# Molecular Mechanics Calculations in Organic Chemistry[1]: Examples of the Usefulness of this Simple Non-Quantum Mechanical Model

By Eiji Ōsawa* and Hans Musso

Various problems arising in experimental organic chemistry can be clarified by molecular mechanics or force field calculations: molecular dynamics (conformational analysis and internal rotation), the search for the most stable isomer of various polycyclic hydrocarbons, reactivity calculations, including solvolysis of bridgehead substituted systems. Such calculations are shown to be useful in elucidating the mechanism of multistep carbonium ion rearrangements, for predicting the structure and stability of anti-Bredt olefins, and also offer an explanation for the selectivity observed in the hydrogenolysis of strained polycyclic small-ring hydrocarbons, for the identification of long bonds and electronic effects, for the analysis of late transition states, and for the product distribution in complex reactions.

## 1. Introduction

The utility of computers in organic chemistry can no longer be disputed, even by conservative chemists. A new field called computer chemistry has been established with its own conferences and journals. Here we would like only to direct attention to this development; on the one hand purely theoretical calculations as well as their heuristic applications[2] and, on the other, those involving computer assisted synthesis[3] and drug design[4].

There are three main categories of theoretical calculations: *ab initio*, and semiempirical molecular orbital (MO) methods[5], as well as empirical force field calculations[6], also called molecular mechanics (MM). Although pure theory can hardly gain from the results of MM calculations, use of this method is becoming more and more popular and its prospects are recognized as highly promising[7–9]. In fact, this is the method of choice for calculating and optimizing structures and energies of molecules containing anywhere from ten to several hundred atoms—the programs are readily accessible from the Quantum Chemistry Program Exchange (QCPE)[10]—and this size of molecule is of considerable current interest to chemists.

## 2. The Force Field Method

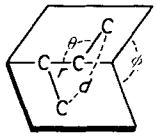
The steric energy ($E_{st}$) and geometrical parameters, such as distances between atoms and bond angles of molecules, can be represented as the sum of terms arising from all stretching ($E_r$) and bending ($E_\theta$) vibrations and torsions ($E_\phi$), as well as from all nonbonding interactions between atoms ($E_d$) [Fig. 1 and eq.(a)].

$$E_{st} = E_r + E_\theta + E_\phi + E_d\,(+ E_{r\phi}\ etc.) \qquad (a)$$

Valence angles down to 90°, which improve the results in strained polycycles like norbornane or cyclobutane derivatives, are taken into consideration by additional terms like the cross term $E_{r\phi}$.

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0101-0001 $ 02.50/0 

Up-to-date accounts of the origin and development of force field methods have been covered in excellent review articles[7-9]. *Engler's* force field (1973)[11] as well as that of *Allinger* (1971)[12] are stored together in program BIGSTRN, and have been used successfully by *Mislow et al.*[13], *Rüchardt et al.*[14,15], *DeTar et al.*[16], *White et al.*[17], *Müller et al.*[18], *Harris et al.*[19], and *Lenoir et al.*[20] among others.



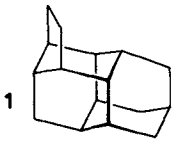


Fig. 1. Intramolecular coordinates used in MM-calculations: r = bond length, θ = bond angle, d = distance between nonbonded atoms, φ = torsion angle.

The most recent steps of refinement hardly influence the results for hydrocarbons. Despite its simplicity with only four terms[21], *Engler's* force field is so well balanced in C/C, C/H, and H/H interactions between nonbonded atoms that it reproduced all observed C—C bond lengths of $C_s$-ethanodiamantane **1**[23,24] with a standard deviation of 0.7 pm, a value as accurate as that obtained by *Altona's* force field known to be excellent for calculation of structures[7f]. Bond angles are reproduced in general within ±1—2° and energy values within ±2 kcal/mol[25]. If similar structures are compared, the mean error decreases further since they, in part, compensate each other.

**1**

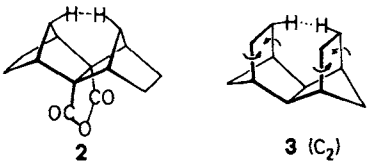
The improvement of force fields at the present time causes changes only after the decimal point[26], and this is of course important for calculating the energies of different conformations of simple molecules. The data in Table 1 indicate how *Engler's* force field may be evaluated in this respect. The hydrogen in this force field is now recognized as somewhat too "hard" and the carbon too "soft"[27]; this leads to an opening of the valence angles in molecules with bulky substituents[28]. A further disadvantage of the program BIGSTRN is its low efficiency in the search for the energy minimum[29].

Table 1. Energy differences $\Delta E$ between the *anti*- and *gauche*-conformations of simple alkanes.

| Compound | $\Delta E_{exp}$ [kcal/mol] | | $\Delta E_{calc}$ [kcal/mol] | |
|---|---|---|---|---|
| | *Verma* [a] | *Engler* [11] | *Allinger* [12] | *Boyd* [b] |
| *n*-Butane | 0.966±0.054 | 0.93 | 0.67 | 0.68 |
| 2-Methylbutane | 0.809±0.050 | 0.78 | 0.44 | 0.59 |
| 2,3-Dimethylbutane | 0.054±0.030 | −0.03 | 0.08 | 0.20 |

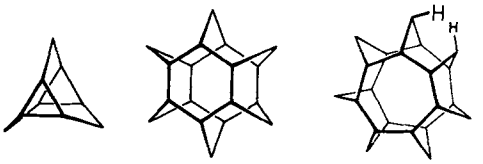
[a] A. L. Verma, W. F. Murphy, H. J. Bernstein, *J. Chem. Phys. 60* (1974) 1540. [b] S. Chang, D. McNally, S. Shary-Tehrany, M. J. Hickey, R. H. Boyd, *J. Am. Chem. Soc. 92* (1970) 3109.

Currently, users are shifting to the more sophisticated second-generation force fields such as MM2[10a,22], MUB-2[27b] or recent versions of the consistent force field[10d,30].



## 3. Conformational Analysis

### 3.1. The *gauche* H—H-Interaction



The somewhat daring proposal by *Wertz* and *Allinger*[31] that nonbonded repulsions between vicinal hydrogen atoms play a dominant role in destabilizing the *gauche* form of *n*-butane aroused considerable attention. Careful examination by at least three other force fields MUB-2[27], *Boyd's*[32] and *Engler's*[33] unanimously indicated that the classical explanation involving repulsion between the methyl groups is more important than the *gauche*-hydrogen interaction. This indicates that the H—H interactions in MMI are too hard.

### 3.2. Very Short C—H···H—C Contacts

All the existing force fields treat hydrogen atoms as being somewhat too rigid at very short H/H contacts (distance < 190 pm) between nonbonded C—H groups[34,35]. The lowest value (168 pm) found in a tetracyclododecane derivative **2**[36] has not quite been obtained by MM-calculations. Recently, applying the consistent force field in a number of related compounds, *e.g.* **3**, *Ermer* has shown that skew twisting of the molecule can occur and that the shift to short wavelength of the C—H vibrational frequencies are correctly reproduced[37].

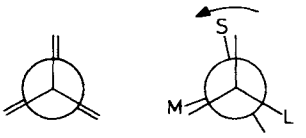
**2** **3** ($C_2$)

**4** **5** **6**

Table 2. C—H···H—C contacts (distances *d* and interaction energies $E_E$), enthalpies of formation ($\Delta H_f$), and strain energies (*SE*) in the asterane-series calculated using the Engler force field[11].

| Asterane | *d* [Å] | $E_E$ [kcal/mol] | $\Delta H_f^\circ$ [kcal/mol] | *SE* [kcal/mol] |
|---|---|---|---|---|
| Diasterane | 1.978 | 2.48 | 64.52 | 93.68 |
| Triasterane **4** | 3.169 | −0.04 | 94.05 | 122.40 |
| Tetraasterane | 2.441 (2.40) [a] | 0.28 | 20.35 | 58.15 |
| Pentaasterane | 2.070 | 1.68 | −0.71 | 46.54 |
| Hexaasterane **5** | 1.903 | 3.37 | 58.70 | 115.40 |
| Heptaasterane **6** | 1.835 | 4.43 | 165.52 | 231.67 |
| Octaasterane | 1.829 | 4.54 | 291.48 | 367.08 |
| Nonaasterane | 1.86 | 4.06 | 423.13 | 508.18 |
| Decaasterane | 1.96 | −0.03 | 550.23 | 644.73 |

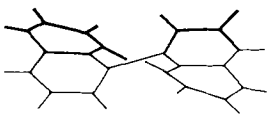
[a] X-ray structure analysis: J. Chesick, J. D. Dunitz, U. von Gizycki, H. Musso, *Chem. Ber. 106* (1973) 150.



This problem also appears in the asterane series (Table 2). For hexaasterane **5** *Engler's* force field still furnishes linear C—H···H—C contacts of distance 190 pm and completely planar six-membered rings. However, in heptaasterane **6** the C—H···H—C repulsion (distance = 183 pm) causes twisting of the cyclohexane boat conformations and puckering of the seven-membered rings. It still remains an experimental challenge to present evidence which indicates above which ring-size asteranes in fact become distorted.

### 3.3. Internal Rotations

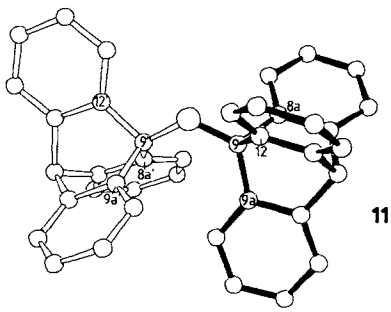
Most structures have been reproduced by MM-calculations very well[38], but this occurs only for the conformation at the energy minimum. An important question is how accurately transition states and energy barriers $E_{rot}$ for the rotation of mobile parts of the molecule can be calculated by these methods. *Allinger's* force field MM2[22] includes torsional contributions by means of a cosine function of the type $K_t/2\cdot(1\pm\cos(n\omega))$ not only for the usual third power ($n=3$) but also for the square and linear terms ($n=1, 2$); hence it looks favored for dealing with this type of problem. Rotational barriers calculated by MM2 are smaller than the observed values, and the discrepancy increases with the steric hindrance around the rotating bond (cf. also Table 3)[39,40]. The biggest problem is the uncertainty in the experimental barriers of *n*-butane, for which no reliable results have been reported from *ab initio* calculations[41].



The simplest way of improving the situation using MM2 would be to increase the third-order torsional force constant for the C—C—C—C system so as to reproduce the observed high barriers in congested molecules, since the difference between the observed and calculated barriers (Table 3) seems to be proportional to the number of eclipsing C—C—C—C units. However, *Allinger et al.* express some reservation towards such a straightforward remedy[41]. We continue to warn the users of the MM2 force field to keep in mind that the calculated barriers of open chain systems may be underestimated[42].

In the course of MM studies of internal rotation, firstly by *Mislow et al.*[43], it was noticed that a transition state in which all three bonds are simultaneously eclipsed, as shown in the Newman projection **7**, never occurs but that the smallest substituent S passes the threshold first, while larger substituents follow as in **8**. The conformers having nonalternating Newman projections are generally difficult to identify experimentally, but can be detected by simulation of the internal rotation process using the MM technique[40]. Highly congested ethane derivatives, like tetra-*tert*-butylethane **9**, exist in such a nonalternating conformation, even at the energy minimum[14,43,44].

**7** ($E_3$) **8** ($F_2BF_2$)

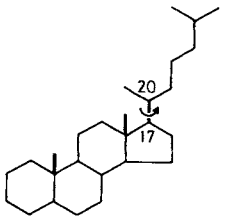


$[(CH_3)_3C]_2CH-CH[C(CH_3)_3]_2$ **9**

**10**

The racemization of the 1,1'-binaphthyl **10** provides another example illustrating that MM-calculations have indicated an initially unexpected reaction course. The experimental barrier of about 22 kcal/mol is reproduced correctly only if the axis of chirality is broken and both H···H interactions are treated consecutively in the calculation. With a rigid axis and simultaneous flipping, *Allinger's* force field[31] yields 35 kcal/mol[45].

The dynamic "gear effect" makes very low barriers of rotations possible even for molecules with bulky substituents: for ditriptycylmethane **11** a rotational barrier of only 1.0 kcal/mol is calculated[46a]; of course, the barrier in the tetramethyl derivative is much higher: a vulue of 14.2 kcal/mol has been found experimentally, whereas the calculated value is 16.5 kcal/mol[46b].



**11**

There was some controversy over restricted rotation around $C_{17}$—$C_{20}$ bond of the steroid systems, *e.g.* cholestane **12**. The failure to freeze this rotation in a *tert*-butyl derivative **13** appeared to suggest a low barrier for **12** also. However, the corrected MM-barrier of **12** is 12 kcal/mol, which can be frozen at low temperatures. The unexpectedly high barrier calculated for **12** relative to that for **13** (8.5 kcal/mol) is the result of a secondary effect arising from β-branching in **12**[40].

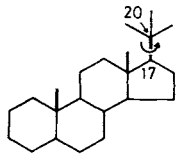


Table 3. Observed and calculated rotation barriers $E_{rot}$ for the central C—C bond of hydrocarbons.

| Compound | | $E_{rot}$ [kcal/mol] exp. [a] | calc. [b] |
|---|---|---|---|
| *n*-Butane | *anti-gauche* | 3.4, 3.6 [c] | 3.35 [c], 3.56 [d] |
| | *anti-anti* | 5.9–6.1 [c] | 4.76, 5.99 [d], |
| 2,3-Dimethylbutane | *anti-gauche* | 4.3 | 6.13 [e] |
| 2,2,3-Trimethylbutane | | 6.9, 7.0 | 3.1 |

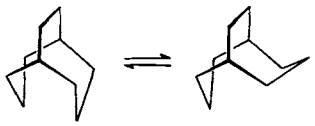
**12**, $\Delta H^{\ddagger}_{calc.}$ = 12 kcal/mol



**13**, $\Delta H^{\ddagger}_{calc.}$ = 8.5 kcal/mol

### 3.4. Dynamics in "Rigid Systems"

The well-known twist motion in bicycles, such as bicyclo[2.2.2]octane **14**, was established experimentally after it had first been predicted from MM calculations[47]. At least two equivalent bonds have to be rotated simultaneously in such rigid polycycles. Energy potential profiles have been calculated for bicyclo[3.3.1]nonane **15** and tricyclo[6.4.0.0$^{4,9}$]dodecane **16**. As seen in Figure 2, the curves of **15** and **16** are not as smooth around the minimum as that of **14**. In spite of the 3-H···7-H repulsion in **15**, the

**14**

**17**

3-H···9-H interaction favors the double-chair conformation without twisting. In **16** there are two such interactions, 2-H···6-H and 3-H···11-H, and the molecule is twisted by 5—7° to avoid this strain, as confirmed by X-ray structural analysis of a derivative[48]. Similarly MM-calculations indicate that in bicyclo[3.3.2]decane **17** the chair-boat conformation predominates[49].

By simple modification of the MM2 program we can simultaneously rotate as many bonds as we please[49–51]. Using this technique we have examined conformational mobility in polycyclic molecules having ethano bridges, *e.g.* tricyclo[4.2.2.2$^{2,5}$]dodecane **18**, tetracyclo[6.2.1.1$^{3,6}$.0$^{2,7}$]dodecane **3**, and perhydrotriquinacene **19**. All of these compounds possess twisted conformations in the ground state[52], but the energy barriers calculated for interconversions between the twist forms are so low that there is no possibility of detecting the process by dynamic NMR. This prediction has been confirmed experimentally for **18**[53] and **19**[54].

**18** ($D_{2h}$)

**19** ($C_3$)

*Ermer's* calculation predicts that all C—H bonds of dodecahedrane are fully exclipsed in the ground state energy minimum[55], and exactly this was recently found by X-ray structural analysis of the dimethyl derivative[56].

## 4. Search for the Most Stable Isomers

The success achieved in adamantane chemistry[57] prompted us to seek the most stable isomer of other $C_nH_m$ polycycles. For all tri-, tetra- and pentacycles with $C_8$ to $C_{14}$ frameworks we now know all the most stable isomers, the "stabilomers" of each family[58]. The strategy is illustrated below for pentacycloundecane. Firstly all the 15358 isomeric pentacycloundecanes are produced by the structure generating programs JAL-30XA and CISGEN; all structures having quaternary C-atoms are then eliminated, because these must be highly strained. Visual inspection of about 500 structures left on the TV screen reveals only one

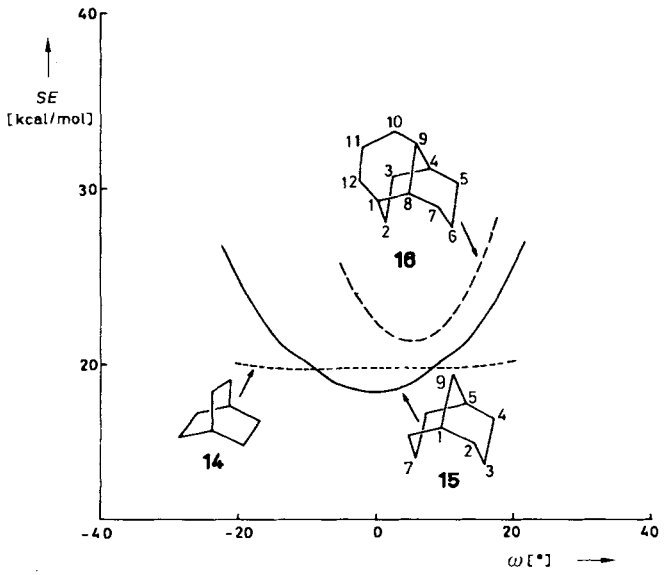


Fig. 2. Strain energies (*SE*) of bicyclo[2.2.2]octane **14**, bicyclo[3.2.1]nonane **15** and tricyclo[6.4.0.0$^{4,9}$]dodecane **16** [49] as a function of torsion angle $\omega$.

Table 4. Enthalpies of formation ($\Delta H_f^0$) and strain energies (*SE*) of optimized structures of some low-energy pentacycloundecanes, calculated using the Engler force field.

| | $\Delta H_f^0$ [kcal/mol] | *SE* [kcal/mol] |
|---|---|---|
| **20** | 9.38 | 42.05 |
| | 18.82 | 51.49 |
| | 19.62 | 52.29 |
| | 23.88 | 56.55 |
| | 32.46 | 65.13 |
| | 30.80 | 63.47 |

structure **20**, that has neither three- nor four-membered rings. To be on the safe side, calculations using MM-methods were performed on five isomers with one cyclobutane unit. Table 4 shows $D_3$-trishomocubane **20** to be far and away the most stable. Thermodynamic isomerization of appropriate precursors with $AlBr_3$ gives a single product (86% yield, Fig. 3)[59], whose structure was later confirmed by X-ray diffraction[60]. Since the number of possible isomers increases exponentially with the size of the molecules,

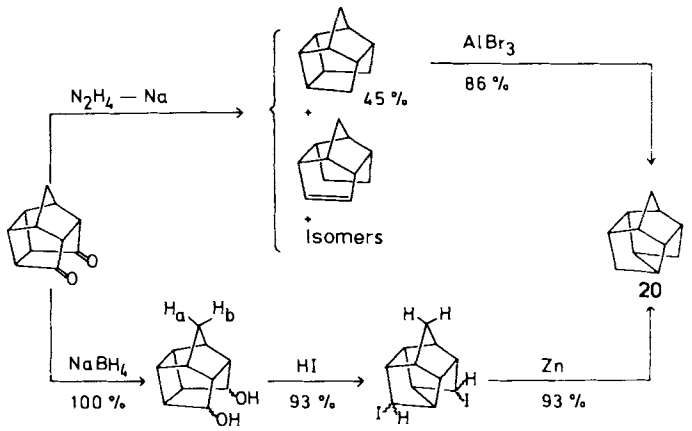

Fig. 3. Synthetic routes to $D_3$-trishomocubane **20**.

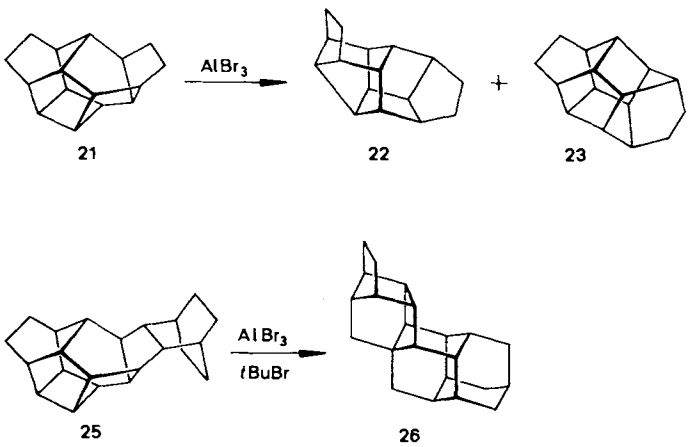
such an approach becomes more difficult with increasing number of C-atoms. Furthermore, a number of local minima having almost the same energy may exist on the energy hypersurface of the products[58]. For example, the thermodynamic rearrangement of the heptacyclic $C_{16}$-hydrocarbon **21** yields two novel cage compounds **22** and **23**, but calculations indicate that both should be less stable than bisnortriamantane **24**[24] (Fig. 4).



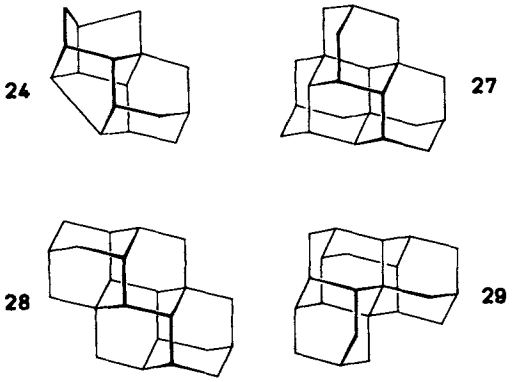


Fig. 4. Examples of rearrangements which do not lead to the most stable isomer under conditions of thermodynamic control.

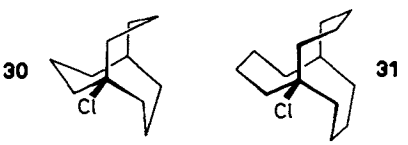
Another notable example of such local minima is the isolation of bastardane **26** in the rearrangement of the nonacyclic $C_{22}$-precursor **25**, instead of the expected tetramantanes **27**—**29**[24,61,62].

## 5. Reactivity Problems

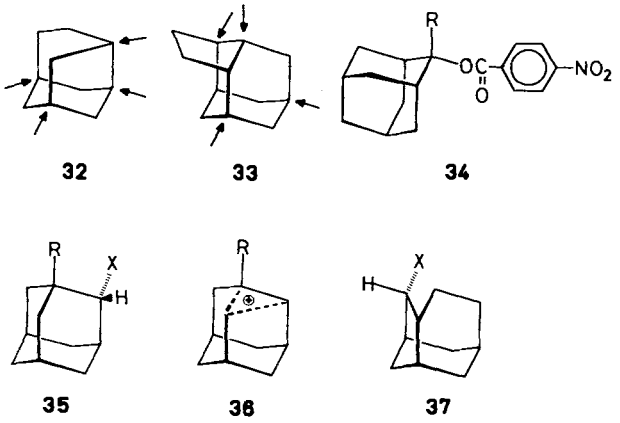
In order to gain insight into chemical reactions from calculations it is necessary to probe the multidimensional potential surface near the transition state region as precisely as possible for troughs, corresponding to stable products, and defiles in which the molecule can be transformed from a labile state into a stable product[63]. In this respect, MM techniques are perfectly suited if the energy is calculated point by point for fixed geometrical parameters.



### 5.1. Solvolysis

With the strong preference of carbenium ions to adopt a planar configuration of the ligands attached to the C atom it is possible to estimate the difference in strain ($\Delta_{st}$) between the strain energy (SE) of the cation and that of the hydrocarbon (HC) [eq. (b)].

$$\Delta_{st} = SE_{cation} - SE_{HC} \quad \text{(b)}$$



$$\log k = \alpha \cdot \Delta_{st} + b \quad \text{(c)}$$

The logarithm of the rate constant $k$ is proportional to $\Delta_{st}$ [eq. (c)], and rates varying over a range of more than $10^{18}$ have been found to conform to equations of type (b) and (c)[64]. The 1-manxyl cation is calculated to have a negative $\Delta_{st}$ value due to the presence of three medium-sized rings in the molecule. In the next higher homolog the $\Delta_{st}$ value should be more negative. 1-Chloromanxane **30** indeed solvolyzes $10^4$ times faster than t-butyl chloride, and the unknown homolog **31** is predicted to be $10^9$ times more reactive ($\Delta_{st} = -21$ kcal/mol)[65].

This method also proved to be capable of explaining the different reactivity in carbenium ion reactions at the bridgehead positions marked with an arrow in protoadamantane **32**[66] or ethanoadamantane **33**[67]. This theory explains the increase in solvolysis rates of adamantane derivatives **34**[68,69] and **35**[70,71] with variation of R(H, $CH_3$, $C_2H_5$, $i$-$C_3H_7$, $t$-$C_4H_9$) neither in terms of anchimeric nor solvation assistance, but predominantly by steric effects[71];

nonclassical ions, such as **36** are not involved[70]. *Smith* and *Harris*[72] have shown the Engler II force field to be useful for explaining the solvolytic behavior of protoadamantane derivatives **37**.

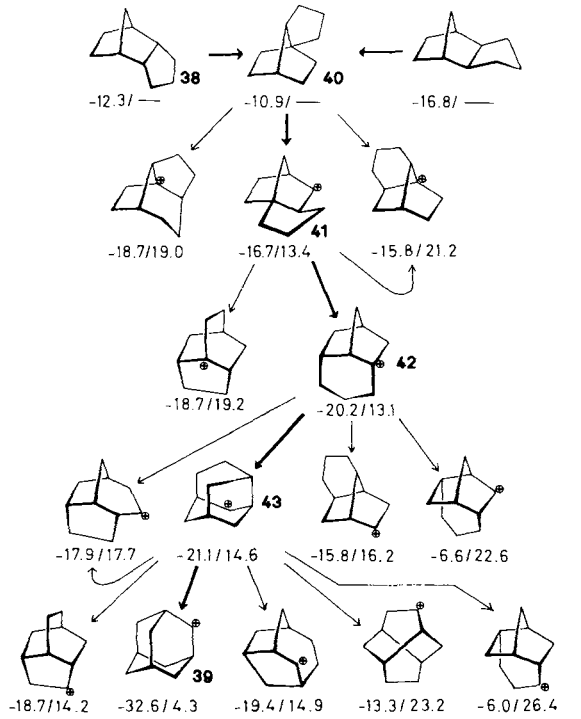
### 5.2. Mechanism of Multistep Carbenium Ion Rearrangements

The Engler I cation force field (Table 5) has been used to elucidate the reaction path along which adamantane is formed from perhydrodicyclopentadiene **38**. The strategy is to calculate the enthalpies of formation of all the carbenium ions resulting from every 1,2-alkyl shift of an intermediate and then to look for the reaction path of lowest energy leading from intermediate **38** to **39** (Fig. 5).



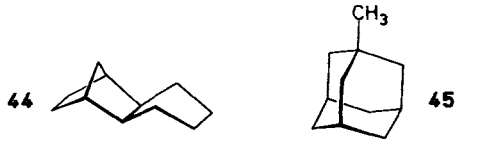


Fig. 5. The most probable pathway for the rearrangement of *endo*-perhydrodicyclopentadiene **38** to adamantane. Enthalpies of formation and activation energies [kcal/mol], calculated using the Engler force field (Table 5), are given below the structural formulas.

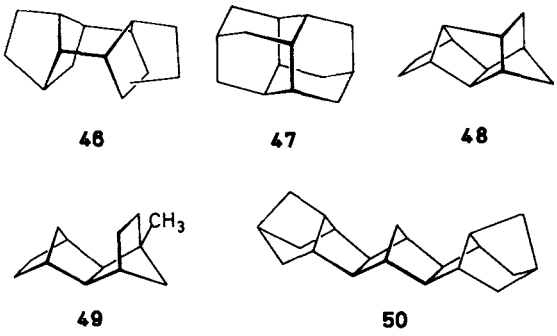
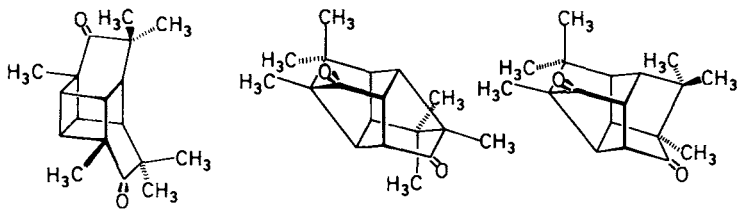
The first shift of an alkyl substituent **38** → **40** must be rate determining since it has never been possible to detect any intermediates. Starting from **41**, however, first **42** and then **43** have been established as intermediates[73,74].



The same result is found when instead of the stability of the cations that of the neutral hydrocarbons is compared. In this way, calculations have been carried out on all 69 tricycloundecanes and from the order of enthalpies of formation it has been shown that the rearrangement of the tricycloundecane **44** to form methyladamantane **45** proceeds on an energy surface with several shallow minima around the deep energy hole of the product **45**; several pathways seem to be possible. About two dozen intermediates could be detected. The most reasonable route involves eight intermediates, six of which have in fact been isolated[75].

**44** **45**

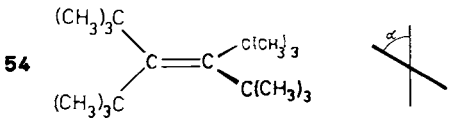
This method has also proved useful for determining the stabilomers of tetracycloundecanes[76], -dodecanes[67,77], -tri- and -tetradecanes[78], as well as of pentacyclotetradecanes[79]. Only five 1,2-alkyl shifts are needed in the rearrangement of tetrahydrobinor S **46** into diamantane **47**:



Correspondingly, the yield (80%) is very high[80,81]. Recently, a general program for describing such isomerizations was presented which confirmed the most favorable path from **46** to **47**[82], and proved to be useful in such complicated systems as **21**→**22**+**23**[24] and heptacyclooctadecane→triamantane[83].

**46** **47** **48** **49** **50**

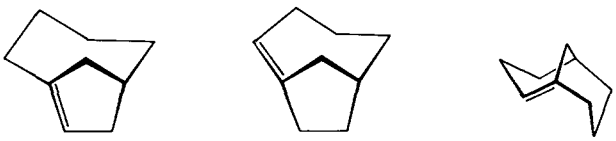
There are polycyclic hydrocarbons, however, built up from norbornane units like **48**[67,77], **49**[78], and **50**[84], which only undergo degenerate interconversions, and from which no single interesting product could be isolated. MM calculations indicate that in these molecules the routes leading to the stabilomers are blocked by exceedingly strained intermediates.



The acid catalyzed isomerization of the polycyclic ketone **51** to give **52**[85] provides another example where MM calculations give a plausible explanation why the energetically favored isomer **53** is not formed, and that no favorable pathway for the establisment of an equilibrium exists between **52** and **53**[86].

**51** **52** **53**

### 5.3. Bredt's Rule



In recent years considerable effort has been invested in the synthesis of "anti-Bredt olefins"—bicyclic bridgehead olefins which contradict Bredt's rule; attempts have also been made to prepare distorted olefins, such as tetra *t*-butyl ethylene **54** in which, due to steric hindrance, a planar arrangement of all the substituents is not possible. Several

**54**

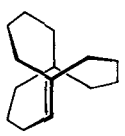
revisions of Bredt's rule have been proposed but none of them have survived. The failure of previous theories can be attributed to their inability to separate the strain of the double bond from the residual strain associated with the carbon skeleton.

*Burkert* pointed out in 1977 that a bridgehead olefin with the double bond in the smaller ring can be more stable than the isomer with the double bond in the larger ring *e.g.* **55** is more stable than **56**[87]. Experimental enthalpies of hydrogenation measured recently by *Roth* and *Lennartz*[88] come very close to the calculated values as shown in Table 6 for **55**, **56** and **57**.

**55** **56** **57**

Table 6. Experimental and calculated heats of hydrogenation of the bicyclo [4.2.1]nonenes **55** and **56**, as well as of bicyclo [3.3.1]non-1(2)-ene **57**.

| | Heat of hydrogenation [kcal/mol] | | |
|---|---|---|---|
| | **55** | **56** | **57** |
| exp. [88] | 36.3 | 42.0 | 37.9 |
| calc. [87, 89] | 39.0 | 54.1 | 47.3 |
| calc. [90] | 35.2 | 40.2 | 39.1 |



*Ermer*[89] has estimated the energy of deformation for double bonds ($V_{oop}$) in many nonplanar compounds. He came to the conclusion that $V_{oop} < 15$ kcal/mol represents the limit for the criterion "stable at room temperature". *Schleyer et al.*[90a] defined olefinic strain (*OS*) as the difference between the total strain energy of the bridgehead olefin *SE*(olefin) and that of the saturated hydrocarbon *SE*(HC), each being in its most stable conformation [eq. (d)].

$$OS = SE(\text{olefin}) - SE(\text{HC}) \qquad \text{(d)}$$

The *OS* values have been calculated with the Allinger MMI-force field[10e,12] for approximately 80 compounds. Comparison with the chemical stability leads to the following rule:

> Compounds with $OS \leqslant 17$ kcal/mol can be isolated, those with $OS = 17-21$ kcal/mol can be detected, possibly at very low temperatures, and those with $OS \geqslant 21$ kcal/mol are unstable and not directly detectable.

In this respect the extremely unstable (*E*)-bicyclo[3.3.1]non-1-ene[90b] ($OS = 44.2$ kcal/mol) should be mentioned; the (*Z*)-isomer **57** (concerning the cyclohexane ring) has been isolated. These rules have had no exception to date. Bicyclo[4.4.4]tetradec-1-ene **58** even has a negative

**58**

*OS* value (−14 kcal/mol), and should, therefore, be a particularly stable anti-Bredt olefin[90a]. The first member of this type of hyperstable bridgehead olefin, bicyclo[4.4.2]dodec-1-ene, was recently synthesized by *de Meijere et al.*[101a].

What we can do to make unstable bridgehead olefins isolable? *Ermer*[89] suggests first using bulky substituents in

close proximity to the strained double bond, an old trick, but his second proposal is quite interesting and new: installation of a second bridge in order to relieve the strain at the double bond ($V_{oop}$ or *OS*) and hence to increase the strain in the remaining molecular framework.

Calculations have been made on twisted olefins of type **54** by *Ermer* and *Lifson*[91]. In spite of numerous attempts, **54** has still not been detected; according to calculations this has an twist angle $\alpha$ of 82°[91]. With a modified twist potential ($V_{oop}$=23 kcal/mol) an angle of 43° is obtained[9]; *Lenoir et al.*[92] and *Simonetta et al.*[93] predict this angle to be 45°. It is time to solve this descrepancy experimentally.

### 5.4. Hydrogenolysis of Strained Hydrocarbons

Normal C—C bonds do not undergo catalytic hydrogenation on Pd, Pt or Ni catalysts at atmospheric pressure and room temperature. Principally, cyclopropane but also cyclobutane derivatives can be opened hydrogenolytically relatively easily because of the high angle strain. In particular, when small rings are incorporated into a strained cage structure they are rapidly hydrogenated under mild conditions. Although there are often several possibilities for which bond is opened first, there are cases in which specifically one product is formed, *e.g.* in the hydrogenation of cubane **59**[94], basketane **60**[95,96], snoutane **61**[96,97], deltacyclane **62**[96-98] (Fig. 6) or barettane **64**[101b].

However, there are other examples, such as triasterane **4**[99] and homocubane **63**[100] (Fig. 6), as well as diademane **65**[101c] and others[101d] in which several of the possible products are formed. Whether only one or several products are formed depends on the following factors: In the small ring compound the longest and most strained bond is

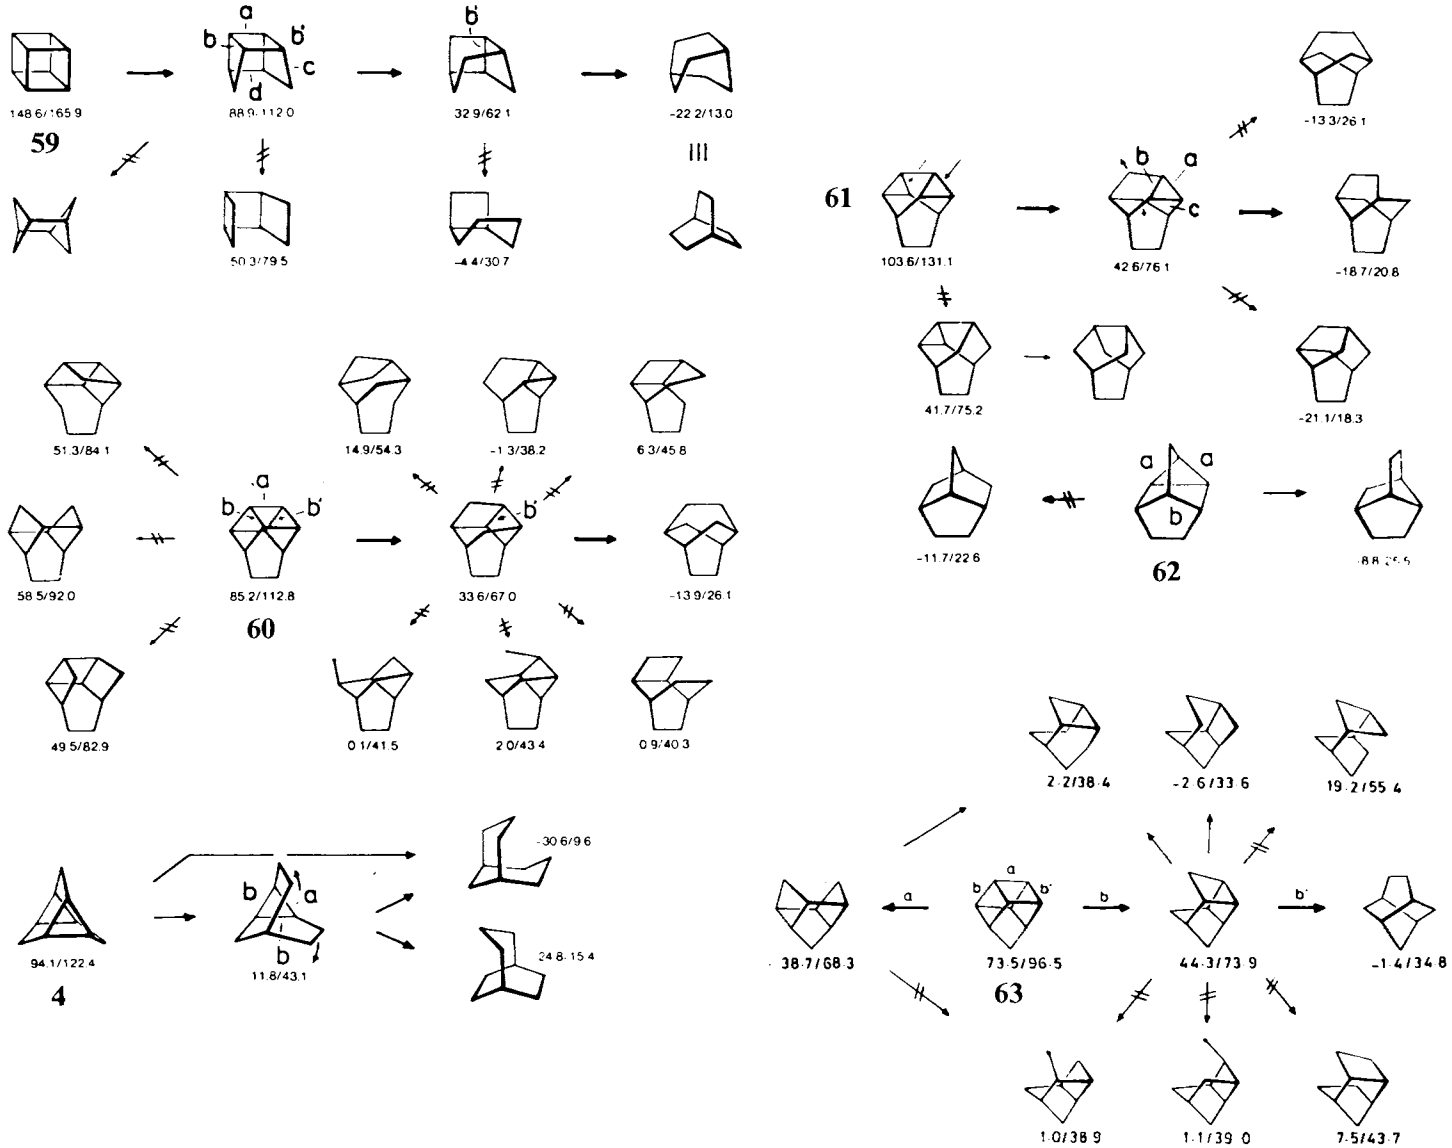


Fig. 6. Catalytic hydrogenation of strained cage hydrocarbons: cubane **59**, basketane **60**, snoutane **61**, deltacyclane **62**, triasterane **4**, and homocubane **63**. The enthalpies of formation and strain energies [kcal/mol] given below the compounds were calculated using the Engler force field [11].

opened first. On the other hand cleavage of the bond which gives most relief of strain during hydrogenolysis should be preferred. If both factors coincide, the reaction gives a specific product. If however, the bonds in the small ring differ by too little or the energy differences of two routes differ by less than 10 kcal/mol, two or more products may be formed. MM calculations are particularly suitable for explaining these correlations: not only the difference in total strain energies between the educt and all the products is given with high accuracy but also the bond lengths and angles (with the separate energy contributions for each bond). In the hydrogenation of the dihydrosnoutane ester **66** (Fig. 7), only bond *a* is opened. That the calculation correctly reproduces the bond length order has been confirmed by X-ray structural analysis[97].

**66**

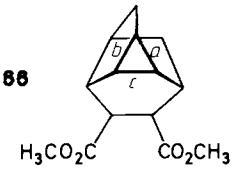

Fig. 7. Bond lengths Å in dimethyl dihydrosnoutanedicarboxylate; calc. $a = 1.538$, $b = 1.515$, $c = 1.530$; found $a = 1.516$, $b = 1.505$, $c = 1.507$.

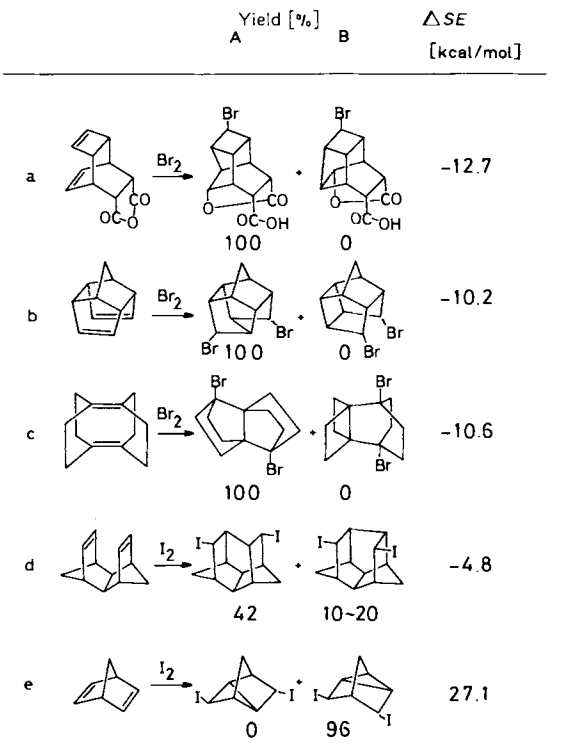

Fig. 8. Formation of C—C bridges in the electrophilic addition of halogens to compounds having double bonds facing each other; the difference in strain energy determines whether the "crossed" or "parallel" product is formed. Calculated using the Engler force field for (a), (b), (d), and (e) [102], as well as using the MM2 force field for (c) [103].

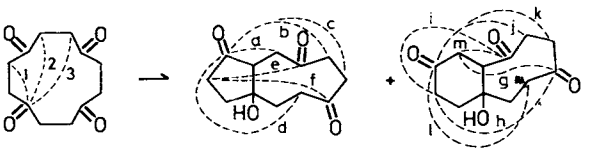
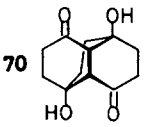
### 5.5. Late Transition States



Although hydrogenations are not reversible and the products are not in equilibrium on the catalyst, the products are often formed according to their thermodynamic stabilities. The transition states resemble the product, and hence occur "late" on the reaction coordinate. The same principle is valid for electrophilic additions to parallel double bonds.

In reactions a—c and e, respectively, (Fig. 8) the "cross" (A) or "parallel" products (B) are formed exclusively, since the observed products are calculated to be stable by more than 10 kcal/mol than the others. Except for example d, where the difference in strain $\Delta SE = SE(A) - SE(B)$ is only −4.8 kcal/mol, both products can be detected[104, 105].



### 5.6. Product Distribution

One of the best applications of the MM method is undoubtedly the calculation of the composition of equilibrium mixtures. Even for closely related structures the relative energies and amount of products should be calculable with high degree of confidence, *e.g.* the adamantoid structures in Table 7[106–108].

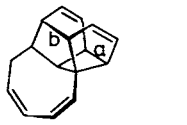
Of the many recent examples[7, 8] only one is presented here in detail. The acid-catalyzed cyclization of cyclododecatetraone **67** proceeds *via* the bicyclo compound **69** to give the dioldione **70** as the sole product[48]. A completely different product was initially expected, at least in low yield. In view of numerous possibilities for intramolecular aldol-type condensations, shown in formulas **68** and **69** by dotted lines, MM calculation of enthalpies of formation of all the possible tricyclic products clearly demonstrate that **70** is stable by more than 16 kcal/mol than the other isomers. This energy difference explains why only **70** was isolated as the main product.

**67** **68** **69**

**70**

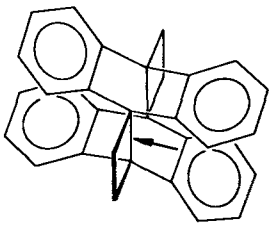
## 6. Electronic Effects and Long Bonds

When C—C bonds are stretched by bulky groups, *e.g.* in highly substituted ethane derivatives, these bonds are always reproduced well by MM calculations[14]; one of the most recent examples is the central C—C bond in pentaphenylethane which has been calculated to lie in the range 1.58—1.60 Å compared to the observed value of 1.61 Å[118].



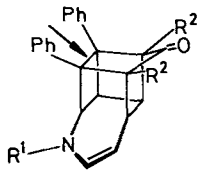
MM methods were unable to reproduce the long bonds correctly in compounds like **71**—**74** (Table 8); some other electronic effect must, therefore, be operating. *Mislow et al.* suggested the "through-bond" coupling of π-orbitals to explain this disagreement, *e.g.* in lepidopterene **74** X-ray

Table 7. Calculated and experimental equilibrium parameters for the isomerization of some adamantanoid systems [a].

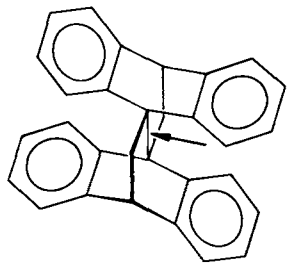


| Isomerization | | $G$ (298) [kcal/mol] | $H$ [b] [kcal/mol] | $S$ [cal/mol·K] | Ref. |
|---|---|---|---|---|---|
| 2-Methyl- ⇌ 1-Methyladamantane | exp. | −2.47 ± 0.19 | −2.6 ± 0.11 | −3.0 ± 0.3 | [106] |
| | calc. | −2.52 | −1.9 | −2.1 | |
| 1-Methyl- ⇌ 4-Methyldiamantane | exp. | −1.88 [c] | −2.14 ± 0.2 | −1.19 ± 0.3 | [107] |
| | calc. | −2.12 [c] | −2.2 | −2.18 | |
| 1,1′-Bi- ⇌ 2,2′-Biadamantane | exp. | −0.51 ± 0.21 | −0.33 ± 0.12 | 5.4 ± 0.3 | [108] |
| | calc. | −0.48 | −0.34 | 5.3 | |

[a] Using the Engler force field [10b, 11]. [b] Corrected for the differences in substitution type. [c] 433 K.



structural analysis gives a value of 1.64 Å, whereas calculation yields 1.57 Å. The bond in question is surrounded by four parallel π-orbitals[110]. Recently it was found, that such elongation of a σ-bond is most effective if this bond is mechanically strained by the molecular framework as in **71**, **72** and **73**[111].



**71**

**72**

**73**, $R^1 = CO_2C_2H_5$, $R^2 = CO_2CH_3$

**74**

Table 8. Long bonds (indicated by an arrow or a/b in the formulas) in cyclobutanes arising from "through-bond" interaction with vicinal π-systems.

| Comp. | | C—C Bond lengths [Å] Exp. [a] | Calc. | Ref. |
|---|---|---|---|---|
| **71** | a | 1.617 ± 0.003 | 1.551 [b] | [109] |
| | b [c] | 1.578 ± 0.003 | 1.547 [b] | |
| **72** | | 1.77 ± 0.01 | 1.574 [b] | [110] |
| **73** | | 1.657 ± 0.005 [d] | 1.565 [e] | [111] |
| | | | 1.643 [f] | |

[a] From X-ray structure analysis. [b] MM2. [c] This is not the cyclobutane bond, but is rather a bond given for purposes of comparison in order to indicate the lengthening of a non-strained bond by π-coupling. [d] $R^1 = COOC_2H_5$, $R^2 = COOCH_3$. [e] MMPI, $R^1 = C_{sp^2}$—H, $R^2 = COOCH_3$. [f] MNDO, $R^1 = CHO$, $R^2 = H$.

## 7. Prospects

The increasingly ready access to fast computers will stimulate the application of all theoretical methods. The superiority of MM methods will still persist for medium to large molecules: In the meantime convincing evidence on larger molecules has accumulated, where the high precision of MM calculations has been confirmed by X-ray structural analysis. In order to optimize computer time there is a need for a data base of accurate structural information for the gas phase. Since most of these data have been obtained from X-ray diffraction results on crystals[112], it is now time to establish a basis set independent of crystal lattice and packing effects[113].

Force fields for hydrocarbons are very accurate indeed, but developments in the future will still be directed to continuously improving these. Much more important is the introduction of parameters for heteroatoms like oxygen[114], nitrogen, silicon[115], halogens[116], and sulfur, as well as force fields for functional groups[7] like ethers, carbonyl and azo groups[117]. In consequence, the programs as well as the computer times will become larger. In future we shall have to put effort into simplifying the problems to be handled by MM-methods to analogs of the simplest hydrocarbon structures possible.

*Professor Paul von R. Schleyer has contributed with many helpful discussions. We would like to thank the Alexander von Humboldt-Foundation (Bonn) and Kureha Chemical Industries AG for financial support of our own research in this field described here. Computer time has been provided by the Rechenzentrum der Universität Karlsruhe, and by both the Hokkaido University and the Institute for Molecular Sciences.*

# Synthetic Gene Fragments in Genetic Engineering— The Renaissance of Chemistry in Molecular Biology**

**By Julian E. Davies* and Hans Günter Gassen**

Chemistry and biology paved the way for a new scientific discipline, molecular genetics. The breathtaking progress in deciphering the genetic machinery of a living being within the last 20 years may be attributed mainly to the experimental skill and ingenuity of molecular biologists. Chemists lost interest in the investigation of biological problems. The advances in genetic engineering exemplify the new demands chemists are confronted with in contemporary science. Following a short introduction on the genetics of bacteria, the article deals with the molecular basis of gene cloning, which is subdivided into *in vitro* recombination of nucleic acids and *in vivo* transformation of cells. Next, the criteria for the selection of passenger DNA, vectors, and host cells are discussed. Recombination and transformation are easy-to-learn experimental techniques, whereas the search for the positive clone requires detailed knowledge of microbiology and the ability to handle of a battery of modern biochemical techniques. Finally, the automated chemical synthesis of gene fragments serves to demonstrate that chemistry is starting to make its comeback into molecular biology.

## 1. Introduction[***]

In the last 100 years synthetic chemistry has produced about 6 million different compounds, which are either reproductions of natural substances or are chemicals which previously did not exist on earth. The synthetic world built up by organic chemists within such a short time period deserves recognition.

A bacterium such as *Escherichia coli* reproduces in 20 minutes under optimal growth conditions. In other words a complete new living being is assembled within a third of an hour. Table 1 lists the main components that must be synthesized during this period of time. If we focus our attention on only two classes of biomolecules, deoxyribonucleic acid (DNA) and the proteins, the synthetic ingenuity of a living cell is clearly demonstrated. The length of the *E. coli* genome is about 1–2 μm, and its molecular weight is $2.4 \times 10^9$. Its DNA contains approximately $4 \times 10^6$ nucleotide pairs, consisting of four different bases, which are linked in an identical manner by the phosphate-ribose backbone. The sequence of the nucleotide pairs has to be an exact replica of the parental genome. Even one incorrectly placed base pair may be lethal for the cell.

Furthermore, *E. coli* must produce about 3500 different proteins within 20 minutes. The larger ones, such as the fatty acid synthetase complex, have a molecular weight of *ca.* $3 \times 10^6$ and contain about 25000 amino acids, which are determined by the nucleotide sequence of the DNA. All proteins must adopt a unique tertiary structure in order to fulfill their function within the bacterium. Cells not only have the capacity to produce these compounds (Table 1), but the amounts of each individual substance produced are strictly regulated according to an exact time plan.

Table 1. Molecular compounds of an *E. coli* bacterium. *E. coli* can be grown in a medium containing only glucose as carbon and energy source. The rest of the culture medium consists of inorganic salts; oxygen is introduced by intensive aeration.

| Compounds | Percentage of total weight | Approximate number of molecular species |
|---|---|---|
| Water | 70 | 1 |
| Proteins | 15 | 3500 |
| DNA | 1 | 1 |
| RNA | 6 | 1000 |
| Polysaccharides | 3 | 50 |
| Lipids | 2 | 20 |
| Intermediates [a] | 2 | 500 |
| Inorganic ions | 1 | 12 |

[a] Intermediates are compounds such as coenzymes or dicarboxylic acids.

Compared with the synthetic capacity of a simple microorganism, today's synthetic organic chemistry is still in the Stone Age. However, one should appreciate the fact that bacteria had *ca.* $3.5 \times 10^9$ years to optimize their synthetic procedures.

In the future, organic chemists may adapt their strategies to use biological pathways in order to avoid high temperatures and pressures and the production of toxic waste substances. Chemists have to learn to use substrate-specific, high turnover-number catalysts such as enzymes and highly reactive, but specific, substrates such as coenzymes. There is still a long way to go, but some encouraging improvements have been made in the synthesis of stereospecific compounds. As a temporary solution to synthetic problems one may alter the synthetic capacity of a living cell by manipulating its genetic program; this process is called genetic engineering.

[**] Based on an introductory lecture delivered by J. E. Davies at the EMBO-Workshop "Prospects of Automation in Gene Synthesis" March 27, 1982 in Darmstadt (see also [100]).

[***] A glossary of genetic terms can be found in *Science 209* (1980) 1435, Lehninger: *Principles of Biochemistry*, Worth Publishers, New York 1982, p. 969, and R. C. King: *A Dictionary of Genetics*. Oxford University Press, New York 1974.

In the following article we use the recent progress in genetic engineering to demonstrate the decline and the advance, as well as the prospects of chemistry in modern biology.

## 2. Both Chemistry and Biology Contributed to Molecular Biology

The deciphering of the genetic apparatus of a living cell actually started with the chemistry of nucleic acids, when in 1859 *Friedrich Miescher* isolated nucleic acids[1]. Only six years later *Gregor Mendel* reported on his experiments with hybrid plants at the Naturforschende Verein in Brünn, and so the genetic approach started[2]. Over the next 50 years many chemists such as *Alfred Kossel, Emil Fischer,* and *Wilhelm Traube* concentrated on the chemistry of nucleic acid components, particularly the bases[3]. Around 1930 *Levene et al.* obtained deoxynucleosides by the enzymatic degradation of DNA and identified deoxyribose as a constituent of DNA[4]. By 1950 the field of nucleic acid chemistry was beginning to enter the stage of maturity. Major contributions came from *Todd, Fox* and *Griffith,* and from *Chargaff*[5]; the linkage and the linearity of the nucleic acid strand were determined. Finally *Watson* and *Crick* formulated the concept of a right-handed double helix, in which the complementary base pairs form the interior of the helix, whereas the ribose-phosphodiester chain is directed outwards (see Fig. 2)[6, 7]. The diameter of the helix is constant, since one base pair always consists of a small pyrimidine and a large purine base. The base pairs are stabilized by formation of two or three hydrogen bonds. Molecular biologists usually specify the molecular weight of DNA in terms of base pairs (bp) or kilo base pairs (kbp). More correctly these comprise a nucleotide pair, *i.e.* G : C or A : U, with a molecular weight of 660 and a "DNA length" of 0.34 nm. Since the manipulation of DNA almost always involves the nucleotide pairs, which only differ in their heterocyclic bases, the term base pair will be used here.

In the meantime numerous scientific techniques have become available for studies of nucleic acid chemistry[8]: paper and ion exchange chromatography, UV absorption spectroscopy, electrophoresis, sedimentation analysis, light scattering, viscosimetric studies, electron microscopy, X-ray diffraction techniques, and the use of radioactive isotopes. The application of each novel technique opened a new vista in nucleic acid chemistry. Soon nucleic acid chemistry became the cornerstone of the rapidly developing field of molecular biology.

The significance of nucleic acid chemistry is related to the role of nucleic acids as genetic material in the living cell. However, despite the work of *Miescher* and many others it took roughly 80 years before *Avery, MacLeod,* and *McCarthy* demonstrated the relationship between DNA and genetics in 1944. They showed that DNA was the bacterial transforming factor, the carrier of hereditary information[9]. This function of the "nuclein" had been postulated previously by *Hartwig* and *Fol* when they examined the function and role of chromosomes. Their experiments led *Hartwig* to state "I believe that I have at least made it highly probable that "nuclein" is the substance that is responsible not only for fertilization but also for the transmission of hereditary characteristics"[10, 11].

Neither the ingenious and prophetic view of *Hartwig* nor the cause and effect experiment of *Avery* convinced the entire scientific community to accept the role of DNA as the hereditary material. Not until the classic experiment of *Hershey* and *Chase* in *1953,* in which the genetic substance of a bacteriophage was clearly shown to be the $^{32}P$-labeled DNA and not $^{35}S$-labeled protein, was the biological role of DNA ultimately accepted[12]. It was then that chemistry and genetics really came together to give us what we now know as molecular genetics or molecular biology.

Since then, the advances in nucleic acid chemistry and molecular genetics have been breathtaking. To name but a few: the mode of DNA replication, the establishment of the genetic code and the role of mRNA, tRNA, and ribosomes in protein synthesis and, last but not least, the chemical synthesis of genes such as tyrosine tRNA and interferon[13].

However, without wishing to be disrespectful to chemists, chemistry then became subordinate to biology, mainly because chemists lost interest in biological problems: a physicist, and not an organic chemist, worked out one of the methods of DNA sequencing. The majority of chemists were not sufficiently interested in DNA chemistry to want to find out how to develop methods for the specific cleavage of phosphodiester bonds in DNA[14]. *Walter Gilbert* sharded the Nobel prize for this development, and DNA sequencing became one of the essential prerequisites of genetic engineering[15].

## 3. The Genetics of a Bacterial Cell

What follows is a short outline of the genetic machinery of a cell which helps to explain the basis of genetic engineering[16]. We will restrict ourselves mainly to prokaryotic organisms since the basic genetic principles are similar in both prokaryotes and eukaryotes. In particular, we will concentrate mainly on one species of bacteria, *Escherichia coli,* which was discovered by the German microbiologist *Escherich.* It is an organism whose major habitat is the lower part of the intestine of warm blooded animals. Things have changed a little bit since then. Nowadays the natural habitat of *E. coli* is a molecular biology laboratory! This small bacterium (1 μm × 2 μm) has played a tremendous role in the development of molecular biology in the research laboratory.

The DNA-encoded protein synthesizing machinery of *E. coli* is shown in Figure 1. Nearly all of the genetic information is stored in a large circular DNA molecule (the genome or the chromosome) which contains about 3500 genes programming protein and RNA syntheses. One unit of information on the DNA is called an operon[17]. It consist of a regulatory region, operator and promoter, and one or more structural genes. A structural gene is a small segment of DNA containing the information for the synthesis of an RNA or a protein (Fig. 2). Frequently the enzymes required for a synthetic pathway, such as the four enzymes

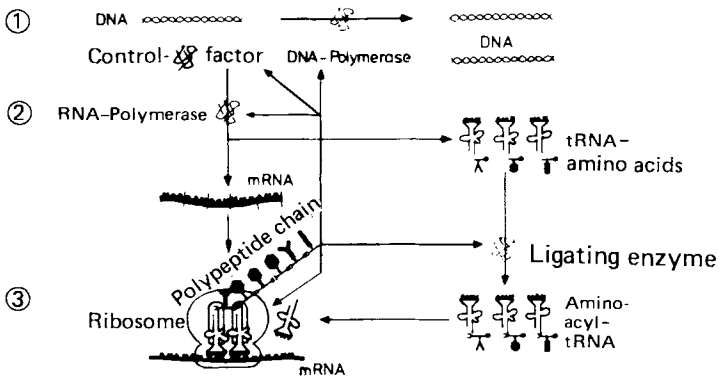

Fig. 1. Flow of information from deoxyribonucleic acid (DNA) to polypeptide chains. The figure shows a highly simplified scheme for the DNA encoded, ribosome-dependent synthesis of proteins in three steps: replication ①, transcription ②, and translation ③. During replication the DNA is doubled with the aid of DNA polymerase and many other enzymes and factors. In transcription the DNA is copied into three types of single stranded RNAs; the messenger (mRNA) as the matrix of genetic information, the ribosomal RNA (rRNA) as building blocks for ribosomes and the transfer RNA (tRNA) as carrier molecules for the amino acids. These are attached to the tRNAs with the aid of aminoacyl synthetases. Ribosomes translate the mRNA using aminoacyl-tRNAs as substrates into the genetically determined sequence of a protein.

involved in the synthesis of tryptophane, are located together on one operon to permit a coordinated regulation of the amounts of catalysts[18]. The promotor is the binding site for the DNA-dependent RNA polymerase, whereas

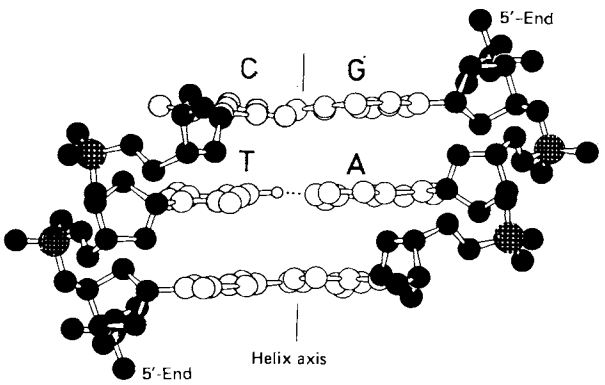

Fig. 2. Three base pair segment of DNA. The (3'→5' and 5'→3') ribose-phosphate chains are shown as solid circles and the P atoms are hatched. The heterocyclic bases adenine, cytosine, guanine, and thymine are almost at right angles to the axis of the helix. A and T, as well as G and C each form a base pair stabilized by two and three hydrogen bonds, respectively.

the operator represents the "on-off" switch for a single- or multi-structural gene (Fig. 3). If a repressor protein binds to the operator, the subsequent genes of an operon are switched off. The repressor can only be displaced from the DNA by a specific inducer—*e.g.* a metabolite. The mRNA is copied as an exact base-complementary replica from the structural part of the operon from one of the two DNA strands, the codogenic strand. As a "short-living" single strand ribonucleic acid, the mRNA delivers the program which in a translation step is deciphered by the ribosomes and transformed into an amino acid sequence, a protein[19]. The amount of protein can also be regulated in the transla-

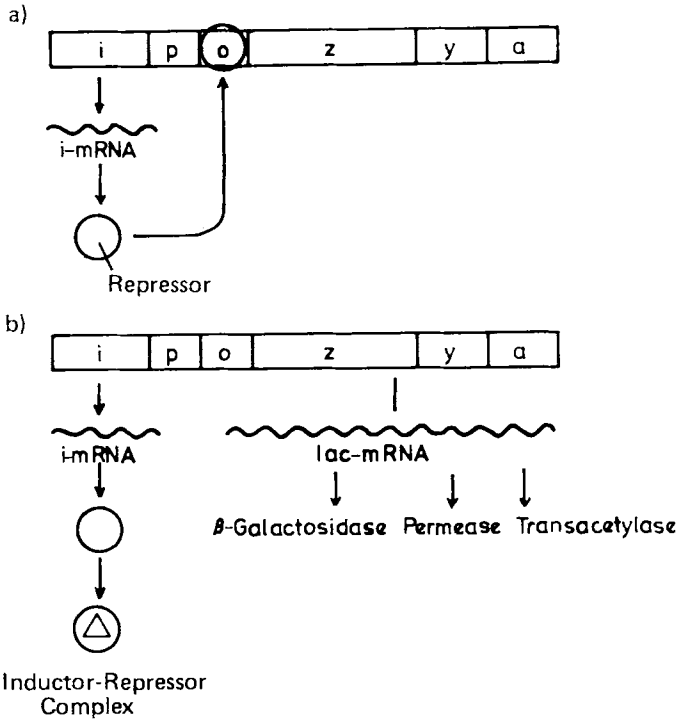

Fig. 3. The diagram shows the organization of the lactose operon (lac operon). The expression of the three enzymes β-galactosidase, permease, and transacetylase, which are necessary for the breakdown of lactose, is controlled by the regulative part of the operon. The promoter region (P), about 40 bp long, represents the binding site for the DNA-dependent RNA polymerase (transcribing enzyme). The operator (O) is the master switch for gene expression. The repressor protein, the product of the distant "i" gene, shuts off transcription. In lac operon the operator consists of 28 bp. The inductor, *e.g.* allolactose, inactivates the repressor. a) A repressor is synthesized which blocks the operator and hence prevents transcription of the structural genes (z, y, a). b) The repressor is deactivated by an inducer by forming an inductor-repressor complex; synthesis of the three enzymes proceeds normally.

tion step. At the 5'-end, the mRNA has a binding site for ribosomes, termed the Shine-Dalgarno sequence[20]. The affinity of this sequence for ribosomes is decisive in determining how often a particular mRNA is used as a program for protein synthesis. In eukaryotes, replication, *i.e.* the copying of the DNA before cell division, and transcription, proceed in the cell nucleus. The synthesis of mRNA is considerably more involved[21].

In 1944 it was discovered that *E. coli* enjoyed the benefit of sexual intercourse[22]; subsequently, sexual transfer mechanisms of bacteria were studied in some detail and in the late 1950's it was found that *E. coli* contained DNA elements that are independent of the central chromosome and that are capable of autonomous replication and expression[23,24]. The discovery of the fertility factor F (sex factor) as an independent autonomous piece of DNA was a crucial event with respect to what we now talk about as gene technology.

Although bacterial cells can exchange parts of their genetic material, unlike eukaryotic cells they do not form true zygotes. In the mating process (conjugation) DNA is transferred from the male bacteria or donor cell to the female bacteria or recipient cell. Male bacteria contain the sex factor, and are termed $F^+$. This small circular DNA, representing 2% of the total genetic material of *E. coli*, de-

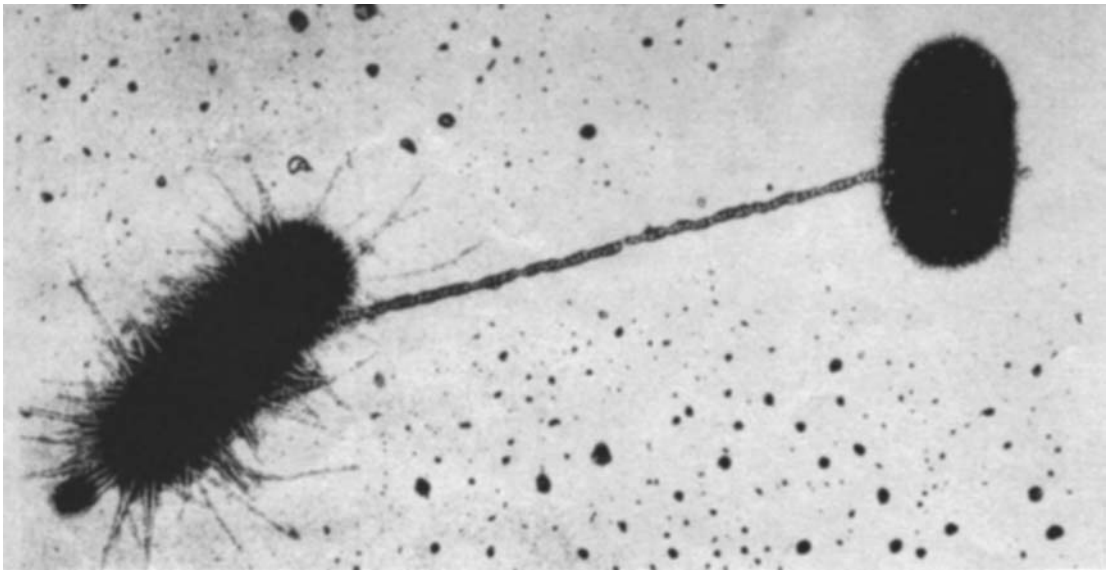

Fig. 4. Conjugation of bacteria. During this process a bridge is formed between the $F^+$ and the $F^-$ bacterium (donor and acceptor, resp.). By a reaction called conjugation DNA can be transferred from donor to acceptor.

termines the sex of a bacterium. A similar DNA molecule, the so-called Hfr-factor (high frequency of recombination) follows integration of the F factor into the chromosome and allows the transfer of the entire chromosome from one cell to the other (Fig. 4).

Shortly after the discovery of sex factors came the finding that bacteria may contain resistance transfer factors (R-factors), which are similar small circular DNA molecules containing the genetic determinants which make bacteria resistant to antibiotics or colicin[25]. These R-factors were first discovered in *Shigella dysenteriae* during an outbreak of dysentery in Japan in 1959. Shigella strains isolated from patients undergoing chemotherapy were found to be simultaneously resistant to four drugs: streptomycin, chloramphenicol, tetracycline, and sulfonamides[26]. When cells of a multiply-resistant strain were mixed with a sensitive strain, multiple resistance was found to be transferred at high frequency to the sensitive recipient. Later it was discovered that all four resistance genes were located on a circular DNA, called a self-transferable plasmid. This demonstrated two important facts, namely that extrachromosomal DNA elements encode proteins and that they can be exchanged between cells[27].

Another equally important event was the discovery of the bacteriophage λ by *Lederberg et al.* in 1951[28]. This phage (49 kbp) may exist as either circular or linear double

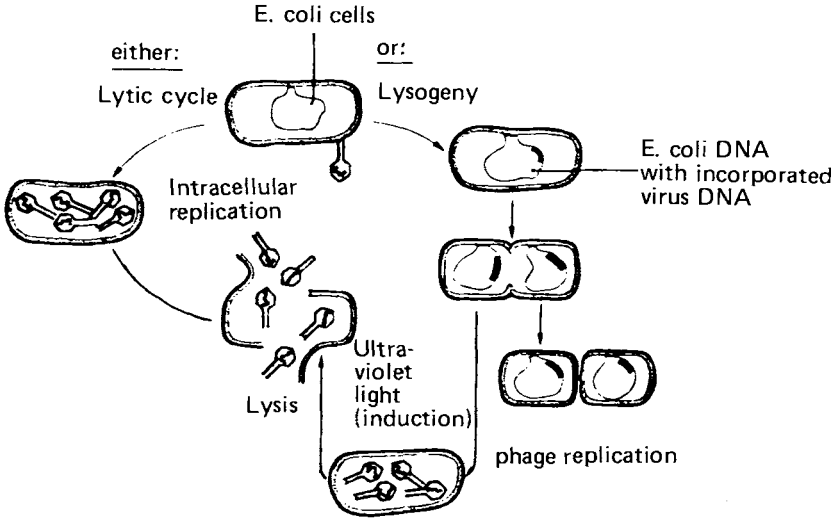

Fig. 5. Lytic and lysogenic life cycle of the bacteriophage λ using *E. coli* as host cell. In the transition from lysogeny to virulence, λ-phages are able to transfer parts of the bacterial genome to other bacteria. Viruses of the λ-phage type are temperate phages, which after infection can either become virulent or remain temperate. The λ-DNA incorporated into the host DNA is termed prophage: cells having prophages in their genome are termed lysogenic bacteria. λ-Phages insert their gene specifically between the lactose and biotin genes (taken from P. Knippers: *Molekulare Genetik*, Thieme, Stuttgart 1981 with the kind permission of the author and publisher).

stranded DNA. In cells the phage DNA is incorporated into the genome of the host, the lysogenic pathway, and thus will replicate together with the bacterial genome. On induction, *e.g.* by UV irradiation, the phage DNA is released and replicates autonomously in a similar manner to a plasmid. After completion of the synthesis of DNA and envelope proteins to generate mature progeny, the phage will finally kill (lyse) its host. During the transition between lysogenic and lytic life cycles the phage may often carry along a piece of the bacterial genome. Genetic material may be transferred from one bacterium to another by phages in a process called transduction (Fig. 5)[29]. The phage λ inserts its DNA into a specific position of the host genome, whereas phages such as P22 insert nonspecifically.

The bacteriophage λ provided scientists working with *E. coli* with an excellent opportunity to carry out genetic manipulations. Over a period of some 15 years, when no *in vitro* recombination was possible, phage λ was used for *in vivo* recombination of genetic material; it provided a mechanism for the specific interbacterial transfer of genetic material. The ability to integrate into the host's chromosome, the ability to inactivate host genes by insertion, and to pick-up genes by directed transduction have been important aspects in the development of gene cloning.

Table 2. Molecular weight *MW* and contour length *l* of some organisms.

| Organism | *MW* [kbp] [a] | *l* [μm] |
|---|---|---|
| Polyoma or SV 40 virus | 5.1 | 1.8 |
| Phage-λ | 48.6 | 17 |
| *E. coli* | 4000 | 1360 |
| Yeast | 13500 | 4600 |
| *Drosophila* [b] | 165000 | 56000 |
| Human | 2900000 | 990000 |
| Plasmid pBR322 | 4.361 | 1.4 |

[a] 1 kbp ≙ 1000 × 660 Da = 660000 Da. 1 kbp represent $2.5 \times 10^{-4}$ of the E. coli genome, however, only $3.4 \times 10^{-7}$ of the human genome. *MW* and *l* of the human genome summarizes all 23 chromosomes and only represents a estimated number. [b] [b] *Drosophila* = fruit fly.

If we compare the molecular weight of the bacterial chromosome with that of F-factors, plasmids, and phages then these represent an insignificant part of the total cellular DNA (Table 2). However, these small molecules are highly significant in terms of the genotype and phenotype of the cell and for biotechnology and genetic engineering. Table 3 summarizes the methods we possess at present that enable the transfer of DNA between the cells of various microorganisms to be accomplished and also enable exchange between plasmid and genome and the converse (Fig. 6). These methods have been refined quite recently and a number of them are applicable to a wide variety of microorganisms other than *E. coli*. The important thing to realize is that we are now able to manipulate the program which guides the synthetic capacity of a cell.

Table 3. Methods used to exchange genetic material between cells.

| Method | Principle |
|---|---|
| Transformation | Introduction of exogenous DNA into a cell, causing it to aquire a new phenotype |
| Transduction | Transfer of genetic material from one cell to another by means of a viral vector |
| Transfection | Infection of cells with isolated viral DNA |
| Conjugation | The process by which DNA is transferred from an $F^+$ to an $F^-$ bacterium |
| Cell fusion | Integration of cell nuclei |

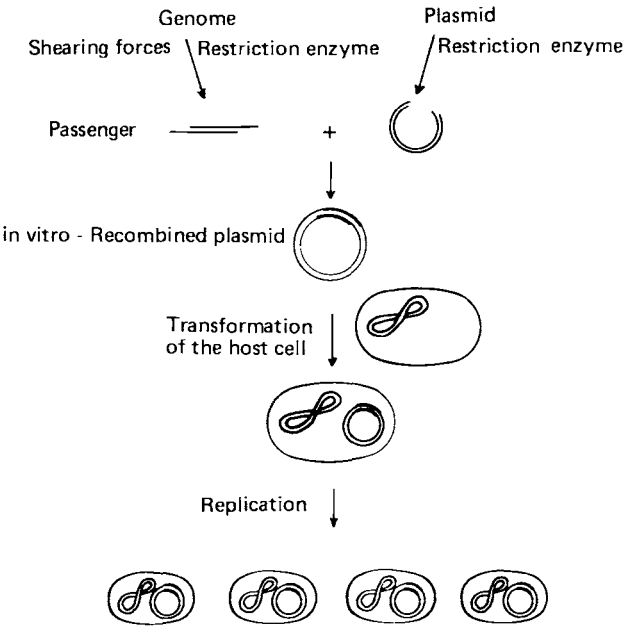

Fig. 6. Insertion of a passenger DNA into a vector. The plasmid can either be linearized by only one restriction endonuclease cut, or a stuffer fragment can be removed by two cuts. By the use of this procedure the size of the vector remains the same when the passenger is inserted.

The small circular DNAs such as F- and R-factors and phages have been used in many ingenious experiments for the manipulation of cellular DNA. They have enabled us to learn a considerable amount about gene structure, gene regulation, and gene expression. However, genetic engineering is not something molecular biologists have dreamed up. This kind of gene exchange between genomes and microorganisms has been taking place for a long time in nature using a variety of methods, often by-passing the guidelines required for *in vitro* recombinant DNA research in laboratories.

## 4. Principles of Genetic Engineering

The fascination of genetic engineering lies in the possibility of purifying and self-propagating a substance by transforming and cloning cells, *e.g.* bacteria[30-37]. By means of genetic engineering, it is possible to uniformly isolate mg quantities of a fragment present in a solution containing one fmol of a DNA fragment as 0.01‰ of a population, a mixture which appears to be completely hopeless to the chemist.

The "reprogramming" of life can therefore be considered as a novel branch of chemistry, which makes possible the self-reproduction of substances. In somewhat simplified terms genetic engineering can be divided into the following steps: 1) Isolation or synthesis of a gene or of a

DNA fragment; 2) Insertion of the fragment into a vector, usually a plasmid; 3) Channeling the vector into a cell, which accepts it as an additional piece of information; 4) Autonomous replication or integration into the host genome; 5) Expression of the foreign gene by the host machinery and hence synthesis of the corresponding RNA and proteins. In order to simplify matters in what follows we classify the first two steps as *in vitro* recombination, and all the others as *in vivo* transformation.

Finally the transformed cells must be reproduced at the expense of the native cells; for this purpose certain growth conditions are necessary, which enable only the transformed cells to replicate by division. When a colony or a clone has formed in a Petri plate, it is isolated in a second Petri plate in such a way that each contains approximately 50 colonies. In a subsequent screening test each clone must be checked whether it contains the desired DNA fragment or the protein as gene product. Frequently 20000 colonies have to be examined before a positive clone is found. A 1 mL liquid culture is first inoculated with this clone and an approximately 10 mL culture with the transformed bacterium is obtained by stepwise scale-up. Decisive in cloning is the screening step, the method of finding the correct positive clone as quickly as possible from 20000 colonies, followed by its selective reproduction.

Taken together, recombination and transformation are often loosely referred to as "cloning". However, cloning is really the process of cell reproduction starting from one original cell; in consequence, the cells produced (clones) contain only cells which are genotypically and phenotypically identical. Cloning diploid eukaryotes is more complex.

First of all let us consider a simple experiment. We remove a definite gene from the central genome, insert it into a plasmid, and reintroduce the modified plasmid into the cell. What advantage does this procedure offer? The *E. coli* chromosome contains $4 \times 10^6$ bp, and the average number of base pairs for one gene is 1150. Thus the central genome contains 3500 genes and one particular gene represents about 0.3% of the total genome. A plasmid contains on average $10^4$ bp. A gene incorporated into a plasmid may represent *ca.* 10% of the genome of the plasmid. Furthermore one can insert genes in tandem duplications on a plasmid, *i.e.* the plasmid may contain up to 10 copies of a single gene under the control of one regulatory unit. With so-called high-copy number plasmids the number per cell may be even further increased. If cells are treated with the antibiotic chloramphenicol, then the replication of the central chromosome is inhibited whereas the so-called Col-E1 plasmids (plasmids carrying the colicin production gene) replicate normally. The cell may turn into a sack full of plasmids with 100—200 plasmids per cell.

All the experimental tricks serve only one goal: to turn a microorganism into a factory for the preferential production of one particular gene (DNA segment) or protein in mg quantities from 1 L cultures.

## 5. The *in vitro* Recombination of Nucleic Acids

Reactions carried out on DNA outside the cell may be summarized as "cutting and splicing" procedures. The cutting of DNA serves two purposes: by cutting the large source genome into fragments of about 10—20 kbp one obtains an overlapping collection that contains all genes. This fragmentation can either be carried out by physical means (the 2 nm × 1.2 mm DNA thread is very sensitive to shearing forces) or by enzymatic hydrolysis with so-called restriction endonucleases (Table 4)[38-40]. These are DNA nucleases which recognize specific four, five, or six base pair sequences, which in double strand DNA have a twofold sequence symmetry (palindromes). They cut the DNA double strand leaving either flush (double stranded ends) or staggered ends (single stranded ends of two, three, or four nucleotides) (Table 4). With a four base pair specificity, a mean fragment length of 256 bp ($4^4$) is obtained, whilst with 6 bp the mean fragment size goes up to 4096 ($4^6$) bp. The perfect manipulation of *ca.* 200 currently known restriction endonucleases for the preparation of DNA fragments of surveyable chain length is a basic requirement for successful genetic engineering (Fig. 7).

Table 4. Origin, sequence type [a], recognition sequence, and average number of recognition sequences of a vector for prokaryotes, pBR322, and for eukaryotes, SV 40, for some of the approximately 200 known restriction endonucleases (restriction enzymes); approximately 50 of the enzymes are commercially available.

| Restriction endonuclease | Origin | Recognition sequenze | Sequence type [a] | Number of recognitions pBR322 | SV 40 |
|---|---|---|---|---|---|
| *Eco*RI | *Escherichia coli* RY13 | GAATCC | II | 1 | 1 |
| *Hind*III | *Haemophilus influenzae* | AAGCTT | II | 1 | 6 |
| *Hpa*II | *Haemophilus parainfluenza* | CCGG | II | 26 | 1 |
| *Pst*I | *Providencia stuartii* | CTGCAG | II | 1 | 2 |
| *Hae*III | *Haemophilus aegyptius* | GGCC | I | 22 | 19 |
| *Hpa*I | *Haemophilus parainfluenzae* | GTTAAC | I | | 4 |

[a] Sequence type I, *e.g.*

*Hae*III —GG|CC— ⇒ —GG + CC— double stranded
—CC|GG— —CC GG— (blunt) ends

Sequence type II, *e.g.*

*Eco*RI —G|AA TTC— ⇒ —G + AATTC— single stranded
—CTT AA|G— —CTTAA G— (sticky) ends

Such DNA fragments containing a gene or portions of a gene are called the passenger DNA. In order to function as a gene within a cell the "passenger" has to be spliced *in vitro* to a plasmid or to a phage DNA; usually phages and plasmids are used to transport the passenger DNA into the cell. The DNA molecule which is used to carry the passenger DNA into the cell is called a vector. Since both vectors are circular DNA molecules, either the plasmid is linearized by one endonuclease cut or alternatively a part of the plasmid DNA is removed by two cuts. In the first procedure one obtains an insertion vector and in the second method a replacement vector (stuffer fragment). The latter is cut by an enzyme having two targets, one on each side of the designated sequence to be removed, and replaced by the foreign passenger. Passenger DNA, plasmid, and other

vector DNA fragments can be separated and purified like other macromolecules by reversed phase chromatography (RPC-5), high pressure liquid chromatography (HPLC) or by polyacrylamide gel electrophoresis (PAGE)[41-43].

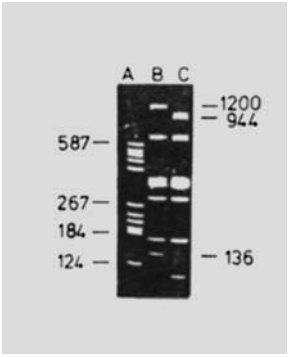

Fig. 7. The formation of a restriction map between vector and passenger is always the prerequisite for a recombination. The DNA fragment is digested by a number of restriction endonucleases of different specificity. The DNA segments obtained are separated by acrylamide gel electrophoresis according to their molecular weight. The individual bands are recognized by their red fluorescence after staining with ethidium bromide. From this type of data a restriction map of the DNA can be assembled, which is absolutely necessary for every recombination experiment. The figure shows the hydrolysis products obtained by digestion of a plasmid and separated by gel electrophoresis. Lane A shows the *Hae* III hydrolysis products of pBR322 as molecular weight standard. The numbers give the molecular weight in bp; Lanes B and C: digestion of pWH233 and pVH51, respectively, by the restriction enzyme *Hinf* I.

For the *in vitro* recombination of DNA, vector, and passenger by splicing, principally two enzymes are required; the oligonucleotide kinase[44] and DNA ligase[45]. DNA ligase is used to form the phosphodiester bonds between the 3'-OH group of one fragment (acceptor) and the 5'-phos-

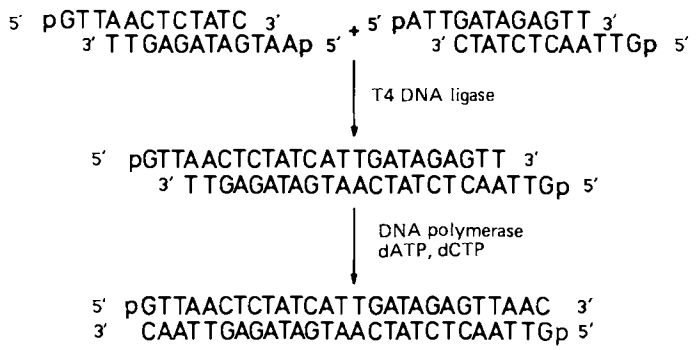

Fig. 8. Mechanism of ligation of two DNA fragments with DNA ligase. Free 5'-hydroxides must first be phosphorylated with ATP and oligonucleotide ligase. The single stranded ends may be furnished with the complementary bases by DNA polymerase.

phate group of the second (donor) (Fig. 8). Radiolabeling of DNA fragments is usually carried out using polynucleotide kinase and [$^{32}$P]ATP as cosubstrate, a procedure which phosphorylates the 5'-OH groups of DNA. With the aid of this technique *ca.* one fmol quantities of oligonucleotide can be detected by autoradiography. The usual enzyme repertoire used in genetic engineering is summarized in Table 5[44,45].

All *in vitro* recombinations follow the simple equation: passenger DNA + vector DNA = recombinant DNA. If a restriction endonuclease of the type *Eco*RI is used for the

Table 5. A selection of enzymes which are used in the *in vitro* recombination of nucleic acids.

| Enzyme | Function |
|---|---|
| Restriction endonucleases (EC 3.1.23) | Sequence-specific hydrolysis of DNA |
| Polynucleotide kinase (EC 2.7.1.78) | 5'Phosphorylation of DNA and RNA, radiolabeling with [$^{32}$P]Phosphate |
| DNA-ligase (EC 6.5.1.1) | Joins DNA from either sticky- or blunt-ended DNA fragments |
| DNA-polymerase (EC 2.7.7.7) | Polymerizes deoxynucleotide triphosphates, requires a single-stranded DNA as a matrix, but a double-stranded origin of replication |
| Terminal deoxynucleotidyl transferase | Tails the 3'ends of DNA or RNA with tracts of homooligonucleotides |
| Reverse transcriptase | Synthesizes DNA from a RNA template |
| S1 nuclease | Hydrolyzes single-stranded DNA (loop DNA) |
| Deoxyribonuclease (EC 3.1.21.1) | Hydrolyzes DNA non specifically |
| Ribonuclease A (EC 3.1.27.5) | Hydrolyzes RNA after (3'→5') pyrimidine nucleotides |
| Alkaline phosphatase (EC 3.1.3.1) | Dephosphorylates RNA and DNA at 5' and 3' ends |

cutting step, both for the isolation of the passenger DNA from the bacterial genome and for the linearization of the vector, then in both fragments we obtain identical four-nucleotide protruding single stranded ends. The single stranded ends of the passenger DNA and the vector are complementary to one another. This allows the formation of an overlapping precomplex between vector and passen-

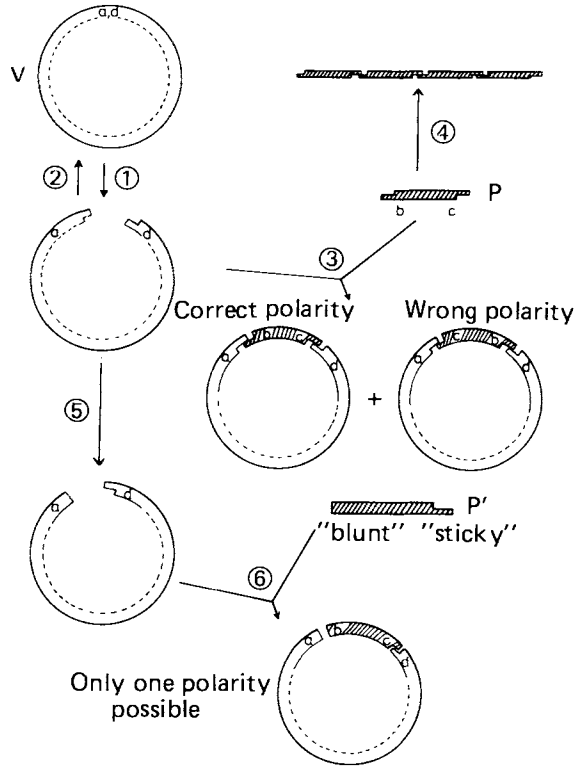

Fig. 9. Pitfalls occurring during recombination of DNA fragments. ① Linearization of a plasmid by a restriction enzyme. ② Recyclization of the linearized plasmid with a linear ligase. ③ Recombination of the vector V and the passenger P; the products, depending on whether they are provided with "suitable" ends or not, can exhibit the correct or incorrect polarity. ④ The passenger P can also oligomerize. ⑤ The linearized vector V contains a "blunt end" since it is cut by a second recombination enzyme. ⑥ Recombination of the vector thus obtained with a suitable passenger P', hence only one product with the correct polarity can be formed.

ger which is stabilized by the formation of hydrogen bonds between four base pairs. The formation of this intermediate facilitates the next step, the covalent joining of the two diester bridges between the DNA fragments. This type of splicing or ligation is termed "sticky-end" ligation. The coupling of DNA fragments with double strands requires higher DNA-ligase concentrations, and this is termed "blunt-end" ligation (Fig. 9).

The recombination of DNA fragments *in vitro* is in general a fairly simple process, but may be complicated by three problems: the passenger can be incorporated into an insertion vector in two different orientations only one of which is required, the passenger DNA tends to oligomerize because of the overlapping "sticky ends", and the vector may recyclize preferentially. Successful recombination is easily monitored by hydrolyzing the recombinant DNA with the restriction enzyme used for construction. The fragments obtained (vector and passenger) are separated and identified by polyacrylamide electrophoresis from their molecular weight (Fig. 7). The correct orientation (polarity) of the passenger within the vector can be identified only by its proper biochemical function. The insertion is unambiguous with respect to the polarity if the vector at one site is cut smoothly and at the second site staggered. An analogously treated passenger can then be inserted only in one direction (Fig. 9, ⑥).

## 6. The *in vivo* Transformation of Cells

In the next step we have to introduce the recombinant DNA in a linear or circular form into the bacterial cell. This is not an easy problem since the cell wall and the cell membrane represent sturdy barriers against macromolecules. The simplest way to introduce a naked DNA into a microorganism is by transformation. The rate of incorporation, however, is very low and only one out of $10^6$ cells may take up a foreign DNA molecule[46a]. When *E. coli* are treated with 10 mM $CaCl_2$ solution, the cell membrane and cell wall become more penetrable (leaky), and the transformation rate is increased by a factor of 1000. Cells treated in this way are called competent cells[46b]. Bacteriophages such as λ or P22 exercise an efficient method of injecting their DNA into the bacterial cell, a procedure called transduction. Mimicking this procedure, the phage genome and passenger, which in the case of λ can be as large as 20—30 kbp, is packaged into the protein head of a λ phage[47]. The phage functions as a transport vehicle that injects the recombinant DNA into the host cell very efficiently. Since this method only functions if the passenger and vector DNA are approximately the size of λ-DNA (49 bp), the procedure can also be used simultaneously to size-select the passenger DNA.

Once inside the cell the foreign linear DNA is either joined head-to-tail to form a circular DNA molecule, a plasmid, or as a lytic phage it may be integrated into the recipient cell genome. If a plasmid contains a so-called "origin of replication", a nucleotide sequence which is recognized by the host DNA polymerase, then the plasmid is replicated with the same efficiency as the host genome[48]. It is segregated into progeny when the cell divides, and hence the number of plasmids in the daughter cell remains constant.

With Col E1 plasmids the number of plasmid copies can, however, be increased if the replication of the bacterial genome is inhibited by a protein synthesis inhibitor such as chloramphenicol. Under these circumstances cells may contain greater than 200 plasmid molecules. If, in addition, the passenger DNA has been inserted in tandem duplications into the plasmid, with an upper limit of 6—10 copies then there may be more than 2000 identical copies of one gene in a bacterial cell[49].

In the next stage of gene expression, the transcription process, mRNA has to be copied from genes encoded on a plasmid. This requires that "upstream" (in the 5′ direction) of the structural gene the regulatory signals for transcription are in the correct positions. These are promoter sequences which act as binding sites for the DNA-dependent RNA polymerase, while another sequence, the operator, binds the repressor protein and acts as a means of regulating the rate of transcription of a gene. Regulation by the repressor is an all or none effect; with the repressor present the gene is not transcribed. When the repressor is removed by an inducer or a metabolite from the medium, then the gene is free for transcription. The affinity of the promoter for the polymerase regulates the rate of transcription of the structural gene and thus the number of mRNA copies made from one gene[50]. Viral genes often contain high efficiency promoters, which guarantee that the viral genes are transcribed at the expense of the host's genes[51].

For most gene transfer experiments one selects a plasmid which already contains a well characterized promoter, for example the lactose promoter[52, 53]. The operator sequence can be partially deleted so that the lac-repressor can no longer bind to the operator. An intact operator can switch the synthesis of a protein on or off. In the case of the lactose operon, the repressor protein is encoded on a distant gene called the i-gene (Fig. 3).

The transcribed mRNA contains a specific sequence, the ribosomal binding site about 10—20 nucleotides upstream of the initiation codon AUG. This binding site shows a high affinity for ribosomes when it contains the Shine-Dalgarno sequence, a spacer of seven nucleotides and the initiator binding codon AUG. The start signal AUG which decodes methionine and the succeeding elongation codons, each of which is a trinucleotide, correspond to the number of amino acids in a protein. The termination codons UAA, UGA, and UAG do not decode an amino acid but function as stop signals to promote the release of the protein chain from the translation machinery[19].

Only when the recombinant plasmid or phage contains these regulatory elements in correct juxtaposition with the inserted passenger gene, is a protein made from the recombinant DNA inside the cell.

## 7. Selecting the Vector

The choice of vector is influenced by many factors including the type of passenger DNA being inserted, the type of restriction endonuclease used, whether or not ex-

pression of the insert is required, and the nature of the host. Commonly used vectors are mostly small plasmids or bacteriophages that have a number of useful restriction endonuclease sites (genetic markers) and a means of identifying bacteria that carry a recombinant DNA molecule (Table 6)[54–56]. Viral vectors have the advantage that they infect cells highly efficiently and reproduce rapidly.

Table 6. Survey of the main types of vectors.

| Vector | Advantages |
|---|---|
| Phage λ, specific insertion | Can incorporate passenger DNA up to 20–30 kbp; high transformation rate |
| Phage P22, unspecific insertion | |
| Plasmids | Low molecular weight, ideal for reconstruction, insertion of genes and promotors: exist multiply in cells and can be amplified [a] |
| Cosmids [b] | DNA can be packaged in the phage λ head |
| Eukaryotic viruses such as SV40 | Infect and transform mammalian cells, can be reconstructed into a "broad host range vector; from *E. coli* the human cells. |

[a] Plasmids can only be amplified if they contain a replication starting point derived from colicine producers. [b] Cosmids are plasmids which contain the cos region of phage λ.

Figure 10 shows everyone's favorite plasmid pBR322 (where p stands for plasmid, BR are the initials of the constructor and the digits represent the less successful predecessors)[57]. Here it may serve to demonstrate the essential features of a good cloning vector. It contains an origin of replication (Or), exists in multiple copies in the cell (20–50), has two antibiotic resistance genes ($Tc^r$ and $Ap^r$) and scattered restriction endonuclease digestion sites. One antibiotic resistance gene may be used to search for bacteria containing the plasmid (a selective marker); an antibiotic such as penicillin or tetracycline is often added to the growth medium to maintain the vector in the cell. By means of this selective pressure, only microorganisms which contain the antibiotic resistance plasmid will survive. The second antibiotic gene used for insertional inactivation, the passenger DNA, is inserted into the gene causing its inactivation. Cells resistant to the drug become sensitive when the plasmid contains the passenger-insert in the middle of the gene (inactivation). Thus the antibiotic resistance genes on a vector can serve two purposes: we can test for the presence of the plasmid in the cell and for insertion of passenger into the plasmid by antibiotic sensitivity/resistance tests (Fig. 11)[58].

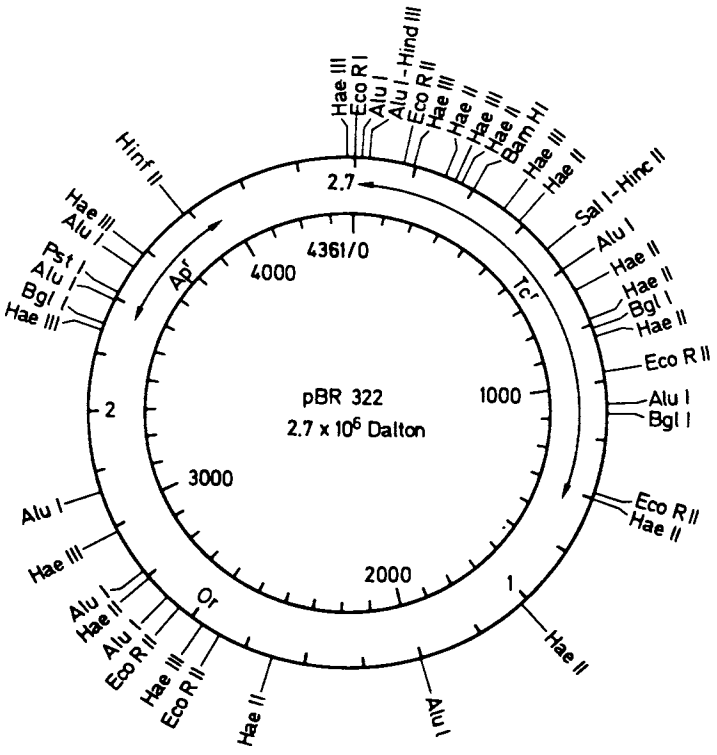

Fig. 10. Restriction map of the plasmid pBR322. The inner circle lists the number of base pairs. In the interspace between the circles we find the origin of replication (Or) and the two antibiotic resistant genes directed to ampicillin ($Ap^r$) and tetracycline ($Tc^r$). The positions at which the various restriction endonucleases cut are indicated on the outer circle.

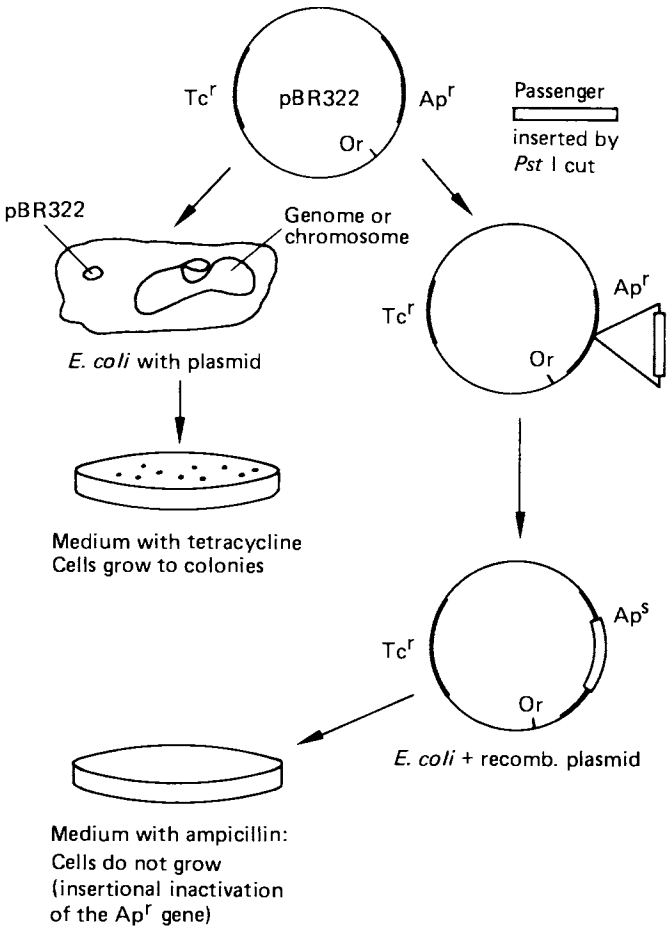

Fig. 11. Function of the two antibiotic resistance genes for selection and screening. Only cells which contain the $Tc^r$ gene can multiply on a tetracycline-containing medium. Following a Pst I cut the passenger is inserted into the $Ap^r$ gene, causing its inactivation. As a consequence cells become sensitive against ampicillin (insertional inactivation).

Plasmids or phages can be altered almost at will by insertions and deletions of foreign DNA fragments. Recombinations are aimed at the inclusion of effective promoters, the introduction of genetic markers, the construction of shuttle vectors, which can exist in different cells such as *E. coli* and yeast, and at reducing the biological hazards (Table 7)[59,60]. Many of the good vectors are patented now-a-days and can be obtained from commercial sources[59–61].

Table 7. Example of a host cell (χ 1776) suited for recombination experiments with plasmids using *E. coli*-plasmids in which a biological hazard may be suspected [a].

| Genotypic modification [b] | Effect |
|---|---|
| dap D8 | Dependence of diaminopimelinic acid in medium |
| min A1 | May form minicells |
| min B2 | |
| sup E42 | Suppression of amber mutants |
| nal A25 | Resistance against nalidixic acid |
| Δ29 (bio H-asd) | Deletion results in dependence of diaminopimelic acid and threonine |
| hsd R2 | Inactive restriction systems, favors transformation |
| F⁻ | Host cell without F factor |

[a] The safety standards are regulated in different ways in every country. Usually there are biological and laboratory safeguards, which have the character of either recommendations or rules. Charon 4A is a modified λ-phage which is often used for the manipulating of human DNA (gene libraries). It contains amber mutations in the gene for phage maturation, for the synthesis of the envelope proteins, and the lysis proteins of the host. Charon 4A can therefore be used to clone eukaryotic DNA. [b] Mutations are selected such that the phages can no longer self replicate *i.e.* it can only exist in the laboratory as part of the bacterium *E. coli* 1776 (biological safety level B2).

## 8. The Choice of the Passenger DNA

The choice of the passenger is of course determined by the research aim. A gene can be isolated preparatively in order to determine the DNA sequence, to delete an operator, to study the cell differentiation process, to transfer a gene from the genome into a plasmid, to cause overproduction of a protein, to produce a gene for a prenatal diagnosis, or to produce human proteins in bacteria[61]. Passenger DNA may be isolated directly by fragmentation of the genome, it can be made as a complementary copy from purified mRNA using reverse transcriptase, or it can be synthesized chemically. Finally it is purified by cloning and produced in preparative amounts.

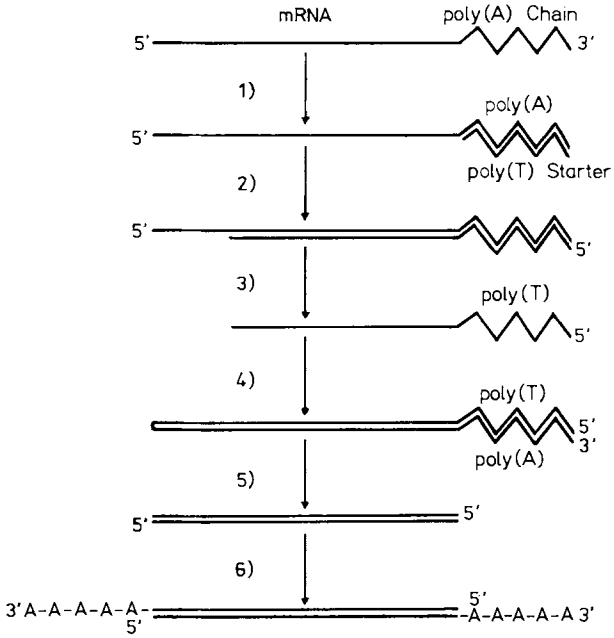

Fig. 12. Six-step synthesis of a double-stranded, complementary DNA (cDNA) using an mRNA as a template. Eukaryotic mRNA can be isolated by affinity chromatography on poly(dT)cellulose, since the mRNA contains a poly(A) segment at the 3'-end. The individual steps are: 1) Affinity chromatography on poly(dT). 2) Synthesis of the complementary strand with the reverse transcriptase and the four deoxynucleoside triphosphates. 3) Hydrolysis of the mRNA matrix strand with ribonuclease A digestion, addition of DNA polymerase I and dNTPs. 4) Duplication of the DNA strand with DNA polymerase. 5) Cleavage of hairpin and removal of tails by specific S1-nucleases. 6) Elongation of double-stranded DNA at the 3'-end by terminal transferase and ATP to form poly (A) tails. The vector is tailed by oligo(dT) tails to allow sticky end ligation of passenger and vector.

In order to establish a gene library, the genome must first be dissected into fragments of approximately 20 kbp size. Each fragment is inserted into a plasmid and the vector is channeled into the bacterium. A collection of all the possible genes in a genome is called a gene library. A collection of recombinant phages is obtained with all genes of a genome in the form of inserts into the phage DNA (Fig. 10). Such libraries exist for *E. coli,* rat, mouse, human, and many other organisms[62, 63].

In eukaryotic genomes the situation is more complex than in prokaryotes, since the structural genes are discontinuous in sequence. They are made up of translated regions (exons) and untranslated regions (introns) and the primary transcription product is processed to give the functional mRNA coding sequence[64]. To obtain a library of the coding regions of the DNA, the entire population of mRNA molecules is re-transcribed by means of the reverse transcriptase into a set of complementary or copy DNAs. Consequently such a collection of structural genes is called a cDNA library. The main steps of these methods are shown in Figures 12 and 13[65].

## 9. The Choice of the Host Cells

For most laboratory experiments *E. coli* is used, since the genetics of this microorganism are well understood and an ever increasing number of useful mutants is available. *E. coli* can be grown conveniently in a simple apparatus, and from a 1 L culture one may obtain 50 g wet weight of cells within 24 h. Laboratory strains of *E. coli* are not pathogens. However, as a producer of protein for industry *E. coli* may have some limitations, especially since as a gram negative bacterium it does not excrete proteins into the medium. Since considerable experience already exists on the large scale cultivation of yeasts, attempts are now being made to construct plasmids which express their passenger genes in yeast. *Bacillus subtilis,* a gram-positive bacterium exports many proteins into the medium. Unfortunately this organism has a number of disadvantages in that less is known about the organism, and there appears to be problems with the plasmid stability[66].

In gene transfer experiments with eukaryotic cells several types of passenger can be used. Simian virus 40 (SV40) is often used as a vector and the recipient cells are usually embryonic cells, such as baby hamster kidney (BHK) or Chinese hamster ovary (CHO)[67–69].

At the moment we don't have perfect vectors and we don't have perfect hosts.

## 10. The Search for the Correct Clone

To understand the problems in recombinant DNA research one has to realize the following: approximately one

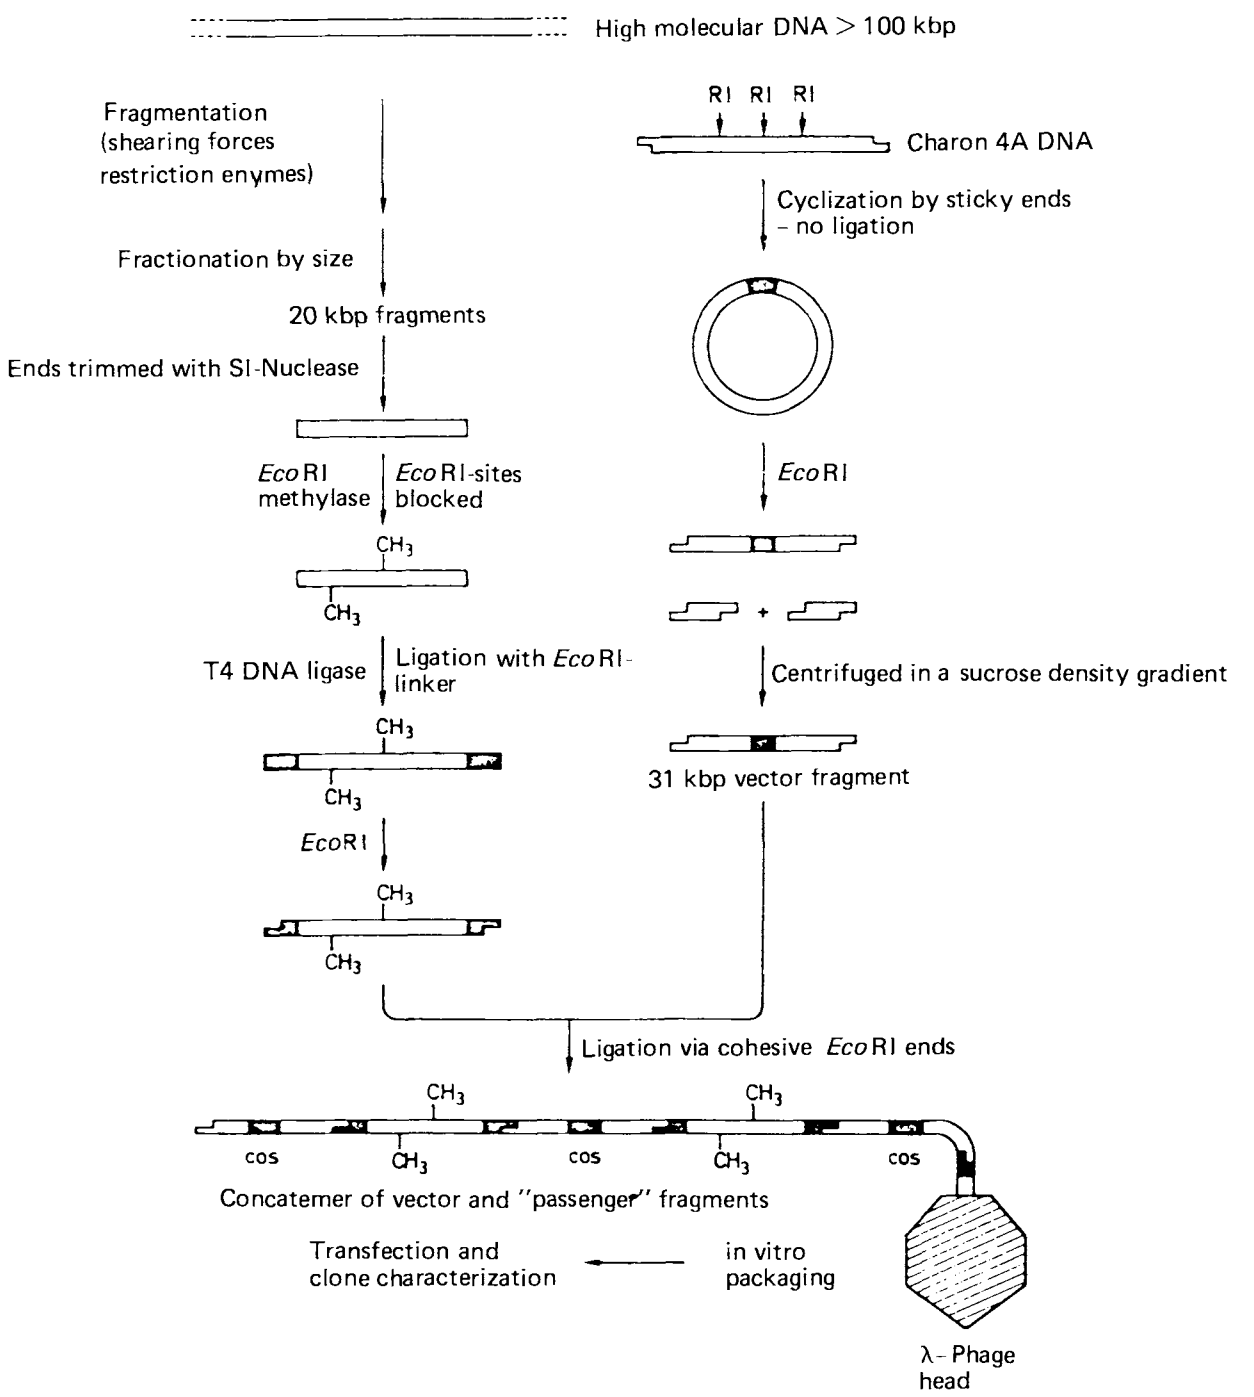

Fig. 13. Strategy for the production of a gene library from Drosophila-DNA after *Maniatis et al.* (*Cell 15* (1978) 687). With kind permission of the author and publisher (taken from R. Knippers: *Molecular Genetik*, Thieme, Stuttgart 1981). If one prepares a DNA library from an eukaryontic organism, then a number of additional tricks have to be used: The foreign DNA is cleaved into large fragments and is ligated to a modified phage vector called Charon 4A (Table 6). This vector contains the cos loci which allow vector plus passenger to be packaged into a phage's head. At first a concatemer is formed which is threaded into the phage's head. The DNA is split at the cos site to fragments 38—53 kbp long. Thus Charon 4A (31 kbp) can harbor 22 kbp of passenger DNA. If the long passenger fragments contain troublesome internal restriction sites they can be blocked by methylation (restriction). After adding *Eco*RI linkers (Fig. 22A) by blunt end ligation, *Eco*RI sticky ends are produced, which allow the oligomerization of the vector into a concatemer.

cell in 1000 takes up the recombinant DNA. Of these only one in 1000 may contain the passenger DNA correctly inserted in the vector. Only then can the cognate protein be made from the inserted gene. Bacteria have the advantage that they divide every 20 min and that $2^{72} = 4{\cdot}7 \times 10^{21}$ cells are produced in less than one day. Ideally these should be identical copies of the parental cell; however, bacterial cells have a relatively high frequency of mutation and may lose or exchange plasmids, and inserted foreign genes may be deleted by *in vivo* cutting and splicing. Therefore, the genetic stability of a recombinant strain is of critical importance[66].

The presence of recombinants can be assayed by antibiotic resistance or sensitivity. Plasmid-containing cells are

resistant to one drug. If the passenger is correctly inserted into the second antibiotic resistant gene then the cells become sensitive to a second drug *e.g.* tetracycline (insertional inactivation) (Fig. 11). This negative test has to be supplemented by a positive assay for the correct insertion of the passenger into the vector. In one very elegant system an enzyme is used which consists of two domains. Cells and plasmids are constructed such that the α-domain of β-galactosidase is located on the plasmid and the β-domain on the central genome[70]. If cells contain the native plasmid then the active enzyme is formed and (5-bromo-4-chloro-3-indolyl)-β-D-galactoside is hydrolyzed to the indole derivative, which in turn is oxidized in air to yield an indigo dye *i.e.* a cell clone with intact plasmid appears blue on the Petri plate. Insertion of a passenger into the plasmid does not result in formation of β-galactosidase and the colonies on an agar plate remain white, since no α-subunit of the enzyme can be synthesized. Thus positive clones (white colonies) can be selected from a background of blue colonies. Another test is based on the hybridization of the passenger with radioactive DNA or RNA directly on a nitrocellulose filter (colony hybridization). Using a radioactively labeled single strand DNA, which is base complemented to the passenger, one can investigate whether a double strand is formed between the test DNA and passenger *i.e.* whether both nucleic acids hybridize[71,72]. An obvious method, and the most informative one, is to assay the bacterial colony for direct expression of the plasmid-encoded protein. Since in the initial stages of cloning only minute amounts of passenger-encoded proteins are made by the host cells it is often difficult to identify the expression of the plasmid-encoded protein. When the enzymatic activity of the protein is to be examined, one needs a mutant host cell which is defective with respect to production of similar enzymatic activity. Plasmid and host cells first build a complementary system, which is capable of producing the enzyme (complementation test).

The enzymatic test has to be sufficiently sensitive to detect a pmol of protein and fast enough that one can test more than 1000 bacterial colonies per day. A more general approach is the use of a radioimmunoassay with radioactive antibodies directed against the protein in question[73]. Newer additions to the analysis of gene expression are the so-called mini- and maxicells. Both have in common the fact that the expression of the host genome can be eliminated, so that only plasmid-encoded proteins are produced[74]. The minicell strains, derivatives of *E. coli* K12, divide in such a way that a minicell without the host chromosome is produced on cell division. However, they maintain the plasmid and the protein synthesizing apparatus necessary for gene expression. With [$^{35}$S] labeled methionine the plasmid-encoded radioactive proteins are synthesized and can easily be analyzed by polyacrylamide gel electrophoresis. In maxicell strains the genome is inactivated by a dose of UV irradiation which destroys the genome but leaves the plasmid intact[75].

In addition to *in vivo* systems for gene expression there are several cell-free protein synthesizing procedures using wheat germ, *E. coli* extracts, reticulocyte lysates and others[76-78]. They show the advantage that linear DNA (in the case of *E. coli*) and mRNA can be translated. The efficiency of these systems is low since the nucleic acid templates are rapidly degraded by cellular nucleases and the endogenous RNA concentration is high. However, appropriate labeling conditions in combination with precipitation with antisera can be used to identify the required product. Furthermore one can inject the DNA directly into the nucleus of a frog oocyte or an embryo cell[79,80].

The vector containing the passenger is then isolated in preparative amounts and the position of the passenger within the plasmid is verified by mapping with restriction endonucleases. Finally, the passenger including flanking DNA regions is sequenced by either the *Maxam* and *Gilbert* or the *Sanger* procedure[81-83]. DNA sequence and gene expression represent the final proof for a successful cloning experiment.

## 11. Processing the Polypeptide Chains

Up to now we have discussed protein synthesis in very simplified terms; a nucleotide sequence of either DNA or RNA is translated into an amino acid sequence of a protein. However, in reality the process is much more complex, particularly in the metabolism of higher organisms. The newly made polypeptide chain often does not attain its final biologically active conformation until it has been subjected to processing or covalent modification. Such changes are called posttranslational modifications[84,85]. Proteins may be modified by glycosidation, phosphorylation, disulfide bond formation, and a whole battery of other substituents: another group of proteins is translated as so-called preproproteins. Insulin from bovine pancreas is translated, *e.g.* by ribosomes, as preproinsulin and has 104 amino acids[86]. The pre- or signal-sequence, which consists of 23 amino acids, directs the ribosomes to the endoplasmic reticulum and causes this protein to be channeled into the interior of the reticulum. Subsequently, the signal sequence is cleaved. Proinsulin, the inactive precursor of insulin contains 81 amino acids. Only after removal of the middle C-peptide does the active enzyme, with 51 amino acids, result. In general, signal sequences channel peptides into the endoplasmic reticulum, or in bacteria into the periplasmic space or the culture medium.

In order to understand the processing and the activation of a protein it is necessary to elucidate the chemical principles of the protein synthesizing machinery of a cell[19], and to understand the chemistry of membranes[87,88], as well as the effect of chemical modifications of individual amino acids on the tertiary structure of proteins[89]. There are many fascinating questions in molecular biology, but until recently chemists were not interested in tackling them.

## 12. Models are to Molecular Biology what Mechanisms are to Chemistry

Figure 1 shows our present understanding of DNA encoded, ribosome-dependent protein synthesis. Over the details little is understood at present. This is especially true for the function of regulatory sequences for mRNA production and translation, for the selection of the cognate tRNA, for the conversion of GTP-stored energy into mRNA movement, and so on.

Even more limited is our understanding of the structure and function of membranes or of the cytoskeleton of cells: there are plasma membranes, nuclear membranes, and the membranes of organelles such as the inner mitochondrial membrane. They all have specific functions in substrate transport, as binding sites for multienzyme complexes, in the production of ATP from proton gradients, and in the generation of electric potentials. We know much about the protein and phospholipid composition of membranes and a variety of models describing membrane function exist. Beautiful names such "fluid mosaic model" most convincingly demonstrate our lack of chemical knowledge[90].

Why is one protein transported through the plasma membrane into the periplasmic space whereas another stays in the cytoplasm? This is an important question for the large scale production of proteins by microorganisms[91,92]. We know that excreted proteins contain signal sequences of approximately 30 amino acids in length, that hydrophobic amino acids are clustered in one part of the signal sequence, and that the occurrence of a proline in a defined position is often of critical importance for the function of signal sequences. But why is a protein, a macromolecule, excreted through the membrane? At present these problems seem to be of no interest to organic chemists. It may be easy to elucidate the configuration of a steroid by X-ray crystallography, but it still takes a battery of techniques and considerable imagination to elucidate the chemistry of membranes.

## 13. Chemical Synthesis of Gene Fragments on Supports: Synthesis Using Syringes and Serum Caps

The synthesis of nucleic acids in the laboratory started about thirty years ago. Early synthetic efforts concentrated on the search for suitable protective groups for the bases and the ribose moiety and selection of the proper condensing agents for phosphodiester bond formation. The phosphodiester approach used at that time enabled, albeit with some effort, the preparation of short oligonucleotides containing 10—20 nucleotides[93]. Using the enzymes oligonucleotide kinase and DNA ligase, which had just been discovered by biochemists, these oligonucleotides were assembled into longer DNA fragments. The synthesis of the structural gene for tyrosine tRNA, a DNA segment containing 200 bp, by *Khorana et al.* highlighted many years of continuous efforts in nucleic acid synthesis[94]. However, in comparing effort and achievement it became clear that chemical gene synthesis was unlikely to become a standard laboratory method. This was due to the low yields in the condensation step, the long reaction times, and especially the time-consuming purification of intermediates. However, the real handicap in DNA synthesis was that DNA could not be sequenced at that time. Thus *Khorana et al.* had to synthesize a tRNA gene since he could deduce the DNA sequence from the known primary structure of a ribonucleic acid, tyrosine tRNA.

With the discovery of genetic engineering techniques for the cutting and handling of DNA fragments of biological interest in combination with the fast and easy sequencing methods for DNA, the situation changed dramatically. However, most experts in the field concentrated on the isolation of gene fragments from natural sources by genetic methods.

It was the chemical synthesis of the structural gene for the human leukocyte interferon, a DNA fragment with 517 bp, which convincingly demonstrated the tremendous progress chemical oligonucleotide synthesis had made (Fig. 14)[95].

This outstanding success in gene fragment synthesis was mainly due to the switch from the phosphodiester ap-

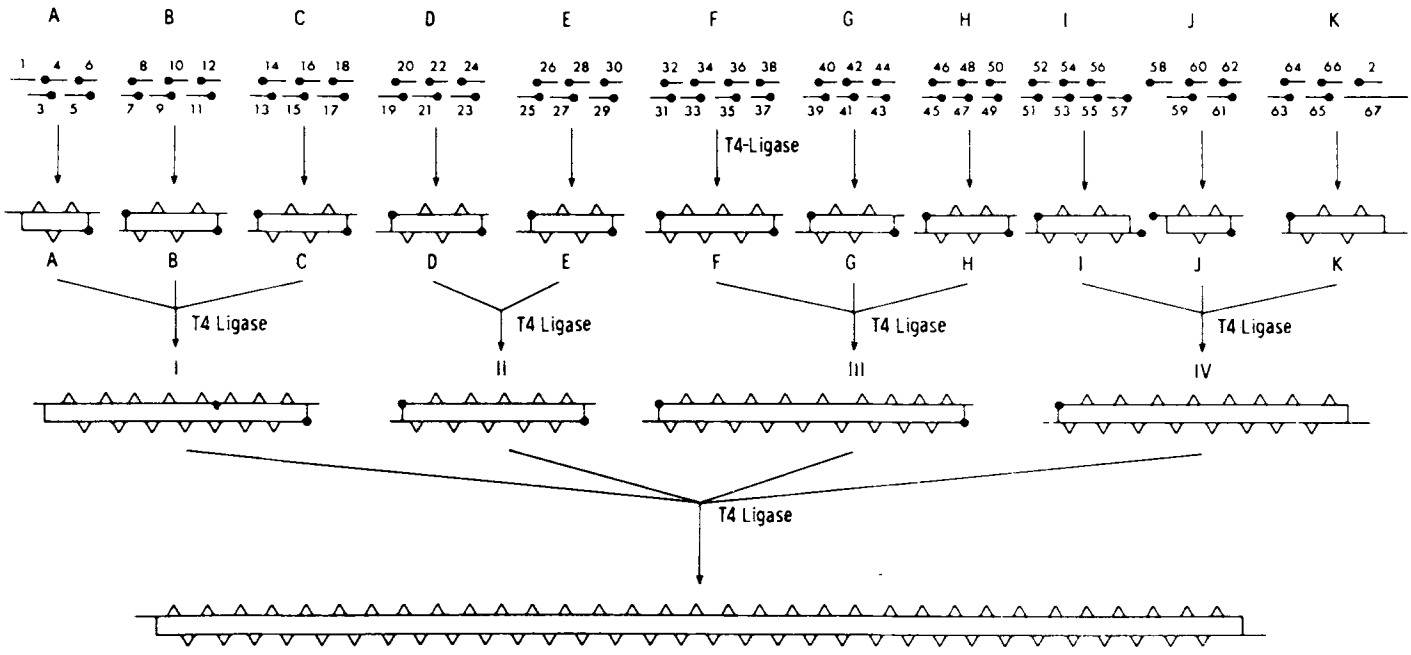

Fig. 14. Synthetic strategy for the preparation of the human leucocyte interferon gene. 67 Oligonucleotide of chain lengths 10—20 were prepared by the phosphotriester approach. By means of T4 DNA ligase they were spliced to yield the structural gene for interferon. Although the product, a 517 bp fragment, only exhibits a low degree of purity, the interferon gene could be enriched by cloning and be isolated.

proach to the triester methodology (Fig. 15) and to the Merrifield-analogous polymer synthesis on supports[96,97]. In addition there were other reasons why developments in this field speeded up tremendously, above all instrumental developments in preparative separation methods, such as HPLC and polyacrylamide gel electrophoresis.

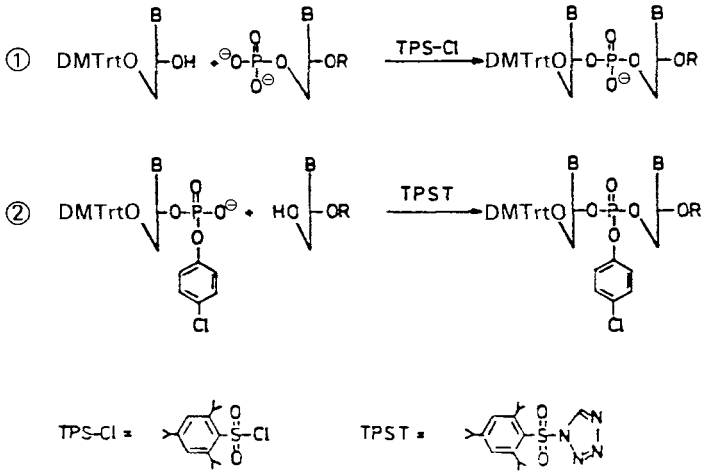

Fig. 15. Chemical principles of the phosphodiester ① and the phosphotriester methods ②. The essential difference between the two methods is that, because of the absence of charge, the triesters are no longer polar and are hence readily soluble in nonpolar solvents. DMTrt = dimethoxytrityl.

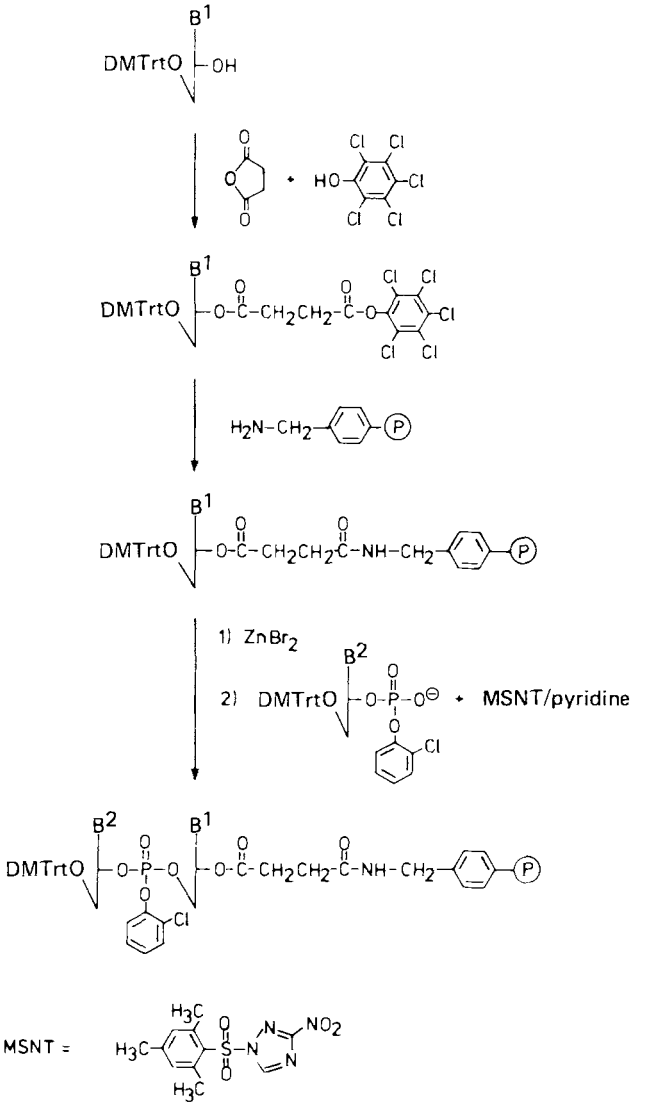
In 1970, using a mechanized "peptide synthesizer", *Merrifield* and *Gutte* made the enzyme ribonuclease A on a polymer carrier. For a protein consisting of 124 amino acids they had to employ 369 reactions, representing 11391 mechanical operations[98]. In the nucleic acid field the coupling of nucleotides on synthetic supports was not efficient enough and the product yields were extremely low[99].

There were two basic reasons for their failures: firstly the supports chosen were not appropriate for the chemical reactions used in DNA synthesis, and secondly the chemical reactions were insufficient in terms of their selectivity and yields to meet the extra demands of a stepwise polycondensation. The classical phosphodiester approach to DNA synthesis proved to be ill-suited since the charged, and thus highly polar, nucleotide diesters are barely soluble in organic solvents and are incompatible with the hydrophobic properties of the solid support. Completely anhydrous conditions and nonpolar solvents, however, are a *conditio sine qua non* for fast and quantitative condensation reactions.

In the phosphotriester approach, as pioneered by *Letsinger et al.* and perfected by *Itakura et al.* and *Gait et al.*, the growing oligonucleotide chains contain uncharged, fully protected phosphates. They are found to be compatible in solvation properties with a variety of polymer supports such as polyamides, polystyrenes and silica[100].

The triester approach can be subdivided; the monomer coupling technique is used as a cost-effective method for the synthesis of oligonucleotides containing up to 20 bases. The method of choice at present is the charged compound coupling reagent method[101-103]. The protected monomers are used as the triethylammonium salts of the phosphodiesters, which are readily soluble in pyridine: 1-(mesitylenesulfonyl) 3-nitrotriazole (MSNT) is used as a condensing agent. With these reagents coupling times are about 45 min at 45 °C and the yields are greater than 95% per coupling (Fig. 16).



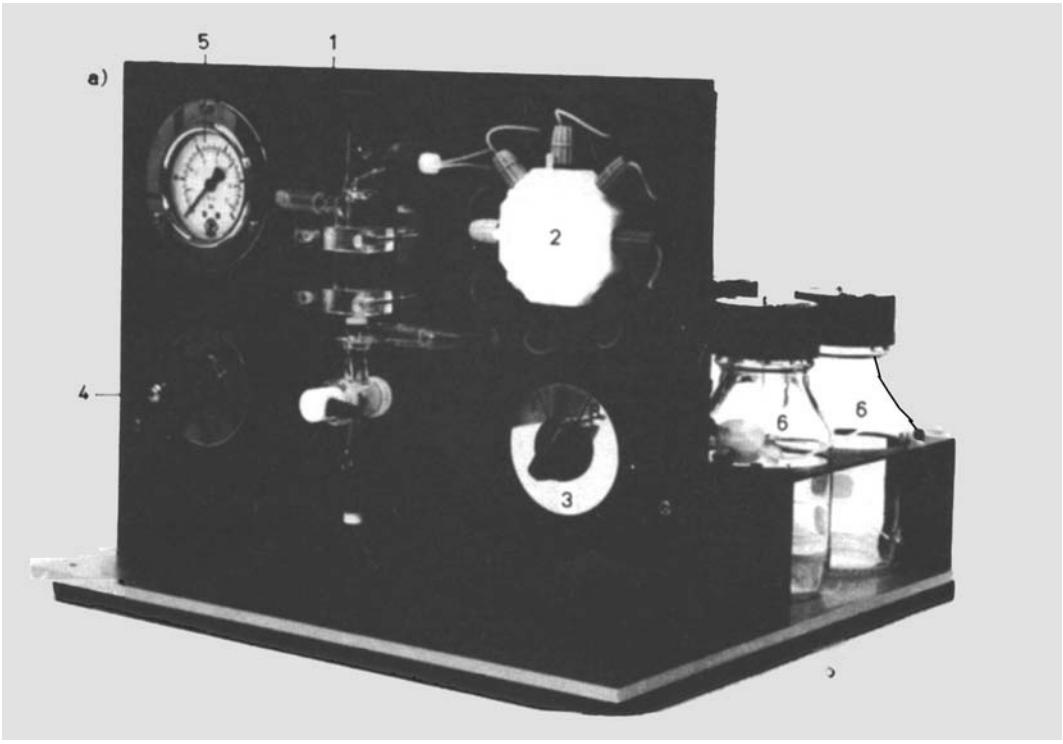


Fig. 16. Functionalization of a polystyrene support with a protected nucleoside, and synthesis of a dinucleotide. The 5'-dimethoxytrityl group of the first nucleoside is removed by $ZnBr_2$. Subsequently, the condensation step follows using the charged-compound coupling method with 1-(mesitylenesulfonyl)-3-nitrotriazole (MSNT) as condensing agent. DMTrt = dimethoxytrityl.

If one wishes to prepare oligonucleotides containing more than 20 bases it is wise to proceed *via* the block-coupling method. This method is identical to the procedure described previously but uses dimers or trimers as coupling compounds and by this means DNA containing up to 40 bases can be prepared. Both types of polymer support syntheses are easily accomplished using a bench-type DNA synthesizer or a fully automated machine as depicted in Figure 17[104].

In recent years a chemically more elegant route for internucleotide bond formation has been developed by *Caruthers et al.*, and is referred to as the "phosphite method"[105,106]. It overcomes the problem of negative charge by first preparing the dinucleotide phosphite ester which in a second step is oxidized by iodine to a phosphate bond.

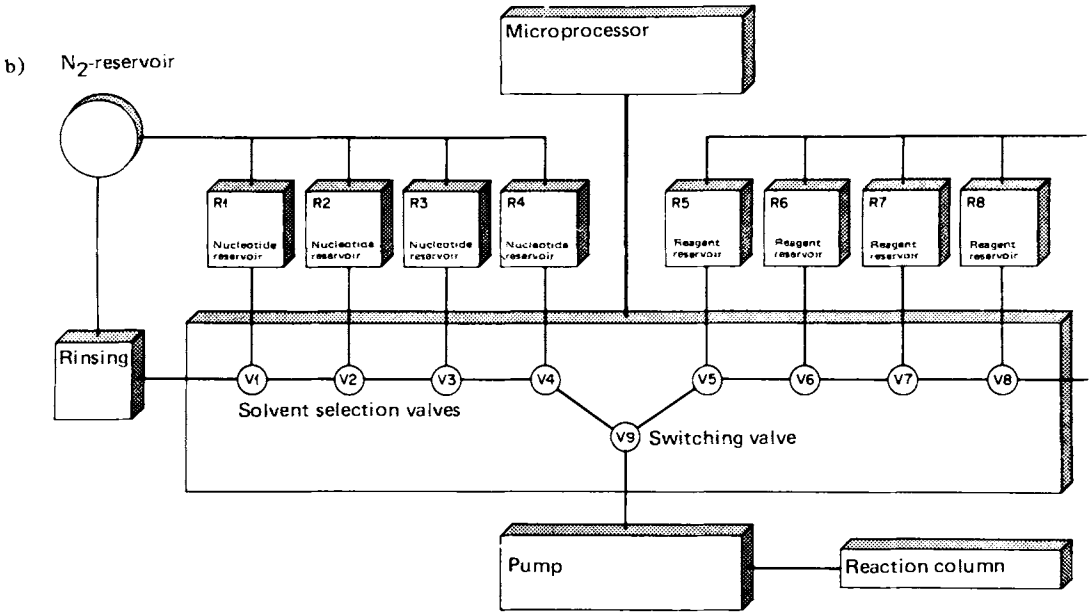

Fig. 17. a) Semiautomatic "DNA synthesizer": 1) reaction column, 2) eight-way valve, 3) three-way valve, 4) pressure control, 5) manometer, 6) reagent bottles. Cook*, Biosearch, San Raffael, CA, USA.

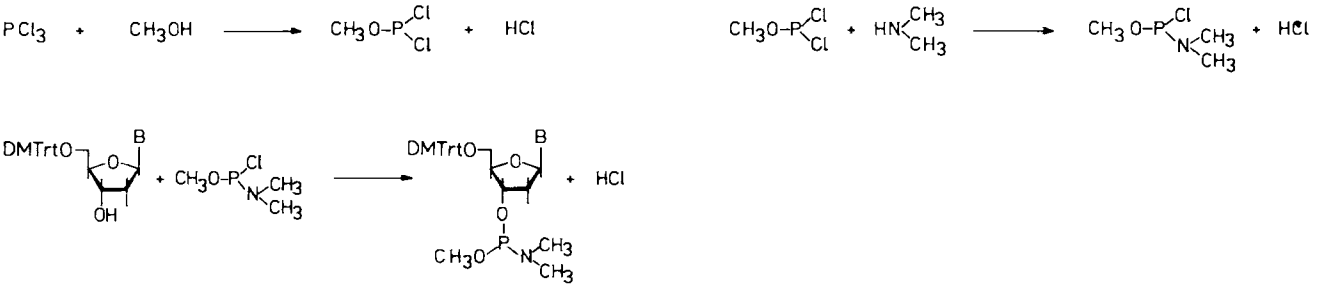

Fig. 18. Scheme for the synthesis of the deoxynucleoside phosphoramidites. DMTrt = dimethoxytrityl, B = thymine or the protected bases $N^6$-benzoyladenine, $N^4$-benzoylcytosine, $N^2$-isobutyrylguanine.

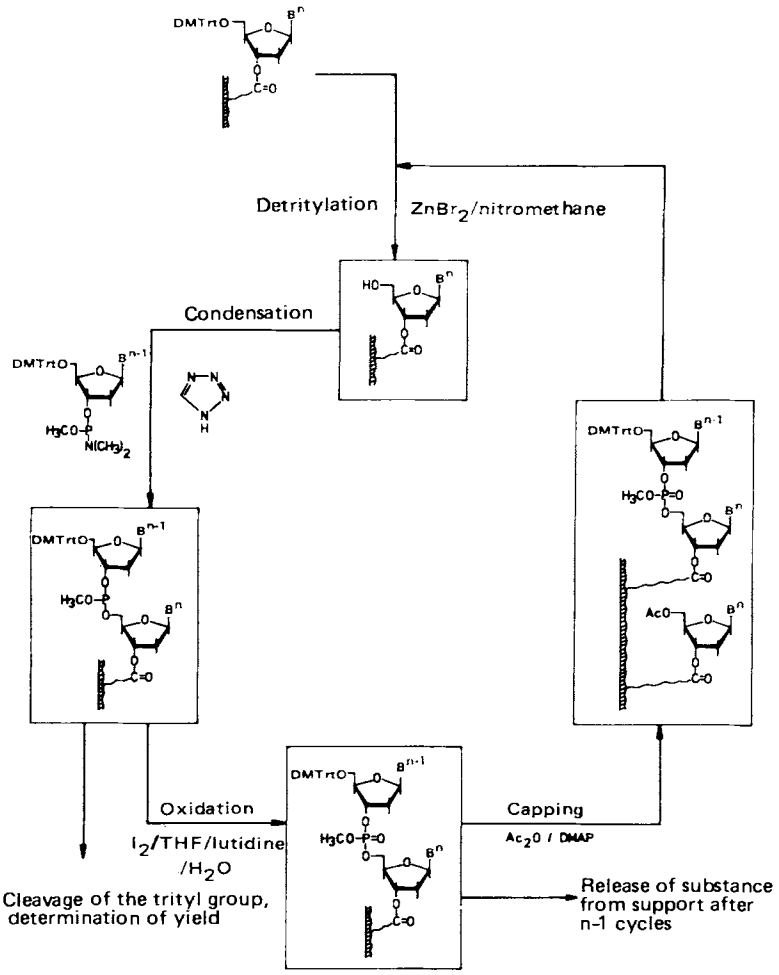

Fig. 19. Synthesis of DNA fragments on a polymer support by the phosphite method.

The preparation of the deoxynucleoside phosphoroamidites from the protected nucleosides and chloro(*N,N*-dimethylamino)methoxyphosphane is a simple and convenient method (Fig. 18)[107]. However, synthesis of the trisubstituted phosphane from trichlorophosphane is very tricky since it is spontaneously pyrophoric when it comes into contact with water. The phosphorylating agent must be highly purified by triple distillation and its purity checked by $^{31}$P-NMR spectroscopy; only when this is fulfilled does the condensation reaction proceed in high yield. With these highly reactive intermediates, called "reaction bombs" by *van Boom et al.*, a new type of synthetic chemistry started in the nucleic acid field[108]. Its tools are the syringe, the serum cap, absolute exclusion of moisture, and ultrapure reagents. Its rewards are coupling times of 5 min at room temperature and yields in the range of 90% (Fig. 19)[100].

Even with 90% yield in each reaction cycle polymer synthesis comes out of phase after about 10 cycles. Therefore, both methods use a capping step: unreacted oligonucleotide chains are blocked by acetylation of the 5′-hydroxyl groups. After completion of the synthesis the protective groups have to be removed and the oligonucleotide is split off the support. Total recovery of oligomer with 20 members is usually 5–10% relative to the nucleoside-activated support (Fig. 20)[109]. The "correct oligonucleotide" can be selected by the bacterium even from a crude mixture of

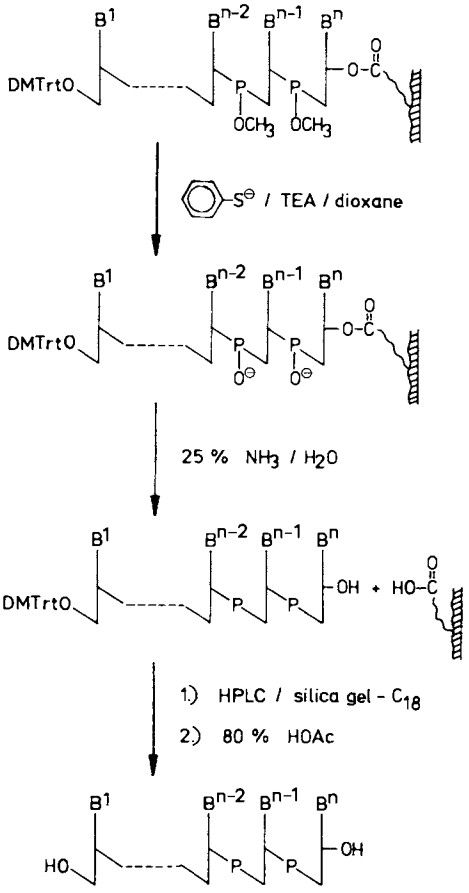

Fig. 20. Individual steps in the release of the oligonucleotide from the solid support and the removal of the protective groups. TEA = triethylamine; silica gel-$C_{18}$ = reversed phase material with $C_{18}$ alkyl residues. The trityl group is removed after an initial separation of the oligonucleotide by reversed phase chromatography with $C_{18}$-silica gel. This allows the separation of the desired oligonucleotide from incomplete and thus trityl-lacking oligonucleotides. Finally the oligonucleotide is purified by HPLC ion exchange chromatography.

oligonucleotides and the DNA sequence reproduced at will by cloning.

For the conventional purification of the nucleotides mainly three techniques are used: 1) reversed phase chromatography and size exclusion chromatography, 2) high pressure liquid chromatography with reversed phase or ion-exchange columns, 3) polyacrylamide gel electrophoresis (Fig. 21). The oligonucleotide bands may be visualized by UV-shadowing using an "intensifier screen" or by autoradiography if the oligonucleotide had been previously labeled with [$^{32}$P]phosphate. Following purification, the sequence of the oligonucleotide has to be confirmed by analysis. This may be done by the *Maxam* and *Gilbert* procedure, as adapted for oligonucleotides, or by two dimensional fingerprinting (wandering spot method)[100].

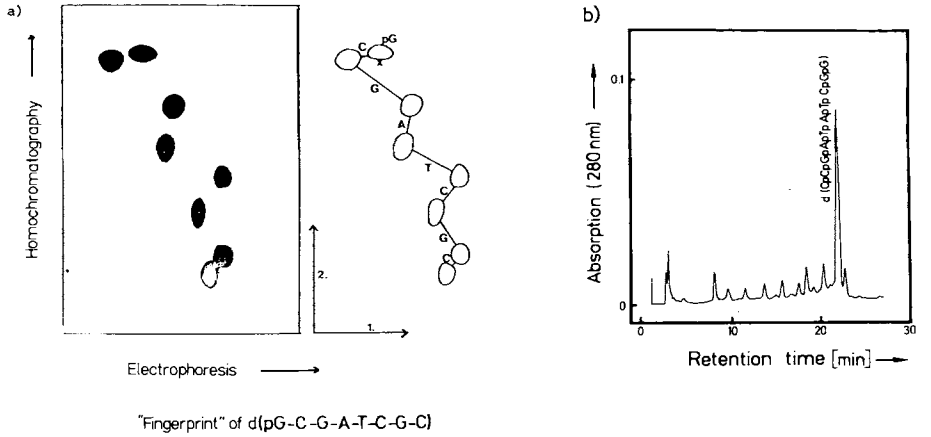

Fig. 21. Sequence determination of chemically synthesized oligonucleotides. a) Two-dimensional separation of oligonucleotides by the "wandering spot" method after limited hydrolysis of snake venom phosphodiesterase (*A. R. Frank, H. Blöcker* in [100], p. 225). b) Separation of a decamer by HPLC using a 4.6 mm × 250 mm ion exchange column (*L. W. McLaughlin, J. V. Krusche* in [100], p. 177).

Obviously the synthesis of the interferon gene by chemical fragment synthesis followed by enzymatic assembly has been a good advertisement for chemical gene synthesis. However, gene synthesis is not a major goal of nucleic acid chemists. The isolation of complete genes is accomplished more easily by cutting plasmids or genomes with a variety of restriction endonucleases. However, it is very difficult to cut out a 20 bp fragment, even from a plasmid, since two convenient restriction sites are usually not very close and the recovery, 20 bp out of $10^4$ bp, is low.

Thus, gene isolation and fragment synthesis are two complementary techniques. Small fragments are needed as linkers and adapters for the introduction of new restriction sites into a plasmid (Fig. 22). They are used to introduce high-affinity promotors or operators into the regulatory unit of the gene. They serve to partially double strand a single stranded DNA either for sequence analysis or for the preparation of copy DNA[110] and are the ideal affinity probes for the isolation of a defined mRNA from the cytoplasm of prokaryotes and eukaryotes[111]. Synthetic methods enable the insertion of unusual nucleotides, such as 5-methyldeoxycytidine, into the regulatory part of a gene and the study of their influence on cell differentiation. Unexplored as yet is chemical mutagenesis[112]. By introducing a small synthetic DNA fragment into a defined position on a genome we can produce proteins which are altered in a chosen amino acid. Using this method we can then study the influence of one amino acid change on the active center of an enzyme and on its catalytic properties. Besides the biological applications, we can now isolate mg-amounts of genes and study the chemical details of protein-nucleic acid interaction.

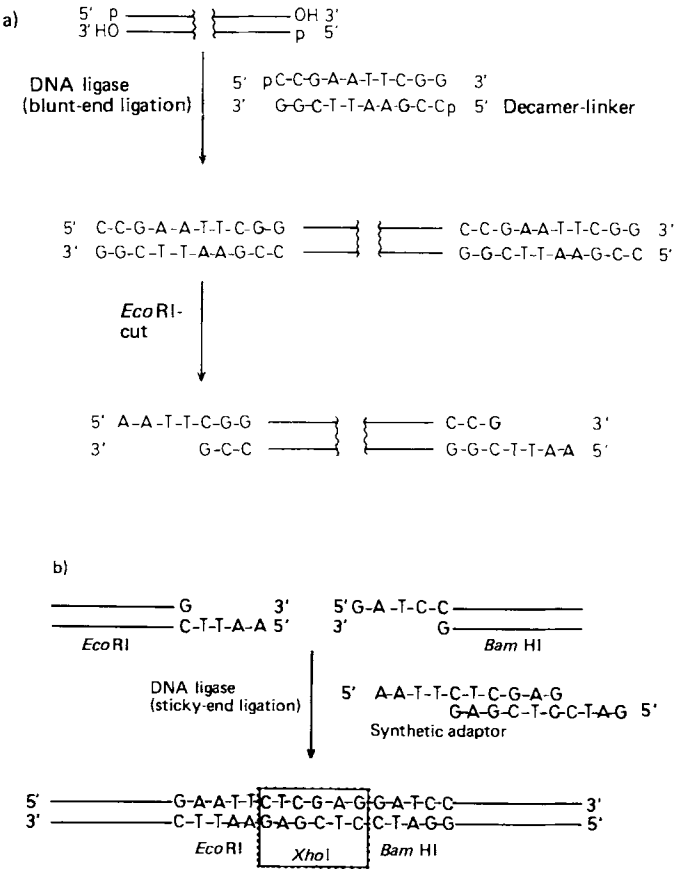

Fig. 22. a) Construction of single strands by "blunt-end" ligation of chemically prepared linker and adaptor with a subsequent *Eco*RI step. Such a fragment can be incorporated into an *Eco*RI linearized plasmid pBR322. b) Use of a synthetic adaptor to create a new restriction site within a DNA fragment (*Xho*I = C↓TCGAG).

## 14. The Future Role of Chemistry in Molecular Biology

In the last 20 years the advances in molecular biology have been dominated by geneticists. But now it seems that chemists are making a comeback. Chemists have learned to isolate, to sequence, and to synthesize genetic material. Of course genetics is only one aspect in the wide field of molecular biology. However, there is some hope that chemists will turn to protein conformation, to cell walls and membranes, and eventually to cell differentiation and information storage. The tackling of the chemistry of the living being requires, besides a good knowledge of chemistry, an open mind, some imagination, and the willingness to accept and to learn.

*The financial support of the Fonds der Chemischen Industrie and the Otto-Röhm-Stiftung to one of us (HGG) is gratefully acknowledged. We are grateful to Mrs. E. Rönnfeldt for her expert help in preparing the manuscript.*

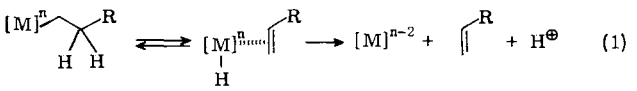
# Organometallic Compounds of Titanium and Zirconium as Selective Nucleophilic Reagents in Organic Synthesis[1]

**New synthetic methods (37)**

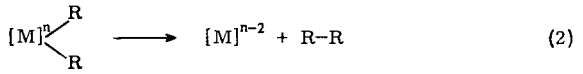
**By Beat Weidmann and Dieter Seebach***

The addition of carbanionic organometallic compounds (usually RLi or RMgX) to a carbonyl group—a key step in numerous syntheses—is not always straightforward. Depending on the substrate, various complications and problems may arise, but in many cases these can be remedied by addition of $(RO)_3TiCl$, $(RO)_3ZrCl$ or $(R_2N)_3TiX$ to the classic lithium and Grignard reagents. This usually leads to formation of stable organo-titanium and -zirconium compounds which react highly selectively with carbonyl groups. For example, $CH_3Ti(OiPr)_3$ reacts five orders of magnitude faster with benzaldehyde than with acetophenone at room temperature; reagents of the type $RTi(OiPr)_3$ add smoothly to nitro-, iodo-, or cyano-subsituted benzaldehyde, and the reactions may be performed in chlorinated solvents or acetonitrile; the zirconium analogues have particularly low basicity and add in high yield to α- and β-tetralones or to substrates containing a nitroaldol group; the inclusion of chiral OR* groups gives enantioselective reagents (up to 90% *ee*); allylic $(RO_3)Ti$-derivatives react only at the more highly substituted carbon atom and, in addition, react diastereoselectively (up to 98% *ds*) with unsymmetrical ketones. Finally, titanium reagents have also been found to effect novel transformations such as direct geminal dialkylation ($C{=}O \rightarrow CMe_2$) and alkylative amination [$C{=}O \rightarrow CR(NR'_2)$]. The modification and fine-tuning ("taming") of carbonyl reactivity obtainable by use of the new reagents is not dearly bought; starting materials are the cheap and harmless "titanates", "zirconates" and the corresponding tetrachlorides.



## 1. Introduction—The Problem

If one considers the development of so-called new synthetic methods, one can hardly avoid the impression that the elements of the periodic table have been "grazed" without consideration of price, toxicity, or availability, and without knowledge of alternative methods already developed. On the other hand, it is clear that there is a multitude of presently awkward synthetic transformations for which—on pure statistical grounds—a solution lies hidden somewhere in the periodic table. In the area of organometallic reagents, those in which the organic part has nucleophilic, carbanionic reactivity occupy a central position. After the work of *Frankland*[2] on organozinc compounds (the first known organometallic compounds) in the middle of the nineteenth century, it was *Grignard* who in 1900 first recognized the seminal importance of organomagnesium compounds for synthetic chemistry[3]. Since then, the Grignard reagents named after him, together with compounds of the other main-group metals such as lithium[4], boron[5], aluminum[6], zinc[7], and cadmium[8], have become an indispensable tool in the hands of the preparative organic chemist. Unfortunately, however, the high reactivity of these classic organometallic compounds is often coupled



[*] Prof. Dr. D. Seebach, Dr. B. Weidmann
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule
ETH-Zentrum, Universitätstrasse 16, CH-8092 Zürich (Switzerland)

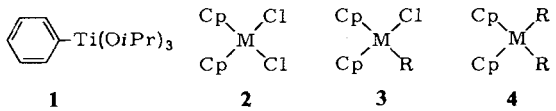
with disadvantages, which may ultimately lead to a lack of selectivity[9]: a) the nucleophilic reagent may only be stable below a certain temperature; b) other carbonyl groups in the substrate must be protected; many other functional groups (*e.g.* CN, $NO_2$, I) may not be present; c) instead of addition, deprotonation (enolate formation) may take place; d) instead of the desired 1,2-addition, 1,4-addition may occur (or *vice versa*); e) allylic nucleophilic reagents can react with or without allylic double bond shifts ($S_E$ *vs.* $S_{E'}$); f) two diastereomeric products may be unselectively formed; g) nucleophilic organometallic reagents of this type can only be modified with difficulty such that they react enantioselectively. Variation of the metal is a classical possibility for the solution of such selectivity problems, but this has often led to the use of toxic metals (cadmium compounds[10] and copper derivatives[11,12]).

It is not surprising that the use of transition metals to modify *carbanion reactivity* was at first not considered. Indeed, for a long time, the only isolable complexes with carbon-transition metal σ bonds ($\eta^1$-complexes)[13] were copper(I) compounds with $d^{10}$-configuration of the metal and the corresponding Pt- and Au-derivatives. The reason for this is that so-called β-H-abstraction [reaction (1), reductive elimination] is much faster with alkyl-transition metal compounds than with the equivalent main-group metal compounds. In addition, oxidative dimerization of two organic residues (with concomitant reduction of the metal) occurs at a transition metal center much more readily [reaction (2)][14]. These two processes may, in fact, be of considerable significance when deliberately employed on a laboratory or an industrial scale[15,16]; they have, however,

(1)

(2)

hindered for a long time the introduction of alkyl-transition metal compounds as carbanionic reagents in synthesis. After the reason for the instability was recognized, inorganic chemists succeeded in isolating an immense number of complexes on keeping to the following "rules"[17]:



a) Use of alkyl groups which either have no hydrogen atom on the β-carbon, or, for steric reasons, cannot form a stable double bond. Typical examples are: methyl, benzyl, neopentyl, trimethylsilylmethyl, phenyl, and 1-norbornyl.
b) Complexation of the metal with strongly coordinating ligands until the stable noble gas configuration is reached (18 electron rule); steric hindrance of β-abstraction is often an added advantage.
c) Use of metals in low oxidation states which cannot easily be further reduced.
d) Synthesis of compounds in which the equilibrium for β-abstraction [Eqn. (1)] lies on the side of the alkyl compound, and which are thus accessible by hydrometalation.

Complexes which owe their stability to having alkyl groups without β-hydrogen atoms [Rule (a)] are of interest to the inorganic chemist for the investigation of the structural and thermodynamical properties of the transition metal-carbon bond. Even should a preparative method emerge from these investigations, however, the restriction to such systems would be a severe limitation. Thus it is the possibilities mentioned under b), c), and d) which are of consequence in the search for sufficiently stable organo-transition metal reagents for organic synthesis.

## 2. Properties of Organo-titanium and -zirconium Compounds without Cyclopentadienyl Ligands—Aim and Limits of the Review

In 1952, *Herman* and *Nelson*[18] described phenyltitanium isopropoxide as the first compound with a carbon-titanium σ bond[19] (Scheme 1). Two further discoveries at the same time stimulated the development of organotitanium chemistry: the synthesis of ferrocene by *Kealy* and *Pauson*[20], and the observation by *Ziegler et al.*[21] that titanium compounds in mixtures with alkylaluminum compounds are extremely active catalysts for the polymerization of olefins.

After elucidation of the structure of ferrocene[22–24], cyclopentadienyl-titanium and -zirconium halides **2** were some of the first compounds to be prepared by the action of cyclopentadienylmagnesium halides on transition metal salts, and from which the σ-derivatives of type **3** and **4**, which have until recently dominated the picture in organic synthesis, are derived[25]. As a result of the work of *Herman* and *Nelson*[18], complexes of the general type **5** have been systematically synthesized mostly for the purpose (as with the Cp-derivatives) of investigating the catalytic effect on olefin polymerization. The chloro derivatives **5**, X = Cl, proved to be rather unstable expect in the absence of easily-abstractable β-ligands, and the stability decreased markedly with increasing degree of alkylation. On the

**1** **2** **3** **4**

M = Ti, Zr

$R_nMX_{4-n}$

**5** M = Ti, Zr; X = Cl, Br, OR', $NR'_2$; n = 1–4

Scheme 1. Various types of organo-titanium and -zirconium compounds with π-ligands (**2**—**4**) and σ-ligands (**1**, **3**, **5**) attached to the metal center. Cp = cyclopentadienyl.

other hand, the alkoxy and, especially the dialkylamino complexes **5**, X = OR' or $NR'_2$, showed a thermal stability which was sometimes fully comparable with that of the Cp-derivatives[26].

The alkoxy and aryloxy derivatives **5**, X = OR', n = 1 were chosen for the first investigations in our group on the use of organo-titanium and -zirconium compounds for the following reasons:

a) There were structural[27] and thermodynamic[28] indications that alkoxy groups do not only form a σ-bond with titanium, but also act as strong π-donors, *i.e.* as 4-electron ligands. This should make an important contribution to the stability of such complexes.

b) There were some indications that compounds of this type can add to carbonyl groups (Gilman-test[29] with *Michler*'s ketone).

c) Titanates—compounds of the type $Ti(OR)_4$—which serve as starting materials for the complexes $R'Ti(OR)_3$ are industrially available and therefore cheap. When purchasing 50 kg batches, 1 kg $Ti(OiPr)_4$ presently costs *ca.* \$ 5.00, 1 kg $Zr(OBu)_4$ *ca.* \$ 10.00.

d) In contrast to compounds of most other heavy metals, hardly any toxic effects of $Ti(OR)_4$ and $Zr(OR)_4$ are known[30], not least because—unlike the Cp-derivatives—they are very rapidly hydrolyzed by water and the resulting oxide-hydrates cannot be reabsorbed.

In the present article, we will concentrate on the applications of the organometallic reagents derived from $Ti(OR)_4$, $Ti(NR_2)_4$ and $Zr(OR)_4$ which do not contain Cp-ligands or additional metals. Some other new, general applications of Ti- and Zr-derivatives will be mentioned in Section 9. No experimental details will be given here because a further article on the subject is currently in preparation, in which the preparative aspect will be given prominence (—with many "recipes"!)[31].

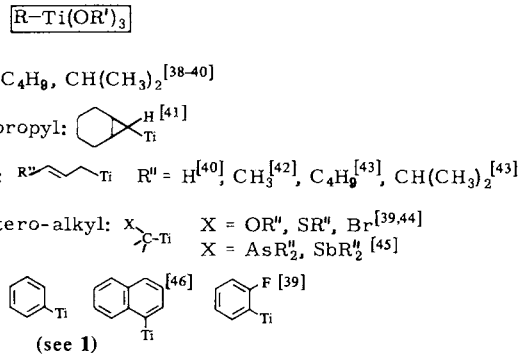
## 3. Preparation of $(R'O)_3TiR$, $(R'O)_3ZrR$, and $(R'_2N)_3TiR$ Compounds in Solution—Metal Exchange from Li- and Mg-Derivatives

Tetraalkoxy- and tetraaryloxy-titanium and -zirconium compounds, the so-called titanates and zirconates are, in general, available by reaction of the corresponding tetrahalides with alcohols. On a laboratory scale, the exchange

$$Ti(OR)_4 \xrightarrow[-\,ROH]{+\,R'OH} Ti(OR')_4 \quad (3)$$

$$ClTi(OR)_3 \xrightarrow[-\,ROH]{+\,R'OH} ClTi(OR')_3 \quad (4)$$

$$TiCl_4 \xrightarrow{LiNR_2} Ti(NR_2)_4 \xrightarrow{tBuOH} Ti(OtBu)_4 \quad (5)$$



$$3\ M(OR)_4 + MCl_4 \longrightarrow 4\ ClM(OR)_3 \quad (6)$$

$$3\ Ti(NR_2)_4 + TiBr_4 \longrightarrow 4\ BrTi(NR_2)_3 \quad (7)$$

$$\left.\begin{array}{l} RLi + ClM(OR')_3 \xrightarrow{-\,LiCl} \\ RMgX + ClM(OR')_3 \xrightarrow{-\,MgXCl} \end{array}\right\} \rightarrow R\text{–}M(OR')_3 \quad (8)$$

$$RLi + XTi(NR'_2)_3 \xrightarrow[-\,LiX]{} R\text{–}Ti(NR'_2)_3 \quad (9)$$

reaction (3) has proved simpler and more flexible. The low boiling alcohols ROH are distilled out of the equilibrium mixture; conditions which also succeed for the trialkoxy-chloro compounds, [Reaction (4)][32a]. Titanium tetra-*tert*-butoxide is prepared by alcoholysis of the tetramino compounds according to reaction (5)[32b]. Trialkoxy-, triaryloxy-, and tris(dialkylamino)-titanium halides and the corresponding $(RO)_3Zr$ halides are best prepared according to reactions (6) and (7)[33,34]. Treatment of the so-obtained monohalides with lithium or Grignard derivatives, the classical nucleophilic σ-organometallic compounds, leads quite generally—and in the case of titanium more rapidly than in the case of zirconium—to the expected organometallic reagents [see Reactions (8) and (9)][26]. Dialkylzinc[35], dialkylcadmium[35], tetraalkyllead[36], and alkylaluminum[37] derivatives have also been described as materials for the alkylation of titanium compounds. The more stable organotitanium compounds which are protected against β-H-abstraction can be isolated without difficulty. Thus, $MeTi(OiPr)_3$ can be obtained as a bright yellow oil which distills without decomposition at 50 °C/0.001 torr and which can be kept unchanged in the refrigerator under argon for at least a month. $PhTi(OiPr)_3$ **1** is precipitated as colorless crystals by cooling a hexane solution, and appears to be even stabler than the methyl derivative when similarly stored. Other organotitanium compounds of this general type are also stable, at least in solution. A list is given in Scheme 2. The reagents with R = butyl, 1,3-di-

Scheme 2. Different types of R—$Ti(OR')_3$ derivatives prepared by addition of organo-lithium or -magnesium compounds in ether or tetrahydrofuran (THF) to $ClTi(OR')_3$ in the same solvents [38—46]. *o*-Fluorophenyltitanium triisopropoxide is isolable in crystalline form at room temperature, whilst the Li- and Mg-derivatives eliminate fluoride above −50 °C [47].

thian-2-yl, and *o*-fluorophenyl are stable enough for reaction at temperatures of up to +25 °C. The suspected α- or β-eliminations do not compete with the desired reactions. Because of the lesser carbanion character of the organic residue attached to titanium, the α-sulfur substituted titanium compounds and the *o*-fluorophenyl derivatives for example are significantly more stable than the Li- and Mg-analogues (see legend to Scheme 2).

## 4. Reactions of Organotitanium Triisopropoxides—Superselectivity of the Additions to Carbonyl Groups

An introduction to the reactivity and selectivity of these compounds for comparison with the corresponding Li- and Grignard-reagents is provided by a study of $MeTi(OiPr)_3$, which can easily be prepared on a large scale and free from metal halides according to reaction (8).

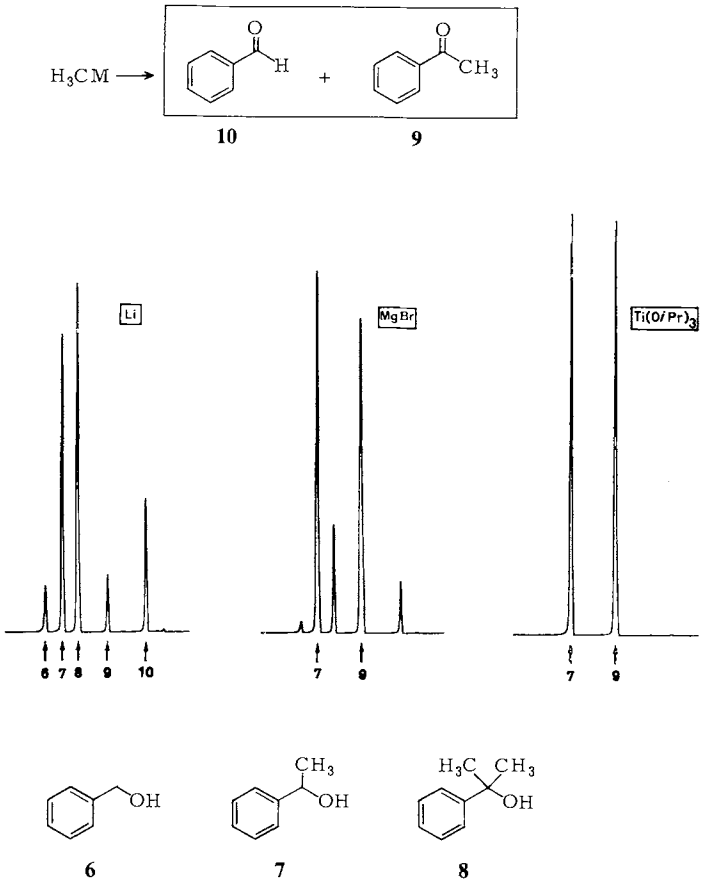


Fig. 1. Comparison of the 1:1:1 reactions of methylmetal derivatives with benzaldehyde and acetophenone in ether at room temperature. The titanium reagent distinguishes perfectly between aldehyde and ketone! (The reactions with $CH_3Li$ and $CH_3MgBr$ are further complicated by the occurrence of aldol reactions between the carbonyl compounds.)

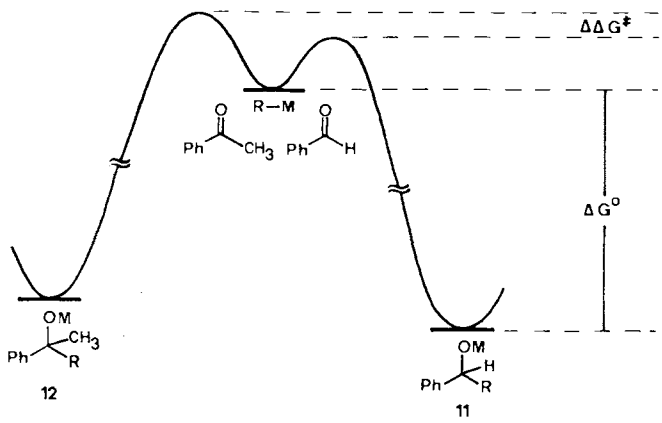
Treatment of a 1:1 mixture of benzaldehyde and acetophenone in ether with 1 equivalent of $MeTi(OCHMe_2)_3$ at room temperature gives a product mixture for which the gas chromatographic analysis is shown in Figure 1[38]. As one sees, there is a difference between the results for methyl-lithium and -magnesium bromide on the one hand, and for the methyltitanium reagent on the other "like day and night". It can be roughly estimated from these experiments that the difference $\Delta\Delta G^{\neq}$ for the addition of methyllithium to benzaldehyde and to acetophenone is less than 1 kcal/mol (see Fig. 2)[48]. By way of contrast, aldehydes react with methyltitanium triisopropoxide at $-50$ to $-20\,^{\circ}C$, whereas ketones require room temperature for reaction. We estimate that the $\Delta\Delta G^{\neq}$ value for the competition reactions shown in Figures 1 and 2 is *ca.* 7 kcal/mol, which corresponds to a ratio of reaction rates of $10^5:1$ at room temperature. As can be seen from the results of further competition experiments (Table 1), all the organotitanium compounds tested by us are able to distinguish between aldehyde and ketone to a similarly high degree. Addition of the R group from $RTi(OiPr)_3$ to esters, thiolesters, nitriles, and nitro groups was not observed and, in addition, no reaction occurred with alkyl halides, aryl halides, and epoxides. Some examples of reactions with substrates having functionality additional to the aldehyde group[39,49,50] are shown in Scheme 3.



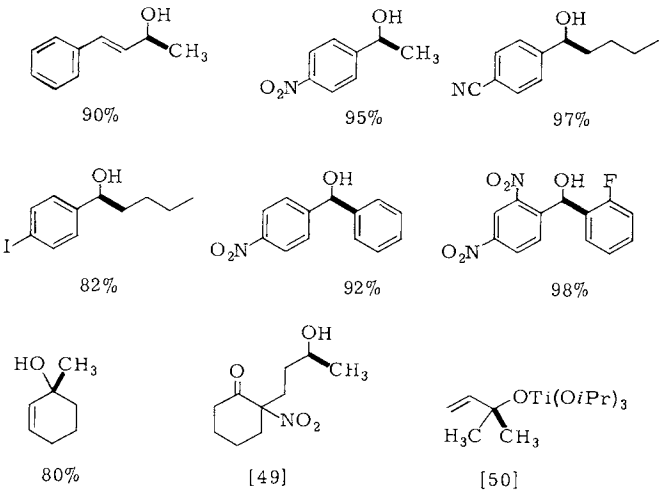


Fig. 2. Selectivity of organolithium and organotitanium reagents in reactions with a 1:1 mixture of benzaldehyde and acetophenone: Reaction energy profile. $\Delta G^0 > 40$ kcal/mol.

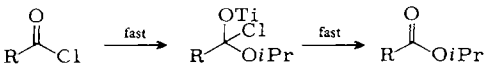

Table 1. Selectivity of organo-lithium and -titanium reagents in reactions with a 1:1 mixture of benzaldehyde and acetophone: Examples.

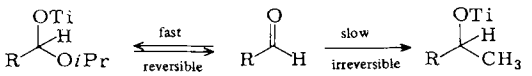
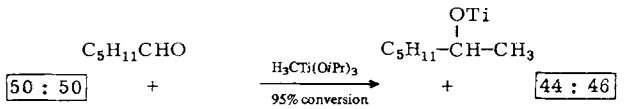
| R— in R—Li and R—$Ti(OiPr)_3$ | Li-reagent $T$ [°C] | 11/12 | Ti-reagent $T$ [°C] | 11/12 |
|---|---|---|---|---|
| $H_3C$— | 20 | 40/60 | 20 | >98/2 |
| $H_5C_6$— | 0 | 40/60 | 0 | >98/2 |
|  | | — | −95→RT | >98/2 |
|  | | — | −80→RT | >98/2 |
|  | −80 | 33/67 | −80→RT | >95/5 |
| $H_5C_6SCH_2^-$ | −50 | 67/33 | 20 | >98/2 |
|  | −70 | 67/33 | 20 | >98/2 |
|  | | — | −95→RT | >98/2 |

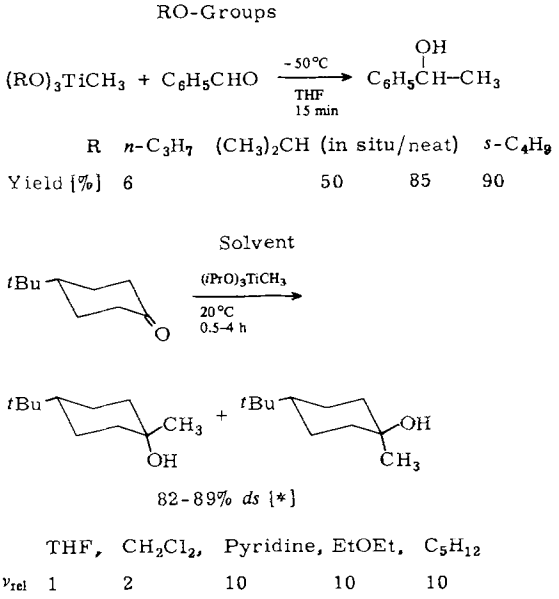


Scheme 3. Products from the reactions of organotitanium triisopropoxides $RTi(OiPr)_3$ with functionalized carbonyl compounds [39]. The bonds made during the reaction are drawn with thick lines. The percentages given refer to isolated yields of $^1H$-NMR spectroscopically pure compounds.



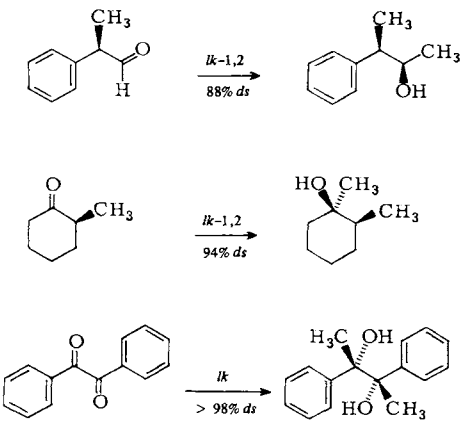
Organic esters are transesterified at room temperature to the corresponding isopropyl esters[38] (cf. also Section 9). Similarly, acid chlorides react at lower temperature to give isopropyl esters and not the expected methyl ketones! This surprising effect may be explained if in both cases the isopropoxy group is transferred faster than the methyl group to the carbonyl center [see Reactions (10) and (11)]. Elimination of chloride in the case of the acid chloride then gives the ester, whereas in the case of the aldehyde, the reversibility of the initial transfer allows ultimate reaction with the methyl group.

(10)



(11)

(12)



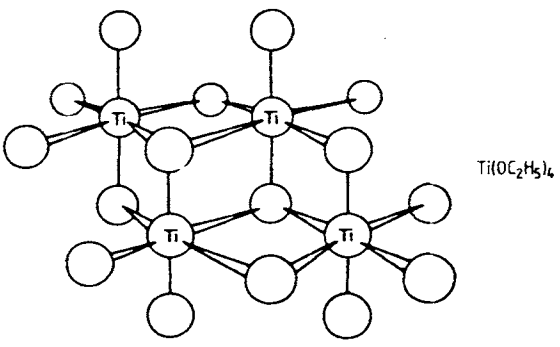
The methyltitanium reagent also cleanly distinguishes between two aldehydes having different degrees of steric hindrance[51] [see Reaction (12)].

By varying the RO-groups attached to the reagent, it can be shown that there is a clear tendency for bulky groups R to increase the reactivity (see Scheme 4 and cf. Section 7). This unexpected result appears plausible when one considers the structural properties of the titanium alkoxides[53]: The X-ray structure analysis of $Ti(OEt)_4$[52] shows that in the crystalline state the compound is present as a tetramer (Fig. 3), so that every metal atom has an octahedral surrounding of oxygen atoms. Cryoscopic molecular weight determinations also show titanium tetra(*n*-alkoxides) to exist as tetramers in concentrated solutions. In more dilute solutions they exist as trimeric aggregates[53]. If, however, the alkyl chain is branched, as in isopropyl and *tert*-butyl titanates, the solutions can be shown to contain monomeric species[53], as for $MeTi(OiPr)_3$ itself[54]. The steric hindrance at the metal center, which hinders aggregate formation, leads therefore to a more reactive (because monomeric) reagent.

Scheme 4. Dependence of the rate of the addition of methyltitanium trialkoxides to aldehydes and ketones on the RO groups (yield, top) and on the solvent (relative rate, bottom) [39].

The reactions are only slightly influenced by solvent, as exemplified in Scheme 4 by the addition of $MeTi(OiPr)_3$ to *tert*-butylcyclohexanone. The diastereoselectivity (% *ds*)[55] of the equatorial attack on this ketone is hardly dependent on solvent[39]. It is worth noting that solvents such as dichloromethane, pyridine, and acetonitrile, which would all react with lithium or Grignard reagents, can be used without difficulty[39]. Further examples of highly diastereoselective carbonyl additions of $CH_3Ti(OiPr)_3$ with 1,2- (see Scheme 5), 1,3-, and 1,4-induction are known[56].

Scheme 5. Further diastereoselective additions of $CH_3Ti(OiPr)_3$ to carbonyl groups [40, 56] (cf. also Scheme 4). The relative topicities of the reactions are specified with the *lk,ul*-nomenclature [57].



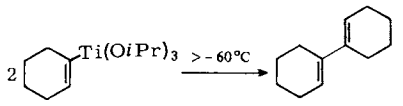


Fig. 3. Crystal structure of titanium tetraethoxide. The ethyl groups have been omitted [52].

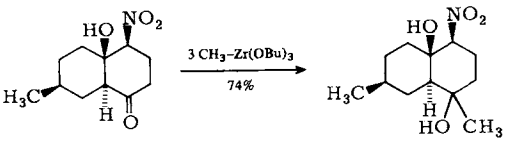
[*] *ds* is the abbreviation for diastereoselectivity: 82—88% *ds* signifies that 82—88% of one diastereomer and 18—12% of the other are formed.

## 5. Organozirconium Tributoxides—High Carbonylophilicity, Low Basicity

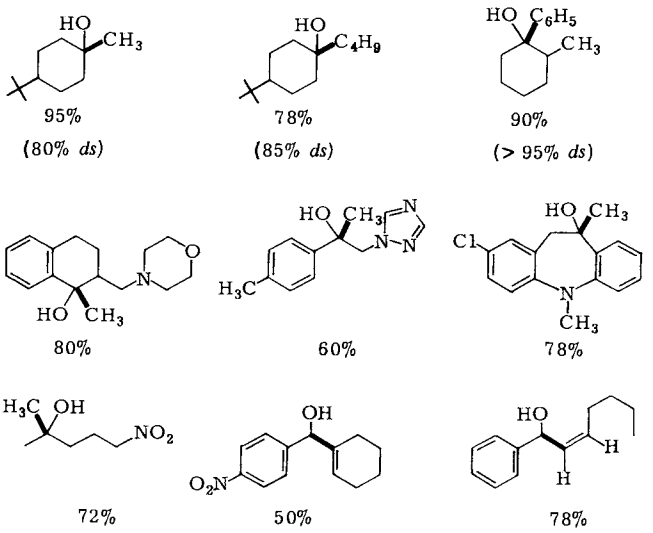
In the reactions of the organotitanium reagents mentioned up to now, the organic group has shown marked nucleophilic, carbanionic reactivity instead of acting as a base. Thus, $RTi(OR')_3$ compounds behave like especially nucleophilic main group metal derivatives with R-metal σ-bonds, this being the case even when R is an allylic ligand (see Section 6). However, in certain cases, the here undesired transition metal character of titanium becomes apparent, which limits the application of reactions of this type. For example, it is not possible to add *vinyl*titanium reagents to carbonyl compounds: On heating a solution of 1-cyclohexenyltitanium triisopropoxide in the presence of benzaldehyde, one observes an oxidative coupling according to reaction (13) with reduction of the metal[58].



(13)

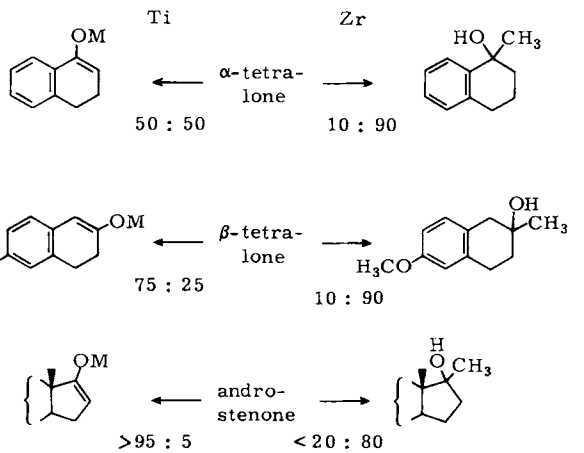
It is also impossible to add *tert*-alkyltitanium compounds: Addition of benzaldehyde to the mostly black solutions derived from chlorotrialkoxytitanium and *tert*-butyllithium gives, besides unreacted benzaldehyde, only benzyl alcohol and the pinacol formed from benzaldehyde, which indicates the presence of reduced titanium compounds[59]. The β-H-elimination (reductive elimination) obviously takes place more rapidly than addition to the carbonyl group in this case.

These limitations led to the investigation of the analogous zirconium compounds, as it was expected that zirconium, an element from the *second* transition metal period, would be less easily reduced. Up to now, investigations[60] have been centered almost exclusively[56] on the most easily available organozirconium tributoxides, for which the following common features and differences in comparison with titanium have come to light:



a) Similar preference for aldehyde- as for ketone-carbonyl groups.
b) Similar behavior to the organotitanium derivatives with respect to diastereoselectivity and compatability with other functional groups; see the list of examples in Scheme 6 and the "shop-window" reaction (14).

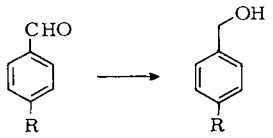
(14)



*one* Diastereomer

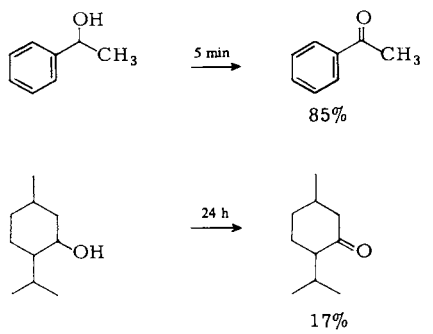
c) Although organotitanium derivatives are certainly much less basic than lithium or Grignard reagents, their *C*-nucleophilicity is not high enough with respect to the carbonyl group of easily enolizable ketones. As emerges from Schemes 6 and 7, the zirconium compounds show a marked affinity for the carbonyl group of these substrates.—The low basicity of the organozirconium compounds is the most useful aspect of these reagents from a preparative point of view.
d) In contrast to the titanium analogues, vinylzirconium compounds are stable for a short time at room temperature and may be added to aldehydes and ketones; see examples in Scheme 6 (bottom).

Scheme 6. Alcohols by reaction of organozirconium tributoxides with carbonyl compounds [60]. The newly made bonds are drawn with thick lines. The adducts obtained from three particularly easily enolizable aryl ketones verify the high nucleophilicity and low basicity of the organozirconium compounds, while the three adducts from substituted cyclohexanones and the reaction product from the *cis*-hexenyl derivative display their diastereoselectivity and configurative stability respectively.



e) α-Branched alkyl groups attached to titanium lead to difficulties: The isopropyl group may be added to *ca.* 60% extent to aldehydes, whilst the *tert*-butyl group only acts as a reducing agent on the metal. In contrast to this, the corresponding zirconium reagents transfer even the *tert*-butyl group to carbonyl compounds to a large extent[60].
f) For reactions of certain organozirconium reagents (as for example butyl-, vinyl-, and *tert*-butyl-zirconium al-

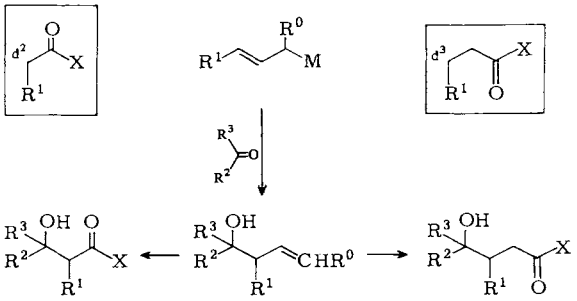
Scheme 7. Comparison of the reactions of methyltitanium and methylzirconium trialkoxides with easily enolizable ketones. The ratios of enolate formation to addition for methyltitanium triisopropoxide are shown on the left; those for methylzirconium tributoxide are shown on the right.



koxides) reduction of the carbonyl compound is observed as well as the desired addition (Table 2). Since

Table 2. Reaction times of the zirconium tetraalkoxide-catalyzed Meerwein-Ponndorf-Verley reduction as a function of the *p*-substituents of benzaldehydes (10 mol-% $Zr(OiPr)_4$, isopropyl alcohol, room temperature).

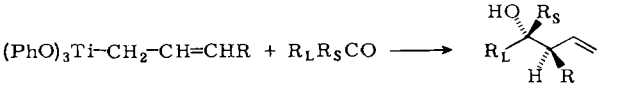
| R | *t* [h] | Yield [%] |
|---|---|---|
| $NO_2$ | 8 | ≈100 |
| C≡N | 24 | >90 |
| Cl | 24 | >90 |
| H | 24 | ≈60 |
| $OCH_3$ | 24 | ≈10 |
| $N(CH_3)_2$ | 24 | <1 |



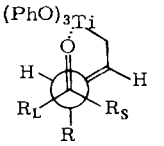
this reduction occurs also with zirconium tetraalkoxides, it must be due to a Meerwein-Ponndorf-Verley reaction rather than β-H-abstraction [see Reaction (1)]. Indeed, *Meerwein* himself showed the effectiveness of zirconium tetralkoxides for this reaction, as well as that of the more conventional aluminum alkoxides[61]. Scheme 8 shows how zirconium tetraalkoxides represent interesting alternatives to aluminum alkoxides[63] with regard to reaction conditions, catalytic effectiveness, and selectivity, particularly also for the analogous Oppenauer oxidation[62].

Scheme 8. Oppenauer oxidation of two alcohols with chloral (in each case 1:1.2, 5 mol-% $Zr(OiPr)_4$, room temperature); note the dramatically different rates of the two reactions.

## 6. Allylic Organotitanium Compounds—Amazing Diastereoselectivity of the Addition to Ketones



Nucleophilic allylmetal derivatives are synthetically equivalent to enolates ($d^2$-reactivity) or $d^3$-reagents[9] (see Scheme 9). If their reactions are diastereoselective, they lead to configuratively pure, branched-chain homoallylic alcohols and thus to β- or γ-hydroxy-carbonyl compounds. They are therefore important for the stereoselective synthesis of open-chain or macrocyclic natural products. Since a review article on this subject has recently appeared in this journal[64], it is only necessary here to deal briefly with the significance of allylic organotitanium derivatives, laying particular stress on the newest results which have not yet appeared in the literature.



Scheme 9. The nucleophilic allylation reagent seen as corresponding to a $d^2$- or a $d^3$-synthon depending on the nature of $R^0$ and way the primary adduct from the addition to aldehydes or ketones is further transformed. In the first case, it serves for the synthesis of aldols. To be preparatively useful, allylic metal derivatives must react regioselectively at the $R^0$- *or* $R^1$-substituted C-atom and diastereoselectively to give *l*- *or u*-isomers.

Reagents of this type, which are derived from hydrocarbons, are most easily prepared from $ClTi(OR)_3$ and allyl-Grignard reagents according to reaction (8)[42,43]. Of those RO-groups tested up to now, the phenoxy group has proved most useful. For a large number of examples, it has been established that the relative topicity *lk* for the joining of the two trigonal centers is preferred (Table 3)[42,43,57]. High diastereoselectivity (*ds*[55]) is observed even with ketones, which is surprising considering the necessarily smaller difference in steric requirements of the groups $R_L$ and $R_S$. Thus, the reagents distinguish equally well between phenyl ($R_L$) and H ($R_S$) as between phenyl ($R_L$) and

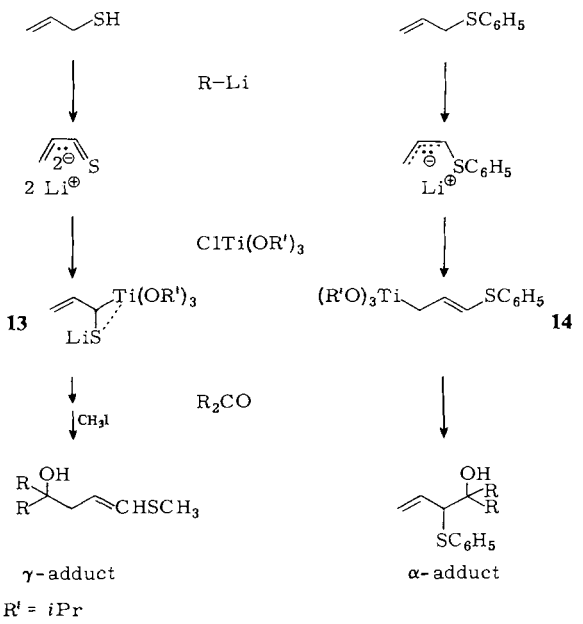


Table 3. Diastereoselectivity (*ds*) for the addition of 2-alkenyltitanium triphenoxide to aldehydes and ketones. Up to now, 28 examples are known [42, 43, 57]. Only for ketones with a small difference in sizes between $R_L$ and $R_S$ (*e.g.* cyclohexyl/ethyl) is the selectivity insufficient for preparative purposes (<70%). The highest induction is observed with aliphatic aldehydes. Other alkoxy or aryloxy groups on titanium (*e.g.* isopropoxy, 2,4,6-trimethylphenoxy) give lower selectivity than the phenoxy group, which has the further advantage that the acidic phenol formed on work-up may be easily removed.—It is also worth noting, that the selectivity increases on going from R = methyl to R = butyl and R = isopropyl, *i.e.* as the group R of the allyl residue attached to Ti gets larger.
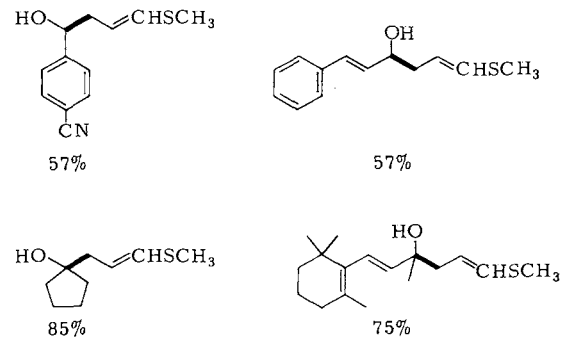
*lk* (if priority $R_L > R_S$)



| $R_L$ | $R_S$ | % *ds* with R = $CH_3$ | $C_4H_9$ | $CH(CH_3)_2$ |
|---|---|---|---|---|
| Ph | H | 85 | 93 | 98 |
| Ph | $CH_3$ | 88 | 87 | 87 |
| Ph | C≡C—$CH_3$ | 72 | 77 | 77 |
| *t*Bu | H | >98 | | |
| *t*Bu | $CH_3$ | >98 | | |

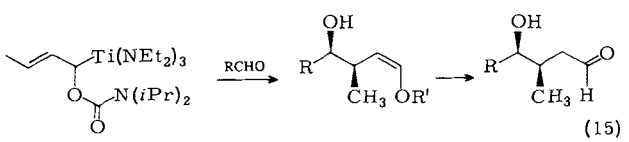
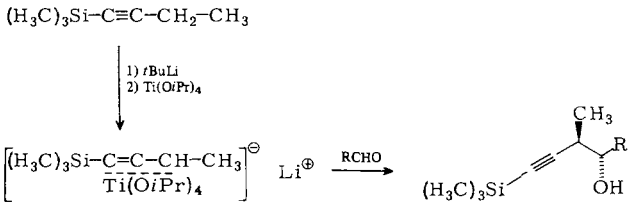
methyl ($R_S$) or *tert*-butyl ($R_L$) and phenyl ($R_S$). To our knowledge, no other examples of such highly diastereoselective addition to ketones are known[65].



Example with **13**:

Example with **14**:

Scheme 10. Titanation of sulfur-substituted allyllithium compounds, which themselves show unsatisfactory α/γ-selectivity. The dilithiated thioacrolein reacts with one equivalent of titanium chlorotriisopropoxide to give the reagent **13** which adds completely (>98%) γ-selectively to aldehydes and ketones (altogether 18 examples). In contrast, the titanated allylphenyl sulfide, reagent **14**, is fully α-selective (examples, bottom right). The structures given for **13** and **14** are based on the assumption that the allyl groups in this type of titanium derivative are $\eta^1$-ligands and react at the unmetalated C-atom (cf. Newmann projection in Table 3) [42, 43, 66].

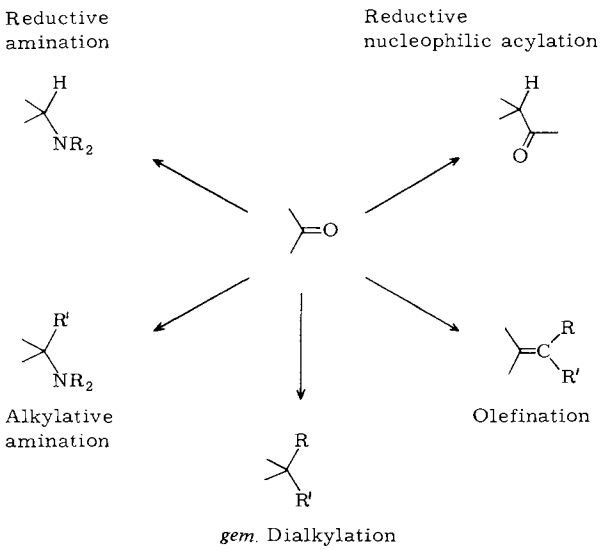


(15)

Hetero-substituted allyltitanium derivatives also show high regioselectivity [see Scheme 10 and Reaction (15)].

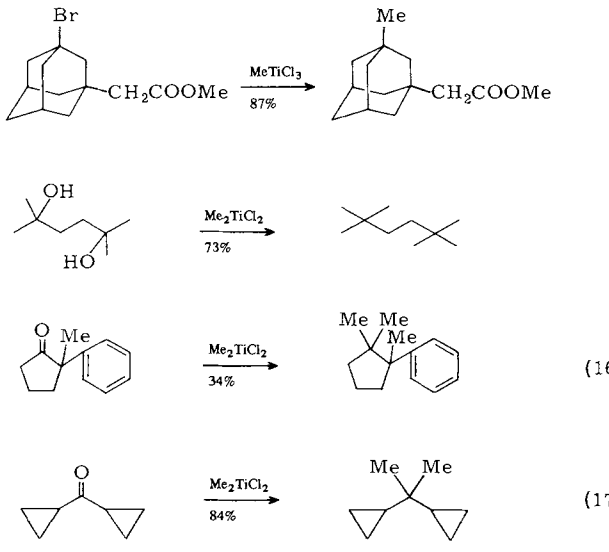
The sulfur-substituted allyl anion derivatives 2-propene-1-thiol and allyl(phenyl) sulfide have, up to now, only been reacted with a maximum of 90% α- or γ-selectivity[67,68]. After treatment with titanium chlorotriisopropoxide, however, the selectivity achieved is so high that the "wrong" isomer cannot be detected by $^1$H-NMR spectroscopy[69].— In the case of the metalated allylurethane [Reaction (15)], the derivatives were compared with Li, Al(*i*Bu)$_2$ and Ti(NEt$_2$)$_3$, and titanium again performed best; it gave almost exclusively the *Z*-enol-urethanes with relative topicity *lk*. These latter compounds may be hydrolyzed to diastereomerically pure β-methyl-γ-hydroxyaldehydes[66,70].

An example of a regio- and diastereo-selective propargylation[71] using an anionic titanium complex is shown in Scheme 11.



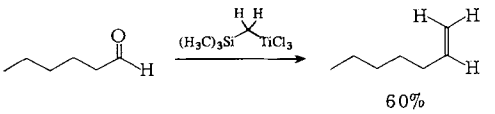
Scheme 11. Diastereoselective synthesis of alkynols by reaction of lithiated allenyl derivatives with aldehydes in the presence of Ti(O*i*Pr)$_4$ [71].—By mixing solutions of MeLi and Ti(O*i*Pr)$_4$ a reagent is formed which behaves neither as methyllithium nor, however, as MeTi(O*i*Pr)$_3$. Acetophenone is extensively enolized[72]. A complex is also formed with Ti(NEt$_2$)$_4$ which does not behave like MeTi(NEt$_2$)$_3$ [72].—Possibly in all three cases ate-complexes of the type (RTiX$_4$)Li are present.

As may also be inferred from the summary of an article concerned with the addition of crotylmetal compounds to aldehydes[64], one can see that the (RO)$_3$Ti-allyl derivatives described here are in general the reagents of choice for stereoselective CC bond formation with relative topicity *lk*. This also applies even when the allyl groups are more highly substituted than with a methyl group (→crotyl), and especially for additions to unsymmetrical ketones.



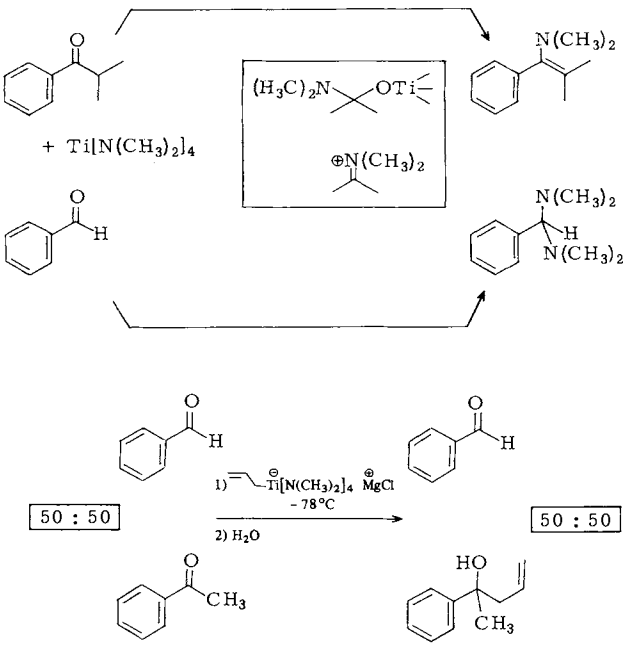
## 7. Geminal Dialkylation and Amination/Alkylation of Carbonyl Compounds—The Dramatic Influence of the Ligands X in RTiX$_3$ and R$_2$TiX$_2$

There exists a group of transformations through which the oxygen of carbonyl derivatives is replaced by other atoms (see Scheme 12). Reagents which perform such reactions in *one* step are particularly useful, *e.g.* Na[B(CN)H$_3$] and an amine (reductive amination)[73], 2-lithio-2-trimethylsilyl-1,3-dithianes and ketene-thioacetal hydrolysis (reductive nucleophilic acylation)[74], or olefination by the Wittig-Horner or Peterson[75] methods. For geminal dialkylation, practically[76] only multi-step methods are known up to now. This is true also of the geminal amination/alkylation reaction reminiscent of the Mannich reaction and the Strecker amino-acid synthesis. The latter two transformations can be realized in one step with organotitanium reagents if, instead of the (RO)$_3$Ti-derivatives, those bearing halide or amino ligands, or having more than one carbon substituent are used.



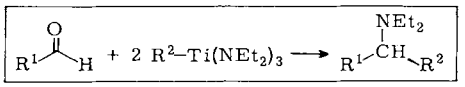
Scheme 12. Examples of the replacement of the oxygen in the C=O group by other atoms. One step reactions of this type represent particularly useful synthetic transformations.

While the organotitanium triisopropoxides mentioned up to now are inert with respect to aliphatic and aromatic halides, the alkyltitanium halides obviously retain enough Lewis acidity of $TiCl_4$ and thus react with typical $S_N1$ active alkylating agents[77,78]. However, since no carbon-chain rearrangement occurs, even in particularly favorable cases, the reaction is certainly not of the $S_N1$ type (see examples in Scheme 13; cf. the *tert*-alkylation of silyl enol ethers catalyzed by $TiCl_4$[79]). Dimethyltitanium dichloride also effects a direct geminal dimethylation of ketones[78] [see Reactions (16) and (17) in Scheme 13].

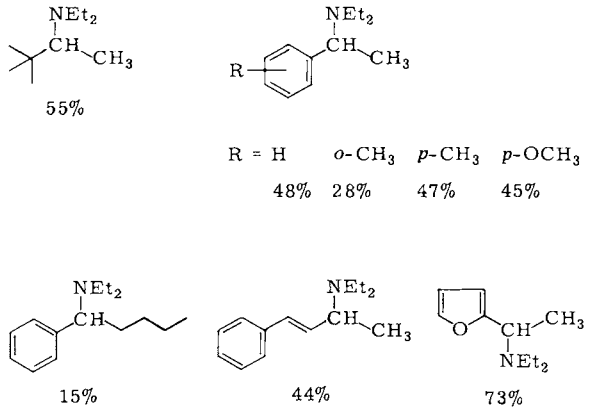


Scheme 13. CC bond formation of the Wurtz type. Replacement of tertiary hydroxy groups with methyl and one-step geminal dimethylation of ketones (without rearrangement of the carbon framework!). Such reactions do not occur when the substrates shown here are treated with $MeTi(OiPr)_3$ [77, 78]. The role of the titanium in the geminal dimethylation is not yet clear: $Me_2TiCl_2$ is prepared from $ZnMe_2$ or reacted in presence of $ZnCl_2$-catalyst [78]. Up to now, no examples of direct geminal dialkylation with alkyl groups other than methyl are known.

The titanium-modified Peterson reagent in reaction (18) demonstrates once more the "tuning" possible for organometallic reagents by which exactly that reactivity desired for the planned applications is obtained: While the lithium or the magnesium derivative reacts similarly with aldehydes *and* ketones[75], the titanium reagent trimethylsilylmethyltitanium trichloride reacts selectively with aldehydes[80]. The corresponding trialkoxides do not react under the same conditions[41].



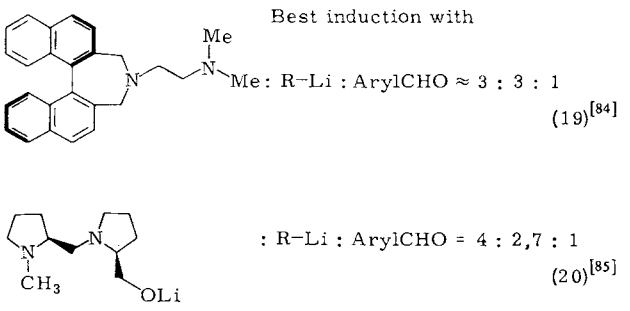
(18)

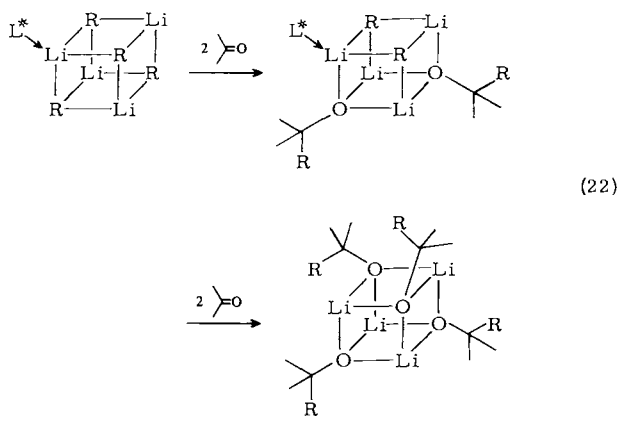


From the most reactive to the most stable $RTiX_3$ derivatives! Because of the donor properties and steric hindrance of the amino groups, the alkyltitanium tris(dialkylamides) show the least tendency to undergo reductive elimination. They can indeed be isolated—sometimes by sublimation at temperatures of over 100 °C[34]. The affinity for oxygen ligands is particularly high in the case of aminotitanium compounds. The known reactions of titanium tetrakis(dialkylamides) with enolizable and non-enolizable carbonyl compounds are shown in Scheme 14. We have found that the easily obtainable methyltitaniumtris(diethylamide) [Reaction (9)] reacts with non-enolizable aldehydes with cleavage of the oxygen function and transfer of both the methyl *and* a dialkylamino group to the carbonyl C-atom

Scheme 14. *First and second conversion:* Reactions of an enolizable and of a non-enolizable carbonyl compound with titanium tetrakis(dimethylamide) to give the enamine and aminal, respectively. The oxygen atom is removed from the organic substrate [81] (cf. also the Weingarten method [82] for the preparation of enamines [34] from ketone or aldehyde + $TiCl_4$ + excess $R_2NH$). *Third reaction:* Reaction of the allyl ate-complex with a 1 : 1 mixture of aldehyde and ketone affords the adduct of the *ketone* with >99% selectivity. Apparently, formation of the titanated hemi-aminal of the aldehyde is preferred, which is stable at low temperature and serves as protecting group, so that the allyl group is transferred to the ketone. "Ketone selectivity" based on the same principle has also been observed with $Ti(NEt_2)_4/CH_3Li$ (see also Scheme 11 [72] and the examples in the review [124]).

(see Scheme 15). All the attempts made so far to elucidate the reaction mechanism show that it is the diethylamino group rather than the methyl group which is first transferred. This behavior of $CH_3Ti(NEt_2)_3$ is reminiscent of the reaction of $CH_3Ti(OiPr)_3$ with acid chlorides [Reaction (10)]. In that case also we were forced to conclude that the hetero-ligand (O*i*Pr) is transferred faster to the carbonyl C-atom than the carbon nucleophile ($CH_3$). For allylic titanium tris(diethylamides) derivatives[51,66,70] the picture is obviously reversed: the allyl group is faster [see *e.g.* Reaction (15)]. The scope and limitations of geminal amination/alkylation are at present under study[72].



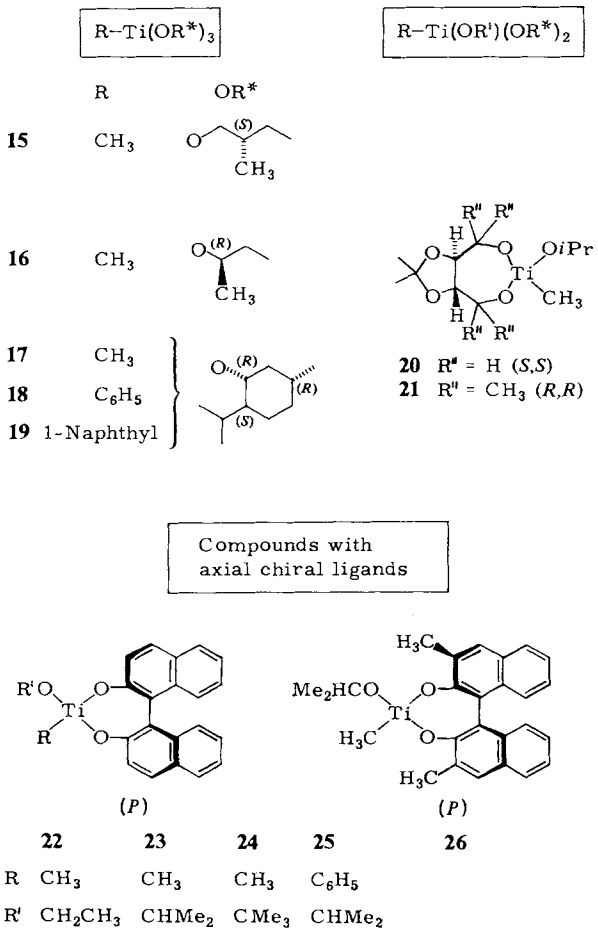


Scheme 15. Geminal diethylamination/alkylation of non-enolizable aldehydes with methyl- and butyltitaniumtris(diethylamide). The mechanism probably involves transfer of an alkyl group to the C-atom of the methyleneammonium ion $R^1CH{=}\overset{\oplus}{N}Et_2$.

## 8. Enantioselective Addition of Chiral Organotitanium Reagents RTi(OR*)$_3$ to Aldehydes— There are Two Sides to Every Carbonyl Group

Many attempts have been made to render the carbanionic, nucleophilic organo-lithium and -magnesium reagents enantioselective by addition of chiral auxiliaries ("enantioface differentiation"). As the examples in Scheme 16 show, it is extremely difficult to know how to go about rationally developing reagents for distinguishing the enantiotopic faces of an electrophilic substrate in this way.

Certain properties of the organotitanium reagents already described may facilitate a rational approach to the designing of enantioselective reagents for addition to carbonyl compounds: (1) Whilst the auxiliaries for organolithium reagents can only bind to the metal center *via* their hetero atoms with relatively weak coordinate forces, for the titanium reagents *charged* hetero atoms can be used[90]. This means that Coulomb forces will, especially in organic media, hinder the dissociation of ligands of this type from the metal. (It is obviously important for the effectiveness of a chiral ligand shell that it should remain intact during

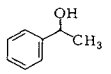


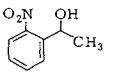
Scheme 16. Asymmetric induction for RLi-addition to aldehydes under the influence of chiral ligands, solvents, alkoxides, and amides [83–86]. "Recipes" (19)—(21) have been successfully applied, in which only a part of the reagent reacts. The reason for this is probably that the chiral modified lithium compounds occur as aggregates and the intermediate products as mixed aggregates [Reaction (22)] [87–89]. Thus, the effective reagent, and therefore the degree of asymmetric induction, is different at the beginning and at the end of the reaction!

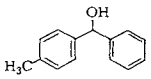
the build up of steric strain when the "wrong" face of a carbonyl group is approached.) (2) In many cases, it can be expected that *mononuclear* titanium complexes will occur (cf. discussion in Section 4), for which a study of the interaction between chiral reagent and substrate is much easier. (3) Not least, the great structural resemblence to modified lithium aluminum hydrides should be pointed out. The extensive work already carried out in this area[91,92] may serve as a guide for the choice of suitable ligands.

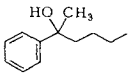
The modification of the organotitanium derivative with chiral ligands is simple. The alcohol or phenol is treated with titanium chloride triisopropoxide and isopropanol is distilled off [Reaction (4)]. The so-obtained chlorotitanium derivative with chiral OR* groups is converted *in situ* into the chiral reagents **15—26** shown in Scheme 17 by treatment with the desired organo-lithium or -magnesium compound. Some of the results already obtained for the enantioselective additions to aldehydes and to one ketone are collected in Table 4[46].

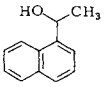
Scheme 17. Chiral organotitanium reagents **15**—**26** from amyl alcohol of fermentation, (*R*)-2-butanol, (*R,S,R*)-menthol, two tartaric acid derivatives [93, 94], and two binaphthol derivatives [95-97].

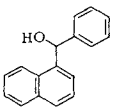












It is not surprising that the derivatives of simple alcohols (with the exception of menthol) effect only a small asymmetric induction, since the alkoxy groups may freely rotate, allowing the adoption of many different conformations. This rotation is frozen in the complexes with bidentate ligands, and this may be the main reason for the greater effectiveness of these systems. Whilst only insoluble, polynuclear complexes were obtained on attempting to form the tartaric acid derivative **20**, **21** has proved to be an effective reagent, which, since it is derived from tartaric acid, has the advantage of being easily obtainable in both enantiomeric forms[94,98,99].

The marked influence of the third alkoxy group in the axially chiral binaphthol derivatives **22**—**26** makes the geometry shown in Figure 4 appear plausible. The high enantioselectivity for the addition of the phenyltitanium reagent **25** to *p*-tolualdehyde is worth noting, as the best examples previously have been limited to the transfer of alkyl groups[99].

As may also be seen from Table 4, the reagents show a strong substrate dependence. Thus it is, for example, better to add methyl to naphthaldehyde than the alternative naphthyl (with **19**) to acetaldehyde.

Enantiomeric excesses (*ee*) of up to nearly 90%, without optimization, have been obtained for reaction partners which either cannot be reacted with chiral modified or-

Table 4. Some examples of the enantioselective addition of the reagents **15**–**26** to aldehydes and to a ketone (valerophenone). As expected (see also Scheme 3) the reactions are "carbonyl selective", and the entire alkyl equivalent is probably transferred with constant enantioselectivity (in contrast to the examples in Scheme 16).

ganolithium compounds, or else do not react nearly so well[99,100]. It appears to us to be just a matter of time before the most broadly applicable OR* group combination, reaction conditions and substrates for these enantioselective additions are found.

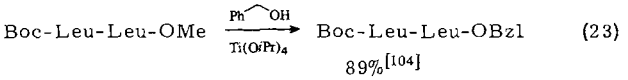
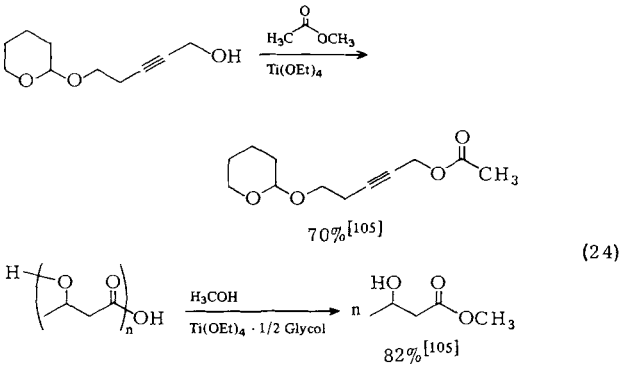
## 9. Other New Applications of Titanium and Zirconium Derivatives in Organic Synthesis—Titanium with its Finger in Every Pie!



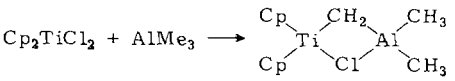
Derivatives of these metals are not just important as components of the Ziegler-Natta catalysts for use in indus-

try. They also play a key role in many other important processes. Thus, they have been employed in many investigations of nitrogen fixation[101]; they are used to effect olefin metathesis[102], and they serve as catalysts for esterification and transesterification on a laboratory as well as an industrial scale (see Scheme 18).

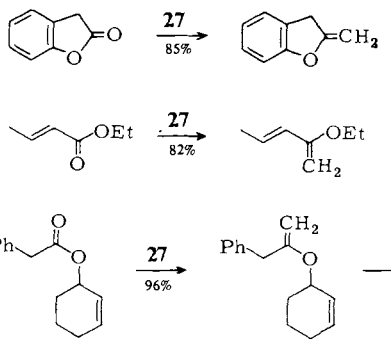


70%[103]

89%[104] (23)

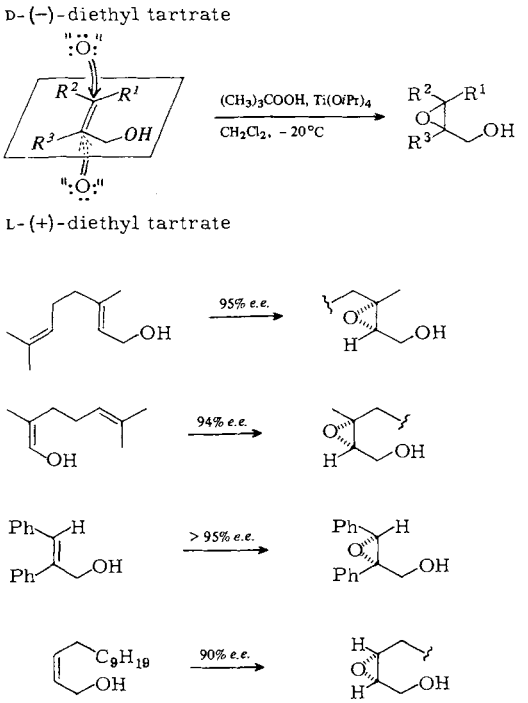


70%[105]



82%[105] (24)

Scheme 18. Titanium catalyzed transesterification [104–106] of acid- and/or base-sensitive substrates. The general scheme at the top shows that, depending on the medium, OH-groups may be esterified, and OCOR-groups saponified or transesterified. The method was first described in the patent literature nearly 3 decades ago, but, until recently, it has been practically unknown in research laboratories, particularly in the universities [103], despite its unique advantages. The examples shown, demonstrate that β-OR-substituted esters neither racemize nor are converted into α,β-unsaturated esters during the reaction. The selectivity of the method can be seen from reactions (23) and (24): amides of carbonic acids—and therefore peptide bonds—remain unaffected, as do acetals and the CC triple bond. Boc esters are only slowly transesterified [104, 106], whereas methyl and ethyl esters react much faster. Many applications of this method in the area of protecting-group chemistry are doubtless still to be discovered.



During the last decade, countless synthetic methods have been discovered and developed which make use of the special properties of titanium and zirconium derivatives. Review articles dealing with several of these applications have appeared in the literature: The hydrozirconation of olefins[25, 107], the use of $TiCl_4$ as a Lewis acid for reactions of silyl enol-ethers[79, 108], and the coupling of carbonyl compounds and olefins with low-valent titanium[108, 109]. In the modification of enolates for diastereo- and enantio-selective aldol reactions it has been found that $Cp_2ZrCl$- and $(iPrO)_3Ti$-enolates react with *ul*-additions, independent of the enolate configuration[110–112]; the *ul* addition of titanium enehydrazinates of aldehydes to aldehydes to give aldol-like products has also been recently reported[125].

Two very different processes involving the use of titanium compounds, one stoichiometric, one catalytic, have recently excited attention: The olefination of esters[113, 114] with the Tebbe reagent **27**[115] (Scheme 19), and the highly

Scheme 19. Methylenation of esters and lactones with the Tebbe reagent **27** according to *Evans, Grubbs et al.* [113]. As reaction (25) shows, this method makes possible a novel application of the Claisen rearrangement.

Scheme 20. Titanium-catalyzed enantioselective epoxidation according to *Sharpless et al.* [116]. Regardless of the substrate structure, particularly of the degree of substitution and the configuration of the olefinic double bond of the allylic alcohol, attack is always at one enantiotopic face, with ≥95% selectivity (→ ≥90% *ee* in the product)! The method has been applied in the preparation of key compounds for the synthesis of methymycin, erythromycin, disparlure, leucotriene C-1 [117], leucotriene A, C, D, and E [118], as well as in the total synthesis of (+)-disparlure and of salt marsh caterpillar moth pheromone [119]. Carbohydrates have also been synthesized by a new sequence depending upon the method [120, 121].

enantioselective epoxidation of allyl alcohols with $Ti(OiPr)_4/tBuOOH$/diethyl tartrate[116] (Scheme 20). It is beyond the scope of this article to attempt to estimate the importance of these applications of Ti- and Zr-reagents. They are mentioned here only to demonstrate the variety of chemistry Ti and Zr display to interest the synthetic organic chemist.

## 10. Final Remarks and Outlook

The development of synthetic methods has reached a stage in which it has become more important to find more and more selective conditions for performing known reactions than to discover entirely new reaction types. Realization of this goal will fulfill the synthetic chemists dream of having reagents which attack polyfunctional substrates completely specifically, at only *one* center, without the necessity of recourse to protecting group techniques. Thus, the present article describes only three new reaction types: direct geminal dimethylation, geminal amination/alkylation of aldehydes and ketones and the olefination of esters and lactones to give enol ethers; the stress lies on carrying out old reaction types "made to measure". Non-toxic titanium and zirconium derivatives can discriminate almost perfectly between the polar C=X groups of aldehydes, ketones, esters, amides, carbon dioxide, nitriles and nitro compounds. The differences in reaction rates with different functional groups are sometimes so high, that selectivities are achieved reminiscent of those obtained in enzyme reactions of natural substrates. On the other hand, the tartaric acid/titanate-catalyzed enantioselective epoxidation of allylic alcohols is actually superior to typical enzymatic transformations in that it proceeds with >95% enantioselectivity almost independent of the substrate structure.

The possibilities for further applications of the novel nucleophilic reagents discovered so far, as well as entirely new discoveries in this area are equally exciting. Thus, it is imaginable that these reagents will become available directly from alkyl halides or olefins avoiding the intermediacy of lithium and magnesium derivatives. A catalytic variation might also be possible!

We are convinced that further selective processes of this type, based on transition metals, will soon be discovered. Thus, for the forseeable future, organic synthesis will not lose its potential to surprise and hence its attractiveness.

The following sentence from *Karl Ziegler* from the year 1965[123] has once more become true: "... the organometallic compounds, that is to say the products of a type of symbiosis between the two main branches of chemistry, which finally led to success".

*The results from our laboratory mentioned here have naturally come about through team work. We wish to thank P. Booth, E. Hungerbühler, R. Lehmann, R. Naef, C. D. Maycock, A. Olivero, A. Planta, M. Schiess, P. Schnurrenberger, T. Weber, L. Widler, M. Yoshifuhi and M. F. Züger for their enthusiasm and their work, for varying lengths of time, in the area of Ti- and Zr-derivatives. We are also grateful to the firm of Dynamit-Nobel AG, Troisdorf for generous supplies of titanates and zirconates. We thank Sandoz AG, Basel for their continuing financial support of our group. Finally, we are indebted to Miss S. Sigrist, Mrs. D. Westen and to Mrs. H. Zass for preparing the manuscript and to Dr. K. Lawson for translating it from German into English.*

## Unusual NMR Phenomena of Anthracene and Phenanthrene Dianions – Thermal Stimulation of Triplet States in Antiaromatic Systems

By *Abraham Minsky, Amatzya Y. Meyer,* and *Mordecai Rabinovitz**

Many aromatic polycyclic benzenoid hydrocarbons undergo a facile reduction process with electropositive metals to yield the corresponding dianions. The $^1$H-NMR spectra of some of these doubly charged species exhibit characteristic high-field chemical shifts, which reflect the existence of an enhanced antiaromatic-paratropic ring current[1–3]. We report here some unusual NMR phenomena which occur in the metal reduction of anthracene **1** and phenanthrene **2** under various conditions.

