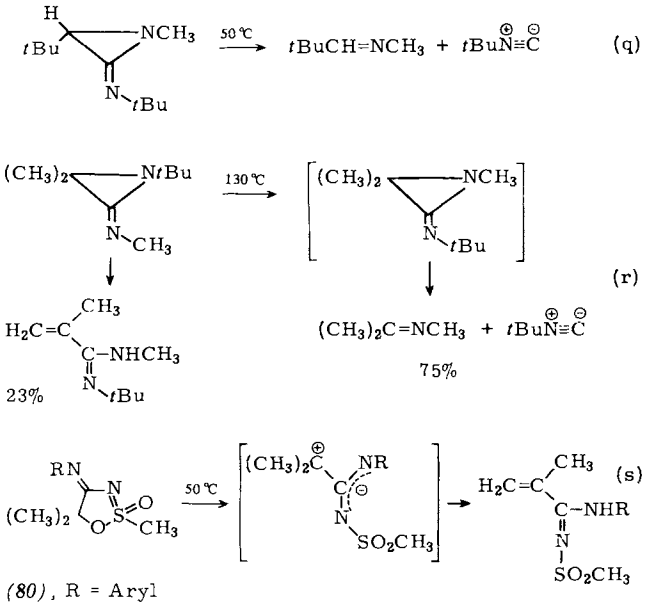
5.3. Aziridinimines



Stable aziridinimines, *e.g. (77)*, were prepared in *Quast*'s laboratory by dehydrohalogenation of α-bromoamidines[76] and by photolysis of alkylidenetetrazolines[55] (see Scheme 16).

(77) (IR: 1805 cm^{-1})

Scheme 16

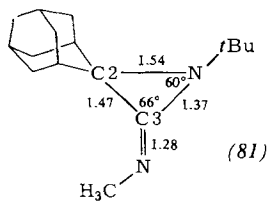


In a preliminary communication, *Teyssié* and co-workers[77] reported the synthesis of *C*-alkoxycarbonyl-substituted aziridinimines *(78)* from diisopropylcarbodiimide and alkyl diazoacetates in the presence of transition metal salts. A more detailed reexamination of this reaction, however, indicated that the products are in fact oxazoline derivatives *(79)*[78].

(78) *(79)*

The aziridinimines exhibit *syn-anti* isomerization of the imino group at ambient temperature[76]. They decompose thermally into imines and isocyanides [eq. (q)]; in some cases the fragmentation products are interpretable in terms of a valence isomerization occurring during thermolysis [eq. (r)][79]. When methyl substituents are present on the ring C-atom, rearrangement into α,β-unsaturated amidines is also observed [eq. (r)]. This isomerization is analogous to that

found for α-lactam *(41)* [eq. (i)], and is also comparable with the thermal rearrangement of the 1,2λ⁶,3-oxathiazolines *(80)* (first thought to be isopropylidenediaziridines!)[80] to methacrylic amidines [eq. (s)][81]. The latter may possibly proceed *via* a ring-opened aziridinimine.



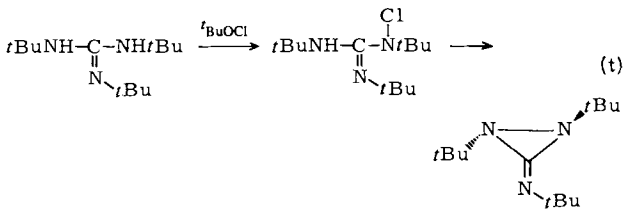
(q)

(r)

(s)

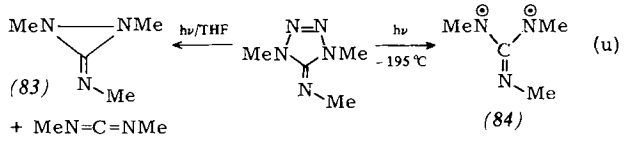
(80), R = Aryl

The spiroaziridinimine *(81)* has been subjected to an X-ray diffraction analysis and the bond lengths and internal angles are shown with the structure[82]. Here again, the same general features are found as with other three-membered rings; *i.e.* long C^2—N bond and short C^3—N and C^2—C^3 bond distances.



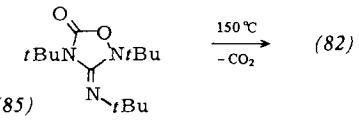
(81)

5.4. Diaziridinimines



Quast and co-workers developed two methods for the synthesis of stable diaziridinimines. The first method consists in reacting *tert*-butylguanidines with *tert*-butyl hypochlorite (molar ratio 2:1); this reaction involves the intermediacy of an *N*-chloroguanidine [eq. (t)]. The reaction, however, is most conveniently carried out with the respective guanidinium perchlorate and *tert*-butyl hypochlorite in the presence of potassium *tert*-butoxide[83]. The second preparative method is photolysis of trisubstituted tetrazolin-5-imines [eq. (u)][55]. Here, dimethyl carbodiimide is obtained alongside *(83)*. When the irradiation was carried out at low temperature (−195 °C), tris(imino)methane *(84)* was identified by ESR[84]. This is the nitrogen analogue of the better known trimethylenemethane[85].

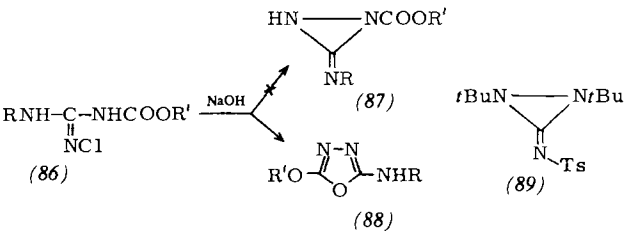
No formation of diaziridinimines by thermal decomposition of trisubstituted tetrazolin-5-imines has been reported,



(t)

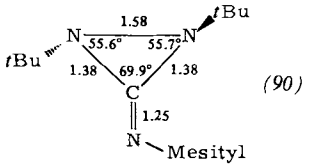
(82) (IR: 1790 cm^{-1})

(u)



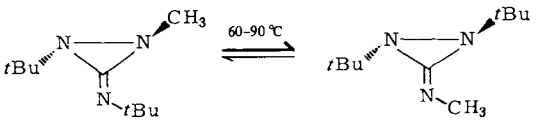
but a closely related reaction *(85)*→*(82)* was observed by *Greene*'s group[86].

(82)



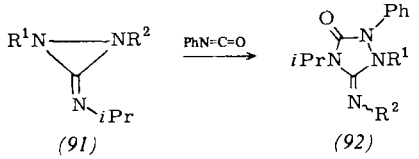
(85)

In a Japanese patent the synthesis of 1-alkoxycarbonyl-substituted diaziridinimines *(87)* was claimed by dehydrohalogenation of *N*-chloroguanidines *(86)*[87]. No spectral data were given to substantiate the structure and a reinvestigation of the reaction products by spectral and X-ray analyses established that 1,3,4-oxadiazoles *(88)* are formed instead[88]. The only functionalized diaziridinimine isolated so far is *(89)*, prepared in our laboratory by utilizing the first method of *Quast*[81].



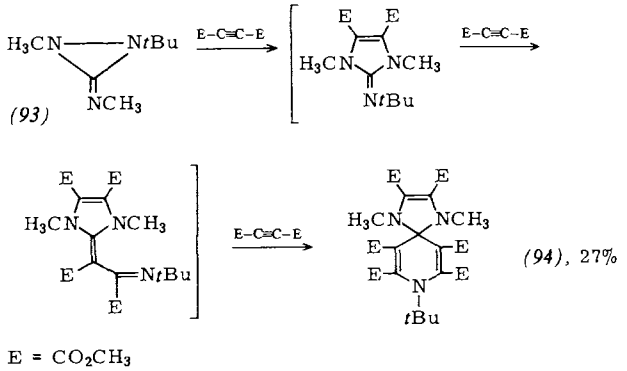
(86) *(87)* *(88)* *(89)*

All the diaziridinimines isolated so far most probably exist in the *trans* configuration. This was ascertained for *(90)* by an X-ray structure analysis[89]. The molecule features a long N—N bond length and short C—N distances (compare the indicated values with the sum of the covalent radii for N—N, 1.50 Å, and C—N, 1.46 Å). In the crystalline state, the aromatic ring is twisted 58.6° out of the plane of the three-membered ring.



(90)

Diaziridinimines decompose thermally into azo compounds and isocyanides[83]. Those substituted with different groups are also susceptible to thermal valence isomerization, favoring the isomer with the less bulky group at the imino nitrogen [eq. (v)][90].

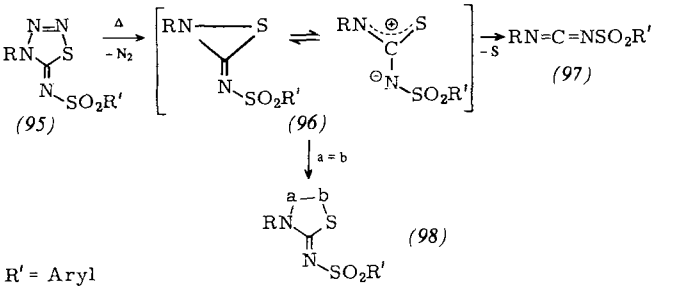


(v)

Diaziridinimines undergo cycloaddition reactions initiated by nucleophilic attack of the imino function on the electrophilic center of the reaction partner. Thus, reaction of *(91)* with phenyl isocyanate occurs readily at low temperature to give iminotriazolinones *(92)*, in which the exocyclic nitrogen of *(91)* becomes part of the five-membered ring[91].

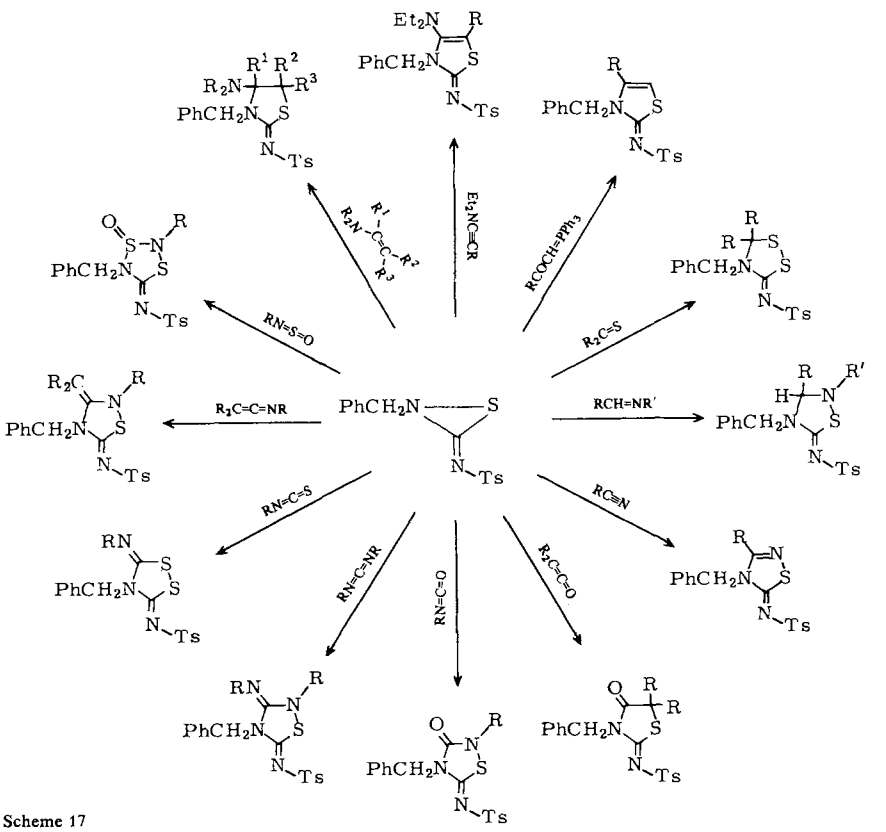
(91) *(92)*

Another beautiful example from *Quast*'s group is the reaction of *(93)* with dimethyl acetylenedicarboxylate at room temperature to give the spiro adduct *(94)*, whose structure was confirmed by X-ray analysis[92]. The mechanism involves three consecutive cycloaddition steps.



(93) *(94)*, 27%

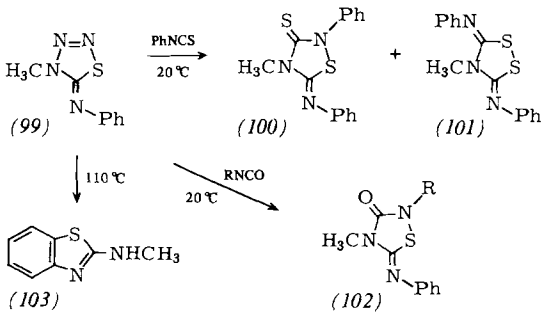
E = CO_2CH_3



5.5. Thiaziridinimines

4-Alkyl-5-arylsulfonylimino-1,2,3,4-thiatriazolines *(95)* (obtained from alkyl azides and arylsulfonyl isothiocyanates) are thermally converted into sulfonylcarbodiimides *(97)* by loss of nitrogen and sulfur[93]. A thiaziridinimine and/or its ring-opened dipolar species *(96)* is postulated as intermediate, since it can be trapped by a large number of unsaturated systems (a=b and a≡b), including enamines, ynamines, carbonyl-stabilized phosphorus ylides, thiocarbonyl compounds, imines, nitriles, heterocumulenes, and *N*-sulfinylamines[93,94]. The adducts of type *(98)* formed from 4-benzyl-5-tosylimino-1,2,3,4-thiatriazoline *(95)*, R = benzyl, R′ = *p*-tolyl, are listed in Scheme 17.

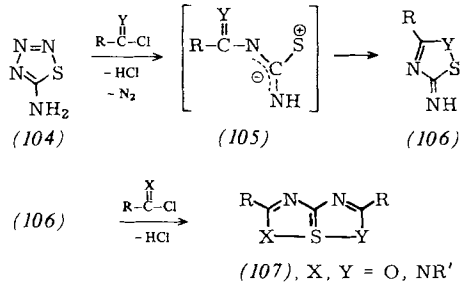
(95) *(96)* *(97)* *(98)*



R′ = Aryl

Scheme 17

All the reactions occur at 60—70 °C, *i.e.* the decomposition temperature of *(95)*, R = benzyl, R′ = tolyl, thus being independent of the nature and concentration of the trapping reagent. Furthermore, the additions are regiospecific, and even stereospecific in the few cases studied so far. We can only speculate about the mechanism of these cycloadditions; *i.e.* concerted with participation of sulfur d-orbitals, or nonconcerted. Much evidence, however, points to a stepwise mechanism. Indeed, *(96)* does not react in a Diels-Alder fashion with furan, 1,3-diphenylisobenzofuran, or 1,2,3,4-tetraphenyl-1,3-cyclopentadiene[95], although this is a characteristic symmetry-allowed behavior of cyclopropanones[6]. The nature of the reaction partners which are polar molecules, also suggests that *(96)* reacts preferentially *via* a polar open-chain betaine[96].

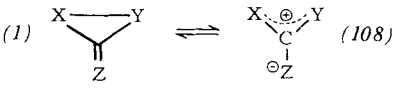


When the arylsulfonyl substituent in *(95)* is replaced by an aryl substituent the behavior towards heterocumulenes is drastically altered. Compound *(99)* now reacts with phenyl isothiocyanate at room temperature to give thiadiazolidine *(100)* as main product in addition to a smaller amount of *(101)* [formed from *(100)* by a Dimroth rearrangement][97].

(99) *(100)* *(101)* *(103)* *(102)*

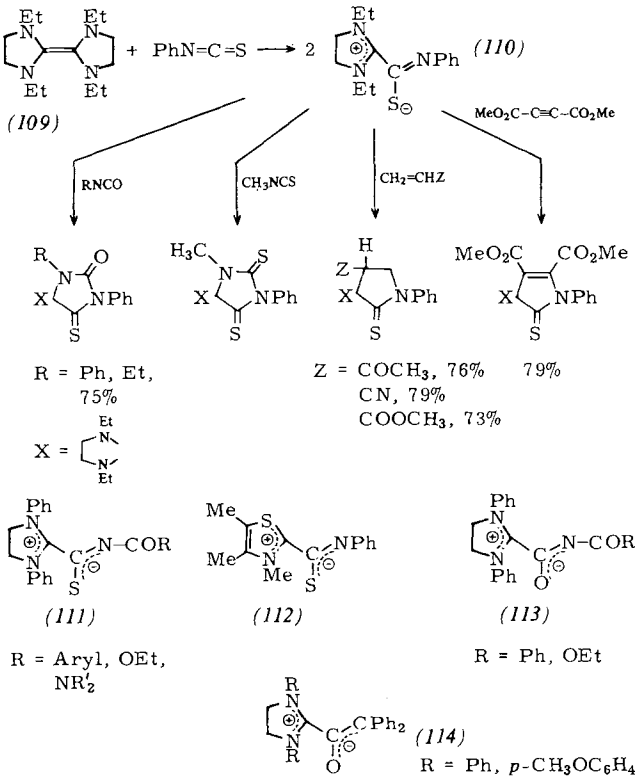
Also, the reaction with isocyanate occurs at 20 °C to give *(102)* in excellent yield[98]. Since *(99)* only decomposes thermally in refluxing toluene to yield benzothiazole *(103)*[99], the reactions with heterocumulenes must be bimolecular processes, not proceeding *via* the intermediacy of the desired thiaziridinimine.

Our research in this field has led to the discovery of an interesting application of undoubtedly widespread interest; namely the synthesis of λ^4-thiapentalenes *(107)* by treating 5-amino-1,2,3,4-thiatriazole *(104)* with acyl chlorides and imidoyl chlorides[100]. The ring-opened thiaziridinimines *(105)* are believed to be the key intermediates in this reaction. They undergo cyclization into *(106)* and reaction with a second molecule of electrophilic reagent to give *(107)*. Since the hydrochloride of *(106)*, Y = NR′, can be isolated, unsymmetrical thiapentalenes *(107)*, X ≠ Y, are also accessible.



(104) *(105)* *(106)*

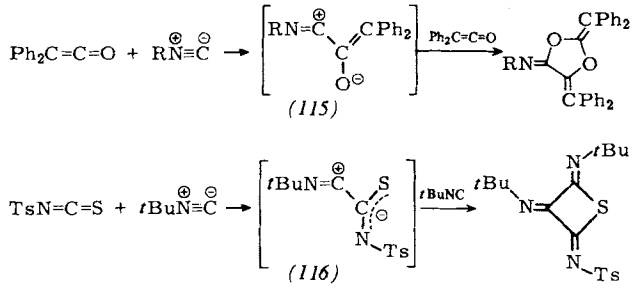
(106) *(107)*, X, Y = O, NR′



6. Externally Stabilized 1,3-Dipoles

In the previous sections, I have suggested that some heterocycles of type *(1)* may possibly react as dipolar systems of type *(108)* in cycloadditions[101]. These reactive species differ from the classical 1,3-dipoles studied by *Huisgen*[102], and also from the 1,3-dipoles which result from thermal or photochemical C—C bond cleavage of aziridines, oxiranes, and thiiranes[103]. Hence, it is appropriate here to mention briefly the literature on this subject.

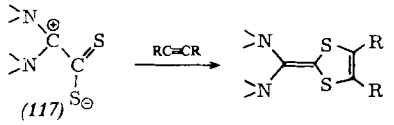
(1) *(108)*



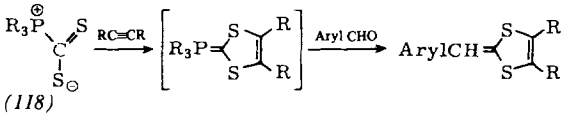
In 1965, *Winberg* and *Coffman*[104] reported the reaction of biimidazolidinylidene *(109)* with phenyl isothiocyanate to give the stable inner salt *(110)* under mild conditions. This yellow-colored dipole undergoes cycloadditions with isocyanates, isothiocyanates, electron-poor olefins, and dimethyl acetylenedicarboxylate (see Scheme 18). Extensions to other electron-rich olefins and nucleophilic carbene progenitors, as well as to other heterocumulenes, were made by several investigators[105]. In many cases, the dipoles were only postulated as reactive intermediates, whereas in other experiments, stable dipoles were isolated and subsequently reacted with isocyanates and substituted acetylenes. Examples of the latter are *(111)*—*(114)*.

(109) *(110)* *(111)* *(112)* *(113)* *(114)*

Scheme 18



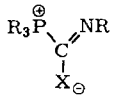
The combination of isocyanides with heterocumulenes would also lead initially to resonance-stabilized zwitterionic adducts[106]. The only two zwitterions of this kind to have been trapped so far are *(115)* and *(116)*[107,108].



(115)

(116)

The stable dipoles *(117)* and *(118)* are prepared from carbon disulfide and peraminoethylenes[104] or triethylphosphanes[109] respectively. They react with acetylenes to give 1,3-dithiol derivatives[110,111].



(117)

(118)

Finally, it is worth mentioning that stable adducts of type *(119)* are also formed from tertiary phosphanes and isothio-

(119), X = S, O

cyanates[112], or isocyanates in some cases[113], but no cycloadditions have been reported thus far[114].

I am grateful to my co-workers, whose names are quoted in the references for their enthusiastic collaboration in this field. I am also indebted to Prof. M. Quast (Würzburg) and Prof. G. Smets (Leuven) for stimulating discussions.

Polarized Low-Temperature Crystal Spectra of Inorganic Complexes

By Peter Day[*]

The electronic spectra of complexes are especially informative if they are recorded for crystals at low temperature or at varying temperature with polarized light. This straightforward technique frequently permits reliable band assignment. Such assignments, being independent of the assumptions of any particular theoretical model, then provide a basis for testing theories of electronic structure.

1. Introduction

When chemists want to measure the electronic spectrum of a molecular complex ion or molecule in the visible or ultraviolet, they usually dissolve it in some suitable solvent and run the spectrum of the solution at room temperature. Under these circumstances, absorption bands are generally broad (rarely less than 10^3 cm^{-1}) and unstructured. In that case, the experimental information content of each band consists of its energy at the absorption maximum, its intensity (often defined as the maximum molar extinction coefficient, but better taken as the integrated band area) and its halfwidth or shape function. We can use all three of these observables to help assign the band, for example to a charge transfer or a ligand field transition, and by matching its energy to the results of some calculation to try and define the electronic symmetry of the excited state. However, even with such a well established procedure as ligand-field theory, the results are often ambiguous. Many generalizations about electronic structures of metal complexes have foundered because of wrongly assigned spectra.

A simple illustration of this fact is the case of the purple permanganate ion, MnO_4^-. Across the visible and near ultraviolet it has four main absorption bands, plus another much weaker one in the near infrared. Since the oxidation state of the manganese is +7, with an effective electron configuration $3d^0$, they cannot be d-d (ligand field) transitions but must be of charge transfer type, *i.e.* excitations of electrons from molecular orbitals mainly localized on the oxygen atoms into the empty d orbitals. In the tetrahedral ion the d orbitals are split into two-fold (e) and three-fold (t_2) degenerate subsets, while the eight 2p orbitals of π-symmetry on the four oxygen atoms are also split into sets labeled e, t_1, and t_2, with degeneracies 2, 3, and 3. In principle, therefore, we could have electronic transitions of any of the filled levels to either of the empty ones, giving a total of six possibilities, even without taking into account splitting of the excited configurations by electron repulsion. From 1952 up to the present, at least a dozen attempts have been made, using various kinds of molecular orbital calculation, to assign the five observed bands to permutations of these orbital excitations. The point I wish to make here is that the seven assignments reported between 1952 and 1970 were all different! Yet the low temperature polarized crystal spectrum described in Section 6.1 contains experimental evidence which uniquely assigns most of the observed bands.

In this article, I want to show how much more information, often of a very precise and unambiguous kind, one can get about the electronic excited states of inorganic molecules and complexes by measuring the spectra of single crystals using polarized light and low temperatures. Figure 1 is a dramatic illustration of the extra information gained by lowering the sample temperature.

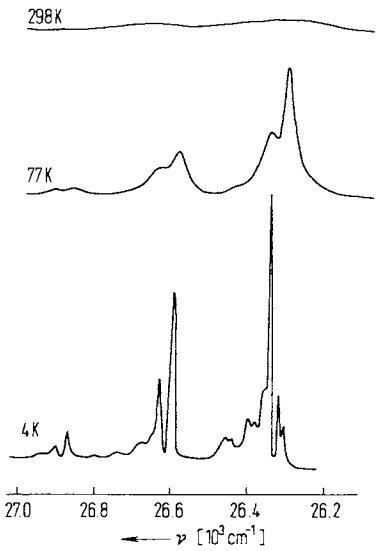

Fig. 1. A ligand field transition in Cs_3CoCl_5 at room temperature, 77 K, and 4 K.

Most of the examples come from our own work, but they are quite representative of many now found in the literature. Also, I shall only deal with complexes, by which I mean molecular species, whether charged or not, which retain their chemical integrity when isolated in dilute solution just as when they are placed in a crystal lattice. Electronic spectroscopy of transition metal ions in continuous lattice solids, like Ni^{2+} in MgO or pure NiO for example, forms a large subject of its own, traditionally closer to solid state physics, although many of the principles I shall describe here apply equally to continuous lattices. There is a very large literature on the electronic spectra of inorganic compounds. Thus, no attempt is made here to treat the theoretical background of the subject, for which reference should be made to textbooks[1] and review articles[2]. Rather, I wish to give an overview, albeit

brief, of some of the methods used to obtain precise and experimentally based assignments of ligand field and charge transfer states on which, ultimately, the tests for theories of electronic structure depend.

2. Why Measure the Spectra of Single Crystals?

There are several answers to this question. The most straightforward is that one may wish to know about the spectrum of a complex which does not exist in solution, perhaps because it is hydrolyzed or transformed to a complex with a different stoichiometry or stereochemistry. A simple example is $CuCl_5^{3-}$. However large an excess of chloride ions one puts into a solution of $CuCl_2$ either in water or dipolar aprotic solvents, the highest complex formed in any appreciable amount is $CuCl_4^{2-}$. Because of lattice energy considerations though, use of a tripositive counterion like $[Co(NH_3)_6]^{3+}$ allows one to crystallize the pentachlorocuprate. Its ligand field spectrum has been recorded for comparison with that of tetrachlorocuprate[3].

Another reason which motivates much work on inorganic crystal spectra is that one may be interested in the interactions between complex ions, due either to magnetic exchange or to charge transfer. For instance, the color of Magnus' Green Salt, $[Pt(NH_3)_4]PtCl_4$, tells one at once that molecular interactions are present in the crystal since the constituent ions $[Pt(NH_3)_4]^{2+}$ and $PtCl_4^{2-}$ are respectively colorless and red[4]. Mixed valency is another frequent source of "non-additive" colors[5]. Several examples of fine structure due to magnetic exchange and the much broader intervalence charge transfer transitions are given later (cf. Sections 6.4 and 4).

Probably the most valuable consequence of building complex ions into a crystal is that the orientations and geometries of the molecules are thereby fixed, so that the polarization vector of the incident light can be defined with respect to the molecular axes. For the detailed quantum mechanics of the interaction between electromagnetic radiation and molecules, reference should be made to the standard quantum chemistry textbooks such as *Eyring, Walter,* and *Kimball*[6]. Suffice it to say here that when an electromagnetic wave passes by, the molecule is subjected to simultaneous electric and magnetic fields, oscillating with the frequency ν of the radiation. If this frequency coincides with the energy difference between the ground state 0 and an excited state n of the molecule through the relationship $E_{0n}=h\nu_{0n}$, the resulting time-dependent perturbation can be thought of as "mixing together" the two wavefunctions ψ_0 and ψ_n. Integrating over time one finds that radiation is absorbed and the molecule undergoes a transition from ψ_0 to ψ_n. The probability of light absorption, represented experimentally by the peak molar extinction coefficient or the oscillator strength, is related theoretically to the magnitude of the off-diagonal matrix element of the appropriate perturbation operator between the two states 0 and n. Now the transition may be brought about by the oscillations of either the electric or the magnetic component of the radiation. In the former case the perturbation operator is the electric dipole operator $\boldsymbol{m}=\sum_i e\boldsymbol{r}_i$ where the summation goes over all the electrons, and in the latter it is the magnetic dipole operator $\boldsymbol{\mu}=(e/2m)\sum_i \boldsymbol{l}_i$. In principle, matrix elements like $\int\psi_n^*\boldsymbol{m}\psi_0 d\tau$ and $\int\psi_n^*\boldsymbol{\mu}\psi_0 d\tau$ are observable properties of the molecule, like the ground state dipole moment $\int\psi_0^*\boldsymbol{m}\psi_0 d\tau$. Consequently, their absolute values have to be independent of the molecular coordinates used to define the wave functions ψ. Put another way, the matrix elements must be totally symmetric to all transformations of the molecular coordinate system or, in the language of group theory, they must span the totally symmetric representation A_{1g} within the point group of the molecule (for nomenclature see ref. [7]; a very useful compilation of group theoretical tables is ref. [8]). In a cubic system the vector $\boldsymbol{r}$ appearing in the electric dipole operator is three-fold degenerate: $\boldsymbol{r}=x+y+z$, for example T_{1u} in the group O_h. Light absorption is then isotropic. However, when the symmetry is lowered from cubic to tetragonal one axis, *e.g.*, z is no longer equivalent to x and y. In the D_{4h} point group z transforms as A_{2u} and x, y as E_u.

A particularly simple example of the assignment of an absorption band using polarized light is provided by the square planar $PtCl_4^{2-}$ ion. This is a low spin d^8 ion with a diamagnetic closed shell ground state, which therefore transforms as A_{1g} in D_{4h}. The crystal K_2PtCl_4 contains stacks of $PtCl_4^{2-}$ ions with their planes all parallel or perpendicular to the planes of the ions (Fig. 2a). For a transition to take place, the arguments just given lead to the general rule

$$\Gamma_0 \times \Gamma_{op} \times \Gamma_n \subset A_{1g} \qquad (1)$$

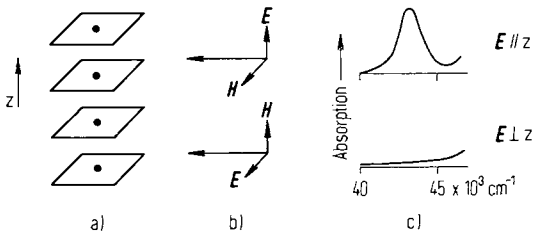

Fig. 2. a) Arrangement of $PtCl_4^{2-}$ ions in the K_2PtCl_4 crystal (schematic); b) directions of polarization of incident light; c) polarized absorption spectra.

where the Γ's are irreducible representations of the ground state, the electronic or magnetic dipole operator and the excited state, respectively. For the two orientations of the electric vector of the incident light, shown in Figure 2b, we therefore have

$$\begin{aligned} &A_{1g} \times A_{2u} \times \Gamma_n \subset A_{1g} \\ &A_{1g} \times E_u \times \Gamma_n \subset A_{1g}. \end{aligned} \qquad (2)$$

The former is satisfied for $\Gamma_n = A_{2u}$, the latter for $\Gamma_n = E_u$. Experimentally one finds[9] that in the ultraviolet there is a very intense band in the crystal spectrum of K_2PtCl_4 at 42500 cm^{-1} when the electric vector of the incident light is parallel to z, but which is absent when $\boldsymbol{E}\|x,y$ (Fig. 2c). Thus, the upper state in question is $^1A_{2u}$, and probably results from a $5d_{z^2}\rightarrow 6p_z$ transition. On the other hand, the first intense band in the spectrum of the isostructural crystal K_2PdCl_4 only appears in $\boldsymbol{E}\|x,y$ so it has to be assigned to a ^1E_u state, most likely a $Cl(p\pi)\rightarrow Pt5d_{x^2-y^2}$ charge transfer transition. Such information could never have been found from a solution spectrum.

Strictly speaking, in the example we have just given, no definitive judgment could be made from the two polarized

spectra as to whether the transition was being allowed by the electric or magnetic dipole mechanism. However, because of the relative magnitudes of the electronic charge and the Bohr magneton, it turns out that even fully allowed magnetic dipole transitions are many orders of magnitude weaker than electric dipole transitions. For uniaxial crystals though, there is a simple test to determine whether a transition is allowed by the electric or magnetic dipole operator. As shown in Figure 3, we measure three polarized spectra, one called the axial (α) spectrum, with the light incident parallel to the unique crystal axis (in which case both electric and magnetic vectors are perpendicular to the axis) and two with the incident light perpendicular. In the latter case, one has the choice of placing the electric vector parallel or perpendicular to the axis (called respectively the π and σ spectra). Compare the three spectra: two will be similar, the other different. Depending on whether the transition is induced by the oscillating electric or magnetic component of the light, the axial spectrum coincides with the σ- or with the π-spectrum, because then these two vectors are parallel. An example, shown in Figure 4, is one of the ligand field transitions of the $CoCl_4^{2-}$ ion in Cs_3CoCl_5. In this tetragonal crystal we see clearly that the axial and σ-spectra coincide, demonstrating the electric dipole character of the transition.

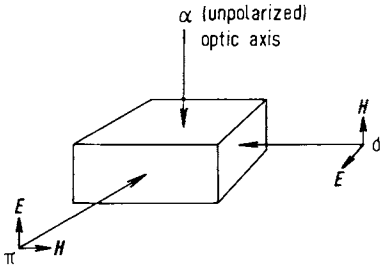

Fig. 3. Measurement of polarized spectra for a uniaxial crystal.

A final reason for measuring the spectra of crystals is that it gives us much the most convenient way of examining the spectra at low temperatures.

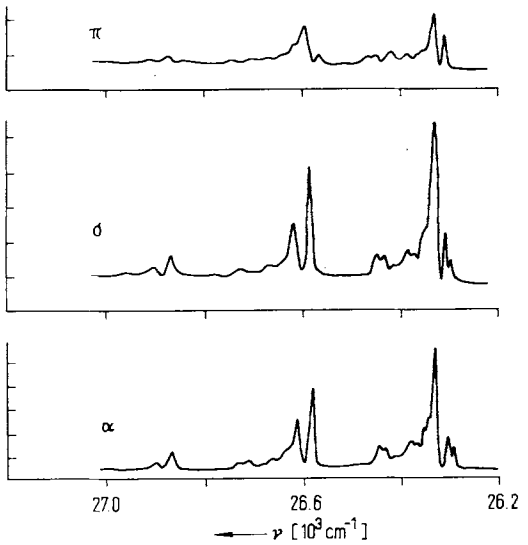

Fig. 4. Axial (α), σ- and π-polarized spectra of a ligand field transition in Cs_3CoCl_5.

3. Why Measure the Spectra of Crystals at Low Temperatures?

A fundamental problem with any kind of spectroscopy is that information about two states, ground and excited, is convoluted into one observable, the energy of the transition between them. How can one uncouple that information and find out about the two states separately? The simplest experiment along these lines is to change the temperature because changes of thermal population among closely spaced sublevels only affect the ground state. In the limit, as we approach absolute zero, all the molecules in the ensemble are in their lowest states and any fine structure observed in the spectrum relates to sublevels of the excited state. There are many sources of sublevels within the electronic ground states of inorganic complexes which, if thermally populated, confuse and broaden the optical spectrum. Bearing in mind that the thermal energy kT corresponding to room temperature is about 200 cm^{-1}, we can cite the following:

1) Skeletal vibrations in the range 100—300 cm^{-1}, (ν(CoN) is about 350 cm^{-1} in $Co(NH_3)_6^{3+}$ and ν(Hg—I) is about 120 cm^{-1} in HgI_4^{2-});
2) Lattice vibrations and librations of complex ions in the range 20—100 cm^{-1};
3) Low symmetry splittings due to the distortion of the complex when placed in the crystal, usually in the range 1—10 cm^{-1} (usually referred to by ESR spectroscopists as "zero-field splittings");
4) Splittings of the order of 5—50 cm^{-1} due to magnetic exchange interactions in dimeric or cluster complexes.

At liquid helium temperature (4.2 K), kT is only about 3 cm^{-1}, so broadening due to the population of these kinds of sublevels is almost entirely eliminated, often with dramatic effects on the resolution and hence on the information content of the spectrum. An example, shown in Figure 5, is a

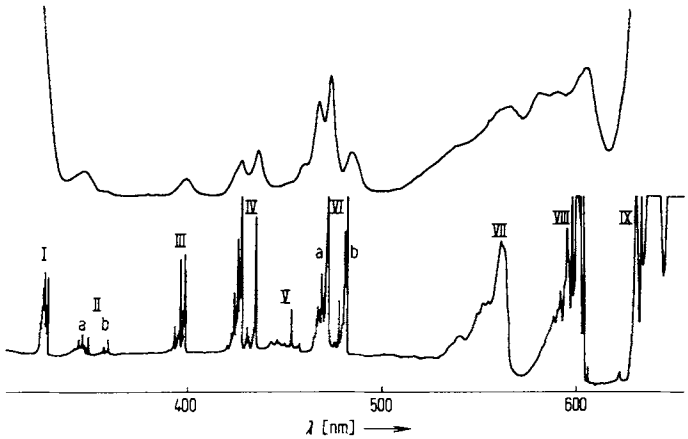

Fig. 5. The spin-forbidden ligand field bands of Cs_3CoBr_5 at room temperature (top) and 4.2 K (bottom) (after [10]).

portion of the ligand field spectrum of $CoBr_4^{2-}$ in Cs_3CoBr_5[10]. In favorable cases such as this one, even very small perturbations of a few cm^{-1} can be used as assignment methods.

Apart from cooling the sample to the lowest available temperature, another approach is to measure the spectrum as a

function of temperature and monitor the changing populations of the ground state sublevels. This can be done in two different ways: if the spectrum is well resolved one can simply monitor the areas of the separate peaks and fit the results to a Boltzmann distribution equation to extract the energy separation between the ground state sublevels directly. For example in $CoCl_4^{2-}$ the ground state of the Co^{II} is $^4A_2$, but in the crystal of Cs_3CoCl_5 the anion is slightly distorted in such a way that the fourfold degeneracy (U' in the double group T_d^*) is lifted and two doublet states result, split apart by 8.4 cm^{-1}. Looking at some of the ligand field bands under high resolution, one sees pairs of bands with just this separation, one member of each pair increasing in intensity with increasing temperature and the other decreasing. On fitting the intensities to the Boltzmann populations in a two-level model an estimate of the separation of the two levels is easily made (Fig. 6)[11].

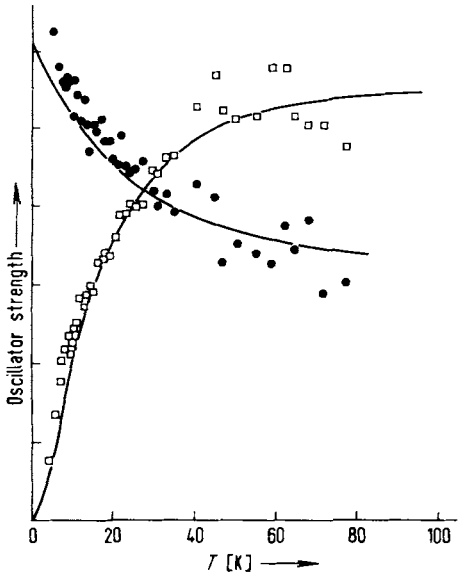

Fig. 6. Temperature dependence of the intensity (oscillator strength, arbitrary units) of a pair of ligand field bands in Cs_3CoBr_5 [11]. The full line is fitted to 11 cm^{-1} separation between the ground state levels.

4. Band Shapes of Broad Absorption Bands

Unfortunately, it sometimes happens that absorption bands remain broad and unstructured, even at very low temperatures. In such cases it may still be possible to extract useful information from the spectrum by measuring it as a function of temperature. For example, Figure 7a shows the first transition of HgI_4^{2-} doped in a crystal of $[(C_2H_5)_4N]_2ZnI_4$ from room temperature to 4.2 K[12]. On cooling it shifts somewhat and narrows, but otherwise remains featureless. What we can measure, though, is its shape or, more particularly, its halfwidth. As we shall describe in more detail below, the band is broadened because the electronic excitation couples to molecular vibrations: the transition obeys the Franck-Condon principle, *i.e.*, it is vertical on a potential energy diagram because the nuclei remain at the same positions in space as an electron is transferred from an occupied to an unoccupied orbital. If the equilibrium geometry of the excited state differs substantially from that of the ground state when it is formed by absorbing a photon it must be in a strongly vibrationally excited state.

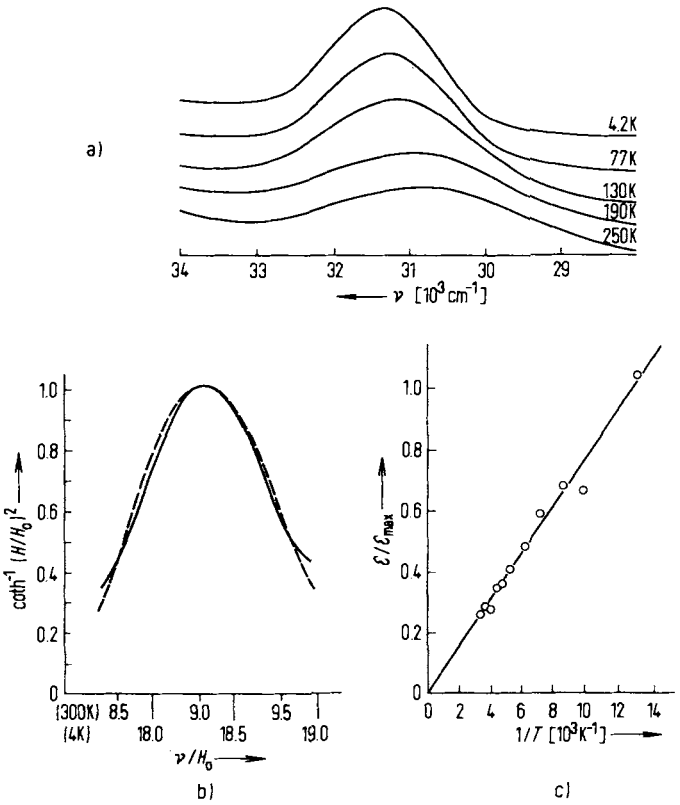

Fig. 7. Treatment of broad absorption bands: HgI_4^{2-} doped into a crystal of $[N(C_2H_5)_4]_2ZnI_4$. a) Axial absorption spectrum at temperatures from 300 to 4.2 K; b) band shape at 300 and 4.2 K; c) halfwidth as a function of temperature [12].

