The pulse sequence INADEQUATE developed by *Freeman et al.*[68] for this purpose is based on the idea that by suitable treatment of the spin system consisting of the AX system of the coupled $^{13}$C nuclei and the intense signal of the parent compound with only one $^{13}$C, the main signal can be suppressed. This is clearly possible if a 90° phase difference exists between the transverse magnetization of the satellites and that of the main signal that allow the selection of the AX magnetization for detection. The pulse sequence shown in Figure 21 achieves this goal. It contains as an important new phenomenon step (d), the so-called *double-quantum coherence*[69].

As shown by *Ernst*, the pulse sequence $90°_x$- $\tau$ -$90°_x$ allows double quantum transitions within the framework of the

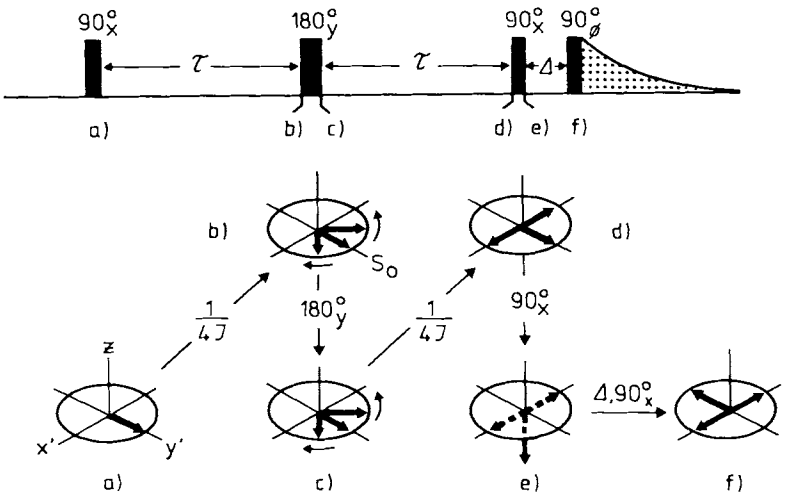

Fig. 21. Pulse sequence of the INADEQUATE experiment[68]. After the initial 90°$_x$ pulse (a) $^{13}C,^{13}C$ coupling leads to a fanning-out of the $^{13}C$ satellites of the A nucleus, which after $\tau = 1/4J$ have a phase difference of 90°, whereas the magnetization $S_0$ of the main signals of molecules with only one $^{13}C$ nucleus is static on the y axis (b). The non-selective 180°$_y$ pulse leaves the rotational sense of the satellites unchanged (c), and after the time $2\tau$, a phase difference of 180° results (d). During this time the main signal retains its direction along the a axis; respective inhomogeneity contributions are refocussed by the 180°$_y$ pulse. The second 90°$_x$ pulse generates double-quantum coherence that cannot be detected directly and directs $S_0$ in the z direction (e). After a short delay $\Delta$ (10 μs), transverse magnetization of the $^{13}C$ satellites is transformed into detectable magnetization by a 90° pulse of variable phase (f) (see Table 2). The doublet components have opposite phase. An additional spin echo sequence $1/4J$- 180°$_x$ - $1/4J$ can be used for refocussing. $^1H$-broadband decoupling is applied during the whole experiment.

Fourier transform method to be excited[70]. This possibility is utilized here, since the 180°$_y$ pulse is only introduced to refocus chemical shift and inhomogeneity contributions. After generation of double quantum coherence, a third 90° pulse of variable phase $\phi$ is applied to prepare the AX magnetization for detection. As shown in Table 2, the detector phase is properly adjusted so that only the AX magnetization can be received.

Table 2. Phase shifts for the selective detection of $^{13}C,^{13}C$-satellites by the INADEQUATE sequence [68] (cf. Fig. 21).

| $\phi$ [a] | $S_0$ [b] | S [c] | $\Psi$ [d] |
|---|---|---|---|
| +x | −y | +x | +x |
| +y | +x | −y | −y |
| −x | +y | −x | −x |
| −y | −x | +y | +y |

[a] Phase of read pulse; [b] Phase of main signal; [c] Phase of satellite magnetization; [d] Detector phase.

The result of an INADEQUATE experiment is shown in Figure 22 for ($\eta^5$-cyclopentadienyl)-$\eta^1,\eta^2$-2,2-dimethyl-3-butenylnickel. Here, an additional $1/4J$-180°$_x$-$1/4J$ sequence[68] was employed to produce absorption signals. The selection of $^{13}C,^{13}C$ coupling constants is achieved by varying the time interval, $\tau$, given by $\tau = 1/4J(^{13}C,^{13}C)$. In the case of unknown compounds $\tau$ must be estimated from the data of similar systems. For the detection of $^{13}C,^{13}C$ coupling constants of different magnitude, a number of experiments with different $\tau$ values are necessary; however, in many cases one $\tau$ value is sufficient to detect two or more coupling constants that differ in magnitude, since the general expression for $\tau$ is given by $(2n+1)/4J(^{13}C,^{13}C)$ $(n = 0, 1, 2)$[71].

If, for an unknown compound the $^1J(^{13}C,^{13}C)$ coupling constants have been determined, the resonances of neighboring C atoms can be assigned through recurrent splittings. The analysis of the spectral data is best carried out using a computer[73]. Since individual C atoms can be recognized with respect to their bonding by the characteristic position of their resonance signals, carbon-carbon connectivity[74] determined by $^1J(^{13}C,^{13}C)$ coupling yields valuable information about chemical structures. The analysis of carbon-carbon linkages is therefore an important area of application for the INADEQUATE pulse sequence, in spite of the fact that a gain in sensitivity is not achieved. In this respect, however, the increasing use of superconducting magnets has a positive effect regarding the amount of compound required, as well as on the total measurement time.

If the delay given in Figure 21 is treated as an additional evolution period, it is possible to detect individual AX systems selectively, since different double quantum frequencies can be used for detection[75]. In this way the assignment of $^{13}C$ resonances and further coupling constants with other nuclei that might be present can be achieved. The selection of AX systems and other signals on the basis of double quantum coherence has also been reported for $^1H$-NMR spectra[76–78].

For non-first order systems (AB) the INADEQUATE sequence is less suitable, and this case has been treated separately[79]. The combination of INADEQUATE with INEPT, which is of interest with regard to sensitivity enhancement, has been described[80] as well as signal selection with the help of $^{13}C,^1H$ coupling constants[81]. Furthermore, the one-dimensional INADEQUATE experiment has been transformed into a two-dimensional experiment by using a variable evolution period (see Section 3.5).

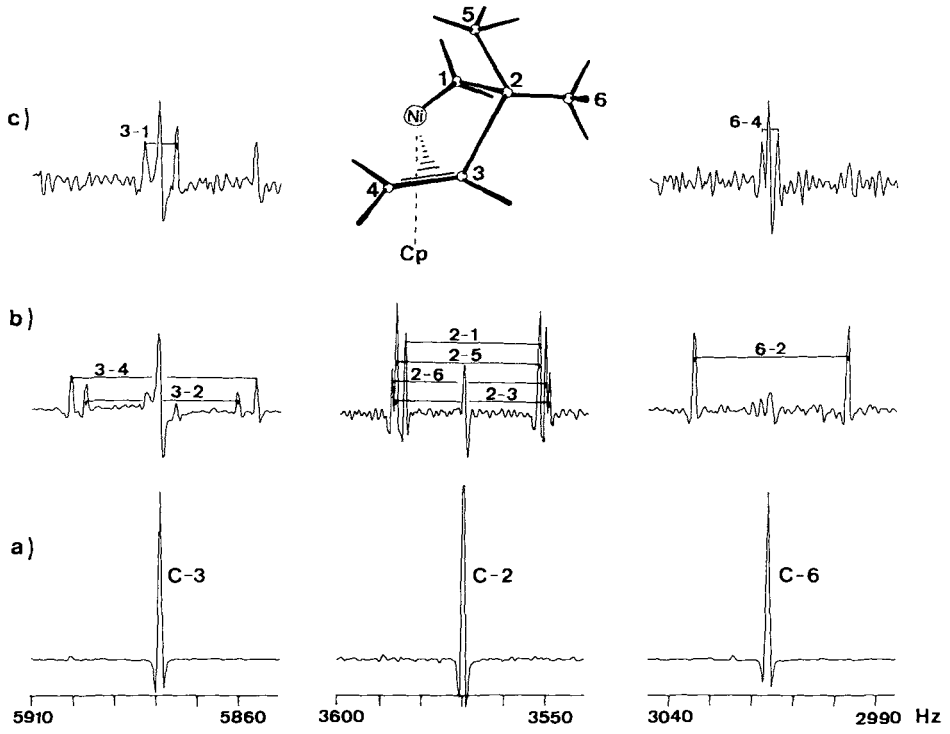

Fig. 22. Use of the INADEQUATE pulse sequence for the determination of $^{13}C,^{13}C$ coupling constants of ($\eta^5$-cyclopentadienyl)-$\eta^1,\eta^2$-2,2-dimethyl-3-butenylnickel [72]; a) signals of C atoms 3, 2, and 6; b) INADEQUATE spectra with $\tau = 6.2$ ms corresponding to $^1J(^{13}C,^{13}C) \approx 40$ Hz; c) as b) with $\tau = 0.08$ s corresponding to geminal and vicinal $J(^{13}C,^{13}C)$ coupling constants; spectral width 5000 Hz, 1600 transients, FID-Gauss multiplication. The result was $^1J(1,2) = 32.1$, $^1J(2,3) = 37.1$, $^1J(2,5) = 34.7$, $^1J(2,6) = 37.1$, $^1J(3,4) = 44.7$, $^2J(1,3) = 8.5$, $^3J(4,6) = 3.2$ Hz.

### 2.4. DANTE[*]: Selective Excitation of $^{13}C$-Resonances

Since pulse excitations are polychromatic, the FT technique has the disadvantage that selective observation of spectral regions is difficult or impossible. Frequency folding leads to problems, and intense solvent lines that may cause data overflow or cover low-intensity signals of interest are not easily eliminated. The possibilities of decreasing the spectral window by suitable frequency filters are limited, and the development of alternative methods for selective excitation was desirable. The techniques proposed[82], known as *tailored excitation*, use excitation functions adapted to the problem under consideration. The necessary software, however, is relatively complicated and practical applications have been rare.

A powerful technique for the selection of individual resonances, which is especially well suited for the analysis of $^1H$-coupled $^{13}C$-NMR spectra where strong overlap of individual multiplets is frequently observed, was introduced by *Freeman et al.*[83]. The idea is that a single $^{13}C$ resonance, whose frequency is determined in the $^1H$-decoupled spectrum, is selectively excited by a special pulse modulation of the RF frequency. $^1H$-coupling is allowed during FID detection, so that the fully coupled multiplet of the $^{13}C$ nucleus in question is recorded without disturbance through overlap with other resonances.

The basis of this method, which is termed DANTE[84], is pulse excitation through a pulse train characterized by small pulse delays $t_r$ and small pulse angles $\alpha$. Such an RF pulse modulation corresponds to a frequency spectrum with sidebands spaced by $1/t_r$, which relative to the pulse frequency $\nu_0$ appear at $\nu_0 \pm 1/t_r$, $\nu_0 \pm 2/t_r$ *etc.*, and which can be regarded as selective pulse transmitters. The correct choice of the transmitter frequency and the repetition rate $t_r$ allow the selective excitation of individual resonances (Fig. 23).

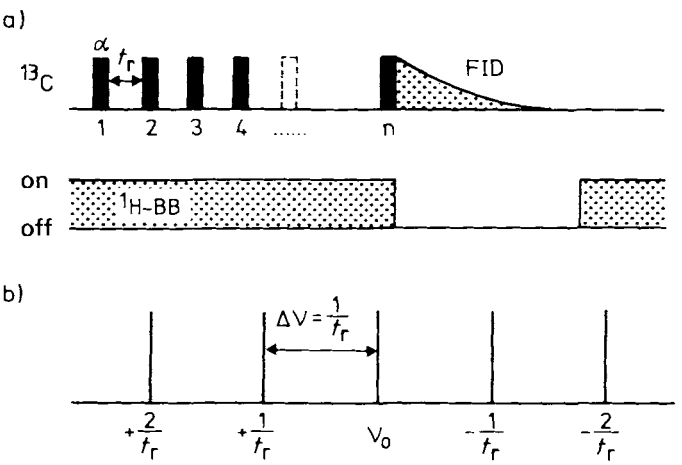

Fig. 23. DANTE pulse sequence for selective excitation of $^{13}C$ resonance [83]. After Fourier transformation small pulse spacings $t_r$ (a) yield the frequency spectrum shown in (b). Using the center band or the first sideband, $^{13}C$-resonances can be selectively excited with simultaneous application of $^1H$ decoupling; $^{13}C,^1H$ coupling is allowed during detection, which results in the measurement of NOE enhanced multiplets. The number of pulses n is chosen in such a way that for the pulse angle, $\alpha = 90°/n$ holds. At the end of the pulse sequence, therefore, a 90° pulse is achieved and the signal intensity at the start of data acquisition is at its maximum. Typical values are $t_r = 2$ µs, $n = 200$, $\alpha = 0.45°$.

[*] DANTE = *d*elays *a*lternating with *n*utation for *t*ailored *e*xcitation.

An application of the DANTE technique is shown in Figure 24 with the $^1$H-coupled $^{13}$C-NMR spectrum of the aromatic carbons of triptycene[85]. At 100.6 MHz the high-field and low-field components of the C-β and C-α multiplets, respectively, are superimposed (Fig. 24a). Selective excitation allows each multiplet to be observed and analyzed separately (Fig. 24b).

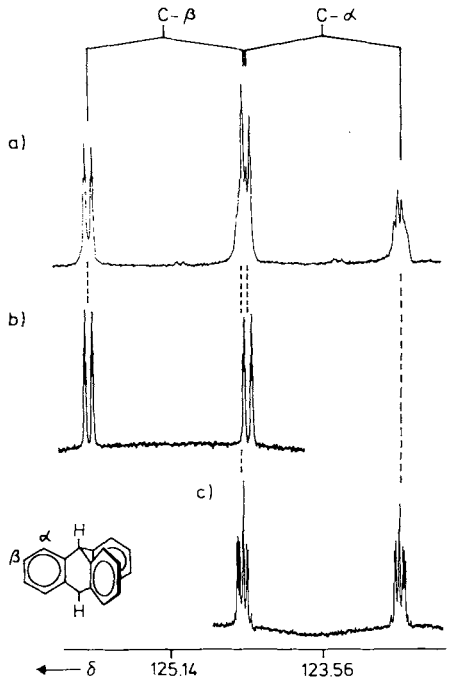

Fig. 24. $^1$H decoupled 100.6 MHz $^{13}$C-NMR spectrum of the aromatic carbon atoms of triptycene [85]; a) conventional spectrum with partial multiplet overlap; b) and c) selective excited C-β and C-α resonances, respectively, with selective decoupling of the benzylic protons. Spectral analysis yields the following $^{13}$C,$^1$H coupling constants: C-α: $^1J = 158.63$, $^2J = 1.54$, $^3J = 8.13$, $^4J = -1.20$ Hz; C-b: $^1J = 159.15$, $^2J_\alpha = 1.13$, $^2J_{\beta'} = 1.32$, $^3J = 7.32$ Hz.

Besides such applications in spectral analysis, the DANTE sequence is a valuable aid for kinetic measurements of reversible first-order reactions on the basis of the saturation transfer method introduced by *Hoffmann* and *Forsén*[86,87]. A detailed discussion of this aspect is given by *Freeman*[83b].

### 2.5. Super Pulse Cycles for Broadband Decoupling

Today, $^1$H-broadband decoupling is a necessary requisite for spectra simplification and intensity enhancement in NMR spectroscopy of heteronuclei. In this respect the increasing use of high-field spectrometers is not without problems, since the enlarged $^1$H-spectral region requires more powerful $^1$H-decouplers. A method recently proposed by *Freeman et al.*[88] is therefore of interest, since it allows the decoupler power to be dissipated over a large frequency range. The basis is again the spin echo experiment (see Fig. 25). As shown in Figure 25a, using a simple diagram for a $^{13}$C, $^1$H pair, detection of $^{13}$C magnetization at intervals $2\tau$, $4\tau$, $6\tau$, *etc.* yields the data of a decoupled multiplet if a 180° ($^1$H) pulse is applied at $\tau$, $3\tau$, $5\tau$, etc. The fact that the doublet components of the X nucleus possess different Larmor frequencies is not "sensed" by the receiver, since magnetization is only sampled when both vectors are superimposed. From Figure 25 it is seen that the receiver detects the spin echo as a non-coupled time signal.

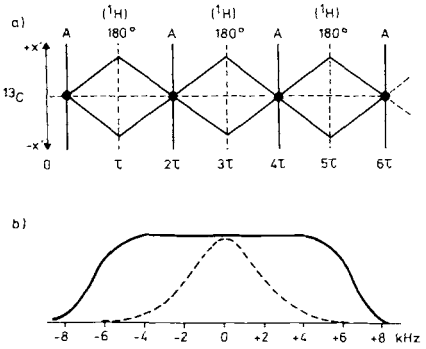

Fig. 25. a) Time dependence of transverse $^{13}$C magnetization of a CH fragment upon application of a sequence of 180° pulses in the $^1$H-spectral region. Data are collected at A and complete $^1$H decoupling is achieved. b) Comparison of the band width of the decoupler field for a conventional modulation technique (curve, ---) and the pulse method described (curve, —). In practice the method described, which is known as MLEV, uses phase cycles for the $^1$H pulses. The choice of the most appropriate phase cycle is presently being investigated [88].

The important practical aspect of this spin-flip method is the fact that, for a given decoupler power, the decoupled spectral region in the $^1$H-NMR spectrum is a factor of 3 larger than that obtained by use of conventional broadband-decoupling modulation techniques (noise modulation, square-wave modulation, *etc.*) (Fig. 25b). This also renders the method interesting for $^{19}$F or $^{31}$P broadband decoupling, since the chemical shift range of these nuclei is much larger than that of protons. Furthermore, maintaining the same frequency region the power of the $B_2$ field can be reduced and the danger of heating the sample is diminished. The nuclear Overhauser effect is established before $^{13}$C excitation. The technique also permits partial decoupling and thus scaling of the respective coupling constants.

## 3. Two-Dimensional (2D-) NMR Spectroscopy

The common feature of the experiments discussed so far was the time sequence *preparation—evolution—detection* shown in Figure 8, where the receiver signal $S(t_2)$ is solely a function of the detection time $t_2$. The same time diagram also forms the basis of two-dimensional NMR spectroscopy[89,90] (2D-NMR); however, with the important difference that the evolution time $t_1$ within a sequence of pulse cycles is now a variable. If over n experiments we increase each evolution period $t_1$ by a constant time increment $\Delta t_1$, the receiver signal will also become dependent on $t_1$. It is thus a function of $t_1$ *and* $t_2$: $S(t_1,t_2)$. Two time-variables imply, however, that the data can be Fourier-transformed twice, *i.e.* with respect to $t_2$ and $t_1$. As a consequence, two frequency variables $F_1$ and $F_2$ are also obtained.

Two-dimensional FT-NMR spectroscopy is always possible if a systematic variation of the evolution period results in a periodic change of a property of the spin system at the end of the evolution time[11]. For example, the origin may be a scalar spin-spin coupling with another nucleus that can be switched on or off by decoupler control during

the evolution period[11,91]. For the signal, which is again decoupled in the detection period, an amplitude- or phase-modulation results. As shown in Figure 26, the first Fourier transformation with respect to $t_2$ yields n conventional spectra, whose data points on the time axis $t_1$ define the modulation frequency, which can be determined by a second Fourier transformation. If, for example, scalar spin-spin coupling during the evolution time results in an amplitude- or phase-modulation through variation of $t_1$, the frequency parameters chemical shift and spin-spin coupling can be separated by a two-dimensional experiment, since the first Fourier transformation with respect to $t_2$ yields the resonance frequency and the second Fourier transformation with respect to $t_1$ the modulation frequency, *i.e.* the coupling constant.

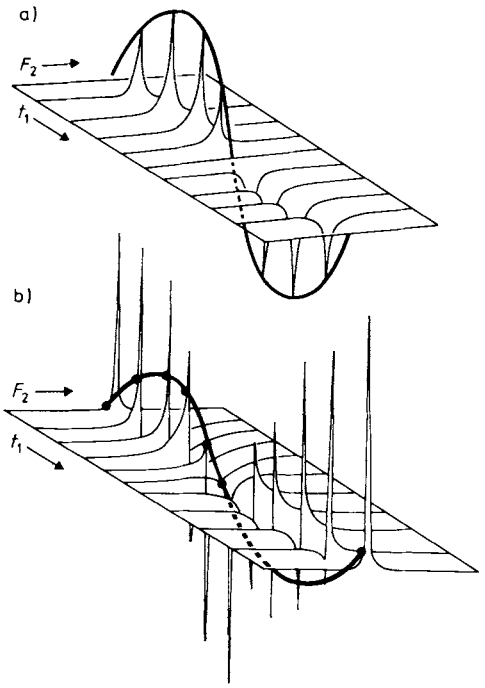

Fig. 26. Two-dimensional NMR spectroscopy through amplitude and phase modulation (a, b, respectively). The figure shows the situation after the first Fourier transformation. The modulation of the signals results from a periodic perturbation of the spin system during the evolution period. Repeated Fourier transformation of the time signal $S(t_1)$ yields the frequency $F_1$.

These relations will be described again for the particular case of a $CH_n$ fragment. We excite the $^{13}C$ resonance with a $90^\circ_x$ pulse and collect the signal information after a variable evolution time $t_1$ with complete proton decoupling[91]. The $t_1$-dependent spin-evolution for a CH and $CH_2$ fragment (doublet and triplet, respectively) is shown in Figure 27. The important point here is that, despite proton decoupling, the coupling information is retained in the detection period, since during the evolution time coupling leads to a periodic change of the amplitude of transverse $^{13}C$ magnetization. The time-domain functions for the doublet and triplet are different, since that of the triplet oscillates at twice the frequency[92] and is positively shifted by a constant amount which results from the central triplet line. Fourier transformation yields in the first case a doublet with lines at $-J/2$, and in the second case a triplet, whose outer lines lie at $\pm J$. This example shows that the $t_1$-dimension contains the scalar coupling constant as an inde-

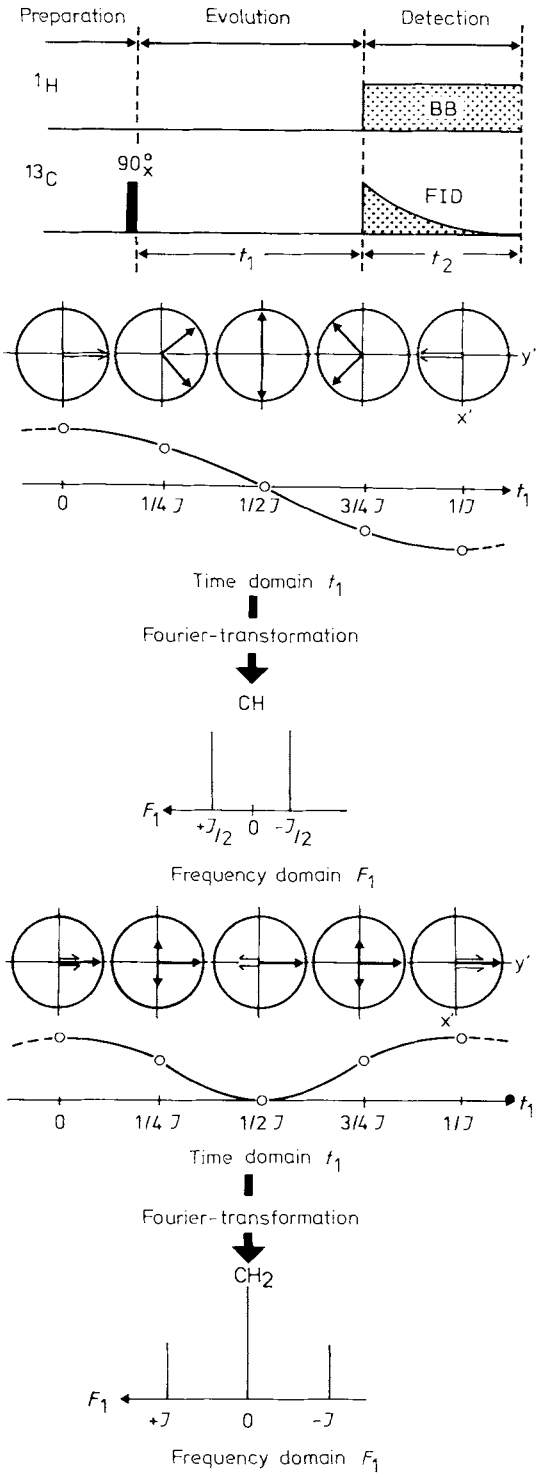

Fig. 27. Simplified time sequence and vector diagram for a *J*-resolved 2D-NMR experiment using the examples of a CH and a $CH_2$ fragment. The vector diagrams in the rotating frame, which has the Larmor frequency of the $^{13}C$ nucleus, show the situation of transverse $^{13}C$ magnetization at the end of the evolution period. $^1H$ decoupling during detection leads to registration of the respective y-components, whose amplitude is modulated as $\cos(\pi J t_1)$ in the case of CH groups, and as $\frac{1}{2}[\cos(2\pi J t_1)+1]$ in the case of $CH_2$ groups. Fourier transformation of the time functions $S(t_1)$ thus defined yields on the $F_1$-axis the frequencies $\pm J/2$ and $+J$, $O$, $-J$, respectively, *i.e.* a doublet and a triplet, since the amplitude-modulated signals can be represented as the sum of two phase-modulated signals of different sign; *e.g.*, for a doublet, $\cos\pi J t_1 = \frac{1}{2}\exp(-i\pi J t_1) + \frac{1}{2}\exp(i\pi J t_1)$ holds. This is equivalent to resolution of the sum $J$ (or $2J$) into its components $\pm\frac{1}{2}J$ (or $\pm J$). The time function $S(t_1)$ of the $CH_2$ fragment is positively shifted by the constant contribution of the center triplet line. Fourier transformation of this constant yields the signal in the center of the $F_1$ axis.

pendent parameter, whereas the chemical shifts are stored in the $t_2$-dimension.

### 3.1. Classification of 2D-Pulse Experiments

In principle, two classes of two-dimensional experiments exist: *J-resolved* and *correlated* 2D spectra. The first type, from which the example discussed above was taken, is characterized by one frequency axis ($F_1$), containing the coupling information, and by another ($F_2$), containing the chemical shifts. In the second type, both frequency axes contain chemical shifts. The connection between the $F_1$ and $F_2$ axes is established through scalar coupling—homonuclear as well as heteronuclear—or through dipolar coupling.

Since two-dimensional NMR spectroscopy is a logical development that starts with the one-dimensional techniques described in the previous section, most 1D experiments can be transformed into 2D experiments by varying the evolution period, and nearly all two-dimensional experiments possess a one-dimensional analog. In Table 3 we have summarized, using a $^{13}C,^1H$ spin system as example, the most important 2D techniques that will be discussed in the following sections, together with the 1D experiments related to them.

corded under the normal conditions for data accumulation. This means that the total acquisition time for the individual $S(t_2)$ signal should not exceed 0.5 h, and for measurements with less sensitive nuclei relatively concentrated samples are necessary[94].

The time-domain signals in the $t_2$ dimension, $S(t_2)$, are transformed by the first Fourier transformation with respect to $t_2$ into the data matrix $S(t_1, F_2)$, where corresponding points on the $F_2$ axis define the time domain function $S(t_1)$. The second Fourier transformation with respect to $t_1$ completes the process $S(t_1,t_2) \rightarrow S(F_1,F_2)$ (Fig. 28). Since even a single Fourier transformation results in a cosine and sine component of the frequency domain signal, phase selection for 2D experiments is relatively complicated.

This problem can be dealt with by using absolute value display, such as is also known for 1D spectra[5]. In this case the signal intensity as a function of the frequency $F_1$ is given by[90]

$$S(F_1) = (u^2 + v^2)^{1/2}$$

where $u$ and $v$ are the cosine and the sine parts, respectively, of the transformed time-domain function. For 2D spectra the following equation holds:

$$S(\pm F_1, F_2) = [(uu \mp vv)^2 + (uv \pm vu)^2]^{1/2}$$

Table 3. Comparison of two-dimensional and one-dimensional pulse sequences and their areas of application in high-resolution NMR spectroscopy (abbreviations, see text).

| 2D-NMR Experiment | Variable $F_1$ | Variable $F_2$ | 1-D-NMR Experiment | Applications, Results |
|---|---|---|---|---|

### 3.2. Data Processing and Graphical Display of 2D-NMR Spectra

A number of important experimental aspects of 2D-NMR spectroscopy will be described in Section 3.7. As a basis for the following discussion only, some remarks concerning data processing and graphical display of 2D-spectra[93] will be made here.

The processing of data obtained from 2D experiments is more demanding for the data system of the spectrometer than is customary with 1D experiments. In order to obtain a satisfactory digital resolution also in the $t_1$ dimension, the number of experiments, which determines the data points in $t_1$, must not be too small. For *J*-resolved spectra 32 time domain signals $S(t_2)$ are often sufficient, which in case of less sensitive nuclei, such as $^{13}C$, have to be recorded under the normal conditions for data accumulation. This means that the total acquisition time for the individual $S(t_2)$ signal should not exceed 0.5 h, and for measurements with less sensitive nuclei relatively concentrated samples are necessary[94].

The time-domain signals in the $t_2$ dimension, $S(t_2)$, are transformed by the first Fourier transformation with respect to $t_2$ into the data matrix $S(t_1, F_2)$, where corresponding points on the $F_2$ axis define the time domain function $S(t_1)$. The second Fourier transformation with respect to $t_1$ completes the process $S(t_1,t_2) \rightarrow S(F_1,F_2)$ (Fig. 28). Since even a single Fourier transformation results in a cosine and sine component of the frequency domain signal, phase selection for 2D experiments is relatively complicated.

This problem can be dealt with by using absolute value display, such as is also known for 1D spectra[5]. In this case the signal intensity as a function of the frequency $F_1$ is given by[90]

$$S(F_1) = (u^2 + v^2)^{1/2}$$

where $u$ and $v$ are the cosine and the sine parts, respectively, of the transformed time-domain function. For 2D spectra the following equation holds:

$$S(\pm F_1, F_2) = [(uu \mp vv)^2 + (uv \pm vu)^2]^{1/2}$$

This strategy has, however, the disadvantage that the signals are broadened at the basis, which complicates spectral analysis if signals of low intensity are close to strong absorption lines. In these cases a line-shape treatment by FID multiplication[95] using an appropriate time function can be helpful.

For the graphical display of 2D-NMR spectra two procedures are currently in use: the *stacked plot* (Fig. 30b)[91,93], which is known from $T_1$ measurements[96], and the *contour plot* (Fig. 30c)[97]. The stacked plot is, in most cases, aesthetically appealing, but often badly arranged and therefore difficult to analyze. In many cases the profile through a cross-section of the 2D diagram[98], however, yields the desired information.

The contour plot is a cross-section through the stacked plot parallel to the x,y-plane at a chosen height. In this

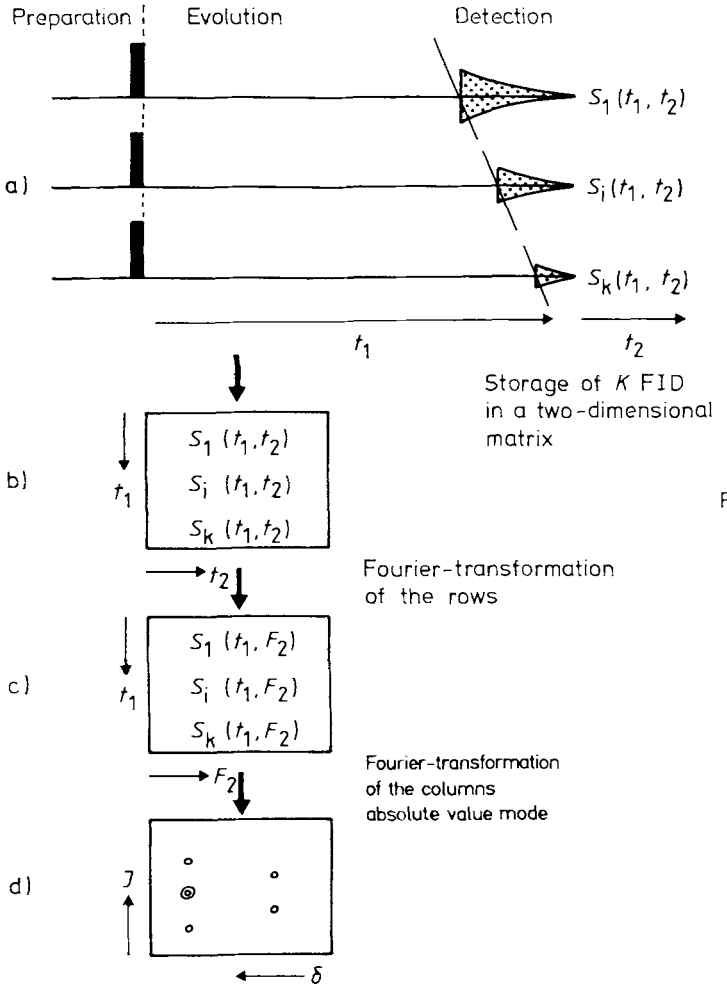

Fig. 28. Data flow in 2D-NMR spectroscopy.

way one obtains a clearly arranged diagram of contour lines that is easy to analyze, in particular for correlated spectra. The use of modern data processing equipment (visual display units, digital plotters) accelerates and facilitates analysis of 2D spectra considerably.

### 3.3. *J*-Resolved 2D-NMR Spectra

As shown in the example mentioned above, a $90°_x$ $^{13}C$ pulse, a variable evolution time, and data acquisition with $^1H$-broadband decoupling are sufficient to perform a heteronuclear 2D *J*-resolved experiment[91]. As already pointed out in the discussion of one-dimensional pulse sequences, additional 180° pulses at the midpoint of the evolution period lead to refocussing of the diverging isochromates. This effect is also used in 2D-NMR spectroscopy. As a consequence of the different effect of a 180° pulse on a hetero- or homonuclear spin system (see Section 1.2.3), the pulse sequences for *J*-resolved $^{13}C$ spectra, where $^{13}C,^1H$ coupling is of interest, are different from those used for $^1H$ spectra, where $^1H,^1H$ coupling is important.

#### *3.3.1. J-Resolved 2D-$^{13}$C-NMR Spectra*

The pulse sequence discussed in Section 3.2 was first used by *Müller, Kumar,* and *Ernst*[91] to separate the parameters $\delta(^{13}C)$ and $J(^{13}C,^1H)$[99]. Of the various versions proposed[93, 100, 101], the *gated decoupler method*[101] is the simplest and that which can be used most generally (Fig. 29). The basis of this pulse sequence is the spin echo experiment as applied to a $^{13}C$,A spin system in the $^{13}C$ region with A decoupling during half of the evolution period. During the preparation period, broadband decoupling can be used on the A channel in order to obtain the necessary NOE enhancement. The pulse sequence is completely identical with that of the SEFT experiment discussed above with the important difference of a variable evolution time $t_1$. In the case of a $^{13}C,^1H$ fragment double Fourier transformation results immediately in a complete separation of the two parameters $\delta(^{13}C)$ and $J(^{13}C,^1H)$.

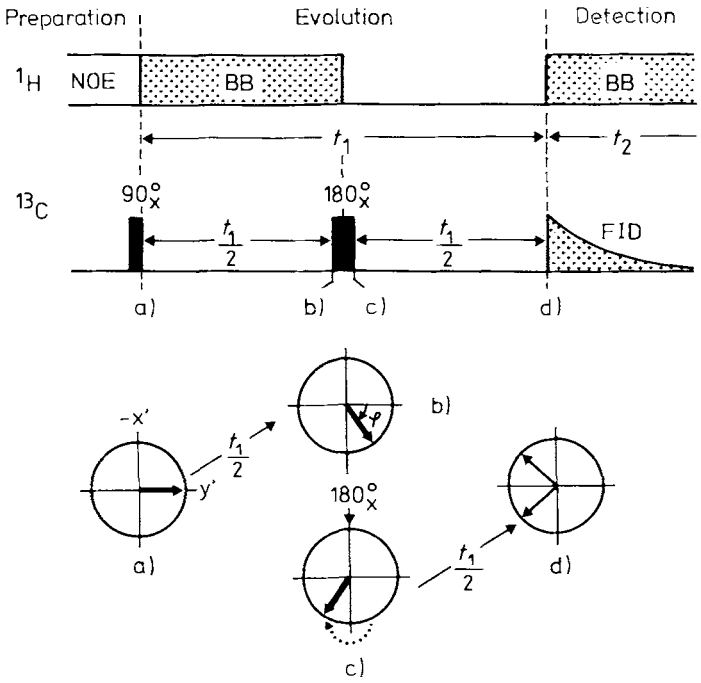

Fig. 29. Pulse sequence and vector representation for *J*-resolved 2D $^{13}C$-NMR spectra using, as example, the gated decoupler method for a CH fragment with $\nu_i > \nu_0$ (see Fig. 1d). At $t_1/2$ the $^{13}C$ magnetization has precessed by the angle $\varphi$ (b). The $180°_x$ pulse shifts the vector into position (c) and allows refocussing of inhomogeneity effects at $t_1$. During the second $t_1/2$ period $^{13}C,^1H$ coupling is allowed. The y-magnetization detected at $t_1$ is $t_1$-dependent (d). $^1H$ decoupling during the preparation period provides nuclear Overhauser enhancement.

For practical applications of this experiment the possibility of disentangling overlapping multiplets is by far the most important aspect. This is convincingly demonstrated using the simple example of a mixture of $\alpha$-deuterated toluenes. As shown in Figure 30, even at 100 MHz the $^1H$-decoupled $^{13}C$ resonances of the $CH_3$, $CH_2D$, $CHD_2$, and $CD_3$ groups are still strongly superimposed. Use of the SEFT sequence with variable $t_1$-time and gated $^2H$-decoupling yields the desired amplitude modulation of the $^{13}C$ signals through $^{13}C,^2H$ spin-spin coupling and, after double Fourier transformation, the $J(^{13}C,^2H)$-resolved 2D $^{13}C$-NMR spectrum, which is shown as a stacked plot in Figure 30b and as contour plot in Figure 30c. It is important to note that the coupling constants on the $F_1$ axis are reduced by half, since the spin multiplets diverge only during half of the evolution period.

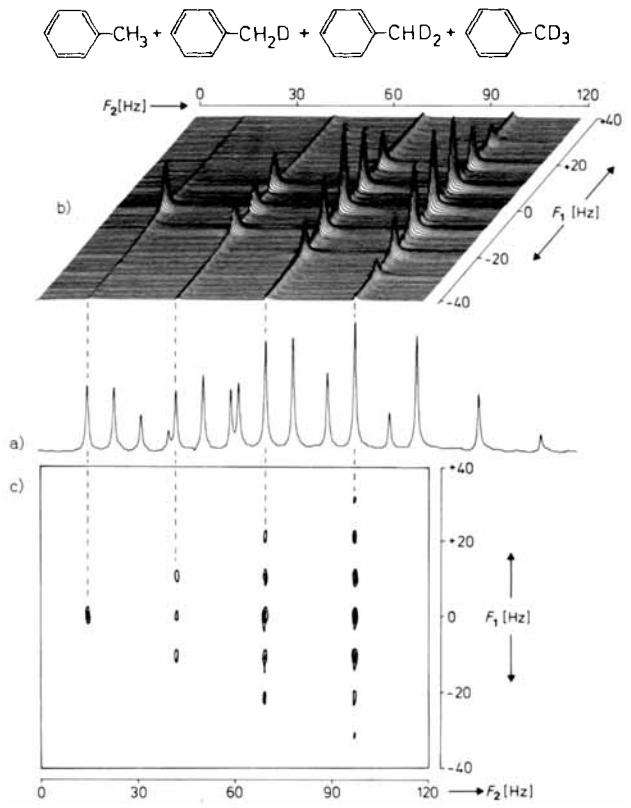

Fig. 30. 100.6 MHz $^{13}$C-NMR spectra of a mixture of toluene, α-[$D_1$]toluene, α-[$D_2$]toluene, and α-[$D_3$]toluene: a) $^1$H-decoupled 1D spectrum; b) stacked plot of the $^1J(^{13}C,^2H)$-resolved 2D spectrum [24] obtained with gated $^2$H-decoupling as stacked plot; c) as b), however as contour diagram.

A straightforward $^{13}$C,$^1$H application from organometallic chemistry is given in Figure 32 (see next page). It deals with the $^{13}$C-NMR spectrum of a mixture of four alkyl-substituted ($\eta^3$-allyl)($\eta^5$-cyclopentadienyl)nickel isomers[102]. The 2D spectra are reproduced as contour diagrams (a) and as stacked plots (b). For comparison, the 1D spectra ($^1$H-decoupled, (c), $^1$H-coupled (d)) are also shown. The desired spectral information can be extracted easily from the contour diagram, where the parameters $\delta(^{13}C)$ and $J(^{13}C,^1H)$ are separated on orthogonal axes. The multiplicities as well as the $^1J(^{13}C,^1H)$ data are obtained by inspection, and differences between $sp^2$- and $sp^3$-hybridized carbon atoms (*e.g.* C-31 and C-34) can immediately be recognized. In striking contrast is the strong overlap of the signals in the conventional $^1$H-coupled spectrum (d). As a further point of importance we note that the result of the experiment does not depend on prior knowledge of the coupling constants, as is the case for applications of one-dimensional pulse sequences, where this information is indispensable for the optimal choice of the evolution period (cf. SEFT, INEPT, and DEPT, Sections 2.1, 2.2.2, and 2.2.3, respectively).

An additional characteristic of this type of 2D spectra is that the multiplets of interest are not superimposed by residual signals of deuterated solvents, since these are treated as singlets with different resonance frequencies. The use of the spin echo technique also has the consequence that the line-width in the $F_2$ dimension is independent of magnetic field inhomogeneity and corresponds to the natural line width of the signals. The resolution of chemical shifts is thus improved relative to one-dimensional experiments. In particular, the gated decoupler method has the advantage that multiplets of strongly coupled spin systems are genuinely reproduced[101b]. This aspect is important, since not only strong coupling[103], but also experimental shortcomings, such as rotational sidebands[104], imprecise pulse-timing, and insufficient pulse power[105] across the spectral window—a difficulty present especially at high fields—lead to artefacts in 2D-NMR spectra.

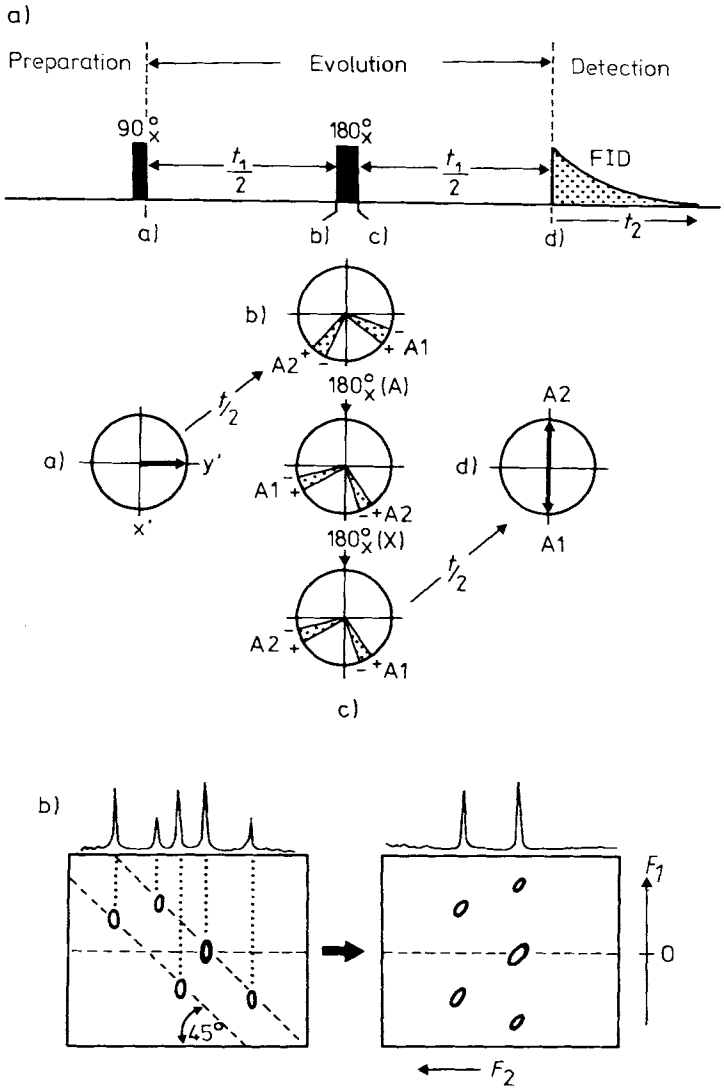

Fig. 32. a) Pulse sequence and vector representation for *J*-resolved 2D $^1$H-NMR spectra using the example of an A nucleus of a homonuclear AX system with $\nu_A > \nu_0$. At a time $t_1/2$ the doublet components A1 and A2 have progressed by different phase angles and at the same time are broadened by field inhomogeneity. The 180°$_x$ pulse inverts A1 and A2 around the x axis, but also changes the spin states of the X nucleus. The Larmor frequencies of the vectors are, therefore, interchanged (see Fig. 7a), and only the inhomogeneity effect refocusses during the second $t_1/2$ period. The y-magnetization detected at $t_1$ is $t_1$-dependent. b) Separation of the parameters $\delta$ and $J$ by tilting the data matrix by 45°.

An interesting variant of the heteroscalar *J*-resolved 2D-NMR experiment is the proton-flip method using a selective 180°$_x$ pulse which inverts only certain $^{13}$C satellites in the $^1$H-NMR spectrum[106]. In this way $^{13}$C,$^1$H long-range couplings can be measured precisely.

### 3.3.2. *J*-Resolved 2D $^1$H-NMR Spectra

For this type of two-dimensional NMR spectra[107] the spin echo experiment is again used, since in the homonuclear case the echo amplitude is a function of the coupling constant $J$(H,H) (cf. Section 1.3). Pulse sequence and vector diagram are given in Figure 31.

Because $^1$H-decoupling is precluded, both spins are also coupled during the detection period. Whereas the $F_1$ dimension contains the coupling information as before, the second frequency variable $F_2$ is now a function of chemical shift *and* spin-spin coupling constant $J$(H,H). An immediate separation of these variables on two frequency axes, therefore, is not possible for *J*-resolved 2D spectra of homonuclear spin systems. As is shown schematically in Figure 31, the individual multiplets lie on a 45° inclined diagonal of the two-dimensional matrix. Rotation of the absolute value spectrum by this angle results, however, in the separation of $\delta$ and $J$, since the projection on the $F_1$ axis now yields the multiplicity and the coupling constants, whereas the projection on the $F_2$-axis gives the chemical shifts[107, 108].

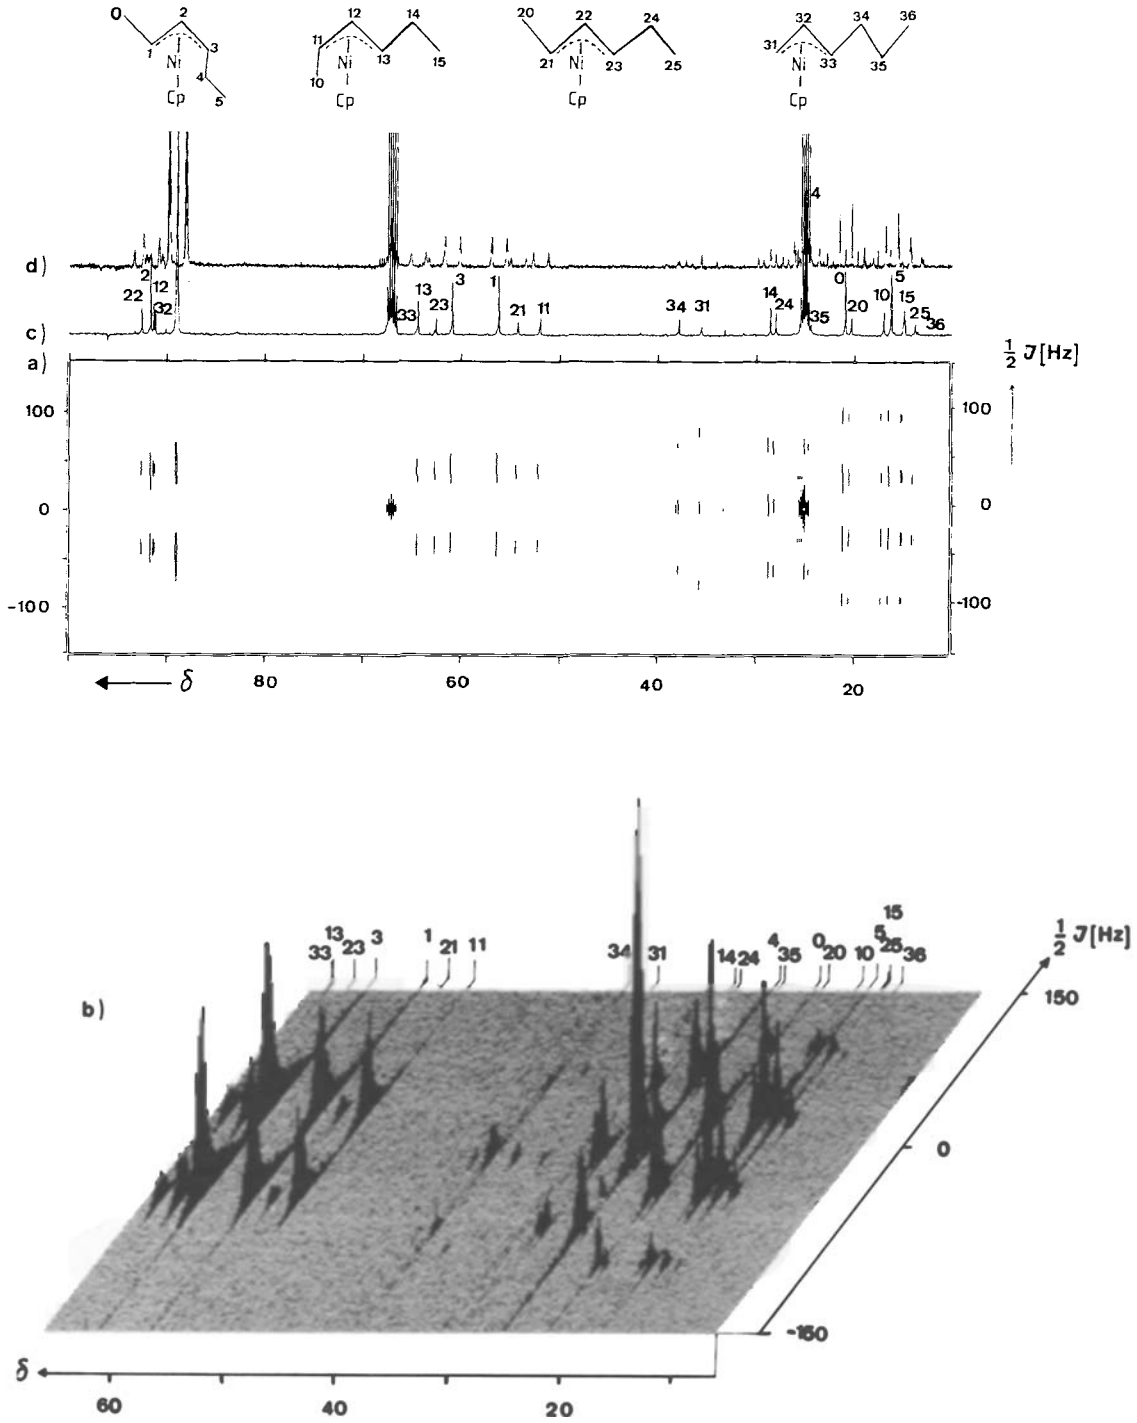

Fig. 31. *J*-resolved 100.6 MHz 2D $^{13}$C-NMR spectrum of a mixture of alkyl-substituted ($\eta^3$-allyl)($\eta^5$-cyclopentadienyl)nickel isomers [102]. a) Contour diagram; b) stacked plot; c) $^1$H-decoupled 1D spectrum; d) $^1$H-coupled 1D spectrum.

An outstanding property of *J*-resolved 2D $^1$H-NMR spectra is the fact that through the projection on the $F_2$-axis a quasi "$^1$H-decoupled $^1$H-NMR spectrum" can be obtained[109]. This type of homonuclear, completely decoupled spectrum is an important aid for spectral analysis, since symmetry arguments on the basis of intensities and line numbers may be used immediately for the interpretation, and the spectra of large molecules can be presented free of overlap. Again, the unravelling of superimposed multiplets is the main application. Here, profiles of suitable cross-sections through the 2D spectrum parallel to the $F_1$-axis allow the representation of individual multiplets to be separated. This is shown in Figure 33 for the mixture of isomeric allylnickel compounds already mentioned above.

In the case of stereoisomers[110], first-order multiplets exist that can also be separated using this technique. Other areas of application are biological macromolecules[111-113], where closely-spaced methyl resonances of amino acids in different positions of the polymer chain can be identified, as well as the relatively complicated $^1$H-NMR spectra of steroids, where the potential of the method has been impressively demonstrated[114]. Finally, the experiment can also be successfully used to separate and assign homonuclear and heteronuclear coupling constants[110, 115, 116]. This rests on the fact that heteronuclear coupling constants are not affected by the pulse sequence and are fully retained in the $F_2$-dimension, as is shown using the example of the $^1$H,$^1$H and $^{31}$P,$^1$H couplings in ($\eta^5$-cyclopentadienyl)(bistriphenylphosphane)vinylruthenium[117] (Fig. 34).

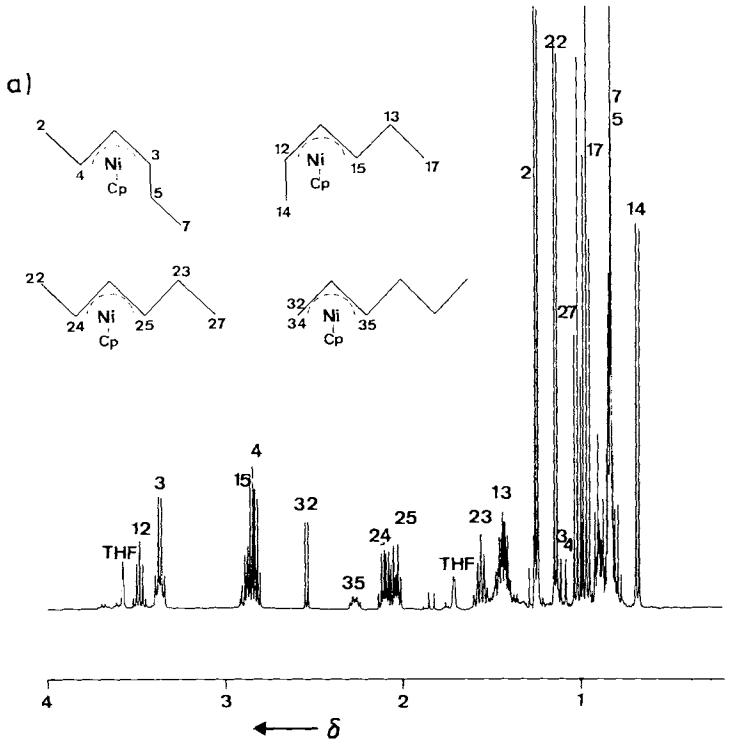

Fig. 33. a) 400 MHz $^1$H-NMR spectrum of alkyl-substituted ($\eta^3$-allyl)($\eta^5$-cyclopentadienyl)nickel isomers; b) selected profiles of cross-sections through the *J*-resolved 2D $^1$H-NMR spectrum that permit representation of individual multiplets free of overlap (cf. *e.g.* the signals of $H^4$ and $H^{15}$, or $H^{24}$ and $H^{25}$).

### 3.4. Correlated 2D-NMR Spectra

So-called correlated 2D-NMR spectra are distinguished from *J*-resolved 2D spectra in that both frequency axes now contain chemical shifts. Experimentally they require an additional time interval, the so-called *mixing time*[98, 118], between evolution and detection period. *Maudsley* and *Ernst*[41] were the first to propose and realize such an experiment. Two types of 2D correlated spectra can be distinguished: both dimensions may be coupled through co-

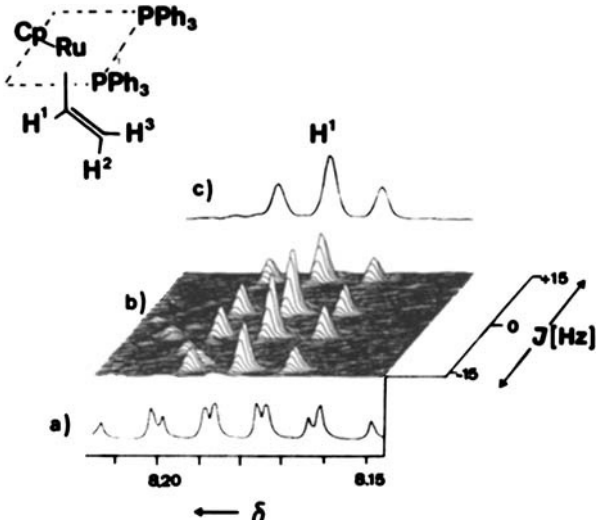

Fig. 34. *J*-resolved 2D $^1$H-NMR spectrum of the vinylic proton H$^1$ of ($\eta^5$-cyclopentadienyl)(bistriphenylphosphane)vinylruthenium [117]. a) Multiplet of the 1D $^1$H-NMR spectrum on the $F_2$-axis yields a triplet due to coupling with two equivalent phosphorus atoms. The doublet of doublets due to H,H coupling with the *cis*- and *trans*-proton is clearly seen on the $F_1$-axis.

herent transfer of transverse magnetization (scalar correlation[89,41]) or through incoherent transfer of magnetization (two-dimensional NOE spectra, two-dimensional chemical exchange spectra[118]).

### *3.4.1. Scalar Correlated 2D-NMR Spectra*

#### *3.4.1.1. Heteroscalar Correlated 2D-NMR Spectra*

If the Larmor frequencies of two different types of nuclei, *e.g.* $^1$H and $^{13}$C, are related through scalar coupling, one refers to heteroscalar correlated 2D-NMR spectra. This method is especially helpful for signal assignments, since it allows one type of nucleus (*e.g.* $^{13}$C) to be assigned from the known assignment of the other type (*e.g.* $^1$H). The pulse sequence generally used to produce heteroscalar correlated spectra contains, as do the INEPT or DEPT methods, a polarization transfer and, therefore, over and above the assignment leads to an enhancement of sensitivity. The fundamental concept is to use the evolution period $t_1$ for the precessional motion of the $^1$H spins, and to

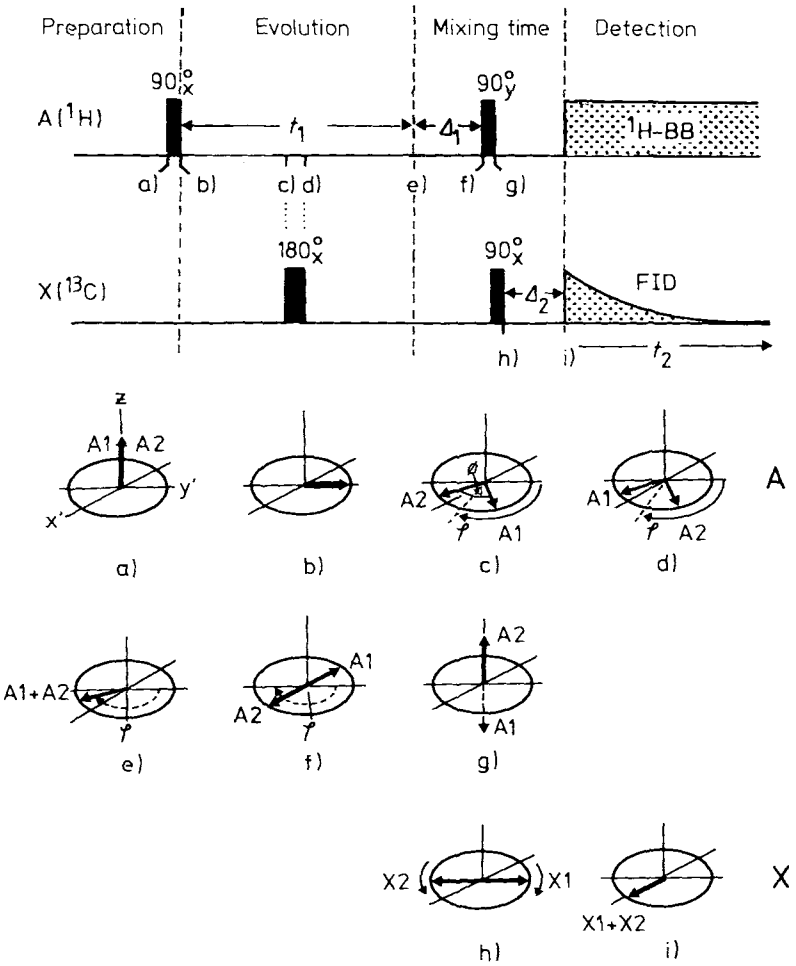

Fig. 35. Pulse sequence and vector representation of a heteroscalar-correlated 2D-NMR experiment using the example of a CH fragment (A = $^1$H, X = $^{13}$C). After a 90°$_x$ $^1$H-pulse both components of the $^1$H doublet rotate in the x,y-plane according to the difference of their frequency to that of the carrier (a–c). A 180°$_x$ $^{13}$C pulse (d) allows for refocussing at (e); $\delta$($^1$H) is retained in form of the angle $\varphi$. This information is transferred to the $^{13}$C nuclei through $^{13}$C,$^1$H spin-spin coupling during the mixing time. Polarization of the $^1$H-magnetization with a 90°$_y$ pulse (g) results in a corresponding polarization of $^{13}$C-magnetization which is transformed into transverse magnetization by the 90°$_x$-$^{13}$C pulse (h). In the remaining mixing time the $^{13}$C vectors precess around their corresponding $^1$H vectors. They are refocussed after $\Delta_2$s and can be detected with simultaneous $^1$H decoupling. The phase modulation obtained depends on the angle $\varphi$.

measure the degree of precession with the $^{13}C$ channel. The transfer of information between protons and carbon-13[119] occurs in the mixing period, which is introduced between the evolution and the detection time. Coupled nuclei yield signals with the coordinates $\delta(A)$, $\delta(X)$.

The pulse sequence for the generation of heteronuclear correlated 2D-NMR spectra is given in Figure 35[119,120]. After the $90^\circ_x$ $^1H$-pulse the components of a CH doublet rotate in the x,y-plane with different Larmor frequencies. The fanning-out angle $\phi$ is determined by the magnitude of the CH coupling, whereas the angle $\varphi$ is determined by the chemical shift of the protons (a—c). The $180^\circ_x$ pulse in the $^{13}C$ channel (d) exchanges the spin states of the protons and, therefore, the relative precessional frequencies of the vectors with the result that they are refocussed at the end of the evolution period $t_1$ (e). Chemical shift information is now contained in the phase angle $\varphi$. After a time $\Delta_1 = 1/2J$ we have $\phi = 180°$. Both vectors are orientated antiparallel and a $90^\circ_y$ pulse transforms them into the $\pm z$-direction, and thus results in a polarization of $^1H$ magnetization. The chemical shift information is now given by the magnitude of the z-components, which depends on the phase angle $\varphi$, since the $90^\circ_y$ pulse only affects the x-components of the vector. For $\varphi = (2N+1)\frac{\pi}{2}$ the longitudinal A magnetization is equal to zero, whereas for $\varphi = 2n\frac{\pi}{2}$ it has its maximum value. As with the SPI experiment, polarization of the protons leads simultaneously to polarization of $^{13}C$ magnetization, which can now be transformed into $\pm y$-magnetization by a $90^\circ_x$ pulse (h). Within the interval $\Delta_2 = 1/2J$, both $^{13}C$ vectors refocus and can be detected as a singlet if $^1H$-decoupling is applied. The polarization achieved, and thus the measured intensity, depends on the phase angle $\varphi$ and is, therefore, a direct function of the Larmor frequency of the protons. In consequence, variation of the evolution period $t_1$ leads to amplitude modulation, which in this case is, however, not a function of the coupling but of the Larmor frequency of the other nucleus. In contrast to the one-dimensional SPI experiment, excitation is non-selective, *i.e.* all resonances of the $^1H$-NMR spectrum are excited at the same time, and polarization transfer is $t_1$-dependent.

The elegance of this type of two-dimensional correlation experiment must be seen in the fact that, using only *one* experiment, connections between two types of nuclei can be established. Previously, this was possible only by means of a series of double-resonance experiments, the results of which are very often difficult to interpret. The correct choice of mixing period allows all the $^{13}C,^1H$ groups of a molecule to be detected. In addition, the problem of line overlap is elegantly eliminated. Especially with large molecules this aspect is of importance[121,122]. As Figure 36 shows, however, also for smaller molecules with less than 20 nonequivalent carbon atoms the assignment of the resonance frequencies becomes unambiguous and is faster than with any other technique.

The correlation character of the method allows an assignment made for one type of nucleus to be transfered immediately to another type. As in all two-dimensional techniques, the elimination of signal overlap is an additional advantage, especially since proton multiplets can now be resolved with the larger dispersion of the $^{13}C$ spectrum. Basically, all nuclei with spin quantum number $I = 1/2$ can be connected in a heteroscalar correlated 2D-NMR experiment. The technique is especially effective in cases where several scalar coupling constants of similar magnitude between protons and less sensitive nuclei exist. Consequently $^{13}C,^1H$[121,122], $^{15}N,^1H$[124], and $^{31}P,^1H$ correlations[125] are of importance in organic chemistry. In organometallic chemistry, phosphorus ligands play an important part, and phosphorus-metal correlations, for instance $^{103}Rh,^{31}P$ or $^{183}W,^{31}P$, will find increasing interest.

### *3.4.1.2. COSY[*] and SECSY[**] Homoscalar-Correlated 2D-NMR Spectra*

Closely related to the SPI and INEPT methods, as well as to heteroscalar correlated NMR spectroscopy discussed in Section 3.4.1.1, are two-dimensional correlations for homonuclear spin systems (for example $A = X = {}^1H$) known as COSY[126] and SECSY[127]. Both frequency axes $F_1$ and $F_2$ now contain the Larmor frequencies of the same nucleus, *e.g.* the $\delta(^1H)$ values.

The basis for COSY spectra is the classical Jeener sequence[11,89] (Fig. 37a), which also results in a magnetization transfer. After the preparation period, a $90^\circ_x$ pulse produces transverse magnetization. The magnetization vectors precess in the x,y-plane according to their Larmor frequency and their spin-spin coupling constants $J$. By analogy to the heteroscalar-correlated 2D experiment the second $90^\circ_x$ $^1H$ pulse can be viewed as the mixing pulse. Since the protons are always coupled, additional mixing times, however, are not necessary.

The second $90^\circ_x$ pulse leads, for a non-coupled A nucleus ($J(A,X) = 0$), to a $t_1$-dependent modulation of the transverse magnetization that depends only on $\nu_A$. The 2D spectrum therefore contains a signal on the diagonal $F_1 = F_2$ (dia peak). For the case $J(A,X) \neq 0$, the A magnetization through the scalar A, X-interaction in the x, y plane also depends on the Larmor frequency $\nu_X$. The 2D spectrum therefore contains the characteristic off-diagonal signals (cross peaks) with coordinates $\delta_A$, $\delta_X$, and $\delta_X$, $\delta_A$, which indicate a scalar spin-spin coupling between A and X. An application of this technique to the field of annulene chemistry is shown in Figure 38 with the correlation diagram for the protons of 9,11-bisdehydrobenzo[18]annulene[128].

Several versions for the Jeener pulse sequence exist. COSY45[126b] uses a $45^\circ_x$ instead of a $90^\circ_x$ mixing pulse and achieves a suppression of signals that are on or near the diagonal. In this method off-diagonal signals are sensitive to the relative signs of the coupling constants. The first to be experimentally verified was the SECSY sequence[127], where the mixing pulse bisects the evolution period (see Fig. 37b). Here, the chemical shifts $\delta_A$ and $\delta_X$ of the normal one-dimensional spectrum appear on the center line of the two-dimensional diagram, and the corresponding cross-peaks have the coordinates $\delta_A$, $(\delta_A - \delta_X)/2$ and $\delta_X$, $(\delta_X - \delta_A)/2$ (Fig. 38b).

[*] COSY = correlated spectroscopy.
[**] SECSY = spin echo correlated spectroscopy.

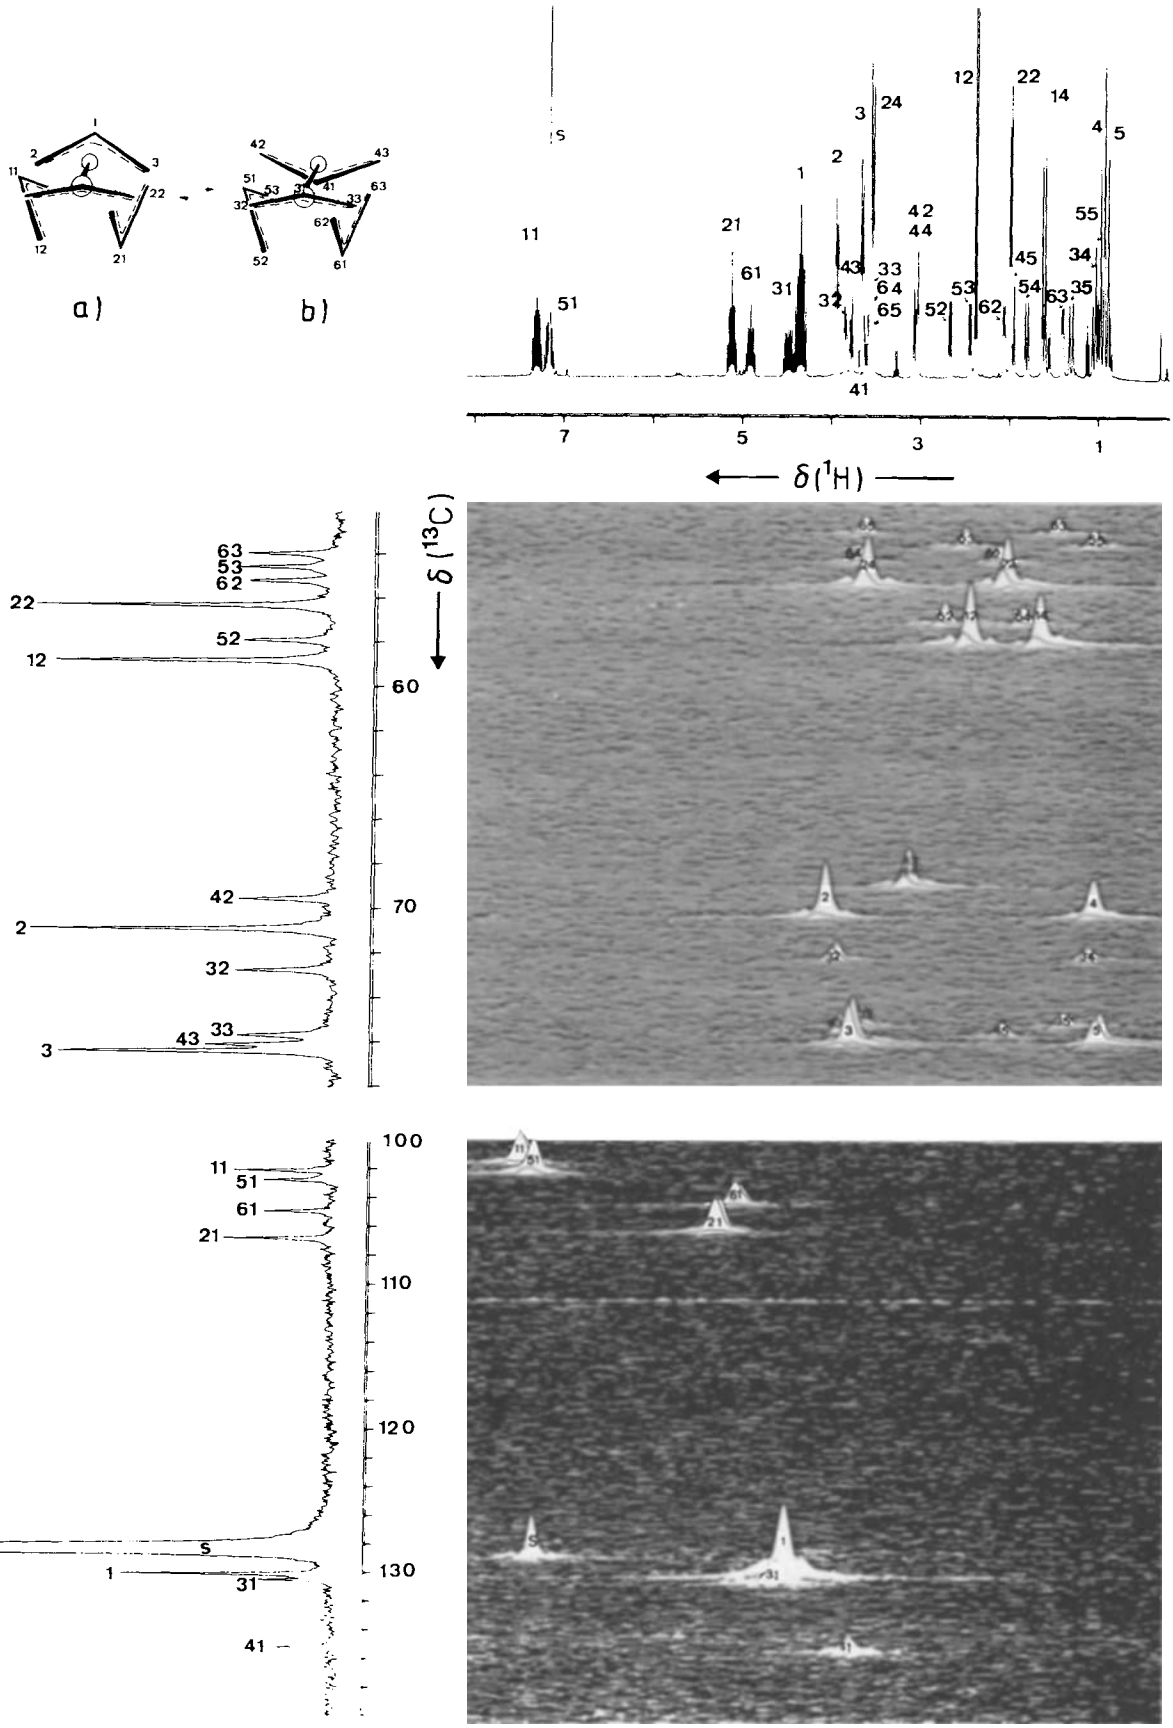

Fig. 36. 2D-$^{13}C,^{1}H$ correlation diagram of *cis*-$(\eta^3$-allyl$)_4Cr_2$ (*a*, signals 1—25) and *trans*-$(\eta^3$-allyl$)_4Cr_2$ (*b*, signals 31—65) in [$D_6$]benzene at 30 °C. The abscissa shows the $\delta(^1H)$- and the ordinate the $\delta(^{13}C)$-values. The 1D-$^1H$ and the $^1H$-decoupled 1D $^{13}C$-NMR spectra are reproduced along the respective frequency axes. The complete assignment of the $^1H$ spectrum has been described[123]. The 2D spectrum confirms this assignment and at the same time allows unambiguous assignment of all $^{13}C$ signals. The digital resolution used for the 2D spectrum led to an extensive loss of the multiplet structure. The signals for the CH fragments 11, 51, 61 and 21 with $\delta(^{13}C) = 100-110$ ppm and $\delta(^1H) = 4.8-7.3$ ppm demonstrate the correlation character of the experiment particularly convincingly ($^{13}C$ measuring frequency 100.6 MHz, acquisition time *ca.* 4 h, dimension of matrix 256 × 4096, dimension of transformation 1024 × 4096.)

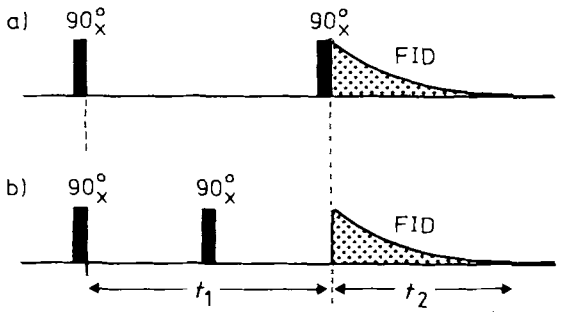

Fig. 37. Pulse sequence for homoscalar correlated 2D-NMR spectroscopy; a) COSY sequence [126]; b) SECSY sequence [127]. With the first 90°x pulse transverse magnetization is generated. The second 90°x pulse has the effect of a mixing pulse and results in an exchange of magnetization between coupled nuclei. The two-dimensional representation of the COSY and SECSY sequences are different (see Fig. 38).

The $F_1$-dimension of the SECSY sequence contains the frequency differences and, therefore, reduces the size of two-dimensional data matrix. The necessary condition is, however, that the Larmor frequencies do not exceed the spectral window, *i.e.* the quantity $\delta_A - \delta_X$ must be smaller than the spectral region for all coupled nuclei.

The advantages of two-dimensional Jeener spectroscopy compared to the classical homonuclear decoupling experiment are that—even in the case of small molecules—less experimental time is required are less, and difficulties arising from small frequency differences between the decoupler field and other resonances in the spectrum are ab-

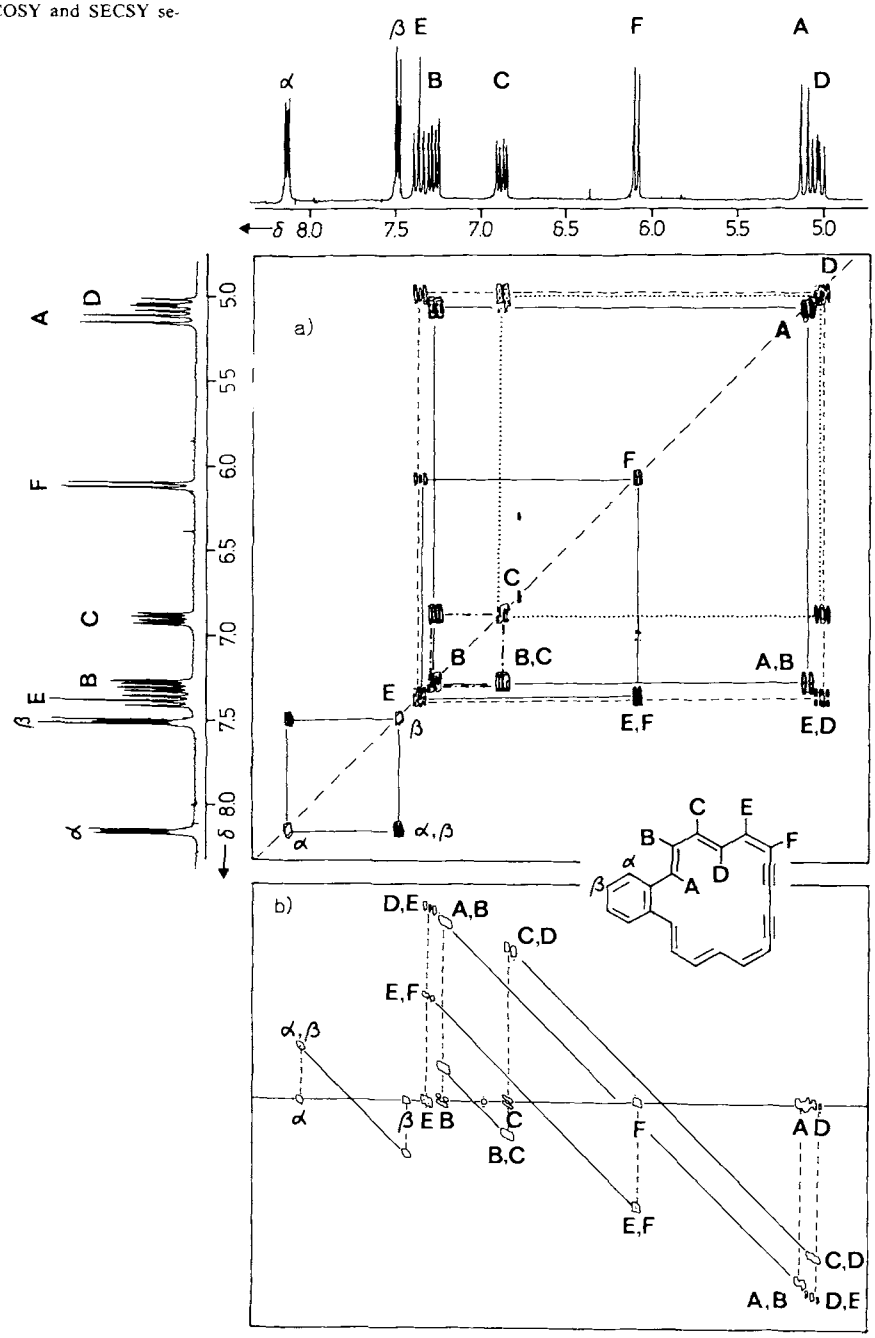

Fig. 38. Homoscalar correlated 2D $^1$H-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene; a) result of a COSY experiment. The cross peaks immediately yield the assignment of the proton sequence in the annulene ring [128]. As an aid in the interpretation, the 1D $^1$H-NMR spectrum is also given (frequency 400 MHz, acquisition time for the 2D experiment *ca.* 4 h, dimension of matrix 256 × 1024, dimension of transformation 256 × 1024). b) Result of a SECSY experiment (acquisition time *ca.* 4 h, dimension of matrix 256 × 1024, dimension of transformation 256 × 1024).

sent. In addition, coupled multiplets are reproduced without overlap (see *e.g.* the contour diagram of Fig. 38). The corresponding one-dimensional experiment—homonuclear decoupling combined with difference spectroscopy—can be complicated by Bloch-Siegert effects[129]. A further advantage is that long-range couplings, which are difficult or even impossible to determine from one-dimensional experiments, can be detected very often easily with the 2D method. By introducing a short constant delay of approximately 0.5 s at the beginning of the evolution period, long-range couplings can be emphasized if the digital resolution is of comparable magnitude to the coupling constants[126b, 130]. A disadvantage of the 2D correlation is that, in many cases, the contour diagrams for large molecules become rather complex. Also, in the COSY45 version many absorptions lie on or near the diagonal, and even at high magnetic field these diagrams are difficult to analyze. This problem can be solved with 2D correlation diagrams based on multiple quantum transitions[11, 71, 131, 132] that allow the suppression or complete elimination of the disturbing diagonal absorptions.

Of special interest is the combination of the Jeener experiment with heteroscalar correlation, since the information obtained from both these experiments yields the carbon skeleton of an organic molecule. Both experiments can be performed either consecutively or within a so-called 2D experiment using correlated coherence (2D-relay-NMR[133]). In the latter case magnetization is first transferred from proton to proton by a Jeener pulse sequence. In the second step this magnetization is transferred to scalar-coupled carbon nuclei. Since the $^{13}$C-NMR spectrum is detected, the larger dispersion of this nucleus is used to check bonding in the molecule through the proton-proton couplings. The problems associated with the accumulation of diagonal signals are thus eliminated.

### 3.5. 2D-INADEQUATE: The Direct Determination of the Carbon Skeleton

As already discussed in Section 2.3, the determination of the $^1J(^{13}C,^{13}C)$ data permits assignment of neighboring carbon atoms for the molecule of interest. This goal is achieved especially elegantly using the two-dimensional version of the INADEQUATE pulse sequence. Here advantage is taken of the fact that the double-quantum frequency $\nu_{DQ}$ of an AX system depends on the transmitter frequency $\nu_0$: $\nu_{DQ} = \nu_A + \nu_X - 2\nu_0$[11, 69]. If we vary the time $t_1$ between the second $90^\circ_x$ pulse, which together with the first produces the double-quantum coherence, and the 90° ($\phi$) read pulse in such a way that $1/t_1$ passes all double-quantum frequencies of the spectrum, the information is obtained as a function of $t_1$ *and* $t_2$ (Fig. 39).

Fourier transformation yields the double-quantum frequencies $\nu_{DQ}$ in the $F_1$-dimension and the normal $^{13}$C chemical shifts in the $F_2$-dimension. Since the $^{13}$C satellite spectrum is detected at the natural abundance level, only 0.01% of the molecules present yield such absorptions, and even if large amounts of compound are available—in the order of several 100 mg—long acquisition times are necessary. It is, therefore, of importance, through the use of quadrature detection, to keep the two-dimensional matrix

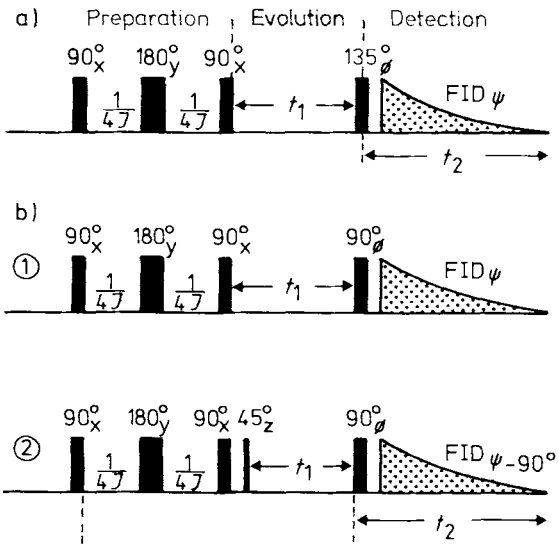

Fig. 39. Pulse sequence for the two-dimensional INADEQUATE experiment with quadrature detection. In case a) positive and negative frequencies are distinguished by a 135° pulse [135]. In case b) the 45° pulse with the sequences ① and ② applied alternately has the same effect [134]; the period $\Delta$ can be neglected if compared to $t_1$.

as small as possible. For this purpose several versions of the INADEQUATE pulse sequence have been proposed[134, 135].

An application of the 2D-INADEQUATE technique is given in Figure 40. In (−)bis[(1*R*,3*R*,4*S*)menthyl]methylphosphane both menthyl groups are diastereotopic and yield ten pairs of $^{13}$C-NMR signals. With the 2D-INADEQUATE experiment it is possible to assign all $^{13}$C resonances of the individual menthyl groups[136]. Subsequently, one can use the $^{31}$P,$^{13}$C couplings to establish the predominant conformation of this molecule at various temperatures; these are of interest in connection with the application of this particular phosphane in the course of catalytic asymmetric syntheses.

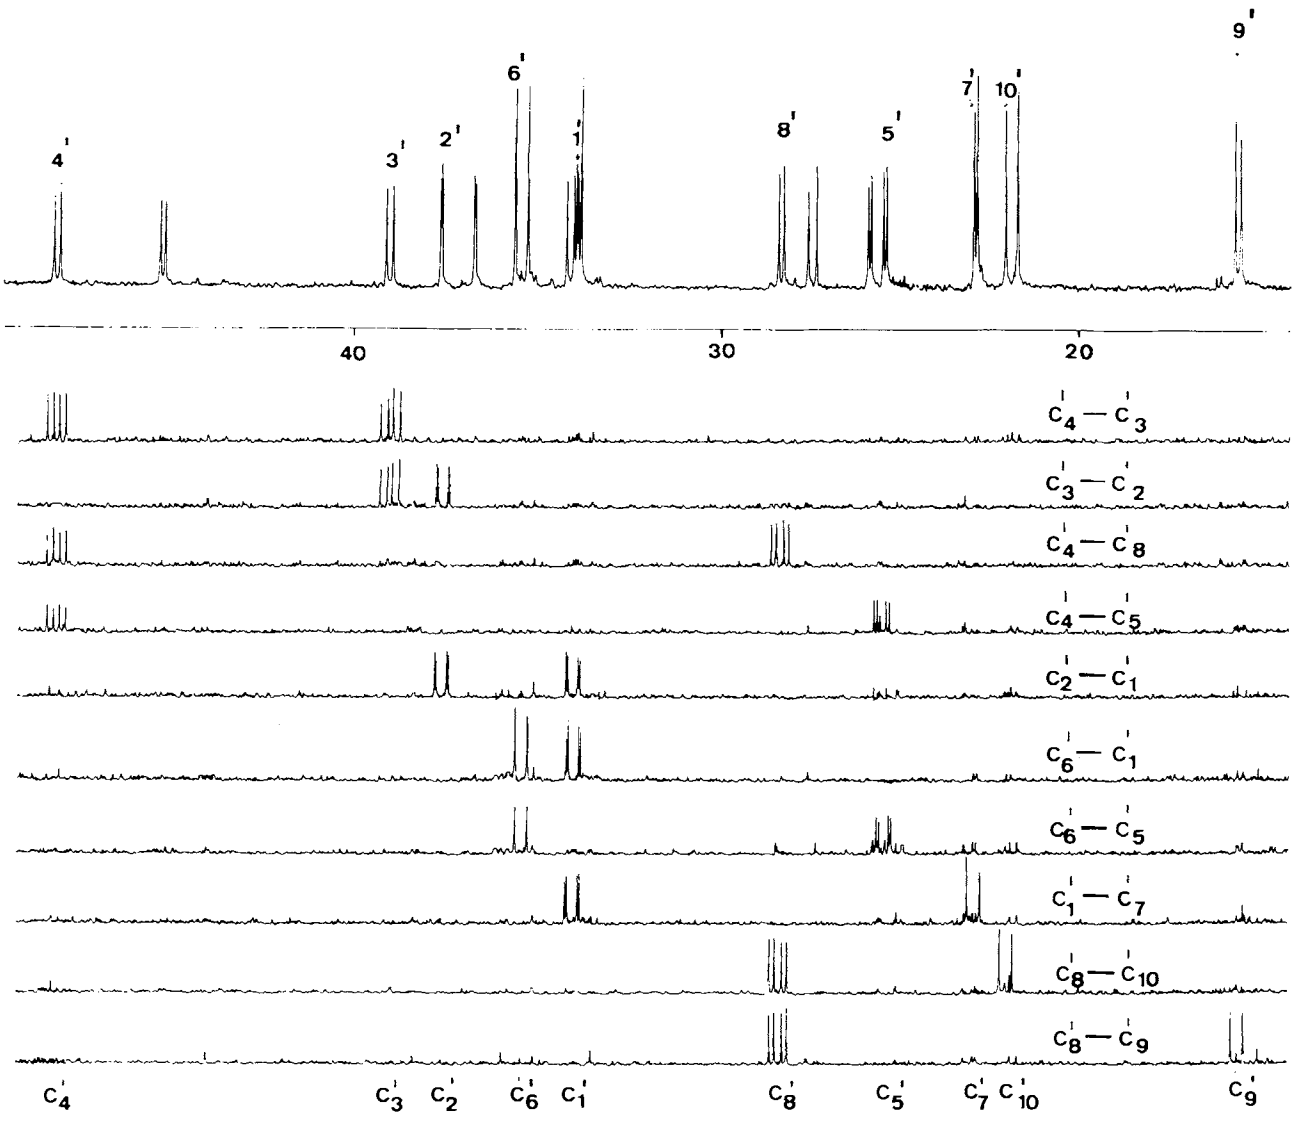
The long acquisition time of the 2D experiment compared to the 1D-INADEQUATE experiment is counterbalanced by a number of advantages: strong coupling in the satellite spectra[79] and insufficient suppression of the main signal are less stringent requirements in 2D compared to 1D spectra. In addition—and this is certainly the most important advantage—the analysis of carbon-carbon connectivity can be undertaken without detailed prior information, even if $^1J$(C,C) varies between 30 and 70 Hz, and spectral widths of 20 kHz are necessary[137]. Of course, a prerequisite for such measurements is that solution containing *ca.* 0.5 g of the compound or neat liquids are used.

### 3.6. 2D Exchange Spectroscopy

Two-dimensional exchange spectroscopy[118] is based on transfer of magnetization, such as occurs in the nuclear Overhauser effect (NOE)[48] or in chemical exchange processes[138]. Experiments on the NOE basis are known as NOESY[*].

As with the COSY experiment, the first $90^\circ_x$ pulse produces transverse magnetization that precesses during the

[*] NOESY = *n*uclear *O*verhauser *e*ffect *s*pectroscopy.



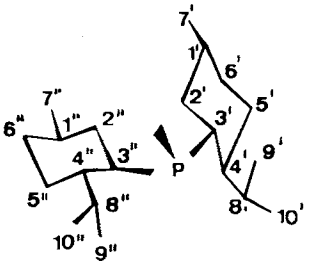


Fig. 40. Two-dimensional INADEQUATE experiment for the $^{13}$C-NMR spectrum of (−)bis[(1*R*,3*R*,4*S*)menthyl]methylphosphane in [$D_6$]benzene at 27 °C [136]. The upper trace shows the $^{13}$C-resonance of 20 different carbon atoms in the $^1$H-decoupled spectrum with the exception of the doublets of the *P*-methyl group. The remaining spectra are $^{13}$C,$^{13}$C satellite spectra of one menthyl group, as obtained from the 2D double quantum diagram. The $^{13}$C main signals for molecules with only one $^{13}$C are completely suppressed. The assignment of all signals to individual menthyl groups is given unambiguously by the double quantum frequency of the individual AX systems and is not based on knowledge of the exact $^1J(^{13}C,^{13}C)$ coupling constants. The $^{13}$C,$^{31}$P coupling constants are retained in the $F_2$-dimension, which also contains the chemical shifts (frequency 100.6 MHz, acquisition time *ca.* 36 h, amount of compound used *ca.* 0.5 g).

evolution period in the x,y-plane. The 90°$_x$ mixing pulse is followed by the mixing time $\Delta$, which is now in the order of the spin-lattice relaxation time $T_1$ or the inverse rate constant of chemical exchange processes. This time is necessary to achieve magnetization transfer arising from dipolar interactions. Scalar interactions, on the other hand, are effective immediately (cf. Section 3.4), and the mixing time varies between 0 (COSY) and $1/J(^{13}C,^1H)$ (heteroscalar correlated). The third 90°$_x$ pulse transforms the resulting z-magnetization into transverse magnetization, which is measured during the detection phase. The 2D data matrix for COSY and NOESY are similar (Fig. 41).

So far, double-resonance methods[5, 139] have been used to investigate geometrical relationships in a molecule with the aid of the nuclear Overhauser effect[48], or to study chemical exchange processes in the region of slow exchange[86]. Both phenomena can be investigated especially effectively and with high sensitivity by difference spectroscopy[123, 140]. Similar advantages hold for two-dimensional exchange spectroscopy, where the total time of measurement can be even shorter.

For medium-sized molecules and at intermediate magnetic field strengths, nuclear Overhauser effects and chemical exchange, respectively, are distinguished in 1D spectra by an increase or decrease in signal intensity. In 2D experiments with nuclei of high isotopic abundance the effect of both phenomena is identical. Where necessary, a differen-

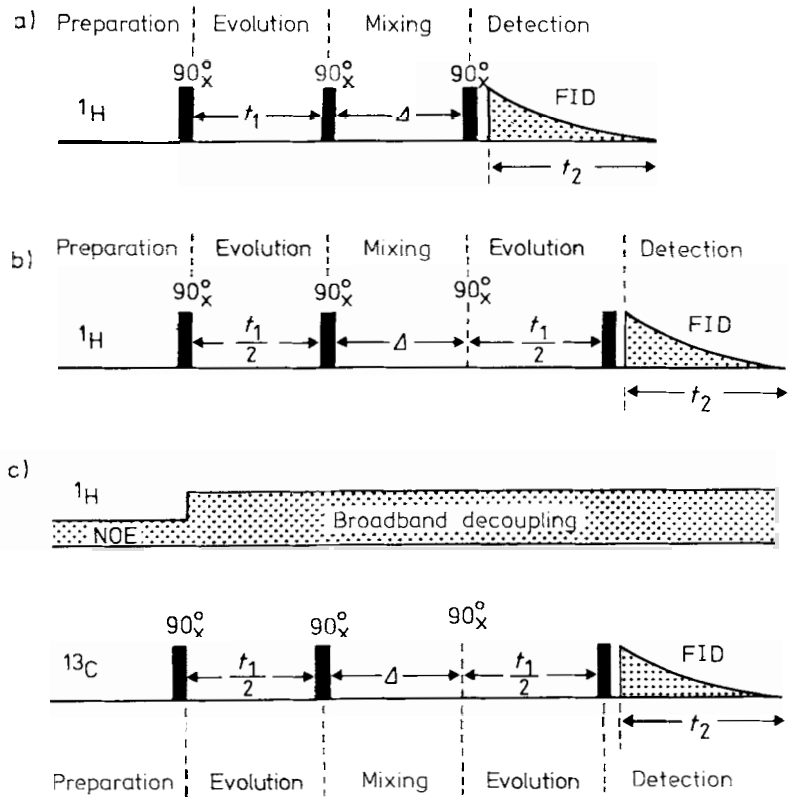

Fig. 41. Pulse sequence for two-dimensional exchange NMR spectroscopy. a) NOESY sequence for 2D $^1$H-NOE spectra with the read pulse at the end of the evolution period (COSY matrix form); b) as a), however with the read pulse at the midpoint of the evolution time (SECSY matrix form); c) shows the pulse sequence for 2D exchange spectra in $^{13}$C-NMR spectroscopy.

tiation can, however, be achieved by variation of the temperature, the mixing time[141], or by phase-sensitive display of 2D spectra. For nuclei with low natural abundance the homonuclear Overhauser effect can be neglected, and the correlation experiment is confined to chemical exchange processes. For protons, 2D-NOE spectroscopy has already been used successfully in a large number of practical applications[142–144].

Turning to chemical exchange, for protons most of the arguments, and for nuclei with $I=1/2$ and relatively low natural abundance, *e.g.* $^{13}$C, nearly all arguments are in favor of the two-dimensional method. In particular, it must be pointed out that the exchange mechanisms very often can be extracted from the 2D matrix by inspection[145,146]. The often lengthy quantitative line-shape calculations that are necessary in 1D-NMR spectroscopy are therefore superfluous with 2D experiments.

As mentioned above, 2D-$^{13}$C exchange spectra lack the possible artefacts arising through nuclear Overhauser effects. The 2D-$^{13}$C exchange spectrum thus appears to be the method of choice for the qualitative investigation of chemical exchange mechanisms, even in the case of small molecules and compounds of moderate solubility. An example of the use of this technique is given in Figure 42.

### 3.7. Experimental Aspects of 2D-NMR Spectroscopy

The absolute value representation of 2D spectra solves the problem of phase correction and at the same time leads to an improvement of the signal-to-noise ratio. It has, however, the disadvantage that the signals are broadened at the basis. This is especially true for *J*-resolved 2D $^1$H-NMR spectra, since because of rotation of the data matrix the absorption and dispersion components overlap. As a consequence, multiplets of components with low concentration are difficult to detect in the presence of intense lines if the absolute value display is used. Apart from certain variations in the experimental **technique**[147], phase programs[148], projection techniques[149], and filter functions[95] play an important role in solving problems of this type in 2D-NMR spectroscopy. Without doubt, the correct choice of preparation time and of suitable filter functions are crucial for the success of a 2D experiment. Filter functions which are symmetric to the midpoint of the time variable $t_2$, so-called pseudoechoes[150], are of special importance in this respect, since they eliminate the symmetrical dispersion components completely and yield centrosymmetric signals. A drawback of such filter functions is the resulting loss of sensitivity; therefore, in many cases phase-shifted sine functions provide a good compromise between sensitivity, resolution, and line shape.

Coupling constants are determined in 2D spectra from profiles of suitable cross-sections. The use of filter functions, absolute-value mode, and spectra of higher order can result in differences between coupling constants derived from 2D spectra and those measured in 1D spectra. In general, however, phase-corrected spectra from phase-sensitive cross-sections lead to complete agreement be-

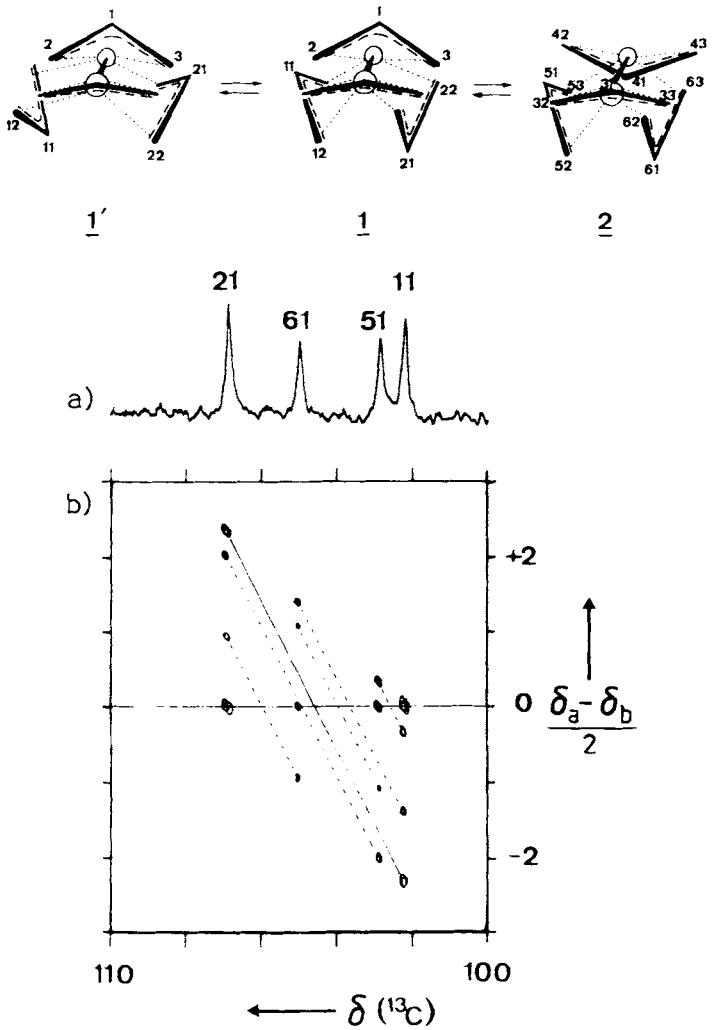

Fig. 42. $^{13}$C-2D exchange NMR spectra for $(\eta^3\text{-allyl})_4Cr_2$ in [D$_6$]benzene [146]. a) 1D-$^{13}$C NMR spectrum at 100.6 MHz; b) correlation diagram obtained with the pulse sequence $90^\circ_x$-$t_1$/2-$90^\circ_y$-$\Delta$-$t_1$/2-$90^\circ_x$-FID; $t_1$ was varied from 0–25.6 ms using 256 increments; the mixing time was 2 s. The horizontal axis ($F_2$-dimension) shows the $^{13}$C-resonances, the vertical axis ($F_1$-dimension) the chemical shift differences. $^{13}$C atoms connected by chemical exchange yield cross signals.

tween the results of both methods[151]. Several procedures for the generation of *J*-resolved 2D absorption spectra are known[149, 152].

Further improvements of the pulse sequence for the detection of *J*-resolved 2D spectra aim at a faster repetition rate[153]. This is especially important for applications involving small molecules and short relaxation times. If fast and sufficiently large data storage is available, the direct acquisition of complete spin echo series can be of advantage[154, 155]. This technique also yields absorption signals relatively easily, requires only short acquisition times, and permits data processing for 2D as well as 1D spectra[155]. The latter aspect is of interest if small molecules are to be detected in the presence of large.

As with conventional 1D spectra, it is of advantage also for 2D heteroscalar correlated spectra to locate both the $^1$H and $^{13}$C pulses in the center of the spectral region. Quadrature detection in the $F_1$- and $F_2$-dimensions requires that negative and positive frequencies be distinguished. The advantage of quadrature detection is the uniform excitation of all signals of one type of nuclei and the reduction of the spectral width. This means that the size of the 2D matrix can be reduced by half, and the signal-to-noise ratio in the $F_1$-dimension is increased by a factor of $\sqrt{2}$, while the acquisition time is decreased by a factor of almost 4. In order to realize this in practice, the phases of both proton pulses and of the receiver are cycled[156]; hence the amplitude modulation produced in the evolution time is transformed into a phase modulation. Generally, heteroscalar correlated 2D experiments use 8 phase cycles[157], which allow quadrature detection in both dimensions and good suppression of erroneous signals, the so-called phantum and ghost peaks.

Similar ideas apply to *J*-resolved[158] and scalar-correlated 2D spectra, such as COSY[126b], SECSY, and NOESY. Here, 16 phase cycles allow quadrature detection and the suppression of ghost peaks[159, 160].

The $^{13}$C-INADEQUATE experiment only detects the satellites; the main signals, which are stronger by a factor of 200, are suppressed. In practice, 32 phase cycles are necessary; however, optimum suppression of the main signals requires 256 phase cycles[80, 130]. A good compromise for 2D-INADEQUATE experiments is 64 phase cycles. In general, phase cycles are of great importance for the elimination of residual magnetization, the suppression of ghost peaks, and faster repetition rate of the experiments.

## 4. Outlook on Practical Applications

As a consequence of the variety of NMR techniques available today, the choice of method best suited to solve the problem at hand is often difficult. In many cases, however, the experimental set-up available enforces restrictions. Therefore, but also for other reasons, 1D techniques will keep their place at the side of 2D methods. 1D spectra normally require shorter acquisition times and can be performed with less sophisticated pulse transmitters. Considering the data systems available today, they also allow better digital resolution. Furthermore the information provided by 1D experiments helps reduce the acquisition time of and the effort required to interpret 2D experiments: 1D information should, therefore, be fully exploited. Practical experience will show quickly where 2D experiments can best be used for particular problems and where they are superior to 1D methods. One should remember that 2D experiments can also be performed using traditional spectrometers at the fields provided by electromagnets, *i.e.* in situations where 1D methods will more often fail than at high fields. Presently, 2D experiments rely less on high field strength than on compounds having good solubility, *i.e.* allowing high sample concentrations to be used.

Polarization transfer, heteronuclear shift correlations, and *J*-resolved 2D-NMR spectra are undoubtedly the most important new techniques that have made considerable contributions to the NMR spectroscopy of less abundant nuclei as well as that of complex natural products. The 2D-$^{13}$C,$^1$H shift correlation is, as far as time requirements are concerned, superior to the 1D technique of selective double resonance. 2D-NOE correlation, on the other hand, improves the methods of detecting neighboring nuclei, not only through the chemical bonds but also through space,

an important step towards complete structure determinations of molecules in solution.

We are certainly not wrong in assuming that the next years will see the development of further experimental techniques—*e.g.* in the field of multiple quantum spectra—and improvements of existing methods with respect to acquisition times and concentration requirements. This development will profit from increasing practical experience gained using the new techniques, which our article may encourage. One thing is already certain: the fascinating physics of spin systems with its numerous practical applications is an important chapter of modern research.

*We are indebted to Dipl.-Chem. P. Schmitt and Dipl.-Chem. J. R. Wesener for performing a number of experiments. Support of our own research by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie is gratefully acknowledged. R. B. thanks Prof. Dr. G. Wilke, Mülheim for continuous support. Finally, our thanks are due to Dr. R. Mynott, Mülheim, for improving the English version of this article.*

[89] The idea of two-dimensional NMR spectroscopy is due to J. Jeener (lecture, Ampère Int. Summer School, Basko Polje, Yugoslavia 1971). R. R. Ernst was the first to recognize its general importance (cf. *Chimia 29* (1975) 179 as well as [11]). An interesting account of the historical development is given in [90a].

# From Environmental Analytical Chemistry to Ecotoxicology—A Plea for More Concepts and Less Monitoring and Testing

**By Werner Stumm, René Schwarzenbach, and Laura Sigg**

The development of cultural and technical civilization has been marked with increasing interference in hydrogeochemical cycles and the production of a growing number of chemicals; this is accompanied by a growing concern on the potential adverse effects of chemicals on biological systems. Assessment of the potential toxicological and ecological effects of pollutants is of central importance. We are of the opinion that this cannot be accomplished by merely evaluating the harmfulness of a substance on the basis of toxicity tests with individual organisms and by monitoring analytically the environment for pollutants. We would like to encourage chemists to participate in the solution of ecotoxicological problems: chemodynamical concepts permit the estimation—on the basis of physical-chemical generalizations and with the help of compound-specific data—of the fate, the distribution, the potential for bioaccumulation in the food chain, and the approximate residence time of pollutants (and thus the attainable residual concentrations) in the environment and therefore to predict the relative risk of different pollutants.

## 1. Introduction

Human society runs on material and energy. In industrialized nations, the anthropogenic energy flow per unit area exceeds biotic energy flux (energy fixed by photosynthesis) by a factor of about ten; organic material produced by industry (*ca.* 150 kg $yr^{-1}$ per inhabitant, or *ca.* 40 g $m^{-2}$ $yr^{-1}$) is within one order of magnitude of that synthesized by nature (net primary production: *ca.* 300 g $m^{-2}$ $yr^{-1}$)[1,2]. The hydrogeochemical cycling of dissolved and suspended materials (*e.g.* phosphorus, heavy metals) is accelerated, and a large number of industrially synthesized chemicals are distributed by various pathways into the environment. Obviously, these anthropogenic activities, considered to be necessary for the maintenance of our civilization and culture, are achieved in many instances not without perturbation of ecosystems and effect on human health. It has been estimated[3] that *ca.* 60000 chemicals are in daily use and that this number increases by 1000 to 1500 substances every year. The evaluation of many of these substances and their impact on nature and human health is among the most important objectives of environmental science.

The *assessment* of this impact of chemical pollution and of the behavior of pollutants in the environment requires qualification and quantification in every respect of the reactions and interactions that occur. In the past, much effort has been directed towards: 1) monitoring the distribution and concentrations of chemical pollutants in the environment; and 2) testing the effects of individual pollutants on individual organisms. However, *monitoring* data can rarely be generalized unless one knows the significant interrelationships and interactions between the parts of an ecological system. Similarly, it is usually very difficult to assess the ecological effects of a given compound from *bioassays* with individual organisms under laboratory conditions.

In view of the great number of existing industrial chemicals, and considering the large amounts of environmental pollutants created every day by human activities, we need to develop and apply general concepts on the behavior and fate of pollutants and to use these concepts as an aid to procuring relevant analytical results. By evaluating the strength of natural and anthropogenic emission sources, and by identifying the relevant pathways, interactions and unit processes that govern the behavior and fate of chemicals in a given natural system, we can improve our ability to understand and predict the future fluxes, distribution,

and effects of pollutants on ecological systems and on human health. This will be illustrated by some selected examples primarily relevant to the aquatic environment.

Over the years, the gross pollutional load on receiving waters has increased, and its character has changed. Up to a few decades ago, most of our wastes derived predominantly from human and animal excreta and other biogenic components, whereas in recent years they have become increasingly overloaded with the discards of modern industrial society (synthetic chemicals, mining products such as phosphates and metals) and by-products of energy production. This change in waste composition has occurred as a result of industrial activities having grown faster than human populations. Many industrial chemicals reach receiving waters indirectly (*via* households, agricultural drainage, the atmosphere). Some of these substances are refractory (*i.e.* not readily biodegradable) and they progressively accumulate in aquatic ecosystems because self-purification and biological waste treatment are not very effective in eliminating such chemicals. We should remind ourselves that water is the most important linkage in all biogeochemical cycles; it acts as a solvent, catalyst and reagent in most ecosystem reactions and processes. In comparison to terrestrial ecosystems, aquatic systems are particularly sensitive to chemical perturbation[2].

## 2. The Ecotoxicological Task

It is the objective of ecotoxicology to assess the hazards associated with pollutants in the environment. It includes 1) the study of the effects of a given chemical on the environment, especially upon ecology and on human health, and 2) the elucidation of the effect of the environment on the pollutant. As has been pointed out by *Baughman et al.*[4,5] and others[6-11], the second part of this objective, until recently neglected, is of particular importance in any *predictive* environmental assessment.

Figure 1 illustrates synoptically the realms and *perspectives of aquatic ecotoxicology*. We consider first the release of a potential pollutant into the aquatic environment. The transfer of the pollutant into various reservoirs (air, water, soil, biota, *etc.*), its ultimate distribution and residual concentration (activity or fugacity[9]) depend on the physical, chemical and biological *compound-specific properties of the pollutant* (vapor pressure, solubility, functional groups, Henry coefficient, lipophility, adsorbability, chemical and biological degradability) as well as on the *properties of the environment* (flow of water, type of interfaces, transport of particles, photosynthesis and nutrient cycles, redox intensity, presence of other constituents, *etc.*).

### 2.1. From Input to Exposure

Let us follow the various steps from the source to the potential ecological effects of a pollutant released into an aquatic ecosystem. The immission is measured as a flow or load (*capacity* factor; mass per unit time or mass per unit time and volume or area). The resulting concentration is a consequence of dilution, transport, and transformation of this chemical. At any point, the *water condition* is characterized by the entity of interacting physical, chemical, and biological factors which are all *intensity* factors (activity, concentration, redox intensity, velocity gradient, temperature, productivity, *etc.*). These intensive variables, above all

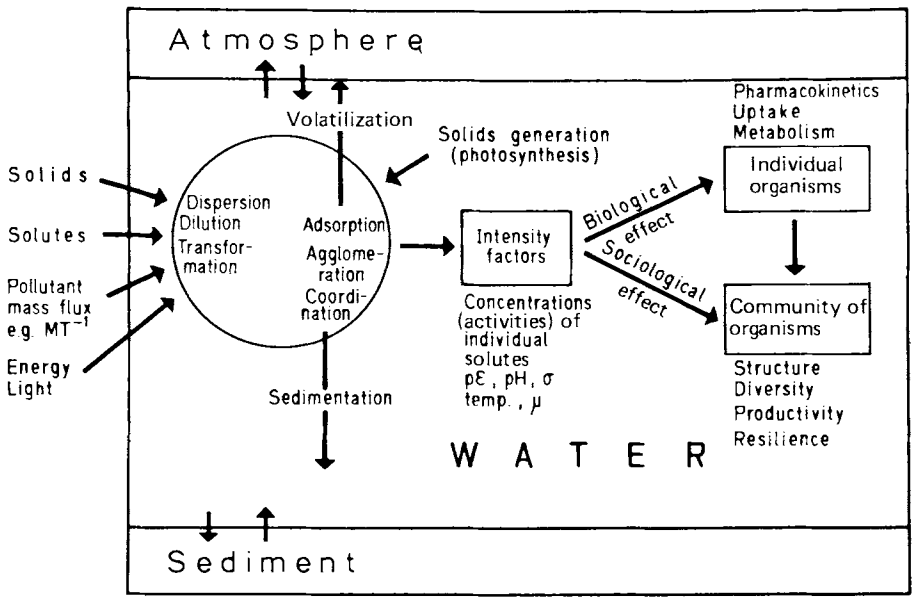

Fig. 1. Aquatic ecosystem transfer and transformation of pollutants by different pathways and various chemical, biological and physical processes. A substance introduced into the system becomes dispersed and diluted: it can become eliminated from the water by adsorption on settling particles or by escape (volatilization) into the atmosphere; it can become transformed chemically or biologically. The residual activities (concentrations) and other intensity factors (pε, velocity gradient, temperature, *etc.*) determine causally physiological, toxicological and sociobiological effects on organisms and their communities.

the concentrations, or, more precisely, the activities of the individual constituents, determine causally the doses (concentration × time) an organism or an ecosystem will receive and thus, in turn, the type of community of organisms present in the ecosystem.

Thus, for an assessment of the exposure and an evaluation of the ecological and hygienic risk, we need to know the residual concentrations of pollutants. An estimate of the ambient concentration of a pollutant based on a prediction of its relevant fate and residence time (considering relevant pathways, exchange processes, biological and chemical conversions) is essential to any hazard assessment. The problem of estimating the dose (activity) is one of the things that distinguishes ecotoxicology from classical toxicology.

The importance of the concentration (activity) of the individual solutes for interpreting the cause/effect relationship depends—in the sense of a simple model—essentially on the thermodynamic statement that, for an equilibrium distribution, the chemical potential (related to the activity) is the same in all phases, *i.e.* in the solution, in the organism, in the sediments, in the gas phase, *etc.*[12]. Under conditions of non-equilibrium, the difference in chemical potential (the activity gradient) is the driving force for the transfer of a substance from one reservoir into another, *e.g.* from water into an organism; but active mechanisms of transport into the inside of a cell are also possible.

### 2.2. The Toxic Effect

The ecological harmfulness of a substance depends on its interaction with organisms or with entire communities of organisms (Fig. 1). The intensity of this interaction depends on the specific structure and on the activity of the substance under consideration; but other factors such as temperature, turbulence, and the presence of other substances are also important. A thorough knowledge of the basic mechanisms by which toxic agents exert their injurious effects (pharmacokinetics, uptake, conversion, degradation and separation, disturbance of regulatory mechanisms in the biological community) is fundamental for an understanding of biological responses. Comparative toxicological research is necessary in order to extrapolate effects observed in laboratory experiments to organisms in nature and from one organism to another or to man.

In evaluating *toxicity,* we need to distinguish between:

1) Substances which have a direct effect on humans, animals and other terrestrial or aquatic organisms (here one often speaks of acute, subacute or chronic toxicity, depending on the time interval within which an effect is observed).
2) Substances which primarily affect the organization and structure of an ecosystem. Here a contaminant may impair the self-regulatory functions of the system or interfere, in a subtle way, with food chains.

*Sociobiological Effects:* While we have some knowledge about the impact of xenobiotic substances on individual organisms, we know less about their impact on ecosystems. In considering biological communities (the biocoenoses) various intra- and inter-species interactions of a sociobiological nature (*e.g.* chemotaxis and chemoreception) have to be taken into account.

The natural distribution of organisms depends primarily on their ability to compete under given conditions and not merely on their ability to survive the physical and chemical environment; a population will be eliminated when its competitive power is reduced to such an extent that it can be replaced by another species[13, 14]. The competitive abilities of an organism are an interplay of its reproductive rates, which are related to food and physiological potential, and the mortality rates from all sources, including predation and imposed toxicity[14]. *Tinbergen*[15] pointed out that there are millions of ways in which an organism can die, but that there is only a very narrow range of ways in which it can survive and leave offspring. Thus, in an ecosystem, a population may be eliminated by the presence of pollutants even at apparently trivial toxicity levels if its competitive ability is marginal, or if it is the most sensitive of the competitors. Often, contaminants at very low concentrations cause changes in the structure of the population by interfering through chemotaxis with interorganismic communication. For example, the survival of a fish population may be rendered impossible by a pollutant (even if it exhibits neither acute nor chronic toxicity to the particular species of fish) if it impairs the food source (zooplankton) or disturbs chemotactical stimuli or mimicks wrong signals (and thus, for example interferes with food finding).

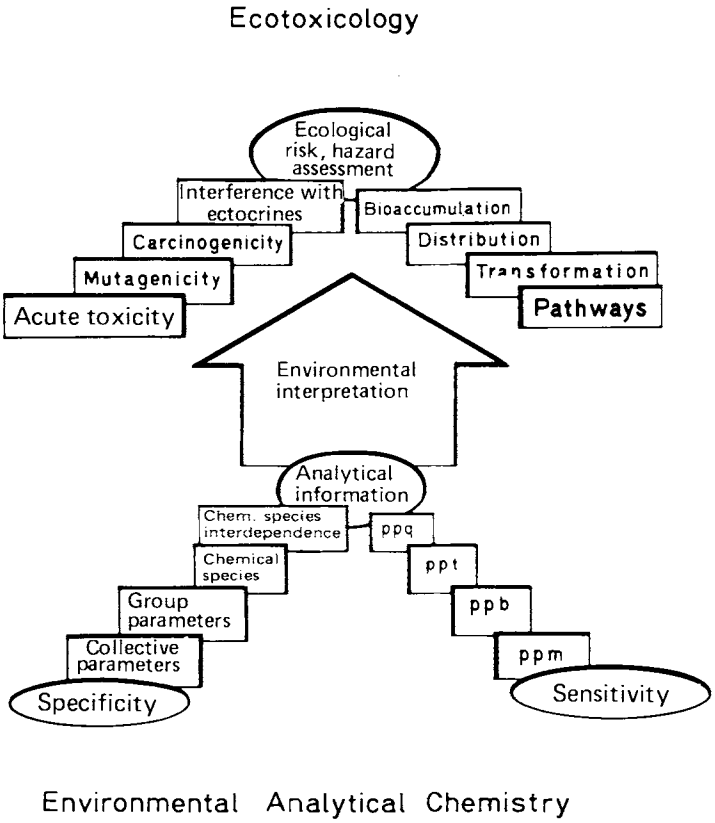

Fig. 2. Interrelationship between environmental analytical chemistry and ecotoxicology; the establishment of cause-effect relationships hinges significantly on the ability to *sensitively* and *selectively* detect individual components in a complex environmental system.

As a consequence of the many microhabitats (niches) that are typically present in a "healthy" water, many species can survive. Because of inter-species competition, most species are present in a low population density. Pollution destroys microhabitats, diminishes the chance of survival for some of the species, and thus in turn reduces the competition; the more tolerant species become more numerous. This shift in the frequency distribution of the species towards a lower diversity of the ecosystem is a general consequence of the chemical impact on waters by substances non-indigeneous to nature[13].

## 3. The Role of Environmental Analytical Chemistry

Figure 2 illustrates the interdependence between environmental analytical chemistry and ecotoxicology, *i.e.* the assessment of the environmental fate and the impact of chemical substances. An understanding of the interaction of chemical compounds in the natural system, that is the mode of their participation in various processes, hinges on the recognition of the compositional complexity of the environment. This requires an adequate analytical methodology, especially the ability to detect individual components (chemical species) *selectively* and to measure them accurately and with the *greatest sensitivity.*

*Specificity:* The environmental behavior and impact of a substance (biological availability, physiological and toxicological effects, adsorbability, chemical, biochemical and geochemical reactivity) are strongly *structure-specific.* Figure 3 illustrates that organic isomers may exhibit remarkable differences in toxicity, chemical reactivity and adsorptivity. The same is true for inorganic constituents. Figure 4 shows the various forms in which metals are thought to occur in natural waters. The different species have different effects. For example $CuCO_3(aq)$ and $Cu(aq)^{2+}$ each affect the growth of algae in quite different ways[16]. Collective

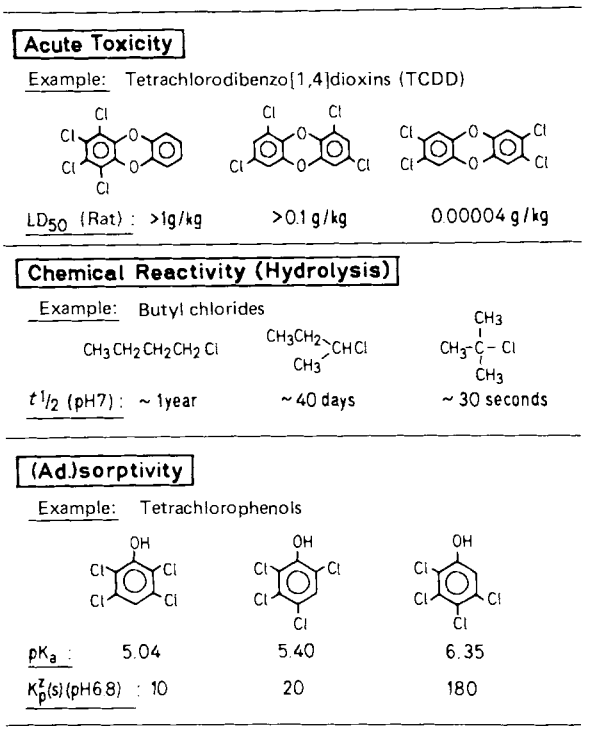

Fig. 3. Chemical and biological reactivity is strongly structure-specific. $LD_{50}$ is the concentration that will produce death in half the population, $t_{1/2}$ is the half-life; $pK_a$ is the neg. log of the acidity constant; $K^z_{p(s)}$ is the distribution coefficient [$m^3\ 10^{-3}\ kg^{-1}$] between a solid (surface) phase (containing 2.9% organic carbon) and the solution.

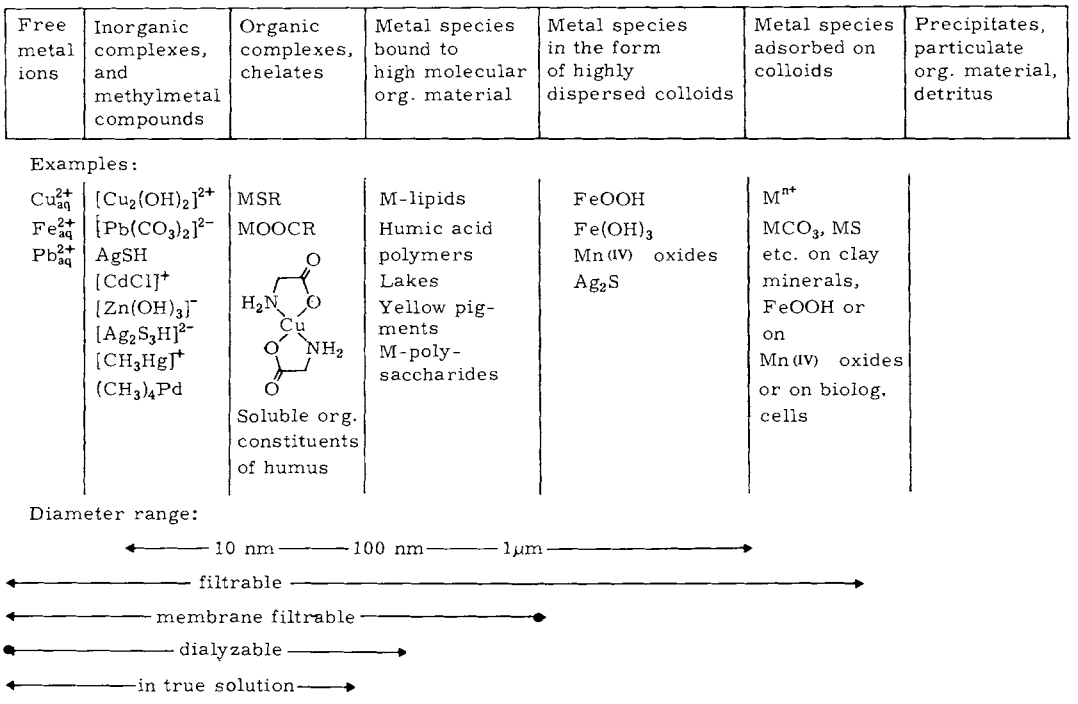

Fig. 4. A knowledge of the forms of occurrence of metals (free metal ion, inorganic or organic complex) is a prerequisite for evaluating biological and chemical effects. It is operationally difficult to distinguish between dissolved and colloidally dispersed substances because membrane filters may not always retain colloids.

parameters such as total organic carbon, copper(II) or total phosphorus, although often useful in establishing total loads, are not suitable for establishing cause-effect relationships between chemistry and biology. For the determination of individual organic chemical species, various methods capable of high selectivity (GC, GC/MS, and HPLC) are available. The specification of metal ions, usually attempted by electrochemical (voltammetric) means is, on the other hand, still a difficult problem.