**1**

**2**

Anthracene **1** was reduced by adding lithium metal to a THF solution of the hydrocarbon[1,2]. The blue-green solution of the dianion exhibited a well resolved high-field $^1$H-NMR spectrum consisting of an AA'BB' multiplet and a singlet. Over the range $-60\,^\circ$C to $+40\,^\circ$C the $^1$H-NMR spectrum remained unchanged. No change could be detected in the $^{13}$C-NMR spectrum, which is identical with that already reported[1].

The Hebrew University of Jerusalem
Jerusalem 91904 (Israel)

A different and rather unexpected situation occurs when sodium is used as reducing agent. The $^1$H-NMR spectrum of $\mathbf{1}^{2\ominus}2\,Na^{\oplus}$ is strongly temperature dependent. At $+40\,^\circ$C the blue solution of the dianion exhibits no signals, whereas at $+20\,^\circ$C three very broad signals at $\delta \approx 3.85$ (2,3,6,7-H), 2.90 (1,4,5,8-H), and 1.65 (9,10-H) are detected. As the temperature was gradually decreased, the signals became markedly sharper. However, even at $-60\,^\circ$C the fine structure expected from an AA'BB' system was not observable. The change in line width of the absorptions was reversible, *i.e.* lowering the temperature produced line sharpening. We could not obtain the $^{13}$C-NMR spectrum of $\mathbf{1}^{2\ominus}2\,Na^{\oplus}$ at room temperature, and even at $-30\,^\circ$C the signal/noise ratio was poor.

The same experiment was conducted in a solution of THF and dimethoxyethane (DME) (95:5). At $+20\,^\circ$C the $^1$H-NMR signals were much sharper than those exhibited in pure THF at the same temperature. Already at $0\,^\circ$C, the signals at $\delta = 3.9$ and 2.9 exhibited fine structure, and at $-30\,^\circ$C the spectrum revealed a well resolved AA'BB' multiplet along with a narrow singlet at $\delta = 1.64$. At this temperature the $^{13}$C-NMR signals were similar to those exhibited by $\mathbf{1}^{2\ominus}2\,Li^{\oplus}$. As with pure THF, the changes in the NMR spectrum as a function of temperature were completely reversible.

When the reduction was carried out with potassium at $-80\,^\circ$C in THF, a $^1$H-NMR spectrum could not be recorded for the dianion, even at $-20\,^\circ$C. At lower temperatures very broad absorptions at $\delta = 3.8$, 2.9 and 1.6 were found.

Reduction of phenanthrene **2** with sodium in THF to the corresponding dianion did not afford NMR signals over the temperature range $-80\,^\circ$C to $+40\,^\circ$C. However, reduction with lithium resulted in very broad, high-field $^1$H-NMR signals at $-30\,^\circ$C. Decreasing the temperature further to $-80\,^\circ$C caused line sharpening, but a highly resolved spectrum could not be recorded. Conducting the experiment in THF/DME (95:5) caused further sharpening. The chemical shifts were similar to those already reported [$\delta = 0.5$ (1,8-H), 2.7 (2,7-H), 1.6 (3,6-H), 0.7 (4,5-H), $-1.9$ (9,10-H)][3]. A clear reversibility of the NMR line shapes as a function of temperature was observed.

All these phenomena are strongly related to factors which dominate the ion solvation equilibrium[4]—highly solvated ion pairs exhibit sharp well-resolved NMR signals, whereas contact pairing results in dramatic line

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0101-0045 $ 02.50/0* 

broadening. Several interpretations are possible, of which the most plausible is based on theoretical considerations which assign a relatively narrow LUMO-HOMO energy gap to antiaromatic species. We presume that the anthracene and phenanthrene dianions are thermally excited triplet state systems in equilibrium with the singlet ground state. At elevated temperatures the excited triplet is highly populated and this results in total disappearance or significant broadening of the NMR signals. Decreasing the temperature causes a relaxation to the singlet ground state as indicated by the observation of NMR signals. This interpretation is consistent with the results of ESR measurements carried out on $\mathbf{1}^{2\ominus}2Na^{\oplus}$ and $\mathbf{2}^{2\ominus}2Na^{\oplus}$. The ESR spectra of the frozen THF solutions (−130 °C) of $\mathbf{1}^{2\ominus}2Na^{\oplus}$ and $\mathbf{2}^{2\ominus}2Na^{\oplus}$ reveal a broad signal centered at 3200 G, along with a sharp signal at 1590 and 1595 G, respectively. The low-field signals are assigned to the $\Delta m_s = 2$ transition, a feature highly characteristic of a triplet state[5].

The presumed singlet-triplet equilibria are not simple thermal processes but are strongly related to factors which dominate the solution equilibria, *i.e.* nature of the counterion and the solvent[4].

## A Model Reaction of an Elementary Step in the Fischer-Tropsch Synthesis: $[C_6Me_6RuH(C_2H_4)PR_3]^+$ from $C_6Me_6Ru(CH_3)_2PR_3$

By *Heidrun Kletzin, Helmut Werner*, Orhan Serhadli,* and *Manfred L. Ziegler*

Studies of the mechanism of the heterogeneous Fischer-Tropsch synthesis have established that the chain-forming step, *i.e.* the coupling of C—C bonds on the surface of the catalyst proceeds *via* successive insertion of methylene groups into the metal-alkyl bonds[1a]. Following a β-H elimination, α-olefins are formed as the initial products of the F.T. synthesis.

Model studies, which are based on reactions *in solution* (*i.e.* in a homogeneous phase), have mainly been directed towards the hydrogenation of CO ligands and the insertion of methylene or alkylidene groups into metal-alkyl bonds[1b]. *Maitlis et al.* showed that thermolysis of the dinuclear complex *cis*-$[C_5Me_5RhCH_3]_2(\mu\text{-}CH_2)_2$ produces, apart from methane, mainly ethylene and propene, which can be explained by single and double $CH_2$-insertion, respectively, into a Rh—$CH_3$ bond[1c]. The *in situ* synthesis of a mononuclear $W(CH_2)CH_3$ complex was achieved by *Cooper et al.*[1d], who allowed the $PF_6$ salt of the paramagnetic cation $[(C_5H_5)_2W(CH_3)_2]^+$ to react with 3-diphenylmethylene-6-triphenylmethyl-1,4-cyclohexadiene (as source of the trityl radical), and isolated the ethylene(hydrido) complex $[(C_5H_5)_2WH(C_2H_4)]^+$ as the major product. In addition to the methyl(methylene) complex $[(C_5H_5)_2W(CH_2)CH_3]^+$, a further intermediate $[(C_5H_5)_2WC_2H_5]^+$ was also postulated.

We have now found that an analogous reaction sequence probably occurs after elimination of a *hydride* ion from a *neutral* (diamagnetic) dimethylmetal compound. Dropwise addition of a solution of $[CPh_3]PF_6$ in $CH_2Cl_2$ to a solution of $C_6Me_6Ru(CH_3)_2PPh_3$[2] **1a** in $CH_2Cl_2$ at −78 °C, and subsequent warming to room temperature, leads, after addition of ether, to formation of a colorless, rather air-stable solid. The yield after recrystallization from $CH_2Cl_2/Et_2O$ is 71%. Elemental analysis and spectroscopic data[3a] confirm the composition $[C_6Me_6RuH(C_2H_4)PPh_3]PF_6$ **2a**. The analogous reaction of $C_6Me_6Ru(CH_3)_2PMePh_2$ **1b** with $[CPh_3]PF_6$ in the molar ratio 1:1 affords $[C_6Me_6RuH(C_2H_4)PMePh_2]PF_6$ **2b**[3a] in 56% yield. We presume that the trityl cation attacks an $RuCH_3$ group of **1** and eliminates a hydride ion. The initially formed cationic methyl(methylene) complex **A** undergoes $CH_2$-insertion (or $CH_3$-migration) to give the isomeric coordinatively unsaturated ethyl compound **B**, from which the product **2** is formed by hydride shift from the β-C atom to the metal. That the solvent is *not* involved in the formation of **2a** or **2b** is proved by the synthesis of pure $RuH(C_2H_4)$ cations in $CD_2Cl_2$.

The $CH_2$-insertion, which mechanistically presumably corresponds to CO-insertion[4a], should proceed very rapidly according to MO calculations[4b]. Apart from our findings and those of *Cooper et al.*, the results of *Thorn* and *Tulip*[4c] are also consistent with this. They found that *mer*-$IrBr_2(C_2H_5)(PMe_3)_3$ is formed from *mer*-$IrBr(CH_3)CH_2OCH_3(PMe_3)_3$ and $BrCH_2OCH_3$, probably also *via* a cationic $Ir(CH_2)CH_3$ intermediate, which spontaneously rearranges to the isomeric $IrC_2H_5$ compound.

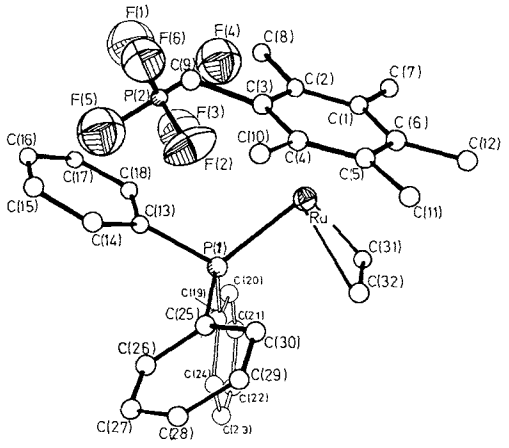

Fig. 1. Structure of **2a** in the crystal. Selected bond lengths [pm]: Ru—P(1) 229.7(2), Ru—C(31) 216.8(10), Ru—C(32) 219.4(9), C(31)—C(32) 141.1(13).

The structure of **2a** has been established by X-ray crystal structure analysis[3b]. Although the position of the hydride ligand cannot be given precisely, the bond angle of 90.2° between P(1), Ru, and the midpoint of C(31)—C(32) confirms the octahedral coordination around ruthenium. Since the $^1$H-NMR spectrum does not change between −80 and +35 °C ([D$_6$]acetone), it seems certain that the ethylene(hydrido)cations **2**$^{\oplus}$ are configurationally stable in solution, and that the equilibrium with the ethyl tautomers—in contrast to the structurally analogous complexes $[C_5H_5RhH(C_2H_4)PR_3]^+$ (R = Me, *i*Pr)[5]—is almost completely shifted to the side of $[C_6Me_6RuH(C_2H_4)PR_3]^+$.

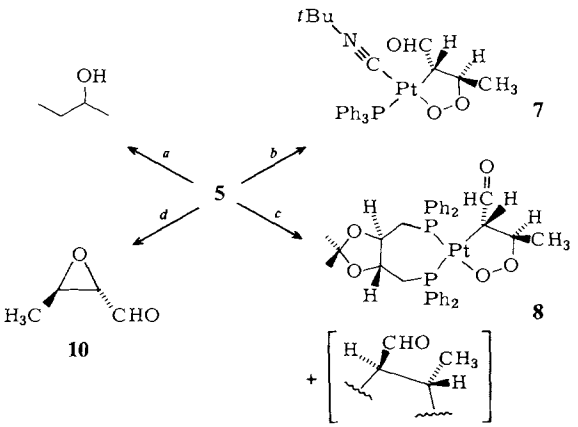
## Kinetic and Thermodynamic Control in the Reaction of $(Ph_3P)_2PtO_2$ with (*E*)-2-Butenal

By *Michael J. Broadhurst, John M. Brown**, and *Robert A. John*

$(Ph_3P)_2PtO_2$ **1** reacts with aldehydes and ketones to form stable adducts **2**[2]. In a small number of cases, electrophilic olefins react with **1** to form related cycloadducts of structure **3** *via* formal Michael addition of a ring-opened platinum peroxide[4]. We report that (*E*)-2-butenal reacts with **1** to form both types of complex sequentially and define the mechanism of their interconversion.



Reaction of excess (*E*)-2-butenal with complex **1** in $CH_2Cl_2$ for a few hours at ambient temperature leads to formation of adduct **4** (m.p. = 130 °C, decomp.), which can be isolated and purified. Redissolution of **4** in $CH_2Cl_2$ in the presence of excess (*E*)-2-butenal causes formation of its isomer **5** (m.p. = 145 °C, decomp.) in quantitative yield after several days at 35 °C. The mechanism of this transformation was established using [4-$^2$H]$_3$-(*E*)-2-butenal[8] and monitoring the reaction by $^1$H- or $^2$H-NMR spectroscopy. Only a pathway requiring displacement of bound (*E*)-2-butenal by deuterated material without reversion to complex **1** is consistent with the relative levels of deuteriated and protiated material at different stages of rearrangement; intramolecular reaction is ruled out. The preferred mechanism is shown in Scheme 1.

Scheme 1. Mechanism for the rearrangement of **4** into [$^2$H$_3$]-**4** and [$^2$H$_3$]-**5**.

The reaction product **5** undergoes a range of ligand displacement reactions (Scheme 2). One $PPh_3$ moiety is displaced by *t*-BuNC with high regioselectivity, and both moieties by chelating bisphosphanes, such as DIOP. Reduction of **5** with $NaBH_4$ led to 2-butanol as the only organic product, whereas **4** gave only (*E*)-2-buten-1-ol under similar conditions. Notably, the reaction of **5** in $CD_2Cl_2$ gave oxirane **10** as the main (90%) organic product (93% stereoselectivity) together with $(PPh_3)_2Pt(CF_3CO_2)_2$. The reaction course is unaffected by a 5 mol excess of $PPh_3$, implying that reaction occurs within the coordination sphere rather than by release of (*E*)-2-butenal and $H_2O_2$[10], followed by epoxidation. The sequence constitutes a formal stoichiometric epoxidation by molecular oxygen[11] and is of considerable relevance to catalytic studies.

Scheme 2. Reactions of **5**. *a:* $NaBH_4$, $CH_3OH$; *b:* *t*-BuNC, $CH_2Cl_2$; *c:* *P,P'*-[2,2-dimethyl-1,3-dioxolane-4,5-bis(methylene)]bis(diphenylphosphane) (DIOP), $CH_2Cl_2$; *d:* $CF_3CO_2H$, $CD_2Cl_2$ or $C_6D_6$.

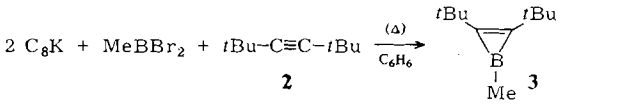
## Synthesis of Borirenes and Diboretenes — a Novel Class of 2π-Aromatic Compounds

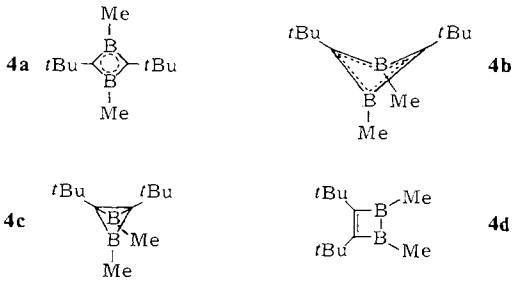


By *Sies M. van der Kerk*, Peter H. M. Budzelaar, Anca van der Kerk-van Hoof, Gerrit J. M. van der Kerk,* and *Paul von Ragué Schleyer*

Despite the fact that theoretical considerations[1] indicate that borirenes should be stabilized to a considerable extent by aromaticity, attempts at their synthesis have thus far met with little success.

From the reaction of di-*n*-alkylacetylenes with the methylboranediyl-generating system $2C_8K/MeBBr_2$[2,3] no borirenes can be isolated; 1,4-dibora-2,5-cyclohexadiene derivatives **1**, their formal dimers, are found instead. It was felt that, if borirenes are instrumental in the formation of dimers, there might be a better chance of trapping them by using an acetylene with bulky substituents as a substrate. Thus, the dimerization to a dimeric derivative might be sterically hindered.

Reactions were carried out between the graphite intercalation compound $C_8K$, $MeBBr_2$, and 2,2,5,5-tetramethyl-3-hexyne (di-*tert*-butylacetylene) **2**[4] in benzene, both under reflux and at room temperature. After work-up, GC/MS investigation of the distillate fractions showed that **1** had not been formed; instead, both reactions produced 2,3-di-*tert*-butyl-1-methylborirene **3**. It is suggestive for the stability of this borirene that in the mass spectrum of **3** the borirene-ring stays intact throughout the fragmentation of the molecule[5a].



+ $tBu_2C_2(BMe)_2$ **4**

In both reactions, but especially in the one carried out at room temperature, a compound of composition $t\text{-}Bu_2C_2(BMe)_2$ **4**[5b], the product of the reaction of two methylboranediyl units with one molecule of di-*tert*-butylacetylene was also formed.

**3** and **4** appear to have similar properties. They are colorless, extremely air- and moisture-sensitive liquids; their boiling points are close to that of di-*tert*-butylacetylene and they could not be separated by distillation. The NMR data[5c] were determined using mixtures and represent the results of preliminary experiments.

Several structures are possible for compound **4**: two 1,3-diboretenes (**4a** and **4b** of symmetries $D_{2h}$ and $C_{2v}$, respectively), a diborabicyclobutane **4c**, and a 1,2-diboretene **4d**. In the mass spectrum of **4** an additional fragment is found with half the molecular mass (rel. intensity 34%). We assign this to the fragment $[t\text{-BuCBMe}]^+$, originating from cleavage of the four-membered ring in a 1,3-diboretene (**4a** or **4b**). Fragmentation of the four-membered ring of the 1,2-diboretene **4d** is not expected to proceed *via* CC bond cleavage. Rather, cleavage of the B—C bonds should occur to produce fragments $[t\text{-}Bu_2C_2]^+$ and/or $[Me_2B_2]^+$ (or $[MeB]^+$), which are not found.

Our assignment of the 1,3-diboretene structure **4a** or **4b** in preference to the alternative 1,2-diboretene structure is supported by the results of extensive calculations on the possible isomers of the compound $(CH)_2(BH)_2$[1]. Further, it has been predicted[1] that of the 1,3-diboretenes the compound with $C_{2v}$ (puckered) symmetry (**4b**) should be the most stable.

The borirene derivative **3** appears to be thermally quite stable, in view of the fact that in the course of one of its syntheses a reflux period (in benzene) of 24 h was involved. This is borne out by the calculated resonance energy of $(CH)_2(BH)$, which is 70—75% of that of its carbocation analogue[1].

## [2+2]-Cycloadditions of Allyl Cations**

By *Herbert Klein, Gerhard Freyberger,* and *Herbert Mayr**

Allyl cations are versatile building blocks for the construction of carbocycles. *Hoffmann* has reported the syntheses of six- and seven-membered ring systems *via* [2+4]- and [3+4]-cycloadditions of allyl cations to 1,3-dienes[1]. We previously found that [3+2]-cycloadditions of allyl cations to alkenes provide an easy access to cyclopentenes[2a], and now report [2+2]-cycloadditions of allyl cations to afford cyclobutane derivatives.

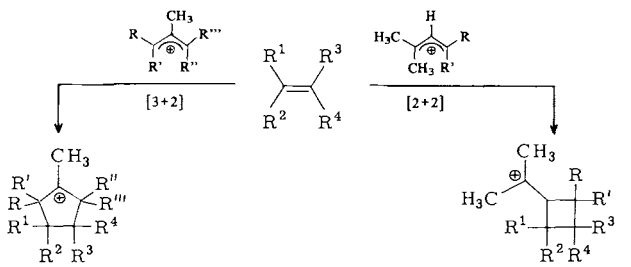
When a mixture of 4-chloro-2-methyl-2-pentene **1** and 2,3-dimethyl-2-butene **2** is treated with zinc chloride-ether at −78 °C, the cyclobutane **3**[3a] is obtained in 72% yield[2]. Similarly, 4-chloro-2,4-dimethyl-2-pentene **4** and 1-ethoxy-2-methyl-1-propene **5** give 80% **6**[3b]. In both cases only one (probably the sterically favored *trans*) isomer is detected by NMR spectroscopy. No linear intermediates were detected. Lewis acid catalyzed rearrangements of **3** and **6** to give thermodynamically more stable five-membered rings, which would have to proceed *via* secondary carbenium ions, were not observed. Treatment of **3** with zinc chloride-ether at 20 °C yields a complex mixture of products, which contains 2-chloro-2,3-dimethylbutane; its formation can be rationalized by [2+2]-cycloreversion of the cyclobutylcarbinyl cation and addition of HCl to **2**.

**1** $(CH_3)_2C{=}CH{-}CH(CH_3)Cl$

\+

**2** $(CH_3)_2C{=}C(CH_3)_2$

$\xrightarrow{ZnCl_2}$ **3**



**4** $(CH_3)_2C{=}CH{-}C(CH_3)_2Cl$

\+

**5** $(CH_3)_2C{=}CHOC_2H_5$

$\xrightarrow{ZnCl_2}$ **6**

2-Alkyl substituted allyl cations and alkenes undergo [3+2]-cycloadditions with formation of tertiary cyclopentyl cations[2a]. We have now obtained four-membered rings by reaction of alkenes with 1,1-dialkylated, 2-unsubstituted allyl cations. Here [2+2]-cycloadditions are preferred since they give tertiary carbenium ions, whereas the corresponding [3+2]-cycloadditions would afford secondary carbenium ions.

[*] Priv.-Doz. Dr. H. Mayr, H. Klein, G. Freyberger
Institut für Organische Chemie der Universität Erlangen-Nürnberg
Henkestrasse 42, D-8520 Erlangen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

However, not all 1,1-dialkylated, 2-unsubstituted allylic systems react to form four-membered rings: under identical conditions reaction of 1-chloro-3-methyl-2-butene with isobutene, 2-methyl-2-butene, and 2,3-dimethyl-2-butene yields exclusively linear addition products[2b]. According to molecular mechanics calculations[4], these acyclic adducts are more stable than the isomeric cyclobutane derivatives. On the other hand, the heat of formation of **3** is calculated[4] to be 3.8 kcal/mol more negative than that of the isomeric 6-chloro-2,4,5,5,6-pentamethyl-2-heptene; *gauche*-interactions destabilize the linear isomer to a greater extent than the cyclic system (*gem*-dialkyl effect[5]). Since steric effects should be similar in the corresponding carbenium ions, the different behavior of **1** and 1-chloro-3-methyl-2-butene in addition reactions with tetramethylethylene **2** can be rationalized.

[2+2]-Cycloadditions of this type can be expected if they are electronically favored over [3+2]-cycloadditions and if steric effects destabilize the linear adducts relative to the four-membered rings.

## NMR Studies of Yeasts Grown on Substrates at "Zero" Level Radioactivity

By *Ricardo Basosi, Claudio Rossi, Enzo Tiezzi**, and *Gianni Valensin*

The cultivation of different protein-rich microorganisms which utilize hydrocarbons (petrochemicals) as sources of carbon and energy has been frequently suggested[3]. The nutritional and biological value as well as the level of toxic substances have still to be studied; the effect induced by a prolonged alimentation on substrates which have less than the natural level of $^{14}$C radioactivity has also still to be investigated.

Since many correlations have been found between the NMR parameters of water and the physiological or pathological states of cells, as well as the conformations of cell constituents[8, 10–12], we have used water relaxation studies

[*] Prof. Dr. E. Tiezzi, R. Basosi, C. Rossi, G. Valensin
Institute of General Chemistry, University of Siena
Pian dei Mantellini 44, I-64100 Siena (Italy)

to investigate rapidly growing populations. The yeasts selected (*Saccharomyces cerevisiae* ATCC 9763, *Candida utilis* CBS 621 and *Saccharomycopsis lipolytica*) can be easily grown on ethanol, glucose and *n*-paraffin substrates. We used an ethanol substrate having various $^{14}C$ levels to ascertain whether a biological effect is apparent after many generations. Moreover the use of ethanol yields a cell biomass having a chemical composition quite similar to that obtained with a glucose substrate.

Cell samples were centrifuged, washed three times, and suspended in distilled water. NMR samples were prepared by adding 0.7 mL $D_2O$ (99.75%) to 0.3 mL of the cellular suspension. The $^1H$ spin-lattice relaxation time ($T_1$) was measured on a Bruker WH-90 NMR spectrometer using the ($\pi$-$\tau$-$\pi/2$) pulse sequence[10, 12]. The relaxation data obtained from *Candida utilis* and *Saccharomyces cerevisiae* with ethanol having various $^{14}C$ levels are shown in Table 1. A concentration of $2 \times 10^8$ cells per mL was used in each case. The error in this value is relatively large (*ca.* 20%). However, the dependence of $T_1$ on cell concentration[3], is not sufficient to account for the observed changes in $T_1$, suggesting a dependence on the level of radioactivity of the substrate, especially in the case of *Candida utilis*. Compared with cells grown on substrates having the "minimum" natural radioactivity, those cultivated on the same substrate without radioactivity give rise to shortening of $T_1$ whereas, in contrast, those grown on the substrate enriched by radioactivity give rise to longer $T_1$ values. A similar trend was shown by measurements on cultures at lower growth levels and also on lyophilized samples, but the effects were much less marked.

Table 1. Spin lattice relaxation times of water protons in *Saccharomyces cerevisiae* ATCC 9763 and *Candida utilis* CBS 621 grown on ethanol at different levels of radioactivity [a].

| Source of ethanol | Radioactivity [disintegrations per min/g] | $T_1$ [s] *Candida utilis* | *Saccharomyces cerevisiae* |
|---|---|---|---|
| Petrochemical | 0.2 | $1.7 \pm 0.1$ | $1.7 \pm 0.2$ |
| Fermentation | 19.0 | $3.6 \pm 0.2$ | $2.9 \pm 0.3$ |
| $^{14}C$ enriched | 6740.0 | $5.3 \pm 0.3$ | $3.9 \pm 0.2$ |

[a] Samples contained $(2 \pm 0.4) \times 10^8$ cells/mL.

Table 2 shows the spin-lattice relaxation data obtained from *Saccharomycopsis lipolitica* cultivated on different carbon and energy sources. The longest $T_1$ value was found for yeast cultivated on a glucose substrate, a "natural" substrate, while the cultures grown on *n*-paraffins displayed relatively shorter $T_1$ values. Similar results were obtained from lyophilized samples of *Candida boidinii* grown on both "natural" (glucose and xylose) and synthetic (methanol and ethanol) substrates[11].

Table 2. Spin-lattice relaxation times of water protons in *Saccharomycopsis lipolytica* grown on different substrates [a].

| Substrate | $T_1$ [s] |
|---|---|
| Glucose | $4.6 \pm 0.3$ |
| $C_{15}H_{32}$ | $3.1 \pm 0.2$ |
| $C_{16}H_{34}$ | $3.7 \pm 0.2$ |
| $C_{15}H_{32} + C_{16}H_{34}$ (1 : 1) | $3.4 \pm 0.3$ |

[a] Samples contained $(2 \pm 0.4) \times 10^8$ cells/mL.

The results reported here, together with those obtained on *Candida boidinii*[5] grown on different substrates, can be interpreted by assuming that the level of radioactivity of the substrate causes a biological effect that is detectable by measurement of the cell-water $T_1$. To our knowledge, this is the first time that "zero level" radioactivity is reported to affect cell behavior. Previously, NMR studies of cell water, besides other techniques, have been used to show biological damage resulting from radioactive sources[12]. Since ESR signals were not detected and the samples were carefully deoxygenated, paramagnetic impurities cannot account for the results. On the contrary, conformational modifications of cell constituents and changes in water content and in the molecular complexity of the sample have been alternatively used to explain the NMR behavior of cell water[8, 10, 12]. As a consequence, the observed change in $T_1$ could reflect any one of these phenomena or any combination of them. However, high levels of radiation are expected to cause cellular damage liberating interstitial water, so that a change in the water content seems the most proper explanation for the water $T_1$ behavior. It is important to underline that this effect becomes detectable only in populations after many generations.

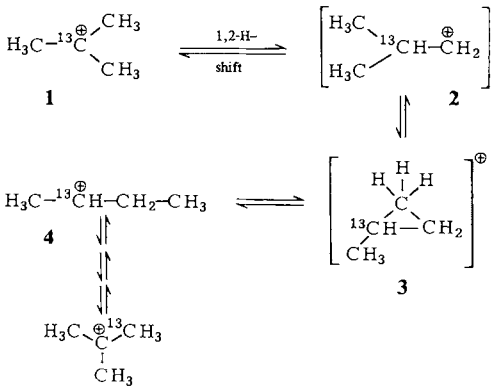
## C-Scrambling in the *tert*-Butyl Cation**



By *G. K. Surya Prakash, Altaf Husain,* and *George A. Olah**

The ease of hydrogen scrambling in secondary and tertiary carbocations in superacid media is well documented[1]. *Saunders* and *Rosenfeld* have shown[2, 3] that *tert*-pentyl and 1-methylcyclopentyl cations in $SbF_5/SO_2ClF$ solutions undergo methyl- and methylene-hydrogen scrambling at 110—140 °C, rendering all C and H atoms equivalent on the NMR time scale. The activation energy $E_A$ for this process was found[2, 3] to be *ca.* 18—19 kcal/mol for both systems. The scrambling was shown to occur *via* secondary cations and protonated cyclopropane intermediates rather than free primary cations.

A similar process is expected to occur in the *tert*-butyl cation. *Saunders et al.* mention[2a] an attempt to observe such a scrambling in the hexadeutero-*tert*-butyl cation at 100 °C, but were unable to observe any H/D exchange. We now wish to report that scrambling does occur in the *tert*-butyl cation **1**, but that the rate of exchange is too slow to be observed by NMR line-broadening experiments.

[**] Stable Carbocations, Part 237. This work was supported by the National Institutes of Health. *G. A. Olah* thanks the Alexander-von-Humboldt Stiftung for a Senior US Scientist Award.—Part 236, see G. A. Olah, A. L. Berrier, L. D. Field, G. K. S. Prakash, *J. Am. Chem. Soc. 104* (1982) 1349.

The cation **1** (60% $^{13}C$ enriched at the cationic center) was prepared from the correspondingly labeled *tert*-butyl chloride in $FSO_3H/SbF_5/SO_2ClF$ solution at −78 °C. A sample was sealed in a 10 mm NMR tube and heated to 70 °C in an oil bath. The $^{13}C$-NMR spectrum of the ion was recorded intermittently at room temperature (Fig. 1). $^{13}C$-scrambling is negligible at room temperature, but is essentially complete in 20 h at 70 °C. Even at 100 °C the rate of scrambling is too slow to be observed by NMR line-broadening, and hence it was not possible to determine any activation parameters for the process. A lower limit of $E_A \approx 30$ kcal/mol[4a] can be estimated for the scrambling process, which should correspond to the energy difference between the *tert*-butyl and isobutyl cations. A similar lower limit of 28 kcal/mol was estimated by *Saunders* and *Hagen*[2b] from the absence of hydrogen scrambling in the hexadeuterio-*tert*-butyl cation.

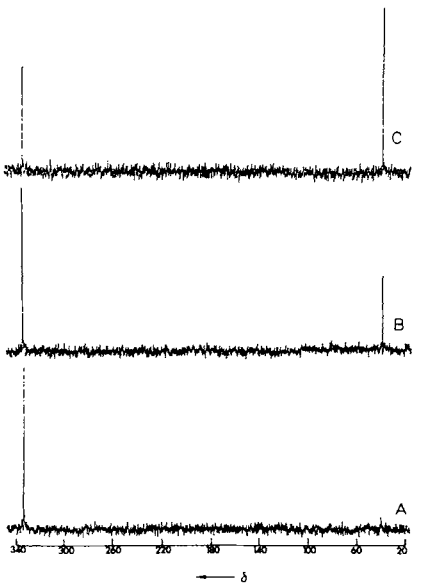

Fig. 1. $^1H$-decoupled $^{13}C$-NMR spectrum (20 MHz) of **1** in $FSO_3H/SbF_5/SO_2ClF$ at room temperature. A: immediately after preparation, B: after 2.5 h at 70 °C, C: after 9.5 h at 70 °C.

The most likely mechanism[4b] for the scrambling process is rearrangement *via* the primary isobutyl cation **2** involving the delocalized protonated methylcyclopropane intermediate (or transition state) **3** to the *sec*-butyl cation **4**. The *sec*-butyl cation scrambles all hydrogens and carbons and reverts back to the *tert*-butyl cation through the well documented pathway[1]. Furthermore, it was shown by *Brouwer*[5] that [1-$^{13}C$]-*n*-butane isomerized in HF/$SbF_5$/pentane solution at 2 °C to [2-$^{13}C$]-*n*-butane without giving isobutane. Under the reaction conditions, however, the protonated methylcyclopropane intermediate (or transition state) is quenched by the hydride-donor *n*-pentane before rearranging to an incipient primary cation leading to isobutane.

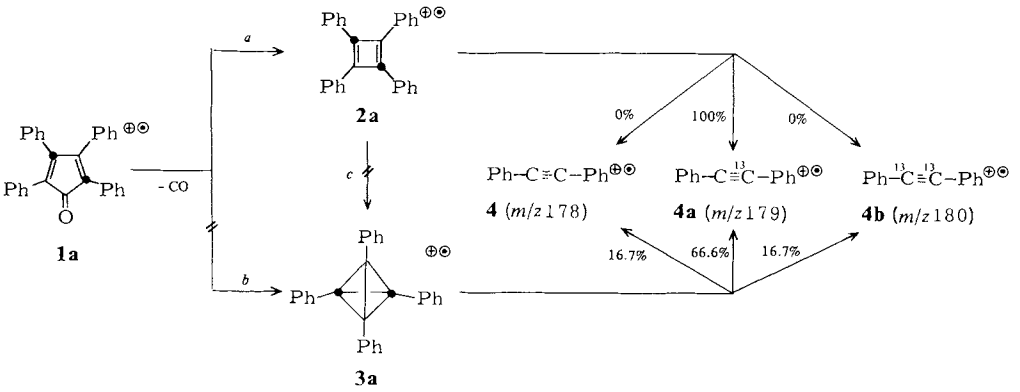
## Generation of the Tetraphenylcyclobutadiene Radical Cation by Ionizing Gas-Phase Decarbonylation**

By *Wolfgang Blum, Harry Kurreck, Wilhelm J. Richter, Helmut Schwarz**, and *Helga Thies*



*Dedicated to Professor Hans-Werner Wanzlick on the occasion of his 65th birthday*

Oxidation of tetra-*tert*-butylcyclobutadiene and -tetrahedrane with $AlCl_3/CH_2Cl_2$ and *t*-$C_4H_9^{\oplus}$, respectively, leads to formation of radical cations[1a], whose ESR and collisional activation spectra are identical. MNDO analysis[1a] of the valence isomerization, tetrahedrane ⇌ cyclobutadiene indicates for the sterically non-hindered tetramethyl system that the tetramethyltetrahedrane radical cation possesses no local minimum on the potential energy hypersurface; it spontaneously isomerizes to the tetramethylcyclobutadiene radical cation[1c]. From this it was concluded that a flattening to the cyclobutadiene system also occurs with the radical cation of the sterically more restricted tetra-*tert*-butyltetrahedrane.

We now report on an independent method of generating the previously unknown tetraphenylcyclobutadiene radical cation **2**. In the decarbonylation of 2,3,4,5-tetraphenyl-2,4-cyclopentadienone **1** ($M^{\oplus\odot}$ = 45% rel. int.) by electron impact ionization (70 eV), a signal is, *inter alia*, observed at *m/z* 356 (35%). The collisional activation mass spectrum[2] using MS/MS conditions[3] with ions of *m/z* 356, mass-selected by a triple quadruple instrument, only contains a single signal at *m/z* 178, which can be assigned to the diphenylacetylene radical cation **4**.

Scheme 1. ● = $^{13}C$.

When the experiment was carried out using the [2,4-$^{13}C_2$]-labeled isotopomer **1a** the following results were obtained: as expected, *m/z* 356 is quantitatively shifted to *m/z* 358, and its MS/MS spectrum contains only a single signal at *m/z* 179 (≙ **4a**) after isotopic correction[4]. The following conclusion can be drawn from this: Decarbonylation of **1** by electron impact ionization leads to an intermediate, which must be a derivative of ionized cyclobutadiene **2**. Generation of a tetraphenyltetrahedrane radical cation **3**, whose existence was postulated previously[5], is completely inconsistent with the data obtained for **1a**. If the tetrahedrane intermediate **3a** were really involved or a carbon scrambling of the $C_4$ moiety in the $[M-CO]^{\oplus\odot}$ ion obtained from **1a** were to occur, then the distribution pattern shown in Scheme 1 should be observed in the formation of the ionized diphenylacetylene isotopomers (**4**, **4a**, and **4b**). This does not occur. The results are only compatible with route *a* and certainly exclude route *b* and isomerization *c*.

[4] A weak signal at *m/z* 180 (6%) can be attributed to incomplete [$^{13}C_2$]-labeling of **1a**. 38% of **1** is present as the [$^{13}C_1$]-isotopomer, and the natural [$^{13}C$]-abundance in the $[M-CO]^{\oplus\odot}$ ion of this species gives rise to the formation of *m/z* 180. A signal at *m/z* 178 is not observed in the MS/MS spectrum of *m/z* 358.

## Novel One-Step Synthesis of Oxocyclopentanecarboxylates by Electrochemical Reduction of Cinnamic Acid Esters

By *Ikuzo Nishiguchi** and *Tsuneaki Hirashima*

The electrochemical reduction of α,β-unsaturated esters in aqueous solution usually gives the corresponding hydrodimers, *i.e.* adipic acid derivatives, as the main products[1c,2]. We have now found that oxocyclopentanecarboxylates **2** are formed in moderate to good yields by electrochemical reduction of cinnamate derivatives **1**. A remarkable solvent effect was observed in this dimerization. For example, exclusively **2a** was obtained in 74–76% yield (Table 2[4]) from **1a** in acetonitrile or dimethylformamide (DMF), whereas electrochemical reduction of **1a** in methanol gave dimethyl 3,4-diphenyladipate **3a** as the sole product[3] in 75% yield.

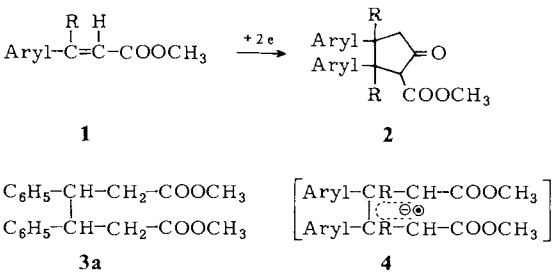

Table 2. Electrochemical reduction of **1a–1h** to **2a–2h** [a].

| | Ar | R | Yield [%] [b] | M.p. [°C] |
|---|---|---|---|---|
| **a** | $C_6H_5$ | H | 76 | 126–127 |
| **b** | $C_6H_5$ | $CH_3$ | 67 | 83–87 |
| **c** | $C_6H_5$ | $C_2H_5$ | 63 | 75–80 |
| **d** | $C_6H_5$ | $C_6H_5$ | 78 | 131–133 |
| **e** | $C_5H_4N$ [c] | H | 62 | 101–104 |
| **f** | *p*-$CH_3OC_6H_4$ | H | 52 | 121–123 |
| **g** | *p*-$CH_3C_6H_4$ | H | 64 | 115–116 |
| **h** | *p*-$ClC_6H_4$ | H | 75 | 134–135 |

[a] Cell, which is fitted with a stirring device, consists of a ceramic diaphragm, Cu cathode, Pt anode, DMF as solvent, tetraethylammonium *p*-toluenesulfonate as supporting electrolyte, at 10–15 °C, cathode potential −1.9 to −2.2 V *vs.* SCE, 4.0 F/mol. [b] Isolated yield. [c] 2-Pyridyl.

Information on the reaction pathway was obtained by electrochemically reducing **1h** and **3a** (molar ratio 1:1) under similar conditions as in Table 2. As a result, exclusively the dimeric cyclization product **2h** was formed in 74% yield, and **3a** was recovered quantitatively: **2a** was not detected. This result clearly shows that the reaction proceeds *via* a dimeric anionic intermediate such as **4**[5], which yields the cyclization product **2** or the simple hydrodimer **3** depending upon the proton-donating ability of the solvent: this also excludes the possibility of Dieckmann condensation of **3** to **2** under the reaction conditions.

## Incorporation of Mercury into Graphite *via* K/Hg Intercalation Compounds**

By *Mordecai Rabinovitz**, *Henry Selig*, and *Jaacov Levy*

The intercalation of metals and salts into the graphite lattice markedly changes the chemical properties and behavior of the intercalated species[1,2]. For example, the reaction of potassium intercalated in graphite with $H_2$ is very fast, even at room temperature, whereas metallic potassium reacts very sluggishly with $H_2$ below 200 °C[3]. We report here the preparation of a series of novel Hg/graphite compounds, which should be interesting electrode materials or reagents. Until now, intercalation compounds of Hg/graphite have only been prepared in the form of ternary compounds with alkali metals[4]. The synthesis of binary compounds, or even nonstoichiometric mixtures of graphite/Hg has hitherto been unsuccessful.

The reaction of $C_8K$ with an equivalent amount of Hg yields $C_8KHg$[4]; it has also been reported that graphite and KHg afford $C_4KHg$. We report that the reaction of $C_8K$ with varying amounts of Hg allows the preparation of a series of compounds, of general formula $C_8KHg_x$. $C_8K$ was prepared by evaporating the stoichiometric amount of potassium over graphite, under an inert gas atmosphere at 200 °C. The potassium intercalate so formed was allowed to cool to room temperature and the calculated amount of mercury was added. The mixture was heated to 80 °C for 10 min, and then cooled to room temperature. When the $C_8KHg_x$ was hydrolyzed with a protic solvent, $C_8Hg_y$ was obtained together with metallic Hg.

$$C_8KHg_x + ROH \rightarrow C_8Hg_y + Hg_{(x-y)} + KOR + 0.5\,H_2 \qquad (a)$$

The formation of $C_4KHg$[4] has previously seen assumed to occur in two stages: firstly, the potassium intercalates with graphite to form $C_8K$, which then reacts with Hg to form $C_4KHg$, in which the Hg atoms form layers between two layers of K atoms. However, although we started with $C_8K$, we failed to obtain $C_4KHg$; instead, the X-ray spectrum was identical with that reported for $C_8KHg$[4] ($D = 10.15$ Å). This is plausible if one takes into account that $C_4KHg$ is unstable in the presence of KHg, and disproportionates to $C_8K$, $C_8KHg$ and Hg. In all the reactions of $C_8K$ with Hg, even in presence of a large excess of Hg, blue $C_8KHg$ was always formed, which then reacts further.

Investigation of the relationship between the initial amount of Hg present and the amount retained in the graphite after hydrolysis gave the following results: Molar ratios of K : Hg from 1 : 1 to 1 : 22.5 resulted in complete reaction of mercury with $C_8K$, and formation of a gray-metallic powder. The results shown in Figure 1 indicate a retention curve that asymptotically approaches 0.120 mol Hg; this corresponds to a stoichiometric formula of $C_8Hg_6$. All the $C_8KHg_x$ ($x \neq 1$) and $C_8Hg_y$ compounds obtained strongly absorb X-ray radiation. This could indicate that Hg atoms are situated randomly between the carbon layers.

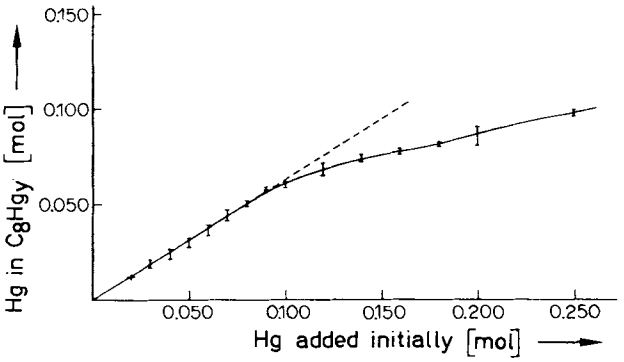

Fig. 1. Plot of amount of Hg in $C_8Hg_y$ after hydrolysis of $C_8KHg_x$ against the amount of Hg originally present.

Thermogravimetric analyses (TGA) of $C_8Hg_y$ indicate that the Hg is lost completely at 400 °C. This suggested that the Hg is intercalated as $Hg^0$. The residual material after TGA exhibits the interlayer spacing of pure graphite.

## 1-Alkynylamines by Electrophilic Amination

By *Gernot Boche**, *Michael Bernheim*, and *Manfred Niessner*

The direct synthesis of 1-alkynylamines, *e.g.* **3**, from 1-alkynes should be possible by electrophilic amination of the readily accessible acetylides **1** with **2**.

$$\underset{\mathbf{1}}{R{-}C{\equiv}C{-}M} \xrightarrow[2]{X{-}N(CH_3)_2} \underset{\mathbf{3}}{R{-}C{\equiv}C{-}N(CH_3)_2}$$

M = metal(derivative); X = anionic leaving group

Actually, the first directed synthesis of 1-alkynylamines was carried out according to this scheme in 1960[1]; however, the yields were so unsatisfactory (1.7%) that alternative synthetic routes had to be developed[2].

$$\underset{}{C_6H_5{-}C{\equiv}C{-}M} \xrightarrow{X{-}N(CH_3)_2} \underset{\mathbf{3a}}{C_6H_5{-}C{\equiv}C{-}N(CH_3)_2}$$

**1a-Li**: M = Li **2α**: X = $CH_3SO_3$
**1a-MgBr**: M = MgBr **2β**: X = $(C_6H_5)_2PO_2$

[*] Prof. Dr. G. Boche, Dr. M. Bernheim, M. Niessner
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, D-3550 Marburg (Germany)

We were able to confirm the earlier observation[1] by allowing **1a-Li** and **1a-MgBr** to react with **2**[4e]: **1a-Li** afforded no **3a** and **1a-MgBr** only traces thereof.

In contrast to this the 1-alkynylcuprates **4**[6,7], which could be prepared from lithium acetylides **1-Li** *via* routes A, B, or C, could be aminated electrophilically.

Route A: $2\,R{-}C{\equiv}C{-}Li + R{-}C{\equiv}C{-}Cu \rightarrow (R{-}C{\equiv}C)_3CuLi_2$ **4**
Route B: $3\,R{-}C{\equiv}C{-}Li + CuCN \rightarrow$ **4** $+ LiCN$
Route C: $3\,R{-}C{\equiv}C{-}Li + CuBr{\cdot}S(CH_3)_2 \rightarrow$ **4** $+ (CH_3)_2S + LiBr$

Even the use of an excess of **2α** or **2β** resulted in amination of only two of the three acetylene groups of **4**; the remaining one precipitates as copper acetylide and hence can, in principle, be reisolated [see equation (1) and routes A–C].

**4a–h** + 2 **2α (β)** → 2 **3a–h** + R–C≡C–Cu + 2 LiX (1)

The results are summarized in Table 1; yields are relative to two acetylene moieties which can be aminated.

Table 1. Reaction of 1-alkynylcuprates **4a–h**, prepared *via* routes A, B, or C, with **2α** or **2β** in ether to give 1-alkynylamines **3a–h**. The products **3a**, **f**, **g** are described; **3b**, **c**, **d**, **e**, **h** were characterized by $^1$H-NMR and mass spectroscopy, as well as by C,H,N-analysis; **2α** can give acetylene coupling products in ≈20% yield.

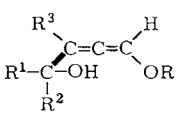
## Regio- and Diastereoselective Synthesis of (4-Hydroxy-3-methyl-1,2-alkadienyl)carbamates from α-Titanated 2-Butynylcarbamates and Aldehydes**

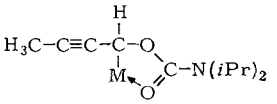
By *Dieter Hoppe** and *Charlotte Riemenschneider*



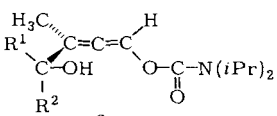
Metalated 2-alkynyl ethers **1** react with carbonyl compounds **2** to give α-adducts of the type **3**[1]. Apart from a few exceptions[1c–d], no isomeric allenes **4** are formed as has also been reported for the tetrahydropyranyl (thp) derivatives **1a–1c**[1b].

**1** **2**

**3**

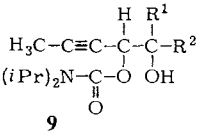


**4**



**1a-c**, R = thp, $R^3 = CH_3$,
M = Li, ZnBr, $Ti(OiPr)_3$

We have now found a method of reversing the regioselectivity. The 2-butynylcarbamate **5** is rapidly lithiated to **6**[2] (*n*BuLi, diethyl ether, 15 min at −78 °C); **6** adds aldehydes and ketones **2** to afford the title compounds **8** (besides **9**) in >80% regioselectivity; **8c** is formed as a diastereomeric mixture (Table 1).



Lithium-metal exchange in **6** (1.1 equiv. $Ti(OiPr)_4$[1b], 10 min at −78 °C) affords the titanium reagent[3] **7**, which forms isomer-free γ-adducts **8c–e** with aldehydes **2c–e**[4]; in each case only one diastereomer is detectable. Diastereoselective allene syntheses of this type—by combination of a centro- and an axial-prochiral moiety—were, to our knowledge, previously unknown[5].

**5**, M = H
**6**, M = Li
**7**, M = $Ti(OiPr)_3$

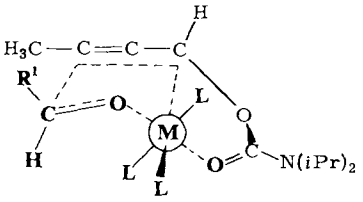
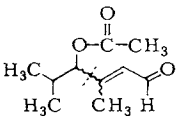
Table 1. Synthesized allenes **8**.

| Educt | $R^1$ | $R^2$ | Product [a] | Yield **8**+**9** [%] | **8** : **9** [b] | Diastereomeric Ratio [b] |
|---|---|---|---|---|---|---|
| **6**, **2a** | $CH_3$ | $CH_3$ | **8a**, **9a** | 76 | >95 : <5 | — |
| **6**, **2b** | $-(CH_2)_4-$ | | **8b**, **9b** | 63 | 82 : 18 | — |
| **6**, **2c** | $(CH_3)_2CH$ | H | **8c**, **9c** | 75 | 87 : 13 | 53 : 47 |
| **7**, **2c** | $(CH_3)_2CH$ | H | **8c** [d, c] | 87 | >95 : <5 | >95 : <5 |
| **7**, **2d** | $CH_3$ | H | **8d** [c] | 89 | >95 : <5 | >95 : <5 |
| **7**, **2e** | $(CH_3)_3C$ | H | **8e** [c] | 59 | >95 : <5 | >95 : <5 |

[a] **8** or **8**-acetate is analytically pure. [b] Determined by $^1$H-NMR spectroscopy on the crude product. [c] The *l*-[3b](*R*R**)configuration has not been confirmed; it is suggested in view of the less hindered transition state (Fig. 1). [d] **8c**, IR (film): 1975 (C=C=C), 1710 $cm^{-1}$ (C=O); $^1$H-NMR ($CDCl_3$, TMS): $\delta = 7.36$ (dq, each $^5J = 2.0$ Hz, 1-H), 1.84 (d, $^5J_{1,3'} = 2.0$ Hz, 3-$CH_3$), 3.84 (dd, $^3J_{4,5} = 6.0$ Hz, $^5J_{1,4} = 2.0$ Hz, 4-H), 0.94, 1.04 (each d, $J = 7.0$ Hz, each 5-$CH_3$).

We presume that—by analogy to metalated allylcarbamates[2, 3c]—the cation $M^{\oplus}$ is fixed by the carbamoyloxy group in the α-position, hence leading to stabilization of the propargylic forms **6** and **7**; these react preferentially *via* propargyl-allenyl inversion[1a] (Fig. 1).





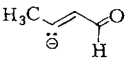


Fig. 1. Transition state of the reaction of **7** with **2c**—**e**; $ML_3 = Ti(OiPr)_3$.

Hydrolysis of the acetate of **8c** ($CH_3OH$, $CH_3SO_3H$, 1 mol-% $Hg(OAc)_2$; $H_2O$) leads to the enal **10** ($E/Z \approx 9:1$;

**10**

**11**

30% yield after chromatographic purification), which rapidly decomposes. Thus **6** and **7** are potentially useful as synthetic equivalents for the β-formylvinyl anion **11**.

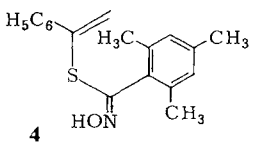
## A Novel Route to Thiocarbonyl Compounds**

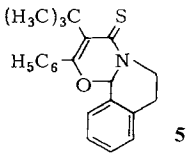
By *Ernst Schaumann**, *Ulrich Wriede*, and *Gerd Rühter*

For the conversion of a carbonyl into a thiocarbonyl group the recommended reagents either usually have to be refluxed with the substrate or require strongly acidic media, and hence often fail in the preparation of labile thiones[1]. We report on a novel route to thiocarbonyl compounds **3**, in which the carbonyl function is initially protected as the dithiolane *S,S*-dioxide **1**[4] and is released by treatment with base[5]. The method is characterized by its mild reaction conditions and, on the whole, by good yields, and appears to be very generally applicable (Table 1).



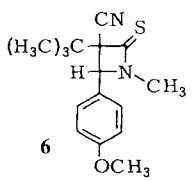
**1** **2** **3**

**a**, $R^1 = R^2 = C_6H_5$, n = 0;



**b**, $R^1 + R^2 =$  , n = 0;

**c**, $R^1 = C_6H_5$, $R^2 = CH_3$, n = 0;
**d**, $R^1 = C(CH_3)_3$, $R^2 = COC_6H_5$, n = 1;
**e**, $R^1 = C(CH_3)_3$, $R^2 = CN$, n = 1;



**f**, $R^1 + R^2 =$  , n = 1

The stable thioketones **3a**, **b** can be isolated. The less stable thioacetophenone **3c** is trapped by mesitonitrile oxide as the addition product **4**. The labile thioketenes **3d**, **e** are converted *in situ* by azomethines into the Diels-Alder adduct **5** and the β-thiolactam **6** as [2+2]-cycloadduct, respectively. In the absence of scavenger the thioketene dimer **7** is obtained from **1f**.

## Exchange of the Apical Tin Atom in the *nido*-Cluster $(CH_3)_5C_5Sn^+$

By *Franz Kohl* and *Peter Jutzi**

Nucleophiles attack the pentagonal-pyramidal cluster $(CH_3)_5C_5Sn^+$ [1] at the apical Sn atom, resulting in a weakening of the $\eta^5$-cyclopentadienyl-tin bond and formation of the adducts $[(CH_3)_5C_5Sn{\leftarrow}Nu]^+$ (*e.g.* with Nu = pyridine[2a], 2,2′-bipyridyl[2b]). From preliminary investigations with electrophiles it follows that these do not attack at the lone pair of electrons of the Sn atom but at the pentagonal base of the cluster. We report here on a reaction which leads *via* cyclopentadienyl-transfer to exchange of the apical atom in the *nido*-cluster.

On reaction of ($\eta^5$-pentamethylcyclopentadienyl)tin trifluoromethanesulfonate **1** with boron triiodide[3] in dichloromethane, precipitation of yellow tin(II) iodide was observed; the product remaining in solution was spectroscopically (NMR, MS) identified as ($\eta^5$-pentamethylcyclopentadienyl)iodoboron trifluoromethanesulfonate **2**[4].

Mechanistically, this reaction can be explained in terms of an electrophilic attack at the cyclopentadienyl ring, as also was observed for the formation of $(CH_3)_5C_5H$ or $(CH_3)_6C_5$ on protonation (with $CF_3SO_3H$) or alkylation (with $CF_3SO_3CH_3$) of **1**[5]. However, the halide transfer is accompanied by a complex reaction sequence, which finally results in exchange of the apical component in the *nido*-complex. This novel type of reaction provides general access to a variety of other cyclopentadienyl-element compounds with *nido*-cluster structure.

## Some Cautions in the Interpretation of Oxidoylide Reactions based on $^{31}$P-NMR Data

By *Edwin Vedejs* and *G. P. Meier*

Synthetically useful species described as β-oxidotylodes ("betaine ylides", type **4**) are formed when alkyllithiums are added to the low temperature Wittig intermediates formed from aldehydes and LiX-containing alkylidenetriphenylphosphoranes[1]. Under these conditions, oxaphosphetanes such as **1** (+LiX) exist to some extent in equilibrium with ionic betaine-LiX adducts **2**[2a], and the deprotonation process can be understood as a typical base-phosphonium salt reaction.

Recently deprotonation of **1** by alkyllithium reagents in the absence of lithium halides has been described[3a,b]. In *salt-free* Wittig reactions, betaines or other ionic species have not been observed by direct methods[2], and hence the mechanism of oxidoylide formation in these examples is unclear. Our own experiments with salt-free **1** contradict some of the published results[3a,b].

**a**, R = $C_6H_5$; **b**, R = H

Homogeneous solutions of **1a** prepared from salt-free ethylidenetriphenylphosphorane in tetrahydrofuran (THF) do not undergo significant deprotonation with *n*-$C_4H_9Li$ or *sec*-$C_4H_9Li$ at −78 °C in contrast to the literature[3a]. Although a red color appears immediately, the $^{31}$P-NMR spectrum shows only traces of new complex signals in the $P^{IV}$ region. A strong, sharp signal of unreacted **1a**[2a] is observed and remains unchanged over 1.5 h at −80±2 °C in THF in presence of *sec*-$C_4H_9Li$. Neither the signal at $\delta = -54$ previously assigned to a metalated oxaphosphe-

[*] Prof. Dr. E. Vedejs, G. P. Meier

Department of Chemistry, University of Wisconsin
Madison, Wisconsin 53706 (USA)

[**] This work was supported in part by the National Science Foundation (GD 43891X).

tane **3**[3a] nor that at $\delta = +12$ attributed to the oxidoylide **4**[3a] was detected. Upon warming the sample to $-30\,^{\circ}C$, the oxaphosphetane signal gradually disappears over *ca.* 45 min (0.1 to 0.3 M solution), and within a few minutes at $-78\,^{\circ}C$ if 1 equivalent of anhydrous LiBr is added to the solution. New $^{31}P$ signals are observed in the range $\delta = 2$—$10$[2c] but these are extremely complex, and suggest the presence of numerous $P^{IV}$ species (aggregates?). In contrast, alkylidenetriphenylphosphoranes give characteristic symmetrical multiplets (aryl H decoupled) or sharp singlets (H noise decoupled)[2a]. We assume that our results differ in part from those previously reported[3a], because the earlier studies used nondecoupled $^{31}P$ spectra[3a] which tend to obscure differences in chemical shift and lineshape information.

*Salt-free* **1b** does react with *sec*-$C_4H_9Li$ at $-78\,^{\circ}C$ to afford **4b** (0.3 M, THF, 20 min). No evidence for **3b** was observed, and the $^{31}P$-NMR signals are again extremely complex ($\delta = 0$—$15$, no distinct maximum). Lithium ion catalysis of oxaphosphetane ring-opening (**1b** → **2b**, X unknown) cannot be ruled out, and **1b** may be more reactive than **1a** for simple steric reasons.

The formation of ylides *synthetically equivalent* to **4a** and **4b** in these experiments is not disputed. However, idealized structures of type **4** should be regarded only as convenient abbreviations for the far more complex species actually present in solution. Both "**4a**" and "**4b**" react with benzaldehyde at $-78\,^{\circ}C$ to give $^{31}P$-NMR signals in the $P^{IV}$ region[4], but assignment of oxaphosphetane structures is only tentative due to poor resolution. In principle, two oxaphosphetane positional isomers can be formed in each case. There is no evidence to show whether or not such positional isomers can interconvert in the absence of lithium halides[3b,5], and the mechanistic details of the oxidoylide condensation step remain essentially unknown[6].

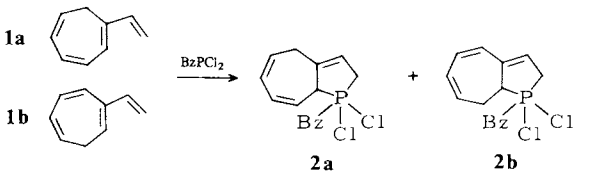
Wittig, H. Eggers, P. Duffner, *Justus Liebigs Ann. Chem. 619* (1958) 10; M. Schlosser, K. F. Christmann, *ibid. 708* (1967) 1; d) M. Schlosser, personal communication (with typical NMR spectra).

[4] **4a** + PhCHO; $\delta = -56$ (width at half-height, 1 ppm at $-78\,^{\circ}C$), disappears on warming to $20\,^{\circ}C$; unassigned minor signals at $\delta = -49$ and $-55$ which do not disappear; some **1a** is regenerated ($\delta = -63$ width 0.2 ppm). — **4b** + PhCHO: $\delta = -51$ (width at half-height 0.3 ppm) no multiplicity resolvable using aryl H decoupling.

[5] In [3b] the reaction of **4b** with $CD_2O$ is not unequivocally interpreted. The formation of $CD_2{=}C(CH_3)CH_2OH + CH_2{=}C(CH_3)CD_2OH$ does not prove that oxaphosphetanes **5** and **6** interconvert *unless* the authors can rule out the initial formation of betaine **7** in the condensation step between **4b** and $CD_2O$. Their argument is valid if the condensation step maintains an intact oxaphosphetane.

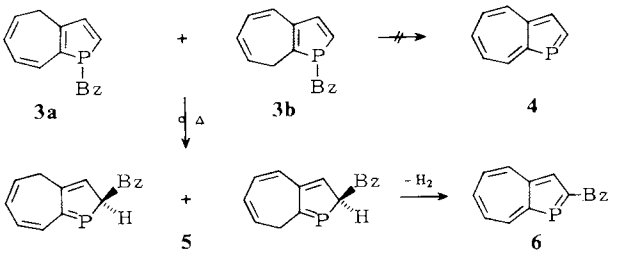
**5** **6** **7**



[6] We retract footnote 12 in [2b], since it assumes an oxidoylide structure which is unrealistic in light of the $^{31}P$-NMR evidence. Recent evidence shows that high oxidoylide regioselectivity does not require a cycloaddition mechanism: E. J. Corey, P. Ulrick, and A. Venkateswarlu, *Tetrahedron Lett. 1977*, 3231.

## 2-Benzyl-1-Phosphaazulene

By *Gottfried Märkl** and *Ernst Seidl*



In contrast to the azaazulenes, azulenes in which one methine group is replaced by trivalent phosphorus of coordination number 2—phosphaazulenes—are unknown.

We report the synthesis of the first member of this novel class of compounds. The mixture of 1-vinyl- and 2-vinyl-1,3,5-cycloheptatriene **1a**/**1b** (40/60), prepared according to the method described by *Dran et al.*[3], reacts with benzyldichlorophosphane in the presence of Cu stearate *via* McCormack cyclization[4] (reaction time *ca.* 4 weeks) to afford the isomeric 1-benzyl-1,1-dichlorotetrahydro-1$\lambda^5$-phosphaazulenes **2a**/**2b**, which firstly precipitate as a greasy mass and then as colorless crystals from the solution of the educts in petroleum ether (b.p. = 50—70 °C).

Bz = $C_6H_5CH_2$

The benzyldichlorophosphoranes **2** can be hydrolyzed to the phosphane oxides; direct dehydrochlorination of **2** with α-picoline in dichloromethane/petroleum ether[5] furnishes the 1-benzyldihydro-1-phosphaazulenes **3a** and **3b** (b.p. ≈ 125 °C/$10^{-2}$ torr).

Contrary to what was expected by analogy to the thermolyses of 1-benzyl-1,2- and -1,4-dihydrophosphorines to give $\lambda^3$-phosphorines, the 1-phosphaazulene **4** is not formed from **3** by elimination of toluene. After **3** had been heated in diphenyl ether or xylene for ≈ 20 min at 300 °C, chromatography on silica gel (eluent: petroleum ether/benzene) and purification by distillation at 120—125 °C/$10^{-2}$ torr afforded a blue-green oil, which from the spectroscopic data surprisingly proved to be 2-benzyl-1-phosphaazulene **6**.

**6** must be formed from **3** *via* a 1,5-shift of the benzyl moiety to give **5**, followed by aromatization with concomitant elimination of hydrogen.

The $^1H$-NMR spectrum (250 MHz, $CDCl_3$) of **6**, displays signals for the ring protons $H^3$; $H^4$, $H^6$, and $H^8$ at $\delta = 7.82$, 8.18, 7.57, and 8.79, respectively, and for $H^5$, $H^7$, and the phenyl protons at $\delta = 7.06$—$7.39$ (m).

The mass spectrum of **6** confirms the empirical formula. The fragmentation scheme is determined from the elimination of phosphorus-containing fragments and from the decomposition to 2-benzyl-$\lambda^3$-phosphorine.

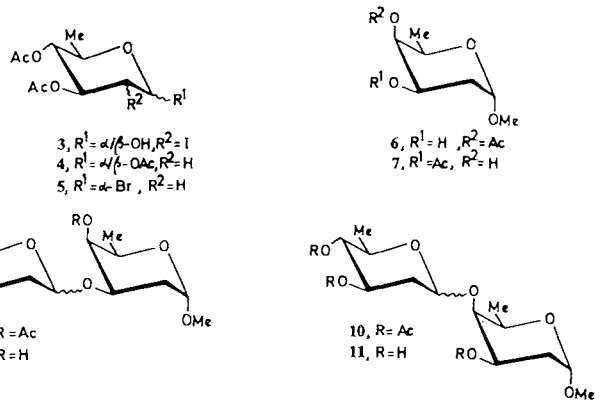
## Synthesis and Structure of the Disaccharide Fragment B-A of Mithramycin**

By *Joachim Thiem** and *Günther Schneider*

*Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday*

Because of its cytostatic properties the aureolic acid mithramycin **1** is used in considerable amounts for the clinical treatment of solid tumors. After the structure of its aglycone chromomycinone and the five monosaccharide components had been identified[1a] we could present spectroscopic evidence and decisively revise older conceptions concerning the linkages of the building units[1b]. However, the type of interglycosidic bonding between the terminal 2,6-dideoxy-D-*arabino* component B and the 2,6-dideoxy-D-*lyxo* sugar A remained uncertain. We could now finally elucidate the structure of mithramycin **1** by synthesis of the disaccharide fragment B-A and spectroscopic comparison with the natural product.

[*] Prof. Dr. J. Thiem, G. Schneider
Institut für Organische Chemie und Biochemie der Universität
Martin-Luther-King-Platz 6, D-2000 Hamburg 13 (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

For the preparation of a reactive D-*arabino* building unit B, D-glucal is converted into the diacetate of 6-deoxy-6-iodo-D-glucal[2a], which is catalytically hydrogenated ($Pd(OH)_2/C$) to 3,4-di-*O*-acetyl-D-quinoval[2b]. Treatment of this with *N*-iodosuccinimide and water in acetonitrile affords the mixture of the β-D-*gluco*-/α-D-*manno*-2-iododiacetates **3** (89%). Renewed reduction together with reacetylation leads to formation of the anomeric 1,3,4-tri-*O*-acetyl-2,6-dideoxy-D-*arabino*-hexopyranoses **4** (55%, α:β = 4:3), which can be cleanly converted in anhydrous benzene with bromo(trimethyl)silane (3.5 h, 20 °C) into the pure 3,4-di-*O*-acetyl-2,6-dideoxy-α-D-*arabino*-hexopyranosyl bromide **5** (88%; for the preparation of the L-compound cf. [3a,b]). The 2,6-dideoxy-D-*lyxo*-monoacetates **6** and **7**[3c] were considered to be most suitable as precursors for the reducing saccharide A[3c].

The preparation of the interglycosidic α- and β-linked disaccharides was accomplished by condensation of the aglycone components **6** and **7** with the glycosyl bromide **5**, whereby the use of toluene/nitromethane (2:1) as solvent and reaction at −45 °C for 1 h in presence of *sym*-collidine, 4 Å molecular sieves and silver trifluoromethanesulfonate, followed by very slow heating to room temperature has proven to be most convenient. After work-up, the mixture of the anomeric disaccharides was separated by twofold HPLC on silica gel (toluene/acetone (7:1) and ethyl acetate/*n*-hexane (1:2)).

In this way, reaction of **5** with **6** furnished the α(1→3)- and β(1→3)-disaccharides **8α** and **8β**, respectively, in 56% yield (**8α** : **8β** = 2:1). On deacetylation with 1.5% methanolic sodium hydroxide, the α(1→3)-disaccharide of type B-A **8α**[4a] yielded the deblocked disaccharide **9α**[4b]; likewise, **8β**[4c] furnished the derivative **9β**[4d].

Correspondingly, it is possible to synthesize the isomeric α(1→4) and β(1→4) disaccharides **10α** and **10β** in 54% yield (**10α** : **10β** = 2:1) from **5** and **7**. Zemplén transesterification of the crystalline **10α**[4e] yields the unblocked compound **11α**[4f], while **10β**[4g] affords **11β**[4h].

In our spectroscopic investigations[1b] of mithramycin **1**[5] no differentiation could be made between interglycosidic β(1→3) and β(1→4) linkages in the B-A fragment of **1**, so the unprotected β(1→3) and β(1→4) disaccharide derivatives **9β** and **11β** were to be used for comparison. Unexpectedly, no assignment was possible by comparison of the $^1$H-NMR data. **1** was therefore converted into its decaacetate **2**, whose spectroscopic data for the decisive B-A part were compared with those of the tetradeoxydisaccharide triacetates **8β** and **10β**.

In the $^1$H-NMR spectrum of **2**[4i], 3A-H is observed at higher field ($\delta = 3.92$) and 4A-H at lower field ($\delta = 5.13$). In

the spectrum of the β(1→4) linked disaccharide peracetate **10β**, however, 3-H appears at lower field ($\delta = 5.18$) and 4-H at higher field ($\delta = 3.87$), *i.e.* an acetyl group is located on C-3 in the *lyxo* building unit, and the interglycosidic bond is different from that in the B-A part of **2**. In contrast, in the β(1→3) linked, acetylated derivative **8β** 3-H ($\delta = 4.16$) and 4-H ($\delta = 5.21$) show only slight deviations in the chemical shifts compared to those of the B-A fragment of **2**. Hence, in mithramycin **1** there is a β(1→3) linkage between the D-*arabino*-(B) and the D-*lyxo*-building unit (A).

## Tellurium as Six-Electron Donor–Synthesis and Structure of $\mu_3$-Te[Mn(CO)$_2$($\eta^5$-C$_5$H$_5$)]$_3$**

By *Max Herberhold**, *Dietmar Reiner*, and *Dietmar Neugebauer*

Formally, the bridging of coordinatively unsaturated transition metal complex fragments by substituent-free main group elements–with participation of all the valence electrons of the bridge-atom–can lead to formation of multiple bonds. Thus, two Cr≡S triple bonds are formulated for the almost linear CrSCr bridge in S[Cr(CO)$_2$($\eta^5$-C$_5$H$_5$)]$_2$ **1**[1], and two Mn=Ge double bonds for the linear MnGeMn bridge in Ge[Mn(CO)$_2$($\eta^5$-C$_5$H$_4$Me)]$_2$ **2**[2]; in the almost planar $\mu_3$-GeMn$_3$ skeleton of the "homologous" complex **3**, the four-electron donor germanium participates in formation of one Mn=Ge double bond and two Mn—Ge single bonds[2]. We now report here on the novel tellurium complex **4**, which according to an X-ray structure analysis has an almost planar $\mu_3$-TeMn$_3$ skeleton. It can therefore be assumed that the central Te atom in **4** functions as six-electron donor and forms a star-shaped arrangement of three Mn=Te double bonds to the [Mn(CO)$_2$($\eta^5$-C$_5$H$_5$)] fragments, in each of which two electrons are missing for completion of the noble gas configuration.

**3** [2]

**4**

The compound **4** is formed on reaction of $TeH_2$, generated *in situ* from $Al_2Te_3$/HCl, with a solution of the THF-stabilized complex fragment [Mn(CO)$_2$($\eta^5$-C$_5$H$_5$)], which is obtained by photolysis of tricarbonyl(cyclopentadienyl)manganese in tetrahydrofuran (THF); as by-product the complex Te$_2$[Mn(CO)$_2$($\eta^5$-C$_5$H$_5$)]$_3$ **5** could also be isolated (yields 47% **4** and 0.8% **5**). To our knowledge these are the first complexes of a metal of the 7th subgroup with substituent-free tellurium.

The IR and NMR spectra of **4** and **5** are almost identical (Table 2). In the mass spectrum of **5** the signal of the molecular ion could not be observed.

Table 2. Spectroscopic data of the complexes **4** and **5**.

| | Te[Mn(CO)$_2$(C$_5$H$_5$)]$_3$ **4** | Te$_2$[Mn(CO)$_2$(C$_5$H$_5$)]$_3$ **5** |
|---|---|---|
| IR: $\nu$(CO) [cm$^{-1}$] in ether solution | 1998 m, 1992 m (sh), 1940 s, 1928 vs, 1909 m, 1886 w | 1994 s, 1982 m (sh), 1935 vs, 1919 vs, 1901 s, 1886 m (sh) |
| $^1$H-NMR: $\delta$(C$_5$H$_5$) in [D$_6$]acetone, 25 °C | 5.23 (s) | 5.23 (s) |
| $^{13}$C-NMR: $\delta$(C$_5$H$_5$), $\delta$(CO) in [D$_6$]acetone, −80 °C | 87.8 (s), 232.0 (s) | |
| MS: *m/z* | 658 [*M*]$^+$ | 658 [*M* − Te]$^+$<br>612 [*M* − Mn(CO)$_2$(C$_5$H$_5$)]$^+$ |

The crystal structure analysis of **4** (Fig. 1) shows an isosceles triangular (to a first approximation equilateral) arrangement of the three manganese atoms. The central tellurium atom lies only 3.4(1) pm above the center of the Mn$_3$ plane. The bond lengths and angles in the [Mn(CO)$_2$($\eta^5$-C$_5$H$_5$)] moieties show no special features; manganese-manganese interactions can be ruled out.

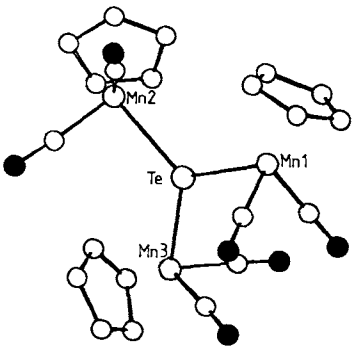

Fig. 1. Molecular structure of **4** in the crystal (black, monoclinic, space group $P2_1/c$, $Z = 4$).

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Although no data for MnTe bond lengths are available for comparison, assumption of formal Mn=Te double bonds for the $\mu_3$-$TeMn_3$ skeleton of the diamagnetic complex **4** according to the noble gas rule seems plausible. The sum of the covalent single-bond radii[3] of tellurium (137 pm) and manganese (117 pm) is greater than the observed MnTe distances (average value 248.5 pm).

## Transition-Metal Substituted Stibanes as Acceptors: $Cp(CO)(L)Fe—SbBr_2 \cdot PMe_3$ (L = CO, $Me_3P$, MeNC)—1:1-Ferriostibane-Trimethylphosphane Complexes[1]

By *Hans-Achim Kaul, Dieter Greissinger, Wolfgang Malisch*, Heinz-Peter Klein*, and *Ulf Thewalt***

One of the CO ligands in the ferriostibane $Cp(CO)_2Fe—SbMe_2$ can be readily substituted by tertiary phosphanes to form an asymmetric metal center[2]. In contrast, we have now found that the reaction of the bromine derivative $Cp(CO)_2Fe—SbBr_2$[3] with $Me_3P$ in benzene leads to addition of the phosphane to the trivalent antimony atom to afford complex **2**, exclusively[4]. A straightforward CO/$Me_3P$ exchange at the metal only takes place in presence of a large excess of phosphane and at higher temperatures (60 °C), without elimination of the Sb-bonded donor. The corresponding exchange with MeNC already proceeds at temperatures above 40 °C.

**1** **2**

The novel complexes, **2**, **3a**, and **3b** have to be described as adducts of trimethylphosphane and the Lewis acid $Cp(CO)(L)Fe—SbBr_2$. Coordination of $Me_3P$ to antimony is confirmed by the high field $^{31}P$-NMR signals [$\delta = -42.3$ (**2**), $-53.1$ (**3a**), $-43.2$ (**3b**)] and by the low-frequency shift of the $\nu CO_{as}$ and $\nu CO_s$ bands of **1** by 20 and 60 $cm^{-1}$, respectively[3].

[**] X-ray structure analysis.

In contrast to the "metal-free" Lewis acids $SbX_3$ (X = Cl, Br)[7, 10], the metal-stibanes do not form complexes with more than one neutral donor[7], and, moreover, their monoadducts are thermally less stable. This applies in particular to **2**, which upon heating completely releases the phosphane.

**3a**, which like **2** and **3b** can be assigned to the $X_3Sb(L)L'$ type of compound (L = ligand, L' = lone pair of electrons), has the molecular structure shown in Fig. 1 with approximately pseudo-trigonal bipyramidal coordination of the Sb atom. In accordance with the electronegativity rule, the two bromine atoms occupy the apical, and the lone-pair of electrons, the transition-metal moiety, as well as the trimethylphosphane the equatorial positions.

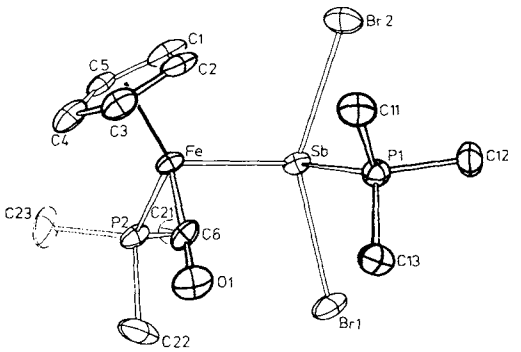

Fig. 1. Structure of **3a** in the crystal. Most important bond lengths [Å] and angles [°]: Sb—Fe 2.551(2), Sb—P(1) 2.596(4), Sb—Br(1) 2.807(2), Sb—Br(2) 2.903(2), Br—Sb—Br 149.1(1), Fe—Sb—P(1) 104.6(1), Fe—Sb—Br(1) 103.8(1), Fe—Sb—Br(2) 103.9(1), Br(1)—Sb—P(1) 82.8(1), Br(2)—Sb—P(1) 77.3(1). Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie-Physik-Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50303, the name of the author, and complete citation of the journal.

The considerable contraction of the Br(1)—Sb—Br(2) angle to 149.1° is mainly caused by the large steric demand of the cyclopentadienyl or trimethylphosphane ligand immediately adjacent to the bromine atoms. Despite this large steric influence of the transition-metal moiety on the $SbBr_2PMe_3$ part of the molecule, the Fe—Sb—P(1) angle is reduced from the ideal value of 120° to 104° which indicates that the lone-pair, known to have the greatest spatial requirement, occupies the equatorial position.

Of particular note are the Sb—P single bond character [bond length 2.596 Å, sum of covalent radii 2.46 Å] as well as the Sb—Br bond lengths of 2.807 and 2.903 Å, respectively, which are unusually long, even taking into account the normal bond lengthening to axial ligands in TBP structures.

The reason for this finding could be the preferential acceptance of the high electron density at the Sb atom, originating from the electron-rich ligands $Cp(CO)(Me_3P)Fe$ and $Me_3P$, by the halogen atoms.

The trimethylphosphane adducts **2**, **3a**, and **3b** provide the first evidence that trivalent compounds of group 5B elements with σ-bonded transition-metal ligands are able to function not only as excellent electron donors but also as acceptors.

## Ring-Opening by [3,3]-Diphospha Cope-Rearrangement**

By *Rolf Appel**, *Johannes Hünerbein*, and *Falk Knoch*

In the reaction of succinic dichloride with phenylbis(trimethylsilyl)phosphane **1** a phospha Cope-rearrangement found to take place was with cleavage of the central CC bond[1]. This observation encouraged us to extend our investigations to cyclic 1,2-dicarboxylic acid chlorides. A corresponding reaction course should, *e.g.*, afford the ten-membered ring system **3** on reaction of *trans*-cyclohexane-1,2-dicarboxylic acid chloride **2** with **1**.

Indeed, it was found that **3** could be isolated in good yields on performing this reaction. We assume that the initial condensation is followed by a migration of the silyl groups with formation of the phospha-alkene, which is likewise unstable and is rapidly converted even at low temperature into 1,2-diphenyl-3,10-bis(trimethylsiloxy)-1,2-diphospha-3,9-cyclodecadiene **3** by sigmatropic shift with concomitant opening of the CC bond.

Consistent with this structure, in the methanolysis of **3** the suberic acid dimethyl ester **5** with $C_8$ unit instead of a

In addition to **3**, varying amounts of 8-phenyl-8-phosphabicyclo[4.3.0]nonane-7,9-dione **4** are also formed depending on the reaction temperature and solvent[4]. **3** (m.p. 112–116 °C) and **4** (m.p. 75–77 °C) were unequivocally identified by elemental analysis, molecular weight determinations (MS and cryoscopic), and by $^{31}P\{^1H\}$-, $^{13}C\{^1H\}$- and $^1H$-NMR findings[2]. The X-ray structure analysis reveals *E*-configuration at both double bonds and *S*-configuration at the phosphorus atoms (Fig. 1)[3,4].

## 1,3-Dithian-2-yl Methyl Ester as Two-Step Protecting Group for the Carboxy Function in Peptide Synthesis**

By *Horst Kunz** and *Herbert Waldmann*

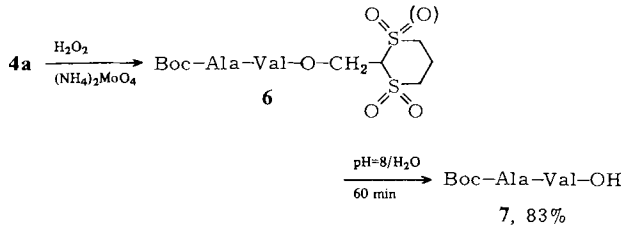
The synthesis of sensitive peptides, especially glycopeptides, requires the use of protecting groups which can be removed under very mild conditions[1]. We have now extended the two-step amino-protecting principle of the 1,3-dithian-2-yl-methoxycarbonyl (Dmoc) group[2], in modified form, to the protection of the carboxy function.

Neither acid-catalyzed esterification nor the chlorosulfite method[3] can be applied to the preparation of amino acid 1,3-dithian-2-yl-methyl(Dim)esters **3** because of insufficient stability of the dithiane methanol **1** towards strong acids.

In contrast, transesterification of the amino acid methyl esters **2** with **1** in presence of aluminum isopropoxide[3] yields the desired amino acid Dim esters **3** directly[4].

Because of their stability towards moderate acids and bases, the Dim esters **3** (characterized as the hydrochlorides by $^1$H-NMR spectroscopy and elemental analysis) can be coupled with Z- and Boc-amino acids using the mixed-anhydride method or ethyl-2-ethoxy-1,2-dihydro-1-quinolinecarboxylate (EEDQ)[5], to give protected dipeptide Dim-esters **4**.

Boc-Ala-OH + H-Val-O-Dim $\xrightarrow{\text{EEDQ}}$ Boc-Ala-Val-O-Dim
**3a** **4a**, 95%



Z-Ala-OH + H-Phe-O-Dim $\xrightarrow[\text{NEt}_3]{\text{Cl—COOEt}}$ Z-Ala-Phe-O-Dim
**3b** **4b**, 75%

Like the Dmoc derivatives[2], the Dim esters are also stable towards trifluoroacetic acid or hydrogen chloride in dichloromethane or ether at room temperature; thus, the Boc group of the dipeptide ester **4a** can easily and selectively

**4a** $\xrightarrow[20\,^\circ\text{C}/60\text{ min}]{\text{HCl/Ether}}$ H-Ala-Val-O-Dim **5**, $\approx$100%

be removed from the dipeptide. In order to deblock the carboxy function from the triethylamine-stable Dim esters **4** the dithiane group is oxidized to the sulfoxide-sulfone or disulfone form **6** by hydrogen peroxide/ammonium molybdate.

**6** is so labile towards bases that complete deblocking of the C-terminal can be carried out even at pH 8 and room temperature in a E1cB reaction.

Thus, the Dim esters provide an effective protection of the carboxy group in syntheses, especially in peptide synthesis, being stable to acids and moderate bases, and easily removable after oxidation. The method cannot be used, however, when oxidizable groups are present in the molecule, *e.g.* in cystein, methionine and tryptophan derivatives.

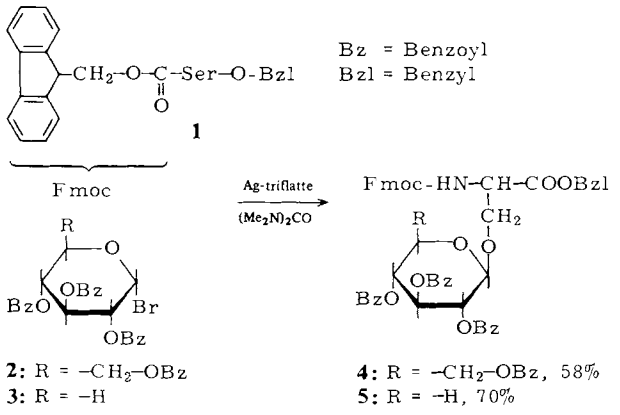
## *O*-Glycopeptide Synthesis using 9-Fluorenylmethoxycarbonyl (Fmoc)-Protected Synthetic Units**

By *Petra Schultheiss-Reimann* and *Horst Kunz**



The *O*-glycosidic bonds of serine and threonine glycopeptides—characteristic substructures of many connective tissue-, serum- and membrane-glycoproteins—are somewhat sensitive towards acids and bases[3]. Whereas serine esters protected at the *N*-terminal with the base-labile 2-triphenylphosphonioethoxycarbonyl (Peoc) group[5] cannot be directly glycosylated, the coupling of the 9-fluorenylmethoxycarbonyl-(Fmoc[8]-)serine benzyl ester **1** with 2,3,4,6-tetra-*O*-benzoyl-α-D-glucopyranosyl bromide **2** can be readily accomplished in presence of silver trifluoromethanesulfonate/tetramethylurea[7a] to give the completely protected β-glucosylserine derivative **4** in good yields. The β-configuration of **4** is confirmed by its $^1$H- and $^{13}$C-NMR spectra. The analogous reaction of **1** with tri-*O*-benzoylxylopyranosyl bromide **3** affords the glycosylated serine derivative **5**.

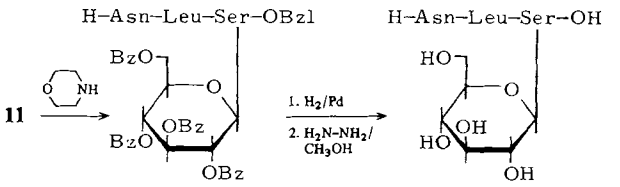
**2**: R = $-CH_2-OBz$
**3**: R = $-H$

**4**: R = $-CH_2-OBz$, 58%
**5**: R = $-H$, 70%

The value of the Fmoc group[8] in glycopeptide synthesis is demonstrated by the highly selective deblocking of **4** using morpholine, to give **6** in essentially quantitative yield.



**6**, 97%
**11**, 81%

Neither aminolysis of the ester groups nor β-elimination of the glyconic moiety[3] is observed. The composition and structure of **6** are confirmed by $^1$H-NMR spectroscopy.

The free amino group of **6** can be coupled with Fmoc amino acids as well as with Fmoc dipeptide **9** in presence of ethyl-2-ethoxy-1,2-dihydro-1-quinolinecarboxylate (EEDQ)[11]. The protected glycotripeptide **11** so obtained in good yield will serve in our investigations as model substance for *O*→*N* transglycosylations.

The amino protecting group can be selectively removed in high yield with morpholine from both the Fmoc glycodipeptide ester, which is formed by condensation of **6** with Fmoc-leucine, and from fully protected glycotripeptide **11**.

**13**, 83%
**15**, 62%

After hydrogenolysis of the benzyl group in **13**, the benzoyl groups can be removed so smoothly with hydrazine hydrate in methanol at room temperature that the sensitive *O*-glycosidic bond is wholly preserved. The structure of the free glucotripeptide **15** is confirmed by NMR.

Thus, the Fmoc group is a valuable tool for directed *N*-terminal chain elongation of sensitive *O*-glycopeptides, whereby the carboxy group of the glycopeptides remains reversibly protected as benzyl ester.

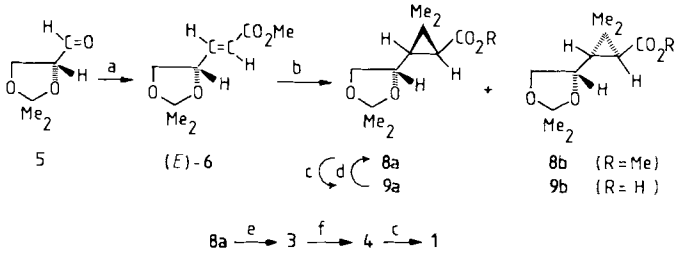
## Diastereo- and Enantioselective Synthesis of (1*R*,3*R*)-Caronaldehyde Acid Methyl Ester and (1*R*,3*R*)-Chrysanthemic Acid Methyl Ester from (*R*)-Glycerinaldehyde Acetonide**

By *Johann Mulzer** and *Michael Kappert*

Certain esters of the (1*R*,3*R*)-chrysanthemic acid **1** and its *cis*-dibromovinyl analogue **2**, which are generally known as pyrethroids, have found widespread application as insecticides[1]. Remarkably, their physiological activity is closely associated with the (1*R*)-configuration; the (1*S*)-enantiomers of **1** and **2** are many times less effective[1]. For this reason suitable routes to optically active **1** and **2** are being intensively investigated. The (1*R*,3*R*)-caronaldehyde acid methyl ester **3** plays a key role in many of these syntheses[2]. We report here on a rational synthesis of optically pure **3** and the conversion of this intermediate into (1*R*,3*R*)-chrysanthemic acid methyl ester **4**.



**1**, X = $CMe_2$, R = H
**3**, X = O, R = Me
**4**, X = $CMe_2$, R = Me

**2**

As shown in Scheme 1, (*R*)-glycerinaldehyde acetonide **5** can be converted without separation of diastereomers with 86% *ee* into **3** (total yield 55% in 5 steps) and **4** (39% in **6** steps). Optically pure **3** and **4** are obtained by hydrolysis of the mixed cyclopropanecarboxylates **8a/b** to the corresponding acids **9a/b**, from which pure **9a** can be isolated by crystallization and then reesterified to **8a**. Further reaction according to Scheme 1 affords **3** (total yield 36%) and **4** (24%) with >99% *ee*. Remarkably, the enantioselectivity of the cyclopropanation increases considerably if the corresponding methyl ester is employed in place of (*E*)-**6**. The diastereomeric ratio at the stage of **8** in this case rises to >98:2; alkaline hydrolysis furnishes diastereomerically pure **9a** in quantitative yield. In this way, **5** is converted into optically pure **4** in 35% total yield without any separation of isomers. Esters other than **8** can also be prepared from **9a** *via* the acid chloride, which opens an entry to a variety of optically pure pyrethroids. This finding is not trivial, as the hydrolysis of **4** to **1** causes 23% racemization, even under mild conditions (5% KOH, MeOH, 22 °C, 14 h).

Present address:
Institut für Organische Chemie der Universität
Universitätsstrasse 1, D-4000 Düsseldorf (Germany)
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF Ludwigshafen.

The key step of our reaction sequence is the enantio- and diastereoselective cyclopropanation of the acrylate derivative (*E*)-**6** with isopropylidene-triphenylphosphane **7**[6]. A rationalization of the high stereoselection in favor of the (1*R*)-isomer is presented in Scheme 2. The assump-

Scheme 1. a: NaH, $MeO_2CCH_2P(O)(OEt)_2$, dimethoxyethane, 22 °C, 1 h, 95%.—b: $Me_2C{=}PPh_3$ **7**, tetrahydrofuran (THF), −78 °C, 1 h, 10 °C, 2 h, 60%.—c: 5% KOH in MeOH, 22 °C, 24 h, quant.—d: $CH_2N_2$, ether, 22 °C, 5 min, quant.—e: $NaIO_4$, 2N $H_2SO_4$/THF, 22 °C, 24 h, 95%.—f: **7**, THF, −30 °C, 1 h, 64%.

tion of a transoid conformation in *E*-(**6**) seems plausible; **7** attacks $C_\beta$ *anti* to O-3—which could be explained in terms of an electrostatic repulsion between $C_\gamma$ and O-3. The zwitterion **10** cyclizes to give **8a** with retention of configuration. Formally (*E*)-**6** thus corresponds to a chiral fumaraldehyde ester-equivalent, in which attack at the C=C bond shows a significant degree of diastereo face control.

Scheme 2.

In order to prepare optically pure compounds the crucial question always is: Can the enantioselective synthesis (defined as "asymmetric induction under the influence of optically active centers, which on further reaction are either eliminated or are converted into achiral centers") compete with other methods such as resolution, isolation from natural sources, or chiral-pool synthesis (defined as "synthesis of an optically active target compounds from an optically active natural product, so that at least one chiral center of the starting material either remains unchanged or is transformed in a stereochemically unambiguous way")? For **1**, **3**, and **4** sufficient data are available[1] to permit a conclusive answer, at least for this particular case: The enantioselective synthesis—whether according to our variant or that of other authors[17]—affords chemical and optical yields comparable to those obtained by optical resolution, whereas the "chiral pool" syntheses starting from 3-carene, pantolactone or α-pinene, clearly appear to be inferior. Although such a comparison is not quite conclusive—one would have to repeat all the reported syntheses under optimized conditions—the results obtained so far emphasize the efficiency of the enantioselective approach.

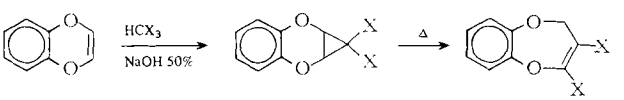
## 2*H*-1,5-Benzodioxepin and 3-Halo Derivatives



By *Gérald Guillaumet, Gérard Coudert**, and *Bernard Loubinoux*

Up to the present, very few benzodioxepin derivatives have been isolated[1]; thus, 2*H*-1,5-benzodioxepin **1** and its 3-halo derivatives **2a** and **2b** were hitherto unknown. These compounds should offer a simple means of preparing 2,3-disubstituted 1,5-benzodioxepins and 3,4-dihydro-1,5-2*H*-benzodioxepins.

**2a**, X = Cl
**2b**, X = Br

We have now prepared the *gem*-dihalocyclopropane derivatives **4a**[3] and **4b** in 95% yields from the readily accessible 1,4-benzodioxine **3**[2] by carbene-addition under "liquid-liquid" phase-transfer catalysis conditions.

**4a**, X = Cl
**4b**, X = Br

**5a**, X = Cl
**5b**, X = Br

**4a** and **4b** are heated at 185 °C for 5 h and 170 °C for 25 min, respectively[4]. The compounds **5a** and **5b** thus obtained are not isolated but immediately reduced to **2** and **1**, respectively[5] (Table 1).

Table 1. Some data for the synthesis of **1** as well as **2a** and **2b**. (THF = tetrahydrofuran, HMPT = hexamethylphosphoric triamide).

| Substrate | Reagent | Solvent [d] | *t* [h] | *T* [°C] | Product | Yield [%] [e] |
|---|---|---|---|---|---|---|
| **5a** | $LiAlH_4$ [a] | Ether | 0.5 | 25 | **2a** [5b] | 85 |
| **5a** | $LiAlH_4$ [b] | THF | 16 | 40 | **1** [5a] | 70 |
| **5b** | $NaBH_3CN$ [c] | HMPT | 22 | 25 | **2b** [5c] | 55 |
| **5b** | $LiAlH_4$ [a] | THF | 40 | 25 | **1** [5a] | 70 |

[a] $LiAlH_4$ : **5** = 2 : 1. [b] $LiAlH_4$ : **5a** = 4 : 1. [c] $NaBH_3CN$ : **5b** = 8 : 1. [d] 5 mL per mmol of substrate. [e] Yield referred to **4a** and **4b**.

## Strong Distortion of the Tetrahedral Geometry in a Spirosilicate: Molecular Structure of Bis(tetramethylethylenedioxy)silane

By *Dietmar Schomburg**

Silicon compounds usually have a tetracoordinated Si atom and exhibit only slight deviations from tetrahedral geometry. Evidence of planar tetracoordinated silicon in bis(*o*-phenylenedioxy)silane has been reported by *Meyer* and *Nagorsen*[1a]. Using a semiempirical MO method (MNDO) a considerably smaller energy difference between tetrahedral and planar structures of silicon compounds is calculated than for the corresponding carbon compounds: nevertheless, in the silicic acid ester mentioned, the tetrahedral structure is 32.9 kcal/mol lower in energy[1b]. It was presumed that further stabilization of the planar structure should occur by pseudooctahedral coordination *via* silicon-electron donor interaction[1].

The only proof for the existence of compounds having planar coordinated silicon would be a total structure analysis. For bis(ethylenedioxy)silane, MNDO calculations indicated a similar energy difference between tetrahedral and planar structures as for the unsaturated compound (34.4 kcal/mol)[1c]. The X-ray structure analysis of its permethylated derivative, therefore, appeared attractive.

The title compound, prepared using a method described by *Frye*[2], crystallizes in the space group C2/c[3] with $Z = 4$. The molecule displays crystallographic $C_2$ symmetry, in which the axis of symmetry passes through the silicon atom and the center of the C—C bonds of the rings (Fig. 1).

The bonding geometry at the silicon atom is distorted tetrahedrally. However, the angle of 88.3° between the planes through O(1), Si, O(1)′ and O(2), Si, O(2)′ shows that no significant planarization has occurred. The strong distortion arises from the incorporation of the Si atom into the five-membered rings. The endocyclic OSiO angles are *ca.* 11° smaller than the tetrahedral angle, and the OCC angles of the rings are also markedly smaller. Whereas the Si—O bond lengths do not deviate significantly from comparable values[4a], the C—O distances are conspicuously long (cf. the mean value 1.476 Å, *e.g.*, with 1.427 Å in $CH_3OH$[4b]). The five-membered rings exhibit a twist conformation, in which the ring carbon atoms are displaced 0.30—0.31 Å away from the plane formed by Si and its neighboring atoms.

The strong distortion of the bonds at silicon and carbon is probably the reason for the stability of the compounds of *penta*coordinated silicon, in which the silicon atom forms the center of a spiro[4.4]octane system[5].

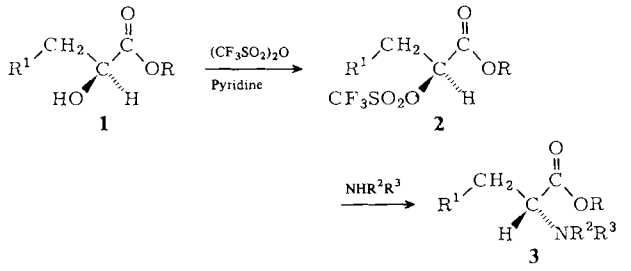
## Trifluoromethanesulfonates of α-Hydroxycarboxylates—Educts for the Racemization—Free Synthesis of *N*-Substituted α-Amino Acids



By *Franz Effenberger**, *Ulrike Burkard*, and *Joachim Willfahrt*

Many *N*-substituted α-amino acids exhibit high biological activity[1]. They can be prepared by substitution at the $NH_2$ group of the respective amino acid; this synthetic procedure is limited, though, by the reactivity of the alkylating or arylating agent as well as by the possibility of

[*] Prof. Dr. F. Effenberger, U. Burkard, Dr. J. Willfahrt
Institut für Organische Chemie der Universität
Pfaffenwaldring 55, D-7000 Stuttgart 80 (Germany)

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0101-0065 $ 02.50/0* 

either elimination or multiple reactions. Alternatively, the desired amino function can be introduced directly by nucleophilic substitution of appropriate α-substituted carboxylic acid derivatives. Especially with α-halo carboxylates, however, this reaction is accompanied by extensive racemization; with α-methanesulfonyloxy and α-toluenesulfonyloxy carboxylic acid derivatives, both racemization and elimination products are formed, *inter alia,* owing to the drastic conditions required[1a,2].

1 2 3

α-Trifluoromethanesulfonyloxy carboxylates **2** are obtained in high yield from α-hydroxy carboxylates **1** and trifluoromethanesulfonic acid anhydride/pyridine[3]. The trifluoromethanesulfonates **2** are fairly stable and can be kept for months at 0—10 °C. Even with weakly nucleophilic amines, however, they are smoothly converted, with Walden inversion, into the corresponding α-amino carboxylates **3**; the compounds **3** are isolated in excellent yield by distillation or filtration through a silica gel column (Table 1).

Comparison of the relative reactivity of various α-substituted ethyl propionates towards benzylamine in refluxing dichloromethane reveals a strong dependence on the nature of the leaving group, not quite expected for $S_N2$ reactions[4]. **2c** is converted quantitatively into **3f** within 20 min; for α-bromo, α-methanesulfonyloxy, α-toluenesulfonyloxy and α-chloro ethyl propionate, on the other hand, conversion to **3f** is only 40, 10, 5, and < 1%, respectively, after 22 h.

The high reactivity of the trifluoromethanesulfonates 2 proves especially advantageous for the synthesis of phenylalaninic and aspartic acid derivatives since in this case poorer leaving groups (*e.g.* $Br^{\ominus}$, $CH_3SO_3^{\ominus}$) strongly favor elimination. The unequivocal stereochemistry of the substitution reaction has been confirmed by reaction of **2** with optically active amines; the diastereomeric amino carboxylates **3** can be differentiated by capillary GLC.

Table 1. *N*-Substituted α-aminocarboxylic esters **3** from **2** and amines in dichloromethane at room temperature [5]. In the reaction scheme, *S*-configuration is given for **2**, and *R*-configuration for **3**.

| Educts | | | | | Products | Yield |
|---|---|---|---|---|---|---|
| **2** | R | $R^1$ | $R^2$ | $R^3$ | **3** | [%] |
| (*S*)-**2a** | Me | Ph | $PhCH_2$ | H | (*R*)-**3a** | 92 |
| | | | Ph | H | (*R*)-**3b** | 93 |
| | | | $-(CH_2)_4-CH(Et)-$ [b] | | (2*R*,2′*R*)-**3c** | 83 |
| (*S*)-**2b** | Et | $EtCO_2$ | $PhCH_2$ | H | (*R*)-**3d** | 93 [c] |
| | | | Ph | H | (*R*)-**3e** | 94 |
| (*S*)-**2c** | Et | H | $PhCH_2$ | H | (*R*)-**3f** | 85 |
| | | | $-(CH_2)_4-$ | | (*R*)-**3g** | 84 |
| | | | $2,6-(CH_3)_2C_6H_3$ | H | (*R*)-**3h** | 92 |
| | | | Ph | Me | (*R*)-**3i** | 75 |
| | | | Ph–CH(Me)– [a] | H | (2*R*,1′*S*)-**3j** | 76 |
| | | | Ph–CH(Me)– [b] | H | (2*R*,1′*R*)-**3k** | 78 |
| | | | $EtCO_2$–CH(Me)– [a] | H | (2*R*,2′*S*)-**3l** | 81 |
| (*R*)-**2c** | | | $EtCO_2$–CH(Me)– [a] | H | (2*S*,2′*S*)-**3m** | 93 |

[a] *S*-form. [b] *R*-form. [c] Addition at −65 °C.

Both *R*- and *S*-α-amino carboxylates can be prepared by the synthetic procedure described here; subsequent hydrolysis of the esters to the corresponding *N*-substituted α-amino carboxylic acids proceeds without detectable racemization.

The reaction mixture is filtered, the solution washed with water, dried over $Na_2SO_4$, concentrated, and the residue (1.36 g) distilled *in vacuo*. Yield 1.24 g (85%) (*R*)-**3f**, b.p. 73 °C/5 × $10^{-3}$ torr.

# BOOK REVIEWS

**Organic Trace Analysis by Liquid Chromatography. By** *J. F. Lawrence.* Academic Press, New York 1981. xii, 288 pp., bound, $ 34.00.

The identification and determination of traces in a great variety of matrixes are gaining importance and therefore call for suitable analytical methods. Capillary gas chromatography and thin-layer chromatography have proved to be particularly useful for separation, but the many possibilities offered by high-pressure liquid chromatography (HPLC) have not yet been fully utilized in this field. It is therefore useful to demonstrate the possibilities and to specify the limitations of this new method in trace analysis.

The ten chapters in this book have the following headings (with the number of pages given in parentheses after each title): General Considerations in Developing a Trace Analytical Technique Employing Liquid Chromatography (17), Pumping Systems (13), Sampling Technique and Injection Ports (12), Chromatographic Columns and Packing Materials (7), Detectors (52), Chromatography Theory (30), Chemical Derivatization (46), Sample extraction and Cleanup (34), Approach to Method Development and Routine Analysis (10), and Applications (41).

About half of the book is thus devoted to general aspects of HPLC and to description of the apparatus used. It is regrettable that the individual components of the HPLC ap-

paratus are not assessed for their applications in trace analysis.

Chapter 6 deals with the theory of chromatography, which the reader will presumably study in other works written by competent authors and giving all the important relationships, such as the dependence of band broadening on the linear velocity, so that wrong conclusions, which can have particularly serious consequences in trace analysis, can be avoided.

In Chapter 7 the author has taken great pains to collect the possible chemical reactions and especially those that are carried out before the separation to improve the sensitivity of detection; no fewer than 335 references are mentioned in this chapter. It would have been desirable to include a critical account of the problems associated with this method (*i.e.* pre-column derivatization) in the determination of traces in complex matrixes.

Chapter 8 deals with the methods of sample preparation and contains 67 references. Chapter 9 discusses in general terms the very important subject of how to choose the right chromatographic system. However, in the case of phase systems, we only find here a brief account of chromatography on silica gel and on materials used in reversed-phase chromatography. No mention is made of ways to utilize specific selectivities, *e.g.* by column switching.

Chapter 10 gives a selection of clinical and biological applications as well as of ones from the fields of environmental protection and food analysis, and these examples give a good idea of the use of HPLC in trace analysis.

The overall impression is that this book is really an introduction to HPLC. There is a large number of useful references, but one misses an evaluation of the methods and apparatus for specific applications.

**Analytiker-Taschenbuch.** Vol. 2. Edited by *R. Bock, W. Fresenius, H. Günzler, W. Huber,* and *G. Tölg.* Springer-Verlag, Berlin 1981. viii, 351 pp., bound, DM 78.00.

It is a pleasure to find that, as expected, the contents of this second volume match those of the first volume[*] published in this "Taschenbuch" series in 1980. The material is again divided into four parts, namely Theory, Methods, Applications, and Miscellaneous data, and within this framework 16 authors working at universities and in industry offer a wealth of information to the analytical chemist.

*J. F. Cordes* (BASF Ludwigshafen and the University of Mannheim) gives a comprehensive survey of *practical quantities and units and the SI system.* The author covers the history of legislation in this field and the work of the ISO, IUPAC, and DIN committees that has led to the current method of dimensioning in analytical chemistry. This will help analytical chemists in the official and commercial sectors.

*H. Bartels* (Ciba-Geigy, Basel) deals with the difficult topic of *automation* of chemical analysis and gives an account of instrumentation in (automated) analysis, together with useful fundamentals that can greatly help in rationalizing laboratory work. It would perhaps have been helpful to distinguish more clearly between mechanization, instrumentation, and automation.

*H. Specker* (University of Bochum) reflects his wide experience in an account of the *extraction of metal halides from aqueous media,* a powerful method for separating cations.

The first contribution in the section on analytical methods, by *W. Brümmer* (E. Merck, Darmstadt), deals with *affinity chromatography.* This is a special form of adsorption chromatography that is particularly useful for biological substances. This excellent chapter is also full of useful information for analytical chemists who do not work in the field of biochemistry.

*C. Wydler* (University of Basel) demonstrates the power of purely physical methods in his contribution on *electron spin resonance of organic radicals in solution.* This chapter constitutes a very useful aid for analysis and the interpretation of ESR spectra, especially by including a list of coupling constants in tabular form.

*H. Englhardt* and *G. M. Ahr* (University of Saarbrücken) call their contribution *HPLC—rapid liquid chromatography.* The treatment of the broad field of high-pressure liquid chromatography is certainly very good, but more information about the separation systems used in the next chapter, possibly in tabular form, would be appreciated.

*G. Schwedt* discusses *gas-chromatographic separation and determination methods in inorganic trace analysis* and gives the principles of derivatization, together with tables of the most important information about the volatile compounds to be prepared, the detectors to be used, the sensitivity limits, and practical applications.

The next chaper is by *R. Klockenkämper* (Institute of Spectrochemistry and Applied Spectroscopy, Dortmund), who also wrote *X-ray spectral analysis in combination with scanning electron microscopy* in Part 1. The new contribution, on *wavelength dispersion spectrometry,* gives useful numerical values, performance figures, and a comparison between wavelength-dispersion and energy-dispersion spectrometers.

Two chapters deal with the electrochemical aspects of analytical chemistry: *New titrations with electrochemical end-point indication* by *E. Schumacher* and *F. Umland* (University of Münster) and *Differential pulse polarography, pulse voltammetry, and pulse inverse voltammetry* by *H. W. Nürnberg* (Jülich Nuclear Research Center). Both authors are highly competent and give an excellent account of the present-day knowledge of ion-selective electrodes.

The part devoted to applications begins with an account of the *chemical detection of organic functional groups* by *W. Huber* (BASF Ludwigshafen). This chapter represents a welcome revival of *chemical* processes and includes very useful tables.

*Methods for the determination of elements in natural waters* by *G. Schwedt* (University of Göttingen) is a short but good survey of the analytical schemes and the methods of determination involved. *Indicators and their characteristics* by *V. Schmidt* and *W. D. Mayer* (Merck, Darmstadt) is a longer account and one that is fundamental to classical analysis. It gives the IUPAC names and the properties of the indicators for aqueous and non-aqueous systems, with a number of tables. *C. E. von der Smissen* (Drägerwerk, Lübeck) deals with filter-type respirators, a highly topical subject. This is an outstanding account of the present-day situation in the domain of work safety and environmental protection.

The last part of the book begins with the *relative atomic weights of the elements* and continues with *threshold limit values* at working premises (with some important tabulated material) and *intoxication-information and treatment cen-*

[*] Cf. *Angew. Chem. 94* (1982) 325; *Angew. Chem. Int. Ed. Engl. 21* (1982) 896.

*ters with a 24-hour service* (in the Federal Republic of Germany), together with addresses of *organizations in the field of analytical chemistry in the German-speaking countries.*

All in all, this book can be highly recommended for all chemists and for responsible authorities in industry and in universities.

*Hanns Malissa* [NB 573 IE]

# On the Description of Complex Inorganic Crystal Structures

By Sten Andersson*

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

To describe a structure is to describe chemistry. A description of structure should be simple yet also open up ways for an understanding of complex structures and their properties. Such interrelationships are gained on inspection and discussion of structures in models of interpenetrating partial structures and on application of symmetry operations to whole structures. Transition regions between interpenetrating partial structures can be approximated to periodic minimal surfaces. Chemical reactions, *e.g.* in ion-exchange, in heterogeneous catalysis, or in molecular separations in complicated zeolites will take place on these minimal surfaces.

## 1. Introduction

To describe a structure is to describe chemistry—and what is chemistry? Whether a substance is a solid, a liquid or a gas, we split it or decompose it into its component parts, *i.e.* building blocks, phases, polyions, molecules, atoms, electrons *etc.* to find out what it is made of. The analysis may be carried out by means of simple chemical methods, diffraction methods or quantum physical methods, and when it is complete we try to put the components of the substance together again to see if we can synthesize what we have just analyzed. When we think we have found out something about a structure and about the effective forces that hold the atoms of a substance together, we try to predict what happens with different combinations of these substances under various conditions of, *e.g.*, temperature and pressure.

Solid substances are almost always crystalline and have structures which are periodic, but the larger the repeat unit the more difficult it becomes to describe the structure. Really large complex structures are beyond comprehension and we cannot explain why they exist. With an appropriate description, however, we may sometimes be led to think that we understand a structure, understand how it is formed, and how to explain its properties.

Recently, on the occasion of *Wilhelm Klemm*'s 85th birthday, a series of review articles appeared in this journal in which *von Schnering, Simon, Hoppe* and *Bronger* outline their methods for the description of crystal structures[1–4]. It is immediately apparent that these descriptions stem from the same school—each of these authors were at Münster at the same time for a number of years—and that they are also strongly influenced by the chemistry of cluster compounds, in its infancy at that time and pioneered by *Harald Schäfer*. Another concept for the description of structures, the concept of "nested polyhedra" was developed by *Parthé* to simplify the description of complex cubic structures[5]. There are, of course, many ways in which to describe a structure, and I doubt whether we can say at this stage that any one is better than another.

Nevertheless, what we expect from a structure description is undisputed:

[*] Prof. Dr. S. Andersson
Oorganisk Kemi 2, Kemicentrum
Box 740, S-22007 Lund (Sweden)

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0202-0069 $ 02.50/0 

1. It should be simple, and should show as many relationships as possible to other structures.
2. It should facilitate the explanation of diffusion and reaction mechanisms.
3. It should be useful in explaining physical properties like conductivity, hardness, *etc.*
4. It should help us to interpret high-resolution electron microscopic lattice images—this often means trying to understand the defect structure of a crystal.

The first statement means, among other things, that a structure description should provide us with many ideas and associations. The description should thus allow us to apply Birkhoff's equation for the aesthetic measure[6]:

$$M = \frac{O}{C}$$

where O may contain elements of the associations (of order) and ideas, and C is the complexity, which in a polygon, for example, is measured by the number of sides. In simple terms this means a structure description should be "beautiful". (When solving the large block structures of various niobium oxides, *Wadsley* and I used to have two criteria for the proposed models: The chemical formula, and the *beauty*[7].) We are reminded of an old definition for beauty—as "that which gives us the greatest number of ideas in the shortest space ot time" (*Hemsterhuis*).

## 2. Simple Structures

The principal idea is that a complex structure is built up of much simpler structures[28]. What are much simpler structures and how can they be combined to give a complex structure? This is what we shall deal with in this article.

Before we outline our methods for the description of complex structures, we shall first describe simple structures. Such structures are, *e.g.*, hexagonal close packing (hcp) of the atoms, cubic close packing (ccp), body centered cubic (bcc), hexagonal primitive (hp), cubic primitive (cp), or just simply primitive packing of lower symmetry (Fig. 1).

Two simple and identical structures can interpenetrate to give a new structure, as shown in Figure 1. Examples are NaCl, diamond, and $Mg_3Cr_2Al_{18}$. Three simple and identical structures can also interpenetrate to give a new structure.

This can be vividly demonstrated using the concept of rod packing[8]: The alloy $Cr_3Si$ has the so-called A15 structure, in which infinite Cr-chains with short metal-metal distances run in three perpendicular directions. One explains *via* this peculiarity the existence of many superconductors with this type of structure, *e.g.* $Nb_3Sn$ and $Nb_3Ge$. These chains with short metal-metal distances are represented by rods (arranged with quadratic mesh) which interpenetrate to form the simple, cubic A15 structure (Fig. 1).

Four simple and identical structures can also interpenetrate—to form the garnet structure $[Ca_3Al_2(SiO_4)_3]$ shown in Figure 2. In this case, we have hexagonal meshes of rods

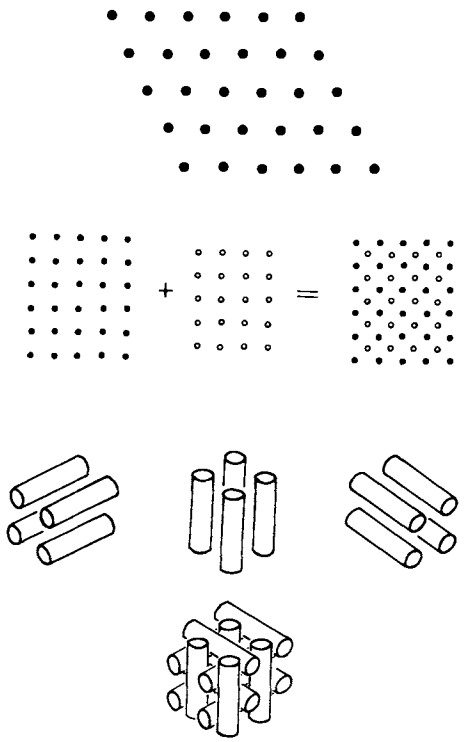

Fig. 1. Top: A simple structure.—Center: Two simple structures interpenetrate.—Bottom: Three simple structures interpenetrate to form the $Cr_3Si$ structure (A15-type).

in each simple structure, where each rod consists of face-sharing octahedra (filled) and trigonal prisms (empty) and all the oxygens are used to form the rods. Tetrahedra and twisted cubes (for the larger cations) are created between the rods by the oxygen atoms of adjacent rods. This structure is also taken up by alloys like $Th_4Bi$, in which all the Th atoms are in the oxygen positions of the garnet structure, and the Bi atoms are in the interstices formed by the Th rods (the large cation position in the garnet structure).

Two simple and different structures can interpenetrate to form a structure. One example is $ReO_3$, shown in Figure 3, another is NiAs, in which the hcp structure of As atoms interpenetrate a hp structure of Ni atoms. In $Cr_3Si$ the silicon structure (bcc) interpenetrates the chromium rod struc-

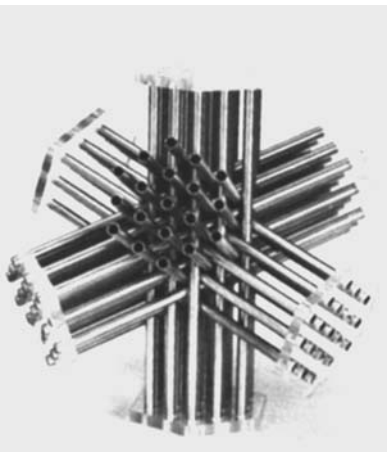

Fig. 2. Four simple structures interpenetrate to form the garnet structure.

ture, which itself consists of three identical interpenetrating structures. In $W_3Fe_3C$ the octahedral structure of tungsten atoms interpenetrates the tetrahedral structure of the iron atoms (Fig. 5) and the carbon atoms in the tungsten octahedra form a third structure, which is the same as that of the zinc atoms in $MgZn_2$, and the oxygen atoms in cristobalite (idealized).

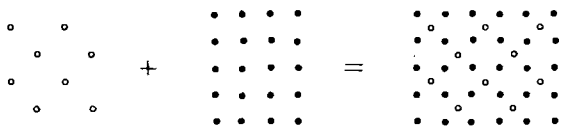

Fig. 3. Two different structures interpenetrate.

Of course, many more examples could be given. Between these simple structures there exist many relationships which we will leave undefined at this stage. Suffice it to say that from one simple structure many other simple structures are easily obtained by small shifts of atoms in various directions. Good examples of these topological operations are found, for example, in *Bärnighausen*'s work[9].

## 3. Complex Structures

"Most isometries are familiar in everyday life. When you walk straight forward you are undergoing a translation. When you turn a corner it is a rotation; when you ascend a spiral staircase, a twist (screw). The transformation that interchanges yourself and your image in an ordinary mirror is a reflection, and it is easy to see how you could combine this with a rotary reflection or a glide reflection, respectively" (from *Coexter*'s Introduction to Geometry). By using a point instead of "you", we describe the symmetry operations that give rise to the 230 space groups. By using *building blocks* of atoms, which may be parts of simple structures, we analogously describe the symmetry operations that give the complex structures. The symmetry operations that describe the space groups leave all distances and angles unchanged, and similarily the building blocks are left unchanged during a transformation.

We thus assume that complex structures can be described as parts of simple, or simpler structures. We shall demonstrate this with a number of examples.

## 4. Parallel Translation

Figure 4 shows how a simple structure (Fig. 1) may be repeated by a single parallel translation to build up a more complex structure. This operation, called crystallographic shear, or slip, produces two interesting new features in the structure: In the shear planes there are triangles of atoms, in which each of the three participating atoms is now pentacoordinated, and the sheared complex structure is more dense than the simple structure. Two examples of formal shear structures are those of compounds $Nb_3O_7F$ and

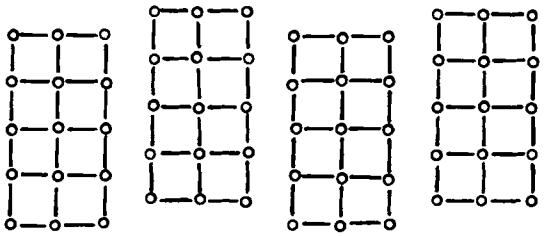

Fig. 4. Shear by parallel shifts.

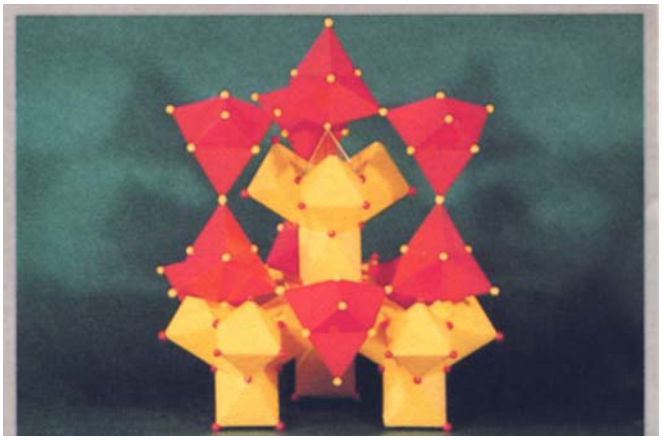
R–$Nb_2O_5$ (Fig. 5). In both cases the simple parent structure type is $ReO_3$.



The structure of $TiNb_2O_7$ (Fig. 5) contains columns of the $ReO_3$ structure ($3 \times 3$ octahedra in size) stretching infinitely in the direction perpendicular to the plane of the picture. The structure is formally derived from double translations of the parent $ReO_3$ structure, or equally well from a single translation of the $Nb_3O_7F$ structure. Figure 5 shows the structure of $NaNb_{13}O_{33}$, which also is derived from a double translation of the parent $ReO_3$ structure or a single translation of the $Nb_3O_7F$ structure.

Two different column sizes of the same $ReO_3$ parent structure type, occurring in the same crystal in an ordered way, are found in the structure of $W_4Nb_{26}O_{77}$[7]. This important compound was first prepared by *Gruehn* in *Schäfer*'s laboratory in Münster. $W_4Nb_{26}O_{77}$ could easily be described as composed of alternate slabs of the oxides $WNb_{12}O_{33}$ and $W_3Nb_{14}O_{44}$, and is called an intergrowth or hybrid compound, the first example of its kind (Fig. 6).

A variation in composition of a compound due to random variations of column or slab size were predicted earlier by *David Wadsley* in Melbourne. He, together with *Sanders* and *Allpress*, were also the first to use the now so well known lattice imaging technique in a classical study on various niobium oxides[10]. I shall always remember my feelings of joy upon receiving his enthusiastic letters, always accompanied by many lattice images of these oxides with random shear planes. After his untimely death we named these faults, now also known to be so common in minerals, metals and alloys, Wadsley defects, in honour of the man who proposed and predicted their occurrence so many years before they were actually discovered. *Schäfer* realized at an early date the importance of *Wadsley*'s pioneering work on oxides, which he wholeheartedly supported.

Nowadays, microscopes are far more better and it is possible to achieve atomic resolution almost routinely. A study by *Bovin et al.* on crystals of $NaNb_{13}O_{33}$ clearly demonstrates this[11]. Columns, sized $3 \times 5$ octahedra and similar in structure to those of $TiNb_2O_7$ (cf. Fig. 5, bottom left), are intergrown with the normal column of the $NaNb_{13}O_{33}$ structure (Fig. 7). Thus, it is vividly clear how the crystal is able to accomodate variations in the sodium content.

It is obvious that for these transition metal oxides structure description is now a well established procedure, with full theoretical and experimental support from computer calculations and high resolution electron microscopy. The structures of many, many more oxides can be developed

$CuAl_2$. If the translation operation is continued as shown in Figure 8, larger columns of $Cr_3Si$ can build into the structure of $Mo_3CoSi$, which can also be derived from the $CuAl_2$ structure.

Complete experimental support for this structure description is obtained from *Stenberg*'s lattice images of $Mo_3CoSi$ (Fig. 9)[13]. Furthermore, we note that the short metal-metal distances, typical for $Cr_3Si$ in three dimensions, are restricted to two dimensions for the single translation structures, and to one dimension for double shear structures.

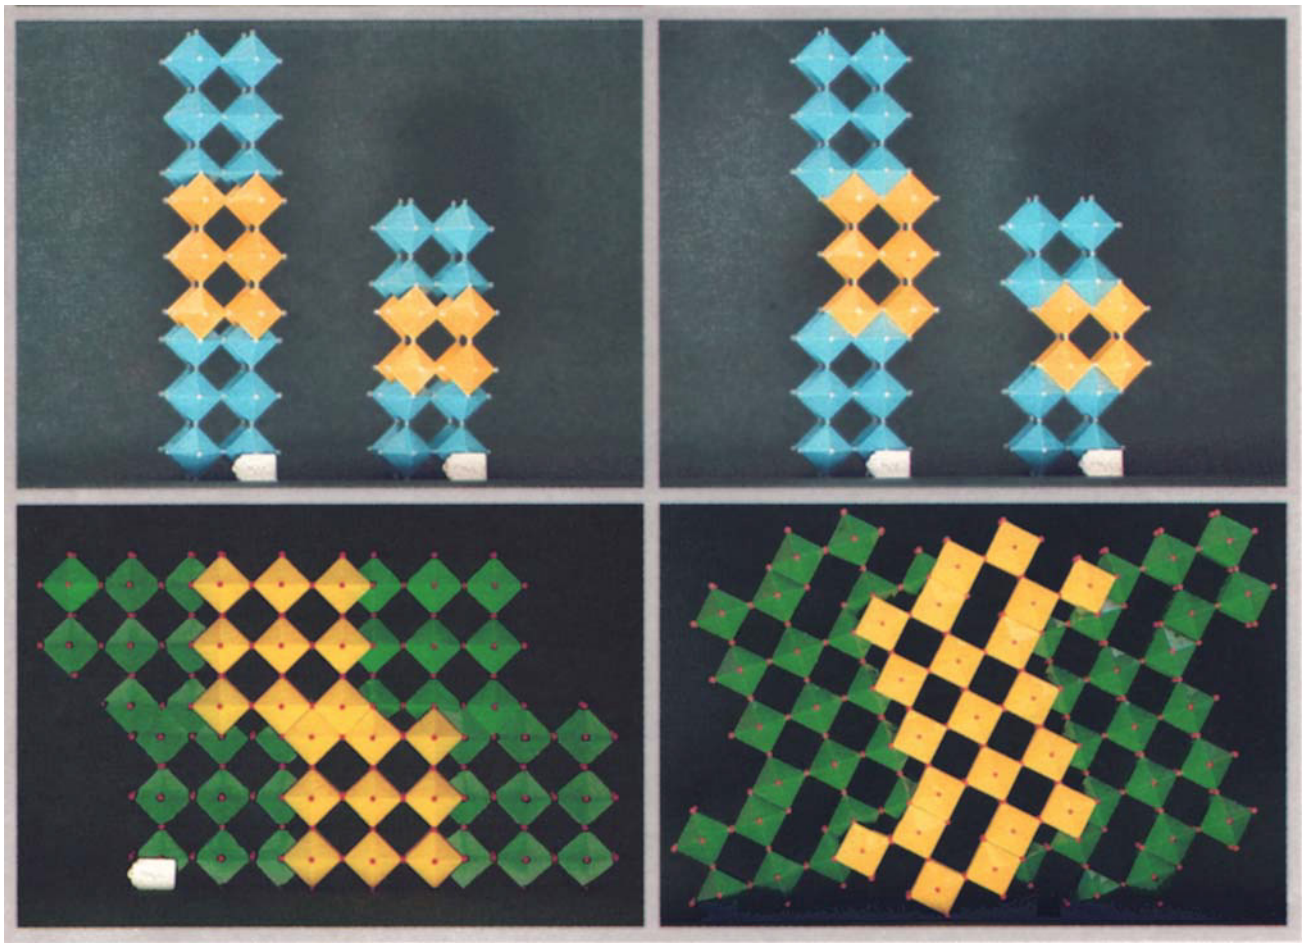


Fig. 5. Top: Structure of $W_3Fe_3C$. The structure of the tungsten atoms (red spheres), with carbon in the center of the (yellow) octahedra interpenetrate the tetrahedral iron structure (yellow spheres).—Center: The structures of $Nb_3O_7F$ (left) and R-$Nb_2O_5$ (right) shown in two different projections.—Bottom: The structures of $TiNb_2O_7$ (left) and $NaNb_{13}O_{33}$ (right).

by simple parallel translation. For further detailed information on this subject the reader is referred to the literature[12].

In Section 2 we described the $Cr_3Si$ structure as a rod structure, but here we can describe it in a slightly different way, as shown in Figure 8. The shaded regions consist of five irregular tetrahedra—an arrangement which *Schubert* calls a "Tetraederstern". In Figure 8 we have applied single and double translation (shear) to the structure and obtained two very important structure types, $Zr_4Al_3$ and

## 5. Parallel Reflection

Figure 10 illustrates twinning of a hcp structure. This simple parallel reflection is called "chemical twinning", or also "unit cell twinning"[14a]. New polyhedra are created in the twin plane by this operation, in this case trigonal prisms. The first example is cementite, $Fe_3C$ (see Fig. 10 and 11). The hcp slabs are four iron atoms wide, and the trigonal prisms in the twin planes contain carbon atoms. If the slabs are alternately 4 and 3 iron atoms wide, we obtain

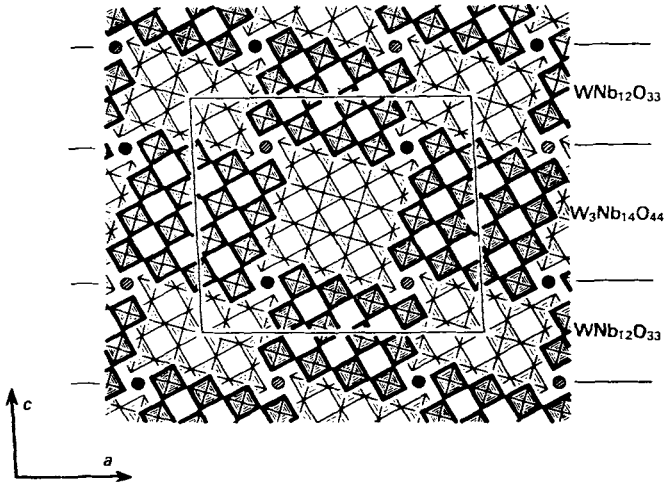

Fig. 6. Structure of the intergrowth or hybrid compound of $W_4Nb_{26}O_{77}$ formed by the components $W_3Nb_{14}O_{44}$ and $WNb_{12}O_{33}$.

the structure of $Fe_5C_2$, which is of the $Pd_5B_2$ type. Variation of stoichiometry can easily be achieved by varying the block size (Fig. 11), and this has recently been verified experimentally by electron microscopy[14b]. There are many

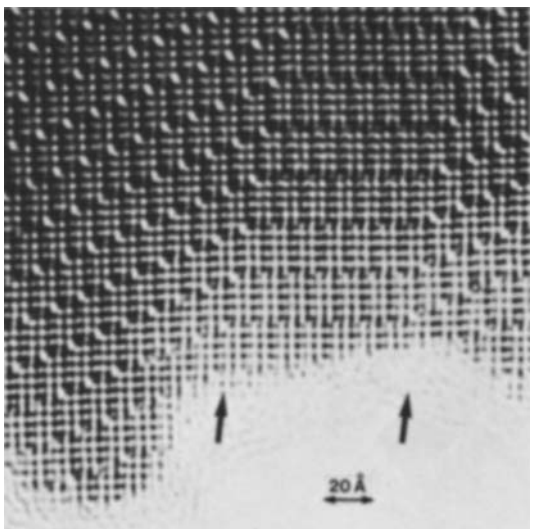

Fig. 7. Lattice image of a defect in a crystal of $NaNb_{13}O_{33}$. The intergrowth of the $NaNb_{13}O_{33}$ structure with a $TiNb_2O_7$-type structure is easily discernible (region between the arrows) [11].

compounds with the $Fe_3C$ structure, of which we shall mention only three here, namely $SbCl_3$, $BiCl_3$, and, as a special case, $XeO_3$. Likewise, ccp nets may be twinned, and this operation also produces trigonal prisms in the twin planes. The structures of $Re_3B$, $CaTi_2O_4$ and lillianite ($Pb_3Bi_2S_6$) are typical examples (Fig. 11). *Parthé*[15] has pointed out that unit-cell twinning is also observed in mixed hcp and ccp structures, for example in $Sc_3Co$ and one modification of TbNi.

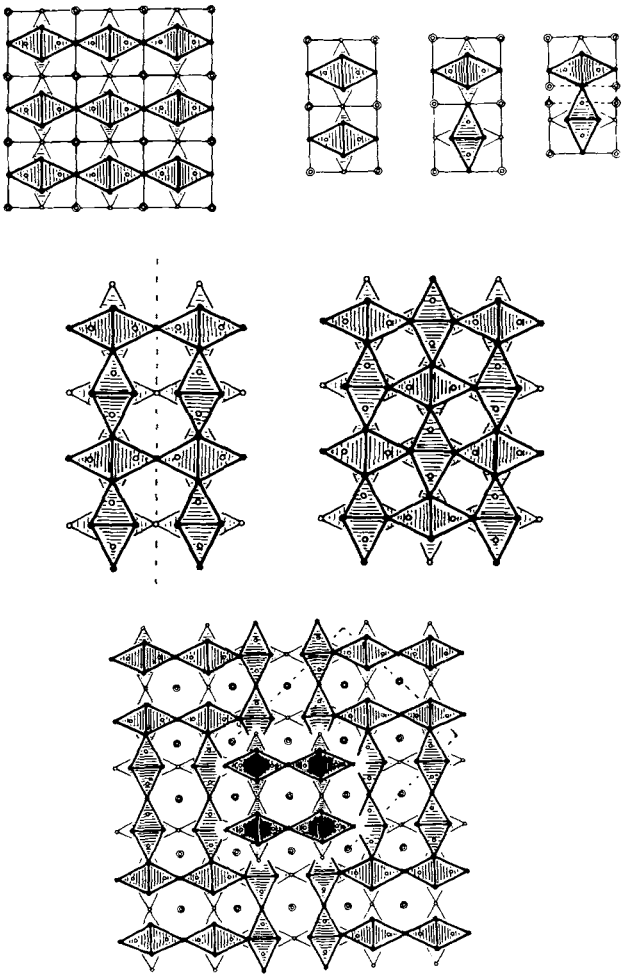

Fig. 8. Top: Structure of $Cr_3Si$ (A15-type) (left) and single steps of the shear operation (right) (cf. text).—Center left: $Zr_4Al_3$ structure (idealized) is formed from the $Cr_3Si$ structure by a vertical shear of each second slab followed by a connection of the tetrahedra-stars. Center right: Structure of $CuAl_2$ formed by an additional shear operation of the same type along the broken line in $Zr_4Al_3$. (In both cases the central atoms are omitted.)—Bottom: The structure of $Mo_3CoSi$ generated by the same shear operation but only of each second slab of $Cr_3Si$.

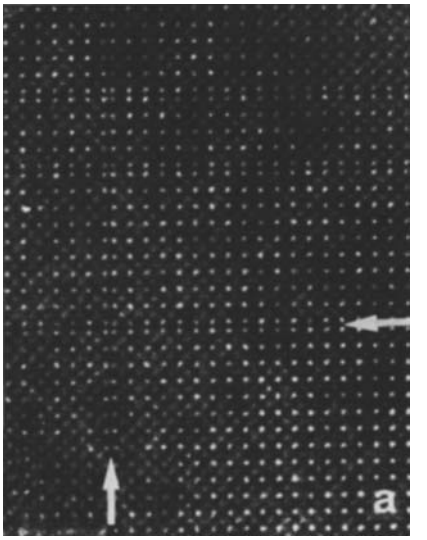

Fig. 9. High resolution lattice image of $Mo_3CoSi$. The light dots are the center of mass of the hexagonal antiprisms, the weaker dots correspond to the square antiprisms. The intersection of the arrows is the $Cr_3Si$ structure.

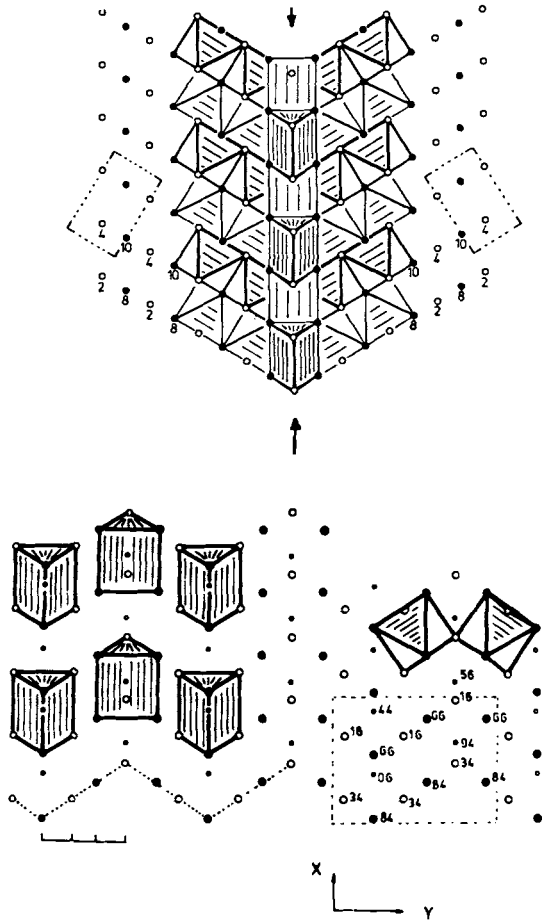

Fig. 10. Top: Twinning in hcp. Heights are in units of 1/12th. Trigonal prisms in the twin planes are shown, as are also some octahedra.—Bottom: The structure of $Fe_3C$ formed by four atom layer slabs (as indicated on the bottom left).

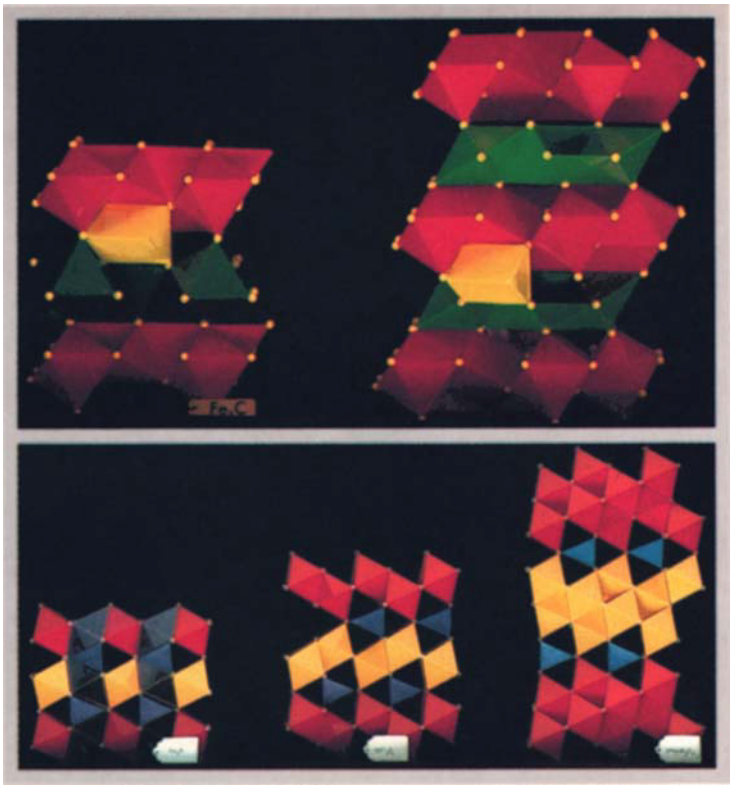

Fig. 11. Top: Structures of $Fe_3C$ and $Fe_5C_2$. Carbon atoms fill the yellow trigonal prisms, between the green and red hcp slabs of the Fe atoms (yellow spheres). Note that the green slabs in $Fe_5C_2$ (right) are not as wide as those in $Fe_3C$ (left).—Bottom: The structure of $Re_3B$, $CaTi_2O_4$ and lillianite (trigonal prisms = blue polyhedra).

Unit-cell twinning of a primitive cubic structure is also possible. One example is the structure of $Ru_4Si_3$ shown in Figure 12 as twinned RuSi (CsCl type), but here the reflection is combined with a translation. $Rh_5Ge_3$ ($Ru_5Si_3$ is isostructural) follows the same scheme, but the slab size is only five atoms wide (Fig. 12), whereas in $Ru_4Si_3$ it is eight atoms wide. Naturally, one expects a crystal to have faults which correspond to various distances between the twin planes. The presence of faults was confirmed in some early electron microscopic studies on $Ru_4Si_3$ crystals, but since no really high resolution was available, we had to make a histogram analysis of the fringes in the one-dimensional lattice images[16]. Figure 13 shows the various *c*-axis lengths found, corresponding to the different RuSi block sizes in the $Ru_4Si_3$ crystal.

## 6. Complex Parallel Intergrowth

The extremely important alloy structure type $W_6Fe_7$ (μ-phase) is best described as an intergrowth of slabs of two structure types, namely those of $Zr_4Al_3$ and $MgCu_2$ (Fig. 14). This suggests that disorder may exist, since the two different slabs can vary in size and orientation; this has in

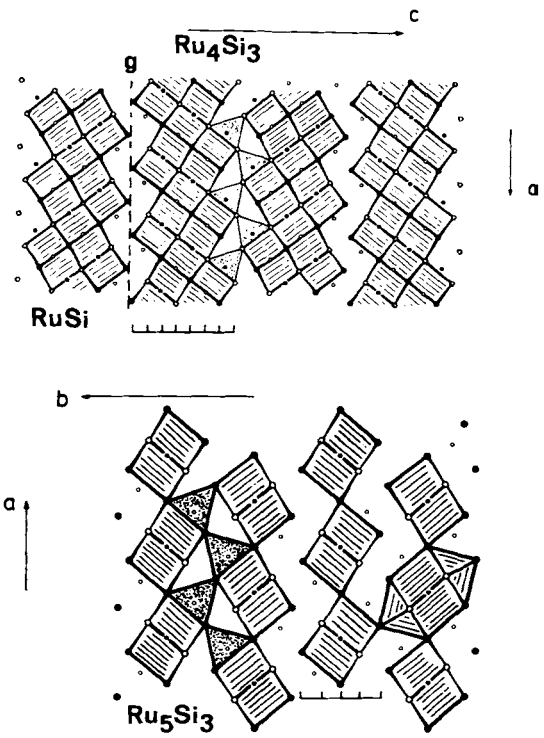

Fig. 12. Top: Structure of $Ru_4Si_3$ formed by RuSi (eight atomic layers).—Bottom: The structure of $Ru_5Si_3$ ($Rh_5Ge_3$) generated by RuSi-slabs (five atomic layers).

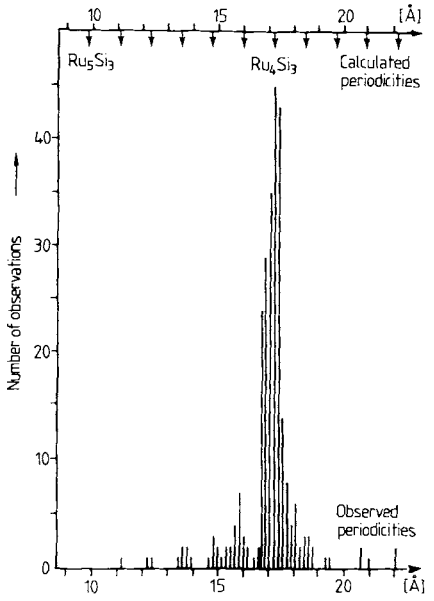

Fig. 13. Frequency distribution of the *c*-axis lengths found in five different crystals of $Ru_4Si_3$.

fact been confirmed by electron diffraction[17]. One of the reasons we include the so-called μ-phase structure here is that it can be sheared and twinned, and thus lends itself for the description of at least three more structures.

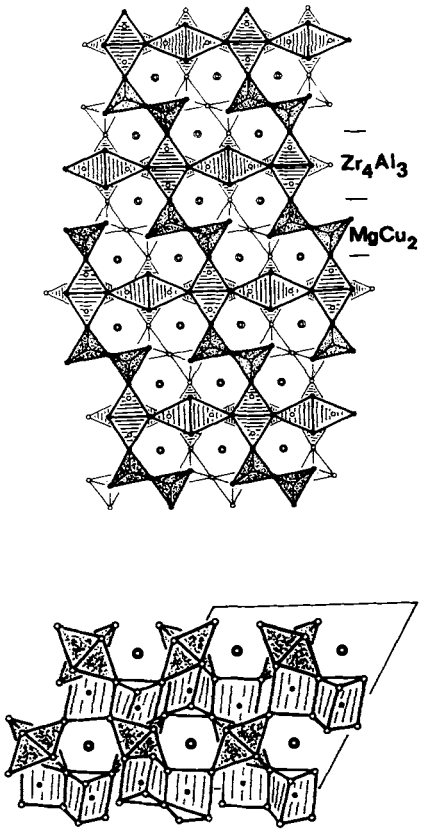

Fig. 14. Top: Structure of $W_6Fe_7$ composed of $Zr_4Al_3$ and $MgCu_2$ slabs.—Bottom: Structure of $Ta_6S$ composed of $Zr_4Al_3$ and $Fe_5C_2$ slabs.

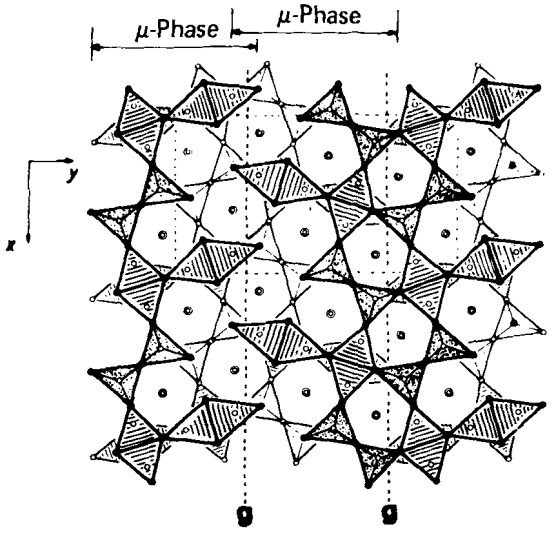
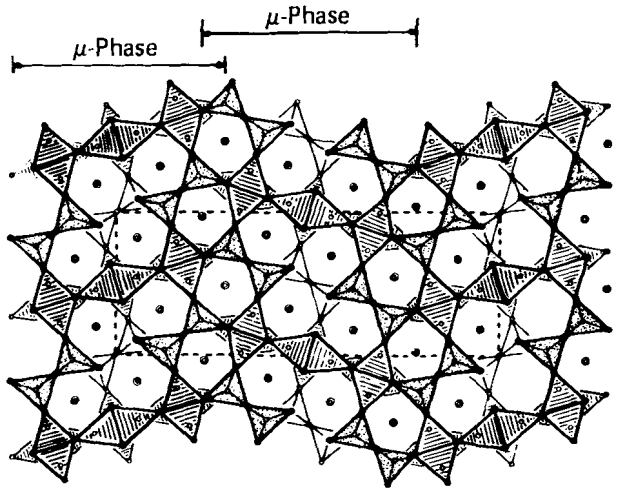
Another spectacular example of intergrowth is found in the crystal structure of $Ta_6S$ (Fig. 14). Slabs of the $Zr_4Al_3$ type are intergrown with slabs of the $Fe_5C_2$ type and thus form the $Ta_6S$ structure. The tantalum atoms occupy the Fe, Zr and Al positions, and the sulfur atoms lie in the trigonal prisms (at the positions of the carbon atoms in $Fe_5C_2$).

## 7. Parallel Translation and Reflection in Combination



We have already given one example of this very common combined operation for describing structures in Section 5. Another example is the M-phase ($Nb_{48}Ni_{39}Al_{13}$) structure, which is accurately derived by twinning and shear of the μ-phase structure (Fig. 15). If the μ-phase slabs are extended in size a hypothetical structure is obtained, and with thinner slabs we get the $FeSiW_2$ structure shown in Figure 15. If the operation is continued by an additional shear, the melilith ($Ca_2MgSi_2O_7$) structure is obtained. Excellent experimental support for this description is again obtained from *Stenberg*'s electron microscopic investigations. Figure 16 shows part of a crystal of the M-phase containing large parts of the μ-phase, sheared and twinned as in the M-phase structure[18].



## 8. Cyclic Operations: Translation and Reflection

A simple example of this is shown in Figure 17, where the tetragonal bronze structure is generated by a cyclic twin operation from the $ReO_3$ structure. A large part of the bronze structure is recognizable in the center; the central octahedron is formed partly by the cyclic operation and then merely completed. In addition, the $BaNb_2O_6$ structure is formed in the twin planes. Naturally, this offers a geometrical model for the formation of the compound by nucleation. Repetition to a larger crystal may then occur if it is energetically possible, *e.g.* if the right ions are present under the right conditions of temperature and pressure.

The structure of $W_5Si_3$ is a further example for this operation: The simple construction of a fourling of the $Cr_3Si$ structure (Fig. 17) enables the demarcation of a column of $W_5Si_3$, whose structure is commonly described with square antiprisms, octahedra, and hexagonal antiprisms. Here also the structure in the center was completed by the insertion of an individual atom.

The $Zr_4Al_3$ structure is obtained by a shear (or translation) operation in the $Cr_3Si$ structure. If a $Zr_4Al_3$ column, similar to the $Cr_3Si$ column above, is used again for a fourling construction we obtain the $Ta_2S$ structure, as shown in Figure 17. *Bursill* and *Hyde* have shown that the tetragonal bronze structure can also be derived by a rotation of one-dimensional columns of the $ReO_3$ structure[19]. A similar transformation mechanism has also been proposed by us for the formation of the $Ni_3P$ and $W_5Si_3$ structures from that of $Cr_3Si$[20].

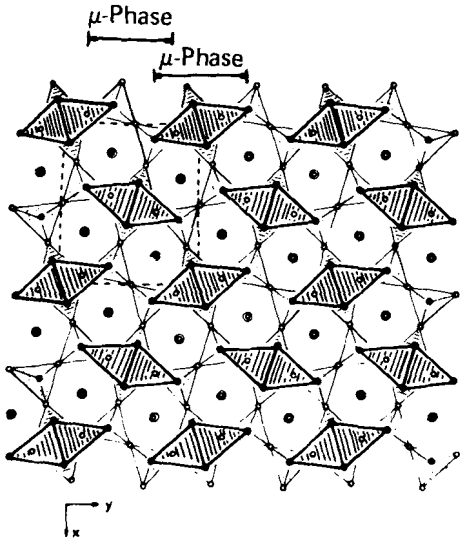


Fig. 15. Top: The M-phase structure. The glide planes (g) transform the intergrowing slabs of the μ-phase into each other.—Center: A hypothetical structure with thicker slabs of the μ-phase.—Bottom: The $FeSiW_2$ structure composed of thinner μ-phase slabs.

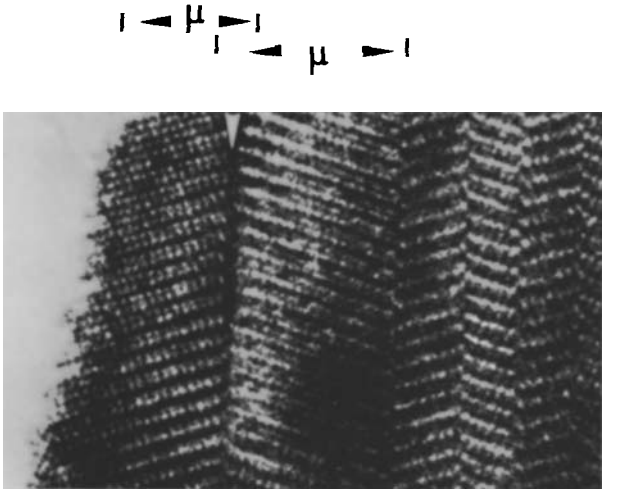

Fig. 16. High resolution lattice image of an M-phase crystal, with large regions of the μ-phase. (One glide plane is indicated by an arrow.)

## 9. Cyclic Intergrowth

Cyclic intergrowth has recently been used by us[21] to describe several structures; here we shall only mention a few cases. Figure 18 shows a simple model for this operation and clearly demonstrates how the important σ-phase (FeCr) structure is very accurately derived by intergrowing $Cr_3Si$ and $Zr_4Al_3$. This provides an alternative but simple and attractive description of the σ-phase, previously described with Kagomé nets.

*Simon* has described the suboxides of the alkali metals discovered by him as cluster compounds with the structural units $Rb_9O_2$ or $Cs_{11}O_3$, respectively[22]. An alternative description is possible for the suboxide $Cs_7O_3$ by a cyclic intergrowth of an hcp structure and the $Zr_4Al_3$ structure (Fig. 18). In the center of this cyclic intergrowth we note a cluster of three face sharing octahedra, namely the $Cs_{11}O_3$ unit, which represents the basis of the $Cs_7O_3$ structure (shown inside the heavy line).

## 10. Complex Applications

The validity and accuracy of this general method for the description of structures has been demonstrated experimentally with high resolution electron microscopy for some groups of compounds. We have shown earlier[23] that some complex alloy structures and even some so-called giant cubic structures could be very accurately described with these methods. Examples are γ-brass, $Rh_7Mg_{44}$, and $Cu_4Cd_3$.

Another unusually complex structure is found in the silicate paulingite $[K_2(Ca,Ba)_{1.3}(Si,Al)_{12}O_{24}\cdot 14H_2O]$, which has a cubic unit cell containing about 2500 atoms[24]. The methods discussed here led to an alternative description of this structure[25], which differs considerably from the one given by *Samson et al.* A reflection operation as initial step

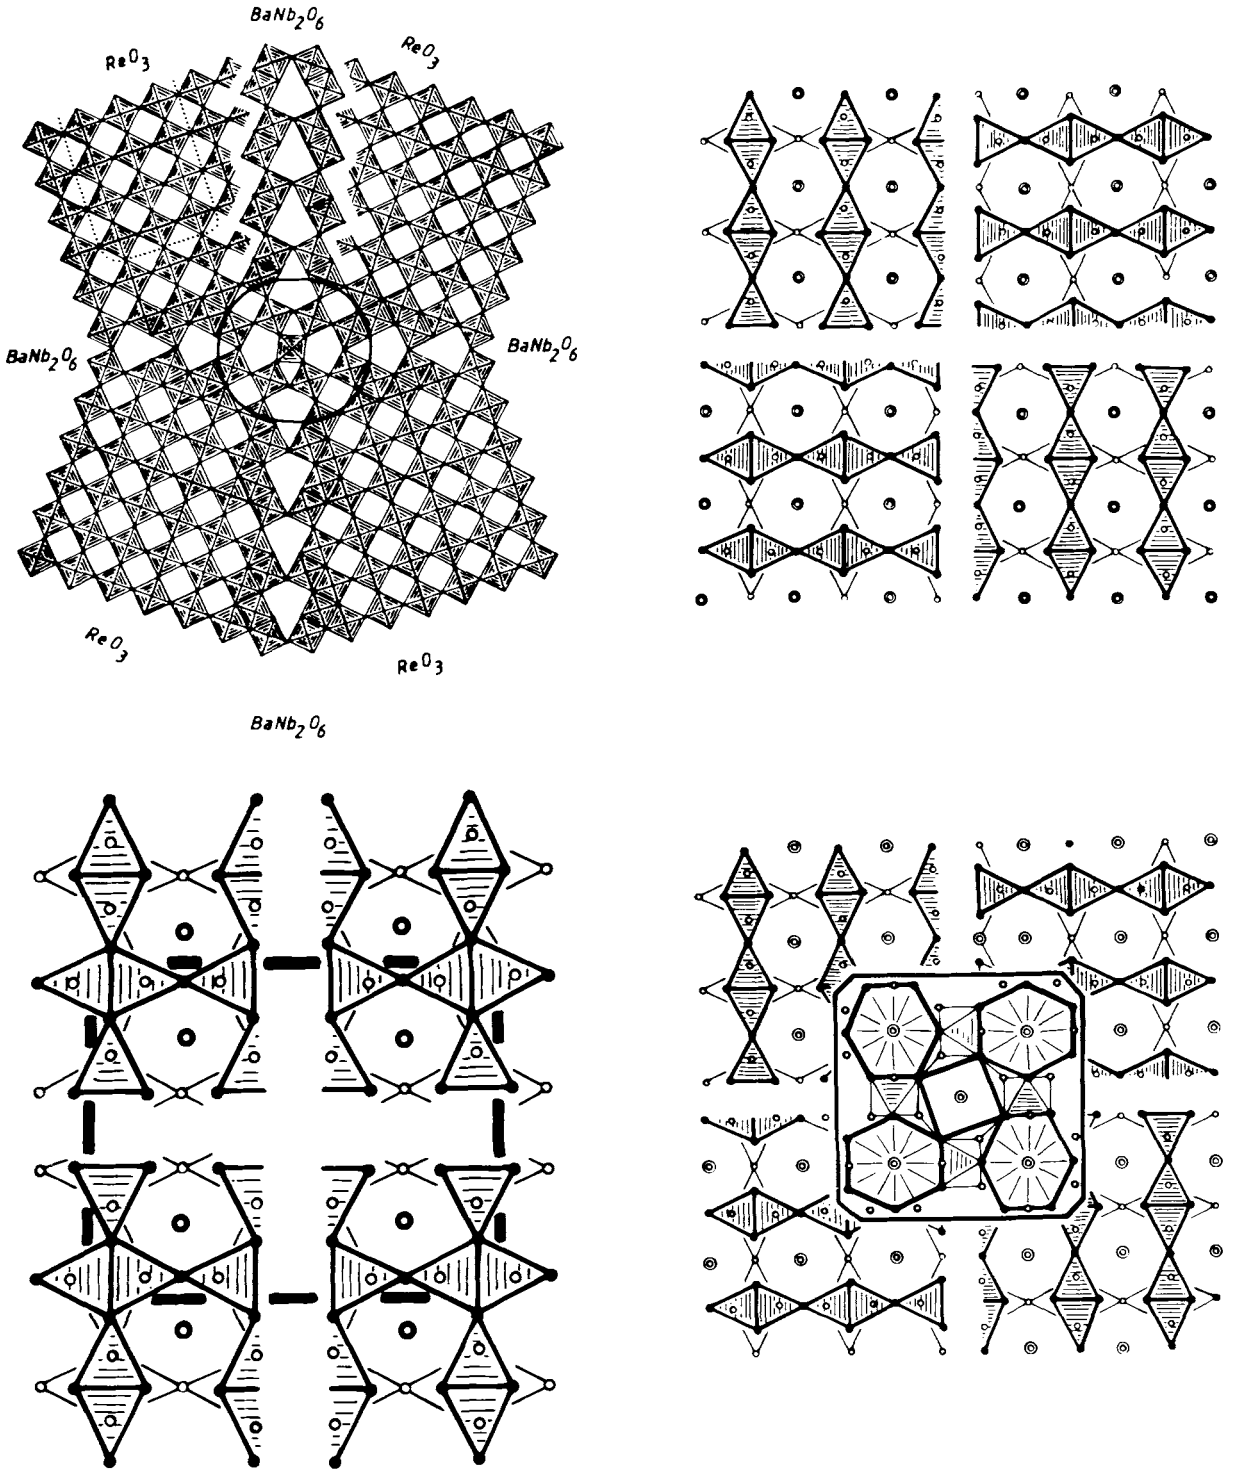

Fig. 17. Top left: A fourling of perovskite (or $ReO_3$) generated by two perpendicular reflections, to give the tetragonal bronze structure in the center (framed). The main structural units of $BaNb_2O_6$ (partially isolated in the upper part) are formed along the twin planes.—Top right: Fourling of the $Cr_3Si$ structure (formed by fourfold rotation) generates the $W_5Si_3$ structure.—Bottom right: Fourling of the $Cr_3Si$ structure with the region of the $W_5Si_3$ structure in the center (framed).—Bottom left: Fourling construction of the $Zr_4Al_3$ structure to give the $Ta_2S$ structure (framed with bold lines).

converted the very simple structure of cristobalite ($SiO_2$) into the gismondine structure ($CaAl_2Si_2O_8 \cdot 4H_2O$)[26]. A fourling of this structure (Fig. 19) formed by two orthogonal reflections generates the structure of merlionite ($K_5Ca_2Al_9Si_{23}O_{64} \cdot 24H_2O$) in the center. This mode of operation also leads to the structure of phillipsite ($KCaAl_3Si_5O_{16} \cdot 6H_2O$) from two pieces of gismondine in the mirror plane region. If a whole packet of atoms is now taken from the center of this fourling construction (only Si atoms are shown in Fig. 20) and put together in three-dimensional space by a translation operation, the paulingite structure is obtained (Fig. 20). The coordinates of all atoms of the paulingite structure, as calculated from the gismondine structure, agree exactly with the data of a crystal

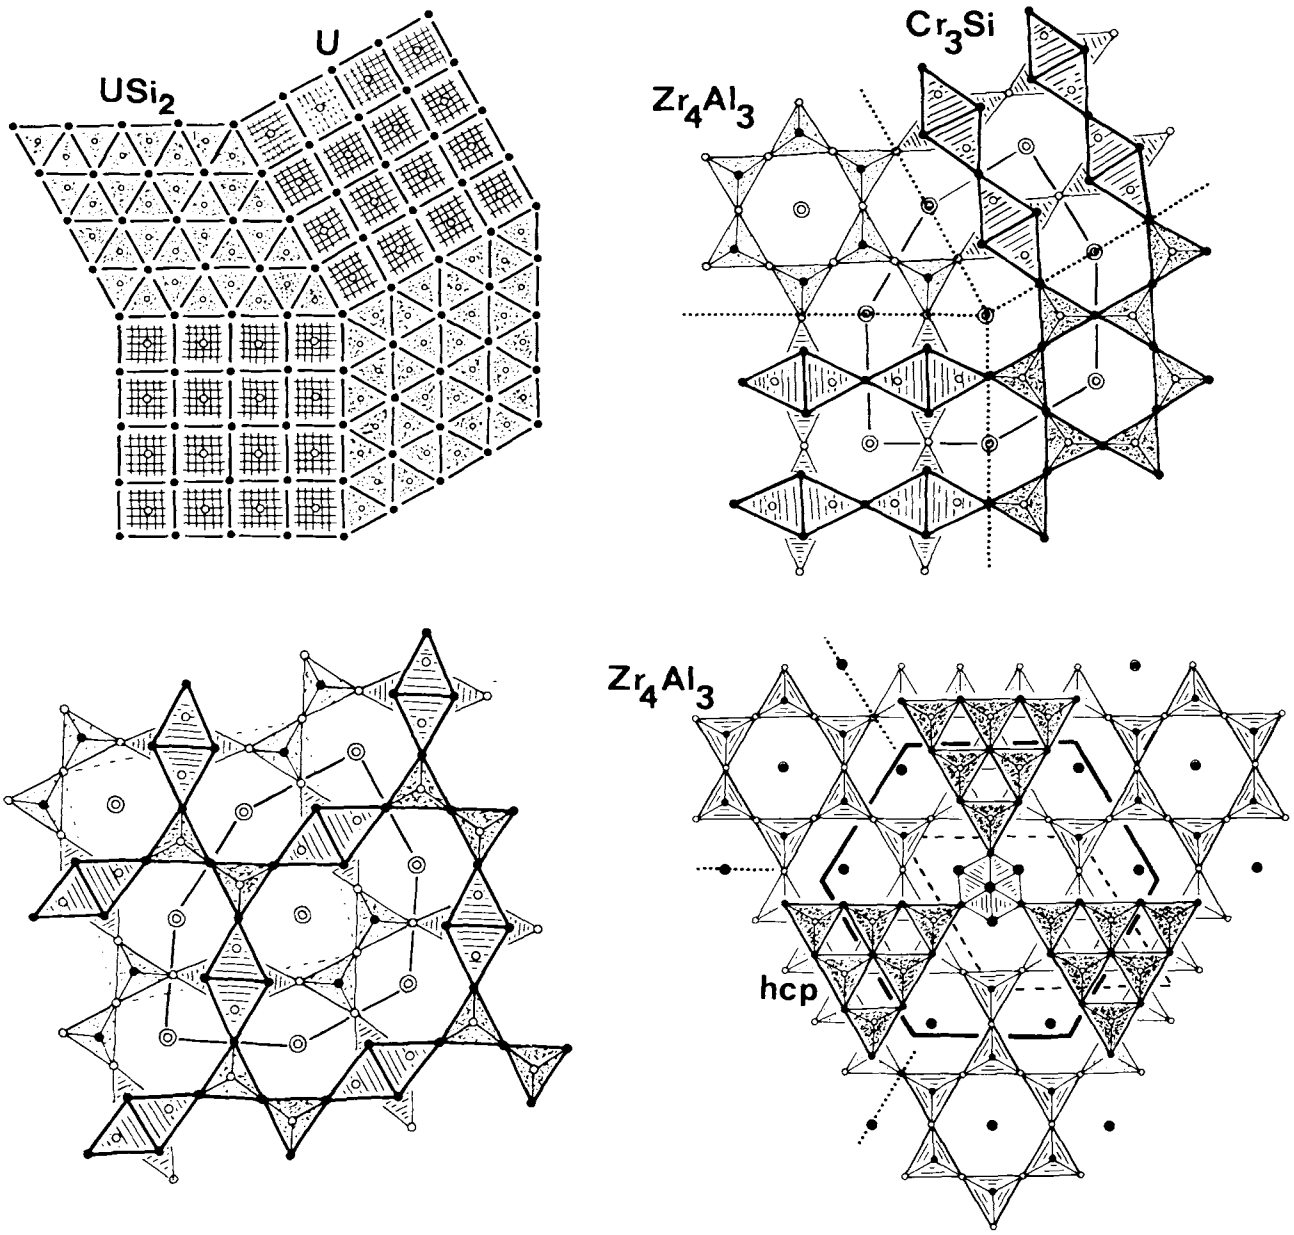

Fig. 18. Top left: Cyclic intergrowth of two simple structures.—Top right: Cyclic intergrowth of the $Zr_4Al_3$ (view along the hexagonal $c$-axis) and $Cr_3Si$ structures to give the σ-phase structure (framed in the center).—Bottom left: The complete σ-phase. The same region as in upper right has been framed in the center.—Bottom right: Cyclic intergrowth of the hcp and $Zr_4Al_3$ structures to give the $Cs_7O_3$ structure (indicated by a bold line). In the center the $Cs_{11}O_3$ cluster is formed (only Cs-atoms). The unit cell is indicated by broken lines.

structure analysis by *Samson et al.*, which again confirms the validity and accuracy of our description[25].

Our method for the description of these large cubic structures can, of course, be used to *solve* unknown complex structures as well. The systematic tracing of relationships to much simpler structures in the reciprocal lattice of a complex structure provides a direct method for structure determination. It was with this in mind that *Fälth* and I undertook the structure determination of a very large cubic structure, that of zeolite N with a lattice constant $a = 36.9$ Å, and about 3500 atoms in the unit cell[27]. Crystals of this zeolite were grown by *Fälth* using a method developed by him for silicates. In the Patterson function we quickly found a simple relationship to the sodalite structure $[Na_4(AlSiO_4)_3Cl]$, and by taking out exactly half of all the atoms from this structure, the remainder could be fitted to the space group of zeolite N, namely Fd3. This accounts for half the number of tetrahedra in the structure shown in Figure 20, and it was clear from this development that a second partial structure still had to be inserted in the sodalite skeleton in order to construct the complete structure of zeolite N. By trial and error we found that this missing part is a fragment of the zeolite K5 structure (Fig. 20). This part was taken in a similar way from the zeolite K5 structure as described for the sodalite fragment, namely with the criterion to fulfill the symmetry of the space group of zeolite N. Both structures, sodalite and K5 thus interpenetrate into the complete skeleton of zeolite N (Fig. 20)[27]—a formidable and elegant example of a structure, generated

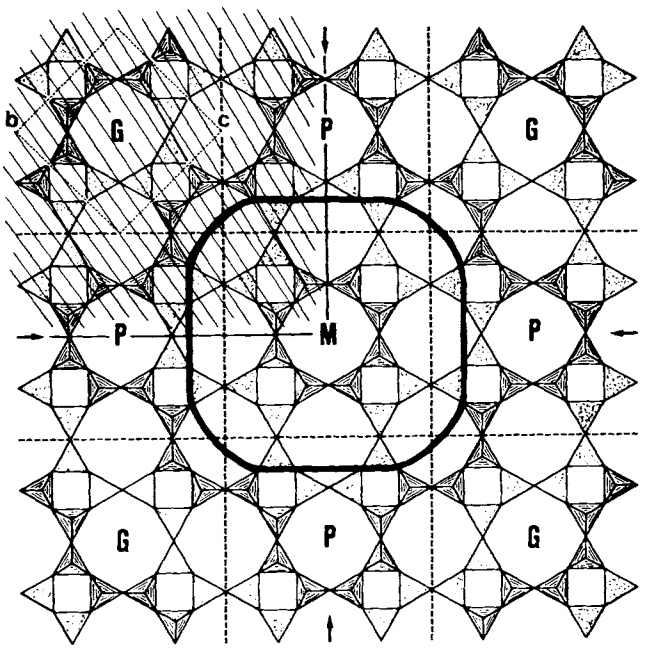

Fig. 19. Fourling of gismondine G (hatched region) and merlionite M in the center. In the region of the mirror planes (indicated by arrows) phillipsite P is formed by two parts of G.

by different interpenetrating complex point systems, which are operated as a whole by symmetry[28].

## 11. Periodic Minimal Surfaces

Some of these interpenetrating structures are hard to describe and understand but if we persist then some new and exciting developments emerge. Consider first:

a) $Cu_4Cd_3$, a pyrochlore-like structure with mainly Cd atoms which interpenetrates a complex Laves phase structure, of mainly Cu atoms.
b) Zeolite N, a sodalite structure which interpenetrates a zeolite K5 structure.
c) $W_3Fe_3C$, a tungsten octahedral structure which interpenetrates a tetrahedral structure of iron atoms (Fig. 5).
d) $Cr_2Mg_3Al_{18}$, where two identical structures interpenetrate.

If we study especially that part of the $Cu_4Cd_3$ structure which is built up of Friauf polyhedra intergrown in a manner typical for Laves phases, then we can recognize that a very smooth surface, close to the interface between the two interpenetrating structures, covers as well as separates the two parts (pyrochlore and Laves phase) in three dimensions. We propose that this interface is *an infinite periodic minimal surface.*

The Schwarz periodic minimal surfaces have been systematically described by *Schoen*[29]. One of the most spectacular is the so called Neovius surface[30]. According to *Hilbert*, it has the diamond symmetry and also contains the famous "monkey saddle"[31] (cf. Fig. 21).

*Scriven*[32] has suggested that a minimal surface might play a role in fluid or liquid crystals and that the structures differ on each side. Other crystallographical applications for these surfaces have been suggested by *Mackay*[33]. Actual use of the concept has been found for a cubic liquid-crystalline phase by *Larsson, Fontell* and *Krog*[34], and *Fontell*[35]. Truncated octahedra are one type of polyhedra that fill space and if half these are taken out of space-filling packing in a primitive way, the cubic liquid structure is obtained. In this case the truncated octahedra share only square faces, and the structure, which corresponds to Schwarz's primitive periodic minimal surface, is the one found by *Larsson, Fontell,* and *Krog.* On the other hand, if half of the polyhedra are removed from the space-filling packing of truncated octahedra in such a way that the remaining polyhedra share hexagonal faces, a cubic face centered structure is obtained (diamond symmetry), which represents half of the Si,Al structure of zeolite N (Fig. 20).

It is clear that the interface between, *e.g.*, the interpenetrating W and Fe structures in $W_3Fe_3C$, the interpenetrating Laves and pyrochlore-like structures in $Cu_4Cd_3$, and the interpenetrating sodalite and ZK 5 structures in zeolite N can all be approximated to a *periodic minimal surface,* as shown in Figure 21 for the tetrahedral part of $Fe_3W_3C$. This is the first periodic minimal surface of *Schwarz*; it has diamond symmetry. We can now continue this description by saying that the skeleton atoms in the Linde A and K 5 zeolites also form a minimal surface[33], like the one found by *Fontell et al.* in their liquid crystals. Faujasite (zeolite X and Y), which belongs to the same family as the zeolite N, as well as the pyrochlore structures may also be treated similarly. Finally, the hexagonal tunnel structures and the hexagonal bronze structures are also topologically related to *Schoen*'s H, or H-T structures[36].

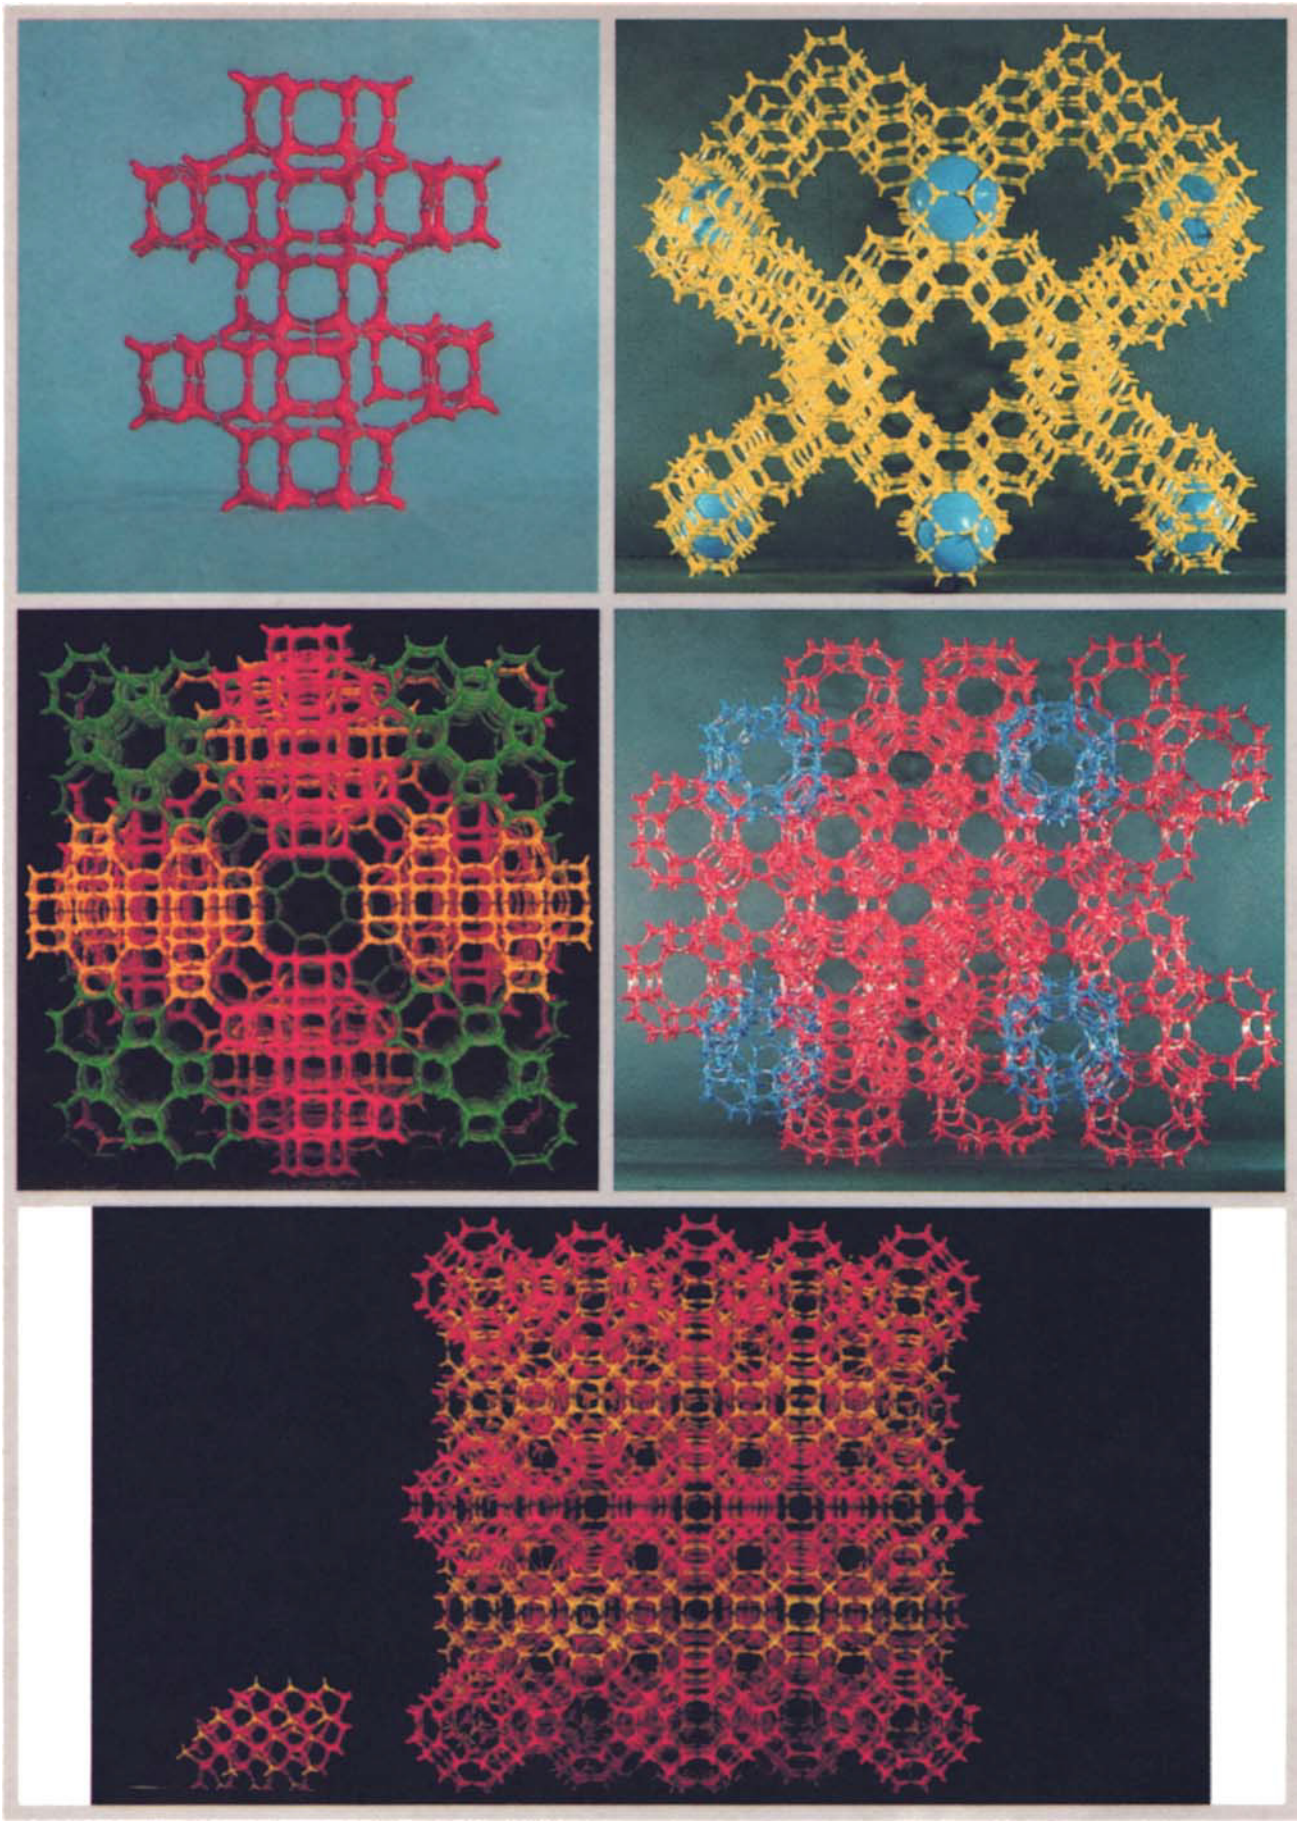
A useful concept in the description of structures has been the close packing of spheres in a plane. Intuitively however, we feel that atoms of different sizes, like Fe and W, Cd and Cu, will pack more efficiently on a curved surface than on a plane. It is obvious therefore, that on these periodic minimal surfaces, atoms will pack with non-Euclidian geometry, and that reactions like ion-exchange, heterogeneous catalysis or molecular separations occur on these minimal surfaces.

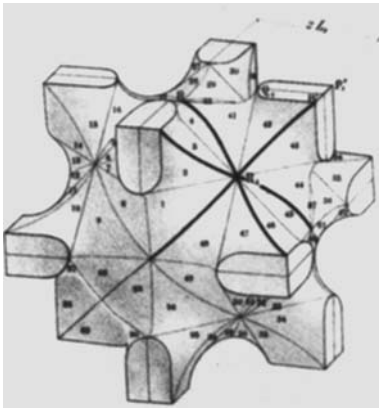
A logical step leads us to three or even four interpenetrating structures, as in $Cr_3Si$ or garnet. Do such minimal surfaces exist in these cases? Can a minimal surface divide space into three or even more interpenetrating subvolumes? This I do not know.

## 12. Concluding Remarks

In this article a number of structures have been described by geometrical methods, which we consider are exact and general, and from which we can obtain some understanding of defect structures and of how transformations and diffusion occur.

Formerly it used to be almost impossible for us to imagine how a complex crystal is formed, but now there is a glimmer of hope. If we assume that Nature treads well





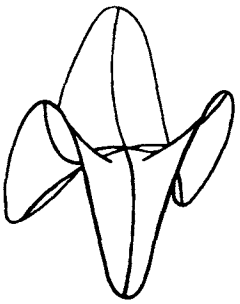


Fig. 20. Top left: A model of a packet of atoms (only silicon atoms are shown) taken out from the fourling center in Fig. 19.—Center left: The paulingite structure.—Top right: The sodalite part of the zeolite N structure. Blue spheres mark the unit cell.—Center right: The ZK5 part of the zeolite N structure. The blue units (identical with red) mark the unit cell. Bottom: The complete structure of zeolite N. A model of quartz in the left corner has been included for the purpose of comparison.

known paths, *e.g.* she builds parts of simple structures first, and then uses the classical symmetry operations, or periodic minimal surfaces, to build complex structures, we begin to feel a sense of excitement at understanding something of the phenomenon.

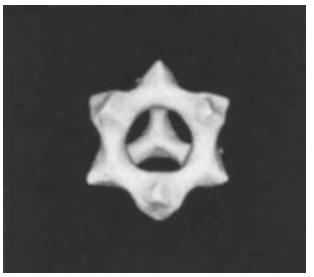

Fig. 21. Top: The *Neovius* minimal surface. The saddle lines of Hilbert's monkey saddle are indicated.—Bottom right: A monkey saddle after Hilbert which builds the surface on which we believe ion exchange, catalysis and molecular sieve reactions occur in structures of, *e.g.*, the faujasite type.—Bottom left: The D minimal surface as formed in the region between the interpenetrating structures of the $W_3Fe_3C$ structure (cf. Fig. 5).

Can we explain why complex structures exist? The achievement of an energy minimum is the plausible but not very helpful answer. The energy minimum is necessary, but is it enough?

It is clear that the transformations discussed above seem to be invariant, or nearly so, and since Nature aspires to attain maximum symmetry we suggest that she prefers complex structures to coexisting phases. We notice that complex structures like $Cu_4Cd_3$ are better packed than the metals, which means that the minimal surface in the interface region contains atoms with very efficient packing. It is here, in the interface region that the five-membered ring or icosahedral packing occurs in the structure.

Having worked on the methods for the description of structures, and having had a very straightforward application in the solution of the giant structure of zeolite N, we are unable to resist making a more human and exultant conclusion: We feel we can at least challenge Nature and solve whatever she is able to repeat.

# Preparation of Solid-State Compounds by Chemical Transport—Interpretation and Control Using the Cooperative Transport Model**

**By Reginald Gruehn* and Hans-Jürgen Schweizer**

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

The demand of solid-state chemists for a method capable of producing interesting solids in a reproducible way is not easily fulfilled. It is well-known that data published on the synthesis of new compounds are often irreproducible after some time—even within the same research group. Some progress has been made by the development of the chemical transport method, which for relatively straightforward cases also allows predictions to be made about suitable experimental conditions. But for complicated phase relationships, and compounds of only slightly differing composition and stability, the experimental conditions could hardly be predicted. Here we present a more advanced transport model, which allows the prior determination of favorable experimental conditions for the preparation of various solids even in complicated systems, based on thermodynamic data. The usefulness of the method is shown using as examples complex systems of binary and ternary metal oxides.

## 1. Introduction

The synthesis of inorganic solids is often associated with considerable problems for the chemist, be it that high-melting substances are difficult to induce to react or that they exhibit a particular sensitivity towards moisture, oxygen, or special impurities, which complicate their manipulation. Among the oldest methods of solid-state synthesis is the reaction of a mixture of components at elevated temperatures[1], a technique which is still widely used, *e.g.* for the preparation of high-melting ceramic materials. The completeness of the reaction sought, *i.e.* the establishment of a state of equilibrium ("equilibration") demands especially high temperatures because of small diffusion coefficients and relatively large diffusion distances (grain size!). Besides a limited choice of temperature no other experimental parameters are available for a direct thermodynamic control of this relatively "crude" preparative method, because the reaction paths are mostly unknown. However, when a solvent phase is present the synthetic methods become comprehensible and more variable; even without detailed calculations they generally give useful information for a directed synthesis based on simple thermodynamic models[2]. Products yielded in this way are mostly crystalline and sometimes even form as large single crystals.

A variety of possibilities is opened up if we use the gas phase as solvent for solids. We are indebted to *Harald Schäfer* for the first detailed description of this field; in his monograph[3] he presented a generally useful concept for the wide-ranging application of "chemical transport reactions", as he called them (cf. Section 2.1). In the laboratory, transport experiments in sealed ampoules are especially useful and we shall discuss this method in particular. For many classes of compounds *Schäfer*[3] showed that chemical transport has clear advantages compared to other preparative methods[2]:

1) Promotion of the reaction ("mineralizer" effect of the transport gas) by increasing the mobility of the building elements of the reactants.
2) Avoidance of formation of impeding coatings; removal of the reaction product or of impurities due to differential migration in the temperature gradient leads to purifying effects.
3) Relatively low reaction temperatures allow both the preparation of compounds which are only stable at moderate temperatures and the formation of "metastable" phases.
4) Formation of well-formed crystalline samples (Fig. 1) and single crystals in suitable sizes for X-ray investigations ($\leq 1$ mm), without special precautions.
5) The extensive reversibility of the heterogeneous reaction facilitates the determination of reproducibile procedures for the synthesis of a substance.
6) The use of suitable equilibrium gas-phases allows the preparation of single-phase compounds with homogeneity ranges.

Furthermore, observations from preparative experiments, *e.g.* whether a reaction actually occurs or not, can give qualitative indications of unknown gaseous species (gas complexes), of kinetic inhibitions of heterogeneous reactions in the condensed phase, and of the thermodynamic parameters of the synthesis. The reaction process in complicated systems, however, can only be comprehended by a complete thermodynamic analysis with the inclusion of all relevant constituents[10]. The aim of this progress report is, therefore, to provide an introduction to the thermodynamic description of steady transport states in systems with closely neighboring phases and to present the various

Crystal growth by chemical transport (scanning electron microscope photographs). a) Cristobalite (top) as a product of recrystallization of quartz glass (ampoule wall, below); effect of $NbCl_5$; 1100 °C; enlargement × 36. b) $Ti_6O_{11}$ as an example of a Magnéli phase [4]; deposited in the less hot zone from the gas phase at 920 °C; transport agent: HCl [5]; enlargement × 155. c) $LaNb_3O_9$ (metastable) as an example of a novel structural type [6]; the same as b), but at 980 °C; transport agent: $Cl_2$ [7]; enlargement × 115. d) $Nb_{12}O_{29}$ (orthorhombic), because of its "block structure" especially well suited for high resolution transmission electron microscopy (TEM) [8, 9]; the same as b), but at 1000 °C; transport agent: $Nb_3O_7Cl(NbCl_5)$; enlargement × 66.

possibilities offered by our transport model as exemplified by several transport systems which have been studied experimentally (cf. also [11–16]).

## 2. Recent Developments

### 2.1. Fundamentals

The prerequisite for chemical transport is a reversible reaction of solid A, to be transported, with a transport agent B, which under the experimental conditions is gaseous [eq. (1)]. Only gaseous products should be formed:

$$a\,A_s + b\,B_g \rightleftharpoons c\,C_g(+ d\,D_g \ldots) \qquad (1)$$

If a closed tube (transport ampoule), which can be thought of as being divided into two subvolumes I and II (Fig. 2), contains a solid phase A which has different chemical potentials in I and II, migration of A is expected to occur in the direction of the potential drop. For a temperature gradient between the subvolumes (the lower temperature is usually termed $T_t$[3]) the sign of the enthalpy of reaction $\Delta_R H$ is decisive for determining the direction of migration. For an endothermic transport reaction the solubility of A in the gas phase increases with temperature. Therefore, A is transported from $T_2$ to the less hot zone at $T_1$ (subvolume I). The solubility can be determined from the equilibrium pressures at $T_1$ and $T_2$, *e.g.* by means of the transport equation [eq. (1)] or by using a system of independent reaction equilibria ($K_p$ method, cf. Section 3.1).

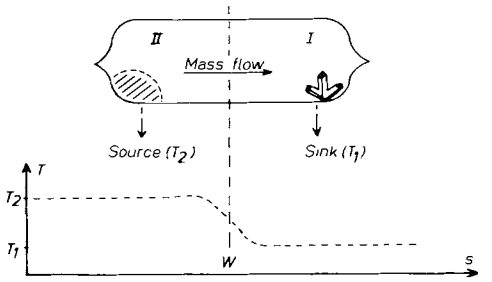

Fig. 2. The principle of chemical transport in a closed tube (transport ampoule) illustrated by an endothermic transport reaction. Due to the different temperatures, the tube can be considered as being divided into two equilibrium volumes (subvolumes I, II) by a hypothetical wall (W). The resulting mass flow of the deposit [*e.g.* A in eq. (1)] is obtained by addition of the gas flows of B (I ⟶ II) as well as C and D (II ⟶ I).

The calculation of the transport rate $n$(A) (cf. Table 1) follows a model which, after establishment of equilibrium in I and II, assumes a steady-state gas flow between the subvolumes due to diffusion (if necessary superposed by a flow due to a change in the number of moles in the transport reaction) after reaching the equilibrium state[3]. The resulting *steady-state* is characterized by the fact that the flows of the source elements (source→sink) correspond to the composition of the precipitated solid. For the calculation of equilibria and transport rates it must generally be assumed that no kinetic inhibitions, *e.g.* of the heterogeneous reaction, occur.

Table 1. Transport of niobium oxides from $SiO_2/NbO_x$-sources ($100/2 \times 10^{-3}$ mol); transport agent $NbCl_5$ ($1.25 \times 10^{-4}$ mol); tube volume ≈ 14 cm³ (∅ = 1.5 cm), $\Sigma P = 3$ atm; deposition temperature = 1300 K; $(T_2 - T_1) = 100$ K.

| Source ($T_2$)<br>Equilibrium phases | Sink ($T_1$)<br>Transported phases[a] | Reduced transport rate ($n_r \times 10^4$)[b]<br>Calculated | <br>Observed |
|---|---|---|---|
| $SiO_2/Nb_{12}O_{29}$ | $Nb_{12}O_{29}$ | 2 | 1 |
| $SiO_2/Nb_{12}O_{29}/NbO_{2.024}$ | $Nb_{12}O_{29}$ | 1 | 2 |
| $SiO_2/NbO_{2+\Delta x_2}$ | $NbO_{2+\Delta x_1}$[c] | 3 | 2 |
| $SiO_2/NbO_2/NbO$ | $NbO_2$ | 5 | 4[d] |
| $SiO_2/NbO$ | NbO | 0.2 | < 0.1[e] |

[a] The model calculation yields the phases at $T_1$ under the assumption that deposition of $SiO_2$ at $T_1$ is inhibited. These phases are also obtained in the experiment. [b] Reduced transport rate $n_r = \Delta P/\Sigma P$; transport rate according to *Schäfer* [3]: $n(A) = \frac{c}{a} \cdot \frac{\Delta P}{\Sigma P} \cdot \frac{T^{0.8} q}{d} \times 1.8 \times 10^{-4}$ [mol h$^{-1}$] (with $T = \frac{T_1 + T_2}{2}$[K]; $q$[cm²] = diameter of the diffusion distance with length $d$ [cm]; a, c = stoichiometry coefficients [eq. (1)]). [c] $\Delta x_2 < \Delta x_1$ ($\Delta x_2 < \varepsilon \Rightarrow \Delta x_1 \leq 0.024$ [68], $\Delta x_2 > \varepsilon \Rightarrow$ transport of $Nb_{12}O_{29}$; for all cases with $\varepsilon = 0.01$, see text). [d] Deposition of α- or β-$NbO_2$ (cf. Section 4.5). [e] The minimal endothermic transport of NbO was also observed by *Schaum* [62] ($\Sigma P \approx 5$ atm, $T_2 = 1400$ K, $\Delta T = 200$ K).

### 2.2. Additional Preparative Possibilities

New transport agents which are optimally adjusted thermodynamically to the reacting solids are of great interest. The investigation of *gaseous halide complexes*, chiefly by *Schäfer*[17-19], has led to considerable advances here.

Highly volatile (monomeric or dimeric) trihalides ($AlX_3$, $GeX_3$, $FeX_3$...) are particularly suitable complexing agents. If the mobility of the metal component M of the solid in a transport system is considerably limited by the low saturation pressures of the halides $MX_n$, the resulting "labile" halide complexes, whose formation and dissociation proceed without kinetic inhibition, make the metal halide $MX_n$ available in high concentrations. By means of this method [transport agent $Al_2Cl_6$; eq. (2)] many metal halides can be transported and thus obtained as single crystals at relatively low temperatures. (400 °C→350 °C[18]).

$$MCl_{2,s} + Al_2Cl_{6,g} \rightleftharpoons MAl_2Cl_{8,g} \qquad \Delta_R H > 0 \qquad (2)$$

M = Mg, Ca, Cr, Mn, Fe, Co, Ni, Cu, Pd, Pt[18]

By analogy, transport agents and complexing agents (halides, hydrogen halides) can be combined for the chemical transport of metals, oxides and chalcogenides[17].

For the growth of *single crystals*, *e.g.* for X-ray structure analysis, the transport method is especially useful when purely thermal processes, such as sublimation or flux techniques, fail for thermodynamic reasons. Thus larger crystals of only slightly thermally stable anhydrous sulfates were obtained, especially those of the transition metals ($Mn^{II}$, $Fe^{II}$, $Fe^{III}$, Co, Ni, Cu, Zn, Cd, Hg, as well as Pb), deposition occurring in the less hot zone (transport agents $Cl_2$, HCl, $HgCl_2$)[20-22]. Another example which shows the advantage of a decrease of the reaction temperature is the chemical transport of fluorides ($AlF_3$, $FeF_3$, $TiF_3$[23], $ScF_3$[24]) with $SiCl_4$.

Preparatively and structurally interesting *metastable* compounds usually remain inaccessible at high reaction temperatures (solid-state reaction). Their formation, however, is considerably supported by low deposition temperatures, imbalanced states (*e.g.* for small $\Sigma P$), or by additives ("impurities"). The competing solid phases differ only slightly in their energy contents, so that nucleation and nuclear growth increase in importance[2,25]. Examples of polymorphism are the various modifications of $Nb_2O_5$[26], $TiO_2$, as well as chalcogenides (ZnS, $NbS_2$)[25]. Metastable compounds have also become accessible in the systems La/Nb/O/Cl[7], Fe/Nb/O/Cl[27], and $NbO_2/NbCl_5$[28]. Even a slight difference in the composition of the metastable solid relative to that of a more stable phase can be taken advantage of. In these cases states of deposition and/or formation with minimal free energy (Gibbs' energy) can be realized[28,29] by choice of suitable gas phase compositions (cf. Section 4.5).

The remarkable physical and chemical properties of *nonstoichiometric* compounds make them a favorite subject for preparative investigations[30-35]. The preparation of nonstoichiometric metal oxides or sulphides by chemical transport in a complex system with a close sequence of phases, generally only leads to reproducible results if the thermodynamics of reactions of the neighboring phases and the transport agent are known. Even small changes in the experimental conditions (temperature gradient, amounts of transport agent, volume of the ampoule) can lead to deposition of heterogeneous solid phases or to other phases of the system (*e.g.* the system Ti/O/HCl[16]; Section 4.2). By choosing suitable starting materials and by fixing the free variables of the transport system (thermodynamic calculation!) it is possible, however, to set up steady transport states which permit continuous crystal growth of the desired phase[28].

Solids with homogeneity ranges show particularly impressively the dependence of the composition of the deposited phase on the composition of the solid in the source subvolume, which in turn depends on the increase or decrease in concentration of elements due to the transport process. These problems were treated in exemplary fashion by *Krabbes et al.*[36] for the transport of $FeS_x$ with $I_2$ ($1 < x \leq 1.15$).

### 2.3. Progress in the Thermodynamic Description

In systems with several closely neighboring phases the calculation of the chemical transport of the *outer phases* ("border phases", cf. Fig. 3) can still be carried out straightforwardly[3] if the formation of solid neighboring phases is excluded by the choice of an appropriate transport agent (TA). Model calculations for "inner phases" are difficult since, due to their limited range of stability (Fig. 3), these phases are easily converted under the experimental conditions into heterogeneous mixtures.

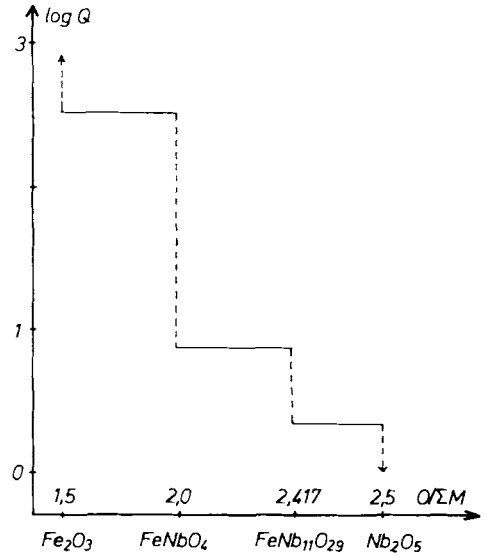

Fig. 3. Isotherm diagram ($T = 1400$ K) for the system $Fe_2O_3/Nb_2O_5/Cl_2$ [27]; ------ = single phase, ——— = two-phase regions; outer phases (border phases): $Fe_2O_3$; $Nb_2O_5$; inner phases: $FeNbO_4$; $FeNb_{11}O_{29}$; O/ΣM is not plotted to scale; $Q = P(FeCl_3)/P(NbOCl_3)$ is defined by the exchange reaction [*e.g.* eq. (4)].

For ternary oxide systems having two binary border phases and one ternary (inner) phase, qualitative rules were first discussed by *Emmenegger*[37]. If the stability of the ternary oxide is comparatively large compared with that of the binary oxides [$\Delta_B G°$(ternary) $\ll \Sigma \Delta_B G°$(binary)], its chemical transport can be treated mathematically

like that of binary oxides ($NiFe_2O_4/HCl$[38]). The composition of the equilibrium gas phase over a homogeneous ternary solid phase of sufficient stability is then variable over a wide range (Fig. 3), so that it can actually be adjusted to a composition which corresponds to the stoichiometry of a transport reaction or a complex system of equations. In consequence, the ternary solid phase remains undecomposed and can be transported as a single phase. However, for the majority of the systems investigated (*e.g.*[7, 16, 27, 28, 39–43]), because of its poor stability the ternary phase becomes heterogeneous in the reaction with the transport gas.

*Wehmeyer*[39] and *Schäfer*[25, 43] treated in detail the possibilities of preserving a homogeneous ternary solid phase during transport experiments. Basically, all statements of *Schäfer*'s transport model depend strictly on the existence of the same condensed phase in both source *and* sink. The partial decomposition of a ternary compound leading to formation of one of the neighboring phases must therefore be prevented by adjusting the experimental conditions, such as temperature, amount of transport agent, or by shifting the equilibrium by adding a gas-phase constituent as well as, if necessary, by the use of another transport agent[43]. The thermodynamic basis for this concept is the equation for the free energy $\Delta_R G$ of the transport reactions of the participating binary border phases:

$$\Delta_R G = \Delta_R G^0 + RT \ln \prod_i P_i^k \qquad (3)$$

The $\Delta_R G$ values indicate whether the ternary compound under consideration remains stable ($\Delta_R G < 0$) (calculated from a suitable set of equations) in presence of its gas phase ($P_i$; $i = 1, \ldots$), or whether decomposition ($\Delta_R G > 0$) is to be expected. If, however, a constituent of the gas phase is added to the transport gas for the stabilization or formation of a single-phase solid, the establishment of a steady-state mass flow between source and sink must be redefined (see below), since the stoichiometry of the gas phase is no longer equivalent in the two subvolumes I and II. In the description of the transport of stable binary compounds ("border phases") it is usually assumed that the gas flow has reached a steady state.

The variable stoichiometry of the gas phase in the transport system causes an additional degree of freedom[27, 44]. Besides the difficulty of suitably fixing this degree of freedom with respect to the starting composition, it is also increasingly more problematic (with increasing number of simultaneous transport reactions) to use $\Delta P_i$ (Table 1) as a measure of the transport effect. We must, therefore, differentiate more strongly between the determination of the transport rate $n$(A) and the equilibrium calculation. This is achieved, in general, by using the concept of solubility $\lambda$ of the solid phase (cf. Fig. 4)[45–47]. *Schäfer* determined $\lambda$ from the ratio of the number of moles of the solid dissolved in the gas phase to the amount of solvent. The transport rate $n$(A) is calculated using the solubility difference $\Delta\lambda(A) = \lambda(T_2) - \lambda(T_1)$ of the solid phase A in source ($T_2$) and sink ($T_1$) (cf. [47]).

Since reaction of the starting phase with the transport gas frequently leads to formation of heterogeneous materials, two-phase material is used to start the reaction. The

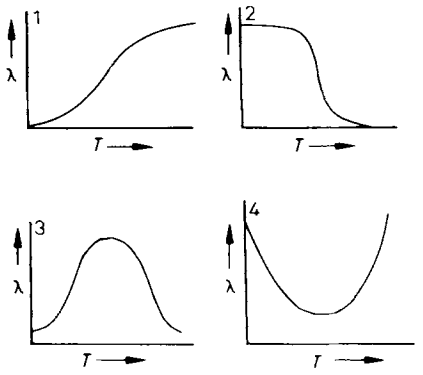

Fig. 4. Solubility $\lambda$ of the solid in the gas phase as a function of temperature ($\Sigma P$ = const.) after *Schäfer*[18]; 1) endothermic, 2) exothermic transport reaction [eq. (1)]; 3) solubility maximum, 4) solubility minimum obtained by combining endothermic and exothermic processes.

composition of the transporting gas phase can, therefore, be adjusted precisely, even in systems with closely neighboring phases (buffer effect of the solid phases), such that constant conditions for the growth of single crystals are established. The isothermal source-equilibria can be described approximately by suitable exchange reactions (after *Gruehn*[40, 48] and *Brunner*[27]), which determine the coexistence of two neighboring phases in multicomponent systems, *e.g.* in the system $Fe_2O_3/Nb_2O_5$[27] (Fig. 3):

$$FeNb_{11}O_{29,s} + NbOCl_{3,g} \rightleftharpoons FeCl_{3,g} + 6\,Nb_2O_{5,s} \qquad (4)$$

$$Q = \frac{P(FeCl_3)}{P(NbOCl_3)}$$

The characteristic composition of the equilibrium gas phase above the heterogeneous solid materials, as well as its width of variation with respect to the range of stability of a single phase compound can be clearly represented by the ratio $Q$ of the partial pressures of the reacting gases ($FeCl_3$, $NbOCl_3$) in an isotherm diagram (Fig. 3). If, however, the solid phases have a range of homogeneity, the situation becomes much more complicated (cf. [50]).

Firstly *Schäfer*[51] and then *Gruehn et al.* tried to derive criteria for the transport of well-defined phases from heterogeneous starting materials using *intersections of the isotherms* of both equilibrium spaces ($T_1$, $T_2$; Fig. 5). The $Q$ values obtained by this graphical method for the deposition subvolume (sink; $T_1$) correspond to a composition of a "metastable" gas phase at $T_1$ ($[Q(T_1)]_*$). The correlated position of equilibrium $Q(T_1)$, has to be determined accurately. This can lead to substantial deviations from the graphically determined phase relations in the sink ($T_1$; Fig. 5).

By considering only diffusion in the absence of laminar flow, *Brunner*[27] successfully used the condition of steady-state transport for the calculation of the previously unknown equilibrium value $Q(T_1)$ for the deposition of iron(III) niobates using $Cl_2$ as transport agent (cf. Section 4.1.2). Independently of this, *Oppermann et al.*[33, 44] discussed a transport model, which allows both gas diffusion and laminar flow of the total gas mass because of changes in the number of moles in the heterogeneous reaction in sink and source. This method also requires information on the nature and number of solid equilibrium phases in at

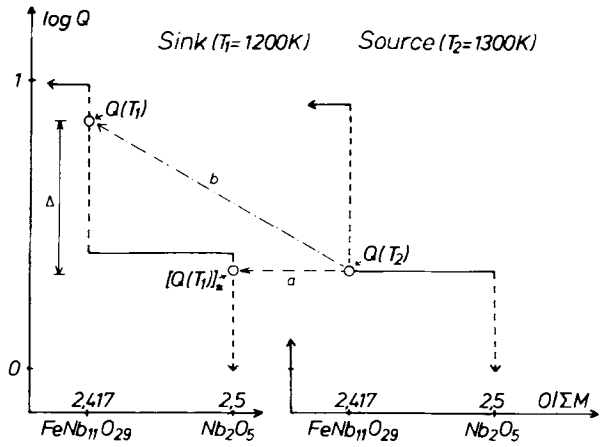

Fig. 5. Isotherms ($T_1$; $T_2$) for the subsystem $FeNb_{11}O_{29}/Nb_2O_5$ [27]. With heterogeneous material at $T_2$ [eq. (4)] the intersecting arrow *a* leads to a metastable gas phase at $T_1$: the arrow *b* indicates the position of equilibrium calculated for $T_1$; for further details see legend to Fig. 3. In the system $AlNb_{11}O_{29}/Nb_2O_5$ [49] the arrow *a*, however, leads to the $AlNb_{11}O_{29}$ region.

least one subvolume; the composition of equilibrium phases in the other subvolume is then determined iteratively using a suitable system of equations, taking into account the conditions of steady-state transport.

## 3. Extended Transport Model for Experiments with Heterogeneous Source Materials

### 3.1. Isothermal Calculation of Equilibria

For the description of chemical transport the result of an isothermal calculation on the position of equilibrium at $T_1$ and $T_2$ is, in general, required. This calculation includes all gaseous and solid constituents *b* which participate in the transport, and which can be formed from the various components *k* of the chemical system under consideration. It should be noted that the number of components *k* is not necessarily identical to the number of elements in the particular system (cf. c).

In general, the equilibria are determined using a system of linearly independent reaction equations, *i.e.* using the equilibrium constant method ($K_p$ method)[41,43,52-54] (*e.g.* computer program GEPA[55]). The use of the $K_p$ method is associated with several assumptions:

a) The nature and number of equilibrium phases *p* must be known, but not necessarily be identical to the phase relations in the initial state;
b) the determination of "stoichiometric" degrees of freedom $f_s$ of the gas phase is dependent on the distribution of elements in the initial and equilibrium states (newly formed phases!);
c) the number of linearly independent reaction equations e is determined by an at first "unknown" number of components k ($e = b - k$).

Whereas the successful establishment of a suitable system of equations [cf. c)] is mainly dependent on experience in using this method, the requirements a) and b) are a matter of principle, since they consider the *problems in relating* experimental to calculated equilibrium states. Especially in systems with closely neighboring phases, the determination of the nature and number of solid equilibrium phases is (in the case of the $K_p$ method) only possible *experimentally, e.g.* using a series of experiments with variable amounts of transport agent. An impedement here is that thermodynamically stable phases might not be formed due to (unknown) kinetic reasons. In addition to this [in systems with several degrees of freedom ($f > 2$)], constraints (*e.g.* pressure equation) on the determination of the "stoichiometric" degrees of freedom of the gas phase with respect to the initial experimental state have to be located.

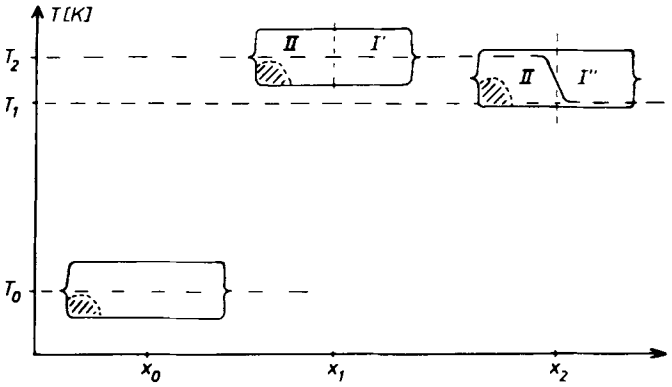

Fig. 6. Model experiment for an endothermic transport process. For the division into subvolumes I and II see legend to Fig. 2: $x_0$, start of experiment at $T_0 = 298$ K; $x_1$, isothermal initial state at $T_2$; $x_2$, metastable initial state (for $T_1$).

Mass-equivalent changes of initial states ($x_0$ in Fig. 6) to afford corresponding equilibrium states ($x_1$) can be unequivocally calculated for closed systems using the free energy function ($\Sigma P, T = \text{const.}$), considering both *mass balances* and the ability of all the solid phases to exchange (Gibbs' phase rule). The numbers of moles $n_i$ and partial pressures $P_i$ of all constituents in the equilibrium phases as a function of the quantitative initial composition $n_i^0$ can be calculated by means of the program EPCBN[56-59], which uses the free energy minimum, *i.e. the G(min) method.* The basic mass balance of the elements in the closed system is to be strictly maintained in each phase of the iterative determination of $G$(min).

On fixing $\Sigma P$ and $T$, the values of the system variables p and $f_s$ are clearly limited by the number of components k of the system ($p + f_s \leq k$). With k equations for mass balances, which are fixed using the initial numbers of moles of the participating elements (≙the experimental initial state $x_0$), all "stoichiometric" degrees of freedom of the gas phase ($f_s \leq k - 1$) can be determined. Due to this property of mass balance, the criterion $G$(min) ($T, \Sigma P = \text{const.}$) allows the determination of the solid equilibrium phases (according to the phase rule) independently of the nature and number of the initial phases.

### 3.2. Thermodynamic Treatment of the Complete Model Experiment

In the simplest case the interpretation of the reaction process in chemical transport experiments is based on the assumption that the reaction of a *single phase* starting ma-

terial (border phase) with a given transport agent leads to an equilibrium gas-phase composition corresponding to the stoichiometry of the transport equation [eq. (1)]. For reversible heterogeneous reactions this also holds for the deposition side, so that the resulting partial pressure differences $\Delta P_i$ of relevant gas particles between source and sink behave like the stoichiometry coefficients (c,d...) in the transport equation. The flow of the source elements thus corresponds to the composition of the initial phase; the conditions of steady-state transport are, therefore, fulfilled.

In all other complicated cases (see *e.g.* Section 2.3), especially if *two-phase* materials are present in *one* of the subvolumes, the above assumption about the relationship between $\Delta P_i$ and the stoichiometry coefficients (c,d...) in the gas phase of the subvolumes no longer applies. For the calculation of the position of equilibrium in the subvolume with fewer phases an additional variable of the gas phase [*e.g.* $Q(T_1)$] must be fixed by considering the conditions of steady-state transport (Section 2.1).

According to Section 3.1 the unequivocal calculation of isothermal equilibria using the $G$(min) method is based on information about the initial states. Statements about the nature of initial state in the deposition subvolume (the subvolume with fewer phases) can be deduced from the course of a model experiment (Fig. 6).

I') is then brought to temperature $T_1$ ($x_2$). In the "metastable" initial state ($x_2$) the composition of the gas phase at $T_1$ in the sink (I'') is identical to that of the equilibrium gas phase at $T_2$ (source). In the model experiment solid precipitates from the supersaturated mother gas phase by establishment of a stable equilibrium state at $T_1$.

For closed systems the previously outlined isothermal change of state can be unambiguously calculated using the free energy function (program EPCBN) (Fig. 7). The determination of the position of equilibrium in the sink (I) by means of the number of moles in the equilibrium gas phase in the source (II) allows the determination of the resulting steady-state mass exchange (diffusion and laminar flow) according to *Schäfer*'s[47] model of solubility. The basis of this method is the conservation of mass for the isothermal, isobaric equilibration in the deposition volume, which is consistent with the steady-state flow of the elements of the solid between the subsystems (cf. Section 2.1 and [58–60]). The *cooperative transport model* describes this steady transport state by coupling the two subvolumes *via* identical mass balances of the gas phase of the source and the resulting equilibrium gas phases at $T_1$, as shown in Figure 7. In this model a special preference is assigned to the labile equilibria in the deposition volume for the establishment of steady transport states. The model, therefore, does not depend on the nature and number of phases in the source

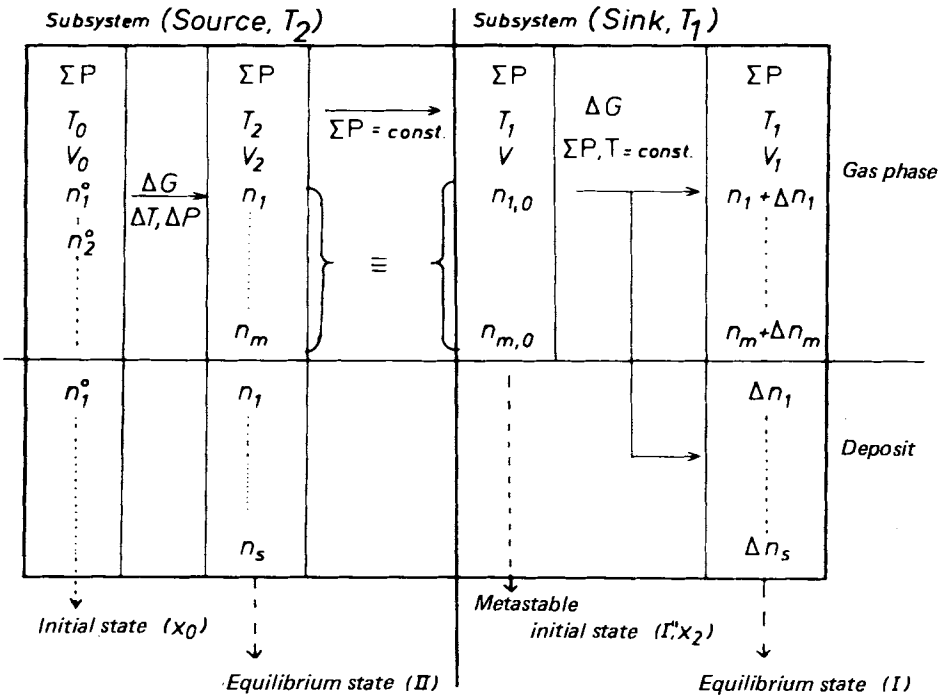

Fig. 7. Scheme of the thermodynamic calculation on the basis of the model experiment (Fig. 6). The equilibration in the individual subvolumes is considered; furthermore the identity of the material of the metastable initial state in the sink and the equilibrium gas phase of the source is taken into consideration.

*Model experiment:* In the first step ($x_1$) the complete transport system is heated from the initial conditions ($x_0$) to temperature $T_2$; one half of the transport ampoule (sink subvolume (II). Also that solid phase is deposited which shows a minimum in the free energy of deposition with respect to subvolume I.

### 3.3. Aids in Interpretating the Thermodynamic Results

*Isotherm diagrams* ($\log Q$ *vs.* composition, cf. Section 2.3, Figs. 3 and 5) are well suited for a clear presentation of stability relationships based on thermodynamic data. Beyond this, these isotherms can also be used for graphical interpretation of the thermodynamics of transport reactions. Statements about experiments with the following questions are possible:

1) Predictions about stability or decomposition of single phase solids in the presence of a transport agent by comparison of the value of $\log Q$, derived from a suitable transport equation, with the form of the $\log Q$-isotherms of the system ($T$, $\Sigma P$ = const.).
2) Approximate determination of equilibrium temperatures for the conversion of a single phase starting solid into a two-phase equilibrium source material (cf. Section 4.2).
3) Transport behavior of heterogeneous source materials.
4) Comparison of different transport agents. A prerequisite for the continuous deposition of single phase material is the suitable choice of thermodynamic parameters ($T$, $Q$, and $\Sigma P$) as well as a mass flow of sufficiently high intensity between source and sink [$n$(A)]. The $Q(T_1)$ value of the sink and the deposition rate $n$(A) are, therefore, suited for an evaluation of different transport agents, if these quantities are normalized to equivalent thermodynamic conditions (amount of solvent, $T$, $\Sigma P$, $\Delta T$).

## 4. Use of the Cooperative Transport Model for the Interpretation of Experimental Results

### 4.1. Preparation of Single-Phase Substances from Heterogeneous Source Materials

#### *4.1.1. Binary Solids—The Chemical Transport of Niobium Oxides; Transport Agent $NbCl_5$*

*Fundamentals:* The preparation of the niobium oxides NbO and $NbO_2$ in pure, coarsely crystalline form was first described by *Schäfer* and *Huesker*[51]. *Gruehn* was able to prepare pure $NbO_x$-phases (especially $Nb_{12}O_{29}$) in gram amounts by chemical transport with $NbCl_5$; a general transport reaction [eq. (5)] for the migration of the niobium oxides ($NbO_x$-phases) to the less hot zone is formulated thus[48]:

$$NbO_{x,s} + (4-x)\,NbCl_{5,g} \rightleftharpoons x\,NbOCl_{3,g} + (5-2x)\,NbCl_{4,g} \qquad (5)$$

*Schaum*[62] combined this reaction with an oxidation step and used it to interpret the transport of $NbO_2$ by $HgCl_2$. Independently of this *Ritschel et al.*[41] discussed the transport of niobium oxides by gaseous $NbCl_5$, $NbOCl_3$, and $NbCl_4$ in the system $NbO_2/Nb_{12}O_{29}/TeCl_4$. Further experimental details for the systems Nb/O/transport agent can be found in [63–65]. Our transport experiments were performed in sealed quartz glass ampoules with the usual dimensions as described in [29] (cf. also Table 2). The assignment and determination of the number of phases were carried out by X-ray analysis (Guinier method, quartz monochromator, $Cu_{K\alpha_1}$ radiation).

Table 2. Transport experiments in quartz ampoules with $NbO/NbO_2$-source materials; $NbCl_5$ as transport agent; $T_2 = 1472$ K, $T_2 - T_1 = 100$ K; ampoule dimensions: $\varnothing = 1.55$ cm, $l = 9$–$11$ cm.

| No. | Initial composition at $T_2$ (source) | | | | | $V$ | $t$ | Residue[a] | Deposit ($T_1$) precipitated | | $\Sigma P$ |
|---|---|---|---|---|---|---|---|---|---|---|---|

[a] (NbO) indicates small amounts of NbO.

According to *Scholz*[61], crystal growth procedures with constant gradients can be described using *energy term diagrams* (Fig. 14), since the crystallization process is determined by the exchange of energy between the energy state of the source material and that of the growing crystal. Here, this procedure is modified on the basis of our chemical transport model, in as far as we do not consider the free energy of isolated solid phases but of heterogeneous equilibrium states (gas + solid phases). This view point is outlined schematically for the chemical transport of β-$NbO_2$ (cf. Section 4.5).

*Thermodynamic Calculations:* Because of reliable thermodynamic data, transport experiments using niobium oxides of the subsystem $NbO/Nb_{12}O_{29}$ and the transport agent $NbCl_5$ are well suited for a complete thermodynamic analysis using the cooperative transport model (cf. [28,66]). As the calculation shows, the transport agent firstly reacts with the starting material by exchange equilibria irrespec-

tive of whether it is single-phase or two-phase. Starting from $NbO_2/NbCl_5$

$$3\,NbO_{2,s} + 3\,NbCl_{5,g} \rightleftarrows 5\,NbOCl_{3,g} + NbO_s \quad (6)$$

a minor amount of the neighboring phase containing less oxygen is first produced. Due to the respective $O_2$-partial pressure the coexisting phases ($NbO_x/NbO_z$; $x<z$) are decisive for the composition of the gas phase. When $SiO_2$ from the quartz glass wall is considered as the third solid phase this leads to the four-component system Si/Nb/O/Cl with two degrees of freedom, so that the equilibrium pressures of the gaseous species $NbOCl_3$, $NbCl_5$, $NbCl_4$, $SiCl_4$, $SiCl_2$, $Cl_2$, and $O_2$ can be calculated after $\Sigma P$ and $T$ have been fixed. Figure 8 shows isotherms of the various gaseous species of coexisting niobium oxide pairs over the range $0<O/Nb<2.417$; the formation of $Nb_5Si_3$[67] on the side of lower O/Nb ratio has not been included.

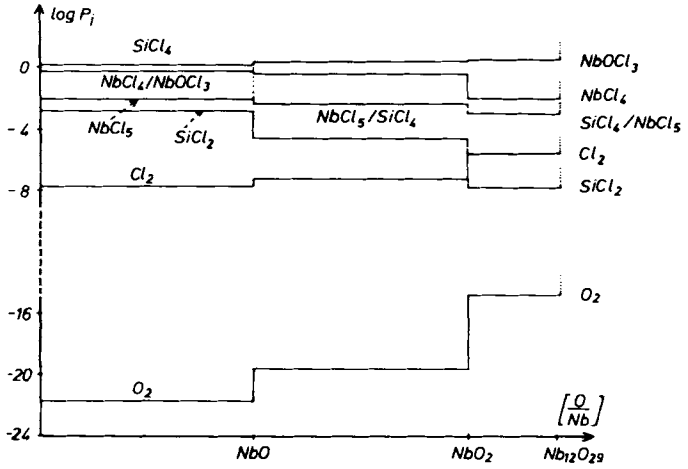

Fig. 8. Isotherms of equilibrium partial pressures [atm] over the heterogeneous source materials $SiO_2/NbO_x/NbO_z$ ($x<z$); addition of $NbCl_5$ (Table 1); calculated for $T=1400$ K and $\Sigma P=3$ atm.