If the motions of the electron and the nuclei are not coupled (*i.e.*, the Born-Oppenheimer approximation is valid) the total wavefunctions of the ground and excited states may be factored into products of electronic and vibrational wavefunctions: *e.g.*, $\psi_n = \psi_n \chi_v$, where χ is a vibrational function. If, as suggested above, we get the total oscillator strength of the band by integrating the band area, this amounts to summing over all transitions from the thermally populated vibrational levels of the ground state to each vibrational level of the excited state:

$$f_{0n} \propto |\langle \psi_n | e\boldsymbol{r} | \psi_0 \rangle|^2 \propto \sum_{v,v'} |\langle \psi_n \chi_{v'} | e\boldsymbol{r} | \psi_0 \chi_v \rangle|^2 \quad (3)$$

Given that the electric dipole operator operates only on the electronic part of the wavefunction, the shape function $G(\nu)$ of the band envelope is obtained by summing over the set of overlap integrals between the vibrational wavefunctions χ_v and $\chi_{v'}$ the purely electronic matrix element $\langle \psi_n | e\boldsymbol{r} | \psi_0 \rangle$ acting as a constant multiplier:

$$G(\nu) \propto \sum_{v,v'} |\langle \psi_n | e\boldsymbol{r} | \psi_0 \rangle|^2 |\langle \chi_{v'} | \chi_v \rangle|^2 P(v) \cdot \delta(\nu - (E_{v'} - E_v)/h) \quad (4)$$

In Eq. (4) P(v) represents the probability that the vth vibrational level of the electronic ground state is occupied. Of course, there are many different modes i with frequencies ω_i.

Then

$$P(v) = \prod \{\exp(-v_i h\omega_i/kT)/[1-\exp(-h\omega_i/kT)]\} \quad (5)$$

For any general case $G(\nu)$ cannot easily be computed. However, by making some rather drastic simplifying assumptions, a tractable expression results. In particular, one assumes that all the modes i have the same frequency or alternatively, and more realistically, that only one mode contributes to the broadening. Furthermore, one supposes that the ground and excited state potential energy surfaces are both harmonic, and merely displaced Δq from one another as shown in Figure 8. The shape function $G(\nu)$ then simplifies to a Gaussian with a halfwidth H which is quite a simple function of temperature

$$H^2 \propto (h\omega)^2 S \coth(h\omega/2kT) \quad (6)$$

where ω is the "effective" vibrational frequency in the ground state and S, called the Huang-Rhys factor[13], is the ratio of the vibrational energy excited in the upper state to the energy of a single vibrational quantum, *i.e.*, $(1/2)\omega^2\Delta q^2/h\omega$. Measuring H as a function of T is thus a means of determining ω, whilst the value of H at $T=0$ gives S and hence Δq, the expansion of the excited state compared with the ground state.

To test Eq. (6) we first have to be sure that the band is well represented by a Gaussian and that the shape does not change with temperature. This is done by plotting $\varepsilon/\varepsilon_{max}$, the ratio of the absorption constant to its maximum value, against ν/H. A Gaussian curve converts to a parabola, as shown in Figure 7b, which also shows that for HgI_4^{2-} the shape is indeed constant with temperature. To obtain ω one then plots $\coth^{-1}(H/H_0)^2$ against $1/T$, giving a straight line passing through the origin, from whose slope ω is found (Fig. 7c). For HgI_4^{2-} the value of ω found in this way is 116 cm^{-1}, remarkably close to the frequency of the totally symmetric Hg—I stretching vibration as found by Raman spectroscopy. The charge transfer spectrum of the ion CoI_4^{2-} behaves in exactly the same way[14].

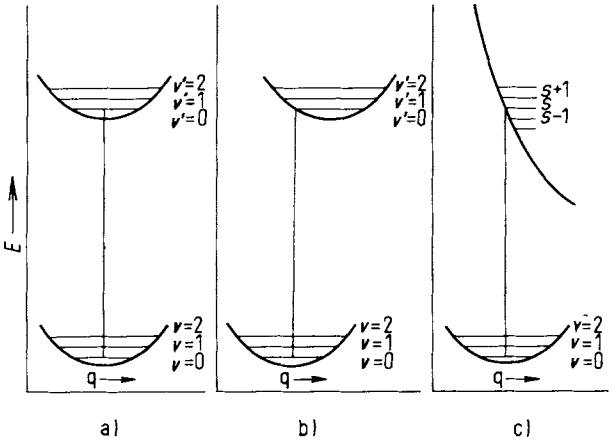

Fig. 8. Ground and excited state potential energy surfaces. a) No change of dimensions in the excited state; b) small change; c) large change.

The ultraviolet spectrum of HgI_4^{2-} remains broad because it results from transfer of an electron from non-bonding orbitals localized on the halogen atoms to the highly antibonding empty 6s orbital on Hg. Even broader are the bands which, in mixed valency compounds, arise from electron transfer between two complex ions containing metals in different oxidation states. For instance, compounds containing the two complex ions $SbCl_6^-$ and $SbCl_6^{3-}$ are dark blue because of an absorption band which does not occur in compounds containing either ion separately[15]. The new band is a charge transfer $Sb^{III} \rightarrow Sb^{V}$. As can be seen from Figure 9a, it is at least 5000 cm^{-1} wide[16]. This is because we are removing an electron completely from one complex ion and placing it on another, a process which must lead to an excited state having an equilibrium geometry very different from that of the ground state. In Figure 9b the variation of halfwidth with temperature is compared with that calculated from eq. (6) with $\omega = 210$ cm^{-1} and $S = 130$[16]. The fit, which is quite good, corresponds to the bond length change (about 0.2 Å) expected on going from MCl_6^{3-} to MCl_6^{2-}. On the other hand, the frequency is not that of either $SbCl_6^{3-}$ or $SbCl_6^-$.

5. How to Measure the Spectra of Crystals at Low Temperatures

We have discussed some of the types of information which are potentially accessible by measuring crystal spectra at low temperatures. How then does one go about it? Technical details of optical spectroscopy are given in a number of books[17]; here I will describe some general principles.

5.1. Cryostats

Liquid helium is now found much more often in chemistry laboratories than it was a few years ago, so we shall not consider any other cryogenic fluids such as liquid nitrogen (b.p. 77 K) or liquid hydrogen (b.p. 20 K). Cryostats for optical spectroscopy are of two main types: static or flow. Also available, though more expensive than cryostats, are various types of closed-cycle or open-cycle refrigerators which are usually based on the Joule-Thomson effect. However, they are much cheaper than conventional cryostats to operate, since they only need gas or, in the case of the closed-cycle systems, only electricity, and are very suitable for laboratories where supply of liquid refrigerants is a problem. On the other hand, they rarely work below about 10 K, and have only a limited cooling capacity.

Static cryostats, nowadays mostly made of metal, consist of an outer vacuum casing within which the can containing the liquid helium is further isolated from heat entry by surrounding it with a copper radiation shield cooled by liquid nitrogen. The sample is then suspended on a rod so that it is immersed in the liquid helium for experiments at 4 K, or in cold flowing gas for work above 4 K. The sample rod usually contains a small heating element, as well as a temperature sensor such as a carbon resistor or a gold/0.03 atomic percent iron *vs.* chromel thermocouple, to enable the temperature to be controlled by a feed-back device. A typical form of static cryostat is shown in Figure 10a. To reach temperatures below 4 K, a second liquid helium container is placed within the main container, insulated from it by another vacuum space but connected to it by a siphon tube. The inner chamber is filled through the siphon from the outer, then closed off, and the pressure above the liquid is reduced by a rotary pump. In this way, temperatures down to about 1.4 K are accessible. To go lower, more specialized methods are needed.

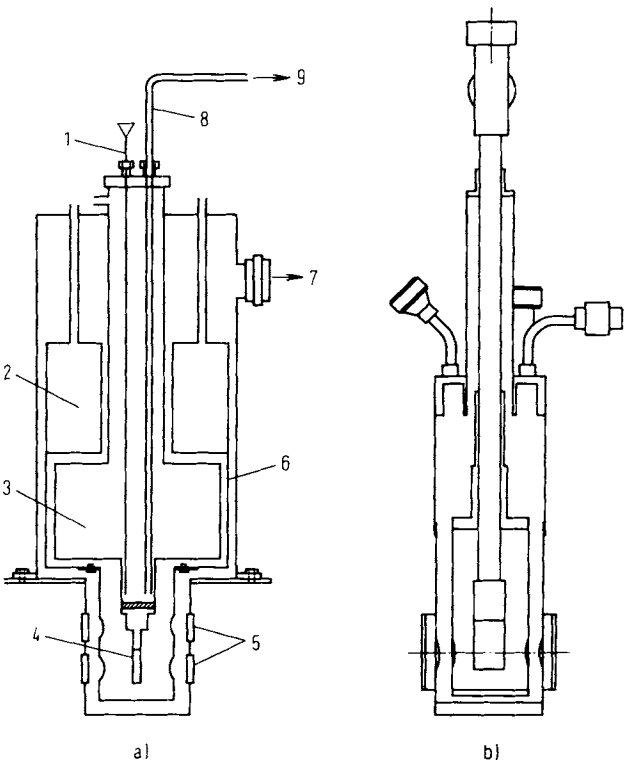

Fig. 10. a) Static cryostat. 1, helium level indicator; 2, liquid nitrogen reservoir; 3, liquid helium container; 4, copper block; 5, quartz windows; 6, copper radiation shield; 7, to vacuum pump; 8, transfer tube; 9, to helium Dewar. b) Flow cryostat [18].

A very convenient form of small cryostat for carrying out short experiments down to about 3.6 K is the continuous flow system shown in Figure 10b[18]. Here the liquid helium is sucked from a storage vessel through the cryostat by a small pump, the flow rate being controlled by a needle valve.

5.2. Sample Mounting

Unless condensing optics are used to focus the light onto the crystal, the minimum crystal dimensions for optical spectroscopy are about 1 mm^2 in area. Of course, the thickness depends upon the extinction coefficients of the bands being measured and the concentration of active chromophore in the crystal. Most conventional double beam spectrophotometers can measure an optical density of about 3 without the effects of stray light becoming too noticeable. Pure solids may have an effective concentration of light absorbing species as high as 5—10 M, so if the molar extinction coefficient of the band in question is 10 l mol^{-1} cm^{-1} the crystal should not be thicker than about 0.2 mm. On the other hand, if one wishes to measure a charge transfer transition, with a molar extinction coefficient of several thousands, the best way is to dilute the chromophore by making a solid solution with an isomorphous but non-absorbing host lattice, for example MnO_4^- in $KClO_4$. If necessary, crystals can be thinned either on a lapping wheel using diamond paste, or with successively finer grades of emery paper, followed by polishing with talc.

After determining its orientation by taking an oscillation or a Laue back-reflection X-ray photograph, the crystal is usually mounted in the cryostat by fixing it over a hole in a copper plate with a small amount of silicone grease, taking care that it is not strained, and that no light passes around its edges.

5.3. Spectrophotometers

Commercial double beam ratio recording spectrophotometers are quite suitable for all except the most sophisticated measurements of polarized low temperature crystal spectra. Important factors to bear in mind are the resolution of the monochromator, determined by the length and the number of lines/mm of the grating; the stray light level, which determines the maximum optical density which can be measured, and the sensitivity and wavelength range of the detection system, which governs the slit width at which one can work, and hence the ultimate resolution possible with a crystal of given size. Taking the Cary 14 or 17 as an example, these in-

struments have monochromators containing both a prism and a grating. The quality of the monochromation is usually expressed as the reciprocal dispersion, in this case about 30 Å mm^{-1} in the visible. The ability of the instrument to resolve closely spaced peaks depends on the width of the entrance and exit slits: at the minimum values usually employed in the Cary (about 0.02—0.05 mm) it has a resolution, or spectral band-pass, of about 1 Å. Normally visible-ultraviolet spectra are expressed in wavenumbers (cm^{-1}), so it is of interest to note that at 4000 Å, on the edge of the ultraviolet, 1 Å is equivalent to about 6 cm^{-1}, while in the red, at 7000 Å, it is about 3.5 cm^{-1}.

More sophisticated monochromators may do considerably better than this. For example, a standard 1 m Czerny-Turner monochromator with a grating having 1200 lines mm^{-1} has a reciprocal dispersion of 8.3 Å mm^{-1} in first order, and can be used to obtain spectral bandpass nearer 0.1 Å, *i.e.*, about 0.5 cm^{-1} in the visible. Quite a different way of obtaining highly monochromatized radiation, now having a large impact on many fields of spectroscopy, is the tunable dye laser. With a given dye one can usually tune the radiation over about 300 Å but dyes are now available to cover the whole range from the near infrared (9500 Å) to the ultraviolet (3500 Å) or, with frequency doubling, to about 2200 Å. As in a monochromator the spectral bandpass of the radiation depends upon the size and quality of the grating used in the laser cavity, but around 0.1 Å is quite readily obtained. Further, by fitting an etalon in the cavity this may be reduced by a further factor of 100. The uses of such very narrow bandpass radiation for inorganic spectroscopy are only now beginning to be explored.

6. Fine Structure in Low Temperature Crystal Spectra

Earlier on in Section 3 we listed some of the sublevels within the electronic ground state which, by becoming thermally populated at room temperature, serve to confuse the absorption spectrum. It is important to realize that such sublevels exist for every excited state, so at low temperatures the fine structure we see in the spectra reflects the sublevel structure of the excited state, and is extremely valuable for assigning the transition. Let us now consider some sources of fine structure, and the kind of information that we can get from them. First of all, we take the fine structure which comes from co-excitation of molecular vibrations.

6.1. Vibrational Structure

The three parts of Figure 8 indicate the three broad subdivisions of behavior when a transition occurs between a ground state and excited state potential energy surface. They correspond to increasingly strong coupling between the electron being excited and the nuclear framework of the complex, a distinction which was originally made a long time ago by *Herzberg* in the spectra of small molecules in the gas phase[19]. We have already discussed in Section 4 the extreme form of case c, when only a broad unstructured envelope is seen. In the other limiting case, when the equilibrium dimensions and the force constants of the molecule are unchanged by the electronic transition, one would anticipate only a single sharp line corresponding to $v=0 \rightarrow v'=0$, because the vibrational wave functions form an orthonormal set. Only when $v=v'$ is the vibrational overlap integral in Eq. (4) nonzero. Case a of Figure 8 applies when the electrons involved in the transition scarcely influence the molecular binding; an extreme example would be an f→f transition in a lanthanoid or actinoid complex. However, there is a complicating factor here because the electronic transition itself is not electric dipole-allowed if the complex is centrosymmetric, owing to the fact that ψ_0 and ψ_n share the same parity. For an electric dipole transition to be observed, the electronic excitation has to be accompanied by creation ($\chi_0 \rightarrow \chi_i'$) or annihilation ($\chi_1 \rightarrow \chi_0'$) of a quantum of some non-totally symmetric vibrational mode. An extension of Eq. (1) is then

$$\Gamma_0 \times \Gamma_0^{vib} \times \Gamma_{op} \times \Gamma_n \times \Gamma_n^{vib} \subset A_{1g}. \quad (7)$$

Applying Eq. (7) to an octahedral complex of an f-block element, for example, Γ_0 and Γ_n would both be u-functions, Γ_{op} is the u while if the temperature is low enough for all the molecules in the crystal to be in their vibrational ground states Γ_0^{vib} is g. Hence, Γ_n^{vib} has to be u.

Just such a situation, which represents a particularly neat example of these arguments, is the UCl_6^{2-} ion, whose spectrum was measured some years ago by *Satten* and his colleagues[20]. The electron configuration of the ion is $5f^2$ and the ground term is $^3H_4$. Fine structure of one of the f→f transitions in $[N(CH_3)_4]_2UCl_6$, in which the UCl_6^{2-} occupies a centrosymmetric site, is shown in Figure 11. There is a clear symmetry about this band system, corresponding components lying at equal frequency intervals on either side of a central point, marked with the arrow. The latter represents the frequency of the purely electronic f→f transition which, because it is u→u, does not appear. What we do see, though, are narrow bands corresponding to the frequency of the purely electronic transition plus or minus the frequencies of single quanta of each of the odd-parity vibrational modes of the octahedral complex. Sum and difference bands are easily distinguished by varying the temperature because the $\chi_1 \rightarrow \chi_0'$ bands lose intensity when the crystal is cooled and the $v=1$ levels become depopulated. The way their intensities vary with the temperature provides an additional check on the ground state vibrational frequencies *via* the Boltzmann population expression [Eq. (5)].

Usually, d-electrons in transition metal complexes are thought of as more heavily engaged in molecular binding than f-electrons in complexes of the lanthanoids and actinoids. In analyzing vibrational fine structure accompanying the d-d transitions of centrosymmetric transition metal complexes we meet the same problem we have just described for UCl_6^{2-}, namely that the absorption is electric dipole-forbidden, this time because it is g→g. However, we can avoid this complication by looking at the spectrum of a tetrahedral complex. If the equilibrium position along a vibrational coordinate in the excited state is slightly (but only slightly) displaced from its position in the ground state, or if the force constant is slightly altered by the excitation, the ground and excited state vibrational wavefunctions no longer form a strictly orthonormal set so that transitions other than $v=v'$ become allowed. On the other hand, the vibrational overlap

integrals $\langle\chi_0'|\chi_v\rangle$, whose squares are called Franck-Condon factors, fall off rapidly in magnitude as v and v' diverge. At low temperature then, we find the $\chi_0 \rightarrow \chi_0'$ band strongest, but followed by a "progression" of increasingly weaker bands from excitation to χ_1', χ_2', ... *etc.* If the potential energy surface remains reasonably harmonic in the excited state, the intervals between its vibrational levels are constant. The progression then manifests itself in a very obvious way, as a series of equally spaced bands. In fact, one of the first things which a spectroscopist does when confronted by a highly structured band system is to search for some constant energy intervals.

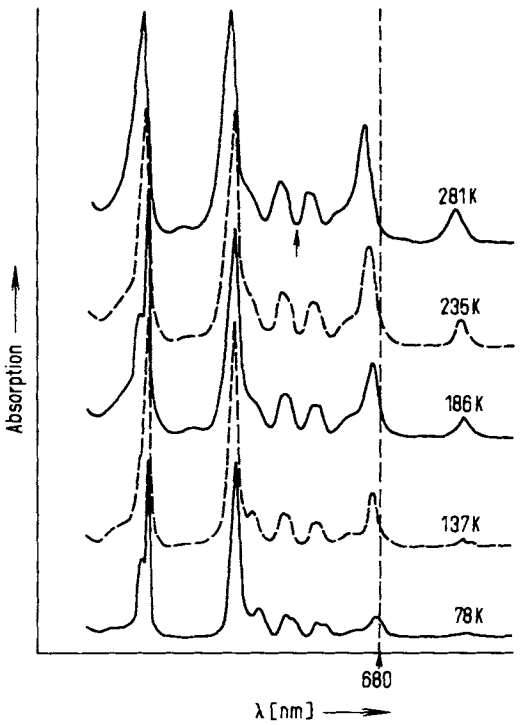

Fig. 11. Part of the f→f spectrum of $[(CH_3)_4N]_2UCl_6$ at various temperatures, showing fine structure due to odd-parity vibrational modes [20].

He is often aided by the fact that the vibrational frequencies in the excited state are not more than 10% or so different from those of the ground state. Consequently, a good knowledge of the crystal's infrared and Raman spectra is a great help.

Nevertheless, even such a simple molecule as a tetrahedron has four intramolecular vibrational modes (a, e, t_1, and t_2), not to mention vibrations of the molecules against one another, or against the counterions in the crystal. Which of them are likely to show up as progressions? The answer is mostly the totally symmetric ones. This is because of the operation of the Born-Oppenheimer approximation. Even if we remove the orthonormality requirement from the vibrational wavefunctions, only multiple quanta can be excited of those modes which are totally symmetric in the point group both of the ground and the excited electronic state. Should the complex change shape on excitation, *i.e.* if the point group of the excited complex, at its equilibrium geometry, is different from the ground state, one may find co-excited modes which, while non-totally symmetric in the ground state's point group, become totally symmetric in that of the excited state. The most common consequence of the breakdown of the Born-Oppenheimer approximation is the Jahn-Teller effect: as *Liehr* remarked[21] many years ago "observation of a progression in a non-totally symmetric mode is a sure sign of Jahn-Teller funny business". However, in this short article, I do not want to consider this particular complication.

An illustration representative of the vibrational fine structure often seen in ligand field spectra is the band system of Figure 4. Three sets of repeating bands are observed; they are separated by intervals of 275 cm^{-1}, very close to the a_1 Co—Cl stretching frequency in the ground state of $CoCl_4^{2-}$ (285 cm^{-1}). Further subsidiary intervals correspond to excitation of single quanta of the e molecular mode, and also various lattice modes. After the vibrational sidebands have been assigned in this particular case, there remain four closely spaced electronic origin bands. These originate from the lowering of symmetry in the ground and excited states as a result of the crystal lattice environment. We shall discuss them further below.

When the molecule changes its dimensions by a larger amount on excitation, as for example in a charge transfer transition when an electron is transferred from an orbital localized on the ligands to one localized on the metal, the first member of the vibrational progression is no longer necessarily the most intense: as a function of v' the vibrational overlap integral $\langle\chi_0|\chi_{v'}'\rangle$ may have its maximum value for $v'>0$. Figure 12 shows a particularly well resolved progression in the visible spectrum of the MnO_4^- ion doped into the tetragonal lost lattice KIO_4[22]. The frequency of the repeat interval is 764 cm^{-1}, which should be compared to the a_1 Mn—O stretching frequency in the ground state, 850 cm^{-1}. Note that this excited state frequency is reduced by a much larger factor than was the case for the ligand field band of $CoCl_4^{2-}$. By assuming that the potential energy surfaces of the two states are harmonic, one can use the set of Franck-Condon factors to calculate how much the molecule is expanded in the excited state: from the very similar spectra of MnO_4^- in the orthorhombic host crystal $KClO_4$, a figure of 0.10 Å has been estimated[23].

Sometimes the nature of the vibration co-excited with the electronic transition can be used to diagnose the type of transition. An interesting set of examples of this way of using vibrational fine structure are the metal-metal bonded dimers such as $Re_2Cl_8^{2-}$, whose structures consist of two planar $ReCl_4$ moieties placed face-to-face with a very short Re—Re distance. Two kinds of electronically excited state can be envisaged in this kind of complex. Either electrons are excited

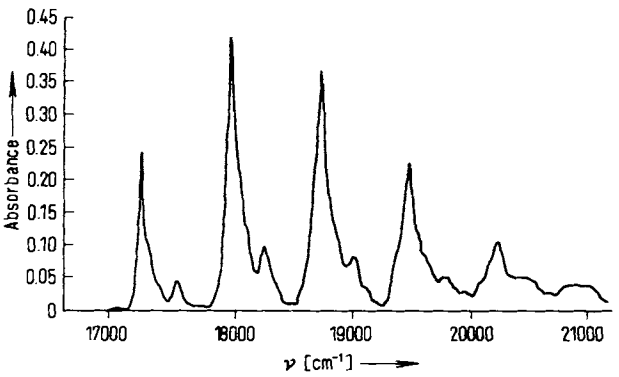

Fig. 12. Part of the axial spectrum of MnO_4^- in tetragonal KIO_4 [22].

from Cl orbitals to empty Re orbitals (charge transfer) or the excitation is from metal-metal bonding orbitals to antibonding ones, in which case the transition is localized within the Re_2 part of the molecule. If the transition were of charge transfer type the vibrational coordinate q in Figure 8 along which the molecule is displaced on going from the ground to the excited state is that of an Re—Cl normal mode. On the other hand if the electron remains within the Re_2 unit, while reducing the Re—Re bond order, then it is the Re—Re distance which is most altered on excitation. In the event (Fig. 13) the vibrational mode co-excited with the 680 nm band in $Re_2Cl_8^{2-}$ is the Re—Re stretching mode (350 cm^{-1}), so the band is assigned to the $\delta-\delta^*$ transition of the Re—Re quadruple bond[24]. Similar conclusions were reached about the visible absorption bands of several complexes containing the Mo_2^{4+} unit, though here there is an interesting complication because much of the intensity appears to arise from vibronic coupling[25].

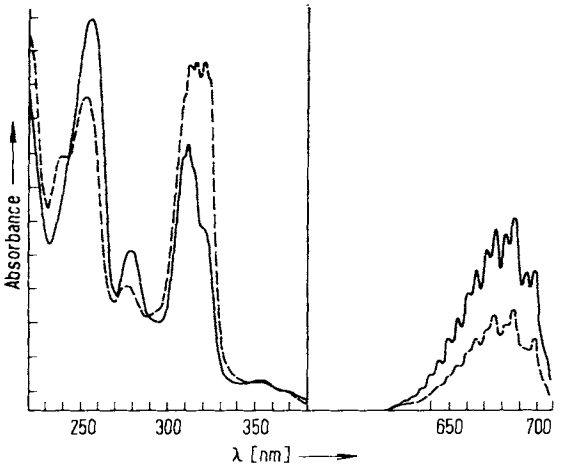

Fig. 13. Polarized absorption spectra of $[N(C_4H_9)_4]_2[Re_2Cl_8]$ at 5 K [24].

6.2. Isotope Vibrational Splittings

A special case of vibrational fine structure occurs when the ligands can exist in more than one isotopic form. Frequencies of metal-ligand vibrations depend on the masses of the vibrating atoms and on the force constant of the bond, which, of course, is unaffected by substituting one isotope for another. Shifts in the frequencies on isotope substitution therefore result from the changed reduced mass alone. Sometimes isotope substitutions are made deliberately to assign vibrational fine structure: for example D for H in aquo-complexes[26] or O^{18} for O^{16} in complexes of the uranyl (UO_2^{2+}) ion[27]. Sometimes, too, one may simply find two isotopes present in ordinary natural abundance. An instance of this effect is shown in Figure 14. One of the ligand field bands of $MnCl_4^{2-}$ in the tetragonal crystal Cs_3MnCl_5 [actually one of the spin-orbit components of $^4T_2(D)$] is accompanied by a progression in the a_1 Mn—Cl stretching mode, much as in the band of $CoCl_4^{2-}$ in Figure 4. However, in the Mn case the bands are particularly sharp and well resolved, so that further substructure becomes apparent[28]. In the first vibrational sideband (*i.e.*, one quantum of the a_1 mode) we see an envelope of at least three bands, each separated from the next by 2.1 cm^{-1}. Chlorine occurs as ^{35}Cl and ^{37}Cl with natural abundances 75.4% and 24.6%, respectively. The tetrachloromanganate complexes in our crystal therefore consist of $[Mn^{35}Cl_4]^{2-}$, $[Mn^{35}Cl_3{}^{37}Cl]^{2-}$, $[Mn^{35}Cl_2{}^{37}Cl_2]^{2-}$, ...*etc.* in

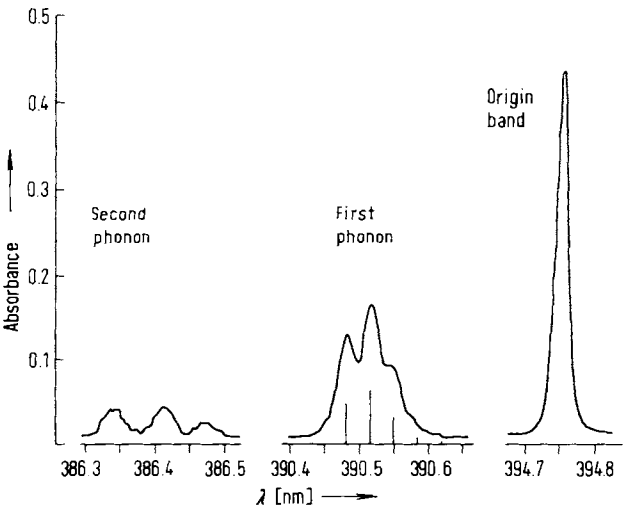

Fig. 14. Isotope fine structure in the vibrational sidebands of a ligand field transition of $MnCl_4^{2-}$ in Cs_3MnCl_5 [28].

statistically determined proportions. Each Cl_4 unit has a slightly different reduced mass (in the a_1 mode the Mn remains stationary) and so gives a sideband at a slightly different frequency. The calculated frequencies and abundances are shown as sticks in Figure 14: agreement with the experimental spectrum is clearly excellent.

6.3. Site Group Splittings

Although complex ions like $CoCl_4^{2-}$ and MnO_4^- may be regular tetrahedral in solution, when they are incorporated into a crystal lattice they will almost certainly occupy sites with lower point symmetry than T_d. Taking the absorption band in Figure 4 as an example, we noticed that after the vibrational sidebands were all accounted for there remained a group of bands constituting the electronic origin. This is shown in greater detail in Figure 15. As noted earlier, the ground state ($^4A_2$ in T_d) is split in the crystal of Cs_3CoCl_5 by a combination of spin-orbit coupling and a small tetragonal distortion to give two doublets (E′ and E″ in D_{2d}^*). Ligand field calculations[11] suggest that the band system in Figures 4 and 15 might be assigned as a transition to a $^2E(T_d)$ state which, like the ground state, would transform as U′ in the double group T_d^*. Also like the ground state, this excited U′ state would be split by the tetragonal site distortion, similarly giving two doublets, E′+E″. In principle, therefore, four transitions are possible, and they can all be assigned by combining temperature dependence and polarization data as shown in Figure 16[11]. Eq. (1) applied to the double point group D_{2d}^* tells us that E′→E′ and E″→E″ are allowed only in *xy*-polarization while E′→E″ and E″→E′ are allowed for both *xy*- and *z*-polarizations. In Figure 15a we see that the lowest energy band A only appears in the *xy*-spectra while temperature variation experiments indicate that it is a "hot" band; 8.4 cm^{-1} to higher energy the next band B has mixed polarization and behaves as a "cold" band. Figure 15b shows

bands A and B in the *xy* polarization at even higher resolution and lower temperature. At 1.3 K band A has disappeared completely. The temperature variation experiments also

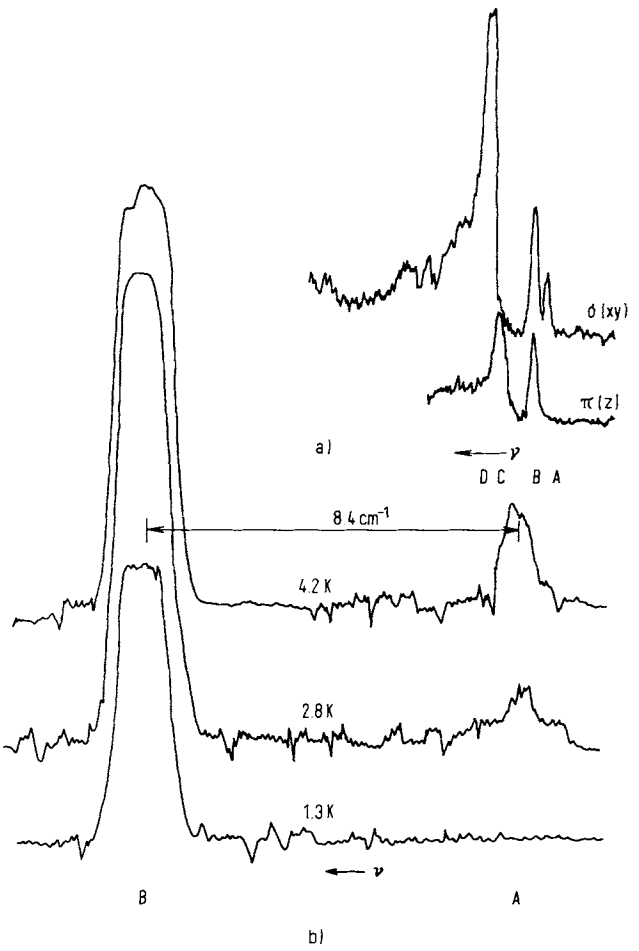

Fig. 15. Electronic origin region of the $^4A_2 \rightarrow {}^2E(D)$ transition of $CoCl_4^{2-}$ in Cs_3CoCl_5: a) under medium resolution; b) under high resolution. Bands A—D refer to Fig. 16.

tell us that the hot band A originates from a level 8.4 cm^{-1} above the lowest, hence the first two bands come from transitions to the same upper level from the two components of the ground state. The third band C, which is also "hot", is of mixed polarization while the fourth D, again "cold", is only seen in the *xy*-spectrum. ESR spectroscopy[30] tells us that the E′ level lies 8.4 cm^{-1} below the E″ in the ground state so the optical data show quite unambiguously that the two levels of the upper state lie in the opposite sequence. The two cold bands are 33 cm^{-1} apart, which is therefore the site-group splitting of the upper ^2E state. By applying the same kind of arguments most of the other dozen or so doublet ligand field states of $CoCl_4^{2-}$ and $CoBr_4^{2-}$ were definitively located and assigned[10,11].

Charge transfer spectra too show many nice examples of site-group splittings which constitute a most valuable assignment tool for this type of transition. Again the MnO_4^- ion provides a good illustration. When doped in the orthorhombic crystal $KClO_4$ the MnO_4^- occupies the ClO_4^- sites, having only C_S point symmetry, *i.e.*, only one remaining element of symmetry, a mirror plane passing through the Cl and two oxygen atoms. Actually in the unit cell of $KClO_4$ there are four ClO_4^- groups but fortunately their mirror planes are all parallel. Permanganate has a closed shell ground state, transforming as $^1A'$. Transitions are allowed to $^1A'$ when the electric vector is parallel to the mirror plane and to $^1A''$ when it is perpendicular. When one examines the electronic origin of the visible band at 4 K for these two polarizations[29] one finds that there are two $^1A'$ bands and one $^1A''$. Since T_2 in T_d is decomposed into $2A' + A''$ in C_S, the experiment clearly defines the tetrahedral parentage of the excited state as $^1T_2$.

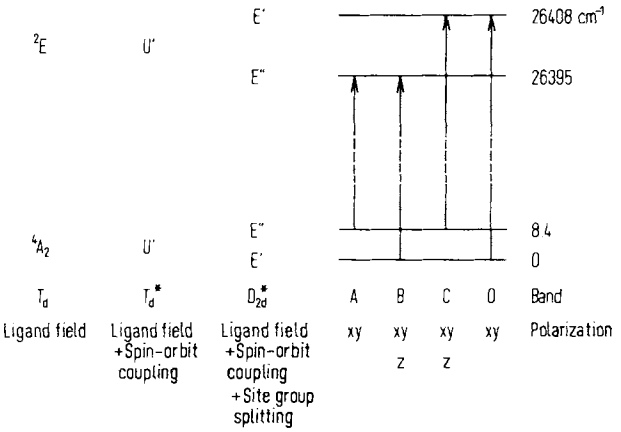

Fig. 16. Site splitting of the $^4A_2 \rightarrow {}^2E$ transition of $CoCl_4^{2-}$ in Cs_2CoCl_5. Labels A—D refer to Fig. 15.

A very similar example is MnO_4^{2-}, a $3d^1$ ion, whose low temperature charge transfer spectrum in a Cs_2SO_4 host crystal is shown in Figure 17[31]. The site group in this lattice is again C_S, which splits the $^2E(T_d)$ ground state into $^2A'$ and $^2A''$. From ESR spectroscopy[32] it is found that the latter lies lower by some 200—300 cm^{-1}. Because of the extra electron the situation is now more complicated than for MnO_4^- and in the T_d point group transitions would be electric dipole-allowed from ^2E to either $^2T_1$ or $^2T_2$ states. Our task is thus to discover which in fact appear in the charge transfer spectrum, and in what order. Selection rules in the Cs_2SO_4 lattice are the same as the ones we have just given for $KClO_4$. Notice that the origin region of the first charge transfer band in Figure 1 consists of two bands in the $\boldsymbol{E}\|\boldsymbol{b}$ spectra and one in the $\boldsymbol{E}\|\boldsymbol{a}$; in the former the electric vector is parallel to the mirror planes through the Mn atoms, in the latter it is perpendicular. Consequently we have the same result as for MnO_4^- in $KClO_4$, namely two A′ and one A″ origin, and the tetrahedral parentage of the first charge transfer band is

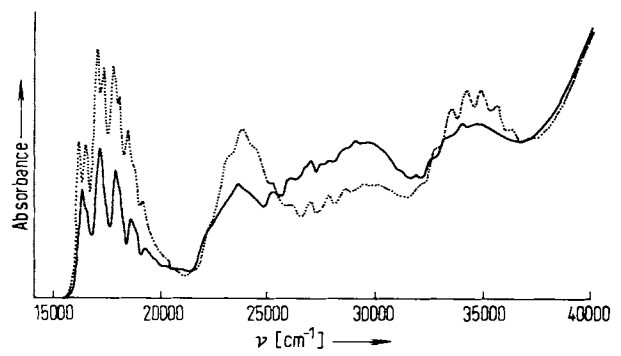

Fig. 17. The polarized charge transfer spectrum of MnO_4^{2-} in Cs_2SO_4 at 4 K [31]. —, $\boldsymbol{E}\|\boldsymbol{a}$; ·····, $\boldsymbol{E}\|\boldsymbol{b}$.

again T_2. As can be seen from Figure 1 the higher energy bands are not sufficiently resolved, even at 4 K, for this means of assignment to be used, but the relative intensities in the two polarizations give a clue to the fact (confirmed by more detailed arguments which we shall not reproduce here) that all except the band near 30000 cm^{-1} also have T_2 parentage.

6.4. Magnetic Interactions

Most metal complexes are monomeric, but a number of classical examples such as the acid and basic "rhodo-" and "erythro"-chromium(III) salts contain pairs or larger clusters of transition metal ions, and in recent years an increasing number of others have been synthesized. If the individual metal ions in the cluster have unpaired electrons there will be some magnetic exchange interaction between them, either ferro- or antiferromagnetic. The ground state of the cluster then consists of a series of sublevels characterized by various values of S_T, the total spin quantum number of the cluster. Consider, for example, a dimeric chromium(III) complex. In the ground state, each Cr atom ($3d^3$, $^4A_{2g}$ in an octahedral ligand field) labeled 1 and 2 carries a net spin of $S_1 = S_2 = 3/2$ so the total spin quantum number of the complex can take integral values from $S_1 - S_2$ to $S_1 + S_2$, *i.e.* from 0 to 3. The sublevels with different S_T have different energies, often described to a good approximation by the Heisenberg hamiltonian

$$H = -J_{12} S_1 \cdot S_2 \qquad (8)$$

which predicts energy intervals between successive levels with increasing S_T of J, $2J$, $3J$. If J in eq. (8) is negative (antiferromagnetic) the $S_T = 0$ sublevel lies lowest while if it is positive (ferromagnetic) $S_T = 3$ is lowest. In the ligand field spectra of dimeric chromium(III) complexes therefore we expect to see groups of bands representing transitions from each of the S_T sublevels of the ground state to various S_T^* sublevels of the excited state. The selection rule $\Delta S_T = 0$ is usually obeyed quite well[33]. Changing the temperature will alter the populations of the S_T sublevels and hence the relative intensities of the bands. A quantitative intensity measurement as a function of temperature serves to identify which S_T sublevel the transition originates from, and, in combination with the observed energy of the band, enables one to map the ground and excited state exchange sublevels.

A good example[34] is the acid "rhodo"-chloride $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5 \cdot 3H_2O$ in which the hydroxyl ion forms a bent bridge between the two Cr atoms. Figure 18 shows the temperature variation of the two most intense bands in the 680 nm ($^4A_2 \rightarrow {}^2E$) region of the ligand field spectrum fitted to fractional populations calculated for the separations of S_T sublevels shown. A value of J of about -33 cm^{-1} gives quite a good fit to the experimentally observed energy levels, with the ratio of the intervals between the sublevels very close to 1:2:3. Comparable experiments have been done with several other dimeric[35] and trimeric[36] chromium(III) complexes, as a testing ground for theories of magnetic exchange.

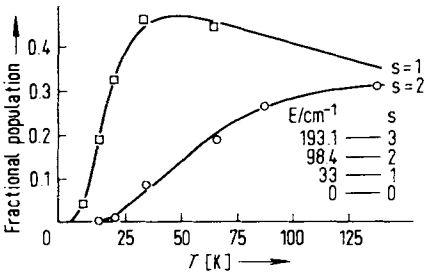

Fig. 18. Temperature dependence of intensity of two exchange-split ligand field bands in $[(NH_3)_5Cr(OH)Cr(NH_3)_5]Cl_5 \cdot 3H_2O$ fitted to the ground state exchange splitting shown inset [34].

7. Conclusion

Electronic absorption spectroscopy is one of the most widely used tools of the inorganic and coordination chemist who wants to learn something about the electronic structures of molecular complexes containing not only transition metal but also B-subgroup cations. By orienting the complex in a crystal and then lowering the temperature the amount of information contained in the visible absorption spectrum is enormously enhanced. Not just the overall polarization of the bands, but the various kinds of fine structure only resolved at low temperature, contribute to a refined view of the excited state's electronic structure. In particular in this article we have tried to show how various observable features in low temperature polarized crystal spectra can give unambiguous symmetry assignments to transitions using only our knowledge of the crystal structure and the group theoretical selection rules and, further, give information about the equilibrium geometry of the excited state. However, the beauty of selection rules based only on symmetry requirements is that they do not depend for their validity on the results of detailed quantum mechanical calculations containing approximations which may or may not be well founded.

It will be clear that such experimentally based assignments, not relying for their validity on the assumptions of any particular theoretical model, are the only possible starting point for assessing how valid these assumptions are. Fitting absorption band energies to the results of ligand field calculations is a long standing sport among inorganic chemists, but it is always wise to be sure, from some other experiment, that the bands being being fitted actually have the assignment which is being put on them. Such advice is doubly necessary in the field of charge transfer spectra, for which no reliably predictive model exists yet. Only by amassing the results of many experiments of the kind described here on the widest possible variety of complexes can we arrive at the experimental basis on which a predictive model must be founded. Basic equipment for measuring low temperature polarized crystal spectra is readily available commercially, and is not difficult to use. In our laboratory we have measured temperature dependent spectra down to as low as 0.8 K using a specially designed cryostat, and spectral bandwidths as small as 0.001 Å could be obtained using a tunable dye laser containing an intracavity etalon. However, very little work on the spectra of inorganic complexes has been reported yet with such low temperatures and high resolving power. More important for the chemist wanting to correlate his results with structural theories is the accumulation of a large body of securely assigned spectra. For the simplest tetra- and hexahalide and tetroxo-complexes the information is

at hand, for mixed complexes and complexes of more elaborate ligands it is only now beginning to be accumulated.

Most of this article was written while a Visiting Scientist at the Xerox Corporation Webster Research Center. I am grateful for the hospitality extended to me by members of the Center.

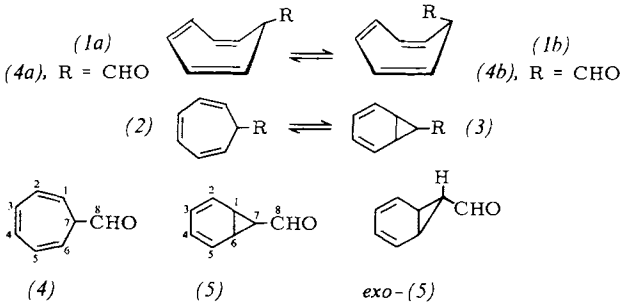
COMMUNICATIONS

Communications are brief preliminary reports of research work in all areas of chemistry which, on account of its fundamental significance, novelty, or general applicability, should be of interest to a broad spectrum of chemists. Authors of communications are requested to state reasons of this kind justifying publication on submission of their manuscript. The same reasons should be clearly apparent from the manuscript. In cases where the editorial staff decide, after due consultation with independent referees, that these conditions are not met, manuscripts will be returned to the authors with the request to submit them for publication in a specialist journal catering for scientists working in the field concerned.