*Sensitivity:* Analytical chemistry has made remarkable progress in improving the sensitivity of detection down to concentrations of $10^{-11}$ M. This has been a great help for studies on natural water systems, since aquatic ecosystems are more sensitive to chemical perturbation than terrestrial ones. The resorption of a substrate or the uptake of a pollutant by aquatic organisms is controlled by enzymatic processes, and these are affected typically by concentrations lower than $10^{-6}$ M. (The Michaelis constant for enzymatically controlled processes is often between $10^{-5}$ and $10^{-10}$ M.) The growth rate of algae has been shown to be affected by free $Cu^{2+}$ ions at concentrations as low as $10^{-10}$ to $10^{-13}$ M, while concentrations as low as $10^{-8.5}$ M are toxic to daphnia and fish[16] (Fig. 5).

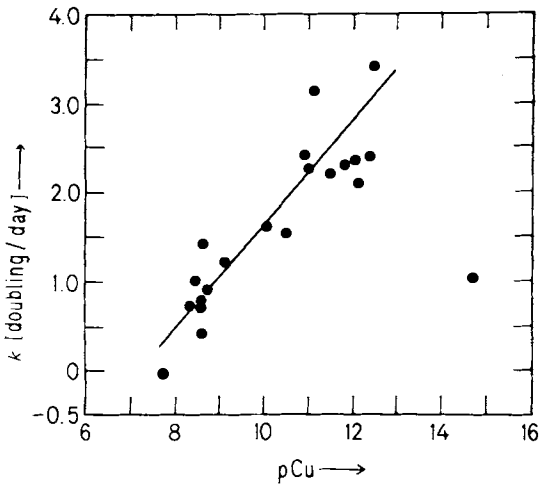

Fig. 5. Effect of "free" $Cu^{2+}_{aq}$ ions on the growth of algae in seawater. pCu was buffered in seawater by $Cu^{II}$ and various complex formers. pCu ($= -\log[Cu^{2+}]$) was calculated from the concentrations of $Cu^{II}$ and complex formers and the pH [16].

*Precision, Accuracy and Sampling:* The decisive prerequisite for any meaningful interpretation is the collection of reliable and accurate data. Because of the extremely low concentrations usually encountered, rather demanding problems have to be met in order to avoid contamination or loss of constituents in all stages, from sampling to sample pretreatment and sample preservation until analytical determination. For example, as shown by *Patterson et al.*[17], most of the results obtained before 1975 for Pb concentrations in seawater were an order of magnitude too high.

## 4. Limitations of Analytical Monitoring and Toxicological Testing

Understandably, the general public requires that the biological effect of pollutants be examined systematically by appropriate toxicity tests and that the environment be surveyed by monitoring programs that search for pollutants and toxicants. Such investigations are important, but we must not overvalue our analytical possibilities and the limited validity of standard toxicity tests.

We are concerned that the present preference and overemphasis of such programs over flexible basic and exploratory research may hinder rather than aid our understanding of nature and of its changing processes[7]. The systematic monitoring of the chemistry of a watershed or of a river or lake is an extremely involved, expensive, and time-consuming enterprise. Because of a lack of understanding of the reciprocal interactions between pollutants and the environment, much of the effort in the past had by necessity to be devoted to measuring, within the momentarily available "analytical window" (for a given methodology), "what is" rather than to projecting "what is likely to be" or "could be made to be". Baseline measurements, as special cases of monitoring, are more promising because they permit recognition of changes in the environment. Unfortunately, baseline records often turn out to be less valuable than one had hoped when the measurements were initiated, because one later realizes that at that time ignorance had prevented both a meaningful definition of the problem and the selection of the best method[17].

Nevertheless, knowledge gained from monitoring data is enhanced significantly if the data can be interpreted in a functional and rational way. To this end, a quantitative knowledge of the hydrological regime (water budget, rainfall, evapo-transpiration, runoff, infiltration) in the area, and information on input and on transformation pathways are required. Field measurements are essential, but they should be supplemented by concurrent laboratory studies on the chemodynamic properties of selected substances of interest in order to establish comparisons between measured field data and concentrations predicted from the "behavior profiles" of chemical species.

*Toxicity tests* are rarely designed to assess chronic toxicity or to evaluate impairment of self-regulatory functions of ecosystems. From an ecological point of view, these latter effects are more important than acute toxicity. Furthermore, one must take into consideration that for each substance (and its degradation intermediates), short and long-term tests with different organisms should be carried out in order to determine whether synergistic and antagonistic effects may occur in presence of other substances or different solution variables. Each negative test result may not mean "zero toxicity".

In addition, the sensitivity of different taxonomic groups to chemicals may vary markedly—even organisms of the same species may respond differently. Thus, results obtained with one kind of organism may not readily be extrapolated to other species. Obviously, new chemicals may be produced and enter the environment faster than they can be tested satisfactorily.

Although we have some knowledge of the effects of xenobiotic substances on individual organisms, our understanding of the impairment of whole aquatic ecosystems is very limited. As we have already seen (Section 2.2), even if no acutely damaging effects on individual organisms are observed, the ecological consequences of such impairment

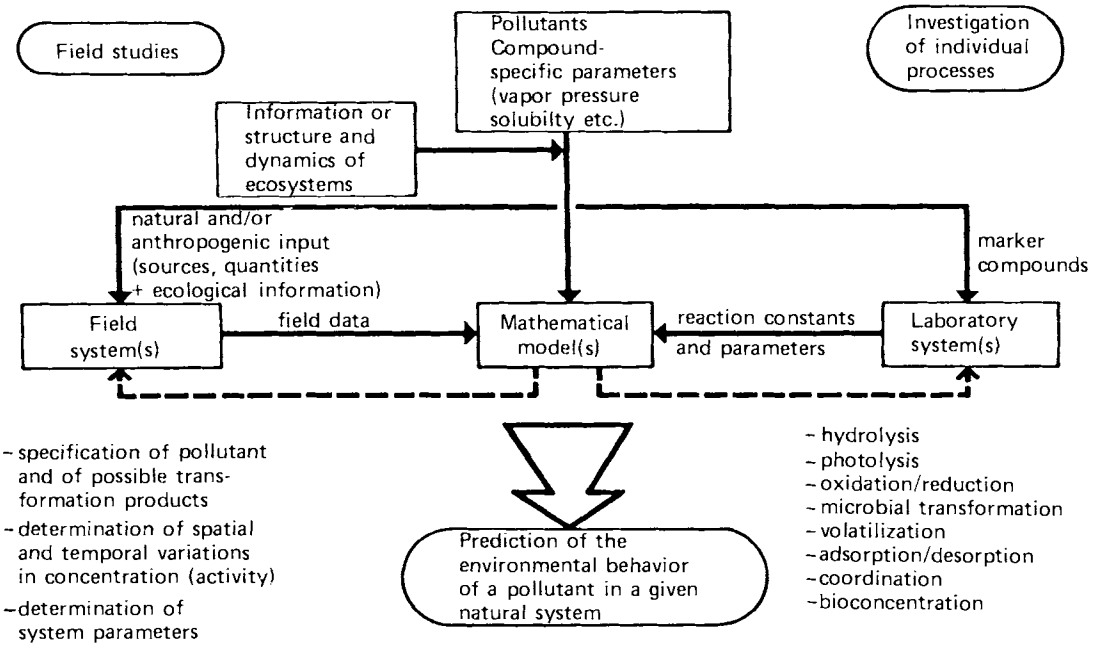

Fig. 6. Development of methods for predicting the environmental behavior of pollutants: General approach. The ecotoxicological and hygienic evaluation of pollutants requires establishing their "behavior profile" in the environment. With the help of simple models, it is in many cases possible to estimate the approximate residual concentrations.

to communities of organisms may often be more detrimental over long time spans than acute toxic effects.

## 5. Concepts for Assessing and Predicting the Environmental Behavior of Pollutants

### 5.1. Development of Predictive Assessment Models

As illustrated in Figure 6, three approaches complement each other in establishing predictive models:

1) A set of data of *compound-specific parameters* (vapor pressure, solubility, lipophility, Henry coefficient, biodegradability, *etc.*) aid in establishing the pollution potential of individual substances and permit one to forecast the manner in which the compounds are distributed in the environment, how fast they may be degraded chemically or biologically, and thus, in turn, to predict their fate and approximate residence time. Thus, a semiquantitative estimate of the ecological impact is obtained. In order to project the distribution of pollutants and how it is influenced by systemic variables, one needs to understand the structure and dynamics of ecosystems and the interactions between the biogeochemical cycles in aquatic ecosystems.

Table 1. Pertinent information to assess fate and residence time of pollutants.

| | *Parameter* | | *Significance* |
|---|---|---|---|
| Transport Paths<br>Mass Flow | production<br>statistics<br>mass balance<br>transport<br>mixing | | immission into environment<br>physical fate |
| Distribution<br>air-water<br>surface-water<br>sediment-water<br>biota-water | (ad)sorption<br>isotherms<br>solubility<br>vapor pressure<br>Henry constant<br>lipophilicity<br>n-octanol-water<br>distribution coeff.<br>mass transfer coefficient | equilibrium | interface transport<br>sedimentation<br>bioconcentration<br>bioaccumulation<br>food chain<br>biolog. retention<br>immission into and from atmosphere<br>dry deposition<br>precipitation scavenging<br>evaporation<br>condensation |
| Molecular<br>Transformation<br>microbial<br>oxidation<br>hydrolysis<br>photolysis | biodegradability<br>equilibrium constants<br>rate constants<br>light absorption | kinetic | residence time<br>half life<br>form of occurrence<br>structure-reactivity<br>correlations<br>photodecomposition |

2) *Laboratory studies* in which individual processes, *e.g.*, with model compounds, can be investigated under conditions where variables are known or kept constant are necessary in order to determine reaction constants and other substance-specific parameters.
3) *Field studies* are necessary in order to determine system parameters and to measure the spatial and temporal distribution of pollutants and to identify the forms of occurrence (species) of these chemicals.

The process of modelling is essential. *Empirical models* require fitting to on-site data and continuous updating with further collection of data. They have low capacity for transferability in time and space and for extrapolation beyond the range of data. *Causal models* based on the principles of physics, chemistry, and biology make possible the explicit incorporation of the effects of changes in land and water environments. In principle, causal models are more readily transferable in space and time. A mixed-model approach will be necessary for predicting the performance of complex systems.

Estimation of the *residence time* of a pollutant in a body of water (or in another reservoir of the environment) with the help of such models is of utmost importance because the residual concentration of the pollutant depends on the residence time. The latter is influenced by hydrological factors (*e.g.*, type of dispersion and loss through the outlet) and by non-hydrological processes (*e.g.* adsorption on settling particles or biomass and chemical and biological transformations).

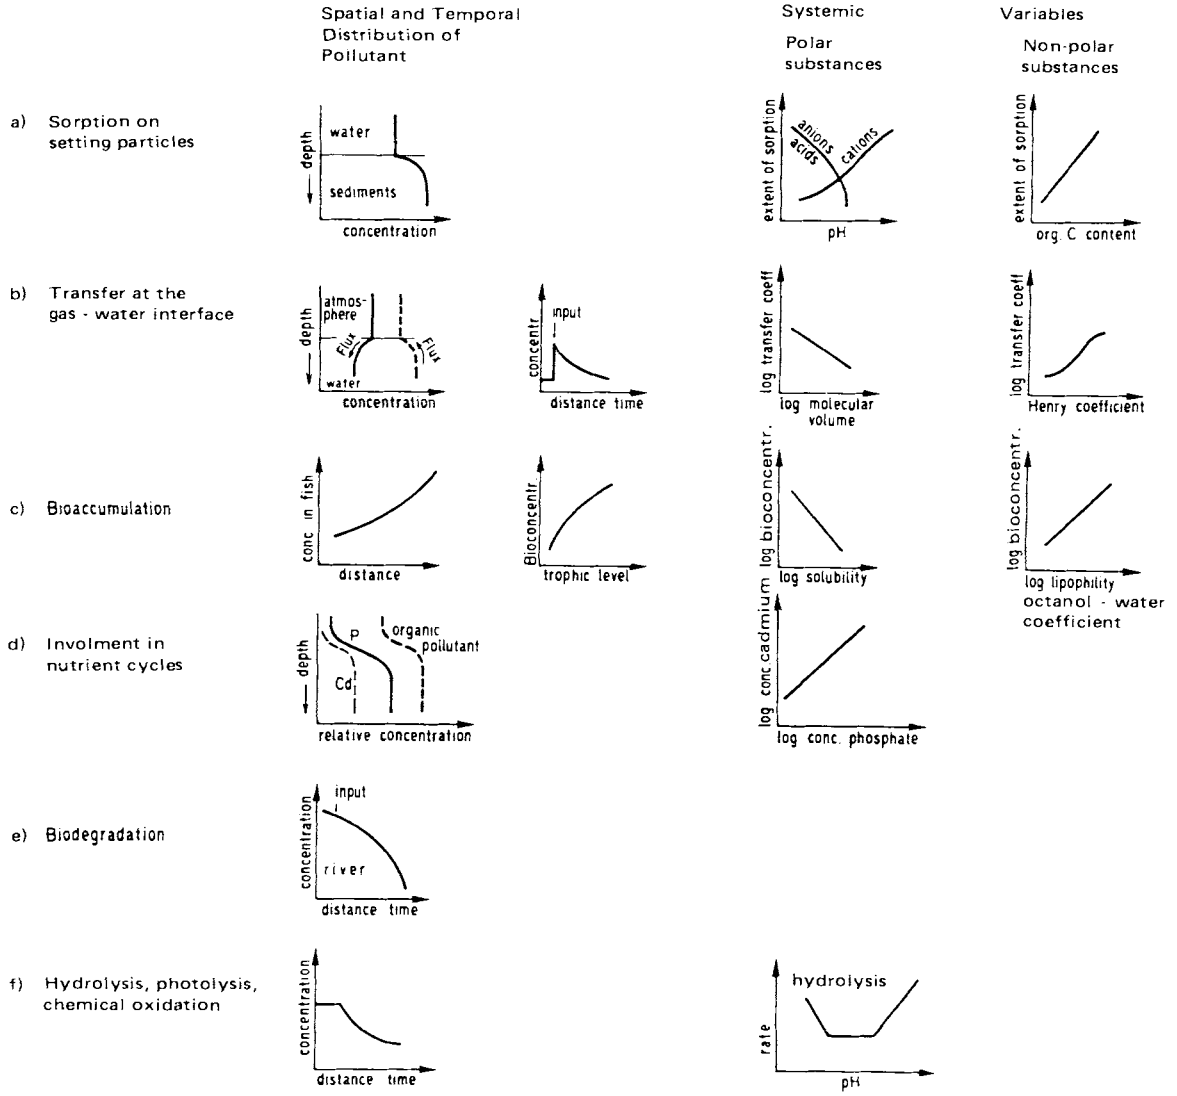

Fig. 7. Illustration of the dependence of spatial and temporal distribution of pollutants on compound-specific and systemic variables: a) The extent of adsorption of polar substances as a function of pH is different for a cationic, anionic or molecular (weak acid) adsorbate; for non-polar lipophilic substances, the extent of adsorption increases with increasing organic C content of the adsorbing particle; b) the concentration gradient at the water/atmosphere interface indicates in which direction the transfer of volatile substances occurs. The specific transfer coefficient is dependent on the Henry coefficient and on the molar volume of the substance as well as on the system-specific parameters such as water turbulence; c) the accumulation of a substance in the food chain is related to its lipophility or to the reciprocal of its solubility; d) nutrients, including certain heavy metals are, for example in oceans, withdrawn from the water during photosynthesis in the top water layers and returned as a consequence of respiration in the same proportions (corresponding to the composition of the biomass) in the deeper water layers; e) biodegradation is autocatalytic and proportional to the microbial biomass available; f) chemical and photochemical transformation processes are influenced by many solution variables, especially pH, light extinction, and concentration of singlet oxygen.

### 5.2. Examples of Relevant Processes

Basic physical, chemical and biological concepts, and unit processes may be modelled in order to predict the behavior of environmental pollutants. Table 1 and Figure 7 identify some of the relevant processes that need to be considered. Some of these processes will be briefly outlined:

*Adsorption:* Particles acting as scrubbing agents by scavenging are important in regulating the concentrations of pollutants. Thus, in water systems, all substances that are strongly adsorbed have small residence times relative to that of $H_2O$. Many xenobiotic substances, hydrophobic substances such as polychlorinated hydrocarbons, as well as polar substances such as lignin sulfonates from the paper industry, or heavy metals, are strongly sorbed to suspended particles. The settling of biogenic particles together with clays is responsible for the dynamic mechanism of elimination of heavy metals in lakes and oceans through transport into the sediments. Surface chemical theory aids in quantifying the extent of the reactions occurring at interfaces[18]. Often, a linear adsorption isotherm

$$[A_{ads}] \approx K_0[A_{aq}]$$

can be used to describe the distribution between solid surface and solution. For polar substances and ions, equilibrium constants have been experimentally determined or approximated from stability constants in electrolyte solutions; the extent of adsorption can thus be predicted as a function of pH and solution variables. The sorption of hydrophobic pollutants on settling particles or sediments and biota can usually be related to the *lipophility* of a substance, *i.e.* the tendency to become soluble in lipids and fats, and the organic carbon content, $f_{oc}$, of the adsorbing particles (Fig. 8). As a measure for lipophility, one usually uses the *n*-octanol/water partition coefficient, $K_{ow}$:

$$K_{ow} = [A_{oct}]/[A_{aq}]$$

As a measure of the distribution coefficient, $K_p$, for many groups of substances, equations of the type

$$K_p = b \cdot f_{oc}(K_{ow})^a$$

may be used[19], where a and b are constants and $K_p$ is expressed in units of volume per mass dry weight and $f_{oc}$ as weight fraction ($f_{oc}$ = organic carbon content of solid material).

*Exchange with the Atmosphere:* Transfer of volatile organic substances from aquatic systems to the atmosphere or *vice versa* can readily be examined in the laboratory. The equilibrium distribution of a compound is given by the Henry coefficient *H:*

$$H = [A_g]/[A_{aq}] = (p_A/RT)/[A_{aq}] = (p_A^0/RT)/[A_{aq}^0]$$

$[A_g]$, $[A_{aq}]$ and $[A_{aq}^0]$ are, respectively, the concentration of A in the gas phase, in aqueous solution and in a saturated solution (=solubility); $p_A$ and $p_A^0$ are, respectively, the partial pressure of A and the vapor pressure of pure A (or the vapor pressure in equilibrium with a solution saturated with A).

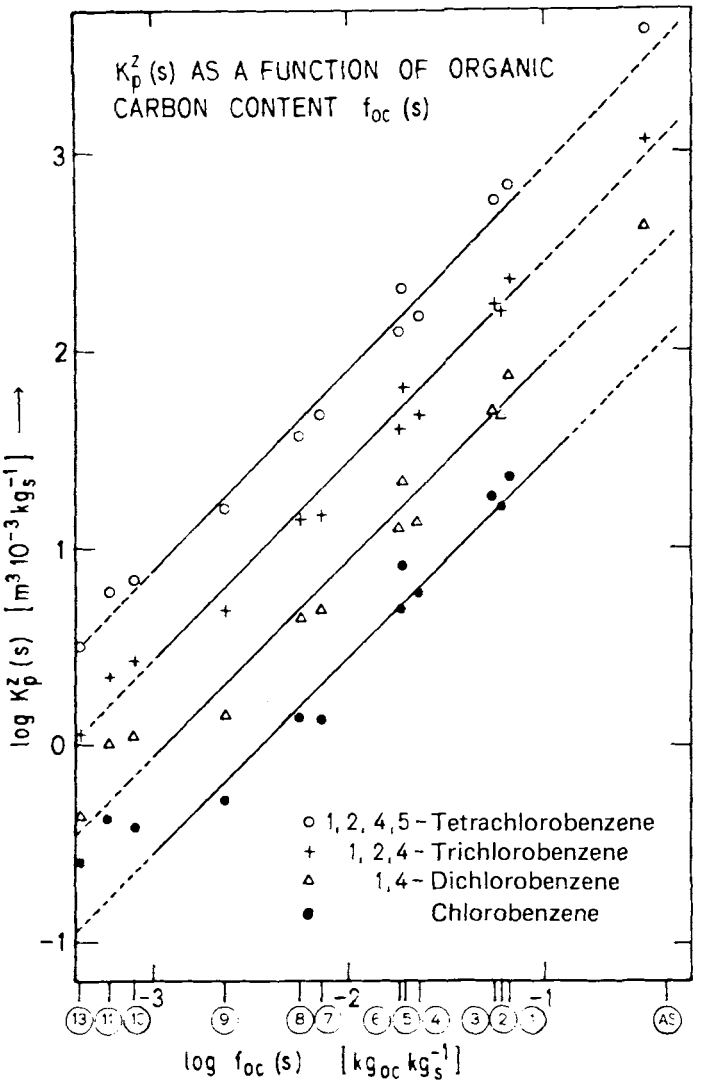

Fig. 8. The distribution of non-polar organic substances between aquatic solids and water (as given by the distribution coefficient $K_p$) is dependent upon the lipophility of the compound and the organic C content of the adsorbing material ($f_{oc}$ = weight fraction). The solid phases considered here are coastal sea and lake sediments (1–5), river sediments (6, 8), solids from aquifers (7, 9–12) and activated sludge (AS). The octanol/water distribution coefficients are, respectively 500, 2400, 11200, and 52000 for chlorobenzene, 1,4-dichlorobenzene, 1,2,4-trichlorobenzene, and 1,2,4,5-tetrachlorobenzene.

The rate of transfer *F* of compound A across the water gas phase boundary can be expressed by

$$F = K_L([A_{aq}] - [A_g]/H)$$

where $K_L$ is the overall gas transfer coefficient ($K_L$ depends on the hydrodynamic conditions; for most volatile substances $K_L$ is of a similar order of magnitude as that of oxygen). Substances having a Henry coefficient larger than *ca.* 0.1 are transferred relatively rapidly from waters of high turbulence to the atmosphere (see example in Fig. 9a). Less volatile compounds (*e.g.* DDT; $H \approx 5 \times 10^{-4}$) have, with regard to gas exchange with the atmosphere, a longer residence time in water; nevertheless, such relatively not very volatile substances "slowly" escape into the atmosphere where they are transported over large distances.

Figure 9b illustrates both; the transfer of a substance from the atmosphere into a lake water, and the "volatilization" of another substance from the lake.

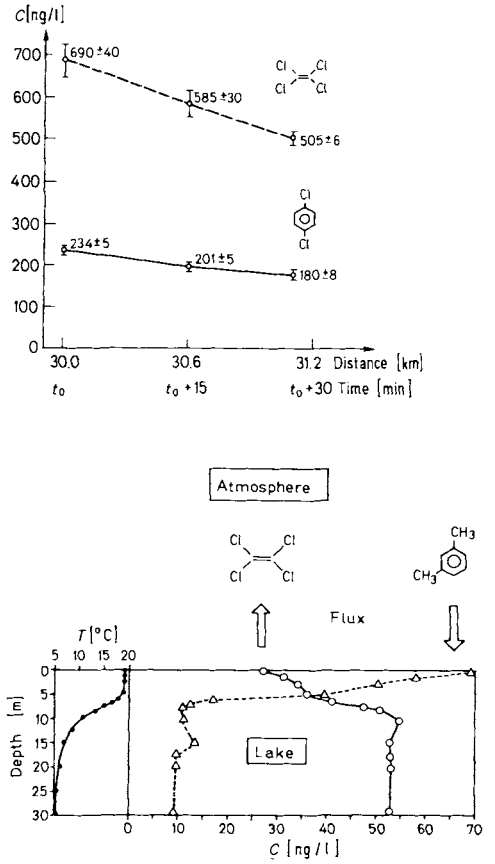

Fig. 9. Gas exchange between surface water and atmosphere is an important process for volatile organic substances. a) Concentration profile of tetrachloroethylene and 1,4-dichlorobenzene along a stretch (1.2 km; average depth 0.42 m) of the River Glatt (Switzerland). Some cascades are responsible for efficient gas exchange. The decrease in concentrations is mainly caused by the escape of these substances into the atmosphere ($t_{1/2}$ (tetrachloroethylene) = 65 min; $t_{1/2}$ (1,4-dichlorobenzene) = 80 min).—b) Exchange of nonpolar organic substances between Lake Zurich and the atmosphere. While 1,3-xylene (a component of gasoline) invades the lake water from the atmosphere, tetrachloroethylene (used in dry cleaning and metal degreasing), a water pollutant, escapes from the water into the atmosphere.

*Microbial Degradation:* Among the molecular transformations, *biodegradability* is one of the most important factors determining the residence time of organic pollutants in the receiving waters. Today, detailed knowledge of the microbiology, the mechanisms and the kinetics of the biotransformation of organic pollutants under natural conditions is still lacking. Many substances are readily altered to the extent that bacteria use their original structural entity, but the metabolites so formed are non- or slowly degradable. For example, as is illustrated in Figure 10, certain nonionic detergents yield ecologically objectionable degradation intermediates that persist in the water much longer than the parent compound[20].

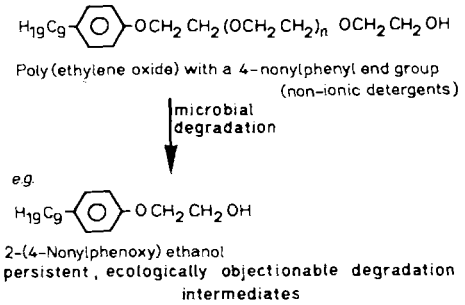

Fig. 10. Example of a group of substances which as a consequence of biological waste treatment is converted into a highly objectionable, relatively refractory degradation intermediate [20].

*Chemical Transformations:* In order to predict the reactivity of organic pollutants, it is often possible to utilize *structure reactivity correlations* because many organic chemicals share common reaction patterns and reactivities among like-structured chemicals; within a class of compounds, the reactivity of a functional group depends on the type and number of substituents. For example, the kinetic hydrolysis constant of organic phosphate esters of the type $(CH_3O)_2P(O)-OR$ can be correlated with the acidity constant of the leaving group ROH[24]. Furthermore, predictions on the dependence of kinetic constants of chemical reactions upon solution variables can often be made (*e.g.*, pH dependence of hydrolysis).

*Bioaccumulation:* Of particular importance in assessing the ecological or toxicological relevance of a pollutant is the question whether the substance is incorporated into the biota. Such incorporation may lead to a retention of the pollutant and its biomagnification in the food chain. Incorporation into biomass is related to the lipophility as measured by the *n*-octanol/water distribution coefficient[21] (Fig. 11). The tendency of certain pollutants to become accumulated in the food chain is much stronger in aquatic ecosystems than in terrestrial ones because the products of photosynthesis are consumed to a much larger extent by herbivores in waters than on land, where the plants are mostly degraded by microorganisms.

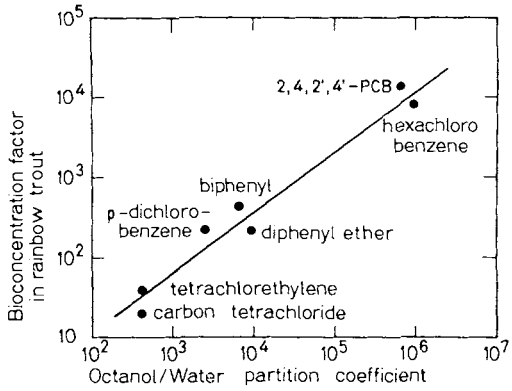

Fig. 11. The lipophility of a substance, as measured by the octanol/water distribution coefficient, is an essential parameter for predicting biomagnification (biostorage and accumulation in the food chain) (calculated from data by *Chiou et al.* [21]). 2,4,2',4'-PCB = 2,4,2',4'-tetrachlorobiphenyl.

## 6. The Consequences

Man's life is accompanied by his concern for safety. The evaluation of ecological and health effects caused by exposure to pollutants is extremely difficult because of our limited knowledge of the impact of chemicals on aquatic ecosystems. As we have tried to show, standard toxicity tests

with single organisms cannot be used to predict the subtle and often chronic impacts of substances on humans and ecology.

As long as our insight into the effect of chemicals on nature is so limited, we must remain very cautious in adopting tolerance levels; in establishing "minimum adverse effect levels", we must demand safety factors that are adequate to protect against the unanticipated effects of yet unsuspected biologically active compounds in the environment. On the other hand, there exists for every substance—even if not accessible experimentally—a certain level of exposure below which damage is highly improbable. The concern for ecosystem protection and safeness cannot exceed a reasonable incremental cost/benefit ratio. The final decision for this balance between ecological and toxicological measures and economics and the public propensity for risk acceptance is after all political; but the environmental scientist should procure better scientific criteria for this decision-making process. Exploratory multidisciplinary research on comparative toxicology, on the cycles of energy and nutrients in ecological communities, and on the impact of chemicals and other stresses upon structure and species distribution frequency can eventually yield criteria that permit the establishment of no adverse effect tolerance levels for substances non-indigeneous to natural systems.

The recommendation made here, *i.e.* to predict, on the basis of substance-specific parameters, the fate, the distribution, the tendency for bioaccumulation and the approximate residence time of potential pollutants, and to estimate their most likely attainable residual concentrations permits a comparison of various substances concerning their relative risks and impairment potential. The confidence in such assessments can be enhanced if field measurements give relative agreement between concentrations predicted and those observed.

Biodegradability and lipophility (lipophilic storage in organisms) are among the most important compound-specific criteria. The best and perhaps most economically feasible way to safeguard aquatic ecosystems and humans against unanticipated effects of organic pollutants is to require: 1) that all substances that are mass-produced and may become dispersed into the environment because they are being used in households, small trades, and agriculture (*e.g.* detergents, cleaning fluids, agrochemicals) have a satisfactory biodegradability; and 2) that in industrial production, the recovery or safe disposal of intermediates and residuals becomes an integral part of the production process.

In establishing priorities on policies in environmental protection, the question arises: What should be of greater concern, human health or "health" of the ecosystem? In answering this question, one needs to consider that the maintenance of resilient ecosystems with a sufficient diversity of organisms, *i.e.* systems that can resist structural and functional displacement, is a prerequisite for the well-being and health of humans.

It is encouraging to find that the ideas and concepts presented here—it may not have been sufficiently evident that much of our ideas have been influenced by the suggestions of *Baughman*[5], *Blumer*[7], *Mackay*[9], *Hapke*[6], *Mill*[10] and *Tinseley*[18]—are, at least partially, gaining some acceptance by the Organization for Economic Cooperation and Development (OECD)[3,22], the American Society for Testing Materials (ASTM)[5], and the US Environmental Protection Agency[23].

The expansion of chemistry will continue to shape our life styles. In the use of chemicals and in further developments, we have to accept the boundary conditions imposed by ecology and human health.

# Stable Carbodications**

By G. K. Surya Prakash, Tarik N. Rawdah, and George A. Olah*

Methods developed for the generation and study of stable carbomonocations can also be employed for similar investigations on carbodications. Trivalent (classical) as well as hexacoordinate (non-classical) carbodications studied under long-lived ion conditions are reviewed with special emphasis on their structural features, and investigated primarily by $^1$H- and $^{13}$C-NMR spectroscopy.

## 1. Introduction

At the turn of the century, the pioneering work of *Norris, Kehrmann,* and *Baeyer et al.* on triarylcarbenium ions generated wide interest in positively charged carbon compounds[1,2]. However, it was left to later investigators (between 1920—1960) like *Meerwein, Ingold, Hughes, Whitmore, Bartlett,* and *Winstein* to formulate the modern concept of carbocations based primarily on indirect kinetic and stereochemical studies[3]. In the early sixties we found ways to observe carbocations of a wide variety in low nucleophilicity superacidic systems[3]. Presently a remarkable number of carbocations are known and these have not only been detected as transients in chemical reactions, but in most cases have been isolated as long lived species under stable ion low nucleophilicity conditions. The structures of these long lived carbocations have been established by NMR, UV, IR, Raman, and X-ray photoelectron spectroscopy and the subject has been extensively reviewed[3].

Interest in carbocations has largely been confined to monopositive carbon species (carbomonocations). The study of dipositive carbon compounds (carbodications), has only more recently been undertaken, but interest in the area is rapidly growing and a review of this fascinating topic seemed timely. There is still very little information available on carbon multiply positively charged compounds (carbopolycations).

Carbodications have frequently been observed in gas phase mass spectrometric studies (without revealing any structural aspects). The first aryl-stabilized carbodications in solution were independently reported by *Hart et al.*[4] and *Volz et al.*[5] in the early sixties. Alkanediyl dications in which the positive charges are separated by two carbon atoms were first prepared by *Olah et al.*[6] in the mid-sixties. Since then significant experimental and theoretical work has been directed towards investigating carbodications. Although a substantial number of carbodications with widely varied structural features have been studied, their numbers are still relatively small when compared to those of carbomonocations. As in the case of carbomonocations, both classical carbodications (with trivalent carbon) and nonclassical carbodications (with penta and higher coordinated carbon) have been prepared and their structural characteristics have been analyzed primarily by NMR spectroscopy. Aromatic carbodications are known but hitherto no homoaromatic carbodications have been reported.

Our review summarizes the work pertaining to the study of stable carbodications generated under long lived stable ion conditions. We will not discuss either gas phase mass spectrometric observation of carbodications or theoretical quantum mechanical studies relating to dicationic species.

## 2. Generation of Carbodications

The most frequently used route for the generation of carbodications is the ionization of precursor dihalides (fluorides, chlorides) or other suitable precursors in superacids like $HF/SbF_5$, $FSO_3H$, $FSO_3H/SbF_5$ ("magic acid") or $SbF_5$ in low nucleophilicity solvents such as $SO_2ClF$ or $SO_2$. Temperatures in the range 0° to −120 °C are employed. In most cases higher temperatures result in decomposition, polymerization or rearrangement reactions. Ionization of diols in superacids can also lead to carbodications in some specific cases.

A second major route for the production of carbodications involves chemical oxidation of some electron rich compounds. Certain alkenes and arenes undergo two-electron oxidations in $SbF_5$ at low temperatures in solvents like $SO_2$ or $SO_2ClF$. In most cases these reactions occur only if the resulting dipositive species are stabilized by field or resonance effects or if the carbodications formed are Hückel type systems with $(4n+2)$ π electrons.

Electrochemical oxidations in polar aprotic solvents such as nitriles and nitro compounds can also be used for the generation of carbodications. This technique has mainly been employed for the generation of dipositive species from aromatic precursors. In most of these oxidations the cation-radical intermediates can be first detected, so low-temperature voltammetry is especially valuable here since homogeneous chemical reactions of intermediates generated at the electrode are greatly slowed down at low temperatures.

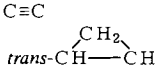
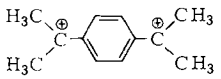
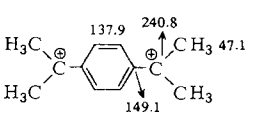
## 3. Classical Carbodications with Trivalent Carbon



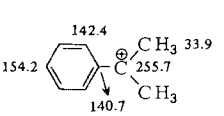
### 3.1. Acyclic Carbodications



The majority of the acyclic carbodications which are reported in the literature have their positively charged centers stabilized by conjugation with one or more adjacent aromatic rings[4]. Typical representatives[6] of these ions are **1**, **2** and **3**. In all these carbodications the positive charge is substantially delocalized over the aromatic ring(s), as evidenced by the deshielding of the *ortho* and *para* H- and C-atoms and the concomitant downfield shift of the corresponding signals in the $^1$H- and $^{13}$C-NMR spectra.



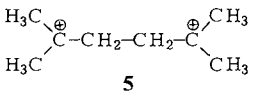
**1a**, X = $OCH_3$
**1b**, X = $N(CH_3)_2$



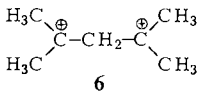
**3a**, X = $CH_2CH_2$
**3b**, X = *trans*-CH=CH
**3c**, X = C≡C
**3d**, X = *trans*- 
**3e**, X = 

**2** 

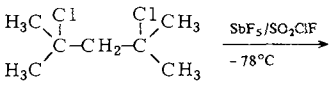
As an example we will discuss the nature of the dication **2**, in which the positively charged centers are appended to C1 and C4 of a benzene ring. The dication **2** was generated[6] from 2,2′-*p*-phenylenedi-2-propanol in $SbF_5/SO_2ClF$ at −78 °C. The $^1$H-NMR spectrum of the ion consists of only two single peaks at $\delta = 4.46$ and 9.28, while the $^{13}$C-NMR spectrum contains only four peaks at $\delta = 240.8$, 149.1, 137.9, and 42.8 consistent with a symmetrical dicarbenium ion structure **2**. Although the $^{13}$C-NMR chemical shifts of **2** are similar to those of the dimethyl(phenyl)carbenium ion (cumyl cation) **4**[7], charge distribution differences between **2** and **4** are apparent. Most notably, the carbenium carbon in **2** is more shielded than that in **4**, while the reverse is true for the methyl groups. The *ipso* carbon atoms in **2** are also reasonably deshielded. It appears that both positive charges are dispersed to a considerable extent into the neighboring methyl groups through hyperconjugative effects. The charge delocalization into the benzene ring is lowered due to coulombic repulsion. Similar effects are also observed in the case of dications **3b** to **3e**[6].



**2**

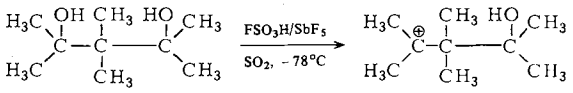


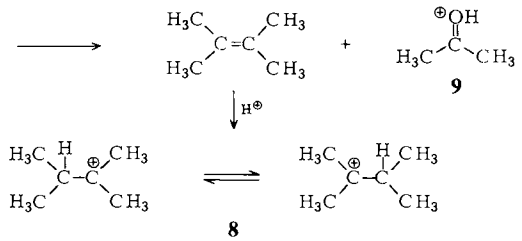
**4**



In the absence of aryl stabilization of the positively charged centers, long lived acyclic carbodications can be formed only if the charge bearing carbons are separated by at least two carbon atoms and the carbenium centers are tertiary[6,8]. The 2,2′-ethylenediisopropyl dication **5** prepared by the ionization of 2,5-dichloro-2,5-dimethylhexane in $SbF_5/SO_2ClF$ at −78 °C shows a triplet at $\delta = 4.24$ and a multiplet at $\delta = 5.04$ in the $^1$H-NMR spectrum. The large $J_{HH}$ coupling (3.0 Hz) in **5** between the methyl and methylene protons is characteristic of coupling across a carbenium ion center. The $^{13}$C-NMR spectrum shows three peaks at $\delta = 331.3$, 52.7 and 47.1 consistent with symmetrical carbenium ion structure **5**. The $^{13}$C-NMR shift of the carbenium ion centers in **5** is almost identical to that observed for the ethyldimethylcarbenium ion[9] at $\delta = 333.8$. The additivity of $^{13}$C-NMR chemical shift relationship[11] also shows the regular dicarbenium nature of the species. The total $^{13}$C-NMR chemical shift differences between dications and their parent hydrocarbons are twice as much as those typically observed for classical carbomonocations[11].

**5**

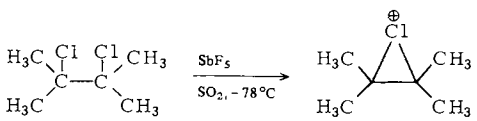




**6**

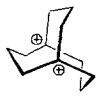
**7**

Attempts[6] to prepare the 2,2′-methylenediisopropyl dication **6** from 2,4-dichloro-2,4-dimethylpentane led to only the monocation **7**[12]. The potential dicarbenium ion **6** has the two carbenium ion centers separated by only one carbon atom and evidently, if this dication does form, it has only a transient existence, rapidly eliminating a proton to give **7**. Attempted[6] blocking of proton elimination by the ionization of 2,3,3,4-tetramethyl-2,4-pentanediol resulted in quantitative cleavage to the equilibrating isopropyldimethylcarbenium ion **8**[13] and protonated acetone **9**.



**9**

**8**

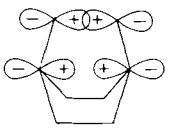


Ionization of 2,3-dichloro-2,3-dimethylbutane, where the two potential carbenium centers are adjacent, gave only the cyclic chloronium ion **10**[14].

**10**

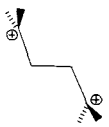
### 3.2. Cyclic and Polycyclic Carbodications

The most interesting examples of bicyclic carbodications are the 1,4-bicyclo[2.2.2]octanediyl[15] and 1,5-bicyclo[3.3.3]undecanediyl[16] dications **11** and **12** respectively, in which the bridgehead C-atoms function as carbenium centers.



**11**   **12**

The dication **11** is formed from the ionization of 1,4-dichlorobicyclo[2.2.2]octane in $SbF_5/SO_2ClF$ at $-78\,^{\circ}C$. The ion **11** was found to be unstable above $-60\,^{\circ}C$; its dicationic character was established by both $^1H$- and $^{13}C$-NMR spectroscopy. The 60-MHz $^1H$-NMR spectrum of **11** at $-90\,^{\circ}C$ shows a singlet at $\delta = 3.45$. The proton-decoupled $^{13}C$-NMR spectrum shows two absorptions at $\delta = 307$ and 43.5 for the carbenium carbons and the methylene carbons, respectively. The 4-chlorobicyclo[2.2.2]oct-1-yl monocation is formed first, from the dichloride precursor, and the second ionization, which gives a distinctly different spectrum for the dication **11**, depends on the experimental conditions[17a].



One would expect a strong coulombic repulsion between C1 and C4 carbons, considering the short distance that separates them. Molecular mechanics force-field calculations in which the electrostatic repulsion between the charged centers is included predict the C1–C4 distance in **11** to be 2.34 Å[15, 18]. According to MINDO calculations this distance comes out to be 1.99 Å[15, 19], thus indicating a shortening of the C1–C4 distance by 0.35 Å on going from the hypothetical monocarbenium ion **13** to the dication **11**, and also a shortening of 0.25 Å on going from the uncharged bicyclo[2.2.2]octane **14** to **13**.

**13**   **14**

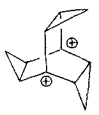
The shortening of the C1–C4 distance in the dication **11** has been attributed to hyperconjugative transfer of electron density to the cationic centers which then leads to symmetry allowed 1,4 bonding. This can be represented pictorially as in **15**[20]. MINDO/3 calculations show that in

 **15**

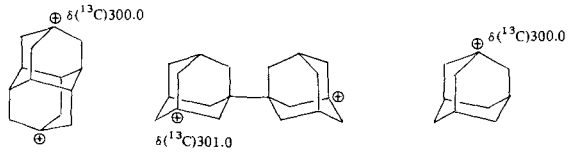
 *cis*-**16**

 *trans*-**16**

order to relieve the electrostatic repulsions between the closely located positive charges of **11**, more than half of the total charge is delocalized over the twelve hydrogen atoms; the residual charge is comparable to that in the monocation **13**. The dication **11** can be considered as a doubly charged sphere with the positive charge distributed over its entire surface. Although the 1,4-interaction is favorable in **11**, this does not mean that 1,4-dications prefer a *cis* over a *trans* conformation (see **16**). MINDO/3 calculations indicate that *trans*-**16** is more stable than *cis*-**16** by 11 kcal/mol after corrections are made for ground state energies[15].



A similar shortening of the C1–C5 distance is predicted in the 1,5-bicyclo[3.3.3]undecanediyl dication **12** (manxanediyl dication) by empirical force field calculations[21]. The bridgehead dication **12** was generated[16] from 1,5-dichloromanxane in $SbF_5/SO_2ClF$ at $-78\,^{\circ}C$. The 60-MHz $^1H$-NMR spectrum of **12** indicates dynamic behavior at $-60\,^{\circ}C$, *i.e.* in this case a rapid bridge-flipping process. This process was frozen out at $-80\,^{\circ}C$ on a 100-MHz instrument indicating an activation energy barrier of about 11 kcal/mol, similar to that observed for the parent hydrocarbon manxane[22]. The $^{13}C$-NMR spectrum shows similar dynamic behavior. At $-85\,^{\circ}C$, there are three carbon resonances at $\delta = 346.2$, 58.7 and 23.5 which are assigned to C1, C2, and C3, respectively.



**12** **17**

The manxyl monocation **17** has also been generated[16] for comparison. It shows five $^{13}C$-NMR signals at $\delta = 356.3$, 57.9, 37.0, 32.7 and 35.7, which are assigned to C1, C2, C3, C4 and C5, respectively. It does not show any fluxional behavior in the NMR spectrum between $-30$ to $-135\,^{\circ}C$, indicating either a rapid ring-flipping process with a lower energy barrier than in **12** (faster than can be detected on the NMR time scale) or a very slow inversion of conformation due to the introduction of the $sp^2$ hybridized carbon at C1 only. Contrary to expectations the bridgehead carbons C1 and C5 in **12** are *ca.* $\approx 10$ ppm shielded relative to C1 of the monocation **17**. It appears that the presence of one or two carbocation centers in the manxane system generates subtle conformational variations, as is borne out by the different energy barriers for the bridge-flipping process in the monocation **17** and in the dication **12**. In the case of the monocation **17** the planarization of the bridgehead C1 carbon does not seem to affect the geometry of C5 significantly, as is indicated by its small coupling constant $J_{CH}$ (120 Hz). This implies that the hyperconjugative interaction in the 1,4-bicyclo[2.2.2]octanediyl dication **11**[15], which causes the C1–C4 carbons to move closer together does not seem to be occurring in the case of the manxanediyl dication **12**[11]. Finally, applying the $^{13}C$-NMR additivity relationship to the dipositive ions **11** and **12** in comparison with their hydrocarbon precursors clearly reveals their trivalent dicarbenium ion nature.

The inability to observe the cyclopropane annelated 1,4-bicyclo[2.2.2]octanediyl dication **18**[23] remains unexplained.

 **18**

Other polycyclic dications such as **19** and **20** have, however, been prepared[17b]. Essentially, they show similar $^{13}$C-NMR spectral characteristics as the monopositive analog, 1-adamantyl cation **21**[17b].

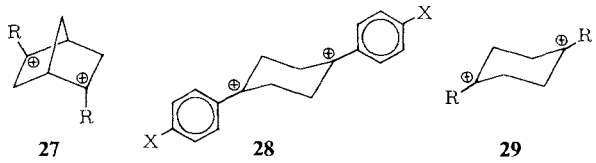
**19** **20** **21**

Attempts to observe circumambulatory rearrangement in the 2,6-*anti*-tricyclo[5.1.0.0$^{3,5}$]octanediyl dication **22** have been unsuccessful[24]. The dication **22** would appear to rearrange instantaneously to the homotropylium ion **23** by proton elimination. However, substituted dications of type **22**, *e.g.* **24**, are quite stable; they are static, and a substantial part of the charge is delocalized into the cyclopropane rings[24].

**22**

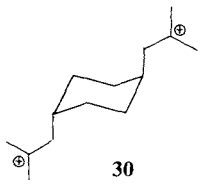
**23** **24**, R = $CH_3$, *c*-$C_3H_5$, $C_6H_5$

The effect of introducing two electron deficient centers into the norbornane skeleton has also been explored[25]. These studies are of particular interest in view of the extensive investigations[3b] on the mode of charge delocalization in the parent 2-norbornyl cation. Application of the so-called tool of increasing electron demand[26] (changing the electron demand of the cationic center by gradually changing the charge delocalizing ability of the adjacent aryl ring) to the substituted 2,5-diaryl-2,5-norbornanediyl dications **25** reveals some interesting $^{13}$C-NMR spectral characteristics.



**25** R = $C_6H_5$, 4-$C_6H_4$–$CH_3$, 4-$C_6H_4$–$OCH_3$, 4-$C_6H_4$–$CF_3$, 3,5-$C_6H_3(CF_3)_2$, $C_6F_5$, OH

**26**



A plot of C1 *vs.* C3 carbon chemical shifts shows an excellent linear fit with a wide variety of substituents, thus indicating **25** as being a normal phenylcarbenium ion. In contrast the monopositive 2-phenyl-2-norbornyl monocations **26** show significant deviations in such a C1 *vs.* C3 plot[27] in the case of electron-withdrawing substituents, due to the onset of nonclassical σ-delocalization. The lack of σ-delocalization in **25** has been rationalized in terms of electronic effects. The coulombic repulsion in **25** is rather significant, and this renders the whole norbornane skeleton electron deficient. However, this effect is partly relieved by the dispersal of charge into the aryl substituents. Charge delocalization into the aryl substituents even in the case of electron withdrawing groups such as 4-$CF_3C_6H_4$, 3,5-$(CF_3)_2C_6H_3$ and $C_6F_5$ is evident from the $^{13}$C-NMR shifts of the *ortho* and *para* C-atoms, which are more strongly deshielded than in the analogous monocations of type **26**[27]. Further evidence for the regular phenylcarbenium ion nature of **25** comes from the observed linear relationship between the chemical shifts of the carbenium centers in **25** and those in 1-aryl-1-cyclopentyl cations[28].

Attempts to generate 2,5-unsubstituted or 2,5-dialkyl-substituted 2,5-norbornanediyl dications **27** have been unsuccessful[25]; on the other hand, it was possible to study the 1,4-diaryl-1,4-cyclohexanediyl dications **28** $^{13}$C-NMR spectroscopically. However, efforts to prepare methyl-substituted and unsubstituted analogs **29** have been futile.

**27** R = $CH_3$, H **28** X = H, $OCH_3$ **29** R = $CH_3$, H

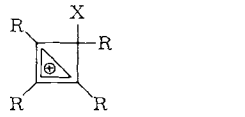
Interestingly, ionization of 1,4-dibutyl-1,4-cyclohexanediol in $SbF_5/SO_2ClF$ at −78 °C resulted only in the rearranged dication **30**, in which the positive charges are separated by six carbon atoms.

**30**

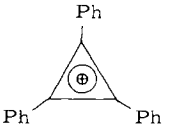
### 3.3. Aromatic Carbodications

#### *3.3.1. Cyclobutadiene Dications*

In contrast to the antiaromatic cyclobutadiene, the cyclobutadiene dication (cyclobutenediyl dication) **31** is predicted by molecular orbital theory and Hückel's rule to have aromatic character and a square planar $D_{4h}$ ground state symmetry **31A**[29]. *Ab initio* molecular orbital calculations[30] suggest that carbodication **31** is not planar but rather prefers a puckered geometry with $D_{2d}$ symmetry **(31B)** instead. This puckering seems to occur despite the loss of resonance energy and the increase in angular strain. The calculated energy difference between the planar and puckered geometries is 2.8 kcal/mol.

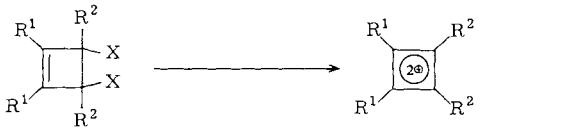


**31A** **31B**



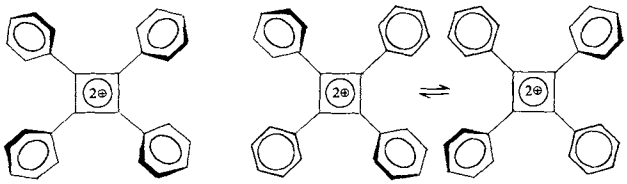
The major reason for the adoption of the puckered geometry **31B** has been attributed to the relief of destabilizing 1,3-interactions which are known to occur in four-membered rings[31]. The *ab initio* calculations indicate that orbital mixing and orbital reorientation which are enhanced through pyramidization also contribute to the stabilization of the puckered form **31B**.

In the gas phase some $C_4H_4^{2+}$ ions have been observed[32,33], and possibly also the unsubstituted carbodication **31**, but their structures could not be determined. As long-lived species in superacid solutions, **31** is still unknown[34]. Attempts to prepare the dication **31** by ionization of 3,4-dichlorocyclobutene in $SbF_5/SO_2ClF$ merely led to the 3-chlorohomocyclopropenyl cation **32** (X = Cl, R = H), which underwent chloride/fluoride exchange at elevated temperatures to give the analogous fluorine derivative.



The stability of the cyclobutadiene dication can be greatly enhanced by the introduction of substituents like fluoro, methyl and phenyl groups[30,34]. Earlier attempts to prepare substituted cyclobutadiene dications were either unsuccessful or the postulated dications were later proved to be actually monocation monodonor-acceptor complexes **32**, $X=X\rightarrow MX_n$[35,36]. We later succeeded[34] in generating a variety of cyclobutadiene dications **34** as long-lived species in superacid media.

**32**

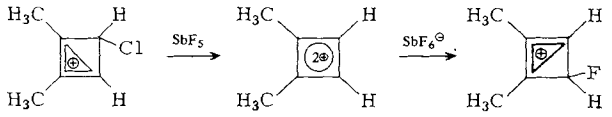


**35**

**33a**, $R^1 = R^2 = Ph$, X = Br
**33b**, $R^1 = R^2 = CH_3$, X = Cl
**33c**, $R^1 = Ph$, $R^2 = H$, X = Br
**33d**, $R^1 = Ph$, $R^2 = X = F$

**34a**, $R^1 = R^2 = Ph$
**34b**, $R^1 = R^2 = CH_3$
**34c**, $R^1 = Ph$, $R^2 = H$
**34d**, $R^1 = Ph$, $R^2 = F$

*Ab initio* calculations on cyclobutadiene dications predict that substituents that are capable of strong π-electron donation render the four-membered ring planar[30]. Thus, the tetrafluorocyclobutadiene dication has been predicted to be planar[30]. The four-membered ring in the tetraphenylcyclobutadiene dication **34a** is most probably planar and, according to the $^1$H- and $^{13}$C-NMR data, *para*-phenyl positions are strongly deshielded, indicating substantial delocalization of the positive charge into the phenyl rings[34]. The dicationic nature of **34a** has been established utilizing the Spiesecke-Schneider relationship (see Section 3.7)[37]. The degree of phenyl conjugation in **34a** proved to be far greater than that in the triphenylcyclopropenylium cation **35**[38]. Due to steric repulsions, the four phenyl rings in **34a** cannot all be coplanar. The existing $^1$H- and $^{13}$C-NMR data can be interpreted in terms of either a static structure **34a**(I) in which all the four phenyl rings are twisted slightly out of the plane of the four-membered ring or alternatively in terms of two dynamically degenerate systems **34a**(II) in which one set of diagonally opposite phenyl substituents are coplanar with the four-membered ring, while the remaining two phenyl rings are rotated out of the plane[34].



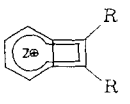
**34a** (I) **34a** (II)

In the 1,2-diphenylcyclobutadiene dications **34c** and **34d** the extent of resonance interaction between the phenyl rings and the double positive charge in the cyclobutadienyl ring[34] is higher than in the tetraphenyl derivative **34a**. Such a strong interaction results in restricted rotation of the phenyl rings in **34c** and **34d** about the *ipso* carbon and four-membered ring carbon bonds. In contrast a free rotation of the phenyl rings is observed in **34a**[34].

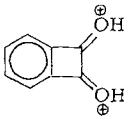
The ionization of tetramethyl derivative **33b** in $SbF_5/SO_2ClF$ at −78 °C to the tetramethylcyclobutadiene dication **34b** initially involves the formation of the homocyclopropenylium ion **32** (X = Cl, $R = CH_3$). This intermediate subsequently ionizes to yield the dication **34b**. *Ab initio* quantum mechanical calculations also predict this cation to have puckered geometry with $C_{2v}$ symmetry instead of the $C_{4v}$ planar structure. The energy difference between the two structures is calculated to be 2.3 kcal/mol and is comparable to the 2.8 kcal/mol difference calculated for planar and puckered geometries of the parent dication **31**[30]. Unfortunately, the above two structural possibilities cannot be probed with NMR spectroscopic studies on symmetrical systems. However, with suitably disubstituted cyclobutadiene dications (with substituents such as benzyl or isopropyl), the above possibilities could be proved either by $^1$H- or $^{13}$C-NMR spectroscopy.

In the $^1$H-NMR spectrum, the tetramethylcyclobutadiene dication **34b** shows a sharp singlet at $\delta = 3.68$. In the $^{13}$C-NMR spectrum two signals are observed at $\delta = 209.7$ and 18.8 for the ring C-atoms and methyl C-atoms respectively. Although the methyl substituent effect in **34b** precludes a quantitative interpretation of the π-electron density residing at the cyclobutenediylium carbons from their $^{13}$C-NMR shieldings, comparison of the NMR shieldings ($\delta = 209.7$) with that predicted by the Spiesecke-Schneider relationship[39] for the unsubstituted cyclobutadiene dication **31** ($\delta = 208.8$) certainly support the formulation of **34b** as a dicationic species delocalizing approximately two-π electrons over a four-carbon atom periphery.

Alkyl substituted cyclobutadiene dications seem to be less stable than the aryl analogues. Attempts to generate the 1,2-dimethylcyclobutadiene dication **36** from 3,4-dichloro-1,2-dimethyl-1-cyclobutene result only in the monocation **37**, which at higher temperatures (−20 °C) undergoes halogen exchange reaction with the counter ion; this reaction probably proceeds *via* the dication **36**.



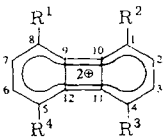
37 36



The 1,3-dihydroxy-2,4-diphenylcyclobutadiene dication was first reported by *Farnum* and *Webster* in 1963[40]. There seems to be enough evidence for considering diprotonated cyclobutenediones as 1,2-dihydroxycyclobutadiene dications rather than diprotonated ketones[41].

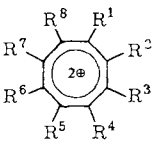
### 3.3.2. Benzocyclobutadiene Dications

The parent benzocyclobutadiene (cyclobutabenzene) dication **38a** is still unknown despite extensive attempts at its preparation by either two-electron oxidation of the parent benzocyclobutadiene or ionization of some dihalobenzocyclobutenes under long-lived stable ion conditions[42]. However, the 1,2-dimethylbenzocyclobutadiene dication **38b** can be readily generated by the ionization of 1,2-diol precursors in superacid solutions at $-78\,^{\circ}C$[42]. This $6\pi$ aromatic dication shows $^1H$- and $^{13}C$-NMR spectral characteristics comparable to those of the previously described cyclobutadiene dications. The diprotonated benzocyclobutenedione was found to exist predominantly as a dioxonium ion **38c'** rather than as a dihydroxybenzocyclobutadiene dication **38c**[42].



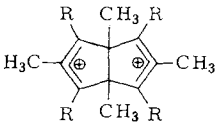
**38a**, R = H
**38b**, R = $CH_3$
**38c**, R = OH

**38c'**



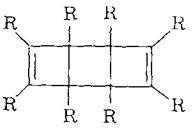
A variety of biphenylene dications **39** have been generated by two-electron oxidations of the corresponding biphenylenes with $SbF_5$ in excess in $SO_2ClF$ solutions at $-10\,^{\circ}C$[42]. The observed $^1H$- and $^{13}C$-NMR deshieldings in these systems confirm the formation of dicationic species. The substantial deshieldings of C2 and C10 and lesser deshielding of C1 indicate that the dications **39a** and **39b** are indeed fully delocalized closed-shell $10\pi$ aromatic biphenylene dications. The unsubstituted dication **39a** has also been observed in some electrochemical studies[43].

**39a**, $R^1 = R^2 = R^3 = R^4 = H$
**39b**, $R^1 = R^2 = R^3 = R^4 = CH_3$
**39c**, $R^1 = R^3 = H$; $R^2 = R^4 = CH_3$
**39d**, $R^1 = R^2 = CH_3$; $R^3 = R^4 = H$

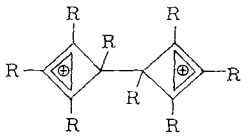


### 3.3.3. Cyclooctatetraene Dications

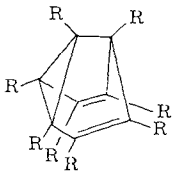
Several fundamental cationic Hückel-systems have remained elusive of preparation and experimental study. Perhaps the most notable of these is the cyclooctatetraene dication **40a**, which has probably been the subject of more investigations than any other related aromatic dication[44–47]. Basically two synthetic routes have been attempted: one involving two-electron oxidation of the parent cyclooctatetraene by superacids[44,45] or electrochemical methods[46], and the other involving ionization of the well known 8-halohomotropylium ions[44,47].



**40a**, $R^1 = R^2 = R^3 = R^4 = R^5 = R^6 = R^7 = R^8 = H$
**40b**, $R^1 = R^4 = CH_3$; $R^2 = R^3 = R^5 = R^6 = R^7 = R^8 = H$
**40c**, $R^1 = R^3 = R^5 = R^7 = CH_3$; $R^2 = R^4 = R^6 = R^8 = H$
**40d**, $R^1 = R^2 = R^3 = R^4 = R^5 = R^6 = R^7 = R^8 = CH_3$
**40e**, $R^1 = R^3 = R^5 = R^7 = Ph$; $R^2 = R^4 = R^6 = R^8 = H$

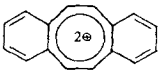


Although the parent cyclooctatetraene dication **40a** itself remains elusive, the methyl (**40b** and **40c**) and phenyl (**40e**) derivatives have successfully been prepared by the two-electron oxidation of the corresponding cyclooctatetraenes in $SbF_5/SO_2ClF$ at $-78\,^{\circ}C$[44]. The $^1H$- and $^{13}C$-NMR data of these dications provide strong evidence that all of these molecules adopt approximately planar geometries[44], despite the excessive strain involved (increased van der Waals repulsion and increase in angular strain[48]). Attempts to generate the octamethyl dication **40d** by two-electron oxidation of the corresponding octamethyl cyclooctatetraene under the experimental conditions which were employed for the preparation of the other cyclooctatetraene dications (**40b**, **40c** and **40e**) resulted in formation of the diallyl dication **41a** instead, and no evidence for **40d** was found. A similar diallyl dication **41b** has been obtained by rearrangement of the dication **40c** above $-20\,^{\circ}C$[44]. Two-electron oxidation of the isomeric *syn*- and *anti*-octamethyltricyclo[4.2.0.0$^{2,5}$]octadiene **42** and octamethylsemibullvalene **43** in $FSO_3H/SbF_5/SO_2$[44] also gives the dication **41a**. Interestingly, two-electron oxidation of **42** in $SbF_5/SO_2ClF$ alone gives the bis(tetramethylhomocyclopropenyl) dication **44**[44b].



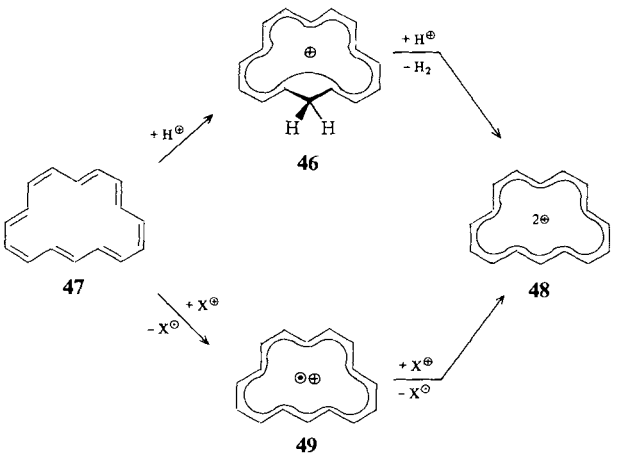
**41a**, R = $CH_3$
**41b**, R = H

**42**, R = $CH_3$



**44**, R = $CH_3$

**43**, R = $CH_3$



The dibenzo[*a*,*e*]cyclooctene dication **45** has also been prepared by the two-electron oxidation procedure and was found to be relatively stable since it can be heated to at least 0 °C without undergoing any isomerization or thermal decomposition. HMO calculations[49] on **45** indicate that the methine (CH) groups of the central eight-carbon ring are substantially electron deficient relative to the rest of the methine groups. This is also substantiated by the $^1H$-NMR chemical shifts[44a,c].

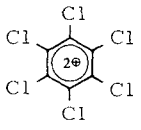
**45**

### 3.3.4. [16]Annulene Dication

Since the protonation of cyclooctatetraene is known to yield the homotropylium ion, *Schröder et al.* reasoned that the homo[15]annulenyl cation **46** can be formed by protonation of [16]annulene **47**[50]. Instead the [16]annulene dication **48** was obtained along with polymeric products in $FSO_3H/SO_2/CD_2Cl_2$ media at $-80\,^{\circ}C$. The $^1H$- and $^{13}C$-NMR data are consistent with the formation of the dication **48**. Attempts to trap this dication with $NaOAc/CH_3OH$ gave only polymeric products. Two possible mechanisms for the formation of **48** have been considered[50]. The first involves initial protonation to the homo[15]annulenyl cation **46**, which undergoes further protolytic cleavage to the dication **48** (by loss of a molecule of hydrogen). The second route is the stepwise oxidation of **47** by the proton or the conjugate acid of sulfur dioxide ($O{=}S{=}\overset{+}{O}H$), where a radical cation **49** is involved as an intermediate. *Schröder et al.*[50] seem to prefer the second mechanism, since no evolution of hydrogen gas has been observed in the reaction.

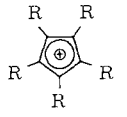
## 3.4. Oxidative Generation of Dications from Arenes

The ease of oxidation of polycyclic aromatic hydrocarbons in the gas phase[51] as well as in solution is well documented[52-61]. Monopositive radical ions and/or dipositive ions have been detected in strong acid solutions[60,61]. Similar species have been observed in anodic oxidations of aromatic compounds in non-nucleophilic solvents[52]. Simple Hückel molecular orbital theory predicts that arenes whose highest occupied molecular orbitals (HOMOs) are at higher energy levels should be prone to two-electron oxidation to dipositive ions. On the other hand, the arenes with low lying HOMOs should be more difficult to ionize[60]. Some polycyclic arenes have also been protonated to the corresponding dipositive ions.



### 3.4.1. Benzene

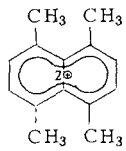
Benzene itself does not undergo two-electron oxidation upon treatment with $SbF_5/SO_2ClF$, but gives instead the benzenium ion **50**[62] by protonation (due to HF impurity in the system). This behavior is in accordance with the simple Hückel molecular orbital theory, which predicts benzene to be the most difficult member in the arene series to be oxidized[60].

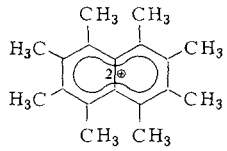


Solid hexachlorobenzene gives a dipositive ion **51** on admixture at room temperature with a viscous solution of $SbF_5$ saturated with $Cl_2$ and subsequent irradiation of the resulting monocation $(C_6Cl_6)^+$ with light of wavelength $\lambda > 3100$ Å at 5 or 77 K[63]. ESR studies on **51** have indicated that this dication is a ground state triplet (or within a few calories/mol of the ground state) as predicted by the simple Hückel method. The two unpaired electrons of **51** occupy degenerate orbitals and the dipositive ion retains the sixfold symmetry of the progenitor hexachlorobenzene itself. The π-electron configuration of **51** is similar to that of the cyclopentadienyl cations **52** which also have triplet ground states[64]. Actually, prolonged irradiation of **51**, particularly with light of wavelength $\lambda > 3100$ Å, yields a species with ESR parameters similar to those of **52b**, and it has been assumed that **51** (or possibly a precursor) under these conditions loses a CCl fragment to produce **52b**[63].

**50**

**51**

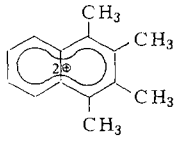




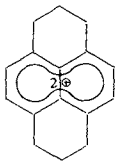
**52a**, R = H
**52b**, R = Cl

### 3.4.2. Naphthalene

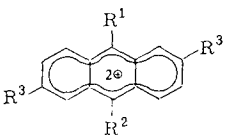
Naphthalene gives the corresponding radical monocation upon treatment with $SbF_5/SO_2ClF$ at $-78\,^{\circ}C$; no evidence for further oxidation to the dication has been found[60,61]. However, the presence of methyl substituents on the ring lowers the ionization potential of naphthalene to the point that stable carbodications can be formed. Thus, the tetramethyl- and octamethylnaphthalene dications **53**[61] and **54** have been prepared under superacid conditions from the corresponding arenes.



**53**



**54**



Attempts to prepare the closely related carbodications of 1,2,3,4-tetramethylnaphthalene **55**[61] or hexahydropyrene **56**[61] in superacids led in each case to an equilibrium mixture of the carbodication and the radical monocation. That the dipositive ion **53** is more stable than the isomer **55** has been attributed to the fact that α-methyl substituents stabilize the dipositive charge better than β-methyl substituents. The formation of dication **53** provides relief of *peri*-strain and furnishes an additional driving force for oxidation. Ring closure between the α-carbons in hexahydropyrene apparently prevents complete oxidation to the dication **56**.

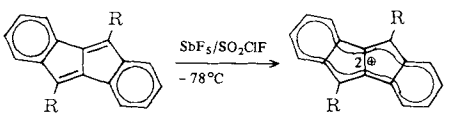
55 

 56

### 3.4.3. *Anthracene*

Unlike benzene and naphthalene, anthracene has a relatively low ionization potential and can be converted into the corresponding carbodication **57a** by two-electron oxidation with $SbF_5/SO_2ClF$[60,58,56]. Alternatively, **57a** can be generated by debromination of 9,10-dibromo-9,10-dihydroanthracene in $SbF_5/SO_2ClF$ solution[58]. Stable dipositive ions **57b–f** have also been obtained in superacids from 9-methylanthracene, 9,10-dimethylanthracene, 2,6-dimethylanthracene, 9-bromoanthracene, and 9-chloroanthracene[58].

**57a**, $R^1 = R^2 = R^3 = H$
**57b**, $R^1 = R^3 = H$; $R^2 = CH_3$
**57c**, $R^1 = R^2 = CH_3$; $R^3 = H$
**57d**, $R^1 = R^2 = H$; $R^3 = CH_3$
**57e**, $R^1 = R^3 = H$; $R^2 = Br$
**57f**, $R^1 = R^3 = H$; $R^2 = Cl$



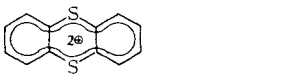
### 3.4.4. *Dibenzopentalene*

Although generation of the 8C-6π aromatic dication **58** of the unknown pentalene **59** has so far proven unsuccessful, *Rabinowitz et al.* have actually been able to prepare the dibenzoannelated derivatives[65].

58 

 59

Upon treatment of dibenzo[*a*,*e*]pentalene (indeno[2,1-*a*]indene) **60** or its 5,10-dimethyl derivative **61** with $SbF_5/SO_2ClF$ at −78 °C, two-electron oxidation furnished the dications **62** and **63**, respectively. The observed $^1H$- and $^{13}C$-NMR spectral deshieldings[65] of **62** and **63** as compared to those of **60** and **61** clearly establishes that **62** and **63** are dications.

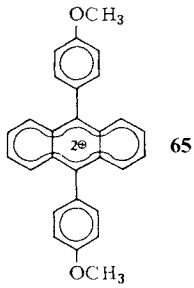


**60**, R = H
**61**, R = $CH_3$

**62**, R = H
**63**, R = $CH_3$

### 3.4.5. *Other Polycyclic Arenes*

Carbodications of higher polycyclic arenes have likewise been generated and studied by $^{13}C$-NMR spectroscopy under superacid conditions[57,58,60,61]. These arenes are listed in Table 1[60]; also listed are systems in which the carbodications are in equilibrium with the radical cations.



Dipositive ions of arenes have been observed in electrochemical oxidations and have also been assumed to be intermediates in some radical cation reactions[53–55]. *Hammerich* and *Parker*[52] have shown that thianthrene **64**, 9,10-bis(*p*-methoxyphenyl)anthracene **65**, and 4,4′-dimethoxybiphenyl **66** dications can be generated by voltammetric oxidation of the corresponding parent aromatic systems. In solvents such as nitriles, nitro-compounds and dichloromethane, reversible electron transfer behavior for oxidation of these three aromatic compounds to radical cations and dipositive ions was observed[52].

64

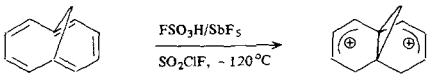
66

65

Table 1. Arene species in $SbF_5/SO_2ClF$ solution.

| Arene | $E_{HOMO}$ [β] [a] | Species in $SbF_5/SO_2ClF$ [b] | Color of dication solution |
|---|---|---|---|
| Benzene | 1.0000 | $C_6H_7^+$ | |
| Triphenylene | 0.6840 | (+·) | |
| Naphthalene | 0.6180 | (+·) | |
| Phenanathrene | 0.6052 | (+·) | |
| Coronene | 0.5392 | (+·) | |
| Chrysene | 0.5201 | (+·) | |
| Dibenzo[*g*,*p*]chrysene | 0.5115 | ++ | Blue |
| Picene | 0.5019 | +· ⇌ ++ | Green-black |
| Dibenz[*a*,*c*]anthracene | 0.4991 | +· ⇌ ++ | Blue-black |
| Dibenz[*a*,*h*]anthracene | 0.4735 | ++ | Green |
| Benz[*a*]anthracene | 0.4523 | ++ | Blue-green |
| Pyrene | 0.4450 | ++ | Green-black |
| Benzo[*a*]perylene | 0.4392 | ++ | Purple |
| Anthracene | 0.4142 | ++ | Purple |
| Benzo[*a*]pyrene | 0.3711 | ++ | Blue |
| Perylene | 0.3473 | ++ | Purple |
| Naphthacene | 0.2950 | ++ | Green |
| Pentacene | 0.2197 | ++ [c] | Green |
| Octamethylnaphthalene | | ++ | Red |
| 7,12-Dimethylbenz[*a*]anthracene | | ++ | Blue-green |

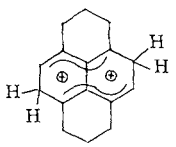
[a] Energy of the highest occupied molecular orbital according to the Hückel method. [b] Dication indicated by ++, monocation by +, radical cation by +·. [c] Dication formed in $SbF_5/SO_2$, but not in $SbF_5/SO_2ClF$; $SbF_5/SO_2$ is a weaker oxidizing agent due to complexation of $SbF_5$ with $SO_2$.



The two consecutive reversible one-electron transfer processes have been reported to occur only if special care is taken to remove residual water from the reaction media. Reaction of the dications **64**, **65**, and **66** with residual water results in irreversibility of the second charge transfer during voltammetry of the corresponding arenes[52].

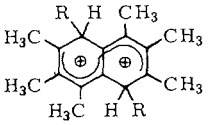
A wide variety of arene radical cation reactions have been suggested to proceed *via* a mechanism involving reactive dications[53–55]. For example, *Shine* and *Murata*[53] have suggested that the preferable mechanism for the reaction of thianthracene radical cations with water involves a carbodication formed by the disproportionation of the radical cation. A similar mechanism has also been proposed for the anodic reaction between pyridine (Pyr) and anthracene (Ant).

$$\begin{aligned} &\text{Ant} &&\rightleftharpoons \text{Ant}^{\ddagger} + e \\ &2\,\text{Ant}^{\ddagger} &&\rightleftharpoons \text{Ant} + \text{Ant}^{2\oplus} \\ &\text{Ant}^{2\oplus} + \text{Pyr} &&\rightleftharpoons \text{Ant Pyr}^{2\oplus} \\ &\text{Ant Pyr}^{2\oplus} &&\rightleftharpoons \text{Further reactions} \end{aligned}$$



### 3.5. Diprotonation of Arenes

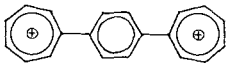
1,6-Methano[10]annulene **67** shows a high reactivity towards sulfonation[66]. This led *Lammertsma* and *Cerfontain*[67] to study protonation of the annulene **67** under superacid conditions. Protonation of the annulene **67** in $FSO_3H/SbF_5/SO_2ClF$ at low temperature gives an interesting cyclopropylenedimethyl dication **68**. It is a diallyl dication in which a substantial portion of the charge is delocalized over the cyclopropane ring.



**67** **68**

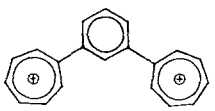
Recently, *Lammertsma*[68] has also obtained the dication **69** by the protonation of hexahydropyrene with "magic acid" in $SO_2ClF$. The dication **69** is the first example of a β,β′-diprotonated naphthalene derivative. *Koptyug et al.* have studied the α,α′-diprotonated 1,2,3,5,6,7-hexa- and octamethylnaphthalenes **70** and **71** under superacid conditions[69].

**69**

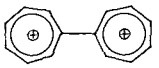


**70**, R = H
**71**, R = $CH_3$

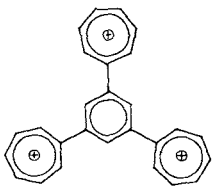
### 3.6. Other Aromatic Dications



The 6π-aromatic tropylium ion **72** has been well studied by many investigators[70] owing to its unusual stability. *Murray* and *Kaplan*[71] generated the di- and tritropylium ions **73**, **74** and **75** in which the seven-membered rings are separated by a benzene ring. Russian workers[72] have been successful in preparing the dication bitropylium **76** by the direct oxidation of bicycloheptatrienyl in $SbF_5/CCl_4$.

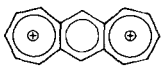


**72**



**73**

**74**



**76**

**75**

The heptalene dication **77**, the benzoditropylium ion **78** and other aromatic dications of this type have been studied theoretically[73], but, despite many attempts, have not been successfully prepared in the laboratory[74].

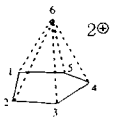
**77**

**78**

### 3.7. Spiesecke-Schneider Relationship

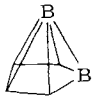
Although earlier workers[75,76] recognized the possibility of a linear relationship between chemical shift ($\delta$) and charge density ($\rho$), the credit for discovery of a good correlation goes to *Spiesecke* and *Schneider*[37,39]. They correlated the charge densities per methine group of the tropylium ion, benzene and cyclopentadienide ion *vs.* their respective $^1$H- and $^{13}$C-NMR chemical shifts. They observed a linear relationship with slopes of 10 ppm/e (e = electron) and 160 ppm/e for the $^1$H- and $^{13}$C-NMR data respectively.

In the early seventies, *Olah* and *Mateescu*[34c] extended the $^{13}$C-NMR chemical shift correlation to a series of mono- and dipositive ions and again obtained a slope of 160 ppm/e, although many aryl-substituted cationic systems were included in the analysis. *O'Brien et al.*[77] have further extended the correlation to a series of nonconjugated and conjugated anions and cations and have obtained similar slopes (156.3 ppm/e) following the general equation



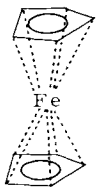
$$\delta_{av} = 289.5 - 156.3\rho_{av}$$

On the other hand, dications by themselves show much larger slopes in such a charge density *vs.* chemical shift plot. In the case of polycyclic arene dications, *Olah* and *Forsyth*[60] obtained a slope of 200 ppm/e. Tetramethylnaphthalene dication **53**[61] shows a deshielding of 192 ppm/e, the octamethylnaphthalene dication **54**[60] an unusual deshielding of 244 ppm/e. This large deshielding has been attributed to steric interactions which might significantly affect chemical shifts in crowded systems. However, monocyclic dications such as tetramethylcyclooctatetraene dication **40c**[44] and [16]annulene dication **48**[50] show much smaller deshieldings of 170 and 153.2 ppm/e, respectively. α,α′-Diprotonated naphthalenes[69] **70** and **71** and the β,β′-diprotonated hexahydropyrene **69** also show deshieldings around 175–180 ppm/e, although they are not Hückel systems with closed shells.



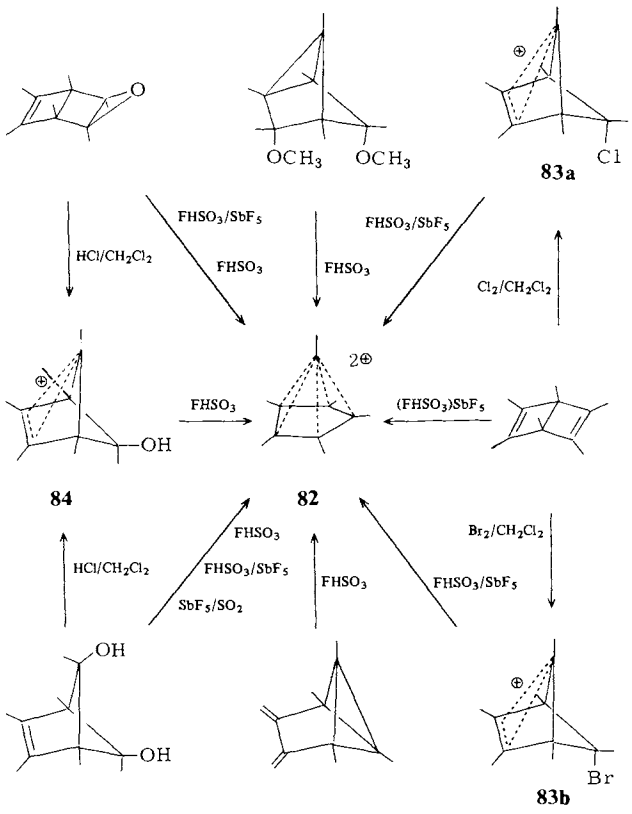
## 4. Hexacoordinate Pyramidal Carbodications

Pioneering investigations to generate carbodications with hexacoordinated carbon atoms have been carried out by *Hogeveen et al.*[78]. The pyramidal dication **79**, which can be considered as structurally related to carborane $C_4B_2C_6$ **80**[79] and ferrocene **81**[80] (following *Williams'* initial suggestion of the pyramidal structure for $C_5H_5^+$ species[79b] based on the $B_5H_{11}$ structure), has resisted attempts at its synthesis, although *ab initio* quantum mechanical



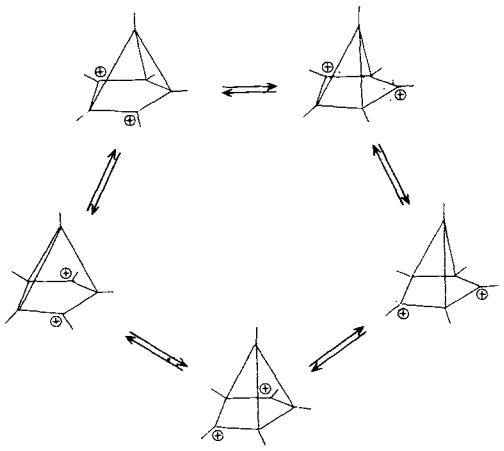
calculations predict this dication to be relatively stable[81]. According to these calculations the most stable structure of **79** is the one in which C6 lies 1.21 Å above the center of the ring[81]. In such a structure the net positive charge on the hydrogen atom of the apical C6 is calculated to be 0.28 units, while 1.71 charge units of the $(CH)_5$ ring is distributed over carbon (0.08 units) and hydrogen (0.28 units).

**79**



**80**

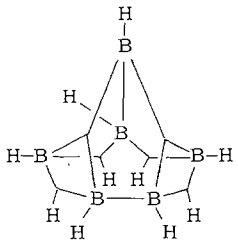
**81**



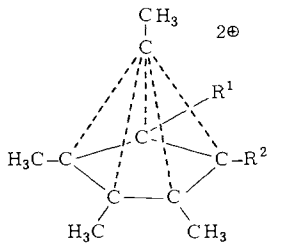
Although the unsubstituted dication **79** is not known, the hexamethyl derivative **82** has been generated at low temperatures from a variety of precursors in superacids[78b].

All synthetic routes have been suggested to involve stepwise ionization *via* the monocations **83** or **84**[78a].

$^1$H- and $^{13}$C-NMR data, the rate of deuterium exchange, the rate of carbonylation and the thermal stability of **82** provide strong evidence for the nonclassical nature of this carbodication[78]. However, the structure can also be considered in terms of the rapidly equilibrating set of structures **85**, which have only one plane of symmetry; during the degenerate process the apical C-atom describes a circle[78].



Although the observed $^1$H- and $^{13}$C-NMR data strongly support the bridged nature of the ion **82**, further definite

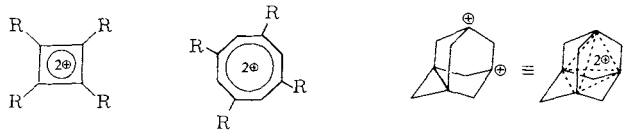


**85**

evidence comes from NMR isotope perturbation studies[82], originally developed by *Saunders et al.*[83] to distinguish classical and nonclassical cations. Very little isotopic perturbation (the degeneracy is not lifted due to $CD_3$ substitution) on the basal carbon signal is observed in the $^{13}$C-NMR spectrum of the dication $[C_6(CH_3)_5CD_3]^{2+}$ indicating that the ion is symmetrically bridged. Other supporting evidence comes from a comparison of the $^{13}$C and $^{11}$B-NMR shifts of the isoelectronic borane $B_6H_{10}$ **86**. *Williams* and *Field*[84] have shown that the $^{13}$C-NMR chemical shifts of a series of nonclassical cations may be compared with the $^{11}$B-NMR chemical shifts of the isoelectronic polyhedral polyboranes.

Recently *Hogeveen et al.*[85] have also prepared the ethyl and isopropyl substituted analogs **87a—d** of the dipositive ion **79**.

**86**



**87a**, $R^1 = CH_3$, $R^2 = C_2H_5$
**87b**, $R^1 = CH_3$, $R^2 = i\text{-}C_3H_7$
**87c**, $R^1 = R^2 = C_2H_5$
**87d**, $R^1 = R^2 = i\text{-}C_3H_7$

## 5. Outlook

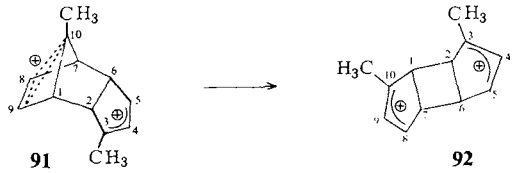
In a short span of less than fifteen years the study of carbodications as directly observable, stable intermediates has shown a remarkable development. Many types of dications, including trivalent (classical) as well as hexacoordinate (nonclassical) systems, have been studied, primarily by NMR spectroscopy. This review, as pointed out earlier, is limited to carbodications under long lived conditions. However, it should be emphasized that a powerful technique is being developed for gas phase studies wherein dipositively charged ions can be detected by doubly charged ion mass spectroscopy. This method will clearly lead to generation of many interesting dications; structures will be suggested for these ions on the basis of quantum mechani-

cal calculations[86]. The challenge will be whether these ions can be observed in the condensed state. There are still a number of systems, such as the Hückel dications of cyclobutadiene (**31**) and cyclooctatetraene (**40**), which are inaccessible in solution. One promising route for their generation appears to be the protolytic cleavage of trimethylsilyl groups from the tetrakis(trimethylsilyl) derivatives **88** and **89**.

5,7-Didehydro-1,3-adamantanediyl dication **90** has been predicted by theory to be a possibly stable nonclassical dication. Attempts to prepare it by a variety of methods[87] have, however, been futile so far, but other approaches may succeed.

**88** **89** **90**

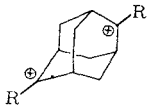
R = $Si(CH_3)_3$



Another powerful technique for elucidating carbodication structures will be by single crystal X-ray structural studies, if single crystals of dication salts can be isolated.

The diversity of dipositive hydrocarbon ions that have been observed and their interesting properties will continue to make this field attractive and the subject of much future research. It also remains to be seen whether dicationic intermediates can be linked to the mechanistic pathway of electrophilic organic transformations and be used as models for specific catalytic reactions.

## 6. Addendum



Since this review was written, several interesting dications have been prepared and characterized under long lived conditions, *i.e.* in superacids at low temperatures. Some of those worth mentioning are:

The *endo*-3,10-dimethyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-diene-3,10-diyl dication **91**[88], which has a novel bishomoaromatic/allylic dication structure. At higher temperatures it stereospecifically rearranges to the symmetrical *cis-anti-cis*-3,10-dimethyltricyclo[5.3.0.$0^{2,6}$]deca-4,8-diene-3,10-diyl dication **92**.

**91** **92**

Several 2,6-disubstituted-2,6-adamantanediyl dications **93** have been prepared and characterized[89]. They are stable only when they contain charge delocalizing substituents such as cyclopropyl or phenyl groups.

**93**

*Support of our work on dications was provided by the National Institutes of Health and National Science Foundation. Dr. T. Rawdah thanks the University of Petroleum Minerals, Dhahran, Saudi Arabia for generous financial support.*

## Three Arguments Supporting a Rectangular Structure for Tetra-*tert*-butylcyclobutadiene**

By *Otto Ermer** and *Edgar Heilbronner*

According to recent theoretical and experimental evidence, cyclobutadiene **1** has a planar rectangular equilibrium structure with $D_{2h}$ symmetry; the optimal square structure ($D_{4h}$) represents a transition state joining two equivalent $D_{2h}$ minima on the potential energy surface[1]. *Irngartinger et al.* interpreted the room temperature X-ray diffraction data of crystalline tetra-*tert*-butylcyclobutadiene **2** in terms of a structure having an almost equilateral four-membered ring[2a]. This led *Borden et al.* to perform quantum mechanical model calculations on **1**, and to conclude that the almost square cyclobutadiene skeleton in the crystal is a plausible equilibrium structure for **2**, since they believed the bulky *tert*-butyl groups to exert a considerable "quadratization effect"[3].

1 2 3 4 5 6

In the formulas, bond lengths determined by X-ray crystallography are given in pm [2].

We give three arguments which, contrary to these conceptions, suggest a rectangular four-membered ring also for **2**:

1. The photoelectron (PE) spectra of **2** to **6**[4] are so closely similar (particularly those of **2** and **3**[4a]) that similar four-membered ring structures may be concluded. Since both the comparison with reliable calculations and the empirical correlation method[4e] lead to an interpretation of the PE spectra of **3** to **6** in terms of the experimentally proven rectangular four-membered ring structures of **3**, **5** and **6**[2], the PE spectrum of **2**[4a] is hardly consistent with a square four-membered ring. In fact, *Schweig* has estimated that a square cyclobutadiene derivative should be approximately 0.7 eV more readily ionizable than a rectangular one. Comparison with other compounds suggests that this estimate is a lower limit.

2. Empirical model calculations based on our force field[5] yield elongations of the double bonds of only 0.6 pm for rectangular **2** and a strain energy reduction of only 1.6 kJ $mol^{-1}$ on going to square **2**. The calculated equidistance of the *tert*-butyl groups also in rectangular **2** is achieved without quadratization essentially by small exocyclic angle deformations at the C atoms of the four-membered ring (C–C=C angles *ca.* 2° larger than C–C–C).

3. The structural model of **2** fitted to the room temperature X-ray intensities is based on *average* atomic positions and has, to a good approximation, $D_{2d}$ symmetry with an almost square four-membered ring[2a]. However, the differences between this $D_{2d}$ structure and the rectangular $D_2$ minimum geometry are so small that the observed structure of higher symmetry may well be a consequence of dynamic or static disorder. In the first case, rectangular $D_2$ minima interconvert in the crystal, *via* the square $D_{2d}$ transition state, to the enantiomeric $D_2$ minima (bond switching), or the disc-shaped molecules execute a (hindered) rotation about the ring axis. In the second case, the crystal contains a statistical distribution of pairs of molecules (with parallel ring planes), in which the partners are mutually rotated by 90° (Fig. 1). The atomic displacements arising from these averaging processes are so small that they are hardly discernible from excessive thermal motion parameters, at least not at room temperature. A rectangular structure for **2** can, therefore, not be ruled out from the available crystallographic results at room temperature. Possibly also low temperature measurements cannot provide a definite answer; such measurements are described by *Irngartinger* and *Nixdorf* in the following communication[2b].

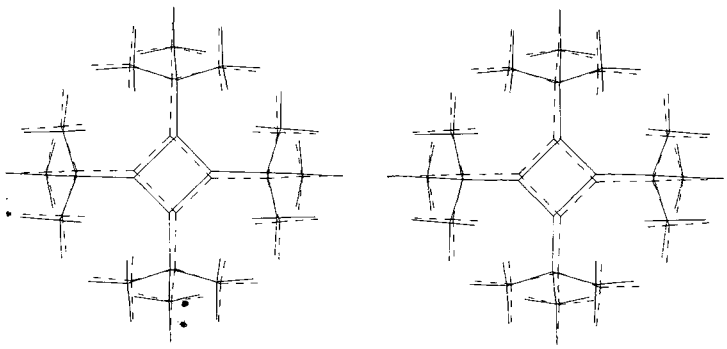

Fig. 1. Proposed disorder model for **2**. The stereoscopic model consists of two calculated rectangular $D_2$ enantiomers mutually rotated by 90° about the ring axis. The averaged structure has $D_{2d}$ symmetry. The distance between the superimposed C atoms of the four-membered rings corresponds to a temperature-factor increase $\Delta U$ of only *ca.* 80 $pm^2$. The remaining atomic positions coincide even more closely.

For the reasons given we conclude that also **2** may have a rectangular four-membered ring structure with dimensions similar to those in **1**, and that the quadratization barriers differ only slightly. The arguments previously put for-

## Bonding Electron Density Distribution in Tetra-*tert*-butylcyclobutadiene—A Molecule with an Obviously Non-Square Four-Membered ring**

By *Hermann Irngartinger** and *Matthias Nixdorf*

We have found by X-ray structure analysis that the sides of the non-planar four-membered ring in tetra-*tert*-butylcyclobutadiene **1** are almost equal (1.464 and 1.483 Å) at room temperature[1a]. Although the actual differences in length are still significant—being of the order of ten times the standard deviation—markedly greater differences of 0.14–0.26 Å occur in the cyclobutadiene derivatives **2** to **4**[1]. In order to explain this discrepancy, we have carried out low-temperature measurements at −30 and −150 °C on **1** and repeated the room temperature measurement with a second crystal on another diffractometer. The repeat measurement yielded, within the limit of error, the same results as earlier. The values at −30 °C (1.466(2) and 1.491(2), 1.493(2) Å) do not seriously differ from the room temperature data. However, measurements of the bond lengths in the four-membered ring at −150 °C yielded the values 1.441(2) and 1.526(1) and 1.527(2) Å, respectively, with a greater difference of 0.086 Å compared to the room temperature data (Fig. 1). Force field calculations and spectroscopic findings likewise clearly indicate a non-square structure for the four-membered ring[2]. The conformation of **1** in the crystal remains almost unchanged at low temperature; within the error of measurement, the angle at which the four-membered ring is folded remains about the same (169.9°).

On the basis of these results we assume that equilibrating effects are operating in the four-membered ring of **1**

**1** **2**, X = S; **3**, X = $CH_2$ **4**

in the crystal at room temperature, due to static or dynamic disorder. Since the bond lengths in the ring differ significantly at room temperature the molecular arrangement in which the double bond is almost parallel to the twofold rotation axis must be more populated than the arrangement perpendicular to it but with otherwise the same orientation of the molecule. This unequal distribution of the disordered molecules is even more pronounced at −150 °C. Whether a completely ordered structure is achieved, is still unclear.

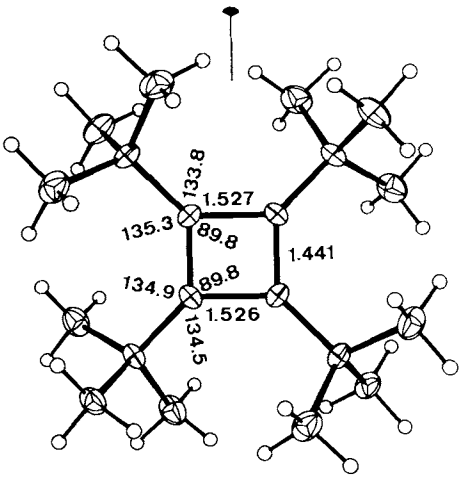

Fig. 1. Bond lengths [Å] and angles [°] of the four-membered ring of **1** at −150 °C; standard deviations 0.002 Å and 0.1° respectively; vibration ellipsoids for 50% probability. Crystallographic data (−150 °C): $a = 17.530(3)$, $b = 9.150(1)$, $c = 11.769(2)$ Å, $\beta = 106.56(2)°$, monoclinic space group C2/c, $Z = 4$. The centric space group derives from statistical tests. Tentative refinement with room temperature data in the space group Cc led to trapezoidal distortion of the four-membered ring. Up to $\sin\theta/\lambda = 1.15$ Å$^{-1}$ ($Mo_{K\alpha}$-radiation) 4813 independent reflections (3184 observed, $I > 3\sigma(I)$); refinement of the C atoms with 953 reflections of higher order ($0.75 < \sin\theta/\lambda < 1.15$ Å$^{-1}$), 11 reflections per variable; $R = 0.048$ [5].

If the low-temperature geometry of the four-membered ring is transferred to the structure at room temperature and an equal population of the two disorder orientations is assumed, then the thermal vibration of 0.0511(5) Å$^2$ vertical to the bisector of the four-membered ring angle and within the ring plane contains a contribution $\Delta U$ of only 0.0009 Å$^2$ (1.8%), thus explaining why no effects of equilibration on the thermal parameters of the four-membered ring atoms were to be observed at room temperature. This value is smaller than that calculated (0.0083 Å$^2$) on the basis of the data for **3**[1a]. The value for **1** has to be set at a higher rate if an incompletely ordered structure is present at low temperatures.

We have experimentally determined the bonding electron density distribution in **1** according to the "X-X" method[3] using the low temperature data (−150 °C) (Fig. 2). The density maxima of the four-membered ring bonds are shifted outwards from the bond axes, so that bent bonds are present, similarly as in the case of **2**[4]. The single bond (with a shift of 0.20 Å) is more strongly bent than the double bond (0.10 Å). Unlike the bond angle of 89.8° (Fig. 1), the angle between the density maxima is 111° (Fig.

2). The maxima of electron densities on the single and double bonds have different values (0.37 and 0.57 e/Å$^3$).

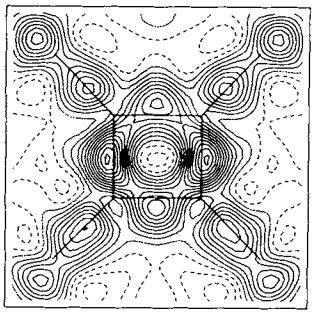

Fig. 2. Deformation densities in the four-membered ring of **1** (2231 $\Delta F$ values from the range $\sin\theta/\lambda < 0.75$ Å$^{-1}$). The contour intervals are 0.05 e/Å$^3$.

Although we cannot rule out equilibration effects also still being effective at low temperatures the differences in the two bond types of the cyclobutadiene system emerge just as clearly in the electron density distribution as in the bond lengths.

## Synthesis and Structure of a Bicyclic SbNP Compound with Intramolecular Donor-Acceptor Bonding**

By *Otto J. Scherer**, *Gotthelf Wolmershäuser*, and *Herbert Conrad*

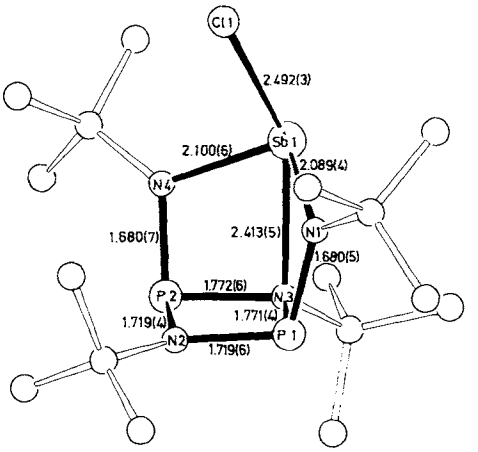
Amino(imino)phosphanes having at least one $(CH_3)_3Si$ group on the amino nitrogen atom are suitable, among other things, for the preparation of various phosphorus-nitrogen-element heterocycles[1]. Treatment of *tert*-butylimino(*tert*-butyltrimethylsilylamino)phosphane **1** with $SbCl_3$ represents a new variant of this reaction; the four-membered ring compound ClSb(NR)PClNR, which is the product expected by analogy to the reaction with $AsCl_3$[2], is not formed, and the reaction yields the SbNP bicycle **2**[3].

**1**

R = $C(CH_3)_3$, R' = $Si(CH_3)_3$

**2**

**2** forms colorless, air-sensitive crystals [m.p. > 130 °C (decomp.)] which are readily soluble in dichloromethane, benzene, and toluene and moderately soluble in ether and pentane. According to the crystal structure analysis, **2** has a planar $P_2N_2$ four-membered ring, which is bridged by a symmetrical NSbN bridge (Fig. 1). The lone pair of electrons of N3 bond coordinatively to antimony; the considerably larger distances 1.771(4) and 1.772(6) Å for P1–N3 and P2–N3, respectively, can therefore be considered as an ideal model for PN single-bond lengths in molecules with trivalent phosphorus.



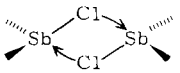


Fig. 1. Molecular structure of **2** (molecule 1) in the crystal. Selected bond angles [°]: Cl1-Sb1-Ne 147.2(1), Cl1-Sb1-N4 95.1(2), Cl1-Sb1-N1 94.5(2), Sb1-N1-P1 107.3(2), Sb1-N4-P2 107.2(2), N1-Sb1-N4 103.5(2), N2-P2-N4 107.3(3), N3-P2-N4 91.8(3), N1-P1-N3 91.6(2), N1-P1-N2 108.0(3), Sb1-N3-P2 92.4(3), Sb1-N3-P1 92.1(2).—Crystal structure data: space group: triclinic $P\bar{1}$: $a = 9.5564(9)$, $b = 9.613(1)$, $c = 31.229(2)$ Å; $\alpha = 79.731(6)$, $\beta = 80.065(6)$, $\gamma = 60.450(8)°$; $V = 2444.0$ Å$^3$, $Z = 4$ (two independent molecules, which do not significantly differ in their individual distances and angles); $\rho_{calc} = 1.369$ g·cm$^{-3}$: 7872 independent reflections, $R = 0.044$, $R_w = 0.050$. Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Energie, Physik, Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CSD 50338, the names of the authors, and the journal citation.

The distorted trigonal-bipyramidal environment at antimony is comparable with that in $Cl_3Sb \cdot H_2NC_6H_5$(A) (A: Sb–$Cl_{(ax)}$ 2.52, Sb–N 2.53 Å, Cl–Sb–N 166.3°[4]). As expected, the greatest difference occurs in the NSbCl axial angle (147.2° in **2**). The $^1$H-NMR spectrum (200 MHz, solvent, $C_7D_8$, TMS int.) exhibits three signal groups at room temperature: $\delta = 1.52$ ("t", $A_9XX'A_9'$ system, 18H (SbN), $|^4J_{PH} + {}^6J_{PH}| = 2.1$ Hz). 1.35 ("t", 9H (PN), $|^4J_{PH} + {}^6J_{PH}| = 1.9$ Hz); 1.25 (s, 9H (PN)). $^{31}$P{$^1$H}-NMR ($C_7D_8$, 85% $H_3PO_4$ ext.): $\delta = 159.8$ (s). Temperature dependent $^1$H-NMR studies of a 30% toluene solution of **2** indicate that the different $(CH_3)_3C$ signals of the $P_2N_2$ four-membered ring coalesce at *ca.* 80 °C, whereas in a 20% solution this occurs at *ca.* 120 °C (extrapolated). This result indicates that the inversion of configuration at anti-

## (*Z*)-2-Methoxy-1,2-diphenylvinyl Alcohol, A Remarkably Stable Enol**

By *John F. McGarrity*, Alex Cretton, Alan A. Pinkerton, Dieter Schwarzenbach,* and *Howard D. Flack*

The isolation and structural determination of simple enols has attracted renewed attention recently[1,2]. Until now the only enols isolated have been stabilized by electron-withdrawing or extremely bulky substituents. Less substituted enols such as, *e.g.*, vinyl alcohol[3] have been observed as intermediates in solution, but have not been isolated prior to tautomerization to their more stable keto forms. We now describe the isolation and characterization of (*Z*)-2-methoxy-1,2-diphenylvinyl alcohol **2**, formed stereoselectively under kinetic control.

The acid-catalyzed methanolysis of benzoyl-α-diazotoluene **1** to yield 2-methoxy-1,2-diphenylethanone **3** occurs *via* an intermediate which can be crystallized directly from the reaction mixture. After complete removal of solvent, the intermediate's spectral characteristics [IR: $\nu_{max}$ 3515 $cm^{-1}$ (enol OH); UV: $\lambda_{max}$ 301 nm ($\varepsilon$=4940); $^1$H-NMR (80 MHz, $CDCl_3$, 25 °C, TMS): $\delta$=3.45 (s, 3H), 5.91 (s, 1H), 7.13 (s, 10H)] indicate structure **2**. This assignment was supported by a variety of characteristic reactions (Scheme 1) and by an X-ray structure analysis at −40 °C (Fig. 1).

Scheme 1. Characteristic reactions of **2**. a: $Et_3N$, $10^{-2}$ M in tetrahydrofuran (THF) −30 °C; b: $O_2$, THF; c: $Ac_2O$, $BF_3 \cdot Et_2O$ −50 °C; d: $(CF_3CO)_2O$, $Et_3N$, THF, −30 °C; e: tetracyanoethylene, $CH_2Cl_2$; f: NaH, THF, $(CH_3O)_2SO_2$.

Initial mechanistic studies on the transformation **1**→**2** indicate that protonation on oxygen followed by loss of nitrogen leads to a vinyl cation. The *Z* stereochemistry of the product is a consequence of kinetically controlled attack of

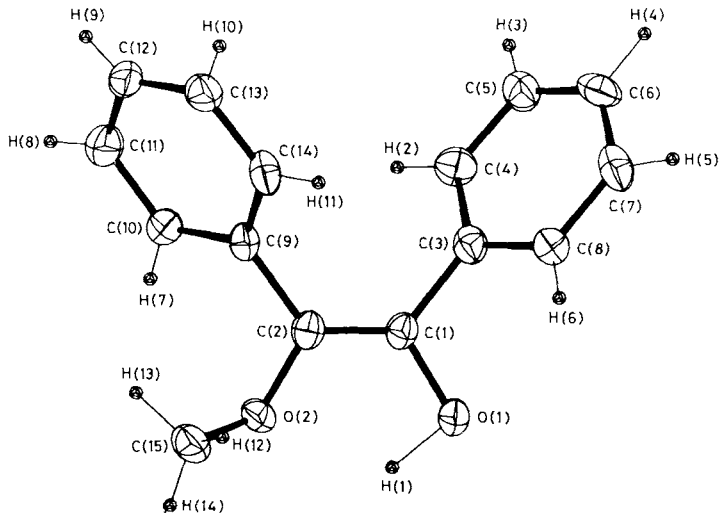

Fig. 2. Crystal structure of **2** · MeOH in the crystal; the solvent atoms are not indicated.

the solvent methanol on the less hindered side of the vinyl cation. Selective attack on this side may also benefit from steering of the incoming nucleophile by hydrogen bonding to the enolic OH group.

## Synthesis of C-α- and C-β-D-Glucopyranosyl Derivatives from *O*-(α-D-Glucopyranosyl) Trichloroacetimidate**

By *Richard R. Schmidt** and *Michael Hoffmann*

Functionally substituted *C*-glycopyranosides occur as subunits of a variety of natural products. The synthesis of these chiral tetrahydropyran intermediates is therefore of topical preparative importance[1]. Especial interest attaches to the C-α- and C-β-D-glucopyranosyl derivatives, whose synthesis has hitherto presented problems[1,2].

Base-catalyzed reaction of tetra-*O*-benzylglucose **1** with trichloroacetonitrile affords directly and almost quantitatively the *O*-(α-D-glucopyranosyl) trichloroacetimidate **2**, which has proven useful for the synthesis of *O*-glycosides and saccharides[3]. An equally facile and highly stereoselective synthesis of C-α- and C-β-D-glucopyranosyl derivatives has now been achieved with various silylated aliphatic *C*-nucleophiles[4] (see Table 1).

Reaction of **2** with trimethylsilyl cyanide in the presence of boron trifluoride etherate or trimethylsilyl trifluoromethanesulfonate as catalyst affords exclusively the β-D-glucopyranosyl cyanide **3β**. Likewise, with 1,4-bis(ethoxy)-1,4-bis(trimethylsiloxy)-1,3-butadiene predominantly the β-anomer **4β** was obtained. Application of these reaction conditions to enol silyl ethers furnished anomeric mixtures; for example, with the enol silyl ether of acetophenone the anomers **5α**, **β** were formed in the ratio 1 : 1. The tendency for direct formation of the α-anomers to take place with this nucleophile could be exploited for the exclusive formation of **5α** using zinc chloride catalyst. Similarly, with the enol silyl ethers of *tert*-butyl methyl ketone and acetone only the α-anomers **6α** and **7α**, respectively, were obtained. Allyltrimethylsilane as *C*-nucleophile under these reaction conditions led almost exclusively to the important 1-allyl-1-deoxy-α-D-glucopyranose **8α**[1a] (α : β = 10 : 1).

The structure of **8α** was confirmed by comparison[1a]. The structures of **3β**—**5β** and **5α**—**7α** follow from their $^1$H-NMR data, from comparison with each of the other anomers[4,5], and, in the case of **4β**, **5α** and **5β**, also from $^1$H-NMR data of the derivatives obtained by debenzylation and acetylation.

## A Novel Synthetic Route to the Aldosterone-Antagonist Spirorenone

By *Karl Petzoldt**, *Henry Laurent*, and *Rudolf Wiechert*

We recently reported the synthesis of the spirorenone **7**, a novel, highly active aldosterone-antagonist[1]. Starting from 3β-hydroxy-5-androsten-17-one **1**, the title compound **7** was obtained in 1.5% overall yield *via* a 15-step synthesis. We now wish to report an entry to **7** involving unexpected reactions, in which the number of synthetic steps is reduced to 11 and the yield of **7** is increased to 5.6% (Scheme 1).

[*] Dr. K. Petzoldt, Dr. H. Laurent, Prof. Dr. R. Wiechert
Forschungslaboratorien der Schering AG Berlin/Bergkamen
Müllerstrasse 170—178, D-1000 Berlin 65 (Germany)

The first step of the synthesis now consists in a microbiological dihydroxylation using the fungal strain *Colletotrichum lini*, whereby two hydroxy groups are introduced into the 7α- and 15α-position of androstenolone **1** to give **2** in 85% yield. This dihydroxylation has already been performed with microorganism cultures of the species *Gibberella saubinetti*[2] and *Glomerella cingulata*[3].

Scheme 1. *A: Collectotrichum lini*, substrate concentration 1 g/L culture broth, fermentation time 36 h; *B*: $BF_3 \cdot (C_2H_5)_2O$ in acetone, −10 °C, 1 min; *C*: HCl conc. in methanol, 0 °C, 10 min; *D*: 35% $HClO_4$ in methyl isobutyl ketone, RT, 4 h; *E*: $(CH_3)_3CCOCl$, 4-dimethylaminopyridine in pyridine, 50 °C, 4 h; *F*: trimethylsulfoxonium iodide ($(CH_3)_3SO^+I^-$), NaOH in dimethyl sulfoxide, RT, 1 H.—Yields [%], melting points [°C] (Mettler FP11, 2 °C/min) and $[\alpha]_D^{22}$-values ($c = 0.5$ in $CHCl_3$): **2**: 85, 218.2, −45.2; **3**: quant., 168.1, +86; **4**: 95, 189.4, +118.4; **5**: 90, 180.8, +83.4; **6**: 91, 240.3, −48.6.

The isomerization of the allylic 7α-hydroxy function, a further essential step of the synthesis, can be accomplished in two ways: either by preparation and subsequent cleavage of the acetonide **3**, which for steric reasons obviously only exists in the 7β,15α-substituted form, or by direct acid-catalyzed epimerization of **2** in methyl isobutyl ketone, whereupon the equilibrium lies 97% on the side of the 7β-triol **4**.

Surprisingly, **4** can be selectively esterified with pivalic acid chloride in presence of 4-dimethylaminopyridine to give the 3β,15α-dipivalate **5**, which could be directly converted under Corey methylation conditions into the 15β,16β-methylene compound **6**. At this point, the synthesis then follows the previously described preparative route[1] and leads after 7 further synthetic transformations to spirorenone **7**.

## GaGaTe, a Novel Defect Tetrahedral Structure

By *Dieter Fenske* and *Hans Georg von Schnering**

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

Systematic experiments to prepare ternary quasi (III—V)-phases yield GaGaTe[1], which at the same time was found to be the only stable compound in the ternary system Ga—Ga—Te by *Kra et al.*[2]. GaGeTe crystallizes from a melt of the elements in the form of dull-grey hexagonal crystals, which cleave like graphite parallel to the hexagonal (001) plane (quartz ampoules; melting of the elements at 1150 K; GaGeTe crystallizes peritectically at 1073 K). The compound is stable towards $H_2O$, air and NaOH (25%). In cold hydrochloric acid (10%), colorless crystalline reaction products occur on the cleavage faces after a few days. GaGeTe is a semiconductor with $\Delta E = 1.1$ eV[3]. From the electron balance (VEC = 4.33) and the structural chemistry of the participating elements a defect tetrahedral structure of the type $3_4 4_4 0_1 6_4$[4a] may be expected. This was confirmed by the structure determination[5].

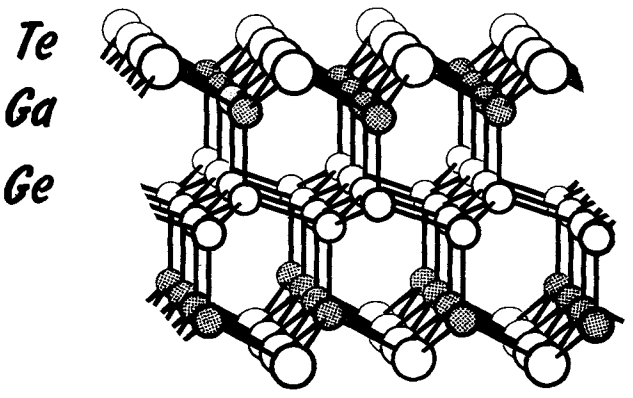

Fig. 1. Two-dimensional structural unit of GaGeTe. Distances [Å]: Ge—Ge = 2.461; Ge—Ga = 2.440; Ga—Te = 2.656; Angles [°]: Ge—Ge—Ge = 110.7, Ge—Ge—Ga = 108.3; Ge—Ga—Te = 118.3; Te—Ga—Te = 99.3; Ga—Te—Ga = 99.3 [5].

GaGeTe presents a novel structure type, characterized by two-dimensional infinite block layers of the type $^2_\infty$[Te—Ga—Ge—Ge—Ga—Te]. The structure (Fig. 1) derives from that of GaSe, $^2_\infty$[Se—Ga—Ga—Se], by insertion of a puckered layer of tetrahedrally bonded Ge-atoms in the form of annelated six-membered rings with chair conformation. The two-dimensional block layers are segments of the diamond structure.

Heisenbergstrasse 1, D-7000 Stuttgart 80 (Germany)
Prof. Dr. D. Fenske
Institut für Anorganische Chemie der Universität
Engesserstrasse Geb. Nr. 3045, D-7500 Karlsruhe (Germany)

Te is bonded to 3 Ga (2.656(3) Å), Ga to 3 Te and 1 Ge (2.440(3) Å) and Ge to 1 Ge and 3 Ge (2.461(3) Å). The intralayer Te–Te distances are 4.048 Å, whereas the interlayer distance is 4.133 Å. The formal description of the compound with $Te^{2-}$, $Ge^{2+}$ and $Ge^0$ takes into account the electronegativities of the elements and shows the relation to the monochalcogenides of gallium. The molecular volume of GaGeTe (49.7 $cm^3\ mol^{-1}$) corresponds exactly to the volume of GaTe and Ge (49.8 $cm^3\ mol^{-1}$), but is noticeably larger than that of the elements (45.8 $cm^3\ mol^{-1}$)[5].

## Are the Previously Described $[ClF_6][CuF_4]$ and $[Cu(H_2O)_4][SiF_6]$ Identical?

By *Hans Georg von Schnering** and *Dong Vu*

*Dedicated to Professor Harald Schäfer on the occasion of his 70th birthday*

In 1980 *Batsanov et al.*[1] published a sensational paper on the occurrence of the compound hexafluorochlorine(VII) tetrafluorocuprate(III) $[ClF_6]^+[CuF_4]^-$. A small portion of crystalline products was obtained, following the shock-wave compression of a mixture of $CuCl_2$ and $CuF_2$. The crystal structure investigation on single crystals revealed square-planar $[CuF_4]$ units and $[ClF_6]$ octahedra. However, the observed paramagnetism and the blue color of the compound significantly contradict the square-planar structure of the $CuF_4$ anions. Instead, diamagnetism and an octahedral $Cu^{II}$-coordination would be expected. Finally, the authors reported, that no chlorine could be detected in the crystalline product on chemical analysis.

Upon discussing these problems[3], aroused by critical comments by *K. O. Christe* at the 10th International Symposium on Fluorine Chemistry in Vancouver (1982), we decided to examine the crystallographic data[1]. First, the determination of the crystal structure seems to be correct ($R = 0.07$). However, we found large discrepancies in the following details: (a) The molar volume was calculated to be 108 $cm^3\ mol^{-1}$, which is unexpectedly large, especially for a high pressure phase (according to *Biltz*[4] it is estimated to be 96 $cm^3\ mol^{-1}$); the experimental density is also 6% smaller than expected. (b) The coefficients of the temperature factors $B$(Cl), $B$(F4) and $B$(F5) are two to three times larger than the values of the corresponding scattering centers of Cu, F1, F2 and F3, respectively; thereby, it is particularly surprising that F4 and F5 form the Cu-coordination.

The following considerations showed that tetraaquacopper(II) hexafluorosilicate $[Cu(H_2O)_4]^{2+}[SiF_6]^{2-}$ would be a perfect candidate to fulfill all of the critia: color, paramagnetism, lack of chlorine, molar volume (an estimated 111 $cm^3\ mol^{-1}$), density, $B_{ij}$ temperature factors, crystal structure and interatomic distances! Since the authors did not report the exact experimental conditions (material of the ampoules, quality of the educt) under which the reaction occurred, we could not reproduce their experiment using a similar apparatus. Therefore, the presence of $H_2O$ and Si is still speculative. We found, that the compound $[Cu(H_2O)_4][SiF_6]$ has been known for a long time and is well characterized[5]. Table 1 shows that lattice constants, space group, and atomic parameters and thus interatomic distances for "$[ClF_6][CuF_4]$"[1] and $[Cu(H_2O)_4][SiF_6]$[5] are identical.

Table 1. Lattice constants and atomic parameters of $[Cu(H_2O)_4][SiF_6]$ **1** and "$[ClF_6][CuF_4]$" **2**. Data of **2** transformed according to *abc*→*cba*.

| | *z* | −0.2402(12) | −0.2412(6) | *x* | |

The fascinating perfluorated cation $[ClF_6]^+$[6] is obviously not obtained in the above mentioned way. For the growth of the crystal $[Cu(H_2O)_4][SiF_6]$ from $CuCl_2$ and $CuF_2$ according to *Batsanov et al.*[1] a small amount of moisture and a quartz-wall are needed.

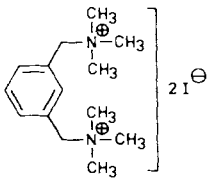
# A Novel Type of Ionic Clathrands for Numerous Inclusion Compounds**

By *Fritz Vögtle**, *Hans-Gerd Löhr*, *Heinrich Puff*, and *Willi Schuh*

For studies of dyestuff ionophores[1] we are interested in crown ethers with azulene building blocks, such as **1**, for whose synthesis[1] *N,N'*-[1,3-azulenylenebis(methylene)]-bis(trimethylammonium) diiodide **2a**[2] has proved valuable.



1: X = S,O

2a: R = R' = $CH_3$

2b: R = $CH_3$, R' = $C_2H_5$

3

In the synthesis of **2a** by alkylation of *N,N'*-[1,3-azulenylenebis(methylene)]bis(dimethylamine)[2] with excess iodomethane followed by crystallization from ethanol, varying amounts of iodomethane and ethanol are retained by **2a**. They are not even removed after drying for several days at 25 °C/0.1 torr. Attempts at recrystallization indicate that **2a** incorporates many types of solvent molecules, generally in stoichiometric ratios (cf. Table 1). Because of its ionic structure and colored azulene building block, the diammonium compound **2a** represents a unique example of the still rare clathrate formers (cf.[3]).

Table 1. Clathrates of the novel clathrands **2a** and the comparable host compounds **2b** and **3** (Selection).

| Clathrand | Mol. ratio Host/Guest | Guest molecules |
|---|---|---|
| **2a** | 1:1 | $C_2H_5OH$, 1-$C_3H_7OH$, 2-$C_3H_7OH$, 1-$C_4H_9OH$, 2-$C_4H_9OH$, 1-$C_5H_{11}OH$, 1,2-$C_2H_4(OH)_2$, $C_2H_5SH$, $(CH_3)_2NCHO$, $CHCl_3$, $CCl_4$, $CH_3I$, $C_2H_5I$, $CH_3NO_2$, 2-$C_3H_7NO_2$, *c*-$C_5H_5N$ |
| | 1:2 | $CH_3COOH$ |
| | 1:3 | $BrCCl_3$ |
| | 3:2 | *i*-$C_4H_9OH$, $CH_3CN$, $(CH_3)_2CO$ |
| | nonstoichiom. | $H_2O$, $CH_2Cl_2$ |
| **2b** | ca. 1:2 | $C_2H_5OH$ |
| **3** | 1:1 | $CH_3OH$ |
| | nonstoichiom. | $CH_3CN$, $CH_3COOH$ |

Table 1 shows the violet to red stoichiometric inclusion compounds of the colored [$\lambda_{max}$ = 624 (sh), 567 (sh), 537 nm; in EtOH[2] "clathrands"[4], **2a**, obtained so far. The guest selectivity emerges from the series of homologous alcohols; whereas methanol does not form a stable inclusion compound with **2a**, stoichiometric clathrates are obtained with ethanol to 1-pentanol. Still higher primary *n*-alcohols as well as secondary and branched ones—with the exception of 2-propanol, 2-butanol, and 2-methyl-1-propanol—do not form inclusion compounds. The novel clathrates decompose at temperatures considerably above those of the boiling points of the guest compounds. This, together with the tendency of the clathrates to crystallize well, may result from the ionic lattice of **2a**.

X-ray structure analysis[5] of the iodomethane adduct of **2a** confirms that a lattice inclusion, a clathrate, is encountered. Iodomethane is located in a crystal lattice cavity between two trimethylammonium groups, two iodide ions, and the herring-bone-pattern alternating stacks of layered azulene rings (Fig. 1).

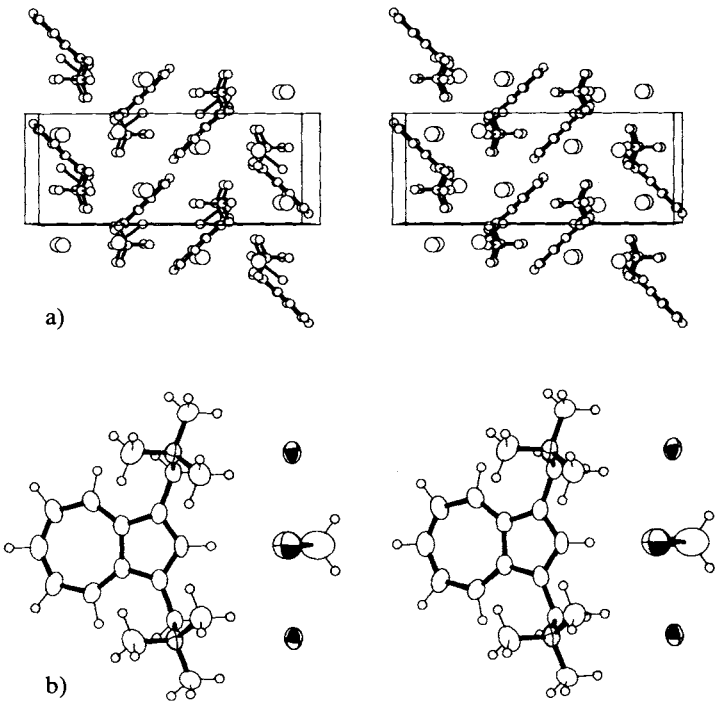


Fig. 1. X-Ray structure of the iodomethane clathrate **2a** · $CH_3I$ (stereoscopic illustrations): a) unit cell, view across the azulene ring planes, b) view perpendicular to the azulene ring plane.

The effect of variations in the host structure of **2a** on its ability to form inclusion compounds was investigated. Under analogous conditions the *m*-phenylenebis(methylene) compound **3**, in fact, yielded inclusion compounds; however with lower stability and with different guest selectivity (Table 1). The bis(ethyldimethylammonium) compound **2b**, prepared by reaction of iodomethane with *N,N'*-[1,3-azulenylenebis(methylene)]bis(dimethylamine) in methanol, crystallizes with difficulty; so far, only with ethanol has an inclusion compound been obtained (Table 1).

## Twist Conformation of Tetrahydrofuran in the Crystal**

By *Peter Luger** and *Jürgen Buschmann*

The preferred conformation of tetrahydrofuran, a fundamental structural element of carbohydrates and other important biological compounds, is not known. Although theoretical and experimental studies have tackled this question, in the final analysis they do not provide a definitive answer. According to the results of force field[1] and *ab initio* calculations[2], the twist form ($C_2$) should be energetically favored; however, the envelope form ($C_s$ is only slightly less stable (1 kcal/mol). Experimental investigations, such as electron diffraction studies[3,4], suggest almost free pseudorotation in the gas phase, but do not definitely rule out static forms.

We have now determined the conformation at temperatures of $-170\,^{\circ}C$ and $-125\,^{\circ}C$ by single crystal X-ray structure analysis. Tetrahydrofuran (THF) crystallizes in the monoclinic space group C2/c with 4 molecules in the unit cell (lattice constants at $-170\,^{\circ}C$: $a=607.6(9)$, $b=891.4(9)$, $c=774.3(11)$ pm, $\beta=106.11(12)^{\circ}$; at $-125\,^{\circ}C$: $a=618.6(2)$, $b=894.0(2)$, $c=783.5(2)$ pm, $\beta=106.41(2)^{\circ}$). Since a DTA plot between $+20\,^{\circ}C$ and $-140\,^{\circ}C$ contained no further signal below the melting point, and X-ray structure studies down to $-170\,^{\circ}C$ always indicated the same lattice, THF (at least down to $-170\,^{\circ}C$) has no further crystalline phases.

As shown by the structural analysis, the molecule lies on the twofold axis of the space group (Fig. 1). In consequence, the molecule possesses ideal $C_2$ symmetry in the crystal. The puckering parameters after *Cremer* and *Pople*[7] are $q_2=34.8(5)$ ($-170\,^{\circ}C$) and 35.5(4) pm ($-125\,^{\circ}C$), and $\varphi_2=90(-)^{\circ}$. The CO, CC, and CH bond lengths, respectively, (CC and CH determined from two and four independent values, respectively) at $-170\,^{\circ}C$ are 142.9(6), 151.1(7), and 105(5) pm, and at $-125\,^{\circ}C$ 143.5(5), 153.1(10), and 109(5) pm.

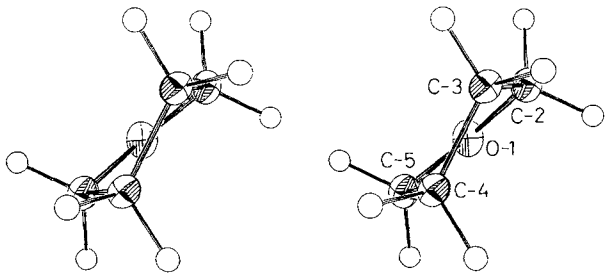

Fig. 1. Molecular model of tetrahydrofuran in the crystal.

Table 2 gives the bond and torsion angles we found; for comparison, the values from electron diffraction studies and from the *ab initio* calculation (4—31G basis set) of *Cremer* and *Pople*[2] are included. The data are in good agreement with each other; only the difference between the COC and the OCC bond angle is not so large in the crystal.