As the O/Nb ratio of the starting material increases, the pressure of $NbOCl_3$ approaches the total pressure at temperatures above 1300 K, whereas the $Nb^{IV}$ fraction of the gas phase [$P(NbCl_4)$] decreases considerably. This characterizes the ability of the transport agent $NbCl_5$ to dissolve preferentially the oxygen-richer phase of a niobium oxide pair because of the considerable thermodynamic stability of the resulting gaseous $NbOCl_3$, which increases with the temperature.

In addition to the isotherms of Figure 8 the relationship between partial pressures of relevant gaseous species at constant $\Sigma P$ and temperature is shown in Figure 9 for the *equilibrium system* $NbO/NbO_2/SiO_2$. As seen in Figure 8 the oxygen partial pressure is so small [$P(O_2)_{1400\,K}=0.24\times10^{-19}$ atm] that only bound oxygen (as $NbOCl_3$) can migrate. The steep rise in the degree of oxidation of the gas phase with increasing temperature is caused by formation of $NbOCl_3$ as the main component instead of $NbCl_4$. Thus, the ratio $O/Nb^{IV}$ of the gas phase at 1150 K corresponds to $NbO_2$, whereas at 1500 K $O/Nb^{IV}=14.7$ is found. A direct connection between the composition of gas phase and that of the source material to be transported ($NbO_2$) can always be formulated in a transport equation but for complex systems with heterogeneous source materials it can only be realized for special values of $T$ and $\Sigma P$ (*e.g.* 1150 K and 3 atm).

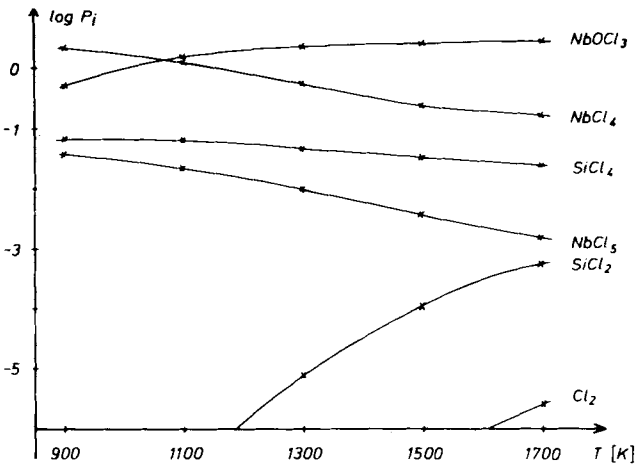

Fig. 9. Temperature dependence of the equilibrium partial pressures [atm] in the system $SiO_2/NbO/NbO_2/NbCl_5$ for $\Sigma P=3$ atm (cf. Table 1).

As we know (Section 2.3) predictions about the nature of the deposited phase(s) by means of isothermal approaches are only reliable to a limited extent for heterogeneous source materials. Using the cooperative transport model the deposition behavior in the system $NbO/Nb_{12}O_{29}$ for different source materials can be calculated for well-defined conditions [$n^0(NbCl_5)$; $\Delta T$; $V$; $\Sigma P$; $T_1$; kinetic inhibition of $SiO_2$-deposition] and then compared with the experimental data (Table 1).

*Interpretation of the Experiments:* In the *transport experiments* the ratio O/Nb of the starting material was varied over the range NbO to $Nb_{12}O_{29}$ using the corresponding $Nb/Nb_2O_5$ mixtures. The amount of $NbCl_5$ employed was such that the $NbOCl_3$ partial pressure at the experimental temperatures ($T_2=1473$ K, $T_2-T_1=100$ K) never exceeded 6 atm. In reference experiments, $CO_2$ was added to produce sufficiently stable deposition conditions *via* the increased buffer effect of the resulting $CO/CO_2$ equilibria (Table 2).

As shown by the *thermodynamic calculation*, niobium oxide is transported by the endothermic flow $I$ of the source elements with
$I(Nb)=I(NbOCl_3)+I(NbCl_4)-I(NbCl_5)$ and
$I(O)=I(NbOCl_3)$. For the steady-state the transport equation [eq. (5)] can be confirmed by means of the solubility differences $\Delta\lambda$ of corresponding gaseous species, which describe the mass exchange between the subsystems, but *not* their complex equilibrium composition (Fig. 9).

Experiments and calculations show in accordance (Tables 1 and 2) that in heterogeneous mixtures of $NbO_{2.024}/Nb_{12}O_{29}$ or of $NbO/NbO_2$ only the respective oxygen-richer niobium oxide migrates as a single phase to the less hot zone (but see Section 4.3). If O/Nb is close to the *upper* phase boundary ($O/Nb>2.01$), transport of $Nb_{12}O_{29}$ primarily occurs followed by a (separate) deposi-

tion of $\alpha$-$NbO_2$ in the hotter part of the zone at $T_1$. The transport of single phase $\alpha$-$NbO_2$ is only possible for source materials having compositions within the homogeneity range ($2.0 \leq O/Nb \leq 2.024$; $T = 1573\,K$[68]) and up to a calculated upper limit $O/Nb < 2.01$; cf. Table 1). The composition of single phase samples of $NbO_2$ was checked using a special microanalytical method[69,70].

At the *lower* phase boundary the transport behavior is extremely sensitive to changes in the O/Nb-ratio of the solid equilibrium phases in the source [$\Delta(O/Nb) < 0.01$]. For $O/Nb \approx 2.0$ it is observed that either single phase $\alpha$- or $\beta$-$NbO_2$, or a mixture of the two, is deposited in the less hot zone. $\alpha$-$NbO_2$ is formed preferentially when the source materials are slightly oxidized by additional $NbOCl_3$ (*e.g.* from $NbCl_5/H_2O$; $NbCl_5/O_2$; especially in experiments with higher total pressure) or by a perturbation in the establishment of isothermal equilibrium between the surface and the interior of a sample (cf. Section 4.4).

The preparation of pure $\beta$-$NbO_2$ single crystals was for the first time successful using source materials with equilibrium composition $O/Nb < 2.0$. Thermodynamic optimization of experiments using $NbCl_5$ as transport agent leads to the following experimental parameters: starting material; $Nb/Nb_2O_5$ (source, $T_2$) with $O/Nb \approx 1.5$; $P(NbOCl_3)_{1500\,K} \leq 2\,atm$, $T_1 = 1400\,K$, $\Delta T = T_2 - T_1 = 100\,K$, duration of experiment $> 70\,h$[29]. If $HgCl_2$[62] or $TeCl_4$[28,41] is chosen as *transport agent*, extensive oxidation of the source materials, which depends on the redox potential of the transport agent, is observed. In order to compare these transport agents with $NbCl_5$, solid equilibrium phases in the source subvolume must be generated (by addition of NbO), which at a given temperature lead to identical $P(O_2)$-values in the respective gas phases. The partial pressures calculated for the heterogeneous equilibrium $NbO/NbO_2/SiO_2/HgCl_2$ (Fig. 10) correspond to those in the system with $TeCl_4$ and thus show that the contribution of gaseous oxides, oxide chlorides, and chlorides of Hg or Te does not exceed the transport barrier $\Delta P_i/\Sigma P = 10^{-5}$. As with the transport agent $NbCl_5$, the niobium oxides migrate *via* the gaseous species $NbOCl_3$, $NbCl_5$, and $NbCl_4$ into the lower temperature zone. The observed sequence of phases with $HgCl_2$ as transport agent is consistent with the results of experiments and model calculations (Table 1) for transport processes starting from heterogeneous source materials with $NbCl_5$ (cf. [66]).

#### 4.1.2. *Ternary Solids—The Chemical Transport of Niobates; Transport Agent $Cl_2$*[27,48,49]

At temperatures $\approx 1300\,K$ the following compounds are formed preferentially in the stable systems $M_2O_3/Nb_2O_5$ (M = Fe, Al): $M_2O_3$, $MNbO_4$, $MNb_{11}O_{29}$, and the high-temperature modification of niobium(V) pentoxide H-$Nb_2O_5$[27,49,71–75] (for further phases, such as $MNb_{24}O_{62}$ cf. [75]). The ternary oxides $MNb_{11}O_{29}$ and $MNbO_4$ can be obtained by heating mixtures of $M_2O_3$ and $Nb_2O_5$, and in well crystallized form[27,48,49] by transport methods.

*$MNb_{11}O_{29}$:* Starting from a heterogeneous mixture of H-$Nb_2O_5/FeNb_{11}O_{29}$[27] or H-$Nb_2O_5/AlNb_{11}O_{29}$[49] with $Cl_2$ as the transport agent, in the Fe/Nb/O-system $FeNb_{11}O_{29}$ is transported to the less hot zone, whereas in the Al/Nb/O-system H-$Nb_2O_5$ is transported. The *opposite* result, however, would be expected (with respect to the deposited phases) if we were to examine the intersection of isotherms (arrow a in Fig. 5).

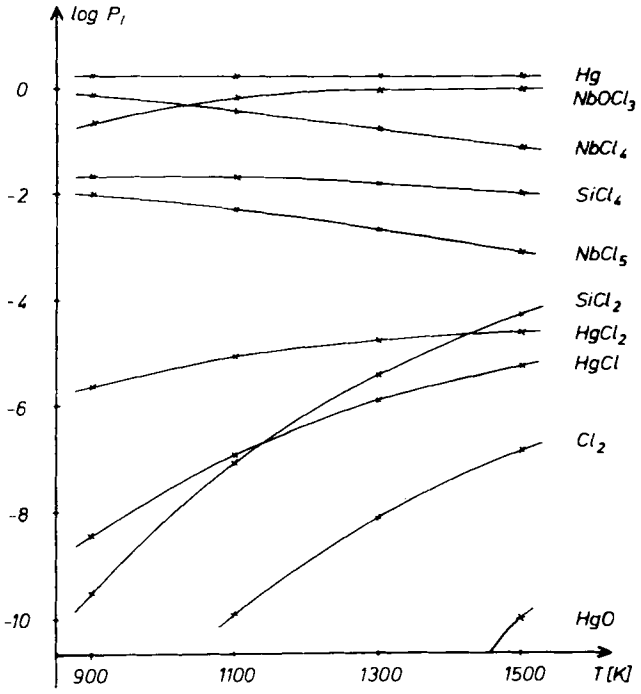

Fig. 10. Temperature dependence of the equilibrium partial pressures [atm] in the system $SiO_2/NbO/NbO_2/HgCl_2$ for $\Sigma P = 3$ atm [66].

Using the cooperative transport model both the different depositional behavior and the discrepancy with the assertions from the isotherms can be explained. The difference is due to a change in the $Q(T_2)$-values on transporting the source gas phase to the sink volume [$\Delta = \log Q(T_1) - \log Q(T_2)$]: This change has a different sign in the two systems. Whereas in the model of the system Fe/Nb/O/Cl an increase in the $Q(T_1)$-value (arrow *b* in Fig. 5) in the direction of the stability region of the phase $FeNb_{11}O_{29}$ leads to formation of the latter, in the system Al/Nb/O/Cl formation of a heterogeneous deposit consisting of $AlNb_{11}O_{29}$ and H-$Nb_2O_5$ could be expected because of a lower $Q(T_1)$-value. Since the solubility $\lambda$ of Al (cf. Section 2.3) in both subvolumes differs only marginally [$\Delta\lambda(T_2 - T_1) \approx 10^{-6}$], only the transport of $Nb_2O_5$ is observed (which is faster by a factor of $10^3$) and not the expected simultaneous transport of both solid phases.

### 4.2. Dependence of the Nature of Transported Phase on Experimental Parameters

Conflicting statements about the chemical transport in binary and ternary systems with closely neighboring phases are often due to insufficient consideration of the complex connections between the variables of the transport system and the nature of deposited phase[31,76,77]. For given solid materials (SM) [$n^0$(SM); O/$\Sigma$M] and defined

ampoule dimensions, the parameters $T$, $\Delta T$ and $n^0$ (nature/amount of transport agent) occur as variable experimental quantities.

In systems with a narrow succession of phases the *temperature gradient* $\Delta T = T_2 - T_1$ [at a constant average transport temperature $(T_1 + T_2)/2$] is of special importance for the phase relationships on the deposition side. Whereas the connection between the temperature gradient $\Delta T$ and transport rate has frequently and extensively been investigated, only few authors have looked at the importance of $\Delta T$ for the *composition* of the precipitated material[31,36,37] Here, we consider the chemical transport of Magnéli phases $Ti_nO_{2n-1}$[4] in this connection (transport agent: HCl or $NH_4Cl$[5,78,79]).

Model calculations by *Seiwert*[5] show that the starting phase $Ti_nO_{2n-1}$ is first oxidized by HCl to a heterogeneous mixture of $Ti_nO_{2n-1}$ and $Ti_{n+1}O_{2n+1}$; the equilibrium gas phase consists mainly of HCl, $H_2$, $TiCl_4$, $TiCl_3$, and $H_2O$ (Fig. 11). The subsequent transport of the oxygen-richer phase (*e.g.* $Ti_5O_9$) can be represented to a first approximation by the following mass equation [eq. (7)][5]:

$$Ti_5O_{9,s} + 362\,TiCl_{4,g} + 183\,H_{2,g} \rightleftharpoons 366\,TiCl_{3,g} + TiCl_{2,g} + 9\,H_2O_g + 348\,HCl_g \qquad (7)$$

After calculation of the position of equilibrium in the two subvolumes the deposition regions of single, homogeneous $TiO_x$ phases were determined as a function of $\Delta T$. For small temperature gradients $\Delta T \triangleq 50$ K, the oxygen-richer phase is always transported from the heterogeneous source material to the subvolume of temperature $T_1$. If larger temperature gradients are chosen, phases with higher O/Ti-ratios are obtained; for $\Delta T = 370$ K only $TiO_2$ is transported (cf. Fig. 11). Diagrams of this kind make it possible to optimize the deposition condition at $T_1$ for each $TiO_x$-phase

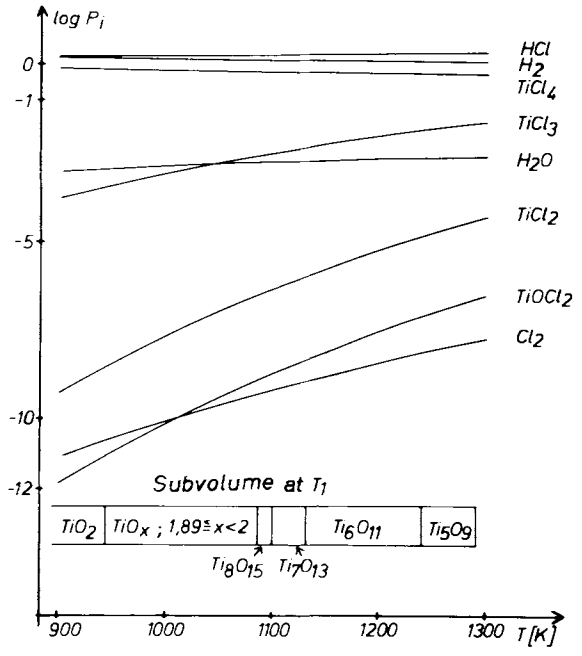

Fig. 11. Temperature dependence of the equilibrium partial pressures [atm] in the system $TiO_x$/HCl for $\Sigma P = 4$ atm and $n^0(HCl) = 1.34 \times 10^{-3}$ mol [5]. For $Ti_4O_7 + Ti_5O_9$ as heterogeneous source materials at $T_2 = 1300$ K the $TiO_x$-phase which occurs at $900 < T_1 < 1300$ K is given.

by a variation of $\Delta T$ (O/Ti in the source material at $T_2$, $n^0$ of the transport agent, and $T_2$ are given).

The formation of a heterogeneous solid (phases I and II) from the homogeneous starting phase I, depending on the nature and amount of the transport agent, is often observed at quite different temperatures ($T_l$; $T_u$, Fig. 12). Since the resulting phase relationships in the source (1, 2 in Fig. 12) can lead to different transport results, a comparison of similar, but complex transport systems without

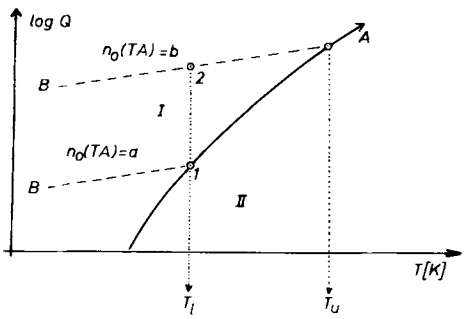

Fig. 12. Temperature dependence of $\log Q$-values for a transport reaction (B) of the solid phase I for two different amounts of transport agent $a < n_0$ (transport agent) $< b$ ($\Sigma P$ = const.) as well as for an exchange equilibrium A; the coexistence line A separates the regions of stability of solids I and II; with $T = T_1$, because of the different amounts of transport agent, *e.g.* the deposit at 1 is heterogeneous whereas at 2 it is homogeneous; for increasing amounts of transport agent the homogeneous/heterogeneous transition is shifted to higher temperatures (TA = transport agent).

consideration of free variables is only possible to a limited extent. Examples are the investigations by *Bald et al.*[80,81] of the transport of anhydrous metal sulfates and their oxide sulfates with various transport agents ($Cl_2$, $HgCl_2$, $I_2$). Experiments with $CuSO_4$ as starting material show the influence of the individual transport agents. With $Cl_2$ as transport agent, single phase $CuSO_4$ is deposited at $T_1$, and pure $CuSO_4$ remains as solid phase in the source volume. With $HgCl_2$, $CuSO_4$ also is transported to $T_1$, whereas $Cu_2OSO_4$ occurs in addition to $CuSO_4$ at $T_2$. The formation of different phases at $T_2$ is attributed to the different chlorinating power of $Cl_2$ and $HgCl_2$, since under the given experimental conditions ($T$, $V$ = const.) the resulting $P(SO_3)$ ($\triangleq Q$-value in Fig. 12) is higher for the transport system with $Cl_2$ ($\Rightarrow CuSO_4$) than with $HgCl_2$ ($\Rightarrow CuSO_4/Cu_2OSO_4$)[81]. The choice of a different transport agent has the same effect as varying the amount of transport agent (Fig. 12).

### 4.3. Influence of Impurities on the Position of Equilibrium

The interior of the ampoule can be contaminated by attack of the vessel material by the reactants as well as by release of impurities from the vessel itself. The example of the *transport of NbO* into the hotter zone (system $NbO/NbO_2/NbCl_5$) shows the influence of $SiO_2$ of the container material as well as of smaller amounts of $H_2O$ (from the quartz wall of the transport ampoules)[14,82,83] on the deposition of this oxide.

*Experimental Procedure* (cf.[29]): Mixtures of $NbO/NbO_2$ or $Nb/Nb_2O_5$ (O/Nb = 1.95) and $Nb_3O_7Cl$ (< 0.4 mmol)

were introduced into the cooler end ($T_1$) of the transport tube (vol. $\approx 4$ cm$^3$). In the "natural" temperature gradient of a silite tube furnace ($100 \leq \Delta T \leq 200$ K) NbO is deposited in the form of single regular NbO-crystallites or of shining golden NbO linings at $T_2$ (*ca.* 22 mg NbO in 6 d). Simultaneously $SiO_2$ (cristobalite layer) migrates to the less hot side ($T_1$).

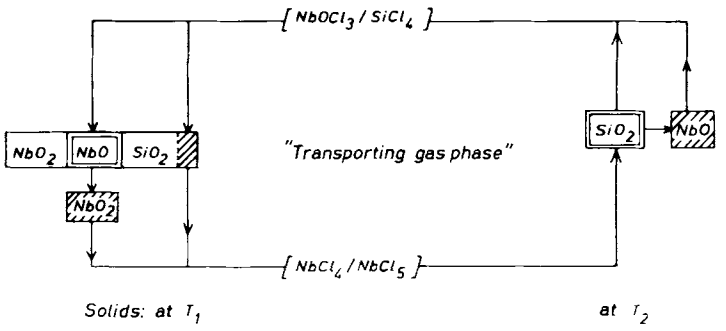

Fig. 13. Influence of the quartz wall on the position of equilibrium, illustrated by the partial chemical transport of NbO to the hotter zone. Solids which react in the exchange equilibrium [eq. (8)] with the gas phase are framed twice; ▨ resulting, □ starting materials.

*Discussion:* Under conditions of extensive exclusion of $H_2O$, migration of NbO to the hotter zone as a consequence of an opposing $NbOCl_3$-flow is related to the existence of an oxygen donor at $T_2$ (Fig. 13). Thus, we observe here the (more special) case of "partial" chemical transport[3], for which the flow of only *one* source element is needed (represented by the reduced transport rate $n_r$, cf. Table 1). If migration of Nb is attributed to the flow of $NbCl_4$, the observed transport rate for NbO [$n_r(\text{obs.}) \leq 2 \times 10^{-4}$] is substantially below the calculated value [$n_r(\text{calc.}) = 5 \times 10^{-3}$]. The lower observed value can be rationalized on the basis of the calculated minimal flow of $NbCl_5$ [$\Delta P(NbCl_5)/\Sigma P \approx 4 \times 10^{-4}$]. If we assume that mainly $NbCl_5$ serves as solvent for the oxygen donor $SiO_2$ at $T_2$, then $\Delta P(NbCl_5)$ limits the deposition of NbO *via* the exchange equilibrium [eq. (8)].

$$2\,SiO_{2,s} + 3\,NbCl_{4,g} + NbCl_{5,g} \rightleftarrows 2\,SiCl_{4,g} + 3\,NbOCl_{3,g} + NbO_{s} \quad (8)$$

The presence of small amounts of $H_2O$ ($< 10^{-5}$ mol, *e.g.* from the container wall[14]) does not change the situation markedly.

If additional $H_2O$ is introduced into the system [$n^0(H_2O) \geq 4 \times 10^{-5}$ mol], NbO can migrate into the hotter zone according to a simpler transport reaction [eq. (9)].

$$NbO_s + 3\,HCl_g \rightleftarrows NbOCl_{3,g} + 1.5\,H_2 \quad (9)$$

A complete calculation for the system containing water yields $n_r(\text{calc}) = 2 \times 10^{-4}$ (for the transport of NbO with HCl from $NH_4Cl$ cf. also [65]). Deposition of $SiO_2$ at $T_1$ is not expected in this case.

The chemical *transport of $TiO_x$-phases* with $TeCl_4$ or $HgCl_2$[16] provides another example of the importance of $H_2O$ for the transport of metal oxides. If $H_2O$ is completely excluded from the system, practically no transport of the *Magnéli phases* takes place[4], since the transport agents used partially oxidize the $TiO_x$ source material, but do not provide sufficiently high partial pressures of gaseous oxides or oxide chlorides for the O-flow; hence, the gas phase remains essentially "oxygen-free". If $H_2O$ [$n^0(H_2O) > 3 \times 10^{-5}$ mol] is present in addition to $TeCl_4$ or $HgCl_2$, the observed transport effect can be attributed to the function of HCl as transport agent (Section 4.2)[5, 16].

### 4.4. Kinetic Influences

The explanations of the chemical transport of binary and ternary solids presented here are strictly based on the calculated thermodynamic models. The reliability of the interpretation of the experimental results thus depends, on one hand, on the accuracy of the thermodynamic data, and on the other to what extent the nature and degree of kinetic inhibitions in the reaction process can be neglected.

In the system $NbO_2/NbCl_5$ (cf. Section 4.1.1), the kinetics of the *equilibration in the source material* determine the nature of the transported phase. At the beginning of the experiment several simultaneous processes have to be distinguished in the source volume:

1) Redox reactions on the surface of the starting material with a variable gas phase.
2) Equilibration between the surface and the interior of the sample.
3) Superposition of isothermal equilibrations [from 1) and 2)] by selective transport of elements of the solid.

The deviations of the O/Nb-value on the surface of the sample from the desired equilibrium value for the overall source material cause the duration of the experiment to influence the result; after reaching an equilibrium state ($> 50$ h) only β-$NbO_2$ is transported (Table 2). Deposition of α-$NbO_2$ can almost completely be suppressed by an isothermal equilibration which precedes the steady-state, as well as by a reduction of the deposition rate ($\Sigma P < 2$ atm).

The importance of the establishment of equilibrium *in the heterogeneous deposits of the sink* was shown by *Schmidt et al.*[15] for the transport of Ge (1123 → 1023 K) in the presence of high initial concentrations of the transport agent $H_2O$. Deposition of an additional solid ($GeO_2$), which appears in minimal amount at the start of the experiment, leads to a drastic change of the transport rate of Ge. Measurement of the experimental transport rate as a function of time (the ampoule is suspended as on a beam-balance) indicates that a sudden drop occurs after a certain time (166 mg/d ⟶ 50 mg/d), followed by a region of constant transport rate for the remainder of the experiment. Model calculations as well as further experiments led to the following explanation: over a short period of time deposition of Ge together with that of hexagonal $GeO_2$ occurs until steady-state transport of Ge is reached. The change of the transport rate with time is based on the transformation (hexagonal ⟶ tetragonal) of $GeO_2$ into its stable modification, which is promoted by extremely small amounts of alkali ("mineralizer"). The change in modification of $GeO_2$ at $T_1$ leads to a substantial shift of the position of equilibrium in this transport system.

### 4.5. Preparation of Metastable Solids

The observed influence of the duration of an experiment on the nature of the deposited phase (Section 4.4) in the system $NbO/NbO_2/NbCl_5$ (Table 2) suggests that the initially formed $\alpha$-$NbO_2$ is not stable with respect to the equilibrium gas phase formed later, and is, therefore, gradually converted into $\beta$-$NbO_2$. This view is supported by observations made during isothermal studies of mixtures of $\alpha$-$NbO_2/NbO$ in the presence of $NbCl_5$. Here, $\alpha$-$NbO_2$ crystals are completely or partially dissolved, whereas newly formed $\beta$-$NbO_2$ grows on the $\alpha$-$NbO_2$ crystals already present.

Although both modifications differ only slightly in composition and thermodynamic stability, the conversion of the $\alpha$- into the $\beta$-form is caused by a slight gain in stability of the subsystem ($\approx 1$ kcal/mol). That solid phase is formed ($\beta$-$NbO_2$), whose formation causes a smaller decrease in concentration for gas particles with low free energy ($NbOCl_3$) [eq. 10]. This "gas phase effect" is strongly dependent on the composition of the $\beta$-$NbO_2$ phase formed and vanishes for strictly stoichiometric $\beta$-$NbO_2$ (O/Nb = 2.00).

$$2.01\,\alpha\text{-}NbO_{2,s} + 0.03\,NbCl_{4,g} \rightleftharpoons 0.04\,NbOCl_{3,g} + 2\beta\text{-}NbO_{1.99,s} \quad (10)$$

The situation can be schematically presented in a "modified" energy term diagram[61] (cf. Fig. 14 and Section 3.3). The $\Delta G^*$ state sketched represents a "metastable" initial state of the sink (Fig. 14), which is caused by transfer of the gas phase of the source volume to the deposition zone ($T_1$). The difference between this $\Delta G^*$ state and the free energy of the source volume ($\Delta G_{source}$) determines the extent of the precipitation of the competing phases $\alpha$-$NbO_2$ and $\beta$-$NbO_2$; the phase actually deposited (here $\beta$-$NbO_2$), however, is determined by the smallest free energy of deposition ($\Delta_R G = \Delta G_{sink} - \Delta G_{source}$) in the system. If the corresponding deposition is kinetically inhibited, the tendency for deposition to occur is shifted to increasing $\Delta_R G$ values.

The simple thermodynamic relationships[28] between $\Delta_R G$-values of competing phases and the corresponding

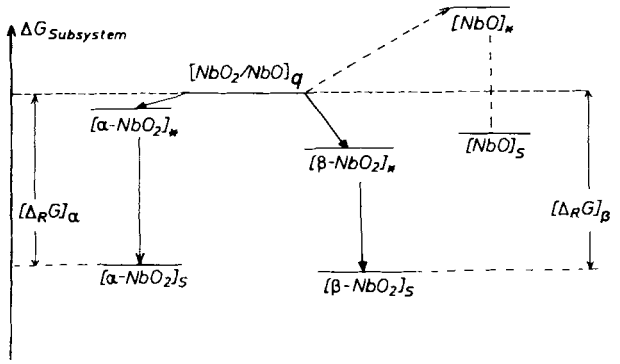

Fig. 14. Energy term diagram for the formation of metastable $\beta$-$NbO_2$. The value of the free energy of deposition ($\Delta_R G$) determines the nature of the transported phase and the transport path leading from the heterogeneous equilibrium substance of the source (index: *q*) *via* a metastable initial state (*) to the lowest-energy deposition level(s). At the given high temperature ($T > 1300$ K and $\Delta T = 100$ K) transport of NbO is impossible because of its energy-rich $\Delta G^*$ state.

gas phase effect allow an approximate interpretation of the deposition behavior of such metastable solids, whose composition differs only slightly from that of a more stable phase.

The thermodynamic calculation used [*G* (min) method] is also suited for the determination of "metastable" intermediate states of a subsystem, such as occur upon transition from the initial state to the steady-state equilibrium. This was confirmed by *Schmidt et al.* for the system $GeO_2/H_2$[11,12].

## 5. Perspectives

The cooperative transport model is based on the thermodynamics of *reversible* equilibria, as well as on the assumption of a *steady-state* mass flow of the elements of the solid between source and sink, which is limited by the choice of appropriate equilibrium states in the subsystems of a transport ampoule. By measuring the deposition process as a function of time using a continuous balance method[15] (cf. Section 4.4) it can be shown, also for individual sections during the experiment, that the transport is a steady-state process.

Perturbation of the position of thermodynamic equilibrium in source and sink caused by heat and mass flows in the transport system have to be taken into account, just as in the kinetic inhibition of heterogeneous reactions.

However, some extensively investigated examples indicate that, aside from thermodynamic equilibrium states, solids can be transported in a steady-state manner as shown by *Vepřek et al.* in experiments on nonisothermal plasmas[84,85]. Industrial applications of this method, *e.g.* the preparation of thin films or the nitridization of metals[86], have already gained some importance. Solids in otherwise inaccessible states can also be obtained, *e.g.* a novel "amorphous" form of elemental phosphorus having unexpected properties[87].

More information on the thermodynamic data of ternary compounds is desirable. Whereas well characterized data for many binary substances are at hand for others, especially ternary solids, we are restricted to estimated values for enthalpies of formation so that the calculation of the transport behavior becomes uncertain. Further measurements are urgently needed.

Experimental details of systems with well characterized thermodynamic data (*e.g.* $GeO_2/H_2$)[12] indicate that for a larger difference in the binary diffusion coefficients "induced" gas flows occur, which lead to a shift of the position of equilibrium in the transport system. For a description of this situation, where the assumption of identical mass balances (Section 3.2)[60] must be abandoned, a "dynamic" model based on the thermodynamics of irreversible processes would have to be developed.

The cooperative transport model allows extensive analysis of the complicated phase relationships in systems with several components, if the restrictions mentioned (kinetic inhibition, steady-state imbalances, reliability of thermodynamic data, average diffusion coefficients) are taken into account: directed syntheses therefore become possible. Use of this model for solid state synthesis could help make novel compounds accessible, especially if they are

only obtainable *via* chemical transport (*e.g.* the "bronze" $Ge_{0.25}WO_3$[88]) or if the required crystalline arrangement can only be reached in this way (*e.g.* for $Ti_7Cl_{16}$[89]). Special techniques, such as the pendulum method[3] or transport in alternating temperature gradients[88] have already been developed for growing single crystals with especially low defect concentrations and defined physical properties (garnets[39], $Fe_2O_3$[90]). On the basis of the currently available experimental data it should also be possible to further optimize technical procedures. For flowing systems *Spear et al.* were able to calculate the deposition conditions for the formation of epitaxial films ($SiO_2$[91], $TiB_2$[93], $Nb_3Ge$[94]) from gas mixtures using the $G$(min) method.

Model calculations based on the free energy function principally allow investigation of the experimental effect of variable thermodynamic parameters ($\Sigma P$, $T$, $P_i$) on structural properties, such as symmetry changes in series of solid solutions[28] or on the concentration and type of defects, *e.g.* in block structures[8]. The possibility of gaining new insight into chemical processes by means of qualitative transport experiments, which was realized fairly early[3], has so far not been fully exploited. Simple thermodynamic considerations have stimulated further investigations and applications, such as the chemical transport of W[10], which led to construction of the halide lamp, or give indications on the existence of new gaseous compounds, such as polysulfides in the system $TaS_2/S_2$[95], the gaseous species causing the migration of $SiO_2$ with $H_2O$[96], or the oxide gas complexes in the system $GeO_2/WO_2$[97]. Even a qualitative understanding of these phenomena requires an appropriate transport model because of the increasing complexity of the chemical systems investigated. Thermodynamic calculations using this model yield a set of parameters which are related to the experiments. On this basis the apparent abundance of seemingly contradictary experimental results can be ordered, interpreted, and compared.

*The transport method was developed by Schäfer over a period of two decades. This article was only made possible by his contributions and the basis which he laid. One of us (R. G.) thanks his mentor for many stimulating discussions which reached far beyond the scope of this review article. We also thank the co-workers L. Bald, H. Brunner, H. Hibst, Th. Kohlmann, V. Plies, W. Redlich, E. Schaum, G. Schmidt, F.-J. Seiwert, M. Spiess, and J. Sturm for their efforts. The Deutsche Forschungsgemeinschaft and the Fonds der Chemie are thanked for financial support.*

# Intermetallic Compounds and the Use of Atomic Radii in Their Description

**By Arndt Simon***

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

Metallic radii, which are obtained from atomic distances in the pure elements, are generally used for the calculation of distances in intermetallic compounds. However, the procedure for using such radii depends on the individual structural type: a) For high coordination numbers and only slightly differing distances between atoms of the same kind and different atoms, all distances in a structure are proportional to the sum of radii, weighted according to the composition. Such a "Vegard" relationship for ordered compounds is obeyed by intermetallic compounds with topological close packings, but strictly only if the various kinds of distances are correlated *via* symmetry relationships. For compounds with low coordination numbers the simple sum of radii holds for atoms participating in the shortest bond (*e.g.* in ionic crystals).—b) The number of neighbors determines the size of each atom. It can be shown that the bond strength-bond length concept, developed for valence compounds, and often dealt with in the literature over the last ten years, is also applicable for alloys. On this basis a formalism is developed which uniformly describes the size of the atoms as a function of the coordination number for both the limiting cases of multiple bonds in molecules and for close packed atomic arrangements in alloys.

## 1. Introduction

Ever since it has been possible to determine atomic distances in molecules and crystals experimentally, efforts have also been made to draw conclusions from such distances about the nature of the chemical bonding. A wealth of empirical data has been collected, from which tables of atomic, ionic, covalent and van-der-Waals radii have been drawn up, and which are fitted to the actual case with the aid of various formulas. The nature of the fit (or better: the fitability) is then used as an indication for bonding criteria such as covalent and ionic bonding, bond order, and coordination number. However, if not enough details about the sample are known, statements about bonding can be wrong.

Let us assume that one is asked to take an X-ray photograph of a sample, whose composition according to conventional chemical analysis practically corresponds to that of cesium and that he actually finds the simple diagram of a face centered cubic (fcc) lattice in which the Cs–Cs distance is only 450 pm as compared to 530 pm in Cs metal. He will be surprised to have found a modification which normally requires more than 20000 bar to produce. Finally, he will have thoughts about the bonds in question, since shorter distances are usually associated with stronger bonds. Hopefully he will find out in time that the sample is, in fact, CsH.

This example is, of course, entirely misleading. As a rule, the chemist will know the composition of the substance whose structure he is to determine by X-ray analy-

[*] Prof. Dr. A. Simon
Max-Planck-Institut für Festkörperforschung
Heisenbergstrasse 1, D-7000 Stuttgart 80 (Germany)

sis. Furthermore, CsH is one of those tricky solids, presenting difficulties which normally do not arise with most molecules.

Nevertheless, this is a good example to illustrate the fact that we tend to draw conclusions about the bonding in a crystal in an indirect way, namely from interatomic distances, bond angles, atomic volumes *etc.*, and tend further to correlate bond lengths with bond orders. Recently determined electronic deformation densities[1] for binuclear transition metal complexes indeed show the huge problems associated with such a correlation, even in relatively simple systems.

The above mentioned interatomic distance arises in a matrix of other atoms and for a discussion of the bonding in solids as well as in individual molecules it is important to know the geometrical strain of the matrix or, to put it in other words, to have a knowledge of the influences of the packing and linkage of all atoms. "Intermetallic phases", those compounds between metals, on which comparatively few studies have been carried out in modern inorganic chemistry, serve as suitable models for investigating this problem, for there are many compounds whose existence is due to an optimal packing of atoms without any participation of strong chemical bonds. What sizes have the atoms in these compounds? Are they describable as rigid or as deformable spheres? In which way do they and the distances between them change when, in addition to the effects of geometrical strain of the packing, strong chemical bonds are formed? Finally, is it true that bond valence concepts fail[2] when one attempts to extend their application beyond classical valence compounds to intermetallic compounds with their often unusual compositions, which do not obey conventional valence rules.

## 2. Starting Points

A well trodden path in the (empirical) attempt at understanding a crystal structure is the search for general criteria for specific atomic arrangements (*e.g.* characteristic radius ratios or space filling in rigid sphere models) and then to check how far the range of existence of real compounds reflects the effectiveness of such criteria. We cannot recount the many authors who have persued studies in this direction. Only *Pearson*'s method[3,4] will be briefly outlined.

### 2.1. Near Neighbor Diagrams (n.n.d.) according to *Pearson*

The atoms M and N in a compound $MN_n$ are treated as deformable spheres, each of which are characterized by radii $r'_M$ and $r'_N$, respectively[*]. In a crystal, the distances $d_{MM}$, $d_{NN}$ and $d_{MN}$ exist. These distances are designated as strain free, when they correspond to a contact of atoms, without deformation of one or the other atom. Hence, for strain free MM contacts we have $d_{MM}=2r'_M$, and accordingly $d_{NN}=2r'_N$, and $d_{MN}=r'_M+r'_N$ for strain free NN and MN contacts. If we choose the formula $(2r'_M-d_{MM})/2r'_N$ as a representation of the strain parameter, then the conditions for strain freeness for the different kinds of distances are describable as linear functions of the radius ratio $r'_M/r'_N$. This procedure will now be outlined using the ZnS (zinc blende)-type structure as example.

As can be seen in Figure 1, the structure of ZnS consists of two face centered cubic (fcc) lattices which are shifted with respect to each other by one fourth of the space diagonal. The shortest interatomic distances are $d_{MM}=d_{NN}=a\sqrt{2}/2$ and $d_{MN}=a\sqrt{3}/4$. From these, one obtains the linear equations for strain freeness of the various atomic distances:

$$\text{MM:}\quad \frac{2r'_M-d_{MM}}{2r'_N}=0$$

$$\text{NN:}\quad \frac{2r'_M-d_{MM}}{2r'_N}=\frac{r'_M}{r'_N}-1$$

$$\text{MN:}\quad \frac{2r'_M-d_{MM}}{2r'_N}=\left(1-\sqrt{\frac{2}{3}}\right)\frac{r'_M}{r'_N}-\sqrt{\frac{2}{3}}$$

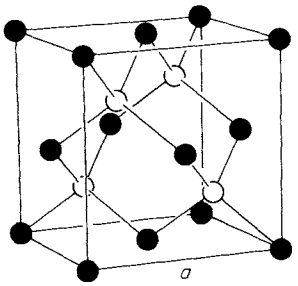

Fig. 1. Unit cell of ZnS ($a$ = lattice constant).

The straight lines shown in Figure 2 represent the geometrical "frame" of the zinc blende structure. Each compound with the ZnS structure is shown as a point in the n.n.d. *via* the experimentally determined distance $d_{MM,exp.}$ and the tabulated radii $r_M$ and $r_N$[*] of the participating elements. As can be seen from Figure 2, all points concentrate around the line of strain-free MN contacts. The conclusion, that the ZnS-type obviously "lives" from MN contacts, corresponds to the usual view of the ZnS structure as a structure with strong bonds between M and N atoms.

One obtains a completely different result—at first sight—for typical intermetallic phases like the so-called Laves phases (Fig. 3). The distribution of points for the existing compounds neglects the straight lines which stand for the strain freeness of the different interatomic distances. We rather get the impression that no preferred contacts in Laves phases exist but that a well balanced adaption is reached by a deformation of all atoms. This result again reflects the usual view that these alloy-like phases lack a preference for bonds between special kinds of atoms and that the only important condition is the formation of a

[*] The notation $r'$ indicates that the radii employed have been fitted to the coordination number. The method of fitting is described in [4], p. 146 and 150 (cf. Section 3.5). The value for close packed spheres is designated as $r$.

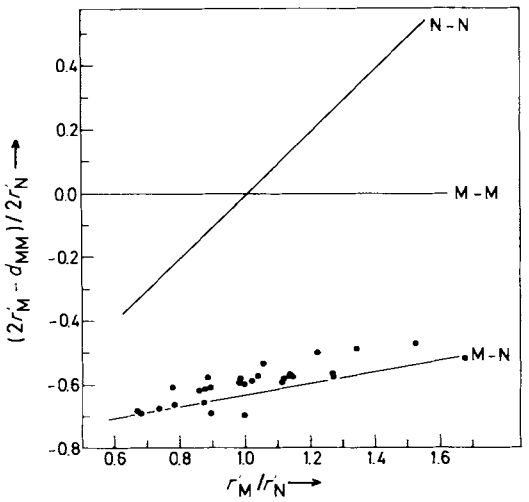

Fig. 2. Near neighbor diagram (n.n.d.) for the ZnS type [4]. The lines correspond to strain freeness of the indicated atomic contacts. The dots characterize real compounds, whose radii have been converted to coordination number 4 (cf. footnote [*] on p. 96).

topologically dense packing. Laves phases represent an ideal system to check the matrix effect, *i.e.* the effect of packing on the origin of individual atomic distances.

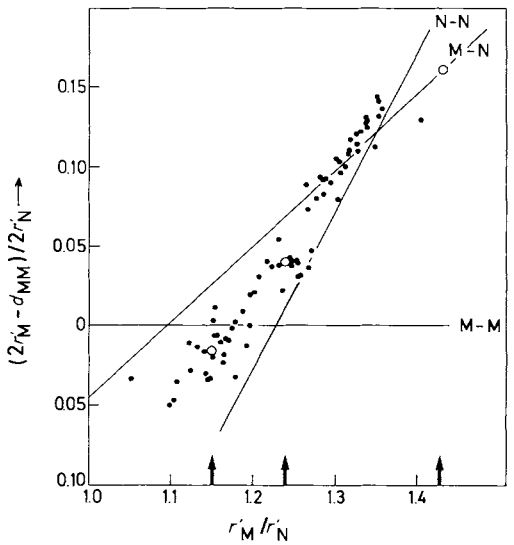

Fig. 3. Near neighbor diagram (n.n.d.) for Laves phases crystallizing in the $MgZn_2$ type. The construction of lines is based on ideal parameters (cf. Section 2.2). The positions of $CsNa_2$ ($r_M/r_N = 1.43$), $KNa_2$ (1.24) and $CsK_2$ (1.15) are especially emphasized.

## 2.2. Laves Phases

Laves phases are intermetallic phases of composition $MN_2$ whose structures are closely related (cf. [4]). In the cubic $MgCu_2$-type (Fig. 4), there is an arrangement of M atoms as in the diamond structure. Each M atom is surrounded by 12 N and 4 M atoms (conventional coordination number cn = 16) and each N atom has both 6 nearest M and 6 nearest N atoms (cn = 12). $MgZn_2$ is a hexagonal stacking variant and $MgNi_2$ shows alternating hexagonal and cubic stacking of the same typical structural units. The interatomic distances for the cubic $MgCu_2$-type are $d_{MM} = a\sqrt{3}/4$, $d_{NN} = a\sqrt{2}/4$ and $d_{MN} = a\sqrt{11/4}/4$. On the premises of ideal positional parameters and $c/a$ ratios, coordination numbers and the relations between corresponding distances are equal in all Laves phases. Starting from the observed distance ratio $d_{MM}/d_{NN} = \sqrt{3/2}$, *Laves* defined the "ideal" radius ratio $r_M/r_N = 1.225$ for a model of rigid spheres. For this "ideal" ratio the M and N atoms just touch each other (according to *Pearson:* strain freeness of the MM and NN contacts). According to *Laves,* phases are found predominantly around this ideal value[5–7]. Should, however, the radius ratio for two metals differ considerably from this value, strong chemical bonds usually stabilize the structure. As a tentative direct proof of this view *Laves* used the compound $KNa_2$[8]: Strong chemical bonds between the atoms are missing and therefore the only reason for the existence of this compound is the closeness of the radius ratio $r_K/r_{Na} = 1.24$ to the ideal value.

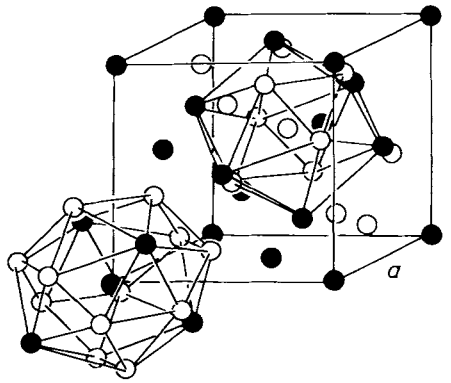

Fig. 4. Unit cell of the $MgCu_2$ structure with coordination polyhedra for Mg and Cu atoms [4]. The full circles represent Mg atoms.

This "proof" became invalid with the preparation and structural characterization of $CsK_2$[9] and $CsNa_2$[10]. Especially the value $r_{Cs}/r_{Na} = 1.43$ for $CsNa_2$ differs greatly from the "ideal", but still the compound cannot balance the geometrically implied destabilization by the formation of strong bonds, as is the case with *e.g.* $KPb_2$, because of the much larger difference in electronegativity in the latter case.

From Figure 3 we can see that none of the phases lie on the point of intersection of the straight lines for strain-free MM and NN contacts (ideal radius ratio); instead, an accumulation around the point of intersection of the straight lines for strain-free NN and MN contacts is observed. The deviation from the horizontal line for strain-free MM contacts is especially notable; the distances $d_{CsCs} = 487$ and 557 pm in $CsNa_2$ and $CsK_2$, respectively[*], are in one case smaller, in the other case larger than the distance in elemental cesium (532 pm). One could be tempted to explain

[*] The lattice constants [8–10] were extrapolated to room temperature on the basis of thermal expansion coefficients, which have been determined by X-rays, for alkali metals and binary mixed crystals [11]: $a = 790.0$, $c = 1312.6$ pm ($CsNa_2$), $a = 749.1$, $c = 1229$ pm ($KNa_2$) and $a = 912.1$, $c = 1484.6$ pm ($CsK_2$).

this shortening of $d_{CsCs}$ in $CsNa_2$ as a strengthening of the Cs–Cs bonds with regard to the element; it can be shown however, that this shortening is due to the matrix in which the Cs atom is embedded.

The influence of the matrix is even more pronounced in the case of $K_7Cs_6$[9], in the structure of which $Cs_2$ pairs with a still shorter distance $d_{CsCs}=469$ pm, are observed. The contraction of about 12% compared to elemental cesium almost reaches that in CsH, which was discussed in Section 1. It could be shown however[12–14], that these distances in $K_7Cs_6$, too, have nothing to do with strong Cs–Cs bonds, but follow almost entirely from the packing of atoms. At this point there is a direct connection to the discussion of bonding between metal atoms in binuclear transition metal complexes which are "forced" into a bridged frame of ligands (cf. Section 1).

The points for $CsNa_2$, $KNa_2$ and $CsK_2$ in the n.n.d. can be linked by a straight line whose analysis leads to an interesting result: the interatomic distances in the three compounds follow the relation $d=F(r_M+2r_N)$. This means that each distance is determined, on the one hand, by the sum of the radii weighted according to the composition, and, on the other, by a factor which accomodates the special geometry. For the shortest distances $d_{MM}$, $d_{MN}$ and $d_{NN}$ the factors are $F_{MM}=0.740$, $F_{MN}=0.708$ and $F_{NN}=0.604$[9]. Obviously the three compounds only obey the geometrical restraints which are the same to all of them in this particular type of structure, for an adjustment of interatomic distances. The straight line for these compounds simply describes the matrix effects, since the chemical bonding is very similar to that in the pure alkali metals.

It is not the size of a *single* atom alone which determines the distances to its neighbors, rather the community of *all* atoms is responsible for *all* distances. A truly democratic principle!

To prevent a misunderstanding: the atoms certainly search an optimal arrangement. Thus the geometrical restraints of the particular structure type could be better described as a condition on the part of the atoms for the formation of a suitable structure. In this context one should mention the interesting result of pseudopotential calculations[12–14] for the binary alkali metal systems. The effective interatomic pair potentials follow from the balance of repulsive interactions of the ionic cores and attractive band-structure contributions (ion-electron-ion interactions). Figure 5 shows that the interatomic distances in the Laves phase $CsK_2$ more or less follow the pair potential functions for a mixture of this composition. The formation of the $MgZn_2$ structure thus corresponds to an accumulation of as many atoms as possible of the correct kind around each atom, approximately at the minimum of the respective pair potential. For $KNa_2$ and $CsK_2$ the observed and calculated[14] lattice constants and positional parameters are in good agreement. It should be mentioned, however, that the existence of $CsNa_2$ cannot be verified by these calculations.

Figure 6 shows that the majority of all Laves phases follow quite closley the straight line which is typical for $CsNa_2$, $KNa_2$ and $CsK_2$. But, especially for those compounds marked by crosses, one observes considerable and systematic deviations. In these compounds the differences

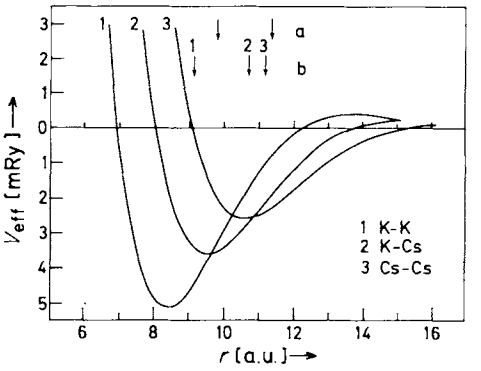

Fig. 5. Effective interatomic pair potentials for an alloy $KCs_{0.5}$ [12, 13]. The arrows indicate atomic distances in the mixed crystal (a) and in the Laves phase $CsK_2$ (b) (cf. text).

in electronegativity are $\Delta\chi > 1$, *i.e.* to a first approximation heteropolar bonds lead to a shortening of distances and to changes in the relative atomic sizes, which manifest themselves in excessively large values for the strain parameters. Here, an interesting way is indicated to distinguish between influences due to the packing (described by the straight line) and those due to chemical bonds (deviations from the straight line). At the same time, however, these deviations which can be easily explained by additional effects, make it quite clear that it is not very meaningful to start an analysis of packing effects in a particular structure type on the basis of *all* known representatives. One should, at first, rather concentrate on the behavior of compounds where these additional effects are likely to be missing.

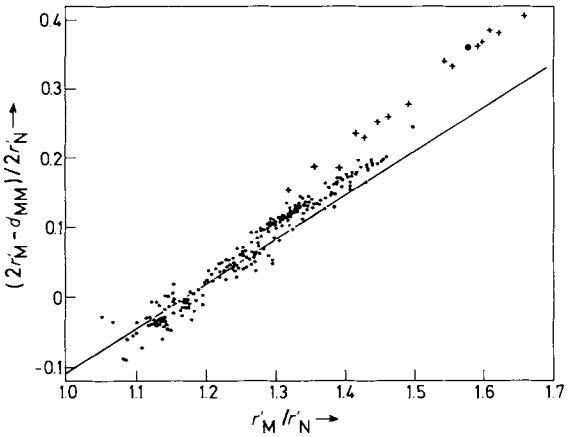

Fig. 6. Strain parameters for all cubic and hexagonal Laves phases [4]. The line drawn includes the points for $CsNa_2$, $KNa_2$ and $CsK_2$. For compounds indicated by crosses the components have electronegativity differences $\Delta\chi > 1.0$.

### 2.3. Vegard's Rule

*Vegard*[15] noticed, on examining mixed crystals of different potassium and ammonium salts, that the lattice constants of a mixed crystal vary linearly with its composition. According to Vegard's rule the averaged shortest atomic distance in mixed crystals of composition $MN_2$ therefore is $d_0=(1/3)(d_M+2d_N)$, where $d_M$ and $d_N$ are the shortest atomic distances in the pure elements M and N. If the structure of the mixed crystal can be regarded as a close

packing, then the averaged shortest atomic distance can be calculated with $d_0 = 2/3(r_M + 2r_N)$ using the tabulated atomic radii for coordination number 12. For other atomic arrangements, *e.g.* in mixed crystals of body centered cubic (bcc) metals, the radii have to be converted to the coordination number in question *via* a factor f, after which Vegard's rule takes the following form:

$$d_0 = \frac{2}{n+1}(r'_M + n r'_N) = \frac{2f}{n+1}(r_M + n r_N) \quad (1)$$

The relation for the ordered Laves phases of the alkali metals corresponds closely to a Vegard relation for disordered phases. But, whereas in the mixed crystal with only *one* factor F = 0.667 only *one* shortest distance is allowed despite different atomic sizes, the different factors F in the ordered phases permit a certain "easing" of the individual interatomic contacts. In the Laves phases of the alkali metals the distances between the larger M atoms are greater by 1.225 than those between the small N atoms. The identical treatment of all atoms is the reason for the non-existence of mixed crystals when the lattice constants of the pure compounds differ by more than 15%. Contrary to this, Figure 6 shows extensive realization of a linear relation of the kind of Vegard's rule within a much larger span of radius ratios for the (ordered) Laves phases.

A complete understanding of Vegard's rule for mixed crystals does not exist to date. In fact there are so many deviations from this rule that most papers deal with explanations for observed deviations rather than with the rule itself. A review[16] of the many models explaining deviations of real systems from the rule indicates that quantitative predictions are only possible to a limited extent. Perhaps we can learn more about the rule from ordered phases, because in these cases the atomic sizes can differ to a much larger extent and because one problem does not exist, namely the general assumption of a completely statistical distribution of atoms in the mixed crystal, an assumption which usually cannot be proven.

As an alternative to the rule of distance additivity, *Biltz*[17] formulated the rule of volume additivity, following the works of *Niggli*[18] as well as of *Fajans* and *Grimm*[19]. Today, this is sometimes curiously called Zen's rule[20]. *Biltz* came to this result by evaluating extensive experimental findings, and he showed in this book that the rules of radii additivity as well as of volume additivity are approximations which may be valid for certain families of substances as well as within one family.

Both relationships are shown graphically in Figure 7 for the Laves phases formed only by alkali metals, for which substantial deviations from a volume additivity are observed. The volumina can be calculated more accurately from the atomic radii weighted according to stoichiometry. The volume contraction of the compounds with respect to the elements results from the higher packing density of atoms of different sizes.

In the following we shall not try to give another proof for Vegard's rule by means of ordered compounds, but look for a way to a quantitative understanding of the empirically found relationship followed so accurately by the alkali metal compounds and to investigate its validity and limits for other classes of compounds.

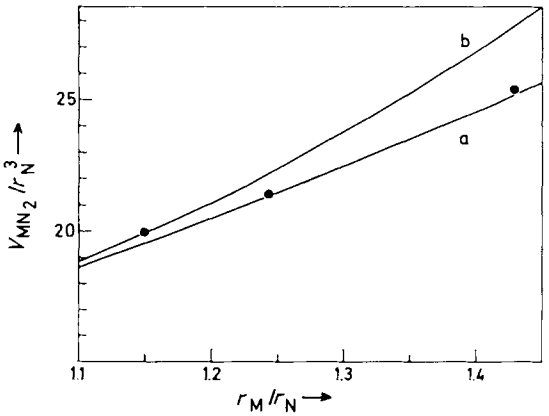

Fig. 7. Reduced volumina of Laves phases $CsK_2$, $KNa_2$, $CsNa_2$ (cf. footnote [*] on p. 97). Tabulated atomic radii [21] were used; the volumina are in each case for one formula unit. The curves represent the limits (a) sum of radii [in analogy to Vegard's rule $V = (2 \times 0.74/\sqrt{3})^3 (r_M + 2r_N)^3$] and (b) sum of volumina [$V = 4\sqrt{2}(r_M^3 + 2r_N^3)$].

The concept of calculating interatomic distances *via* radii which are weighted according to the composition is not new. *Shoemaker* and *Shoemaker*[22] used this approach to analyze Frank-Kasper phases[23,24], whose structures are composed of close packed tetrahedra. *Villars et al.*[25] proceed in the same way, when they try to predict new intermetallic compounds. Obviously *Pauling*[26] was the first to come up with this idea, after *Geller*[27] had doubted the validity of the "resonating valence bond theory" for A15 compounds (β-W or $SiCr_3$ type), which he described with a special set of linearly weighted atomic radii. *Pauling* could show that the conventional atomic radii changed only up to 5% and when weighted 1 : 3 according to the composition gave a much better agreement with experiment than *Geller*'s special radii. The answer from *Geller*[28] was followed by a reply from *Pauling*[29] where he strengthened his arguments by means of the $AuCu_3$ type compounds. The last act of the play is worth quoting[30]: "The writer believes that his position regarding the various aspects of the β-W type structure has been made abundantly clear in his two papers (Geller, 1956, 1957) and, therefore, that there is no point in his further discussing this most recent paper (Pauling, 1957)".

## 3. Searching

The obvious and essential difference between covalent or salt-like structures on the one hand and alloys on the other is a correspondence of shortest interatomic distances to the simple sum of radii in the former case, but to a weighted sum of radii, according to the composition, for the latter compounds. Near neighbor diagrams can be used to investigate which relationship actually holds, because each way of weighting corresponds to a line. Furthermore, this form of presentation has been chosen here, because a wealth of data about known compounds has already been classified and graphically represented in the published diagrams[4].

### 3.1. Stoichiometric and Geometric Relationships

The analysis shall at first be restricted to alloys of composition $MN_n$, which follow a Vegard law for ordered phases (cf. Section 2.3) and will only later be treated in general. A linear relationship between atomic sizes - given by their radii - and the atomic distances in a structure is represented by a straight line in the n.n.d., which is derived from the expression $d_{MM} = F_{MM}(r'_M + n r'_N)$ with $F_{MM} = 2 - 2\alpha$:

$$\frac{2r'_M - d_{MM}}{2r'_N} = \alpha \frac{r'_M}{r'_N} - n(1-\alpha) \qquad (2)$$

Equations (1) and (2) lead to

$$\alpha = 1 - \frac{d_{MM}}{d_0(n+1)} \qquad (3)$$

The result for alloys[31] is shown schematically in Figure 8. For each value of n there exists a fan of straight lines, whose origin in the n.n.d. lies at $-n/-n$. Within a group of compounds of equal composition $MN_n$ (n = const.) the different structure types can be distinguished by different slopes $\alpha$ for the respective straight lines, which thus represent "leading lines" for the different types.

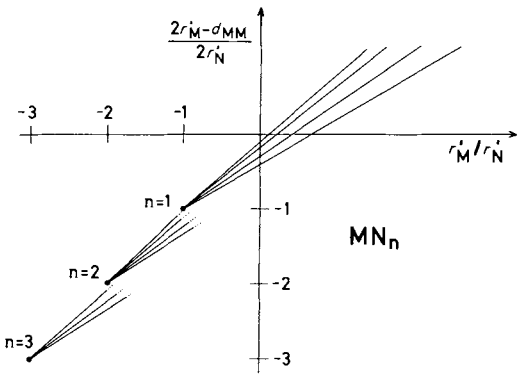

Fig. 8. The representation of structure families for alloy phases with constant composition $MN_n$ (n = const.) corresponds, according to eq. (2), to a fan of lines with origin $(-n/-n)$ in the n.n.d. [31].

All quantities in equation (3) are defined by composition and crystal structure. For the ZnS type presented in Section 2.1, *e.g.*, $n = 1$, $d_{MM} = a\sqrt{2}/2$ and $d_0 = d_{MN} = a\sqrt{3}/4$. The line constructed for the ZnS type using eqs. (2) and (3) is identical to the line for strain-free MN contacts. Above all, however, those alloys are described correctly by eq. (3), whose structures are not dominated by the condition of strain freeness for MN contacts, as shall be shown in the following. An example for this is the $AuCu_3$ family.

### 3.2. The $AuCu_3$ Structure

Atoms in a face centered cubic (fcc) lattice have 12 equidistant neighbors. If face centers and corners of the unit cell are occupied by different atoms M and N, we obtain the simple $AuCu_3$ type which is formed by many intermetallic compounds. Since both kinds of atoms are still surrounded as in close packing, we can use the unchanged tabulated metallic radii[21] for a calculation of strain parameters and radius ratios. Thus complications due to erroneous adaptations of radii to coordination numbers do not exist.

The interatomic distances are $d_{MM} = a$ and $d_{MN} = d_{NN} = a/\sqrt{2}$; with $d_0 = d_{MN} = d_{NN}$, we obtain a value for the slope of $\alpha = 0.6465$. The result is identical to the statement that the contact distances between atoms in cubic close packed mixed crystals and in the likewise cubic close packed compound $AuCu_3$ follow the simple Vegard's rule $[d_0 = (2/4)(r_M + 3r_N)]$.

As shown in Figure 9, the calculated line for the $AuCu_3$ type is a good description of the various representatives of this type in the n.n.d. and it is thus almost a "backbone"

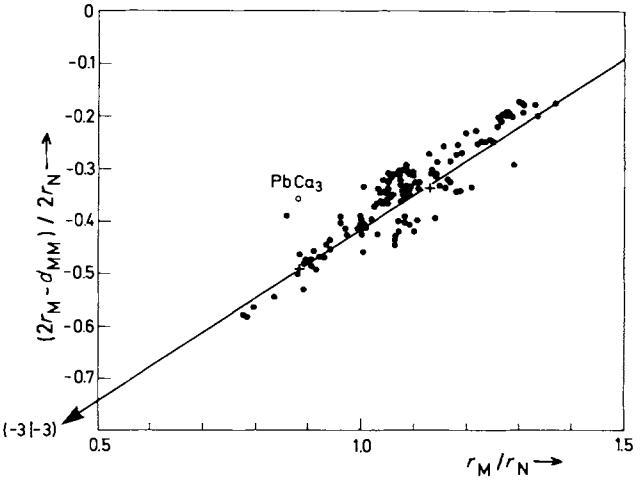

Fig. 9. Distribution of compounds of the $AuCu_3$ type [32, 33] in the near neighbor diagram. The line includes the point with coordinates $(-3/-3)$ and has a slope $\alpha = 0.6465$. The phases $AuCu_3$ and $CuAu_3$ are indicated by crosses. As example for deviations due to large differences in electronegativity of the participating elements, $PbCa_3$ is emphasized.

for the family. The pair $AuCu_3$ and $CuAu_3$ is especially emphasized. The calculated lattice constants agree well with the experimental values [$a_{0,exp.} = 395.3$, $a_{0,calc.} = 396.2$ pm for $CuAu_3$ (mixed crystal) and $a_{0,exp.} = 374.8$, $a_{0,calc.} = 373.0$ pm for $AuCu_3$]. Considerable deviations from the expected positions are found, not unexpectedly, for those phases which are formed from metals with large differences in electronegativity, like $LiAu_3$ or $PbCa_3$ (cf. discussion for Fig. 6).

### 3.3. Structure Fields for Compounds MN

Alloy-like and salt-like compounds of composition MN should group around straight lines in the n.n.d. whose slopes vary depending on the structure, but which have the same point of intersection $(-1/-1)$ because of their identical atomic ratio and, for salts, because of the simple radii additivity. A few structure types of this composition MN are given in Figure 10. The dots representing the many individual phases were taken from *Pearson*[4]. The radius values $r'$ are fitted to the different coordination numbers (cf. footnote on p. 96). The calculated leading lines, using eqs. (2) and (3) with $d_0 = d_{MN}$, correspond to the lines constructed by *Pearson* for strain free MN contacts.

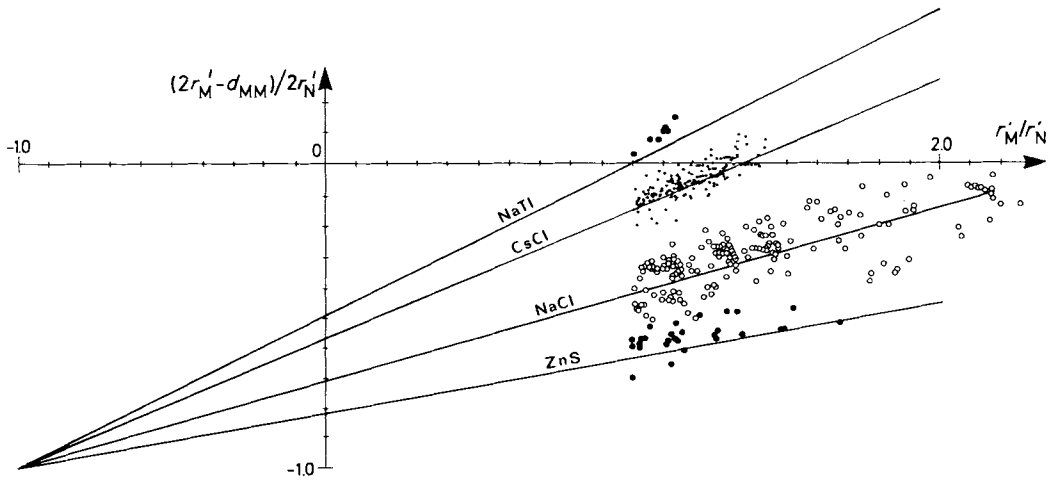

Fig. 10. Representation of compounds belonging to the NaTl, CsCl, NaCl and ZnS types in the near neighbor diagram. The distribution of compounds was taken from the individual diagrams [4] and takes into account the respective coordination numbers (cf. footnote [*] on p. 96). The compounds group around a line, constructed using eqs. (2) and (3), which corresponds to the line of strain free MN contacts.

The accumulation of all phases around the respective straight lines for strain free MN contacts does not necessarily lead to the conclusion that bonds between M and N atoms are decisive for the structure (cf. Section 2.1), but this concentration is a consequence of the composition MN and the condition that atoms of the same kind are always at least as far apart as atoms of different kinds. Conclusions about the chemical bonding in this type should not be drawn from the fact that the compounds follow the lines for strain free MN contacts, but rather from their deviation from the proper line which is specific for the structure and stoichiometry. These deviations can appear as a distribution of points for individual compounds, but they can also show as a systematic deviation of all compounds, as in the case of the NaTl type.

This last mentioned NaTl type is especially interesting. The deviations of the compounds of this type from the "structure specific line" are easily understandable. LiZn, LiCd, LiAl, LiGa, LiIn, NaIn and NaTl are binary representatives of this type. As can be seen from Figure 11, M and N atoms each form diamond structures which are shifted with respect to each other by $a/2$. *Zintl*[34] explained this as due to the simultaneous existence of strong heteropolar and homopolar bonds. We can write $Na^+Tl^-$ for NaTl; the $Tl^-$ ions which are isoelectronic to the elements of the 4th main group form a covalently bonded framework with diamond structure whose vacancies are filled with the cations. This simple explanation of the structure is confirmed by the results of perturbation calculations[35], which show that electron density is transferred from the Na atoms to the regions between the Tl atoms. In this interpretation strong chemical bonds are responsible for the volume contraction, and thus for the resulting position of all Zintl phases above the straight line in Figure 10. It is interesting to note that all compounds follow the condition of strain free NN contacts[4] which corresponds to the above mentioned description of chemical bonding in Zintl phases. Nevertheless, one should recall the close relationship of these phases to typical alloy systems like the brasses, which are formed at other valence concentrations (*Hume-Rothery*[36]).

The special feature of the NaTl structure as compared to other MN types is the fact that the shortest MM, NN and MN distances are identical. Thus, the various distances all correspond to $d_0$, contrary to *e.g.* ZnS. With this equality of all different kinds of distances the NaTl type becomes an "ordered mixed crystal" of composition MN (cf. Section 2.3). Therefore, it is not astonishing that the field of existence for this type is very small (Fig. 10) and does not substantially exceed the value $r_M/r_N = 1.15$. An arrangement of atoms as in the CsCl type, which is found in a large number of intermetallic phases[32] (*e.g.* $CsAu = Cs^+Au^-$, but also LaMg), is obviously not quite so sensitive in its span of tolerable radius ratios.

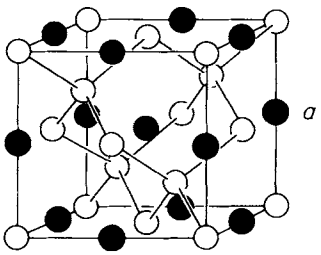

Fig. 11. Unit cell of the NaTl structure. The diamond-like thallium partial structure (empty circles) is emphasized.

Another consequence of this equality of $d_{MM}$, $d_{MN}$ and $d_{NN}$ in the NaTl type is the fact that the value $\alpha$ for the slope of the line reaches a maximum for MN types in this case. For arbitrary compositions the slope of the lines cannot take higher values than $\alpha = 1$. Knowing the upper limit of the fan of lines for MN types, we immediately search for the lower limit. For three-dimensionally linked structures the ZnS type constitutes this lower limit. But even smaller values for $\alpha$ are possible when the three-dimensional linkage is broken down into units of lower dimensionality. For the structure of BN a value $\alpha = 1 - \sqrt{3}/2 = 0.134$ is calculated. Under the premises that van-der-Waals contacts represent the shortest possible distances for crystals with diatomic molecules one even obtains values $\alpha \leq 0$

(*e.g.* for CO). But, since intra- and intermolecular distances are not strictly correlated, well-defined straight lines no longer exist in these cases.

### 3.4. Elements as "Limits" of MN Structures

The structure types shown in Figure 10 were chosen because the simple sum of radii and the weighted sum, according to composition, are identical and because for all these types elements exist, which can be regarded as limits of the various structure types. It can be seen from Figure 12, that both the NaTl and the CsCl type result in a bcc lattice when M and N are equal. This lattice therefore appears on both lines. The cubic primitive lattice of α-polonium is the limit for the NaCl structure, whereas the diamond structure is the equiatomic extreme for the ZnS type.

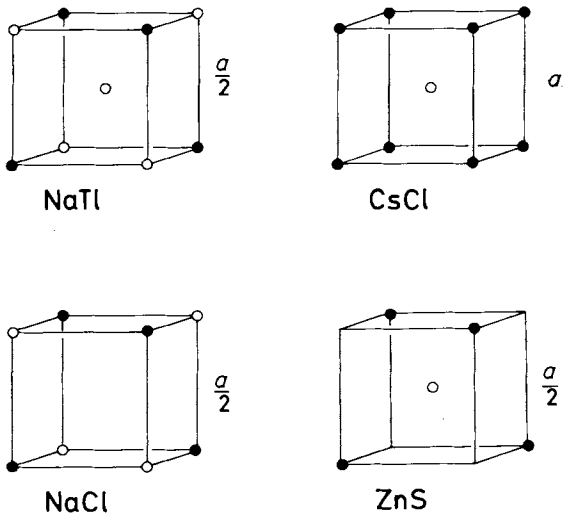

Fig. 12. Arrangements of neighboring atoms in the NaTl, CsCl, NaCl, and ZnS types. For identical atoms the NaTl and CsCl types degenerate to the bcc lattice, the NaCl type to a cubic primitive lattice and the ZnS type yields the diamond structure.

In the elements, $r_M$ is equal to $r_N$ and there are no heteropolar contributions to the bonding. These structures can therefore be used for calibrating the lines calculated according to eqs. (2) and (3), and for the generalization from the individual structure specific $r'$-values to the tabulated metallic radii. How do the shortest atomic distances, which for elements are equal to twice the radius, change as a function of the coordination number?

Table 1 contains a comparison of experimentally determined atomic distances and calculated distances for the elements mentioned here, using the tabulated metallic radii[21]. Since the actual coordination numbers are not taken into account, considerable deviations obviously occur between observed and calculated values. It is however notable, that the ratio of these values remains nearly constant for the bcc metals, although the largest given distance is more than twice the shortest distance. For the other elements variations in the ratio of up to *e.g.* 8% are observed, as in the case of grey tin compared to diamond. If one queries the reason for this disagreement, a (superficial) explanation is easily found, but a more comprehensive treatment has far-reaching consequences.

Table 1. Comparison of experimentally determined atomic distances in some elements [37] with the sum of metallic radii according to [21].

| Structure type | Element | $d_{exp.}$ [pm] | $2r$ [pm] [21] | $d_{exp.}/2r$ |
|---|---|---|---|---|
| Body centered cubic lattice | α-Fe | 248.2 | 255.4 | 0.972 |
| | W | 274.1 | 281.6 | 0.973 |
| | Li | 303.9 | 312.4 | 0.973 |
| | K | 462.8 | 475.2 | 0.974 |
| | Cs | 531.8 | 546.2 | 0.974 |
| Primitive cubic lattice | P(6) | 238 | 256 | 0.930 |
| | α-Po | 336.6 | 352 | 0.956 |
| Diamond | C | 154.5 | 183.2 | 0.843 |
| | Si | 235.2 | 263.8 | 0.892 |
| | Ge | 245.0 | 273.8 | 0.895 |
| | α-Sn | 281.0 | 309.0 | 0.909 |

### 3.5. Metallic Radii

Distances between atoms in an element are simple to measure with high precision. As such they are, however, little help in predicting interactomic distances in chemical compounds. In a uniform procedure, reference values from the individual values, *e.g.* "atomic radii", have to be extracted and various functions can be used for this purpose. Since these radii are combined for the description of distances in compounds, it is meaningful to use just one normalizing function for all values.

The disagreements in the values given in Table 1 are due to the fact that the metallic radii, which are used today by many chemists, crystallographers, metallurgists and physicists[21], have been obtained from the atomic distances in elements by using different functions. Only the function used for the determination of the individual radii is suitable for conversion of the value based on cn = 12 to arbitrary coordination numbers. Therefore only the radii measured as half the atomic distance in fcc element lattices need no further discussion. The radii determined from hcp lattices, however, already include various assumptions: In which way is the *effective* coordination number taken into consideration in these cases as a function of the $c/a$ ratio? Fortunately, there are some bcc elements which also crystallize in a fcc lattice and thus present an empirical function for the conversion of all other bcc metals. But: the user of the tables must not apply any other correction function for the radii concerned. Especially problematical are all radii of non-metallic and semi-metallic elements, because they have been extrapolated from structures with small coordination numbers, which often cannot be described with classical integer values. This extrapolation is carried out according to the procedure described by *Pauling*[38], and the function used is of a substantially different form than the above mentioned function. Table 1 indicates the size of the error which occurs if we treat *Pauling*'s radii for the fourth group elements in analogy to the radii for the bcc metals.

We could of course use those metallic radii which were obtained by *Pauling*[38] himself with the aid of only one function. This however presupposes that the experimental data available at present are correctly described by this function.

## 4. Finding

The preceding discussion leads to a question of central importance in chemistry which has often been dealt with, not only in the early days but also to a large extent in recent years. It arises from the wish to make predictions about bond lengths or ionic distances in a compound with the aid of normalized distances and a suitable function. This function should be as simple as possible and the distances derived should have the same accuracy as those found by experiment.

Ionic radii usually refer to cn = 6 (NaCl structure) as normalized state, metallic radii to cn = 12. The calculation of interatomic distances in a compound by means of a simple or in some way weighted sum of radii presupposes that the radius $r_i$ of the i-th atom in a structure is fitted to the environment with the aid of a function $f_i$:

$$r_i' = f_i r_i \tag{4}$$

Chemists concerned with bond lengths in molecules are probably more used to single bonds as the normalized state, a reference state which has also become customary in the discussion of complicated solid state structures. Since, however, "coordination number" and "bond strength" are closely related and one could be exchanged for the other, the different reference states actually only correspond to a shifting of the origin.

Before finding a suitable function f, two problems have to be solved:

1) Which color has the chameleon "coordination number"[39]?
2) Does it have the same color as the branch named "chemical bond", to which it clings?

### 4.1. Coordination Number

From the point of view of the bond length-bond strength concept[40], atoms form strong bonds to some, but not necessarily all neighboring atoms. The distribution of bonding electrons (or charges) of an atom (or ion) over its neighbors is reflected in the individual bond lengths to the various atoms of the coordination sphere. "The number of bonds is called the coordination number"[40]. But what is the coordination number of the atom, surrounded by 12 neighbors, in a noble gas crystal, according to this definition; is it vanishingly small, or do the atomic distances obey completely different laws on changing the coordination number? This question is justified, because the intermetallic phases which are treated here neither represent van-der-Waals crystals nor ionic crystals, so that "coordination number" could again mean something else.

The coordination number is in fact a description of the environment of an atom reduced to one single number. The arbitrary act lies in the choice of which atoms are included in the environment. One criterion could be, that the neighboring atoms should touch the central sphere. Then the $I^-$ ion in LiI[39] would have the coordination number 18; but we could get used to that. Problems arise at a different point: For a structure type as a whole this procedure does not allow statements to be made about characteristic coordination numbers, because these are in each case functions of the radius ratios (which radii?) of the particular compounds.

Usually structures are described using the centers of gravity of the various atoms. If one adheres to this description, to such an extent that the thus "unsubstantial" atoms become indistinguishable, the coordination numbers are independent of the individual representatives of a particular structure type. Different pathways are then open. They lead to values of effective coordination numbers (ecn), which not only take nearest neighbors into account, but also, albeit with less weight, more distant atoms. The effective coordination number can be related to the valency v of the central atom and to the mean bond strength $\bar{s}$ of all individual bonds:

$$v = ecn \cdot \bar{s} \tag{5}$$

The "vectorial" path consists of the construction of perpendicular faces in the middle of all lines connecting the center with the centers of surrounding atoms[23] and counting the faces of the resulting polyhedron (Wigner-Seitz-cell, Voronoi polyhedron). The counting is accomplished with various weighting schemes depending on a) the sizes of the various faces of the polyhedron[39,41], or b) the volume of each pyramid, formed by face and center[41], or c) the solid angle at the top of each pyramid[42,43].

On the "scalar" path, only the *distances* to a given central atom are used for a determination of its coordination number. It has been suggested[44], that one should search for the largest gap in the spectrum of distances, to count all distances up to this value with a weighting of $1/d_j$ and to forget all others. However, the determination of a "largest gap" sometimes asks for a good eye, and is left to anyone's discretion. The procedure will be more unbiased, if the search for the gap and the task of forgetting is left to a rapidly converging function, such as ECoN (effective coordination number) proposed by *Hoppe*[*]: The individual contributions of all neighbors to the coordination number are summed together and each contribution $ECoN_j$ quickly becomes vanishingly small with increasing atomic distance $d_j$ according to $ECoN_j = \exp[1-(d_j/\bar{d})^6]$. The reference distance $\bar{d}$ corresponds to a "mean fictive" atomic or ionic size[45,46], which is determined beforehand from the structure.

[*] According to [45, 46] the mean fictive ionic or atomic diameters $\bar{d}$ for each independent ion (atom) are calculated first (as radii: MEFIR or MEFAR = Mean Fictive Ionic (Atomic) Radius).
The empirical probability density function, simplified for the special case of atoms of equal size

$$ECoN(h\rightarrow i) = \sum_{i}\sum_{j=1}^{\infty} n(h\rightarrow i)\cdot\exp\left[1-\left(\frac{d(h\rightarrow i)_j}{\bar{d}(h\rightarrow i)}\right)^6\right]$$

leads to the "effective coordination number" ECoN, by referring all distances to the fictive size $\bar{d}_{M,N}$ of ions and atoms respectively (n = frequency of a specific distance).

Superficially, the function ECoN only fulfills the duty of forgetting the atoms at large distances. Its importance, however, is far-reaching; for it can be shown[47] that each term of the sum $ECoN_j$ corresponds to *Pauling*'s bond strength-bond length relationship in merely a modified form. The result fulfills the generally formulated criteria[41] for obtaining coordination numbers, *i.e.* ECoN represents an approximation which is equivalent to the "vectorial" path. Its utility depends on the accuracy of the approximation.

The thought of using the fictive atomic size $2 \cdot$"MEFAR" $= \bar{d}$, which was employed for the ECoN calculation, to determine f in eq. (4) immediately springs to mind. The idea is promising, since the distances in the bcc lattice $d_0/\bar{d} = 0.976$ are in good agreement with the values tabulated in Table 1. But one may not rejoice: Despite the even smaller ratio expected for the diamond structure, a value of 1.000 is calculated. The result of the conventional coordination number ECoN = cn = 4 is payed for with a loss of information, how to handle the radii for this result. Therefore we choose another procedure.

### 4.2. Bond Length-Bond Strength Concepts

Since the time of *Goldschmidt*'s work[48] we have known that the atomic distances in ionic crystals increase with increasing coordination number. An interpretation of this was soon found[49]: Ionic distances result from the balance of Coulomb attraction and Born repulsion. For a change of the coordination number the repulsion term is essentially proportional to the number of ion contacts, *i.e.* proportional to cn, whereas the attraction term changes only slightly—proportional to the ratio of Madelung factors A[50]:

$$d = d_0 (A_0 \cdot cn / A \cdot cn_0)^{1/a-1} \qquad (6)$$

To a first approximation ($A_0 \simeq A$), it is the change of the coordination number which determines the atomic or ionic size. The reason is the rapid increase of the repulsion which determines the Born exponent *a*. If the coordination numbers cn in (6) are replaced by the effective coordination numbers ecn and these in turn by valency and bond strengths (cf. (5)), this formal step leads to a relationship between distances *d* and bond strengths s, which, with the approximation $A \simeq A_0$ for small differences in coordination number (N = a − 1),

$$s = s_0 (d/d_0)^{-N} \qquad (7)$$

represents the fundamental principle of a great number of papers, associated with the names *Donnay, Allmann, Brown* and *Shannon*[2,40,51-62], who made important progress in representing atomic distances in crystal structures.

With eq. (7) the approach has essentially changed: Now, the attraction, the bonding between atoms, and not the repulsion seems to be in the foreground. The step to the empirical description of the relationship between bond order and bond length of covalent bonds by *Pauling*[38] is thus only marginal.

The lengths of the CC single, double and triple bonds follow the well-known relation (*Pauling*[38]):

$$d = d(1) - F \lg s. \qquad (8)$$

For integral bond orders (= bond strengths) s = 1, 2, 3 we have the factor $F = 71$ pm; $d(1)$ represents the single bond distance. *Pauling* assumed that partial bonds ($s \leq 1$), *e.g.* in metals, can also be described by the same expression, but with $F = 60$ pm.

*Pauling*'s relation is based on the plausible idea that the bond strength of each individual bond decreases when the available valence electrons of an atom are distributed over increasingly more bonds to neighboring atoms (ecn > 1). The elongation of interatomic distances on going from a bcc lattice (ecn < 12) to a close packed structure thus becomes easily understandable.

If variations of the factor *F* in eq. (8) are also allowed outside the given range, this equation also describes ionic distances with satisfying precision[59]. Obviously we can use all equations (6), (7) and (8) to describe the dependence of atomic sizes or radii on the coordination number, although the equations were developed for various bonding types, and seemingly different forces lead to the change in atomic size. A closer comparison of the three relationships, however, reveals a significant variance: In equations (6) and (7) the difference in atomic distance with altered coordination number (or bond strength) is proportional to the atomic size. Contrary to this, the change in distance should be constant using equation (8), independent of the atomic size[*].

The transition of some elements from the bcc lattice to close packed structures allows a crucial test of the relationships. Figure 13 clearly shows that the increase in distance associated with this transition is largely proportional to the atomic size[63]. It is obviously independent of the valence

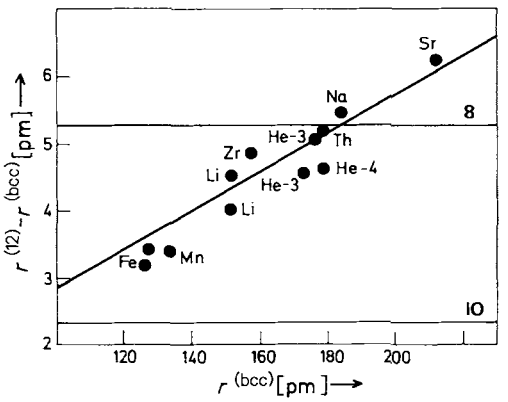

Fig. 13. Decrease of the atomic radius on transition of a close packing into the body centered cubic (bcc) lattice for metals (and helium), which crystallize in both arrangements [63]. The corrections calculated according to *Pauling* [eq. (8)] (drawn for coordination numbers 8 and 10) are independent of the atomic size.

[*] One could argue at first that the atomic size enters the conversion *via* the valency (v), *i.e.* few binding electrons are equivalent to a large atomic diameter. We can easily convince ourselves that v remains unconsidered:
$d^{(ecn)} = d(1) - 60 \times \lg(v/ecn)$ and
$d^{(12)} = d(1) - 60 \times \lg(v/12)$, *i.e.*
$d^{(12)} - d^{(ecn)} = 60 \times \lg(12/ecn)$

electron concentration of the element, and, on the average, corresponds to the line which represents the condition of equal volumina for both modifications. The factor for a conversion of distances from one modification into the other, derived from the line representing the condition $\Delta V = 0$, is once again f = 0.972.

To force atoms with large differences in atomic size into a uniform description, equation (8) is simplified one step too far. If the equation is changed slightly to fulfill the condition of proportionality

$$d = d(1)(1 - A \ln s), \tag{9}$$

it can be shown that A is not constant, but can be represented as a function of the valency of an element: $A \simeq (B + \ln v)^{-1}$.

Starting from the single-bond distances[64] $d_{C-C} = 154.5$ pm (diamond), $d_{N-N} = 146$ pm ($H_4N_2$) and $d_{O-O} = 146.7$ pm ($H_2O_2$), we get the following double and triple bonds when B = 3.6: $d_{C=C} = 133.0$ pm (exp. 133.4), $d_{C\equiv C} = 120.4$ pm (exp. 120.4), $d_{N=N} = 124.4$ pm (exp. 122.4), $d_{N\equiv N} = 111.9$ pm (exp. 109.4), $d_{O=O} = 123.0$ pm (exp. 121.1). The calculated values using eq. (9) correspond slightly better to the experimental distances than the values calculated with the aid of eq. (8). Apart from this, eq. (9) describes the transition from close packed arrangements to the bcc lattice correctly (cf. Section 4.3) and can also be applied to calculate interatomic distances in alloys, *e.g.* in Laves phases (cf. Section 6.2).

Equation (9) demonstrates that the prelogarithmic factor $F$ in (8) must show considerable variations as a function of $d(1)$ and the valency v, and also as a function of the value chosen for B (cf. Section 7). For element-oxygen bonds, values between $75 \leq F \leq 110$ pm are quoted in the literature[56]. In fact, $F$ follows the values for $d(1)$ and v quite closely and, as expected, becomes a maximum for the monovalent cations. A direct comparison of calculated distances using eq. (9) and recent values for element-halogen and element-chalcogen bonds[40] is, however, only possible to a limited extent, because for the latter bonds also the reference distances for a bond strength s = 1 deviate from *Pauling*'s values. Another, more important reason for the difficulty in comparing calculated and observed distances directly, is the fact that the dependence of the bond distance is based on only *one* bond strength (*e.g.* that of the cation). In principle, this procedure is in agreement with *Pauling*'s[65] valence sum rule. Generally speaking, differences in dependence of bond distance on bond strength hold for the cation (or Lewis acid) and anion (or Lewis base) according to eq. (9). These differences are hidden in the averaged values. A further incrementation of distances yielding radii for the atoms therefore seems sensible and desirable, also within the framework of modern bond strength-bond length concepts[40, 51–62].

### 4.3. Coordination Number and Atomic Radius

The discussion has shown that many ways exist for determining the effective coordination number of an atom in a crystal structure. The following step, the adjustment of the atomic size to a special coordination number, can be made in different ways, starting from the tabulated radii $r$ for close packed spheres.

Somewhat "heterogeneous", but numerically simple, is the following procedure. Eq. (9), calibrated with reference to carbon-carbon multiple bonds, yields, together with eq. (5), the simple expression:

$$f = r^{(ecn)}/r = 0.59 + 0.38 \lg(ecn) \tag{10}$$

Using this expression one obtains, *e.g.*, f = 0.973 for the bcc lattice in very good agreement with the experiment, if a value of ecn ≃ 10.2 is used, which is obtained *via* the polyhedron-procedure[43]. The "scalar" path *via* ECoN provides a simpler alternative for the polyhedron-procedure. In connection with eq. (5), however, we already mentioned the problems arising with ECoN, which are associated with the relativity of the function. If ECoN is "stripped" to its essentials and all distances $d_j$ of an atom to its neighbors are referred to the shortest distance $d_{i0}$, one obtains for each atom the relationship (ecn ≃ ECoN'):

$$ECoN'_i = \sum_{j=0}^{\infty} \exp\left[1 - \left(\frac{d_{ij}}{d_{i0}}\right)^5\right]. \tag{11}$$

The exponent 5 is chosen in such a way that the atomic sizes in the bcc lattices are correctly represented in connection with eq. (10). The system of equations (10), (11) describes the following examples of selected intermetallic phases with sufficient accuracy. The procedure is convenient, since it is adequate, due to the rapid convergence of function (11), to include only those distances which exceed the respective shortest distance by less than 50%. Yet the "heterogeneous" procedure is unsatisfactory because of the different character of the individual steps. Moreover, the weakness of this procedure becomes evident for small coordination numbers, in which case function (11) suppresses second-nearest neighbors too much (cf. Section 7). The heterogeneous procedure is therefore only an indication of the indivisibility of chemistry.

The "homogeneous" way uses the same function to determine the effective coordination number ecn as well as to calculate atomic sizes as a function of coordination numbers. With the bond strength-bond length relationship (7) both steps can easily be carried out. With this relationship the effective coordination number ecn* is first calculated, and then the radius adaption *via* f* to this coordination number.

The valency v of an atom i corresponds to the sum of all bonds of this atom:

$$v_i = \sum_j s_{ij} = \sum (d_{ij}/d(1)_i)^{-N} = ecn^*_i (d_{i0}/d(1)_i)^{-N}$$

The single bond distance $d(1)$ corresponds to the value s = 1 (as is indicated by the name). The effective coordination number $ecn^*_i$ indicates how many atoms at a distance $d_{i0}$ saturate the valency of the central atom in place of the quasi-infinite number of atoms with distances $d_{ij}$ in the whole lattice.

$$ecn^*_i = \sum_{j=0}^{\infty} (d_{ij}/d_{i0})^{-N} \tag{12}$$

The second step follows immediately:

$$f^* = r^{ecn^*}/r = (ecn^*/\text{“12”})^{1/N} \quad (13)$$

Writing "12" for the coordination number in a close packed structure indicates the price which has to be payed for the transparency of this procedure. With N = 6, *i.e.* a value which is used for the exponent in many halide and oxide systems[40] one obtains ecn* = 14.45 in the close packed structure instead of the conventional and familiar value 12, and even with N = 8, ecn* = 12.79 is still increased. If the effective coordination number is regarded as a measure of the interactions of an atom with its total surroundings, however, this increase is sensible[41].

A disadvantage of function (12) compared to function (11) is the rather slow convergence. The calculations for the following examples were therefore carried out with N = 8 and summations up to a distance ratio $d_j/d_0 = \sqrt{3}$. The value ecn* = 12.67 obtained for close packing, which has to replace "12" in eq. (13), leads to an error of only 0.1% in f as compared to the complete lattice sum.

## 5. Result

The description of a crystal structure by means of atomic distances only, leads to a loss of information about directions. Tortuous paths, using effective coordination numbers for the atoms, can partially compensate this loss of information. Whereas each single value, taken for itself, does not mean anything, the combination of all values contains a hidden statement about the total arrangement. The entire structure can be described as sum of the individual atoms, each of which are adjusted to the entirety. For a structure with atoms of equal size, the atomic size is identical to the respective shortest distance $d_{i0}$ to its neighboring atoms. If we assume that this statement is, on average, also valid for atoms of different size, we get the following expression, with $z$ being the number of atoms in the unit cell:

$$\sum_{i=1}^{z} 2f_i r_i/d_{i0} = z \quad (14)$$

In this expression each sum contains the individually shortest distance $d_{i0}$ for the i-th atom. One can easily show that the relation (14) is freed from this "relativity" by expressing each f, by the two equations (12) and (13), *i.e.* the result becomes independent of the chosen reference distance ($\sqrt[8]{12.67}/2 = 0.6868$).

$$\sum_{i=1}^{z} \left( \sum_{j=0}^{\infty} d_{ij}^{-8} \right)^{1/8} r_i = 0.6868 z \quad (15)$$

If the distances $d_j$ for a cubic crystal are given by fractions of the lattice constant (*e.g.* $z = 1$ in the primitive cell, $d_0 = a\sqrt{3}/2$, (8×), $d_1 = a$ (6×), $d_2 = a\sqrt{2}$ (12×), ... for the bcc lattice) one directly obtains the lattice constant $a$ as a function of the metallic radii. If $d_j$ refers to $d_{MM}$ (cf. Section 2.1) one obtains this kind of distance as a function of the metallic radii and it becomes possible to calculate the slope α of the Vegard line in the n.n.d., already corrected for the coordination numbers.

For a summation in equations (14) and (15) over all atoms $z$ of the unit cell, both equations represent generalizations of (1) and refer to mixed crystals as well as ordered alloys. In these systems an almost identical weighting is given to *all* atoms for the formation of *all* interatomic distances. This expression, however, cannot be generally valid, but only holds in those cases where the spectrum of distances in a compound contains only slightly differing values for all the various kinds of distances. This asks for high coordination numbers, which are typical for the topologically close packed alloy structures. On the other hand, structures with relatively low coordination numbers, occurring in most compounds with strong covalent or ionic bonds, are dominated by the shortest bonds. Thus if the distance $d_0$ in a structure is of the kind $d_{MN}$, and this distance is shorter than $d_{NN}$ and $d_{MM}$, the summation in eqs. (14) and (15) can be terminated at i = 2 in the simplest case, if the terms of the sum are arranged according to increasing $d_{i0}$. In this case the well-known relationship with simple radii additivity is valid, $d_0 = f_M r_M + f_N r_N$, independent of the composition. The result signifies strain free MN contacts[4] and can be represented as a straight line in the n.n.d. which intersects the line calculated for a weighting according to the composition at $r_M/r_N \simeq 1$, has a smaller slope α′ than this line, and almost includes the point (−1/−1).

If the shortest distance occurs between atoms of the same kind (*e.g.* $d_0 = d_{NN}$), usually belonging to the majority component, these distances can, but not necessarily must, dominate all others. In this case, all distances follow $d_0 = 2f_N r_N$ and the structure field is described by the line with slope α″ = 1.

Summary: A structure type is characterized in the n.n.d. by a "leading line", which corresponds to a Vegard behavior and which is obtained by weighting the radii according to the composition. This line passes the field of compounds crystallizing in this type close to $r_M/r_N = 1$. To what extent the compounds follow this "leading line" over a wide range depends on the spectrum of distances in the given structure type. A small value for the slope α of the leading line corresponds to a large difference in distances

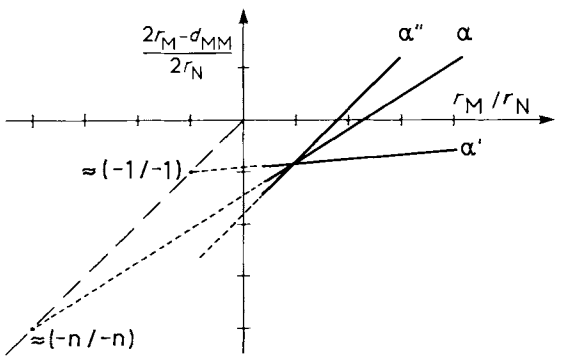

Fig. 14. Schematic representation of the distribution of phases in the n.n.d. The line with slope α resulting from a weighting of radii according to the composition forms a "leading line". In the case of shortest distances $d_{MN}$, the compounds follow the line for a simple sum of radii (α′); if the distances $d_{NN}$ are the shortest ones, they alone can determine the dimension of the compound (α″). The resulting near neighbor diagrams are constructed with the radii for close packing.

of the various kinds and to small coordination numbers in the structure, so that the compounds follow the condition of simple radii additivity for the distances $d_{MN}$ ($\alpha'$). If the shortest distance is $d_{NN}$, the slope of the corresponding line is $\alpha''=1$ and thus at its maximum.

The result is shown schematically in Figure 14.

## 6. Examples

The heading "Democracy and Individuality" was rejected. Table 2 contains the results of calculations for structure types explained in the following.

### 6.1. Elements

At this point only the radii of those elements are discussed which have been dealt with in Section 3.4. Table 3 gives a comparison of atomic radii for the bcc metals at NTP. The correction function of *Teatum, Gschneidner,* and *Waber*[21] corresponds closely to the function used in this work. The values agree to within 0.7 pm; overall, the newly calculated radii are somewhat larger than the published values. The relevance of the radii calculated using eqs. (12) and (13) for the elements of the fourth main group still has to be tested (cf. Section 7). After all, both modifications of tin can be described quite satisfactory within the same formalism using only *one* radius value. In the structure of (metallic) white tin (β-Sn) each atom is surrounded by the following neighbors: $4\times302.2$, $2\times318.2$, $4\times376.8$, $8\times442.0$, $4\times476.4$ and $4\times493.1$ pm. According to eq. (12) the atoms in β-Sn have the effective coordination number ecn* = 6.575. With this value one obtains (eq. (13)) the shortest distance $d_0=298$ pm; with eqs. (10) and (11) one obtains $d_0=299$ pm.

### 6.2. Once Again Laves Phases

In a thorough analysis of all well-characterized Laves phases *Pearson*[66,67] shows that these structure families are very inhomogeneous with respect to the compounds belonging to them. For the $MgCu_2$ type the distribution of points in the n.n.d. (Fig. 6) can be separated into several groups. The lattice constants of compounds belonging to one of the various groups (*e.g.* lanthanoids (Ln)/platinum metals; Ln/Mn, Ln/Al) can be represented with high precision by linear functions of the atomic radii with up to 4 fitted parameters. The chemistry—packing and chemical bonding—of this class of compounds lies hidden in 9 equations with 23 free parameters for the $MgCu_2$ type and 20 equations with altogether 56 parameters for the $MgZn_2$ type[68]. The approach in earlier attempts to come to the simplest possible and most uniform description for the entire family at the expense of accuracy in an individual

Table 2. Data and linear equations for the representation of some structure types in the near neighbor diagram [4] ($x=r_M/r_N$; $y=(2r_M-d_{MM})/2r_N$; α, α', α'' cf. Section 5). The calculations were carried out using equations (10), (11) or (15). Distances in pm.

case[69], is deliberately ignored here in order to reach the high accuracy of the single case.

Our result is given in Figure 15, which represents the calculated specific line for the $MgCu_2$ and $MgZn_2$ types (ideal $c/a$-ratio) together with the positions for some compounds between aluminum and the lanthanoids. The latter have been chosen to show the influence of weak, but additional chemical interactions.

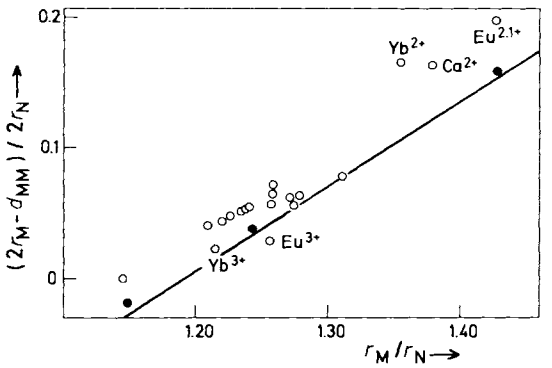

Fig. 15. Representation of compounds $CsK_2$, $KNa_2$, $CsNa_2$ (full circles), $ScAl_2$, $YAl_2$, $LnAl_2$ and $CaAl_2$ (empty circles) *vs* the structure-specific line in the n.n.d. for Laves phases, calculated using eq. (15). Under the premise of different "metallic valencies" for the lanthanoid atom, different positions for one and the same compound result, as is emphasized for $EuAl_2$ and $YbAl_2$.

The distribution of values for the lanthanoid compounds is in part due to the fact that the number of electrons which are donated to the conduction band for the various lanthanoid systems is not exactly known. The value of the radius for the calculation of both strain parameter and radius ratio is therefore undetermined. Do we have to choose the value of "metallic valency" $\simeq 2$ (194 pm) or 3 (174 pm) for $YbAl_2$? For this reason the compounds of Ce, Eu and Yb are not included in the detailed analysis[66].

The example of the phase $CaAl_2$ shown additionally in Figure 15 reveals that the valence difference does not only influence the geometrical construction, but leads to chemical consequences which determine its position in the diagram. $EuAl_2$ shows the same deviation from the line as $CaAl_2$, if the value 2.1 is used for the "metallic valency". It must be concluded that Eu is in the same valence state in this compound as in the element. The position of $YbAl_2$ with respect to the specific line, however, indicates that it is better described with a valency 3 (which differs from that in the element) or with a state somewhere between 2 and 3, if we consider its position with respect to the other lanthanoid phases. In fact, *Iandelli*[70] had already been able to show by magnetic measurements for the compound that the ytterbium is present in a temperature dependent "mixed valence state", whose $Yb^{3+}$ fraction at room temperature amounts to approx. 17%.

The problems discussed above do not occur with the Laves phases of alkali metals. Using eq. (15) one calculates a value of $\alpha = 0.65$ for the slope of the specific line, which is in good agreement with the experimentally found slope ($\alpha = 0.63$[9]) for $KNa_2$, $CsNa_2$, and $CsK_2$. This result verifies the assumption that the interatomic distances in these compounds correspond almost exclusively to an optimization of the packing (cf. Section 2.2). The calculated interatomic distances show such a good agreement with the experimental values (Table 4) that the assumption of ideal positional parameters, on which the determination of experimental values is based, is strongly supported.

Table 4. Comparison of experimental (cf. footnote [*] on p. 97) and calculated interatomic distances [pm] using (15) or (10), (11) for $KNa_2$, $CsNa_2$ and $CsK_2$ [8-10]. The experimental values were obtained with the positional parameters $z(M) = 1/6$ and $x(N) = 5/6$.

### 6.3. The $SiCr_3$ Type

Some representatives of this structure type comprising 70 phases like $SnNb_3$ and $GeNb_3$, which is usually incorrectly called the A15, β-W or, correctly, $SiCr_3$ type, have gained great importance as superconductors having the highest known critical temperatures. The structure is shown in Figure 16; as essential feature the chains of transition metals should be emphasized. These are arranged perpendicularly to each other. Many papers associate the structural aspect of superconductivity with these chains.

Even after the already mentioned dispute[26-30] (cf. Section 2.3), several attempts were made to describe the geometrical conditions of A15 phases with special atomic radii[71,72]. Can the dispute between *Geller* and *Pauling* be decided?

The atomic separations within the chains ($d_{NN} = a/2$) are the shortest in the $SiCr_3$ type, but the (more frequent) distances $d_{MN} = a\sqrt{5}/4$ are only larger by 12%. We can expect that both kinds of contacts—as in the $AuCu_3$ family—determine the structure. Figure 17 shows the result of calculations for A15 phases. The distribution of the compounds

in the n.n.d. could be taken directly from a recent paper[73] on this class of compounds. The line shown with slope $\alpha$ corresponds to a weighting of radii according to the composition. The additional line with slope $\alpha'$, which represents the condition of a simple sum of radii for M and N atoms, as proposed by *Geller*, only yields a good description of the structure field close to the radius-ratio $r_M/r_N = 1$. *Pauling* had the better position in the dispute[26-30]. Obviously the description of atomic distances with the aid of radii summations weighted according to the composition is the best approximation for A15 phases over its whole range of existence. The deviations for large values of the radius-ratio, however, indicate that the chemical bonds between the transition metal atoms give rise to smaller lattice dimensions than would be expected just from an analysis of the packing.

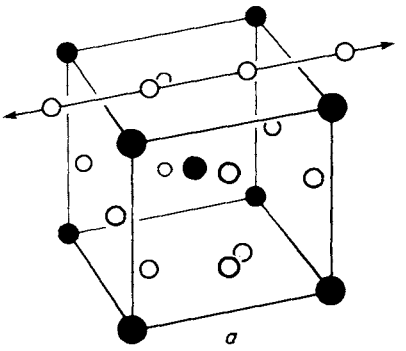

Fig. 16. Unit cell of the (A15, β-W) $SiCr_3$ structure. The chain formed by the transition metals (empty circles) is emphasized.

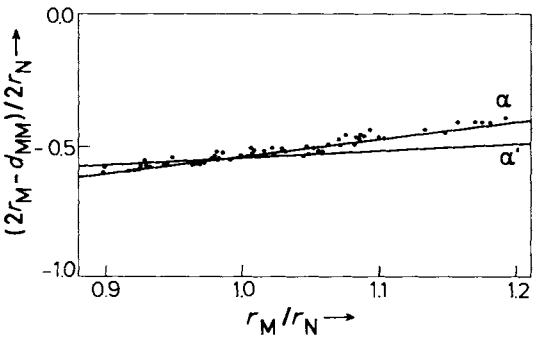

Fig. 17. Distribution of representatives of the $SiCr_3$ type in the near neighbor diagram [73]. The line with slope α corresponds to the radius-lattice constant relation as given by *Pauling* [26]; it is almost identical to the line calculated using eq. (15). A simple sum of radii ($d_{MN} \sim r_M + r_N$) corresponds to the line with slope α'.

*Pauling*[26] used the equation $a = 0.8944(r_M + 3r_N)$ for calculating the lattice constants of A15 compounds; according to equation (15) we find the expression $a = 0.8929(r_M + 3.01 r_N)$.

If one looks at a former representation of A15 phases in the n.n.d.[3,4], deviations to increasingly smaller strain parameters become evident, when the radius-ratio falls below 0.8. Interestingly, the positions of compounds in this range can be described quite well by the line given in Table 2 corresponding to dominating NN contacts (slope $\alpha'' = 1$). This result bears the fascinating aspect that a structure type contains general restrictions which are of different importance for various combinations of elements with respect to a critical radius-ratio. Conclusions of this kind, however, cannot be drawn unambiguously from[3,4], since the compounds with a radius-ratio smaller than 0.8 are β-W ($W_3O$) and $Cr_3O$. What is their real composition and what size has the oxygen atom?

### 6.4. $BaCd_{11}$ and $BaHg_{11}$, "Contaminated Metals"

For a composition $MN_2$ or $MN_3$ one might ask why M and N atoms should influence the formation of all interatomic distances $d_{MM}$ to the same extent. For a compound $MN_{11}$ this is quite obvious: The M atoms are so far apart that distances $d_{MM}$ must be mainly influenced by the size of the N atoms. The question is rather whether there is any chance for the M atoms to have a correcting influence at all?

$BaCd_{11}$ and some other compounds of this type have a complicated tetragonal structure[74], in which the M atoms are surrounded by 22 N atoms and the N atoms by 14, 12 and 12 M and N atoms as nearest neighbors. The coordination polyhedra are characterized by a fan of closely separated distances for the central atoms.

The same holds for the $BaHg_{11}$ type. In the cubic structure[75] 20 N atoms are arranged around the M atom, whereas the four crystallographically different N atoms are each surrounded by 12 N, 3 M and 9 N, 2 M and 8 N, and 1 M and 11 N atoms.

Both structures have been chosen for a comparison, firstly because they fulfill the condition $n \gg 1$, and secondly because the combination of previously reported n.n.d.'s[4] yields distinctly separate fields for both structure types, in which the respective compounds concentrate. Figure 18 shows that the lines which have been calculated according to eqs. (12) and (13) using the positional parameters for $BaCd_{11}$ and $BaHg_{11}$ (cf. Table 2) describe both classes of compounds quite well. In particular, the difference between the two lines is a very good indication of the relative position of the structure fields with respect to each other. For both families, deviations from the respective Vegard line are observed, which can be associated with the simplified calculation of the lines, since for the determination of the effective coordination number only those atoms are considered which belong to the "classical" coordination polyhedra. It is however notable that the rapidly converging function (11) in combination with (10) leads to a result which is identical within the accuracy of drawing. This means that the too large values for the strain parameter in these compounds, which were determined experimentally, are obviously due to chemical effects, which were also discussed for the Laves phases: All compounds contain alkaline earth or rare earth metals, *i.e.* especially electropositive elements besides Zn, Cd and Hg. The formation of heteropolar bonds causes a contraction of the structure with an increase of the strain parameter.

Especially notable are the deviations for the $BaCd_{11}$ structure. The compounds are much better described by the line with slope $\alpha''$ (dominating NN contacts). The same

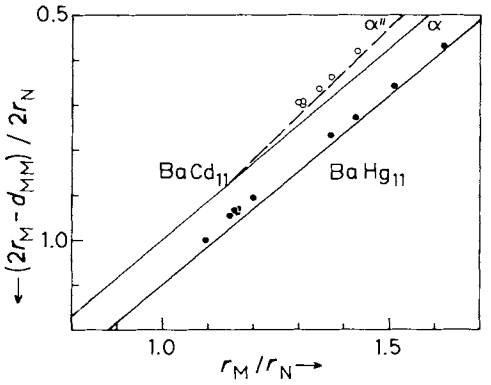

Fig. 18. Near neighbor diagrams for the representatives of the $BaCd_{11}$ and $BaHg_{11}$ types [32]. The interatomic distances in $BaHg_{11}$ follow the sum of radii, weighted according to the composition (slope $\alpha$); in contrast, the distances in $BaCd_{11}$ are almost exclusively determined by the size of the N atoms (slope $\alpha''$).

result, namely "participation in the decision" of the minority component in the case of $BaHg_{11}$, but a "dictatorship" of the majority component in $BaCd_{11}$, was obtained by *Pearson*[76]. He offers an explanation for the difference: If the N atoms which surround the M atom have variable positional parameters, the difference in size of various M atoms is "neutralized" by the immediate environment ($BaCd_{11}$); if however the surrounding N atoms occupy special positions ($BaHg_{11}$), this difference in size is transferred to the entire lattice. Thus, an additional restraint for the validity of Vegard's rule for ordered compounds exists. Besides a suitable spectrum of distances it is the symmetry of the structure which has to be considered, at least for large values of n.

### 6.5. $AsNa_3$ as an Example for Strong Heteropolar Bonds

The $AsNa_3$ type is found for 20 different compounds which are predominantly ionic. Besides the compounds of alkali metals with elements of the 5th main group, which are all insulators or semiconductors, typical intermetallic compounds like $HgMg_3$ and $PtMg_3$ also crystallize in this structure type[32]. Starting from the structure of wurtzite, the hexagonal analogue of zinc blende, the $AsNa_3$ structure results from a filling of all tetrahedral sites with N atoms and introduction of more N atoms, which form chains parallel to the *c*-axis. M atoms are surrounded by 11 N atoms, the N atoms by 3 or 4 M atoms. That the actual environment is only inadequately described with theses statements is seen in Table 2. Here the almost identical effective coordination number is notable despite very different geometrical arrangements around the N atoms.

In contrast to the other structures discussed so far in Section 6, the shortest distance $d_o$ (=294.3 pm) in the crystal structure of $AsNa_3$ is of the kind $d_{MN}$. The next longer distance also belongs to this kind. According to Section 5, we should expect that all other distances are dominated by the shortest ones. The assumption is correct. *Pearson* has already shown that the compounds of the $AsNa_3$ type follow the line of strain free MN contacts very closely. The line constructed with a simple sum of radii describes the structure field of the $AsNa_3$ type very accurately (Fig. 19). This line intersects the "leading line" for Vegard behavior at $r_M/r_N = 0.92$; the latter intersects only one end of the structure field for the $AsNa_3$ representatives. Most compounds crystallizing in this type have strongly reduced strain parameters as compared to the calculated line with slope $\alpha'$. As in the preceding example this is to be expected, since the strong heteropolar bonds in the $AsNa_3$ structure lead to a contraction of the lattice which is not incorporated in the radii employed.

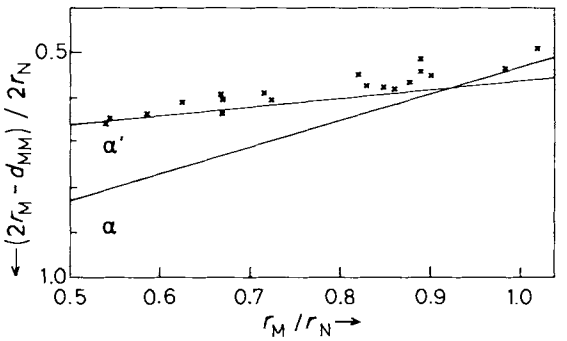

Fig. 19. Distribution of compounds of the $AsNa_3$ type [32] in the near neighbor diagram. The lines were calculated using eqs. (10) and (11) ($\alpha$ and $\alpha'$). With strain parameters as given by *Pearson* [4] the compounds follow the line with slope $\alpha'$ even closer. His values, however, do not refer to the shortest MM-distances.

### 6.6. The $CaF_2$ Type; Link between Intermetallic Phases and Ionic Crystals

When the empty tetrahedral sites in the ZnS structure (Fig. 1) are occupied by N atoms, the well-known fluorite structure results. The M atom is surrounded by a cube of N atoms each of which in turn is surrounded by a tetrahedron of M atoms. Counting the conventional way yields cn=8 for each M atom and cn=4 for each N atom. But what is sauce for the bcc lattice is sauce for the fluorite. Each N atom only has 4 M atoms as neighbors, but the 6 N atoms belonging to the closer environment are only 15% further apart, so that, *e.g.*, with eq. (11) an effective coordination number ECoN′=6.09 results. One might accept this value, at least for intermetallic compounds with atoms of nearly equal radii (cf. [39]).

Numerous compounds crystallize in the $CaF_2$-type structure (or its anti-type). The fluorides and chalcogenides of main group metals are colorless, and thus already indicate the kind of chemical bonding. But also typical intermetallic compounds with metallic properties like $AuIn_2$ or $PtSn_2$ occur with this structure.

Figure 20 summarizes the results of calculations for this structure type. The compounds in which both components are metals, gather, when characterized by the respective metallic radii, in a narrow interval around the intersection of lines with slope $\alpha$ (radii weighted according to the composition) and $\alpha'$ (simple sum of radii). It cannot be decided, to which condition the compounds pay tribute: they unify both conditions $d_{MN} \approx r_M + r_N$ and $d_{MN} \approx r_M + 2r_N$. For typical salt-like compounds, however, the expected simple sum of radii holds for the $d_{MN}$ distances. The positions for fluorides and oxides are considerably spread out,

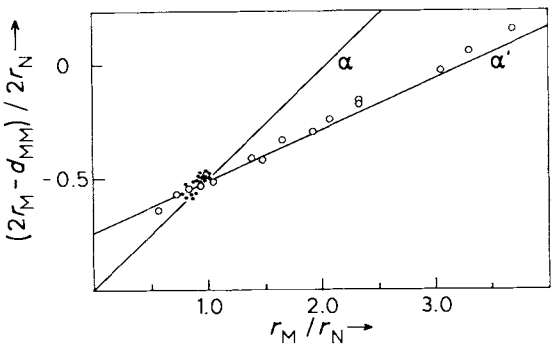

Fig. 20. Distribution of some compounds with $CaF_2$ structure in the near neighbor diagram. The positions of compounds formed by metallic components (dots) were calculated with atomic radii. The positions for the salt-like oxides, calculated with ionic radii, follow the condition of a simple sum of radii [*].

but this is understandable: Using the metallic radii for sodium and (extrapolated) oxygen, a position for $ONa_2$ in the diagram can be calculated, but this position is not very close to reality. It is much more realistic to assume a complete electron transfer to the (fluorine) or oxygen atom and then to describe the atoms by their ionic radii[*]. As can be seen, the worlds of intermetallic phases and ionic crystals are close neighbors.

## 7. Concluding Remarks

According to Section 4.2 the ratio of the distances of nearest neighbors in metals with close packing on the one hand and a bcc lattice on the other follows the same law as the ratio of the distances of carbon atoms in diamond and in a molecule with carbon-carbon double bonds. Even a noble gas crystal obeys this law up to a certain extent, although in this case concepts like valency or bond strength do not allow a description of the effective forces.

Helium crystallizes in a bcc lattice as well as with cubic close packing or hexagonal close packing[37]. The observed changes in the distances between the atoms at the phase transition largely correspond to those which are found for metals (Fig. 13). The changes are correctly described by eqs. (10) and (13), which do not explicitly contain a valency dependence.

The van-der-Waals interactions between noble gas atoms are described to a good approximation by a Lennard-Jones potential; the lattice constants of the solids can be calculated quite accurately with the potential determined for the gas phase[78]. With this potential a distance between nearest neighbors in the bcc lattice results at the energy minimum, which indeed is shortened by a factor of 0.978 as compared to the close packed structure[**]. But any hope that noble gases might provide a law as to how distances are related to coordination numbers, soon disappears. Due to the rapid increase in the repulsion potential, which is not opposed by strong bonding forces, the noble gas atoms reject any additional deformation; for the primitive cubic lattice (α-Po) almost the same value of f is calculated as for the bcc arrangement. An extrapolation to small coordination numbers is impossible with this type of bonding. Since the interaction potential of a noble gas does not help any further, perhaps the criterion of constant volumina, inspite of changing coordination number, might be of help. But little reflection on this point is necessary: The diamond structure corresponds to a bcc lattice, which is only half occupied. The waste of space is impossibly compensated by a compression of the atoms. As Figure 21 is intended to show, the truth is somewhere between the individual extremes of (a) rigid spheres, which do not allow any adjustment to a given structure and (b) non-rigid spheres, which compensate for the reduced space filling at low coordination numbers by correspondingly smaller atomic sizes. Helium is close to one extreme: Only for almost close packed structures do the weak van-der-Waals bonds affect the atomic size in the same way as strong chemical bonds. The elements C, N and O are close to the other extreme: Over a wide range of coordination numbers the connecting line $f = 0.59 + 0.38 \lg(ecn)$ [equation (10)] is almost identical to the condition of constant volumina.

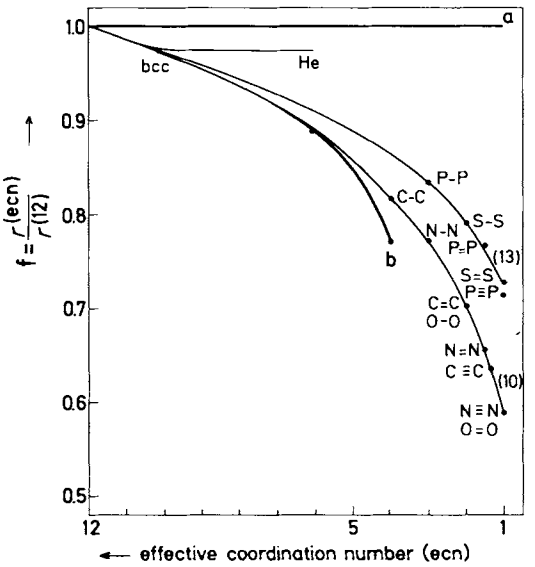

Fig. 21. Atomic sizes as function of the effective coordination number. The limits are given by (a) the model of rigid spheres, and (b) the model of constant volumina for isotropic changes of the sizes of the atoms in the bcc-lattice, the primitive lattice of α-Po and in the diamond structure. The multiple bonds of C, N and O are well represented by relation (10); for the elements P and S [79, 80] the relative changes in bond lengths are smaller and better represented by eq. (13) with N = 8. The He crystal is described by a Lennard-Jones potential [**].

Some explanations are required in order to gain a better understanding of Figure 21. With 3-dimensional structures (bcc, α-Po, diamond type) the effective coordination number is normalized to ecn = 12 for close packed structures. Taking N = 8 for, *e.g.*, the diamond structure, we get the

[*] *Pauling*'s radii [38] were used. To allow for a comparison with lines calculated for metallic radii, the ionic radii tabulated for cn = 6 were converted to the close packing with the aid of eq. (10). *Shannon*'s radii [77] lead to an almost identical result, provided one starts from the values for cn = 6; only the values for Li-compounds yield strain parameters too large.

[**] A summation of all Lennard-Jones potentials over all atom pairs yields the bonding energy $U \sim \sum \left(\frac{\sigma}{p_{ij} d}\right)^{12} - \sum \left(\frac{\sigma}{p_{ij} d}\right)^{6}$ of the noble gas crystal; the partial sums for the fcc lattice have values $(\sum p_{ij}^{-12})_{fcc} = 12.13$ and $(\sum p_{ij}^{-6})_{fcc} = 14.15$. For the bcc lattices one obtains $(\sum p_{ij}^{-12})_{bcc} = 9.15$ and $(\sum p_{ij}^{-6})_{bcc} = 12.25$. The ratio of equilibrium distances follows *via* $dU/dd = 0$ as $d_0^{(bcc)} = 0.978\, d_0^{(fcc)}$.

value ecn* = 4.24 according to eq. (12) and thus ecn = 12 × (4.24/12.67) = 4.02. The result is almost identical to ECoN′ = 4.00. Good agreement is also found for α-Po and the bcc lattice; therefore, the calculated curves (using eqs. (10) and (13)) can be compared for the same values of the effective coordination number. The calculation of coordination numbers for single and double bonds was simplified by considering only nearest neighbors. For example, at a coordination number 3, phosphorus[79,80] forms 3 single bonds (221 pm); in the $P_2$ molecule each P atom has the coordination number 1 and forms a triple bond to its neighboring atoms (189.4 pm). For the double bond (203.4 pm) an effective coordination number 1.57 is calculated using eq. (12) with single bond and double bond distances, instead of the value 1.5 according to eq. (5). The curve (13) quite accurately represents the relative change of distances (= change of size) for the elements P and S in single and multiple bonds. The larger differentiation of distances in C, N and O is represented by the curve calculated using eq. (10)[*]. The disagreement observed for the atomic radii of the fourth group elements (Table 1) is due to representation of the elements by different curves. This is also the basic reason why the additive correction of distances (radii) according to eq. (8) works rather satisfactory *via* an error compensation.

Equilibrium distances between atoms are the result of a balance between attractive and repulsive interactions. From this point of view not only the formal similarity of the descriptions for various bond types like covalent, ionic, metallic and van-der-Waals bonds can be rationalized, but also the fact that not all atoms have the same capability. The rapid increase of repulsive forces limits the mutual approach of atoms. The relationship (10), which is calibrated to the shortest bonds in chemistry, obviously represents the maximum possible approach. The relative change of distances in C, N and O as function of the coordination number is much larger than for the elements P and S, which have a fully occupied Ne shell.

In Section 3.5 the problems arising from the application of different correction functions was mentioned for the derivation and use of atomic radii. From Figure 21 it becomes clear, that even for the simplest case of an atom surrounded by identical atoms, the atomic size cannot be described as a function of the environment by only one expression for all elements. However, whereas according to [21] the radii are treated with different correction functions depending on the coordination number, Figure 21 indicates that different functions are necessary for different atoms (or more precisely for atoms with different cores). On the average, the system of equations (12) and (13) used here yields satisfactory results with N = 8 for the intermetallic compounds under discussion. A more sophisticated procedure, however, must permit variations of the exponent N[*]. There is hope in arriving at a consistent system of metallic radii which is a prerequisite for discussion of additional chemical interactions that reach beyond packing effects (*e.g.* interactions due to different electronegativities).

The attentive reader will have noticed that the aim and center of interest have changed during the writing of this review. At first the question of how the relative amounts of elements in an intermetallic compound determine the atomic distances, was in the foreground. Our discussion has shown that in close packed arrangements with high coordination numbers, as in alloys, *all* atoms together determine *all* distances, at least when the different kinds of distances are correlated *via* the symmetry. If only few neighbors saturate the valency of an atom (low coordination number) the shortest distances in the structure are only determined by the size of the atoms forming these bonds. The shortest distances then dominate all others, provided there is a correlation.

At a later state of the work another aspect increasingly became dominant, namely, that concepts and formal descriptions of bonds in molecules could be used almost unchanged with intermetallic systems, although seemingly unbridgeable contrasts exist. One side follows a valency principle and obeys clear-cut stoichiometric rules. The other side, according to current views, exists outside the border line of a valency concept and thus does not follow the rules, as they are familiar to every chemist, on the composition of compounds. Nevertheless, Figure 21 demonstrates or recalls that both sides are not in principle different but represent uniformly describable limits of the same phenomenon, namely the chemical bond.

*I thank H.-G. von Schnering and V. Heine as well as my co-workers for many helpful discussions and also W. J. Westerhaus for the careful translation of the text. Generous support of this work by the Fonds der Chemischen Industrie is gratefully acknowledged.*

[*] Problems with ECoN′ for small coordination numbers have already been mentioned in conjunction with eq. (11): The carbon atom linked to other C atoms *via* a single and triple bond, would have the coordination number ECoN′ = 1.08 (instead of 1.33 according to eq. (5)). If an exponential representation according to eqs. (12) and (13) using N ≈ 4.3 is chosen for the elements C, N and O, a good agreement between bond lengths and the corresponding coordination numbers is reached in the "homogeneous" way, as in the case of P and S.

# Thio- and Seleno-Compounds of Main Group Elements—Novel Inorganic Oligomers and Polymers

**By Bernt Krebs***

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

During the last decade modern preparative and structural methods have led to novel and often unexpected oligomeric and polymeric main group element-sulfur compounds having remarkable bonding and structural properties and reactivities. Examples of important new developments in this area are: the discovery of boron sulfides $B_8S_{16}$ and $(BS_2)_n$ and of ion-conducting air-stable thioborates with tetrahedrally coordinated boron; the successful use of boron sulfides in organic and inorganic syntheses; the preparation of different homologous series of molecular polynuclear thio- and selenoanions of Ga, In, Si, Ge and Sn, and of new polynuclear sulfide- and selenide-halides of Si and Ge as interesting reagents for inorganic and organic reactions; the synthesis of argyrodite($Ag_8GeS_6$)-like phases with remarkable solid-state properties; and the characterization of the S–H···S type hydrogen bridge in thiocarbonic acid and thiophosphinic acids, which is of importance for an understanding of certain interactions in sulfur-containing biomolecules.

## 1. Introduction

Compounds of sulfur with other main group elements are remarkable for their extraordinarily variable bonding characteristics, which extend from ionic sulfides of the alkali and alkaline earth metals to sulfur compounds of boron, aluminum and silicon, which are highly sensitive to hydrolysis, to the polymeric sulfides of germanium, tin, arsenic and antimony, which are able to form thioanions, to molecular sulfides of carbon and phosphorus, and to molecular compounds with nitrogen or halogens, where, in

[*] Prof. Dr. B. Krebs
Anorganisch-Chemisches Institut der Universität
Corrensstrasse 36, D-4400 Münster (Germany)

contrast to all the other types of compounds mentioned, sulfur is the electropositive reaction partner. It is obvious that these variations in bond properties lead to a wide range of chemical and physical characteristics as well as to a variety of practical applications. Comprehensive reports and reviews have recently appeared in the literature concerning several sectors of this rather heterogenous chemistry, *e.g.* the large and highly topical area of sulfur-nitrogen compounds[1,3], other aspects of non-metal sulfur compounds[2,3] or carbon-sulfur compounds[4].

The following progress report summarizes some important new developments in the chemistry and structural chemistry of sulfur compounds of semimetals and metals of the 3rd to 5th main groups. This sector of chemistry, which has progressed considerably over the last few years, is of special interest because of its relation to both molecular chemistry as well as solid-state chemistry.

## 2. Boron Sulfides and Boron Selenides

### 2.1. Synthetic Methods

Although the first investigations on boron-sulfur compounds were already reported by *Berzelius*[5] and *Wöhler*[6] ("Dreifachschwefelbor") early in the last century, so far remarkably little is known about binary and ternary sulfides and selenides of boron. The reason for this undoubtedly stems from the fact that boron chalcogenides are extraordinarily sensitive towards exchange reactions with oxygen and towards hydrolysis (at least in the case of trigonally coordinated boron) and that the amorphous boron previously used as starting material was not pure, thus making the preparation of pure compounds difficult.

In the synthesis of binary phases from the elements, or of ternary phases from sulfides of the components by fusion reactions in evacuated ampoules at elevated temperatures, it is necessary to employ special techniques because of the high aggressivity of B–S and B–Se-systems towards most container materials. In uncoated quartz glass ampoules, for example, $B_2S_3$ reacts quantitatively at temperatures above about 400 °C according to

$$2\,B_2S_3 + 3\,SiO_2 \longrightarrow 2\,B_2O_3 + 3\,SiS_2$$

with complete S/O exchange; similar reactions occur with ternary thioborates. For clean syntheses the following have proven most effective: a) coatings on the inner walls of quartz glass ampoules with glassy carbon, prepared by thermal decomposition of acetone-vapor, b) closed graphite crucibles or open corundum finger crucibles in evacuated quartz ampoules (possibly with a temperature gradient in the reaction vessel), and c) closed tantalum crucibles in which the reactions can be performed under a protective gas atmosphere. Boron nitride can also be used as a crucible material[7,8].

Of the solid boron sulfides $B_2S_5$[7,9], $BS_2$[10–13], $B_2S_3$[9,14–21], BS[22,23] and $B_{12}S$[24,25] mentioned in the literature, only the existence of $B_2S_3$ has so far been proven as a unique phase (cf. also [22,23]), although only a few reliable spectroscopic, thermodynamic and structural data are available, even for this compound[18,23]. In a similar way this is also true for $B_2Se_3$[26–31], which can be obtained from the elements at 850 °C. The formation of $B_2S_5$, which was reported to occur as a solid phase by reaction of amorphous boron with excess sulfur at 590 °C[7,9], could not be reproduced in subsequent investigations[11,32,33]. Solid $BS_2$ is postulated from the thermal analysis of the system B/S with high sulfur contents[11,23], while BS is claimed to develop in two modifications at a pressure of 60 kbar and 1400–1500 °C[23,34]. On heating boron and sulfur rapidly to 1600–1700 °C, a boron-rich phase $B_{12}S$ was obtained, which, considering the bonding in icosahedral structures, is probably better formulated as $B_{12}SB$[24,25].

Considerable progress has been made over the last few years through the structural characterization of $B_2S_3$ and the preparation of new oligomeric and polymeric sulfides and selenides of the composition $BS_2$ and $BSe_2$, which will be dealt with subsequently.

### 2.2. $B_2S_3$

$B_2S_3$ is a colorless glassy solid and is extremely sensitive to hydrolysis. It is prepared, *e.g.*, by a) reaction of boron with sulfur or $H_2S$ in an inert gas atmosphere, b) reaction of boron with metal sulfides (*e.g.* FeS, ZnS, $Al_2S_3$), c) conversion of metal borides (*e.g.* $MgB_6$, $FeB_2$) with sulfur or $H_2S$, d) thermal decomposition of cycloborothianes (*e.g.* $H_3B_3S_6$, $B_3S_3Br_3$), or e) by thermolysis of metal thioborates, in all cases at elevated temperatures of about 400–900 °C[9,14–21,23].

No suitable procedures were hitherto available for purifying the reaction products, so that in many earlier preparations considerable amounts of impurities (at least 5%) have to be assumed. With this aspect in mind, the thermal decomposition of molecular compounds, which can be purified more easily, is the method of choice for the synthesis of pure samples[9,21]. This is exemplified by the decomposition of the trimeric cyclic metathioboric acid $H_3B_3S_6$[35–38] according to

$$3\,BBr_3 + 6\,H_2S \xrightarrow[CS_2,\,C_6H_6]{40-80\,^\circ C} H_3B_3S_6 + 9\,HBr$$

$$2\,H_3B_3S_6 \xrightarrow{100-200\,^\circ C} 3\,H_2S + 3\,B_2S_3$$

However, with the precautions mentioned, pure preparations can also be obtained from the elements.

Like the homologous compounds $B_2O_3$ and $B_2Se_3$, $B_2S_3$ also shows a distinct tendency towards formation of glassy phases. Crystalline samples are more difficult to obtain, *e.g.*, by vacuum distillation of glassy $B_2S_3$ at 550–600 °C[19], by reaction of boron with FeS under He at 700–730 °C[16,17] and as a product of the thermolysis of $H_3B_3S_6$[9,21]. Single crystals suitable for X-ray structure analysis could only be obtained by controlled thermal decomposition of heavy metal thioborates, *e.g.* according to

$$2\,Ag_3B_5S_9 \underset{650\,^\circ C}{\overset{750\,^\circ C}{\rightleftharpoons}} 3\,Ag_2S + 5\,B_2S_3$$

$$Pb_2B_2S_5 \underset{800\,^\circ C}{\overset{850\,^\circ C}{\rightleftharpoons}} 2\,PbS + B_2S_3$$

employing reversible formation-dissociation equilibria of the ternary phases[8,39–42].

The structure of $B_2S_3$ was first determined in 1977 using these (twinned) crystals. The compound is monoclinic[40,41,43] and forms a remarkable layer structure. It consists of planar six-membered $B_3S_3$ and four-membered $B_2S_2$ rings which are coupled *via* S bridges to form planar two-dimensional polymeric layers (Fig. 1). Within the

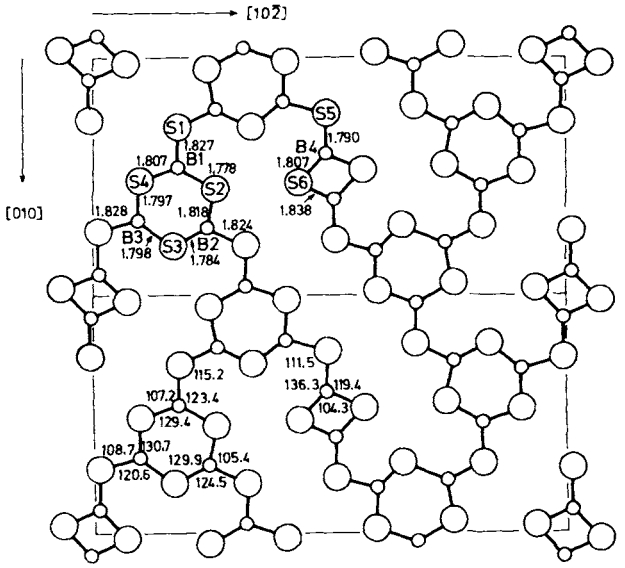

Fig. 1. Layer structure of $B_2S_3$ (two unit cells) with bond lengths [Å] and bond angles [°].

layers, zigzag chains of six-membered rings run parallel to *b*; each six-membered ring is connected to a six-membered ring of a neighboring chain by way of a four-membered ring (located at a center of inversion). All boron atoms have trigonal-planar coordination. Whereas the structure and bonding of the $B_3S_3$ ring correspond to those found for trimeric metathioboric acid $H_3B_3S_6$ and its alkali metal salts[8,38,40,44], the 1,3,2,4-dithiadiboretane ring is highly interesting because the four-membered ring structures in $[BSN(C_2H_5)_2]_2$[45] and in $(BSSH)_2$ and $(BSSC_2H_5)_2$[35-37] could hitherto not be characterized. The very short transannular B...B- (2.237 Å) and S...S distances (2.878 Å) in the strained four-membered ring are remarkable; the mean B–S bond length in the ring (1.823 Å) is slightly larger than the mean value over all B–S bonds of the structure (1.808 Å).

Apart from the trigonal-planar coordination of the boron atoms, the $B_2S_3$ structure has no common features with the three-dimensionally polymeric $B_2O_3$ crystal structure[46,47]. In $B_2O_3$-I, chains of corner-linked planar $BO_3$-triangles running in three different directions are conneted *via* further corners to form a three-dimensional polymer (Fig. 2).

The comparison of the $B_2S_3$ and $B_2O_3$ structures with the recently discovered structure of the metastable high-pressure modification $B_2O_3$-II of much higher density[48,49] (Fig. 3) is particularly instructive. $B_2O_3$-II can be prepared at 65 kbar/1100 °C; it contains tetrahedrally coordinated boron, and its kinetic stability is shown by its insolubility in concentrated acids. From experience in the successful synthesis of thioborates with tetrahedrally coordinated

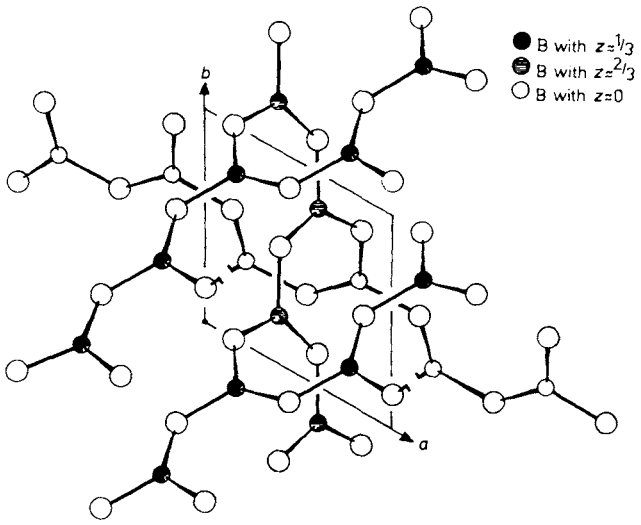

Fig. 2. Crystal structure of $B_2O_3$-I (normal pressure modification [46, 47].

boron ($Ag_6B_{10}S_{18}$, $Pb_4B_4S_{10}$[8,40,42,50]; cf. Section 3) it cannot be ruled out that a similar high pressure form of $B_2S_3$ may exist.

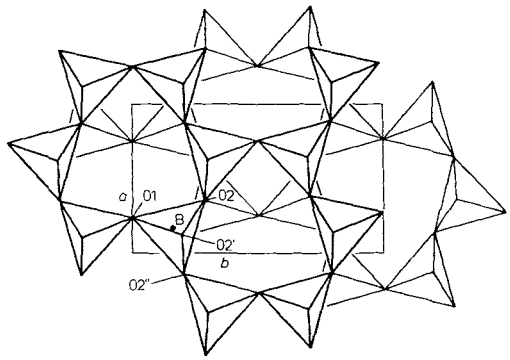

Fig. 3. Structure of the high pressure modification $B_2O_3$-*II* [48].

In spite of the difficulties in its handling, $B_2S_3$ has recently proved to be a valuable starting material for the preparation of new boron compounds as well as an effective sulfurizing agent in organic and inorganic syntheses under mild conditions employing its high reactivity towards proton-containing reagents. Thus, it reacts with alcohols, thiols, amines and carboxylic acids with evolution of $H_2S$ to give $B(OR)_3$, $B(SR)_3$, $B(NHR)_3$, $(BNR_2S)_3$, and $B(OCOR)_3$, respectively[51-57]; acyl complexes such as $(C_5H_5)Fe(CO)_2COR$ and $(CO)_5MCOR$ (M = Mn, Re) react to give dithiocarboxylate complexes $(C_5H_5)Fe(CO)S_2CR$ and $(CO)_4MS_2CR$[57]; $WCl_6$, $NbCl_5$, $TaCl_5$ and $MoCl_5$ are sulfurized to form $WSCl_4$, $NbSCl_3$, $TaSCl_3$, and $MoSCl_3$, respectively[58]. Using $B_2S_3$ as sulfurizing agent for the vanadyl group, the V=S unit in thiovanadyl complexes[59] was obtained for the first time.

### 2.3. $B_6S_{16}$, an "Inorganic Porphin"

A novel and unexpected molecular boron sulfide as well as another crystalline product, both of them having the composition B : S = 1 : 2, were obtained by us on reacting

the elements or $B_2S_3$ and sulfur in a closed system with a temperature gradient[32,33,60,61].

Crystalline colorless $B_8S_{16}$ is formed, *e.g.*, within a narrow zone in the cooler part of the reaction tube, if a $B_2S_3$/S mixture (1 : 1.5) is heated quickly to about 300 °C at $10^{-4}$ bar in a closed protected quartz glass tube in a two-zone furnace with a sharp temperature profile (300/100 °C). Under inert gas, the compound, which is highly sensitive to hydrolysis, melts under normal pressure at 115 °C with decomposition. The crystals consist of discrete, exactly planar $B_8S_{16}$ molecules, the macrocyclic porphin-like arrangement of which contains four 1,2,4,3,5-trithiadiborolane rings joined over sulfur bridges[62] (Fig. 4). Within the limits of error, the molecule has $D_{4h}$-symmetry. The mean bond length (1.811 Å) corresponds to that in $B_2S_3$ (1.808 Å[40,41]) and also indicates strong (n-p)π interaction, in agreement with the planarity of the molecule and the results of the MO-calculations.

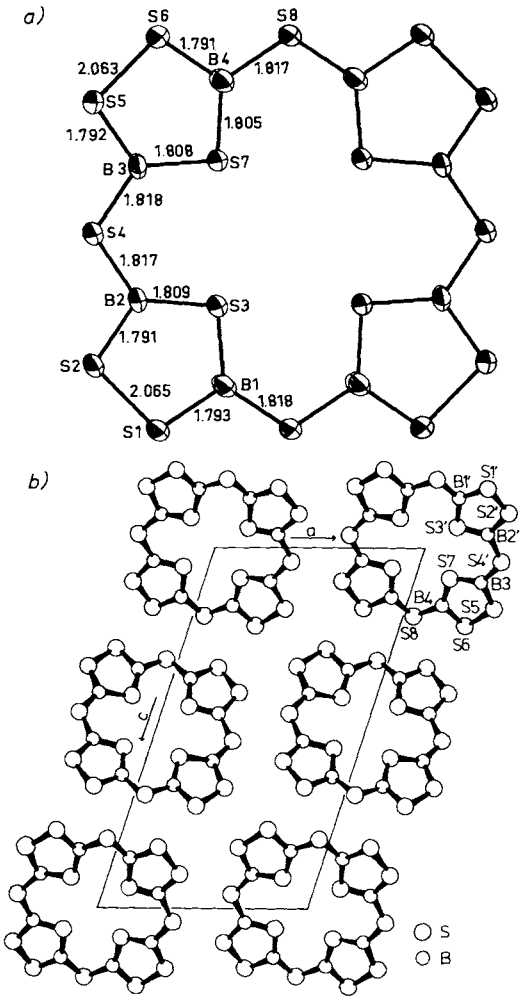

Fig. 4. a) $B_8S_{16}$ molecule with bond lengths [Å] and bond angles [°]. b) Packing of the molecule in the crystal structure.

The significant difference in the two types of B–S bond lengths within the five-membered rings (1.789 and 1.822 Å) corresponds well with the trend of the calculated π-bond orders for trithiadiborolanes[63] and for $B_8S_{16}$[64,65] (Fig. 6). The similarity of the structural characteristics to those of dimethyl- and dichloro-1,2,4,3,5-trithiadiborolane in the gas phase[66,67] shows remarkable constancy of the bonding in the stable five-membered ring, being independent of the substituents. This constancy is also indicated by very similar vibrational spectra (Fig. 5).

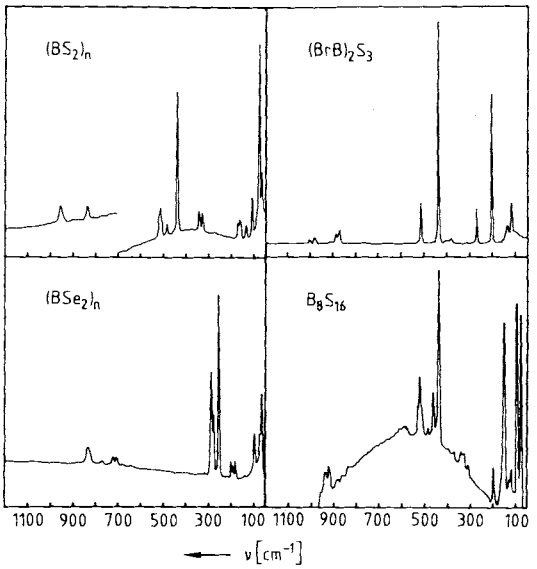

Fig. 5. Raman spectra of 3,5-dibromo-1,2,4,3,5-trithiadiborolane, of $B_8S_{16}$, and of crystalline $(BS_2)_n$ and $(BSe_2)_n$.

The comparison of the bond properties of $B_8S_{16}$ with those of the topologically analogous porphin system is of theoretical and preparative interest with respect to the potential use of the $B_8S_{16}$ macrocycle as a quadridentate ligand in metal complexes. The geometry of the planar molecule (transannular S···S distance about 4.60 Å, cf. Fig. 4) enables a planar coordination of the quadridentate system. Complex formation is observed especially with $d^8$- and $d^9$-transition metals ($Ni^{2+}$, $Pt^{2+}$, $Cu^{2+}$). Indeed, the cyclization of the trithiadiborolanes is favored by these metals. However, the preparative chemistry of $B_8S_{16}$ is complicated by its poor solubility in non-polar solvents and its marked instability towards polar ones. Some quantitative evidence on the bonding is obtained from results of Hückel-MO-calculations on the 32π-electron system of $B_8S_{16}$ as compared to the 26 and 28π-electron systems of porphin and of the porphin dianion[64,65] (Fig. 6).

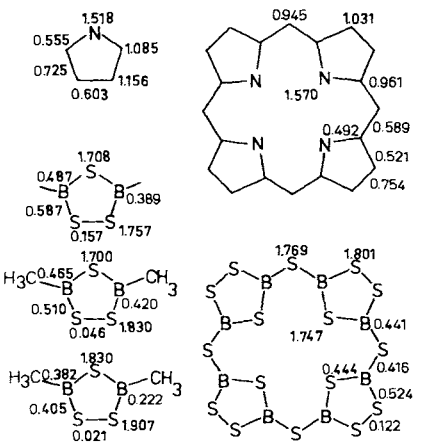

Fig. 6. π Charge densities and π bond orders in $B_8S_{16}$ determined from simple Hückel MO calculations as compared with the $B_2S_3$ ring, with pyrrole, and with porphin [64]. In addition (lower left), values from CNDO/2 and CNDO/S MO calculations for the $(H_3CB)_2S_3$ system are given [63, 65].

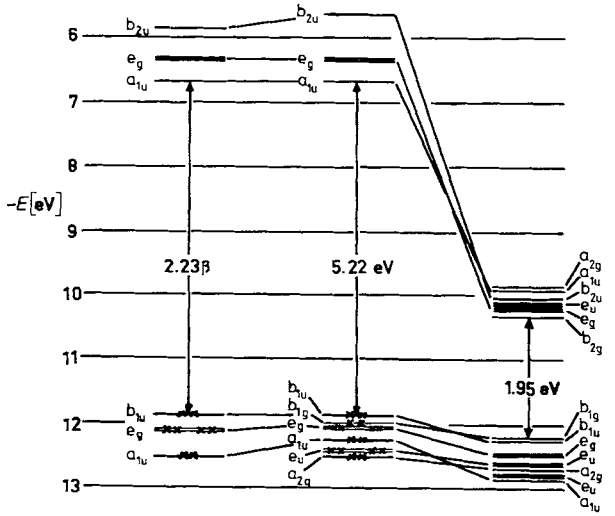
In analogy to the simple $(RB)_2S_3$ system there is considerable $\pi$ bonding in $B_8S_{16}$ with remarkable similarities of the relative distribution compared to that in porphin. The difference in HOMO-LUMO energies ($\pi$-$\pi^*$ transition energy) is only slightly dependent on the semiempirical heteroatom parameters and is, in accordance with electronic spectra, large compared to porphin. The "electron-rich" $B_8S_{16}$ system with more strongly antibonding MO's being occupied has, as expected, a lower delocalization energy and a lower topological resonance energy as compared to porphin. A considerable influence on the size of the HOMO-LUMO gap is observed by inclusion of the 3d-AO's of sulfur in the base set and by the choice of the semiempirical parameters for these functions[65] (Fig. 7). The calculations for $B_8S_{16}$ and for a hypothetical $[CuB_8S_{16}]^{2+}$ complex show qualitatively that $B_8S_{16}$ is a less effective complex ligand as compared to porphin, but that the stabilities of possible transition metal chelates should be comparable to those of macrocyclic thioether complexes.



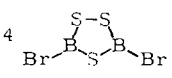


Fig. 7. Energy diagram of $B_8S_{16}$ in the region of the HOMO-LUMO gap (indicated by arrows). Left: simple Hückel calculations; center: extended Hückel calculation without d-AO's of sulfur; right: with d-AO's [65].

Another promising route for the synthesis of $B_8S_{16}$ has been found in the formation of the macrocycle from the components by thiolysis of the halogen-substituted trithiadiborolanes[68-71]. In this way the reaction of 3,5-dibromo-1,2,4,3,5-trithiadiborolane with $H_2S$, with dry $Na_2S$, or with $H_2CS_3$ as $H_2S$-generating agent[72] according to

$$+ 4\ SC(SH)_2 \longrightarrow B_8S_{16} + 4\ CS_2 + 8\ HBr$$

yields the porphin-like $B_8S_{16}$, together with polymeric $(B_2S_4)_n$ chains consisting of S-linked five-membered $B_2S_3$-rings[32,33,60,61,73].

### 2.4. $(BS_2)_n$ and $(BSe_2)_n$

In a slightly modified reaction of $B_2S_3$ with sulfur (cf. Section 2.3), fixing the temperature of deposition at 120–250 °C, surprisingly a new phase is formed, which has been identified by X-ray structure analysis as one-dimensionally polymeric $(BS_2)_n$[32,33,61] (Fig. 8). Similarly to $B_8S_{16}$, this compound consists of trithiadiborolane rings linked by

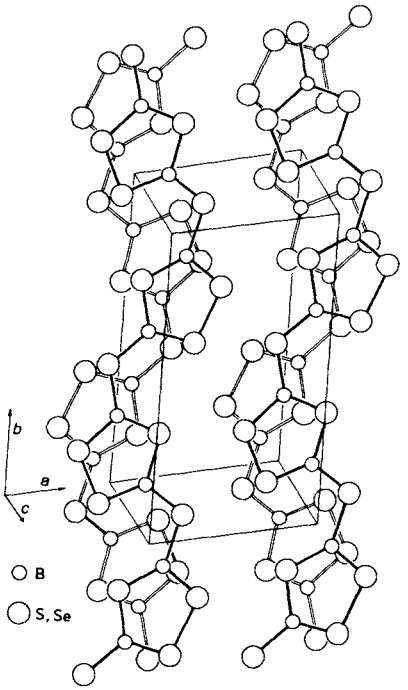

Fig. 8. Crystal structure of $(BS_2)_n$ and $(BSe_2)_n$.

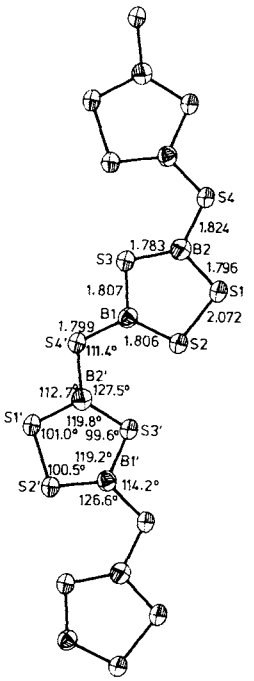
sulfur atoms. The chains are exactly planar. As shown in Figure 9 the bonding is very similar to that in $B_8S_{16}$. The S···S distance between neighboring $B_2S_3$ rings is remarkably short, indicating weak bonding interaction which stabilizes the configuration of the chains. In the isotypic $(BSe_2)_n$, which was prepared in much the same way and which is the first boron selenide to have been structurally



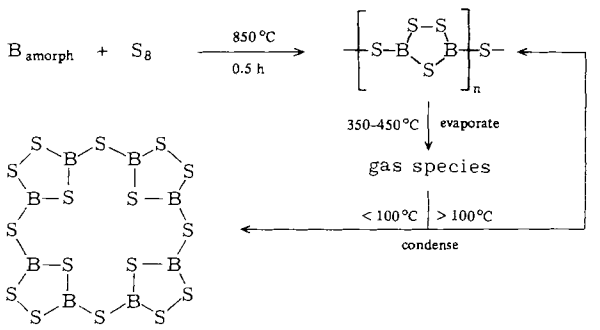


Fig. 9. $(BS_2)_n$-chain with bond lengths [Å] and bond angles [°]. The distance S2...S3' is 3.167 Å.

characterized[32,33,61], the corresponding Se···Se distance is 3.295 Å (B–Se bond lengths 1.90–1.98 Å, Se–Se distance in the ring 2.347 Å).

In a simplified way the synthesis of $B_8S_{16}$ and $(BS_2)_n$ (and analogously of $(BSe_2)_n$) is possible as a concerted reaction according to the following scheme:

$(BSe_2)_n$ can be transported chemically with $I_2$ in a temperature gradient from 300 to 200 °C[32,74].

### 2.5. Mass Spectra and $^{11}$B-NMR Spectra

The mass spectra of the boron sulfides and selenides show remarkable differences[14–18,32,33,75,76]. For stoichiometric $B_2S_3$ as well as for sulfur-rich samples a great number (*ca.* 30) of different fragments between $B_2S_3^+$ and $B_{10}S_{17}^+$ are found at temperatures of 300–650 °C for which $(B_2S_3)_n^+$ and $(BS_2)_n^+$ must be considered parent ions. The volatility of the sulfide (which is polymeric as solid $B_2S_3$) and the relative intensity of the molecular ion $B_8S_{16}^+$ and of its fragments increase considerably with an excess of sulfur over the composition $B_2S_3$ in the solid sample. This finding, which could not be explained previously, is well in accordance with the stability of the cyclic $B_8S_{16}$ molecule.

In the mass spectrum of $B_2Se_3$ and more selenium-rich samples up to $BSe_2$, however, essentially only $BSe^+$, $BSe_2^+$, $B_2Se_2^+$, $B_3Se_2^+$, $BSe_3^+$, $B_2Se_3^+$, and $B_3Se_3^+$ are observed[33,74,76]. This points to a porphin-like $B_8Se_{16}$ molecule being unstable in contrast to the polymeric $(BSe_2)_n$ chain.

Important results regarding the structure of glassy boron chalcogenide systems were recently obtained from $^{11}$B-broad line-NMR experiments[77] (cf. also [78–83]). In this method, which is very well suited for the investigation of noncrystalline boron compounds, the line-shape of the NMR signals is primarily determined by the interaction of the $^{11}$B nuclear quadrupole moment with the electrical field gradient generated by chemical bonding, and so reflects the state of hybridization of the boron atoms. With regular tetrahedral coordination, the spectrum shows a sharp line not influenced by quadrupole effects, whereas, $sp^2$ hybridization results in 2nd order quadrupole splitting (Fig. 10).

In the course of the study[77–79] the bond formation of boron with sulfur and selenium was monitored NMR-spectroscopically. The investigations confirm the existence in the glass of the binary compounds $B_2S_3$, $BS_2$ and $BSe_2$, which can be prepared in almost quantitative yield, and whose NMR signals indicate that the boron atoms are trigonally planar coordinated. The compounds $B_4S$, BS, $B_2S_5$, $B_4Se$ and $B_2Se_3$ (!) published in the literature *(vide supra)* could not be detected. According to the NMR data about one third of the S atoms in $B_2S_3$ can be substituted by Se without losing the homogeneity of the phase. A sample "$B_2Se_3$" disproportionates into $BSe_2$ and an amorphous boron-rich subselenide, whose B : Se ratio depends on the reaction conditions. Compound formation between boron and tellurium (with the exception of possible boron-rich tellurides) could not be observed.

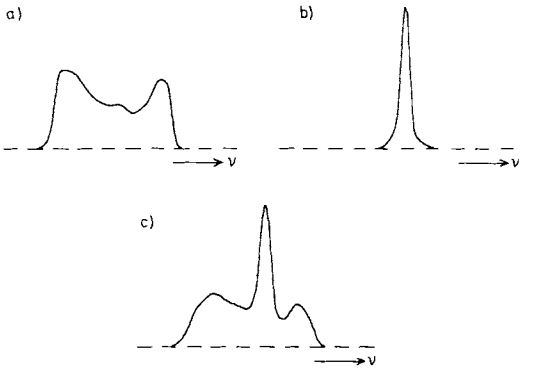

Fig. 10. $^{11}$B-NMR broad line spectra (integrated line form) of (a) trigonally planar and (b) tetrahedrally coordinated boron-sulfur compounds. (c): Spectrum of a $B_2S_3/Tl_2S$ mixture in a 10 : 1 molar ratio (superposition of signals for trigonally planar and tetrahedrally coordinated boron).

The exact value of the quadrupole-coupling constants of $sp^2$-hybridized boron compounds is influenced by the extent of the (n-p)π bonding by which excess electron density is transferred from the non-bonding electron pairs of the substituents into the free p-orbital of the boron atom. The symmetry of the electronic environment of the $^{11}$B core is increased with concomitant lowering of the quadrupole-coupling constant. The data for the boron chalcogenides investigated (cf. Fig. 11) indicate significantly more π-bonding in $BS_2$ and $BSe_2$ than in $B_2S_3$. This demonstrates the increased donor-effect of the disulfide bridge (B–S–S–B) as opposed to the sulfide bridge (B–S–B), and agrees with the trends derived from the CNDO- and simple Hückel-calculations on trithiadiborolanes and $B_8S_{16}$ (cf. Fig. 4 and 6).

The quantitative interpretation of the $^{11}$B quadrupole coupling constants of $B_2O_3$ and $B_2S_3$ indicates significantly smaller double bonding character in the B–S bonds than in the B–O bonds. From the analysis of the $^{11}$B line shape the next-neighbor-structure in glassy $B_2S_3$ is definitely more uniform than in the $B_2O_3$ glass, owing to different connecting principles of the trigonal planar units. In spite of this, added network modifiers seem to have an almost identical influence in both glasses. As in analogous oxide systems[84], tetrahedrally coordinated boron is produced by the additional chalcogen also in $B_2S_3/Tl_2S$ glasses (Fig. 10). Above 33.3 mol-% $Tl_2S$ the concentration of these units decreases again; parallel to this the sudden change of the $^{205}$Tl-resonance parameters indicates the formation of a new configuration with trigonal $sp^2$-hybridized boron atoms as well as much more covalent Tl–S bonds. However, the glassy structure accepts these species only in low

concentration; above 57 mol-% $Tl_2S$, separation of a crystalline phase of the probable composition $Tl_3BS_3$ is observed.

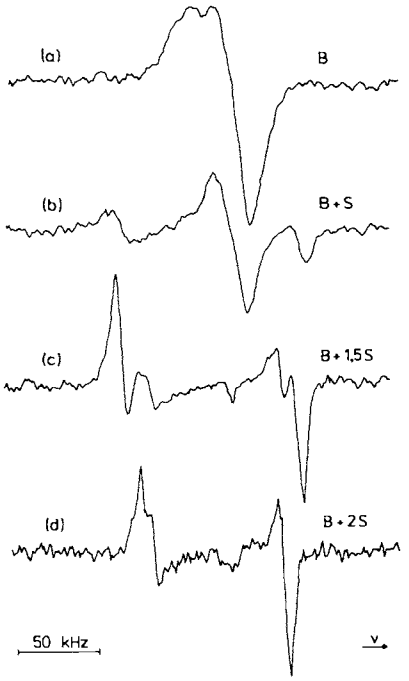

Fig. 11. $^{11}$B-NMR-study of compound formation in the boron-sulfur system (measuring frequency 7.06 MHz). The first derivatives of the frequencies are recorded. Besides elementary (amorphous) boron in (b) the signals of $B_2S_3$ appear, which reach their maximum in (c). In (c) weak signals of $BS_2$ with smaller quadrupole splitting are already present, which occur in the spectrum (d) with maximum intensity.

## 3. Thioborates

As in the case of binary boron chalcogenides there are a number of references in the literature on ternary phases, which, however, are incomplete and partly contradictory. Information about the structure and bonding have been obtained only recently. Generally, high temperature reactions of the solid elements or the binary sulfides in closed systems are employed as preparative methods. As reaction products (frequently insufficiently characterized) alkali, alkaline earth and heavy-metal salts $M^{I}BS_2$[44,85–90], $M^{II}(BS_2)_2$[91,92], $M^{I}_4B_2S_5$[86,90], $M^{II}_2B_2S_5$[39,50,92,93], $M^{I}_3BS_3$[86,89], $M^{I}_8B_2S_7$[86,90], $M^{I}_5BS_4$[94] and $M^{I}_4B_6S_{11}$[89] are described, as well as "perthioborates" $M^{I}_2B_2S_5$[95] and $M^{I}BS_3$[89,95] and the sulfur-deficient phases CuBS and AgBS[87,96].

Sulfur can also be introduced by $H_2S$ (*e.g.* according to $3K_2S+6B+9H_2S \rightarrow 2K_3B_3S_6+9H_2$)[22]. Interesting methods of preparation employ tetrahydroborates and sulfur. Without solvents, metathioborates $MBS_2$ (M = Li, Na, K) are formed at 200–300 °C[97,98], while hydrothioborates $Li[BH_3SH]$ and $Li[B_3S_2H_6]$ are discussed as reaction products in solution[97], as is also a $BH_2S_3^-$ ion, which is supposed to be in equilibrium with a cyclic $H_2B(S_3)_2BH_2^{2-}$[99].

Successful structure analyses of some of these phases and of some new compounds led to progress in an understanding of the structural and bonding principles in question. The thioborates $M^{I}BS_2$ are derivatives of the trimeric cyclic metathioboric acid $H_3B_3S_6$ (cf. Section 2.2), which can be obtained, *inter alia*, by reaction of $BBr_3$ with $H_2S$ in $CS_2$ or $C_6H_6$ solution[36,100], and, like the acid, they therefore resemble the corresponding oxo-compounds $H_3B_3O_6$ and $M^{I}_3B_3O_6$. The crystal structures of $H_3B_3S_6$[38], $Na_3B_3S_6$ and $K_3B_3S_6$[8,40], in accordance with the vibrational spectra[8,44], show exactly planar six-membered ring molecules. $Na_3B_3S_6$ and $K_3B_3S_6$ are isotypic and crystallize rhombohedrally (space group $R\bar{3}$, $a=9.080$ (9.390) Å, $\alpha=112.70$ (111.46)°[8,40,42]). As shown in Figure 12, the terminal B–S bonds of the anions are significantly shortened compared to those in the acid ( and to all bonds of $B_2S_3$), indicating here remarkably higher $\pi$-bond orders.

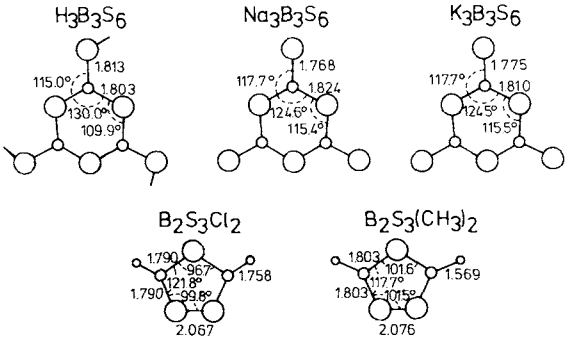

Fig. 12. Molecular geometry of metathioboric acid $H_3B_3S_6$ as compared to the $B_3S_6^{3-}$ ions in $Na_3B_3S_6$ and $K_3B_3S_6$.

The unusual and surprising coordination number 4 of boron towards sulfur is observed in the two heavy metal thioborates $Pb_2B_2S_5$[8,40,50] and in the new $Ag_3B_5S_9$[8,40,42], which does not belong to any known formula type. In both compounds, tetrahedral $BS_4$-groups are linked to larger units *via* corners, in the case of the black $Pb_2B_2S_5$ to quasi-isolated tetrameric adamantane-like $B_4S_{10}^{8-}$ anions (Fig. 13). The stability of the highly negatively charged ion, which is isostructural and iso-valence-electronic to $P_4O_{10}$, $P_4S_{10}$ and $Ge_4S_{10}^{4-}$, is remarkable; however, it must be assumed that this high formal charge is reduced by stabilizing covalent bond contributions to the $Pb^{2+}$ cations.

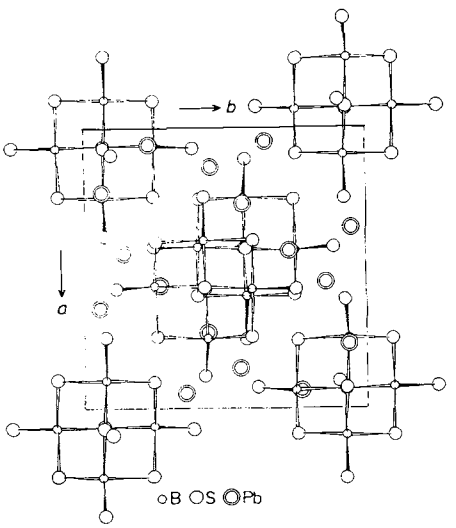

Fig. 13. Adamantane-like $B_4S_{10}^{8-}$ anions in the structure of $Pb_2B_2S_5$.

In the dark-red $Ag_3B_5S_9$, ten $BS_4$ tetrahedra form rigid $B_{10}S_{20}$ "super-tetrahedra" which may be regarded as fragments of the diamond (zinc blende) structure. The super-tetrahedral $B_{10}S_{20}$ units are linked over all four corners into a layer-like framework with the stoichiometric composition of $B_{10}S_{16}S_{4/2}^{6-} = B_{10}S_{18}^{6-}$ (Fig. 14). According to the model of significant π-bonding in trigonally planar coordinated boron compounds, the B–S bond lengths in the tetrahedra, with mean values of 1.927(14) Å in $Pb_2B_2S_5$[8,40] and 1.915(5) Å in $Ag_3B_5S_9$[8,40], are considerably longer than the values in the region of 1.79–1.81 Å for planar $BS_3$-groups[101].

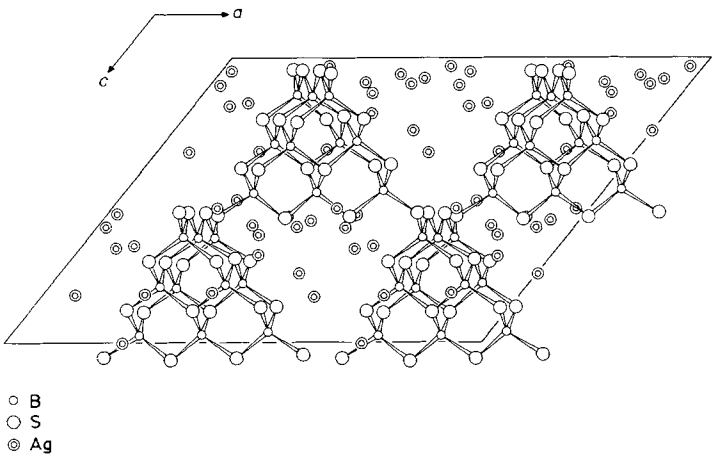

Fig. 14. $Ag^+$ ion-conducting $Ag_3B_5S_9$: Section of the structure with corner linked $B_{10}S_{20}$ "supertetrahedra" and partially occupied silver positions.

There is special chemical interest in the absolute stability of both compounds with regard to hydrolysis and oxidation as opposed to all planar coordinated BS compounds; the electronically rather saturated boron in the $BS_4$ polyhedra is effectively shielded against nucleophilic attack. This stability, which in this case is enhanced by the heavy metal coordination of sulfur, can also be expected in other boron compounds tetrahedrally coordinated by sulfur. $Ag_3B_5S_9$ is of special interest because it is a $Ag^+$ ionic conductor already at room temperature. In the crystal structure[102] the 6 $Ag^+$ ions of the asymmetric unit are distributed over 18 partially occupied sites with occupancy factors ranging from 0.10 to 0.84 and with coordination numbers of 2, 3 and 4, so that there are favorable conditions for mobility of the $Ag^+$ ions[8,42,209].

So far, there is no model in thioanion chemistry for the structure of the first "perthioborate" $TlBS_3$[103], which is obtained in crystalline form from a 1:2:5 mixture of $Tl_2S$, B and S at 800 °C with subsequent annealing at 170/350 °C[89,103]. The polymeric chain-shaped $(BS_3^-)_n$ anion consists of corner-sharing, practically undistorted $BS_4$ tetrahedra ($d_{BS} = 1.927$ Å); two corners of each tetrahedron are part of $S_2$ groups ($d_{SS} = 2.09$ Å) which form additional bridges to neighboring tetrahedra (Fig. 15). The molecular structure can also be described as a poly-spirocyclic system of non-planar B–S–S–B–S five-membered rings with boron atoms as bridgehead centers (Fig. 16).

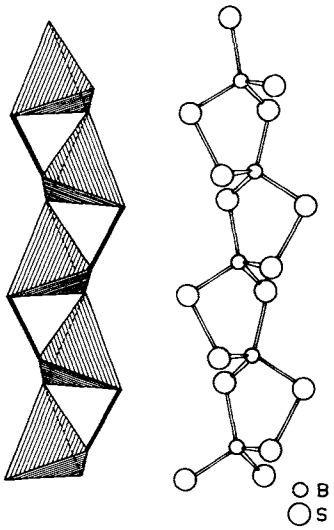

Fig. 15. $(BS_3^-)_n$ chain in the crystal structure of $TlBS_3$ (cf. also Fig. 26) in two different representations. The structure of this novel perthioanion may be considered as an addition product of $(BS_2)_n$ (Fig. 9) and $S_2^{2-}$ ions.

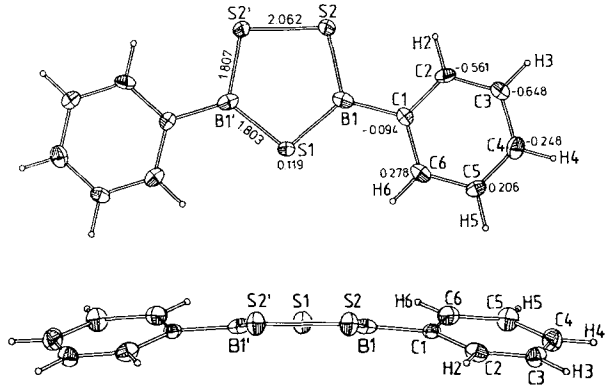

Fig. 16. Non-planarity of the 3,5-diphenyl-1,2,4,3,5-trithiadiborolane molecule. The $B_2S_3$ ring has envelope configuration. The plane of the phenyl ring is tilted by 21.0° with respect to the B1S2S2'B1' plane, and by 18.8° with respect to the B1S1S2C1 plane. The $BS_2C$ triangle is exactly planar. Bond lengths in Å. The numbers in the right part of the upper figure give the distances of the atoms from the B1S2S2'B1' plane.

The relation to the $(BS_2)_n$ and $(BSe_2)_n$ chain-structures (Fig. 8 and 9) is remarkable: $(BS_3^-)_n$ can be formed in a simple way according to

$$(BS_2)_n + \frac{n}{2} S_2^{2-} \longrightarrow (BS_3^-)_n$$

by nucleophilic addition of the $S_2^{2-}$ ions to the boron atoms with accompanying $sp^2 \rightarrow sp^3$ extension of the coordination and formation of new (non-planar) $B_2S_3$ rings. Interesting relationships also exist between the $(BS_3^-)_n$ configuration and the different $(GeS_3^{2-})_n$ and $(SnS_3^{2-})_n$ chain structures (Fig. 26).

## 4. Remarks on the BS Bonds

The concept that significant π bonding through the interaction of p electrons of sulfur with the $p_z$ orbital of $sp^2$-hybridized boron is present in trigonal-planar sulfur compounds like in BF, BO and BN compounds, has been con-

troversial for some time[104-106]. Arguments against π bonding are, *e.g.*, spectroscopically determined stretching force constants of 2.5 to 2.85 N/cm for $(CH_3S)_3B$, $(CH_3)_2S-SH$, $(CH_3)_2B-SCH_3$ and $(CH_3)_2B-S-B(CH_3)_2$[106], which are not larger than the estimated single bond value[107] (see Table 1). Besides the reactive properties of many BS compounds (*e.g.* of thioboranes or of planar cyclic trithiadiborolanes[108,109]), ionization energies from mass spectra[110], PE spectra of the thioboranes $(CH_3S)_nB(CH_3)_{3-n}$[109] and of sulfur-containing five-membered ring heterocycles[111], the mentioned CNDO/2 and CNDO/S-MO calculations on trithiadiborolanes[63,64] as well as *ab initio* calculations on $H_2B-SH$[112] support the presence of significant (n-p)π bonding contributions.

Another argument for an effective π overlap is the exact planarity (within the limits of error) of the $sp^2$-$BS_3$, $BS_2R$ and the $BSR_2$ systems (*e.g.* [38,40]) structurally characterized so far. In this context the non-planarity of $B_2S_3(C_6H_5)_2$, as a further derivative of the trithiadiborolane series, is all the more surprising[113] (Fig. 16). Only the $BS_2C$ unit is strictly planar, while the $C_6H_5$ rings are twisted around the BC bond. This indicates reduced BC π bonding; (n-p)π overlap in the S1B1S2 fragment, using suitable hybridized orbitals of sulfur, is, however, possible.

With values of *ca.* 1.78—1.82 Å (mean value 1.80 Å) for trigonally coordinated and *ca.* 1.92—1.94 Å (mean value 1.93 Å) for tetrahedrally coordinated boron, the B—S bond lengths are remarkably constant in all compounds examined so far[23], while the difference in the two values is considerably greater than in the homologous systems $BCl_3$ (1.76 Å) and $BCl_4^-$ (1.84 Å). This, together with the experimental B—C single bond lengths of 1.55 Å in $B_2S_3(C_6H_5)_2$[113] (Fig. 16) and of 1.58 Å in trimethylborane[114] suggests single bond covalent radii of 0.93 Å for tetrahedrally coordinated boron as well as 0.85 Å for trigonal-planar boron[115]. These values (cf. [23]) correspond better to the new experimental data than the *Pauling* values[116] of 0.88 and 0.81 Å.

## 5. Thiogallates and Thioindates—New Synthetical Methods and New Structural Principles

Ternary chalcogenides of gallium and indium are usually prepared by high-temperature melt or solid-state reactions (*e.g.* [117-122]), since in polar solvents solvolysis was to be expected. By nucleophilic degradation of $Ga_2S_3$ and $In_2S_3$ in concentrated aqueous sulfide solutions, however, molecular thiogallates and thioindates as well as analogous seleno compounds have recently been synthesized[123-127] (see also [128]). Over a wide concentration range, $Ga_4S_{10}^{8-}$, $Ga_4Se_{10}^{8-}$, $In_4S_{10}^{8-}$ and $In_4Se_{10}^{8-}$ are the predominant species which can be isolated, in the form of strongly hydrated, colorless alkali metal salts (*e.g.* $Na_8In_4S_{10}\cdot 14H_2O$, $K_8Ga_4S_{10}\cdot 14H_2O$)[123-127]. X-ray structural analyses of these phases show that the anions, like $B_4S_{10}^{8-}$ in $Pb_2B_2S_5$, are adamantane-like and have almost ideal $T_d$ symmetry (Fig. 17). Their thermal and solvolytic stability is remarkable.

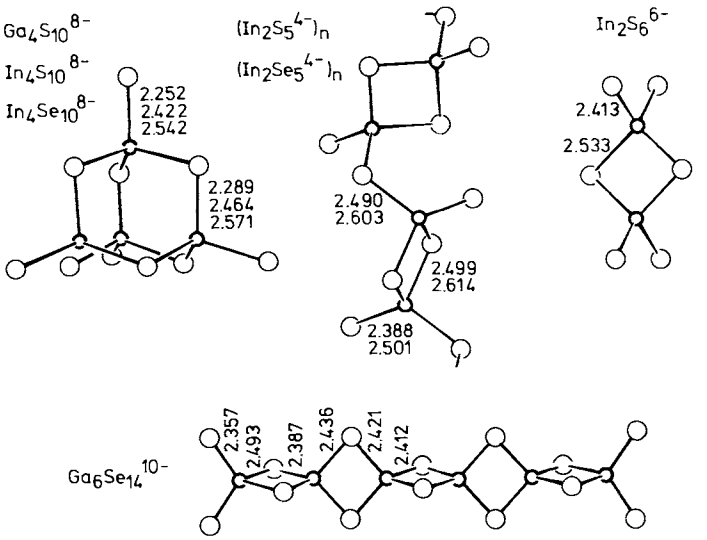

Fig. 17. Adamantane-like $Ga_4S_{10}^{8-}$, $Ga_4Se_{10}^{8-}$, $In_4S_{10}^{8-}$ and $In_4Se_{10}^{8-}$ from aqueous solution, as well as $(In_2S_5^{4-})_n$, $(In_2Se_5^{4-})_n$, $In_2S_6^{6-}$ and $Ga_6Se_{14}^{10-}$ prepared by high-temperature methods, with bond lengths [Å].

Anhydrous thioindates and thiogallates of the alkali metals and their seleno analogues known so far have the composition $MInS_2$, $MGaS_2$, $MInSe_2$ and $MGaSe_2$ (M = Li, Na, K, Rb, Cs), and have been investigated in earlier systematic structural work[117,118] and in connection with high-pressure transformations[119]. According to these investigations $NaInS_2$ and $NaInSe_2$[117] as well as the high-pressure modification $KInS_2$-III[119] belong to the α-$NaFeO_2$-type with octahedral coordination of In; the high-pressure forms $KInS_2$-II and $RbInS_2$-II are isotypic with TlSe ($InS_4$ tetrahedra)[119], whereas the structural principle of the important stable form of the K, Rb and Cs compounds was hitherto unknown, owing to extensive disorder and twinning problems. Recently, the structural principle could be solved in $KInSe_2$[129,130]: The compound does not form the predicted $KFeS_2$-type chain structure (which is realized in $CsGaS_2$[120]) but shows a layer structure in which adamantane-like $In_4S_{10}$ groups are linked two-dimensionally *via* corners. K is in trigonal-prismatic coordination (Fig. 18). This type of structure corresponds to that of $TlGaSe_2$, which was structurally characterized in 1978[131] and which, as a semiconductor, is of some importance for opto-electronic applications[132].

Other novel thioindates and selenogallates could be obtained by unconventional reactions of rubidium with indium monosulfide or of cesium with gallium monosele-

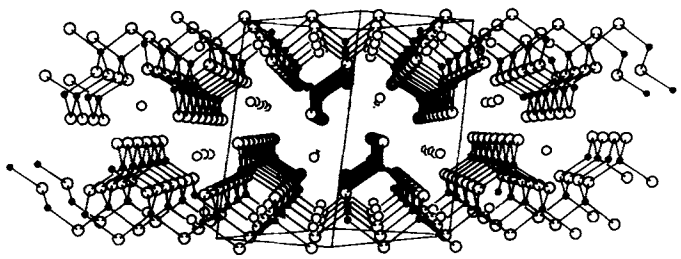

Fig. 18. $KInSe_2$ and $TlGaSe_2$ structures: layers of corner-linked adamantane-like $In_4Se_{10}(Ga_4Se_{10})$ groups.

nide. In the first case $Rb_4In_2S_5$ and $Rb_6In_2S_6$[133] are formed which contain dimeric $In_2S_6$ units of two edge-sharing $InS_4$ tetrahedra. In $Rb_4In_2S_5$, as well as in the similar $Rb_6In_2Se_5$[129], these units are linked to form polymeric $(In_2S_5^{4-})_n$ and $(In_2Se_5^{4-})_n$ chains by corner-sharing; in $Rb_6In_2S_6$ they exist as isolated $In_2S_6^{6-}$ ions (Fig. 17). In the case of the Ga/Se/Cs reaction the 19 Å-long, edge-coupled, unusual $Ga_4Se_{14}^{10-}$ ion is obtained in the compound $Cs_{10}Ga_4Se_{14}$[134], which was also characterized by X-ray structural analysis (Fig. 17).

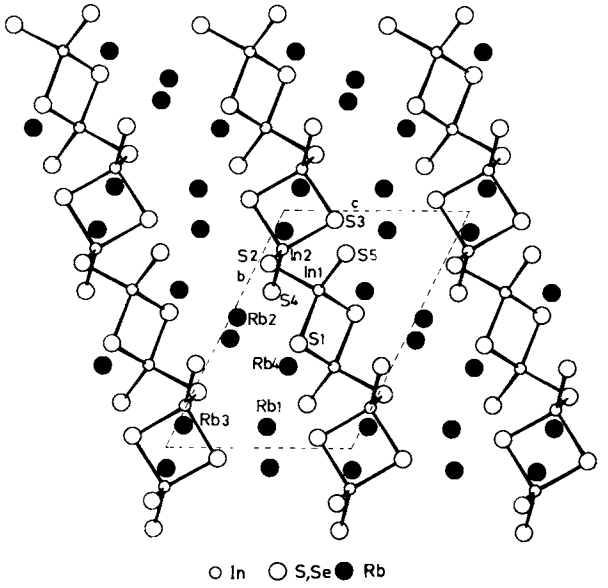

Fig. 19. $(In_2S_5^{4-})_n$ and $(In_2Se_5^{4-})_n$ chain structure in the unit cell of $Rb_4In_2S_5$ [133] and $Rb_4In_2Se_5$.

A selenogallate $Na_2Ga_2Se_3$ with Ga–Ga bonds (2.40 Å) can be synthesized from a 2:2:3 mixture of the elements at 990 °C; the structure contains, in a distorted $NaCrS_2$-type, layers of linked $Ga_2Se_6$ groups with staggered conformation[135].

## 6. Thiosilicates, Thiogermanates, and Thiostannates

Particularly impressive developments have been taking place over the last decade in this area of thioanion chemistry. Preparative work in solution at normal temperature and also in the area of high-temperature melt and solid-state reactions in conjunction with modern methods of X-ray structure analysis and of Raman spectroscopy has enabled a system of monomeric, oligomeric and polymeric thioanions to be developed. In spite of essentially different principles of formation and structure, and of different chemical properties (see below), some features of this new class of compounds are reminiscent of the diversity of the corresponding oxygen compounds, particulary the silicates.

A systematic survey, in particular of the solid state and structural aspects of ternary sulfides of silicon, germanium and tin[136] has recently been published[137] which summarizes the important literature up to 1976, so that in this review our account of some recent remarkable developments in this field will concentrate mainly on the molecular aspects.

### 6.1. Polynuclear Thio- and Selenoanions from Condensation Reactions

Every student of chemistry who, in his practical inorganic training, has learned the qualitative analytical separation procedures for cations by means of precipitation of the sulfides, is familiar with the formation of thioanions of tetravalent tin, of arsenic, and of antimony. In textbooks these are correctly formulated as $SnS_4^{4-}$ or $SnS_3^{2-}$ and as $AsS_3^{3-}$, $SbS_3^{3-}$, $AsO_xS_{4-x}^{3-}$ or $SbO_xS_{4-x}^{3-}$; however, up to 1970 no further information about the chemistry of these monomeric tetrahedral ions had been published. On critical examination it could not be understood why thionanions should not be able to enter into similar condensation reactions in solution as the corresponding oxoanions. Indeed, in the case of thiogermanates and thiostannates a series of new polythioanions can be successfully prepared by conventional nucleophilic degradation of the polymeric sulfides $GeS_2$ and $SnS_2$ with aqueous alkaline sulfide solutions. For the isolation of pure phases an exact control of the pH value and the concentration ratio of the individual reaction components is necessary. Like the thioanions of the neighboring elements of the 3rd and 5th main groups, the thioanions are colorless and, as alkali metal and alkaline earth salts, are readily soluble in water. So far, the following thiogermanates and thiostannates have been generated in solution, isolated as crystalline phases, and have been structurally completely characterized:

- monomeric species $GeS_4^{4-}$ and $SnS_4^{4-}$ as well as corresponding selenoanions $GeSe_4^{4-}$ and $SnSe_4^{4-}$, which are present as undistorted tetrahedral (hydrated) ions in solution and in the crystalline salts[138–141] (Fig. 20);

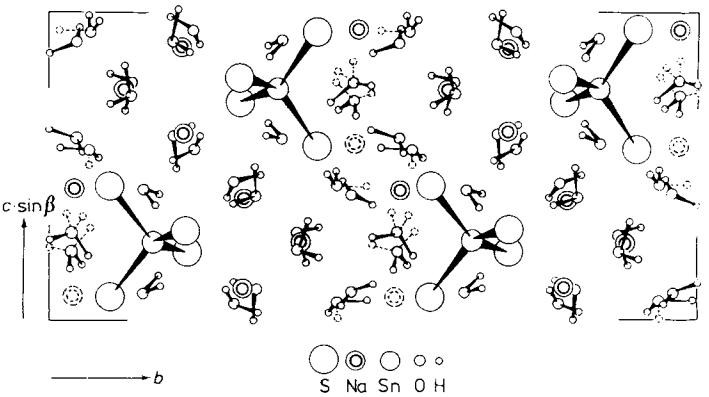

Fig. 20. Structure of $Na_4SnS_4 \cdot 14\,H_2O$. The $Na^+$ ions are coordinated octahedrally by $H_2O$ molecules; the thioanions and $H_2O$ molecules are linked by OH···S hydrogen bridges. Part of the Na-$H_2O$ system is disordered in the crystal [138].

- dimeric species $Ge_2S_7^{6-}$, $Ge_2Se_7^{6-}$, $Sn_2S_7^{6-}$ and $Sn_2Se_7^{6-}$, composed of two corner-sharing tetrahedra, the structures of which correspond to familiar oxoanions such as $Si_2O_7^{6-}$, $P_2O_7^{4-}$, $S_2O_7^{2-}$ or $Cr_2O_7^{2-}$ and represent the first step of the tetrahedral condensation reactions[142];
- a new type of dimeric species $Ge_2S_6^{4-}$, $Ge_2Se_6^{4-}$, $Sn_2S_6^{4}$ and $Sn_2Se_6^{4-}$, consisting of two edge-sharing tetrahedra[143–145];

- polymeric species $(GeS_3^{2-})_n$ and $(SnS_3^{2-})_n$, formed by corner-sharing tetrahedral chains which are produced by crystallization from solutions with similar intermediate pH values (Fig. 25) and which are isomeric with $Ge_2S_6^{4-}$ and $Sn_2S_6^{4-}$[146];
- tetrameric adamantane-like species of the composition $Ge_4S_{10}^{4-}$, $Ge_4Se_{10}^{4-}$, $Sn_4S_{10}^{4-}$ and $Sn_4Se_{10}^{4-}$, which are produced as the predominant condensation products in solutions of lower pH-values (depending on the system, between pH = 7 and pH = 3), *i.e.* at higher degrees of protonization of the thioanions and sulfide anions taking part in the condensation reactions[147-149] (Fig. 21);

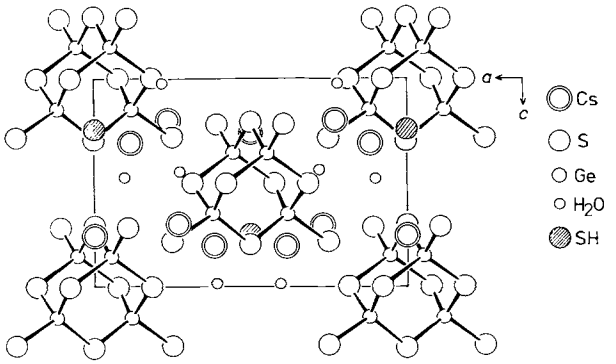

Fig. 21. Adamantane-like $Ge_4S_{10}^{4-}$ ions in the crystal structure of $Cs_4Ge_4S_{10} \cdot CsSH \cdot 4H_2O$.

- $Ge_8S_{19}^{6-}$, which is formed from two adamantane-like species by condensation over one corner[150, 151] (Fig. 22);

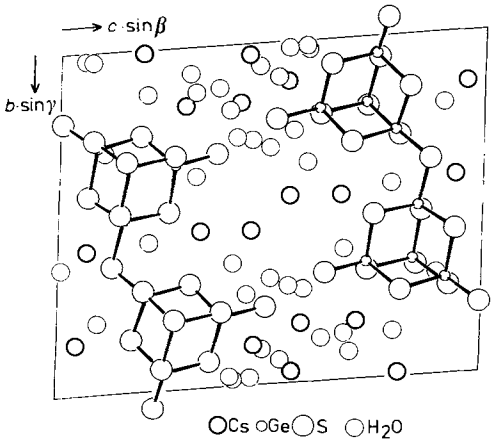

Fig. 22. $Ge_8S_{19}^{6-}$ ions in $Cs_6Ge_8S_{19} \cdot 12H_2O$.

- in the case of tin, at pH = 3 a novel macro-polyanion of the composition $Sn_{10}O_4S_{20}^{8-}$ having unusual structural properties[151, 152] (Fig. 23).

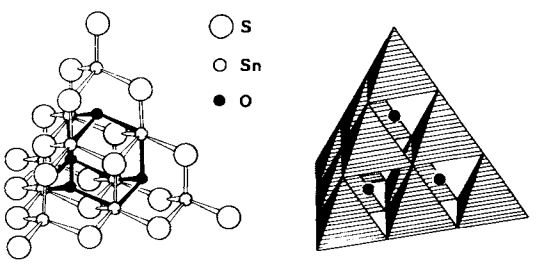

Fig. 23. $Sn_{10}O_4S_{20}^{8-}$, the largest known molecular main group thioanion. The oxygen atoms are bonded to only three of the four neighboring Sn atoms [152].

All the types of ions mentioned are listed in Figure 24. Figure 25 schematically presents the stability ranges of thiogermanates in aqueous solution. Generally it can be recognized that in comparison to the condensation reactions of oxoanions, *e.g.* of silicates and germanates, the pH ranges for comparative degrees of condensation are shifted to lower values in the case of sulfur compounds due to their markedly higher acidity.

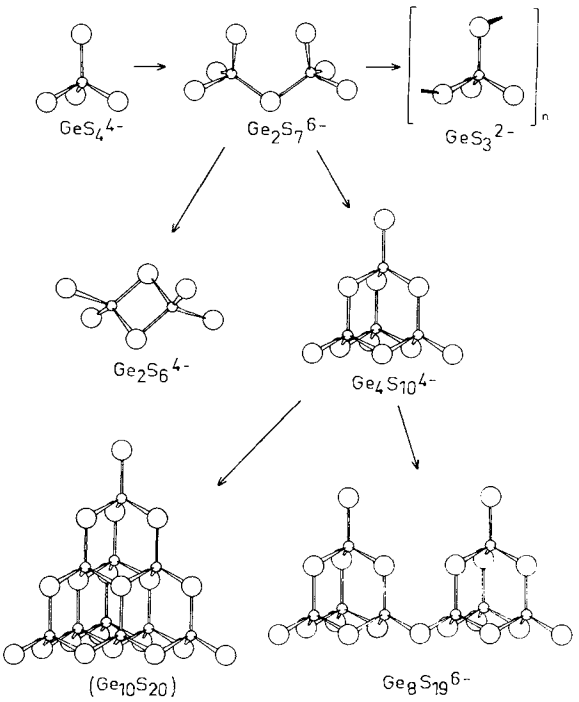

Fig. 24. Condensation paths of thioanions in aqueous solutions, shown for the thiogermanates. The $X_{10}Y_{20}$ "supertetrahedron" at the lower left has not yet been prepared in the case of germanium; it is realized in $Sn_{10}O_4S_{20}^{8-}$ with inserted oxygen atoms (Fig. 23), and in the corner-linked polymeric anion $(B_{10}S_{18}^{6-})_n$ of $Ag_3B_5S_9$ (Fig. 14).

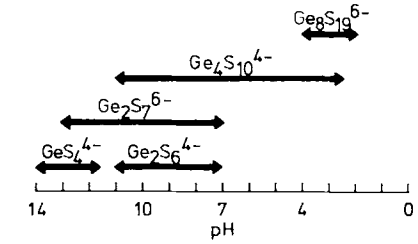

Fig. 25. Ranges of existence of oligomeric thiogermanate anions in aqueous solution.

Like the dimeric and tetrameric ions the simple tetrahedral species produced in solution (Fig. 20) have features in common with several water-free phases, which were prepared by solid-state reactions[137] and correspond to the tetrahedral structural units in the phases $M_4^IM'S_4$, $M_2^{II}M'S_4$ and $M_4^{III}(M'S_4)_3$ (with $M^I$ = Na, Tl, Cu; $M^{II}$ = Mg, Ca, Sr, Ba, Pb, Mn, Fe, Eu; $M^{III}$ = rare earth metal; M' = Si, Ge, Sn) or in chalcopyrite-type phases like $Cu_2M^{II}GeS_4$ or $Cu_2M^{II}SnS_4$ (cf. [137]).

The edge-sharing of the tetrahedra in $Ge_2S_6^{4-}$ and related species, just as in the similar $In_2S_6^{6-}$ and $In_2Se_6^{6-}$ ions and in formally analogous thio-compounds of the

transition metals such as $Fe_2S_6^{6-}$[153], shows a general structural principle which appears to be typical for certain sulfur and selenium compounds, whereas it is realized only in exceptional cases in oxygen compounds[154]. Important examples illustrating this are the structures of $SiS_2$ and of $SiSe_2$ (edge-sharing tetrahedral chains[155, 156]) in contrast to the different modifications of $SiO_2$[157], and, furthermore, the silicon sulfide halides $(SiSCl_2)_2$ and $(SiSBr_2)_2$ (cf. Section 7) and unusual edge-sharing of tetrahedra in the high-temperature modifications of $GeS_2$ and $GeSe_2$[160]. $Ge_2S_6^{6-}$ and its related ions may formally be considered to be dimeric fragments of the polymeric $SiS_2$ chain structure. The "metathiostannate" $SnS_3^{2-}$ of the earlier literature is thus identified by structural analysis as a hexathiodistannate $Sn_2S_6^{4-}$.

The structural principle of the $(GeS_3^{2-})_n$ and $(SnS_3^{2-})_n$ chains, *e.g.* in $K_2SnS_3 \cdot 2H_2O$[146], corresponds to the "Zweiereinfachketten" in silicate chemistry[161] and is also realized in the water-free phases $PbGeS_3$[162] and $Na_2GeS_3$[163] in cation-dependent variants, as well as in a modified form in the novel $TlBS_3$ phase[103] (Fig. 26).

The adamantane-like $Si_4S_{10}^{4-}$ and analogous $Si_4Se_{10}^{4-}$ cannot be prepared in solution due to the sensitivity of the Si–S bond towards solvolysis, but it is a product of high-temperature reactions, *e.g.* as $Na_4Si_4S_{10}$[164]. Water-free thio- and selenogermanates (*e.g.* $Na_4Ge_4S_{10}$[165], $Ba_2Ge_4S_{10}$[164], $Tl_4Ge_4S_{10}$[166], $Tl_4Ge_4Se_{10}$[167]) can be prepared in the same way from high-temperature solid-state and melt reactions, in contrast to the crystalline phases from solution (for example $Cs_4Ge_4S_{10} \cdot 3H_2O$[148] and $Na_4Ge_4S_{10} \cdot 17H_2O$[151]). The adamantane-like thiogermanic acid $H_4Ge_4S_{10} = Ge_4S_6(SH)_4$ can be obtained in dimethylformamide as monomeric solvated molecules which, however, tend to polymerize if its isolation in the solid state is attempted[149].

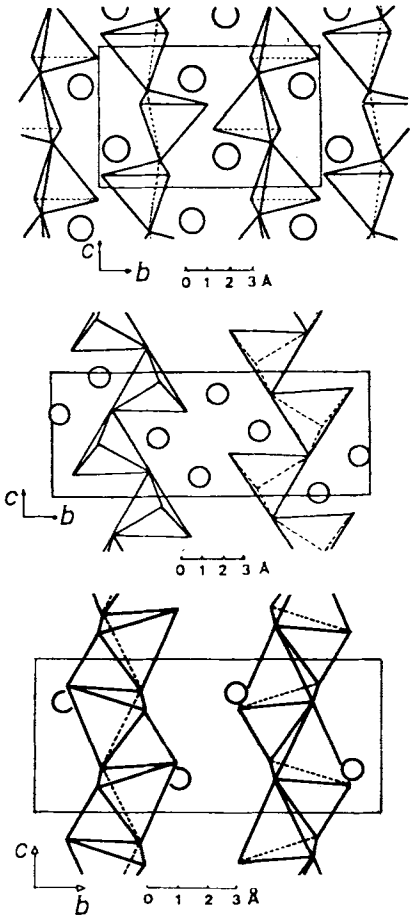

Fig. 26. Different configurations of the $(GeS_3^{2-})_n$ chains of tetrahedra and cation distribution in $PbGeS_3$ [162] and $Na_2GeS_3$ [163] as compared to the disulfide-bridged similar $(BS_3^{3-})_n$ chain in $TlBS_3$. All three structures have "Zweiereinfachketten" [161].

The tetrameric thioanions of silicon, germanium and tin complete a remarkable series of isoelectronic species of the elements of the 5th–3rd main groups which extends from the neutral molecules $P_4O_{10}$ and $P_4S_{10}$ to the ions $M_4^{IV}S_{10}^{4-}$ and $M_4^{IV}Se_{10}^{4-}$ ($M^{IV}$ = Se, Ge, Sn) and to the aforementioned highly charged ions $M_4^{III}S_{10}^{8-}$ and $M_4^{III}Se_{10}^{8-}$ ($M^{III}$ = B, Ga, In). Table 1 presents some bonding parameters of this class of compounds, which show typical common bonding characteristics of main group element chalcogenoanions (cf. Fig. 17).

Table 1. Structural and bond data of isoelectronic oxides, sulfides, thio- and selenoanions with adamantane-like structures as compared to simple tetrahedral anions. Bond lengths in Å, force constants in N/cm.

| | Bond lengths | | | Force constants | | | |
|---|---|---|---|---|---|---|---|
| | $d_{M-S(O)}$ | | | $f_{M-S(O)}$ | | | |
| | terminal | bridge | $d_1$ | terminal | bridge | $f_1$ | Ref. |
| $P_4O_{10}$ | 1.43 | 1.60 | 1.71 | 11.2 | 5.38 | 4.00 | [169] |

The rounded bond lengths given are partly mean values of several compounds.
$d_1$: sum of the covalent single bond radii, corrected according to *Schomaker-Stevenson* = "single bond distance".
$f_1$: force constant to be expected for a single bond, estimated according to *Siebert* [107].
$f_{M-S(O)}$: stretching force constant from normal-coordinate analysis.

It becomes quite clear, *e.g.*, that the ions of the 4th main group, in accordance to their simple valence structures, contain essentially single bonds. However, π-bonding is also quite weak in $P_4S_{10}$ and thio- and selenoanions of the 5th main group elements. This is in complete contrast to the corresponding oxo compounds and to the strongly π-bonded thio- and seleno-compounds of the transition metals, *e.g.* of $V^V$, $Mo^{VI}$, $W^{VI}$, and $Re^{VII}$[168]. There is, howev-

er, a typical shortening of the terminal bonds to the negatively charged, stronger (n-d)π-donor S and Se atoms compared to the bridge bonds. This effect increases with decreasing number of terminal S or Se atoms per central atom. In the adamantane-like ions of boron, gallium, and indium there are four additional negative charges localized on the central cage. The total bond orders being significantly lower, there is practically no recognizable tendency for π-strengthening of terminal bonds.

Valuable analytical information for the spectroscopic identification of the adamantane-like cages is the symmetric vibration $\nu_2(A_1)$, which is very strong in the Raman spectrum, and which is characteristic for each species (cf. Table 2).

Table 2. Wave numbers of the symmetric stretching vibrations $\nu_2(A_1)$ of adamantane-like oxo- and thio-compounds.

As shown in Figures 22 and 24, the $Ge_4S_{10}$ units in $Ge_8S_{19}^{6-}$ are linked in a parallel fashion so that the ion as a whole, like $Ge_4S_{10}^{4-}$, represents a section of the zinc blende structure. The ion is formed upon acidification of aqueous thiogermanate solutions to pH = 2.5, and it is the largest anion to be isolated prior to precipitation of polymeric $GeS_2$ on slightly stronger acidification.

### 6.2. Thio-oxoanions of Germanium and Tin

In $Sn_{10}O_4S_{20}^{8-}$, ten parallel corner-sharing $SnS_4$ tetrahedra are polymerized to a $Sn_{10}S_{20}$ "supertetrahedron" in the same way as in the $B_{10}S_{20}$ units of $Ag_3B_5S_9$ (Fig. 14); four additional O atoms, inserted in tetrahedral voids, complete the coordination of six of the ten Sn atoms to give distorted $SnS_4O_2$ octahedra[152]. So far, this is the only thio-oxostannate which is stable as a molecular ion in aqueous solution, and it can be isolated as hydrated alkali salts (*e.g.* $Cs_8Sn_{10}O_4S_{20}\cdot 13H_2O$[152], $Na_8Sn_{10}O_4S_{20}\cdot 32H_2O$[150]) (Fig. 27).

Novel thio-oxogermanates can also be obtained from aqueous solution. The anions $GeS_2(OH)_2^{2-}$ and $GeS_3OH^{3-}$[175,176] (Fig. 28), formed from stoichiometric sulfide-hydroxide mixtures, are protonated at the oxygen atoms. The remarkably low acidity of the oxygen functions

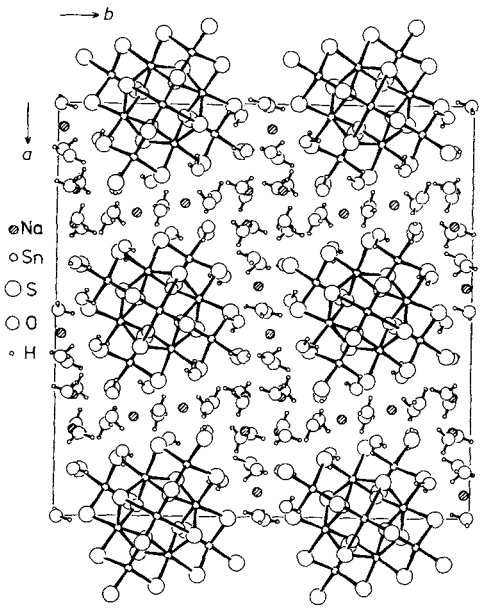

Fig. 27. Arrangement of the $Sn_{10}O_4S_{20}^{8-}$ ions in the $Na_8Sn_{10}O_4S_{20}\cdot 32H_2O$ structure, which is stabilized by an extensive OH···S hydrogen bridge system between the hydrated cations $[Na(OH_2)_6]^+$ and the thioanions.

distinguishes these ions from the thiophosphates $PS_xO_{4-x}^{3-}$ and thioarsenates $AsS_xO_{4-x}^{3-}$, in which the mesomeric stabilization of the $PO_{4-x}$ and $AsO_{4-x}$ fragments favors deprotonization. More highly condensed thiooxogermanates also ought to be obtainable from solution. High-temperature solid-state reaction of BaS, ZnO and $GeS_2$ furnished $S_3GeOGeS_3^{6-}$ as a $Ge_2S_7^{6-}$-type thiooxo anion in the phase $Ba_2ZnGe_2S_6O$, which, however, is associated through $ZnS_4$ tetrahedra[177].

Most of the alkali metal thiogermanates and thiostannates and the analogous seleno-compounds isolated from solutions crystallize strongly hydrated with typical compositions of $Na_4SnS_4\cdot 14H_2O$[138], $Na_4SnSe_4\cdot 16H_2O$[141],

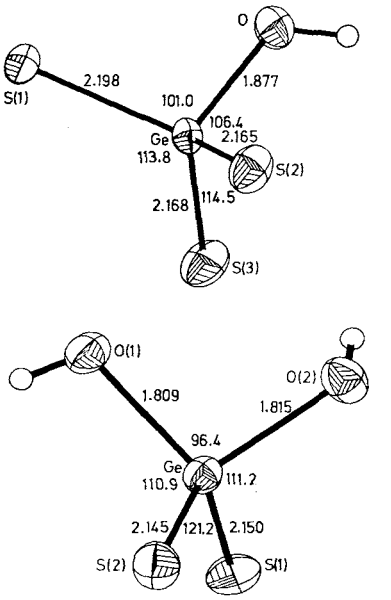

Fig. 28. $GeS_3OH^{3-}$ ion in the structure of $Na_3GeS_3OH\cdot 8H_2O$ and $GeS_2(OH)_2^{2-}$ ion in solid $Na_2GeS_2(OH)_2\cdot 5H_2O$ with bond lengths [Å] and bond angles [°] [174].

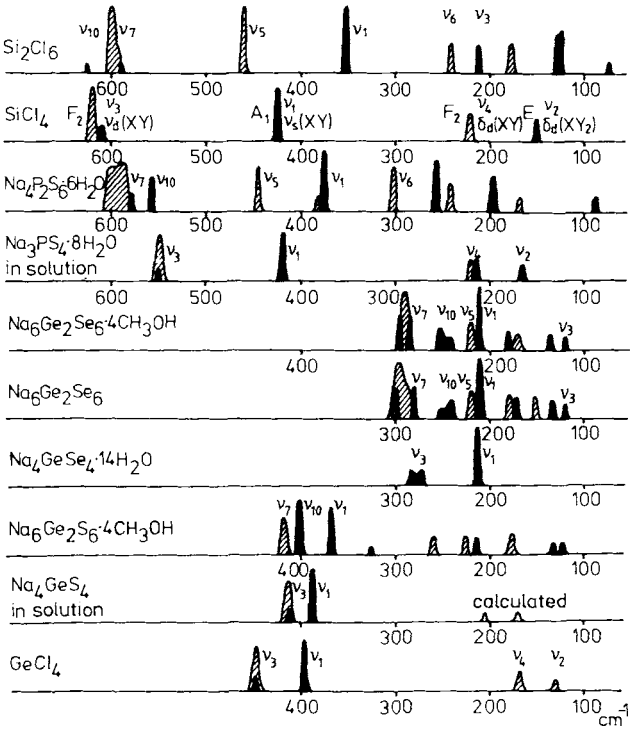
$Na_4Ge_2S_6 \cdot 14H_2O$[144], $K_2SnS_3 \cdot 2H_2O$[146], $Cs_4Ge_4S_{10} \cdot 3H_2O$[148], $Cs_6Ge_8S_{19} \cdot 12H_2O$[150], $Na_2GeS_2(OH)_2 \cdot 5H_2O$[176], $Na_3GeS_3OH \cdot 8H_2O$[175] *etc.* All these compounds contain extensive and structurally well characterized O–H···S and O–H···Se hydrogen-bridge systems between the hydrated cations (*e.g.* octahedral $Na(OH_2)_6^+$ groups) and the thio- or seleno-anions, so that they represent important model systems for this hydrogen-bridge type. In this respect Schlippe's salt $Na_3SbS_4 \cdot 9H_2O$, which is related to the phases under discussion, is especially well characterized[178–180].

### 6.3. Thio- and Seleno-compounds with Si–Si and Ge–Ge Bonds

Some thio-compounds with Si–Si and Ge–Ge bonds which have only recently been synthesized are of special chemical interest. $(S_3Ge-GeS_3)^{6-}$ and $(Se_3Ge-GeSe_3)^{6-}$ are formed by nucleophilic decomposition of glass-like $Ge_2S_3$ and $Ge_2Se_3$, respectively, with methanolic $Na_2S$[181, 182]. Their molecular structure can be deduced from the similarity of the vibrational spectra with those of $Si_2Cl_6$ and of $P_2S_6^{4-}$ (Fig. 29). In the same way, novel mixed thio- and seleno-bromogermanates $GeS_3Br^{3-}$ and $GeSe_3Br^{3-}$ can be identified by vibrational spectroscopy as products of the cleavage of the Ge–Ge bonds in $Ge_2S_6^{6-}$ and $Ge_2Se_6^{6-}$ with $Br_2$[183].



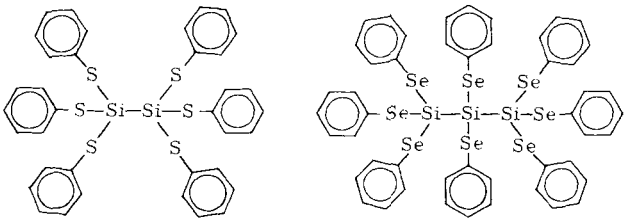


Fig. 29. Survey of the infrared bands (hatched) and Raman bands (solid) of different thio- and seleno-compounds with related compounds for comparison [181].

Novel air- and moisture-stable disilane and trisilane derivatives $Si_2(SR)_6$ **1** (Fig. 30), $Si_3(SR)_8$, and $Si_3(SeR)_8$ **2** are interesting products of the amine-catalyzed thiolysis of halogenosilanes[184, 185], *e.g.* according to

$$Si_3Br_8 + 8C_6H_5SeH + 8N(C_2H_5)_3 \xrightarrow[-20\,^\circ C]{\text{toluene}} Si_3(SeC_6H_5)_8 + 8(C_2H_5)_3NHBr$$

**2**

They can serve as important reagents for the synthesis of new Si-S and Si-Se compounds by cleavage with $Br_2$.

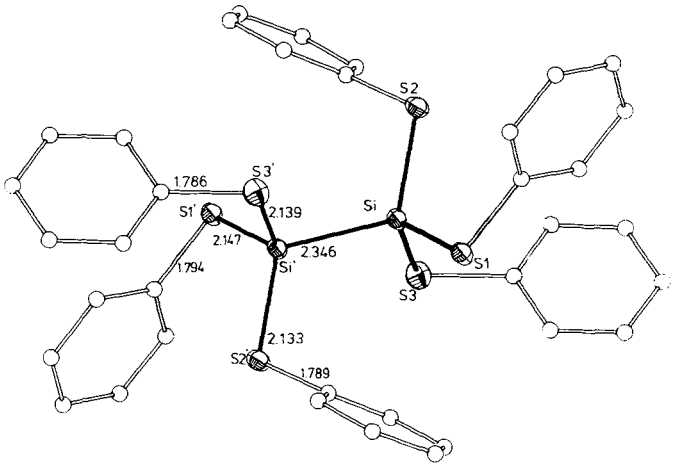

Fig. 30. Molecular structure of $Si_2(SC_6H_5)_6$ 1 with bond lengths [Å].

### 6.4. Higher Coordination Numbers in Thiostannates

In the thio- and seleno-compounds dealt with in this article, coordination numbers higher than four are found only in the case of In and Sn, where the compounds, with the exception of $Sn_{10}O_4S_{20}^{8-}$[151, 152], are solid-state materials which are prepared by high-temperature methods. $Na_4Sn_3S_8$[186] (Fig. 31) and $Tl_2Sn_2S_5$[187] contain five-coordinated $Sn^{IV}$ in a trigonal bipyramidal surrounding (axial and equatorial bond lengths: 2.59 and 2.43 Å, respectively).

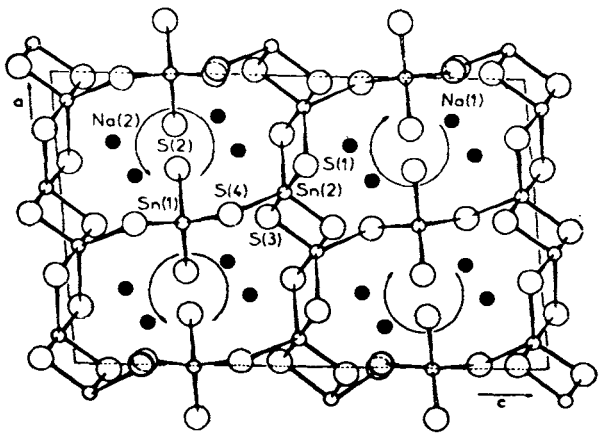

Fig. 31. Five-coordinated tin in $Na_4Sn_3S_8$: The trigonal bipyramids about Sn(2) form chains in the *ab* plane which are linked to helices parallel to b *via* the $SnS_4$ tetrahedra about Sn(1) [186].

Octahedrally coordinated Sn is observed in LT-$Na_2SnS_3$[188] (NaCl-type), in $Sn_2S_3$[189] and $PbSnS_3$[190] ($NH_4CdCl_3$-type), and in $La_2SnS_5$[191] (Sn–S 2.56 Å). Systematic $^{119}$Sn-Mössbauer investigations of thio- and selenostannates[192, 193] confirm the structural findings. In the case of $Na_4Sn_3S_8$, *e.g.*, two doublets are observed for the $SnS_5$ and the distorted tetrahedral $SnS_4$ polyhedra, with isomer shifts of 1.19 and 1.30 mm/s relative to $BaSnO_3$ and with quadrupole splittings of 0.54 and 1.40 mm/s[193].

### 6.5. Argyrodites—Example of a Class of Silver Ion Conductors

The mineral argyrodite $Ag_8GeS_6$, as a thiogermanate, is the prototype of an increasing number of sulfide materials which are of current interest because of their structural and physical properties[174, 194–203]. Argyrodite and the related phases $Ag_8MX_6$ with M = Si, Ge, Sn and X = S, Se, Te[196] form a cubic, face-centered, highly symmetrical structure at elevated temperatures. On cooling, they pass through one or several phase changes with stepwise lowering of the symmetry. Depending on the modification they have different electronic and/or ionic conductivities, which are (as in the case, *e.g.*, of AgI) especially large in the highly symmetrical high-temperature (γ-) modifications. Several argyrodite-related phases with tri- or pentavalent central atoms such as $Ag_9GaS_6$[204, 205], $Ag_7PS_6$, $Ag_7AsS_6$[206, 207], and the corresponding selenium compounds show similar electric properties.

An insight into the bonding and ion-conducting properties of argyrodites became possible through the first successful structural analyses of argyrodite-like phases, initially of $Cd_4GeS_6$[208] and $Cd_4SiS_6$[172], and later of the first "genuine" argyrodites α-$Ag_8SiS_6$[174] (Fig. 32), α-$Ag_8GeS_6$[197], γ-$Ag_8GeTe_6$[199], β-$Ag_8GeSe_6$[200], and related phases such as $Cu_6PS_5Br$[203] and $Ag_7GeS_5I$[201].

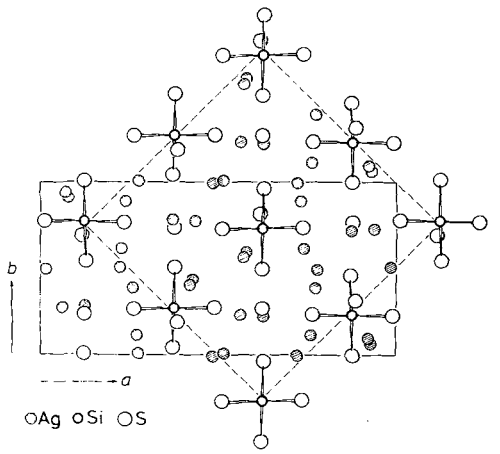

Fig. 32. α-$Ag_8SiS_6$: Example of an argyrodite structure with ordered cation distribution (low-temperature modification) [147]. The compound can be regarded as a "double salt" $Ag_8(SiS_4)S_2$ with $SiS_4^{4-}$ and $S^{2-}$ anions. The relation to the cubic high-temperature form (pseudo-cubic superstructure) is indicated. α-$Ag_8GeS_6$, the genuine argyrodite, is isotypic with α-$Ag_8SiS_6$.

As the structures show, they differ essentially in varying degrees of order in the cation lattice, while the characteristic anionic partial structure, in principle, remains intact. The arrangement of the chalcogenide ions can be described as a system of interpenetrating 12-icosahedra and 16-polyhedra (Frank-Kasper and Friauf polyhedra) (cf. *e.g.* [199, 201, 203]) in which each atom of one polyhedron centers another polyhedron (Fig. 33).

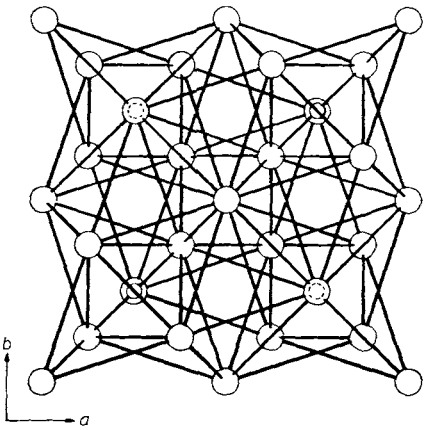

Fig. 33. Framework structure of the Te atoms in the cubic, $Ag^+$-conducting argyrodite phase γ-$Ag_8GeTe_6$ [199]. Ge (small circles) fills, in an ordered manner, 4 of the 136 tetrahedral voids of the unit cell and the 32 $Ag^+$ ions of the cell are distributed statistically over 116 other voids.

This icosahedral structure forms a system of face-sharing tetrahedral voids in which or between which the $Ag^+$ ions of the HT modifications are distributed more or less statistically with coordination numbers, 2, 3, or 4. Both factors—kind of anion packing and the low occupancy in the Ag sites—give optimal conditions for $Ag^+$ conductivity (the same is true for $Cu^+$-containing phases; cf. Fig. 34 and ref. [209]). With regard to these concepts, it appears

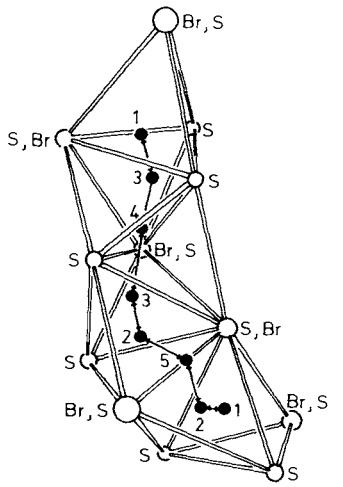

Fig. 34. Possible diffusion path of the $Cu^+$ ions in the $Cu^+$ ion-conducting argyrodite-analogous icosahedral structure of $Cu_6PS_5Br$ [203].

plausible that no ionic conductivity will be observed in the ordered low-temperature modifications. An ordered distribution is observed in the more silicon-rich argyrodite derivative $Ag_{10}Si_3S_{11}$, where, remarkably, two different thiosilicate groups are present[173] (Fig. 35).

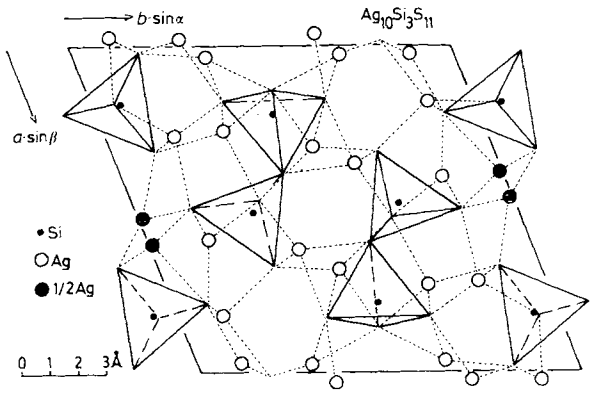

Fig. 35. $Ag_{10}Si_3S_{11}$: Argyrodite-related thiosilicate with two different anionic groups $SiS_4^{4-}$ and $Si_2S_7^{6-}$. The $Ag^+$ ions are essentially ordered.

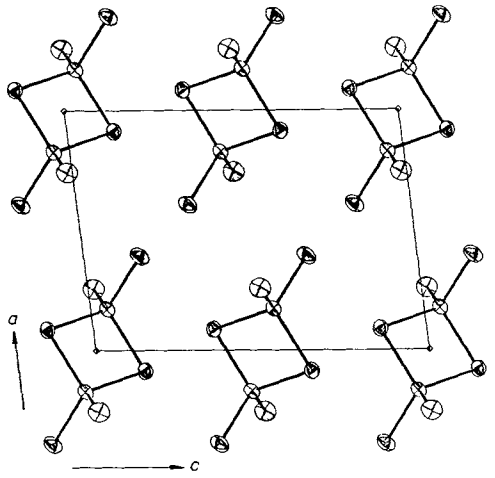
## 7. Sulfide and Selenide Halides of Silicon and Germanium

The molecular sulfide halides $(SiSX_2)_2$, with X = F, Cl, Br, are of preparative interest as reagents for the synthesis of different SiS compounds. They are obtainable by reaction of $SiX_4$ with $H_2S$[210–213] (cf. also [214]). Their 2,2,4,4-tetrahalo-1,3,2,4-dithiadisiletane structure (Fig. 36) is analogous to $Ge_2S_6^{4-}$ and to dimeric thiophosgene $(CSCl_2)_2$[215]. It was initially derived spectroscopically[216], and has now been confirmed by X-ray structural analysis of $(SiSCl_2)_2$ and $(SiSBr_2)_2$[184, 185, 217, 218].



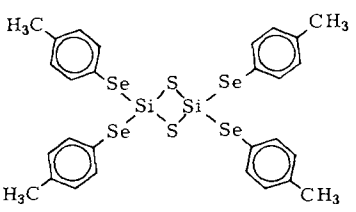


Fig. 36. $(SiSCl_2)_2$: Molecular and crystal structure. $(SiSF_2)_2$ and $(SiSBr_2)_2$ are similar.

Reactions with thiolates or their selenium analogues lead, *e.g.*, to substitution without cleavage of the central $Si_2S_2$ ring. Thus, by reaction of $(SiSBr_2)_2$ with selenols in pyridine/$CS_2$, novel mixed Si–S–Se compounds such as **3** can be synthesized[184, 185, 217].

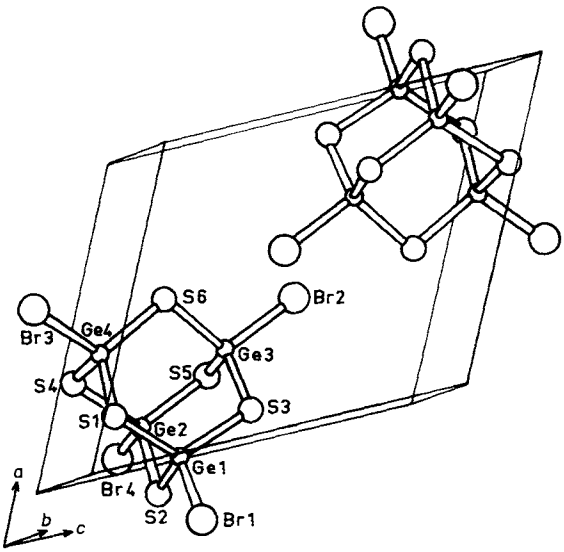
**3**

A new class of adamantane-like silicon sulfide halides is produced by dismutation of $(SiSCl_2)_2$ or $(SiSBr_2)_2$ according to

$$3(SiSX_2)_2 \longrightarrow 2SiX_4 + Si_4S_6X_4 \quad (X = Cl, Br)^{[184, 185, 217]}$$

According to $^{29}Si$-NMR investigations[219] at least one additional species is present in the reaction mixture besides $(SiSBr_2)_2$ ($\delta = -47.1$), $SiBr_4$, and $Si_4S_6Br_4$ ($\delta = -27.1$), which might be a further member of a homologous series $Si_nS_{2n-2}X_4$ (X = Cl, Br) which was mentioned earlier[210].

The extraordinary stability of the adamantane cage is also demonstrated by the recently synthesized first sulfide halides and selenide halides of germanium: $Ge_4S_6Br_4$ and $Ge_4S_6I_4$ (Fig. 37)[220, 221] are synthesized from $GeBr_4$ or $GeI_4$ and $H_2S$ in $CS_2/AlBr_3$ or $CS_2/AlI_3$ as molecular solids stable to hydrolysis, which can serve as reagents for the introduction of the $Ge_4S_6$ cage. $Ge_4Se_6I_4$ ($d_{Ge-Se}$ = 2.353(2), $d_{Ge-I}$ = 2.507(2) Å) is isotypic with $Ge_4S_6I_4$ and can be isolated in crystalline form by $CS_2$-extraction from glasses of the composition $Ge_2Se_3I_2$, which are prepared from the elements[184, 185, 218] (cf. also [222]). It is useful for syntheses in a similar way to $Ge_4S_6Br_4$.