The Dynamic Behavior of 2,4,6-Cycloheptatriene-1-carbaldehyde[**]

By *Metin Balci, Hartmut Fischer*, and *Harald Günther*[*]

Ring inversion and valence tautomerism are well-known dynamic processes in cycloheptatrienes[1]. While steric effects, besides possible electronic factors, play a major role[2] in determining the position of the conformational equilibrium *(1a)*⇌*(1b)* in C^7-substituted derivatives, the cycloheptatriene-norcaradiene equilibrium *(2)*⇌*(3)* is largely controlled by the acceptor properties of the substituents R[3]. According to MO calculations[4] this influence should increase

along the series CN < COOH < CHO; so far, this prediction has been confirmed experimentally for R = CN and COOH[5]. We have now examined the influence of the aldehyde group for cycloheptatrienecarbaldehyde[6] *(4)* by high-field NMR spectroscopy (^{1}H: 400 MHz, ^{13}C: 100 MHz) and have found that the dynamics of the molecule are more complicated than expected.

Already at room temperature the highfield position of the H(1,6) signal ($\delta = 5.28$) would suggest that a considerable proportion of 7-norcaradienecarbaldehyde *(5)* is present at equilibrium. In agreement with this, strong broadening of the H(7) and H(1,6) signals takes place on cooling, until at $-100\,^\circ$C, the spectra of *(4)* and *(5)* are observed (Table 1). Further lowering of the temperature then leads—at first surprisingly—to renewed line-broadening in the spectrum of *(4)*, which after signal splitting finally shows two signals of similar intensity each for both H(7) as well as H(8). Consequently, in the system investigated a conformational equilibrium *(4a)*⇌*(4b)* must also exist besides the valence tautomerism *(4)*⇌*(5)* (Fig. 1).

The interpretation of the ^{1}H-NMR spectrum is confirmed by the temperature-dependence of the ^{13}C-NMR spectrum (Table 1). Here also, the signals of C(1,6,7)—particularly sensitive for the valence tautomerism[7]—show the strongest temperature effect. Below $-134\,^\circ$C the ring inversion is documented by the renewed broadening of the signal due to C(7), and in particular of the CHO signal, until superposition of the ^{13}C spectra of *(4a)*, *(4b)*, and *(5)* is reached at $-156\,^\circ$C; thus, to our knowledge, *(4)* is the first monosubstituted cycloheptatriene in which ring inversion has been demonstrated to accompany valence tautomerism.

As integration of the ^{1}H-NMR low-temperature spectrum shows, at $-145\,^\circ$C *ca.* 7% of *(5)* is present besides the cyclo-

[c] CD_2Cl_2; 0.1 M. [d] CD_2Cl_2/vinyl chloride (1:2); 0.3 M. [e] $J < 5$ Hz. [f] $J = 9.2$ Hz. [g] CD_2Cl_2; 0.3 M.

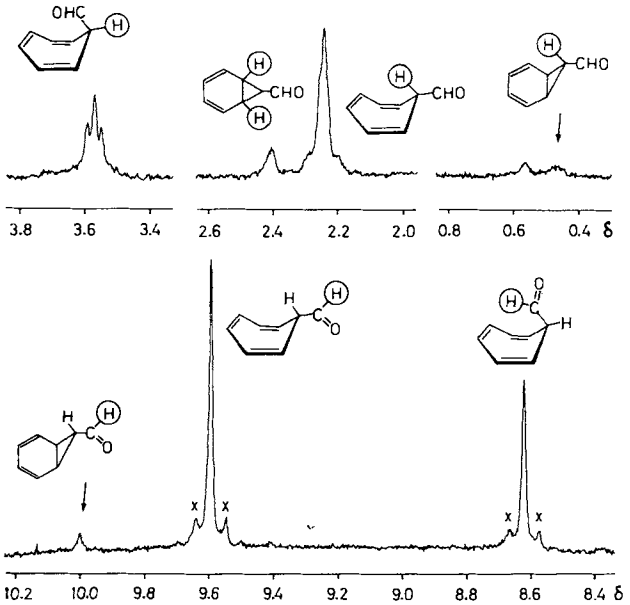

Fig. 1. ^{1}H-NMR spectrum of the system *(4b)*⇌*(4a)*⇌*(5)* at $-152\,^\circ$C in $CDCl_2$/vinyl chloride (1:2); spectrometer frequency 400.16 MHz, δ values ref. to TMS. Rotational sidebands at (×).

heptatrienes *(4a)* and *(4b)*. For the equilibrium *(4a)*⇌*(5)* we obtained $K = 8.9$ and hence ΔG^0 ($-145\,^\circ$C) = 2.3 kJ/mol in favor of *(4a)*. If we ignore possible complications by the entropy factor[8], then the above-mentioned sequence for the substituent effect is confirmed, for we found only 3% of the Buchner acid *(3)*, R = COOH, in equilibrium [ΔG^0 ($-150\,^\circ$C) = 3.8 kJ/mol in favor of *(2)*, R = COOH][5], and 7-norcaradienecarbonitrile could still not be detected. In contrast to the α-proton in the cyclopropanecarbaldehyde, H(7) is shielded in *(5)* by $\Delta\delta = -1.35$, so that *(5)*, like the Buchner acid, must be present in the *exo* configuration. Apparently, only this configuration allows the bisected geometry of the aldehyde group and thus optimum electronic interaction with the three-membered ring.

The difference in the free enthalpy between the conformers *(4a)* and *(4b)* is only 0.5 kJ/mol at $-145\,^\circ$C and is thus smaller than in the case of the nitrile (ΔG^0 ($-133\,^\circ$C) = 1.6 kJ/mol[5]). According to the ^{1}H-NMR data the *exo* configuration *(4a)* likewise predominates in *(4)*, with H(7) being shielded and H(8) deshielded. In agreement with this the H(7) signal of the *endo* conformer *(4b)* at $\delta = 3.57$ shows the typical *cis*-coupling $J(1,7)$[9] for the cycloheptatriene with $J = 9.2$ Hz. However, no report can be made on the stabilization of *(1a)* relative to *(1b)* by the substituents CN, COOH, and CHO until the ΔH^0 values are known since the entropy term may be important.

A Facile Route to a Sensitive Terpene Alcohol—Regio-unselective Metalation of α-Terpinene as Key Step[**]

By *Manfred Schlosser, Herbert Bosshardt, Annelis Walde,* and *Manfred Stähle*[*]

The monoterpene alcohol "anthemol" (4-isopropyl-1,3-cyclohexadienemethanol) *(4a)* has practically vanished from the scene since its debut in 1879[1]. We saw a challenge in the synthesis of this compound, providing an opportunity to test once more the efficiency of our novel access to allylic and dienylic primary alcohols. The one-pot method[2] consists of three reaction steps: metalation of a conjugated or homoconjugated diene, reaction with fluorodimethoxyborane, and oxidation with alkaline hydrogen peroxide solution. Terpinene *(1)* served as an inexpensive starting material. It was attacked by the butyllithium/potassium *tert*-butoxide reagent[3] with surprising ease (90 min, −45 °C, tetrahydrofuran). The borylation/oxidation reaction sequence afforded, however, only 44% of anthemol[4] together with 50% of *p*-cymene (4-isopropyl-1-methylbenzene) *(4b)*. While allylic methyl groups are generally deprotonated much faster than such methylene or even methine groups[5], the metalating agent attacks the allylic methyl and each of the methylene groups of α-terpinene with almost equal probability. Thus there arise the three pentadienylpotassium species: *(2a)*, with a serpent-like, partly exocyclic delocalization region, as well as *(2b)* and *(2c)*, in which delocalization involves a horseshoe-shaped, endocyclic region. After borylation with $FB(OCH_3)_2$, the intermediates formed from *(2b)* and *(2c)* apparently eliminate $HB(OCH_3)_2$ and are converted into the aromatic hydrocarbon *(4b)*. Addition of deuterium oxide to the organometallic intermediates *(2)* leads to deuterated α- and γ-terpinene [*(3a)*, 47% yield; *(3b)*, *(3c)*, each 24% yield], while reaction with chlorotrimethylsilane gives 4-isopropyl-1-(trimethylsilylmethyl)-1,3-cyclohexadiene [*(5a)*, 36%], 1-isopropyl-4-methyl-3-trimethylsilyl-1,4-cyclohexadiene [*(5b)*, 29%], and 4-isopropyl-1-methyl-3-trimethylsilyl-1,4-cyclohexadiene [*(5c)*, 29%][4].

Pentadienylpotassium compounds with horseshoe-shaped delocalization area ("U conformation") can form an *open-sandwich structure*[2b,6] and should therefore be energetically favored. The unexpected ease of formation of intermediates *(2b)* and *(2c)* is in full accord with this assumption.

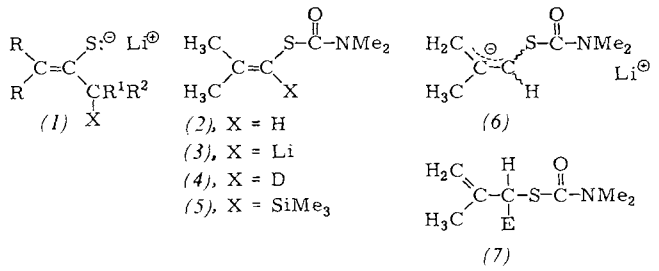
α-Carbamoyloxymethyl-Substituted Lithium Enethiolates from 1-(*N,N*-Dimethylcarbamoylthio)-2-methyl-1-propenyllithium[**]

By *Dieter Hoppe, Ludger Beckmann,* and *Rainer Follmann*[*]



Owing to the kinetic instability of most thioaldehydes and thioketones[1], synthetic entry to the hitherto little investigated enethiolates *(1)*, X = H[2], is greatly restricted; enethiolates of type *(1)*, X = acyloxy or alkyloxy derived from thioketones are to our knowledge unknown. We now report on the synthesis of lithium α-(*N,N*-dimethylcarbamoyloxymethyl)enethiolates *(9)* from the readily accessible *S*-vinyl thiocarbamate *(2)*[3], which proceeds with concomitant chain lengthening. The key step is the vinyl deprotonation of the ester *(2)*[4] to the lithium compound *(3)*: The nucleophilic building block *(3)* transfers a latent enethiolate group, which is liberated in the carbonyl adducts *(8)* by intramolecular migration of the dimethylcarbamoyl group from the sulfur to the alkoxide oxygen.

The ester *(2)*[3] was deprotonated with lithium diisopropylamide (LDA), or better with *tert*-butyllithium, at −78 °C in

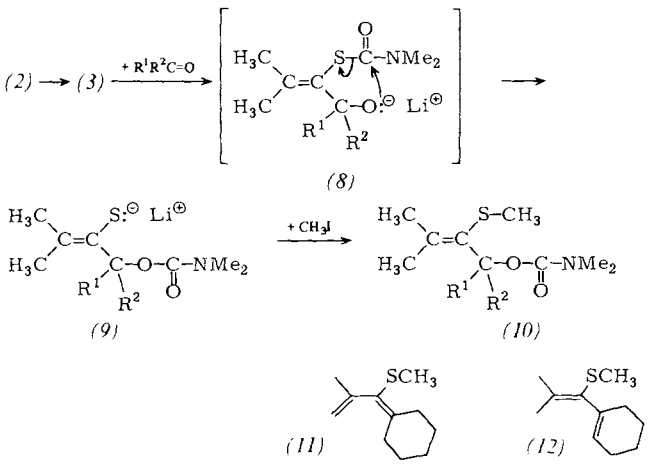
[**] Metalated Nitrogen Derivatives of Carbonic Acid in Organic Synthesis, Part 14. This work was supported by a Postgraduate Grant from the Konrad-Adenauer-Stiftung for *L. B.*—Part 13: *D. Hoppe, L. Beckmann*, Justus Liebigs Ann. Chem. *1979*, 2066.



tetrahydrofuran (THF)/hexane and the product *(3)* detected as vinylsilane *(5)*[5] (yield 51 and 76%, resp.) after treatment with chlorotrimethylsilane. Reaction of *(3)*—generated with LDA—with CH_3OD gave 54% of the deuterium compound *(4)*[6], which on renewed lithiation and protonolysis lost 50% of the labeling. Hence, the presence of a resonance-stabilized allyl anion *(6)*[7] as intermediate[8] is ruled out.

(1) *(2)*, X = H; *(3)*, X = Li; *(4)*, X = D; *(5)*, X = $SiMe_3$

(6)

(7)

(8)

(9) *(10)*

(11) *(12)*

(8), *(9)*, *(10)*: *(a)*, $R^1 = H$, $R^2 = C_6H_5$; *(b)*, $R^1 = R^2 = CH_3$; *(c)*, $R^1 + R^2 = -(CH_2)_5-$

Reaction of *(3)* with benzaldehyde at −78 °C gave the lithium enethiolate *(9a)*, which we trapped as methyl vinyl thioether *(10a)* in 64% yield with methyl iodide, without the initial adduct *(8a)* being isolable. Acetone and cyclohexanone analogously afforded the compounds *(10b)*[5] and *(10c)*[5] in 26% and 44% yield, respectively. That the carbamate *(10)* is in fact present—and not the *O*-methylated isomer [from *(8)*]—follows from the carbonyl absorptions of *(10)* in the IR spectrum around 1690 cm^{-1} [*(2)*: $\nu_{S\ C\ O} = 1655\ cm^{-1}$], from the resonances of the SCH_3 groups in the ^{1}H-NMR spectrum between $\delta = 2.1$ and 2.2, and from the thermolysis of *(10c)* at 160—210 °C to a mixture[5] of the methylthiobutadienes *(11)* and *(12)* in the ratio 45:55, yield 82%.

Procedure

Solution of *(9a)*: 4.0 ml (5.6 mmol) of a 1.40 N solution of *tert*-butyllithium in *n*-hexane is added dropwise at −78 °C to a stirred solution of *(2)*[3] (0.80 g, 5.0 mmol) in 10 ml of anhydrous THF under N_2 and the mixture stirred for 1 h. After addition of 0.58 g (5.5 mmol) benzaldehyde in 5 ml THF, stirring is continued for a further 1.5 h.

(10a): A fine stream of methyl iodide (0.78 g, 5.5 mmol) is slowly pipetted into the solution of *(9a)* at −78 °C and the reaction mixture allowed to warm to 20 °C after 1 h. Removal of solvent by distillation, partition of the residue between diethyl ether (30 ml) and water (15 ml), drying over sodium sulfate, and removal of solvent afforded a colorless oil, which was purified by chromatography on silica gel (neutral) with ether/pentane (1:1); yield 0.89 g (64%) *(10a)*. $R_F = 0.33$; IR (film): 1690 (C=O), 1660 cm^{-1} (C=C); ^{1}H-NMR (CCl_4): $\delta = 7.2$ (m, C_6H_5), 6.87 (s, CH); 3.0, 2.9 (br, s, $N(CH_3)_2$), 2.08 (s, SCH_3), 2.08, 1.80 (s, CH_3).

1,5-Dihydropentalene by Tandem Carbene-Carbene Rearrangement[**]

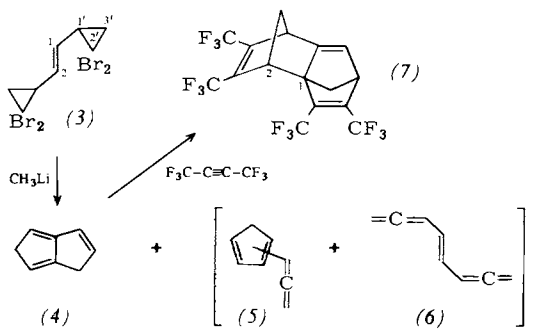
By *Udo H. Brinker* and *Ilona Fleischhauer*[*]

Carbene-carbene rearrangements involving a 1,3-carbon shift *(1)*→*(2)* and subsequent 1,2-hydrogen shift open up a facile entry to cyclopentadienes[1].

(1) *(2)*

• = ^{12}C

Consecutive carbene-carbene rearrangements of the type *(1)*→*(2)* for the synthesis of multi-annelated, unsaturated cyclopentane structures[2] are not known.



We have found that reaction of *trans*-1,2-bis(2,2-dibromocyclopropyl)ethene *(3)* with methyllithium gives 1,5-dihydropentalene *(4)*[3] as a main product.

Addition of dibromocarbene ($CHBr_3$, K-*tert*-butoxide) to *trans*-1,3,5-hexatriene (molar ratio 3:3:1) gives, besides the monoadduct[4] (15—20%), the *trans*-1,2-bis-(2,2-dibromocyclopropyl)ethene *(3)* [m.p. 92—93 °C (from methanol), ^{1}H-NMR (60 MHz, $CDCl_3$): $\delta = 5.45$—5.70 (dd, 2 olefinic H,

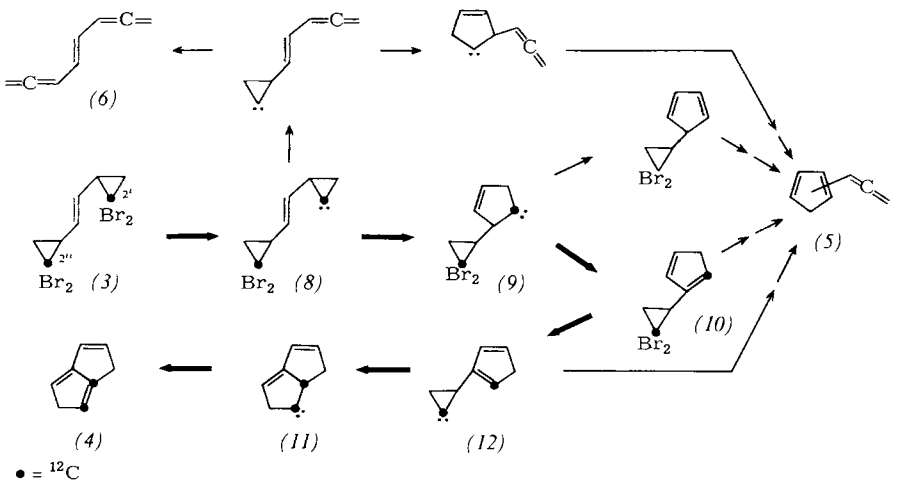
Universitätsstr. 150, D-4630 Bochum 1 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. *I. F.* thanks the Studienstiftung des Deutschen Volkes for a study grant. We thank Dr. *W. Dietrich* and Priv.-Doz. Dr. *H. Duddeck* for recording the ^{13}C-NMR spectra.

$J_{1,1'}=5$ Hz, $J_{1',2}=2.5$ Hz), 1.45—2.60 (m, 6 cyclopropyl H)] in 40—50% yield. Reaction of *(3)* with methyllithium (molar ratio 1:2.2, ether) at −40 °C and −70 °C yields three major products. Since the reaction mixture already polymerizes at



room temperature under argon, the crude mixture was directly hydrogenated (Pt/C, 10%; 1.5 h, −70 °C (−40 °C) to +25 °C). The resulting compounds[5] *cis*-bicyclo[3.3.0]octane, *n*-propylcyclopentane and *n*-octane suggest that 1,5-dihydropentalene *(4)*, propadienyl cyclopentadiene *(5)* and 1,2,4,6,7-octapentaene *(6)* are the major products of the reaction of *(3)*. The structure of 1,5-dihydropentalene *(4)* is further supported by the fact that *(4)* can be trapped with hexafluoro-2-butyne as main product (50—60%) from the crude reaction mixture[6]. The initial Diels-Alder adduct of *(4)* undergoes renewed reaction with the dienophile to give the 1:2 adduct *(7)*, which has already been synthesized *via* an independent route[6].

carbene rearrangement with 1,3-carbon shift to give *(9)* and subsequent 1,2-hydrogen shift to give *(10)*. Reaction of *(10)* with the second equivalent of methyllithium leads to *(12)*, which once again makes a structurally integrated vinylcyclopropylidene unit available. Renewed carbene-carbene rearrangement *(12)*→*(11)* and subsequent 1,2-hydrogen shift afford 1,5-dihydropentalene *(4)*. For consecutive carbene-carbene rearrangements of this type we propose the term tandem carbene-carbene rearrangement.

The reaction of *(3)* (C-2′, C-2″ = ^{12}C)[8] and subsequent treatment of the crude product mixture with hexafluoro-2-butyne under the given conditions confirm this mechanistic interpretation. Comparison of the ^{13}C-NMR spectra ($CDCl_3$) of labeled and unlabeled 3,4,9,10-tetrakis(trifluoromethyl)tetracyclo[6.2.1.1^{2,5}.0^{1,6}]dodeca-3,6,9-triene *(7)* reveals the absence of the signals at δ = 73.1 and 45.5, which were assigned to C-1 and C-2 in *(7)* with natural isotope distribution. C-2′ and C-2″, separated by five carbon-carbon bonds in the educt *(3)*, are directly connected in 1,5-dihydropentalene *(4)* after tandem carbene-carbene rearrangement.

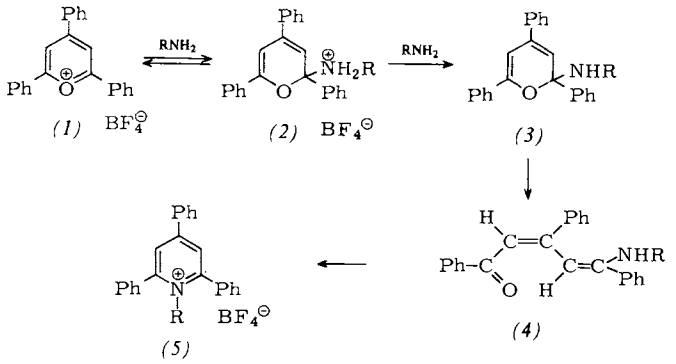
For the formation of *(4)*, *(5)*, and *(6)* in the reaction of *(3)* with methyllithium there are the following possibilities: 1,2,4,6,7-octapentaene *(6)* could be formed by twofold cyclopropylidene-allene rearrangement. Propadienylcyclopentadiene *(5)* can be regarded as the product of a carbene-carbene rearrangement[7] involving a 1,3-carbon shift followed by a 1,2-hydrogen shift and an additional cyclopropylidene-allene rearrangement. The sequence of these competing rearrangements cannot be established.



The formation of *(4)* can be conceived as the result of a sequence of carbene-carbene rearrangements[7] and 1,2 hydrogen shifts. Reaction of *(3)* with the first equivalent of methyllithium affords carbene *(8)*, which undergoes a carbene-

Mechanism of the Pyrylium/Pyridinium Ring Interconversion. Mild Preparative Conditions for Conversion of Amines into Pyridinium Ions

By *Alan R. Katritzky, Ruben H. Manzo, Jeremy M. Lloyd,* and *Ranjan C. Patel*[*]

^{13}C-NMR studies have demonstrated that excess *n*-butylamine reacts with 2,4,6-triphenylpyrylium tetrafluoroborate *(1)* by rapid ring-opening to the "vinylogous amide" *(4)* followed by slow reclosure to give the pyridinium salt[1]. Extensive spectrophotometric kinetic studies with a variety of amines and pyryliums have now clarified the reaction mechanism: the ultraviolet spectra of species *(1)*, *(4)*, and *(5)* are readily distinguished.

The sequence *(1)*→*(4)* is base catalyzed. For amines of $pK_a > 8$, excess of amine acts as base. For aniline, and for *m*- and *p*-nitroaniline, the sequence *(1)*→*(4)* becomes fast in the presence of NEt_3 as catalyst. For pyryliums possessing a 2- or 6-phenyl or 2- or 6-methyl group, the equilibrium of type *(1)*⇌*(4)* is displaced extensively towards *(4)*: however, if both the 2- and 6-positions are occupied by *tert*-butyl or by fused rings, appreciable quantities of the pyrylium salt remain in equilibrium.

The rate-determining step in the reaction of *(1)* with excess *n*-butylamine is the ring closure *(4)*, R = *n*Bu→*(5)*, R = *n*Bu which is found kinetically to be first order in *(1)* and zeroth order in $nBuNH_2$. The rate depends on the solvent (relative rates in dimethylformamide, acetonitrile, and dichloromethane were 1:20:270).

The rate of ring closure *(4)*→*(5)* varies strongly with the structure of the amine. Taking the rate for $nBuNH_2$ as unity, rates for amines RCH_2NH_2 were 1.3—0.7 and for amines $RR'CHNH_2$ were 0.01—0.002, while those for aniline and *m*-nitroaniline were respectively 0.02 and 0.0007 (obtained by extrapolation). Ring closure is clearly hindered both sterically and electronically by electron withdrawal.

The ring closure *(4)*→*(5)* is strongly acid catalyzed. Addition of two moles of AcOH to a mixture of *(1)* and $iPrNH_2$ [after the formation of the intermediate *(4)*] increased the rate 325 times; the rate for the $nBuNH_2$ reaction was too fast to measure under these conditions. Catalysis by AcOH of the reactions of *(1)* with $iPrNH_2$ and with $PhNH_2$ obey equations of the Michaelis-Menten type indicating a pre-equilibrium of vinylogous amide and catalyst to give protonated vinylogous amide which then reacts further by a unimolecular pathway[2].

The influence of successive basic and acidic catalysis of the reaction of *(1)* with aniline is shown in Figure 1. Such catalysis can dramatically improve preparative procedures for converting pyrylium into pyridinium. The pyrylium salt, amine, and triethylamine (equimolar quantities) are stirred in CH_2Cl_2 for 5 min to form the vinylogous amide, 2 mol of AcOH is added, the mixture kept 15 min and diluted with diethyl ether to yield the pyridinium.

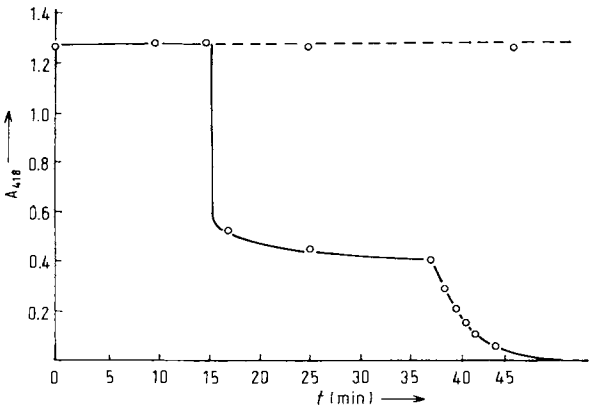

Fig. 1. Plot of absorption at 418 nm of a CH_2Cl_2 solution of 2,4,6-triphenylpyrylium perchlorate (6.1×10^{-3} M) and aniline (12.2×10^{-3} M). The solid line shows the variation when triethylamine (to bring to 6.1×10^{-3} M) was added after 16 min and acetic acid (to bring to 2.46×10^{-2} M) was added after 37 min. The dotted line shows the unchanged absorbance in the absence of NEt_3 (acetic acid was added as before after 37 min).

In this way the following improvements have been made:

(i) For amines RCH_2NH_2 reaction times have been reduced from *ca.* 12 h (*e.g.* ref. [3]) to 20 min, while at least maintaining the yield (≥80%).

(ii) For amines $RR'CHNH_2$ reaction times have been reduced from 12—30 h used to prepare iodides[4] to 20 min to obtain the more generally useful tetrafluoroborates in excellent yield (≥73%)[5].

(iii) Reaction of arylamines with 2,4,6-triphenylpyrylium previously required much stronger conditions: 80 °C for aniline[4] and *m*-nitroaniline[6] and refluxing dimethylformamide for *p*-nitroaniline[7]. Provided reagents are rigorously dried, the above procedure at 20 °C gives the 1-phenyl-, 1-(*m*-nitrophenyl)-, and 1-(*p*-nitrophenyl)pyridiniums in 77, 66, and 47% yield, respectively. The last two yields can be raised to 81 and 69% by slightly longer reaction times (at 20 °C).

(iv) Uncatalyzed reactions of even amines RCH_2NH_2 with more complex pyryliums can be very slow: thus at 20 °C the reaction of *n*-$BuNH_2$ with 2-*tert*-butyl-5,6-dihydro-4-phenylnaphtho[1,2-*b*]pyrylium is incomplete after 7 days at 20 °C: the catalyzed reaction leads to quantitative conversion at 20 °C in 15 min. Amines $RR'CHNH_2$ do not react with 5,6-dihydro-2,4-diphenylnaphthopyrylium in the absence of AcOH; the catalyzed reaction proceeds quantitatively at 20 °C in *ca.* 10 min.

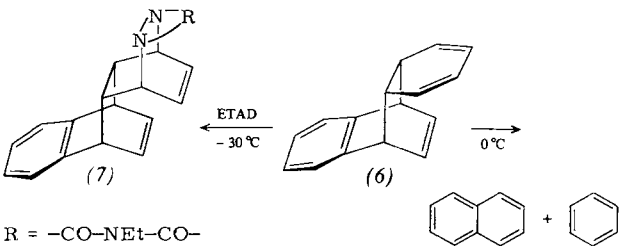
9,10-Benzotricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene—A Diels-Alder Adduct of Benzene and Naphthalene[**]

By *Wolfram Grimme* and *Hans Günter Köser*[*]



In Diels-Alder reactions benzene reacts neither as diene[1] nor as dienophile; however, its indirectly accessible [2+4]-cycloadducts are of interest regarding their retrocleavage. The decomposition is irreversible and exothermic, occurs already at low temperature, and can be easily measured both kinetically and calorimetrically. In the case of the Diels-Alder dimer of benzene, the "*o,p'*-dibenzene", whose tricarbonyliron complex is stable[2], retrocleavage occurs so readily that the free cycloadduct cannot be isolated, even at $-20\,^{\circ}C$. The Diels-Alder adduct of benzene and naphthalene, the title compound *(6)*, is more stable. It can be synthesized *via* the tricarbonyliron complex *(5)*, prepared analogously to the "*o,p'*-dibenzene"-tricarbonyliron[2].

[2+2]-Cycloaddition of dichloroketene, obtained by reaction of dichloroacetyl chloride with triethylamine, to the benzo-analog *(1)*[3] of *Nenitzescu*'s hydrocarbon furnished the dichlorocyclobutanone *(2a)* (37% yield; for physical data see Table 1), which on treatment with tri-*n*-butylstannane in boiling cyclohexane was partially dechlorinated to *(2b)* (81%). After reduction to the alcohol *(2c)* with $NaBH_4$ in 80% dioxane, reaction with methanesulfonyl chloride/trimethylamine in ether gave the ester *(2d)*. Subsequent elimination with sodium in liquid ammonia/ether afforded the valence isomer *(3)* of the title compound [57% from *(2b)*].

Opening of the bicyclohexane moiety in *(3)* was accomplished by heating with $Fe_2(CO)_9$ in hexane (20 min, 50 °C); subsequent chromatography on aluminum oxide (activity 2—3) with pentane as eluent afforded the tetracarbonyliron complex *(4)* (25%) followed, with ether, by the tricarbonyliron complex *(5)* of the title compound (25%). Further *(5)* could be obtained by thermolysis of *(4)* in boiling toluene. The higher temperature and migration of iron to the *exo* side of the cyclohexadiene moiety in *(5)* would indicate that *(4)* is not directly isomerized, but presumably first dissociates and is then opened by attack of a carbonyliron on the concave side of the bicyclohexene unit. For liberation of the benzene-naphthalene adduct *(6)*, *(5)* was oxidized at $-20\,^{\circ}C$ with ceric ammonium nitrate in acetone; after 20 minutes the reaction mixture was partitioned between pentane and saturated aqueous $CaCl_2$ solution. After drying and concentration of the pentane solution at $-20\,^{\circ}C$, 9,10-benzotricyclo[6.2.2.0^{2,7}]dodeca-3,5,9,11-tetraene *(6)* was obtained as colorless crystals (92%), which were further purified by chromatography on silica gel (pentane, $-20\,^{\circ}C$).

Compound *(6)*, to our knowledge the first Diels-Alder adduct of two standard arenes, reacts with 4-ethyl-1,2,4-triazolinedione (ETAD) in chloroform at $-30\,^{\circ}C$ to give *(7)*, and already rapidly decomposes into its components benzene and naphthalene at 0 °C. The rate of retrocleavage was determined in *n*-hexane on the basis of the increasing naphthalene absorption at 311 nm at nine temperatures between 0 and 14.1 °C.

The reaction is of first order, the rate constant of which is given by the following Arrhenius equation[4]:

$$\log k = (12.07 \pm 0.60) - (19\,550 \pm 770)/2.303\,RT$$

We ascribe the enhanced stability of the benzene-naphthalene adduct *(6)* over that of "*o,p*-dibenzene" to the fact that in

Table 1. Physical data of the compounds *(2a)*, *(2b)*, *(3)*, *(4)*, *(5)*, *(6)*, and *(7)*. The ^{1}H-NMR spectra were recorded at 90 MHz in $CDCl_3$ [*(4)* and *(5)* in C_6D_6], the UV spectra in *n*-hexane.

both cycloreversions the gain in aromatic resonance energy is already utilized in the transition state; for *(6)* it is about 3.2 ± 1.0 kcal/mol smaller than for *"o,p*-dibenzene"[5]. Despite the highly negative heat of reaction of *ca.* -35 kcal/mol the transition state occurs late, *i.e.* it lies on the side of the components. The weakly negative entropy of activation, on the other hand, shows that the arenes are formed in a highly ordered transition state, which still has no new degrees of freedom. Hence, in the retrocleavage the adduct *(6)* passes through a reaction profile typical for Diels-Alder reactions in the reverse direction, and the frontier orbital model[8] developed for the forward reaction should hold here too.

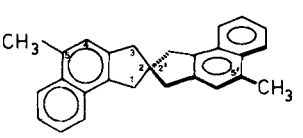
(+)-(2*R*)-5,5'-Dimethyl-2,2'-spirobi(2,3-dihydro-1*H*-cyclopenta[*a*]naphthalene)— A Chiral Spirohydrocarbon Containing Orthogonal Naphthalene Units[**]

By *Horst Neudeck* and *Karl Schlögl*[*]



Optically active 2,2'-spirobiindanes of known chirality and enantiomeric purity—such as (+)-(2*R*)-*(1)*, $R^1 = R^2 = H$—are accessible *via* chiral tricarbonylchromium complexes of the corresponding 1-oxoindans[2]. This enables the synthesis of numerous 5,5'-di- and 5,5',6-trisubstituted 2,2'-spirobiindans[3,4], which are of particular interest for testing approximations for chirality functions[1,3].

We have now synthesized the title compound, a hitherto unknown spirosystem *(10)*[5] containing two mutually orthogonal naphthalene units, which should be of interest, *inter alia*, because of its chiroptic properties (cf. [6]).

Optically pure (2*R*)-*(1)* ($R^1 = R^2 = H$, $[\alpha]_D^{20} = +4.6°$ in acetone)[2] was acylated with succinic anhydride/$AlCl_3$ in nitrobenzene to the bis-oxo acid *(2)* (cf. Table 1) whose dimethyl ester *(3)* could be smoothly hydrogenated with H_2/Pd—C in 2-propanol to the bis-butyrate *(4)*. The corresponding dicarboxylic acid *(5)* could be cyclized with polyphosphoric acid (5 h, 100 °C) to the biscyclohexenone *(6)*. The hydrocarbon *(7)* was accessible from *(6)* by hydrogenation (H_2/Pd—C in propanol/benzene), and the diol *(8)* by reduction with $LiAlH_4$. *(8)* was dehydrated with *p*-toluenesulfonic

this connection, there has been increasing interest in developing catalysts active at low temperature for the water gas shift reaction, and in establishing a convenient homogeneous hydrogenation system using carbon monoxide and water[2].

During the course of our studies on the selenium-catalyzed carbonylation of various compounds with carbon monoxide[3], we found that metallic selenium is readily reduced to selane (H_2Se) by carbon monoxide and water in the presence of base under mild conditions [eq. (1)].

$$Se + CO + H_2O \xrightarrow{Base} H_2Se + CO_2 \quad (1)$$

The yield of H_2Se is quantitative. The reaction proceeds at 25 °C/1 bar CO, but is accelerated at higher pressure and temperature. To obtain solvent-free H_2Se[4], water can be used as reaction solvent; in this case 60 °C and 5 bar were required. Acidification of the reaction mixture with sulfuric acid liberated H_2Se[5], which was trapped in a receiver cooled to −196 °C (see *Experimental*).

We assume that the reaction proceeds *via* carbonyl selenide[6] [eq. (2)].

$$Se + CO \xrightarrow{Base} Se{=}C{=}O \xrightarrow{H_2O} HSe{-}COOH \rightarrow H_2Se + CO_2 \quad (2)$$

It could prove possible to develop a catalytic cycle on this basis.

Experimental

Metallic selenium (0.400 g, 5 mmol), water (10 g), and *N*-methylpyrrolidine (1.04 ml, 10 mmol) are placed with a magnetic stirring bar in a 50-ml stainless steel autoclave, and the apparatus is then flushed several times with CO and finally charged with CO at 5 bar. The reaction is carried out at 60 °C for 7 h with vigorous stirring. On completion of the reaction (reaction mixture becomes pale yellow and homogeneous) the resulting gas (4.5 mmol CO_2) is collected in gas sampler and analyzed. Cautious addition of well degassed aqueous sulfuric acid (10 N; 10 ml, *ca.* 50 mmol) to the solidified solution mixture at −78 °C followed by distillation from the autoclave at −5 °C/10 torr directly into a tube cooled at −196 °C gives H_2Se containing CO_2. Trap-to-trap distillation at −41 to −39 °C/760 torr affords pure H_2Se (b.p. −41.3 °C). The yield (82%) was determined by gravimetry after oxidation of H_2Se with oxygen at room temperature in the presence of triethylamine (2.02 g, 20 mmol) in THF (10 ml) to give selenium (0.320 g, 4.1 mmol) and water.

X-Ray Structure Analysis of Bis(*O,O'*-diphenyldithiophosphato)tin(II), a Bicyclic Dimer Held Together by η^6-C_6H_5/Sn^{II} Interactions[**]

By *J. L. Lefferts, M. B. Hossain, K. C. Molloy, D. van der Helm,* and *J. J. Zuckerman*[*]

The tin(II) dithiophosphate ester $Sn[S_2P(OC_6H_5)_2]_2$, m.p. 125.5—126.5 °C, has been synthesized by the reaction of dimethoxytin(II) with *O,O'*-diphenyldithiophosphoric acid (molar ratio 1:2) in benzene:

$$Sn(OCH_3)_2 + 2\,HSP(S)(OC_6H_5)_2 \rightarrow 2\,CH_3OH + Sn[S_2P(OC_6H_5)_2]_2$$

and characterized by ^{119m}Sn Mössbauer [$I.S. = 3.78 \pm 0.02$; $Q.S. = 1.06 \pm 0.04$ mm/s] and mass [$m/e = 682$ (2.9%) M^+] spectrometry, as well as by elemental analysis. A triclinic single crystal of space group $P\bar{1}$ [$a = 10.499(5)$, $b = 13.948(7)$, $c = 9.291(4)$ Å; $\alpha = 99.18(6)°$, $\beta = 95.71(5)°$, $\gamma = 91.80(5)°$] was studied by $Mo_{K\alpha}$ X-radiation and refined to a final *R* value of 2.9% for 5517 reflections.

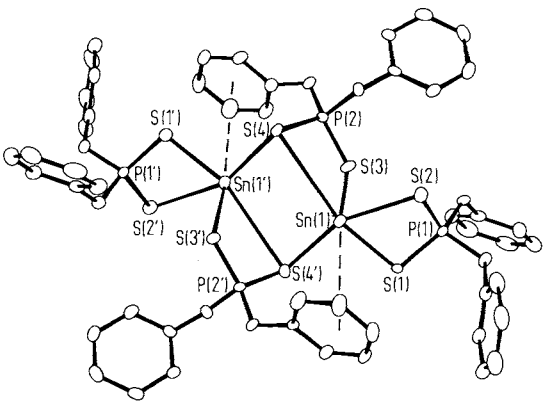

Fig. 1. Molecular structure of dimeric bis(*O,O'*-diphenyldithiophosphato)tin(II) $\{Sn^{II}[S_2P(OC_6H_5)_2]_2\}_2$ held together by bifurcated, three-coordinated sulfur atoms and η^6-C_6H_5 interactions with the tin(II) lone electron pairs.

[**] Oxy- and Thio-Phosphorus Acid Derivatives of Tin, Part 3. Our work is supported by the U.S. Office of Naval Research and the National Science Foundation (Grant No. CHE-78-26584) (*J. J. Z.*) and the National Cancer Institute, U.S. D.H.E.W. through Grant No. CA-17562 (*D. v. d. H.*).—Part 2: *K. C. Molloy, M. B. Hossain, D. van der Shelm, J. J. Zuckerman,* Inorg. Chem. *18*, 3507 (1979).

The centrosymmetric dimer shown in Figure 1 contains one ligand bridging two tin atoms intermolecularly while simultaneously chelating one tin atom in an extremely anisobidentate fashion, *via* the three-coordinated (S4) and S(4′). A second ligand is involved in normal chelation as is found in the tin(II) dithiocarbamate $Sn[S_2CN(C_2H_5)_2]_2$[1] and dithiocarbonate $Sn[S_2COCH_3]_2$[2]. A planar Sn_2S_2 four-membered ring such as is found in Sn_2S_3[3] and $(CH_3Sn)_4S_6$[4] is circumscribed by an $[SnSPS]_2$ eight-membered ring in an arrangement reminiscent of the eight-membered centrosymmetric rings formed by the tin(IV) atoms and dichlorophosphate groups in the dimeric $[Cl_3SnPO_2Cl_2 \cdot POCl_3]_2$[5]. Our structure contrasts with those adopted by lead(II) diethyldithiophosphate in which the metal atoms are chelated in monomers[6a], and its diisopropyl analogue in which the metal atom is coordinated by six sulfur atoms, two of which are bonded intermolecularly to give a polymeric lattice[6b].

Unlike these structures, the dimeric title compound is held together by two coordinate bonds at 3.0248(7) emanating from S(4) and S(4′) atoms plus a long π-interaction at 3.655 Å along the S(3)—Sn(1) and S(3′)—Sn(1′) vectors to the center of one of the phenyl groups of an ester group of the bridging ligand of the second monomeric unit (Fig. 2). This phenyl group is oriented in a spatially significant position perpendicular to the assumed vector of the tin lone pair producing a distorted octahedral (ψ-6) geometry at the metal center. π-Interactions with tin(II) lone pairs are found in η^6-$C_6H_6Sn(AlCl_4)_2 \cdot C_6H_6$[7a] and η^6-$C_6H_6SnCl(AlCl_4)$[7b] where the distances to the center of the rings lie in the range 2.74 to 2.90 Å, long with respect to transition metal-arene distances. Our dimer is unusual, however, for two reasons. Firstly, to our knowledge[8] we have here the only example of an η^6-C_6H_5 main group π-bond; and secondly, the only known example of such an interaction contributing to the formation of a dimer from the constituent monomers.

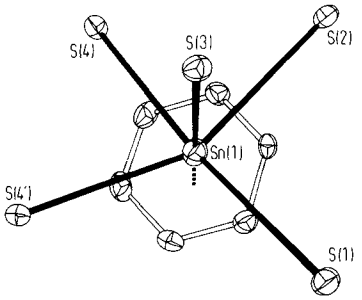

Fig. 2. The η^6-C_6H_5 Sn^{II} vector. The distance to the center of the ring is 3.655 Å.