Table 2. Bond angles, torsion angles, and puckering amplitude $q_2$ of tetrahydrofuran determined by X-ray structure analysis (XR), electron diffraction (ED), and *ab initio* calculation (AI).

| | XR (−170 °C) | XR (−125 °C) | ED [3] | ED [4] | AI [2] |
|---|---|---|---|---|---|
| COC [°] | 108.2(4) | 109.8(3) | 110.5 | 111.6 | |
| OCC [°] | 107.4(4) | 106.7(4) | 106.5 | 105.6 | |
| CCC [°] | 102.0(4) | 101.9(3) | 101.8 | 101.9 | |
| C5-O1-C2-C3 [°] | −11.5(4) | −11.7(3) | −11.6 | −11.8 | |

## *syn*-Benzene Dioxide/1,4-Dioxocin Systems *via* a Diels-Alder Route

By *Hans-Josef Altenbach, Burkhard Voss,* and *Emanuel Vogel**

In 1968 *Witkop et al.*[1] proved that the arene oxides or arene oxide/oxepin systems[2], which shortly before this had been discovered in the course of experiments directed at verifying the Hückel rule, play a central role in the metabolism of aromatic compounds; as a consequence, the chemistry of these compounds has rapidly become an interdisciplinary area of research. The *syn*-benzene dioxides **1**[3], which were described later and which exist in equilibrium with 1,4-dioxocins, were also recognized to be biochemically relevant[4]; however, they are only accessible

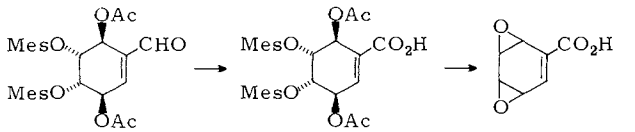
with difficulty. We report here a versatile synthetic pathway leading to *syn*-benzene dioxides and their dioxocin valence tautomers *via* a Diels-Alder route.

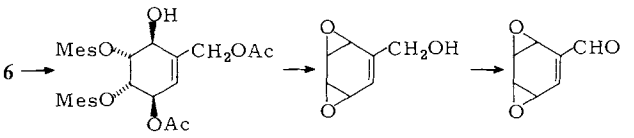


**1** **2**

**a**, R = H [3a]
**b**, R = Br [3b]
**c**, R =  [4]
**d**, R = $CO_2H$
**e**, R = COCl
**f**, R = $CH_2OH$
**g**, R = CHO

*trans,trans*-1,3-Butadienylene diacetate **3**, a valuable diene component for the synthesis of natural products with highly oxygenated cyclohexane-frameworks *via* Diels-Alder routes[5], reacts with excess propiolaldehyde to give the adduct **4** (m.p. = 79—80 °C, 89%). $OsO_4$-catalyzed oxidation of **4** with hydrogen peroxide (cf. Scheme A) leads to *cis*-hydroxylation of the 4,5-double bond to give a diol, to which, based on the assumption that the attack of the oxidant occurs from the sterically more favorable side of the ring, we assign the structure **5** (m.p. = 174—175 °C, 60%). Attempts to convert the bismesylate **6** (decomp. 167 °C, 71%) of the diol **5** with KOH in aqueous methanol into the *syn*-benzene dioxide **1g** afforded aromatic products—presumably as a result of an initial attack of the base at the conjugated double bond in the sense of a Michael reaction. As an alternative, the acid **7**, instead of the aldehyde **6** (Scheme A), or the corresponding alcohol and its isomer **8**, respectively (Scheme B), can be treated with base.

**3** **4** **5**



**6** **7** **1d**

Scheme A. **3**→**4**: No solvent, 70 °C, 30 h; **4**→**5**: acetone/$H_2O$, $OsO_4$/30% $H_2O_2$, 0 °C, 72 h; **5**→**6**: $CH_2Cl_2$/$NEt_3$, MesCl, −15 °C/RT, 40 min; **6**→**7**: acetone $CrO_3/H_2SO_4/H_2O$, 0 °C, 30 min; **7**→**1d**: MeOH, $KOH/H_2O$, −10 °C/RT, 30 min.

**6** can best be oxidized to **7** (decomp. 189 °C, 92%) using Jones' reagent. Treatment of **7** with base yields, as uniform product, the *syn*-benzene dioxide carboxylic acid **1d** (m.p. = 145—146 °C, 81%). The dominance of the epoxide ring closure in **7** can be attributed to formation of the carboxylate, which suppresses nucleophilic additions to the double bond. In refluxing tetrachloromethane **1d** isomerizes almost completely within 24 h to 1,4-dioxocin-6-carboxylic acid **2d** (m.p. = 93—94 °C). Heating either **1d** or **2d** in methanol leads to an equilibrium mixture containing the valence tautomers in the ratio 32:68.

Derivatization of the acid **2d** to the methyl ester or amide can advantageously be carried out *via* the acid chloride **2e**, prepared by means of sulfinyl chloride, since this can readily be isolated as a uniform valence tautomer upon recrystallization (m.p. = 32 °C, 90%).

**8** **1f** **1g**

Scheme B. **6**→**8**: $CH_2Cl_2$, $NaBH_4/H_2O$, RT, 3 h; **8**→**1f**: MeOH, $KOH/H_2O$, −10 °C/RT, 30 min; **1f**→**1g**: acetone, $MnO_2$, RT, 45 min.

Contrary to expectations, reduction of the aldehyde **6** with $NaBH_4$ does not afford the corresponding alcohol, but—*via* an acyl migration which does not influence the synthetic concept—the isomeric alcohol **8** (m.p. = 109—110 °C, 75%). This rearrangement apparently proceeds from the alcoholate, which is formed by attack of a hydride ion at the aldehyde function in **6**. As suggested by the behavior of **7**, treatment of **8** with base also leads smoothly to epoxide ring-closure; moreover, the primary OAc group is hydrolyzed, so that **1f** is isolated as the reaction product (m.p. = 93 °C, 60%). **1f** is readily oxidized by $MnO_2$ to **1g** (m.p. = 40 °C, 50%). Finally, heating **1g** in acetone leads quantitatively to the relatively volatile 1,4-dioxin-6-carbaldehyde **2g**, which was proved to be a uniform valence tautomer by NMR spectroscopy (short path distillation, 70 °C bath temp. 0.2 torr, 94%).

**2e** and **2g** are attractive starting materials for the synthesis of the natural product LL-Z1220 **1c**.

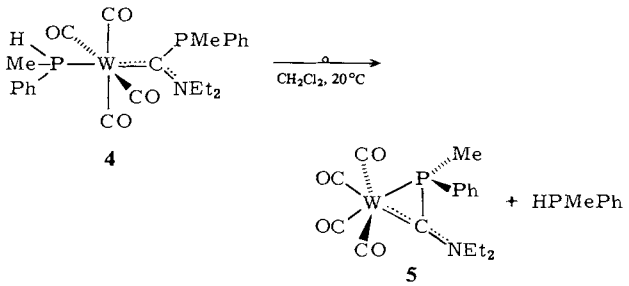
## Synthesis and Structure of $(CO)_4W[C(NEt_2)PMePh]$, A Novel Cyclic Carbene Complex[1]



By *Ernst Otto Fischer**, *Rudolf Reitmeier*, and *Klaus Ackermann*

Numerous neutral aminocarbene complexes of the type $[(CO)_5M[C(NEt_2)X]]$, which are usually inaccessible *via*

[*] Prof. Dr. E. O. Fischer, R. Reitmeier, Dr. K. Ackermann

conventional direct routes, have been synthesized by addition of anionic nucleophiles $X^-$ to the carbyne carbon atom of the cationic aminocarbyne complex in the compounds $[(CO)_5MCNEt_2]BF_4$ (M = Cr, W)[2,3]. If the same carbyne complexes are allowed to react with strongly reducing nucleophiles such as $R_2E^-$ (R = alkyl, aryl; E = element of the 5th main group) then some completely different types of products can be formed, *e.g.* the μ-bis(aminocarbene) complex $[(CO)_5MCNEt_2]_2$, by reductive $C_\alpha C_\alpha$ coupling of two carbyne fragments[4,5]. With very strongly reducing nucleophiles this reductive dimerization can become the dominating competing reaction over the addition of the nucleophile. Thus, in the reaction of $[(CO)_5WCNEt_2]BF_4$ **1** with potassium methylphenylphosphide the major product is the biscarbene complex $[(CO)_5WCNEt_2]_2$ **2**; as by-products, the mononuclear adduct $[(CO)_5W\{C(NEt_2)PMePh\}]$ **3** and the *trans*-carbene-phosphane complex **4** can also be isolated[5]. On warming in solution, the latter complex exhibits the remarkable property of undergoing dissociation of the phosphane ligand with spontaneous rearrangement to give the novel cyclic carbene complex **5**:

The complex **5**, whose structure has been confirmed spectroscopically as well as X-ray crystallographically, is one of the few compounds in which a carbene ligand is component of a three-membered metallacycle containing a further main group element[9].

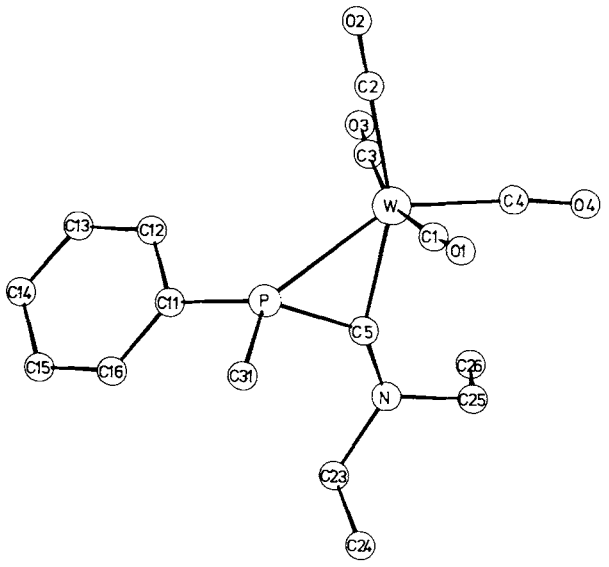

Fig. 1. Molecular structure of tetracarbonyl[$\eta^2$-diethylamino(methylphenylphosphino)carbene]tungsten **5** in the crystal.

Important bond lengths [pm] and angles [°] with standard deviations.

| | | | |
|---|---|---|---|
| W–P | 246.5(3) | W–C5 | 210.8(10) |
| P–C5 | 180.7(10) | N–C5 | 127.7(12) |
| P–W–C5 | 45.7(3) | C5–P–C11 | 114.1(5) |
| W–P–C5 | 56.7(3) | C5–P–C31 | 109.6(5) |
| W–P–C11 | 127.4(3) | W–C5–P | 77.6(4) |
| W–P–C31 | 126.4(4) | N–C5–P | 133.5(8) |
| C11–P–C31 | 105.9(5) | N–C5–W | 148.7(8) |

**5** constitutes the first example of a possible transition state of the carbene-carbyne rearrangement to be characterized by X-ray structure analysis. The PMePh group has not migrated, *i.e.* it is still bound to the carbene carbon atom C5, but its coordination to the metal atom and the elimination of the *trans*-ligand have already taken place. The atomic distances in the three-membered ring are essentially very little different from the corresponding atomic distances in strain-free compounds. Two carbonyl ligands as well as the N, C23, C25 atoms of the amino group lie in the plane of the three-membered ring. Hence, a good overlapping of the orbitals of the metal and nitrogen atoms suitable for π-interactions is guaranteed. The very short C5–N distance makes the amino group seem to be the most important donor in the competition for the vacant orbital of the carbene carbon atom; however, the C5–W bond length is also relatively short in comparison to C–W bond lengths in other tungsten-carbene complexes. Also interesting is the coordination of the phosphorus atom: On the one hand, the tetrahedral angle to C5, C11 and C31 of the starting complex is still recognizable, on the other C31, C11, and W surround the phosphorus atom in an almost trigonal-planar arrangement.

Metallacyclic carbene complexes such as **5** are potential intermediates of the carbene-carbyne rearrangement[3],

$$[(CO)_5M\{C(NR_2)X\}] \longrightarrow trans\text{-}[X(CO)_4MCNR_2]$$

whose mechanism is under investigation.

## Redox Intercalation Reactions of $VOPO_4 \cdot 2H_2O$

By *Jack W. Johnson** and *Allan J. Jacobson**

The layered, mixed-oxide hydrate $VOPO_4 \cdot 2H_2O$[1] reacts with neutral ligands, such as pyridine, to form intercalation compounds characterized by direct bonding of the ligand to metal atoms of the host layer[2]. However, since $VOPO_4 \cdot 2H_2O$ contains readily reducible $V^{5+}$ ions, it can also undergo redox intercalation reactions analogous to

[*] Dr. J. W. Johnson, Dr. A. J. Jacobson
Corporate Research Science Laboratories,
Exxon Research and Engineering
P.O. Box 45, Linden, NJ 07036 (USA)

those of the reducible binary oxides and the layered dichalcogenides[3].

$VOPO_4 \cdot 2H_2O$ was reduced with a wide variety of mild aqueous reducing agents. In the course of the reduction, cations are incorporated into the interlayer spaces. The basic tetragonal structure of the lattice[1] is maintained; the *a* axis remaining essentially constant at *ca.* 6.2 Å, whereas the *c* axis corresponding to the interlayer spacing is modified.

A convenient reducing agent for intercalation of most monovalent and divalent cations is the aqueous iodide ion [eq. (a)], although other aqueous reducing agents, including $SO_3^{2-}$, $NO_2^-$, $Sn^{2+}$, $Fe^{2+}$, $NH_2OH \cdot HCl$, and $N_2H_4 \cdot 2HCl$, were also effective in forming redox intercalates of $VOPO_4 \cdot 2H_2O$. In Table 1 a series of compounds, $A_xVOPO_4 \cdot yH_2O$, formed by the iodide method are listed. $VOAsO_4 \cdot 2H_2O$ reacts similarly to $VOPO_4 \cdot 2H_2O$[4].

$$VOPO_4 \cdot 2H_2O + \frac{x}{n} M^{n+}I_n + yH_2O \longrightarrow M_{x/n}VOPO_4 \cdot (2+y)H_2O + \frac{x}{2}I \quad (a)$$

Table 1. Intercalation compounds $A_xVOPO_4 \cdot yH_2O$ produced by redox intercalation with iodides in aqueous solution [5].

| A | x | y | c [Å] |
|---|---|---|---|
| Li | 1.0 | 2.1 | 6.41 |
| Na | 0.26 | 2.0 | 6.70 |
| Na | 0.46 | 2.0 | 6.52 |
| Na | 0.68 | 2.0 | 6.53 |
| K | 0.69 | 1.5 | 6.38 |
| Rb | 0.51 | 1.8 | 6.48 |
| Cs | 0.25 | 1.8 | 6.87 |
| Cs | 0.50 | 1.8 | 7.06 |
| Mg | 0.19 | 3.5 | 9.79 |
| Ni | 0.23 | 2.9 | 9.18 (6.61) |
| $NH_4$ | 0.48 | 2.0 | 6.76 |
| $N(CH_3)_4$ | 0.33 | 2.0 | *ca.* 9.2 |

The degree of reduction (x in $A_xVOPO_4 \cdot yH_2O$) depends on the reaction conditions and on the nature of the metal cation. Complete reduction of $V^{5+}$ to $V^{4+}$ is observed for lithium ($x = 1$) but, in general, lower values of x are observed. Both two-phase and single-phase regions are observed as x is varied. For example, intercalation of $Na^+$ ions gives two distinct nonstoichiometric phases with $0.16 \leq x \leq 0.33$ and $0.48 \leq x \leq 0.68$. The layer separations for the sodium phases center on 6.70 and 6.52 Å, respectively. These layer spacings are less than the interlayer separation in $VOPO_4 \cdot 2H_2O$ (7.4 Å) due to the introduction of a strong electrostatic interaction between cations and negatively charged layers upon intercalation. The water contents (y) of the monovalent intercalation compounds at ambient humidity are in the range 1.8 to 2.1 $H_2O/VOPO_4$, the lower values being observed for the larger cations. However, for small divalent cations with charge/radius ratios of greater than 2.59 $Å^{-1}$, two distinct hydrates are formed. For example, $Ni_{0.23}VOPO_4 \cdot yH_2O$ forms hydrates with layer spacings of 6.61 Å and 9.18 Å. Organic and organometallic cations, such as $N(CH_3)_4^+$ and $Co(C_5H_5)_2^+$, also intercalate $VOPO_4 \cdot 2H_2O$ but give products less crystalline than those of the simple cations.

Intercalation of $VOPO_4 \cdot 2H_2O$ and $VOAsO_4 \cdot 2H_2O$ leads to localized $V^{4+}$ sites. The IR spectrum of $VOAsO_4 \cdot 2H_2O$ exhibits a single absorption at 1010 $cm^{-1}$, assigned to the V=O stretching frequency. In $Na_{0.5}VOAsO_4 \cdot 2H_2O$, the vanadyl (V=O) absorption is split into two bands at 1013 and 992 $cm^{-1}$, corresponding to $V^{5+}=O$ and $V^{4+}=O$, respectively. In $VOPO_4 \cdot 2H_2O$ the phosphate bands mask the vanadyl region of the IR spectrum. These are the first intercalation reactions involving transfer of electrons/ions in which the transferred charges are so strongly localized that the process proceeds chemically but not electrochemically.

[3] R. Schöllhorn "Solvated Intercalation Compounds of Layered Chalcogenide and Oxide Bronzes" in M. S. Whittingham, A. J. Jacobson: *Intercalation Chemistry*, Academic Press, New York 1982, pp. 315–360; R. Schöllhorn, *Angew. Chem. 92* (1980) 1015; *Angew. Chem. Int. Ed. Engl. 19* (1980) 983.

[4] The reaction takes place in the course of minutes at room temperature, with the yellow suspension of $VOPO_4 \cdot 2H_2O$ turning green as $V^{4+}$ is produced in the solid phase, whereas the clear supernatant turns red-brown as $I_3^-$ is produced. The amount of solvent ($H_2O$) should be minimized because of the slight solubility of $VOPO_4 \cdot 2H_2O$. The structurally analogous $VOAsO_4 \cdot 2H_2O$ (N. G. Chernorukov, N. P. Egorov, I. A. Korshunov, *Zh. Neorg. Khim. 23* (1978) 2672) reacts similarly to give brown intercalation compounds. Attempts at electrochemical intercalation were unsuccessful due to the low conductivity of both host materials and their intercalation compounds.

[5] The compounds are generally quite crystalline. The layer spacings determined experimentally are equal to the tetragonal *c* axis or *c*/2 when cation order is present. The spacings depend on $H_2O$ activity, those presented in Table 1 being observed under ambient laboratory conditions. The x and n values are determined by microanalysis, redox titrimetry, and thermogravimetric analysis.

## Addition of a Phosphaalkyne to Metal-Metal Multiple Bonds**

By *Gerd Becker, Wolfgang A. Herrmann*, Willibald Kalcher, Gangolf W. Kriechbaum, Claudia Pahl, C. Thomas Wagner,* and *Manfred L. Ziegler*

Following the first demonstration of the existence of phosphorus-carbon multiple bonds (1961) the chemistry of the main group elements took on new dimensions with the synthesis of stable phosphaalkenes **A** and phosphaalkynes **B**[2a,b].

**A** $\ddot{P}=C$ $\quad\quad$ $:P\equiv C-$ **B**

A broad spectrum of complexation chemistry involving these ligands is now also beginning to emerge[4c], thus calling for a more systematic investigation of this class of substances than hithertofore. In this context, and especially with a view to possible metathetic reactions, we have now

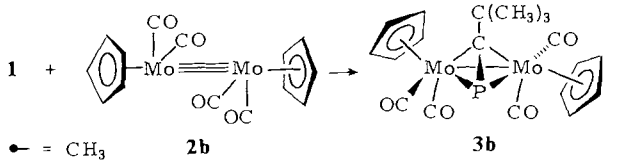
examined the conveniently accessible 2,2-dimethylpropylidynephosphane **1**[6] regarding its behavior towards metal-



$(CH_3)_3C-C\equiv P$ **1**

metal multiple bonds. The present communication demonstrates for the first time the close analogy between the complex chemistry of phosphaalkynes and that of alkynes.

The phosphaalkyne **1** adds rapidly and quantitatively to the Rh=Rh bond in **2a** and to the Mo≡Mo bond in **2b**, even below −60 °C. The crystalline, air- and moisture-stable products **3a** and **3b** resemble the analogous products

**2a** **3a**

**2b** **3b**

obtained with alkynes regarding their mode of formation and constitution[9].

The addition of **1** to the Rh=Rh bond of **2a** proceeds *via* insertion of the ligand into one of the two Rh–CO bonds, whereby the cyclic structural element of **3a** is formed regiospecifically. Like its phenylacetylene analogue (cf. [9]), **3a** is a rigid molecule ($^{13}C$-NMR data).

The molybdenum complex **3b** (Fig. 1) contains an organometallic tetrahedrane skeleton; the CP moiety added to

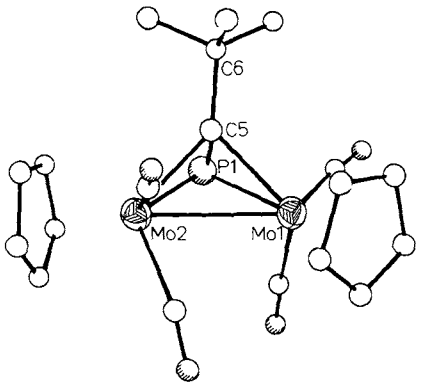


Fig. 1. Structure of the $\mu,\eta^2$-phosphaalkyne complex **3b** in the crystal (H atoms not shown). Monoclinic (from diethyl ether/*n*-hexane 20/80 vol.-%); C2/c, $Z=8$; $a=2702(9)$, $b=882.9(5)$, $c=1695(5)$ pm; $\beta=103.37(2)°$; 3570 independent reflections different from zero ($2° \le 2\theta \le 54°$); $R_{aniso}=0.031$, $R_w=0.027$. Selected bond lengths [pm] and angles [°]: Mo(1)–Mo(2) 301.4(0), Mo(1)–P(1) 249.7(1), Mo(2)–P(1) 244.2(1), Mo(1)–C(5) 222.4(4), Mo(2)–C(5) 222.2(4), P(1)–C(5) 171.9(3), C(5)–C(6) 154.5(6); Mo(1)–P(1)–Mo(2) 75.2(0), Mo(1)–C(5)–Mo(2) 85.3(1), Mo(1)–P(1)–C(5) 60.4(1), Mo(2)–P(1)–C(5) 61.7(1), Mo(1)–C(5)–P(1) 77.4(1), Mo(2)–C(5)–P(1) 75.4(1), Mo(1)–Mo(2)–C(5) 47.4(1), P(1)–C(5)–C(6) 127.9(3).

the Mo≡Mo bond is located vertically above the Mo–Mo bond. The incorporation of **1** into **2b** has the same consequences as the incorporation of alkynes regarding any changes in geometry of the components: The PC bond does not, as formally expected, assume the length of a single bond (182–187 pm), but has the length of a typical double bond (171.9(3) pm). Likewise, only a double bond is formed on addition of C≡C-, M≡C- and As≡As systems to **2b**[21,22].

## Synthesis of $[C_5H_5Rh(PhC\equiv CH)P(iPr)_3]$ and $[C_5H_5Rh(=C=CHPh)P(iPr)_3]$: Mechanism of the Conversion of an Alkyne Ligand into a Vinylidene Ligand

By *Justin Wolf, Helmut Werner*, Ohran Serhadli,* and *Manfred L. Ziegler*

Recently, metal complexes containing the ligands :C=C′RR′ ("vinylidenes"), which are unstable in the free form, have been attracting increasing attention[1]. They are generally prepared by reaction of 1-alkynes with coordinatively unsaturated metal-complex fragments such as $[C_5H_5Mn(CO)_2]$ or $[C_5H_5Fe(CO)_2]^{\oplus}$ generated *in situ*. During these reactions the 1-alkyne is first coordinated to the metal (**A**) and then undergoes transformation in the coordination sphere of the metal, giving the corresponding vinylidene complex (**C**). The question *how* this takes place has hitherto not been answered; in no instance has the postulated intermediate **B** been detected[1c,d].

**A** **B** **C**

In an analogous way to the preparation of the alkyne complexes *trans*-$[RhCl(C_2R_2)(PR'_3)_2]$ (R = Me, Ph; R′ = *i*Pr)[2], we have now synthesized compound **1** (74% yield; yellow, air-sensitive crystals; m.p. 97 °C) by reaction of phenylacetylene with the complex $RhCl[P(iPr)_3]_2$, which is obtained from $[RhCl(C_8H_{14})_2]_2$ and excess $P(iPr)_3$[3]. Due to the position of the $\nu(C\equiv C)$ stretching frequency at 1825 $cm^{-1}$ in the IR spectrum (KBr), we assume **1** to have a

[*] Prof. Dr. H. Werner, J. Wolf
Institut für Anorganische Chemie der Universität

metallacyclopropene structure (with a 16-electron configuration at the metal). In solution, partial isomerization **1** → **2** takes place, implicating the oxidative addition of the 1-alkyne at the metal. Consequently, in the $^1$H-NMR spectrum (100 MHz, [D$_8$]toluene, 35 °C) one observes two virtual quartets at $\delta = 1.23$ and 1.35 for the phosphane-CH$_3$ protons of **1**/**2**, a doublet at $\delta = 4.07$ ($J$(RhH) = 2.6 Hz) for the PhC$_2$H-proton of **1**, as well as a triplet of doublets at $\delta = -27.70$ ($J$(PH) = 12.7, $J$(RhH) = 42.0 Hz) for the hydrids hydrogen atom of **2**.

Addition of pyridine to an ether solution of **1**/**2** shifts the equilibrium completely, resulting in the formation of the alkynyl(hydrido)-complex **3**[3], for which an octahedral structure is assumed. The colorless crystals are stable under argon, but decompose rather rapidly in solution at room temperature. The $^1$H-NMR spectrum (100 MHz, [D$_8$]toluene, 8 °C) shows two virtual quartets at $\delta = 1.15$ and 1.19 for the diastereotopic PCHC*H*$_3$-protons as well as a pseudo-quartet in the high-field region ($\delta = -17.30$; $J$(PH) = $J$(RhH) = 14.0 Hz) for the hydrido ligand. The appearance of only one signal at $\delta = 36.09$ (d, $J$(RhP) = 96.8 Hz) in the $^{31}$P-NMR spectrum of **3** proves that the two phosphane ligands are in *trans* position.

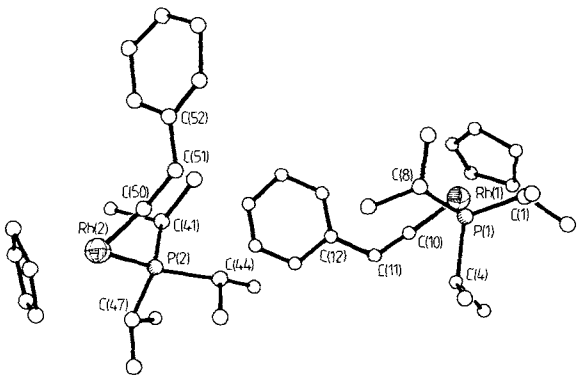
$$\underset{\mathbf{1}}{RhCl(PhC_2H)(PR'_3)_2} \rightleftharpoons \underset{\mathbf{2}}{RhCl(H)(C_2Ph)(PR'_3)_2} \xrightarrow{py}$$

R' = *i*Pr

$$RhCl(H)(C_2Ph)(PR'_3)_2(py)$$

**3**

Compound **1** reacts with $NaC_5H_5$ in tetrahydrofuran (THF) (*i.e.* under the same conditions as used for the preparation of [$C_5H_5Rh(C_2R_2)P(iPr)_3$] (R = Me, Ph)[2]) to give the alkyne complex **4** (90%; orange colored oil)[3], which is characterized by its *IR* spectrum [$\nu$(C≡C) = 1770 cm$^{-1}$; hexane] and $^1$H-NMR spectrum [100 MHz, $C_6D_6$, 30 °C; $C_5H_5$: $\delta = 5.30$ (d × d, $J$(PH) = 1.4, $J$(RhH) = 0.7 Hz); PhC$_2$*H*: $\delta = 5.58$ (d, $J$(RhH) = 3.2 Hz)] (Scheme 1). If, on the other hand, the pyridine complex **3** is allowed to react with $NaC_5H_5$ in THF, the vinylidene complex **6** (isomeric to **4**) is obtained (65%; orange colored crystals, briefly air-stable; m.p. 95 °C)[3]. The presence of a phenylvinylidene ligand is confirmed by the spectroscopic data [IR (KBr): $\nu$(C=C) = 1615 cm$^{-1}$; $^1$H-NMR (60 MHz, $C_6D_6$, 30 °C): $C_5H_5$: $\delta = 5.23$ (m); C=C*H*Ph: $\delta = 4.42$ (d × d, $J$(PH) = 4.6, $J$(RhH) = 1.6 Hz); $^{13}$C-NMR (90 MHz, $C_6D_6$, 30 °C): *C*=CHPh: $\delta = 316.99$ (d × d, $J$(PC) = 27.7, $J$(RhC) = 67.7 Hz); C=*C*HPh: $\delta = 116.31$ (d × d, $J$(PC) = 4.4, $J$(RhC) = 14.4 Hz)] and the crystal structure analysis[4]. The asymmetric unit contains two independent molecules (Fig. 1), which mainly differ with respect to the RhC and CC bond lengths of the vinylidenerhodium moiety. The RhC bond lengths are significantly shorter than in rhodium-carbene complexes (193.0(11) to 200.6(15) pm)[5], thus indicating, in agreement with the $^{13}$C-NMR data, a high degree of multiple bonding. The RhCC arrangement is almost linear; RhCC angles in the two independent molecules are 173.0(13) and 174.6(14)°.



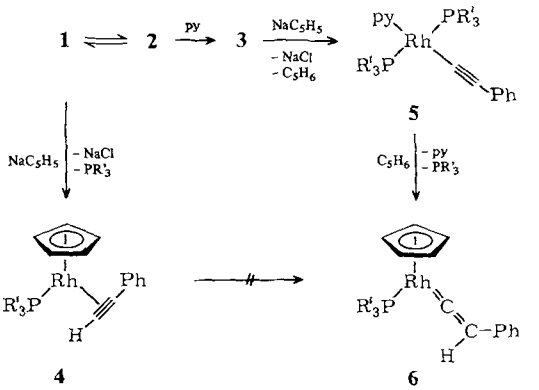


Fig. 1. Structure of **6** in the crystal. The figure shows the two independent molecules in the asymmetric unit. Selected bond lengths [pm]: Rh(1)–P(1) 226.6(6), Rh(1)–C(10) 182.0(16), C(10)–C(11) 129.5(21), Rh(2)–P(2) 227.6(6), Rh(2)–C(50) 175.1(16), C(50)–C(51) 140.6(21).

Scheme 1. R' = *i*Pr.

The mechanism of the reaction of **3** and $NaC_5H_5$ was confirmed by the isolation of the intermediate **5**. According to earlier suggestions[1c,d], we had presumed that replacement of Cl by $C_5H_5$ and elimination of pyridine and P(*i*Pr)$_3$ would lead to intermediary formation of the alkynyl(hydrido)complex [$C_5H_5RhH(C_2Ph)P(iPr)_3$], which, after intramolecular H-shift, would then afford the product **6**. If, however, a solution of **3** in THF is treated rapidly at 0 °C with an equimolar amount of $NaC_5H_5$ and work-up is carried out in the cold, then yellow, air-sensitive crystals of **5** are obtained in 68% yield. The IR spectrum shows, instead of the two bands of **3** at 2180 [$\nu$(RhH)] and 2100 cm$^{-1}$ [$\nu$(C=C)], one frequency at 2055 cm$^{-1}$, which is assigned to the C=C stretching vibration. **5** reacts with $C_5H_6$ at room temperature to give **6** in almost quantitative yield. The rearrangement **4** → **6** is not detectable, either on prolonged standing or on irradiation.

In conclusion, our results show for the first time that a vinylidene ligand is in fact formed from an alkyne ligand *via* an alkynyl(hydrido) intermediate. The mechanism, however, does not involve an intramolecular H shift (from the metal to carbon) but a two-step elimination/addition reaction. The second step involves the protonation of an alkynyl ligand, which has already been used by others for the synthesis of vinylidene complexes[6].

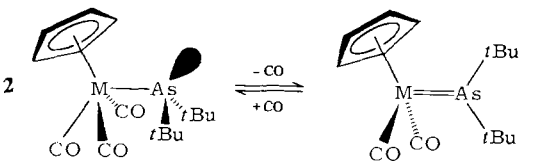
## Dicarbonyl($\eta^5$-cyclopentadienyl)(di-*tert*-butyl-$\lambda^4$-arsanediyl)molybdenum and -tungsten—The First Complexes with a Metal-Arsenic Double Bond**

By *Michael Luksza, Sigrid Himmel,* and *Wolfgang Malisch**



Transition-metal substituted arsanes of type **1**[2a, b] are distinguished from triorganoarsanes by their increased Lewis basicity, which, *e.g.*, is expressed by a marked tendency to coordinate to metallic centers[2b]. A special case of this reaction type is the formation of a four-membered ring with loss of CO, which occurs on heating in toluene or on irradiation[2a] (Cp = $\eta^5$-cyclopentadienyl).

**1**

M = Mo, W

We have now observed that the metalated arsanes **2a, b**[2c], which possess sterically demanding *tert*-butyl ligands at the donor center, lose carbon monoxide already at 60 °C in benzene and that *without* aggregation occurring! The mononuclear complexes **3a, b** are formed in which, for the first time, a metal-arsenic double bond is realized[3].

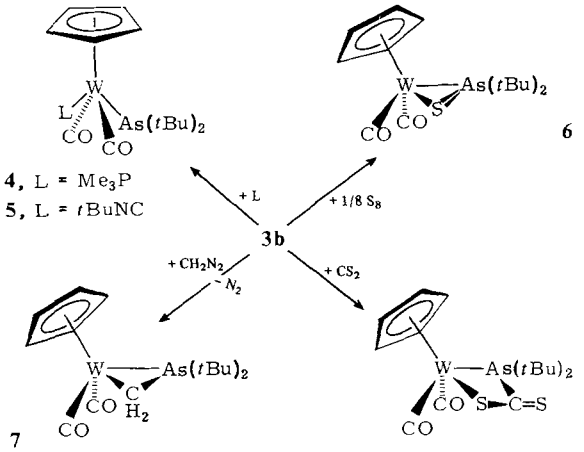
**a**, M = Mo; **b**, M = W

The blue and deep violet crystals of **3a** and **3b**, respectively, are extremely soluble in benzene and undergo spontaneous addition of carbon monoxide (25 °C, normal pressure, benzene). Their molecular masses have been determined cryoscopically and by mass spectrometry; their constitution follows from the data in Table 1.

The "perpendicular" orientation of the *tert*-butyl groups at the trigonal-planar arsenic atom to the cyclopentadienyl- and $M(CO)_2$ -plane, predicted by *Hoffmann et al.*[4], follows from the anisochronism of the alkyl ligands. This is detectable in the $^1$H-NMR spectrum of **3a/b** below

Table 1. Characteristic data for **3a, b, 7,** and **8**.

**3a**: M.p. = 108–110 °C.—$^1$H-NMR ([D$_8$]toluene, 25/–75 °C): $\delta$ = 5.47/5.55 (s, 5H, $H_5C_5$), 1.60 (s, 18H, $H_3C$)/1.80 (s, 9H, $H_3C$), 1.34 (s, 9H, $H_3C$).—IR (pentane): $\nu CO_s$ = 1947 (vs), $\nu CO_{as}$ = 1873 (s) cm$^{-1}$



**3b**: M.p. = 125–127 °C.—$^1$H-NMR ([D$_8$]toluene, 25/–60 °C): $\delta$ = 5.13/5.23 (s, 5H, $H_5C_5$), 1.61 (s, 18H, $H_3C$)/1.66 (s, 9H, $H_3C$), 1.24 (s, 9H, $H_3C$).—$^{13}$C-NMR ($^1$H-coupled) ($C_6D_6$): $\delta$ = 231.75 (s, $^1J(^{13}C^{183}W)$ = 180.05 Hz, CO), 90.51 (d, $^1J(HC)$ = 177.64 Hz, $C_5H_5$), 61.42 (s, $CCH_3$), 30.67 (q, $^1J(HC)$ = 123.46 Hz, $CCH_3$).—IR (pentane): $\nu CO_s$ = 1936 (vs), $\nu CO_{as}$ = 1861 (s) cm$^{-1}$

**7**: M.p. = 98 °C (decomp.).—$^1$H-NMR ([D$_8$]toluene, 25/–40 °C): $\delta$ = 5.04/5.08 (s, 5H, $H_5C_5$), 1.15 (s, 18H, $H_3C$)/1.43 (s, 9H, $H_3C$), 1.12 (s, 9H, $H_3C$), 0.64/0.53 (s, 2H, $H_2C$).—IR ($C_6H_6$): $\nu CO_s$ = 1922 (vs), $\nu CO_{as}$ = 1837 (s)

**8**: M.p. = 100–102 °C.—$^1$H-NMR ($C_6H_6$): $\delta$ = 4.90 (s, 5H, $H_5C_5$), 1.49 (s, 9H, $H_3C$), 1.15 (s, 9H, $H_3C$).—$^{13}$C-NMR ($^1$H-coupled) ($C_6D_6$): $\delta$ = 268.24 (s, $CS_2$), 244.38 (s, $^1J(^{13}C^{183}W)$ = 137.33 Hz, CO), 231.25 (s, $^1J(^{13}C^{183}W)$ = 161.75 Hz, CO), 90.64 (d, $^1J(CH)$ = 179.36, $C_5H_5$), 46.59 (s, $CCH_3$), 42.61 (s, $CCH_3$), 29.71 (q, $^1J(CH)$ = 125.91, $CH_3$), 29.41 (q, $^1J(CH)$ = 129.68 Hz, $CH_3$).—IR ($C_6H_6$): $\nu CO_s$ = 1944 (vs), $\nu CO_{as}$ = 1863 (s); $\nu C{=}S$ = 1075 (m) cm$^{-1}$

–48.5/–46 °C, *i.e.* at room temperature rotation relative to the metal-arsenic double bond is rapid: $\Delta G^+$ (224.6/227 K) is 10.9/11.1 kcal/mol. Although **3a, b** prefer this sterically unfavored conformation due to donor-acceptor orbital $\pi$-interaction between the centers of the molecular fragments $Cp(CO)_2M^{\ominus}$ and $(tBu)_2As^{\oplus}$, the reaction **2a, b** → **3a, b** proceeds extremely readily: the *tert*-butyl groups at the sp$^2$ arsenic atom in **3a, b** are considerably less sterically constrained than they would be at the bridging sp$^3$ arsenic atom of the dinuclear compound $[Cp(CO)_2M–As(tBu)_2]_2$.

Participation of the nonbonding lone-pair of electrons on the arsenic of **2a, b** in the MAs double bond of **3a, b** is indicated by the inactivity towards MeI. With HCl in ether, **3b** forms *trans*-$Cp(CO)_2[ClAs(tBu)_2]W–H$[2a]. The nucleophiles $Me_3P$ and *t*BuNC add rapidly and stereospecifically *trans* to the arsenic ligand to form **4** and **5**, respectively[1, 5a]. The "double bond activity" of **3b** is principally expressed by the reaction with sulfur to afford **6**, and with diazomethane to afford **7**, which opens up a completely novel route to three-membered metallacycles[5b].

As shown by [2+2]cycloaddition of $CS_2$ to give **8**, this reaction principle can also be used for the synthesis of larger heterocycles. **6** and **7** are characterized by their dynamic behavior, which has to be attributed to rotation of the $\eta^2$-bonded ligands $(tBu)_2As{=}S$ and $(tBu)_2As–CH_2$, respectively [$\Delta G^+$ (268/248 K) = 15.4/12.4 kcal/mol].

## Synthesis of an [18]Annulene Dioxide: An Oxygen-Bridged [18]Annulene Possessing Equivalent Kekulé Structures

By *Haru Ogawa**, *Naomi Sadakari*, *Taiji Imoto*, *Izumi Miyamoto*, *Hidefumi Kato*, and *Yōichi Taniguchi*

The [18]annulene trioxide **1**[1a,b] was characterized, on the basis of the very low field proton resonances and on the remarkably similar electronic spectrum to that of [18]annulene itself, **2**, as a delocalized 18π Hückel arene. We report here on the synthesis and properties of the [18]annulene dioxide **3**, for which two equivalent Kekulé structures (**3a** and **3b**) can be written—as for benzene.

Double Wittig reaction of 2,5-furandialdehyde **5** with trimethylenebis(triphenylphosphonium bromide) **6** (15% excess) in DMF at 85 °C (LiOMe as base) under high-dilution conditions leads, in a "one pot synthesis", to **3** (presumably *via* thermal dehydrogenation of the cycloolefin **7**). **3** was obtained as sole annulene; it could be separated by chromatography on $SiO_2$ (*n*-hexane) as green platelets (m.p. 235 °C, yield 3.0%). The $^{13}$C-NMR spectrum of **3** ($CDCl_3$) exhibited only five resonance lines. The $^1$H-NMR spectrum ($CDCl_3$, 100 MHz) clearly indicates that **3** contains only four types of H-atoms, suggesting the formulation **3c** [$\delta = -5.89$ ($H_a$, 2H, $J_{trans} = 13.5$ Hz), 9.13 ($H_f$, 4H, s), 9.20 ($H_c$, 4H, $J_{cis} = 10.8$ Hz), 10.00 ($H_b$, 4H, q, $J_{cis} = 10.8$ Hz, $J_{trans} = 13.5$ Hz)]. The aromatic character of **3c** was confirmed by the existence of a pronounced diatropic ring current. The observed large chemical shift difference between the inner ($H_a$) and outer ($H_b$) protons is the highest one ever recorded in the [18]-[2], bridged [18]-[3,7], and didehydro[18]annulene series[4]. The electronic spectrum of **3** is remarkably similar to that of [18]annulene **2**.

It may be concluded from these findings that the two oxygen bridges in **3** keep the 18π perimeter in a rigid and planar centrosymmetrical conformation with no bond length alternation. In contrast, another counterpart **4**, consisting of the same building blocks (*i.e.* two furan rings and ten $sp^2$ CH groups) is less planar, and consequently less diatropic[3].

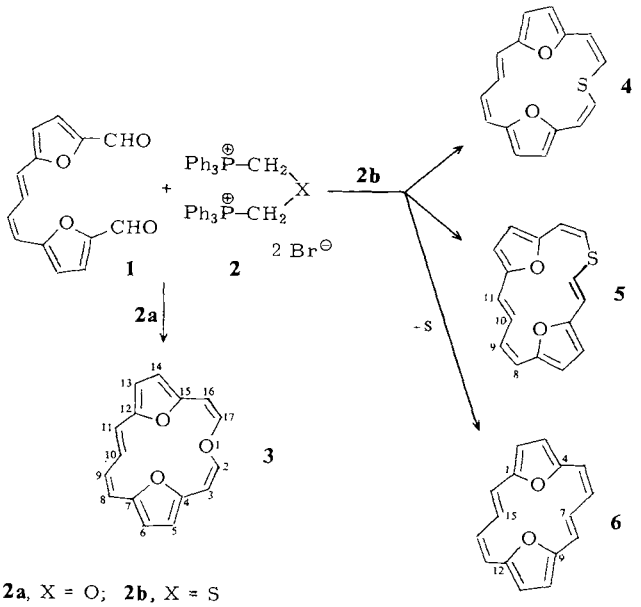
## Synthesis of Hetero[17]annulene Dioxides and a [16]Annulene Dioxide Using Furan Building Blocks



By *Haru Ogawa**, *Chiyuki Fukuda*, *Taiji Imoto*, *Izumi Miyamoto*, *Hidefumi Kato*, and *Yōichi Taniguchi*

Recent investigations of bridged [18]annulenes[1,2] have demonstrated that aromatic π-delocalization is not hampered even by twisting of the perimeter. Results gained from hetero[17]annulenes[3a,4,5] indicated that the diatropicity depends on the structures and that slight structural perturbations may be sufficient to destroy the π-bond delocalization. Therefore, it is of interest to investigate the effect of incorporating furan part structures into hetero[17]annulenes, whose conformations are expected to be considerably twisted. For this purpose we prepared **3**, **4**, and **5** as models.

Double Wittig reaction of the dialdehyde **1**[2] with **2a** gave oxa[17]annulene dioxide **3** as the sole isomer [m.p. 236 °C, yield 8.0%]. In contrast, reaction of **1** with **2b** led to two stereoisomeric thia[17]annulene dioxides **4** (m.p. 227 °C, yield 2.2%) and **5** (m.p. 176 °C, yield 2.0%), together with [16]annulene dioxide **6** (m.p. 182–184 °C, yield 2.0%). The chemical shifts of the H-8, H-9, H-10, and H-11 protons (spin decoupling) showed that **3**, **4** and **5** are 18π-diatropic systems. The signals of the outer protons are

**2a**, X = O; **2b**, X = S

shifted to lower field compared to those of the atropic dihydro[18]annulene dioxide (**4**, $CH_2-CH_2$ instead of S), and those of the inner proton(s) to higher field. The difference in chemical shifts of H-11 and H-10 ($\Delta\delta$) clearly shows that the diamagnetic ring current decreases along the series **5** > **4** > **3** ($\Delta\delta = 4.36$, 3.51, and 1.54 ppm, respectively).

Isomerization **5** → **4** could occur upon heating or simply by acid catalysis ($CF_3COOD$, NMR spectroscopy). Back-isomerization *via* protonated species $\mathbf{4H^+} \rightarrow \mathbf{5H^+}$ was unsuccessful, presumably due to the low $pK_a$ of sulfur. In this respect, the thia[17]annulene system cannot form a "closed" chemical cycle of four sequential steps, as occurs in [15]annulenone dioxide[6] (model of $H^+$-pumping cycle of bacteriorhodopsin).

The structure of **6** was confirmed by $^1H$- and $^{13}C$-NMR spectroscopy. The very low-field resonances of the inner protons (2H, H-7, H-15: $\delta = 17.18$) and the high-field resonances of the outer protons (10H, $\delta = 4.41-4.93$ ppm) observed confirm that **6** is strongly paratropic. The electronic spectrum of **6** is closely similar to that of [16]annulene (broader bands at $\lambda_{max} = 278$ and 530 nm, no vibrational structures), indicating that **6** is a 16π system with alternating bond lengths.

The furan ring, therefore, serves as a useful building block—even more suitable in some cases than acetylenic moieties—for twisted heteroannulenes as well as of [4n+2]- and [4n]annulenes, in which the ring current is to be determined.

## The First X-Ray Structure Analysis of a Thiadiphosphirane**

By *Masaaki Yoshifuji**, *Kaori Ando*, *Katsuhiro Shibayama*, *Naoki Inamoto*, *Ken Hirotsu**, and *Taiichi Higuchi*

Phosphorus-containing small ring systems—particularly three-membered ring compounds—are of topical interest[1a,b]. *Baudler et al.*[1c] have reported the synthesis of 2,3-di-*tert*-butyl-1,2,3-thiadiphosphirane, but so far there have been no reports on the X-ray structure analysis of such compounds.

By using the extremely bulky 2,4,6-tri-*tert*-butylphenyl group to sterically protect a phosphorus-phosphorus double bond we have been able to isolate a true "phosphobenzene", the diphosphene **4**, as a stable compound[2a].

Aryl = 2,4,6-$t$Bu$_3$C$_6$H$_2$

We now wish to report the preparation and characterization of *E*-2,3-bis(2,4,6-tri-*tert*-butylphenyl)-1,2,3-thiadiphosphirane **2** and 2,4,6-tris(2,4,6-tri-*tert*-butylphenyl)-1,3,5-trithia-2,4,6-triphosphorinane **3**[5]. **2** and **3** were obtained by reaction of 2,4,6-tri-*tert*-butylphenylthiophosphonic dichloride **1** with magnesium turnings[2c,3]. **2** is a colorless, odorless, thermally and photolytically insensitive compound, which is quite stable toward atmospheric mois-

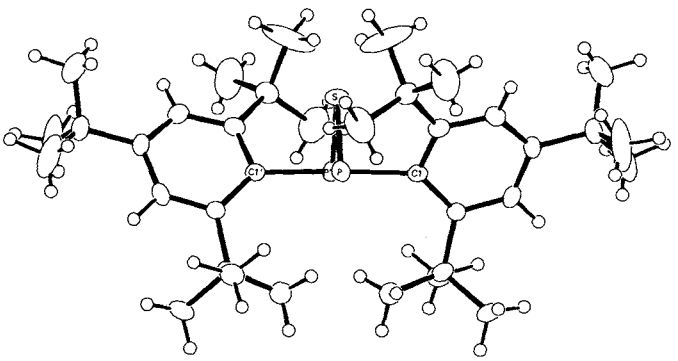

Fig. 1. Structure of **2** in the crystal. Monoclinic, C2/c, $a = 18.529(7)$, $b = 9.506(4)$, $c = 20.760(9)$ Å, $\beta = 100.4(1)°$, $Z = 4$. $Mo_{K\alpha}$-radiation, $\lambda = 0.7107$ Å, $R = 0.059$ for 1107 reflections with $I > 3\sigma(I)$. Important bond lengths and angles: P–P 2.249(3), P–S 2.103(3) Å; ∢ SPP 57.7(1), PSP 64.6(1)°. Further details of the crystal structure investigation can be obtained on request from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CSD 50386, the names of the authors, and complete citation of the journal.

ture and oxygen over a long period of time[4a]. It was also obtained by reaction of **4** with elemental sulfur (60% yield). Reaction of **2** with chlorine affords 2,4,6-tri-*tert*-butylphenylphosphonic dichloride almost quantitatively after hydrolysis[2a].

The yields of compounds **2**, **3**[4b], and **4** (20—60%, 1—8%, and 1—40%, respectively) depend on the ratio **1** : Mg.

**3** had already been synthesized *via* an alternative route by *Çetinkaya et al.*, who also carried out a crystal structure analysis.

The molecule **2** contains a two-fold crystallographic axis, which bisects the P–S–P angle (Fig. 1). The atoms P, C1, P′, and C1′ form a plane (deviation 0.02 Å); the interplanar angle between a benzene ring and the plane P, C1, P′, C1′ is 59.3°. The benzene rings are distorted to a boat form, in which the largest distortion (14.4°) is a little smaller than in bis(2,4,6-tri-*tert*-butylphenyl)phosphinic chloride (18.5°)[2b].

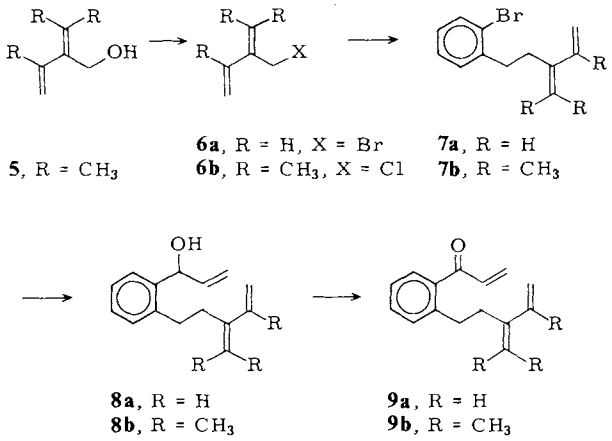
## The Tricyclo[9.3.1.0$^{3,8}$]pentadecane System—A Short Synthesis of a C-Aromatic Taxane Skeleton

By *Kenneth J. Shea** and *Peter D. Davis*

The taxanes, including taxusin **1**, comprise a group of naturally occurring substances isolated from the European *Taxus baccata*, Japanese *T. cuspidata*, and related species (Taxaceae)[1]. Inspection of the parent taxane ring system **2** reveals a novel fused-bridged tricyclo[9.3.1.0$^{3,8}$]pentadecane ring skeleton that embodies a bridgehead double bond (C11—C12) and a trimethyl-substituted A ring. Neither taxane nor any of the natural derivatives have previously been synthesized[5]. Our approach to the synthesis of the taxane skeleton involves a type II intramolecular Diels-Alder cycloaddition [reaction (a)].

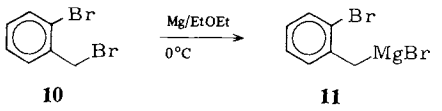


The key intermediates in our synthesis are the trienones **9a** and **9b** (Scheme 1). Their preparation involves reaction of the Grignard reagent **11**, prepared directly from di-

bromide **10**, with the butadiene derivatives **6a** and **6b**, respectively. Thus, when a solution of 2-bromomethyl-1,3-butadiene **6a** in tetrahydrofuran (THF) is treated with a solution of **11** in ether, the bromodiene **7a** is isolated in 54% yield.

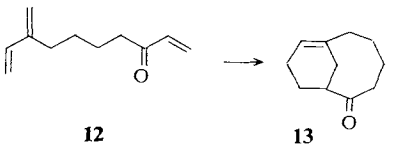
To synthesize the taxane derivative **4**, the alcohol **5**[9] was converted quantitatively into the chloride **6b** using Meyers' method. Treatment of **6b** with a two-fold excess of **11** in THF furnished the diene **7b** (43%).

The dienophile moiety of **9** was introduced in two steps from **7**: metalation (*s*BuLi, −78 °C) followed by reaction with acrolein to afford **8**, whose oxidation with pyridinium dichromate in $CH_2Cl_2$ yields the trienones **9a** (50%) and **9b** (63%).



Scheme 1.

When a 1 M solution of the triene **9a** is heated for 1 h in xylene at 185 °C a single cycloadduct is isolated by column chromatography in 70% yield. All spectral data are consistent with structure **3**. **9a** is *ca.* $10^6$ times more reactive than the non-benzannulated derivative **12** [$t_{1/2}$(**9a**) = 1 h (65 °C), $t_{1/2}$(**12**) = 15 h (155 °C)]. The rate increase that results from annulation is probably a general phenomenon of intramolecular Diels-Alder reactions.



When a 0.1 M solution of **9b** in xylene is heated at 155 °C for 93 h, a single cycloadduct, **4**, is isolated in 70% yield. The vinyl region in the $^1$H-NMR spectrum exhibits three methyl peaks (250 MHz, $CDCl_3$, TMS: $\delta = 1.29$, 1.10, and 0.70). Significantly, the $^{13}$C-NMR spectrum reveals a very low-field doublet (62.89 MHz, $CDCl_3$, TMS: $\delta = 62.9$)

attributable to the $sp^3$-bridgehead C atom: the 14.4 ppm shift downfield relative to cycloadduct **3** is consistent with the β-effect produced by *gem*-dimethyl substituents at C-15[14], confirming the regiospecificity of the cycloaddition.

# BOOK REVIEWS

**Reactive Intermediates.** Volumes 1 and 2. Edited by *R. A. Abramovitch*. Plenum Press, New York 1980 and 1982. xiii, 522 pp., bound, $ 49.50 and xv, 599 pp., bound, $ 59.50.

It is intended that the series "Reactive Intermediates" shall provide articles concerning relatively new areas of reactive intermediate chemistry, at irregular intervals. In this it complements another series, also entitled "Reactive Intermediates" (edited by *M. Jones Jr.* and *R. A. Moss*, so far two volumes), which reports mainly on advances in well-known intermediates (carbanions, carbonium ions, radicals, carbenes and nitrenes).

The first volume contains contributions on: the preparation and reactions of atomic carbon (*P. B. Shevlin*, 36 pp., the dependence of the products formed on the mode of generation of the atomic carbon is exhaustively discussed); metal atoms as reactive intermediates (*K. J. Klabunde*, 112 pp., deals with experimental techniques, including commercial apparatus, as well as applications in organometallic synthesis and in matrix isolation spectroscopy); aminium radicals (*Y. L. Chow*, 112 pp., surveys chemical, photochemical and electrochemical amine oxidations and the homolysis of *N*-chloramines and *N*-nitrosamines); arylcarbenes in the gas phase (*C. Wentrup*, 56 pp., discusses automerizations and ring contractions that the author has investigated by isotopic labeling); and metal salt-catalyzed carbenoids (*D. S. Wulfman* and *B. Poling*, 191 pp., give a detailed account of the carbenoid concept and the mechanism of methylene transfer together with numerous references to preparative applications of metal salt-catalyzed reactions of diazoalkanes).

Volume 2 contains contributions on: arylnitrenes in solution (*E. F. V. Scriven*, 54 pp., with emphasis on the singlet-triplet problem and the reaction route to azepines); nitrile ylides and nitrenes from 2*H*-azirines (*A. Padwa* and *P. H. J. Carlsen*, 64 pp., *Huisgens'* work on the cycloadditions of nitrile ylides is appraised and photochemical and intramolecular variants are discussed); radical cyclization by intramolecular addition (*J.-M. Surzur*, 174 pp., the influence of substituents, chain length, and heteroatoms on the cyclization of unsaturated radicals is treated in a clearly set-out arrangement of the extensive material. Alongside the kinetic and stereochemical aspects, attention is particularly paid to the synthesis of bicyclic and polycyclic compounds); and the reactions of silicon atoms and silylenes (*Y.-N. Tang*, 70 pp., insertion and addition reactions have analogies with and show differences from carbon atoms and carbenes, *e.g.* the 1,4-addition to conjugated dienes is preferred). There are also contributions on five-membered hetarynes (*M. G. Reinecke*, 160 pp., intermediates with formal triple bonds in furan, pyrrole and thiophene rings are rarer than previously assumed. Many reactions for which such intermediates were postulated take other pathways, which are critically reviewed here; reactions where genuine hetarynes are formed are differentiated) and on the mechanism of the Favorskii rearrangement (*A. Baretta* and *B. Waegell*, 58 pp., where the influence of stereochemistry and of the ring strain of the α-haloketone on the course of the reaction is interpreted by varying participation of cyclopropanone and oxyallyl intermediates).

All the contributions are by experts who have experimental experience in their fields. It is apparent to the reader that the investigation of reactive intermediates is progressing quickly and with high standards, even though the spectacular achievements of the pioneer era are absent. The broad range of topical, thorough and critical reviews makes this work a worthwhile addition to every chemical library. The fact that he must pay the full price, even though only one or two articles may interest him personally, may deter the private purchaser. If he buys inspite of this he will be rewarded by a stimulating view "over the garden fence".

*Wolfgang Kirmse* [NB 581 IE]

**Techniques of Chemistry.** By *A. Weissberger, Vol. 17:* **Applications of Lasers to Chemical Problems.** By *R. Evans.* Wiley-Interscience, Chichester 1982. xii, 291 pp., £ 42.50.

This volume of *"Weissberger"* is a consequence of the fact that, ever since their first technical realization by *Maiman* in 1960, lasers have found their place in analytical chemistry. Considering the continuing active development of laser applications, it is a difficult task to produce a handbook which puts useful information into the hand of the practising chemist.

The first chapter by *J. Wilson,* entitled "Laser Sources", is definitely too short with its 35 pages. The literature is only cited up to 1978. Those intending to use lasers do not find enough helpful information; the reference to the "Laser Focus Buyers Guide" is not sufficient. A reference to the standard volume by *W. Koechner* would have been appropriate in the section on solid state lasers. In the section on dye lasers, the argon-ion laser pumped continuous wave dye laser, which has become a spectroscopist's workhorse, has only been mentioned in passing. There is little about nonlinear optics, and parametric oscillators are only mentioned in connection with a review article from 1969, which is outdated.

The longest chapter with 146 pages, entitled "Applications of Lasers in Analytical Chemistry" by *J. C. Wright,* provides much more information and covers the literature up to 1981 with 394 references. The main attention is focused on spectroscopic methods, particularly on those having extremely high sensitivity: absorption and fluorescence spectroscopy, photoionization and photodissociation methods, coherent Raman spectroscopy and two-photon spectroscopy. A good, comprehensive survey is made of these methods; for example the sensitivities realizable by the various methods are tabulated for 44 elements. In the section on coherent Raman techniques, the numerous possibilities for interactions arising from the nonlinear terms in the expression for the polarizability, are exhaustively discussed. The spectroscopic methods based on these interactions, which may also possess resonant character, *e.g.* CARS (Coherent Anti-Stokes Raman Scattering), are discussed with applications.

The chapter "Ultraviolet and Visible Laser Photochemistry" by *I. R. Evans* complements the contribution to volume 9 of this series by *S. C. Pyke* and *M. W. Windsor* which has the title "Chemical Measurements in the Picosecond and Shorter Time Range". It gives an overview of selected investigations in the nanosecond range. After a rather informative section on experimental techniques, a short section dealing with work on reaction kinetics follows. The rest of the chapter is concerned with multi-photon processes. The choice of examples seems somewhat limited in view of the numerous investigations that have been carried out in this field.

The final chapter by *A. M. Ronn* on "Infrared Laser Photochemistry" may not be very long (46 pages), but it is very readable and offers a clear introduction to the problems of this topic. First the dependence of reaction velocity of bimolecular gas reactions on the selective excitation of molecular vibrational modes by single photons is dealt with. The rest contains a discussion of multi-photon dissociation by infrared photons, giving some typical examples.

Considering the high price of £ 42.50, the book will hardly find its place in a private library, because its contents will be outdated very soon.

*Alexander Müller* [NB 579 IE]

**Industrial Electrochemistry.** By *D. Pletcher.* Chapman & Hall, London 1982. xii, 325 pp., bound, £ 22.50.

Much progress has been made in industrial electrochemistry in the past twenty years. Classical processes such as the electrolysis of water and alkali metal chlorides have been revolutionized by new material technologies. Some entirely new fields have emerged such as fuel cells, the electrochemical synthesis of organic compounds, and the large-scale industrial use of electrodeposition of paint, while other fields, like storage batteries and the electrolytic production of aluminum have remained comparatively little changed. The aim of this book is to depict the present state of industrial electrochemistry, and this aim is well achieved. The author deals with all fields of applied electrochemistry, including some, such as batteries and electrochemical analysis, that would not be expected on the basis of the title. Basically only processes that are actually carried out in industry are discussed, to the exclusion of their historical development and projects now in progress. The literature cited mainly consists of monographs, and key patents are not given as such.

The book is divided into eleven chapters. The electrochemical and chemical process-engineering fundamentals are discussed at the beginning in an elegant and precise manner. The accurate definitions given for the material yield and current efficiency are useful, but the space-time yield is discussed only in general terms, although it is easy to derive a relationship for it.

The next chapters deal with electrolytic processes in inorganic chemistry, including those used for the extraction and purification of metals. In the case of the diaphragm process used in the electrolysis of alkali metal chlorides, the latest electrolyzers are described. It should have been mentioned here that the asbestos suspension is applied to the iron mesh cathodes by a vacuum process. The term "DSA expanded anode" in Table 3.3 does not only mean an expanded-metal structure, but also stretching after fitting to ensure a close contact with the diaphragm.

Organic electrochemical syntheses are still dominated by the Monsanto process. Its new variant, using undivided cells, which was first announced in 1981, is described in detail. In the table summarizing the minor processes, 2,5-dihydrofuran is mistakenly given as the educt in the anodic methoxylation of furan.

The book does justice to the great variety of electrochemical surface treatments practised nowadays, such as electroplating, anodizing, electrodeposition of paint, electroforming and electrochemical machining. Cathodic deposition of paint is now widely used not only in the USA but also in Europe. Equation 7.6 is misleading: according to *Gerischer,* the electrode reaction in cyanide-type silver baths takes place *via* low-coordinated complexes. Further chapters are devoted to anticorrosion measures and to the electrochemical purification of effluents.

This handsome book is richly illustrated, mainly from British sources. It gives a succinct account of the present state of industrial electrochemistry, including its peripheral applications. It is for this reason that it represents a valuable addition to the many existing books in which a more theoretical and fundamental approach has been adopted. A future edition should include production figures and the competing chemical processes. The book describes what there actually is and not what there once was or what might be one day, but then, that was precisely the author's aim.

*Fritz Beck* [NB 576 IE]

# Phosphorothioate Analogues of Nucleotides—Tools for the Investigation of Biochemical Processes

By Fritz Eckstein*

Nucleoside phosphorothioates are analogues of nucleotides with a wide range of applications. Thus, on the one hand, in many but not all cases they are more stable against hydrolysis than the unmodified nucleotides—a property which they share with other nucleotide analogues. On the other hand, however, they are good substrates for many, but not all reactions where the nucleotide or the phosphorothioate group is transferred to an acceptor other than $H_2O$. As a consequence, once incorporated into a system such as DNA, phosphorothioates cannot be easily removed.

What makes these compounds unique to a certain extent is the chirality at the phosphorus center if two nonequivalent residues are linked to the phosphorothioate group. This opens the way for the use of these compounds to investigate stereochemical aspects of enzymatic reactions. In addition to these properties, there are those expected from exchange of an oxygen for a sulfur atom in a phosphate group, *e.g.* the increased affinity towards mercury derivatives and the large chemical shift of the $^{31}$P-NMR signals.

If one considers how many biologically interesting compounds contain phosphate groups, the considerable interest in these nucleotide analogues is not surprising.

## 1. Introduction[**]

Nucleoside phosphorothioates are analogues of nucleotides in which a non-bridging oxygen atom of a phosphate group is replaced by sulfur atom. For phosphate groups such as the α- and β-phosphate groups of ATP, which are linked to two non-identical residues, this exchange leads to chirality at phosphorus and thus to the existence of a pair of diastereomers. This property makes the phosphorothioate analogues of nucleotides, in particular those of ATP, interesting compounds for enzymatic phosphoryl and nucleotidyl transfer reactions, since they facilitate the determination of the stereochemical course of the reaction. This development has progressed rapidly in the past five years, as can be seen from the large number of review articles dealing with this subject[1–9]. This use of nucleoside phosphorothioates in bioorganic chemistry has been complemented by those in biochemistry and molecular biology, which are based mainly on the generally higher stability of phosphorothioates towards hydrolytic cleavage relative to the corresponding phosphates. These various developments will be discussed in this progress report.

## 2. Synthesis and Structure

### 2.1. Nucleoside Di- and Triphosphates

Almost all phosphorothioate analogues of the various ribo- and deoxyribonucleoside 5'-mono-, -di-, and -triphosphates have been synthesized in the meantime (Fig. 1). Their syntheses are straightforward, although the yields

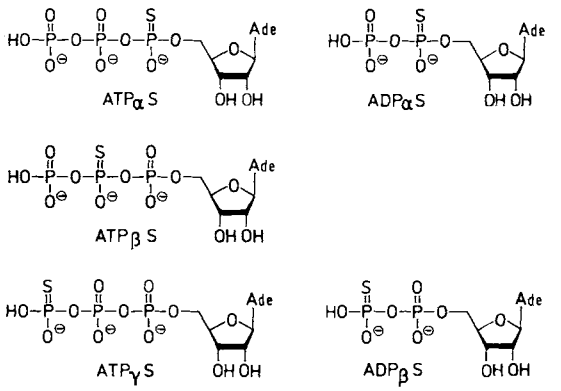

Fig. 1. Structural formulae of the phosphorothioates of ATP and ADP.

are not always satisfactory. For analogues with a terminal phosphorothioate group, such as (d)NTP$_\gamma$S and (d)NDP$_\beta$S, the simplest synthetic route is the activation of *S*-(β-cyanoethyl)phosphorothioate with diphenyl phosphorochloridate and reaction with (d)NDP or (d)NMP, followed by treatment with alkali to cleave the β-cyanoethyl group[10] (Fig. 2). Two routes are available for the synthesis of the

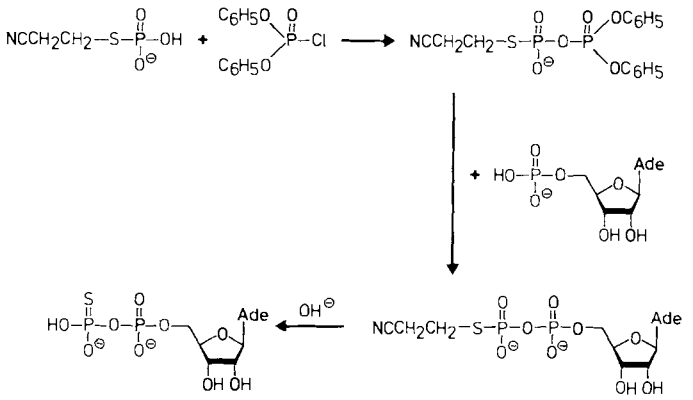

Fig. 2. Synthesis of ADP$_\beta$S. ATP$_\gamma$S is synthesized using ADP instead of AMP.

analogues of (d)NDP or (d)NTP having the phosphorothioate group in the α-position. In both methods the nucleoside is allowed to react with $PSCl_3$ to give (d)NMPS. Subsequent phosphorylation can be accomplished by activation with diphenyl phosphorochloridate and reaction with phosphoric acid or pyrophosphoric acid[11,12], a method which was introduced by *Michelson* for the synthesis of normal nucleoside di- and triphosphates[13] (Fig. 3).

It should be noted that in this reaction the oxygen of the phosphorothioate moiety is more nucleophilic than the sulfur atom. In contrast, on activation with carbonyl diimidazole or dicyclohexylcarbodiimide the sulfur becomes more nucleophilic and complete loss of sulfur is encoun-

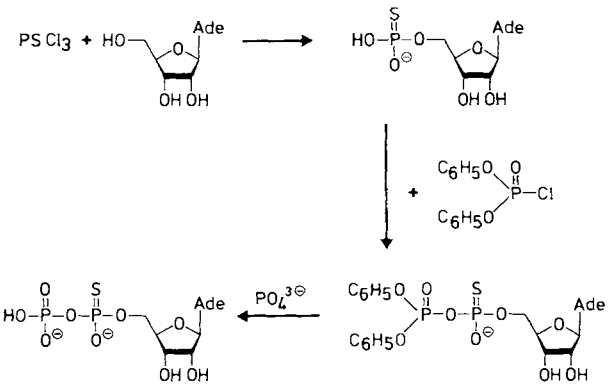

Fig. 3. Synthesis of ADP$_\alpha$S. ATP$_\alpha$S is synthesized using pyrophosphate instead of phosphate.

tered[11]. This synthesis produces both diastereomers of (d)NDP$_\alpha$S or (d)NTP$_\alpha$S in an approximate ratio of 1:1. They can be distinguished by $^{31}$P-NMR spectroscopy[14,15] or separated by HPLC[16,17]. Separation of the mixture of diastereomers can be achieved, at least in some cases, by chromatography on DEAE-Sephadex[16,18]. Where this is not possible, separation can be achieved by selective enzymatic phosphorylation of one of the diastereomers of (d)NDP$_\alpha$S to the corresponding (d)NTP$_\alpha$S by kinases[12,16]. Thus, pyruvate kinase[12], or better phosphoglycerate kinase[19], phosphorylate a diastereomeric mixture of ADP$_\alpha$S selectively to the A-isomer of ATP$_\alpha$S which, if necessary, can be freed of contaminating ATP$_\alpha$S B by reaction with acetyl CoA synthetase[20]. The residual B-isomer of ADP$_\alpha$S can be phosphorylated by creatine kinase to ATP$_\alpha$S B[12], which in turn can be freed of ATP$_\alpha$S A by reaction with hexokinase and glucose[21]. Combinations of enzymatic reactions have also been worked out for the synthesis of the diastereomers of GTP$_\alpha$S[16]. For the preparation of ATP$_\alpha$S A the enzymatic phosphorylation of AMPS with pyruvate kinase and adenylate kinase, which proceeds with very high stereospecificity[14,15], is considerably simpler but, unfortunately, is restricted to the synthesis of this compound (Fig. 4). Despite intensive efforts, no enzyme system has been found so far to synthesize ATP$_\alpha$S B preparatively from AMPS. The diastereomers of (d)NDP$_\alpha$S can be obtained from the diastereomers of (d)NTP$_\alpha$S by hydrolysis with myosin[12].

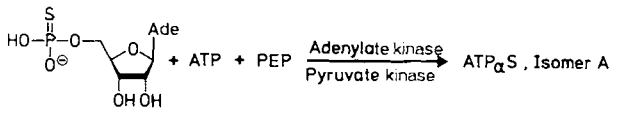

Fig. 4. Enzymatic synthesis of ATP$_\alpha$S A.

An alternative synthesis of dNDP$_\alpha$S, which is particularly attractive for organic chemists, is the condensation of dNMPS after activation with diphenyl phosphorochloridate with AMP protected at the sugar residue, as described for the synthesis of dTTP$_\alpha$S[22] and dCTP$_\alpha$S[23] (Fig. 5). The mixture of isomers resulting from this reaction can readily be separated on DEAE-Sephadex. After removal of the sugar protecting group, the adenosine is removed by oxidation with $NaIO_4$: the separated diastereomers of dNDP$_\alpha$S

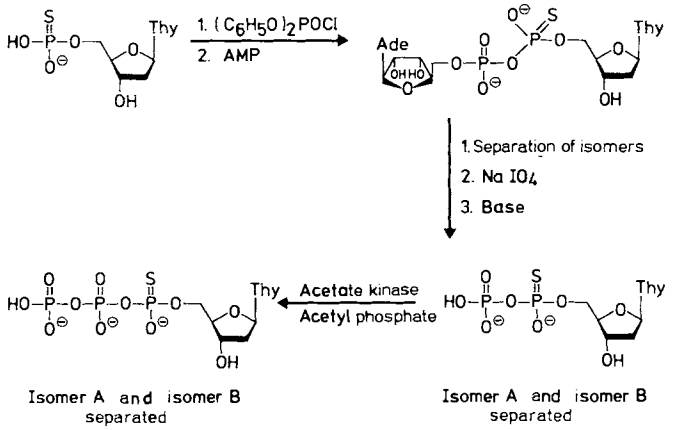

Fig. 5. Synthesis of the diastereomers of dTTP$_\alpha$S. To simplify matters the protecting group on AMP is not shown.

are obtained, which can then easily be phosphorylated enzymatically to the diastereomers of dNTP$_\alpha$S. This method was originally developed for the stereospecific syntheses of [$\alpha$-$^{18}$O]ADP$_\alpha$S, [$\beta$-$^{18}$O]ADP$_\beta$S, and [$\gamma$-$^{18}$O]ATP$_\gamma$S[24,25]. Recently it has also been extended to the preparation of the diastereomers of the phosphorothioate analogue of NAD, in which the phosphorothioate group is localized at the 5'-position of adenosine[26] (Fig. 6).

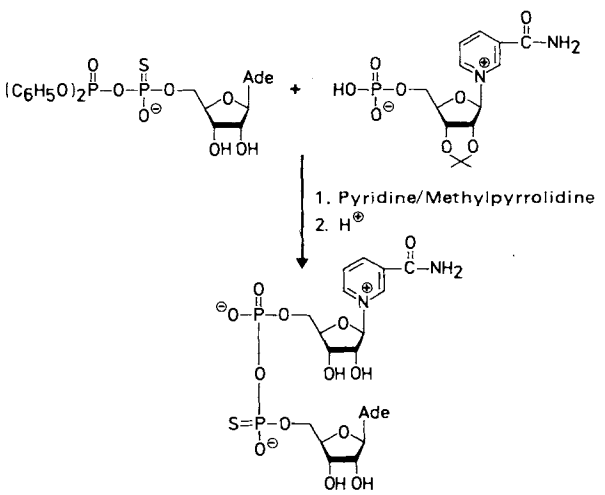

Fig. 6. Synthesis of a phosphorothioate analogue of NAD.

The assignment of the absolute configuration to the A and B diastereomers of ATP$_\alpha$S was accomplished by comparison of their different substrate properties with snake venom phosphodiesterase. Only the B-diastereomer is cleaved by this enzyme[27,28]. Of the isomers of Up(S)A also only one is cleaved, and this forms the *endo*-isomer of uridine 2',3'-cyclophosphorothioate on reaction with RNase A. Since this is the product of transesterification of a substrate with the ($R_p$)-configuration[29,30], the reactive isomer of Up(S)A must also have the ($R_p$)-configuration. It follows that also ATP$_\alpha$S B must have this configuration (Figs. 7, 8). This assignment has been confirmed by a stereospecific synthesis of [$\alpha$-$^{18}$O]ADP$_\alpha$S[31].

The diastereomers of (d)NTP$_\beta$S are prepared by enzymatic phosphorylation of (d)NDP$_\beta$S[12]. On phosphorylating ADP$_\beta$S with pyruvate kinase, the main product is

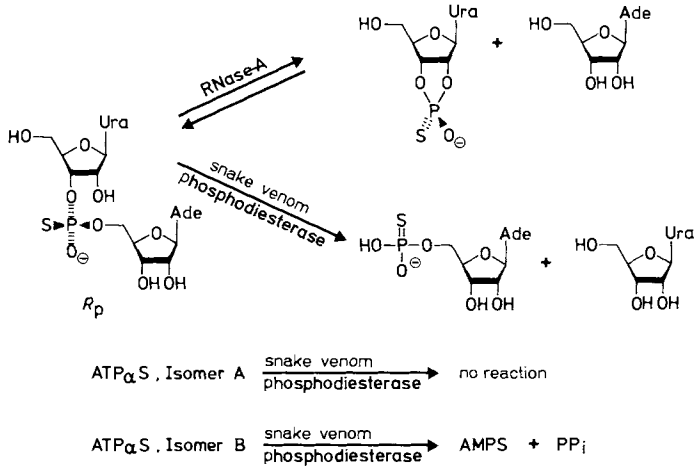

Fig. 7. Enzymatic reactions of Up(S)A and ATP$_\alpha$S for the determination of the absolute configuration of the diastereomers of ATP$_\alpha$S.

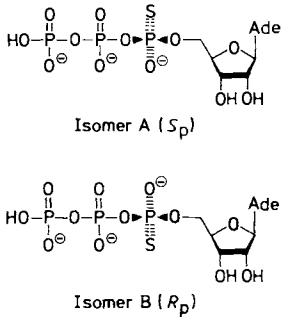

Fig. 8. Absolute configuration of the diastereomers of ATP$_\alpha$S.

ATP$_\beta$S A. The B-isomer can be removed by incubation with hexokinase and glucose[21,32a]. Diastereomerically pure A-isomer can be prepared by phosphorylation with phosphoglycerate kinase[32]. Acetate kinase produces predominantly ATP$_\beta$S B, which can be freed from traces of the A-isomer by reaction with myosin[21] (Fig. 9). The diastereomers can be distinguished by their $^{31}$P-NMR spectra[14,15]. A similar sequence of enzyme reactions has also been worked out for the diastereomers of GTP$_\beta$S[16].

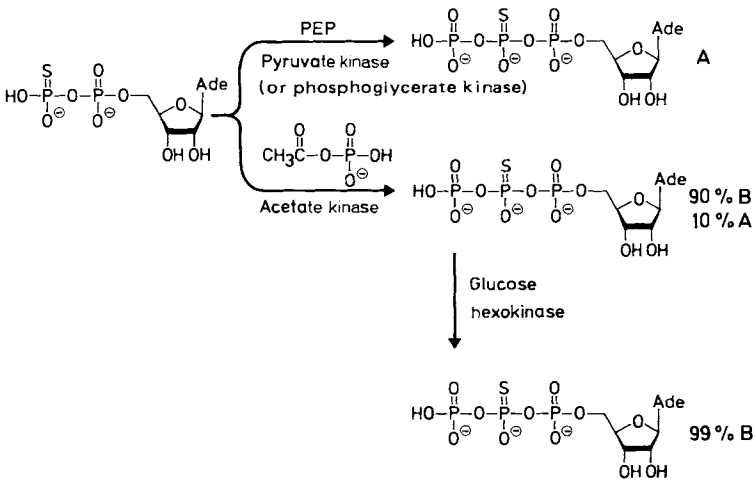

Fig. 9. Enzymatic synthesis of the diastereomers of ATP$_\beta$S.

The configuration of the diastereomers of $ATP_{\beta}S$ is based on comparison of their substrate properties with hexokinase; in the presence of $Mg^{2+}$ only the B-isomer is a substrate[32]. Also, only one of the diastereomers of β,γ-$Co(NH_3)_4ATP$ functions as a substrate[33]. Its configuration was determined as β,γ-Λ by X-ray structural analysis of $Co(NH_3)_4$-triphosphate, which was obtained by removal of the adenosine residue[34]. Since it was assumed that all substrates of a particular enzyme must have the same configuration, $MgATP_{\beta}S$ B also was assigned the Λ-configuration, which corresponds to the ($S_p$)-configuration (Fig. 10). This assignment has been independently confirmed[24].

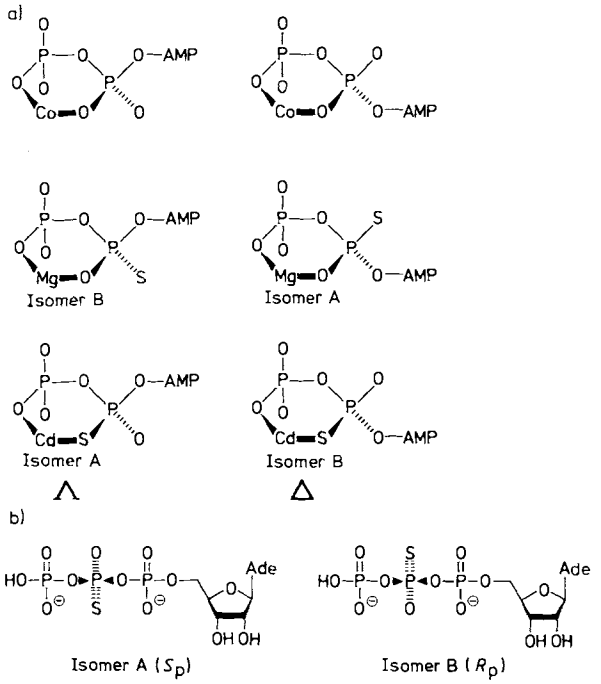

Fig. 10. a) Determination of the absolute configuration of the diastereomers of $ATP_{\beta}S$ by comparison of the substrate properties with those of the diastereomers of $Co(NH_3)_4ATP$ with hexokinase. The isomers in the left half (Λ-configuration) are the substrates. b) Absolute configuration.

## 2.2. Nucleoside 3',5'-Cyclic Phosphorothioates

For enzymatic investigations also the phosphorothioate analogues of nucleoside 3',5'-cyclic phosphates, particularly those of cAMP and cGMP, are of interest. The diastereomers of cAMPS were obtained by conversion of benzoylated cAMP into the anilidate and separation of the diastereomers by preparative thin layer chromatography; reaction with $K/CS_2$ under retention of configuration then leads to the isomers of cAMPS[35]. This has also been extended to the synthesis of the diastereomers of cGMPS[36], cCMPS, and cUMPS[37] (Fig. 11). The configurations were assigned from the $^{31}$P-NMR spectra of the anilidates[35].

A straightforward synthesis of the diastereomers of cAMPS is provided by the cyclization of adenosine 5'-bis(*p*-nitrophenyl)phosphorothioate by potassium *tert*-butoxide[38]. After work-up and chromatographic separation on DEAE-Sephadex, the ($S_p$)-isomer of cAMPS crystallizes out. The assignment of configuration was made using the results of *Stec et al.*[35]. The non-crystalline ($R_p$)-isomer

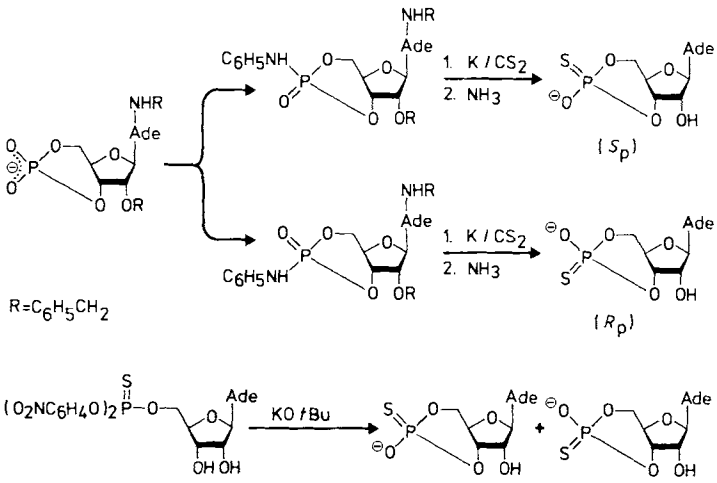

Fig. 11. Synthesis of the diastereomers of cAMPS.

is also obtained but in considerably lower yield. The diastereomers of cUMPS and cCMPS can also be obtained in this way, and the ($S_p$)-isomer of cUMPS is also obtained in crystalline form[23]. cGMPS can be prepared more straightforwardly, albeit in very low yield, by activation of GMPS with diphenyl phosphorochloridate and subsequent cyclization[39].

## 2.3. Dinucleoside Phosphorothioates

The chemical synthesis of the diastereomers of dinucleoside phosphorothioates has, particularly recently, attracted attention for determining the configuration of enzymatically prepared phosphorothioate internucleotidic linkages in polydeoxynucleotides. The first successful separation of such diastereomers was accomplished with a diribonucleoside phosphorothioate, Up(S)A. This was prepared by the triester method using β-cyanoethyl phosphorothioate to thiophosphorylate the 3'-OH group of appropriately protected uridine using triisopropylbenzenesulfonyl chloride as condensing agent in the first step; condensation with the 5'-OH group of appropriately protected adenosine followed in the second step[40]. After removal of the uridine 5'-OH protecting group, the diastereomers could be separated by chromatography on silica gel, and after removal of the β-cyanoethyl group by treatment with triethylamine/$H_2O$ (β-elimination) the diastereomers of Up(S)A were obtained. The configurational assignment was carried out by reaction with RNase A to afford uridine 2',3'-cyclic phosphorothioate (see Section 2.1)[27]. The diastereomers can be distinguished by $^{31}$P-NMR spectroscopy as well as by HPLC. Using this synthetic route *ca.* 20% of the normal dinucleoside phosphate, in this case UpA, is also formed by direct nucleophilic attack at the phosphorus center: this, however, can easily be separated chromatographically. The diastereomers of Tp(S)T[22,41], d[Tp(S)A][42], d[Cp(S)G], and d[Gp(S)C][43] have also been synthesized by this triester method (Fig. 12a), but could only be separated by HPLC after removal of all the protecting groups.

From the experience accumulated so far, it seems that, because of the better yields obtained, the phosphite method is better suited for the synthesis of these compounds. The first synthesis with this method using di-

chloro(phenoxy)phosphane has been described for Up(S)A[44], but the diastereomers could not be separated. Dichloro(methoxy)phosphane has been used successfully for the synthesis of Ap(S)A, and in this case the diastereomers were separated chromatographically[45]. In the meantime, also the diastereomers of Tp(S)T[46], d[Gp(S)A][47], d[Cp(S)T] and d[Gp(S)T][23] have been synthesized by this method using chloro(dimethylamino)methoxyphosphane (Fig. 12b). The configuration was assigned in all cases by hydrolysis with snake venom phosphodiesterase, which only cleaves the ($R_p$)-diastereomer[26], or with nuclease P1, which only cleaves the ($S_p$)-diastereomer[41]. The second method is preferred because the hydrolysis produces considerably cleaner products.

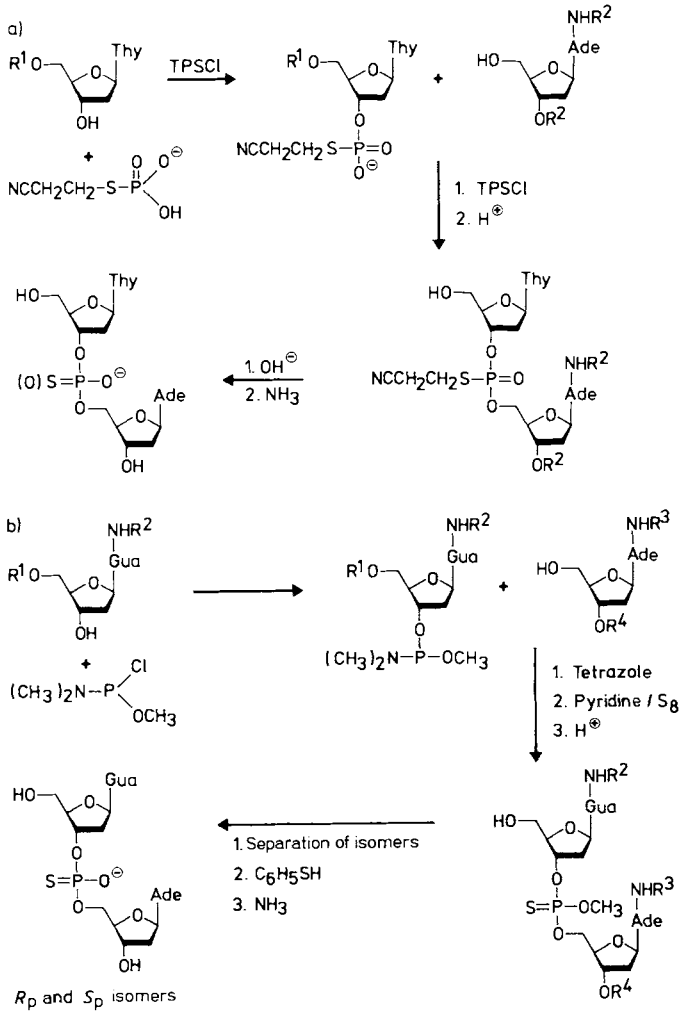

Fig. 12. Synthesis of dinucleoside phosphorothioates examplified by d[Tp(S)A]. a) Triester method. b) Phosphite method.—$R^1$ = dimethoxytrityl; $R^2$ = isobutyryl; $R^3$ = benzoyl; $R^4$ = methoxyacetyl; TPSCl = triisopropylbenzenesulfonyl chloride.

In the meantime sufficient $^{31}$P-NMR and HPLC data are available to postulate that the diastereomer having the larger down-field chemical shift in the $^{31}$P-NMR spectrum and the shorter retention time on reversed phase HPLC columns has the ($R_p$)-configuration.

### 2.4. Exchange of Sulfur by Oxygen Atoms

The diastereomers of the various nucleoside phosphorothioates can be stereospecifically labeled with $^{17}$O or $^{18}$O by reaction with bromocyanogen[48], *N*-bromosuccinimide[49], or bromine[50] in the presence of $H_2{}^{17}O$ or $H_2{}^{18}O$ (Fig. 13). With nucleoside 3′,5′-cyclic phosphorothioates,

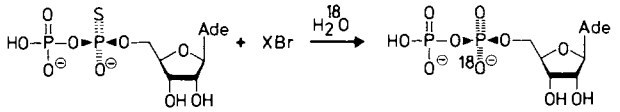

Fig. 13. Exchange of sulfur by oxygen in nucleoside phosphorothioates. X = CN, Br, or succinimide.

such as cAMPS and cTMPS, the two last-mentioned reactions proceed with approximately 80% inversion at phosphorus[49,50,39], but no data are yet available for the reaction of this system with bromocyanogen. When this reaction was performed using *N*-bromosuccinimide and Tp(S)T, the only dinucleoside phosphorothioate with which it has been carried out so far, it proceeded stereospecifically with inversion of configuration at phosphorus[41]. The stereoselectivity of the exchange of sulfur by oxygen in the diastereomers of $ADP_\alpha S$—all three exchange reactions have been performed—cannot easily be determined with sufficient accuracy. It has been determined for the $Co(NH_3)_4$[α-$^{18}$O]ADP complex by $^{31}$P-NMR spectroscopy, where probably up to 10% of the other diastereomer cannot be detected because of poor signal resolution[48,49], or by $^{31}$P-NMR spectroscopy of the diastereomeric methyl esters of [$^{16}$O,$^{17}$O,$^{18}$O]cAMP, obtained by enzymatic hydrolysis of [α-$^{18}$O]ADP in $H_2{}^{17}O$ to give [$^{16}$O,$^{17}$O,$^{18}$O]AMP, followed by cyclization and methylation. Here also the determination of the diastereomeric purity is unsatisfactory[50]. Despite these limitations it was found that all three reactions proceed with inversion of configuration.

A more precise determination, however, has recently become available, and this uses the reaction of $GDP_\alpha S$ A with *N*-bromosuccinimide, since the resulting [α-$^{18}$O]GDP could be used after phosphorylation to [α-$^{18}$O]GTP as substrate for guanylate cyclase. The [$^{18}$O]cGMP obtained in this way consisted of only one isotopomer, as determined with high accuracy by $^{31}$P-NMR spectroscopy of the methyl esters (see Section 3.1, Fig. 18). This result allows it to be concluded that the exchange reaction with $GDP_\alpha S$ as well as the enzymatic cyclization proceed stereospecifically, at least within the limits of detection of this method[39]. This probably also implies that the *N*-bromosuccinimide reaction will proceed similarly with other $NDP_\alpha S$. A more detailed investigation has revealed that the pH value probably plays an important role in all three exchange reactions. Under reaction conditions where the solutions are buffered at pH 7—8, the oxygen is not only introduced at the α-, but also at the β-phosphate group if the β-phosphate group is not protected by a cyanoethyl group. It has been proposed that this "scrambling" involves the formation of intramolecular *cyclo*-diphosphate[51]. When this reaction is performed using $ATP_\alpha S$, oxygen is introduced in all three reactions into the α- as well as the γ-position *via* intermediate formation of a six-membered ring follow-

ing nucleophilic attack of the γ-phosphate on the α-phosphate group[48,49,50]. For this reason in the preparation of [α-$^{18}$O]NTP the corresponding NDP$_\alpha$S is allowed to react with $H_2{}^{18}O$ to afford [α-$^{18}$O]NDP, which is then phosphorylated by a kinase to yield [α-$^{18}$O]NTP.

This method of exchange is also of interest for the stereospecific introduction of $^{17}$O. $^{17}$O-Labeled nucleotides prepared in this way have been used for EPR[52] and $^{17}$O-NMR spectroscopic studies[53,54,55] to determine the structure and configuration of nucleotide metal complexes.

## 3. Application to the Solution of Mechanistic Problems of Enzymatic Reactions

### 3.1. Investigation of the Stereochemical Course of Enzyme Reactions

One of the main applications of nucleoside phosphorothioates is the investigation of the stereochemical course of enzymatic phosphoryl and nucleotidyl transfer reactions[1-9]. Up to now, approximately 40 enzymes have been investigated using the phosphorothioate method (Table 1). The results have been discussed in detail in numerous review articles[5-9], so that only the results of more recent investigations mainly of DNA polymerases will be discussed here. The basic idea of such studies is that information on the stereochemical course of enzymatic transfer reactions should allow distinction to be made between a one-step and a two-step substitution reaction in which a covalent enzyme intermediate occurs. In the first case inversion, and in the second case retention of configuration at the phosphorus atom should be observed.

The stereochemical course of the reactions catalyzed by *E. coli*-DNA-dependent DNA polymerase I (Kornberg enzyme)[55,56,57] as well as by *E. coli*-DNA-dependent RNA polymerase[27] were described relatively early. More recently, other polymerases, such as phage T4 and T7 DNA polymerases[42,58], have been investigated and a rather simple method developed for the determination of the stereochemical course of the reactions catalyzed by these enzymes. Polymerization of TTP and dATP$_\alpha$S, of which so far only the ($S_p$)-isomer has been found to be a substrate on poly[d(A-T)] as template-primer, produces a polymer which contains alternating phosphate and phosphorothioate groups: poly[d(T$_s$A)].

This polymer can be degraded by the 5′→3′ nuclease activity of the Kornberg enzyme, which hydrolyzes only phosphate diesters but not phosphorothioate diesters[55-57] to d[pTp(S)A]. Hydrolysis with alkaline phosphatase produces d[Tp(S)A], whose configuration can be determined by comparison with that of chemically synthesized diastereomers ($^{31}$P-NMR spectroscopy or HPLC) (Fig. 14). Investigations with the enzyme reverse transcriptase have shown that the determination of configuration can also be carried out on the polymers by $^{31}$P-NMR spectroscopy, as long as the chain-lengths are not too long and that they give a sharp signal[22]. All these polymerase-catalyzed reactions proceed by inversion of configuration at phosphorus.

Table 1. Stereochemical course of enzymatic phosphoryl and nucleotidyl transfer reactions.

| Enzyme | Stereochemical Course | Ref. |
|---|---|---|
| A) *Investigations with $^{16}$O-Phosphorothioates* | | |
| Ribonuclease A transesterification step | Inversion | [29, 30] |
| Ribonuclease T$_1$ | Inversion | [180] |
| Ribonuclease T$_2$ | Inversion | [40] |

| Creatine kinase | Inversion | [214] |
| Staphylococcal nuclease | Inversion | [72] |
| Spleen phosphodiesterase | Retention | [66] |
| Phosphoglycerate mutase | Retention | [215] |
| Nuclease P1 | Inversion | [41] |

The stereochemical course of the reaction catalyzed by a DNA polymerase 3′→5′ exonuclease has also been determined for the phage T4 enzyme by comparison of the configuration of the product [$^{18}$O]dAMPS with that of the substrate [α-$^{18}$O]dATP$_\alpha$S. This was carried out by enzymatic

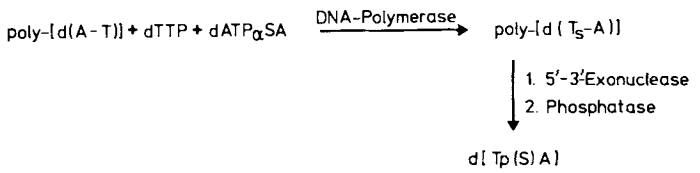

Fig. 14. Determination of the stereochemical course of a reaction catalyzed by a DNA polymerase. The product d[Tp(S)A] is compared by HPLC or NMR spectroscopy with diastereomers synthesized chemically. In all cases the configuration thus determined is $R_p$.

phosphorylation of [$^{18}$O]dAMPS with pyruvate kinase and adenylate kinase to give [α-$^{18}$O]dATP$_\alpha$S having an ($S_p$)-configuration[56]. $^{31}$P-NMR spectroscopy can be used to determine whether the $^{18}$O is localized only at $P_\alpha$ or whether it bridges $P_\alpha$ and $P_\beta$[59,60] (Fig. 15). $^{18}$O was found exclusively at $P_\alpha$ in the product [α-$^{18}$O]dATP$_\alpha$S. This indicates retention of configuration which, since the polymerization reaction proceeds with inversion of configuration, implies inversion of configuration also for the exonuclease reaction[18]. This method of analysis has wide applications and was also used *inter alia* for the determination of the stereochemical course of reactions involving nuclease S1 using the ($S_p$)-isomer of d[Tp(S)A][61].

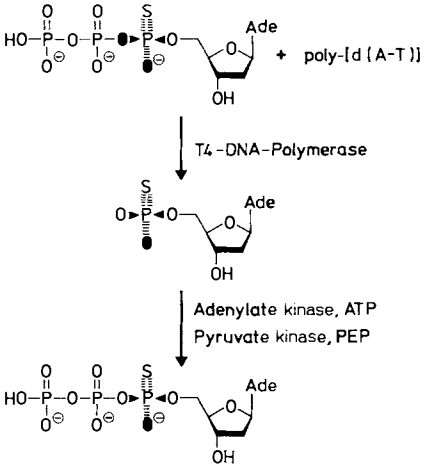

Fig. 15. Determination of the stereochemical course of the reaction catalyzed by the 3'→5' exonuclease of phage T4 DNA polymerase. The configuration of [α-$^{18}$O]dATP$_\alpha$S is analyzed by $^{31}$P-NMR spectroscopy. ● = $^{18}$O.

An elegant application of the phosphorothioates is the investigation of the stereochemical course of ATPase reactions where [γ-$^{18}$O]ATP$_\gamma$S is used in the presence of $H_2{}^{17}O$[9]. The determination of the configuration of the chiral $^{16,17,18}$O-thiophosphate produced in these reactions is carried out by enzymatic incorporation into ATP$_\beta$S, whose configuration can be determined by $^{31}$P-NMR spectroscopy taking advantage of the fact that the quadrupole moment of $^{17}$O broadens the $^{31}$P signals so much that they practically disappear. Thus, the analysis is narrowed down to determining whether $^{18}$O is localized at $P_\beta$ or whether a $P_\gamma$-$^{18}$O-$P_\beta$ bridge is involved[9,62] (Fig. 16). An elegant and impressive analysis!

Of course the question arises with all these stereochemical investigations employing nucleoside phosphorothioates whether the stereochemical course of an enzymatic reaction is different with these analogues than with the normal substrates. This can be clarified by allowing the enzyme to react both with the nucleoside phosphorothioates and with the natural substrate. For investigations involving the natural substrate, the phosphate group to be transferred clearly has to be chiral. This can be achieved by stereospecific incorporation of $^{17}$O and $^{18}$O. *Knowles et al.*[4,63], *Lowe et al.*[64], and *Gerlt et al.*[65] have developed methods for the synthesis of the substrates as well as for the analysis of the products, but this will not be discussed here in detail. One method for the synthesis of such substrates by stereospecific exchange of sulfur by $^{18}$O or $^{17}$O has been discussed in Section 2.4.

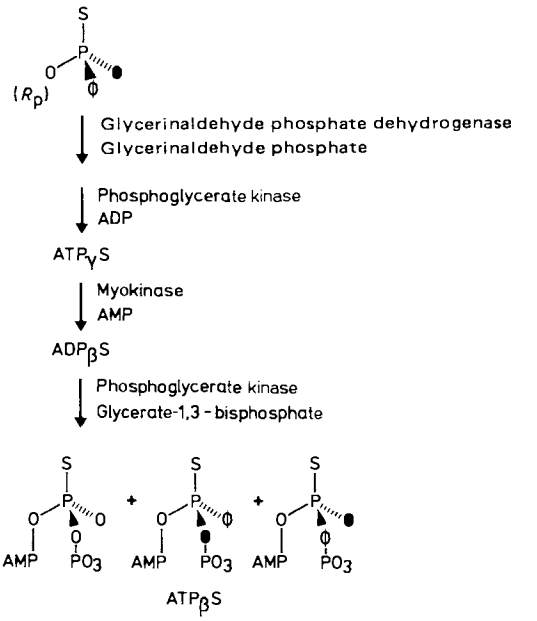

Fig. 16. Determination of the configuration of the ($R_p$)-enantiomer of [$^{16}$O,$^{17}$O,$^{18}$O]thiophosphate. The end product [β-$^{16}$O,$^{17}$O,$^{18}$O]ATP$_\beta$S is analyzed by $^{31}$P-NMR spectroscopy. O = $^{16}$O; Ø = $^{17}$O; ● = $^{18}$O.

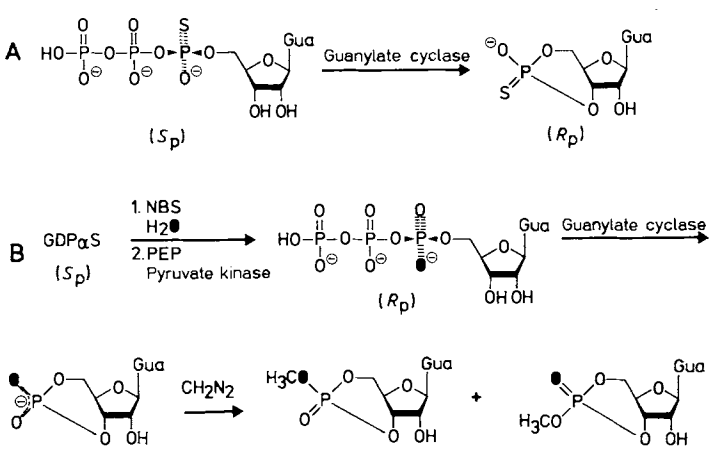

Fig. 17. Determination of the stereochemical course of the reaction catalyzed by guanylate cyclase. ● = $^{18}$O.

For the six enzymes which have been studied by both methods (see also Table 1), and for which guanylate cyclase is described as an example in Figure 17, no difference in the stereochemical course of the reaction could be

detected. This justifies using the results of investigations of the stereochemical course of reactions with phosphorothioates to extrapolate to those of the normal substrates. Phosphorothioates are easier to manipulate than those involving $^{18}O$-compounds because the product analysis is simpler and smaller amounts of material are required. Complications can arise from the slower reaction rates often encountered, particularly when secondary reactions can occur at the substrate or the product, *e.g.* desulfurization has been observed in the reactions with snake venom phosphodiesterase or nuclease S1[27,61]. Up till now there is, however, only one enzyme, spleen phosphodiesterase, where the phosphorothioate method failed; here because of the slow rate of hydrolysis, a transphosphorylation prevails[66].

Of the *ca.* 50 enzymes studied with respect to the stereochemical course of the reactions catalyzed by them, *ca.* 40 show inversion and 10 retention of configuration at the phosphorus atom (Table 1). The simplest interpretation of these results is that 4/5 of the enzyme reactions proceed by a single-step mechanism. This simple interpretation is complicated by the fact that inversion is the result only of substitution reactions at phosphorus in which the incoming nucleophile as well as the leaving group occupy apical positions in the trigonal bipyramidal transition state or intermediate (in-line mechanism). If the incoming group occupies an apical but the leaving group an equatorial position, pseudorotation must occur for the reaction to proceed, and this results in retention of configuration (adjacent mechanism)[67,68] (Fig. 18). Accordingly, retention of configuration does not necessarily have to be the result of two substitution reactions each of which proceeds with inversion. For half of the enzymes which show retention a covalent enzyme intermediate can be detected or is at least plausible, and hence with these enzymes retention of configuration can be interpreted as the result of two subsequent substitution reactions, each proceeding with inversion.

For the other half, a covalent enzyme intermediate has either not yet been found or has not even been sought, so that the possibility still exists that retention is the result of

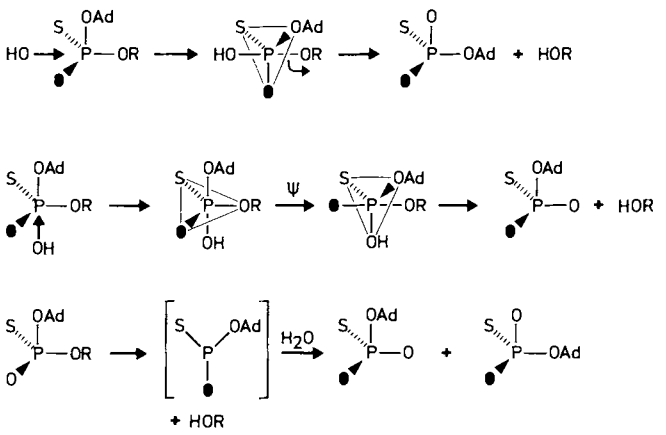

Fig. 18. Stereochemical consequences of substitution reactions at phosphorus in phosphates. Ad = adenosine; ● = $^{18}O$.—Top: in-line mechanism results in inversion of configuration. Middle: adjacent mechanism requires pseudorotation (ψ) and results in retention of configuration. Bottom: elimination-addition mechanism *via* metaphosphate should result in racemization, at least in non-enzymatic reactions.

a single substitution step involving pseudorotation. However, it is considered probable that also for these enzymes the reaction proceeds by a two-step mechanism. Even more complicated interpretations can be considered. Thus, any odd number of substitution reactions of the in-line type leads to inversion, and hence this does not necessarily have to be the result of only one such reaction. In addition, inversion could also be explained by a two-step mechanism the first reaction of which proceeds with inversion but the second with retention, or *vice versa*. However, as long as the simplest interpretations suffice there is no compelling reason to complicate the arguments. For a specific discussion of the importance of the elimination-addition mechanism in enzyme reactions the article by *Knowles*[4] should be consulted.

So far only two X-ray structure analyses of nucleotidyl transfer enzymes, RNase A and staphylococcal nuclease, exist where the structures of the active sites can be described with sufficient precision to enable a mechanism to be delineated[69,70]. The stereochemical analysis of the reactions of both enzymes reveals that inversion of configuration occurs[29,30,71,72], which is in full agreement with the structural analysis (for a detailed discussion of Staphylococcal nuclease see [72]).

### 3.2. Structure of the Mg-ATP Complex in Enzymatic Reactions

Phosphorothioate analogues, particularly those of ATP, have proved to be suitable for the description of the structure of the Mg-ATP complex involved in enzymatic phosphoryl and nucleotidyl transfer reactions[2,3,5,73]. They are therefore useful additions to the exchange-inert $Cr^{III}$- and $Co^{III}$-ATP complexes[74,75]. Phosphorothioate analogues are often considerably better substrates, whereas the $Cr^{III}$ and $Co^{III}$ complexes are more suitable for unambiguous determination of coordination of the metal to the γ-phosphate group.

The use of the phosphorothioate analogues of ATP for studies of this type rests on the observation that in the presence of $Mg^{2+}$ the B-isomer of $ATP_{\beta}S$, and in the presence of $Cd^{2+}$ the A-isomer is the preferred substrate for hexokinase[32]. As already discussed in connection with the configurational assignment of the diastereomers of $ATP_{\beta}S$ (Section 2.1), also only the β,γ-Λ-configuration of the diastereomer of the $Co(NH_3)_4ATP$-complex is a substrate[33]. This result served as the basis for the determination of the configuration of Mg-$ATP_{\beta}S$ B and $CdATP_{\beta}S$ A as β,γ-Λ[32] (Fig. 10a). The different behavior of the diastereomers as substrates in the presence of $Mg^{2+}$ and $Cd^{2+}$ is explained by the preferential coordination of $Mg^{2+}$ to oxygen and of $Cd^{2+}$ to sulfur; this can also be observed by NMR spectroscopy[32]. Other cations such as $Co^{2+}$, $Zn^{2+}$, and $Mn^{2+}$ do not show this preference so strongly; consequently both diastereomers of $ATP_{\beta}S$ are substrates. These results indicate that the cations have to be coordinated to the phosphorothioate group during the enzymatic reaction. If the metal ion were to dissociate and to be replaced, for example, by a positively charged group of the active site of the enzyme, this reversal could not be explained since it is not

Table 2. Structure of the metal-ATP complex at the active site of enzymes as analyzed by the phosphorothioate method.

| Enzyme | $P_\alpha$-Specificity [a] | $P_\beta$-Specificity [a] | Structure of the β,γ-metal-ATP complex [b] | Ref. |
|---|---|---|---|---|
| *E. coli*-DNA polymerase I | $S_p$(Mg–Zn) | $S_p$(Mg)–$R_p$(Zn) | Δ | [56] |

| Met-tRNA synthetase | $S_p$(Mg) | $S_p$(Mg)–$R_p$(Zn) | Δ | [219] |
| Pyridoxal kinase | $S_p$,$R_p$(Mg,Cd) | $S_p$(Mg)–$R_p$(Cd) | Δ | [129] |
| Protein kinase | — | $S_p$(Mg)–$R_p$(Cd) | Δ | [220] |
| Thermophilic bacterium PS3 ATPase | $S_p$(Mg–Cd) | $S_p$(Mg)–$R_p$(Cd) | Δ | [197] |
| Carbamate kinase | $S_p$,$R_p$(Mg) | $R_p$(Mg,Cd) | — | [221] |
| Glutamine synthetase | $R_p$(Mg)–$S_p$,$R_p$(Co) | $R_p$(Mg)–$S_p$,$R_p$(Co) | Λ | [221] |
| Carbamoylphosphate synthetase | $R_p$(Mg)–$S_p$(Cd) | $S_p$(Mg)–$R_p$(Cd) | — | [221, 222] |
| Phosphoribosylpyrophosphate synthetase | $S_p$(Mg)–$S_p$,$R_p$(Cd) | — | — | [223] |

[a] $S_p$(Mg–Cd) indicates that the enzyme retains the preference for the $S_p$-diastereomer (isomer A) for $ATP_\alpha S$ or $ATP_\beta S$, irrespective of whether $Mg^{2+}$ or $Cd^{2+}$ are used as activating cations; $R_p$(Mg)–$S_p$(Cd) indicates that the enzyme prefers the $R_p$-diastereomer in the presence of $Mg^{2+}$ but the $S_p$-diastereomer in the presence of $Cd^{2+}$ (or $Zn^{2+}$). [b] Δ and Λ indicate the screw sense of the β,γ-metal-ATP complex [33].

clear why this group should in one case bind preferentially to oxygen and in the other to sulfur.

With all the enzyme reactions investigated with the diastereomers of $ATP_\alpha S$ and $ATP_\beta S$ it is always found—with one exception[19]—that reversal of stereoselectivity at the β-phosphate occurs and—with two exceptions[76,77]—that this never occurs at the α-phosphate (Table 2). Therefore, it can be assumed for the β-phosphate that the metal ion is bonded at the β-position, and for the α-phosphate that no coordination of the metal ion to the α-position occurs. This second statement is ambiguous since it is quite conceivable that the geometry of the active site could exert certain constraints on formation of the metal complex, forcing, *e.g.*, an otherwise unfavorable Mg→S coordination upon it. This and similar assumptions must also be made to explain those situations in which the stereoselectivity is very pronounced for one metal ion but not for the other, as, for example, with RNA polymerase[78] where the ratio of activities for $ATP_\beta S$ A/B in the presence of $Mg^{2+}$ is 1.11 and for $Cd^{2+}$ 0.003. A similar situation exists for myosin, where the corresponding values are 3000 and 1.3[79].

A description of the metal-ATP complex on the basis of the results obtained in this way is not entirely straightforward. It can, however, be assumed that the metal ion is bound at some stage of the enzymatic reaction, presumably during the rate determining step, to that phosphorothioate at which reversal of stereoselectivity is observed. Observation of reversal of stereoselectivity only at the β-phosphate usually leads to proposal of a bidentate β,γ-Mg-ATP complex; for thermodynamic reasons a β-monodentate complex is considerably less stable than a six-membered cyclic β,γ-complex. But such a complex cannot be detected with phosphorothioate analogues. This interpretation, however, is consistent with the results obtained from the exchange-inert $Cr^{III}$- and $Co^{III}$-ATP complexes, in as much as comparisons of hexokinase[33,80], creatine kinase[76,81], arginine

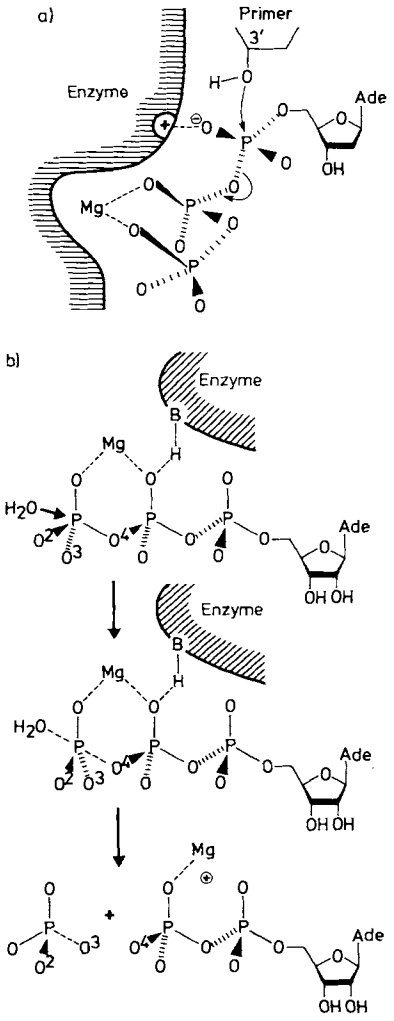

Fig. 19. Structure of the Mg-ATP complex at the active site of a) *E. coli* DNA-dependent DNA polymerase I and b) myosin.—The coordination of the metal to the β-phosphate group of ADP was determined by EPR measurements on [β-$^{17}$O]ADP [84].

kinase[77,81], and adenylate kinase[77,82] are possible. Difficulties arise in the interpretation of the results for creatine and arginine kinase, where reversal is observed at the α- as well as at the β-phosphate of ATP. This could be explained either by the presence of a bidentate α,β- or a β,γ-MgATP complex giving rise to an α,β-ADP complex as product. The solution to the problem seems to be a tridentate α,β,γ-Mg-ATP complex, as deduced from EPR measurements of the [α,β$^{17}$O]ADP-Mn-nitrate-creatine-enzyme complex[52,83]. Such a complex clearly is consistent with a β,γ-ATP structure for the substrate and a α,β-ADP structure for the product. How the results obtained for phosphoglycerate kinase (reversal at α- but not at β-phosphate) can be explained is not yet clear[19].

As seen in Table 2 there is no clear-cut preference for a particular configuration of the metal·ATP complex by these enzymes. It should be mentioned, however, that all DNA and RNA polymerases studied so far accept exclusively the ($S_p$)-isomer as substrate, irrespective of the cation present.

Figure 19 shows the results obtained using the phosphorothioate method to investigate the stereochemical course of the reaction, as well as the structure of the MgATP substrate complex for myosin[79] and DNA polymerase[56]; this shows what a detailed picture of the arrangement of the substrate in the active site can be gained by such studies. Of course, they allow no conclusions to be drawn on the participation and function of functional groups of the protein; this remains the realm of X-ray structure analysis.

## 4. Application to the Solution of Biochemical Problems

### 4.1. Incorporation of Phosphorothioate Groups into DNA

Phosphorothioate groups can easily be incorporated into DNA by enzymatic polymerization of dNTP$_\alpha$S[85]. Of all the DNA polymerases studied so far, *E. coli*-DNA polymerase I[56,57], phage T4 and T7 DNA polymerases[42,58], *M. luteus*-DNA polymerase[43,87], and reverse transcriptase[22] use only the ($S_p$)-isomer of dNTP$_\alpha$S as substrate, and inversion of configuration at phosphorus is always observed. Mammalian DNA polymerase β also polymerizes dNTP$_\alpha$S, although the stereospecificity has not yet been determined[86]. This also applies to *E. coli* cells treated with ether[85]. All systems have in common that the phosphorothioate analogue is incorporated with polymerization rates similar to those of normal triphosphates.

DNA modified by phosphorothioate groups differs in some respects from natural DNA. It was found rather early[85] that double stranded circular ΦX174 or fd DNA in which only the (−)strand had been modified by incorporation of dAMPS instead of dAMP had the same sedimentation coefficient as natural DNA, but that the buoyant density in neutral CsCl was *ca.* 0.4% larger: this might arise from the higher atomic weight of sulfur compared to oxygen. This DNA is infectious and has a $T_m$ value 1-2° below that of unmodified DNA. Lower $T_m$ values have also been observed recently for phosphorothioate analogues of other polymers, such as poly[d(G$_s$C)] ($\Delta T_m$ −2 °C)[43], but also poly[d(A$_s$T)] ($\Delta T_m$ −15 °C) and poly[d(T$_s$A)] ($\Delta T_m$ −5 °C)[87,88]. The reason for this is not clear. The CD spectra, at least of the analogues of poly[d(G-C)], are identical with that of the unmodified polymer[43]. It has not yet been investigated how well DNA modified in this way can serve as a template for DNA-dependent RNA and DNA polymerases. The phosphorothioate groups influence the transition of the polynucleotides from the B to the Z conformation at different rates. Thus, the transition of poly[d(G$_s$C)] is considerably facili-

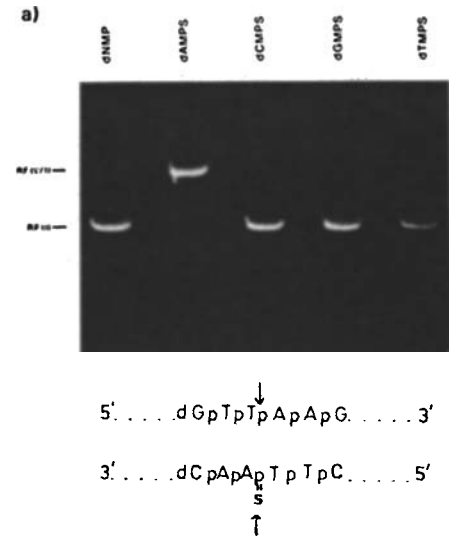

Fig. 20. Inhibition of reactions catalyzed by restriction endonucleases by incorporation of phosphorothioate groups at the site of cleavage. a) Reaction with *Hind*II. b) Reaction with *Hpa*II.—The enzyme *Hind*II cuts fd DNA once to linearize the circular DNA. The enzyme *Hpa*II cuts eight times to yield 8 fragments of different length. The letters A to H describe these fragments. RF IV is circular, covalently closed double-stranded DNA; RF III is double-stranded linear DNA; RF II is circular double-stranded DNA with at least one cut in one of the strands. The fragments were analyzed by gel electrophoresis and stained with ethidium bromide[90].

tated compared to poly[d(G-C)], but practically does not occur with poly[d($C_s$G)].

The transition can be followed by UV, CD, laser-Raman, and $^{31}$P-NMR spectroscopy. Also, poly[d($G_s$C)] is, in contrast to poly[d($C_s$G)], very antigenic and the antibodies produced are specific for Z-DNA. An explanation of this different influence of the phosphorothioate groups is not yet clear[43]. These results indicate a role of the phosphate groups in this conformational change which had previously not been considered, and it is to be hoped that the DNA-analogues will provide deeper insight into the process. The $^{31}$P-NMR spectra of the partially thiophosphorylated polymers poly[d($T_s$A)], poly[d($A_s$T)], poly[d($C_s$G)], and poly[d($G_s$C)] enable assignment of the $^{31}$P-NMR signals in the unmodified polymers to be made, since the signals of the phosphorothioate groups are strongly shifted to lower field[43, 87].

Besides these differences between natural and thiophosphorylated DNA, others are observed in interactions with enzymes. As already mentioned, the phosphorothioate internucleotidic linkage is resistent to the 5′→3′ nuclease of polymerase I (see Section 3.1). This increased stability to nucleases seems to be a rather general phenomenon. Thus, these modified internucleotidic linkages are also not degraded by exonuclease III. This has been used to stabilize 5′-ends of one strand of double-stranded DNA against degradation[89].

Also all restriction enzymes investigated so far hydrolyze phosphorothioate internucleotide linkages more slowly than phosphate linkages. This could be shown for fd DNA molecules where only the (−)strand but not the (+)strand, which had been used as a template for polymerization, was modified[90]. By replacing one deoxynucleoside triphosphate by the corresponding phosphorothioate in the polymerization, four samples were prepared in each of which the 5′-phosphate group of another nucleotide was modified. A comparison of the degradation of these four DNAs by six restriction enzymes shows that, in general, only a modification exactly at the cleavage site, but not in other positions within the recognition sequence, slow down the hydrolysis considerably (Fig. 20). This observation, which has not yet been treated quantitatively, suggests that phosphorothioates might be used to stabilize DNA against degradation by restriction enzymes.

The 3′→5′ nuclease activity of viral and bacterial DNA polymerases is responsible for the excission of non-complementary base pairs during polymerization and is therefore responsible, wholly or partly, for the fidelity of replication in these systems[91] (Fig. 21). If the phosphorothioates were either not or only more slowly degraded by this nuclease, an increase in the error rate in replication would be expected, and an estimation of the contribution of the 3′→5′-nuclease to fidelity should be possible. For the determination of fidelity of replication amber-mutants of circular single-stranded viral DNA which upon incorporation of non-complementary bases during replication, *i.e.* incorrect incorporation, revert to the wild type are particularly well suited (Fig. 22). Even a few revertants can be determined accurately in a large population because each viable virus in a bacterial culture betrays itself by formation of a plaque after being spread on agar film. The number of non-reverted mutants can be estimated in a separate experiment by suppression of the mutation by addition of suppressor tRNA.

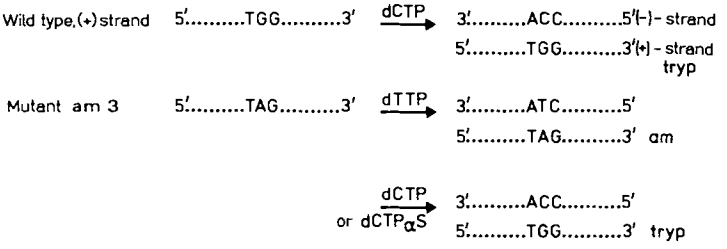

Fig. 22. ΦX174-mutant am3. The positions 586—588 are shown. In the mutant, G is replaced by A. This triplet codes for the amino acid tryptophan (tryp) in the wild-type; in the mutant it is a non-sense codon (cf. also text).

The fidelity of replication of the (+)strand of Φ174 am3 was investigated in such a system in the presence of dCTP$_\alpha$S instead of dCTP[86]. It was found that with *E. coli*-DNA polymerase I the error rate increased by a factor of 20, and with phage T4 DNA polymerase by a factor of 500.

Use of a DNA polymerase which does not possess a 3′→5′ nuclease activity for the polymerization did not influence the error rate. These results show that these nuclease activities play a role in determining the fidelity of replication. They also open the way for target-directed mutagenesis by incorporation of nucleoside phosphorothioates at particular positions, such as at restriction nuclease cleavage sites[92].

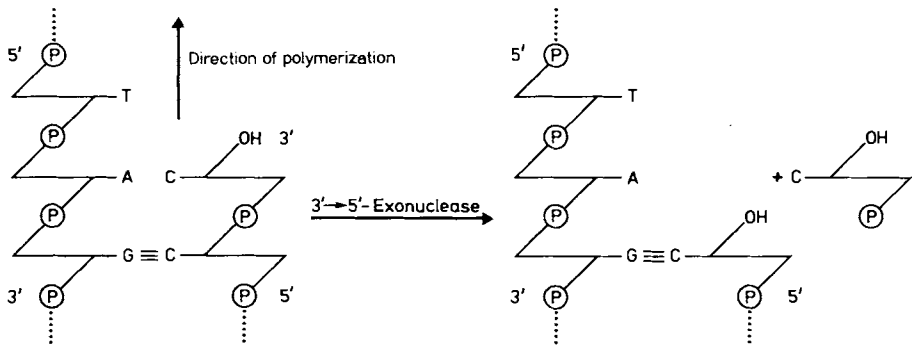

Fig. 21. Schematic representation of the function of the 3′→5′ exonuclease activity of DNA polymerases in preventing incorporation of non-complementary nucleotides.

Because of the impermeability of cell membranes the incorporation of phosphorothioate into the DNA of intact cells *via* deoxynucleoside thiotriphosphates is not possible. However, cells can be made permeable by treatment with ether or toluene[85]. This barrier can also be overcome by the use of thiophosphate. It could be shown with HeLa cells that thiophosphate can be incorporated into nucleotides such as $ATP_\gamma S$ and $GTP_\gamma S$ and subsequently be transferred to other acceptor molecules, *e.g.* histones[93]. In cell cultures of African green monkey cells infected with SV40 it was observed that $ATP_\gamma S$ can also thiophosphorylate thymidine and phosphorothioate, and can thus, after further phosphorylation in the cells to $dTTP_\alpha S$, be incorporated into DNA[94]. Although in these experiments only 3—12 phosphorothioate groups were incorporated into the viral DNA (5226 base pairs), this seemed to have been sufficient to isolate it on Hg-Sepharose!

### 4.2. RNA and DNA Molecules with Terminal Phosphorothioate Groups

Phosphorothioate can also be incorporated into RNA using the corresponding polymerases and $NTP_\alpha S$. So far this seems to have been carried out only for poly-[r(A-U)][78,95,96], the 3′-end of tRNA[97,98], and poly rA[99]. A series of investigations, however, report incorporation of phosphorothioate groups using $ATP_\gamma S$ and $GTP_\gamma S$ into the 5′-end of various RNAs in *Physarum polycephalum* and in isolated nuclei of yeast, mouse myeloma, and *Xenopus'* oocytes, as well as separation of this newly synthesized RNA from endogenous RNA by chromatography on Hg-Sepharose[100-106]. Using various $NTP_\gamma S$ this technique also allows the determination of the nucleotide at the 5′-end of the RNA and makes it possible to determine which promoter starts the RNA synthesis.