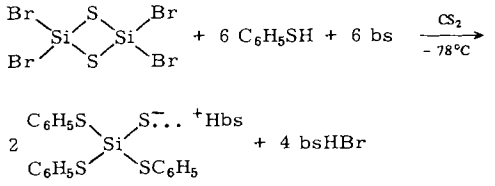


Fig. 37. Arrangement of molecules in the triclinic unit cell of the adamantane-like $Ge_4S_6Br_4$ [221]; $Si_4S_6Br_4$ ($d_{Si-S}$ 2.125, $d_{Si-Br}$ 2.181 Å) is isotypic with $Ge_4S_6Br_4$.

## 8. Organosubstituted Thiosilicates—A New Class of Compounds

It is possible by reaction of the chalcogenide halides of Si and Ge in non-polar solvents to synthesize a number of novel organosubstituted thiosilicates, which can be used as potential ligands in transition metal complexes. Nucleophilic attack of $Si_2S_2Br_4$ by thiolate and cleavage of the ring according to

(bs = pyridine, quinoline etc.)

affords the $(C_6H_5{-}S)_3SiS^-$ monoanion, the structure of which is shown in Figure 38[184,185].

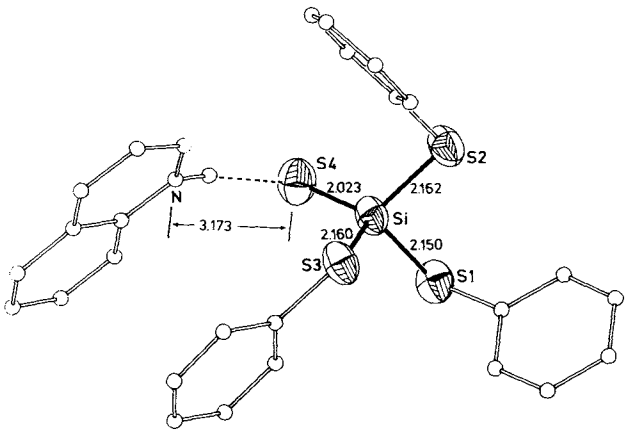

Fig. 38. Molecular structure of pyridinium-tris(phenylthio)silanethiolate $Si(SC_6H_5)_3SHNC_5H_5$ (bond lengths in Å). The Si–S(thiolate) bond is exceptionally short.

If the adamantane-like $Si_4S_6Br_4$ is employed, addition of $H_2S$ yields the tetrameric organothiosilicate dianion, which is isolated as an ion pair with the base (Fig. 39)[184,185] according to

$$Si_4S_6Br_4 + 6\,bs + 2\,C_6H_5{-}SH + 2\,H_2S \xrightarrow[-20\,^\circ C]{CS_2} Si_4S_6(SC_6H_5)_2(S^- \cdots {}^+Hbs)_2 + 4\,bsHBr.$$

In both types of ions the Si – S bond lengths of 2.02 – 2.04 Å are the shortest observed so far. As in $Si_4S_{10}^{4-}$ (2.04 Å[164]), this indicates unusually strong π-bonding.

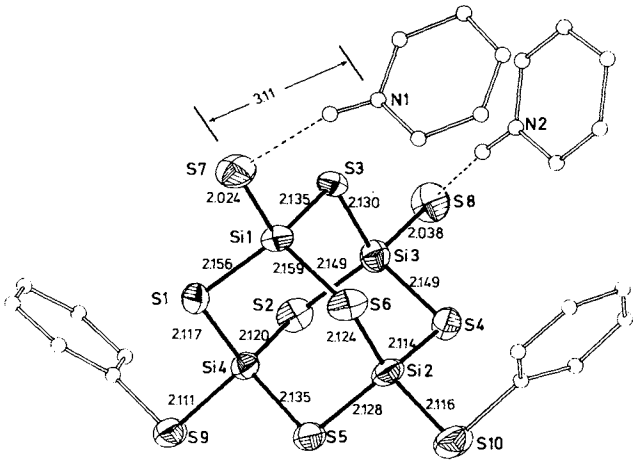

Fig. 39. An organothiosilicate dianion: Molecular structure of dipyridinium-bis(phenylthio)-2,4,6,8,9,10-hexathia-1,3,5,7-tetrasilaadamantanedithiolate $Si_4S_6(SC_6H_5)_2(SHNC_5H_5)_2$ (bond lengths in Å).

## 9. Thioanions of Main Group Elements as Ligands in Metal Complexes

Thioanions of the main group elements have a lesser tendency to function as ligands in transition metal complexes than corresponding transition metal thioanions such as $MoS_4^{2-}$ and $WS_4^{2-}$[168]. Although they are electron pair donors, there is no stabilizing electron-delocalization over energetically low π-orbitals as in the strongly π-bonded transition metal thioanions. Whereas the strongly π-bonded planar trithiocarbonate ion $CS_3^{2-}$ forms several stable complexes, *e.g.* with $Cr^{3+}$, $Co^{3+}$, $Ni^{2+}$, $Cu^+$, $Zn^{2+}$, $Cd^{2+}$, $Pd^{2+}$ and $Pt^{2+}$[223], so far little is known about tetrahedral thioanions of Si, Ge and Sn as complex ligands. $Cs_2NiGe_4S_{10}$ is formed as an amorphous yellow-brown polymeric complex according to[149,224]

$$Cs_4Ge_4S_{10} \xrightarrow[EtOH/HAc/H_2O]{NiAc_2} Cs_2NiGe_4S_{10}$$

The electron spectrum indicates octahedral coordination of nickel with mono- or bi-dentate ligation. Organosubstituted complexes are prepared according to

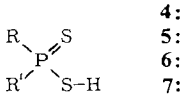
$$(R_2GeS)_3 \xrightarrow{Na_2S} R_2Ge(S^-)_2 \xrightarrow[EtOH/HAc/H_2O]{NiAc_2} \left[R_2Ge(S)_2Ni(S)_2GeR_2\right]^{2-}$$

R = $C_2H_5$, $C_6H_5$

and precipitated with large organic cations[149,224]; very little is known about their properties.

Also in the 5th main group, there are only few examples of complexes with pure thioanions $MS_4^{3-}$ (M = P, As, Sb) as ligands. Such are the polymeric mixed-ligand complexes $[Ni_3en_6(AsS_4)_2]$ and $[Ni_3phen_5(AsS_4)_2]$[225] as well as $[Ni_3en_6(PS_4)_2]$, $[Ni_3en_6(SbS_4)_2]$ and $[Coen_2AsS_4]$ with octahedral coordination of the transition metals[226].

## 10. S–H···S Hydrogen Bridge Bonds in Thioacids



Some thioacids of the main group elements, especially trithiocarbonic acid $H_2CS_3$ and a number of substituted dithiophosphinic acids RR'P(S)SH, have proved to be important model systems for the characterization of the hitherto largely unknown S–H···S-type hydrogen bridge bond.

Hydrogen bridges between sulfur as donor and acceptor are generally quite weak. The bond enthalpies of S–H···S bridges are smaller by a factor of ten compared to those of hydrogen bridges of the homologous oxygen[227]. Reasons for this are the low polarity of the S–H group and the comparatively diffuse character of the acceptor electron pair.

Detailed knowledge about S–H···S bridge bonds and their structural activity is important because of the occurrence of sulfur in numerous biologically active compounds and their influence on equilibrium configurations, redox potentials, and reactivities[228].

S–H···S hydrogen bridges can be inferred from the frequencies of the S–H stretching vibrations. The greatest shifts from the frequency of the free SH group was found in the derivatives of the dithiophosphoric and dithiophosphinic acids[229–231]. Being *ca.* 200 $cm^{-1}$ they are greater by a factor of ten than the shifts in monofunctional mercaptans[232,233]. Similarly large shifts of the S–H vibrations as in the thioacids of phosphorus could be observed only in trithiocarbonic acid[234]; effects due to S–H···S association in dithiocarbonic acids[235] and in dithiotropolone[236] are only about half as great. The first quantitative struc-

tural data on S–H···S hydrogen bridges were obtained by X-ray structural analyses of disubstituted dithiophosphinic acids **4**–**8**.

**4**: R, R' = phenyl
**5**: R, R' = 3,5-dimethylphenyl
**6**: R, R' = *p*-tolyl
**7**: R = ethyl, R' = phenyl
**8**: R, R' = 3,4-dimethylphenyl

Here the strongest S–H···S bridge bonds known so far have bond enthalpies of about 12 kJ mol$^{-1}$[237] and S···S distances between 3.75 and 3.84 Å[231,238,239]. The limiting S···S distance calculated for pure van der Waals contacts of a linear S–H···S configuration (4.35 Å) is longer by *ca.* 0.5–0.6 Å. Predictions about the existence of extremely strong symmetrical S–H···S bridges with bonding enthalpies of about 15 kcal mol$^{-1}$ and S···S bridge distances of *ca.* 3.49 Å in the system $H_2S/SH^{\ominus}$, as were published in the literature on the basis of *ab initio* calculations[240], could not be confirmed by experiment. In the compound $[(CH_3)_3(C_7H_7)N][SH]\cdot 2H_2S$, prepared in liquid $H_2S$[241], the observed S···S distances are of the same magnitude as in the dithiophosphinic acids, thus ruling out symmetrical bridges.

Further information on S–H···S hydrogen bridge bonding has been obtained from crystal structure analyses of two modifications of trithiocarbonic acid[241,242] and dithiotropolone[243]. In the substituted dithiophosphinic acids the individual molecules are associated through almost linear S–H···S hydrogen bridges to form either centrosymmetric cyclic dimers (in **6**, **7** and **8**) or helically twisted chains (in **4** and **5**), with the thiophosphoryl group functioning as acceptor also in the chain associates. Its polar character favors considerably the extent of the S–H···S associations. In contrast to the dimeric carboxylic acids with their planar arrangement of the bridge atoms, the planes of the associated P(S)S groups in **6**, **7** and **8** are separated from each other by *ca.* 3.5 Å. The H atoms are twisted about the P–S bonds out of the P(S)S-planes in such a way that almost linear S–H···S bridges result. A similar arrangement of the P, S and H atoms can be observed in the chain-like associate of **5**. Within the spiral-shaped chains of **4** all atoms of the P(S)SH group are in one plane, with the H atoms in a *trans* position to the S atom of the thiophosphoryl-group. Figures 40, 41 and 42 show the three principles of association as exemplified by **7**, **5** and **4**. Structural and spectroscopic data on these systems are listed in Table 3.

Table 3. Distances [Å] and angles [°] as well as spectroscopic data [cm$^{-1}$] for the S–H···S hydrogen bridges in substituted dithiophosphinic acids. The $\Delta\nu$ values refer to $\nu_{S-H}=2570$ cm$^{-1}$ for the dilute solutions of the monomeric acids in $CCl_4$.

| | $d$(S···S) | ∢P–S···S | ∢P=S···S | ∢S–H···S | $\nu_{S-H}$ | $\Delta\nu_{S-H}$ |
|---|---|---|---|---|---|---|
| **4** [a] | 3.790 | 98.9 | 96.7 | 170 | | |
| **4** | 3.837 | 99.4 | 97.4 | 166 | 2340 | 230 |
| **5** | 3.763 | 89.0 | 115.1 | 159 | 2350 | 220 |
| **6** | 3.746 | 98.0 | 115.6 | 173 | 2325 | 245 |
| **7** | 3.810 | 88.9 | 109.6 | 168 | 2380 | 190 |
| **8** | 3.832 | 107.9 | 115.9 | 163 | 2400 | 170 |

[a] At −133 °C.

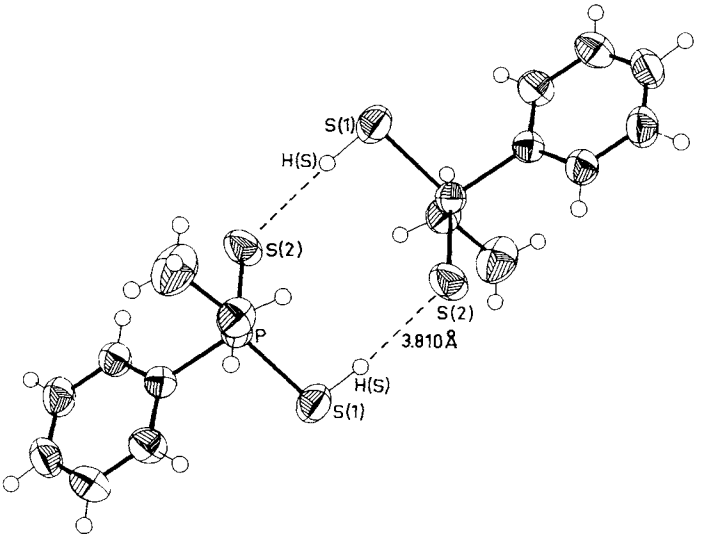


Fig. 40. $(C_6H_5)(C_2H_5)P(S)SH$ **7**: Cyclic dimers by association through S–H···S hydrogen bridges.

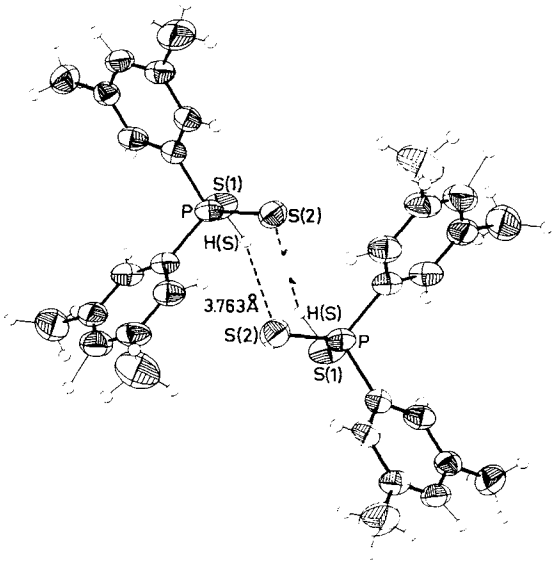

Fig. 41. $(C_8H_9)_2P(S)SH$ **5**: Projection of a molecular chain produced by association through S–H···S hydrogen bridges.

With the exception of **4**, an essentially linear relation results between S···S bridge distances and the S-H frequency shifts, as is also true for weak O–H···O hydrogen bridges[244]. This correlation implies a uniform electronic hydrogen-acceptor system ($sp^2$-hybridized free electron pairs) for the S–H···S bridges in **5**–**8**; in **4** the acceptor functions are p-electron pairs, which are perpendicular to the planes of $sp^2$-hybrid orbitals of the thiophosphoryl S atoms.

In the two modifications of trithiocarbonic acid there are also intermolecular S–H···S bridges, which, according to low-temperature structure analyses, are in part distinctly nonlinear. Unlike α-$H_2$-$CS_3$, in which all H-acceptor functions are thiocarbonyl groups, bridges occur between the SH groups in β-$H_2CS_3$. The S···S distances of the S–H···S bridges vary between 3.80 and 3.97 Å.

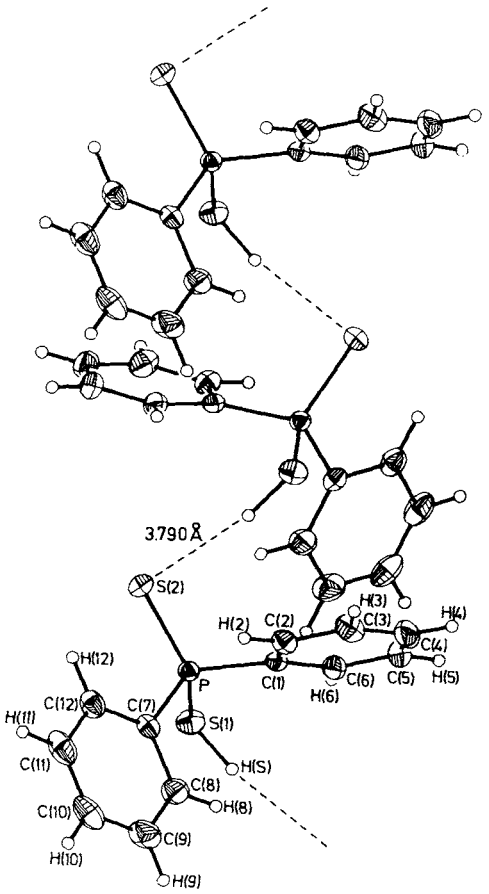

Fig. 42. $(C_6H_5)_2P(S)SH$ 4: Chain of molecules formed through S–H···S hydrogen bridges (−133 °C).

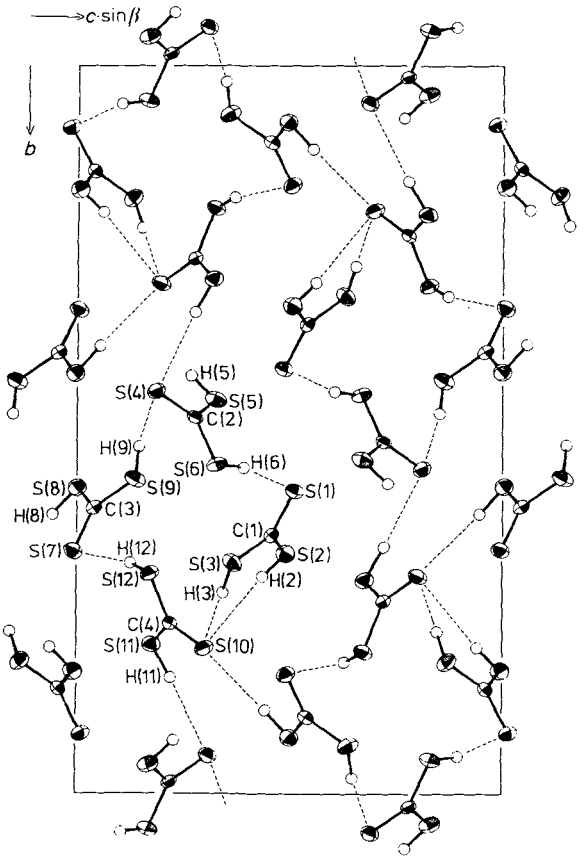

Fig. 43. α-$H_2CS_3$: Projection of the unit cell with S–H···S hydrogen bridges (−133 °C).

In both modifications the $H_2CS_3$ molecules are planar. Whereas the conformation of the molecules in β-$H_2CS_3$ is uniform with idealized symmetry $C_s$, in α-$H_2CS_3$ there are three molecules with symmetry $C_s$ together with one molecule with $C_{2v}$ symmetry and neighboring H-atoms. Figure 43 shows a projection of the unit cell of α-$H_2CS_3$, in which the hydrogen bridges and the different conformations can be recognized. In dithiotropolone (Fig. 44) intramolecular S–H···S bridge bonds were detected for the first time. This type of bridge cannot be linear because of the geometrical constraints of the molecule. The S–H···S bridge bond angle is 133° with a S···S separation of 3.12 Å and a H···S distance of 2.08 Å.

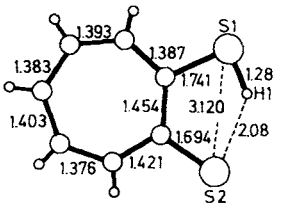

Fig. 44. Dithiotropolone: Molecular structure with intramolecular S–H···S hydrogen bond (−133 °C).

## 11. Final Remarks and Outlook

The chemistry and structural chemistry of the thio-compounds of 5th main group elements, which will be the subject of a later review, is quite extensive and has also progressed considerably during recent years, especially in the field of solid-state chemistry of the thioarsenates(III) and thioantimonates(III). While the chemistry of the thio- and selenoarsenates(V) and their antimony analogues is still restricted to the simple tetrahedral ions $AsO_xS_{4-x}^{3-}$ and $SbO_xS_{4-x}^{3-}$, a greater number of differently condensed polynuclear thiocompounds with the oxidation state +3 could be characterized[245]. Some interesting novel thiophosphates have been reported recently. Besides $(S_3P{-}PS_3)^{4-}$[246,247] and a number of its derivatives, $P_2S_8^{2-}$[248] with a six-membered $PS_2PS_2$ ring and $P_4S_8^{4-}$[249] with a central planar $P_4$ ring have been synthesized.

Remarkable new developments in the less extensive field of thio-compounds of the chalcogens are the synthesis and structural description of some thiotellurates(IV) with $TeS_3^{2-}$ anions[250,251] and the first synthesis of a dithiosulfate $SO_2S_2^{2-}$ stabilized by coordination to Mo in the complex $[(S_2)OMoS_2MoO(S_2SO_2)]^{2-}$[252].

What kind of developments are to be expected? The results reviewed here on the synthesis, structural chemistry, bonding, and reactivity of novel sulfur and selenium compounds of the 3rd–5th main group elements show the following trends, opening new paths in this field of inorganic chemistry:

New classes of attractive polynuclear and polymeric inorganic compounds can be prepared by consistent use of the ability of the trigonal-planar (B), tetrahedral (Ga, In, Si, Ge, Sn) or pyramidal (As, Sb) monomeric building blocks to undergo condensation and to polymerize to polynuclear units. In this borderline field between molecular and solid-

state chemistry the possibilities of the synthetic methods are variable, since reactions in polar and nonpolar solvents can be used successfully besides conventional solid-state methods of synthesis. Here, further efforts will have to concentrate on the mechanisms of formation and on the equilibria in solution which have to be known for new successful syntheses. A second important field to be investigated is the preparation of new mixed polynuclear thio-oxo compounds which can serve as a basis for more "silicate-like" products with intermediate chemical and physical properties. The chalcogenides and chalcogenoanions can be used as valuable starting materials for many other inorganic and organic syntheses, as is shown by the successful use of the boron sulfides in organic synthetic reactions or the potential of $B_8S_{16}$ or thiogermanates as ligands in transition metal complexes. Further intensive research work is also necessary in this field in the future.

Polynuclear chalcogenide halides can be employed for the preparation of novel organosilicon sulfur compounds and of the corresponding germanium analogues. The potential of the reactions presented here is still far from being exhausted. In this field, *e.g.*, novel organosubstituted thioanions can be employed for the synthesis of Si and Ge sulfur compounds not obtainable with known starting materials, which can produce new Si–S–R and Ge–S–R compounds for practical applications.

The ion-conducting and other electrical properties of the $Ag^+$ and $Cu^+$ thio-compounds which have been exemplified here by $Ag_3B_5S_9$ and the argyrodites, will be a field of further very active chemical and physical research in the near future.

The structural results referred to in this review have made important contributions to the problem of bonding in main group thio- and seleno-anions, and especially to the question of the existence of $\pi$-contributions in the boron-sulfur and boron-selenium bonds as well towards an understanding of the novel S–H···S hydrogen bond type. However, also in this field many questions remain open and will have to be answered by further research.

*I sincerely thank my co-workers, past and present, who have contributed to the work cited in this article, for their active and enthusiastic cooperation over many years. I am also indebted to Dr. G. Henkel and to Dr. H. Eckert for valuable discussions. Continuous support of our research by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen, by the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie is gratefully acknowledged.*

[101] A direct relation of the interatomic distances to $\sigma$ and $\pi$ bond strength, however, cannot be obtained without difficulties, and it must take into account that (a) the B–S bonds in the $BS_4$ tetraedra have charge-dependent $\sigma$ bond orders $< 1$ and that (b) the $\sigma$ bond lengths depend on the hybridization of the central atom.

[136] A remark concerning nomenclature: The term "thio salt" with "thioanions" *vs.* the term "ternary sulfide" for a solid phase $A_xB_yS_z$ is preferable in those cases where discrete (also polymeric) $B_yS_z$ structural units can be recognized; criteria for this are significantly stronger (and more covalent) B–S bonds relative to weaker A···S bonds (with more ionic character). Example: $Na_6Sn_2S_7$ is a sodium thiostannate, $ZnAl_2S_4$ is rather a zinc aluminum sulfide, the bond character of Zn–S and Al–S being not very different.

# Catalysis by Molecular Metal Clusters

**By Earl L. Muetterties* and Michael J. Krause**

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

Molecular metal clusters form a very large and diverse family. They present the opportunity of modeling the intermediates involved in surface mediated catalytic reactions, of providing a source of very reactive mononuclear metal fragments, and of effecting catalytic cycles in which the cluster remains intact. The last mentioned aspect is the subject of this review article. The state-of-the-art of cluster catalysis is critically analyzed. The possibilities offered by molecular metal catalysts of performing catalytic reactions at multimetal atom sites are also discussed.

## 1. Introduction

Catalysis of inorganic and organic reactions by metal atoms is a well-established area of scientific and technological investigation. Metal atom catalysts[1a] or potential catalysts may be classified[1b,c] as follows:

1) Surfaces of metals, alloys, metal oxides, sulfides, and halides.

2) Metal atoms dispersed in a low temperature matrix or immobilized on a support.

3) Small metal clusters (without ligands)—sufficiently small to be distinguished from metals.

4) Molecular mononuclear metal complexes.

5) Molecular polynuclear metal complexes

Classes 1)[2] and 4)[3] have been studied extensively and have been the subjects of reviews and monographs. Although classes 2) and 3) are of great theoretical interest, experimental studies of "naked" metal atoms or "naked" clusters have been limited since even at very low temperatures they form larger aggregates. Generally, these potential catalysts must be immobilized on a support to prevent aggregation, but even then there is evidence that the metal atoms are mobile under very mild conditions. This class of supported catalysts is now a broad area of intensive study[4]. A comparitave study of these classes of metal catalysts should provide important insights, but more detailed investigations are required. It should then be possible to delineate the electronic and structural factors that significantly change the catalytic activity as the nuclearity of the metal framework increases. This review article presents a critical analysis of the state-of-the-art of molecular cluster catalysis with emphasis on reaction mechanisms.

Molecular metal clusters[**] present catalysis research with at least three major opportunities. The first is that they can serve as models of chemisorbed molecules or molecular fragments on surfaces of metals or metal oxides and sulfides, *etc.*[4–8]. Structure and stereochemistry can be determined readily and precisely for molecular species like clusters, but cannot be established precisely for chemisorbed species apart from simple cases such as CO and NO. Comparison of the spectroscopic data of clusters with those of chemisorbed species can provide information on the structure of the latter[9]. The use of clusters as models of surfaces has been analyzed in substantial detail[7,8] and will not be reviewed here. Secondly, molecular clusters enable the generation of reactive mononuclear fragments[13,14] of high catalytic activity by thermally or photochemically initiated scission of all metal-metal bonds in the cluster. For example, $Fe_3(CO)_{12}$ reacts thermally with alkenes at 80 °C to form [Fe(CO)$_4$(alkene)] complexes which are catalytic intermediates in alkene isomerization[14a]; $[Ru_3(CO)_9\{P(C_6H_5)_3\}_3]$ is partially or fully fragmented by photolysis to give species that initiate alkene isomerization[15]. The third opportunity, and the one addressed in this article, is catalysis by clusters. In this analysis, special emphasis is given to mechanistic features. Also considered are potentially unique reactions catalyzed by molecular metal clusters in which more than one metal atom site participates in the transformation ("multimetal atom site reactions"). The review is not comprehensive.

Molecular metal clusters comprise an extremely diverse family in which the *formal* oxidation state of the metal atoms may vary from +3 to 0 or even have slightly negative values[15,16a]. Potentially, clusters with metal atoms of high oxidation state can mimic metal oxide or metal sulfide catalysts and those of low metal atom oxidation state can mimic metallic catalysts. Few studies have been reported for the former class of clusters but a number of exploratory studies have been described for clusters in which the metal atoms have a low or zero oxidation state, and we will focus on such clusters in this article.

One interesting feature offered by metal clusters is the possibility of performing unique catalytic reactions. Specific possibilities are unusual stereoselectivity or chemosel-

[**] Some scientists classify clusters as those metal complexes with three or more metal atoms mutually bonded to each other; however, it is more common today, and semantically correct, to refer to dinuclear metal complexes with a metal-metal bond as clusters and this classification will be used here.

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0202-0135 $ 02.50/0* 

ectivity due to participation of more than one metal atom in key steps of the catalytic cycle[6]. Another is cluster catalysis of reactions that either cannot be effected or are very difficult to effect at single metal atom centers. Examples are the hydrogenation of the triple bonds in CO, $N_2$, $CN^-$, RCN, and RNC. All of these species can be catalytically hydrogenated on metal oxide or metal surfaces or catalytically reduced by the nitrogenase enzymes, but none has been catalytically hydrogenated *with facility* by molecular metal catalysts in solution[6].

Metal clusters have an extremely broad chemistry, and many aspects of this relate directly to metal cluster catalysis. An illustrative list of important related studies is the relation between large metal clusters and metal particles[16a], the use of support-bound clusters for catalysis[4, 16b], cluster-mediated organic chemistry[11], ligand mobility in clusters[16c], changes in cluster shape due to variations in the electron count[16d], modes of cluster activation[16e], activation of $H_2$ by clusters[16f], "unsaturated" clusters[16g], substrate binding and modification over triangular cluster faces[16h], the binding of acetylene on clusters[16i], the variety of reactions offered by mixed metal clusters[16j], the possibility of cluster chirality[16k], mechanistic studies of metal-metal bond reactivity[16l], and the stepwise reactions of C atoms[16m], CO[16n], and RCN molecules[16o] bound to several metal atoms of a cluster. All this work forms the basis for the following discussion of the catalytic reactions and their possible mechanisms in the presence of transition metal clusters.

## 2. Carbonylmetal Clusters

Carbonylmetal clusters constitute the largest group of clusters in which the metal atom has a low oxidation state. These include dinuclear and trinuclear clusters, those with tetrahedral $M_4$ and octahedral $M_6$ cores, and the largest cluster which has 38 platinum atoms with a $Pt_{38}$ core of $O_h$ cubeoctahedral symmetry[15, 16a]. No carbonylmetal clusters appear to possess high catalytic activity and most of the reported reactions with these "catalysts" required relatively high temperatures. Nevertheless, these clusters exhibit a stoichiometric chemistry that provides insight *vis-a-vis* intermediates in reactions catalyzed by metal surfaces[7, 8].

Metal-metal and metal-carbonyl bond energies appear to be comparable in most carbonylmetal clusters[7, 8, 17], but their magnitudes are small compared to those of bonds between elements of the first and second rows. Hence, catalytic or stoichiometric carbonylmetal cluster reactions may involve scission of one or all metal-metal bonds. The trend in metal-metal bond energies is that for a given group they increase in going from 3d to 4d to 5d metals; this trend holds both for clusters and for bulk metals. Clusters based on 3d metals therefore exhibit a proclivity for fragmentation, whereas those based on 5d metals like osmium and iridium show a marked resistance to metal-metal bond scission. For example, $Fe_3(CO)_{12}$ reacts with alkenes at 80 °C[14a] to form $[(\eta^2\text{-alkene})Fe(CO)_4]$[18] complexes, which can initiate catalytic isomerization of olefins. In contrast, $Os_3(CO)_{12}$ does not even react with alkenes at moderate temperatures, and at higher temperatures the reaction proceeds by scission of an Os—CO bond, not an Os—Os bond, to give $[H_2Os_3(CO)_9]$ clusters with vinylidene and with acetylene groups[19]. Furthermore, carbonyl clusters based on 3d metals can be used as sources of $LM(CO)_x$ fragments under relatively mild reaction conditions for the synthesis of heteronuclear carbonylmetal clusters. Some syntheses of heteronuclear carbonylmetal clusters by fragmentation reactions are illustrated [Eqs. (a) and (b)][20, 21].

$$2(\mu_3\text{-RC})Co_3(CO)_9 + [(\eta^5\text{-}C_5H_5)Fe(CO)_2]_2 \xrightarrow{h\nu} 2[(\mu_3\text{-RC})Co_2(CO)_6Fe(\eta^5\text{-}C_5H_5)(CO)] + Co_2(CO)_8 \quad (a)$$

$$2(\mu_3\text{-RC})Co_3(CO)_9 + [(\eta^5\text{-}C_5H_5)NiCO]_2 \longrightarrow 2[(\mu_3\text{-RC})Co_2(CO)_6Ni(\eta^5\text{-}C_5H_5)] + Co_2(CO)_8 \quad (b)$$

In contrast, thermal synthesis of heteronuclear metal clusters using clusters consisting of 4d or 5d metals requires rather severe conditions [Eq. (c)][22].

$$Ru_3(CO)_{12} + Os_3(CO)_{12} \xrightarrow[90\ h]{175\ °C} Ru_2Os(CO)_{12} + RuOs_2(CO)_{12} \quad (c)$$

Metal-metal bond scission can be an important reaction step in cluster reactions such as ligand substitution, a specific class of reactions that often represents key steps within a catalytic cycle. For ligand substitution in mononuclear metal complexes, a mechanistic distinction can be made between dissociative (comprising a preequilibrium step in which an intermediate of lower coordination number is formed by scission of a metal-ligand bond), associative (involving an intermediate of higher coordination number) and interchange (no detectable intermediate). The number of possible reaction mechanisms for clusters is higher because metal-metal bond cleavage may occur along the reaction pathway. For example, two reaction mechanisms have been proposed for the thermal reaction of $Mn_2(CO)_{10}$ and of $Re_2(CO)_{10}$ with phosphanes ($PR_3$) to give $M_2(CO)_9PR_3$ and $M_2(CO)_8(PR_3)_2$[23]: either scission of the metal-metal bond [Eq. (d)] or M—CO bond scission [Eq. (e)].

$$M_2(CO)_{10} \rightleftharpoons 2\,M(CO)_5 \xrightarrow{PR_3} \text{products} \quad (d)$$

$$M_2(CO)_{10} \rightleftharpoons CO + M_2(CO)_9 \xrightarrow{PR_3} \text{products} \quad (e)$$

Metal-metal bond scission does not occur despite the high temperatures of 120—160 °C. Double labeling studies[24, 25] with $^{185}Re_2(CO)_{10}$ and $^{187}Re_2(CO)_{10}$ as well as with $Mn_2(^{12}CO)_{10}$ and $Mn_2(^{13}CO)_{10}$ have established that Eq. (e) prevails for both manganese and rhenium.

In the ligand substitution reactions of $Co_2(CO)_8$[23] there is a greater diversity in reaction mechanism and products. With relatively poor electron donors like $As(C_6H_5)_3$ or

bulky phosphanes, $Co_2(CO)_8$ probably reacts *via* initial cleavage of the Co–CO bond to yield $Co_2(CO)_7L$ and $Co_2(CO)_6L_2$ species. In contrast, less bulky trialkylphosphanes form $[Co(CO)_3PR_3]^+[Co(CO)_4]^-$ products with obvious Co–Co bond scission at some step along the reaction pathway.

Mechanistic studies of ligand substitution reactions of trinuclear and tetranuclear carbonylmetal clusters, *e.g.* $Ru_3(CO)_{12}$, $Co_4(CO)_{12}$, and $Ir_4(CO)_{12}$, are currently being performed[23]. With the exceptions of $Fe_3(CO)_{12}$ and possibly $Ru_3(CO)_{12}$, complete fragmentation into mononuclear products is not a facile process. Definitive characterization of the mechanism of ligand substitution has not been achieved to date. Some of the substitutions may proceed *via* M–CO predissociation and others by M–M bond dissociation. If only one M–M bond is cleaved, this kind of mechanism cannot be distinguished by metal atom labeling (as described for $Re_2(CO)_{10}$ and $Mn_2(CO)_{10}$) from M–CO bond scission.

Also critical to a basic understanding of potential cluster catalytic reactions are mechanistic studies of oxidative additions, since these are steps in catalytic cycles involving, for example, hydrogenation. An example of an oxidative addition involving mononuclear metal complexes is addition of hydrogen [Eq. (f); a specific example from cluster chemistry is shown in Eq. (g)].

$$H_2 + ML_x \rightleftharpoons H_2ML_x \quad (f)$$

$$H_2 + Os_3(CO)_{12} \rightleftharpoons H_2Os_3(CO)_{10} + 2CO \quad (g)$$

Mechanistic studies of oxidative additions have not been reported for carbonylmetal clusters.

## 3. Reaction Mechanisms

Because metal clusters can fragment, especially at high temperatures, characterization of catalytic cycles, even those in which the cluster precursor preserves its nuclearity throughout the cycle, is difficult. Even quantitative recovery of the precursor after many catalytic cycles establishes nothing about the nuclearity of the catalytically active intermediates. Kinetic data alone rarely provide substantive insights into details of the catalytic cycles and cannot be used to "prove" catalysis by clusters. Spectroscopic monitoring of the catalytic reaction can be helpful, but there are many possible pitfalls in the interpretation of such data: detectable species may not be intermediates; intermediates may be so short-lived as to escape spectroscopic detection; a reaction system may be so complex, irrespective of whether the catalytic precursor[1a] is mononuclear or polynuclear, that detectable species present under catalytic conditions may have a large range of nuclearity—a potpourri of possible catalytically active intermediates. An important question in "cluster catalysis" applies also to mononuclear precursors: are the intermediates mononuclear or polynuclear in character? Nevertheless, under ideal conditions, it is possible to detect catalytic intermediates by spectroscopic techniques or even to isolate them by studying the reactions as a function of temperature, especially for those reactions that are fast at or near room temperature.

The problem of molecular features of catalytic reaction cycles is complex and generally requires chemical, kinetic, spectroscopic, and labeling studies for insight. There is no precise protocol for experimental definition of cluster catalysis. Each spezific system must be considered on its own merits using the experimental data that can be obtained. The challenge here is great and the answers are feasible for some, although not all systems, given the techniques now practicable.

In the following sections, implicated catalytic reactions are discussed first in terms of an illustration of scope and catalytic systems for which some mechanistic data are available. Most of these discussions are limited to"zero-valent" metal clusters, namely the carbonyl clusters and a closely related group of alkyl isocyanide compounds. Finally "reactive" metal clusters, particulary coordinately unsaturated metal clusters, are considered.

## 4. Multiplicity and Variety of Metal Cluster Catalyzed Reactions

The scope of catalytic reactions initiated by metal clusters is given in Table 1. It should, however, be particularly borne in mind that this listing is not comprehensive and that no presumption about the nuclearity of the actual intermediates should be made in any of the reactions listed. Also, we call attention to recent general reviews of cluster catalysis[42].

Table 1. Metal Cluster catalyzed Reactions.

| Reaction | References |
|---|---|
| alkene isomerization | [14b, 26, 27] |
| reduction of CO and of ketones | [28] |
| alkene hydrogeneration | [26, 27] |
| hydroformylation of alkenes | [27, 29, 30, 41] |
| ketone hydrogenation | [31] |
| Fischer-Tropsch-synthesis | [32] |
| hydrogenation of alkyl cyanides and -isocyanides | [33, 34] |
| synthesis of methanol from CO and $H_2$ | [35, 36] |
| synthesis of polyols from CO and $H_2$ | [36] |
| hydrogenation of nitrobenzene to aniline | [27, 30, 38] |
| hydrogenation of amides | [37] |
| alkyne hydrogenation | [27] |
| alkyne cyclization to arenes | [40] |
| aminomethylation [a] | [41] |
| hydroxymethylation [b] | [41] |
| water gas shift reaction | [39] |

[a] $RCH{=}CH_2 + 3CO + H_2O + HNR'_2 \longrightarrow RCH_2CH_2CH_2NR'_2 + 2CO_2$

[b] $RCH{=}CH_2 + 3CO + 2H_2O \longrightarrow RCH_2CH_2CH_2OH + 2CO_2$ or $RCH(CH_3)CH_2OH + 2CO_2$

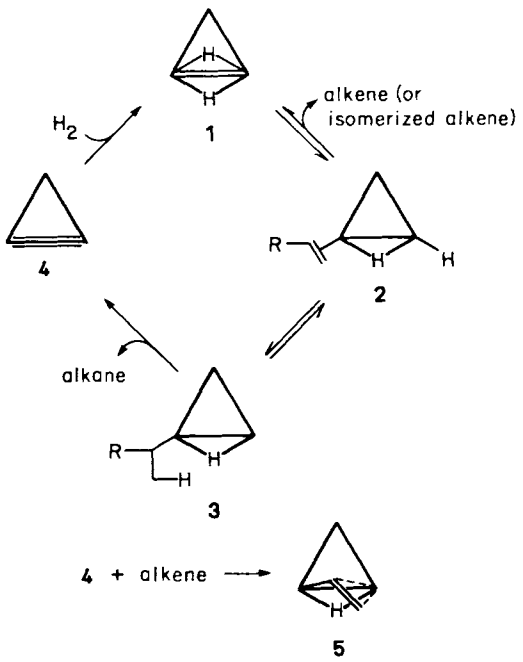
## 5. Hydrogenation of Alkenes, Ketones, and Carboxylic Acids, and Isomerization of Alkenes

The coordinatively unsaturated cluster $[(\mu\text{-}H)_2Os_3(CO)_{10}]$ reacts with two equivalents of ethylene to form ethane and $[(\mu\text{-}H)Os_3(\mu\text{-}CH{=}CH_2)(CO)_{10}]$[26]. Analogous reactions occur with other terminal alkenes with rates which are sensitive to electronic and steric properties of the alkene; rates decrease along series vinyl acetate >

ethylene > propylene or isobutylene[26]. With the dihydrido complex as catalyst, hydrogen and alkene are converted into alkane and, depending upon the olefin, into isomerized alkene. For example, hydrogen and 1-hexene were slowly converted into hexane and a mixture of 2- and 3-hexene (alkane : alkene ratio 31 : 69) at 50 °C and *ca.* 3.4 atm[26]. The formation of the internal hexenes indicates the reversibility of the alkene coordination and the alkyl-forming insertion reaction. Accumulation of 2- and 3-hexenes is consistent with the observation that $[(\mu\text{-H})_2Os_3(CO)_{10}]$ does not react with internal alkenes such as cyclooctene. With functionally substituted alkenes, intermediate hydrido(alkyl) clusters were isolated and characterized from reaction with $(\mu\text{-H})_2Os_3(CO)_{10}$. These species react with hydrogen to form the alkane and the initial cluster $[(\mu\text{-H})_2Os_3(CO)_{10}]$. All these results provide substantial support for the proposed mechanism of the catalytic reaction cycle (Scheme 1)[26]. Only two of the intermediates in the cycle have not been detected either directly in the catalytic reaction or by independent synthesis. One of these is the alkene complex $[H(\mu\text{-H})Os_3(\eta^2\text{-alkene})(CO)_{10}]$ **2**, which should not occur in high concentration, and the other is either $Os_3(CO)_{10}$ **4** or $[Os_3(CO)_{10}(\eta^2\text{-alkene})]$. It should be noted in this catalytic cycle, based on a coordinately unsaturated cluster precursor, that CO ligand dissociation is not an integral feature. The experimental data indicate that the cluster is intact throughout the catalytic cycle, and this is consistent with the relatively high Os–Os bond energy.

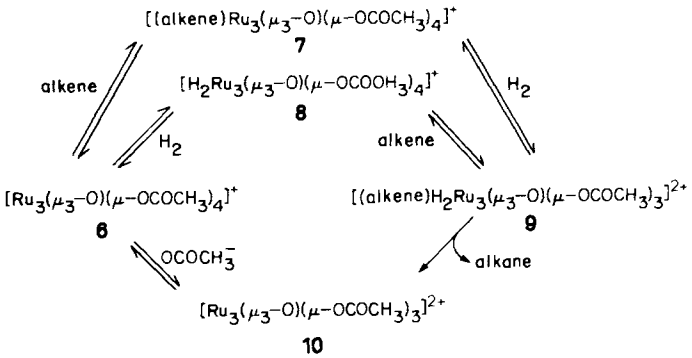
Only a few catalytic reactions have been reported involving clusters in which the formal oxidation state of the metal atoms is high. One such cluster $[Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_6(OH_2)_3]^+(OCOCH_3)^-$ has been used in the hydrogenation of alkenes and alkynes. This complex, in which the ruthenium atoms have the +3 oxidation state, is not strictly a cluster because the Ru–Ru distances are probably > 3 Å. Catalysis of reactions involving alkene hydrogenation proceeds at *ca.* 80 °C and 1 atm in dimethylformamide (DMF). Surprisingly, the reactivity of the unsaturated molecules decreases along the series: cyclic alkene > internal alkene > terminal alkene > terminal alkyne. Kinetic studies[43] established a rate equation with a first-order dependence on the concentrations of alkene, hydrogen, and ruthenium cluster. The first reaction steps for this system[43] are shown in Eqs. (h) and (i).

$$[Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_6(OH_2)_3]^+(OCOCH_3)^- + (DMF) \longrightarrow [Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_6(DMF)_x]^+(OCOCH_3)^- + 3\,H_2O \quad (h)$$



$$[Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_6(DMF)_x]^+(OCOCH_3)^- + H_2 \longrightarrow [HRu_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_5(DMF)_x]^+(OCOCH_3)^- + CH_3COOH \quad (i)$$

The hydrido cluster, which could be characterized, is a catalyst for the isomerization of alkenes in the absence of hydrogen. It has been postulated that the hydrido complex adds to alkenes and that this alkene complex then undergoes a reversible insertion reaction to form the alkyl analog of the hydrido complex. The final two steps in the proposed cycle are addition of $H_2$ and elimination of alkane to reform the hydrido cluster. However, more important for the hydrogenation is another cycle involving reductive elimination of acetic acid from the hydrido cluster [Eq. (j)].



$$[HRu_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_5(DMF)_x]^+(OCOCH_3)^- \longrightarrow CH_3COOH + \underset{\mathbf{6}}{[Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_4(DMF)_x]^+(OCOCH_3)^-} \quad (j)$$

The reduced cluster, **6**, is not fully characterized but has been postulated to provide entry to the major catalytic cycle by reaction with $H_2$ or the alkene. The steps[43] postulated in the cycle are shown in Scheme 2.

The activation of hydrogen by **6** (Scheme 2) is postulated to be heterolytic with only one ruthenium atom in-

Scheme 1. The catalytic cycle, proposed by *Keister* and *Shapley* [26] for alkene hydrogenation initiated by the $[(\mu\text{-H})_2Os_3(CO)_{10}]$ cluster. The $Os_3$ core is represented by a triangle; each osmium atom has three terminal CO ligands, which are not depicted. Multiple lines in the triangles imply metal-metal bond orders approaching two and three in intermediates **1** and **4**. Species **1**, **2**, and **5** are reasonably well defined; **3** and **4** have only been postulated. Intermediate **4**, $Os_3(CO)_{10}$, could also be $[Os_3(CO)_{10}(\eta^2\text{-alkene})]$.

Scheme 2. Depicted here is the postulated [43] major catalytic reaction cycle for alkene hydrogenation by the catalyst precursor $[Ru_3(\mu_3\text{-O})(\mu\text{-OCOCH}_3)_6(OH_2)_3]^+(OCOCH_3)^-$ in dimethylformamide. The reduced cluster, **6**, is formed in several steps from the precursor *via* solvation by the amide [Eq. (h)] and the steps shown in Eq. (i) and (j). Omitted from the formulas in the cycle are dimethylformamide molecules and the acetate counter ion; in the conversion of **7** and **8**, respectively, into **9** an acetato ligand is cleaved and this is also not shown. The conversion of **10** into **6** is assumed to be irreversible. If it were reversible, complex **6** might provide entry to the cycle and would not be a catalytic intermediate [43].

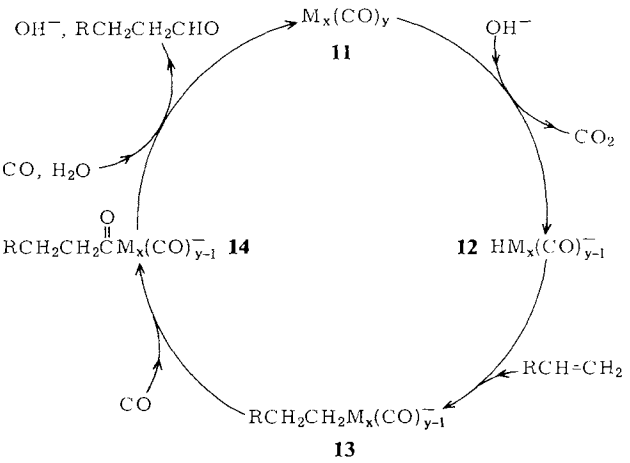
volved in this step and in the complexation of the alkene. Although all experimental results for the catalytic cycle are fully consistent with the proposed mechanistic features, neither the character of the intermediates beyond **6** nor the number of ruthenium atoms involved in the $H_2$ addition step have been definitively established. It should be noted that in this cluster-based catalytic cycle, dissociation of an acetate ion is an integral step.

Catalytic hydrogenation of ketones to alcohols by $[(\mu\text{-H})_4Ru_4(CO)_{12}]$ occurs at 100 °C and 100 atm[44a]. The rate of hydrogenation appears to be first order with respect to cluster, ketone, and hydrogen partial pressure as indicated from a series of experiments involving cyclohexanone in tetrahydrofuran[44a]. In this reaction, the ruthenium cluster is recovered unchanged. No catalytic cycle has been proposed for this system. The data do not preclude the possibility of cluster fragmentation within the catalytic cycle. A qualitative indication of the mechanism was provided by the hydrogenation of $(CD_3)_2CO$ to give $CD_3CH(OH)CD_3$ as the sole product: in the reduction sequence the ketone is not present in the enol form and must be bound through the carbonyl oxygen atom.

Phosphane derivatives of $[H_4Ru_4(CO)_{12}]$ are catalyst precursors for the hydrogenation of aliphatic carboxylic acids and anhydrides at 130 atm and 20 °C[44b]. In one of the systems, IR studies showed the presence of carbonylruthenium carboxylates. $[Ru(CO)_2(OCOCH_3)\{P(n\text{-}C_4H_9)_3\}]_2$, which was isolated from the $\{H_4Ru_4(CO)_8[P(n\text{-}C_4H_9)_3]_4\}$ system, was independently shown to be a catalyst precursor.

In contrast to the hydrogenation of ketones catalyzed by $[(\mu\text{-H})_4Ru_4(CO)_{12}]$, the analogous reaction with $Rh_4(CO)_{12}$ clearly involves cluster fragmentation. For this system *Heil* and *Marko*[45] found that the reaction order is proportional to one-sixth of the concentration of $Rh_4(CO)_{12}$.

A number of clusters initiate isomerization of alkenes. As mentioned previously, $Fe_3(CO)_{12}$ is one such species, but in this case the key catalytic intermediates[14] are monomeric, *i.e.* $[(\eta^2\text{-alkene})Fe(CO)_x]$ complexes. As mentioned above isomerization of alkenes by clusters is initiated by $[(\mu\text{-H})_2Os_3(CO)_{10}]$[26] and $[HRu_3(\mu\text{-O})(\mu\text{-OCOCH}_3)_5(DMF)_x]^+(OCOCH_3)^-$[43]. $[(\mu\text{-H})_4Ru_4(CO)_{12}]$ as well as its phosphite and phosphane derivatives are also catalysts for the isomerization of alkenes[46]. For the isomerization of 1-pentene at 70 °C, the initial rate is proportional to the ruthenium cluster concentration and the cluster is unchanged in the course of the catalytic cycle[46]. The nature of the catalytic intermediates has not been established and no catalytic cycle was postulated, although a CO ligand dissociation step and allylmetal intermediates were implicated for the catalytic cycle.



## 6. Hydroformylation of Alkenes

In hydroformylation, alkenes react with CO and either $H_2$ or $H_2O$ to form aldehydes [Eqs. (k) and (l)]

$$RCH{=}CH_2 + CO + H_2 \longrightarrow RCH_2CH_2CHO \quad (k)$$

$$RCH{=}CH_2 + 2\,CO + H_2O \longrightarrow RCH_2CH_2CHO + CO_2 \quad (l)$$

Various clusters such as $Rh_6(CO)_{16}$[29,47], $[H_4Ru_4(CO)_{12}]$[47], $Os_3(CO)_{12}$[47], $[H_2Os_3(CO)_{10}]$[47], $[H_4Os(CO)_{12}]$[47], $Ir_4(CO)_{12}$[47], $[Pt_3(CO)_6]_5^{2-}$[47], $Ru_3(CO)_{12}$[29,47], $[Co_4(CO)_8(\mu_2\text{-CO})_2(\mu_4\text{-PC}_6H_5)_2]$[27], and $[Co_2(CO)_8M(\eta^5\text{-}C_5H_5)(\mu_3\text{-CCH}_3)]$ (M = Mo, W)[27] are catalyst precursors for one or both of these reactions. Reaction (l) requires the presence hydroxide ion. Typically, the cluster reacts with an $OH^-$ ion to form an anionic hydrido cluster which reacts further as shown in Scheme 3[29]. For example, hydroformylation with $[(\mu\text{-H})_4Ru_4(CO)_{12}]$ as the catalyst precursor appears to generate a $[H_3Ru_4(CO)_{12}]^-$ intermediate. The acyl derivatives that model the acyl intermediate **14** shown in Scheme 3 have been characterized for other clusters[48].

Scheme 3. Hypothetical mechanism for the hydroformylation of alkenes catalyzed by clusters.

The reaction in Eq. (k) is also catalyzed by clusters. It has been proposed that $[Co_4(CO)_8(\mu_2\text{-CO})_2(\mu_4\text{-PC}_6H_5)_2]$ retains its framework throughout the catalytic cycle[27], and that the intermediates in the cycle model are those typically proposed for hydroformylation reactions, *i.e.* those catalyzed by mononuclear metal complexes[49]. No experimental data to support this hypothesis were presented.

Catalytic hydroformylation reactions do not require multimetal atom site catalysis although unique selectivities might be achieved with cluster catalysts, *e.g.* a selectivity to branched or to linear products.

## 7. Hydrogenation of Aromatic Nitro Compounds

Nitrobenzene has been catalytically hydrogenated to aniline using cluster catalyst precursors. For example, *Pettit et al.*[38,50] used water, CO, and a base with a diverse group of clusters as catalyst precursors. Some of the more active of these were $Rh_6(CO)_{16}$, $Os_3(CO)_{12}$, $[H_4Os_4(CO)_{12}]$, $Ru_3(CO)_{12}$, and $Ir_4(CO)_{12}$. All of these catalyze the water-gas shift reaction (see Section 9), but the rates are lower than for the hydrogenation of nitrobenzene to aniline[38,50]. Hence, an intermediate hydrido cluster must transfer hydride ion directly to nitrobenzene. Anions such as $[HRu_3(CO)_{11}]^-$ are probably important intermediates for the ruthenium system (see Section 8). Nitrobenzene has

also been converted into aniline by hydrogen using $[(\eta^5\text{-}C_5H_5)Fe(\mu_3\text{-}CO)]_4$ as the catalyst precursor[27], which was recovered unchanged at the end of the catalytic reaction. It was shown that a mononuclear fragment $[(\eta^5\text{-}C_5H_5)Fe(CO)_2H]$, does not catalyze this hydrogenation reaction.

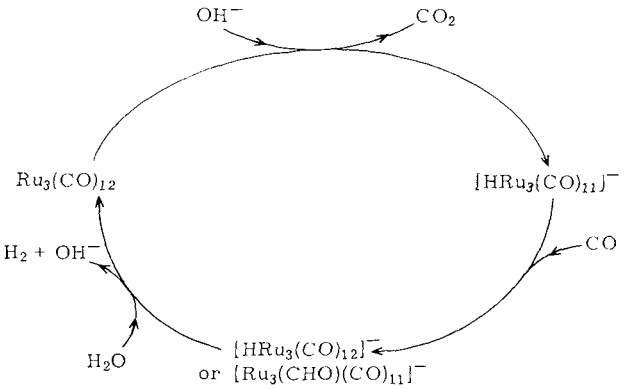
To date, mechanistic studies have not been reported for the hydrogenation of nitrobenzene initiated by clusters. Even though some or all of these systems *may* have only cluster intermediates in the catalytic cycle, cluster intermediates, *per se*, are not necessary conditions for this type of catalytic reaction. Hydrogenation of aromatic nitro compounds probably does not involve multimetal atom site catalysis.

## 8. Alkyl Group Exchange and H/D Exchange in Amines

Using cluster reactions *Laine et al.*[51–53] have attempted to model the basic steps in the hydrodenitrogenation reaction, *i.e.* the removal of nitrogen as ammonia from aromatic nitrogen compounds. Basic to the hydrodenitrogenation reaction is cleavage of C–N bonds. *Shvo* and *Laine*[52] found that $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$ and $Ir_4(CO)_{12}$ catalyze the fast exchange of alkyl groups in tertiary amines in the presence of water (presence is essential) at 125–150 °C. The observed rates exceed those for palladium-black catalyzed reactions which require temperatures of 200 °C. Postulated intermediates are "iminium" ($R_2C{=}NR_2^+$) cluster complexes and aldehyde-*s*-amine cluster complexes. The latter are postulated to form by hydrolysis of the iminium derivatives. No definitive mechanistic information is available for these very interesting alkyl group exchange reactions initiated by clusters.

These same clusters also catalyze H/D exchange in tertiary amines; here very unusual stereoselectivities occur which can serve as a model for reactions catalyzed by Pd-black[51,53]. The reaction mechanism proposed appears plausible, although no kinetic or spectroscopic studies have been presented: it involves iminium clusters *(vide supra)*, amino substituted ethylidyne clusters with $(\mu_3\text{-}R_2NCH_2C)M_3$-frameworks, and $(\eta^2\text{-}R_2NCH_2CHR)M_3$ clusters as intermediates. Formally, these three types of intermediate have analogs in cluster chemistry[7] and there are specific analogs for the postulated iminium derivatives[54]. Only for the ruthenium system, could a post-catalytic reaction species be isolated, the imino derivative $[HRu_3(\mu\text{-}\eta^2\text{-}CH_3C{=}NC_2H_5)(CO)_9]$. The relevance of this cluster to the proposed catalytic cycle was not established but it could represent a local energy minimum, off the catalytic cycle for the proposed minimum intermediate. For the mechanism it was postulated that multimetal atom sites are involved. The unusual stereoselectivity of the H/D exchange reactions may be unique to multisite catalyses.

Relevant also to the hydrodenitrogenation reactions, are the hydrogenation studies of *Fish et al.*[55], who established that $[H_4Ru_4(CO)_{12}]$ is an effective catalyst precursor for the hydrogenation of such arenes at 180 °C. The cluster was recovered unchanged from these reactions. No mechanistic studies have been completed yet.



## 9. Water-Gas Shift Reaction

In the water-gas shift reaction, which is of substantial technological importance, water is reduced by carbon monoxide to give $H_2$ [Eq. (m)].

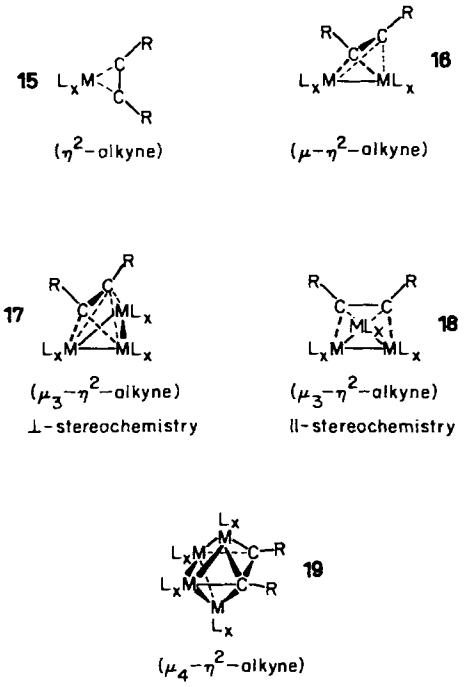
$$H_2O + CO \rightleftharpoons H_2 + CO_2 \qquad (m)$$

The first reports of catalysis of the water-gas shift reaction by molecular metal complexes in the solution state included the observation[39,56] that $Ru_3(CO)_{12}$ in ethoxymethanol in presence of KOH effected, at a low rate, catalysis of the shift reaction at *ca.* 100 °C. Studies with labeled solvent established that $H_2O$ was the source of $H_2$. A catalytic cycle can also be effected with $[H_4Ru_4(CO)_{12}]$ as initiator. Tetranuclear carbonylruthenium species have been proposed[57] as the major catalytic intermediates in this system; however, recent studies[58] indicate that trinuclear Ru clusters are the major intermediates, especially under flow reaction conditions. According to Eq. (n) the hydrido cluster anion $[HRu_3(CO)_{11}]^-$ is formed and this reacts with $H_2O$ and CO to produce $Ru_3(CO)_{12} + H_2$; the deutero cluster produces HD. Thus, the net effect is a transfer of hydride ion, ultimately to a water molecule, thereby forming $H_2$ and regenerating $OH^-$ ion. One of the proposed[58] catalytic cycles is shown in Scheme 4. For a discussion of $[H_4Ru_4(CO)_{12}]$ transformations in the catalytic system, the reader is directed to the article by *Bricker, Nagel,* and *Shore*[58].

$$Ru_3(CO)_{12} + OH^- \longrightarrow HRu_3(CO)_{11}^- + CO_2 \qquad (n)$$

Scheme 4. Proposed mechanism for the $Ru_3(CO)_{12}$-catalyzed water-gas shift reaction [58].

Many other clusters[59], *e.g.* $Ir_4(CO)_{12}$, $Os_3(CO)_{12}$, $Rh_6(CO)_{16}$, and $[Pt_{15}(CO)_{30}]^{2-}$, initiate catalysis of the water-gas shift reaction, as also do many simple mononuclear metal complexes[56]. There is nothing magical about clusters for this specific catalytic reaction. Multi-atom sites are not a requirement[56] for any of the catalytic reaction steps—the only requirement is that a good hydride transfer species be readily generated.



Some clusters that initiate the water-gas shift reaction also form species that can catalyze hydroformylation and hydrogenation reactions. Combination of these reactions

then allows the use of CO + $H_2O$ as the source of the hydrogen reactant (see Sections 6 and 7).

## 10. Alkyne Hydrogenation Reactions

Alkyne hydrogenation may yield an alkene or an alkane as initial product, according to whether the hydrogenation product dissociates from the metal center(s) of the catalytic intermediate. If the product is an alkene, *cis*- or *trans*-isomers or both may be formed. In those systems in which the metal complex catalyst intermediate is mononuclear a *cis*-isomer is invariably formed. Because of possible chemoselectivity and stereoselectivity a study of an alkyne hydrogenation can be more mechanistically informative than that of alkene hydrogenation[60]. A number of dinuclear or polynuclear metal complexes have been reported to catalyze alkyne hydrogenation[60-69]. Some have been studied mechanistically and the salient features are described here.

Alkynes bind to a single metal atom to form ($\eta^2$-alkyne)metal bonds; the alkyne ligand can function formally as a two-electron up to a four-electron donor. Scheme 5 shows the various ways in which alkynes can bond to metal atoms in clusters.

Scheme 5. Five modes (**15**—**19**) of binding of alkynes to metal atoms of clusters. Specific examples of the bridging modes are [$\mu$-$\eta^2$-alkyne)$Co_2(CO)_6$], [($\mu_3$-$\eta^2$-alkyne)$Fe_3(CO)_{10}$]($\perp$-stereochemistry), [($\mu_3$-$\eta^2$-alkyne)$Os_3(CO)_{10}$] (||-stereochemistry), and [($\mu_4$-$\eta^2$-alkyne)$Co_4(CO)_{10}$].

Studies of a variety of dinuclear ($\mu$-$\eta^2$-alkyne)$M_2L_x$ complexes have shown that some are initiators for alkyne hydrogenations and some have been shown to be true cluster catalysts[60-69]. The coordinatively unsaturated nickel(0) complex [{($\eta^4$-1,5-cyclooctadiene)Ni}$_2$($\mu$-$\eta^2$-$C_2Ph_2$)] is an effective initiator of alkyne hydrogenation and gives rise to *cis*-alkenes; alkyne trimerization is a competing catalytic reaction[61,63]. All the data for this $d^8$-metal system suggest that the catalyst intermediate for the alkyne hydrogenation is the dinuclear complex. Nevertheless, the dimer also reacts with alkyne to form a mononuclear species [Eq. (o)], which has been isolated[61] and crystallographically defined[64].

[{($\eta^4$-1,5-cyclooctadiene)Ni}$_2$($\mu$-$\eta^2$-alkyne)] + alkyne
$\rightleftharpoons$ 2[($\eta^4$-1,5-cyclooctadiene)Ni($\eta^2$-alkyne)] (o)

This mononuclear complex is probably the active catalyst for the competing alkyne trimerization reaction but it does not react with hydrogen to give alkenes.

A true cluster catalytic cycle was established for alkyne hydrogenation by [{($\eta^5$-$C_5H_5$)Mo(CO)$_2$}$_2$($\mu$-$\eta^2$-alkyne)][65]. Here, alkynes such as 2-butyne, 3-hexyne, $C_2H_2$ and $C_2D_2$ give *cis*-alkenes. No fragmentation of the cluster under catalytic reaction conditions was detected: using a mixture of [($\eta^5$-$C_5H_5$)Mo(CO)$_2$]$_2$($\mu$-$\eta^2$-alkene) and [($\eta^5$-$CH_3C_5H_4$)Mo(CO)$_2$]$_2$($\mu$-$\eta^2$-alkene), no cross-labeled dimer in the recovered catalyst was detected by mass spectrometry. Studies[65] of the rate of alkyne exchange, CO ($^{13}$CO) exchange, and inhibition of the catalytic reaction by CO strongly implicated CO-dissociation from the saturated dimer as the first step in the catalytic cycle. In the terminal steps of the catalytic cycle, the *cis*-alkene is eliminated and the dimer [($\eta^5$-$C_5H_5$)Mo(CO)$_2$]$_2$ is formed, which reacts rapidly with acetylene to reform the initial ($\mu$-$\eta^2$-alkyne) complex.

Under relatively severe conditions, the tetranuclear cluster [($\eta^5$-$C_5H_5$)Fe($\mu_3$-CO)]$_4$ is reported[27] to catalyze hydrogenation of alkynes (as well as of activated olefins and nitrobenzene). At 7—70 atm $H_2$ and 130—140 °C, the turnover rate for 1-pentyne conversion to largely 1-pentene is *ca.* 15 $min^{-1}$. The cluster was recovered unchanged from the reactions. Also, it was demonstrated that [($\eta^5$-$C_5H_5$)Fe(CO)$_2$H], a possible cluster fragmentation product, was not a catalyst for alkyne hydrogenation. The data, although not inconsistent with cluster catalysis, are insufficient to establish molecular character of the catalytic cycle.

In the small group of zerovalent metal clusters in which all ligands are alkyl isocyanides,

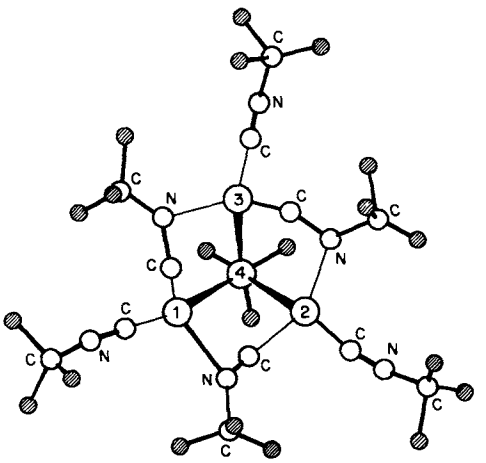


Fig. 1. Structure of the coordinately unsaturated cluster, [$Ni_4$[$\mu$-$\eta^2$-CNC$(CH_3)_3$]$_3$[CNC$(CH_3)_3$]$_4$], in the crystal [40]. The nickel atoms form an irregular $C_{3v}$ tetrahedron with one enlarged face (Ni1Ni2Ni3). Each nickel atom is terminally bonded to one isocyanide ligand through the carbon atom only (the CNC unit of the isocyanide terminally bound to Ni4 is eclipsed by the Ni4 atom in this projection). The remaining three isocyanide ligands bridge the long tetrahedral edges (Ni—C—N—Ni bonding).

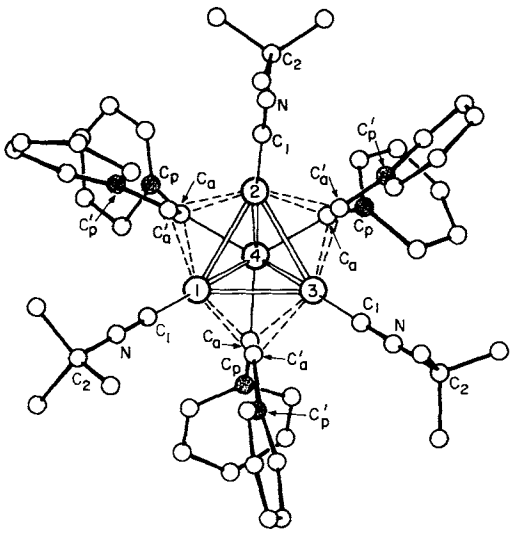
$[Ni_4\{\mu\text{-}\eta^2\text{-}CNC(CH_3)_3\}_3\{CNC(CH_3)_3\}_4]$ (Fig. 1) initiates alkyne hydrogenation at 20 °C that largely yields *cis*-alkenes[66]. This cluster and the derivative alkyne complexes discussed below do not react with alkenes nor do they effect alkene hydrogenation. Thus, the cluster chemoselectivity in the catalytic reactions is easy to explain.

The $Ni_4$-cluster reacts with diarylalkynes[67-69] to form $[Ni_4(\mu_3\text{-}\eta^2\text{-alkyne})_3\{CNC(CH_3)_3\}_4]$ (Fig. 2) and $[(\eta^2\text{-alkyne})Ni\{CNC(CH_3)_3\}_2]$. The tetranuclear alkyne-nickel cluster is the catalytic precursor in alkyne hydrogenation and is the nickel species recovered from the reaction mixtures[67-69]. Hydrogenation rates are first order with respect to alkyne cluster concentration. The data, however, do not definitively establish that fragmentation of the cluster does not occur in one or more steps of the cycle.



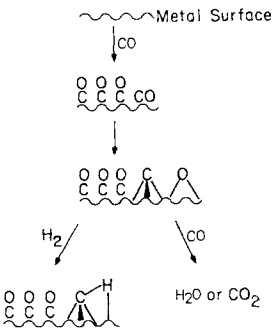


Fig. 2. Structure of $[Ni_4(\mu\text{-}\eta^2\text{-}C_6H_5C{\equiv}CC_6H_5)_3\{CNC(CH_3)_3\}_4]$ in the crystal [67], viewed normal to the triangular base along the (idealized) threefold axis. Ni atoms are represented by large open circles, and C and N atoms by small open circles. Ni4 is the unique apical nickel atom which lies on the pseudo-threefold axis. C atoms $C_a$ and $C'_a$ represent the acetylenic C atoms. $C_a$ is bonded to two basal Ni atoms and to Ni4; $C'_a$ is bonded to only two basal Ni atoms.

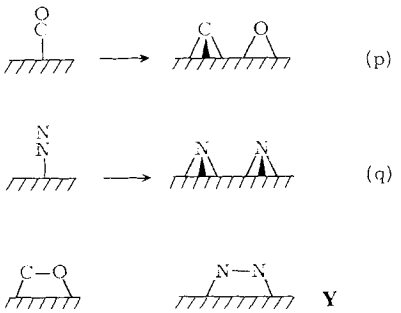

## 11. Hydrogenation of CO, $CN^-$, RCN, RNC, and $N_2$

In the preceding section, mechanistic features of the hydrogenation of alkynes by cluster precursors were discussed. Generally, this catalytic cycle is very easy to maintain with mononuclear metal complexes, clusters, or on metal surfaces. Multisite metal atom catalysis is not a requirement of this type of reaction. In sharp contrast, it is relatively difficult to effect hydrogenation of the triple bonds in molecules or ions like CO, $CN^-$, alkyl cyanides, alkyl isocyanides, and $N_2$. Typically, the catalysts of choice for these hydrogenations are solid-state materials, *e.g.* metals, alloys, metal oxides, and metal carbides, although some molecular compounds have been reported to be catalysts. Conditions are generally quite severe: temperatures of 200–300 °C and elevated pressures are necessary for reasonable reaction rates in the hydrogenation of CO or $N_2$. It is extremely difficult to gather incisive mechanistic data for such high temperature reactions in which transient reaction intermediates occur. Most studied has been the hydrogenation of CO to give hydrocarbons (the methanation reaction and Fischer-Tropsch synthesis) and of $N_2$ to give ammonia. For solid-state metallic or metal carbide catalysts, a dominant first step appears to be dissociative chemisorption of CO to form surface-bound carbon and oxygen atoms[70] and of $N_2$ to give surface-bound nitrogen atoms[71]. Scheme 6 shows a model for the metal-surface catalyzed hydrogenation of CO to give hydrocarbons. In the next section the reduction of $N_2$, RNC, RCN and $CN^-$ by nitrogenase is discussed. These reactions may involve participation of multimetal atom sites in the reduction steps.

Scheme 6. The first step of a possible mechanism for the Fischer-Tropsch synthesis.

The triple bonds of CO or $N_2$ are not cleaved at a single metal site of mononuclear metal complexes. An early postulate[6] in cluster catalysis was that hydrogenations, such as those of CO and $N_2$, which proceeded with difficulty might be more facile than with mononuclear metal catalyst precursors, since multimetal atom site reactions are possible and, in particular, these could achieve the formal analog of dissociative chemisorption of CO and $N_2$ on metal surfaces. The reactions described in Scheme 6 and Eqs. (p) and (q) proceed through intermediates or transition states of type **X** and **Y**, respectively.

Models of the intermediate or transition state for the CO case may be found in a number of metal clusters in which both the oxygen and the carbon atoms are bound to metal atoms. The first well-characterized species of this group was $[HFe_4(\mu\text{-}\eta^2\text{-}CO)(CO)_{12}]^-$ (Fig. 3)[72]. In addition, it has been shown that carbonylmetal clusters are converted into carbidometal clusters under a variety of conditions, and are thus formally models for the overall process

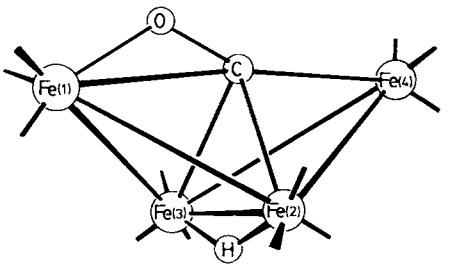

Fig. 3. Structure of the $Fe_4$-core of the cluster ion $[HFe_4(\mu\text{-}\eta^2\text{-}CO)(CO)_{12}]^-$[72]. The iron atoms have a butterfly structure and a hydrido ligand bridges the basal edge. Each iron atom has three terminal CO ligands which are indicated only by line projections. Unique is the bridging CO ligand in which both the oxygen and the carbon atoms are bonded to the Fe-framework atoms. The C-O bond order in this bridging ligand is substantially reduced, as evidenced by the relatively long C–O bond distance of 1.26 Å (typical cluster carbonyl C–O distances are *ca.* 1.1 to 1.14 Å for CO ligands that are bound only through the carbon atom).

of dissociative chemisorption of CO on metal surfaces. Using labeling experiments and NMR studies, ***Bradley et al.***[73, 16m] have demonstrated in an iron and a ruthenium system that the carbido C atom is derived from a CO molecule [Eqs. (r) and (s)]

$$Fe(^{13}CO)_5 \xrightarrow{Mn(CO)_5^-} [Fe_6{}^{13}C(^{13}CO)_{16}]^{2-} \quad (r)$$

$$Ru_3(^{13}CO)_{12} \xrightarrow{Mn(CO)_5^-} [Ru_6{}^{13}C(^{13}CO)_{16}]^{2-} \quad (s)$$

Also *Tachikawa et al.*[75] have shown that carbido clusters in which the carbido C-atom has a coordination number of four can react with hydrogen to form C–H bonds [Eq. (t)].

$$[Fe_4(\mu_4\text{-}C)(CO)_{12}]^{2-} \xrightarrow{Ag^+} [Fe_4(\mu_4\text{-}C)(CO)_{12}] \xrightarrow{H_2} [HFe_4(\mu\text{-}\eta^2\text{-}CH)(CO)_{12}] \quad (t)$$

The existence of a cluster model of the transition state for the dissociative chemisorption of CO and the stoichiometric cluster reactions that simulate the CO dissociation and the hydrogenation of the carbido C atom suggests that cluster catalyzed hydrogenation of CO might be feasible. In principle, this concept could be extended to $N_2$, $CN^-$, RCN, and RNC. Actually, there are clusters in which cyanides and isocyanides are bonded to metal atoms through both the carbon and nitrogen atoms, as well as stoichiometric cluster reactions[160, 76] that hydrogenate these triple bonds. No metal clusters have yet been described with $N_2$ or $CN^-$ bound to metal atoms through both atoms.

Although cluster precursors have been reported for the catalytic conversion of CO into hydrocarbons, it is not known whether the catalytic intermediates are actually clusters. A major problem in mechanistic studies of such systems is that the reaction conditions are relatively severe and all or most intermediates are transient. Also, under conditions of high temperature and high CO pressures most carbonylmetal clusters enter into facile equilibria[77, 78] with carbonylmetal complexes whose nuclearity may range between one and 12 to 15. It is extremely difficult to accurately assess the molecular features of the catalytic cycle or cycles.

One of the most noteable examples of carbonylmetal catalyzed CO-$H_2$ reactions is the hydrogenation of CO to ethylene glycol using soluble anionic carbonylrhodium compounds[36, 77, 79]. At CO pressures of *ca.* 1000 atm and temperatures of 200 to 290 °C, ethylene glycol is produced relatively selectively; methanol and other polyalcohols are the major byproducts. A detailed FT-IR study[77] of these reaction systems as a function of temperature (50–220 °C) and CO pressure (500–1000 atm) showed that below 180 °C the predominant species present in solution are $[Rh(CO)_4]^-$ and $[Rh_5(CO)_{15}]^-$. Above 180 °C, clusters of higher nuclearity, such as $[H_nRh_{13}(CO)_{24}]^{5-n}$, and possibly $[Rh_{14}(CO)_{25}]^{4-}$, $[Rh_{15}(CO)_{28}]^{3-}$, and $[Rh_{12}(CO)_{30}]^{2-}$ are favored. These results are consistent with the fact that Rh–Rh bond energies generally are lower than Rh–CO bond energies. Despite these very elegant spectroscopic studies, the carbonylrhodium system is too complex to allow realistic characterization of the reaction mechanism in the catalytic cycle. The catalytic cycle or cycles in this system may be based solely on mononuclear metal species, solely on cluster intermediates, or both.

Solutions of carbonylmetal clusters, *e.g.* $Os_3(CO)_{12}$ or $Ir_4(CO)_{12}$, react with $H_2$ and CO under very mild conditions (150–180 °C, 1–2 atm CO) to produce $CH_4$ and other hydrocarbons, but the rates are so low that it is unclear whether the reactions are truly catalytic[80, 81]. Another problem in cluster-initiated CO hydrogenation is encountered with the less robust $Ru_3(CO)_{12}$ cluster. Initial studies suggested that this cluster catalyzed the conversion of CO and $H_2$ into hydrocarbons at 250–300 °C and 1–200 atm[82]. However, a later study established that ruthenium metal, generated by thermal decomposition of $Ru_3(CO)_{12}$, was the actual catalyst[35, 83]. Also, at *ca.* 250 °C and 1300 atm it was shown that $Ru_3(CO)_{12}$ and other ruthenium mononuclear and cluster complexes initiated catalytic conversion of CO and $H_2$ into methanol[35, 83]. Kinetic and spectroscopic studies for this reaction at 25 °C indicated that the catalysis is propagated by $Ru(CO)_5$, rather than by a cluster[35, 83]. However, the data were insufficient to establish a reaction mechanism.

Other reports of cluster-initiated catalysis of CO-hydrogenation involve $Ir_4(CO)_{12}$[84, 85] in a NaCl-$AlCl_3$ melt at 160 °C and 1 atm (formation of methane, ethane, propane, and higher branched alkanes), $[Os_2(CO)_6Br_4]$[86] in solution in $BBr_3$ at 180 °C and 1–2 atm (formation of alkanes as well as methyl, ethyl, propyl and butyl bromides), and $[Os_2(CO)_6Cl_4]$[86] in solution in $BCl_3$ at 110 °C and 1–2 atm (formation of hydrocarbons only). In the first system, the $Ir_4(CO)_{12}$ catalyst precursor was converted into a carbonyliridium species that was not charaterized, and in the last two systems the carbonylosmium halides were recovered unchanged. It was proposed that Ir-CO-Al and Os-CO-B interactions facilitated the hydrogenation reaction, but no catalyst intermediates were characterized and the nuclearity of the catalytic intermediates was not established. In these three systems, the $AlCl_3$ or $BBr_3$ "solvents" were consumed because the oxygen atoms of the CO molecules which are converted into hydrocarbons or alkyl halides are eventually bound to aluminum or boron.

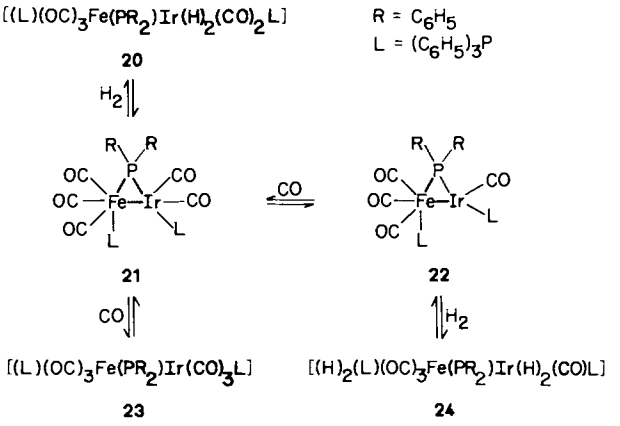
It is improbable that any CO hydrogenation reaction initiated by a carbonylmetal cluster will provide definitive

mechanistic insight. Possibly a metal cluster which does not contain CO ligands and one that does not strongly bind CO will be found that will catalyze CO hydrogenation at temperatures low enough that the intermediates will be sufficiently long lived to allow spectroscopic characterization.

Cluster-initiated catalytic hydrogenation of $N_2$ or $CN^-$ has not been reported, but appears to be possible. Catalytic hydrogenation[34] of acetonitrile and of alkyl isocyanides can be realized using the coordinately unsaturated cluster $[Ni_4\{\mu\text{-}\eta^2\text{-}CNC(CH_3)_3\}_3\{CNC(CH_3)_3\}_4]$. With $Ni[CNC(CH_3)_3]_4$ as the isocyanide source and temperatures of 90 °C, hydrogenation of the isocyanide proceeds with high selectivity to give $(CH_3)_3CNHCH_3$ with only small amounts of the cleavage product $(CH_3)_3CNH_2$. The tetranuclear nickel cluster also catalyzes the hydrogenation of acetonitrile to ethylamine at 90 °C but at a very low rate[34]. Neither $Ni(CNR)_3$ nor $Ni(CNR)_4$ are catalyst precursors for this type of hydrogenation. The mechanism of the cluster-initiated reaction is not known, but possibly the $Ni_4(CNR)_7$ cluster or a $Ni_4(CNR)_6$ species derived from it is an active intermediate. Certainly, the bond order of the isocyanide group is substantially reduced in the $\mu\text{-}\eta^2$ binding established for the parent $Ni_4(CNR)_7$ (Fig. 1).

*Yoshida, Okano,* and *Otsuka*[33] have reported that $[HRh\{P(iC_3H_7)_3\}_3]$ and $[H_2Rh_2(\mu\text{-}N_2)\{P(cyclohexyl)_3\}_4]$ catalyze the hydrogenation (20 °C, 1 atm) of nitriles to give primary amines. The mechanism of this intriguing catalytic reaction was not established but since it proceeds under quite mild conditions, it may be amenable to low temperature NMR studies.

## 12. Biological Reaction Cycles Based on Molecular Metal Clusters



Electron transfer is the prime function of the nonheme iron proteins, the ferredoxins. These $Fe_4$-clusters have a cubane-like structure with alternating iron and sulfur atoms at the vertices and with iron-iron distances that range from 2.7 to 2.8 Å. The $Fe_4S_4$ core is bonded to the protein through an Fe-S bond (Fe from the cluster, S from protein cysteine).

Biological fixation of nitrogen may proceed through multimetal (iron and molybdenum) sites of the nitrogenase enzymes but the nature of $N_2$ binding and the activation steps have not been established for any of the enzymes. The enzymes can also reduce the triple bonds in the cyanide ion, alkyl cyanides, alkyl isocyanides, and acetylenes. Recent reviews provide critical accounts of the state of the art of modeling the active sites[87] and of the biological studies[88].

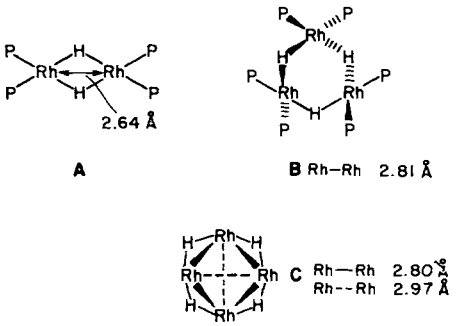
## 13. Coordinately Unsaturated Clusters

An efficient catalyst precursor patently should provide easy entry to an intermediate in the catalytic cycle or be a real intermediate. The majority of isolable metal clusters are coordinately saturated with all low lying molecular orbitals filled, and have a relatively large energy gap between the HOMO and LUMO. For many of these clusters entry into a catalytic cycle requires scission of a metal-ligand or a metal-metal bond. In carbonyl clusters, the dissociation energy for loss of the first CO molecule varies widely. One way to lower this energy is to initially replace one or more CO ligands in the cluster with weak-field ligands, such as acetonitrile. The paradigm would be a carbonyl cluster in which a carbonyl ligand on every metal atom has been replaced with a weak-field ligand. We have attempted to synthesize such clusters but have not been able to obtain the ideal case. For example, successive replacement of CO by acetonitrile by photoexcitation of $[Fe_3(\mu_3\text{-}PC_6H_5)_2(CO)_9]$ yielded $[Fe_3(\mu_3\text{-}PC_6H_5)_2(CO)_7(NCCH_3)_2]$. Unfortunately, both acetonitrile ligands were on the same iron atom and the cluster was not notably active as a catalyst precursor[89]. In $Os_3(CO)_{12}$, two CO ligands on different osmium centers have been replaced by acetonitrile, but a tris(acetonitrile) derivative has not been reported[90]. To date, no catalytic process has been reported for $[M_x(CO)_y(L)_z]$, where L is a weak-field ligand. Nevertheless, this basic strategy for generating reactive cluster catalysts is sound and should be successful, especially for the $[M(CO)_x(L)]_y$ class of clusters.

Another tack exploits the relatively weak metal-metal bonds in clusters, particularly those between 3d metals, which upon scission provide vacant coordination sites at two (or more) neighboring metal atoms. In order to inhibit complete dissociation of the cluster into mononuclear molecular fragments, O, S, RP, and $R_2P$ ligating atoms or groups are employed. This strategy has been pursued by a number of groups, including those of *Adams*[76d], *Geoffroy*[91], and *Vahrenkamp*[92]. One system designed by *Geoffroy et al.*[91] is based on a dinuclear $Fe^0\text{–}Ir^I$ complex in which a long Fe-Ir separation is supported by a bridging $P(C_6H_5)_2$ ligand, and both metal sites are coordnatively saturated. Ligand dissociation and association, as well as ox-

Scheme 7. Outlined here is the chemistry of a coordinately unsaturated iron-iridium complex. The structure of **21** has been determined by X-ray crystallography [91]. The FePIr angle is 81.62(7)°, which is thus considerably compressed from the regular tetrahedral angle for tetracoordinate $P^{III}$; the Fe–Ir distance is 2.960(1) Å, a value substantially larger than the sum of the metallic radii. A bonding interaction was proposed and was characterized as a Fe ⟶ Ir donor-acceptor bond following an earlier proposal by *Vahrenkamp* for analogous complexes. Addition of CO and of $H_2$ to the iridium center is proposed to proceed through Fe-Ir bond scission to form **23** and **20**, respectively. Loss of CO from **21** generates **22**; this complex adds $H_2$ to both metal centers to give **24**. The tetrahydrido complex **24** is shown here without a direct Fe–Ir bond, although in the original publication a two-center two-electron Fe–Ir bond was proposed [91].

idative addition reactions are outlined in Scheme 7. Such approaches to coordinately unsaturated clusters should yield clusters which are catalytically active, but none has been reported to date.

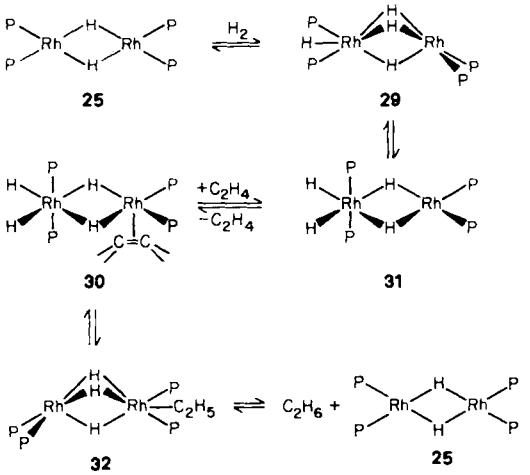


A focal point of our research interest has been coordinately unsaturated metal clusters in which every metal atom has a vacant coordination site[93-103]. In this type of cluster, ready advantage can be taken of the possible unique features of multi-site catalytic reactions. Presently, this potentially large family of unsaturated clusters is limited to the platinum clusters synthesized by *Gregson et al.*[105,106] and to rhodium clusters of the general formula $[(\mu\text{-H})RhL_2]_x$ $(x=2-4)$[93-104]. In the Rh clusters each rhodium atom is planar four-coordinate ($H_2ML_2$) and in addition has an "open" coordination site. To date, the clusters in Scheme 8 have been characterized; their structures are shown in Scheme 9. The platinum clusters[105,106] include triangular $[H_2PtP(tC_4H_9)_3]_3$, trigonal bipyramidal $[H_8Pt_5\{PC_6H_5(tC_4H_9)_2\}_5]$, tetrahedral $[H_2Pt_4\{P(tC_4H_9)_3\}_4]$ and $[H_8Pt_4\{PC_6H_5(iC_3H_7)_2\}_4]$ with two relatively long Pt–Pt bonds. The last compound is formally related to **28**[103]. These clusters should prove interesting as catalysts.

$[(\mu\text{-H})RhL_2]_2$ **25a**, L = $P(OiC_3H_7)_3$[94,96,98]; **25b**, L = $P[N(CH_3)_2]_3$[102]

$[(\mu\text{-H})RhL_2]_3$ **26a**, L = $P(OCH_3)_3$[93,97,98]; **26b**, L = $P(OC_2H_5)_3$[98]

**27**[104] $\left[(\mu\text{-H})Rh\left(\begin{array}{c}CH_3O\\CH_3O\end{array}\!\!>\!P\!-\!CH_2\!-\!CH_2\!-\!P\!<\!\begin{array}{c}OCH_3\\OCH_3\end{array}\right)\right]_4$ $[(\mu\text{-H})Rh(\eta^4\text{-1,5-cyclooctadiene})]_4$ **28**[103]



Scheme 8.

Scheme 9. The dinuclear $[(\mu\text{-H})RhL_2]$ complexes have a coplanar array of P, Rh, and H atoms. Each Rh atom has a coplanar four-coordinate form (A). The $Rh_2H_2$ bonding is best described in terms of two closed four-center two-electron molecular orbitals (of $a_{1g}$ and of $b_{2u}$ symmetry). Precise structural details for the dimer **25a** were afforded by X-ray and neutron crystallographic studies [94–96]. An analogous set [93, 96] of crystallographic studies on the trimer **26a** established square-planar stereochemistry for each Rh atom (B). Because each Rh–Rh interaction comprises only one Rh–H–Rh three-center two-electron bond, the Rh–Rh distance is longer, and this trinuclear cluster is more susceptible to fragmentation than the dimers. An X-ray crystallographic study [103] of the tetramer **28** established a $D_{2d}$ tetrahedral array of Rh atoms with two long Rh–Rh distances (C). One description of the tetramer is that it consists of a puckered ring of $H_2Rh$(diene) units with three-center two-electron Rh–H–Rh bonds are in the trimer.

All the $[(\mu\text{-H})Rh(PY_3)_2]_x$ clusters are highly reactive, a feature that complicates their manipulation in the laboratory but that facilitates the study of their catalytic reactions[98]. These reactions proceed at room temperature or below and involve many long-lived intermediates, which can be detected spectroscopically or even isolated at very low temperatures.

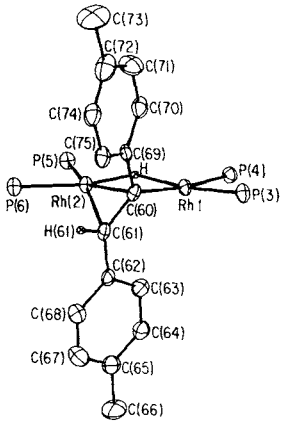
The dinuclear and trinuclear clusters **25a** and **26a**, respectively, are effective initiators of the catalytic hydrogenation of alkenes and alkynes. Mechanistic discussion of these catalytic cycles is limited here to those initiated by the dimer **25**, because these are relatively simple (Scheme 10)[98]. For terminal olefins the reaction rate is limited by hydrogen diffusion rates at 25 °C. The reaction is initiated by addition of hydrogen, not by addition of alkene. Hydrogen addition is fast, converting the brown-black dimer **25** into the green hydrogen adduct $[H_4Rh_2\{P(OiC_3H_7)_3\}_4]$ **29**, which reacts immediately with alkene to give alkane and the dimer **25**. At very low temperatures (*ca.* −120 °C) the hydrogen adduct forms an olefin complex **30** which at *ca.* −85 °C forms the dimer **25** and alkane.

Scheme 10. Mechanism of the hydrogenation of alkenes by **25a**. The first step, addition of hydrogen, is fast and reversible and is well characterized. The structure of the primary hydrogen adduct **29** in solution has only been determined spectroscopically. The excited state of the complex **31** was implicated by dynamic $^1$H-NMR spectroscopy and is supported by an X-ray crystallographic study [102] of the tetrahydrido complex of $[(\mu\text{-H})Rh\{P[N(CH_3)_2]_3\}_2]_2$. Low temperature NMR studies provided evidence for the next step of olefin addition to the active hydrogen adduct **31**, in which a four-coordinate $Rh^I$ occurs. The olefin complex is probably converted in two steps into alkane and educt complex **25**, *via* the intermediate **32** (not detected).

The dimer **25a** also catalyzes the hydrogenation of alkynes, although at a rate which lies an order of magnitude lower than that of alkanes[98,101]; in presence of a mixture of hydrogen, internal alkenes, and alkynes the alkyne is hydrogenated first to give the corresponding alkene. The alkene produced has solely the *trans*-configuration; an extraordinarily result, since all other reported molecular and solid-state systems produce *cis*-alkenes as the first-formed product.

Internal alkynes react with the dimer **25a** to form initially an intermediate with a bridging alkyne intermediate that can be intermediate spectroscopically detected by NMR at *ca.* −80 °C. Above −80 °C, an insertion reac-

tion occurs whereby a derivative with a bridging vinyl group, **34**, is formed. This intermediate, stable in the absence of $H_2$ or excess alkyne, has been crystallographically defined for the molecules derived from 2-butyne and di-*p*-tolylacetylene (Fig. 4). The significant feature of this inter-



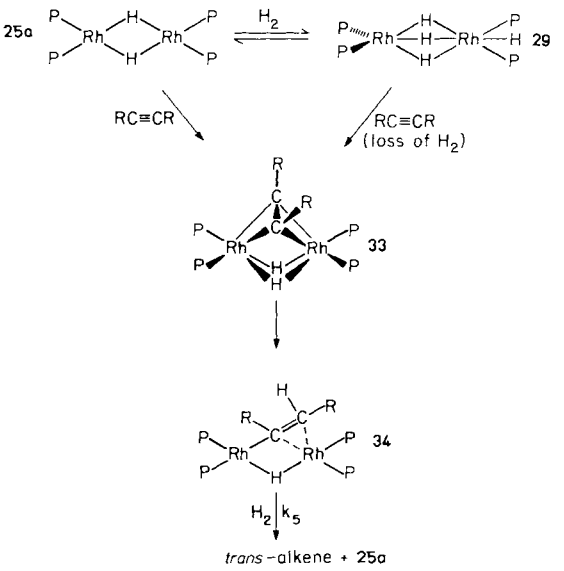


Fig. 4. Structure of the bridging vinyl complex **34** (Scheme 11) derived from di-*p*-tolylacetylene and **25a** [101]. Not depicted here are the hydrogen atoms associated with the *p*-tolyl groups, and the isopropoxy groups bonded to the P atoms. Notable features are the near coplanar array of the four P atoms, the two Rh atoms, and the bridging H atom, as well as the *trans*-arrangement of the *p*-tolyl substituents of the bridging vinyl group.

mediate is the *trans*-stereochemistry of the vinyl ligand, a fact that fully accounts for the stereoselective feature of the catalytic cycle. The next step, which is rate determining, is addition of hydrogen to the vinyl derivative and the final step is presumably migration of a hydrogen atom to the vinyl group to give the alkene and **25a**. Scheme 11 shows the catalytic cycle[101].

Scheme 11. Mechanism of the hydrogenation internal alkynes catalyzed by **25a**. Every intermediate has been detected by low temperature NMR spectroscopy, and the vinyl derivative characterized by X-ray crystallography (see Fig. 4) [101].

The dimer-mediated catalytic cycle is short-lived because alkyne addition competes with hydrogen addition to the vinyl intermediate is. This process leads to formation of a monomeric species

$[RHC{=}\overline{CRCR{=}CR{-}Rh\{P(OiC_3H_7)_3\}_2}]$ which is also an alkyne hydrogenation catalyst but one that produces *cis*-alkenes[101].

Coordinately unsaturated molecular metal clusters offer several advantages. They are extremely reactive and the intermediates in the catalytic cycles are amenable to characterization. Also, they escape fragmentation, not because the metal atom framework is necessarily so stable but because molecules can be incorporated and hydrogen oxidatively added without the necessity of metal-ligand or metal-metal bond scission. Nevertheless, strong-field ligands like CO or phosphites react rapidly, even at low temperatures, to produce relatively inert mononuclear metal complexes[98,99]. Thus, none of these clusters are effective catalysts for hydrogenation of CO. Finally, the alkyne hydrogenation demonstrates that catalytic reactions can be initiated by clusters wherein more than one metal atom site takes part in the catalytic cycle.

## 14. Prospects

Ever since the potential of molecular metal cluster catalysts began to be discussed, recurrent questions to reported claims of cluster catalysis have been: "Is it really a cluster catalyzed cycle?", "How do you know that monomeric species are not the active catalytic intermediates?", "Is the real catalyst metal particles formed by decomposition of the cluster?". All such questions are relevant to any catalytic cycle ostensibly effected in solution, irrespective of whether the catalyst precursor is monomeric or polynuclear. But none of these questions addresses itself directly to the basic issues in cluster catalysis. Cluster catalysts will only gain significance if they catalyze reactions that are unfeasible with monomeric metal complexes or that are stereoselectively or chemoselectively distinct from those initiated by such complexes. To date, only one unique cluster catalyzed reaction has been discovered: the selective hydrogenation of internal alkynes to *trans*-alkenes by the dinuclear complex **25a** (Section 13). Presumably other catalytic reactions of this type will be uncovered through studies of reactive clusters in which all or most metal atoms have either vacant coordination sites or an easily exchangeable ligand. Critical here are exploratory synthetic studies directed at such clusters.

Also critically needed is a more detailed understanding of basic types of cluster reactions such as ligand substitution, oxidative addition, reductive elimination, insertion, and redox reactions. This understanding is essential for the logical design of clusters that can function as true cluster catalysts and that may initiate unique types of catalytic reactions.

Investigations of the reaction mechanisms of catalytic cycles initiated by very reactive metal clusters should prove valuable in enlarging the base of understanding in cluster chemistry and for the design of new cluster catalyts. The possibility of incisive and informative mechanistic data generally will be higher for catalytic reactions that can be effected at low temperatures. The probability of relatively high concentration catalytic intermediates will be far higher for these systems than those that require high

temperatures. Finally, we note the inevitability of the unexpected and suggest that there should be more exploratory catalytic studies of *all* classes of metal clusters.

*The work described here which was carried out in the authors' laboratory was supported by the National Science Foundation. We are indebted to Mr. O. R. Krause for a search of patent literature, to Dr. R. M. Laine for information concerning unpublished data, and to E. J. Wucherer, R. M. Wexler, M. Kulzick, and R. T. Price for critical comments.*

[1] a) The catalyst introduced into a reaction system is more accurately described as the catalyst precursor because the active catalytic species may be formed under the reaction conditions. b) Catalysts are conventional classified as homogenous or heterogenous. However, is general classification is at best misleading in that even interfacial catalytic reactions can be homogenous because they occur largely in a single phase, although it may be predimonantly two dimensional. c) This classification obviates the need for imprecise and inelegant descriptions like "heterogenezing of a homogenous catalyst". *e.g.* anchoring or immobilizing a molecular catalyst to a unit support does not alter the nature of the catalysis. The effect of supporting the molecular species may however, inhibit reactions that normally would occur with the same species in solution, although metal atoms are mobile to varying degress on such surfaces. This mobility is sensitive to the nature of the gaseous reactants: CO has a marked tendency to "mobilize" metal atoms.

[9] In the characterization of chemisorbed acetylene and hydrogen on Pt(111) the results of IR studies indicated [10] that 1) the surface species was ethylidyne ($CH_3C$) and 2) that the α-carbon atom was over a three-fold surface site and symmetrically bonded to three platinum atoms (the CC-bond vector is normal to the $Pt_3$-plane). The paradigm for this species in cluster chemistry is $[(\mu_3\text{-}CH_3C)Co_3(CO)_9]$ [11]. A comparative vibrational spectroscopic analysis of this cluster with the data for acetylene/hydrogen chemisorbed on Pt confirmed the ethylidyne hypothesis [12].

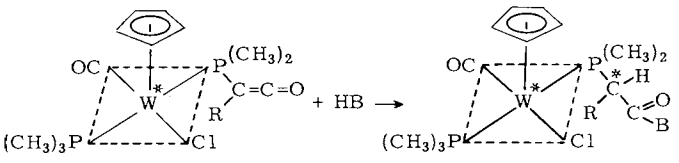
## Generation and Stabilization of Phosphanyl- and Arsanylketenes within the Coordination Sphere of Tungsten[1]**

By *Fritz Roland Kreissl**, *Mathias Wolfgruber*, *Werner Sieber*, and *Helmut Guido Alt*

Ketenes of the general formula RR'C=C=O, in which R and/or R' are bonded to the terminal ketene C atom *via* an element of group IVb (Si, Ge, Sn), VIb (O, S), or VIIb (F, Cl, Br) have been synthesized in great variety and thoroughly characterized[2]. Analogues with elements of group Vb are only known, for example, for a few phthalimidoketenes[9]: in contrast phosphoranylideneketenes $R_3P{=}C{=}C{=}O$[11] and their metal complexes are viewed as ylides. We have now succeeded for the first time in synthesizing phosphorus- and arsenic-substituted ketenes within the coordination sphere of a transition metal and stabilizing them as ligands.

The cleavage of the ketene function from the $\eta^2$-ketenide complexes $[\eta^5\text{-}C_5H_5(CO)\{P(CH_3)_3\}W(\eta^2\text{-}C(R)CO]$[14] by compounds containing halides, such as dichloromethane or thionyl chloride[1], has already proved itself as a method for the preparation of novel ketene derivatives. By analogy, reactions with halogenated phosphanes and arsanes should open up a preparative route to phosphanyl- and arsanylketenes, respectively. Reaction of chloro(dimethyl)phosphane with carbonyl($\eta^5$-cyclopentadienyl)($\eta^2$-4-methylphenylketenyl)(trimethylphosphane)tungsten **1a**, as well as of chloro(diphenyl)arsane with carbonyl($\eta^5$-cyclopentadienyl)($\eta^2$-methylketenyl)(trimethylphosphane)tungsten **1b** in dichloromethane at room temperature leads in high yield to the phosphanyl-, and arsanylketene complexes **2a** and **2b**, respectively.



**1a, b** **2a, b**

**a**: $R = C_6H_4{-}CH_3{-}$ (4), $XR'_2 = P(CH_3)_2$
**b**: $R = CH_3$, $XR'_2 = As(C_6H_5)_2$

The result that despite variation of R, X, and R' similar ketene complexes are formed, leads one to expect a larger range of application of this synthesis.

At *ca.* −78 °C conversion of **1a** into **2a** proceeds *via* an isolable intermediate with a WCP three-membered ring[16]. The expected release of the ketene ligand from the metal could not be observed. The ketene structure of **2a** was also confirmed by addition of methanol and dimethylamine.

**2a** **3, 4**

**3**: $B = OCH_3$; **4**: $B = N(CH_3)_2$

Addition of a proton to the prochiral C atom generates a second chiral center in the molecule, and in consequence **3** and **4** are obtained as diastereomeric mixtures. This manifests itself principally in the $^1$H-NMR spectra, which each exhibit a double set of signals, apart from the signals of the $PCH_3$-protons. In the $^{31}P\{^1H\}$-NMR spectra two doublets for the $P(CH_3)_2$ groups occur in each case.

The diamagnetic complexes **2a–4** are isolated as orange colored solids, which are soluble in dichloromethane, ether, and pentane, the compositions and structures of which were confirmed by elemental analysis, IR, $^1$H-, $^{31}$P-, $^{13}$C-NMR, and mass spectroscopy. The IR spectra of **2a** and **2b** exhibit a characteristically very sharp absorption at 2100 $cm^{-1}$, and in the $^{13}C\{^1H\}$-NMR spectrum signals in the typical chemical shift region of ketene C atoms [$CD_2Cl_2$, −20 °C; **2a**: $\delta = 184.8$ ($J(^{31}P\text{-}^{13}C) = 21.5$ Hz), 39.2 (39.6); **2b**: $\delta = 185.0$, 20.4]. In addition to the molecular ion the mass spectra (EI, 70 eV) of **2**, **3**, and **4** exhibit a fragmentation at *m/z* 388, which arises by cleavage of the intact ketene, ester, and amide ligands, respectively. This suggests the possibility of a preparative route to free phosphanyl- and arsanylketenes.

# The First $^{13}$C-ENDOR Investigation of an Organic Triradical in the Quartet State; Synthesis of a Triply $^{13}$C-Labeled Trisgalvinol**

By *Klemens Schubert, Burkhard Kirste,* and *Harry Kurreck**

$^1$H-ENDOR (Electron Nuclear Double Resonance) spectroscopy has hitherto been used successfully for the investigation of organic multi-spin systems with weak electron-interaction up to a tetraradical in the quintet state[2], whereas $^{13}$C-ENDOR studies, besides those on doublet molecules, have been restricted to diradicals in the triplet state[3]. We report here on the synthesis of the triply $^{13}$C-labeled trisgalvinol **5**, which serves as key compound for the generation of mono-, di-, and triradicals. The Scheme opposite outlines the synthesis of labeled trimesic acid ester **4** from 97% enriched $Ba^{13}CO_3$ and the conversion of **4** into **5**.

Figure 1 shows the ESR and ENDOR spectra of the mono-, di- and triradicals accessible from **5** by alkaline $K_3[Fe(CN)_6]$-oxidation. The $^1$H- and $^{13}$C-ENDOR signals for all oxidation steps can be detected. The triradical gives

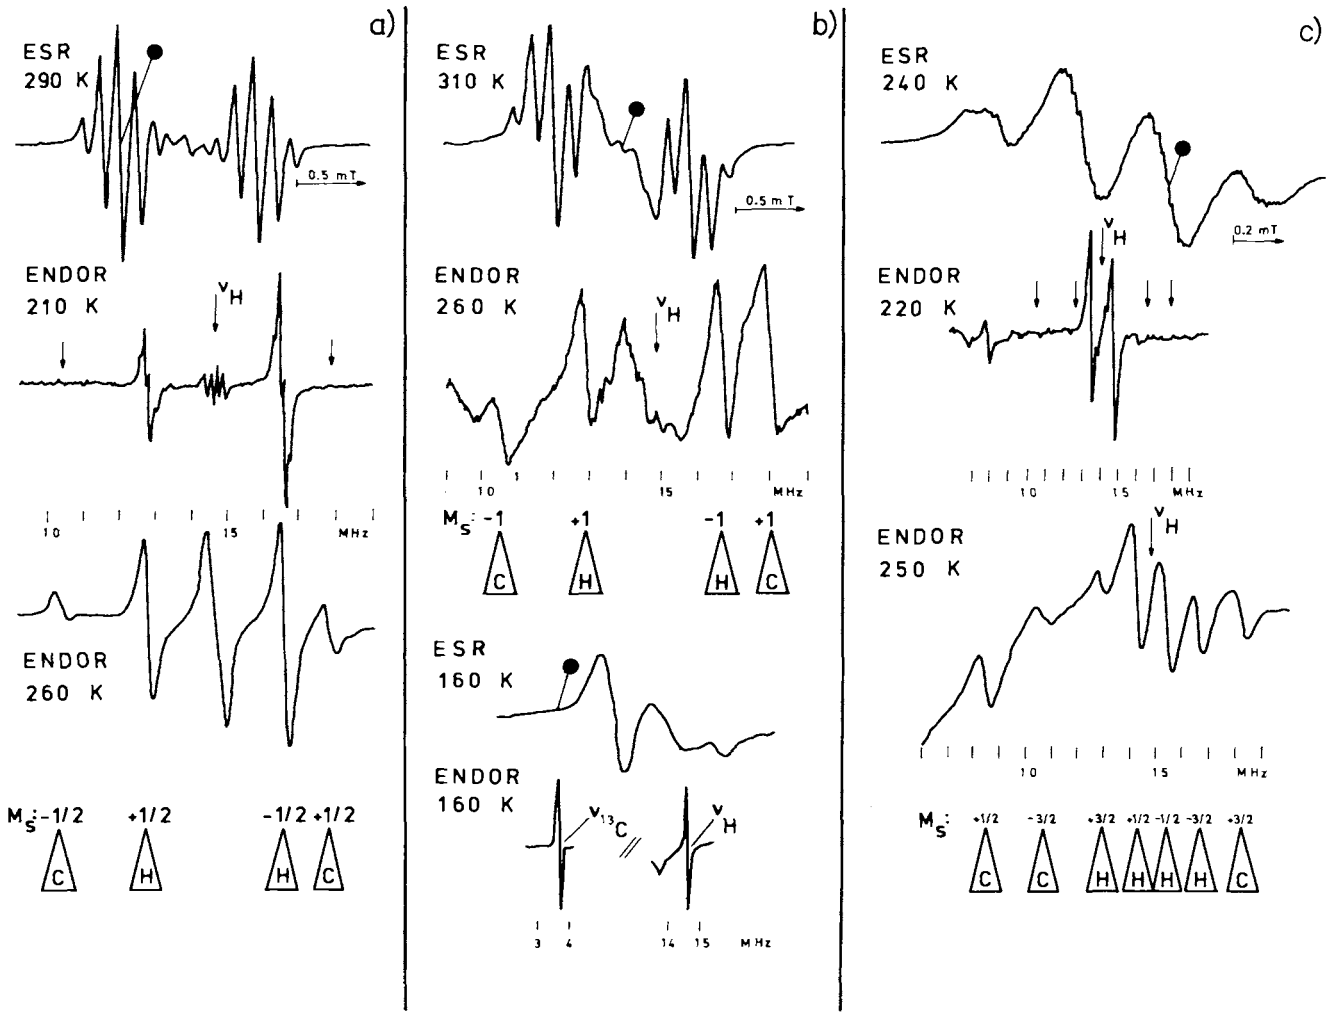

Fig. 1. ESR and ENDOR spectra of **5** in various oxidation states (in toluene). The arrows indicate the calculated resonance positions of signals which appear only at higher temperatures and RF power levels. The bold points indicate the ESR positions chosen for the ENDOR measurements. The RF power levels (P) are naturally cavity-dependent and thus only relative values. They can be converted approximately into field strengths in a rotating frame, $B_{rot}$ [mT] $\simeq 0.07\sqrt{P}$[W]. In our spectrometer configuration the RF power is not constant over the frequency range used. a) Doublet: ESR: $MW_{290K} = 2$ mW; ENDOR: $MW_{210K} = 50$ mW, $RF_{210K} = 25$ W (14 MHz), $MW_{260K} = 50$ mW, $RF_{260K} = 110$ W (15 MHz). b) Triplet: ESR: $MW_{310K} = 2$ mW; ENDOR: $MW_{260K} = 200$ mW, $RF_{160K} = 110$ W (15 MHz), ESR: $MW_{160K} = 6.3$ mW, ENDOR: $MW_{160K} = 200$ mW, $RF_{160K} = 110$ W ($\nu_H$), $RF_{160K} = 330$ W ($\nu_{^{13}C}$). At 160 K the toluene solidifies vitreously. c) Quartet: ESR: $MW_{240K} = 2$ mW, ENDOR: $MW_{220K} = 20$ mW, $RF_{220K} = 55$ W (14 MHz), $MW_{250K} = 200$ mW, $RF_{250K} = 120$ W (15 MHz).

rise to *two* pairs of ENDOR lines for each set of equivalent nuclei, *i.e.* the 12 equivalent *m*-protons and the three equivalent $^{13}$C-nuclei, originating from NMR transitions in the $\pm 1/2$ and $\pm 3/2$ $M_S$ states. This corresponds to the ENDOR resonance condition $\nu_{ENDOR} = |\nu_N - M_S a^S|$, provided $|J| \gg |a|$.

The experimental results of the investigation of the organic multi-spin systems reveal the superiority of ENDOR spectroscopy over conventional ESR. In addition to

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0202-0150 $ 02.50/0 

markedly better resolution and the possibility of selecting the desired species in a mixture by suitable positioning of the external magnetic field, the ENDOR experiment shows *unequivocally* that both the $^1$H- as well as the $^{13}$C-ENDOR signals have to be assigned to diradicals in the triplet state or to triradicals in the quartet state. For the quartet state ($S=3/2$), $|J| \gg |a|$, $a^q_{^{13}C} = -9.4$ MHz and $a^q_{H_m} = +1.2$ MHz holds in the case of small dipolar coupling ($D=22$ MHz).

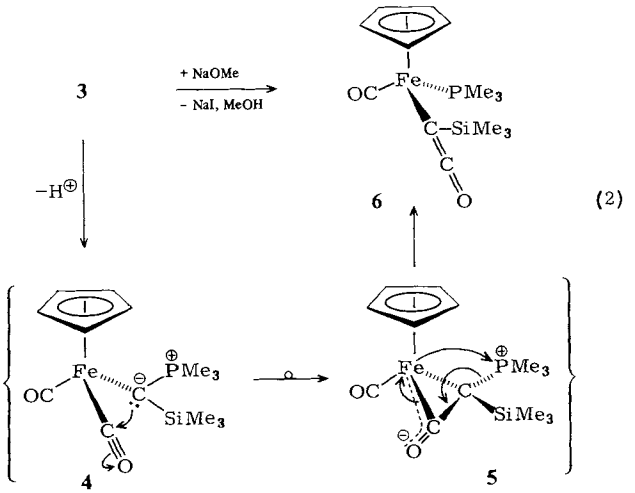
## Metal-Induced Carbonylation of a Phosphane-Stabilized "Carbyne Ligand": Conversion of a Phosphorus Ylide-Carbonylmetal Adduct into an $\eta^1$-Ketenyl Complex[1]

By *Siegfried Voran* and *Wolfgang Malisch**

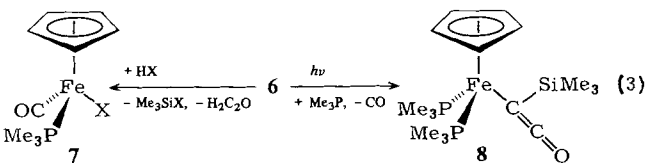


Trialkyl(alkylidene)phosphoranes react with metal-coordinated carbon monoxide *via* addition at the carbon and transylidation[2]. For the $R_3\overset{\oplus}{P}-CH=C(\overset{\ominus}{O})-$ moiety formed by this process at the metal a strong $\pi$-interaction between ylide- and acyl-carbon has been proved, making the carbon monoxide a component of an enolate group[2]. We have now investigated whether carbonyl ligand and ylidic system can be also connected, when the latter is generated directly at the metal center.

The cationic ylide complex **3**, obtainable from the iron iodide **1** and the silylated phosphorus ylide **2**, provides a suitable precursor for the synthesis of a model substance, since silyl substituents usually favor the formation of carbanionic centers.

(1)

Although **3** is inert towards transylidation with **2** or $Me_3P=CH_2$ it can be smoothly deprotonated with sodium methoxide. However, instead of the corresponding neutral complex **4**, its isomer **6** is obtained, containing an $\eta^1$-bonded ketenyl-ligand, which formally derives from the insertion of the carbyne $C(SiMe_3)$ into an Fe–CO bond. **6** forms deep-red crystals (m.p. 65 °C), is very readily soluble in pentane and cyclohexane, and is briefly stable towards air [IR(pentane): $\nu CO_{ketene}$ 2025 (s), $\nu CO$ 1938 (s) $cm^{-1}$].



(2)

The plausible rearrangement **4** → **5** → **6** represents a novel type of reaction for metal-ylides[5a,b].

The attempt to perform an $Me_3Si/H$ exchange on **6** with HCl (or $HOSO_2CF_3$) leads to degradation of the metal-ketenyl arrangement with formation of **7**, $Me_3SiCl$ and ketene, which polymerizes under the reaction conditions.

**6** can be converted photochemically in the presence of trimethylphosphane into **8**, which like **6**, shows, neither in boiling benzene nor in acetonitrile, $\eta^2$-coordination with ligand elimination which is characteristic for ketenyl complexes of molybdenum and tungsten[5b].

[*] Prof. Dr. W. Malisch, S. Voran
Institut für Anorganische Chemie der Universität
Am Hubland, D-8700 Würzburg (Germany)

The intramolecular carbonylation of a carbyne-metal fragment outlined in Scheme (2) is in our opinion of significance in connection with the homogeneously and heterogeneously catalyzed reduction of CO with $H_2$[7a,b], even though there is so far evidence in only one case for the existence of M≡CR units as primary essential species for the carbon-carbon coupling in the Fischer-Tropsch synthesis[7c]. The ketenyl derivatives synthesized from such species by CO addition possibly occur, *inter alia*, as intermediates during formation of oxygen-containing organic compounds. Moreover, reaction (2) shows that the CR part of a metal-bonded ylide moiety $R_3P{=}C-$ is synthetically available and behaves like a carbyne ligand[8].

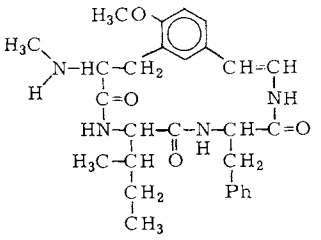
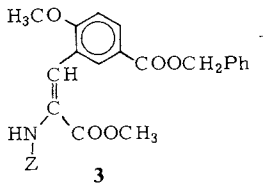
## Total Synthesis of Mucronin B**



By *Ulrich Schmidt** and *Ute Schanbacher*

Over the last twenty years approximately 80 peptide alkaloids have been isolated and clarified[1]. They complex alkaline metal ions and function as ionophores in plants. In the majority of cases they are active against gram-positive bacteria and fungi. Some inhibit the transfer of energy in chloroplasts.



Recently we reported the first total synthesis of a 13-membered peptide alkaloid—of ziziphin A **1**[2a] - and we now describe the first total synthesis of a peptide alkaloid—of mucronin B **2α**[3]—having a 15-membered ring system. As characteristic structural unit it contains a benzene ring with a 12-membered "handle" over the *m*-position. In contrast to the 12- and 13-membered peptide alkaloids, which are derived biogenetically from tyrosine and contain a β-phenoxy amino acid in the ring, in the 15-membered compounds the handle is not linked to the benzene ring *via* a phenol ether function but *via* a C–C bond. The biogenesis of these compounds presumably starts from a *m*-phenylenedialanine.

The dehydroamino acid **3** serves as starting material for the synthesis of mucronin[2b]. After *N*-methylation, hydrogenation, and introduction of the Boc group to afford **4**, the carboxy group was transformed into the aminoethanol size chain (**4** → **5** → **6**). Hydrolysis of **6** to give the amino acid and coupling with Ile-Phe-$OCH_3$ led to the tripeptide **7**, which was converted into the pentafluorophenyl ester **9**, the educt for the ring closure. Cyclization proceeded by "catalytic hydrogenation under high-dilution conditions"[2c]. The high yields (85%) of ring compounds **10α** and **10β**[4] provide further evidence for the superiority of this ring-closure method, compared to conventional methods, for the synthesis of 12- to 15-membered cyclopep-

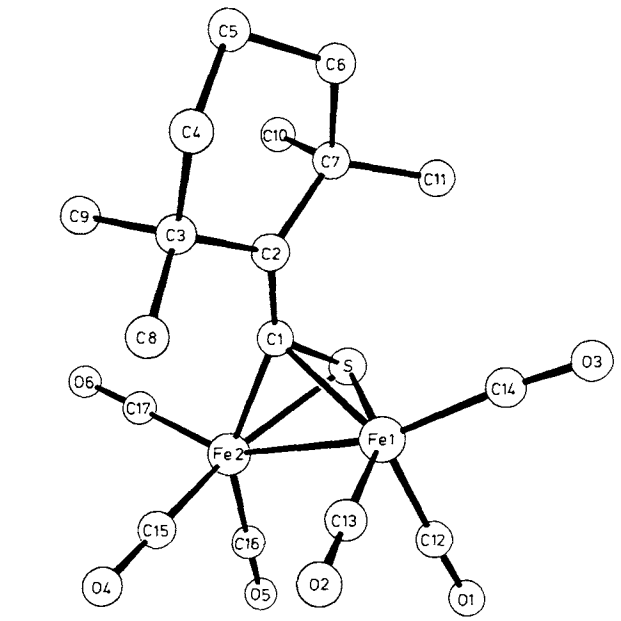
## Reversible Opening of a Thioketene-Iron Cluster Containing a $\mu_2$-$C_2$,$\mu_2$-*S*-Thiocarbonyl Group[1]

By *Henning Umland, Frank Edelmann, Detlev Wormsbächer,* and *Ulrich Behrens**

In previously known metal complexes the thiocarbonyl group of thioketones, thioketenes, and carbon disulfide functions mostly as a two-electron donor. X-ray crystallographic analysis of the thioketene-iron cluster **2** has established for the first time a C=S group which provides six electrons for the metal-ligand bonding. In addition, **2** exhibits a further special structural feature: a dipolar molecule with positive charge on C2 (metal-stabilized carbenium ion) and the negative charge delocalized over the tetrahedral $Fe_2CS$ cluster framework (cf. formula **2a** and Fig. 1). Rotation about the C1-C2 axis is not observed up to 100 °C (stabilization of the carbenium ion by hyperconjugation). [**2a**: $^1$H-NMR (270 MHz, [$D_8$]-toluene, 95 °C): $\delta = 0.91$ (s, $2CH_3$), 1.04 (s, $2CH_3$), 1.17 (m, $CH_2$), 1.30 (m, $2CH_2$); $^{13}$C-NMR (22.63 MHz, $CDCl_3$, 30 °C): $\delta = 118.7$ (C1), 219.3 (C2), 44.6, 45.8 (C3, C7), 38.5, 39.1 (C4, C6). 16.8 (C5), 32.4, 34.4 (C8, C11), 211.1 (CO)].

The most characteristic property of the hexacarbonyl compound **2a** is its smooth reaction with triphenylphosphane at room temperature to afford the half-opened cluster **8a**; the dinuclear iron complex reacts analogously with trialkylphosphanes and phosphites. The structure of **8a** was determined by X-ray crystallography[4].

Photochemically induced scission of CO from **8a** leads to the closed cluster **2b**. By further addition of phosphane and renewed elimination of CO this reaction cycle can be repeated to form the disubstituted compound **2c**. All CO-eliminations are reversible. The stepwise exchange of CO by $PPh_3$ in **2** stabilizes the carbenium ion markedly [$^{13}$C-NMR: $\delta = 219.3$ (**2a**), 210.4 (**2b**), 183.7 (**2c**)].



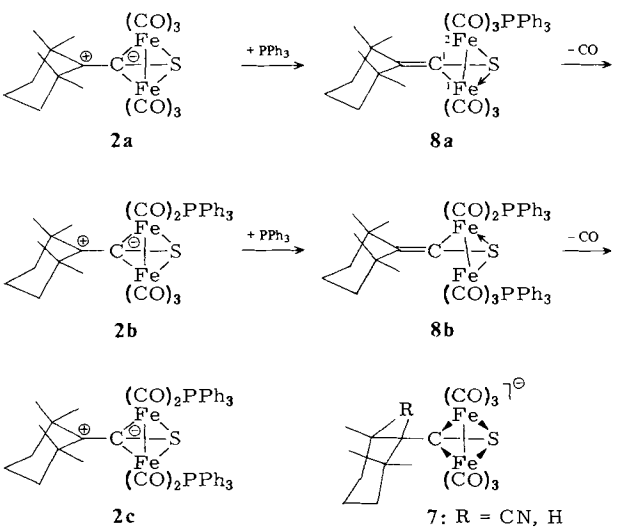


Fig. 1. Structure of the thioketene complex **2a** in the crystal. $R = 0.045$. Selected bond lengths [pm] and angles [°]: C1–Fe1 206.4(9), C1–Fe2 193.8(10), C1–S 173.3(10), Fe1–S 222.9(3), Fe2–S 222.0(3), Fe1–Fe2 251.8(2), C1–C2 136.1(14); C2–C1–Fe1 113.4(7), C2–C1–Fe2 155.2(8), C2–C1–S 129.8(8), C3–C2–C1 118.7(9), C7–C2–C1 121.7(9), C7–C2–C3 118.3(9) [5].

In contrast to phosphanes, anions such as $CN^-$ or $H^-$ (from $BH_4^-$) add to **2a** to afford the negatively charged complexes **7**, with retention of the closed tetrahedral cluster.

## A Diphosphene as Tetrahedrane Building Block: Synthesis of $[Fe_2(CO)_6(P_2tBu_2)]$**

By *Heinrich Vahrenkamp** and *Doris Wolters*

Diorganodiphosphenes $R_2P_2$ are stable in the free form only when bearing very bulky substituents R[1]. To our knowledge, unlike the analogous compounds $Ph_2As_2$ and $Ph_2Sb_2$, they were previously unknown in the form of complex ligands[2][***]. We have now succeeded in carrying out a directed synthesis of an $R_2P_2$ species (R = *t*Bu) in the ligand sphere of a complex.

The doubly *t*BuPH-bridged dinuclear complex **1**[3] was deprotonated with MeLi (ether, 0 °C); *in situ* oxidation of the intermediate with 1,2-dibromoethane (ether, 0 °C→RT), evaporation to dryness, dissolution in *n*-hexane, and chromatography on silica gel, (*n*-hexane/benzene, 10:1) furnished the complex **2** (red crystals, m.p. 120 °C (decomp.) 11% yield).

Complex **2** was identified by elemental analysis and spectra: IR ($C_6H_{12}$): $\nu = 2053$ (m), 2015 (s), 1988 (vs), 1968 (s), 1958 (m) $cm^{-1}$; NMR ($CDCl_3$): $\delta = 1.52$, $J = 22.0$ Hz, EI-MS: $m/z$ 456 ($M^+$). A crystal structure analysis revealed the molecular geometry given in Figure 1[4].

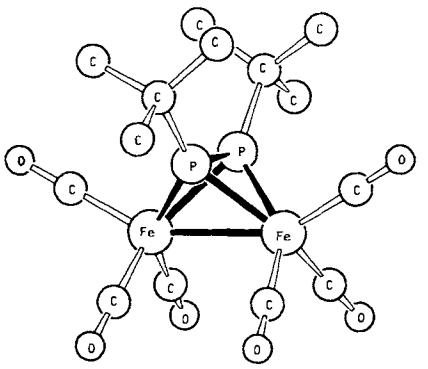

Fig. 1. Structure of $[Fe_2(CO)_6(P_2tBu_2)]$ **2** in the crystal [4]. Bond lengths: Fe-Fe 274.0(1), P-P 205.9(3), Fe-P 221.2–223.2(2) pm.

[**] This work was supported by the Fonds der Chemischen Industrie and the Rechenzentrum der Universität Freiburg. We thank Dr. *K. Steinbach*, Marburg, for recording the mass spectrum.

[***] Note added in proof (January 10, 1983): A mononuclear complex of $P_2(SiMe_3)_2$ has recently been described: B. Deppisch, H. Schäfer, *Z. Anorg. Allg. Chem. 490* (1982) 129.

The tetrahedrane molecule **2** is isoelectronic and structurally related to the $R_2N_2$- and $S_2$-analogues[5]. However, whereas the N–N bond in $[Fe_2(CO)_6(N_2Me_2)]$ and the S–S bond in $[Fe_2(CO)_6S_2]$ are about the same length as a normal N–N or S–S single bond, the P–P bond in **2**, with a length of *ca.* 206 pm, is markedly shorter than a P–P single bond in oligophosphanes; it is almost the same length as the P–P bond in the diphosphene $P_2(C_6H_2tBu_3)_2$ (203 pm)[1]. Hence, the classification of the ligand $P_2tBu_2$ in **2** as diphosphene appears justified.

To achieve an 18-electron balance for each iron atom, the diphosphene must function as a 6-electron ligand (one π-electron pair and two n-electron pairs). According to *Hoffmann*'s isolobal relationship[6] $[(CO)_3FE^{\ominus} \rightarrow \delta \leftarrow CH$ and $RP^{\oplus} \rightarrow \delta \leftarrow CH]$ the complex **2** can be regarded as a derivative of the tetrahedrane $(CH)_4$.

## Photochemical Four-Electron Redox Reaction of Hexaazidoplatinate(IV)**

By *Arnd Vogler** and *Joachim Hlavatsch*

In many transition-metal complexes intramolecular photoredox reactions occur, in which an electron is transfered from a ligand to the metal (one photon-one electron redox reaction). In contrast, only a few photo-induced two-electron transfer reactions are known. Reactions of this type are meeting with increasing interest in connection with photosynthesis or in the photochemical cleavage of water[1]. Reductive eliminations are particularly straightforward intramolecular two-electron redox reactions of metal complexes. Here, two ligands are oxidatively cleaved off and the metal is reduced by two units by the electrons from the ligands. Some reactions of this type have also been observed to occur photochemically[2] (one photon—two electron redox reaction). We now report on two consecutive reductive photoeliminations (two photon—four electron redox reaction). By this means $Pt^{IV}$ is reduced to $Pt^0$ *via* $Pt^{II}$, whereas in total four ligands are oxidatively cleaved off.

Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Fonds der Chemischen Industrie.

The complex ion $[Pt(N_3)_6]^{2-}$, first synthesized and characterized by *Beck et al.*[3], has a charge-transfer band ($N_3 \rightarrow Pt$) at $\lambda_{max} = 308$ nm ($\varepsilon = 37\,154$)[3]. Irradiation of a solution of $[Pt(N_3)_6]^{2-}$ in $CH_2Cl_2$ with light of wavelength $\lambda = 314$ nm led to photolysis of the complex ion. Over the complete absorption region of the ion between 590 and 285 nm[4] the extinction decreased by the same ratio at all wavelengths. Simultaneously, bubbles of nitrogen were evolved from the solution. From this observation we conclude that photolysis according to

$$[Pt^{IV}(N_3)_6]^{2-} \longrightarrow [Pt^{II}(N_3)_4]^{2-} + 3\,N_2$$

occurs. The decrease in extinction is accounted for by the considerably smaller absorption of the primary photolysis product $[Pt(N_3)_4]^{2-}$ over the entire absorption range relative to that of $[Pt(N_3)_6]^{2-}$[3]. Upon complete absorption of light ($A \geq 2$) by $[Pt(N_3)_6]^{2-}$ the photolysis proceeds with zero order. Irradiation with light of wavelength $\lambda = 314$ nm gives a quantum yield $\Phi = 0.27$.

If irradiation is further continued the solution becomes black due to precipitation of colloidal platinum. As a consequence this caused an increase in extinction which became larger with decreasing wavelength, such as is expected for light scattering by the colloidal particles. Simultaneously, evolution of bubbles of nitrogen continued. Moreover, azide was released, which could be quantitatively determined by spectrophotometry of its $Fe^{III}$ complex[2a]. These observations are consistent with the following secondary photolysis.

$$[Pt^{II}(N_3)_4]^{2-} \longrightarrow Pt^0 + 3\,N_2 + 2\,N_3^-$$

The same result was also obtained by direct photolysis of $[Pt^{II}(N_3)_4]^{2-}$[3] in a separate experiment. The quantum yield for the photolysis of $[Pt(N_3)_4]^{2-}$ is $\Phi = 0.17$ at an excitation wavelength of $\lambda = 314$ nm.

Formation of colloidal platinum during the photolysis of $[Pt(N_3)_6]^{2-}$ and of $[Pt(N_3)_4]^{2-}$ is also interesting in connection with heterogeneous catalysis by platinum metal. It is known that the catalytic activity increases as the size of the colloidal particles decreases[1]. Photolysis of azidoplatinate complexes could lead to better control of the particle size.

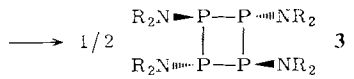
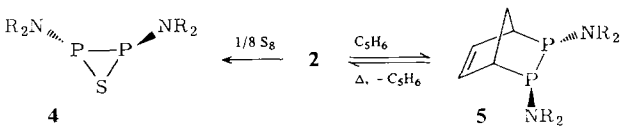
## Tetrakis(trimethylsilyl)diaminodiphosphene**



By *Edgar Niecke** and *Reinhold Rüger*

The synthesis of the first stable diphosphene has recently been reported[1]. We have now found that base-induced "HCl"-elimination from the diphosphene **1**[2] affords entry to a novel, further example of this interesting class of compounds with phosphorus-phosphorus (p-p)π bonding.



**1** R = $SiMe_3$ **2**

The pyrophoric diaminodiphosphene **2** is a ruby-red liquid at room temperature. In solution, the compound is stable for several days; without solvent it dimerizes within hours to the cyclotetraphosphane **3**[3a,b], which can be isolated as a crystalline, colorless, almost inert solid.

The synthetic potential of **2** has already been demonstrated by its reactions with sulfur or cyclopentadiene, which lead to cycloaddition products—the thiadiphosphirane **4**[3a,c] and the 2,3-diphosphanorbornene **5**, respectively, each of which forms only one isomer. According to the NMR data[4] only the *trans*-form of **5** is formed.

**4** **5**

No cycloreversion takes place in the case of **4**, at least up to 150 °C, whereas **5** already decomposes above 40 °C into its components, and it can thus serve as a storable source of the diphosphene.

The composition and structure of the tetrasilylated diaminodiphosphene **2** and its reaction products **3**—**5** are confirmed by elemental analysis, mass spectra (**2**—**4**), and NMR data[4]. Noteworthy is the extremely large downfield shift of the $^{31}P$-NMR signal of $\delta = 572$ in the case of **2** (30% in $CD_2Cl_2$, $H_3PO_4$ ext.)[5]. The $^1H$-, $^{13}C\{^1H\}$- and $^{29}Si\{^1H\}$-NMR spectra (30%, in $CD_2Cl_2$, TMS int.) show the groups of signals with pseudo-triplet structure that are to be expected for free rotation about the P–N bond: $\delta(^1H) = 0.32$ (1.2 Hz), $\delta(^{13}C) = 3.4$ (8.4 Hz), $\delta(^{29}Si) = 7.1$ (2.8 Hz).

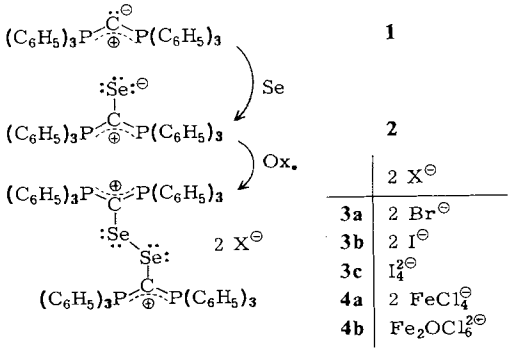
[4] **2**: MS (70 eV) $m/z$ 382 ($M^+$, 4%), 73 (R, 100%). **3**: decomp. 230 (5) °C; $m/z$ 764 ($M^+$, 6%), 73 (R, 100%); $\delta(^{31}P)=63.8$, $\delta(^{13}C)=5.1$, $\delta(^{29}Si)=9.5$. **4**: b.p. = 105–108 °C/0.1 torr; $m/z$ 414 ($M^+$, 9%), 73 (R, 100%); $\delta(^{31}P)=-21.9$, $\delta(^{13}C)=4.6$ ($|J_{CP}+J_{CP'}|=11.6$ Hz), $\delta(^{29}Si)=9.2$ ($|J_{SiP}+J_{SiP'}|=6.5$ Hz). **5**: decomp. 40–45 °C; $\delta(^{31}P)=57.4$, 64.2 ($J_{PP}=330.2$ Hz), $\delta(^{13}C)=5.7$ ($|J_{CP_A}+J_{CP_B}|=13.0$ Hz), 39.2 (22.5 Hz), 47.2 (51.3 Hz), 54.3 (43.6 Hz), 128.3 (12.2 Hz), 134.8 (12.3 Hz), $\delta^{29}Si=6.8$, 7.8 ($|J_{SiP_A}+J_{SiP_B}|=12.2$, 12.4 Hz).

[5] The phosphorus nucleus with $\delta=561$ is similarly strongly deshielded in the diaminodiphosphene $(Me_2tBuSi)_2N-P=P-N(SitBuMe_2)_2$: E. Niecke, R. Rüger, M. Lysek, S. Pohl, W. Schoeller, unpublished. Even stronger deshielding has been found in the dialkyldiphosphene $(Me_3Si)_3C-P=P-C(SiMe_3)_3$: A. H. Cowley, J. E. Kilduff, T. H. Newmann, M. Pakulski, *J. Am. Chem. Soc. 104* (1982) 5820; C. Couret, J. Escudié, J. Stagé, *Tetrahedron Lett. 23* (1982) 4941.



[6] *Experimental:* A solution of **1** (20.9 g, 0.05 mol) and $LiNtBuSiMe_3$ (7.5 g, 0.05 mol) in diethyl ether (150 mL) was stirred for 5 h at room temperature, whereupon the solution turned deep-red. After removal of precipitated LiCl by filtration and of most of the solvent and $HNtBuSiMe_3$ by evaporation, the resulting residue was fractionated by short-path distillation. The diphosphene 2 distilling over at 84–87 °C/0.1 torr was collected in an ice-cooled receiver. Yield 8.6 g (45%). The residue contained essentially **3**, which was isolated by recrystallization from petroleum ether (100–140 °C) as a pure crystalline solid, which is practically inert towards water.

## Oxidative Coupling of the Selenolate Functions in $(C_6H_5)_3PC(Se)P(C_6H_5)_3$: Crystal Structure of $[[(C_6H_5)_3P]_2CSe]_2^{2\oplus}Fe_2OCl_6^{2\ominus}\cdot 4CH_2Cl_2$ Containing a Linear Fe–O–Fe Axis

By *Hubert Schmidbaur**, *Christian E. Zybill*, and *Dietmar Neugebauer*

Redox systems with thiolate/disulfide or selenolate/diselenide pairs are currently of widespread interest. We recently discovered that addition of chalcogen atoms to hexaphenylcarbodiphosphorane **1** under mild conditions furnishes novel thiolate/selenolate zwitterions **2**, in which the cationic component is formed from a carbodiphosphorane moiety[4]. The thiolate-analogous behavior of these compounds suggested the possibility of an oxidative coupling to give products containing disulfide or diselenide bridges. Preliminary redox-potential measurements indeed demonstrated[5] that, *e.g.*, **2** can be oxidized electrochemically already at a potential of *ca.* −0.36 V.

The use of chemical oxidizing agents on a preparative scale in an inert solvent allowed the isolation of crystalline products which contain the diselenide dication corresponding to **2**. Thus, elemental bromine or iodine yield the halides or polyhalides **3a–c**, respectively. The constitution of the anion in the salt **3c** is still uncertain, though spectroscopic investigations (FIR and Raman data) indicate the presence of the dianion $I_4^{2\ominus}$ [6].

| | 2 X⊖ |
|---|---|
| **3a** | 2 $Br^{\ominus}$ |
| **3b** | 2 $I^{\ominus}$ |
| **3c** | $I_4^{2\ominus}$ |
| **4a** | 2 $FeCl_4^{\ominus}$ |
| **4b** | $Fe_2OCl_6^{2\ominus}$ |

[*] Prof. Dr. H. Schmidbaur, Ch. E. Zybill, Dr. D. Neugebauer
Anorganisch-chemisches Institut der Technischen Universität München
Lichtenbergstr. 4, D-8046 Garching (Germany)

With four equivalents of anhydrous $FeCl_3$ in dichloromethane the tetrachloroferrate(III) **4a** was obtained along with two parts of $FeCl_2$. However, on working with solvents not previously dried or on addition of stoichiometric amounts of water, the μ-oxo-hexachlorodiferrate(III) **4b** was generated, which precipitates as red-brown triclinic crystals.

X-ray diffraction analysis of **4b** (still containing 4 molecules of $CH_2Cl_2$) confirmed the structure of the dication (Fig. 1) and of the dianion (Fig. 2).

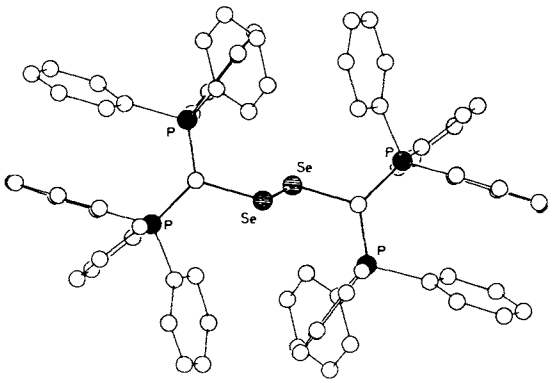


Fig. 1. Structure of the cation in $[[(C_6H_5)_3P]_2CSe]_2^{2\oplus}Fe_2OCl_6^{2\ominus}\cdot 4CH_2Cl_2$.

Interestingly, the structural details of **1** as determined repeatedly by X-ray diffraction[3] show remarkably little alteration on conversion of **1** into the selenide **2**[4] and on subsequent oxidation to **3**, **4**. The ylidic C atoms in **4b** are planar configurated, as in **2** ($P_2CSe$). The Se–Se bond, which contains a crystallographic center of symmetry, is not unusual at $d(SeSe)=249.2(2)$ pm.

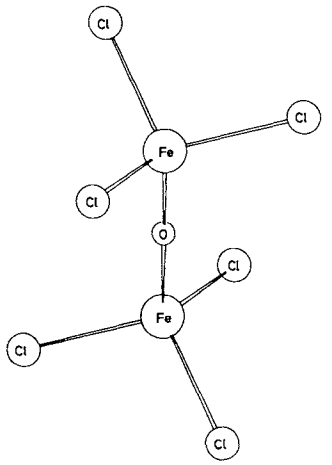

Fig. 2. Structure of the anion in $[[(C_6H_5)_3P]_2CSe]_2^{2\oplus}Fe_2OCl_6^{2\ominus}\cdot 4CH_2Cl_2$.

The $Fe_2OCl_6^{2\ominus}$ anion is also centrosymmetric in the crystal lattice (Fig. 2). The IR absorption $\nu_{as}$(FeOFe) is found at 832 $cm^{-1}$, $\nu$(FeCl) at 378 and 321 $cm^{-1}$. Associated with this symmetry are a staggered arrangement of the 2×3 chlorine atoms and also the linearity of the Fe–O–Fe axis. This linear geometry is novel for the $Fe_2OCl_6^{2\ominus}$ anion as well as for all other known compounds with $Fe^{III}-O-Fe^{III}$ bridging which show strongly bent oxo linkages[8]. The magnetic behavior of such complexes and

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0202-0156 $ 02.50/0 

other aspects of their structure are currently under investigation.

## Some Substituent Effects in the Photocycloaddition of Dihalomaleiimides to Uracils**

By *Géza Szilágyi* and *Heinrich Wamhoff**

*Dedicated to Professor Alexander Schönberg on the occasion of his 90th Birthday*

As model reactions in photochemotherapy[1] we have studied the photoreactions of the 1,3-dimethyluracils **1a—e** and of 1,3-dimethyl-6-azauracil **6** with dibromo-*N*-methylmaleiimide **2** and with the phenyl-substituted dichloro-*N*-phenylmaleiimides **7a—c**, very few reports on which have so far appeared in the literature[3,4]. Of particular interest in such reactions are the substituent effects and the tendency for cycloaddition (→ **3a—d**, **4b**, **8a**, **b**) and photosubstitution (→ **5a**, **c**, **9a—c**) to take place.

Long-wavelength UV-irradiation (Hg high-pressure lamp HPK 125 W, $\lambda > 313$ nm) of 10 mmol **1a—e** with equimolar amounts of **2** in acetone (200 mL solvent and sensitizer) yielded, aside from the *cis,anti,cis*- and *cis,syn,cis*-[2+2]-cycloadducts **3a—d** and **4b**, the photosubstitution products **5a**, **c**.

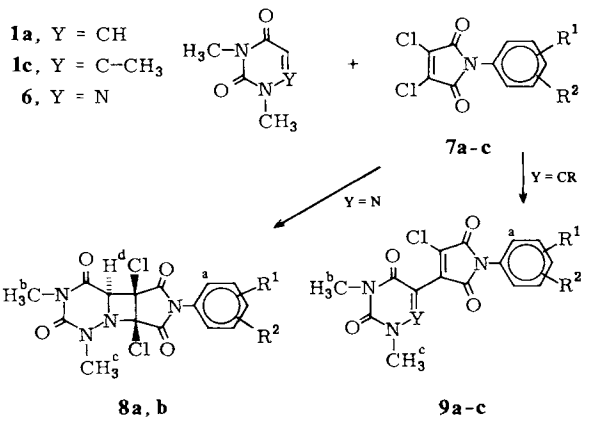
According to Table 1, the steric effect is the controlling factor for the direction and stereochemistry of the fusion in the reaction of **1a—c** and **2**. In comparison to the reaction of **1a** and **2**[4] the preparative yields of cycloadducts

Table 1. Preparative yields of **3a—d**, **4b**, and **5a**, **c**.

| Educt | $R^1$ | $R^2$ | Products; Yield [%] | | | | | |
|---|---|---|---|---|---|---|---|---|
| **1a** | H | H | **3a** | 41 | — | | **5a**[1] | 1 [a] |
| | | | | | | | **5a**[2] | 7 [b] |
| **1b** | $CH_3$ | H | **3b** | 8 | **4b** | 3 | — | |
| **1c** | H | $CH_3$ | **3c** | 1 | — | | **5c** | 29 [c] |
| **1d** | $CH_3$ | $CH_3$ | **3d** | 7 | — | | — | |
| **1e** | $NO_2$ | H | — | | — | | — | |

[a] **5a**[1]: $R^3$ = Br. [b] **5a**[2]: $R^3$ = 1,3-dimethyl-5-uracilyl. [c] **5c**: $R^3$ = Br.

**3b**, **d** are lower in the case of the 5-methyl- **1b** and 5,6-dimethyluracils **1d**, even though no alternative 5-substitution is possible. The introduction of the bulky and electron-withdrawing 5-nitro residue prevents any photoreaction[9]. On the other hand, reaction of the sterically hindered 6-methyluracil **1c** with **2** leads to only traces of the cycloadduct **3c**, together with exclusively the 5-substitution product **5c**. These findings are in agreement with observations on the influence of the substituents on C-5 and C-6 on the uracil photodimerization[10].



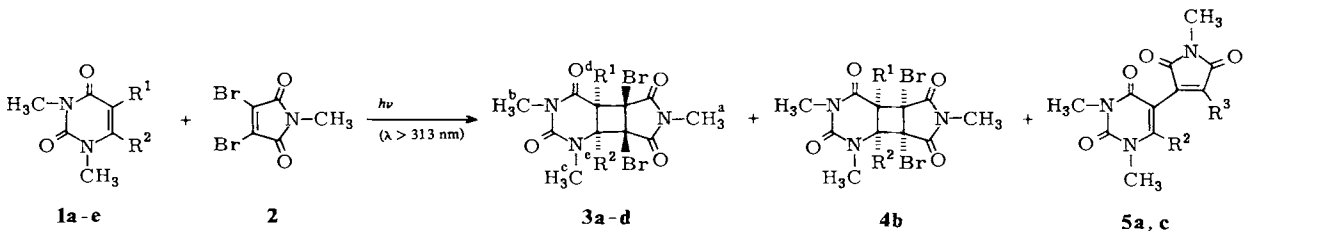


Table 2. Preparative yields of **8a**, **b** and **9a—c**.

| Educts | | $R^1$ | $R^2$ | Products; Yield [%] | | | |
|---|---|---|---|---|---|---|---|
| **1a** | **7a** | 3-Cl | 5-Cl | — | | **9a** | 31 |
| **1c** | **7a** | 3-Cl | 5-Cl | — | | **9b** | 13 |
| **6** | **7a** | 3-Cl | 5-Cl | **8a** | 62 | — | |
| **1a** | **7b** | 4-$CO_2$Et | H | — | | **9c** | 6 |
| **6** | **7b** | 4-$CO_2$Et | H | **8b** | 47 | — | |
| **1a/6** | **7c** | 4-$CH_3$ | H | — | | — | |

[***] Alexander-von-Humboldt Fellow 1979/80.

*N*-substitution of the dichloromaleiimides **7a—c** also plays a significant role (see Table 2). On irradiation, **2** is known to react with **6** and **1a** exclusively with cycloaddition[1,4]. The photoreaction of **7a**, **b** with **1a**, **c**, on the other hand, leads merely to substitution products, electron withdrawing substituents on the aryl group (**7a**, **b**)

markedly promoting the tendency to substitution; donors (**7c**) lead to the opposite effect. **7a, b** undergo smooth [2+2]-cycloaddition on reaction with the 6-azauracil **6**. The stereochemistry of the coupling of **3a—d** and **8a, b** follows from the $^1$H-NMR data; **3a**[4] analogously shows *cis,anti,cis* stereochemistry. **1b** and **2** yield, aside from **3b**, the isomer **4b** with *cis,syn,cis* stereochemistry; the signal of the $C-CH_3$ protons is correspondingly diamagnetically shifted by the vicinity of the imide-C=O (**3b**: $\delta = 1.67$; **4b**: $\delta = 1.40$).

## Synthesis of the Thionitrosylrhenium Dication $[Re(CO)_5(NS)]^{2+}$; Reactions and Structure of the Thiazylfluoride Complex $[Re(CO)_5(NSF)]^+$

By *Rüdiger Mews** and *Chao-shiuan Liu*

Several different routes exist to thionitrosyl complexes[1]. We have found that thiazylfluoride complexes, which can be readily prepared from the corresponding $SO_2$ derivatives, are suitable precursors for the preparation of the thionitrosyl ligand in complexes.

$$[Re(CO)_5(SO_2)]^+AsF_6^- + NSF \xrightarrow[-30\,^\circ C]{SO_2} [Re(CO)_5(NSF)]^+AsF_6^- + SO_2$$
**1**

As in free NSF[3], a fluoride ion can be removed by fluoro-Lewis acids, *e.g.*

$$\mathbf{1} + AsF_5 \xrightarrow[-30\,^\circ C]{SO_2} [Re(CO)_5NS]^{2+}(AsF_6^-)_2$$

leading, in quantitative yield, to the hexafluoroarsenate of the pentacarbonyl(thionitrosyl)rhenium dication[2b]. The novel compound **2** was identified by elemental analysis and IR spectroscopy. As expected, the CO stretching frequencies in the dication [$A_1$ 2219 (m), B 2191 (w), E 2157 (s), $A_1$ 2073 $cm^{-1}$ (m)] are shifted very strongly to higher wavenumbers; due to the doubly positive charge and the "soft" thionitrosyl ligand (good $\pi$ acceptor), backbonding from the central atom to the CO ligands should only be very weak, and the CO bonds correspondingly strong. Compared to **1**, the MCO deformation and MC stretching frequencies [546 (m), 524 (m), 491 (w), 318 $cm^{-1}$ (m)] are shifted to lower wave numbers. The SN stretching frequency is observed at 1371 $cm^{-1}$, and hence lies approximately 80 $cm^{-1}$ higher than in all previously known thionitrosyl complexes[1].

The hexafluoroantimonate **3** corresponding to **2** could be obtained in low yield from $Re(CO)_5Br$ and $NS^+SbF_6^-$.

$$NS^+SbF_6^- + Re(CO)_5Br \longrightarrow [Re(CO)_5NS]^{2+}(SbF_6^-)_2 + \cdots$$

## Chromatographic Resolution of Cyclic Organic Compounds on a Λ-Tris(1,10-phenanthroline)ruthenium(II) Montmorillonite Column

By *Akihiko Yamagishi** and *Ryuichiro Ohnishi*

A number of methods have been developed for the resolution of optically active organic molecules[1]. We describe here the first example of the use of an absorbent consisting of clay modified by an optically active metal complex.

The column (length 3 cm, outer diameter 1.2 cm) was filled with sodium montmorillonite, whose cation-exchange sites were replaced to 67% with Λ-Ru(phen)$_3^{2+}$ (Λ ≙ *R*-enantiomer) ions[2]. About 100 mg of the enantiomeric mixture to be separated was loaded onto the column

[*] Dr. Akihiko Yamagishi

Hokkaido University, Sapporo 060 (Japan)
Dr. Ryuichiro Ohnishi
Research Institute for Catalysis
Hokkaido University, Sapporo 060 (Japan)

and eluted with water (0.02 mL $min^{-1}$). The concentration and degree of resolution of the enantiomers were measured by UV absorption and ORD spectroscopy ($\lambda = 210$–700 nm).

The first group of compounds studied were acyclic (±)-α-amino acids, such as alanine, serine, threonine, asparagine, and lysine. The total amount of every amino acid loaded was recovered within the first 4 mL eluted. No optical activity was detected in the eluates (error limit 0.01° $cm^{-1}$, $\lambda = 210$—700 nm), *i.e.* these compounds were not resolved to a measurable extent. When (±)-proline was eluted, however, the eluates exhibited an ORD spectrum. Amino acid analysis of the eluates indicated that they only contained proline as a solute. Accordingly, neither decomposition of proline nor replacement of the ligand in the rhodium complex occurred during elution. The molecular rotation at 250 nm ($[m]_{250}$) varied with the elution volume from an initial negative value (−33°) to a final positive value (+34°). Since $[m]_{250}$ for (*S*)-proline is −880°, it is concluded that (*S*)-proline was eluted first with 3.8% followed by (*R*)-proline with 3.9% enantiomeric purity. These values were improved to 14 and 16%, respectively, when the fractions for $V = 0$—3 mL and 3—7 mL were chromatographed again.

Table 1. Resolution on a Λ-Ru(phen)$_3^{2+}$ montmorillonite column [a].

| Compound | $[m]_\lambda$ [b] *ee* [%] [c] | $\lambda$ [nm] | Configuration |
|---|---|---|---|
| proline | −33 (+34) [3.8 (3.9)] | 250 | *S*(*R*) |
| 5-oxoproline | +390 (−1000) [12 (30)] | 230 | *R*(*S*) |
| 5-methyl-2-pyrrolidinone | +250 (−560) [19 (43)] | 230 | *S*(*R*) |
| γ-valerolactone | +20 (−39) [5 (29)] | 250 | *R*(*S*) |
| 2-piperidinecarboxylic acid | −11 (+54) [6.8 (33)] | 300 | *S*(*R*) |
| 4-thiazolinecarboxylic acid | −20 (+98) [2.3 (12)] | 300 | *S*(*R*) |

[a] Eluent: water. [b] Rotation values of the first and the last fractions are shown without and in parenthesis, respectively. [c] Values in the square brackets show the corresponding enantiomeric excess (*ee*).

This success, together with the failure to resolve acyclic α-amino acids, led us to attempt the resolution of other kinds of *cyclic* organic compounds. Five of these (Table 1) were successfully resolved, but five others (xylose, 2-methylpiperidine, 2-ethylpiperidine, 3-piperidinecarboxylic acid, and α-acetyl butyrolactone) were not.

The present findings indicate that clay-metal chelate adducts are highly promising absorbents for the chromatographic resolution of enantiomeric mixtures of organic compounds. In addition, the systems are interesting as models for the propagation of chirality in nature during chemical evolution. Indeed, clay modified by optically active metal complexes could lead to the resolution of amino acids.

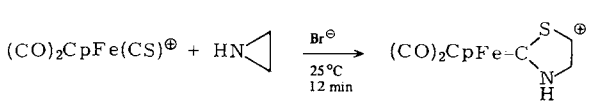
## Expansion of Three-Membered Heterocycles to Five-Membered Cyclic Carbenes—Novel Reactions of Aziridine, Oxirane, and Thiirane with CO and CS Ligands in Iron, Ruthenium, and Manganese Complexes**

By *Mono M. Singh* and *Robert J. Angelici**

Aziridine **1**, oxirane **2**, and thiirane **3** react with carbonylmetal complexes and undergo ring opening; initial reaction is at the metal centers[3, 4b]. So far, however, there have been no reports of direct reactions of CO or CS ligands with **1**, **2**, or **3**. We describe here some novel reactions of **1**, **2**, and **3** with these ligands in certain carbonylmetal compounds, yielding cyclic carbenes as the end products. Thus, reaction of **1** with the metal complexes **4a**—**d** and the ammonium bromide $Br(CH_2)_2NH_3^+Br^-$ (molar ratio 1:1:1) in $CH_3CN$ affords the cyclic amino(oxy)carbenes **5a**—**d**.

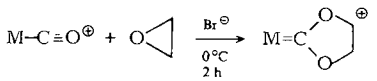


**4a-d** **1** **5a-d**

**a**, M = CpFe(CO)$_2$; **b**, M = CpMn(CO)(NO); **c**, M = CpRu(CO)$_2$; **d**, M = CpFe(CO)(PPh$_3$); anions: $PF_6^-$

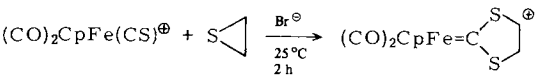
**5a**—**d** are obtained as crystalline hexafluorophosphates in 98%[7], 87%[7], 87%, and 70% yields, respectively, by extraction of the vacuum-dried residue with $CH_2Cl_2$ and precipitation with ether at −20 °C. Several other halides, such as $Br(CH_2)_3NH_3^+Br^-$, NaBr, $(nBu)_4N^+Br^-$, $Et_3NH^+Br^-$ and $(nBu)_4N^+I^-$ were also observed to catalyze the reaction of **1** with **4a**. **5a** is still obtained in 80% yield on decreasing the concentration of the $Br(CH_2)_2NH_3^+Br^-$ tenfold.

Similarly, reaction of **1** with the carbonyl(thiocarbonyl)-complex **6** in THF in the presence of $Br^-$ furnishes the cyclic amino(thio)carbene **7** in 83% yield.



**6** **1** **7**

[*] Prof. Dr. R. J. Angelici, Dr. M. M. Singh
Department of Chemistry and Ames Laboratory U. S., DOE
Iowa State University, Ames, IA 50011 (USA)



[**] Ames Laboratory is operated for the U. S. Department of Energy by Iowa State University under Contract No. W-7405-Eng-82. This research was supported by the Office of Basic Energy Sciences, Chemical Sciences Division.

Reaction of **2** in excess with **4a—d** in the presence of $Br^-$ in $Br(CH_2)_2OH$ as solvent leads to formation of the cyclic dioxycarbenes **10a—d** in 81%[7], 80%, 73%, and 81% yields, respectively. High yields (>70%) of **10a**, **10b**, and **10d** are also obtained when $Br(CH_2)_3OH$ is used instead of $Br(CH_2)_2OH$.

**4a-d** **2** **10a-d**

Unlike **1** and **2**, **3** does not react with **4a—d** to form the oxy(thio)carbene. However, it does form the dithiocarbene **13**[10] on reaction with **6** in presence of NaBr.

**6** **3** **13**

All the cyclic carbene compounds have been fully characterized as $PF_6^-$ salts by elemental analysis, and IR and $^1H$- and $^{13}C$-NMR spectral data. The formation of carbene ligands has been conclusively proven by the $^{13}C$-NMR signals of the carbene carbon atoms [($CD_3CN$), **5a—d**: $\delta = 220.24, 228.56, 206.28, 234.20$; **10a—d**: $\delta = 242.51, 253.43, 227.08, 254.00$; **7**: $\delta = 234.36$; **13**: $\delta = 295.40$].

## Optically Active Iron Complexes with Tetrahedral Structure

By *Henri Brunner** and *Wolfgang Miehling*

Most of the previously documented optically active organometallic compounds of the transition elements have an (arene)$ML^1L^2L^3$-type structure[1]. These complexes are designated as pseudotetrahedral, because the central metal is bound to four ligands, and consequently only the isomeric "image" and "mirror image" tetrahedral structures are possible. The geometry of these compounds is, however, octahedral with the 6 π-arene ligand, frequently benzene or cyclopentadienyl, occupying three *cis*-positions of the octahedron. This is born out, in particular, by the angles between the ligands $L^1$, $L^2$ and $L^3$ to the metal atom, which are always approximately 90°[2]. Optically active organometallic compounds of elements of the transition series with actual tetrahedral structure are, as yet, unknown.

A plausible strategy for the synthesis of such compounds would be the use of $Fe(CO)_2(NO)_2$ as starting material, a member of the pseudo-$Ni(CO)_4$ series in the sense of the nitrosyl-shift principle[3]. Replacement of a CO group in $Fe(CO)_2(NO)_2$ by another two-electron ligand, *e.g.* a phosphane, and of an NO group by another three-electron ligand, *e.g.* an aryldiazenyl group, would result in the Fe atom in the compounds $Fe(CO)(NO)(NNR)PR_3$ being a center of chirality. On using a pure phosphane enantiomer, *e.g.* one of the aminophosphanes (*S*)-$PPh_2\{N(R)CHMePh\}$[5] of Scheme 1, each complex is formed in the form of two diastereomers **a** and **b**, which differ only in the configuration at the Fe atom.

| R | R'=R''=H | R'=H, R''=$CH_3$ | R'=R''=$CH_3$ | R'=R''=$C_6H_5$ |
|---|---|---|---|---|
| H | **1a, b** | **2a, b** | | |
| $CH_3$ | **3a, b** | **4a, b** | **5a, b** | **6a, b** |
| $CH_2C_6H_5$ | | | **7a, b** | |

Scheme 1

The anion $Fe(CO)_3(NO)^-$ reacts with diazonium ions $arylNN^+$ in acetone at −78 °C to give the complex $Fe(CO)_2(NO)(NNaryl)$, which is unstable at room temperature[6]. However, if one equivalent of aminophosphane is added at −78 °C, further exchange of CO takes place with formation of the complexes **1—7** (Scheme 1), which can be isolated in 40—65% yield after warming to room temperature: **1** and **2** as readily decomposable red oils, **3—7** as stable reddish-brown powders.

The IR spectra of the complexes **1—7** in pentane solution each show sharp, very intense bands for $\nu_{CO}$ (1975—1980), $\nu_{NO}$ (1730—1735) and $\nu_{NN}$ (1662—1682 $cm^{-1}$). The diastereomers **a** and **b** of complexes **3**, **4**, and **6** do not differ in their $^1H$-NMR spectra. In the case of compounds **3** and **4** substituted in the *p*-position or without substituents on the diazoaryl moiety this is not surprising, but is, however, for the complex **6** which has phenyl substituents on the *o*-position. Only the compounds **5** and **7**, substituted by methyl in the *o*-positions, showed different chemical shifts in the *o*-$CH_3$ signals [$\delta = 2.22$ (**7a**) and 2.28 (**7b**), $C_6D_6$], the $C^*CH_3$, and the $NCH_3$ signals, from which the diastereomeric ratio **a** : **b** can be determined.

None of the diastereomers of complexes **3—7** can be enriched by fractional crystallization. In contrast, the diastereomeric pairs of **4**, **5**, and **7** can be separated by preparative liquid chromatography on Merck-Lobar B-columns.

Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] Optically Active Transition Metal Complexes, Part 82. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG, Ludwigshafen.—Part 81: I. Bernal, W. H. Ries, H. Brunner, D. K. Rastogi, *Inorg. Chem.*, in press.

For this purpose, 200—300 mg of each of the complexes in petroleum/ether 5:1 were chromatographed on a two-column system[5]. In all three cases the $(+)_{436}$-diastereomer **a** was eluted more rapidly then the $(-)_{436}$-diastereomer **b**.

In the case of complex **7** a distinct partition into two zones is achieved after passage through three columns, corresponding to a complete separation of **7a** and **7b**. In contrast, in the case of complexes **4** and **5** a broad zone is formed after passage through four columns in which **a** is enriched in the fronts and **b** in the tails. As shown by the CD spectra, the front and tail fractions can be obtained in high optical purity by cutting out the central part of the zone.

Of all the compounds investigated the diastereomers of **7** are the easiest to separate and to detect by $^1$H-NMR spectroscopy. Therefore, **7a** was chosen for investigation of the configurational stability at the Fe atom. No epimerization occurs up to 50 °C in $C_6D_6$ solution in a sealed $^1$H-NMR tube, with or without addition of free *N*-benzylaminophosphane (*S*)-$PPh_2$\{N(Bz)CHMePh\}; at about 55 °C the epimerization **7a** $\rightleftarrows$ **7b** takes place within a few hours. However, the fact that the change of configuration at the Fe atom is accompanied by side reactions *e.g.* formation of $Fe(NO)_2[PPh_2\{N(Bz)CHMePh\}]_2$ prevents kinetic measurements.

## Dicyanoketene: Flash Vacuum Thermolysis of Alkyl Dicyanoacetates**

By *James E. Gano**, *Roy H. Jacobson*, and *Richard H. Wettach*

A need to know the spectral data of dicyanoketene[2], **2**, prompted a search for a direct and unambiguous synthesis of this compound[3]. Although precedent suggested (a) dehydration of dicyanoacetic acid with phosphorus(v) oxide, (b) pyrolysis of metal enolates of alkyl dicyanoacetates, and (c) pyrolysis of alkyl dicyanoacetates would all produce dicyanoketene, [4] only route (c) proved successful.

Methyl dicyanoacetate **1a**[5], which slowly became yellow upon storage at room temperature, was purified by vacuum sublimation.

**1a** **2** **3a**

[*] Prof. Dr. J. E. Gano, R. H. Jacobson, Dr. R. H. Wettach
Department of Chemistry, Bowman-Oddy Laboratories
University of Toledo, Toledo, OH 43606 (USA)

[**] Financial support of this work by the Research Corporation and The University of Toledo Faculty Research Award and Fellowship program, and the technical assistance of L. Cooley, J. Werstler, and W. Opdycke are gratefully acknowledged.

For generation of **2**, **1a** was sublimed into an oven, which was directly attached to a mass spectrometer operating at a low (≈9 eV) ionizing voltage[6]. At an oven temperature of 500 °C the peak characteristic of **1a** (*m/z* 59, $CO_2CH_3$) was almost entirely replaced by peaks clearly characterized by dicyanoketene (*m/z* 92 and 64, $(NC)_2C$) and methanol (*m/z* 32 and 31)[3b].

When the products of pyrolysis of **1a** were codeposited with argon directly on a CsI window cooled to 12 K, infrared bands appeared assignable to residual **1a** and methanol. Dicyanoketene appeared at 2251 (w), 2246 (m), 2175 (vs), 1081 (w), and 571 (m) $cm^{-1}$[6]. When the argon was omitted during the deposition, the thin film (Fig. 2) showed broader bands for residual **1a**, methanol ($\nu$ = 1130 (w), 1030 (m, broad) $cm^{-1}$) and dicyanoketene ($\nu$ = 2230 (w), 2175 (vs), 1090 (vw) and 580 (w) $cm^{-1}$).

Clearly, dicyanoketene is an extremely reactive intermediate. Upon slowly warming the thin film devoid of argon, the dicyanoketene absorptions (Fig. 2) started disappearing near 60 K as the methanol absorption also disappeared (probably by sublimation) and new bands appeared ($\nu$ = 2295 (s), 2090 (s), 1125 (m) and 745 (w) $cm^{-1}$)[9]. Dicyanoketene has been reported elsewhere to react below 100 K[2].

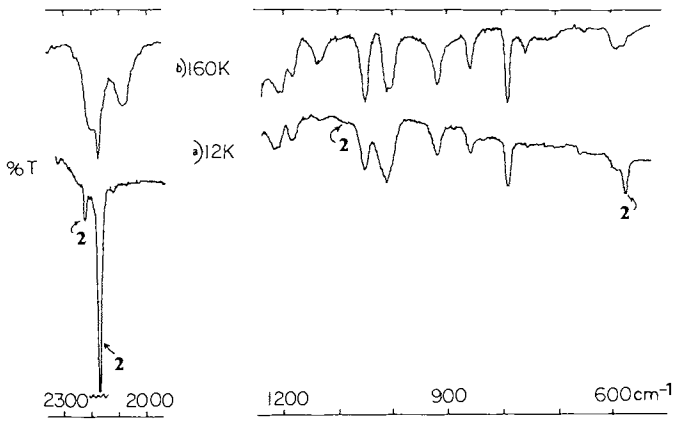

Fig. 2. IR spectrum (CsI window) of the oven effluent, which contains dicyanoketene **2**, on pyrolysis of **1a**. (a) Window temperature 12 K, (b) window temperature 160 K.

[2] Dicyanoketene appears to be an intermediate in the low-temperature photolysis of 1,3-dioxolane-2-methylenedicarbonitrile; *J. E. Gano et al.*, Nouv. J. Chim., in press.
[3] During the tenure of this work, an alternate route to dicyanoketene, requiring multiple steps to obtain a rather unstable precursor, was reported: a) R. Neidlein, E. Bernhard, *Angew. Chem. 90* (1978) 395; *Angew. Chem. Int. Ed. Engl. 17* (1978) 369; b) A. Hotzel, R. Neidlein, R. Schultz, A. Schweig, *ibid. 92* (1980) 751 and *19* (1980) 739; c) W. H. Gilligan, M. J. Kamlet, *Tetrahedron Lett. 1978*, 1675.
[4] a) D. C. England, C. G. Krespan, *J. Am. Chem. Soc. 88* (1966) 5582; b) D. F. Sullivan, R. P. Woodbury, M. W. Rathke, *J. Org. Chem. 42* (1977) 2038; c) T. J. Jorwski, S. Kwiatowski, *Rocz. Chem. 44* (1970) 691.
[5] a) F. Arndt, H. Scholz, E. Frobel, *Justus Liebigs Ann. Chem. 521* (1935) 95; b) some new spectral data of **1a**: $^1$H-NMR ($CDCl_3$): $\delta$ = 4.72 (1 H), 3.99 (3 H); $^{13}$C-NMR ($CDCl_3$): $\delta$ = 157.8 (C=O), 107.8 (CN), 55.9 ($CH_3$, $J_{C,H}$ = 150 Hz), 29.3 (CH, $J_{C,H}$ = 129 Hz).
[6] The oven was fitted with a quartz tube (I.D. 0.8 cm, length ≈15 cm), which was lightly packed over one third its length with quartz wool. The

orifice led directly into the ionization chamber of a mass spectrometer (Nuclide 12—90 G). Peak positions in argon are accurate to $\pm 1.5$ $cm^{-1}$.

[9] Attempts to identify this product have so far proved unsuccessful. Clearly **2** does not simply react with methanol to give the ester **1a** nor does it undergo [2+2]-cycloaddition to form a β-lactone or 1,3-diketone. Tetracyanoallene is a very attractive possibility.

## FT-FIR Spectroscopy of Ligand-Free Metal Clusters; Matrix Effects on the Molecular Geometry of Trichromium, $Cr_3$**

By *Geoffrey A. Ozin**, *Mark D. Baker*, *Steven A. Mitchell*, and *Douglas F. McIntosh*

We report here the first infrared spectroscopic data for a ligand-free triatomic metal cluster, $Cr_3$, immobilized in solid Ar or Xe matrices. In freshly deposited Cr/Ar and Cr/Xe condensates, prepared under conditions which are conducive to the co-isolation of Cr atoms, and $Cr_2$ and $Cr_3$ species, but not higher clusters[11] (Cr : noble gas = $1/10^3$ to $1/10^4$ at 12 K), Cr–Cr stretching and deformational modes were observed in the IR spectrum between 350 and 95 $cm^{-1}$. The FIR spectra at various Cr : Ar ratios and thermal annealing conditions are shown as examples in Figure 2 (Table 1 in the Supplement contains the assignments of the bands to the vibrational modes of the various $Cr_3$ clusters).

Our results indicate that the preferred structure of $Cr_3$ for a particular choice of experimental parameters is influenced by whether it is produced during the agglomeration stage of the film deposition process or from diffusion controlled nucleation reactions induced by thermal annealing of the condensate. Thus, in freshly deposited Xe matrices at 12 K, $Cr_3$ shows a single broad band centered around 210 $cm^{-1}$, which can be ascribed to the single IR-active E′ vibrational mode of the $D_{3h}$ equilateral triangular form. In Ar matrices, on the other hand, this same $Cr_3$ species is observed centered around 215 $cm^{-1}$ only after annealing to 40 K (Fig. 1). Annealing the Xe matrices containing the $D_{3h}$ form of $Cr_3$ to 25—75 K, however, generates $Cr_3$ with angles between 60—90° and those with *ca.* 120°. In Ar matrices, larger angle $Cr_3$ molecules tend to be preferred in freshly deposited as well as in films annealed at 25 K. Between 25 and 40 K these $Cr_3$ clusters are transformed into the thermally favored 60—80° small angle structures.

A normal coordinate calculation for $Cr_3$ as a function of angle (60—180°) proved to be particularly valuable for assigning the isomeric and isotopic contributions to the FT-FIR bands: these establish that the contribution to the band width from $Cr_3$ isotopomers lies in the range 8—10 $cm^{-1}$ for $\nu_1$ and $\nu_3$ stretching modes, and in the range 2—8 $cm^{-1}$ for the $\nu_2$ deformation mode. Furthermore, for the $D_{3h}$ isomer of $Cr_3$ the position of the bands and their shape are virtually identical in Ar and Xe, indicating that phonon and/or vibronic coupling contributions to the band widths are comparable, although not necessarily negligible, in these matrices. The origin of the pronounced band widths in the FIR absorptions of $Cr_3$ in Ar matrices under low dispersion conditions (Fig. 2A) can, therefore, be understood in terms of contributions from isotopomers, phonon and/or vibronic coupling, inhomogeneous effects, as well as from a distribution of structural isomers (angles vary between 100 and 150° in quench-condensed films, and collapse to 60—80° on annealing at 40 K). In contrast, conditions of high dispersion of $Cr_3$ in Ar tend to favor narrower band widths and better resolved FIR spectra (Fig. 2C), which permit a clearer identification of individual $Cr_3$

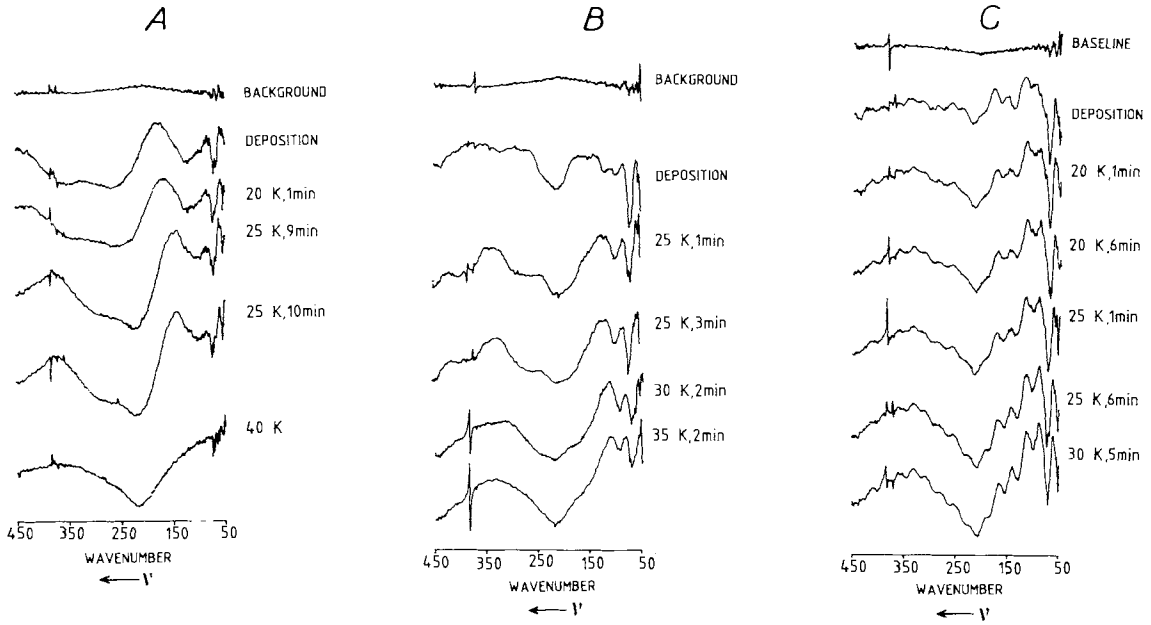

Fig. 2. FT-FIR spectra of Cr/Ar matrices for Cr : Ar ratios of *ca.* $1:10^3$ (A), *ca.* $2.5:10^4$ (B), *ca.* $1:10^4$ (C) deposited at 12 K and annealed at the temperatures indicated. Peak to peak noise at 200 $cm^{-1}$ = 0.5%.

Panning* proved to be invaluable.

clusters (angles from 60° to at least 130°). Under conditions of high dilution the $Cr_3$ isomers with larger angles (100—130°) appear to be favored on deposition at 12 K, whereas the smaller angle forms (60—90°) seem to be preferred in films annealed at 40 K.

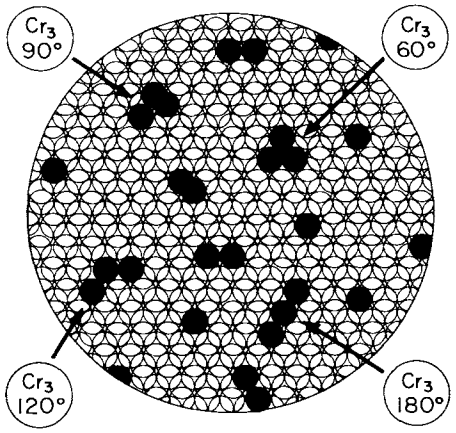

Fig. 4. Possible structures (schematic) of $Cr_3$ clusters in Ar or Xe matrices.

In summary, this study demonstrates for the first time that FT-FIR spectroscopy is a viable and useful technique for probing the vibrational and structural properties, and interaction with the support for "ligand-free" metal clusters. The FIR cluster data provide a valuable adjunct to the complimentary information from Raman, resonance Raman, and resonance fluorescence spectroscopic studies[7-9]. $Cr_3$ immobilized in Ar and Xe matrices at different metal concentrations and thermal conditions can occur in a range of molecular geometries ranging from equilateral triangular to that of almost linear (Fig. 4). It is evident that the $Cr_3$ cluster must have a rather shallow potential energy surface[16], and that variation of the experimental conditions can produce extremely subtle perturbations which profoundly influence the cluster geometry. The results underscore that even a "weak" interaction between a support and a molecular metal cluster can markedly influence the electronic, vibrational, and geometrical properties of such a supported metal cluster[17].

## Novel Synthesis of Acetylenes

By *Hans-Jürgen Bestmann**, *Kamlesh Kumar*, and *Wolfgang Schaper*

Phosphorus ylides **1** can be acylated with acid chlorides **2** in a reaction involving transylidation. The products obtained are the phosphonium salts **4** together with the acyl ylides **3**[1,2], the best yields of which are obtained if, as we have found out in the meantime, the reaction is carried out with **1** prepared from the corresponding salts **4** and sodium bis(trimethylsilyl)amide[1b]. Thermolysis of **3**[3] only leads to pure acetylenes **7** when $R^1$ and $R^2$ are aryl groups or when $R^2$ is an ester group[4]. This also holds true for the reaction of **3** with $PCl_5$ or Vilsmeier reagents and subsequent cleavage of the resulting β-chlorovinylphosphonium salts with bases[5]. The methodology described in this communication now enables directed conversion of the acyl ylides **3** into the acetylenes **7**.

Reaction of the ylides **3** with trifluoromethanesulfonic anhydride **5** furnishes the triflates **6**. Subsequent treatment of the salts **6** with sodium amalgam in tetrahydrofuran leads to formation of the acetylenes **7** along with triphenylphosphane **8** and sodium triflate **9** (for examples cf. Table 1).

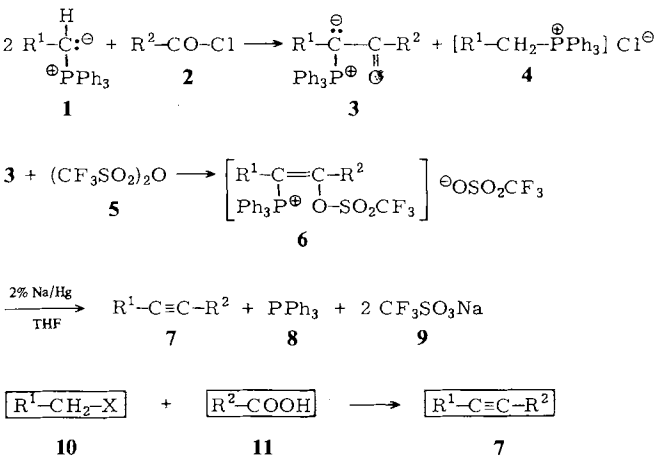

Table 1. Yields and melting or boiling points of products **3**, **6**, and **7**.

| $R^1$ | $R^2$ | **3** Yield [%] | **3** M.p. [°C] | **6** [a] Yield [%] | **6** [a] M.p. [°C] | **7** [b] Yield [%] | **7** [b] B.p. [c] [°C/torr] |

# BOOK REVIEWS

**Protein-Protein-Interactions.** Edited by *C. Frieden* and *L. W. Nichol,* John Wiley & Sons, New York 1981, 403 pp., bound, £ 36.95.

The publication of this book is timely, because interactions of proteins with themselves, with other macromolecules and with small ligands have proved to be of great significance for operation and control of biochemical processes. Moreover, in the last two decades, important advances have been made in the experimental and theoretical clarification of interacting macromolecular systems. Eleven authors with international reputation have contributed to this book, which summarizes the most important recent developments made in this field, covering the literature up to 1979/80.

In the opening chapter, *L. W. Nichol* gives a short general introduction (28 pages), defining the basic thermodynamic and kinetic properties of protein systems. Starting with the behavior of a non-interacting protein in solution, self-interacting protein systems, mixed two-component systems, and multicomponent heterogeneous systems are treated.

In the second chapter, a detailed account of structural and energetic aspects of protein-protein interactions is given by *L. J. Banaszak, J. J. Birktoft* and *C. D. Barry*. The treatment is well balanced giving equal consideration to each of these aspects. Thus, the authors devote about 50 pages to structure, symmetry and conformation, and 35 pages to interatomic forces and calculations of conformations. The wide range and the depth of the critical exposition of experimental and theoretical approaches to structure determination and prediction makes this chapter, which is the longest of the book, one of its highlights. The strategy is typical for crystallographers, namely to focus mainly on X-ray crystallographic studies while neglecting solution studies. The treatment of the hierarchical levels of protein structure is up-to-date including a description in terms of super-secondary structures, domains, lobes and symmetrical and non-symmetrical assemblies *etc.* In an Appendix, energy minimization, empirical structure predictions, Monte Carlo calculations *etc.* are considered with regard to environmental effects, molecular dynamics and protein folding.

*D. J. Winzor* gives an excellent survey (40 pages) of the present state of the art in the theory and application of mass migration methods, such as sedimentation velocity, gel chromatography, electrophoresis, activity transport *etc.* Reversibly self-associating systems, as well as association-dissociation equilibria of heterogeneous systems are dealt with. Reactions which are considered are not limited to protein-protein-interactions, but also include protein-ligand interactions in a wider sense. Thus, monomer-oligomer equilibria that may result from exclusive or preferential binding of substrates or (allosteric) effectors to monomers or oligomers are discussed. These processes are of importance for enzyme regulation, gene expression, hormone action, immune response, *etc.*

An introduction to boundary analysis is given in a separate chapter by *D. J. Cox* and *R. S. Dale*. Instead of considering all available simulation methods (Bethune-Kegeles, Cann-Goad, Dishon-Weiss-Yphantis, *etc.*), the authors treat only the "distorted grid simulation" *(Cox)* and the "finite element simulation" *(Claverie)* since these are considered as particularly effective methods. *P. D. Jeffrey* deals with classical "equilibrium methods" for the characterization of interacting mixtures of macromolecules in solution in terms of stoichiometry and equilibrium constants. He does so in an admirably concise manner, starting with a unified formal description of thermodynamically non-ideal homogeneous and heterogeneous multicomponent systems. Within this framework, protein-protein-interactions may be interpreted on the basis of second (or higher) virial coefficients making use of the "Adams-Fujita approach".

*G. G. Hammes* describes fluorescence methods. After giving basic definitions, fluorescence polarization and resonance energy transfer are treated. The latter is the "pièce de résistance" of *Hammes'* contribution. He provides a knowledgeable and helpful introduction to the use of energy transfer in the study of protein-protein interactions. The usefulness of this approach is exemplified by work with antibodies and by Hammes' own work with chloroplast coupling factor. Finally, the use of energy transfer for distance measurements between molecules on cell surfaces is introduced, an aspect which is presently receiving a lot of attention.

*C. Frieden* deals with the kinetics of associating-dissociating enzyme systems. This author has made important contributions to the field of kinetics of allosteric enzymes

and has developed the concept of the "hysteretic" enzyme. Introducing his topic, he makes the point that a careful comparison of kinetic with binding data may help to distinguish certain kinds of enzyme regulation but that a comparison is only valid when enzyme substrates and enzyme-substrate complexes are at equilibrium. *Frieden*'s critical treatment of activity as a function of enzyme concentration is masterly and should be read by every kineticist interested in control of enzyme activity. It rests firmly on the author's own studies. Computer programs were developed for the evaluation of kinetic data using a numerical integration for solving differential equations. The importance of rate measurements for the attainment of monomer-polymer equilibria is emphasized, and suitable methods for the correlation of molecular weight and activity of an enzyme are discussed. Interactions of enzymes with other proteins (with and without enzymic function) and with cellular structures (*e.g.* membranes, cytoskeleton and nucleic acids) are considered, and the model character of immobilized enzymes and coupled enzyme reaction chains is emphasized. In view of the physiological importance of association-dissociation reactions of enzymes, which drastically alter the kinetic and regulatory behavior of enzymes when monomer and polymer exhibit different kinetic properties, *Frieden*'s contribution should encourage all enzymologists concerned with rate controlling enzymic processes to purchase this book.

In Chapter 9, *L. W. Nichol* and *D. J. Winzor* deal with ligand binding. Although the thorough theoretical treatment provides a sound basis for practical applications with useful hints for the experimenter, on a whole, this chapter does not turn out as well as the others. Most of the important aspects of ligand binding considered in this chapter have already been dealt with in detail elsewhere, and, unfortunately, the treatment of some specific problems does not meet up with the present state of the art.

In contrast, the chapter contributed by *S. N. Timasheff* on self-assembly of long rodlike structures exemplifies what makes this book attractive and worthwile. A single system, namely the polymerization of tubulin, which *Timasheff* and his colleagues have investigated in detail, is used to develop lucid theories on the linear and nucleated polymerization of proteins based on *Osawa*'s theory of the helical polymerization of actin. Especially valuable are *Timasheff*'s remarks on current methodology: Drawing from a wealth of his own experience he outlines not only the merits but also the limitations of light-scattering, viscosity and centrifugation methods which are widely used for the analysis of polymerizing proteins.

This book has not been written for graduate students. Rather, it is directed at the researcher engaged in the physical study of interacting proteins and enzymes. For this group of biochemists enzymologists and molecular biologists the book is of great use and fills a need. As a Matter of fact, it will be difficult to find another recent publication which is of so much practical value. Theory, practical application of methods and critical evaluation of data are treated in depth, so that the reader rarely needs to consult original papers. However, the book is by no means perfect: There is inevitably some redundancy and overlap, and in some cases the treatment is too detailed, reflecting more the enthusiasm of the authors rather than the needs of the user. Moreover, certain aspects, for example elementary step kinetics, have been neglected. But despite these criticisms, we can recommend this book without reservations to everybody who has to deal with protein-protein interactions in his research. Thus, the number of potential users should be large, for who does not need to come to terms with a quantitative treatment of protein-protein interactions, which are of such fundamental importance for an understanding of structure, function and regulation of proteins and enzymes *in vitro* and in the living cell.

# The Versatile Chemistry of 1,4-Diazines: Organic, Inorganic and Biochemical Aspects

By Wolfgang Kaim*

In chemical research attention is increasingly being focussed on composite "complex" systems with special properties and functions. As components of such systems 1,4-diazines are steadily gaining in popularity. Here, 1,4-diazines means pyrazine and its derivatives as well as compounds with partial pyrazine structure; examples are quinoxaline, phenazine, pteridine, flavin and their derivatives. All these compounds are characterized by a low lying unoccupied π-molecular orbital and by the ability to act as bridging ligand. Due to these two properties 1,4-diazines, and especially their parent compound pyrazine, possess a characteristic reactivity. 1,4-Diazines may be employed to study inter- and intramolecular electron transfer in organic, inorganic and biochemical reactions. In the redox system of 1,4-diazines the paramagnetic 7π-electron intermediate exhibits exceptional stability, whereas the 1,4-dihydro-1,4-diazines with 8π-electrons in a six-membered ring are not generally accessible due to their potential antiaromaticity and their large excess of π electrons. Its inherent bifunctionality and the low lying unoccupied molecular orbital permit pyrazine to form coordination polymers having unusual electrical and magnetic properties. Finally, the phenomena observed for pyrazines may be used in the interpretation of the reactivity of naturally occurring 1,4-diazines, such as flavins and bioluminescent natural products.

*"Wer nur (an)organische Chemie versteht, versteht auch die nicht recht"*[**].

*(After G. C. Lichtenberg, 1742–1799)*

## 1. Introduction

The ring system of pyrazine **1** forms the common structural unit of 1,4-diazines. The reactions of 1,4-diazines may be described either in terms of "conventional" chemistry, generally corresponding to that of other aromatic heterocycles[1], or in terms of a reactivity characteristic of only this particular system.

**1**

The aim of the present review is to illustrate this special reactivity with the aid of selected examples, to discuss possible model interpretations thereof, and to indicate some potential applications. Organic as well as inorganic and biochemical results are discussed, giving an indication of the versatility of this system.

## 2. Premises

The replacement of two opposite CH-groups in benzene by nitrogen atoms has the following consequences: The degeneracy of the π-frontier orbitals is removed (Fig. 1); the $B_{3g}$ orbital, which is not influenced by the 1,4-perturbation, becomes the only highest occupied π-orbital. The lowest unoccupied molecular orbital (LUMO) is now $B_{1u}$, whose energy is lowered by the CH→N exchange.

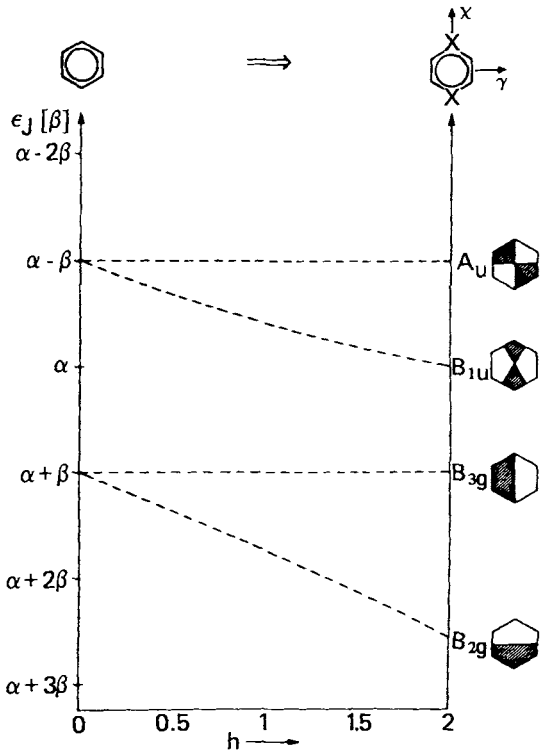

Fig. 1. The frontier orbitals of pyrazine as text book case [2a]: According to the Hückel model, perturbation of the benzene π-system by CH→N exchange in positions 1 and 4 may be represented by an enlargement of the Coulomb integral $\alpha_N = \alpha_C + h \cdot \beta$ (X = N). The relation $\alpha_N > \alpha_C$ (positive $h$) corresponds to the larger effective nuclear charge or the greater "electronegativity" of the nitrogen atom. The molecular orbitals $B_{1u}$ and $B_{2g}$ are energetically lowered, while orbitals $A_u$ and $B_{3g}$ remain unaltered by the 1,4-perturbation (nodal plane through 1 and 4). In pyrazine **1** $B_{2g}$ and $B_{3g}$ are occupied, $h_N \approx 0.5$ [2b]. The same correlation diagram may be used for planar 1,4-dihydropyrazine **9**, in which case $B_{1u}$ is also occupied ($h_N \simeq 1.0$ [3]—1.5 [2b]). The sequence of π-orbitals given by the HMO model is confirmed by quantitative calculations for pyrazine [4] and 1,4-dihydropyrazine [5].

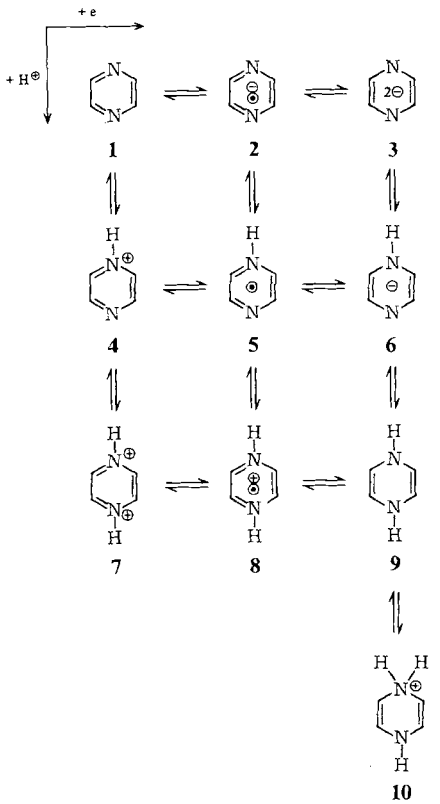
This model is supported by the reactivity of pyrazine. Compared to benzene, **1** is an electron-deficient molecule and already takes up an electron in the gas phase[6] as well as in solution[7,8]. Accordingly, the organic chemistry of pyrazine is characterized by easy nucleophilic attack[1] (IP = ionization potential[9], EA = electron affinity[6]).

$$\mathbf{1}^{+} \xleftarrow[\text{IP} \approx 9.5\ \text{eV}]{-e} \mathbf{1} \xrightarrow[\text{EA} \approx 0.4\ \text{eV}]{+e} \mathbf{1}^{-}$$

On the other hand, the oxidation of pyrazine is not an energetically favored process; the ionization potential of **1** is somewhat higher than that of benzene (IP = 9.25 eV)[9]. In the condensed phase the pyrazine radical cation may only be formed by radiolytic methods and is rather unstable[10]. UV, ESR[10] and photoelectron spectroscopic studies[9] show that in the first ionization step an electron is lost from a σ-orbital.



Because of the introduction of two nitrogen atoms pyrazine contains two unshared electron pairs arranged orthogonally to the π-system.

In the HMO approximation σ- and π-systems are separable[2], but the N-electron pairs influence each other because of through bond and through space interactions[9]. Since the electron pairs are oriented in opposite directions, pyrazine **1** is a bifunctional, bridging ligand which does not form chelates (μ-pyrazine). In fact, **1** and related 1,4-diazines form both monomeric 1:2 adducts (Sections 3 and 4) and polymeric coordination compounds (Section 5) with numerous electrophiles.

## 3. Coordination of $H^{\oplus}$: The Pyrazine/1,4-Dihydropyrazine Redox System

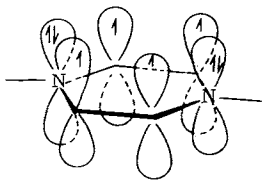
The simplest electrophilic coordination partner of pyrazine is the proton. The combination of stepwise protonation with a two step redox reaction results in a scheme characteristic of Weitz redox systems[11] (Scheme 1).

Scheme 1. The pyrazine/1,4-dihydropyrazine redox system.

According to *Hünig et al.*[11], Weitz redox systems differ from quinonoid[12] and other systems through the incorporation of coordination atoms *into* the ring and through the aromaticity of the *oxidized* forms. Several species from Scheme 1 are known:

The protonated pyrazines **4** and **7** have been detected in strong acids[13, 14]; the low basicity of pyrazine in the first step ($pK_a = 0.6$) and especially in the second step ($pK_a = -6$)[14] is remarkable. For comparison: the acidity constant of the pyridinium ion is 5.2[15].

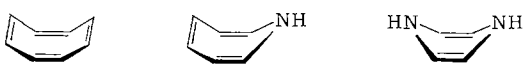
The reduction of pyrazine in aprotic media leads first, in a reversible step, to the radical anion **2**[7]; reduction to the dianion **3** cannot be observed electrochemically[16]. From the potential difference $E(2/3) - E(1/2) > 0.82$ V[16] the formation constant $k_{SEM}$[11] of the radical anion **2** may be estimated to be $k_{SEM} > 10^{15}$, an exceptionally high value[11].



$$k_{SEM} = \frac{[2]^2}{[1][3]} = 10^{(\Delta E/0.059\,V)}$$

Protonation changes the redox potentials since the formation of the radical intermediates **5**[17] and **8**[17, 18] is then increasingly favorable. In strongly acidic aqueous solution two separate reduction steps have been detected: The stable radical cation **8** is formed first; further electron uptake, however, does not lead to the neutral 1,4-dihydropyrazine **9** but, after addition of a further proton, to the 1,4-dihydropyrazinium ion **10**[19].

$$\mathbf{1} \xrightarrow[+e]{+2H^{\oplus}} \mathbf{8} \xrightarrow[+e]{+H^{\oplus}} \mathbf{10}$$

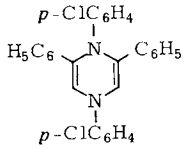


$E_{1/2} = -0.09 \times pH - 0.308$ [V] (*vs.* SCE)[19b]

Compound **9** is of especial interest: Whereas in the quinonoid redox system[12] the reduced neutral form is an aromatic hydroquinone, in the Weitz redox system (Scheme 1) the analogous stage is represented by the potentially "antiaromatic"[20] 1,4-dihydropyrazine[5, 21–24]. The antiaromaticity of **9** and also of **3** and **6** would arise as a result of the cyclic conjugation of a total of 8 (4n)π-electrons[20], including the unshared electron pairs of the two nitrogen atoms.

It should be noted that heteroconjugation gives rise to a smaller antiaromatic destabilization than expected for an isoconjugated system[25]. For **9** an antiaromatic destabilization of 12 kJ/mol has been calculated[5].

The cyclic conjugation of all 8π-electrons is bound by steric requirements. In the boat conformation the six-membered ring **9** does not tolerate such large single bond torsional angles $\theta$ as the related 8π-electron systems cyclooctatetraene **11**[26] ($\theta = 56°$[27]) and 1*H*-azepine **12**[28] ($\theta \simeq 60°$ and 30°[29]), but enforces a closer to planar structure[23].



**11** **12** **9**

However, due to the different positions of the *N*-substituents conformational isomerism is possible[23, 30, 31] (angle $\varphi$).

**9**

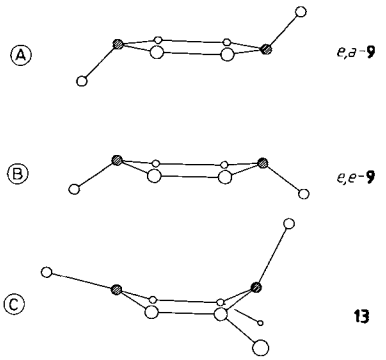
The extent of cyclic 8π-electron delocalization in **9** depends on the shape of the boat conformation. A geometry-optimized MNDO calculation was carried out[32] in order to obtain a quantitative estimate of the structural effects involved in the redox system **7/8/9**. The results are presented in Figure 2 and Table 1, where they have been compared with structural parameters of the stable derivative **13**.

**13**

Table 1. Calculated (**7**, **8**, **9**) [30] and experimental (**13**) [31] structures of pyrazine derivatives. According to a geometry-optimized MNDO calculation, an increasing localization of the C-C double bond is observed in the redox system **7/8/9**. This corresponds to decreasing aromatic delocalization. For **7** and **8** the conformation of minimum energy is found to be planar; for **9** two conformations of minimum energy are obtained [32]. In agreement with calculations for 1-substituted 1,4-cyclohexadienes [34], diaxial arrangement of the N—H bonds does not produce a conformation of minimum energy, due to the repulsion between the hydrogen atoms in the ring and the larger substituent (in this case the N electron pair). The structural X-ray analysis [31] of a 1,2,4,6-tetraaryl-1,4-dihydropyrazine **13** shows the more marked boat conformation and the bending into an axial conformation as the result of steric hindrance. Hence, cyclic 8π-electron conjugation becomes impossible: The compound is stable [33]. (Atomic distances $d_{XY}$ in pm, $\theta$: torsional angle CCNCC.)

| Cpd. | $d_{CC}$ | $d_{CN}$ | $d_{NH}$ | $\theta$ [°] | Structure |
|---|---|---|---|---|---|
| **7** | 143 | 137 | 103 | 0 | planar |
| **8** | 139 | 139 | 101 | 0 | planar |
| *e,a*-**9** | 136 | 143 | 101 | 0.8 | Fig. 2 Ⓐ |
| *e,e*-**9** | 135 | 143 | 101 | 8.3 | Fig. 2 Ⓑ |
| **13** | 133 | 144<br>141 | — | 27.2<br>37.3 | Fig. 2 Ⓒ |

It can be seen that for **9** all conformations of minimum energy deviate only slightly from the planar ring structure.



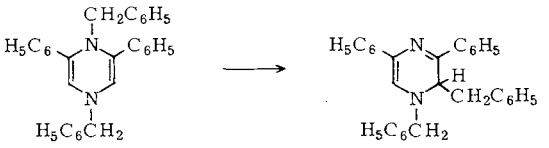


Fig. 2. Computer-drawn conformations of the 1,4-dihydropyrazines *e,a*-**9**, *e,e*-**9** and **13** (Table 1) [32]. Nitrogen atoms are striped; for reasons of clarity *C*-protons are omitted and the phenyl substituent in **13** [33] is represented by a single carbon atom.

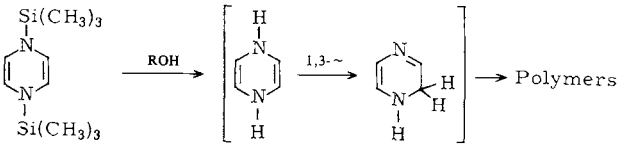
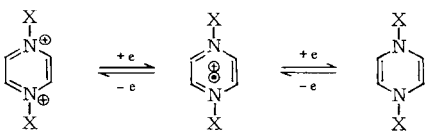


A further interesting aspect of 1,4-dihydropyrazine **9** is its isosteric relationship with benzene. In the HMO approximation[2], *i.e.* assuming the molecule to be planar with a cyclic delocalized π-system, not only **1** but also **9** may be described by the correlation diagram in Figure 1. This is accomplished simply by filling the lowest unoccupied molecular orbital of pyrazine **1** with two electrons and by adding a correction to the Coulomb integral parameter $h_N$ (Fig. 1). In 1961 *Streitwieser*[3] already predicted that the molecule **9** would contain an occupied antibonding MO; thus compound **9** should be very electron-rich and should endeavor to give up at least one electron. This is no doubt one reason for the ready formation and unusual stability of the radical intermediates with 7π-electrons (cf. Table 2).

Attempts to prepare 1,4-dihydropyrazine **9** in the condensed phase have been unsuccessful. Electrolytic reduction of strongly acidic aqueous solutions of pyrazine leads to **8**, but not to **9**. Instead, one obtains the further protonated and therefore *no longer* cyclically conjugated compound **10**, which decomposes with opening of the heterocyclic ring[19]. Another possible reaction for **9** is the 1,3-hydrogen shift observed in numerous derivatives, *e.g.* **14**[22,36-39], and in the related 1*H*-azepine **12**[28].

**14** **15**

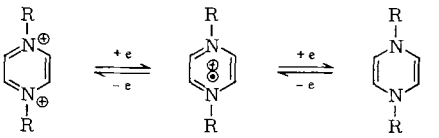


Both unsubstituted 1,2-dihydropyrazine **16** and the 1,4-isomer **9**[1] have yet to be prepared; thus, attempts to hydrolyze 1,4-bis(trimethylsilyl)-1,4-dihydropyrazine **17** failed to give any low molecular weight products[40,41].

**17** **9** **16**

## 4. Monomeric *N*-Coordination Compounds of Pyrazine

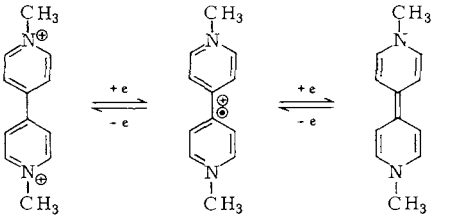
Pyrazine **1** and its reduction products **2** and **3**, in addition to coordinating with protons, also coordinate with numerous other organic and inorganic electrophiles. In the following sections the influence of various electrophiles X on the properties of the components of the redox system (Scheme 2) will be discussed. Some characteristic spectroscopic parameters have been compiled in Tables 4 and 5 (Sections 4.2 and 4.6).



**A** **B** **C**

Scheme 2. The pyrazine dication/1,4-dihydropyrazine redox system.

### 4.1. Pyrazines according to Scheme 2, with X = R (R = Alkyl, Aryl)



Due to the low basicity of pyrazine, the use of conventional alkylating agents only leads to formation of the monoquaternary salts; oxonium salts are required for production of diquaternary species **18A**[42]. These may thus be readily prepared and, in certain solvents, be examined spectroscopically (cf. Table 4). However, even when stored carefully they are unstable[16,42]; discoloration occurs, accompanied by the formation of free radicals[16]. When these compounds are dissolved in alcohols[42,43] or in water[16], one obtains persistent, concentrated solutions of the radical intermediate **18B**. The mechanism of radical formation is still unclear[42] (but cf. Scheme 3).

**18A** **18B** **18C**

R = $C_2H_5$: $\lambda_{SEM}$ = 350 nm; $k_{SEM}$ = $10^{13}$

The unusual stability of the radical cation **18B** is reminiscent of the behavior of the paraquat or methyl viologen radical cation **19B**[11,44] (see Section 6.2). A comparison of the redox systems **18**, R = $C_2H_5$, and **19** reveals a higher oxidation potential, larger formation constant and shorter wavelength light absorption for the pyrazinium radical intermediate[11,16].

**19A** **19B** **19C**

$\lambda_{SEM}$ = 600 nm; $k_{SEM}$ = $10^7$

According to the HMO model the easy reducibility of the diquaternary species **18A**, in comparison to the neutral compound **1**, is related to the increase in the Coulomb integral at the nitrogen atoms[2b]. Thereby the energy of the lowest unoccupied molecular orbital is lowered (Fig. 1), so facilitating electron acceptance by the system.

In the case of *C*-unsubstituted systems **18** the 1,4-dihydropyrazine stage **18C** could not be isolated. The chemistry of some stable, but highly substituted 1,4-dialkyl- and 1,4-diaryl-1,4-dihydropyrazines has been reviewed by *Schmidt*[23]. *All* such derivatives contain bulky substituents in the 2,6-positions (**13**, **14**). The reason for the stability of these molecules may be seen in Table 1 and Figure 2: Steric repulsion between the vicinal substituents in the 1, 2, and 6 positions prevents conjugation of the free electron pair on N-1 with the rest of the π-system. Thus, an antiaromatic destabilization with corresponding chemical (Table 3) and spectroscopic consequences (cf. Table 4) is no longer possible. In all other cases the system tries to avoid

the unfavorable 8 π-electron situation (Table 3), sometimes by the formation of other isomers (1,2- and 2,5-dihydropyrazines)[45]. As examples, the syntheses of radical cations of the type **18B** may be cited.

Thus the most stable oxidation state of the 1,4-dialkyl- and 1,4-diarylpyrazine system **18** is neither the oxidized nor the reduced form, but the paramagnetic intermediate (Table 2). This is confirmed by further examples of electron transfer reactions[46,47] (cf. Scheme 3):

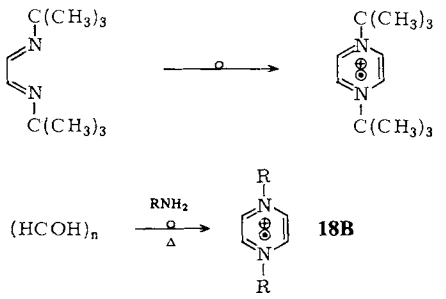


Table 2. Molecular strategies for generating the cyclic 7 π-electron-configuration in 1,4-diazine radical intermediates.

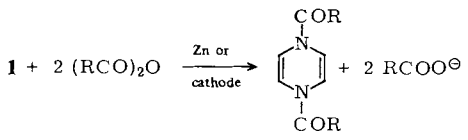
- Electron addition in the gas phase [6] (positive electron affinity)
- Electron uptake in solution [7, 8, 19]
- (Photo-)Reduction of pyrazinium ions [17, 18b] and pyrazine dications [16, 42, 43]
- Reduction by SET reaction [a] with alkyl- and arylmetal compounds as well as metal hydrides [62, 69–72]
- Reduction by metal ions [136, 140]
- Oxidation of 1,4-dihydropyrazines by $O_2$ [22a, d, 35, 88]
- Oxidation and dehydrogenation of 1,2,3,4-tetrahydropyrazines [24c]
- Oxidation and ring expansion [185]
- Ring closure and SET reaction [46, 47, 67]



[a] SET = *S*ingle *E*lectron *T*ransfer).

Table 3. Molecular strategies to avoid the cyclic 8 π-electron configuration in 1,4-dihydro-1,4-diazines

- Reoxidation to the pyrazine [21, 69]
- One-electron oxidation to the radical cation (cf. Table 2)
- Addition of electrophiles ($H^{\oplus}$, $R^{\oplus}$) to the nitrogen atom [19, 181]
- Addition of $H_2$ [21, 22d, 24a, 163], $H_2O$ [53] or RSH [22d] to the double bond
- Retro-Diels-Alder reaction [21]
- 1,3-Hydrogen shift [22b–e, 36–38]
- Formation of unexpected isomers [35, 39, 45]
- Stabilization by conformative reasons [23, 35] and by *C*- [88] or *N*-acceptor substituents [24b, 48, 49, 51]

### 4.2. Pyrazines according to Scheme 2, with X = COR (R = H, Alkyl, Aryl, OR', $NR'_2$)

Due to the π-acceptor function of the carbonyl group, *N*-acylation of the redox system (Scheme 2) causes a stabilization of the reduced form **C**. Accordingly, *N*-acyl-1,4-dihydropyrazines are known[21,48] (cf. Section 7.3); however,

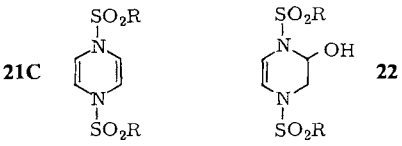
**20C**

R = H, $CH_3$, $C(CH_3)_3$, $C_6H_5$, $N(CH_3)_2$ [49], $OC_2H_5$ [51]

parent compounds of the type **20C** have only recently been described by *Gottlieb* and *Pfleiderer*[49].

Compounds **20C** do not possess any unusual properties; they are colorless, stable in air, and their $^1$H-NMR spectra do not reveal the paratropic[50] characteristics expected for a cyclic conjugated 4n π-system (Table 4).

Table 4. Chemical shifts δ of the ring protons in pyrazines and 1,4-dihydropyrazines. The outer ring protons of "aromatic" pyrazine derivatives with 6 π-electrons show the expected downfield shift (diatropic [50] behavior). Most 1,4-dihydropyrazines are stabilized by steric or electronic modification and do not demonstrate paratropic [50] characteristics. However, a clear upfield shift is detected in unsubstituted *N*-silyl derivatives **17** (and **29**), indicating the presence of cyclic 8 π-electron conjugation [24].



| Compound | Type | Solvent | δ | Ref. |
|---|---|---|---|---|

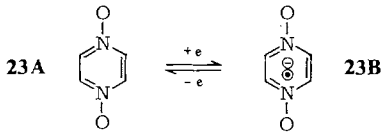
[a] Average value for *cis*/*trans*-isomers.

The corresponding derivatives of urea (1,4-dihydro-1,4-pyrazinedicarboxamides)[49] and urethanes (1,4-dihydro-1,4-pyrazinedicarboxylates)[51] may be prepared by electrochemical methods.

### 4.3. Pyrazines according to Scheme 2, with X = $SO_2R$ (R = Aryl)

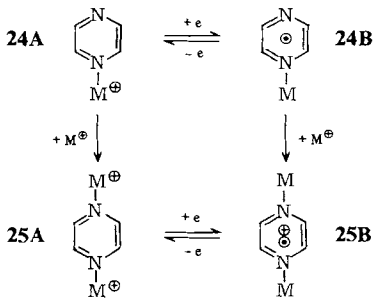
Earlier reports[52] concerning a 1,4-bis(phenylsulfonyl)-1,4-dihydropyrazine **21C**, R = $C_6H_5$, have been refuted by more recent work[53].



However, due to the acceptor function of the $SO_2R$-group compounds **21C** would be expected to be stable. Evidence for the presence of **21C**, R = *p*-$CH_3C_6H_4$, was found in experiments by *Eisner* and *Williams*[53], who isolated **22** as a product of hydrolysis.

### 4.4. Pyrazines according to Scheme 2, with X = $O^{\ominus}$

1,4-Pyrazine dioxide **23A** is a weaker base than pyrazine[54]. Because of the acceptor effect of the coordinated oxygen atoms **23A** is more readily reduced than **1**, forming a stable radical *anion* **23B**, whose ESR spectrum indi-

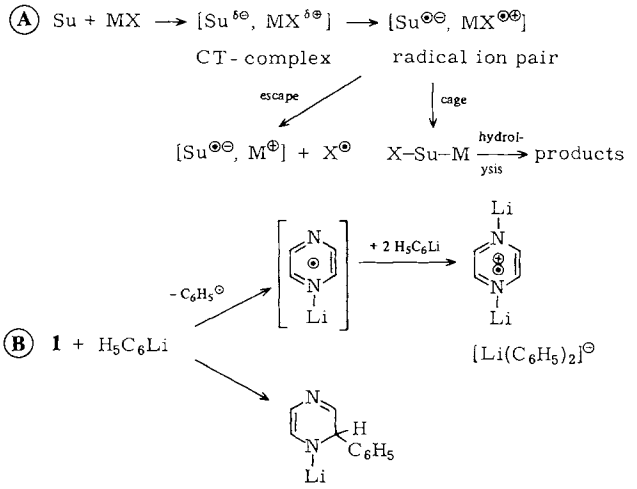


cates that the unpaired electron is delocalized towards the oxygens[55] (cf. Table 5).

The free electron pairs on the oxygen atoms cause **23A** to be a bifunctional ligand for electrophiles, particularly for metal ions[56].

### 4.5. Pyrazines according to Scheme 2, with X = M (M = Alkali Metal)

As a weak base pyrazine does not form very stable complexes **24A** and **25A** with alkali metal cations[57]. However, upon its formation by alkali metal, the radical anion **2** coordinates very readily with the corresponding $Li^{\oplus}$, $Na^{\oplus}$ or $K^{\oplus}$ ions. As a result one obtains paramagnetic ion pairs **24B**[58] or "triple ions" **25B**[59].



In the 1 : 1 adducts **24B** the metal cation is not fixed to pyrazine at one coordination site, exchange processes take place in the range of the ESR time scale of approx. $10^{-7}$ s[58,60]. 1 : 2 Radical complexes **25B** (triple ions) are formed at low temperatures[61] and especially after addition of soluble alkali metal salts[59].

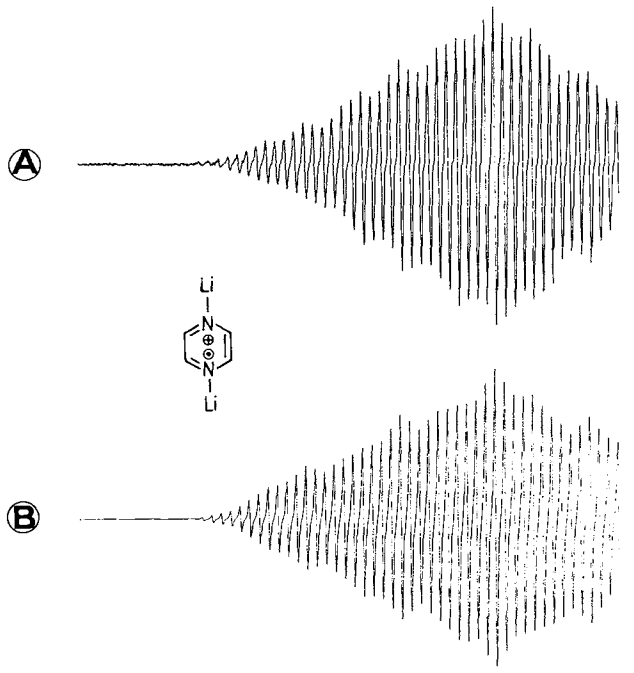
These triple ions are also formed in the reaction of pyrazine with organometallic reducing agents in coordinating solvents[62,63].

$$\mathbf{1} \xrightarrow[LiAlH_4]{LiR} \mathbf{25B},\ M = Li$$

Such reactions, in which radicals are formed from two diamagnetic compounds, occur *via* an intermolecular electron exchange. They may be taken as an indication of a *s*ingle *e*lectron *t*ransfer (SET) mechanism[64] (Scheme 3, Fig. 3). In the reaction of pyrazine with electron transfer reagents the formation of diamagnetic products is as expected[65] (Scheme 3Ⓑ); however, the presence of polymeric byproducts is characteristic for SET reactions of N-heterocycles[65,66].

Alkali metal/pyrazine radical complexes have also been detected in the reaction of ethylenediamines with *n*-butyllithium[67]. This provides further proof of the tendency to form the 7 π-electron intermediate (cf. Table 2).

Scheme 3. Ⓐ Intermolecular single electron transfer (SET) mechanism for the reduction of a substrate Su by an organometallic compound MX (X = H, R; M = metal ion or metal fragment). The reaction between donor (MX) and acceptor (Su) leads, *via* a charge transfer complex, to formation of a radical ion pair, which may undergo two possible reactions in the solvent cage. Migration of the particle to be transferred X *within* the cage (cage reaction) leads to formation of a diamagnetic metal complex, whose hydrolysis gives the desired reaction product. On the other hand, dissociation of a free radical $X^{\odot}$ out of the solvent cage (escape reaction) gives a paramagnetic complex, which if sufficiently stable may be observed. The effectiveness of the SET reaction and the ratio of cage to escape products depend on numerous external factors, such as temperature, solvent and irradiation.—Ⓑ In the reaction of pyrazine with phenyllithium one observes the following: A diamagnetic reaction product, the expected 1,2-dihydropyrazine addition product, may be detected at low temperatures [65a]. However, as suggested by the NMR line widths [65a], radicals are formed in the solution. According to the ESR spectrum (Fig. 3) triple ions of type **25B** are produced with excess phenyllithium [62].



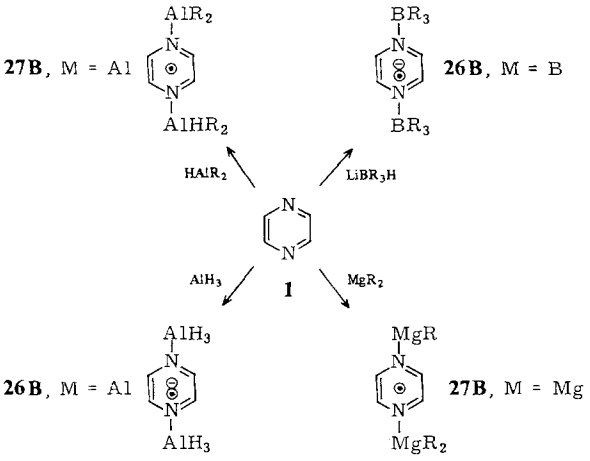


Fig. 3. In the reaction of pyrazine with excess phenyllithium in tetrahydrofuran a stable radical is formed, whose high resolution ESR spectrum (low field region) is shown in Ⓐ. Its graphic reproduction by computer-controlled spectrum synthesis Ⓑ was carried out with the coupling constants given in Table 5 and a line width of 0.013 mT. The radical formed is the triple ion [59, 62] [$Li^{\oplus}$, $1^{\ominus}$, $Li^{\oplus}$] of type **25B** (cf. Scheme 3).

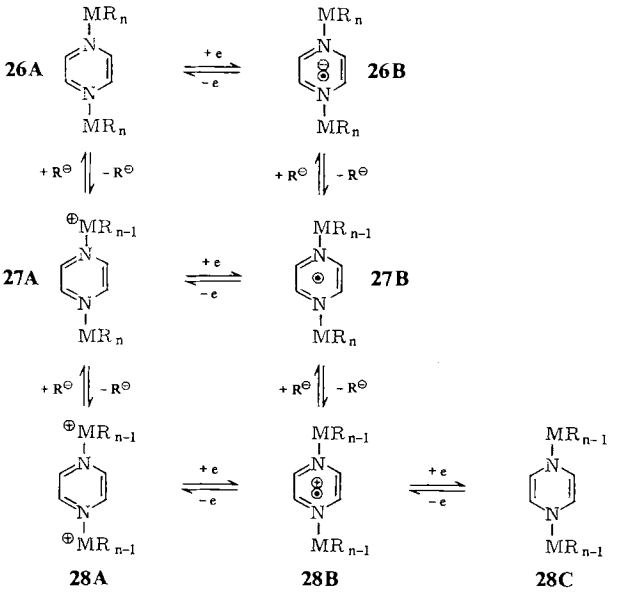


### 4.6. Pyrazines according to Scheme 2, with $X = {}^{(\ominus)}MR_n$ (M = Main Group Metal; R = H, Alkyl, Aryl)

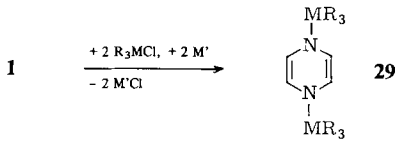
Electron-deficient organometallic compounds $MR_n$ form 1:2 adducts **26A** with pyrazine, *e.g.*, complexes with $B(C_2H_5)_3$[68], $Al(CH_3)_3$[69] and $Zn(C_6H_5)_2$[69] (Table 4). Due to π-backbonding into the LUMO of ligand **1** (see Section 4.7), the electronic spectra of some of these complexes exhibit charge transfer bands at long wavelengths[69]. For very electron-rich organometallic compounds and metal hydrides, such as LiR[62], $MgR_2$[70], $AlR_2H$[71], $AlH_3$[72], $BH_3$[69] and $LiBR_3H$[69], a complete electron exchange replaces the charge transfer and one observes stable radical complexes, formed by SET mechanisms (cf. Scheme 3).