The existence of the Sn_2S_2 ring is confirmed on close inspection of the phosphorus-sulfur distances. The more tightly bound to a metal the dithiophosphate sulfur is, then the longer its bond to phosphorus[9]. For example, in the purely chelating ligands in our structure atom S(1) makes a relatively short tin bond [S(1)—Sn(1) = 2.6230(6) Å] and a relatively long bond to phosphorus [S(1)—P(1) = 2.0016(8) Å]. Atom S(2) does the opposite [S(2)—Sn(1) = 2.8300(6), S(2)—P(1) = 1.9670(8) Å]. Thus we conclude that atom S(2) is double-bonded to P(1). However, comparison of the two ligands bonded to each tin atom reveals that although the bridging sulfur-tin bond is significantly longer [S(4)—Sn(1′) = 3.0248(7) Å] than the corresponding chelating bond [S(2)—Sn(1) = 2.8300(6) Å], the presumably P=S distances are quite similar [P(2)—S(4) = 1.9636(8), P(1)—S(2) = 1.9670(8) Å]. This unexpectedly long P(2)=S(4) distance must arise because of the electron withdrawal along the S(4)—Sn(1) vector at 3.3914(6) Å, thus confirming the interaction between these two atoms. In $\{Cu^I S_2P[OCH(CH_3)_2]_2\}_4$, on the other hand, the three-coordinated sulfur atoms that bridge two metal centers form equal or stronger sulfur-metal bonds than the sulfurs bonded to only one metal atom. In that case electron withdrawal from the bridging sulfur-phosphorus P=S bond so lengthens this distance that it actually becomes longer than the adjacent P–S single bond[10].

1,2,3-Triazolo[4,5-*d*][1,3]thiazine, a New Heterocyclic System

By *Adrien Albert* and *Albert Dunand*[*]

When 4-amino-5-aminomethyl-3-benzyl-1,2,3-triazole *(1)* is stirred at 20 °C with carbon disulfide and ethanolic sodium ethoxide or methanolic ammonia, the expected (non-basic) dithiocarbamate [anion *(2)*] is formed exclusively (^{1}H-NMR evidence). Heating these mixtures does not lead to the expected[1] 9-benzyl-1,6-dihydro-8-azapurine-2-thione *(3)*, but instead to a compound richer in sulfur and poorer in nitrogen which could be a triazolothiazine of structure *(4)* or *(6)*. A single-crystal X-ray analysis of the *S*-methyl derivative *(8)* has now shown the parent to have the structure *(4)*.

[*] Prof. Dr. A. Albert, Dr. A. Dunand

The methylthio group of *(8)* was easily displaced by nucleophiles and gave, for example, the 5-amino and 5-hydrazino derivatives, m.p. 165 and 159 °C, respectively. It appears that this new heterocycle, the substitution of which can be so easily modified, could provide many interesting new compounds as candidate drugs.

The transfer of the methylene group from nitrogen to sulfur in the reaction *(2)* → *(4)* is contrary to the usual direction of isomerism (*e.g.* thiocyanates → isothiocyanates). The same unusual shift furnished the (non-basic) by-product *(7)*. That this transfer may occur at the dithiocarbamate stage *(2)* is indicated by a change in the ^{1}H-NMR spectrum when water is added to the cold mixture of the diamine *(1)*, carbon disulfide, ammonia, and methanol. The initial spectrum of the *N*-alkyl dithiocarbamate *(2)* changes to that of the *S*-alkyl dithiocarbamate *(5)* (see Table 1).

Table 1. ^{1}H-NMR data of intermediates *(2)* and *(5)* and products *(4)* and *(8)*. δ values, in $(CD_3)_2SO$ [a].

(2), 8.30* (1H, NH), 7.22 (5H, Ph), 5.85* (2H, NH_2), 5.35 (2H, CH_2Ph), 4.58 (2H, d**, CH_2NH coupled with NH

(4), 7.19 (m, 5H, Ph), 5.60 (2H, CH_2Ph), 425 (2H, CH_2S)

(5), 7.99* (2H, SC NH_2), 7.22 (5H, Ph), 5.77* (2H, 4-NH_2), 5.27 (2H, CH_2Ph), 4.00 (2H, s, CH_2S)

(8), 7.31 (5H, Ph), 5.72 (2H, CH_2Ph), 4.40 (2H, CH_2S), 2.58 (3H, Me)

[a] *: vanishes on addition of D_2O; **: d becomes s on addition of D_2O.—For comparison, the CH_2S signal in the sulfide *(7)* is δ = 3.63.

The *S*-methyl derivative *(8)* of the thione forms triclinic crystals ($P\bar{1}$, $a = 8.742$, $b = 9.717$, $c = 9.823$ Å, $\alpha = 110.09°$, $\beta = 113.70°$, $\gamma = 102.17°$, $Z = 2$). The molecular configuration was determined by conventional crystal structure analysis (diffractometer data[2], $R = 5.1\%$) (see Fig. 1).

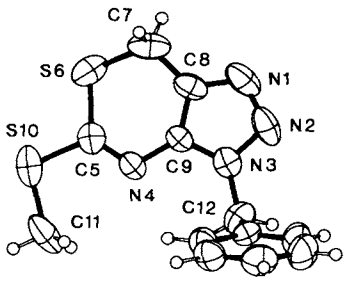

Fig. 1. Crystal structure of 3-benzyl-3,7-dihydro-5-methylthio-1,2,3-triazolo[4,5-*d*][1,3]thiazine *(8)* [2].

The 1,2,3-triazole ring is completely planar. The thiazine ring has a half-boat like conformation with the torsional angles C(9)—N(4)—C(5)—S(6) = 2.6(5)° and S(6)—C(7)—C(8)—C(9) = −30.4(5)°; C(7) and N(4) lie slightly above and below the triazole plane, respectively. While the C(sp^3)—S bonds are only marginally different, C(7)—S(6) (1.798(5) Å) and C(11)—S(10) (1.7811(7) Å), the two C(sp^2)—S bonds differ significantly by having C(5)—S(6) (1.779(4) Å) larger than C(5)—S(10) (1.733(4) Å) in relation with more N—C—S—C torsion around C(5)—S(6) (−24.6(4)°) than around C(5)—S(10) (−8.2(4)°). The methyl hydrogen atoms' observed locations are consistent with a staggered configuration around the S(10)—C(11) bond. The benzyl substituent also has an energetically favored configuration, the C(12)—C(phenyl) bond being almost perpendicular to the triazole ring, and the N(3)—C(12) bond is only 10° out of perpendicular to the benzene ring.

Procedure

(4) [and *(7)*]: The diamine *(1)*[3] (1.0 g, 0.005 mol), pyridine (20 ml), CS_2 (3.8 g, 10 equiv.), and triethylamine (1.0 g, 2 equiv.) are heated in a bath at 115 °C for 6 h. The mixture is taken to dryness *in vacuo* at 90 °C, and the residue shaken with 1 N KOH (12.5 ml). Filtration from the sulfide *(7)* [m.p. 173 °C (from 50% aqueous ethanol); MS, $m/e = 406$ (M^+)] and acidification of the filtrate to pH 3.5 gives *(4)* in 60% yield, crystals from 50% aqueous ethanol [m.p. about 190 °C with effervescence. MS: $m/e = 262$ (M^+)].

(8): Compound *(4)* (0.131 g), 1 N NaOH (0.6 ml), and CH_3I (0.085 g, 1.2 equiv.) are stirred for 15 min at 20 °C. After filtration, a 91% yield of *(8)* is obtained [m.p. 127 °C (from cyclohexane)].

Exceedingly Mild Desulfurization of Thiols by Sodium Triethylhydroborate and Transition Metal Chlorides[**]

By *Howard Alper* and *Trish L. Prince*[*]

Desulfurization reactions are of considerable current interest, particularly with reference to their possible application to the removal of sulfur from fuel oil, coke, and other energy sources. One of us has recently begun a search for new desulfurization processes[1]. We now wish to report a simple and exceedingly mild method for the desulfurization of thiols.

Mixed hydride/transition metal halide reagents have come into increased use in recent years[2]. Treatment of 2-naphthalenethiol *(1a)* with anhydrous ferrous chloride and sodium triethylhydroborate [molar ratio 1:2:4] in tetrahydrofuran at −78 °C gives naphthalene *(2a)* in 81—85% yield.

$$\underset{(1)}{RSH} + Na[(C_2H_5)_3BH] + MCl_n \rightarrow \underset{(2)}{RH} + \underset{(3)}{RR} + \cdots$$

2,2′-Binaphthyl *(3a)* appears as a reaction by-product if $CoCl_2$ is used instead of $FeCl_2$. VCl_3 gave less fruitful results. Table 1 lists examples.

Table 1. Desulfurization of thiols *(1)* to hydrocarbons *(2)* and didehydrodimers *(3)* with $Na[(C_2H_5)_3BH]/MCl_n$.

	R =	MCl_n	Yield [%] [a] *(2)*	*(3)*
a	2-Naphthyl	$FeCl_2$	81—85	
		$CoCl_2$	72	27
		VCl_3	23	
b	2,5-Dichlorobenzene	$CoCl_2$	84	
c	4-Methoxybenzyl	$FeCl_2$	63	
d	Triphenylmethyl	$FeCl_2$	59	8
e	1-Dodecyl	$FeCl_2$	78	

[a] Isolated yields. Products identified by comparison of analytical and spectral data with those of authentic materials.

[*] Prof. Dr. H. Alper, T. L. Prince
Department of Chemistry, University of Ottawa
Ottawa, Canada K1N 9B4

[**] We are indebted to the Natural Sciences and Engineering Research Council for support of this research.

This desulfurization reaction not only occurs with aromatic thiols, but with benzylic and nonaromatic thiols as well. Yields are good and product isolation is simple.

General procedure

The thiol *(1)* (1.5 mmol) in THF (2—3 ml) is added to anhydrous metal chloride (3.0 mmol) in THF (2 ml). After addition of THF (8 ml), the reaction mixture is stirred at room temperature for 15—25 min, cooled to −78 °C, and then a 1 M solution of $Na[(C_2H_5)_3BH]$ in THF (6.0—6.2 ml) is added by syringe. The solution is stirred for 15—20 min at −78 °C, and then allowed to warm to room temperature with stirring. Moist sodium sulfate is added, followed by water (10 ml), and the reaction mixture is filtered. The products are then extracted from the filtrate by methylene chloride or chloroform; further purification, if necessary, is by column chromatography.

General Method for Preparation of Multidentate Fluorophosphane Ligands[**]

By *Ernest R. Cromie, George Hunter,* and *David W. H. Rankin*[*]

Although fluorophosphanes are well known as monodentate ligands[1], very little work has been done with multidentate fluorophosphanes[2], and few suitable ligands are readily available. They are of interest because they can bond in a number of different ways: for example, $CH_3N(PF_2)_2$ may form two bonds to a single metal atom[3] or a bridge between two metal atoms[4]. We report here a reaction which may be used to prepare a wide variety of fluorophosphanes which may prove to be useful multidentate ligands.

We have observed that bis(difluorophosphino)sulfide *(1)*[5] reacts with organic and inorganic mono- and polyhydroxy compounds *(2)* to give difluorophosphane sulfides *(3)* and the desired difluorophosphinoxy compounds *(4)*.

$$\underset{(1)}{S(PF_2)_2} + \underset{(2)}{ROH} \rightarrow \underset{(3)}{SPF_2H} + \underset{(4)}{ROPF_2}$$

The product *(4)* is normally much less volatile than *(3)*, and may therefore easily be obtained in a pure form. Use of an excess of hydroxy compound *(2)* should be avoided, as a slow substitution reaction of *(3)* occurs, yielding less volatile products (SPFHR, $SPHR_2$).

The group R may be almost any organic group, such as primary, secondary, or tertiary alkyl, aryl or acyl, and inorganic "hydroxides" such as phosphoric acid may also be used. With 1,2-diols PF_3 is eliminated from the initial products to give 2-fluorodioxaphospholanes, which may also be of interest as ligands.

Similar reactions also occur with primary and secondary amines and, more slowly, with thiols. Thus, by choosing a suitable substrate, a product may be made with almost any desired spatial arrangement of fluorophosphino groups. Two typical syntheses are described, that of bis[2-(difluorophosphinoxy)ethyl]sulfide *(5)* and that of phosphoryltrioxytris(difluorophosphane) *(6)*.

(5) $S(CH_2CH_2OPF_2)_2$ $OP(OPF_2)_3$ *(6)*

Experimental

Preparation of *(5)*: Compound *(1)*[5] (4 mmol) is condensed into a glass ampoule (at −196 °C) containing $S(CH_2CH_2OH)_2$ (1.7 mmol) and the reagents are warmed to room temperature for 45 min. After the volatile products have been distilled out at −78 °C, *(5)* (1.4 mmol, 80% yield) is obtained in a pure form by distillation *in vacuo* at room temperature. Subsequent manipulation of *(5)* is by syringe in an inert atmosphere[6].

Preparation of *(6)*: Compound *(1)* (16.5 mmol) is condensed into a glass ampoule (at −196 °C) containing 100% H_3PO_4 (4.5 mmol). On warming to room temperature, effervescence occurs and the solid material disappears. After 30 min, the volatile products are removed, and *(6)* (4.3 mmol, 95% yield) is obtained as a clear liquid, involatile at −45 °C, by fractional condensation *in vacuo*[7].

^{195}Pt-NMR Spectroscopy of Catalytically Active Complexes. Extremely Large Spin-Spin Coupling between Platinum and Tin[**]

By *Karl-H. A. Ostoja Starzewski* and *Paul S. Pregosin*[*]

Platinum-phosphane complexes in combination with tin(II) chloride are excellent homogeneous catalysts for hydrogenation and hydroformylation reactions[1]. As part of our study[2] on the NMR characteristics of the active intermediates formed in these reactions, we found $^1J(^{195}Pt^{119}Sn)$ in *trans*-$[PtCl(SnCl_3)(PEt_3)_2]$ to be 28954 Hz, which represents the *largest one-bond spin-spin coupling constant* ever observed (cf. Table 1)[3].

Table 1. ^{195}Pt-NMR data for some platinum-tin complexes [a].

Compound	$^1J(^{195}Pt^{119}Sn)$	$\delta(^{195}Pt)$	$\Delta\delta$ [b]
trans-[PtCl(SnCl$_3$)(PEt$_3$)$_2$] [c]	28954	−4780	−864
trans-[Pt(SnCl$_3$)$_2$(PEt$_3$)$_2$] [d]	20410	−5152	−618 [e]
trans-[PtH(SnCl$_3$)(PEt$_3$)$_2$] [f]	9067	−5302	−426
trans-[PtH(SnCl$_3$)(PPh$_2$CH$_2$Ph)$_2$] [f]	10955	−5322	−428
trans-[PtH(SnCl$_3$)(PPh$_3$)$_2$] [f]	11512	−5195	−354
trans-[Pt(C(CO$_2$Et)=CHCO$_2$Et)(SnCl$_3$)(PPh$_3$)$_2$] [g]	11320	−4771	−469

[a] Chemical shifts (δ values rel. to external Na_2PtCl_6) and coupling constants (in Hz). [b] $\Delta\delta = \delta[PtX(SnCl_3)(PR_3)_2] - \delta[PtX(Cl)(PR_3)_2]$. [c] In CD_2Cl_2 at −40 °C. [d] In $(CD_3)_2CO$ at −50 °C. [e] $\delta[PtCl_2(PEt_3)_2] - \delta[Pt(SnCl_3)_2(PEt_3)_2]$ divided by 2. [f] In CD_2Cl_2 at −70 °C. [g] In CD_2Cl_2 at room temperature.

The differences between the $^1J(^{195}Pt^{119}Sn)$ values for the series of complexes *trans*-[PtH(SnCl$_3$)(PEt$_3$)$_2$], *trans*-[Pt(SnCl$_3$)$_2$(PEt$_3$)$_2$], and *trans*-[PtCl(SnCl$_3$)(PEt$_3$)$_2$] may be understood in terms of the NMR *trans* influence series (H > SnCl$_3$ > Cl)[4]. There is some precedence for the similarity of *trans* influence in carbon and hydride ligands[4] so that the coupling constants of 11512 Hz for *trans*-[PtH(SnCl$_3$)(PPh$_3$)$_2$] and 11320 Hz for *trans*-[PtL(SnCl$_3$)(PPh$_3$)$_2$], L = C(CO$_2$Et)=CHCO$_2$Et, appear reasonable.

The large absolute value of $^1J(^{195}Pt^{119}Sn)$ can be understood in terms of the Fermi contact expression used by *Pople* and *Santry*[5]:

$$^1J(AB) \propto \gamma_A \gamma_B |\Psi_{ns_A}(0)|^2 |\Psi_{ns_B}(0)|^2 \pi_{A,B}$$

$$\pi_{AB} = \sum_{i}^{occ} \sum_{j}^{unocc} ({}^3\Delta E_{i\to j})^{-1} C_{iA} C_{jA} C_{iB} C_{jB}$$

The relatively large gyromagnetic ratios $\gamma_A \gamma_B$ for tin[6] and platinum combine with the relatively large expectation values $|\Psi(0)|^2$ for heavy metals[7] to afford a product which will be much larger than for most nuclei. Thus, typical $^1J(^{119}SnX)$ values are: for X = ^{1}H (Me_3SnH), 1744 Hz[8a]; ^{31}P (Me_3Sn—PRR′), 460—832 Hz[8b]; ^{207}Pb (Me_3Sn—$PbMe_3$), 3570 Hz[8a]. Furthermore, the presence of the three electron-withdrawing chlorine substituents on tin are recognized to result in an enhanced coupling constant[7]. This result stems from an increase in π_{AB}, presumably due to an enhanced amount of s-character in the metal-metal bond.

The values $\delta(^{195}Pt)$ are shifted to higher field by several hundred ppm when a Cl^- ligand is replaced by $SnCl_3^-$ *e.g.* from −3916 for *trans*-[PtCl$_2$(PEt$_3$)$_2$], to −4780 for *trans*-[PtCl(SnCl$_3$)(PEt$_3$)$_2$]$_2$. This is in keeping with the exceptional sensitivity of $\delta(^{195}Pt)$ to changes within the coordination sphere. It appears that ^{195}Pt-NMR spectroscopy will be an extremely sensitive probe for molecular structure in this catalytically active system.

Metal-Catalyzed Synthesis of Cyclic Carbonates from Carbon Dioxide and Oxiranes

By *Michael Ratzenhofer* and *Horst Kisch*[*]

The reactions of carbon dioxide are attracting renewed interest with regard to the use of readily available primary chemicals in organic synthesis[1]. Its reaction with methyloxirane *(1)* gives polycarbonates[2] or the monomeric carbonate 4-methyl-1,3-dioxolan-2-one *(2)*[3], depending upon the reaction conditions. All the catalytic processes known so far for the synthesis of *(2)* operate at elevated CO_2 pressure (5—200 atm) and elevated temperature (100—200 °C)[3,4]. We now wish to report catalysts that are active at room temperature and normal pressure.

(1) *(2)*

Addition of *(1)* to a mixture of a metal halide and a Lewis base under CO_2, is shown by IR spectroscopy to lead to the formation of *(2)*, $\nu(CO) = 1800$ cm^{-1} in *(1)*. Pure *(2)* is ultimately isolated directly from the reaction flask by simple vacuum distillation. Thus the $MoCl_5/PPh_3$ catalyst system gave the best conversions and yields at a molar ratio of 1:6 of the components and a 100 to 200-fold excess of *(1)* relative to $MoCl_5$ (see Procedure and Table 1).

The best catalysts were found to be mixtures of triphenylphosphane and the halides of aluminum, molybdenum, or iron. Neither of the catalyst components on its own is able to induce formation of *(2)*. Transition metal compounds in low oxidation states such as *trans*-$(N_2)_2$W(diphos)$_2$ or $CoCl(PPh_3)_3$ fail to catalyze the reaction; however, the latter compound does become active at high temperature and high pressure[3].

Preliminary mechanistic studies have been performed with the $AlCl_3$/Lewis base catalyst system: reaction of *(1)* with

Table 1. Activity of some catalyst systems for the synthesis of *(2)* from carbon dioxide and *(1)* under normal conditions of pressure and temperature (7 d reaction time, in 10 ml of *(1)* as solvent).

MX_n/Lewis base [a]	$[MX_n]$ [mol/l]	Yield of *(2)* [b]	Turnover number [c]
$AlCl_3/PPh_3$	0.14	47	46
$AlCl_3/NEt_3$ (1:3)	0.23	52	32
AlI_3/PPh_3	0.1	46	67
$TiCl_4/PPh_3$	0.09	15	24
$CrCl_3/PPh_3$ (1:3)	0.19	< 1	< 1
$MoCl_5/PBu_3$	0.1	55	79
$MoCl_5/PPh_3$ (1:5)	0.15	78	76
$MoCl_3(C_4H_8O)_3/PPh_3$	0.063	13	31
$MoCl_5/NEt_3$	0.084	36	61
WCl_6/PPh_3	0.044	36	29
$FeCl_3/PPh_3$	0.185	75	58
$CoCl_2/PPh_3$ (1:5)	0.034	76	32
$NiBr_2/PPh_3$	0.16	20	18

[a] Molar ratio 1:6 unless stated otherwise. [b] Isolated product (% based on weigh-in of *(1)*). [c] mol *(2)*/mol MX_n.

$AlCl_3$ under argon is strongly exothermic and yields $[MeCH(Cl)CH_2O]_3Al$[5]. We found that this chloroalkoxide takes up CO_2 in the ratio of 1:1; the IR spectrum of the product (KBr) shows strong bands at 1610 and 1430 cm^{-1} which are probably due to a metal alkyl carbonate formed by insertion of CO_2 into one of the Al—O bonds of the alkoxide[6]. The dioxolanone *(2)* arises from the aluminum alkyl carbonate only after addition of PPh_3, pyridine, or NEt_3. The final reaction step occurs only in polar solvents such as tetrahydrofuran, oxetane, or methyloxirane.

The method described above is the simplest procedure available for the synthesis of cyclic carbonates from carbon dioxide and oxiranes. The disadvantage of the relatively long reaction time of about seven days is offset by the advantages of mild reaction conditions, very good yields (90—100% based on reacted oxirane), and recovery of unreacted oxirane. On use of a chiral base, the catalyst system could in principle permit a facile synthesis of chiral dioxolanones. Preliminary experiments with $MoCl_5$ and (*R*)-(+)-dimethyl-1-(phenylethyl)amine, (+)-brucine, (*R,R*)-(−)-1,2-bis(dimethylamino)cyclohexane, (−)-2-menthyldimethylphosphane, (+)-bis(2-menthyl)methylphosphane, and (+)-2,2-dimethyl-4,5-bis(diphenylphosphinomethyl)-1,3-dioxolane ("diop") have so far proved unsuccessful, however[7].

Procedure

Methyloxirane *(1)* (100 ml, 1430 mmol) is slowly added dropwise to molybdenum pentachloride (2.0 g, 7.3 mmol) and triphenylphosphane (11 g, 42 mmol) in a two-neck flask under CO_2 atmosphere. The solution is stirred for seven days at room temperature and then vacuum distilled: unreacted *(1)* (50 ml, 50%) distils over first, followed by the pure product *(2)* at b.p. 45—50 °C/0.1 torr; yield: 68.7 g (47% based on weigh-in of *(1)*, 94% based on reacted *(1)*); turnover number, 92 mol/mol $MoCl_5$. Experiments with other catalysts were performed analogously.

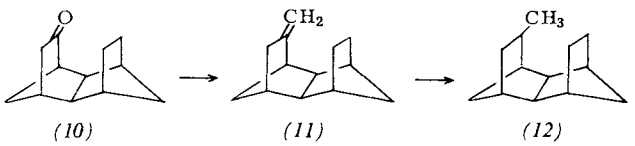
[**] Results of Non-bonded Interactions, Part 1. This work was supported by the Deutsche Forschungsgemeinschaft.

Replacement of the inner hydrogen atom R (R′ = H) by an alkyl group is predicted by model studies to lead to a strong increase in strain energy; Table 1 lists the enthalpies of formation and strain energies calculated with the force field[2] (Bigstrin[4]) for *(1)* and *(2)*, R = CH_3, $CH(CH_3)_2$, and $C(CH_3)_3$, R′ = H, and for *(1)* and *(2)*, R′ = CH_3, $CH(CH_3)_2$, $C(CH_3)_3$, R = H. The calculated strain energy is larger for the "inside" compounds (R = alkyl) than for the "outside" compounds (R′ = alkyl); the energy difference is considerably greater than between 2-*exo*- and 2-*endo*-methylnorbornane[2] (see Table 1).



We have synthesized the epimeric 4-methyl derivatives of the *endo-endo- (1)* and *exo-endo* series *(2)*. Starting from *endo-endo*-tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodec-4-ene *(4)*[5] and the *exo-endo* isomer *(7)*[5] we obtained the cyclopropyl compounds *(5)* and *(8)*, respectively, by repeated treatment with

(4) *(5)* *(6)*

Analogously, *exo-endo*: *(7)* ⟶ *(8)* ⟶ *(9)*

CH_2N_2 in ether in the presence of CuCl (each in about 70% yield); they were purified by distillation (b.p. 119—120 °C/13 torr). *(5)* and *(8)* can be converted by treatment with hydrogen (60 atm) in glacial acetic acid into *(6)* and *(9)*, respectively (85%), which can be distilled (b.p. 110—111 °C/13 torr).

(10) *(11)* *(12)*

Analogously, *exo-endo*: *(13)* ⟶ *(14)* ⟶ *(15)*

The inside methyl compounds *(12)* and *(15)* are formed from the isomeric ketones *endo-endo- (10)*[6] and *exo-endo*-tetracyclo[6.2.1.1^{3,6}.0^{2,7}]dodecan-4-one *(13)*[6]. Wittig reaction with methyltriphenylphosphonium bromide/*n*-butyllithium in tetrahydrofuran at 175 °C over a period of 7 d affords the methylene compounds *(11)* (10%) and *(14)* (51%), respectively which were analytically pure after distillation (b.p. 60—62 °C/1 torr). Catalytic hydrogenation over Pd/C in ethanol (60 atm H_2 pressure, 50 °C, 17 h) gives the methyl isomers *(12)* (86%) and *(15)* (88%). *(12)* was purified by vacuum sublimation (m.p. 57—60 °C), while *(15)* was distilled (b.p. 50—60 °C/0.6 torr).

The new compounds *(5)*, *(6)*, *(9)*, *(11)*, *(12)*, *(14)*, and *(15)* have been completely characterized by elemental analysis and spectral data (mass, IR, and ^{1}H-NMR spectra)[7] (see Table 2). The methyl derivatives *(6)* and *(12)*, as well as *(9)* and *(15)*, which differ in their gas chromatographic retention times, are stereochemically pure within the detection limit of *ca.* 0.1%. This shows that cyclopropanation and hydrogenation occur exclusively from the outside direction. In contrast to 2-*endo*-methylnorbornane the inside isomers *(12)* and *(15)* cannot be equilibrated with Lewis acids to give the outside epimers since rearrangement to the thermodynamically more stable adamantane derivatives is much faster[7].

The NMR signals of the methyl protons of the inside and outside isomers differ by $\Delta\delta \approx 0.35$. Characteristic IR bands are observed above 3000 cm^{-1} (ν_{CH}); the shift from the normal position at 2950 cm^{-1} can be regarded as a measure of the intramolecular H...H contact distances which can be interpreted on the basis of quantum mechanical concepts in terms of an increase in the CH force constants as a result of compression[8]. These frequencies can be qualitatively correlated with the calculated H...H contact distances; this shows that the ethano bridge in the *endo-endo* skeleton is more strongly twisted in order to avoid steric hindrance by the inside methyl group.

Compounds with inside alkyl groups such as *(12)* and *(15)* are suitable as models for the quality of non-bonded interaction terms in force field calculations; the calculations are to be tested by X-ray structure analysis of suitable derivatives.

2-*tert*-Butyl-2*H*-isoindole: A Partner for Reactions with Electrophiles[**]

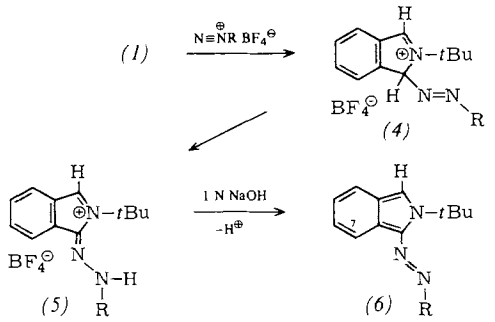
By *Richard Kreher* and *Götz Use*[*]

The *o*-quinonoid heteroarene *(1)* is readily accessible from *N*-*tert*-butyl-isoindoline *N*-oxide by reaction with acetic anhydride/triethylamine (6 h/0 °C)[1]. It shows remarkable thermal stability and is one of the few compounds in this series[2] which can be protonated, alkylated, and subjected to electrophilic substitution.

Reaction of *(1)* with 70% perchloric acid gives the crystalline perchlorate *(2a)* and that with triethyloxonium tetrafluoroborate affords the stable 2-*tert*-butyl-3-ethyl-1*H*-isoindolium tetrafluoroborate *(3)*. In this reaction, the 1*H*-isoindolium salt *(2b)* formed in a prior kinetically controlled process rearranges *via* a 1,3-proton shift into the more stable salt *(3)* (Table 1).

Table 1. Analytical data of compounds *(1)*, *(2a)*, and *(3)*.

(1), yield 90%; b.p. 97—98 °C/0.1 torr; ^{1}H-NMR ($CDCl_3$): $\delta = 7.19$ (s, H-1, H-3), 1.54 (s, *t*Bu); UV (methanol): $\lambda_{max} = 223$ ($\log \varepsilon = 4.68$), 266 (3.25), 270 (3.22), 277 (3.27), 289 (3.09), 329 nm (3.59)



(2a), yield 99%; dec. pt. 241—243 °C; ^{1}H-NMR (CF_3CO_2H): $\delta = 9.46$ (t, $J = 2$ Hz, CH), 5.42 (d, $J = 2$ Hz, CH_2); UV (CH_3OH/1% $HClO_4$): $\lambda_{max} = 217$ ($\log \varepsilon = 3.98$), 224 (3.86), 275 nm (4.16)

(3), yield 96%; dec. pt. 160 °C; ^{1}H-NMR (CF_3CO_2H): $\delta = 5.37$ (s, CH_2), 3.58 (q, $J = 8$ Hz, CH_2), 1.88 (s, *t*Bu), 1.63 (t, $J = 8$ Hz, CH_3); UV (CH_3OH/1% $HClO_4$): $\lambda_{max} = 216$ ($\log \varepsilon = 3.96$), 223 (3.82), 272 nm (4.15)

Conditions for electrophilic substitution reactions of *(1)* therefore appear favorable, and it is indeed found to react *via* substitution with arenediazonium tetrafluoroborates. A cationic σ complex *(4)* is probably formed, which rearranges to the more stable isoindolium salt *(5)*.

The structure of the crystalline tetrafluoroborates *(5)* follows primarily from the ^{1}H-NMR and IR spectra (1 H singlet for CH=N, broadened singlet at $\delta = 10.2$—10.4 for NH; intense IR band at 3310 cm^{-1}) (Table 2).

The thermally stable and chemically reactive isoindolium salts *(5)* can be converted by 1 N NaOH into the crystalline, intensely colored azo compounds *(6)* with a long-wave absorption band between 480 and 530 nm. The coupling constant ($J_{ortho} = 8$ Hz) shows that the ^{1}H multiplet separated in the ^{1}H-NMR spectrum should be assigned to the *peri*-proton H-7 (Table 2).

(a), R = *p*-Cl–C_6H_4; *(b)*, R = *p*-C_2H_5OCO–C_6H_4; *(c)*, R = *p*-O_2N–C_6H_4

Table 2. Analytical data of compounds *(5a—c)* and *(6a—c)*. ^{1}H-NMR of *(5)* in CF_3CO_2H, of *(6)* in $CDCl_3$, UV of *(5)* in CH_3OH/1% $HClO_4$, of *(6)* in CH_2Cl_2.

(5a), yield 94%; dec. pt. 201—203 °C; ^{1}H-NMR: $\delta = 9.13$ (s, H-1), 2.08 (s, *t*Bu); UV: $\lambda_{max} = 243$ ($\log \varepsilon = 4.37$), 470 nm (4.05)

(5b), yield 88%; m.p. 202—203 °C; ^{1}H-NMR: $\delta = 9.24$ (s, H-1), 2.11 (s, *t*-Bu); UV: $\lambda_{max} = 266$ ($\log \varepsilon = 4.39$), 464 nm (3.82)

(5c), yield 99%; dec. pt. 212 °C; ^{1}H-NMR: $\delta = 9.32$ (s, H-1), 2.10 (s, *t*Bu); UV: $\lambda_{max} = 233$ ($\log \varepsilon = 4.23$), 264 (3.95), 325 (4.16), 458 nm (3.62)

(6a), yield 86%; m.p. 102 °C; ^{1}H-NMR: $\delta = 8.58$ (m, $J_{ortho} = 8$ Hz, H-7), 1.87 (s, *t*Bu); UV: $\lambda_{max} = 264$ ($\log \varepsilon = 3.92$), 310 (3.74), 482 nm (4.54)

(6b), yield 88%; m.p. 123 °C; ^{1}H-NMR: $\delta = 8.71$ (m, $J_{ortho} = 8$ Hz, H-7), 1.88 (s, *t*Bu); UV: $\lambda_{max} = 260$ ($\log \varepsilon = 3.86$), 295 (3.98), 492 nm (4.59)

(6c), yield 89%; m.p. 172 °C; ^{1}H-NMR: $\delta = 8.73$ (m, $J_{ortho} = 8$ Hz, H-7), 1.94 (s, *t*Bu); UV: $\lambda_{max} = 256$ ($\log \varepsilon = 3.92$), 319 (3.77), 530 nm (4.63)

Accordingly, 2*H*-isoindoles can be coupled, like substituted pyrroles[3] and indoles[4], with arenediazonium ions, provided that the reaction conditions can be adjusted to the reactivity of the 10π system.—2-*tert*-Butylpyrrolo[3,4-*b*]quinoxaline[5] also forms crystalline hydrazo compounds with arenediazonium salts.

Procedure

(5): Compound *(1)* (1.0 g, 5.77 mmol) in anhydrous acetone (10 ml) is stirred into an ice-cooled suspension of arenediazonium tetrafluoroborate (5.8 mmol) in anhydrous acetone (15 ml) under pure dry nitrogen over 15 min. After 2 h at 0 °C, the colored precipitate is filtered off under suction, washed with a little ice-cold anhydrous acetone and with ether and dried *in vacuo* over P_2O_5.

Structure of Metal-Free Corrinoids from *Rhodopseudomonas sphaeroides*

By *Bernd Dresow, Gerhard Schlingmann, William S. Sheldrick,* and *Volker B. Koppenhagen*[*]

Metal-free corrinoids are of interest as potential precursors in the biosynthesis of vitamin B_{12} and as starting materials for the preparation of vitamin B_{12} analogues containing other metals. So far they have mainly been obtained from the sulfur-containing purple bacterium *Chromatium vinosum,* but the yields are so low (*ca.* 1 mg/100 g wet bacteria, *i. e. ca.* 0.05 mg/l), that the preparation of larger amounts is extremely time consuming and expensive[1]. On investigating further phototrophic bacteria for their ability to form metal-free corrinoids we found that *Rhodopseudomonas sphaeroides* under cobalt-deficient conditions releases up to 3 mg/l of these compounds into the medium[2]. We thus succeeded for the first time in isolating this class of substance on a gram scale.

Unlike *Chromatium vinosum, Rhodopseudomonas sphaeroides* produces nucleotide-free polycarboxylic acids, which at this biogenetically early stage are probably recognized by the organism as "inappropriate products" and are excreted. From the culture medium of *Rhodopseudomonas sphaeroides* we isolated a mixture of isomer-free hydrogenobyrinic acid monamide *(1)* (20%) and hydrogenobyrinic acid diamide (80%). The position of the amide function in *(1)* was determined by conversion of *(1)* into hydrogenobyrinic acid *c*-lactone *(2)*[3]. *(2)* could be identified after incorporation of the central $Co(CN)_2$-group and esterification with methanol/sulfuric acid, as dicyanocobyrinic acid hexamethyl ester *c*-lactone.

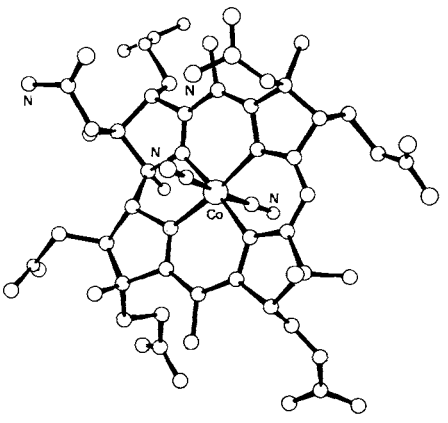

Fig. 1. Molecular structure of dicyanocobyrinic acid *a,c*-diamide *(3)* [4].

The two amide positions in the resulting biosynthetic hydrogenobyrinic acid diamide could be determined by X-ray structure analysis of the corresponding $Co(CN)_2$-containing product *(3)* and were assigned to the side chains *a* and *c* (Fig. 1). The *c*-amide function could also be determined independently by lactonization.

(3) crystallizes orthorhombically together with three water molecules[4]. Owing to the network of intermolecular hydrogen bonding, which stabilizes the crystal structure, the isotropic temperature factors of the O and N atoms of the potential OH- and NH_2-groups are relatively low (0.039—0.092 $Å^2$). In addition, the heteroatoms within a side chain have very similar temperature factors; the differences are 0.01 $Å^2$ or smaller. This facilitates an analysis of the isotropic temperature factors for placement of the OH- and NH_2-functions, thus leading to formulation as an *a,c*-diamide. This formulation is further supported by the lengths of the H bridges: on the side chains *a* and *c* they are 2.85—2.96 Å, as is typical for N...O bridges, on the remaining side chains they are 2.56—2.79 Å, which is typical for O...O bridges. The bond lengths and angles in *(3)* are similar to those in other metal-containing corrinoids.

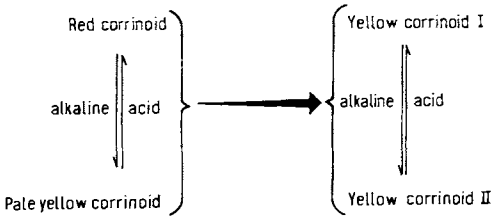
Structure of Yellow Metal-Free and Yellow Cobalt-Containing Corrinoids

By *Gerhard Schlingmann, Bernd Dresow, Volker B. Koppenhagen, Wulf Becker,* and *William S. Sheldrick*[*]

All red metal-free corrinoids, which have hitherto been isolated from phototrophic bacteria, are irreversibly converted under alkaline conditions into a yellow form. Such yellow products also occur in larger amounts in the culture filtrate of fermentations with *Rhodopseudomonas sphaeroides* or *Rhodopseudomonas capsulata*[1]. Elucidation of the structure of the yellow corrinoids is of importance in view of their possible further use in the synthesis of vitamin B_{12} antimetabolites.



We have been able to demonstrate that on treatment with bases of any sort, red metal-free corrinoids are converted with initial change of color from red to yellow into a deprotonated form, which on immediate reneutralization is reconvertible into the red starting compound[2]. On prolonged treatment with alkali, a further irreversible transformation into a stable yellow corrinoid form takes place. Depending on the pH, this yellow corrinoid is either protonated (yellow

corrinoid I) or deprotonated (yellow corrinoid II) (Scheme 1).

Scheme 1. Transformation of metal-free corrinoids.

For the structure elucidation, the model compound hydrogenobyrinic acid *a,c*-diamide (150 mg) was converted with 0.2N KOH in the absence of oxygen into its yellow form. Subsequent incorporation of the $Co(CN)_2$-group and esterification with methanol/sulfuric acid afforded the yellow compound *(1)* as main product, which crystallizes from methanol/ether (Fig. 1).

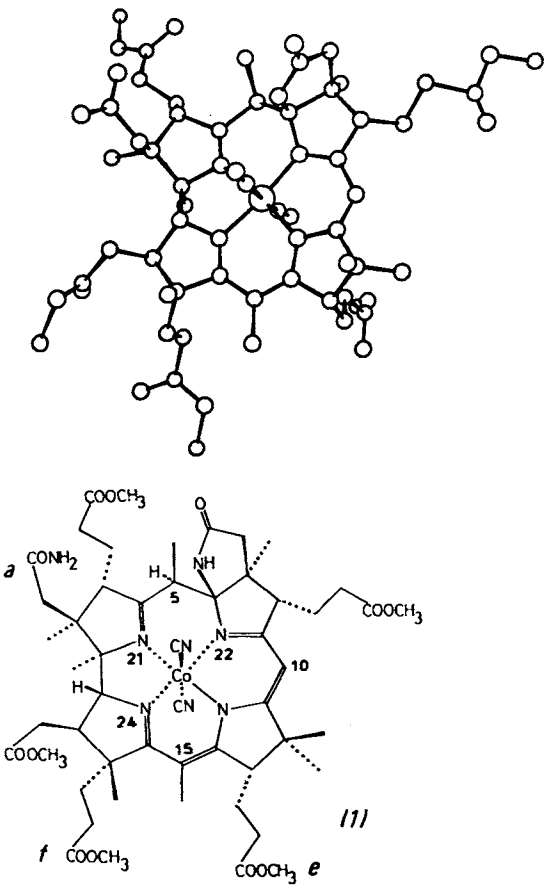

Fig. 1. 6-Aminodicyano-5,6-dihydrocobyrinic acid pentamethyl ester *a*-amide-*c*-lactam (gCoPSE) *(1)*.

(1)·0.5 H_2O ("gCoPSE") crystallizes triclinically with two independent molecules in the crystal lattice[3]. In both molecules the C-5 methyl group is located above the "plane" of the molecule. The *a*-amide and *f*-methoxycarbonyl functions of the first molecule, as well as the water molecule, are disordered. The conformation of the side chain *e* in the first molecule is very different from that in the second.

The chromophore in *(1)* consists of a conjugated system of four double bonds distributed over nine atoms between N-22 and N-24 of the macrocycle. The three bonds (C-10)—(C-11), (C-14)—(C-15), and (C-16)—(N-24) exhibit stronger double-bond character than the remaining bonds. (N-12)—(C-4) exists as an isolated double bond. Breakage of the corrin chromophore between C-5 and C-6 leads to no significant change in the bond angles with respect to the octahedral arrangement of the central cobalt atom. But the almost planar coordination of the four N atoms to the Co, observed in the other corrinoids, is here somewhat more tetrahedrally distorted (distances of the N atoms from the plane = ±0.06—0.08 Å); and the deviation of the macrocycle from the central plane through the four N atoms and the cobalt atom is more pronounced, not only in the region of the B ring but also in the region of the D ring. The B ring has an envelope conformation (cobyric acid: half-chair conformation)[4].

While yellow metal-free corrinoids are irreversibly formed from red metal-free corrinoids under alkaline conditions (Scheme 1), the compounds containing cobalt are readily converted into the corresponding red cobalt-containing compounds under the influence of bases. Here, deprotonation at C-5 and simultaneous opening of the lactam ring leads to reformation of the double bond between C-5 and C-6. *(1)* could be converted into dicyanocobyrinic acid pentamethyl ester *a,c*-diamide in this way by treatment with *t*-BuOK. Like hydrogenobyrinic acid *a,c*-diamide[5], on treatment with alkali and incorporation of cobalt, hydrogenobyric acid or hydrogenobalamin also form yellow cobalt-containing compounds, which once again are transformed into cobyrinic acid and cobalamin, respectively, on treatment with alkali (KCN).