Problems can arise from enzymatic transfer of the phosphorothioate group to preexisting RNA molecules, since this gives a wrong picture of the supposedly newly synthesized RNA[107,108]. *Stallcup et al.* had the idea of using

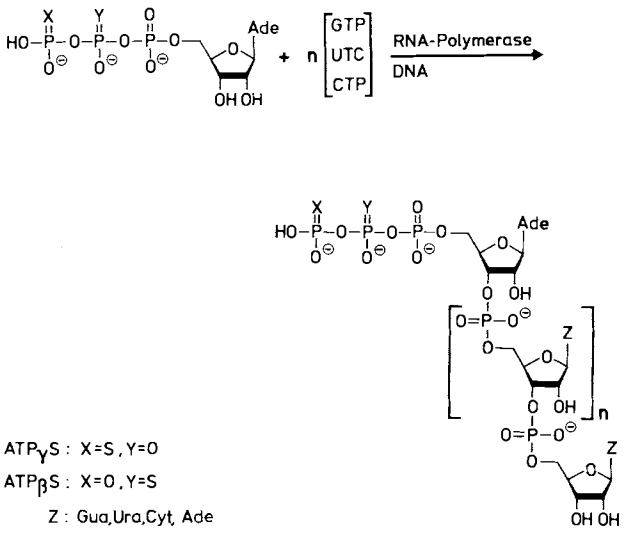

Fig. 23. Incorporation of phosphorothioate groups into the 5′-end of RNA with $ATP_\gamma S$ or $ATP_\beta S$.

$NTP_\beta S$ instead of $NTP_\gamma S$ in the polymerization (Fig. 23) to avoid this transfer[109,110]: these compounds also are good substrates for RNA polymerases[78]. The RNA molecules obtained in this way can also be separated on Hg columns and the transfer of phosphate to other RNA molecules does not interfere, since they are not retained on Hg-Sepharose.

This route is not applicable for the incorporation of terminal phosphorothioate groups into DNA, because DNA polymerases are unable to initiate new chains but can only polymerize onto a 3′-end of an existing polynucleotide. However, the phosphorothioate group of $ATP_\gamma S$ may be transferred to the 5′-end of DNA by polynucleotide kinase[111] (Fig. 24), but this reaction is considerably slower than that with ATP.

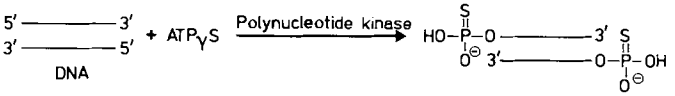

Fig. 24. Incorporation of 5′-phosphorothioate groups into DNA.

### 4.3. Thiophosphorylation of Proteins

Phosphorylation and dephosphorylation of proteins seem to be two of the most frequently used reactions in nature for the regulation of enzyme activity[112,113]. They are catalyzed by protein kinases and phosphatases. Particularly with complex systems it is often difficult to isolate and study proteins in the fully phosphorylated state. Since phosphorothioate esters, such as AMPS, are hydrolyzed extremely slowly by phosphatases it was obvious to examine whether thiophosphorylated proteins are also stable towards phosphatases. This requires that protein kinases accept $ATP_\gamma S$ as a substrate. The first system to be investigated in this connection was glycogen phosphorylase, which is activated by phosphorylation. It turned out that the phosphorothioate residue was transferred by the kinase and that glycogen phosphorylase was activated. The phosphatase could not remove this residue any further so that the phosphorylase was frozen-in in the activated state[114]. This principally demonstrated the applicability of phosphorothioate groups for the study of such problems.

The role played by phosphorylation of the myosin light-chains in smooth muscle for the activation of the enzyme, and thus for the contraction of muscle, was also explained in this way. Muscle contraction is triggered in this system by $Ca^{2+}$ ions, but it was not clear whether this was due to direct interaction between $Ca^{2+}$ and myosin, as in molluscs[115], or whether $Ca^{2+}$ activates a protein kinase, which catalyzes the phosphorylation of the myosin light-chains, and that phosphorylation is the direct trigger of contraction. That the latter is the case could be shown by thiophosphorylation (also on muscle fibers), since the competing dephosphorylation activity which normally complicates such investigations could be suppressed[116-119]. The role of phosphorylation of myosin in skeletal muscle fibers was also investigated in this way[120]. In further studies thiophosphorylation of the myosin light-chains was used for the purification of the phosphatase by affinity

chromatography[121]. Also in cases where phosphorylation of a protein leads to inactivation, such as with pyruvate dehydrogenase, thiophosphorylation can be used for the elucidation of the significance of this step[122]. In addition, for elucidating the significance of the phosphorylation of the receptor and other membrane proteins by the epidermal growth factor thiophosphorylation appears to be interesting because of its increased metabolic stability[123]. Thiophosphorylation may possibly also be of help for studies of phosphorylation of the insulin receptor[124,125] or of the $Ca^{2+}$ transport system in cholinergic synaptic vesicles[126].

Histones are also thiophosphorylated by $ATP_\gamma S$ in the presence of protein kinase. This reaction was not only demonstrated *in vitro*[127], but also (see Section 4.1) *in vivo* with HeLa cells: the $^{35}S$-thiophosphate was first incorporated into $ATP_\gamma S$ and $GTP_\gamma S$ and then transferred to the protein[101]. Thiophosphorylated proteins of this type can be isolated on Hg-Sepharose. This method should be of use for the isolation of other proteins which are normally phosphorylated in the cell. Microtubuli-associated proteins are also thiophosphorylated by $ATP_\gamma S$[128].

Except for the inefficient system of SV40 infected cells there are no known examples for the enzymatic thiophosphorylation of nucleosides and sugars. However, it is reasonably certain that apart from the hitherto described kinases others will also accept $ATP_\gamma S$ as substrate, as the recently published example of pyridoxal kinase demonstrates[129] (Fig. 25).

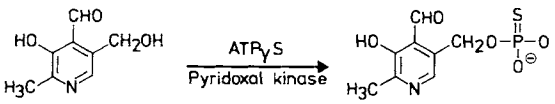

Fig. 25. Enzymatic synthesis of pyridoxal phosphorothioate.

### 4.4. Stabilization of Nucleotide-Protein Complexes with $ATP_\gamma S$ and $GTP_\gamma S$

In coupled reactions in which ATP or GTP are cleaved the question arises how far the reaction would proceed without cleavage of ATP simply by formation of a ATP-enzyme complex, or in other words for which step of the reaction ATP cleavage is necessary. Hydrolytically stable analogues of ATP and GTP should provide the answer to this question. The imido analogues AMPPNP and GMPPNP have been widely used for this purpose[130]. More recently, however, the phosphorothioate analogues $ATP_\gamma S$ and $GTP_\gamma S$ have also been used for studies of such systems.

The first ATPase to be investigated with $ATP_\gamma S$ was myosin[2]. In the kinetic analysis this ATP analogue helped to unambiguously identify the conformational change of the protein on binding of the substrate. This was possible because the actual hydrolysis step for the analogue is considerably slower than that of ATP, so that changes in the fluorescence spectrum of the protein on binding the substrate can be distinguished unambiguously[131,132].

The use of $ATP_\gamma S$ to study reactions catalyzed by recA protein has also turned out to be extremely profitable. This protein is essential for genetic recombination in *E. coli:* in the presence of ATP it catalyzes the *in vitro* hybridization of single-stranded regions with homologous regions in double stranded DNA to form so-called D-loops, which migrate along the DNA until a complete strand exchange takes place (branch migration) (Fig. 26). In addition, in the

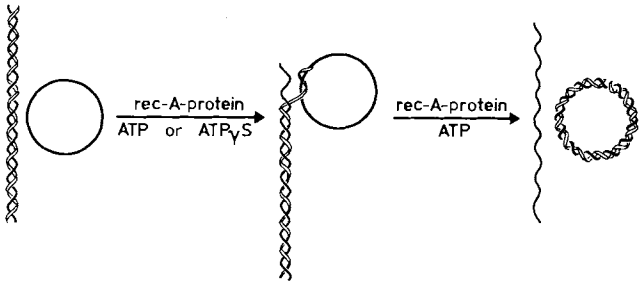

Fig. 26. Function of recA protein as a function of ATP or $ATP_\gamma S$ (cf. also text).

presence of DNA and ATP this protein cleaves various repressors such as λ, lexA, and P22[133,134]. For both reactions it is of interest to know, whether, and if so, for which step ATP hydrolysis is necessary. This question was investigated with $ATP_\gamma S$, since it is resistant to hydrolysis by recA protein. According to these studies the formation of the D-loop does not require ATP hydrolysis but branch migration does[135–138]. The D-loop is so stable in the presence of $ATP_\gamma S$ and recA protein that the complex can be investigated by electron microscopy, which has revealed that in this complex the DNA is unwound, a result[139–141] which had been presumed earlier[142]. The protease activity of recA protein against repressors cannot be observed in the presence of $ATP_\gamma S$, which leads to the conclusion that hydrolysis of ATP is not essential for this activity[143–147].

*E. coli* DNA polymerase III is also not able to cleave $ATP_\gamma S$. With this enzyme cleavage of ATP might be necessary for the formation of a DNA-enzyme complex. In the presence of $ATP_\gamma S$, which cannot be cleaved by this enzyme, the complex dissociates, leading to inhibition of polymerization[148,149]. This suggests that hydrolysis of ATP is necessary for translocation of the enzyme at the replication fork from one primer to the next.

When aminoacylated tRNA binds to the Tu-factor of ribosomes programmed by mRNA another nucleoside triphosphate, in this case GTP, is hydrolyzed. The accuracy of the anticodon-codon recognition determines the accuracy of protein biosynthesis. Comparison of the rate of hydrolysis of GTP with that of $GTP_\gamma S$ indicates that the latter is cleaved *ca.* 2500 times more slowly[150]. A consequence of this is that the complex consisting of $GTP_\gamma S$, Tu-factor, ribosome, and tRNA has a considerably longer lifetime than the corresponding complex with GTP. This leads to a decrease in error rate during translation. Apparently in protein biosynthesis nature puts more emphasis on speed rather than accuracy, at least in this step.

The difference of *ca.* 2500 in the rates of hydrolysis of GTP and $GTP_\gamma S$ in this system is similar to that observed in myosin for ATP and $ATP_\gamma S$ (*ca.* 1000)[131]. Clearly two examples are not sufficient to formulate a rule, but it is interesting to speculate whether this difference might not correspond to the difference in reactivity of γ-phosphate

and γ-phosphorothioate groups towards nucleophilic attack. Detailed fast-kinetic measurements on other ATPases and GTPases are needed to clarify this point. In the non-enzymatic hydrolysis of trialkyl phosphates and trialkyl phosphorothioates a difference of 100 had been found[151].

A GTP binding protein, which consists of two subunits and shows GTPase activity, is also involved in the activation of the hormone-regulated adenylate cyclase[152]. Since GMPPNP and particularly $GTP_\gamma S$ exhibit a practically irreversible and considerably higher activation of the cyclase than GPT this suggests that this effect arises from resistance to the GTPase[153,154]. This idea is inconsistent with a more recent interpretation which suggests that this protein does not show any GTPase activity, and that activation by $GTP_\gamma S$ and GMPPNP is the result of dissociation of the subunits[155]. Since adenylate cyclase is a membrane-bound enzyme, studies of it are often carried out on complex biological systems which are not highly purified. Also, because of their stability, the analogues GMPPNP and $GTP_\gamma S$ are of value here, since there is a possibility that the normal nucleotide GTP is rapidly degraded in this system, and hence its effect cannot be determined accurately. This also applies to GDP, which is assumed not to activate the cyclase but rather to inhibit it by competition with GTP. GDP can readily be degraded to GMP or phosphorylated to GTP so that difficulties arise in unambiguously identifying its effect. A rather stable analogue is $GDP_\beta S$, which is neither degraded by phosphatases nor phosphorylated by kinases. Indeed it could be shown that it inhibits the cyclase[156–160].

The activation of the cyclase by hormone resembles the photo-activation of cyclic phosphodiesterase in the process of vision. In both systems a GTP binding protein transmits the signal from an excited receptor to an enzyme which regulates the cellular concentration of a cyclic nucleotide, cAMP in one and cGMP in the other case. The GTP binding protein involved in the process of vision also shows GTPase activity which puts the enzyme into the non-stimulated stage similar to the protein G/F in the cyclase system. The GTPase activity of both proteins is irreversibly activated by ADP-ribosylation by cholera toxin[161]. Not only GMPPNP but also $GTP_\gamma S$ has been employed in this system as a non-hydrolyzable analogue of GTP, as has $GDP_\beta S$ as an analogue of GDP[161–165]. It is to be expected that these analogues and cGMPS (Section 2.2)[36,39] will be of use for further investigations of this interesting system.

### 4.5. Interaction of cAMPS with Proteins

Also cAMPS differs from cAMP by its greater metabolic stability[38]. Since the last review of the properties of cAMPS[2], the separation of the diastereomers has been achieved (Section 2.2). This made it possible to analyze the products of a previous synthesis of cAMPS[38]. It turns out that the crystalline product obtained in this synthesis is the $(S_p)$-isomer. The $(R_p)$-isomer, which is produced in small amounts, can be separated by chromatography on DEAE-Sephadex. Since all the studies reported in [2] have been carried out with the crystalline isomer, all the results refer to the $(S_p)$-isomer.

Investigations of this type have been extended to other systems and in some cases the different effects of the $(S_p)$- and the $(R_p)$-isomer have been studied, particularly with protein kinases. It was found for protein kinase I that the $(S_p)$-isomer binds better than the $(R_p)$-isomer, but for protein kinase II this trend is reversed[166–168]. The catabolite-activator protein (CAP) also binds the $(S_p)$-isomer[169] and is activated by it, although not as strongly as by cAMP[170]. As described previously[2], cAMPS has been used for studies of chemotaxis in *Dictyostelium discoideum*[171]. Its greater metabolic stability compared to cAMP, its ability to penetrate cells[2,172], and its structural similarity to cAMP should make cAMPS particularly suitable for investigations of the effect of cAMP, and might, under certain circumstances, have advantages over currently used analogues. The availability of the $(S_p)$-isomer commercially will support this development.

### 4.6. Phosphorothioate Analogues of Phospholipids

A new field of application for phosphorothioate analogues is currently being opened up by incorporating phosphorothioate groups into phospholipids. Thus, the two diastereomers of 1,2-dipalmitoyl-*sn*-glycero-3-thiophosphoryl choline (Fig. 27) have been synthesized[173–177]. They can be distinguished by $^{31}P$-NMR; however, their absolute configuration has not yet been determined.

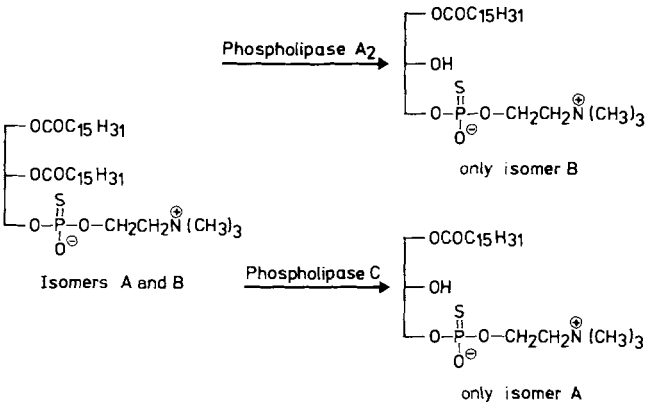

Fig. 27. Separation of diastereomers of 1,2-dipalmitoyl-*sn*-glycero-3-thiophosphoryl choline.

Phospholipase $A_2$ preferentially hydrolyzes that diastereomer whose signal exhibits a shift to low field[175–177]. If this diastereomer is designated B, the product of its hydrolysis is the B-isomer of *lyso*-palmitoyl-thiophosphoryl choline. This can be separated from the A-isomer of the unreacted dipalmitoyl-thiophosphoryl choline by chromatography and then allowed to react with palmitoic acid anhydride to afford the B-isomer of dipalmitoyl-thiophosphoryl choline. This method of separation of the diastereomers using enzymes is reminiscent of the separation of the diastereomers of $ATP_\alpha S$[12] (see Section 2.1). Phospholipase C also shows stereoselectivity, and in this reaction the isomer which is resistant against phospholipase $A_2$ is the preferred substrate[175–177]. These two examples also show that enzymes react stereospecifically or stereoselectively, even if they do not directly attack the chiral phosphorus center.

The phosphorothioate analogues form liposomes, whose transition from gels to the liquid crystalline phase at 44 °C occurs only at slightly higher temperature than that of natural phospholipids (41 °C). $^{31}$P-NMR spectroscopy reveals that aqueous dispersions of phosphorothioate analogues of phospholipids form typical phospholipid bilayers[174]. Since the $^{31}$P-NMR signals of phosphorothioates are shifted strongly to low field relative to those of phosphates, it is expected they can be used to investigate the mobility and structural properties of specific lipids in a mixture. Furthermore, they could be of interest because of their increased metabolic stability in situations where turnover of phospholipids is important for cellular functions. Methods for the incorporation of phosphorothioate analogues into biological membranes are currently being developed. Thus, it was found that *sn*-glycerol-3-phosphorothioate was taken up by the active transport system of *E. coli* strain 8 specifically *via* the active transport system for glycerol phosphate, and incorporated into phospholipids. At higher concentrations this compound is bacteriocidal for strains which have an active transport system for glycerol phosphate[178].

## 5. Conclusion

This progress report indicates that nucleoside phosphorothioates have found wide application in biochemistry. This has arisen because the exchange of oxygen by sulfur in phosphate groups of nucleotides has consequences which are further reaching than initially expected. The existence of diastereomers and the increased affinity of the phosphorothioate groups for $Hg^+$ is not surprising, although the large number of applications of these properties to the solution of biochemical problems is astonishing. What is really remarkable is that the difference between the affinities of nucleotides and nucleoside phosphorothioates towards proteins, if it exists at all, is only very small. This provides further evidence that the active sites of proteins are not rigid but rather, within certain limits, flexible and adaptable structures. At first sight it seems difficult to comprehend that not all enzymatic reactions involving phosphorothioates are slowed down by a similar degree as expected by the lower chemical reactivity of phosphorothioates. Nevertheless, many enzymatic transfer reactions proceed almost as well as the corresponding reactions with the natural substrate (*e.g.* reactions with DNA and RNA polymerases but not with polynucleotide kinase and pyridoxal kinase), but hydrolytic reactions proceed much more slowly (*e.g.* reactions with phosphatases and nucleases). In general it seems that conformational changes in the proteins are rate determining in enzymatic reactions and not in the actual chemical step[179]. Unfortunately, so far only two kinetic studies of enzyme reactions involving nucleoside phosphorothioates have been performed; myosin and Tu-factor[131, 150]. For both of these it has been shown that the chemical step is significantly slower with the analogues, and at least for myosin becomes partially rate determining. Thus, a possible explanation for the similar reaction rates of the enzymes cited above is that the chemical step with the phosphorothioates becomes similar to the normally rate-determining conformational change, so that the steady-state rate is hardly influenced. However, more detailed investigations are clearly required to test this hypothesis.

It is not easy to predict in which direction studies with phosphorothioates will develop. After the investigation of the stereochemical course of approximately 50 enzyme-catalyzed phosphoryl and nucleotidyl transfer reactions this area has lost its novelty appeal. They will probably gain increased significance for investigation of the phosphorylation of proteins, in particular of their regulation. Following current trends, the exploitation of the special properties of phosphorothioate groups in DNA and RNA, particularly their stability against enzymatic degradation, will also probably gain increasing interest. This tendency will certainly be stimulated by the ever increasing number of commercially available nucleoside phosphorothioates, including those with radioactive labels.

What is quite certain is that the development of phosphorothioate analogues of phospholipids is only beginning, and the synthesis of analogues of sugars other than those present in nucleosides has not yet begun.

Nucleoside phosphorothioates seem to be ideally suited for a cooperative effort between chemists, biochemists, biologists, and molecular biologists. On the one hand, through familiarity with these compounds chemists gain access to the biological sciences and, on the other, biological scientists gain insight into problems, whose solution requires structural modifications of the molecules they are interested in. It is to be hoped that nucleoside phosphorothioates will also remain a productive link in the future.

*All the results reported here from my group could only be accomplished through the enthusiastic, stimulating, and critical collaboration of my colleagues Drs. V. W. Armstrong, P. A. Bartlett, P. M. J. Burgers, B. A. Connolly, H. Gindl, R. S. Goody, B. V. L. Potter, P. J. Romaniuk, P. D. Senter, and D. Yee whom I would like to thank for their contributions. These studies were supported, in part, by the Deutsche Forschungsgemeinschaft as well as by the award of fellowships by the Alexander-von-Humboldt Stiftung and the Royal Society. I thank P. Grosse for her patience in typing this manuscript.*

# Bond-Forming Initiation in Spontaneous Addition and Polymerization Reactions of Alkenes

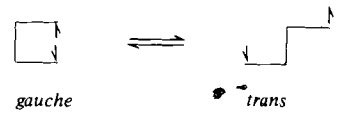
By H. K. Hall, Jr.*

Spontaneous addition and polymerization reactions of alkenes of different electron-densities result in a wide variety of small organic molecules and high polymers. Tetramethylenes are proposed as key intermediates, *i.e.* resonance hybrids of 1,4-diradical and zwitterionic limiting structures. Their character is determined by the substituents at the terminals: Zwitterionic character is favored by strong donors, such as alkoxy and dialkylamino groups, at the carbenium center and strong acceptors, such as two cyano groups, at the carbanion center; diradical character is favored by acceptor groups, such as diesters and cyano-esters, at the acceptor end, and aryl and vinyl groups as donors. Zwitterionic tetramethylenes initiate ionic homopolymerization, while diradical tetramethylenes initiate alternating copolymerization, thus providing an extremely sensitive technique for the detection and characterization of these intermediates. The effects of the donor and acceptor substituents can be arranged as an "Organic Chemist's Periodic Table", wherein the areas of mechanistic change clearly emerge and which provides predictive capability.—This unifying concept of *bond-forming initiation* is extended to spontaneous addition and polymerization reactions of heteroatom acceptor molecules and 7,7,8,8-tetrasubstituted quinodimethanes and of compounds possessing labile σ-bonds, such as halogens and peroxides. Radical-ion pairs, charge-transfer complexes and adventitious impurities are excluded as significant initiators.

## 1. The Tetramethylene Concept

### 1.1. Introduction

Spontaneous addition and polymerization reactions between alkenes of different electron densities lead to a wide variety of products, including small molecules and polymers. The small molecules include cyclobutanes, 1-butenes, Diels-Alder adducts (from styrenes), ene-reaction products (from alkylethylenes), and pyrans (from unsaturated esters). The modes of formation of the small molecules have been interpreted in terms of 1,4-diradicals, 1,4-zwitterions, and concerted processes. The polymers can be either homopolymers of one or both alkenes, or copolymers. Radical-ion pairs, charge-transfer (CT) complexes, 1,4-diradicals and 1,4-zwitterions have been postulated as intermediates for the polymerizations. Occasionally, CT complexes have been regarded as precursors of free radicals. So far, there has been no concept which could equally interpret both addition as well as polymerization, and enable useful predictions to be made.



In recent years, tetramethylene intermediates have been extensively studied on a theoretical basis. Tetramethylenes with terminal substituents are currently viewed as resonance hybrids of varying diradical and zwitterionic nature. In this paper we postulate that they frequently function as key intermediates in cycloadditions and polymerizations. This concept can be extended to reactions in which π- and σ-bonds participate.

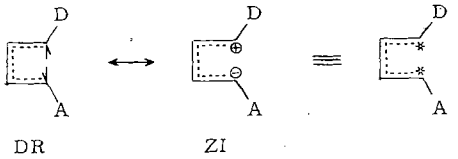
### 1.2. Unsubstituted Tetramethylene

*Hoffmann et al.*[1] first studied theoretically the parent tetramethylene. Later studies showed the existence of two energy minima on the potential energy surface, corresponding to the *gauche* and the *trans* conformers[2].

Different starting compounds furnish tetramethylenes in different conformations; thus, tetramethylenes are formed in the *trans* conformation from two alkenes, but in the *gauche* form on thermolysis of pyridazine[3]. The reactions of the extremely reactive tetramethylenes depend on their origin and conformation[4,5]. Recently, unsubstituted tetramethylene was prepared, and it was confirmed that its subsequent reactions are conformation-dependent[6]. In the case of this species the reactions compete with rotation about the central CC bond.



The terminals can interact with each other by "through-bond interaction", analogous to hyperconjugation. "Through-bond coupling makes the terminal centers even in the *trans*-conformation, cognizant of each other"[7]. Even in the extended form, the carbon p-orbitals adopt the 90°-90° conformation to favor maximum through-bond interaction[8]. Recent reviews[9] summarize much of this information.

The identification of tetramethylene intermediates as highly unstable molecules allows us to discuss their chemistry and conformational behavior.

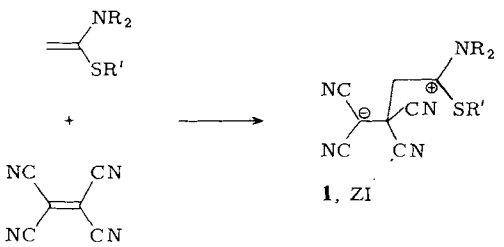
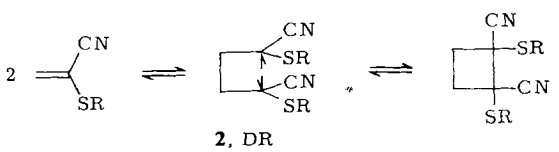
### 1.3. Donor-Acceptor-Substituted Tetramethylenes



Of great significance is the conclusion drawn by *Salem* and *Rowland*[10], and by *Huisgen*[7] that 1,4-diradical (DR) and 1,4-zwitterionic (ZI) forms of tetramethylene are not different entities, but rather are the extremes of a continuum. The tetramethylene is regarded as a resonance hybrid of the DR- and ZI-forms. An asterisk denotes 0—1 electron or 1—2 electrons. This applies also for the *trans* conformation. The abbreviations A and D mean acceptor and donor substituents, respectively.

The non-commital designation with two asterisks will be used to denote the unused valences of the tetramethylene. Predominant zwitterionic or diradical character will be assigned in each case on the basis of experimental results (see Section 2). The character of the tetramethylene is determined by the nature of the terminal substituents. Although not stated in the literature, it is reasonable to expect that donor and acceptor substituents at the terminals will greatly increase tetramethylene stability by push-pull through-bond interaction.

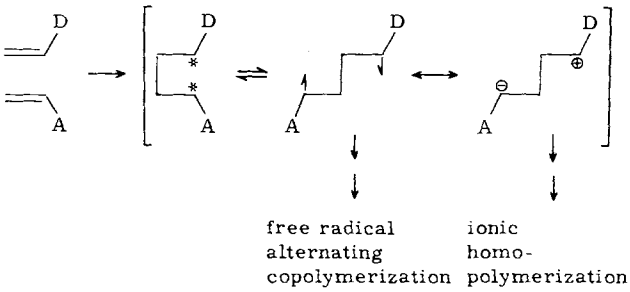


β-Substituents have no influence on the diradical or zwitterionic character of the tetramethylene. However, they play an important role in that they favor the *gauche* conformation of the tetramethylene over the *trans* (extended) form of the parent tetramethylene through the "*gem*-dimethyl" effect. *Gauche* conformations will favor the formation of small molecules because of the proximity of the terminal atoms. Furthermore, steric hindrance by the β-substituents will retard bond formation at that position.

The high reactivity of these tetramethylene intermediates, even in highly stabilized cases, has generally enabled them to escape direct detection or isolation. A stable tetramethylene of type **1** possessing extreme zwitterionic character was prepared by *Gompper et al.*[11] by reaction of ketene *S,N*-acetals with tetracyanoethylene (TCNE); according to *Huisgen* it exists in the *trans*-form[7].

**1**, ZI

Tetramethylenes of type **2** with diradical character are stabilized by captodative substitution[12,13].



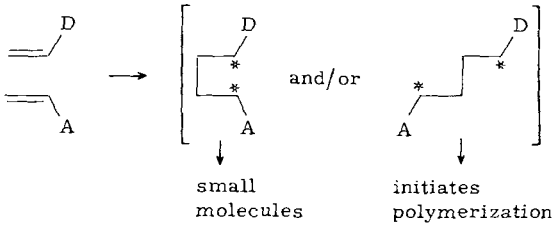
**2**, DR

### 1.4. Indirect Evidence for Tetramethylene Intermediates

Various criteria have been applied to reactions which lead to small molecules. They include detection or trapping of intermediates[7,14-20], stereochemical effects[21], substituent effects and orientation phenomena[21,22], kinetic effects[22-26], effects of solvents[22,27-29] or pressure on the reaction rate[30], and rearrangement of donor substituents[30-34,15,28]. According to *Gompper*[35], detection or trapping is the most decisive evidence for the existence of an intermediate.

### 1.5. Trapping by Initiation of Polymerization

A potentially extremely effective way of trapping an intermediate is by allowing it to initiate polymerization. This technique has great advantages. First: The *amplification*. A small amount of reactive species will lead by chain reaction to an easily detectable yield of polymer. Such a technique should be especially suitable for the detection of very difficultly identifiable intermediates such as tetramethylenes. Second: *The structure of the polymer will diagnose the diradical or zwitterionic nature of the tetramethylene.* Homopolymers of either one or both alkenes indicate the existence of a 1,4-zwitterionic intermediate, while alternating copolymers can only be formed from a diradical intermediate.



The nature of the polymerization, and of the tetramethylene, can be confirmed by addition of an inhibitor which appropriately suppresses either ionic or radical polymerization. The presence of a third monomer, which can only polymerize *via* a radical mechanism, will support the radical character of the intermediate by formation of terpolymers[36]. Finally, if both small molecules and polymers form competitively from a common intermediate, dilution will favor the former.

## 2. Alkene-Alkene Reactions: Tetramethylenes with All-Carbon Skeleton

The literature was searched for spontaneous addition and polymerization reactions of alkenes with one another. Reactions deliberately initiated by free radical and ionic sources or by irradiation, and many Diels-Alder reactions, were not taken into account. On the other hand, special value was attached to those reactions in which a spontaneously formed polymer is either the sole product or one of the products. This survey is not intended as a complete literature review, but rather as a critical discussion of the

reactions involved. Our goal was to compare the polymerization behavior of various alkene pairs with their behavior in addition reactions, as deduced by the methods of physical organic chemistry.

The alkenes are presented systematically in Table 1, being listed in order of increasing acceptor ability of the acceptor substituents. Within each group, the alkenes are listed in order of increasing electron donor ability of the donor substituents. Table 1 also contains some alkene dimerizations.

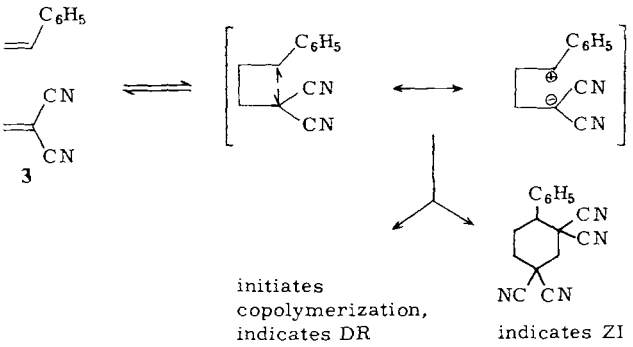
*,* denotes +, − and/or ↿, ↾

### 2.1. Dimerizations

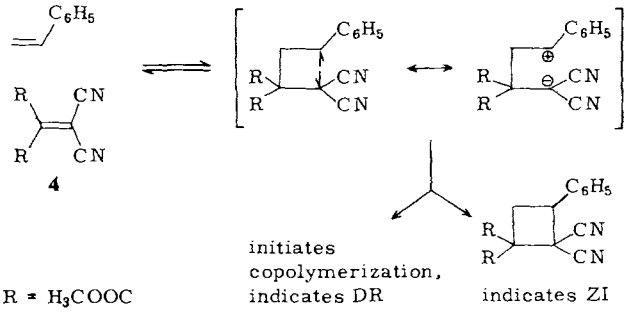
Thermal dimerizations have been extensively studied. Ethylene[37] and acrylonitrile[68] cyclodimerize to cyclobutanes, while styrene[38] undergoes [2+2] and [4+2] cycloaddition. Methyl methacrylate and methacrylonitrile[47,48,122] yield mostly unsaturated dimers (ene-reaction) along with cyclobutanes. *Pryor et al.*[19,38] showed that the polymerization kinetics of styrene were bimolecular and postulated the Flory diradical tetramethylene intermediate, which was further supported by other investigators[123]. Kinetic investigations on methyl methacrylate[47,122] and on fluoroalkenes[41] led to the conclusion that diradical tetramethylenes are the intermediates. Since polarity differences play no part in dimerizations, the latter uniformly follow a diradical mechanism.

### 2.2. Cycloadditions and Polymerizations *via* Diradical Tetramethylenes

Spontaneous addition and polymerization reactions between alkenes of different polarity are more rapid than dimerizations. Bimolecular initiation occurs 100 times more rapidly in the cross-initiation between styrene and methyl methacrylate than in the respective homopolymerizations[50]. Bimolecular initiation was also found in the spontaneous polymerization of 1,2-dimethoxyethylene and maleic anhydride[73]. Numerous other examples are given in Table 1.



The polar substituents of these diradicals lead to an additional stabilization through the push-pull effect. Polar effects on monoradical behavior are already well known. Even the reaction of dimethyl cyanofumarate and *p*-methoxystyrene still proceeds *via* a diradical mechanism, as witnessed by the formation of copolymer[80].



Dilution or addition of solvent causes a shift from copolymer formation to cyclobutane formation in several cases. Typical examples are, *inter alia*, the reactions of dimethyl (dicyanomethylene)malonate with styrene[80], methyl 2,5-dihydro-2,5-dioxo-3-furancarboxylate with styrene[90], and isobutyl vinyl sulfide with trimethyl ethylenetricarboxylate[83]. This is consistent with the intermediacy of a common precursor for the formation of copolymers and small molecules.

A third, non-polar monomer, polymerizable through a free radical mechanism, proves the free radical nature of the copolymer formation by forming terpolymers. Methyl methacrylate as the reaction medium for *p*-methoxystyrene and trisubstituted alkenes possessing cyano and methoxycarbonyl substituents resulted in terpolymers only in those cases in which the tetramethylene had shown diradical character by spontaneous alternating copolymerization[124].

### 2.3. Transition from Diradical to Zwitterionic Behavior

Diradical behavior persists even when the substituents might reasonably have been expected to favor zwitterionic behavior, as in the reaction of dimethyl cyanofumarate or dimethyl dicyanofumarate with *p*-methoxystyrene[98]. Eventual transitional behavior from diradical to zwitterionic is shown by the following alkene pairs: vinylidene cyanide **3** with styrene[103,105] and dimethyl dicyanomethylenemalonate **4** with styrene[80] (for other examples see Table 1).

The orientation of the substituents in these cycloadducts is consistent with zwitterionic behavior of the tetramethylene.

### 2.4. Zwitterionic Tetramethylenes

A very strong donor group at one of the terminal carbons and a very strong acceptor group at the other lead to zwitterionic intermediates. Such donors feature nitrogen substituents, *p*-dimethylaminostyrene, *N*-vinylamines or *N*-

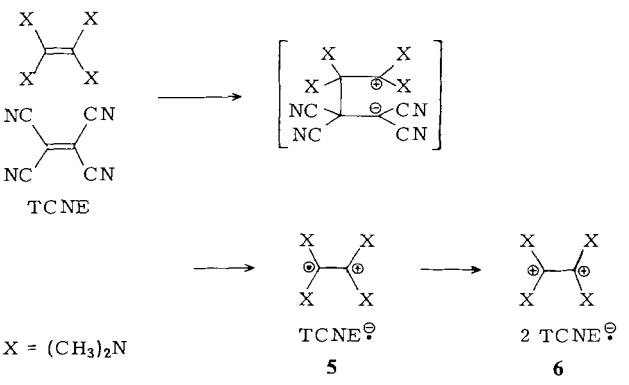
vinylcarbazole. At the acceptor end, two cyano groups favor zwitterionic behavior. Due to Coulombic attraction between the termini, higher yields of small molecules, such as cyclobutanes and 2:1 cyclohexane adducts, are observed in these cases. Homopolymerization is only observed where the propagating ion is highly stabilized. *N*-Vinylcarbazole and vinyl ethers meet this requirement for carbenium ion propagation, nitroethylene and vinylidene cyanide for carbanion propagation.



### 2.5. Transition from Zwitterions to Ion-Radical Pairs

When very strong donors and acceptors are present at both termini, single electron transfer takes place. A borderline case is found in the reaction of the enamine of cyclohexanone with tetracyanoethylene[120]. At low temperature, a stable 1,4-zwitterion is formed. At room temperature, electron-transfer gives the radical-ion pair which *via* hydrogen transfer leads to the observed products.

### 2.6. Stable Ion-Radical Pairs

Finally, at the very extremes of donor and acceptor abilities, radical-ion salts are formed, for example **5** and **6**.

The β-substituents hinder bond-formation, and the highly symmetric structures facilitate extensive stabilization of the radical ions[121].

## 3. Reactions of Alkenes with Azo and Carbonyl Compounds

### 3.1. 1,2-Diazatetramethylenes

Our concept of bond-forming initiation can be extended to the reactions of donor molecules with acceptors which contain π-bonded heteroatoms. Extensive studies on the reactions of diethyl azodicarboxylate and 4-phenyl-1,2,4-triazoline-3,5-dione showed that a variety of small molecules and polymers are formed and present a complete analogy to the all-carbon systems (Table 2).

In the reactions of diethyl azodicarboxylate with very electron-rich olefins—*N*-vinylcarbazole and vinyl ethers—zwitterionic intermediates lead to homopolymers or cyclobutanes. With almost all other olefins, hydrogen shift leads to the ene-reaction product. Cyclopentene and cyclohexene are exceptions; here a radical chain reaction is preferred. Bond-forming initiation is *one* possible interpretation for this spontaneous initiation (for other possible interpretations see Section 8.1). Diethyl azodicarboxylate undergoes [4+2] cycloadditions with *cis*-dienes. These various reaction paths correspond completely to those observed in alkene-alkene reactions, namely non-chain small molecule formation, on the one hand, and free radical chain copolymerizations on the other. The $-\overset{*}{N}-COOCH_3$ group is borderline as regards preferred diradical or zwitterionic behavior, comparable to a $-\overset{*}{C}(CN)-COOR$ group in a tetramethylene with carbon skeleton.

4-Phenyl-1,2,4-triazoline-3,5-dione is extremely electrophilic due to its imide structure. Accordingly, it forms a zwitterionic intermediate with most of the alkenes quoted in Table 2. Hydrogen-shift will then lead to the ene-reaction product, or diazacyclobutanes will be formed. With alkenes which contain strong donor groups, the diazacyclobutane formation is reversible. (The copolymers obtained by reaction of triazolinedione with vinyl ethers or *N*-vinylamines are presumably formed by polyrecombination of 1,4-zwitterions, and not *via* a radical mechanism—see Section 8.1.) In several cases, Wagner-Meerwein rearrangements confirm zwitterionic behavior[31,32]. The triazolinedionyl group is similar to two cyano groups at the terminal as regards favoring zwitterionic behavior. With *cis*-dienes, Diels-Alder adducts are formed, although not with 2,5-dimethyl-2,4-hexadiene. Interestingly, an equilibrium between a diradical and zwitterionic diazatetramethylene was postulated; the zwitterion could in fact be trapped with acetic acid[125].

### 3.2. 1-Oxatetramethylenes

The reactions of the very electrophilic hexafluoroacetone with alkenes have been interpreted exclusively in the context of zwitterionic intermediates[126]. The zwitterion could be trapped by inducing cationic polymerization of allyl glycidyl ether. The reactions of bis(trifluoromethyl)ketene with electron-rich alkenes likewise proceed *via* zwitterionic intermediates, as shown by the homopolymerization of the vinyl ether[127]. On the other hand, dimethyl mesoxalate reactions were shown by the deuterium isotope effect to be concerted[128].

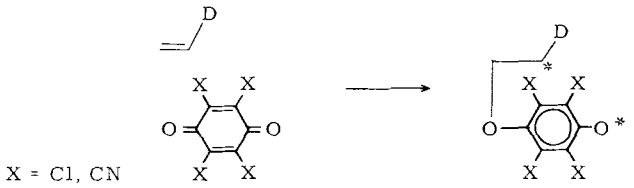
[a] See footnote [a] of Table 1. [b] Acetic acid adduct of tetramethylene

The reactions of donor molecules with acceptor molecules which contain π-bonded heteroatoms follow the same trends as the reactions of the alkenes. Due to the extreme electrophilic character of these nitrogen and oxygen acceptors, the corresponding heterotetramethylenes often have zwitterionic character.

## 4. Reactions of Alkenes with *p*-Quinodimethanes and Quinones

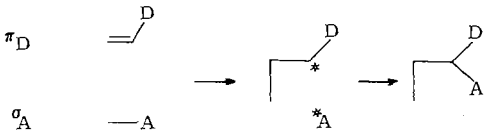
### 4.1. Tetramethylenes Containing *p*-Phenylene Groups

The concept of bond-forming initiation can be further extended to the polymerization reactions of 7,7,8,8-tetra-substituted quinodimethanes (Table 3), which act as acceptors towards some donor alkenes. Here, no small molecules are formed, but the pattern of the observed polymerizations is identical with that observed for acceptor alkenes.



7,7,8,8-Tetrakis(methoxycarbonyl)quinodimethane copolymerizes spontaneously with styrene and other vinyl monomers, suggesting a diradical intermediate. 7,7,8,8-Tetracyanoquinodimethane copolymerizes with styrene. This indicates that a *p*-phenylene-containing tetramethylene has more diradical character than the corresponding alkene-derived tetramethylene, because the former possesses an aryl group at the reactive center. However, 7,7,8,8-tetracyanoquinodimethane induces cationic polymerization of vinyl ethers *via* a zwitterionic intermediate. This intermediate could be trapped with methanol[16, 17]. The more electrophilic 7,7,8,8-tetracyano-2,3,5,6-tetrafluoroquinodimethane can cause the less electron-rich β-chloroethyl vinyl ether to homopolymerize cationically.

With the less electrophilic chloro-substituted quinodimethanes, the copolymers obtained are not alternating, but contain excess quinodimethane. These cases can be considered as borderline between the bond-forming initiation mechanism as proposed here, and the diradical coupling mechanism demonstrated for the parent unsubstituted xylylene[153] (see Section 8.1).

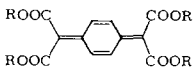


### 4.2. Tetramethylenes Containing *p*-Phenylenedioxy-Groups

The electrophilic quinones, tetrachloro-*p*-benzoquinone (chloranil) and dichlorodicyano-*p*-benzoquinone can copolymerize or induce ionic polymerization of various alkenes. The high electronegativity of the oxygen-substituted *p*-phenylene group favors zwitterion character for the tetramethylene intermediates (Table 3).

## 5. Reactions of Alkenes with Halogens and Peroxides

Some σ-bonds are about as weak as π-bonds. The general picture of bond-forming initiation can be extended to such labile σ-bonds.



*,* denotes +,− or ↿,↾

Numerous such mechanisms for the reactions of single-bonded molecules with alkenes which spontaneously give rise to free radicals have already been dealt with in reviews by *Pryor*[19] and by *Harmony*[166] under the heading "molecule-assisted homolysis". Molecule-assisted heterolysis is also known, as, *e.g.*, in the reaction of bromine and other reagents with alkenes.

The fragments combine to give small molecules, corresponding to the small molecules in alkene reactions. The character of the *,*-centers must be determined by physical organic methods, *e.g.* by analysis of solvent effects, structural effects, *etc.* However, if the fragments escape the

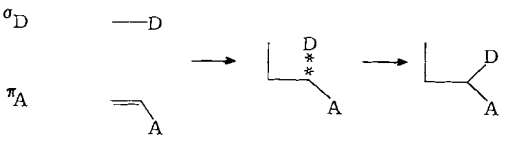
solvent cage, they may initiate chain reactions, corresponding to polymerization. *Pryor*[19] and *Harmony*[166] both describe a number of such free radical chain reactions. Just as zwitterion-initiated polymerizations are rarer than diradical ones, we found very few spontaneously initiated ionic chain reactions (see Table 4).

### 5.1. Halogens

*Poutsma*[167] described the spontaneous thermal addition of chlorine to various alkenes. Ionic non-chain addition competes with free radical chain addition. Thus, this is a borderline situation. *Poutsma*'s evidence for the occurrence of these two competing pathways includes: spontaneous reactions even in the dark at −78 °C, no oxygen effect, good structure-property relations, solvent effects, dilution effects, trapping of Cl· by cyclohexane, and the effect of free radical inhibitors.

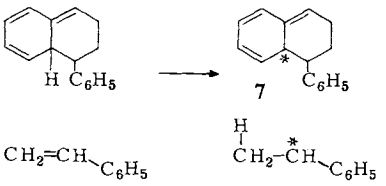
*,* denotes +,− and/or ↿, ↾



Reactions of bromine with alkenes mostly proceed *via* an ionic pathway[168]. In contrast, iodine reacts with styrene by a radical pathway[169]. Fluorine is so reactive that it could only be studied with tetrachloroethylene, with which it spontaneously forms radicals[170].

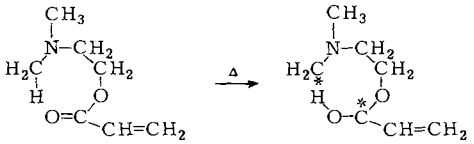
### 5.2. Peroxides

Peroxides react spontaneously with alkenes[171]. A "direct reaction", predominantly ionic, is found to compete with a radical chain reaction. Benzoyl peroxide reacts spontaneously with *N*-vinylcarbazole to produce bimodal polymers, one formed ionically and one by a free radical path[172–175]. This may be due to competing ions and radicals from bond-forming initiation. Alternatively in this case, single electron transfer may provide a viable pathway.



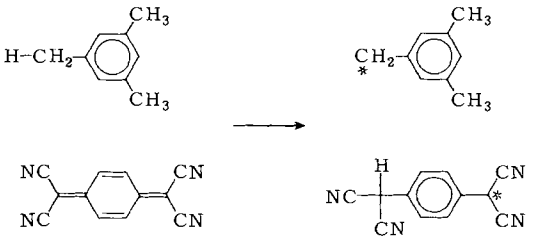
## 6. Reactions of Alkenes with Compounds Containing Aliphatic C–H Bonds

Turning to $\sigma_D+\pi_A$ reactions, a number of cases of hydrogen transfer involve bond-forming initiation. The carbon-hydrogen bond is strong, but its bond energy is regained.

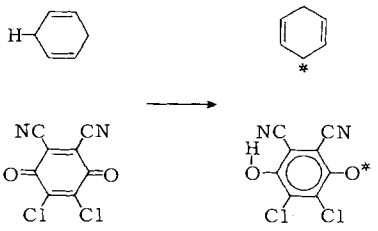


*,* denotes +,− and/or ↿, ↾

The spontaneous polymerization of styrene appears to involve reactions of 1-phenyl-1,2,3,8a-tetrahydronaphthalene (the Diels-Alder adduct of styrene) with other styrene molecules[176–178]. (Only one resonance form of the product **7** is shown.) In this case, the asterisks correspond to radical centers, as shown by the free radical polymerization of styrene.



Intramolecular bond-forming initiation occurs in the polymerization of dimethylaminoethyl acrylate[179].



Here the asterisks indicate radicals, as shown by the ready free radical polymerization initiated in this way.

Again, polar character facilitates these reactions. The reaction of tetracyanoquinodimethane with mesitylene[180] or with *p*-methoxytoluene[181] is another case of $\sigma_D+\pi_A$ reaction. Here radical character is displayed, and the reactions proceed readily.

The reaction of dichlorodicyano-*p*-benzoquinone with 1,4-cyclohexadiene[182] can be described in our terms as $\sigma_D+\pi_A$ bond-forming initiation.

Here the asterisks can be identified as +, −, attributable to the electronegativity of oxygen (see Table 4).

## 7. An "Organic Chemist's Periodic Table"

Previous surveys of cycloaddition reactions have not taken into account the results from polymer chemistry. However, the mechanistic information obtained from the polymerization criteria is entirely consistent with the physical organic chemistry data. In particular, *Huisgen*'s expectation[7] that the terminal substituents determine the character of the tetramethylene is abundantly confirmed by our survey. At the donor terminal, phenyl and vinyl groups prefer to stabilize a diradical, while hard donors, such as nitrogen and oxygen, favor a zwitterion. At the acceptor terminal, diester, cyano-ester, anhydride and chlorine favor diradical character, while two cyano-groups favor zwitterionic character.

That the terminal substituents determine tetramethylene character in both organic and polymer reactions, is revealed by systematic presentation in an "Organic Chemist's Periodic Table for Alkenes" (Fig. 1)[84, 193]. In this format, the acceptor alkenes have been listed, as in Table 1, according to increasing acceptor behavior. We found it possible on the basis of general chemical experience to arrange the donor alkenes in such a manner that the Periodic Table shows a region of mechanistic change. In such a presentation covalent bonds would be favored in the center, while ionic bonding would be favored toward the lower and right-hand side. Moreover, increasing reactivity would be expected as one proceeds downwards and to the right.

The Periodic Table also displays monotonically increasing reactivity as we proceed toward more powerful donor and acceptor groups. This is due to the push-pull stabilization of the tetramethylene, whether diradical or zwitterionic. As the reaction partners become respectively more electropositive and electronegative, a transition from covalent to ionic bonding occurs.

This "Periodic Table" enables predictions to be made concerning new reactions. The reactions of azo and carbonyl compounds as well as the other reactions discussed here, can also be included in this "Periodic Table".

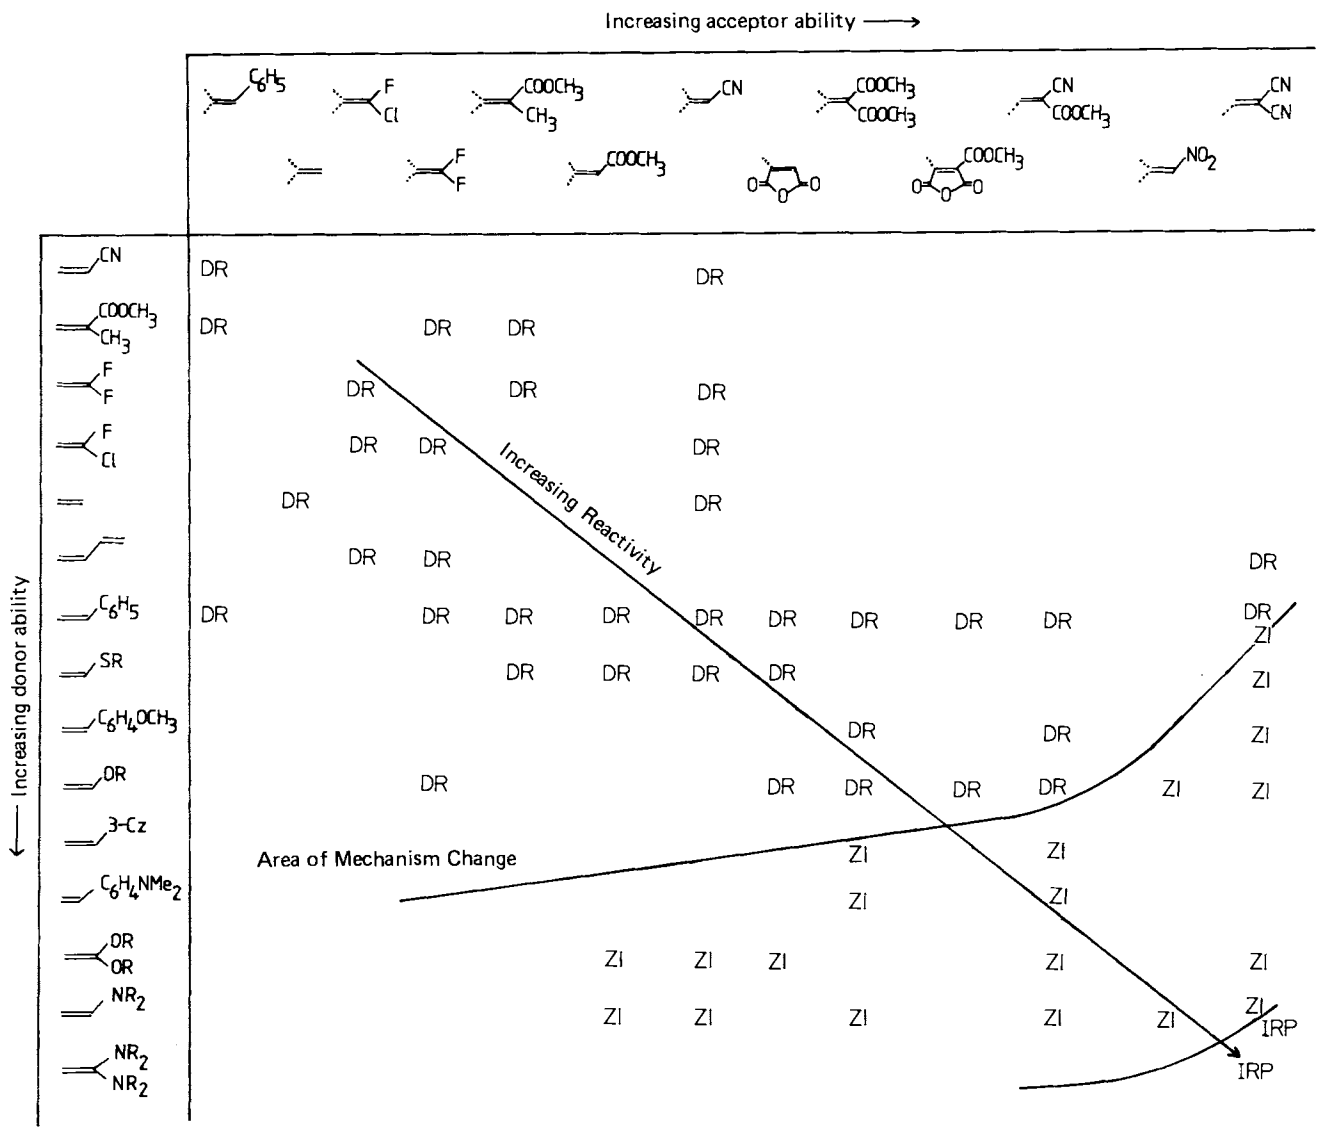
## 8. Critique of Method

### 8.1. Remarks on Polymerization

For the polymerization method to be viable, certain criteria must be complied with. The donor and/or acceptor reaction partners must be mono- or 1,1-disubstituted alkenes in order to be homopolymerizable by radical or ionic pathways. Trisubstituted acceptors will copolymerize with monosubstituted donors under free radical conditions, but will not homopolymerize. Tetrasubstituted acceptors copolymerize in only a few cases and do not homopolymerize.

Furthermore, the solvent also must allow polymerization to take place. For free radical polymerizations, most solvents other than those containing halogen- or nitro-groups can be used. For cationic polymerization, dichloromethane, toluene, and benzene are best. Donor solvents must be avoided[194], except for very reactive carbenium ion monomers such as *N*-vinylcarbazole and vinyl ethers, where weak donor solvents such as acetone or acetonitrile can be used. For anionic polymerization tetrahydrofuran, glymes and amide solvents are favored, but protolytic or acceptor solvents cannot be used. For ionic polymerizations, the solvent may affect zwitterion formation and subsequent polymerization differently. A polar non-donor solvent[24, 194] may permit carbenium ion polymerization in cases where a polar donor solvent impedes it. For example, tetracyanoquinodimethane induces cationic polymerization of β-chloroethyl vinyl ether in ethylene carbonate, whereas copolymerization takes place in acetonitrile (see Table 3). Finally, dilution is expected to favor cycloadducts over polymers; this has been found in several cases[90].

For ionic polymerization initiated by a zwitterion, other difficulties arise when we consider the possibility of propagation by carbenium ions in the presence of carbanions or vice versa, or even of simultaneous cationic and anionic polymerization. The latter was observed in the reactions of vinylidene cyanide[16, 103, 105] and of nitroethylene[78]. One of the prerequisites for such a reaction is that the ions are extremely well stabilized by resonance or steric hindrance. Dichlorodicyano-*p*-benzoquinone is able to initiate the cationic polymerization of vinyl ethers, because its anion is highly stabilized[17]. A second contributing factor for simultaneous cationic and anionic polymerizations is phase separation[197] or microphase separation[195, 196], wherein the growing end is preferentially surrounded by like monomer. The third, and probably most important factor, is that the anion can lose an adjacent leaving group, leaving a free carbenium ion to initiate cationic polymerization. Butadienes have been formed in a number of cases where a very stable zwitterion is formed; hydrogen cyanide is elim-



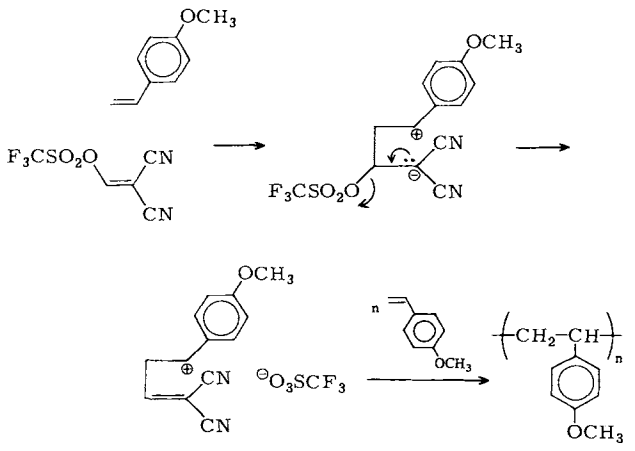


Fig. 1. The Periodic Table of spontaneous reactions of alkenes. DR: diradical mechanism, ZI: zwitterionic mechanism, IRP: mechanism *via* a radical ion pair.

inated in the reaction of *N*-vinylcarbazole and tetracyanoethylene[25], leading to cationic homopolymerization of the former. Cationic polymerizations can be effectively initiated by using di- or tricyanoethylenes containing a β-chloro or β-trifluoromethanesulfonate group as leaving group[198].

Finally, carbenium ions and carbanions can coexist in concentrations suitable to cause polymerization, as seen in radiation polymerizations.

As initiators, diradicals can convert by rotation into the *trans*-conformation, or can be formed in this conformation. Accordingly, they will be more effective initiators than 1,4-zwitterions. In keeping with this idea, far more radical copolymerizations occur in the reactions under discussion than ionic homopolymerizations. As noted by *Huisgen*[7,22], zwitterions are likely to remain in the coiled *gauche*-conformation because of Coulombic attraction. As a result they are likelier to collapse to small molecules, the particular type being determined by the conformation; thus, they may not be very effective initiators for ionic polymerization.

We considered whether coupling of tetramethylenes may contribute to copolymer formation. Polymer formation by coupling of zwitterionic intermediates has been reviewed by *Saegusa*[199]. The very stable zwitterions from 1-phenyl-1,3,4-triazoline-3,5-dione and vinyl ethers were postulated to form copolymers by this route[142]. Coupling

of diradicals contributes to copolymer formation from quinodimethanes. Coupling would be evidenced by head-to-head structures in the former case and by formation of copolymers possessing other than 1 : 1 composition ratios in the latter.

### 8.2. Remarks on the Formation of Small Molecules

The formation of cyclohexenes and ene-reaction products *via* [4+2] and [2+2+2] reactions, respectively, competes with the stepwise [2+2] cycloadditions, which lead to cyclobutanes and 1-butenes. If the donor group is aryl, the Diels-Alder reaction may occur into the ring; in the case of vinyl groups, cyclohexene formation can compete with cyclobutane formation; with alkyl groups, hydrogen shift can lead to ene-reaction products. If the acceptor group is an ester, pyran formation can compete with cyclobutane formation in an inverse electron-demand hetero-Diels-Alder reaction[82].

Current theory postulates a sharp distinction between [2+2] (concerted reaction, disallowed thermally) and [4+2] (concerted reaction, allowed thermally) cycloadditions[200,201]. Nevertheless, other researchers are inclined to consider a range of possibilities, from completely stepwise to completely concerted reactions for the [4+2] cycloadditions. Stepwise hetero[4+2] cycloadditions have been described[46]. For the all-carbon cases, *Gilchrist* and *Storr*[202] describe reactions in which zwitterionic intermediates are so stabilized, that a stepwise [4+2] cycloaddition becomes a viable alternative, and more examples can be found in the literature[18,35,92,203-208]. *Firestone*[209] proposes a spin-paired diradical stepwise mechanism, even for moderately polarized Diels-Alder reactions. Similar considerations apply to ene-reactions[210], which can range from concerted to stepwise in cases where the zwitterion is especially stabilized electronegatively.

It is still not clear for [4+2] reactions where non-concerted reactions end and concerted ones begin[211]. The polymerization criterion may prove useful in further defining the line of demarcation.

### 8.3. Unimportance of Charge-Transfer Complexes and Radical-Ion Pairs in Thermal Initiation

Charge-transfer complexes and radical-ion pairs have been invoked as initiating species (for reviews, see *e.g.* [24,212]). We believe that neither of these contributes significantly, and that the tetramethylenes are the true initiators.

Charge-transfer complexes are certainly formed in many of the reactions we are considering. The same donor-acceptor character facilitating formation of push-pull tetramethylenes also favors formation of charge-transfer complexes. However, such complex formation is only a weak molecular interaction and primarily affects spectral properties rather than reactivity. Nevertheless, charge-transfer complex equilibrium constants between donor and acceptor monomers parallel their increasing reactivity in spontaneous polymerization, as noted by *Iwatsuki* and *Yamashita*[213]. These investigators also noted transitions from copolymerization to ionic polymerizations and then to stable products as the equilibrium constants increased, reminiscent of our "Periodic Table" presentation (above).

With regards to radical-ion pairs as intermediates, *Shirota* and *Mikawa*[24] and *Tazuke* and *Okamura*[66] observe that electron transfer is energetically unfavorable for weak electron-donating and electron-withdrawing monomer pairs.

In the case of alkenes with few substituents, it is very unlikely that a radical-ion pair could be formed without collapsing to a tetramethylene, thereby gaining the whole energy of a chemical bond. If formed, the two should undergo instant radical recombination in the solvent cage, accelerated by Coulombic attraction.

Further evidence against the radical-ion mechanism is offered by the steric effects of the substituents at the β-positions. Trimethyl ethylenetricarboxylate is much more reactive than tetramethyl ethylenetetracarboxylate, even though the latter has a greater electron-affinity as measured by cyclic voltammetry[214]. Similarly, tricyanovinyl trifluoromethanesulfonate is less reactive than 2,2-dicyanovinyl trifluoromethanesulfonate[198].

Even in the case of tetracyanoethylene, which is known to form an extremely stable radical-anion, *Huisgen*[7,22] finds no evidence of single electron transfer in the reaction with vinyl ethers. Still more striking is the formation of a stable zwitterion in the reaction of ketene *S,N*-acetals with tetracyanoethylene with no evidence of single electron transfer[11]. Cycloadditions of vinyl sulfides to tetracyanoethylene proceed through a zwitterionic intermediate, and not through an ion-radical pair[23,27]. Enamines such as dimethylvinylamine add to tetracyanoethylene *via* zwitterionic intermediates[35]. Only in extreme cases, such as the reaction of tetrakis(dimethylamino)ethylene[121,215] or the enamine of cyclohexanone[120] with tetracyanoethylene, does electron transfer occur. Along similar lines, initiation of the reaction of *N*-vinylcarbazole with benzoyl peroxide could involve electron transfer[172]. Such a course is known for the reaction of dimethylaniline with benzoyl peroxide[216].

Finally, evidence against the electron-transfer concept in copolymerization is that when radical cations of a vinyl ether are deliberately synthesized by electrochemical methods, they are known to dimerize[217]. No such products are ever reported in the cycloaddition and polymerization reactions.

On all the above grounds, we can state that single electron transfer will be seen only in the cases where greatly hindered and highly resonance-stabilized radical-ions can be formed.

### 8.4. Impurities, Inhibitors, and Initiators

Trace impurities in a reaction mixture might accelerate the reaction or cause a change of mechanism. Such cases have been encountered on occasion.

Free radical reactions can be accelerated by peroxides, light, or oxygen. For example, the copolymerization of norbornene and sulfur dioxide was formerly believed to proceed *via* coupling of spontaneously formed diradi-

cals[218]. However, this copolymerization was later shown to be initiated by traces of peroxide impurities[219].

With regard to acidic impurities initiating cationic polymerization, *Shirota* and *Mikawa*[24] showed that traces of 2,5,6-trichloro-3-hydroxy-*p*-benzoquinone were the true initiators in the tetrachloro-*p*-benzoquinone-promoted polymerization of *N*-vinylcarbazole. *Stille et al.*[220] described the cationic polymerization of vinyl ether initiated by tricyanoethenol impurity in tetracyanoethylene.

Finally, even diffuse laboratory light induces the radical reactions of nitroso compounds with alkenes[221].

Nevertheless, we exclude impurities or other adventitious effects as responsible for the reactions under discussion. Firstly, impurities are as likely to inhibit as to initiate chain reactions. Secondly, many of the reactions take place rapidly and reproducibly in absence of air or light. Thirdly, the structure-property relation shown in the "Periodic Table" is reassuringly consistent.

Deliberately added inhibitors can, of course, be used to suppress chain reactions in favor of the molecular reactions. Conversely, deliberately added initiators can be used for favoring ionic or radical chain reactions. As noted above, the donor or acceptor character of the solvent can be used to influence ionic polymerizations. In these ways the chemist can control the outcome of the reaction and thus obtain the desired product.

## 9. Outlook

It is well known that reactive particles combine with each other. Thus, free radicals combine or disproportionate at nearly diffusion-controlled rates. Carbenium ions combine very readily with carbanions.

Also well known are reactions in which a reactive particle reacts with a molecule to form a new molecule and a new reactive particle. Such chain reactions are familiar for both free radical and ionic chain carriers.

To round off matters symmetrically, our theory describes reactions of neutral molecules with each other to generate reactive particles. These particles then lead directly to products in non-chain fashion, or can initiate chain reactions, either free radical or ionic. The variety of reactions we have discussed in this article makes it clear that this third process possesses wide generality.

In the future we hope to incorporate all of the cases we have discussed into an extended "Organic Chemist's Periodic Table" for all types of donor and acceptor molecules. Before this can be done much additional experimental information must be obtained.

Other reactions may fall under this scheme, *e.g.* spontaneous reactions of unsaturated molecules such as allenes, alkynes, ketenes, singlet oxygen, sulfur dioxide, and sulfur trioxide. Lewis acids may complex with the acceptor alkene to increase its electrophilicity and shift its position in the "Periodic Table". Oxidation of alkenes and hydrocarbons by electrophiles containing Cr=O and Mn=O bonds may also fit into our scheme.

A quantitative treatment would be highly desirable. As to the reactants, quantitative measures of donor and acceptor ability such as oxidation- and reduction-potentials, nucleophilic- and electrophilic-reactivities, *etc.*, may be considered. Use of Taft constants to correlate reactivities may be useful. As to the tetramethylenes, theoretical studies should be a great help in determining their stabilities and their zwitterionic or diradical nature.

The solvent must also play a crucial role in these reactions, a further facet of this field of chemistry which calls for closer study in the future.

*The author is greatly indebted to his colleagues, Dr. Husam Rasoul, Dr. Mohamet Abdelkader, Dr. Anne Padias, Dr. Pierre Nogues, and Dr. Robert Sentman for their contributions both experimental and interpretative. Generous financial support was provided by the Division of Materials Research of the National Science Foundation, Grant DMR-81-06018.*

*He is also greatly indebted to Professor Hiroshi Sumitomo of Nagoya University and to the "Japan Society for the Promotion of Science" for a Senior Visiting Fellowship, May—July 1981, which provided an opportunity for fruitful discussion with numerous Japanese scientists who have contributed to this field. This work was first presented at the May 1981 Meeting of the Polymer Society of Japan in Kyoto. It was also presented at the Macromolecular Symposium of the International Union of Pure and Applied Chemistry (Amherst, MA, July 1982) and at the Welch Symposium (Houston, TX, November 1982).*

# Electron Diffraction with the Transmission Electron Microscope as a Phase-Determining Diffractometer— From Spatial Frequency Filtering to the Three-Dimensional Structure Analysis of Ribosomes

By Walter Hoppe*

*Dedicated to Professor Adolf Butenandt on the occasion of his 80th birthday*

Chemists recognize X-ray crystal structure analysis and electron microscopy as powerful methods of analysis. In the last 20 years the basic ideas of X-ray diffraction analysis have been extended to the field of electron microscopy, whereby an image-forming apparatus is converted into an electron diffractometer, and through which an old dream of crystallographers can be realized—the measurement of the phase shift of scattered waves, a prerequisite for the direct calculation of structures. Its most important area of application, like that of the X-ray diffractometer, is in three-dimensional structure analysis—in all fields of science. However, beyond crystallography, aperiodic structures (comparable to crystals with a single unit cell) can also be analyzed three-dimensionally. In this progress report, the development of the first idea (spatial frequency filtering) to the analysis of ribosomal particles is outlined. Attention will be focused primarily on quantitative methods for the measurement of scattered rays, which are also usable beyond the conventional limit of resolution, down to atomic resolution. In the course of this work in 1968, the principle of the three-dimensional analysis of native biological crystal structures using the electron microscope, as worked with today in many laboratories, was developed. In Munich, however, further research focused on the three-dimensional analysis of aperiodic and individual (especially biological) objects. The analysis of 50S-subunits of the procaryotic ribosome of *E. coli* showed surprisingly good reproducibility of the results (although only within the same orientation), allowing the deduction of almost ideal average model structures from a limited number of particles.

## 1. Introduction

It was not easy to find a suitable title for a report on the research work which has been carried out in our laboratory in the field of structural chemistry over the past number of years. "Three-dimensional electron microscopy" soon proved to be too narrow, and missed the important aspect of quantitative analysis, *i.e.*, the measurement of the amplitude and phase of scattered waves, which is important for the determination of the potential distribution (which corresponds to the electron density distribution in X-ray diffraction). If the electron microscope is used as a phase-determining diffractometer, then three-dimensional electron microscopy corresponds in principle to three-dimensional X-ray crystal structure analysis. Different types of diffractometer have been developed using similar basic designs of electron microscope. Aside from the methodological aspects of our work, a selection of the structural findings (especially on ribosomal particles) which are of particular interest to the chemist are outlined, so as to give the reader an idea of the "state of the art" of this technique.

## 2. The Development of Phase-Determining Diffractometry with the Conventional Transmission Electron Microscope (CTEM)

### 2.1. "Computers" that Work with Light

In the fifties, the light diffractometer was a popular tool of crystallographers. The impetus behind its use stemmed from the "two-wave microscopy" of *Boersch*[1,2], who suggested that masks, fashioned according to the diffraction diagram of a crystal, be brought into the diffraction plane of a microscope working with monochromatic coherent light. Theoretically, an image of the crystal lattice (more exactly, a two dimensional projection of the crystal lattice) should appear in the image plane of the microscope. In two-wave microscopy, the diffraction diagram is created, without using a lens, with the radiation of the first wavelength (X-rays); the function of the lens is reproduced by the radiation of the second wavelength (light). This idea fascinated many people at that time, including *Sir W. L. Bragg*[3].

Two-wavelength microscopy illustrates, in a simple fashion, one of the fundamental features of structural analysis with diffraction methods. The analysis proceeds in two steps. In the first—physically important step—scattered

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0606-0456 $ 02.50/0 

rays are produced which contain the complete information on the structure of the object. In the second step these data are combined, in a way that is equivalent to the mathematical operation of Fourier transformation. The direct result is the structure of the object being investigated. Actually, once the data of the scattered waves have been collected, a physical instrument is no longer needed. The combining of the data can also be done using a suitably programmed computer. Indeed, the coupled light lens has the function of such a computer—the apparatus is therefore commonly referred to as a "light-optical analogue computer".

Although today the much more accurate digital computers (acting as "computer lenses") have taken over this task as well, the light-optical computer has not yet lost its value. It should be remembered that both X-rays and light rays have wave characteristics, and that the wavelength of light is longer than that of X-rays by a factor of about $10^3$. When a light-optical apparatus, corresponding geometrically to an X-ray diffractometer but working with monochromatic light, is built, then in principle the same scattering effects are produced as with X-rays if the objects are enlarged by this factor of about $10^3$. Such an apparatus is called a light diffractometer. The light diffractometer (Fig. 1a) enables rapid checking of structural models. All that is needed is a mask with small holes in the presumed positions of the atoms. Naturally such a check can also be carried out very quickly today with a real computer. Despite this, the light diffractometer has remained useful, especially in electron microscopy (see also Sections 2.5 to 2.7).

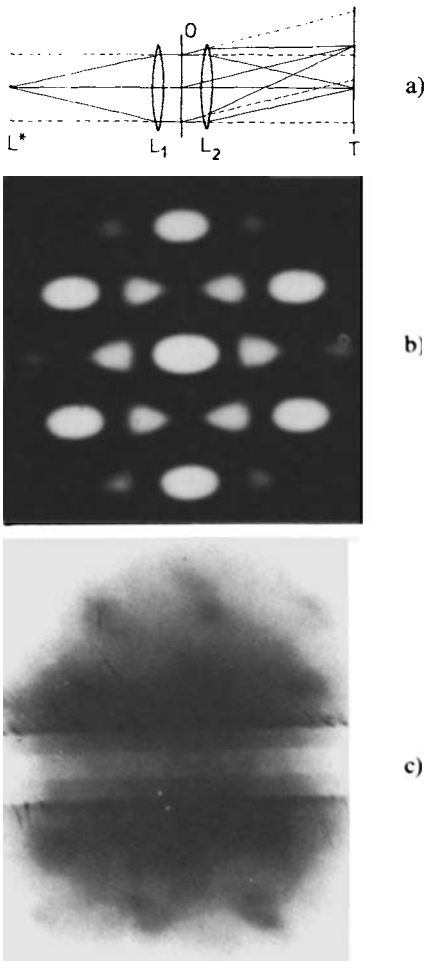

Fig. 1. a) The principle of the light diffractometer. It produces a diffraction image from the object O. The lenses $L_1$ and $L_2$ are unimportant; they should only ensure parallelism of the primary beam and of the scattered rays, despite the relatively short distance to the monochromatic light source L* and the detector (film) T. If they are left out, the distances have to be greatly enlarged. When using X-rays the lenses are left out, but the atomic dimensions of the object are so small that the light source and detector can always be assumed to be infinitely far away. The dashed lines delineate the beam in the absence of the lenses.—b) Light diffractometer diffraction image of a model (mask with holes at the sites of atoms) of naphthalene.—c) Image of the Fourier transform of anthraquinone in the diffuse background scattering of crystals [4]. Because of the geometry of the Weissenberg pictures, the strong "aromatic" maxima lie on lines.

The light diffractometer is especially useful for unravelling the inner symmetries of the object under examination. Thus, for example, owing to the regular hexagonal arrangement of the atoms in arene molecules, characteristic light diffractograms are obtained, typified by the hexagonal positioning of strong scattering maxima (Fig. 1b). However, in the case of a crystal, these molecular scattering diagrams are only seen through the "windows" of the crystal reflections, which makes their investigation difficult. Even as long as thirty years ago, it was shown that they also appear in the continuous scattering background of the X-ray diagrams of single crystals[4]. Figure 1c shows such a molecular scattering diagram in the background of a "Weissenberg" diagram of an anthraquinone crystal. For some time, the study of the diffuse background was relevant to the structural analysis of organic molecules, and was actually used in the constitutional analysis of ecdysone[5]. Since the development of "direct methods", however, the evaluation of additional scattering data (besides the single crystal reflections) is only useful in special cases.

### 2.2. Correction of the Spherical Aberration in the Electron Microscope by Ring Diaphragms

In 1961, a light diffractometer was also to be built in our laboratory for the purpose of studying diffuse X-ray scattering. It was known that one of the main sources of error in the electron microscope is spherical aberration (the refractive power of a magnetic lens increases strongly towards the outer edge, so the outer rays have a shorter focal length than those near to the axis). Therefore, a student named *Menzel* was given the task of testing, through analogous experiments with a home-built light diffractometer, whether the spherical aberration could be eliminated by simply combining a series of exposures which are recorded with ring diaphragms of increasing radius. When this is performed with an electron microscope, the position of the focussing plane would have to be synchronously corrected by changing the objective's current strength. However, we did not attach very great importance to this principle of correcting the spherical aberration. Naturally, the large decrease in the working aperture of the lens is troublesome, since all the scattered rays outside the transmitted rings are lost through shielding. The given task nevertheless fulfilled its purpose, and *Menzel*[6] not only built a good light diffractometer, but also was able to show that sharp image points can indeed be depicted, albeit with additional appearance of a strong background. Strangely enough, the idea of image forming with several ring diaphragms in

electron microscopy has also been discussed in more recent times.

### 2.3. Spatial Frequency Filtering in the Electron Microscope

Although we had never devoted a great deal of effort to this problem, we could not dismiss it: if the temporal sequence of a series of ring diaphragms could be replaced by a spatial sequence of concomitantly operating ring diaphragms, then the intensity of the transmitted light should naturally increase dramatically. At this juncture a little knowledge of wave optics is essential. When a point object—*e.g.* an atom—is irradiated, it acts as the center of a spherical wave. The wavefront is then the surface of a sphere with the point object as its origin. The optical function of a perfect lens is to invert this spherical surface so that a new image-sided spherical wave surface is formed, whose origin is the image-point. The detailed explanation of how the lens does this (in the case of light, by retardation of the waves in the glass) is not necessary for this discussion. The characteristic of an imperfect lens is that it is not able to produce a fully spherical surface. In the extreme case, *i.e.* if no lens is used at all, the wave surface of the object acts at the same time as the wave surface of the image, and this is actually curved in the wrong direction (away from the image point). *Fresnel* had already found that even in this case, an image will be possible if a system of a sequence of ring diaphragms is placed between the object and the image. This Fresnel lens is, of course, of particular interest when working with rays for which there are no lenses, *e.g.* with X-rays. The author had always toyed a little with the idea of building an X-ray microscope with Fresnel lenses, but had soon discovered that the ring distances would have to be of the order of magnitude of atomic distances[*]. On incorporation of a magnetic lens in an electron microscope, the image-sided wave surface is not especially good, but at least it is properly curved. Thus, the idea arose that it should be possible to place a ring plate, working on the principle of the Fresnel lens, between the lens and the image. Owing to the very small discrepancy between real and ideal wave surfaces, in this case, it was to be expected that such a correction plate would show fewer and much wider rings than a real Fresnel lens[7,8]. As shown in Figure 2, this zone correction plate is a "spatial frequency filter".

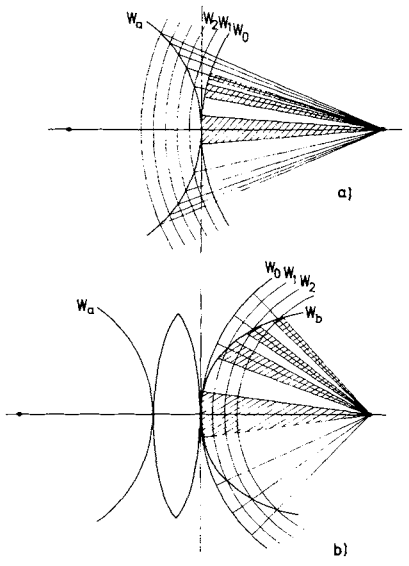

Fig. 2. Principle of the Fresnel lens (a) and of the zone correction plate (b). In (a), the image-side wave surfaces $W_0$, $W_1$, $W_2$ ..., at intervals of $\lambda$ intersect the object-side wave surface $W_a$ at the Fresnel lens and in (b) the defective image-side wave surface $W_b$ at the zone correction plate. In both cases, correct imaging is obtained with a ring-shaped diaphragm system (not shown), which allows passage of in-phase rays (phase shifting $0 \rightarrow \pi$) (shaded), but screens out oppositely phased rays (phase shifting $\pi \rightarrow 2\pi$).

Spatial frequency filtering constitutes one of the most decisive steps which have led to phase-determining diffractometry. In principle, the correction of spherical aberration with the zone correction plate enables improvement of the resolving power of the microscope down to atomic resolution. Right at the outset, plates (with about ten rings) were calculated[7,8], which should allow a resolution of about 0.15 nm (see Section 2.7).

### 2.4. The CTEM—A Diffractometer

A characteristic feature of the conventional transmission electron microscope (CTEM) is that the object is illuminated by a parallel monochromatic primary beam (Fig. 3a). This type of illumination, which would not be feasible with the light microscope because of the appearance of Fresnel fringes (there, a convergent polychromatic light beam is used for illumination), is, in principle, exactly the same as that which the crystallographer uses in his diffractometer. Indeed, if the lower part of Figure 3a, including the lens, is removed, then the scheme is that of a diffractometer: a parallel beam of radiation impinges on an object and sends scattered rays out in all directions. For a complete diffractometer, only one more fitting (a Goniometer) is needed, with which the object can be tilted with respect to the primary ray.

The principal similarity between the construction of an electron microscope and that of an X-ray diffractometer was realized early on by the electron microscopist. If a small crystal is used as the object and the image-forming microscope lenses are omitted, or, put another way, the image of the distribution of the rays is formed on the aperture diaphragm, then instead of photographing the image of the crystal we can photograph its diffraction diagram in the CTEM. The remarkable thing is that the electron microscope—using optical criteria—is actually a poor microscope but an excellent diffractometer. However, as experience in conventional electron microscopy has told us, good microscopy is possible even with this poor microscope if its peculiarities are taken into consideration.

*Boersch* noted in 1947 that atoms can be considered in analogy to phase objects in light optics[9]. Phase objects are structures in which only the refractive index changes but no absorption takes place. They are therefore invisible in the light microscope, but *Zernike* showed that they can be

[*] This idea was later taken up again with respect to an apparatus for far ultraviolet and soft X-rays, after new possibilities for the miniaturization of such a ring diaphragm system became experimentally within reach, at least for wavelengths in the region of 10 nm [G. Schmahl, D. Rudolph, B. Niemann, *Phys. Bl. 38* (1982) 283].

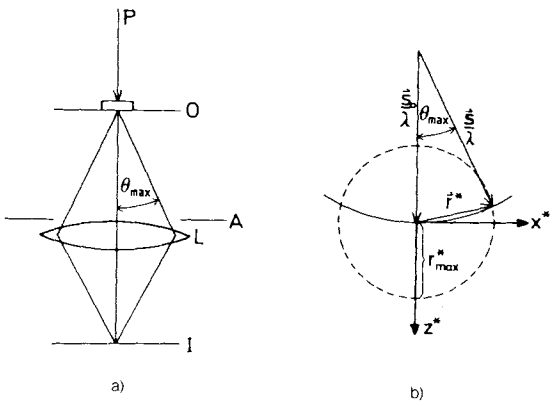

Fig. 3. The "diffractometric" ray path of the conventional transmission electron microscope (CTEM). a) The primary beam P (parallel, monochromatic) penetrates the object O, which scatters rays within a scattering cone with $\theta_{max}$, which are led through the lens L with the aperture A to give the image I. b) Pictorial representation of the scattering in the reciprocal space by Ewald's sphere of propagation: $\vec{s}_0/\lambda$ the vector of the primary wave, $\vec{s}/\lambda$ the vector of the scattered wave, $\vec{r}^*$ the spatial vector in the reciprocal space, $r^*_{max}$ the radius of Ewald's sphere of propagation (dashed), x*, y*, z* the coordinates of the reciprocal space. For very small wavelengths $\lambda$ (for 100 kV electrons, $\lambda$ is only 0.0037 nm!) the scattering angles $\theta$ become very small, and Ewald's sphere can be replaced by its tangential plane. The vectors of the reciprocal space $\vec{r}^*$ then lie in this plane (x*, y* plane). In electron microscopy they are also called spatial frequencies. Each scattered ray therefore corresponds to a reciprocal vector $\vec{r}^*$ (spatial frequency). The amplitude $/F/$ and phase shift $\phi$ of a scattered ray (referred to the primary beam) are designated, in crystal structural analysis (also adopted by us for electron microscopy) as the structural factor $F_{\vec{r}^*} = /F_{\vec{r}^*}/\exp i\phi$. Through the imaging process, $\phi$ becomes $\phi+\gamma$ ($\gamma$ = wave aberration). A "spatial frequency filter" in the ray path of the scattered rays can correct the phase error. The first electron microscopic spatial frequency filter was the zone correction plate. Since phase errors up to the maximum $\pi$ can be allowed in an imaging process, the zone correction plate filters out disturbing spatial frequencies having phase errors between $\pi$ and $2\pi$ (cf. Fig. 2 and Fig. 5). Later, zone correction plates were also developed which corrected the phase error by deceleration of the scattered ray in carbon layers of different thicknesses.

made visible by additionally shifting the mutual phases of irradiating rays and of scattered rays by 90°. This so-called phase contrast method has been an important part of the experimental procedure of light microscopy for decades. It should be mentioned that atoms are also phase objects with respect to X-rays. However, this is of no consequence in crystal structure analysis, because here the primary ray is screened off (*i.e.* one is performing a "dark field operation"). In bright-field electron microscopy with the CTEM one reaches the surprising conclusion, however, that the quest for an ideal lens is actually meaningless: no contrast can be obtained in the imaging of an atomic object. *Zernike*'s trick—of inserting a small plate in the aperture plane of the microscope, and thus enabling modification of the phase between the primary and the scattered rays in the desired way—meets with difficulties in the case of the electron microscope. Surprisingly, however, phase contrast (at least to a certain degree, and certain resolution) can also be produced by replacing the ideal lens by a lens with spherical aberration. This is because the spherical aberration produces an additional phase shift, and one must consider whether this phase shift can be exploited for phase contrast imaging.

With regard to the imaging of atoms, *Scherzer* incorporated into the imaging theory the phase object character of atoms[10]. Since the scattering of electrons is "weak" in the usual voltage range (50–100 kV), the hypothetical atomic images are calculated in a linear approximation[*]. This may seem paradoxical: it is the strong scattering of electrons (orders of magnitude stronger compared to X-rays) which enables the imaging of an object consisting of few atoms. However, the excited scattered rays are still substantially weaker than the exciting primary beam.

The fact that the linear theory suffices for thinner preparations in electron microscopy is of considerable practical importance, similarly as in the X-ray structure analysis of crystals, where the linear theory is known as the kinematic theory. Linear approximations are also used in some—but not all—holographic imaging procedures. One finds for the contrast $g$ in the center of an atomic image,

$$g=(I_0-I)/I_0 \tag{1}$$

the relationships[10]:

$$g=(2\pi e^2/h v_0)\int_0^{\theta_{max}}(Z-f_R)(\sin\gamma)\theta^{-1}\,d\theta \tag{2}$$

$$\gamma=(\pi C_s\theta^4/2\lambda)-(\pi\Delta z\theta^2/\lambda) \tag{3}$$

($I_0$ = bright field intensity, $I$ = intensity in the center of the atom; $e$ = electron charge, $h$ = Planck's constant, $v_0$ = electron velocity; $Z$ = atomic number; $f_R$ = X-ray atomic scattering factor; $\theta$ = scattering angle; $\theta_{max}$ = maximum scattering angle allowed by the lens; $C_s$ = spherical aberration; $\lambda$ = wavelength, $\Delta z$ = defocussing). In optics, $\gamma$ is called the wave aberration (cf. Fig. 3b, see also [7,8]). $\sin\gamma$ is the imaginary part of $\exp i\gamma$; when using amplitude objects, $\sin\gamma$ in (2) has to be replaced by $\cos\gamma$. The function characterizing the spherical aberration, $\exp i\gamma$, corresponds to the pupil function in light optics. Its component describing the imaging properties of weakly scattering objects ($\cos\gamma$ in the case of amplitude objects, $\sin\gamma$ in the case of phase objects) is also called the transfer function. Figure 4 shows $\exp i\gamma$ for a voltage of 100 kV and a rotationally symmetrical magnetic lens with a spherical aberration constant of 1 mm (lenses with spherical aberration constants of this order of magnitude are used in the modern CTEM apparatus), as a function of the scattering angle $\theta$ for different defocussings. Taking case a) first: here the image plane is placed in the focussing plane of the paraxial rays (Gaussian focus). Notice that $\sin\gamma$ is almost zero up to $\theta=5\times10^{-3}$ rad. If an aperture diaphragm were to be placed at this angle, then an atomic object would show no contrast. In this region the lens acts practically as an ideal lens without a *Zernike*'s phase plate, and thus cannot be used for the imaging of phase objects. Only when the scattering angle is larger does $\sin\gamma$ have values larger than zero, so that a contrast is built up in the center of the atom. However, above $\theta\approx9\times10^{-3}$ rad $\sin\gamma$ changes its sign—the integral in (2) becomes smaller with increasing $\theta$. It is therefore advisable to limit the scattering rays building up the image to this angle.

[*] If a large bright-field amplitude $A$ and a small (complex) image amplitude $\rho$ are added, and the intensity is calculated by squaring $((A+\rho)(A+\rho^*)=A^2+A(\rho+\rho^*)+\rho\rho^*)$, then the small term $\rho\rho^*$ can be neglected. The image intensity is proportional to the real part of the amplitude.

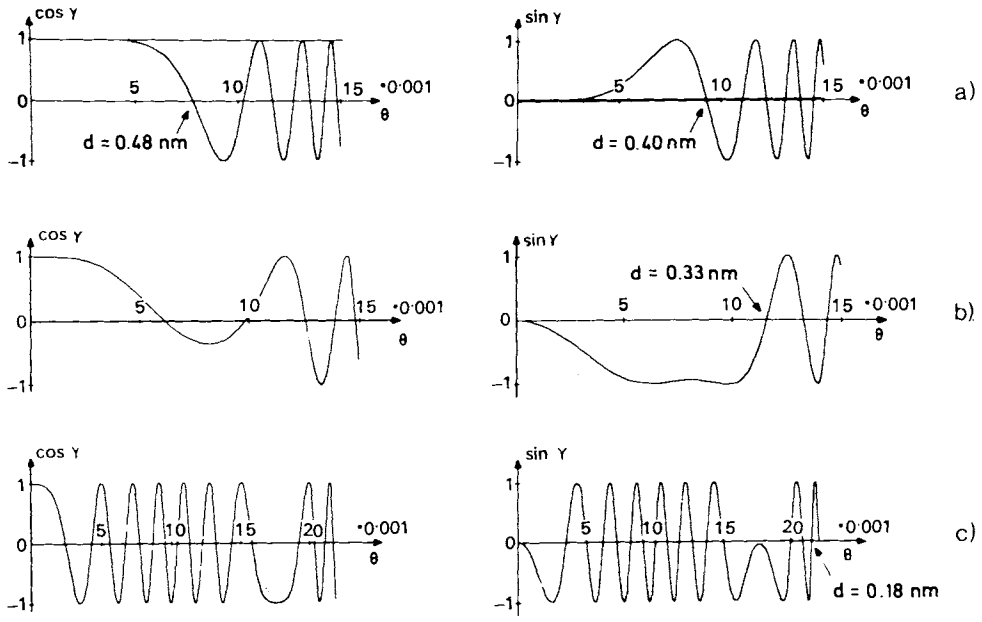

Fig. 4. Pupil functions $\exp i\gamma$ for different defocussings [30]: left, the amplitude component $\cos\gamma$, right, the phase component $\sin\gamma$. Defocussings: a) $\Delta z = 0$ (Gaussian focus), b) $\Delta z = 67{,}5$ nm (Scherzer focus), c) $\Delta z = 310$ nm (zonal correction focus). $U = 100$ kV; $C_s = 1$ mm.

Hence, the phase contrast is indeed produced by the spherical aberration; without the spherical aberration, $\sin\gamma$ would never vary from zero. *Scherzer*[10] tried to improve the contrast by additional defocussing, and succeeded in doing so at a certain value (underfocus) (Fig. 4b): this was found to be 67.5 nm for a spherical aberration of 1 mm; for other spherical aberrations this value changes in accordance with a formula given by *Scherzer*. The range up to the change of sign of $\sin\gamma$ is thereby enlarged, and the scattered rays with low scattering angles can also contribute more to the formation of the image than in the case of the Gaussian focus.

In order to extend the phase contrast principle to our zone correction plate it is necessary to calculate $\sin\gamma$ for even larger defocussings (see image point calculations[11-14]), so that the wave aberration $\gamma$ oscillates strongly (Fig. 4c). If $\sin\gamma$ is now "filtered" through a ring diaphragm system so that the sign is not changed (with gaps in the screened-out places), then in the image point integral (2) all terms of the same sign with increasing $\theta$ are added, and increase both the contrast and the resolution. Figure 5 illustrates how the zone correction plate screens out the unwanted parts of $\sin\gamma$ with opposite sign.

The question then arises of whether the screened-out parts have a disruptive influence on the image. According to image point calculations[11-14], the background variations are somewhat increased, but the form of the image points remains unaffected. Figure 4c shows that with a given defocussing of 310 nm, almost a doubling of the resolution limit compared with Scherzer focus can be reached with 8 oscillations of $\sin\gamma$ (comparable to 8 dark rings). A further increase of resolution, however, soon leads to difficulties, since the number of oscillations increases very rapidly. But, a factor of more than 2 is unnecessary in order to analyze atomic structures. On the other

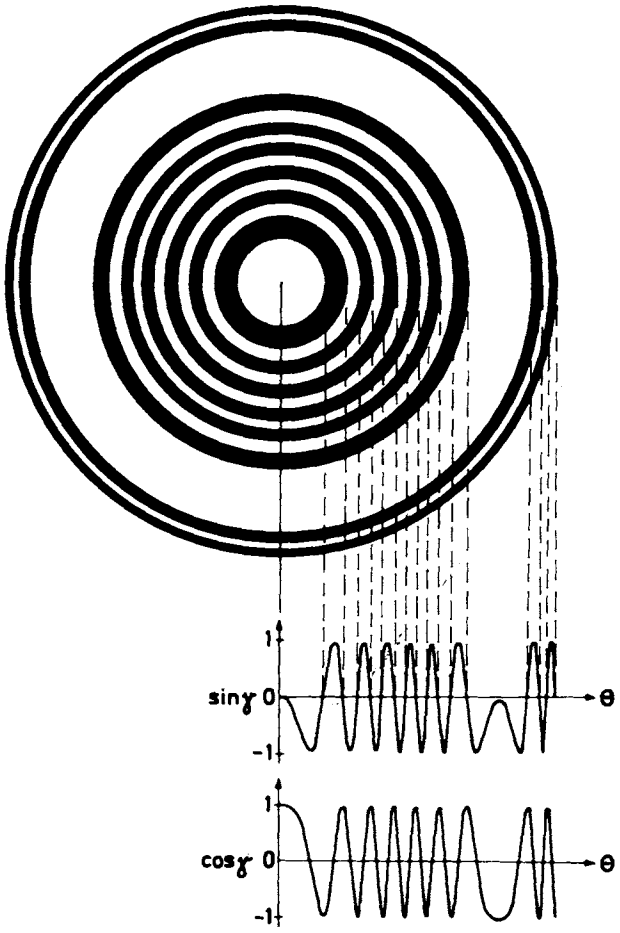

Fig. 5. Phase component of the pupil function (phase contrast transfer function) and design of the zone correction plate. The positive regions of $\sin\gamma$ are screened out. Note that in contrast to the general case (cf. Fig. 2 and Fig. 3), the phase error $\gamma$ (wave aberration) of the transferred structural factors $F_{\vec{r}}$ no longer changes continuously, but jumps from band to band by $\pi$ (three ray interference of the spatial frequency $+\vec{r}^*$, $-\vec{r}^*$, primary ray); the structural factor amplitudes $F_{\vec{r}}$ are therefore weighted by a function $(/\sin\gamma/)$. $U = 100$ kV; $C_s = 1$ mm; $\lambda/\theta_{max} = 0.18$ nm.

hand, the spherical aberration of round magnetic lenses can be pushed only a little under the limit of 1 mm (using 100 kV), (Scherzer's theorem[15]).

### 2.5. The Imaging of the Transfer Function in the Light Diffractogram

As deliberations on the zone correction plate were coming to maturity we still did not possess an electron microscope in our laboratory. On discussing the experimental realization of our ideas, experts told us that secondary errors in electron microscopy (current instability, voltage instability, mechanical drift in the object stage) already made it very difficult to reach double the theoretical minimal image point distance (Scherzer's resolution distance). During a visit to the Siemens' electron microscopy research and development laboratories in Berlin, I was informed about the work of *Thon*, who was studying the dependence of carbon foil granulation on the defocussing of the objective. Electron microscopic investigations on carbon foils had shown that the granular-like image is strongly dependent on the defocussing. *Lenz*[16] had developed a theory explaining the different granulations by changes in the properties of the lens with different defocussing, in which *Thon* incorporated the spherical aberration. To test this theory, the most often occurring distances in many micrographs were measured and their statistical average compared to the theoretical mean[17]. The technical quality of the series of micrographs was excellent. Point distances in the range of Scherzer's resolution distances could be measured. I suggested replacement of the troublesome single measurement of the distances by an investigation of the autocorrelation function (which directly yields a statistic of the distances), or by an investigation of the square of the image Fourier transform (equivalent to the autocorrelation function). This last type of analysis seemed to be especially convenient experimentally. Its execution is simple, if the plate with the electron micrograph is used directly as an object in the light diffractometer. The light diffractometer then directly forms an image of the square of the Fourier transform. *Thon* accepted an invitation to carry out experiments on this in our laboratory. For the experiments, the light diffractometer that *Menzel* had already built was used (see Section 2.2). Even the first pictures showed ring-shaped structures in the light diffractogram. Afterwards *Thon* systematically continued these experiments in Berlin using a light diffractometer with a laser instead of a high-pressure mercury lamp[18]. The light diffractograms showed (as expected from theory) ring-shaped structures modulated by the square of $\sin\gamma$ (see Fig. 6a). These diagrams immediately proved that atoms are phase objects and that the linear theory suffices for the description of the scattering. If the atoms had been amplitude objects (that is, if the electron beam had been absorbed in the atoms), then the light diffractogram would have had to have been modulated by $\cos\gamma$ (cf. left side of Fig. 4). If the linear theory of the phase contrast had not sufficed, then the ring structure would have disappeared.

### 2.6. Spatial Frequency Filtering in the CTEM using the Zone Correction Plate

Some time later, in collaboration with our colleagues in Berlin and Tübingen (we had by then also become involved with experimental electron microscopy), investigations were carried out on filtering by the zone correction plate in the CTEM (see Section 2.3)[19,20]. *Möllenstedt et al.* in Tübingen had developed a special electron-optical technique for etching very fine diaphragm systems[21], which enabled the production of suitable zone correction plates. The direct imaging of $\sin^2\gamma$ in light diffractograms of carbon foils allows adjustment of the filter with control of the proper positioning of the open rings, and rings to be covered up in the light diffractogram. Figure 6 shows the light diffractograms of the same foil before and after the positioning of the zone correction plate; each even-numbered ring zone in Figure 6a is screened off in Figure 6b. Naturally, it is the linear transfer of the real part of the amplitude (see footnote p. 459), after the phase shifting of $\pi/2$ (phase contrast), that enables the direct imaging of the zone correction plate. In Figure 6b, even the clamps on the sides of the rings are pictured.

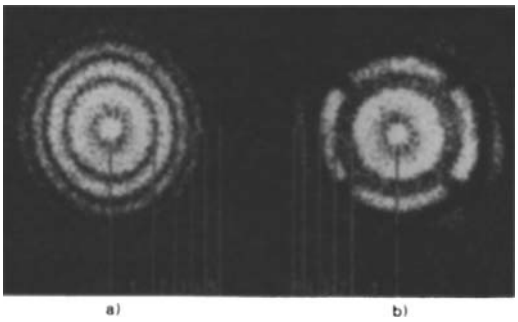

Fig. 6. Light diffractogram of a carbon foil: a) before insertion, b) after insertion of a zone correction plate.

Figure 7 shows one of the first successful spatial frequency filterings in electron microscopy. Here, as in other optics, the resolution is limited by the aperture of the lens, which itself limits the maximum scattering angle $\theta_{max}$. This law has already been used in the discussion of the function $\exp i\gamma$ (pupil function; cf. Fig. 4), where it was shown how the largest usable aperture angle $\theta_{max}$ increases on going from the Gaussian focus to the Scherzer focus, and finally to the spatial frequency filter focus.

The spatial frequency of a scattered ray according to Figure 3, is a two-dimensional vector in the x*,y*-plane. Due to the small scattering angles in electron microscopy, its absolute value corresponds to the scattering angle of the scattered electron beam $\theta$, divided by the wavelength $\lambda$. We always use the reciprocal value of the maximum spatial frequency (the radial limitation in the spatial frequency plane) $\lambda/\theta_{max}$, as the limit of resolution. The resolution defined in this way (dimension length) is also called the crystallographic resolution $d_{cryst}$, since the analogous term is used in crystallography for the definition of resolution (*e.g.* in the crystal structure analysis of proteins). In analogy to light-optical resolution, $d_{cryst}$ corresponds to the smallest distance with which two image points in an image

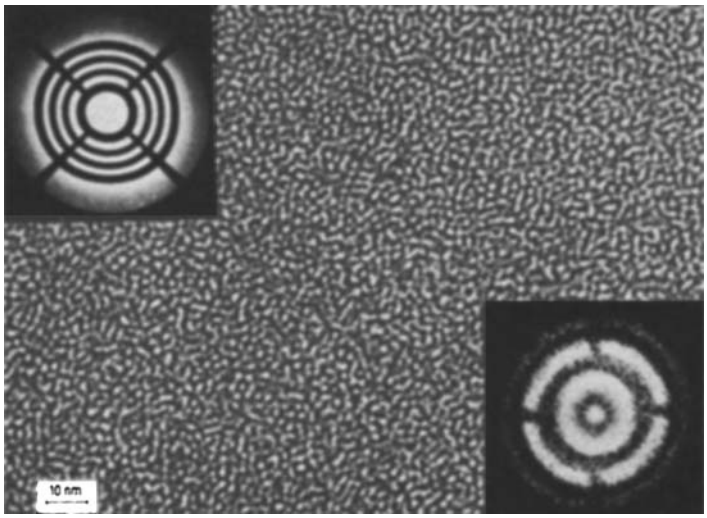

Fig. 7. Spatial frequency filtering in the electron microscope (Elmiscop 101 with a $C_s = 1.35$ mm special objective). Above left: zonal correction plate (after *Möllenstedt et al.*) photographed in the electron diffraction image of the foil; below right: light diffractogram of the foil. The light diffractogram of the foil does *not* encompass the boundaries of the electron diffraction diagram (limited monochromaticity to the thermal cathode).

can be separated. Note, that this definition is somewhat pessimistic, the exact calculation yields an additional factor of 0.85 when using the light-optical definition of resolution for coherent illumination. Sometimes, in electron microscopy publications, even the factor of 0.6 is placed before $\lambda/\theta_{max}$ (called nominal resolution). However, this definition of resolution is somewhat confusing, since this factor corresponds to incoherent illumination, which does not apply in the CTEM. Hence, on studying the literature of electron microscopy, care must be taken that the different definitions of resolution do not lead to false conclusions. The crystallographic resolution has the advantage that it allows the direct comparison between electron microscopy and X-ray crystallography. In the right-hand part of Figure 4 the (crystallographic) limits of resolution under the three different conditions are 0.4, 0.33, and 0.18 nm. When $d_{cryst} = 0.18$ nm, the atomic structure can be excellently interpreted—as protein crystallography has shown—assuming, naturally, that the protein structure has been determined three-dimensionally. Even atomic models down to a resolution of 0.28 nm are routinely constructed; however, the atomic maxima in the electron density synthesis are no longer resolved. Because of the known, and limited, atomic configurations, simple "pattern recognition" models can, however, be established. It follows from this, that with spatial frequency filtering, the barrier to atomic resolution can indeed be broken through.

In Figure 7, however, the light diffractogram (bottom right) of the CTEM-micrographs is only sufficient for a resolution of 0.3 nm (rather than of 0.2 nm). This was disappointing, because we had hoped that contrast would be extended at least to the edge of the strong area of the electron scattering diagram. Since the light diffractogram images the square of the Fourier transform (see Section 2.5), the image will at best give a resolution that corresponds to the reciprocal limit of the light diffractogram. The limit of resolution is not defined by the aperture diaphragm of the objective, but by the expansion of the scattering diagram in the spatial frequency area; beyond this limit, even the best lens cannot improve on the resolution. This effect was investigated in more detail by *Hirt*[22]. The Maxwellian distribution of the electron velocities at the hot cathode prevents the radiation from being totally monochromatic, even with the best possible stabilization. With a larger scattering angle, the scattering intensity will be diminished, and will finally become immeasureably small. By using a cold cathode (field emission gun) the range of speed of the electrons can be narrowed to such an extent that intense scattering appears up to the edges of the zone correction plate. An increase in the accelerating voltage also leads to a better monochromaticity of the radiation; for example, it was possible to demonstrate a crystallographic resolution of 0.18 nm (Scherzer's resolution 0.28 nm) in the light diffractogram using CTEM pictures at 200 kV[23]. For these pictures (Fig. 8) a cryomicroscope was used ($T = 4.2$ K), which offers a further advantage: decreasing of the thermal vibrations of the atoms, and therefore a general increase in the scattering intensities.

### 2.7. Replacement of Light Diffractometry by Computer Calculations

As before, the readily obtainable diffractogram serves as an invaluable aid for the assessment of the quality of an electron micrograph (see Fig. 9).

However, for quantitative analysis, light diffractometry is too imprecise, and has to be replaced by calculations. For this, it is necessary to bring an electron micrograph into a computer retrievable form. The micrograph is therefore scanned, in the course of which the length of the sides of the scanning elements (Pixel) must not surpass half, at most, of the linear resolution. The density of the micrograph in each of these Pixels is determined. Since electron rays, the same as X-rays but in contrast to light rays, increase the density of the photoplate proportionally to the intensity (linear relationship up to a density of $S = 1$), it is possible to determine the intensity profile of the picture with a densitometer. The large amount of data being handled necessitates that the densitometer should scan automatically. Fourier analysis, which can be carried out using a routine program for Fourier transformation, leads to a two-dimensional density diagram that is equivalent to the light diffractogram but which not only produces the square of the Fourier transform, but also the Fourier transform itself (with amplitude and phase).

### 2.8. *A posteriori* Spatial Frequency Filtering Outside the Microscope

Let us look again at Figure 6. As previously explained, in the right-hand part (b), the even numbered (misphased) spatial frequency rings are screened off by the zone correction plate (filtering off), and are therefore missing in the formation of the image. The Fourier transform of a normal bright-field micrograph could also be produced by calculation, and on image formation (by calculation), the mis-

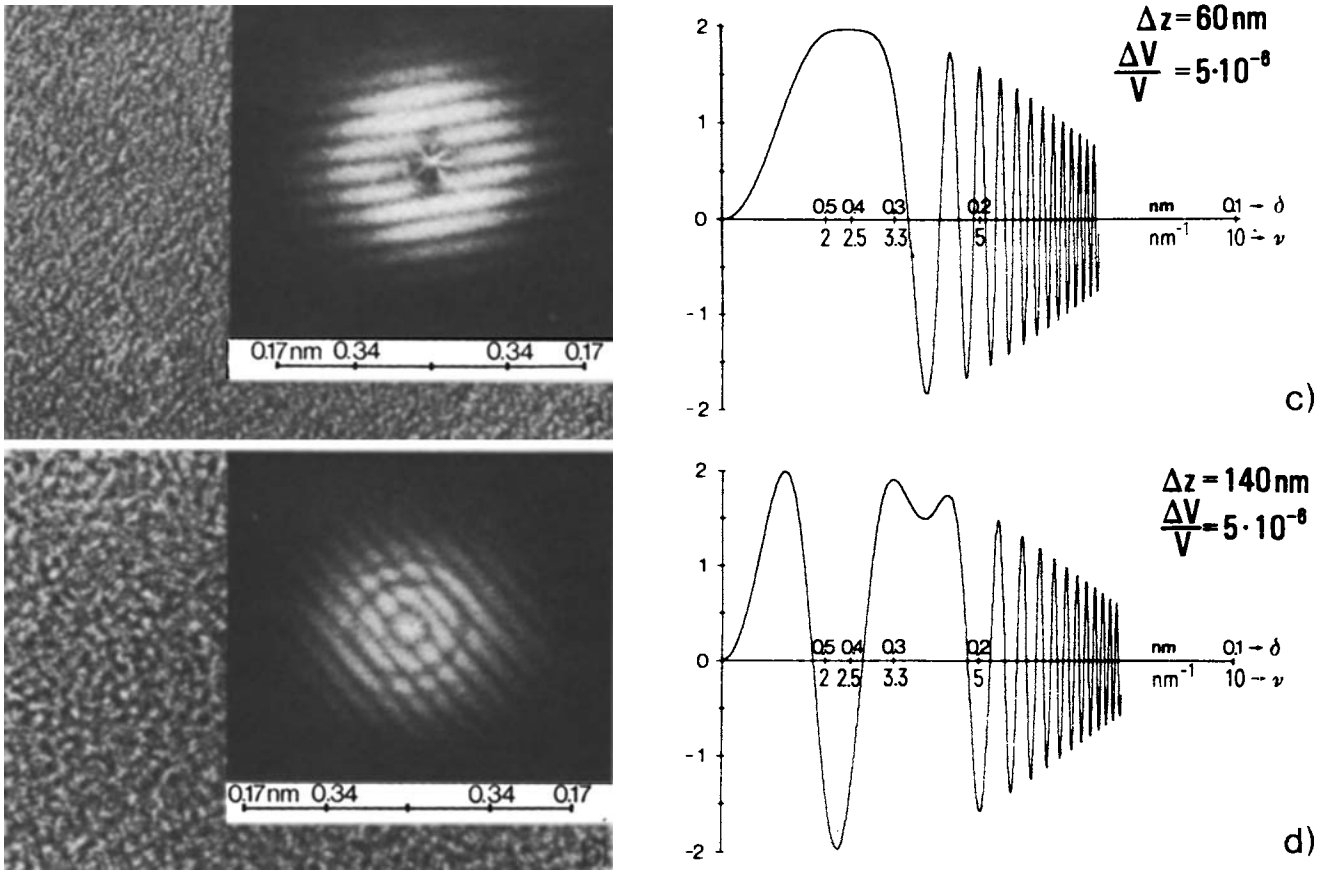

Fig. 8. Exceeding the conventional limit of resolution with central illumination [23] (for inclined illumination, cf. Fig. 11). Photographs taken with the cryomicroscope using an acceleration voltage of 200 kV and $C_s = 1.35$ mm: a) in the proximity of the Scherzer focus ($\Delta z = 40$ nm), b) defocussed for image reconstruction. Note in a) and b) the parallel dark fringes produced by overlaying of two equal, slightly shifted micrographs (resolution test with Young's fringes, see [24b]).—c) and d), phase contrast transfer functions for a) and b). The transfer function c) shows narrow oscillations outside the central region (Scherzer region) that can be scarcely resolved for reconstruction. In contrast to this, the zones in d) are considerably broader (cf. also Fig. 4), which—with regions of sufficient size (see [30])—allows reconstructions. The resolution test with Young's fringes indicates significant regions also in the frequency filtering regions with non-resolvable zones, therefore they are recognizable in a) also outside the strong mid region (Scherzer region). The resolution in the diffractogram (reduction of speckle) can be increased, according to [30], by increasing the illuminated region of the specimen, so that the delineation of the zones (and therefore also the reconstructability) can be improved. An increase in the resolution of the image by reconstruction in case a) should however only be possible to a limited extent, whereas the broad zones in case b) allow reconstruction up to the limit of the Young's fringes (corresponding to 0.18 nm resolution).

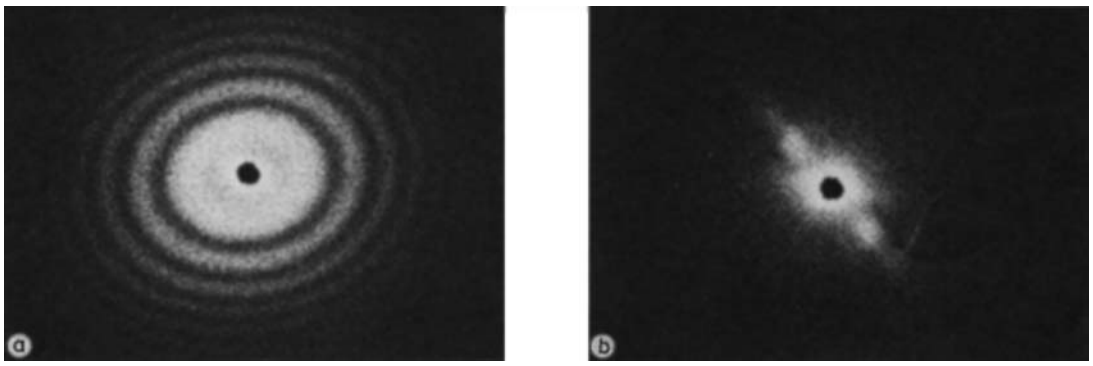

Fig. 9. Light diffractograms for the diagnosis of electron micrographs. a) The light diffractogram has elliptical zones: axial astigmatism (magnetic field non-spherical, adjustment of stigmator inexact); this causes no disturbance with suitable reconstruction. b) Lateral drift of the specimen. Light diffractogram extended in one direction only, micrograph unusable. The reconstructable resolution can be recognized from the extension of the diffractogram. For determination of the absolute limit of significant details (also in non-reconstructable regions), Young's resolution test is necessary (cf. Fig. 8).

phased areas are simply omitted. The picture formed in this way and the image produced by the zonal correction diaphragm should be the same (within the scope of the linear approximation). It is more advantageous to include the misphased scattering areas for the image formation, but then to shift (correct) their phase by the amount $\pi$. In addition, even the weakening of Fourier amplitudes near the zero positions can be compensated for by calculation

(amplitude filtering), but care must be taken, as the noise in these regions is increased at the same time.

Our first calculations of this kind were discussed in 1970 at symposia on new electron microscopic methods in Hirschegg[24] and in London[25]. Soon after the publication of the work on zone correction plates[7,8] *Hanssen et al.*[26] had pointed out that spatial frequency filtering—in the optical instrument and *a posteriori*—had already been developed in light-optics, although for entirely different physical tasks. They applied the light-optical "Linear Transfer Theory" to the situation in the electron miscoscope, whereby essentially the relations inferred by *Scherzer*[10] and ourselves[7,8] had only to be reinterpreted in another way[26]. *Schiske*[27] and *Hanssen*[28] independently proposed transfer of the *a posteriori* filtering from light-optics to electron microscopy. This was realized experimentally in the works previously mentioned[24,25] and in "analogue computations" in a double light diffractometer[29]. A further proposal[27,28] suggested that the corrected image should not be constructed from a single micrograph, but rather from a series of micrographs of the same part of the object taken at a different focus. In this way, the influence of the gaps in the spatial frequency spectrum on the quality of the corrected image should be eliminated (see Section 3.4.2).

## 2.9. A Consistent Theory

Of fundamental significance[30–32] in the use of the electron microscope as a phase-determining diffractometer, is that the microscope is no longer needed to form an image, but is used purely as a measuring instrument for the collection of the characteristic data (structure factors) of the rays scattered by the object under study. As in X-ray structure analysis, these scattering data can be used in various ways.

If it is indeed true that the atoms can be interpreted as pure phase objects, then for electron rays, as with X-rays, Friedel's law applies: the centrosymmetrically related spatial frequencies of a diffractogram show the same intensities, and the corresponding (equally sized) phases have opposite signs. In the case of bright-field image formation, the linear approximation means that, physically, the interferences between the individual scattered rays can be neglected[*]. Therefore, corresponding to the classical definition of the phase in X-ray crystal structure analysis, only the phase difference between the primary and the scattered ray is measured. Luckily, a separate experiment is not necessary for each scattered ray (from the standpoint of the optimal usage of the primary electrons, this would be disastrous); the phases can be determined from the superposition of all the scattered rays with the primary ray by Fourier analysis. However, with a limitation: centrosymmetrically related spatial frequency vectors lead to similar kinds of interference images that coalesce. They can no longer be separated ("three-ray interference"). This can be ignored if Friedel's law is applicable, since the one spatial frequency will be ascribable to the other. The phase-determining diffractometer/electron microscope is therefore basically only suited for scattering diagrams for which Friedel's law applies.

### 2.9.1. *Anomalous Scattering*

It is already known from X-ray crystallography that both sides of the scattering diagrams can show different intensities and phases. This "non-Friedel" case occurs if some of the atoms in the structure scatter anomalously. This concerns heavy atoms which have an absorption edge in the wavelength region of the rays being used. The scattering from these atoms proceeds with a certain (small) phase shift $\eta$ with respect to that of the non-anomalously scattering atoms, and this effect leads to the inequality of both halves of the scattering diagram. Such anomalous scattering also occurs with electron rays, albeit likewise weak, but significantly stronger than with X-rays. In practice, this too is only noticeable with heavy atoms. It was first noticed in the electron diffraction of gases. Similarly as in X-ray diffraction, it can be described by complex atomic scattering factors. However, there is a special case of anomalously scattering atoms in which Friedel's law applies, namely when only one kind of atom is present. The electron microscope is then once again a perfect interferometer which accurately records the diffraction spectrum of the object (naturally, within the limits of the linear approximation). The phase shifting of the anomalous scattering $\eta$ can easily be taken account of if $\gamma$ in equation (3) is replaced by $\gamma-\eta$ (in the special case of a pure amplitude object, with $\eta=\pi/2$)[30].

What do we do when mixed structures, *i.e.* structures with various kinds of atoms are present? This is the case, for example, in the structure analysis of "heavy atom stained" organic compounds. As already mentioned, the centrosymmetrically related spatial frequency vectors of both halves of the diffraction diagram together make a sum whose single components can no longer be discerned. If, however, at least two micrographs with different defocussings are used, then the weighting of the components will be different due to the influence of the transfer function, through which a separation becomes possible[27,30]. This becomes even simpler[31] if only one of the two centrosymmetrically coupled rays is allowed entry to the image plane. If half a plane is covered in the aperture diaphragm, then only half of the diffraction pattern will be recorded, and a second micrograph is necessary for recording the other half, with the complementary half-plane being concealed. Admittedly two micrographs are necessary in order to transfer the complete experimental information, but calculations show that—other than with the central beam bright-field micrograph —no weakening of scattered wave amplitudes takes place. However, all the phases of the Fourier spectrum of the spatial frequencies are now wrong, but by knowing the transfer function, the phase errors can be calculated and corrected. The transfer function can either be determined from a third micrograph (with central beam illumination), or be calculated from both the half-plane micrographs. The latter procedure, however, is only exact in the case of a centrosymmetrical diffraction dia-

[*] They only have to be considered in the case of an approximation to the second order of magnitude.

gram (*e.g.* of a pure phase object), but it should also be possible in other cases, since $\gamma$ is only dependent on a few parameters according to equation (3) (cf. Figures 10 and 11 for procedures with oblique illumination). With the exception of experiments on the discrimination of heavy atoms[36], this possibility has not yet been exhausted in structural analyses, but belongs to the reservoir of methods for the future. Besides determinations of the complex function, the unweighted recording of the amplitude of the scattered rays is of special interest.

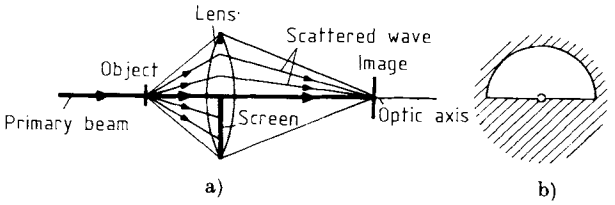

Fig. 10. Complex image reconstruction according to the complementary half-plane procedure [31]. a) Schematic construction of the imaging arrangement.—b) Half-diaphragm (the small ring marks the penetration point of the primary ray). For the second micrograph, the diaphragm must be removed, and a complementary diaphragm inserted.

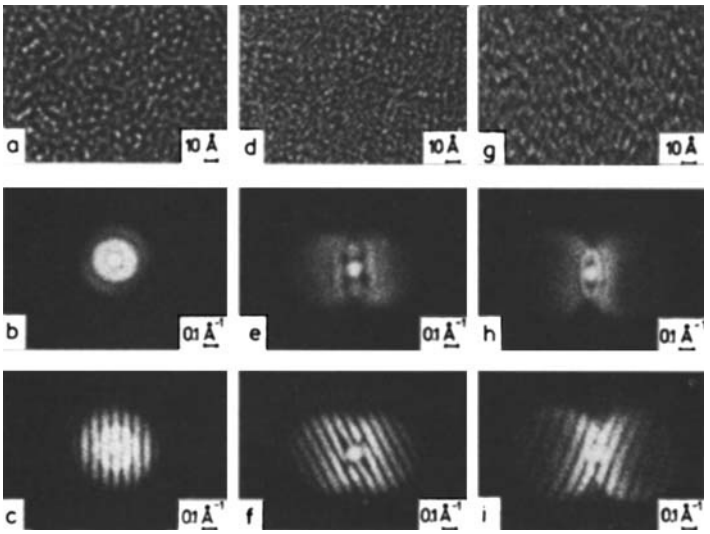

Fig. 11. Complex image reconstruction with inclined illumination [33–35]. Using inclined illumination a resolution down to the atomic limit can be achieved, even with thermic cathodes (with 100 kV). However, the total image must then be compiled from several partial images (synthetic aperture). Light diffractograms reveal the (anisotropic) increase in the transferred spatial frequency area on increasing the angle from 0° (a, b, c) to 0.66° (g, h, i). In the latter case, a limit of resolution of 0.16 nm can be measured. The procedure is complicated and of low intensity, but excellently demonstrates the possibilities that an electron microscope offers on its use as a phase-determining diffractometer.

Another possibility for the analysis of structures with different kinds of atoms is offered by approximation procedures, in which the separation of phase and amplitude parts of the scattering is dispensed with. Such a procedure is usual in X-ray structural analysis, where, however, the influence of anomalous scattering is much smaller. Approximation is also used in our analysis of "heavy atom stained" organic compounds. Here—in contrast to what is usual in light optics—it is important not to discriminate into phase and amplitude objects, but into "differently mixed" objects with the extreme case of the pure phase object (pure amplitude objects do not appear in electron microscopy). In this way, not only is the important link between phase and amplitude parts of anomalously scattering atoms taken into account, but also, the influence on the transfer function can easily be surveyed. Figure 12 shows, for example, the transfer functions at different defocussings for $\eta = 0.25$ (corresponding approximately to platinum according to the table of atomic scattering factors[37]) and for $\eta = 0$ (light atoms). It can be seen that the differences—with the exception of the immediate proximity of the primary ray—are not very great. The experimental zero positions will lie somewhere between the zero transition points of both transfer functions. It can also be seen that the weakening of the amplitudes of the scattered rays near to the zero positions is greatly advantageous here, for the unstable phases, which are anyway in a very narrow range, are associated with a strong weakening of the amplitudes, so that the form of the image is little influenced. Despite renunciation of a complex reconstruction, both heavy atoms as well as light atoms are well reproduced; the errors of this approximation procedure play hardly any role. A short time ago, in our laboratory, *Typke et al.*[38] experimentally determined the magnitude of the anomalous scattering for some heavy atoms (cf. Fig. 13).

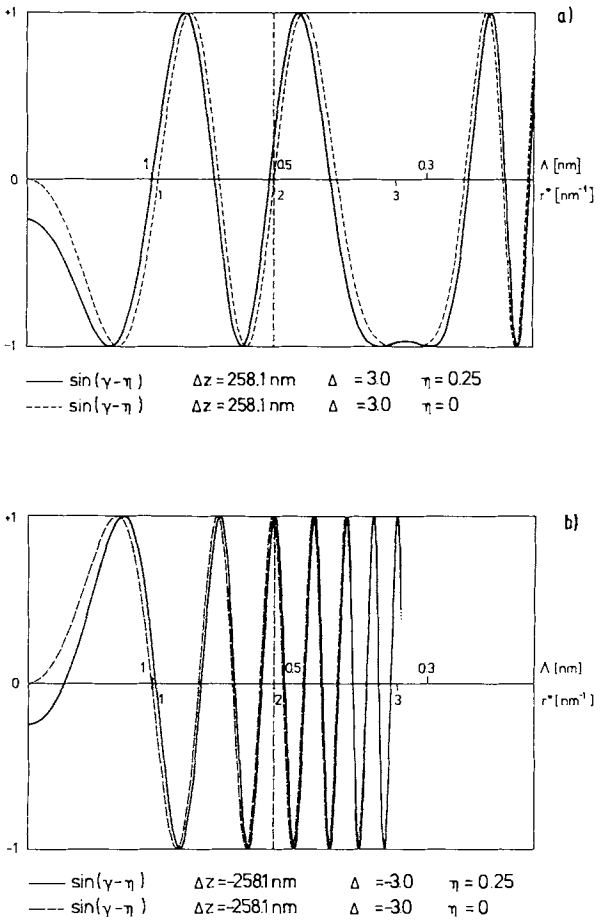

Fig. 12. The function $\sin(\gamma - \eta)$ for $\eta = 0$ and $\eta = 0.25$ (from [36]): a) underfocussed, b) overfocussed.

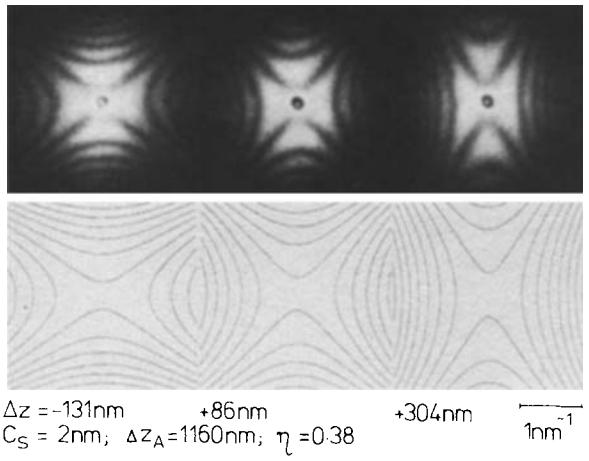

Fig. 13. Light-optical diffractograms of electron micrographs of a carbon foil shadowed with platinum. Due to the relatively large astigmatic difference $\Delta z_A$ (1160 nm), the zero lines in the diffractogram (corresponding to the gaps in the transfer function) are hyperbolic in the inner region (shown for three defocussing values of $\Delta z$ in comparison with the calculated curves). Because of the anomalous scattering of the platinum atoms, this also applies for the innermost zero line, which with a pure weak phase object, would go through the center (cf. [38]). The images show that the electron microscope is also utilizable as a Fourier interferometer for the study of physical parameters (for further refinement of our methods, a more exact knowledge of the anomalous scattering is important).

At the "double symposia" in Hirschegg and in London in 1970, *Erickson* and *Klug* reported on the influence of amplitude filtering on the defocussing-dependency of the reflections of catalase crystals stained with uranyl acetate[39], and thereby experimentally proved[*] the concept which we had formulated the previous year[30-32]. Particularly noteworthy was the finding that the linear theory even remains valid for strongly scattering specimens—we had previously only experimented with light-atom structures.