The composition of these radical complexes varies due to the low basicity of pyrazine and also of the pyrazine radical anion[62,72]: **2** may coordinate with two molecules (to give **26B**), two cations (to give **28B**), or with one neutral molecule and one cation (to give **27B**). Complexes of the last type have very complicated ESR spectra[69,71] and undergo intramolecular exchange processes[70a].

In SET reactions of complex organometallic compounds ($LiAlH_4$[62], $LiBR_3H$[69]) several reaction pathways are possible, and, according to the position of the coordination equilibrium, one observes different radicals and their products. This radical product selectivity[72] should also furnish clues to the selectivity of the "cage" reaction (Scheme 3), which leads to diamagnetic compounds.

Organometallic halides, such as $R_3SiCl$, $R_2BCl$ and $R_2AlCl$, also form complexes with pyrazine[69]. Formally, these compounds correspond to quaternary salts such as **18A**. They can generally be dehalogenated by reduction with an alkali metal, so giving a positively charged radical complex **28B**. Such species may also be prepared by alkali metal reduction of pyrazine/organometal complexes[70,73,74], due to the electrolytic dissociation of metal alkyls in coordinating solvents[75].

$$2\,MR_n \rightleftharpoons [MR_{n-1}]^{\oplus} + [MR_{n+1}]^{\ominus}$$



By varying the Coulomb integral $\alpha_N$[76], the results of electron spin resonance investigations on the radical complexes **28B** (Table 5) may again be interpreted in terms of the HMO model[2]. The ESR coupling constant $a_H$ and thus the distribution of the unpaired electron correlate with the squares of the Hückel coefficients in the singly occupied molecular orbital $B_{1u}$ (Fig. 4).

Table 5. ESR coupling constants $a_x$ [μT] of pyrazine π-radical ions. The sequence in which the coupling constants of the ring protons $a_H$ increase shows the influence of charge, polarization (Fig. 4) and delocalization of the *N*-coordinated species.

| Compound | Type | Solvent [a] | $a^{1}_{H}$ | $a^{14}_{N}$ | $a_X$ (X) | Ref. |
|---|---|---|---|---|---|---|
| $[1(O)_2]^{\ominus}$ | **23B** | DMF | 137 | 949 | — | [55] |
| $[1(W(CO)_5)_2]^{\ominus}$ | **38B** | THF | 254 | 823 | 286 ($^{183}$W) | [93] |

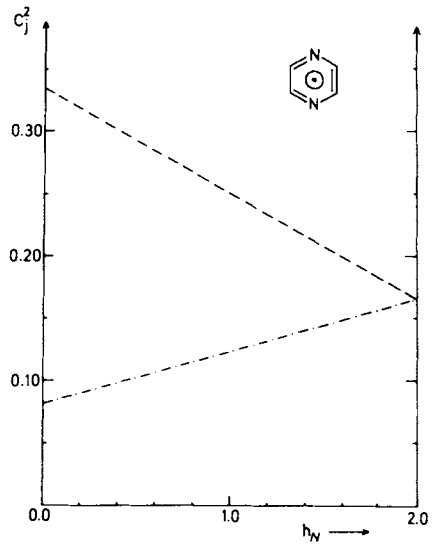
| $[1(H)_2]^{\oplus}$ | **8** | THF | 316 | 745 | 805 ($^{1}$H, N) | [18, 73] |

[a] DMF = dimethylformamide, THF = tetrahydrofuran.

The $R_3SiCl$ and $R_3GeCl$ adducts of pyrazine may readily be completely dehalogenated, giving 1,4-dihydropyrazines **29**[24,40,77] (type **28C**; **29**, $MR_3 = SiMe_3 \equiv$ **17**).

M' = Li, Na, K
$MR_3$ = $Si(CH_3)_3$ (≙ **17**),
$SiH(CH_3)_2$, $Si(tC_4H_9)(CH_3)_2$, $Si[Si(CH_3)_3]_3$, $Ge(CH_3)_3$

Although compounds **29** are quite stable thermally, other properties, such as their color and ready inflammability in air, are indications of the antiaromatic character expected for a "true" 1,4-dihydropyrazine system. From the special properties of the silicon-nitrogen bond[78] it is



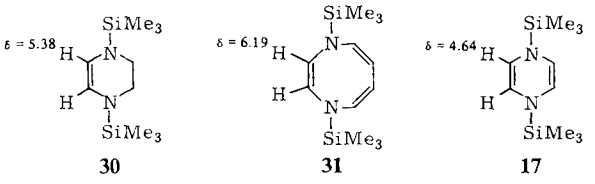


Fig. 4. In planar π-radicals the ESR coupling constants of α-*C* protons are proportional to the squares of the Hückel coefficients of the singly occupied molecular orbital [2c]. For the pyrazine $B_{1u}$ orbital (Fig. 1) the squares of the coefficients in the 1,4- (----) and 2,3,5,6-positions (-·-·) are linearly dependent on the perturbation parameter $h_N$; $c_N^2 = 1/3 - 1/12h_N$ and $c_C^2 = 1/12 + 1/24h_N$ [63]. The coupling constant $a_H$ (Table 5) should increase with growing $h_N$ (increasing N "electronegativity").

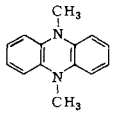
clear that **17** does not undergo a 1,3 shift Si–N→Si–C as readily as the NR derivatives (bond order Si–N > 1). Furthermore, due to the widening of angles at the nitrogen atom[78,79] considerable conjugation between olefinic π-electrons and the free N-electron pairs takes place. Therefore, compounds **29** serve as excellent models[24,41] for the hypothetical planar 1,4-dihydropyrazine **9**.



Comparison with non-conjugated **30** and a reference compound containing 10 π-electrons **31**[80] clearly demonstrates an upfield shift for the ring protons in the $^1$H-NMR spectrum of the 8 π-electron compound **17**. This shift confirms the "antiaromatic" character of the 1,4-dihydropyrazine system[5] (Scheme 4).

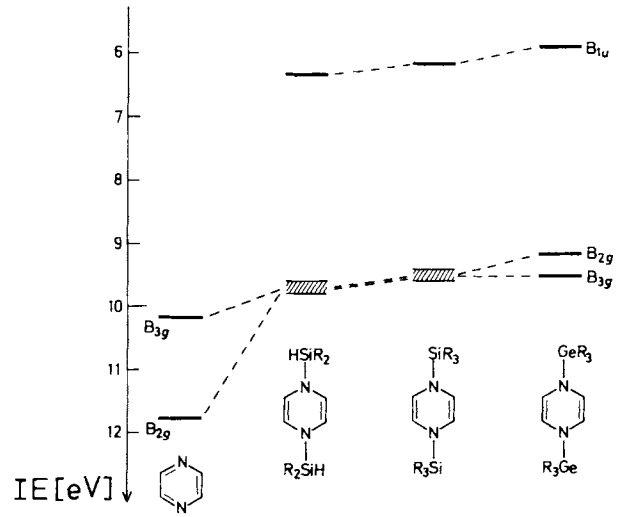
Scheme 4. The $^1$H-NMR spectrum shows the presence of cyclically conjugated π-electrons. In aromatic compounds with 4n+2 π-electrons the outer proton signals are shifted downfield (diamagnetic ring current), whereas in the antiaromatic case (4n π-electrons) the opposite effect, *i.e.* upfield shift, is to be expected (paratropism [50]). Compared with the non-conjugated compound **30**, the 10 π-electron system **31** [80] shows a downfield shift, while the 8 π-electron compound **17** has an almost equally large upfield shift of its *N,N'*-bis(trimethylsilyl)endiamine protons [24c].

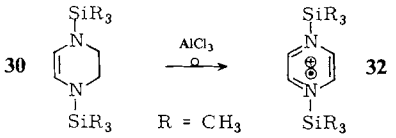
With a first vertical ionization energy of 6.16 eV[24] (adiabatically: 5.7 eV) **17** belongs to the electron-richest main group element compounds (Table 6). Moreover, for the red trimethylgermyl derivative $IE_1^v = 5.87$ eV has been determined[24b] (cf. $IE_1$(Na) = 5.1 eV).

Table 6. First vertical ionization energies $IE_{1,2}^v$ [eV] of electron-rich main group element compounds.

| Compound | Type | $IE_1^v$ [eV] | $IE_2^v$ [eV] | Ref. |
|---|---|---|---|---|
|  TTF | | 6.83 | 8.69 | [81] |
|  TMPD | | 6.75 | 8.35 | [82] |
|  | | 6.19 | 8.32 | [83] |
|  | | 5.95 | 7.5 | [84] |
|  | **17, 29** | 6.16 | 9.5 | [24b] |
|  | **29** | 5.87 | 9.15 | [24b] |
|  | **68** | 6.57 | 8.00 | [85] |
|  | **80** | 6.50 | 8.35 | [24c] |

Using Koopman's theorem the remaining π-ionizations also allow an excellent correlation with the expected orbital sequence given in Figure 1 (Fig. 5).





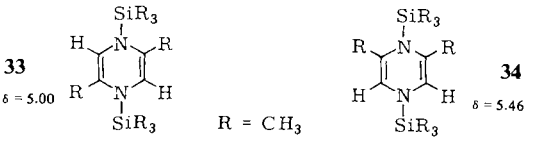


Fig. 5. Using Koopman's theorem $IE_n = -\varepsilon_{SCF}^j$ ionization energies *IE*, determined by photoelectron spectroscopy, may be correlated with orbital energies $\varepsilon^j$ (Fig. 1). A comparison of π-ionizations of pyrazine **1** [9] and three 1,4-dihydropyrazines [24b] shows that the ionization assigned to the $B_{3g}$ orbital remains constant at approx. 10 eV (nodal plane through positions 1 and 4). On the other hand, organometallic substitution in the 1,4 position lowers the ionization energies of the π-molecular orbitals with large Hückel coefficients $c_N$. This not only affects the bonding orbital $B_{2g}$ but also the antibonding orbital $B_{1u}$, which in 1,4-dihydropyrazines is occupied. A lowering of the ionization energies occurs in the sequence of *N*-substituents $HSiR_2$, $SiR_3$, $GeR_3$, since the $\pi_S$ and $\pi_S^*$ orbitals have comparable Hückel coefficients [2].

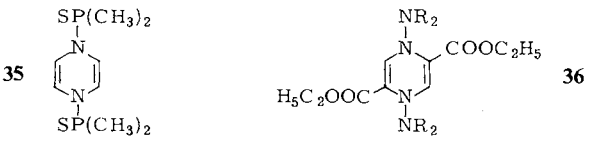
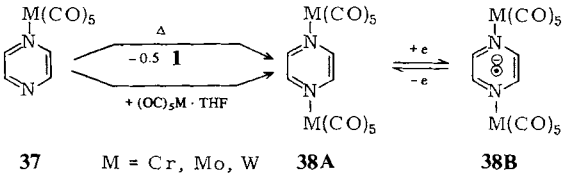
The spectroscopic properties of compounds **29** (≙ **28C**) are in agreement with their chemical reactivity, especially their sensitivity towards oxidation[40,77]. The controlled oxidation of **28C** with $AlCl_3$[86] leads to the paramagnetic intermediate **28B**[87]. The radical **32** is also formed in the reaction of the tetrahydropyrazine **30** with $AlCl_3$ in dichloromethane. This is a further example of the strong tendency to form the 7 π-electron intermediate (Table 2).



The thermal stability of *N*-trialkylsilyl-1,4-dihydropyrazines permits one to study substituent effects in greater detail. The, at first sight surprising, results of NMR, UV and photoelectron spectroscopic studies[24] showed that the compounds become *less* electron-rich with increasing *C*-methyl substitution. Such behavior contradicts the "normal" (+I)-substituent effect of an alkyl group[86]. However, the results may be interpreted in the light of the discussion on the conformation of 1,4-dihydropyrazines[24] (Table 1, Fig. 2):

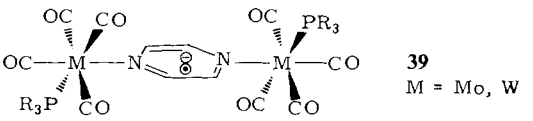
Increasing *C*-methylation leads to increasing steric interaction with the bulky $R_3Si$-groups and thus a larger deviation from the planar conformation of the ring and of the *N*-substituents. The impairment of the cyclic 8 π-electron conjugation is not compensated by the donating effect of the methyl groups. In agreement with this model and with Figure 2, the effect observed[24] for dimethyl derivatives of **17** was found to be smallest in the 2,5-isomer **33** (no vicinal arrangement of substituents) and largest in the 2,6-isomer **34**.



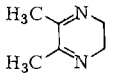
Obviously the 1,4-dihydro-1,4-diazine system is characterized by considerable structural flexibility, which is caused by the unfavorable presence of 8 π-electrons. In the following sections the consequences of this flexibility on the possible structures of reduced phenazines (Section 6.1) and on the redox behavior of flavoenzymes (Section 7.1) will be demonstrated.

The derivatives **35**[69] and **36**[88] are related to the organoelement-substituted 1,4-dihydropyrazines **29**. The stability of **35** is due to the π-acceptor effect of the thiophosphinyl group[89], while **36** is stabilized by the ester substituents attached to the heterocyclic ring. As in the case of many other 1,4-dihydro-1,4-diazines (Table 2), compound **36** is already oxidized to the radical cation by atmospheric oxygen[88].

### 4.7. Pyrazines according to Scheme 2, with $X = {}^{\ominus}M(CO)_5$ (M = Cr, Mo, W)



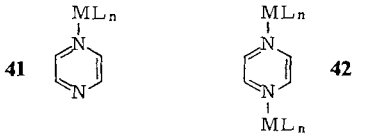
Binuclear bis(pentacarbonylmetal) complexes **38A** are formed from the mononuclear derivatives **37** by a thermal solid state reaction[90] or upon addition of $THF \cdot M(CO)_5$[91].



Compounds **38A** are colored and, as has been demonstrated for the tungsten complex[92], give rise to two charge transfer bands in the region between 450 and 600 nm which may be differentiated in Resonance Raman experiments. *Both* electronic transitions occur from occupied metal-centered orbitals to the lowest unoccupied molecular orbital $B_{1u}$ of pyrazine. This is named a *m*etal-to-*l*igand *c*harge *t*ransfer (MLCT)[92].

The addition of one electron to **38A** occurs reversibly at reduction potentials markedly raised by the coordination[91]. However, stable radical anions **38B** (M = Mo, W) have only been obtained by *in-situ* complex formation[93]. The ESR data (cf. Table 5) confirm the predominantly ligand-like character of the singly occupied molecular orbital in **38B**. The stability and spin distribution of radicals **18B** and **38B** are in agreement with *Hoffmann*'s concept of an isolobal relationship between $R^{\oplus}$ and $M(CO)_5$[94].

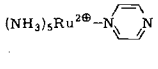
Substitution reactions may be carried out with radical complexes **38B**; with phosphanes, bis[tetracarbonyl(phosphane)metal] complexes **39** are formed[69].

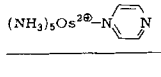


Besides pyrazine itself[90,91,95-99], 2,3-dihydropyrazines such as **40** are also suitable complexing ligands for carbonylmetal species[101] because of their 1,4-diazabutadiene structure[100]. However, the coordination modes of these compounds are not yet certain[101].

### 4.8. Pyrazines according to Scheme 2, with $X = ML_n$ (M = Transition Metal, L = Ligand)

Pyrazine forms numerous monomeric 1:1 (**41**) and 1:2 complexes (**42**) with transition metal compounds.





Not only inorganic ions and molecules, such as $Ni^{2\oplus}(aq)$[102], $[IrCl_5]^{n\ominus}$[103], $Re_3Cl_9$[104] or $OsO_4$[105], but also coordinatively unsaturated organometallic fragments, *e.g.* $Fe(CO)_4$[97], $Rh(CO)_2Cl$[98], $[Rh(PR_3)_2(CO)]^{\oplus}$[99], $ZrR_4$[106], $Yb(C_5H_5)_3$[107a], $U(C_5H_5)_3$[107b], $Pt(C_2H_4)Cl_2$[108], may form coordination compounds with pyrazine. Except for the effects of differing basicities[97,99,104], many of these compounds are comparable to the corresponding pyridine complexes. However, some of these coordination compounds are of special interest for the following reasons: Electron-rich $d^6$ metal fragments such as $L_nFe^{II}$ or $L_nRu^{II}$ can undergo a charge transfer interaction with the π-system of electron-deficient pyrazine. One indication of this interaction is the appearance of intense MLCT bands in the visible region.

In binuclear complexes an interaction between both coordinated metal fragments is possible. The distance between two coordinated metal atoms in μ-pyrazine complexes is *ca.* 600—800 pm, and the question of whether, to which extent, and in which manner an electron interaction between the two coordinated species takes place *via* the ligand is of considerable interest, especially in relation to electron transfer in biological systems[109]. In pyrazine there is not only the π-system with a low lying LUMO (Fig. 1) but also the σ-system including the two *N*-electron pairs[110] available for electron transfer propagation. According to recent theoretical investigations[111] it seems likely that in pyrazine *both* transfer mechanisms can play a role.

*1:1 Complexes:* Similarly to the pentacarbonyls $M(CO)_5$[112], the low spin $d^6$ species of divalent iron[113–115], ruthenium[116] and osmium[117] may backbond into the LUMO of pyrazine. This backbonding results in the appearance of intense MLCT bands in the visible region of the spectrum[113–117] and in accompanying photochemical processes[118], in a reduction of the metal-pyrazine distance[119], and in a drastic increase of the basicity of the second nitrogen atom in the ligand (Table 7). In such cases binuclear complexes **42** are formed without difficulty[120,121].

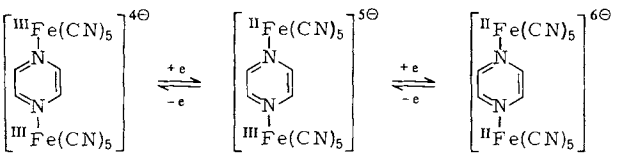


Table 7. Acidity constants $pK_a$ of pyrazine and pyrazinium ions. Coordinated $(NH_3)_5Ru^{II}$ and $(NH_3)_5Os^{II}$ metal fragments can π-backbond into the lowest unoccupied ligand orbital and thus cause an exceptional increase in basicity of the free nitrogen atom.

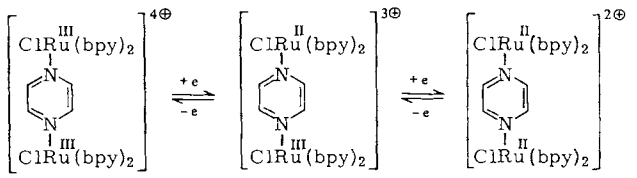
| Compound (conjugated base) | Type | $pK_a$ | Ref. |
|---|---|---|---|
|  | 4 | −6 | [14] |
|  | 41 | −0.8 | [116] |
|  | 1 | +0.6 | [14] |
|  | 41 | +2.5 | [116] |
|  | 41 | +7.4 | [117] |

*1:2 Complexes:* If the *N*-coordinated ions and not, as described in Sections 4.1 to 4.7, the pyrazine is the redox-active or spin-carrying species, then for binuclear complexes new phenomena appear:

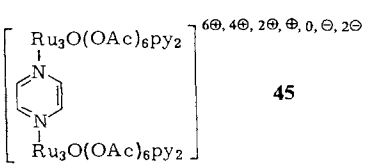
a) The electrochemistry of these complexes is generally characterized by several reversible redox steps, in which first of all the coordinated metal ions take up or lose electrons[122].
b) Mixed valence compounds which contain the same metal fragment, at least formally, in different oxidation states are especially interesting. The ground states of such systems may be unsymmetrical (localized valences) or symmetrical (delocalized valences)[123].
c) If two different metal ions are coordinated to the same ligand, then the mechanism and rate of a possible electron transfer *via* the ligand are of predominant interest (inner-sphere electron transfer)[124].
d) The coordination of two paramagnetic ions may lead to a molecular magnetic exchange interaction ("superexchange") between the two centers; the spins may couple giving either a ferromagnetic or an antiferromagnetic type of interaction[125].



Re a): Due to the coordination of two redox-active metal fragments to pyrazine, the binuclear complex establishes a multistep redox system. If the interaction between the coordinated ions is small the two potentials are similar[122]. Examples are the systems **43** and **44**[121,126].

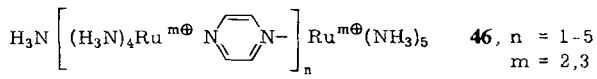
**43A** **43B** **43C**

$\lambda_{IT}$ = 1200 nm; $k_{SEM} \approx 50$



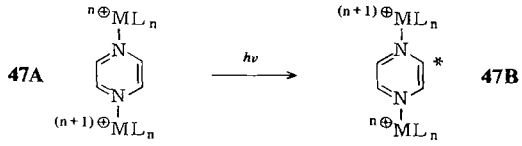
From the two potentials of a two-step system one may again calculate a stability constant $k_{SEM}$ for the intermediate. In this way the mixed-valence ions **43B** and **44B** are found to be relatively stable towards disproportionation (IT = intervalence transfer).

**44A** **44B** **44C**



$\lambda_{IT}$ = 1300 nm; $k_{SEM}$ = 100

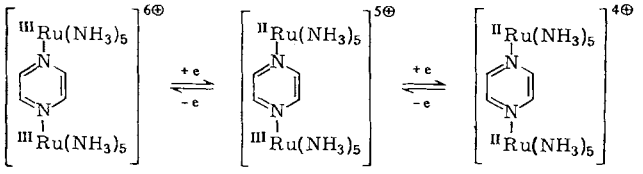
The number of accessible separate oxidation states increases further upon coordination of cluster compounds[127b] which store electrons[127a] (**45**) or upon con-



**45**

struction of multiple bridges with μ-pyrazine (**46**)[128]. These compounds are interesting intermediates on the way to the formation of coordination polymers (Section 5); the crowding of discrete energy levels marks the beginning of an energy band behavior[127b].

**46**, n = 1-5, m = 2,3



Re b): According to the classification of *Robin* and *Day*[123] mixed-valence compounds of the type **43B** or **44B** may occur as localized, unsymmetrical or as delocalized, symmetrical species. In the first case, if there is only a weak interaction between the coordinated ions of different valence, one would expect a long wavelength absorption in the electronic spectrum, due to an IT or MMCT process (cf. Fig. 6) (MMCT = metal-to-metal charge transfer).

**47A** **47B**

Due to the Franck-Condon principle the electronic transition from **47A** to **47B** occurs considerably faster than the change in geometry accompanying movement of nuclei. For only small differences in coordination geometry (*e.g.* $Fe^{II}/Fe^{III}$ or $Ru^{II}/Ru^{III}$[119]) the amount of energy $E_0$ (Fig. 6) required for this process is very small, and the corresponding absorption often takes place in the near infrared[129]. The rate constant of intramolecular electron transfer in **44B** has been calculated to be *ca.* $10^{-8}\ s^{-1}$[130].

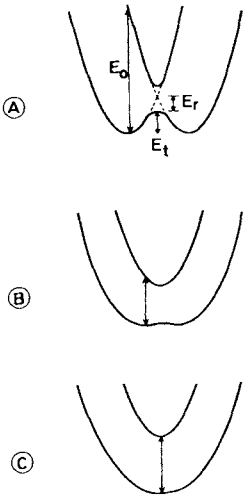
Originally a localized structure, *i.e.* $Ru^{II}/Ru^{III}$ instead of $Ru^{II\,1/2}/Ru^{II\,1/2}$, was also assumed for the "Creutz-Taube" complex **48B**[120], which is related to **44B**.

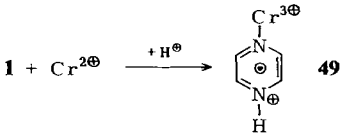
**48A** **48B** **48C**

$\lambda_{\text{"IT"}} = 1570$ nm; $k_{SEM} = 4 \times 10^6$

However, certain data, such as the large formation constant and the position and symmetry of the long-wavelength absorption band[131], were not compatible with this description. In the meantime the lengthy, controversial discussion[132] surrounding the nature of this ion appears to have been settled[119] by recent theoretical[133] and experimetal results: **48B** is a borderline case with a very small barrier to delocalization appearing between the localized forms (Fig. 6). The absorption in the IR could then be assigned to a "normal" $^2A_{1g} \rightarrow {}^2A_{2u}$ transition[134]. The height of the delocalization barrier $E_t$ does not only depend on the distance between the metal ions[135] but also on the degree of electronic interaction between the metal fragments and the bridging ligand ("resonance energy" $E_r$, Fig. 6)[119].

The pentaammineruthenium ions in **48B** experience quite a considerable interaction *via* the electron system of pyrazine, while in the related mixed-valence complex **44B** this interaction is distinctly smaller. In this case pyrazine obviously has to compete with 2,2'-bipyridyl, which is also easily reduced[7], for the metal charge available for back-bonding. This is further confirmation of the importance of low-lying π*-molecular orbitals for intramolecular electron transfer[120].





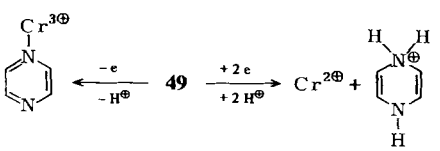


Fig. 6. Thermal and light-induced intramolecular electron transfer reactions in a binuclear mixed-valence complex may be described by potential curves along one configuration coordinate. Ⓐ In the case of localized valences with a small exchange interaction across the bridging ligand, a thermally surmountable energy barrier $E_t$ exists between the two equivalent states. The "resonance energy" $E_r$ is a measure of the exchange interaction occurring *via* the ligand. The optical transition ($E_0$) corresponds to an IT or an MMCT process (cf. **47A** → **47B**). Ⓑ Growing interaction between the localized valences *via* the bridging ligand leads to an increase in resonance energy and a decrease in the thermal barrier, until in case Ⓒ a symmetrical species of "delocalized" valence is formed [119, 123, 129].

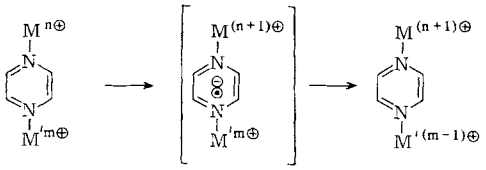
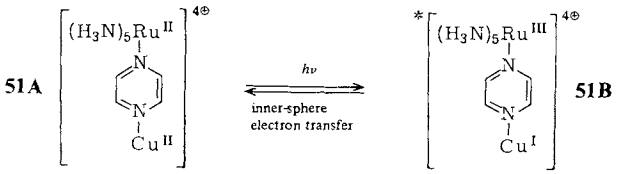
Re c): The low-lying LUMO of pyrazine is not only useful for the study of charge transfer interactions but also for investigations into complete electron exchange in the ground state. A striking example is the reaction of **1** with $Cr^{2\oplus}$ to give **49**, which leads to coordination of the metal, electron transfer to the ligand, and to the addition of a proton onto the reduced ligand[136].



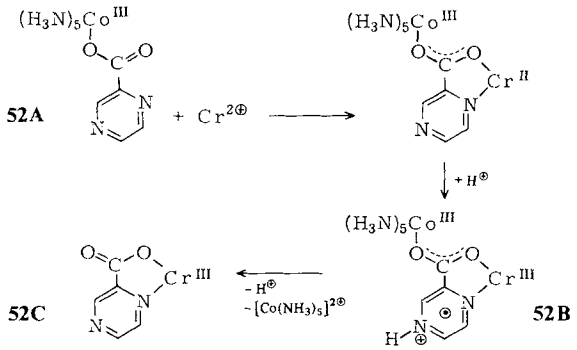
**1** + $Cr^{2\oplus}$ → **49**

The electrochemistry of complex **49** is also informative[137], since it reveals two well-known aspects of the pyrazine system, namely the stability of cation **10** (*i.e.*, the instability of 1,4-dihydropyrazine **9**), and the low basicity of the oxidized compound **1** (Section 3).



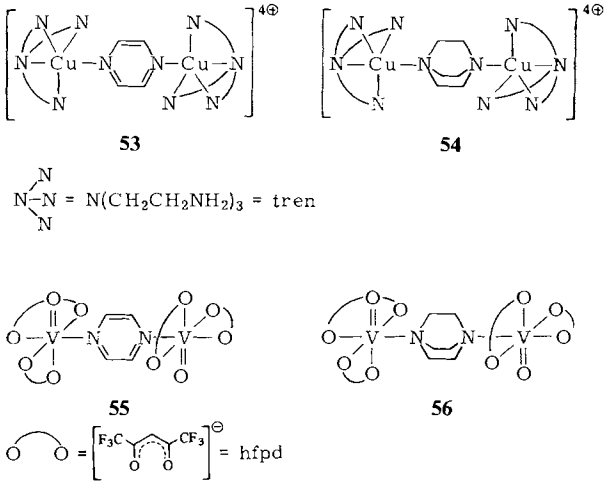
**50** **10**

The coordination of two different redox-active metal ions to pyrazine permits one to carry out kinetic studies on the ligand-bridged (inner-sphere) electron transfer between the metal centers[124]. In the radical ion mechanism of inner-sphere electron transfer the bridging ligand—an ion or molecule—has to take up the electron for a certain time[138]. The pyrazine molecule is obviously capable of carrying out this function.



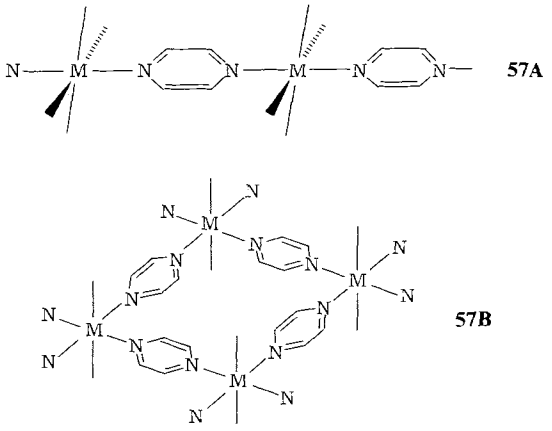
Two instructive examples of the use of the pyrazine system are provided by the complexes **51A** and **52A**.

Complex **51A** has the MLCT band in the visible region, which is typical of such $Ru^{II}$ compounds. If electron transfer to **51B** is induced by flash photolysis, this absorption band fades ("electron transfer photochromism"). The kinetics of the regeneration of **51A** indicate the presence of a unimolecular electron transfer relaxation[139].

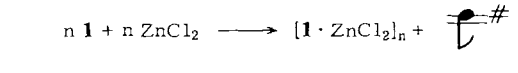


The reduction of the $Co^{III}$-pyrazinecarboxylate complex **52A** by $Cr^{2\oplus}$ was expected to occur *via* an inner-sphere radical ion mechanism. Kinetic measurements and pulse radiolysis studies have confirmed the existence of the postulated intermediate **52B** (cf. **49**)[140].

Re d): In monomeric pyrazine complexes magnetic interactions between coordinated metal ions have seldom been observed[134]. However, studies on complexes **53**—**56**[141] have shed light on the mechanism of such exchange interactions.



For pyrazine, mechanisms involving not only its π- but also its σ-system have been discussed[111], whereas the likewise bifunctional ligand 1,4-diazabicyclo[2.2.2]octane (DABCO) only has a σ-system available[110]. An antiferromagnetic spin-spin interaction has been observed only in

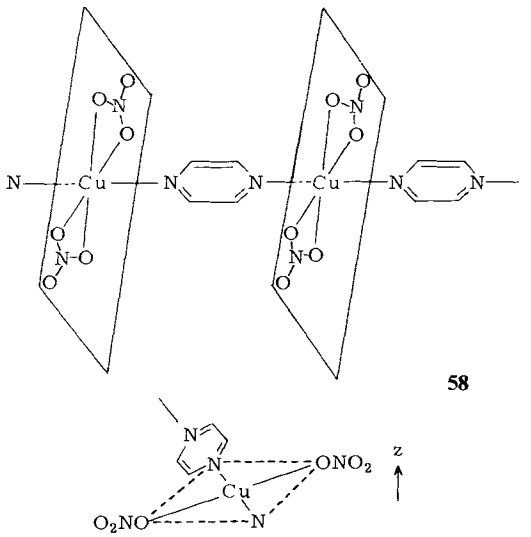


those $Cu^{II}$ and $V^{IV}$ complexes in which pyrazine acts as bridging ligand[141] (cf. Table 8). These findings demonstrate that the participation of the pyrazine π-system is necessary for the formation of a magnetic interaction. In the following section further evidence for this effect will be provided by a comparison of polymeric $Cu^{II}$-pyrazine complexes.

## 5. Coordination Polymers containing Pyrazines

The series of compounds **46** demonstrates how coordination oligomers and polymers may be produced by coordination of the bridging ligand μ-pyrazine with polyfunctional metals. In fact such complexes have long been known[142]. Depending on the coordination properties of the metal they may exist as chain (**57A**) or sheet polymers (**57B**).

Metal salts especially[142–144], but also quadruply bonded metal dimers[145] and metalloporphyrins[146] are suitable multiply unsaturated coordination partners. Incidentally, the formation of the polymeric adduct **1** · $ZnCl_2$ is accompanied by an acoustic emission[144].



In polymeric complexes of anisotropic structure, electrical[147] and magnetic[148] properties are of interest. The following discussion concentrates on the magnetic exchange phenomena in $Cu^{II}$-μ-pyrazine complexes (Table 8).

Table 8. Magnetic exchange parameters $J$ [$cm^{-1}$] of pyrazine-bridged $V^{IV}$ and $Cu^{II}$ complexes of low dimensionality Positive and negative signs indicate ferro- and antiferromagnetic exchange behavior, respectively.

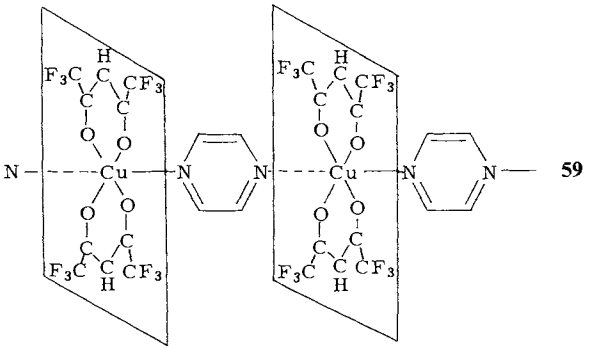
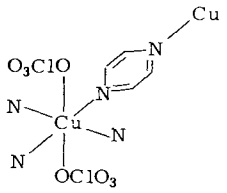
[a] Inter-dimer exchange.

$[Cu(NO_3)_2 \cdot 1]_n$ **58** has been the subject of numerous investigations[149–151]. It is a linear coordination polymer in which the nitrate ions lie in a plane perpendicular to the Cu-pyrazine chain[150]. The substance behaves as a one-dimensional Heisenberg antiferromagnet (Table 8). In an elegant study employing various 1,4-diazines *Richardson* and *Hatfield*[151] were able to show that the variation of the antiferromagnetic coupling correlates neither with the σ-basicity nor with steric factors but with the energy of the $\pi \rightarrow \pi^*$ transition. This result already indicates the presence of an exchange mechanism involving the pyrazine π-system. It is interesting that this is confirmed by the structure of complex **58**, since the $CuN_2O_2$ unit forms an angle of $\gamma = 48°$ with the pyrazine plane, thus permitting sufficient overlap between the spin-bearing $d_{z^2}$ metal orbital and the π-system of the ligand[150,151].

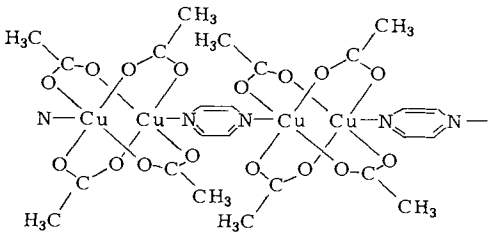


**58**



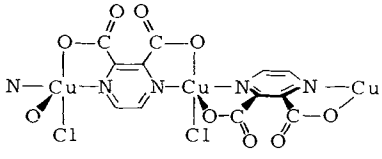
In $[Cu(hfpd)_2 \cdot 1]_n$ **59**, with two bidentate hexafluoropentanedionate ligands hfpd, an overlap of the spin-carrying orbital with the pyrazine π-system is not possible due to the coordination geometry at the metal. Accordingly, *no* magnetic exchange interaction is observed[152].

The use of the very weak base $ClO_4^{\ominus}$ as anion for $Cu^{II}$ in $[Cu(ClO_4)_2 \cdot (1)]_n$ **60** permits four pyrazine molecules to coordinate to the metal, so forming a two dimensional



**59**

sheet polymer of type **57B**. In **60** the angle lying between the laminar plane and the plane of the pyrazine molecules is 66°, so that an interaction between the spin-carrying $Cu^{II}$ orbitals and the pyrazine π-system is possible, and a two dimensional, antiferromagnetic exchange interaction may be observed[153] (Table 8).

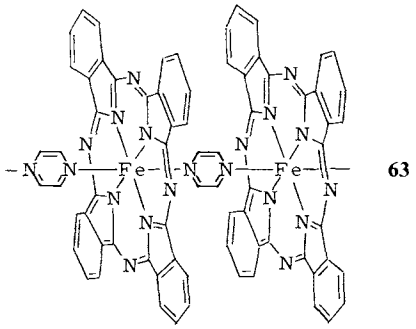


**60**

For $[Cu_2(OAc)_4 \cdot 1]_n$ **61** there are two possible magnetic exchange interactions: the "direct" interaction between neighboring copper atoms in the dimer $Cu_2(OAc)_4$ and inter-dimer exchange *via* the pyrazine bridges. Measurements of ESR line widths indicate that the latter process also takes place[154] (Table 8).

**61**

Pyrazinecarboxylates are anionic, bidentate bridging ligands with good complexing properties[155]. Reaction of $CuCl_2$ with 2,3-pyrazinedicarboxylic acid furnishes $[Cu(pzdc) \cdot HCl]_n$ **62**, whose structure has been shown by X-ray analysis to be a polymeric chain with alternating orthogonal heterocyclic bridges[156].



**62**

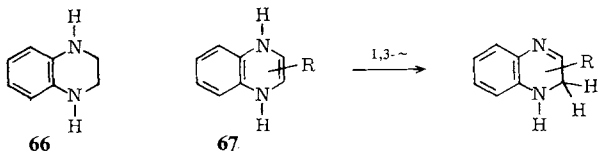
In contrast to previously characterized pyrazine coordination polymers, compound **62** exhibits one dimensional *ferro*magnetic behavior (Table 8), which had previously only been observed for complexes with a bridging *atom*. A requirement for ferromagnetic behavior is that the spin-

carrying orbitals be orthogonal[157]. Hence, this result provides fresh evidence for the π-transfer mechanism of magnetic exchange with pyrazine bridging ligands. Still in doubt is the extent to which occupied and/or unoccupied π-orbitals take part in the exchange mechanism[151]; theoretical studies leave both options open[111].

The low dimensionality of polymeric pyrazine-metal complexes and thus the potential availability of "polymeric π-systems" have prompted investigations into the conductivity of such substances. In general, theoretical[147] expectations have not been fulfilled. Studies on pyrazine[158,159] and 2,5-pyrazinedicarboxylate complexes[160] have shown no marked rise in conductivity due to their polymeric structures. However, *Schneider* and *Hanack*[161] recently described a system, in which a $10^6$-fold increase in conductivity was observed on going from a monomeric 1:2 adduct to the polymeric complex **63**:

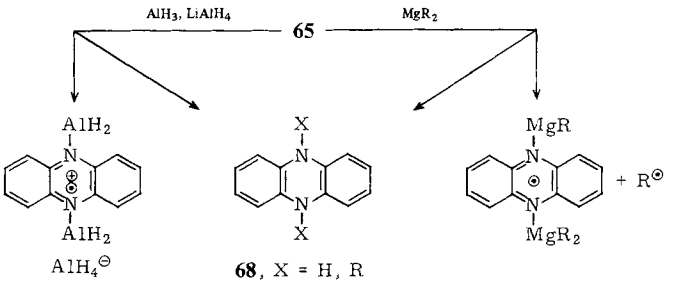
**63**

## 6. Modification of Pyrazines



### 6.1. Annelation of Benzene Rings

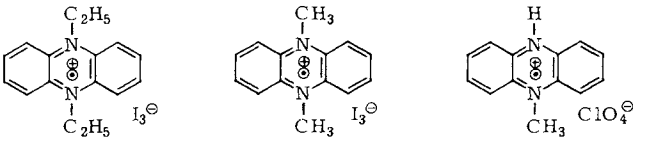
The 1,4-diazines quinoxaline **64** and phenazine **65** differ from pyrazine **1** in that their π-frontier orbitals are closer together and in that *N*-coordination of sterically bulky groups is more difficult due to *peri* interactions[93].



**64** **65**

However, **64** and **65** would be expected to demonstrate the same reactivity as pyrazine, although in modified form. For example, they take up electrons even more readily than pyrazine[7], and stable radical intermediates are known[162]. The 1,4-dihydro compounds also become more stable. The 1,2,3,4-tetrahydro derivative **66**[163,164] is formed by reduction of quinoxaline **64**, while substituted 1,4-dihydroquinoxalines **67** play a role as intermediates in color-bleach photography processes[37b].

**66** **67**

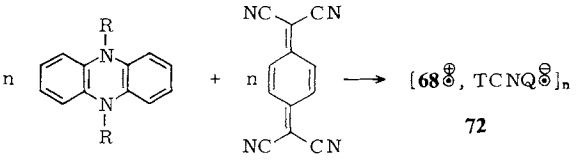


The dihydrophenazines **68** are stable, well-known compounds[165] which are formed by reduction of **65**[166] by an SET mechanism[69].

$AlH_4^{\ominus}$ **68**, X = H, R

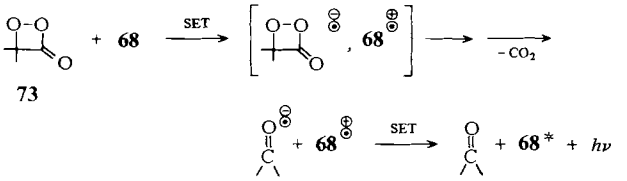
Due to the low-lying LUMO of **65**, compounds **68** are not as electron-rich as their monocyclic analogs[24b,c,85] (Table 6). However, the greater stability of compounds **68** promotes their use as electron transfer reagents.

The radical salts **69**—**71** already exhibit a variety of different conformations[167,168], as would be expected from Section 4.6. The dihydro compounds **68** tend to form π-



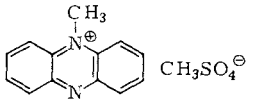
**69** **70** **71**

Planar Boat Twist



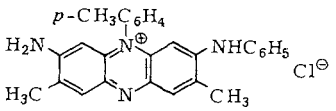
complexes. Deeply colored donor-acceptor complexes (**65**, **68**) of the quinhydrone type[165,166] are already obtained during preparation of the dihydro compounds.

The much investigated molecular π-complexes between reduced phenazines and the acceptor TCNQ also exhibit a large variety of structures, *e.g.*, columnar structures containing mixed or separated stacks of molecules[169]. Such donor-acceptor complexes of low dimensionality are of interest because of their potentially high conductivities ("organic metals")[170].



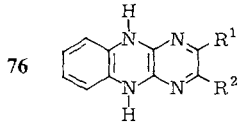
**68** TCNQ **72**

1,4-Dihydrophenazines **68** are also widely used as electron donors in photochemical investigations[171]. In connection with the reactivity of naturally occurring 1,4-dihydro-1,4-diazines (Section 7), it should be noted that reduced phenazines are employed as electron transfer activators in the chemiluminescence of dioxetanones (α-peroxylactones) **73**[172].

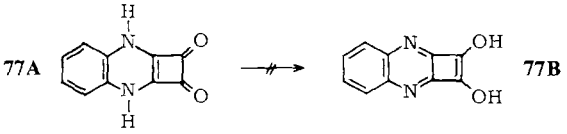


**73**

The stability of its redox states, its "physiological" redox potential and the presence of a free coordination site have led to the widespread use of *N*-methylphenazinium methyl sulfate **74** as electron acceptor in biochemical investigations[173]. Closely related to **74** are phenazine dyes such as Perkin's mauveine **75**[174].



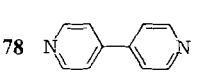
**74**



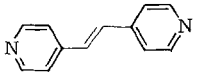
**75**

Stable 1,4-dihydro-1,4-diazines are also known in other fused ring systems[175,176]. The squaric acid amide **77A**[176] possesses a remarkable stability, since here the formation of a more strongly antiaromatic cyclobutadiene system **77B** is avoided.

**76**



**77A** **77B**



### 6.2. Separated N-Atoms

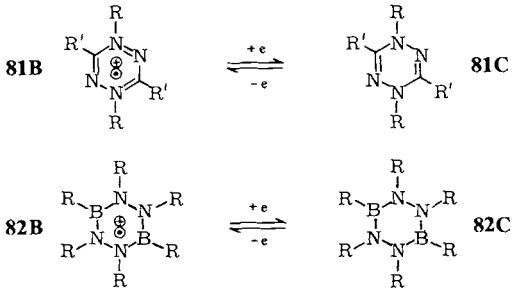
4,4'-Bipyridyl **78** and (*E*)-1,2-di-4-pyridylethene **79** are closely related to the 1,4-diazines.

Other than in quinoxaline **64** and phenazine **65**, *N*-coordination in these compounds is as sterically unhindered as in pyrazine, so that even *N,N'*-coordination compounds with large metal fragments may be formed[135,177].

**78**

**79**

*Hünig et al.* have studied the redox system of *N,N'*-disubstituted 4,4'-bipyridyls in detail[11], and in many cases the observed phenomena are comparable to the results for pyrazine. Due to the presence of a low-lying LUMO 1,1'-dihydro compounds such as **80** are not quite as electron-rich as the corresponding reduced pyrazines (Table 6).

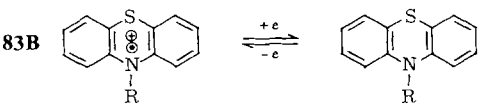


**80**

The position and reversibility of the first redox potential of the diquaternary compound **19A** (methyl viologen, paraquat) and the intense blue color of the radical cation **19B** have led to the widespread use of this redox pair as electron transfer reagent. Examples of its application are found in bio-electrochemistry[178], in photochemical systems for the conversion of solar energy[179], and in plant protection[180].

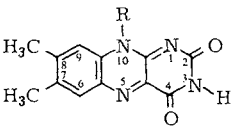
### 6.3. Substitution in the Ring

1,4-Dihydro-1,2,4,5-tetrazines (CH→N) **81** and 1,2,4,5-tetraaza-3,6-diboracyclohexanes (C=C→N–B) **82** are isoelectronic with 1,4-dihydropyrazines. Both **81C** (R = $CH_3$, R' = H)[181] and **82C** (R = $CH_3$[182a], twist conformation[182b]) are, in fact, electron-rich compounds (*IP*(**82C**) = 6.83 eV[183]) and form stable radical cations **81B**[184] and **82B**[185].

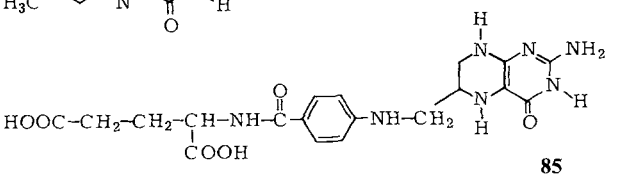


**81B** **81C**

**82B** **82C**

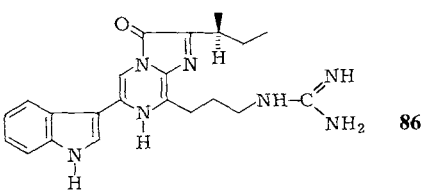


The replacement NR→S in 1,4-dihydropyrazines leads to 4*H*-1,4-thiazines. These compounds should also still be quite electron-rich. The pharmacologically important phenothiazines **83C** are characterized by a tendency, which may be of physiological significance, to form stable radical cations **83B**[186].



**83B** **83C**

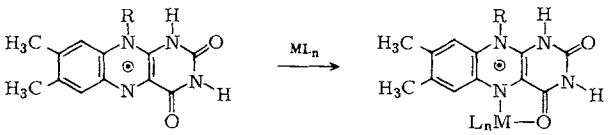
## 7. 1,4-Diazines in Biochemistry



Several important groups of naturally occurring compounds contain the 1,4-diazine structure. Some typical examples are riboflavin (vitamin $B_2$) **84** (R = ribityl), tetrahydrofolic acid **85**, quinoxaline antibiotics of the Streptomyces type[187] and luciferins from marine organisms **86**[188].

**84**

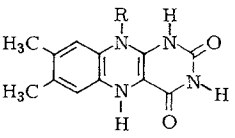
**85**



**86**

The specific reactivity of 1,4-diazines described in Sections 2–6 plays a role in the chemistry of flavoenzymes in particular. In view of the comprehensive reviews of this

field by *Hemmerich et al.*[189-191], *Bruice*[192] and *Walsh*[193], in the present article an attempt will be made to relate this reactivity to that observed for the parent system.

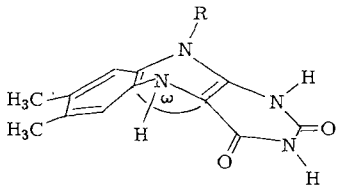


### 7.1. Flavoenzymes

Flavoenzymes fulfill a series of important functions in biochemical redox processes. Among other things they act as dehydrogenases, as one- *and* two-electron transfer reagents, and as activators of molecular oxygen[191-193]. The redox-active group of the flavocoenzymes FMN and FAD[189-193] is the tricyclic isoalloxazine system **84**, which contains the 1,4-diazine structure in its central ring. Due to the presence of the 2,4-pyrimidinedione ring the redox and coordination chemistry of **84** is more complicated than that of the simpler 1,4-diazines. Although it also constitutes a two step redox system in which electrophiles may coordinate, this coordination takes place at N-5 and N-1[190]. The coordination of metals to N-5 is favored by the chelate effect of O-4; the paramagnetic intermediate **87**, in particular, readily forms such complexes[194-198].

**87**

The fully reduced, N-10-substituted form, 1,5-dihydroisoalloxazine **88**, contains the 1,4-dihydropyrazine structure in its central ring, which determines the reactivity of this compound[191].



**88**

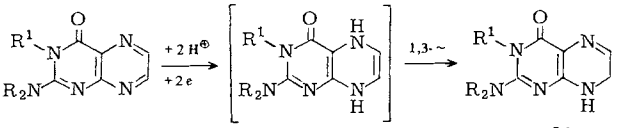
The following characteristics of the flavin system are related to its 1,4-diazine substructure:

a) The presence of a two step redox system in flavins implies that stable radical intermediates exist (cf. **87**). Stable "semiquinones" of flavins were first isolated in 1937[199] and have since been characterized by numerous further studies, especially by ESR spectroscopy[189]. Recently, high resolution ESR/ENDOR studies have finally established that the unpaired electron in the flavin radical cation is mainly localized in the central ring[200].

The stability of the radical corresponds to the electron transfer reactivity of the flavin system[31,191]. Similarly to pyrazines (Scheme 3), flavins react as one electron acceptors with carbanions[192]. "Perturbed" flavins such as the 5-deaza derivatives, which do not contain the 1,4-diazine structure, do not exhibit SET reactivity nor do they form any stable radicals[191]. However, by altering their coordination to the apoprotein, flavocoenzymes may switch from one to two electron transfer and thus act as mediators, for example, between NAD⊕/NADH (2e) and iron-sulfur proteins (1e) in biological redox chains[183].

b) During redox reactions the structure of the tricyclic system **84** alters in a characteristic way. The molecular geometry of oxidized isoalloxazines (**84**) is planar[201], whereas that of the reduced species (**88**) is the nonplanar boat or "butterfly" conformation[191,202]. This change in geometry is in agreement with the structures of minimum energy of the pyrazine system (Fig. 2, Table 1).

c) The electrochemical potentials of flavoenzyme redox systems vary over a range of 0.6 V and obviously depend on the type of apoprotein present[30,193]. The apoprotein can force the flexible (see Section 4.6) 1,5-dihydro system to adopt a certain conformation. Moreover, the affinities of the single flavin redox stages to the apoprotein (σ-coordination) differ markedly[193].

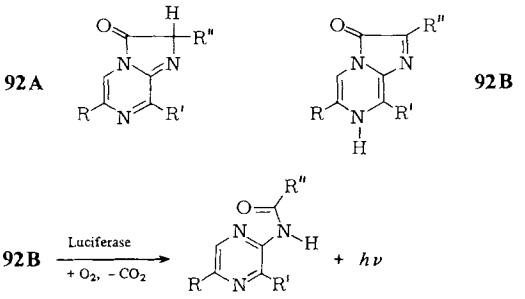


d) During their redox reactions flavoenzymes may act as dehydrogenases because they have at least one coordination site free for electrophiles ($H^{\oplus}$ or $R^{\oplus}$)[191-193]. Furthermore, flavins are suitable electron transfer substrates for transition metals[198].

e) Due to the one-electron reactivity of 1,5-dihydroflavins **88** (formation of paramagnetic oxidation products) their reaction with $^3O_2$ is not spin forbidden. Thus flavins are the only oxygen-activating enzymes which do not have to contain paramagnetic transition metal ions. According to recently published results[203] the activation of $^3O_2$ probably occurs *via* a radical ion pair [**87**, $O_2^{\ominus}$] (SET, see Scheme 3) and with formation of flavin peroxide adducts. Such peroxide species also play a role in bacterial bioluminescence, in which 1,5-dihydroflavins, $^3O_2^{\ominus}$, an aldehyde and the enzyme luciferase are essential components[204] (see Section 7.3).

Further similarities between the chemistry of simple 1,4-diazines and the reactivity of flavins may be found in the field of photochemistry[205] and in the tendency to form π-complexes[206].

### 7.2. Pteridines



The 1,4-diazine reactivity observed for the isoalloxazine system **84** is also found in modified form for the pteridines **89**, *e.g.*, in the formation of stable radicals[207]. Similarly to quinoxaline **64**[37], complete reduction of pteridines leads *via* a 1,3-hydrogen shift to 7,8-dihydro derivatives **91** and not to antiaromatic isomers **90**[38].

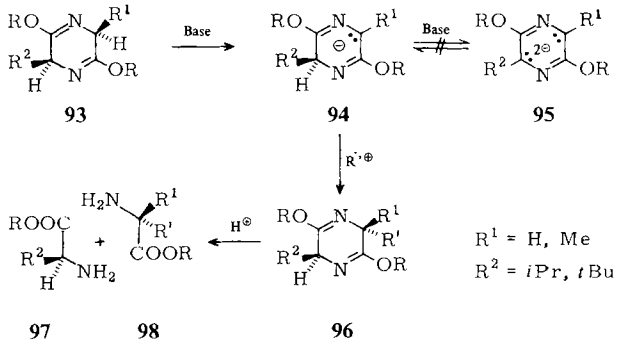
**89** **90** **91**

### 7.3. Imidazo[1,2-*a*]pyrazine-3-ones

Numerous marine organisms exhibit the phenomenon of bioluminescence[188,208]. In many cases the substrates[188] for the ring opening in presence of luciferase[209], which leads to light emission, have been found to be imidazo[1,2-*a*]pyrazine-3-ones **92** (cf. **86**). These may occur as 2*H*-(**92A**) or as 7*H*-tautomers (**92B**)[209,210].

Spectroscopic studies of the model compound **92**, R, R′ = H, R″ = $CH_3$, have established that **92B** is the favored tautomer[210]. The luciferase reaction then corresponds to an aromatization of the (formally) antiaromatic 1,4-dihydropyrazine system. Hence, as in the chemiluminescence during dihydrophenazine- and dihydroflavin-catalyzed decomposition of dioxetanones **73**, the involvement of the electron-rich system **92B** in an electron transfer interaction constituting the first step of oxygen activation should be considered.

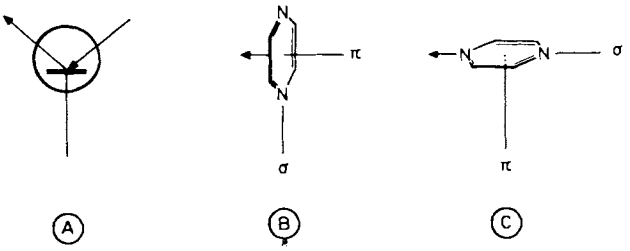
## 8. Summary and Outlook



In the preceding sections the special reactivity of 1,4-diazines has been illustrated by examples from several different branches of chemistry.

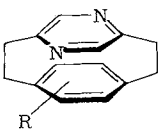
The redox system of 1,4-diazines is characterized by the exceptional stability of the paramagnetic intermediate. In *N,N′*-dialkylated pyrazines the cyclic 7 π-electron configuration even becomes the favored and only stable oxidation state. Thus one finds one-electron reactivity to be characteristic of 1,4-diazine chemistry, which in this sense is similar to that of inorganic transition metal ions. Consider, for example, SET mechanisms, $^3O_2$ activation, conducting radical ion complexes, and electron transfer chemiluminescence.

The completely reduced state with 8 π-electrons in a six-membered ring exhibits a large excess of electrons. Furthermore, certain 1,4-dihydropyrazines clearly exhibit antiaromatic behavior. There exist numerous, effective (Scheme 5) methods to avoid this unfavorable electronic situation (Table 3), one significant consequence being the large structural flexibility of 1,4-dihydro-1,4-diazines.



The 1,4-diazine system is also an instructive example of how σ-coordination and π-redox reactivity may influence one another (Scheme 6).

Such interrelated reactivities have model character for more complex chemical and biochemical processes. In the enzymatic and non-enzymatic fixation of molecular nitrogen, for example, one observes the cooperation between the

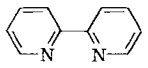


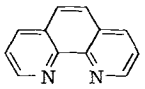
Scheme 5. The reluctance of pyrazines to form the antiaromatic 8 π-electron system (Table 3) is of synthetic value [211]: 3,6-Bis(alkoxy)-2,5-dihydropyrazines **93**, produced from optically active cyclic dipeptides by a Meerwein alkylation, react with strong bases to form the monoanions **94**. Further metalation to the pyrazine dianion **95** (8 π-electrons!), with an accompanying loss of optical information, does not take place. Instead, diastereo-selective alkylation of **94**, followed by hydrolysis of **96** leads to very good yields of almost pure enantiomers of α-amino acid esters **97** and **98**.

σ-coordination through an electrophile and the uptake of electrons ("reduction") by the π-system[213], as in the present case[212]. Such an interdependence between σ- and π-reactivities also exists for the biochemically important metalloporphyrins[214].

Scheme 6. Pyrazine as a "molecular device", in analogy to the transistor Ⓐ: *N*-Coordination governs the redox potential and the π-electron distribution Ⓑ (Table 5, Fig. 4), in return, the *N*-basicity may be modified by uptake of electrons or merely by π-backbonding into the lowest unoccupied molecular orbital Ⓒ (Table 7).

Although pyrazine itself does not tend to form π-complexes[215], its introduction into a cyclophane system **99**[216] leads to the presence of a detectable intramolecular charge transfer interaction.





**99**

This is yet another case in which the π-interaction may be greatly influenced by σ-coordination (protonation) at the nitrogen atom. Due to the lowering of the pyrazine LUMO (Fig. 1), increasing solvent acidity causes a considerable bathochromic shift of the charge transfer band in **99**[216].

Similarly to the classical complexing agents 2,2′-bipyridyl **100** and 1,10-phenanthroline **101**, pyrazine is an easily reduced σ-ligand[7].

However, in contrast to **100** and **101** pyrazine is a linearly bridging and not a chelating ligand. This bridging

function permits the formation of binuclear complexes and coordination polymers, and in many cases the π-system of the ligand is of great importance for the propagation of electronic exchange interactions.

**100**   **101**

A report on heterocyclic systems with 8 π-electrons from 1975 ends with the following paragraph[23]: "Some of these systems are excellent models for biologically relevant systems. Further model studies should help us to answer questions of electron-transfer properties and proclivity to radical formation, as well as those concerning the influence of ligands and conformations on redox properties, to mention just a few". The present article not only presents answers to these questions but shows that the study of 1,4-diazines has opened up new perspectives.

As demonstrated by the examples of typical 1,4-diazine reactivity, these compounds have become increasingly attractive molecular building blocks of more complex systems. Two main objectives of future research on 1,4-diazine chemistry are:

Further stable or metastable derivatives of pyrazine are required for comparison with theoretical predictions, which are easily available. The most attractive of these compounds is certainly the unsubstituted 1,4-dihydropyrazine **9**. Another topic of current interest lies in the field of low dimensional materials with interesting magnetic and electrical properties[217]; recent experiments with 1,4-diazine components have been quite promising[156, 161, 169].

*A review covering several branches of chemistry would scarcely be possible without personal experience in various fields and at different universities. I therefore would like to express my sincere thanks to Prof. E. Daltrozzo, Prof. H. Bock and Prof. F. A. Cotton. My own research work referred to in this article has been supported in many ways by Prof. Bock. I also owe thanks to my co-workers on these projects, U. Lechner-Knoblauch and B. Roth, and to Professors A. Alberti, A. Hudson, S. Hünig, K. N. Raymond and H. Taube for kindly providing preprints of their work. Generous support by the Fonds der Chemischen Industrie, by the Deutsche Forschungsgemeinschaft, and by the Karl Winnacker-Stiftung is gratefully acknowledged.*

# Dye Diffusion Systems in Color Photography

**By Christian C. Van de Sande***

*In memoriam Otto Bayer*

Dye diffusion instant color photography has been a commercial success ever since its introduction in 1963. No doubt this is partly due to the spectacular nature of this innovation, and for the same reason it has never really rid itself of its gadget image. Moreover, the picture quality was inferior to that of traditional color photography. Photographic materials are now available whose image quality approaches that of the traditional color print. It is not well known that chemistry, and organic chemistry in particular, is the cornerstone of these new photographic products. Insights from this field have spurred creativity, not only in the fields of dye and polymer chemistry, but above all in the search for more efficient and, hopefully better, dye diffusion transfer systems. The result of all these efforts is a finely tuned microscale chemical factory which continues to open rewarding perspectives for the photographic industry.

## 1. Introduction

Dye diffusion transfer systems are becoming increasingly important in color photography. To a large extent this is due to the success of their most popular application, instant color photography. But recently, other interesting applications for both the amateur and professional photographer have been introduced which make it possible to obtain copies of colored originals within a few minutes, without a complicated processing sequence. The chemistry behind such materials is relatively unknown outside the community of photographic scientists. A previous, less-detailed review[1b], although published in a reference work on photography of outstanding quality, remained relatively unnoticed (cf. [1c]). The present review is intended to bring some of the chemistry involved in dye transfer systems to the attention of a much broader readership.

With conventional photographic materials the final image is located in the layer which initially contained the light-sensitive silver halide (Fig. 1, left). In black and white pictures it is composed of metallic silver, and in color images of dye particles. In diffusion transfer materials the image is created in a layer which is not the initial light-sensitive layer (Fig. 1, right). During development, active components migrate from the light-sensitive layer to a receiving layer where the image particles are formed. The recorded image is, therefore, transferred by diffusion.

A black and white image is produced when the mobile components are soluble silver salts which are converted into metallic silver on silver nuclei present in the receiving layer. Such systems will not be dealt with here and the reader is referred to the literature for more information[2,3]. We will rather concern ourselves with those diffusion transfer systems which produce a dye image. The discussion of these systems will be limited to the organic chemistry of imagewise or anti-imagewise diffusion of components which give rise to a dye image in the receiving layer.

Due to limitations of space the chemistry of the dyes and polymers involved in diffusion transfer color photography can only be touched upon (see [4]).

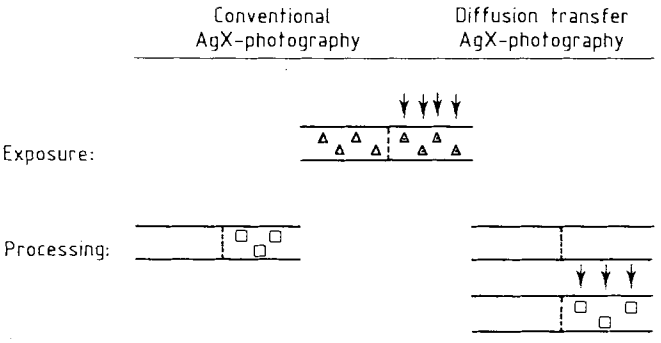

Fig. 1. Comparison between conventional and diffusion transfer systems. Characteristic for the latter is diffusion of active components from the initially light-sensitive layer to a remote layer (image build-up occurs by deposition of these components). The fate of the silver halide in the initially light-sensitive layer of a diffusion transfer material depends on several factors, but is irrelevant here. △: Non-exposed silver halide; ▲: exposed silver halide; □: image.

## 2. Basics

To produce colored images the mobile active components of a diffusion transfer system must lead to formation of dyes in the receiving layer. Irrespective of the composition of these components—dyes, dye precursors, or dye-forming reagents which react in the receiving layer—to obtain a transferred image their diffusion must be correlated with the exposure of the sensitive layer from which they originate. For photography this leaves us with two alternatives:

- *imagewise diffusion: i.e.* proportional to the amount of silver halide developed;
- *anti-imagewise diffusion: i.e.* as a negative function of the amount of silver halide developed.

A colored image can be obtained by either means.

The subtractive color system[5] for photographic registration of colored objects makes use of superposition of three silver halide containing layers (Fig. 2), which are sensitive to the blue (B), the green (G), and red regions (R) of the spectrum. An active component, which produces the complementary color of the spectral region to which the layer is sensitized, is associated with each layer: yellow for the B layer, magenta for the G layer, and cyan (blue-green) for the R layer.

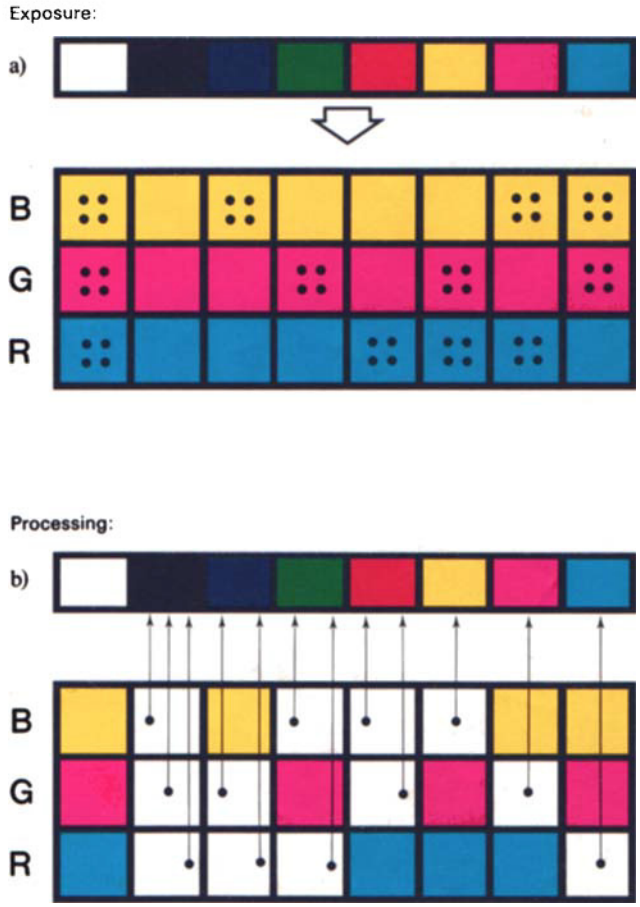

Fig. 2. Anti-imagewise diffusion yields correct (*i.e.* positive) images. Dye release then occurs as a negative function of the exposure dose of the layer in which the dye or the dye-precursor is incorporated. For a blue original, for example, dye release occurs from the green-sensitive G-layer (magenta dye) and from the red-sensitive R-layer (cyan dye). Since magenta is white minus green and cyan is white minus red, superposition of these two dyes in the receiving layer yields a blue image. a) Object; :: exposed silver halide. b) Image receiving layer; ⊷ diffusible components.

Let us assume that we have found a way to obtain anti-imagewise diffusion and that a blue object has been recorded (Fig. 2). A latent image is thus produced in the blue-sensitive layer (B). Processing leads to diffusion of components from the G and R layers, resulting either in formation or deposition of magenta and cyan dyes in the receiving layer. The combination of these two dyes yields a blue image of the blue original. A similar procedure applies to all other colors and hues (see Fig. 2), from which it can be deduced that anti-imagewise diffusion yields correct or positive transfer images: systems which cause anti-imagewise diffusion are therefore referred to as positive-working. Conversely, imagewise diffusion yields complementary or negative transfer images: such systems are referred to as negative-working. These points only apply to normal, negative-working silver halide containing layers (as in Fig. 2), which upon development produce metallic silver in amounts directly proportional to the exposure dose. In some cases, however, it can be arranged that upon development the silver halide layers produce metallic silver as a negative function of exposure dose[6]. Imagewise diffusion is then required to obtain a positive transferred image. Throughout this article normal silver halide is assumed, unless otherwise stated.

Knowing that imagewise or anti-imagewise diffusion can lead to a useful image, one is faced with the problem of its practical realization. Clearly, the mobility of the active ingredients is modified as a function of the exposure dose of the silver halide in their immediate neighborhood, and this leaves two alternatives:

- The active components are initially mobile in alkaline media and become immobilized during processing or
- they are initially immobile and are mobilized during processing.

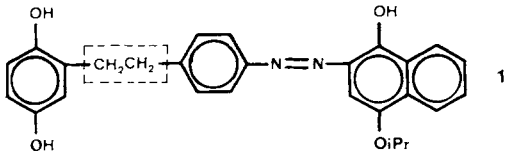
There is a way to achieve such exposure-controlled mobility changes: the exposure dose can be chemically translated into "amount of reducible silver halide", "amount of developer used", and hence "redox equivalents". This is the key to the solution: *molecules whose mobility can be redox-controlled are needed.*

Nearly thirty years have elapsed since the first patent describing the practical realization of this problem was filed by Polaroid[7]. In the meantime, virtually all important photographic companies have spent a considerable amount of effort in devising and optimizing systems involving this principle. Four important categories can be distinguished:

- redox-controlled solubility changes;
- systems based on chromogenic coupling reactions known from color photography;
- redox-controlled cleavage reactions;
- reactions with silver ions.

These methods will be discussed in the following four sections. A separate section will treat some less important systems.

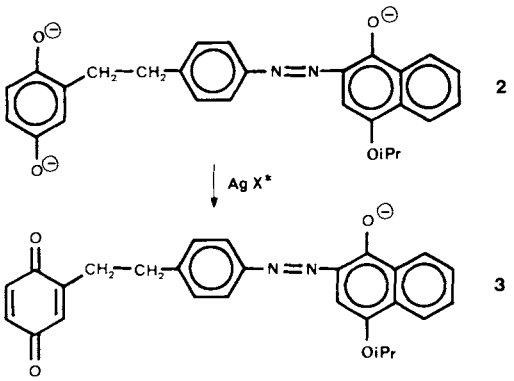
## 3. Redox-Controlled Solubility Changes



### 3.1. The Dye-Developer System

The dye-developer system is the most important system based on redox-controlled solubility changes. Conceived by *Rogers* at Polaroid Corporation[7], it provided the basis for the Polaroid instant color film, which was introduced in 1963, and is still employed in today's Polaroid color films. The "active components" in this system are *dye-developer molecules.*

Dev–Link–Dye

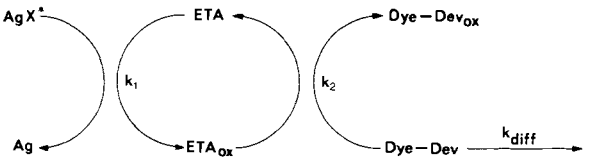


As the name suggests these molecules contain a developer moiety *Dev* (*e.g.* a hydroquinone or *p*-aminophenol unit)

as well as a dye (or dye precursor) moiety. Both fragments are linked by an insulating group (*Link*), whose main function is to electronically insulate the *Dye* and *Dev* portions: redox changes in the *Dev* moiety are then unable to affect the chromophore of the *Dye* moiety directly. An additional requirement for this *Link* is that it should be hydrolytically stable under the development conditions and for the duration of the development process (order of magnitude: minutes). **1** is an example of an early dye-developer molecule: the ethylene group effectively links the hydroquinone fragment to the magenta azonaphthol dye. More recent developments in dye-developer chemistry have primarily focused on achieving better light stability, and have resulted in the introduction of premetallized (*i.e.* metal-ion complexed) dyes in the Polacolor 2 material (1975). More details on this topic can be found in[4].

1

The dye-developer molecules are present in the material as a very fine emulsion in a gelatine binder which may also contain the light-sensitive silver halide. Alternatively, the silver halide may be incorporated into an adjacent layer. In the alkaline medium of the development phase these molecules ionize, dissolve, and consequently become diffusible. In exposed areas these ionized dye-developer molecules (*e.g.* **2**) are oxidized (Scheme 1) to form immobile quinones (*e.g.* **3**)[8], as a result of development of the exposed silver halide (AgX*) (Scheme 1).



2

3

Scheme 1. Oxidation of the dye-developer molecule **2** to **3**.

If no oxidation takes place (as in unexposed areas) the ionized dye-developers (*e.g.* **2**) migrate to the receiver layer (or sheet) where they are mordanted. The system leads to anti-imagewise diffusion and yields a positive transferred image if normal silver halide layers are used (see Section 2).

Although the dye-developer molecules could principally act as developers for exposed silver halide (by definition!) this function has been assumed by a conventional auxiliary developer molecule (*e.g. p*-tolylhydroquinone) for reasons which will become clear after an analysis of the kinetics of the system. Scheme 2 gives a schematic representation of the reactions which take place in the exposed areas. The *electron transfer agent* (ETA) is the auxiliary developer which reduces exposed silver halide at a rate $k_1$, whereby it is converted into its oxidized form $ETA_{ox}$. This in turn then oxidizes (rate $k_2$) the dye-developer molecules: this oxidation reaction regenerates ETA, which consequently serves no other purpose than to pump electrons from dye-developer molecules to exposed silver halide.

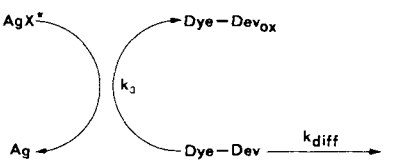
Scheme 2. Redox reactions in the dye-developer system (exposed areas). ETA (*E*lectron *T*ransfer *A*gent) assists in the development. The insulating group "*Link*" has been omitted.

To function properly this system must meet several requirements. Firstly the redox potentials of the systems involved must be such that the processes described by Scheme 2 produce a sufficiently negative free energy change in the system. This amounts to the requirement

$$E^0(\text{Dye–Dev}) < E^0(\text{ETA}) < E^0(\text{Ag/AgX*}) \qquad \text{(a)}$$

which limits the choice of dye-developer as well as that of ETA.

Considering the system from a point of view of kinetics, it is clear that good differentiation between exposed and non-exposed areas will only be achieved if the rates $k_2$ and $k_{diff}$ comply with the following inequality:



$$k_2 \gg k_{diff} \qquad \text{(b)}$$

If this is not fulfilled, *i.e.* if diffusion of dye-developer effectively competes with its oxidation, unwanted transfer of dye will occur in exposed areas leading to color fog. The interaction rate $k_2$ is a composite of the diffusion rate $k'_{diff}$ of $ETA_{ox}$ and the actual redox interaction rate, and therefore complies with the relation

$$k'_{diff} > k_2 \qquad \text{(c)}$$

Combination of inequalities (b) and (c) indicates that in a practical system the diffusion rate of $ETA_{ox}$ must exceed that of dye-developer. This is achieved by the selection of small and compact ETA molecules (*e.g. p*-tolylhydroquinone or 1-phenyl-3-pyrazolidinone (phenidone)).

One may ask why an ETA is necessary. If it were to be omitted (see Scheme 3), development (rate $k_3$) of exposed silver halide would consist of a composite of actual redox

Scheme 3. Simplified but impractical dye-developer system.

reaction and diffusion of dye-developer to the grains. Inequality (d) would then hold, *i.e.* migration of dye-developer molecules to the receiving layer would compete strongly with their oxidation, leading to formation of color fog.

$$k_3 < k_{diff} \qquad (d)$$

Although the mechanism outlined in Scheme 2 provided the foundation for the Polaroid instant material, a multitude of problems had to be solved before it became a commercial reality (see [3],[4]). Figure 3 gives an idea of the complexity of an integral film of Polaroid design.

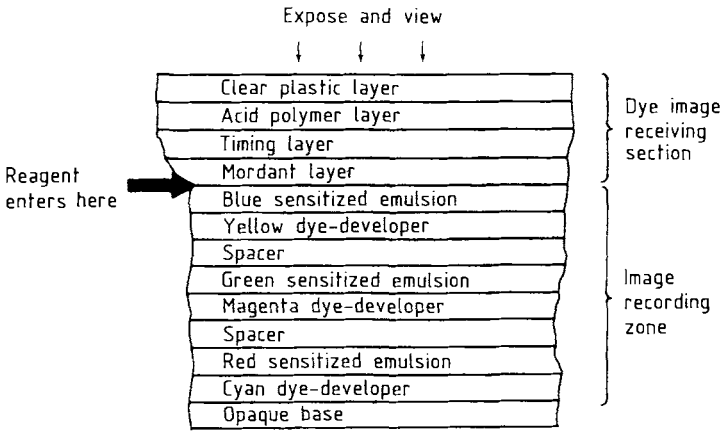


Fig. 3. Schematic section through an integral film unit of Polaroid design (see text).

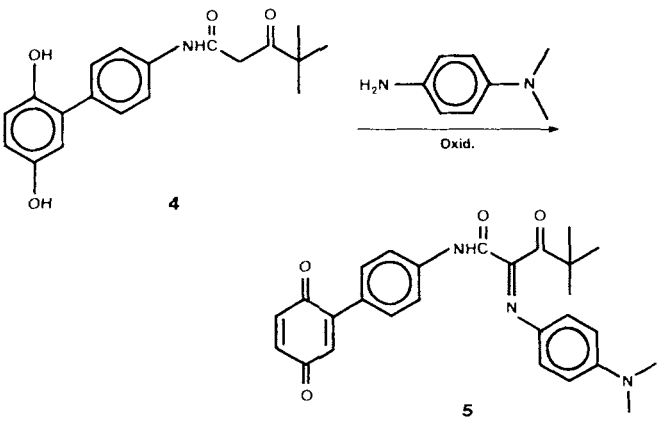
After exposure, such a film unit is ejected from the camera through a pair of rollers which rupture a container located at the edge of the unit holding the processing solution. This "solution" is a viscous paste containing alkali, water, titanium dioxide, and opacifying dyes which protect the image recording zone and allow formation of the image in daylight. A dye-developer layer is located below each sensitive layer: this arrangement is necessary because the dye-developers absorb in the same spectral region to which the associated silver halide layers are sensitized. Inclusion of the dye-developers in the AgX layers would have caused severe reduction in photographic sensitivity, even if their absorption were shifted to shorter wavelengths by conversion into alkali-labile derivatives (*"shifted dye-developers"*[9]). The image-receiving section contains a mordant layer to capture the transferred dyes, an acid layer to neutralize the excess of alkali present in the processing liquid, and a timing layer to monitor the time of neutralization.

A disadvantage inherent to the dye-developer system is that the diffusing or mordanted dye-developer molecules are still redox active and may, therefore, be oxidized by $ETA_{ox}$ on their way through other image recording layers of (see Fig. 3), or undergo aerial oxidation in the mordant layer. These lead to improper color rendition and formation of yellow fog, respectively.

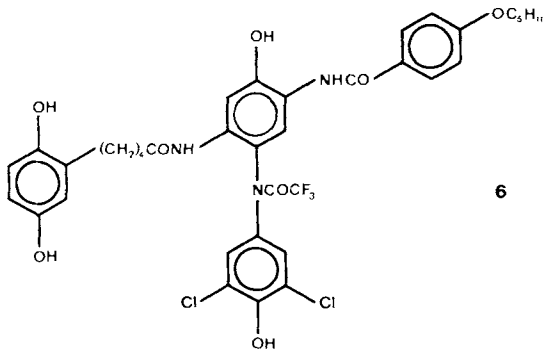


Oxidation by $ETA_{ox}$ can be limited to some extent by accurate control of the development in, and the diffusion from, the three light-sensitive layers: only when development of the blue-sensitized layer and all redox reactions therein have ceased does development start in the green-sensitized layer *etc.* Precisely these two imperfections in the Polaroid dye-developer system have stimulated a search for other dye-transfer systems (see Sections 4–7).

### 3.2. Coupler Developers

An alternative to shifted dye-developers are the so-called *coupler developers*[10,11]. These are virtually colorless molecules (*e.g.* **4** in Scheme 4) of the type

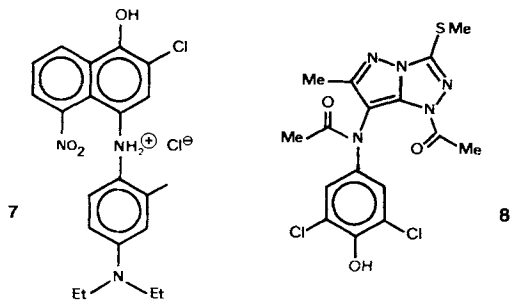
Dev–Link–Coup



where *Dev* and *Link* have the same meaning as before and *Coup* represents a chromogenic coupler group. Such coupler residues are known from conventional color photography[12]. Like dye-developers, coupler-developer molecules are immobilized by oxidation as a function of exposure dose. Residual coupler-developer migrates to the receiving layer where it is mordanted. Color formation can then occur in two ways (Scheme 4). 1) The receiving layer

Scheme 4. Immobilization of coupler-developers **4** in exposed areas leading to formation of **5**.

is separated from the photosensitive unit, and is subsequently immersed in a color developer solution followed by an oxidizing solution[10]. 2) Alternatively an oxidant can be incorporated into the receiving layer and a color developing agent elsewhere in the material[11]. Chromogenic coupling then takes place in the mordant layer without separation or additional processing steps.

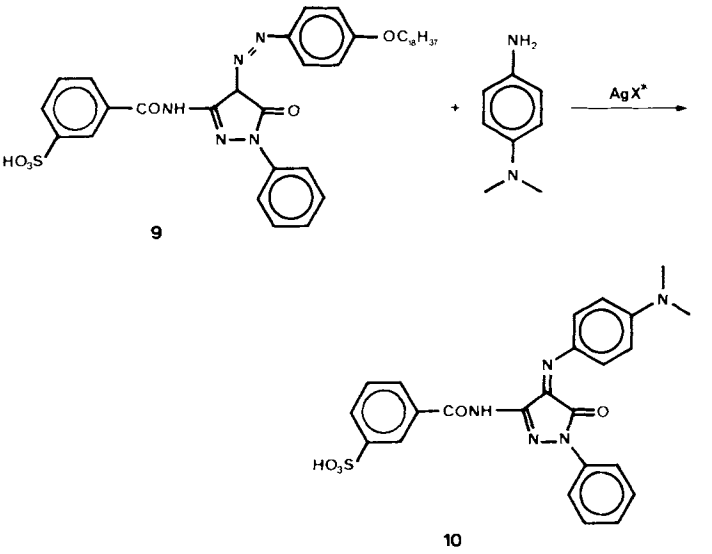


Closely related to coupler developers are the so-called *oxichromic developers*[13]. These are developers containing stabilized (*i.e.* protected) reduced azomethine or indophenol structures (*e.g.* **6**). Since these molecules are colorless, they can be incorporated directly into the sensitive emulsion layers. Differentiation between exposed and non-exposed areas occurs as for dye-developers. Dye formation results by deblocking (*e.g.* alkaline cleavage of the trifluoroacetyl group in **6**) and aerial oxidation or, better, interaction with oxidants incorporated into the receiving layer. Organic peroxides[14], iodosyl compounds[15], and nitroxide radicals[16] have been proposed in this respect.

6

### 3.3. Leuco Dyes

In some instances leuco dyes can be used as a very special kind of oxichromic dye-developer in which developer and reduced dye form the same structural moiety[17–19]. They must be able to reduce exposed silver halide, the leuco dye must be sufficiently mobile in the alkaline medium, and the oxidized leuco dye must be immobile in the alkaline medium. Imagewise immobilization as a function of exposure dose and migration of residual leuco dyes to an oxidizing mordant layer produce a positive image. A particularly interesting category are the leuco-indoaniline or leuco-azomethine dyes[20] and their derivatives (*e.g.* 7, 8)[21]. Since the free leuco dyes are too sensitive to aerial oxidation, hydrochlorides or acylated derivatives are used.



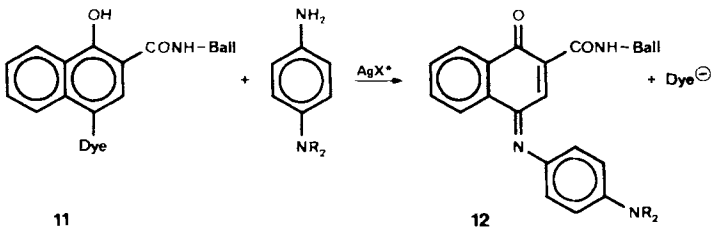
7 8

## 4. Systems Based on Chromogenic Coupling Reactions

Considerable effort has been directed at modifying oxidative coupling reactions known from color photography[12] to meet the requirements of diffusion transfer photography. Crucial is that the coupling reaction results in formation of a mobile dye or that a mobile dye becomes immobilized. Although much activity has been invested in optimizing the systems described in Sections 4.1—4.6 no commercially viable material is available. For the systems discussed in Sections 4.1—4.3 and 4.5, this is almost certainly due to staining of the receiving layer(s) by aerial oxidation of excess color developer.

### 4.1. The "Diffusible Dye Release" System

There are two straightforward methods[22–24] of exploiting classical chromogenic coupling reactions[12] for diffusion transfer photography.

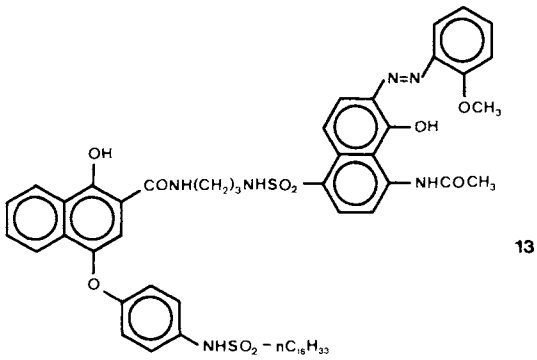


9 10

Scheme 5. Formation of diffusible dye **10** by release of a ballast group (*i.e.* diffusion impeding) from the coupling position of a coupler molecule **9**.

Couplers, such as compound **9** (Scheme 5), which contain an immobilizing ballast group in the coupling position, are initially non-diffusing but release this ballast group upon coupling. A diffusible dye (here the magenta dye **10**) is thereby generated and contains one or more solubilizing groups (*e.g.* $SO_3H$) which assist in achieving the required diffusion rate.

Alternatively, diffusible dye-releasing couplers[25] can be used. Such couplers are immobilized by the presence of a ballast group (Ball) in any except the coupling position (see **11** in Scheme 6).



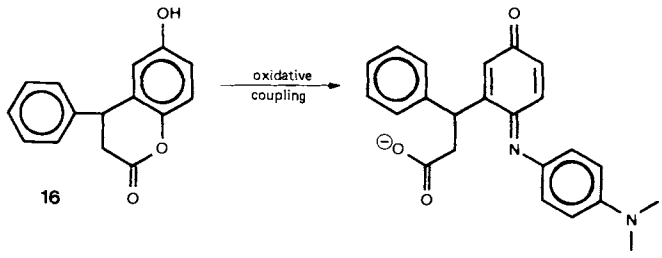
11 12

Scheme 6. Diffusible dye release from a coupler molecule **11** (with a ballast group) containing a dye moiety in its coupling position.

Additionally, they are substituted at the site of coupling by a solubilized dye residue. Upon reaction with oxidized color developer, these *DDR* (diffusible dye release) couplers[25] release the diffusible dye. The other coupling product having a ballast group is colored (cyan in the case of **12**), but this is of no significance since it remains in the original layer.

Couplers of these two types cause imagewise dye-diffusion and, therefore, require positive-working light-sensitive layers (see Section 2)[6] if a positive transferred image is required. However, couplers containing a ballast group at the coupling position and a dye residue at another position (*e.g.* **13**) allow the use of normal negative-working silver halide layers if the retained image is used instead of the transferred dye image[26].

13



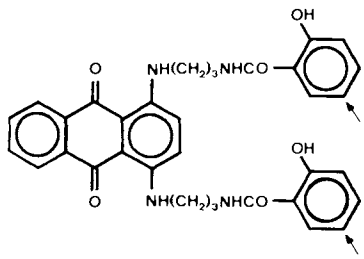
Chromogenic coupling of species such as **13** leaves only colorless ballast groups in the light-sensitive layer because the indoaniline dye produced migrates to the receiving layer. Since the degree of coupling is proportional to exposure, an anti-imagewise distribution of retained coupler results and if the incorporated dyes are complementary to the sensitivity of the silver halide layer, a positive retained image remains (cf. Fig. 2).

The kinetics of the system can be tuned to the photographic specifications to a limited extent by varying the kinetics of the coupling reaction; this can be achieved *via* structural changes in either the coupler residue or the color developer itself. An interesting third alternative is to interpose a *timing group* (as shown in Scheme 7) between a diffusible dye and the coupling position of a DDR coupler. Upon coupling with oxidized color developer the combination of timing group and dye is released. The timing group temporarily slows down migration of the dye to the receiving layer since subsequent intramolecular reaction in the timing group is required to obtain a diffusible dye: this provides a means of correctly timing dye release. Both the cyclization reaction[27] (as in **14**) and quinonemethide formation[28] (as in **15**) are useful timing mechanisms.

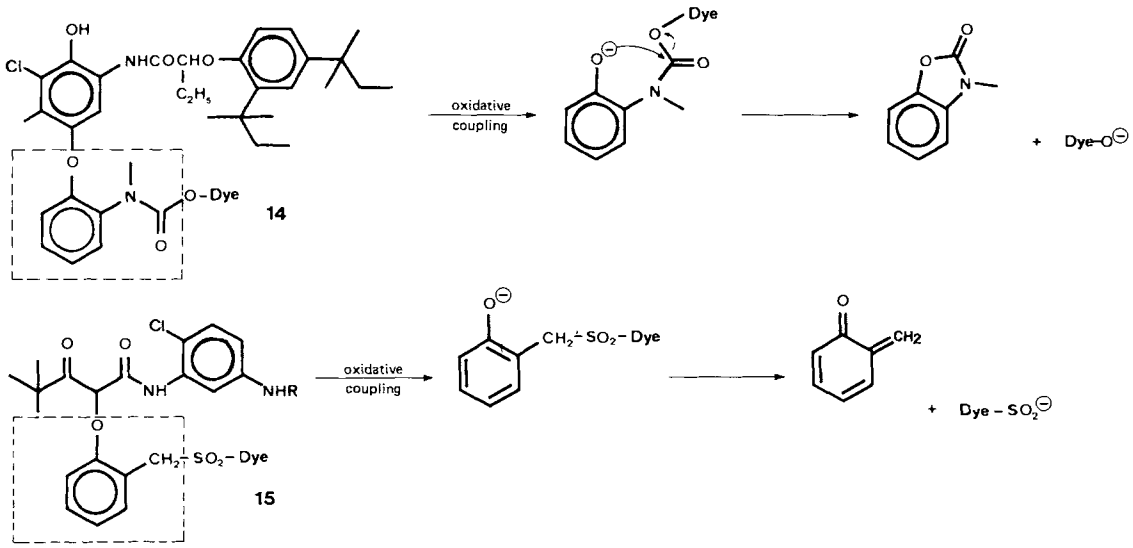
A disadvantage of DDR couplers which contain a releasable dye is their light absorption with concomitant loss of photographic speed when they are incorporated into a sensitive layer. "Shifted dyes" as well as oxichromic dyes (acylated leuco-dyes)[13b] are, once again, possible solutions.

### 4.2. Chromogenic Formation of a Solubilizing Group

A variant of the compounds dealt with in Section 4.1 are two-equivalent couplers, such as **16**[12], in which the leaving group is a sulfonic or carboxylic acid precursor and which is bonded to the mainframe of the coupler molecule *via* a ring (Scheme 8)[29].



16

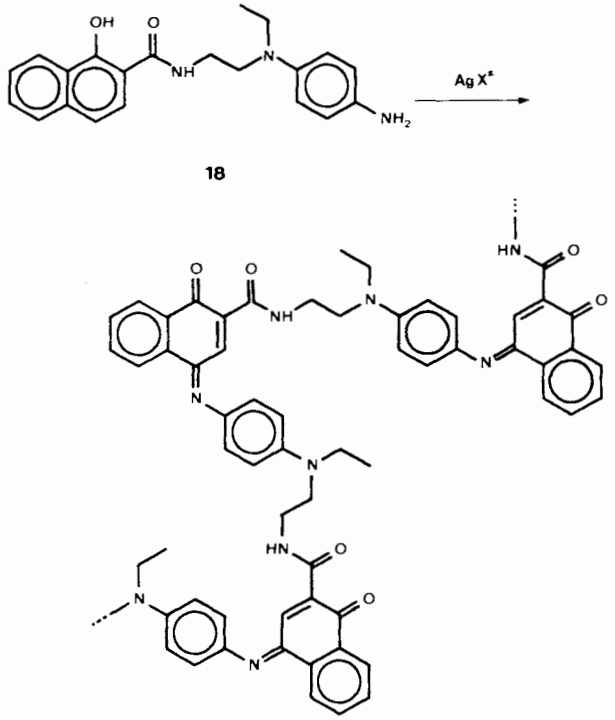


Upon coupling with oxidized color developer a solubilizing group is generated. Since a ballast group is absent it is doubtful whether this system provides enough differentiation of mobility.

### 4.3. Coupling Dyes

Dyes can not only be made diffusible by means of the classical coupling reaction but also non-diffusing[30,31]. This is achieved using dyes, such as **17**, which contain one or more coupling sites (indicated by arrows) for the oxid-

17

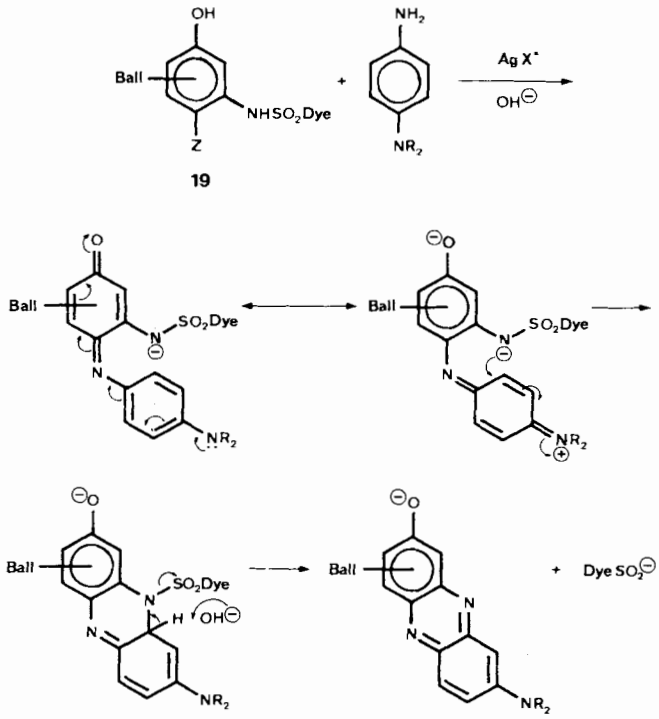


Scheme 7. Two-stage dye release from the couplers **14** and **15** by use of timing groups (framed).

ized color developer. Oxidative coupling removes solubilizing groups (phenolic hydroxyls in **17**) and increases the bulk of the molecule, hence hindering diffusion. In contrast to the systems discussed in Section 4.1 and 4.2, this is a positive-working system (anti-imagewise diffusion).

### 4.4. Auto-Coupling Developers

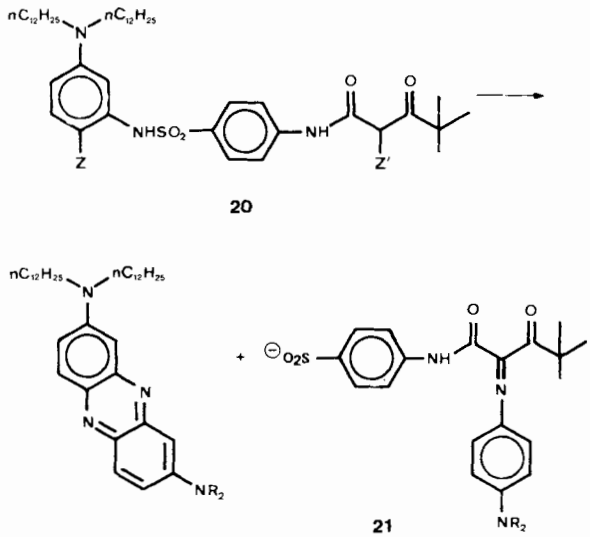
Upon oxidation, molecules such as **18**, which contain both a coupler and a color developer moiety, are able to couple intermolecularly to form polymers (Scheme 9)[32]. When they are incorporated into a sensitive layer auto-coupling developers are immobilized in exposed areas.



Scheme 9. Oxidation of the auto-coupling developer **18** leading to a polymeric coupling product.

Unreacted auto-coupler (predominantly in unexposed areas) diffuses into the receiving layer, where an oxidant causes the immobilization and the dye-forming coupling reaction. Because of the anti-imagewise diffusion, this is a positive-working transfer system.

### 4.5. The Azine System

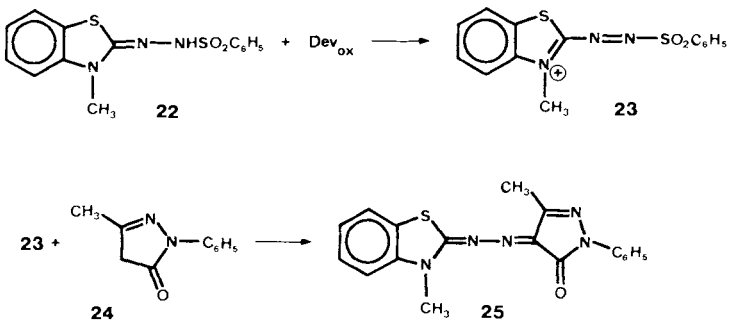


*m*-Sulfonamido-substituted phenols (*e.g.* **19**, Scheme 10) or anilines, as well as their naphthalenic analogs, are known to cyclize to azine dyes following oxidative coupling with color developers[33]. This reaction can be used for diffusion transfer purposes (Scheme 10) if the *m*-sulfonamido substituent contains a dye moiety and if the coupler contains a ballast group (*i.e.* an immobilizing group)[34,35]. The substituent Z can be hydrogen or any group[12] which can be replaced by oxidized color developers (halide, alkoxy, arylthio, *etc.*). According to Scheme 10,

Scheme 10. Release of dye from *m*-sulfonamido substituted phenols **19** by means of chromogenic coupling and subsequent cyclization.

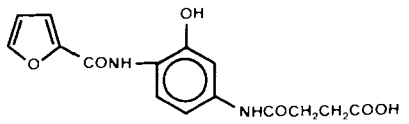
sulfinate solubilized dyes are released in the cyclization step.

Instead of a dye, a solubilized coupler residue (*e.g.* from **20**, Scheme 11) can be released[36]. Formation of the actual diffusible dye (*e.g.* **21**) requires a second oxidative coupling reaction.



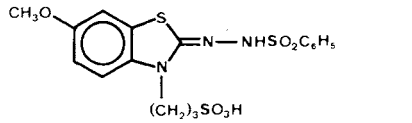
Scheme 11. Formation of azomethine (or indophenol or indoaniline) dye and its release by phenazine formation.

Both versions of azine-forming couplers are characterized by imagewise dye diffusion: the systems are therefore negative-working. An additional disadvantage of the coupler releasing version is that between four (Scheme 11, Z, Z' ≠ H) and eight equivalents (Z = Z' = H) of silver halide are required.



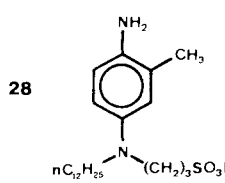
### 4.6. The Sulfonyl Hydrazone System

Because they can react with phenolic or activated methylene couplers (*e.g.* **24**) known from traditional color photography[12] (Scheme 12) sulfonyl hydrazones, especially those derived from cyclic amidines (*e.g.* **22**, Scheme 12), have been extensively studied by *Hünig et al.*[37]. Colored products (*e.g.* **25**) are formed and the reaction can be used as the basis for an alternative color photographic chemistry (in contrast to that of Fischer[12]).

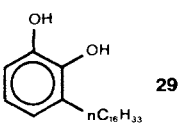


Scheme 12. Oxidative coupling of the sulfonyl hydrazone **22** with the coupler **24**, which contains an active methylene group, to yield the colored product **25**.

The coupling reaction is suited for diffusion transfer if both the coupler (*e.g.* **26**) and the sulfonyl hydrazone (*e.g.* **27**) present in the emulsion layer are diffusible in alkaline media[38]. In non-exposed areas both coupler and sulfonyl



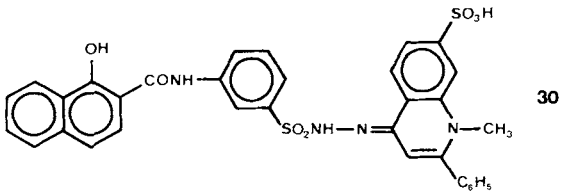
**26**



**27**

hydrazone diffuse to a receiving layer which contains an oxidant. This instigates coupling between these two components to produce a dye, which is subsequently mordanted. In exposed areas either of the two mobile components can be immobilized, depending on the nature of the bulk developer. If an *N,N*-dialkyl-*p*-phenylenediamine containing a ballast group is used (*e.g.* **28**), oxidative coupling with its oxidation product immobilizes the coupler. If, however, a pyrocatechol is used (*e.g.* **29**) diffusion of sulfonyl hydrazone is hindered by oxidative coupling.

Due to the ballast group neither **28** nor **29** are active developers for exposed silver halide. Hence, a small amount



**28**

**29**

of a very mobile developer, *e.g.* 1-phenyl-3-pyrazolidone, is used as an electron transfer agent (ETA) between the bulk developer, containing ballast group, and exposed silver halide[39]: in exposed areas ETA is oxidized to $ETA_{ox}$ which oxidizes the bulk developer to regenerate ETA (cf. Scheme 2). The system produces anti-imagewise dye formation in the receiving layer and is therefore positive working.

Good color rendition requires that three coupler/sulfonyl hydrazone pairs be used (each associated with one of the sensitive layers), which have one partner (coupler or sulfonyl hydrazone) in common. Otherwise, unwanted mixed couplings could occur in the receiving layer. Hence, four color-forming components are incorporated into the material. This number can be reduced[38] to three if both coupler and sulfonyl hydrazone are combined into diffusi-

**30**

ble molecules such as **30**. The three molecules must either contain the same coupler or the same sulfonyl hydrazone.

## 5. Redox-Controlled Cleavages

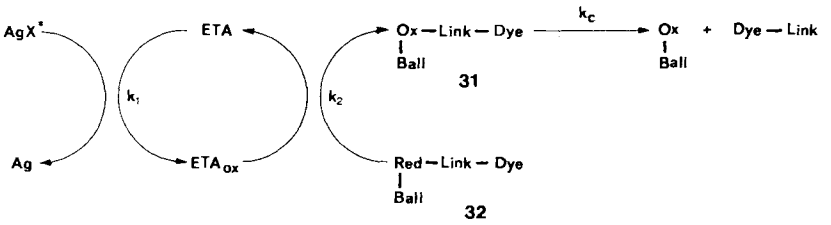
Dye-developer and related systems have the disadvantage that the diffusing molecules can undergo unwanted oxidations on their way through other light-recording layers and, once mordanted, are sensitive to aerial oxidation (cf. Section 3.1). On the other hand, use of systems containing color developers results in formation of stains from their aerial oxidation. Both for these practical reasons, as well to avoid patent infringement, other systems have been sought by virtually all companies active in color photography. Among the alternatives, the most important group is based on redox-controlled cleavage reactions[40]; with the exception of the Polaroid system all other commercial dye-transfer systems belong to this category.

Ball-Redox-Link-Dye

1. Ball-Ox-Link-Dye ⟶ Ball-Ox + Link-Dye

2. Ball-Red-Link-Dye ⟶ Ball-Red + Link-Dye

Fig. 4. There are two classes of DRR systems: 1) oxidatively cleavable, 2) reductively cleavable systems. See text for additional information.



The active molecules in a dye-releasing redox system contain (see Fig. 4) a redox moiety *Redox*, linked to a dye or dye precursor moiety, and carry a ballast group *Ball*, which renders the whole molecule non-diffusing. Characteristic for the *Link* between *Redox* and *Dye* (or dye pre-

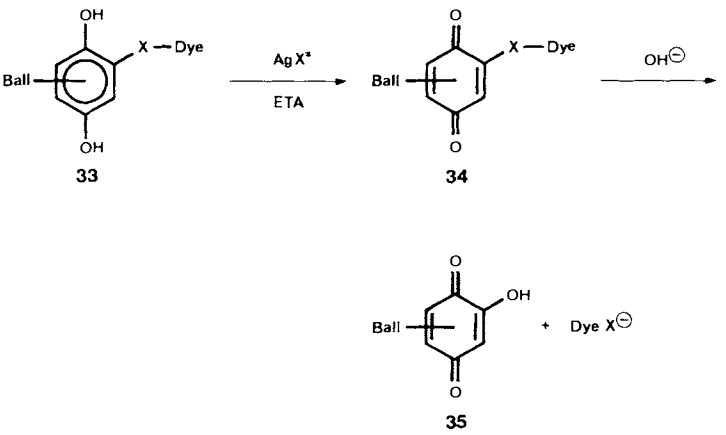
cursor) is that under the conditions of development it is labile in only one redox state and stable in all others. Hence, release of dye is redox-controlled and can be correlated with the exposure dose of sensitive silver halide *via* the development process. For photographic applications two subgroups in the *DRR* family[40] are considered:

- Systems releasing dyes or dye precursors in their oxidized state (type 1 in Fig. 4);
- Systems releasing dyes or dye precursors in their reduced state (type 2 in Fig. 4).

### 5.1. Dye Release in the Oxidized State

All systems based on oxidative cleavage reactions make use of compounds with ballast groups of the type represented by **32** (Scheme 13): their redox system is in its reduced state. The ballast group is necessary to immobilize these molecules, but as a result they are unable to reduce silver halide directly. A mobile developer, which acts as an electron transfer agent (ETA) between **32** and exposed silver halide, is therefore required. Scheme 13 shows all the reactions involved in exposed areas. In non-exposed areas no interaction occurs, and consequently no dye transfer takes place. In exposed areas ETA develops exposed silver halide (AgX*) and is itself oxidized to $ETA_{ox}$. The latter oxidizes **32** to **31**, regenerating ETA, and finally **31** decomposes releasing the dye. The other product of this cleavage, the redox moiety or "carrier" with the ballast group, is immobile and remains in the layer. Diffusion of the dye is imagewise, and all systems based on oxidative cleavage are negative-working.

Scheme 13. Generalized reaction scheme for oxidatively cleavable DRR systems.

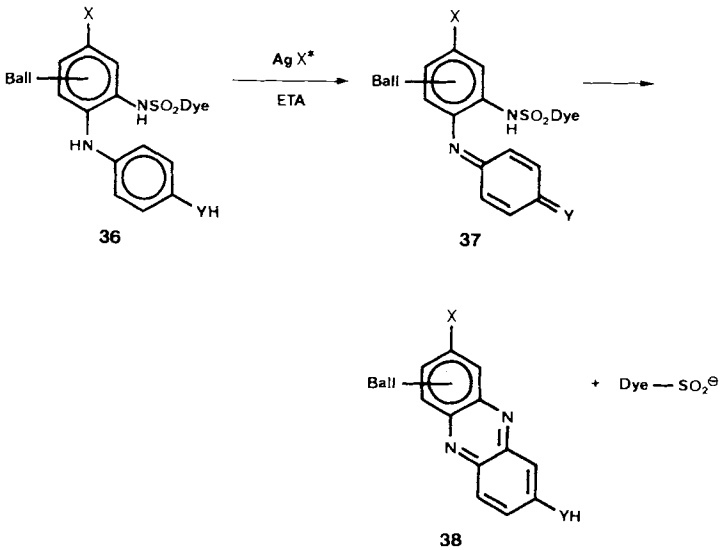


The redox potentials of the participating redox systems must satisfy the condition:

$$E^0(\text{Redox}) < E^0(\text{ETA}) < E^0(\text{Ag/AgX*}) \qquad \text{(e)}$$

Moreover, the cleavage reactions and the diffusion of the released mobile dyes must be sufficiently fast in order to obtain satisfactory photographic performance. Build-up of $ETA_{ox}$ is undesired since side-reactions can then occur and hence the situation $k_1 \gg k_2$ is to be avoided.

#### 5.1.1. Addition-Elimination Reactions in Benzoquinones

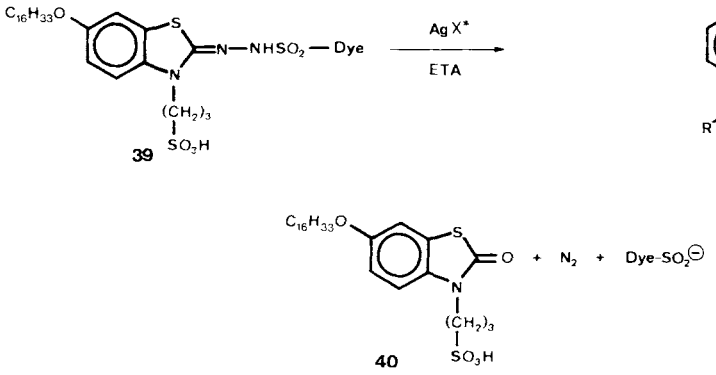


Hydroquinone derivatives **33** with ballast groups are inactive developers. In combination with a diffusible developer—which functions as an electron transfer agent—they undergo imagewise oxidation to yield *p*-benzoquinones **34** (Scheme 14). In the alkaline development medium these undergo an addition-elimination sequence[41] and thereby release diffusible dyes[42,43].

Scheme 14. Dye release *via* addition-elimination reactions at substituted *p*-benzoquinones, such as **34**. X = O, S, $SO_2$.

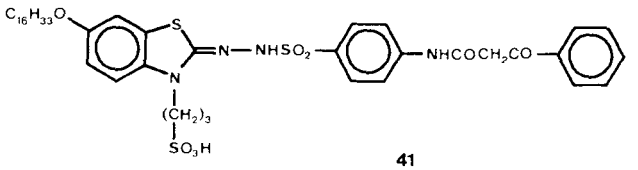
#### 5.1.2. Cyclization to Azines

Anilinophenol (or anilinoaniline) derivatives **36** having ballast groups[35,44] undergo imagewise oxidation with oxidized developer (Scheme 15).



Scheme 15. Dye release by oxidation and subsequent cyclization of appropriately substituted diphenylamines **36**. X = H, OH, $NH_2$; Y = O, NH.

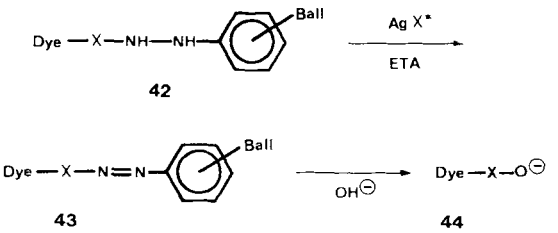
The product **37**, which resembles the coupling product of *m*-sulfonamidophenols (see Scheme 10), undergoes a dye-releasing ring closure to give a phenazine **38** with ballast groups *via* the same mechanism described in Scheme 10. Sulphinate solubilized dyes are released.



### 5.1.3. Cleavage of Sulfonyl Hydrazones

Oxidation of sulfonyl hydrazones leads to azosulfones, which are cleaved by nucleophiles[37]. Several methods have been elaborated of adapting this chemistry to diffusion transfer conditions. Sulfonyl hydrazones, such as *e.g.* **39**, with ballast groups are oxidized by oxidized ETA in exposed areas to yield an azosulfone, which undergoes alkaline cleavage to afford a diffusible sulfinate-solubilized dye (Scheme 16)[39,45,46].

Compounds like **41** are also useful in combination with color developers[47]. Instead of a dye they contain a releasable coupler moiety, which, subsequent to oxidative cleavage, can diffuse and produce a dye *via* a classical coupling reaction.

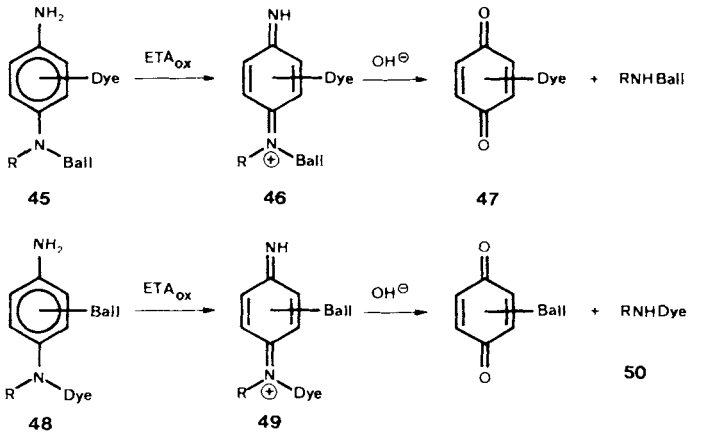


Scheme 16. Dye release by oxidative cleavage of sulfonyl hydrazones **39**.

It is also possible to interchange ballast and dye (or coupler) moieties in **39** or **41**.

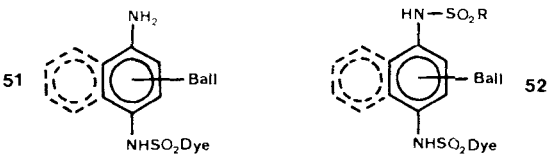
### 5.1.4. Cleavage of Hydrazides

Closely related to the sulfonyl hydrazones **39** and **41** are hydrazides[48], such as **42**, which undergo oxidation by oxidized developer to yield acylazo or sulfonylazo compounds **43** (Scheme 17).



Scheme 17. Oxidative cleavage of acyl or sulfonyl hydrazides. X = CO, $SO_2$.

These[49] undergo alkaline hydrolysis to release diffusible dyes **44**.

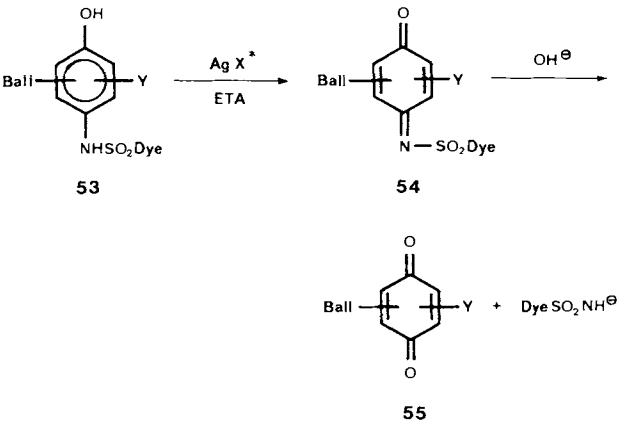


### 5.1.5. Hydrolysis of Quinone Imines

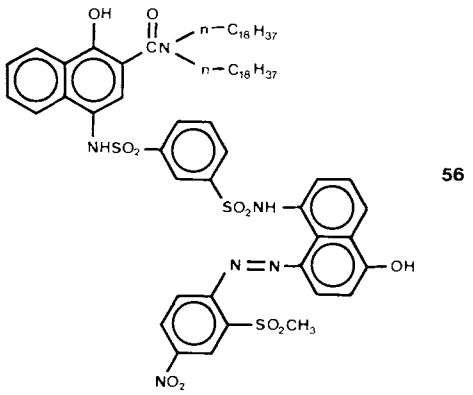
A well-known side reaction of color development is the deamination of oxidized *p*-phenylenediamines by alkaline hydrolysis[50]. On the basis of this reaction[51], two types of compounds (**45** and **48**) can be used for dye transfer as illustrated in Scheme 18. In **45** and **48** the relative positions of ballast group and dye differ, but both produce quinone imines **46** and **49**, which undergo hydrolytic cleavage to give the ballast-free and, hence, more mobile dyes **47** and **50**, respectively. With regard to the behavior of dye-developers (see Section 3.1), compounds **48** are preferred.

Scheme 18. Dye release by deamination of oxidized *p*-phenylenediamines **46** and **49**.

The *p*-sulfonamides **51**[52,53] and **52** are also suitable[54,55].



### 5.1.6. 4-Sulfonamido-Substituted Phenols and Naphthols



Closely related to the deamination of oxidized color developers, discussed in the previous section, is the alkaline hydrolysis of *N*-sulfonyl quinonemonoimides **54**[52,53,56]. These species result from the imagewise oxidation of *p*-sulfonamido-substituted phenols **53** having ballast groups, and release sulfamoyl-solubilized dyes (Scheme 19).

The substituent Y in **53** *e.g.* can also be an annelated benzene ring. From the naphthalene derivative **56** a cyan dye can be released. Examples of variations of the system are 4-sulfonamido-substituted phenols[57,58] having four additional substituents, tetrahydronaphthalene derivatives[59], and 4-sulfonamido-substituted naphthols having ballast groups in the 7-position[60].

The chemistry of *p*-sulfonamido-substituted naphthols has been successfully used in the Eastman-Kodak integral image transfer material[61] (Fig. 5).

Scheme 19. Dye release by oxidation of 4-sulfonamido substituted phenols **53** (or naphthols) and subsequent hydrolysis of the resulting *p*-quinone imine derivatives **54**.

**56**

Its construction differs substantially from that of the Polaroid material shown in Figure 3, particularly with respect to the arrangement of the light-sensitive layers relative to the image receiving section. This has to do with the fact that with the Eastman-Kodak film exposure and viewing occur from opposite sides. With the Polaroid film, the exposure and viewing directions are the same.

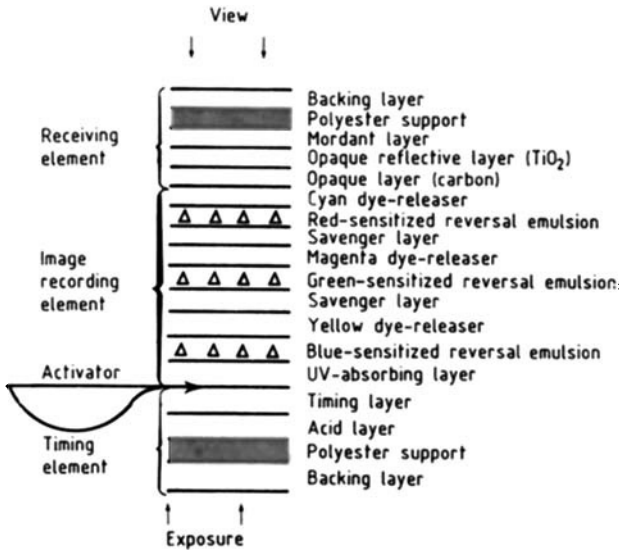


Fig. 5. Schematic structure of a Kodak integral film unit (see text for additional information).

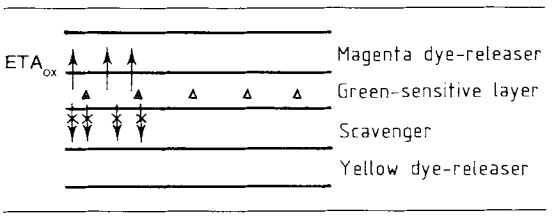
Another innovation is the presence of the two scavenger-layers for oxidized developer. Their use is illustrated in Figure 6. In an exposed area of the green-sensitized layer, development of the latent image produces $ETA_{ox}$, which can either diffuse to the layer in which the magenta dye is released or to the layer in which the yellow dye is released. The latter is unwanted, and the purpose of the scavenger layer is to block diffusion of $ETA_{ox}$ in the wrong direction by means of a *scavenger*. This is a non-diffusing reducing substance which reconverts $ETA_{ox}$ into ETA.



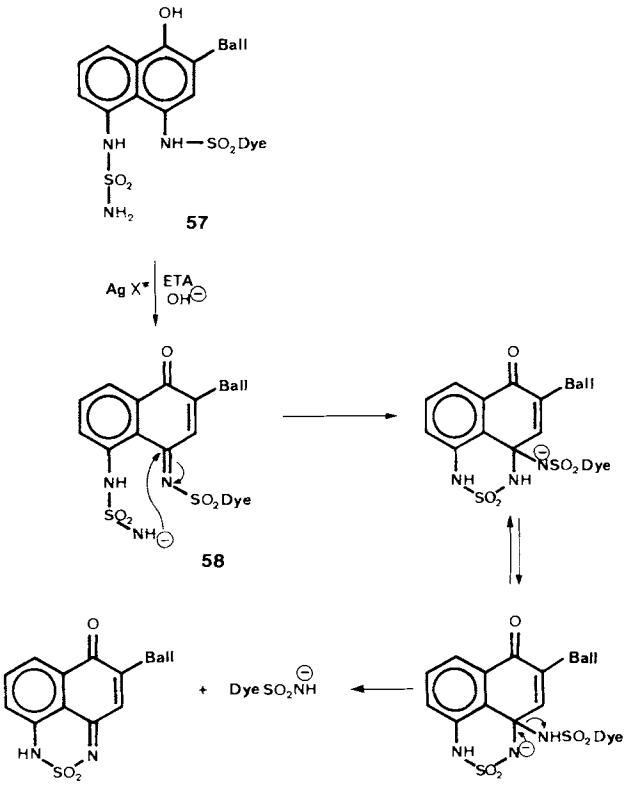


Fig. 6. Function of a scavenger layer. It blocks unwanted migration of oxidized electron transfer agent ($ETA_{ox}$) by reconverting it into ETA (see text for details).

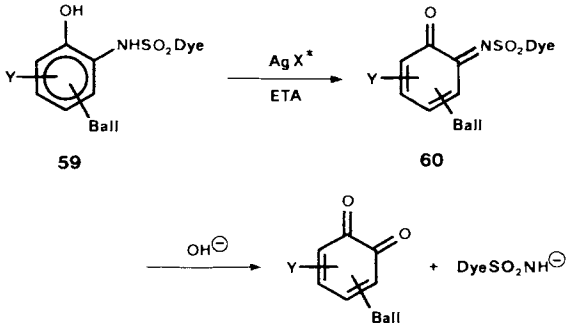
The opaque layers in the receiving element (Fig. 5) protect the image-recording element from daylight once the unit is ejected from the camera. Daylight protection from the other side is provided by components in the activator fluid.

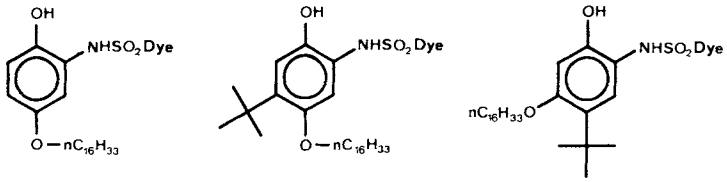
As described in Section 5.1 a rapid cleavage reaction is required (rate $k_c$ in Scheme 13). Structural variations, such as those cited above, are however of limited effect. A more efficient modification is the introduction of a nucleophilic substituent at a *peri*-position to the sulfonamido function[61] as *e.g.* in **57** (Scheme 20). Neighboring group parti-



Scheme 20. Faster and less pH-dependent dye release in the 4-sulfonamidonaphthol system by neighboring group participation.

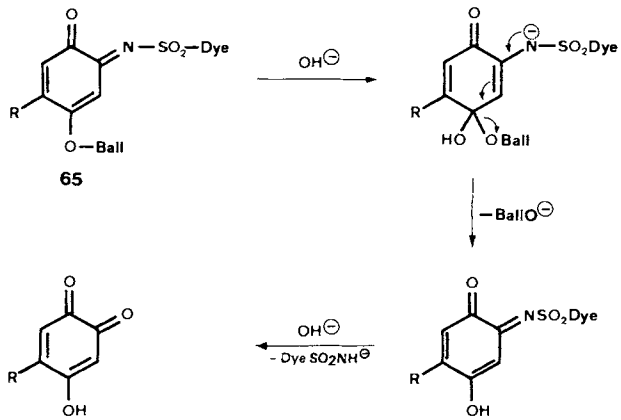
cipation in **58** should lead to much faster monomolecular release of dye, which should also be considerably less pH-dependent than its the bimolecular analog[62].

### 5.1.7. 2-Sulfonamido-Substituted Phenols and Naphthols



2-Sulfonamido-substituted phenols or naphthols undergo imagewise oxidative cleavage[63–67], presumably *via* a mechanism (Scheme 21) analogous to that outlined for their 4-isomers (Scheme 19).

59 60 61



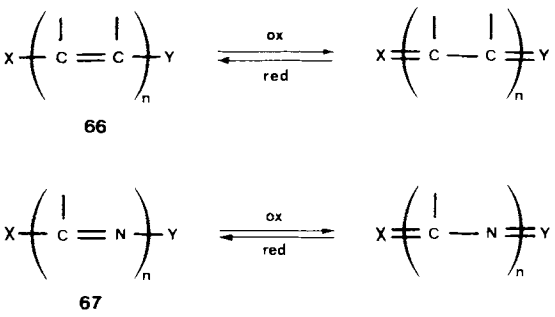
Scheme 21. Dye release by oxidation of 2-sulfonamido-substituted phenols **59** and subsequent hydrolysis of the resulting *o*-quinone imine derivatives **60**.

The topic has been extensively investigated in the Fuji laboratories[64–67], and several structural variations, *e.g.* compounds **62**—**64**, have been proposed. The 2-sulfonamido system has found commercial application in the recently launched Fuji instant photographic material.

62 63 64

Dye release may not always involve direct hydrolysis of the sulfonylimino group in **60**[68]. In compounds of type **65**

65

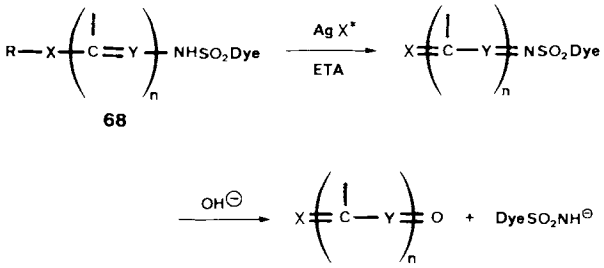


Scheme 22. Stepwise hydrolysis of some substituted *o*-quinone imine derivatives **65** (cf. Scheme 21).

the hydroxide ions initially attack the alkoxy- rather than the imino-substituted C atom (Scheme 22). The ballast group is removed *via* an addition-elimination reaction, followed by subsequent hydrolysis of the imino group.

Faster and less pH-dependent dye release can be achieved by neighboring group participation of nucleophilic substituents in the *o*-position to the sulfonamido group[61], by analogy to the effect of *peri*-substituents in 4-sulfonamido substituted 1-naphthols (see Section 5.1.6).

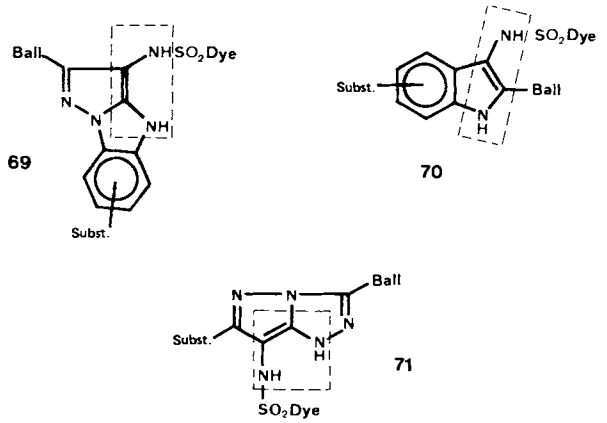
### 5.1.8. Other Sulfonamido Systems



According to the Kendall-Pelz rule[69,70], compounds containing the substructure **66** or **67** (see Scheme 23) are

66 67

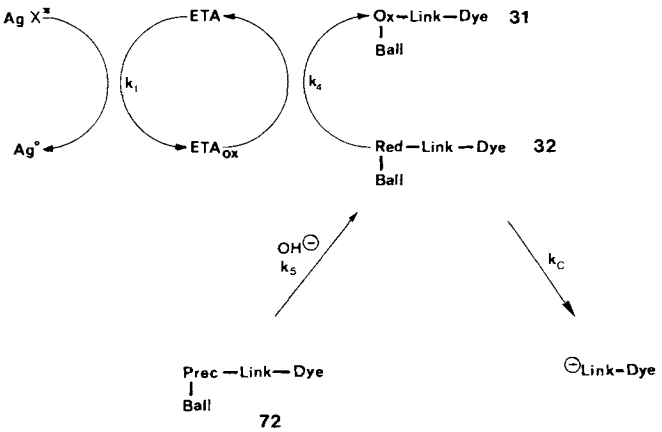
Scheme 23. The Kendall-Pelz rule predicts which compounds are potential silver halide developers. X, Y = OH, O-Acyl, $NR_2$, NHR; R = H, alkyl, acyl.



potential developers for silver halide. The sulfonamido-substituted phenols in Sections 5.1.6 and 5.1.7 follow this rule (X = OH, Y = $NHSO_2$-Dye, n = 2 or n = 1). The Kendall-Pelz rule, therefore, predicts that all molecules containing the moiety **68** could be potentially useful DRR compounds (see Scheme 24). The realization of this fact

68

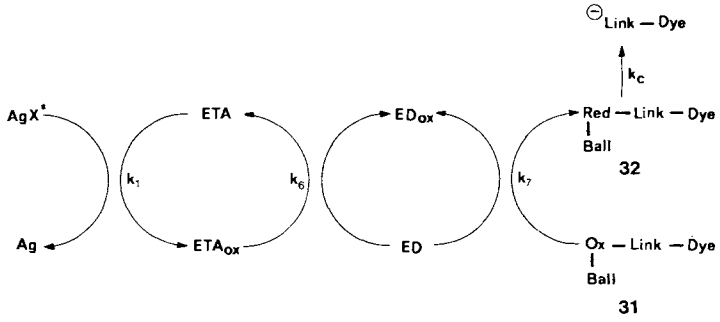
Scheme 24. Generalization of the sulfonamidophenol system on the basis of the Kendall-Pelz rule. X = O, NH; Y = CR', N; R = H, acyl.



prompted Agfa-Gevaert to develop systems based on sulfonamido-substituted pyrazolo[2,3-*a*]benzimidazoles **69**[71] and indoles **70**[72–75]. Proposals from other sources involve *e.g.* 5-hydroxypyrazoles[76], ketones[77], and pyrazolo[3,2-*c*][1,2,4]triazoles **71**[78] with sulfonamido substituents in the 4-, α-, and 7-position, respectively (for a review of other possibilities see [79]).

### 5.2. Dye Release in the Reduced State

In contrast to the situation for oxidatively cleavable DRR systems (see Section 5.1) there is no single general scheme applicable to reductively cleavable DRR systems. This is because for some cases the reduced inactive DRR compounds can be incorporated into the photographic material and activated by contact with alkali. The inactive form can contain either an undissociated version of the redox system (Prec) or an alkali-labile derivative.



Scheme 25 applies to such inactivated DRR molecules. For this operating mode the acronym *IHO*[80] has been coined. Here again the electron transfer agent (ETA) is necessary because of the presence of ballast groups in the DRR compounds (see Section 5.1). In non-exposed areas the alkaline medium converts the inactive precursor **72** into **32** by dissociation or deblocking (rate $k_5$); subsequent cleavage (rate $k_c$) releases diffusible dye. In exposed areas the cleavage reaction competes with oxidation (rate $k_4$) of **32** by $ETA_{ox}$ to the stable oxidized counterpart **31**.

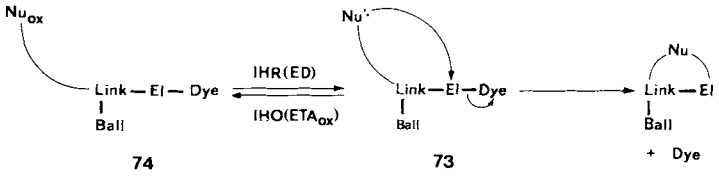
Scheme 25. Generalized reaction scheme for reductively cleavable DRR systems operating in the IHO mode [80].

If $k_4 \gg k_c$ oxidation effectively immobilizes dye, and good differentiation of exposed and non-exposed areas is achieved. This condition is not easily fulfilled, since in most IHO systems $k_c$ is very large *(vide infra)*. The use of protected derivatives rather than the undissociated parent redox system in **72** can alleviate the problem to some extent, since it allows an increase in the concentration of $ETA_{ox}$ by slowing down (relative to the unprotected analogue) conversion of **72** into **32**. As a consequence, the reaction **32** → **31** becomes more competitive. With large values of $k_c$, the competing cleavage reaction in exposed areas is always a nuisance.

The only way to overcome this is to use the *IHR* mode of operation (Scheme 26)[81]. In contrast to the IHO mode, a fourth redox pair $ED/ED_{ox}$[82] is required. It concerns

Scheme 26. Generalized reaction scheme for reductively cleaving DRR systems operating in the IHR mode [81].

ballast group-substituted reducing agents capable of reducing **31** to **32**, as well as $ETA_{ox}$ to ETA. In exposed areas, development of the latent image causes imagewise formation of $ETA_{ox}$, which oxidizes the electron donor ED to $ED_{ox}$, thereby removing the electron donor necessary for reduction of **31**. In unexposed areas ED is not attacked (no $ETA_{ox}$) and reduces **31** to **32**, thus causing release of dye. Several prerequisites must be fulfilled to achieve satisfactory performance. The redox potentials should correspond to inequality (f). The first and third inequalities



$$E^0(\mathrm{ED}) < E^0((\mathbf{31})/(\mathbf{32})) < E^0(\mathrm{ETA}) < E^0(\mathrm{Ag/AgX^*}) \qquad \text{(f)}$$

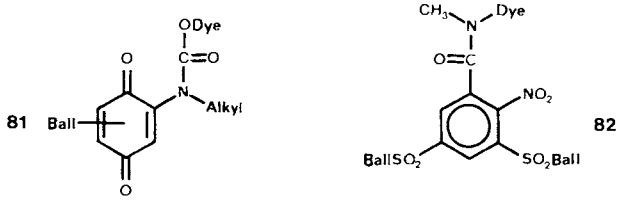
follow from the above description of the course of the reaction. The second ensures that ETA does not reduce **31** directly (in competition with ED) which would otherwise occur because of its high mobility (in contrast to ED substituted with ballast groups). From the kinetic point of view the condition $k_6 \gg k_7$ must be met in order to consume the electron donor in exposed areas. Both redox reactions are diffusion controlled and consequently the condition is fulfilled by using an electron donor with ballast groups and a very mobile $ETA_{ox}$. Also, $k_1 > k_6$ must be avoided, since this would lead to build up of $ETA_{ox}$.

Finally, the preceding discussions indicate that reductively cleavable DRR systems are positive working (see Section 2), irrespective of their operating mode. This is a great advantage over oxidatively cleavable systems, since it permits use of normal, negative-working silver halide layers!

#### 5.2.1. *Cleavage by Cyclization*

For an important group of reductively cleavable DRR systems dye is released by cyclization[83–86]. Both IHO and IHR modes are possible.

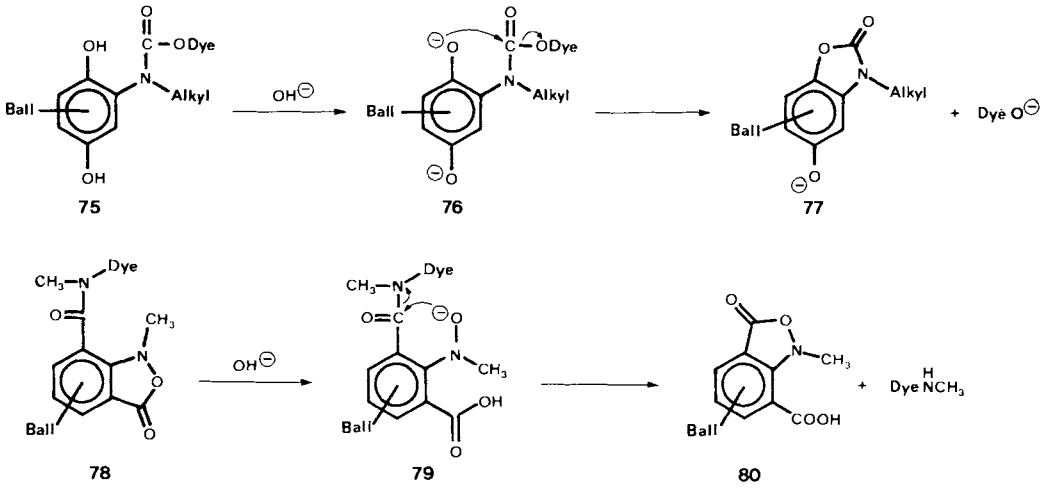
Scheme 27. Reductive dye release by cyclization reactions.



In the IHO mode[87] the ballast group-substituted active molecules **73** (see Scheme 27) contain an oxidizable nucleophilic group *Nu* (or a *Nu*-precursor) as well as an electrophilic group *El* bearing the fragment (*e.g.* a dye) to be released. Intramolecular attack of *Nu* on *El* yields the free fragment, *i.e.* in this case the dye. Oxidation of *Nu* to $Nu_{ox}$ (by $ETA_{ox}$) makes cyclization impossible. In an alternative application, the substituents are exchanged: cleavage of the ballast group then releases the rest of the molecule.

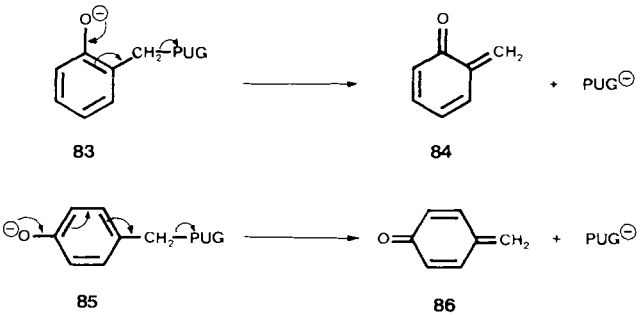
Two patent applications have been made for *IND* systems[87] by Eastman Kodak: one is based on *N*-(2,5-dihydroxyphenyl)urethanes **75**[73] and the other on benzisoxazolones **78**[84] (see Scheme 28). The system **75**→**76**→**77** makes use of the extremely high rate of cyclization ($k_{obs} > 2\,sec^{-1}$!) of *N*-(2-hydroxyphenyl)carbamates[88] in alkaline media, and provides the possibility of oxidative inactivation of the phenolic function by incorporation into a hydroquinone group.

**78**→**79**→**80** is an example of a system in which the redox system (a hydroxylamine anion, see **79**) is protected (see discussion of Scheme 25) as an alkali-labile derivative (benzisoxazole **78**). Here use is made of rapid cyclization[89] of 2-(hydroxylamino)benzamides to benzisoxazoles (*e.g.* **80**). Oxidation of **79** by $ETA_{ox}$ converts the hydroxylamine anion into a nitryl radical, which is unable to act as a nucleophile.



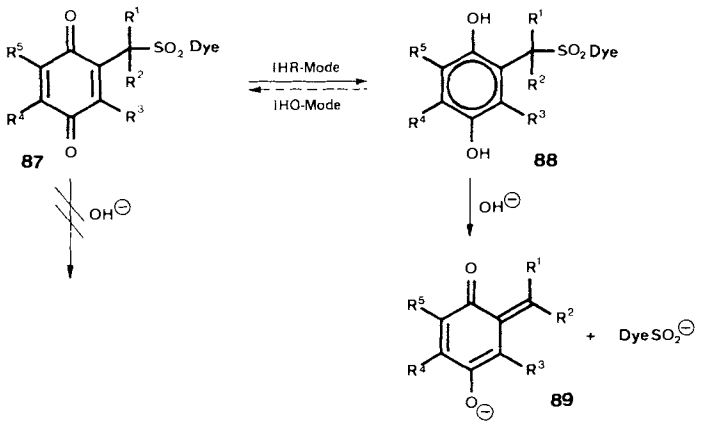
In the IHR mode[90] compounds **74** are used containing an oxidized nucleophilic group $Nu_{ox}$ (Scheme 27), which by electron acceptance (*i.e.* reduction by ED, see Scheme 26) is converted into the active nucleophile *Nu* (in **73**): this initiates cyclization and concomitant dye release.

Both of the IHO mode cyclizing systems have an IHR mode counterpart containing the oxidized redox function. Compounds **81** correspond to **75**, whereas the nitro group in **82** is the oxidized precursor of the hydroxylamine function in **79**. Because of their electron withdrawing effect the two sulfonyl substituents, reduce the electron density at the nitro function in **82** and make it amenable to reduction by practical ED compounds (instead of *e.g.* by $H_2$ or $NaBH_4$[89]).



### 5.2.2. *Quinonemethide Formation*

2- and 4-Hydroxybenzyl derivatives of photographic reagents have been described as their alkali-labile precursors[91,92]. The release of the photographically useful groups (PUG in Scheme 29) is caused by formation of the quinonemethides[93] **84** and **86**.



Scheme 28. Examples of cyclization-based DRR systems operating in the IHO mode (IND systems [87]).

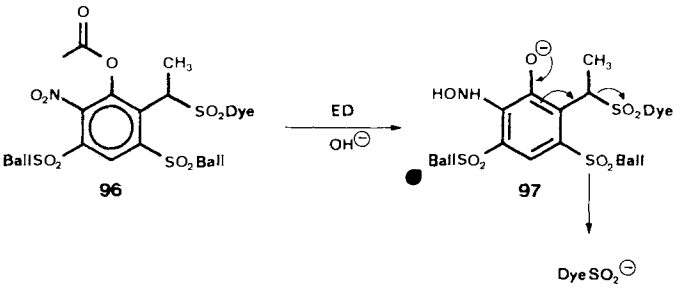
Kinetic data[94,95] suggest that some hydroxybenzyl sulfones could react sufficiently fast at high pH-values to be

Scheme 29. Release of photographically useful groups, PUG (*e.g.* dyes) by quinonemethide formation.

of practical use for diffusion transfer purposes. As discussed in Section 2, this requires that the reactions shown in Scheme 29 should be redox-controlled, and this is readily achieved by incorporation of the phenolic function into a hydroquinone (or catechol) unit. This is the basis of the Agfa-Gevaert quinonemethide system (Scheme 30).

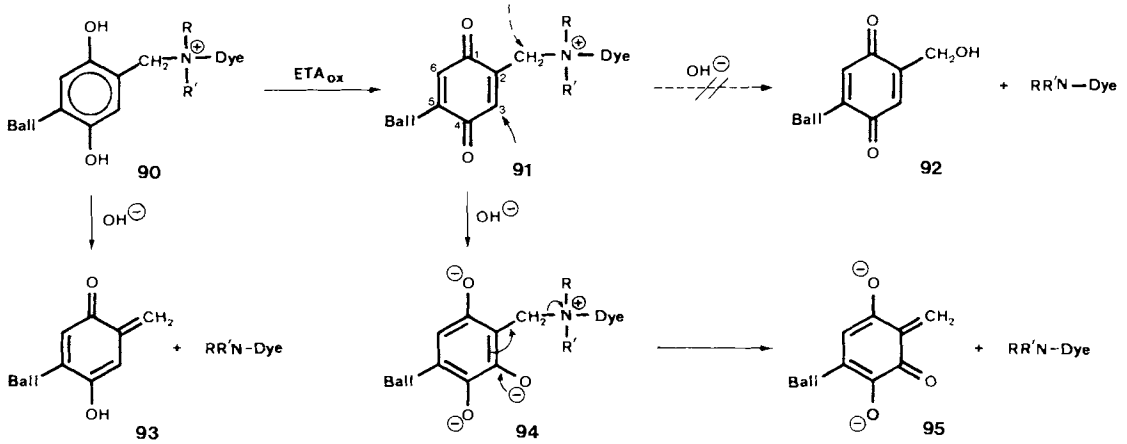
Scheme 30. Use of redox-controlled formation of quinonemethides, such as **89**, for anti-imagewise dye release (see text for additional explanations).

In the IHO mode[80] the hydroquinones **88** are incorporated into the material[96,97]. One of the substituents $R^1$–$R^5$ acts as a ballast group, which makes **88** non-diffusing. In exposed areas, oxidation of **88** to **87** by $ETA_{ox}$ (cf. also Scheme 25) blocks cleavage, whereas in non-exposed areas quinonemethide **89** and diffusible dye are formed.



In the IHR mode[81] the quinones **87** are incorporated into the material[98,99]; in this case their use (see Scheme 26) necessitates the introduction of an electron donor (ED). In exposed areas this ED is oxidized by $ETA_{ox}$, and is no longer available for reduction of **87**. In unexposed areas **87** is reduced to **88** by unspent ED and undergoes alkali-induced dye release.

In this context mention should be made of an earlier system based on dye releasing hydroquinone derivatives of type **90** having a quaternary ammonium group bonded to an α-methylene group[100].

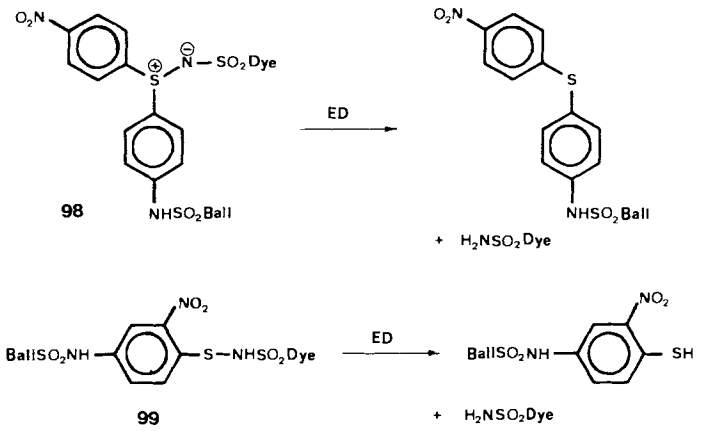


The system produces imagewise dye release (**90**→**91**→**92**, Scheme 31) assuming that hydrolysis ($S_N2$ type!) of **90** is sufficiently slower than that of **91** to differentiate between exposed and non-exposed areas. This rationale does not hold. In our opinion the strong inductive attraction which the positively charged nitrogen atom exerts on the enone CC double bond must be considered. As a result C-3 in **91** becomes a very strong electrophilic center[101], much stronger than C-5 and C-6, and, hence, becomes the preferential site of attack. Hydroxide addition to **91** followed by enolization leads to **94**, in which the normal quinonemethide mechanism operates to release the dye.

It could be asked why the direct formation of **93** from **90** does not compete with the longer route **90**→**91**→**94**→**95**. The higher electron density in **94** with respect to doubly ionized **90** makes reaction **94**→**95** faster than **90**→**93**. Since oxidation of **90** with $ETA_{ox}$ is extremely fast, one is, therefore, forced to conclude that the conversion **91**→**94** is also faster than cleavage of **90** to **93**. In view of the reactivity of C-3 in **91**, this is not entirely surprising. In any case, in the IHO mode[100] the competition between reactions **90**→**93** and **90**→**95** in exposed areas precludes good differentiation between exposed and non-exposed areas. On the other hand, the IHR mode is unpractical because the reactivity of **91** makes it impossible to incorporate into a gelatine layer.

For the system in Scheme 30 the sulfonyl group does not strongly activate the enone CC double bond. Hence, the—here unwanted—side reaction of the type **91**→**94** is strongly retarded and quinonemethide formation

Scheme 32. Quinonemethide formation is blocked by a deactivating nitro group; reductive deblocking in alkaline medium releases dye.



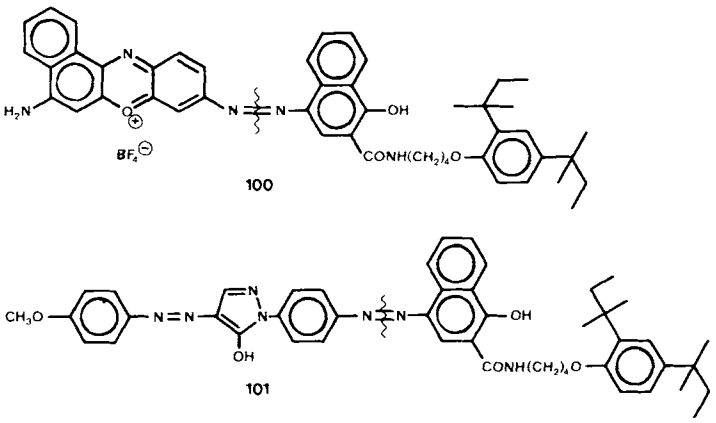
Scheme 31. How is the dye released from **90**?

**88**→**89** dominates. A substituent at C-3[97–99] helps to differentiate between exposed and non-exposed areas.

Another application of quinonemethide chemistry makes use of the deactivating effect of a nitro group (Scheme 32)[102]. Only after reduction of the nitro group in **96** by unspent ED (*i.e.* in non-exposed areas) and subsequent hydrolysis of the acetyl group is dye release (in **97**) possible. The system is a hybrid of the nitro-*BEND*[90] (*e.g.* compound **82**) and the quinonemethide systems (Scheme 29).

### 5.2.3. *Sulfilimines and Sulfenylsulfonamides*

Characteristic for the systems discussed in Sections 5.2.1 and 5.2.2 is that the redox system and the bond to be cleaved are separate chemical entities which can interact if the redox system is in its reduced state. Other potentially useful systems[103] are conceivable in which the redox system and the bond to be cleaved form a unit: here "true reductive-cleavage" is necessary to bring about dye release. So far, only sulfilimines (*e.g.* **98**) and sulfenylsulfonamides (*e.g.* **99**) have been claimed for this class[104]. These compounds can undergo reductive S–N bond cleavage[105, 106], which can be used (see Scheme 33) in an IHR-type system (see Scheme 26).

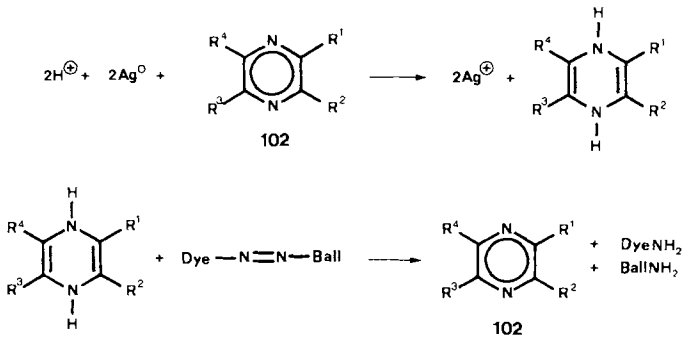


Scheme 33. Direct reductive cleavage of sulfilimines **98** and sulfenylsulfonamides **99**.

### 5.2.4. *Dye-Bleach Chemistry*

All dye-transfer systems discussed so far operate in the alkaline development medium. The *silver dye-bleach process*[107], however, functions in strong acid and can also be adapted to diffusion transfer[108–110]. The basic reaction involved is the reductive cleavage of an azo bond in acidic media.

$$\text{Dye–N=N–Ball} + 4\,H^{\oplus} \longrightarrow \text{Dye–NH}_2 + \text{Ball–NH}_2 \qquad \text{(g)}$$



Examples of *bleach-type dye releasers* are **100** and **101**. Upon reduction, the indicated azo compounds are cleaved and an oxazine and azopyrazolone dye, respectively, are released. Also useful are phenazine, thiazine, acridine, pyrylium, rhodamine[108], as well as anthraquinone dyes[109].

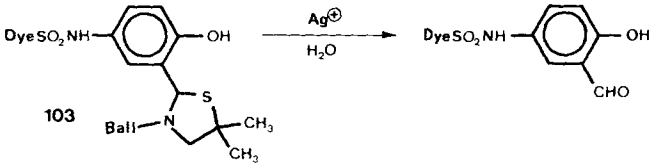
In a first mode of operation, exposure is followed by treatment with an acidic solution of a *Dymodev* compound[111]. In non-exposed areas unspent *Dymodev* "*dy*e *mo*difiying and *dev*eloping" compound reduces the azo bond, resulting in release of dye and its diffusion. In exposed areas the *Dymodev* compound is consumed in developing the silver halide and is not available for dye release. Anti-imagewise dye transfer occurs, *i.e.* the system is positive working.

Alternatively, the material is first subjected to conventional black and white development: a silver image results. Subsequently the azo bond is reduced in a dye-bleach bath[112] (see Scheme 34); **102** is an example of a dye-bleach catalyst. Dye diffusion occurs imagewise and a negative-transferred image results.

The dye-bleach procedures outlined here are not limited to azo compounds: hydrazide, azoxy, imino, and α-amino carbonyl functions can also be used[109].

Scheme 34. Two-stage dye diffusion based on dye bleach chemistry. After a black and white development step producing metallic silver, the material is exposed to an acidic solution of a dye-bleach catalyst **102**. The catalyst is reduced by $Ag^0$ and in turn subsequently reduces the azo bond, thereby releasing dye and regenerating **102**.

## 6. Reaction with Silver Ions

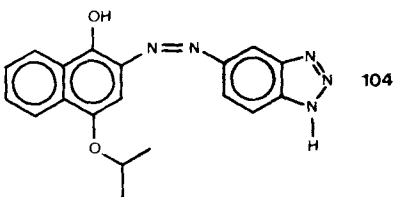


In the previously discussed systems redox-controlled mobility changes are achieved by incorporation of a redox system into a dye or dye precursor. Another possibility is to use dyes or dye precursors which contain no active redox system (under the conditions of development), but are able to react with free silver ions. In presence of complexing agents for $Ag^+$, the development step should yield an anti-imagewise distribution of silver ion complex and free

silver ions, and thus induce an anti-imagewise interaction with dye precursor. Patent applications have been made for both complexation and argentolysis.

### 6.1. Argentolytic Reactions

Thioaminals[113,114] have been patented which undergo argentolysis to form their ketone or aldehyde precursors. In a first application[113] mobile ketones or aldehydes are released which migrate to a receiving layer and condense with an active methylene compound to yield a dye (anti-imagewise, positive-working system). Useful methylene compounds include α-cyanoacetanilides, 1,3-dimethylthiobarbituric acid, and malonitrile. Alternately, both carbonyl and methylene compounds capable of diffusing can be liberated anti-imagewise. This version is required for multicolor material.

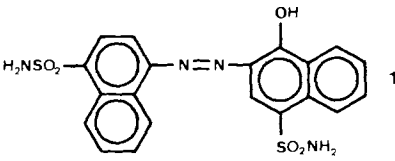


Far more attractive is the second application[114] involving compounds such as **103**, which contain the partial structures –S–C–N– or –S–C–N= (or vinylogs thereof) and release a diffusible dye by argentolysis (see Scheme 35). A similar result is obtained with thiol esters of the type Ball–S–CO–Dye[115].

Scheme 35. Argentolytic cleavage of (cyclic) thioaminals.

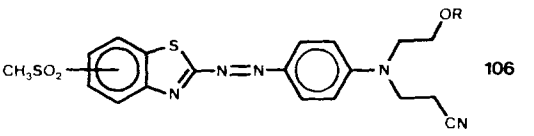
### 6.2. Complexation

Heterocycles, such as benzotriazoles and thiazolethiols, form strong complexes with $Ag^+$ ions which are insoluble in aqueous media. In consequence, dye molecules such as **104** which contain such moities are immobilized anti-imagewise upon development[116].



104

Dye diffusion occurs imagewise and yields a negative transferred image. The same result can also be achieved by incorporating the silver salts of such heterocyclic dyes into a material[117]. In exposed areas the metallic silver produced during development strongly catalyzes dissociation of these salts and reduction of the $Ag^+$ ions thus liberated.

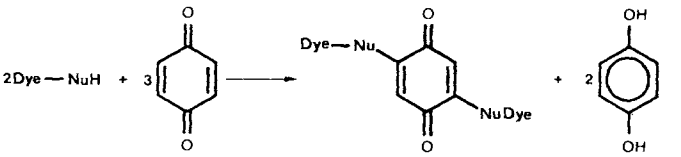


## 7. Other Systems

### 7.1. pH-Controlled Diffusion

Dyes can be used[118] which are only diffusible in alkaline media (*e.g.* **105**). The developer fluid contains the stoichiometric amount of alkali required for the reduction of the silver halide present. As a result, all the alkali is consumed in fully exposed areas, and no dye-diffusion can occur. In non-exposed areas unspent alkali converts the dyes into ions which migrate to a receiving layer (positive-working system). In another modification[119] dyes can be used which are non-diffusing in alkaline medium: for example,

105

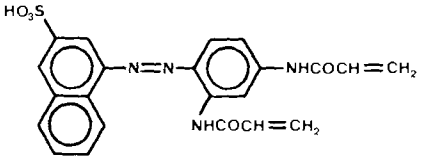


106

**106** first becomes mobile following protonation. Since development of exposed silver halide causes a decrease in pH, imagewise dye migration could be achieved (negative-working system).

### 7.2. Immobilization by Addition Reactions

p-Benzoquinones add nucleophiles such as amines or electron-rich alkenes (*e.g.* enamines)[41]. This property can be used[120] to immobilize dyes if the latter contain a sufficiently nucleophilic function (*Nu*), which can add to the *p*-benzoquinone generated in exposed areas when a hydroquinone is used as developer (Scheme 36). Since *p*-benzoquinone has four reactive centers, more than one addition occurs and the mobility of the dye is drastically reduced.



Scheme 36. Dye immobilization by addition to *p*-benzoquinone. Since the adducts are more electron-rich than hydroquinone, they are oxidized to quinones.

Due to steric effects probably only two molecules add, presumably at C-2 and C-5[41]. Introduction of two nucleophilic groups into the dye molecule leads to polymerization. Since immobilization occurs imagewise, a positive-working system is involved.

Not only dyes, but any dye-forming component can be similarly immobilized to yield an anti-imagewise distribution of this component in a receiving layer. It only requires that this layer also contains a reactant with which the component can react to form a dye. A system of this type is based on the addition of enamines to *p*-benzoquinones[121].

### 7.3. Immobilization by Polymerization

Dye molecules, such as **107**, which contain polymerizable functions can be oxidatively immobilized if the oxidation product of the silver halide developer is an active initiator for polymerization[122]. Suitable developers are acylhydrazides or sulfonylhydrazides, as well as hydroxylamines.

**107**

## 8. Concluding Remarks

The present review article illustrates how vast the field of dye diffusion photography is, particularly for organic chemists. Organic chemistry is, in fact, the source of all the systems discussed. Quite likely this trend will continue, since new ideas and mechanisms are constantly appearing: the source is certainly not drying out. This is fortunate, since only a few of the systems proposed and studied have found commercial application. Although all systems described here fulfill the basic requirement of exposure-modulated diffusion, most of them apparently have not met the exacting photographic requirements, even after extensive optimization. We will undoubtedly witness the discovery of new mechanisms for dye diffusion transfer in the near future[123]. Rewarding perspectives continue to be opened, particularly with regard to image quality. In view of growing competition from constantly improving electronic imaging systems, this is gratifying.

*I am indebted to Dr. J. Jaeken for introducing me to the field of dye diffusion transfer, to Dr. W. Janssens for the many valuable discussions, and to the entire staff of the Chemistry Department for their continuing assistance.*

# Symmetry Breaking and Non-Born-Oppenheimer Effects in Radical Cations

By Horst Köppel, Lorenz S. Cederbaum*, Wolfgang Domcke, and Sason S. Shaik

The various electronic states in which molecules can exist are often considered to be independent. In this article we turn our attention to the limitations of this assumption, namely the interaction between different electronic states through the nuclear motion. This interaction can have several important consequences, two of which are discussed in some detail. One is a distortion of the molecular framework, leading to a lowering of the symmetry of a molecule in excited or ionic states compared to the neutral ground state. General aspects of this symmetry lowering are outlined and interpreted with the aid of typical examples. The other consequence considered is the ability of the nuclei to "jump" between different molecular potential energy surfaces (non-Born-Oppenheimer effects). The nature of this behavior is analyzed and it is argued that the "jumping" can be very fast and efficient, dominating completely the nuclear motion. To exemplify our general ideas we refer to the photoelectron spectra of ethylene and related compounds and demonstrate that they are governed by strong non-Born-Oppenheimer effects. It emerges that the Franck-Condon principle fails in the analysis of their vibronic structure.

## 1. Introduction

A knowledge of molecular structure is of primary importance in chemistry. Besides the intrinsic interest in the structure as such, it contains essential information on bonding properties, chemical reactivity *etc.* and has therefore been the subject of numerous investigations. Almost equally important is the phenomenon that most molecules *change* their shape when going from the neutral ground state to electronically excited or ionized states. Often this amounts to a decrease in the molecular symmetry. For example, many linear molecules, such as $CO_2$[1a], $CS_2$[1b], HCN[1c] or $C_2H_2$[1d] are known to become bent upon electron excitation[1e] or electron attachment[1f]. Symmetrical $XY_2$ molecules can acquire unequal bond lengths ($SO_2$[2a], $NO_2$[2b], $ClO_2$[2c]), planar molecules may become nonplanar ($H_2CO$[3a], HCOF[3b], $Cl_2CS$[3a]). Among many other examples we mention asymmetric ring distortions in benzene[4a] and in *p*-benzoquinone[4b], and a twisting around the central C=C bond in ethylene[5a], stilbene[5b] and thioindigo[5c]. Clearly, the phenomenon of symmetry lowering or symmetry breaking in electronically excited states is so widespread that it deserves special attention and calls for an explanation.

In the following article we present and discuss a mechanism that enables one to *understand* the observation of symmetry breaking in electronically excited or ionic states. To be sure, the amount of the distortion can, in principle, always be determined by calculating the potential surface (the potential energy of the molecular system) point by point, either by ab initio or by semiempirical techniques. What we have in mind here, however, is rather to *explain* the experimental findings in simple terms, to relate the distortion to a few elementary molecular parameters and to rationalize the trends observed in chemically related compounds.

The mechanism we wish to describe is commonly termed "vibronic coupling" in the literature. It deals with the *interaction of two (or more) energetically close-lying electronic states of a molecule through the nuclear motion.* This leads to a joint *vib*rational and elec*tronic* motion in the molecule and can account also for other interesting observations (see below). Distortions of the nuclear framework are described in this approach in terms of a mutual repulsion of the potential energy surfaces of the interacting states. Under certain well defined conditions this leads to a double minimum structure of the lower surface which just corresponds to a lower symmetry of the respective state compared to the neutral ground state.

Vibronic coupling is a well established subject in optical spectroscopy and there is a wealth of literature available on the subject[7, 8]. As already mentioned, the explanation of symmetry lowering[4] and related "anomalous" potential curves[8l, q] is only one aspect of the mechanism. It can account also for many other features of the vibrational structure of electronic bands which are not understood within the picture of independent electronic states. For example, one often observes[8e, p] vibronic bands which are symmetry forbidden according to the usual selection rules for electric dipole transitions[7d]. This is rationalized in terms of a "borrowing" of intensity from another electronic state[7b]. Closely related is the loss of mirror symmetry[8n] between an absorption and the corresponding emission band[7d]. Finally, what appears to us most interesting, is the observation that the high energy electronic bands often exhibit a much more diffuse (large molecules) or erratic (small molecules) fine structure than the low energy bands[8d, g]. In this case regular vibrational progressions are completely absent and *the nuclear motion no longer takes place on a single potential energy surface*[8d] (non-Born-Oppenheimer

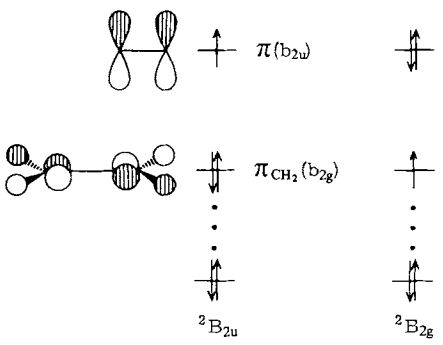
or nonadiabatic effects). It appears that these latter effects might occur even more often than the aforementioned effect of symmetry breaking. They have been identified in a large number of aromatic and heteroaromatic molecules[8d-s]. In this connection, benzene[4a], pyrazine[8m] and naphthalene[8g] have been particularly well studied. A quite different class of molecules is provided by the mixed-valence compounds[8t] and by molecular dimers[8a-c]. However, despite considerable effort a quantitative analysis of the data has so far mostly proven impossible. Even for a molecule as small as $NO_2$, after decades of work the clarification of the interactions remains an outstanding challenge to experimentalists and theoreticians[8u].

It is not the purpose of this article to review all these developments in the field in detail. Rather, we wish to focus on a particular area where considerable progress has been made over the past few years, namely the field of molecular ions[9] (especially radical cations). Such a limitation is justified, not only because of the increasing interest in molecular ions themselves[6], but for several other reasons. Firstly, a rather accurate theoretical description of the vibronic coupling effects in ions has proven possible, allowing for a detailed understanding of the nuclear motion in the interacting electronic states[9]. This was realized through concentrating on rather small systems where accurate (ab initio) computational schemes are available. The results can also help towards an understanding of larger chemical systems. Secondly, an interpretation of the effects is usually simpler in the case of ions than in the case of excited states of the neutral species, since the interaction between the ionic *states* can be reduced to an interaction between molecular *orbitals*. For excited states of the neutral molecule a description in terms of orbitals and orbital interactions is generally only a poor approximation and often completely impossible[10]. For ions, the orbital picture allows for an attractive visualization of the effects and for the use of simple qualitative (semiempirical) schemes to estimate their magnitude. Finally, from the experimental point of view, for ionization spectra there exist neither the dipole selection rules nor the emission process ("inverse" to the ionization) which are pertinent to the absorption spectra[11]. Hence, increased importance attaches to the aforementioned diffuseness of the bands, since this is now the dominating dynamic effect (*i.e.* involving the nuclear motion) of the vibronic coupling. Besides the effect of symmetry lowering, the nonadiabatic nature of the nuclear motion will therefore be the second cornerstone of this article. Anticipating our findings, the nonadiabatic effects turn out to be surprisingly strong, due to the intimate interplay of several modes participating in the vibronic coupling.

Nonadiabatic transitions between different potential energy surfaces are important not only in spectroscopy but also in many other chemical processes. Often, for example, fragmentation of a molecule occurs even if a bound electronic state is populated initially (predissociation[7d]). Typical *photoreactions* proceed *via* light-excitation of the reactants and subsequent formation of the product molecules in the ground state. Conversely, in chemiluminescent reactions the products are formed in excited states under thermal conditions, *i.e.* starting with ground state reactants[7u]. All these observations are rationalized in terms of nonadiabatic transitions between the different potential energy surfaces. However, the discussion is usually only qualitative and only takes a single nuclear coordinate into consideration. The present work should contribute to an understanding of nonadiabatic nuclear motion—and especially the influence of *several* nuclear degrees of freedom—in more detail than was possible before. Thus, it could be an important step to a more quantitative calculation of the corresponding chemical reaction rates.

We might emphasize at this juncture that our concept is of course *not* restricted to molecular ions. Only in our applications shall we refer to the case of ionization or, more precisely, to the vibrational structure of photoelectron bands[11]. To have something specific in mind we will use the photoelectron spectra of the hydrocarbons

$$H_2C{=}(C{=})_nCH_2 \quad \mathbf{1} \quad (n = 0\text{–}3)$$



and some related compounds as examples. First of all, let us mention the photoelectron spectrum of butatriene (**1**, n = 2). This spectrum exhibits three low energy bands, of which the central one could not be assigned to any of the high binding molecular orbitals, and was termed "*the mystery band*"[12]. No such band was observed in the spectrum of the tetramethyl and tetra-*tert*-butyl derivatives of butatriene[12a]. Interestingly, the complex band structure for butatriene broadly resembles that for allene[13a] (**1**, n = 1) and for pentatetraene[13c] (**1**, n = 3), which was attributed to a Jahn-Teller instability[13b]. Even in the simplest member of the series, ethylene (**1**, n = 0), the first photoelectron band corresponding to the π molecular orbital is quite complex, and shows a strong excitation of the torsional mode[14]. On the other hand, in substituted ethylenes like fluoroethylene, the first band is accompanied mainly by a normal progression of the C=C stretching mode[15]. What we have here is a family of compounds whose members exhibit a different degree of vibronic coupling, depending on the number of double bonds and the number and type of substituents. The spectra of these compounds indicate that the *vibronic coupling always involves the torsional mode together with at least one stretching mode*. Thus, the vibronic coupling that we are going to describe involves many active modes, all of which contribute simultaneously to the spectral and geometrical features of the ion.

For the exposition of our general ideas we will begin with the smallest member of the family—the ethylene molecule. We will first attempt to gain an insight into the determinants affecting the structure of its positive ion, and then develop simple rules for understanding the structure—spectrum relationship. The chemical significance of the mechanism shall then be explored by studying the structural and spectral features of the higher homologues of ethylene and of some of their derivatives.

## 2. The Vibronic Coupling Model and the Adiabatic Potential Energy Surfaces

The two lowest electronic states of the ethylene cation arise by removal of an electron from either of the two high lying ground state-occupied molecular orbitals, $\pi(b_{2u})$ and

$\pi_{CH_2}(b_{2g})$. These are the $^2B_{2u}$ and the $^2B_{2g}$ states, respectively, in $D_{2h}$ symmetry, each of which we describe by a single configuration:

(1)

Why do we restrict ourselves to these two ionic states? Simply because they are close in energy and the ionic ground state is well separated from the other ionic configurations, in the valence region[9b].

Consider now a torsion of the terminal $CH_2$ groups around the central C=C bond. When the twisting is effected, the two orbitals acquire the same symmetry and hence can have non-vanishing overlap. Since both orbitals involve similar atomic wave functions at the C atoms (2p type functions perpendicular to the C=C double bond) this overlap may become quite large. As a result, the electronic Hamiltonian operator of the molecule will have a substantial nondiagonal element between the two configurations (1). The true ionic states, defined as eigenvectors of the Hamiltonian, are therefore a mixture of these configurations.

To investigate the consequences of this mixing we formulate now a suitable model Hamiltonian $\mathscr{H}$. As we are dealing with two electronic states, we represent the Hamiltonian as a $2\times 2$ matrix

$$\mathscr{H} = \begin{pmatrix} H_{11} & H_{12} \\ H_{21} & H_{22} \end{pmatrix} \tag{2a}$$

where the element $H_{11}(H_{22})$ is the energy of the pure configuration $^2B_{2u}$ ($^2B_{2g}$) and the nondiagonal element $H_{12}$ is responsible for the mixing that occurs upon twisting[16]. The elements $H_{ij}$ (i, j = 1, 2) are functions of the nuclear coordinates. In what follows we use the normal coordinates of the neutral molecule[17]. For the moment we include only the torsion or twisting coordinate $Q_u$ and the C=C stretching coordinate $Q_g$ ($Q_g = Q_u = 0$ represents the equilibrium geometry of the ground state of the neutral molecule). In the vicinity of the equilibrium geometry of the neutral molecule the matrix elements $H_{ij}$ (i, j = 1, 2) can be approximated by the following simple expressions:

$$H_{ii} = \frac{\omega_g}{2} Q_g^2 + \frac{\omega_u}{2} Q_u^2 + E_i + \kappa_i Q_g \quad (i = 1, 2)$$
$$H_{12} = \lambda Q_u = H_{21} \tag{2b}$$

Here the first two terms in $H_{11}$ and $H_{22}$ describe the harmonic potential energy surface of the neutral molecule in its electronic ground state; $\omega_g$ und $\omega_u$ are the vibrational frequencies of the C=C stretching- and torsional-modes, respectively. The other terms account for the changes in the potential energy that occur upon ionization. $E_i$ (i = 1, 2) denotes the energy of either of the ionic states at $Q_g = Q_u = 0$, measured with respect to the neutral species. The terms $\kappa_i Q_g$ (i = 1, 2) and $\lambda Q_u$ are responsible for the change in shape of the potential curves on going from the neutral molecule to the ion. The parameters $\kappa_i$ and $\lambda$ are the so-called coupling constants[9, 18].

In order to find out which modes should be taken into account in the Hamiltonian we take recourse to symmetry considerations. Elementary selection rules tell us that the mode $Q_u$ must have the symmetry of the product of the electronic states in order to produce a mixing. In the case of the ethylene cation, we have

$$B_{2u} \times B_{2g} = A_u \tag{3}$$

and $A_u$ is just the symmetry of the torsional mode. The mode $Q_g$, on the other hand, can be any of the totally symmetric modes and, in principle, all of these modes should be retained. It is only for the purpose of illustration that we confine ourselves here to the C=C stretching mode.

What are the meaning and chemical implications of the above Hamiltonian? To develop a qualitative feeling we will examine now the adiabatic potential energy surfaces, *i.e.* the energies of the true ionic states, which follow from eq. (2).

Let us start by ignoring the totally symmetric mode. The adiabatic potentials $V_1$ and $V_2$ are the eigenvalues of the $2\times 2$ matrix $\mathscr{H}$. A simple calculation gives

$$V_1 = \frac{\omega_u}{2} Q_u^2 + \frac{1}{2}\left[E_1 + E_2 - \sqrt{(E_1 - E_2)^2 + 4\lambda^2 Q_u^2}\right] \tag{4a}$$

$$V_2 = \frac{\omega_u}{2} Q_u^2 + \frac{1}{2}\left[E_1 + E_2 + \sqrt{(E_1 - E_2)^2 + 4\lambda^2 Q_u^2}\right] \tag{4b}$$

They are drawn in Figure 1c for parameters representing ethylene. The lower of the two curves, representing the ionic ground state, exhibits a double minimum, *i.e.* two

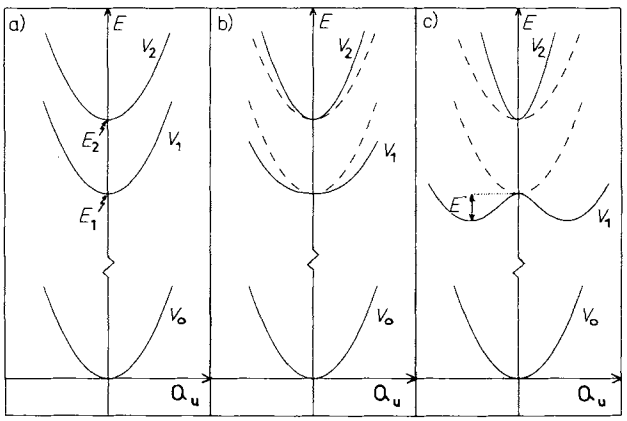


Fig. 1. Diabatic (dashed lines) and adiabatic (full lines) torsional potential curves for the two lowest cationic states of ethylene ($V_1$ and $V_2$ according to eq. (4), schematic). In each case the potential curve $V_0$ of the neutral state is also shown, assuming the same frequency $\omega_u$ for all the states. $E_1$ and $E_2$ are the vertical ionization potentials. Vibronic coupling is shown only for the ionic states.—a) A case of zero coupling $\lambda = 0$.—b) The limit of weak vibronic coupling.—c) A case of a strong vibronic coupling; $E^*$ is the barrier for becoming planar.

symmetric minima at nonzero values of the torsional coordinate $Q_u$ and a maximum at the planar geometry $Q_u = 0$. This means that the ionic ground state is nonplanar, with a torsional angle at equilibrium given by the minima of the lower surface $V_1$.

The appearance of the nonplanar equilibrium geometry might seem surprising at first sight. Let us therefore try to interpret it on a more qualitative level, in terms of orbitals and orbital interactions. There are two basically different contributions to the ionic potential energies. One is the repulsive diagonal term, $1/2\omega_u Q_u^2$, which expresses the reluctance of the *pure* configurations ($^2B_{2g}$ and $^2B_{2u}$) to distort. This just reflects the behavior of the $\pi$ orbital which is occupied by 1 electron in the $^2B_{2u}$ state and by 2 electrons in the $^2B_{2g}$ state and whose energy increases upon twisting (in the same way the presence of two electrons in the $\pi$ orbital makes the neutral molecule planar). Secondly, the effect of orbital mixing must be taken into account. In the $^2B_{2u}$ ground state it involves three electrons, two of which occupy the $\pi_{CH_2}$ orbital which is stabilized by the interaction, and one occupies the $\pi$ orbital which is destabilized by the interaction (cf. Fig. 2a). The net result is roughly the stabilization of one electron[19a]. If this gain in binding energy is sufficiently large (as in ethylene), it overcomes the previously discussed energy rise inherent in the twisting of the $\pi$ orbital. Consequently, the potential of the ground state cation exhibits a double minimum, leading to a nonplanar structure. Unlike the ground state, the upper cationic state which originates from the planar $^2B_{2g}$ state, remains planar, since now the net result of distortion is the destabilization of one electron (Fig. 2b).

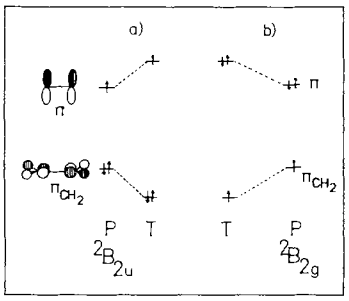

Fig. 2. The $\pi$-$\pi_{CH_2}$ orbital interaction upon distortion of the $CH_2$-terminal groups in the ethylene cation from planarity at some angle $0° < \alpha < 90°$. P denotes planar and T twisted conformation.—a) The ground state of the cation.—b) First excited state of the cation.—Note the difference of the orbital population in the two states. The energy changes shown are due only to the orbital interaction.

We can gain more insight into the reasons behind the distortion of the ground state cation away from planarity, if we consider the bonding characteristics of the cation. The doubly occupied lower orbital of the twisted cation is now $\pi_{CH_2}$ mixed with some of the $\pi$ orbital which is C=C bonding. Thus, there is a net gain of C=C bonding upon distortion in the ground state of the cation (Fig. 2a). Exactly the opposite situation obtains in the upper cationic state. Here there are two electrons in the $\pi$ orbital which combines with it some of the C=C antibonding $\pi_{CH_2}$ orbital. The net result is a weakening of the C=C bonding upon distortion and, therefore, the preferred geometry of the upper cationic state remains planar (Fig. 2b).

The importance of this orbital interaction for the stabilization of a nonplanar structure of the radical cation and the Rydberg state of ethylene was noted quite some time ago by *Mulliken*[19b,c], who gave this interaction the name "isovalent hyperconjugation", meaning the delocalization of electrons from a pure p or $\pi$ orbital to a pseudo $\pi$ orbital ($\pi_{CH_2}$). The result of this delocalization is a strengthening of the C=C bonding, which was described by *Mulliken* in terms of additional resonance structures which contain a full $\pi$ bond[19b].

We have now managed to relate the predictions of the vibronic coupling model for ethylene to simple molecular orbital considerations. We see from this example that vibronic coupling is a mechanism that leads to a lowering of the symmetry of cations as compared to the neutral molecules. This effect is of course not limited to ethylene. It governs the behavior of the whole family of ethylene derivatives and facilitates an understanding of the different trends observed in this group of chemically related compounds[9a-d] (cf. Section 4). It is neither limited to the above type of symmetry lowering (planar-to-twisted) nor to the case of ionization. In a completely analogous way, the mechanism is effective in the case of radical anions and electronically excited states of the neutral molecules[7,8]. It is responsible also for quite different distortions[4], such as nonlinearity of linear molecules in excited or ionic states[9e], unequal bond lengths in symmetric triatomic molecules[20] or Jahn-Teller type distortions in non-degenerate electronic states[9g]. In principle, most of the examples mentioned in the introduction, as well as many other similar cases, are candidates for the vibronic coupling mechanism. This concept is therefore considered as a powerful tool that can explain why many molecules are less symmetric in excited or ionic states than in the neutral ground state.

One of the important aspects of the vibronic coupling model is that it enables one to predict the geometries of cations, anions and molecules in excited electronic states using only symmetry arguments and simple molecular orbital concepts. Knowing the symmetries of the molecular orbitals, it is easily found from a selection rule such as eq. (3) which non-totally symmetric mode can operate in a particular example. This determines the type of distortion that is possible. Furthermore, there are simple qualitative criteria which allow one to estimate the strength of the distortion. As an illustration, let us consider the barrier height $E^*$ by which the unsymmetric (nonplanar) structure is energetically stabilized. It is given by eq. (4)

$$E^* = \begin{cases} \dfrac{\omega_u}{8\lambda^2}\left[\dfrac{2\lambda^2}{\omega_u} - |E_2 - E_1|\right]^2 ; & \dfrac{2\lambda^2}{\omega_u} > |E_2 - E_1| \\ 0 ; & \dfrac{2\lambda^2}{\omega_u} < |E_2 - E_1| \end{cases} \quad (5)$$

The ratio between the barrier height $E^*$ and the energy gap $|E_2 - E_1|$ thus depends only on the following dimensionless combination x of parameters

$$x = \frac{2\lambda^2}{\omega_u |E_2 - E_1|} \quad (6)$$

as depicted in Figure 3.

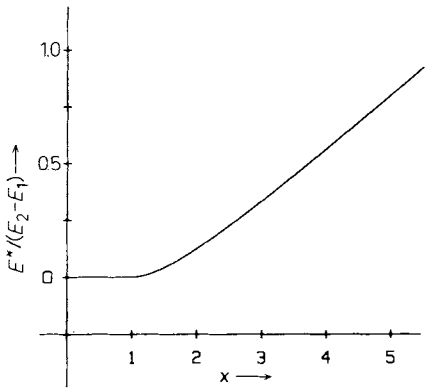

Fig. 3. The dependence of the barrier height $E^*$ on the dimensionless quantity x according to equations (5)—(6). $E^*$ represents the amount by which the unsymmetric configuration is stabilized energetically. For values of x smaller than unity no distortion occurs, *i.e.* $E^*=0$. In the opposite limit ($x \gg 1$) there is an approximately linear dependence of the barrier height on x.

This quantity and hence the barrier height become large with increasing vibronic coupling constant $\lambda$ and decreasing energy gap $|E_2-E_1|$. The strength of the distortion therefore depends on the balance between these two opposing factors. If the ratio x is smaller than unity the double minimum in the lower surface $V_1$ vanishes and the vibronic coupling is reflected only in the difference in curvature of the two potential curves: The upper curve $V_2$ is steeper near the minimum than that of the molecular ground state $V_0$, whereas the lower curve $V_1$ is relatively flat[8l,q] (cf. Fig. 1b). This is plausible, since in the limiting case of no coupling ($x=0$) both potential curves must exhibit identical shapes, the minima occurring at the symmetric configuration $Q_u=0$ (Fig. 1a).

To decide whether the coupling leads to a distortion in a particular molecule one must therefore calculate the coupling constant $\lambda$ and energy gap $|E_2-E_1|$ and check whether the ratio x is larger than unity. The frequency $\omega_u$ can be taken from experiment. We have already indicated above for ethylene how the constant $\lambda$ can be related to the mixing of orbitals that occurs upon the appropriate deformation. More quantitatively it is given by either of the following equivalent expressions[21]

$$\lambda = (E_2-E_1)\int \pi^*(r)\,\partial/\partial Q_u\,\pi_{CH_2}(r)\,d^3r \tag{7a}$$

$$\lambda = \frac{1}{\sqrt{8}}\left[\partial^2(V_1(Q)-V_2(Q))^2/\partial Q_u^2\right]^{1/2} \tag{7b}$$

(the integration in eq. (7a) is over the electronic coordinates, and both expressions are to be evaluated at the equilibrium geometry of the neutral molecule). Similarly, also the energy gap can be approximated on the orbital level. In the case of ionization it roughly equals the energy difference of the mixing orbitals (Koopmans' theorem[22]). Thus, simple estimates and well known chemical approximation schemes can be used to apply the vibronic coupling concept to a particular case of interest.

We have now ascertained the relation between vibronic coupling and symmetry lowering in excited or ionic states, taking the ethylene cation as an example. We have, however, neglected so far the totally symmetric mode that appears in our Hamiltonian, eq. (2). To establish the impact of the latter mode on the vibronic coupling, we note that from eq. (2) the energy gap $E_2-E_1$ of the interacting states has to be replaced now by the following function of the additional coordinate $Q_g$

$$\Delta E = E_2-E_1+(\kappa_2-\kappa_1)Q_g \tag{8}$$

Therefore (cf. discussion to eqs. (5)—(6)), the barrier height $E^*$ and the shape of the torsional potential depend on this coordinate. In other words, the totally symmetric stretching modulates the energy gap and, hence, the coupling strength.

The importance of the modulating or tuning effect according to eq. (8) depends on the difference of $\kappa_1$ and $\kappa_2$. These constants are defined as the derivatives of the potential curves with respect to $Q_g$ at the equilibrium geometry of the neutral molecule (indicated below by a subscript "0"). In order to estimate these derivatives for ethylene we again use Koopmans' theorem[22] and inspect the negative derivatives of the corresponding orbitals which partake in the coupling

$$\kappa_i = -\left(\frac{\partial\varepsilon_i}{\partial Q_g}\right)_0; \quad \varepsilon_i = \text{orbital energy} \tag{9}$$

From the nodal properties of the two orbitals, it is obvious that $\kappa_1<0$, since the $\pi(b_{2u})$ orbital is C=C bonding, whereas $\kappa_2>0$, since the $\pi_{CH_2}(b_{2g})$ orbital is antibonding in the same region. This is shown in Figure 4a along with a plot of the potential curves as a function of the stretching coordinate $Q_g$ in Figure 4b.

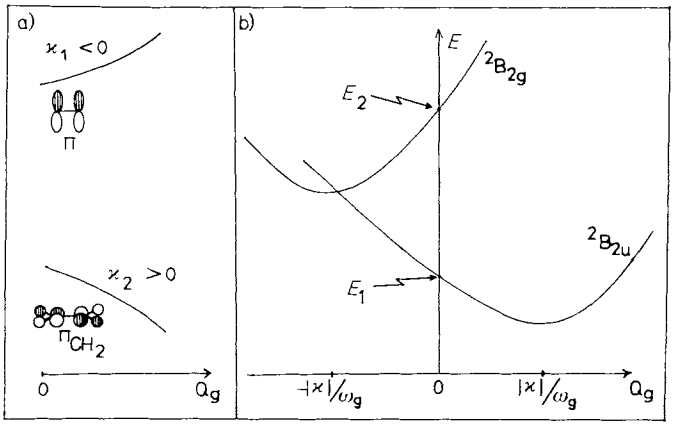

Fig. 4. a) The behavior of the $\pi(b_{2u})$ and $\pi_{CH_2}(b_{2g})$ molecular orbitals upon C=C stretching. The coupling constants $\kappa_1$ and $\kappa_2$ behave as the negative values of the corresponding slopes.—b) The $^2B_{2u}$ and $^2B_{2g}$ diabatic potentials along the stretching coordinate, $Q_g$, assuming $|\kappa_1|=|\kappa_2|=|\kappa|$. Note the modulation of their energy gap as $Q_g$ is varied.

One can see that as a result of the opposite signs of $\kappa_1$ and $\kappa_2$, the totally symmetric mode can modulate the energy gap of the two states. For positive $Q_g$, *i.e.* as the C=C bond is stretched beyond its value in the neutral molecule, the gap $\Delta E$ widens. On the other hand, for negative values of $Q_g$, *i.e.* when the C=C bond is shortened, the energy gap becomes smaller. Eventually, at some negative value of $Q_g$ the two states coincide and then reverse their order.

This tuning of the energy gap will affect the magnitude of the coupling of the two states upon twisting. This is illustrated in Figure 5, where we have plotted the torsional potentials at different values of $Q_g$.

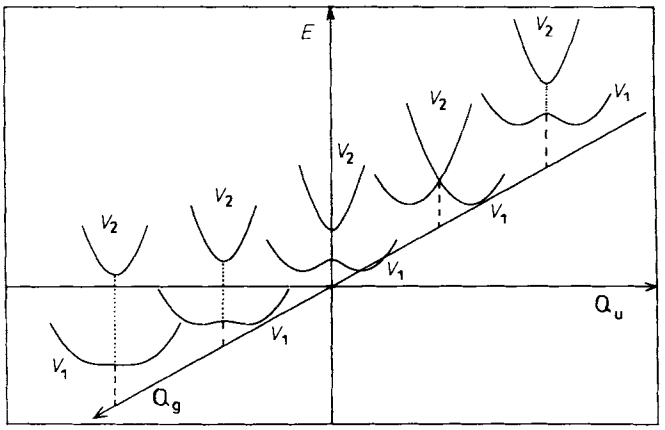

Fig. 5. A plot of the torsional potentials $V_1$ and $V_2$ of the two lower ionic states at different $Q_g$ values. Note how the depth of the minima varies as $Q_g$ changes. This indicates the tuning up or down of the vibronic coupling.

It can be seen that towards positive values of $Q_g$, as the gap widens, the barrier to planarity decreases (cf. eq. (5)) and eventually it vanishes completely. According to our calculations[9b] the absolute minimum of the lower potential surface of $C_2H_4^+$ occurs at positive $Q_g$. Indeed, it is quite obvious from Figure 4 that at the optimum value of $Q_g$ for the radical cation the energy gap is larger than at $Q_g = 0$, which will lead to a decrease of the coupling. In general, whenever the modulating effect of the stretching mode is strong, *i.e.* the signs of $\kappa_1$ and $\kappa_2$ differ, this will lead to a quenching of the distortion. When the signs of $\kappa_1$ and $\kappa_2$ are equal, the totally symmetric mode can lead either to a quenching or an enhancement of the distortion.

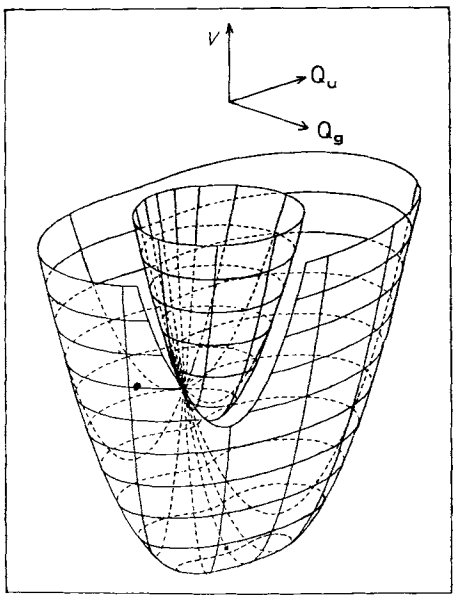

Fig. 6. A plot of the adiabatic potential surfaces $V_1$ and $V_2$ of the lower ionic states as functions of the C=C stretching coordinate $Q_g$ and the torsional coordinate $Q_u$. The surfaces are represented by a system of cuts in coordinate space and by equipotential lines. The cuts originate from the geometry of intersection where the surfaces touch each other ($Q_g = -3.3$, $Q_u = 0$). At the bottom of the lower surface the double minimum nature of the torsional potential is discernible. Vibrational motion on the upper surface can practically always reach the point of intersection and, hence, interconvert to the lower surface.

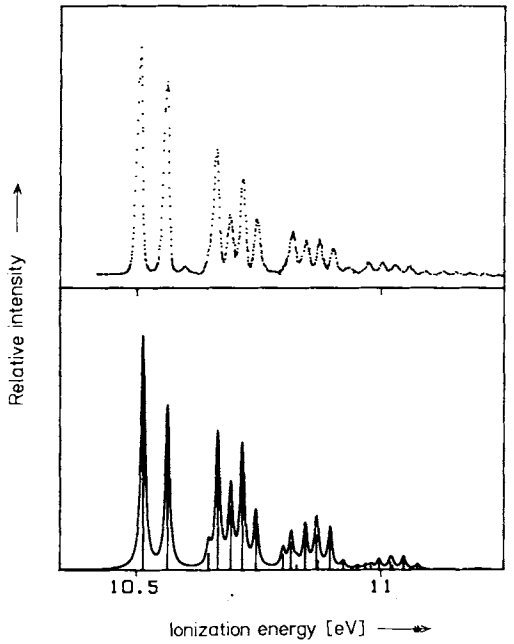
Going in the opposite direction—for negative values of $Q_g$—the two potentials approach each other and the barrier of the lower surface increases in accord with increasing coupling of the two states. At some negative value of $Q_g$ both surfaces coincide for $Q_u = 0$ (planar geometry). This degeneracy is lifted in first order when the system moves in an arbitrary direction away from the geometry of intersection. That is, the upper surface rests on the lower one like a cone on the apex of another cone. This is termed a conical intersection[23]. Figure 6 shows the potential surfaces of the two cationic states as a function of the twist and the C=C stretching coordinates. They exhibit a conical intersection on the negative $Q_g$ axis at $Q_g = -3.3$; $Q_u = 0$.

The conical intersection is most important for the behavior of the nuclear motion, since in its vicinity the nuclei can easily jump between the different surfaces[9d], leading to what are known as nonadiabatic effects. These will be discussed in more detail in the next section.

## 3. The Photoelectron Spectrum and the Nonadiabatic Effects

So far we have considered only the static aspects of the vibronic coupling mechanism, namely the adiabatic potential energy surfaces and the corresponding geometries of the ionic states. In the static calculations the nuclear kinetic energy operator $T_N$ and, hence, the nuclear motion on the potential surfaces is ignored. In this section we turn to the problem of the nuclear motion on these surfaces. Such a study is important for at least two reasons. Firstly, it is a prerequisite for comparing the predictions of the vibronic coupling with experiment. In optical spectroscopy the vibrational structure of the electronic bands contains information on the geometry changes that occur during the electronic transition. In the case of vibronic coupling this allows one to deduce the extent of the distortion from the excitation strength of the appropriate nontotally symmetric mode in the experimental spectrum. To this end, however, the problem of nuclear motion must be resolved. Secondly, a study of the nuclear motion is interesting in itself because it furnishes information about the significance of the "jump" between the different surfaces. These nonadiabatic effects are usually considered negligible in chemical processes. We shall see that in the presence of conical intersections (cf. Fig. 6) they can be extremely fast and efficient. This poses the question whether they are not of more importance in chemical phenomena than is usually believed.

Let us again consider ethylene as an example. Figure 7 shows the experimental recording of the first band of the photoelectron (PE) spectrum of this simplest alkene. The band represents the removal of an electron from the outermost occupied orbital of the $H_2C{=}CH_2$ molecule, and its fine structure reflects the vibrational motion in the corresponding ionic state (ground state).



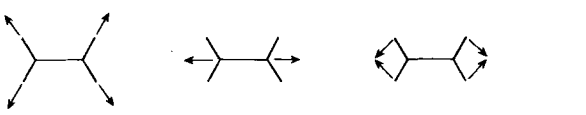


Fig. 7. The first band in the photoelectron spectrum of ethylene. Top: the experimental recording [14f]. A supersonic molecular beam has been used to achieve high resolution. The curve represents the number of counts of photoelectrons as a function of their kinetic energy. The ionization energy is obtained by subtracting the kinetic energy from the energy of the incident photon (here 21.1 eV). Bottom: the calculated spectrum is given by the vertical lines (for the values of the parameters used cf. Table 1). To compare with experiment they are subsequently broadened to give Lorentzians of suitable width (here 0.01 eV). The sum of these Lorentzians is drawn above the lines as a continuous envelope and reproduces the observations accurately.

Three progressions of vibrational modes can be distinguished. They have been attributed[14] to the C=C stretching mode $\nu_2$, the C–H bending mode $\nu_3$, and the torsional mode $\nu_4$. However, the determination of the equilibrium geometry of $C_2H_4^+$ from these data has not been attempted[14].

We now try to reproduce the observations by means of the vibronic coupling mechanism. To this end we have to include the nuclear kinetic energy $T_N$,

$$\hat{\mathscr{H}} = \mathscr{H} + \begin{pmatrix} T_N & 0 \\ 0 & T_N \end{pmatrix} \tag{10}$$

and solve for the exact quantum mechanical eigenstates of the Hamiltonian $\hat{\mathscr{H}}$. The computation of the spectrum is then straightforward[9]. Before presenting the result, two remarks are appropriate. Firstly, as is evident from the experimental spectrum in Figure 7, we should include all three totally symmetric modes (**2**—**4**) of ethylene, not just the C=C stretching mode (**3**).

$\omega_1 = 0.3915$ $\omega_2 = 0.2054$ $\omega_3 = 0.1710$ eV

**2** **3** **4**

Secondly, numerical values are needed for the energies and coupling constants which enter into our Hamiltonian. In our case we choose a so-called Green's function calculation[24], which is known to yield accurate ionization potentials and, hence, also coupling constants[9]. Since the spectrum turns out to depend sensitively on these parameters, some of them are subsequently slightly readjusted to improve the agreement with the observations. The final result of the calculation is included in Figure 7, the values of the parameters are collected in Table 1.

Table 1. Energies, coupling constants and frequencies used in the calculation of the first photoelectron band of ethylene (Fig. 7). For the second band (Fig. 8) slightly different values of the totally symmetric frequencies have been employed [9f]. All quantities are in eV.

| | $^2B_{2u}$ | $^2B_{2g}$ | $\omega$ |
|---|---|---|---|
| $E$ | 10.750 | 12.650 | – |
| $\kappa(\nu_1)$ | 0.025 | −0.362 | 0.360 |
| $\kappa(\nu_2)$ | −0.178 | 0.249 | 0.155 |
| $\kappa(\nu_3)$ | 0.155 | 0.107 | 0.180 |
| $\lambda$ | 0.404 | | 0.110 |

The calculated and experimental spectra agree in all essential details. This is conclusive evidence that the vibronic coupling concept indeed applies to the lowest states of the ethylene cation and that we have arrived at an accurate description of the potential energy surfaces of these states[25]. According to the calculation the three lines following the transition to the zero vibrational level represent (in the order of increasing energy) excitation of the torsional, C=C stretching, and C–H bending modes. The appearance of the C=C stretching mode is attributed to the elongation of the C=C bond that occurs upon ionization of the $\pi$ electron (1.41 Å as against 1.33 Å in the neutral molecule). In the same way the excitation of the torsional mode reflects the distortion of the ion from planarity: using the parameter values of Table 1 and searching for the energetic minimum of the full four-dimensional potential surface we get[9b] a torsional angle of $\approx 25°$ for the equilibrium geometry of $C_2H_4^+$. The optimized barrier to planarity turns out to be $\approx 0.03$ eV.

The quality of the calculated spectrum leaves no doubt about the nonplanarity of the ethylene cation[25]. It should be mentioned that also the ab initio (Green's function) data predicts $C_2H_4^+$ to be nonplanar, although the torsional angle turns out to be too small[9b]. The question of the nonplanarity of $C_2H_4^+$ has been examined before by pointwise calculations of the torsional potential curves. Whereas ab initio results have been controversial, most semiempirical calculations yielded a nonplanar cation[26]. In the present work we have settled this question[27] and have also specified the mechanism leading to the nonplanarity of $C_2H_4^+$.

In the discussion of the photoelectron band we have tacitly assumed the Franck-Condon principle[28] to be applicable. This is not justified a priori. In the calculated spectrum also the effects of jumping between different surfaces are included, which the Franck-Condon principle neglects. One can, however, recalculate the spectrum and enforce the nuclei to stay on a given surface throughout, *i.e.* neglect the nonadiabatic effects[9d]. If one does this for the first PE band of ethylene, one gets virtually the same result as before. This shows that nonadiabatic effects are negligible and the vibrational motion proceeds solely on the lower of the two surfaces, corresponding to the ionic ground state.

The reason for this behavior can be visualized from Figure 6. Upon ejecting an electron from the $\pi(b_{2u})$ orbital the ion is left (speaking classically) on the lower surface at the equilibrium geometry of the neutral species, $Q_g = Q_u = 0$. At this point its internal energy is well below the minimum energy of the upper potential surface. Therefore the nuclei will not jump from the lower to the upper surface *simply because their energy content is insufficient to reach the latter!*

The situation changes, of course, if we consider the vibrational motion which starts on the upper potential surface. This occurs upon ionization out of the $\pi_{CH_2}(b_{2g})$ molecular orbital. Indeed, the second photoelectron band looks completely different from the first band. We show it in Figure 8 together with the result of the exact calculation and the Franck-Condon calculation[9f].

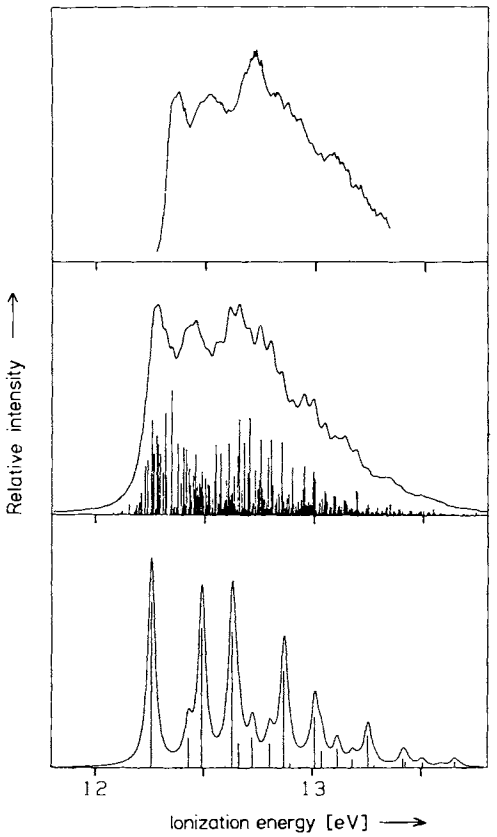

Fig. 8. The second band in the photoelectron spectrum of ethylene. Top: The experimental recording [11a]. Center: The spectrum according to the full vibronic coupling calculation. A line width of 0.04 eV has been used corresponding to the lower experimental resolution (for more details see Fig. 7). Bottom: The Franck-Condon spectrum. Whereas the exact calculation reproduces the observations quite well, the Franck-Condon spectrum bears no resemblance to experiment. Therefore the vibrational motion is not even approximately confined to the upper potential energy surface.

In the exact calculation we use the same Hamiltonian as before. In the Franck-Condon calculation we apply the Franck-Condon principle to the upper potential energy surface of the vibronic coupling model. The exact calculation reproduces the experiment quite well: The envelope exhibits three broad humps and different slopes of the low and high energy wings of the band, just like the experimental spectrum. Therefore the vibronic coupling mechanism is seen to govern also the first excited ionic state. Surprisingly *the Franck-Condon spectrum fails completely to reproduce the observations*. The comparison with the exact calculation reveals striking nonadiabatic effects, not only with regard to the intensity distribution but also with regard to the *number* of spectral lines (the exact spectrum consists of more than 1000 individual lines!). Moreover, the nonadiabatic effects extend over the entire energy range of the band including the lowest vibrational levels of the $^2B_{2g}$ state. This gives direct evidence that the *nuclear motion is not even approximately confined to the upper potential energy surface.*

Another way of looking at the phenomenon is to follow the time evolution of the nuclear motion. In Figure 9 we have plotted the probability that the nuclei are on the upper surface as a function of the time $t$ that has elapsed since the ionization out of the $\pi_{CH_2}$ orbital. Since this ionization process transfers the molecule to the upper potential surface, the probability is unity at $t = 0$. If the vibronic coupling were to vanish ($\lambda = 0$), the nuclei would stay on the upper surface and the probability would remain unity throughout.

We see from Figure 9 that because of the vibronic coupling the *confinement to the upper surface lasts only for the extremely short time of $10^{-14}$ s, i.e. about a period of vibration.* After that time the probability fluctuates around a constant value which is considerably smaller than unity. It is roughly given (within our model) by the relative density of vibrational levels of both surfaces. In other words, after an initial rapid decay the nuclei move essentially freely between both surfaces with a relative occupation probability determined only by statistical factors.

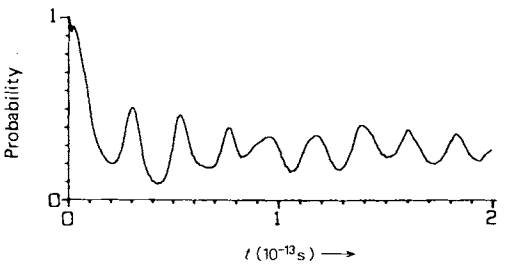

Fig. 9. The probability of the $C_2H_4^+$ nuclei residing on the upper potential energy surface as a function of the time that has elapsed since the ionization out of the $\pi_{CH_2}$ orbital. The confinement to the upper surface lasts only $\approx 10^{-14}$ s. After that time the nuclei interconvert freely between both surfaces. This behavior accounts in a natural way for the strong nonadiabatic effects in the photoelectron spectrum (Fig. 8).

Typically, nonadiabatic (or nonradiative) decay times determined experimentally range from $\approx 10^{-6}$—$10^{-10}$ seconds[7p,q]. The present value is more than four orders of magnitude smaller. It just represents the strong nonadiabatic effects found before in the spectrum in a different manner. The ultrafast nonadiabatic decay makes it plausible that the Franck-Condon principle fails completely in the calculation of the spectrum.

A closer examination reveals that the strong nonadiabatic effects are intimately connected with the existence of several modes[29]. If only a single mode (torsion) is retained they vanish almost completely: In this case the Franck-Condon spectrum becomes virtually exact and the probability of population of the upper surface (Fig. 9) remains

practically unity. The additional totally symmetric modes bring the potential energy surfaces close together and thus enhance the probability that the nuclei jump between the different surfaces. At the extreme situation, when a conical intersection exists and is accessible energetically (as in the ethylene cation), the nuclei interconvert freely between the surfaces and the nuclear motion behaves completely nonadiabatically.

It now becomes clear why the adiabatic approximation has proven so successful in the assignment of highly resolved electronic spectra of diatomic molecules[8v]. Most of the previous work on the vibronic coupling problem in polyatomic molecules has also been confined to a single vibrational mode and, consequently, only moderate nonadiabatic effects have been reported. In contrast, in all the polyatomic molecules we have analyzed to date we find that several modes participate in the coupling and lead to strong nonadiabatic effects for the upper electronic state. Furthermore, many conical intersections are meanwhile becoming known from ab-initio calculations[30], which illustrates that they are a common phenomenon, even in small polyatomic molecules. This holds all the more for larger systems of chemical interest.

The importance of the nonadiabatic effects in radical cations is also indicated by the generally diffuse photoelectron spectra of polyatomic molecules[11]. The present mechanism can explain this diffuseness through the demolition of the vibrational progressions that occurs and the high density of vibronic lines. Further evidence comes from the absence of detectable emission in most organic radical cations[31] (including the ethylene cation[31c]). This suggests rapid radiationless decay with decay times $< 10^{-12}$ s. We have seen above that the present mechanism (conical intersections) leads to decay times of $\approx 10^{-14}$ s. Thus it constitutes a prototype of rapid radiationless decay that *explains* the ultrashort decay times and makes the frequent absence of detectable emission understandable.

To summarize, Sections 2 and 3 provide an overview of the basic impact which the vibronic coupling exerts on the structural features of molecules as well as on the behavior of the nuclear motion. It appears remarkable that a *single* mechanism can explain such different classes of phenomena as distortions of the molecular shape, excitation of nontotally symmetric modes (in the low energy electronic band), diffuseness of the high energy band, and the absence of detectable emission.

## 4. Vibronic Coupling in Alkenes, Allenes and Cumulenes

The general ideas have been illustrated above by referring to the ethylene cation. It is interesting now to inquire about the trends occurring in a series of chemically related compounds. In this way we can gain more insight into the chemical significance of the vibronic coupling mechanism.

### 4.1. Substituted Ethylenes

Let us start by considering the effect of chemical substitution in ethylene. Clearly, the substituent can exert its electronic influence either through the value of $\lambda$ or of $E_2 - E_1$. The variation of $\lambda$ (eq. 7) can be predicted if one describes the molecular orbitals as a linear combination of atomic orbitals. Retaining only the terms belonging to the carbon atoms, one obtains an expression with integrals over atomic orbitals multiplied by products of the atomic orbital coefficients in the $\pi$ and $\pi_{CH_2}$ molecular orbitals. Since substitution tends to "dilute" the atomic orbital coefficients on the carbon atoms[32], one expects that, generally, $\lambda$ will become smaller upon substitution.

The other factor is $E_2 - E_1$, *i.e.* the difference between the vertical ionization potentials. As we discussed before in reference to Figure 2, this quantity can be related to the energy gap of the two orbitals, $\pi$ and $\pi_{CH_2}$ (eq. 2). Thus we must inquire about substituent effects on the energy levels of these orbitals. Notable among the substituents is fluorine. What it usually does is to leave the energy of the $\pi$ orbital largely unaffected, but to decrease the energy of the $\pi_{CH_2}$ orbital through its inductive effect[32]. Perfluorination just accentuates this effect, and it is commonly known among photoelectron spectroscopists as the "perfluoro effect"[33]. In order to understand this effect, we should see how one reconstructs the $\pi$ and $\pi_{CH_2}$ orbitals of ethylene. Figure 10a shows the reconstruction of these orbitals by interacting the orbitals of two $CH_2$ fragments.

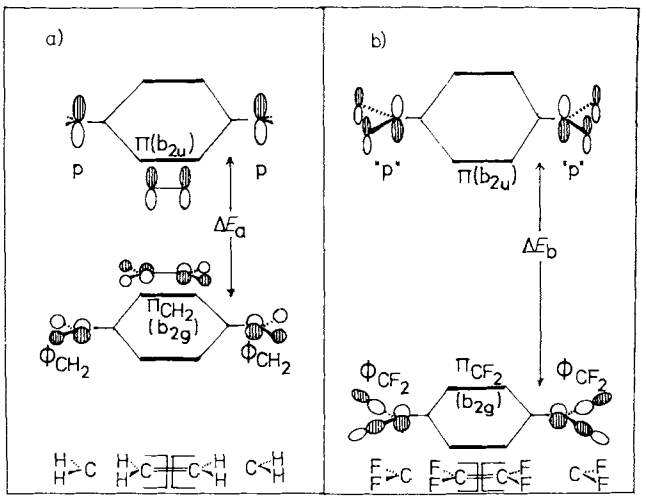

Fig. 10. Interaction diagram which describes the reconstruction of the $\pi$ and $\pi_{CX_2}$ molecular orbitals (X = H, F) of ethylene and tetrafluoroethylene, from the appropriate fragment orbitals of two $CX_2$ (X = H, F) units. The fragments are indicated by brackets in the molecular formulas.—a) The interaction diagram for ethylene, $C_2H_4$. The fragment orbitals are p and $\phi_{CH_2}$. $\Delta E_a$ is the resulting energy gap of the $\pi$ and $\pi_{CH_2}$ molecular orbitals.—b) The interaction diagram for $C_2F_4$. The fragment orbitals are "p" and $\phi_{CF_2}$. Note that $\varepsilon(\text{"p"}) \approx \varepsilon(p)$ and $\varepsilon(\phi_{CF_2}) < \varepsilon(\phi_{CH_2})$. The resulting $\pi$-$\pi_{CF_2}$ energy gap is $\Delta E_b$. Note that $\Delta E_b > \Delta E_a$ because of the large energy gap of the fragment orbitals "p" and $\phi_{CF_2}$.

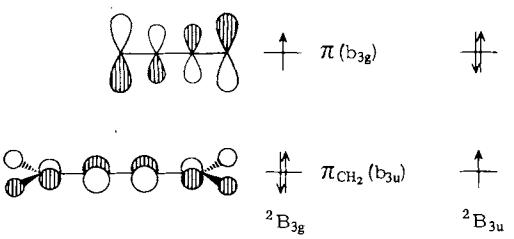
The $\pi$ orbital results from the in-phase combination of two pure carbon p orbitals, whereas $\pi_{CH_2}$ results from the out-of-phase combination of the two fragment orbitals which are C–H bonding (*i.e.* $\phi_{CH_2}$) and, hence, low lying. Thus, the intrinsic large energy difference between the fragment orbitals p and $\phi_{CH_2}$ leads to a relatively large energy gap for the molecular orbitals (see Table 1).

Let us replace the hydrogens by fluorines. Now, we have two $CF_2$ fragments. Each fragment has a "p" orbital which

arises from the antibonding combination of the fluorine p orbitals with the carbon p orbital. As a result of this antibonding character, the "p" orbital has a higher energy than the pure p orbital of carbon. This effect is counterbalanced, however, by the above mentioned inductive effect of fluorine. Therefore the resulting $\pi$ orbital of $C_2F_4$, which is the in-phase combination of the two fragment "p" orbitals will have a similar energy as the $\pi$ orbital of $C_2H_4$.

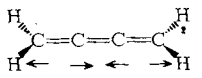
The other orbital in question is the $\pi_{CF_2}$ orbital. This orbital arises from the out-of-phase combination of the $\phi_{CF_2}$ orbitals. There are several orbitals of this type, all of which are lower lying than the analogous $\phi_{CH_2}$ fragment orbital, but in Figure 10b we show only one $\phi_{CF_2}$ orbital per fragment. This fragment orbital is considerably lower in energy than the $\phi_{CH_2}$ orbital because it is essentially a C–F bonding orbital. The resulting $\pi_{CF_2}$ orbital is therefore, likewise more energetically favorable than the $\pi_{CH_2}$ orbital (compare Fig. 10a with 10b). Consequently, the $\pi$-$\pi_{CF_2}$ energy gap is much larger than the corresponding $\pi$-$\pi_{CH_2}$ gap. Once again, what sets up the final gap, is the energy difference of the two fragment orbitals. This becomes larger upon fluorine substitution and, hence, it will lead to a larger value of the energy gap.



How this difference affects the vibronic coupling and the structure of the ground state ion is quite obvious from our discussion with reference to Figure 2. Since the nonplanarity of the cation is dependent upon the magnitude of the interaction of the two molecular orbitals $\pi$ and $\pi_{CX_2}$ (X = H, F), then replacement of H by F will lead to a considerably weaker interaction. Thus, the fluorinated cation will behave as expected for cases of weak coupling, and will most likely remain planar. The weakening effect will obviously depend on the degree of substitution and will become more pronounced as the number of fluorine atoms increases. This weakening of the vibronic coupling will leave its marks on the PE spectrum. This is indeed the impression one gets from the first bands (corresponding to the $\pi$ ionization) in the photoelectron spectra of vinyl fluoride and the difluoroethylenes[34], which show a normal progression in the C=C stretching mode. However, some high resolution PE results will be needed in order to evaluate the magnitude of the vibronic coupling in this family of compounds.

What is the situation with substituents other than F? Our experience with substituent effects[32] shows that most usual chemical substituents which are electron donors, like $CH_3$, OR, $NR_2$ *etc.*, will raise the energy of the $\pi$ orbital considerably and will change the $\pi_{CH_2}$ type orbital to a lesser extent. On the other hand, electron acceptors, like CN or COH, will lower both orbitals but will affect more the $\pi_{CH_2}$ type orbital[32]. The conclusion is that within the family of substituted ethylenes, the electronic factors $\lambda$ and $E_2 - E_1$ will favor strong vibronic coupling effects mostly in the unsubstituted parent ion $C_2H_4^+$.

Until now we have neglected effects of steric congestion[35]. It has been claimed[26] that in the case of tetramethyl substitution the distortion from planarity is larger than in ethylene itself, mainly because of the effects of steric hindrance of the methyl groups. This should hold all the more for isopropyl or other bulkier substituents[26]. In the vibronic coupling model the effects of steric hindrance are contained in the torsional frequency $\omega_u$. Indeed, when comparing ethylene and the tetramethyl derivative and correcting for the different masses, the torsional frequency is smaller by a factor $\approx 1.6$ in the latter molecule[36]. This favors a larger vibronic coupling in the derivative. The energy gap of the interacting states is taken as 2.4 eV (difference of the two lowest ionization potentials[37]). Neglecting totally symmetric modes and taking $\lambda$ from ethylene, one finds with eq. (5) for the energy barrier to planarity a value of 0.18 eV and a torsional angle of 42° at equilibrium. This compares favorably with the previously reported values of 0.22 eV and 40°, respectively[26,38]. It is therefore to be expected, that steric congestion will generally lead to an increase of the vibronic coupling strength.



### 4.2. The Butatriene Radical Cation

The principles which govern the spectrum of butatriene and the geometry of its ion are almost the same as were described for ethylene. The two adjacent ionic states arise by ionization from the $\pi(b_{3g})$ and $\pi_{CH_2}(b_{3u})$ molecular orbitals.

(11)

Inspecting these MOs, one notices that the nodal properties across the terminal bonds are exactly the same as those across the C=C bond of ethylene. Consequently, the linear coupling constants for the totally symmetric mode **5**, $\kappa_1$ and $\kappa_2$, will have different signs, and the two states $^2B_{3g}$ and $^2B_{3u}$ will behave much the same as the two corresponding ionic states of ethylene (Fig. 2 and 4). In addition, the two states are coupled *via* an $A_u$ type motion

**5**

which consists in an opposite torsion of the two $CH_2$ termini. This can result in a cation which is nonplanar and which has a short central C=C bond. Therefore, the butatriene problem is not much different from the ethylene problem in its essential features. Considering that $\lambda$ is expected to be smaller than in the case of ethylene owing to the dilution of the AO coefficients (cf. Section 4.1), one asks oneself why the photoelectron spectrum of butatriene is upset by the bothersome "mystery band"[12], whereas that of ethylene is not? The answer to this question can be found in the much smaller energy gap in the case of butatriene. In fact, both our Hartree-Fock and Green's function computations[9a] predict that the difference between the vertical ionization potentials is much smaller than that in ethylene (*e.g.*, 0.72 eV in $C_4H_4$ *vs* 2.4 eV in $C_2H_4$ using Green's function values). This means that the vibronic coupling effects are stronger in the butatriene case.

The ab initio calculations also show that among the four totally symmetric vibrations it is indeed only the mode **5** that has to be considered. Once again, slight adjustment of the parameters (the values are given in Table 2) furnishes the theoretical spectrum, which is depicted in Figure 11 along with the experimental recording.

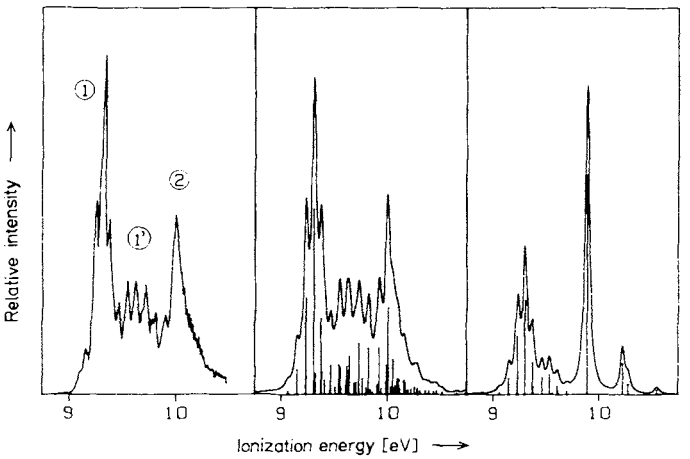


Fig. 11. The first band system in the photoelectron spectrum of butatriene. Left: The experimental recording [12a]. The bands ① and ② have been attributed to ionization out of the outermost occupied orbitals of butatriene. Band ①' was termed a "mystery band" [12a]. Center: The spectrum according to the full vibronic coupling calculation. For the values of the parameters cf. Table 2 (line width 0.04 eV). Right: The Franck-Condon spectrum. The Franck-Condon calculation is realistic only for low vibrational energies and fails completely for the high energy part of the band system. The mystery band is clearly seen to be a nonadiabatic effect.

There is almost perfect agreement between theory and experiment. Therefore, the vibronic coupling mechanism accurately describes the nuclear motion also in the butatriene radical cation. To reveal the origin of the "mystery band" we have recalculated the spectrum according to the Franck-Condon principle, *i.e.* discarded the possibility that the nuclei jump between the individual potential energy surfaces. The result is included in Figure 11. By comparing the exact calculation and the Franck-Condon calculation one can see that for low energies the vibrational motion is indeed confined to a single potential energy surface (that of the ionic ground state). This is just the energy range where vibrational progressions are still discernible in the exact spectrum. On the other hand, for energies at and above the center of the band system the exact line structure is highly erratic and completely different from the FC line structure. Note that the conical intersection of the two potential energy surfaces occurs at an energy of $\approx 9.7$ eV. In other words, *as soon as the upper potential surface becomes energetically accessible the vibrational motion can no longer be attributed to either of the ionic states but is determined by the joint nuclear motion on both potential energy surfaces.* This is the same behavior as observed in the ethylene cation. The main difference between both examples is the smaller energy gap in the present case, which leads to the overlapping of the bands and the formation of the mystery band.

Using the parameters of Table 2, one finds that the geometry of the cation is nonplanar with $\alpha = 46°$. This is in complete contrast to the predictions of ab-initio computations (STO-3G), which predict a planar geometry[12a]. Once again, the reason for the failure of the STO-3G calculation may be the underestimation of the effect owing to a much too large an energy gap[27].

Table 2. Energies, coupling constants and frequencies used in the calculation of the photoelectron spectrum of butatriene (Fig. 11). All quantities are in eV.

| | $^2B_{3g}$ | $^2B_{3u}$ | $\omega$ |
|---|---|---|---|
| $E$ | 9.450 | 9.850 | – |
| $\kappa$ | −0.212 | 0.255 | 0.258 |
| $\lambda$ | 0.318 | | 0.091 |

Before we proceed any further, we must make sure that we understand all the qualitative features behind the results. Especially interesting is the energy gap factor. Why is it smaller for butatriene than for ethylene? This can be rationalized if one uses an interaction diagram to reconstruct the $\pi$ and $\pi_{CH_2}$ orbitals of the two systems. Such a diagram for ethylene has been shown before in Figure 10a. We have concluded then that the intrinsic larger energy difference between the fragment orbitals, $\phi_{CH_2}$ and p, sets the value of $E_2 - E_1$, leaving it large. The situation in butatriene is quite different and the $\pi(b_{3g})$ and $\pi_{CH_2}(b_{3u})$ orbitals remain close in energy since they originate from fragment orbitals of about *equal* energies. This is illustrated in Figure 12, where we have reconstructed the $\pi$ and $\pi_{CH_2}$ molecular orbitals of butatriene by the union of two different fragments, in a way which best demonstrates the effect.