These findings would suggest that the action of alkali on natural metal-free corrinoids leads to inerruption of the corrin chromophore between C-5 and C-6 through formation of a lactam ring as in *(1)*.

A Pyrazine-Bridged Heme Dimer Absorbing at 800 nm

By *Jürgen-Hinrich Fuhrhop, Mohamed Baccouche,* and *Marlies Bünzel*[*]

Pyrazine takes up electrons from complexed redox-active metal ions (Co^{II}, Ru^{II}) in anti-bonding π-orbitals of one N atom, whereupon the basicity of the other N atom is so strongly enhanced that dinuclear complexes can be formed. If these complexes contain ions of different valency state (Ru^{II}/Ru^{III}) then charge transfer bands of modest intensity appear in the near IR (oscillator strength *ca.* 0.03)[1]. We

[*] Prof. Dr. J.-H. Fuhrhop, Dr. M. Baccouche, Dipl.-Chem. M. Bünzel
Institut für Organische Chemie der Freien Universität
Takustr. 3, D-1000 Berlin 33 (Germany)

have found that the electron-rich central ions of metal-porphyrins form similar electron donor-acceptor complexes with pyrazine, in which an efficient electron transfer takes place between two porphyrin ligands situated *ca.* 1 nm apart from each other. Such EDA complexes are of interest in connection with the synthesis of redox chains, in analogy to those of respiration and photosynthesis[2].

Hemin (iron(III)-protoporphyrin chloride) was dissolved in 0.1 N NaOH and reduced with dithionite in the presence of air to give the heme (iron(II)-protoporphyrin), which has a broad absorption band around 560 nm (see Fig. 1). The reduction could also be carried out with ascorbic acid acid or hydroquinone under inert gas. These heme solutions were titrated with pyrazine in 0.1 N NaOH. At a heme:pyrazine ratio of 2:1 the broad band at 560 nm was split into two narrower bands at 570 and 530 nm. The visible part of the spectrum almost corresponds to that of iron(II)porphyrin complexes with two axial pyridine ligands. In order to obtain such bis(pyridine) complexes in aqueous solution, however, the heme:ligand ratio must be about $1:10^5$[3]. In the case of pyrazine a semiequimolar amount suffices under the given reaction conditions.

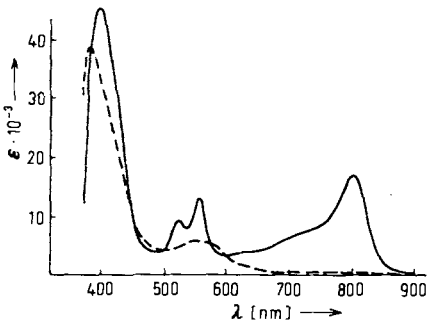

Fig. 1. Electron spectrum of heme in 0.1 N NaOH (---) and after addition of pyrazine (heme:pyrazine = 2:1) (—).

In addition, the heme-pyrazine solution showed an intense band in the near IR at 800 nm (oscillator strength *ca.* 0.1), which likewise reaches its maximum intensity at a heme:pyrazine ratio of 2:1. The solution was stable for several days and did not decompose even on irradiation with visible light (30 min; 1000 W halogen lamp, 30 cm). On warming to 60 °C, the band became broader but regained its original shape on cooling. On passage of carbon monoxide, or on addition of 10% methanol, acetone or hydrochloric acid, the band irreversibly disappeared. The heme could also be oxidized to hemin in this solution, and subsequently demetalated and esterified with diazomethane; dimethyl protoporphyrinate was isolated as sole product in 60% yield. From these experiments we conclude that the pyrazine is not covalently bonded to the porphyrin periphery in the 800-nm complex.

4,4′-Bipyridyl gave analogous changes in the visible spectrum, but no IR bands. No changes were observed in the spectrum with low concentrations of imidazole. Readily soluble iron(II) complexes of porphyrinsulfonic acids also showed no changes in the spectrum on titration with equimolar pyrazine or 4,4′-bipyridyl solutions.

Attempts to measure the NMR spectra and molecular weights of the pyrazine complexes met without success in the presence of the required excess of dithionite. The titration data with pyrazine, however, make the formation of a $(heme)_2$pyrazine complex very likely, for which we propose the structure of a cofacial pyrazine-bridged heme dimer (Fig. 2).

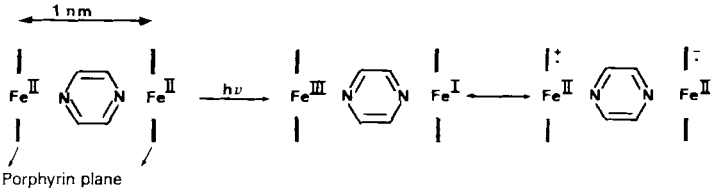

Fig. 2. Proposed structure for the pyrazine-bridged heme dimer and structures induced by excitation with light.

The electronic spectrum closely resembles that of dimeric metalporphyrin radicals; in these cases the bonds in the near IR were ascribed to the allowed direct electron transfer between two porphyrin chromophores[4]. According to *Briegleb*, the observed band shape is also indicative of a charge transfer origin[5]. Porphyrin π-radical anions also absorb in the neighborhood of 800 nm[6]. From the spectrum of the title compound it can be deduced that an aromatic double-bonded axial ligand to the iron(II) ion enables an efficient photoinduced electron transfer even over a distance of 0.8—1.0 nm.

We ascribe the extremely high formation constant of the dimer to a hydrophobic effect: The original iron(III)porphyrin derivative is present as μ-oxo dimer in aqueous solution. On reduction a cofacial heme dimer is most likely still retained, in which pyrazine is incorporated and provides further stabilization. The separation of the dimer by organic solvents or acids (protonation) is irreversible, because the formation constant of the iron-pyrazine bond in a heme monomer is just as low as in the case of pyridine, and therefore no complexation occurs.

The pyrazine-bridged heme dimer is a further example of the inner-sphere electron transfer of metal complexes of pyrazine[7], and, moreover, demonstrates for the first time the possibility of π electrons of the porphyrin ligand spreading over distances of up to 10 Å.—We are currently examining the possible exploitation of the photochemically induced charge separation in subsequent redox processes of the complex.

Matrix Isolation of OSiS: IR Spectroscopic Evidence for the Si=S Double Bond[**]

By *Hansgeorg Schnöckel*[*]

While the force constant $f(SiO)$ of monomeric SiO_2 isolated in an argon matrix[1] could not be unequivocally deter-

[*] Dr. H. Schnöckel
Anorganisch-chemisches Institut der Universität

[**] This work was supported by the Deutsche Forschungsgemeinschaft. I am indebted to Prof. *H. J. Becher* for valuable discussions and to *H. J. Göcke* for experimental cooperation.

mined from the position of the asymmetric stretching vibration, it should be calculable for a substituted molecule OSiX on the basis of additional isotopic shifts. The OSiS molecule has now been prepared in an argon matrix and studied by IR spectroscopy.

Apart from the SiO bond, that between Si and S is of particular interest in this molecule. A true Si=S double bond has so far been found only in SiS ($f(SiS) = 4.94 \times 10^2$ N m^{-1})[2], which is only stable as a monomeric species at high temperature. OSiS, the first example of a compound of tetravalent silicon containing a Si=S double bond, is formed in an argon matrix by reaction of SiS[3] with atomic oxygen generated by microwave excitation[1]. A linear OSiS molecule would exhibit two stretching vibrations of equal symmetry and an orthogonal deformation mode[4]. In addition to strong absorption bands of unreacted SiS, the matrix spectrum of ^{16}OSiS shows two bands of medium intensity[5] between 1200 and 1300 cm^{-1}, which can be assigned to the fundamental vibration ν(SiO) and the overtone 2ν(SiS). Because of an interaction effect (Fermi resonance) the true frequency of these bands is shifted and the intensity of the fundamental is diminished in favor of the overtone. For the isotopic molecule ^{18}OSiS this effect is eliminated[6] and therefore the overtone 2ν(SiS) is no longer observed[7]. Thus,

Table 1. IR absorption of Ar matrix-isolated OSiS (cm^{-1}).

	ν(SiO)	ν(SiS)	2ν(SiS)
^{16}OSiS	1265.4	643.0	1290.2
^{18}OSiS	1232.9	632.7	—

since the accurately measurable ^{16}O/^{18}O shift of ν(SiO) is falsified as a result of Fermi resonance, the potential function can only be reliably determined by means of the ^{16}O/^{18}O splitting of the Si–S vibration. However, the intensity of this vibration is almost an order of magnitude less intense than the Si–O vibration and the ^{16}O/^{18}O shift of ν(SiS) therefore has a relatively large error of 10.4 ± 0.4 cm^{-1}. This splitting and the vibrational frequencies of ^{18}OSiS (Table 1) make it possible to calculate the following force constants:

f(SiS): 4.86 ± 0.06 [10^2 N m^{-1}]
f(SiO): 9.0 ± 0.1 [10^2 N m^{-1}]
f(SiS/SiO): 0.2 ± 0.1 [10^2 N m^{-1}]

The values for f(SiO/SiS) and f(SiO) confirm the force constants previously discussed for molecular SiO_2[1]. Since force constants of about 2.28×10^2 N m^{-1} have been calculated for Si–S single bonds in various other compounds[8a], corresponding to the predictions of the Siebert rule[8b] (2.22×10^2 N m^{-1}), a bond order of 1.9 results for the Si–S bond in OSiS; this value is almost identical to that of the CS bond in COS (1.93)[9].

Comparison of all the bond orders in the COS and OSiS molecules [CO (2.4), CS (1.93); SiO (2.01), SiS (1.9)] shows that the CO bond has a special position among the four bonds considered, exhibiting considerable strengthening relative to a double bond. In contrast, the multiple bonds between main group elements of the 3rd row (SiS) or between 2nd and 3rd row (CS, SiO) do not significantly exceed a bond order of 2 as a result of reduced orbital overlap.

[3] SiS is formed in a Knudsen cell when a mixture of H_2S and Ar is passed over elemental Si at *ca.* 1500 K.
[4] A normal coordinate analysis with plausibly estimated force constants predicts the stretching vibrations of OSiS to lie in the regions ν(SiO) = 1300–1200 cm^{-1} and ν(SiS) = 700–600 cm^{-1}.
[5] A third absorption band at 1226 cm^{-1} arises from SiO; examination of our experiments with ^{18}O atoms suggests that it might have been formed in a matrix reaction SiS + O ⇌ SiO + S.
[6] Although more ^{16}O atoms than ^{18}O atoms reach the matrix in the experiment with enriched $^{18}O_2$ ($I_{Si^{16}O}/I_{Si^{18}O} = 1.4$), the intensity of the ν(SiO) bond (^{18}OSiS) is greater than that of the ν(SiO) bond (^{16}OSiS).
[7] Calculation of the Fermi shift from the frequency of ν(SiS) and the observed frequency of the overtone also shows that 2ν(SiS) of ^{18}OSiS must be masked by the fundamental ν(SiO) of ^{16}OSiS.

Novel Selenoantimonate(III) Anions in $Ba_4Sb_4Se_{11}$[**]

By *Gerhard Cordier, Ralph Cook,* and *Herbert Schäfer*[*]

Preparative and structural investigations on alkali metal thioantimonates(III) have shown that the wide variety of structures of their highly-condensed anionic moieties arise from three basic units—ψ-SbS_3 tetrahedra, ψ-trigonal SbS_4 bipyramids, and ψ-SbS_5 octahedra[1]. However, there is no definite information available about the structures of corresponding compounds containing the higher homologues of sulfur. In $Ba_4Sb_4Se_{11}$, a compound of unusual stoichiometry and structure, besides the presence of Se_2^{2-} anions (Se–Se distance 236.7 pm), three different isolated anionic Sb–Se groups has been demonstrated by complete X-ray structure analysis on single crystals[2]. They are depicted in Figure 1 together with bond lengths and bond angles. Besides dis-

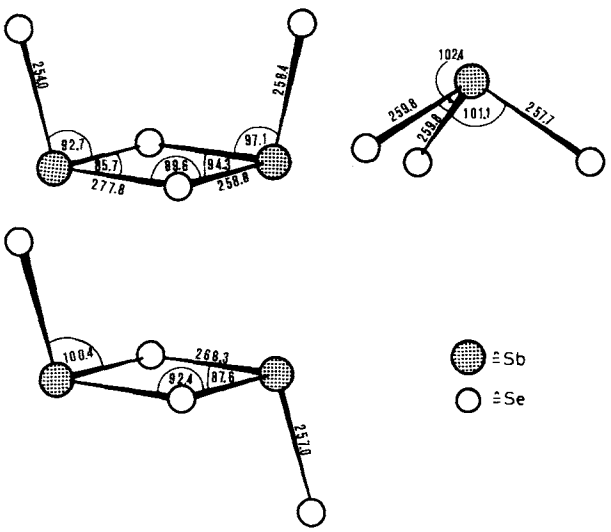

Fig. 1. The selenoantimonate(III) ions in $Ba_4Sb_4Se_{11}$. The unit cell contains one *trans*-$Sb_2Se_4^{2-}$, two *cis*-$Sb_2Se_4^{2-}$, two $SbSe_3^{3-}$ and two Se_2^{2-} ions together with eight Ba^{2+} ions.

torted trigonal $SbSe_3$ pyramids, *i.e.* ψ-tetrahedra, two different dinuclear Sb_2Se_4 units are observed, representing the *cis*- and *trans*-configuration of two $SbSe_3$ pyramids linked to each other *via* a common edge. This simple linkage resulting in surprisingly small isolated units is so far unique in the structural chemistry of compounds of trivalent antimony.

Experimental

A mixture of anhydrous barium acetate, antimony, and selenium (molar ratio $Ba(CH_3COO)_2:Sb:Se = 1:1:10$) is fused at 600 °C under argon in an alumina crucible. After cooling, the sintered mass is finely ground in a mortar, then heated again to 650 °C, maintained at this temperature for 2 h, and finally allowed to cool slowly over a period of 12 h. The regulus is broken up and the excess of selenium removed by sublimation in a vacuum at 320 °C, leaving behind dark-gray prismatic crystals.

Dimerization of S_6O to $S_{12}O_2$: Crystal Structure Analysis of $S_{12}O_2 \cdot 2SbCl_5 \cdot 3CS_2$[1]

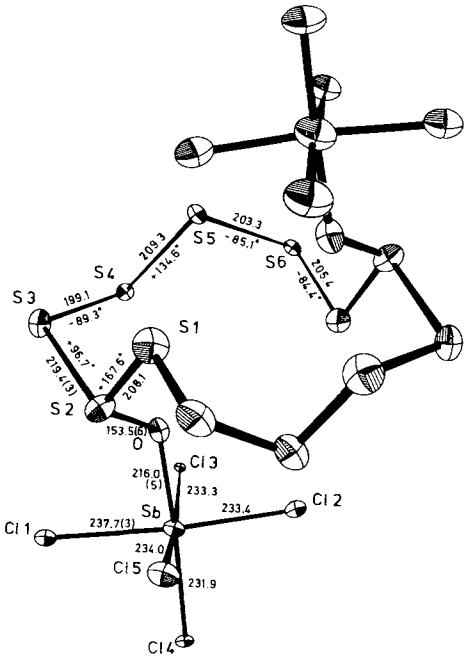
By *Ralf Steudel, Jürgen Steidel,* and *Joachim Pickardt*[*]

cyclo-Hexasulfur monoxide is formed on oxidation of S_6 with trifluoroperacetic acid[2]. However, it has not yet been obtained as crystals large enough to permit determination of its molecular structure. An attempt to prepare better crystalline adducts of S_6O with $SbCl_5$ by analogy with numerous sulfoxide-metal complexes[3] afforded (at −50 °C in CS_2) orange crystals of $S_{12}O_2 \cdot 2SbCl_5 \cdot 3CS_2$ *(1)*; their X-ray structure analysis[4] provides the first information about the structure of a *cyclo*-polysulfur dioxide.

On exposure to air, the initially clear crystals of *(1)* turn cloudy within 1 min as a result of efflorescence with liberation of CS_2, and ultimately form a yellow oil. In CS_2 at room temperature partial decomposition is already detectable after 10 min, yielding $SOCl_2$, SO_2, S_8, and $SbCl_3$ (SO_2 possibly by hydrolysis of $SOCl_2$).

The asymmetric SO stretching vibration of the $S_{12}O_2$ ligand was observed at 940 cm^{-1} in the IR spectrum (CS_2 solution); the symmetrical SO vibration expected in the Raman spectrum has not yet been detected.

The $S_{12}O_2 \cdot 2SbCl_5$ molecules occupy lattice sites of C_i symmetry. The conformation of their ring differs drastically from that of *cyclo*-dodecasulfur S_{12} (D_{3d} symmetry)[5], showing striking variations in the SS internuclear distances and a particularly striking value of 168° for two SSSS torsional angles, which exceeds the values found so far for sulfur homocycles by 45°. The principal molecular parameters are shown in Figure 1. The O atoms occupy axial positions relative to a mean plane through the S_{12} ring. The $SbCl_5$ groups and the bridging O atoms have an almost octahedral geometry. Only van der Waals interactions occur with the CS_2 molecules not shown in Figure 1.



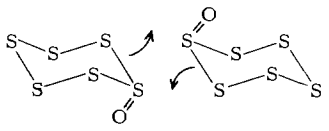


Fig. 1. Internuclear distances [pm] and torsional angles [°] of $S_{12}O_2 \cdot 2SbCl_5 \cdot 3CS_2$ *(1)*. The torsional angles to the O atom are S6′ S1 S2 O: 87.4° and S4 S3 S2 O: 9.6° (S6′ is obtained by reflection of S6 in the inversion center).

Valence angles [°]							
S2	S1	S6	100.3(1)	S4	S5	S6	101.6(1)
S1	S2	S3	94.4(1)	S1	S6	S5	107.5(1)
S2	S3	S4	103.9(1)	S1	S2	O	104.7(2)
S5	S4	S3	103.8(1)	S3	S2	O	103.4(2)

Formation of the centrosymmetric $S_{12}O_2$ molecule, which is still unknown in the free state, from S_6O can be explained in terms of a dipolar addition:

The chair conformation of the six-membered rings of the two S_6O components can still be seen in $S_{12}O_2$. Thus dimerization of a sulfur ring has now been observed for the first time.

Procedure

Freshly distilled $SbCl_5$ (0.5 ml) is added to a stirred solution of β-S_6O[2] (500 mg, 2.40 mmol) in dried CS_2 (100 ml) prepared at −10 °C, and the mixture is immediately cooled to −50 °C. After one week, crystals of *(1)* (150 mg; 10%) precipitate which are isolated at −30 °C on a glass frit, washed with pentane (−30 °C), and dried *in vacuo*. The crystals release CS_2 in the final step; they should therefore be stored in the mother liquor at −50 °C (where they can be kept for at least 5 weeks).

Syntheses with Metalloid Derivatives: Preparation of Macrocyclic Dicarbamates

By *Abraham Shanzer, Nava Shochet, Dov Rabinovich,* and *Felix Frolow*[*]

The difficulty in directing condensation reactions to provide ring products in preference to polymeric materials represents the major barrier towards the efficient synthesis of macrocyclic structures[1]. In order to overcome this barrier various cyclization procedures have been recommended: dilution[2a] and double activation methods[2b], and the use of mercury salts[2c] or metal templates[2d]. We have found an alternative method, in which metalloid derivatives serve as covalent templates for the construction of ring compounds from acyclic precursors. Once the construction of the organic shell has been completed, the metalloid template is easily removed by mild hydrolytic cleavage of the weak metalloid-heteroatom bond. The feasibility of this approach will be demonstrated in this communication by the preparation of macrocyclic dicarbamates from ethylene glycol and diisocyanates using dibutyltin as covalent template.

The synthetic sequence involves condensation of ethylene glycol with dibutyltin oxide to give the known distannoxane derivative *(1)*[3]. Treatment of the latter with organic diisocyanates results in insertion[4] of the N=C group between the Sn –O bonds, affording the tricyclic intermediate *(2)*. Subsequent addition of a few drops of water cleaves the labile Sn –N bonds[5] and releases the macrocyclic dicarbamates *(3)*. Applying this procedure macrocyclic dicarbamates *(3a)*, $n = 6$[6], and *(3b)*, $n = 5$, have been prepared in a simple two step process. The compounds gave correct analyses and characteristic spectra in agreement with the assigned structures. Compound *(3a)* was in addition characterized by a single crystal X-ray structure analysis (Fig. 1).

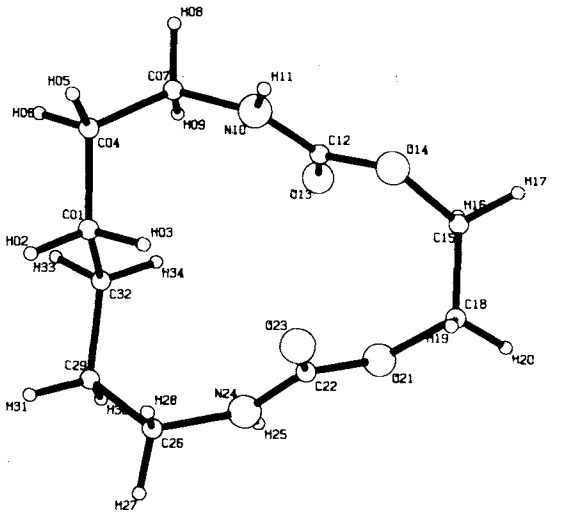

Fig. 1. Crystal structure of *(3a)*. The measurements were performed on an Enraf-Nonius CAD-4 diffractometer with $Mo_{K\alpha}$ radiation; space group C2/c, $a = 16.805(1)$, $b = 8.452(1)$, $c = 17.067(1)$ Å, $\beta = 104.88°$, $V = 2342.5$ Å^3, $Z = 8$, $\rho_{calc} = 1.32$ g/cm^3, $\rho_{obs} = 1.31$ g/cm^3; 2531 independent reflections ($\theta \leq 27°$), solution by direct methods (MULTAN), refinement to $R = 0.039$, torsion angles:

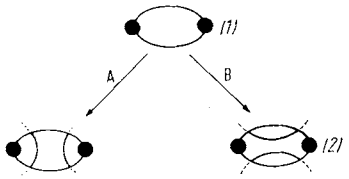
C32	CO1	CO4	CO7	62.4°	CO1	CO4	CO7	N10	− 53.1°
CO4	CO7	N10	C12	121.5°	CO7	N10	C12	O14	180.0°
N10	C12	O14	C15	171.5°	C12	O14	C15	C18	− 98.8°
O14	C15	C18	O21	71.4°	C15	C18	O21	C22	− 99.5°
C18	O21	C22	N24	−178.4°	O21	C22	N24	C26	−174.8°
C22	N24	C26	C29	−116.2°	N24	C26	C29	C32	− 58.7°
C26	C29	C32	CO1	− 58.6°	C29	C32	CO1	CO4	−172.6°

The two carbonyl oxygen atoms in *(3a)* are almost perpendicular to the equatorial plane of the molecule and their deviations above or below this plane are equal (1.48 Å). This arrangement of the carbonyl groups, which define an internal polar cavity, seems to be typical for such structures.



Likewise, in cyclic peptides such as enniatin[7] an alternating orientation of the carbonyl oxygen atoms above and below the plane of the ring is also observed.

The formation of the cyclic dicarbamates *(3)* from distannoxane *(1)* and diisocyanates indicates the dual function of the metalloid template as activating and guiding unit. Activation is achieved by the electropositive character of the tin, which increases the nucleophilicity of its attached functional groups[8]. Stereochemical guidance, on the other hand, is inferred by the rigidity of the ring structure. The latter directs condensation reactions to proceed intramolecularly and thereby reduces competitive polymerization processes. Direct condensation of ethylene glycol with hexamethylene diisocyanate (160—170 °C, 8—20 h, dilution technique) has been reported to yield less than 5% of the desired macrocyclic product *(3a)*[6].

The exclusive formation of the macrocyclic dicarbamate in preference to the tetracarbamate deserves particular attention. Insertion of diisocyanates into the distannoxane *(1)* could *a priori* occur by either of the two alternative pathways A or B (Scheme 1).

Scheme 1.

The isolation of cyclic dicarbamates in favor of cyclic tetracarbamates implies predominant insertion *via* pathway B. This reaction mode may be attributed to a deactivation of the geminal Sn—O bond after completion of the first insertion process.

The use of dibutyltin as covalent template for the controlled condensation of acyclic substrates represent a systematic approach towards the preparation of macrocycles. The advantages of covalently bonded metalloid templates over metal templates, are ready removal of the metalloid after completion of the template reaction and broad range of applicability, as a large variety of organometalloid compounds may function as template.

Experimental

A solution of *(1)* (2.36 g, 4.0 mmol) in CCl_4 (30.0 ml) was treated under reflux dropwise with a solution of hexamethylene diisocyanate (1.29 ml, 8.0 mmol) in CCl_4 (9 ml). After the addition had been completed the reaction mixture was heated under reflux for one hour. 5.0 ml of aqueous THF (5%) was then added, and the resulting precipitate of dibutyltin oxide removed by filtration and the filtrate concentrated. Crystallization of the residue from benzene/petroleum ether (1:1) afforded 0.64 g (35%) of the dicarbamate *(3a)*, m.p. 168 °C.—*(3b)*, m.p. 164 °C, was prepared analogously.

Syntheses with Metalloid Derivatives: Preparation of Heterocycles[**]

By *Abraham Shanzer*[*]

The synthesis of nitrogen heterocyclic compounds has most frequently been achieved by either intermolecular or intramolecular condensation of difunctional substrates[1,2]. While the preparation of symmetric compounds has been based on the use of symmetric precursors, the preparation of unsymmetric systems hitherto required unsymmetric substrates that are much more difficultly accessible. We have recently introduced the use of metalloid derivatives as covalent templates for the preparation of macrocyclic compounds[3]. In this communication we wish to describe the application of metalloid templates for the synthesis of non-symmetric heterocycles from symmetric precursors. The key step is the unsymmetric transannular ring closure of templated, cyclic intermediates, and its feasibility is demonstrated by the synthesis of perhydrotriazepines.

Specifically, acyclic diamines *(1)* have been added to dimethylsilicon isocyanate *(2)* or diisothiocyanate *(3)* as templates to provide cyclic, silylated diureas *(4)* and *(5)*, respectively. Condensation of the latter with carbonyl diimidazole *(6)* or thiocarbonyl diimidazole *(7)* and subsequent hydrolytic removal of the silicon template afforded the perhydrotriazepines *(8)*[4], *(9)* or *(10)*, respectively. While the diones *(8)*

[**] This work was supported by the Israel Academy of Sciences and Humanities. The author wishes to thank Mrs. *Sara Rubinraut* for skillful technical assistance, Dr. *Z. Zaretski*, for the mass spectral analysis, and Mr. *M. Greenberg* for the measurements of the NMR spectra.

are well-known compounds[4], the thiooxoketones *(9)* and dithiones *(10)* are new compounds. Their structures have been determined by high resolution NMR and mass spectrometry; an X-ray structure analysis[5] of *(9a)* confirmed the assignments.

The first step of the synthesis—the formation of the cyclic diureas *(4)* or *(5)*—is supported by the hydrolysis of *(4)* to *(11)* in quantitative yields. The second step—the unsymmetric transannular ring closure (see Scheme 1)—might well be

Scheme 1.

accelerated by the concurrent regeneration of the isocyanate or isothiocyanate group and release of the imidazole moiety.

The above mentioned successive application of two reagents permits the synthesis of the unsymmetric product *(9)* in two ways: from *(1)* with *(2)* and *(7) via (4)* or with *(3)* and *(6) via (5)*. Moreover, this approach replaces composite reagents (carbonyl isocyanates[4] or isothiocyanates[6]) by simple ones [*(2), (3), (6), (7)*].

Experimental

A 0.5 M solution of *(1a)* in benzene is gradually mixed at room temperature with a 0.5 M solution of *(3)* in benzene (using a Sage syringe pump; Orion, Research Inc.). The resulting crystalline precipitate is dissolved in DMF and treated with 1.5 equivalents of *(6)* and heated for 30 min under reflux. The reaction mixture is then allowed to cool to room temperature and the product hydrolyzed by addition of 10 ml of 5% isopropanol and heating for 15 min under reflux. Evaporation of the solvent yields a syrup-like oil from which the azepine *(9a)* is isolated by chromatography in 70% yield.—*(8)* and *(10)* were prepared under analogous reaction conditions in comparable yields.

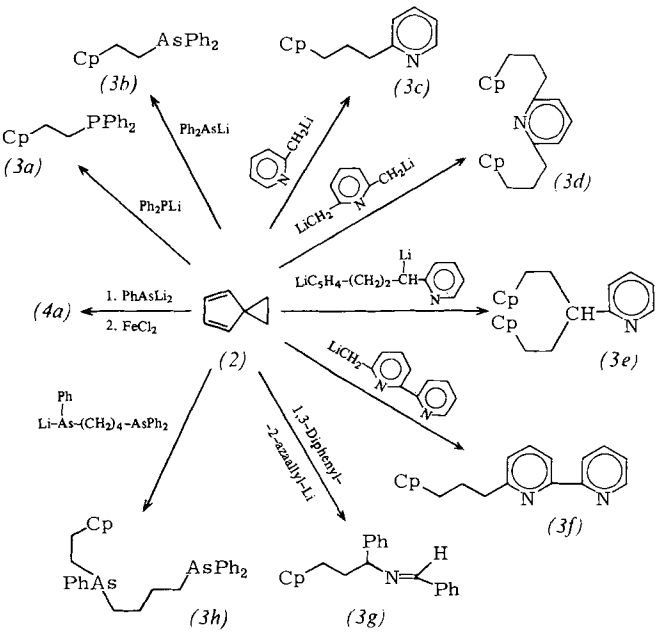
Coupling of Well-Established Organotransition Metal Chemistry Donor Groups to Multielectron Ligands[**]

By *Thomas Kauffmann, Johann Ennen, Harald Lhotak, Alfons Rensing, Fritz Steinseifer,* and *Annegret Woltermann*[*]



In organo-transition metal reagents and catalysts used for organic syntheses there are generally two different types of ligands: "active ligands" (bold type in examples *(1a)—(1c)*), which directly participate in the reactions, and "passive ligands" which—*cum grano salis*—have merely the task of donating electrons to the transition metal to fill its valency shell and of accepting back-bonding electrons.

(1a) 1e-Active ligand *(1b)* 2e-Active ligand *(1c)* 3e-Active ligand

The passive ligands are usually not optimal (poor thermodynamic stability of the bond to the transition metal; susceptible to nucleophilic attack, like CO or Hal; toxic, like CO). To overcome these deficiencies it is recommended that polydentate multielectron ligands, obtained by linear, branched, or cyclic[1] coupling of proven donor groups, be used as passive ligands. However, since there is a variety of metals of various electronic structures available in the d elements, a complementary variety of easily accessible multielectron passive ligands is required. As replacement for the three passive ligands in *(1a), e.g.*, a 9e-ligand would be necessary. The recently published[2] synthesis of compound *(3a)* (7e-ligand), obtained in our laboratory *via* another route, urged us to report on the coupling of the cyclopentadienyl (Cp) group with 2e- and 4e-donor groups.

Reaction of the readily accessible spirohydrocarbon *(2)*[3] with nucleophiles and subsequent treatment with water afforded the thermolabile, undistillable compounds *(3a)—(3h)*[4], which were purified by column chromatography and characterized by their ^{1}H-NMR (Table 1), IR, and mass spectra. Some of the yields might possibly be improved.

For characterization, some of the anionic ligand systems were converted with $FeCl_2$ into ferrocene derivatives without prior hydrolysis. The surprisingly high yield of the *ansa*-ferrocenes *(4a)* and *(4b)* is presumably due to the fact that—other than in earlier attempts[5] to synthesize such ferrocenes from biscyclopentadienes (max. yield 2.6%)—the biscyclopentadiene derivatives were generated directly in the stable anionic form and reacted.

Multiple Electron Resonance Spectroscopy. Edited by *M. M. Dorio* and *J. H. Freed.* Plenum Press, New York 1979. xii, 512 pages, bound, $ 49.50.

As in NMR, multiple-resonance methods have recently found wide application in the study of complex spin systems in the field of ESR. In principle, what is observed is the change in the intensity or structure of an electron resonance transition caused by the simultaneous disturbance of a spin system by irradiation at one or more transition frequencies corresponding to nuclear (ENDOR and Double ENDOR or TRIPLE process) or electron resonance transitions (ELDOR process). The effects are a key to the relaxation behavior and/or, due to the higher resolution, provide structural information. Among these processes we may also rank those in which the spin concentration is varied with time and which provide essentially kinetic data. The present book deals with the whole field in 14 sometimes rather cursory articles written by experts.

After a brief historical introduction *(M. M. Dorio), D. Leniart* describes the instrumentation and the experimental procedures for ENDOR and ELDOR, several—sometimes commercial—spectrometer configurations and experimental effects being described in detail. *J. Freed* then presents the theory in his usual precise but rather telegraphic manner, with special emphasis on the connection between the observable effects and relaxation processes. The chapter by *N. M. Atherton* on ENDOR in liquid solutions stresses applications in the analysis of complex ESR spectra of radicals in solution. Zeeman modulation effects in the structure of ESR, ENDOR, and ELDOR spectra are described in detail by *L. A.* and *L. R. Dalton.* A review of ENDOR and ELDOR on radicals and solvated electrons in unordered matrices is given by *L. Kevan* and *P. A. Narayana*; *L. D. Kispert* summarizes the corresponding results on monocrystalline samples. The chapter by *C. P. Scholes* and *R. H. Sands* deals with biologically-oriented applications of electron double resonance in heme compounds and iron-sulfur proteins. *H. C. Box* writes on applications in radiation biophysics, and *M. M. Dorio* on those in the field of polymers. *M. D. Kemple* summarizes ENDOR on molecules in the optically excited triplet state, and finally *K. Moebius* and *R. Biehl* introduce the TRIPLE-resonance technique on radicals in solution, which they have developed extensively in recent years. There is also a chapter by *H. Levanon* on the principles and uses of the time variation of concentrations by means of optical irradiation, for which the author, quite superfluously, invents a new name—"Optical Perturbation EPR" (OPEPR) and which, unfortunately, is not very representative. A short subject index concludes the book.

Over-all, the book offers a splendid summary of the current state of multiple-electron resonance. It is an important source of information for specialists in electron resonance and can serve as a basis for advanced students. It is too demanding and too heterogeneous from the point of view of the presentation to be suitable as an introduction for non-specialists.

Hanns Fischer [NB 500 IE]

Liquid Crystals and Biological Structures. By *G. H. Brown* and *J. J. Wolken.* Academic Press, New York 1979. 187 pages, bound, $ 19.00.

A reader taking up a book with the above title, implying a biophysical-chemical bias, might well expect a comparison of liquid crystals and biomembranes. He will be disappointed, for the book has little to do with such subjects. The chapter on membranes—appended at the end—is all of six pages long and the main illustration in it is a cartoon of a membrane.

What, then, is the aim of this book? The main section (Chapters 5—11) describes all kinds of molecular and cellular structures such as occur in living organisms. Although the selection is somewhat arbitrary, there is a nice collection of instructive figures especially from the visual system. The text, however, is very superficial and not suitable for an introduction. At every conceivable and inconceivable opportunity the authors refer to the importance of ordered, non-crystalline formations in biology and point out that there should be consequently a close relationship to the physics of liquid crystals. These vague statements culminate on page 144 in the following sentences on the ageing—of man: "It is not known how the ageing process takes place, but the liquid crystalline state of matter must certainly be considered.", and then, after exactly 14 lines, the following is offered as a conclusion: "... ageing could be delayed or modified chemically by hydration and dehydration." Hydration of liquid crystals is the fountain of youth? The useful information contained in this chapter can also be found—and in scientifically faultless form—in textbooks on cell biology and biochemistry, and wrapping it up in simplifying pseudophysical arguments, as this book does, is fatal.

The biological part of the book is preceded by a good introduction to the field of liquid crystals (Chapters 1—4) although the liquid crystalline polymers have been overlooked. This section gives a brief outline of the physics and nomenclature of nematic and smectic metaphases. However, since other books on liquid crystals also do this, and the volume as a whole in no way lives up to its aim of demonstrating a connection between the physics of liquid crystals and biological structures, this is not a book to be recommended.

Peter Fromherz [NB 501 IE]

Air Pollution Chemistry. By *John D. Butler,* Academic Press, London—New York—San Francisco. 1st edit., viii, 408 pp., numerous figures and tables, bound, £ 25.00.

The significant efforts exerted by governments, industries and engaged individuals in keeping our environment clean have considerably increased the need for detailed knowledge concerning the chemical behavior of pollutants in the atmosphere. Not long ago, the only way to obtain such information was a laborious consultation of the technical journals specializing in these matters. In recent years, the situation has improved in that a number of monographs have appeared on the market which make the available knowledge more readily accessible and, at the same time, provide a reasonably comprehensive overview of atmospheric chemistry. The present book provides a good summary of present knowledge of atmospheric chemistry but contains in addition much detailed information germane to problems of local air pollution, thus justifying its title. The book is written from the view-point of a physical chemist and is based on second and third year undergraduate lecture courses to students of chemistry. An intermediate level of presentation is adopted. The text is well ordered and treats in seven chapters: 1. health factors; 2. sources, sinks and removal mechanisms of emissions to the atmosphere; 3. air sampling and collection; 4. analysis of pollutants by instrumental methods; 5. atmos-

pheric reactions; 6. meteorological aspects of pollutant dispersions; 7. urban atmospheres.—Under each heading a great amount of material has been assembled, mostly in tabular form, and is discussed in detail. The literature referenced at the end of each chapter originates mainly from the sixties and seventies prior to 1977. The citations are not intended to be exhaustive but provide a fairly good survey.

The on the whole positive evaluation of the book unfortunately is dampened by two shortcomings. The preface makes apparent the intent of the author to use the book for teaching purposes. In this respect, the text does not meet the didactic requirements. Since the curriculum of chemists generally does not include the fundamentals of meteorology, a short introduction into the meteorological terminology seems required. For example, the term stratosphere is mentioned first on page 51 but its meaning becomes clear from a diagram on page 272. The terms "aerosol" (p. 51) and "dry deposition" (p. 102) are similarly introduced without explanation. A second weak point is the sometimes uncritical presentation of material taken from the literature. One example concerns the sources and sinks in the budget of atmospheric nitrogen and sulfur compounds. Although the figures given agree quite well with current concepts, there is no discussion of the problem in obtaining reliable estimates, and one does not learn either how such figures are derived. Another example: the description of the spark source mass spectrometer on page 205 conveys the impression that this instrument is widely employed for the analysis of dust particulates. This, however, is not true.

With these reservations one can recommend the book to all persons who have an active interest in the problems of air chemistry and air pollution. Today, the number of readers within this circle is no longer small.

Peter Warneck [NB 502 IE]

Gel Chromatography, Theory, Methodology, Application. By *T. Kremmer* and *L. Boross.* John Wiley and Sons, Chichester, 1979.

This English translation of a book that appeared in Hungary in 1974 concentrates almost exclusively on aqueous gel chromatography on soft, swellable, stationary phases. Since the manufacturers of these gels have generously provided a detailed literature service, it is no problem to collect such data into a single coherent text. Although "the most recent" developments of the method are discussed, it is nevertheless astonishing that there is no mention of the technique of instrumental liquid chromatography, now familiar for a decade. After all, from the apparatus point of view this technique has its origins partly in gel chromatography and has given rise to a reconsideration of gel chromatography.

Part I, Principles (about 30 pages) gives a practically complete survey of the available soft gels in addition to some data on common xerogels. Surprisingly enough, the "carbon molecular sieve" of gas chromatography is included here. The "Theory" section (about 60 pages) gives models of the gel-chromatographic separation process, of band broadening, and of molecular weight determination. Sentences like "To use gels in chromatography, gel particles must be produced" and others of similar ilk must be attributed to the translation. Part II (about 70 pages) deals with the methods and techniques, including thin-layer chromatography. Finally, Part III (about 90 pages) discusses the uses of gel chromatography for the separation of proteins, nucleic acids, and carbohydrates. Separations of low molecular compounds and inorganic salts on soft gels are also described.

Newcomers to the field of aqueous gel chromatography will find many practical hints and a survey of the problems and possibilities of this classical method. The more experienced student is, however, referred to "Modern Size-Exclusion Chromatography" by *W. W. Yau, J. J. Kirkland* and *D. D. Bly,* published simultaneously by the same company.

Computer Simulation of the Kinetics of Complicated Gas Phase Reactions

By Klaus H. Ebert, Hanns J. Ederer, and Gunther Isbarn[*]

Dedicated to Professor Matthias Seefelder on the occasion of his 60th birthday

Modern digital methods and powerful computers make it possible to simulate the time behavior of chemical reactions. These calculations can be performed on systems containing an almost unlimited number of elementary reactions. Generally, however, the reaction models used should contain only those elementary reactions which describe the bulk of the conversion. Such a reaction model may be obtained by reduction of the complete set of elementary reactions. Another possibility is analysis of the chemical system starting from conditions ensuring a simple chemistry, which is generally the case at low temperatures and low conversions. The reaction model may then be extended into the range of the reaction variables (temperature, time) of interest. Mathematical simulations may be helpful during the development of the reaction model, and sometimes even decisive. These methods were applied to the pyrolysis of ethylbenzene and *n*-hexane, and to CO oxidation. They yield information on the reaction paths, the importance of particular elementary reactions, and reaction stability. Furthermore, quantitative data can be obtained concerning the influence of single elementary reactions on the product distribution. The sensitivity matrix shows, *e.g.*, whether the determination of kinetic parameters of an elementary reaction from kinetic data of the overall reaction is possible in principle, and how high the accuracy of the rate constants should be for simulation of the reaction. Both results are important for modeling chemical reactions.

1. Introduction

The rapid development of modern computers has markedly advanced the possibilities and the potency of chemical kinetics. Until recently the time behavior of only those chemical reactions could be determined exactly whose rate laws could be expressed as a system of differential equations which can be integrated analytically. This is possible with elementary chemical reactions, which cannot be subdivided, and with a few simple reaction systems. It is not possible to obtain exact analytical expressions for the time dependence of most of the chemical systems of practical interest. Therefore the solution of the simultaneous differential equations requires other methods.

For reactions involving radicals—and that is the majority of all homogeneous gas phase reactions—the best known approximation method for solving such systems of differential equations is the assumption of a steady state[1]. This approxi-

mation implies that the reactive intermediates are consumed as fast as they are produced, resulting in a zero net formation rate. This greatly simplifies the mathematical treatment (see Section 3.2).