### 2.9.2. *Consideration of the Curvature of Ewald's Sphere of Propagation*

Discrete formulation with spatial vectors and atomic scattering factors had proven especially useful for the handling of structural analysis problems in X-ray diffraction. Consequently introduced into our work since 1969[30], it led to the separation of "partial amplitude scattering (angle $\eta$)" and "phase scattering"—a separation which would have made little sense in light optics. On extension of the theory of electron diffraction to thick specimens (within the validity of single scattering)[30], the complication arose that the transfer functions of the atoms become dependent on their position along the optical axes of the instrument. This complication could be eliminated by replacement of the two-dimensional spatial frequency area by the three-dimensional reciprocal space (Fourier space)[30]. The Ewald's sphere of propagation (see Fig. 3b) then comes back into play, and thus, electron microscopy becomes now, in every detail, a variant of the diffraction methods in structure research. When dealing with scattering at the surface of the sphere of propagation, complex image reconstruction is unavoidable even with pure phase objects—and one must fall back on the "methods in store" (cf. Figs. 10 and 11). "Phase-determining diffractometry with the electron microscope as a tool" is still a recent method, but the door to three-dimensional analysis down to atomic resolution, in analogy to X-ray structural analysis, is open. This also applies for the aperiodic case; even it can be considered as "crystal structure analysis" in the widest sense, if a small piece of aperiodic material is regarded as a "crystal with one unit cell". The electron microscope thereby loses its property as an image-forming apparatus (however, it can be further used as such for readout and presorting of the submicroscopic entities) and the lens is replaced by the computer for generally three-dimensional images.

### 2.10. Automation of Phase-Determining Diffractometry

The development of the electron microscope into a "robot" is therefore indicated. A robot works not only fast and reliably, but also enables any chemist, biologist, mineralogist *etc.* to carry out complicated physical procedures without any specialist knowledge, using a "black box"[40]. It is remarkable that the prerequisites for the automation of phase-determining diffractometry are even better than in X-ray structure analysis; the phases can be measured directly, whereas in the latter case they have to be determined indirectly. Although the demands on the computer are greater, the incredible advances in computer technology allow for no faint-heartedness even if the conditions of a dedicated computer—now common in X-ray diffraction analysis—are imposed. Of interest is the shift in the problems of development. Whereas formerly, in the case of X-ray structural analysis, the translation of the relatively simple measuring methods into the robot's technology gave difficulties, today these are marginal. On the other hand, articulation of the meticulous adjustment and measuring operations in conformity with robots, which are so difficult in electron microscopy, requires special attention[*].

An electron microscopist of the good old stamp may at first pity the "degradation" of the electron microscope to a measuring instrument. But, is it not true that the computer creates new, incredible, possibilities for the electron microscope? Phase-determining diffractometry is—within the framework of kinematic approximation—just as quantitative a procedure as X-ray crystal structure analysis. Both are based on measurements; it should be noticed that even the density curves of X-rays and electron rays are analogous, and that in both cases quantum-counting direct detectors can also be used[43]. Phase-determining diffractom-

[*] The theoretical basis of this contribution was inaccurate: in the basic equation (5), in which the influence of the light atoms has apparently been neglected, the authors have added the phase part and amplitude part of the heavy atom scattering as if they had been independent of each other, whereby the correct transfer function $\sin(\gamma-\eta)$ is obtained as an approximation. With a small amplitude part, this has scarcely any influence on the numerical results; only when $\eta \approx \pi/4$ (for uranium from about $\theta/\lambda = 7.5\ \mathrm{nm}^{-1}$) do incorrect factors, of the order of magnitude of $\sqrt{2}$, and phase errors, emerge.

[*] It can only be remarked in passing that the on-line diffractometer [41, 42] and the on-line correlation computer [40] are important aids to adjustment.

etry is not limited to periodic structures, and can be used in all areas of chemistry, from inorganic chemistry to biochemistry. It also offers the prospect of atomic analysis—not as a vague presumption, but rather as a precise, theoretically-founded procedure, and one that is, experimentally, already realizable for the most part.

### 2.11. The Scattering Absorption Contrast

Looking back, it seems remarkable that the fundamental relationship between electron microscopy and light-optic phase contrast microscopy was not fully utilized until the sixties, although *Boersch* had already noted in 1947 that atoms scatter and do not absorb[9]. For sure, a reason for this was that, even in the light microscope, the method of phase contrast is not trivial—it is so much easier to view an object as it is (if necessary also after staining). Actually, even thin structures, stained with heavy atoms, show some contrast in the Gaussian focus of the electron microscope at low resolution. Because of the anomalous scattering, heavy atoms are not colorless, but light grey. But strong phase objects (thick objects) can also behave as amplitude objects (non-applicability of the linear approximation, quadratic phase contrast), similarly as to how air bubbles can easily be seen in water when using the light microscope. This becomes more complicated if multiple scattering takes place. In earlier electron microscopy, the source of the contrast was not important, the images being seen "as if" they came from absorbing material. Even today, one must revert to the phenomenological approach if the range of applicability of the linear theory is relinquished; but nowadays, attempts are made when calculating the bright-field intensity, to take the quadratic terms into account.

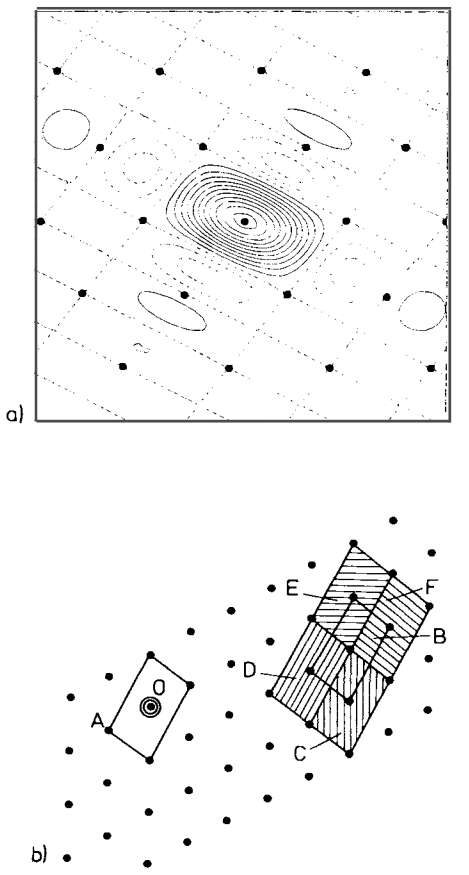

Fig. 14. "Phenomenological" description of a variant of ptychography [46]. In a scanning transmission electron microscope, a structure is impressed, according to a), on the (coherent) scanning probe. The lattice reflections enlarge according to b) to sharply defined spots, which overlap one another (with interference). On scanning, the intensities in the overlapping regions vary in unison with the phase differences of the reflections. For recording the micrographs, the usual one-channel detector has to be replaced by a position-sensitive area detector for electrons (*e.g.* according to [43]).

### 2.12. What is "Ptychography"?

This name describes some (almost forgotten) procedures for determining the amplitudes and phases of scattered electron waves without lenses, which with today's knowledge are especially applicable in the case of crystals[44]. They are based on the mutual interference of scattered rays—in contrast to holography, in which all scattered rays are superimposed with *one* reference wave. A variant of these procedures has recently been realized[45]. Another variant should be relatively easily realizable in the scanning transmission electron microscope, and should enable the evaluation of diffractograms with almost any resolution that is needed (Fig. 14)[46]. In the case of inorganic crystals, and perhaps also in the case of radiation-sensitive organic crystals, these procedures could easily develop into being competitors for the methods described in Sections 2.3—2.10.

### 2.13. Highly Ordered Biological Structures

In crystallography textbooks, the laws of diffraction are usually "amalgamated" with periodicity and symmetry. But, just as the laws of diffraction can be abstracted from periodicity and symmetry[61], using periodic and/or symmetrical patterns, the laws of symmetry can be abstracted from the diffraction theory. X-ray crystallography has led to the study of objects transformed into the reciprocal space (Fourier space). Periodicity and symmetry produce certain Fourier structures in which it does not matter whether the object is an electron density distribution or another—even macroscopic—density distribution. This naturally also applies for micrographs obtained by imaging the respective objects in the electron microscope. Once again, it does not matter whether it is a question of qualitatively correct images, or—as in the extension of the kinematic theory to electron microscopy outlined in this review—of parallel projections of potential distributions.

Qualitative electron microscopical images of contrasted, periodic and symmetrical biostructures have been investigated since the early sixties using Fourier principles, whereby the light diffractometer (see Section 2.1) has served as an especially convenient "calculating machine" for Fourier transformation[47]. By exploiting the Fourier-distribution of the object—known as filtering—certain structural properties are especially accentuated. This filtering, which concerns the object under investigation, has nothing to do with the spatial frequency filtering that we introduced, which concerns the optical properties of the objective. A special kind of "object filtering" is possible in

the case of two-dimensional lattices, whose Fourier transform shows strong, grid-like arranged maxima (corresponding to the periodicity), and a background (arising from individual differences in the unit cell pictures). By filtering out the background, and averaging all the distorted entities by a further Fourier transformation (*e.g.* in a light diffractometer), a strictly periodic structure can be produced. The averaging was first carried out on high-dose micrographs (good electron statistics, but preparation and irradiation artefacts). Electron microscopic work on periodic unstained and native biostructures has been published since 1968 (see Section 3.3).

## 3. Three-Dimensional Analysis

### 3.1. The Problem

Considering the electron microscope and the X-ray diffractometer as analogue instruments already implicates all applications which are possible with a diffractometer. These include, above all, the three-dimensional analysis of the structures under study. In the fifties, X-ray crystal structure analysis of projections (along the edges of the unit cell) was followed by three-dimensional analysis of the electron density in the unit cell, since it was clear that only the true[*] three-dimensional analysis (for which the kinematic theory had afforded the theoretical background) could lead to elucidation of the construction of complicated structures. Fortunately, the tools which were necessary for complex information processing were developed at the same time, namely, automatic measuring machines and electronic calculating machines. In electron microscopy, as in crystal structure analyses, the object specimens are far too thick, relative to the lateral resolution, so that overlapping of the structural details prevents a consequent analysis. Three-dimensional electron microscopy was not simply achieved in an analogous way, but had its origin, in part, in general procedures of image processing[48–50].

This is not surprising, due to the original image-forming character of the electron microscope. The "transfunctionalization" of the bright-field electron microscope into a phase-determining diffractometer for electron diffraction signifies a development away from the admittedly attractive, but only qualitative "peep" microscopy (a term given by *Ernst Ruska*), to quantitative structural research.

### 3.2. Tomographic Procedures

#### *3.2.1. The Polytropic Montage*

In *Hart*'s contribution[49], the term "three-dimensional" does not even appear. He describes his method a "polytropic montage", with which electron micrographs taken at different angles are superimposed on top of one another in such a way that single layers of the specimen are thrown into sharp relief. By changing the overlapping parameters, different layers can be rendered predominant. A similar principle had been referred to much earlier in X-ray diagnostics as "tomography". If X-ray shadow pictures of a body are made at different angles, then they contain projections of all the superimposed layers, which are, however, overlaid using different amounts of shifting. If such pictures are superimposed in such a way that one layer is placed in the same orientation in all the pictures, then this layer will predominate, whilst the other layers are shifted with respect to each other, and, to a certain degree, average themselves out (Fig. 15).

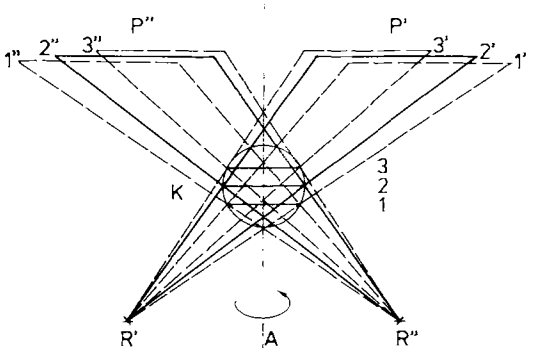

Fig. 15. Principle of circular tomography. The layers of the body K (*e.g.* 1, 2, 3) are imaged with shifts in the X-ray shadow diagram. The shifts depend on the location of the X-ray tube (*e.g.* position R′ or R″). If the pictures P′ and P″ are shifted one over the other in such a way that the layer pictures 2′ and 2″ become congruent, then only 2 is highlighted in the overlapping image. In circular tomography, R rotates about the axis A. In the electron microscope, central projection is replaced by parallel projection (R infinitely far away; imaging of the object at large depth of focus). The change in direction of projection is achieved by tilting of the specimen. The plane of the image (P′, P″) is therefore perpendicular to the direction of the projection. A certain, but easily managable, distortion of the projection images is produced (squares are imaged as rectangles).

#### *3.2.2. Electron Microscopic Computer Tomography*

In the sixties, it was found that disturbances caused by insufficient averaging-out of the unwanted layers in tomography, are largely mathematically correctable, especially when one kept to parallel projections, instead of central projections (which called for new X-ray imaging apparatus). The "reconstruction" of a three-dimensional image of a body becomes especially easy to view if different directions of projection are adjusted by the rotation of the body about one axis; with an asymmetrical body, the axis of choice does not, in principle, matter (computerized tomography, see Figure 16).

This computerized tomography is very well suited for extension to electron microscopy[48]. The parallel projection is guaranteed by image formation with great depth of focus[49], through which superimposed layers of the specimen appear projected over one another in the electron micrograph. Microgoniometers can be used to rotate the specimen (*e.g.* in the way that "tilt cartridges" are used in electron microscopy) and finally, the computerized analysis follows in analogy with calculation methods, if the

[*] This means the substitution of the two-dimensional image function $\rho(x,y)$ (*e.g.* on an electron micrograph) by the three-dimensional image function $\rho(x,y,z)$ (in electron microscopy, z extends along the optical axis). To be distinguished from image stereoscopy, in which a two-dimensional image is replaced by two two-dimensional images slightly tilted towards one another, whose view gives a spatial impression, but does not give the inner construction.

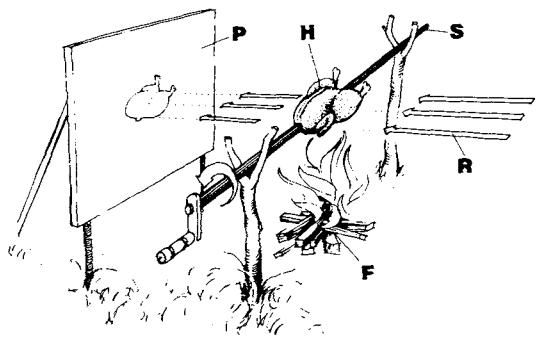

Fig. 16. "Tomographic chicken grill". The chicken H on the skewer S is grilled by the fire F. On turning the skewer, pictures of the chicken at equal angular increments $\Delta\alpha$ are produced on the plates P with parallel X-rays. In electron microscopy, the X-rays are replaced by electron rays; parallel projection is achieved by imaging with great depth of focus. The "grilling" of the "chicken" is (unfortunately) done by the electrons themselves.

image is transformed into a digital field of numbers, *e.g.* by densitometry. The "grilling", which is not normally the case in X-ray tomography, is (unfortunately) brought about by the electron rays themselves: at a dose necessary for image formation, they destroy the organic substance (*e.g.* biological macromolecules), which means that special methods of specimen preparation must be used.

Thus, irradiation-resistant inorganic structures are imprinted on the specimen (positive and negative staining), which allows recognition of the primarily interesting features of the organic structure. They can also be imaged with high irradiation doses, where generally, structural details are only relevant down to the so-called biological resolution ($\geq 1.5$ nm). Care must always be taken, because, even on stabilization of the structure after the very rapid destruction of the organic substance, slow changes cannot be ruled out[51], and the laws of "staining" are in no way trivial—the principle of the filling of gaps with an amorphous heavy-atom glass in negative contrasting is, *e.g.*, certainly only approximate[*].

[*] To define the term "computerized tomography" more precisely (to differentiate it from "diffractometry"): Tomography can be carried out both in real, as well as in reciprocal space, whereby the mathematical procedures of image processing are formally related to the procedures of crystallography. All three-dimensional methods necessitate a set of pictures taken with the illuminating rays in different directions (cf. Fig. 15 and 16 and [50]). There are, however, characteristic differences: (a) Tomography is based on central or parallel projections, (b) in tomography the physics of the imaging process is unimportant.—Tomography can be used in such diverse areas as X-ray diagnostics and radio astronomy (corresponding to (b)). In contrast, in diffractometry the physical imaging process (scattering process) is important; in X-ray diffractometry the requisites of "projections" (see (a), planar sections in the reciprocal space in the case of parallel projections) are only applicable in an approximate way, in special cases (small angle scattering). The reciprocal space is transected by a spherical surface. This also applies in diffractometry using the electron microscope. Of course, it is useful in practice that the spherical surface can be approximated by a plane, owing to the short wavelength of the electrons at a not too high resolution. In a diffractometry theory, there must be a defined correlation between scattering and structure. It can only be applicable to an approximation (neglect of multiple scattering in the kinematic theory, use of linear theory for phase measuring). Using these criteria, the procedure of *DeRosier* and *Klug* [48] is "tomographic", not only because it absolutely necessitates parallel projections, but primarily because here, a phenomenological imaging theory (scattering absorption contrast based on the logarithms of the densities) is used, without taking spherical aberration into account. In our image-point calculations with spatial frequency filtering the kinematic scattering theory and the linear approximation had already been used since 1965 [11—14]. This theory (with spatial frequency filtering), was adopted in Cambridge in 1970 [39]. In electron microscopy, however, consideration of the lens properties is especially important, since different kinds of "images" are obtained using different defocussing. In the Gaussian focus, for example, the linear approximation is not applicable. The first three-dimensional image reconstructions in electron microscopy (fatty acid synthetase [81]) are consistent with diffractometry theory. A phenomenological imaging theory is completely unusable at high resolution (accelerating voltage of the order of magnitude of 100 kV), because, in such a case, the curvature of the sphere of reflection, as well as the change of sign in the spatial frequency spectrum, has to be taken into consideration. However, there are conditions under which work can only be qualitative: thick objects, multiple scattering (see Section 2.11). Qualitative analyses have recently been described [93].

### 3.2.3. *Three-Dimensional Analysis via Symmetry*

The experimental work on three-dimensional electron microscopy by *DeRosier* and *Klug*[48] did not, however, correspond exactly to the model in Figure 16. With respect to the analysis of highly-ordered biological structures (especially helical structures)[48], in the model case the chicken would have to be replaced by a macroscopical helix, *e.g.* a helical spring whose axis is identical to the skewer axis. Simple geometric considerations show that a sinusoidal curve must appear as the image (parallel projection). When the skewer is rotated, the sinusoidal curve retains its shape, but appears to move along the axis, one full turn corresponding to a shift of the sine curve by one period. This means that, in such a case, all tomographic pictures can be derived from a single image, and so, of course, for three-dimensional analysis, one X-ray or electron diffraction picture would suffice. However, if this model is refined to a helix on which identical subunits are threaded like pearls, then identical projections appear merely on rotation through small, discrete angle increments $\Delta\alpha$ (*e.g.* for tobacco mosaic virus $\Delta\alpha = 3.7°$). A discrete set of tomographic pictures is obtained (*e.g.* 49 pictures with tobacco mosaic virus), which, in most cases, suffice for a three-dimensional analysis at biologically-significant resolution. With anglular increments that are too large, intermediate layers can either be taken from images with incidentally different positions of the objects, or the specimen can be tilted inside the region of the anglular increments. The three-dimensional structure of the tail of the T4 phage was determined in this way[48].

The method of producing projections by symmetry relationships (instead of by measuring) can also be used with other highly symmetrical structures (*e.g.* with spherical viruses). The experimental simplicity of the analysis is fascinating, especially in the case of helical structures with small angle increments—no tilting of the specimen is necessary, and the micrographs can be taken with a conventional microscope[52].

This does not yet constitute a three-dimensional analysis in the strictest sense, since the identity of experimentally determined projections and projections deduced *via* symmetry is correct only to a relatively crude approximation. The specimen lies on a foil, and is covered with contrast medium; these components certainly have no helical, nor even cylindrical, structure. The helix in the specimen could also have been squashed; this is not revealed in every case on enlarging the micrograph[*]. Despite these limitations,

these kinds of experiments have yielded a lot of valuable information on the structure and function of macromolecules—*e.g.* on the mechanism of contraction of the phage tails.

Regarding the term "macromolecule", it should be noted that from the standpoint of the content of information (expressed, for example, by the sum of all atomic coordinates), it is of great importance whether a highly symmetrical molecule (*e.g.* tobacco mosaic virus (TMV)), or an unsymmetrical molecule (*e.g.* ribosome), is under study. The content of information in the former case can be lower by orders of magnitude. Often a small subunit (the truly unsymmetrical structure—like the base sequence of the RNA in viruses—is neglected) repeats itself, according to a law of symmetry, which can usually be given with few parameters—in the case of a helix, with its polarity, diameter, pitch, and number of subunits per turn. Their number plays hardly any role compared to the considerably larger numbers of parameters necessary to describe the subunit, so—according to information theory—such a macromolecule can practically be taken as the "subunit molecule". This concept can be extended even further. As already mentioned, a biological helix is a "string of pearls" consisting of "equal" subunits wound in the form of a screw. From the viewpoint of three-dimensional analysis, such a helix can directly be seen as a "tilting device", which brings single subunits into the orientations necessary for structural analysis. This is associated with both an advantage, as well as a disadvantage: on the one hand, many subunits form an image, whereby averaging takes place on artefacts of preparation and irradiation damage (object filtering[47]); on the other hand, this principle apparently functions only for smaller structures—a helix similar to TMV with ribosomes as subunits would be so enormous, that this would go far beyond the applicability of the kinematic theory, because of its thickness. This has the consequence that the proper three-dimensional information—expressed, *e.g.*, as the number of resolution elements N in the "reconstruction volume" of the subunit—is very small (order of magnitude 10) because of the limited biological resolution.

Nevertheless, the aesthetic charm of highly symmetrical helical and spherical ornaments is immense—it is pleasing, in a certain way, that the long-forgotten dreams of *Dorothy Wrinch*, who had postulated extremely symmetrical protein structures in her cyclol theory[53], have come true, at least in this field.

Furthermore, this information-based description of the molecule also applies for the X-ray diffraction experiments of highly symmetrical macromolecules like the TMV protein[54]. However, the high molecular weight complicates the measurement—an immense number of scattering data have to be determined—but the high symmetry facilitates the analysis. On discussing helical structures, the possibility of three-dimensional X-ray analysis of fiber diagrams must be mentioned. It was the precursor of electron microscopic analysis, and could be carried very far, for example, with TMV[55].

[*] Recent investigations on a spherical virus (turnip yellow mosaic virus) seem to confirm these fears.

### 3.3. The Analysis of Native Periodic Structures

The tomographic procedures[48,49] and our contribution[50] to three-dimensional electron microscopy had different origins. Dissatisfaction with the fact that in the case of biological specimens irradiation damage necessitated contrasting tricks, and bad resolution seemed to be inevitable, stimulated a search for ways which could lead, in analogy to X-ray crystallography, to an electron-ray crystallography of native proteins. We immediately directed our attention to the possibility of the diffractometric determination of amplitude and phase of the crystal reflections using electron-microscopic methods, for the methods of spatial frequency filtering, and hence electron-microscopical diffractometry, had been developed in our laboratory.

The first hurdle was specimen preparation. Protein crystals contain about the same amount of solvent as the protein itself. On drying, the crystalline order is almost completely lost. It was therefore necessary to find a vacuum-resistant material that could replace the solvent without disturbing the crystalline order. Of the known embedding materials for electron microscopy, hydrophilic polymers proved to be the most useful. The alternative, that water should be left in the crystal and its evaporation prevented[56] by modified experimental procedures, such as electron microscopy with humid object chambers, or low-temperature microscopy (at $-180\,^{\circ}C$, ice has a vapor pressure of $10^{-20}$ bar), seemed far from promising in the initial stages of research. As test structures, we used crystals of myoglobin and erythrocruorin, and tested the preservation of their structure X-ray crystallographically. For specimen preparation, special procedures were developed (for example, cross-linking of the proteins with glutaraldehyde to render them insoluble).

Figure 17b shows a precession diagram of a myoglobin crystal embedded in Vestopal. Here, it can be seen that the order is much worse than in a water-containing crystal (Fig. 17a). The disturbance of the crystal order takes place only in the last step of the preparation, on transformation of the monomeric embedding material into the polymer; diagrams of the crystal soaked with the monomer show an unchanged order of the protein molecules[57]. It is therefore recommended to lower the vapor pressure by non-covalent forces (lowering of the temperature) instead of by polymerization through covalent cross-linking. The range of materials that can be used as substitutes for water is therefore broader. Of course, water itself—as already mentioned, and as was later proven experimentally[58]—can also be used. Its anomalous behavior on crystallization, however, can only be overcome by certain tricks, for example, by supercooling (shock-like deep-freezing), or by the generation of a non-anomalous ice modification at high pressure[59]. On substitution of the water, new parameters can be varied (vapor pressure curve), and also mixtures (partial distillation) can be tried out. In any case, today there is scarcely any doubt—for ice[58] and organic monomers[57] it has been proven—that a preparation of native structures of biomolecules for high resolution electron microscopy is possible.

As a temporary aim of our work[80], the X-ray crystallographic resolution of 0.8 nm that we reached, was consid-

ered satisfactory (Fig. 17). Electron diffraction on thin layers of crystals prepared without contrasting yielded clear crystal reflections, which on comparison with the X-ray diagrams showed an analogous intensity distribution. These diffraction diagrams using the normal conditions of irradiation in the electron microscope—still without the minimal dose technique introduced by *Williams et al.*[60] (not to be confused with the low dose technique)—were visible for only a few seconds. The poorer resolution in the electron diffraction diagram (1.2 nm instead of 0.8 nm) can perhaps be attributed to radiation damage during the adjustment operation. However, most important was the fact that the possibility of carrying out an electron ray analysis of native proteins (and therefore also that of other biogenic macromolecules) had been demonstrated.

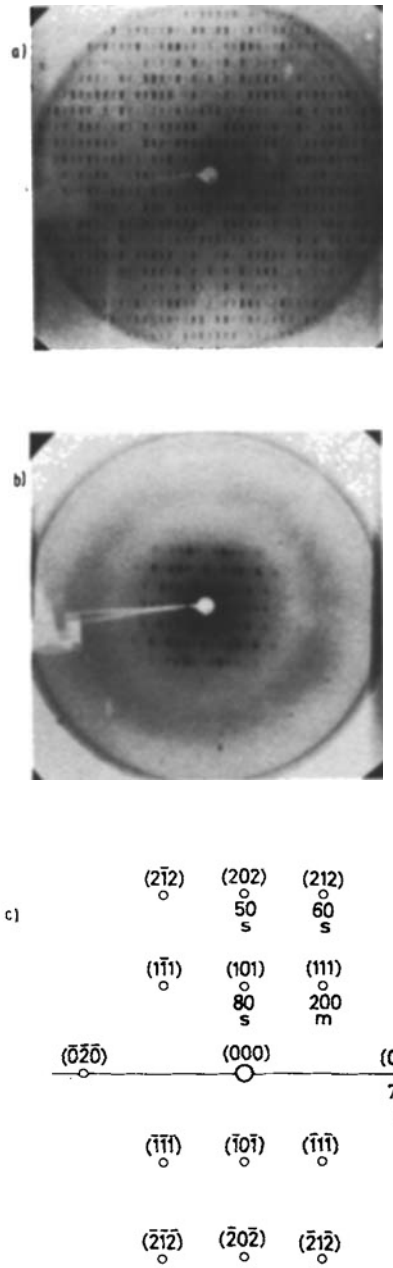

Fig. 17. a) X-ray diffraction diagram (precession diagram) of a sperm whale myoglobin crystal (hk0 projection) in mother liquor. b) Precession diagram after crosslinking of the proteins with glutaraldehyde, and dehydration and embedding in Vestopal (polymerized). c) Electron diffractogram of a thin ultramicrotome section of a crystal embedded in Vestopal (schematic). In addition to the indexing, absolute values of the structural factors measured by X-rays and (beneath) the estimated electron ray intensities (st = strong, m = middle, s = weak) are given (after [50]).—In a "supplement" [57], different embedding materials, primarily water soluble materials, were also tested, and an electron micrograph of an unstained microtome section was shown, which seemed to be unordered ("granulated"), but showed single reflections in the light diffractogram.

A law in structure research, the reciprocity law, states that structural information in one of the two dual spaces—real space and reciprocal space—must always correspond to an analogous information (transformed into the other space). When applied to our problem, it means that the same information on the structure of the crystal must be contained in the image of the native crystal lattice in the electron microscope as in the diffraction diagram. However, it contains information about the phases, which indeed the diffraction diagram also contains, but which is lost on the transformation of the amplitude into intensity (in contrast to the intensity formation in the image plane)[50]. However, the influence of the measuring instrument, the electron microscope (phase object, spherical aberration) must be taken into account (cf. Sections 2.3—2.10). For the changing of direction of the projection (for three-dimensional analysis) differently orientated ultramicrotome sections of the crystal were proposed[50], with which, in electron microscopy also, the whole reciprocal space is accessible. The same goal can be achieved by changing the orientation with the aid of a goniometer ("tilting"), as is otherwise usual in crystallography.

Why a crystal structure analysis of native biogenic macromolecules is possible with the electron microscope is made clear in the following reference[24a]: "Let us first start with a not very encouraging discussion concerning the physical possibility of "molecular microscopy". It is the strong interaction of electrons with atoms which makes it possible to collect in a reasonable time enough scattered electrons for the recognition of single atoms. But there is also the unhappy situation that for light atoms the cross-sections for elastic and inelastic scattering are of the same order of magnitude. That means that the number of elastic and inelastic collisions is approximately the same. In crystal structure analysis there are many equivalent molecules—in a small protein crystal, *e.g.*, $10^{17}$! It is therefore highly improbable that a molecule will be hit more than once by an incident quantum. Therefore the elastically scattered quanta will find untouched molecules and can build up diffraction patterns of the non-distorted molecule". Now, the averaging principle is a fundamental principle of crystallography; it is dealt with in text books[61], is used in the X-ray diffraction analysis of statistical superpositions of molecules with different conformations[62], and is applied to stained electron microscopical molecular pictures, which show differences produced by preparation and radiation damage (high dose pictures)[47,48]. Remarkably, however, it was not until much later that averaging to eliminate irradiation damage was given any attention[50,24a] (work on information theory[63] cited in this context[58] contains no remark on this possibility), perhaps because it only became known later[64] that the ratio of inelastic to elastic collisions with atoms, also in the case of X-rays (substitution of the electrons by X-ray quanta) is very

large. It is actually almost larger by a factor of 10 compared with electron rays, *i.e.* X-rays are very destructive[*].

From 1970 onwards *Glaeser*[58] systematically investigated the radiation damage of organic structures, and demonstrated in computer simulations how the influence of the radiation damage can be reduced by crystallographic averaging. Using these preliminary studies as a basis, *Henderson* and *Unwin* succeeded in performing the diffractometric three-dimensional analysis of a native crystal (purple membrane from *H. halobium*) by the use of spatial frequency filtering (see Sections 2.2—2.10)[**]. Such structural analyses have become very popular in recent years[66]. However, it soon became obvious that preparation of a specimen suitable for high resolution encountered difficulties in the case of very large molecules; even without radiation damage, resolutions of less than or equal to 2 nm are difficult to obtain. Similar difficulties are also encountered in the X-ray crystallography of macromolecular structures. Highly symmetrical organic macromolecules (*e.g.* helical structures) could easily be investigated in their native states using the low-dose technique. Low-dose experiments on stained TMV[67,68] have demonstrated how new details (above all in the nucleic acid sector) become visible on changing to the non-damaged molecule.

### 3.4. Three-Dimensional Electron Microscopy of Individual Structures ("Real" Three-Dimensional Electron Microscopy)

#### *3.4.1. Why "Individual" Structures?*

X-ray crystallography has developed from small beginnings to be one of the most important branches of science. What would our understanding of matter (and therefore, of chemistry) be today if the diffraction method had not given us such a detailed knowledge of the atomic architecture of compounds—up to the proteins? This is true, of course, only for highly ordered, periodic aggregates (like single crystals). However, there also exists the world of individual structures which are not exactly reproducible, but which are of importance not only in biology (although there especially) but also for chemical reactions in the most general sense. How paltry is our knowledge here!

Just think of "platinum black", an inorganic catalyst for reactions of organic molecules, whose particulate form hardly ever repeats itself. Or a biological membrane: its enzyme pattern on the surface leads us to suspect topological interactions, which optimize sequences of enzyme reactions. Enzyme complexes like fatty acid synthetase may be precursors of such "factories". Again, the structure is not repeatable, but its principle of construction is important for biochemistry.

A method which is fundamentally suited to experiments in this problematical sector is to be found in microscopy. For example, cells, which are individually so different, but which also show structural similarities, can be identified under the light microscope. On investigating individual structures by conventional electron microscopy, the molecular, but not of course the atomic region, was approximated. But even this method had in many ways its limitations. One of its most important being the information-destroying restriction to projections of spatial bodies.

Phase-determining diffractometry, with its combination of the principles of structural research and microscopy, promised to provide the most interesting insights into the wide field of aperiodic and individual structures (with possibilities for use in all areas of chemistry).

In Munich, therefore, although X-ray diffraction and neutron diffraction[69]—as well as protein crystal structure analysis in the electron microscope[50]—were not totally ignored, our efforts were concentrated on the further methodological development of electron diffraction for the investigation of individual and aperiodic structures in the electron microscope. Atomic resolution was not attainable using thermal cathodes, or, only incompletely so, (with synthetic aperture techniques[33–35]). The laborious development of better monochromatic field emission guns in our own laboratory would have been unjustified, as such a program of studies was already under way and proving successful elsewhere; today, field emission cathodes are commercially available (although they are costly). Three-dimensional analysis, however, was fascinating at any resolution; it was also to be expected that in lower resolution investigations the general stability problems would be of less trouble. A self-imposed handicap was the concentrating of our efforts on biological structures, for that presented the complex problem of radiation damage. It is not without envy that we look at inorganic electron microscopy, in which, completely conventionally and with incredibly high irradiation doses, imaged crystal projections yield practicable contributions to topological chemical questions[70]. The energy transferred in elastic scattering processes is carried off without damage to the object. But, on the other hand, biochemical and biophysical investigations are especially interesting. Moreover, conventional electron microscopy had already shown what valuable information can be won in spite of radiation damage, if the object is prepared in a suitable way (cf. Fig. 18).

The success of the low-dose analysis of native periodic structures (Section 3.3) has unfortunately misled many into regarding high-dose analysis of contrasted structures as being "retrogressive". However, in the case of individual structures, high-dose analysis must be resorted to. The object to be studied, *e.g.*, a macromolecule, is by no means to be regarded as isolated. In reality, reaction products are observed, from the reactions of the compounds actually of interest with the reagent of preparation, the supporting

[*] A measure of the damage caused by the rays is given by the ratio of inelastic collisions—which are able to but do not have to change a structure—to the elastic collisions. Formerly, the damage caused by the rays was often correlated (also in high-voltage electron microscopy) with the reciprocal scattering cross-section. Naturally, this is meaningless regarding imaging problems, where the number of the scattered quanta (electrons) is important.

[**] Compared to the first experiments on the structure analysis of native crystals[50], it is methodologically noteworthy that the analysis on a two-dimensional crystal (membrane crystal) has been carried out, enabling a link to the methods of analysis for individual structures (cf., *e.g.*, [81]); even the determination of the common origin (after translation into reciprocal space; cf. Section 3.4.2). This holds for three-dimensional crystals (such as in [50]) only with limitations (cf. [77, 96]).

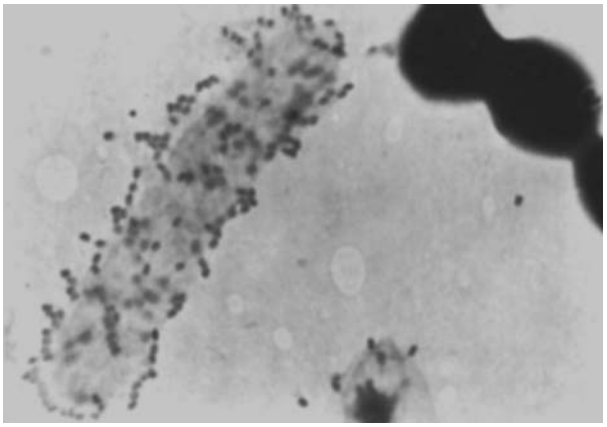

Fig. 18. Discovery of bacteriophages with the electron microscope. As long ago as the 16th December 1939, *H. Ruska* had submitted an article for publication (*Naturwissenschaften 28* (1940) 45) in which it was reported that bacteriophages had been discovered on lysis of *E. coli* cells. The micrograph shown here is reproduced from a later communication (H. Ruska, *Naturwissenschaften 29* (1941) 367) after the phage tails, which were "often pointed into the inside of the bacteria" had been observed for the first time, on the attack of bacteriophages on *Proteus* cells. [I thank *C. Ruska*, Institut für Biophysik der Medizinischen Akademie, Düsseldorf, for permission to reproduce this micrograph.]

foil, and the radiation. "Radiation damage" is also chemistry. Even if the radiation reactions can be eliminated in any way, the preparation reactions are still there. And these can highly influence the structure of the object. Even with identical molecules the reaction product is only reproducible under exactly the same reaction conditions. For comparison: if several people write the letter "a", it can look different in each case, although it is still "a". Here, we are dealing with one of the fundamental problems of computerized character recognition, which in information theory is studied as "pattern recognition". By varying common structural characteristics the concept of the letter "a" is reached. Primitive comparisons and averaging have to be replaced by the ideas of "pattern recognition" in the electron microscopy of individual structures too. As a calculable reaction product, "radiation damage" loses its horror; the electrons are simply a further, although undesired, partner in the reaction. The reaction conditions can be controllably varied, *e.g.* by trapping the emitted electrons with acceptors or by lowering the temperature.

Only three-dimensional investigations lead to inequivocal structural results. For a given projection, as many structures as wanted can be produced by exchanging image elements along the direction of projection. In addition, there are components lying, accidentally, above or beneath this projection (*e.g.* support foil). It is also important that a high enough radiation dose should be used, to ensure significant imaging of the spatial structure. Only then can changes in the structure be assigned to chemical changes, for example, in the distribution of contrasting material. With the necessarily high doses, a slow change of the structure during the exposure (after the rapid destruction of the native structure) cannot be ruled out. The three-dimensional procedure should therefore work in such a way that it yields the average structure (as in conventional microscopy). And finally, the electron microscope itself should be free of errors, otherwise no decision can be made as to whether a structural change is due to the object, or is simulated by the spherical aberration. For this reason, the tomographic procedures are incomplete. Only correct spatial frequency filtering with determination of the structure of the image points, guarantees a sufficiently quantitative procedure.

This is often misunderstood; only recently, it was suggested that individual structures of identical particles should be made more "similar" by reducing the resolution, and thereby reducing the "noise". This is something like proposing to a cell biologist to image his cells less sharply in order to iron out their individual differences (which are designated as "noise"). He can of course do this, and in this way gets a "unit cell" by subsequent superimposition, but all the fine details—*e.g.* in the nucleus—are lost.

The light microscopist, studying his cells individually, can do it better: he does "pattern recognition" intuitively. One only has to bear in mind the really quite crude preparation procedures in order to understand how different "identical" particles can look. However, the rich preparative experience potential collected in conventional electron microscopy, should also not be underestimated. But only by three-dimensional analysis can it be thoroughly explored and made usable. In the future, directed improvements of the preparation methods are therefore to be expected.

Naturally, this should not mean that the averaging of the same kinds of "reaction products" of identical particles is unnecessary. Statistical procedures will always be necessary in order to study the regularities in a population of entities. But the chemistry involved should not be forgotten. From the development of low-dose analysis, it can be seen how errors of judgement in the microscopy of individual structures were made. The individual image consists practically only of real, uninterpretable electron noise. However, for example, the "granulation" so characteristic of each electron micrograph with high resolution (cf. Fig. 23) is not noise, even if the electron microscopist refers to it as "structural noise"[*].

### *3.4.2. Methodological Aspects*

#### *The Necessary Radiation Dose*

On going from two-dimensional diffractometry (fixed direction of the primary ray) to three-dimensional diffractometry, some new questions arise. Thus, it was feared that the large number of pictures on rotating the object (cf. Fig. 16) would result in an extreme radiation load on the speci-

[*] The averaging described concerns particles which were measured to an electron-statistically significant degree. But naturally the integral dose per particle can also be reduced, whereby the single particles show strong electron noise that can only be reduced on averaging. Thereby, the influence of radiation can be studied. In the borderline case of very low radiation doses (analysis of native structures), the projections necessary for the carrying out of the three-dimensional reconstruction can, because of the interchangability of the operations, also be averaged first of all, and afterwards, reconstruction can be made with the averaged projection[94]. This procedure basically corresponds to crystallographic reconstruction (cf. Section 3.3), in which the three-dimensional reconstruction is built up from the averaged (through the crystal) single projections in the same way.

men. We have demonstrated[71] (which was surprising and raised doubts[72]), that for a two-dimensional micrograph (with spatial frequency filtering), about the same amount of electrons are necessary as for a three-dimensional analysis with the same electron-statistical significance. In the first case, the whole dose is applied in the taking of one image, in the second case, it is evenly distributed over the taking of the series of images. "Equally significant" means that in both cases an object detail (*e.g.* a heavy atom group) can be recognized, with the same ratio of signal to noise, whereby in the first case it is assumed that it can be discriminated due to the fanning out in the z-direction (the direction of the optical axis) and also determined in its z-coordinates. In order to understand this[73], think of the object as being divided into a series of thin sections (having the thickness of the z-resolution). A micrograph is made of each section. This is obviously the optimal procedure, because the other sections do not become impaired by the electrons that are necessary for the imaging of one section. Calculation shows that three-dimensional diffractometry works as economically as does two-dimensional analysis (or to be more precise, admittedly, only if the curvature of the sphere of reflection can be neglected). This *Gedanken-experiment*[73] also reveals the source of the misunderstanding[72]. Naturally, the images of the sections are more poorly contrasted than the image of the unsliced thick object. If only the last one is to be seen, then a few electrons suffice. However, then, no details can be seen in the two-dimensional image of the object (electron noise!).

*Determination of the Common Origin*

A second problem concerns the phase correlation of the structural factors of the tilted images. It would not be necessary if—as in tomography—the axis of rotation could be rotated with the exactness of the resolution. This is not possible in electron microscopy—the resolutions lie in the order of magnitude of nanometers, the mechanical precisions in the order of micrometers. We worked out the procedure of cross-correlation of slightly inclined projections for the determination of the common origin of all Fourier sections[74,75], and developed this theory, first of all for the ideal case of point atoms[75] and later for real atoms[76]. Note that it is also used for the analysis of native crystals[65] after translation in the reciprocal space[77].

*Number of Images*

From each picture, the structure factors on a spherical surface in the reciprocal space can be determined (cf. Fig. 3b), which in the case of average resolutions can be approximated by their tangential plane. In three-dimensional analysis, a discrete bundle of such surfaces (cf. Fig. 20) is determined, between which one must interpolate in order to obtain the continuous structural factor distribution in reciprocal space. Use of the Whittaker-Shannon interpolation theorem shows[78] that the minimum number of images is dependent on the resolution and on the size of the object. Our formula for the number of projections[78] was confirmed by *Crowther et al.*[79]. Later, however, this problem proved to be more complicated. These calculations[78] refer to the ideal case of an undisturbed three-dimensional image point that is independent of location. Allowing for the background disturbance increasing a little, or the image points on the edges of the reconstruction area being somewhat more badly resolved than in the middle, the number of projections can be reduced by up to a factor of 2. Thus, in the Cormack procedure known from computerized tomography, which reconstructs a cylindrically shaped body (cylinder axis identical with tilt axis), the region in the proximity of the axis is somewhat more sharply imaged than next to the cylinder surface. We use this procedure—after exact testing of the dependency of the image point on the location—in many of our reconstructions, because the surroundings of the object under study (the reconstruction area is always larger than the particles) are less interesting, and with the present state of the experimental technique, a limitation of the number of images seems to be economically necessary. This is because the whole experiment would be ruined by one, or a few, abortive images of a series (above all in the case of drift, cf. Figure 9b). It can be assumed that with further experimental improvements (above all, by automation), the question of the minimum number of images will be less important.

*Blind Region in Reciprocal Space*

The limitation of the range of rotation in electron microscopy—because it is fundamental—is more crucial. As an illustration, imagine a thin plate (specimen on a support) as the object in the "tomographic grill" (Fig. 16). If this plate stands edgewise, there is no transmission, and, in addition, mountings limit the range of angles. In electron microscopy the preparation can generally be tilted by about $\pm 60°$ away from the horizontal position, *i.e.* the rotation in Figure 16 has to be replaced by a tilting of about $\pm 60°$. This has unfortunate consequences for the image point shape, which in the ideal case should be sphere-like (as in crystallography). From Figure 19 it can be seen that instead of a sphere, an anisotropic pattern is formed, which shows the electron-optical resolution in the direction of the tilting axis ($\Delta y$), perpendicular to this, but determined, not only by the electron-optical resolution, but also by the angle increment $\Delta\alpha$ (in other words, by the number of images). Thereby, the length of the image points in the direction of the optical axis ($\Delta z$) is longer by a factor n than perpendicular to it ($\Delta x$); n depends on the angular range ($n = 1.8$ when $\alpha = \pm 60°$). $\Delta x = \Delta y$ can, of course, always be achieved by reducing $\Delta\alpha$, however, the elongation of $\Delta z$ is always present. Undesirable, are two deep, closely neighboring side minima in the x-direction. Otherwise, however, the background is only slightly disturbed by diffraction ripples. Especially noteworthy is the fact that the weighting of the transfer functions with their zero positions scarcely influences the image point shape and the background noise. After determination of the transfer function for each picture (which can be very different), the real image point of this reconstruction is calculated. Figure 19b shows one result. The cumbersome averaging by a series of focussings[26,27] can therefore be omitted in three-dimensional analysis—the averaging also works with tilted projections.

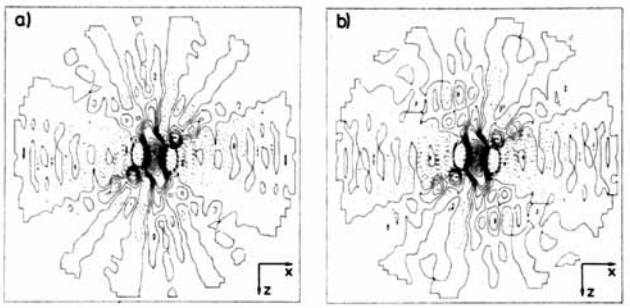

Fig. 19. Image point problems in three-dimensional electron microscopy. Because of finite resolution, an image point is always an extended object, in the ideal case in two dimensions with circular symmetry, in three dimensions (crystallography) with spherical symmetry. The limited range of tilting angle of goniometers is the reason for the asymmetry and the anisotropy. On tilting about an axis, the three-dimensional reconstruction body can be thought of as being divided into a series of layers perpendicular to the tilting axis (y-axis), which are arranged at intervals equal to the y-resolution ($\Delta y$). a) Imaging of the image point in the x,z-plane on tilting between $+60°$ and $-54°$, ideal weight function, contour lines $<0$ dashed, contour line spacing 6% (above the density +30% the contour line spacing increases to 8%). Image point height normalized to 1; background noise well under 10% with the exception of two neighboring side minima. These effect a certain deformation of the reconstructions in the x-direction (cf. test calculations [81c]). Important is that the side minima can only influence the immediate surroundings of the image points, and thus, large falsifications of the total reconstruction are impossible. Naturally, astigmatic distortions have to be taken into consideration when interpreting the analyses. On overlapping of reproducible, equally orientated structures, (with different directions of the tilting axis) the influence of the negative minima largely averages out, whilst the anisotropy along z remains. Unfortunately, an averaging of differently orientated particles (which could produce an almost spherically symmetrical averaged image point) meets with difficulties, owing to orientation effects, at least with current preparation procedures. b) Same image point as in a), but calculated with the aid of experimental transfer functions. Note the surprisingly large similarity to a), which makes the averaging of the influences of spatial frequency gaps according to [26, 27] unnecessary. By weighting the transfer functions, however, the image point height is reduced by about 25% (non-optimal contrast transfer with respect to the hypothetical ideal case (error-free microscope and Zernike plate)).

Does this strongly anisotropic image point suffice? Our situation is similar to that of a person with an astigmatic eye. If the resolution in the direction of the lengthened image point is sufficient, he is able to read; deformations in the other directions are then only slightly disturbing. For application in electron microscopy, this means that $\Delta z$ should be the same size as the required resolution (*i.e.* about 2 nm with stained biological structures). This is not difficult to achieve, since the electron microscopic resolution is always rather high in the case of individual structures. The granulation is always seen, so to speak, in the heavy atom glass, which is not interesting in itself (if its laws are not to be studied), but which helps to reach a sufficient z-resolution. For this reason, we usually work with a $\Delta x$ range of about 1 nm. As test calculations have shown, the negative, closely neighboring minima only disturb the nearest surroundings with very steep edges, (they produce a kind of Fresnel fringe); these fringes, and the randomness of the structure in the directions of sharper reproduction, must be "overlooked". Figure 20 systematically shows the whole reconstruction procedure.

The disturbance by negative minima can be totally eliminated with "conical tilting"[49] using special reconstruction procedures[78b]. Figure 21 shows an image point which is rotationally symmetrical and which already seems to be lengthened by only $n = 1.4$ in the z-direction with 45° tilting. The negative minima have totally disappeared. The image geometry is, however, more complicated than with simple tilting on a single axis (Fig. 19) but should be controllable. Because of this surprisingly convenient form of image point, experiments to replace the flat support foils used in electron microscopy by needles (whiskers)[80], and

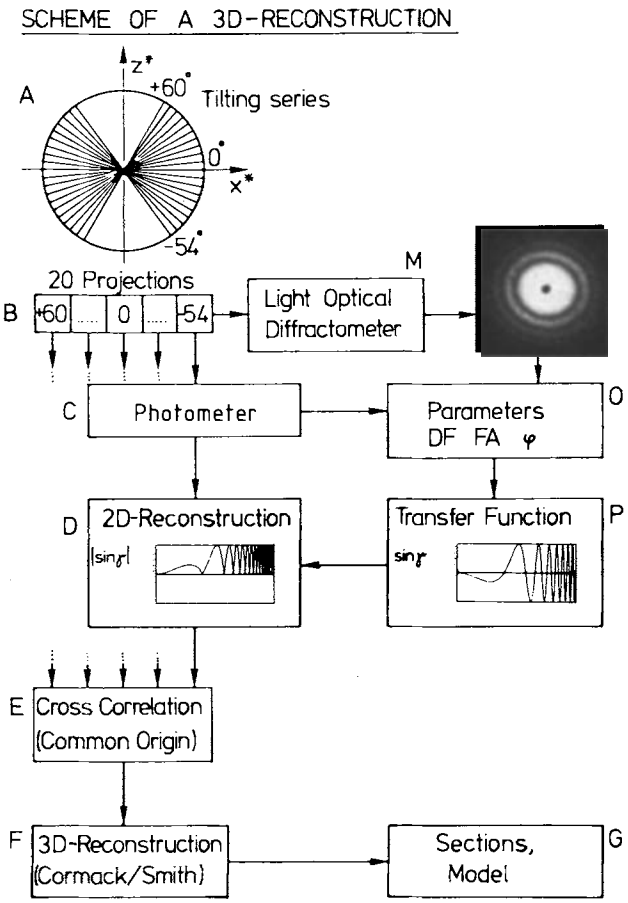

Fig. 20. Flow diagram of a reconstruction on tilting about one axis. A: Occupation of the reciprocal space with Fourier sections; the coordinates x*, y*, z* are parallel to the coordinates x, y, z in the real space, central sections (corresponding to the projections in the real space) are drawn in the tilting angle range of $-54°$ to $+60°$ at angular increments of 6° (projected along y*). Note the "blind" region in the reciprocal space, which is not filled with sections and therefore causes the anisotropies of the image point as discussed in Figure 19. B: Block of micrographs, which are measured in the automatic densitometer C (after testing in the light diffractometer M, which gives the light diffractograms N). From these (semi-quantitative) and from the densitometer data, the parameters O (defocussing, axial astigmatism) are obtained for the correction of the structure factors (transfer functions P). In step D, this correction (two-dimensional image reconstruction, also called image restoration) is made. In the next step, the determination of the common origin of all projections (and hence that of the three-dimensional body) is accomplished. The last step is the actual three-dimensional synthesis (sections G).

thus to reach a kind of "rotating molecule method" with spherical image points, were stopped. In spite of indisputable theoretical advantages, this would have meant a changing of the whole technique of specimen preparation in electron microscopy. Three-dimensional microscopy should, however, be "seamlessly" coupled to conventional microscopy.

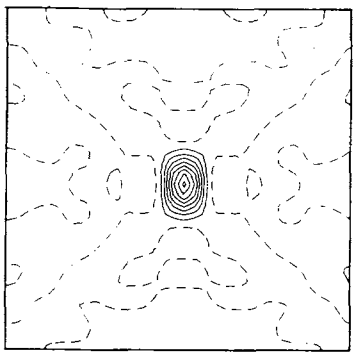

Fig. 21. Image point by conical tilting, If the primary beam is guided onto the surface of a cone, which corresponds to circular tomography in geometry (cf. Fig. 15 and [49]), then, with a modified reconstruction program [78b], an image point can be derived, which is, however, lengthened in the z-direction, but which appears circular in the x,y-plane (think of the figure as being rotated about the z-axis perpendicular to the plane of the paper) and produces no negative minima. If, therefore, the z-resolution $\Delta z$ is properly chosen, then no more problems arise on interpretation than when a spherical image point (diameter $\Delta z$) would be present—the anisotropy actually produces a "reducing" of the image point (in the x,y-direction). Notice, however, that in certain "pathological" occupations of the reciprocal space with structure factors (in which these lie mostly in the non-measured blind region of the reciprocal space), difficulties can arise. With asymmetrical structures, such difficulties are hardly to be expected.

### 3.5. Use of Three-Dimensional Electron Microscopy in the Structural Investigation of Ribosomes

With a resolution of 2 nm, smaller biomolecular particles—for example, the TMV protein, phage proteins, coat proteins of spherical virus molecules, bacteriorhodopsin, *etc.* (molecular weights of the order of 20000)—also show only a few details in three-dimensional analysis (number of image points of the order of 10). The situation is different if (asymmetrical) particles with molecular weights of several millions are being studied—structures are obtained which, even with this low resolution, show the complexity of smaller proteins (resolution 0.2—0.3 nm; more than 1000 image points). Clearly, these are cases in which projections will have to remain uninterpretable.

The first real three-dimensional analysis of an electron-microscopic object was published in 1974[81]. As shown in Section 3.2.3, difficulties might be encountered in investigations with the production of the projections by symmetry operations. The first three-dimensional crystal structure analysis (for which these limitations, with exception of the averaging of similar objects, do not apply) was published in 1975[65]. In collaboration with *Lynen et al.* in Munich, we studied the structure of fatty acid synthetase of yeast ($M_r \approx 2.3 \times 10^6$)[81]. At that time, our experimental technique was not perfected ($\alpha = \pm 45°$, $\Delta\alpha = 10°$), and also the total dose was higher than that required for recording the micrographs (no minimal dose technique). Later, stimulated by work on label triangulation methods (cf. [69]), we turned to the structure analysis of ribosomes (ribosomes of *E. coli*, $M_r \approx 2.7 \times 10^6$). It was no accident that the first investigations in this new field of individual analysis were not carried out on real aperiodic structures[*], but on chemically reproducible, although very large, particles, which could in theory also have been investigated using crystallographic methods. The identical chemical structures enable comparison of the reaction products—dependent on preparation conditions such as orientation towards the support foil, *etc.* Further, in the case of the ribosomes, the strong ionic character of the protein-RNA complex is interesting, which also leads to the assumption of staining of structural details in the inner particle (positive staining). Above all, however, ribosomes are molecular structures which are biologically very important, occur in all forms of life, and through which the synthesis of proteins takes place. They are not only highly differentiated in their (totally asymmetric) structure, but are also highly differentiated in their function. Depending on the cell (prokaryote, eukaryote) and functional assignment (cytoplasm, mitochondria), they can show large differences (*e.g.* in molecular size and form), but—especially as sequence analysis of RNA strands have shown—are closely related to one another. In the last few years ribosomes, especially from *E. coli*, have been intensively investigated chemically; today, for example, practically all the sequences of the approximately 50 (different) ribosomal proteins are known. Characteristic is the capability of the ribosome, after its segregation into the single proteins and nucleic acid strands, to aggregate back into intact and active ribosomes, a capability which is utilized in the label triangulation investigations for the determination of the native protein topology (see [69]). The ribosomes are easily divided into two subunits of different sizes; 30S and 50S subunits[*] for prokaryotes, 40S and 60S subunits for eukaryotes. It is obvious that these subunits should next of all be investigated separately.

#### *3.5.1. Conventional Electron Microscopy of Ribosomes*

Because of the size of the particles, and their relative stability toward preparation procedures with staining, they were investigated electron microscopically fairly early on—actually, they were discovered in this way. But, however, there is hardly any other object with which the limits of conventional electron microscopy are made so drastically clear than with ribosomes—in spite of, or perhaps because of the ingenious experiments to characterize structural details immunologically or with other labels.

It was not only due to their size, but also to the complete lack of symmetry, that—in contrast to the somewhat equally sized spherical viruses (with which the ribosomal particles were first of all compared)—no structural laws could be found, and in the best case, only the outlines of the particles could be recognized. The surroundings and the particles are covered with a general granulation ("structural noise") (cf. Figures 22 and 23). Only a short while ago, (long after the beginning of our analyses) were defined structures inside the particles revealed, by the averaging of micrographs of equally oriented particles[82,83],

[*] Exceptions are investigations on the analysis of the action of complement on vesicles [91], and preliminary high resolution investigations on amorphous carbon [92].

[*] Classification according to the sedimentation constant in the ultracentrifuge.

which, as projections of thick bodies, can tell us little[*]. Even the seemingly simple problem of the determination of the shape found no satisfactory solution. Three-dimensional bodies were tentatively "invented", which—projected in different directions—should explain the different molecular images appearing in the micrographs. In a way, this is a primitive form of the three-dimensional analysis of projections; however the number of projections is extremely low (of the order of 5), and their respective angles are unknown. Furthermore, it is fully unknown, whether structural changes are associated with the different orientations of the specimen. It is understandable that in different laboratories, different models were found.

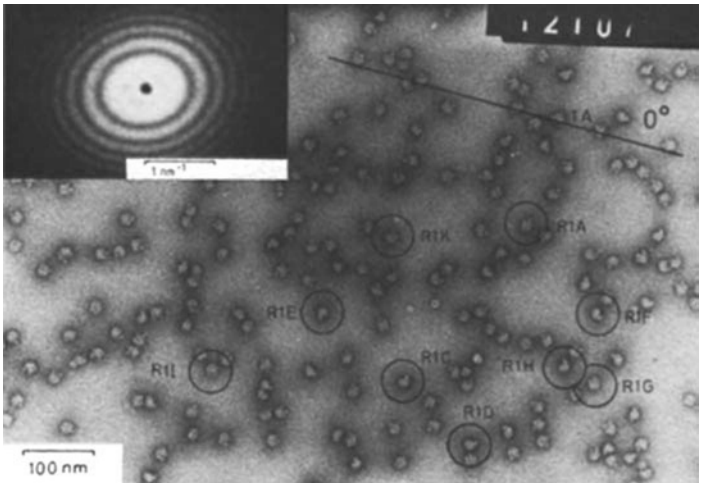

Fig. 22. One of the 21 micrographs (0° tilt) from the +60° to −60° series of micrographs (−60° micrograph discarded due to drift) taken at angular increments of 6°: ribosomal 50S subunits from *E. coli* without L7 and L12 stalks. Enlargement of 79300, mean defocussing $\Delta z = 827$ nm, axial defocussing difference $dz = 386$ nm, dose $\approx 7 \times 10^3$ e/nm$^2$. Reconstructed particles marked, direction of the tilting axis drawn in.

### 3.5.2. *Three-Dimensional Analysis of Stained Ribosomal Particles*

The large experimental expenditure in the case of these specimens[**] makes it necessary to limit the analysis to a few particles. With today's priority of averaging methods in electron microscopy, this would seem to imply a severe limitation, but this is not true. On comparing structures (in the general sense) not only the number of structures, but also the number of structural details are important. A classic example is the "fingerprint" of criminology. Even a comparison of two fingerprints is enough to prove the identity. In the case of the three-dimensional analysis of ribosomes, the number of characteristic details is especially large (corresponding to the volume of the particle), and thus the information content of the analysis is considerable. Of course, it is necessary to choose a high enough radiation dose so that the electron statistical significance suffices for significant recognition of the details. We work with doses of about $1.5 \times 10^5$ e/nm$^2$—this is a factor of about $10^3$ more than in the analysis of native crystals. The results, similarly as in crystallography, can be represented quantitatively in contour maps of the single sections. We chose the contour line distance in such a way that it corresponds to the double or triple amount of the electron statistical standard deviation—differences between reconstructions of different particles are therefore certainly not noise, but are produced chemically (and radiation chemically). To prove that no significant changes occur during a series, we expose a "radiation damage series", under the same conditions but without tilting (at another site on the specimen). The mathematical measure of the similarity of two images is the cross correlation coefficient $C_k$[*]. We test the constancy of the images in the radiation damage series with cross correlation, visual examination, and by calculating the difference. Of course, the organic substance is totally destroyed, even on recording the first micrograph—its skeleton, however, is very stable against further radiation; the reconstruction procedures average out smaller changes (as the theory shows). However, with a dose of about $10^5$ e/nm$^2$, recrystallization of the contrasting material slowly begins[51,84]; therefore, this dose should not be exceeded to any great extent. Since our experiments are done under minimal dose conditions, no further loading occurs through adjustment processes.

Our reconstructions[85] were done on uranyl salt-stained 30S and 50S subunits of *E. coli* in different orientations. 3—5 particles were investigated in each orientation. A simple trick enables us to avoid having to do separate tilting series for each particle. On choosing the proper preparation conditions, relatively many particle projections are imaged (about 500) on a micrograph (magnification about 80000). These micrographs show different "shapes", whose differences are explained by different orientations and by influences of specimen preparation. Often, shapes occur which are especially characteristic and similar in outline, which the electron microscopist—as already mentioned—interprets as different projections of a three-dimensional body. In the literature, they are referred to by different names—*e.g.* asymmetric and symmetric forms with 30S subunits, kidney and crown forms with 50S subunits. In the tilting series, approximately the same number of ribosomes are imaged on each micrograph of the series, so that the three-dimensional preparation under study is actually a population of ribosomes. Subsequently, the single particle pictures to be reconstructed are chosen, and measured in an automatic densitometer. Note the immense information capacity of the photoplate, which will make it difficult to replace it electronically. With the 20 μm scanning raster (diameter of the probe on the specimen 0.25 nm

[*] The experimental averaging in [82] agrees very well with the projection of our 3-D model.

[**] We thank Dr. *M. Stöffler-Meilicke*, Max-Planck-Institut für Molekulare Genetik, Berlin, for the preparation of ribosomal particles and ribosomes from *E. coli*.

[*] $C_k = C_{12}/\sqrt{C_{11}^2 C_{22}^2} \cdot C_{12}$ is the magnitude of the cross-correlation maximum, $C_{11}$ and $C_{22}$ are the magnitudes of the autocorrelation maxima of the structures compared. With the supposition that the cross correlation maximum lies in the zero position (*i.e.* that both images were exactly in line, by correlation), then $C_{12}$ equals the integral over the products of the densities of both images. $C_{11}$ and $C_{22}$ correspond to the integral over the square of the densities of the single images. When both images are the same, $C_k = 1$; with different images $C_k$ decreases. With two random structures, $C_k = 0$.

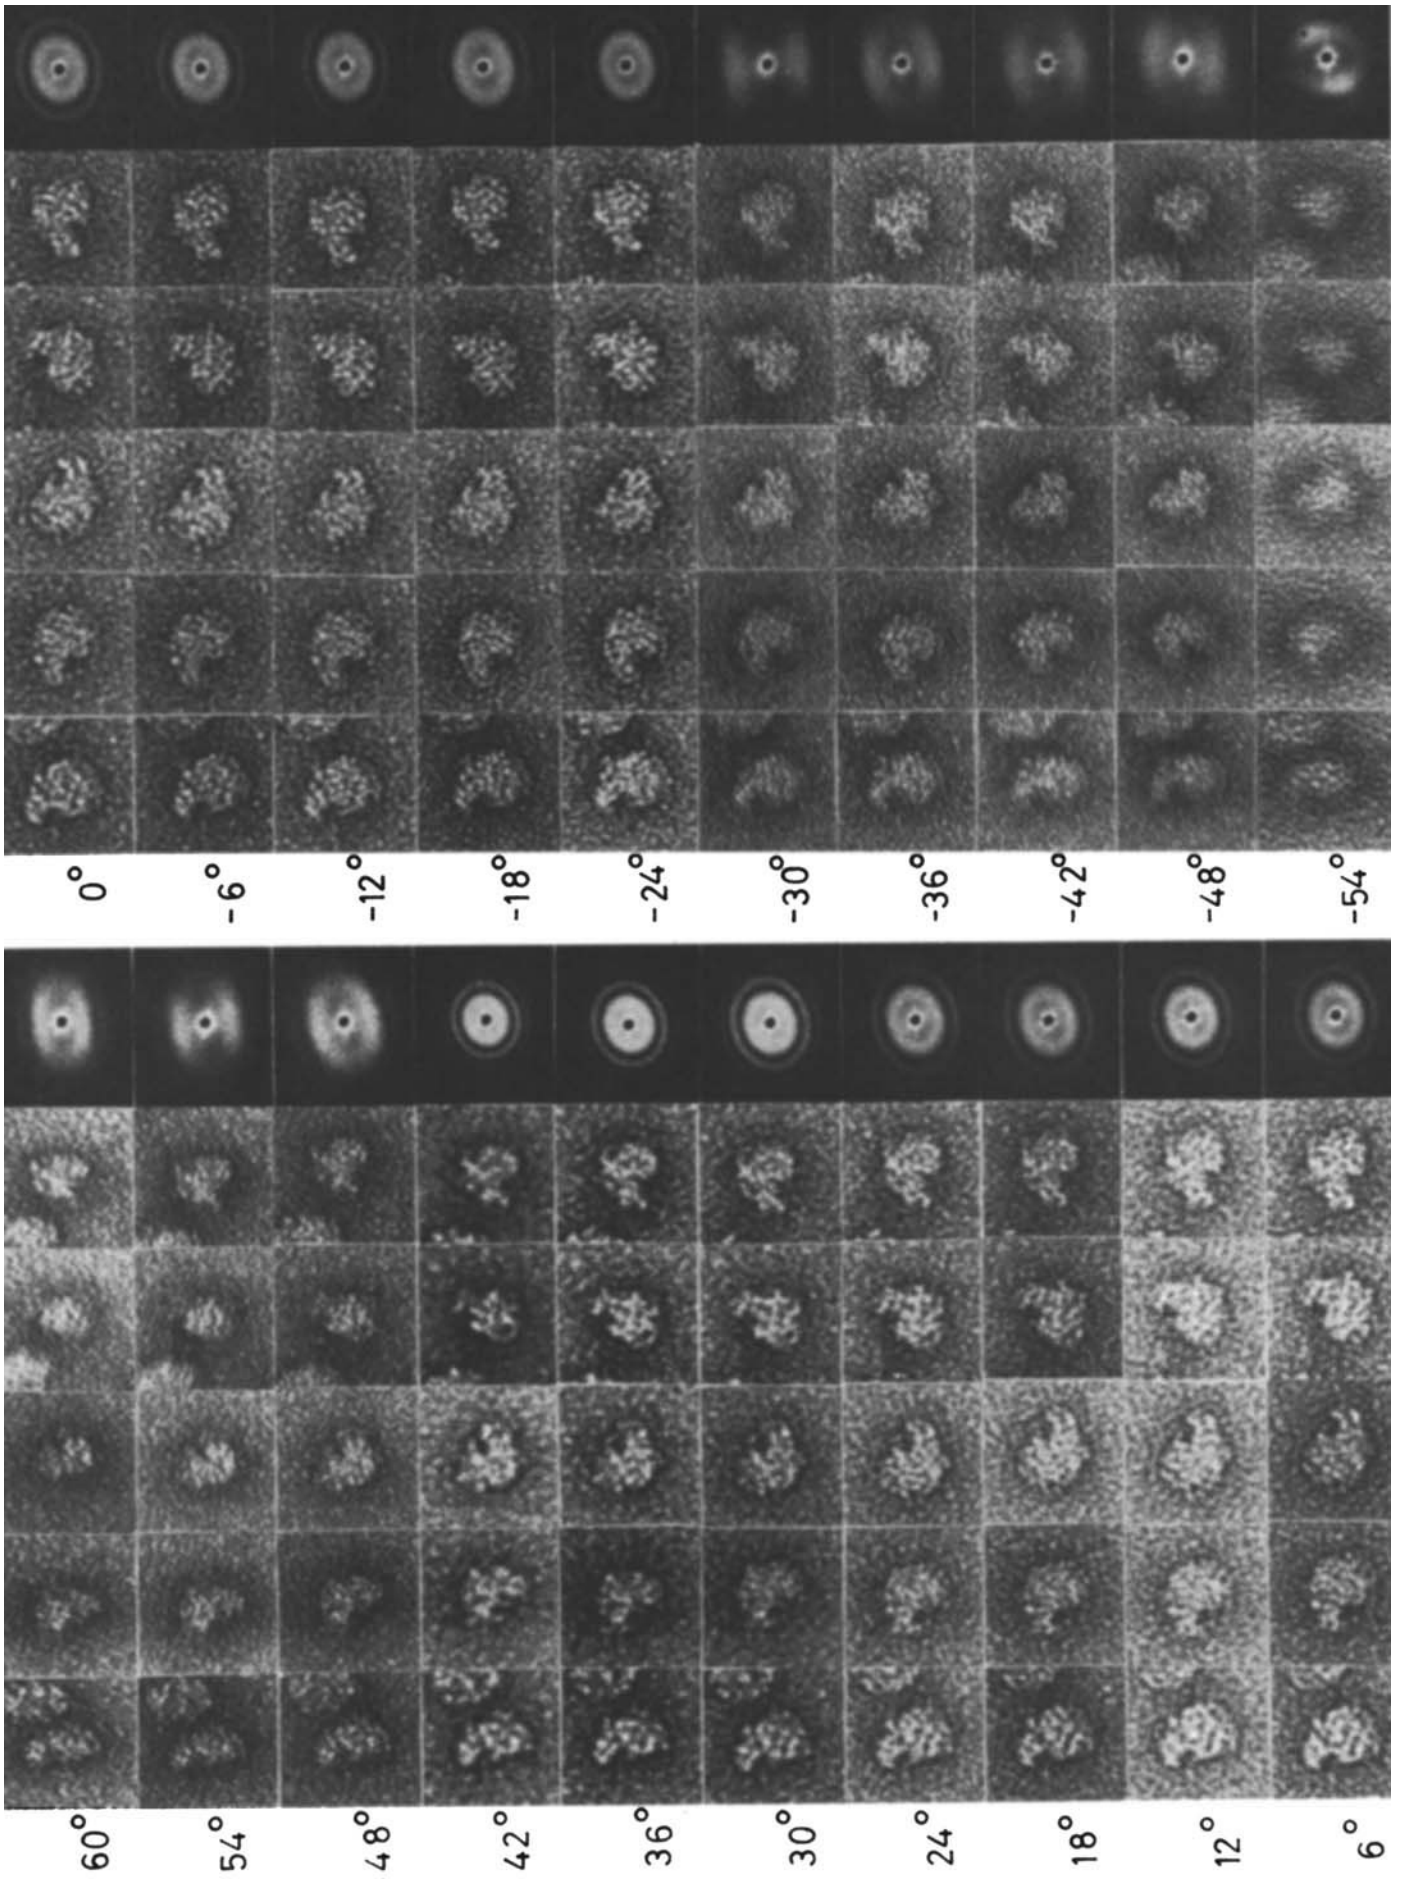

Fig. 23. Gallery of all "kidneys" studied, of the series $\alpha = +60°$ to $-54°$, $\Delta\alpha \approx 6°$, with their respective light diffractograms. Designation, from left to right: R1D, R1C, R1E, R1F, R1H (cf. Fig. 22).

with an enlargement of 80000[*]), which we mostly used, a $6 \times 9$ cm$^2$ photoplate contains $13.5 \times 10^6$ image elements, a series with 20 pictures $2.7 \times 10^8$ image elements! From this information, only a very small fraction is used. With higher tilting angles the defocussing in the preparation changes to a large extent. This does not matter, since it is determined by calculation, and corrected. For the same reason, it is also immaterial whether the focus on the reference position (with which it is adjusted and which is at a distance of several micrometers from the picture position) varies somewhat, due to mechanical inexactness or because of the not completely planar specimen surface.

Figure 22 shows a 0° micrograph taken from a series of 21 micrographs of a population of 50S subunits stained with uranyl formate (z-resolution 2 nm), which were isolated in such a way that two of the 34 proteins of the subunit (L7 and L12) were split off. These proteins—closely related in their chemical structure, and present in up to 4 copies—are located, as comparative conventional analyses had shown, in a lateral rod-shaped protrusion (stalk) of the subunit. We have investigated subunits with and without the stalk, in parallel, since we were interested in how this chemical operation influences the inner structure of the subunit. As already mentioned, artificial and natural modifications of the structure of the ribosomes of different kinds are characteristic of ribosome chemistry—we are dealing here with a simple model case. In the micrograph, the chosen particles of two orientations are marked (kidneys R1C, R1D, R1E, R1F, R1H, crowns R1A, R1G, R1I, R1K). Figure 23 shows a gallery of all micrographs of 5 chosen kidneys, in a tilt series, together with their light diffractograms. The micrographs show such strong, and such random differences, that the experimental evidence could almost be regarded as being obscure. But this is incorrect—on the contrary, it is remarkable how exactly electron optics "draw", if lens aberrations are corrected. The micrograph can perhaps be compared with projections of fruits which are dug up from moist and loamy earth and seem like accidentally formed clumps of earth, but which are highly ordered within.

Generally, it can be said that particles in the same orientation have structures which differ a little in detail (different staining and radiation influences), but which are surprisingly reproducible in their general proportions. They can also be superimposed to give a well resolved average structure, whereby, however, a correlation of the slightly different orientations becomes necessary by laborious three-dimensional correlation procedures. By way of contrast, the structures of differently orientated particles show large differences; the first suspicion, that the particles flatten strongly by surface forces on drying, has fortunately not been confirmed (see also [86]). The staining material forms a ring around the particles (cf., *e.g.*, Fig. 24); with thick specimens, in particular, (*e.g.* oriented in edgewise positions) the staining intensity inside the particle varies

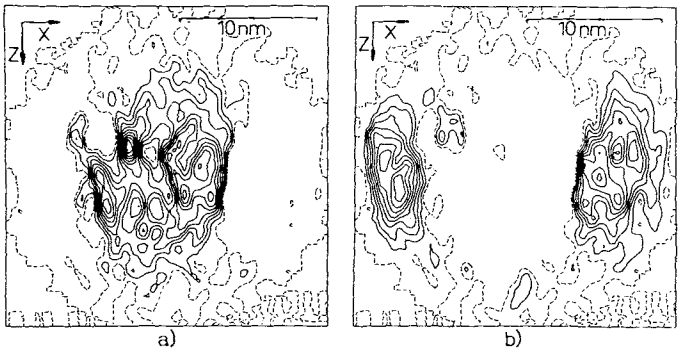

Fig. 24. "Looking around the corner" in three-dimensional electron microscopy. With a three-dimensional body, projections can be calculated in any direction, which can also correspond to micrographs which would not be accessible due to the imaging geometry. A projection of the "kidney" averaged from R1C, R1D, R1E, R1F (cf. Fig. 22) in the direction of the y-axis is shown: a) positive regions, b) negative regions. Note: in a) a general decrease in contrast from the middle plane to above and below, which corresponds to the decrease in contrast in the layers. However, the bordering of the particles above and below can be seen, since the differently structured foils above and below the particles already average themselves out (the projections of the foils appear with lower contrast); in b) primarily the projection of the ring-shaped contrast middle region is conspicuous. The particle area seems "more positive" than the surroundings, due to the normalization, which equates the total integral from the positive densities with the integral of the negative densities.

from above to below. The middle layers are the most strongly stained. All particles show contrasted channel-like regions inside—the assumption arises that, at least for the largest part, positively stained RNA is being dealt with. Note that in the reconstruction the areas of high scattering density are negatively depicted. Because of the normalization (phase contrast!), areas with weak scattering ability seem positive in all reconstructions, whereby positive maxima correspond to areas with especially *low* scattering ability. Up to now we have investigated the 50S subunit more precisely, since with its compactness, drastic changes of form are not likely to appear—in the case of the 30S subunit we see evidence for not inconsiderable orientation-dependent changes of shape.

Naturally, it is not possible to present all the details of these complicated investigations in a progress report. Figure 25 shows a section through 4 contrasted 50S particles in crown form (after correlation of the orientation). For sake of clarity, only the contour lines of the non-contrasted structure are represented—the channel-like contrasted structures therefore appear white. To facilitate the comparison, common negative areas are depicted with "guiding" dots—they are also contained in the mid-structural section AV2. After correlation, the three-dimensional cross-correlation coefficients lie between 0.25 and 0.3. Actually, their values are surprisingly low, considering the really pronounced similarities in Figure 25. The reason for this lies in the great sensitivity of the cross-correlation coefficients towards *all* individual changes. We can try, however, using principles of pattern recognition, to mark out and compare the fundamental structural information—in this case, the special channel-like staining. Here, two steps can be distinguished. In the first step, the same overall structure is demanded (no distortion is allowed); however, the abstraction from details such as, for example, intensity and struc-

[*] From Fourier principles, the scanning elements may maximally have half the diameter of the resolution elements. With the scanning calibration, pictures with a resolution of up to 0.5 nm can therefore be worked with, so that adequate certainty is ensured with the necessary reconstruction resolution of about 1.0 nm (in the x, y plane).

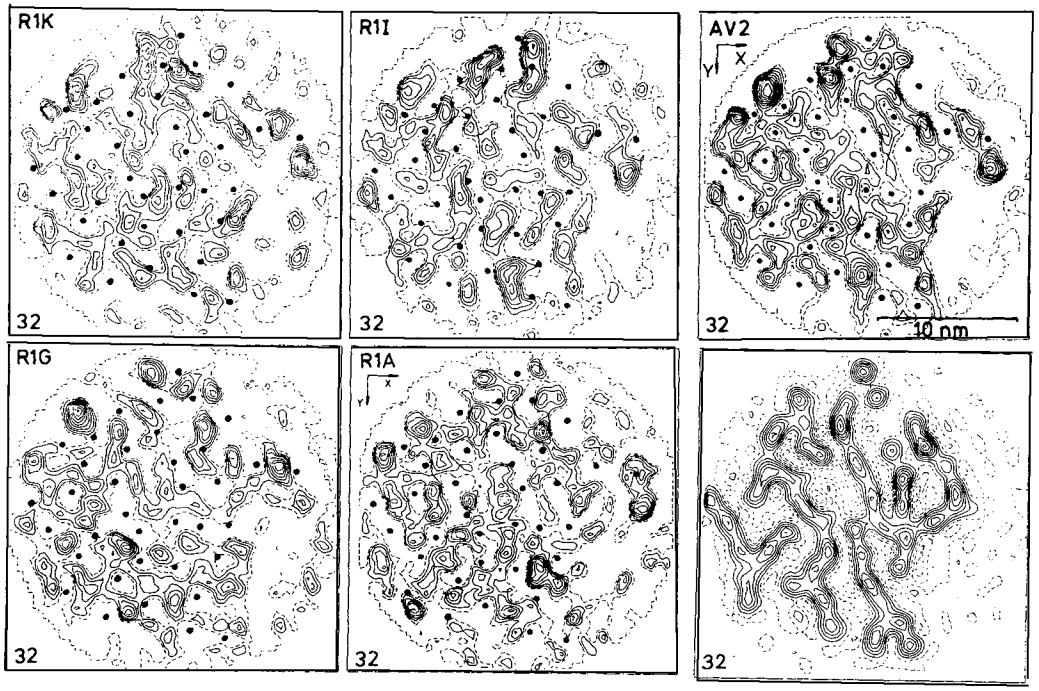

Fig. 25. Analysis of the crown form of ribosomal 50S particles (without stalks). The reconstruction body is a cylinder (extension along the tilting axis (y)) with a diameter of $D = 23.8$ nm and a length of $L = 23.8$ nm. It is divided into cubic scanning elements of edge length $D/64 = 0.37$ nm. The resolution is $\Delta x \approx 1.3$ nm, $\Delta z = 2.0$ nm; $\Delta Y$ equals the mean electron optical resolution, which varies in the micrographs between 0.7 and 1.0 nm (as a standard value we assume that $\Delta y = 1$ nm). The reconstruction body can be cut into layers in any orientation and, for example, 64 x,y-layers are obtained perpendicular to the optical axis (z-axis). For comparison, however, the single particles must be three-dimensionally correlated with one another in respect to location and orientation. In all layers, the comparison shows surprisingly strong similarities. As examples, the most central sections (No. 32) of the "crowns" R1A, R1G, R1I, R1K (cf. Fig. 22) are shown. As already made clear in Figure 24, negative areas correspond to structural elements with high scattering ability, especially with contrasted structures. The use of the zero line for characterization of the separation of weakly contrasted structures (light atomic structures, positive) from strongly contrasted structures (heavy atomic structures) is somewhat arbitrary. For clarity, the contour lines in the negative areas are not shown. To facilitate comparison, the common negative regions of the single particles are marked by guiding dots. The averaged structure AV2 has practically the same resolution (only small distortion of the particles) and now shows even more clearly the channel-like negative regions; in addition, beneath section 32 of AV2, the section 32 of a "model" of the structure of AV2 is shown, which is produced by occupation of the negative regions with points at a distance of 2 nm. If this model is imaged with a resolution of 2 nm, tube-like objects emerge, since neighboring point images blend with each other (see picture). Note that in the model, the contrasted areas are positively marked (not negative as in the contour line charts!). Analogous models of the single particles have cross-correlation coefficients of $\approx 0.7$ with respect to each other (instead of 0.25—0.3).

ture in the stained areas or in the region of the light atom structure is required. The guiding dot concept offers a possibility for this. If guiding dots are arranged at the approximate resolution distance in the negative regions in each single structure, then on Fourier mapping with 1.5 nm resolution (at which the dots become smeared[87]), a tube-like model of the contrasted structure is obtained. Figure 25 (AV2) shows one section. The models obtained from the different structures can be correlated with each other, and a (three-dimensional) correlation coefficient between 0.6 and 0.7 is obtained—a clear indication of how analogous the structures of the single particles really are. However, it should be noted that the simplest method of model building (if no large distortions are present) would actually be an averaging of sufficient single structures—this procedure, however, is very laborious.

Exactly the same analysis was carried out on 50S subunits with the L7, L12 stalk. It can only be referred to as surprising, how exactly the average structure of four subunits with "stalk" AV3 is in agreement with the average structure without "stalk" AV2 (Fig. 26)—the correlation coefficient $C_k$ is about 0.5. As Figure 26 shows, the structure AV4 averaged from AV2 and AV3 (the stalk was cut out by calculation in these comparisons) is now only a little different from AV2 and AV3. The chemical splitting of the stalk therefore does not touch the rest of the structure at all. Incidentally, these two analyses can be interpreted as an excellent consistency test for the method. We are concerned with chemically different, electron microscopically different preparations, and—last but not least—analyses in very different defocussing ranges[*]. During the next analysis steps attempts were made to compare "crowns" and "kidneys" with each other. For the calculations, the tube models were taken because they have a reciprocal space that is filled equally (without blind regions)—an important requirement for a good correlation with large angular differences. The correlation converges very well; however, only a cross-correlation coefficient of $C_k = 0.26$ could be reached, a clear sign of how much the specimen

[*] The second analysis was carried out near to the Scherzer focus. The associated decrease in the lower spatial frequencies led to a lowering of the general contrast of the images.

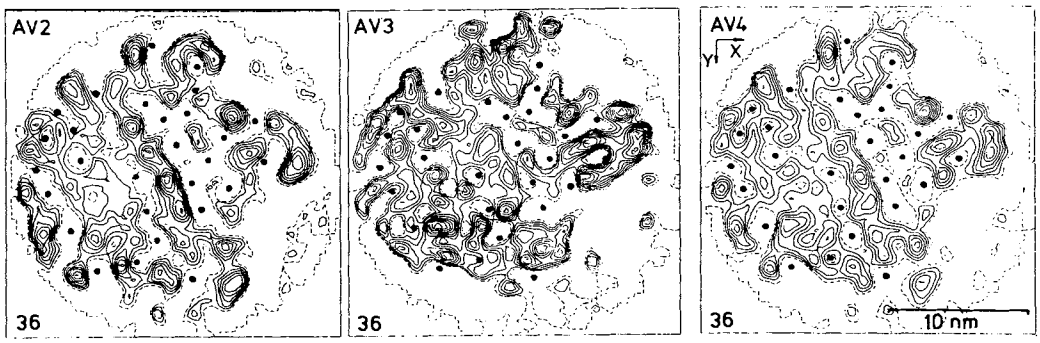

Fig. 26. Comparison of the average structures of each of four 50S subunits "without L7 and L12 stalks" (AV2) and "with L7 and L12 stalks" (AV3) (Sections Nos. 36). In AV3, the stalk is mathematically cut off. The reconstruction body of AV3 was later reduced to the size of the reconstruction body of AV2; the correlation coefficient between AV2 and AV3 is $\approx 0.5$. The structure AV4 averaged from AV2 and AV3 is very similar to AV2 and AV3.

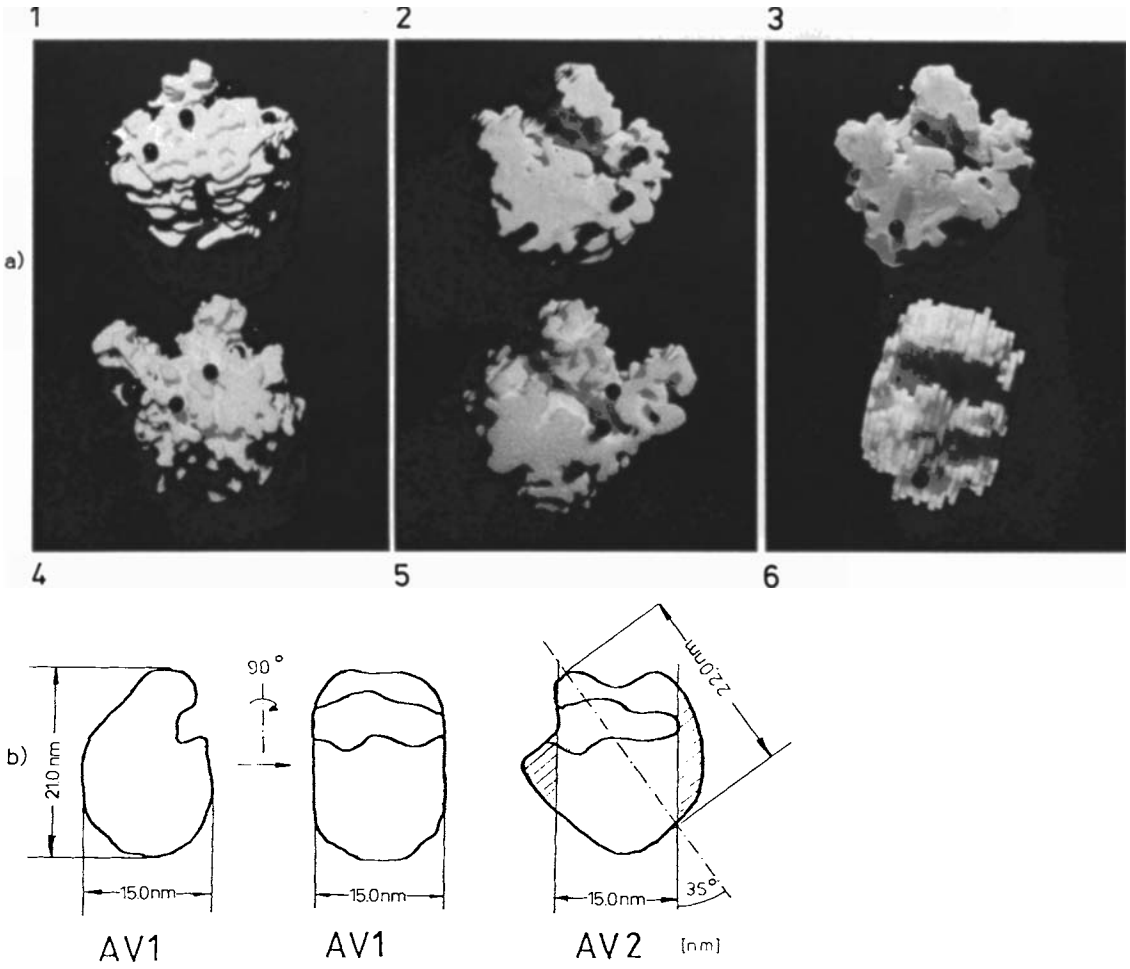

Fig. 27. a) Comparison of the models of the 50S subunit (crown orientation) without stalk [photographed from above (1) and from below (2)] and the 50S subunit (crown orientation) with stalk [photographed from above (4) and from below (5)]; comparison of the model of the "crown" [without stalk (3)] with the "kidney" [without stalk (6)]. Because of the low contrast of the most upper and lower layers, these are not shown in the model of the kidney. The small and large black points indicate areas where channels penetrate the surface. Regions marked by large black points correspond to regions in which the RNA, according to earlier conventional pictures (with marking using respective effectors), comes to the surface. b) Schematic representation of the mutual orientations of "kidney" and "crown" (average structures AV1 and AV2, see Figures 25 and 26). AV1 shows the orientation of the foil; on turning about the longitudinal axis by 90°, AV1′ is obtained. The longitudinal axis of AV1′ is tilted by 35° towards the longitudinal axis of AV2. Areas lying above and below are not easily recognizable in the only weakly contrasted "kidney", and so have not been shown in the model.

preparation conditions influence the structure. As already mentioned, one should not speak of the structure of the ribosomes, but of reaction product structures. However, in spite of this the general deformation is so low that the shape can be derived from the combination of both results. With a reconstruction of crown or kidney alone, the particle borders only partially on the staining material, so that the determination at the bottom (in respect to the support foil) and with sandwich preparations (as in our case) at the top gives difficulties (Fig. 27).

### 3.5.3. *The Structure of the Uranyl-Contrasted 50S Ribosomal Subunit from E. coli in Crown Form*

From our investigations it is clear that the 50S particle is especially well imaged structurally, in its crown form. It lies flat on the base, is well stained, and is easily distinguishable against the staining material. Further, an averaged structure of 8 particles (AV3) is present, and experiments have shown that changes in the inner structure of preparations with and without stalk are negligably small. Since the "accidental" structures of the support foil already averaged out well on the averaging of 8 particles[*], the demarcation "below" and "above" can be well recognized (even though their confirmation by the kidney structure is very valuable). Cross-correlation coefficients can then be calculated in different averaging combinations, which agree well with the statistical expectations. Of particular interest is the cross-correlation coefficient with the (extrapolated) averaging structure from "infinitely" many particles, which is so large with $C_k = 0.8$, that only small differences are to be expected with respect to the structure, determined from an infinite number of particles. This means, however, that practically the same results occur as with a hypothetical "crystal". The tilt of the particles with respect to the z-direction (about 3—4°) is also considered, which cannot be corrected in crystal analysis. Figure 28 shows the complete structure of the averaged particles.

### 3.5.4. *Radiation Damage in Ribosomal Particles*

In a further analysis, we were more closely concerned with the problem of the influence of the radiation[88]. We had produced a tilting series of 30S subunits with a 3° angular increment, which actually consisted of two 6° series tilted against one another by 3°. With this it was possible not only to carry out a reconstruction of larger areas or with higher resolution, but also to compare both 6° series (after correction of the tilting), in order to study the influence of the radiation[**]. However, the radiation load of the second series was much larger than we would normally tolerate. Actually, a comparison shows changes, the cross-correlation coefficient has the order of magnitude $C_k = 0.7$. The reconstructions show, that on comparison of the fine details, care must be taken; migration of heavy atoms occurs on irradiation[*]. It is important (and actually to be expected) that the general proportions do not change—distortions are therefore surely caused largely by the specimen preparation. Note, incidentally, that even with this overloading of radiation the similarity of both structures of the same particle, which have been loaded differently with radiation, is larger than with two different particles of the same orientation.

### 3.5.5. *Pattern Recognition with Consideration of Distortions*

These experiments prove that ribosomal 50S particles in crown form (the same applies for the kidney form) show the general structural relations—otherwise, on averaging, a drastic reduction of the resolution would have to occur. They also explain the jump of the cross-correlation coefficients between single particles, from about 0.25 to about 0.7, if pattern recognition of the first kind (no distortions) is made (cf. Fig. 25). Of particular value are those results for the investigations of aperiodic structures, with which averaging is not possible—it is to be expected that the result can be interpreted in a topologically meaningful way. The analysis of the 30S structure in different orientations should become interesting with such kinds of topologically smoothed models, because the analysis of crowns and kidneys already show clear topological differences. Then, pattern recognition procedures of the second kind have to be worked out, which—somewhat in analogy to the comparison of different types of handwriting—tolerate distortions, too. Then, simple averaging processes do not suffice any longer.

## 4. Outlook

The problems of ribosomal analysis made it especially clear how valuable the further development of the methods are (if possible, with automation). What is really interesting is the function. Structural analyses have no use in themselves but should lead to an understanding of the ribosomal "protein factory". Therefore, we do not believe that a single analysis of a native crystal—as important as it would naturally be—would offer very much for an understanding of ribosomal function. Reactions have to be carried out, and reaction products with small and large partners have to be investigated. Only a born optimist would hope that all the reaction products would be crystallizable. Actually, conventional ribosomal microscopy already shows us the way. The reaction products are studied not only with the preparation reagents, but also with many effectors. The not very helpful two-dimensional methods have only to be replaced by three-dimensional analysis. It is by no means self-evident that the "dirty" ribosomal "dumplings" have shown defined and reproducible structures on the inside in spite of crude preparation and irra-

[*] If the cross-correlation coefficient for two particles equals $C_k$ and the assumption is made that the particles are only disturbed by "white noise" (no changing of the general proportions) then the correlation coefficients can be calculated between the average structure from $n_1$ particles, and the average structure from $n_2$ particles:

$$C_{1,2} = C_k \Big/ \sqrt{\left[C_k + \frac{1}{n_1}(1 - C_k)\right]\left[C_k + \frac{1}{n_2}(1 - C_k)\right]}$$

If $n_2$ equals infinity, then it follows that

$$C_{1,\infty} = \sqrt{C_k / C_k + \frac{1}{n_1}(1 - C_k)}$$

(I thank Dr. *R. Henderson*, Cambridge, for the reference to these statistical relationships). The quasistatistical behavior was tested by calculation of different experimental averagings.

[**] The total dose after the first series was $9.6 \times 10^4$ e/nm$^2$, after the second series $20.1 \times 10^4$ e/nm$^2$. But note that in the first case the effective dose for the imaging is only half as great as the total dose (this applies to all series without preirradiation), since the partial images come from particles irradiated for different times (in the first picture, actually from unirradiated particles) (average load $4.3 \times 10^4$ e/nm$^2$). With the second series this load is about three times as great as in the first series ($14.7 \times 10^4$ e/nm$^2$), because of the pre-irradiation.

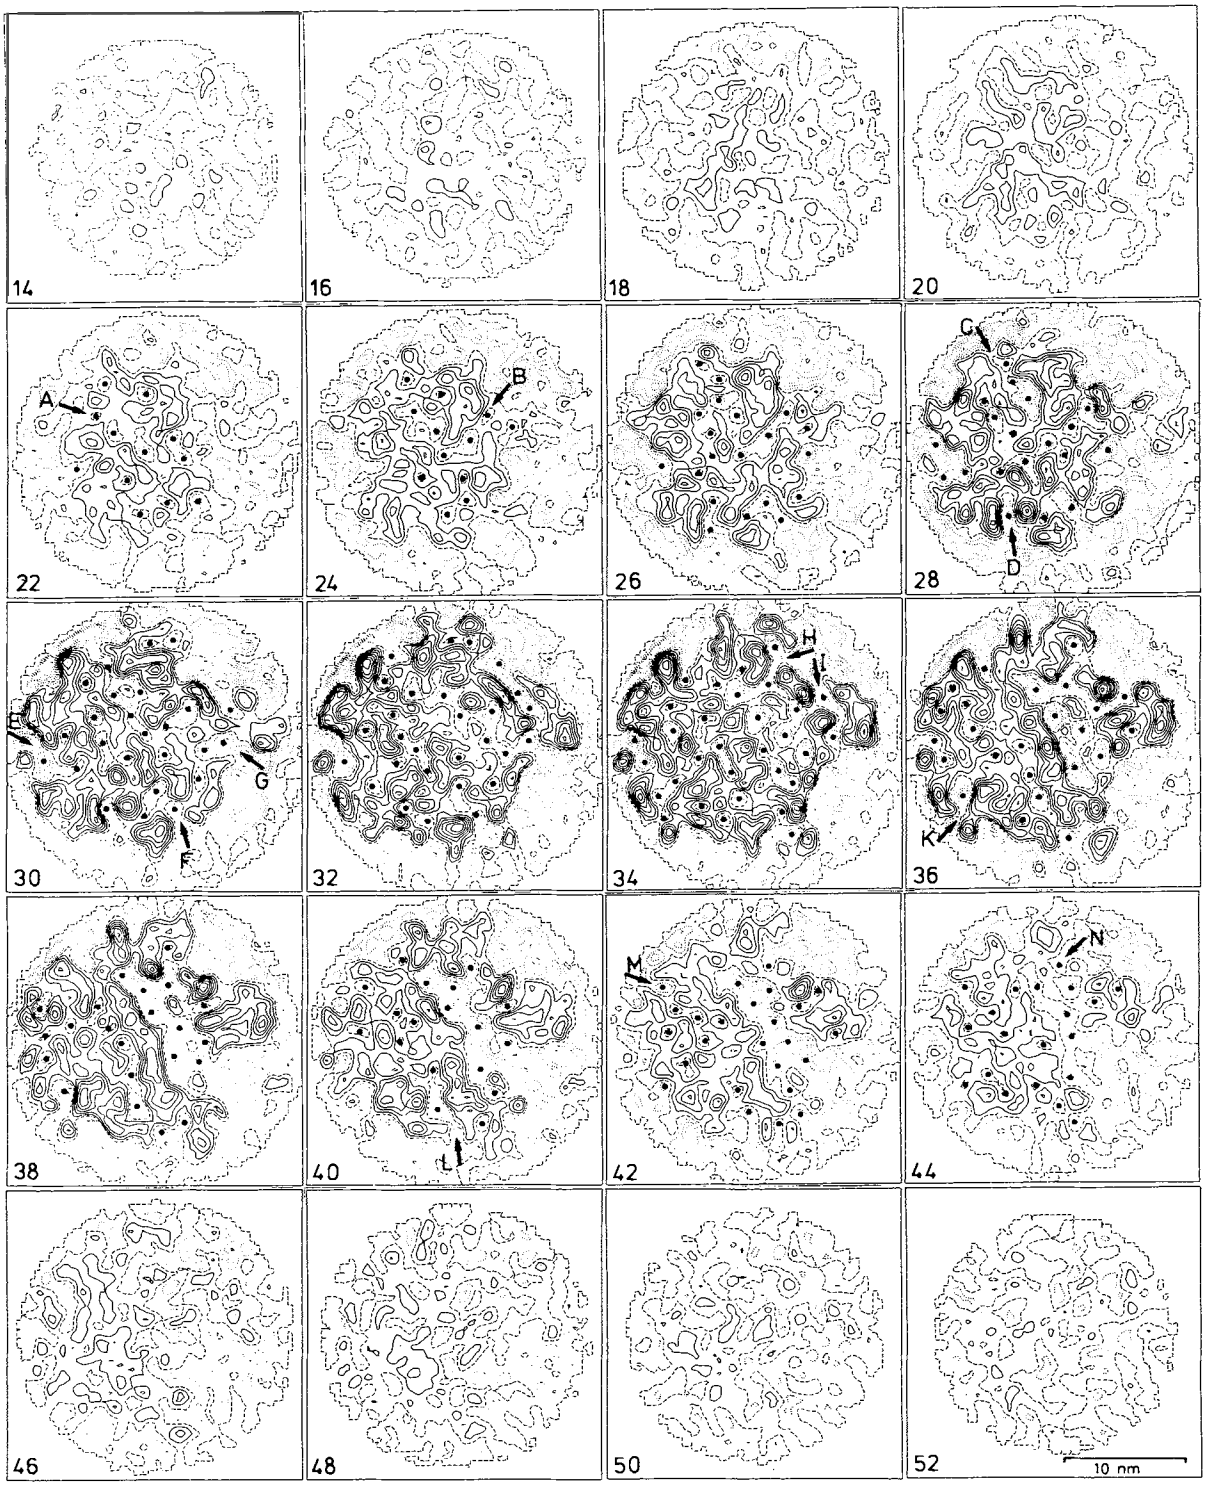

Fig. 28. Almost an "artificial crystal" of the uranyl stained 50S subunit in the crown orientation. The reproducibility of the single particles (dose about $10^5$ e/nm$^2$) is so excellent that even an averaging of 8 particles yields a correlation coefficient for the (hypothetical) "crystal structure" of $C_k = 0.8$. Averaging of a further arbitrary number of particles would not change the model in any major way. Representation of the structure in 64 layers in the distance of 0.4 nm; the even-numbered layers from 14 to 52 are imaged (zero line dashed, positive areas with solid lines, negative areas shown with dots). Positive (negative) contour lines form weak (strong) scattering regions, high positive maxima therefore correspond to especially weakly scattering parts of the structure. The contour line spacing is arbitrary, but the structure corresponds, to a good approximation, to the distribution of potential in the particles distorted by the influence of the image point. Resolution in the z-direction *ca.* 2 nm, in the x,y-plane 1.0 to 1.5 nm. Characteristics: contrasting of different strengths in the single layers, strongest in the middle layers. The particles extend from about layer 20 to layer 46. From layer 22 to layer 44, guiding dots at a spacing of about 2 nm (in the channels) are marked in the negative regions. Their imaging in the 2 nm resolution yields a tube-like model structure (see Fig. 25). The bottom side of the subunit is relatively planar, with a relatively narrow groove, which does not, however, cut through the whole particle. Note the strong contrasting in the groove. The more complicated channel structure on the inside, which should correspond, for the greater part, to the ribosomal RNA, is more weakly contrasted. However, one has to be careful on interpretation, since artefacts of staining can appear (staining variability stronger than radiation-induced variability!). Investigations by other preparative methods are yet to be carried out. The structure shows several penetration points of the stained channels (A to N) to the surface, whereby according to results with conventional labeling microscopy, C should correspond to the 3′ end of the 23S RNA and G to the 3′ end of the 5S RNA. Note, too, the highly differentiated surface, which borders the particles and the negative contrasting material.

diation. They could have been disturbed much more strongly—even then, it would have been a significant result that would have had to be accepted.

But, naturally, it is also desirable to study individual organic structures without the "corset" of heavy atom staining. We believe that in this case, investigations at low temperatures (liquid helium) would help further. At room temperature the real structural catastrophies actually develop secondarily. Bonds become broken, large and small fragments are formed. The small fragments try to break free, and finally, after a mass reduction of about 40%, a skeleton remains, which perhaps (given luck) can still show some relation to the native structure—we do not know.

The experimentally proven advantage of cryomicroscopy is that no mass reduction occurs. We can assume that on the whole, the low molecular fragments keep their place, hence, the spatial architecture should survive. At the moment, there is little sense in speculating on what really happens. Perhaps the idea of trace structure analysis (cf. [46]) can be used, and extrapolated to the native original state. But one can certainly experiment along these lines, since it is now possible to build high-resolution cryomicroscopes (cf. [23]).

A microscope ideal for cryomicroscopy would be one in which the relative change of direction is produced electronically by the tilting of the primary beam (instead of tilting the specimen). In this way, no location errors occur, which necessitate a further determination of the common origin. This is of importance with low radiation doses, with which the present correlation methods may fail. Serious proposals have already been put forward here[89], and attempts have actually been made at their realization[90].

The enhancement of the resolution down to the atomic limit has not yet been mentioned—it goes almost without saying that this will have to be attempted. As this report tries to demonstrate, if the newly-developed field emission guns are used, then experimental methodology is no longer the limiting factor. Admittedly, a great deal of preparative chemistry (not only in the biological field) remains to be learnt. However, atomic resolution must be coupled with three-dimensional analysis. Matter is "porous", only in three dimensions—and only then can one also use structural limitations in the analysis, as we had suggested some time ago[24a]. Cross-checking in the chemical "sense" (bond lengths and angles) will facilitate the analysis.

Finally, a remark for contemplation: It is the strong interaction between atoms and electrons which (in principle) enables the determination of the position of an atom by the scattering of electrons, in an incredibly short time. Centuries of measuring time would be needed to reach the same goal with X-rays. Thus, a great deal of experimental information is obtainable in a very short time—in contrast the volume of experimental data obtainable by using even the most sophisticated X-ray or neutron diffraction analysis is tiny. However, its accomplishment is only possible with very effective computers. Phase-determining electron diffractometry is a real child of our computer age.

*The long period of 20 years, covered in this report, makes it impossible to thank all my co-workers personally. More than 50 diploma and doctoral theses concern our work carried out in the field of electron microscopy—from instrumental techniques to informational theoretical contributions. I therefore ask to be pardoned if I only mention a few collaborators of the last few years: E. Demm, B. Grill, R. Guckenberger, H. Hebert (Guest from the Karolinska Institute, Stockholm), R. Hegerl, U. Jakubowski, V. Knauer, G. Nützel, H. Öttl, H. R. Tietz, D. Typke. With the construction of an He-cryomicroscope, work will be possible in an important part of the subject in our laboratory. I thank Dr. I. Dietrich and her co-workers (Siemens AG, Munich) for their collaboration. I also wish to thank the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for financial support.*

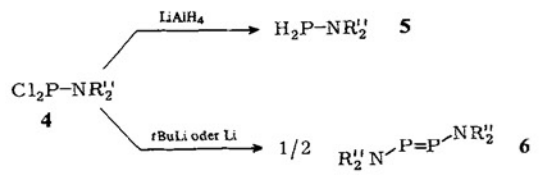
## Diaminodiphosphenes—Synthesis, Crystal Structure and Bonding Properties**

By *Edgar Niecke**, *Reinhold Rüger*, *Manfred Lysek*, *Siegfried Pohl*, and *Wolfgang Schoeller*



Compounds containing Si=Si and P=P bonds are of current interest[2]. We recently reported on the synthesis of the tetrakis(trimethylsilyl)diaminodiphosphene **1**[2f] by elimination of HCl from 1,2-bis[bis(trimethylsilyl)amino]-1-chlorodiphosphane[3]. We have now found that the diphosphenes **1** and **2** can be obtained directly from the corresponding lithium amides, *i.e.* without previous isolation of the intermediates. Further, it was found that when an equimolar mixture of both lithium amides is present the reaction leads to **3**, the first representative of an unsymmetrically substituted diphosphene, along with **1** and **2** as by-products.

**1**, R = R' = $SiMe_3$
**2**, R = $SiMe_3$, R' = *t*Bu

**3** $(Me_3Si)_2N-P=P-N(tBu)SiMe_3$

Attempts to prepare the diphosphene **6** analogously from the bulky aminodichlorophosphane **4** failed; this reaction afforded only the aminophosphane **5**. However, the tetrakis(*tert*-butyldimethylsilyl)diaminodiphosphene **6** could be obtained by reaction of **4** with lithium or *tert*-butyllithium.

R'' = $tBuMe_2Si$

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The highly pyrophoric diphosphenes **2** and **3** resemble **1** in their reaction behavior—their tendency to undergo dimerization decreases along the series **1** > **3** > **2**. Compound **6**, which is crystalline at room temperature, does not dimerize. A striking feature of all diaminodiphosphenes **1**—**3** and **6** is their thermochemistry, which is characterized by a change in color from intense red (25 °C) to yellow (< −100 °C).

The $^{31}P$-NMR spectra of **2**, **3**, and **6** show the typical strong deshielding of the $^{31}P$ nucleus that is to be expected for this class of compounds (Table 1). The observed upfield shift of the $^{31}P$-NMR signal [$\Delta\delta^{31}P(1,2) = 73$ ppm] on successive replacement of the trimethylsilyl groups by *tert*-butyl groups is possibly due to an increasing population of the coplanar conformation (*vide infra*). This could also explain the temperature-dependence of the $^{31}P$-NMR signal. The PP interaction ($^1J_{PP} = 670$ Hz)—observed for the first time in **3**—reflects an unusual bonding situation for the central PP bond (compared with the values for diphosphanes, especially the value for the *trans*-(*S,R/R,S*)-tetrakis(trimethylsilyl)diaminodiphosphane[3] ($^1J_{PP} = 148$ Hz)).

Table 1. $^{31}P$-NMR data (chemical shifts) of diphosphenes [a].

| Compound | δ value | Ref. |
|---|---|---|
| $[P-C(SiMe_3)_3]_2$ | 599.6 | [2d] |
| | 598.6 | [2e] |
| $[P-N(SiMe_3)_2]_2$ | 572 | [2f] |
| $[P-N(tBuMe_2Si)_2]_2$ **6** | 561 | |
| $P-N(SiMe_3)_2$ | 544 | |
| ‖ **3** | | |
| $P-N(tBu)SiMe_3$ | 507 | |
| $[P-N(tBu)SiMe_3]_2$ **2** | 499 | |
| $[P-C_6H_2-2,4,6-tBu_3]_2$ | 492.4—494 | [2a—d] |
| $[P-C_6H_2-2,4,6-Me_3]_2$ | 492 | [2g] |
| $[P-NC_5H_6-2,2,6,6-Me_4]_2$ | 472 | [2h] |

[a] In solution with $H_3PO_4$ as external standard.

The X-ray structure analysis shows that the PP bond length in **6** is similar to that in the aryl-substituted diphosphene $(2,4,6-tBu_3C_6H_2-P)_2$[2a] (Fig. 1). Unexpected is the almost bisorthogonal conformation in **6** (angle between the normals to the SiNSi and PPN planes: 77.5°). In contrast the isovalent tetrakis(trimethylsilyl)tetrazene[7a] has a coplanar $Si_2N-N=N-NSi_2$ framework[7b]. The associated strongly repulsive interaction between the non-bonding electron pairs on the nitrogen and the phosphorus atoms in **6** is presumably one of the causes for the unusually long PN bond length (176.9 pm).

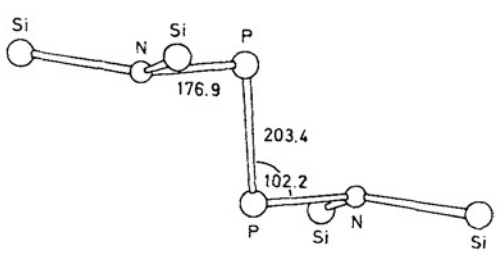

Fig. 1. Central skeleton of tetrakis(*tert*-butyldimethylsilyl)diaminodiphosphene **6** with important bond lengths [pm] and angles [°].

According to SCF calculations on the parent compound of the diaminodiphosphene system (Fig. 2) the coplanar conformation (left) is energetically favored compared to the bisorthogonal conformation (right) [STO-3G; $H_2N-P=P-NH_2$: 53 kJ/mol; $H_2N-N=N-NH_2$; 143 kJ/mol]. Both conformations are stabilized on formal re-

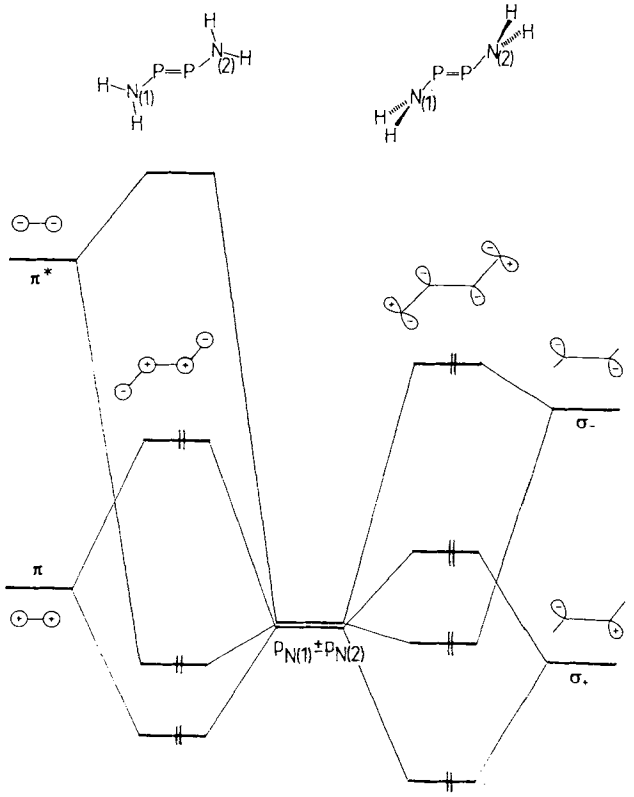

Fig. 2. Interaction diagram of the two non-bonding p-orbitals of the amino groups with the π-orbitals of the PP double bond (left) or the non-bonding electron pairs on the phosphorus atoms (right) forming a coplanar or bisorthogonal diaminodiphosphene.

placement of the hydrogen atoms by silyl groups, owing to the electron-acceptor activity of the latter; however, the bisorthogonal conformation is more highly stabilized, owing to the higher energy of its HOMO. This already leads, in the case of the fully silylated diaminodiphosphene **1**, which has a smaller rotation barrier than the corresponding tetrazene, to preference for the bisorthogonal form in the ground state of the molecule.

## Prostacyclin Synthase, a Cytochrome P450 Enzyme

By *Hermann Graf, Hans Heinrich Ruf,* and *Volker Ullrich**

Prostacyclin ($PGI_2$), **2**, is a physiologically highly potent intercellular transmitter substance, which causes relaxation of smooth muscle and platelet aggregation[1]. Its biosynthesis involves an unusual rearrangement of 9,11-epidioxy-15-hydroxy-5,13-eicosadienoic acid ($PGH_2$), **1**.

The mechanism of this enzymatic isomerization is not yet known. Starting out from our work on oxygen activation by cytochrome P450-dependent monooxygenases, we postulated a possible role for a $Fe^{III}$-heme-thiolate center at the catalytic site of $PGI_2$ synthase[2]. Such heme-thiolate containing enzymes are characterized spectroscopically by a typical low-spin EPR signal and by a red-shift of the Soret band of the $Fe^{II}$–CO complex to 450 nm[3]. Since these two spectral properties clearly define a cytochrome P450 enzyme we purified $PGI_2$ synthase in order to test our hypothesis.

$PGI_2$ synthase was obtained in pure form as a homogenous protein of about 49000 d by affinity chromatography of detergent-solubilized pig aorta microsomes. The absorption spectrum of the oxidized enzyme corresponds almost exactly to those of the cytochrome P450 monooxygenases known so far (Fig. 1, A). Reduction of the enzyme by Na-dithionite in the presence of CO shifted the Soret band to 450 nm, although very slowly ($t_{1/2} \approx 5$ min) (Fig. 1, B); complete reduction did not occur. In contrast to microsomal monooxygenase P450 from liver enzymatic reduction by $NADPH_2$ after addition of $NADPH_2$-cytochrome P450 reductase did not occur.

The EPR spectrum of the protein at low temperature is shown in Figure 2, A. For comparison the spectrum of a monooxygenase P450 isolated from liver microsomes is also shown (Fig. 2, B). $PGI_2$ synthase exhibits the typical $g$-values of P450-monooxygenases, although a somewhat larger anisotropy is observed ($g_x = 2.46$; $g_z = 1.90$). Such variations, however, are common with other P450 enzymes[4].

Thus, having established that $PGI_2$ synthase is a cytochrome P450 enzyme, the question of the function of the hemin-thiolate group in the catalysis of the rearrangement arises. In contrast to the P450-monooxygenases this reaction does not require an external source of electrons, and hence the $Fe^{III}$ is not reduced to $Fe^{II}$. This is similar to the non-physiological transfer of an oxygen atom (oxene) from iodosyl benzene[5] or organic peroxides to substrates (RH) of P450 monooxygenases (Scheme 1).

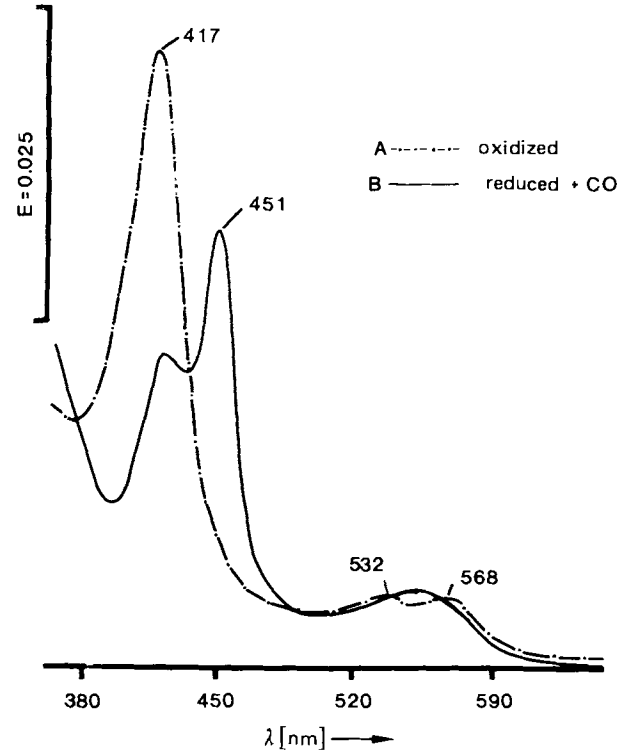

Fig. 1. Absorption spectra of prostacyclin synthase.

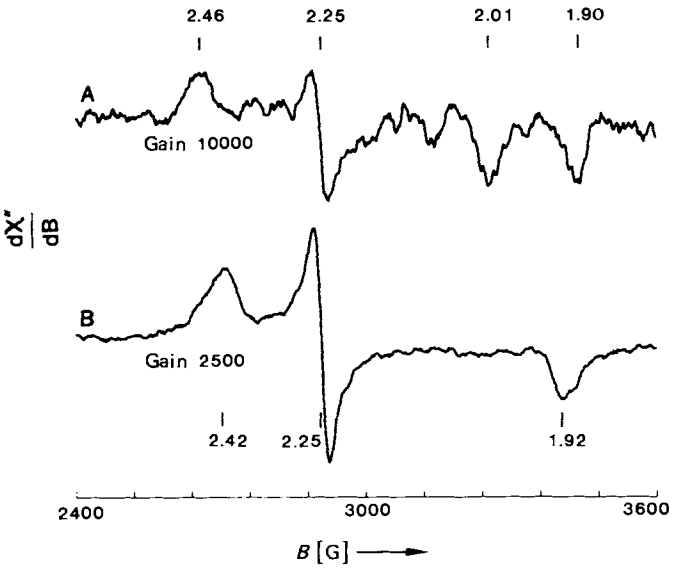

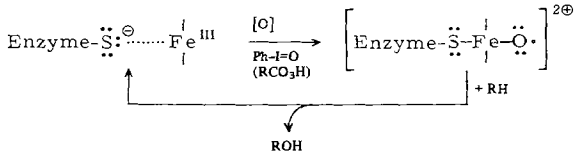

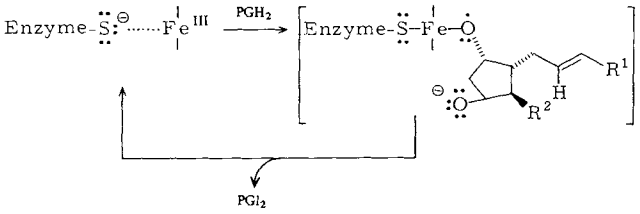

Fig. 2. EPR spectra of prostacyclin synthase (A) and cytochrome P450 of liver microsomes (B).

Scheme 1.

By analogy, the $PGH_2$-isomerization can be formulated as a heterolytic cleavage of the peroxide bond generating an activated 9-O atom (Scheme 2). It appears, therefore, that both cytochrome P450 enzyme systems have in common a mechanism of oxygen activation which apparently relies on the *trans*-thiolate ligand.

Scheme 2.

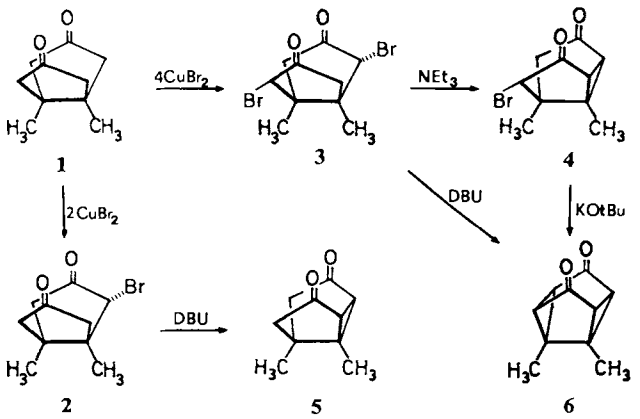
## Through-Bond Interaction *via* Strained σ-Bonds—The Synthesis and PE Spectrum of 1,5-Dimethyltetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione**

By *Gerhard Jähne* and *Rolf Gleiter**

The interaction between lone pairs or π-systems *via* the molecular σ-frame depends critically on the relative energies of the corresponding basis orbitals. To increase the σ/n or σ/π interaction highly strained σ-bonds are very effective, as shown by comparison of the PE spectrum of [2.2]paracyclophane with that of [1:2;9:10]bismethano[2.2]paracyclophane[1].



To extend this concept we have synthesized 1,5-dimethyltetracyclo[3.3.0.0$^{2,8}$.0$^{4,6}$]octane-3,7-dione **6** and its tri- and bicyclic precursors **5** and **1**, respectively, as shown in Scheme 1.

The starting point of our synthesis is 1,5-dimethylbicyclo[3.3.0]octane-3,7-dione **1**[2], which when treated with $CuBr_2$ in ethyl acetate/chloroform[3] leads to the *exo*-2-bromo- and the *exo,exo*-2,6-dibromo derivatives **2** and **3** in 60 and 70% yield, respectively. Transannular elimination of HBr can be achieved with 1,5-diazabicyclo[5.4.0]undec-5-ene (DBU) in dry acetonitrile at 50 °C under nitrogen to give **5** (70%, m.p. = 140–142 °C). The conversion of **3** to **6** can be achieved in 80% yield in one step using DBU as base, or in two steps *via* **4**.

In Table 1 we list the ionization energies corresponding to the first two bands of the PE spectra of **1**, **5**, and **6**. For

[**] Financial support from the Stiftung Volkswagenwerk and the BASF AG is gratefully acknowledged. We thank Dr. D. Krauss, E. Wallenwein, Dr. P. Kunzelmann, G. Rissmann, G. Schwebel, and W. Haseloff for measurements and discussions concerning the mass- and NMR-spectra.

Scheme 1.

comparison, the splitting ($\Delta n$) between the first two bands in cyclohexane-1,4-dione is 0.1 eV[4], and in bicyclo[3.3.0]octane-3,7-dione 0.33 eV[5].

Table 1. Comparison of the first two measured vertical ionization energies ($I_{v,j}$), the highest occupied MO energies according to MINDO/3 ($\varepsilon_j$), and the energy difference between them ($\Delta n$) for **1**, **5**, and **6**. All values in eV.

| Compound | band | $I_{v,j}$ | $\Delta n$ | Assignment | $\varepsilon_j$ | $\Delta n$ |
|---|---|---|---|---|---|---|
| **1** | ① | 9.31 | 0.27 | 6 $a_2$ ($n_-$) | − 9.62 | 0.29 |
| | ② | 9.58 | | 8 $b_2$ ($n_+$) | − 9.92 | |
| **5** | ① | 9.08 | 0.50 | 13 a″ ($n_-$) | − 9.41 | 0.49 |
| | ② | 9.58 | | 19 a′ ($n_+$) | − 9.90 | |
| **6** | ① | 8.86 | 0.94 | 5 $a_2$ ($n_-$) | − 9.05 | 1.03 |
| | ② | 9.80 | | 8 $b_2$ ($n_+$) | −10.08 | |

We assign the first band to ionization from $n_-$ and the second to ejection of electrons from $n_+$. This assignment is supported by the shape of the bands and by MINDO/3[6] calculations.

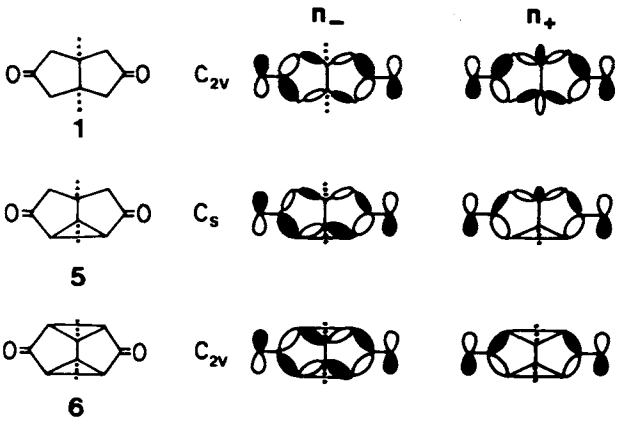

Fig. 2. Schematic representation of the MO's $n_-$ and $n_+$ of **1**, **5**, and **6** according to MINDO/3 calculation.

Figure 2 shows a steady increase (decrease) of the $\sigma/n$ interaction for $n_-$ ($n_+$), and thus explains the increase in the energy difference between the first two bands in the PE spectra of **1**, **5**, and **6**. The calculated distances between the oxygen atoms in **1** (6.2 Å), **5** (5.0 Å), and **6** (4.8 Å) preclude any significant through-space interaction between the 2p lone pairs on oxygen.

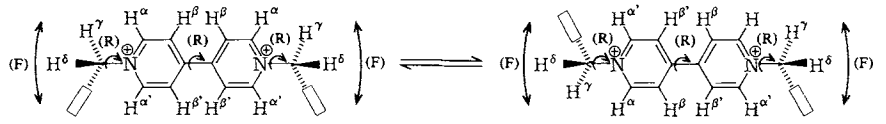
## Phanes with Two 4,4′-Bipyridinium Moieties—A New Class of Compounds**

By *Wolfram Geuder, Siegfried Hünig**, and *Adolf Suchy*

(1,4)Pyridinophanes, *i.e.* phanes in which one of the bridges is bonded to the pyridine nitrogen atom, were, to the best of our knowledge, not previously known. Here, we report for the first time on phanes having two 4,4′-bipyridinium moieties linked *via* two *o*- or two *m*-xylene bridges (*o,o*-**4**; *m,m*-**4**) or *via* one *o*- and one *m*-xylene bridge (*o,m*-**4**).