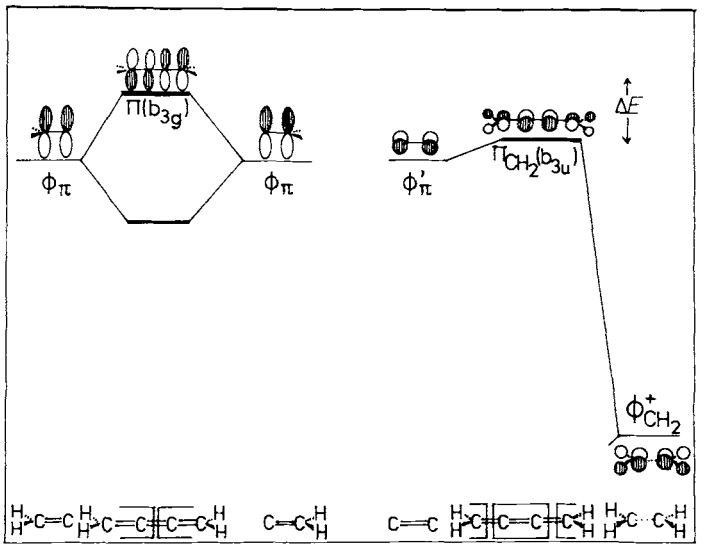

Fig. 12. Interaction diagram which describes the reconstruction of the $\pi$ and $\pi_{CH_2}$ molecular orbitals of butatriene from fragment orbitals. $\pi$ arises from the out-of-phase combination of the two out-of-plane $\pi$ type orbitals ($\phi_\pi$) of the terminal $C{=}CH_2$ fragments. The $\pi_{CH_2}$ orbital arises from the union of the in-plane-$\pi$ type orbital ($\phi'_\pi$) of the central C=C fragment with the positive combination ($\phi^+_{CH_2}$) of the in-plane orbitals of the two terminal $CH_2$ fragments. The fragments are indicated by frames and brackets in the molecular formulas.

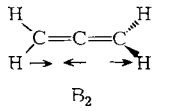
Thus the $\pi(b_{3g})$ orbital, in the left hand part of Figure 12, results from the union of two degenerate out-of-plane $\pi$-type orbitals each belonging to a $C{=}CH_2$ fragment, and labeled as $\phi_\pi$. The $\pi_{CH_2}(b_{3u})$ orbital, on the other hand, is re-

constructed from the union of a $\pi$-type fragment orbital ($\phi'_\pi$) of the central C=C unit, with a low lying $\phi^+_{CH_2}$ orbital, which is the in-phase combination of two $\phi_{CH_2}$ orbitals belonging to the fragment $H_2C\ldots CH_2$. Thus, the two molecular orbitals $\pi(b_{3g})$ and $\pi_{CH_2}(b_{3u})$ originate from fragment orbitals $\phi_\pi$ and $\phi'_\pi$, which are roughly degenerate and the result is that the molecular orbitals $\pi$ and $\pi_{CH_2}$ remain close in energy, being separated by a very small energy gap.

The interaction diagram in Figure 12 will help us understand why derivatives like tetramethyl-, tetra-*tert*-butyl- and tetrafluoro-butatriene[12] do not exhibit the "mystery band". A partial reason may be the prospective decrease of the coupling constant $\lambda$ upon chemical substitution, which we have discussed before. But this certainly cannot be the full story, in view of the striking differences in the spectra[12]. Therefore, we must look again at the energy gap factor, $E_2-E_1$.

The line of reasoning is very similar to the one used for discussing substituent effects on the energy gap in the case of ethylene. Let us go back to Figure 12 and consider the case of a donor substituent such as in the tetramethyl derivative. As a result of replacing H by $CH_3$, the energy of $\phi_\pi$, the $\pi$ type orbital of the fragment $C{=}C(CH_3)_2$, will increase, whereas $\phi'_\pi$, the $\pi$-type orbital of the central C=C fragment, will not be affected by the terminal substitution. This energy gap between the fragment orbitals $\phi_\pi$ and $\phi'_\pi$ will now be reflected in $E_2-E_1$, which will increase.



Replacing H by F will similarly increase the $\phi_\pi-\phi'_\pi$ energy gap and, in addition, $\phi^+_{CF_2}$ will be much lower than $\phi^+_{CH_2}$, so that the resulting gap will be even larger than in the case of methyl substitution. This is indeed reflected in the experimental spectrum, and the measured values of $E_2-E_1$ for the tetramethyl, tetra-*tert*-butyl and tetrafluoro derivatives respectively are 1.22 eV[12a], 1.17 eV[12a], and 2.65 eV[12b], all much larger than that for the parent unsubstituted compound.

Once again, we encounter the same trend. In a family of compounds generated by substitution of the same cumulene, the vibronic coupling effects are weakened by chemical substitution. This will be reflected both in the PE bands and in the degree of geometric distortion of the ground state cation (note that the effects of steric hindrance will be less pronounced than in ethylene due to the larger separation of the terminal C atoms). The substituted cations will distort away from the geometry of the neutral molecule *less than* the unsubstituted cation, and their PE bands will appear *less complex*.

### 4.3. The Jahn-Teller Effect in Allene and Pentatetraene

Allene and pentatetraene form a group where the lowest cationic state is doubly degenerate ($^2$E). The vibronic coupling effect in this group is known as the Jahn-Teller effect[7i]. It consists of a coupling by two vibrational modes: the torsional mode, $B_1$, describing the twisting of the $CH_2$ termini about the C=C=C axis, and a stretching mode, but a non-totally symmetric one, $B_2$ (**6**).

A symmetry analysis of the Hamiltonian reveals that it is almost identical to eq. (2) except that certain parameters

**6**

coincide[9c]. As a consequence, the conical interesection of the adiabatic potential surfaces is now right in the center of the Franck-Condon zone or, equivalently, of the PE band. Thus, strong nonadiabatic effects will always be present in the spectrum. This is confirmed by calculation[9c] (cf. Fig. 13), which gives regular progressions (torsional mode) only for low energies and an erratic line structure for high energies. The behavior is very similar to that of the butatriene molecule.

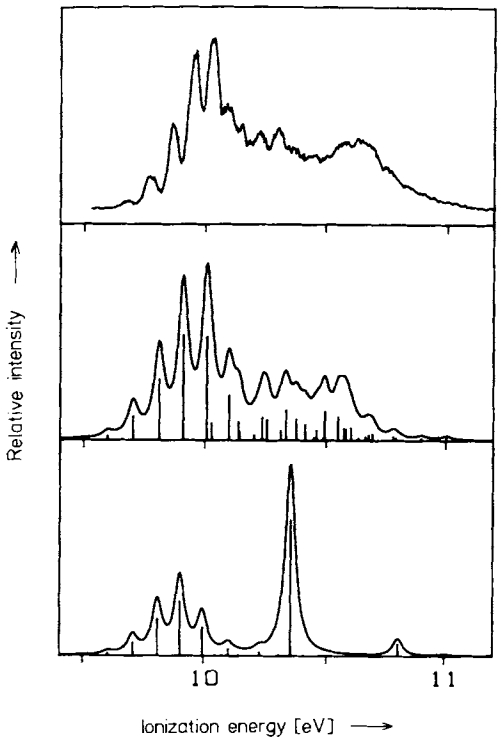


Fig. 13. The first band in the photoelectron spectrum of allene representing ionization out of a degenerate orbital (symmetry e). Top: The experimental recording [13a]. Center: The spectrum according to the full vibronic coupling (Jahn-Teller) calculation [9c]. Bottom: the Franck-Condon spectrum. As in the butatriene molecule the Franck-Condon calculation fails completely for the high energy part of the band. For low energies vibrational (torsional) progressions are still discovered in the exact calculation. The similarity between both examples shows that Jahn-Teller type effects are not limited to degenerate states but occur likewise in case of near-degeneracy (strong vibronic coupling).

With regard to the cationic structure, only either the $B_1$ or the $B_2$ coordinate can change in the Jahn-Teller case. For both allene and pentatetraene this is found to be the torsional angle[9c], with values of 51.6° and 38° at equilibrium, respectively. Clearly, the behavior is uniform throughout the "cumulene series".

The close analogy between the Jahn-Teller effect and the vibronic coupling in the other members of the cumulene series deserves some attention. The impact of the Jahn-Teller effect on symmetry breaking and nonadiabaticity of the nuclear motion is well recognized in the literature. We see from the present comparison that these "Jahn-Teller type" phenomena likewise occur if the electronic states are

nondegenerate but sufficiently close in energy. Therefore the vibronic coupling mechanism can be considered as a generalization of the Jahn-Teller effect to nondegenerate electronic states. In other words all the phenomena pertinent to the Jahn-Teller effect are not *restricted to highly symmetrical molecules with degenerate electronic states but will occur also in many others which are less symmetric and possess only nondegenerate states.*

The effect of substituents in the odd-carbon members is also similar to that in the even-carbon members. Substitution will generally remove the degeneracy of the $^2$E cationic state and will create a nonvanishing energy gap. Therefore, it is expected to reduce the magnitude of the vibronic coupling, much the same as it does in the derivatives of other "cumulenes".

### 4.4. Substituent Effects in the "Cumulene Family"—an Overview

We have now achieved to some extent an overview of the structure of the ground state cations of "cumulenes" and of the shape of the bands in their PE spectra. The picture which has emerged is quite appealing and deserves special attention.

The extent of the vibronic coupling effects is determined mainly by the energy gap of two uppermost occupied orbitals of the neutral molecule. When this gap is small, the cation distorts away from the neutral geometry, and the photoelectron spectrum in this energy region will be upset by nonadiabatic effects. When this energy gap is large, the distortion of the cation is smaller and so are the nonadiabatic effects in the first PE band.

Since we now know the pattern of substituent effects on the energy gap, we can map the vibronic coupling effects in all the cumulenes in two "dimensions". The first is the "dimension" of the number of carbon atoms. As we vary the number of carbon atoms the energy gap oscillates: it is nonzero for all the even-carbon members, and it vanishes for all the odd-carbon members. As the number of carbon atoms increases, the oscillations become tempered and converge to zero. This convergence is quite fast, since already for butatriene the gap is $\approx 0.5$ eV.

Let us consider first the even-carbon members. In this subset, ethylene has the largest energy gap ($\approx 1.9$ eV), and this decreases as the even number of carbon atoms increases. Thus, within this subset, vibronic coupling effects increase along the series, as we indeed witnessed on comparing the results of ethylene and butatriene. Both exhibit strong nonadiabatic effects, but the cation of the latter exhibits a larger distortion from planarity ($\alpha = 46°$ *vs* $25°$).

In the second subset, that of the odd-carbon members, the energy gap is zero throughout the series, and, hence, the vibronic coupling effects are always strong. The distortion of the cation away from the geometry of the neutral molecule now depends on the balance of two opposing trends. The torsional frequency, $\omega$, which determines the energy rise inherent in the twisting, decreases as the number of carbons increases. The second factor, $\lambda$, also decreases in the same direction owing to the dilution of the atomic orbital coefficients in the increasingly delocalized molecular orbitals. Our best fit calculations show that the values of $\omega$ for allene and pentatraene are 0.107 eV and 0.08 eV, respectively, whereas, the respective values of $\lambda$ are 0.24 eV and 0.21 eV. These values indicate that the effect on $\lambda$ will be less pronounced, and that the variation in $\omega$ will dominate the distortion in the odd-carbon members. This is confirmed on comparing the degree of distortion away from the geometry of the neutral molecule ($\alpha = 90°$), in the radical cations of allene ($\alpha = 51.6°$) and of pentatetraene ($\alpha = 38°$).

The second "dimension" is the "dimension" of chemical substitution. In the subset of even-carbon members, increasing degree of substitution causes an increase of the energy gap and, hence, it often leads to a decrease in the vibronic coupling effects. In the subset of odd-carbon members, mono- and di-substitutions on one terminus increasingly remove the degeneracy of the $^2$E state of the cation and lead to a decrease of the vibronic coupling. A higher degree of substitution achieves exactly the opposite effect, and the tetrasubstituted derivative has again a degenerate $^2$E ionic state.

## 5. Outlook

We have described in this article a mechanism (vibronic coupling) which allows one to gain an insight into two quite different chemical phenomena: the lowering of the molecular symmetry in ionic or excited states and the nonadiabatic behavior of the nuclear motion, *i.e.* the ability of the nuclei to jump between different potential energy surfaces. Such a unified description appears to us to be very attractive from a conceptual point of view. Of course, the value of the approach rests on its ability to describe the behavior of actual molecules. This has been demonstrated here for the series of "cumulene" cations. In all cases the fine structure of the photoelectron spectra could be accurately reproduced, from which information on the structure of the cation in the ground state could be derived.

What could the future perspectives look like? Detailed applications of the type shown above have been limited to comparatively small polyatomic molecules. This was motivated by the availability of accurate computational methods and well resolved experimental spectra for these systems, both essentials for a detailed verification of the mechanism. Often, however, one is interested in larger molecules and focuses on qualitative trends rather than on extensive calculations. The present results should provide a sound basis from which one can also proceed to understand larger systems of chemical interest. For instance, the quantities appearing in the Hamiltonian can be approximated on the orbital level and the standard semiempirical schemes can be used[4] to calculate them. Often, still simpler reasoning should be successful, for example, for comparing chemically similar compounds. In this way, the present approach can also be extended to larger molecules and reveal information about their interactions.

With regard to the nuclear motion, we have witnessed surprisingly strong nonadiabatic effects, *i.e.* an extremely efficient "jumping" of the nuclei between different potential energy surfaces. This is intimately connected to conical intersections of these surfaces, which in turn owe their existence to the interplay of several vibrational modes. *The*

*importance of the multi-mode effects for the nuclear motion can hardly be overestimated.* They should be even more pronounced for larger molecules with more internal degrees of freedom. Many absorption spectra of aromatic molecules exhibit indeed an erratic or diffuse fine structure, which was attributed to nonadiabatic effects[8d-s]. It is suggested that these be analyzed in terms of a multi-mode vibronic coupling mechanism as above.

More generally, the strong nonadiabatic effects are expected to be of some relevance also for non-spectroscopic applications, such as the theory of radiationless transitions or of chemical reactions. An important class of radiationless transitions involves a jump between different potential energy surfaces, thereby quenching the observed fluorescence intensity. If the transition proceeds within $< 10^{-12}$ s, no fluorescence is expected. Indeed, fluorescence is not observed in the majority of organic radical cations[31] studied to date. The same applies for higher excited states of a given multiplicity in neutral molecules (Kasha's rule[39]). Conical intersections of potential energy surfaces and the associated nuclear dynamics can in a natural way account for these observations and it is expected that this mechanism will indeed be found to operate in a large class of molecules and ions.

With regard to chemical reactions, these involve geometry changes along more than a single molecular mode. The question arises whether one can interpret chemical reactivity in terms of a many-mode vibronic coupling mechanism[7r-t,40]. To be sure, in most treatments of the problem a reaction coordinate is introduced which is taken as a sort of average trajectory of the nuclear motion on the potential energy surfaces. However, the present investigation shows that near an intersection of potential surfaces the nuclear motions can in no sensible way be decoupled any more. Thus, it lends serious doubt to the idea of a "reaction coordinate" when conical intersections of potential surfaces are involved. Conical intersections of potential energy surfaces may play an important role in many photochemical processes. It should be remembered that this type of chemical reaction always consists in (at least) one nonadiabatic transition between different potential energy surfaces[7u]. The present findings suggest that the multidimensionality of the nuclear motions be taken into consideration in order to gain a better insight into photochemical reaction dynamics.

[10] Quite generally, the independent electron model represents a better approximation for (low energy) ionic states than for excited states of the neutral molecule (Koopmans' theorem [22]). In addition, the interacting excited states of neutral species often differ in the quantum number of more than a single electron. Since the vibronic coupling operator is effectively a one electron operator [7k, 8e] the interaction vanishes within the single particle picture and occurs only by virtue of electron correlation effects. In the case of ions, the interacting states usually differ by the quantum number of a single electron and the vibronic coupling exists on the single particle level of approximation. This also appears to be the reason why the vibronic coupling effects are often stronger in ions than in the neutral molecules.

[16] Electronic states such as the pure configurations (1) which diagonalize the electronic part of the molecular Hamiltonian only for a specific nuclear geometry are called diabatic states. For an illustrative discussion, see reference [7c].

[17] Normal coordinates are derived from regular coordinates by a standard transformation cf. E. B. Wilson, J. C. Decius and P. C. Cross: *Molecular Vibrations*, McGraw-Hill, New York, 1955). In the present work we use dimensionless normal coordinates which are obtained from the normal coordinates by multiplication by $(\omega/\hbar)^{1/2}$. In the one-dimensional case the dimensionless normal coordinates are related to regular coordinates by $(\mu\omega/\hbar)^{1/2}$, where $\mu$ is the reduced mass of the atoms performing the motion and $\omega$ is the frequency.

[18] In the original formulation in [9a, b] the normal coordinates are replaced by boson operators b and $b^+$, with $Q=(b+b^+)/\sqrt{2}$. When comparing with the previous work all values of the coupling constants must therefore be divided by the factor $\sqrt{2}$.

[21] The first form, eq. (7a), allows estimation of the coupling constant in a simple way from the overlap of the $\pi$ orbital with the slightly rotated $\pi_{CH_2}$ orbital. The second form, eq. (7b), is advantageous for numerical computations since only energies and no wave functions are needed.

[22] According to Koopmans' theorem, the ionization potentials are given up to first order in the electron interaction by the negative values of the orbital energies from which the ionization occurs (cf. T. Koopmans, *Physica 1* (1933) 104).

[25] Throughout the computations, the spectrum of $C_2D_4$ was calculated along with the experimental spectrum; the results compare favorably with the observations.

[26] Cf. D. J. Bellville, N. L. Bauld, *J. Am. Chem. Soc. 104* (1982) 294, and references cited therein.

[27] One might wonder why extensive ab initio calculations came short of reproducing the nonplanarity of the cation. We believe one reason has to do with the variational treatment, during which the energy of the lower cationic state $^2B_{2u}$ is minimized and, simultaneously, the energy of the higher state $^2B_{2g}$ becomes much too high. Since the geometry of the cation depends on the coupling of these two states, then the ab initio treatment would tend to underestimate their mixing, leading to a planar cation.

[28] The Franck-Condon principle is the common tool in optical spectroscopy to assign the vibrational structure of electronic bands [7d]. It requires that the nuclear motion proceeds on a single potential energy surface before and after the electronic transition. The relative vibrational intensities are approximated by the squared overlaps of the vibrational wave functions of these surfaces. See reference [7d] for more details and many examples.

# Linear Control of Temperature with Time—A New Approach to Reaction Kinetics

By Erhard Koch*

The temperature dependence of the rate of chemical reactions has been known for a long time; very often it is characterized by the Arrhenius plot. However, kinetic methods that take this phenomenon into account in *one* measurement in a planned manner have been applied to reactions in solution only in isolated examples—with the exception of the temperature jump method developed by *Eigen et al.* for fast reactions, based on a stepped temperature program. A mathematical analysis, however, reveals to the chemist that from the point of view of information theory the course of the reaction rate *versus* time under conditions of constantly increasing temperature is the measured signal which should lead to the most effective understanding of the reaction mechanism. Analysis of the measured peaks, which may overlap, allows the characterization of reactions either in the solid state or in solution by "mechanistic coordinates", which extend the concept of reaction order. Their behavior allows further experiments to be planned, enabling elementary steps to be eliminated. Each reacting system can be characterized kinetically by one series of experiments using different starting concentrations for each reactant and, additionally, using different heating rates. The experimental verification of these considerations can be seen in *ca.* 1400 DTA and UV experiments for *ca.* 120 different systems. Furthermore, the example of the oscillating Belousov-Zhabotinsky reaction shows that "fast" reactions frequently may also be recognized. A test for proposed reaction mechanisms is provided by integration programs which allow immediate comparison between experimental and theoretical signal curves.

## 1. Introduction

For several years the field of reaction kinetics has been undergoing far-reaching changes[1]. This branch of research—supported by mathematics—aims at providing an understanding of the mechanisms of complex chemical reactions. Recently, bifurcation theory, stability analysis, reaction kinetics at low temperatures, self-organization of reaction mechanisms[2], and nonlinear irreversible thermodynamics have provided novel contributions. In addition, the development and miniaturization of computers have improved the mathematical tools decisively: now, simulation of processes in proposed networks[3,8]—in futurology this is even used to construct global models[4]—can also be considered as an efficient new tool for the chemist, since analytical solutions are no longer required[5,6]. Nowadays processes involving some hundred elementary steps can be computed in advance[7].

In order to take full advantage of these possibilities in chemical kinetics we require the development of new experimental methods which allow systematic solution of the central problem of "inverse reaction kinetics"[8], *i.e.* the determination of the underlying reaction mechanism and the activation data for all elementary steps from an experimental signal curve.

Alternatives to currently preferred isothermic kinetic methods are techniques using temperature programs[9-15], termed "thermoanalytical methods"[10,16,17]. These are superior to the isothermal techniques in many respects, especially for the economical description of processes in natural or artificial surroundings, since they provide data on a reaction over the complete range of temperature using only *one* experiment. For a *linear* increase of temperature with time, the reaction mechanism may be displayed in a "mechanistic diagram"[3,18-21]. The verification of this concept, even for complicated mechanisms having fast partial steps, appears to be a promising method of solving the problem of inverse reaction kinetics.

Thermoanalytical methods are usually used for heterogeneous reactions in the solid state, but less frequently for the homogeneous organic reactions in solution discussed here; with solids, mechanisms based on topochemical considerations occur. The efficiency of these methods was shown by their application to exotic problems, such as the pyrolysis of lunar samples or the study of the thermostability of atomic waste dumps. This article, therefore, also discusses the application of the theory of mechanistic coordinates to heterogeneous kinetic models[21,24], and thereby reveals astonishing kinetic selectivity.

## 2. Signals and Measurement Methods

A suitable measure for the progress of a reaction is its rate $v$. An unknown chemical reaction can be more effectively interpreted by considering the *derivative* instead of the *integrated conversion* curves[11,25-31].

If in a system with $p$ elementary processes the temporal change $y$ of a quantity $x$ is followed, it is found for many measurement methods that

$$y(t) = \frac{dx}{dt} = \sum_{i=1}^{p} y_i(t) = \sum_{i=1}^{p} \lambda_i \cdot v_i(t) = \sum_{i=1}^{p} \lambda_i k_i \cdot \pi_i \qquad (1)$$

[*] Dr. Erhard Koch

The quantities $\lambda_i$ are indication parameters containing the complete change of the property $x_i$ ($=x_{\infty i}-x_{0i}$) in the partial step i for the selected method. Thus, in a volumetric measurement $\lambda_i$ is the number of moles of evolved gas; in the measurement of UV extinction $\lambda_i$ is the product of layer thickness and extinction coefficient. The $\lambda_i$'s may depend on temperature (*e.g.* reaction enthalpies in calorimetric and extinction coefficients in spectroscopic methods). They are *exactly* constant only for methods based upon the change of numbers of moles (*e.g.* gas volumetry, mass spectroscopy, thermogravimetry[32]).

The products $k_i \pi_i$ are the mass-action terms for the elementary processes i, and characterize the internal kinetic processes. It applies

1. To an unimolecular step A $\longrightarrow$ products: $\pi_i=[A]_i$
2. To a bimolecular step A + B $\longrightarrow$ products: $\pi_i=[A]_i \cdot [B]_i$

The time-dependences of the concentrations (terms $\pi_i$) can be found by integration of the basic set of differential equations. The graphic representation of the course of the reaction for each reaction path consists in the *isothermic case* of a monotonically decreasing curve (Fig. 1). The maximum height of the signal *i.e.* the initial value of the reaction rate cannot be exactly determined experimentally, since in first-order reactions the system must be heated to the reaction temperature, whereas in a bimolecular reaction the second reactant has to be added. The adjustment of temperatures and of the concentrations thus leads to time delays and to errors in the temperature. Further, the *final part* of the isothermal curve, indispensable for formal kinetic reasons, cannot often be used because of long reaction times, especially for second-order reactions.

Measurements in which the temperature is increased in a *defined way* are much more suitable than isothermal measurements: If only the temperature coefficient differs significantly from unity, a bell-shaped reaction signal is shown, which has a defined beginning given by the first deviation from the base line and corresponds to the lowest characteristic initial temperature (cf. Section 3.1). Furthermore, both the maximum and final temperatures contain a considerable amount of information; the final temperature is reached much faster than in isothermal experiments because of the monotonically increasing rate constants (Fig. 1). These temperatures, and the width and asymmetry of this signal characterize kinetic properties.

Under conditions of *programmed temperature increase* eq. (1) is valid without limitations if the dependence of the $\lambda_i$'s on temperature is considered. The rate coefficient $k_i$ is given approximately by the Arrhenius equation

$$k_i = k_{\infty i} \exp(-E_i/RT) \tag{2}$$

## 3. Nonisothermal Reaction Kinetics of Elementary Processes

In developing analytical relationships for *temperature-programmed* runs of chemical reactions it is found that a *linear increase of the temperature of the system with time* leads to especially useful criteria for the reaction analysis by mathematical expressions. Because of linear superposition of the individual signals [eq. (1)] complex processes can be described comparatively readily thus simplifying the precalculations and analyses performed by computer.

### 3.1. Specific Time and Specific Temperature Differences

The advantages of a linear increase of temperature with time can be shown by some striking empirical rules found for *elementary first-order signal curves*.

Under homogeneous conditions the temperature program $T=T_0+mt$ affords the following derivative conversion curve when the Arrhenius equation (2) applies:

$$v(t)=k(T)[A]=k_\infty [A]_0 \exp\left[-\varepsilon/t - k_\infty \int_0^t \exp(-\varepsilon/\xi)\,d\xi\right] \tag{3}$$

$$\varepsilon = \frac{E}{m \cdot R} = \text{relative activation energy}$$

$m$ = heating rate

The term $\exp(-\varepsilon/t)$ describes the initial slow growth of the signal curve, determined by the increasing rate coefficient $k(t)$. The integral term is decisive for the later decay because of consumption of reactant A.

The lower limit of the time integral in eq. (3) corresponds to a temperature of absolute zero. The integral can be split into two partial integrals (limits $0/t_0$ and $t_0/t$, see Section 3.2) by introducing the time $t_0$ for the start of the signal; compared to the second integral, the first can be neglected. In the following discussion, the time $t$ refers to the time if the measurement were to have started at absolute zero.

No explicit analytical expression exists for the time integral[34–37]. However, introducing an unknown time function $u(t)$

$$\int_0^t k(t)\,dt = u(t)k(t) \tag{4}$$

and using an approximate solution for $\int k(t)\,dt$, arrived at by series expansion of the so-called exponential integral, and neglecting all terms higher than the second[37–39], gives:

$$\int_0^t k(t)\,dt = \frac{RT^2}{m \cdot E} k(t) = \frac{t^2}{\varepsilon} k(t) \tag{5}$$

Comparison of eq. (4) with eq. (5) and introduction of $T$ from eq. (2) gives

$$u(t) \approx \frac{RT^2}{m \cdot E} = \frac{t^2}{\varepsilon} = \frac{E}{Rm(\ln k_\infty - \ln k(t))^2} \tag{6}$$

At the maximum of the curve, the product of $u(t)$ and $k(t)$ is unity, since the term in brackets in the derivation of eq. (3) disappears

$$\begin{aligned} dv/dt &= [A]_0 \left(\frac{\varepsilon}{t^2} - k\right) k \exp(-uk) \\ &= [A]_0 \left(\frac{1}{u} - k\right) k \exp(-uk) \end{aligned} \tag{7}$$

By including the approximation equation (6), which is exact for high frequency factors $k_\infty$, $u(t)$ at the maximum ($=u_m$) may be iteratively computed from the activation parameters and the heating rate:

$$u_m = \frac{E}{R m (\ln k_\infty + \ln u_m)^2} \tag{8}$$

where $u_m$ has the dimension of time. Since this parameter allows the computation of all interesting signal features we term it the "specific time". In eq. (8) the product of $u_m$ and the heating rate $m$ is specific for each reaction ("specific temperature difference"). It depends only on activation parameters; the term $\ln u_m$ in eq. (8) functions only as a correction term.

The significance of the *specific time* may be compared with that of the *half-time* in isothermal kinetics (Fig. 1): In an isothermal rate law the product $k \cdot t$ in the exponential term determines the course with time; for the nonisothermal case it is substituted by the product $u \cdot k$. The role of the independent variable "time" is formally assumed by the rate "constant", which now becomes a time-dependent variable.

Compared with the enormous variations in $k$, the factor $u$ is nearly constant; with a linear heating rate it is more characteristic of the reaction than an isothermal rate constant, since it comprises the complete range of the experiment. Along with the initial temperature and the peak temperature it unequivocally describes all the characteristics of the signal of an elementary reaction.

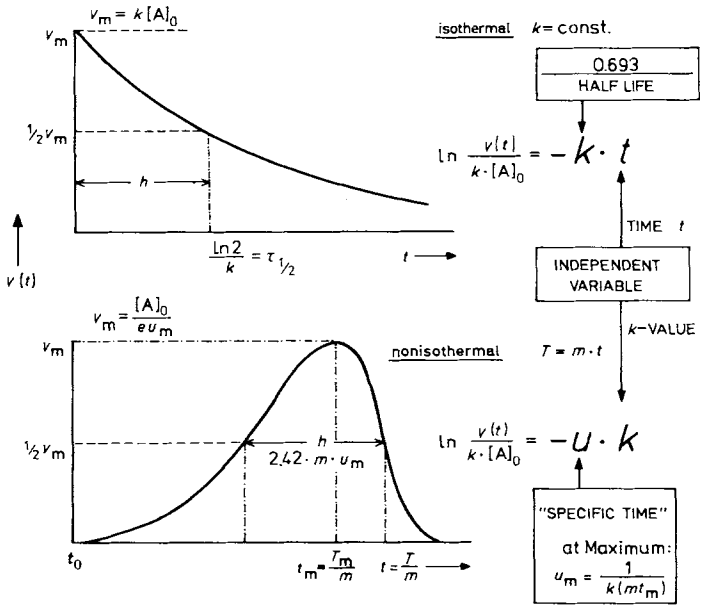

Fig. 1. First-order isothermal and nonisothermal rate laws and their corresponding rate signals.

### 3.2. Onset and Height of a Signal

The height of a peak follows directly from eq. (3) and eq. (5) with $k_m = 1/u_m$

$$v_m = [A]_0/e u_m \quad (e = 2.71828\ldots) \tag{9}$$

The initial time $t_0$ and temperature $T_0$ of the observed signal follow from the first observed deviation from the base line (threshold $\chi = v(t_0)/v_m = 0.5\%$)[37] from

$$k(t_0) = k_\infty \exp(-\varepsilon/t_0) = k_\infty \exp(-E/RT_0) = \chi/e u_m \tag{10}$$

### 3.3. Half-Width, Peak-Width, and *M* Index

The importance of the half-width for the determination of the mechanism follows from the introduction of a temperature difference $\Delta T$ in the Arrhenius equation:

$$\Delta T = T_2 - T_1 = \frac{E \cdot \ln(k_2/k_1)}{R(\ln k_\infty - \ln k_1)(\ln k_\infty - \ln k_2)} = \frac{E \cdot \ln(k_2/k_1)^2}{R(\ln k_\infty - \ln \hat{k})^2} \tag{11}$$

where $k_1$ and $k_2$ are the rate coefficients for $T_1$ and $T_2$ and, according to the mean value law, $\hat{k}$ lies between $k_1$ and $k_2$. For all striking temperature differences $\Delta T$ (such as half-width $h$, signal-width, distance between the two points of inflection) and *linear increase of temperature*, the quotient $k_2/k_1$ becomes almost independent of the activation parameters of the elementary reaction under consideration[37,40]. Hence, assuming $\Delta T = h$ the ratio

$$M = \frac{E}{h(\lg k_\infty - \lg \hat{k})^2} = \frac{R}{\lg^2 e \ln(k_2/k_1)} = \frac{m u_m R}{h(\lg e)^2} \tag{12}$$

which we term "*reaction type index*"[20,37,41] also becomes invariant. If $\hat{k}$ is viewed as the reciprocal specific time $u_m$ defined by eq. (8), then all typical differences of temperature and time become proportional to this quantity:

$$\Delta T = m \Delta t = m \ln(k_2/k_1) \cdot u_m \tag{13}$$

### 3.4. Reactions of n-th Order

The term "reaction of n-th order" is considered here as a process, whose reaction rate may be formally supposed to be proportional to the power n of only *one* concentration ($-\mathrm{d}[A]/\mathrm{d}t = k \cdot [A]^n$). This definition is more restricted than usual. Its existence is based on the possibility of substituting all other variable concentrations of the rate law by a *single one*.

It will be shown here that only this *scheme of order* based on a mathematical formalism enables a satisfactory discussion and classification of the kinetic phenomena. The factor of proportionality $\ln(k_2/k_1)$ follows from computer simulations[44] for a reaction of n-th order (unit concentration of the reactants) as

$$\ln(k_2/k_1) \approx 2.25 \times n^{0.52} = \begin{matrix} 2.25 \pm 0.04 & \text{(first-order)} \\ 3.23 \pm 0.14 & \text{(second-order)} \end{matrix} \tag{14}$$

The complete signal width is given by

$$n = 1: \ \ln \frac{k_2}{k_1} = 2.9 - \ln \chi \tag{15}$$

$$n \neq 1: \ \ln \frac{k_2}{k_1} = n \ln \frac{n}{n+1} + (n-1) \ln [A]_0 - n \ln \chi \tag{16}$$

During registration of the "bell signal" and with $\chi = 0.5\%$, the rate coefficient for a first-order elementary process always increases by three, however, for a second-order process by as much as five orders of magnitude[37]. An additional value typical for the reaction order[20] is the "shape index" which characterizes the asymmetry of the peaks. It was introduced by *Kissinger*[9,42,43] some thirty years ago. For $n > 1$ Kissinger's formula shows increasing deviations from reality. We, therefore, developed a general empirical relationship (for $0.6 < n < 10$) by computer simulation. For $n = 1$ and $n = 2$ it has also been successfully verified experimentally[44].

$$S = \frac{n^2(1.21 + 0.21n)}{n^2 + 1.59} (\approx 0.63n^2 \text{ for } n < 1)^{[43]} \quad (17)$$

The shape index $S$ and the reaction type index $M$ have proved to be especially valuable in characterizing complex processes. We therefore term these quantities "mechanistic coordinates".

## 4. Signals of Complex Processes

### 4.1. Series of Reactions

By reaction mechanism we mean the combination of all the elementary steps involved in the conversion of the educt (or educts) into the final product(s). When considering the most simple "mechanisms" of a system that contains only *two elementary processes* of first-order (EP1; index 1) we have to discuss four elementary types

1. Reactions with *consecutive* coupling (consecutive reactions F11). The second reaction can only occur after the first.
2. Reactions with *concurring* coupling (concurrent reactions P11). Both reactions proceed from the same educt(s), and each individual reaction reduces the rate of the other.
3. Reactions with *reversible* coupling (opposing reactions G11). The educt can be re-formed from the product.
4. *Uncoupled* reactions (independent reactions U11). Two different reactions step from two different educts (or pairs of educts), possibly yielding the same product.

If reactions of second-order (index 2) or of the bimolecular AB type (index $\bar{2}$) are also taken into consideration, *concurring consecutive* reactions (F1a, F2a, F$\bar{2}$a), in which the final product reacts again with the educt, and *autocatalytic* reactions (1a), in which product makes the reaction possible by acting as bimolecular, but unchanged reactant, ensue as special cases.

### 4.2. Nonisothermal Classification Criteria

The bell shape of the signals described yields a number of classification criteria for complex reactions (Table 1).

Table 1. Criteria for the interpretation of derivative signals of complex processes. The indication parameters $\lambda_i$ of the continuing processes [eq. (1)] must have the same sign. EP1 = elementary process of 1st order, P22 = two parallel processes of 2nd order, etc. (cf. Table 6).

| No. | Quantity | Behavior/Interpretation | | | Remarks |
|---|---|---|---|---|---|
| Whole curve | | | | | |
| 1 | Number of peaks | is smaller than or equal to the number of elementary steps; is equal to the number of slower successive steps | | | Competing processes show only one peak |
| Isolated Signals [19, 45] | | | | | |
| 2 | Sign of the signal | Change of sign | ⇒ | Opposing reactions with $\vec{E} > \vec{E}$ | Peak pairs |
| | | | | *Corresponding processes?* | |
| 3 | Initial temperature $T_0$ of a peak (relative to $\chi$, eq. [10]) for sinking initial concentration of the reaction-determining reactant | remains constant | ⇒ | type: EP1 or P11 | Only when cross-terms or catalytic processes are absent: $T_0$ characterizes the reaction which forms the basis of the peak; $\theta_m$ characterizes |
| | | converges to a limiting value | ⇒ | type: P12 | |
| | | increases without limit | ⇒ | type: EP2 or P22 | |
| | | | | *Previous processes?* | the kinetic flux at this point of the reaction scheme, *i.e.* previous reactions! |
| 4 | Relative signal height $\bar{\theta}_m$ for sinking initial concentration of the reaction-determining reactant | remains constant | ⇒ | no or unbranchend reaction sequence or branches of type | |
| | | converges to a limiting value | ⇒ | continues by unimolecular steps of type P12 branches | |
| | | disappears | ⇒ | continues by at least *one* bimolecular step of P12 branching | |
| Overlapping signals | | | | | |
| 5 | Shape index $S$ [a] | constant = $S_1$ or $S_2$ | ⇒ | EP1/2 (if also $M = M_{1(2)}$) | Only for linear temperature increase: $M$ from eq. (12) [11, 13, 33, 46], cf. Table 6 and [20]. |
| 6 | Reaction type index $M$ [a] | constant = $M_1$ or $M_2$ | ⇒ | EP1/2 (if also $S = S_{1(2)}$) | |

[a] To be extrapolated to absent thermal feedback [44,48]; $M_1 = 0.0019$, $M_2 = 0.0013$ kJ/mol/K; $S_1 = 0.58$, $S_2 = 1.15$.

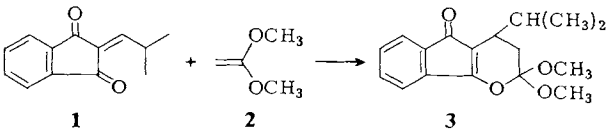
*Isolated peaks* are specifiable kinetically by the dependence of the initial temperature on concentration (see eq. (10). The relative signal height gives information on possible branching reactions (cf. Fig. 1).

### 4.3. The Mechanistic Diagram

In order to characterize more distinctly a single, possibly overlapped peak, a "mechanistic diagram", obtained by plotting the reaction index $M$ versus the shape index $S$, may be used. All mechanistic points corresponding to a reaction of n-th order should, because of the validity of equations (12), (14), and (17), lie on a universal decreasing curve[47]. The simplest complex reactions, which consist of the fundamental mechanisms of the P, F, G, and U type, respectively, show typical regions that include the source points for elementary processes of first and second order[3, 19, 20].

The "mechanistic coordinates" $M$ and $S$ appear to be equivalent for the kinetic diagnosis, however, they yield different kinds of information. This follows from the different methods used for their determination. The $S$ factor may be extracted directly from the derivative conversion curves[43], whereas the computation of the $M$ index requires a reference reaction. A plausible method of relating $M$ to the activation parameters of the initiating reaction[19, 20, 45, 49] leads to errors at the onset of the signal curve because of the noise level. If gross activation data are used to determine $M$ then the optimizing criteria become more important as the reaction increases in complexity. Depending on the definition of the reference reaction, different patterns of the "mechanistic regions" relative to the $M$ axis follow (cf. Fig. 9a/b).

## 5. Evaluation of Differential Curves



### 5.1. Conversion Curves of Elementary Processes

The rate coefficient for the rate law of a reaction of n-th order is given by

$$k(T)=k(m\cdot t)=\frac{v(t)}{\left(\int_0^\infty v\,\mathrm{d}t-\int_0^t v\,\mathrm{d}t\right)^n} \qquad (18)$$

The temperature dependence of $k$ yields the order n and the activation parameters. Since for elementary processes in homogeneous kinetics n is only 1 or 2, and less usually 3 (collision reactions of neutral molecules in the gase phase), it was not optimized. A noninteger value of n may formally characterize a complex process, but is irrelevant for mechanistic considerations. For n = 1 and n = 2 (or a reaction A + B → products; AB type[47, 50]) it may be tested which of these proposals affords the best approximation. For this purpose the complete curve (net data) as well as the first 25% of the curve (initial data, cf. Section 7.2) were used.

The method of evaluation may be tested directly *e.g.* by temperature-programmed UV reaction photometry at a fixed wavelength[51–54]. In order to evaluate equipment specifically developed for this purpose[55], we used a reaction that had been previously studied isothermally[56], the 1,4-addition of isobutylideneindanedione **1** to 1,1-dimethoxyethene **2**, which was performed pseudo-unimolecularly in presence of a large excess of **2**.

**1** **2** **3**

The computer calculation[50, 55] using eq. (18) affords a satisfactory Arrhenius plot ($r = 0.9956$) for the recorded curve of the extinction change at 392 nm, corresponding to an activation energy of 41.8 kJ/mol and an $A$ factor of $4.05 \times 10^{-5}$ $M^{-1}$ $s^{-1}$: isothermal reaction spectroscopy in toluene gave 40.9 and $3.23 \times 10^4$, respectively, and in acetonitrile 44.9 and $3.03 \times 10^7$, respectively[56]. Since the polarity of ether lies between that of toluene and of acetonitrile, our new result may be considered reasonable. With DTA we found that increasing the concentration of **1** by a factor of 1000 gave values of 53.2 kJ/mol and $4.28 \times 10^7$ $M^{-1}$ $s^{-1}$.

Hitherto, eq. (18) has been applied to thermoanalytic data from solid samples (thermogravimetry, differential scanning calorimetry). Under these conditions local variations in the temperatures or in the concentrations frequently cause difficulties[57, 58].

### 5.2. Kinetic Measurements by Differential Thermal Analysis

To experimentally verify the relationships and rules found for nonisothermal conditions[13, 48, 60, 107] we have usually preferred a special form of differential thermal analysis (DTA)[61, 62], which can also be used as a thermokinetic method[59]. The signal, the temperature difference $\theta(t)$ between sample and a reference material, can be viewed as a delayed differential conversion curve with delayed decay. Eq. (1) can be applied directly only in the limiting case of an infinitely high cell constant $c$, under which conditions no measurable temperature difference occurs[44]. Generally, for equipment with uniform temperature distribution eq. (19) applies

$$\frac{\mathrm{d}\theta}{\mathrm{d}t}=\frac{V}{c\cdot C_p}\sum_{i=1}^{P}\frac{\mathrm{d}q_i}{\mathrm{d}t}-c\,\theta(t)=\frac{V}{c\cdot C_p}\sum_{i=1}^{P}\Delta H_i v_i(t)-c\,\theta(t) \qquad (19)$$

$V$ is the volume of the sample and $C_p$ its heat capacity.

The total heat flow $\dot{Q}=\sum\dot{q}_i$ generated by the reaction can, according to eq. (1), be represented as the sum of the products of the reaction rates $v(t)$ and the enthalpies $\Delta H$ in the individual branches of the reaction scheme[33, 40, 41].

DTA is often used uncritically in studies of the solid state[13, 57, 63] where it is assumed that the measured signal[43, 64, 69, 70] $\theta(t)$ and reaction rate according to eq. (1) are synchronous. This is generally inadmissible and can only yield the approximately correct kinetic data in individual cases by compensation of opposing errors, *e.g.* inhomogeneities in temperature[65, 66]. In the solid state or in nonstirred solutions the spatially complex interrelations of reaction and transport processes preclude an exact and

straightforward evaluation. For our studies we therefore developed an *apparatus for DTA studies of solutions,* in which a stirring device guarantees satisfactory validity of eq. (19)[48,59,60,67]. Assuming different cell constants $c$ and various maximum differences in temperature, our model computations have led to several empirical approximation equations, which can even be worked out on a simple pocket calculator. Thus, the typical mechanistic coordinates of a reaction [cf. eqs. (11) and (12)] can be expressed in terms of the ideal values of the reaction rate curve which corresponds to a DTA curve with infinitely high $c$ and, hence, to a vanishing temperature difference[44,47].

A DTA plot can be evaluated by comparison with a theoretical curve, by use of reaction rates computed by means of eq. (19) or, more easily, using an equation reported by *Botchardt* and *Daniels*[68] that gives $k(t)$ directly[69,70].

Using our DTA equipment we have studied many processes that proceed practically *via* one elementary step, and have always observed good agreement with activation parameters determined isothermally[69-71]. Furthermore, the experimental signal curves could be readily reproduced from these values by numerical integration.

### 5.3. Conversion Curves of Complex Processes

The large number of kinetic phenomena from isothermal reaction kinetics are further increased by the influence of one controlling parameter, the heating rate; such a variety can only be made fully comprehensible and rendered useful for reaction analysis using a computer[3,11,13,41,44,46,47]. We use three different types of computer programs (cf. Fig. 2)[19,40,70]:

1. Evaluation programs which accept and calculate the various kinds of data from the experimental curves under the assumption of an elementary step. The results are optimized activation parameters and related kinetic data such as the mechanistic coordinates.
2. Simulation programs which, starting from a kinetic model or from data predetermined by an evaluation program, calculate a theoretical signal curve, and compare this with experimental curves.
3. Search programs which extract data for the given combination of reactants (systems) and for given ranges of the selected parameters from an experimental library. From the tabulated series produced, any input and/or results' parameters can be mutually compared and displayed graphically.

#### 5.3.1. *Pre-evaluation Assumpting an Elementary Process*

The experimental curves should first be evaluated assuming an *elementary* step, because calculation of the reaction type index $M$ requires the activation data of a reference reaction. If one is dealing with an elementary reaction, then the real activation data are produced. For a complex process indications of how to split the curve into elementary signals are provided[20] (cf. Section 6.3). The behavior of the mechanistic coordinates strongly limits the possible types of reactions (cf. Section 4.3).

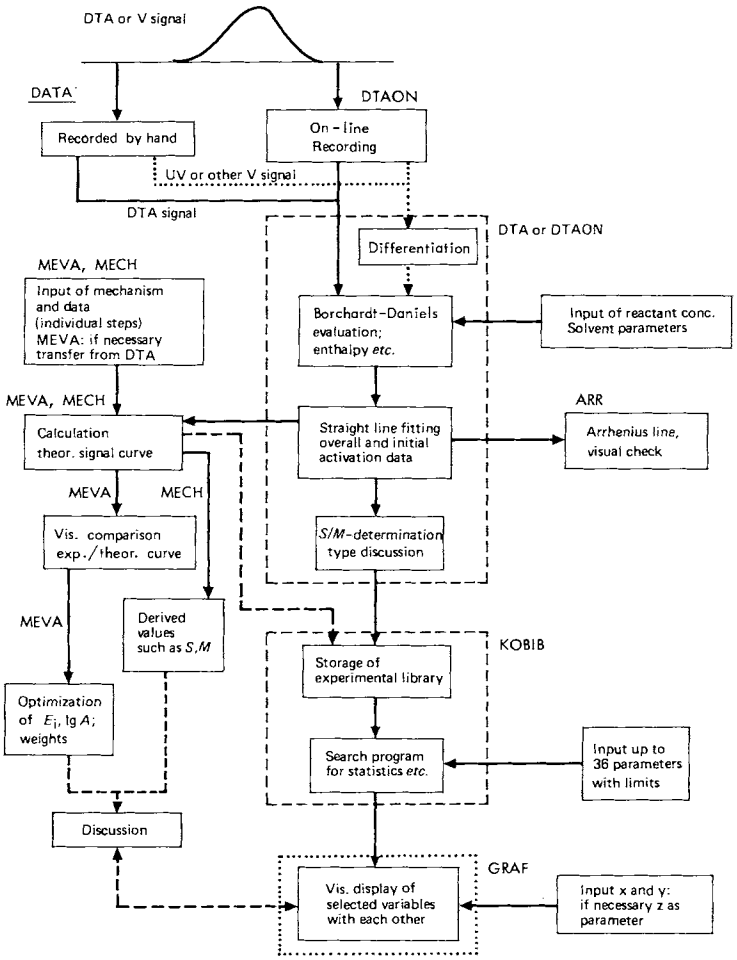


Fig. 2. Scheme for data processing and data compilation.

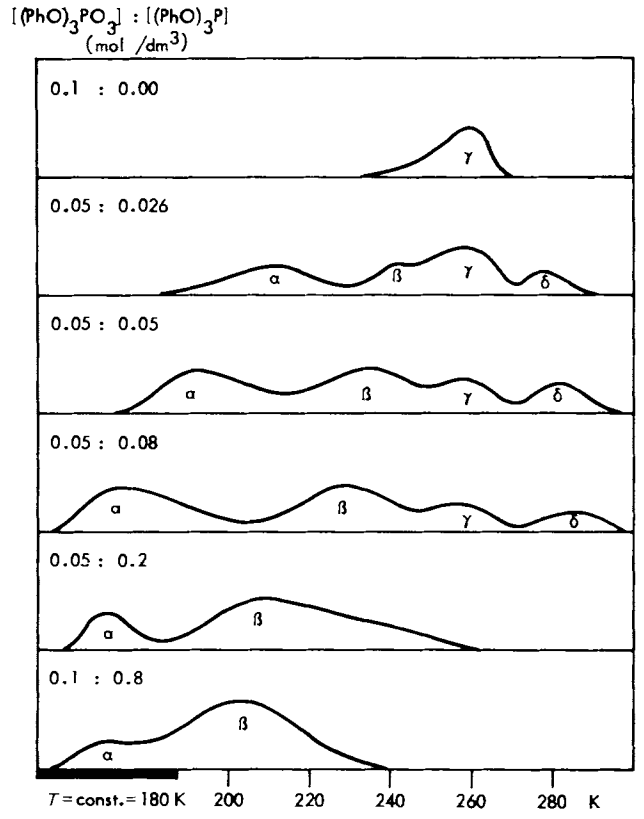
#### 5.3.2. *Isolated Signals*

When a number of *isolated* peaks is present, which only overlap at a particular range of reactant concentrations, the kinetic criteria 1–4 of Table 1 in combination with the systematic selection of reaction partners are often sufficient to ascertain the overall mechanism. For example, in the decomposition of triphenyl phosphite-ozonide **4** in presence of triphenyl phosphite above 190 K[72,73], up to seven elementary processes can be involved. Figure 3 shows that completely different signal curves with up to four peaks can be obtained simply by changing the $(PhO)_3PO_3$ : $(PhO)_3P$ component ratio. The phosphite itself acts as a scavenger for the ozonide (reaction 1 in Fig. 3). A change in its concentration causes a shift of the peaks of bimolecular processes along the temperature axis, whereas unimolecular peaks such as the actual decomposition reaction (reaction 2; γ peak) remain unchanged in position.

As in isothermal kinetics, the influence of the starting concentrations of the reactant(s) forms the basis for the determination of the reaction mechanism.

#### 5.3.3. *Overlapping Signals*

The detailed investigation is based on the position and trends of the $S/M$ points[18,20,74] and is facilitated by comparative numerical integration.



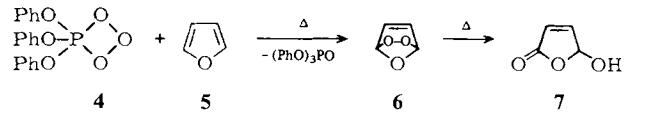


Fig. 3. DTA curves for the decomposition of triphenyl phosphite-ozonide (≙ $PO_3$) in presence of increasing amounts of triphenyl phosphite (≙ P)

Reactions:

| | | | |
|---|---|---|---|
| 1 | $P + PO_3 \longrightarrow PO_2 + PO$ | | (α-peak) |
| 2 | $PO_3 \longrightarrow PO + O_2$ | | (γ-peak) |
| 3 | $2\,PO_2 \longrightarrow PO_3 + PO$ | } | (β-peak) |
| 4 | $2\,PO_2 \longrightarrow (PO_2)_2$ | } | |
| 5 | $P + PO_2 \longrightarrow 2\,PO$ | } | |
| 6 | $(PO_2)_2 \longrightarrow 2\,PO + O_2$ | | (δ-peak) |

Computer programs which calculate the kinetic measurement curve directly from a given model allow the comparison of the proposed mechanistic model of a reaction with the real process—a procedure which was not available to classical chemistry. However, the possibilities offered by such programs[5,7,45,75] should not be overestimated. Even if one finds a suitable model for a complicated process, for example with 20 reaction steps, this still requires 60 different parameters, *i.e.* 20 activation energies, 20 frequency factors, and 20 (in some cases even more) indication parameters. Some of these parameters may be calculated from others and it may often be possible to use literature data for some of the steps. Nevertheless the remaining variation possibilities are so large that, despite progress in computer techniques, the problem of finding the appropriate reaction mechanism and the optimum values of *all the parameters* only by comparative numerical integration does not appear to have been solved for such large numbers of individual processes. On the other hand, the value of a model is only apparent when a large number of curves having different boundary conditions can be exactly reproduced, because only then have the calculated kinetic parameters sufficient significance.

Figure 4 shows the computer printout for a relatively easily understandable case with experimental (bar chart) and theoretical best fit curves (solid line) for the formation and subsequent decomposition of the ozonide-like peroxide **6**. If furan **5** is allowed to react directly with triphenyl phosphite-ozonide **4**, whose decomposition above 240 K is thought to involve singlet oxygen[71,73], then DTA curves are produced, whose simulation can be performed with the help of data given in Figure 4. Hence, in this case two consecutive processes are involved, resulting in two overlapping peaks: these correspond to the oxidation and the isomerization of the oxidation product[74,76].

4 5 6 7

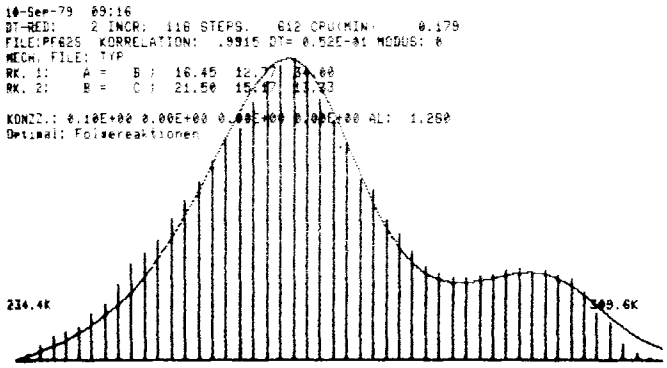

Fig. 4. Thermal formation and isomerization of epidioxidihydrofuran **6**.

Table 2 shows the data for reactions of different complexities which have been similarly determined. For those elementary processes which have been individually investigated, the activation parameters have been confirmed using the Borchardt-Daniels equation[41,70,72,74,76].

### 5.3.4. *Reactions with Fast Consecutive Steps*

The kinetics of *successive reactions* where the second step is much faster than the first are determined only by the initiating reaction. Although this may appear to be trivial, in this particular case computer simulation may often involve unacceptably long computation times.

Such problems always arise when the rate constants of the corresponding individual steps differ from one another by large orders of magnitude ("stiff" systems). Such systems are quite common in chemical kinetics, and in the last few years special application programs have been developed[5–7,75,77].

For nonisothermal simulation of successive reactions of this type, in which the second reaction continuously slows down, a transition range is observed in which the signal is split into two peaks. In particular, this splitting is of major importance for the investigation of *intermediates* which are the prerequisite for the *existence of consecutive steps*. By application of integration programs developed by *Gear*[77] to reaction systems where the second step is much faster than the first, it was found that the gross index ($M_g$) as well as initial index ($M_0$) can still show differences from the elementary values. Whereas the $S$ value shows the limiting value $S_1$ (Table 3), a variation of $\geq 5\%$ in $M$ must be considered as significant; often the $M$ value enters this toler-

Table 2. Simulation of experimental DTA curves of some complex processes between 140 and 400 K. $r$ = correlation coefficient; $E$ and $\Delta H$ in kJ/mol; $k_\infty$ in $s^{-1}$.

| Reactants | [Solvent] | Intermediates | Final products/ remarks | Type | Step | $E$ | $\lg k_\infty$ | $-\Delta H$ | $r$ |

ance range only when $k_2 > 10^4 k_1$. Consequently, by careful nonisothermal investigation of apparently elementary processes it is possible to obtain information about intermediates.

### 5.3.5. *Reactions with Kinetic Feedback*

The concept of the *initial reaction* of a complex process becomes problematic either if *reversible processes* lead back to the educt or if *chemical feedback systems*[23] are involved so that the educt reacts again with the product(s). Typical examples for this are oscillating reactions which can be interpreted using nonlinear *differential equation systems* and which exhibit close relationships to the thermodynamics of systems in far-from-equilibrium states and to biochemistry[23, 40, 78].

At present, the best known reaction of this type is the oscillating oxidation of malonic acid (MA) by bromate which is catalyzed by Ce salts or ferroin in presence of bromide (Belousov-Zhabotinsky reaction). *Field* and *Noyes*[79] have developed a simple model ("Oregonator") which reproduces almost quantitatively the main kinetic properties of this system, especially the oscillations:

Tentative assignment [79]

| | | |
|---|---|---|
| A + Y = X | (M1) | Formation of $HBrO_2$ from $HBrO_3^-$ and $Br^-$ |
| X + Y = P | (M2) | Termination reaction $HBrO_2$ and $Br^-$ |
| B + X = 2X + Z | (M3) | Formation of $Ce^{IV}/HBrO_2$ from $BrO_3^-$ and $HBrO_2$ |
| 2X = Q | (M4) | Disproportionation of $HBrO_2$ |
| Z = fY | (M5) | Re-formation of $Br^-$ and $Ce^{III}$ |

Net reaction fA + 2B = fP + Q
A = B = $[BrO^-]$; Y = $[Br^-]$; X = $[HBrO_2]$; Z = $[Ce^{IV}]$;
Q, P = final products = HCOOH, CO, dibromo-MA, monobromo-MA
f = number of $Br^-$ formed from two $Ce^{IV}$ ions.

This reaction (cf. [84]), many details of which have not yet been completely investigated, served as a model for the further development of nonisothermal kinetic methods[78].

Stable oscillations occur only when the system is open, *i.e.* when the reserves of bromate are maintained constant.

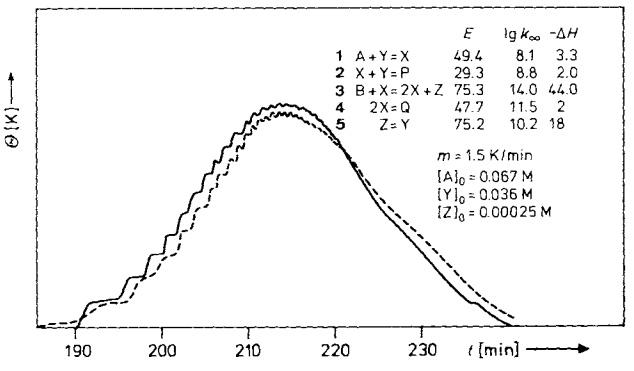

Fig. 5. Oscillating DTA curves for the Belousov-Zhabotinsky reaction: —— experimental; --- theoretical.

If, however, the reaction is carried out in a closed system, for example as in a DTA experiment, only damped oscillations occur (Fig. 5). They are mainly caused by the strongly exothermic (M3) process. For this a overall activation energy of 67 kJ/Mol has been discussed[80].

The oscillative fine structure is caused by the energy changes in the limiting cycle which is based on the variations in the maximum concentration of the $Ce^{IV}$-salt in one pass. Their visible detection in the DTA apparatus requires a much higher concentration than with UV spectroscopic or potentiometric measurements ($\approx 10^{-2}$ M instead of $\approx 10^{-4}$ M). The frequency, amplitude, and temperature position of the calorimetric oscillations are reproducible, and can be closely simulated assuming that the "Oregonator" mechanism applies (Fig. 5) when the parameters are adjusted for each experiment[78,81].

Study of the unstructured DTA signal curve provides insight into the kinetics of essential steps responsible for the consumption of bromate. In this case lower concentrations of catalyst can be used to enable comparison of the results of the isothermal experiments with those reported in the literature.

Almost half of the curves from 50 experiments with $Ce^{III}$ chloride or ferroin as catalyst could be described by simple bimolecular reactions[47,50] despite changed heating rates, bromate, and catalyst concentrations (Table 4). In contrast, a large part of the rest can be described by the following three-step mechanism[78,82,83].

| | | |
|---|---|---|
| A + B = C | (S1) | bimolecular initiation |
| A + C = 2C + D | (S2) | autocatalytic step |
| D = B + E | (S3) | regeneration of bromide |

By limiting the number of steps to three the termination reactions (M2) and (M4) are neglected, which requires the assumption of widely differing reaction enthalpies (up to 1:50, cf. Table 4). This is an indication that the three apparently elementary steps (S1)–(S3) have to be considered only as the *representative rate-determining reactions* for the more extensive part mechanisms[78,84]. A systematic analysis of fast consecutive steps should make use of the results discussed in Sections 5.3.4 and 6.2; in the meantime 24 elementary steps for this reaction have been discussed[84]. A possible solution at present would be to extend the preliminary approximate nonisothermal model by using the results obtained on the subsystems ($Br^- + BrO_3^-$, $Ce^{4+}$ + malonic acid *etc.*)[3]. It will be shown later in detail that a nonisothermal investigation offers many starting points for recognising the kinetic part-structures of a reaction mechanism.

Table 4. Kinetic data and enthalpies of the oscillating Belousov-Zhabotinsky reaction for the three-step mechanism from DTA curves (cf. text).

Unit of time: min; $[KBr]_0 = 0.053$ M
Universal activation energies: $E_1 = 49.3$, $E_2 = 79.7$, $E_3 = 41.8$ kJ/mol

11 Experiments with ferroin as catalyst
$[KBrO_3]_0 = 0.04$, 0.06, 0.075 or 0.10 M (0.10 in 5 cases); Heating rates: 0.6–1.6 K/min; correlation coefficient: $0.970 \pm 0.036$

| Step | $\lg k_\infty$ | $k_{298}$ | $-\Delta H$ (kJ/mol) |
|---|---|---|---|
| 1 | $7.59 \pm 0.34$ | 0.097 | 8–130 |
| 2 | $13.43 \pm 0.61$ | 0.33 | 6– 80 |
| 3 | $5.17 \pm 0.38$ | 0.008 | 15–197 |

7 Experiments with $CeCl_3 \cdot 6H_2O$ as catalyst; $[KBrO_3]_0 = 0.06$, 0.10, 0.12 or 0.14 M;
Heating rates: 0.5–1.5 K/min; correlation coefficient: $0.964 \pm 0.044$

| Step | $\lg k_\infty$ | $k_{298}$ | $-\Delta H$ (kJ/mol) |
|---|---|---|---|
| 1 | $7.57 \pm 0.43$ | 0.092 | 4– 15 |
| 2 | $12.93 \pm 0.39$ | 0.105 | 42–133 |
| 3 | $5.18 \pm 0.32$ | 0.008 | 72–238 |

## 6. Summary of Phenomena in Homogenous Kinetics

Using the search programs mentioned in Section 5.3 it is possible to test all the currently stored data, presently comprising *ca.* 1400 measurements on about 120 different systems (Table 5), under various aspects. In this respect, it is not only possible to search the complete data for representative samples but also to consider series of experiments determined by the type of reactant and/or by definite ranges of some 40 parameters specifying the conditions or results.

Table 5. Systems studied under nonisothermal conditions.

| |
|---|
| Unimolecular reactions |
| Decomposition of diazonium salts, triphenyl phosphite-ozonides, epidioxides, hydroperoxides, and pentazoles |
| Pseudo-unimolecular reactions |
| Addition of solvents to unstable peroxides |
| Scavenging reactions of unstable olefins with dienes |
| Oxidation of dienes |
| Quasi-elementary bimolecular reactions |
| Diels-Alder reactions |
| Reduction and scavenging reactions of peroxides and ozonides |
| Thermal oxidation reactions |
| Reaction of CH-active compounds with ozone |
| Reactions involving the formation of peroxides and trioxides |
| Bromination of peroxides |
| Benzoylation of alcohols |
| Complex reactions |
| Decomposition of sulphoxides [88], sulfides, boranes, phenylthiatriazole |
| Reactions of trioxides |
| Decomposition of peroxides, ozonides or their scavenging reactions |
| Reactions of $Fe(CO)_4$- and $Ni^0$ phosphite complexes |
| Reactions with hydrazine, diazomethane, $HN_3$, and their photoproducts |
| Catalyzed oscillative oxidations with bromate |
| Uncatalyzed oscillative oxidation of arenes with bromate [106] |
| Autocatalyzed oxidation of malonic acid with $KMnO_4$ |
| Reaction of iodate with hydrogen peroxide, also in presence of $MnSO_4$ |

When one considers the components which are present in less than stoichiometric proportions then the following reaction types appear in the proportions indicated.

1. First-order reactions (unimolecular; area 1 Fig. 9; 12%)
2. Second-order reactions (bimolecular; for different reactants, molecular proportions 1 : 1, area 2; 4%)
3. Bimolecular reactions, reactants in nonequimolar proportions (areas A and 2 after correction; 27%)
4. Complex reactions with rate law of n-th order ($n \neq 1$, $n \neq 2$; 7%)
5. Other complex reactions (areas Ø, B–H; 50%)

The given percentages should only be seen as approximate, because the results depend upon the limits which define the elementary areas (3% of the $S$ or $M$ value) and also partly upon the selection of the problem to be investigated.

### 6.1. Relationships for Elementary Processes

A *first-order reaction* which is often used for test purposes is the decomposition of benzenediazonium sulfate, formed by diazotization of aniline in acidic media at 273 K (Fig. 6a–d)[60,85]. Figure 6a shows the mechanistic points $S/M$ for all the experiments which have been carried out in the aniline concentration range $<0.5$ M and for $0.1 < m < 5$ K/min. The sensitivity of this particular method is shown by the fact that only under optimum experimental conditions (such as excess of nitrite) do the resulting $S/M$ points lie near the *first-order source point*. In addition to the reaction type, the total activation energies of approximately first-order reactions are independent of the heating rate (Fig. 6b).

If thermal feedback is not too large then the maximum recorded temperature difference of the DTA curve is proportional to the concentration of the reactants[19]; here this is the concentration of aniline used for the reaction (Fig. 6c) because diazotization proceeds practically quantitatively.

The initial temperature $T_0$ of the DTA curve and the relative signal height $(\theta_m/[A]_0)$ turn out, as expected, to be independent of the initial concentration. On the other hand $T_0$ of a *rate curve* increases monotonically *with the heating rate* because of the temperature dependence of the initial rate coefficient [eq. (10)]:

$$T_0 = m t_0 \approx \frac{E}{R(\ln k_\infty - \ln k_0)} = \frac{E}{R\{\ln k_\infty + (1 - \ln\chi) + \ln(u_m m) - \ln m\}} \quad (20)$$

For the peak temperature $T_m$, the same relationship holds, but without the term $(1 - \ln\chi)$ in the denominator. The specific temperature difference $(u_m m)$ is practically independent of the heating rate, and for the decomposition reaction it is *ca.* 7.8 K. For the DTA curves rather complicated, but formally similar expressions for the typical temperatures are found[19]. In spite of this it is possible to satisfactorily describe the observed influence of heating rate on DTA by adjusting the sensitivity limit $\chi$ in eq. (20), (Fig. 6d).

Pure *second-order signal curves* are only rarely observed. Usually the results do not exactly obey the strict nonisothermal criteria of a bimolecular reaction of the type EP2, thereby indicating side reactions[47,50]. Indeed, it follows from the law of mass action that the requirements for the quantitative course of a bimolecular reaction with a 1 : 1 ratio of the components are highly unfavorable. In this case possible competitive reactions of first order would be most highly favored.

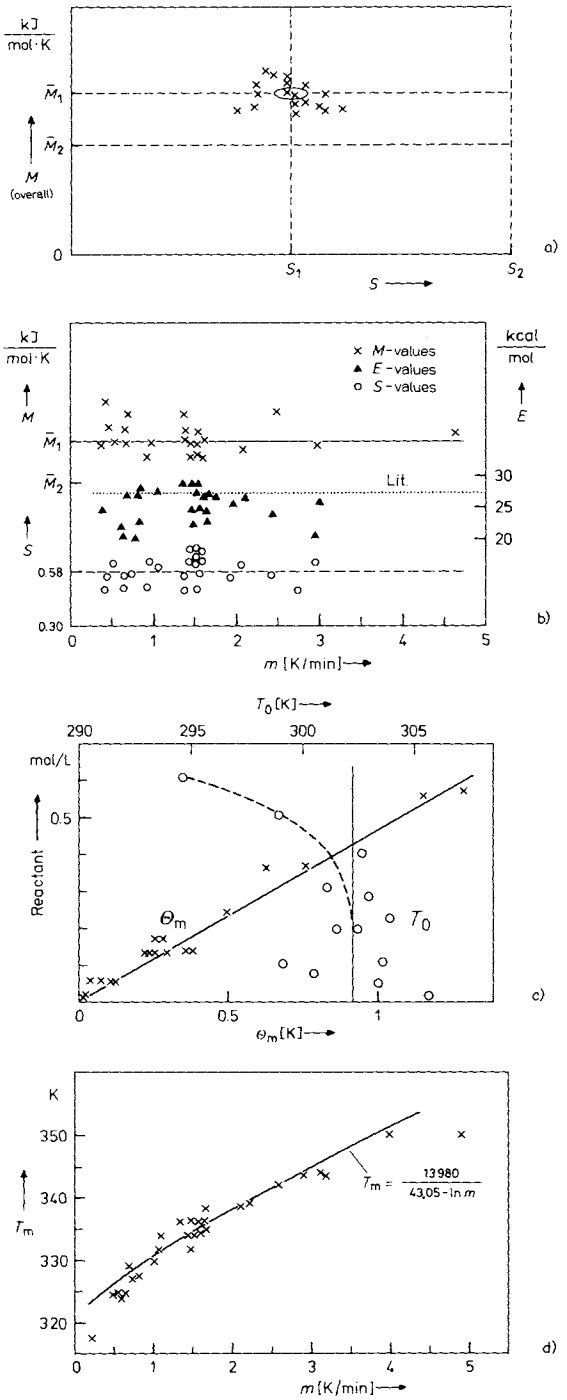

Fig. 6. Various correlations for the decomposition of benzenediazonium sulfate in dilute sulfuric acid: a) Mechanistic coordinates ($M$ and $S$); b) $M$-index, shape index $S$ and activation energy $E$ *vs.* heating rate $m$; c) relative signal height $\Theta_m/c_0$ and initial temperature $T_0$ *vs.* concentration $c_0$; d) Peak temperature $T_m$ *vs.* heating rate $m$.

The quantitative relationships are similar to those of elementary signal curves of first order. However, for some values the initial concentration is involved, *e.g.* for the half-width and the mechanistic coordinates (see also Fig. 8a; cf. [37,47]). An increase in concentration produces a similar effect to that of raising the $A$ factor, and the characteristic temperatures are shifted to lower values.

### 6.2. Bimolecular Processes

A preliminary kinetic investigation of *bimolecular processes* is of use in optimizing organic preparative procedures, since the observation that kinetically complex relationships are involved is only an expression of the fact that the main product cannot be prepared in 100% yield. The results of reactions with nonequivalent concentrations are especially interesting (AB-type)[47,50], because particularly in low-temperature reactions poor solubility may often prevent the use of large excess of one component. The mechanistic coordinates of experiments with two reactants of different concentrations (Fig. 8b/c) belong mainly in area C or A, and only rarely in E or others. On the other hand, use of coordinates corrected for a 1:1 ratio leads to a grouping near the horizontal line $M=\bar{M}_2=0.013$ kJ/mol/K. Since only a small fraction of experiments show the corrected $S$ value of 1.15 corresponding to a reaction of second order, the major proportion of these reactions must be complex. This is also shown by the values found for overall $A$ factors which lie above the realistic limit ($\lg A=17$), particularly when $M$ differs markedly from $\bar{M}_2$.

At very high initial concentrations, large thermal feedback caused by the heat of reaction is to be expected. This can lead to difficulties in interpretation because the solution shows inhomogeneities; in extreme cases an explosion may occur. For this reason the correlation coefficients of the optimized Arrhenius straight lines decline with large peak heights (Fig. 7).

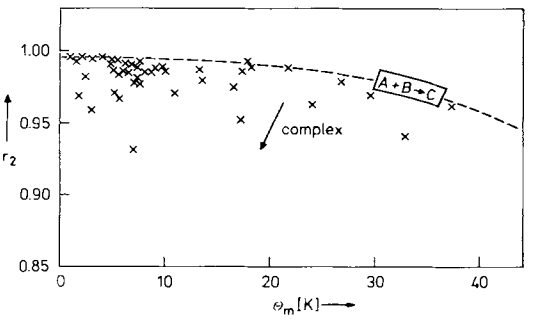

Fig. 7. Correlation coefficient for the expected bimolecular processes as a function of the DTA peak heights $\Theta_m$.

### 6.3. Complex Processes

It is possible to describe complex reactions by interpreting the signal curves by two parameters depending differently on the reaction order. This opens a route to answering questions on apparent elementary reactions and, hence to those involving the rate-determining step (cf. Sections 5.3.4/5).

Figure 8 shows the results of about 50 different experiments with initial temperatures of 200 to 260 K. For the selection of the correct reference reaction, the concentration of *one reactant* or the concentrations of *two reactants* were considered. Only a small fraction of the experiments having *expected unimolecularity* (Fig. 8a) actually correspond to an overall unimolecular reaction. Only for these cases are the overall activation parameters representative of *one* reaction. In most of the other cases, only the $M$ index conforms to the expected type EP1 ($M\approx 0.019$), whereas the remainder fall predominantly into the area of autocatalytic reactions or concurring successive reactions ($M>\bar{M}_1=0.019$)[20,21,45]. The number of points near the curve for reactions of n-th order are low[40] (cf. Fig. 9a/b).

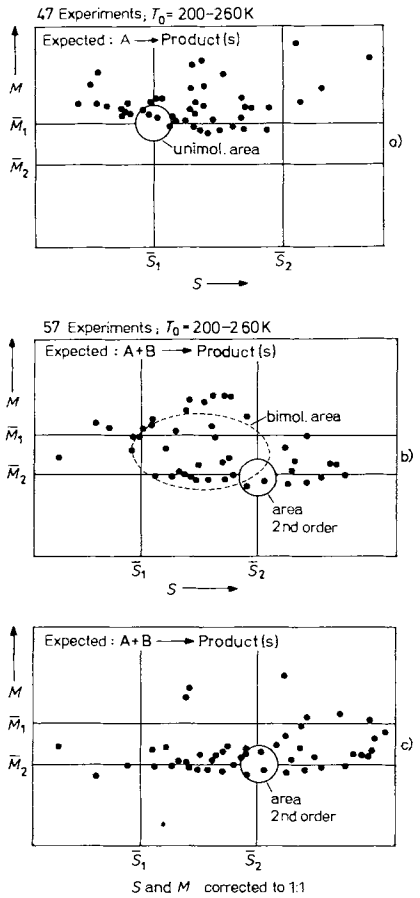

Fig. 8. Overall $M/S$ characteristics of various types of reactions: a) expected unimolecularity, b) expected bimolecularity c) as b), but after readjustment to a 1:1 molar ratio.

The results for the examples of *expected bimolecularity* are similar. The $M$ index shows the expected concentration in the A area and near the horizontal line $M=\bar{M}_2=0.013$ kJ/mol/K (Fig. 8b). After recalculation on the basis of a 1:1 molecular ratio ($[A]_0=[B]_0$) this preference becomes even greater (Fig. 8c). Even after recalculation, the $S$ factor seldom corresponds to that of a reaction of 2nd order. Most of the experimental results are located in the area $S>S_1$; $\bar{M}_2<M<\bar{M}_1$. Reactions with $M<\bar{M}_2$ or those which are of pure n-th order are rare.

If instead of the overall $M$ indices, the initial $M$ indices are taken as the basis, then a shift in the opposite direction takes place; for *experiments expected to be unimolecular*, the $M$ values of cases, which "do not fit" decline from $\bar{M}_1$, in part, to $M_2$. In contrast, for experiments *expected to be bimolecular* they rise from $\bar{M}_2$ to considerably more than $M_1$. The initial $M$ values appear to be even more specific than the overall values; until now, their wide application has been difficult because of the observed scattering which can be up to $\pm 10\%$. Even in experiments under practically similar conditions, differences in the complexity can hardly be completely ruled out. The variations can therefore often be explained by the kinetic effect of amplified variations in the starting conditions, and this is typical for the reaction mechanisms involved. Large kinetic amplification effects are shown, for example, by mechanisms having *feedback reactions* when a "triggering" of an otherwise inhibited reaction can suddenly take place by a minimal change in the initial conditions[23, 86]. Such phenomena are shown by the variances of the different parameters which for the Belousov-Zhabotinsky-reaction have been determined by a series of experiments in which the concentrations of the reactants or the heating rates were varied[81, 83, 87].

What reaction types in the mechanistic diagram now lead to satisfactory straight lines in the Arrhenius plot? Experience shows that even after correction to a 1 : 1 molecular ratio an "elementary" $M$ or S does not result, and an exact straight line is not obtained, *i.e.* formally the kinetics of such reactions have to be defined by at least two elementary processes. If one picks out only those cases *which are expected to be unimolecular* with $S \approx S_1$, then it is indicated that only with $M \approx \bar{M}_1 = 0.019 \pm 12\%$ is the expected high correlation coefficient of more than 0.99 obtained. As soon as $M$ diverges markedly from $\bar{M}_1$, the linear conformity becomes poorer; on the other hand, when $M \approx \bar{M}_1$ the shape index can vary widely around $S_1 = 0.56$ (by $\pm 20\%$) without leading to unsatisfactory fitting of the straight lines. In experiments on reactions *expected to be bimolecular* the upper limit for allowed $M$ values when $S \approx S_2$ lies about 20% above $\bar{M}_2$.

A linear relationship between $\ln k$ and $1/T$ is, therefore, with the exception of the precluded temperature dependence of the frequency factor, not a sufficient experimental criterion for the presence of an elementary process. For example, a bimolecular autocatalytic process (area 1a in Fig. 9a; A + B = 2 B) would produce a point lying above the elementary point 2 for smaller concentrations of B. Assuming an elementary process of 2nd order, the interpretation would give an Arrhenius straight line with good correlation ($r > 0.994$), but with unrealistically high activation parameters, since the signal for such a process would be too narrow.

The kinetic analysis of a reaction system may be carried out more selectively by investigating the *influence of the initial concentration* of one of the reactants on the parameters obtained according to Section 5.3.1 (Table 6). For many parameters, computer simulations show, depending upon the mechanism, concentration/parameter correlations with one or more *sections with a constant or an asymptote*. We were able to confirm this by means of concentration series for 20 different systems[3, 107]. A parameter should be *especially selective* in determining a reaction mechanism when it shows *a maximum number of such constant sections*, since each of these would be ascribed to a *rate-determining step* of the reaction mechanism.

Table 6. Concentration dependence of nonisothermal parameters and reaction mechanism. EP = Elementary process; Pxx = Concurring processes of the same order; Gxy = Elementary process of second-order etc. The valuation numbers represent the contribution of constant sections (cf. text).

| Parameter | Valuation | Behavior and interpretation of the concentration dependence $f(c_0)$ |
|---|---|---|
| Peak temperature $T_m$ | 0.67 | Similar to the initial temperature; for processes inhibited by feedback, however, increases for small concentrations |
| Initial activation energy $E_0$ | 0.70 | Characterizes the initial reaction: constant ⇒ EP, Gxx, Gxy or Pxx; decreasing ⇒ simple autocatalytic process; step(s) ⇒ Pxy |
| Overall activation energy $E$ | 0.71 | Describes optimal overall reaction. Can be determined more accurately then $E_0$; almost equivalent information on mechanism |
| Special index $I_{mech}$ [18, 37] | 0.76 | $I_{mech} = 1 \Rightarrow$ formal overall reaction of n-th order |
| Relative signal height $\theta_m/c_0$ | 0.80 | Typical for orders of previous branches: Pxy or EP, Pxx or no pre-reaction at all (see Table 1) |
| Initial temperature $T_0$ | 0.81 | Characterizes the classification of the reaction type: constant ⇒ EP1, P11; decreasing ⇒ EP2 or P22; step(s) ⇒ Pxy; rising ⇒ inhibition. In overlapping peaks the initial reaction is characterized. |
| Overall frequency factor $k_\infty$ | 0.81 | $k_\infty(c_0)$ is to be interpreted similarly $E(c_0)$; $> 10^{16} \Rightarrow$ complex reaction |
| Initial reaction type index $M_0$ | 0.84 | Constant ⇒ EP or special mechanism types; Variant ⇒ steps or asymptotes can in some cases represent EPs |
| Shape index $S$ | 0.92 | Areas of elementary steps as for $M_0$ or $M$ but trend curves of different type $S = f(c_0)$. The curve $M_0 = f(S)$ is typical for mechanism. |
| Overall reaction type index $M$ | 0.94 | Like $M_0$ but the functions $M = f(S)$ are shifted or different |

A statistical analysis of our results under this aspect showed that of all the quantities shown in Table 6, the reaction-type indices and the shape indices have the most constant sections[107]. The "mechanistic coordinates", therefore, have to be considered as the fundamental parameters. Even for two-reaction models they show an elementary limiting behavior characteristic of the reaction mechanism for very high or low concentrations or heating rates[19,20,40].

## 7. Heterogeneous Mechanisms in the Mechanistic Diagram

### 7.1. Problems in the Kinetic Analysis of Solid-State Reactions

The advantages of performing measurements with increasing temperature also apply to solid-state reactions[89,90], even when the behavior of species produced photo- or radiochemically at very low temperature is investigated[48]. In this way DTA curves with a number of peaks can be recorded subsequent to irradiation of hydrazoic acid at 20 K in methanol. These correspond to reactions of thermally produced products, such as nitrenes and H atoms[105].

However, the quantitative analysis of such signals is difficult because for *solid-state reactions* the kinetic conditions can hardly be compared with those of homogeneous kinetics[21,89,90]. In place of concentration, a formal conversion parameter $x$ (fractional conversion), which changes from 0 to 1 in course of the reaction, has been introduced.

$$x = \frac{[A_i]_0 - [A_i]}{[A_i]_0} \tag{21}$$

On the whole, one does not use additive terms such as in eq. (1)[24,63,89-100] in these complex processes, rather, only *one* rate constant is assumed so that consecutive or parallel reactions have to be interpreted for a *number of sections*[24,89,90,95-100]. *Sestak et al.*[24] have suggested a general rate law which covers most of the known heterogeneous mechanisms (Table 7).

$$\frac{dx}{dt} = k x^m (1-x)^n [-\ln(1-x)]^p \tag{22}$$

For $m = p = 0$, $n \neq 0$ eq. (22) is transformed to the rate law of n-th order; cases where $m > 0$, $n = 0$, $p = 0$ (power law) and $m = 0$, $n = 0$, $p > 0$ correspond to a strong autocatalytic character in the homogenous kinetics.

The difficulties encountered in interpretating kinetic data (inhomogenities in temperature and concentration, restriction to only one reaction coefficient) mentioned at the beginning of this section are further augmented by others[25,95,101]. The significance of "activation energy" in the solid-state is a difficult problem[24,25,57,102]. In homogenous kinetics, the Arrhenius equation is explained by the statistical distribution of energy over the reactant molecules present. But in the solid state a molecule, because of its lack of translational energy, cannot receive the surplus energy from its nearest neighbor. Many solid-state reactions, however, can only be explained with the aid of relatively high activation energies so that this quantity must have another significance.

A second problem is concerned with the relationship between the reactants present and the reaction rate, which in homogenous kinetics is always present because of the law of mass action. However, in most of the mechanisms detailed in Table 7, the relationship between fractional conversion and the reaction rate is based on topochemical models. For example, for surface reactions (types R1, R2, R3) it is difficult to imagine how the reaction rate should be dependent on the fraction of unreacted molecules which are far removed from the surface. Here, the previously frequently applied rate laws should rather be de-

Table 7. The most important rate laws for reactions in the solid state.

| Logogramm | m | n [Gl. (22)] | p | Name/Remarks | |
|---|---|---|---|---|---|
| Mechanisms controlled by phase boundary | | | | | |
| R1 | 0 | 0 | 0 | Polanyi-Wigner: | one-dimensional movement of the phase boundary |
| R2 | -0 | 1/2 | 0 | | two-dimensional movement of the phase boundary |
| R3 | 0 | 2/3 | 0 | Hume-Colvin: | three-dimensional movement of the phase boundary (Contracting sphere mechanism) |
| Mechanisms controlled by diffusion | | | | | |
| D1 | −1 | 0 | 0 | Parabolic law: | one-dimensional diffusion |
| D2 | 0 | 0 | −2 | | two-dimensional diffusion |
| D3 | 0 | 1/3 | −1 | Jander: | three-dimensional diffusion |
| Mechanisms controlled by nucleation growth | | | | | |
| NP1/2 etc. | ≤1 | 0 | 0 | Nucleation power law: m = 1/4, 1/3, 1/2, 1 | |
| A2 | 0 | 1 | 1/2 | Avrami: | two-dimensional growth of phase boundary |
| A3 | 0 | 1 | 2/3 | Avrami-Erofe'ev: | three-dimensional growth of phase boundary |

rived from geometrical concepts than from the point of view of a molecule which is activated to react.

The *significance of the frequency factor* in solid-state reactions is even more difficult, and a number of concepts have already been developed (cf. [24, 102]).

Despite all of these problems in interpretation it is apparent (especially in thermogravimetric measurements) that many solid-state reactions can be satisfactorily described by means of eq. (22), even though the coefficients m, n, and p are relatively poorly defined: in most cases it is, therefore, not possible to specify a definite reaction mechanism[21, 96, 97, 103].

### 7.2. Selection of Reference Reaction and Theoretical Studies

In the theory of homogenous kinetics, reactions of either 1st or 2nd order could be used as a reference for the reaction type index. For a formal initial reaction of n-th order, the initial activation energy calculated from the initial part of the differential conversion curve is practically independent of the order of the reaction; in eq. (18), the partial integral is then small compared to the total integral so that introduction of the conversion variable $x$ gives

$$k(t) = \frac{\dot{x}(t)}{\left(1 - \int_{t_0}^{t} \dot{x}\,dt\right)^n} \quad \lim_{t \to t_0} = \dot{x}(t) \tag{23}$$

Efforts should now be made to achieve an A factor which is independent of the initial concentrations of the reactants. The *reaction of 1st order* is, therefore, the most suitable reference for comparison of homogenous and heterogenous reactions in an extended mechanistic diagram[3].

By generation and re-evaluation of conversion curves with different assumed activation parameters it is easy to determine the mechanistic parameters for all the mechanisms in Table 7; $M$ can then be related to

- activation data *selected* for model curves (theoretical $M$-indices)[20] (not shown here)
- activation parameters evaluated from eq. (18) or from the DTA-programs based on the Borchardt-Daniels equation *from the initial range* assuming 1st order (initial $M$, Fig. 9a)
- activation parameters *from the whole curve* (overall $M$, Fig. 9b)

The resulting mechanistic diagrams differ only in the ordinates. Since the *theoretical M* indices are of little practical value, we compare here only the "re-evaluated" initial and overall values. For comparison, some of the homogeneous kinetic areas[3] are also shown. While these are always clustered around the elementary points of first or second order and extend to areas H and B (high $S$- and low $M$-values), most of the heterogeneous mechanisms are found in the area Ø (small $S$, large $M$) and near the $S/M$ curve for n-th order. The surface-controlled mechanisms (R) can, in part, be easily confused with those controlled by diffusion (D), *i.e.* D1 with R1 or D3 with R2[97, 98, 103]. Similarly, the Avrami equations (A) lead to initial diagram functions

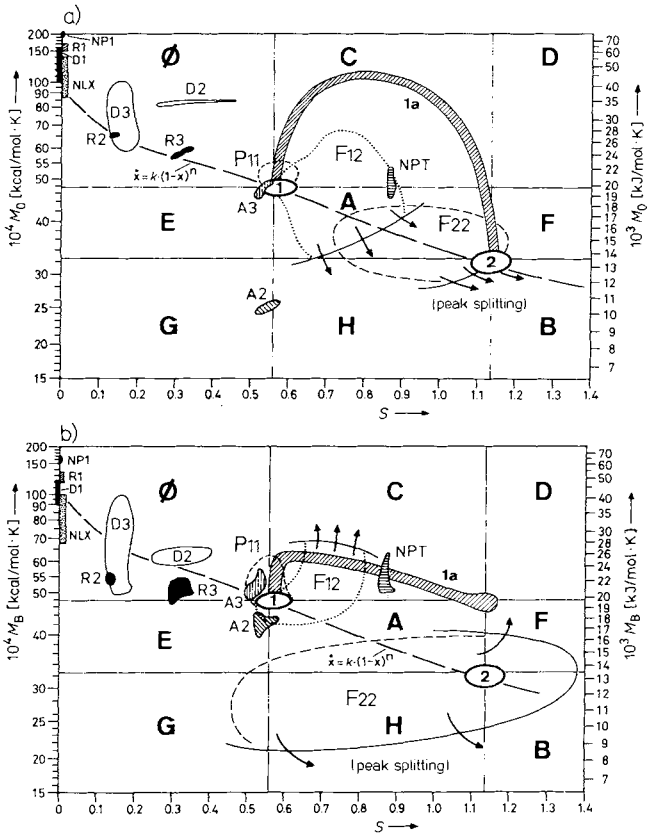

Fig. 9. Mechanistic diagram with the most important heterogeneous and some homogenous reaction mechanisms [3, 20] (cf. Section 4.1 and Table 7; heating rates 1.5–5 K/min; $A$ factors $10^6$–$10^{14}$ $s^{-1}$): a) with initial $M$ values; b) with overall $M$ values.

which differ only slightly from a first-order reaction. In contrast, Prout-Tompkins kinetics (NPT) and the nucleation-growth mechanisms (NP) can be easily identified.

The thermal decomposition of nickel oxalate is a relatively attractive system for which the Prout-Tompkins mechanism (m = 1, n = 1, p = 0 in Table 7) has been definitely established by thermogravimetric and isothermal measurements[104]. If theoretical curves are generated from the given kinetic data ($E = 100.5$ kJ/mol, $k_\infty = 1.4 \times 10^{10}$ $s^{-1}$) and the mechanistic coordinates calculated assuming that a first-order reaction prevails throughout, then for initial $M$ and a chosen heating rate of 5 K/min a point within the theoretically determined Prout-Tompkins area is produced (Fig. 9a).

This kind of characterization of heterogeneous reactions which can be described by eq. (22) should even enable identification of the mechanisms of reactions having very similar conversion curves. Thus, the kinetics of diffusion and phase controlled mechanisms have been compared with one another thermogravimetrically by *Criado* and *Morales*[103], with the result that types R1 and D1 or R3 and D3 in Table 7 cannot be differentiated. But Figure 9 shows that R3 and D3 have distinctly different mechanistic coordinates. For the decomposition of $CaCO_3$ under discussion here, the coordinates $S = 0.142$ and $M_0 = 0.0485$ are found for the D3 mechanism (three-dimensional diffusion), whereas for the R3 mechanism (three-dimensional movement of the phase interface) the values $S = 0.318$, and

$M_0 = 0.02406$ are found. Because the $M$ value gives a better fit, R3 is the more probable mechanism.

However, such a detailed selection of the reaction mechanism as in homogeneous kinetics does not appear to be possible, because the criterion of the *concentration dependence of phenomena,* which is important for practical reaction kinetics, can be applied only with difficulty (*e.g.* dilution of the sample with inert material after pulverization). Furthermore, because during the course of the reaction the mechanism often changes and, therefore, the introduction of several rate constants is essential, it is only in rare cases that the whole experimental curve can be described by additive combinations like eq. (1) or even by eq. (22).

## 8. Outlook

Analysis of reactions using linear control of temperature with time, which first led to success in the investigation of the chemistry of compounds available only by low temperature photosynthesis[48], appears theoretically to be a widely applicable kinetic method. It is especially suited for the clarification of reaction mechanisms over a wide temperature range. DTA experiments, some UV measurements, and thermogravimetric results from the literature served to check the models produced by computer programs. Our results confirm that "slow" chemical reactions in solution are mostly complex, but according to the new concept they can be classified kinetically over a wide temperature range. For elementary reactions the same activation parameters were found as by isothermal measurements[69-71], and many complicated reactions could be split into elementary processes. UV measurements appear to be a promising additional tool for the future, since kinetic studies using selected wavelengths can concentrate on part structures of the participating species[55].

By means of these possibilities it is often feasible with this new concept to discover the reaction mechanism and calculate the parameters underlying its individual steps. The best proof of a proposed model is provided by the definitive reproduction of random experimental signal curves using univariant data for all elementary steps.

Often, *fast successive* steps are also indicated by nonisothermal measurements. Occasionally a variation in the $M$ value is shown directly; if they compete with other steps they either influence the indication parameters [cf. eq. (1)] of the previous slow reactions or, after branching, the $A$ factors of the slow successive steps[21]. Even fast initial processes ($k_{298}$ up to *ca.* $10^{11}$ $s^{-1}$) with activation energies of 10–20 kJ/mol, which until now could be evaluated only using relaxation and pulse techniques, can be followed directly by low temperature measurements in suitable solvents—if necessary using very high heating rates[9, 13, 28].

Hence, using simulation methods, such areas as diffusion kinetics, photochemical kinetics, or the kinetics of oscillating reactions can now, in part, be investigated. It is, therefore, worthwhile to follow the path of nonisothermal reaction analysis outlined here in order to investigate and classify the kinetic phenomena in chemistry more effectively than was previously possible.

*I wish to express my thanks to the co-authors of my publications cited here, to my co-workers Messers. B. Stilkerieg, G. Lindner, and Mrs. C. Mummerz, and also to the computer section of the Max-Planck-Institut für Kohlenforschung, especially to Mr. K. Boll and Mr. H.-D. Schmitz. Valuable suggestions in the preparation of this manuscript were made by Prof. Dr. O. E. Polansky, Dr. H. Hermann, and Dr. P. Potzinger. These are gratefully acknowledged.*

## Direct Synthesis of a [13]Annulenide Ion**

By *Bernd C. Becker, Gerd Neumann, Hans Schmickler,* and *Klaus Müllen**

The failure of all attempts to obtain the long elusive 9b-methylphenalene **1** from ionic phenalene precursors[2] underscores the difficulty of initiating reaction at the angular centers of *peri*-annelated polycyclic π-systems. We now wish to report the synthesis of an analogue of **1** with 14π-perimeter (**6a**) by reductive alkylation of aceheptylene **2**.

The directed conversion of anions of an unsaturated compound by kinetically controlled addition of electrophiles[1] requires knowledge of the charge distribution in such anions. Thus, for the preparation of an analogue of **1**, a *peri*-annelated tricycle is required whose anions have a high π-charge density at the central quaternary C atom. According to MO models[3] this requirement is fulfilled in the aceheptylene **2**, first synthesized by *Hafner*[4]; the selection of **2** is experimentally supported by the NMR spectra of the diamagnetic dianion $\mathbf{2}^{2-}$ (dilithium salt)[6]: On reduction of **2** the carbon atom C-10b experiences by far the greatest charge-induced shielding, recognizable by the extreme upfield shift of the $^{13}$C-NMR signal [$\Delta\delta_C = -61.2$].

Methylation of $\mathbf{2}^{2-}/2Li^+$ [tetrahydrofuran (THF), dimethyl sulfate, −20 °C] furnishes a mixture of the three dimethyl adducts **3**, **4** and **5b**, which are separable by column chromatography and subsequent preparative gas-chromatography, and whose structures have been elucidated NMR spectroscopically. A notable feature of all derivatives is that a methyl group is incorporated at the inner position 10b. An independent chemical proof for the structure of the orange-yellow **5b** was provided by deprotonation (THF, potassium hydride, room temperature) to the bridged 13-center 14π-system **6b** [$^1$H-NMR (90 MHz, [D$_8$]THF): $\delta = 8.1-6.8$ (ring protons); 3.15 ($CH_3$ on C-6); −3.90 ($CH_3$ on C-10b)].

This synthetic strategy is impaired by the fact that three different adducts are formed, only one of which is suitable for the production of monocyclic conjugated π-structures. If, however, the reductive methylation of **2** is carried out with dimethyl sulfate in liquid ammonia at −78 °C, only the monomethyl derivative **5a** is formed (58% after chromatographic purification on silica gel). **5a** is also formed in small yields on addition of methyllithium to **2**, followed by hydrolytic work-up.

The structure of **5a** (especially the position of the newly formed methylene group), which is of importance regarding knowledge of the hydromethylation and secondary reactions of **5a**, has been elucidated by assignment of all the resonances in the complex $^1$H-NMR-spectrum [$^1$H-NMR (300 MHz, $CDCl_3$): $\delta = 6.22$, 6.08 (H-1, H-2); 5.66 (H-3); 6.11 (H-4); 6.07 (H-5), 3.79, 2.81 (H-6, H-6'); 5.65 (H-7); 5.75 (H-8); 6.01 (H-9); 5.88 (H-10); 1.41 ($CH_3$)].

Deprotonation of **5a** affords the salt **6a** [green solution; $^1$H-NMR (300 MHz, [D$_8$]THF): $\delta = 7.69$ (H-1); 8.11, 8.16 (H-3 and H-6); 6.96, 7.09 (H-4 and H-5); −3.75 ($CH_3$); $^{13}$C-NMR (75 MHz, [D$_8$]THF): $\delta = 144.1$ (C-2a); 119.2 (C-6a); 120.1, 118.9, 111.7, 110.9, 108.6 (C-1, C-3 to C-6); 43.4 (C-10b); 20.5 ($CH_3$)]. Characteristic for the 14π-perimeter system **6a** are the extreme upfield resonance of the "inner" methyl protons and—despite excess charge—the pronounced deshielding of the ring protons. Both observations support the expected diatropism of the cyclopentadienyl homologue **6a**, the first salt of a [13]annulenide ion.

Both the temperature as well as the choice of electrophile influence the course of the trapping reaction of $\mathbf{2}^{2-}$: When the reaction is carried out in boiling ammonia the yields are poorer, and on methylation with methyl chloride or methyl bromide increasing amounts of reoxidized educt **2** are obtained because the C-halogen bond is reductively cleaved. Under the conditions of the Birch reduction ($NH_3$, liq.; Li, 2eq.; −78 °C; methanol as source of protons), three dihydro derivatives are formed[4], in which, according to the spectroscopic data, an azulene fragment is preserved in each case. A rapid H-shift in the primary adduct is plausible under the reaction conditions.

The systems **5a** and **6a**, which are readily accessible by reductive methylation, appear suitable for further modification of the ring skeleton.

## Successive Electron Transfers in Molecules with Two Electrophoric Groups: Novel Singlet, Doublet, and Triplet States**

By *Walter Huber, Heinz Unterberg,* and *Klaus Müllen**

Successive electron transfers to molecules containing two or more electroactive groups can lead to ionic products having completely different structures, whose characteristic features are the charge distribution and the spin multiplicity. Such reactions play an important role in biological processes[1]. For our studies in this sector we used as model compounds the anthracenophane **1** and the 1,n-di-9-anthrylalkanes **2**—**4**, in which the electronic interaction of two anthracene moieties should differ drastically on steric grounds.

**1**

**2**, n = 2
**3**, n = 3
**4**, n = 4

We have succeeded in generating for the first time the dianion of **1**[2] as well as the complete series of radical monoanions, dianions, radical trianions and tetraanions of **2**—**4**[3] and in characterizing them by NMR and/or ESR spectroscopy. (For chemical proof of structure and Table of spectroscopic data see Supplement.)

The ESR spectra of the radical anions $\mathbf{2}^{\cdot-}$—$\mathbf{4}^{\cdot-}$ ($K^+$, dimethoxyethane (DME)/hexamethylphosphoric triamide (HMPT) 2:1) consistently show five sets of coupling constants for each four equivalent hydrogen atoms and one set for two equivalent hydrogen atoms. This finding confirms that the spin density is distributed over both electrophores in the time scale of the experiment. Furthermore, the $^1$H-coupling constants can be assigned in such a way that they correlate surprisingly well with the corresponding values in $\mathbf{1}^{\cdot-}$. Thus, independently of the length of the polymethylene chain, $\mathbf{2}^{\cdot-}$—$\mathbf{4}^{\cdot-}$ behave analogously to the anthracenophane $\mathbf{1}^{\cdot-}$ (with enforced proximity of the anthracene fragments)[6].

The dianions $\mathbf{1}^{2-}$ and $\mathbf{2}^{2-}$ ($2K^+$ or $2Li^+$) give highly resolved $^1$H- and $^{13}$C-NMR spectra, thus indicating the existence of singlet states [$\mathbf{1}^{2-}/2K^+$: $^1$H-NMR (300 MHz, [D$_8$]tetrahydrofuran (THF), −30 °C): $\delta = 5.11$ (H-1, H-4, H-5, H-8), 5.55 (H-2, H-3, H-6, H-7), 1.84 ($CH_2$); $^{13}$C-NMR (75 MHz, [D$_8$]THF, −30 °C): $\delta = 116.2$, 117.2 (C-1—C-4, C-5—C-8), 112.6 (C-9, C-10), 141.9 (C-11—C-14), 23.2 ($CH_2$); $\mathbf{2}^{2-}/2K^+$: $^1$H-NMR: $\delta = 7.33$ (H-1, H-8), 6.55 (H-2, H-7), 6.04 (H-3, H-6), 6.55 (H-4, H-5), 5.07 (H-10), 4.17 ($CH_2$); $^{13}$C-NMR: $\delta = 122.5$, 125.7, 124.4, 111.2 (C-1—C-4, C-5—C-8), 120.7 (C-9), 85.2 (C-10), 144.7, 139.4 (C-11—C-14), 76.4 ($CH_2$)]. From the inherent symmetry shown by the spectra it follows that the excess charge, as in the radical anions, is distributed over both anthracene rings.

The charge distribution and the spin multiplicity of $\mathbf{2}^{\cdot-}$ and $\mathbf{2}^{2-}$, however, critically depend on the experimental conditions: The observation of seven different ESR coupling constants for $\mathbf{2}^{\cdot-}$ (6 × 2 H, 1 × 1 H) in a solvent-counterion system [$K^+$, 2-methyltetrahydrofuran (MTHF)], which enables an intimate interaction between anion and cation, must be ascribed to localization of the spin density in one anthracene moiety. A triplet diradical (zero field parameter $D = 8.4$ mT) can be detected ESR spectroscopically for $\mathbf{2}^{2-}/2K^+$ in a glass (MTHF or HMPT, −170 °C).

All attempts to characterize $\mathbf{3}^{2-}$ and $\mathbf{4}^{2-}$ ($2K^+$, [D$_8$]THF) by well resolved $^1$H-NMR spectra have so far failed. However, also here, triplet states can be detected ESR spectroscopically [$2K^+$, MTHF or HMPT (glass), −140 °C to −170 °C; $D = 5.5$ and 3.5 mT, respectively].

The transition to the corresponding radical trianions and tetraanions produces novel bonding features. According to the ESR coupling constants the spin density in $\mathbf{2}^{3\cdot-}$—$\mathbf{4}^{3\cdot-}$ remains localized in an electroactive moiety in each case, even in solvents with effective cation solvation. Also significant is that the coupling constants in $\mathbf{2}^{3\cdot-}$—$\mathbf{4}^{3\cdot-}$ deviate only slightly ($\Delta a_H \leq 0.04$ mT) from those in $\mathbf{2}^{\cdot-}$—$\mathbf{4}^{\cdot-}$ (MTHF, localization of the spin density) and, to a good approximation, are twice as large as the values measured for $\mathbf{2}^{\cdot-}$—$\mathbf{4}^{\cdot-}$ in DME/HMPT (delocalization of the spin density).

The NMR spectroscopic properties of the tetraanions $\mathbf{2}^{4-}$—$\mathbf{4}^{4-}$ correspond to those of the anthracene dianion and 9-methylanthracene dianion. $\mathbf{2}^{4-}$—$\mathbf{4}^{4-}$ are thus made up of two essentially independent dianion fragments.

For the anions derived from **2**, "*anti*" or "*syn*" conformations are plausible, with different interaction of the redox centers. The analogy of the (symmetric) spin density distribution in $\mathbf{1}^{\cdot-}$ and $\mathbf{2}^{\cdot-}$ and the π-charge distribution in the singlet dianions $\mathbf{1}^{2-}$ and $\mathbf{2}^{2-}$ can best be explained in terms of a preferred dianthrylethane conformation with eclipsed or partially eclipsed π-moieties. This hypothesis does not apply in the case of the triplet state of $\mathbf{2}^{2-}$ (or of $\mathbf{3}^{2-}$ and $\mathbf{4}^{2-}$): The mean distance of the unpaired electrons in triplet $\mathbf{2}^{2-}$ estimated from the zero-field parameter $D$ is 6.9 Å ($\mathbf{3}^{2-}$: 8.0 Å, $\mathbf{4}^{2-}$: 9.3 Å), a value which is more consistent with an *anti*(*s-trans*) arrangement of the electrophores.

## 1-Lithio-1-phenylcyclopropanes—Structure and Dynamics**

By *Detlef Hoell, Christoph Schnieders,* and *Klaus Müllen**

Lithiocyclopropanes **1** are ideal model systems for configuratively stable carbanions[1–3]. Their properties can be changed drastically by variation of the substituents R. We report here on the structure and dynamics of the 1-lithio-1-phenylcyclopropanes **2a—5a** and the stereochemistry of the metalation reaction. Compounds **2a—5a** could have covalent or, as in benzyllithium, partial ionic structures; depending on the relative energy of **3a** and $\overline{\mathbf{3a}}$ an inversion of configuration should also be detectable.

For the preparation of **3a—5a**, the reaction of the bromides **3c—5c** with lithium at low temperatures proves to be superior to the alternative method of metalation of **3b—5b** with *n*-butyllithium/potassium *tert*-butoxide[5].

The structure of the lithiated compounds could be proven chemically by protonation, by oxidation with oxygen, and by oxidative coupling with $Cu^{II}$ salts; thus, **3a** furnished respectively the hydrocarbon **3b**, the alcohol **6**, and the bicyclopropyl system **7** (as a mixture of the *meso*- and (+)/(−)-forms). Insight into the relevant bonding situation is provided by the following NMR-spectroscopic findings (see Table 1): 1) The low-temperature $^1$H- and $^{13}$C-NMR spectra of **3a** (< −60 °C) indicate non-equivalence of the geminal methyl groups, which is consistent only with fixation of the metal on one side of the plane of the three-membered ring. 2) The upfield shift of the $^1$H-NMR and $^{13}$C-NMR phenyl signals of **3a** compared to those of **3b** (higher charge density in the phenyl moiety of **3a** than in that of **3b**). 3) The downfield shift of the $^{13}$C-NMR signal of C-1 on going from **3b** to **3a** (as opposed to an upfield shift of the corresponding signal on lithiation of the parent cyclopropane system), which is indicative of an increased $sp^2$ character of the carbanionic C-atom in **3a**.

Also characteristic for the structure of **3a** are the dynamic properties. Above −45 °C the two $^1$H-NMR signals of the methyl groups in **3a** broaden and finally coincide, as is to be expected on the NMR time scale for a rapid conversion **3a** ⇌ **3a'**. The activation barrier of this process, with $\Delta G^{\neq}$ (4 °C) = 56 ± 2 kJ mol$^{-1}$ ($\Delta S^{\neq} = -137$ JK$^{-1}$ mol$^{-1}$), is distinctly smaller than that estimated for the corresponding transformation in the case of lithiocyclopropane.

All findings can be explained in terms of the contribution of an ionic borderline structure to the ground state of the (predominating) covalent lithiocyclopropane **3a**; however, the participation of temperature-dependent ion-pair equilibria cannot be ruled out. The assumption that the inversion of configuration in **3a** proceeds *via* a transition state with stronger ionic character is supported by the fact that solvents with stronger (weaker) cation solvating properties accelerate (decelerate) the conversion. The inversion barrier is higher at lower substrate concentrations. This and the stronger negative activation entropy point to the participation of aggregate structures.

| **5a** | [b] | 0.8 [b, c] | 1.24 | 0.9 [b, c] | 6.24 | 6.6 [b] | 5.84 | | |
| | | | | | *$^{13}$C-NMR* | | | | |
| | C-1 | C-2 | C-3 | C-4 | C-5 | *o*-C | *m*-C | *p*-C | *ipso*-C |
| **3a** | 46.5 | 19.2 | (29.5, | 32.1, | 25 [b]) [c] | 123.0<br>124.1 | 126.7<br>127.9 | 112.2 | 163.9 |
| **3b** | 29.8 | 18.9 | 18.3 | (20.3, | 27.4) [c] | 127.3 | 128.4 | 125.5 | 140.2 |
| **3c** | 46.2 | 23.4 | 27.9 | (23.2, | 26.1) [c] | 129.2 [c] | 128.2 [c] | 127.5 [c] | 142.4 |

[a] The spectra of **3a—5a** were measured in [D$_8$]THF at −80 °C [300 MHz ($^1$H-NMR) and 75 MHz ($^{13}$C-NMR)], the spectra of **3b** and **3c** in $CHCl_3$ at room temperature (20 MHz). [b] Partially superposed signals make it difficult to determine the chemical shifts exactly. [c] The assignment of the signals is not confirmed experimentally.

The hindrance to rotation of the phenyl moiety due to partial double bond character of the C-1-C-phenyl bond leads to pairwise splitting of the signals of the *ortho* and *meta* phenyl protons in the $^1$H-NMR spectrum of **3a** below −10 °C. The characteristic preference of a conforma-

[*] Prof. Dr. K. Müllen, D. Hoell, C. Schnieders
Institut für Organische Chemie der Universität
Greinstr. 4, D-5000 Köln 41 (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie. We thank Prof. Dr. G. Boche, Universität Marburg, for helpful discussions and for communication of unpublished results.

tion with non-bisecting arrangement of cyclopropane and phenyl ring for the lithio system is supported by the equivalence of the *ortho*- and *meta*-phenyl protons in **2a**.

The inversion of configuration implicates an enantiomeric conversion in the case of **3a**, but a diasteromeric conversion in the case of **4a**. Investigation of compounds of type **4** should provide information about the stereochemical course of the metalation and quenching reactions. We have prepared **4c** in diastereomerically pure form. The metalation of pure **4c**, however, like that of a 1:1 mixture of **4c** and **5c**, leads to a 5:1 mixture of the lithio derivatives **4a** and **5a**. Presumably the configurationally labile cycloproplyl radicals occur as intermediates[23], from which the thermodynamically more stable product is formed. Depending on the temperature of the trapping reaction the following mixtures are obtained on protonation: 25 °C, **4b** : **5b** ≈ 1.3 : 1; −78 °C, **4b** : **5b** ≈ 2 : 1. Obviously, the diastereomeric ratio of the organolithio systems cannot be determined correctly by this reaction.

## Carbonyl Olefinations with Organomolybdenum Compounds**

By *Thomas Kauffmann**, *Beate Ennen*, *Jörg Sander*, and *Raphael Wieschollek*

Molybdenum(V) chlorides appear to react in a surprising way with $CH_3Li$ (molar ratio 1:2) in THF to give methylene-Mo complexes: In a systematic, comparative study[1c] of the carbanionoid reactivity induced by d- and f-metals we found four molybdenum compounds which react with aldehydes and ketones with carbonyl olefination. We ascribe these reagents, hitherto prepared only in the form of brown solutions, the structures **1**, **2b**, **3b**, and **4b**. They each possibly exist—as formulated in **1**—in equilibrium with a dimer. The most easily accessible reagent **1** is formed when $MoCl_5$ is allowed to react with 2 moles of $CH_3Li$ in THF/ether (≈8:2) at −70 °C and the mixture warmed to 20 °C. Approximately 1 mole of $CH_4$ (found, 0.85 mole) is liberated.

$$MoCl_5 \xrightarrow[-\,CH_4\ -\,2\,LiCl]{+\,2\,CH_3Li} \underset{\mathbf{1}}{Cl_3Mo{=}CH_2} \rightleftharpoons 1/2\ Cl_3Mo\begin{matrix}CH_2\\ \\ CH_2\end{matrix}MoCl_3$$

This reaction is reminiscent of a previously described synthesis of alkylidene-metal compounds (M = Nb, Ta), the mechanism of which is still unclear:

$$(Me_3C{-}CH_2)_3MCl_2 + 2\,LiCH_2{-}CMe_3 \longrightarrow (Me_3C{-}CH_2)_3M{=}CH{-}CMe_3 + CMe_4 + 2\,LiCl$$

The reagents **2b**, **4b** and **3b** were prepared analogously to **1** by reaction of $CH_3Li$ with the previously documented compounds **2a**[5] and **4a**[6] or with the hitherto unknown compound **3a** (1 mol **4a** + 1 mol NaOEt) in solution (molar ratio 2:1, 3:1 and 2:1, respectively).

**2a** $Cl_3Mo(THF)_2 \longrightarrow$ **2b**

**3a** $(EtO)_3MoCl_2 \longrightarrow (EtO)_3Mo{=}CH_2$ **3b**

**4a** $(EtO)_2MoCl_3 \longrightarrow$ **4b**

Table 1. Reaction of molybdenum reagents with carbonyl compounds in THF/ether (≈8:2) at −70 °C and subsequent warming to +20 °C in 15 h followed by hydrolysis with water. Yields determined gas-chromatographically.

| Reagent | Substrate | Molar Ratio Reagent/ Substrate | Yield [%] of Olefin of Type **5** | Recovery of Carbonyl Compound [%] |
|---|---|---|---|---|
| **1** [a] | Heptanal | 2:1 | 65 | 25 |
| | Benzaldehyde | 2:1 | 65 | 30 |
| | *p*-Methoxy-benzaldehyde | 2:1 | 84 | 3 |
| | Acetophenone | 2:1 | 53 | 41 |
| **2b** | *p*-Methoxy-benzaldehyde | 2:1 | 93 | 0 |
| | Acetophenone | 2:1 | 49 | 39 |
| | Benzophenone | 2:1 | 2 | 80 |
| **3b** | Heptanal | 2:1 | 67 | 0 |
| | Benzaldehyde | 1:1 | 25 | 72 |
| | Benzaldehyde | 2:1 | 45 | 41 |
| | Benzaldehyde | 3:1 | 70 | 19 |
| | *p*-Methoxy-benzaldehyde | 2:1 | 31 | 48 |
| | Acetophenone | 3:1 | 2 | 94 |
| **4b** [a] | Heptanal | 1:1 | 32 | 50 |
| | Hexanal | 1:1 | 44 | 45 |
| | Benzaldehyde | 1:1 | 24 | 51 |
| | *p*-Methoxy-benzaldehyde | 2:1 | 4 | 72 |
| | Acetophenone | 3:1 | 2 | 91 |

[a] No reaction with benzophenone.

For the carbonyl olefination the reagents were generated by addition of $CH_3Li$ to the respective molybdenum(V) chloride at −70 °C. After addition of the carbonyl compound the mixture was stirred for 1–2 h and then slowly warmed to 20 °C. From Table 1 it follows, *inter alia* (reactions with *p*-methoxybenzaldehyde and acetophenone), that the reactivity increases along the series **4b** < **3b** < **1** ≈ **2b**.

$$\underset{\mathbf{1}}{Cl_3Mo{=}CH_2} + O{=}CRR' \xrightarrow[-\,70\text{–}20\,^\circ C]{THF} Cl_3Mo{-}\underset{\displaystyle O-CRR'}{\underset{|}{CH_2}} \longrightarrow \underset{\mathbf{5}}{CH_2{=}CRR'} + \underset{\mathbf{2a}}{Cl_3Mo(THF)_2}$$

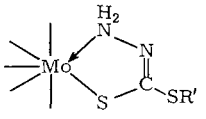
## $[Mo\{N_2C(S)SC_2H_5\}\{NH_2NC(S)SC_2H_5\}\{(CH_3)_2NCS_2\}_2]$ – A Sulfur-Rich Haptacoordinated Diazenidohydrazido(1–)molybdenum Complex**



By *Rainer Mattes** and *Heinz Scholand*

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

Hydrazido(2–) and diazenido complexes of molybdenum are presumably intermediates in the reduction of coordinated dinitrogen; they can be prepared *inter alia* by allowing oxomolybdenum compounds to react with disubstituted or monosubstituted hydrazines[1a]. Although a plausible mechanism for the reaction leading to hydrazido(2–) complexes was recently postulated[1b], the course of the reaction to the diazenido complexes is still largely unexplained (postulated intermediates are hydrazido(1–) complexes, M-NHNHR, which can be oxidized by atmospheric oxygen[1]). We have now obtained "mixed" diazenidohydrazido complexes of composition

$[Mo\{N_2C(S)SR'\}\{NH_2NC(S)SR'\}\{R_2NCS_2\}_2]$

($R=CH_3$, $C_2H_5$ and $R'=CH_3$, $C_2H_5$; **1**: $R=CH_3$, $R'=C_2H_5$) by allowing $MoO_2(R_2NCS)_2$ ($R_2NCS_2=N,N$-dialkyldithiocarbamate) to react with alkyldithiocarbazates $NH_2NHC(S)SR'$[2]. In these complexes the hydrazido(1–) ligand is not monodentate (–NHNHR) but is bonded as an *N,S* chelate[3]:

Further oxidation to the bis(diazenido) complex was not observed. The novel compounds are diamagnetic and molybdenum has the formal oxidation state +IV. The 18 electron rule is fulfilled; diazenido and hydrazido ligands function as 3e donors. $NH_2$ stretching vibrations occur at 3180 and 3140 $cm^{-1}$ in the IR spectrum (KBr) of **1**; we assign the sharp bands of intermediate intensity at 1577 $cm^{-1}$ to $\nu(N=N)$, and the very intense, broad bands at 1540—1520 $cm^{-1}$ to the $\nu(C=N)$ vibration. The $^1H$-NMR spectrum ($CDCl_3$) exhibits a singlet at $\delta=7.16$ for the $NH_2$ protons, in addition to multiplets for the $NCH_3$, $CH_2$ (2 quartets), and $CCH_3$ groups.

X-ray structure analysis of **1** (cf. Fig. 1) indicated that the central molybdenum atom has a distorted pentagonal-bipyramidal coordination. The chelate ring of the hydrazido(1–) ligand lies in the equatorial plane, together with three of the four sulfur atoms of the two $Me_2NCS_2$ ligands; the remaining sulfur atom and the diazenido ligand occupy the two apices of the coordination polyhedron. The Mo-diazenido group is almost linear (Mo-N1-N2: 178(1)°); the distances Mo-N1 (177(1) pm) and N1-N2 (121(1) pm) suggest multiple bonding and considerable electron delocalization; the distance N2-C is 136(1) pm and the angle N1-N2-C 120(1)°. The framework atoms of the diazenido ligand and those of the hydrazido ligand lie in a plane. The N–N distance in the chelate ring of the latter is 145(1) pm, the C–N distance of 123(1) pm corresponds to the formulation as a double bond, and the Mo–N distance (amino group) of 225.0(8) to a normal coordinative bond[4]. The Mo–S distances in the equatorial plane vary between 246.4(4) and 252.6(4) pm; $Mo-S_{ax}$ is longer (256.2(4) pm) due to the *trans*-effect of N1.

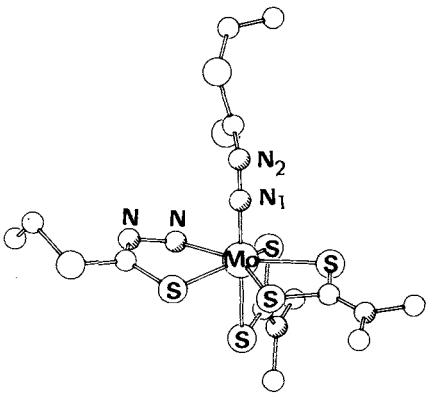


Fig. 1. Molecular structure of complex **1** in the crystal. Space group Pbca, $a=1509.2$, $b=2217.4$, $c=1424.7$ pm, $Z=8$; 3076 reflections with $F>4\sigma(F)$, 253 parameters, $R=0.075$, $R_w=0.085$. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CDS 50315, the names of the authors, and the journal citation.

Our structural investigation indicates that different substituents on N2 decisively influence the bonding relationship in the diazenido group and, hence, the reactivity of the nitrogen atoms. Thus, the Mo-N1 and N1-N2 distances in the diazenido complex $[Mo\{Me_2NCS_2\}_3\{N_2C(O)OEt\}]$ with the electronegative ethoxycarbonyl substituent are 173.2(5) and 127.4(7) pm, respectively[5].

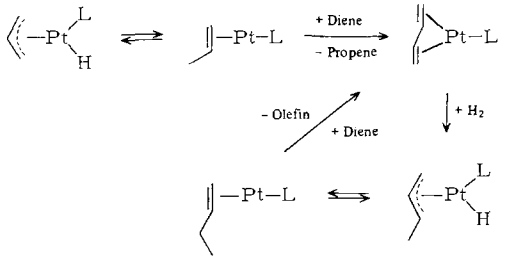
## Allyl(hydrido)platinum(II)-Catalyzed Partial Hydrogenation of Dienes

By *Roberta Bertani, Giovanni Carturan*,* and *Alberto Scrivanti*

We previously observed that $[(\eta^3\text{-}C_3H_5)Pt(L)H]$ **2** is stable in toluene between $-80$ and $-30\,^\circ C$, but decomposes with evolution of propene above $-20\,^\circ C$[3]. This represents the collapse of the 14-electron $Pt^0$ intermediate **3**, the occurrence of which has been demonstrated by variable temperature NMR spectroscopy.



**a**, L = $P(C_6H_{11})_3$; **b**, L = $PtBu_3$

The $^1$H-NMR spectrum of "**2b**" at $-32\,^\circ C$ clearly indicates the presence of the isomer **3b** ($\delta = 5.86$, $H^a$, $J_{H^a-CH_3} = 6.3$ Hz; 4.93, $H^b$, $J_{H^b-H^c} = 10.2$, $J_{H^b-Pt} = 83$ Hz; 5.03, $H^c$, $J_{H^a-H^c} = 15.3$, $J_{H^c-Pt} = 103$ Hz). Equilibrium **2b** $\rightleftharpoons$ **3b** (70:30) is slowly established at this temperature; at $-81\,^\circ C$ only **2b** is detected. A leading example of this type of equilibrium was reported some years ago for the complex $[(\eta^3\text{-}C_3H_5)Ni(PF_3)(H)]$[6]; other cases refer to $d^6$ organometallic complexes[7].

The hydrido complexes **2** are low temperature catalysts for the selective partial hydrogenation of conjugated diolefins to monoolefins (butadiene→1-butene; isopropene→2-methyl-1-butene; 2,3-dimethylbutadiene→2,3-dimethyl-1-butene). The course of these reactions at $-78\,^\circ C$ under conditions of constant $H_2$ pressure was studied by gas chromatography. After addition of diene, immediate and quantitative evolution of propene occurs; this also happens in the absence of $H_2$, whereas in the absence of diene the $Pt^{II}$ complex **2** does not react with $H_2$ at low temperature. Kinetic profiles of diene concentration as a function of time are linear up to 95% substrate consumption; the reaction is, therefore, pseudo-zeroth order. All reactions display *ca.* 100% selectivity; *i.e.* the monoolefins are not further hydrogenated.

The kinetic data (see table in Supplement) indicate a linear dependence of $k_{obs}$ on $H_2$ pressure; this suggests that $H_2$ activation should be the rate determining step. The reduction in catalytic activity upon increasing the temperature may, therefore, be related to the reduction in the concentration of dissolved $H_2$. These arguments suggest the simplified catalytic mechanism shown in Scheme 1.

It is noteworthy that the selectivity of the process arises from the occurrence of the equilibrium **2** $\rightleftharpoons$ **3** and from the fact that $H_2$ activation must be attributed to diene-$Pt^0$ intermediates. Apart from other possible speculations on alternative or parallel steps, the proposed scheme is consistent with the chemistry of $\eta^3$-allyl(hydrido)transition-metal derivatives[9] and strongly coordinatively unsaturated complexes[10].

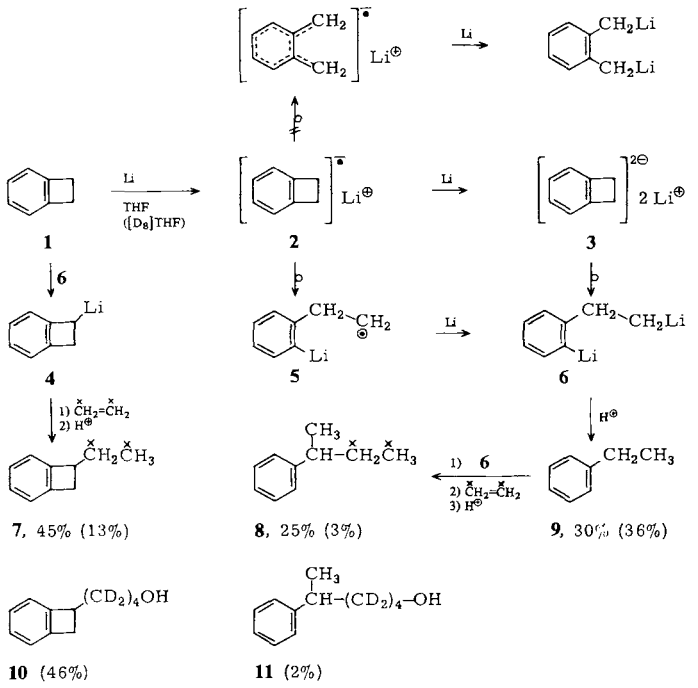
## Unexpected Ring-Opening of Benzocyclobutenes upon Reaction with Lithium in Tetrahydrofuran



By *Adalbert Maercker*, Willi Berkulin,* and *Peter Schiess*

Although the conrotatory ring-opening of the benzocyclobutene radical anion is thermally allowed, previously reported results were revoked shortly after their publication[1].

We have found a completely different reaction path—scission of a $C_{aryl}-CH_2$ bond—in the reaction of benzocyclobutene (1,2-dihydrocyclobutabenzene)[**] **1**[2] with lithium powder in tetrahydrofuran (THF). The expected *o*-xylene was not detected, even in trace amounts. Instead, after hydrolysis ethylbenzene **9** and its subsequent product **8**, which may have been formed *via* the dilithio compound **6**, was obtained (Scheme 1; the relative yields were determined by gas chromatography: after four weeks at room temperature conversion was only 20%). Due to the long reaction time **6** metalates some of the educt **1** and the product **9** at the benzyl position. Solvent is cleaved to form ethylene, which readily adds to benzyllithium compounds[3]; the ethylene adducts **7** and **8** are formed in this

[**] According to IUPAC rules, benzocyclobutenes are termed 1,2-dihydrocyclobutabenzenes.

Scheme 1.

way. That the ethyl group in these compounds actually originates from THF could be established by use of perdeuteriotetrahydrofuran ([$D_8$]THF; relative yields in parenthesis, conversion after 4 weeks: 6%). Carbon atoms marked with an asterisk bear in this case two deuterium atoms.

However, due to the isotope effect protophilic decomposition of the solvent takes place considerably more slowly[4], and hence its nucleophilic cleavage to alcohols **10** and **11** becomes more important.

Scheme 2.

In principal, ring opening of the benzocyclobutene **1** can not only occur at the stage of radical anion **2**, but also at that of the dianion **3**. To clarify this we allowed α-methylbenzocyclobutene[5] to react with lithium powder in THF (Scheme 2). After a week the conversion was 10%. Formation of cumene **19** and *n*-propylbenzene **14** in the ratio of *ca.* 12:1 suggests dianion **16** as intermediate, which should preferentially react further *via* the primary alkyllithium compound **18**. Ring-opening at the stage of the radical anion **15** should result in formation of *n*-propylbenzene **14** as the major product *via* the secondary radical **12**. Additionally, the corresponding ethylene adducts are also obtained. Reaction of a mixture of α-methylbenzocyclobutene and **1** indicates that the latter is cleaved approximately twice as rapidly. The rates of separate runs, however, are not comparable, since the yields are markedly dependent on the nature of the lithium powder and on the mixing procedure.

## Synthesis and Structure of $\mu_2$-Oxobis[chloro(tetra-*p*-tolylporphyrinato)molybdenum(IV)]: A Complex with Central $Mo^{IV}-O-Mo^{IV}$ Unit

By *Jocelyne Colin, Bernard Chevrier, André De Cian,* and *Raymond Weiss**

The oxo chemistry of molybdenum(V) is dominated by binuclear μ-oxo complexes. Recently, the synthesis and structure of two mixed valence ($Mo^{IV}-O-Mo^{V}$) μ-oxo complexes were also reported[1]. In contrast, so far no molybdenum(IV) μ-oxo derivative has been structurally characterized. We have now isolated and characterized such a complex [Cl(TTP)Mo−O−Mo(TTP)Cl)], TTP=*meso*-tetra(*p*-tolyl)porphyrinate(2−), and examined its remarkable magnetic behavior.

Reaction of the dichloro complex $MoCl_2$ (TTP)[2] with an excess of *N*-phenylhydroxylamine in presence of small amounts of pyridine in toluene as solvent leads to rapid formation of a finely crystalline, air-sensitive red solid, which was identified by an X-ray structural study as a binuclear μ-oxo species. In the IR spectrum of this novel complex, a medium-strength band appears at 730 $cm^{-1}$ which we tentatively assign to the μ-oxo ligand. The corresponding bands in $Mo_2O_3$(TPP) and $Mo_2O_3$(OEP) appear at 615 and 630 $cm^{-1}$, respectively[3] (TPP = tetraphenylporphyrinato, OEP = octaethylporphyrinato anions), while in the case of the $Mo^{V}/Mo^{IV}$ mixed valence complex, $[Mo_2O(S_2CNEt_2)_6]BF_4$, this band is observed at 655 $cm^{-1}$[1]. An intense band appears at 280 $cm^{-1}$, which we ascribe to the Mo−Cl stretching vibration[2]. The UV/VIS spectrum shows four absorptions: $\lambda_{max}(\lg\varepsilon) = 5.90$ (3.50), 5.54 (4.11), 508 (3.88), and 430 nm (5.35).

Surprisingly, the magnetic susceptibility follows the Curie law between 4.2 and 293 K. The magnetic moment ($\mu_{eff} = 2.82\ \mu_B$ per Mo atom) is consistent with a high spin $d^2$ configuration with no magnetic exchange interactions between the two metal centers through the μ-oxo bridge.

Similarly, no such magnetic couplings occur in $Mo_2O_3(TPP)$ and $Mo_2O_3(OEP)$[3].

Suitable single crystals of the dichloromethane solvate $[Mo(TTP)Cl]_2O \cdot 2CH_2Cl_2$ were obtained from a $CH_2Cl_2$/ether mixture under anaerobic conditions. The result of the X-ray structural analysis[4] (cf. Fig. 1) shows quite clearly that gross structural features are similar to those observed in the other known μ-oxo metalloporphyrins[5a].

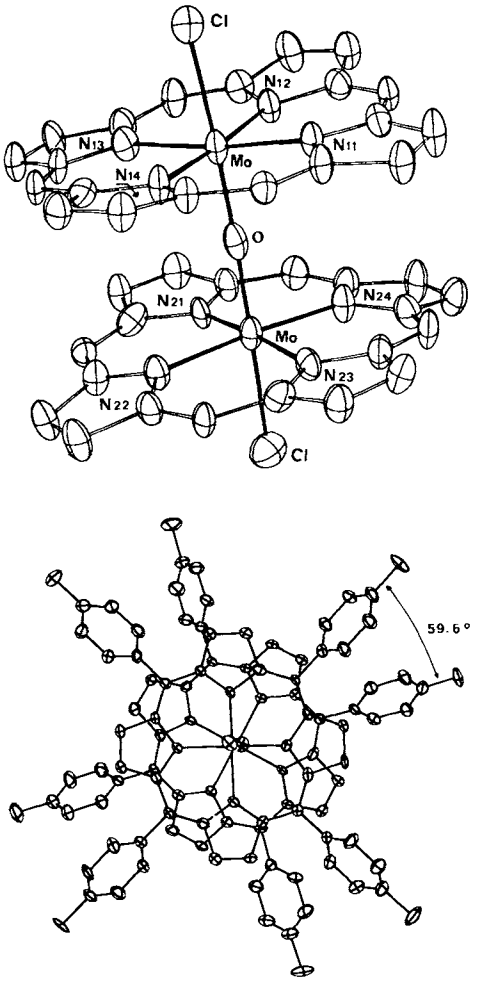

Fig. 1. Structure of the binuclear complex $[Mo^{IV}Cl(TTP)_2]O$ in the crystal (above: without tolyl groups; below: viewed along the MoOMo axis).

The two Mo atoms are displaced 0.08 Å from the $N_4$-plane of their TTP ligands in the direction of the bridging oxo atom; the distance between the best planes (24-atoms) of the chelate rings is 4.007 Å. As in the other known TPP and TTP complexes with $-O-$[5a], $-N=$[5b], and $=C=$[5c] bridges, the proximity of the two rings leads to a staggered conformation (torsion angle 59.6°) and to small dihedral angles between the substituent rings at the periphery and the porphyrin rings (50–62°). Moreover, both porphyrin rings are significantly nonplanar (quasi $D_{2d}$ ruffling). The mean values of the most important distances are: Mo–N 2.080(6)±0.019 Å, Mo–O 1.851(6)±0.006 Å, Mo–Cl 2.407(3)±0.007 Å; the MoOMo angle is 177.5(3)°.

The pathway by which the Mo–O–Mo linkage is formed is still unclear. The reaction of *N*-substituted hydroxylamines with FeCl(TPP) leads under the same experimental conditions to mononuclear nitroso complexes [Fe(py)(RNO)(TTP)][6].

## Zircona- and Hafnacyclobutenes—A New Route to Metallacyclobutanes

By *Johannes W. F. L. Seetz, Gerrit Schat, Otto S. Akkerman,* and *Friedrich Bickelhaupt**

Transiton-metal cyclobutanes have recently been the subject of intensive study. We report here the first general method for their preparation: the reaction of 1,3-dimagnesioalkanes with metal dihalides. The prerequisite for this long-known synthetic principle is the recently developed facile synthesis of 1,3-bis(bromomagnesio)propane **1a** from 1,3-dibromopropane **2a**[15a] and of its 2,2-dimethyl derivative **1b** from **2b**[15b]. The effectiveness of the new method is demonstrated using the example of the metallacyclobutanes of group IVB metals.

**a** : R = H ; **b** : R = Me ; Cp = Cyclopentadienyl

Reaction of **1b** with dichlorodicyclopentadienyltitanium, -zirconium or -hafnium yields the metallacyclobutanes **3b**, **4b**, and **5b**, respectively, which were characterized by elemental analysis (**4b**, **5b**), reaction with bromine to afford **2b**, as well as by their spectra. The high-field shift of the $^{13}$C-NMR signal of the quaternary carbon atom in the 2,2-dimethyl derivatives is particularly characteristic; this is caused by a shielding effect of the $Cp_2M$ frag-

ment, which is only possible in a four-membered ring (Table 1).

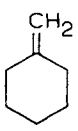

Table 1. NMR data of **3b**, **4b**, and **5b** [a].

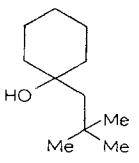
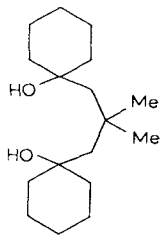
| | $^1$H-NMR δ-values [b] | | | $^{13}$C-NMR δ-values ($^1J_{CH}$ [Hz]) | | | |
|---|---|---|---|---|---|---|---|
| | $CH_3$ | $CH_2$ | $C_5H_5$ | $CH_3$ | $CH_2$ | $C_2H_5$ | C(β) |
| **3b** | 1.01 | 2.46 | 5.43 | 38.1, q (124) | 83.4, t (137) | 110.8, d (172) | 5.4, s — |
| **4b** | 1.19 | 1.87 | 5.57 | 40,2, q/m (125) | 66.4, t (133) | 109.2, d/m (171) | 7.4, s — |
| **5b** | 1.28 | 1.81 | 5.53 | 39.7, q (124) | 71.7, t (130) | 108.9, d (173) | 7.4, s — |



[a] Bruker WM 250 spectrometer; in [$D_8$]toluene at −30 °C. [b] All signals are singlets.

Analogous attempts to prepare **3a** and **4a** provided only indirect evidence for formation of the metallacyclobutanes in low yield: treatment of the reaction mixture with bromine yields **2a** (< 1 to 5%) and larger amounts of 1,2,3-tribromopropane, which indicates the presence of an allylmetal compound formed by β-hydrogen scission.



In accord with calculations[9], the stability of the metallacyclobutanes increases from titanium to hafnium: the half-lives of the 2,2-dimethyl derivatives are *ca.* 1—2 h (**3b**), 3 h (**4b**), and 9 d (**5b**). Noteworthy is the fact that **4a**, **4b**, and **5b** have not been described previously; presumably they are not accessible using the route[1] described for titanacyclobutanes.

**6**

**8**

**9**

**3b**, **4b**, and **5b** exhibit surprising differences in chemical behavior: upon reaction with cyclohexanone (diethyl ether, 0 °C) only **6** is formed from **3b**; from **4b**, besides traces of **6**, the major products **8** and **9** (ratio 45:55) are formed, and from **5b** only **8** is obtained. We presume that **3b** fragments to a metal-carbene complex (and isobutene)[18], which reacts with cyclohexanone to afford **6** *via* a Wittig-type reaction. In contrast, with **4b** and **5b** normal addition of the alkylmetal compound to the carbonyl group occurs; the difference in reaction behavior of **4b** and **5b** requires further clarification.

## Synthesis and Structure of $[AsPh_4][Ru_6H(\mu\text{-}O{=}CNMe_2)_2(\mu\text{-}CO)_4(CO)_{14}]\cdot Me_2C{=}O$; A Cyclic Hydrido-Hexametallic Anion**

By *Neil M. Boag, Carolyn B. Knobler,* and *Herbert D. Kaesz**

We were interested in examining single crystals containing the triruthenium anion $[Ru_3(\mu\text{-}O{=}CNMe_2)(\mu\text{-}CO)_3(CO)_7]^-$, which we obtained quantitatively as the hexamethylguanidium salt, **1a**, by treating $Ru_3(CO)_{12}$ with $C(NMe_2)_4$[1]. Since crystals of **1a** proved unsuitable for X-ray study we prepared the potassium salt, **1b**, by deprotonation of the neutral precursor **2**.

$$[Ru_3(\mu\text{-}H,\mu\text{-}O{=}CNMe_2)(CO)_{10}] + KOH/MeOH \xrightarrow[25\,^\circ C,\ 3\ h]{THF/CO\ (1\ atm)} K[Ru_3(\mu\text{-}O{=}CNMe_2)(CO)_{10}] \quad (1)$$

**2** → **1b**

The salt, **1b**, is a convenient starting material for metathetic reactions. For its synthesis, however, the conditions cited in reaction (1) must be strictly adhered to, since degradation of **2**, probably by attack of $OH^-$ at the carbon of coordinated CO, competes with the desired deprotonation. Rapid addition of base gives rise to a dark microcrystalline contaminant, which proved to be the tetraphenylarsonium salt of the title compound, **3**. We were able to obtain **3** in 45% yield by simply adding the base to a refluxing THF solution of **2** in the *absence* of carbon monoxide and then adding $AsPh_4Cl$.

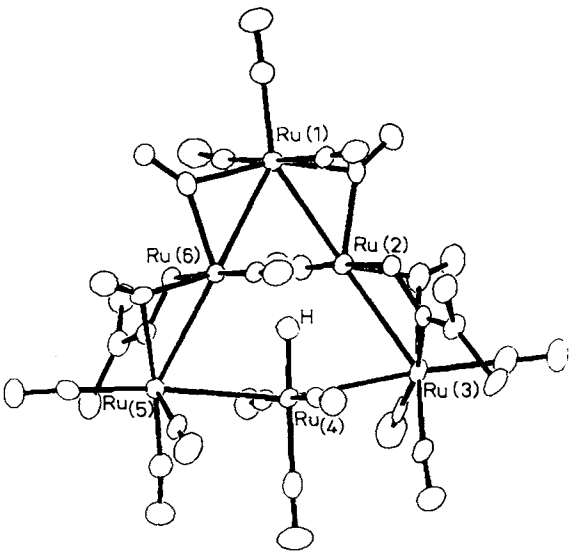

Fig. 1. ORTEP projection of the hexanuclear anion of the title compound **3** in the crystal.

The crystal structure of **3** (Fig. 1) was determined from data collected at −156 °C. The metal framework of the anion is a puckered six-membered ring consisting of two intersecting planes: Ru2, Ru4, and Ru6 define one plane, while Ru1, Ru3, and Ru5 define the second. The two

[**] This work was supported by U. S. National Science Foundation (H. D. K.) and a NATO-SERC Fellowship (N. M. B.).

planes intersect at the line defined by Ru4 and Ru1. An H atom is located on this line *inside* the metal ring at a separation of 1.50(11) Å from Ru4 and at an average distance of 2.07 Å from Ru2 and Ru6.

A six-membered metal ring, containing no transannular linkages, achieves a closed-shell configuration with 96 ($6 \times 16$) valence electrons. A recently reported planar hexametallic cluster, $Os_6(CO)_{17}[P(OMe)_3]_4$[2], contains 90 valence electrons, and attains a closed shell with a fully-formed internal triangle and three metal-metal bonds in the range 2.834—2.848 Å. By contrast, the title anion contains 92 valence electrons, six of which are derived from the two bridging $O{=}CN(Me)_2$ groups; *two* cross-ring metal-metal bonds are required to attain a closed valence-shell. Rather long separations, approximately 0.3 Å longer than Ru—H—Ru separations previously observed for other compounds of this type, are found for the central triangle (Ru2—Ru6 3.242(2), Ru4—Ru2 3.226(2), and Ru4—Ru6 3.213(2) Å). This appears to be a compromise between the requirements of a closed valence-shell and forces opposing the closed approach along any two edges of the central triangle.

## Synthesis and Structure of Metallocene Cations of the Vb Elements Arsenic and Antimony

By *Peter Jutzi*, Thomas Wippermann, Carl Krüger,* and *Hans-Jürgen Kraus*

The existence of cationic $\eta^5$-cyclopentadienyl complexes of the type $(R_5C_5)_2M^+$ (M = Vb element), isoelectronic with the IVb-metallocenes $(R_5C_5)_2M$ (M = Ge,Sn,Pb), has been suggested on the basis of NMR spectroscopic findings[1] as well as theoretical considerations[1b]. We have now been able to isolate the first such "metallocenium" ions as tetrafluoroborates and, in one case, to determine the crystal structure.

On reaction of bis(pentamethylcyclopentadienyl)fluoroarsane or -stibane[2] with boron trifluoride or boron trifluoride-diethyl ether, respectively, in hexane at −20 °C, abstraction of fluoride takes place with concomitant formation of the corresponding bis(pentamethylcyclopentadienyl)element cation.

$$(Me_5C_5)_2MF + BF_3 \rightarrow (Me_5C_5)_2M^+BF_4^-$$
$$\mathbf{1}: M = As,\ \mathbf{2}: M = Sb$$

The salts **1** and **2** are very sparingly soluble in hexane but readily dissolve in polar and aprotic solvents; they crystallize from dichloromethane as yellow or orange crystals, whose identity is confirmed by analytical and spectroscopic data.

The NMR spectra[3] of **1** and **2** indicate the existence of dynamic structures in solution, whereas an X-ray structure analysis carried out on **1**[4] shows that the cyclopentadienyl ligands are not ideally *pentahapto*-bonded to the central atom in the cation; rather a distortion in the sense of a *di*- and *trihapto*-coordination is observed (cf., in Fig. 1, the respective bond lengths and the tilting of five methyl groups away from the ring plane (C6: 12°, C7: 3.8°, C10: 3.2°, C17: 9.7°, C18: 10.3°)). Such a deviation from the ideal *pentahapto*-structure had already been indicated in the case of decamethylstannocene[5]. As expected, the two cyclopentadienyl rings in **1** are not coplanar, the angle between them is 36.5°.

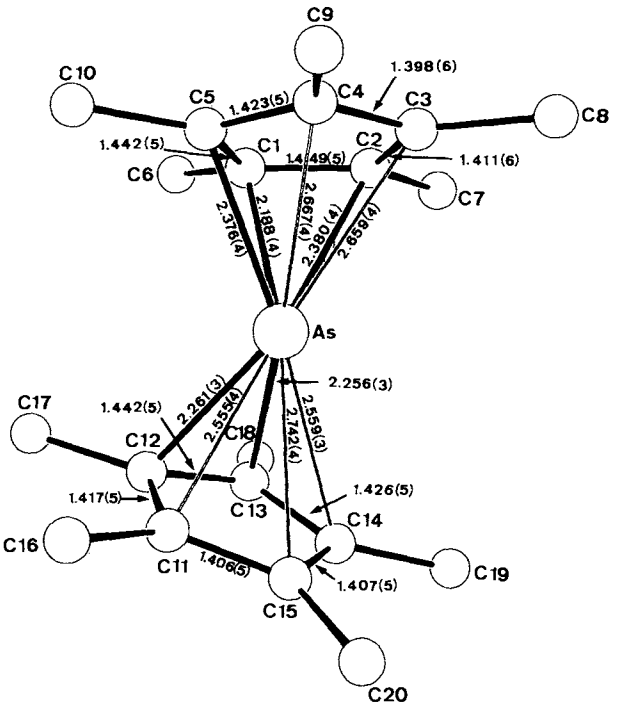

Fig. 1. Structure of the cation of **1** in the crystal.

For the stability of such cations the choice of the anion is decisive: species with $AlCl_4^-$, $BCl_4^-$ or $SbCl_6^-$ as counterions defy isolation.

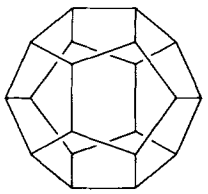
## Cautionary Example of Incorrect Structural Assignment Due to Crystallographic Disorder**



By *Otto Ermer**

In the course of crystal structure analyses, disorder phenomena often prove to be perturbations of unclear origin, which lead to unreliable structural parameters or, in the extreme case, can even prevent the derivation of a qualitatively correct structural model. As a spectacular example, the crystal structure analysis of the secododecahedrene **1**[1] at room temperature is reported here. The present study was stimulated by our interest in non-planar double bonds[2a]. According to empirical calculations using our force field[2b], **1** has marked pyramidal distortions at the $C_{sp^2}$ atoms (out-of-plane bending; cf. the calculated double bond torsion angles in the formula diagram). Furthermore, its short calculated H···H distance of 1.906 Å is noteworthy.

Crystals of **1** were optically isotropic and gave X-ray photographs with Laue symmetry m3 ($T_h$), corresponding to a cubic crystal system. An all-face centered lattice and the space groups F23 or Fm3 followed from the systematic extinctions. The cell constant $a = 10.895(5)$ Å was measured on a four-circle diffractometer. There are four $C_{20}H_{20}$ formula units per unit cell resulting in a plausible density $\rho_{calc} = 1.337$ g cm$^{-3}$ (due to lack of material a macroscopic density measurement was not performed). For an ordered structure, these crystallographic data impose molecular symmetry T or $T_h$. Clearly, this condition cannot be met by the unsymmetrical secododecahedrene **1**, and hence a disordered structure must be concluded: the high crystallographic symmetries apply only for a molecular structure *averaged* over time and/or space.

1

2

An ordered crystal structure would in the present case be possible if it were assumed that the crystals examined did not consist of the secododecahedrene **1** but of the highly symmetrical dodecahedrane **2**[1]. Gaseous **2** has $I_h$ symmetry[2a,3], whose highest possible crystallographically allowed subgroup is $T_h$. Originally, we had indeed assumed an ordered structure and, based on simple structural-chemical and geometrical criteria, constructed a dodecahedrane crystal structure model in the centrosymmetric space group Fm3. Subsequently, this model was optimally fitted by least-squares to a set of 68 reflection intensities measured on a diffractometer at room temperature ($Mo_{K\alpha}$ radiation; $\sin\theta/\lambda < 0.48$ Å$^{-1}$). The final $R$ value was 0.048 ($R_w = 0.051$; $w = 1/\sigma^2(F_o)$; C refined anisotropically, H isotropically)[4]. It should be noted that in later test calculations direct methods also produced appropriate dodecahedrane structure models. The very plausible results of the refinement are shown in Figure 1 and correspond entirely to expectations for the crystal structure of an almost spherical hydrocarbon: highly symmetrical space group, high crystallographic molecular symmetry, (cubic) closest packing, relatively high thermal motion in the crystal and, hence, somewhat shortened CC bond lengths[4].

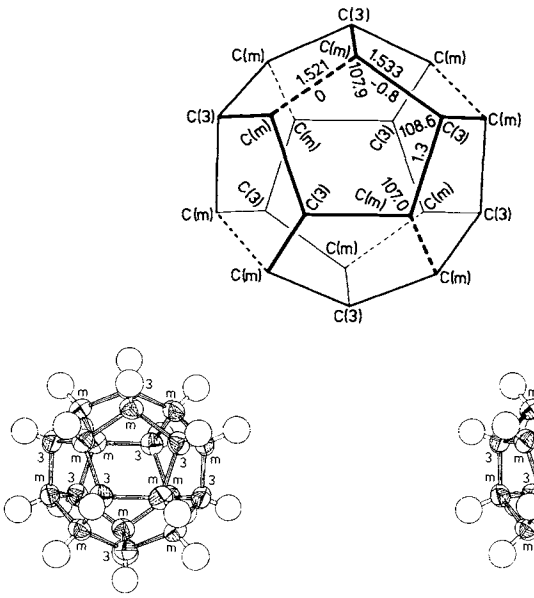


Fig. 1. Geometry (above; estimated standard deviations for distances, angles, and torsion angles, formally *ca.* 0.004 Å and 0.3°, respectively) and thermal motion (below; 10% ellipsoids) of the dodecahedrane model refined on the room temperature intensities of the secododecahedrene **1**. The C atoms on the threefold axes are designated by C(3) and those on the mirror planes by C(m). The C(m)–C(m) bonds are dashed in the top drawing in order to illustrate the $T_h$ symmetry[4].

The crystallographic identification of the material studied as dodecahedrane raised doubts based on the chemistry of the substance[5]. Therefore, a $^1$H-NMR spectrum was recorded of a fragment of the crystal which had been used for the X-ray intensity measurements. This spectrum showed unequivocally that the crystal consisted of the secododecahedrene **1**, as originally presumed[5]. Accordingly, the crystal structure of **1** at room temperature is disordered in such a way that it can be described well by an ordered structural model of **2**. Probably the still rather spherical secododecahedrene **1** adopts 30 statistically distributed preferred orientations in the crystal, in each of which the line interconnecting the methylene C atoms is parallel to a dodecahedral edge. A structure averaged over these orientations differs only slightly from that of dodecahedrane **2**.

The present experiences may serve as a cautionary example that a satisfactory $R$ value and even physically highly plausible structural results do not always safeguard against incorrect assignments in crystal structure analyses.

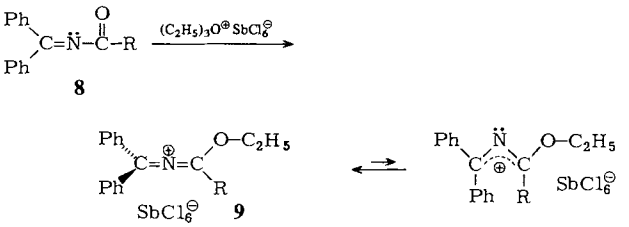
## Reactions of *N*-Methylenecarboxamides with Electrophiles: 1-Alkoxy-2-azaallenium Salts and *N*-Acyl(methylene)ammonium Salts**

By *Ernst-Ulrich Würthwein*, Rainer Kupfer,* and *Claus Kaliba*

Like the simpler amides, *N*-methylenecarboxamides **4**[4] are ambident nucleophiles which can be attacked by electrophiles at oxygen or at nitrogen. Alkylation at the oxygen atom is expected to yield 1-alkoxy-2-azaallenium salts **5** or 1-alkoxy-2-azaallyl cations **6**; attack at the nitrogen atom should lead to *N*-acyl(methylene)ammonium salts **7**[5].

**7** **4** **5** **6**



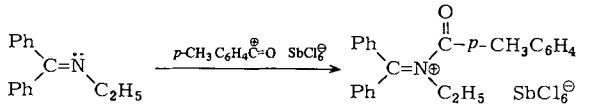
The *N*-methylenecarboxamides **8a, b** were synthesized by acylation of diphenylmethaneimine. These were then alkylated with oxonium salts or protonated with strong acids. All products are stable, hygroscopic, crystalline solids, which can be purified and fully characterized (Table 1). According to their $^{13}$C-NMR-spectra, the alkylation products **9a, b** have 1-ethoxy-2-azaallenium structures of type **5**. This structural assignment is supported, in particular by the $^{13}$C-chemical shifts of the methylene groups (**9b**: $\delta=73.32$; ether-region). Both phenyl groups give rise to only four signals, even at low temperatures (*e.g.* **9a**: $-70$ °C, $CDCl_3$, 25.15 MHz), which is consistent with the formulated allene-type structure ($C_s$ symmetry). Strong IR absorptions at 1695 and 1700 cm$^{-1}$, respectively, are ascribed to C=N=C– heteroallene stretching vibrations[7].

The *N*-acylated methyleneammonium salt **11**, which is isomeric to **9b**, was synthesized from *N*-diphenylmethylene(ethyl)amine and *p*-methylbenzoylium hexachloroantimonate. The $^{13}$C-chemical shift of its methylene group ($\delta=55.33$) is typical for an *N*-ethyl(methylene)ammonium salt. The two phenyl groups give rise to eight signals, in accordance with the planar $C_s$-structure **11**. These spectroscopic data indirectly support the favored alkylation of *N*-methylenecarboxamides at the oxygen atom.

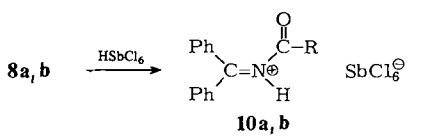
Table 1. Physical data and yields for the compounds **9**, **10**, and **11**.

| Cpd. | IR $\nu$ [cm$^{-1}$] | $^{13}$C-NMR [$\delta$ values] [c] C=N– | –N–C–O– | $-CH_2-$ | M.p. [°C] | Yield [%] |
|---|---|---|---|---|---|---|
| **8a** | 1640, 1690 [a] | 164.11 | 184.83 | — | 43.5—44 | 71 |
| **8b** | 1620, 1650 [b] | 167.41 | 179.19 | — | 153.5—154.5 | 63 |
| **9a** | 1585, 1700 [b] | 168.33/173.31 [d] | | 71.65 | 97—102 (dec.) | 66 |
| **9b** | 1585, 1695 [b] | 169.67/176.22 [d] | | 73.32 | 158—159.5 (dec.) | 45 |
| **10a** | 1580, 1758 [b] | 189.68 | 170.00 | — | 113—117 (dec.) | 70 |
| | | 188.20 | 169.81 [e] | — | | |
| **10b** | 1600, 1735 [b] | 190.44 | 166.63 | — | 109—114 (dec.) | 63 |
| **11** | 1585, 1725 [b] | 188.92 | 171.36 | 55.33 | 126—129 (dec.) | 64 |

[a] In $CHCl_3$. [b] In Nujol. [c] 25.15 MHz, 25 °C, solvent: $CDCl_3$ (**8a, b, 9a**); $CD_3NO_2$ (**9b, 10a, b, 11**). [d] Assignment uncertain. [e] Solvent: $SO_2$, $-70$ °C, $CF_3SO_3H$-excess.



**8**



**9**

**a**, R = $CH_3$ **b**, R = *p*-$CH_3C_6H_4$

The $^{13}$C-NMR data of the protonated derivatives **10a, b** are very similar to the data of **11**, but they differ significantly from those of the *O*-alkylated compounds **9a, b**. In particular, the low temperature $^{13}$C-NMR spectra (liquid $SO_2$, excess of trifluoromethanesulfonic acid) indicate the favored nitrogen protonation: the C=N-signal is found at $\delta=189.99$, the C=O signal at $\delta=170.00$; eight signals for the two phenyl groups and the IR-absorptions (at 1758 and 1735 cm$^{-1}$, respectively) provide further evidence for attack at the nitrogen atom (c.f. also[8]).

**11**

**10a, b**

Quantum mechanical calculations (*ab initio*, 3—21G[9]) support the experimental results. A twisted cisoid conformation (dihedral angle C=N–C=O: 25.4°) is predicted as

[*] Dr. E.-U. Würthwein, R. Kupfer, C. Kaliba

Henkestrasse 42, D-8520 Erlangen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

the most favorable structure for the unsubstituted *N*-methyleneformamide; the *s-cis*-conformer is 0.11 kcal/mol, the *s-trans* conformer 2.90 kcal/mol higher in energy.

Both according to experiment as well as to calculation, the protonation of formamide takes place preferentially at the oxygen atom. *N*-methylenecarboxamides, on the other hand, are predicted by the calculations to be attacked at the nitrogen atom. Oxygen protonation is less favorable by 7.00 kcal/mol. 1-Hydroxy-2-azaallyl cations are much higher in energy (19.6 kcal/mol for the *endo*-isomer) than the linear allenium ions.

Calculations on the structure of the 1-hydroxy-2-azaallenium ion reveal its unusual dynamic properties. An energy of only 4 kcal/mol is necessary to convert the linear allene-like form into a 150°-bent structure; the methylene groups remain twisted during this motion. Favorable compromises in the overlap between the π-electron systems and the lone pairs on nitrogen and oxygen are responsible for the unusual molecular flexibility predicted for these ions by the calculations.

## Straightforward Preparation and Stabilization of 2-*trans*-4,7 : 10,13-Diepoxy[15]annulenone

By *Haru Ogawa**, *Tadashi Inoue*, *Taiji Imoto*, *Izumi Miyamoto*, *Hidefumi Kato*, and *Yōichi Taniguchi*

Although the 2-*trans*-[15]annulenone **4** with two oxygen bridges has been prepared[1], its fugitive existence has precluded further studies. We now report a [15]annulenone–hydroxy[15]annulenylium ion cycle, from which **4** could be isolated as predominant isomer. It was also found that the ground state of **4** could be stabilized by $H_2O$ to form a 14π-annulenylioolate **5**, R = H (Scheme 1).

The *cis*-annulenylium ion **2** was formed by dissolving **1** in $CF_3COOD + CD_2Cl_2$ (1 : 5) at −60 °C [$^1$H-NMR: AB system centered at $\delta = 8.61$ and 8.99 ($J_{cis} = 9.77$ Hz), 4H, H-2, H-3, H-14, and H-15; singlet at $\delta = 9.06$, 6H, H-5, H-6, H-8, H-9, H-11, and H-12].

On warming the solution the $^1$H-NMR spectrum changed dramatically to give nine outer proton resonances ($\delta = 8.85 - 10.30$) and one inner proton resonance ($\delta = -3.68$, $J_{trans} = 14.6$ Hz), indicating that the *cis-trans* equilibrium **2** ⇌ **3** shifts considerably towards **3** (**3** : **2** ≈ 12 : 1). Addition of saturated $NaHCO_3$ solution to **3**, which could be regenerated at 25 °C in $CF_3COOD$, followed by chromatographic separation ($CH_2Cl_2$, $Al_2O_3$, activity III) gave pure **4**. **4** proved to be diatropic; the outer protons absorb in the region $\delta = 6.82 - 8.18$ (9H) and the inner proton at $\delta = 4.54$ ($J_{trans} = 16$ Hz, in $CDCl_3$, 27 °C).

Scheme 1. The [15]annulenone–hydroxy[15]annulenylium ion cycle.

The chemical shift of the inner proton is highly temperature- and solvent-dependent. In $D_3COD$ progressive high-field shifts occur on cooling [$\delta = 2.51$ (0 °C), 1.85 (−25 °C), and 0.57 (−55 °C)]. Such large shifts were also observed at 25 °C on increasing the $D_2O$ content [$\delta = 3.02$ ($D_3COD$ : $D_2O$ = 100 : 0), 2.60 (100 : 16), 1.31 (100 : 40), 0.87 (100 : 56)]. These observations indicate that the dipolar stretched form **5** is formed by H-bonding to stabilize the *trans* geometry.

Kinetic measurements of the isomerization **4** → **1** (UV spectroscopy) confirmed these results. As expected, the rates of isomerization, which could be best approximated by eq. (1), became slower in aqueous solvents indicating that $k_{H^+}$ in $CH_3OH$ is *ca.* 3 times greater than $k_{H^+}$ in 25% aqueous $CH_3OH$, and that $k_{H^+}$ (in acetone)/$k_{H^+}$ (in 25% aqueous MeOH) is at least several thousand.

$$\text{rate} = (k_{H^+}[H^+] + k_{therm})[\mathbf{4}] \quad (1)$$

A significant feature of the annulenone cycle is the fact that a series of cooperative conformational changes could occur in succession to drive it by a protonation-deprotonation sequence. Interestingly, similar transformations occur in bacteriorhodopsin[6]. Thus, the cycle could provide the first example of a "closed" cycle[5], whose rates and equilibria can be investigated as a model of a biological cycle using conventional kinetics and thermodynamics[5].

## Can Radicals Participate in Pericyclic Reactions? Model Reactions for Electron-Transfer Induced Valence Isomerization of 1-Arylindenes**

By *Herbert Kiesele**

Theoretical predictions state that pericyclic radical reactions should be forbidden, since they violate the principles of conservation of orbital- and of spin-symmetry[5]. Nevertheless, more and more examples for electron-transfer (ET) induced valence isomerizations have been reported, which, according to the concordant opinion of the authors, proceed *via* radical anions and are to be considered as pericyclic reactions[7]. This contradictory situation invites a more thorough study of ET induced valence isomerizations.

As a first example we selected the sigmatropic [1,5] shift in 1-arylindenes, which can be induced oxidatively (anodically), thermally, photochemically, and reductively (cathodically), and hence enable comparison of different oxidation states and electron configurations (Scheme 1).

Scheme 1. Thermal, photochemical, and ET induced reactions of 2',3'-dihydro-1,1'-spirobiindene **1a**. DME = 1,2-dimethoxyethane; Crpt. = [2.2.2]cryptand.

Preparative, electrochemical, and spectroscopic studies on a series of indene derivatives indicated that the reductive aryl shift proceeds exclusively *via* diamagnetic *dianions*, whose formation is favored thermodynamically by preceeding ion pair equilibria.

When the generation of dianions is prevented by complexing the counter ions with a macrocyclic ligand or by addition of an appropriate redox reagent (Scheme 1), relatively persistent radical anions[12] are obtained at low temperatures, which undergo dimerization and fragmentation at room temperature (cf. Supplement). The different reactions of the individual oxidation states (and electron configurations) are outlined in Scheme 1 using the dihydrospirobiindene **1a** as example; Table 1 shows how the product distribution changes with the reaction conditions.

The "alternating" tendency of neutral molecules[14], radical anions, and dianions to rearrange, confirms the "Yamaguchi rules", which allow linear transition states (fragmentation) for open-shell species but forbid cyclic ones.

According to our most recent observations, the ET induced ring-opening of cyclobuta[1]phenanthrene can proceed not only *via* a radical anion, but als *via* a dianion. The radical ring-opening, however, only occurs if ion pairs can form[21]. This result provides further confirmation for the efficiency of orbital- and spin-symmetry barriers in pericyclic radical reactions. But this example also shows that the barriers can be circumvented by ion pairing.

Table 1. Alkali metal reduction of **1a** in DME at room temperature.

| Reaction conditions [a] | Fragmentation [b] **3a** | Rearrangement [b] **6a** |
|---|---|---|
| K | 20 | 80 |
| K/[2.2.2]cryptand | 100 | — |
| K/biphenyl | 100 | — |

[a] Fused glass apparatus; the reaction mixture was quenched with oxygen-free EtOH/AcOH. [b] Relative yields [%]; for isolated yields and side products, see Supplement.

## The Structure of Tris(diphenylthiophosphinoyl)methanide, a Mesomerically Stabilized Carbanion**

By *Samuel O. Grim**, *Richard D. Gilardi*, and *Samuel A. Sangokoca*

The carbanion $[\{(C_6H_5)_2P(S)\}_3C]^-$, **1**, is a novel and versatile ligand which reacts by metathesis with metal halides to form cage complexes in which it behaves as singly negatively charged, tridentate, six-electron donor[1]. The anion **1** is prepared by proton abstraction[1a] from the neutral parent compound, $[(C_6H_5)_2P(S)]_3CH$, **2**, which was first reported by *Issleib et al.*[2]. It is also similar to the analogue $[\{(CH_3)_2P(S)\}_3C]^-$, **3**, which was recently reported by *Karsch*[3]. **1** and **3** are presumably mesomerically stabilized[3] by partial delocalization of the electronic charge of the central carbon through phosphorus onto the sulfur atoms. Maximum delocalization occurs if the anionic carbon has planar geometry.

The X-ray crystallographic structure of **1**, isolated as the stable tetra-*n*-butylammonium salt, has now been solved (cf. Fig. 1) and is the first such molecular structure to be determined. The salient features of the structure are as follows: First, the geometry about the central carbon is planar, with a mean P–C–P bond angle of 119.9°, although there is considerable deviation from the mean. The carbon is displaced only 6.8 pm from the plane of the three phosphorus atoms. Secondly, two of the sulfurs lie on one side

[**] Polydentate Ligands Containing Phosphorus, Part 10.—Part 9: [1a].

of this plane, while the third sulfur lies on the opposite side. This arrangement is similar to that of the stable conformation[4] of **2** and is expected for steric reasons, although NMR data[1a] indicate that there is no restricted rotation about the phosphorus central-carbon bonds in **1**,

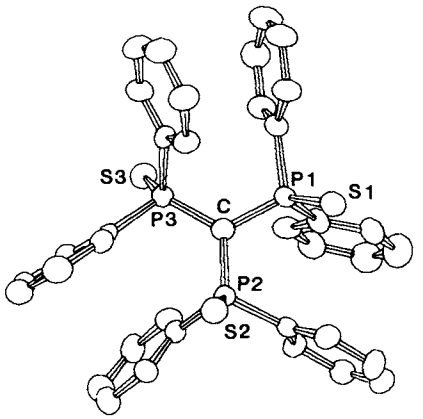

Fig. 1. Structure of **1** as the $n$-$Bu_4N^+$ salt, which crystallizes along with one acetone molecule. Space group $P2_1$, $a=1189.4$, $b=1933.1$, $c=1259.9$ pm, $\beta=111.42°$, $Z=2$; 3644 reflections, $R=0.070$. Most important bond lengths [pm] and angles [°]: P1-S1, 197.4; P2-S2, 197.2; P3-S3, 198.1; P1-C, 176.7; P2-C, 177.4; P3-C, 174.6; P1-C-P2, 116.0; P2-C-P3, 122.0; P2-C-P3, 121.6.

even at temperatures as low as 178 K. Thirdly, as expected for a mesomerically stabilized compound of this type, the P–S bond order decreases and the P–C (central) bond order increases in going from the neutral parent compound **2** to the anion **1**. This is indeed the case and is reflected by P–S bond lengths, which are greater in **1** (mean, 197.6 pm) than in **2** (mean, 194.4 pm)[4] and by the P–C (central) bond lengths, which are shorter in **1** (mean, 176. 2 pm) than in **2** (mean, 188.3 pm)[4]. The structure bears a striking resemblance to the structure of the mesomerically-stabilized dication, $[(CH_3)_3P]_3C]^{2+}$, **4**, which has a planar geometry at the central carbon and which has one unique and two stereochemically equivalent phosphonium groups[5a]. The P–C (central) bond length (175 pm) in **4** is similar to that in **1** (176.2 pm) but both are longer than in ylides such as $Ph_3P{=}CH_2$ (166.1 pm)[5b] and $Ph_3P{=}C{=}PPh_3$ (162.4 pm)[5c].

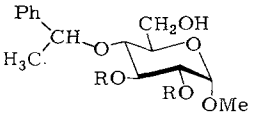
## Formation, Structure, and Synthetic Use of Gluco- and Galactopyranoside Acetophenone Acetals with 1,3-Dioxane Rings

By *András Lipták** and *Péter Fügedi*



There are only two examples in the literature concerning the preparation of 4,6-*O*-α-methylbenzylidene-hexopyranosides[1]. In both cases principally one of the diastereomeric acetals was formed, and an equatorial phenyl group proposed for these derivatives by analogy with the corresponding benzylidene derivatives[2].

Reinvestigation of the acetal exchange reaction (dimethylformamide, *p*-toluenesulfonic acid, room temperature) between acetophenone dimethyl acetal and glucopyranoside derivatives **1**—**3** revealed formation of both isomeric acetals, whereby the products of kinetic control (**5**—**7**), isolable in yields of 20—30%, were readily converted into the thermodynamically favored isomers **9**—**11**. Under equilibrium conditions the latter accumulate exclusively and can be isolated nearly quantitatively. The galactopyranoside derivative **4** reacted similarly to give **8** and **12**.

The configurations of the acetal carbons were assigned from $^1H$ and $^{13}C$ chemical shifts of the C-2′ substituents; these data are highly diagnostic in 2,2-disubstituted 1,3-dioxanes. For an axial methyl group the $^1H$-NMR signals are observed at lower[3] and the corresponding $^{13}C$-NMR signals at higher field[4] than in the equatorial isomer. In the present case the products of kinetic control (**5**—**8**) (Table 1) surprisingly proved to be the (*R*)-isomers with axial methyl groups, whereas the products of the thermodynamic control (**9**—**12**) were the (*S*)-isomers with axial phenyl groups.

Table 1. Selected data for compounds **5**—**16**.

| Compound | M.p. [°C] | $[\alpha]_D$ [a] | $^1H$-NMR [b] | $^{13}C$-NMR [c] |
|---|---|---|---|---|
| **5** | 107—109 | + 29 [d] | 1.68 [e] | 20.9 [e] |
| **6** | 95—96 | + 64 | 1.72 | 21.8 |
| **7** | 112—113 | − 57 | 1.73 | 22.1 |
| **8** | 85 | − 71 | 1.69 | 22.1 |
| **9** | 168—170 | +209 [d] | 1.43 [e] | 31.8 [e] |
| **10** | syrup | +154 | 1.55 | 31.9 |
| **11** | syrup | +106 | 1.55 | 32.0 |
| **12** | 118 | + 21 | 1.65 | 32.3 |
| **13** | syrup | +192 | 1.52 | |
| **14** | syrup | +126 | 1.44 | |
| **15** | syrup | +140 | 1.46 | |
| **16** | syrup | + 33 | 1.43 | |

[a] In chloroform. [b] C—$CH_3$, in $CDCl_3$, TMS internal standard, δ values. [c] C—$CH_3$, in $CDCl_3$. [d] In pyridine, *δ* values. [e] In [$D_6$]dimethyl sulfoxide.

This result is in marked contrast to earlier conceptions of carbohydrate acetals of this type, but agrees well with the finding of *Eliel* et al.[3] that in a 2-methyl-2-phenyl-1,3-dioxane derivative the axial phenyl isomer is more stable by 2.55 kcal/mol. This can be explained by the fact that in the "perpendicular" rotamer an axial phenyl group can avoid unfavorable interactions with other H atoms[3].

Hydrogenolytic ring-cleavage of the diasteromeric α-methylbenzylidene acetals with $LiAlH_4$—$AlCl_3$[6] exhibited a high degree of regio- and stereoselectivity. The (*R*)-isomers gave only the 4-*O*-(α-methylbenzyl)derivates **13** and **14**, whereas the (*S*)-isomers afforded the 6-*O*-(α-methylbenzyl) derivatives **15** and **16**. In both cases only one of the two possible diastereomeric ethers was formed; the configurations of the new chirality centers are being investigated. The regioselectivity is reminiscent of the results obtained in the reduction of the five-membered *exo*- and *endo*-benzylidene acetals of carbohydrates[6].

Because compounds **10** and **11** are the only products of acetalization in equilibrium, and their hydrogenolysis with $LiAlH_4$—$AlCl_3$ results in 6-ethers, a new route is opened for the preparation of glucopyranosides selectively unprotected at position 4.

# BOOK REVIEWS

**Properties of Ligands and Solutions.** By *J. N. Murrell* and *E. A. Boucher*. John Wiley & Sons, Chichester 1982. x, 288 pp., bound, £ 8.90.

This book is an excellent introduction to the fundamentals of the science of liquids, its 13 chapters giving a brief but clear account of virtually all topics of interest to chemists, biologists, physical chemists, and other scientists.

Chapter 1 is a short introduction and Chapter 2 deals with intermolecular forces. Chapter 3 outlines the modern theories and models of liquids, including the latest developments in statistical thermodynamics and computer simulations. The thermodynamic properties of pure liquids are discussed in Chapter 4, and liquid crystals (though rather briefly) in Chapter 5. The topics dealt with in Chapters 6 and 7 are respectively: mixtures of non-electrolytes, and the phase behavior of multicomponent systems. Chapter 8 is devoted to polar liquids and Chapter 9 to aqueous electrolyte solutions. The authors discuss chemical equilibria in solution in Chapter 10 and polymer solutions and their special characteristics in Chapter 11. Chapter 12 deals with the problems of liquid boundary layers and adsorption phenomena and Chapter 13 gives an account of colloidal systems.

The book is not limited to general and standard cases but often gives direct applications of particularly interesting systems. For example, Section 8.5 discusses the structural model of water that has emerged from the various investigations. Wherever possible, the statistical and thermodynamic models are explained as far as is necessary for understanding the principles.

Although the aim of the book is to give an introduction, which in fact it does, it presupposes some background knowledge in various areas: from thermodynamics, the basic relationships, from statistical mechanics only the Max-

well-Boltzmann distribution law and the partition function, and from quantum mechanics a few fundamental concepts of the theory of chemical bonding.

The sequence of the topics is almost invariably from the easier to the more difficult (for example, non-electrolytes are discussed before electrolytes and colloids), because the material was originally used for a course of lectures at the University of Sussex. The book is most suitable for accompanying such a course of lectures for scientists, but it can also be recommended to interested students for self-study. The very good style and makeup of the book justify its price.

*Rüdiger N. Lichtenthaler* [NB 577 IE]

**Macrocyclic Polyether Syntheses.** By *G. W. Gokel* and *S. H. Korzeniowski*. Springer-Verlag, Berlin 1982. xviii, 410 pp., bound, DM 238.00.

The chemistry of macrocyclic polyethers (crown ethers) and of their hetero-analogues has shown a meteoric rise in its 15 years of history, which is also reflected in the number of crown compounds synthesized so far. This number is so large that often even experts cannot decide whether a certain macrocyclic compound exists or whether a given structural element has already been used as a component of a crown compound. However, this book settles the matter, for it lists 2369 compounds with their structural formulas in 86 tables, giving their ring size, melting point, and the yields of the various ligands. This number far surpasses any given in previous monographs on crown ethers. When it comes to the methods of synthesis, however, the book gives only the essentials in a brief account at the beginning of each of Chapters 3—8, the rest being left to the 750 references listed (it would have been useful to include a separate index for the methods).

On the other hand, the whole of Chapter 2 is devoted to the "Template Effect", a device useful for raising the yield of simple crown ethers but playing only a subordinate role in the synthesis of more complex ligand systems. Space could therefore have been saved here and utilized to discuss some more general synthetic strategies.

The first chapter (Introduction and General Principles) describes how the various types of crown compounds are built up and deals at length with their nomenclature. The oxirane oligomerization (Section 1.4) would have fitted in better in Chapter 2 ("template catalysis"), while the account of polyazamacrocyclic compounds (Section 1.5) could have been better treated in Section 1.3.2 ("Aza-crowns"), so as not to violate the definitions established earlier.

The bulk of the information is contained in Chapters 3—8, in which the material is divided as follows: Chapter 3: Syntheses of Oxygen Macrocycles (simple crown ethers and crown ethers with aromatic residues, both with up to 81 members in the ring, together with lariat ethers and polytopic ligand systems). Chapter 4: Syntheses of Aza-crowns (including heteroaromatic and chromoionophores, but not the large field of ligands with a porphine structure and Schiff base-type ligands complexing with transition-metal ions). Chapter 5: Crown Esters and Macrocyclic Polyether Lactones. This chapter also covers thioesters, many crown ether amides, and urea derivatives, so that it would have been more accurate to use the word "lactams" instead of "lactones" in the heading. Chapter 6: Miscellaneous Macrocycles (*e.g.* with heteroatoms other than oxygen or nitrogen, also acetal-type and polymer-bound crown compounds). Chapter 7: Open-chained Equivalents of Crown Ethers (linear and branched podands with up to 88 atoms in the chain and with special donor end groups; also octopus molecules and synthetic ionophores). Chapter 8: Cryptands and Related Polycyclic Systems (including lipophilic and large-lumen bicyclic and oligocyclic compounds with N and C bridgehead atoms, as well as polymer-fixed cryptands and spherands).

The backbone of these chapters is formed by the extensive tables, which are most clearly laid out and graphically well presented. Captions and footnotes are added to clarify difficult points. Perhaps the order of chapters 7 and 8 could have been reversed to take the polycyclic compounds before the open-chain ones.

Readers interest in an inventory of all the known crown compounds or in an encyclopedia of the usual methods of synthesizing neutral ligands are advised to acquire this book. However, one should not expect anything on the complexing characteristics of the ligands, because the book does not even touch on this subject. The reader interested in this must turn to the many previous studies, to which this book constitutes a welcome addition that will often save a laborious literature search. The reader will soon realize its value as an inventory of the structural components and other structural details of crown ethers when using it as a starting point for new syntheses. The book should therefore be bought by all libraries, even though its very high price might at first be discouraging.

# Magic-Angle-Spinning NMR (MAS-NMR) Spectroscopy and the Structure of Zeolites

By Colin A. Fyfe, John M. Thomas*, Jacek Klinowski, and Gian C. Gobbi

After outlining the chemical features and properties which make zeolites such an important group of catalysts and sorbents, the article explains how high-resolution solid-state NMR with magic-angle spinning reveals numerous new insights into their structure. $^{29}$Si-MAS-NMR readily and quantitatively identifies five distinct $Si(OAl)_n(OSi)_{4-n}$ structural groups in zeolitic frameworks ($n=0,1,\ldots 4$), corresponding to the first tetrahedral coordination shell of a silicon atom. Many catalytic and other chemical properties of zeolites are governed by the short-range Si, Al order, the nature of which is greatly clarified by $^{29}$Si-MAS-NMR. It is shown that, as expected from Pauling's electroneutrality principle and Loewenstein's rule, both in zeolite X and in zeolite A (with $Si/Al=1.00$) there are no $-Al-O-Al-$ linkages. In zeolite A and zeolite X with $Si/Al=1.00$ there is strict alternation of Si and Al on the tetrahedral sites. Ordering models for Si/Al ratios up to 5.00 (in zeolite Y) may also be evaluated by a combination of MAS-NMR experiments and computational procedures. $^{29}$Si-MAS-NMR spectra reveal the presence of numerous crystallographically distinct $Si(OSi)_4$ sites in silicalite/ZSM-5, suggesting that the correct space group for these related porosilicates is not Pnma. $^{27}$Al-MAS-NMR clearly distinguishes tetrahedrally and octahedrally coordinated aluminum, proving that, contrary to earlier claims, Al in silicalite is tetrahedrally substituted within the framework. In combination, $^{29}$Si- and $^{27}$Al-MAS-NMR is a powerful tool for monitoring the course of solid-state processes (such as ultrastabilization of synthetic faujasites) and of gas-solid reactions (dealumination of zeolites with silicon tetrachloride vapor at elevated temperatures). They also permit the quantitative determination of *framework* Si/Al ratios in the region $1.00<Si/Al<10\,000$. Since most elements in the periodic table may be accommodated within zeolite structures, either as part of the exchangeable cations or as building units of the anionic framework, there is immense scope for investigation by MAS-NMR and its variants (cross-polarization, multiple pulse and variable-angle spinning) of bulk, surface and chemical properties. Some of the directions in which future research in zeolite science may proceed are adumbrated.

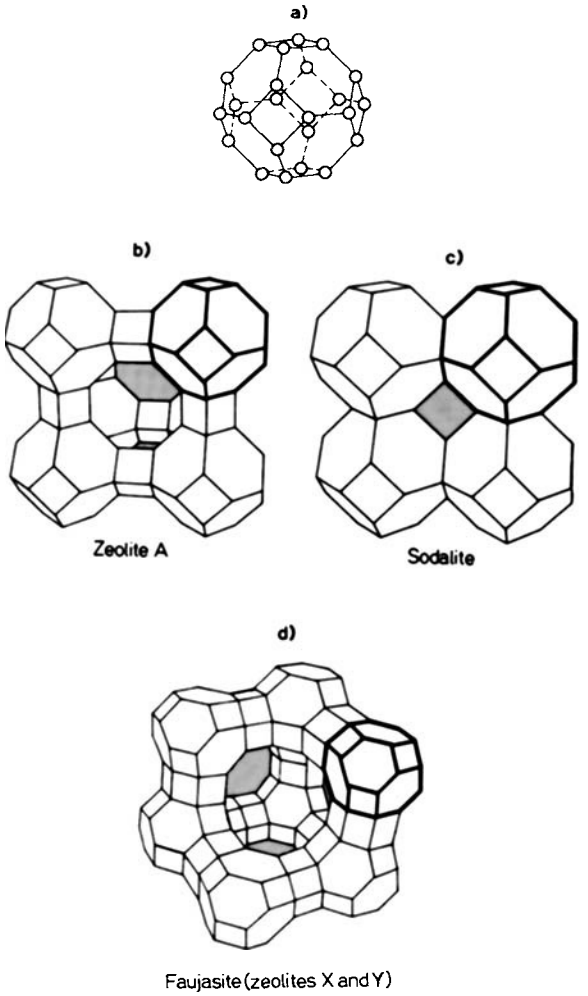
## 1. Introduction

Zeolites are microporous, crystalline aluminosilicates of general formula $M_{x/n}[(AlO_2)_x(SiO_2)_y]\cdot m\,H_2O$. They may be regarded as open structures of silica, $SiO_2$, in which aluminum has been substituted in a fraction $x/(x+y)$ of the te-

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0404-0259 $ 02.50/0 

trahedral sites. The net negative charge of the aluminosilicate framework is neutralized by exchangeable cations, M, of valence n; and the void space, which may be more than 50% of the crystal volume, is occupied by m molecules of water per unit cell. Depending upon the particular structure of the zeolite, the porosity may consist of one-, two- or three-dimensional networks of interconnected channels and cavities of molecular dimensions (Fig. 1). If the zeolitic water is removed, many other molecular entities may be accommodated in the intracrystalline cavities including $CO_2$, $NH_3$, hydrocarbons, alkanols and a wide range of other organic and inorganic species.



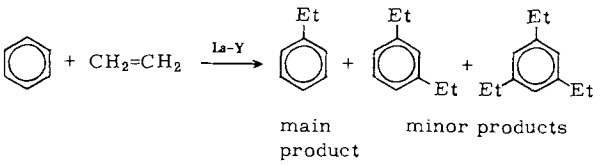


Fig. 1. a) The truncated octahedron building block (also termed "cuboctahedron", "sodalite cage" or "β-cage"). Tetrahedral atoms (denoted as o) are located at the corners of polygons with oxygen atoms (not shown) approximately half-way between them.—b) The structure of zeolite A formed by linking the sodalite cages through double four-membered rings.—c) The sodalite structure formed by direct face-sharing of four-membered rings in the neighboring sodalite cages.—d) The faujasite structure formed by linking the sodalite cages through double six-membered rings.—Non-framework cations are not shown.

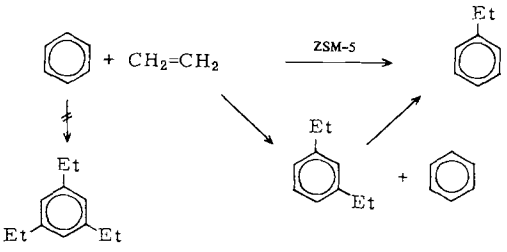
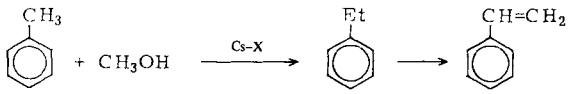


There are, at present, 37 identified types of zeolitic minerals and well over 100 synthetic zeolites. The unit cell stoichiometry of the idealized, naturally occurring zeolite faujasite is $Na_{56}[(AlO_2)_{56}(SiO_2)_{136}]\cdot 250\,H_2O$, and that of the closely related synthetic zeolite, known as Linde A, is $\{Na_{12}[(AlO_2)_{12}(SiO_2)_{12}]\cdot 27\,H_2O\}_8$. Some other elements, notably Be, Mg, B, Ga, Ge and P can take the place of Si and Al in the zeolitic framework: there have been claims that many other elements, including transition metals, may enter the framework substitutionally. The term "porotectosilicate" has been suggested[1] as a general description of porous zeolite-like materials.

## 2. Zeolites as Sorbents and Catalysts with Shape-Selectivity



The remarkable sorptive properties of zeolites have long been recognized, as has their ion-exchange capacity[2–6]. They are capable of ionic and molecular sieving, the size and shape of the admitted species being determined by the dimensions of the aperture openings in the zeolite. The ease with which they undergo ion exchange is utilized commercially in water softening, in the treatment of brackish water, in the recovery of precious metals (as complex cations), and in the removal of radioactive species from solution[7,8]. By appropriate adjustment of their cation composition, certain zeolites may be "tuned" further to serve as efficient gas separation agents (separating, for example, methane from ethane or oxygen from nitrogen). But, most importantly, zeolites, particularly those with relatively high Si/Al ratios and rich in free protons, exhibit impressive activity and selectivity as catalysts for the cracking, hydrocracking and isomerization of hydrocarbons[8–11]. Indeed, in these functions, faujasitic zeolites are amongst the most widely used of all commercial catalysts: they far surpass the performance of their silica-alumina gel predecessors, and possess the useful property of being sufficiently thermally stable to withstand regeneration at high temperatures[12]. Faujasitic zeolites are the premier components in fluidized cracking catalysts for the petroleum industries. Two examples will serve to illustrate the additional catalytic potential of zeolites: the ethylation of benzene over $La^{3+}$-exchanged zeolite Y (a synthetic faujasite) occurs at 200 °C with close to 100 percent selectivity[13]; likewise, the conversion of toluene by methanol to ethylbenzene (and thence to styrene) over a $Cs^+$-exchanged zeolite X is also very efficient[13b] (cf. Scheme 1).

a) Ethylation of benzene on La-Y

b) Ethylation of benzene on ZSM-5

c) Ethylation of toluene on Cs-X

d) Synthesis of *p*-methylstyrene on ZSM-5

Scheme 1.

In the early 1970's a new class of porotectosilicates was discovered[14, 15a]. Members of the highly siliceous ZSM series (for *Z*eolite *S*ocony[15b] *M*obil) possess optimal pore diameters (*ca.* 5.5 Å, see Fig. 2) and attractive catalytic properties including the ability to synthesize gasoline from methanol as well as ethylbenzene from ethylene and benzene in a manner which could well supplant the traditional Friedel-Crafts procedure[16] (Scheme 1). The particular member that catalyzes these reactions is ZSM-5, the unit cell formula of which is $H_x[(AlO_2)_x(SiO_2)_{96-x}]\cdot 16\,H_2O$, with $x<27$ and typically about 3. A crystalline microporous solid called silicalite is very closely similar in framework to ZSM-5[17]. Silicalite is organophilic and hydrophobic and removes from water by preferential adsorption, alkanols, certain alkanes and some other organic entities. In the patent describing the preparation and properties of silicalite it is claimed that this porotectosilicate contains no constitutional aluminum. We show later that $^{27}$Al-MAS-NMR indicates otherwise (cf. Section 6).

An important attribute of both ZSM-5 and silicalite, and of many other zeolites, as was first recognized by *Weisz et al.*[14b, 18], is their shape selectivity. Because of the dimensions and the geometry of the channels only certain reactants may, for example, enter and diffuse through crystals of ZSM-5. Likewise, shape restrictions are imposed upon the transition states accessible to the catalytic reactions that take place in the intracrystalline regions and upon the products that may diffuse out from within the catalyst particle.

Early work on the sorptive properties of zeolites, notably on the mineral chabazite, was summarized by *McBain* more than 50 years ago[3]. Subsequent work on structure, syntheses and properties has been comprehensively reviewed in texts by *Barrer*[4], the founder of the modern study of zeolites, and by *Breck*[5], who along with *Milton* and other collaborators at the Union Carbide Corp. also made extensive contributions to the subject. Other reviews dealing with catalytic performance[6, 7-11], structure[19-21] and general chemical properties[22] are available.

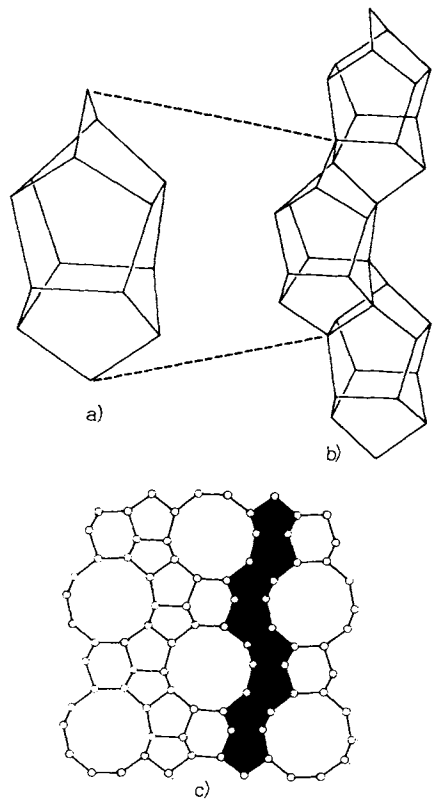


Fig. 2. a) The "pentasil unit", the building block of ZSM-5/silicalite and ZSM-11.—b) Pentasil units are linked into chains, one of which is shown in the *c* direction.—c) In the structure of ZSM-5/silicalite the chains are interlinked to form a three-dimensional framework in which there are ten-membered ring openings (≈ 5.5 Å in diameter) running along the [010] direction. In this portion of the *ac* structural projection, O denotes a tetrahedral site.

## 3. Structural Considerations

Whereas the overall framework structure of most zeolites can be satisfactorily determined by conventional X-ray methods, the detailed Si, Al ordering within the tetrahedral framework itself—a factor of great importance since it governs the catalytic performance and the myriad other properties of zeolites—cannot, in general, be readily extracted from X-ray crystallography. This arises partly because of the similar scattering powers of Si and Al, but also because it is very difficult to obtain single crystals of sufficient quality and dimension. This is especially true for synthetic zeolites which are usually obtained as fine powders: In some cases they may consist of intergrowths of closely similar structural types. Different approaches adopted to tackle this problem, mainly with faujasitic zeolites, have included: (i) X-ray powder diffractometry involving careful measurement of lattice parameters as a function of aluminum content[23]; measurement (from X-ray single-crystal data) of bond lengths and bond angles[20, 24] and the determination of cation positions which are necessarily correlated with the location of anionic Al centers in the framework[25]; (ii) theoretical studies involving electrostatic and statistical calculations[26-28]; (iii) measurements of the change of zeolitic acidity on successive extraction of aluminum from the framework[29]; (iv) examination of the kinetics of crystallization[30]; (v) a combined diffraction-*cum*-adsorption approach used particularly effectively by *Kokotailo et al.*[21b] for the study of porotectosilicates; and (vi) use of refined infrared absorption measurements, which are often revealing in identifying the location of the loosely bound protons (*i.e.*, the "active sites") in zeolitic catalysts[31, 32].

Apart from the last-named, and the single crystal X-ray procedure, all these methods are indirect and most are of

limited applicability. Significant progress has, however, recently been made in the structural elucidation of zeolites because *three* powerful new techniques have been introduced to supplement the rather incomplete information provided by X-ray diffraction and other methods:

*High-resolution electron microscopy* (HREM), which, in favorable circumstances, is capable of determining the structural characteristics of solids in real space[33-38], has brought to light a hitherto unknown tunnel structure. It has also characterized several quasi-crystalline zeolites[34-41] and, in conjunction with optical diffractometry, has elucidated[42] the nature of the intergrowths that may form between ZSM-5 and its closely related analogue, ZSM-11.

*Rietveld neutron diffraction (powder) profile analysis* has achieved a degree of structural refinement for zeolite Linde A which rivals that obtained by X-ray single-crystal methods[43,44] so far as Al, Si ordering and cation position are concerned. The Rietveld neutron diffraction approach to crystal structure determination is a promising and effective new technique, the great merit of which is that it is applicable to polycrystalline materials in general. Provided long-range order may be assumed and some preliminary model structure is known in broad outline, refinement of the observed and calculated line-profiles (intensity of scattering *versus* $2\theta$) permits the structure to be fully determined. In the case of zeolites, dehydrated samples have to be used because of the strong scattering of neutrons by water. Rietveld X-ray powder profile analyses are now quite widely developed[44b] for the structural determination of (ordered) powdered materials in general, and are already in use for the characterization of hydrated zeolites.

*High-resolution solid-state NMR with magic-angle spinning (MAS-NMR),* which is the sole technique upon which we shall concentrate in this account, since it has, to date, had the greatest single impact in the structural elucidation of zeolites in terms of the Si/Al distribution. When, as is described below, the zeolitic samples are spun rapidly at the magic angle of 54°44′ to the magnetic field (magic-angle spinning = MAS), the NMR spectra comparable to those displayed by species in solution are obtained. The spectra, in turn, enable us to establish the immediate chemical environment of the tetrahedrally coordinated Si "centers" and readily to distinguish tetrahedral from octahedral Al, the latter being often produced when zeolitic catalysts are subjected to various chemical treatments. Many other important structural issues have now been resolved by $^{29}$Si- and $^{27}$Al-MAS-NMR and some hitherto unanswerable questions have been greatly clarified (see Table 1).

Table 1. A summary of the information obtainable from the application of $^{29}$Si- and $^{27}$Al-MAS-NMR to the study of zeolites.

1. Identifies five distinct structural groups $Si(OAl)_n(OSi)_{4-n}$ ($n = 0, 1, \ldots 4$).
2. Confirms exact alternation of Al and Si among tetrahedral sites in zeolite A and zeolite X, when Si/Al = 1.00.
3. Monitors the course of solid-state (or gas-solid) reactions.
4. Quantitatively determines framework Si/Al ratios (for Si/Al ≈ 1.0 to > 1000).
5. Resolves numerous crystallographically distinct $Si(OSi)_4$ sites in silicalite (ZSM-5).
6. Readily distinguishes tetrahedral from octahedral Al.
7. Proves that Al in silicalite is tetrahedrally substituted within framework.
8. Elucidates nature of short-range Si, Al order.

## 4. High-Resolution Solid-State MAS-NMR Spectroscopy as Applied to Zeolites

### 4.1. Principles

In the last decade, techniques and equipment have been developed which yield NMR spectra of moderate resolution from solid samples. These have been described in detail elsewhere[45] and are only briefly reviewed here with especial emphasis on the aspects relevant to the study of zeolites.

The NMR spectra of abundant nuclei such as $^1$H in the solid state are dominated by the direct dipole-dipole interactions between the nuclei resulting in characteristic, broad, featureless absorptions ("wide-line" NMR). These interactions are orders of magnitude larger than the chemical shift and spin-spin couplings, the observation of which in solution, where the dipolar interactions average to zero, has made high-resolution NMR the most widely used technique for the structural elucidation of soluble chemical species. Although, in principle, it is possible to remove the dipolar interactions in the case of abundant nuclei, the finite efficiency of the experiment coupled with the small range of proton chemical shifts greatly limit the use of solid-state NMR of abundant nuclei.

However, in the case of "dilute" nuclei, where there is a low concentration of magnetically-active spins of the nucleus of interest in the sample, it has been demonstrated[46-48] that it is possible to obtain spectra of moderate resolution for a whole range of nuclei in the solid state. The total magnetic interaction, $H_{tot}$, appropriate for a dilute "spin 1/2" nucleus such as $^{13}$C in the presence of an abundant one such as $^1$H is given by:

$$H_{tot} = H_{ZEEMAN} + H_{^1H\text{-}^{13}C(DIPOLAR)} + H_{^{13}C\text{-}^{13}C(DIPOLAR)} + H_{^{13}C(CSA)} \quad (1)$$

The $^1$H-$^{13}$C dipolar interactions (the second term on the RHS of equation (1)) involve different nuclear species and can be removed by a powerful dipolar decoupling field applied at the proton resonance frequency. The $^{13}$C-$^{13}$C dipolar term involves interactions between nuclei of the same spin; but because of the dilution of $^{13}$C in the sample caused by the low (1.1%) natural abundance of $^{13}$C, this term is negligible. The only remaining line broadening contribution is the chemical shift anisotropy, $H_{^{13}C(CSA)}$, which results from the different chemical shieldings of nuclei caused by their different orientations to the magnetic field. In solution, the random motion of the molecules produces an average (isotropic) value of this shielding; but in the solid a broad envelope characteristic of the chemical environment of the nucleus results. This remaining interaction may be averaged to the isotropic chemical shift value, producing a "high-resolution" spectrum, by mechanical spinning of the sample about an axis inclined at the so-called "magic angle" of 54°44′ to the magnetic field vector, as first described by *Andrew et al.*[49] and *Lowe*[50]. Spinning frequency must be comparable to the frequency spread of the signal.

We see how this "magic angle" arises by examining the equation for the Hamiltonian describing the chemical shift anisotropy as modified by sample spinning.

$$H_{CSA} = (3\cos^2\theta - 1)(\text{other terms}) + (3/2\sin^2\theta)\sigma_i I_z B_0 \qquad (2)$$

where $\theta$ is the angle subtended by the axis of spinning with respect to the direction of the magnetic field, $B_0$, and $\sigma_i$ and $I_z$ are respectively, the isotropic chemical shielding and the spin angular momentum. When $\theta = 54°44'$, the prefactor to the first term becomes zero, leaving only the second term, the value of which is now $\sigma_i I_z B_0$, which, in turn, yields the isotropic chemical shift. Spinning at frequencies less than the frequency spread of the shift anisotropy pattern yields a spectrum consisting of a central peak at the isotropic chemical shift value of the same line width as before but flanked by a series of "spinning sidebands" separated by the spinning frequency and with intensities that approximate the profile of the shift anisotropy pattern.

A combination of high-power decoupling and magic-angle spinning (MAS) produces a spectrum of moderate resolution, the signals of which occur at the isotropic (average) shift values similar to those in solution. In addition, the intensity of the signals arising from the dilute nuclei in the system may be substantially enhanced from the magnetization of the abundant nuclei (usually protons) in the sample by use of the "cross-polarization" (CP) pulse sequence introduced by *Pines, Gibby,* and *Waugh*[51]. It should, however, be noted that this technique does not affect the widths of the signals and therefore the *resolution* of the experiment and that the resulting enhancements may be quite different for chemically different nuclei producing spectra which may not normally be quantitatively reliable. The first combined CP/MAS experiment was reported by *Schaefer* and *Stejskal*[52], and in recent years there have been numerous applications of these techniques to a variety of chemical systems in the solid state[45-48].

So far as zeolites are concerned two important points may be made:

1. Although the above discussion has been presented in terms of $^{13}C$, the experiment is equally applicable to a whole range of nuclei, *e.g.*, $^{29}Si$, $^{57}Fe$, $^{113}Cd$, $^{119}Sn$, $^{207}Pb$. Further, it is not necessary that the "dilution" criterion be satisfied by way of low isotopic abundance of the magnetically active nucleus; spectra may be obtained from 100% abundant nuclei such as $^{31}P$ or $^{27}Al$ as long as the term corresponding to the third one in equation (1) is small. This may be attained by physical dilution, which is relatively easy for almost all nuclei except $^{1}H$ which, in addition to being of common occurrence, has the highest magnetic moment and largest dipolar intensities of all nuclei. Thus MAS-NMR spectra may, for example, be obtained for every nucleus in a typical zeolitic system ($^{23}Na$, $^{29}Si$, $^{27}Al$, $^{17}O$, *etc.*).
2. Usually there are no $^{1}H$ nuclei covalently bonded to the framework of zeolites (this applies to many other inor-

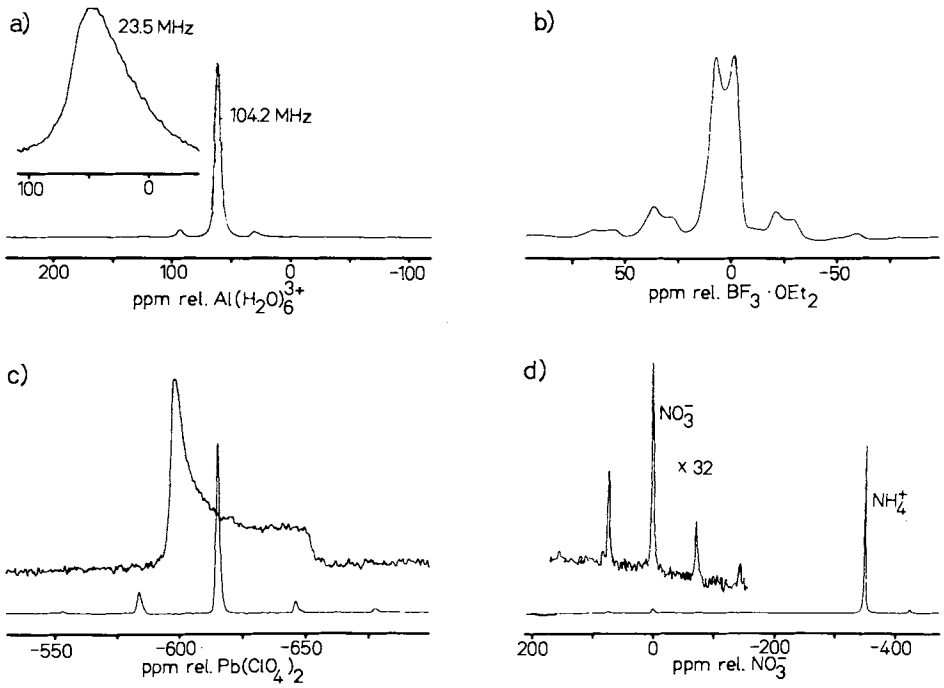

Fig. 3. Solid-state magic-angle-spinning NMR spectra: a) $^{27}Al$ spectra of zeolite Y at 23.5 MHz (7771 scans, 25 Hz line broadening, 0.1 s relaxation delay) and at 104.2 MHz (2656 scans, no line broadening, 0.1 s relaxation delay). Note the spectral improvement at higher field.—b) $^{11}B$ spectrum of Corning 7070 glass at 128.4 MHz (13775 scans, 25 Hz line broadening, no relaxation delay). Note the characteristic pattern of the residual quadrupolar interaction.—c) $^{207}Pb$ spectra of $Pb(NO_3)_2$ at 83.4 MHz. The powder pattern (420 scans, 20 Hz line broadening, 2 s relaxation delay) is shown above the spinning spectrum (230 scans, 20 Hz line broadening, 2 s relaxation delay).—d) $^{15}N$ spectrum of $^{15}NH_4{}^{15}NO_3$ at 40.5 MHz (2978 scans, 40 Hz line broadening, 1 s relaxation delay). The $NO_3^-$ portion of the spectrum, magnified 32 times, is also shown. The small absorptions in the spectra are due to spinning sidebands (see text).

ganic solids). This means that the term corresponding to the second one in equation (1) vanishes. High-power decoupling is rendered unnecessary and cross-polarization not possible, thus reducing the experiment to one of simple MAS of the sample, which can easily be carried out using a conventional high-resolution NMR spectrometer available to most chemists, as indicated in Figure 3 for a variety of systems. Further, there are advantages in performing the experiment at as high a magnetic field strength as possible. For nuclei with spin half ($I=1/2$) such as $^{29}Si$, there is a very substantial gain in resolution due, at least in part, to the superior field homogeneity and stability of superconducting solenoid magnets. With quadrupolar nuclei of non-integral spins (of which $^{27}Al$ with $I=5/2$ is particularly important in the present context), the $(m=1/2)\leftrightarrow(m=-1/2)$ transition which is observed is independent of the quadrupolar interaction to first order as illustrated in Figure 4; but it is affected by second order quadrupolar effects. These vary inversely with the magnetic field and the best spectra will, therefore, be obtained at the highest available field strength (Figure 3a). In our own work we have used[53] a high-resolution Bruker WH-400 narrow-bore spectrometer with a home-built MAS broad-banded probe fitted with a standard Andrew-Beams[54] spinning assembly capable of observing $^{29}Si$ (80 MHz), $^{27}Al$ (104 MHz) and $^{11}B$ (128 MHz) directly, and additional nuclei with modification. The spectra shown in the present account are thus easily obtainable using simple techniques and widely available equipment.

The first application of these techniques to the investigation of zeolites was made by *Lippmaa* and *Engelhardt*[55], who, in a pioneering paper[56], showed clearly that up to five peaks could be observed for $^{29}Si$-spectra of various zeolites (cf. Fig. 5), corresponding to the five possible Si environments: $Si(OAl)_4$; $Si(OAl)_3(OSi)$; $Si(OAl)_2(OSi)_2$; $Si(OAl)(OSi)_3$ and $Si(OSi)_4$. Further, and most importantly, they showed that characteristic ranges of these isotropic shifts could be assigned as shown in Figure 6 and used for further investigations of zeolite structures in terms of the microenvironments of the nuclei. Further investigations[57-75] have expanded the range of nuclei studied and the techniques used (cf. Sections 4.2-8); it is to be noted that the

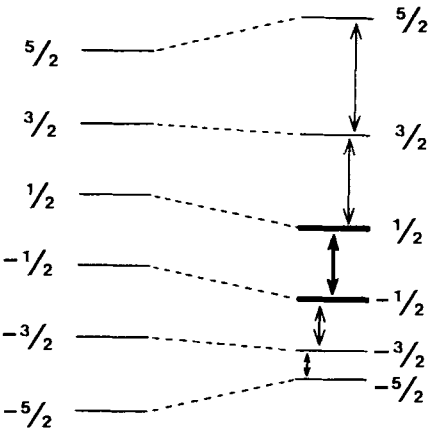

Fig. 4. Energy level diagram for a spin 5/2 nucleus showing the effect of the first-order quadrupolar interaction on the Zeeman energy levels. The $(m=1/2)\leftrightarrow(m=-1/2)$ transition (shown in bold lines) is independent of the quadrupolar interaction to first order but is subject to second-order quadrupolar effects (see text).

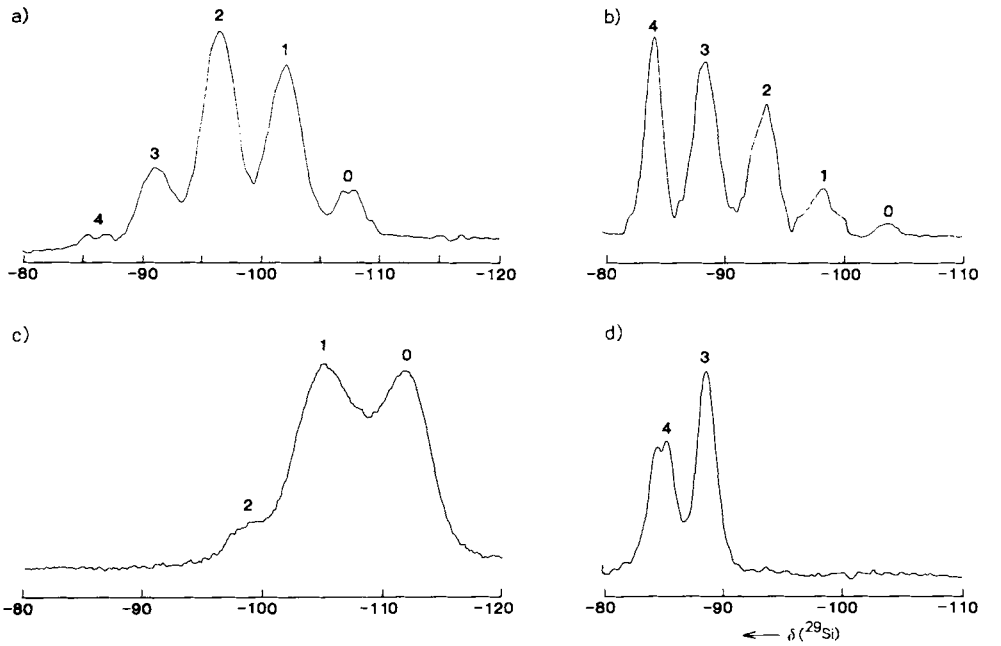

Fig. 5. $^{29}Si$-MAS-NMR spectra at 79.80 MHz of four zeolites. Numbers above peaks are the n in Si(n Al), the five possible environments of an Si atom (cf. Fig. 6): a) gmelinite; b) analcite; c) mordenite; d) zeolite Z.

assignment of the $^{29}$Si-coordination remains, as before, central to the application of the technique.

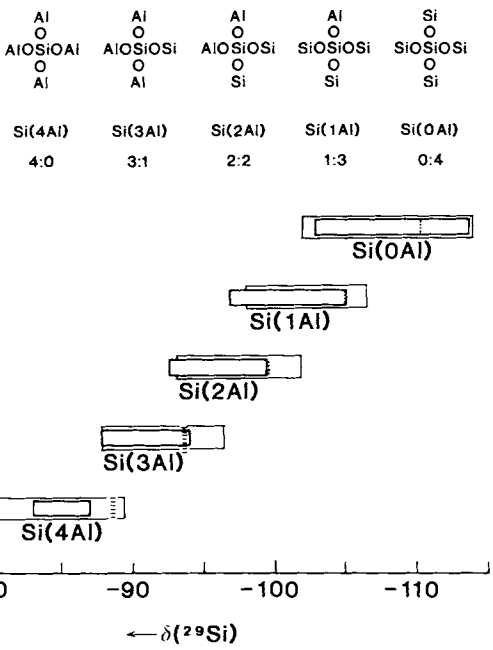

Fig. 6. The five possible local environments of a silicon atom together with their characteristic chemical shift ranges. The chemical shifts of the five resonances of zeolite ZK-4 are shown in broken vertical lines. The inner boxes represent the $^{29}$Si shift ranges suggested in the earlier literature (refs. [56a] and [59]). The outer boxes represent the recently extended $^{29}$Si shift ranges (taken from refs. [56b] and [74b]).

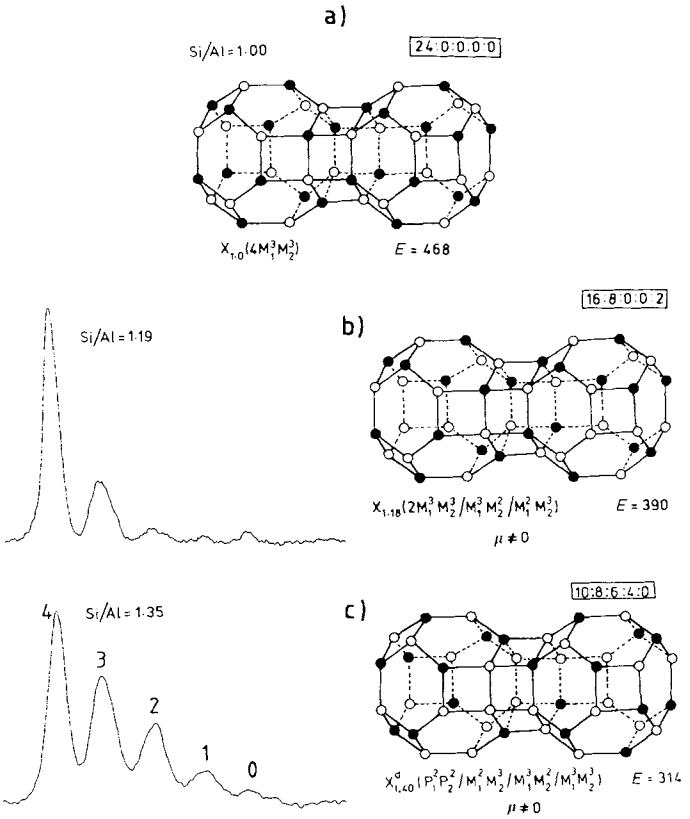

Fig. 7. a) The Si,Al ordering scheme in a hypothetical zeolite X (synthetic faujasite) with Si/Al = 1.00. Tetrahedrally-bound Si and Al atoms are denoted by ○ and ●, respectively. The ratio of the populations of the basic Si(nAl) building units, Si(4Al):Si(3Al):Si(2Al):Si(1Al):Si(0Al) corresponding to the scheme is given in the upper right-hand corner. The type of linking of the sodalite cages, using notation developed in [74a] is given below the structure. $E$ is the calculated electrostatic energy for the double cage in units of $(qe)^2/a$.—b) and c) In the left-hand column are given high-resolution $^{29}$Si-MAS-NMR spectra of two zeolites NaX of the compositions indicated (determined from the spectra using eq. (3)). Numbers above NMR peaks refer to the n in Si(nAl). In the right-hand column are the corresponding most probable structures based on electrostatic and other considerations (see text) for the nearest "ideal" Si/Al ratio. $\mu \neq 0$ denotes net dipole moment in double sodalite cage; the meaning of other symbols as in (a).

## 4.2. Determination of Zeolite Composition by $^{29}$Si-MAS-NMR Spectroscopy — Si,Al Ordering in Zeolites X and Y

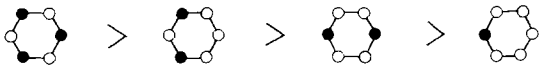
The $^{29}$Si-MAS-NMR spectrum of zeolite X when Si/Al = 1.0 consists of one peak corresponding to $Si(OAl)_4$ (also written for simplicity Si(4Al)). *It therefore follows that there is strict ordering* within the aluminosilicate framework, the Al and Si alternating as tenants of the tetrahedral sites. In other words, Loewenstein's rule[76], which states that two Al atoms cannot be adjacent on tetrahedral sites, is obeyed. As the Si/Al ratio progressively increases, all five peaks, corresponding to $Si(OSi)_{4-n}(OAl)_n$ with n equal to 0, 1, ... 4, appear until, at the higher values of the ratio, typically Si/Al > 2.0, the Si(4Al) peak disappears and the Si(nAl) peaks, with n small, grow in relative intensity as expected from the gradual build-up of the more siliceous faujasite (Fig. 7). By convention Si/Al ratios between 1.0 and 1.5 are designated zeolite X; beyond that ratio faujasitic zeolites are designated zeolite Y.

The fact that there is strict alternation of Al and Si amongst the tetrahedral sites when Si/Al = 1.0, prompts us to enquire whether, as the Si/Al ratio increases, the charge-deficient ions ($Al^{3+}$) adopt ordering schemes according to some readily comprehensible principles. For example, Loewenstein's rule may still be obeyed. $^{29}$Si-MAS-NMR permits us to demonstrate that this is indeed the case in zeolites X and Y. If the immediate neighborhood of every Al tetrahedral site is $Al(OSi)_4$ (*i.e.*, Al(4Si)) then each Si–O–Al– linkage in a Si(nAl) structural unit incorporates 1/4Al atom. It follows[60, 71, 74], therefore, that the Si/Al ratio in the tetrahedral aluminosilicate framework is given by

$$(Si/Al)_{NMR} = \sum_{n=0}^{4} I_{Si(nAl)} \; / \; \sum_{n=0}^{4} 0.25\, n\, I_{Si(nAl)} \qquad (3)$$

We note, in passing, that this equation is valid for all zeolites irrespective of structural type, and represents a powerful new quantitative method of determining *framework* Si/Al ratios, provided no Al–O–Al linkages are present.

In a series of ten zeolites X and Y of different composition, synthesized under conditions that excluded coprecipitation of extra-framework aluminosilicate, it has been found[74] that the Si/Al ratios determined by X-ray fluorescence and by MAS-NMR (see Table 2) are in very good agreement. Loewenstein's rule clearly holds, at least on the spatially-averaged basis—it is not inconceivable that there may be a few local infractions where Al–O–Al linkages are formed as kinetically stabilized structural defects. *Mel-*



*chior et al.*[65] reached the same conclusion when they demonstrated that, for a series of faujasitic zeolites, the observed intensities of Si(nAl) signals conformed to a 1/R (where R = Si/Al) dependence rather than to a 1/(R+1) dependence, which would imply a truly random (non-Loewensteinian) distribution of aluminum atoms in the tetrahedral sub-lattice.

Table 2. Comparison between $^{29}$Si-MAS-NMR and X-ray fluorescence (XRF) as methods of determining Si/Al ratios of zeolites X and Y (see text and eq. (3)).

| Sample No. | Si/Al Ratio by XRF [a] | | Si/Al Ratio by $^{29}$Si-MAS-NMR [b] |
|---|---|---|---|
| 1 | 1.19 | Zeolites X | 1.14 |
| 2 | 1.35 | | 1.39 |
| 3 | 1.59 | Zeolites Y | 1.57 |
| 4 | 1.67 | | 1.71 |
| 5 | 1.87 | | 1.85 |
| 6 | 2.00 | | 1.98 |
| 7 | 2.35 | | 2.46 |
| 8 | 2.56 | | 2.69 |
| 9 | 2.61 [c] | | 2.56 |
| 10 | 2.75 | | 2.69 |

[a] The fluorescence measurements were kindly carried out by Dr. *A. E. Comyns* and his colleagues (Laporte Industries), who also supplied us with the samples. [b] The normalized intensities of individual $^{29}$Si-peaks are given in the original paper [74]. Sample 1, for example, had the following peak intensities: Si(4Al), 64.0; Si(3Al), 26.5; Si(2Al), 6.2; Si(1Al), 1.4; and Si(0Al), 1.9 with $\Sigma I_{Si(nAl)} = 100$. Using equation (3), the framework Si/Al ratio is computed to be 1.14. [c] Composition of this sample determined by energy-dispersive X-ray analysis using analytical electron microscopy.

We may proceed to calculate average populations of the five configurations Si(nAl) (n = 0, 1, ... 4), which is tantamount to computing the relative intensities of the $^{29}$Si-MAS-NMR signals, $I_{Si(nAl)}$, in all zeolite structures that comply with Loewenstein's rule, but in which the Si,Al ordering is otherwise random. Since each Al in the framework must be surrounded by four Si atoms, the probability of the occurrence of an Si–O–Al linkage is p (= 1/R). The probability of occurrence of Si–O–Si, the only other type of permitted linkage, is (1 – p). The probabilities of the five possible configurations are thus given by the binomial formula as: $p^4$ for Si(4Al), $4(1-p)p^3$ for Si(3Al), $6(1-p)^2p^2$ for Si(2Al), $4(1-p)^3p$ for Si(1Al), and $(1-p)^4$ for Si(0Al). A comparison of the observed $I_{Si(nAl)}$ intensities with those computed on the basis of the constrained (by Loewenstein's rule) random model reveals rather poor agreement at low values of the Si/Al ratio, but somewhat better agreement as the ratio increases. There are clearly some other factors, besides those of avoidance of Al on adjacent tetrahedral sites, governing the distribution of the aluminum atoms in the framework. We have analyzed[74a] these additional factors elsewhere, and taken into account the fact that there are other independent items of information which suggest that there is some tendency for Si,Al ordering, beyond that associated with Loewensteinian behavior. The first item is the report that there are discontinuities[23,77a] in the plot of the (cubic) unit cell dimension versus Si/Al ratio. The second is that there are different electrostatic repulsion energies for various occupancies of individual six-membered rings in the faujasite structure:

Sequences of decreasing electrostatic repulsion energy for complete sodalite cages, as well as for preferred occupancies of "double-six" prisms may also be constructed.

A viable method of determining possible preferred Si,Al ordering schemes by means of $^{29}$Si-MAS-NMR spectroscopy can now be described. From the experimentally (NMR) determined ratio of the populations of Si(nAl) units for each specific (Si/Al) ratio in the zeolite X and Y family, bearing in mind the above-mentioned restrictions and the need to comply with cubic crystal symmetry ($a_0 = 24.7$ Å), a series of likely ordering schemes is constructed. Approximate estimates of energies of electrostatic interactions ($Al^{3+} \cdots Al^{3+}$ repulsions) are expressed in units of $(qe)^2/a$, where $qe$ is the effective charge placed on an Al site and $a$ is the T–O–T distance. For most Si/Al ratios more than one ordering scheme is compatible with the Si(nAl) intensities determined by $^{29}$Si-MAS-NMR. The choice between the competing ordering schemes is finally made on the basis of three criteria:

1. goodness of fit of experimental and model-generated Si(nAl) intensities;
2. compliance with cubic symmetry and unit cell repeat;
3. minimal electrostatic repulsion within the aluminosilicate framework.

It is worth emphasizing that MAS-NMR yields spatially and temporally averaged information, that the sharpness of the spectral peaks reflects the degree of crystallinity but does not connote long range order, that the total peak intensities may enable the space-group to be ascertained (cf. Section 6), that, apart from zeolites yielding single-peak $^{29}$Si-spectra, MAS-NMR cannot *directly* determine structure (and, therefore, the Si, Al ordering schemes).

The most likely ordering for the compositions corresponding to the spectra on the left-hand side of Figure 7 are given on the right of that figure. Attempts have been made to interpret observed $^{29}$Si-MAS-NMR intensities for a family of faujasites in terms of what may be designated a "constrained random" basis for Si, Al ordering, the constraint being obedience to Loewenstein's rule. While our earlier data, obtained at lower field[58], lent some credence to this view, our data at higher field[74a] do not support it. It has to be admitted, however, that, as the Si/Al ratio increases beyond 2.4 the constrained random model is not altogether unrealistic.

It may legitimately be argued that the procedures for estimating electrostatic energy are oversimplified; and that the zeolite structures and thus Al,Si ordering adopted within them are not at thermodynamic equilibrium. Taken all in all, however, we believe that the present approach offers considerable insight, not otherwise attainable, into the precise population of, and distribution within, the aluminosilicate framework of zeolites. A similar approach could, with profit, be applied to many other recalcitrant structural problems involving inorganic solids, both crystalline and amorphous. As discussed elsewhere, this approach does

offer support for the view that a discontinuity in the unit-cell parameter should occur at a well-defined Si/Al ratio. It transpires that the repulsion energy per number of Al ions in the unit cell changes abruptly at a Si/Al ratio of close to 2.0. The approach also throws some light on the effect of second-nearest (tetrahedral) neighbors on chemical shifts.

### 4.3. Determination of Zeolitic Composition by $^{27}$Al-MAS-NMR Spectroscopy

As discussed in the previous section, the Si/Al ratio of any zeolite can be derived from $^{29}$Si-MAS-NMR spectra provided that Loewenstein's rule is obeyed. However, as the silicon content of the material increases, the determination of composition by this method becomes progressively less reliable and fails for the porotectosilicates encompassing silicalite and ZSM-5 where the intensity of Si(n Al) signals cannot be reliably measured (not even when n = 1). In these circumstances $^{27}$Al-MAS-NMR can be used to estimate the composition. First, it is to be noted that the technique can readily and quantitatively distinguish between tetrahedrally and octahedrally coordinated aluminum (cf. Fig. 8). Again, the areas of the two peaks are directly proportional to the amounts of aluminum in each coordination. Furthermore, the 100 per cent isotopic abundance of $^{27}$Al and its relatively short spin-lattice relaxation times (the nucleus is quadrupolar) makes $^{27}$Al-MAS-NMR especially sensitive. By adding to the sample increments of materials containing known amounts of octahedrally or tetrahedrally coordinated Al and repeating the $^{27}$Al-MAS-NMR experiment, one may[69] measure accurately the Si/Al ratio even in very siliceous materials, such as silicalite, where this ratio can exceed 1000 (cf. Section 6). Si/Al ratios in excess of 10000 may be estimated in this way.