Another method of solving complicated systems of differential equations is numerical integration, in which the time behavior is evaluated by stepwise computation. If there is a large difference in the rates of production and consumption of the various species, which is always the case in the initial period of radical reactions, very short time intervals have to be used for the calculations. In classical integration methods (*e.g.* Runge-Kutta methods[2]) this will entail considerable computational effort. Modern integration methods use variable time intervals, and are available as computer programs. Short time intervals are chosen in the area of large changes in the concentration of the species, and longer time intervals are used if these changes are smaller. Nevertheless, numerical integration of a large number of nonlinear simultaneous differential equations usually requires an enormous computational effort which can only be mastered with modern high capacity computers. Modern numerical methods tend to decrease computing time and storage size without reducing the quality of the results. Results are considered as "exact" if a reduction of the time intervals does not have any effect on the results.

Before studying the differences in the results of kinetical calculations obtained by the "exact" method and by assuming a steady state, it is useful to check how well the laws of chemical kinetics generally describe the time behavior of a chemical reaction. The classical theory of the rates of thermal reactions[3,4] is based upon two fundamental equations[*]. The time law describes the rate of homogeneous gas phase reactions in dependence upon the partial pressures:

$$\frac{dn_i}{dt} = \sum \pm k_o^1 n_m + \sum \pm k_{p,s}^2 n_p n_s \qquad (1)$$

The first term of the right side contains the components of first order reactions, and the second term those of second order reactions. The sign indicates the production (+) or the consumption (−) of the species n_i in the reaction considered. The temperature dependence of the reaction rate constant can usually be expressed by the Arrhenius equation:

$$k = A \exp(-E_a/RT) \qquad (2)$$

The number of elementary reactions participating in a chemical reaction system can vary within wide limits. Examples of reactions consisting of only few elementary reactions (*e.g.* formation of hydrogen halides from the elements) can be found in any textbook of physical chemistry. Most of the gas phase reactions of practical interest consist of many—often several hundred—elementary reactions. Of course, they will all participate to some extent in the reaction, but the question to be answered is: which reactions determine the kinetic behavior and which exert such a slight influence that they may be neglected? Reaction mechanisms with a large number of elementary reactions almost exceed the capabilities of even the most powerful computers. As a rule of thumb, the computational effort increases with the square of the number of differential equations.

It is therefore very important that complicated reaction mechanisms be reduced to a reaction model which describes the reaction with sufficient accuracy while still being suitable for kinetic calculations using either the "exact" method or the steady state assumption.

2. Reaction Models

Reaction models should be made up of elementary reactions because of their general applicability. With a knowledge of the kinetic constants, absolute values of the reaction rates can be calculated. The number of elementary reactions increases with the number of atoms present in the reactants. For the fairly simple decomposition reactions of such small molecules as butane or pentane there exist more than 500 "possible" elementary reactions, even with the limiting assumption that no products are formed with a molecular weight exceeding twice that of the parent compound[5]. On addition of other reactants, such as oxygen, water, *etc.*, the number of elementary reactions is multiplied. However, a reaction model fulfills its purpose if it describes well enough the course of the reaction within the interesting range of the reaction variables (p, T), or if it provides answers to specific questions. It may happen that the production rate of a particular by-product is of more importance than an exact description of the formation of the major products.

Of course, the lower the number of elementary reactions, the simpler becomes the mathematical treatment. However, an upper limit for this number cannot be given in general because the complexity of a reaction model also depends on the number of the participating species. However, if the number of elementary reactions approaches 50, a reduction should be considered.

It is usually not easy to decide from the kinetic constants whether a particular elementary reaction belongs to the group of those which are involved in an "important" reaction path within the conversion, and therefore cannot be neglected. Furthermore, a reaction model has to be self-consistent and to contain reactions accounting for the consumption of all radicals. A useful approach to model reduction is the combination of certain species or elementary reactions; this is called lumping. However, the "kinetic constants" of the lumped reactions rarely remain constant, and the applicability of the corresponding rate expression is consequently limited. Lumping is favored if similar species (*e.g.* radicals from unsaturated hydrocarbons) form the same major product (*e.g.* soot)[6-9].

In minimizing the number of elementary reactions for a reaction model the chemist usually adopts a different meth-

[*] Both laws are based upon the Boltzmann distribution of molecular energies, which is satisfied within the usual reaction conditions of most chemical reactions. Chemical reactions are undergone predominantly by the energy-rich molecules of the ensemble; therefore, weak interactions, which are responsible for the numerous deviations of thermodynamic properties from "ideality", are of little or no influence. In general, eqs. (1) and (2) are satisfied well. This means that reaction rates can be calculated with high accuracy in a wide range of the reaction variables if the values of the kinetic constants are known exactly. The accuracy of the calculations is usually very good relative to the experimental methods available for determining reaction rates. This is true without limitation for the elementary reactions which cannot be further subdivided and whose behavior is described by the stoichiometric equation. It should be noted that at low pressure energy transfer may influence the reaction rates, and that the assumption of the Boltzmann distribution may loose its validity in very fast reactions—at high temperatures or in reactions with a very low activation energy. Both possibilities cause deviations from eqs. (1) and (2).

od. He tries to analyze the reaction mechanism using experimental data, and in so doing he first looks for the initial reactions and then proceeds to formulate those elementary reactions describing the fate of the reactive intermediates. In this way, the construction of a reaction model is continued by considering known chemical principles and attempting to formulate the formation of the products and intermediates with a minimum set of elementary reactions. Additional investigations about particular elementary reactions[10–12] are sometimes useful. Simultaneous kinetic calculations and quantitative comparisons with the experimentally determined product distribution may also be helpful in formulating the reaction model.

It is convenient to start the development of a reaction model at low temperatures and low conversions, where the number of elementary reactions is small, and to extend it into the interesting regions of the reaction variables. This method is then always applicable if the model contains only few initial reactions, and if these form only few primary intermediates, as in the thermal decomposition of ethylbenzene (see Section 4.3). Furthermore, this method allows a clear description of reaction behavior and prediction of variations in the reaction behavior caused by variations of the reaction conditions or by the addition of various reactants.

3. Mathematical Methods

3.1. Numerical Treatment of Rate Equations

For numerical treatment, the reaction model is transformed into a system of differential equations containing one differential equation for each species taking part in the reaction. In general this is not difficult. If the number of species is greater than ten, the system should be evaluated by computer. The transformed reaction model consists of linear and quadratic terms depending on the unimolecular or bimolecular nature of the corresponding elementary reactions. (In radical recombination reactions, third order terms may occur too.)

To obtain a numerical solution of the differential equation system the values of the kinetic parameters (activation energy, pre-exponential factor) of each elementary reaction are needed. The number of elementary reactions whose kinetic constants are known with satisfactory accuracy is still small; such data have been compiled in tables[13–16]. If the kinetic constants are not known, their values should be estimated from chemical analogy or from thermodynamic considerations[16–18].

The kinetic constants of reactions of the same type often vary within close limits. These "band widths" are compiled in Table 1 for five types of reactions, which represent most of the elementary reactions occurring in the pyrolysis of hydrocarbons.

Table 1. Types of reactions in the pyrolysis of hydrocarbons and band widths of the kinetic parameters A [s^{-1}; ls^{-1} mol^{-1}] (pre-exponential factor) and E_a [kJ mol^{-1}] (activation energy); M,M′: stable molecules; R,R′: radicals.

Type no.	Elementary reaction	$\log_{10}A$	E_a
(1)	M → R+R′	15—17	200—360
(2)	M+R → R′+M′	7—11	30— 50
(3)	R → M+R′	12—15	100—180
(4)	R+R′ → M (+M′)	7—11	0
(5)	R → R′	10—12	50— 80

For these estimates, it is important to have information about the sensitivity of the reaction model to variation of the values of respective reaction constants. More detailed data on the sensitivity of a particular model and its temperature dependence can be obtained only by simultaneous computations (cf. Section 5.2). Occasionally in simple systems quantitative data are available on the sensitivity of reaction constants, *e.g.* of the activation energy of unimolecular initial reactions. In complicated systems it is mostly very difficult, if at all possible, to predict the effect of the variation of a particular kinetic constant on a model. For some elementary reactions it is evident, however, that they do not affect the reaction model noticeably, even if the rates are varied considerably.

Large differences in the sensitivities appear in all systems of differential equations in which the time constants differ by orders of magnitude; such systems are called 'stiff'.

The well-known Runge-Kutta methods[2] are not suitable for the numerical integration of stiff differential systems. Because of the huge difference in the time behavior of the individual elementary reactions the time step size has to be set extremely small in order to obtain correct results. Errors introduced by excessive step sizes in the initial period of the reactions are propagated also in regions of higher conversions. The computer time required to cover high conversions of a reaction is then extremely long.

Fast methods for the solution of stiff differential equation systems have become an important field of research in numerical mathematics. All modern "stiff solvers" contain an efficient self-adjusting optimum step size control, *i.e.* rapid variations require small step sizes, slow variations permit large step sizes[19]. A further important point is the algorithm for the numerical stability of a stiff solver. The algorithm has to prevent the accumulation of computational errors.

The program of *Gear*[20], which is very often used by chemists, is based on a "multistep predictor-corrector" algorithm which also controls the step size. The program has been very successful; until now no case of a "wrong" solution of a chemical problem is known.

Other methods for solving stiff differential equation systems are the implicit Runge-Kutta method of *Wanner*[21] and the semi-implicit algorithm of *Deuflhard*[22] which requires a considerably smaller computer storage size than the program of *Gear*.

3.2. The Steady State Assumption

The most important and most frequently applied approximative method in treating differential equation systems in chemical kinetics is based upon the quasi-steady state assumption (QSSA). In this approximation, the right-hand sides of the differential equations for the reactive intermediates are set equal to zero in order to transform these differential equations into algebraic equations. As a result, the remaining reduced system of differential equations (for the reactants and the stable products) is substantially less stiff than the original system. This may permit either an analytical solution of the differential equation system or the appli-

cation of considerably simpler numerical integration methods (*e.g.* Runge-Kutta). The QSSA does not mean, however, that the concentrations of all reactive intermediates are set constant during the reaction. According to the mathematical treatment with the singular perturbation theory[23-27], which will not be outlined in detail, there exist two types of radicals[28] depending mainly on the type of reactions in which the radical is consumed: type r_m, whose concentrations remain approximately constant, and type r_n, whose concentrations decrease according to a function similar to that governing the disappearance of the reactant in the course of the reaction.

The QSSA, as usually applied by chemists, neglects the time behavior of the initial period of the reaction in which the concentrations of all radicals increase to a limiting value corresponding to the "steady-state" value[*]. Generally, the smaller the steady-state concentrations are, the lower will be the conversion at which the steady state is attained. Therefore, the QSSA is better fulfilled at low temperatures and high pressures. The question then arises whether there exists a quantitative measure for the applicability of this approximation. The differential equations of the radicals can be transformed into a set of dimensionless differential equations. This procedure and a suitable rearrangement attributes a dimensionless constant ε_i to each dimensionless differential quotient. The ε_i-values are composed of reaction rate constants and initial concentrations of the reactants, and it can be shown that they are characteristic values for the applicability of the QSSA. Although theory supplies exact solutions for calculating the ε_i-values, in most cases more or less rough estimations are more readily available which give satisfactory information on the applicability of the QSSA.

For thermal decomposition reactions (*e.g.* the pyrolysis of ethylbenzene; cf. Table 2) the numerical values of ε_i for the two groups of radicals r_m and r_n are approximated by equations (3) and (4), respectively:

$$\varepsilon_m = \frac{\text{rate constant of initial reaction}}{(\text{rate constant of the reaction } (r_m + M)) \times M_0} \quad (3)$$

$$\varepsilon_n = \frac{\text{rate constant of initial reaction}}{\text{rate constant of the reaction of } r_n} \quad (4)$$

(M_0 = initial concentration of the educt M). In cases in which there are more than one initiation or consecutive reactions of the radicals, the sum of the rate constants of these reactions has to be used. As the number of the reactions involved in consumption of a certain radical is usually small, calculations of ε_i can be easily performed if the corresponding kinetic constants are known. The values ε_m and ε_n obtained have to be multiplied by a value η_0 which considers that part of the reactant M reacting *via* the initial reaction.

Finally, the magnitude of the product $\varepsilon_i \times \eta_0$ is the quantitative measure for the applicability of QSSA[28,29]. Comparisons of QSSA calculations with "exact" calculations show that QSSA is a good approximation if $\varepsilon_i \times \eta_0 \leq 10^{-2}$. Rough estimations can be carried out up to $\varepsilon_i \times \eta_0 = 10^{-1}$. Theoretical studies confirm the general existence of these critical values[30]. Another question is whether the $\varepsilon_i \times \eta_0$ values of all radicals participating in the reaction have to be calculated. For the model of hydrocarbon pyrolysis only the $\varepsilon_i \times \eta_0$-values of the "important" radicals have to be considered; "important" radicals are those formed in the reactions of the starting materials and those which react with the starting materials.

As an example, the comparison of QSSA data with the "exact" calculations of the ethylbenzene pyrolysis are shown in Figure 1. The conversion of the reactant and of three "important" radicals as a function of time at 950 K are shown[28]. The results show that the highest $\varepsilon_i \times \eta_0$-values are obtained for the CH_3 radical, and that the deviations are already considerable at $\varepsilon_i \times \eta_0 = 10^{-2}$. Furthermore, it is shown that disagreement is higher at low pressures.

4. Applications

4.1. Oxidation of Isobutane and Isopentane

The peroxide-initiated oxidation of isobutane and isopentane at relatively low temperatures was chosen as one of the first examples of the application of modern numerical methods of integration to complicated homogeneous gas phase reactions. The reaction models contained 20 and 32 elementary reactions, respectively[31]. The product distribution of both reactions showed good agreement with experimental data. Another result of the calculations was that the concentrations of some of the radicals remained nearly constant over a longer period of reaction time, confirming the existence of a steady state under these conditions.

4.2. Pyrolysis of Alkanes

A fundamental study of *Allara* and *Edelson* deals with the thermal decomposition of propane, *n*-butane, and *n*-pentane[5]. Very extensive reaction models were used which contain almost all the possible elementary reactions (293, 515, and 586, respectively), assuming that the products have a molecular weight not greater than twice that of the reactant. The authors adopted the philosophy "that it is far better to err on the side having too many reactions than too few". The calculations were compared with experimental data only for the pyrolysis of propane, and then only for the formation of methane. Nethertheless, interesting information was obtained by the calculations, *e.g.* on the contributions of particular reaction paths to the conversion, or on the concentration-time relation of selected radicals during the reaction, and on changes in the reaction behavior due to global variations of the reaction constants.

Froment et al.[32] studied a similar problem. A reaction scheme consisting of 133 elementary reactions was compiled, and it was assumed that this master set is applicable to the pyrolysis of saturated and unsaturated hydrocarbons generally. In order to set up a special reaction model, a suitable selection of elementary reactions (50 to 80) was taken from the master set by "trial and error" methods. The mathematical treatment of those reaction models was carried out using *Gear*'s program. Comparison of the calculated results with experimental data from a pilot reactor demonstrated that product distributions of the cracking reactions of ethane, propane, *n*-butane, and isobutane as well as of the corre-

[*] Quantitative information about the initial period can be obtained, however, by a suitable transformation of the time within the set of differential equations.

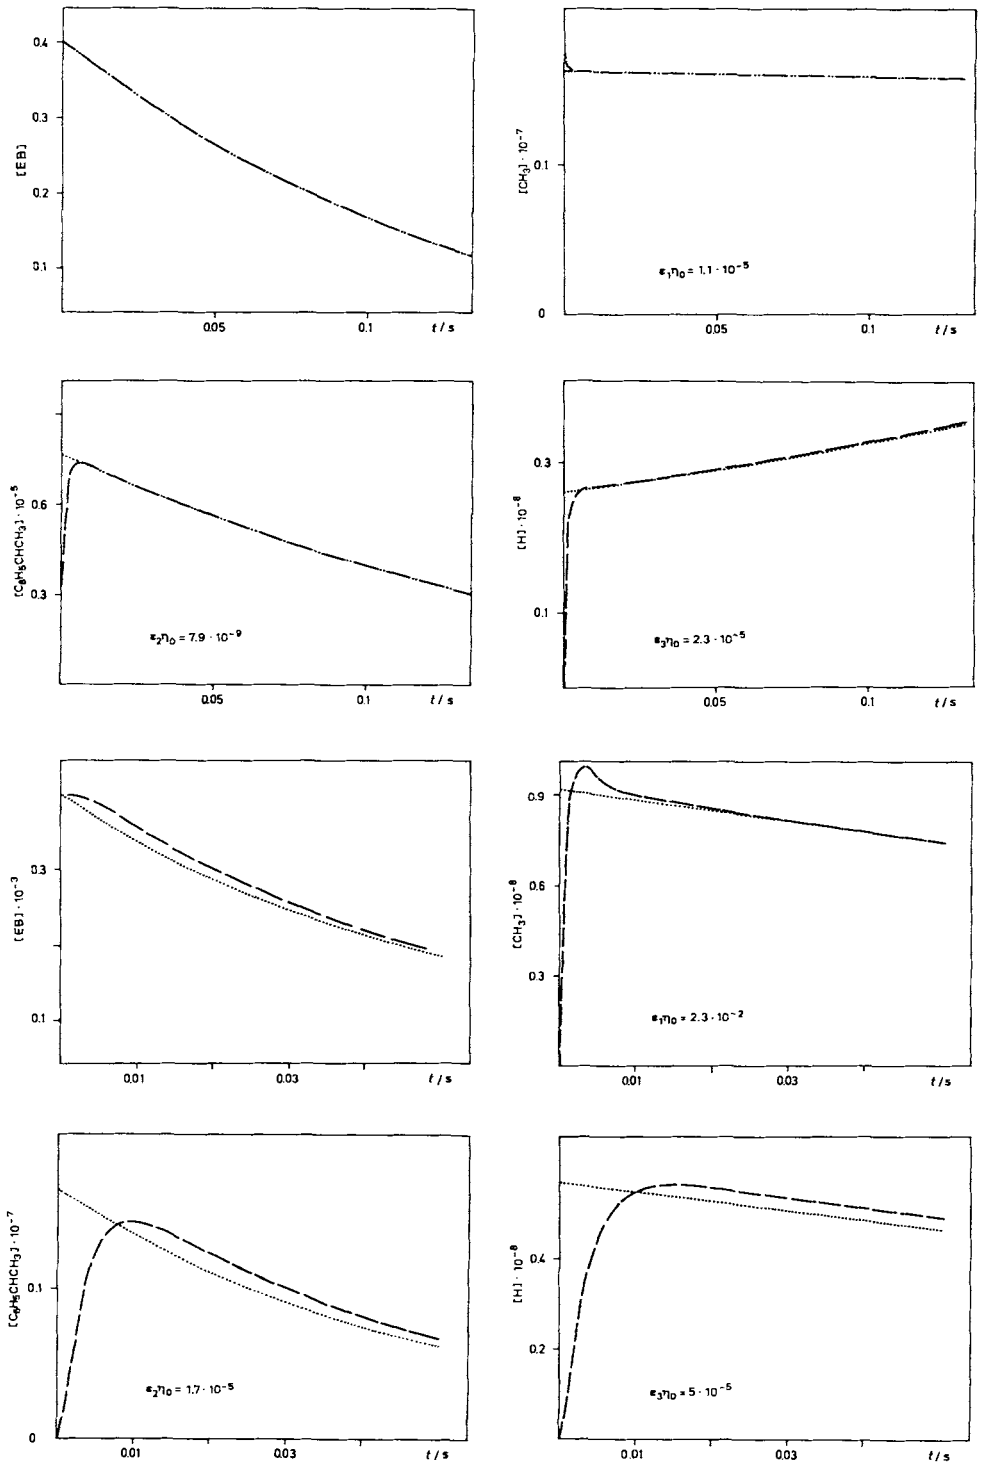

Fig. 1. Variation of concentration with time (time-conversion diagram) of ethylbenzene (EB), methyl, α-methylbenzyl, and hydrogen radicals at 950 K and 3×10^6 Nm^{-2} (30 bar) (left row) and at 3×10^3 Nm^{-2} (0.03 bar) (right row) according to QSSA (·····) and "exact" calculations (-----).

sponding olefins could be simulated satisfactorily. Distributions of the unstable products and the temperature profile along the flow reactor were further points of information obtained from the calculations. Simulation of the decomposition reactions of mixtures of the above mentioned hydrocarbons showed that the combination of reaction models by simple addition of the respective elementary reactions gave results in good agreement with experimental data. This is to be expected as long as the elementary reactions are independent and do not influence one another.

4.3. Pyrolysis of Ethylbenzene

The thermal decomposition of ethylbenzene was thoroughly investigated experimentally and computationally[33]. In order to establish the reaction model (Table 2) the stable and unstable species formed at low pressures (10^{-2} mbar) and 600—1400 K were determined by mass spectrometry[34]. Figure 2 shows the results, containing only those masses whose signal area contributed at least 1.5% to the total signal area. (Because of the different ionization propabilities of the

particular species this selection is somewhat arbitrary.) Up to 1100 K the following species were detected (the figures in parenthesis refer to the possible reaction(s) of formation in Table 2): methane (3), ethylene (8—11), benzene (4), benzyl (1), toluene (14), styrene (7), α-methylbenzyl (3—5), and bibenzyl (15), as well as undecomposed reactant.

reactions (6, 10, 11). Reactions involving a hydrogen atom attack on the aromatic ring are well known in the literature[14, 15, 35]. The experimental styrene-benzene ratio (Fig. 3) was used to adjust the competitive reactions (7) and (8), the ethylene-styrene ratio (Fig. 4) was used for the adjustment of the competitive reactions (5) and (6). With the model of Table 2 the experimental results were in good agreement up to 1150 K. At higher temperatures the formation of benzene and toluene was markedly higher than the calculated values. The model could only be adapted by adding a second initial reaction (2) and the consecutive reaction (9). With these the reaction model of the pyrolysis of ethylbenzene was increased to 15 elementary reactions.

(13)	CH3 + CH3	→	C2H6	(10.34/ 0.0)	(16)
(14)	H + C6H5CH2	→	C6H5CH3	(11.0 / 0.0)	a
(15)	C6H5CH2 + C6H5CH2	→	C6H5CH2CH2C6H5	(11.9 / 0.0)	a

Numerical integrations were performed with the most simple reaction models developed from these results (Table 2) using *Gear*'s program. The kinetic constants of the elementary reactions were taken from the literature. Values of constants not known in the literature were estimated from analogous reactions. The calculated results were compared with experimental data from a laboratory flow reactor using a gas chromatograph for analysis[33].

The mass balance showed that part of the ethylene is formed from cleavage reactions of the aromatic ring already at relatively low temperatures. This was accounted for by

Figure 5 shows that the model simulates the reaction very well at relatively short reaction times and within a wide temperature range. As Figure 6 shows, the agreement of the time-conversion plots is not as good. The simulations of the

benzene and ethylene formation agree reasonably well, but the calculated conversion values of ethylbenzene and styrene disagree strongly with the experiments. A possible reason is the existence of reactions of styrene, decompositions, as well

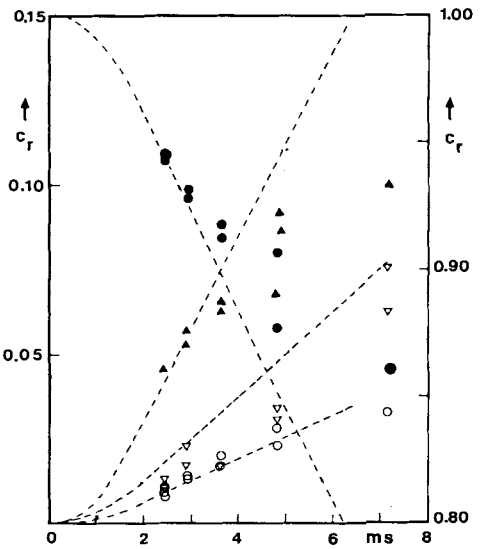

Fig. 6. Comparison of relative molar concentrations as function of time at 950 K (see Fig. 5).

as reactions with radicals. Because these reactions are very similar to those of ethylbenzene, the calculations for benzene and ethylene are not so strongly affected.

4.4. Pyrolysis of *n*-Hexane

In the last few years the pyrolysis of *n*-hexane has been investigated more intensively[36 40]. Hexane is a kind of key substance. The molecule is large enough to be considered as a model for higher paraffins, but the product distribution is not too complicated. In order to describe the reaction at relatively low temperatures and conversions a reaction model consisting of 38 elementary reactions[28] is satisfactory (Table 3). Calculations showed that the reaction rate determined in a static apparatus by the overall pressure rise can be simulated well enough (Fig. 7). Table 4 shows that experimental and calculated product distributions also agree well. At higher conversions, however, product reactions have to be considered, the reaction model then extends to about 100 elementary reactions.

The decomposition and isomerization reactions of the C_6H_{13} radicals (23—28) are of particular importance[42 48]. Calculations showed that the ratio *n*-hexyl/1-methylpentyl has a decisive influence on the ratio of the products ethylene/propene, and that in the temperature range studied the rate of the isomerization of *n*-hexyl → 1-methylpentyl is considerably higher than the rate of decomposition of the radicals. Therefore the equilibrium, which is shifted in the direction of 1-methylpentyl is established rapidly, and the most important decomposition reaction is (24). Application of the β-rule to the decomposition reactions of the C_6H_{13} radicals indicates a ratio of reactions (23—26) of about 1:14:1.5:9. This also confirms the importance of (24).

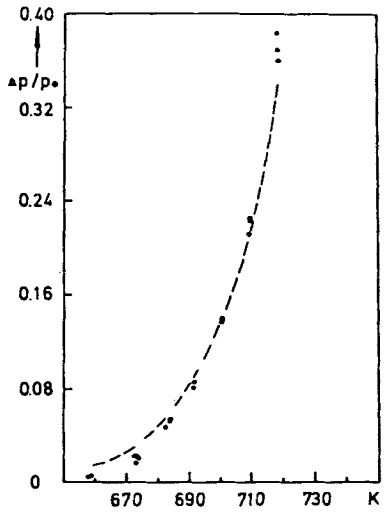

Fig. 7. Pressure rise in the pyrolysis of *n*-hexane (• experimental values; ---- calculated curve).

4.5. Oxidation of Carbon Monoxide

Pilling and *Noyes* have done some work on the oxidation of carbon monoxide by oxygen in the presence of water[49,50]. This reaction is explosive in a particular pT range. The reaction model used consists of 24 elementary reactions, selected mainly from chemical considerations. Most of the kinetic constants were taken from the literature (Table 5). For regions showing a nonexplosive behavior, computations were carried out for a flow reactor assuming a steady state and taking into account heat flow across the reactor wall. The concentrations of the radicals, the reaction rates of the elementary reactions, and the rate of heat formation inside the reactor were calculated. The heat flow was determined as a function of temperature, pressure, and the geometry of the reactor. The explosion limit was defined as the temperature at which the heat formed in the reaction cannot be completely removed.

The calculations indicate that the "critical" temperature is highly dependent on traces of water. An increase in water content from 1 to 10 to 100 ppm lowers the critical temperature from 1100 to 1000 to 900 K. Further the calculations showed that the influence of water occurs essentially *via* the reaction chains (4), (5) and (4), (12), (18) (Table 5).

4.6. Reactions in the Atmosphere

A number of publications deal with photochemically initiated reactions in the atmosphere[29,58]. Topics of interest are

C5H10	2.24	0.46

by "mathematical modeling" is an important tool in chemical kinetics. In mathematics this is called the "inverse problem". A non-linear least-squares fit in dependence of the reaction parameters is performed using possibly weighted experimental data and values calculated from the model (W_i = weighting factors):

$$\sum_{i}^{n} (x_{i,\text{exp.}} - x_{i,\text{calc.}})^2 \times W_i = F(\doteq \min) \tag{5}$$

Function F should be minimized.

Table 5. Reaction model of CO oxidation (computer diagram). a: Kinetic parameters evaluated by analogy.

Reaction No.	Elementary reaction			$\log_{10}A/E_a$	Ref.
(1)	CO + O2	→	CO2 + O	(8.35 /251.2)	(51)
(2)	CO + O + M	→	CO2 + M	(8.00 / 0.0)	(52)
(3)	H2O + O	→	2OH	(10.76 / 75.4)	(53)
(4)	CO + OH	→	CO2 + H	(8.49 / 2.5)	(55)
(5)	O2 + H	→	OH + O	(11.35 / 70.3)	(54)
(6)	OH + O	→	O2 + H	(10.40 / 0.0)	(55)
(7)	H2O + H	→	H2 + OH	(10.92 / 84.2)	(53)
(8)	H2 + O	→	OH + H	(10.24 / 39.6)	(53)
(9)	H2 + OH	→	H2O + H	(10.36 / 21.8)	(55)
(10)	OH + OH	→	H2O + O	(9.76 / 3.8)	(53)
(11)	OH + H + M	→	H2O + M	(11.00 / 0.0)	(56)
(12)	O2 + H + M	→	HO2 + M	(9.51 / -4.2)	(54)
(13)	HO2 + OH	→	H2O + O2	(10.70 / 4.2)	(57)
(14)	HO2 + H	→	H2O + O	(10.70 / 4.2)	(57)
(15)	HO2 + H	→	H2 + O2	(10.40 / 2.9)	(57)
(16)	HO2 + H	→	2OH	(11.40 / 8.0)	(57)
(17)	HO2 + O	→	O2 + OH	(10.70 / 4.2)	(57)
(18)	CO + HO2	→	CO2 + OH	(8.00 / 41.9)	(57)
(19)	HO2 + HO2	→	H2O2 + O2	(10.00 / 4.2)	(57)
(20)	H2O2 + OH	→	H2O + HO2	(10.00 / 7.5)	(54)
(21)	H2O2 + H	→	H2 + HO2	(10.37 / 38.5)	(54)
(22)	H2O2 + H	→	H2O + OH	(11.50 / 37.7)	(54)
(23)	H2O2 + O	→	HO2 + OH	(10.70 / 5.0)	a
(24)	H2O2 + M	→	2OH + M	(14.07 /190.5)	(54)

the influence of particular substances emitted from the earth's surface on the ozone layer in the upper atmosphere, and the formation of smog. One of the most interesting examples was the formation of the Los Angeles smog, which was studied using a model of 92 elementary reactions[29]. In this work, the main problem is the formulation of suitable reaction models. The calculated time dependence of the reaction systems agreed relatively well with the experimental data obtained in a smog chamber. The computations are rather complex because of fluctuations in the radiation density and because of the need to include diffusion processes and convective transport phenomena in the calculations, which are difficult to describe exactly.

Though experimental results can be only partly explained by model computations, important information has been attained on the participation of particular substances in smog formation, and there is no doubt that these methods will help to increase our understanding of chemical reactions in the atmosphere and their further consequences.

5. The "Inverse Problem"

5.1. Evaluation of Kinetic Constants

Besides the "simulation" of chemical reactions, the evaluation of kinetic constants of particular elementary reactions

The usual mathematical methods for the solution of such optimization problems can be divided into two groups:

1) Direct search methods: For each experimental value a corresponding value has to be calculated according to a model. The set of optimal parameters is obtained by a systematic search of certain parameter sets, frequently expressed as lattice points in higher dimensions.

2) Descent methods: These methods require in addition to the function F also the partial derivatives of F with respect to the parameters. These derivatives are used to find the steepest descent to the minimum of F.

Bremermann and *Milstein* tested a number of different methods from each group[59]. A direct search method with random vectors proved to be most effective and robust. The direction indicating the variation of the parameter vector is chosen by a random number generator. The "best" parameter set in this direction is determined by a special iteration method. This new parameter set is the starting point for the next random vector, and the calculation is continued until the new random vectors do not result in further improvements of the parameter sets. This method was applied to experimental data from the Calvin photosynthesis cycle[61]. The reaction model consisted of 22 reactions with 18 species. Optimal reaction constants were calculated for all reactions. The model calculation agreed very well with the experimental time behavior of the 18 species within the course of the reaction.

Another method, which is often more effective although more cumbersome, is the frequently used "trial-and-error" approach. The "improvement step", *i.e.* the selection of the new parameter set, is executed "manually" taking into account all the previous results.

In the numerical optimization procedure it is the "stiff solver" subroutine which demands the greatest proportion of computer time. Therefore, the greatest potential for improving the method lies in this area. The steady-state assumption decreases the computational effort considerably. Various parameters or relations between parameters can then often be evaluated and described by simple linear regression. Thus it is hardly surprising that nearly all parameter fittings in complex reaction systems assume QSSA conditions.

It may happen that in such a parameter optimization procedure the minimum of the function F can be determined, but no satisfactory consistency between the experimental and the calculated values is obtained. This is a clear indication that the chemistry of the reaction model is incorrect.

5.2. Sensitivities of Kinetic Parameters

If for a reaction mechanism one of the optimization methods yields a set of parameter values which fits the experimental results well, an often heard objection is that almost any conceivable set of data can be simulated by so many parameters (even the shape of an elephant!), and that all these sets of parameters will describe the measurements more or less correctly. This objection is fundamentally wrong, as can be clearly demonstrated by an error analysis of the individual parameters. This is best done by evaluating a sensitivity matrix, which contains the variations of the concentrations of the different chemical species in dependence of the variations of the parameters of the individual elementary reactions. Such sensitivity matrices also depend on temperature, initial conditions, and reaction time. Table 6 shows the sensitivity matrix of the model for hexane pyrolysis (Table 3) at 718 K and initial concentrations of 0.0023 mol/l within the steady-state region.

The columns contain the stable compounds, and the rows contain the elementary reactions. The elements of the matrix represents the percentage change in concentration of a particular species if the reaction constant of the corresponding elementary reaction is increased by a factor of 2. (In fact, however, the coefficients were calculated with the assumption of a differential variation of the system.) Negative values indicate that the concentrations decrease. The matrix of Table 6 was calculated assuming a steady state, which remarkably reduced the computational effort. A comparison shows that in this case the agreement of the QSSA values with the "exact" values is better than 0.1% under the conditions chosen.

The matrix demonstrates that there are only a few reaction constants which significantly influence the concentrations of most of the products. Most rate constants are "insensitive" and their absolute values have little influence on the product

Table 6. Sensitivity matrix of the reaction model of the pyrolysis of *n*-hexane (see Table 3) (computer diagram).

distribution. From different sensitivity matrices evaluated on the basis of different experimental parameters a new matrix can be calculated containing the variances (standard deviations) and covariances of the reaction parameters[60]. These variances depend again on the experimental conditions (number of measurements, initial conditions, temperature, *etc.*) and on the accuracy of the experimental data. Thus, if a given kinetic parameter is to be evaluated with greater accuracy from experimental data, the experimental conditions must be such that the variance becomes as small as possible. This can also be done by selecting special initial conditions, *e.g.* by the addition of reactants which increase the sensitivity of the elementary reaction in question. Another possibility is the selection of another reaction system in which this particular elementary reaction has *a priori* a high sensitivity.

6. Outlook

Work on the kinetics of complicated chemical reactions with the aim of solving all the details of a given mechanism and its dynamics were considered to be more or less hopeless until recently, because no methods were available for evaluating more general quantitative conclusions from the experimental materials. Today the very opposite seems to apply.

Computational methods for kinetic treatment of even complicated chemical systems have been developed to a high standard, and they will surely be further improved. As computer capacity becomes much more readily available in the future, these methods will become more generally applicable. The quality of the reaction model will then be the limiting factor. The quality of models, however, largely depends on the accuracy with which the kinetic constants of the particular elementary reactions are known. Therefore methods of experimental determination and evaluation of kinetic constants will become more important.

The application of such methods will initially be focused upon more special problems such as the effect of additional substances on reaction rates and product distributions. Within this kind of work the "inverse problem" and sensitivity analysis play an important part in obtaining quantitative information. The scope of these methods will be enhanced if they can be extended to the computation of heterogeneous reactions too. For this type of reaction, absorption, desorption, and diffusion processes have to be included in the reaction scheme. This does not mean that the reaction models become more complicated. On the contrary, in catalytic processes the number of "important" elementary reactions is comparatively small.

Although the methods outlined above may be viewed with skepsis, perhaps due to the complicated mathematics involved, they nevertheless supply detailed information about the mechanism and time dependence of complicated reactions and permit a fast and reliable simulation of the influences of different parameters on chemical reactions. This is a significant progress in chemical kinetics.

Cyclodextrin Inclusion Compounds in Research and Industry

By Wolfram Saenger[*]

α-, β-, and γ-Cyclodextrins are cyclic oligosaccharides consisting of six, seven, or eight glucose units, which can be obtained on a large scale from starch. They form inclusion compounds with smaller molecules which fit into their 5—8 Å cavity. These (crystalline) complexes are of interest for scientific research as, contrary to the classical clathrates, they exist in aqueous solution and can be used to study the hydrophobic interactions which are so important in biological systems. Cyclodextrins also serve as models both for polymeric starch and, in the form of their polyiodide complexes, for "blue iodine-starch". As cyclodextrins catalyze several chemical reactions they and their functionalized derivatives provide useful enzyme models. Cyclodextrins can be used to advantage in the production of pharmaceuticals, pesticides, foodstuffs, and toilet articles—the (micro-encapsulated) active and aromatic substances enclosed within them are protected from the effects of light and atmosphere and can be easily handled and stored in powder form. Substances which are not very soluble in water become more soluble in the presence of cyclodextrins—creams and emulsions can be stabilized, and the growth and yield of grain harvests can be increased. Cyclodextrins can be chemically modified for many different purposes; polymerized cyclodextrin or cyclodextrin bound to a polymer carrier have already been employed in gel inclusion and affinity chromatography.

1. Introduction

The increasing number of publications and patents dealing with inclusion compounds shows that general interest in their physical and chemical properties has grown considerably over the past twenty years. This is due, on the one hand, to the fact that the study of inclusion compounds in fundamental research furnishes information about non-covalent, intermolecular forces and that they also serve as models for studying topochemical problems and the mode of action of enzymes. On the other hand, inclusion compounds are also utilized in laboratories, industry, and the home as ion exchangers, as catalysts in chemical reactions, or for the microencapsulation of sensitive, active, and aromatic substances.

The most important property of inclusion compounds is that a "host" component can admit "guest" components into its cavity without any covalent bonds being formed. Montmorillonites, kaolinites, zeolites, tobernite, transition metal chalcogenides, graphite, and clathrates formed with water[1-6] are all known inorganic host components; urea, deoxycholic acid, tri-*o*-thymotide, *Dianin*'s compound, hydroquinone, crown ethers, and cyclodextrins are organic host components[1,7-18]; biological macromolecules such as ionophoric antibiotics, starch, and enzymes[1,8,19-21] can also take up guest (substrate) components. This article will only deal with the inclusion compounds of cyclodextrins as these substances best demonstrate the possibilities that this class of compounds offers to the research or industrial chemist.

Cyclodextrins were first isolated in 1891 by *Villiers* as degradation products of starch[22] and they were characterized as cyclic oligosaccharides in 1904 by *Schardinger*[23,24]. It is for this reason that cyclodextrins (cycloamyloses) are described by some authors, especially in the older literature, as Schardinger dextrins. In 1938 *Freudenberg et al.* reported that cyclodextrins are constructed from α(1→4)-linked glucose units[25]; the molecular weights of the most common α-, β-, and γ-cyclodextrins were, however, determined much later[26-28] (Figs. 1 and 2, Table 1). *Freudenberg et al.* recognized that cyclodextrins could form inclusion compounds[28] and, like *French et al.*[25,29], worked out procedures for synthesizing pure cyclodextrins. The formation of the cyclodextrin guest complexes was studied systematically by *Cramer et al.*[8,13,30]; *Cramer* also discovered that cyclodextrins have a catalytic action in some reactions[31] and described racemate resolution with cyclodextrins[32]. These experiments laid the foundations for the chemistry discussed in this review.

The present article can only concentrate on some features of general interest as the number of publications dealing with cyclodextrin inclusion compounds alone amounts to more than 600. In the last 25 years several review articles and books on this subject[1,8-17,33-36] have appeared; one book[37],

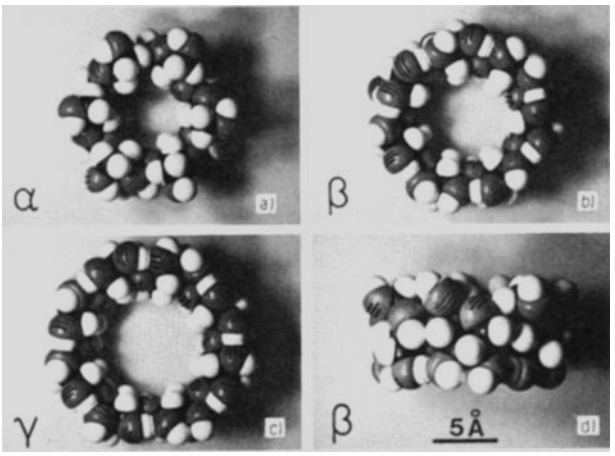

Fig. 1. a) α-Cyclodextrin from the O(6) side, b) and c) β- and γ-cyclodextrins respectively as seen from the O(2), O(3) side with a closed ring of O(3)...O(2) hydrogen bonds between adjacent glucose units; d) side view of β-cyclodextrin (CPK model). All of the cyclodextrins have a ring height of approximately 8 Å (cf. Fig. 2).

and can therefore be utilized for synthesizing interesting new oligo- and polysaccharides[45,46] (G = glucose unit).

As the enzymes never detach entirely specific lengths, the resulting cyclodextrins contain 6—12 glucose units per ring[47]. A five-membered cyclodextrin is unlikely due to ring strain[48] and has not been observed. The main fractions contain α-, β-, and γ-cyclodextrins (with 6, 7, or 8 glucose units respectively); the relative quantities of these three groups depend on the type of enzyme employed and can be influenced by the addition of organic compounds[10,34].

The glycosyl transferase from Bacillus No. 38-2 has proved to be a highly suitable enzyme for the industrial production of β-cyclodextrin. It is still active at 80 °C and at pH 6—10, *i.e.* under conditions which prevent damage by other microorganisms[34]. 80% of the starch is converted to β-cyclodextrin with only small amounts of the other cyclodextrins being produced in the medium[40]. This method has the advantage that there is no need to add an organic compound (which is often toxic) in order to obtain good yields of β-cyclodextrin.

Table 1. Some physical properties of the cyclodextrins. Height of the cyclodextrin ring: 7.9—8 Å (measured with the aid of CPK models).

Cyclodextrin	No. of glucose units	Mol. wt.	Water solubility [a]	$[\alpha]_D^{25}$ (after [29])	Cavity diameter [Å] [b]	External
α	6	972	14.5	150.5 ± 0.5	4.7—5.2	14.6 ± 0.4
β	7	1135	1.85	162.5 ± 0.5	6.0—6.4	15.4 ± 0.4
γ	8	1297	23.2	177.4 ± 0.5	7.5—8.3	17.5 ± 0.4

T	Solubility [c] in					
	water	ethanol	*n*-propanol	glycerol	dimethyl formamide	dimethyl sulfoxide

45 °C	3.1	0.1	0.1	0.8		

[a] g/100 ml solution at room temperature (according to [29]). [b] As measured on CPK models (see Fig. 1); the smaller value is for the ring of H atoms bonded to C(5) and the larger value for the ring of H atoms bonded to C(3). [c] g β-cyclodextrin/100 ml solution (according to [36]).

which only describes the chemistry of the cyclodextrins and their use as enzyme models, contains over 300 references.