These macrocyclic tetracations could not be synthesized using the usual dilution methods, but could be prepared surprisingly easily by two-phase reaction of aqueous solutions of *o*-**3a** or *m*-**3a** (1 mmol in 10 mL $H_2O$) with 2 mmol of crystalline *o*-**1b** or *m*-**1b** by stirring the suspension at 20 °C. After three weeks *o,o*-**4b** (60%), *o,m*-**4a** (50%) (by reaction of *o*-**1b** with *m*-**3a** or *m*-**1b** with *o*-**3a**), and *m,m*-**4a**

*syn*-4 *anti*-4

Table 1. 400 MHz $^1$H-NMR data (δ-values) of **4** and **5** as $PF_6$ salts in [$D_6$] dimethyl sulfoxide at 25 °C. The pyridinium protons appear as doublets ($J$ = 6.5 Hz); geminal coupling of the benzyl protons: $J$ = 15 Hz.

| Compound | $H^\alpha$ | $H^{\alpha'}$ | $H^\beta$ | $H^{\beta'}$ | $H^\gamma$ | $H^\delta$ | Phenylene |
|---|---|---|---|---|---|---|---|
| *syn-o,o*-**4** | 9.43 | 8.27 | 8.52 | 7.97 | 6.49 (d) | 6.09 (d) | 8.07 (mc), 7.91 (mc) |
| *anti-o,o*-**4** | 9.33 | 8.33 | 8.40 | 8.21 | 6.47 (d) | 6.09 (d) | 8.07 (mc), 7.91 (mc) |
| *o,m*-**4** | *o:* 8.90<br>*m:* 9.26 | | *o:* 8.36<br>*m:* 8.57 | | *o:* 6.52 (d; $H^\gamma$), 6.09 (d; $H^\delta$), *m:* 6.06 (s) | | *o:* 8.09 (mc), 7.95 (mc), *m:* 7.71 (mc), 6.26 (s) |
| *m,m*-**4** | 9.37 | | 8.51 | | 6.05 (s) | | 7.86 (d), 7.62 (t), 7.31 (s) (2 : 1 : 1) |
| **5** | 9.50 | | 8.76 | | 6.01 (s) | | 7.62 (s) |

(30%), respectively, were isolated (after precipitation as the $PF_6$ salts and anion-exchange with $Et_4NCl$ in nitromethane)[1]. Using this method *o,o*-**4b** (25%) is formed even from **2** and *o*-**1b**.

The precursors *o*-**3** and *m*-**3**[1], as well as the salt of the ion **5**[1] are readily accessible. The purity of all products was monitored by thin-layer chromatography ($SiO_2$, MeOH/$H_2O$/50% aqueous $EtNH_3Cl$ (6 : 2 : 2). The composition and structure of the three isomers of **4a** were determined by mass spectrometry (FAB-MS[2]: *m/z* 520 (**4**); 555 (**4** + Cl); 590 (**4** + 2Cl) and NMR spectroscopy (also by comparison with the bisbenzylpyridinium ion **5**). In the phanes **4** rotation (R) of the pyridine rings and flipping (F) of the phenyl rings (*syn*- and *anti*-**4**) have to be borne in mind, as indicated by inspection of the upper half of the molecule (Table 1).

$^1$H-NMR spectroscopic studies indeed reveal that the internal mobility of the macrocycles changes dramatically from *o,o*-**4** *via* *o,m*-**4** to *m,m*-**4** with increasing size of the bridges. This is associated with an increase of the separation of the bipyridinium groups from 290 pm *via* 290 pm/510 pm to 510 pm[3].

*o,o*-**4**: Rotation (R) and flipping (F) are frozen-in. The $^1$H-NMR spectrum exhibits two sets of signals for *syn-o,o*-**4** and *anti-o,o*-**4** (2.5 : 1). The assignment reflects the expectation that the para- and diatropic effects of both phenylene bridges increase in *syn*-**4**, but not in *anti*-**4**. Compared to **5** ($H^\alpha$, $\delta$ = 9.50) the large high-field shift of the signal of $H^{\alpha'}$, which lies above the plane of the *o*-phenyl ring, is particularly noticeable [$\delta$ = 8.27 (*syn-o,o*-**4**), 8.33 (*anti-o,o*-**4**)], so that the difference between the chemical shifts of $H^\alpha$ and $H^{\alpha'}$ in *syn-o,o*-**4** increases to 1.16 ppm. In contrast, the ring current of the rotationally hindered pyridinium groups shifts the benzylic $H^\gamma$ signal *ca.* 0.5 ppm to low field relative to that of the model compound **5**, whereas the proton $H^\delta$, which lies over the long axis of the molecule and is orientated outwards, behaves "normally". This assignment is consistent with the fact that in *syn*- and *anti-o,o*-**4** $H^\delta$ has the same chemical shift, whereas the $H^\gamma$-signals differ by approximately 0.02 ppm.

*o,m*-**4**: Even the ring expansion of *ca.* 220 pm on one side is sufficient to reduce the barrier to rotation of all four pyridinium rings. The 2 × 2 doublets ($H^\alpha$, $H^\beta$) arise from the different bridge members. In contrast, the phenylene bridges can only undergo flipping on the *m*-side.

*m,m*-**4**: Introduction of the second *m*-phenylene bridge results in complete (R) and (F) mobility, and hence the signals largely correspond to those of the open-chain model compound. A discrepancy, which confirms the ring structure, arises from the high-field shift of both isolated *m*-phenylene protons: their signal is shifted in *m,m*-**4** to $\delta$ = 7.31 [*m*-**3**: $\delta$ = 7.55]; in the somewhat more narrower *o,m*-**4** the signal of the corresponding proton appears at $\delta$ = 6.26.

*Temperature effects:* In the 90 MHz $^1$H-NMR spectrum the pyridinium signals of *o,o*-**4** coalesce at 50 °C ($CF_3CO_2D$) ($\Delta G^+ \approx 65$ kJ/mol). In *o,m*-**4** rotation of the pyridinium rings adjacent to the *o*-bridge slows down at −40 °C ($CD_3CN$) (broad $H^\alpha$ and $H^\beta$ signals). At +70 °C the rate of flipping of the *o*-bridge increases (very broad $H^\gamma$ and $H^\delta$ signals). Inspection of Stuart-Briegleb and Dreiding molecular models suggests that *o,o*-**4** should have considerably higher barriers to rotation.

Furthermore, the ring systems are interesting as multistep redox systems (possible π-merization of the double radical cations[4]) and as host molecules for inclusion compounds. Using the same synthetic principle the preparation of related phanes having other ring members is being undertaken.

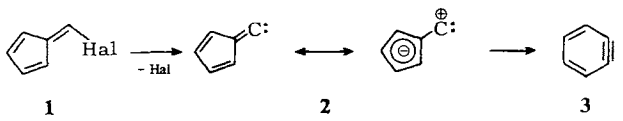
## 1,2-Benzynes from 6-Halopentafulvenes**



By *Klaus Hafner**, *Hans-Peter Krimmer*, and *Bernd Stowasser*

6-Halopentafulvenes **1** are readily accessible by reaction of acylcyclopentadienes with phosgene or oxalyl halides and have proven very useful as educts for the synthesis of a variety of pentafulvenes functionally substituted at the

[*] Prof. Dr. K. Hafner, H.-P. Krimmer, B. Stowasser

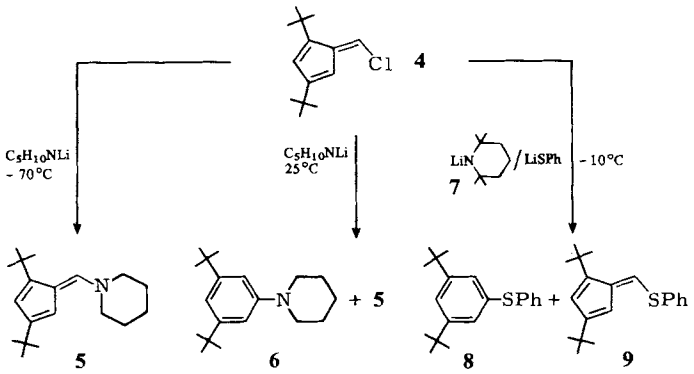
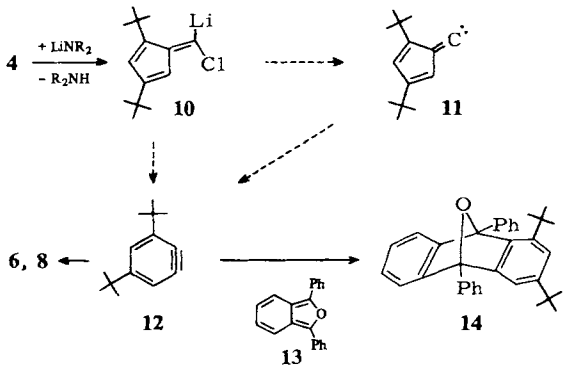
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.



exocyclic C-atom[1]. α-Elimination of hydrogen halide from **1** should furnish the hitherto unknown pentafulvenylidenecarbene **2**.

**1** **2** **3**



According to quantum chemical calculations by *Apeloig et al.*[2], **2** is expected to be highly electrophilic and undergo rearrangement into the 1,2-benzyne **3**, which should be 14 kcal·mol$^{-1}$ more stable than **2**.

To check this prognosis we have investigated the reaction of the stable 1,3-di-*tert*-butyl-6-chloropentafulvene **4** with bases. Reaction of **4** with lithium piperidide in tetrahydrofuran (THF) at −70 °C affords 1,3-di-*tert*-butyl-6-piperidinopentafulvene **5** in 76% yield[3,4a] with retention of configuration. On the other hand, the same reaction at 25 °C leads to 1,3-di-*tert*-butyl-5-piperidinobenzene **6** in 61% yield[4b] and only 6% of **5**, while reaction with lithium 2,2,6,6-tetramethylpiperidide **7** in presence of an excess of lithium thiophenolate in THF at −10 °C leads to 54% of 3,5-di-*tert*-butyldiphenyl sulfide **8**[4c] and 6% of 1,3-di-*tert*-butyl-6-phenylthiopentafulvene **9**[1].

**5** **6** **8** **9**

These findings confirm the quantum chemical predictions. From **4** the carbenoid **10** can be generated, and from this the carbene **11**, which obviously rapidly rearranges into 3,5-di-*tert*-butyl-1,2-benzyne **12**. This subsequently reacts with nucleophiles[5a], whereupon **6** and **8** are formed regioselectively under the influence of the bulky *tert*-butyl groups. So far, however, it cannot be ruled out that **12** is generated directly from **10** by a rearrangement analogous to the Fritsch-Buttenberg-Wiechell reaction[5b]. Attempts to trap the carbene **11** by [2+1]-cycloaddition have so far remained unsuccessful. On the other hand, by means of 1,3-diphenylisobenzofuran **13** it was possible to trap the 1,2-benzyne **12** formed on reaction of **4** with **7** as the Diels-Alder adduct **14** (50%)[4d].

## The Cation Di-μ-oxo-*trans*-dioxobis[(1,4,7-triazacyclononane)molybdenum(v)](*Mo—Mo*) and its Acid-Catalyzed *cis*-Isomerization**

By *Karl Wieghardt**, *Manfred Hahn*, *Wolfgang Swiridoff*, and *Johannes Weiss*

Dinuclear molybdenum(v) complexes with the central structural element di-μ-oxodioxobis(molybdenum(v)), $Mo_2O_4^{2+}$, are diamagnetic; their short Mo–Mo distance (254–258 pm) is interpreted as originating from a metal-metal single bond[1a–d,f]. The $Mo_2O_2$ four-membered ring is puckered and both terminal oxo groups are always located in a *cis*-arrangement[1a,d,f]. This configuration is apparently the most thermodynamically stable; a structure with *trans*-oxo groups has not previously been reported.

We now report the preparation and structure of the first $Mo_2O_4^{2+}$ complex with *trans*-oxo groups, as well as its irreversible acid-catalyzed conversion into the stable *cis*-form. Hydrolysis of the monomeric, paramagnetic complex **1** in aqueous solution containing $NaHCO_3$ leads to formation of the diamagnetic, green, dinuclear cation **2**. After addition of NaI, the crystalline iodide **2**·2I is obtained. The reaction of aqueous solutions of **2** with dilute perchloric acid under argon affords cherry-red solutions from which red, diamagnetic **3**·2I can be precipitated upon addition of NaI. In solution, **3** undergoes acid-catalyzed reaction to yield **4**, a diamagnetic, yellow, dinuclear μ-oxo complex of molybdenum(v) (for spectroscopic data, see Table 1).

Selected bond angles [°]: Mo–O2–Mo′ 82.6(2), O2–Mo–O2′ 97.5(2), O1–Mo–O2 103.2(2), O1–Mo–O2′ 104.1(2), O1–Mo–N2 163.3(2). Bottom: Structure of the cation in **4**·2SCN·KSCN. $P2_1n$; $a=1045.8(2)$, $b=1220.0(2)$, $c=2077.3(3)$ pm, $\beta=99.52(2)°$, $Z=4$, $R=0.032$ (2614 observed reflections). Selected bond angles [°]: Mo1–O3–Mo2 82.7(1), Mo1–O4–Mo2 81.5(1), O3–Mo1–O4 92.9(1), O3–Mo2–O4 92.6(1), O1–Mo1–O3 108.3(1), O1–Mo1–O4 110.3(1), O2–Mo2–O3 108.9(1), O2–Mo2–O4 108.5(1).

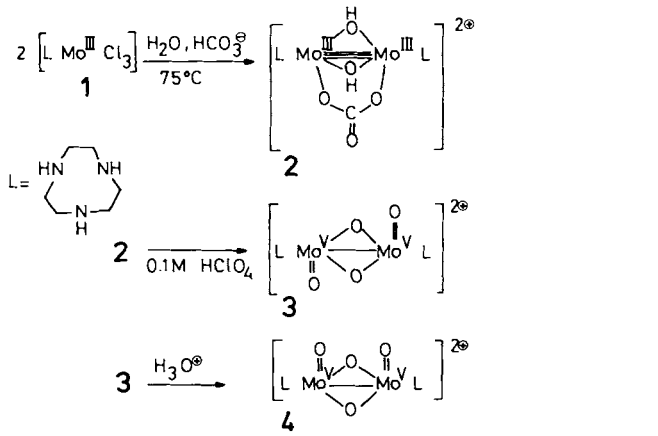

Table 1. UV/VIS ($\lambda_{max}$ [nm]: $\varepsilon$ [$L\,mol^{-1}\,cm^{-1}$]) and selected IR data [$cm^{-1}$] of the complexes **2**–**4** in aqueous solution (pH 7).

| | UV-VIS [a] | IR |
|---|---|---|
| 2 | 735 (sh), 630 (71), 450 (sh), 366 ($1.2\times10^3$) | $\nu$(C=O) 1535, $\nu$(C–O) 1300 |
| 3 | 525 (380), 312 ($3.6\times10^3$) | $\nu$(Mo=O) 909, $\nu_{as}$(Mo–O) 720, $\nu_s$(Mo–O) 410 |
| 4 | 378 (390), 284 ($7.0\times10^3$) | $\nu$(Mo=O) 940, $\nu_{as}$(Mo–O) 735, $\nu_s$(Mo–O) 420 |

[a] The molar absorption coefficients are calculated per dimeric cation (*not* per Mo center).

The crystal structure analysis of **3**·2I proves the existence of a dinuclear molybdenum(v) cation. Each Mo atom has a distorted octahedral environment (two edge-sharing octahedra, Fig. 1a). The terminal oxo ligands occupy *trans*-sites; the $Mo_2O_2$ four-membered ring is planar. In the isomeric **4**·2SCN·KSCN the terminal oxo groups are *cis* and the $Mo_2O_2$-ring is puckered.

The environment of the $Mo^V$ centers in **3** and **4** is almost identical; within the limits of experimental error all the Mo–Mo, Mo–N, Mo–O, and Mo=O bond lengths are the same. Only the O–Mo–O angles in **4** are somewhat larger than those in **3**.

The kinetics of the irreversible *trans-cis*-isomerization indicate that a protonated form of **3** is involved in the rate-determining step. The rate law (30 °C, ionic strength 1.0 mol/L) is

$$\frac{-d[\mathbf{3}]}{dt}=\frac{d[\mathbf{4}]}{dt}=k_{AH}(1+K_{AH}[H^+]^{-1})^{-1}[\mathbf{3}]$$

where $k_{AH}=6.4\times10^{-4}$ L mol$^{-1}$ s$^{-1}$ and $K_{AH}=2.8$ mol L$^{-1}$.

## Reactions at the Counter Electrode in Electroreductions under Aprotic Conditions in One-Compartment Cells

By *Rainer Engels**, *Cornelis J. Smit*, and *Wim J. M. van Tilborg*

Cathodic syntheses in aprotic media are normally carried out in divided cells so as to avoid reoxidation of the (primary) products at the anode. Such syntheses, however, are usually limited to the laboratory scale owing to the complicated and expensive cell constructions, the high ohmic resistance, and especially the short lifetime of the ion-exchange membrane[1]. We now report on a generally applicable method for solving this problem.

Table 1 (selected data). Reactions at the counter electrode during electroreductions in one-compartment cells.

| No. | Conducting salt/ Substrate | Foot potential [a] [V vs. SCE] | (Primary) Oxidation products |
|---|---|---|---|
| 1 | Bis(tetraethylammonium) oxalate (DTEAOx) [b] | +0.2 | $CO_2$ |
| 5 | Tetraethylammonium formate (TEAForm) [b] | +0.7 | $CO_2+H^+$ |

[a] 0.1 M in acetonitrile, platinum anode. [b] Prepared by neutralization of tetraethylammonium hydroxide with the appropriate acid.

The anodic oxidations of the oxalates[3] and formates listed in Table 1 proceed rapidly at relatively low potentials, independent of the anode material. They are therefore particularly well suited for limiting the counter elec-

[h] Without additional carbon dioxide. [i] In *N,N*-dimethylformamide at a mercury cathode. [k] Material yield, isolated. [l] *cis/trans* = 38/62.

trode potential in reductions. The anodically evolved carbon dioxide can be used in reductive carboxylations, but application of the counter electrode reactions (see Table 2/3) is by no means restricted to carboxylations.

As Table 2/3 shows, the selectivity of the cathodic reaction can strongly depend on the type of counter electrode reaction. Thus, the reductive electrocarboxylation of dimethyl maleate[5] in presence of DTEAOx affords a mixture of the mono- and dicarboxylated monomers (**1**, **2**) and dimers (**4**, **5**), but no hydrodimer **3**. However, the protons formed during the anodic oxidation of TEAForm shift the selectivity of the reaction towards **1** as main product along with **3** as byproduct. A similar change in the selectivity is found in the reductive carboxylation of butadiene[6]. Changing from DTEAOx to TEAForm shifts the selectivity of the reaction in favor of the $C_{10}$-dicarboxylic acids **8**—**10**. In the electrocarboxylation of acetophenone the carboxylated alcohol **14** is formed in moderate amounts along with the pinacol **15**. If, on the other hand, acetophenone is reduced in presence of DTEAOx without additional carbon dioxide under conditions suitable for the pinacolization[11] then only **15** is formed. The cleavage of the tosyl group from 1,10-ditosyl-1,10-diaza[18]crown-6 proceeds in excellent yield, thus providing a simplified route to 1,10-diaza[18]crown-6.

As these examples demonstrate, the oxidations of the oxalates and formates enable a variety of cathodic electrosyntheses to be carried out under anhydrous conditions in one-compartment cells—a prerequisite for scaling-up the reactions to the industrial scale.

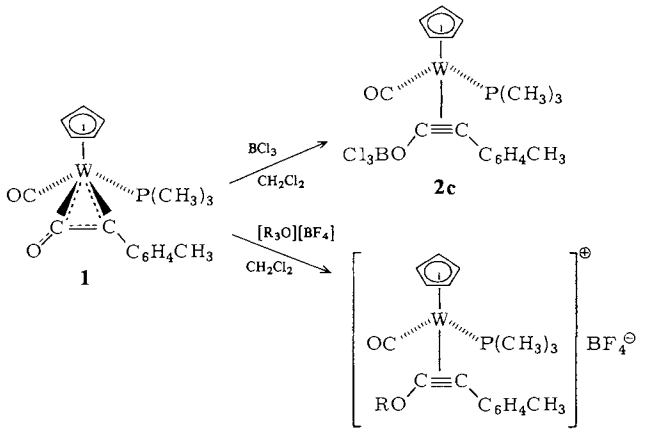
## Ketene-Alkyne Conversion using Lewis Acids**

By *Fritz R. Kreissl**, *Werner Sieber*, and *Mathias Wolfgruber*



Mild carbonylation of carbyne complexes, *via* CC bond formation, leads to $\eta^1$- and $\eta^2$-ketenyl compounds[2]. These react with Lewis bases, such as phosphanes, carbon monoxide, or isocyanides, to afford $\eta^1$-ketenyl compounds. With halophosphanes and haloarsanes they react to give phosphanyl- and arsanylketene complexes[6], from which an intermediate having a CPW ring system could be isolated. Use of higher pressures of CO leads to deoxygenation of the $\eta^2$-ketenyl *via* the stage of the $\eta^1$-ketenyl compounds to yield σ-bonded alkyne derivatives[8].

In contrast, π-bonded alkyne complexes are formed by reaction of the $\eta^2$-ketenyl compounds with Lewis acids: thus at dry-ice temperature both alkyl cations and boron trichloride add to the ketene oxygen atom of **1** with concomitant conversion of the $\eta^2$-ketenyl into an $\eta^2$-alkynyl ligand. Comparable alkyne complexes have recently been

[**] Transition-Metal Ketene Compounds, Part 13. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Priv.-Doz. Dr. H. G. Alt (Universität Bayreuth) is thanked for the NMR measurements.—Part 12: W. Sieber, M. Wolfgruber, D. Neugebauer, O. Orama, F. R. Kreissl, *Z. Naturforsch. B38* (1983) 67.

obtained in the reaction of $Cl[P(CH_3)_3]_4WCH$ with CO in the presence of aluminum trichloride[9].

The products **2a** and **2b** can be isolated as orange salt-like solids, whereas **2c** is a diamagnetic beige molecular solid; all three compounds are soluble in dichloromethane. The compositions and structures of the products were determined by elemental analysis and by mass-, IR-, and NMR-spectroscopy. In each case the $\nu$CO solution spectrum ($CH_2Cl_2$) exhibits a very intense band at 1975, 1976, and 1970 $cm^{-1}$, respectively. The $^1H$-NMR spectra of the novel acetylene complexes have the expected number of signals in the correct intensity ratios. The $^{13}C\{^1H\}$-NMR spectrum ($CD_2Cl_2$, $\delta$-value rel. $CD_2Cl_2 \triangleq 54.2$ ppm) of **2b** contains 12 signals: W–CO 223.4 [$J$(WC) = 135.0, $J$(PC) = 6.8 Hz]; C≡*C*O 228.8 [$J$(WC) = 66.7, $J$(PC) = 6.0 Hz]; *C*≡CO 193.7 [$J$(WC) = 32.5; $J$(PC) = 6.0 Hz]; $C_6H_4$ 141.6, 133.4, 130.0, 129.4; $C_5H_5$ 93.6; $OCH_2$ 72.3; $P(CH_3)_3$ 21.8 [$J$(PC) = 37.6 Hz]; $CH_3$ 21.5; $CH_2CH_3$ 15.1. The strong deshielding of the alkyne C atoms in **2** suggests a 4π-electron ligand[12], whereas the relatively large WC coupling constants indicate high σ-bond contributions[15] between the central metal atom and the two carbon atoms; a second limiting structure for the description of the complexes, a metallacyclopropene system, therefore, cannot be excluded. In each case the $^{31}P\{^1H\}$-NMR spectra ($CD_2Cl_2$, $\delta$-value rel. ext. $H_3PO_4$) of **2a**–**2c** exhibit a singlet accompanied by tungsten satellites: −17.2 [$J$(WP) = 394.3 Hz], −17.3 [394.3], and −16.0 [399.8], respectively. In the mass spectra (FD) of **2a** and **2b**, the signals of the cations appear at $m/z$ 499 and 513, respectively, in addition to signals at 547 and 561, respectively, whose relative intensities are markedly dependent on the temperature of the emitter; this corresponds to $CO/P(CH_3)_3$ exchange in the cations.

## The Zirconocene-Induced Coupling of Butadiene with Carbonyl Compounds**

By *Gerhard Erker**, *Klaus Engel*, *Jerry L. Atwood*, and *William E. Hunter*

Additions of aldehydes and ketones to alkyltitanium and alkylzirconium compounds are attracting increasing attention as synthetically useful reactions, often with surprisingly high selectivities. Since X-ray structure analyses[2] have shown (*s-cis*-diene)zirconocene complexes exhibit substantial alkylmetal character it was tempting to consider the regioselective coupling of isoprene with aldehydes and ketones at the bis(η-cyclopentadienyl)zirconium unit as being a further example of this reaction type[3].

Reaction of the equilibrium mixture of (*s-trans*- and *s-cis*-$\eta^4$-butadiene)zirconocene **1** ⇌ **2** (25 °C: 45/55) with benzophenone, acetone, cyclododecanone, acetophenone, pinacolone and isobutyraldehyde (**3a**–**f**) leads to the or-

ganometallic products **4a**–**f** having a oxazirconacycloheptene structure; this was confirmed by X-ray structure analysis in the case of **4a** (Fig. 1). Hydrolysis of **4** affords mixtures of the alcohols **5** and **6**.

Addition of **3** to **2** was expected to give directly the seven-membered metallacycles **4** with *cis*-configurated double bond. Surprisingly, however, **4a**–**f** are not formed in this way. In the equilibrium mixture **1** ⇌ **2** the (*s-trans*-$\eta^4$-butadiene)zirconocene **1** reacts more rapidly with **3** than its isomer **2** with **3**, even at room temperature. This becomes impressively confirmed upon reacting the mixture of **1** and **2** (45:55) with benzophenone **3a** at low temperatures. Above −25 °C slow formation [$\tau_{1/2}(-20\,°C) \approx 1$ h] of **4a** is found to take place. The thermally-induced equilibration **1** ⇌ **2** is "frozen in"[2]; reaction of **1** with **3a** is the sole reaction recorded $^1H$-NMR spectroscopically.

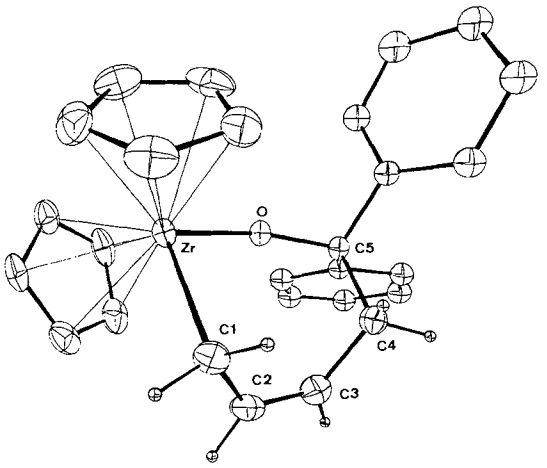
[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Fonds der Chemischen Industrie.

No thermally-induced reaction is observed at $-50\,^{\circ}C$, even after several hours, whereas **1** reacts photochemically (Philips HPK 125; Pyrex filter) with **3a** within a few minutes. (*s-cis*-Butadiene)zirconocene **2** also proves to be no



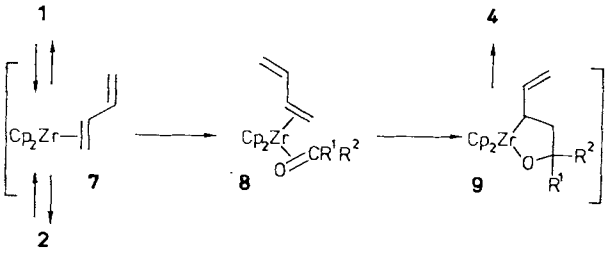


Fig. 1. Structure of **4a** in the crystal. Selected bond lengths [Å]: Zr–O 1.946(4), Zr–Cl 2.311(7), C1–C2 1.468(9), C2–C3 1.351(9), C3–C4 1.498(8); bond angles [°]: Zr–O–C5 150.5(4), O–Zr–Cl 91.9(2).

longer inert towards **3a**: on reaction with the mixture of the isomers **1** and **2**, **2** is consumed at a similar rate as **1**, with formation of **4a**.

These observations suggest that—analogous to the reaction of **1** ⇌ **2** with olefins[4]—**4** is formed from the intermediary product ($\eta^2$-butadiene)zirconocene **7**[9] *via* the intermediates **8** and **9**. Therefore, it appears that the selectivity control of the zirconocene-induced coupling of conjugated dienes with aldehydes and ketones may in some cases depend decisively on the formation and properties of intermediary ($\eta^2$-diene)metallocene complexes[10].

## *cis*-1,2-Di(9-anthryl)ethylene: Photochemical Isomerization by Intramolecular Diels-Alder Reaction

By *Hans-Dieter Becker**, *Kjell Sandros*, and *Kjell Andersson*

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

As part of a study of the relationship between molecular geometry and excited state reactivity, we recently prepared *cis*-1,2-di(9-anthryl)ethylene **1** in order to compare its photochemical and photophysical properties with those of its *trans*-isomer **2**[1–3]. Attempts to induce photochemical *trans*→*cis* isomerization were not successful, but irradiation of **1** in cyclohexane ($\lambda > 300$ nm) produced the *trans*-isomer **2** in nearly quantitative yield, together with small amounts of the [4π+4π] cycloaddition product **3**[2]. At low conversion of **1**, however, equal quantum yields (0.0007) were estimated for both the geometrical isomerization to **2** and the cycloaddition to **3**.

We have now investigated the wavelength dependence of the photochemical isomerization of **1** and found a novel intramolecular cycloaddition in which the 1,2-bond of an anthracene π-system participates as a dienophile in a Diels-Alder reaction.

Irradiation of **1** (20 mg) in cyclohexane (900 mL) at 50 °C for 6 h under argon ($\lambda > 392$ nm) results in complete isomerization. After separation of the *trans*-isomer **2** (37% yield) **3** remains and, surprisingly, the novel dissymmetric photo-isomer **4** (50% yield, colorless crystals, m.p. *ca.* 180 °C, decomp.).

The high-resolution mass spectrum, the 270 MHz $^1$H-NMR spectrum, and the electronic absorption spectrum are consistent with the structure **4** (Fig. 3a). Evidence for this structure was also obtained by dehydrogenation with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ), which afforded the triptycene derivative **5** (yellow crystals, m.p. 293 °C). The structure of **5** is supported by its $^1$H-NMR spectrum and by its electronic absorption spectrum, which

[*] Dr. H.-D. Becker, Dr. K. Sandros, K. Andersson

is typical of the planar 9-vinylanthracene chromophore [$\lambda_{max}$ ($\varepsilon \times 10^{-3}$): 440 (13), 414 (10.4), 391 (4.9), 371 (1.9), 314 sh (3.2), 271 (66)].

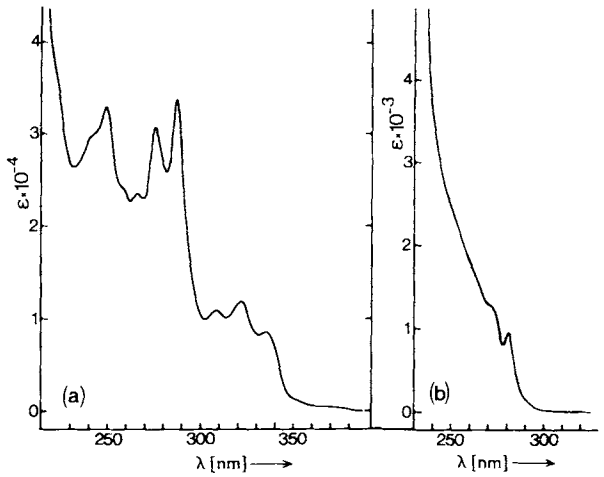

Fig. 3. Electronic absorption spectra of cycloaddition products **4** (a) and **3** (b) in cyclohexane.

Upon photo-excitation ($\lambda < 360$ nm) in cyclohexane, **4** undergoes smooth cycloreversion to give **1**: the quantum yield of this reaction is 0.20, exceeding that of the formation of **4** from **1** by a factor of 300. Hence, **4** can be obtained only when its photo-excitation is prevented by use of appropriate filters. The quantum yield for the photolytic cycloreversion of **3** → **1** is three times as high as that of the reaction **4** → **1**, but its UV spectrum (Fig. 3b) precludes photo-excitation when **1** is irradiated in Pyrex apparatus.

The low concentration of **1** employed in the experiment described above (20 mg in 900 mL cyclohexane) is of critical importance for the photochemical formation of **4**. Numerous attempts to obtain **4** by photochemical isomerization of higher concentrations of **1** in cyclohexane failed since the *trans*-isomer **2**, whose solubility at room temperature is only 2 mg/L, always precipitated soon after commencement of irradiation, and became the major product. Surprisingly, the efficiency of *cis-trans* isomerization surpasses that of the intramolecular cycloaddition **1** → **4** after precipitation of **2** has commenced. Absorption spectroscopy indicates that when most of the incident light is absorbed by crystalline **2** the photochemical formation of **4** from **1** virtually ceases, while the rate of conversion of **1** into **2** is enhanced. The use of other solvents in which **2** is more soluble than in cyclohexane is impaired by the fact that the quantum yield of *cis-trans* isomerization is solvent dependent[2]: specifically in cyclohexane solution can the intramolecular Diels-Alder reaction of **1** to afford **4** compete efficiently with the geometrical isomerization leading to **2**.

## $(PhC{\equiv}CLi)_4(tmhda)_2$, A Polymeric Organolithium Compound with Cubic $Li_4C_4$ Structural Units**

By *Bernd Schubert* and *Erwin Weiss**

For systematic investigations on the structure of organolithium compounds we prepared some phenylethynyllithium compounds containing additional diamine ligands: [(PhC≡CL)$_2$tmeda], [(PhC≡Li)tmpda]$_2$ **1** and [(PhC≡CLi)$_4$(tmhda)$_2$] **2** (tmeda = *N,N,N',N'*-tetramethylethylenediamine, $Me_2N(CH_2)_2NMe_2$; tmpda = *N,N,N',N'*-tetramethylpropanediamine, $Me_2N(CH_2)_3NMe_2$; tmhda = *N,N,N',N'*-tetramethylhexanediamine, $Me_2N(CH_2)_6NMe_2$).

The length of the diamine ligand obviously has a large influence on the composition and structure of these compounds. Thus, **1** is a dimer with two phenylethynyl bridges[1], isostructural to the phenyl compound (PhLi·tmeda)$_2$[2].

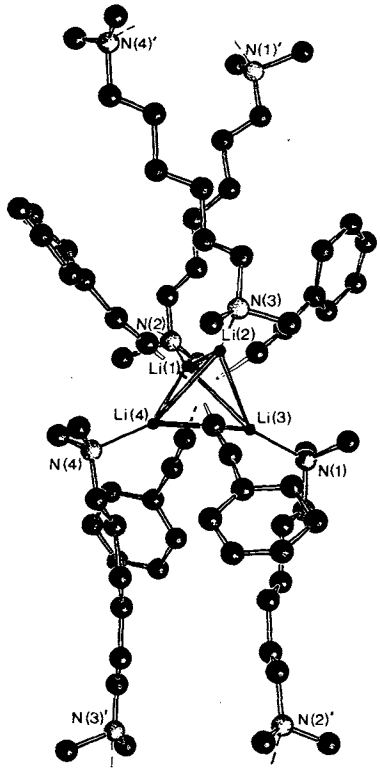

Fig. 1. SCHAKAL diagram of the structure of **2** in the crystal. Monoclinic, $P2_1/n$, $a = 1574.7(9)$, $b = 1563.9(9)$, $c = 2140.3(8)$ pm, $\beta = 102.87(4)°$, $\rho_r = 1.003$ g cm$^{-3}$, $Z = 4$; $Mo_{K\alpha}$-radiation, solution by direct methods (MULTAN 78), refinement (SHEL X) to $R = 0.092$ with 1515 reflections (anisotropic temperature factors, H not determined). Most important distances (pm, average values): Li–Li 272(2), Li–C 220(1), Li–N 211(2), C≡C 124(2) pm [6].

The longer chain diamine tmhda adds to PhC≡CLi with formation of the 1:2 compound **2**. Surprisingly, the X-ray structure analysis (Fig. 1) revealed that **2** contains a distorted cubic $Li_4C_4$-unit similarly as in $(CH_3Li)_4$ and $(CH_3Li)_4(tmeda)_2$ **3**[4]. Structurally analogous are the

$Li_4O_4$-units in Li-enolates[5]. Adjacent $(PhC{\equiv}CLi)_4$-units in **2** are each bound by pairs of tmhda ligands, giving rise to high polymer strands with helix-like structure. In **3**, tmeda links the $(CH_3Li)_4$-unit in a different way, with formation of a three-dimensional network structure.

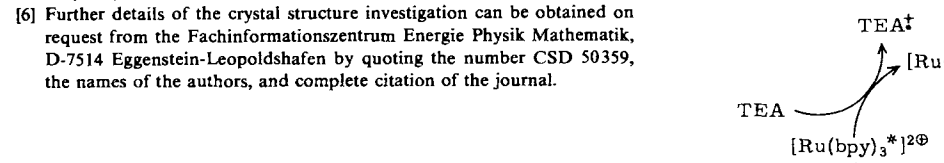
## Selective Generation of NADH by Visible Light**

By *Rainer Wienkamp* and *Eberhard Steckhan**



We recently reported on the reduction of $NAD^{\oplus}$ to NADH by the electrochemically generated two-electron transfer agent $[Rh(bpy)_2]^{\oplus}$[1]. In this way, the rhodium complex suppresses formation of enzyme-inactive dimers, which normally are formed in direct electrochemical reductions. We have now succeeded in preparing enzyme-active NADH from $NAD^{\oplus}$ using visible light in the presence of the photochemically generated bipyridinerhodium(I) complex. In this reaction tris(2,2′-bipyridine)ruthenium(II) functions as the sensitizer and 2,2′,2″-nitrilotriethanol (triethanolamine, TEOA) as an electron donor in the usual way[2] [eq. (a)]. The quantum yield for the photoproduct $[Rh(bpy)_2]^{\oplus}$ is 0.13[2b].

(a)

A 0.42 M aqueous solution of TEOA (80 mL) containing 200 μmol $[Rh(bpy)_3]_2(SO_4)_3$, 100 μmol $[Ru(bpy)_3]SO_4$, and 300 μmol $NAD^{\oplus}$ was adjusted to pH 9.7 with concentrated $H_2SO_4$; this mixture was then irradiated with a slide projector (300 W halogen lamp) and a circular 25 W fluorescent lamp without a lense system to focus the beam and in the absence of a filter. After 4 h 60 μmol, after 6.75 h 90 μmol, and after 24 h 230 μmol NADH formed (established after filtration over Dowex 50 WX4 by enzymatic reduction of cyclohexanone with horse liver alcohol dehydrogenase). At a detection limit of *ca.* 0.5 μmol NAD dimers could not be observed. In the absence of the relay compound $[Rh(bpy)_3]^{3\oplus}$ photoreduction of $NAD^{\oplus}$ to NADH did not occur. Aliphatic ketones were neither reduced by $[Ru(bpy)_3^*]^{2\oplus}$ nor by $[Rh(bpy)_2]^{\oplus}$. At higher concentrations of $NAD^{\oplus}$ conversion rates of 10 to 15 μmol/h were maintained, however, because of its photosensitivity NADH formation is reduced at irradiation times of longer than 24 h. In future experiments the UV irradiation ($\lambda < 400$ nm) must, therefore, be filtered out.

The recent proposal by *Kiwi*[3] to store solar energy by reducing $NAD^{\oplus}$ using the strong reducing agent $[Ru(bpy)_3]^{\oplus}$, formed from photochemically excited $[Ru(bpy)_3^*]^{2\oplus}$ and triethylamine (TEA) in $CH_3CN/H_2O$ (7 : 3) as electron donor leads, in contrast to the statements of the author, not to enzyme-active NADH but to NAD dimers [eq. (b)]. The alleged formation of NADH was studied exclusively by absorption spectroscopy at 340 nm ($\varepsilon_{NADH} = 6220\ M^{-1}\ cm^{-1}$). We have established that the NAD radicals, generated by one-electron reduction, react as described in the literature [4] practically exclusively to afford enzyme-inactive NAD dimers, which can be detected by thin-layer chromatography. No enzyme activity was observed in the presence of horse liver alcohol dehydrogenase with cyclohexanone as substrate. Since both NADH and the NAD dimer absorb at 340 nm ($\varepsilon_{NAD_2} = 6650\ M^{-1}\ cm^{-1}$), this method of detecting NADH is unsuitable. Because of the instability of the photoproduct $[Ru(bpy)_3]^{\oplus}$ under the reaction conditions, the bipyridineruthenium(II) complex used by *Kiwi* has only a moderate lifetime.

(b)

Since oxidation of TEOA leads to formation of aldehydes, our system is not yet suitable for the continuous internal regeneration of NADH in the presence of an alcohol dehydrogenase with a carbonyl compound as substrate. Use of other donors and the possibilities of electrochemical regeneration of the $Ru^{II}$ complex from the $Ru^{III}$ compound could improve the system.

## Novel $\eta^3,\sigma$-Sulfur Double-Ylide Chromium Complexes by *endo*-Hydride Addition to Cationic ($\lambda^6$-Thiabenzene 1-Oxide)chromium Complexes**

By *Lothar Weber** and *Roland Boese*

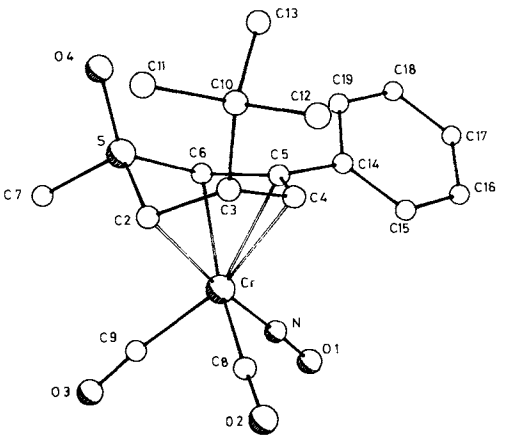
The unsaturated hydrocarbon ligands of cationic transition-metal complexes have electrophilic character and add nucleophiles *via* kinetically controlled *exo*-addition[1].

In the reaction of the cations **1a—d** with $LiBHEt_3$ we observed the rare case of *endo*-addition of hydride to a $\pi$-bonded organic ligand[3]. As a result compounds **2**, having a novel double-ylidic ligand, are formed from the cationic ($\lambda^6$-thiabenzene 1-oxide)chromium complexes [(1-oxo-$\lambda^6$-thiin)chromium) complexes] **1**[7].

**1a-d** **2a-d**

| 1, 2 | a | b | c | d |
|---|---|---|---|---|
| $R^1$ | Ph | Me | Me | *t*Bu |
| $R^2$ | Ph | Ph | Me | Ph |

The *exo*-position of the 3-*tert*-butyl group in **2d**, determined by X-ray structure analysis (Fig. 1), establishes *endo*-addition of the hydride. In addition, the double-ylidic heterocycle is coordinated as a 4—6$\eta$,2$\sigma$ ligand to the $Cr(CO)_2(NO)$ fragment.



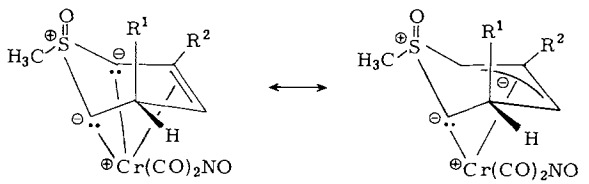


Fig. 1. Structure of the complex **2d** in the crystal [4]. Selected distances [pm] and angles [°]: Cr-S 283.9(1), Cr-C2 221.9(4), Cr-C4 224.7(4), Cr-C5 219.3(4), Cr-C6 217.1(4), S-O4 145.6(3), S-C2 171.0(4), S-C6 169.8(4), S-C7 177.9(4), C2-C3 152.2(5), C3-C4 150.3(5), C4-C5 138.2(5), C5-C6 145.6(5); C2-S-C6 95.0(2), S-C2-C3 114.9(3), C2-C3-C4 103.2(3), C3-C4-C5 123.8(3), C4-C5-C6 121.8(3), C5-C6-S 117.8(3).

The $\eta^3$-allyl moiety is considerably distorted, and hence the bond relationships can be reproduced best by the resonance structures **A** and **B**.

In contrast to phosphorus ylides, double-ylide ligands with sulfonium centers are rare. Compound **2d** is the first complex having such a ligand which has been characterized by X-ray structure analysis[9].

## Addition of Alkanethiols to Diketene—a Correction

By *John G. Dingwall** and *Brian Tuck*

*Hertenstein*[1] has recently reported that the acid catalyzed addition of alkanethiols to diketene gives $\beta$-lactones **1**, in contrast to the previously reported formation of the crotonic acid derivative **2a** from the acid catalyzed addition of thiophenol to diketene[2]. The thermal stability and spectral data reported by *Hertenstein* are inconsistent with the literature values[3,4] for 4-(alkylthiomethyl)oxetan-2-ones **1** and with our own observations. The IR and the NMR data (Table 1) led us to believe that the products isolated were the thermally stable isomeric $\gamma$-lactones **3**, one of which, **3a**, was previously observed[3] as a product of the thermal decomposition of $\beta$-lactone **1a**.

| [a] | 111–115°/0.06 | 1780 | 2.25–3.00 m (4H) | 3.55 m | 4.25, 4.26 ($J_{AB}=12.3$ Hz) |

[a] Compound **3a** from [1], considered there to be a β-lactone (≡ **1b**). According to the data presented here, however, it is identical to the γ-lactone **3b**.

We have reinvestigated the reaction of butanethiol with diketene under the conditions outlined by *Hertenstein*[1], and have found that the product can be either γ-lactone **3b** or the crotonic acid derivative **2b**.

Addition of butanethiol to a solution of diketene in ether at 0–5 °C generally resulted in a spontaneous, mildly exothermic radical reaction giving β-lactone **1b** in high yield. The structure of the β-lactone was confirmed by its IR and NMR (Table 1) spectra. Attempted distillation of **1b** resulted in its rapid decomposition at 80–90 °C to give a mixture containing γ-lactone **3b** (12% isolated yield). Similarly, treatment of a solution of **1b** in ether with concentrated sulphuric acid at 0–5 °C gave a mixture from which the γ-lactone **3b** was obtained in 19% yield.

The spectral data in Table 1 for **1** and **3** exhibit features characteristic of β-lactones [$\nu$(C=O), 1820 $cm^{-1}$, $\delta(H_b)$ *ca.* 4.5] and of γ-lactones [$\nu$(C=O), 1780 $cm^{-1}$, $\delta(H_b)$ *ca.* 3.6], respectively. The thermal stability and spectral data of *Hertenstein*'s lactones are clearly more consistent with the γ-lactone structure, suggesting that he isolated further reaction products of initially formed β-lactones (radical products).

When the radical reaction was suppressed by an inhibitor (*tert*-butylcatechol), addition of concentrated sulphuric acid to a mixture of butanethiol and diketone gave the crotonic acid derivative **2b**[5], analogous to the product **2a** obtained from thiophenol and diketene. The IR spectrum of the crude reaction mixture revealed that neither β- nor γ-lactones were formed.

[5] Diketene (21.0 g, 0.25 mol) is added to a cooled (0–5 °C) solution of butanethiol (22.5 g, 0.25 mol) and *tert*-butylcatechol (0.25 g) in ether (100 mL). Concentrated $H_2SO_4$ (25.0 g) is then added dropwise with stirring. On warming to room temperature, an exothermic reaction occurs and the mixture is left for a further 2 h at room temperature. The ether solution is washed with water, dried ($MgSO_4$), and the product distilled or crystallized from petroleum ether to give 3-butylthiocrotonic acid **2b** (30%), m.p. 78–80 °C; IR (Nujol): $\nu$(C=O) = 1645 $cm^{-1}$, $\nu$(C=C) = 1565 $cm^{-1}$; $^1$H-NMR ($CDCl_3$): $\delta$ = 0.95 (m, 3H), 1.56 (m, 4H), 2.82 (m, 2H), 2.41 (d, $J$ = 1 Hz, 3H, $CH_3-C=$), 5.52 (d, $J$ = 1 Hz, 1H, $-CH=$), 12.25 (s, 1H, $CO_2H$).

## 2D-NMR Spectroscopy in Annulene Chemistry: Complete Assignment of the $^{13}$C-NMR Spectrum of 9,11-Bisdehydrobenzo[18]annulene by $^1$H,$^{13}$C Shift Correlation

By *Peter Schmitt* and *Harald Günther**

*In memoriam Franz Sondheimer*

The unambiguous assignment of $^{13}$C resonances in the $^{13}$C-NMR spectra of annulenes and their ions is of vital importance for the study of bonding and charge density. However, most of the traditional assignment techniques[1] fail, since the various methine fragments have insufficiently different spin-spin coupling constants and relaxation times. Selective $^1$H-decoupling is time consuming and, in view of the signal overlap that usually exists, of limited value, especially at lower magnetic field strengths.

Here it is shown that two-dimensional (2D)-$^1$H,$^{13}$C shift correlation[2] is the method of choice to solve this problem, since the $^1$H assignment, which can be derived very often in a straightforward manner from ring current effects and $^1$H,$^1$H coupling constants, may be transferred in only one experiment to the $^{13}$C-NMR spectrum, thus identifying each $^1$H,$^{13}$C pair. The basis of this method is magnetization transfer due to heteroscalar $^{13}$C,$^1$H spin-spin coupling through one bond.

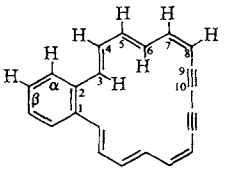

Figure 1a shows the 1D-$^{13}$C-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene **1**[3] with the chemical shift as-

[*] Prof. Dr. H. Günther, P. Schmitt

Postfach 210209, D-5900 Siegen 21 (Germany)

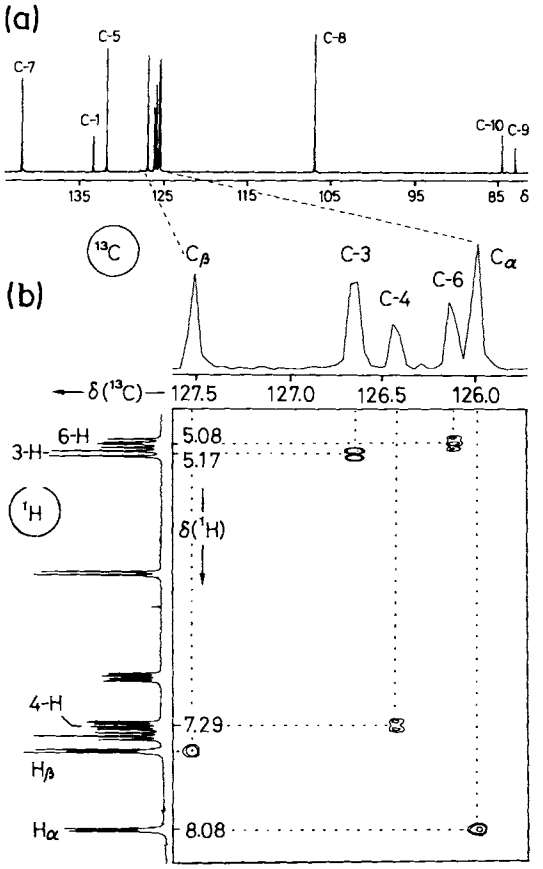

Fig. 1. a) 100.6 MHz $^{13}$C-NMR spectrum of 9,11-bisdehydrobenzo[18]annulene (0.1 M in $CDCl_3$) at 40 °C with $^{1}$H broadband decoupling (sweep width 16 kHz, 64 K data points, acquisition time 2 s, relaxation delay 4 s, 8504 transients, total acquisition time 14 h); b) section of the heteroscalar $^{1}$H,$^{13}$C correlated 2D spectrum (contour diagram) with the 400 MHz $^{1}$H-NMR 1D spectrum [3b] as ordinate and the projection of the 2D-$^{13}$C-NMR spectrum onto the abscissa; pulse sequence after [2] with $^{1}$H phase cycles [4] and a mixing time of 3 ms ($\approx 1/2\,{}^{1}J(^{13}C,^{1}H)$); data matrix format 128 × 2048, 128 accumulations, acquisition time 0.26 s, relaxation delay 3.6 s, sweep widths 4 kHz ($^{13}$C) and 1400 Hz ($^{1}$H), total time of measurement 17.8 h.

signment derived from the 2D correlation experiment. The power of the 2D technique is convincingly demonstrated by considering a section of the $\delta(^{1}H)/\delta(^{13}C)$ correlation diagram covering the $^{13}$C resonances between 126 and 128 ppm that amply illustrates the direct $^{1}$H,$^{13}$C assignment transfer. The assignment of the quarternary carbons C-1, C-9, and C-10 was made from the conventional $^{1}$H-coupled spectrum, which yields a singlet for C-1 and, due to geminal and vicinal $^{13}$C,$^{1}$H coupling, a doublet of doublets for C-9 (X part of an ABX system), together with a doublet ($^{3}J = 14.4$ Hz) for C-10. This spectrum also provided all the $^{1}J(^{13}C,^{1}H)$ data. The results are collected in Table 1.

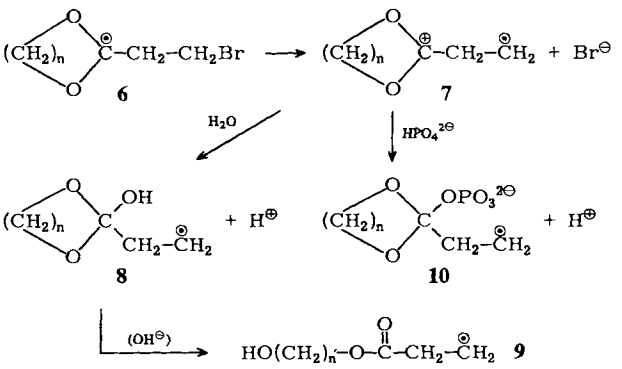
## 1,1-Dialkoxytrimethylene Radical Cations



By *Günther Koltzenburg, Günther Behrens,* and *Dietrich Schulte-Frohlinde**

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

In aqueous solution the radical **1** dissociates very rapidly into $Br^{\ominus}$ and the 1,1-dialkoxyethylene radical cation **2**, which can be detected by ESR spectroscopy and which reacts with $H_2O$, $OH^{\ominus}$, and $HPO_4^{2\ominus}$ to afford the radicals **3**, **4**, and **5**, respectively[1].

We have now found that radical **6a**, which is homologous to **1**, surprisingly decomposes under similar conditions to give the radicals **8a–10a** (Table 1), which are homologues of **3–5**. The 1,1-dialkoxytrimethylene radical cation **7a** is assumed to be an intermediate. The ring-homologous radical **6b** behaves analogously.

**6a–10a**, n = 2; **6b–10b**, n = 3

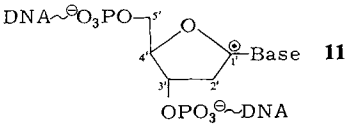
Table 1. ESR spectroscopic results on aqueous solutions of 2-(2-bromoethyl)-1,3-dioxolane and -1,3-dioxane, $10^{-2}$ M, 3 °C, H-abstraction by $SO_4^{\ominus}$ radical anions (generated from $S_2O_8^{2-}$ in a photolytic flow system [1]). Borate ($10^{-2}$ M) was used as a buffer at pH 9 and 10.



| Additional Conditions | Precursor Radicals | Observed Radicals [a] | Hyperfine Splittings [mT] 2H(α) | 2H(β) |
|---|---|---|---|---|
| pH 4.5 | **6a** | **8a** [b] | 2.23 | 2.58 |
| | **6b** | **8b** | 2.23 | 2.59 |
| pH 10 | **6a** | **9a** | 2.23 | 2.72 |
| | **6b** | **9b** | 2.23 | 2.73 |
| pH 9 | **6** | [9] > [8] [c] | | |
| pH 10 and $10^{-2}$ M $HPO_4^{2-}$ | **6a** | [10] ≈ [9] [c] | 2.22 | 2.64 (**10a**) |
| | **6b** | | 2.22 | 2.63 (**10b**) |
| pH 10 and $10^{-1}$ M $HPO_4^{2-}$ | **6** | [10] ≫ [9] [c] | | |

[a] Additionally, small signals were observed from radicals formed by H abstraction from ring positions. [b] $g = 2.0026$. [c] **8**, **9**, and **10**: steady-state concentrations of the species **8a**, **b**, **9a**, **b**, and **10a**, **b**, respectively.

$H^{\oplus}$ and $Br^{\ominus}$ were determined acidimetrically and argentometrically, respectively. For both radicals **6a** and **6b**, generated by pulse radiolysis, a half-life of $(6 \pm 1) \times 10^{-6}$ s at 20 °C was determined by measurement of the conductivity changes (for method see [1]). This half-life is assigned to the formation of **7** from **6**, which is followed by a more rapid reaction with water to yield **8** and $H^{\oplus}$. In alkaline solution a ring opening reaction (**8** → **9** ensues (Table 1).

In the presence of phosphate a competing reaction (**7** → **10**) occurs; at pH 10 and $10^{-2}M$ phosphate both the radicals **9** and **10** are formed in equal concentration (Table 1); hence, the reactions (**7** → **8**) and (**7** → **10**) have approximately the same rate. Thus, $k(HPO_4^{2\ominus}) \cdot [HPO_4^{2\ominus}] = k(H_2O)$. Assuming that the reaction with phosphate is diffusion controlled [$k(HPO_4^{2\ominus}) \approx 5 \times 10^9\ M^{-1}\ s^{-1}$] a half-life of the order of $10^{-8}$ s is obtained, which we assign to the lifetime of the trimethylene radical cations **7** in water. Cations of the type $ArylC^{\oplus}(CH_3)OCH_3$ have lifetimes of this order of magnitude in water[2]; the cations $(CH_3O)_3C^{\oplus}$ and $ArylC^{\oplus}(OCH_2)_2$ are longer lived[3].

Loss of a halogen anion at C-3 of an alkyl radical with the unpaired electron at C-1 has not been described previously. It remains an open question whether the loss of $Br^{\ominus}$ is preceded by a 3,1-migration[4] of bromine. Formation of the ions $Br^{\ominus}$ and **7** in water is made possible by solvation. Deprotonation of the radical cations to form alkyl radicals was not observed.

**11**

The loss of $Br^{\ominus}$ from **6** is considered to be a further model reaction for radical-induced strand breaks of DNA in water[5]; thus, possibly also DNA-1'-radicals **11** might undergo strand breaks by the loss of a phosphate group from the 3'-position (or in further analogy from the 5'-position).

## The Crystal and Molecular Structure of Bis(1,8-naphthalenedioxy)silane—A Contribution to the Controversy over Planar, Four-Coordinated Silicon in Orthosilicic Acid Esters**

By *W. Bibber, C. L. Barnes, D. van der Helm,* and *Jerold J. Zuckerman**

A controversy has developed in this journal concerning the structure of bis(*o*-phenylenedioxy)silane **1**, which was synthesized directly from elemental silicon by one of us twenty years ago[1].

**1**

**2**

The glassy, probably polymeric product has recently been crystallized with difficulty and shown to have a space group ($P2_1/c$), which is different from that of its orthocarbonic acid ester analogue **2** (Pccn). The latter contains the expected tetrahedral *spiro*-C atom (∢O-C-O 108.3—111.7°), but the structure of **1** could not be determined because the crystals were not stable enough. However, it was claimed that the two Si atoms in the unit cell (assuming the space group assignment is correct) must sit on centers of symmetry requiring that the $SiO_4$ system be planar[2]. This conclusion is supported by theoretical arguments which predict only a small energy difference between tetrahedral and planar silicon[2,3]. It has been claimed that the π-system of pyrocatechol should facilitate the planarization[2].

These claims have been challenged on the basis that if **1** were to have a P2/c space group, this would not require planar silicon; that possible disorder in the crystal would preclude assignment of molecular symmetry from the space group; and that it was the hydrolysis product, pyrocatechol, which has similar unit cell dimensions, that was actually examined[4]. Counter-arguments are also available[5].

We report here the structure of bis(1,8-naphthalenedioxy)silane **3** (Fig. 1).

The angles at the spiro-Si atom of **3** are tetrahedral [mean ∢O-Si-O 109.48(6)°; range 106.90(6)—111.61(6)°]. There are no short intermolecular contacts to suggest

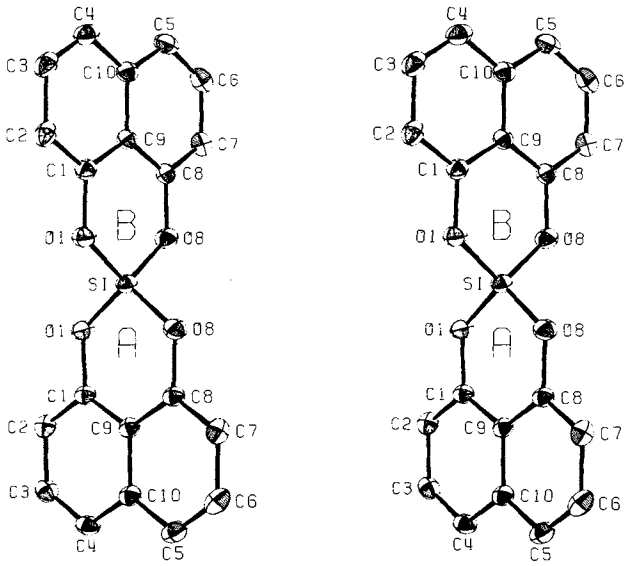

Fig. 1. Stereoview of the structure of the orthosilicic acid ester **3** in the crystal.

transformation to an octahedral geometry at silicon by interaction with donor orbitals of the oxygen atoms of neighboring molecules. The 1,8-dioxy system is held planar by the naphthalene group to give the six-membered ring homologue of **1**. The intramolecular distances in **3** are O1–O8 2.601(2) Å (mean) [2.250 Å in **2**[2]], O(1A)–O(1B) 2.676(2) Å, and O(8A)–O(8B) 2.646(2) Å [in **2**: 2.285 Å[2]], O(1A)–O(8B) and O(1B)–O(8A) 2.655(2) and 2.668(2) Å, respectively.

Thus definitive evidence for a planar, four-coordinated silicon atom remains elusive[8].

## Aerial Oxidation of Benzene in the Presence of Electrochemically Generated $Cu^+$ Ions

By *Tatsuyuki Kinoshita, Junji Harada, Sotaro Ito,* and *Kazuo Sasaki**

Recently, the oxidation of aromatic compounds using Fenton's reagent has attracted growing interest[1,2,4–6]. *Walling et al.*[2] and *Steckhan et al.*[3] reported that phenol can be produced continuously by means of electrolytic regeneration of $Fe^{2+}$ ions. In these studies is was noted that the presence of $Cu^{2+}$ ions improves the efficiency of Fenton's reagent. Recently, we showed[8] that in the presence of $Cu^+$ ions $O_2$ oxidizes benzene very efficiently; the presence of $H_2O_2$ is not necessary. Here we wish to report that the reaction can be operated continuously when the active species, $Cu^+$ ions, are regenerated electrochemically.

A small H-shaped glass cell having a sintered glass separator was used as the reaction vessel. The cathode (working electrode) material was a graphite rod (surface area 9.3 $cm^2$). The cathode potential was adjusted with a potentiostat to 0.1 V (*vs.* SCE). At this potential, $Cu^{2+}$ ions are selectively reduced to $Cu^+$: in order to stabilize the $Cu^+$ ions, a solvent consisting of 0.1 N $H_2SO_4$ and acetonitrile (9 : 1 (v/v)) was used. Benzene (1 mL) was added to the catholyte (16 mL) and air was bubbled in at controlled rates. The average current varied from 30–100 mA, depending on the $CuSO_4$ concentration. The reaction products were analyzed by HPLC.

The major product was phenol; hydroquinone and catechol were also formed together with a few unidentified compounds; biphenyl could not be detected. The ratio phenol : hydroquinone varied depending on the concentration of $CuSO_4$ (Table 1). The coulombic efficiency (mol product per *F*) is *ca.* 10% at 10 mmol/L $CuSO_4$ and 6 – 7% at 100 mmol/L $CuSO_4$.

Table 1. Yield of phenol and hydroquinone (HQ) together with coulombic efficiency (in parenthesis) as a function of the $Cu^{2+}$ concentration and air flow rate.

The reaction is highly pH-dependent, and pH control during the electrolysis is necessary. When the glass frit separator was replaced by a cation exchange membrane and a hydrogen electrode employed as counter electrode, the operational characteristics were much improved. Under these conditions, the coulombic efficiency remained constant at 8% throughout the entire electrolysis, in the course of which 500 mAh was passed.

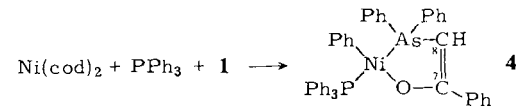
## Novel Nickel-Oligomerization Catalysts with Arsenic-Oxygen Chelate Ligands**

By *Wilhelm Keim**, *Arno Behr*, *Brigitte Limbäcker*, and *Carl Krüger*

Chelate ligands have an unusual controlling effect on nickel catalyzed oligomerization and polymerization of ethylene[1,2]. In this communication arsenic-containing chelate ligands are presented for the first time as oligomerization-catalysts.



Reaction of benzoylmethylenetriphenyl-$\lambda^5$-arsane **1** with bis(1,5-cyclooctadiene)nickel [Ni(cod)$_2$] in toluene yields an in-situ catalyst which oligomerizes ethylene under mild conditions ($T$=40 °C, $p$=15 bar). Almost exclusively linear olefins (>95%) are formed at conversions of up to 70%; the proportion of α-products exceeds 70%. Activities of 1600 mol ethylene per mol nickel and per hour are achieved.

If the methine proton in **1** is replaced by a further electrophilic benzoyl group one obtains dibenzoylmethylenetriphenyl-$\lambda^5$-arsane **2**. Reaction of Ni(cod)$_2$, **2** and triphenylarsane in the molar ratio 1 : 1 : 1 yields a catalyst system which oligomerizes ethylene with conversions of up to 99.9%. This increase in conversion is due to the strong resonance stabilization in the ylide **2** compared to in **1**. However, the linearty of the products obtained with **2** is only 60 to 80%. The arsenic-containing chelate ligands **1** and **2** show a higher ionic interaction between ligand and central atom than the analogous phosphorus compounds. This difference, however, is counter-balanced by an increased π-portion in the chelate ligand, *e.g.* by incorporation of a further benzoyl group (**2**).

Unusual is the behavior of the chelate ligand diphenylarsinoacetic acid **3**. Diphenylphosphinoacetic acid leads to good ethylene conversions and almost 100% linearity and 99% α-fraction[3], whereas with **3** only butenes and hexenes are obtained with a conversion below 1%. This difference can be explained in terms of the size of the chelate ring. Diphenylphosphinoacetic acid reacts with nickel to give a five-membered ring chelate[3]; diphenylphosphinopropionic acid (with an additional $CH_2$-group) can form only a six-membered ring chelate. Surprisingly, this complex is completely inactive. In the ligand **3** the arsenic atom, which is larger than the phosphorus atom, can now likewise lead to an expansion of the five-membered ring and thus to lower catalyst activity.

The isolation of a catalytically active complex was possible in the case of the ligand **1**. In the stoichiometric reaction of Ni(cod)$_2$, **1** and triphenylphosphane in toluene at room temperature (12 h), the complex **4** could be isolated (yellow-brown crystals, m.p. 165 °C, yield 52%). The spectroscopic data and crystal structure analysis[4,5] show that the arsenic ylide complex **4** is constructed analogously to the phosphorus ylide complex[1]. The ylide ligand in **4** is also planar (C7: −0.017 Å, C8: 0.015 Å). Other than in the case of the phosphorus ylide complex[1], however, the nickel atom tends to deviate from planarity in the direction towards tetrahedral coordination. Furthermore, a marked shortening of the Ni–P distance *trans* to the arsenic (2.208(1) Å) compared to 2.230 in the phosphorus ylide complex is observable[5].

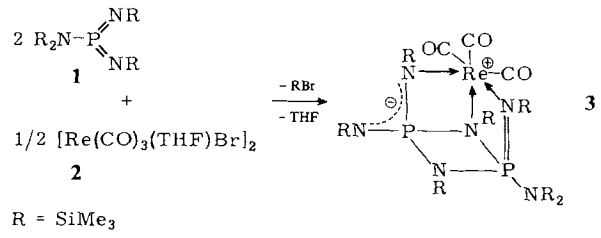
## $P(NSiMe_3)_3^{\ominus}$ — A Derivative of the Monomeric Metaphosphate Ion as Building Block for a Tricyclic Rhenium Complex**

By *Otto J. Scherer**, *Jürgen Kerth*, and *Manfred L. Ziegler*

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*



The synthesis of $R_2N-P(=NR)_2$, R = $SiMe_3$ **1**[1], the first derivative of the monomeric metaphosphoric acid $HOPO_2$ stable at room temperature[2], immediately raised the question whether the derivative **B**, formally corresponding to the monomeric metaphosphate ion **A**, could also be prepared.

Starting from $[Re(CO)_3(THF)Br]_2$ **2** and **1** we obtained the tricyclic rhenium complex **3**[4], which could be for-

[**] This work was supported by the Fonds der Chemischen Industrie through a grant to J. K.

mally derived from the monomeric $Re(CO)_3(THF)Br$ by replacing $Br^-$ by ligand **B** and the tetrahydrofuran (THF) by the double ylide **1** as 4-electron donor, and coupling the two ylide units together. Attempts to prepare **3** under the same conditions from **2** and the dimer of **1**[3a] met without success.

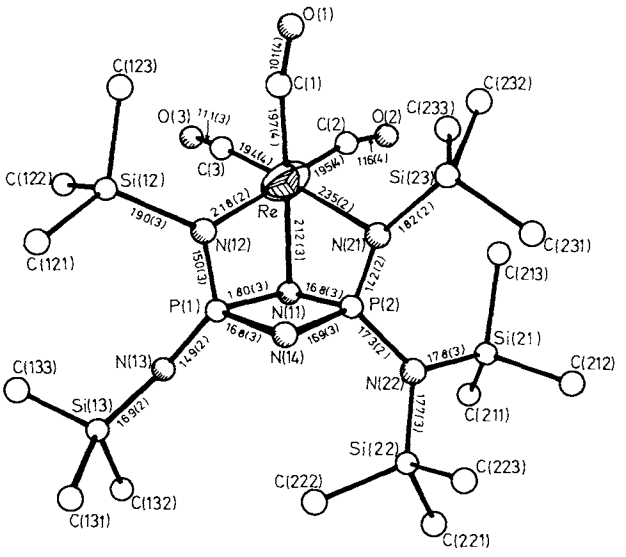

Fig. 1. Structure of 3 in the crystal (the $Me_3Si$ groups at N11 and N14 have been omitted for clarity). Bond lengths in pm. Selected bond angles [°]: N11-Re-N12 65.8(9), N11-Re-N21 64.1(9), N12-Re-N21 89.6(9), P1-N12-Re 106.1(13), P1-N11-Re 98.0(12), N11-P1-N12 89.8(13), P2-N21-Re 96.6(11), P2-N11-Re 97.7(11), N11-P2-N21 100.3(14), N11-P1-N14 85.0(13), N11-P2-N14 88.8(13), P1-N11-P2 90.8(14), P1-N14-P2 94.7(15).

**3** forms bright yellow crystals which are sensitive to hydrolysis and are readily soluble in pentane, benzene, and $CH_2Cl_2$. The $^1$H-NMR spectrum[4b] contains signals for protons of seven different $(CH_3)_3Si$ groups; this is consistent with an additional hindrance to rotation about the $R_2N-P$ bond.

The crystal structure analysis[5] confirms that **3** forms a distorted cube with a missing corner (Fig. 1). The P2–N21 bond length of 142(2) pm is unusually short; it comes within $3\sigma$ of the lowest limiting value of the shortest P=N bond length of 150.5(4) found so far[3b] in monophosphazenes. Due to the poor quality and high sensitivity of the crystals, the structure determination is relatively inaccurate. This short P=N bond length ($U$ value of P2 ($U_{eq}$) and N21: 0.042(4) and 0.042(7) Å$^2$, respectively) should therefore not be overvalued. Worth mentioning is the almost linear arrangement of the exocyclic $Me_3Si-N=P$-moiety (Si13–N13–P1 173.9(19)°).

# BOOK REVIEWS

**Chemical and Enzymatic Synthesis of Gene Fragments. A Laboratory Manual.** Edited by *H. G. Gassen* and *A. Lang*. Verlag Chemie, Weinheim 1982. x, 250 pp., bound, DM 78.00.

This book, which consists essentially of the edited protocols of an EMBO course, describes the current situation in the chemical and enzymatic synthesis of DNA. The book fills a gap by particularly emphasizing the methodological and experimental aspects and therefore is a valuable collection of methods for the synthesis, purification and analysis of DNA and RNA fragments. The chemical section surveys the synthesis of protected 2′-deoxyribonucleosides, the synthesis of DNA dimers and the synthesis of oligodeoxynucleotides on polymer carriers, according to the phosphate triester and phosphite triester methods. The biochemical section describes, *inter alia*, the ligation of DNA fragments, the construction of recombinant plasmids and the use of RNA-ligase for the synthesis of oligonucleotides. Finally, there is a chapter on the purification and analysis of DNA and RNA fragments by chromatography and sequencing techniques.

Because of the nature of the subject the choice of themes in this volume lacks uniformity. In spite of this it contains a great deal of valuable information, so that it constitutes a veritable handbook for those who wish to take up DNA synthesis.

The editors mention in the foreword that the methods have now become so simple that they can be employed by

non-chemists. The reviewer believes this statement to be overoptimistic. Even chemists, who are not themselves experienced in nucleotide chemistry, will not directly be able to synthesize, purify, analyze and enzymically ligate defined, oligonucleotide chains solely by having this excellent collection of experimental data at hand. However, anyone who wishes to initiate work on the synthesis of DNA is recommended to study this book.

*Hubert Köster* [NB 588 IE]

**Carbocationic Polymerization.** By *J. P. Kennedy* and *E. Maréchal*. John Wiley and Sons, Chichester 1982. xx, 510 pp., bound, £ 55.50.

On the one hand, the technical preparation of polymers by cationic polymerization is limited to a few monomers *e.g.* isobutylene, vinyl ether and trioxane. On the other hand, about 5—7% of all scientific publications on polymers are concerned with the mechanism, kinetics or thermodynamics of cationic homo- and copolymerization, with monomer or oligomer synthesis.

It is, therefore, to be welcomed, that two competent authors, with many years of experience in the field, have now produced a broad-based review of this constantly developing area.

The two introductory chapters pay special attention to the individualities of cationic polymerization, as well as explaining some general concepts and the nomenclature. Compounds are defined as "cationic monomers" that are "cationizable" and able to cationize other molecules of the same compound, independent of whether a high molecular weight polymer is formed thereby. About 200 compounds (with few exceptions, unsaturated hydrocarbons), which conform to this definition, are assembled in a table. Most of them, however, only form oligomers. Unfortunately, literature references are not included in the table; the reader is referred to an earlier book by *J. P. Kennedy* (Cationic Polymerization of Olefins: A Critical Inventory; Wiley, Chichester 1975). Further tables list commonly used initiators, of the Brønstedt acid, carbocation salt and Friedel-Craft compound types. The chemistry of carbocationic polymerization is dealt with very thoroughly in Chapter 4. For the most thoroughly investigated monomers such as styrene, isobutylene, vinyl ether and some of the longer chain α-olefins, the initiation reactions (including photo- and electroinitiation), the propagation, termination and transfer reactions and the "inifer method" developed by *Kennedy* are described. The emphasis in all this is on the chemical aspects. A relatively short chapter on kinetics follows.

Chapters 6 and 8 on the formation of copolymers are worth particular mention. After a critical discussion of the methods of parameter determination follows a table encompassing 643 polymerization systems (oxacycles are excluded) with $r_1$ and $r_2$ values taken from the literature and after recalculation according to the Kelen-Tüdös method. Then follows a discussion of theoretical considerations for the calculation of the reactivity together with the effect of experimental conditions as well as of steric and electronic factors. The chapter on block and graft copolymers prepared by carbocationic reactions is very stimulating. The chapter on "macromolecular engineering" conveys the impression that this field is in a state of flux and that all the possibilities have not yet been exploited. The last chapter gives a short outline of the industrial application and technical aspects with emphasis on polyisobutylene and polyvinyl ether. A short section by *R. W. Lenz* and *J. E. Chandler* describes step-growth polymerizations proceeding *via* a Friedel-Craft alkylation mechanism, by reference to a few examples.

Each chapter is accompanied by a comprehensive list of references, arranged according to the authors (numbered references would have been much more appropriate here). The subject index is adequately comprehensive and very helpful. The printing and formulae are good and free from all but minor errors. The formulae on page 437 do not correspond to the text; isobutylene and PiB have to be substituted for styrene and PSt. The discussion of vinylamine on page 33 is superfluous, since this monomer does not exist.

This book can be heartily recommended to all who are active in polymer chemistry or who would like to achieve a quick, comprehensive survey. It is to be desired that advanced students have access to it in their departmental libraries and are, thus, stimulated to study it.

*Rolf C. Schulz* [NB 590 IE]

**Topics in Current Chemistry 103: Preparative Organic Photochemistry.** By *P. Margaretha*. Springer Verlag, Berlin 1982. x, 89 pp., bound, DM 48.00.

The lively development of organic photochemistry and its successful application in the synthesis of natural products makes a topical review of synthetically attractive phototransformations desirable. *Margaretha* attempts to supplement the book of the same title by *A. Schönberg* published in 1968. However, as the author states in the introduction, it would be a difficult task to present the current state of organic photochemistry, which has, in the meantime, acquired an interdisciplinary character, according to this example. A subjective selection has been made of the plethora of examples of application and an attempt has been made to fill in gaps in the literature. This has been partially successful. This little book commands the attention of the practising chemist with a sceptical attitude to photochemistry and, furthermore, it offers the beginner an easy entry to the field.

After a general introduction to photochemistry follow chapters on cleavage, addition and substitution reactions. Next the multitude of rearrangements are treated as are reactions with singlet oxygen. The book terminates with references to experimental technique. The shortest possible, theoretical treatment of photochemistry in the introduction conveys some of the fascination of the mechanistic aspects. The subjective choice of the examples has led to some of the chapters being too short, so there are limits to their representative nature. For example the subsection on nitrogen extrusion, alongside the transformations treated there are also important applications in the field of natural product synthesis. It is also noticeable that the work of important groups, such as that of *G. Berson*, is not represented. A final criticism is concerned with the guidelines contained in the addendum which summarize the experimental techniques. Because of their brevity they do not contain very much information and do not refer to indispensable reference works like that of *Calvert* and *Pitts*.

In spite of the faults mentioned the book fulfils the desired aim. Its strength lies in the clear presentation which quickly brings the reader into contact with the important

aspects of the subject. It indicates very well, how the wealth of mechanistic knowledge enables photochemical reactions to be incorporated into directed, synthetic sequences. It will not only interest students but also help the practising chemist to break new ground.

# A Quarter Century of Thin-Layer Chromatography—An Interim Report

By Egon Stahl*

*Dedicated to Professor Wilhelm Fresenius on the occasion of his 70th birthday*

Thin-layer chromatography (TLC) has been in general use since 1958. The prerequisites were the use of very small particle size material in the layers and the demonstration that not only lipophilic mixtures but also mixtures of cardiac glycosides, alkaloids, sugars, and amino acids could be separated quickly and simply on silica gel layers. The impressive separations obtained using the method later encouraged attempts to use adsorbants having such, narrow-range small particles in column chromatography. In order to achieve sufficient flow rates the use of high pressures was necessary. Thus, high pressure or high performance liquid chromatography (HPLC) was born, whose godfather, as far as instrumental development is concerned, was gas chromatography (GC). Today, chromatography is classified according to the nature of the transport phase: liquid, gas, or "electro" chromatography. Sample preparation often requires more time than the actual separation. Rapid thermal separation and application techniques (TAS, TFG) have brought advantages to TLC. As before, the art of chromatography consists in choosing the appropriate mobile phase, stationary phase, and separation technique. Gradient TLC offers new possibilities; for example, gradient layers make it possible to obtain selective information on the individual components of a mixture and also allow significant focussing effects to be achieved. Sequential and centrifugal TLC have paved the way for further advances. The questions arise whether the standard conditions, formulated 25 years ago, are still applicable and how the variations which have been introduced should be judged. Group- and substance-specific methods of detection are discussed in addition to universal methods. Quantitation is critically discussed and it is concluded that HPLC has the better chance in the future. Combination and coupling techniques ease the positive identification of individual substances. Finally, it is discussed why TLC is the simplest, most versatile, most cost effective, and most widely used chromatographic method and reasons are proposed as to why it will remain so for the foreseeable future.

## 1. Historical Introduction

The principle of thin-layer chromatography, that is a thin, separating layer on a glass plate, has been known for almost 100 years (cf. Table 1). The question arises as to why neither the pioneering research of *Beyerinck*[1] nor subsequent contributions led to the general adoption of the method. My first contribution to this physico-chemical separation technique, with the publication in 1956 of an article[6] entitled "Dünnschicht-Chromatographie" (thin-layer chromatography), a term which was new at the time,

was ignored just as much as its predecessors. The breakthrough only occurred when Merck was persuaded to produce a special grade of silica gel for thin-layer chromatography (TLC) and Desaga to manufacture the basic equipment and accessories. These were both first presented in 1958 at the International Chemistry Exhibition (ACHEMA) in Frankfurt am Main, and aroused great interest.

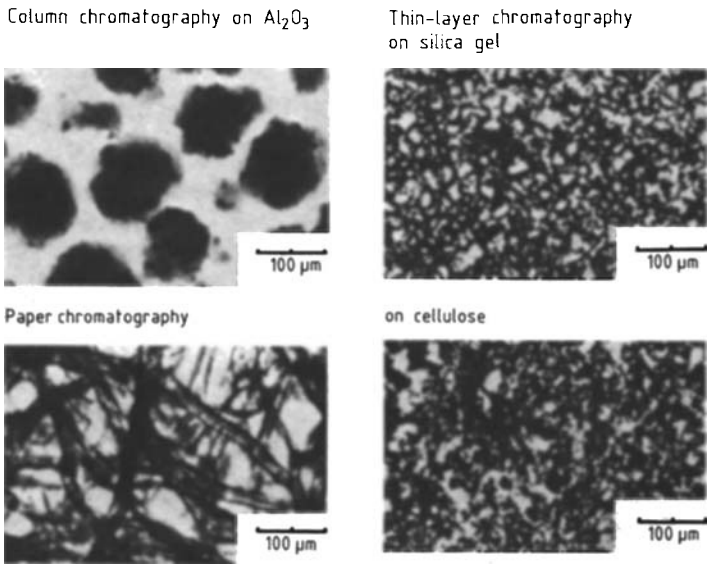

Fig. 1. Comparison of particle sizes of adsorbents for classical column chromatography, paper chromatography, and thin-layer chromatography.

Thin-layer chromatography was soon in general use under the recommended standard conditions[7]. The real scientific advance, however, was not the possibility of manufacturing thin layers, but the use, based on our years of investigation, of a much finer particle-sized material than previously had been used as a stationary phase in chromatography (cf. Fig. 1). The first commercial adsorbents for TLC, however, left something to be desired; the problem was the difficult manufacturing technique required to produce fine particle sizes and narrow fractions.

The fact that TLC was not limited to the separation of terpenes[4], but that a form of partition chromatography of *e.g.* cardiac glycosides, saponins, alkaloids, amino acids, and sugars is also possible on thin silica layers, was also a further advance. The range of applications could, therefore, be extended to numerous separation problems in chemistry, biology, and medicine. The first laboratory handbook on thin-layer chromatography appeared in 1962, under the combined authorship of a group of specialists, and led to a further dissemination of the method[8].

Table 1. Development of thin- layer chromatography.

| Year | Authors | Method designation | Ref. |
|---|---|---|---|
| 1889 | Beyerinck | Simple diffusion experiment | [1] |
| 1938 | Izmailov, Schraiber | Drop-chromatography | [2] |
| 1949 | Meinhard, Hall | Surface chromatography | [3] |
| 1951 | Kirchner, Miller, Keller | Chromatostrip technique | [4] |
| 1954 | Reitsema | Chromatoplate technique | [5] |
| 1956 | Stahl | Thin-layer chromatography | [6] |
| 1958 | Stahl | TLC standardization, basic equipment, Kieselgel G Merck | [7] |
| 1962 | Stahl (Edit.), Bolliger, Brenner, Gänshirt, Mangold, Seiler, Waldi | TLC Laboratory Handbook | [8] |

The instrumental development of gas chromatography (GC) occurred almost in parallel with the further development of thin-layer chromatography, but it was some time before it was realized that GC is not a universal separation method and that the classical Tswett column chromatography also exists. The separating capacity of fine particle size layers used in thin-layer chromatography stimulated attempts to pack columns with these materials. Since almost nothing would pass through such closely packed columns it was necessary to force the solvent through by the application of pressure. Thus, high pressure liquid chromatography was a necessary consequence of the fine particle size of the packing. Thin-layer chromatography has, in this manner, undoubtedly decisively influenced the further development of chromatographic techniques. A caricaturist might see the development as shown in Figure 2.

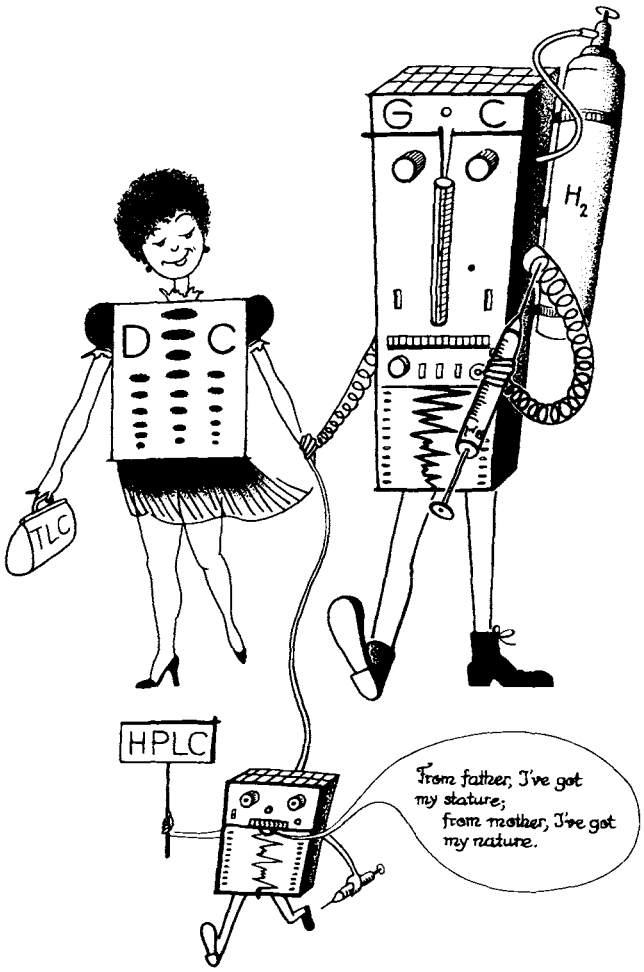

Fig. 2. A happy family.

## 2. Chromatographic Techniques Today

To obtain a topical view of chromatographic processes it is appropriate to classify them into three large groups according to the "transport phase"; that is into liquid, gas

and electro chromatography (Fig. 3). Liquid chromatography includes classical column chromatography, paper chromatography, thin-layer chromatography, and high pressure liquid chromatography, as well as exclusion chromatography.

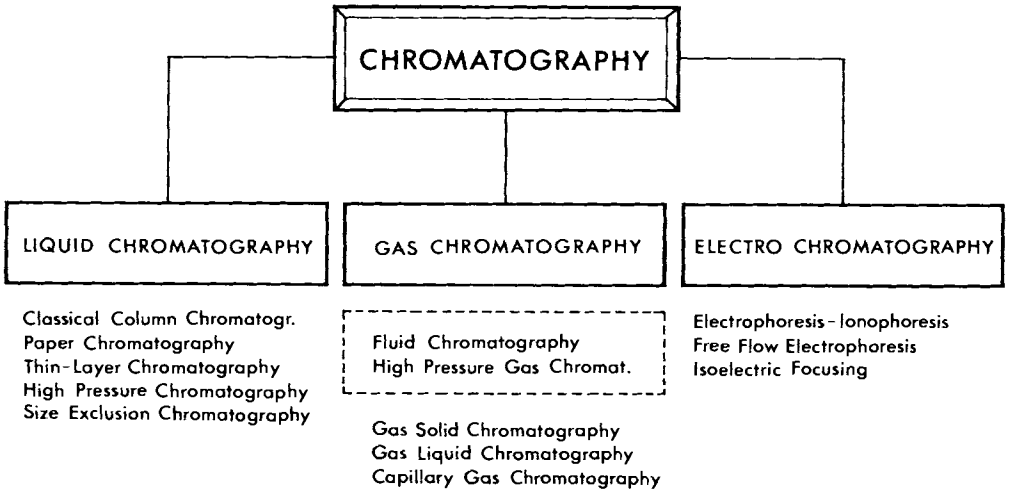

Fig. 3. Classification of chromatographic methods according to the mobile phase.

If one wishes to compare the advances made in chromatography it is first necessary to divide these methods, which are intrinsically complex, into their three components and to analyze each of these individually. The scheme shown in Figure 4 indicates the three main components of each chromatographic method together with the preceding and following steps. Advances of varying degrees have been made in all five chromatographic steps in the last few years.

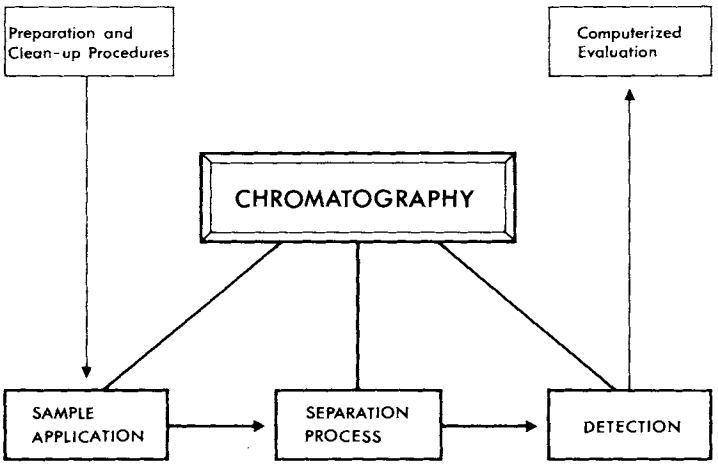

Fig. 4. Chromatography is a three-stage process; sample preparation and quantitative evaluation are also involved.

Experience has shown that sample preparation, clean-up, and preparation of the application- or injection-solution are often more time consuming than the actual chromatography. Since 1968, we have, therefore, developed methods for transporting the substances from the sample directly "on line" onto the thin layer without the use of solvents. Suitable for this purpose are, *inter alia*, thermal techniques and microextraction with supercritical gases. The thermo-micro application of substances (TAS) technique can be used to transport essential oils from drugs and many other substances directly, within 1 or 2 minutes, onto the thin layer[9, 10]. Further development led to thermofractography[11], a technique that has seen relatively little application until now.

## 3. Chromatographic Parameters

The first step, *sample application* (cf. Fig. 4), is important for the success of chromatography. It must be adapted to the particular problem and to the sensitivity of detection. The amount of sample may be more and more reduced, but it must be remembered, that trace components will then, in most cases, be undetectable, because the sensitivity of detection is inadequate. As a rule of thumb, when the purity of a substance is to be checked a relatively large sample should be used in order to detect trace components; if, however, a mixture of substances is to be investigated the amount applied should be reduced in order to provide a better overview. The sample applicator should be as cheap as possible conformable with the desired success. It is remarkable that manual application in a streak, as recommended in most cases by the European Pharmacopeia, leads to improved chromatograms and allows clear, qualitative evaluation.

The actual heart of the chromatographic process is the *separation* itself (Fig. 4). Figure 5 presents schematically the range of variables available in thin-layer chromatography. It rests on the skill of the user to adjust and compensate the manifold possibilities in order to achieve an optimal separation.

The scheme indicates that three main parameters must be considered; the choice of the *stationary* and the *mobile phases* and of the most suitable *separation technique*. The particular advantage of thin-layer chromatography is that it is simple to adjust these parameters with respect to each other and to check the success of the separation. The introduction of pre-manufactured separation layers at the be-

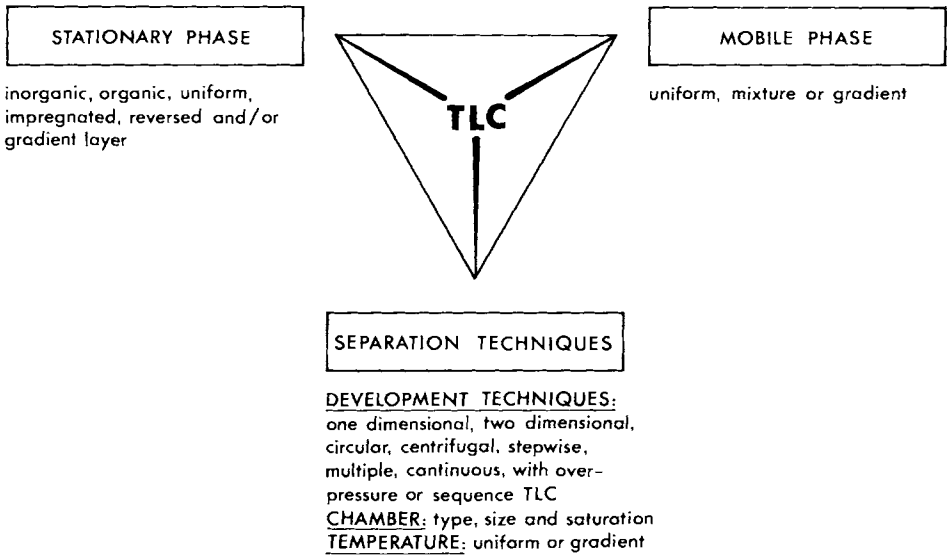

Fig. 5. The multitude of variable parameters in thin layer chromatography which must be mutually adjusted to achieve optimal conditions.

ginning of the 1960s was certainly a success as far as further dissemination of the method was concerned. It is to be hoped that even more and diverse layers with different separating properties will come onto the market. The industrial manufacture of derivatized silicas (RP phases) that allow reversed phase chromatography without impregnating the layer is a step in the right direction. A successful future can be predicted for such adsorbents and ready-prepared layers. Industrially manufactured gradient layers would be desirable: layers with so-called concentration zones are a step in this direction. The introduction of gradient layers was a milestone in the further evolution of thin-layer chromatography[12-14]. The new possibilities it opened up will be demonstrated with the aid of the following examples.

As is well-known, a gradient layer can be developed in three directions: the chromatogram can be developed across the gradient or in two directions along it. The pH

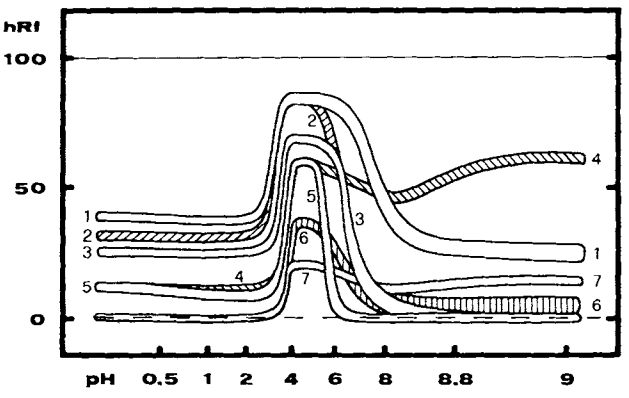

Fig. 6. pH-*T*-gradient TLC of seven sulphonamides: 1 sulfaphenazole, 2 sulfisoxazole, 3 sulfacetamide, 4 sulfanilamide, 5 sulfathiazole, 6 sulfisomidine, 7 sulfaguanidine. Mobile phase: benzene-2-propanol (80+20), 2×12 cm, chamber saturation. Detection: fluorescamine, $UV_{365}$.

gradient layers are particularly interesting. If, for example, a mixture of seven sulfonamides is chromatographed, it can be seen from the shape of the curves that, apart from sulfanilamide and sulfaguanidine, they are amphoteric substances. The pH-*T*-chromatogram (Fig. 6) shows, furthermore, that no pH region exists where all seven substances can be separated from each other.

The separation of the seven most common benzodiazepines on a pH-*T*-gradient layer is also interesting[15]. In the developed chromatogram (Fig. 7) the basic character of the substances is evident; the separation takes place in the sequence of the $pK_a$ values.

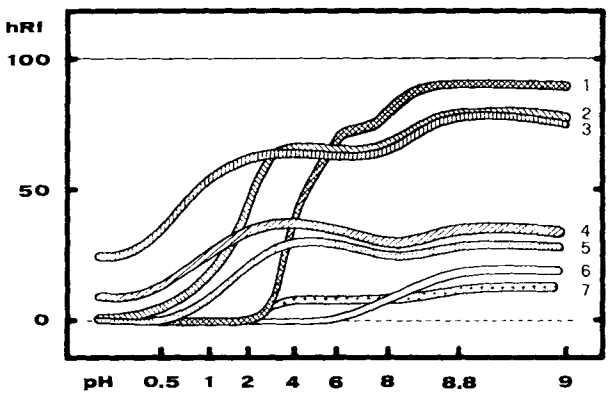

Fig. 7. pH-*T*-gradient TLC of seven benzodiazepines viewed under long wavelength UV light after being sprayed with sulfuric acid: 1 medazepam, 2 diazepam, 3 flunitrazepam, 4 clonazepam, 5 nitazepam, 6 flurazepam, 7 chlordiazepoxide. Mobile phase chloroform-acetone (90+10), 2×10 cm, chamber saturation. Detection: 8 N sulfuric acid, $UV_{365}$.

Such pH-*T*-gradients are very well suited to the study of decomposition phenomena, for metabolic studies, and for the detection of impurities in syntheses. No other technique enables such subtle differences to be detected. A fur-

ther possibility is to develop the plate along the gradient. We have discovered a focussing effect in this mode[14, 16]. Whereas with increasing developing distances the zones normally become broader, in TLC-focussing, by analogy to the phenomenon of isoelectric focussing, narrowing, on occasions pronounced, of the bands occurs. As shown in Figure 8, more than 20 components can be detected in a mixture (developed in the acidic to basic direction) on a gradient, whereas only 9 components are resolved in conventional chromatography on a uniform layer. The problems associated with manufacturing gradient plates can surely be overcome.

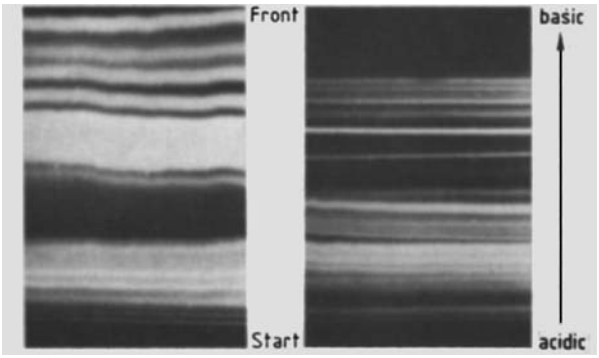

Fig. 8. Focussing of a mixture of fluorescent dyestuffs by thin-layer chromatography on a gradient from "acidic" to "basic" (on the right); for purposes of comparison, a standard, uniform silica gel layer is shown on the left.

Adhesive stability and abrasion resistance are important for both gradient and normal, monotonic layers. These parameters must be neither too high nor too low. A special apparatus for measuring the abrasion resistance of layers has proved of value in testing binders[17]. An "abrasive weight" of 200 g seems optimal. As before, suitable organic plastic binders are, unfortunately, not available commercially for those who wish to manufacture their own TLC layers.

There have not been any spectacular developments in *mobile phases*. The eluotropic series has proven itself in adsorption TLC and the classification of solvents according to polarity and approximately according to dielectric constant can be advantageous. Benzene should not be used as a solvent on account of its established toxicity; toluene or the somewhat more polar dichloromethane should be employed instead. An attempt to market solvent mixtures with increasing dielectric constants did not meet with success. The old proven technique of gradient elution has also failed to establish itself in thin-layer chromatography.

The largest number of degrees of freedom in thin-layer chromatography are available in choosing the *separation technique*. Alongside the possibilities of ascending development and descending development there is also the possibility of horizontal development in special chambers. Further variations are two-dimensional, centrifugal and radial development. Stepwise development has also proven very useful, as has multiple development. Recently, horizontal development in so-called mini-chambers, which enable economies to be made on solvents, has aroused renewed interest. A pressurized TLC chamber (Chrompres 10)[18] and the ingenious "sequence TLC"[19] are new. All these techniques offer particular advantages, and it is necessary to understand them properly in order to utilize them to advantage.

The classical TLC development troughs have seen little change. Very small chambers have come into use and are used as dipping chambers[20]. As well as the established low temperature TLC[21], use of a temperature gradient during development[22] has been investigated. The temperature gradient causes increasing evaporation of solvent and, hence, focussing of the zones[23, 24]. In order to separate substances that are almost insoluble at room temperature, as for example many organic dyes and pigments, TLC at 150 °C on silica gel using suitable solvents that can be classified according to their elution effect can be recommended[25]. Centrifugal TLC has attracted great interest in the last few years and has led to the development of the "Chromatotron" in the United States. In this device the mixture is separated on a spinning disc (Ø 24 cm), which carries a thin separating layer of 1 to 4 mm thickness. The advantage of centrifugal TLC lies in its ability to rapidly separate preparative quantities of from 0.1 to 1 g (Fig. 9). We also have investigated this method[26] in order to establish its advantages and disadvantages.

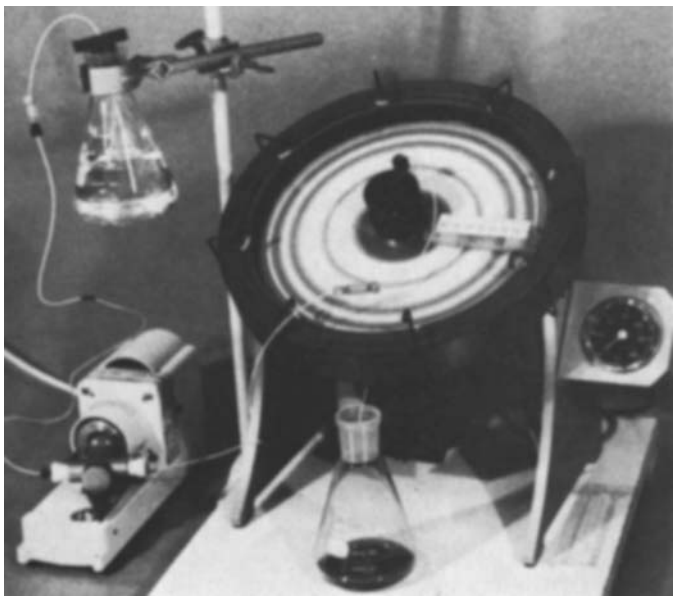

Fig. 9. Centrifugal TLC with the Chromatotron for preparative separation of a mixture of substances.

## 4. Standard Conditions and Variations

Our discussion of the three parameters of thin-layer chromatography raises the question of whether the standard conditions formulated 25 years ago are still valid today. The scheme laid out in Figure 10 shows the variations put forward up till now. In choosing the standard conditions we were striving for a handy, square plate which was versatile enough to accommodate all possibilities. We suggested 20 × 20 cm for its size, a layer thickness of 0.25 mm, and a 10 cm long separation zone. The early introduction of these standard conditions for TLC has simplified the

task of all manufacturers producing accessories, up to and including expensive scanners.

The standard conditions have been modified in five ways (cf. Fig. 10). For example, for preparative purposes the plates have been increased to a width of 100 cm and the layer thickness to 1–2 mm; this technique was christened "preparative TLC" or "layer chromatography"[27]. Nowadays, however, the tendency is more and more to use standard 20 × 20 cm plates for preparative work[28].

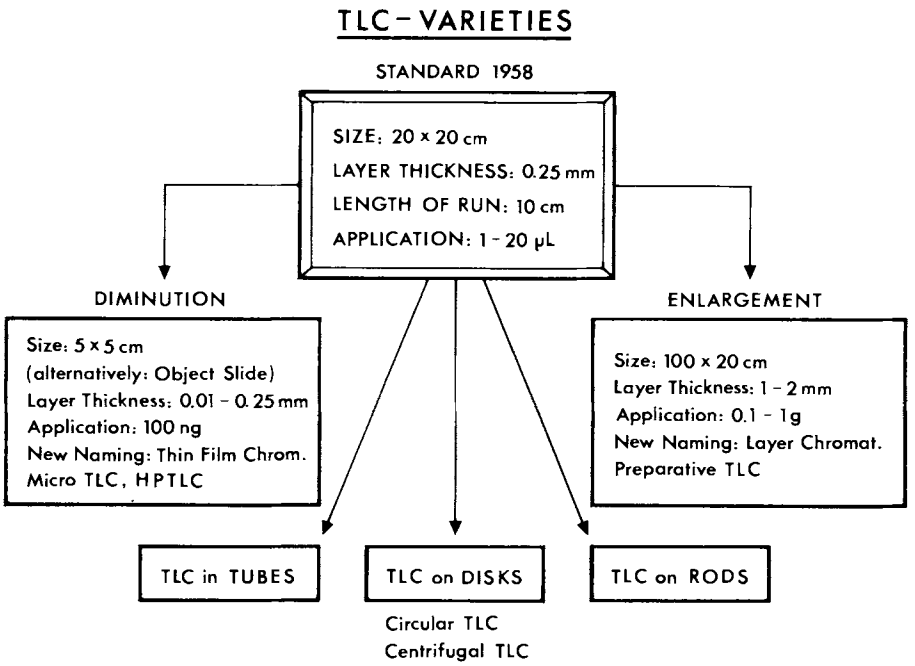

Fig. 10. Variations to the standard conditions for TLC formulated in 1958.

Another development has been to reduce the format to that of a microscope slide or a projection slide (5 × 5 mm). This raises the question of whether the separation zone is long enough. The advantages and disadvantages of this micro TLC or thin-film chromatography[29], which recently has come to include HPTLC or nano-TLC[30], must also be considered from the point of view of costs. Sometimes it is forgotten that subsequent coupling processes often require µg amounts of substance, which cannot be provided by a nano-TLC method. The future will decide whether the time is yet ripe for a smaller format. If it is, then the work of *Szekely*[31], who indicated that this can be done economically by dividing normal commercial 20 × 20 cm plates into four handy 10 × 10 cm plates, should be remembered. Suitable solvent-saving developing troughs are commercially available.

TLC in *tubes* was also advocated at one time; this variant, however, is now almost forgotten. TLC on glass *rods* is also scarcely utilized. For the historical record, I would like to interpolate that 33 years ago I performed chromatography on magnesia rods and grooves, and it was this that ultimately led me to TLC. TLC on plates also includes the circular TLC proposed by *Ismailov* and *Schraiber*[2], which preceded "circular filter paper chromatography". The attempts of many authors—ourselves included—have, as yet, failed to achieve the breakthrough for this method.

## 5. Detection in Thin-Layer Chromatography

Detection of the separated substances is essential in every chromatographic method. It is possible today to separate chromatographically molecule A from molecule B or molecule C; it is, however, not always possible to demonstrate such a separation because the detectors are too insensitive.

The detection problems are very different in the various chromatographic methods. In gas chromatography and high pressure liquid chromatography the separated substances are detected at some expense in a flowing system. This requires flow-through detectors and potentiometric recorders. The number of possible methods in these techniques is, therefore, strictly limited. The situation for TLC is quite different. Here, detection is performed after all the components have been separated, *i.e.* under stationary conditions. The possibilities here are enormous and this is an extraordinary advantage of the method.

As well as destructive methods using aggressive reagents, many non-destructive detection methods are available in TLC. As a rule, it has been found advantageous to initially use one or more non-destructive detection methods, *e.g.* examination of the chromatogram with several wavelengths of UV light—possibly using a fluorescent layer—and only then to resort to one or more destructive reactions that cause, for example, coloration.

For objective evaluation, the numerous detection reactions can be divided into three large groups (Fig. 11). Depending on the problem, either one or other of them will be preferred or they will be used consecutively. For mixtures of unknown composition, techniques capable of detecting as many of the components as possible are required; a universal detector is needed. This aim is only partially realizable with TLC, *e.g.* by UV absorption on

fluorescent layers or by oxidation reactions that produce coloration and ultimately carbonize all organic materials.

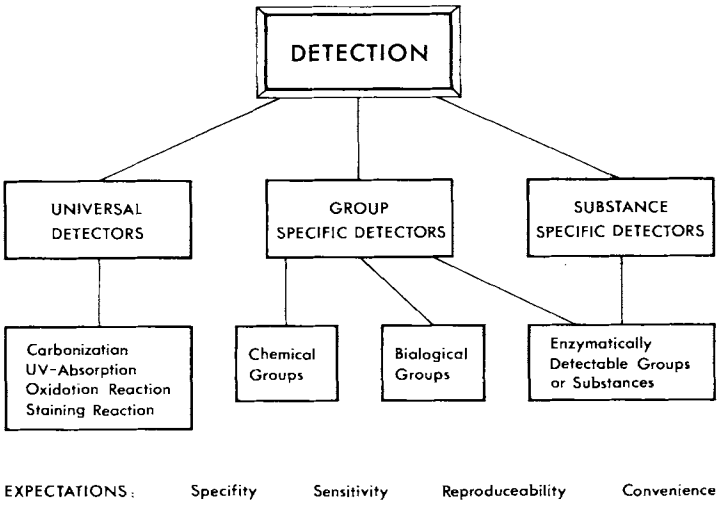

Fig. 11. Arrangement and classification of the numerous possibilities for visualization (detectors!) in TLC.

Currently, sulfuric acid-aldehyde reagents are most frequently used for detecting the separation of mixtures of natural products. It has recently been shown that the reaction takes place stepwise, and that anisaldehyde is the most suitable of the many aldehydes investigated[32]. The application of the ANSA reagent (8-anilino-1-naphthalenesulfonic acid) represented a great step forward in the detection of unreactive lipids, hydrocarbons, fats, and plasticizers[33]. Only at the end of last year an improvement on this, in itself a sensitive reagent, was suggested; the TNS reagent[34] (6-*p*-toluidino-2-naphthalenesulfonic acid). The INPTC reagent, a tetrazolium chloride derivative which reacts with plasticizers, long-chain fatty acids, higher aliphatic aldehydes, and other substances to produce different colors[35], is also worth mentioning here.

After the "universal" reagents the group-specific detection methods claim attention. One class reacts specifically with particular functional groups, for example with phenolic, alcoholic or carbonyl groups; the other class can be designated as "biological detectors".

Of all the reagents that react with chemical groups fluorescamine (Fluram Roche) has undoubtedly excited the greatest interest in the last decade. It was described by *Weigele et al.* for the detection of primary amino groups, and partially displaced the classical ninhydrin reaction. The possibilities for its application (*e.g.* [37–40]) have in no way been exhausted, as may be demonstrated by the following example. In the last few years, in Spain 300 people have died and more than ten thousand have become ill as a result of consuming cooking oil contaminated with aniline (2 ppm) and with anilides (up to 2000 ppm). Aniline and, in particular, the anilides could only be detected with difficulty. On the one hand, complicated sample preparation was followed by analysis and detection by GC-MS, and, on the other, non-specific TLC detection was used, *e.g.* using potassium permanganate. Only later was it shown, using only a 10 μL sample, that the anilides can be thermally cleaved in 90 sec with soda lime (TAS method) and that the aniline formed can be reliably detected at concentrations down to 1 ppm using the fluorescamine reagent[41]. The fluorescence reaction of aniline with *o*-phthalaldehyde is slightly less sensitive. If this method had been available at the beginning of the catastrophy then it would have been possible to analyze hundreds of samples per day and to quickly confiscate large amounts of the oil.

A further group-specific reagent, the long-established 4-nitrobenzylpyridine (NBP), is very interesting in this context; using it, it is possible to detect alkylating agents on the chromatogram[42–45]. It is widely known that alkylating agents, such as epichlorohydrin, are strongly carcinogenic; recently, *Braun et al.* have demonstrated the alkylating activity of valepotriates in valerian species[46] using this simple method.

Further advances in the field of TLC detectors can be made by systematically developing reagents that react with functional groups to form colored or fluorescent products.

The application of so-called biological detectors is very useful in certain problems, since certain biological activities can be established on the microgram scale using certain techniques. For example, using TLC it can be established what substances in a microbiological culture have antibiotic activity and against which microorganisms they are active. Parallel investigations can establish which of the substances on the chromatogram are hemolytic (cf. [47]).

The field of application of such biological detectors is a very broad one. The use of small organisms such as aedes larvae as "guinea pigs" to detect the insecticidal activity of synthetically modified pyrethrum compounds by TLC (TRT method)[48] is only one example.

The advantages of substance-specific detection in TLC have been largely neglected. The solution of some problems is facilitated when it is possible to detect one substance in a mixture, specifically, for example glucose in a mixture of sugars. This can be realized using a fermentation reaction catalyzed by glucose oxidase. The possibility of detecting specific substances in this manner will probably be restricted to enzymatic detection systems even in the future.

*Geike*[49,50], in particular, has made considerable advances in detecting plant protection agents with enzymic detectors. He was able, for example, to detect insecticidal carbamates enzymatically, recognize phosphatase inhibitors, and discover trace metals by this method. The area has been reviewed up to 1974 by *Mendoza*[51].

In this connection, a new investigation of a sensitive, enzyme-catalyzed color reaction for the detection of hydrogen peroxide and other peroxides on TLC plates ought to be mentioned[52]. The technique of allowing substrates to react with enzymes at the point of application, followed by TLC separation, is also of interest. TLC plates with concentration zones have been used successfully in this context. A contribution towards elucidating the structures of high molecular weight glycosphingolipids has been made on TLC layers using this method[53].

Finally, it is appropriate to make some observations on the sensitivity of detection in TLC. In spite of the relatively simple facts the situation is often unclear. The sensitivity

of the detection system used for a substance can vary by as much as a factor of 100 or even 1000. A simple diagram illustrates this (Fig. 12). A mixture of the four substances A,

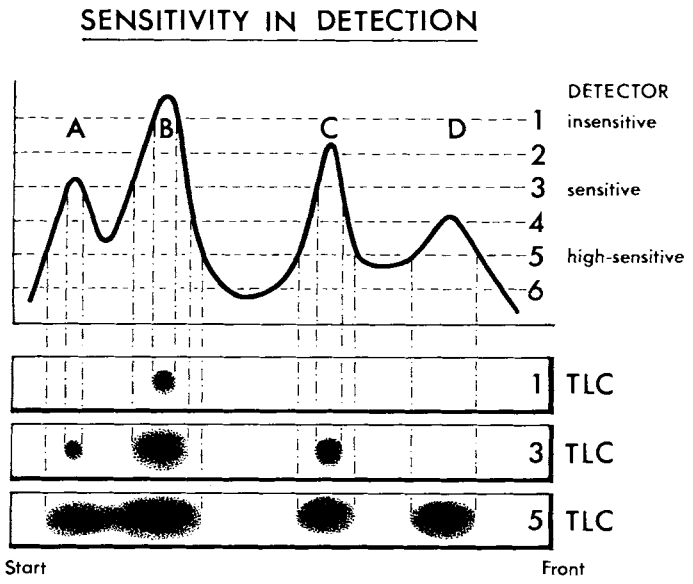

Fig. 12. Schematic representation of the sensitivity of detection using the example of a mixture of four substances and visualizing reactions of varying sensitivities.

B, C, and D at different concentrations is separated and the substances visualized using three reagents of varying sensitivity (1, 3, and 5). With sensitive reagent No. 3, three zones can be made out, as shown in the scheme; however, with the less sensitive reagent No. 1, only one is detected. The very sensitive reagent No. 5 indicates that substances A and B overlap, and that next to C there is a small amount of highly diluted substance D. Depending on the problem posed one can choose what one wants to see.

## 6. Quantitative Evaluation of TLC

In addition to simply scraping off the separated zone and eluting the substance, which is subsequently determined quantitatively, photometers were used right from the beginning of thin-layer chromatography, just as they were for the evaluation of paper chromatograms and electrophoresis strips. In the 1960s, special photometers were manufactured for TLC and were further developed in the 1970s. A top-quality instrument in this field was the computer-controlled TLC spectrophotometer from Zeiss. The high cost of such sophisticated machines and the development of HPLC raise the question as to which method is preferable for routine purposes. Without doubt, the evaluation by TLC has the advantage that many samples can be run on a chromatogram alongside each other, whereas HPLC can only cope with one sample at a time. However, sample removal and quantitative evaluation are an integral part of the instrument in HPLC and it is not necessary to set up an expensive measuring station. In my opinion, the argument lies in favor of HPLC. It is strengthened by the possibility of round-the-clock, automatic sample injection.

Consideration of all the facts leads to the conclusion that complicated, computer-controlled instrumentation does not represent a realistic, long-term solution for TLC. It is my belief that the simple, cheap, visual comparison of zone sizes is more suitable than an expensive instrument. Some specialists who possess such an instrument and the manufacturers will criticize this opinion, but not the majority of scientists who utilize chromatographic methods and are not tied to one particular technique. In my opinion, the various chromatographic techniques are complementary in the hands of a competent analyst, who is able to use them as a conductor uses his orchestra.

## 7. Combination and Coupling Techniques

The $R_f$ values in TLC are coefficients, but not physicochemical constants. Thus, they are only of limited value for identification purposes. For this reason, the combination or coupling of TLC with other more conclusive methods is of particular importance. In the simplest case, it can be seen that performing and observing one or more color reactions, which are often used for detection, already constitutes another criterion for identification. This is, however, insufficient for identification purposes. In addition, TLC can be combined with other chromatographic techniques. These should be chosen so that the separation takes place according to different principles; *e.g.* after adsorption TLC, partition TLC or reversed-phase TLC should be used, or occassionally also TLC on a layer impregnated with silver nitrate. Depending on the problem at hand, TLC and GC can, of course, also be coupled.

Coupling with spectroscopic techniques is particularly desirable. The simplest case is coupling with UV-VIS spectroscopy, which enables the spectrum of the zone in question to be recorded. Coupling with IR spectroscopy after microtransfer of the particular zone is, however, much more informative. The easiest method of performing the transfer from the layer is to use the commercially available, compressed, potassium bromide pyramids ("Wick Stick", "Spectro-Tip").

Coupling with mass spectrometry is particularly powerful in terms of positive identification; however, manual transfer is essential. The amount of material available per TLC zone is important in all these methods. All the combination and coupling techniques mentioned can be realized using standard TLC methods and loadings in the µg range.

The importance and esteem in which a method is held can be estimated both by the number of publications and the number of books which have appeared on it. In the 1960s, it was more or less possible to keep abreast of the exponentially increasing numbers of publications in which TLC was used. The method then became a general-purpose tool, which was perhaps mentioned in the experimental section of a publication. The situation with books is different[8, 29, 30, 54–85]. I deliberately subtitled the first book on TLC ("Dünnschicht-Chromatographie") a "Laboratory Handbook". Written together with six colleagues, who contributed their individual experience, it became a best seller and was translated into several languages. When the

developments mentioned above necessitated a second edition it required 24 co-authors, who presented a summary and critique of the greatly increased body of information in the various fields.

In the meantime, special literature compilations and annual special issues devoted to the method are published in leading journals or appear separately. After the appearance of the 2nd edition, which encompassed 1000 pages, it did not appear necessary to produce a 3rd edition of the Laboratory Handbook. My co-workers and I have devoted almost a decade to the development of microthermal techniques that can be coupled with TLC. Additionally, I have investigated the extraction of natural products with supercritical gases; here, too, the initial work was a combination of the technique with thin-layer chromatography.

## 8. Retrospect and Outlook

It may sound presumptuous, but TLC has enriched science and medicine enormously. Chemical reactions, increases in concentration, and isolations can be followed visually. Pharmacognosists do not have to limit themselves to the microscopic analysis of the "packaging material", but can quickly separate and visualize the active components of the drugs.

Finally, it remains to discuss the future of TLC. TLC is the most employed separation technique for the following reasons:

1. It offers the greatest freedom in the easy choice of stationary and mobile phases.
2. It offers a large number of different development techniques.
3. It offers the largest number of methods of detection.
4. It is possible to separate and visualize many samples and reference mixtures simultaneously.
5. Simple methods are available for combining and coupling with microextraction and identification techniques.
6. Thin-layer chromatography is the simplest and most economical chromatographic technique for fast separation and visual evaluation.

These and other advantages justify the prediction that TLC will retain its place in the world's laboratories and increase in importance. It is not a very spectacular technique, but it is extraordinarily useful. It only remains to say that the hectic development of chromatography and spectroscopy in the last 25 years has placed tools in our hands, which until now could only be used to a small extent because of the multiplicity of unsolved problems. A large chasm has opened between the arsenal of modern, available techniques and the results that have been gained using them. If we seize our chances, success will not evade us!

# Metal Complexes of Sulfur Ylides: Coordination Chemistry, Preparative Organic Chemistry, and Biochemistry

**By Lothar Weber***

In recent years both acyclic and cyclic sulfur ylides have proved to be interesting and versatile ligands in preparative organometallic chemistry. In addition to paralleling the coordination chemistry of their phosphorus analogues, sulfur ylide complexes show specific structural and chemical features; they are becoming more important in preparative inorganic and organic chemistry, and may also be biochemically relevant as methylene transfer agents. Recent studies of the complexes of the ylidic $\lambda^4$-thiabenzenes and $\lambda^6$-thiabenzene 1-oxides have frequently demonstrated unexpected and novel reactions, and thereby enriched the chemistry both of ylides and of carbonylmetals.

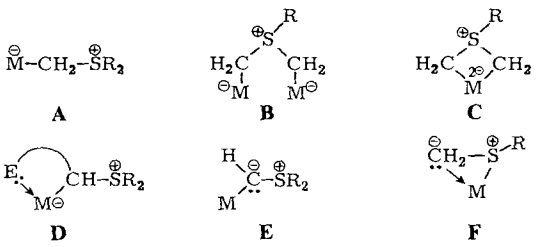
## 1. Introduction

Phosphorus ylides[1] belonged to the synthetic armoury of organic chemists for 20 years before inorganic chemists began to take an increased interest in them. As powerful electron donors, these exceptionally versatile ligands form with almost all metals a wide range of complexes having surprisingly stable metal-carbon bonds. Ylide complexes enrich our knowledge of structural chemistry; in addition, several exhibit exceptional catalytic activity or are of pharmacological importance. The coordination chemistry of phosphorus ylides has been reviewed by *Schmidbaur*[2], *Weber*[3], and *Kaska*[4].

A similar fate awaited sulfur ylides. Some fifteen years after their introduction as synthetic reagents in organic chemistry, *Trost* described them in a monograph as "emerging synthetic intermediates"[5]. Only then did some research groups begin to study the ligand properties of these fascinating compounds, which had long since become indispensable reagents to the organic chemist[6].

This article reports on the synthesis, structure, and chemical properties of sulfur ylide complexes, underlines their relevance in preparative organic and organometallic chemistry, and presents comparisons to, and contrasts with, the chemistry of phosphorus ylides.

## 2. Sulfur Ylides as σ-Ligands



### 2.1. Metal Complexes of Acyclic Sulfur Ylides

Sulfur ylides are zwitterions in which a carbanion center is stabilized by a directly neighboring sulfonium center. Open-chain sulfur ylides can be coordinated as terminal ligands to a metal center (**A**), in the same way as phosphorus ylides. Their monoanions can coordinate as bridging double ylides (**B**) or as chelating ligands (**C**). Chelate com-

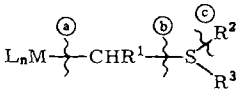
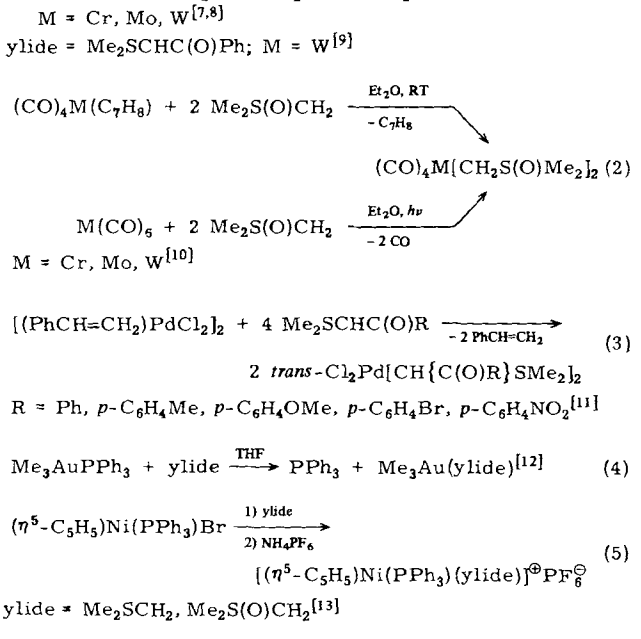
plexes are also formed if, in addition to the ylide function, a further donor atom is present in the molecule (**D**). The ylide function itself may be substituted with metal atoms at the carbanion center (**E**), or a complexed metal may additionally act as substituent at the sulfonium center (**F**), whereby in the last-mentioned case this substituent can also function as an intramolecular coordination center.



**A** **B** **C**

**D** **E** **F**



### 2.1.1. Terminal Ligands

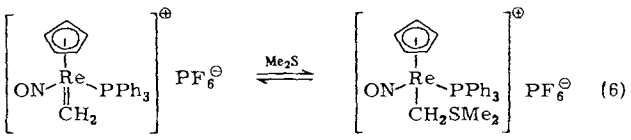
Complexes of type (**A**) are generally synthesized by forming the bonds ⓐ, ⓑ, or ⓒ (cf. Scheme 1); the indirect routes *via* ⓑ and ⓒ are not dependent on the ability of the free ylide to exist separately. This enables unstable ylides to be synthesized at a protecting metal center.

Scheme 1. Routes to ylide complexes of type **A**.

*Bond Formation* ⓐ: Most complexes of the type discussed here are prepared by ligand exchange reactions, normally of labile ligands such as ethers, alkenes, nitriles, halides, or even tertiary phosphanes. Exchange of CO is usually achieved photochemically.

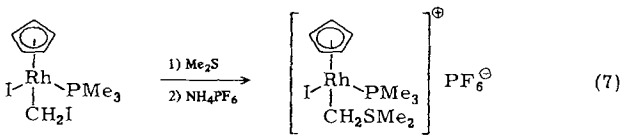
THF = tetrahydrofuran
ylide = $Me_2S(O)CH_2$, $Me(Me_2N)S(O)CH_2$;
M = Cr, Mo, W[7,8]
ylide = $Me_2SCHC(O)Ph$; M = W[9]

M = Cr, Mo, W[10]

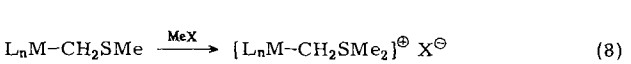


R = Ph, *p*-$C_6H_4Me$, *p*-$C_6H_4OMe$, *p*-$C_6H_4Br$, *p*-$C_6H_4NO_2$[11]

ylide = $Me_2SCH_2$, $Me_2S(O)CH_2$[13]



*Bond Formation* ⓑ: In the protecting coordination spheres of transition metals, the synthesis and stabilization of thermolabile $Me_2SCH_2$ is achieved by sulfane addition to carbene complexes[22a].