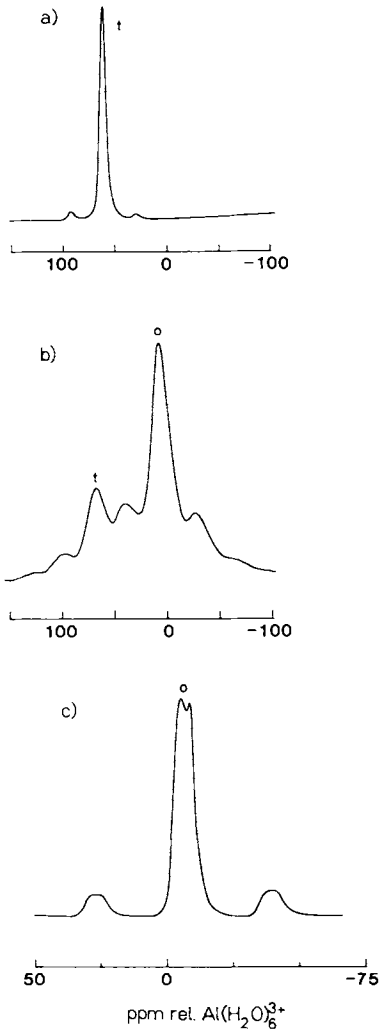


Fig. 8. $^{27}$Al-MAS-NMR spectra at 104.22 MHz: a) The spectrum of zeolite NaY showing a single resonance due to tetrahedral coordination of framework aluminum. — b) Alumina, $\gamma$-$Al_2O_3$, showing both tetrahedral (t) and octahedral (o) coordination of Al. — c) The mineral beryl showing only octahedral coordination of Al.

Extensive measurements of $^{29}$Si spectra of aluminosilicates indicate that tetrahedral aluminum tends to favor situations where a central aluminum is surrounded, *via* oxygen bridges, by four silicons, *i.e.* Al(4Si). Crystallographically non-equivalent tetrahedral Al atoms have, however, been resolved in silicalite[69], and in zeolite omega[73c]. $^{27}$Al-MAS-NMR is not, in general, as powerful as $^{29}$Si-MAS-NMR in determining the ordering within the zeolitic aluminosilicate framework. Because of the relative insensitivity of the $^{27}$Al-MAS-NMR chemical shift to the occupants of the second and further coordination shells, a rather broad $^{27}$Al single peak is usually observed. On the basis of our recent measurements[74b] on gallosilicate zeolites the same appears to be true of $^{71}$Ga-MAS-NMR.

## 5. Modifying the Zeolitic Framework by Chemical Means

Faujasitic solids have been the subject of numerous studies, the objective of which was to remove the Al from, or to modify its distribution within, the tetrahedral sub-lattice while at the same time retaining the original topology and crystallinity of the parent open structure[78]. Acid-leaching and use of reagents such as EDTA, gaseous $Cl_2$, or acetyl acetone have been used for this purpose, but none of these reagents is as effective as two others which we shall describe in this section. One of these involves[64,79,80] dealumination using $SiCl_4$; the other entails heat treatment of the ammonium-exchanged zeolite where ammonium ions have replaced the sodium ions originally present. This latter process is currently preferred, commercially, for effecting "ultrastabilization", a term used to describe the production of extremely effective cracking and hydrocracking zeolitic catalysts that possess high thermal stability. $^{29}$Si- and $^{27}$Al-MAS-NMR can be used to monitor, for the first time, the subtle changes that accompany these processes[66,67,70,72].

### 5.1. Dealumination of Faujasitic Zeolites by $SiCl_4$

After recognizing the success with which the aluminum may be removed, as volatile $AlCl_3$, from alumina when reacted at red heat with $SiCl_4$—a reaction described well over a hundred years ago[79c,d]—*Beyer* and *Belenykaja*[79a] recently demonstrated that zeolite Y can be dealuminated in like fashion *without collapse of the crystal structure.* We have ourselves confirmed that this is an effective means of

converting zeolite Y to faujasitic silica, since the final Si/Al ratio may be *ca.* 100. X-ray powder diffraction, infrared spectroscopy[79b] and high-resolution electron microscopy[64,80], all show that there is no significant difference in the pore system following extensive dealumination by $SiCl_4$. The overall reaction may be written:

$$Na_x[(AlO_2)_x(SiO_2)_y] + SiCl_4 \longrightarrow Na_{x-1}[(AlO_2)_{x-1}(SiO_2)_{y+1}] + AlCl_3 + NaCl$$

However, it can be seen from the $^{27}$Al-MAS-NMR spectrum (Fig. 9a–c) that, as well as the diminished peak corresponding to residual tetrahedral Al (*i.e.*, $Al(OSi)_4$ groups) and the emergent octahedral Al, which is occluded by the framework, there is an additional peak indicative of tetrahedral Al arising from $Na^+(AlCl_4)^-$ ion pairs also occluded in the zeolite. Upon washing this dealuminated zeolite with water, the $Na^+(AlCl_4)^-$ is largely removed or converted to the hydrated ion $[Al(H_2O)_6]^{3+}$ which may then function, in place of the original $[Na(H_2O)_n]^+$, as the neutralizing "exchangeable" cation. (It is significant that from Figure 9c we can deduce that the amount of octahedral $[Al(H_2O)_6]^{3+}$ is *ca.* a third of the residual tetrahedral aluminum as required for charge balance.)

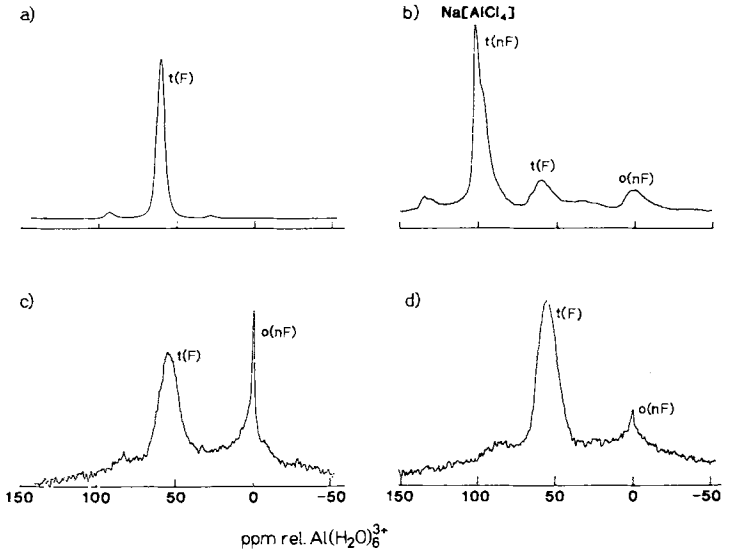

Fig. 9. Dealumination of zeolite NaY using $SiCl_4$ vapor studied by $^{27}$Al-MAS-NMR spectroscopy at 104.22 MHz: a) Parent NaY zeolite; b) dealuminated material before washing; c) after washing with dilute acid; d) after repeated washing. Note that the aluminum jettisoned from the zeolitic framework is first of all bound tetrahedrally (as $Na^+AlCl_4^-$, see text), but after washing adopts octahedral coordination. t(F) = tetrahedral (framework), t(nF) = tetrahedral (non-framework), o(nF) = octahedral (non-framework).

The $^{29}$Si-MAS-NMR spectrum shown in Figure 10b also refers to a Na–Y sample dealuminated by $SiCl_4$. The single peak in this spectrum arises from Si(0Al), *i.e.* from Si(4Si) groupings: essentially all other groupings have been eliminated in the course of dealumination. The chemical shift of this peak ($\delta = -107.0$) is very close to that found in quartz[56]. The sharpness of the peak further signifies the high degree of homogeneity and crystallinity of the faujasitic silica produced by this process.

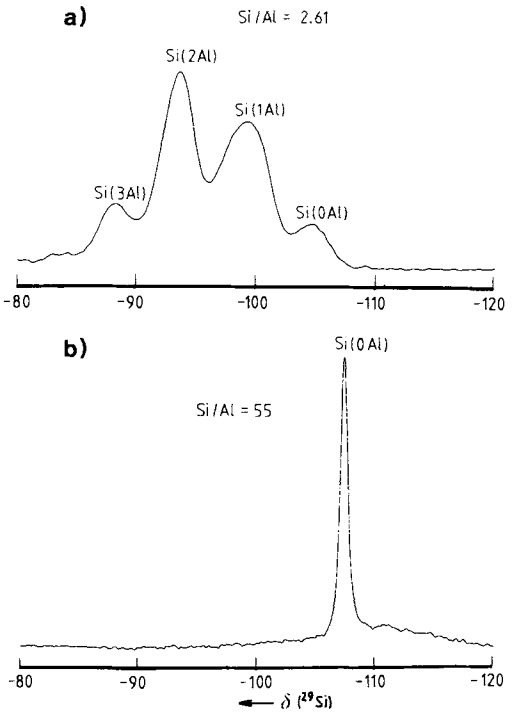

Fig. 10. Dealumination of zeolite NaY using $SiCl_4$ vapor studied by $^{29}$Si-MAS-NMR spectroscopy at 79.80 MHz: a) Parent material; b) after "complete" dealumination (corresponding to the $^{27}$Al-MAS-NMR spectrum in Fig. 9d).

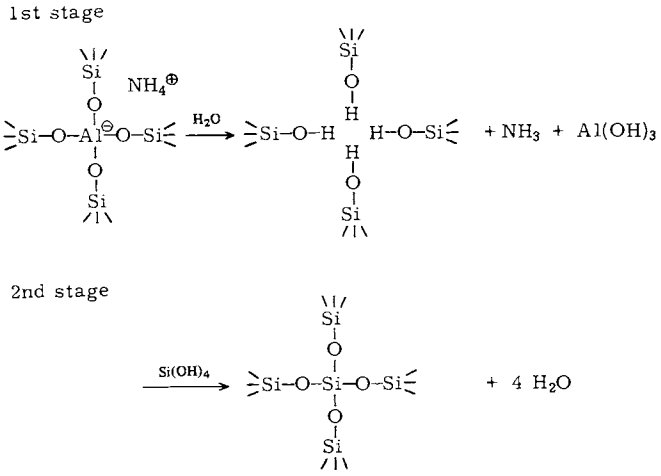
Wet chemical analysis of the global Si/Al ratio of this sample yielded a value of 55. But since Al has been removed from the tetrahedral sites and some of it retained, ultimately as neutralizing octahedrally coordinated $[Al(H_2O)_6]^{3+}$, the true framework Si/Al ratio is significantly greater than 55. It is possible to determine the amount of extra-framework Al directly from the absolute intensity of the $^{27}$Al spectrum as previously indicated, and the method constitutes one of the few reliable sensitive techniques for measuring the amount of Al *not* substitutionally incorporated into a zeolite framework.



MAS-NMR has recently enabled us to show[81] that mordenite, another industrially important zeolite, can also be dealuminated by $SiCl_4$, and so also may zeolite omega[73c]. It is clear that this method of dealumination is potentially widely applicable to other zeolites as well as to clays, gels, amorphous and crystalline silica-aluminas. It is of great commercial interest that the $^{29}$Si-MAS-NMR spectrum of dealuminated ZSM-5 approaches that of silicalite[81b,c]. It has been claimed[79b,82] that elimination of framework aluminum may be effected by other volatile reagents including $PCl_3$, $TiCl_4$ and $CrO_2Cl_2$.

### 5.2. Charting the Course of Ultrastabilization of Zeolites

Faujasitic zeolites are good cracking catalysts, but in their "as-prepared" condition they are too acidic and insufficiently thermally stable to be useful as hydrocracking catalysts[10]. However, the process of ultrastabilization[83,84], which entails hydrothermal treatment of the ammonium-exchanged form of synthetic faujasite, $NH_4^+$–Y,

under well-defined conditions, results in the production of a $H^+$–Y zeolite possessing desirable thermal stability and high internal surface area, which is admirably suited for hydrocracking reactions. Ever since ultrastabilization was first discovered, there has been much speculation[78b–d] as to what, precisely, was occurring at the atomic scale inside the zeolite. That aluminum was being removed from the framework and ammonia eliminated from the $NH_4^+$ ions was obvious, but what reorganization occurred within the framework? (cf. Scheme 2). Thanks to MAS-NMR this question can now be partly answered.

In a series of four samples subjected[67] to different types of hydrothermal treatment $^{29}$Si-MAS-NMR clearly shows how Al is removed from the framework, and how the resulting vacancies in the framework are subsequently reoccupied (see Scheme 2) by silicons from other parts of the crystalline sample (Fig. 11). The $^{27}$Al-MAS-NMR spectra for the same four samples show[67] directly how the occluded octahedrally-bound Al builds up at the expense of the tetrahedrally-bound variety. Hydrothermal dealumination studies, using $^{29}$Si-MAS-NMR have also been carried out by *Engelhardt et al.*[60,70] and by *Maxwell et al.*[66]. The

Scheme 2.

use of cross-polarization MAS-NMR by the first-named group makes possible the detection of "surface" Si atoms to which are attached one or two hydroxyl groups, as the cross-polarization technique discriminates in favor of these

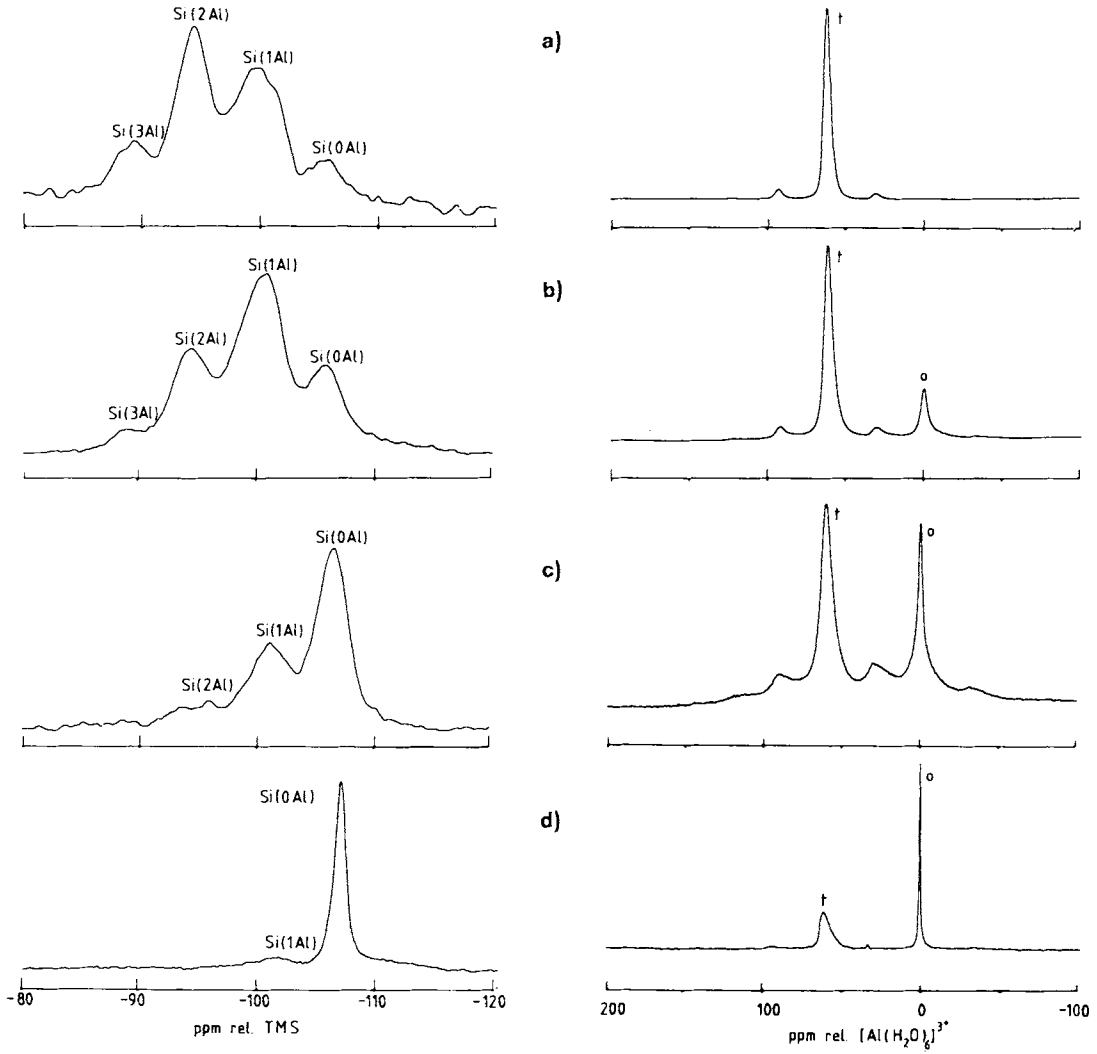


Fig. 11. High-resolution $^{29}$Si- (79.80 MHz) and $^{27}$Al-MAS-NMR studies (104.22 MHz) of the ultrastabilization of zeolite Y: a) Parent $NH_4$-Na-Y zeolite; b) after calcining in air for 1 h at 400 °C; c) after heating to 700 °C for 1 h in the presence of steam; d) after repeated ion exchange, heating and prolonged leaching with nitric acid. t = tetrahedral, o = octahedral.

atoms due to their proximity to the "abundant" $^1H$ spins in the system. These resonances may then be identified in the "normal" spectrum and an estimate made of their concentration (the CP spectra are not quantitatively reliable for this purpose). It would appear that, apart from situations where the Si/Al ratio is large, the concentration of such groups is relatively small, given the number of Al atoms removed. This, in turn, suggests that a process of "healing" takes place subsequent to dealumination (cf. second stage of Scheme 2).

## 6. Resolving Crystallographically Distinct Tetrahedral Sites in Silicalite and ZSM-5

The framework structure of the new, thermally stable, crystalline porous silica called silicalite is topologically closely similar if not identical to that of the shape-selective catalyst ZSM-5 (cf. Fig. 2). It has been claimed[17a,85] that silicalite has no aluminum in the framework and, hence, no exchangeable cations, and that such aluminum as may be adventitiously present in silicalite is in the form of $Al_2O_3$. It could therefore be argued that, strictly speaking, silicalite is not a zeolite. We have recently shown[69] by MAS-NMR that:

- the aluminum in silicalite is readily detectable by $^{27}Al$-MAS-NMR;
- all the aluminum is tetrahedrally coordinated to oxygen;
- there are at least two distinct types of tetrahedral framework sites occupied by the aluminum;
- the Si/Al ratio can be easily estimated;
- several crystallographically distinct sites for silicon in the lattice may be directly detected.

Figure 12a shows the $^{29}Si$-MAS-NMR spectrum of silicalite. The chemical shift range of all the peaks is characteristic of $Si(OSi)_4$ groupings in highly siliceous materials. The observed multiplicity arises from the crystallographically non-equivalent tetrahedral environments of the $Si(OSi)_4$ sites. The spectrum may be simulated by a minimum of nine Gaussian signals, the intensities (peak areas) of which are approximately in the ratio 1 : 3 : 2 : 3 : 10 : 1 : 1 : 2 : 1 (see Fig. 12b). Using the intensities of the well-resolved lowest- and highest-field signals as base units (generating functions) of one, the total intensity of the peaks in the Si(4Si) multiplet is found to be approximately 24. This result suggests that the space group of silicalite is one which contains 24 non-equivalent sites in the structural repeat unit. In particular, it signifies that $Pn2_1$ or $P2_1/n$ are more likely space groups for silicalite than Pnma, which has only 12 distinct sites. To date, the detailed structure and space group of ZSM-5 and silicalite do not seem to have been satisfactorily resolved by single-crystal X-ray methods, and the MAS-NMR results emphasize that view. These results further suggest that other space-groups, possibly $P2_12_12_1$, could be more appropriate than the currently favored (on X-ray grounds) Pnma.

The $^{27}Al$-MAS-NMR spectrum of silicalite (Fig. 13) shows an absorption centered at $\delta = 55.6$, clearly characteristic of tetrahedral coordination. The peak shows fine structure arising from at least two components, indicating

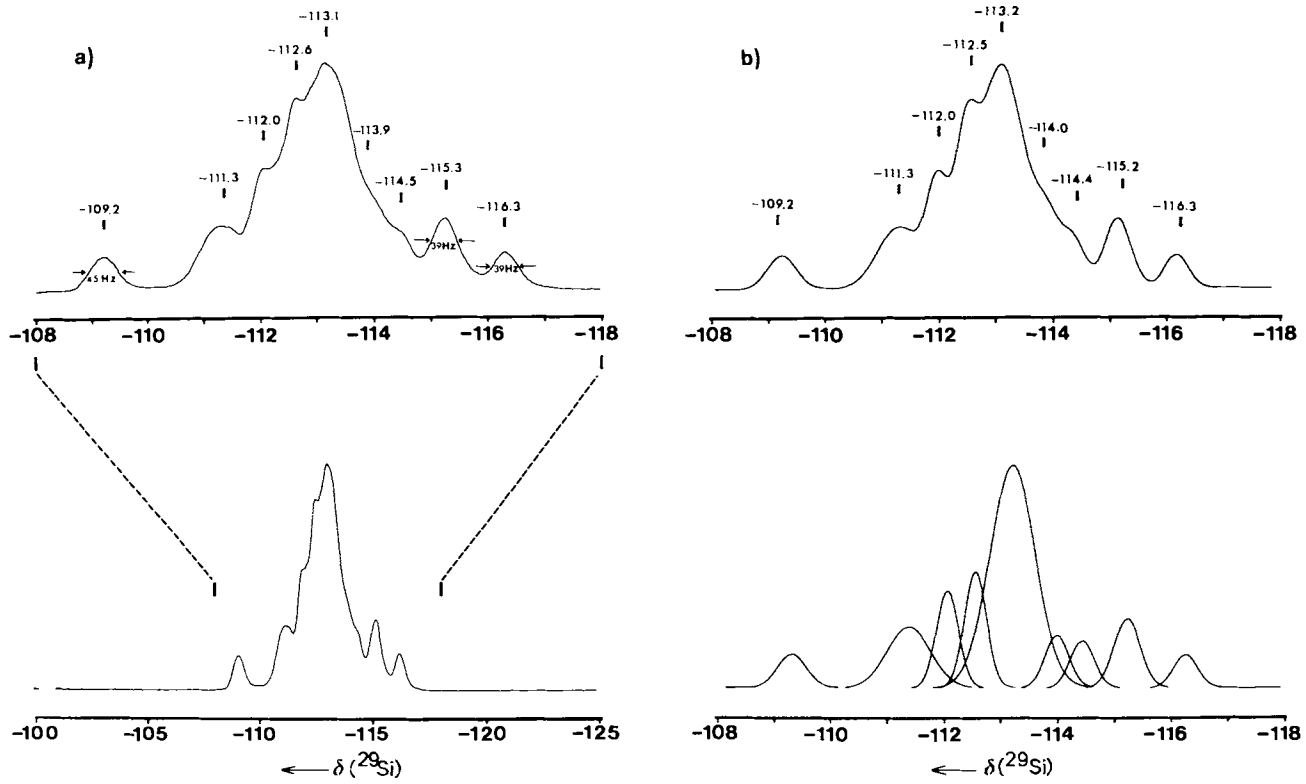

Fig. 12. a) High-resolution $^{29}Si$-MAS-NMR spectrum of silicalite at 79.80 MHz. 6550 free induction decays were accumulated; repetition time 5 s.—b) The spectrum given in (a) can be computer-simulated using the minimum number of nine Gaussian-shaped peaks, shown individually below the simulated spectrum. The areas of the peaks are from left to right, in the ratio 0.98 : 2.70 : 2.19 : 2.63 : 10.35 : 1.30 : 1.61 : 1.87 : 0.82 (see text).

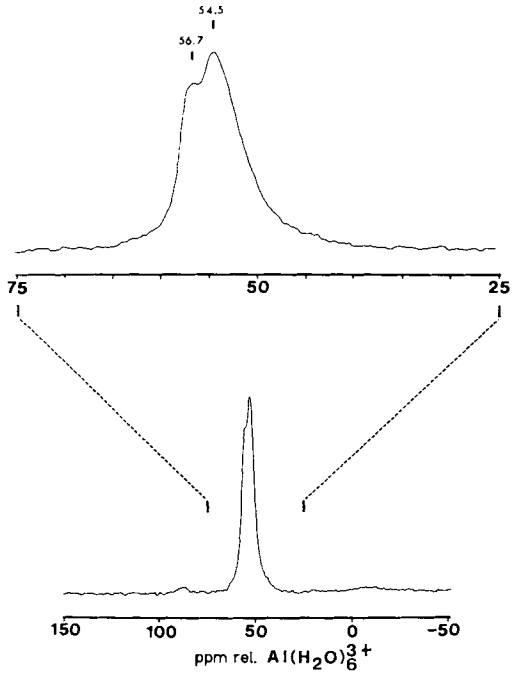

Fig. 13. High-resolution $^{27}$Al-MAS-NMR spectrum of silicalite at 104.22 MHz. 176214 free induction decays were accumulated; repetition time 0.1 s. Note the absence of octahedrally coordinated aluminum in the sample.

the presence of crystallographically non-equivalent sites for tetrahedral aluminum. The amount of aluminum present is very small, but it is clear that all of it is tetrahedrally-bound and constitutional, and not present as occluded $Al_2O_3$ impurity, since the various forms of $Al_2O_3$ which we have investigated for comparison show an intense MAS-NMR peak at $\delta = 9 \pm 1$ (signifying predominantly octahedrally-bound Al) and, in some forms, a relatively small peak at $\delta = 72 \pm 3$ arising from tetrahedral coordination. (These are the kind of spectral features to be expected, for example, from $\gamma$-$Al_2O_3$.) Furthermore, a peak at $\delta = -106$ corresponding to Si(1Al) may be observed in $^{29}$Si-MAS-NMR spectra of a commercial grade silicalite recorded under conditions of high gain. A quantitative determination of aluminum concentration in the sample of high purity silicalite was carried out by adding a known amount of reference compound containing octahedrally-coordinated Al and comparing the intensities of the two signals. This gave a Si/Al ratio $\geq 1000$.

## 7. The Structure of Zeolite A

X-ray structural investigations of hydrated and dehydrated single crystals of Na-exchanged zeolite A yield results which indicate[86,87] that the symmetry of the structure is cubic, space group Fm3c, and that, in particular, there is strict alternation of the Si and Al amongst the tetrahedral sub-lattice. This is equivalent to a so-called 4:0 ordering scheme: each Si or Al is surrounded tetrahedrally *via* an oxygen bridge by four Al or Si; and it indicates that Loewenstein's rule[76], defined earlier, is obeyed (Fig. 14a). One of the most remarkable results of the early $^{29}$Si-MAS-NMR work on zeolites was the observation[55,56] that, in the spectrum of Linde A, there is a single sharp resonance centred at $\delta = -89.0 \pm 1$. This result was confirmed by ourselves[57,88a] and others[65,89]. On the basis of the chemical shift ranges found by *Lippmaa, Engelhardt et al.*[56] (see Fig. 6), this result pointed to a 3:1 rather than 4:0 ordering, *i.e.*, to ordering in which each Si atom is linked tetrahedrally *via* an oxygen bridge to *three* Al atoms and *one other* Si atom and *vice versa*, so that, in view of the inevitable occurrence of Al–O–Al bonds with this ordering scheme, Loewenstein's rule appeared to be systematically violated. *Lippmaa* and *Engelhardt*'s original conclusion that 3:1 ordering exists in zeolite A was drawn because the resonance at $\delta = -89.0 \pm 1$ in zeolite A coincides almost exactly with the position of the 3:1 peak in faujasitic zeolites.

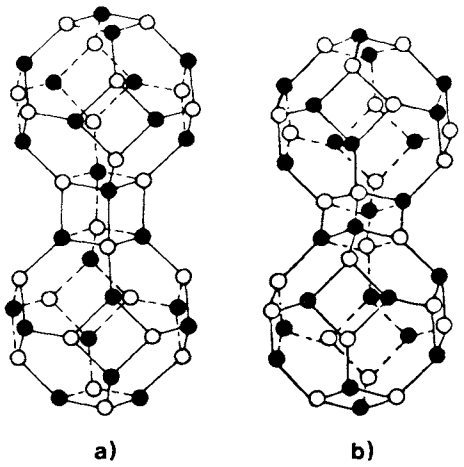

Fig. 14. a) The original model for the structure of zeolite A: Two sodalite cages (cubooctahedra) are linked through double four-membered rings. At the vertices of the cubooctahedra Si (○) and Al (●) atoms alternate such that 4:0 coordination results, *i.e.* each Si is surrounded tetrahedrally by four Al atoms, *via* oxygen bridges, which are not shown for simplicity. This double unit of cubooctahedra repeats itself three-dimensionally resulting in a cubic (Fm3c) space group. Exchangeable cations are not shown.—b) An alternative model in which cubooctahedra are slightly distorted (not shown) and again repeat themselves three-dimensionally, yielding a rhombohedral space group $R\bar{3}$. The ordering scheme within the aluminosilicate framework is such that each Si atom is surrounded by three Al atoms and one Si atom, and each Al atom by three Si atoms and one Al atom (3:1 coordination). Al–O–Al bridges are an integral feature of the structure. In this model, there are centers of inversion at the mid-points of the double four-membered rings. Notwithstanding earlier interpretations, $^{29}$Si-MAS-NMR supports the 4:0 ordering scheme (see text).

*Bursill et al.*[88a], accepted the validity of this conclusion and set about a detailed re-examination of the foundations upon which the 4:0 model of the structure of zeolite A was based. They had discovered[89b] that dehydrated Na-A exhibited a slight but unmistakable rhombohedral distortion and that, therefore, the space-group assignment Fm3c, which had been used for the structural refinement for the 4:0 structure, was not valid. Furthermore, many of their electron diffraction patterns appeared[88a] to be irreconcilable with the 4:0 ordering scheme. They therefore concluded that Al–O–Al linkages were probably responsible for the rhombohedral distortion, and were able to show how a cubic structure (space group Pn3n) for zeolite A could be assembled from rhombohedral units. They also found[88b] that encouraging structural refinement of their

neutron diffraction data could be obtained in space group $R\bar{3}$. All this, as well as the fact that some measured X-ray reflections of dehydrated Na-A are incompatible[86-88] with the Fm3c space-group, led *Bursill et al.*[88] to propose a new model for the structure of zeolite A (see Fig. 14b).

This new model was, however, soon scrutinized in the light of yet more recent discovery. First, *Rayment* and *Thomas*[90] showed, by X-ray powder diffractometry, that the crystal symmetry of Na-A is a function of the degree of hydration and of temperature, the rhombohedral form being favored only when the samples are desiccated and at low temperature. In the hydrated condition the structure is cubic. Secondly, using neutron diffraction, *Cheetham et al.*[43,44a] found that the rhombohedral distortion, present in Na-A, is vanishingly small in dehydrated Tl-A (using the *same* sample but with the $Na^+$ largely replaced by $Tl^+$), and in dehydrated Ag-A, and that Fm3c was a more appropriate (through not entirely satisfactory) space group than Pn3n to interpret their powder diffraction data. Then, independent $^{29}$Si-MAS-NMR experiments by *Thomas et al.*[71] and by *Melchior et al.*[75] on zeolite ZK-4, which has the same aluminosilicate framework as zeolite A but a Si/Al ratio greater than unity[91], pointed strongly in favor of the 4:0 rather than the 3:1 scheme, so that the structural model shown in Figure 14a was reaffirmed[44] for zeolite A. It has recently come to light[91b] that cancrinite, which, like zeolite A, was also thought to violate Loewenstein's rule, probably does not do so. $^{29}$Si-MAS-NMR results on cancrinite samples of different Si/Al ratios point to 4:0 ordering when Si/Al = 1.0.

In view of the fact that $^{29}$Si-MAS-NMR had first of all raised doubts about the authenticity of the accepted structural model of zeolite A, and that the very same technique (applied to ZK-4) had later vindicated the model, we shall here summarize the essential features of the MAS-NMR study of ZK-4. This study has also led to extension of the chemical shift ranges for the various tetrahedral functional groupings in zeolites generally (Fig. 6).

The fact that zeolite A exhibits only one sharp $^{29}$Si-resonance itself signifies that Si,Al ordering is pronounced, just as with zeolite X discussed earlier. But does this peak imply a 3:1 or 4:0 arrangement? By taking zeolite ZK-4, with Si/Al ratios substantially in excess of unity, the $^{29}$Si-MAS-NMR spectrum must exhibit several resonances corresponding to $Si(OAl)_n(OSi)_{4-n}$, as with zeolites X and Y (see Fig. 7). One of the peaks in the spectrum of ZK-4 should therefore correspond to the peak in the spectrum of zeolite A. (It has already been established that, *for a given aluminosilicate structure*, $^{29}$Si-chemical shifts of $Si(OAl)_4$ and $Si(OAl)_3(OSi)$ peaks are only marginally affected by variation of the Si/Al ratio.) Thus, assignment of the signal in the spectrum of zeolite A is in principle possible by matching it with one of the peaks in the spectrum of ZK-4, even though the ordering pattern of the latter is different from that of zeolite A. Moreover, by determining the Si/Al ratio independently (using analytical electron microscopy) one may further test[71] whether the resonance at $\delta = -89$ is attributable to 3:1 or to 4:0 by comparing the $(Si/Al)_{NMR}$ ratio, calculated using equation (3) with that obtained by electron microscopy using X-ray emission intensities, $(Si/Al)_{XRE}$.

The $^{29}$Si-MAS-NMR spectrum of ZK-4 does indeed contain several peaks (Fig. 15); and good agreement between $(Si/Al)_{NMR}$ and $(Si/Al)_{XRE}$ ratios are obtained if the resonance at $\delta = -89 \pm 1.0$ is assigned to $Si(OAl)_4$ rather than to $Si(OAl)_3(OSi)$. It will be recalled that, in zeolites X and Y (synthetic faujasites) the $Si(OAl)_4$ resonance lies between $\delta = -83.7$ and $-84.1$. We believe that the relatively large difference between these two $Si(OAl)_4$ resonances stems from the occurrence of considerable strain in the zeolite A (ZK-4) framework. The strained double four-membered rings, which give rise to T–O–T angles close to 180°, affect the value of the chemical shift at which the $^{29}$Si-nucleus resonates. Just as with silicalite, which also has T–O–T angles close to 180°, the resonances for a given functional grouping are shifted to more negative values. The strong influence that structural strain and, hence, unusual T–O–T angles may exert upon $^{29}$Si chemical shifts is well illustrated in the recent work of *Jarman*[91c] on sodalites. This fact can, of course, be turned to advantage in structure determinations.

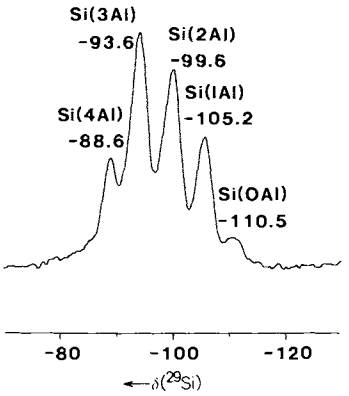

Fig. 15. $^{29}$Si-MAS-NMR spectrum at 79.8 MHz of zeolite ZK-4 showing five peaks, at the chemical shift values indicated, corresponding to the silicon environments shown in the figure.

Two broader issues are raised by the results obtained with ZK-4. First, now that the original 4:0 model for Si,Al ordering is reinforced, it is relevant to enquire more deeply into the interpretation of the neutron diffraction and electron diffraction data[88] on zeolite A; second, a revised tabulation of $^{29}$Si-chemical shifts is called for in the case of the zeolites. So far as the first of these two points is concerned, excellent agreement has been obtained[43,44] between the T–O bond distances determined by Rietveld analysis of neutron powder data on the one hand and by single crystal X-ray analysis on the other. The electron diffraction data that implied the occurrence of three-fold superlattices in zeolite A when the crystals were viewed along the ⟨110⟩ axes can be interpreted[92] in terms of the facile twinning of zeolite A on {111} planes. (Such twins are readily revealed in scanning electron microscopic studies.) The second point has prompted us to construct a revised tabulation (Fig. 6) which indicates how much the ranges of resonances previously published have to be extended. This information can now be used to help identify the individual groupings present within strained structures, including possibly amorphous or quasicrystalline aluminosilicates.

## 8. Future Prospects

With the application of multinuclear MAS-NMR spectroscopy many other currently intractable structural problems in zeolite chemistry are likely to be resolved. It is especially noteworthy that many zeolitic structures can be synthesized with the framework made up of atoms all of which have NMR-active nuclei: Si, Al, O, Be, B, Ga, Ge, P, *etc.* Whereas it is unlikely that the richness of information retrievable from $^{29}$Si-MAS-NMR, and to a lesser degree $^{27}$Al-MAS-NMR, will be matched with nuclei of all these elements, it is nevertheless significant that an environmental probe exists for each atomic constituent of the framework structure. Moreover, the majority of the exchangeable cations in zeolites have NMR-active nuclei: Fe, Rh, Ag, Cd, Tm, Yb, Pt, Hg, Tl, Pb (all possessing spin 1/2), and Na, Mg, K, Ca, Sc, Ti, V, Cr, Mn, Co, Cu, Zn, Ga, Rb, Sr, Cs, Ba, La (all quadrupolar). Some of these elements are also capable of being incorporated into the framework structure.

In the case of quadrupolar nuclei of non-integral spin such as $^{27}$Al, improved spectral resolution may be obtained by spinning at angles other than 54°44′ *if quadrupolar effects are the dominant interaction*[45,93]. In the present context, successful application of this technique has been made in the $^{27}$Al-spectra of cordierite crystallizing from its vitreous precursor and of various minerals where the quadrupolar effects are much larger than those in zeolites[94]. Stereochemical issues alone are likely to be clarified by use of MAS-NMR techniques for the appropriate nucleus. In addition, many of the guest species or reactants accommodated within the cavities and tunnels of a zeolite, or bound to its active centers, possess amenable NMR nuclei, $^{13}$C, $^{1}$H, $^{2}$H, $^{14}$N, $^{15}$N and $^{31}$P especially. The prospects of resolving some hitherto inaccessible aspects of zeolite structural chemistry are therefore good, especially when it is recognized that previous $^{13}$C-NMR studies of rather mobile organic guests in aluminosilicate hosts have already produced useful information. Two studies of relevance in this connection are those of *Derouane et al.*[95] who, in a simulated *in situ* study, followed the conversion of methanol, in contact with ZSM-5, to gasoline and our own[96] on sheet silicate intercalates where the concentration of intercalated isomers (*e.g.* xylene and ethylbenzene) or the interlamellar tautomeric equilibrium of acetylacetone could each be quantitatively determined. Using $^{1}$H-MAS-NMR it proved[97] possible to obtain two very sharp peaks, in the ratio of 6 : 4, from relatively immobile *p*-xylene intercalated within a synthetic hectorite. Combined $^{1}$H- and $^{2}$H-MAS-NMR as well as $^{13}$C-MAS-NMR, with or without cross polarization of the kind already carried out to determine the nature and location of organic bases in ZSM-5 zeolites[98] and uncalcined silicalite[99] are already viable techniques. The use of benign probes, such as $N_2$, Xe or Kr, which are ideally suited for testing the range of different environments within the zeolites is also feasible by MAS-NMR.

The particular advantage that CP/MAS affords in discriminating surface species has already been seen in the studies of untreated and derivatized silicas and silica gels[100] and of ultrastabilized zeolites[70]. In this way it has been possible to identify such groups as $Si(OH)_1$, $Si(OH)_2$, and $Si(OH)_3$ at silica or zeolite internal surfaces. By introducing organic derivatives (deuterated if appropriate[101] and containing, for example, $^{13}$C, $^{31}$P, or $^{19}$F) to the internal or external surfaces of aluminosilicates, a great deal more is likely to be learnt about the catalytic properties and specific acid sites of these materials from the relevant MAS-NMR studies. The structures of a variety of the new, technically important, ceramics[94,102] that can be formed by heat-treatment of various cation-exchanged zeolitic precursors, are eminently amenable to multinuclear MAS-NMR studies. The detailed mechanism of zeolite dealumination (in which the groups $Si(OAl)_4$, $Si(OAl)_3(OSi)$, *etc.* are eroded at different rates by exposure to $SiCl_4$ vapor), or of the exchange of oxygen between the framework and its environment under mild conditions can now be investigated directly. Our preliminary measurements[99] using $^{17}$O-MAS-NMR reveal that the oxygens in the linked $SiO_4^{4-}$ and $AlO_4^{5-}$ zeolite tetrahedra are much more labile than was formerly suspected.

*We acknowledge support from the Universities of Cambridge and Guelph and from B. P. Research Centre, Sunbury. C. A. F. was the recipient of financial aid from the Natural Sciences and Engineering Council of Canada. We are grateful for the cooperation of numerous colleagues (listed in the references). The NMR spectra were obtained at the South-Western Ontario High-Field NMR Facility, Manager, Dr. R. E. Lenkinski.*

[1] a) The term porotectosilicates has been proposed by *Barrer* to encompass that class of siliceous crystalline materials which includes both zeolites and solids that resemble zeolites in crystal structure but which may not be capable of ion exchange. Tectosilicates are characterized by the fact that the $SiO_4$ tetrahedra are linked at all corners to form three-dimensional arrays. The recent discovery of new families of crystalline microporous borophosphates [1b], $BPO_4$, and aluminophosphates [1c], $AlPO_4$, which possess structures reminiscent of, if not identical to, those of many zeolites but which are partly- or non-siliceous, suggests that a new term is needed to encompass these materials. We suggest "porotectophosphates", which could encompass elements other than Al in the structure, as such a generic name; b) J. # Structure and Evolution of the "*Atmungsferment*" Cytochrome c Oxidase

**By Bernhard Kadenbach***

*In memory of the 100th anniversary of Otto Warburg's birth*

Approximately 50 years ago, *Otto Warburg* received the Nobel Prize for his fundamental work on the "*Atmungsferment*". But not until the end of the fifties was it possible to isolate this complicated membrane enzyme, which is necessary for respiration and energy production in most living organisms on earth. Since then, intensive research has been performed to elucidate the mechanism of reduction of oxygen to water and the coupled translocation of protons across the membrane which is involved in ATP synthesis. Until now the results have been unsatisfactory because the four catalytic heavy-metal redox centers are bound to proteins, the structures of which have begun to be studied only recently. In the course of this research, it was discovered that cytochrome c oxidase from bacteria contains only two or three, whereas the enzyme complex from animals contains thirteen different protein components. The present article analyzes the possible functions of the various protein subunits and, using the example of cytochrome c oxidase, shows that biochemical evolution proceeds in such a way as to increase regulatory capacity.

## 1. Historical Survey

The catalytic role of iron in cellular respiration was proven first by *Otto Warburg* in 1924. He found that this process involved a change in the valence of the metal ion: $Fe^{3+}$ is reduced by an organic substance to $Fe^{2+}$ and oxidized by molecular oxygen to $Fe^{3+}$[1]. In 1926, *Warburg* discovered that hydrocyanic acid and carbon monoxide inhibit respiration, and that the inhibition by CO could be reversed by the action of light. This enabled him to determine the action spectrum of the respiratory enzyme, and this agreed well with that of other iron porphyrins, such as hemoglobin and the cytochromes described by *Keilin* in 1925[2]. *Warburg*'s "*Atmungsferment*", however, adsorbs at longer wavelengths and results, in contrast to the known red hemins, in the green color of the hemin component[3]. In 1931 *Otto Warburg* received the Novel Prize for Medicine and Physiology for this work.

The action spectrum, measured by *Warburg* with intact yeast cells[3], corresponds well with the difference spectrum of isolated green cytochrome c oxidase[4].

A dispute arose between *Warburg* and *Keilin* over the question whether the cytochromes a, b and c[2], first observed in 1886 by *McMunn* using a manual spectroscope and denoted histo- or myohematins[5,6], and rediscovered by *Keilin* in 1925, are directly involved in the oxidation of respiratory substrates by molecular oxygen[7]. The controversy was ended in 1939 by *Keilin*'s discovery that cytochrome a was made up of two components: one of these, de-

[*] Prof. Dr. B. Kadenbach
Fachbereich Chemie der Universität
Hans-Meerwein-Strasse, 3550 Marburg (Germany)

noted cytochrome $a_3$ or cytochrome oxidase, reacts with CO and HCN and has the same spectrum as *Warburg*'s "*sauerstoffübertragendes Ferment*"[8,9].

After isolation methods for cytochrome c oxidase were developed in the fifties, the molecular properties of the enzyme could be investigated in detail. They have been described in a series of excellent review articles[10–26].

## 2. The Function of Cytochrome c Oxidase

Cytochrome c oxidase (EC 1.9.3.1, also termed cytochrome oxidase or cytochrome $aa_3$) represents the oxygen-activating enzyme of cellular respiration and is present in almost all eukaryotic cells, where it is located in the inner membrane of mitochondria. In several aerobic bacteria cytochrome c oxidase is also found, where, however, it is located in the plasma membrane.

Cytochrome c oxidase, the terminal enzyme of the respiratory chain, transfers four electrons from cytochrome c to molecular oxygen, leading to the formation of water without producing toxic intermediates, such as $H_2O_2$ or the superoxide radical $O_2^-$. The four reducing equivalents originate from the respiratory substrates, which transfer hydrogen equivalents mainly *via* the coenzyme NADH to the respiratory chain. In the respiratory chain, which consists of flavoproteins, non-heme iron proteins, ubiquinone and cytochromes[27], the redox energy of the reducing equivalents is diminished stepwise from one component to the next, whereby the energy released is used at three sites (NADH-dehydrogenase complex, cytochrome $bc_1$ complex, and cytochrome c oxidase) for the synthesis of ATP (Fig. 1).

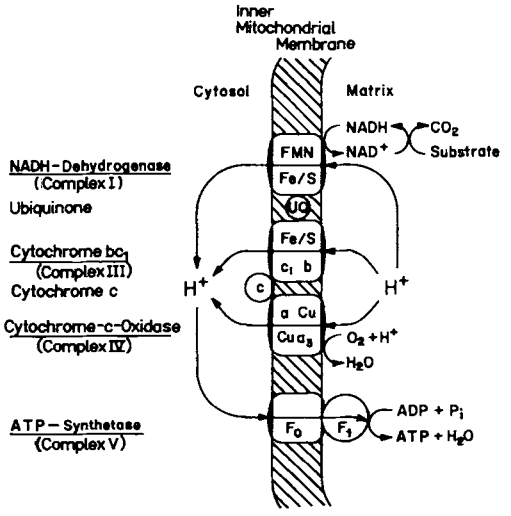

Fig. 1. Schematic representation of the respiratory chain of mitochondria. The respiratory chain is made up of several multiprotein complexes I–V, which are freely mobile in the lipid phase of the inner membrane. Hydrogen and electron transfer between the complexes occurs *via* the lipid ubiquinone (UQ) and *via* cytochrome c (c), a soluble protein that is bound from the outside to the membrane complexes; these processes are coupled at three sites with a proton translocation from the matrix into the cytosol. The succinate dehydrogenase complex (complex II) does not translocate protons and is omitted from the figure. The proton gradient is used by the ATP-synthetase for the formation of ATP from ADP and inorganic phosphate ($P_i$).

According to *Mitchell*'s "chemiosmotic hypothesis", the "energy-rich intermediate" of this reaction is represented by a proton gradient across the membrane, the "protonmotive force" ($\Delta P$), which is made up of an electrical ($\Delta\Psi$) and a concentration potential ($\Delta p$H) [eq. (a)][28].

$$\Delta P = \Delta\Psi - \frac{RT}{F}\Delta p\mathrm{H}\,; \quad \left(\Delta p = \frac{\mu \mathrm{H}^+}{F}\right) \tag{a}$$

Many results prove that this proton gradient represents the "energy-rich intermediate" of oxidative phosphorylation, the most important process of energy production in all aerobic cells which was searched for over a period of almost two decades. The membrane bound ATP synthetase complex uses this proton gradient to synthesize ATP from ADP and inorganic phosphate ($P_i$)[27].

Cytochrome c oxidase, the third energy conserving component of the respiratory chain, is composed of several polypeptides ("subunits"), two heme a groups, two copper ions, as well as bound phospholipids (cardiolipin essentially[29–31]). The two heme a groups, although chemically identical, can be distinguished by spectroscopy: in the $Fe^{II}$ form cytochrome $a_3$ binds $O_2$ and CO, and in the $Fe^{III}$ form HCN, $HN_3$, and $H_2S$; cytochrome a, in contrast, does not bind these components, as previously shown by *Keilin* and *Hartree*[8]. This points to a different environment or to different complexing ligands for the two heme a groups. Indeed, both heme a groups are localized in different polypeptides of the enzyme complex (polypeptides I and II)[32], although ESR spectroscopic studies indicate only a distance of 10—14 Å between them[33]. In addition, both copper ions are localized within polypeptide II, which indicates that the four redox centers of the enzyme are in close proximity to each other. This seems to be essential for the mechanism of oxygen reduction, where $4e^-$ from the four redox centers are rapidly transferred to $O_2$ (2nd order rate constant at room temperature: $10^{-8}$ M$^{-1}$ s$^{-1}$[35]). Using a number of physical methods (low temperature absorption spectroscopy, ESR, CD, and MCD spectroscopy, X-ray diffraction, EXAFS, ENDOR, magnetic susceptibility measurements, Mössbauer and resonance Raman spectroscopy) the mechanisms of electron transport from cytochrome c to $O_2$, as well as the structural environment of the four redox centers, were examined. Figure 2 shows a simplified scheme of current conceptions[26,36,37].

The Y-shaped, three-dimensional structure of the cytochrome c oxidase complex could be determined by electron microscopic studies of two-dimensional crystals[38,39]. Both upper ends of the "Y" protrude into the matrix, and the lower end into the cytosol. Whereas the binding site for $O_2$ is uncertain[21,40], the protons required for the formation of water according to equation (b)

$$O_2 + 4e^- + 4H^{\oplus} \longrightarrow 2H_2O \tag{b}$$

originate from the matrix[40]. This involves the transfer of four charge equivalents across the membrane.

From equation (b), the formation of a proton gradient through cytochrome c oxidase is not apparent. *Mitchell* neither postulated this in his hypothesis[28], nor did he find it in any of his experimental studies[41]. *Wikström et al.*, in contrast, were able to establish using intact mito-

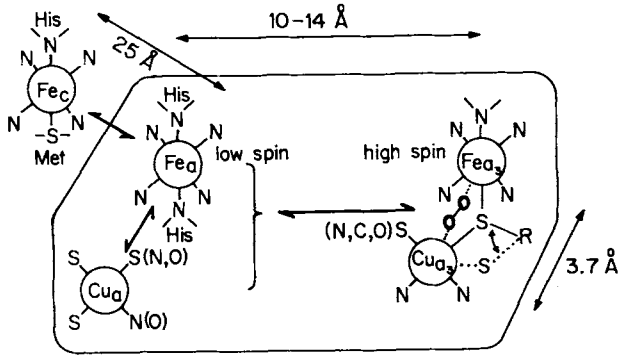

Fig. 2. The active center of cytochrome c oxidase (schematic). At the four redox centers of the enzyme the N-atoms of the porphyrin systems are indicated by one bond, that of histidine (5th and 6th ligands of iron) by three bonds. The exact nature of the four ligands at the copper atoms is not yet known. In some cases the identity of the atom through which the ligand is attached to Cu is still not clear (other possibilities are shown in parenthesis). The four redox centers are reduced successively by reduced cytochrome c ($Fe_c$) *via* cytochrome a ($Fe_a$). The 6th coordination site of cytochrome $a_3$ ($Fe_{a3}$) in the oxidized state ($Fe_{a3}^{3+}/Cu_{a3}^{2+}$) is occupied by sulfur, which forms a bridge between Fe and Cu. After reduction of both redox centers, the sulfur arm opens up and $O_2$ is bound between $Fe_{a3}$ and $Cu_{a3}$, whereby a peroxide intermediate is formed ($Fe_{a3}^{3+}-O^- - O^- - Cu_{a3}^{2+}$, "compound B"). Thereafter two electrons are transferred almost immediately from $Fe_a + Cu_a$ to the peroxide intermediate. It is not yet known when and from what source the four protons for the formation of water originate.

chondria[42–44], as well as with isolated cytochrome c oxidase which had been reconstituted in liposomes[45], proton pump activity from the matrix to the cytosol or across the membrane, respectively. The measured $H^+/e^-$ stoichiometry was *ca.* 1. Other authors corroborated the same results, although the measured $H^+/e^-$ stoichiometry was always $< 1$[40,46].

The functional unit of cytochrome c oxidase is a dimer of the complex which contains four heme a groups and four copper ions. This follows from electron microscopic studies of two-dimensional crystals[39] and from sedimentation analysis on the isolated enzyme dissolved in detergent[47,48]. Also, the complete inhibition of enzyme activity after covalently binding only 0.5 mol azidoarylcytochrome c per mol cytochrome $aa_3$[49] points to a dimer complex as the functional unit. The monomeric enzyme could certainly transfer electrons from cytochrome c to $O_2$ but the proton pump activity seems to occur only through the dimeric enzyme complex, as put forward in the "reciprocating site model" of *Wikström et al.*[26].

## 3. Polypeptide Composition of Animal Cytochrome c Oxidase

The many subunits of animal cytochrome c oxidase are associated so strongly in the enzyme complex through noncovalent bonds that they are not even separated during dissolution of the membrane by detergents such as Triton X-100 or Na-cholate (the first step in isolating the enzyme). *Hackenbrock et al.* have shown that the cytochrome c oxidase complex is not firmly associated with the other enzyme complexes of the respiratory chain within the "two-dimensional liquid" of the biological membrane: specific antibodies lead to aggregation of the enzyme complex[52]; enlargement of the membrane surface area by fusion with protein-free liposomes leads to dilution of the enzyme complex in the membrane, which is visible by electron microscopy, and is accompanied by a reduction of the rate of electron transport, *via* the respiratory chain, from NADH to $O_2$[53]. The mobility of the enzyme complex in the membrane is also evident from the change in dichroism after photolysis of the cytochrome c oxidase-CO complex with a linear polarized laser flash. The observed relaxation time of several 100 μs indicates that the enzyme complex rotates around an axis perpendicular to the membrane[54]. ESR measurements on spin-labeled cytochrome c oxidase reconstituted in liposomes yielded a rotation of the enzyme complex with a correlation time of 40[55] or 34 μs at 4 °C[56].

The close association of several polypeptides to give a complex of defined spatial structure points to a specific function for the various subunits. It was, therefore, of great interest to find out which and how many polypeptides constitute the enzyme complex. This proved to be an especially difficult problem, particularly because the term "subunit" was interpretated differently. We define all polypeptides that are firmly associated within the complex as subunits, irrespective of these could have a catalytic or regulatory function.

The two most important methods for analyzing the polypeptide composition of the cytochrome c oxidase complex are: 1) Separation of the subunits (either dissociated in 2% Na-dodecylsulfate (SDS) or in 10–70% acetic acid solution) by gel filtration, based on their different molecular weights, and identification of the isolated proteins by *N*-terminal amino acid determination or sequence analysis. Using this method two research groups have identified twelve[57] or eleven[58] different proteins, from which six or seven were found to occur in stoichiometric and five in substoichiometric amounts. 2) Separation of the SDS-dissociated subunits by SDS-gel electrophoresis, also based on different molecular weights. With this most commonly used separation system[59,60], animal cytochrome c oxidase is usually separated into only seven polypeptide bands. By analogy to the most carefully investigated enzyme from yeast, where also seven subunits were identified[61,62], it was generally assumed that the animal enzyme also consists of seven subunits[16,17,19,20,22,26,50,53,55,61,63–75], although often more than seven polypeptide bands were found[55,68,69,71,73,76–79].

By further improving the SDS-gel electrophoretic separation system, we were able to separate highly purified animal cytochrome c oxidase into thirteen different polypeptide bands (Fig. 3)[24,80], representing intrinsic components of the enzyme complex as shown by various results: the isolated enzyme from different organs (liver, kidney, heart) of different mammals and from chicken always exhibited thirteen different polypeptide bands[81–83]; all polypeptides had a different amino acid composition[84], occurred in stoichiometric amounts[81], and all of them could be immunoprecipitated from a Triton X-100 extract of total rat liver mitochondria with a specific antiserum against polypeptide IV[84]. Specific antibodies for the isolated polypeptides I, II, III, IV, Vab, VIa, VIbc, VIIabc, and VIII reacted only with the corresponding polypeptides, whereby proteolytic artifacts were eliminated[86]. The com-

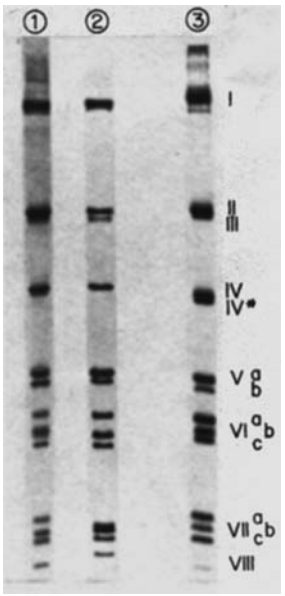

Fig. 3. Polypeptide composition of animal cytochrome c oxidase, which was isolated from mitochondria of porcine heart ①, bovine heart ②, and rat liver ③ according to the procedure in [81]. After high-performance SDS-gel electrophoresis [80], the protein bands were stained using Coomassie blue R 250.

plete amino acid sequences of twelve polypeptides of the bovine heart enzyme all differ from one another[85].

## 4. Polypeptide Composition of Cytochrome c Oxidase from Species in Different Developmental Stages

In studying the biosynthesis of the enzyme, the polypeptide composition of cytochrome c oxidase from *Neurospora crassa* and from yeast was carefully analyzed, and eight[87,88] and seven[61,62] different subunits, respectively, identified. An interesting observation made was that the three largest polypeptides (I, II, and III) are coded by mitochondrial DNA and synthesized in the mitochondria, whereas all other polypeptides are coded on nuclear DNA and synthesized in the cytoplasm[63,89], as demonstrated schematically in Figure 4. Also in animal cytochrome c oxidase the large polypeptides I—III are synthesized in the mitochondria, and the other polypeptides in the cytoplasm[90–94]. The information for the directed transport of the polypeptides synthesized in the cytoplasm into the mitochondria is contained in additional amino acid sequences of 2000—6000 dalton ("signal peptides"), which are cleaved proteolytically during or after transport through the mitochondrial membrane[95–99].

Recently, cytochrome c oxidase was also isolated from bacteria and the surprising observation was made that this enzyme contains only two [100–103] or three[104,105] subunits. Nevertheless, the isolated enzyme is functionally active. After reconstitution of the two-subunit enzyme from *Paracoccus denitrificans* in liposomes, an electron transport-dependent proton translocation was found with a stoichiometry of $0.6\,H^+/e^-$[106]. The ability of the enzyme from *P. denitrificans* to actively pump protons has not yet been explained, since the corresponding proton translocating polypeptide III of the eukaryotic enzyme (cf. Section 5) is absent.

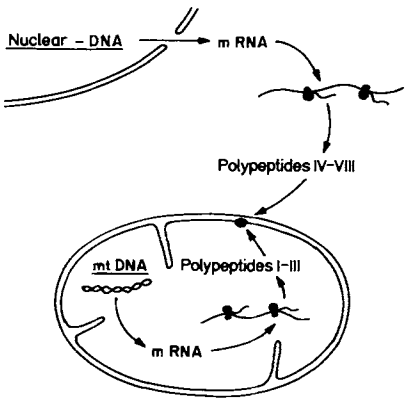

Fig. 4. Coordinated biosynthesis of cytochrome c oxidase in mitochondria and in the cytoplasm. The information for polypeptides I—III is coded on mitochondrial DNA (mtDNA) and, after transcription into mRNA, the proteins are synthesized on mitochondrial ribosomes. The polypeptides are then anchored on the inner membrane. The polypeptides IV—VIII are coded on nuclear DNA. They are synthesized on cytoplasmic ribosomes. The transport of the precursor proteins to the inner mitochondrial membrane occurs with the help of additional signal sequences which are cleaved off during passage through the membrane. The mechanism of assembly of the intact enzyme complex (binding of two heme a and two copper ions) is not known.

The polypeptides of cytochrome c oxidase from prokaryotes are related to the mitochondrial-synthesized polypeptides of the yeast enzyme: An antiserum against polypeptide II from *P. denitrificans* reacted with polypeptide II of the yeast enzyme and *vice versa*[25]. The amino acid sequences of the polypeptides I, II, and III from higher animals are also related to the corresponding polypeptides from yeast, as shown by comparison of the yeast, bovine, and human mitochondrial DNA sequences[107–112]. Between polypeptide II from yeast and bovine, a sequence homology of 49% was found, and between bovine and human 72%[111].

## 5. Mitochondrial-Synthesized Polypeptides I-III—Carriers of Catalytic Activity

The findings described in Sections 3 and 4 suggest that only the polypeptides I-III synthesized in the mitochondria are required for the catalytic function of the animal enzyme. This assumption was supported by the localization of both heme a groups in equal amounts in polypeptides I and II, as well as of both copper ions in polypeptide II[32]. The localization of the copper ions in polypeptide II also follows from its amino acid sequence which is very similar to those of the copper-binding proteins azurin and plastocyanin[113]. Polypeptide II also contains the binding site for cytochrome c, which binds through the same lysines of a defined surface area (Lys-8, -13, -72, -87) to the electron acceptor (cytochrome $aa_3$), as well as to the electron donor (cytochrome $bc_1$)[114–116]. From kinetic data two binding sites for cytochrome c, a high-affinity and a low-affinity site, were defined at the oxidase[114,117]. The high-affinity binding site is located at polypeptide II, as was shown by cross-linking of cytochrome c with the reagent 3,3′-dithiobis(succinimidopropionate)[118] and with the

photoreactive azido-3-nitrophenylcytochrome c (modified at Lys-13)[49,67,119]. Low-affinity bound cytochrome c, modified at Lys-13 or Lys-22, reacts only with phospholipids[49].

Polypeptide III seems to contain the proton channel of the oxidase: as in ATP-synthetase[120], *N,N'*-dicyclohexylcarbodiimide inhibits proton translocation in reconstituted cytochrome c oxidase vesicles[121] with concomitant partial inhibition of respiratory activity and specific covalent binding to polypeptide III[122,123]. Thus all known functional activities of cytochrome c oxidase (electron transport from cytochrome c to $O_2$ and proton translocation) can be attributed to the three polypeptides I—III synthesized in the mitochondria. We therefore refer to them as *catalytic subunits*. Although no definite function for the ten polypeptides synthesized in the cytoplasm which are firmly associated with polypeptides I—III is yet known, the following findings indicate a "regulatory" or "modifying" function, mediated by conformative interaction with the catalytic subunits I—III.

## 6. Tissue-Specific Isoenzymes of Animal Cytochrome c Oxidase

By comparing the polypeptide pattern obtained by SDS-gel electrophoretic separation of cytochrome c oxidase from the liver and heart of the same animal, we found different molecular weights for the polypeptides VIa, VIIa, and VIII synthesized in the cytoplasm[82,83]. The different bands were eluted from the acrylamide gel, and the *N*-terminal amino acid sequences determined[124,125]. As seen in Table 1, the *N*-terminal sequences of polypeptides VIa, VIIa, and VIII from bovine liver and heart are different but still very similar. In contrast, the twelve *N*-terminal amino acids of polypeptides IV and Va from the bovine liver and heart enzymes are identical. Two conclusions can, therefore, be drawn: 1) For each of the polypeptides VIa, VIIa, and VIII there exist two different genes in the bovine genome; 2) the corresponding genes for the different polypeptides from liver and heart originate from a common precursor gene and developed independently of each other in the course of evolution.

Table 1. Comparison of the *N*-terminal amino acid sequences of some polypeptides of cytochrome c oxidase from bovine heart and liver. The polypeptides of the bovine heart enzyme were isolated by gel chromatography, those from bovine liver from the gel bands after SDS-gel electrophoresis [124, 125].

| Polypeptide | Tissue | *N*-Terminal amino acid sequence |
|---|---|---|
| IV | heart | $H_2N$-Ala-His-Gly-Ser-Val-Val-Lys-Ser-Glu-Asp-Tyr-Ala |
| | liver | $H_2N$-Ala-His-Gly-Ser-Val-Val-Lys-Ser-Glu-Asp-Tyr-Ala |
| Va | heart | $H_2N$-Ser-His-Gly-Ser-His-Glu-Thr-Asp-Glu-Glu-Phe-Asp |
| | liver | $H_2N$-Ser-His-Gly-Ser-His-Glu-Thr-Asp-Glu-Glu-Phe-Asp |
| VIa | heart | $H_2N$-Ala-Ser-Ala-Ala-Lys-Gly-Asp-His-Gly-Gly-Thr- |
| | liver | $H_2N$-*Ser*-Ser-*Gly*-Ala-*His*-Gly-*Glu*-*Glu*-Gly-*Ser-Ala*- |
| VIIa | heart | $H_2N$-Phe-Glu-Asp-Arg-Val-Val- |
| | liver | $H_2N$-Phe-Glu-Asn-*Lys*-Val-Ala-(Phe) |
| VIII | heart | $H_2N$-Ile-Thr-Ala-Lys-Pro-Ala- |
| | liver | $H_2N$-Ile-*His-Ser*- Lys- Pro-*Pro*-(Phe) |

In order to study the immunological relationship of cytochrome c oxidase polypeptides from different organs and species, the method of immunodetection after protein transfer onto nitrocellulose ("western blot") was used. The polypeptides, separated on an acrylamide gel, were transferred electrophoretically onto nitrocellulose and incubated with a specific antiserum. Polypeptides which reacted with the antibody were visualized with fluorescein-labeled protein A, which binds specifically to immunoglobulins. We found large differences in the immunological reactivity of the tissue-specific polypeptide VIa from different tissues of the rat (liver, heart, skeletal muscle) with an antiserum against rat liver cytochrome c oxidase. The reactivity of the tissue-unspecific polypeptides I—V from the same organs of different species (*e.g.* rat and blackbird) with the antiserum was, however, very similar[86]. We conclude that the time elapsed since tissue-specific polypeptides of the same species evolved separately must be considerably greater than that elapsed since mammals and birds developed separately.

## 7. Cytoplasmical-Synthesized Polypeptides IV-VIII— Modulators of Catalytic Activity

The different amino acid sequences of the polypeptides VIa, VIIa, and VIII in liver and heart have an influence on the catalytic activity of the cytochrome c oxidase: Compared to the enzyme from bovine heart, that from bovine liver exhibited a higher initial rate $V_{max}$ and different $K_m$-values for the high-affinity, as well as for the low-affinity binding sites for cytochrome c. These differences were measured on intact membranes, on membranes dissolved in deoxycholate, and also on the isolated enzymes[126].

The physiological meaning of these differences could be based on the different composition of the enzyme in liver and heart mitochondria. In the outer membrane of liver mitochondria a NADH-cytochrome $b_5$ reductase was found which oxidizes extramitochondrial NADH[127-129].

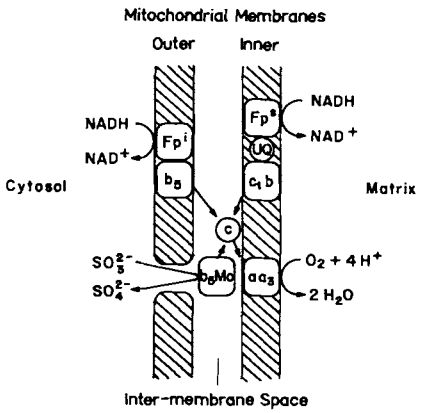

Fig. 5. Schematic representation of the electron transport pathways in liver mitochondria *via* cytochrome c to cytochrome c oxidase. Cytochrome c ©, a small water-soluble protein, is located in the intermembrane space and transfers electrons in all mitochondria from the cytochrome $bc_1$ complex to cytochrome c oxidase ($aa_3$). In liver mitochondria electrons can also be transferred from the rotenone-insensitive NADH-dehydrogenase of the outer membrane ($Fp^i$) *via* cytochrome $b_5$ ($b_5$), and from the sulfite oxidase ($b_5$Mo), located in the intermembrane space, *via* cytochrome c to cytochrome c oxidase. $Fp^s$: rotenone-sensitive NADH-dehydrogenase; UQ: ubiquinone.

In the intermembrane space of liver mitochondria, a soluble sulfite oxidase was found that contains molybdenum and a $b_5$-type heme as prosthetic groups, and which oxidizes sulfite to sulfate[130-133]. The sulfite oxidase represents the terminal step of sulfur metabolism in higher animals and can account for approximately 20% of the oxygen consumption of the liver (maximal rate of sulfite oxidation in perfused rat liver at 30 °C: 1.2 μmol/g wet weight/min[132], compared with an $O_2$ consumption of *in vivo* rat liver of *ca.* 3 μmol/g wet weight/min[134]). The sulfite oxidase and the NADH-cytochrome $b_5$ reductase in liver mitochondria transfer electrons *via* cytochrome c to the oxidase as well as the cytochrome $bc_1$ complex of the respiratory chain (Fig. 5). Liver mitochondria appear to be adapted to these additional electron donors: the ratio of cytochrome c + cytochrome $c_1$ to cytochrome $aa_3$ is greater than that of *e.g.* heart mitochondria (Table 2). The different catalytic activity of liver and heart cytochrome c oxidase[126] could be explained by the differences in the electron transport pathways.

Table 2. The ratio of the amounts [nmol/mg mitochondrial protein] of cytochrome $c+c_1$ to cytochrome $aa_3$ is different in liver and heart mitochondria.

| Tissue | $c+c_1$ | $aa_3$ | $(c+c_1)/aa_3$ | Ref. |
|---|---|---|---|---|
| bovine liver | 0.23 | 0.08 | 2.9 | [126] |
| bovine heart | 0.47 | 0.68 | 0.69 | [126] |
| rat liver | 0.38 | 0.27 | 1.4 | [135] |
| rat heart | 0.83 | 0.98 | 0.85 | [135] |
| chicken liver | 0.44 | 0.36 | 1.2 | [135] |
| chicken heart | 0.49 | 0.63 | 0.78 | [135] |

Upon incubating isolated cytochrome c oxidase from bovine heart with trypsin, polypeptides VIa, b, and c are completely, and polypeptide I *ca.* 50% cleaved, whereas the other polypeptides are not changed[83]. Simultaneously, the affinity of the enzyme to cytochrome c is reduced by 50% and $V_{max}$ increased (Fig. 6). This result points to a modifying influence of the polypeptides VIa, VIb, and/or VIc on the catalytic activity of the enzyme.

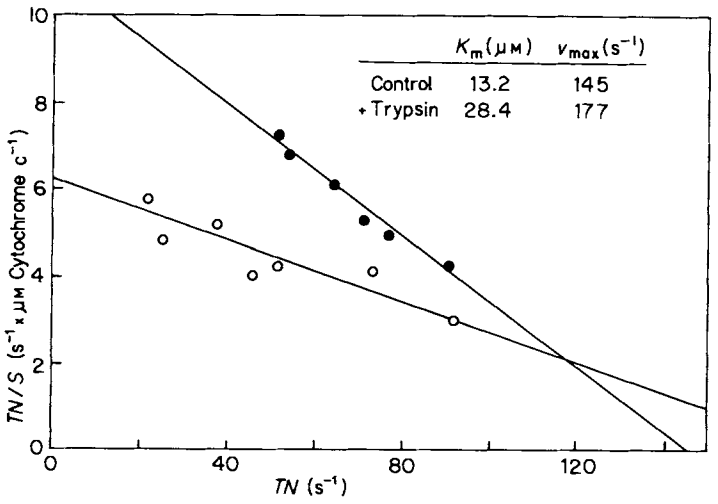

Fig. 6. Effect of trypsin on the kinetic properties of cytochrome c oxidase. Cytochrome c oxidase isolated from bovine heart (2 mg/mL) was dissolved in 2% solution of Na-cholate containing 20 mg/mL asolectin and 50 mM Na-phosphate at pH 7.6, and incubated for 30 min at 23 °C in the presence and absence of 0.02 mg/mL DPCC-trypsin. The enzyme activity was measured photometrically with 2—20 μM reduced cytochrome c [135]. In the reciprocal representation according to *Eadie-Hofstee*, the molecular activities (*TN*) are given in mol cytochrome c × $s^{-1}$ per mol cytochrome c oxidase. *S*: concentration of cytochrome c. • control, o+ tripsin.

Isolated cytochrome c oxidase from rat liver was incubated with the cleavable cross-linking reagent 3,3'-dimethyldithiobis(propionimidate). The reaction products were analyzed by two-dimensional SDS-gel electrophoresis in the absence and presence of β-mercaptoethanol, which cleaves the adducts again. The polypeptides VIa and VIb were only cross-linked with polypeptides II and Va, and polypeptide VIc only with polypeptide II[136]. This indicates that polypeptides VIa, VIb, and VIc are located in the close proximity of polypeptide II, which contains the binding site for cytochrome c. This assumption is corroborated by findings of *Bisson* and *Montecucco*, who cross-linked the cytochrome c—cytochrome c oxidase complex and found not only adducts between cytochrome c and polypeptide II but also between cytochrome c and polypeptides VIa, b, and/or c[137].

These results indicate a "regulatory" or "modifying" effect of the cytoplasmical-synthesized polypeptides. At present, their physiological meaning can now only be presumed: The respiratory rate, normally controlled by the supply of ADP ("respiratory control")[138], could be additionally regulated in a tissue-specific way by the type of substrate available (intramitochondrial NADH, sulfite, extramitochondrial NADH). Some polypeptides could function as substrate-specific receptors that modify the activity *via* a conformational change. The coupling of respiration and proton translocation could be variable[24] and regulated by tissue-specific polypeptides, which may, for example, represent receptors for cellular effectors (cAMP, cGMP, $Ca^{2+}$, $P_i$, thyroid hormones *etc.*). By partially "uncoupling" electron and proton transport, more heat would be produced, and thus a tissue-specific regulation of thermogenesis would be conceivable.

## 8. The Evolution of Cytochrome c Oxidase

Comparison of cytochrome c oxidase from mammals with that from prokaryotes reveals an astonishing structural and functional similarity that has remained unchanged during the course of more than two billion years of independent evolution: 1) Both enzymes react with animal cytochrome c, although at different rates[25, 100]. 2) The active center of both enzymes contains two heme a and two copper ions[25]. 3) In both cases electron transport from cytochrome c to $O_2$ is coupled with an active proton translocation across the membrane[40, 45, 46, 106]. This uniformity of respiration in most aerobic organisms was already recognized by *Otto Warburg*, who wrote in 1928[139]: "Entsprechend gibt es in der Natur nicht nur 1 Atmungsferment, aber der Mechanismus der Atmung in einem bestimmten Fall ist, wie der Mechanismus des Sauerstofftransports, ein bestimmter und einheitlich. Wie zum Transport des Sauerstoffs, so benutzt die Natur zur Verbrennung durch Sauerstoff *vorwiegend einen* Mechanismus. Denn das Atmungsferment in Hefezellen und Chorion, in Leber-

zellen und Blutplättchen, in Leukozyten und Seeigeleiern verhält sich im Prinzip gleich"[*].

In spite of this, with increasing differentiation and specialization of cells we find a growing complexity of the enzyme, which is reflected in its increasing number of "subunits". While the same function ($O_2$-reduction and proton translocation) in the prokaryotic enzyme is carried out by two or three polypeptides, in unicellular eukaryotic organisms seven or eight polypeptides are involved in the enzyme complex. The differentiation to multicellular organisms, composed of specific organs, is connected with a further increase in the polypeptide number (in mammals up to thirteen), as well as with a multiplication and independent evolution of tissue-specific polypeptides in the same organism (Fig. 7).

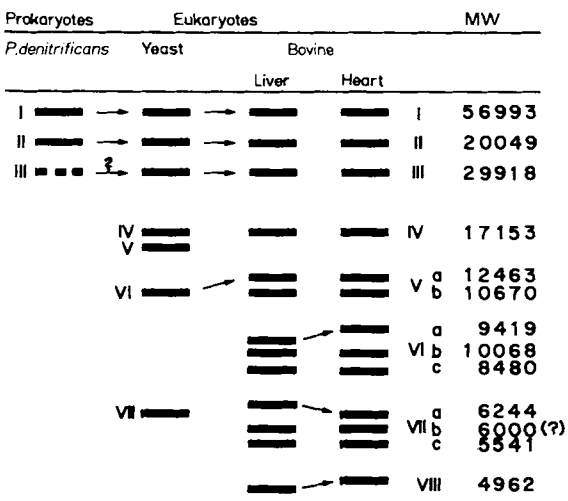

Fig. 7. Evolution of the cytochrome c oxidase complex. The bands represent individual polypeptides that correspond to the bands of SDS-gel electrophoresis. MW is the relative molecular mass of the bovine heart polypeptides [85] calculated either from the DNA-sequence (I, III) or from the amino acid sequence. The arrows indicate evolutionary relationships. The relationship of the other bands between bovine liver and heart has established yet not been. The homology of polypeptide VI from yeast with V from bovine heart was demonstrated [142].

If we consider the mitochondrial-synthesized polypeptides I—III as catalytic and the cytoplasmic synthesized as regulatory or modifying subunits of the enzyme complex, the evolution of cytochrome c oxidase is reflected by an increase in regulatory capacity. Here a general principle of the evolution of biological systems becomes evident: The basic principles of energy and substrate metabolism (respiration, glycolysis), as well as the storage and expression of information (DNA-replication, protein synthesis) have remained unchanged during the course of evolution in all living organisms. The regulation of the various steps, however, has changed and has led to extremely complicated mechanisms in highly differentiated organisms (*e.g.* regulation of glycogen synthesis and degradation[140, 141]).

[*] "Correspondingly, in nature not only is there 1 *Atmungsferment*, but the mechanism of respiration in a particular case is, as the mechanism of transport of oxygen, specific and uniform. Just as in the transport of oxygen, nature uses *predominantly one* mechanism for combustion by oxygen. Because, in principle, the *Atmungsferment* in yeast cells and chorion, in leukocytes and sea urchin eggs behave the same".

## 9. Outlook

Since the discovery of the *Atmungsferment* by *Otto Warburg* in the twenties, our knowledge about this enzyme has grown enormously. But with every new finding the number of unanswered questions increased. At present, intensive research is being carried out to determine the structure of the active center and the mechanism of $O_2$-reduction. Here, a detailed interpretation can be expected in the near future. Far more difficult appears to be the investigation of the coupling of electron transport and proton translocation in the cytochrome c oxidase complex. So far, the mechanism of the directed proton transport cannot be explained for any of the proton translocating membrane enzymes, although for one enzyme (bacteriorhodopsin) the amino acid sequence and the three-dimensional structure are known. Of particular interest is the occurrence of isoenzymes of cytochrome c oxidase in different organs of higher animals which differ in their catalytic and structural properties as well. The differences presented in this progress report point to a complex regulation of the enzyme. Intensive research on the structural differences of the polypeptides as well as on the functional meaning of the various subunits is necessary to provide an understanding of the adaptation of respiration and the associated ATP synthesis to the specific requirements of the different tissues of higher organisms.

*I would like to thank Prof. R. Thauer for his helpful criticism, Mrs. Roller-Müller for typing the manuscript, the Deutsche Forschungsgemeinschaft (SFB 103, A2) for grants, and the Fonds der Chemischen Industrie for a generous donation.*

# Proximity Effects in Organic Chemistry—The Photoelectron Spectroscopic Investigation of Non-Bonding and Transannular Interactions**

**By Hans-Dieter Martin* and Bernhard Mayer**

Classical structural formulas often convey the impression *only those* relationships between the atoms are of importance which hold a molecule together as symbolized by the chemical bonds. However, many interactions between atoms or groups of atoms are not adequately denoted in this manner. Nevertheless, their existence can have important consequences for *ground state energies* (*cis*-difluoroethylene is more stable than *trans*-difluoroethylene), *conformations* (the *syn* form of methyl vinyl ether is more stable than the *anti* form), *reactivities* (an *endo* cyclopropane ring in 7-*anti*-norbornyl derivatives accelerates solvolysis by a factor of $10^{14}$), *UV spectra* ("superposition" of the π-systems of acridine and purine—bonded through a four-membered chain—results in hypochromism), *CD spectra* (the inherently symmetrical but dissymmetrically perturbed chromophore of 2-deuterionorbornadiene allows the observation of three transitions in the near UV), and *ESR spectra* (the long-range coupling with H-4 in the bridgehead bicyclo[2.1.1]hex-1-yl radical equals 22.5 G). Since orbital interactions are involved in most intramolecular effects of this kind, *photoelectron spectroscopy* has proven an informative and valuable extension to other methods.

## 1. Introduction

### 1.1. Substituent Effects

The empirical knowledge that functional groups profoundly determine the reactivity of organic compounds led to the formulation of the concept of substituent effects. These can be broadly divided into three categories: polar or electrostatic effects, as well as conjugational and steric effects[1]. The discussion of the polar effects and their subdivision into inductive and field components (through-bonds and through-space, respectively) fills an important and voluminous part of the literature[2] but for our purposes is less decisive. Classical π-conjugation and π-delocalization may or may not occur within groups or chromophores which interact with each other in a non-bonding manner. Steric effects (steric hindrance) are generally associated with non-bonding compression and repulsion; in principle they can, however, be either repulsive or attractive[3].

Because the effects treated in this review do not, by definition, concern the relationships between neighboring atoms, these will be treated only with regard to a possible relay action. Orbital interactions between neighboring atoms have already been reviewed[4–7]. A summary of important 1,2-interactions is shown in Figure 1.

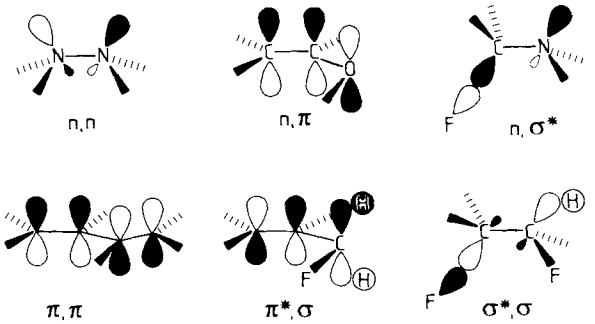

Fig. 1. 1,2-Interactions [4—6] between orbitals on neighboring atoms. The relaying action of these vicinal 1,2-contacts is of importance for longer range effects: n = localized lone pair of electrons; π = p-orbital in a π-system; σ = localized two-center σ-orbital [8]. The nomenclature is as in [4—6]. n,n: hydrazine; n,π: enol ethers; n,σ*: fluoromethylamine; π,π: 1,3-dienes; π*,σ: 3-fluoropropene; σ*,σ: 1,2-difluoroethane.

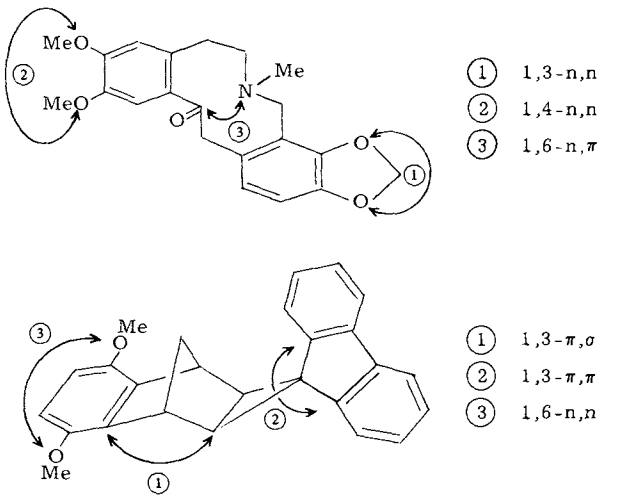
Institut für Organische Chemie I der Universität
Universitätsstraße 1, D-4000 Düsseldorf (Germany)

[**] Because the term neighboring group participation is reserved for "through space" interactions between substituent and reaction center [19], all interactions between non-neighboring groups or orbitals (distance ≥ 1,3) are designated as proximity effects in this article, irrespective of whether they are "through space" or "through bond" in nature.

### 1.2. Classification

The classification of non-bonding interactions ($\geq 1,3$) used here is shown in Figure 2. Topology rather than the nature of the interaction is decisive in this classification, *e.g.* the question is one of the extent to which two electron pairs in a 1,4-relationship "feel" each other[9a].



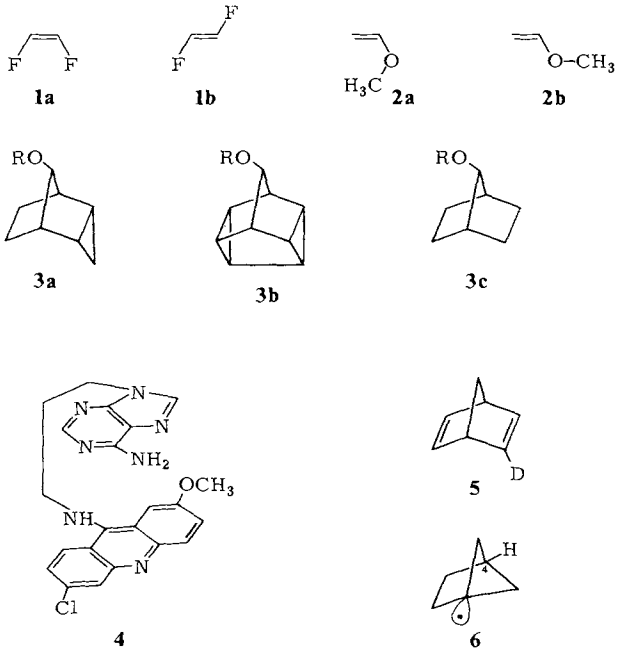


Fig. 2. Classification of non-bonding interactions used in this article. The examples, *i.e.* the alkaloid cryptopine and the spirocyclic fluorene, contain several groups or chromophores relevant to transannular interactions and show interesting neighboring group participation effects [8b].

### 1.3. Examples

The importance of non-bonding interactions as well as their influence on ground and excited states, transition states, and the relationship with PE spectroscopy is illustrated by the following examples.

#### *1.3.1. Ground State Energies*

*cis*-1,2-Difluoroethylene **1a** is $1080 \pm 120$ cal/mol more stable than the *trans*-isomer **1b**. Different explanations have been given[5, 10–15] for this *cis-effect* (see also Chap. V, 13 in [5]). The following results are derived from *ab initio* calculations[13], also taking polarization functions and correlation energies[10] into account: with a sufficiently large basis set the Hartree-Fock approximation predicts that **1a** is more stable than **1b**; also, the *steric attraction* of the F atoms in **1a** cannot be neglected (Fig. 3a). Hence, nonbonding interactions of this kind could also be detectable by PE spectroscopy.

#### *1.3.2. Conformations*

The *syn*-form **2a** is more stable than the *anti*-form **2b**. A plausible reason may be found in the attractive 1,4-$\pi,\sigma$-interaction (Fig. 3b). This has consequences for the PE spectrum[4].

#### *1.3.3. Reactivities*

That **3a** and **3b** are several orders of magnitude more reactive than **3c** can be ascribed to the stereoelectronically favored participation of the three-membered ring leading to formation of a homoaromatic transition state[16] (Fig. 3c). This $\pi$-type $\sigma$-participation ($\pi\sigma$[17a]) can also be detected by means of the $\rho^+$ values of arylated derivatives having increased electron demand[17–19] (Fig. 3d). Photoelectron spectroscopy ought to be able to detect such delocalization of electrons in three-membered rings, even (or especially) in cases where the reaction has not progressed so far that nuclear displacements have occurred and a bridged homoaromatic ion has been formed.

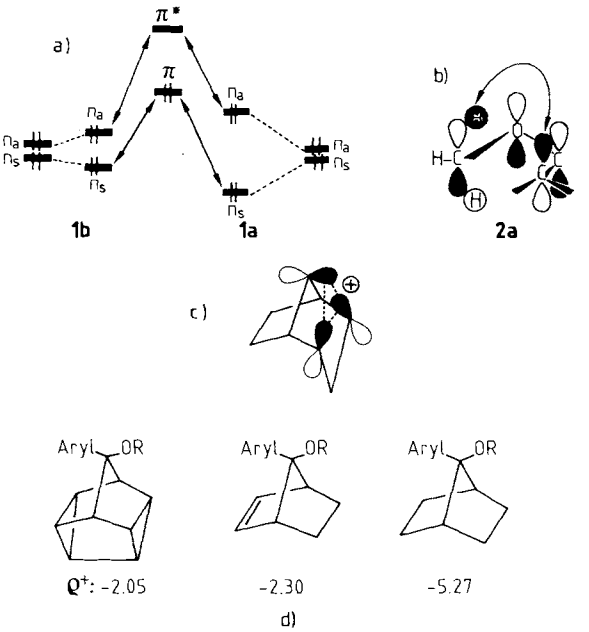

Fig. 3. a) $\pi$-Orbital interactions in **1a** and **1b**. The larger splitting $n_a/n_s$ in **1a** has the consequence that, *inter alia*, the two-electron interaction, $\Delta E_{\pi^* n_a} = 2(H_{\pi^* n_a} - SE_{n_a})^2/(E_{n_a} - E_{\pi^*})$, is more important in **1a** than in **1b** [5, 13] ($H$ = Interaction parameter, $S$ = Overlap integral). The symmetry elements are: $\sigma$ in **1a**, $C_2$ in **1b**. b) Attractive 1,4-$\sigma,\pi$-interaction in **2a** [4, 5]. c) Homoaromatic ion in the solvolysis of **3a**. d) "Tool of increasing electron demand" with $\rho^+$ values indicating $\pi\sigma$- or $\pi$-participation [17a]. The $\rho^+$ values were derived using species with Aryl = *p*-$CH_3OC_6H_4$, $C_6H_5$, *p*-$CF_3C_6H_4$, 3,5-$(CF_3)_2C_6H_3$; R = *p*-$O_2NC_6H_4CO$.

### 1.3.4. UV and CD Spectra

These spectra may exhibit effects (batho- and hypsochromic shifts; hyper- and hypochromic effects) indicative of interactions between two non-conjugated (*i.e.* non-neighboring) chromophores in a molecule. The reason may be found in a non-zero direct overlap of non-neighboring atomic orbitals, or in the transmission properties of other suitable orbitals (electron delocalization). However, it should be borne in mind that a delocalization of the excitation energy is possible even with a vanishing overlap (exciton delocalization)[20–25]. The molecules **4** and **5** represent typical examples of this. The contribution made by PE spectroscopy in the interpretation of unusual UV phenomena in homoconjugated π-systems will be illustrated using the example of norbornadiene **7** (Fig. 4). The locally ex-

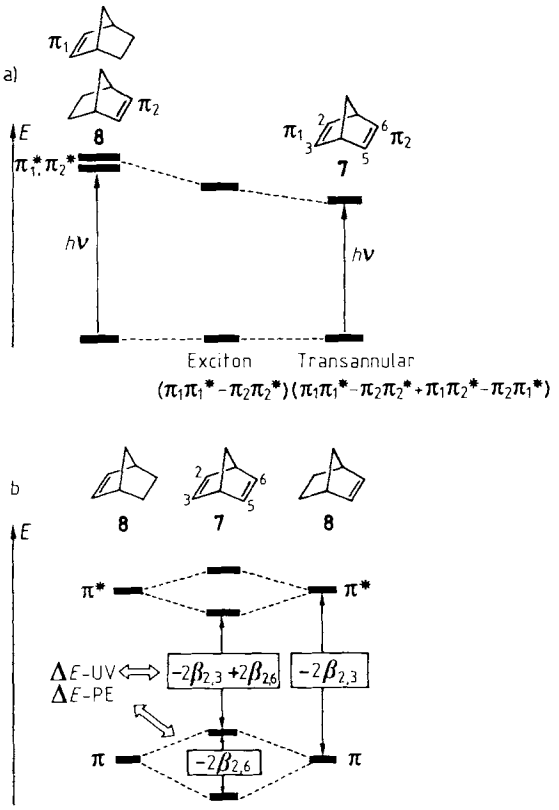

Fig. 4. Relationship between transannular π-overlap and UV properties in **7** [20—22]. a) Model with exciton and charge-resonance states. b) Simple LCAO model with UV and PE spectroscopic energy differences.

cited configurations of one of the two double bonds of **7** mix with each other and lead to a first excited minus-exciton state ($^1Ex^-$), which is in reasonable agreement with experiment[20, 21]. If the transannular overlap of the π-orbitals $\pi_1$ and $\pi_2$ is also taken into account, as expressed by the resonance integral $\beta_{2,6}$, the exciton state will also interact with the minus charge-resonance state ($^1CR^-$) in which a $\pi_1$ electron has been excited into the $\pi_2^*$ orbital. This latter interaction is given by $2\beta_{2,6}$[21]. Of course, the value of the transannular $\beta_{2,6}$ is significantly smaller than that of the vicinal resonance integral $\beta_{2,3}$; the following approximate relationship holds: $\beta_{2,6} \approx 0.3\beta_{2,3}$[26] (Fig. 4a). The influence of the transannular resonance integral $\beta_{2,6}$ on the UV spectrum of **7** is even more evident in the LCAO model[21, 22] (Fig. 4b): the HOMO-LUMO difference in **7** is $\Delta E = -2\beta_{2,3} + 2\beta_{2,6}$, *i.e.* in this model norbornadiene **7** should absorb at approximately $2\beta_{2,6}$ longer wavelength than norbornene **8**. The difference between the occupied MO's of **7** also amounts to $2\beta_{2,6}$. Such differences are measurable by PE spectroscopy.

### 1.3.5. ESR Spectra

Long-range interactions and spin density distributions in radicals have been thoroughly investigated[27]. The mechanism of these interactions can also be analyzed by means of the paramagnetic NMR contact shift[28]. The coupling constant $a_M$ with nucleus M can be resolved into spin delocalization $a_d$ and spin polarization $a_{sp}$ components[27a, b], whose magnitudes and signs are often decidedly dependent on stereochemistry. Furthermore, spin delocalization may also be discussed in terms of through-space and through-bond interactions which may mutually influence each other. Figure 5 illustrates the interpretation of the $a_{H4}$ values in bicyclo[2.2.1]hex-1-yl **6** and bicyclo[2.2.2]oct-1-yl **9** as a combination of through-bond and through-space terms[27c]. Orbital interactions of this type should be measurable using PE spectroscopy, *e.g.* in the diamine 1,4-diazabicyclo[2.2.2]octane **10**.

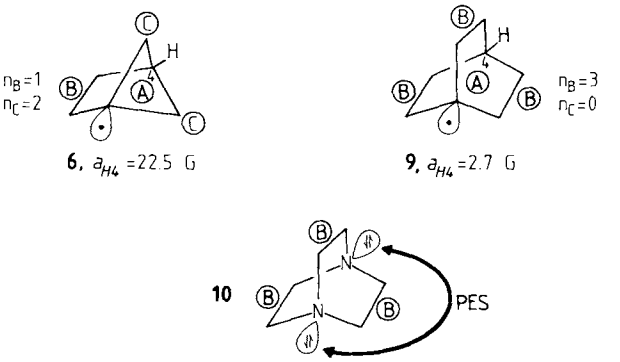

Fig. 5. Spin delocalization in bridgehead radicals [27c, f].
$a_{H4} = (A - n_B B + n_C C)^2$
A: "through space"; B: "through 3 bonds"; C: "through 2 bonds".
The coupling routes A and C amplify each other in **6**. Routes A and B compensate each other in **9**. The analogous interaction between the electron lone-pairs of both N atoms in **10** can be measured by PE spectroscopy [218].

## 2. Nomenclature and Terminology

The following is a description of some concepts which are important in proximity effects. They are not, however, always used in a consistent manner.

*Homoconjugation:* This denotes the through-space interaction between π-bonds that are separated from each other by formal isolators, such as $(CH_2)_x$. The concept was derived from observations made on the cholesteryl system and the cyclobutenyl cation[29]. Compounds **4** and **7** represent further examples of homoconjugation.

*Transannular Conjugation:* This has been used to describe homoconjugation involving π-overlap only[30]. It is only one extreme of the more general phenomenon of homoconjugation.

*Homoaromaticity:* Homoaromatics are cyclic $(4n+2)$ π-systems interrupted in one or more places by saturated centers, but whose geometry is such that overlap of the p orbitals is maintained across the formally isolating gap[29c-e]. Classical examples of homo-, bishomo-, and trishomoaromatics are found in the chemistry of carbocations. Homoconjugative interactions in neutral closed-shell systems seem, with possibly only a few exceptions[31d], to lead to destabilization[31a]. This homoaromatic conjugation also plays no role in mono- or bicyclic anions[31b,c]. Only in cations is the energy difference between the low-lying LUMO and a HOMO of the proper symmetry sufficiently small. The same holds for bicycloarenes[32].

*Hyperconjugation:* This expression, coined by *Mulliken*[33], describes the overlap of suitably oriented σ-bonds ($CH_3$, $CH_2$, C–C) with π-systems (*e.g.* the π*,σ interaction shown in Fig. 1). Hyperconjugation is important in stabilizing conformations of ions[34,35], and hence also in PE spectroscopy.

*Homohyperconjugation:* Whereas hyperconjugation can be comprehended as a β- or a 1,2-vicinal effect (Fig. 1), homohyperconjugation describes the corresponding γ- or 1,3-through-space effect[36a]. Experimental evidence has been obtained from ESR[28a,36b,c], PES[37a,b], and electron transmission spectroscopic studies[38].

*Through-Space and Through-Bond Interactions:* These involve homoconjugative and multiple hyperconjugative interactions, respectively[9].

*Spiro-, Lati-, and Longicyclic Conjugation:* These terms characterize topologies formed by union of two or three polyene ribbons[32]. The interaction between the π units in these polycycles is composed of homo- and hyperconjugation.

*Subjacent Orbital Control:* This is an electronic factor which favors symmetry-forbidden concerted reactions[39a]. For example, the pericyclic transition state of the suprafacial 1,3-sigmatropic shift can be electronically stabilized by participation of the $\psi_1(S)$ allyl orbital.

*Superjacent Orbital Control:* n-Orbitals are repulsively destabilized by vicinal adjacent lower-lying C–H σ-orbitals

$$E_{\text{repuls}} \approx 2 \cdot S^2 (E_n + E_\sigma) - 4 S H_{n\sigma}$$

higher-lying C–X σ*-orbitals (X = Cl, OR, *etc.*) stabilize attractively[39b]

$$E_{\text{attract}} \approx 2 (H_{n\sigma^*} - S \cdot E_n)^2 / (E_n - E_{\sigma^*})$$

$S$ = overlap integral, $H$ = interaction parameter

This results in a preference for conformations in which the n- and σ*-orbitals are nearly eclipsed. The *anomeric effect* may be rationalized in this manner[40].

*σ-Conjugation:* This concept was developed to describe the 1,2-vicinal conjugation of a vacant p-orbital with a σ-bond without bridging[18,41]. This is a special case of hyperconjugation. The cyclopropylmethyl cation is a particularly interesting and problematic example: a change in the bond lengths leads to stabilization over and above normal hyperconjugation[19,42].

*σ,π-Conjugation and Vertical Stabilization:* Polarizable σ-bonds stabilize neighboring cationic centers without leading to a change in bond lengths and bond angles[43]. This, too, is a case of hyperconjugation for which the more fitting description "vertical stabilization" is used. Since these interactions are important in all Franck-Condon processes, they will also be of importance in PE spectroscopy.

π-Conjugation: The classical $p_\pi p_\pi$-conjugation in the allyl cation, for example, is the result of allylic overlap of a vacant cationic p-orbital with a double bond[18].

*n-, σ-, π-, and π,σ-Participation:* Reactive centers can be stabilized in a non-vertical manner by homoconjugated n- or π-orbitals or by appropriate σ-bonds. Bridging and/or rearrangement may result[17-19,41]. *Neighboring group participation* can be defined by the nature of the electrons involved, that of the participating group, and the size of the ring formed in the transition state, *e.g.* n-$NH_2$-5-participation[19].

*Perpendicular Conjugation:* This is a type of homoconjugation in which the participating p- or π-orbitals form a more or less perpendicular structure. This kind of conjugation is realized in some polycycles or propellanes[44].

*Non-Bonding Interactions:* Attractive dispersion forces, repulsion between electron shells, and electrostatic interactions can occur between non-bonded atoms. Non-bonding interactions (potential: $V_{nbi}$) play a significant role in aliphatic compounds, alicycles, and biopolymers[3,45-49]. The following heading describes a different type of non-bonding attraction.

*Steric Attraction:* The stabilizing two-electron interaction

$$\Delta E = 2 (H_{ij} - S_{ij} \cdot E_i)^2 / (E_i - E_j)$$

can also occur between atoms not bonded directly with each other provided the wave functions are of appropriate phase[5,50].

*Supraannular Effect:* Axial electron-withdrawing substituents in the 4-position in cyclohexenes purportedly interact electronically with the π-bond. It is doubtful whether such an effect exists[51].

*cis-Effect:* This term covers the higher stability of many *cis*-disubstituted ethylenes compared with their *trans*-isomers (see Section 1.3.1)[5,10-15].

*Circumannular Conjugation:* This describes the interaction between oppositely situated π-centers across an interposed $CH_2$ group, and is especially evident in four-membered rings. It is a hyperconjugative effect which is distinct from the direct transannular homoconjugation[52a-d].

*The Frangomeric Effect:* This refers to an increase in reactivity due to synchronous fragmentation[52e].

*Nonequivalent Orbital Extension:* π-Orbitals can rehybridize and distort unsymmetrically under the influence of neighboring σ-orbitals, for example. The geometry of the molecule is altered by the tilting of the π-orbitals[52f].

*π-Electron Steric Effect:* This effect describes the axial-equatorial equilibrium in 1-methoxy-3-(methylene)cyclohexane as a result of dipole-dipole and orbital interactions[52g].

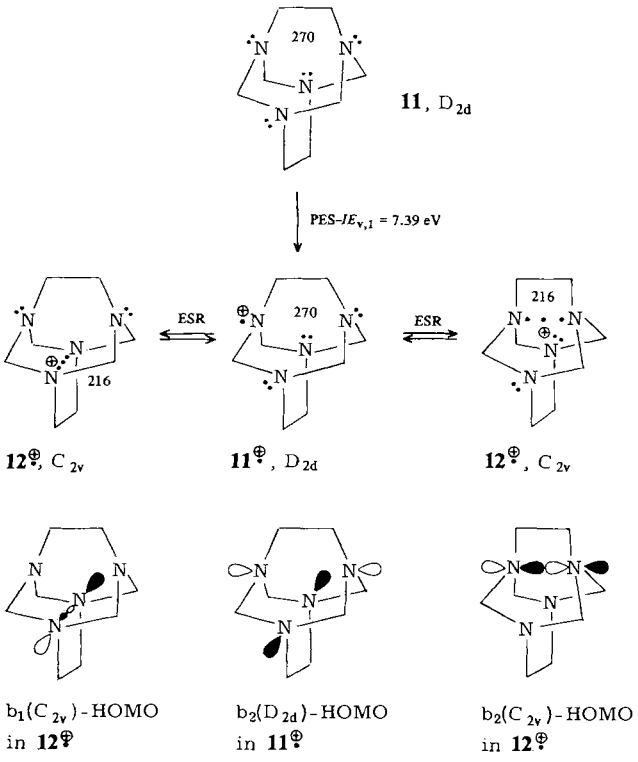
## 3. Method

Reviews on photoelectron spectroscopy at various levels[53-60] as well as monographs for further study[61-66] are available. The uninitiated reader is advised to study the following references in the sequence given: [56, 58, 59]→[53, 54]→[62, 63].

### 3.1. Vertical Ionization

Photoelectron spectroscopy allows the experimental determination of vertical ionization energies $IE_v$, more rarely adiabatic ionization potentials. In vertical ionization occuring on a time scale of *ca.* $10^{-15}$ s, the internuclear distances remain unchanged during the transition and the process can be represented by a vertical line in a plot of the potential energy against nuclear separation. The vertical ionization energy is of importance in the discussion of proximity effects for two reasons. Firstly, it allows a determination of orbital energies using Koopmans' approximation (see Section 3.2). Secondly, chemists are normally interested in interactions concerning the neutral non-ionized ground state. Hence, if one wishes to obtain information on the neutral ground state from the radical cation, it is sensible to examine a radical cation in which the geometric parameters such as internuclear distances and bond angles have remained constant. This is the "vertical ion". The vertical ionization potential $IE_v$ corresponds to the distance between the potential curves for the molecule and the ion at the nuclear configuration $R$ at which the lower curve exhibits its minimum. The value of $IE_v$ is usually determined from the maximum $E_{max}$ of the PE band. This is, however, not entirely correct: it is better to take the centroid $E_{cg}$ of the band[62,67]. Thus, for example, $E_{max}$ of the second band of $N_2$ lies at 16.91 eV, whereas $E_{cg}$ is 17.02 eV[67].

In connection with proximity effects, the value of $IE_v$ is of importance as a measure of *vertical stabilization* (cf. Section 2)[19,43]. According to *Traylor et al.*, a substituent stabilizes a developing positive center vertically if the geometry remains invariant upon approaching the transition state. Otherwise, the stabilization is said to be non-vertical. Thus σ,π-hyperconjugation is a vertical stabilization; however, bridging is a non-vertical stabilization. Therefore, if substituent effects on rates of reaction are found to correlate with the ionization energies $IE_v$ (or with the frequencies of charge-transfer bands), this is a clear indication of vertical stabilization in the transition state[68]. Tetraazatricyclo[4.4.1.1$^{4,9}$]dodecane **11** offers an instructive example of the difference between vertical and non-vertical radical ions (Fig. 6)[69]. If the PE spectrum of **11** ($D_{2d}$ symmetry) is analyzed in terms of vertical ionization in the gas phase, the orbital structure obtained is that of a $D_{2d}$ ion of the same geometry. The unpaired electron in this ion occupies a $b_2$-HOMO. However, if the $D_{2d}$ ion is generated in solution, it undergoes distortion to a $C_{2v}$ ion, which has roughly the same energy, but is more strongly solvated because of the presence of a transannular three-electron σ-bond between the two N atoms. This equilibrating $C_{2v}$ ion $\mathbf{12}^{\oplus}$ can be detected by ESR spectroscopy (Fig. 6). Only the "vertical" $D_{2d}$ ion can give information on the proper-



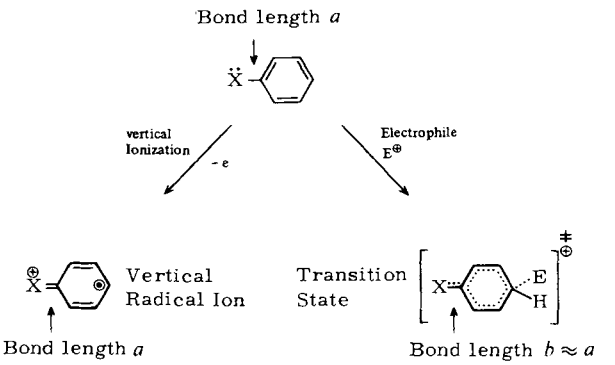


Fig. 6. Vertical and non-vertical ionization of **11**. NN distances (MINDO/3) in pm [69]. PE ionization gives $\mathbf{11}^{\oplus}$, $D_{2d}$; $\mathbf{12}^{\oplus}$, $C_{2v}$, is more stable in the condensed phase.

ties of the ground state ($D_{2d}$ symmetry) of **11**, *e.g.* the magnitude of the transannular overlap. Vertical ionization energies can also yield information on how substituents influence the reactivity of a particular system. That the vertical $b_1$ ionization energies of substituted benzenes $C_6H_5X$ correlate with the substituent constants σ indicates that at least a sizable part of the stabilization of the transition state by the substituent is of a vertical nature; accordingly, no significant geometrical change should occur[43,70].

### 3.2. Use of Koopmans' Theorem

According to Koopmans' theorem[71], the negative SCF orbital energies, $-\varepsilon_k^{SCF}$, for a closed shell molecule equal—to a first approximation—the vertical ionization energies:

$$-\varepsilon_k^{SCF} = IE_{v,k}$$

In this approximation the ionic state is described in terms of the molecular orbitals pertaining to the ground state. Both electron correlation and electron reorganization are neglected. The reliability of the approximation is usually due to cancellation, to a certain extent, of the two effects. The assignment of orbital energies to the ionization energies is a prerequisite for the use of PE spectroscopy to study neighboring group effects and requires, therefore, that Koopmans' theorem be valid. This approximation can be used for the valence electrons in connection with conformational analysis. No difficulties are expected, even in the case of highly localized orbitals capable of reorganization, as long as the nature of the orbital is not influenced by a conformational change[4]. In order to be of use in the study of proximity effects, the relevant orbitals must have so-called Koopmans' defects of the same sign and magnitude. The Koopmans' defect $\Delta K$ is defined as the difference between the *ab initio* Hartree-Fock orbital energy $\varepsilon_k^{ai}$ and the experimentally determined vertical ionization energy $IE_{v,k}$[71c]:

$$\Delta K(k) = -(\varepsilon_k^{ai} + IE_{v,k})$$

Koopmans' defects concern both π- and σ-orbitals, as is clearly seen from $F_2$ and $N_2$; in both cases the theorem is invalid. These two molecules are excellent candidates to provide an explanation for the defects by means of symmetry arguments. If, for example, in $F_2$ only the three highest occupied orbitals, $1\pi_g$, $3\sigma_g$, and $1\pi_u$, together with the LUMO, $3\sigma_u$, are considered, $\Delta K$ is described by the following dominant term[71d]:

$$\Delta K_i = [V_{ijkl}^2 + V_{ijlk}^2 + (V_{ijkl} - V_{ijlk})^2]/(\varepsilon_i + \varepsilon_j - \varepsilon_k - \varepsilon_l)$$

Here, i denotes the orbital to be ionized ($1\pi_g$, $3\sigma_g$, or $1\pi_u$), j the unoccupied orbital $3\sigma_u$, and k and l the other two occupied levels. $V_{ijkl}$ symbolizes $\langle\varphi_i(1)\varphi_j(2)|r_{12}^{-1}|\varphi_k(1)\varphi_l(2)\rangle$, and $\varepsilon$ denotes the orbital energy. The magnitude of the integral $V_{ijkl}$, which can be estimated using relatively simple symmetry arguments, determines $\Delta K$. The Koopmans' defects of the occupied orbitals in $F_2$ are shown in Figure 7. Although Koopmans' theorem may be expected to be valid

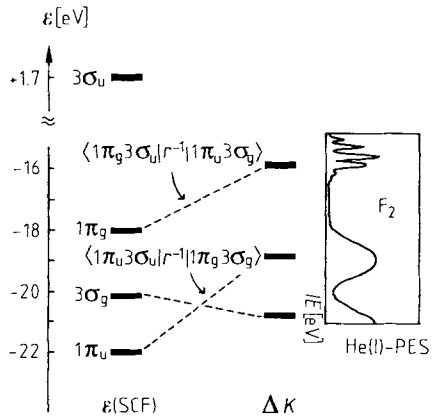

Fig. 7. Invalidity of Koopmans' theorem for $F_2$ [71c, d]. $\varepsilon$(SCF): *ab initio* orbital energy, $\Delta K$: Koopmans' defect. The important contributing integrals are indicated for the large defects from $1\pi_g$ and $1\pi_u$.

for the range of valence electron energies of interest here[71h], exceptions are known. These include formamide[66, 71h, i], acrolein[66, 71l–n], and nitrosomethane[71o–p] (Fig. 8). It is instructive, therefore, to examine the Koopmans' defects of valence electrons in some groups relevant to proximity effects: *cis*-1,2-difluoroethylene, **1a**, glyoxal, **13**, diazene, **14**, cyclopropane, **15**, norbornadiene, **7**, formamide, acrolein, and nitrosomethane. Proximity effects occur in some of these examples: 1,4-n,n-interactions are operative in **1a** and **13** and 1,3-π,π-interactions occur in **7**. Three-membered rings and azo groups are interesting partners for neighboring group effects. Figure 8 illustrates calculated and measured ionization energies, as well as the

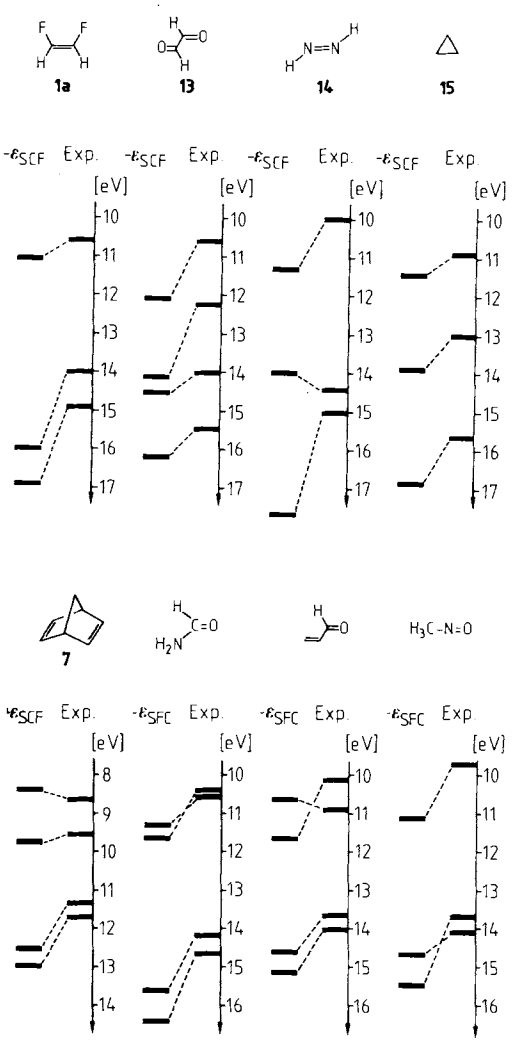

Fig. 8. Koopmans' defects for valence electrons: **1a** [71j], **13** [72a], **14** [72b], **15** [71c], **7** [72c], formamide [66, 71h, i], acrolein [71l–n], and nitrosomethane [71o, p]. As a rule, Koopmans' approximation may be assumed to be valid for molecules of this type in this energy range. Exceptions: formamide, acrolein, and nitrosomethane.

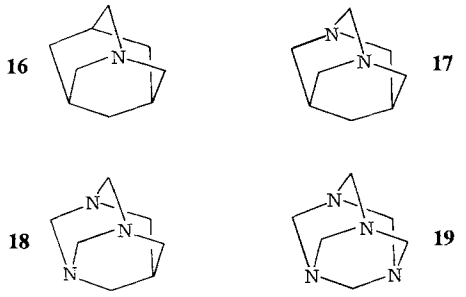

corresponding Koopmans' defects. Despite often sizable $\Delta K$ values, the sequence is usually maintained: a crossover is rarely observed for molecules of this type in this energy range. Rule of thumb[71k, o]: if in linear or planar molecules a low-lying π(σ) virtual orbital and a π(σ) occupied valence orbital exist, significant corrections to the valence ionization energies of σ(π) orbitals may be expected.

## 4. Interactions of the X,X-Type

### 4.1. n,n-Interactions

#### *4.1.1. 1,3-n,n-Interactions*

For geometrical reasons, 1,3-n,n-interactions may be expected in the azaadamantanes **17**—**19**.

The analysis will start with the monoamine **16**, in which the ionization energy of the nitrogen lone pair $IE_{1,v}=7.95$ eV[73,74]. In **17**, two effects caused by the second nitrogen atom need to be considered: a) the inductive or polar effect, which is associated with the electronegativity, and b) direct overlap of n-orbitals.

The inductive effect causes a *stabilization* of the average

$$\overline{IE_v(n)}=\frac{1}{m}\sum IE_{v,i}(n)=A_n$$

similar to that in azaarenes[77]. This can be interpreted as a stabilization of the n-basis orbital energies:

$$\Delta\overline{IE_v(n)}=\Delta A_n=\frac{1}{m-1}[A_n(\text{poly(m)azaadamantane})-A_n(\text{mono-azaadamantane})]$$

(m=2, 3, 4)

From the ionization energies $IE_v(n)$ the following values of $\Delta A_n$ are obtained for compounds **16**—**19**, respectively: 0.32, 0.37, and 0.47 eV. This inductive influence of n(N)-orbitals, which is in general possible for all polar groups, can be quantitatively correlated with the inductive substituent constants. The quinuclidine moiety has been the subject of detailed studies which show that the ionization energies are altered over a distance of three σ-bonds (or through space in the interior of the cage) by substituents in position 4 (Fig. 9)[78].

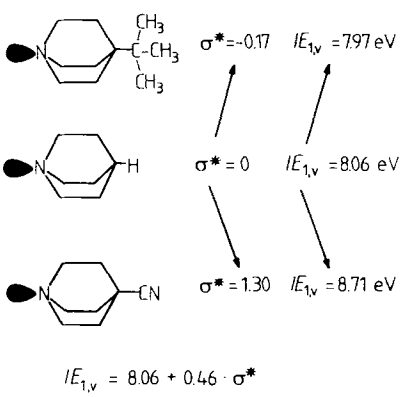

Fig. 9. Ionization energy as a function of inductive substituent constants using quinuclidine as an example [78].

Further analysis requires either the introduction of an interaction parameter $H_{nn}=\langle n_1|H|n_2\rangle$, obtainable either theoretically or from experimental data, or by direct evaluation of empirical $H_{nn}$ values from the observed spectrum (Fig. 10). It should be noted that the value of

$$H_{nn}=\langle n_1|H|n_2\rangle=1/2(IE_{v,1}(\mathbf{17})-IE_{v,2}(\mathbf{17}))=-0.52\,\text{eV}$$

obtained in this manner may, in principle, be a composite of several effects, even if only the direct overlap was taken into account in Figure 10.

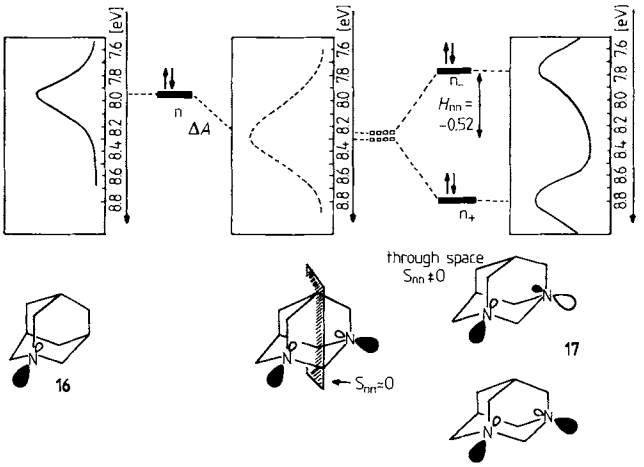

Fig. 10. 1,3-n,n-Homoconjugation in **17** as a consequence of inductive stabilization $\Delta A$ and direct overlap ($S_{nn}\neq 0$) [73—76]. The fictive spectrum in the center is for $S_{nn}=0$ and without through-bond coupling.

For the triazaadamantane **18** ($C_{3v}$ symmetry) two bands separated by $3\times 0.52=1.56$ eV are expected using this value of $H_{nn}$; furthermore, the intensity of the first band should be about twice that of the second. This expectation is confirmed by the PE spectrum of a methyl derivative[73] for which a separation of 1.8 eV was found, in surprisingly

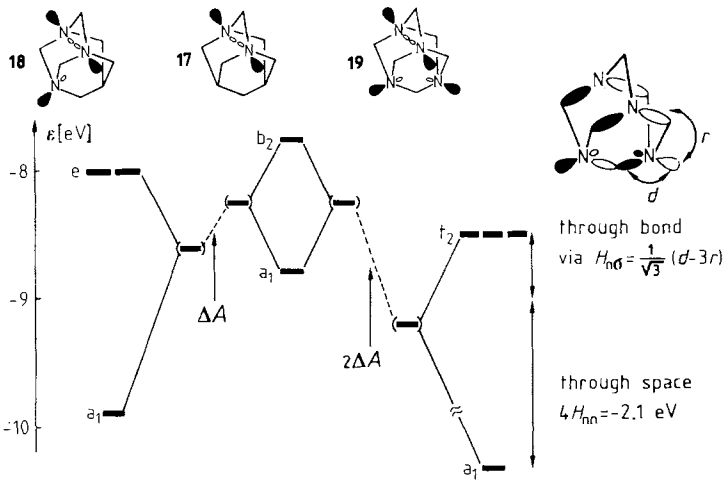

Fig. 11. 1,3-n,n-Interactions in di-, tri-, and tetraazaadamantanes **17**—**19** [73—76]. The energies correspond to experimental ionization energies. Levels in parenthesis represent estimated basis energies of the n-electrons. $\Delta A$: inductive effect. Through-bond coupling is described using equivalent orbitals (EO) [76, 79].

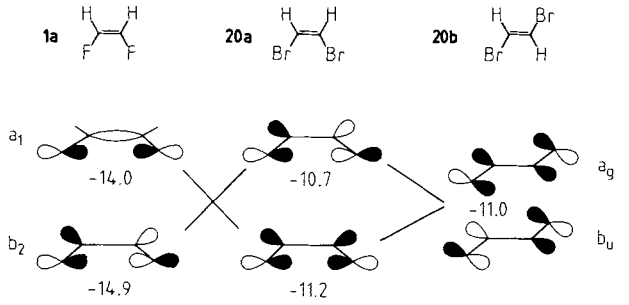
good agreement with the prediction (Fig. 11). Finally, the last member of this series, the tetraazaadamantane **19**, is interesting because of its high symmetry ($T_d$). Using the same value of $H_{nn}$ as for **18**, two bands with relative intensities of *ca.* 3 : 1, separated by $4H_{nn} \approx 2.1$ eV are predicted (Fig. 11). The observed band separation of at least 3.6 eV indicates the occurrence of additional interactions and, at the same time, illustrates the limits of the naive treatment. One effect ignored so far is the through-bond[9] interaction between n(N)-orbitals and interposed σ-bonds. It is, therefore, indicated in Figure 11 how such mixing with σ-levels of the same symmetry can lead to an increased $t_2$-$a_1$ separation.

### *4.1.2. 1,4-n,n-Interactions*

In Section 1.3.1 it was shown that non-bonding interactions in **1** might also be observable in the PE spectrum. Corresponding predictions for the orbital energies of **1a** and **1b** have been made[80]. Somewhat surprisingly, however, the spectra of **1a** and **1b** are extraordinarily similar and can hardly be distinguished within the limits of experimental error[71j]. The similarity is reproduced both by HAM/3 and GF calculations. Nevertheless, *ab initio* calculations[10,80] confirm that steric attraction may be expected as a result of charge transfer from the $n_a$- to π*-orbital: a positive F,F-π overlap population is computed[79]. Considerable 1,4-through bond couplings between the n-levels and the interposed π- or σ-orbitals associated with the C—C bond are found. Difluoro- and dibromoolefins show an interesting difference (Fig. 12): whereas in **1a** mixing with the C—C σ-bond leads to the sequence $a_1$ above $b_2$, in *cis*-dibromoethylene **20a** direct homoconjugation dominates with the result that the level ordering is now $b_2$ above $a_1$[81]. This through-space coupling disappears in the *trans*-isomer **20b**: the two levels ($a_g$, $b_u$) are now degenerate.



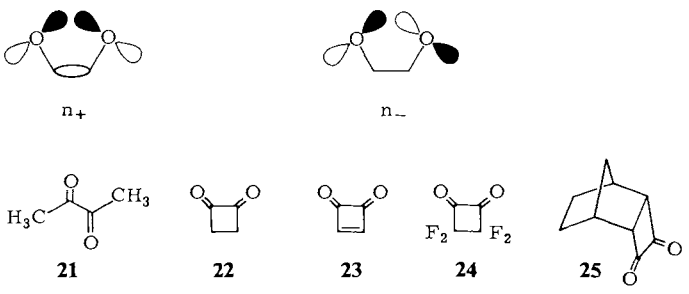


Fig. 12. Interplay between 1,4-n,n-through-bond coupling and direct 1,4-n,n-homoconjugation in difluoro- and dibromoethylene [71j, 81]. Energies in eV.

1,4-n,n-Interaction in α-dicarbonyl compounds is of particular importance, since it is closely associated with their color[20-22,82-93]. This is exemplified by the four-membered ring α-diketones **22**—**25**[85-91] (Table 1). A splitting $\Delta n \approx 2.2 \pm 0.3$ eV is found for all the diketones **21**—**25**, which can be considered as a measure of comparable 1,4-n,n through-bond coupling. Accordingly, other reasons must be found for the drastic color differences between these compounds: in **23** destabilization of $\pi^*_{CO}$ by $\pi_{CC}$[89], in **24** a larger inductive lowering of $\pi^*_{CO}$ than of $n_+$[90,91,99],

and in **25** a raising of the $n_+$ level by the inductive effect of the alkyl group[88].

Table 1. 1,4-n,n-Coupling in α-diketones. Different $n_+ \pi^*_+$ transition energies are found in spite of comparable n,n-interactions. This is due to several different effects.

### *4.1.3. 1,5-n,n-Interactions*

1,3-Diketones and their tautomeric enols exist in equilibrium, which is markedly influenced by the solvent. The PE spectrum of 2-methyl-1,3-cyclopentanedione **26** is shown schematically in Figure 13[94]. The two tautomers

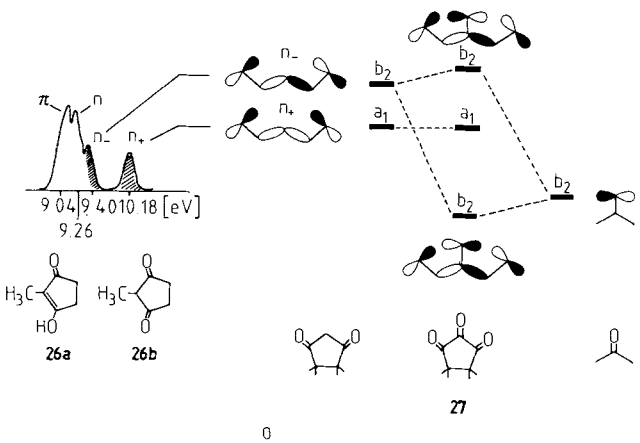

Fig. 13. Keto-enol equilibrium and PES of **26**. Hatched bands belong to **26b** [94]. The orbital sequence $n_- > n_+$ is confirmed by comparison with **27** [95].

give rise to four bands; the enol form dominates, and its two highest occupied MO's (π,n) have almost identical energies. The observation of two n-*IE*'s for the diketone is of interest: this arises from a 1,5-n,n coupling over the four σ-bonds[83,91]. The orbital sequence, $n_- > n_+$, could be elucidated by comparison with the tricarbonyl compound **27**[95].

*Peri*-substituted naphthalenes are examples of molecules with intramolecular steric hindrance resulting in exceptional properties. 1,8-Bis(dimethylamino)naphthalene, **28**, ("proton sponge") has a $pK_a$ value of 12.34 and is thus

more basic than normal aliphatic amines. This can be ascribed to a lowering of the strain energy on protonation. The PE spectrum of **28** demonstrates that an n,n-repulsion between the somewhat twisted amino groups is also present (cf. Fig. 14)[96]. The larger $n_-/n_+$ splitting in **28** relative to that in **29** is remarkable, as is the fact that not only direct homoconjugation but also through-bond interaction with lower lying naphthalene σ-orbitals of appropriate symmetry are responsible for this splitting.

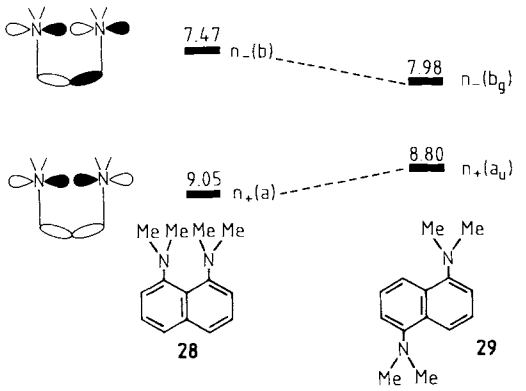

Fig. 14. Simplified representation of 1,5-n,n-repulsions in **28** and **29**. In reality the system is twisted and a clean σ-π separation cannot be expected [96] ($C_2$ conformation in **28**. The large splitting in **28** is the combined result of homo- and hyperconjugation which separate in the same direction.

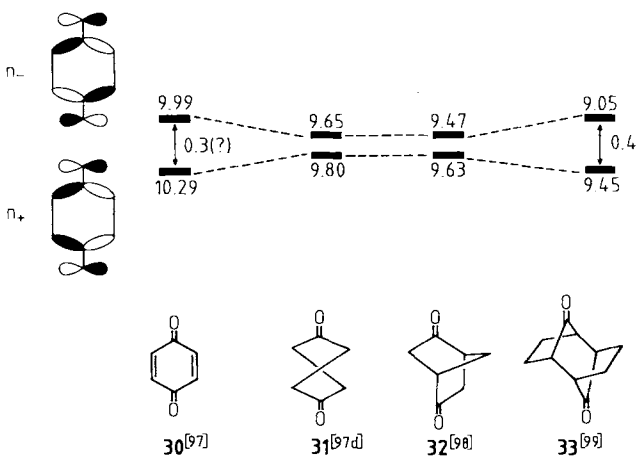
### 4.1.4. 1,6-n,n-Interactions

The PE spectrum of *p*-benzoquinone **30** has been the subject of considerable discussion[82,97]. The first four ionization energies of **30** are ascribed to two n- and two π-orbitals. Depending on the assignment, a value of at least 0.07 eV and at most 1.01 eV is obtained for the 1,6-n,n-coupling. If the first two bands are described as $n_-(b_{3g})$ and $n_+(b_{2u})$, respectively[97a,c] a n,n-splitting of 0.30 eV is obtained, whose absolute value compares well with that found for the three diketones **31**—**33**[97d,98,99]; however, the sign of the splitting remains uncertain (*i.e.*, $n_+ > n_-$ or $n_- > n_+$, Fig. 15). It is, in principle, possible that a purely electronic model with its associated orbital sequence fails to give an adequate description of *p*-benzoquinone, and that vibronic coupling between the states may have to be taken into account because of the small splitting between the ion states (PE bands). In addition, the geometry of **30** is not sufficiently well defined to allow sophisticated and costly calculations[97e].



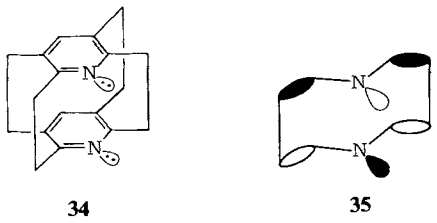


Fig. 15. 1,6-n,n-Interaction in γ-diketones. The size of the splitting in **30** and the sequences for **31**—**33** are uncertain. For fundamental difficulties in interpreting the PE spectrum of **30**, see text.

An entirely different topology for the 1,6-n,n coupling occurs in the diaza-phane **34**[100]. Its order of magnitude is 0.8 eV. The very small overlap integral $\langle n_1/n_2\rangle \approx 0.01$ signals the dominance of a through-bond mechanism, possibly occurring *via* **35**.

### 4.1.5. 1,7-n,n-Interactions

Bicyclo[3.3.0]octane-3,7-dione with $\Delta n = 0.33$ eV is the only δ-diketone to be described so far[91]. However, the tetraketone **36** was recently synthesized, and its dicarbonyl chromophore was found to exhibit an exceptionally large transannular $n_+/n_+$-coupling of 0.7 eV[87]. Since this interaction is also found in **37**, it is clearly a through-bond phenomenon. The cyclohexane σ-orbital of $b_2$-symmetry proves to be an effective transmitter. Although the $\pi_{CC}$-bond in **36** possesses the proper symmetry, it behaves as an effective insulator. The sensitivity of such σ-conjugations toward changes in the topology is shown by the bishomoadamantanetetraone **38**, in which the α-dicarbonyl groups are also separated by four σ-bonds, but whose topology is fundamentally different. No $n_+/n_+$-splitting greater 0.15 eV is observed in **38**. The σ-framework in adamantane does not possess any effective orbitals that could enable a clear discrimination between $1/\sqrt{2}(n_+ + n'_+)$ and $1/\sqrt{2}(n_+ - n'_+)$ (Fig. 16).

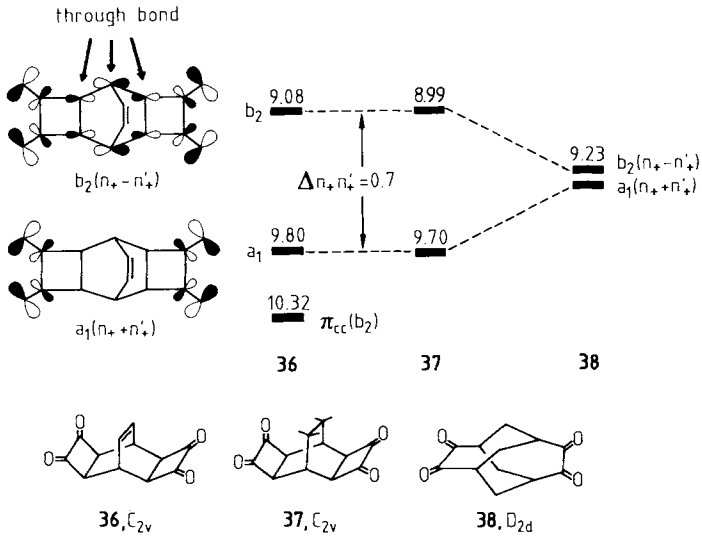

Fig. 16. Sizable 1,7-n,n-coupling *via* σ-bonds in **36** and **37**, as well as negligible n,n-conjugation in **38** [87] (experimental *IE*'s in eV). The calculated splitting, $\Delta n_+ n'_+ = 0.75$ eV (STO-3G), agrees well with the experimental value.

## 4.2. π,π-Interactions

### *4.2.1. 1,3-π,π-Interactions*

Since 1960 norbornadiene **7** has been a key compound for the study of transannular interactions[26]. The transannular conjugation of the two π-bonds is evident from the chemical[101], photochemical[102], and UV spectroscopic[20,103] properties. Norbornadienes have been proposed as reservoirs for storage of solar energy[102b,c]. Only limited information is obtainable from the UV spectrum; however, clearer results are provided by photoelectron spectroscopy[104], electron impact spectroscopy[105], circular dichroism[25a], and electron transmission spectroscopy[106]. Such studies have not only allowed an experimental determination of the theoretically predicted orbital energy differences (Fig. 17), but also, using **39** and **40** as reference compounds, of the sequence in **7**. This relies on the fact that in **40** the exocyclic π-bond must necessarily have $b_1$ symmetry; in **39** this orbital mixes only with the highest lying π-orbital of **7**, thereby defining the symmetry of the latter as $b_1$.

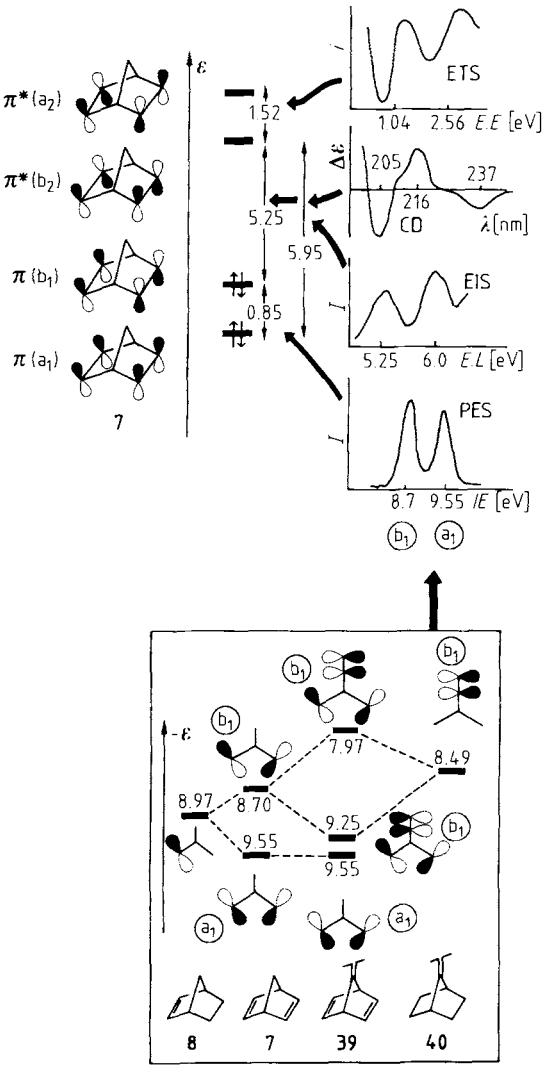

Fig. 17. Orbital energy differences in norbornadiene **7** obtained by different methods. PES: photoelectron spectroscopy [104]; EIS: electron impact spectroscopy (*E.L.* = energy loss) [105]; CD: circular dichroism [25a]; ETS: electron transmission spectroscopy (*E.E.* = electron energy) [106]; (I = intensity, i = current). Energies in eV. The orbital sequence $b_1 > a_1$ in **7** can be established with the aid of compounds **39** and **40**: only the higher orbital in **7** mixes with the exocyclic π-orbital $b_1$, the energy of which is known from the spectrum of **40** [104a].

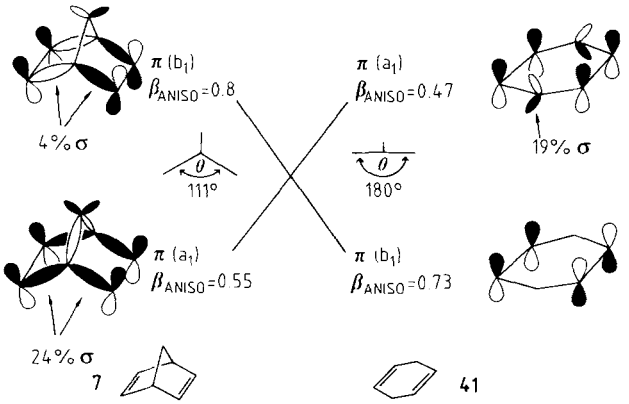
The experimental spectrum is reproduced exactly by *ab initio* calculations which take reorganization and correlation effects (see Section 3.2) into account. The calculations also provide an independent confirmation of the assignment made on the basis of **39**, and at the same time demonstrate the validity of Koopmans' theorem in **7** (see Fig. 8)[72c]. Apart from thes direct homoconjugative 1,3-π,π-interactions in **7**, π,σ-hyperconjugations should also be considered. The fact that in 7,7-difluoronorbornadiene both the $a_1$ and the $b_1$ π-orbitals are stabilized by the F-effect, even although the latter orbital has a node at the bridge bond, demonstrates a σ-contribution[107]. The relay action becomes evident by determining which σ-orbitals ("precanonical") combine linearly with the π-orbitals to give the canonical orbitals. Figure 18 shows the two relevant relay



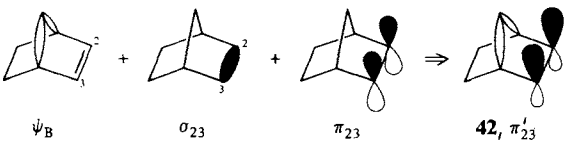


Fig. 18. Through-bond interactions in **7** and **41** within the concept of relaying σ-orbitals, and their dependence on the dihedral angle θ. Note that in **7** ($\theta = 111°$), not only $\pi(a_1)$, but *also* $\pi(b_1)$ experiences σ-coupling. In 1,4-cyclohexadiene **41**, in contrast, only $\pi(a_1)$ can mix with a precanonical $\sigma(a_1)$ for symmetry reasons. Consequently, the orbital sequence changes from $b_1 > a_1$ to $a_1 > b_1$ [9, 107–109]. This assignment is supported by the anisotropy parameter $\beta_{ANISO}$ [112]; the value of β is higher for the antisymmetric than for the symmetric orbital.

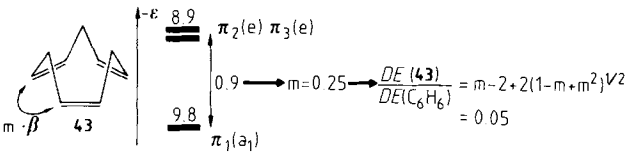
orbitals, $\sigma(a_1)$ and $\sigma(b_1)$, as determined by SPINDO-calculations, together with their percent contribution to the π-orbitals. An important trend becomes apparent: as the dihedral angle flattens to 180°, $\pi(b_1)$ can no longer participate in σ-coupling for symmetry reasons, and, as a consequence, the orbital sequence is reversed ($a_1 > b_1$)[9, 107–109]. Chemical consequences of 1,3-π,π-homoconjugation in **7** and of hyperconjugation in **8** include a) the ready photocyclization to quadricyclane following excitation $\pi(b_1) \rightarrow \pi^*(b_2)$[102], b) homo-Diels-Alder reaction under the polarizing influence of a dienophile[110], and c) *exo*-stereoselectivity resulting from non-equivalent orbital distorsion of the inclined and now hybridized π-orbitals[52f,111].

The *exo*-hybridization was explained using perturbation theory

$$\pi'_{23} = \pi_{23} + a \cdot \sigma_{23} + b \cdot \psi_b (a > 0,\ b < 0)$$

as shown in **42**. However, calculations indicate that the out-of-plane bending angle of the C–H bond in **7** amounts to only 2.3°[52f].

1,3-π,π-Homoconjugation plays a fundamental role in homoaromatic systems (see Section 2). The interesting question whether homoaromatic stabilization and/or interaction between the π-orbitals occurs in the neutral homoconjugated 1,4,7-cyclononatriene **43** can be unambiguously answered[113]: neither bond lengths and bond angles nor enthalpies of hydrogenation give any indication of a ground state stabilization. On the other hand, the PE spectrum of **43** shows an appreciable splitting between the π(e) and π(a$_1$) levels[113a,249,268] (Fig. 19). The interaction



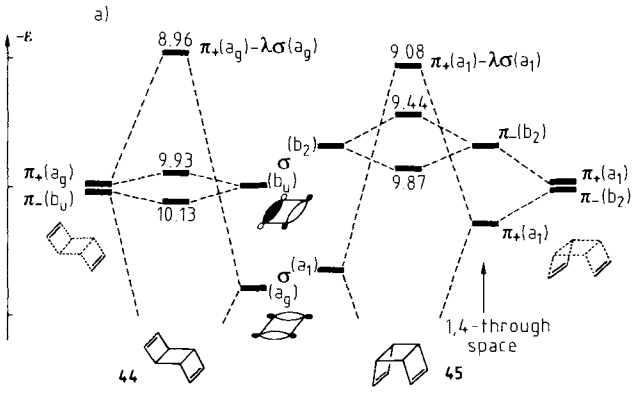


Fig. 19. Homoconjugation and homoaromaticity in **43**. A value $m = 0.25$ is calculated from the splitting, $\pi(e) - \pi(a_1) = 0.90$ eV, using $\beta = -2.4$ eV. Consequently, $DE(\mathbf{43}) = 0.05 \times DE$(benzene) [113a].

can be described by the resonance integral $\beta' = m \cdot \beta = 0.25\beta$, where $\beta$ represents the resonance integral of, *e.g.* butadiene ($\beta = -2.4$ eV). This gives a value of $\beta' = -0.60$ eV. A comparison of the delocalization energies ($DE$) in benzene and in **43** indicates why this appreciable 1,3-homoconjugation does not lead to ground state stabilization. For $m = 0.25$, the ratio $DE(\mathbf{43})/DE$(benzene) has the value 0.05, *i.e.* $DE(\mathbf{43}) \approx 1.8$ kcal/mol (in benzene, $DE \approx 36$ kcal/mol). This value is much too small to be detectable in view of the steric and conformational strain of the σ-framework in **43**[113a].

### 4.2.2. 1,4-π,π-Interactions

In analogy with the situation described in Section 4.1.2, 1,4-π,π-interactions are strongly dependent on topology. The *anti*-dimer **44** and *syn*-dimer **45** of cyclobutadiene provide instructive examples (Fig. 20). Although a change from pure through-bond coupling in **44** to mixed interaction in **45** is already evident from the form of the PE spectrum, the exact orbital sequences in these two compounds are a matter of dispute[107,114]. The interpretation given in Figure 20 extends the sequence given in [114a] inasmuch as it also considers mixing between the $\pi_-$-combination and a corresponding σ-orbital; this is similar to the situation in norbornadiene. According to HAM/3-calculations, and in contrast to previous conceptions, the extent of this mixing is not negligible (Fig. 20b). This analysis resolves some inconsistencies: the second and third levels in **45** are approximately first-order linear combinations of $\pi_-(b_2)$ and $\sigma(b_2)$, in which the relative π- and σ-contributions are markedly dependent on the geometry! The main consequence of the different topologies is that $\Delta E(\pi_+ - \pi_-) \approx 1$ eV in **44** and $\Delta E(\pi_+ - \pi_-) \approx 0.4$ eV in **45**.

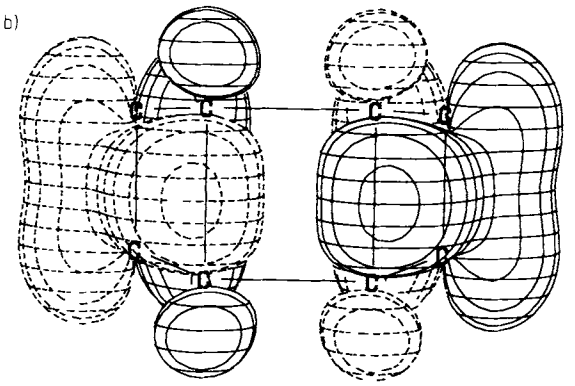

Fig. 20. a) 1,4-π,π-Interactions in **44** and **45** [114]. Qualitative interpretation according to the HAM model. The basis π-energies [114e] correspond to an inductively destabilized ethylenic π-bond. Different $\sigma(b_u, b_2)$ basis energies are obtained for **44** and **45** [114a]. The through-space homoconjugation amounts to *ca.* 0.6 eV. The sequences in **44** and **45** are in good agreement with the results of HAM/3 [114i] and MNDO calculations [114f] but are sensitive to the geometry. There is significant mixing of $\pi_-$ with $\sigma(b_u, b_2)$. Small changes in the geometry (MMI *versus* MMII calculations) result in differing π- and σ-contributions to the second and third orbitals in **44** and **45**. b) Second highest occupied orbital, $\pi_-(b_2) - \sigma(b_2)$ of **45** according to HAM/3 [114i] ($\varepsilon_{calc.} = -9.74$ eV; $\varepsilon_{exp.} = -9.44$ eV).

Whereas in **45** the π-orbitals overlap in a σ-manner, an interesting case of a pure 1,4-p,p-homoconjugation of the π-type is observed in **46**. However, the effect reveals itself only in the second lowest unoccupied orbital ($\pi_2^*$), and not in the occupied orbital ($\pi_2$)[115]. Consequently, electron transmission spectroscopy rather than its pendant, PE spectroscopy, is applicable. One suggestion for this is that the wave functions of anions are appreciably more diffuse and hence more sensitive to long-range effects than those of the neutral molecules or cations (Fig. 21).

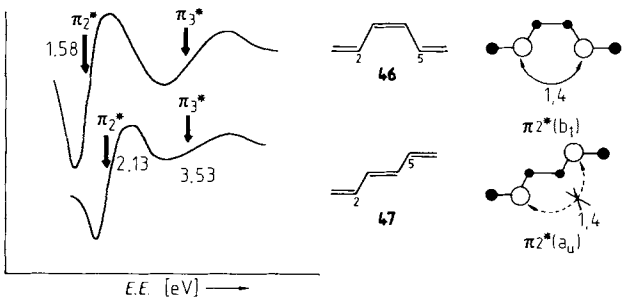

Fig. 21. 1,4-π,π-Interaction between C-2 and C-5 in **46**, measured from the electron transmission spectra of **46** and **47** [115] (*E.E.* = electron energy, *i* = current).

#### 4.2.3. 1,5-$\pi,\pi$-Interactions

The laticyclically conjugated dienyl cation **48** is of fundamental interest to an understanding of the factors which determine the chemical reactivities of dienols **49**[32,116]. Further information on long-range $\pi,\pi$-couplings in these systems may be expected from PE spectroscopic studies of the dienes **50**—**52** with isodrine and aldrine frameworks.

**48** **49**

However, the problem is complicated by the fact that the through-space and through-bond interactions do not operate in opposing directions as in **45**; rather, they are additive[9].

This leads to sizable splittings. The participating effects can, however, be partly separated[117,396] by analysis of the three topologies **50**—**52**. In **50** the symmetry-allowed $\pi$-combinations can *only* mix with $\sigma$-orbitals of the same symmetry (orbital interaction through four bonds, OIT-4-B[117d,e]). In **51** the 1,5-homoconjugation (through space) produces an additive effect[117a]. The two $\pi$-bonds in **52** are no longer symmetry-equivalent, so that the through-bond interaction deviates from that found in **50** and **51**[117] (Fig. 22).

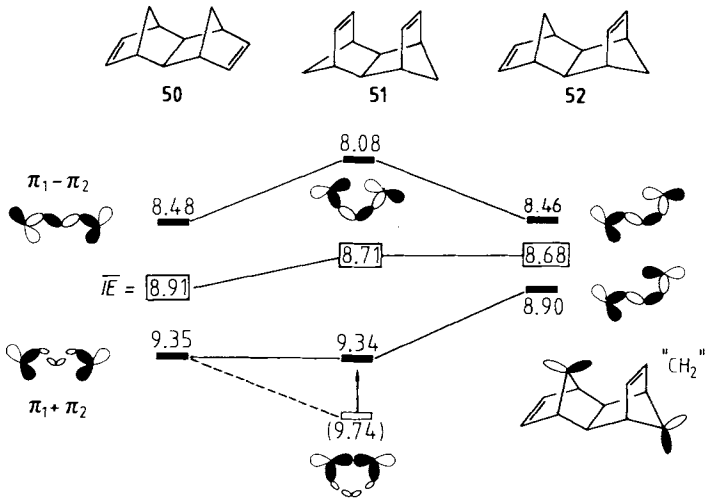

Fig. 22. Orbital interactions through four bonds (OIT-4-B) and 1,5-homoconjugation in **50**—**52** [117]. In **50**, $\pi_1-\pi_2$ is more highly destabilized by the $\sigma$-skeleton than $\pi_1+\pi_2$ (so-called depression effect) [117d, e]. Homoconjugation in **51** acts in concurrence; however, $IE_2$(**51**) is not found to be *ca.* 9.7 eV: rather, $IE_2$(**51**)$\approx IE_2$(**50**). The $\pi_1+\pi_2$ combination is more highly destabilized than in **50**, as also seen from the position of $\overline{IE}=(IE_1+IE_2)/2$ and from the band shape [117a]. This homoconjugation disappears again in **52**: the two non-symmetry-equivalent $\pi$-orbitals are closer together [117a]. Also the "$CH_2$" group has been proposed as a relaying $\sigma$-orbital in **52** [117f].

It is noteworthy that the mean $(IE_1+IE_2)/2$ for **50** is lower than for **51** and **52**. If only homoconjugation were of importance when going from **50** to **51**, one should expect $IE_2\approx 9.74$ eV. The decrease in $IE_2$ to 9.34 eV and that of the mean value to 8.71 eV can be interpreted in terms of an increased through-bond coupling with $\pi_1+\pi_2$. The band shape supports this interpretation: in **50** the second PE band is sharp and narrow, whereas in **51** it is just as broad as the first[117a,d]. This increased $\sigma$-coupling is maintained in **52**, as seen from the mean value, $\overline{IE}$; however, 1,5-homoconjugation is absent. As a result, $\pi_1-\pi_2$ is stabilized, and $\pi_1+\pi_2$ is destabilized by the same amount. It is also interesting to note that the $\sigma$-"$CH_2$"-orbital has been proposed to be responsible for the relay action in **52**; this is what one would intuitively expect because of the transannular strain[117f].

#### 4.2.4. 1,3-$\pi_{AB},\pi_{AB}$-Interactions

Homo- and hyperconjugation between bonds other than CC multiple bonds can only be adequately analyzed by PE spectroscopy if their ionization energies differ significantly from those of the $\sigma$-electrons. However, for $>C=O$, $-N=N-$, and other groups this is often not the case. More favorable situations occur if the number of $\sigma$-orbitals is kept small, or if the A=B bond is easily ionized. This is observed in malononitrile **53**[118] and tetramethyl-1,3-cyclobutanedithione **54**[119]. There is a surprising range of

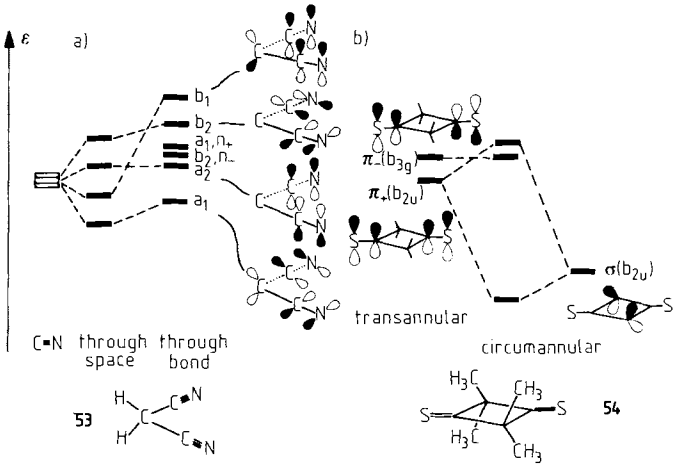

Fig. 23. a) 1,3-$\pi_{CN},\pi_{CN}$- and b) 1,3-$\pi_{CS},\pi_{CS}$-interactions in **53** [118, 310] and **54** [119]. The $\sigma$-contributions to $\pi(b_2)$ are omitted in a). The n-orbitals are not shown; their treatment would belong in Section 4.1.3.

possible interactions in **53**: $p_\pi p_\pi$ and $p_\sigma p_\sigma$ interactions represent 1,3-homoconjugations, $\pi$-$CH_2$-$\pi$ and $\sigma$-$CH_2$-$\sigma$ interactions are hyperconjugative, and the n,n-interaction is a through-bond coupling over four bonds (OIT-4-B). The resulting orbital sequence is given in Figure 23a. In **54** the $\pi$-orbitals are just discernable from the $\sigma$-levels and are split by 0.5 eV. However, in this case 1,3-circumannular hyperconjugation is more dominant than transannular 1,3-homoconjugation (Fig. 23b). This through-bond coupling between diagonal $\pi$-bonds in cyclobutane rings has been extensively studied in 1,3-dimethylenecyclobutane[52b] and trimethylenecyclobutane[52a] (cf. Section 2). It is also important for the interpretation of the UV spectrum of tetramethyl-1,3-cyclobutanedione[52c].

### 4.3. Arene, Arene-Interactions

The interactions between two nonannelated arenes or heteroarenes are fundamental, not only to an understand-

ing of the coupling between weakly interacting chromophores, their electron or energy delocalization[20,21], but also to the related thermodynamic preference for complex formation. The coplanar intercalation of heteroarenes such as proflavine, ethidium bromide, or quinacrine in the stacking of nucleic acid bases in DNA causes a hypochromic effect[20,23,24,120]. This hypochromism may be interpreted as a result of delocalization of the excitation energy. The effect is observable also in compounds like **4** in the "stacked" conformation[24]. It has been shown that the direct overlap of π-systems can also lead to hypochromism[23,121]. Effects of this type will be described below.

#### *4.3.1. 1,3-Arene, Arene-Interactions*

The topology of triptycene makes this system ideal for transannular homo- and hyperconjugation[122]. The effects will be similar to those in barrelene (bicyclo[2.2.2]octatriene)[123]. Furthermore, delocalization of energy upon electronic excitation of a benzene moiety may be expected. The ESR spectrum of tribenzotriptycene **55** shows interesting temperature dependence[124]. At 20 K the spectrum is very similar to that of naphthalene. At 77 K the two outer doublets disappear. This can be explained in terms of a thermally-activated transfer of excitation energy between the naphthalene moieties, *i.e.*, the excitation energy of a naphthalene unit is localized at low temperatures, at higher temperatures it delocalizes and the ESR signals are exchange-broadened (Fig. 24a). Electron delocalization is measurable in the PE spectrum of triptycene **56** (Fig. 24b).

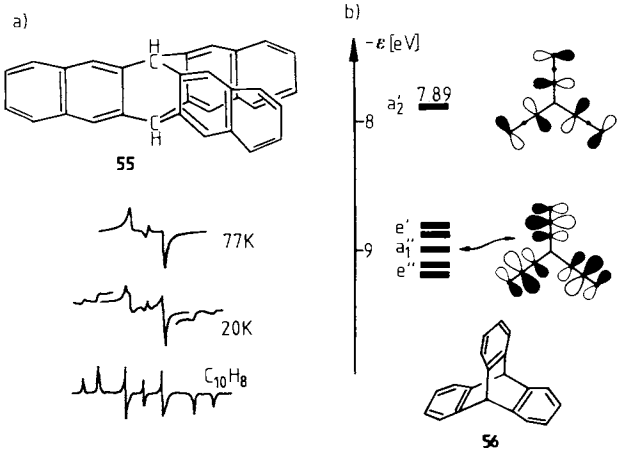

Fig. 24. a) Temperature-dependent ESR spectrum of **55** at 77 K with delocalization of excitation energy, and at 20 K with localized energy. ESR spectrum of naphthalene at 77 K is also shown [124]. b) Ionization energies of **56** assigned using a simple ZDO model [125]. 1,3-Homoconjugation causes a destabilization of $a_2'$ to 7.89 eV.

Here, the $a_2'$-level is more strongly destabilized than $a_1''$ by transannular 1,3-homoconjugation. The total electron delocalization (through-space and through-bond) is satisfactorily described by the ZDO model using an empirical interaction parameter

$$\beta_{ij} = \langle p_i | H | p_j \rangle = -0.55 \text{ eV}$$

for the 1,3-homoconjugation between the atomic orbitals[125].

#### *4.3.2. 1,4-Arene, Arene-Interactions*

[2.2]Paracyclophanes have been intensely studied because of their non-planar benzene rings, anomalous bond lengths and bond angles, and transannular π,π-interactions[126,127,131,317–320,367,409]. Significant 1,4-interactions can be expected because of the short intramolecular distance (270 pm) between the bridged carbon atoms in the two benzene rings of **57**. If 1,4-homoconjugation dominates in **57**, two PE bands would be expected to move toward lower ionization energies: these two bands would correspond to the antibonding combinations $\pi(b_{2g})$ and $\pi(b_{3g})$. Actually, three ionization energies were discernible in the first PE band[127]. A plausible reason is hyperconjugative destabilization of $\pi(b_{3u})$ (Fig. 25).

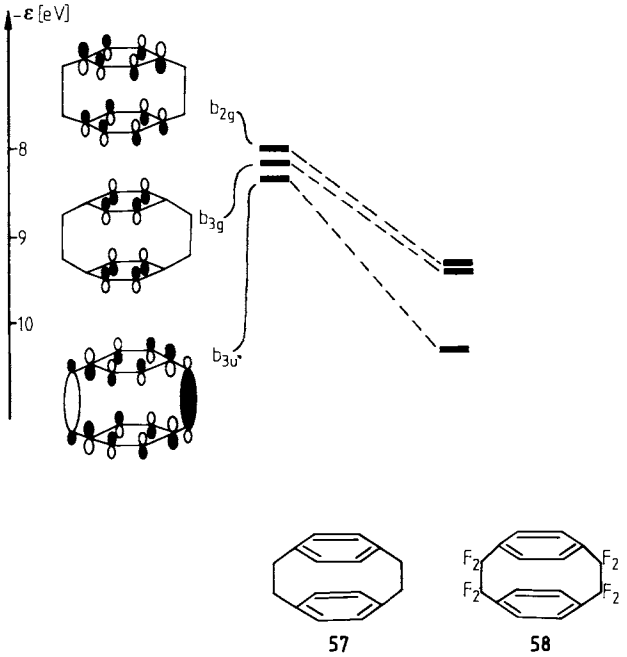

Fig. 25. 1,4-Homoconjugation and 1,4-through-bond interactions in **57** and **58**. In **57** destabilization results in similar ionization energies for $\pi(b_{2g})$, $\pi(b_{3g})$, and $\pi(b_{3u})$. In **58** hyperconjugation is suppressed by fluorine substitution, and $\pi(b_{3u})$ is lowered more than $\pi(b_{2g})$ and $\pi(b_{3g})$ [127].

Confirmation of this conclusion is provided by the PE spectrum of octafluoroparacyclophane **58**. Replacement of arene methyl groups by trifluoromethyl groups results in stabilization of the π-orbitals by about 0.5 eV; corresponding σ-orbitals may be stabilized by an even larger amount (the "fluoro effect"[128]). For this reason, less effective hyperconjugation and through-bond interaction may be expected in **58**. Consequently, $\pi(b_{3u})$ separates from the other π-orbitals and moves toward higher ionization energies. Just this is seen in the spectrum of **58** (Fig. 25). Thus, hyperconjugation with σ-bonds may to a large extent be "annulled" by perfluorination. Homoconjugation, described by the parameter $\tau = \langle p_i | H | p_j \rangle$, is found to be dependent on the intramolecular distance $D$ in a series of cyclophanes[127b]

$$\tau = 3.9 - 0.013 \times D.$$

### 4.3.3. 1,5-Arene, Arene-Interactions

The effective interaction, $(IE_{1,v} - IE_{2,v})/2$, in the isodrine parent compound **51** is $-0.63$ eV (see Fig. 22). If in this compound the two double bonds are replaced by benzene rings, a correspondingly large splitting of the benzenoid levels is expected. The geometry of **59** has been determined by X-ray structure analysis[129]. The benzene-benzene repulsion leads to the transannular distances $d_1 = 304$ and $d_2 = 382$ pm (Fig. 26).

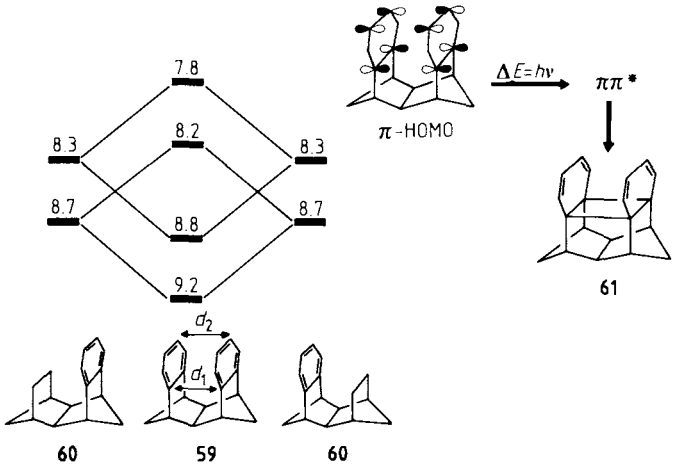

Fig. 26. 1,5-Homoconjugation in **59**. An average value ($\beta_{Av} = -0.5$ eV) is assumed for the nonequal transannular resonance integrals. The numbers given are experimental ionization energies. Photochemical excitation of an electron from the $d_1$-antibonding π(HOMO) to a π*-orbital leads to bond formation, giving **61** [129].

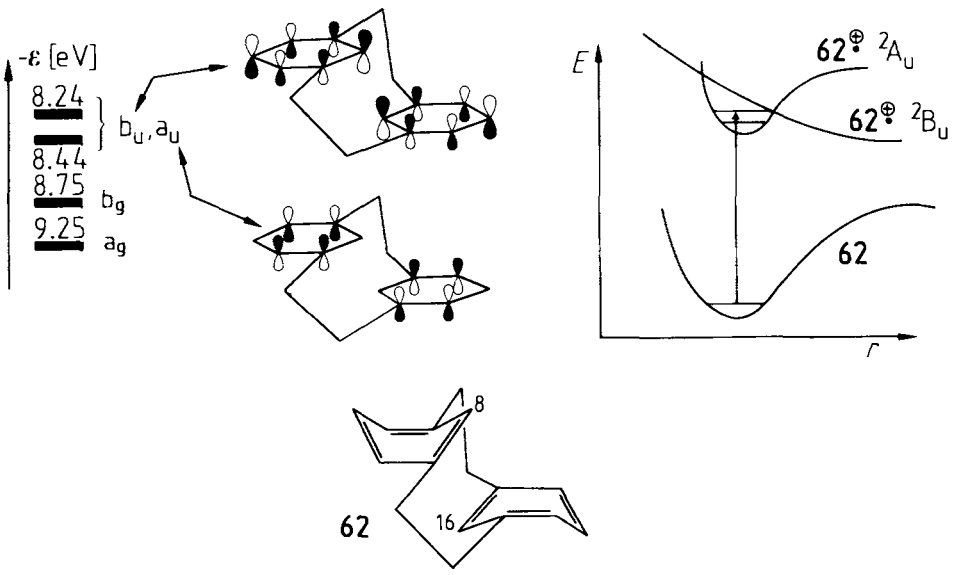
For this reason, the resonance integrals $\beta$ between the corresponding atomic orbitals of the two benzene rings will not be equal: the larger is related to the distance $d_1$ and a smaller to $d_2$. To a first approximation it is reasonable to use an average resonance integral $\beta_{av}$ for all benzenoid carbon atoms. By analogy to **56** and **57** a value $\beta_{av} = -0.5$ eV is plausible. In this way the first four orbital energies of **59** are well reproduced using the ionization energies of **60** (Fig. 26). Thus, the HOMO in **59** exhibits an appreciable degree of antibonding character between the two centers separated by the distance $d_1$. A bond across $d_1$ may be formed by photo-excitation of an electron from the HOMO level. Indeed, **61** is formed upon photolysis[129]. In conclusion, photo-induced processes in olefins such as **51**, arenes such as **59**, and azo-compounds with isodrine structure[159] follow a scheme largely determined by orbital sequences.

### 4.3.4. 1,6-Arene, Arene-Interactions

The molecular geometry and reactivity of the [2.2]metacyclophanes[130] make these compounds just as interesting as the *para*-isomers. The two molecular halves of **62** form a step-like system in which the benzene rings are deformed into boat-like conformations (Fig. 27). The transannular distance between the opposing benzenoid carbon atoms C-8 and C-16 is 268 pm. The reactivity of **62** is determined by this transannular interaction. Two principal electrophilic substitution routes (*a* and *b*) have been discussed.

In any event, the electrophile (or other reagent) may induce transannular ring closure. Since the π(HOMO) of **62** is an important factor in such a substitution reaction, the reactivity may be predicted from the position and electron density of this orbital. Four "arene" bands, the first two of which are very close in energy, are found in the PE spectrum of **62** (Fig. 27). The small energy separation has prevented a definitive ordering of $IE_{1,v}$ and $IE_{2,v}$[131]: $\pi(a_u)$ is dominated by a destabilizing 1,4-through-bond interaction, whereas 1,6-homoconjugation dominates in $\pi(b_u)$. The removal of an electron from $\pi(b_u)$ diminishes 8,16-antibonding and thus favors transannular ring closure. The reactivity observed on photo-excitation or interaction with an



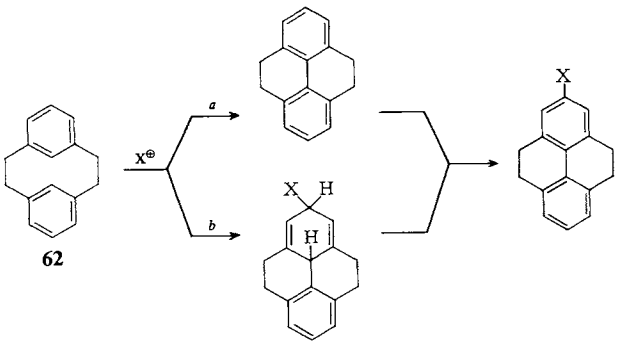


Fig. 27. PE spectrum and interaction in **62** [131]: $\pi(b_u)$ is predominately destabilized by a 1,6-homoconjugative interaction, and $\pi(a_u)$ by a 1,4-through bond interaction. The crossing of the $^2A_u$ and $^2B_u$ states is shown in the energy diagram, which makes both of these accessible [131b].

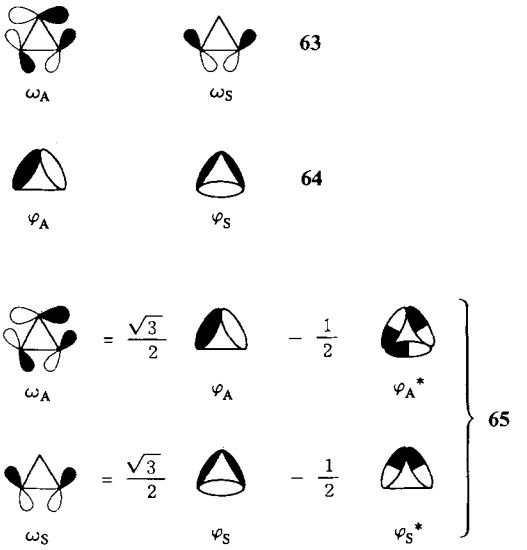
electrophile is in accord with this scheme. Clearly, the 8,16-overlap measured in the vertical radical cation **62**$^{\oplus}$ is also present in the ground state, where it exerts a destablizing effect. This has consequences for the molecular geometry and the heat of formation. Even if $\pi(b_u)$ should be assigned to $IE_{2,v}$ rather than $IE_{1,v}$, the decisive function of $\pi(b_u)$ is maintained because the potential curves for the radical ions cross due to the small energy difference between $\pi(b_u)$ and $\pi(a_u)$ (Fig. 27).



### 4.4. σ,σ-Interactions

Energies and symmetries of valence MO's in linear and branched hydrocarbons are subjects of long-standing interest; moreover, σ-bonds play a fundamental role in organic reactivity. Nevertheless, relatively little information on this subject is obtainable from PE spectra. This is due to a large conformational flexibility and a lack of vibrational fine structure which often lead to broad, unresolved, and difficult-to-analyze PE bands ("σ-mountains"). It is understandable, therefore, that highly symmetrical rigid molecules having high energy σ-orbitals have been particularly well studied[336]. Examples are neopentane[76], adamantane[76], cyclopropane[65,66], cyclobutane[79,132], quadricyclane[133], and cubane[134]. Besides *ab initio* and semiempirical SCF calculations, localized CC- and CH-orbitals are used advantageously in the interpretation of σ-effects[76,79,117b-d,134,135].

#### *4.4.1. 1,3-σ,σ-Interactions*

The two highest occupied MO's of cyclopropane **15** are degenerate; their ionization energies are $IE_{v,1} = 10.60$ eV and $IE_{v,2} = 11.30$ eV (Jahn-Teller splitting)[65,66]. These orbitals are the most important for interaction with other groups or chromophores, and can be represented by the Walsh and Förster-Coulson-Moffit models **63** and **64**, respectively[79,136].

It should be noted that the two models become equivalent only after inclusion of antibonding orbitals[79,136]. This is easily seen from the relevant transformation (**65**) and it should be borne in mind in the discussion of PE spectra. The dispirotricyclic compound **66** provides an interesting example of 1,3-σ,σ-interaction[137]. In this article the following basis orbitals *suffice* for the interpretation of the PE spectrum and interactions in dispiro[2.1.2.1]octane **66**: $\omega_A$, $\omega_S$, and $\pi_{CH_2}$. The basis energies and interaction parameters shown in Figure 28 lead to a satisfactory agreement

with the observed spectrum and, above all, the mechanism of σ,σ-interaction becomes apparent: it is dominated by a circumannular 1,3-through bond coupling *via* hyperconjugation of $\omega_A$ with $\pi_{CH_2}$, together with direct transannular 1,3-homoconjugation.

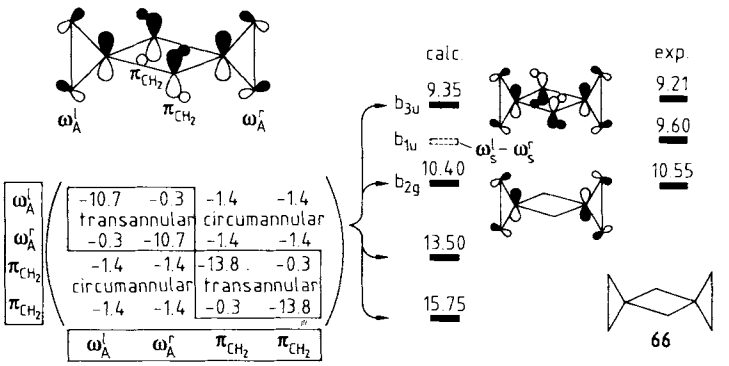


Fig. 28. 1,3-σ,σ-Homoconjugation (transannular) and 1,3-through bond interaction (circumannular) in **66** [137]. The basis orbitals are $\omega_A$ and $\pi_{CH_2}$. Note that, for symmetry reasons, $\omega_S$ cannot interact with $\omega_A$ or $\pi_{CH_2}$. The calculated orbital energies are obtained by diagonalization of the matrix. Calculated and experimental energies are given in eV.

#### *4.4.2. 1,4-σ,σ- and 1,5-σ,σ-Interactions*

The heat of formation of *syn*-tricyclo[4.2.0.0$^{2,5}$]octane **67** is 5.8 kcal/mol higher than that of the *anti*-isomer **68**[138]. This strain energy is in part reflected in structural data[139], and caused by transannular H,H-repulsion. According to *ab initio* calculations[114b], the MO's which make the larger contribution to the CH-bonds in **67** and **68** have different energies: the transannular repulsion in **67** leads to a destabilization by *ca.* 1 eV (Fig. 29). It is noteworthy that this difference is also predicted by HAM/3 calculations ($IE_{8,v}(\mathbf{68})^{HAM} = 12.48$ eV; $IE_{7,v}(\mathbf{67})^{HAM} = 12.01$ eV). Furthermore, the $b_g$(CH)-orbital in **68**, which presumably corresponds to an ionization energy of 12.5 eV, is destabilized in **67** and gives rise to a band at 11.9 eV in the PE spectrum[140].

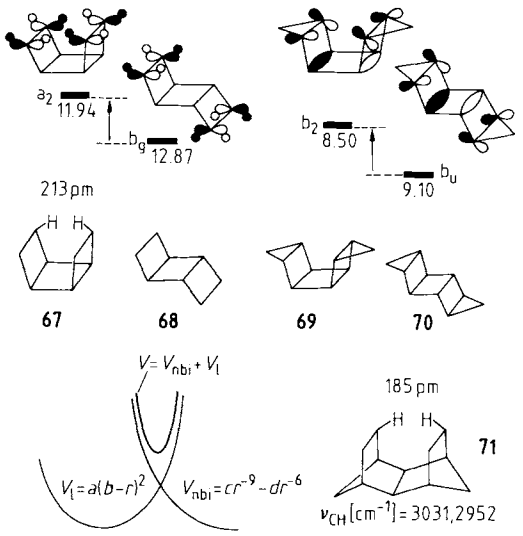

Fig. 29. Transannular non-bonding 1,4- and 1,5-σ(CH),σ(CH) interactions. The orbital energies [eV] of **67** and **68** are from *ab initio* calculations [114b], those of **69** and **70** from the PE spectra [114e]. The effect of transannular strain on CH stretching vibrations is shown in **71**. The frequency increase is interpreted in terms of the increase in curvature arising from a superposition of the two curves, $V_{nbi}$ (non-bonding interaction) and $V_l$ (bond stretching) [47].

Cyclopropanation of the outer CC-bonds in **67** and **68** to **69** and **70**, respectively, causes a shift of the σ-bonds of high p-character in a direction suitable for PE analysis. In **69** the $\sigma(b_2)$-orbital is destabilized by direct, transannular homoconjugation. This decreases the ionization energy by 0.6 eV relative to the $\sigma(b_u)$-level of **70**[114e] (Fig. 29). Strong non-bonding interactions between opposite CH-bonds prevail in the *endo,endo*-tetracyclododecane **71**[47]. Here, the PE spectrum shows ionization energies of 9.50, 9.90, 10.20, and 11.10 eV, resulting from destabilizing effects of the kind described for **67**[117a, 140]. The higher strain energy of the *endo,endo*- relative to that of the *exo,exo*- and *exo,endo*-isomers is reflected in a higher heat of formation (cf. the dienes **50** and **52**, respectively)[141]. Vibrational frequencies constitute important indices of non-bonding repulsion; they have been thoroughly studied in the case of **71**[47, 142]. The frequency is found to increase as a result of the summation of the potentials for bond stretching and nonbonding H,H-interaction ($V = V_{nbi} + V_l$), *i.e.*, tantamount to an increased curvature of the potential curve (Fig. 29).

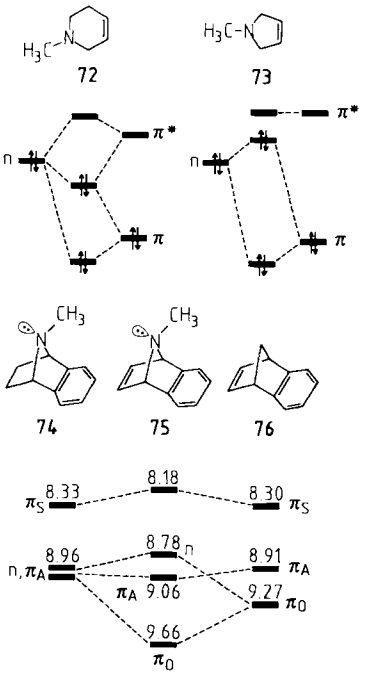
## 5. Interactions of the X,Y-Type

An analysis is usually more complicated when unequal rather than symmetry-equivalent groups or chromophores interact. The reason is clear: the interaction gives rise to second-order shifts, $\delta\varepsilon$, which in spite of significant resonance integrals are often too small, since the energy difference between the basis orbitals is too large. This is impressively illustrated by an example[113a]: using a typical interaction parameter $\langle\phi_1|H|\phi_2\rangle = -0.33$ eV and an energy difference $\Delta E = 1.6$ eV, one obtains $\delta\varepsilon = (0.33)^2/1.6 = 0.07$ eV!

### 5.1. n,π-Interactions

#### 5.1.1. 1,3-n,π-Interactions

Homoallylic and bishomoallylic conjugations between n(N) and π(CC), as in **72** and **73**, have been thoroughly studied[28, 143]. The difference between the two couplings is due to the low symmetry of **72**; n(N) mixes both with π(CC) and with π*(CC). In contrast, in **73** with $C_S$-symmetry, the interaction between n(N) and π*(CC) is symmetry forbidden (Fig. 30).



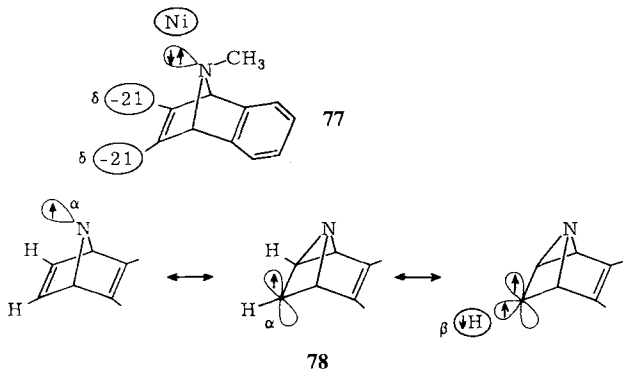


Fig. 30. Difference between homoallylic and bishomoallylic interactions in **72** and **73**. 1,3-n,π-Interaction in **75**: $\pi_S$ and $\pi_A$ are the benzene orbitals, $\pi_0$ the norbornene-type π-orbital and n the N lone-pair *syn* to the isolated double bond in **75**. These are short-hand notations; the 9.66 eV orbital in **75** is more correctly described as $\pi_0 + \lambda\pi_s + \mu \cdot n$ [143b, f].

Homoallylic systems like **72** are not only destabilized by repulsive n,π-4e-interactions, but also stabilized by attractive n,π*-2e-mixing. Since the latter is absent in bishomoallylic systems such as **73**, the analysis of the PE spectra should be more straightforward. The azabenzonorbornadiene **75** is a good example[143b, f]. If the HOMO is assigned to $\pi_S$(aromatic) rather than to n(N)[143f], the destabilizing influence of $\pi_O + \lambda\pi_S$ on n(N) is clearly seen in the correlation between **74**, **75**, and **76** (Fig. 30).

Supplementing these PE studies, the spin delocalization in **74** and **75** has also been investigated[28, 147]. To this end the paramagnetic contact shifts induced by bis(pentanedionato)nickel are measured. The contact shift $\delta$ (which can be positive or negative) is proportional to the hyperfine coupling constant $a$, and hence to the spin density of the unpaired electron at the proton. In this manner the transmission of the electron spin and the nature of the underlying mechanism can be ascertained. Large negative shifts ($\delta = -21$) and hence spin densities are found for the vinylic protons in **75** (see **77**)[28a]. Of the various possible mechanisms of spin transmission (*i.e.* spin polarization, homoconjugation, and homohyperconjugation), only direct delocalization into the π-system, compatible with the symmetries of the n- and $\pi_O$-orbitals involved, would ap-

pear to account for the transfer of β-spin to the protons (see **78**)[28a]. Interestingly, this overlap is also noticeable in the PE spectrum (Fig. 30).

### 5.1.2. 1,4-n,π-Interactions

The relative basicities of the azaadamantanes **16**, **79**, and **80** indicate a marked influence of the methylene or carbonyl groups[144a]. Since the same sequence is found in the gas phase and in solution, it is tempting to try to correlate this with the ionization energy ($H_2O$: p$K_b$ (**16**) 2.96, p$K_b$ (**79**) 4.16, and p$K_b$ (**80**) 5.43). Surprisingly, however, **79** rather than **16** has the lowest ionization energy in this series: $IE_{1,v}(\mathbf{79}) < IE_{1,v}(\mathbf{16}) < IE_{1,v}(\mathbf{80})$. The reason for this is a combination of through-bond couplings and inductive effects. A comparison of the orbital energies of **16**, **79**, and **81** reveals a striking increase in the energy differences: $IE_2(\mathbf{79}) - IE_1(\mathbf{79}) > IE_1(\mathbf{81}) - IE_1(\mathbf{16})$. σ-Couplings and, to a smaller extent, inductive effects may be responsible. The stabilization of the π-orbital in **79** is reminiscent of the "depression effect" in **50** (Fig. 22); this causes the stable π+π-combination to be of lower energy than the π-orbital in the monoolefin[117d,e]. The σ-delocalization of the nitrogen lone-pair in **79** reveals itself not only in a loss of vibrational fine structure in the corresponding PE band, but also in a decreased basicity (despite a smaller $IE_{1,v}$!) In contrast, the energy of the nitrogen lone-pair orbital in **80** is lowered by 0.27 eV ($IE_{1,v}(\mathbf{80}) = 8.21$ eV). Undoubtedly, this is due to the inductive effect of the carbonyl group. Usually, one does not distinguish between σ-inductive and field effect contributions to the inductive stabilization of ion states in PE spectroscopy[2]. It appears, however, that in many cases the field effect dominates or at least contributes to the stabilization[78, 145]. In **80** the stabilization of n(N) by CO can also be understood in these terms[144]. The electrostatic stabilization of $IE$(n) by the dipolar carbonyl group leads to a value of 0.33 eV in good agreement with that observed, $\Delta IE = 0.27$ eV (Fig. 31). This is also the reason for the reduced basicity *vis-a-vis* **79**.

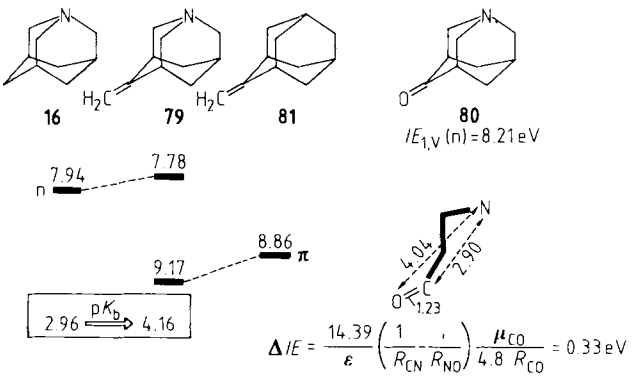

Fig. 31. 1,4-n,π-Through-bond interaction in **79** and relation to basicity. Stabilization of the N lone pair from 7.94 to 8.21 eV caused by an inductive 1,4-field effect. Energies in eV; distances in Å. $\mu_{CO} = 2.8$ D; $\varepsilon = 2$ [144a]. $R$ = distance.

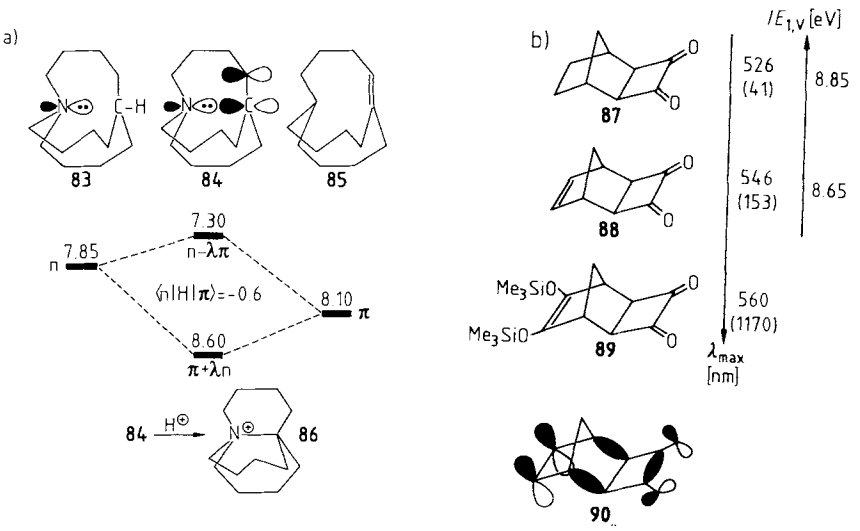
### 5.1.3. 1,5-n,π-Interactions

The inverse Diels-Alder reaction between cyclobutenes **82** and tetrazines is markedly influenced by substituents on the bridge of the norbornene moiety[146]. Donors, *e.g.* $OCH_3$, increase the rate of reaction; acceptors, *e.g.* COR, slow it down. Direct 1,5-n,π-homoconjugation destabilizes the cyclobutene π-orbital, thereby increasing the frontier orbital interaction with the tetrazine.

Such 1,5-homoconjugative interactions are measurable by PE spectroscopy. In the bridgehead amine **83**, whose N atom is pyramidalized on the inside and is weakly basic,



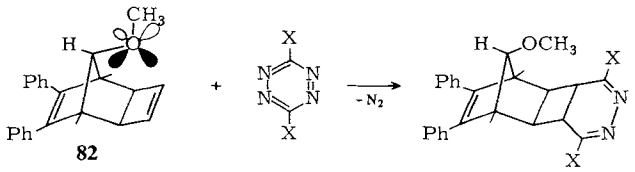


Fig. 32. a) 1,5-n,π-Homoconjugation in **84** [147]. Energies in eV. b) 1,5-n,π-Through-bond interaction (**90**) in the diketones **88** and **89**. UV(cyclohexane): $\lambda_{max}$ [nm] ($\varepsilon$). **87** is orange, **88** red, and **89** violet [88, 89].

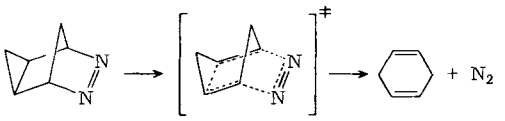
82



X = 2-Pyridyl

the N lone-pair ionizes at $IE_{1,v} = 7.85$ eV[147]. The introduction of a bridgehead double bond in compound **84** leads to a dramatic splitting of the orbital energies *via* 1,5-through-space conjugation (basis π-energy in **85**, −8.1 eV). The measured interaction parameter, $H_{n\pi} = \langle n|H|\pi\rangle = -0.64$ eV, is comparable with those in phanes (Section 4.3.2) and isodrines (Section 4.2.3). The chemical properties of **84** are a direct consequence of this homoconjugation. **84** is extremely easily oxidized and undergoes C-protonation to give **86**. It behaves as a homoconjugated enamine (Fig. 32a).

A σ-coupled 1,5-n,π-interaction is observed in the unsaturated diketones **88** and **89**. Both absorb at considerably longer wavelengths than the saturated analog **87**; indeed, **89** is violet[88,89]! The ionization energies of **87** and **88** indicate that the color change is due to increased $n_+$-HOMO energies: the double bond causes a decrease of 0.20 eV in the ionization energy ($IE_1$); the effect in **89** is expected to be even larger. The coupling mechanism is indicated in **90** (Fig. 32b). Not only a bathochromic shift but also a hyperchromic effect is observed.

### 5.2. 1,3-n,σ-Interactions

The thermal and photochemical decompositions of azo-compounds have been intensely investigated because of the important role they play in the formation and study of free radicals[148]. The azo-compound **91** is unstable due to the *exo*-cyclopropane ring which participates in a symmetry-allowed pericyclic transition state.

91 41

The thermal lability of cyclopropanated azo-compounds of this type is markedly dependent on the dihedral angle between the diazanorbornane skeleton and the cyclopropane ring[148,149]. Thus, the kinetic stability increases from **91** to **93**[149], the prismane derivative **93** being strikingly stable (Fig. 33). The angle $\Theta$ is the most obvious structural variable in this series, and it is reasonable to conclude that a decrease in $\Theta$ leads to increased stability. This is readily understood by considering that in the transition state involved in the decomposition of **91** one of the cyclopropane bonds must be partly broken and overlaps efficiently with the CN-bonds as the nitrogen molecule departs. This overlap in the transition state should be described well by the orbital interaction between the three-membered ring and the C−N=N−C group which occurs in the ground state or in the vertical radical cation. Because of the molecular $C_S$-symmetry and the requirement of efficient overlap, only the symmetric orbitals $\omega_S$ (in **63**) and $\varphi_S$ (in **64**),

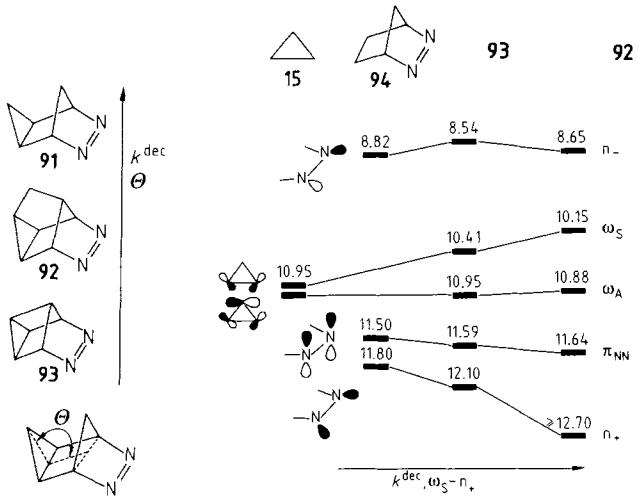


Fig. 33. Relative kinetic thermal stability of azo-compounds **91**—**93**: $k^{dec}$ is the relative first-order rate constant for thermal elimination of $N_2$. Correlation of ionization energies [eV] for **15**, **92**, **93**, and **94**. $k_{dec}$ and $\Theta$ increase in the series **93** < **92** < **91**. The orbital energy difference ($\omega_s - n_+$) increases in the series **93** < **92** [149].

together with the $n_+$- and π(NN)-levels can be involved. The instabilities and the orbital energy differences $\omega_S - n_+$ have the same sense, *i.e.*, the better the overlap between the cyclopropane ring and the C−N=N−C fragment, the lower is the activation energy for the thermal decomposition. The thermal stability of **93** is seen even in its photochemical reactivity[102a]: there is still an activation energy of *ca.* 6 kcal/mol for $N_2$ extrusion in the excited $S_1$ state. At lower temperatures this may not be available, and in consequence **93** isomerizes to diazacyclooctatetraene instead.

### 5.3. π,σ-Interactions

#### *5.3.1. 1,3-π,$\sigma_{CC}$-Interactions*

Increases in the rate of solvolysis due to favorably oriented cyclopropane rings are among the most remarkable neighboring group effects[16-19]. The relative rates measured for the compounds **3a**, **3b**, and **3c** are approximately $10^{14} : 10^{12} : 1$. The extraordinarily strong π,σ-participation is indicated in particular by the degenerate rearrangement of **3b** and by a comparison of $\rho^+$-values ("tool of increasing electron demand", Fig. 3d)[17,18,150]. The ion **95**, which exists in super-acid solution, has $C_{3v}$-symmetry[151]. Since the vertical ionization energy (Section 3.1) is an indicator of possible stabilization of ions possessing the same geometry as the ground state, PE spectroscopy ought to be able to give information on the $C_{2v}$-radical cation **96**. The intramolecular interactions from the cyclopropane rings and the *exo*-methylene double bond are recognizable in the PE spectrum of **97** (Fig. 34)[152]. The dominant 1,3-π,σ-homoconjugation is evident. In correlating the orbital energies of **97**, **98**, and **99** it must be considered that the introduction of the *exo*-methylene double bond results in a small inductive stabilization of the σ- or π-orbitals present (cf. Section 4.1.1). A value of −0.15 eV for this inductive effect can be determined from the PE spectrum of 5-methylene-2-norbornene[153]. Thus, 1,3-π,σ-homoconjugation with a resonance integral $\beta = -0.33$ eV gives information not only about the extent of the interaction in **97**, but also

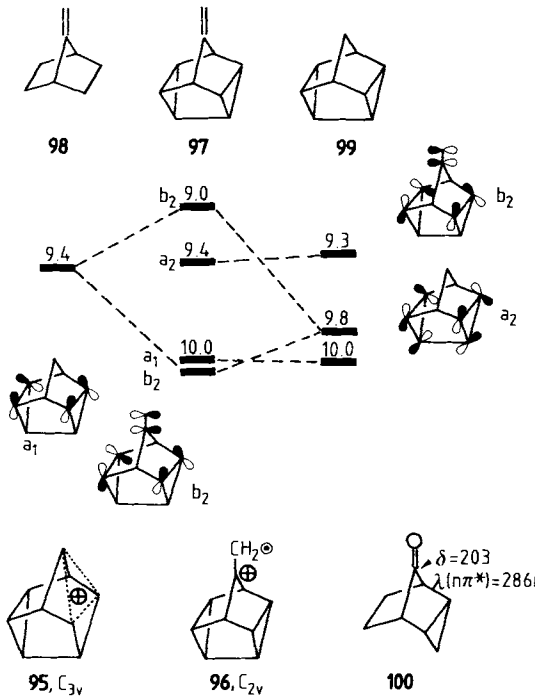

Fig. 34. Cation **95** ($C_{3v}$ symmetry) observed in solution [151], and vertical radical cation **96** ($C_{2v}$ symmetry) generated by photoionization of **97** [152]; 1,3-π,σ-homoconjugation in **97**. Energies in eV. The basis energies in **99** are 0.15 eV more stable than the observed ionization energies due to the inductive effect of the exocyclic double bond. Homoconjugation in ketone **100** is evidenced by $^{13}$C-NMR shifts and nπ*-excitation energies [155].

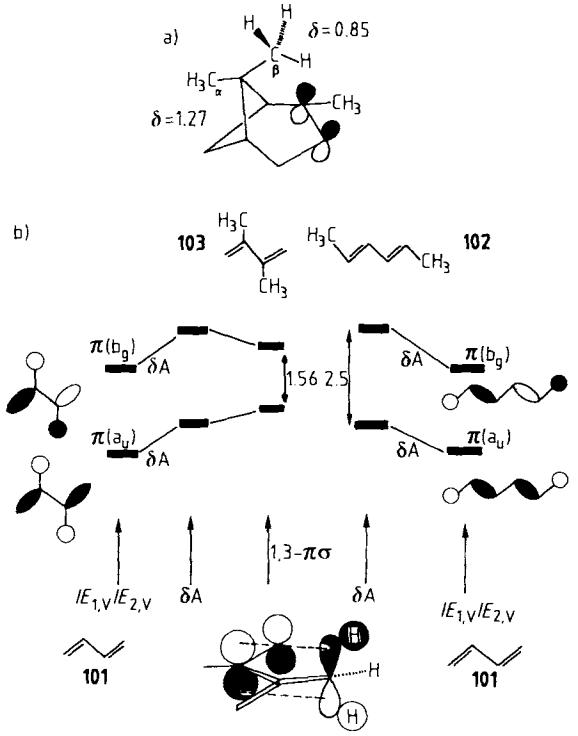

Fig. 35. π,σ-Effects. a) Shielding of the double bond in α-pinene due to magnetic anisotropy [156]. b) 1,3-π,σ-Orbital interaction in **103** using ionization energies of **101** as starting point. δ*A* is the inductive effect of the methyl groups. $CH_3$-π-overlap leads to a smaller splitting, $\pi(b_g)-\pi(a_u)$, for **103**, but not for **102** [37a].

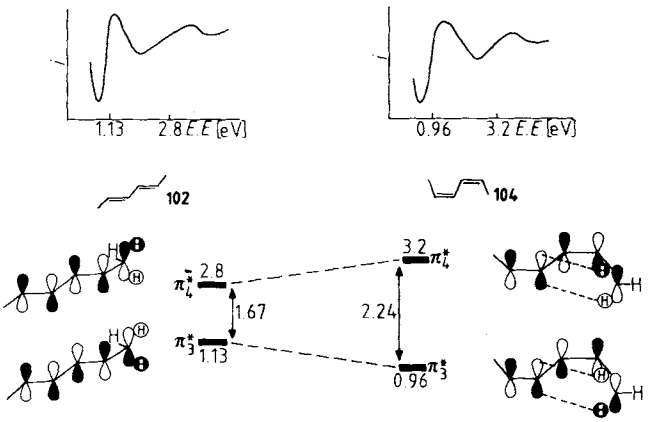
on the orbital sequence in **99**. One can make the following statement on the influence of the solvolysis rate: if only the vertical stabilization of the radical ion **96** were important, acceleration of the solvolysis rate by perhaps $10^4$ by the cyclopropane rings could be expected[154]. The observed value of $10^{12}$ strongly indicates the importance of non-vertical π,σ-participation with homoaromatic stabilization of the ion **95**[152a]. Further information on homoconjugation with *endo*-three-membered rings can be obtained from $^{13}$C-NMR chemical shifts and nπ*-excitation energies of the ketones **100**[155].

### 5.3.2. 1,3- and 1,4-π,$\sigma_{CH}$-Interactions

Important shielding effects in $^1$H-NMR spectroscopy are linked to interactions between π-orbitals and CH-bonds *via* magnetic anisotropy[156]. For example, the protons of the β-$CH_3$ group facing the π-bond in α-pinene appear at $\delta=0.85$, and the α-$CH_3$ protons at $\delta=1.27$ (Fig. 35a). The π,$\sigma_{CH}$-interactions observable by PE or electron transmission spectroscopy are of a fundamentally different nature. Using a simple LCBO model, the PE spectrum of butadiene **101** can be described in terms of a direct interaction between the two occupied π-orbitals; the resonance integral $B_{ab}=\langle\pi_a|H|\pi_b\rangle=-1.21$ eV signifies a strong conjugation[37a]. Substitution at positions 1 and 4 by methyl groups has hardly any influence on the value of $B_{ab}$ ($B_{ab}$(**102**) $=-1.25$ eV). On the other hand, methyl groups in positions 2 and 3 clearly cause a smaller splitting: $B_{ab}$(**103**) $=-0.78$ eV (Fig. 35b). This surprising result can be understood using the pseudo-π orbitals of the methyl groups. The π-levels of **101** are inductively destabilized by $\delta_A$ by the methyl groups. In **103** a further effect occurs: the through-space conjugation between the pseudo-π-$CH_2$ and $\pi_a$- or $\pi_b$-orbitals. This homoconjugation has a stabilizing effect on the higher orbital, a destabilizing effect on the lower, and thus results in a smaller overall splitting[37a].

The existence of such a through-space effect is also indicated by measurements of electron affinities (*i.e.* π*-orbital energies)[38]. A significantly larger $\pi_3^*$-$\pi_4^*$ gap for **104** than for **102** is found by transmission spectroscopy (Fig. 36). In the simplest case, the π-orbitals of the methyl-substituted dienes are described by the linear combination, $\pi^*-\pi(CH_3)$. Therefore, 1,4-π,σ-homoconjugation stabilizes $\pi_3^*$(**104**) and destabilizes $\pi_4^*$(**104**) relative to the energies of the orbitals $\pi_3^*$(**102**) and $\pi_4^*$(**102**). As already mentioned in connection with **46** (Fig. 21) the diffuse character of anion states manifests itself in far-reaching through-



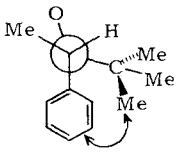


Fig. 36. Electron transmission spectra of **102** and **104** [38]. The pseudo-π-orbitals are shown for only one of the methyl groups. 1,4-π,σ-Homoconjugation in **104** stabilizes $\pi_3^*$ and destabilizes $\pi_4^*$ (*E.E.* = electron energy, i = current).

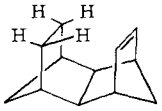
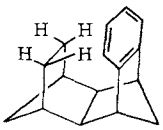


space effects, more so than for neutral molecules or cations; this also applies to **104**.

### 5.3.3. *1,5-π,σ- and 1,5-Arene,σ-Interactions*

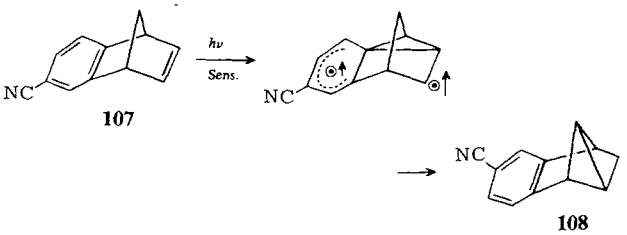


An attractive interaction between methyl groups and arenes has been deduced from NMR and X-ray analysis of benzyl *tert*-butyl sulfoxides and *e.g.* in the α-methyl derivative is largely responsible for the stabilization of conformation **105**[157].

**105**

**106**

**60**



Only a few PE spectroscopic investigations of arene, σ-interactions have been reported. The strikingly low value of 8.60 eV for $IE_{1,v}$(**106**)[158] relative to that of 8.97 eV for norbornene **8** can be ascribed to the transannular strain between the ethano bridge and the π-bond. The calculated H($CH_2$)–H(C=C) distance is 229 pm[47]. It can be concluded that a similar relationship exists between the $CH_2$ group and the arene in **60**. Here, the first two ionization energies ($IE_{1,v}$ and $IE_{2,v}$ = 8.30 and 8.70 eV, respectively[129]) are markedly reduced compared to those in benzonorbornene ($IE_{1,v}$ = 8.45 and $IE_{2,v}$ = 8.95 eV[125b]). This transannular influence on π-orbitals is satisfactorily reproduced by semiempirical calculations (CNDO/2, INDO, and MNDO)[159].

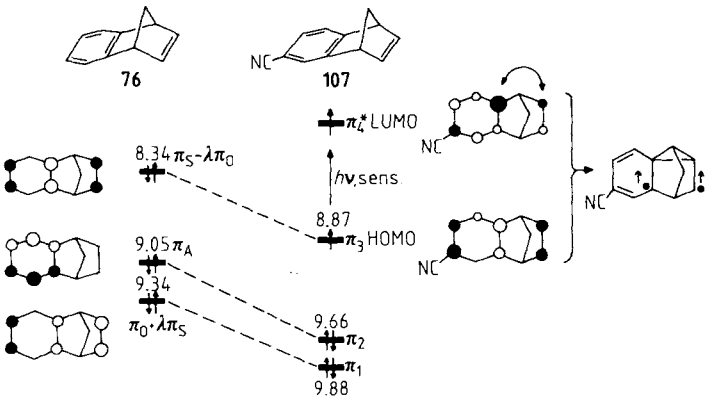
## 5.4. 1,3-Arene, π-Interactions

The triplet sensitized photochemical di-π-methane rearrangement of benzonorbornadiene is remarkably regioselective[160]. Both donors and acceptors in *ortho*-position favor *ortho*-ring closure, whereas acceptors in the *meta*-position effect *para*-bridging (**107** → **108**).

The orbital sequences of **107** and the parent compound **76**, determined both by PE spectroscopy and STO-3G calculations, provide the key to an explanation[160, 161, 358, 373].

In **76** the symmetrical benzene π-orbital ($\pi_S$) is destabilized, not only by the alkyl substituents, but also by 1,3-homoconjugation with the symmetrical olefinic π-orbital ($\pi_O$): $\pi_S - \lambda\pi_O$ becomes the HOMO, $\pi_O + \lambda\pi_S$ appears at $IE_{3,v}$, and $\pi_A$ is assigned to the second measured ionization energy $IE_{2,v}$ because for symmetry reasons this orbital cannot participate in transannular overlapping (Fig. 37). The −I and −M effects of the *meta*-nitrile function in **107** result in a drastic lowering of the orbital energies. Furthermore, the cyano group effects a polarization of the benzene orbitals. The LUMO ($\pi_4$) allows formation of the lowest triplet configuration, $\pi_3\pi_4$. The preferred transannular ring closure is immediately predictable from the magnitudes of the coefficients: it occurs in the position *para* to the nitrile function. The photochemical reactivity of donor substituted benzonorbornadienes can be interpreted in an analogous manner.

**107** **108**



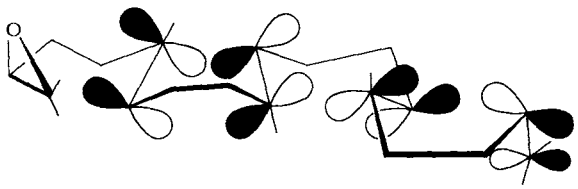


Fig. 37. 1,3-Homoconjugation in **107** and **76**: $\pi_3$ is antibonding, $\pi_4$ bonding with respect to transannular bond formation. Hence, triplet sensitized excitation generating the $\pi_3^1\pi_4^1$ configuration increases transannular bonding, especially in the position *para* to the nitrile group in **107** [160, 161].

## 6. Summary and Outlook

In this article is has been attempted to illustrate how PE spectroscopy may be used to analyze non-bonding orbital or electrostatic interactions between n-, π-, and σ-systems. In this respect, PE spectroscopy is a valuable complement to other methods used in the investigation of proximity effects, *i.e.* methods employing magnetic, electronic, vibrational, kinetic, or ground state measurements. Apart from purely spectroscopic and chemical questions, specific interactions in bioorganic chemistry[162] and molecular pharmacology[163] will become important areas of inquiry in the future. Phenomena such as drug-receptor interaction, orbital steering, and steric compression may be studied using suitable model substances. As an example, the biochemical key reaction in the stereospecific synthesis of steroids is the cyclization of squalene epoxide by the enzyme squalene oxide cyclase. The enzyme serves to fix the carbon skeleton in a conformation conducive to transannular orbital overlap:

Undoubtedly, this is one of the most remarkable and fascinating cases of homoconjugation, and it will be an exciting task to analyze this process using models of proper stereochemistry, applying the methods described in the present article.

Necessarily, only a limited selection of examples could be treated here. For this reason, the appendix gives references to further work where similar interactions are described.

*We are indebted to Professor H. Prinzbach, who aroused our interest in proximity effects, and to Professor E. Heilbronner, who pointed out how such interactions can be analyzed by PE spectroscopy. Our thanks are due to Professors R. Gleiter and P. Rademacher for numerous discussions and measurements. Our own synthetic and spectroscopic work would not have been possible without the enthusiastic efforts of our co-workers, whose names are found in the references. This work enjoyed generous financial support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.*

## Seleno- and Telluroformaldehyde as Bridging Ligands in Organometallic Complexes**

By *Wolfgang A. Herrmann**, *Josef Weichmann*, *Ricardo Serrano*, *Klaus Blechschmitt*, *Heike Pfisterer*, and *Manfred L. Ziegler*

*Dedicated to Professor Hermann Schildknecht on the occasion of his 60th birthday*

Originating from the work of *Roper et al.*, the organometallic chemistry of formaldehyde has opened new perspectives in the field of metal-catalyzed hydrogenation of carbon monoxide[5]. Among the heavier congeners of the series $CH_2=X$ (X = S, Se, Te), only thioformaldehyde has unambiguously been characterized in the free state by spectroscopic means[6] and also stabilized by complexation[9]. By way of contrast, only tentative spectroscopic evidence is available for selenoformaldehyde. Finally, neither the character of a reactive intermediate was demonstrated for telluroformaldehyde nor has any organometallic derivative of this species been reported up to the present. Using a novel synthetic strategy, namely addition of methylene to bonds between main group elements and transition metals, we have now succeeded in synthesizing the first organometallic complexes of seleno- and telluroformaldehyde, in which these species function as bridging ligands[***].

The precursor compounds **1**, **2**, **4**[11-13] used in this work have been synthesized by reacting the metallic modifications of selenium and tellurium with the tetrahydrofuran complexes of composition $(\eta^5\text{-}C_5R_5)Mn(CO)_2THF$ (R = H, $CH_3$). The $\mu_2$-selenium and $\mu_3$-tellurium complexes thus obtained react rapidly and quantitatively at −70 °C with

M = $(\eta^5\text{-}C_5Me_5)Mn(CO)_2$ (**1b**,**3b**)
$(\eta^5\text{-}C_5H_5)Mn(CO)_2$ (**1a**,**2**,**3a**,**4**,**5**)

Scheme 1.

diazomethane with concomitant elimination of dinitrogen to give deep blue, air-stable, crystalline products having the general formula $(\eta^5\text{-}C_5R_5)_2Mn_2(CO)_4(X{=}CH_2)$ (**3a**, **3b**, **5**).

[**] Transition Metal Methylene Complexes, Part 41. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Spanish Ministry of Education (Fellowship *R. S.*).—Part 40: W. A. Herrmann, Ch. Bauer, M. L. Ziegler, H. Pfisterer, *J. Organomet. Chem. 243* (1983) C 54.

[***] Note added in proof (March 13, 1983): This method has also been successful in the preparation of the analogous thioformaldehyde derivative [M. Herberhold, W. Ehrenreich, W. Bühlmeyer, *Angew. Chem. 95* (1983) 332; *Angew. Chem. Int. Ed. Engl. 22* (1983) 315]. Other synthetic routes to thio-, seleno- and telluroformaldehyde complexes are reported by W. Paul, H. Werner, *ibid. 95* (1983) 333 and *22* (1983) 316, and by C. E. L. Headford, W. R. Roper, *J. Organomet. Chem.*, in press. - The synthetic strategy described in the present paper has successfully been used for the synthesis of the first germylidene complex, $(\mu_3\eta^2\text{-}GeCH_2)[(\eta^5\text{-}C_5H_5)Mn(CO)_2]_3$ (W. A. Herrmann, F. Weichmann, unpublished results).

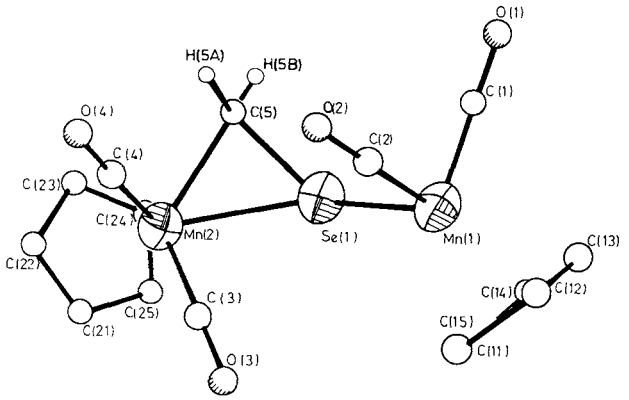
The structural features of the novel dinuclear complexes (Scheme 1) have been established by IR-, $^1$H-NMR, $^{13}$C-NMR and mass spectroscopy. Aside from spectroscopic characterization, the structure of **3a** has been examined by single-crystal X-ray diffraction techniques (Fig. 1). The



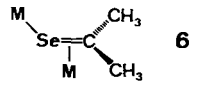


Fig. 1. Crystal structure of the novel $\mu_2,\eta^2$-selenoformaldehyde complex **3a**. Monoclinic, space group $C_{2h}^5$-$P2_1/n$; $a = 1561.6(6)$, $b = 1315.2(5)$, $c = 1599.9(4)$ pm; $\beta = 103.95(3)°$, $Z = 4$; 2599 reflections, $R_w = 0.039$. For details of the crystal structure investigation see *Angew. Chem. Suppl. 1983*, 363–395.

| Bond Lengths [pm] | | Bond Angles [°] | |
|---|---|---|---|
| Se(1)–Mn(1) | 237.1(2) | Se(1)–C(5)–Mn(2) | 76.7(4) |
| Se(1)–Mn(2) | 248.8(2) | Se(1)–Mn(2)–C(5) | 48.0(3) |
| Se(1)–C(5) | 190.0(11) | Mn(2)–Se(1)–Mn(1) | 121.5(1) |
| Mn(2)–C(5) | 210.4(12) | C(5)–Se(1)–Mn(1) | 112.2(3) |
| | | Mn(2)–Se(1)–C(5) | 55.4(4) |

molecule **3a** consists of two $(\eta^5$-$C_5H_5)Mn(CO)_2$-fragments that are connected with each other by means of the bridging chalcogen atom Se(1). A metal-to-metal bond is clearly not present in the molecule ($d$(Mn–Mn) > 380 pm). Since each organometallic fragment is missing two electrons to conform to the EAN rule, a formal Mn(1)=Se(1) double bond is to be postulated; the relatively short interatomic distance of 237.1(2) pm also lends support to this view. The bond length between Se(1) and C(5) is indicative of a single bond (190.0(11) pm). The same argument holds for the Mn(2)–C(5) distance, which is even longer (210.4(12) pm) than the corresponding bond length in the dimetallacyclopropane-type methylene complexes of composition $\mu$-$CH_2[(\eta^5$-$C_5H_4R)Mn(CO)_2]_2$ (R = H, $CH_3$)[16]. The question as to whether the cyclic geometry corresponds to an olefin-type $\pi$-complexation of the selenoformaldehyde ligand to the metal center Mn(2) or if this structure is more consistent with the requirements of a $\mu$-methylene derivative of a manganese-selenium framework, Mn–$CH_2$–Se, is open to further debate. The bonding theory of dimetallacyclopropanes favors the description of the present compound as a $\mu_2,\eta^2$-selenoformaldehyde complex, and the striking high field shift of the $CH_2$-signal in the $^{13}$C-NMR spectra of **3a**, **b** also supports this view[16].

The general applicability of our new synthetic method is exemplified by the stepwise construction of a related selenoketone ligand. Thus, compound **6** has cleanly been obtained by the reaction of 2-diazopropane and the organometallic precursor **1b**. This reaction also follows the very same methodology: the isopropylidene moiety is released,

**6**

M=$(\eta^5$-$C_5Me_5)Mn(CO)_2$

with $N_2$-elimination, from the diazo precursor and is transferred to one of the manganese-selenium bonds of **1b**. The structure of the resulting selenoketone complex **6** has been established by complete elemental analysis and spectroscopy.

## A Binuclear Complex with a Thioformaldehyde Bridge**

By *Max Herberhold**, *Wolfgang Ehrenreich*, and *Wolfgang Bühlmeyer*

According to a method developed by *Herrmann et al.*[1], selenium- and tellurium-bridged transition metal complexes such as $[\eta^5$-$C_5H_5)Mn(CO)_2]_2Se_n$ (n = 1, 2)[2a] and $[(\eta^5$-$C_5H_5)Mn(CO)_2]_3Te$[2b] are converted by diazomethane into new compounds which contain seleno- and telluroformaldehyde, respectively, as $\mu_2,\eta^2$-bridging ligand (**2**, **3**). We report here on the analogous thioformaldehyde complex **1**, which extends the series and enables comparisons to be made.

**1**, X = S
**2**, X = Se
**3**, X = Te

**1** was first obtained in 1981 in low yield (50 mg, 2.4%) from a reaction of the tetrahydrofuran-stabilized complex fragment $[(\eta^5$-$C_5M_5)Mn(CO)_2]$ with $K_2SN_2$[2c] when we extracted the residue of the reaction mixture with $CH_2Cl_2$. A more efficient synthesis of **1** makes use of $CH_2N_2$ as a source of methylene[1]; it is not necessary[3] to isolate the intermediate sulfur complexes $[(\eta^5$-$C_5H_5)Mn(CO)_2]_2S_n$ (n = 1, 2)[2a].

The composition of the blue, diamagnetic binuclear complex **1** emerges from its elemental analysis and mass spectrum; its structure can be derived from the IR and NMR spectra and their similarity with those of the selenoformaldehyde complex **2** studied by X-ray analysis (Table 1).

In the $^1$H-NMR spectrum of **1** the two methylene protons of the thioformaldehyde bridge are observed as a AB system; a surprisingly large difference between the two $\delta$ values is found in polar solvents. The AB system of the methylene protons is shifted to lower fields and $^2J$(H,H)

Monomeric thioformaldehyde is unstable under normal conditions; the small number of its transition metal compounds known so far comprises either mononuclear complexes containing $CH_2$=S as a hetero-olefin ligand[5a–c] or trinuclear complexes containing a $CH_2S$ bridge[5d]. **1** is the first binuclear complex of thioformaldehyde.

Engl. 22* (1983) 59; *Angew. Chem. Suppl. 1983*, 10—22; c) M. Herberhold, W. Ehrenreich, *ibid. 94* (1982) 637 and *21* (1982) 633, and *1982*, 1346—1352, respectively.

[3] Procedure: A solution of 408 mg (2 mmol) $C_5H_5Mn(CO)_3$ in 300 mL THF is photolyzed and—after addition of 640 mg (20 mmol) sulfur—stirred for 12 h at 0 °C. The dark-green solution of the sulfur complexes $[(C_5H_5)Mn(CO)_2]_2S_n$ (n = 1, 2) is brought to dryness; the residue is taken up in diethyl ether and combined with an etheral solution of *ca.* 50 mmol diazomethane at −78 °C. The mixture is slowly warmed to 0 °C (evolution of $N_2$) and stirred for 2 h. The solvent is removed, and the crude product **1** is purified by column chromatography (silicagel, −30 °C, exclusion of light). Using pentane/$CH_2Cl_2$ (5:1), small amounts of $C_5H_5Mn(CO)_3$ (yellow), $[(C_5H_5)Mn(CO)_2]_2CH_2$ (red-brown) and $[(C_5H_5)Mn(CO)_2]_2S_n$ (n = 1, 2; green) are washed out, and **1** is subsequently eluted as a deep-blue zone with pentane/$CH_2Cl_2$ (1:1). Crystallization from pentane/$CH_2Cl_2$ at −30 °C. Blue-black crystals which are air-stable for short periods, dec. 90 °C; the solutions are light-sensitive. Yields 250 mg (63%).

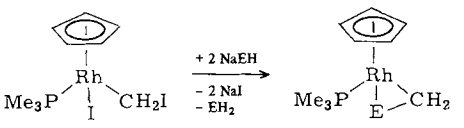
## Synthesis of $[(\eta^5\text{-}C_5H_5)Rh(PMe_3)(\eta^2\text{-}CH_2E)]$ with E = S, Se, Te: Thio-, Seleno-, and Telluroformaldehyde as Ligands in Mononuclear Rhodium Complexes**

By *Wilfried Paul* and *Helmut Werner**



The first example of a mononuclear thioformaldehyde complex, $[(CO)_2Os(PPh_3)_2(\eta^2\text{-}CH_2S)]$ **1**, was described by *Roper et al.*[1]. Corresponding transition-metal compounds with seleno- or telluroformaldehyde as ligands were, to the best of our knowledge, unknown[***]. During studies with carbenoid-metal complexes it was found[2] that rhodium complex **2** reacts with neutral as well as anionic nucleophiles by cleavage of the $CH_2$—I bond. Thus, with $PPh_3$ and $SMe_2$ salts of the cations $[(C_5H_5)Rh(CH_2L)(PMe_3)I]^+$ (L = $PPh_3$, $SMe_2$) are formed, whereas with NaOMe the neutral compound $[(C_5H_5)Rh(CH_2OMe)(PMe_3)I]$ is obtained[2]. Surprisingly, with NaOH in the presence of a phase-transfer catalyst isomerization of **2** occurs to give $[(C_5H_5)Rh(CH_2PMe_3)I_2]$[4].

Using NaSH, NaSeH or NaTeH as substrates in the reaction with **2** (tetrahydrofuran, 25 °C, molar ratio **2** : NaEH ≈ 1 : 10), we have now succeeded in preparing complexes **3**—**5** in good yield (E = S: 48%; E = Se: 72%; E = Te: 24%). The composition of the crystalline, slightly air-sensitive compounds (**3**: pale yellow, **4**: red-violet, **5**: dark green) has been confirmed by elemental analysis and mass spectra.

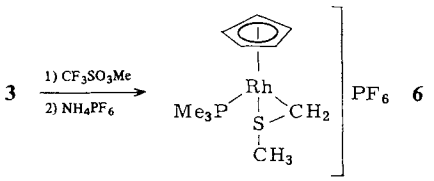
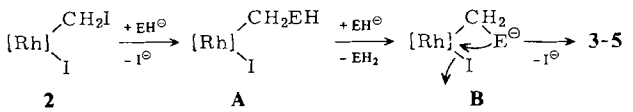
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and through gifts of chemicals by BASF AG and DEGUSSA.



[***] Note added in proof (11. 3. 1983): In the meantime, the synthesis of osmium complexes of selenoformaldehyde and telluroformaldehyde from formaldehyde precursors has been achieved: C. E. L. Headford, W. R. Roper, *J. Organomet. Chem. 244* (1983) C 53. The formation of dinuclear complexes with $CH_2Se$ and $CH_2Te$ as ligands is described by W. A. Herrmann *et al.*, *Angew. Chem. 95* (1983) 331; *Angew. Chem. Int. Ed. Engl. 22* (1983) 314; *Angew. Chem. Suppl. 1983*, 363-395.



**2** **3**, E = S; **4**, E = Se; **5**, E = Te

We assume that in the new chalcogenoformaldehyde complexes **3**—**5** a rigid RhCE three-membered ring is present, *i.e.* the $CH_2E$ ligands are not coordinated like ethene (at least not at room temperature). Consequently, the molecules should be chiral and thus show *two* signals for the diastereotopic $CH_2E$-protons in the $^1$H-NMR spectrum. [**3**: $\delta(CH_2)$ 3.19 ddd, $J(HH)=2.0$, $J(RhH)=1.2$, $J(PH)=3.3$ Hz; 4.49 ddd, $J(HH)=2.0$, $J(RhH)=2.0$, $J(PH)=0.5$ Hz. **4**: $\delta(CH_2)$ 4.26 ddd, $J(HH)=1.2$, $J(RhH)=0.8$, $J(PH)=8.3$ Hz; 5.31 ddd, $J(HH)=1.2$, $J(RhH)=2.2$, $J(PH)=0.6$ Hz. **5**: $\delta(CH_2)$ 5.50 ddd, $J(HH)=0.6$, $J(RhH)=0.6$, $J(PH)=10.2$ Hz; 6.63 ddd, $J(HH)=0.6$, $J(RhH)=2.0$, $J(PH)=0.6$ Hz]. In the $^1$H-NMR spectrum of the *achiral* compound **1** only *one* signal for the $CH_2S$-protons is observed[1].

Complex **3** reacts smoothly with methyl trifluormethanesulfonate to form the corresponding S-methylated cation, which is isolated as the $PF_6$ salt **6**. The yellow solid is highly soluble in acetone or $CH_2Cl_2$. Complex **1** also reacts with $CF_3SO_3Me$ in an analogous manner[1].

In the straightforward synthesis of complexes **3**—**5**, which at least for E = S and Se leads to good yields, the species $CH_2E$, which are very unstable in the monomeric form (cf. [7,8]), are generated and trapped in the coordination sphere of a transition-metal. Presumably, initial nucleophilic substitution on **2** affords intermediate **A**. Following deprotonation of **A**, the more nucleophilic chalcogen atom of **B** displaces the iodide bonded to rhodium.