2. Synthesis of Cyclodextrins

Cyclodextrins can be obtained by enzymatic degradation of starch[23-25,29], a linear polysaccharide consisting of α(1→4)-linked glucose units arranged into a left-threaded screw with six glucose units per turn (V-amylose[38,39,20]). Cyclodextrin glycosyl transferases, a type of amylase, can detach a turn from the starch helix and link the two ends of this fragment to give a cyclic molecule. There are certainly many organisms which contain glycosyl transferases[40], but only those enzymes from *Bacillus macerans*[10,24], *Bacillus megaterium*[41], an alkaline bacillus[42], *Krebsiella pneumoniae M 5 al*[43], and *Bacillus stereothermophilus*[44] have been examined in more detail. All of these glycosyl transferases act according to the scheme

$$G_n \underset{\text{Coupling}}{\overset{\text{Cyclization}}{\rightleftharpoons}} G_{(n-x)} + \text{Cyclodextrin } (= \textit{cyclo}\text{-}G_x)$$

3. Biochemical Properties and Toxicity

The utilization of the sweet tasting cyclodextrins in the pharmaceutical and food industries depends to a large extent on the effects they have on living organisms. The toxicity of β-cyclodextrin (*Thomas* and *French*; cited in [10]) determined with rats is probably accounted for by the fact that the β-cyclodextrin used was not quite pure. In 1963 it was discovered that in rats ^{14}C-labeled α- and β-cyclodextrins, similarly to ^{14}C-starch, are incorporated into tissues and organs[49]. It is remarkable that on feeding ^{14}C-starch the ^{14}C-level of the $^{14}CO_2$ expired reached a maximum after about 1 h whereas, in the case of ^{14}C-β-cyclodextrin, the maximum appeared after approximately 9 h; the total quantity of expired $^{14}CO_2$ when related to the carbohydrate consumed was about equal in both experiments (Fig. 3). The cyclodextrins are not metabolized as rapidly as starch; this is because they are cleaved more slowly by α-1,4-glucanohydrase than linear dextrins[10] and are not hydrolyzed by enzymes which attack terminal groups. The metabolism of degraded cyclodextrins and starch is, however, comparable.

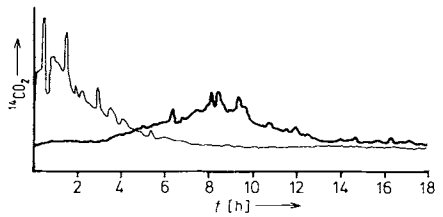

Fig. 3. $^{14}CO_2$ expired by rats after being fed with ^{14}C-labeled starch (—) and ^{14}C-labeled β-cyclodextrin (—) (according to [49]).

Tests for determining the acute toxicity of β-cyclodextrin on mice and rats gave such high LD_{50} values (Table 2[50]) that these compounds can scarcely be considered as having a toxic action. Long term tests carried out over a period of 6—9 months on rats, rabbits, and beagles led to similar conclusions[51 53]. No anatomical or histopathological changes

Table 2. Acute toxicity of β-cyclodextrin (according to [50]).

	LD_{50} [g/kg]	
	Mouse (♂ and ♀)	Rat (♂ and ♀)
Oral	>12.5	>12
Subcutaneous	> 0.9	> 1.5
Intraperitoneal	> 0.9	> 1.2

could be detected after feeding 0.2, 0.4, and 0.6 g β-cyclodextrin/kg body weight for 6 months to rats and dogs; neither embryotoxic nor teratogenic effects nor mutations were observed in rats[53]. Other studies on rats showed that renal necrosis occurred after daily subcutaneous, intraperitoneal, or intravenous injection of 0.45 g β-cyclodextrin/kg body weight. No ill effects could be demonstrated after giving doses of 0.1 g/kg 1, 2, 4, or 7 times daily, whereas daily doses of 0.9 g/kg resulted in death within 4 d[54].

All toxicity tests have shown that orally administered cyclodextrin is harmless. According to reports of the FAO, enzymatically modified starch—this includes cyclodextrins—is also toxicologically harmless[55].

The biochemical properties of cyclodextrins can be defined in more detail if they are allowed to act as substrates for purified enzymes. Cyclodextrins are metabolized by glucanotransferase from *Klebsiella pneumoniae*[56], cyclodextrinases in Taka diastase[57], and by amylases from *Aspergillus niger* and *oryzae* and *Bacillus polymyxa*[34]. They are largely resistant to the action of amylases from *Bacillus subtilis* and human saliva[34] and in general to the action of amylases which degrade linear polysaccharides from their terminus. Cyclodextrins also act as competitive inhibitors for phosphorylase[34,58] and β-amylase[34,59] from potatoes, for pancreatic amylase (which can simultaneously bind three β-cyclodextrin molecules in its active center[60-62]), and for pullulanase from *Aerobacter aerogenes*[63].

4. Synthesis of Cyclodextrin Inclusion Compounds

The most remarkable property of the cyclodextrins is their ability to form inclusion compounds with a variety of molecules which apparently only have to satisfy one condition—they must fit entirely or at least partially into the cyclodextrin cavity. The method used for the synthesis of the cyclodextrin·guest complexes depends on the properties of the guest components[8,30,34].

1) Equimolar quantities or a ten-fold excess of water-soluble substances are dissolved directly in concentrated hot or cold aqueous solutions of the cyclodextrins. The inclusion compounds crystallize out immediately or on slow cooling or evaporation.

2) Substances which are not water-soluble are dissolved in ether, chloroform, benzene, *etc.* and are then shaken with or layered over or underneath a concentrated aqueous cyclodextrin solution. In the case of layering, crystals are formed at the interface or as a precipitate. The inclusion compounds must be washed with an organic solvent to remove any adhering substances.

3) The first two procedures are suitable for the laboratory preparation of cyclodextrin inclusion compounds. For their industrial synthesis, the kneading procedure is more suited. Here the liquid or dissolved guest components are added to a slurry of the cyclodextrin and 2 to 5 times as much water. On stirring in a mixer, the viscosity of the mixture usually increases, giving a paste which can then be dried, powdered, and washed. If the inclusion compounds are readily soluble in water or decompose on drying, it is advisable to lyophilize them. They then retain their finely dispersed form which is of advantage, especially in the pharmaceutical industry, as it has a high solubility.

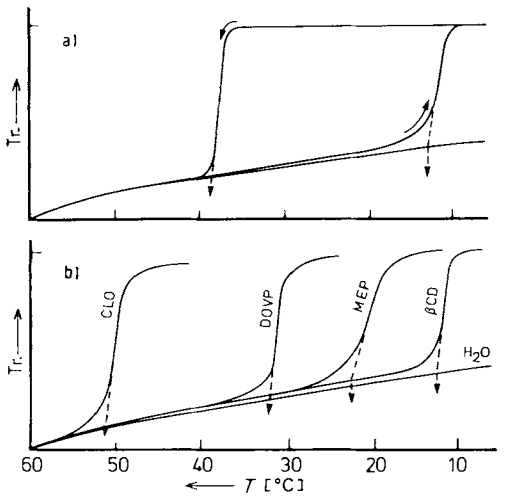

Fig. 4. Turbidity curves a) for 3 per cent. aqueous β-cyclodextrin solutions and b) for these solutions with additives. β: β-cyclodextrin alone; MEP: +0.45% 3-methyl-1-pentyn-3-ol; DDVP: +0.582% *O*-(2,2-dichlorovinyl)-*O*,*O*-dimethylphosphate + 25% ethanol; CLO: +0.57% clofibrinic acid (according to [64]). The turbidity (Tr.) is plotted against temperature. H_2O indicates the zero line (pure water); the hysteresis in a) shows that supersaturation (supercooling) occurs on crystallization of β-cyclodextrin.

The crystallization of β-cyclodextrin and β-cyclodextrin inclusion compounds from aqueous solutions has been studied by monitoring the turbidity which appears on cooling[64,65] (Fig. 4). Solutions of up to 2% β-cyclodextrin show a single phase in the temperature range examined (2—60 °C), whilst at a concentration of 3% crystals separate out at temperatures of below 13 °C. This process is reversible, but there is considerable hysteresis (Fig. 4a). Similar experiments with β-cyclodextrin and guest molecules demonstrate that, in general, the onset of turbidity depends strongly on the concentration of the guest molecule (cf. Fig. 4b).

5. Characterization of Inclusion Compounds

5.1. Inclusion Compounds in the Solid State

During the synthesis of cyclodextrin inclusion compounds the guest components could be enclosed within the cavity, thus forming a true complex, or merely aggregate to the outside of the cyclodextrin molecule.

The first systematic study of 54 guest components within α-, β-, and γ-cyclodextrins[30] showed that the law of constant proportions applies to the inclusion. Complexes with a constant guest/cyclodextrin ratio always crystallized out regardless of the molar ratio guest/cyclodextrin in aqueous solution (or in a mixture with ether). The ratio was 1:1 in only a few cases and sometimes varied within the series α-, β-, γ-cyclodextrin. The ratios were, however, always constant and indicated a real inclusion phenomenon.

Inclusion complexes can be detected quickly and directly by physical methods. In the case of crystalline substances, X-ray powder diagrams can be made. If the diffraction pattern does not correspond to those of the pure components, a true inclusion complex may exist (Fig. 5)[66-68].

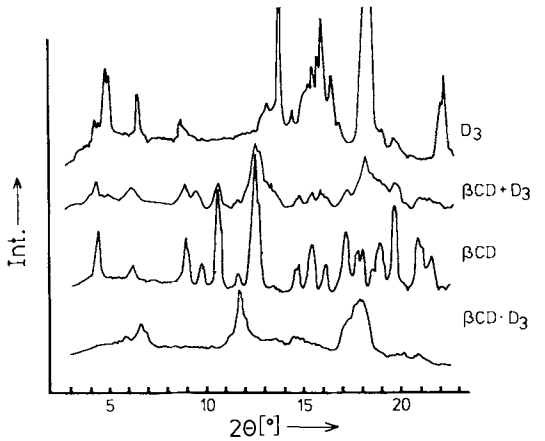

Fig. 5. X-Ray diffraction diagram of crystalline β-cyclodextrin (βCD), vitamin D_3 (cholecalciferol, D_3), a mixture (βCD + D_3), and the complex (βCD·D_3). The intensity maxima of βCD + D_3 correspond with those of βCD and D_3, whereas the maxima of the complex βCD·D_3 are different and indicate a true inclusion complex as opposed to a mixture (according to [257]).

TAS (Thermomikro-Abtrenn-Transfer- und Auftragsverfahren von Substanzen, thermomicro-separation-transfer and application of substances) provides another method for detecting inclusion complexes[65,69]. Several mg of the complex are put into a sample tube together with wet silica gel or starch which are able to release water vapor; the open end of the tube is drawn out into a capillary. The tube is slowly heated, a thin layer chromatography plate is held in front of the capillary opening and as the temperature increases the plate is moved. The escaping water vapor carries volatile substances which are adsorbed onto the TLC plate. In the case of inclusion compounds, the guest components are driven off at considerably higher temperatures. The behavior of marjoram oil is typical. In its pure form or in admixture with β-cyclodextrin it escapes at 100 °C but when complexed with β-cyclodextrin it can first be detected chromatographically at temperatures above 160 °C.

Thin layer chromatography can be similarly employed if a solvent can be found in which the complex is sufficiently stable[65]. The free guest component or a guest/cyclodextrin mixture exhibits a higher R_f value than the inclusion complex. As an equilibrium always exists between the associated and dissociated components, the guest component can migrate somewhat but is on the whole retarded.

In the case of sublimable guest molecules, vacuum sublimation can be utilized to monitor complex formation[65]. Salicylic acid vaporizes at 150 °C/5 torr, whereas its complex with β-cyclodextrin does not sublime.

IR spectroscopic techniques are not generally suitable for detecting the inclusion of compounds. On the one hand, the cyclodextrin bands change only slightly on complex formation; on the other hand, the fraction of the guest molecule contained in the complex is less than 25% and bands which could be assigned to the guest molecule are easily masked by the bands due to cyclodextrin and the ever-present water of crystallization.

Single crystal X-ray structure analysis is the best method for detecting complex formation. The precise geometrical relationships between the guest and host molecules can be established and interactions can be identified. This technique is, however, too complicated for routine use. Several results of X-ray structure analysis will be considered in more detail in Section 6.1.2.

5.2. Inclusion Compounds in Solution

Whereas clathrates generally only form inclusion compounds in the solid state (this is due to the special crystal lattice of the host component), cyclodextrin complexes exist in aqueous solution. They can therefore be elegantly studied by spectroscopic or calorimetric methods.

If a guest component absorbs light in the visible or UV range[70-77], if it fluoresces[78-81] or is a free radical[82-85], then formation of an inclusion complex can be followed by titrating with cyclodextrin (Fig. 6). Changes in the circular dichroism (CD) of the guest component on addition of cyclodextrin can be similarly exploited. It is interesting that even achiral molecules which do not exhibit any CD bands become CD-active due to the chirality of the cyclodextrin[74,77,86,97]. Recently, NMR methods have contributed

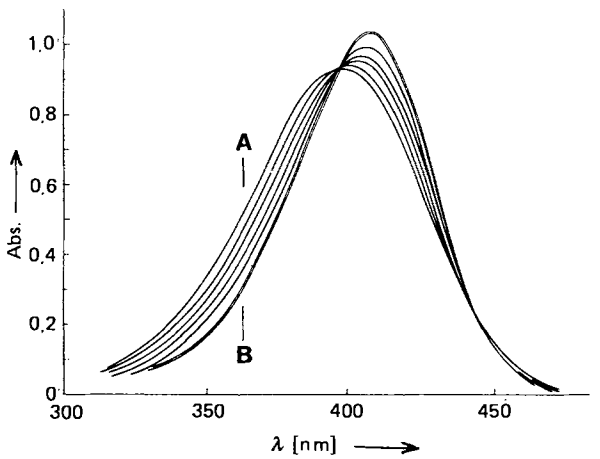

Fig. 6. Spectrum of the *p*-nitrophenolate anion (5×10^{-5} mol/l, pH = 11, 20 °C) on addition of increasing concentrations of α-cyclodextrin; from A to B: 0, 10^{-4}, 2.5×10^{-4}, 5×10^{-4}, 10^{-3}, 5×10^{-3}, 10^{-2} mol/l (according to [73]).

greatly to the understanding of guest/cyclodextrin interactions. As a result of the development of the high resolution spectrometers the original qualitative data[97,98] were so improved that it became possible to make quantitative statements about the thermodynamic and kinetic parameters of complex formation[99 102,74,76]. Atomic interactions between the guest and host can be identified and geometrical relationships can thus be established. Whereas X-ray structure analysis reflects the atomic details of the static complex in the solid state, NMR spectroscopy allows its dynamic properties in solution to be studied[100-102] (Fig. 7).

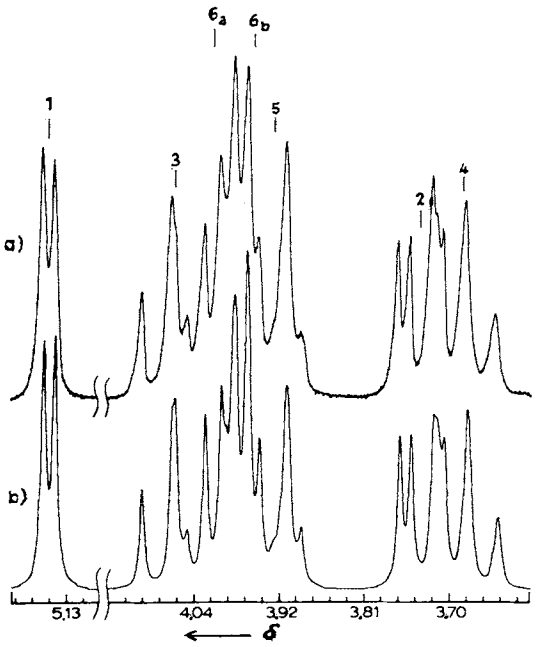

Fig. 7. a) 220 MHz-^{1}H-NMR spectrum of 0.1 M α-cyclodextrin in D_2O (68 °C, pD = 7.5) and b) computer-simulated spectrum (according to [101]). The numbers denote the H atoms (see Fig. 2).

Inclusion of a guest molecule can also be followed by monitoring changes in its conductivity[67-94,103,106-108] and polarographic properties[109,110], apparent changes in its basicity[76,77], increases or decreases in its solubility in the presence of cyclodextrin[111,112], or by measurement of supersonic relaxation[113]. Microcalorimetry is an important method for directly measuring the thermodynamic properties of complex formation[114-116].

6. Cyclodextrins as Model Compounds

6.1. The Inclusion Process and the Structure of the Cyclodextrin Complex

Complex formation between cyclodextrins and their guest molecules is the subject of a comprehensive literature[8,10-14,73-116]. A great deal of interest has been shown in this phenomenon due to the fact that two components associate with each other without any specific interactions taking place and because parallels can be drawn with many biochemical processes.

6.1.1. Thermodynamics and Kinetics of the Inclusion Process

Complex (CS) formation between the cyclodextrin (C) and guest (substrate, S) components according to

$$C + S \rightleftarrows C \cdot S \qquad K_D = [C] \cdot [S]/[C \cdot S] \quad [mol/l]$$

can be quantitatively described by the dissociation constant K_D. Depending on the nature of the substrate, K_D can be determined by the methods mentioned previously[73-116] or by employing competition of a substrate in cyclodextrin-catalyzed ester hydrolysis[117-121]. The most common studies are those which exploit light absorption (Fig. 6); K_D is obtained by plotting the absorption change of the substrate (at a constant wavelength) against the cyclodextrin concentration according to *Benesi* and *Hildebrand*[122]. Isosbestic points signify a 1:1 equilibrium. In the case of a 2:1 inclusion according to the scheme

$$2C + S \underset{}{\overset{K_{D1}}{\rightleftharpoons}} C \cdot S + C \overset{K_{D2}}{\rightleftharpoons} C_2 \cdot S$$

(as has been established for methyl orange in aqueous solution[73], and later in the crystalline state[123]), one isosbestic point for K_{D1} is found at low cyclodextrin concentrations.

On further addition of cyclodextrin a new isosbestic point for K_{D2} appears because the elongated methyl orange molecule is able to accommodate two cyclodextrin rings.

If two different substrate molecules S^1 and S^2 are simultaneously offered to the cyclodextrin, they can compete for the cyclodextrin molecule:

$$\begin{array}{ccc} & C + S^1 + S^2 & \\ {\scriptstyle K_{D1}}\swarrow & & \searrow{\scriptstyle K_{D3}} \\ C \cdot S^1 + S^2 & \overset{K_{D2}}{\rightleftharpoons} & C \cdot S^2 + S^1 \end{array}$$

This scheme can be utilized to obtain K_D for equilibria which cannot be measured directly[73,124]. The cyclodextrins behave like enzymes which can competitively bind substrates and inhibitors in their active centers. Preferential binding of one of the components is determined in both cases by the dissociation constants K_D.

The K_D values for several cyclodextrin inclusion compounds are compiled in Table 3. Generally speaking, the values all lie close to 10^{-3} mol/l and are characteristic of weak intermolecular interactions. It is remarkable that there is no obvious correlation between the chemical properties (functional groups) of the guest molecules and the dissociation constants. Inclusion thus does not seem to depend primarily on the character of the guest.

The thermodynamic parameters enthalpy (ΔH) and entropy (ΔS) can be obtained from the temperature dependence of the dissociation constant. ΔH is always negative, *i.e.* the complex dissociates when the temperature is increased. ΔS can be positive or negative—this indicates that, depending on the guest molecule, several forces are involved in complex formation. Very exact ΔH and ΔS values can be derived from calorimetric measurements[114-116]. If ΔH is plotted against ΔS (according to [125]) for different guest molecules, a linear relationship (compensation) is seen; an "isoequili-

Table 3. Thermodynamic parameters of some cyclodextrin inclusion compounds at 25 °C (for further K_D and ΔH values see Tables 4 and 5).

Substrate	Cyclo-dextrin	K_D [mol/l]	ΔH [kcal/mol]	ΔS [cal·mol^{-1}·K^{-1}]	Method [a]	Ref.

Benzoylacetic acid	β	9.8×10^{-3} [c]	− 5.7	− 8.6	Ki	[121]

[a] Sp, Ca, Ki signify spectroscopic, calorimetric and kinetic methods respectively. [b] At 14 °C. [c] At 50.3 °C.

brium" temperature can be determined from the slope of the resulting straight line (Fig. 8)[75, 115, 126]. As compensation is generally correlated with the participation of water molecules in complex formation[125], it must be assumed that the guest molecule loses its hydration sphere on entering the cyclodextrin cavity, and that water molecules are expelled from the "empty" cyclodextrin cavity.

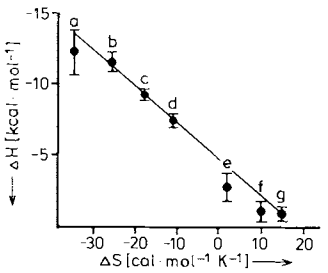

Fig. 8. $\Delta H/\Delta S$ compensation for some of the substrates listed in Table 3 (according to [115]). a) to g) signify anilinium perchlorate, 4-aminobenzoic acid, benzoic acid, hydrocinnamic acid, pyridine, L-tyrosine, L-phenylalanine, The linear relationship reveals that water participates in complex formation; an "isoequilibrium temperature" of 265 K is obtained from the slope of the straight line.

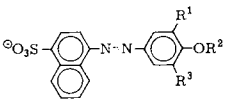

The thermodynamic parameters give a macroscopic picture of the inclusion process which can be described in detail by means of kinetic data. The rate constants k_D for dissociation and k_R for recombination of the cyclodextrin · substrate complex C·S

$$C + S \underset{k_R}{\overset{k_R}{\rightleftharpoons}} C \cdot S \qquad K_D = k_D/k_R$$

can be obtained by relaxation[73, 113] and mixing techniques[73]; they are compiled in Tables 4 and 5.

The dyes of the type 4-(4-hydroxyphenylazo)-1-naphthalenesulfonate listed in Table 4 form 1:1 complexes with α-cyclodextrin as only the phenyl group can penetrate the cavity. The thermodynamic parameters (K_D) do not reveal any significant differences between the azo dyes as regards complex formation and thus indicate that the intermolecular guest/host interactions are similar; the kinetic parameters, however, demonstrate that as the volume of the substituent (H, CH_3, C_2H_5) which is *ortho* to the hydroxy group increases, the inclusion and dissociation processes slow down by a factor of 10^5. This can be accounted for by the fact that the hydroxyphenyl group must thread in and out of the α-cyclodextrin ring; furthermore, the hydrophobic methyl and ethyl groups could stabilize the hydration sphere surrounding the hydroxy group and thus increase steric hindrance. Complex formation can be subdivided into several steps[73]: 1) Approach of the substrate and α-cyclodextrin. 2) Elimination of water molecules from the α-cyclodextrin cavity and the im-

Table 4. Thermodynamic and kinetic parameters for the formation of complexes between α-cyclodextrin and *p*-nitrophenol, *p*-nitrophenolate, or azo dyes of 4-(4-hydroxyphenylazo)-1-naphthalenesulfonate type (according to [73]).

mediate vicinity of the hydroxyphenyl group. 3) Assimilation of these water molecules by the surrounding water (gain in entropy). 4) Interaction of α-cyclodextrin and the substrate as a result of van der Waals forces and possibly formation of hydrogen bonds. 5) Reconstitution of the hydrated structure around the finished complex.

The parameters for the formation of inclusion compounds from β-cyclodextrin and salts are compiled in Table 5[113].

Table 5. Thermodynamic and kinetic parameters for the formation of complexes between β-cyclodextrin and several anions (according to [113]).

Substrate	K_D [mol/l]	k_R [mol^{-1} s^{-1}]	k_D [s^{-1}]
$Cl^{\ominus}$	0.39	5.4×10^7	2.1×10^7
$Br^{\ominus}$	0.15	4.5×10^7	6.9×10^6
$I^{\ominus}$	0.055	6.5×10^7	3.6×10^6
$SCN^{\ominus}$	0.10	4.4×10^7	4.4×10^6

$ClO_4^{\ominus}$	0.037	2.0×10^9	7.4×10^7

The substrate molecules are so small that there is no steric hindrance, the complexes are therefore formed more quickly than those of the azo dyes; the reactions are not, however, diffusion controlled. As the stripping off of the hydration sphere surrounding the anions cannot be rate determining, a (slower) conformational change of β-cyclodextrin on inclusion was inferred. One such change, due to rotation of a glucose unit, could be directly monitored kinetically[113], spectroscopically[127], and crystallographically[128-131] for α-cyclodextrin but not for the more rigid β-cyclodextrin. As will be described in Section 6.1.2, rotation of the O(6)H groups about the C(5) C(6) bonds may be considered as a conformational change.

6.1.2. Structure of the Cyclodextrin Inclusion Compounds

The cyclodextrins and their adducts can be crystallized from water and examined by X-ray crystallography as "empty" molecules or as inclusion complexes. Depending on the size and ionic or molecular character of the substrate, "chan-

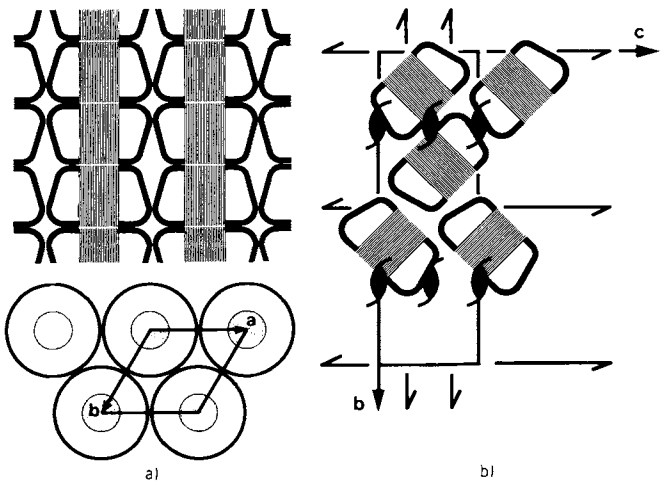

Fig. 9. Schematic representation of the arrangement of cyclodextrins in crystals. The cavities are hatched. a) Channel structure as seen from above and from the side (hexagonal packing of the stacks); b) cage structure (space group $P2_12_12_1$). The lens-shaped structures and arrows represent crystallographic screw dyads. The size and nature (ionic or molecular) of the guest molecule determines which of the two structures is adopted (according to [132]).

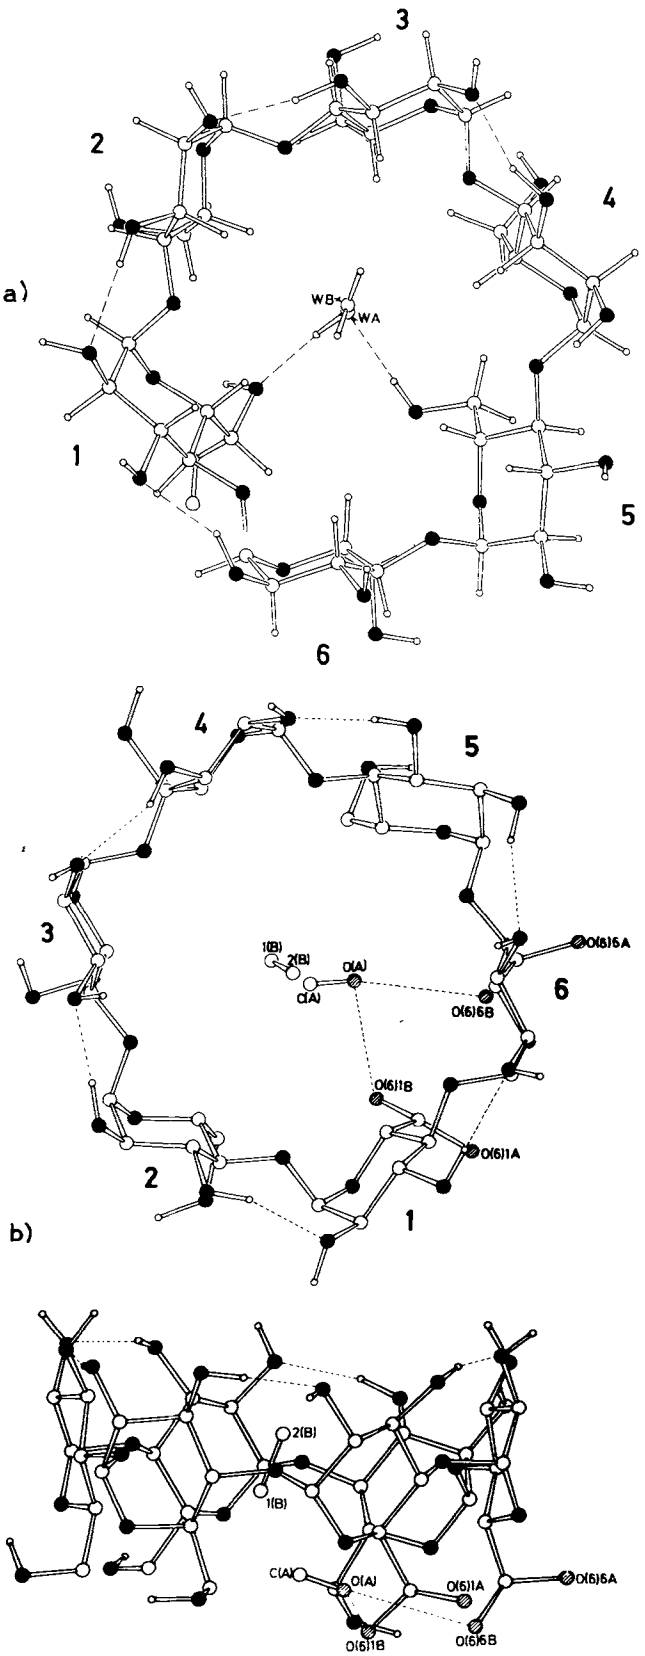

Fig. 10. Results from X-ray structure analyses of cage structures of a) α-cyclodextrin·6H_2O (according to [128]) and b) α-cyclodextrin·CH_3OH·4H_2O (according to [129]). ○ = H, ○ = C, ● = O; ◎ in (b) denotes disordered OH groups at C(6) and in the methanol molecule, the H atoms bonded to C are not shown in (b). O H...O hydrogens bonds in (b) form a ring between the O(2)H and O(3)H groups of adjacent glucose units; in (a) this ring is interrupted at the "inwardly" rotated glucose (numbered 5). (a) Contains two molecules of water (WA, WB), (b) contains one methanol molecule in two statistically occupied positions [O(A) C(A); 1(B) 2(B)]; in each case one of these molecules is hydrogen bonded to O(6)H groups ((+)-*gauche* conformation). The four molecules of water which lie "outside" the cyclodextrin molecule are not shown.

nel" or "cage" structures are formed in which the cyclodextrin molecules are stacked like coins in a roll or arranged in a herring-bone pattern[132] (Fig. 9).

In addition to the α-cyclodextrin complexes formed with water[128], methanol[129], and polyiodide[133] shown in Figures 10 and 11, complexes with iodine[134], krypton[135], *n*-propanol[136], *p*-iodoaniline[137,138], dimethyl sulfoxide and methanol[139], *m*-nitrophenol[140], methyl orange[123], and potassium acetate[141] have also been analyzed. In the case of β-cyclodextrin, the crystal structures of its complexes with water[142], *n*-propanol[143], *p*-iodophenol[143], 2,5-diiodobenzoic acid[144], and *p*-nitroacetanilide[145] have been determined; the structures of γ-cyclodextrin complexes with propanol/water[146] and water[147] have recently been described.

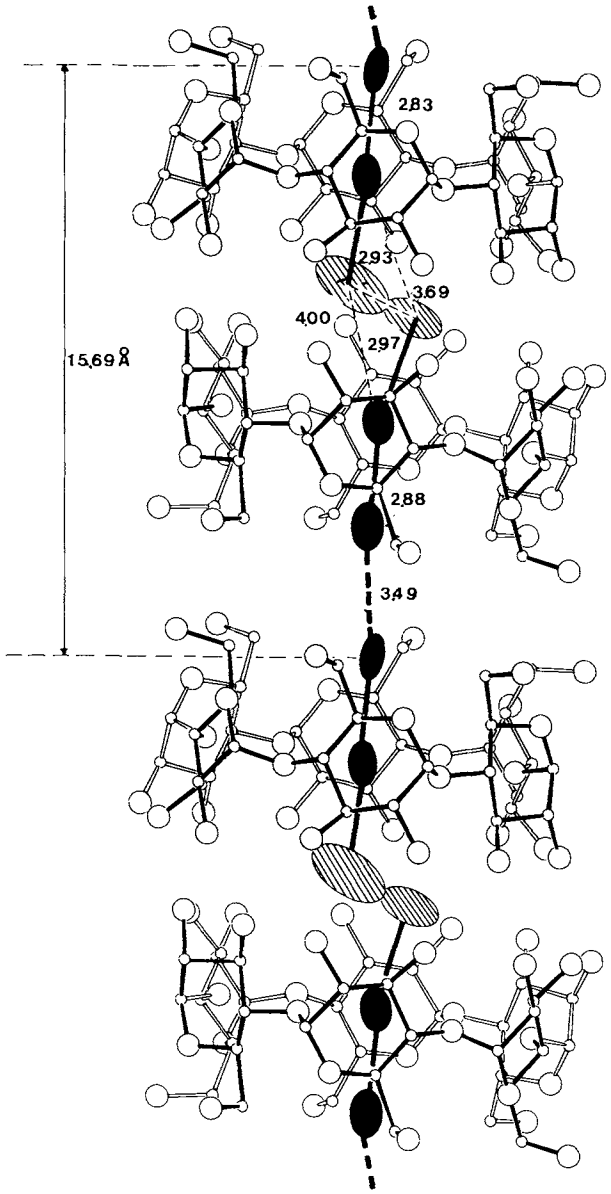

Fig. 11. Greatly simplified side view of the channel structure of the complex (α-cyclodextrin)$_2$·LiI_3·I_2·8H_2O. ○ = C, ○ = O, ● = I, ⊗ = disordered iodine, the iodine atoms are represented as thermal ellipsoids. Water molecules, cations, hydrogen atoms and hydrogen bonds between O(2)H, O(3)H and O(6)H groups have been omitted for the sake of clarity (according to [133]). I...I^- distances and the translation period along the channel axis are given (in Å). The mean I...I distance, 3.14 Å agrees with the values of ≈3.1 Å obtained for the iodine-starch complex [166] and other α-cyclodextrin-polyiodide complexes [316].

Comparison of the crystal structure analyses of the α-, β-, and γ-cyclodextrin complexes reveals that the cyclodextrins always have a "round", slightly conical form whose narrower opening contains the O(6)H groups whereas the wider opening is occupied by the O(2)H and O(3)H groups. The glucose units always have a C1-chair conformation, the C(6)—O(6) bonds are preferentially directed away from the center of the ring (torsion angle O(5)—C(5)—C(6)—O(6) is (−)-*gauche*); these bonds can, however, turn "inwards" (torsion angle O(5)—C(5)—C(6)—O(6) (+)-*gauche*) after formation of hydrogen bonds between the O(6)H group and the guest molecule.

Intramolecular hydrogen bonds O(3)—H...O(2) and O(3)...H—O(2) exist between the secondary hydroxy groups of adjacent glucose units. These interactions stabilize the cyclodextrin macrocycle (Figs. 2 and 10) and cause a significant broadening of the γ_{OH} bands in the IR spectrum as compared with normal alcoholic OH bands[97,148]. Deuterium exchange as followed by means of ^{1}H-NMR spectroscopy showed that these hydrogen bonds are very stable even in dimethyl sulfoxide solutions[148,149]. The values of the equilibrium constants for the equation

$$2\ \text{Cyclodextrin-OH} + D_2O \rightleftharpoons 2\ \text{Cyclodextrin-OD} + H_2O$$

are 0.75 and 0.65 for α- and β-cyclodextrin respectively; these values are smaller than that for amylose (0.85) and indicate that the interactions in amylose (polymer) and α-cyclodextrin are weaker than those in β-cyclodextrin. The X-ray data show that the mean O(2)...O(3) distances are clearly different in α-, β-, and γ-cyclodextrins (3.00, 2.86, and 2.81 Å respectively); the interactions in α-cyclodextrin are weaker and its flexibility is thus greater than is the case for β- and γ-cyclodextrins—a statement which is in agreement with deuterium exchange studies as well as with theoretical[48] and spectroscopic data[127].

The interactions between the guest molecule and the surrounding cyclodextrin are generally weak and are largely due to van der Waals and dispersion forces. It is for this reason that small molecules are often statistically disordered within the cyclodextrin cavity[129,135,136,142–144,146,147], even if hydrogen bonds are formed with the O(6)H groups. The guest molecule apparently strives to fill up the cyclodextrin cavity and if this is not possible for spatial reasons, it begins to "rattle".

The structure of α-cyclodextrin·6H_2O (Fig. 10a) is unusual. When α-cyclodextrin is complexed with included methanol, krypton and *n*-propanol, the guest molecules are statistically disordered and occupy several positions; (empty) α-cyclodextrin has a "round" structure with a ring of hydrogen bonds between the O(2)H and O(3)H groups. When water is the guest molecule, however, α-cyclodextrin is somewhat collapsed; two of the O(3)—H...O(2) bridges are opened and one glucose unit is rotated inwards to allow formation of a O(6)...H_2O hydrogen bond. This rotation causes steric strain within the macrocycle[128]; the α-cyclodextrin in this complex has a higher energy than in all other complexes.

NMR studies have revealed that, in aqueous solution, aromatic guest molecules such as *p*-iodoaniline and *p*-nitrophenol interact with the H atoms at C(3) and C(5) inside the cy-

clodextrins[101,149,150] to form a complex which has a structure similar to that found in the crystalline state[137,138,140]. Nitrophenol enters the cavity from the O(2), O(3) side with its nitro group, it can penetrate further into β-cyclodextrin than α-cyclodextrin and is more strongly bonded by α-cyclodextrin. It has been deduced from ^{2}H- and ^{13}C-NMR data obtained with deuterated cinnamic acid derivatives that the mobility of the substrate within the complex is greater than that of the cyclodextrin and that the interaction between guest and host is only weak[100].

6.1.3. The Driving Force for Complex Formation

As long as the cyclodextrin inclusion compounds have been known, the intermolecular interactions responsible for complex formation have been discussed[8,10,37,73,130,151]. It has been shown that several forces act simultaneously. The extent to which each of them is involved is related to the substrate concerned.

The dependence of the binding constants on substrate polarizability[118,152] indicates that, in general, van der Waals forces predominate; the formation of hydrogen bonds between the guest and (preferentially) the O(6)H groups of the substrate has been demonstrated crystallographically. Hydrophobic interactions[153,73,154] are also involved—on inclusion within the cyclodextrin cavity the guest molecule must expel the water molecules already present and strip off its own hydration sphere. The liberated water molecules are taken up by the bulk water; they gain degrees of freedom and contribute to the stability of the complex owing to the resulting increase in entropy.

As inclusion is largely independent of the chemical properties of the guest molecule, it has also been suggested that forces inherent in the cyclodextrin contribute to association. The water enclosed within the "empty" cyclodextrin cavity could exert such a force; this water is in an unfavorable, hydrophobic environment, it cannot satiate its (tetrahedral) hydrogen bond potential and is thus "activated"[154,142]. On expulsion, complex formation is favored by a gain in entropy as well as by a gain in potential energy[118,119].

As α-cyclodextrin in its "empty" state is strained (Fig. 10a)[128], energy is also gained if this strain is relieved on complex formation and if the ring of hydrogen bonds is formed between the O(2)H and O(3)H groups of adjacent glucose units[130]. This gain in energy can only occur with α-cyclodextrin; "empty" β- and γ-cyclodextrins are not strained[142,147].

Although more recent experiments[152,154-156] and theoretical considerations[157,158] have shown that van der Waals forces and hydrophobic interactions probably dominate in complex formation, the other forces discussed above inherent in the "empty" cyclodextrin·water complex may also be involved; the extent to which these forces contribute depends on the nature of the enclosed guest molecule. The inherent ring structure of the cyclodextrins is, however, decisive as inclusion complexes are only formed if there is a good spatial fit between the guest and host components.

6.2. Cyclodextrins as Starch Models

As cyclodextrins represent closed turns detached from the starch helix, it seemed obvious that they could be used as models for starch. IR spectroscopy studies showed that starch and cyclodextrins exhibit similar C1-glucose conformation[159]; information about the possible helical forms of the starch molecule was obtained from potential energy calculation[159]; information about the possible helical forms of the from crystallographic data[160]. Detailed investigations assumed that two-, four-, six-, seven-, and eightfold helices were constructed from a flexible glucose unit in order to explain the observed polymorphism of starch[161]; the recently determined crystal structures of β- and γ-cyclodextrins have provided a firm basis for these studies. It should finally be mentioned that it would hardly be possible to interpret starch X-ray diagrams if the structures of the cyclodextrins were not known[38,39,161,162].

6.3. Cyclodextrin·Polyiodide Inclusion Compounds as Models for the Blue Iodine-Starch Complex

The blue iodine-starch complex has been known since 1814[163] and was studied in detail on account of its unusual color properties for both practical and theoretical reasons[20,164,165]. X-ray diffraction studies on fibers of the iodine-starch complex only gave the dimensions of the starch helix and showed that polyiodide chains were located in the channel-like cavities within the helix with a mean I...I distance of 3.1 Å[166]; the nature of the iodine-starch interactions was, however, still unknown and became the subject of controversial discussions[20,166].

A solution of α-cyclodextrin, iodine and iodide produces almost black, metallic crystals. In these, α-cyclodextrin molecules are piled up in stacks. The cavities form channels in which, analogous to the starch-iodine complex[166], polyiodide is enclosed (Fig. 11). The arrangement of the α-cyclodextrin-polyiodide stacks within the crystal depends on the countercation[167] as the latter can interact with hydroxy groups or water molecules and thus influence the packing of neighboring stacks[133]. The α-cyclodextrin·polyiodide complexes with Li^+ and Cd^{2+} as counterions have been examined in detail. The polyiodide chains have differing structures and in the case of the Li^+ complex they can be considered as alternating $I_2...I_3^-...I_2...I_3^-$ whereas in the Cd^{2+} complex $I_5^-...I_5^-...I_5^-$ is found. The I_2, I_3^-, or I_5^- units interact strongly with one another as the longest I...I distances ≈ 3.5 Å are about 0.8 Å shorter than the sum of the van der Waals radii for iodine. It was concluded that the deep color of these complexes is a result of charge transfer within the iodine chains and that the dominant interactions between the iodine and the surrounding α-cyclodextrin are merely H...I van der Waals contacts with the inwardly directed H atoms at C(3) and C(5). The I...O charge transfer interactions[168,169] previously proposed on the basis of spectroscopic data can be ruled out.

The α-cyclodextrin-polyiodide complexes with Li^+ and Cd^{2+} counterions have been compared with the iodine-starch complex by means of resonance-Raman[170,171] and Mössbauer[171] spectroscopy. It was demonstrated that iodine starch does not contain detectable quantities of unperturbed I_2 or I_3^- but has instead I_2, I_3^-, or I_5^- units which interact with one another, and which are similar to the units found in the model α-cyclodextrin·polyiodide complexes.