**1**

Here, the ylide complex **1** is in equilibrium with the starting materials. The formation of complexes of this type is determined, in general, by the size and basicity of the sulfane and by the size and electrophilicity of the alkylidene ligand[22a]. In contrast, only very electron-rich phosphorus ylide complexes tend to decompose to phosphane and alkylidene complexes[22b-e] (for the reversible reaction of Fischer carbene-metal complexes with phosphanes cf. [3,39f]).

The rhodium-$CH_2SMe_2$ unit can be synthesized by substitution of the corresponding iodomethyl complex[23].

*Bond Formation* ⓒ: The alkylation of alkylthiomethyl complexes leads in many cases to complexes of sulfur ylides.

| $L_nM$ | $Cp(CO)_2Fe$[24] | $Cl(Ph_3P)_2(CO)_2Os$[25] |
|---|---|---|
| MeX | $(Me_3O)BF_4$, $MeSO_3F$ | $MeSO_3CF_3$ |

| $L_nM$ | $ClL_2Pt$ (L = $PPh_3$, $PPh_2Me$)[26] |
|---|---|
| MeX | $MeSO_3F$ |

*Bonding and Molecular structure:* In the compounds discussed in this section, the ylide ligand is always linked to the metal atom by a σ-bond. As in the analogous complexes of phosphorus ylides, the metal-carbon σ-bond is remarkably stable, both chemically and thermally. In general, phosphorus ylides are stronger donor ligands than the corresponding sulfur ylides, as revealed by a comparison of IR data for $(CO)_5Cr$(ylide) [ylide = $Ph_3PCH_2$, $Ph_2MePCH_2$, $PhMe_2PCH_2$, $(MeO)_3PCH_2$, $Me_2S(O)CH_2$,

$Me(Me_2N)S(O)CH_2$[27]] and by ESCA measurements on $Me_3Au(ylide)$ [ylide = $Me_3PCH_2$, $Ph_3PCH_2$, $Me_2SCH_2$, $Me_2S(O)CH_2$[12b]].

X-Ray structure analysis of $Me_3Au[CH_2S(O)Me_2]$[12b], as well as of $[(tBuCH_2)_2SMe]^{\oplus}[(tBuCH_2)_2SCH_2ZnI_3]^{\ominus}$[28], $[(\eta^5\text{-}C_5H_5)(CO)_2FeCH_2SMe_2]^{\oplus}[SO_3F]^{\ominus}$[24b], and (±)-*trans*-$Cl_2Pd[CH\{C(O)Ph\}SMe_2]_2$[11] demonstrates the existence of metal-carbon single bonds.

### 2.1.2. Bridging and Chelating Ligands

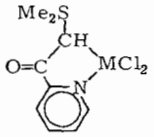
In contrast to the analogous phosphorus ylide compounds, coordination compounds of sulfonium double-ylide

$$[(PhCH{=}CH_2)PdCl_2]_2 \xrightarrow[\text{DMSO}]{4\ Me_2S(O)CH_2/2\ NaI} \text{(Me, CH}_2\text{, I, Pd, Pd, I, CH}_2\text{, O, S, CH}_2\text{, CH}_2\text{, S, Me)} + 2\ NaCl + 2\ (Me_3SO)Cl + 2\ PhCH{=}CH_2 \quad (9)$$

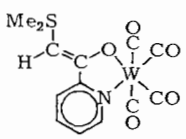
DMSO = dimethylsulfoxide

derivatives (type **B** or **C**) are rare. The anions $[(CH_2)_2S(O)Me]^{\ominus}$ and $[(CH_2)_2SMe_2]^{\ominus}$ can act as bridging or chelating ligands. The deprotonation of the ylide occurs by transylidation[11].

Metalalkyl compounds contain strongly basic ligands, which can deprotonate coordinated $Me_2S(O)CH_2$. However, the products are usually coordination polymers, whose structures could not be determined[14,29].



$$nR_2M + 2\,n\ Me_2S(O)CH_2 \longrightarrow \left[\text{(O, Me, S, CH}_2\text{, CH}_2\text{, M, M, CH}_2\text{, CH}_2\text{, S, Me, O)}\right]_n + 2n\ RH \quad (10)$$



| M | Zn | Cd |
|---|---|---|
| R | Et | Me, $Me_3SiCH_2$ |

A dinuclear rhenium complex with a bridging sulfur double ylide can be synthesized indirectly by twofold addition of a methylene complex to a methanethiolate ion[22a].

$$2\left[\text{(ON, Re, PPh}_3\text{, CH}_2\text{)}\right]^{\oplus} \xrightarrow{\ominus SCH_3} \left[\text{(ON, Re, PPh}_3\text{, ON, Re, PPh}_3\text{, CH}_2\text{, S, CH}_2\text{, CH}_3\text{)}\right]^{\oplus} \quad (11)$$

Chelate complexes of type **D** can also be formed if the sulfur ylide carries a further donor atom. Dimethylsulfonio-2-picolinoylmethanide forms palladium and platinum

M = Pd, Pt

complexes in which it is bonded to the metal *via* the ylide group and the pyridine N atom; in a tungsten complex, however, the donor atoms are pyridine N and "carbonyl" oxygen[9,30,31].

### 2.1.3. Metal-Substituted Ylides

Whereas numerous phosphorus ylides have a metal substituent at the carbanion center[3], few metal-substituted sulfur ylides (type **E**), such as **2a**–**2c**, have been reported[32,33].

$$Me_2S(O)CH_2 \xrightarrow[-\ nBuH]{+\ nBuLi} \text{(Me, CH}_2\text{, S, O, CH}_2\text{, Li}^{\oplus}\text{)} \xrightarrow[-\ LiCl]{+\ Me_3GeCl} \text{(Me, CHGeMe}_3\text{, S, O, CH}_3\text{)} \quad \textbf{2a} \quad (12)$$

$$3\ Me(Me_2N)S(O)CH_2 + 2\ Me_3MCl \longrightarrow 2\ [Me_2(Me_2N)S(O)]Cl + \text{(Me}_2\text{N, C(MMe}_3\text{)}_2\text{, S, O, CH}_3\text{)} \quad \begin{matrix}\textbf{2b},\ M = Ge\\ \textbf{2c},\ M = Sn\end{matrix} \quad (13)$$

Transition-metal-substituted sulfur ylide complexes of the form **2d** are unknown. They might be regarded as carbyne complexes stabilized by a sulfane and would be of interest synthetically as methylidyne transfer agents. This would be analogous to alkylidene transfer by sulfur ylide complexes (see Section 2.3).

$$L_nM\text{–}C(R^1){=}SR_2^2 \xrightarrow[-\ R_2^2S]{} [L_nM{\equiv}CR^1]$$

**2d**

### 2.1.4. $\eta^2$-Methylthiomethyl Complexes

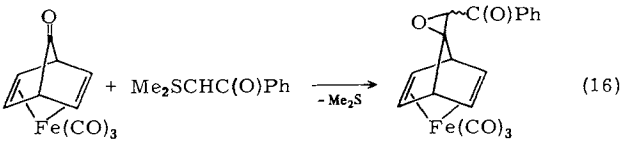
Compounds containing the structural group **F** can be formally regarded as ylide complexes. A carbanion center occupies the α-position to a sulfonium center, at which the metal atom acts as a substituent (and as acceptor). Such compounds are accessible by intramolecular ligand exchange from $\eta^1$-methylthiomethyl complexes.

$$L'L_nM\text{–}CH_2SMe \xrightarrow[-\ L']{\Delta\ \text{or}\ h\nu} \text{(L}_n\text{M, CH}_2\text{, S, Me)} \quad (14)$$

| $L_nM$ | $(PPh_3)_2Pd$[34] | $(CO)_4Mn$[35] | $Cp(CO)_2M$ (M = Mo, W)[35] |
|---|---|---|---|
| L' | Cl | CO | CO |

*S*-Methylation of $\eta^2$-thioformaldehyde ligands also leads to cationic complexes of type **F**[25].

$$(\eta^2\text{-}CH_2S)Os(CO)_2(PPh_3)_2 \xrightarrow{CF_3SO_3Me} \left[\text{(O, PPh}_3\text{, C, S–CH}_3\text{, Os, O, C, CH}_2\text{, PPh}_3\text{)}\right] CF_3SO_3^{\ominus} \quad (15)$$



The existence of three-membered metallacycles with CS single bonds has been confirmed by X-ray crystallographic analysis[36,37].

## 2.2. Reactions of Coordinated Ligands with Acyclic Sulfur Ylides

Transition-metal centers have an appreciable and varied influence on organic molecules: they can behave as protecting groups by coordinating to polyfunctional species, thus allowing selective reactions[38]; thermolabile moieties can be stabilized by complex formation, and hence made available for directed reactions[39]. Metal atoms can also often activate ligands and catalyze many processes[40]. The reactions described in this section involve nucleophilic attack of sulfur ylides on the Lewis acid centers of a number of molecules in the coordination sphere of metal complexes.

### 2.2.1. *Aldehydic and Ketonic Carbonyl Groups*

Norbornadien-7-one is stabilized by the $Fe(CO)_3$ fragment; the chemistry of its CO group can thus be studied[41].

(16)

Reactions of this type involving sulfur ylides have been little studied, but seem very promising. It might be possible, for instance, to allow the 2,4-cyclohexadienone ligand (isomeric with phenol) of tricarbonyl(cyclohexadienone)iron[42a-c] to react with ylides, a reaction impossible with free phenol[42d]. α,β-Unsaturated carbonyl compounds usually form cyclopropanes on reaction with sulfur ylides; this reaction would be blocked by coordination at a metal center, possibly opening the way for the alternative epoxidation. Acylferrocenes can be converted in good yield into other derivatives using $Me_2SCH_2$[43].

$$Fc\text{–}C(O)R \xrightarrow[DMSO/THF]{Me_2SCH_2} Fc\text{–}CHR\text{–}CHO \qquad (17)$$

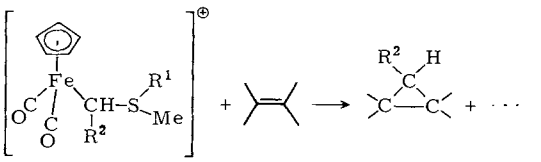
Fc = $(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4)$; R = H, Me, Ph

### 2.2.2. *Carbonyl Ligands*

In contrast to the more strongly nucleophilic phosphorus ylides, such as $Ph_3PCH_2$ or $Me_3PCH_2$[44], sulfur ylides do not add to the CO ligands of $M(CO)_6$ (M = Cr, Mo, W). The force constants of the CO stretching vibrations provide a measure of the electrophilicity of coordinated carbon monoxide ($k$ = 16.49, 16.42, 16.41 mdyn/Å for $[M(CO)_6]$, M = Cr, Mo, W, respectively[45]). The higher electrophilicity of the CO ligands in $Fe(CO)_5$ ($k_{ax}$ = 17.0, $k_{eq}$ = 16.4 mdyn/Å) and $[(\eta^5\text{-}C_5H_5)Fe(CO)_3]^{\oplus}$ ($k$ = 17.6 mdyn/Å[46]), allows $Me_2S(O)CH_2$ to add to the carbonyl group, followed by its rapid transylidation[27,47].

$$Fe(CO)_5 + 2\ Me_2S(O)CH_2 \longrightarrow (Me_3SO)^{\oplus}[(CO)_4Fe{=}C(O)CHS(O)Me_2]^{\ominus} \qquad (18)$$

$$[(\eta^5\text{-}C_5H_5)Fe(CO)_3]^{\oplus}PF_6^{\ominus} + 2\ Me_2S(O)CH_2 \longrightarrow (Me_3SO)PF_6 + (\eta^5\text{-}C_5H_5)(CO)_2Fe[C(O)CHS(O)Me_2] \qquad (19)$$



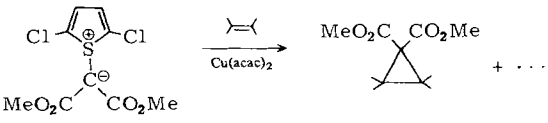
The products can be regarded as sulfonioacyl-metal complexes or as sulfur ylides substituted by ferriocarbonyl moieties.

Apart from the reaction of $Me_2S(O)CH_2$ with the SiCl function of chlorosilyliron complexes[48], periphery reactions of sulfur ylides with small ligands remain largely uninvestigated. The results of reactions of carbene, carbyne, olefin, and isocyanide complexes with phosphorus ylides[49] may serve as guidelines for the corresponding reactions of sulfur ylides.

## 2.3. Sulfur Ylide Complexes as Synthetic Building Blocks

### 2.3.1. *Cyclopropanation*

Sulfur ylides normally form cyclopropane derivatives only with activated alkenes; however, stereospecific alkylidene-transfer to electron-rich olefins is possible using complexed ylides[24,50].

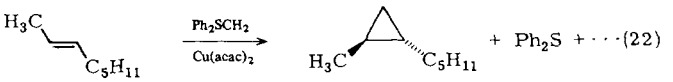


(20)

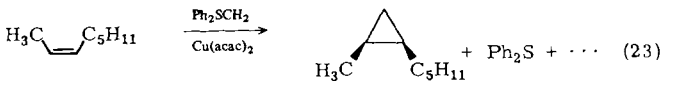
$R^1$ = Me, Ph; $R^2$ = H, Me

Unlike other reagents for cyclopropanation, ylide-iron complexes are readily accessible and easy to handle. The reaction conditions are largely determined by the leaving group properties of the sulfane.

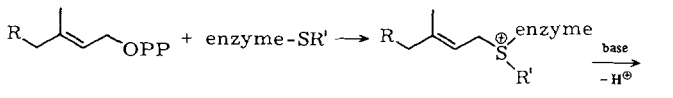
*McCormick* and *Gladysz*[22a] have shown that sulfur ylide complexes are in equilibrium with the free sulfanes and reactive alkylidene complexes. It is, therefore, reasonable to assume that the reactive species in cyclopropanation is a carbene complex: cyclopropanations using carbene complexes have been described frequently in the literature[51].



In this context, analogies between sulfur ylide complexes and diazoalkanes are apparent[52]. *Salomon* and *Kochi*[52a] use a sulfur ylide complex as a model for cyclopropanation reactions[52a]. *Tamblyn et al.*[53] demonstrated a relationship between formation of sulfur ylides and catalytic cyclopropanation with ethyl diazoacetate, both of which occur *via* carbenemetal complexes[53]. *Porter et al.*[54] reported that the metal-catalyzed (Cu, Rh) cyclopropanation of olefins with a sulfur ylide is appreciably more efficient than with the corresponding dimethyl diazomalonate.

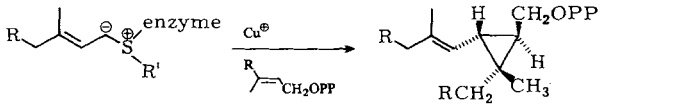


(21)

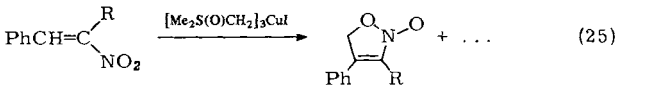


The ease and safety in preparing and handling sulfur ylides make them, in combination with copper salts, attrac-

tive cyclopropanation reagents. Furthermore, unlike $N_2$, the sulfane leaving group can be modified to control the reactivity of the ylide-copper complex. There is evidence that sulfonium salts and sulfur ylides are important in the biosynthesis of cyclopropanes[55-57]. *Cohen et al.* discovered that (diphenylsulfonio)methanide, which is inert to olefins such as *cis*- and *trans*-2-octene, forms the corresponding cyclopropanes stereospecifically in the presence of copper salts[58].



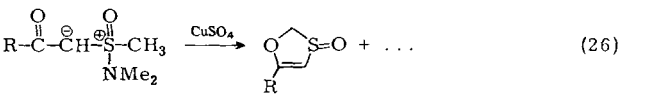
Since ylide formation is possible even under physiological conditions, a metabolic pathway involving sulfur ylide complexes of copper has been proposed for the biosynthesis of presqualene pyrophosphate[58].



(24)

R = geranyl; PPO = pyrophosphate

### 2.3.2. Synthesis of Heterocycles

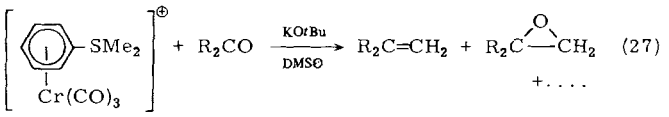


Although β-nitrostyrenes are converted into resins by free $Me_2S(O)CH_2$, they react with a copper complex of the ylide to give good yields of 2-isoxazoline *N*-oxides[59a].

(25)

R = H, Me

*Johnson et al.* have reported the conversion of carbonyl-stabilized [(dialkylamino)methyl(oxo)sulphonio]methanides into 1,3-oxathiol *S*-oxides, catalyzed by $CuSO_4$. Here, again, an ylide complex is postulated as reactive intermediate[59b].



(26)

R = Me, Ph, *p*-$C_6H_4Cl$, *p*-$C_6H_4NO_2$, $PhCH_2$

### 2.3.3. Wittig Reactions

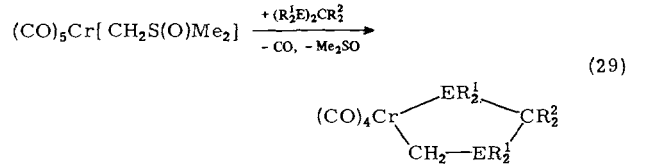
Unlike phosphorus ylides, which react with carbonyl groups to afford olefins, sulfur ylides react with aldehydes and ketones to give oxiranes. The coordination of the arene moiety of $Ph(Me)SCH_2$ to the $Cr(CO)_3$ group drastically alters this behavior of the ylide: with diaryl ketones the main products are alkenes[60].

(27)

R = Ph, *p*-$C_6H_4NMe_2$

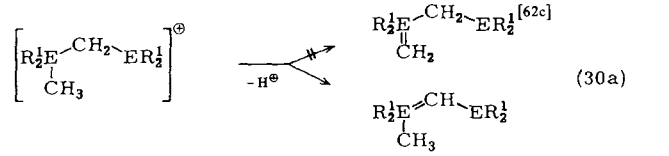
Electron withdrawal by the $Cr(CO)_3$ group increases the electrophilicity of the sulfonium center and allows deoxygenation of the primary adduct. This synthetic method is, however, confined to benzophenone derivatives, because of the reduced carbanion activity in the ylide complex. In addition, it is believed that the transition state leading to olefin formation is considerably stabilized by two aryl substituents.

### 2.3.4. Coordination Compounds of Unstable Ylides



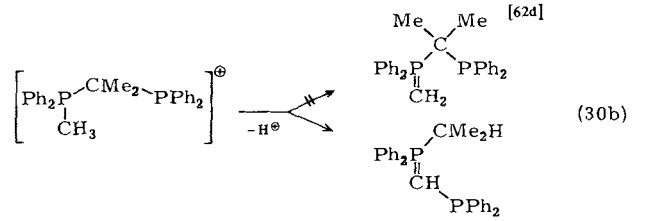
Alkylidenemetal fragments can be transferred from sulfur ylide complexes to phosphanes and arsanes[61].

(28)



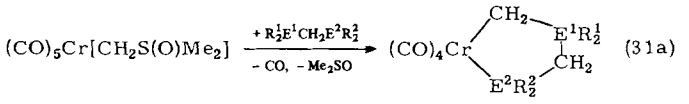
$ER_3$ = $PPh_3$, $PPh_2Me$, $PPhMe_2$, $P(OMe)_3$, $AsPh_3$

This process is relevant to the synthesis of complexes of unstable ylides, such as $(MeO)_3PCH_2$. Compounds of the form $(R^1_2E)_2CR^2_2$ give chelate complexes of ylide ligands that are unstable in the free state and subject to rearrangements[62a,b].

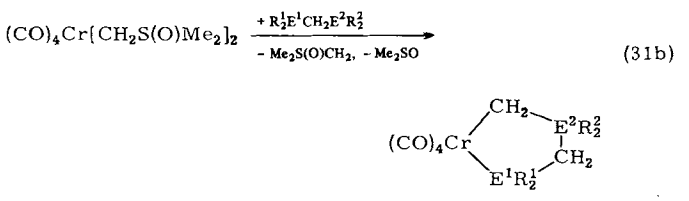


(29)

| $ER^1_2$ | $PPh_2$ | $PMe_2$ | $P(NMe_2)_2$ | $AsPh_2$ | $PPh_2$ |
|---|---|---|---|---|---|
| $R^2$ | H | H | H | H | $CH_3$ |

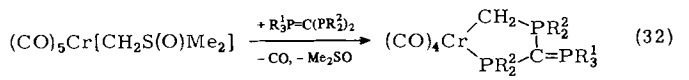


[62c] (30a)



[62d] (30b)

The use of non-symmetrically substituted reagents allows regioselectivity of chelate synthesis by suitable choice of the sulfur ylide complex.

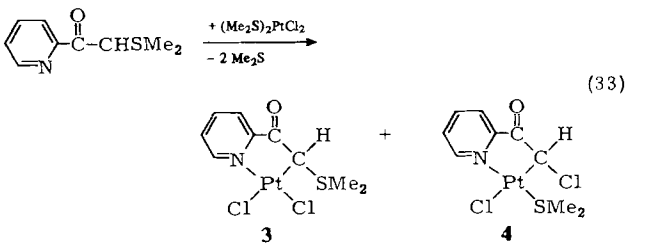


(31a)

(31b)

The first step in reaction (31a) is the displacement of $Me_2SO$ by $E^1R_2^1$, the more nucleophilic end group of $R_2^1E^1CH_2E^2R_2^2$; formation of product in reaction (31b) consists of attack of $E^1R_2^1$ on the chromium atom of the coordinatively unsaturated species $\{(CO)_4Cr[CH_2S(O)Me_2]\}$[62b].

The use of diphosphino-substituted ylides[62f,g] facilitates the synthesis of novel polyfunctional ylide ligands (reaction (32))[62e].

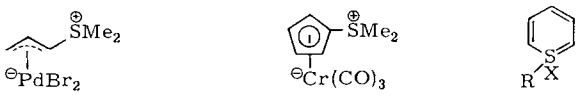


(32)

| $R^1$ | Me | Ph | Ph |
|---|---|---|---|
| $R^2$ | Me | Ph | Me |

### 2.3.5. α-Haloalkyl Complexes

Both the ylide complex **3** and the isomeric chelate complex **4**, with the (2-picolinoyl)chloromethyl ligand, can be isolated from the reaction of $PtCl_2(SMe_2)_2$ with $Me_2SCHC(O)-C_5H_4N$. Compound **4** is formed from **3** by removal and complexation of $Me_2S$, and 1,2-migration of a chloride ion from the metal to the neighboring carbon atom.

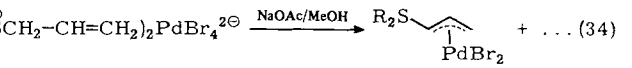


(33)

**3** **4**

This corresponds to the retrosynthesis of sulfur ylide complexes from halomethyl complexes and sulfanes (cf. reaction (7)).

## 3. Sulfur Ylides as π-Ligands

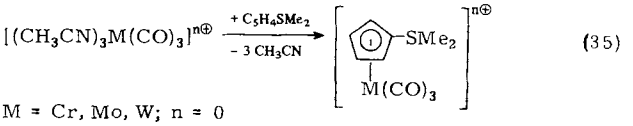


If the carbanion function is stabilized by mesomerism with vinyl substituents or by incorporation into a cyclic diene system, the resulting sulfur ylide can behave as an $\eta^3$- or $\eta^5$-ligand in π-interactions with metal centers.

The $\lambda^4$-thiabenzenes[64] (X = lone pair) and their oxides (X = O) differ from the sulfoniocyclopentadienides[63] in that the onium center is a ring member. The nature of $\lambda^4$-thiabenzenes was formerly disputed. *Price et al.* considered $\lambda^4$-thiabenzenes[66a,c,e], $\lambda^4$-thianaphthalenes[66b,d], and $\lambda^4$-thiaanthracenes[66b] to be novel aromatic species, but *Hortmann et al.*[64a] and *Mislow et al.*[64b,c] showed that at least some of *Price*'s compounds were polymers, and that aryl-substituted $\lambda^4$-thiabenzenes are extremely thermolabile species with ylidic character. MO calculations on the parent compound[67], and NMR[64b,c,68] and X-ray crystallographic data[69] on substituted thianaphthalenes confirm the ylidic nature of these non-planar heterocycles.

### 3.1. $\eta^3$-Sulfoniopropenide Ligands

(Dialkylsulfonio)-2-propenides (-"allylides") are unstable and undergo [2,3]sigmatropic rearrangements with allylic inversion[5]. *Nishiyama* managed to fix and stabilize species of this type at a palladium template[70].



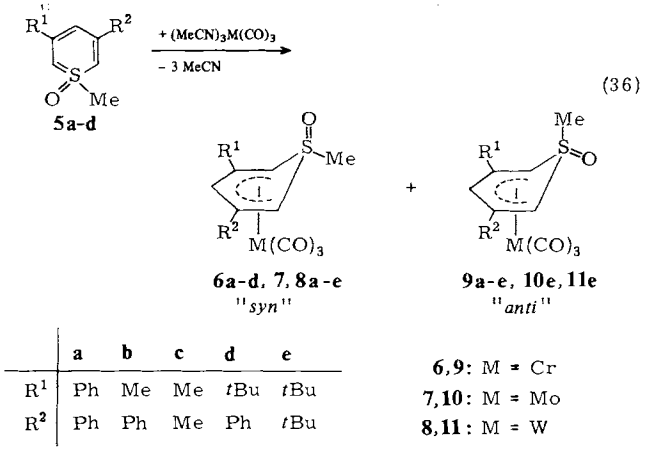
(34)

R = Me
$R_2$ = $(CH_2)_4$

These complexes decompose at 70 °C in $[D_6]$-$Me_2SO$ to afford 1,3,5-hexatriene.

### 3.2. $\eta^5$-Sulfoniocyclopentadienide Ligands

The different electronic shielding of the ring protons in $C_5H_4SMe_2$ are balanced out by complexation to $M(CO)_3$ (M = Cr, Mo, W, $Mn^+$, $Re^+$). The synthesis of the complexes proceeds by exchange of labile acetonitrile ligands in the corresponding starting materials.



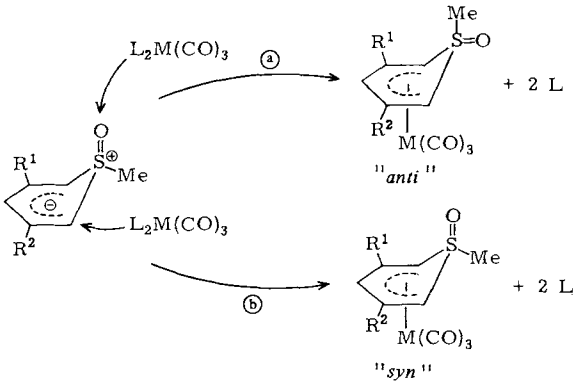
(35)

M = Cr, Mo, W; n = 0
M = Mn, Re; n = 1

The crystal structure of the chromium complex shows that there are no bonding interactions between the metal and the sulfonium center[71].

### 3.3. Preparation and Structure of λ⁶-Thiabenzene 1-Oxide Complexes

The $\lambda^6$-thiabenzene 1-oxides **5a—5d** act as $\eta^5$-6π-ligands towards $M(CO)_3$ fragments (M = Cr, Mo, W). The formation of two isomers, differing in the relative orientation of metal and oxosulfonium center, is observed only for chromium[72,73].



(36)

| | a | b | c | d | e |
|---|---|---|---|---|---|
| $R^1$ | Ph | Me | Me | *t*Bu | *t*Bu |
| $R^2$ | Ph | Ph | Me | Ph | *t*Bu |

In contrast, the di-*tert*-butyl derivative **5e** affords only the *anti*-isomer **9e**[*] with $Cr(CO)_3$, but both *syn*- and *anti*-isomers **7e**, **8e**, **10e**, and **11e** with $Mo(CO)_3$ and $W(CO)_3$[73].

The formation of the *anti*-complexes probably starts with attack of coordinatively unsaturated species, such as $(MeCN)_2M(CO)_3$, on the "hard" oxygen of the oxosulfonium center (Scheme 2, pathway ⓐ), whereas attack on the "soft" π-system leads to the *syn*-configurated compound (pathway ⓑ).

Scheme 2. Reaction pathways leading to *syn*- and *anti*-isomers of $\lambda^6$-thiabenzene 1-oxide complexes.

This would also explain why chromium, as the hardest metal, also forms *anti*-complexes. In **5e** the small chromium atom of $[(MeCN)_2Cr(CO)_3]$ is sterically blocked from the π-system, and thus only the *anti*-compound **9e** is formed. The spatial demands of the bulky *tert*-butyl groups in **5e** force the larger and "softer" molybdenum and tungsten also to proceed by the otherwise unfavorable reaction pathway ⓐ, again leading to *anti*-isomers.

The crystal structures of the free ylide **5a**[74] and the isomeric chromium complexes **6a** and **9a**[72] confirm the $\eta^5$-coordination of all five coplanar carbon atoms of the non-planar heterocycle at the metal center. **5a** adopts the *"syn"*-configuration in the crystal, the sulfur atom laying 39.5 pm above the plane of the carbon atoms[75]. In the two $Cr(CO)_3$ complexes the sulfur atoms move a further 36 and 23 pm, respectively, away from this plane.

[*] Complexes with the *syn*-configuration have the 1-alkyl group and the metal atom on the same side of the ring; in the *anti*-configuration, they are on opposite sides.

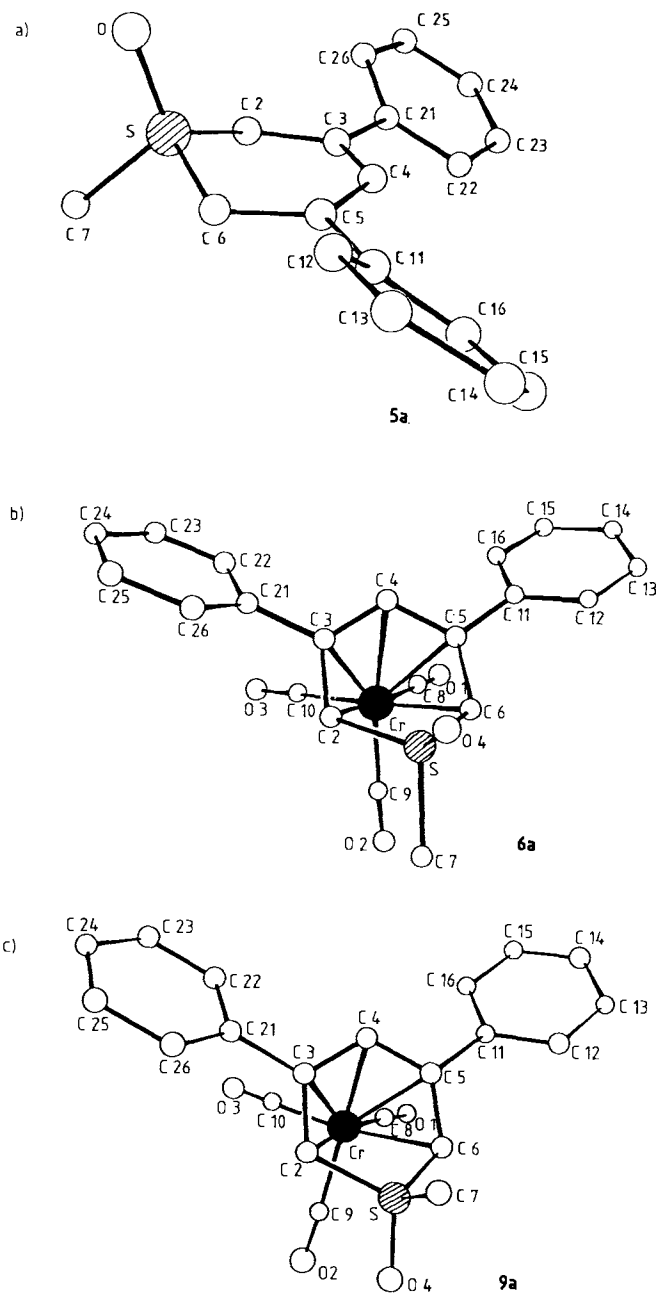


Fig. 1. Structures of molecules **5a**, **6a** and **9a** in the crystal. Selected bond parameters (distances [pm], angles [°]):

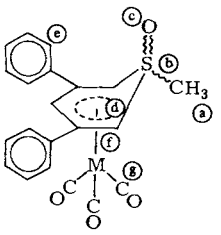
| | **5a** | **6a** | **9a** |
|---|---|---|---|
| Cr...S | — | 289.8(2) | 280.7(1) |
| S–O4 | 147.6(5) | 144.6(7) | 144.9(1) |
| S–C2 | 166.2(6) | 171.1(8) | 172.0(2) |
| S–C6 | 169.3(6) | 169.5(8) | 170.6(2) |
| S–C7 | 182.1(7) | 181.1(9) | 177.1(2) |
| C2–C3 | 142.9(8) | 142.2(10) | 142.5(3) |
| C3–C4 | 136.6(9) | 141.1(9) | 141.2(3) |
| C4–C5 | 139.8(9) | 140.7(10) | 140.8(3) |
| C5–C6 | 141.0(9) | 143.2(10) | 142.8(3) |
| planar ($C_2-C_6$) | 39.5 | 76 | 63 |
| Interplanar angle | 157.8° | 146° | 137° |

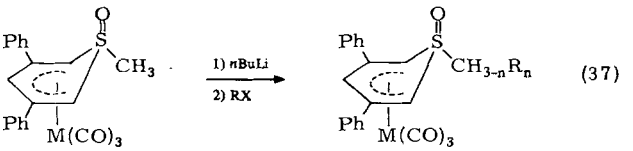


These structures are noteworthy in view of the coordination behavior of $\lambda^5$-phosphabenzenes[76]. The loss of planarity of the free heterocycles on complexing to $Cr(CO)_3$[76f] shows that in their complex chemistry $\lambda^5$-phosphabenzenes, like $\lambda^6$-thiabenzene 1-oxides, behave as

ylidic ligands, whose onium centers are not involved in bonding with the metal atom[77].

### 3.4 Chemical Properties of λ⁶-Thiabenzene 1-Oxide Complexes

Reports on λ⁶-thiabenzene 1-oxides have mostly been restricted to the preparation of the rings, but their chemistry has not been intensively investigated: reports have included their reduction[64a–c,65i], H/D exchange[65b,h–k], bromination and nitration[65h,i], and reactions at substituents[65b,k].

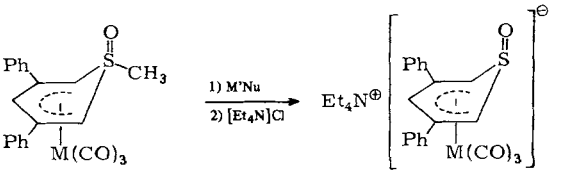


The electron density of the ring is appreciably reduced by coordination to the $M(CO)_3$ group and transferred to the metal. This electronic modification of both structural elements of the complexes makes possible a series of reactions that cannot be carried out with the free ligand or with the $M(CO)_3$ group in other chemical environments. The chemical properties of polyfunctional λ⁶-thiabenzene 1-oxide complexes are usually investigated with the 3,5-diphenyl derivatives; here reactions at positions ⓐ–ⓖ are possible (Scheme 3).

Scheme 3. Reactive centers of λ⁶-thiabenzene 1-oxide complexes.

#### 3.4.1. Alkylation of the $SCH_3$ Group

The influence of the electron-withdrawing $M(CO)_3$ unit markedly increases the acidity of the hydrogen atoms of the $SCH_3$ group (Scheme 3: ⓐ), facilitating alkylations in the two-phase system aqueous $NaOH/CH_2Cl_2$[78]. The $SCH_3$ group can also be lithiated with $n$-$C_4H_9Li$, and the resulting organolithium compound treated with a variety of electrophiles RX[78].

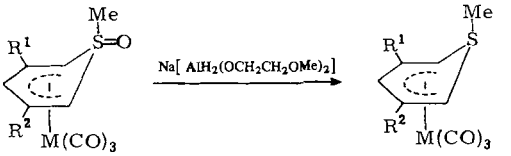


RX = MeI, $C_3H_5Br$, $PhCH_2Br$, $Me_3SiCl$, $Me_3GeCl$, $Me_3SnCl$, MeHgCl

n = 1,2

Chlorination of the *S*-alkyl group can be achieved by reaction of the lithium derivatives with $Cl_3CCN$[78].

#### 3.4.2. Demethylation to η⁵-Thiacyclohexadienyl 1-Oxide Complexes

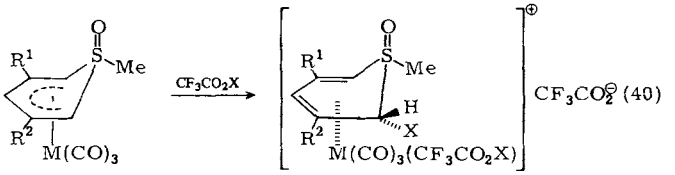


λ⁶-Thiabenzene 1-oxide complexes having the *syn*-configuration are demethylated by "soft" nucleophiles such as $Na_2[Fe(CO)_4]$, $LiPPh_2$, $Li[BHEt_3]$; the products can be converted into stable tetraethylammonium salts by metathesis with $[Et_4N]Cl$. The anions contain the novel thiacyclohexadienyl 1-oxide ligand[79,80], which is a weaker donor than the familiar η⁵-cyclopentadienyl ligand.

M'Nu = $Na_2[Fe(CO)_4]$, $LiPPh_2$, $Li[BHEt_3]$

#### 3.4.3. Deoxygenation to λ⁴-Thiabenzene Complexes

The complex hydride $Na[AlH_2(OCH_2CH_2OMe)_2]$ reacts differently than $Li[BHEt_3]$ with λ⁶-thiabenzene 1-oxide complexes: whereas the *syn*-complexes, in an uncharacteristic way, decompose, the *anti* complexes are reduced to λ⁴-thiabenzene complexes **12**[81].

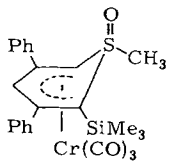


**9–11** **12**

The reduction of **5a** with $Cl_3SiH$ or $LiAlH_4$, however, gives thiopyrans and not the unstable λ⁴-thiabenzenes[64a]. The presence of the $M(CO)_3$ protecting group is necessary to stabilize the cyclic ylide.

#### 3.4.4. Protonation

The relatively long wavelength ν(CO) absorption bands indicate appreciable accumulation of electron density at the metal carbonyl groups in λ⁶-thiabenzene 1-oxide complexes **6**–**8**[72]. In order to investigate the basicity of the metal atoms, the complexes were dissolved in $CF_3CO_2H$; the molybdenum and tungsten derivatives were protonated at the α-position of the ring (relative to the oxosulfonium center)[82]. Deuteration experiments indicate *endo*-addition to the ring, presumably *via* prior protonation of the metal. In the tricarbonyl(cyclopentadienylide) complexes, on the other hand, the metal-hydrogen bond remains stable[83].



X = H, D

*Silylation of the Ring*

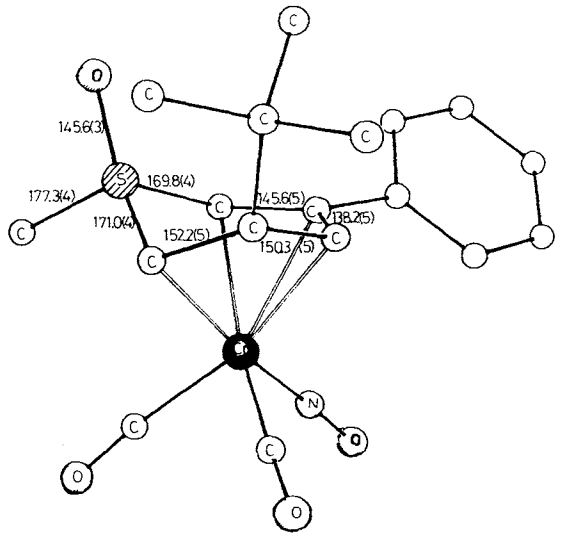
The reaction of **6a** with excess $n$-$C_4H_9Li$, followed by reaction with $Me_3SiCl$ and chromatographic separation on

$SiO_2$, leads, in a manner analogous to reaction (37), to complex **13**, with the silyl group in the α-position of the ring.

**13**

*endo-Hydride Addition*

The coordination of the $\lambda^6$-thiabenzene 1-oxide to the $(CO)_2Cr(NO)$ cation (see Scheme 3: ⑧) brings about a marked decrease in electron density at the 3- and 5-positions of the ring; these thus acquire electrophilic characteristics. Complexes of novel double ylide sulfonium compounds[85] can then be formed by *endo*-hydride addition reactions of unusual reaction type[84]. Figure 2 shows the molecular structure of **14d**.



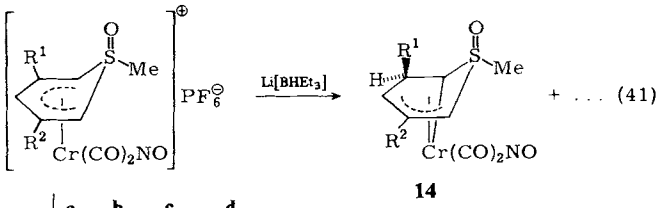


Fig. 2. Molecular structure of **14d** with selected bond lengths.

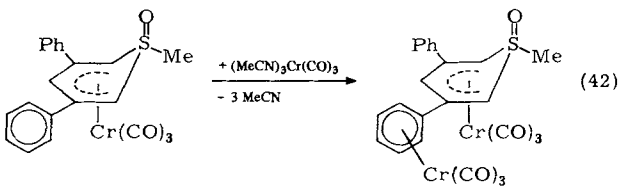
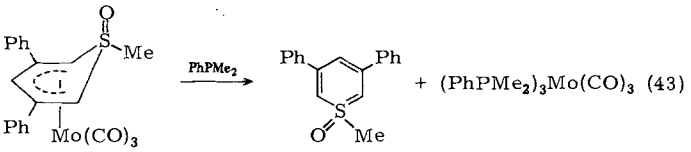


| | a | b | c | d |
|---|---|---|---|---|
| $R^1$ | Ph | Me | Me | *t*Bu |
| $R^2$ | Ph | Ph | Me | Ph |

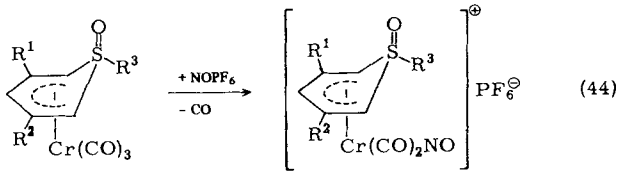
**14**



*3.4.5. Complex Formation at Phenyl Substituents*

The phenyl substituents of $\lambda^6$-thiabenzene 1-oxide ligands also exhibit donor properties, although coordination of the phenyl group (Scheme 3: ⑥) prior to that of the central heterocycle is never observed[27].

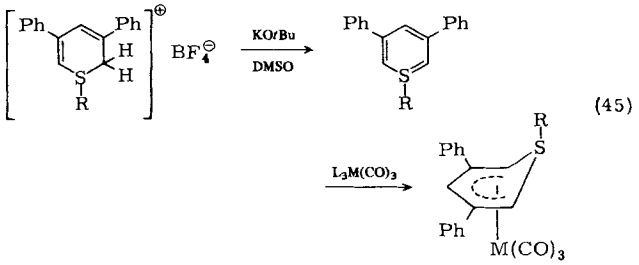
*3.4.6. Rupture of the Metal-Ring Bond*



If the electron density of the $\lambda^6$-thiabenzene 1-oxide has been modified by coordination to a metal, and the activated species subsequently allowed to react further, the last step in the cycle is often the removal of the chemically altered ligand. **5a** is quantitatively displaced from complexes by excess $PhPMe_2$ in boiling THF[27].

**5a**

*3.4.7. Displacement of CO*



In the *syn*-configurated ($\lambda^6$-thiabenzene 1-oxide)chromium complexes **6**, a CO ligand can easily be replaced by the isoelectronic $NO^+$ ion, without breaking the metal-ring bonds[86].

Cationic arene(dicarbonyl)nitrosyl complexes of molybdenum and tungsten are, as yet, unknown; all attempts to prepare them have led to loss of the arene ligand[87]. Use of electron-donating or bulky groups ($R^1=R^2=Ph$; $R^3=CH(SiMe_3)_2$, $CH(CH_2Ph)_2$; $R^1=R^2=t$Bu, $R^3=Me$) on the $\lambda^6$-thiabenzene 1-oxide ligand stabilizes the metal-ring bond to such an extent that cationic dicarbonyl(nitrosyl)molybdenum and -tungsten complexes with organic 6π-ligands become accessible[86].

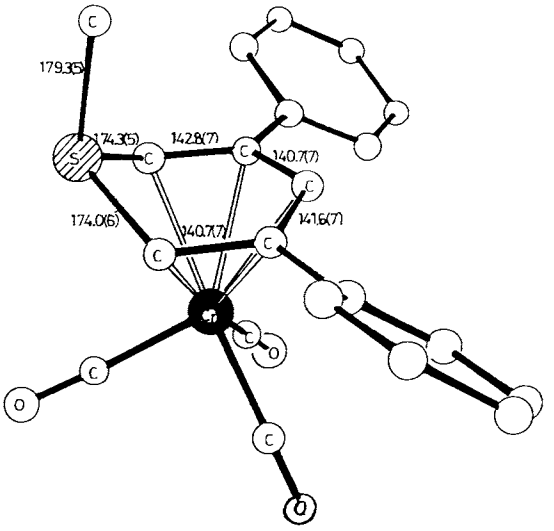
### 3.5. Preparation and Structure of $\lambda^4$-Thiabenzene Complexes

$\lambda^4$-Thiabenzene complexes of type **12** are accessible by deoxygenation of $\lambda^6$-thiabenzene 1-oxide complexes (cf. Section 3.4.3). This process is, however, dependent on the existence of complexes, such as **9**—**11**, having the *anti*-

R = Me, Et; M = Cr, L = MeCN; M = Mo, W, $L_3 = C_7H_8$

configuration. In some cases the synthesis can be achieved by trapping $\lambda^4$-thiabenzenes generated *in situ*[88].

Structural changes associated with the coordination of the $\lambda^6$-thiabenzene 1-oxide **5a** to the $Cr(CO)_3$ group are known. Information on the structure of the thermolabile $\lambda^4$-thiabenzene derivative analogous to **5a** can be obtained from the X-ray structure analysis of its $Cr(CO)_3$ complex **12a** and by comparison with data for **5a**, **6a**, and **9a**. In the stable, crystalline **12a** (Fig. 3) the heterocycle is bonded to the chromium atom through the five coplanar carbon atoms (as in the *anti*-complex **9a**). The sulfur atom lies 75 pm above this plane and is directed away from the chromium ($d$(Cr–S) = 288 pm). The methyl group occupies the axial *"anti"*-position at the pyramidal sulfur: *syn/anti* isomerism has not been detected. The ylidic nature of these heterocycles is thus established by means of their coordination chemistry. It is possible that the free ligand has a similar configuration.



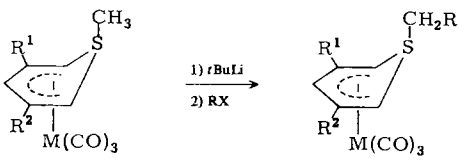


Fig. 3. Molecular structure of **12a** with selected bond lengths.

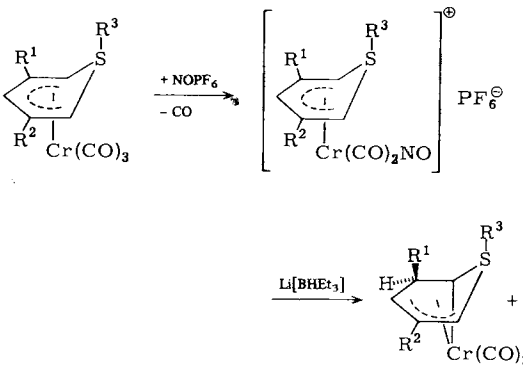
### 3.6. Chemical Properties of $\lambda^4$-Thiabenzene Complexes

Because of their thermolability, the chemistry of $\lambda^4$-thiabenzene complexes has been little investigated[64a,89–91]. The stabilizing influence of the $M(CO)_3$ template should, as with $\lambda^6$-thiabenzene 1-oxide complexes, allow a wide variety of reactions of $\lambda^4$-thiabenzenes to be investigated; some preliminary results have been obtained.

#### *3.6.1. Metalation and Alkylation of the $SCH_3$ Group*

The hydrogen atoms of the $SCH_3$ group are sufficiently acidic to allow lithiation and subsequent reaction with electrophiles. The $\lambda^4$-thiabenzene ligands thus formed have not yet been obtained by other methods[88b].

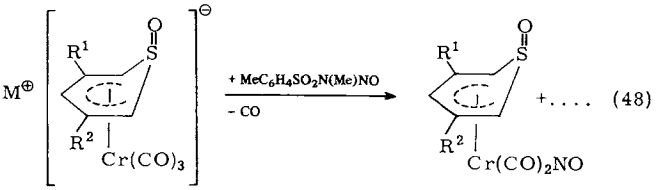


(46)

RX = MeI, $C_3H_5Br$, $PhCH_2Br$, $Me_3SiCl$, $Me_3GeCl$

#### *3.6.2. Nitrosylation*

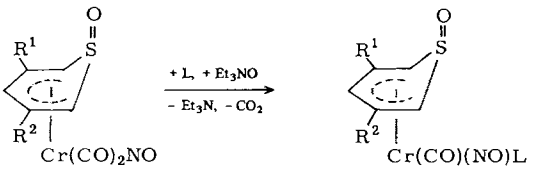
Cationic $\lambda^4$-thiabenzene complexes are obtained by substitution of CO by $NO^+$; the ring ligand exhibits electrophilic properties and, in preliminary studies, has been shown to add hydride ion (cf. reaction (41))[92].



(47)

### 3.7. Chemical Properties of $\eta^5$-Thiacyclohexadienyl 1-Oxide Complexes

The $\eta^5$-thiacyclohexadienyl 1-oxide complexes synthesized as described in Section 3.4.2 possess structures similar to those of the corresponding *syn*-$\lambda^6$-thiabenzene 1-oxide complexes **6**—**8**. Demethylation appreciably increases the nucleophilicity of the complexes. Like other complex anions, they are valuable synthetic building blocks in organometallic chemistry.

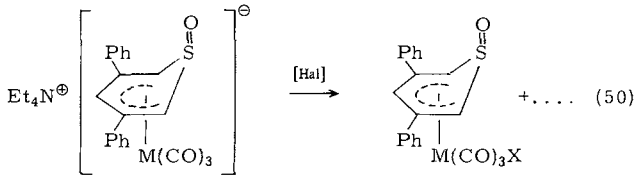


#### *3.7.1. Ligand Displacement*

The chromium complexes are easily nitrosylated to give neutral complexes[93].

(48)

A further ligand L can be introduced by the amine oxide method to give chiral complexes[93].

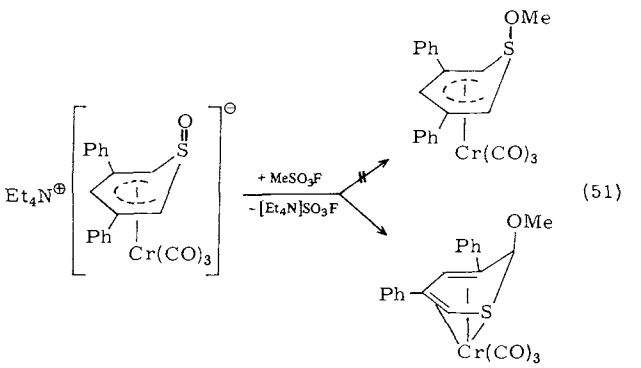


(49)

L = $PPh_3$, $PPh_2Me$, $PPhMe_2$, $C_5H_5N$

#### *3.7.2. Halogenation*

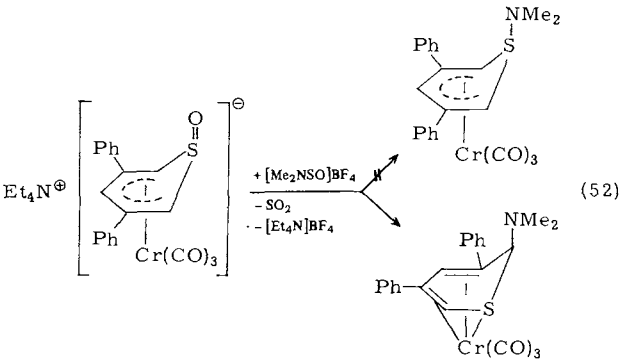
The molybdenum and tungsten complexes are halogenated by $PhICl_2$, $C_5H_5N \cdot Br_2$, or $I_2$[80].



M = Mo, W
[Hal] = $PhICl_2$, $C_5H_5N{\cdot}Br_2$, $I_2$; X = Cl, Br, I

(50)

### 3.7.3. Alkylation



"Hard" alkylating agents attack the oxosulfonium center. A 2*H*-thiopyran complex is isolated, rather than the expected isomeric *S*-methoxylated $\lambda^4$-thiabenzene complex[94].

(51)

### 3.7.4. Amination

By analogy to the work of *Kresze et al.*[95], it should be possible to synthesize 1-amino-$\lambda^4$-thiabenzene complexes by reaction with $[Me_2NSO]^+BF_4^-$. Here also, however, only the isomeric 2*H*-thiopyran complex can be isolated, whose structure is confirmed by X-ray crystallography[94].

(52)

The rearrangements described in reactions (51) and (52) are novel in organometallic chemistry and may perhaps best be compared with the Pummerer rearrangement. The chirality of the complexes obtained from reactions (48), (49), (51), and (52) raises the question of whether asymmetric syntheses are possible.

## 4. Summary and Prospects

The coordination chemistry of open-chain sulfur ylides show similarities to, but also clear differences from, the chemistry of phosphorus ylides. The differences arise, as in the organic chemistry of these compounds, from the greater leaving-group tendency of diorganosulfanes or sulfoxides. Thus, some sulfur ylide complexes function as metal-alkylidene transfer reagents. Whereas free sulfur ylides can cyclopropanate only activated olefinic double bonds, they undergo an umpolung upon complexing to metals; in so doing they acquire electrophilic properties, and are then able to cyclopropanate electron-rich olefins. This reaction type is also feasible *in vivo* and may be of biochemical relevance. The tendency of sulfoxides to act as good leaving groups enables (formally) the $[(CO)_4Cr{=}CH_2]$ fragment to be transferred from the ylide complexes $(CO)_4Cr[CH_2S(O)Me]_2$ and $(CO)_5Cr[CH_2S(O)Me_2]$ to methylenebisphosphanes and -arsanes, thus forming coordination compounds of unstable phosphorus ylides. The regiospecificity of this reaction is clearly determined by the nature of the organometallic complex. The thermolabile $\lambda^4$-thiabenzenes can act as ylidic $\eta^5$-ligands at suitable metal centers, and can thus be stabilized. This is achieved by trapping the free rings *in situ* or by reduction of *anti*-$\lambda^6$-thiabenzene 1-oxide complexes. The crystal structure of the $Cr(CO)_3$ complex rules out any heteroaromaticity of the ligand ring and suggests a structure similar to that of the corresponding oxide for the free ylide ligand.

$\lambda^6$-Thiabenzene 1-oxides form a series of structurally fascinating complexes with $M(CO)_3$ (M = Cr, Mo, W); these undergo a variety of interesting reactions, which enrich our knowledge of organometallic chemistry. $\eta^5$-Thiacyclohexadienyl 1-oxide complexes display an interesting rearrangement of the coordinated ligand, comparable to the Pummerer rearrangement, on reaction with "hard" electrophiles.

The chemistry of organometallic complexes and sulfur ylides as reaction partners is, hence, far from exhausted; indeed, the reactions with coordinated ligands have been scarcely investigated. It should also be noted that, despite the wide range of known sulfur ylides, only a few have been studied as ligands. This is clearly due, at least in part, to their high reactivity; but this also suggests the possibility of generating reactive metal ylide complexes and thus extending the synthetic tools of the preparative chemist.

*I should like to thank Prof. Dr. Günter Schmid for generous support of our work. Frau D. Vehreschild-Yzermann, Frl. M. Stoffel, Frl. M. Utzat, Herr D. Wewers, and Herr U. Meyer are thanked for committed and conscientious collaboration; Dr. R. Boese and Prof. Dr. C. Krüger (Mülheim a. d. Ruhr) and their co-workers for X-ray analyses; and Prof. Dr. B. M. Trost for hospitality during my stay at the University of Wisconsin, Madison. The Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and Degussa (Hanau) and Hoechst AG (Werk Knapsack) provided financial support.*

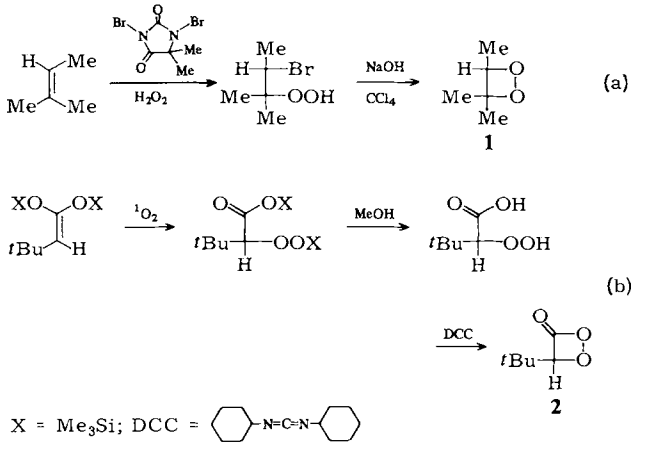
# Four-Membered Ring Peroxides as Excited State Equivalents: A New Dimension in Bioorganic Chemistry



**By Waldemar Adam* and Giuseppe Cilento**

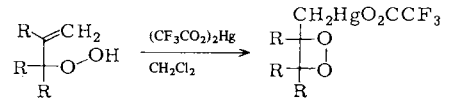
*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

Consideration of chemiluminescent and bioluminescent processes invariably brings to mind the four-membered ring peroxides, 1,2-dioxetanes and α-peroxylactones. Nevertheless, while chemiluminescence and bioluminescence are well established fields of scientific study, isolable and characterized "high-energy" molecules such as the 1,2-dioxetanes and α-peroxylactones are of relatively recent vintage, about a decade. These intriguing compounds produce electronically excited products which manifest themselves by light emission during their thermal decay; more importantly, these transformations are involved in luminescent as well as dark enzymatic processes. It is not our intention to present a comprehensive overview in this progress report, but rather to focus on those aspects which require further study.

## 1. Synthesis

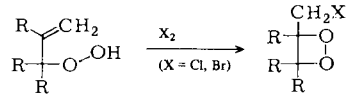
The isolation of the first stable 1,2-dioxetane, the trimethyl derivative **3**, prepared by the Kopecky sequence [reaction (a)], was reported in 1969[3], while the first α-peroxylactone (1,2-dioxetanone), the *tert*-butyl derivative **2**, was obtained in 1972 [reaction (b)][2]. Since then, well over a hundred dioxetanes **3** and about a dozen α-peroxylactones **4** have been isolated and characterized.

Besides reactions (a) and (b), which have become established classical routes, photooxygenation has proved to be a method of quite general synthetic utility. Provided ene-reactions and Diels-Alder additions do not figure as menacing side reactions, photosensitized singlet oxygenation of olefins and ketenes [reaction (c)] constitutes a convenient and facile approach to the four-membered cyclic peroxides **3** and **4**[3]. Substituents used include alkyl, aryl, alkoxy, aryloxy, dialkylamino, and recently even thioalkyl[4,5] and thioaryl groups[4], leading to the first sulfur-substituted 1,2-dioxetanes **5** and **6**, respectively. In **5** and **6** the spiroadamantane substitution stabilizes the dioxetane ring sufficiently to allow spectroscopic characterization of these labile species.



**5** **6**

The advantages of the singlet oxygenation method [reaction (c)] over the classical Kopecky route [reaction (a)] are the usually higher yields, mild conditions, and low temperatures. Most importantly, by using an appropriate sensitizer (tetraphenylporphine, polymer-bound rose bengal, *etc.*) and deuterated solvents (chloroform, dichloromethane, acetone, *etc.*) very labile dioxetanes and α-peroxylactones can be detected by $^1$H- or $^{13}$C-NMR spectroscopy without requiring isolation.



Methods of more limited scope include peroxymercuration[6], peroxyhalogenation[7], silica gel-catalyzed rearrangement of *endo*-peroxides[8], electrochemical oxygenations[9], and ozonation of vinylsilanes[10]. A method of promising synthetic potential entails base-catalyzed ring-opening of epoxides[11], leading to hydroxy-substituted dioxetanes **12**. The functionalized dioxetanes **7**, **8**, **11**, and **12** should provide opportunities of preparing derivatives bound to biomolecules such as sugars, steroids, fatty acids, proteins, pyrimidines, purines, *etc.*, which should be interesting substrates for biological testing.

This summarizes the repertoire of synthetic methods for 1,2-dioxetanes and α-peroxylactones. As is typical for the preparation of four-membered rings, the yields are low

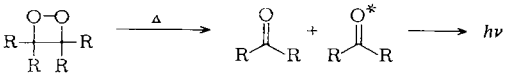
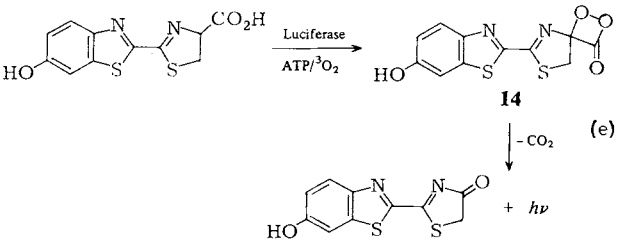
12

and the methods limited. In addition, these "high-energy" compounds are thermally and photolytically labile and undergo acid- and base-catalyzed decomposition, nucleophilic and electrophilic attack, and worst of all, dissociation by traces of transition-metal ions.



13

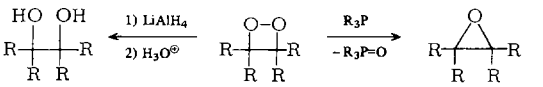
Consequently, much pioneering and challenging work awaits synthetic chemists to improve this unfavorable situation, especially if biologically relevant four-membered ring peroxides are to be prepared. But even simple species for mechanistic scrutiny, for example the parent dioxetane **13**, present a formidable synthetic challenge. Its transitory existence is claimed on the basis of the observed formaldehyde chemiluminescence in the gas phase singlet oxygenation of ethylene[12]. Attempts to prepare isolable quantities by low-temperature photosensitized singlet oxygenation of a solution of ethylene in $CFCl_3$ failed. Not even traces of peroxidic material was detected. However, after persistent efforts, *ca.* 10 mg of the parent 1,2-dioxetane **13** was recently isolated *via* the classical Kopecky route. The observed chemiluminescence on thermal decomposition and the characteristic NMR spectra support this success[13].



## 2. Characterization

The most characteristic property of four-membered ring peroxides is their ability to emit light upon decomposition [reaction (d)]. In chemistry this is referred to as chemiluminescence and in biology as bioluminescence. One of the best studied and mechanistically most understood bioluminescent reactions is firefly bioluminescence [reaction (e)],

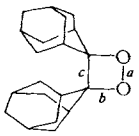
(d)



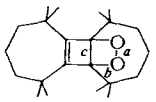
in which luciferin is converted enzymatically by luciferase and ATP into the corresponding carbonyl product (oxyluciferin), $CO_2$, and light *via* the intermediary α-peroxylactone **14**[14]. However, although all dioxetanes and α-peroxylactones emit light, even if often only rather feebly, the corollary is far from true that all luminescent chemical or biological autoxidations involve four-membered ring peroxides. While in chemistry it is, at least in principle, possible to isolate the suspected dioxetane and α-peroxylactone, or synthesize them independently, in biology the evidence is indirect and circumstantial. To the best of our knowledge no genuine biologically derived dioxetane or α-peroxylactone has yet been isolated or independently synthesized. Unquestionably, demanding but potentially rewarding work lies ahead on this score.

(e)

Even if the four-membered ring peroxides in question can be prepared and isolated, what criteria other than light emission [reaction (d)] can be employed for their definitive characterization? In view of the large volume of accumulated data[15], spectroscopic identification is convenient and reliable. The carbonyl frequency at *ca.* 1870 $cm^{-1}$ is particularly characteristic of α-peroxylactones, whereas for dioxetanes NMR spectroscopy is usually helpful. Dioxetanyl protons usually lie in the chemical shift range $\delta = 4.5$–5.5 and the ring carbon atoms between $\delta = 80$ and 110.

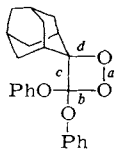


For their chemical identification several criteria can be useful. Of course, besides light emission on thermolysis, the products are usually the expected carbonyl fragments. Reduction of dioxetanes by $LiAlH_4$ to the respective 1,2-diols and deoxygenation to the corresponding epoxides by phosphanes are helpful procedures [reaction (f)], but other reliable and general chemical transformations need to be developed.



(f)

By far the most rigorous method, providing important structural parameters such as bond lengths and bond angles, is X-ray structure analysis. However, its general use is limited. On the one hand, the dioxetane must be crystalline and have good reflecting properties; on the other, since dioxetanes are radiation sensitive, the crystals must survive X-ray exposure. Despite these limitations, considerable progress has been made along these lines. The first X-ray structures reported concern the "superstable" dioxetanes



**10**[16] and **15**[17], derived from 2,2-biadamantylidene and the sterically hindered cyclobutadiene, respectively. More recently we have added the dioxetanes **16**—**21** and even the bisdioxetane **22** to the list[18]. The latter compound is interesting in that the two dioxetane rings are arranged *anti* to another and are considerably puckered, but the dioxane ring is planar. This is particularly surprising in view of the dioxetanes **17**—**19**, in which the reverse applies. Thus,

[a] $10^3\,k$ (370.2 K), determined by chemiluminescence measurements under isothermal conditions [18b].

here the dioxetane ring is essentially planar, but the dihydrodioxin ring boat-like. The greatest degree of puckering is observed in **10**; this arises to a large extent from steric interactions of the adamantyl groups (see Section 4). Of course, **15** is necessarily planar in view of the fused cyclobutene ring. In the future one can expect to see intensified activity in acquiring structural data of this type, particularly since the few examples discussed here do not allow *a priori* predictions to be made concerning the degree of dioxetane ring puckering. It must be stressed at this point that no X-ray structure analyses of α-peroxylactones have been reported so far since stable α-peroxylactones of good crystalline quality have not yet been isolated.

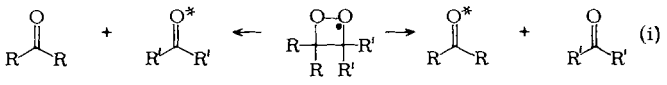
## 3. Excitation Yields

We have seen that a characteristic feature of four-membered ring peroxides is their ability to generate electronically excited carbonyl products, *e.g.* aldehydes, ketones, esters, carboxylic acids, and anhydrides. In this sense we consider these "high-energy" molecules as *excited state equivalents*, since they serve as chemical or even biological precursors to excited states. Such chemienergized excited states derived from four-membered ring peroxides behave identically to their photoenergized equivalents in their photophysical and photochemical properties. Thus, among the known photophysical phenomena, excited states of this type display direct chemiluminescence (DC) in the form of fluorescence (singlet states) and phosphorescence (triplet states), or undergo energy transfer chemiluminescence (ETC) with an appropriate luminescing photoacceptor (lumophore), which subsequently either fluoresces or phosphoresces (Scheme 1). In this respect it is completely immaterial whether the four-membered ring peroxide is of chemical or biological origin, except that in the latter cases such emissions are termed bioluminescence. The chemienergized carbonyl product can undergo direct photochemical transformations such as rearrangements, isomerizations, fragmentations, or cycloadditions, but can also sensitize such photochemical transformations *via* energy transfer to an appropriate photoactive acceptor (Scheme 1).

Scheme 1.

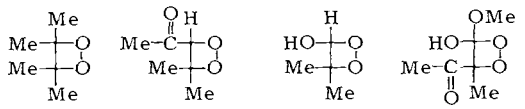
One of the central analytical problems concerns the determination of the excitation parameters, *i.e.* the efficiency of singlet ($\phi^S$) and triplet ($\phi^T$) excited state generation during decomposition of 1,2-dioxetanes or α-peroxylactones. Specifically, for mechanistic reasons it is desirable to know the total chemiexcitation efficiency ($\phi^T+\phi^S$) and the efficiency of spin state selection ($\phi^T/\phi^S$). Of course, for this purpose either the quantum yield of the photophysical processes can be measured or the chemical yield of the photochemical reactions determined (Scheme 1). These methods have been described in detail[19], and only the salient features and problems, especially with enzymatically generated excited states, will be considered here.

### 3.1. Luminescence Probes

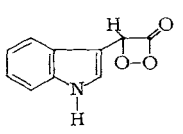


For luminescence techniques, by means of which the quantum yield is experimentally established, the key mathematical relationships for direct (DC) and energy transfer (ETC) chemiluminescence are given in equations (g) and (h), respectively. In the case of DC, the chief prerequisite is that the identity of the excited carbonyl product is

$$\phi_{DC} = \phi_{exc} \cdot \phi_{lum} \quad (g)$$



$$\phi_{ETC} = \phi_{exc} \cdot \phi_{ET} \cdot \phi_{lum} \quad (h)$$

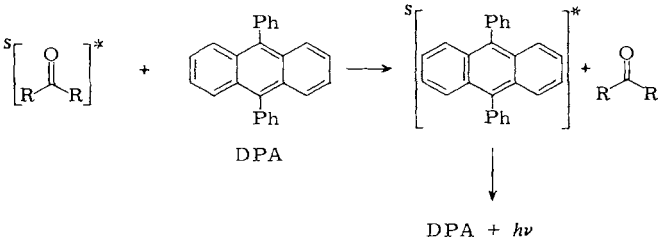


$\phi_{DC}$ = direct chemiluminescence yield; $\phi_{ETC}$ = energy transfer chemiluminescence yield; $\phi_{exc}$ = chemiexcitation yield ($\phi^S$ for singlets and $\phi^T$ for triplets); $\phi_{lum}$ = luminescence yield of excited carbonyl product or lumophore; fluorescence yield ($\phi_{fl}$) for singlets and phosphorescence yield ($\phi_{ph}$) for triplets; $\phi_{ET}$ = energy transfer efficiency of excited carbonyl product to the lumophore

known. This is not a trivial matter, especially for unsymmetrically substituted dioxetanes, which can chemienergize either or both of the possible carbonyl fragments [reaction (i)], particularly in biological molecules in which

(i)

the dioxetane has been postulated as a transient intermediate. If, however, the chemiexcited carbonyl excited state is known with certainty and its luminescence efficiency available or determinable, then to determine the desired $\phi_{exc}$ it is only necessary to measure $\phi_{DC}$ by the usual photometric methods[19]. Since under normal conditions the observed emission is usually fluorescence, this provides direct access to singlet quantum yields ($\phi^S$). Only under special circumstances can triplet excitation yields ($\phi^T$) be measured by direct phosphorescence. For example, under degassed conditions the triplet yield of acetone from tetramethyl-1,2-dioxetane **23** has been reported[20], and the triplet yield of methylglyoxal from dioxetane **24**[21] could be determined directly, since such α-dicarbonyl excited states undergo direct phosphorescence. Significantly, the direct emission observed in the enzymatic autoxidation of isobutyraldehyde by horseradish peroxidase (HRP) in the presence of a chelating ligand (EDTA, pyrophosphate) has been identified as derived from triplet acetone produced from the hypothetical intermediary dioxetane **25**[22]. However, when the HRP enzyme is replaced by hemin, autoxidation of isobutyraldehyde to triplet excited acetone still occurs, except that its phosphorescence can no longer be observed directly[23]. Consequently, it was postulated that in the HRP-catalyzed autoxidation the triplet acetone was screened by the enzyme against quenching by oxygen, but in the hemin-catalyzed autoxidation of isobutyraldehyde it was not. An intermediate case is the HRP-catalyzed autoxidation of methyl 2-methylacetoacetate, which affords triplet biacetyl, presumably *via* the dioxetane **26**, as indicated by its directly observable phosphorescence[24]. Here, the triplet biacetyl is also not screened by the enzyme against quenching by oxygen; but since, compared to triplet acetone, triplet biacetyl phosphoresces quite efficiently, its phosphorescence can be observed directly near oxygen completion. These unusual results are of considerable biological significance.

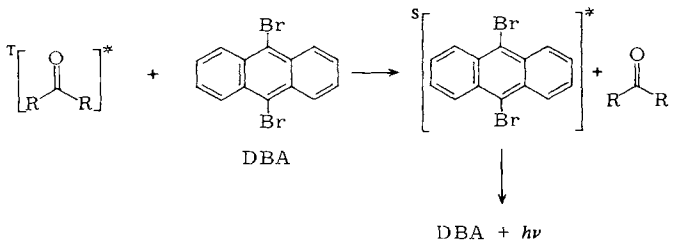


**23** **24** **25** **26**

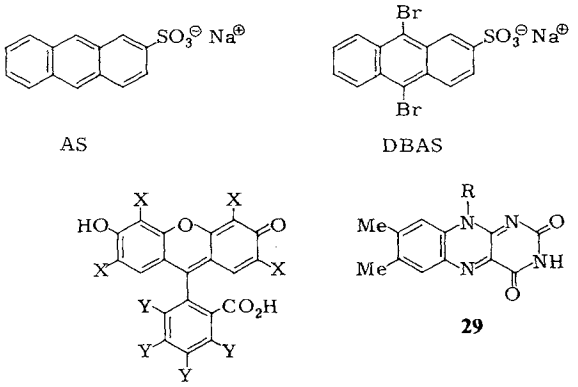
**27**

In general, it can be said that DC is a convenient method, but has limited scope. The most serious disadvantages are that triplet yields can seldom be determined, the excited-state product must be known, and the fluorescence and phosphorescence yields must be sufficiently large to enable quantitative determination[19].

Energy transfer chemiluminescence (ETC) has by now established itself as the most popular technique for the determination of excitation yields. It was pioneered by the Russian school[25] for monitoring the excited carbonyl products responsible in the chemiluminescence accompanying hydrocarbon autoxidation. With the proper choice of lumophore to which the excitation energy of the chemienergized carbonyl excited state is transferred, singlet ($\phi^S$) and triplet ($\phi^T$) yields can be obtained photometrically[26].



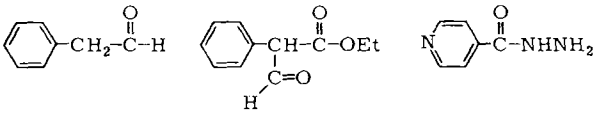
For studying singlet excited states 9,10-diphenylanthracene (DPA) is frequently used as a lumophore; its fluorescence is sensitized *via* singlet-singlet energy transfer by the chemienergized carbonyl product. In practice the DPA quantum yield ($\phi_{ETC}^{DPA}$) is measured at infinite DPA concentrations under conditions where Stern-Volmer kinetics apply ($\phi_{ET}^{DPA} = 1.00$), and since the fluorescence yield of DPA is known, the singlet quantum yield ($\phi^S$) can be calculated from eq. (h)[19].



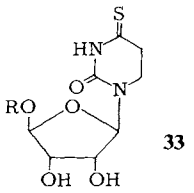
9,10-Dibromoanthracene (DBA) has been widely used to study triplet excited states. Through spin-orbital coupling the bromine atoms catalyze the spin-forbidden triplet-singlet energy transfer from the chemienergized triplet carbonyl product to DBA, thereby sensitizing its fluorescence. Here the DBA quantum yield ($\phi_{ETC}^{DBA}$) is determined at infinite DBA concentration using Stern-Volmer kinetics ($\phi_{ET}^{DBA} = 0.25$), and since the fluorescence yield of DBA is known, the triplet yield ($\phi^T$) can be obtained from eq. (h)[19].

The convenience of these luminescent techniques cannot be overemphasized. They are simple to carry out, sensitiv-

ity is merely limited by the quality of the photometric equipment on hand, and most importantly the exact nature of the chemienergized excited states involved in the energy transfer need not to be known. It should, therefore, not be surprising that such methods are extensively used in assessing excitation yields, particularly in biological systems[27].



For this purpose water-soluble lumophores have been developed, such as sodium 2-anthracenesulfonate (AS) and sodium 9,10-dibromo-2-anthracenesulfonate (DBAS). Thus, in the HRP-catalyzed autoxidation of isobutyraldehyde, generation of triplet acetone was confirmed by showing that fluorescence of DBAS, but not of AS, could be sensitized[22]. In addition, fluorescence of **28a—c**[28] and flavins **29**[29] could be stimulated effectively by triplet acetone generated from HRP-catalyzed autoxidation of isobutyraldehyde (**28a**: fluorescein; **28b**: eosin; **28c**: rose bengal).



Similarly, the lumophores **28** and **29** could be sensitized by HRP-catalyzed autoxidation of straight-chain aldehydes, which presumably occurs *via* triplet aldehydes derived from intermediary dioxetanols such as **25**[30]. However, triplet excited 3-indolecarbaldehyde, produced in the HRP-catalyzed autoxidation of 3-indolacetic acid *via* the postulated α-peroxylactone **27**[31], could not be detected with flavins. When this enzymatic autoxidation was carried out in the presence of micelle-solubilized chlorophylls, these lumophores fluoresced strongly, thus indicating that electronically excited 3-indolecarboxaldehyde occurs as an intermediate[32]. Cationic (CTAB), anionic (SDS), and neutral (Brij-35 and Triton X-100) micellar solutions of chlorophylls all gave excellent results.

Thus, this novel detection system holds great promise for the search of enzymatically generated triplet carbonyl products *via* peroxidase-catalyzed autoxidation of appropriate substrates, provided a chemically induced electron exchange luminescence (CIEEL) process can be excluded. For example, using micellar solutions of chlorophylls it was possible to detect triplet carbonyl products in the HRP-catalyzed autoxidation of phenylacetaldehyde **30**[33], ethyl 2-formyl-2-phenylethylacetate **31**[34], and isonicotinic acid hydrazide **32**[35].

**30** **31** **32**

Even complex biomolecules can serve as lumophores to monitor enzyme-generated triplet excited carbonyl products. Thus, in the HRP-catalyzed autoxidation of 3-indoleacetic acid in the presence of $tRNA^{Phe}$, emission from the 4-thiouridine moiety **33** could be sensitized[36]. In a control

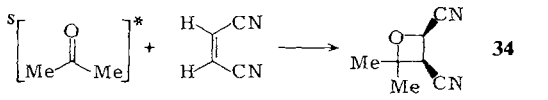
**33**

experiment it was shown that photoenergized 3-indolecarboxaldehyde sensitized the same emission. When $tRNA^{Phe}$ is replaced by yeast tRNA, which lacks the thiouridine group, no sensitization is observed. More recently it has been found that triplet acetone, triplet straight-chain carbaldehydes, and triplet 3-indolecarbaldehyde, all generated from the appropriate substrate *via* HRP-catalyzed autoxidation, elicit red emission from intact chloroplasts[37]. Processes other than energy transfer could be excluded.

After having presented the advantages of energy-transfer chemiluminescence (ETC) to detect and quantitate chemically and/or biologically generated excited states, its limitations should now also be pointed out. Clearly, in order to be efficient, the excitation energy of the lumophore must be low enough to cause exothermic energy transfer. For simple carbonyl excited states, such as acetone, benzaldehyde, methyl benzoate, *etc.*, the choice of an appropriate lumophore is not difficult, because all of these species have relatively high excitation energies. Even DPA and DBA or AS and DBAS suffice, although their singlet excitation energies are as high as *ca.* 70 kcal/mol. However, for extensively conjugated carbonyl excited states whose singlet excitation energies lie below 50 kcal/mol and triplet excitation energies below 30 kcal/mol, the choice of appropriate lumophore is problematic. If lumophores with sufficiently low excitation energies are used, *e.g.* porphines or rubrene, an electron exchange luminescence (CIEEL) mechanism may be promoted[38]. Satisfactory solutions to these analytical problems have not yet been provided.

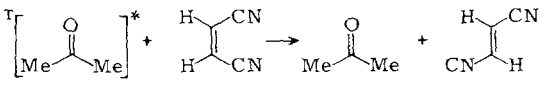
### 3.2. Chemical Titrations

As outlined in Scheme 1, in this type of detection system the chemienergized excited state undergoes a known photochemical transformation either directly or *via* energy transfer. The mathematical relationships for the determination of the excited state yields are given by eqs. (j) and (k). In practice the chemical yield ($\phi_{chem}$) of photoproduct



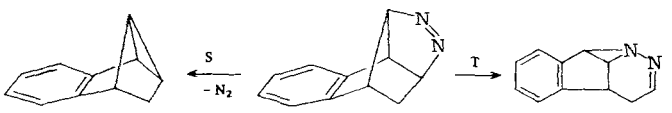
$$\phi_{chem} = \phi_{exc} \cdot \phi_{photo} \quad (j)$$

$$\phi_{chem} = \phi_{exc} \cdot \phi_{ET} \cdot \phi_{photo} \quad (k)$$



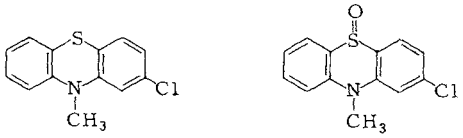
$\phi_{chem}$ = direct or sensitized yield of chemienergized photoproduct; $\phi_{exc}$ = chemiexcitation yield ($\phi^S$ for singlets and $\phi^T$ for triplets); $\phi_{photo}$ = yield of photoenergized photoproduct; $\phi_{ET}$ = energy transfer efficiency

must be determined either spectroscopically or chromatographically; the photochemical yield ($\phi_{photo}$) is usually known or can be determined readily by the usual photomechanistic techniques for photochemical reactions. For sensitized photochemical reactions, the energy transfer efficiency is determined at infinite concentration of photoacceptor under Stern-Volmer kinetics ($\phi_{ET} = 1.0$). All the necessary experimental data is, therefore, available to calculate $\phi_{exc}$ either from eq. (j) or (k). If the direct or sensitized photochemical transformation is singlet-state specific, singlet yields ($\phi^S$) are obtained, but if it is triplet-state specific, then triplet yields ($\phi^T$) are obtained. Such photochemical determination of excitation yields is commonly referred to as "chemical titration" of chemienergized excited states.



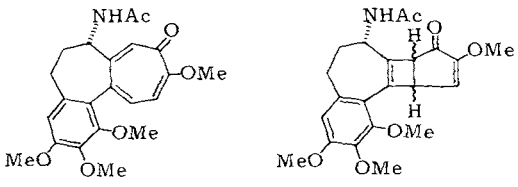
The now classical example of sensitized chemical titration by energy transfer is shown in reaction (l). Thus, singlet and triplet excited acetone react with maleonitrile to give the oxetane **34** and fumaronitrile[39]. Hence, $\phi^S$ and $\phi^T$ can be determined in one experiment from eq. (k) by quantifying the chemical yield of the photoproducts.

(l)



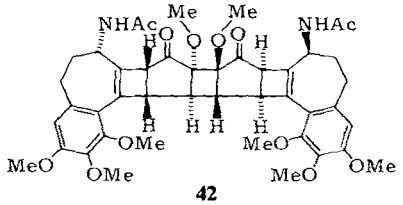
A more recent spin state-specific chemical titrant of chemienergized singlet and triplet excited carbonyl products is the azo compound **35**, which on singlet sensitization gives the tetracyclic hydrocarbon **36**, and on triplet sensitization the aziridine **37**[40]. Numerous other examples of such sensitized and direct chemical titrations of chemienergized carbonyl excited states have been compiled[19].

**36** **35** **37**



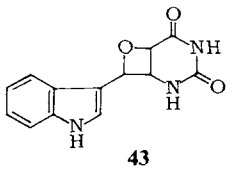
The major advantage of these chemical titrations is that no special photometric equipment is necessary to measure quantum yields. Instead, the chemical yield of photoproduct is determined by standard spectroscopic and chromatographic techniques. Furthermore, one has at one's disposal a wide range of photochemical transformations. Again, sensitized chemical titrations are more convenient than the direct, since in the former the exact nature of the chemienergized excited state need not to be known. Moreover, in direct chemical titrations for each specific case a specific dioxetane or α-peroxylactone needs to be synthesized as an excited state equivalent. In sensitized chemical titrations, however, only a suitable photoacceptor needs to be sought, whose excitation energy, of course, must lie below that of the chemienergized excited state so that energy transfer is efficient. It is not surprising, therefore, that sensitized chemical titrations of this type have been used to monitor enzymatically generated excited states. For example, the 7% yield of isopropyl alcohol found when the HRP-catalyzed autoxidation of isobutyraldehyde is carried out in ethanol has been attributed to reduction of the intermediary triplet acetone by ethanol[22d].

In the meantime a number of such dark photobiological transformations have been reported[27]. For example, HRP-catalyzed autoxidation of isobutyraldehyde in the presence of chloropromazine **38** affords the sulfoxide **39** and the radical cation of **38**[41]. It is known that chloropromazine is



**38** **39**

photooxidized *via* triplet sensitization[42], implicating triplet-triplet energy transfer from enzymatically produced triplet acetone. In this respect DBAS serves as inhibitor, presumably by quenching triplet acetone. Quantitative estimates indicate that the yield of triplet acetone in this peroxidase-catalyzed autoxidation is almost 100%. Similarly, the interconversion of the phytochromes $P_R$ and $P_F$ is sensitized by enzymatically generated triplet acetone derived from HRP-catalyzed autoxidation of isobutyraldehyde[43].

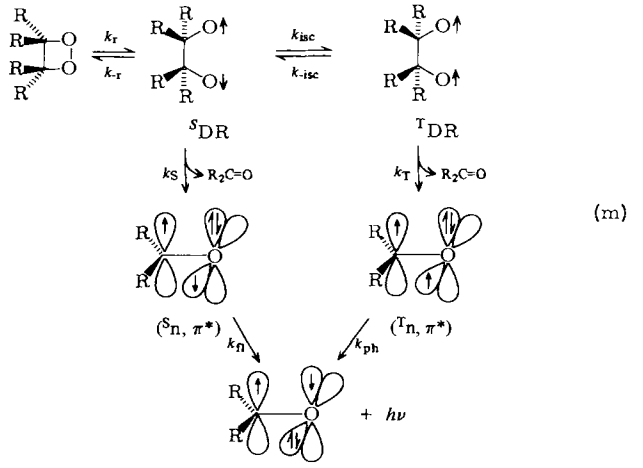


**40** **41**

**42**

One of the most intriguing and significant studies along these lines entails sensitized conversion of colchicine **40**

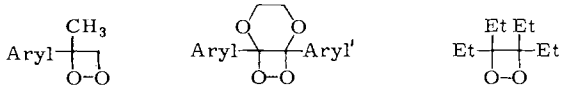
into β- and γ- **41** and α-lumicolchicine **42** by triplet acetone generated in the HRP-catalyzed autoxidation of isobutyraldehyde[44]. The chemical yield ($\phi_{chem}$) is approximately 7%. What is especially significant is that this photochemical transformation takes place in *Colchicum autumnale L.*, even in parts not exposed to light[45]. It is, therefore, conceivable that in the living organism triplet excited states are produced endogenously, which sensitize the colchicine-lumicolchicine conversion by energy transfer. The fact that α-lumicolchicine **42**, a photodimer of β-lumicolchicine **41**, is produced under biological conditions in the dark has important implications for dimerization of thymine mediated by endogenously generated excited states. In this connection a photoadduct between lysozyme and riboflavin has recently been isolated from the HRP-catalyzed autoxidation of isobutyraldehyde[46]; formation of the Paterno-Büchi adduct **43** between enzymatically generated triplet 3-indolecarbaldehyde and the uridine group of tRNA has been demonstrated[36b]. From this chemical titration it was estimated that the triplet excitation yield ($\phi^T$) of 3-indolecarbaldehyde in the HRP-catalyzed autoxidation of 3-indoleacetic acid approaches *ca.* 20%.



**43**

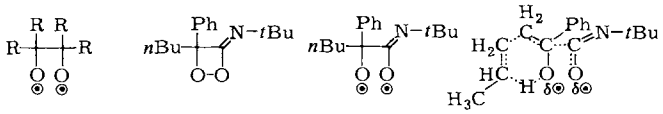
Clearly, chemical titration techniques provide a powerful and convenient tool for the detection and quantitation of enzymatically generated excited states allegedly derived from intermediary 1,2-dioxetanes and α-peroxylactones. Together with the luminescent probes, they provide a wide spectrum of generally applicable analytical methods. The future should witness further intensified activity in this still virgin territory of bioorganic chemistry.

## 4. Mechanistic Incognita



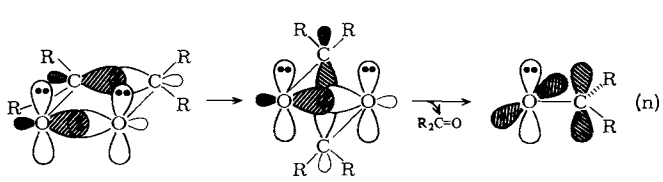
To account for the thermal stability of dioxetanes and α-peroxylactones, and to explain their ability to generate electronically excited states, a thorough understanding of the mechanism of their thermal decomposition is essential. It is, therefore, hardly surprising that since the discovery of dioxetanes intensive efforts have been expended on this perplexing mechanistic problem[15]. Two extreme mechanistic views have persisted over the last decade, each backed up by convincing experimental data. Based on thermokinetic calculations[47], the diradical mechanism (m) was proposed as the best explanation of the thermal stability of dioxetanes (eq.m). Furthermore, the high propensity of triplet state generation, *i.e.* the ($^T$n,π*) state of the carbonyl product, can be accounted for by imposing the kinetic conditions $k_{isc} > k_S$ and $k_T > k_{-isc}$.

Recently, evidence to support the diradical mechanism has been presented which uses Hammett correlations of substituent effects on the decomposition rates of 3-aryl-3-methyl-1,2-dioxetanes **44**[48] and 2a,6a-diarylperhydro[1,2]dioxeto[3,4-*b*][1,4]dioxins **45**[49], and the influence



(m)

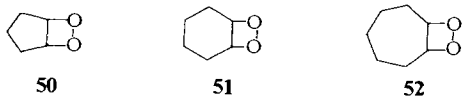
of steric effects on the rates of thermolysis of 3,3-dialkyl- and trialkyl-1,2-dioxetanes[50]. However, one of the biggest drawbacks of the diradical mechanism is its failure to account for the unusual stability of the tetraethyl-1,2-dioxetane **46**[51].



**44** **45** **46**

Trapping experiments would constitute the most unequivocal proof for the involvement of diradical intermediates such as **47** in the thermolysis of 1,2-dioxetanes. However, although no positive results have been reported yet, an interesting observation concerns the formation of acetophenone and propene in the thermolysis of the dioxetane derivative **48**. The diradical **49**, which fragments *via* the transition state **49**$^{\ddagger}$, was proposed as precursor of the observed product[52].

**47** **48** **49** **49**$^{\ddagger}$



Neither has it been possible so far to detect dioxetane diradicals spectroscopically. For example, multiphoton infrared excitation of tetramethyl-1,2-dioxetane in the gas phase did not result in detection of diradical intermediates, thus limiting their lifetimes to less than 5 ns[53]. Still more convincing evidence that such diradicals, if indeed formed, must be extremely short-lived (less than 10 ps) is provided by the fact that they were not even detected by picosecond spectroscopy in the 264 nm pulsed photolysis of tetramethyldioxetane in acetonitrile using a mode-locked neodymium phosphate laser[54].

(n)

In the alternative mechanism (n), which involves simultaneous oxygen-oxygen and carbon-carbon bond scission, dioxetane decomposition occurs concertedly[55] (eq. n). Puckering of the four-membered ring allows optimal alignment of the hatched orbitals shown in the formulae to form an n,π* excited state of the carbonyl product. To explain the high yield of triplet excited product it has been proposed that enhanced spin-orbital coupling occurs during puckering[56].

Recent evidence in favor of this decomposition mode is provided by the series of dioxetanes **50**—**52**[57]: the activation parameters (Table 2) clearly show that the fused six-membered ring dioxetane **51** is considerably more thermally unstable than the homologues **50** and **52**[58]. This dependence of the thermal stability on ring size can hardly be explained in terms of the diradical mechanism (m). It was argued[57] that in dioxetane **51** the four-membered ring is puckered and thus already partway along the decomposition coordinate of the concerted mechanism (n), whereas in dioxetanes **50** and **52** the four-membered rings can be planar, and thus require greater thermal activation to acquire the twisted transition state. Examination of Dreiding models corroborates this proposal.

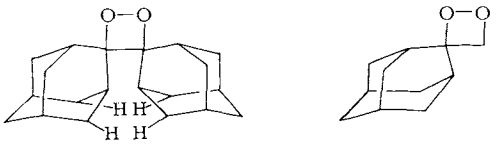
**50** **51** **52**

Table 2. Activation parameters of the bicyclic 1,2-dioxetanes **50**–**52** [a].

| Dioxetane | $\Delta H^{+}$ [kcal/mol] | $\Delta S^{+}$ [cal/mol/K] | $\Delta G^{+}$ (333.2 K) [kcal/mol] | $10^4\,k$ (333.2 K) [$s^{-1}$] |
|---|---|---|---|---|
| **50** | 25.3±0.3 | +1.6 | 24.8 | 3.8 |
| **51** | 21.9±0.3 | −2.1 | 22.5 | 110 |
| **52** | 25.4±0.3 | +1.9 | 24.8 | 4.0 |

[a] Determined by chemiluminescence measurements under isothermal conditions [58].

To test this hypothesis, the set of crystalline dioxetanes **17**—**19** were prepared and their activation parameters and crystal structures determined[18b]. As the structural data show (Table 1), the dihydrobenzodioxin annelation unfortunately necessitates essentially planar four-membered rings in all three dioxetanes. It is, therefore, not surprising that the rate constants for their decomposition are almost the same (Table 1). Challenging work lies ahead to synthesize a set of crystalline dioxetanes with fixed puckered or planar geometries, *e.g.* of type **53** and **54**. It is known that **53** is considerably more thermally labile than **54**[59]. Crystal structure analysis might provide an answer to this interesting mechanistic problem.



**53** **54**

Clearly, experimental evidence has been amassed both for and against the diradical and concerted mechanisms[15]. To resolve this dichotomy, a number of studies on the thermal stability and excitation parameters have recently been performed. For example, the complete set of methylated 1,2-dioxetanes **1**, **13**, **23**, and **55**—**57** have been prepared and their activation parameters determined (Table 3)[13]. The principal intention here was to test the substituent effect of one particular alkyl group, in this case methyl, by measuring the activation parameters under identical conditions in the same laboratory, and thus avoid the great divergence in results of this type as indicated by a recent compilation[60]. The rate constants in Table 3 display a pronounced substituent effect, *e.g.* the parent 1,2-dioxetane **13** decomposes about 75 times faster than the tetramethyl-1,2-dioxetane **23** at 343.2 °K, and the change in activation enthalpy ($\Delta H^{+}$) per methyl substituent is *ca.* 1 kcal/mol. While this significant substituent effect provides evidence in favor of the concerted mechanism, thermokinetic calculations[47] assuming a diradical decomposition pathway also predict a monotonic increase in the thermal stability of 1,2-dioxetanes on increasing methylation.

It is also interesting to mention that the efficiency of chemienergization increases with increasing methylation, the increase being mainly in the triplet yield. This is consistent with the empirical trend that the triplet yield ($\phi^{T}$) increases with the activation energy[61].

A persisting problem is to provide an explanation for the unusual thermal stability of the 1,2-dioxetane **10** with two spiroadamantane moieties. Even a single spiroadamantane moiety significantly stabilizes such dioxetanes against thermolysis[4,62]. Because of the rigid geometry of

**10** **58**

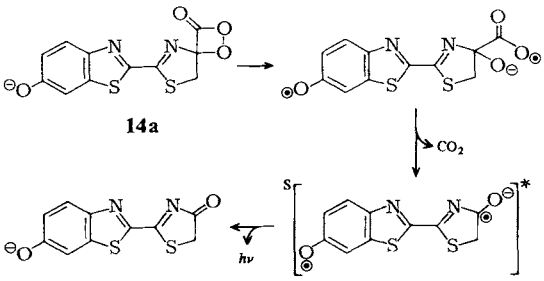
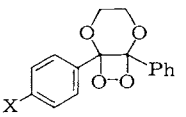
[a] Determined by chemiluminescence measurements under isothermal conditions [13].



the adamantyl group, the four equatorial methylene H atoms in **10** are interlocked[16].

One consequence of this is that **10** has one of the most puckered dioxetane rings (torsional angle *ca.* 21.3°). The interlocking of these H atoms prevents further twisting of the four-membered ring, and the diradical mechanism, therefore, seems to be the more plausible. In this context it would be important to investigate the, as yet unknown, spiro[adamantanedioxetane] **58**, since in this molecule such stabilization arising from interlocking of H atoms is not possible.

It should be evident that a mechanistic explanation for even such a straightforward molecular property as the thermal stability of these intriguing dioxetanes has not been satisfactorily solved experimentally. The dichotomy of diradical and concerted pathways persists! Considerable mechanistic work is essential to resolve these problems. Theoretical studies have provided some progress. The most recent and sophisticated calculations[63] suggest the diradical mechanism; however, irrespective of their sophistication, all quantum-mechanical methods used predict a puckered transition state, both for the concerted as well as for diradical decomposition[60]. Consequently, theoreticans also have plenty of food for thought. Apart from accounting for the thermal stability of these "high-energy" compounds, a still more significant problem is to provide an explanation for the efficiency of generation of excited states in terms of their structures. A novel and provocative hypothesis is that an exciplex between the two carbonyl fragments is formed as the initial excited-state species in the decomposition of 1,2-dioxetanes[48]. In fact, exciplex emission has been observed for indole-substituted dioxetanes[64]. Such effects might also account for a number of poorly understood empirical trends in the excitation parameters[19]. Clearly, molecular spectroscopists should also get involved here.



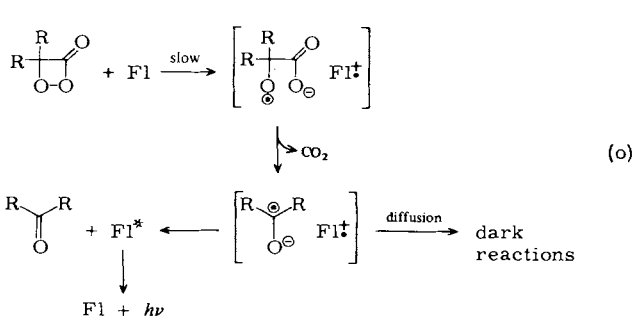
Still more perplexing is the unusual ability of dioxetanes to chemienergize preferentially triplet excited carbonyl products. Of significance and importance in this context is the still poorly understood phenomenon of energy-surface crossings. A qualitative treatment[65] emphasizes the potential of such a view, and more intensive action along these lines appears mandatory.

Mechanistic work on the decomposition of four-membered ring peroxides of biological importance is even more difficult because compounds of this type are too labile to be isolated. Nevertheless, significant progress has been made in understanding the mechanism of luciferin bioluminescence[14], especially that of the firefly [reaction (e)]. With the recognition of the phenomenon of chemically induced electron exchange chemiluminescence (CIEEL) between peroxides and easily oxidized fluorescers[38], model studies confirmed that the catalyzed luminescent decomposition of α-peroxylactones belonged to this novel category of chemiluminescence reactions [reaction (o)][66]. This then enabled the high quantum yield (*ca.* 90%) of singlet excited states observed in luciferin bioluminescence to be rationalized. Thus, reaction (p) represents an intramolecular version of the model process (o)[67]. Significant in this context is the long-known fact[68] that efficient production of singlet excited states requires the phenolate form **14a** of the α-peroxylactone **14**. In **14a** the benzenethiazole group

(p)

behaves as the electron donor and the α-peroxylactone moiety as the electron acceptor; however, since this takes place intramolecularly, electronically excited oxyluciferin is produced efficiently after decarboxylation. In fact, a recent model study[69] of the dioxetane **59** provides convincing evidence for this hypothesis. Thus, while the unsubstituted dioxetane **59** (X = H) gave a large triplet yield of excited product, the phenolate derivate **59** ($X = O^{\ominus}$) gave predominantly a singlet excited product. Clearly, intramolecular CIEEL must also operate here analogously to the α-peroxylactone **14** of firefly luciferin. In the future other examples of such intramolecular electron exchange chemiluminescence will surely be discovered.

**59**, X = H, OH, OMe, $O^{\ominus}$



Another area of biological investigation in which important progress has been made are energy-transfer phenomena involving enzymatically generated excited states[27]. Only some of the recent highlights will be presented here. For example, in normal triplet-singlet energy transfer involving free collisions [eq. (q)], the Stern-Volmer constant [eq. (r)] for triplet acetone quenching should not exceed that ob-

$$^{T}D^{*} + A_0 \longrightarrow D_0 + {}^{S}A^{*} \qquad (q)$$

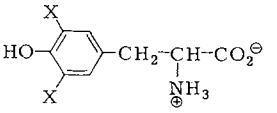
$$K_{SV} = k_{ET} \cdot \tau_0 \qquad (r)$$

D = Donor; A = acceptor; $k_{ET}$ = effective rate constant of energy transfer; $\tau_0$ = unquenched donor lifetime

served for molecular oxygen, *i.e.* $K_{SV}$ is *ca.* $2 \times 10^{-3}$ to $5 \times 10^{3}$ L mol$^{-1}$. Frequently, however, $K_{SV} \geqq 10^{4}$ L mol$^{-1}$. Since the Förster criteria[70] for long-range triplet-singlet energy transfer are not met in all cases, one may infer from these high $K_{SV}$ values that the acceptor is very near the ac-

(o)

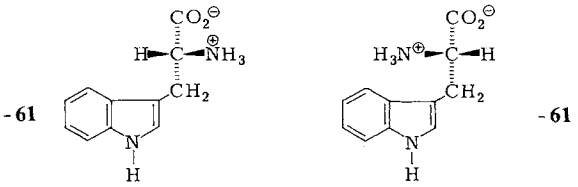
tive site prior to excitation by the donor. This proximity, therefore, facilitates triplet-triplet energy transfer [eq. (s)]. This mechanism may even apply when the Förster overlap



$$^{T}D^{*} + A_0 \longrightarrow D_0 + {}^{T}A^{*} \qquad (s)$$

criterion is met. Such a case appears to be the quenching of enzymatically generated acetone phosphorescence by the xanthene dyes **28**[28]. When the integrated sensitized dye emissions and the fluorescence yields are taken into account, the relative efficiencies of populating the singlet excited state of the dye are found to be 1 : 15 : 100, respectively, for fluorescein, eosin, and rose bengal. The significantly greater $S_1$ yield with rose bengal most probably arises because the triplet energy of the acetone donor is first transferred to an upper triplet state of the dye acceptor: the iodine atoms (heavy atom effect) in the rose bengal favor formation of its singlet excited state *via* enhanced intersystem-crossing [eq. (t)]. If only the traditional Förster mechanism [eq. (q)] were to operate, fluorescein would have had the highest relative efficiency.

$$\begin{aligned} {}^{T}D^{*} + A_0 &\longrightarrow D_0 + {}^{T_2}A^{*} \\ {}^{T_2}A^{*} &\longrightarrow {}^{S}A^{*} \\ {}^{S}A^{*} &\longrightarrow A_0 + h\nu \end{aligned} \qquad (t)$$



Evidence in support of this hypothesis is provided by the chemienergized fluorescence of DBA by triplet acetone generated thermally from tetramethyldioxetane. By analogy to eq. (t), an upper triplet state ($T_2$) of DBA is first produced *via* allowed triplet-triplet energy transfer; subsequently, the intramolecular heavy atom effect enhances intersystem-crossing from the $T_2$ to the $S_1$ state[71]. This mechanism appears also to apply to the energy transfer from enzymatically generated triplet acetone to DBAS as acceptor. In this context it is of interest to mention that energy transfer to AS occurs as efficiently as to DBAS; however, no fluorescence is observed with AS since it lacks the bromine atoms of DBAS to promote intersystem-crossing of the $T_2$ to the $S_1$ state. Instead, internal conversion of the $T_2$ to the $T_1$ state of AS is favored; the $T_1$ state, however, does not emit.

A further interesting case of energy transfer concerns the tyrosine derivatives **60**. Thus, when triplet acetone is chemienergized by thermolysis of tetramethyldioxetane in the presence of these tyrosines, the Stern-Volmer quenching plots (monitored by DBAS) are linear[72]. Except for the parent tyrosine, **60a**, the quenching rate constants approach those operating under diffusion control conditions. Presumably the energies of the $T_2$ states are too high, so that the $T_1$ states of the tyrosines **60b—d** are energized directly. The intramolecular heavy atom effect cannot, therefore, be observed experimentally for these quenchers, since the energy transfer process of eq. (t) is not accessible energetically. However, if triplet acetone is generated enzymatically *via* HRP-catalyzed autoxidation of isobutyraldehyde, the Stern-Volmer quenching plots for the parent tyrosine **60a** and its dichloro derivative **60b** are almost linear, whereas for the dibromo **60c** and especially for the diiodo **60d** derivatives, the corresponding plots have a marked upward curvature. A heavy atom effect is also discernible with **60c** and **60d**. A static contribution to quenching in the presence of the enzyme involving enzyme-protected triplet acetone seems to operate.

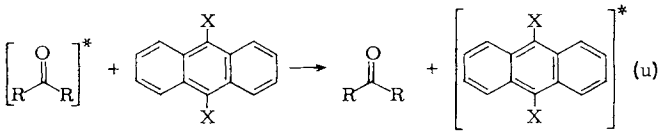
**60a**, X = H
**60b**, X = Cl
**60c**, X = Br
**60d**, X = I

The protective role of the enzyme is most convincingly demonstrated in the quenching of enzymatically generated acetone phosphorescence by D- and L-tryptophan **61**[73]. Thus, when D-tryptophan is present, competitive quenching by L-tryptophan is very inefficient; however, when the converse applies, quenching by D-tryptophan is still observed. This chiral discrimination precludes the possibility that triplet acetone and the quencher exist freely in solution under these conditions, since triplet acetone generated by thermolysis of tetramethyldioxetane is quenched equally efficiently by D- and by L-tryptophan. The chiral discrimination by the enzymatically generated triplet acetone probably involves a collisional complex of the quencher and the active site of the enzyme prior to energy transfer.

-61 -61

*D*-61 *L*-61

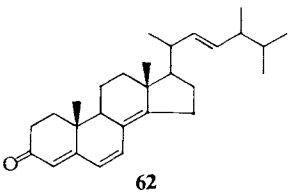
Several features about these unusual results with enzymatically generated triplet acetone still remain unsolved. For example, complete quenching by quinones can be observed even at concentrations much lower than that of the enzyme[74]. Under these conditions the quencher can encounter at most one acetone triplet during the lifetime of the latter (*ca.* $10^{-5}$ s). Quenching by long range energy transfer must, therefore, operate. In this respect the Förster overlap criterium is fulfilled for some, but not all quinones. Quenching by electron transfer or charge transfer interaction is unlikely because both triplet acetone and quinones are electron acceptors.



A further important unresolved question concerns how the excited species transfers energy to organelles such as chloroplasts and to acceptors in micelles. When the triplet energy donor is shielded by the protecting enzyme, energy transfer may require the intermediacy of exposed groups of the macromolecule or of the organelle. For micelles the acceptor presumably resides at or near the micellar surface. No doubt, interesting results should be forthcoming in this fascinating bioorganic discipline.

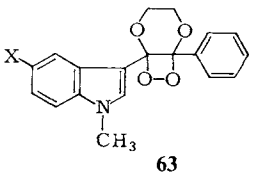
## 5. Photological Divertissement

The fact that 1,2-dioxetanes and α-peroxylactones are masked electronically excited states, defined here as "excited state equivalents", clearly has important consequences in the elucidation of photophysical, photochemi-



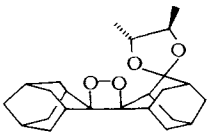
cal, and photobiological phenomena[*]. As implied in Scheme 1, chemically and biologically photoenergized excited states behave in the same way as excited states generated by the action of light. Clearly, chemi- and bioenergization provide fascinating opportunities to study photological problems in an unconventional manner, also referred to as photochemistry[75] and photobiology[76] in the dark. The fundamental difference, however, in these two approaches is that photoenergized generation of excited states competes with photoabsorption by the substrate, whereas chemi- and bioenergization entail straightforward conventional techniques, with the proviso, however, that the four-membered ring peroxides must first be synthesized. This is frequently not a trivial task and presumably has restricted more frequent use of these "high-energy" molecules. Nevertheless, the preparation of the stable dioxetane **10** is an undergraduate laboratory experiment[77], and the synthesis of the more labile tetramethyldioxetane **23** can be mastered by a proficient laboratory technician in a few days. Consequently, there are no excuses for not employing these interesting molecules.

As a divertissement, a number of photophysical, photochemical, and photobiological problems will be presented in which 1,2-dioxetanes and α-peroxylactones have been employed as "excited state equivalents". This selection should serve to encourage more intensive activity in this promising area. In this context a number of problems will be outlined that could possibly be tackled with the aid of four-membered ring peroxides.

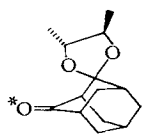


In photophysics, dioxetanes lend themselves particularly well to energy transfer studies. By means of photoenergization it would be difficult to transfer excitation energy from a weakly absorbing donor to a strongly absorbing acceptor, especially if the absorption bands extensively overlap. A specific example is given in eq. (u), in which an excited carbonyl compound (weakly absorbing donor) transfers its excitation energy to the 9,10-disubstituted anthracene (strongly absorbing acceptor) (X = Ph: DPA; X = Br: DBA). Clearly, with conventional photoenergization all the light is preferentially absorbed by anthracene. However, by heating the appropriate dioxetane in the presence of the anthracene acceptor the desired excited carbonyl product is generated *via* chemienergization, and competitive photoabsorption problems are, therefore, circumvented. Hence, important photophysical data, which were previously difficult to obtain, can be acquired for the triplet-singlet energy transfer of chemienergized acetone to 9,10-dibromoanthracene (DBA) in solution and in polymer matrices[71,78]. The singlet-singlet energy transfer of chemienergized acetone to ergostatetraenone **62** could also be studied in an analogous way[78g].

[*] No collective term exists in the dictionary for photobiology, photochemistry, and photophysics, so that we shall define the term photology, as the *science* (logia) of *light* (phos).

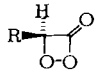


**62**



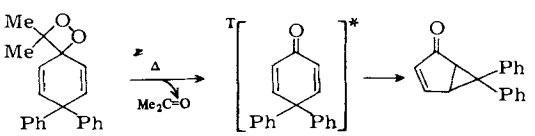
**63**

Unconventional energy transfer studies of this type hold great promise for biologically important acceptors. Even macromolecules and organelles (chloroplasts) can be selectively energized by four-membered ring peroxides. The feasibility of such studies has already been demonstrated with enzymatically generated excited states[37], but authentic dioxetanes should prove more convenient.



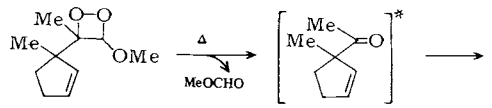
With the observation of exciplex emission[64] in the direct chemiluminescence of the indolyldioxetanes **63** and the suggestion that exciplex formation might be quite general in dioxetane decomposition[48], a number of stimulating problems present themselves. For example, the optically active dioxetane **64** causes circularly polarized fluorescence of the chiral adamantanone **65**[79]. In fact, circularly polarized bioluminescence has been observed for the firefly[80] arising from the achiral oxyluciferin [reactions (e) and (p)], while the adamantanone **65** possesses a permanent chiral center. A chiral excited state of the oxyluciferin arising from exciplex formation might possibly be the cause of circularly polarized bioluminescence in the firefly. Consequently, it would be of interest to synthesize an optically active α-peroxylactone **66**, or for that matter a 1,2-dioxetane, which subsequently leads to an achiral product, but whose intervening chiral excited state (presumably an exciplex) might emit polarized chemiluminescence. An interesting luminescent probe for elucidating excited state geometries thus presents itself.

**64**



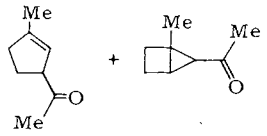
**65**

**66**



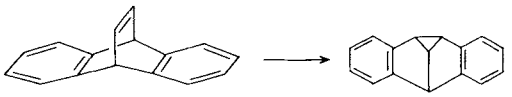
Bisdioxetanes, for example the benzoic acid anhydride dimer **22**[81], should be excellent precursors for the thermal generation of upper excited states, since each dioxetane ring represents the equivalent of a trapped photon. Possibly "biphotonic" processes might be included in such unconventional studies.

In photochemistry, use of chemienergization to tackle mechanistic problems has been surprisingly rare. The value of dioxetanes is clearly evident in the decomposition of **67**, where they chemienergize the formation of enone **69** *via* the $^3n,\pi^*$ excited state of dienone **68**[82]. In this manner a long standing photomechanistic problem of whether $n,\pi^*$ or $\pi,\pi^*$ triplet states are involved in dienone rearrangement could be resolved.



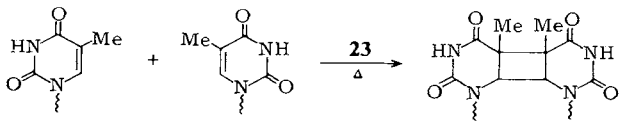
**67** **68** **69**

By analogy, the dioxetane **70** proved useful in elucidating the photomechanistic details of the rearrangement of the excited enone **71** to **72** and **73**[83]. Comparison of the yields of the 1,3-acyl shift product **72** with those of the oxa-di-π-methane (ODPM) product **73** of the chemi- and photoenergized enone **71** leads to the conclusion that a n,π* triplet is the principal precursor for the 1,3-acyl shift and a π,π* triplet for the ODPM process.



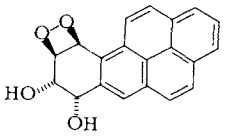
**70** **71**

**72** **73**



In this exploitation of chemienergization the specific excited-state equivalents, dioxetanes **67** and **70**, had to be synthesized. Of course, this is not always a simple task as already mentioned in Section 1. It is considerably more convenient to sensitize a particular photochemical reaction by energy transfer *via* a chemienergized carbonyl excited state as donor. For example, using tetramethyl-1,2-dioxetane **23**, a clean source of triplet acetone, it could be confirmed that the rearrangement of azoalkane **35** to aziridene **37** is a spin-specific triplet reaction[40]. Similarly, using chemienergized triplet acetone the di-π-methane rearrangement of dibenzobarrelene **74** to afford semibullvalene **75** was also shown to be a spin-specific triplet process[84]. In the future such photochemical applications of dioxetanes should certainly become more frequent.

**74** **75**



For the application of four-membered ring peroxides to photobiological problems a rather extensive compilation of the possibilities was made right at the beginning of this field[75,85]. Significant progress was achieved once enzymatic generation of electronically excited triplet states was established[27]. A number of problems have been solved, but many still remain.

Thus, considerable attention has been devoted to photodamage of DNA by thymine dimerization in view of its connection with carcinogenesis[86]. A key experiment[87] was the demonstration that chemienergized triplet acetone, generated from the tetramethyl-1,2-dioxetane **23**, caused formation of thymine dimers **76** in DNA. Subsequently, it

**76**

was shown that bioenergized triplet acetone, generated by HRP-catalyzed autoxidation of isobutyraldehyde, promoted single strand breaks[88] and altered the circular dichroism[89] in DNA. As supporting evidence that enzymatically produced triplet acetone was the damaging species, is the fact that such damage can, in part, be inhibited by DBAS. That a metabolic system can generate excited states *in situ* from intermediary dioxetanes has recently been demonstrated in the degradation of benzo[a]pyrene by liver microsomes. The accompanying weak chemiluminescence was attributed to the intervening dioxetane **77**[90].

**77**

If chemi- and bioenergized triplet excited states can lead, *via* energy transfer, to thymine dimerization in DNA, the photochemical reversion of such damage should, in principle, also be reasible in this manner. Indeed, model studies reveal that photoenergized excited indoles[91] and quinones[92], species that can be generated enzymatically in the dark, induce splitting of thymine dimers **76**.

Another area of great challenge and potential is photoaffinity labeling[94]. For example, the carbonyl functions of hormonal ligands, *e.g.* steroidal ketones, could be masked in the form of dioxetanes or α-peroxylactones. After complexation with the receptor, decomposition of the dioxetane would release the electronically excited ligand, which would become permanently bound to the receptor, thereby revealing the specific binding site. The advantage of such "photoaffinity labeling in the dark" is that it could be performed *in vivo* in aqueous systems.

Stimulating problems of bioorganic significance in which "excited state equivalents" should prove of interest concern photoregulation mediated by phytochromes[95], plant growth hormones involving 3-indoleacetic acid[96], the conversion of ergosterol into vitamin D[97,98], and the isomerization of retinal[99], *etc.* In addition, the opportunity of creating a radically new line of chemotherapeutic agents presents itself.

We shall close with the following citation[100], which best describes our contention that the fun has just begun: "Already today preparative photochemistry plays its own role within the methods of chemistry in view of the special possibilities it offers. However, its real importance arises from the abundant interdisciplinary connections, through which chemical problems caused by biological radiation become especially typical".

*The authors wish to express their deep gratitude to Professor Frank H. Quina (Universidáde de São Paulo) for his unfailing and unselfish assistance. Appreciation is extended to former and present students for their dedicated, diligent, and stimulating collaboration. Generous financial support by the Financiadora de Estudios e Projetos (Rio de Janeiro), the Conselho Nacional de Desenvolvimento Científico e Tecnologico (Brasilia), Fundacáo de Ampazo á Pesquisa do Estado de São Paulo (São Paulo), the Deutsche Forschungsge-*

*meinschaft, the Fonds der Chemischen Industrie, the Fritz Thyssen Stiftung, the Alexander von Humboldt Stiftung, and the Volkswagenwerk Stiftung is acknowledged. The latter deserves special emphasis since it presently sponsors the collaborative efforts of the Brazilian and German groups.*

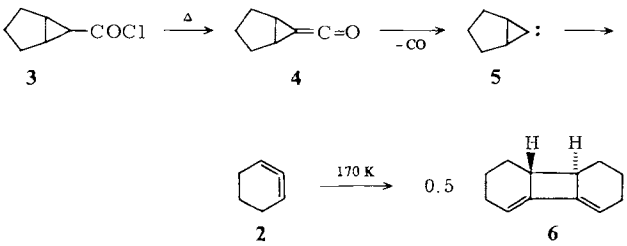
## 1,2-Cyclohexadiene**

By *Curt Wentrup**, *Gerhard Gross*, *André Maquestiau*, and *Robert Flammang*



The structure of 1,2-cyclohexadiene has been a matter of controversy. Calculations and experiments have suggested a planar zwitterionic or diradicaloid ground state **1**[1]. However, it was recently shown in elegant trapping experiments that the species is chiral in solution at room temperature, but that optical activity is lost at 80 °C[2]. This indicates that the trapped species is the nonplanar allene **2** and that at 80 °C it either interconverts with the planar structure **1** or racemizes *via* a planar transition state.

1 2

* signifies ⊕/⊖ or ⊙

We now wish to report the direct spectroscopic observation of **2**, which conclusively proves that the ground state of 1,2-cyclohexadiene is an allene. **2** was generated by vacuum pyrolysis of bicyclo[3.1.0]hexane-6-carbonyl chloride **3** at 800 °C/$10^{-4}$ torr. This leads initially to the ketene **4** ($\nu = 2126\ cm^{-1}$), which under the reaction conditions rapidly loses CO, presumably to give the carbene **5**. The latter undergoes ring opening to the allene **2**, which was collected on a KBr window and characterized by a sharp and strong infrared absorption at 1886 $cm^{-1}$, persisting at temperatures between 11 K (Ar matrix) and 170 K (neat substance). The absorption disappeared at the latter temperature with concomitant formation of the dimer **6**, which has previously been isolated during a preparation of **5** in solution by an alternative route[3]. **6** was isolated by preparative gas chromatography and identified by direct comparison with an authentic sample.

3 4 5

2 6

The identity of **2** was also ascertained by pyrolyzing **3** in a reactor placed immediately before the ion source of a Varian MAT 311A mass spectrometer. The CID-MIKE mass spectrum demonstrated the formation of an ion ($m/z = 80$) whose intensity increased with increasing temperature. At the same time, the intensities of peaks due to the starting material **3** diminished.

Confirmation of the reaction pathway **3** → **2** may also be obtained from the analogous formation of allene by pyrolysis of cyclopropanecarbonyl chloride, as observed by IR and mass spectrometry in the present study and previously by photoelectron spectroscopy[4].

The observation of an allenic absorption for **2** at 1886 $cm^{-1}$ clearly identifies this molecule as a ground state allene. Ring strain and an obvious deviation from linearity causes a shift by approximately 70 $cm^{-1}$ from the normal position of the C=C stretching vibration in allenes. This conclusion is also supported by very recent *ab initio* calculations[5].

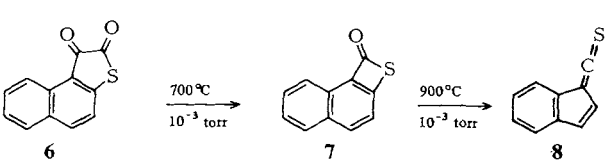
## Thietones, Oxetones, and Azetones**

By *Curt Wentrup** and *Gerhard Gross*

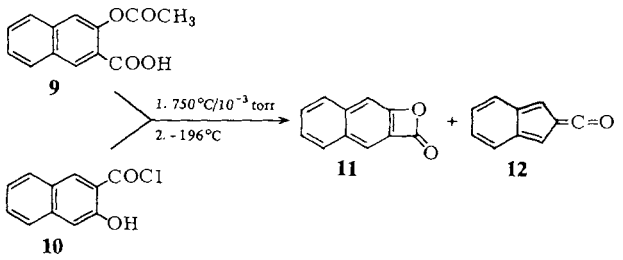
Unsaturated four-membered heterocycles are rare, and no substantiated preparations of stable thietones, oxetones, or azetones have been described. We now wish to report the first isolation of a stable thietone, namely naphtho[2,3-*b*]thiet-2-one **2**, obtained in 25% yield as yellow crystals, m.p. 85 °C, by flash vacuum pyrolysis of 3-mercapto-2-naphthoic acid **1** at 840 °C/$10^{-3}$ torr. The structure of **2** is established by elemental analysis and spectroscopic properties[1]. **2** is indefinitely stable in the crystalline state, but a mixture of dimers and trimers slowly precipitates from solutions at room temperature. Reaction with methanol gives the methyl ester **3** in quantitative yield, and pyrolysis at 900 °C/$10^{-3}$ torr leads to elimination of CO and formation of 2-thiocarbonyl-2*H*-indene **4**, isolated on a KBr window at −196 °C. Compound **4** absorbs in the IR at 1742 $cm^{-1}$, disappears above −100 °C, and reacts with methanol at −120 °C to give the methyl ester **5**.



1

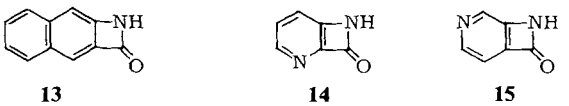
2 4 3 5

The corresponding naphtho[2,1-*b*]thiet-2-one **7** was obtained in quantitative yield by pyrolysis of the dione **6**[2]. **7** is less stable than **2**, dimerizing within 30 min at room temperature. A solution of **7** in $CH_2Cl_2$ reacts with methanol at −40 °C to give the methyl ester of 2-mercapto-1-naphthoic acid in quantitative yield. Pyrolysis of **6** at 900 °C/$10^{-3}$ torr gives the thioketene **8** (IR: 1739 $cm^{-1}$), which is stable below −40 °C and reacts with methanol to furnish *O*-methyl 3-indenethiocarboxylate.



6 7 8

[*] Prof. Dr. C. Wentrup, G. Gross
Fachbereich Chemie der Universität
Lahnberge, D-3550 Marburg (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

The naphthothietones are considerably more stable than benzothietone, the latter having been observed only in a low-temperature matrix[3a] and in the gas-phase using photoelectron spectroscopy[3b]. Also benzoxetone is reported to be unstable[4], but naphtho[2,3-*b*]oxetone has been described as a stable crystalline compound[5]. The compound described is certainly not monomeric. The real naphtho[2,3-*b*]oxetone, the monomer **11**, is obtained by pyrolysis of either **9** or **10** at 750 °C/$10^{-3}$ torr, absorbs in the IR at 1893 and 1874 $cm^{-1}$, is stable till −40 °C, and reacts at this temperature with methanol to give methyl 3-hydroxy-2-naphthoate in 20% isolated yield. In the pyrolyses of **9** and **10** a further, weak IR absorption due to the ketene **12** is observed at 2127 $cm^{-1}$, increasing in intensity with increasing temperature, and also obtained by pyrolysis of methyl 2-indenecarboxylate to which it reverts below −100 °C in the presence of methanol.

9 11 12 10

Naphtho[2,3-*b*]azet-2(1*H*)-one **13** (1778 $cm^{-1}$; stable till 0 °C), azeto[3,2-*b*]pyridin-2(1*H*)-one **14** (1807 $cm^{-1}$; stable till −40 °C), and azeto[2,3-*c*]pyridine-2(1*H*)-one **15** (1809 $cm^{-1}$; stable till 0 °C) were generated by analogous pyrolyses (750 °C/$10^{-3}$ torr) of the corresponding aminocarboxylic acids or esters thereof.

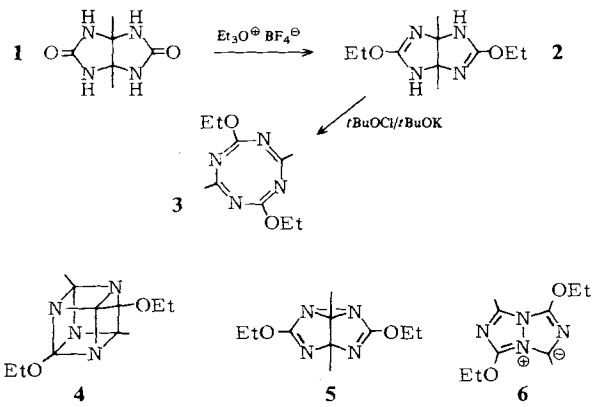
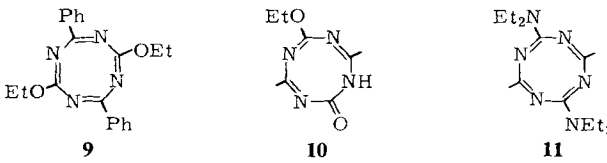
## 1,3,5,7-Tetrazocines**

By *Rudolf Gompper** and *Marie-Luise Schwarzensteiner*



The prognosis that donor-substituted semibullvalenes have a bishomoaromatic ground state is corroborated

[*] Prof. Dr. R. Gompper, M.-L. Schwarzensteiner
Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)



[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

neither by tetramethyl 3,7-diacetoxy-1,5-dimethyltricyclo[3.3.0.0$^{2,8}$]octa-3,6-diene-2,4,6,8-tetracarboxylate[2] nor by similar compounds[3]. Even with a 2,6-diazasemibullvalene[4] only a rapid Cope rearrangement was observed. However, because of the relatively weak NN bond, 1,5-dialkyl-2,4,6,8-tetraazasemibullvalenes should represent the best models for bishomoaromatic semibullvalenes. We report here on attempts to synthesize systems of this type.