**2** **A** **B**

## Equilibria in the Formation of $A_4B_3$ Molecules**

By *Roger Blachnik** and *Ulrike Wickel*

Molecules of type $A_4B_3$ (Fig. 1) having the compositions $P_xAs_{4-x}S_3$ and $P_4S_xSe_{3-x}$ (x = 1, 2, 3 and 1, 2, respectively) have hitherto only been detected in mixed crystals[5,6] formed from melts of the pure components.

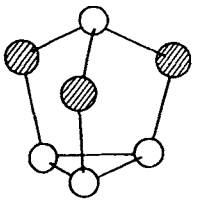

Fig. 1. Structure of $A_4B_3$ type molecules. ○ = P, As; ◎ = S, Se.

We have now been able to isolate such species in pure form by high performance liquid chromatography on an RP-18 column (solvent $CS_2$, eluent methanol/water). *Steudel et al.* had already separated $S_{8-x}Se_x$ mixtures in a similar way by HPLC. The concentrations of the individual species in the mixtures could previously only be determined approximately from mass spectra. Assuming that the extinction coefficients of the molecules in the series $P_xAs_{4-x}S_3$ and $P_4S_xSe_{3-x}$ change linearly with x we were able to plot the concentration curves presented in Figure 2 using data obtained from HPLC measurements.

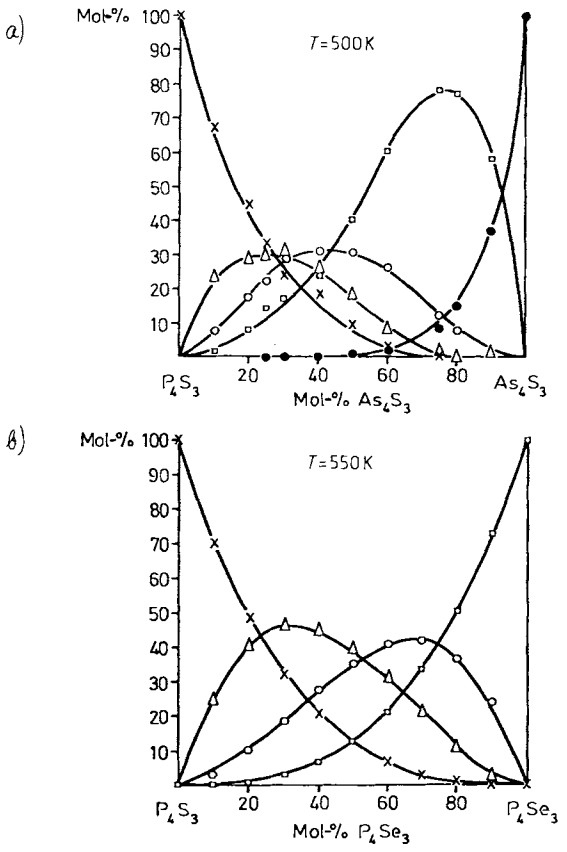

Fig. 2. a) Concentration curves in the system $P_4S_3/As_4S_3$ for $P_4S_3$ (×), $P_3AsS_3$ (△), $P_2As_2S_3$ (○), $PAs_3S_3$ (□), $As_4S_3$ (●).—b) Concentration curves in the system $P_4S_3/P_4Se_3$ for $P_4S_3$ (×), $P_4S_2Se$ (△), $P_4SSe_2$ (○), $P_4Se_3$ (□).

[*] Prof. Dr. R. Blachnik, U. Wickel
Anorganische Chemie, Fachbereich 8 der Universität—Gesamthochschule
Postfach 1012 40, D-5900 Siegen (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

The results illustrate the influence of the bond energies on the formation of various species. In the system $P_4S_3/P_4Se_3$ the number of phosphorus-chalcogen bonds is not altered by the "mixed" molecules that are formed; the reaction is thus entropy-controlled, and therefore the distribution of the products is statistical and temperature-independent. The bond energy of a PS bond is higher than that of an AsS bond; therefore, for the reaction

$$P_4S_3 + 3\,As_4S_3 \longrightarrow 4\,PAs_3S_3$$
(6 P–S bonds) (12 P–S bonds)

there is a considerable gain in energy. Hence, in mixtures of $P_4S_3$ and $As_4S_3$ the formation of the molecule $PAs_3S_3$ with an apical phosphorus atom is preferred (cf. Fig. 1). The concentration of this species decreases with increasing temperature.

Novel molecules of type $A_4B_3$ can be obtained in pure form *via* separation of the molecular mixtures. All the compounds form plastic phases at elevated temperatures. Aside from the possibility of preparing derivatives of these molecules, a way is now also open for studying the transformation into the plastic phase as a function of the molecular structure. The $A_4B_3$ systems also exemplify how the formation of the same molecular structure can be controlled either by the entropy or by the enthalpy.

## $[Co_3\{\mu_3\text{-}S\}\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: The First Trinuclear Cobalt Cluster with Tetrahedral $CoS_4$-Coordination**

By *Gerald Henkel**, *Wolfgang Tremel*, and *Bernt Krebs*

Increasing interest has recently been focussed on compounds of cobalt with sulfur and sulfur-containing ligands, chiefly because a comparison of isostructural polynuclear Co–S- and Fe–S-complexes is expected to enable important conclusions to be drawn about the bonding in such species.

The only Co-complex known to have tetrahedral S-coordination, in which short metal-metal distances have been found, is $[Co_8S_6(SC_6H_5)_8]^{4-}$[7]. The analogous iron complex $[Fe_8S_6(SC_6H_5)_8]^{4-}$, however, which is considered as parent compound of a $[(RS)_nMoFe_7S_6(SR)_7]^{z-}$ cluster (with $n=1$, 2 or 3) recently postulated as a model for the active site of nitrogenase[7,8], has so far not been detected.

During investigations of the $FeCl_2/X/Y$ system ($X=RS^-$, $S^{2-}$, 1,1-dithiolate; $Y$=1,4-dithiolate), which led, *inter alia*, to a direct synthesis of the $Fe^{II}$ cluster $[Fe_3S(SRS)_3]^{2-}$ [SRS = *o*-xylene-α,α′-dithiolate ($S_2$-*o*-xyl) (**1**) or durene-α,α′-dithiolate ($S_2$-dur) (**2**)][11], we have also synthesized the title compound $[Co_3S(S_2\text{-}o\text{-}xyl)_3]^{2-}$ **3**. Complexes **1** and **2** claim interest as possible model compounds for the [3-Fe] centers of some ferredoxins[14]. **3** is obtained analogously to **1** or **2** by treatment of the precipitate initially formed in the reaction of $CoCl_2/Na_2S_2$-*o*-xyl with $S^{2-}$ in methanol and, by precipitation with $(CH_3)_4NCl$, can be isolated as $[(CH_3)_4N]_2[Co_3S(S_2\text{-}o\text{-}xyl)_3]\cdot 2CH_3OH$ **4**. The salt **4** crystallizes in the monoclinic space group $P2_1/c$, $a=1341.6(4)$, $b=1956.9(6)$, $c=1629.8(4)$ pm, $\beta=90.60(2)°$, $Z=4$ at $T=140$ K. The structure was determined from single crystal diffractometer data ($R_1=0.031$, $R_2=0.034$). In Figure 1, the $Co_3S_7$ skeleton of the anion **3** is accentuated by vibration ellipsoids.

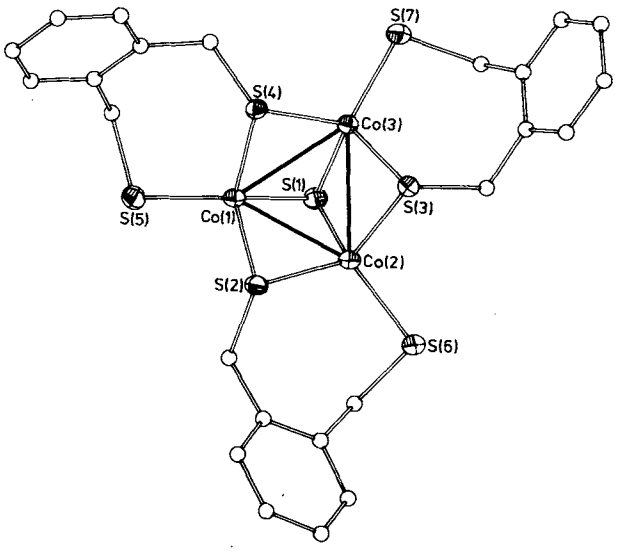

Fig. 1. Structure of the anionic cluster **3** with vibration ellipsoids of the Co and S atoms (140 K, 50% probability), Selected bond lengths [pm] (σ: 0.1 pm): Co(1)–Co(2) 271.5, Co(1)–Co(3) 282.5, Co(2)–Co(3) 280.0, Co(1)–S(1) 226.4, Co(2)–S(1) 226.6, Co(3)–S(1) 229.5, Co(1)–S(2) 228.1, Co(2)–S(2) 229.7, Co(1)–S(4) 232.7, Co(2)–S(3) 231.6, Co(3)–S(4) 231.5, Co(3)–S(3) 231.0, Co(1)–S(5) 223.8, Co(2)–S(6) 222.6, Co(3)–S(7) 224.6; S–Co–S angles [°] (σ: 0.03°): Co(1) 102.38 to 119.19, Co(2) 103.56 to 117.46, Co(3) 99.90 to 119.78. Further details of the crystal structure investigation can be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen, quoting the depository number CSD 50378, the name of the author, and full citation of the journal.

In comparison to **2**, with $C_{3v}$ symmetry of the metal-sulfur skeleton, **3** contains only one mirror plane; besides two rather longer metal-metal distances one short bond length [Co(1)–Co(2) 271.5(1) pm] is observed[15]. These distortions are obviously determined electronically, since the central $Co_3S_7$ moiety in **3** contains three valence electrons more than the isostructural $Fe_3S_7$ moiety in **2**. The CoS bonds of the $(\mu_3\text{-}S)Co_3$ pyramids are of different lengths. Also the bond lengths in the Co(1)–S(2)–Co(2) bridge are on average *ca.* 3 pm shorter than the other $(\mu_2\text{-}S)Co$ bonds. Since the average CoS bond lengths for Co(1) and Co(2) in **3** (227.8 and 227.6 pm, respectively), are significantly shorter than for Co(3) (229.2 pm), Co(1) and Co(2) should be electronically equivalent, but different from Co(3), which is also in accordance with the short metal-metal distance.

The UV/VIS spectrum of a solution of **3** in $CH_3CN$ shows a broad band (center *ca.* 1480 nm) with shoulders at 1520 and 1415 nm [$^4A_2 \rightarrow {}^4T_1(F)(\nu_2)$] as well as the broad flank of a LMCT band increasing steeply below 800 nm ($\lambda_{max}=406$ nm), which superposes the d-d band in the VIS region [$^4T_2 \rightarrow {}^4T_1(P)(\nu_3)$] of the tetrahedrally S-coordinated

cobalt. The $\nu_3$ band, split into three components, is still noticeable by shoulders at 761, 692 and 570 nm. Spectroscopic investigations show that **3** is less sensitive to oxidation than the analogous iron compounds **1** and **2**. Reaction of **3** with a large excess of thiophenolate leads to degradation of the cluster.

[15] The metal-metal distances in trinuclear Co complexes, which aside from bridging S-atoms also contain carbonyl or cyclopentadienyl ligands, are in some cases substantially shorter than in **3**; cf., *e.g.*, A. B. Rives, Y. Xiao-Zeng, R. F. Fenske, *Inorg. Chem. 21* (1982) 2286.

## $[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_2\{SC_6H_5\}_2]^{2-}$ and $[Fe_2\{o\text{-}(SCH_2)_2C_6H_4\}_3]^{2-}$: Binuclear Thiolatoiron(II) Anions with Tetrahedral $FeS_4$-Coordination**

By *Gerald Henkel**, *Wolfgang Tremel*, and *Bernt Krebs*

Polynuclear $Fe^{II}$-thiolate complexes whose molecular skeletons consist of sulfur polyhedra sharing edges are hardly known. To this class of complexes belong the anion $[Fe_3S(S_2\text{-dur})_3]^{2-}$ **1**[1] ($S_2$-dur = durene-α,α'-dithiolate), an interesting species because of the similarity of its coordination unit and the [3-Fe]-center of *Desulfovibrio gigas* (Dg Fd II)[2], as well as $[Fe_2(SEt)_6]^{2-}$ **2**[4] and $[Fe_2(S_2\text{-dur})_2(S_2CNMe_2)_2]^{2-}$ **3**[5]. During investigations on the system $FeCl_2/X/Y$ [X = *o*-xylene-α,α'-dithiolate ($S_2$-*o*-xyl) or $S_2$-dur; Y = $RS^-$, $RSe^-$, $S^{2-}$, $Se^{2-}$ or 1,1-dithiolate] we have isolated two novel anions $[Fe_2(S_2\text{-}o\text{-xyl})_2(SPh)_2]^{2-}$ **4** and $[Fe_2(S_2\text{-}o\text{-xyl})_3]^{2-}$ **5**[11] as $[Me_4N]_2[Fe_2(S_2\text{-}o\text{-xyl})_2(SPh)_2]\cdot 1/3\,MeCN\cdot 2/3\,THF$ **6** and $[Me_4N]_2[Fe_2(S_2\text{-}o\text{-xyl})_3]\cdot 5\,MeOH$ **7**, respectively. Both **4** and **5** are potential models for the active centers of the reduced form of desulforedoxin, a [2 Fe]-protein without labile sulfur from *Desulfovibrio gigas*[15]. In addition, we have found a direct synthetic route for the trinuclear cluster $[Fe_3S(S_2\text{-}o\text{-xyl})_3]^{2-}$ **8**, which has a structure similar to that of **1**.

Reaction of $FeCl_2$ with equimolar amounts of $Na_2S_2$-*o*-xyl in methanol affords a dark brown precipitate having the composition $FeS_2$-*o*-xyl. On addition of thiophenolate the binuclear anion **4** is formed; in an analogous way addition of selenophenolate furnishes the anion $[Fe_2(S_2\text{-}o\text{-xyl})_2(SePh)_2]^{2-}$. Treatment of the precipitate with $K_2S$ or Na/NaHS in methanol affords the trinuclear anion **8**, while treatment with $K_2Se$ furnishes the analogous product $[Fe_3Se(S_2\text{-}o\text{-xyl})_3]^{2-}$. On reaction with $NaS_2P(p\text{-tol})_2$, **5** was obtained as unexpected secondary component of a product mixture in which also **8** could be detected.

The salt **6** crystallizes from acetonitrile/tetrahydrofuran/ether in space group $R\bar{3}$ of the trigonal system, the salt

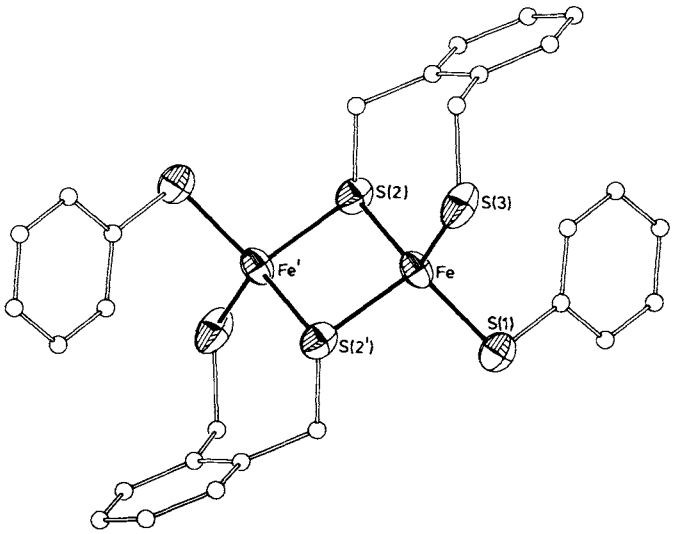

Fig. 1. Structure of the anion **4** in the crystal of **6**, with vibration ellipsoids of the Fe and S atoms (140 K, 50% probability). Selected bond lengths [pm] (σ: 0.1 pm): Fe–Fe' 297.7, Fe–S(1) 230.3, Fe–S(2) 236.8, Fe–S(2') 236.3, Fe–S(3) 230.3; SFeS angles [°] (σ: 0.05°): 102.03 (S(2)-Fe-S(2')) to 115.80 (S(1)–Fe–S(3)).

**7** from methanol in space group $P2_1/n$ of the monoclinic system. The $Fe_2S_6$ frameworks of their complex anions consist of $FeS_4$ tetrahedra, whose edge-to-edge linking leads to short metal-metal distances (297.7(1) pm in **4**, 287.9(1) pm in **5**).

The central $Fe_2S_2$ ring in **4** is exactly planar. The $Fe_2S_6$ framework has $D_{2h}$ symmetry; a comparable framework (Fe–Fe 297.8 pm) is found in the complex **2**, which contains exclusively monofunctional SR ligands.

In the anion **5** with $C_{2v}$ symmetry of the $Fe_2S_6$ framework, the surprising structural characteristic is a handle-like $S_2$-*o*-xyl bridge spanning the $Fe_2S_2$ ring, leading to generation of a nine-membered heterocycle in the polycyclic system. Thus, **5** derives from **4** by replacement of the monothiolate ligands by a dithiolate group bound to two

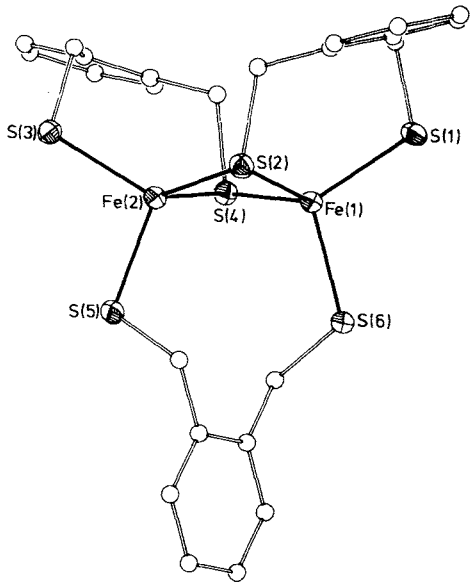

Fig. 2. Structure of the anion **5** in the crystal of **7**, with vibration ellipsoids of the Fe and S atoms (140 K, 50% probability). Selected bond lengths [pm] (σ: 0.1 pm): Fe(1)–Fe(2) 287.9, Fe(1)–S(1) 230.6, Fe(1)–S(2) 236.6, Fe(1)–S(4) 235.1, Fe(1)–S(6) 231.4, Fe(2)–S(2) 236.1, Fe(2)–S(3) 229.1, Fe(2)–S(4) 236.9, Fe(2)–S(5) 231.1; SFeS angles [°] (σ: 0.04°): 102.11 (S(2)-Fe(1)-S(4)) to 119.31 (S(2)-Fe(2)-S(3)).—Further details of the crystal structure investigations are available on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen quoting the number CSD 50397, the name of the author, and complete citation of the journal.

[**] This work was supported by the Fonds der Chemischen Industrie.

Fe atoms. Due to the short S...S distance in the "handle" the central $Fe_2S_2$ ring in **5** is no longer planar but folded along the S...S vector; the mean S...S distance in the two equivalent dithiolate ligands is 393.1 pm, and is thus 32.2 pm shorter than the distance in the ligand with non-bridging S atoms (425.3(1) pm). The metal-metal distance of 287.9(1) pm in **5** is *ca.* 10 pm shorter than in **4**; this could be due to steric effects.

The complexes **1**, **2**, **4** and **5** differ from the adamantane analogues $[Fe_4(SPh)_{10}]^{2-}$[10] in the coupling of the $FeS_4$ tetrahedra. In the case of corner-linkage, Fe–Fe distances of *ca.* 393 pm are achieved, while edge-linkage leads to shorter distances and thus stronger metal-metal interactions in FeS clusters.

The electronic spectrum of **4** (in MeCN) shows no bands in the VIS region ($\lambda > 400$ nm), while absorption increases strongly in the UV region through charge-transfer transitions. The spectrum of **5** (in dimethylformamide) shows a characteristic band at 360 nm. In the spectrum of **8**, a characteristic band is found at 345 nm which is suitable for identification.

## 1,5-Dimethylverdazyls, Hydrazidinyl Radicals with Pyramidal 1,5-Nitrogen Atoms**

By *Franz A. Neugebauer** and *Rolf Siegel*

The reaction of 2,4-dimethylthiocarbonohydrazide **1** with aldehydes in the molar ratio 1:1 yields as the major product colorless 1,4,5,6-tetrahydro-1,2,4,5-tetrazine-3(2*H*)-thiones **2**, some of which undergo desulfurization with Raney nickel, with retention of the hexahydro-1,2,4,5-tetrazine framework, to give **3**. The constitution of these compounds is assigned from the $^1$H-NMR spectra.

By dehydrogenation of **2** (*e.g.* with $FeCl_3$ in formic acid) we obtained the monomeric 6-thioxoverdazyl radicals **4**. **4a** crystallizes from dichloromethane to form dark red crystals; ESR spectrum (toluene, 220 K): $a(N_{2,4}) = 0.637$, $a(N_{1,5}) = 0.545$, $a(H_{CH_3}) = 0.545$ (6H), $a(H_{CH}) = 0.053$ mT, $\langle g \rangle = 2.0037$. **4b** forms violet needles; ESR (benzene, 293 K): $a(N_{2,4}) = 0.635$, $a(N_{1,5}) = 0.540$, $a(H_{CH_3}) = 0.540$ (6H) mT, $\langle g \rangle = 2.0037$. The crystals can be stored unchanged for several months at $-10$ °C; however, at room temperature **4a** and **4b** start to decompose after *ca.* one day.

Dehydrogenation of **3**, *e.g.* with tetrakis(4-methylphenyl)hydrazine in toluene, results in formation of violet (**3a**) or green (**3b**) paramagnetic solutions. However, the generated 1,5-dimethylverdazyls (**5**) contained therein, which apparently also do not dimerize, have thus far eluded isolation. Comparison of the ESR spectra [(toluene, 293 K); **5a**: $a(N_{1,5}) = 1.155$, $a(N_{2,4}) = 0.616$, $a(H_{CH_3}) = 0.396$ (6H), $a(H_{CH}) = 0.109$, $a(H_{CH_2}) = 0.035$ mT, $\langle g \rangle = 2.0037$; **5c**: $a(N_{1,5}) = 1.123$, $a(N_{2,4}) = 0.611$, $a(H_{CH_3}) = 0.408$ (6H) mT, $\langle g \rangle = 2.0037$] with those of previously known verdazyl types[4] reveals the following differences (cf. also Fig. 1):

- $a(N_{1,5})$ is considerably larger (factor 2)
- $a(H_{CH_3})$ proves to be markedly smaller (factor 0.6),
- the ESR spectra are temperature dependent: because $a(N_{1,5})$ increases with decreasing temperature ($\approx 10\%/100$ K, Fig. 1).

The anomalously large $a(N_{1,5})$ coupling constant (increased s character of the spin-bearing orbital of those atoms) and its pronounced negative temperature coefficient indicate that the 1,5-nitrogen atoms have a nonplanar equilibrium geometry, *i.e.* are pyramidal. The smaller $a(H_{CH_3})$ coupling constant is also consistent with a pyramidal arrangement of the substituents, since the angle between the axis of the spin-bearing orbital and the *N*-methyl bond becomes greater than 90°[5].

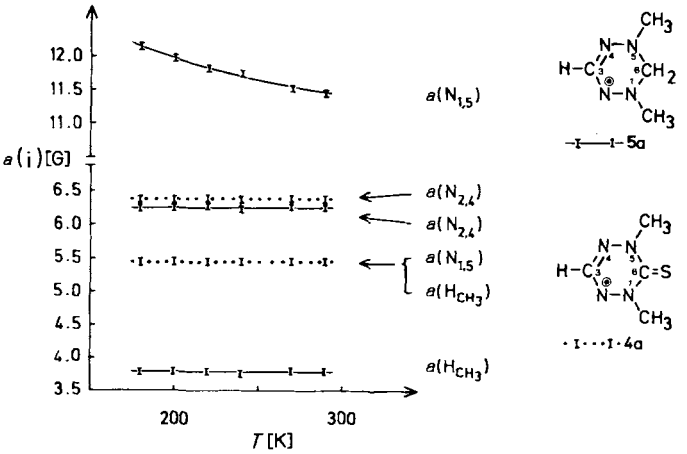

Fig. 1. Temperature dependence of the dominating coupling constants of **4a** and **5a** in cyclopropane (1G = 0.1 mT).

[**] Verdazyls, Part 31.—Part 30: F. A. Neugebauer, H. Fischer, *J. Chem. Soc. Perkin Trans. 2* (1981) 896.

1,5-Dimethylverdazyls, **5**, are apparently the first hydrazyl derivatives[6] in which a nonplanar substituent arrangement at the tricoordinate nitrogen has been detected experimentally. This nonplanarity is largely cancelled, not only by aryl substituents ($CH_3 \rightarrow C_6H_5$) but also by electron acceptor bridges [$>CH_2 \rightarrow >C=S$ (**4**); $>CH_2 \rightarrow >C=O$][4].

## Tetraethoxyallene: Equivalent of the Fictive Malonic Ester Dianion—A Versatile Synthetic Building Block**

By *Rolf W. Saalfrank** and *Walter Rost*

Donor/acceptor-substituted allenes are ambiphilic, and react at the central atom (C-2) with both nucleophiles and electrophiles[1]. Correspondingly, it is predicted that 1,3-donor/donor-substituted allenes have dinucleophilic properties.

We have now employed tetraethoxyallene **3**[2,5] (Table 1) as an equivalent for the fictive malonic ester dianion. As expected, **3** reacts with phosgene **4A** or thiophosgene **4B** (Z = good leaving group) with elimination of two moles of ethyl chloride (per mol **3**) to give bis(ethoxycarbonyl)ketene **6A** (Table 1) and bis(ethoxycarbonyl)thioketene **6B**, *via* the non-isolable intermediates **5A** and **5B**, respectively. **6B** spontaneously dimerizes to 1,3-dithietane-2,4-diylidenebis(malonic acid diethyl ester).

| 4-6 | A | B | C | D |
|---|---|---|---|---|
| X | O | S | $C(CN)_2$ | O |
| Y | C | C | C | C |
| Z | Cl | Cl | Cl | Cl–C(=O)–R– |

| 4D/5D/7 | a | b | c | d |
|---|---|---|---|---|
| R | $(CH_2)_2$ | $(CH_2)_3$ | $(CH_2)_4$ |  |

Attempts to prepare the allene **6C** with the "phosgene-equivalent" dichloromethylenemalononitrile **4C**[8] failed. In this case cleavage of the second mole of ethyl chloride does not take place and one can isolate the ethyl 3-chloro-4,4-dicyano-2-(diethoxymethylene)-3-butenoate **5C** (Table 1).

Table 1 (in part). Data for the compounds **3**, **6A**, and **5C**.

**3**: B.p. = 82 °C/0.05 torr; IR (film): 1905 $cm^{-1}$ (C=C=C); $^1$H-NMR (60 MHz, $CDCl_3$): $\delta$ = 1.32 (t, 12H, $CH_3$), 3.80 (q, 8H, $OCH_2$); $^{13}$C-NMR (25.15 MHz, $CDCl_3$): $\delta$ = 13.89 ($4CH_3$), 63.70 ($4CH_2$), 115.15 (=C), 148.12 (2 =$C(O)_2$)

**6A**: B.p. = 81 °C/0.1 torr; IR (film): 2142 $cm^{-1}$ (=C=O); $^1$H-NMR: $\delta$ = 1.30 (t, 6H, $CH_3$), 4.28 (q, 4H, $OCH_2$); $^{13}$C-NMR: $\delta$ = 14.35 (2 $CH_3$), 48.26 (=C), 61.34 (2 $CH_2$), 161.05 (O–C=O), 184.59 (C=O)

**5C**: B.p. = 125 °C/0.05 torr; IR (film): 2220 $cm^{-1}$ (CN), 1700 $cm^{-1}$ (C=O); $^1$H-NMR: $\delta$ = 1.32 (t, 3H, $CH_3$), 1.45 (t, 6H, 2 coinciding $CH_3$), 4.23 (q, 2H, $OCH_2$), 4.43 (q, 4H, 2 coinciding $OCH_2$)

If, as in compounds **4Da–d**, Z is not a leaving group, then reaction with **3** with elimination of ethyl chloride initially furnishes the intermediates **5Da–d**, which subsequently undergo intramolecular ring closure and renewed loss of ethyl chloride, with formation of the lactones **7a–d**[10]. As exemplified by the synthesis of diethyl 1,3-dihydro-3-oxo-2-isobenzofuranylidenemalonate **7d**, 2,3-annelated 4-alkylidene-2-buten-4-olides should be generally accessible *via* analogous reactions.

| **5**  | 279 | 110 | 6 | 0 | − 9 | 10 | 0 | 7 | 0 | 0 | 0 | 2 | 0 |

[a] Positive sign indicates a shift to high field of the signals of the deuterated compound relative to those of non-deuterated. Spectra were recorded in [$^2H_6$]acetone at 100.6 MHz using a Bruker WH-400 spectrometer; in each case *ca.* 2 : 1 mixtures of deuterated and non-deuterated compounds were used. The spectral width was limited to a minimum in order to collect a large number of data points and hence achieve a high precision. Assignment of the signals follows by standard methods and for difficult cases was verified using the 2D-INADEQUATE technique. Errors amount to 0.5 ppb.

addition to the isotopic perturbation of equilibria[2] there is considerable interest on the influence of deuterium on π-systems[3]. Under discussion are the mechanisms of interaction which have been invoked to clarify the isotope shifts[4]. According to the Born-Oppenheimer approximation, a deuterium substituted molecule has the same electronic properties as an unsubstituted one; all differences in the NMR data should therefore originate from different zero point vibrations. This model predicts positive signs for most isotope effects, *i.e.* a shift to high field. Some authors presume an "isotope-induced" inductive effect, whereas others correlate long-range isotope effects with the reduced capacity of deuterium to undergo hyperconjugation, although strictly speaking this is a violation of the Born-Oppenheimer approximation[5].

We have prepared the compounds **1**—**5** (Table 1), which allow the observation of the $^2H$ isotope effects on the $^{13}C$ chemical shifts of conjugated C=C bonds arranged in long chains. As shown in Table 1, extremely long-range deuterium effects (over 12 bonds in **5**) occur together with a change of sign of the isotope effect at certain sites.

The ethene bridge in **3**, the ethyne bridge in **4**, and the butadiene bridge in **5** are polarized as if the deuterium were a "real" substituent with different electronic properties than hydrogen. Here, hyperconjugation cannot be the reason, since $^2H$ is bonded directly to an aryl moiety. The results question the general validity of the so far discussed mechanism of NMR isotope effects.

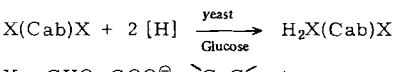
## Electromicrobial Reduction Using Yeasts**



By *Helmut Günther, Cornelia Frank, Hans-Jürgen Schuetz, Johann Bader,* and *Helmut Simon**

Aerobic and facultative aerobic microorganisms, particularly yeasts, have been used for decades to obtain chiral compounds by stereospecific reduction of substituted unsaturated compounds[1]. In this connection, two types of reaction are distinguished [eqs. (a) and (b)].

We have previously indicated the principal disadvantages of such methods[4,5]. In the anaerobic mode using yeast and glucose as electron donor, per mol of NADH 1 mol acetaldehyde is formed, which is then preferentially reduced consuming NADH; in the aerobic mode a considerable amount of the NADH formed as intermediate is reoxidized in the respiration chain. The desired reaction therefore always occurs as a side reaction.

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0404-0322 $ 02.50/0* 

We report here on the possibility of stereospecifically reducing compounds with yeasts *(Saccharomyces cerevisiae, Candida utilis, Kluyveromyces fragilis, inter alia)*, which are supplied electrons from continuously electrochemically reduced methylviologen ($MV^{+}$). An example is the formation of (*R*)-1,2-propanediol from hydroxyacetone by *S. cerevisiae* in the presence and absence of additional NAD.

In the absence of NAD the propanediol is formed only slowly; with glucose as electron donor, the propanediol is produced just as slowly with or without NAD. Addition of catalytic amounts of NAD results in relatively rapid formation of propanediol. Using two methods we were able to show that the NADH is actually formed by the yeast. 1) The formation of NADH from NAD, catalyzed by crude extract of yeast, and the corresponding decrease in concentration of $MV^{+}$ can be observed photometrically. 2) Figure 3 shows that current flows in an electrochemical cell containing intact yeast cells and $MV^{+}$ upon addition of NAD. After the cell has taken up a charge corresponding to the amount of NAD, only NADH and no NAD could be detected in solution. Addition of hydroxyacetone results in an increase in the current to a level somewhat above that resulting from the formation of NADH. These results suggest that reactions (c)—(e) occur in the electrochemical cell in the presence of yeast.

$$2\,MV^{\oplus\ominus} + 2\,e \longrightarrow 2\,MV^{+} \qquad (c)$$

$$2\,MV^{+} + H^{\oplus} + NAD^{\oplus} \xrightarrow{\text{yeast}} NADH + 2\,MV^{\oplus\oplus} \qquad (d)$$

$$H^{\oplus} + NADH + CH_3COCH_2OH \xrightarrow{\text{yeast}} NAD^{\oplus} + CH_3CHOHCH_2OH \qquad (e)$$

Total:

$$CH_3COCH_2OH + 2\,H^{\oplus} + 2\,e \longrightarrow CH_3CHOHCH_2OH \qquad (f)$$

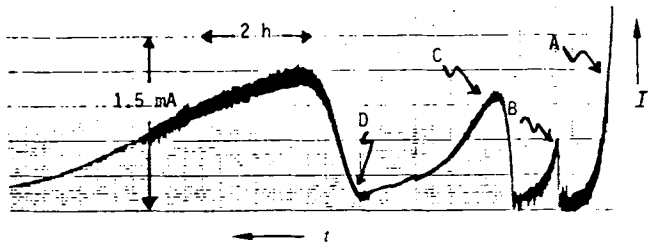

Fig. 3. Current as a function of time for the electromicrobial reduction of hydroxyacetone in an electrochemical cell. A: Reduction of $MV^{\oplus\oplus}$ (4 mM), B: Addition of *S. cerevisiae*; C: Addition of NAD (1.5 mM); D: Addition of hydroxyacetone (5 mM). The increase in the current after addition of yeast presumably involves the reduction of traces of oxygen and endogenic electron acceptors of the yeast.

To date we have obtained rates of formation of *ca.* 0.4 μmol NADH per min and 20 mg yeast (dry weight). This corresponds to a current of 1.3 mA. In the reduction of hydroxyacetone the rate of formation of NADH is rate determining; hence, after addition of hydroxyacetone the current is not larger than in presence of NAD alone (Fig. 3).

The (*R*)-1,2-propanediol thus obtained showed an optical rotation of $[\alpha]_D^{25}$ +20.1° ($H_2O$; $c = 8$). This is close to the highest value ($[\alpha]_D^{25}$ +20.76°) reported in the literature[6].

Compared to cofermentations, the electrochemical reduction by yeast has the following advantages: 1) After addition of catalytic amounts of NAD the reductions are much faster; this arises because the rate-determining step for the formation of NADH is not the glycolysis. This is regulated by the concentration of ATP and is presumably difficult to influence. Introduction of the ratio product/(biocatalyst × time) as a figure of merit gives a value approximately ten times greater for our method than for a bioreduction of hydroxyacetone described in *Organic Synthesis*[7]. Since the products have to be separated from considerably less biocatalyst, and other metabolic products of the biocatalyst are also not formed, they are considerably easier to isolate. 2) A reduction and its rate can be continuously monitored by measuring the current. 3) Reactions between substrate and/or product and reactive intermediates of glycolysis cannot occur.

The catalysis of the reduction of NAD by *intact* yeast cells is surprising. Apparently, NAD can enter the cells and leave again as NADH. So far it is not known which enzymes catalyze reaction (d).

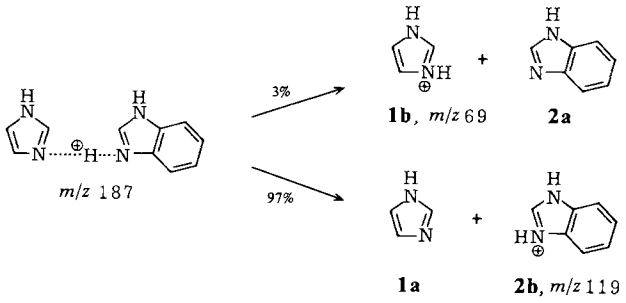
## The Relative Basicities of Imidazole and Benzimidazole

By *Javier Catalan**, *José Elguero*, *Robert Flammang*, and *André Maquestiau*



Values in the literature show that imidazole **1a** is more basic than benzimidazole **2a** by *ca.* 1.5 $pK_a$ units. However, theoretical results strongly suggest that in the gas phase the intrinsic basicity of **1a** should be lower than that of **2a**.

**1a** **1b** **2a** **2b**

Three criteria have been used to discuss the proton affinities of these 1,3-diazoles: 1) The calculated value of the energy change ($\Delta E = -7.1$ kcal/mol) for the isodesmic reaction **1b** + **2a** → **1a** + **2b** is comparable with experimental values on the effects of benzoannelation determined on other systems[15]. 2) The charge density on H-3 is smaller in **1b** (0.811) than in **2b** (0.823), indicating that **2b** should be the weaker acid[20]. 3) The charge density on N-3 in **1a** (5.239) is smaller than that in **2a** (5.266), indicating that **2a** should be more basic[21].

Dr. R. Flammang, Prof. Dr. A. Maquestiau
Laboratoire de Chimie Organique, Université de l'Etat à Mons
19 Avenue Maistriau, B-7000 Mons (Belgium)

To verify this prediction the relative proton affinities of **1a** and **2a** have been determined by mass spectrometry using *Cooks*' method[23]. The MIKE (mass analyzed ion kinetic energy) spectrum of the benzimidazole-imidazole protonated adduct (*m/z* 187) showed formation of protonated benzimidazole **2b** (*m/z* 119) to be 40 times greater than that of protonated imidazole **1b** (*m/z* 69). As expected[23], the interaction of the adduct with a collision gas (CID/MIKE) somewhat increases the relative abundance of protonated imidazole (**2b** : **1b** = 13). Both experiments show unambiguously that benzimidazole **2a** is more basic than imidazole **1a**. From the experimental proton affinity of imidazole (223.3 kcal/mol)[16], the calculated $\Delta E$ value for the isodesmic reaction **1b** + **2a** → **1a** + **2b**, and the experimental results for the annelation effect (*ca.* −6 kcal/mol)[15] the proton affinity for benzimidazole ought to lie in the range 228–230 kcal/mol.

A plausible explanation for the inversion of basicity in **1a** and **2a** on going from the gas phase to aqueous solution takes into account hydrogen bonding between the solvent and both neutral and protonated species. But the main reason is a polarizability effect[29] due to the annelated benzene ring. It disappears in water by dispersion of the positive charge through the hydrogen bonds.

INDO calculations (optimized geometries) give energies and charge densities in accord with the experimental results.

## A Novel Lead-Oxygen Structural Group: $Pb_8O_4^{8+}$

By *Hans-Lothar Keller**

Like the thallium compound $TlPb_8O_4Br_9$ **1**[11], the tetragonally crystallizing $Pb_9O_4Br_{10}$ **2** also contains remarkable and novel $Pb_8O_4$-groups in the crystal structure (Fig. 1).

[*] Dr. H.-L. Keller
Institut für Anorganische Chemie der Universität
Olshausenstr. 40, Haus N13a, D-2300 Kiel (Germany)

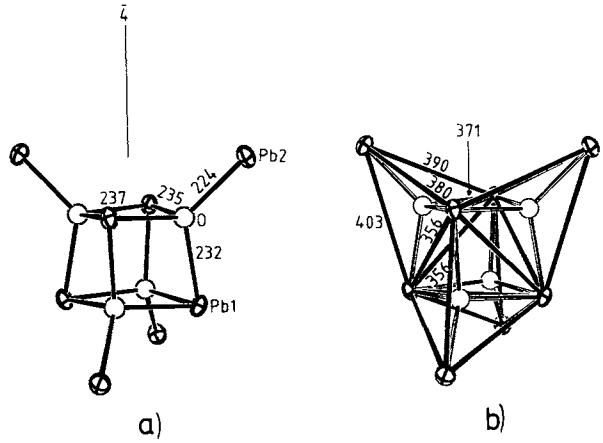

Fig. 1. The $Pb_8O_4$ group in $TlPb_8O_4Br_9$ **1** [1]: a) without, and b) with emphasis of the $Pb_4$-tetrahedra centered by O atoms (distances in pm).

Nucleus of this structural unit is a $Pb_4O_4$-cube with point symmetry $\bar{4}$, reminiscent of the "cubane" units in $[Pb_4(OH)_4](ClO_4)_4 \cdot 2H_2O$[7] and $Sn_{21}Cl_{16}(OH)_{14}O_6$[8]. However, unlike in the latter two compounds, in **1** and **2** there is a further lead atom above each corner of the cube occupied by oxygen atoms. This lead atom is located on the extrapolated diagonal of the cube. The oxygen atoms are thus tetrahedrally surrounded by lead atoms. Four of these $OPb_4$-tetrahedra are each coupled to one another *via* three edges and thus build the $Pb_8O_4$-unit, which can be regarded as an isolated polynuclear metallo-complex[9]. The charges of the outer Pb-ions are compensated by Br-ions, whereby the whole $Pb_8O_4$-group is enveloped (Fig. 2). Two of these lead-oxygen units separated by a bromide ion matrix are present in each unit cell.

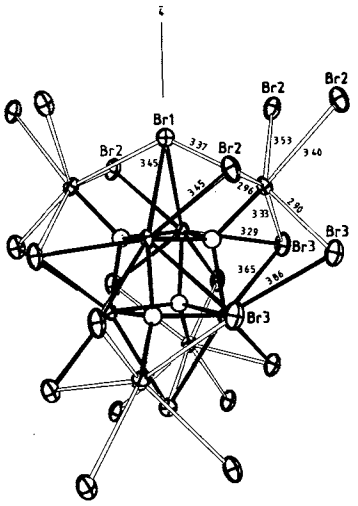

Fig. 2. The $Pb_8O_4$ group with bromide-ion environment in $TlPb_8O_4Br_9$ [1].

In **1** and **2**, slightly distorted tetragonal prisms formed from bromine atoms are stacked one on top of the other parallel to the fourfold symmetry axes in the unit cell. In **1**, every next but one prism is centered with thallium atoms; the prisms in between are unoccupied and elongated along [001] compared to the occupied prisms (Fig. 3a). Interatomic distances between thallium and bromine correspond to those in TlBr[10]. In **2**, the tetragonal prisms are considerably more elongated and compressed than in **1**;

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0404-0324 $ 02.50/0* 

the elongated prisms accomodate bromine atoms, the compressed neighboring prisms lead atoms (Fig. 3b).

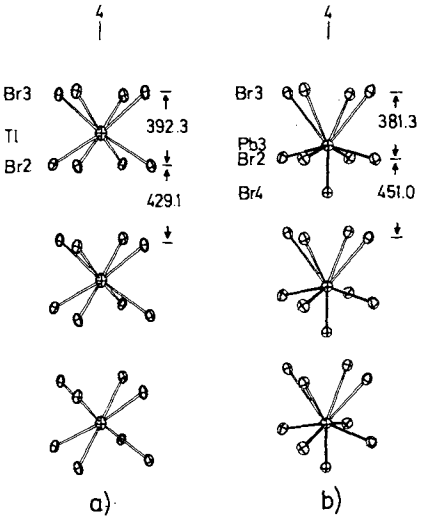

Fig. 3. The sequence of tetragonal prisms formed from Br-ions parallel to [001] in: a) $TlPb_8O_4Br_9$, and b) $Pb_9O_4Br_{10}$. The five nearest Br neighbors of Pb3 are emphasized by filled connecting lines. Further details of the crystal structure determination can be obtained on request from the Fachinformationszentrum Energy Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the number CSD 50365, the name of the author, and full citation of the journal.

The latter atoms are shifted from the center in the direction of the square basal plane, leading to a short Pb–Br-distance of 257.7 pm. To a first approximation each such Pb-ion shows a one-sided fivefold environment of bromine (Fig. 3b, filled connecting lines to Br2 and Br4). This at first sight unusual environment might be explained in terms of the effect of the lone pair electrons (on Pb3) if these are oriented in the opposite direction of the short Pb–Br-distance. For the lead atom in question, in contrast to the other, pseudotetrahedrally coordinated lead atoms, there results in the primary neighborhood a pseudooctahedral environment. This suggests comparison with a $BiCl_5^{2-}$ group in the bismuth subchloride $Bi_{24}Cl_{28}$[11].

## Isotope Effects in the Low-Pressure, High-Pressure, and Thin-Layer Chromatography of the Lanthanoids

By *Alfons Hufnagel* and *Hermann Specker**

During experiments on the HPLC separation of the lanthanoids we were able to detect an isotope effect in the case of the isotopes samarium-154 and samarium-144[1]. The total separation factor G, as defined by *Heumann*[2], was 1.06. The detection was accomplished mass spectroscopically. In continuation of these experiments we have now investigated the lanthanoids cerium and europium. Both elements have proven to be especially suitable for such studies regarding their natural isotopic composition and their subsequent determination by neutron activation analysis. Table 1 lists the physical properties of the isotopes used for the measurement of the isotopic enrichment.

Table 1. Physical properties of the isotopes employed. $T_{1/2}$ = halflife, $E$ = γ-energy, $P$ = emission probability (absolute intensity).

| Stable nuclide | Abundance [%] | Active nuclide | $T_{1/2}$ | $E$ [keV] | $P$ [%] |
|---|---|---|---|---|---|
| $^{140}Ce$ | 88.48 | $^{141}Ce$ | 32.5 d | 145.45 | 47 |
| $^{142}Ce$ | 11.07 | $^{143}Ce$ | 33 h | 293.3 | 43.3 |
| $^{151}Eu$ | 47.8 | $^{152}Eu$ | 12.7 y | 344.3 | 27 |
| $^{153}Eu$ | 52.2 | $^{154}Eu$ | 8.5 y | 123.1 | 40.46 |

In the first series of experiments, $Ce(NO_3)_3$ was subjected to multiple repurification and then chromatographed on two low-pressure columns coupled in cascade [Lobar, Merck, size A (240-10), Li Chroprep Si 60 (40–64 μm)]. 50 μL of a 1 M $Ce^{3+}$-solution (≙ 7 mg $Ce^{3+}$) in methanol/$HNO_3$ (3 : 1) was introduced onto the column *via* a three-way tap. Elution was carried out with a mixture of diisopropyl ether/tetrahydrofuran/$HNO_3$ (65%) in the ratio 100 : 20 : 5. The consistently reproducible retention time for cerium was 187 min, the peak width 39 min. After fractionation of the cerium peak into three twelve-minute fractions the respective "head" and the "tail" fractions were very carefully worked-up and then irradiated (neutron flux $10^{14}$ n $cm^{-2}$ $s^{-1}$). The absolute content of cerium in each of the fractions was not measured; for measurement of the isotope effect according to the aforementioned definition of the total separation factor G, we calculated the quotients of the net count rates of the characteristic γ-emission lines of the isotopes Ce-143 to Ce-141 in the "head" fraction and in the "tail" fraction. From ten single measurements an enrichment of the heavier isotope was found in the "head" fraction of the cerium peak with a mean total separation factor of 0.65 : 0.59 = 1.102 at the 99.9% confidence level.

In the case of HPLC- and TLC-enrichment we used previously activated cerium and europium samples as starting material. The eluent used in the HPLC separation [HPLC "Constametric" pump, Knauer columns (250 × 4.6 mm), silica gel 60 Li Chrosorb, particle size 7 μm, pore size 60 Å] was diisopropyl ether/tetrahydrofuran/$HNO_3$ (100 : 35 : 4), the amount of sample 150 μg $Ce^{3+}$ and 0.38 μg $Eu^{3+}$, respectively. The monitoring was carried out with a continuous flow NaI(Tl) scintillator. On the basis of the chromatograms obtained, five 1-minute fractions were collected in each case and the individual fractions measured γ-spectroscopically. For the cerium isotopes a total separation factor of 1.085 was obtained; this result was also measured at the 99.9% confidence level, from 18 measurements. The corresponding factor in the case of europium amounted to 1.03, at the same confidence level. According to our investigations so far, the different average total separation factors measured for the elements cerium and europium are not in the first instance the result of different fractionation but rather of different retention times. We

[*] Prof. Dr. H. Specker, Dr. A. Hufnagel
Lehrstuhl Anorganische Chemie I der Universität
Postfach 102138, D-4630 Bochum 1 (Germany)

are at present investigating the step heights in our sample carrier-eluent systems, so as to enable calculation of the element separation factors.

So far, TLC has proven to be the most efficient chromatographic method for the separation of the lanthanoids[3] [Merck plates, silanized silica gel (0.25 mm), size 20 × 20 cm, without fluorescence indicator]. We therefore resorted to TLC for the enrichment of the europium isotopes. The zones in conventional chromatography cannot, of course, be reproducibly defined as "head" and "tail" zones and so separated. It is known, however, that the zones can be concentrated by constricting the flow of eluent[4]. In this way the zones could indeed be separated into "head", "tail" and "middle" zones. Diisopropyl ether/tetrahydrofuran/$HNO_3$ (100:50:5) was used as eluent. In the case of the isotopes europium-154:europium-152 we obtained a total separation factor of 1.06 from 21 single measurements on the "head" and "tail" zones. The corresponding depletion in the "tail" zones was also confirmed from 23 single measurements at the 99.9% significance level. To our knowledge an isotope effect has hitherto never been detected in inorganic TLC. In the case of the isotope effects so far detected, an enrichment of the heavier isotopes in the "head" fraction or "head" zone was found in all cases during column and thin-layer chromatography, respectively. This is consistent with the chromatographic methodologies developed by us for the separation of lanthanoids using the same eluent system.

## Capping of Metal Atom Triangles in Clusters by $R_3PAu$ Moieties**

By *Eckehart Roland, Klaus Fischer,* and *Heinrich Vahrenkamp**

The growth of metallic microcrystallites or metal-rich clusters requires the incorporation of the monometal species at energetically favored face positions. Sporadic examples suggest that the additional species is bonded preferentially over triangles or quadrangles of metal atoms[1]. The recently[2] discovered exchange of hydride ligands for $R_3PAu$ moieties in clusters offers a method of studying these types of growth reactions systematically. Previously, a $R_3PAu$ moiety could be incorporated as a $\mu_2$-bridge across two metal atoms[3] or as a $\mu_3$-bridge across three metal atoms[2,4]. We have now found that incorporation of two $R_3PAu$ moieties leads to a repetition of the $\mu_3$-bridging principle.

Deprotonation of $H_2Fe_3(CO)_9S$ or $H_2Ru_2Co_2(CO)_{12}$ by KH in tetrahydrofuran (THF) leads to dianions which react smoothly with $Ph_3PAuCl$ to give the pentanuclear cluster **1** (47%, black crystals, m.p. = 150 °C) or the hexanuclear cluster **2** (38%, black crystals, m.p. = 133 °C). **1** and **2** were identified by crystal structure analysis (see Figs. 1 and 2, as well as Table 1).

$(Ph_3PAu)_2Fe_3(CO)_9S$ **1**

$(Ph_3PAu)_2Ru_2Co_2(CO)_{12}$ **2**

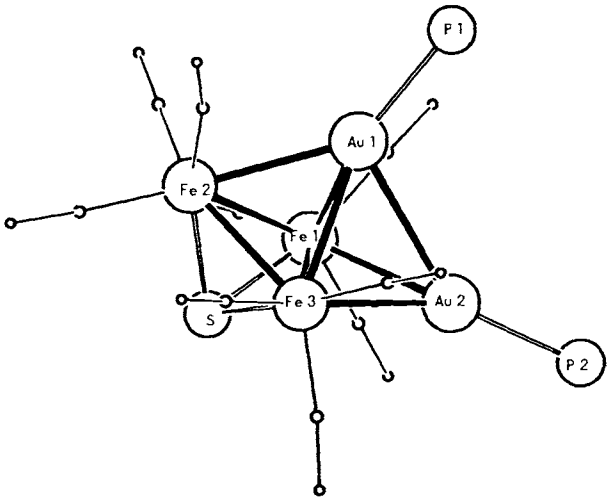

Fig. 1. Molecular framework of **1** in the crystal (small circles represent CO ligands; phenyl groups are not shown).

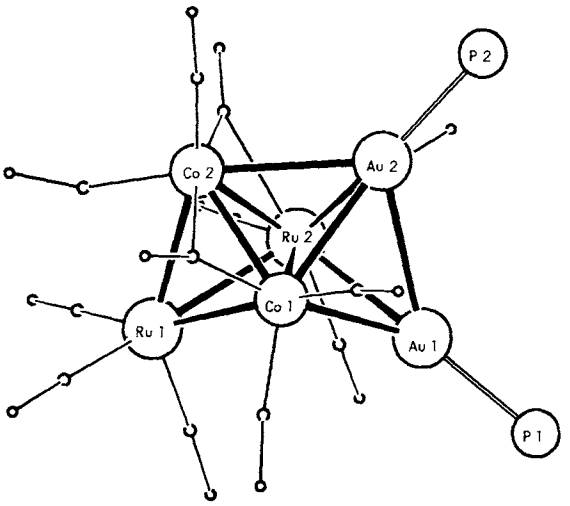

Fig. 2. Molecular framework of **2** in the crystal (small circles represent CO ligands; phenyl groups are not shown).

The stepwise growth of the clusters is apparent from their structures. One of the two gold atoms is located over a triangular face of the starting material, and the other over a triangular face formed by addition of the first gold atom. Of the metal-metal bonds, the inner (Fe1-Fe3 and Co1-Ru2, respectively) are extraordinarily long. This indicates a tendency of these bonds to rupture; the simultaneous formation of the Au2-S and Ru1-Au1 bonds, respectively, would lead to an octahedral cluster framework. By analogy, the growth of polymetal species can be comprehended as a sequence of $\mu_3$-cappings and reorganizations. Recently described triply gold-bridged ruthenium clusters[11] exhibit the same structural principle, whereas the carbido cluster $[CFe_4(CO)_{12}(AuPR_3)_2]$[12], obtained in a

nondirected way from $[Fe_4(CO)_{13}]^{2-}$, contains the gold atoms in $\mu_4$-positions as components of an octahedral framework. **2** is the first hexanuclear cluster to be constructed stepwise from simple building blocks ($KCo(CO)_4$, $[Ru(Co)_3Cl_2]_2$, $Ph_3PAuCl$), and is hence a unique example for the directed synthesis of clusters.

## Construction of an Alternating (Rh, Rh, Ir, Ir)$_\infty$-Columnar Structure *via* a Quasiracemate**

By *Volker Schurig**, *Wolfgang Pille*, and *Werner Winter*

The chiral, square-planar $d^8$ metal chelate dicarbonylrhodium(I) 3-trifluoroacetylcamphorate **1**[1a] has recently been reported as representing an interesting example for the striking influence of the relative chirality of the β-diketonate ligands on cooperative phenomena in the crystalline state[1b]. Thus, whereas the identically configurated molecules in the crystalline *yellow* enantiomers of **1** pack *via* a zig-zag arrangement of the metal atoms, the oppositely configurated molecules in the crystalline *red-green* (dichroic) racemate stack *via* a columnar structure with a one-dimensional metal atom chain.

(1*S*)-**1**: $R^1 = CF_3$, $M^1 = Rh$
(1*R*)-**2**: $R^2 = CH_3$, $M^2 = Rh$
(1*R*)-**3**: $R^2 = CF_3$, $M^2 = Ir$

It has been suggested[1b] that the influence of the heterochiral ligands in the racemate may be exploited to prepare highly ordered solid-state structures with alternating molecular properties by combining *quasienantiomers* of similar structure in a "zipper-like mode" to stable *quasiracemates* ("active racemates"[2]).

Having succeeded in obtaining a red-green (dichroic) quasiracemate from yellow dicarbonylrhodium(I) (1*R*)-3-*acetyl*camphorate (1*R*)-**2** and yellow dicarbonylrhodium(I) (1*S*)-3-*trifluoroacetyl*camphorate (1*S*)-**1**, we attempted to construct a columnar structure with alternately arranged homologous central atoms. When equimolar amounts of the yellow crystalline quasienantiomer dicarbonyl*rhodium*(I) (1*S*)-3-trifluoroacetylcamphorate (1*S*)-**1** and the yellow crystalline quasienantiomer of opposite configuration dicarbonyl*iridium*(I) (1*R*)-3-trifluoroacetylcamphorate (1*R*)-**3** are mixed, a crystalline black-violet (dichroic) quasiracemate forms spontaneously from the solution (*n*-hexane) or by a slow solid-state reaction.

The crystal structure of the quasiracemate (1*S*)-**1**/(1*R*)-**3** (space group C2, $a = 27.808(8)$, $b = 9.384(3)$, $c = 13.486(3)$ Å, $\beta = 117.57(2)°$, $Z = 4$ for the dimeric entity[3a]) is close related to that of the racemate (1*S*)-**1**/(1*R*)-**1** (space group C2/c, $a = 24.726(1)$, $b = 9.365(1)$, $c = 13.447(1)$ Å, $\beta = 91.56(1)°$, $Z = 8$)[3b]: the *b*- and *c*-axes in the quasiracemate and racemate have a similar length, whereas the extended *a*-axis in the quasiracemate corresponds to the [101]-axis in the racemate. In both columnar structures (Fig. 1), *anti*-orientated racemic and quasiracemic pairs of molecules (*R*,*S*), respectively, stack in such a way that an

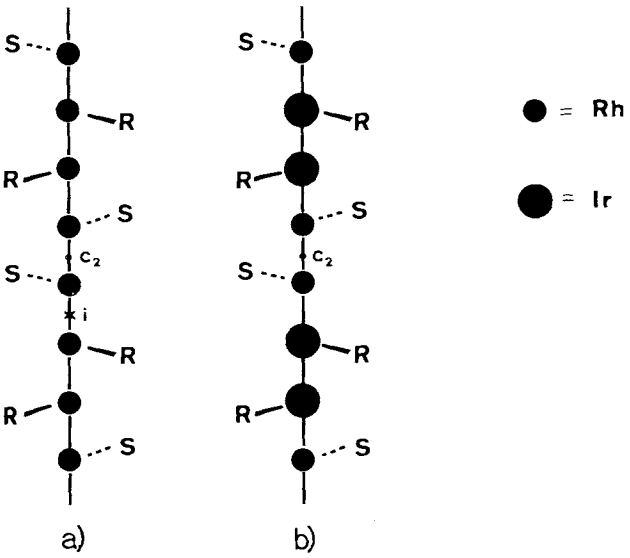

Fig. 1. Construction of an alternating (Rh,Rh,Ir,Ir)$_\infty$ columnar structure (b) *via* control by chiral ligands. Structural comparison between a) racemate [prepared from (1*S*)-**1** and (1*R*)-**1** (1:1)] and b) quasiracemate [prepared from (1*S*)-**1** and (1*R*)-**3** (1:1)].

overall alternating arrangement of ligands $(R,R,S,S)_\infty$ along the *c*-crystal axis results[4]. Thus, mixing the pure quasienantiomers (1*S*)-**1** and (1*R*)-**3** produces the quasiracemate as a *highly* ordered columnar structure with a one-dimensional $(Rh,Rh,Ir,Ir)_\infty$ chain of central atoms. The Rh–Rh, Ir–Ir, and Rh–Ir distances are 3.36, 3.36, and 3.43 (±0.02) Å, respectively. In the quasiracemate the metal chain is not strictly linear, since the Rh–Rh and Ir–Ir moieties are slightly displaced in the crystal lattice; the distance between the axes, which contain all Rh and Ir atoms, respectively, is 0.6 Å.

The pair-wise stacking in the crystalline quasiracemate enforced by the chirality of the molecules represents a new type of one-dimensional metal chain[5]. The tailor-made synthesis of quasiracemates appears, therefore, to be a highly promising method for the construction of collective solid-state structures having alternating molecular parameters.

## Synthesis of a Tetranuclear Manganese(IV) Cluster with Adamantane Skeleton: $[(C_6H_{15}N_3)_4Mn_4O_6]^{4+}$

By *Karl Wieghardt**, *Ursula Bossek*, and *Walter Gebert*

Stable complexes of manganese(IV) are hardly known in aqueous solution[1]. Some dinuclear μ-oxo-manganese(IV) compounds have been obtained by oxidation of $Mn^{II}$ by $O_2$ in alkaline media[1a]. Oxidation of $H_2O$ to molecular oxygen by tetrameric complexes of $Mn^{IV}$ (4e acceptor) has been discussed in connection with photosynthesis, although until now there were no examples of such compounds[1b].

We have now found that aqueous alkaline solutions of the cyclic amine 1,4,7-triazacyclononane react with manganese dichloride and oxygen to produce black solutions, from which, after addition of NaBr, black crystals of $[(C_6H_{15}N_3)_4Mn_4O_6]Br_{3.5}OH_{0.5}\cdot 6H_2O$, **1**, can be isolated[2]. The X-ray structure analysis of **1** indicates that a tetranuclear, oxo-bridging cation is formed (Fig. 1). The four Mn centers occupy the corners of a tetrahedron, and an O-bridging atom is located above the middle of each of the six edges.

The $Mn_4O_6$ moiety corresponds to an adamantane skeleton, as recently described for $[F_{12}Ta_4O_6]^{4-}$[3]. Each Mn atom is surrounded in a distorted octahedral configuration by three N atoms and three O atoms. The average values of the Mn–N and Mn–O distances are in excellent accord with those in $[(bpy)_2Mn^{IV}O_2Mn^{III}(bpy)_2]^{3+}$[4].

Redox titration of **1** with $[Fe(CN)_6]^{2-}$ at pH 5 indicates consumption of two equivalents per $Mn^{IV}$; this corresponds to the two-electron reduction of $Mn^{II}$. The visible absorption spectrum exhibits two maxima at 552 ($\varepsilon = 2.6\times10^3$ L mol$^{-1}$ cm$^{-1}$ per tetrameric unit) and 336 nm ($1.7\times10^4$). An intense band in the IR spectrum at 730 cm$^{-1}$ is characteristic of vibrations of the $Mn_4O_6$ cluster[5]. The magnetic moment of **1** adheres to the Curie-Weiss law over the range 93–293 K with $\theta = 37$ K and $\mu_{eff} = 3.96(2)\,\mu_B$ per $Mn^{IV}$; this corresponds to the spin-only value for a $d^3$ electron configuration of the $Mn^{IV}$ centers. The cation of **1** is stable in neutral and alkaline solutions.

[5] Interestingly, similar bands were found for the novel clusters $Cp_6Ti_6O_8$, $Cp_5V_5O_6$, $Cp_4Cr_4O_4$ ($Cp^-$ = cyclopentanienide): F. Bottomley, D. E. Paez, P. S. White, *J. Am. Chem. Soc. 104* (1982) 5651. This indicates the structural relationship of these clusters with the cation of **1**.

## $(C_5H_5)_6Ni_2Zn_4$— The First Zinc-Containing Mixed-Metal Cluster**

By *Peter H. M. Budzelaar, Jaap Boersma,* and *Gerrit J. M. van der Kerk**

In previous studies we found that dicyclopentadienylzinc, $Cp_2Zn$, is a useful starting material for the preparation of cyclopentadienylzinc-transition metal compounds[1]. By reaction of $Cp_2Zn$ with $Ni(cod)_2$ (cod = 1,5-cyclooctadiene) we have now been able to prepare $(C_5H_5)_6Ni_2Zn_4$ **1**[2], the first compound with a NiZn bond. This first zinc-containing mixed-metal cluster is extremely sensitive to hydrolysis and oxidation, particularly in solution.

A single-crystal X-ray diffraction study was undertaken in order to unambiguously establish the nature of **1**. It was found that **1** crystallizes in space group $P4_2/mnm$ of the tetragonal system with 2 formula units in a cell of dimensions $a = 9.352(5)$ Å and $c = 16.32(1)$ Å. The molecular framework consists of an octahedral arrangement of 4 equatorial zinc atoms and 2 apical nickel atoms, each having an $\eta^5$-bound cyclopentadienyl group attached to it (Fig. 1a). In accord with this symmetric structure, the $^1H$-NMR spectrum (90 MHz, solvent $C_6D_6$, TMS) shows two singlets ($\delta = 6.23$ and 4.64) in the intensity ratio 2 : 1 due to the cyclopentadienyl groups bound to zinc and nickel, respectively.

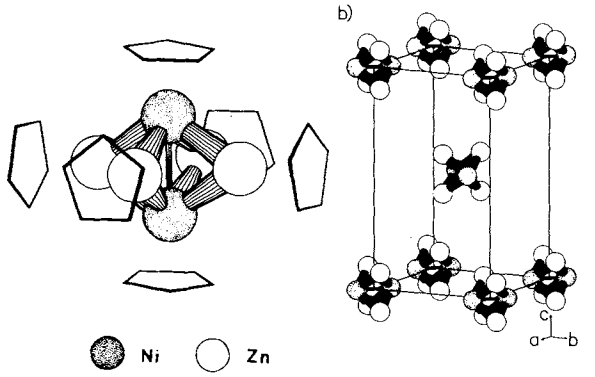

Fig. 1. a) Structure of $Cp_6Ni_2Zn_4$ **1** in the crystal. All cyclopentadienyl groups are disordered; only one orientation of each is shown. b) Packing of the $Ni_2Zn_4$ clusters of **1** in the unit cell [5].

Figure 1b shows the packing of the clusters in the unit cell. The metal octahedron, which has an almost perfect 4/mmm symmetry, is compressed along the NiNi axis; the NiZn distance is 2.40 Å, the NiNi distance 2.56 Å, and the ZnZn distance 2.79 Å. This last distance is very close to the non-bonded ZnZn distance of 2.78 Å found in $(CpZn)_2Co(Cp)PPh_3$[1]. Simple electron-counting, similarly to that used in the case of the iridium-copper cluster $Ir_2Cu_4(PPh_3)_2(C{\equiv}CPh)_8$[3], indicates that the metal framework in **1** is held together by 5 bonds. Since the NiNi distance of 2.56 Å is longer than that found in metallic nickel (2.50 Å) it may be assumed that interaction between the two nickel atoms will not be very strong. This leaves a bond order of between 0.50 and 0.63 for each of the eight NiZn bonds. In view of the close similarity of the covalent radii of nickel and cobalt, the NiZn single bond length should be very similar to the CoZn bond length in $(CpZn)_2Co(Cp)PPh_3$[1] and $Zn[Co(CO)_4]_2$ (2.30 Å)[4]. The significantly larger bond length in **1** is therefore in agreement with the proposed lower bond order.

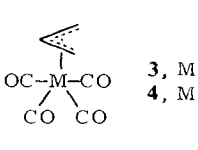
## Heavy Atom Effect in the Photoelectron Spectra of Transition Metal Complexes**



By *Michael C. Böhm* and *Rolf Gleiter**

The bands in photoelectron spectra are frequently assigned exploiting the fact that the intensities of the bands are a sensitive function of the wavelength of the radiation employed [*e.g.* He(I), He(II), Ne(I)] if the ejected electron is prevailingly localized at an element heavier than C (*e.g.* S, Se, Te and Ni, Pd, Pt)[1].

We describe here an alternative approach, namely that of varying the heavier element. This strategy is especially applicable in the case of transition metal compounds (replacement of a 3d atom by an isovalent electronic 4d or 5d atom). To demonstrate the utility of this principle we show in Figure 1 the He(I) PE spectra of the bis($\eta^3$-allyl) com-

plexes of Ni and Pt, **1** and **2**[2], as well as those of the $\eta^3$-allyl(tetracarbonyl) complexes of Mn and Re, **3** and **4**, respectively[3]. The ionization energies of these compounds are listed in Table 1. The bands corresponding to ionizations, which are predominantly localized at the metal atom (bands ② to ⑤ in the case of **1** and **2**, and bands ① to ③ in the case of **3** and **4**), split and become sharper when the 3d metal atom is replaced by a 4d or 5d metal atom. The reason for this splitting is the increasing covalent interaction between the nd orbitals (n = 3—5) of the metal atom and the orbitals of the organic ligands, which becomes greater with increasing principal quantum number of the metal atom. Slight differences in the covalent interaction are thereby enhanced. A prerequisite for the use of this heavy atom effect is a low symmetry of the complex, since degenerate levels are additionally propagated as a result of a Jahn-Teller effect and a rigid arrangement of the ligands.

Table 1. Ionization energies (I) of **1** to **4**. In the assignment, only the valence orbitals were considered.

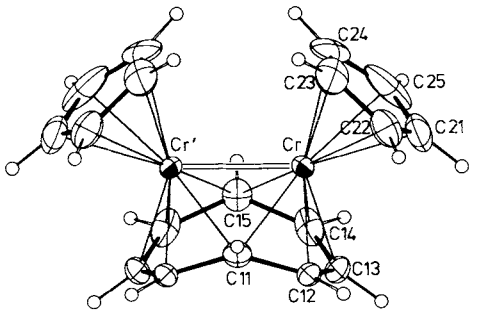
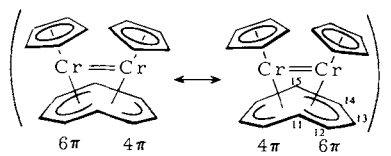
by the complexes $[(C_8H_8)Ti]_2C_8H_8$ and $[(C_5H_5)Co]_2C_8H_8$, whose bridging $C_8H_8$ rings are, however, nonplanar[1]. The second, synfacial variant is realized in $[(C_8H_8)Cr]_2C_8H_8$ **1**[2a] as well as in the complex $[(C_5H_5)V]_2C_8H_8$ **2**, which we prepared from $VCl_2$, $NaC_5H_5$, and $K_2C_8H_8$[2b]. A compound **3** having the analogous composition to **2**, $[(C_5H_5)Cr]_2C_8H_8$, was previously synthesized using another method $[(C_5H_5)_2Cr + Na_2C_8H_8]$ and characterized by X-ray crystallography[3a]. Surprisingly, in **3** a $C_8$ chain occurs, whose terminal C atoms are σ-bonded to the Cr atoms.

**1** **2** **3**

By allowing $CrCl_2 \cdot THF$ to react with $NaC_5H_5$ and $K_2C_8H_8$[4] we have now obtained compound **4** which, according to its elemental analysis and mass spectrum, also has the composition $C_{18}H_{18}Cr_2$ but which, in contrast to **3**, is characterized by simple NMR spectra [**4** ([D$_8$]toluene, 27 °C); $\delta(^1H) = 4.22$ (s, 10H), 3.89 (s, 8H); $\delta(^{13}C) = 74.53$, 86.55]. The X-ray structure analysis reveals that **4** has an analogous structure to **2**, and is hence an isomer of **3** (Fig. 1)[3b].





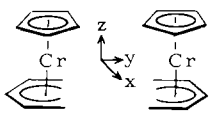


Fig. 1. Structure of **4** in the crystal (ORTEP representation, thermal vibrational ellipsoids with 30% probability). Mirror plane perpendicular to the Cr–Cr axis. Space group Pnma, $a = 1184.9(3)$, $b = 1577.8(3)$, $c = 764.1(2)$ pm, $Z = 4$. $R_w = 0.052$ (weighting $w = 2.6/\sigma^2_{F_o}$) for 693 independent reflections ($I > 2\sigma$; CAD4, Enraf-Nonius, MoK$_\alpha$). Important bond lengths [pm]: Cr–Cr' 239.0(2), Cr–C11 226(1), Cr–C12 207(1), Cr–C13 210(1), Cr–C14 205(1), Cr–C15 225(1), Cr–C21 220(1), Cr–C22 221(1), Cr–C23 219(2), Cr–C24 217(2), Cr–C25 220(2), C11–C12 142(1), C12–C13 141(2), C13–C14 139(2), C14–C15 144(1), C11···C15 310(2). Angles between the "best planes": at C(11)–C(15) axis: 131.4°, between C(11–15) and C(21–25): 16.2°. Distances Cr–C(11–15) 149 pm, Cr–C(21–25) 186 pm. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie-Physik-Mathematik, D-7514 Eggenstein-Leopoldshafen, by quoting the depository number CSD 50382, the names of the authors and the journal citation.

**4** can be considered as a combination of two "half-open" chromocene molecules[5a], **5**, which share the atoms C11–C15. The dinuclear complex **4**, which as opposed to the paramagnetic monomer chromocene ($S = 1$) is diamagnetic, displays a bond distance $d(Cr{-}Cr) = 239$ pm. Compared to other species with Cr–Cr bonds[5b], this distance suggests a Cr=Cr double bond.

**4**

**5**

A metal-metal bond order of 2 would also result from the interaction of two chromocene moieties of individual electron configuration ... $(e_2; xy, x^2-y^2)^3(a_1; z^2)^1$; the different overlap qualities of the $e_2$ and $a_1$ orbitals in **4** imply an MO sequence which—occupied by $2 \times 4$ electrons—leads to the configuration $(e^2)^4(a_1)^2(a\uparrow)^2$ for **4**. This is corroborated by the finding that the radical cation $\mathbf{4}^{\odot\oplus}$, generated electrochemically from **4**, has an orbitally non-degenerate ground state [$\langle g \rangle$ (dimethoxyethane, 27 °C) = 2.024, $a(^{53}Cr)$ not resolved]. Finally, the formation of **4** as a resonance hybrid secures that in each of the two canonical forms one Cr atom has an 18e shell.

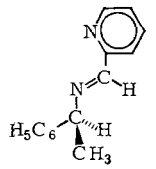
## Enantioselective Hydrosilylation of Acetophenone with Rhodium/Thiazolidine Catalysts**

By *Henri Brunner*, Georg Riepl,* and *Helgard Weitzer*

We recently reported on the enantioselective hydrosilylation of prochiral ketones with (cod)Rh-pyridine imine catalysts (cod = 1,5-cyclooctadiene)[1]. With the catalyst system $[(cod)RhCl]_2$/**1** (Rh : **1** ≈ 1 : 13) an enantiomeric excess (*ee*) of up to 57.3% was achieved in the reaction acetophenone → 1-phenylethanol (substrate : Rh = 110 : 1)[1].



With catalyst systems whose pyridine imine component is obtained from (−)-3-aminomethylpinane and 2-pyridine-

Institut für Anorganische Chemie der Universität
Universitätsstrasse 31, D-8400 Regensburg (Germany)

[**] Asymmetric Catalyses, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and BASF AG.—Part 9: see Ref. [1].

carbaldehyde, the *ee* value can be increased to 78% (substrate : Rh = 100 : 1, Rh : ligand = 1 : 15); L-valine methyl ester and L-alanine methyl ester as amine components in the Schiff base condensation, respectively, yield only slight or no enantiomeric excess. The best catalyst system for the model reaction is obtained from $[(cod)RhCl]_2$ and **2**, the

**1**

**2**

condensation product of L-cysteine methyl ester and 2-pyridinecarbaldehyde. With the Rh/thiazolidine system an enantiomeric excess of up to 86.7% is achievable (Table 1).

Table 1. Enantioselective hydrosilylation of acetophenone with diphenylsilane without solvent. Catalyst system: $[(cod)RhCl]_2$/**2**. The (*R*)-enantiomer is always formed as main product.

| Rh/2 | Rh/ Substrate | $T$ [°C] | $t$ [h] | Yield Chem. [%] | Opt. [% *ee*] |
|---|---|---|---|---|---|
| 1/9 | 1/210 | 0→20 | 38 | 99 | 83.2 |
| 1/5 | 1/210 | 0→20 | 20 | 96 | 80.0 |
| 1/2 | 1/210 | 0→20 | 20 | 96 | 74.7 |
| 1/1.6 | 1/210 | 0→20 | 43 | 95 | 72.3 |
| 1/5 | 1/860 | 0→20 | 65 | 94 | 78.2 |
| 1/5 | 1/1220 | 0→20 | 40 | 93 | 75.0 |
| 1/5 | 1/1710 | 0→20 | 65 | 92 | 78.9 |
| 1/5 | 1/2800 | 0→20 | 40 | 43 | 73.6 |
| 1/5 | 1/210 | −10 | 115 | 79 | 83.6 |
| 1/9 | 1/210 | −15 | 235 | 98 | 86.7 |

The Rh/thiazolidine system is also far superior to the Rh/Schiff base systems with regard to reaction rate and stability. High enantiomeric excesses are possible with the pyridine imine ligands only at substrate-rhodium ratios of up to 200 : 1[1]; in contrast, the Rh/thiazolidine catalyst leads to high conversion *and* high enantiomeric excess under the same conditions at substrate-rhodium ratios of up to 2000 : 1 (Table 1).

In the condensation of 2-pyridinecarbaldehyde with 1-phenylethylamine, 3-aminomethylpinane, alanine methyl ester and valine methyl ester, Schiff bases are formed which show characteristic low chemical shifts of the proton of the CH=N group in the $^1$H-NMR spectrum ($\delta = 8.0-8.7$). The $^1$H-NMR spectrum of the thiazolidine derivative **2** exhibits two doublets for the CHSN protons at $\delta = 5.84$ and 5.66 ($^3J_{HH} = 11.4$ Hz), in the intensity ratio 58 : 42; this finding is attributed to the presence of two diastereomers (the (2*R*,4*S*)-diastereomer is shown in the formula), which differ only in the configuration at C2. The diastereoselectivity in the formation of **2** corresponds to that in the oxazolidine ring closure of aldehydes and ephedrine[2]. It is surprising that an almost stereospecific synthesis of 1-phenylethanol is possible with a 58 : 42 diastereomeric mixture of the thiazolidine **2** and $[(cod)RhCl]_2$.

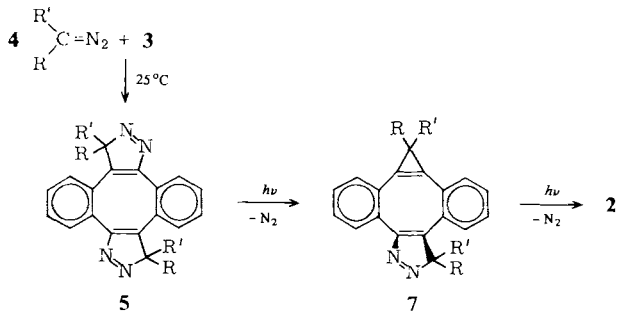
## A Novel Planar Antiaromatic Dibenzo[8]annulene**

By *Heinz Dürr**, *Günter Klauck*, *Karl Peters*, and *Hans Georg von Schnering*

*Dedicated to Professor Georg Wittig*

Cyclopropene double bonds are intermediary in character between the normal olefinic CC double bond and the CC triple bond. For this reason dibenzo[*a*,*e*]dicyclopropa[*c*,*g*]cyclooctene **2**, a cyclooctatetraene derivative in which two >C=C< units are each replaced by a cyclo-



**1** **2** **3**

propene ring, should be ranked between the olefinic dibenzo[*a*,*e*]cyclooctene **1** and the antiaromatic[1] [8]annulene **3**[4]. Compound **3** is planar[5] and relatively stable (transannular interactions see [6]).

We have checked, 1) whether the cyclopropene rings in **2** enforce a planar structure on the framework of **1**; 2) to what extent the planarity in **2** renders an antiaromatic [8]annulene possible.

For the synthesis of **2** the diyne **3** was first allowed to react with the diazo compounds **4a**–**d** to give the bis-3*H*-pyrazoles **5a**, **b** and the bis(spiro-3*H*-pyrazoles) **5c**, **d**.

**5** **7**

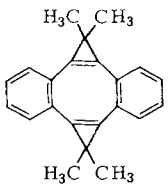
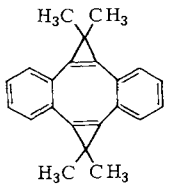
[**] Photochemistry of Small Rings, Part 42. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 41: E. Lüddeke, H. Rau, H. Dürr, H. Schmitz, *Tetrahedron 33* (1977) 2677.

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0404-0332 $ 02.50/0* 

Stepwise photochemical elimination of $N_2$ from **5** ($\lambda > 310$ nm, pyrex filter) then led *via* the cyclopropapyrazoles **7** to the biscyclopropenes **2**. According to an X-ray structure analysis[7] **7a** exists in the boat conformation with the three-membered ring and five-membered ring in *trans* orientation. **7b—d** could not be obtained in analytically pure form.

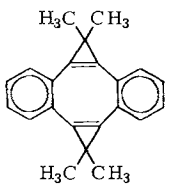


**8**



**9**

The $^1$H-NMR signals of the methylcyclopropene protons of **2a** ($\delta = 1.30$) are shifted about $\Delta\delta = 0.18$ upfield compared to those of **8** ($\delta = 1.47$), **9** ($\delta = 1.48$), and **7a** ($\delta = 1.48$). The protons of the benzene rings in **2a** ($\delta = 6.67 - 6.93$) are also shielded compared to those in **7a** ($\delta = 7.04 - 7.80$). This is unequivocally consistent with a paramagnetic ring current in **2a**. Consequently, **2a** appears to exist as a planar, paratropic, antiaromatic dibenzo[8]annulene, for which the resonance structures **2a** and **2a'** apply rather than **2a''**, in the classical sense of the resonance concept.



An X-ray structure analysis confirms that **2a** has an almost planar structure[7]. The bond lengths in **2a** and **3** ($C_a-C_b$ and $C_b-C_c$ in **2a**: 139.1 and 137.1 pm, respectively; in **3**: 138.9 and 136.9 pm, respectively) closely resemble each other. Despite structural differences the angular deformations are also essentially similar.

**2a**

**2a'**

**2a''**

Thus, in analogy to **3**, **2a** is to be regarded as a planar antiaromatic [8]annulene. So far, very few planar [8]annulenes have been reported in the literature.

## Stereospecific Reactions of Chiral Chlororuthenium(II) Complexes with Grignard Reagents

By *Giambattista Consiglio**, *Franco Morandini*, *Gianfranco Ciani*, and *Angelo Sironi*

Compounds with metal-carbon $\sigma$ bonds are mainly prepared by reaction of halometal complexes with organometallic derivatives of the main group elements. The stereochemical aspects of such "metathesis" reactions are largely unknown. $(-)_{365}$-$[(\eta^5\text{-}C_5H_5)Fe(CO)(PPh_2R^*)I]$ reacts with methyllithium to afford both diastereomeric methyliron complexes in the ratio 68 : 32[1]. On the basis of CD spectra, a reaction path involving retention of the configuration at iron was postulated. Because of the epimerization of the educt during the reaction, it could not be determined whether the reaction proceeds stereoselectively or stereospecifically.

**1**, **2** **3**, **4**

$[(S)_{Ru}, (R)_C]$: **1**, **3**; $[(R)_{Ru}, (R)_C]$: **2**, **4**

We report here that $CH_3MgBr$ reacts stereospecifically and with retention of configuration at Ru with $(S)_{Ru}$, $(R)_C$-[CpRuCl(prophos)] **1** (absolute configuration determined by X-ray structure analysis[2]) or with its diastereomer $(R)_{Ru}$, $(R)_C$-[CpRuCl(prophos)] **2** (prophos = propylenebis(diphenylphosphane)[3], Cp = $\eta^5$-cyclopentadienyl) to give $(S)_{Ru}$, $(R)_C$-[CpRu($CH_3$)(prophos)] **3** or $(R)_{Ru}$, $(R)_C$-[CpRu($CH_3$)(prophos)] **4**. The reaction of **1** [$^{31}$P-NMR (36.43 MHz, [D$_8$]toluene, room temperature): $\delta(P_a) = 86.4$, $\delta(P_b) = 61.3$, $J_{P-P} = 30.2$ Hz[4] with excess (molar ratio $\approx 1:8$) $CH_3MgBr$ ($\approx 2$ M in $Et_2O$) in [D$_8$]toluene under an inert gas atmosphere at room temperature was followed in an NMR tube. **3** [$\delta(P_a) = 100.0$, $\delta(P_b) = 74.1$, $J_{P-P} = 35.2$ Hz[4]; $^1$H-NMR (90 MHz): $\delta(Ru)CH_3 = -0.49$, $J_{P-H} = 5.7$ and 6.5 Hz] is formed quantitatively within 4 h. Complex **4** [$\delta(P_a) = 93.6$, $\delta(P_b) = 85.0$, $J_{P-P} = 32.9$[4]; $\delta(Ru)CH_3 = -0.21$, $J_{P-H} = 4.8$ and 6.4 Hz] is formed analogously from **2** [$\delta(P_a) = 80.9$; $\delta(P_b) = 74.1$, $J_{P-P} = 36.7$ Hz[4]]. Within the limits of detection of the NMR experiment **4** is not formed from **1** nor **3** from **2**.

**1** was also allowed to react with $CH_3MgBr$ on the preparative scale; after removal of the solvent, **3** was dissolved in toluene and crystallized by slow diffusion of *n*-pentane. The crystal structure of **3** (Fig. 1) proves that the configuration of the Ru atom is retained upon alkylation.

As in the case of the $[CpRuCl(PPh_3)_2]$ complex[5], **1** and **2** do not undergo alkylation with *s*-$C_4H_9MgBr$[5]; rather,

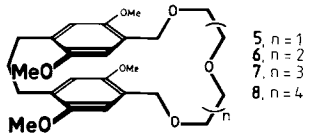
## Cation-Induced Charge-Transfer Absorption of Intramolecular Quinhydrones with Oligooxaparacyclophane Structure[1]

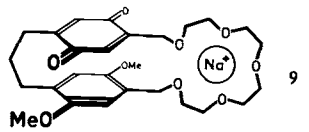
By *Helmut Bauer, Jan Briaire,* and *Heinz A. Staab**



The dependence of the charge-transfer (CT) absorption on distance, orientation, and mutual fixation of donor and acceptor components in quinhydrones of the [n.n]paracyclophanes (n = 2—5) were studied[1,2]. For the intramolecular quinhydrones **1–4**, which are oligooxa derivatives of [3.m]paracyclophanes (m = 9, 12, 15, and 18), it was anticipated that donor and acceptor are not optimally arranged for CT transition due to the width and flexibility of the macrocyclic rings. Because of the crown ether partial structure of these molecules, however, complexation of cations with suitable ionic radius should result in a greater rigidity of the macrocycle and in an approach of donor and acceptor regions; as a consequence, a change in CT-absorption was expected.

The synthesis of **1—4** starts from tetramethoxyoligooxaparacyclophanes **5–8**. **5** (m.p. 85—95 °C, mixture of *pseudoortho* and *pseudogeminal* isomers)[3a] was obtained from 4,4′-trimethylenebis(2,5-dimethoxybenzyl alcohol)[4] and

**1**, n = 1
**2**, n = 2
**3**, n = 3
**4**, n = 4



diethylene glycol ditosylate (sodium hydride, tetrahydrofuran, dilution principle; 20% yield). Analogously, reaction of 1,3-bis(4-bromomethyl-2,5-dimethoxyphenyl)propane[4] with tri-, tetra-, and pentaethylene glycol, respectively, led to **6** (m.p. 88—89 °C, 35% yield)[3a], **7** (m.p. 82—85 °C, 21%)[3a], and **8** (m.p. 67—69 °C, 22%)[3a].

**5**, n = 1
**6**, n = 2
**7**, n = 3
**8**, n = 4

Partial oxidative demethylation of **5–8**, respectively, with diammonium hexanitratocerate[5] yielded **1** (42%)[3b], **2** (65%)[3c], **3** (97%)[3d], and **4** (82%)[3e], respectively.

The UV/VIS spectrum of **3** has a CT absorption ($\lambda_{max}=462$ nm, $\varepsilon=324$; in chloroform), which upon complexation with $Na^+$ (NaSCN, chloroform) shows a remarkable increase in intensity ($\varepsilon=874$, Fig. 1), together with a bathochromic shift of 16 nm. This change in the CT absorption, which is also visually easily observable, is reversed by addition of the stronger ligand 4,7,13,16,21-pentaoxa-1,10-diazabicyclo[8.8.5]tricosane (Cryptofix® 221). To explain this complexation effect we assume that the reaction **3** → **9** results in a conformational change which brings the donor and acceptor regions of the molecule closer together. This is supported by the fact that, relative to those of **3**, in **9** the signals of the two benzoquinone protons in the $^1$H-NMR are shifted to highfield by $\Delta\delta=0.10$ and 0.23 ppm (in $CDCl_3$) as a result of a stronger transannular anisotropy effect of the neighboring aromatic ring. Crystals of **9** may be obtained (m.p. 152—153 °C, decomp.) from a solution in chloroform/methanol by precipitation with ether.

**9**

With the lower analogues **1** and **2**, $Na^+$ ions do not show any significant effect on the CT absorption; for the higher analogue **4** ($\lambda_{CT}=442$ nm, $\varepsilon=213$) the complexation effect of $Na^+$ with $\Delta\varepsilon=162$ is significantly smaller than for **3**. $K^+$ ions change the CT absorption of **1** and **2** scarcely at all, and that of **3** significantly less than $Na^+$ ions; with **4**, however, they result in an enhancement of the intensity by $\Delta\varepsilon=139$ and in a bathochromic shift of 23 nm. It seems to us that in compounds **1**—**4** a principle of cation-selective ligands with a "built-in CT indicator" is realized which may be of some general interest.

# BOOK REVIEWS

**Elektronenstruktur organischer Moleküle. Grundbegriffe quantenchemischer Betrachtungsweisen.** By *Martin Klessinger*. Verlag Chemie, Weinheim 1982. xv, 331 pp., bound, DM 78.—.

This book by *M. Klessinger* is the first volume of a six-part series entitled "Physikalisch Organische Chemie" and treats the current quantum chemical models of theoretical organic chemistry in nine chapters and a detailed appendix. The first chapter deals with the orbital concept in atomic and molecular systems, while the second one introduces the HMO (Hückel molecular orbital) model for simple systems and the third gives a short introduction to the basic principles of group theory and symmetry of fermion systems. The interactions between orbitals in a range of organic molecules are discussed in the fourth chapter and correlated with experimental results (photoelectron spectroscopy). Then the most important aspects of the application of perturbation theory are discussed. The basics of SCF (self-consistent field) models and various types of correlation diagrams (orbital correlation diagrams, configuration and state diagrams) are introduced in the next two chapters. Finally, important MO models of theoretical chemistry are treated together with quantum mechanical aids for the interpretation of such models (population analysis, energy fragmentation, localization procedures *etc.*).

All the chapters are constructed so as to be highly instructive; each time the main points of a theme are presented in a short introduction. The demands on the reader are then increased stepwise, without noticable gaps or jumps in the discussion. The numerous problems at the end of each chapter allow a continuous check on the text that has been worked through. Such an organized layout should make the volume attractive for a potential readership over and above theoretically and physically oriented organic chemists. The subject matter covers, on the one hand, the fundamental principles of quantum mechanics (the variational method, perturbation theory, Hellmann-Feynman relation) and, on the other hand, presents almost all the important models in applied theoretical (organic) chemistry that have been developed in the last 50 years. Many topics are treated at a level of intensity which is not to be found in comparable text books. The explanations of correlation technique (with many up to date references), the treatment of reactions in the ground state and photochemical reactions, the comparison of MO and VB results for reactive systems, together with the discussion of the various types of reaction hypersurfaces are all particularly effective. The layout of the text could perhaps have been made even clearer by combining chapters six and eight.

This textbook can, in any event, be unreservedly recommended to a wide readership. The construction of the book, the diagrams and the layout of the formulas could scarcely be more painstaking. This simplifies, in particular, the working through of the mathematical and quantum mechanical equations. The price of the book is reasonable in view of the amount of information it provides. It is to be hoped that the volumes of "Physikalisch Organische

Chemie" that follow maintain the high instructional quality and, thus, help to fill a considerable informational gap in the chemical literature. A good start has been made with *M. Klessinger*'s book, which deserves to find its way into a large number of textbook collections and private libraries.

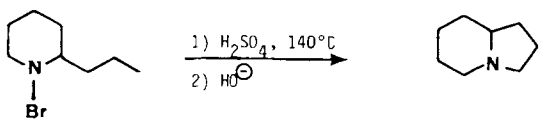
# Homolytic Cyclizations of *N*-Chloroalkenylamines

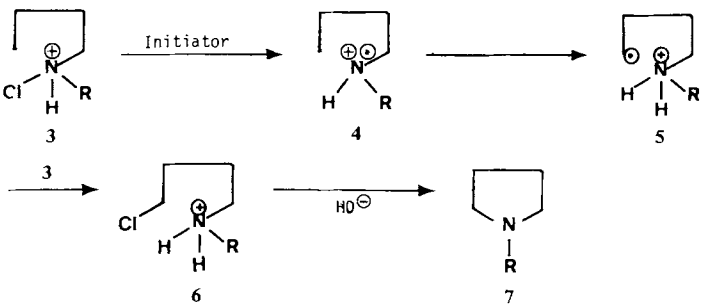
New synthetic methods (38)



By Lucien Stella*

*Dedicated to Professor Jean-Marie Surzur on the occasion of his 50th birthday*

Many *N*-chloroalkylamines with double bond(s) dissociate homolytically to give chlorine atoms and aminyl radicals which undergo intramolecular cyclization reactions. Here, the nature of the aminyl radicals (neutral, protonated, or complexed to metal salts) appears to be important. The reactivity varies strongly from one species to another, and their selectivities can be different towards addition, substitution, abstraction, or dimerization reactions. A good synthetic tool appears to be the "complexed radical", which is generated under mild conditions. A variety of β-functionalized, substituted, fused, or bridged azaheterocycles with alkaloid part structures thus become easily accessible in high yields, in a regio- and, possibly, stereoselective manner. Many examples are discussed illustrating the synthetic possibilities, limitations, and mechanistic features of this cyclization process.

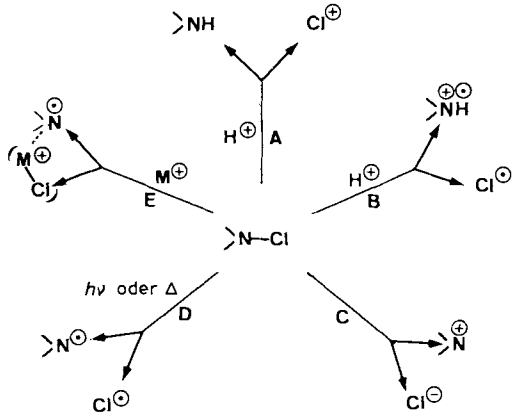


## 1. Introduction

The basis for the use of aminyl free radicals in organic synthesis—although unrecognized as such—was laid almost a hundred years ago. In the period 1881–1885, *Hofmann*[1] made the surprising discovery that the treatment of *N*-bromo-2-propylpiperidine **1**, an *N*-halodialkylamine, with hot sulfuric acid leads to a tertiary amine: this was later shown[2,3] to be octahydroindolizine **2**.

**1** **2**

*Löffler* and *Freytag*[4] extended the Hofmann reaction to simple secondary amines and found it to be a general method for synthesis of pyrrolidines[5]. *Wawzonek* and *Thelen*[6], and later *Corey* and *Hertler*[7] about 70 years after its discovery, established a free radical chain mechanism for this reaction.



The protonated *N*-chloroamine **3** undergoes homolytic cleavage under the influence of heat, light, or initiators. The protonated aminyl radical **4** obtained intramolecularly abstracts a sterically favorably orientated hydrogen atom to afford, regioselectively, an alkyl radical **5**, which in turn abstracts a chlorine atom to form a chloroalkylammonium ion **6**: this then cyclizes in the presence of base to

afford the cyclic tertiary amine 7. In 1963 *Wolff*[5] presented a comprehensive survey of this reaction, known today as the Hofmann-Löffler-Freytag reaction.

Besides their selective behavior, which at that time was astonishing, *N*-chloroamines have proved to be useful synthons for ionic or radical aminations and chlorinations. Thus, in protonating media they can lead spontaneously to amine and chlorine(I) ions (Scheme 1, path A) or, in the presence of initiators, to ammoniumyl ions and chlorine atoms (path B). In non-protonating media, solvolysis can produce aminylium and chloride ions by heterolytic dissociation (path C), whereas photolysis or thermolysis afford aminyl radicals and chlorine atoms (path D). Finally, in the presence of reducing metal salts, a redox process generates an aminyl radical complexed to the metal salt, and a chloride ion (path E).

Scheme 1. $>NH^{\oplus\odot}$: Ammoniumyl ion, amine cation or protonated aminyl radical; $>N^{\oplus}$: aminylium ion; $>N^{\odot}$: aminyl radical.

A review article[8] which presented a comprehensive discussion of these various modes of reaction appeared in 1970. More recently, a number of publications[9–13] have stressed the value of the homolytic reactions of *N*-chloroamines in synthetic organic chemistry, especially for the amination of olefinic[9,13] and aromatic[12] compounds, and for the chlorination of saturated aliphatic compounds[12]. As in the Hofmann-Löffler-Freytag reaction, many of these reactions of aminyl radicals do not afford mixtures of products or tars but, in contrast, proceed with very high regioselectivities and good yields. This is, for example, the case when *N*-chloroamines add to alkenes and conjugated dienes[13] under conditions favoring generation of free radicals.

In principle, addition of aminyl radicals to a CC double bond can also occur intramolecularly. The reaction pathways of the alkyl radical thus formed proceed either *via* transfer of a chlorine atom to give β-chloroazaheterocycles, or by addition to strategically located double bonds, or by substitution of aromatic rings to form polycyclization products. These reactions are of interest both for synthesis and for the mechanistic problems they pose. Despite increasing interest in the chemistry of aminyl radicals[16–19], until recently[14,15] the synthetic possibilities presented by their intramolecular addition to CC double bonds remained in the background—in contrast to the well-known corresponding reactions involving carbon-centered radicals[20–23]. The present review points out that, under carefully controlled conditions, homolytic heterocyclizations of *N*-chloroalkenylamines have interesting applications which compete in originality and usefulness with ionic reactions of the same substrates.

This article deals first with the reactions of aminyl radicals as a function of their nature (neutral, protonated, or complexed to a metal salt). The different behavior of monoolefinic *N*-chloroamines under various reaction conditions is then examined, including competition between 1) ionic and radical reactions, 2) between radical abstraction and radical addition reactions, and 3) between radical addition and radical substitution reactions. A number of factors are identified which allow classification of the reactions of aminyl radicals and selection of experimental conditions for organic synthesis: complexed aminyl radicals cyclize to mono- or polycycles. This constitutes a "redox cyclization" of the substrate. Ionic and radical cyclizations of *N*-chloroalkenylamines are compared.

## 2. Characteristic Reactions of Aminyl Radicals

### 2.1. Neutral Aminyl Radicals

Besides thermal or photolytic decomposition of 2-tetrazenes[18,24–27], neutral aminyl radicals can also be generated by photolysis of *N*-chlorodialkylamines in neutral media[28–31]. Generally, neutral dialkylaminyl radicals dimerize to hydrazines and disproportionate to Schiff bases and amines[24–27]. In the presence of olefins they show a strong tendency to abstract hydrogen[25,32,33] in preference to addition reactions. However, they are not useful dehydrogenating agents, since mixture of products are obtained in low yields[26]; intramolecular abstraction of hydrogen (Hofmann-Löffler-Freytag type) is not observed[34]. However, aminyl radicals add to styrene and to α-methylstyrene[35] as well as to arenes[36], but not in the presence of non-aromatically bonded atoms[26,37]. Similarly, addition to ethene (no reactive hydrogen atoms) has been reported[27], but no yields given.

The sluggishness of neutral dialkylaminyl radicals to add to olefins, as well as their strong tendency towards non-selective abstraction of hydrogen seemed to rule out reactions that could be of preparative value.

### 2.2. Protonated Aminyl Radicals

Homolytic decomposition of *N*-chlorodialkylamines in acidic media leads to generation of protonated aminyl radicals[9,10,12], which behave very differently from neutral species. Indeed, the positive charge eliminates the tendency to dimerize or disproportionate. The most important difference is the pronounced tendency of the protonated radicals to add efficiently to many types of unsaturated hydrocarbons[9] and arenes[12,38] in preference to abstracting allylic or benzylic hydrogen atoms. However, protonated aminyl radicals can also abstract hydrogen atoms very selectively in intramolecular[5] (the Hofmann-Löffler-Freytag reaction is faster than intermolecular additions[39]) as well as in intermolecular reactions [$(\omega-1)$ effect[12]]. The homo-

lytic amination of olefins and arenes can be limited or eliminated by the competitive electrophilic chlorination which takes place with electron-rich substrates[9,12].

### 2.3. Aminyl Radicals Complexed to Metal Ions

The decomposition of *N*-chloroamines catalyzed by reducing metal salts in neutral solution generates aminyl radicals complexed to metal ions[13,40]. As in the case of protonation, complexation is presumed to take place *via* the lone pair of electrons of the aminyl radicals. This might increase their electrophilic character and induce a reactivity intermediate between that of neutral and protonated species[41]. Hence, it is not altogether surprising that complexed, like neutral aminyl radicals, do not undergo Hofmann-Löffler-Freytag reactions[34] or selective intermolecular abstractions [$(\omega-1)$ effect is not observed[12]]. Like protonated species, complexed aminyl radicals do not dimerize or disproportionate but add efficiently to dienes, acetylenes, and alkenes[42-45]. Moreover, use of a non-acidic medium in many cases prevents electrophilic chlorination, which is the main limiting reaction of protonated *N*-chloroamines[46,47].

A significant difference in the *cis*- to *trans*-ratios occurs in the adducts of cyclohexene with protonated and complexed aminyl radicals. Thus, addition of *N*-chloropiperidine in acidic media gives a mixture of *cis*- and *trans*-products, whereas in non-acidic solvents mainly the *cis*-isomer is obtained[40]. This stereoselectivity was explained by coordination of the unprotonated radical by the metal salt, which of course is not expected with the protonated species.

Although homolytic substitution of activated aromatic compounds can proceed highly regioselectivity using complexed aminyl radicals[48], strongly acidic media are preferred for highest yields and the low reactivity of the strongly deactivated protonated aromatic amines formed[12].

It is noteworthy that the mild experimental conditions required for generation of complexed aminyl radicals can prevent undesired reactions. This is of particular interest for sensitive systems which could be decomposed by strong acids.

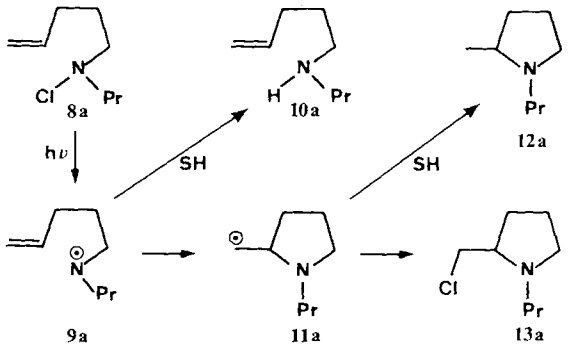
## 3. Synthesis of Monocyclic Compounds

### 3.1. *N*-Chloro-4-alkenylamines

#### 3.1.1. Monosubstituted Double Bonds

*Cyclizations of Neutral Aminyl Radicals:* Unexpectedly, we obtained very strong evidence for intramolecular addition of neutral aminyl radicals[28]. It is clear in this particular case, where the two reacting groups are strategically situated in the same molecule, that very favorable entropy effects come into play. Photolysis of *N*-chloro-*N*-propyl-4-pentenylamine **8a** was studied in various neutral solvents, and the results are shown in Table 1.

In aqueous acetic acid, where *N*-chloroamines exist as free bases[7], photolysis of **8a** gives only 2-chloromethyl-



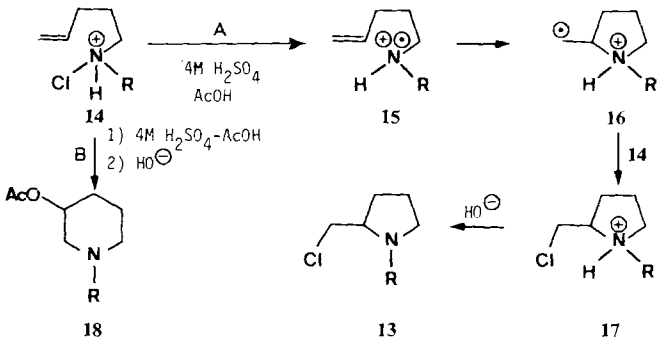


Table 1. Photochemical Cyclization of *N*-chloro-*N*-propyl-4-pentenylamine **8a** in non-protonating solvents (SH), which can function as H donors.

| Solvent | Yield [%] | **10a** : | **12a** : | **13a** |
|---|---|---|---|---|
| AcOH-$H_2O$ (1:1) | 70 | 0 | 0 | 100 |
| MeOH | 72 | 14 | 49 | 37 |
| *i*PrOH | 62 | 29 | 61 | 10 |

pyrrolidine **13** in 70% yield. This appears to be an attractive synthetic method which takes place under quite mild conditions. The relative yields in Table 1 are in good agreement with the participation of the radicals **9a** and **11a**. In particular, 1) formation of **13a** rules out the expected intermolecular reaction of a Cl atom[49], 2) the exclusive formation of the five-membered ring radical **11a** is a characteristic feature of homolytic intramolecular additions of radicals[15], and 3) the reactions of radicals **9a** and **11a** depend only on the ability of the solvent to act as an H donor; the stronger this ability, the higher the amount of **10a** and **12a** produced, and the lower that of **13a**. The hypothesis that the aminyl radical thus generated is not neutral is invalidated by the different behavior of protonated and complexed aminyl radicals (see below), and by the similar behavior of aminyl radicals generated by photolysis of *N*-chloroamines or tetrazenes[18,31].

*Cyclizations of Protonated Aminyl Radicals:* In view of the clear electrophilic character of protonated aminyl radicals, it can be expected that they cyclize more ready than their neutral counterparts. The first systematic investigation of this type of reaction[50] with protonated *N*-chloroamines **14** brings certain characteristic features to light. The main results are collected in Table 2 (see Schemes 2 and 3).

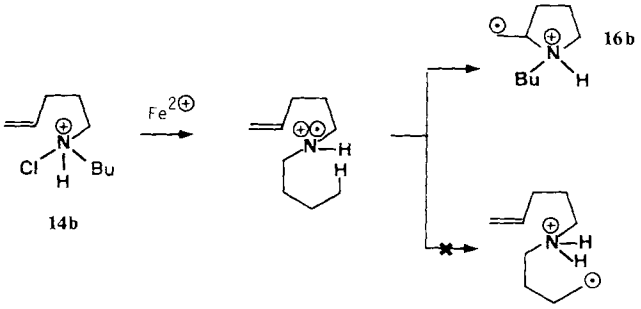
Heat, UV light, and metal ions ($Fe^{2+}$) can catalyze the homolytic cyclization; the best yields are obtained with the last two methods mentioned. Intramolecular addition of protonated aminyl radical **15** to **13** is favored by performing the reaction at room temperature in the absence of oxygen and under conditions of relatively high acidity (4 M $H_2SO_4$ in AcOH). As indicated by the inhibitive effect of oxygen and catalytic amounts (1—2%) of metal-ion initiators, the homolysis follows a mechanism with a long reaction-chain propagated by the radical **15**. The exclusive formation of the primary radical **16** resulting from regioselective cyclization to the five-membered ring strongly suggests that the intramolecular addition is kinetically controlled. Initiation of the reaction by heat and/or subsequent work-up at relatively high temperature ($T > 60$ °C) can result in rearrangement of the primary product[51]. Thus, the 2-chloromethylpyrrolidines **13** can undergo the well-known ring expansion[52] to the 3-chloropiperidines **21** *via* the bicyclic aziridinium salt **20**[50], which can also react with nucleophiles other than the chloride ion (acetate ions, for example) leading to a mixture of β-functionalized piperidines **18** and pyrrolidines **19**, whose the ratio is dependent on the nature of the nucleophile (Scheme 3)[53].



Scheme 3.

In the absence of initiators or in presence of oxygen, **14** reacts exclusively by ionic chlorination leading to **18** (see Scheme 2).

Interestingly, the product resulting from rearrangement of a protonated aminyl radical by a Hofmann-Löffler-Freytag reaction is not formed when intramolecular 1,5-addition to the double bond is possible[54] (Table 2).

Moreover, this is also the case for *N*-chloro-5-alkenylamines when allylic activated δ-hydrogen atoms are present [see **38** → **39** (Section 3.2) and **137** → **138** + **139** (Section 4.5)].

In contrast, *N*-chlorodialkylamines undergo facile Hofmann-Löffler-Freytag rearrangements at the expense of intermolecular free radical addition to simple alkenes[41,55].

*Cyclizations of Aminyl Radicals Complexed to Metal Ions:* When applied to the olefinic *N*-chloroamines **8**, the experimental conditions described by *Minisci et al.* for the intermolecular addition of *N*-chloroamines to olefins in the presence of redox systems[44] gave only very poor yields (less than 20%) of heterocyclic compounds[51]. The search for appropriate conditions for the intramolecular reaction led us to a solvent consisting of 50% aqueous acetic acid[50]. This mixture dissolves the metal salts and the *N*-chloroamines. The best yields of heterocyclization products are obtained using titanium trichloride as reducing agent (Table 3). Due to its high solubility and decoloration when oxidized, this salt allows control of the exact quantities (*ca.* 0.1 equivalents) and time required for complete

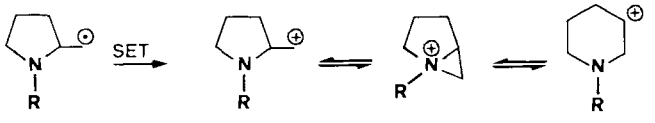
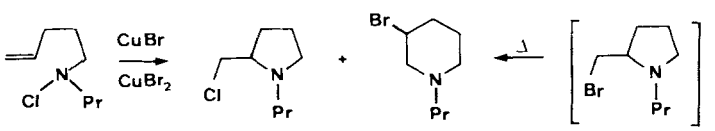
[a] Together with 9% amine **10a**.



reaction. Although they do not offer the same advantages, copper(I) and iron(II) salts are also suitable reducing agents; however, in order to avoid reducing the aminyl radicals to amines[50] they should be used in the presence of twice as much copper(II) or iron(III) salts. Larger amounts (0.2 to 0.45 equiv.) of metal salts, however, complicate the further work-up.

The mechanism of the reaction depends on the nature of the metal salts: homolytic fission of the N–Cl bond effected by the reducing metal salt produces, in every case, a metal-complexed aminyl radical **22**, which undergoes cyclization by intramolecular addition to the double bond.

Two principal ways for reaction of the resulting carbon-centered radical **23** can be envisaged[13]: 1) reaction with the oxidizing species $(MCl)^+$ in a redox chain process, 2) reaction with the *N*-chloroamine **8** and abstraction of a chlorine atom in a typical radical chain reaction. In both cases catalytic amounts of metal salts are required.

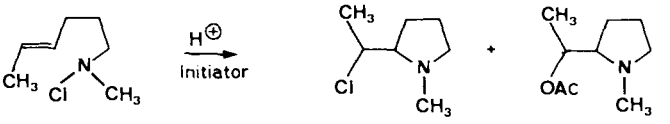


There are two main types of interactions between alkyl radicals and metal salts[56]: the selective transfer of a ligand bonded to the metal ("ligand transfer") and the selective oxidation of the alkyl radical to a carbocation ("electron transfer").

On the basis of extensive investigations by *Kochi*[56], we can expect that, as in intermolecular addition reactions of *N*-chloroamines to alkenes[13], "ligand transfers" are involved when copper(II) and iron(III) chlorides are used. This process is in good agreement with the exclusive formation of the 2-chloromethylpyrrolidine system **13**. "Electron transfer" oxidation of the non-complexed carbon-centered radical **11** should result in a five-membered ring carbocation **24**, which is very prone to rearrange to the piperidine ring species **25** *via* a bicyclic aziridinium ion (cf. **20**)[52] (SET = single electron transfer).

**11** **24** **25**

Furthermore, the use of a stoichiometric amount of copper(II) bromide clearly confirms the "ligand transfer" mechanism. Under these conditions the 3-bromopiperidine **26** resulting from the rearrangement of the initially formed thermally unstable 2-bromomethylpyrrolidine **27** is isolated in 23% yield together with 17% 2-chloromethylpyrrolidine **13a**[34].

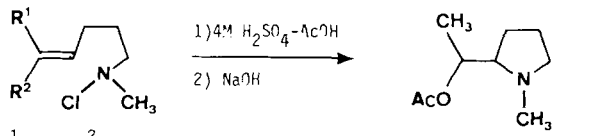


**8a** **13a** **26** **27**

When the reactions are carried out using titanium trichloride, the development of a redox chain mechanism *via* a "ligand transfer" process is unlikely. In this particular case further evidence clearly shows that a typical radical chain reaction takes place (see Section 4.1).

### 3.1.2. *Disubstituted Double Bonds*

In highly acidic media exclusively competitive ionic chlorination becomes important when the double bond of the *N*-chloroalkenylamine is disubstituted by alkyl groups (Table 4).



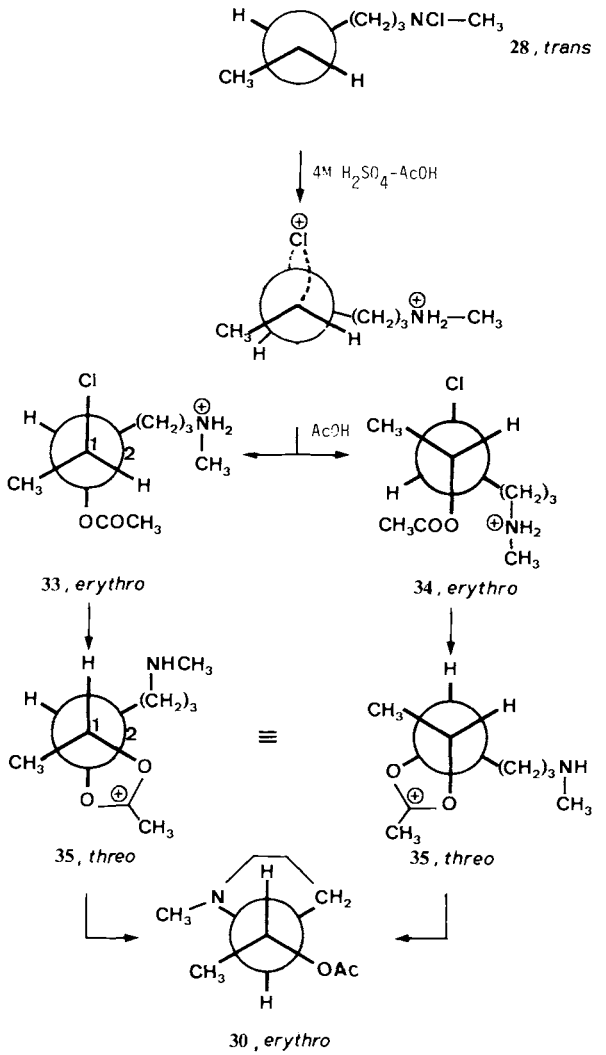
**28** **29** **30**

Table 4. Cyclization of *N*-chloro-*N*-methyl-*trans*-4-hexenylamine **28** in 4 M $H_2SO_4$-AcOH solution.

| Conditions | Yield [%] | |
|---|---|---|
| | **29** | **30** |
| $FeSO_4$, $N_2$, 25 °C | 3 | 47 |
| *hν*, $N_2$, 25 °C | 5 | 50 |
| Δ, $N_2$, 110 °C | 34 | 12 |

With radical initiators the protonated *N*-chloroamine **28** leads to a mixture of *erythro*- and *threo*-2-(1-chloroethyl)-1-methylpyrrolidine **29** and *erythro*-1-(1-methyl-2-pyrrolidinyl)ethyl acetate **30**[57]. It was demonstrated[57,58] that the acetate **30**, which occurs in pure *erythro*-configuration, is not formed from the mixture of chlorides **29** but directly by the ionic pathway (see below)[57,58].

The electrophilic chlorination of *N*-chloroalkenylamines, which competes with the homolytic heterocyclization can also be useful for synthetic purpose because it leads to regio- and stereoselective heterocyclizations[58]. Hence *trans*-*N*-chloro-4-hexenylamine **28** in 4 M $H_2SO_4$–AcOH mixture forms the *erythro*-pyrrolidine **30**[58], whereas under the same conditions the *threo*-pyrrolidine **32** is formed from *cis*-*N*-chloroamine **31**[59].



**28**, $R^1$ = H, $R^2$ = $CH_3$
**31**, $R^1$ = $CH_3$, $R^2$ = H

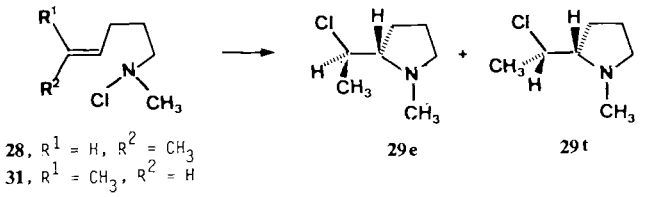
**30**, *erythro*, 42%
**32**, *threo*, 55%

This result can be rationalized as follows[58]. The *trans*-chloroacetylation of the *trans*-double bond of **28** produces two *erythro*-chloroacetates (**33** and **34**). The next two steps consist essentially of two $S_N2$ reactions, which both lead to an inversion, so that the net result is a retention of configuration. For example, starting from the *erythro*-chloroacetate **33**, the *threo*-ion **35** is formed by inversion of the configuration at C-1. The cyclization leading to the *erythro*-aminoacetate **30** then induces inversion of the configuration at C-2.

As for the stereoselectivity, the regioselectivity can be also explained by neighboring group participation with anchimeric assistance; the lowest conformational energy is for the cyclization leading to a five-membered ring[58].

Considering now the redox mechanism of the cyclization of *N*-chloroalkenylamines in non-protonating media, we expect that if the metal in a polydentate complex per-

mitted a relatively rigid transition-state an efficient stereospecific radical reaction should occur. Thus, we employed[60] *trans*- **28** and *cis*-*N*-chloro-*N*-methyl-4-hexenylamine **31** as substrates which react with reducing metal salts to form *erythro*- **29e** and *threo*-2-(1-chloroethyl)-1-methylpyrrolidine **29t** (Table 5).



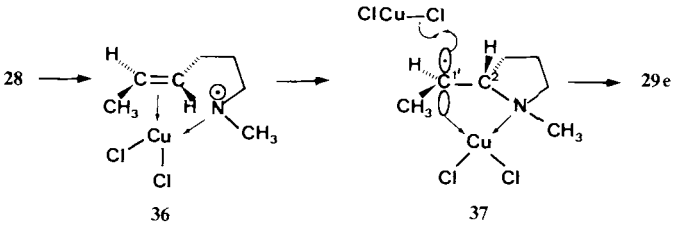


Table 5. Stereoselective cyclization of **28** and **31** with redox systems.

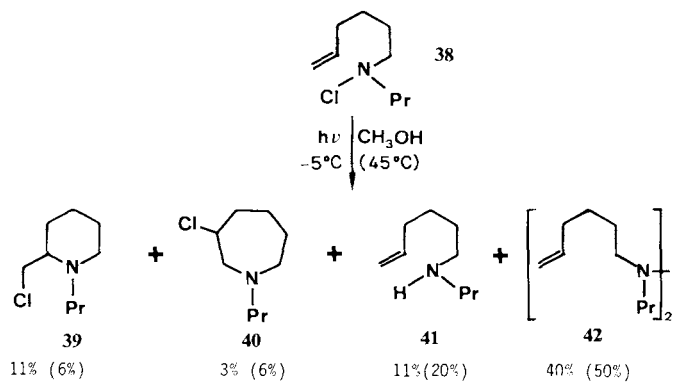
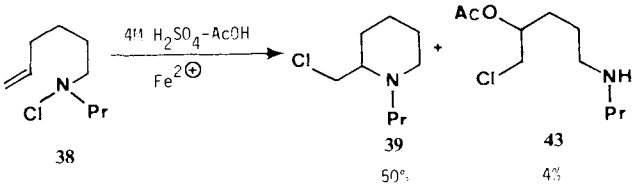
| Substrate | Metal salt(s) | Yield [%] | **29e** | : | **29t** |
|---|---|---|---|---|---|
| **28** | $TiCl_3$ | 74 | 58 | | 42 |
| **28** | $CuCl$-$CuCl_2$ | 81 | 100 | | 0 |
| **28** | $FeCl_2$ | 78 | 100 | | 0 |
| **31** | $TiCl_3$ | 79 | 42 | | 58 |
| **31** | $CuCl$-$CuCl_2$ | 79 | 9 | | 91 |
| **31** | $FeCl_2$ | 76 | 0 | | 100 |



These results are in accord with the following interpretation: the carbon centered radical formed in the cyclization abstracts a Cl atom from the *N*-chloroamine in a typical radical chain reaction, if titanium salts are used, or transfers a Cl atom from copper(II) or iron(III) chloride in a redox chain mechanism. The *cis*-*N*-chloroamine **31** preferentially forms the *threo*-isomer **29t** and the *trans*-*N*-chloroamine **28** the *erythro*-isomer **29e**, *i.e.* the intramolecular addition is *trans (anti)*. This highly stereospecific *trans*-addition strongly suggests hindered rotation about the C2–C1′ bond in the radical **37**, and can be attributed to the coordination of the radical to the metal salt.

The result may also imply that the rate of chlorine transfer, which is higher for redox chain reactions than for typical radical chain reactions[56], controls the extent of stereospecificity. Such stereochemical behavior supports the concept that stereoselective biosyntheses could consist of controlled radical reactions[61].

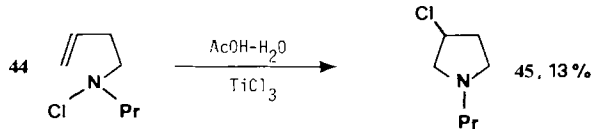


### 3.2. *N*-Chloro-3-alkenyl- and *N*-Chloro-5-alkenylamines

That the absolute rate constants for the cyclization of the neutral *N*-propyl-4-pentenylaminyl radical **9** are not amenable to measurement, indicates clearly that this process is slow ($k_c < 10^3\ s^{-1}$ at 80°)[90]. Nevertheless, on the basis of their main features, the cyclization of neutral alkenylaminyl radicals resembles those of analogous oxygen and non-stabilized carbon-centered radicals[14,15]. Thus, while the photolysis of *N*-chloro-*N*-propyl-3-butenylamine **44** (lower homologue) in methanol leads only to the parent amine[34], the *N*-chloro-*N*-propyl-5-hexenylamine **38** (higher homologue) can cyclize, leading in low yields to a temperature dependent ratio of a mixture of 2-chloromethylpiperidine **39**, 3-chloroazacycloheptane **40**, together with amine **41** and hydrazine **42**[34].

The behavior of *N*-chloro-3-alkenyl- and *N*-chloro-5-alkenylamines was also studied in protonating solvents[57]. With *N*-chloro-3-alkenylamines formation of protonated aminyl radicals does not lead to cyclization but to β-frag-

mentation. With the *N*-chloro-5-alkenyl isomer cyclization, for example, of **38** occurs and gives the 2-chloromethylpiperidine **39** in 50% yield together with a small amount of the β-chloroacetate **43**.

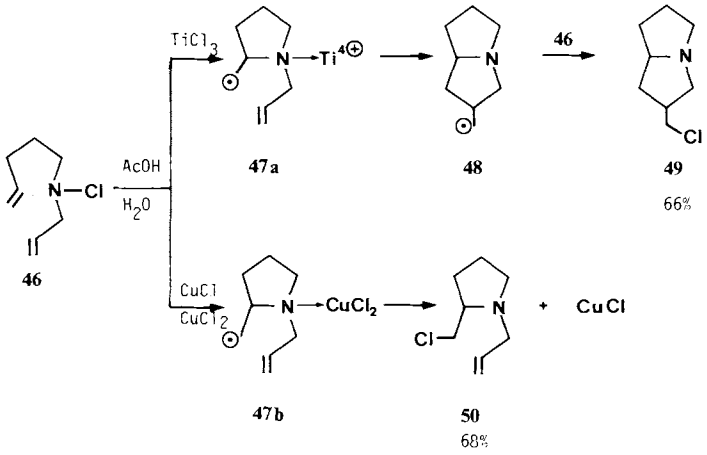


It appears that the intramolecular addition of the protonated aminyl radical is a very efficient process since the Hofmann-Löffler-Freytag reaction, which should be favored in this case by the production of a radical stabilized by allylic conjugation, is not observed[54].

It is noteworthy that the cyclization of protonated *N*-chloro-5-alkenylamine **38** is a little less efficient than that of the 4-alkenyl homologue **14**, but is much more efficient than that of its neutral counterpart.

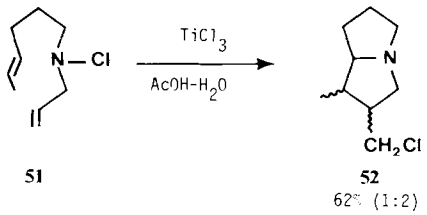
In a non-protonating medium the clean reaction of **38** with titanium trichloride gives, selectively, the 2-chloromethylpiperidine **39** in 72% yield[34]. Compared with the non-selectivity and low yields obtained by photolysis in neutral solution, this result provides good evidence that aminyl radicals generated in the presence of a redox system are not really free but coordinated to metal salts.

Furthermore, from *N*-chloro-3-butenylamine **44**, which is in general too strained to undergo radical cyclization, the 3-chloropyrrolidine **45** is obtained after complexation, although in lower yield[34].



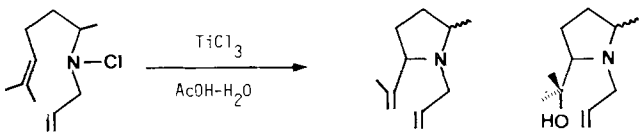
## 4. Synthesis of Polycyclic Compounds

### 4.1. Acyclic *N*-Chloroamines with Two Double Bonds

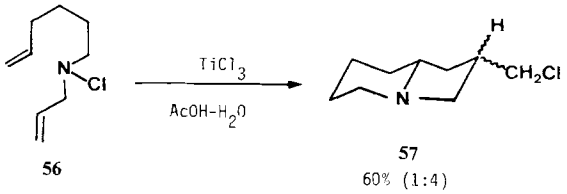


When treated with titanium trichloride in aqueous acetic acid, the readily available *N*-allyl-*N*-chloro-4-pentenylamine **46** leads smoothly to the 2-chloromethylpyrrolizidine **49**[62]. The cyclization of **46** to the five-membered ring leads to the carbon-centered radical **47a**: this undergoes further homolytic cyclization, which appears to be faster than the transfer of chlorine.

This result is a clear indication that the reaction does not proceed *via* a redox chain but rather *via* a typical radical chain mechanism involving transfer of a Cl atom from the *N*-chloroamine **46**. It was indeed well-known that transfer of chlorine from copper(II) chloride, for example, is faster than cyclization of the 5-hexenyl radical[63].

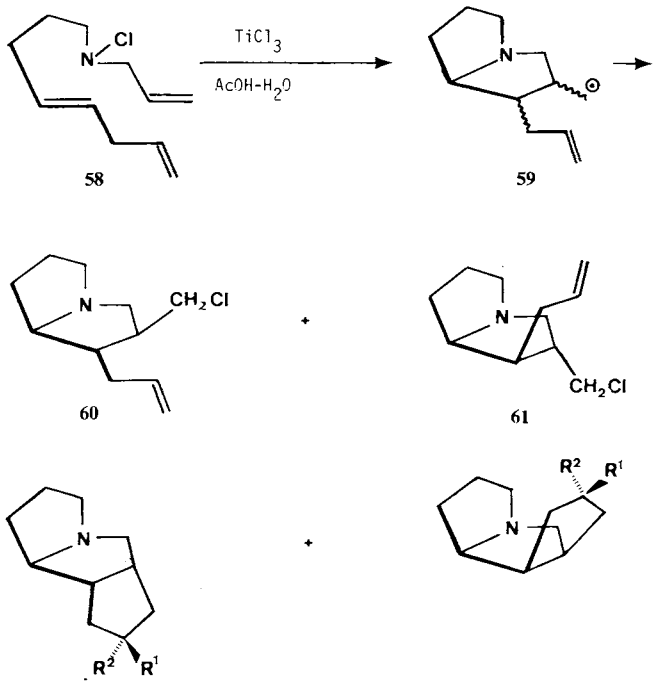


This is also confirmed by **46**[64]: when it is treated in the same solvent with copper(I) chloride in the presence of copper(II) chloride, no bicyclic product **49** can be detected, and *N*-allyl-2-chloromethylpyrrolidine **50** is formed exclusively.

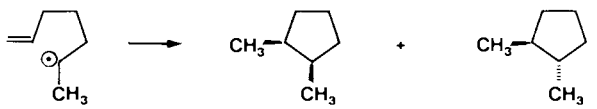


The synthesis of bicyclic products by double intramolecular addition reaps advantage from the radical chain process induced by titanium trichloride. Thus, the *N*-allyl-*N*-chloro-*trans*-4-hexenylamine **51** reacts similarly to **46** with this reducing salt forming a 1:2 mixture of the two diastereoisomeric 2-chloromethyl-1-methylpyrrolizidines **52**[65].

However, the substitution pattern of the double bond of the pentenyl moiety influences the course of the reaction: with the more substituted *N*-allyl-*N*-chloro-1,5-dimethyl-4-hexenylamine **53**, the second radical cyclization does not occur; only monocyclic products **54** and **55** are isolated, resulting, respectively, from dehydrochlorination and hydrolysis of the parent tertiary chloride formed initially[65].

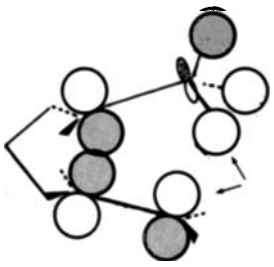


Under the same conditions the higher homologue of **46**, *N*-allyl-*N*-chloro-5-hexenylamine **56**, undergoes an analogous bicyclization to give a 1:4 mixture of the two isolable isomers of 2-chloromethylindolizidine **57**[65].



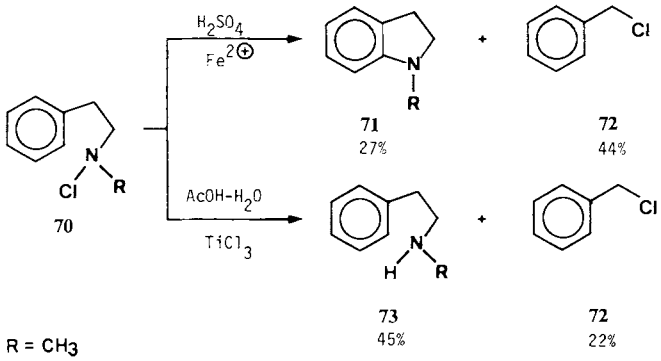
Thus a single synthetic operation, involving two sequential radical cyclizations, provides a direct access to fused azabicyclic systems.

### 4.2. Acyclic *N*-Chloroamines with Three Double Bonds



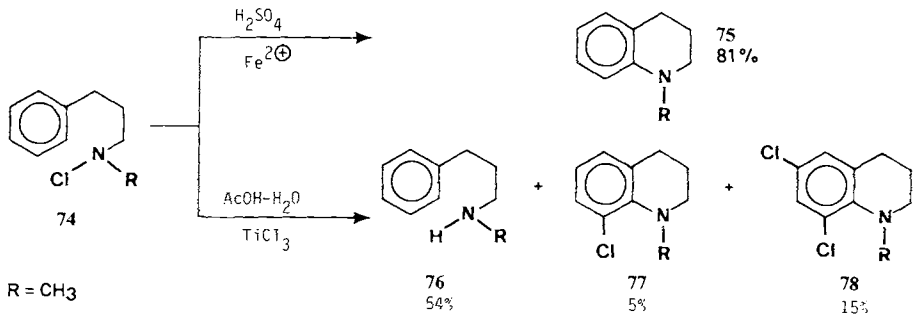
The only known triple homolytic cyclization of a suitable *N*-chloroamine with three double bonds demonstrates the possibility of inducing unexpected stereoselective syntheses with radicals. Excluding the monocyclic product, which has never been obtained using titanium salts, we can expect the two bicycles **60** and **61** and the four tricycles **62**, **63**, **64**, and **65** from the *N*-chloroamine **58**.

In fact we obtained[64], in 75% overall yield, a mixture of six isomeric bicycles and tricycles. Structures have not been assigned to the four minor components (present in 11, 6, 6, and 4% relative yield), but the major components are a tricycle (46%) and a bicycle (27%). It is noteworthy that the tricyclic product represents nearly half of the overall yield. This unexpectedly high amount derives from the favorable stereoselectivity in the second radical cyclization. Thus, for an efficient final cyclization, the intramolecular addition leading to the carbon-centered radical **59** must produce a methylene radical *syn* to the allylic chain. Such stereoselectivity is not altogether surprising in radical cyclizations: for example, in a simpler case, *Beckwith et al.*[66] obtained a mixture of 70% *cis*- **67** and 30% *trans*-dimethylcyclopentane **68**.



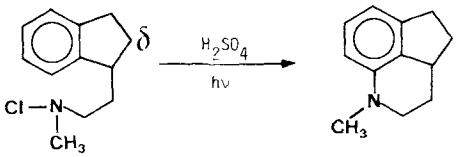
The explanation put forward by *Beckwith et al.*[66] for this surprising *cis*-mode of cyclization also accounts for our results. Orbital symmetry considerations afford a different view to that of simple thermodynamic approaches: hyperconjugative mixing of the half-filled π orbital with the adjacent CH-σ and CH-σ* orbitals produces a modified delocalized orbital which is of similar symmetry to the acceptor π* orbital. Thus, in the transition state **69** leading to the *cis*-disubstituted product, there is a secondary attractive interaction between the alkyl substituent and the olefinic bond which is not available to the transition state for *trans*-cyclization.

In view of the need for stereoselective bond-forming cyclizations, more attention should be given to this polycyclization.



### 4.3. *N*-Chloro(arylalkyl)amines

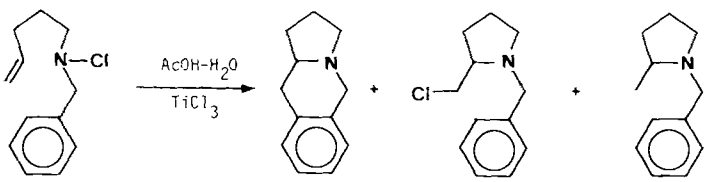
The cyclizations of *N*-chloroamines are not limited to additions to olefinic bonds: additions to aromatic rings can also occur. Such reactions have been used to synthesize indolines and tetrahydroquinolines. The $Fe^{2+}$ catalyzed decomposition of *N*-chloro-2-phenylethylamine **70** in concentrated sulfuric acid[67] leads to *N*-methyldihydroindole **71** and benzyl chloride **72**, while the mild reaction of titanium trichloride in aqueous acetic acid[34] gives only the amine **73** and benzyl chloride **72**.



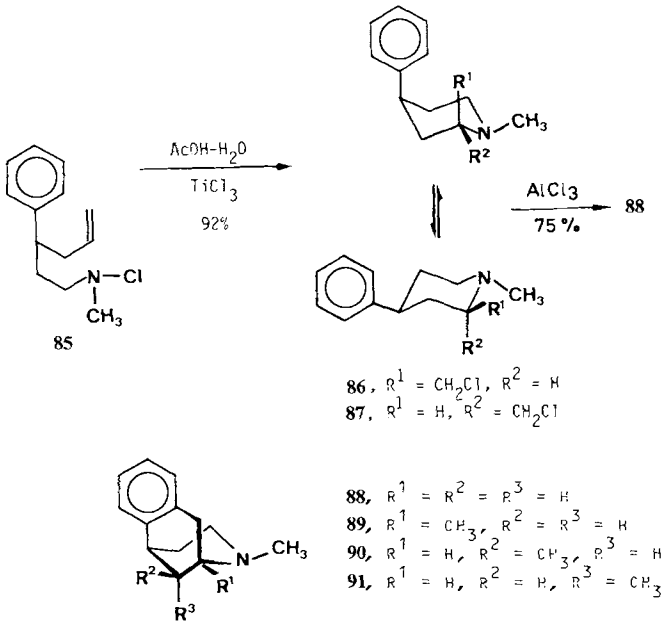
With **70**, which can be compared to *N*-chloro-3-alkenylamines (see Section 3.2), it appears that a protonating is more favorable than a complexing medium. Furthermore, with *N*-chloro-3-phenylpropylamine **74** (similar to *N*-chloro-4-alkenylamines **8** and **14**) no β-scission occurs and the *N*-methyltetrahydroquinoline **75** is formed in 81% yield in concentrated sulfuric acid[67] in presence of $Fe^{2+}$. In contrast, treatment of **74** with titanium trichloride in aqueous acetic acid leads only to low yields of cyclization products **77** and **78**, which result from further electrophilic chlorination of **75**[34].

These results clearly show that when electrophilic chlorination of the substrate does not compete with formation

of protonated aminyl radicals, a strongly acidic medium is more favorable: the radical intermediate cyclizes more efficiently and the protonated aromatic amines formed are deactivated towards further electrophilic reactions.



Similarly, photolysis of the *N*-chloroamine **79** in concentrated sulfuric acid gives the *N*-methylhexahydrocyclopentaquinoline **80** in 90% yield[68].

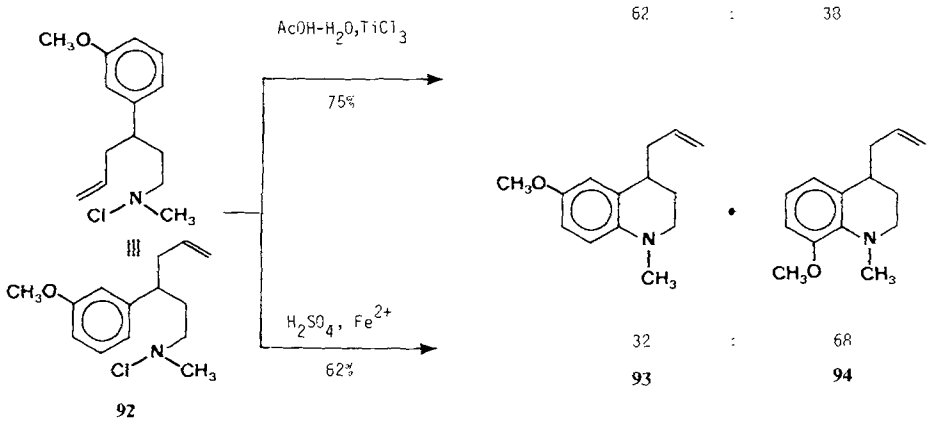


With the *N*-chloroamine **79** δ-hydrogen abstraction by the protonated aminyl radical could have led to a hexahydroindenopyrrole. However, the preference of this intermediate for intramolecular aromatic substitution dominates the reaction, thus leading to **80** as the sole product. This result should be contrasted with the fact that *N*-chlorodialkylamines are known to undergo facile Hofmann-Löffler-Freytag rearrangement at the expense of homolytic intermolecular addition to benzene[12].

### 4.4. *N*-Alkenyl-*N*-chloro(arylalkyl)amines

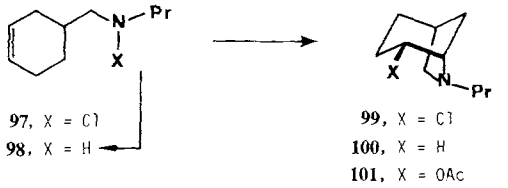
Two successive radical cyclizations involving an olefinic double bond and an aromatic ring should lead to a new route to benzo-annelated indolizines, such as **82**[62]. In contrast to the reaction **46**→**49**, a mixture of products is obtained in the reaction of *N*-chloro-*N*-benzyl-4-pentenylamine **81** with titanium trichloride. The formation of hexahydropyrrolo[1,2-*b*]isoquinoline **82** involves as a second cyclization step an intramolecular aromatic substitution which is more difficult than intramolecular addition to a double bond. Thus, we also obtained the monocyclization products **83** and **84**, which result from transfer of chlorine and hydrogen.

Using the same strategy a radical approach to *N*-methylbenzomorphan **88**, an analgesic compound related to morphine[69], has been developed. When the *N*-chloroamine **85** is allowed to react with titanium trichloride in aqueous acetic acid, a 4:1 mixture of *cis*- **86** and *trans*-2-chloromethyl-1-methyl-4-phenylpiperidine **87** is obtained in 92% yield[70].



Under these conditions no *N*-benzomorphan **88** can be detected, since the unfavorable diaxial conformation would result in further aromatic substitution of the intermediate carbon centered radical: chlorine atom transfer from **85**, therefore, dominates the reaction.

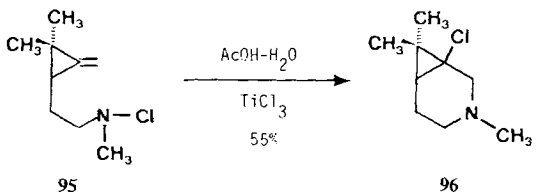
However, as for *cis*- **86**, which is the major product, inversion of the 2,4-diequatorial to the 2,4-diaxial conformer takes place in boiling cyclohexane and, in the presence of aluminum trichloride the benzomorphan **88** is formed in 75% yield[70].



This attractive method, which leads in eight steps from benzaldehyde to benzomorphan, has been used to synthesize 1,2- **89**, 2,9α- **90**, and 2,9β-dimethylbenzomorphan **91**[71].

From these reactions it can be deduced that the complexed aminyl radical exhibits a stronger preference for the double bond than for the benzene ring. But, when the benzene ring is activated by a methoxy group the reverse is observed[71].

The complexed aminyl radical reacts preferentially with the activated aromatic ring and substitution in the *p*-posi-



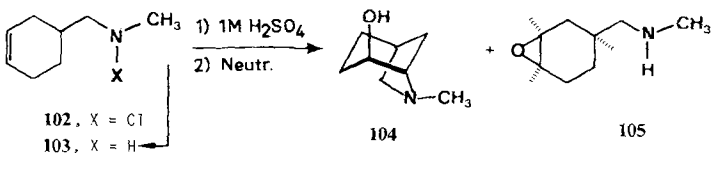
tion is favored. The protonated aminyl radical exhibits the same preference, but the *o/p* regioselectivity is reversed. The same trend is observed in intermolecular aromatic substitutions when instead of complexed[72], protonated aminyl radicals are used[73].

### 4.5. *N*-Chloroamines with Methylcyclopropyl or Cycloalkenyl Groups

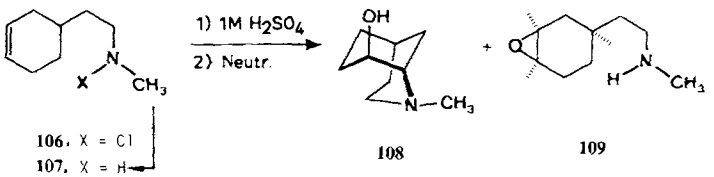
Cyclizations of *N*-chloroamines with methylcyclopropyl or cycloalkenyl groups in which the double bond is or not incorporated into a ring can lead to *ortho*-fused and bridged azapolycycles.

Ring-closure of *N*-chloro-*N*-methyl-2-(1,1-dimethyl-2-methylenecyclopropane)ethylamine **95** by titanium trichloride in aqueous acetic acid results in the 3-azabicyclo[4.1.0]heptane derivate **96**[30]. The overall *endo*-regioselectivity observed is in disagreement with Baldwin's rules[74] and with the general behavior of irreversible radical cyclizations[14, 15]. Molecular models clearly show that the five-membered transition state is not favored by the rigid dimethylcyclopropane bridge. However, although steric effects are known to alter regioselectivity[75, 76], such a complete change leading to a six-membered ring was unforeseen.

Depending on the reaction conditions, the *N*-chlorocyclohexenylmethylamine **97** leads to the azabicyclo[3.2.1]octanes **99**, **100**, and/or **101** (Table 6)[29].



Using titanium trichloride in aqueous acetic acid, the *endo*-chlorinated compound **99** is formed exclusively. Such stereoselectivity is often observed with bridged bicyclic radicals, and is generally interpreted on the basis of steric effects[77]. It appears in this case that the chlorine transfer is easier by *endo*-approach of the *N*-chloroamine to the intermediate bicyclic carbon-centered radical.

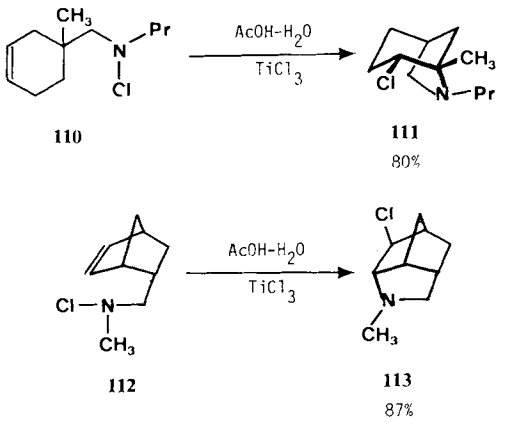


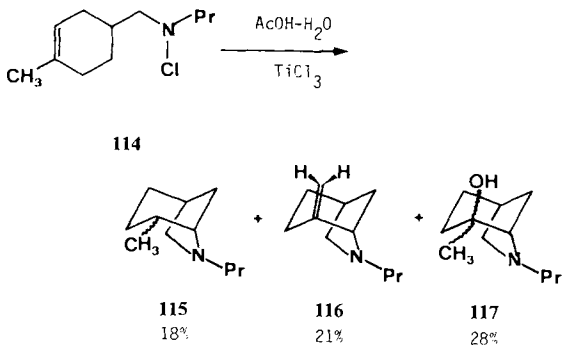
Photolysis in neutral media affords, besides the parent amine **98**, a mixture of compounds **99** and **100** resulting, respectively, from transfer of chlorine and hydrogen.

Table 6. Reactions of *N*-chloro-*N*-propyl-3-cyclohexenylmethylamine **97**.

| Solvent | Conditions | Yield [%] | **98** : | **99** : | **100** : | **101** |
|---|---|---|---|---|---|---|
| AcOH-$H_2O$ | $TiCl_3$ | 77 | 0 | 100 | 0 | 0 |
| MeOH | *hv* | 60 | 23 | 59 | 18 | 0 |
| *i*PrOH | *hv* | 65 | 69 | 5 | 26 | 0 |
| 4M $H_2SO_4$-AcOH | *hv* | 52 | 0 | 23 | 0 | 77 |
| 4M $H_2SO_4$-AcOH | air | 52 | 0 | 17 | 0 | 83 |

In highly acidic media, either with or without photolytic initiation, ionic chlorination of the disubstituted double bond to give acetate **101** is preferred. Similarly, when the *N*-chloroamine **102** is refluxed in 1 M sulfuric acid a mixture of **103**, **104**, and **105** is obtained in the ratio 1 : 13 : 8. Under the same conditions, the *N*-chloroamine **106** leads to a 1 : 4 : 2 mixture of **107**, **108**, and **109**. No yields were given in the last two cases[78].

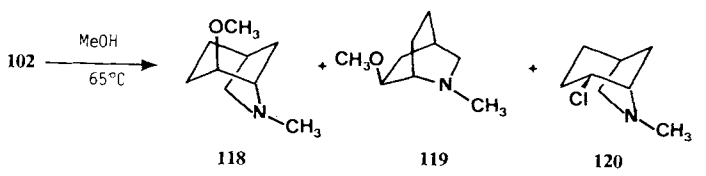




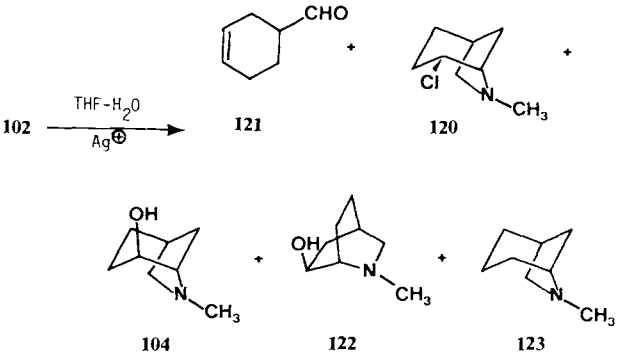
In contrast, electrophilic chlorination of the double bond is never observed in aqueous acetic acid. The following reactions illustrate the scope and limitations of the mild reduction of *N*-chloro-cycloalkenylamines by titanium trichloride.

Starting from **110** the *endo*-chlorinated azabicycle **111** is again obtained[79], while cyclization of **112** results in the

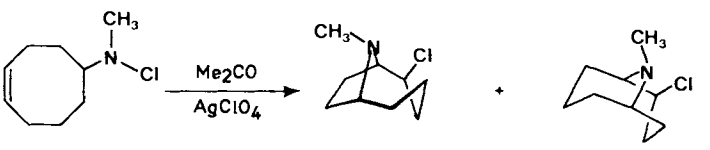
*exo*-chlorinated azatricycle **113**[79]. Mechanistically, this inversion of stereoselectivity can be rationalized on the basis of steric effects.



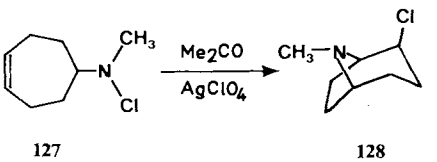
Even when the double bond is trisubstituted, as in **114**, regioselective intramolecular addition of the complexed aminyl radical is observed[79].



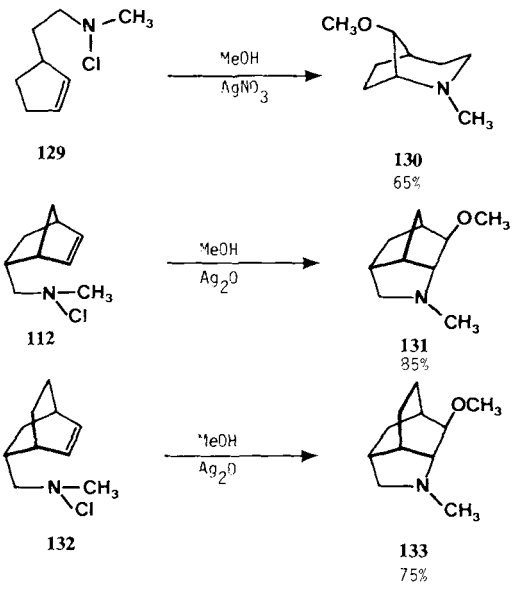
Very probably **115** arises from hydrogen atom transfer, whereas **116** and **117** are formed by dehydrochlorination and solvolysis, respectively, from the parent *endo*-tertiary chloride. Analogously, on photolysis in methanolic solution **114** gives a 45:55 mixture of **115** and **116** in 75% yield[79].



The high regio- and stereoselectivities generally observed when aminyl radicals coordinated to titanium salts are involved contrast with the low yields and complex mixtures of products obtained by thermolysis or ion-catalyzed solvolysis of **102**[80]. Thus, refluxing a methanolic solution of **102** results in the recovery of 40% of the parent amine **103** and formation of three cyclization products **118**, **119**, and **120** in 15, 23, and 13% yields, respectively.



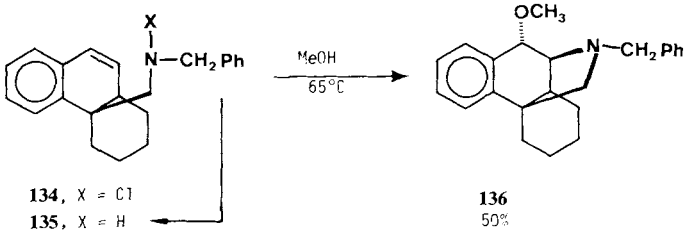
Solvolysis of **102** in aqueous tetrahydrofuran (THF) catalyzed by silver ions gives a more complex mixture of products consisting of **103** (17%), **104** (14%), **120** (12%), **121** (18%), **122** (19%), and **123** (16%).



These reactions are unsatisfactory for the synthesis of azabicycles and have been rationalized by *Gassman et al.* as indicating the involvement of triplet and singlet aminylium ions[80,81]. Although it is beyond doubt that both silver ion-promoted and non-catalyzed solvolysis of *N*-chloroamines can proceed *via* aminylium ions[31], it was proposed that under these conditions a homolytic can compete with the heterolytic process to form cyclized products from unsaturated *N*-chloroamines[82]. The following examples were regarded as being consistent with this. Thus[83,84], the reaction of the *N*-chloro-cyclooctenylamine **124** with stoichiometric amounts of silver perchlorate in refluxing acetone yields **125** (25%) and **126** (14%). Under the same conditions, the *N*-chloro-cycloheptenylamine **127** affords a single bicycle **128** in 7.5% yield. To rationalize the stereospecific *cis*-addition of nitrogen and chlorine to the double bond coordination of the catalyst to nitrogen[83] or internal return of chlorine during solvolysis by silver ion[81] have been proposed.

With silver oxide in refluxing chloroform[85], the *N*-chloroamine **112** leads, in 75% yield, to the same *exo*-chlorinated bicycle **113** previously obtained by reaction of **112** with titanium trichloride (see above).

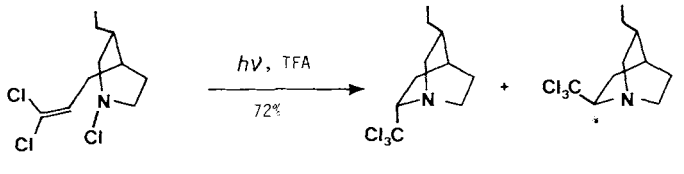
Whatever the importance of the homolytic process may be, the selective transformations **129** → **130**[81,82], **112** → **131**[85], and **132** → **133**[85] illustrate nicely that solvolytic conditions may provide a simple route from *N*-chloro-cycloalkenylamines to bridged azapolycycles containing *trans*-orientated amino and methoxy substituents.



129 → 130 (65%)

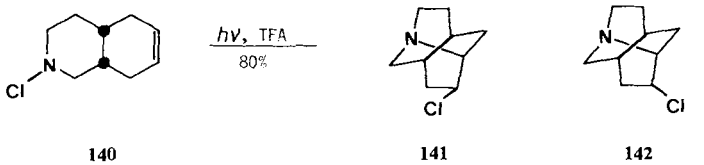
112 → 131 (85%)

132 → 133 (75%)



Similarly, refluxing a solution of the *N*-chloroamine **134** in methanol produces 20% amine **135** and 50% *N*-benzyl-10-*trans*-methoxy-D-normorphinan **136**. This compound is the only cyclized product recovered from the reaction[87].

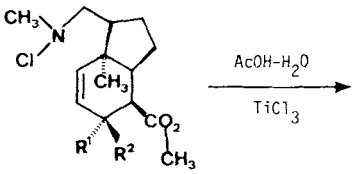
**134**, X = Cl
**135**, X = H



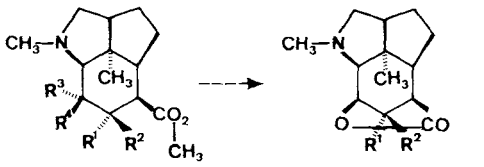
**136**
50%

As in intermolecular reactions of protonated *N*-chloroamines with olefins[41,55], ionic chlorination of the double bond can be eliminated by introducing electron-withdrawing groups. Thus, irradiation of a solution of **137** in trifluoroacetic acid (TFA) affords a 1:1 mixture of trichloromethylquinuclidines **138** and **139**[88]. These substituted quinuclidines were used as intermediates in a total synthesis of *Chinchona* alkaloids.

**137** → **138** + **139**



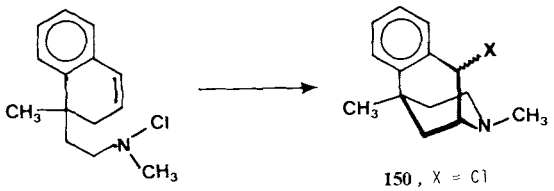
An exception to five-membered ring formation and to the non-ionic pathway in the case of a disubstituted double bond is provided by the homolytic cyclization of *N*-chloro-*cis*-octahydroisoquinoline **140**, leading to a 4:3 mixture of β-chloroazatwistanes **141** and **142**[89].



**140** → **141** + **142**

Consideration of models clearly shows that the very propicious closure of the six-membered instead of the five-membered ring is probably due in this particular case to much less important non-bonding interactions in the transition state leading to the staggered azatwistanes **141** and **142** than in that leading to the eclipsed isomer.

In recent attempts to synthesize the natural dendrobine alkaloid **148**, redox cyclization of the *N*-chloroamines **143** and **144** has been examined. In the presence of titanium trichloride the crude chloropyrrolidine derivate **145** was obtained from **143** and allowed to react with lithium iodide in refluxing lutidine to give 8-*epi*-dendrobine **147** (45%)[91]. Under the same conditions **144** reacts in a similar manner leading to **146** (20—30% yield, not optimized).



**143**, $R^1$=H, $R^2$=iPr
**144**, $R^1$=iPr, $R^2$=H

**145**, $R^1$=H, $R^2$=iPr, $R^3$,$R^4$=H,Cl
**146**, $R^1$=iPr, $R^2$=H, $R^3$=Cl, $R^4$=H

**147**, $R^1$=H, $R^2$=iPr
**148**, $R^1$=iPr, $R^2$=H

The synthetic approach to benzomorphans discussed in Section 4.4 does not allow further substitution of the benzylic carbon atom by a methyl group[71]. Since this substitution pattern is important for analgesics, we developed another strategy for the synthesis of 2,5-dimethylbenzomorphans. Depending on the reaction conditions (Table 7), *N*-chloroamine **149**, easily obtained in a nine-step sequence from levulinic acid, leads to 2,5-dimethylbenzomorphans **150**, **151** or **152** functionalized in the 8-position[59].

**149**

**150**, X = Cl
**151**, X = OAc
**152**, X = OH

Table 7. Cyclizations of the *N*-chloroamine **149** to benzomorphan derivatives **150–152**.

| Conditions | Product | Yield [%] |
|---|---|---|
| AcOH-$H_2O$, $TiCl_3$ | **150** | 63 |
| 4 M $H_2SO_4$-AcOH | **151** | 82 |
| 4 M $H_2SO_4$-$H_2O$ | **152** | 81 |

The stereochemistry of the C-8 substituents has not yet been assigned, although these reactions probably take place stereoselectively.

## 5. Concluding Remarks

Accumulated evidence points to the synthetic potential of homolytic heterocyclizations of *N*-chloroalkenylamines. From the examples given a set of rules can be derived enabling the behavior of *N*-chloroamines to be classified and predicated in terms of solvent, temperature, catalyst, and the nature of the various functional groups which can react inter- and intramolecularly with aminyl radicals. Particular mention should be made of exclusively *exo*-regioselective cyclizations leading to five- and six-membered ring heterocycles including substituted, fused, and bridged systems (for an exception see the reaction **95** → **96**). In addition to steric, stereoelectronic, and metal salt effects the kinetic control of cyclizations may further influence the outcome, as indicated by many stereoselective syntheses and by one stereospecific synthesis **28** → **29e**; **31** → **29t**). The combination of intramolecular addition of aminyl radicals with other radical cyclizations provides additional possibilities for the synthesis of polycyclic systems.

It therefore appears that aminyl radicals, and especially complexed aminyl radicals, provide the organic chemist with the opportunity of synthesizing complex molecules using mild and simple redox reactions in both a regio- and a stereoselective manner. They are thus good synthetic tools for the synthesis of heterocycles.

*Our own work mentioned in this article was carried out in the laboratory of Professor Jean-Marie Surzur, at the University of Marseille. It is a pleasure to dedicate this review to him in grateful recognition for his inspiration, contribution, and support. I have also great pleasure in expressing thanks to my colleagues who have worked on one or another parts of this program: Drs. Jean-Luc Bougeois, Jean Lacrampe, Robert Nouguier, Bernard Raynier, Jean-Louis Stein, and Prof. Paul Tordo. The financial support of the Centre National de la Recherche Scientifique is gratefully acknowledged.*

# Modern Pulse Methods in High-Resolution NMR Spectroscopy

**By Reinhard Benn* and Harald Günther***

The introduction of Fourier transform methods has not only remarkably enhanced the sensitivity of high-resolution NMR spectroscopy, thus allowing measurements to be made on less sensitive nuclei of the Periodic Table, but also has paved the way for the development of a large number of new experimental techniques. On the one hand, procedures already known have been improved and can now be performed more rapidly, and, on the other, completely new experimental approaches have become available. This situation resulted mainly from the introduction of programmable pulse transmitters and the separation of the experiment into preparation, evolution, and detection. In particular, the concept of two-dimensional spectroscopy has opened up new possibilities important for the analysis of complicated spectra and is able to provide information previously not accessible. As elsewhere, optimum application of the techniques and correct interpretation of the results require sound understanding of the underlying physical principles. Since a rigorous mathematical treatment is complicated and does not necessarily improve the comprehensibility, this article attempts to give an illustrative presentation of the new pulse techniques within the framework of the Bloch vector model. After a short introduction covering the basic principles, one-dimensional pulse techniques that can be applied using standard experimental equipment are dealt with. The main areas of application are signal assignment, sensitivity enhancement for measurements on less abundant nuclei, and selective excitation of individual resonances. Subsequently, the various techniques of two-dimensional NMR spectroscopy are treated: these enable shift correlations for different types of nuclei to be made, the presentation of spin multiplets without overlap, and the analysis of geometrical relations as well as of chemical exchange phenomena.

## 1. Introduction

The introduction of pulse Fourier transform methods undoubtedly started a new era of NMR spectroscopy that resulted in an unpredicted and intensive development of new experimental techniques. Whereas at the beginning enhancement of sensitivity was the most important aspect and attention focussed quite naturally on $^{13}C$-NMR spectroscopy, we are now witnessing progress in the NMR spectroscopy of less abundant nuclei[1] and in solid state spectra[2] that nobody would have dreamed of even a few years ago. In addition, NMR spectroscopy of macroscopic systems and NMR imaging techniques have opened completely new applications in physiology and medicine, the potential of which has not yet been fully uncovered[3].

This expansion towards new applications is matched by an equally impressive growth of new experimental techniques which have decisively enlarged the classical repertoire of the NMR spectroscopist and eliminated many of the older CW (continuous wave) techniques. Above all, the more extensive integration of computers into the NMR experiment provided the basis for a large number of investigations that are computer-controlled, since times in the order of ms and μs are involved and the treatment of large quantities of data becomes necessary.

Accordingly, the last few years have seen the development of pulse experiments also in the field of high-resolution NMR spectroscopy, where on the one hand the sensi-

tivity problem connected with the NMR measurement of less abundant nuclei was solved and, on the other, spectral information has now become available that was previously difficult to obtain. The potential of these techniques—whose introduction was accompanied by a burgeoning system of shorthand notations not easily deciphered by non-experts—has, however, not yet been fully recognized by the majority of NMR users. The reason for this must be seen both in an insufficient understanding of the physical background and by the fact that these techniques very often have been used for the first time to obtain the NMR spectra of proteins and other macromolecules. While the potential of the new techniques is particularly impressively demonstrated with complicated molecules, the complex structure of these systems and their spectra make the experiments difficult to understand.

In the following progress report an illustrative presentation of the new developments will be given and—using small molecules as examples—we shall try to make the mechanisms of the new pulse techniques and the information they can provide more transparent[4]. In this context the phenomenological presentation of the basic principles within the framework of the Bloch vector model will be emphasized. For obvious reasons a complete literature survey and a comprehensive discussion of the experimental aspects will not be given.

Section 2 deals with *one-dimensional* pulse sequences with different goals (signal assignment, sensitivity enhancement, selective excitation), whereas Section 3 is devoted to *two-dimensional* experiments. Of particular interest here are those techniques that allow correlation of spectral parameters (chemical shifts, spin-spin coupling constants) of different nuclei, for example $^1H$ and $^{13}C$, with the aim of displaying the spectral information without overlap.

### 1.1. The FT-NMR Experiment

Let us first recall the basic principles of the Fourier transform NMR experiment[5]. For the nucleus of interest, the resonance signals of different Larmor frequency present in the spectral window chosen form the so-called *macroscopic magnetization* $\boldsymbol{M}$ of magnitude $M_0$, parallel to the external field $\boldsymbol{B}_0$ (Fig. 1a).

A strong radio frequency field $\boldsymbol{B}_1$, a so-called RF pulse[6], produced by a radio frequency coil on the x-axis, carries $\boldsymbol{M}$ away from the z-axis. The duration and power of the RF pulse determine the direction of $\boldsymbol{M}$ after the pulse. If a so-called $90^\circ_x$ or $\pi/2$ pulse is applied, $\boldsymbol{M}$ points along the positive y-axis (Fig. 1b). The *longitudinal* or *z-magnetization* is thus transformed into a *transverse magnetization*. With the power of the RF sources used in modern spectrometers this process requires 5—20 μs.

The Larmor frequencies of the various nuclear magnetic moments present vary and, as a consequence, the vector $\boldsymbol{M}$ now splits into its components (Fig. 1c). The magnetic vectors rotating in the x,y-plane produce a voltage in the receiver coil that is detected as the NMR signal. If we plot for an individual vector the time dependence of the intensity of its y-component, that is, the voltage, $U$, induced in

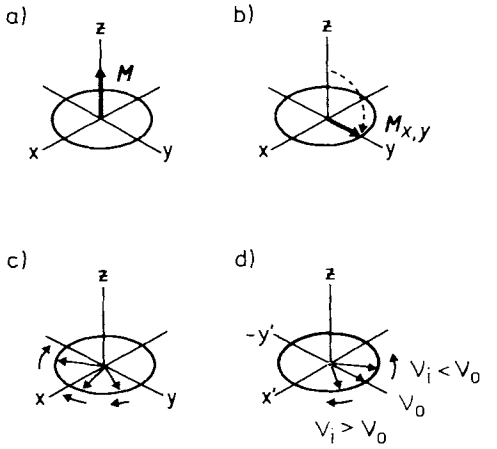

Fig. 1. a) Macroscopic magnetization $\boldsymbol{M}$ in the laboratory frame; b) transverse magnetization $\boldsymbol{M}_{x,y}$ after a $90^\circ_x$ pulse; the effect of pulses is described by the "right-hand rule", where the thumb gives the direction of the pulse and the bent fingers the rotational sense of the magnetization vector; c) Larmor precession of the individual nuclear magnetic moments of different Larmor frequency in the laboratory frame; d) as c), however, in the rotating frame K'(x',y',z) (cf. text).

the receiver coil, and if we take into account transverse relaxation, *i.e.* the loss of transverse magnetization as a consequence of relaxation processes, a damped oscillation of frequency $\nu_i$ results that is known as the *free induction decay* (FID) (Fig. 2).

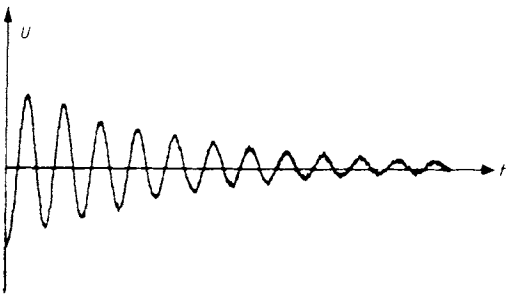

Fig. 2. Free induction decay (FID) or time signal of a NMR line. The damped sine wave is characterized by the time constant $T_2^*$ and the frequency $\nu_i$. $T_2^*$ is the *effective* transverse relaxation time that contains contributions from transverse relaxation and from field inhomogeneity.

Fourier transformation of this time signal yields the well-known NMR signal or spectrum. The frequency measured is the difference between the transmitter or carrier frequency, $\nu_0$, and the Lamor frequency, $\nu_i$, of the particular spin, and is usually in the order of several kHz.

For the description of NMR experiments the concept of the "rotating frame", introduced by *Torrey*[7], is convenient. It uses a coordinate system K' that rotates in the same sense and with the same frequency, $\nu_0$, as the rotating field vector of the RF field. Within the rotating frame vectors that correspond to signals with frequencies $\nu_i > \nu_0$ rotate clockwise, whereas those corresponding to signals with $\nu_i < \nu_0$ rotate anti-clockwise: a signal with $\nu_i = \nu_0$ is static in the rotating frame (Fig. 1d).

Furthermore, it is helpful to remember that each vector is characterized by its Larmor frequency, by its orientation in the rotating frame, and by its lifetime. The Larmor frequency determines the *position of the signal* in the spectrum—that is the chemical shift—whereas the orientation

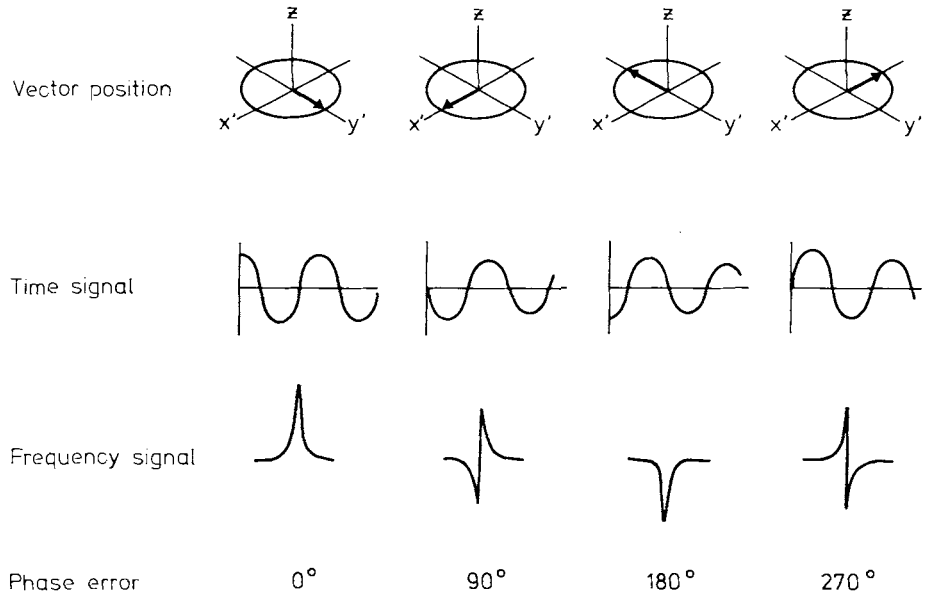

Fig. 3. Precession of transverse magnetization: relation between vector orientation, time signal, frequency signal, and phase error.

at the beginning of data accumulation determines the phase with respect to the rotating frame and, therefore, the *signal phase* (Fig. 3). In this context it is of importance that the detector of the NMR spectrometer is phase-sensitive, since the dispersion signals with phase errors of 90° and 270° can be suppressed. As a consequence, the adjustable detector phase allows the selection of certain components of the transverse magnetization for detection, a vital aspect for many of the pulse experiments to be discussed. Finally, the effective transverse relaxation time $T_2^*$ determines the time dependence of transverse magnetization and, since $\omega_{1/2}=1/\pi T_2^*$, the half-width, $\omega_{1/2}$, of the NMR signal.

### 1.2. The Fate of Transverse Magnetization

In order to understand the principles of the new pulse experiments it is necessary to investigate the time dependence of transverse magnetization more closely. Three effects are important: transverse relaxation, the inhomogeneity of the external magnetic field $\boldsymbol{B}_0$, and spin-spin coupling to neighboring nuclei.

#### *1.2.1. Transverse Relaxation*

Transverse magnetization can be reduced by different relaxation mechanisms. According to $\omega_{1/2}^{(n)}=1/\pi T_2$, the transverse relaxation determines the natural half-width, $\omega_{1/2}^{(n)}$, of the NMR signal. In the following discussion transverse relaxation is always assumed.

#### *1.2.2. Inhomogeneity of the $B_0$ Magnetic Field*

Within the framework of the classical macroscopic description of the NMR experiment, not only is the macroscopic magnetization $\boldsymbol{M}$ a sum of components, but also each individual vector $\boldsymbol{v}_i$ is the vector sum of the various nuclear magnetic moments that have the same chemical environment, and therefore precess with the same Larmor frequency. Since inhomogeneity of the external field $\boldsymbol{B}_0$ cannot be avoided, the ideal situation that all nuclear magnetic moments experience the same field strength $\boldsymbol{B}_0$ does not hold. Rather, the local field varies over the sample volume ($\boldsymbol{B}_{\text{local}}=\boldsymbol{B}_0\pm\Delta\boldsymbol{B}$). After excitation, the individual vectors $\boldsymbol{v}_i$ fan out since, according to the resonance condition $\nu_i=\gamma\boldsymbol{B}_{\text{local}}$, those in areas with $\boldsymbol{B}_{\text{local}}>\boldsymbol{B}_0$ rotate faster and those in areas with $\boldsymbol{B}_{\text{local}}<\boldsymbol{B}_0$ slower than the average. It is easy to appreciate that this process causes transverse magnetization to finally disappear (Fig. 4). The effect of field inhomogeneity is taken into account by introducing an *effective* transverse relaxation time, $T_2^*$, that contains contributions from true relaxation as well as from inhomogeneity. In practice, field inhomogeneity makes by far the most

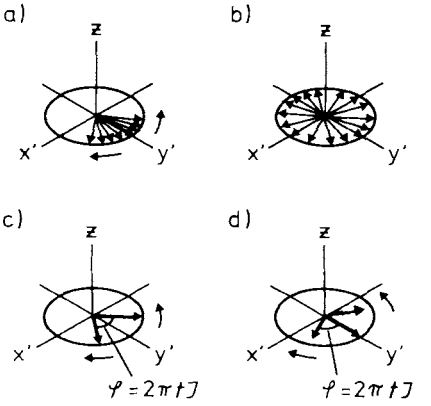

Fig. 4. a) Fanning-out of the transverse magnetization in the rotating frame K' as a consequence of the inhomogeneity of the external field $\boldsymbol{B}_0$; b) after time $T_2^*$ the vector sum in the x,y-plane is zero; c) transverse magnetization of nucleus A under the influence of scalar spin-spin coupling to a neighboring X nucleus (AX system); d) transverse magnetization of nucleus A under the influence of scalar spin-spin coupling to two neighboring $X_2$ nuclei ($AX_2$ system). In the case of c) and d) the frequency of the A nucleus was chosen as the frequency for the rotating frame. The precessional frequencies of the components of the multiplet are, therefore, $\pm\frac{1}{2}J$ and $+J, 0, -J$, respectively; relaxation and inhomogeneity effects are neglected.

important contribution to the disappearance of transverse magnetization and, therefore, to the line-width in high-resolution NMR spectroscopy.

### *1.2.3. Spin-Spin Coupling*

If a nucleus A experiences scalar spin-spin coupling to a neighboring nucleus X[8], the excitation is followed by a separation of its transverse magnetization $M^{A}_{x,y}$ into different vectors corresponding to the various components of the spin multiplet. This situation is depicted in Figures 4c and 4d for a doublet and a triplet, respectively. Spin decoupling causes the vectors of a multiplet to be static within the rotating frame, since their Larmor frequencies become identical if $\nu_A = \nu_0$. The momentary y-magnetization of the vectors is thus "frozen in" by the application of a decoupler field $B_2$, and the magnetization detected at $\nu_A$ is the resultant of the y-components of the individual vectors.

## 1.3. The Spin Echo Experiment

For most of the new pulse methods the spin echo experiment[9] is of central importance. If the fanning-out process of the individual magnetic vectors after the initial 90°$_x$ pulse described above has proceeded for a time $\tau$, the vectors can be inverted by the application of a 180°$_x$ pulse. Since the rotational sense of their motion is unchanged, the vectors refocus along the negative y-axis and a spin echo signal is recorded after time $2\tau$. The amplitude of the signal now differs from the initial value only through true relaxation losses (Fig. 5).

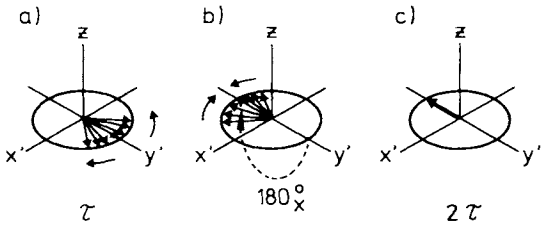

Fig. 5. The spin echo experiment; a) state of the transverse magnetization at time $\tau$ after the 90°$_x$ exitation pulse; b) effect of the 180°$_x$ pulse; c) state of the transverse magnetization after time $2\tau$; since for the pulse width $t_p \ll \tau$ holds (typical values are $t_p = 20$ µs, $\tau = 5$ ms), changes of the spin system during the pulse can be neglected.

It follows that the spin echo experiment causes cancellation of all effects that result from different Larmor frequencies—including those of chemical shifts—and that lead to a fanning-out of the macroscopic transverse magnetization after the exciting pulse. A simple experiment serves to demonstrate this.

For this purpose we use the well-known frequency-dependent phase error that results during the FT experiment if data collection is delayed to a time $t_0$ after the exciting pulse[10]. Due to their divergent Larmor frequencies the precession of the individual magnetic vectors in the rotating frame has progressed by different amounts and the phases of the corresponding NMR signals differ (Figs. 6a and b). If we now apply a 180°$_x$ pulse at $t_0$ and start data collection at $2t_0$, the phase difference is eliminated since the vectors refocus within the second $t_0$ period (Figs. 6c and d).

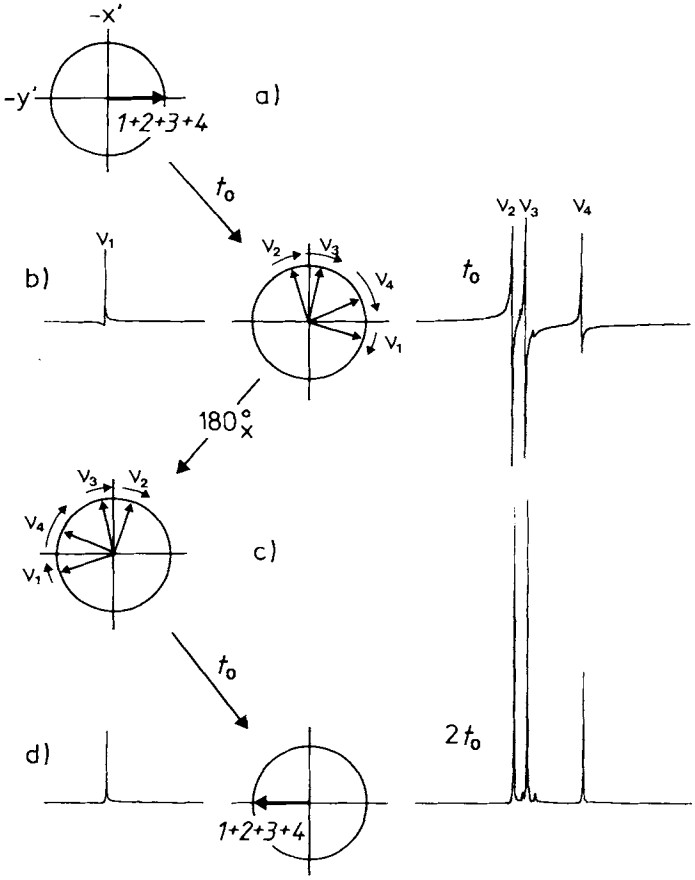

Fig. 6. Phase correction by a spin echo experiment for the aromatic $^{13}C$ resonances of ethylbenzene; a) situation after excitation; b) after a time $t_0$ the precession of the individual components of the macroscopic magnetization around the field axis has progressed by distinct amounts as a consequence of their different Larmor frequencies. Data collection yields a spectrum with frequency-dependent phase errors; c) a 180°$_x$ pulse at $t = t_0$ inverts the vector system and after $t = 2t_0$ again leads to superposition, the spin echo. The phase differences in the experimental spectrum vanish (d). In order to obtain an absorption mode spectrum an additional phase correction of 180° was applied in case d).

A situation distinct from that described above is met if spin-spin coupling to a neighboring nucleus occurs. Since the pulse methods to be discussed almost exclusively rest on the effect of spin-spin coupling, we shall treat this aspect in more detail using the example of a two-spin system. Several situations have to be distinguished.

For a *homonuclear* AX-system the 180°$_x$ pulse is not selective, *i.e.* it is felt by the A as well as by the X nucleus. Within the vector diagram this means that the multiplet vectors are reflected on the x,y-plane: Inversion is accompanied by a change of rotational sense, since the 180°$_x$ pulse also interchanges the spin states of the neighboring nucleus. Refocussing to the spin echo is not observed (Fig. 7a).

In the *heteronuclear* case, *e.g.* with an AX-system consisting of a $^1H$ and a $^{13}C$ nucleus, two variants are possible. If we observe the $^{13}C$ resonance and apply a 180°$_x$ pulse at this frequency, refocussing occurs and—as in the case of the chemical shift—a spin echo is detected after a time $2\tau$

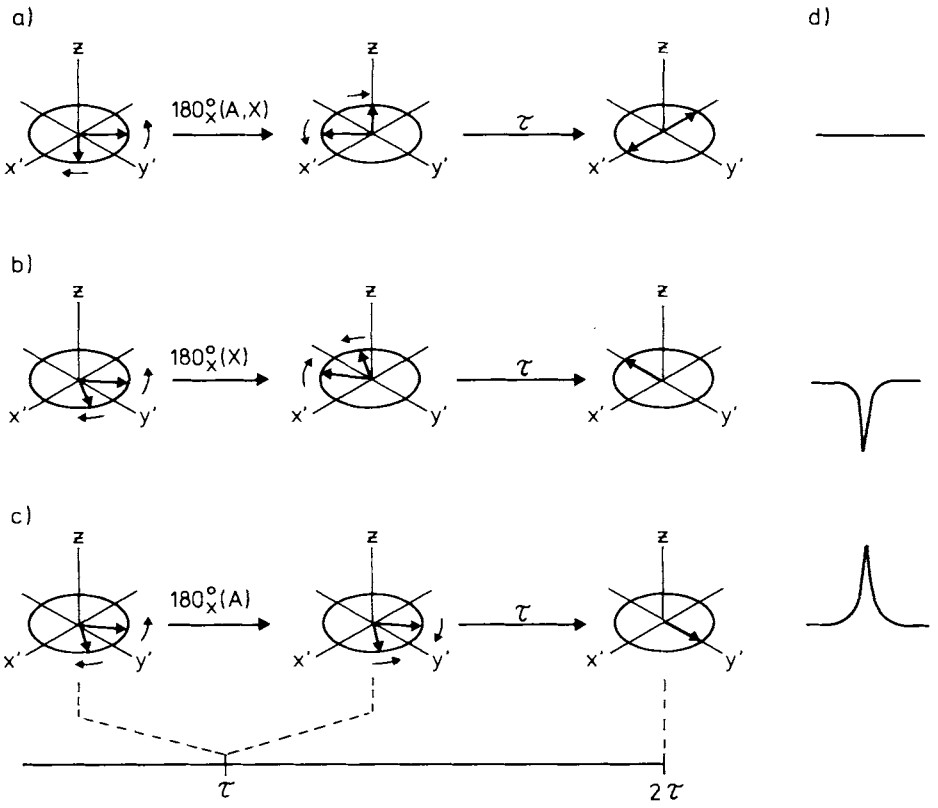

Fig. 7. Spin echo experiment with an AX system; vector diagram for the X nucleus; a) homonuclear case; b) heteronuclear case with $180^\circ_x$ pulse for the X nucleus; c) heteronuclear case with $180^\circ_x$ pulse for the A nucleus; d) X echo at $t=2\tau$ with simultaneous A decoupling.

(Fig. 7b). On the other hand, a $180^\circ_x$ pulse at the frequency of the A nucleus changes the rotational sense of both X vectors and, after a time $2\tau$, also leads to a spin echo signal, whose phase, however, differs by 180° (Fig. 7c). Finally, two $180^\circ_x$ pulses applied simultaneously to the A and X regions lead to a situation that corresponds to that described for the homonuclear case.

These considerations can now be completed by taking into account the effect of inhomogeneity. For each individual X vector in Figure 7 it results in an additional fanning-out process that can, however, be cancelled out by a selective $180^\circ_x$ pulse at the X nucleus. Only the experiments shown in Figures 7a and 7b thus lead to a refocussing of the effects of inhomogeneity and of chemical shifts, which can be treated in the same way as the previously mentioned frequency-dependent phase errors. This is an important practical aspect, since the carrier frequency $\nu_0$ normally is not identical with the Larmor frequency of the X nucleus as has been assumed until now in the simplified treatment presented here.

### 1.4. The Evolution Time

The most important feature of the new pulse experiments is the so-called *evolution time*, $t_1$, during which the spin system—in some cases under the influence of further pulses—evolves. However, the spin system has to be prepared for evolution, and the evolution time is therefore preceded by the *preparation time*. Data collection starts at the end of the evolution period with the *detection time* (Fig. 8)[11].

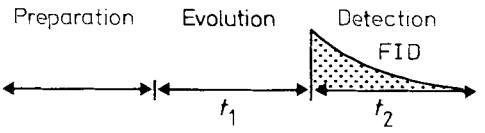

Fig. 8. Time sequence of modern pulse experiments [11].

These time sequences allow the state of the spin system at the start of the detection period to be varied and, therefore, affect the informational content of the whole experiment. For this purpose suitable pulses, whose effects on the magnetization vectors have been discussed earlier, can be used, but, in addition, scalar spin-spin interactions, which can be applied periodically by gating the decoupler channel, are of importance. Alternatively, dipolar couplings or the magnetization transfer between nuclei of different Larmor frequencies arising from dynamic processes can be used. Very often a spin echo sequence is a direct or indirect part of the experiment, which secures that at the end of the evolution period the effects of chemical shifts and of field inhomogeneity are refocussed. In other words, as far as these effects are concerned the spin system is in the same situation when data collection starts as it is in the normal FT experiment directly after the excitation pulse.

## 2. One-Dimensional Pulse Sequences

### 2.1. SEFT[*]: Assignment of $^{13}C$-NMR Signals

The modulation of transverse magnetization through spin-spin coupling[12,13] can be used in a simple manner in $^{13}C$-NMR spectroscopy *via* spin echo experiments with gated $^1H$-decoupling to distinguish between signals of quarternary C atoms, and CH, $CH_2$, and $CH_3$ groups[14–23]. In the case of large molecules this method is superior to the well-known off-resonance $^1H$-decoupling experiment, where strong overlap of partially decoupled multiplets makes the assignment difficult or even impossible. In its simplest form, known as SEFT[14], it yields singlets that differ by 180° in their phase.

The SEFT pulse sequence, which relies on spin echo modulation through $^1J(^{13}C,^1H)$ coupling is shown in Figure 9. The $^1H$-decoupler is active during the first half of

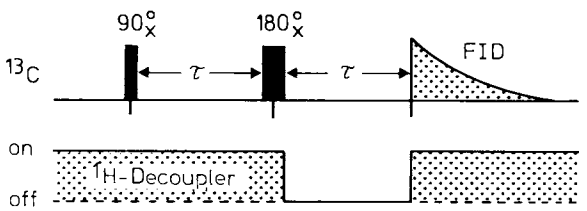

Fig. 9. The SEFT pulse sequence [14].

the spin echo sequence and during data acquisition. In the second $\tau$ period transverse $^{13}C$ magnetization is modulated through spin-spin coupling to the protons. The vector diagrams relevant for the correct choice of time interval $\tau$ are shown in Figure 10. Neglecting relaxation effects, the $\tau$-dependence of the receiver signal, $I$, for CH, $CH_2$, and $CH_3$ groups can be described by a cosine dependence:

$$I(\mathrm{CH}) = I_0 \cos(\pi\tau J)$$
$$I(\mathrm{CH_2}) = \tfrac{1}{2} I_0[1+\cos(2\pi\tau J)]$$
$$I(\mathrm{CH_3}) = \tfrac{1}{4} I_0[3\cos(\pi\tau J)+\cos(3\pi\tau J)]$$

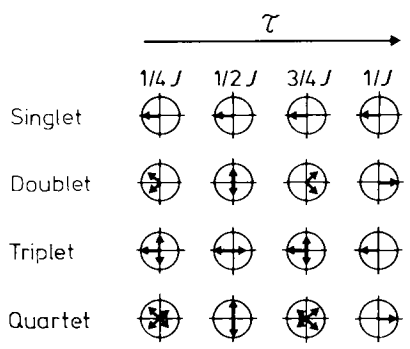

Fig. 10. Vector diagrams for the transverse magnetization of simple first-order spin multiplets for quarternary C atoms, and CH, $CH_2$, and $CH_3$ groups and their dependence on the evolution period $2\tau$. The diagram shows the situation after the 180°x pulse, where the $^1H$-broadband decoupler is switched on again. In the rotating frame the vectors are static and the receiver detects the sum of their y components. For $\tau = 1/J$ the signal phase alternates by 180°, for $\tau = 1/2J$ only the signals of quarternary carbon atoms are detected.

[*] SEFT = *s*pin *e*cho *f*ourier *t*ransform.

The graphical representation (Fig. 11) facilitates the choice of an appropriate $\tau$-value.

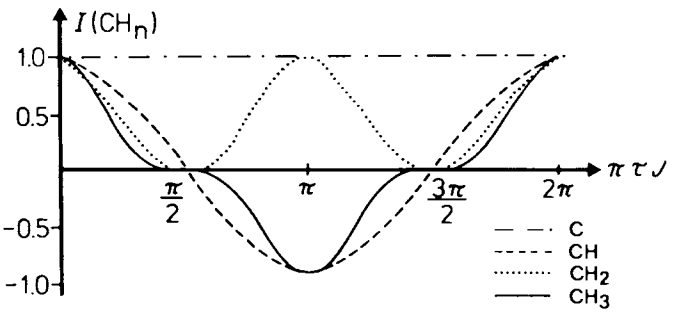

Fig. 11. Time dependence of $^1J(^{13}C,^1H)$-modulated $^{13}C$ magnetization for quarternary C atoms, and CH, $CH_2$, and $CH_3$ groups [21].

As seen from Figure 11, with $\tau = 1/J$ it is possible in only *one* experiment to distinguish between signals of quarternary and methylene C atoms, on the one hand, and those of methine and methyl carbons on the other, since for both groups of resonances a phase difference of 180° exists. The signals of quarternary C atoms and those of $CH_2$ groups have a positive, and those of CH and $CH_3$ groups a negative phase. A further experiment with $\tau = 1/2J$ only yields signals arising from quarternary C atoms. To be able to distinguish CH and $CH_3$ resonances different proposals exist[14–21], none of which, however, is fully satisfactory, since the situation is complicated by changes in the $^1J(^{13}C,^1H)$ values. According to Figure 11, the region $\pi/2 \mp 20\%$ should be appropriate for identifying CH resonances on the basis of their relative intensities and positive or negative phase, respectively (Figure 12).

A practical disadvantage of the SEFT sequence may be seen in the use of 90° pulses, which call for relatively long relaxation delays between individual pulse cycles, and consequently lead to low repetition rates for data accumulation and an increase in the total measurement time. *Patt* and *Shoolery*[22] have eliminated this limitation by the introduction of an additional $\Delta$-180°x-$\Delta$ sequence ($\Delta \approx 1$ ms) which inverts the negative z-magnetization resulting from smaller flip angles.

The application of the SEFT pulse sequence with $^1H$- and $^2H$-decoupling provides an interesting possibility of eliminating the signals from deuterated solvents which often complicate $^{13}C$-NMR spectra. As can be derived from the appropriate vector diagrams for $\tau = 1/3\,^1J(^{13}C,^2H)$ the sum of the y-components of the multiplet lines for CD, $CD_2$, and $CD_3$ groups is zero. Accordingly, the signals of these groups can be eliminated if $^2H$-decoupling is used[24]. An application is given in Figure 13. SEFT pulse sequences that make use of $^2H$- and/or $^1H$-decoupling can also be applied to the analysis of deuterated and partially deuterated compounds, since they allow the $^{13}C$ signals of C, CH, $CH_2$, $CH_3$, CHD, $CHD_2$, $CH_2D$, and $CD_3$ groups to be distinguished[25,26].

Finally, *Bolton*[27] has described a method that can be used to simplify $^1H$ spectra, since only singlets and the central triplet lines are observed. As shown in Figure 10, these lines are independent of the evolution period in a

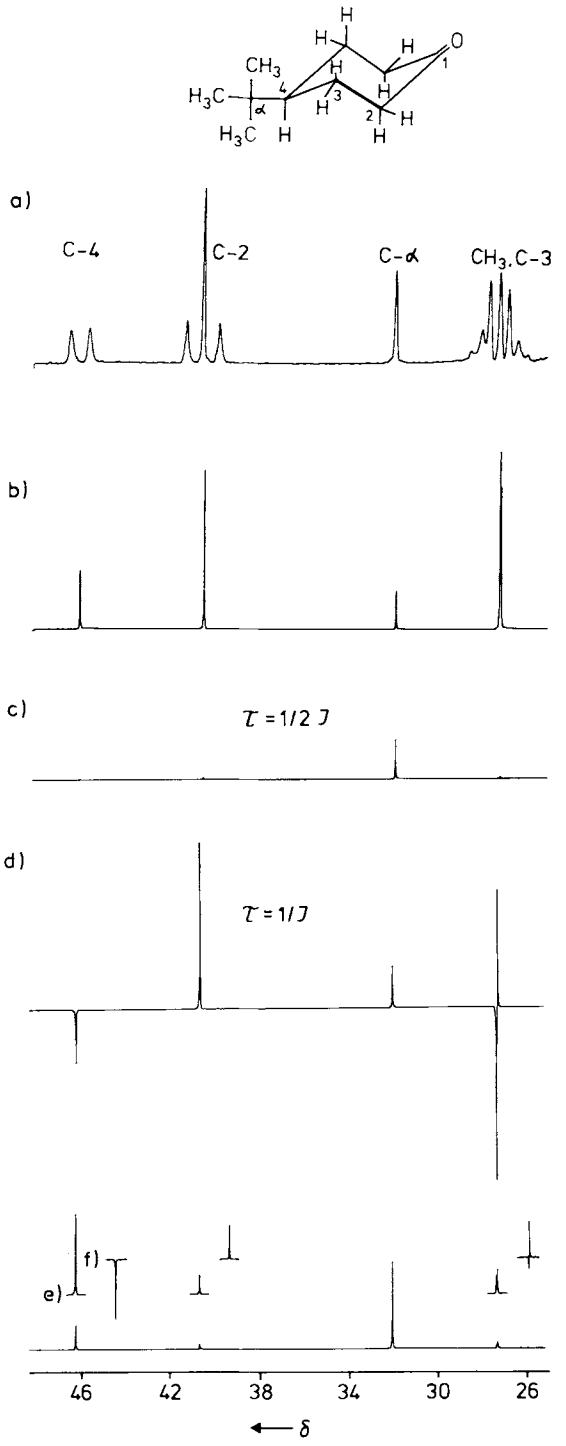

Fig. 12. SEFT experiment on 4-*tert*-butylcyclohexanone; 100.6 MHz $^{13}$C-NMR spectrum, aliphatic region: a) "off-resonance" $^1$H-decoupled; the resonances of C-3 and $CH_3$ are superimposed at $\delta = 27$. b) $^1$H broadband-decoupled. c) SEFT spectrum with $\tau = 1/2J$ ($J = 125$ Hz, $\tau = 4$ ms) for the detection of the resonance of the quarternary carbon $C_\alpha$. d) SEFT spectrum with $\tau = 1/J$ (8 ms); besides the $C_\alpha$ resonance only the signals of $CH_2$ groups show positive phases. The signals superimposed at $\delta = 27$ are now clearly differentiated through phase selection. e) SEFT spectrum for the distinction of CH and $CH_3$ resonances with $\tau = 3.52$ ms. This corresponds to a phase angle of 79° and, according to Figure 11, the signal with the highest relative intensity must be assigned to the methine resonance. An experiment with $\tau = 4.44$ ms ($\theta = 100°$) confirms this (f).

spin echo experiment. By varying $\tau$ in a series of n experiments and summing up the time signals, all absorptions except those mentioned should be averaged out. This has been verified experimentally when n is as low as 4.

Elimination of $^{13}$C-NMR signals of [D$_6$]acetone in the spectrum of ethylbenzene; a) superposition of the solvent signal with the signal of the $CH_2$ groups; b) complete elimination of the solvent signal; c) total spectral region; at L, signals of $^{19}$F lock compound 1,2-dibromotetrafluoroethane [24].

## 2.2. Signal Enhancement Through Polarization Transfer

Low sensitivity has always been a shortcoming of NMR spectroscopy. Today, however, the use of high $B_0$ fields and fast data accumulation made possible by the application of the Fourier transform technique have solved this problem for protons and other nuclei with relatively large magnetic moments, such as $^{19}$F, $^{203}$Tl, $^{205}$Tl, and $^{31}$P, in almost 95% of the cases met with in practice. With the exception of $^3$H, however, all other NMR active nuclei are less sensitive than the nuclei mentioned above, and this situation is very often aggregated by low natural abundance and long relaxation times. Methods for enhancing the sensitivity, therefore, continue to be of great importance.

### 2.2.1. *The SPI[*] Experiment*

Let us discuss a two-spin system consisting of a sensitive and an insensitive nucleus, *e.g.* $^1$H,$^{13}$C or $^1$H,$^{15}$N, where the population of the energy levels in equilibrium is given by the Boltzmann law

$$N_q/N_p = \exp(\Delta E/kT) = \exp(-\gamma\hbar B_0/kT) \approx 1 - \frac{\gamma\hbar B_0}{kT}$$

The population difference between two states $E_q$ and $E_p$ is therefore determined by the gyromagnetic ratio $\gamma$ of the nucleus that changes its spin state during the transition $E_p \rightarrow E_q$. For states involving the sensitive nucleus (A, large $\gamma$) a larger population difference results than for those of the less sensitive nucleus (X, small $\gamma$) (Fig. 14).

If through a selective population inversion involving an A transition the respective spin populations are interchanged, the energy level diagram of Figure 14b results, which now shows enhanced absorption and emission for the X transitions. The Boltzmann distribution that deter-

[*] SPI = *s*elective *p*opulation *i*nversion.

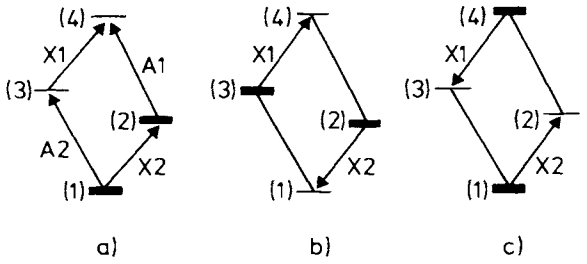

Fig. 14. Population of the energy level diagram of an AX system consisting of a sensitive nucleus (A) and a less sensitive nucleus (X). a) Equilibrium state (the population differences for the X nucleus have been neglected); b) perturbed equilibrium after selective population inversion between the states (1) and (3); for the X lines enhanced absorption (X1) and emission (X2) result; c) as b), however for the states (2) and (4); X1 shows emission and X2 enhanced absorption.

mined the spin populations for the sensitive nucleus now governs those of the less sensitive nucleus. This phenomenon is known as *polarization transfer*.

Experimentally, population inversion can be achieved through a $180^{\circ}_{x}$ pulse applied at the frequency of an A line. Within the framework of Fourier transform methods, however, special techniques are required for selective pulses (see Section 2.4). Yet it proved possible to use the $^1$H-decoupler for this purpose[28].

The method, which became known as the SPI or SPT[*][29] experiment, was first performed with the $^{13}$C,$^1$H spin system of chloroform[28]. It is easily carried out if the $^{13}$C doublet is recorded with the $^1$H-decoupler applied at the frequency of one of the $^{13}$C satellite lines immediately before the $^{13}$C pulse (Fig. 15). The decoupler pulse then leads to a population inversion between those $^1$H levels that are connected by the respective satellite line.

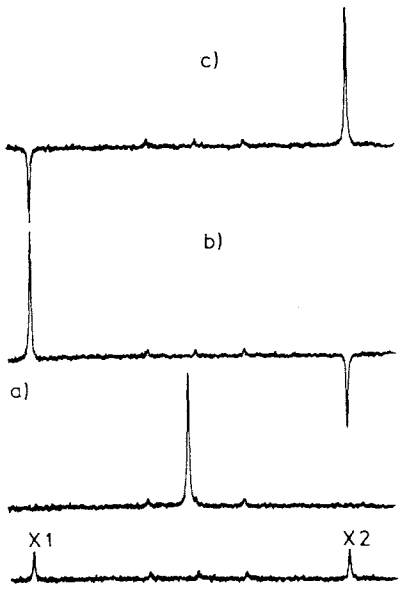

Fig. 15. The SPI experiment with $CHCl_3$ [28]; a) $^1$H-decoupled and $^1$H-coupled $^{13}$C-NMR spectrum; b) and c) with population inversion as Figs. 14b and 14c, respectively.

The SPI experiment is important for signal assignments[30] as well as for measurements of insensitive nuclei[31-34]. In addition, just as the INDOR[**] experiment in CW-NMR spectroscopy, it can be used to determine the relative signs of coupling constants and for spectral analyses[35-40]. Of most general interest is the possibility of sensitivity enhancement of $^1$H-coupled spectra of less abundant nuclei ($^{13}$C[31,33], $^{15}$N[34], $^{29}$Si[32]). The increase in intensity for a first-order $A_nX$-spin system ($A = {}^1H$, $X = {}^{13}C$) is given by comparison with the Pascal triangle, which describes the normal intensity distribution (Fig. 16). An important limitation of the SPI method, however, is to be seen in the fact that only *one* line at a time in the $^1$H spectrum can be perturbed.

| a) | n | b) |

### 2.2.2. *The INEPT[***] Pulse Sequence*

A crucial step forward was possible after it was recognized that polarization transfer can also be achieved *non-selectively* through a proper pulse sequence[41]. The INEPT method[42] introduced by *Morris* and *Freeman* has this advantage and goes beyond the limits of the SPI experiment.

The basic pulse sequence of the INEPT method is shown in Figure 17 together with the translation into a vector diagram.

The important elements are the modulation of the transverse magnetization of the sensitive nucleus (A) through coupling to the less sensitive nucleus (X) and the simultaneous application of two $180^{\circ}_{x}$ pulses in the A and X frequency regions. The vector arrangement obtained after the evolution period $2\tau$ for the doublet components of the A nucleus can be transformed into the characteristic arrangement of a selectively inverted spin system through application of a $90^{\circ}_{y}$ pulse. Within the energy-level diagram this corresponds to a population inversion of one A line and leads to polarization of the X lines. An example is given in Figure 18 with the $^{15}$N-NMR spectrum of 9-methylpurine. The evolution period of the INEPT pulse sequence is based on one particular AX coupling constant and must be estimated if $J$(A,X) is not known. For $^{15}$N-NMR spectroscopy of unsaturated heterocycles the geminal $^{15}$N,$^1$H coupling constants, which are in the order of 10 Hz ($\tau = 1/40$ s), are suitable for this purpose[43,44]. If NH or $NH_2$ groups are also present, then a second experiment with $\tau = 1/4\,{}^1J({}^{15}N,{}^1H)$ ($\approx 1/250$ s) must be performed.

Typical for INEPT NMR-spectra that display spin-spin coupling is the zero intensity of the central lines of odd

[*] SPT = selective *p*opulation *t*ransfer.

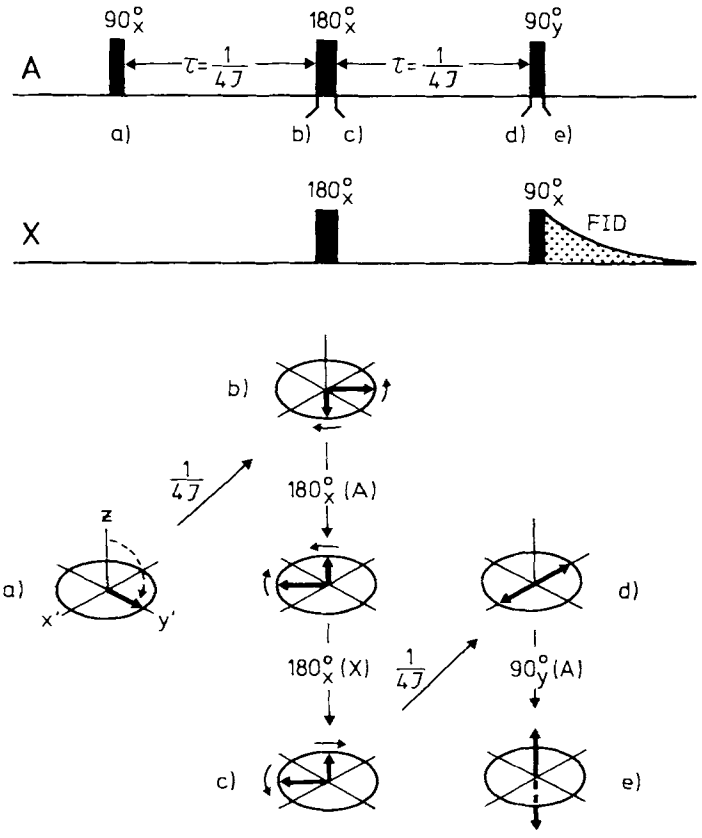

Fig. 17. Pulse sequence of the INEPT method [42] for an AX system (*e.g.* A = $^{1}$H, $^{19}$F, or $^{31}$P; X = $^{13}$C, $^{15}$N, or $^{29}$Si). The vector diagram shows only the A magnetization in the rotating frame ($\nu_0 = \nu_A$). After 90°$_x$ excitation (a) the transverse magnetization of the nucleus A is modulated by spin-spin coupling to the less sensitive nucleus X. After time $\tau = 1/4J$ a phase difference of 90° exists between both doublet vectors (b). A 180°$_x$ pulse in the A as well as in the X frequency region leads to the vector diagram (c) so that after time $2\tau$ state (d) is reached. A 90°$_y$ pulse now inverts the magnetization of one proton line (e). This corresponds to selective population inversion. The polarization of the spin system is detected by a 90°$_x$ pulse in the frequency region of the less sensitive nucleus, whose lines show emission or enhanced absorption. Refocussing is achieved by an additional spin echo sequence, for a doublet 1/4*J*-180°$_x$(A,X)-1/4*J*. The X resonance can then be detected as a positively polarized doublet or—with simultaneous $^{1}$H decoupling during the detection period—as a singlet.

multiplets as well as the inversion of half of the multiplet lines (NH: −1, +1; $NH_2$: −1, 0, +1; $NH_3$: −1, −1, +1, +1). The integrated total intensity of a multiplet in the INEPT spectrum is therefore zero. An additional pulse sequence allows the signals to be refocussed with correct phase so that normal multiplets are observed, or singlets when the protons are decoupled[45,46].

The success of a polarization transfer experiment is determined largely by the relaxation time of the sensitive nucleus: this determines the time necessary for the perturbed spin system to return to the equilibrium state, and must be long enough to prevent reestablishment of the normal Boltzmann distribution during the pulse sequence. Therefore, prolongation of the measurement, as in the refocussing experiment is very often accompanied by sensitivity losses; in the case of macromolecules with short $^{13}$C-$T_2$ and $^{13}$C-$T_1$ values that are shorter than those of the respective protons, the method may even fail[47]. On the other hand, since sensitive nuclei, such as $^{1}$H or $^{19}$F have appreciably shorter relaxation times than *e.g.* $^{13}$C, the repetition rate during data accumulation can be much higher than the less sensitive nucleus would otherwise permit. The total measurement time is therefore reduced; for $^{15}$N measurements, typically by a factor of 2—3.

A further important aspect is that the intensity enhancement in suitable cases can be much larger than that obtained with the well-known nuclear Overhauser effect (NOE). Furthermore, negative $\gamma$ values are not a disadvantage because sensitivity enhancement for NOE experiments is governed by the sum $1+\gamma_A/2\gamma_X$[48], whereas for polarization transfer experiments the ratio $\gamma_A/\gamma_X$ is important[31,33,42]. An additional cumulative effect is observed for degenerate lines.

Interesting INEPT experiments with metal nuclei have been carried out by *Brevard et al.*[49,50]: here protons (for $^{109}$Ag and $^{103}$Rh[49]), but also $^{31}$P nuclei (for $^{57}$Fe, $^{103}$Ru, and $^{183}$W[50]) were used as polarization sources. $^{29}$Si{$^{1}$H} and $^{119}$Sn{$^{1}$H} experiments have been reported by *Doddrell et al.*[51].

Table 1. Maximum signal enhancement factors, $\eta_{NOE}$ and $\eta_{INEPT}$, for nuclear Overhauser and INEPT experiments, respectively, with X{$^{1}$H} spin systems.

| X | $^{11}$B | $^{13}$C | $^{15}$N | $^{29}$Si | $^{57}$Fe | $^{103}$Rh | $^{109}$Ag | $^{119}$Sn | $^{183}$W |
|---|---|---|---|---|---|---|---|---|---|
| $\eta_{NOE}$ | 2.56 | 2.99 | −3.94 | −1.52 | 16.48 | −16.89 | −9.75 | −0.41 | 13.02 |
| $\eta_{INEPT}$ [a] | 3.12 | 3.98 | 9.87 | 5.03 | 30.95 | 31.77 | 21.50 | 2.81 | 24.04 |

[a] For $^{19}$F or $^{31}$P as polarization source (A) these data are reduced by the factor 0.941 ($\gamma_{^{19}F}/\gamma_{^{1}H}$) and 0.407 ($\gamma_{^{31}P}/\gamma_{^{1}H}$), respectively.

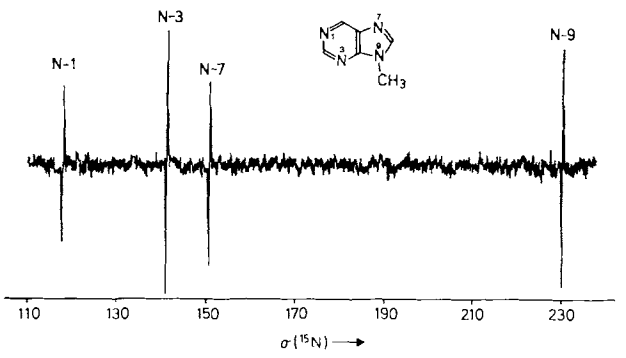

Fig. 18. INEPT-$^{15}$N-NMR spectrum of 9-methylpurine [44]. Frequency 40.53 MHz, 6293 transients, spectral width 6024 Hz, total acquisition time 4.75 h. The $\sigma$-scale refers to external $CD_3{}^{15}NO_3$.

### 2.2.3. *The DEPT[*] Pulse Sequence*

A pulse sequence which is somewhat less critical to the choice of the A,X coupling constant and which yields X multiplets without the artefacts involving relative intensity and line number observed with the INEPT method was recently proposed by *Doddrell et al.*[52]. The method, called DEPT, is characterized in Figure 19: compared to INEPT it differs in the $\tau$-value, which is now $1/2J$, and in the variable length $t_p$ of the last $^{1}$H pulse.

Polarization transfer methods can also be employed for the assignment of resonance signals[53], and the DEPT se-

[*] DEPT = *d*istortionless *e*nhancement by *p*olarization *t*ransfer.

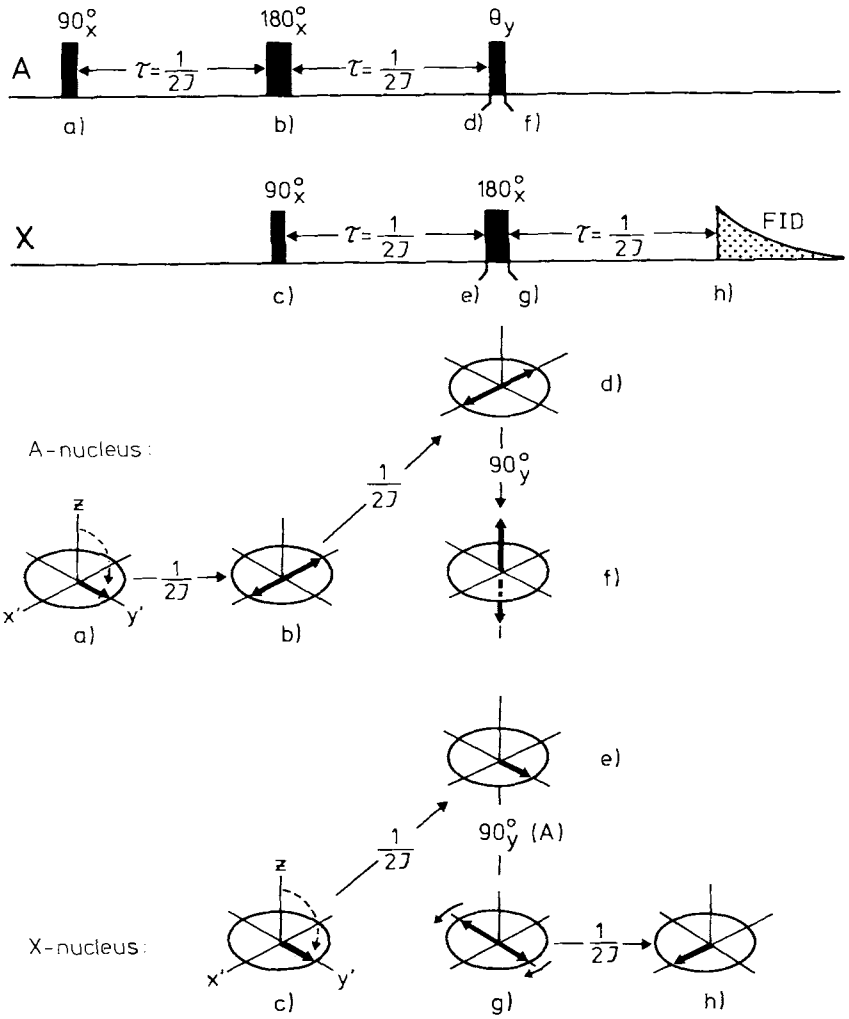

Fig. 19. DEPT pulse sequence [52] and vector diagram for an AX system. After the first 90°$_x$ pulse (a) the transverse A magnetization is modulated through coupling to the X nucleus. After time $\tau = 1/2J$ a phase difference of 180° exists between both doublet vectors (b). A 180°$_x$ pulse in the A region is used for refocussing inhomogeneity contributions. At the same time, a 90°$_x$ pulse in the X region creates transverse $^{13}C$ magnetization (c). Since neither A nor X z-magnetization is present, A and X are practically decoupled. During the next period, $1/2J$, both vectors are static in their rotating frames (d and e, respectively). At $t = 2\tau$ a 90°$_y$ pulse in the A region ($\theta = 90°$) polarizes the A magnetization (f). At the same time this causes polarization of the X magnetization (g). The reestablished z-magnetization in the region of the A nucleus leads *via* spin-spin coupling to refocussing of the X vectors in the last $1/2J$ period (h). X magnetization can now be detected with uniform phase as a doublet or—with simultaneous A decoupling—as a singlet at $t = 3\tau$. If the 90°$_y$ pulse in the A region is neglected, the DEPT pulse sequence consists of two spin echo sequences in the A and X regions, respectively, that are mutually shifted in time. If, on the other hand, the second $\tau$ period and the 180°$_x$ refocussing pulses are eliminated, the INEPT pulse sequence is obtained.

quence seems especially well suited for this purpose[54]. For $^{13}C$-NMR spectra the phase properties of the magnetization of quarternary C atoms and CH, $CH_2$, and $CH_3$ groups were studied and it was shown that pulse angles $\theta$ of $\pi/4$, $\pi/2$, and $3\pi/4$, respectively, for the last $^1H$ pulse enable subspectra to be edited for CH, $CH_2$, and $CH_3$ groups. For the detection of $CH_2$ and $CH_3$ groups, difference spectra must be used. An example is shown in Figure 20.

Other authors have described the selection of $^{13}C$ satellites in $^1H$-NMR spectra[56] and of signals of deuterated carbons in $^{13}C$-NMR spectra[57] using polarization transfer methods. In addition, the INEPT sequence has been used for spin-lattice relaxation time measurements of $^{13}C$[58], $^{29}Si$[59], $^{15}N$[59,60], and was also applied to nuclei with spin quantum numbers $I > 1/2$[61,62]. The advantages and disadvantages of the INEPT and DEPT sequences as well as improvements of these methods for the detection of $^1H$-coupled multiplets in the normal absorption mode have been described recently by *Sørensen* and *Ernst*[63].

### 2.3. INADEQUATE[*]: Determination of $^{13}C,^{13}C$ Spin-Spin Coupling Constants in Molecules with Natural $^{13}C$ Abundance

Spin-spin coupling constants between $^{13}C$ nuclei[64] are of great interest with respect to questions of structure and

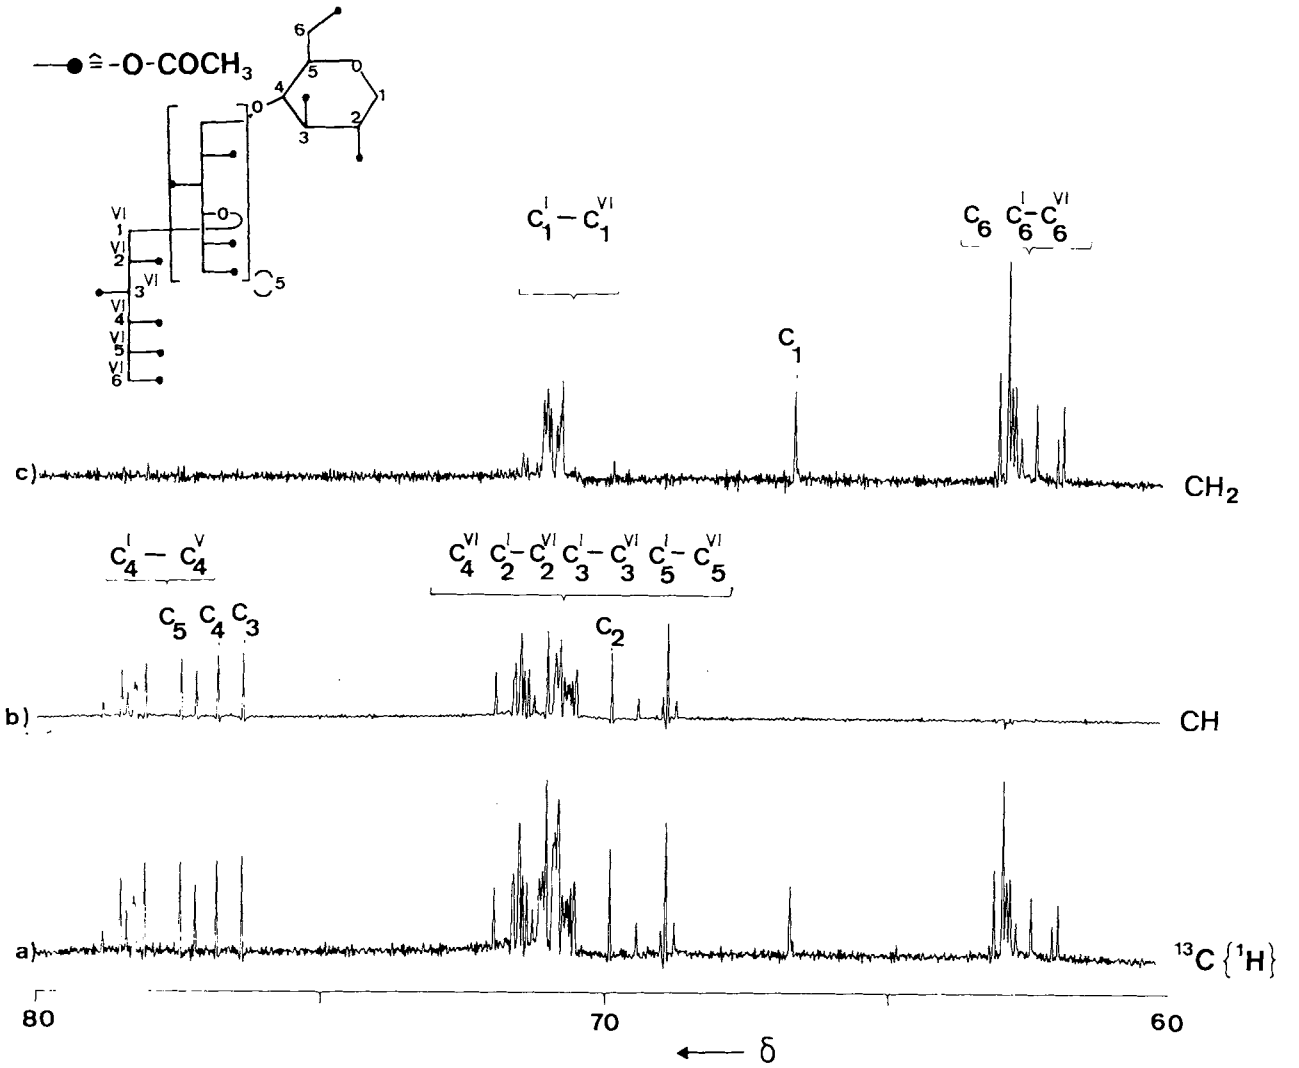

Fig. 20. DEPT $^{13}$C-NMR spectra of a polysaccharide [55]; a) decoupled at 100.6 MHz, $\delta_{TMS}$ scale. For the DEPT sequence the selection of CH and $CH_2$ resonances was achieved with $J = 145$ Hz ($\tau = 3.448$ ms); b) experiment with the phase angle $\theta = 90°$ (see below) for the selective detection of the CH resonances; c) difference spectra of two experiments with phase angles $\theta = 45°$ and 135°, respectively, for the selective detection of $CH_2$ resonances. It would have been difficult to analyze the region around $\delta = 70$ ppm on the basis of a conventional "off-resonance" $^1$H-decoupled spectrum. Signal selection with the DEPT pulse sequence requires measurement of 4 different spectra with pulse angles of $\theta_1 = 45°$, $\theta_2 = 90°$, $\theta_3 = 135°$, and $\theta_4 = 90°$, respectively, for the last $^1$H-pulse using the same number of transients. For the different types of signals the following relations hold[54]: $S(CH)$: $S(\theta_2) + S(\theta_4)$; $S(CH_2)$: $S(\theta_1) - S(\theta_3)$; $S(CH_3)$: $S(\theta_1) + S(\theta_3) + 0.707[S(\theta_2) + S(\theta_4)]$.

bonding in organic chemistry since they yield information directly related to the carbon skeleton of the compound studied. The $^1J(^{13}C,^{13}C)$ data are of particular value because of their dependence on the hybridization of the carbon[64,65] and consequently on the type of CC bond. Furthermore, they can be used to establish connectivities between carbon atoms[66], a central aspect for structure determination which was recognized relatively late, despite successful biochemical studies using $^{13}$C,$^{13}$C double labeling techniques[67]. The reason for this must certainly be seen in the experimental difficulties that prevent routine determination of $^{13}$C,$^{13}$C coupling constants.

The necessary condition for the observation of $^{13}$C,$^{13}$C coupling constants is the presence of two anisochronous $^{13}$C atoms in a molecule. Because of the low natural abundance of $^{13}$C (1.1%) this condition is, however, met only for few molecules in the sample ($\approx 0.011\%$). Line splittings as a result of $^{13}$C,$^{13}$C couplings are present in the $^{13}$C-NMR spectrum only as weak satellites accompanying the intense signals of molecules with one $^{13}$C atom; in particular, small coupling constants are difficult to measure. Since synthetic enrichment is possible only in a few exceptional cases, experimental methods which facilitate the measurement of $J(^{13}C,^{13}C)$ data are of interest.