6.4. Cyclodextrins as Enzyme Models

Racemic mandelic acid esters are hydrolyzed 1.38 times more rapidly in the presence of cyclodextrin than in its absence. In this process, partial optical activation occurs[172]; the cyclodextrins thus possess, like enzymes, specific catalytic properties. This finding led to an intensive study of cyclodextrins as enzyme models. The results have been recently summarized in a monograph[37] (see also [12]).

Table 6. Reactions catalyzed by cyclodextrins (according to [37]). f_{max} = maximum acceleration factor related to the uncatalyzed reaction. K, N, U respectively denote that the catalysis proceeds *via* a covalently bound intermediate, does not involve such an intermediate, or proceeds *via* an as yet unknown mechanism.

Reactions	Substrate	f_{max}	Nature of catalysis
Ester hydrolysis (asymmetric induction)	Phenyl esters	300	K
	Mandelic esters	1.4	U
Amide hydrolysis	Penicillins	89	K
	N-Acylimidazoles	50	K
	Acetanilides	16	K
Cleavage of phosphoric and phosphonic esters	Pyrophosphates	>200	K
	Diaryl methylphosphonates	66	K
Cleavage of carbonates	Aryl carbonates	19	N
Intramolecular acyl migration	2-Hydroxymethyl-4-nitrophenyl pivalate	6	N
Decarboxylation	Glyoxylate ion	4	N
	Cyanoacetate ion	44	N
Oxidation	α-Hydroxyketones	3	N

Table 6 shows several of the chemical reactions which are catalyzed by cyclodextrins. The catalyses can be divided into two groups depending on whether or not the cyclodextrin forms a covalently bonded intermediate. The former case can be formulated in general as[118,119]:

$$\begin{array}{l} S + C \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} C\cdot S \xrightarrow{k_2} P^1\text{—}C + P^2 \xrightarrow{k_3} P^1 + C + P^2 \\ \quad\downarrow k_{un} \\ P^1 + P^2 \end{array}$$

k_{un} is the rate constant for the uncatalyzed reaction without cyclodextrin (C), whilst k_1 reflects the rate of "enzyme-substrate" complex formation (C·S). k_2 describes the formation of the covalent intermediate P¹—C which is hydrolyzed according to k_3 to give cyclodextrin and the end product. In the second case, catalysis is a result of a "microsolvent" effect of the "microheterogeneous" cavity[8] within the cyclodextrin; there is no intermediate P¹—C but all other reaction steps are analogous. Since the substrate reacts in the form of an inclusion complex (C·S), the reaction rates must asymptotically approach a limiting value with increasing cyclodextrin concentration (analogous to Michaelis-Menten kinetics[173]) [118,174-182]; furthermore, inhibition must occur if an inert molecule is added which can compete with the substrate for the binding site of the cyclodextrin[118,167,173,175]. Both phenomena have been studied in many cyclodextrin-catalyzed reactions and indicate that, as cyclodextrins show the behavior typical of enzymatic reactions, they serve as good enzyme models.

The hydrolysis of phenyl esters in the presence of cyclodextrins has been investigated in particular detail[118,119,177] as a great deal is known about the analogous biochemical system—ester cleavage by chymotrypsin[173]. Phenyl acetates are best hydrolyzed in the presence of cyclodextrins at pH ≈ 11[119,37]; this indicates that the cyclodextrin attacks the carboxy group of the substrate nucleophilically with its deprotonated secondary hydroxy groups acting as the active species (Fig. 12). The unexpectedly low pK_a value of these hydroxy groups (≈ 12.2) has been confirmed by independent measurements[119,183] and is probably due to stabilization of the negative charge by inductive effects and hydrogen bonding between the neighboring O(2)H and O(3)H groups. It has been shown that the primary O(6)H group is not involved by using β-cyclodextrin permesylated in this position[184,119].

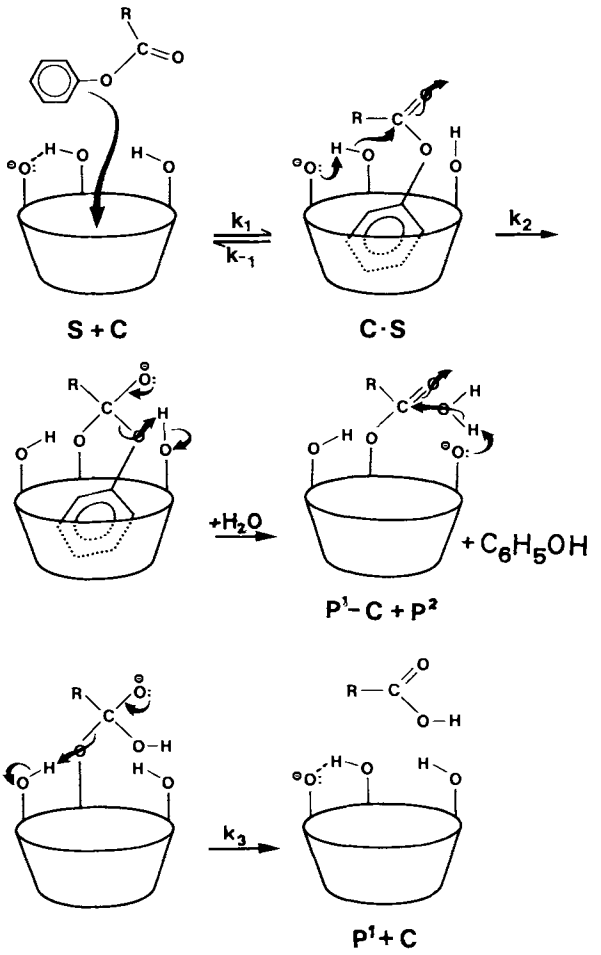

Fig. 12. Schematic representation of the hydrolysis of phenyl acetate (S) to acetic acid (P¹) and phenol (P²) as catalyzed by cyclodextrin (C).

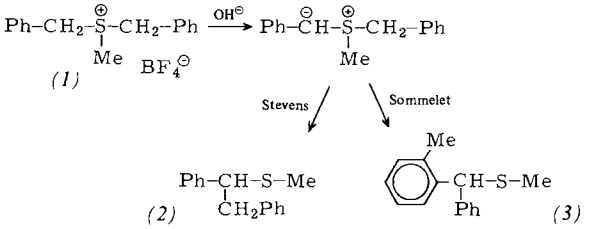
Experiments with *meta*- and *para*-substituted phenyl acetates revealed that the catalysis as expressed by the ratio k_2/k_{un} depends very strongly on the geometry of the substrate[118]. k_2/k_{un} values of 3.3 and 95 (at pH = 10.6 and 25 °C) were obtained for *para*- and *meta*-toluyl acetate respectively, the corresponding values under the same conditions for *para*- and *meta-tert*-butylphenyl acetate (their substituents are much larger) were 1.1 and 260 respectively. These data can be explained by assuming that the substituent penetrates the cyclodextrin cavity axially and that, in the case of *para* substitution, the orientation of the acetate group is largely axial. When, however, the substituent is in the *meta* position, the acetate group is brought in the vicinity of the



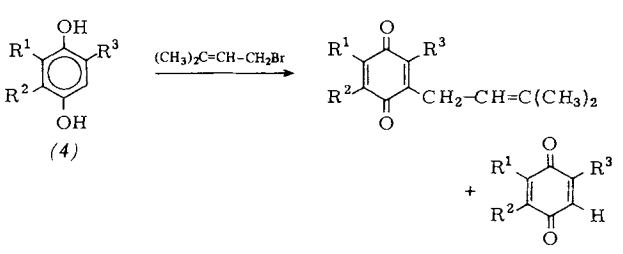
ring formed from hydrogen bonds between O(2)H and O(3)H so that a sterically favorable interaction can take place.

Attack of the O(2) or O(3) substituents produces the P¹—C intermediate which has been isolated in several cases[119,185,186]. Depending on the substrate, liberation of cyclodextrin from P¹—C by hydrolysis (step k_3) can be several 100 fold slower[119,185] than the formation (k_2) of P¹—C; the cyclodextrins are therefore not ideal enzymes. The first catalytic step is comparable both for chymotrypsin and cyclodextrin; it must, however, be remembered that cyclodextrin shows its optimal activity in the strongly alkaline range whereas chymotrypsin is optimally active in the neutral range (pH ≈ 8), and that step k_3 is very rapid for the enzyme but slow for cyclodextrin. During the course of a long evolution the enzyme chymotrypsin was specialized in the hydrolysis of esters and amides (peptide bonds) whereas cyclodextrins can moderately accelerate many reactions (Table 6).

Attempts have been made to facilitate cleavage of the intermediate P¹—C by substituting the O(2) or O(3) of the cyclodextrin with various groups, thus simulating the active center of chymotrypsin in which serine and histidine chains are situated opposite one another and form part of a "charge relay" system[173,187]. Substitution (probably at C(6)) of cyclodextrin with imidazolyl had little effect[188] but incorporation of a histamine residue at C(3) gave a cyclodextrin derivative which (at pH = 8.37 and 25 °C) was more effective in hydrolyzing *p*-nitrophenylacetate than unsubstituted cyclodextrin[189]. Other substitutions with basic groups accelerated the hydrolysis considerably[189-191]. Like ester hydrolyses, amide hydrolyses are catalyzed by cyclodextrins; examples are penicillin derivatives[181], acetanilide[182] and *N*-acylimidazole[185]. The cleavage of diarylpyrophosphate proceeds with participation of Ca^{2+} *via* a P¹—C type intermediate (phosphorylated cyclodextrin[175]); this substance has been synthesized and used as an enzyme model for the hydrolysis of *p*-nitrophenyl tetrahydropyranyl ether and for tritium exchange in the methylene group of *p-tert*-butylphenacyl alcohol[192]. Covalent P¹—C intermediates are also formed in the hydrolysis of diarylmethylphosphonates, diarylcarbonates[193], organophosphorus compounds, and thiophosphates[194].

If the cyclodextrin catalysis does not involve an intermediate P¹—C, the "microsolvent" effect[8,37] and the steric properties of the inclusion complex on which the chemical reaction is carried out play important roles. The decarboxylation of activated carboxylic acids such as 2-cyano-2-phenylpropionic acid[195-197], substituted acetoacetic acids[196], and trihaloacetic acids[196] are typical examples of the "microsolvent" effect. Other examples are the oxidation of α-hydroxyketones to α-diketones[198], the hydrolysis of 2,4-dinitrophenylsulfonate[199] and the elimination of HCl from the insecticide trichlorophone (*O*-(2,2,2-trichloro-1-hydroxyethyl)-*O,O*-dimethylphosphate)[200]. Inhibition of reactions (negative catalysis) is observed in the decomposition of hydroperoxide in water[201], of alkyl esters such as methyl and ethyl benzoates, and the ethyl ester of *trans*-cinnamic acid[119,176,183]. This effect will be encountered again when the utilization of cyclodextrins for the micro-encapsulation of chemically unstable compounds is discussed (Section 9.1).

Rearrangements are also influenced by cyclodextrins as the three-dimensional structure of the complexed substrate is different from that of the free substrate. The benzidine rearrangement of hydrazobenzene requires a sandwich-like transition state and is slowed down by α- and β-cyclodextrins by a factor of approximately 10[202]. The rearrangement of dibenzylmethylsulfonium tetrafluoroborate *(1)* in an alkaline medium is of interest. In the absence of cyclodextrin the products *(2)* and *(3)* are formed by Sommelet and Stevens reactions in the ratio 0.38:1 *via* an ylide. In the presence of cyclodextrin, however, the ratio *(2)/(3)* is shifted to 1.5:1[203].



(1) *(2)* *(3)*

A still greater effect is found when anisole is chlorinated by HOCl in the presence of α-cyclodextrin[204,205]. If cyclodextrin is not added, *para*- and *ortho*-isomeric chloroanisoles are produced in the ratio 1.48:1. This ratio increases to 21.6:1 as the α-cyclodextrin concentration is raised. The formation of *ortho*-chloroanisole is reduced to less than 1% if the free cyclodextrin is replaced by a polymer synthesized from α-cyclodextrin and (chloromethyl)oxirane (epichlorohydrin) under basic conditions[205]. The HOCl chlorination is probably the result of formation of a cyclodextrin hypochlorinated at C(3) which attacks the enclosed anisole. The reaction is of the second order without cyclodextrin but of the first order if cyclodextrin is added. The course of the Reimer-Tiemann reaction, in which *para*- and *ortho*-formylated phenol is produced from phenol and chloroform under alkaline conditions, can be similarly controlled[206]; increasing quantities of β-cyclodextrin shift the *para/ortho* ratio which is 0.95:1 in the absence of cyclodextrin, to 19:1.

The Fries rearrangement of phenyl acetate is also affected by cyclodextrin[207]. On irradiating the substrate, *para*- and *ortho*-hydroxyacetophenones are formed in the ratio 1:1 together with the hydrolysis product, *viz.* phenol. Addition of β-cyclodextrin alters the *para/ortho* ratio to 6.2:1, increases the rate of rearrangement by a factor of 3.5, and suppresses phenol production.

Substitution of cyclodextrins with 1,4-diaminoethane[208], polyamines[209], or pyridinecarbaldehyde oxime[210] furnishes derivatives which can complex metal ions and which can be considered as models for metalloenzymes. The cyclodextrins can also be modified by bridging one side so that the interior of the molecule becomes more hydrophobic and complex formation with the substrate is favored[211,80].

(4)

The importance of the cyclodextrins in preparative chemistry has been underlined in several recent publications. The allylation-oxidation reaction of hydroquinone derivatives *(4)* proceeds with yields of between 71 and 86% depending on the substituents R^1, R^2, and R^3 in the presence of β-cyclodextrin; if cyclodextrin is omitted the yields amount to 12—35%[212]. This reaction has been employed for synthesizing vitamin K_1 and K_2 derivatives in one step with yields of 40–60% (without cyclodextrin 12–22%)[213]. The conversion of prostaglandin A_1 to its B_1 isomer is also of interest; this reaction is accelerated by α- and β-cyclodextrin[214,215].

7. Chemical Modification of Cyclodextrins

As has already been described in Section 6 and [216], many cyclodextrin derivatives have been synthesized which contain functional groups derived from imidazole, polyamines, histamine, hydroxamic acid, *etc.* in place of their primary or secondary hydroxy groups. The starting material for these compounds is often monosubstituted 6-*O*-*p*-toluenesulfonylcyclodextrin which can be synthesized according to [217]; this compound can be converted to 6-azido- or 6-halogeno-6-deoxycyclodextrin and other products.

All primary hydroxy groups react with *p*-toluenesulfonyl chloride[184,218,219] or better still with mesitylenesulfonyl chloride[220]; the products can undergo further reactions. In a recent study, perbenzoylated α- or β-cyclodextrin was used[221] to introduce 6-amino-, 6-azido-, 6-methoxy-, 6-amino-2,3-dimethoxy- or 6-azido-2,3-dimethoxy substituents and also to synthesize the corresponding 2,3-dibenzoyl derivatives with 6-azido, 6-amino, or 6-methoxy substituents which can be employed for the synthesis of further derivatives. Tritylation of the O(6)H groups permits the synthesis of symmetrical triamino-α-cyclodextrin[222]. Methylation of heptakis(6-bromo-6-deoxy)-β-cyclodextrin with dimethylsulfate/$Ba(OH)_2$ furnishes the 2-*O*-methyl derivative which, after replacing the 6-bromine atom with benzoate and hydrolysis, can be converted to 2-*O*-methyl-β-cyclodextrin[223]. Alkylation of β-cyclodextrin with 3-bromopropene gives heptakis(2,6-*O*-diallyl)-β-cyclodextrin whose seven glucose units can all be 3-*O*-alkylated[224].

The following quantitative and non-quantitative substitutions of the cyclodextrins will be mentioned: the aminations [cyclodextrin-$(OC_2H_4NH_2)_n$, -$(NH_2)_n$, -$(NCH_3(CHO))_n$], esterifications [cyclodextrin-$(ONO_2)_n$, -$(OSO_3H)_n$, -$(OPO_3H_2)_n$, -$(OCOC_6H_5)_n$, -$(OCOR)_n$, -$(OCO(CH_2)_x$-COOH$)_n$], etherifications [cyclodextrin-$(OCH_3)_n$, -$(OCH_2CO_2Na)_n$, -$(O(CH_2)_xR)_n$, -$(OCH_2CHOHCH_2OH)_n$, -$(O(CH_2CH_2O)_mR)_n$, -$(O(CH_2)_mSO_3H)_n$] tabulated in [34] and the cross-linkages resulting in cyclodextrin polymers discussed in Section 8.

Cyclodextrins are very stable in an alkaline medium but are hydrolytically cleaved by strong acids. The opening up of the macrocycle proceeds 3–5 times more slowly than the degradation of the resulting linear oligosaccharides[225–229]. The oligosaccharides have been characterized[227] and the thermodynamic parameters of the reaction, which depends very strongly on temperature and acid concentration, have been determined[229]. If β-cyclodextrin solutions are cooled in the presence of HCl, HBr, or HI, a stable complex crystallizes out which contains roughly two bound equivalents of acid per β-cyclodextrin[230]. The HI complex can be formulated as (β-cyclodextrin·HI·H_2O)·HI·$7H_2O$; only one HI is enclosed, the other one being located "outside" the cyclodextrin[142].

The γ-radiolysis of β-cyclodextrin in oxygen-free solutions involves free radicals and is probably initiated by loss of a hydrogen atom from C(5)[231]. The glucose radical formed opens up the C(1)—O(5) bond; the C(1)—O(4) bond with the adjacent glucose is broken and a linear heptasaccharide is produced in which the opened glucose unit is its reducing terminal. This unit is cleaved hydrolytically to give a hexasaccharide and, in a subsequent reaction, shorter oligosaccharides. The γ-radiolysis of β-cyclodextrin in the solid state is described in [232].

Cyclodextrins can be threaded like beads onto a linear polymer, without forming any covalent bonds with it; two such preparations have been reported. If vinyl derivatives are reacted in dimethylformamide[233] or chlorides of dibasic acids in water[234] at high temperatures in the presence of β-cyclodextrin, the free reagents and those enclosed within the β-cyclodextrin polymerize to give linear structures, some of which are enclosed by the cyclodextrin. In the case of vinyl polymerization, the maximal proportion of cyclodextrin on a weight basis was 72%.

8. Cyclodextrin Polymers

The special properties of cyclodextrins are largely retained when they are linked together to form polymers. If the degree of polymerization is sufficiently high, the cyclodextrins bound within the matrix become insoluble[235,236]. In initial studies the cross-linkage of heptamino-β-cyclodextrin by hexamethylene diisocyanate was reported[237]; later, direct block polymerization of α-, β- and γ-cyclodextrins by di- or polyfunctional reagents[238–240] and bead polymerization were described[241]. If cyclodextrins are linked to polyethers, water-soluble polymers are produced[242–245]; the polymerization of β-cyclodextrin acrylate (obtained by acylation of cyclodextrin with included *m*-nitrophenylacrylate) yielded a macromolecule (molecular weight 10^4—10^5) which is water-soluble and, as it only has one linkage site per cyclodextrin, exhibits almost the same properties as the free cyclodextrin[246,247]. The cyclodextrins can also be bound to polymeric resins such as Sepharose 6B[248].

The characteristic physical data for the swelling capacity of these polymers can be determined[235,240,246,247] and an "apparent void concentration" obtained which expresses the cyclodextrin concentration (mol cyclodextrin/g resin)[249]. Polymerized cyclodextrins are preferentially used for chromatography ("gel inclusion chromatography")[249]. A HETP optimum (HETP = "height equivalents of a theoretical plate") of 0.7—0.8 was found at room temperature for aromatic amino acids run on a β-cyclodextrin polymer with a flow rate of 10—20 ml/h[235]. Several applications of gel inclusion chromatography are described in Section 9.

The complexation behaviors of monomeric and polymer-fixed cyclodextrin can be different. Small gas molecules which form 1:1 complexes are not bound by the polymer as strongly as by the monomer. In the case of larger guest molecules which can react with two cyclodextrins, the polymer complexes were shown to be more stable than those formed

with free cyclodextrin; this is due to the fact that the high local concentration of the cyclodextrin within the polymer allows cooperativity between adjacent molecules[250].

9. Applications of Cyclodextrins

The practical application of cyclodextrins has gained in importance over the past few years. This is reflected especially by the increasing number of patents. As inclusion represents a micro-encapsulation, this phenomenon contributes in particular to the stabilization of sensitive toxic substances and improves their handling and dosage. Cyclodextrins bound to polymers are also highly suited for column chromatography; a remarkable agricultural application has recently been reported.

9.1. Micro-encapsulation

Each guest molecule within an inclusion complex is individually surrounded by cyclodextrin and is thus, from the microscopical point of view, encapsulated. As this can lead to advantageous changes in the chemical and physical properties of the guest molecule, experiments have been performed with the aim of introducing micro-encapsulation by cyclodextrins into industries which manufacture drugs, foodstuffs, plant protective agents, and toilet articles. The use of cyclodextrin complexes in industry brings about the following improvements[15-17,34-36]:

I) Stabilization of light- or oxygen-sensitive substances

II) Modification of the chemical activity of guest molecules
   a) Reactive substances are protected by inclusion and can be mixed with other substances without any risk.
   b) Reactions can be made selective by inclusion of functional groups.
   c) Reactions can be promoted or suppressed (see I).

III) Fixation of very volatile substances
   a) Storage and handling are improved, especially in the case of toxic substances.
   b) The quantity of the volatile substance required can be reduced since little or no vaporization takes place.
   c) The quantities of aromatic and physiologically active substances can be better measured out.

IV) Modification of the physicochemical properties of guest molecules
   a) Substances which are sparingly soluble in water are made more soluble by the addition of cyclodextrins or they can be more easily emulsified.
   b) Powdered, freeze-dried cyclodextrin complexes are finely dispersed and more soluble than uncomplexed guest molecules which are only sparingly soluble in water.
   c) Pigments can be masked or the color of substances can be altered as inclusion generally produces changes in the spectrum of the molecule.
   d) Unpleasant tastes can be suppressed.

Several examples will be mentioned in order to illustrate these applications.

I: The most active components of "Dalmatian insect powder" from *flores pyrethri* are pyrethrins, *i.e.* derivatives of chrysanthemummonocarboxylic acid ester and their synthetic analogues[251]. They are very toxic towards insects but are harmless for warm-blooded animals. Pyrethrins are yellowish, light-sensitive oils and their use is therefore limited. Inclusion in β-cyclodextrin gives a powder which is easy to handle, very stable, and toxic for insects long after its application (Fig. 13a, Table 7[34,252]). The insecticide DDVP (*O*-(2,2-dichlorovinyl)-*O*,*O*-dimethylphosphate) is also unstable in its pure form but can be used to advantage after inclusion within β-cyclodextrin[253].

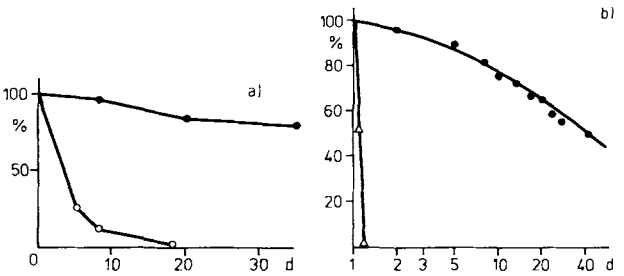


Fig. 13. Stabilization of active substances by β-cyclodextrin. a) Decomposition of allethrin (a pyrethrin) in a talc mixture (○) and when complexed with β-cyclodextrin (●). The samples were sprayed onto glass plates and exposed to sunlight (according to [252]); b) decomposition of vitamin D_3 (cholecalciferol) in its free form or in a mixture with β-cyclodextrin (△) and when complexed with β-cyclodextrin (•) at 80 °C (according to [257]).

Table 7. Decline in the activities of resmethrin and pyrethrins (in their free forms and when complexed with β-cyclodextrin) against the pine caterpillar *Dendrolinus spectabilis* Butler. Pine branches were immersed in aqueous solutions containing the doses indicated (according to [252]).

Active cpd.	Formulation	Dose [%]	Caterpillars killed [%] after 0	1 weeks	2
Resmethrin	Emulsifiable concentrate	0.1	100	0	0
		0.05	100	0	0
	Inclusion complex	0.1	100	90	90
		0.05	100	100	40
Pyrethrins	Emulsifiable concentrate	0.1	90	10	0
		0.05	50	0	0
	Inclusion complex	0.1	90	100	90
		0.05	100	100	40

Other unsaturated substances which are unstable when exposed to air and light can, like these insecticides, be stored after micro-encapsulation. The extremely labile vitamin D_3 (cholecalciferol) should be mentioned here; the chemical, physical, and pharmacological properties of its β-cyclodextrin complex[254-256] have been studied in detail[257]. The thermal stability of this complex is considerably higher than that of pure vitamin D_3 (Fig. 13b); after complexation the oxygen uptake measured in a Warburg apparatus is very low even after 20 days and the light sensitivity is much lower than that of uncomplexed vitamin D_3. The cyclodextrin complexes of prostaglandins I_2 (prostacyclin)[258], F_{2a}[259], E_2 (dinoprostone)[35,260], and E_1 have been shown to have similar advantageous properties. Prostaglandin E_1 is now commercially available in the form of its α-cyclodextrin complex [Ono Pharmaceuticals Co. Ltd. (Japan)][261-265] and has been clinically tested[266].

β-Cyclodextrin has also been shown to have a stabilizing influence on benzocaine[267], procaine, atropine, aspirin, phe-

nylbutazone[268], salicylic acid, ascaridole, the ethyl ester of chaulmoogric acid[269], and linoleic acid[269,270]. Indomethazine is stabilized by β- but not by α-cyclodextrin[271]. Azapropazone[271] and the insecticide trichlorophone[34,200,272] are, however, deactivated more rapidly by β-cyclodextrin. Similarly, β-cyclodextrin promotes the isomerization of prostaglandin A_1 to prostaglandin B_1[215] and the dechlorination of chlorpromazine[273]. Cyclodextrin inclusion also affects the stability of phenothiazines[274].

The stabilization of aromatic substances by cyclodextrins is of importance for the foodstuff and toilet article industries[34,36,275-277]. Anethole which is normally sensitive to oxidation, becomes largely resistant after inclusion within β-cyclodextrin; the oily aromatic substances contained in camomile, onions, dill, garlic, caraway, horseradish, and mustard can be stabilized in the form of easy-to-handle, powdered substances by inclusion within β-cyclodextrin. Interestingly the principal and subsidiary components are complexed to the same extent; the full taste and smell are thus retained[34,36]. The conservation of aromatic substances is also utilized in toilet articles such as bath additives[278] and toothpaste (neohesperidine dihydrochalcone)[279].

II: Particular mention should be made of the stabilization of nitroglycerin by inclusion within β-cyclodextrin[280]. The crystalline adduct can easily be made into tablets and is no longer explosive. Further applications have already been described (see I).

III: Inclusion of ethylene in cyclodextrin furnishes an easy-to-handle powder which can be used to control plant growth[281]. The bitter taste of protein hydrolyzates can be suppressed by cyclodextrin[282]; the previously mentioned, volatile, aromatic substances (see I) are fixed by inclusion. Allicin, the antibacterial, antifungicidal, evil-smelling, unstable active substance of garlic can be largely "neutralized" by inclusion in β-cyclodextrin[283]; the volatile insecticide DDVP (see I) can be stabilized against the influences of light and the atmosphere and is retained within the cyclodextrin cavity.

IV: Admixture of 1—3% cyclodextrin stabilizes emulsions. This has been demonstrated with mayonnaise made from edible oil which can be beaten without egg on addition of β-cyclodextrin; margarine or butter creams can be stabilized by β-cyclodextrin[284]. The yield of meringue from egg white (cm^3 foam per g egg white) is improved on addition of β-cyclodextrin; this beaten egg white is more stable for a period of months (at −15 °C) than egg white without cyclodextrin[285].

There are many examples to demonstrate the effect of cyclodextrins on the solubility of substances which are sparingly soluble in water. The solubility of the guest component increases linearly with the amount of cyclodextrin added, in some cases the solubility passes through a maximum (Fig. 14). The most important of such studies concern the water solubility of fatty acids[111,270,286], of amines such as procaine, lidocaine, meperdine, adipherine, the steroids cortisone acetate and testosterone[287], hydroxybenzoic acids[112], an anthranilic acid derivative[288], benzocaine, aspirin, *p*-aminobenzoic acid, tetracycline, sulfadiazine, morphine, vanillin, ephedrine, sorbic acid[289], several phenyl-substituted carbonic acids[290], ketoprofene and other antipyretic agents[291,292,106], vitamin D_3[36], coumarin anticoagulants[293], sulfonamides[294] and barbiturates[295]. Cyclodextrin com-

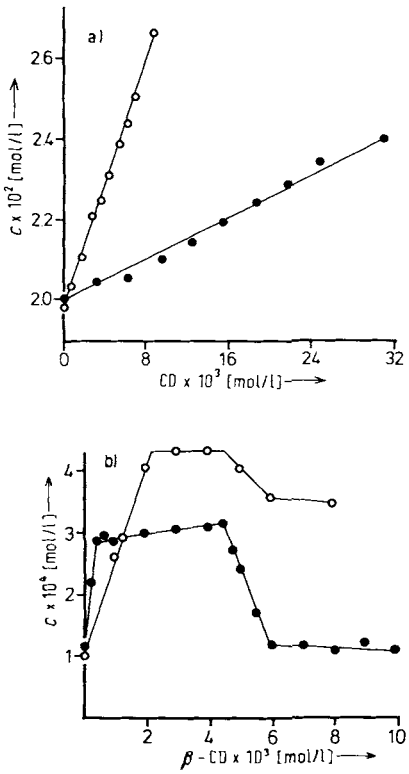

Fig. 14. Increase in the solubility of substances sparingly soluble in water brought about by addition of cyclodextrins. a) Aspirin with α- (●) and β-cyclodextrin (○) at 30 °C (according to [289]); b) cortisone acetate (○) and testosterone (●) with β-cyclodextrin at 30 °C (according to [287]).

plexes in powder form often dissolve not only more easily but also more rapidly than the guest components[296] (Fig. 15). Even if the complexes do not dissolve, they are absorbed

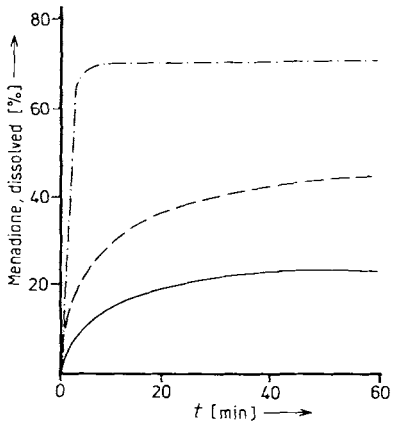

Fig. 15. Rate of solution of menadione (—), of a menadione/β-cyclodextrin mixture (---) and the menadione·β-cyclodextrin complex (·····) in water, pH = 7.5, 37 °C (according to [296]).

by living organisms very well due to the fact that they are finely dispersed. This leads to a more rapid and, in many cases, more potent action. Tests on rabbits and dogs showed that the antipyretic substances flufenamic acid, ibuprofene, and ketoprofene were detected much sooner in blood and urine when they were administered orally as their β-cyclodextrin complexes than when they were given in their free forms[297] (Fig. 16). Inclusion of the anti-rheumatic agent indomethazine in β-cyclodextrin improved but did not acceler-

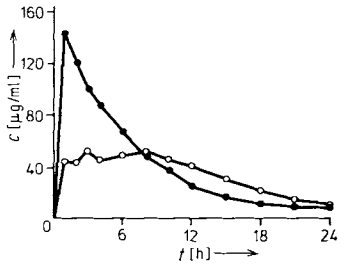

Fig. 16. Ketoprofene concentration in the blood of rabbits after oral administration of 100 mg lyophilized ketoprofene. β-cyclodextrin complex (•), lyophilized ketoprofene (○) (according to [297]).

ate its action; its ulcerogenic properties were almost totally suppressed[36,298]. T-labeled stearic acid and ^{14}C-labeled icosatrienic acid were fed to rats in their free forms and as their β-cyclodextrin complexes. The distribution of the radioactivity in urine, blood, and lymph was then monitored. Here too the cyclodextrin complexes were taken up more quickly and efficiently than the uncomplexed compounds[35].

It is known that an overdose of drugs, including barbiturates, can be partly removed by peritoneal dialysis. Rats were injected intraperitoneally with a physiological saline solution corresponding to 15% of the body weight with and without 1.5% β-cyclodextrin; a phenobarbital solution (100 mg/kg body weight) was simultaneously injected into a sublingual artery. Samples taken from the peritoneum at intervals of 15 min showed that the cyclodextrin solutions took up three times as much barbiturate as the control solutions.

Utilization of cyclodextrins also permits the chromatographic separation of prostaglandins A, B, and E[300] and allows vitamin K_1 and K_2 derivatives to be synthesized in one step[214].

Another application for cyclodextrins was discovered after it had been observed that they dramatically increase the fluorescence intensity of dansyl derivatives[301]. As these derivatives play an important part in peptide analysis, the detection limit can be improved considerably.

9.2. Cyclodextrin Polymers in Gel Inclusion Chromatography

The cyclodextrin polymers described in Section 8 are preferred as filling materials for column chromatography (gel inclusion chromatography[249,302]). When compared with customary Sephadex, it is apparent that cyclodextrin polymers have the advantage that they strongly retard molecules of an appropriate size and molecules with similar molecular weights or even isomers can be separated. *o*- and *p*-nitrophenol[239], benzoic and *o*-chlorobenzoic acid[249] are examples; these substances can be well separated on cyclodextrin polymers but not on Sephadex. Similar separations have been achieved with amino acids—particularly those with aromatic side groups[235,239]. Chromatography of nucleosides and nucleotides on cyclodextrin polymers also produced successful results; the polymers select, subject to the pH value, according to the position of the phosphate group in the sugar residue[303,304]. Diastereomers of the Cr-ATP complex have been separated on a cyclodextrin polymer[305]. Oligonucleotides, RNA fragments, and intact tRNA are not suitable for chromatography on these polymers but good results are obtained if diethylaminoethyl groups are incorporated because these groups serve additionally as anion exchangers[306]. Phenols are also bound well by cyclodextrin polymers[236] and can thus be filtered out from cigarette smoke. The different affinities of non-branched and branched paraffins for soluble cyclodextrin resins cross-linked to epichlorohydrin[307,308,236] could be exploited in oil refineries; a similar effect was demonstrated for urea adducts about fourty years ago.

The polymer-linked cyclodextrins can be used to advantage for affinity chromatography of amylases which bind cyclodextrins as inhibitors but do not act upon them enzymatically. β-Amylase from potatoes, for example, is retarded by a column filled with α-cyclodextrin-Sepharose whilst the closely related α-amylase passes through the column without hindrance. After the separation the β-amylase was eluted with α-cyclodextrin[248].

The cyclodextrins can also act catalytically in the polymer complex. As has already been described for the chlorination of anisole[205] (see Section 6.4), polymerized β-cyclodextrin controls the *o/p* ratio more effectively than the monomer; the *p*-nitrophenyl esters of fatty acids are likewise hydrolyzed up to three times more rapidly in the presence of a β-cyclodextrin polymer than in the presence of free β-cyclodextrin[246].

9.3. Racemate Resolution with Cyclodextrins

One application of the cyclodextrins, particularly of cyclodextrin polymers, which seems to be of promise is the resolution of racemates by means of complex formation—this was already described in 1959[32]. As cyclodextrins themselves are optically active molecules they form a diastereomeric pair with each included racemate; the two components of the pair exhibit different physical properties:

$$\left.\begin{array}{l}\text{D}(+)\text{-Cyclodextrin}\cdot(+)\text{-antipode}\\ \text{D}(+)\text{-Cyclodextrin}\cdot(-)\text{-antipode}\end{array}\right\}\ \text{Diastereomers}$$

If a 5—10 fold excess of a cyclodextrin solution is mixed with a racemate, one of the cyclodextrin·antipode complexes precipitates out preferentially resulting in partial racemate resolution. This phenomenon was first demonstrated with the esters of mandelic, phenylchloroacetic, and atrolactic acids, with 2,2′- and 4,4′-dichlorobenzoin, cinnamic acid dibromide (2,3-dibromo-3-phenylpropionic acid), and dibromosuccinic acid[32]. In these cases, 3—10% enantiomeric purity was achieved. Much better yields, with up to 84% enantiomeric purity of the included antipode, were obtained when separating racemic isopropyl methylphosphinates and their ethyl analogues with α- and β-cyclodextrins[309]. Racemates of chiral sulfinyl compounds such as sulfoxides, sulfinates, and thiosulfinate *S*-esters could be resolved into their antipodes after inclusion in β-cyclodextrin; an enantiomeric purity of 15% (in the case of isopropyl methanesulfinate up to 68%) was usually achieved in one separation step[310].

The catalytic action of α-cyclodextrin on a racemate has been investigated using (*S*)-(+)- and (*R*)-(−)-sarin (isopropyl methylphosphonofluoridate)[311]. Here too partial racemate resolution occurs as a result of preferential hydrolysis of an antipode. Whereas the dissociation constants show that (*S*)-(+)-sarin is bound 7 times more strongly by α-cyclodextrin than (*R*)-(−)-sarin, the rate constants (which reflect the

nucleophilic attack by the secondary hydroxy groups (O(2)H or O(3)H) of α-cyclodextrin on the sarin phosphorus atom) demonstrate that (*R*)-(−)-sarin reacts 36 times faster than (*S*)-(+)-sarin. It is evident that a higher affinity is not synonymous with a quicker reaction. The same conclusion was also drawn in the cyclodextrin-catalyzed hydrolysis of substituted phenyl acetates[118].

9.4. Cyclodextrins in Agriculture

As already mentioned in Section 9.1, cyclodextrins can be employed for the molecular encapsulation and thus stabilization of unstable or very volatile insecticides and herbicides.

Surprisingly, cyclodextrins can also be used to improve the yields of grain harvests[312]. If the grain is treated with an aqueous β-cyclodextrin solution before being sown, germination is delayed by about ten days; this is because some of the amylases which degrade the starch depot of the seeds are at least partially inhibited. The young plants are at first smaller than plants from untreated seeds but soon grow more quickly and vigorously finally giving a 20—45% larger harvest. Cyclodextrins also have a beneficial effect on the customary treatment of the seed with herbicides as these substances suppress not only the growth of weeds but also that of the grain. The delay in germination and the subsequent improved plant growth largely compensate for the adverse effects of the herbicide.

10. Outlook

Cyclodextrins can be employed in a large variety of ways owing to the fact that they can form complexes with almost all small molecules having a diameter of 5—8 Å. In the next few years the processes reponsible for the formation of cyclodextrins from starch, their modification, complex formation, and catalytic properties will still be interesting topics for the research worker; as far as the applied use of cyclodextrins is concerned, attention will be concentrated on the micro-encapsulation of sensitive aromatic substances, pharmaceuticals, herbicides, and insecticides and on chromatography with cyclodextrin polymers. The current price of α- and β-cyclodextrins (36 and 25 DM/5 g[313] respectively) is much too high for industrial purposes, but with production of at least 200 t per year the price of the cyclodextrins may well become reasonable enough for technical purposes[317]. It is to be hoped that the chemical spirit of invention will soon discover so many other fields of applications for the cyclodextrins that it will be profitable to manufacture them on an industrial scale.

I would like to thank Professor Friedrich Cramer, one of the pioneers of cyclodextrin research, for his generous support and interest shown while I carried out the studies cited in this article. These studies were helped by the enthusiastic assistance of K. Beyer, Dr. B. Hingerty, K. Lindner, Dr. P. C. Manor and Dr. M. Noltemeyer who were generously supported by grants from the Max-Planck-Gesellschaft, the Deutsche Forschungsgemeinschaft, the Alexander-von-Humboldt-Stiftung, and NATO. I thank Dr. Takaji Fujiwara, Osaka University, for translation of the Japanese publication[34], Dr. Mifune, Teijin Co. (Tokyo), and Dr. Szejtli, Chinoin (Budapest) for their frank exchange of information. I am also grateful to the Yamada Science Foundation for a four-week stay in Osaka which made a very great contribution to the writing of this article.

[197] The mechanism proposed in [196]—participation of a hydrogen bond between cyclodextrin and oxo- or cyano group of the substrate—is considered unlikely in [37] (p. 53) because the reaction is insensitive to the geometry of the substrate and pH value and to the absence of buffer catalysis [195]; a nonspecific microsolvent effect is proposed instead.

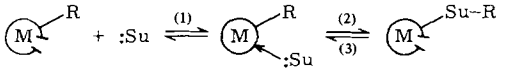
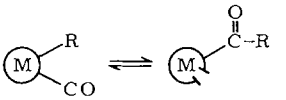
Trimethylphosphane Complexes of Nickel, Cobalt, and Iron—Model Compounds for Homogeneous Catalysis



By Hans-Friedrich Klein[*]

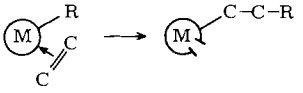
One of the greatest achievements of organometallic chemistry in the last ten years has been the experimental proof that transition metal-to-carbon bonds are thermodynamically about as stable as those between main group elements and carbon. The present contribution demonstrates how simply constituted alkylnickel, -cobalt, and -iron complexes are obtained by means of a kinetic stabilization using suitable neutral ligands and what information these model compounds can provide with respect to the course of processes in homogeneous catalyses.

1. Introduction



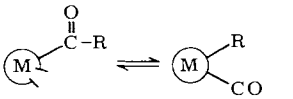
1.1. Key Reactions at the MC Bond

The crucial steps of a large group of practically important catalytic processes in homogeneous phase[1-3] may be described by the following scheme:



A transition metal center M, protected in solution by a number of ligands or by solvent molecules (circle), is substituted by a functional group R. In the cases of interest, R is a hydrogen or an alkyl group. Substrate molecules are induced to react as they occupy a vacant coordination site at the metal (open circle) and subsequently react with R in the first coordination sphere. Formally we consider:

Reversible coordination of unsaturated substrate molecules [reaction (1)];
insertion reactions [reaction (2)],
reversible: *e. g.*

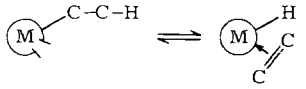


R = H, Alkyl

("Oxo synthesis", Fischer-Tropsch synthesis)
irreversible: *e. g.*

R = Alkyl

(olefin oligomerizations, Ziegler-Natta polymerizations)
elimination reactions [reaction (3)] reversible:
e. g. decarbonylation



R = H, Alkyl

and β-elimination

(detachment of a polymer chain from a metal center)

Two σ-bonded groups R can depart from a metal after a coupling reaction (4). As the formal oxidation number of the metal decreases by two units this step is conventionally termed "reductive elimination".

R = R′ = H: *e.g.* hydrogenation of olefins;
R = H, R′ = alkyl: reversible C—H scission in hydrocarbons;
R = R′ = alkyl: reversible C—C scission in hydrocarbons.

As a necessary requirement, R and R′ have to occupy *cis* positions.