Based on our experience gained in synthesizing the above-mentioned semibullvalenetetracarboxylic acid esters, 1,5-dimethylglycoluril should be an appropriate educt[2]. 3,7-Diethoxy-1,5-dimethyl-2,4,6,8-tetraazabicyclo[3.3.0]octa-3,7-diene, **2**, is obtained upon heating **1** and triethyloxonium tetrafluoroborate to 90–100 °C (yield 20–25%; m.p. = 248 °C). **2** reacts with *tert*-butyl hypochlorite and potassium *tert*-butoxide to afford a compound (yield 50%; colorless crystals, m.p. = 26 °C) having the empirical formula $C_{10}H_{16}N_4O_2$. From the spectroscopic data [$^1$H-NMR: solvent $CDCl_3$, room temperature, 60 MHz): $\delta = 1.32$ (t, $J = 6$ Hz; 6H, $OCH_2CH_3$), 2.11 (s; 6H, $CH_3$), 4.20 (q, $J = 6$ Hz; 4H, $OCH_2CH_3$); $^{13}$C-NMR ($CDCl_3$, 80 MHz): $\delta = 14.02$ ($CH_3$), 23.99 ($OCH_2CH_3$), 64.33 ($OCH_2CH_3$), 160.29 (=C–$CH_3$), 173.40 (=C–OEt); $^{15}$N-NMR ($CDCl_3$, 200 MHz): $\delta = 206$], which indicate the presence of only sp$^2$-hybridized framework C atoms, only one type of vinyl $CH_3$-group, and N atoms, neither the tetraazasemibullvalene **5**, the structures **4** and **6**, nor bicyclooctatriene derivatives are involved. Consequently, the compound must be 2,6-diethoxy-4,8-dimethyl-1,3,5,7-tetrazocine **3**.

2,6-Diethoxy-4,8-diphenyl-1,3,5,7-tetrazocine, **9**, can be prepared using the same method (yield 65%; m.p. = 151 °C). According to an X-ray structure analysis[8], **9** has the boat conformation. Compounds **3** and **9** represent the first tetraazacyclooctatetraenes. Previous attempts to prepare these types of compounds have always led to isolation of tetraazapentalenes[9].

When a solution of **3** in ether is stirred for a few days in the presence of silica gel 6-ethoxy-4,8-dimethyl-1,3,5,7-tetrazocin-2(1*H*)-one **10** (m.p. = 86 °C) results. Heating **3** and diethylamine gives the tetrazocine **11** (yield 81%; b.p. = 130 °C/0.01 mbar).

## Photolysis of the Cyclopentadienyl(hydrido) Complexes $C_5H_5M(CO)_3H$ (M = Cr, Mo, W) in Matrices and in Solution: Characterization of $[C_5H_5W(CO)_2H]_2$ and $[C_5Me_5W(CO)_2H]_2$**

By *Helmut G. Alt**, *Khalil A. Mahmoud*, and *Antony J. Rest*

The dissociation energy of transition metal-hydrogen bonds is considerably higher than that of the corresponding transition metal-carbon single-bonds[1]. In the photolysis of carbonylhydrido complexes it is, therefore, to be expected that the initial step should involve removal of the carbonyl ligands and formation of highly reactive hydrido complex fragments. We have irradiated ($\lambda > 300$ nm) the compounds $C_5H_5M(CO)_3H$ (M = Cr, Mo, W) in solution and isolated the subsequent reaction products. To account for the primary step, the photolysis was also performed in gas matrices (Ar, $CH_4$, $N_2$, CO) at 12 K; the photolysis products were characterized by IR spectroscopy. In all cases, with the exception of the CO matrix, the initial step of the photoreaction, the removal of a CO ligand and the formation of the 16e-fragment $C_5H_5M(CO)_2H$, could be detected.

$$C_5H_5M(CO)_3H \underset{\lambda > 370\ nm}{\overset{290 < \lambda < 370\ nm}{\rightleftharpoons}} C_5H_5M(CO)_2H + CO$$

[*e.g.* $C_5H_5W(CO)_3H$: $\nu(CO) = 2025.5$, 1939.5, 1935.1 cm$^{-1}$, $\lambda_{max} = 305$ nm; $C_5H_5W(CO)_2H$: $\nu(CO) = 1956.4$, 1872.0 cm$^{-1}$; free CO: $\nu(CO) = 2138.0$ cm$^{-1}$; in argon matrix at 12 K]. The reaction can be reversed if the products of the initial step are irradiated with visible light ($\lambda > 370$ nm). The fragments $C_5H_5M(CO)_2H$ can be stabilized in the matrix by ligands L (L = $N_2$, $C_2H_4$, $^{13}$CO) or in solution (L = $C_2H_4$, THF, $PMe_3$), leading to formation of *cis/trans*-

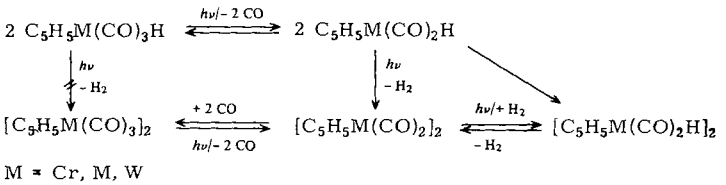
isomers of $C_5H_5M(CO)_2(L)H$[3]. In the CO matrix at 12 K we observed, furthermore, the formation of the radicals $C_5H_5M(CO)_3$ and CHO[4], which indicate the photoinduced removal of the metal-hydrogen bond.



Photolysis of the three carbonylhydrido complexes $C_5H_5M(CO)_3H$ (M = Cr, Mo, W; *ca.* 2 mmol in 300 mL pentane) at 15 °C leads to various products. The yellow, highly air-sensitive $C_5H_5Cr(CO)_3H$ is completely converted within 20 min into $[C_5H_5Cr(CO)_2]_2$, and CO and $H_2$ are evolved. No intermediates were detected upon investigation of the reaction by $^1$H-NMR spectroscopy in [$D_8$]-toluene at −40 °C. $C_5H_5Mo(CO)_3H$ is considerably more photostable than the Cr derivative, and complete photoinduced dehydrogenation requires *ca.* 3 h. The major product $[C_5H_5Mo(CO)_3]_2$ and a minor product $[C_5H_5Mo(CO)_2]_2$ could be isolated. Upon UV irradiation for 5 h the extent of reaction of the colorless $C_5H_5W(CO)_3H$ is only *ca.* 80%. Predominantly $[C_5H_5W(CO)_2]_2$ is found in the reaction solution in addition to small amounts of $[C_5H_5W(CO)_3]_2$, although the major product is a dark brown precipitate [decomp. 115 °C (under $N_2$); yield *ca.* 55%], whose IR, NMR, and mass spectrum indicate a dinuclear complex $[C_5H_5W(CO)_2H]_2$ [MS: *m/z* 612 ($M^+$) relative to $^{184}$W]. We propose the following structure for the complex which dissociates in solution.

The nature of the two bridging hydrido ligands can be clearly determined from the $^1$H-NMR spectrum [$\delta$(WHW) = −13.24, [$D_6$]acetone, −30 °C] due to the intensity of the tungsten satellites [$J$(W,H) = 83.1 Hz; 24% of the signal intensity]. The two $C_5H_5$ ligands exhibit only one singlet ($\delta$ = 6.14). Only two CO-bands occur in the IR spectrum (1930 and 1860 cm$^{-1}$, in toluene), thus confirming the symmetric structure of the dinuclear complex. Comparable data are known for the osmium complex $[C_5Me_5Os(CO)H]_2$[7].

The photolysis of a solution of the pentamethylcyclopentadienyl derivative $C_5Me_5W(CO)_3H$ in pentane proceeds analogously: the major product, the red-brown complex $[C_5Me_5W(CO)_2H]_2$ is eluted from the chromatographic column by toluene [m.p. > 300 °C; yield 65%. IR (pentane): $\nu$(CO) = 1920, 1848 cm$^{-1}$; $^1$H-NMR ([$D_6$]-acetone): $\delta$ = 1.85 (s, 15), −9.30 (s, 1), $J$(W,H) = 82.8 Hz; $^{13}$C-NMR ([$D_6$]-acetone: $\delta$ = 102.3 ($C_5$), 9.9 ($Me_5$), 225.1 (CO); MS: *m/z* 752 ($M^+$) relative to $^{184}$W].

The diamagnetic compounds $[C_5H_5W(CO)_2H]_2$ and $[C_5Me_5W(CO)_2H]_2$ are the first examples of doubly hydrido-bridged neutral complexes which formally possess a W=W bond. We presume that photolysis of the educt $C_5H_5M(CO)_3H$ in solution proceeds according to:

The fragment $C_5H_5M(CO)_2H$, which is generated initially, predominantly undergoes photoinduced dehydrogenation; the radicals thus formed may dimerize to give $[C_5H_5M(CO)_2]_2$, which in turn adds hydrogen photochemically. This assumption is corroborated experimentally: $[C_5Me_5Mo(CO)_2]_2$ rapidly takes up hydrogen upon being UV irradiated to form the 1 : 1 adduct $[C_5Me_5Mo(CO)_2H]_2$ [IR (pentane): $\nu$(CO) = 1929, 1858 cm$^{-1}$; $^1$H-NMR ([$D_6$]acetone): $\delta$ = 1.90 (Me), −10.01 (MoHMo)], which could not be detected in the photolysis of $C_5Me_5Mo(CO)_3H$. Since photolysis of $C_5H_5Cr(CO)_3H$ and $C_5Me_5Cr(CO)_3H$, respectively, in solution leads only to observation of $[C_5H_5Cr(CO)_2]_2$ and $[C_5Me_5Cr(CO)_2]_2$, direct photoinduced dehydrogenation of the parent complexes is precluded. In contrast to the Mo and W derivatives, $[C_5H_5Cr(CO)_2]_2$ and $[C_5Me_5Cr(CO)_2]_2$ are not able to add CO at standard pressure[10].

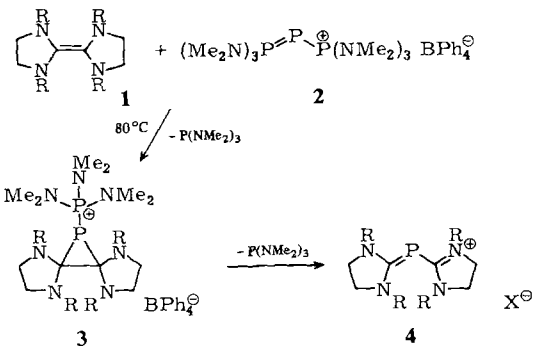
## 2-Phosphaallyl Cations by Formal Insertion of P$^\oplus$ into the C=C Double Bond**

By *Alfred Schmidpeter**, *Siegfried Lochschmidt*, and *Angela Willhalm*

Isoelectronic substitution of the central carbon atom of (linear) allenes by N$^\oplus$ leads to 2-azaallyl cations, whose structures, depending on the nature of the substituents, are either bent or linear. In addition to these alternatives **A** and **B**, a covalent form **C** is also feasible for the corresponding 2-phosphaallyl halides.



**A** **B** **C**

Electron-donating substituents should favor form **A**, whereas electron-attracting substituents should favor form **C**. Examples of **A** are the classical phosphamethine cyanines, in which the carbon atoms are members of heterocycles. One example for **C**, (X = Cl), having $Me_3Si$-substituted carbon atoms is also known.

Particularly form **B** makes one think that phosphaallyl cations could formally be accessible by insertion of P$^\oplus$ into an olefin. A comparable insertion of the C atom isoelectronic to P$^\oplus$ occurs in the conversion of an olefin into an allene[7]. By analogy, the conversion of an olefin into a phosphaallyl cation could commence from $PCl_3$, which in the course of the reaction would have to be reduced to P$^\oplus$. As we have previously reported, this reduction can be per-

formed separately and the $P^{\oplus}$ stabilized as a bisphosphane complex[10]. The complex with tris(dimethylamino)phosphane, the 1,1,1,3,3,3-hexakis(dimethylamino)-1$\lambda^5$,3$\lambda^5$-triphospha-2-enium tetraphenylborate **2**, is particularly easy to handle[11]. In order to accept $P^{\oplus}$ from **2**, however, the olefin must be particularly electron-rich. Thus, the biimidazolidinylidene **1** reacts with **2** in the way suggested to afford the phosphaallyl tetraphenylborates **4** (X = $BPh_4$; R = Me, Et), displacing two equivalents of tris(dimethylamino)phosphane.

The reaction could commence by electrophilic attack of **2** and proceed *via* a phosphiranylphosphonium intermediate, which, however, has not yet been detected.

There is a second, more general and more effective route to amino-substituted 2-phosphaallyl cations[14]: for example, tetramethylchloroformamidinium chloride, **5**, reacts with tris(trimethylsilyl)phosphane, **6**, to form tetrakis(dimethylamino)phosphaallyl chloride, **7**, X = Cl[15].

In the same way the phosphaallyl chloride, **4**, (X = Cl, R = Me) is formed from 2-chloro-1,3-dimethylimidazolidinium chloride.

All of the products **4** and **7** are remarkably insensitive towards oxidation and hydrolysis. In compounds with X = Cl the chloride can be exchanged by other anions without significant alteration of the chemical shifts in the resulting NMR spectra. This result confirms their ionic character. In **4**, $\delta(^{31}P)$ is −93, but in **7**, in contrast, −20, which indicates that in the second case the positive charge is less strongly transferred to the nitrogens. Irrespective of the differences in degree, however, both cases should be of the structural alternative **A**.

## Crystal Structure of 2,4,5,7,9,10-Hexaoxa-1,3,6,8-tetraphenyltricyclo[6.2.0.0$^{3,6}$]decane: An Authentic Bisdioxetane**

By *Waldemar Adam**, *Ernst Schmidt*, *Eva-Maria Peters*, *Karl Peters*, and *Hans Georg von Schnering*

*Dedicated to Professor Giuseppe Cilento on the occasion of his 60th birthday*

The stable product of the photooxygenation of tetraphenyl-1,4-dioxin was assigned the bisdioxetane structure **1**[1], since it thermally decomposed with formation of benzoic anhydride and emission of light. Elemental analysis and

iodometric peroxide titration were consistent with the empirical formula $C_{28}H_{20}O_6$. While chemiluminescence is indicative but not necessarily definitive for 1,2-dioxetanes[2], the cited evidence is in principle also consistent with the alternative structures **2** and **3** for this unusual "benzoic anhydride dimer"[3]. $^1$H-NMR is uninformative in this structural problem and $^{13}$C-NMR ($\delta$ = 107.80 ppm for the dioxetane carbon) cannot differentiate between the possible alternatives. Since **1** is the first bisdioxetane[4] to be reported, it was essential that an X-ray structure analysis be carried out. Aside from confirming the bisdioxetane structure **1**, we expected information about the stereochemical arrangement of the two dioxetane rings, *i.e.* whether they are oriented *syn* or *anti* with respect to each other.

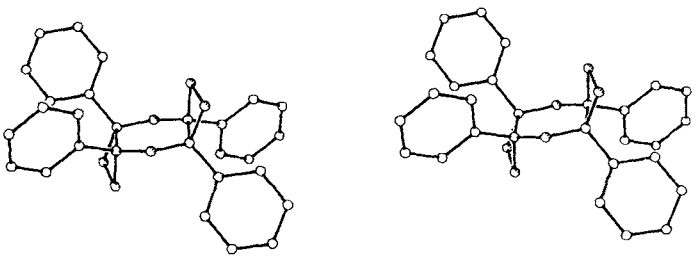

Fig. 1. Stereodiagram of the structure of **1**. Space group $P2_1/n$; $a$ = 1417.3, $b$ = 766.6, $c$ = 1036.7 pm, $\beta$ = 90.00°, $Z$ = 2, $\rho_{calc.}$ = 1.304 g·cm$^{-3}$, 1653 $F > 3\sigma(F)$, R = 0.062.

The $C_{28}H_{20}O_6$ product was prepared as described[1], and well defined crystals were grown by low-temperature re-

crystallization from petroleum ether/dichloromethane (m.p. 111 °C, pale yellow prisms). X-ray structure analysis[5] confirmed beyond any doubt (Fig. 1) that this product is the "benzoic anhydride dimer" **1**, the first authentic bis-dioxetane. As expected, the dioxetane rings are arranged *anti* to each other. Surprisingly, however, they are appreciably puckered (dihedral angle *ca.* 16.3°). The dioxane ring is almost planar; it has a markedly flattened chair conformation (all atoms deviate about 8 pm from the equalizing plane). Presumably, in an almost planar dioxane ring the non-bonding repulsive forces between the dioxetane oxygen atoms and the *syn*-oriented phenyl groups are minimal (inspection of Dreiding models indeed suggest this to be the case).

On the other hand, the related dioxetane **4** (m.p. 113–116 °C, pale yellow prisms from *n*-pentane), prepared by singlet oxygenation of diphenylbenzodioxin[6] (Fig. 2) has

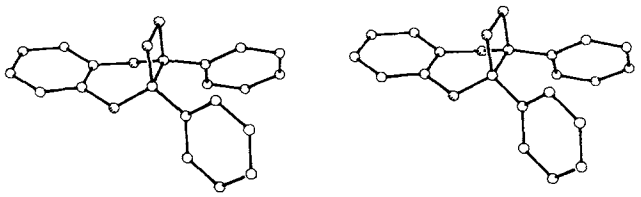

Fig. 2. Stereodiagram of the structure of **4**. Space group $P2_1/a$; $a = 1923.2$, $b = 1239.3$, $c = 1320.6$ pm, $\beta = 93.44°$, $Z = 8$, $\rho_{calc} = 1.346$ g·cm$^{-3}$, 2332 $F > 3\sigma(F)$, $R = 0.084$.

an almost planar dioxetane ring (dihedral angle *ca.* 0.8°) and a puckered dihydro-1,4-dioxin ring. In **1** and **4** the oxygen-oxygen bond lengths are 150.0 and 155 pm, respectively, the dioxetane carbon-carbon bond lengths 155.5 and 161 pm, respectively.

## Lithiumcarbamoyl-bis(ethene)nickel(0)

By *Klaus Pörschke**, *Günther Wilke*, and *Carl Krüger*

Reaction of (cdt)NiCO **1**[1] with organolithium compounds or lithium amides in ether/pmdta as solvent leads to formation of the thermolabile lithiumacyl- or lithiumcarbamoyl-nickel(0) complexes {(pmdta)LiO(R)C}Ni(cdt) (R = $CH_3$ (**2**), $C_6H_5$ (**3**), $NMe_2$ (**4**))[2], which may be regarded as precursors of *carbonyl-free* and *olefin-containing* carbene complexes. We have now been able to replace the triene ligand cdt in **4** by ethene and to isolate the 16e-complex **5** in crystalline form.

$$\underset{\mathbf{1}}{(cdt)NiCO} + (pmdta)LiNMe_2 \xrightarrow[-40°C]{Ether} (pmdta)LiOC(NMe_2)Ni(cdt)\ \mathbf{4}$$

$$\mathbf{4} + 2\ C_2H_4 \xrightarrow[-10°C]{Ether} (pmdta)LiOC(NMe_2)Ni(C_2H_4)_2 + cdt\ \ \mathbf{5}$$

cdt = *trans,trans,trans*-1,5,9-cyclododecatriene
cod = 1,5-cyclooctadiene
cot = cyclooctatetraene
pmdta = pentamethyldiethylenetriamine
tmeda = tetramethylethylenediamine

The yellow-brown crystals of the pmdta-stabilized lithiumcarbamoyl-bis(ethene)nickel(0) **5**, which are stable at room temperature, are readily soluble in polar organic solvents such as ether, tetrahydrofuran (THF) and acetonitrile, moderately soluble in toluene, and only sparingly soluble in pentane. As shown by the NMR spectra, the pmdta ligand is released on dissolution of **5** in THF; the slight electrical conductivity of such a solution ($\Lambda = 0.014$ cm$^{-2}/\Omega$M; 0.1 M, 0 °C) infers a very weak dissociation into ions.

Methanolysis of **5** in presence of cod yields dimethylamine, which was detected gas-chromatographically, and the expected amounts of ethene, as well as CO, $Ni(CO)_4$ and $Ni(cod)_2$. Apparently, the nitrogen atom in **5** is protonated by weak acids, with dissociation of the carbamoyl group. The bonded ethene in **5** is quantitatively liberated by cot. An exchange between bonded and excess ethene cannot be detected by NMR spectroscopy at room temperature. **5** reacts with CO at −78 °C, the CO replacing the ethene to give the 18e-complex **6**, which can also be prepared from $Ni(CO)_4$ or **4**[2].

$$\mathbf{5} + 3\ CO \xrightarrow[-78°C \rightarrow 0°C]{Ether} (pmdta)LiOC(NMe_2)Ni(CO)_3 + 2\ C_2H_4\ \ \mathbf{6}$$

The 400-MHz $^1$H- and 75.5-MHz $^{13}$C-NMR spectra of a solution of **5** in [$D_8$]-THF are temperature-dependent between +20 °C and −80 °C, and show a remarkable complexity at −80 °C. At 20 °C they are consistent with a trigonal-planar coordination of the nickel atom by the two ethene ligands and the carbamoyl ligand, whereby—referred to the NMR time scale—all ligands freely rotate about the axis of coordination, while rotation of the $NMe_2$ group about the bond to the carbamoyl C-atom is appreciably restricted. The strong shielding of the ethene C-atoms and H-atoms in **5**, which compares with that in {(pmdta)$LiCH_3$}Ni($C_2H_4$)$_2$ **7**[3] in [$D_8$]-THF, points to a high negative charge on the bis(ethene)nickel moiety of the complex through the lithiumcarbamoyl ligand. Lowering of the temperature leads to freezing-in of the ethene rotation (< −20 °C) and to the appearance at −80 °C of two detectable isomers, A and B (*ca.* 1 : 1.5), which presumably differ in the bonding of the lithium atom to the carbamoyl ligand (Li–O- and Li–N contacts).

**5** is present in only one form in the crystalline state. As shown by X-ray structure analysis (Fig. 1), the planar bis(ethene)nickel moiety, whose structural data are already known[3,4], is linked to the likewise planar carbamoyl moiety *via* a short Ni–C bond. The plane of the carbamoyl system is nearly perpendicular (84°) to the trigonal coordination plane of the transition metal. The geometry of the carbamoyl ligand deviates only slightly from that of formamide and its complexed derivatives. The lithium atom, which is surrounded by a highly distorted tetrahedral array

## Structure Determination by $^{13}$C-NMR Spectroscopy Using an INADEQUATE Pulse Sequence: Differentiation of Heteroatom-Substituted Organic Constitutional Isomers by means of $^{13}$C-$^{13}$C Coupling Constants**

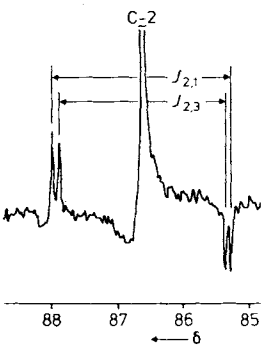
By *Joachim Buddrus**, *Hans Bauer*, *Hans Gotthardt*, and *Rüdiger Jung*

The differentiation of constitutional isomers of organic compounds whose hydrogen atoms are largely or completely substituted by heteroatoms often presents difficulties. Conventional $^{13}$C-NMR spectroscopy certainly provides signals; however, in many cases these cannot be interpreted unambiguously. Here we show that by analyzing the $^{13}$C-$^{13}$C satellites of a $^{13}$C-NMR spectrum the bonding pattern of C atoms can be obtained, thus enabling the different constitutions of such compounds to be distinguished. To measure the satellites the main $^{13}$C-NMR signals were reduced in intensity using the double quantum coherence technique (INADEQUATE pulse sequence[1]); this method was introduced by *Freeman et al.*[2], but previously has been rarely used[3] to solve constitutional problems.

Chlorination of 1-ethoxypentachlorobutadiene leads to formation of pentachloro-3-butenoyl chloride, **1**, or pentachloro-2-butenoyl chloride **2**[4].

**1** **2**

The $^{13}$C-NMR signal of the aliphatic C atom at $\delta = 86.8$ is shown in Figure 1; it consists of two pairs of satellites with coupling constants of 67.3 and 62.6 Hz, which also are observed on the signal of the carbonyl C atom and on that of an olefinic C atom, respectively. This result is consistent only with structure **1**, which is also consonant with the results of IR and UV studies[5].



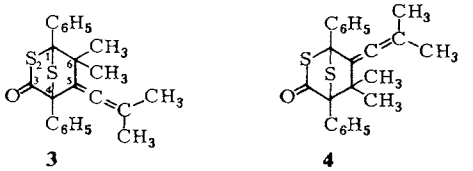


Fig. 1. Part of the one-dimensional $^{13}$C-INADEQUATE-NMR spectrum of **1** at 25 MHz (JEOL FX-100). Sample solution: 2.5 mL **1**, 0.3 mL $CDCl_3$, and *ca.* 10 mg $Cr(acac)_3$ (as relaxation reagent). Pulse sequence: 90°(x)-$\tau$-180°(±y)-$\tau$-90°(x)-$\Delta$-90°($\phi$)—accumulation of data; $\tau$ adjusted for $J_{CC} = 65$ Hz. 12704 sweeps, repetition time 5 s (total measurement time 16 h).

The 1,3-dipolar cycloaddition of 2,5-dimethyl-2,3,4-hexatriene to 2,5-diphenyl-1,3-dithiolylium-4-olate affords the heterobicyclic constitutional isomers **3** and **4**, which can be separated, but not differentiated by conventional spectroscopic methods.

**3** **4**

The $^{13}$C-NMR signals of the two bridgehead C atoms of the major isomer are shown in Figure 2. The signal at $\delta = 79.6$ exhibits two pairs of satellites with coupling constants 31.9 and 49.7 Hz, which also occur on the signal of the aliphatic quaternary C atom and on that of an aromatic C atom, respectively. The signal at $\delta = 75.6$ exhibits three

Lehrstuhl für Organische Chemie der Universität-Gesamthochschule
Gaussstrasse 20, D-5600 Wuppertal 1 (Germany)

[**] This work was supported by the Minister für Wissenschaft und Forschung des Landes Nordrhein-Westfalen and by the Minister für Forschung und Technologie der Bundesrepublik Deutschland (J. B., H. B.), as well as by the Fonds der Chemischen Industrie (H. G.). J. B. and H. B. thank Dr. W. Auf der Heyde and Dr. W. Kimpenhaus, Chemische Werke Marl-Hüls for supplying a sample of pentachloro-3-butenoyl chloride.

pairs of satellites (in part, overlaid) with coupling constants 41.8, 42.6, and 52.3 Hz: the first coupling constant is also observed on the signal of the carbonyl C atom, the second on that of an allenic C atom, and the third on that of an aromatic C atom. These results are consistent only with structure **3**.

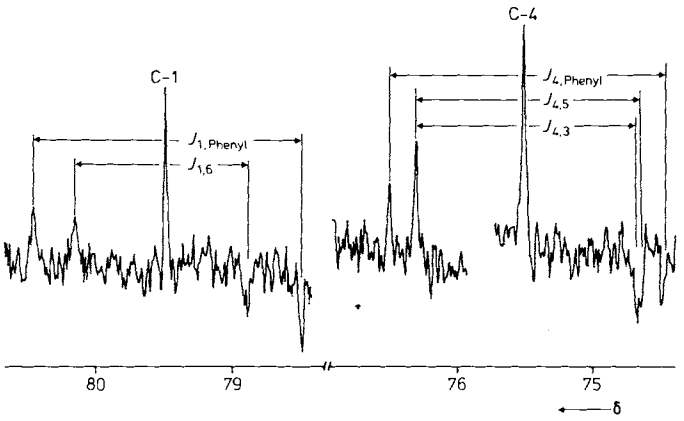

Fig. 2. Part of the one-dimensional $^{13}$C-INADEQUATE-NMR spectrum of **3** at 25 MHz. Sample solution: 1 g **3** and *ca.* 10 mg Cr(acac)$_3$ in 1.5 mL $CDCl_3$. Pulse sequence as in Fig. 1; $\tau$ adjusted for $J_{CC}=45$ Hz. 33 400 sweeps, repetition time 6.1 s (total measurement time 57 h). The residual signals of the solvent were not recorded.

The advantage of the INADEQUATE pulse sequence is that it enables structures such as **1** and **2**, or **3** and **4** to be differentiated unequivocally, without having to draw upon reference compounds.

## A General Method for the Synthesis of Heterometal Clusters of the $M_2Fe_2S_4$-Cubane Type (M = Cr, Mo)

By *Henri Brunner, Heike Kauermann,* and *Joachim Wachter**

Interest in the cubane-like molecules $Cp_4M_4S_4$ (Cp = $\eta^5$-$C_5H_5$; M = Cr, Mo, Fe, Co) has so far been directed at the problem of the metal-metal bond[1] rather than at expanding the system with new ligand-metal combinations. The multifarious properties of cubane-like $Fe_3MoS_4$ clusters[2] stimulated a search for generally applicable methods for the synthesis of such heterometal clusters. Expansion of a precursor containing four sulfur atoms and two cyclopentadienyl-6A metal groups by two each of the isoelectronic groups MCp (M = Cr, Mo), $Mn(CO)_2$, Fe(NO) or Co(CO) offers a facile entry to the $M_4S_4$ skeletal framework. This concept was successfully tested by reaction of the sulfur-rich pentamethylcyclopentadienyl complexes $Cp'_2Cr_2S_5$ **1** and $Cp'_2Mo_2S_4$ **2** with $Co_2(CO)_8$ to give $Cp'_2M_2Co_2S_4(CO)_2$ ($Cp' = \eta^5$-$C_5Me_5$; M = Cr, Mo)[3].

**3**: M = Cr
**4**: M = Mo

We have now been able to confirm the general validity of the concept: Irradiation of the green and blue solutions, respectively, of **1** and **2** in tetrahydrofuran in the presence of two equivalents of $[Fe(CO)_3NO][Ph_3PNPPh_3]$ affords the red-brown diamagnetic complexes **3** and **4**, respectively, in 40–50% yield[4a]. The isomer of **2** containing terminal sulfur ligands, complex **5**, also reacts analogously. The composition of the products $Cp'_2M_2Fe_2S_4(NO)_2$ is confirmed by elemental analysis and mass spectra. Since we have so far been unable to grow single crystals of the products, the confirmation of the structure rests primarily on spectroscopic data. The 70 eV mass spectrum of **4** shows the molecular ion and the successive cleavage of all ligands from the $Mo_2Fe_2S_4$ skeleton, with appearance also of the doubly positively charged ion for each fragment, whereas the molecular ion **3** can be observed only in the field-desorption mass spectrum (from toluene solution). A single sharp methyl signal appears in each of the $^1$H-NMR spectra, at $\delta = 1.90$ in the case of **3** and at 1.96 in the case of **4** ($CDCl_3$ solution). The IR spectra[4b] contain absorption bands for the NO- and the $C_5Me_5$-groups, but no further metal-ligand vibration bands. The disappearance of the strong $\nu$(Mo=S) bands of **5** (485 cm$^{-1}$) and of the absorptions of the $\mu_2,\eta^2$-$S_2$- and $\mu_2,\eta^1$-$S_2$-ligands in **1** (599, 495, 445 cm$^{-1}$) in favor of a weak absorption at 386 cm$^{-1}$ can best be interpreted in terms of an equal distribution of four S-atoms over all metal centers in the form of $\mu_3$-ligands.

The novel heterometal clusters **3** and **4** represent a link between the $Cp_4Mo_4S_4$ cluster, for which MO considerations point to metal-metal interactions[5a], and the isoelectronic $(NO)_4Fe_4S_4$ complex, for which X-ray structure investigations have confirmed a distorted cubane-structure with four Fe–Fe bonds[5b].

## Biomimetic Synthesis of Primary Enamides by Decarboxylation of α,β-Dehydroamino Acids**

By *Ulrich Schmidt** and *Albrecht Lieberknecht*

*Dedicated to Professor Adolf Steinhofer on the occasion of his 75th birthday*

Primary enamides[1] are produced by lower organisms from amino acids, probably by decarboxylation of α,β-dehydroamino acids. We have also succeeded in performing this reaction *in vitro*. Decarboxylation of aliphatic and aromatic *N*-acyldehydroamino acids[2] offers the simplest route to primary enamides; it is superior to previously described methods[3] and, in addition, opens the possibility of synthesizing (*E*)- and (*Z*)-enamides stereoselectively.

Aromatic and aliphatic *N*-acyldehydroamino acids[4] decarboxylate within an hour at 145 °C in the presence of bases and copper powder to afford enamides in 50—75% yield. On the whole, the reaction can be stereoselectively controlled (exceptions: examples 5 and 10 in Table 1): solutions of aromatic (*Z*)-*N*-acyldehydroamino acids in diglyme react with copper powder and pyridine to give predominantly (*Z*)-enamides ($Z : E \approx 80 : 20$); in contrast, with quinoline and copper powder predominantly (*E*)-enamides are obtained ($Z : E \approx 10 : 90$). Under these conditions (*Z*)-enamides rearrange to (*E*)-enamides. The decarboxylation can also be performed on dehydropeptides (examples 7 and 8).

### *Procedure*

A solution of α-(*N*-acetylamino)cinnamic acid (205 mg), copper powder (200 mg), and quinoline (166 mg) in 5 mL diglyme under nitrogen is heated to 145 °C in an oil bath. The volatile components are subsequently removed *in vacuo*: the residue is taken up in chloroform, filtered, and extracted with $KHSO_4$ solution. After medium pressure chromatography on silica gel Lichroprep Si60 (15—25 μ) using ethyl acetate/petroleum ether 19 mg *cis*- and 102 mg *trans*-β-acetylaminostyrene were isolated.

Table 1. Decarboxylation of *N*-acyldehydroamino acids to afford enamides [a].

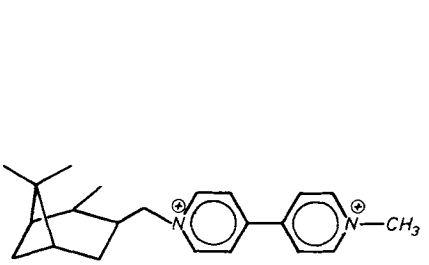
## Asymmetry of Emission Quenching and Product Formation in an Asymmetrically Sensitized Photoreaction**

By *Hermann Rau** and *Richard Ratz*



Asymmetry in photoreactions of chiral molecules sensitized by one enantiomer of a chiral donor may be monitored by determining the asymmetry of emission quenching and the optical induction found in the remaining educt and/or in the photoproduct[1]. *Irie et al.*[2] have observed asymmetries ($\kappa = k_q(S-R)/k_q(R-R)$) in electron-transfer emission quenching of (−)-(*R*)-1,1′-binaphthyl by enantiomeric pairs of optically active amines to the extent of up to $\kappa = 7.9$ at −10 °C. The highest asymmetry observed at room temperature ($\kappa = 4.0$), if maintained in an overall photochemical decomposition reaction, would lead to an enantiomeric purity of the educt $P_{en} = (c_R - c_S)/(c_R + c_S)$ of more than 60% at 63% extent of reaction. If this could be realized, then asymmetric photochemistry would become a viable preparative method.

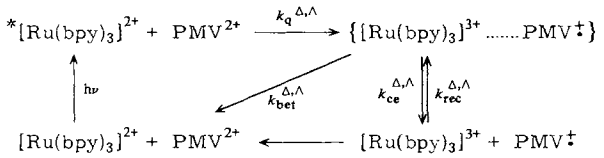
(3S)-(-)

Λ



Δ

N ⌒ N = 2,2'-bpy

In order to compare the degree of asymmetry of the quenching reaction and the photoreaction we selected a well-known photoredox system[3], tris(bipyridyl)ruthenium(II)/viologen. Δ-(−)-$[Ru(bpy)_3]Cl_2$ and Λ-(+)-$[Ru(bpy)_3]Cl_2$ were used as donors and 1-methyl-1'-[(3*S*)-(−)-3-pinanylmethyl]-4,4',bipyridinium dichloride ($PMV\text{-}Cl_2$) as an acceptor.

According to *Kalyanasundaram* and *Neumann-Spallart*[4] the reaction proceeds as shown in Scheme 1. These authors found that the yield of dissociated radicals $\phi_{redox} = k_{ce}/(k_{ce}+k_{ret}) = 0.25$.

Scheme 1.

We have determined the asymmetry of the emission quenching using both steady state and dynamic emission quenching techniques[5] and Stern-Volmer evaluation: $k_q(\Delta\text{-}[Ru(bpy)_3]^{2+}/S\text{-}PMV^{2+}) = 2.02\times10^8$ dm$^3$ mol$^{-1}$ s$^{-1}$ and $k_q(\Lambda\text{-}[Ru(bpy)_3]^{2+}/S\text{-}PMV^{2+}) = 3.34\times10^8$ dm$^3$ mol$^{-1}$ s$^{-1}$ were found. From this $\kappa = k_q^{\Lambda}/k_q^{\Delta} = 1.66$. Since the enantiomeric purity of the donors was 92% (Δ) and 54% (Λ), respectively, the calculated value of $\kappa$ for pure enantiomers is 1.95.

The asymmetry of the product formation can be determined from the different ellipticities of $PMV^{+\cdot}$ in the reactions of the two diastereomeric combinations. Electron transfer leading to re-formation of the educts ($k_{bet}$) can be prevented partially and concomitantly the formation of the product $PMV^{+\cdot}$ can be favored if a large amount of ethylenediaminetetraacetic acid as the Na salt is added. Under the chosen conditions, the latter is irreversibly reduced more rapidly than $PMV^{+\cdot}$ by $[Ru(bpy)_3]^{3+}$ generated in the photoreaction. Unfortunately, the molar ellipticity of the $PMV^{+\cdot}$ radical ion (which may be generated by reduction with Zn in high concentration) is so small that there is no possibility of determining the ellipticity of $PMV^{+\cdot}$ in experiments starting from racemic $PMV^{2+}$[1]. Hence, we used the transient absorption[5] of $PMV^{+\cdot}$ immediately after the laser flash to determine the asymmetry of the photoreaction. We obtained $\kappa = (k_q^{\Lambda}/k_q^{\Delta})(\phi_{redox}^{\Lambda}/\phi_{redox}^{\Delta}) = 1.12\pm0.05$ for both the combinations Δ-$[Ru(bpy)_3]^{2+}/S\text{-}PMV^{2+}$ and Λ-$[Ru(bpy)_3]^{2+}/S\text{-}PMV^{2+}$. Extrapolation to the pure enantiomers gives $\kappa = 1.32$ ($\kappa - 1$: ±40%).

The results indicate that a considerable amount of the asymmetry found in the quenching step is lost in the competing back electron transfer ($k_{bet}$) and ion pair dissociation ($k_{ce}$) steps. The diastereomeric ion pair formed preferentially ($k_q^{\Lambda} \approx 2k_q^{\Delta}$), has a 1.5 times higher rate of electron back transfer, too. Currently we are investigating other systems to determine whether the phenomenon described here is more general.

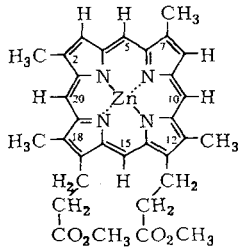
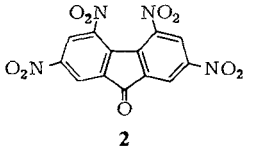
## Deuteroporphyrin-IX Dimethyl Ester: Assignment of the $^1$H-NMR Spectrum by NOE Measurements in Presence of a Diamagnetic Shift Reagent



By *Klaus Witthohn* and *Hans Brockmann Jr.**

Repeated attempts have been made to assign the $^1$H-NMR signals of natural porphyrins[1,2]. The use of intramolecular Nuclear Overhauser Effects for this purpose has only seldom met with success[3,4], since overlapping in the region of the methyl- and bridge-methine protons frequently preclude selective irradiation experiments.



In the presence of electron-acceptors such as tetranitrofluorenone **2**, zinc deuteroporphyrin-IX dimethyl ester **1a**

**1a**
**1b**, 2 H instead of Zn

**2**

as well as the zinc-free porphyrin **1b** form donor-acceptor complexes with greatly altered $^1$H-NMR spectra[9]. Owing to the rapid establishment of equilibrium between complex and free donor and acceptor, **2** can be used as NMR shift reagent for porphyrins which removes signal overlapping at suitable concentrations and enables NOE studies to be carried out (Fig. 2).

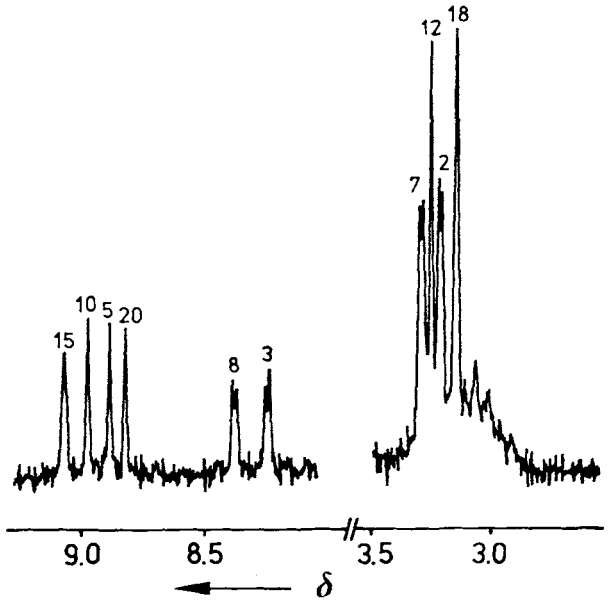

Fig. 2. 80-MHz $^1$H-NMR part spectrum of **1a** in presence of **2**; $CDCl_3$, TMS int. standard, 309 K.

We have performed NOE experiments on an equimolar solution of **1a** and **2** in $CDCl_3$. Irradiation at the resonances of the methyl- as well as the α-located methylene protons of **1a** causes integral increases of individual bridge-methine proton signals of between 15 and 25 percent (Table 1).

In addition, in the normal homonuclear decoupling experiment the allyl coupling ($J = 1.5$ Hz) between the methyl protons and 3-H and 8-H is removed.

Table 1 (selected data). $^1$H-NMR NOE double resonance experiments (80 MHz), $CDCl_3$, δ-values, 309 K.

| | Irradiation | Integral increase |
|---|---|---|
| | 4.00 | 9.07 (16%) |
| | 3.36 | 8.85 (15%) |
| **1a** + **2** | 3.28 | 8.95 (25%) |
| | 3.20 | 8.78 (25%) |
| | 3.14 | 8.78 (16%) |

These results, and those of the investigations on **1b** and **2**, unequivocally lead to the signal assignments listed in Table 2. Moreover, they can be extended to the interpretation of the $^1$H-NMR spectra of pure **1a** and **1b** if the alteration of the individual signals with concentration of shift reagent is taken into account (Table 2). These assignments

## Azatriphosphetidines as Cyclotrimers of an Iminophosphane—Synthesis and Crystal Structure**

By *Edgar Niecke**, *Reinhold Rüger*, *Bernt Krebs*, and *Mechthild Dartmann*

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*

Frontier orbital theory predicts that on passing from methylenephosphane **A** to iminophosphane **B** an orbital crossing [**A**: HOMO = $\pi_{(P=C)}$/LUMO = $\pi^*_{(P=C)}$, **B**:

[*] Prof. Dr. E. Niecke, Dr. R. Rüger

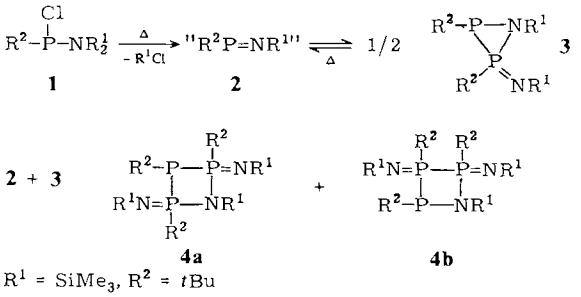
[**] Phosphazenes of Coordination Number 2 and 3, Part 24. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.—Part 23: [1b].

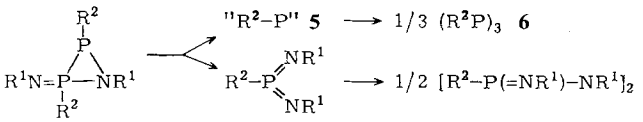


HOMO = $\sigma_{(P)}$/LUMO = $\pi^*_{(P=N)}$] occurs[1a]. We recently found experimental evidence for this prediction; reversible formation of an iminophosphane from its dimer, formed by [2 + 1] cycloaddition[1b].

A B

By means of insertion reactions the "carbene-like"[2] iminophosphanes should act as synthetic building blocks for phosphorus heterocycles.

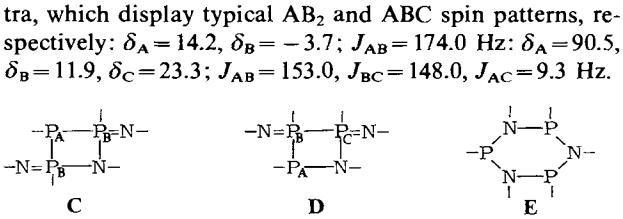
We have now found that the azadiphosphirane **3**[3a], which is readily accessible from **1** by elimination of chloro(trimethyl)silane, undergoes an insertion reaction at 140 °C with the intermediate *tert*-butyl(trimethylsilylimino)phosphane **2** to afford the two isomers **4a** and **4b**, which possess the previously unknown azatriphosphetidine framework.



**1** **2** **3**

**2 + 3** **4a** + **4b**

$R^1$ = $SiMe_3$, $R^2$ = *t*Bu



The preferred formation of **4a** (**4a** : **4b** = 6 : 1) and, hence, the insertion of **2** into the $\lambda^3$–PN bond of **3** suggests that the "carbene analogues", **2**, have electrophilic character, as predicted by theoretical studies[3b].

Side products of the reaction (< 25%), arising by fragmentation of **3**, are the cyclotriphosphane **6**[3c], as well as *cis*- and *trans*-diazadiphosphetidine **8**[3d], which are, respectively, stable oligomers of *tert*-butylphosphanediyl, **5**, and *tert*-butylbis(trimethylsilylimino)phosphorane **7**[3d].

**3** **7** **8**

Pure **4a**, which can be isolated from the reaction mixture, is a crystalline, readily oxidizable solid; its composition has been determined by elemental analysis and molecular weight determination[4]. Its constitution and that of **4b** as 1,2$\lambda^5$,3,4$\lambda^5$-azatriphosphetidine (**C**) and 1,2$\lambda^5$,3$\lambda^5$,4-azatriphosphetidine (**D**)—isomers of the cyclo-$\lambda^3$-triphosphazane system (**E**)—are derived from the $^{31}P\{^1H\}$-NMR spectra, which display typical $AB_2$ and ABC spin patterns, respectively: $\delta_A = 14.2$, $\delta_B = -3.7$; $J_{AB} = 174.0$ Hz: $\delta_A = 90.5$, $\delta_B = 11.9$, $\delta_C = 23.3$; $J_{AB} = 153.0$, $J_{BC} = 148.0$, $J_{AC} = 9.3$ Hz.

**C** **D** **E**

The configuration of **4a**, with *trans*/*trans*-arrangement of the *tert*-butyl groups at the $\lambda^5$-phosphorus atom relative to the substituents at the $\lambda^3$-phosphorus atom in an almost planar four-membered ring, was proved by X-ray structure analysis (Fig. 1).

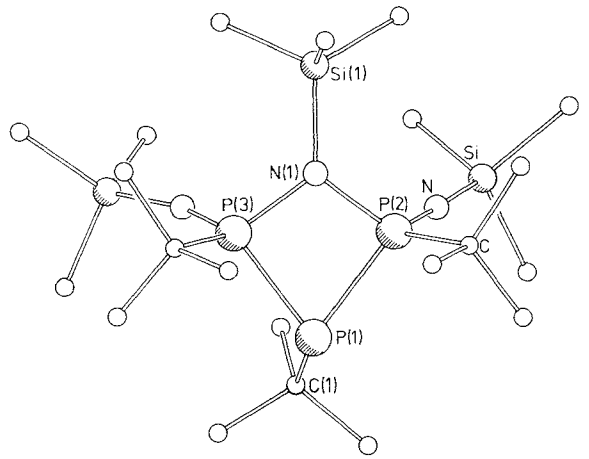


Fig. 1. Molecular structure of **4a** (without H atoms) in the crystal [monoclinic, $P2_1/m$, $a = 969.7(2)$, $b = 1922.9(4)$, $c = 901.9(2)$ pm, $\beta = 106.0(2)°$, $V = 1616.4 \times 10^6$ pm$^3$, $\rho_{calc.} = 1.08$ g/cm$^3$, $Z = 2$ measured at −130 °C]. The structure was determined by direct methods (MULTAN) from 2716 single-crystal diffractometer data and refined to $R = 0.067$ [3a]. Most important bond lengths [pm] and angles [°]: P(1)–P(2) 223.2(4), P(1)–P(3) 219.5(4), N(1)–P(2) 172.7(9), N(1)–P(3) 170.9(9), P(1)–C(1) 186.8(8), N(1)–Si(1) 179.5(6); P(2)–P(1)–P(3) 74.8(2), P(2)–N(1)–P(3) 103.0(4), P(1)–P(2)–N(1) 87.7(3), P(1)–P(3)–N(1) 89.4(3), P(2)–N(1)–Si(1) 126.5(5), P(3)–N(1)–Si(1) 126.0(5).

[4] Procedure: **3** (21 g, 60 mmol) is heated to 140 °C in a glass bomb tube for 1 h. The cooled reaction mixture is dissolved in 5 mL pentane and stored at −30 °C until crystallization has occurred (4–5 d). After decanting the mother liquor and one recrystallization from a small amount of pentane, pure **4a** is obtained (7.5 g, 35%); decomp. 250–255 °C. Based on $^{31}P$-NMR findings, the mother liquor still contains **4b** (20%), **5** (15%), and *cis*/*trans*-**8** (20%). Data for **4a**: $M_+$ (cryoscopic in $C_6H_{12}$): 516, 520 (calc. 525); $^1H$-NMR (30% in $CDCl_3$, TMS int.): $\delta = 0.05$ (P=NSiMe$_3$); 1.19 (*t*BuP=N), $^3J_{HP} = 18.5$, $^4J_{HP} = 1.0$ Hz, 1.43 (*t*BuP), $^3J_{HP} = 15.0$, $^4J_{HP} = 3.2$ Hz.

## 1-(1,3-Butadienyl)triazoles from 1-Vinyltriazoles and Electron-Rich Alkynes—Cleavage to "Push-Pull" 1,3-Butadienes**

By *Hans Schubert* and *Manfred Regitz**

1-Vinyl-1,2,3-triazoles exhibit typical azolide reactivity and, as mild vinylating reagents, *e.g.* of methylenephosphoranes, have found valuable use in synthetic chemistry[3]. Their synthetic potential can be considerably increased by insertion of electron-rich alkynes, either between the nucleus and the side-chain or in the side-chain itself.

Fachbereich Chemie der Universität
Erwin-Schrödinger-Strasse, D-6750 Kaiserslautern (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Reaction of the triazole **1a** with the alkynylamine **3a** or alkynyl ether **3b** in chloroform leads to formation of the title compounds **6a** and **7a** or **6b**, respectively. The α-diazoimidate **2b** (which must be in equilibrium with small amounts of **1b**[4]) reacts with **3a** to give **6c** and **7c**. **6a/7a** and **6c/7c** can be separated by column chromatography and identified by mass spectrometry and $^1$H-NMR spectroscopy (for typical data of **6a** and **7a** see Table 1).

We assume that branching in the reaction starts from the charge stabilized dipole **4**; it either rearranges to **6** (main reaction, route B)[5] or undergoes ring-close to give **5**, followed by electrocyclic ring-opening to give **7** (side-reaction, route A).

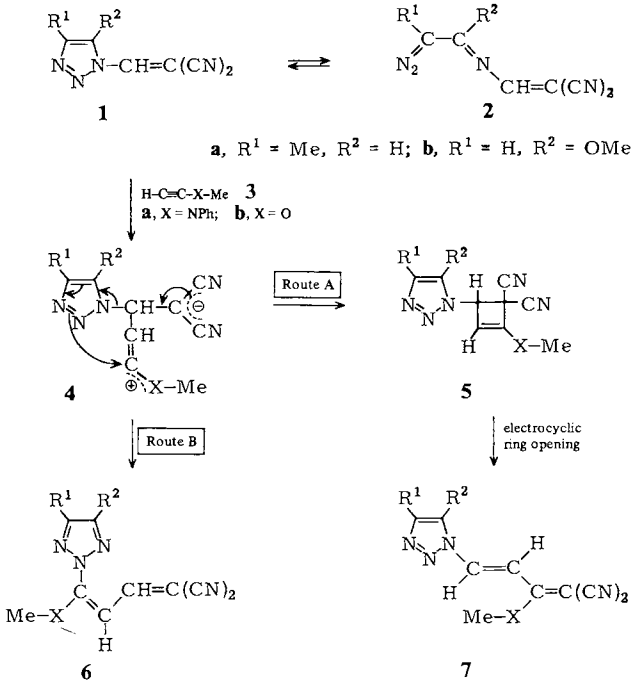

Table 1 (selected data). 1-(1,3-Butadienyl)triazoles **6** and **7** that have been synthesized.

| Triazole | $R^1$ | $R^2$ | X | Yield [%] | M.p. [°C] |
|---|---|---|---|---|---|
| **6a** [a, b] | Me | H | NPh | 45 | 137 |
| **7a** [a, b] | Me | H | NPh | 21 | 184 (dec.) |
| **6b** | Me | H | O | 50 | 122 |
| **6c** | H | OMe | NPh | 31 | 114 |
| **7c** | H | OMe | NPh | 20 | 161 (dec.) |

[a] MS (70 eV): **6**: $m/z$ 290 (62%, $M^+$), as expected no peak for $M^+ - N_2$; **7a**: $m/z$ 262 (41%, $M^+ - N_2$) but only weak molecular peak (5%). [b] $^1$H-NMR ($CDCl_3$, 200 MHz): **6a**: $\delta = 5.85$ (d, 1H, $^3J_{H,H} = 12.3$ Hz, H-2); **7a**: $\delta = 6.47$ (d, 1H, $^3J_{H,H} = 14.4$ Hz, H-2).

The insertion reaction **1** → **6** can be used for the preparation of "push-pull" 1,3-butadienes[6]: cleavage of **6b** with sodium methoxide affords **8a**; reaction with sodium methoxide and sodium isopropoxide in ethanol and isopropanol, respectively, with additional displacement of the $OCH_3$ group, leads to formation of the butadienes **8b** and **8c**, respectively. Cleavage with sodium salts of *N*-methylaniline and diethylamine provides access to the mixed-substituted 1,3-butadienes **8d** and **8e** (Table 2).

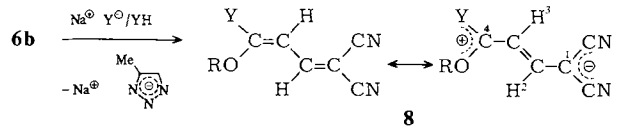

Table 2 (selected data). "Push-Pull" 1,3-butadienes that have been synthesized.

| Butadiene | R | Y | Yield [%] | M.p. [°C] |
|---|---|---|---|---|
| **8a** | Me | OMe | 58 | 102–102 |
| **8b** [a] | Et | OEt | 68 | 108 |
| **8c** | *i*Pr | O*i*Pr | 52 | 57–58 |

## Synthesis and Structure of $[\{[CH_3C(CH_2PPh_2)_3]IrP_3\}_3Cu_5Br_4]CuBr_2$—A 21 Atom Ir/Cu/P/Br Cluster

By *Franco Cecconi, Carlo A. Ghilardi*, Stefano Midollini,* and *Annabella Orlandini*

We recently reported that the reaction between (triphos)$CoP_3$[3] (triphos = $CH_3C(CH_2PPh_2)_3$) and copper(I) bromide (molar ratio 1:3) yields the adduct $[\{(triphos)CoP_3\}_2(CuBr)_6]$[5], which contains an unprecedented hexagonal $Cu_6$-unit held together by two (triphos)$CoP_3$-fragments[5]. We now report that when (triphos)$IrP_3$[6] is allowed to react with CuBr in the molar ratio 1:2, a novel ionic compound, $[\{(triphos)IrP_3\}_3Cu_5Br_4]CuBr_2$, is obtained.

The title compound was prepared by allowing a suspension of CuBr (1 mmol) in $CH_2Cl_2$ (10 mL) to react with a continuously stirred solution of (triphos)$IrP_3$ (0.5 mmol) in the same solvent (30 mL) for *ca.* 30 min at room temperature. Evaporation of the solvent gave orange crystals, which were recrystallized from nitroethane/*n*-butanol. The

Istituto per lo Studio della Stereochimica ed Energetica dei Composti di Coordinazione del CNR
27 Via F. D. Guerrazzi, I-50132 Firenze (Italy)

compound, which is air-stable, behaves as a 1 : 1 electrolyte in nitroethane.

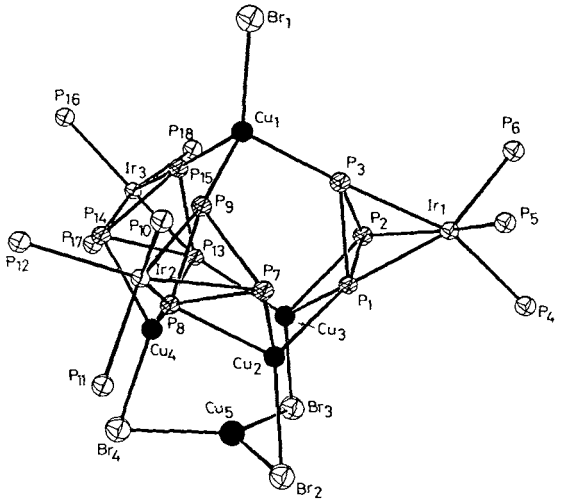

Fig. 1. Framework of the cluster cation $[\{(triphos)IrP_3\}_3Cu_5Br_4]^+$ in the crystal. Monoclinic, space group $P2_1/a$; $a = 44.558(22)$, $b = 18.869(9)$, $c = 17.361(8)$ Å, $\beta = 93.80(4)$, $\rho_{calc.} = 1.637$ g cm$^{-3}$ for $Z = 4$. The structure was solved by the heavy-atom method and refined to $R = 0.067$ and $R_w = 0.072$ for 10065 reflections with $I \geq 3\sigma(I)$ ($2\theta \leq 100°$); $Cu_{K\alpha}$ irradiation. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen 2, by quoting the depository number CSD 50434, the names of the authors, and the journal citation.

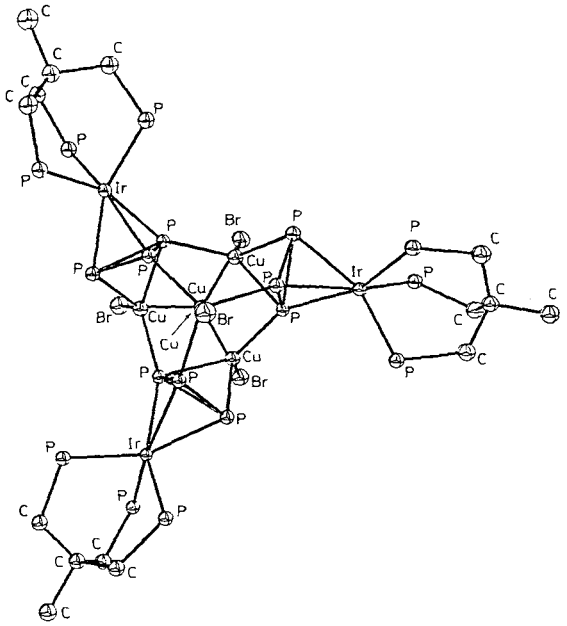

Fig. 2. Perspective view of the $[\{(triphos)IrP_3\}_3Cu_5Br_4]^+$ cation along the pseudo threefold axis passing through Br1, Cu1, and Cu5. For the sake of clarity the phenyl rings have been omitted. Selected distances (average values): CuCu (upper edge) 4.637(2), CuCu (lower edge) 2.795(13), CuCu (equatorial edge) 3.017(28), CuBr (tetrahedral) 2.360(3), CuBr (trigonal) 2.396(10), CuBr (digonal) 2.221(10), IrP(triphos) 2.292(3), IrP($P_3$) 2.427(10), CuP 2.308(6)–2.422(6) Å.

In the cluster cation, whose inner core possesses a pseudo threefold axis of symmetry (Figs. 1, 2), three molecules of (triphos)$IrP_3$ are held together *via* the $P_3$-groups by the central $Cu_5Br_4$-framework. The five Cu atoms are at the vertices of a distorted trigonal bipyramid, whose upper edge (4.637(2) Å (av)) is much longer than both the lower and the equatorial edges, (average lengths: 2.795(13) Å and 3.017(28) Å, respectively). The overall inner core geometry may be described in terms of a $Cu_5$-trigonal bipyramid, whose lower edges are bridged by Br atoms, while each upper triangular face is unsymmetrically capped by the $P_3$-group of one (triphos)$IrP_3$ fragment.

The Cu atoms display three different coordination geometries with four different geometric environments; the Cu atom at the lower vertex bridges three Br atoms trigonally, its displacement from the $Br_3$-plane being 0.08 Å. Each equatorial Cu atom is tetrahedrally coordinated by one bridging Br atom and by three P atoms of two different $P_3$-groups. The fifth Cu atom, which lies at the apex of the elongated pyramid, is tetrahedrally coordinated by one terminal Br atom and by three P atoms of three $P_3$-groups. Finally, the $CuBr_2^-$ anion is almost linear (Br–Cu–Br = 178.4(3)°).

## Topotactic Redox and Exchange Reactions of Ruthenium(III) Halides

By *Robert Schöllhorn**, *Robert Steffen*, and *Klaus Wagner*

A large variety of transition metal chalcogenides and oxides with low dimensional structures are known to represent suitable host lattices for reversible intercalation reactions *via* topotactic electron/ion transfer[1,2]. We report here on intercalation reactions of α-$RuCl_3$ (layered structure) and $RuBr_3$ (chain structure) which demonstrate that binary metal halides with appropriate structure and electronic properties are principally able to undergo reactions similar to those of the host lattice types mentioned above.

α-$RuCl_3$ is an anisotropic semiconductor with a layered structure of the $AlCl_3$-type[3] in which intercalation of solvated and unsolvated guest ions can be accomplished either by electrochemical or chemical techniques. Cathodic reduction of α-$RuCl_3$ in aqueous electrolytes containing alkali, alkaline earth or transition metal ions leads to the uptake of solvated guest ions into the van der Waals gap between the $(RuCl_3)_\infty$ units with a corresponding increase in the interlayer spacing $d$ (Table 1).

$$RuCl_3 + \frac{x}{n}A^{n+} + x\,e^- + y\,H_2O \rightleftharpoons A^{n+}_{x/n}(H_2O)_y[RuCl_3]^{x-} \quad (1)$$

[*] Prof. Dr. R. Schöllhorn, R. Steffen, K. Wagner
Anorganisch-chemisches Institut der Universität
Corrensstrasse 36, D-4400 Münster (Germany)

Table 1. Intercalation compounds of α-$RuCl_3$: Dependence of interlayer spacing $d$ upon guest species [atomic ions hydrated, or solvated with dimethyl sulfoxide (DMSO) or formamide (FA); molecular guest ions unsolvated; Cp = cyclopentadienyl ligand]; interlayer spacing in empty host lattice $d = 573$ pm.

| Guest species | $d$ [pm] | Guest species | $d$ [pm] | Guest species | $d$ [pm] |
|---|---|---|---|---|---|
| $Li^+$ | 1103 | $Mg^{2+}$ | 1118 | $Zn^{2+}$ | 1078 |
| $Na^+$ | 1115 | $Ca^{2+}$ | 1125 | $Cd^{2+}$ | 1132 |
| $K^+$ | 826 | $Sr^{2+}$ | 1136 | $Na^+$/DMSO | 1598 |
| $Rb^+$ | 828 | $Mn^{2+}$ | 1096 | $Na^+$/FA | 1592 |
| $Cs^+$ | 870 | $Co^{2+}$ | 1075 | $Cp_2Co^+$ | 1085 |
| $NH_4^+$ | 828 | $Ni^{2+}$ | 1082 | $CH_3NH_3^+$ | 827 |

The hexagonal lattice parameters of the black $K^+$- and $Na^+$-compounds are $a = 610$, $c = 2478$, $d = c/3 = 826$ pm and $a = 605$, $c = 3345$, $d = c/3 = 1115$ pm, respectively. The maximum charge transfer to the $RuCl_3$ layers corresponds to $x = 0.5$ (*e.g.* $K_{0.5}^+(H_2O)_y[RuCl_3]^{0.5-}$); the reaction proceeds *via* a two-phase and a one-phase region (occurrence of nonstoichiometric compounds with $1/3 \leq x \leq 1/2$). As observed in the case of the hydrated chalcogenides[1,4], cations with a charge/radius ratio of $z/r > 100$ pm$^{-1}$ form bilayer hydrates ($d \approx 1100$ pm), while for cations with $z/r < 100$ pm$^{-1}$ only monolayer hydrates are stable ($d \approx 800$ pm). The hydrated phases are able to undergo rapid ion-exchange with atomic and molecular ions, which offers an alternative route for the preparation of a large number of new compounds. Similarly, solvate exchange reactions with neutral polar molecules is possible. The products of cathodic reduction in aqueous acids depend strongly upon the acid concentration. Hydrogen bronzes $H_xRuCl_3$ are obtained from $H_2SO_4$ solutions (*ca.* 70 wt-%); with decreasing acid concentration a series of hydrated hydronium phases $(H_3O)_x^+(H_2O)_y[RuCl_3]^{x-}$ with $x_{max} = 0.5$ can be isolated: monolayer hydrate ($d = 874$ pm), double layer hydrate ($d = 1126$ pm), triple layer hydrate ($d = 1538$ pm).

Unsolvated cations such as $Na^+$, $Cu^+$, $Ag^+$ can be intercalated by cathodic reduction of α-$RuCl_3$ in organic aprotic electrolytes (propylene carbonate, acetonitrile *etc.*), leading to formation of ternary phases [eq. (1) for $y = 0$]. Intercalation of $Ag^+$ leads to $Ag_{0.4}^+[RuCl_3]^{0.4-}$, while two phases $Cu_{0.5}^+[RuCl_3]^{0.5-}$ and $Cu_1^+[RuCl_3]^{1-}$ are found on intercalation of $Cu^+$. $CuRuCl_3$ shows a slight contraction of the $c$-axis as compared to the host lattice; hexagonal lattice parameters are $a = 609$, $c = 1678$, $d = c/3 = 559$ pm. α-$RuCl_3$ can be considered as a variant of the $CdI_2$-type structure $\square_{1/3}Ru_{2/3}Cl_2$ with regular defects (□) on octahedral sites within the layers. We assume, therefore, that small or "soft" ions such as $H^+$, $Li^+$, $Cu^+$ may occupy lattice sites (octahedral or tetrahedral, respectively) *within* the layers[5].

The reactions discussed above are reversible; on anodic oxidation the "empty" host lattice α-$RuCl_3$ is regenerated. Chemical intercalation is possible with reducing agents as the electron donors, *e.g.* dithionite or hydrazine. The reaction of α-$RuCl_3$ with aqueous solutions of $Na_2S_2O_4$ results in the formation of a black phase identical with that described for cathodic reduction in aqueous $Na^+/H_2O$. It is interesting to note that on prolonged exposure of the host lattice to $Na_2S_2O_4$ solution a drastic reversible color change is observed to a yellow transparent phase ($x \approx 1$) which cannot be obtained by the electrochemical technique, obviously because of an electronic transition. The fact that $Na_2S_2O_4$ may enforce a higher reduction stage is attributed to the Donnan equilibrium. A small but finite concentration of reducing anions is present inside the interlayer space, so that electron transfer from the outer surface to the bulk of the solid is not limited under these conditions by the electronic transport properties of the host matrix units.

An interesting point is that α-$RuCl_3$ is able to react with neutral Lewis bases (*e.g.* $NH_3$, pyridine, alkylamines) at room temperature to form intercalation compounds, *e.g.* $(NH_3)_xRuCl_3$ ($d = 850$ pm, $x_{max} = 1.5$), $(C_5H_5N)_xRuCl_3$ ($d = 1147$ pm, $x_{max} = 0.7$). Similar reactions of chalcogenide host lattices were shown earlier to be correlated with partial redox disproportionation of the guest species and formation of ionic species[1,4].

$RuBr_3$ has an orthorhombic structure of the $TiI_3$ type and can be described as consisting of $(RuBr_3)_\infty$ chains of face-sharing $RuBr_6$ octahedra with rather short metal/metal distances[3]. Electrochemical or chemical reduction in electrolytes containing atomic or molecular cations leads to reversible intercalation of solvated or unsolvated guest species, depending upon the polarity of the solvent, with a corresponding increase in the interchain distances. The maximum charge transfer for $Cu^+$ and $Ag^+$ intercalation (aprotic electrolyte) corresponds to $[RuBr_3]^{0.5-}$. Orthorhombic lattice parameters of $Ag_{0.5}RuBr_3$ are $a = 687$, $b = 1171$, $c = 584$ pm. The interchain distance of the hydrated black-violet products is dependent upon the ambient water vapor pressure. The hydronium phase shows strong two-dimensional lattice disorder and yields colloid solutions upon the influence of shear forces. Pronounced line broadening is observed on reoxidation of the intercalated products to $RuBr_3$.

The reactions discussed above provide access to an interesting and promising new field in the chemistry of intercalation compounds, since many transition metal halides exhibit structures and electronic properties related to those of the ruthenium compounds.

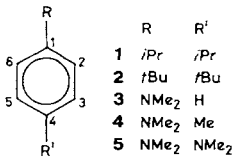
## Efficient Method for Generation of Radical Anions from Benzene Derivatives of Low Electron Affinity**

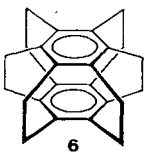
By *Fabian Gerson** and *René Heckendorn*

In the past two decades, the radical anions of numerous benzene derivatives in solution have been characterized by ESR spectroscopy[1]. Nevertheless, hyperfine data are still



[*] Prof. Dr. F. Gerson, R. Heckendorn
Physikalisch-chemisches Institut der Universität
Klingelbergstrasse 80, CH-4056 Basel (Switzerland)
[**] This work was supported by the Swiss National Science Foundation.

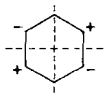
missing for the radical anions of several simple mono- and *p*-disubstituted benzenes of low electron affinity. The equilibrium of the reaction of such a derivative **X** with solvated electrons



$$\mathbf{X} + e_{solv.} \rightleftharpoons \mathbf{X}^{\ominus}$$

lies largely to the left, so that the concentration of the radical anion is too low for spectroscopic studies. A shift of the equilibrium to the right can be achieved by lowering the temperature[2a]; however, this procedure is limited by the freezing point of the solution. More effectively, $[\mathbf{X}^{\ominus}]$ is increased by raising the concentrations of **X** and $e_{solv.}$. While **[X]** is readily increased by starting with a larger amount of **X**, a ten- to hundredfold increase in $[e_{solv.}]$ can be accomplished by irradiating the deep-blue solution of potassium in 1,2-dimethoxyethane at low temperatures[2b]. It is known[2b,c] that the blue color arises from a diamagnetic species, in which an electron pair is attached to the cation $K^{\oplus}$, and which is usually referred to as the anion $K^{\ominus}$. In contrast to $[K^{\ominus}]$, $[e_{solv.}]$ is rather small, as indicated by the low intensity of the pertinent ESR signal ($g = 2.0021 \pm 0.0001$). Irradiation of the solution by visible light leads to the fading of the blue color and to an increase in $[e_{solv.}]$, manifested by a strikingly large enhancement of the ESR signal[2b]. When a compound **X** is present in the solution, this signal of $e_{solv.}$ is partly or completely replaced by the ESR spectrum of $\mathbf{X}^{\ominus}$, due to the reaction of **X** with $e_{solv.}$.

To begin with, this method was tested on mesitylene, which, hitherto, could be converted into its radical anion only under special conditions[3]. The coupling constants of the ring and methyl protons (0.282 and 0.493 mT, respectively) measured by us agree with those reported previously[3]. Subsequently, the radical anions of *p*-diisopropylbenzene **1**, *p*-di-*tert*-butylbenzene **2**, *N,N*-dimethylaniline **3**, *N,N*-dimethyl-*p*-toluidine **4**, and *N,N,N',N'*-tetramethyl-*p*-phenylendiamine **5** were generated for the first time[4].



| | R | R' |
|---|---|---|
| **1** | *i*Pr | *i*Pr |
| **2** | *t*Bu | *t*Bu |
| **3** | $NMe_2$ | H |
| **4** | $NMe_2$ | Me |
| **5** | $NMe_2$ | $NMe_2$ |

**6**

The data provided by the ESR spectra of these radical anions are given in Table 1. They point to a single occupancy of an orbital which correlates with the "antisymmetric" benzene-LUMO, as is expected in view of the substituent effects.

The method can also be applied to other compounds of low electron affinity—for example, "superphane" **6** which is not reduced by standard procedures[5]. A coupling constant of $0.185 \pm 0.005$ mT for 12 equivalent protons was derived from the ESR spectrum of the radical anion of **6** ($g = 2.0030 \pm 0.0002$); this result means that, on the hyperfine time-scale, the unpaired electron is localized in one benzene ring.

Table 1. $^1$H- and $^{14}$N-coupling constants (mT) and *g* values for the radical anions of **1**–**5**.

| Cpd. | H(2,6) [a] | H(3,5) [a] | H(4) [b] | Substituent [b] | *g* [c] |

## Tetrakis(trimethylsilyl)plumbane, The First Organosilicon-Lead Compound**

By *Lutz Rösch** and *Uwe Starke*

Molecules with Si–Pb bonding were hitherto unknown. This is surprising since organometallic compounds of both lead[1] as well as of silicon[2] with bonding to all other elements of the 4th main group are well known. We have now been able to obtain the first organosilylplumbane by reaction of $PbCl_2$ with $Mg(SiMe_3)_2 \cdot DME$ (DME = 1,2-dimethoxyethane)[3].

$$2\,PbCl_2 + 2\,Mg(SiMe_3)_2 \xrightarrow{Et_2O,\ -78\,^{\circ}C} Pb(SiMe_3)_4 + Pb + 2\,MgCl_2$$

$Pb(SiMe_3)_4$ can be isolated as pale yellow, moderately light-sensitive crystals, which are soluble in hydrocarbons and in ethers. The solutions are stable for several hours at room temperature. On heating, the crystals start to decompose at 80 °C. The composition of the new compound was confirmed by elemental analysis and by its IR, Raman, $^1$H-NMR, and mass spectra. The mass spectrum contains the ion with calculated isotopic pattern and the expected frag-

ment ions. The $^1$H-NMR spectrum (benzene solution) shows a singlet in the neighborhood of the TMS standard, flanked by Si- and Pb-satellites.

The IR and Raman spectra are consistent with the spectra of the homologous compounds $E(SiMe_3)_4$ (with E = C, Si, Ge, Sn) investigated by *Bürger et al.*[2]. As expected, the lead compound has the two lowest $ESi_4$ valence vibrations (305, 302 $cm^{-1}$) of this series; however, the shift is small compared to the corresponding bands of $Sn(SiMe_3)_4$ (325, 311 $cm^{-1}$)[2] and gives no indication of a particular weakening of the Pb–Si bond.

Our synthesis of $Pb(SiMe_3)_4$ started from a $Pb^{II}$ compound. In analogy to the synthesis of tetraorganolead compounds it may be assumed that $Pb(SiMe_3)_2$ and $Pb_2(SiMe_3)_6$ occur as intermediates.

$$PbCl_2 + Mg(SiMe_3)_2 \longrightarrow Pb(SiMe_3)_2 + MgCl_2$$
$$3\,Pb(SiMe_3)_2 \longrightarrow (Me_3Si)_3Pb{-}Pb(SiMe_3)_3 + Pb$$
$$2\,Pb_2(SiMe_3)_6 \longrightarrow 3\,Pb(SiMe_3)_4 + Pb$$
$$\text{or: } Pb_2(SiMe_3)_6 \longrightarrow Pb(SiMe_3)_4 + Pb(SiMe_3)_2$$

$Pb(SiMe_3)_2$ has so far never been detected, whereas the occurrence of $Pb_2(SiMe_3)_6$ could be confirmed mass spectroscopically[4].

## Novel Surface-Modified Solids by Topochemical Oxidation of Zintl Anions**

By *Robert C. Haushalter**

Although Zintl phases[1] and Zintl anions[2,10,11] have been known for many years, their chemical reactivity has rarely been investigated[10]. We have found that many Zintl anions can be topochemically oxidized by reducible solids to give a large class of new surface-modified materials. Thus, *e.g.*, it was possible to metallize certain organic polymers (polyimide, polyacetylene) non-electrochemically *via* a novel reduction-intercalation-deposition scheme[3] (cf. Fig. 1: steps ⓐ and ⓑ). We now report that many anisotropic inorganic solids, and even certain metals, can be surface-metallized with Zintl anions by a similar mechanism. Furthermore, unique bimetallic surfaces can be prepared by utilizing the reducing power of the solids obtained from the reduction-intercalation-deposition reaction to reduce metal cations from solution (Fig. 1: step ⓒ).

When single crystals of graphite are treated with ethylenediamine (en) solutions of $K_4Sn_9$[10] (36 h, 25 °C), elemental analysis of the product shows an Sn/K ratio ≈ 2; scanning electron microscopy (SEM), electron microprobe/energy dispersive X-ray analysis (EM/EDX) and powder X-ray diffraction (XRD) show that crystalline tin is deposited only on the edges of the graphite layers. This anisotropic metallization is presumably due to the much greater rates of diffusion of $K^+$ between the graphite layers in the crystals compared to diffusion rates perpendicular to the layers. Thus, the Sn crystals are deposited on the surface where the Zintl anion ($Sn_9^{4-}$) is oxidized and the cations ($K^+$) are intercalated in the graphite lattice. The electrons and $K^+$ can be removed from the graphite lattice by treatment with oxidants (*e.g.* treatment with benzophenone generates the $K^+$ salt of the blue benzophenone radical anion; see Fig. 1: step ⓓ).

Likewise, golden metallic $HfTe_2$ crystals rapidly turn silver-gray when treated with $K_4Sn_9$ in en-solution, and SEM and EM/EDX again show tin deposited primarily on edges of the flat crystals.

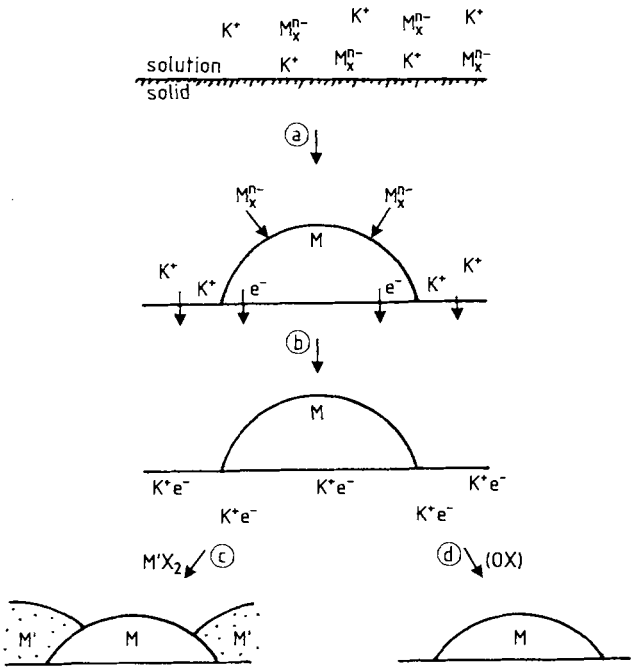

Fig. 1. Schematic illustration of the surface modification of solids by the oxidation of Zintl anions (for example $K_4M_9$): ⓐ Treatment of a solid surface with a Zintl anion in a solution of the polyanion. ⓑ Once a nucleation site forms, a metal crystal grows on the surface of the solid by the decomposition of the Zintl $M_x^{n-}$. The Zintl anion's electrons are transferred through the growing metal crystal to reduce the solid while the Zintl anion's counterions combine with the substrate to balance the charge from the reduction. ⓒ The now oxidizable potassium-containing solid enables reduction of a metal salt ($M'X_2$) with formation of a bimetallic surface. ⓓ A "pure" surface metal crystal obtained by action of an electron acceptor in connection with ⓑ.

[**] This work was supported by the U. S. Department of Energy (Contract No. W-31-109-Eng-38). I thank B. Tani for assistance with the SEM analysis.

Some of the more electronegative transition metals can also be surface metallized by Zintl anions *via* a similar mechanism. Treatment of Pt foil with $K_4Pb_9$ in en (24—48 h, 25 °C) gives lead crystals surrounded by a potassium-rich phase (XRD, SEM, EM/EDX). The potassium-rich phase is not present as $K^+$ as it retains considerable reducing power. Reaction of this K/Pb surface with reducible metal cations, like $Pd^{2+}$, leads to deposition of the metal onto the surface to give a bimetallic surface, and $K^+$ goes into solution (Fig. 1: ⓒ). Other transition metal substrates (*e.g.* Au), and other Zintl anions and reducible metal cations can be used similarly to form many bimetallic surfaces. The second stage of the formation of these bimetallic surfaces, *i.e.* reduction of the cation $M^{n+}$ (cf. Fig. 2b) can be viewed conceptually as the reverse of the oxidation of the Zintl anion $M_x^{n-}$ at a solid surface (Fig. 2a).

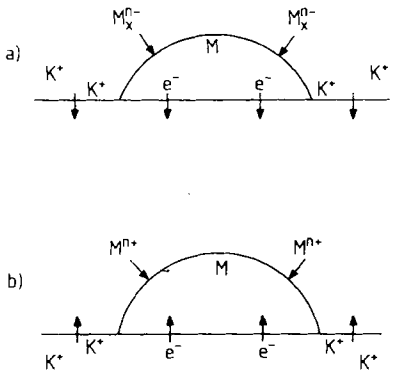

Fig. 2. Contrast of the surface oxidation of Zintl anions with the reduction of metal cations by reduced, intercalated solid. a) The oxidation of Zintl anions to the metal with simultaneous reduction, intercalation of the solid, b) reduction of metal cations accompanied by oxidation, deintercalation of the solid.

The common feature of these reactions is the deposition of metal crystals on the surface of a solid by oxidation of Zintl anions on the surface of the growing metal crystal, transfer of the electrons through the metal crystal to the substrate, which is then intercalcated by cations to balance the charge. The reaction type is general and has allowed the preparation of many surface-modified materials not accessible by other preparative techniques.

## Quenching of the Aromaticity of the 5-Dibenzo[*a,d*]cycloheptenylium Ion by Complexing with $(CO)_3Cr$

By *Alberto Ceccon, Alessandro Gambaro, Annamaria Romanin,* and *Alfonso Venzo**

Thermodynamic and kinetic data[1] show that the π-coordination of an aryl ring by a tricarbonylchromium group anchimerically stabilizes benzylic carbenium ions; this has been demonstrated, primarily, by NMR spectroscopic data[2]. Tropylium ions are, as suggested by the $pK_{R^+}$ values, likewise stabilized by $(CO)_3Cr$ groups—albeit by a different mechanism[1c]. We report here on the $pK_{R^+}$ values and $^1$H-NMR spectra of the free and of the $(CO)_3Cr$-complexed 5-dibenzo[*a,d*]cycloheptenylium ions **1** and the 10,11-dihydro analog **2**.

We compare UV data and $pK_{R^+}$ values for the free and complexed ions, obtained by ionization of the corresponding alcohols in trifluoracetic acid/$H_2O$, with the data for the diphenylcarbenium ion **3**. The coordination with the $(CO)_3Cr$-residue stabilizes the cation **2a** ($\Delta pK_{R^+} = +3.5$) almost as equally as well as **3a** ($\Delta pK_{R^+} = +3.3$). A quite different behavior is observed, however, in the case of **1a**;

**1** **2** **3**

**a**, R = H; **b**, R = $(CO)_3Cr$

here the thermodynamic stability is strongly reduced on complexation with $(CO)_3Cr$ ($\Delta pK_{R^+} = -2.4$). Since the free ion **1a** is about 5 $pK_{R^+}$ units more stable than the dehydro analog **2a**, the complexed ions **1b** and **2b** show a comparable stability. These findings, which are not consistent with the effects usually induced by the $(CO)_3Cr$ group, can be explained on the basis of $^1$H-NMR data.

For the $^1$H-NMR investigations, solutions of the carbenium ions were obtained by protonation of the corresponding alcohols in $CD_2Cl_2$ at 200 K with $HSO_3F$. The 5-H singlets were assigned by comparison with the $^1$H-NMR spectra of 5-deuterio derivatives. In the case of the uncomplexed ions it is found that in **2a** the positive charge is delocalized over the aryl rings, whereas in **1a** it is not. In **1a** the 5-H signal is shifted further downfield than in **2a** (Table 2); this is attributed to a strong diatropic ring current in the central ring of **1a**[7]. This is also responsible for the large downfield shift of the signals of the olefinic protons; with $\delta = 9.18$ these signals lie in the same region as the signal of tropylium tetrafluoroborate ($\delta = 9.30$).

The coordination with $(CO)_3Cr$ causes an upfield shift of all signals in both carbenium ions (see Δ-values in Table 2). For **2b** the complexation effects closely resemble those found for the $(CO)_3Cr$-complex of the di(*p*-tolyl)carbenium ion[2a]: The signals of the complexed aryl ring and the 5-H signal are shifted further upfield than the signals of the $CH_2$ groups and the uncomplexed aryl ring. The

[a] $\delta$-values referred to TMS; 90 MHz. [b] In $CD_2Cl_2$ saturated with $HSO_3F$; $T = 243$ K. [c] The $(CO)_3Cr$ is bonded to the ring bearing the 1-H—4-H atoms. [d] $\Delta_{1b-1a} = \delta_{1b} - \delta_{1a}$. [e] Complicated multiplet. [f] Mean difference.

smaller charge delocalization into the uncomplexed ring is also revealed in the alternating Δ-values ($\Delta^9_{2b-2a} \approx \Delta^7_{2b-2a} < \Delta^8_{2b-2a} \approx \Delta^6_{2b-2a}$; $\Delta^1_{2b-2a} = \delta^1_{2b} - \delta^1_{2a}$). The most striking effect caused by introduction of the $(CO)_3Cr$ group is the large upfield shift of the "side chain" protons 10, 11-H (of the same order of magnitude as in the case of the 1-H—5-H signals). Moreover, all $\Delta_{1b-1a}$ values are greater than the corresponding $\Delta_{2a-2b}$ values. The $\Delta_{1b-1a}$ values of the protons of the uncomplexed aryl ring are not alternating ($\Delta^6_{1b-1a} \approx \Delta^9_{1b-1a} < \Delta^7_{1b-1a} \approx \Delta^8_{1b-1a}$).

We assume that the diatropic character of the central ring in **1a** is substantially reduced on complexation with $(CO)_3Cr$; this explains the decrease in thermodynamic stability in the transition **1a** → **1b**.

Comparison of the results obtained on the aromatic 5-dibenzo[*a*,*d*]cycloheptenylium ion **1a** with those of the antiaromatic anion 5-dibenzo[*a*,*d*]cycloheptenide[10] reveals that complexation of an aryl ring with $(CO)_3Cr$ causes a dramatic decrease in the extended diatropic or paratropic ring current; the aromatic species is destabilized, the antiaromatic is stabilized.

## A Simple Route to 2-Vinylimidazoles

By *Alan S. Rothenberg**, *David L. Dauplaise*, and *Hans P. Panzer*

2-Vinylimidazoles are an interesting class of compounds because of their unique polymerization characteristics, which set them apart from the more familiar 1-vinylimidazoles[1]. They have previously been available only by a lengthy and tedious sequence involving condensation of β-hydroxypropionimidate with an aminoacetaldehyde dimethyl acetal, followed by dehydration of the resulting 2-(β-hydroxyethyl)imidazole[2]. Alternatively, the hydroxyethylimidazole could be converted into the corresponding β-bromide and dehydrobrominated to 2-vinylimidazole[3]. Since low yields of 2-vinylimidazoles result from either of these routes, only limited quantities of 2-vinylimidazoles have previously been available, and little is known about their polymerization behavior.

We now wish to report the first practical laboratory method for the preparation of significant quantities of 2-vinylimidazoles. This route uses the classical condensation of an aldehyde and an α-dicarbonyl compound with ammonia to provide the imidazole ring system[4, 5]. However, by using 5-norbornene-2-carbaldehyde **1**, the Diels-Alder adduct of acrolein and cyclopentadiene, as the aldehyde component, a 2-(5-norbornen-2-yl)imidazole **2** is obtained which is readily convertible into the 2-vinylimidazole **3** and cyclopentadiene by a retro-Diels-Alder reaction. Various α-dicarbonyl compounds can be used to prepare differently substituted 2-vinylimidazoles; however, best results are obtained in reactions using glyoxal. In this case, yields of about 90% are achieved in each of the two steps.

*Procedure*

**2**: Anhydrous ammonia (25.5 g, 1.5 mol) is added dropwise to a vigorously stirred mixture of **1** (61 g, 0.5 mol; *endo*/*exo* = 80/20) and 80% glyoxal powder (36.25 g, 0.5 mol) in methanol (150 mL) at −10 °C. The temperature is maintained at −10 °C, stirring is continued for four hours, and the reaction temperature is then allowed to rise to ambient temperature. The product is poured into water (2 L) and the precipitated solid collected on a filter, washed with water and vacuum dried to provide 74 g (90%) of **2** as a white solid, m.p. 209–210 °C.

**3**: A 20% solution of **2** in methanol is continuously fed at a rate of up to 3 mL/min to the top of a 60 cm long vertically mounted pyrolysis tube, 30 cm of which is packed with ceramic beads. The tube is heated to 500 °C and the vapors are swept through the apparatus by a flow of $N_2$ (200 mL/min) from top to bottom, with the methanolic

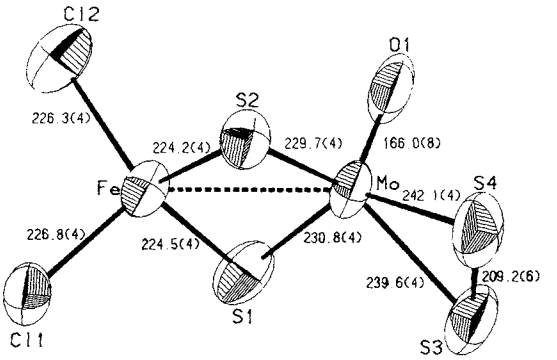
## $[Cl_2FeS_2MoO(S_2)]^{2-}$, a Novel Bimetallic Complex with Unusual Electronic Structure and a Substituted Tetrachalcogenometalate as "Ligand"

By *Achim Müller*, Sabyasachi Sarkar, Hartmut Bögge, Rainer Jostes, Alfred Trautwein,* and *Uschi Lauer*

Heterometal complexes and clusters which can be of biochemical importance (*e.g.* in connection with the elucidation of the structure of the FeMoS cluster of nitrogenase[1,2]), are, *in general,* rarely accessible *via* conventional preparative routes. In special cases $d^0$-thiometalates of the type $MO_{4-n}S_n^{2-}$ (M = Mo, W; n = 2, 3, 4), which have unique ligand properties, have proven to be ideal synthetic reagents[2]. We have now been able to synthesize a heterometal complex which *formally* contains a substituted thiometalate, the chelate ligand $[S_2MoO(S_2)]^{2-}$, **1**. Substituted thiomolybdates have so far never been isolated.

Reaction of $MoOS_3^{2-}$ with $FeCl_2$ and sulfur ($S_8$) in dimethylformamide (DMF) leads to formation of black-green $(PPh_4)_2[Cl_2FeS_2MoO(S_2)]\cdot DMF$, which we characterized by elemental analysis, magnetic measurements, $^{57}$Fe-Mössbauer, IR, and UV/VIS spectra, MO calculations, and a complete crystal structure analysis. The complex anion $[Cl_2FeS_2MoO(S_2)]^{2-}$, **2** (Fig. 1), contains a distorted tetrahedrally coordinated Fe central atom with two chloro ligands and the novel bidentate "perthiomolybdato" ligand, **2**, derived from the "tetrahedrally shaped" $MoOS_3^{2-}$ by $S^{2-} \rightarrow S_2^{2-}$ substitution. The FeCl distances almost correspond to those observed in $[Cl_2Fe(MoS_4)]^{2-}$ and $[Cl_2Fe(MoS_4)FeCl_2]^{2-}$. The $FeS_2MoO(S_2)$ group in **2** is similar in structure to the $MoS_2MoO(S_2)$ moiety in $[(S_2)OMo^VS_2Mo^VO(S_2)]^{2-}$, **3** (dihedral angles $FeS_2Mo$ 158.5° and $MoS_2Mo$ 148.8°). The FeMo distance is 275.2(2) pm.



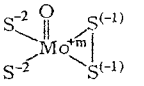


Fig. 1. Structure of the anionic complex **2** in crystals of $(PPh_4)_2[Cl_2FeS_2MoO(S_2)]\cdot DMF$. Atomic distances in pm.

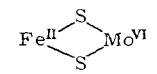
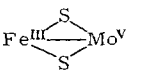


Substitutions of thiomolybdates(VI) have so far proved impossible, because reactions with both nucleophiles (*e.g.* $CN^-$) as well as with electrophiles (*e.g.* sulfur or $H^+$) lead to reduction of the $Mo^{VI}$[2], yielding predominantly multinuclear Mo compounds.

The $^{57}$Fe-Mössbauer spectrum ($IS = 0.40 \pm 0.01$, $QS = 1.75 \pm 0.01$ mm/s at room temperature rel. to α-Fe), which is characteristic for $Fe^{II}$-"high-spin" complexes with tetrahedral coordination and *extraordinarily strong acceptor ligands,* reveals interesting electronic properties of **2**. A comparison of the isomeric shift with that of $[Cl_2Fe(MoS_4)]^{2-}$ ($IS = 0.48$, $QS = 2.10$ mm/s) shows that the ligand **1** effects a more pronounced Fe→L electron delocalization than $MoS_4^{2-}$[2]. In **1** the (unoccupied) MOs with Mo-4d character lie, in part, energetically much lower relative to the non-bonding S-3p level than they do in $MoS_4^{2-}$. Whereas the $M'(S_{br})_2M$ moieties in known thiometalato complexes are almost planar[2], in **2** an FeMo distance typical for $Fe(S_{br})_2Mo$ systems is realized (despite the longer $MoS_{br}$ bonds) by bending of the $FeS_2$- and $S_2Mo$-planes, owing to relatively strong Fe-Mo interaction.



It seems important in the bio-inorganic chemistry of molybdenum that the "fragment" **1**

(with m = 5 in the case of **3**, and between 5 and 6 in the case of **2**) can manifestly exist with different electron populations. In the case of **2** the electronic structure can best be described in terms of the "valence structures" (therefore the designation "ligand" for **1** can be considered only in a formal sense). This would indicate that a re-

and

## Selective Reductive Dehalogenation of Tertiary and Benzylic Halides with $Zn(BH_4)_2$ in Diethyl Ether**

By *Sunggak Kim**, *Chang Yong Hong*, and *Sungbong Yang*

The reductive dehalogenation of organic halides is an important reaction which is frequently used in organic synthesis, and considerable progress has been made in the development of various synthetic methods for such conversion[1]. $Zn(BH_4)_2$ is a well-known useful reagent for the reduction of alkali-sensitive compounds[2a], the selective 1,2-reduction of enones[2b], and the stereoselective reduction of β-keto esters[2c]. However, no successful report has appeared about the application of $Zn(BH_4)_2$ for the reduction of organic halides[3]. Here, we describe an efficient method for the selective reduction of tertiary and benzylic halides to afford the corresponding hydrocarbons using zinc borohydride; hereby, primary and secondary alkyl halides, and aryl halides are not attacked[4].

Addition of $Zn(BH_4)_2$ in dimethoxyethane to tertiary alkyl halides such as **1** gives only *ca.* 5% of the alkane in 24 h at room temperature; however, the reaction proceeds smoothly when diethyl ether is used as solvent.

$$RX + Zn(BH_4)_2 \xrightarrow{Et_2O} RH$$

R = tertiary or benzylic alkyl moiety; X = Cl, Br

The tertiary halides **1**, **2**, **4**, and **5** are rapidly reduced in excellent yields. Of special synthetic significance is that no eliminations occur, in contrast to what is often encountered in $S_N1$ reactions. Surprisingly, the tertiary trifluoroacetate **3** is recovered unchanged after 1 h reaction. Secondary benzyl halides such as **6** and **7** are reduced to the corresponding hydrocarbons within 1 h, whereas primary benzyl halides such as **8** and **9** are reduced rather slowly. Allyl and vinyl halides such as **10** and **11** are not reduced to the corresponding alkenes, but polymerize almost instantly[5]. $Zn(BH_4)_2$ in diethyl ether is inert towards primary and secondary alkyl halides such as **12** and **13**, and aryl halides such as **9**. 1,2-Dibromo-1-phenylethane is exclusively reduced to 1-bromo-2-phenylethane; this opens up a general route to β-arylethyl halides.

Table 1. Reduction of organic halides by $Zn(BH_4)_2$ in diethyl ether at room temperature.

| Educt | *t* [h] | Product | Yield [%] [a] |

[a] The yields refer to isolated products. The numbers in parentheses indicate the GLC yields. [b] The educts are recovered in essentially quantitative yields. [c] The halides are completely converted into polymeric products.

### *Experimental*

Reduction of 1-bromoadamantane **4**: To a stirred solution of 1-bromoadamantane (430 mg, 2 mmol) in anhydrous $Et_2O$ (6 mL) is added a 0.5 M solution of $Zn(BH_4)_2$ (4 mL) in ether at room temperature. The reaction mixture is stirred at room temperature under a nitrogen atmosphere for 4 h and then hydrolyzed with a saturated aqueous $NH_4Cl$ solution (1 mL). After addition of $Et_2O$ (20 mL) the mixture is washed with $H_2O$ (10 mL) and saturated NaCl solution (20 mL), and dried over $MgSO_4$. Adamantane (255 mg, 94%) is obtained as the only product after removal of solvent.

## Highly Selective Extraction of Uranyl Ions by Acyclic Ligands Containing L-Phenylalanine Moieties**

By *Maurizio Delcanale, Rosangela Marchelli*, Alessandro Mangia, Arnaldo Dossena,* and *Giuseppe Casnati*

Selective extraction of uranyl ions from aqueous solutions containing other ionic species is an interesting subject theoretically and has great practical significance[1]. We recently reported the synthesis[4] and complexing properties[5] of the ligands **1–4**, in which two L-phenylalanine moieties are linked by oligoethylene oxide bridges. Here we report that these ligands are particularly effective and selective in extracting uranyl ions from aqueous solutions into an organic phase (dichloromethane).

**1**, X = O
**2**, X = O O
**3**, X = O O O
**4**, X = O O O O

The extraction was performed by stirring a solution of ligands **2—4** in $CH_2Cl_2$ ($10^{-2}$—$10^{-3}$ M) for 2 h with an aqueous solution of $UO_2(NO_3)_2$ or $UO_2(OAc)_2$ over a wide concentration range ($10^{-2}$—$10^{-5}$ M) at various pH values and different $L/UO_2^{2+}$ ratios. The degree of extraction is influenced by the concentration of the ligand and increases with the ligand/$UO_2^{2+}$ molar ratio to give complete extraction (98%) with a 70-fold excess of ligand. The anion has little effect on the extraction. Extraction efficiency reaches a maximum when the pH of the aqueous phase is *ca.* 4.

The high selectivity of the ligands **2—4** for $UO_2^{2+}$ was ascertained by competition experiments with other cations. Of all metals present, either in the same concentration ($Cu^{2+}$, $Ni^{2+}$) or in large excess (1000 ppm : 1 ppm; $Na^+$, $K^+$, $Mg^{2+}$, $Ca^{2+}$), only $Cu^{2+}$ was extracted in traces (2.7%); the total percentage of $UO_2^{2+}$ extracted remained unchanged. The complexed $UO_2^{2+}$ ions can be totally liberated from the organic phase by treatment with 0.1 M HCl for a few minutes. The recovery of the ligand is very satisfactory, *ca.* 90% remaining practically unaltered in the organic phase.

$UO_2^{2+}$ forms at least two types of complexes with the ligands **1—4**, whereby the ligands occur as dianion: 1:1 complexes (greatest amount at pH ≈ 3.5) and 2:1 complexes (greatest amount at pH 4.5). The former complexes are more stable than the latter by 2—3 $\log K$ units: $\log K_1$ 5.44 (**1**), 6.10 (**2**), 5.28 (**3**), 5.43 (**4**).

The $^{13}C$-NMR spectra of the free ligands and of the complexes in methanol show that the amide- and carboxy-CO groups are involved in complexation to $UO_2^{2+}$; in the presence of $UO_2^{2+}$ ions the corresponding signals undergo significant downfield shifts (*ca.* 1 ppm), whereas the signals of the C atoms adjacent to the ether O atoms show no or very small changes in shift (*ca.* 0.2 ppm). This, therefore, indicates that the $UO_2^{2+}$ ion is complexed preferentially by compounds having carboxylate groups than by those with crown ether moieties[9].

In conclusion, compounds **1—4** are effective and selective ligands for the extraction of $UO_2^{2+}$; since they also readily release the $UO_2^{2+}$ ions again they could be used, *e.g.,* in the field of decontamination.

# BOOK REVIEWS

**Multiple Bonds between Metal Atoms.** By *F. A. Cotton* and *F. R. Walton.* John Wiley and Sons Ltd., Chichester 1982, xiv, 466 pp., bound, £ 35.00.

The authors report on a new area of chemistry, in whose opening up and development they were decisively involved, on multiple bonds between transition metal atoms. Cotton explained the very short ReRe distance in the $Rh_2Cl_8^{2-}$ ion in 1964 by assuming a quadruple bond between the metal atoms. This was later confirmed and the idea was extended to dinuclear complexes of other metals; fifteen years later the trickle has become a flood, with almost a 100 publications a year from many research groups. For this reason the time was ripe for assembling the multitude of individual reports, which are now too unwieldy to cover completely, into a monograph.

The first section is devoted to a historical synopsis (and to the clarification of priority). The treatment of individual systems is undertaken in six sections occupying a total of 300 pages: quadruple bonds between Re and Tc atoms, between Mo and W atoms as well as between Cr atoms; triple bonds, double bonds and finally single bonds in dirhodium complexes and complexes isoelectronic with them. A final section, entitled "Physical, spectroscopic and theoretical results", summarizes the present, quantitative picture concerning the stability, the structure and the chemical bonding of this type of MM bonded dinuclear

complexes. The monograph presents a comprehensive survey of the preparation and structural characterization, and the chemical reactions and catalytic activity of a fascinating class of substances, in the light of modern understanding of chemical bonding. In the process, what is already understood is treated and that which is, until now, unclarified is adequately mentioned. Thus, the MM bond does not exhibit a simple correlation between bond order and length, like that familiar to every chemist for the main group elements.

It is usual to outline the possible *readership*. The theme and presentation make this book of interest to every chemist, whether he is only taking a general interest in what is possible over and above the CC triple bond or if he is seeking details of a new class of compound. The reviewer sees a limitation of the possible *purchasers* of the book only in its price, which is high; but that applies, nowadays, to every specialist book.

It is also usual to offer criticism in a review. In this instance little is required; at most the fact that the discussion of supershort CrCr bonds (*ca.* 185 pm) is carried out in several sections of the book and that a chapter is devoted to chromium without even mentioning the short bond in $Cr_2$ of 168 pm, which is interpreted as a six-fold linkage (*J. Phys. Chem. 86* (1982) 3914).

*Arndt Simon* [NB 586 IE]

**Ullmanns Encyklopädie der technischen Chemie.** Edited by *E. Bartholomé, E. Biekert, H. Hellmann, H. Ley* (deceased), *W. M. Weigert* (deceased), and *E. Weise*. Verlag Chemie, Weinheim 1982. 4th edit., vol. 21: Schwefel bis Sprengstoffe [Sulfur to Explosives]. xiv, 697 pp., bound, DM 525.00.

With entries on sulfur, silicon, and their compounds this volume of the 4th edition of Ullmann[*] covers important areas of industrial inorganic chemistry, although these entries also extend into organic chemistry, as in the case of silicones and sulfur dyes. Other inorganic subjects are discussed in the entries on selenium and its compounds (8 pages), rare earths (37 pages), silver and its compounds and alloys (54 pages), and sintered iron and steel (29 pages). The book also offers entries on silk (7 pages), soap (18 pages), sorbic acid (5 pages), sera and vaccines (38 pages), and spasmolytics (13 pages). Four entries from the field of applications deal with cutting and welding (22 pages), solar technology (37 pages), mirrors (4 pages), and explosives (61 pages). This last list illustrates the large and diverse field in which chemistry has found applications. Although each application also contains elements of several other branches of science, it is interesting to see how much chemistry is needed in various fields, whether classical, such as the production of mirrors, or topical, such as solar technology.

As for the production and presentation, this volume too has the well-known Ullmann quality, which has by now become a byword.

# From Macromolecules to Biological Assemblies (Nobel Lecture)**

By Aaron Klug

## 1. Introduction

Within a living cell there take place a large number and variety of biochemical processes, almost all of which involve, or are controlled by, large molecules, the main examples of which are proteins and nucleic acids. These macromolecules do not of course function in isolation but often interact to form ordered aggregates or macromolecular complexes, sometimes so distinctive in form and function as to deserve the name of organelles. The properties of the individual macromolecules in a cell are often expressed in such biological assemblies. It is on some of these assemblies on which I have worked for over 25 years and which now form the subject of this lecture.

The aim of our field of structural molecular biology is to describe the biological machinery, in molecular, *i.e.* chemical, detail. The beginnings of this field were marked just over 20 years ago in 1962 when *Max Perutz* and *John Kendrew* received the Nobel prize for Chemistry for the first solution of the structure of proteins. In the same year *Francis Crick, James Watson,* and *Maurice Wilkins* were likewise honoured, having received the Nobel prize for Medicine for elucidating the structure of the double helix of DNA. In his Nobel lecture *Perutz* recalled how 40 years earlier, in 1922, *Sir Lawrence Bragg,* whose pupil he had been, came here to thank the Academy for the Nobel prize awarded to himself and his father, *Sir William Bragg,* for having founded the new science of X-ray crystallography, by which the atomic structure of simple compounds and small molecules could be unravelled. These men have not only been my predecessors, but some of them have been something like scientific elder brothers to me, and I feel very proud that it should now be my turn to have this supreme honour bestowed upon me. For the main subjects of my work have been both nucleic acids and proteins, the interactions between them, and the development of methods necessary to study the large macromolecular complexes arising from these interactions.

In seeking to understand how proteins and nucleic acids interact, one has to begin with a particular problem, and I can claim no credit for the choice of my first subject, tobacco mosaic virus. It was the late *Rosalind Franklin* who introduced me to the study of viruses and whom I was lucky to meet when I joined *J. D. Bernal*'s department in London in 1954. She had just switched from studying DNA to tobacco mosaic virus (TMV), X-ray studies of which had been begun by *Bernal* in 1936. It was *Rosalind Franklin* who set me the example of tackling large and difficult problems. Had her life not been cut tragically short, she might well have stood in this place on an earlier occasion.

## 2. Tobacco Mosaic Virus

Tobacco mosaic virus (TMV) is a simple virus consisting only of a single type of protein molecule and of RNA, the carrier of the genetic information. Its simple rod shape results from its design, namely a regular helical array of these protein molecules, or subunits, in which is embedded a single molecule of RNA. This general picture (Fig. 1) was already complete by 1958 when *Rosalind Franklin* died. It is clear that the protein ultimately determines the architecture of the virus, an arrangement of $16\frac{1}{3}$ subunits per turn

of a rather flat helix with adjacent turns in contact. The RNA is intercalated between these turns with three nucleotide residues per protein subunit and is situated at a radial distance of 40 Å from the central axis and is therefore isolated from the outside world by the coat protein. The geometry of the protein arrangement forces the RNA backbone into a moderately extended single-strand configuration. Running up the central axis of the virus particle is a cylindrical hole of diameter 40 Å, which we then thought to be a trivial consequence of the protein packing, but which later turned out to figure prominently in the story of the assembly.

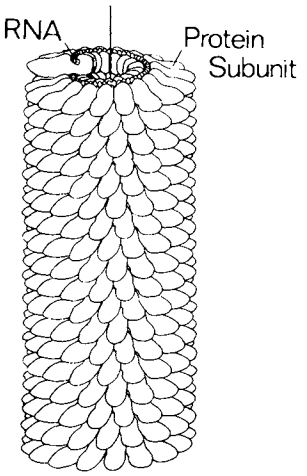

Fig. 1. Diagram summarizing the results of the first stage of the structure analysis of tobacco mosaic virus [71]. There are three nucleotides per protein subunit and 16⅓ subunits per turn of the helix. Only about one-sixth of the length of a complete particle is shown.

At first sight, the growth of a helical structure like that of TMV presents no problem of comprehension. Each protein subunit makes identical contacts with its neighbours so that the bonding between them repeats over and over again. Subunits can have a precise built in geometry so that they can assemble themselves like steps in a spiral staircase in a unique way. Subunits would simply add one or a few at a time onto the step at the end of a growing helix, entrapping the RNA that would protrude there and generating a new step, and so on. It was in retrospect thus not too surprising when the classic experiments of *Fraenkel-Conrat* and *Williams* in 1955[6] demonstrated that TMV could be reassembled from its isolated protein and nucleic acid components. They showed that, upon simple remixing, infectious virus particles were formed that were structurally indistinguishable from the original virus. Thus, all the information necessary to assemble the particle must be contained in its components, that is, the virus "self assembles". Later experiments[7] showed that the reassembly was fairly specific for the viral RNA, occurring most readily with the RNA homologous to the coat protein.

All this was very satisfactory but there were yet some features which gave cause for doubt. First, other experiments[8] showed that foreign RNAs could be incorporated into virus-like rods and these cast doubt on the belief that specificity *in vivo* was actually achieved during the assembly itself. Another feature about the reassembly that suggested that there were still missing elements in the story was its slow rate. Times of 8 to 24 hours were required to give maximum yields of assembled particles. This seemed to us rather slow for the assembly of a virus *in vivo*, since the nucleic acid is fully protected only on completion. These doubts, however, lay in the future and before we come to their resolution, I return to the structural analysis of the virus and the virus protein.

### 2.1. X-Ray Analysis of TMV: The Protein Disk

After *Franklin*'s death, *Holmes* and I continued the X-ray analysis of the virus. Specimens for X-ray work can be prepared in the form of gels in which the particles are oriented parallel to each other, but randomly rotated about their own axes. These gels give good X-ray diffraction patterns but because of their nature the three-dimensional X-ray information is scrambled into two dimensions. Unscrambling these data to reconstruct the three-dimensional structure has proved to be a major undertaking, and it was only in 1965 that *Holmes* and I obtained the first three-dimensional Fourier maps to a resolution of about 12 Å. In fact, only recently has the analysis by *Holmes* and his colleagues in Heidelberg (where he moved in 1968) reached a resolution approaching 4 Å in the best regions of the electron density map, but falling off significantly in other parts[9]. At this resolution it is not possible to identify individual amino-acid residues with any certainty and ambiguities are too great to build unique atomic models. However, the map, taken together with the detailed map of the subunit we obtained in Cambridge (see below) yields a considerable amount of information about the nature of the contacts with RNA[10].

These difficulties in the X-ray analysis of the virus were foreseen, and by the early 1960's I came to realise that the way around this difficulty was to try to crystallize the isolated protein subunit of the virus, solve its structure by X-ray diffraction and then try to relate this to the virus structure solved to low resolution. We therefore began to try to crystallize the protein monomer. In order to frustrate the natural tendency of the protein to aggregate into a helix, *Leberman* introduced various chemical modifications in the hope of blocking the normal contact sites, but none of these modified proteins crystallized. The second approach was to try to crystallize small aggregates of the unmodified protein subunits. It had been known for some time, particularly from the work of *Schramm* and *Zillig*[11], that the protein on its own, free of RNA, can aggregate into a number of distinct forms, besides that of the helix. I chose conditions under which the protein appeared to be mainly aggregated in a form with a sedimentation constant of about 4S, identified by *Caspar* as a trimer[12]. We obtained crystals almost immediately but we found[13] them to contain not the small aggregate hoped for, but a large one, corresponding to an aggregate with a sedimentation constant of 20S. The X-ray analysis showed that this was built from two juxtaposed layers, or rings, of 17 subunits each and we named this form the two-layer disk (Figs. 2 and 4). Our initial dismay in being faced with such a large structure, of molecular weight 600000, was tempered by the fact that

the geometry of the disk was clearly related to that of the virus particle. The cylindrical rings contained 17 subunits each compared with $16\frac{1}{3}$ units per turn of the virus helix, so that the lateral bonding within the disks was therefore likely to be closely related to that in the virus. We also showed, by analysing electron micrographs, that the disk was polar, *i. e.* that its two rings faced in the same direction as do successive turns of the virus helix.

### 2.2. Protein Polymorphism

These results on the structure of the disk which showed that it was fairly closely related to the virus helix made me wonder whether the disk aggregate might not be fulfilling some vital biological role. It had been easy to dismiss it as perhaps an adventitious aggregate of a sticky protein or a storage form. The polymorphism of TMV protein was first

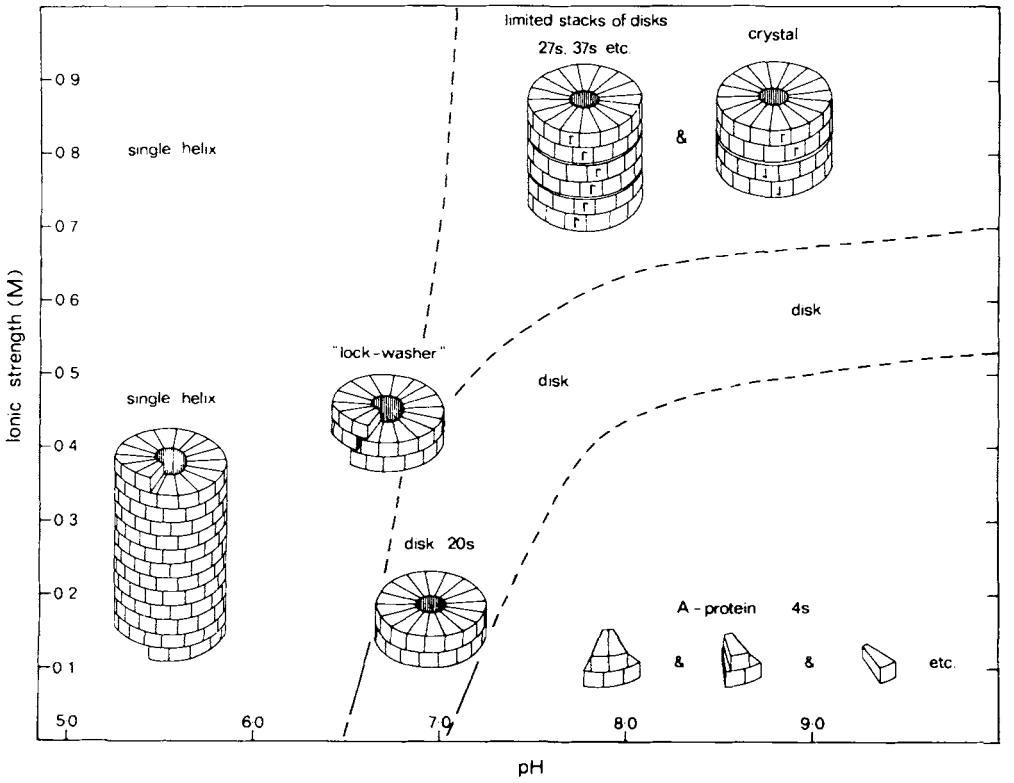

Fig. 2. Diagram showing the ranges over which particular forms of TMV protein participate significantly in the equilibrium in dependence of pH and ionic strength [17]. This is not a conventional phase diagram: a boundary is drawn where a larger species becomes detectable and does not imply that the smaller species disappears sharply. The "lock-washer" indicated on the boundary between the 20S disk and the helix is not well defined and represents a metastable transitory state observed when disks are converted into helices by abrupt lowering of the pH.

This was the first very large structure ever to be tackled in detail by X-ray analysis and it took about a dozen years to carry through the analysis to high resolution. The formidable technical problems were overcome only after the development in our laboratory of more powerful X-ray tubes and of special apparatus (cameras, computer-linked densitometers) for data collection from a structure of this magnitude. (In fact we had begun building better X-ray tubes in London to use on weakly diffracting objects like viruses.) The 17-fold rotational symmetry of the disk also gives rise to redundant information in the X-ray data, which was exploited in the final analysis[14], to improve and extend the resolution of a map based originally on only one heavy atom derivative. The map at 2.8 Å resolution[15] has been interpreted in terms of a detailed atomic model for the protein (Figs. 3 and 4), although the individual interactions upon RNA binding have yet to be deduced.

considered in some detail by *Caspar* in 1963[12] who foresaw that some of the aggregation states might give insight into the way the protein functions. Quantitative studies of aggregation started by *Lauffer* in the 1950's[16] concentrated upon a rather narrow range of conditions, the main interest being in understanding the forces driving the aggregation (these are largely entropic). Because of the scattered nature of the earlier observations, *Durham, Finch* and I began a systematic survey of the aggregation states as a result of which the broad outline became clear[17,18]. The results can be summarised as a phase diagram (Fig. 2).

At low or acid pH, the protein alone will form helices of indefinite lengths that are structurally very similar to the virus except for the lack of the RNA. Above neutrality the protein tends to exist as a mixture of smaller aggregates from about trimer upwards, in rapid equilibrium with each other, commonly referred to as A-protein. Near pH 7 and at about room temperature the dominant form present is

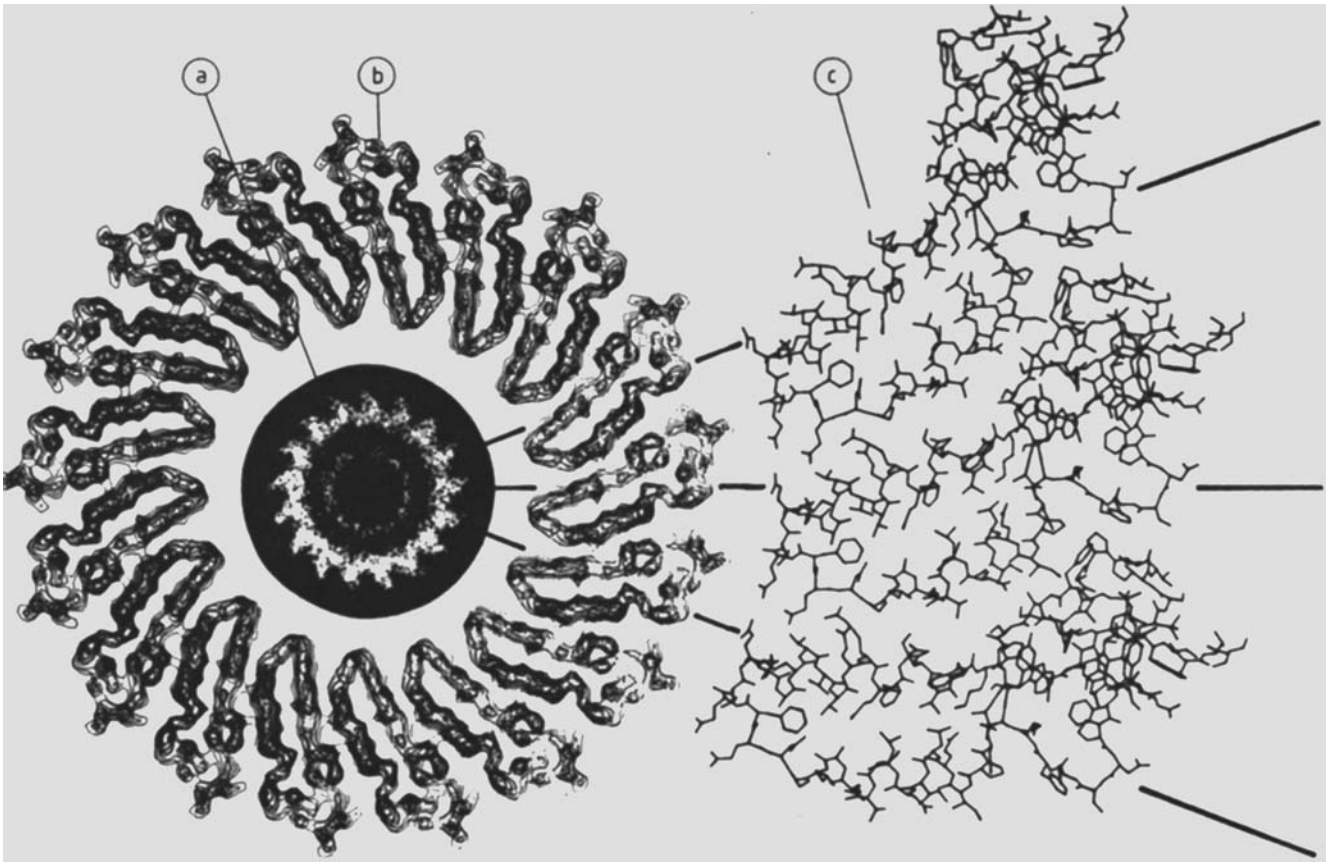

Fig. 3. The disk viewed from above at successive stages of resolution. From the centre outward there follow: ⓐ a rotationally filtered electron microscope image at about 25 Å resolution [72]; ⓑ a slice through the 5 Å electron density map of the disk obtained by X-ray analysis, showing rod-like α-helices [26]; ⓒ part of the atomic model built from the 2.8 Å map [15].

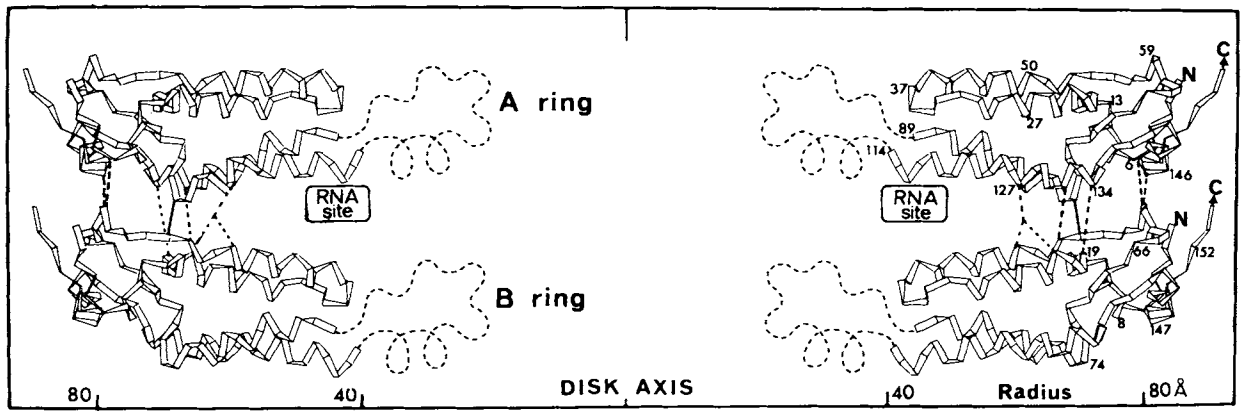

Fig. 4. Section through a disk along its axis reconstructed from the results of X-ray analysis to a resolution of 2.8 Å [15]. The ribbons show the path of the polypeptide chain of the protein subunits. Subunits of the two rings can be seen touching over a small area toward the outside of the disk but opening up into the "jaws" toward the centre. The dashed lines at low radius indicate schematically the mobile portion of the protein in the disk, extending in from near the RNA binding site to the edge of the central hole.

the disk which is in a relatively slow equilibrium with the A-form in the ratio of about 4 : 1. The dominant factor controlling the state of aggregation of the coat protein is thus the pH. The control is mediated through groups, probably carboxylic acid residues, as identified by *Caspar*[12], that bind protons abnormally in the helical state, but not in the A-form. Thus, the helical structure can be stabilised either in the virus by the interaction of the RNA with the protein, or, in the case of the free protein, by protonating the acid groups. These groups thus act as a "negative switch", ensuring that under physiological conditions the helix is not formed, and thus that enough protein in the form of disks or A-protein is available to interact with the RNA during virus assembly.

### 2.3. A Role for the Disk

The disk aggregate of the protein therefore has a number of significant properties. It is not only closely related to the virus helix, but also is the dominant form of the protein under "physiological" conditions; moreover, disk forms had also been observed for other helical viruses. These strengthened my conviction that the disk form was not adventitious but might play a significant role in the assembly of the virus. What could this role be?

Assembly of any large aggregate of identical units such as a crystal can be considered from the physical point of view in two stages: first nucleation and then the subsequent growth, or, in more biochemical language, as initiation and subsequent elongation. The process of nucleation—or, crudely, getting started—is frequently more difficult than the growth. Thus, a simple mode of initiation in which the free RNA interacts with individual protein subunits does pose problems in getting started. At least 17 separate subunits would have to bind to the flexible RNA molecule before the assembling linear structure could close round on itself to form the first turn of the virus helix. This difficulty could be avoided if a preformed disk were to serve as a jig upon which the first few turns of the viral helix could assemble to reach sufficient size to be stable. This mode of nucleation of helix assembly could also furnish a mechanism for the recognition by the protein of its homologous RNA. The surface of the disk presents a set of 51 ($=17\times3$) nucleotide binding sites which could interact with a special long run of bases, resulting in an amplified discrimination that might not be possible with a few nucleotides. It thus seemed that the disk could solve both the physical and biological requirements for initiating virus growth and conferring specificity on the interaction. This hypothesis is illustrated in Figure 5. It turned out that all the details in this diagram are wrong, but yet the spirit is correct. As *A. N. Whitehead* once observed, it is more important that an idea should be fruitful than it should be true.

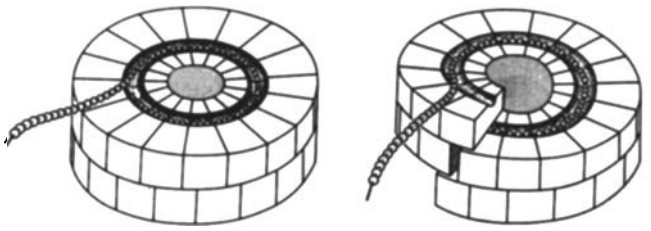

Fig. 5. The role of the disk as originally conceived: the specific recognition of a special (terminal) sequence of TMV-RNA initiates conversion of the disk form of the protein (left) into two turns of a helix (right). (See Fig. 7, for the mechanism finally established.)

This proposed mechanism of nucleation required that the disk be able to dislocate into a two-turn helix to form the beginning of the growing nucleoprotein rod. To test this, we carried out a very simple experiment, the pH drop experiment[19]. This showed that an abrupt lowering of the pH would convert disks directly, within seconds, into short helices—or lock-washers (Fig. 2), which stack on each other to give longer nicked helices, which in due course anneal to give more perfect helices. This conversion is an *in situ* one, not requiring dissociation and then reassociation into a different form. The success of this experiment encouraged us to proceed to experiments with RNA itself, the natural "substrate" of the virus protein.

The first reconstitution experiments carried out by *Butler* and myself proved to be dramatic[20]. When a mixture was made at pH 7 of the viral RNA and a disk preparation, complete virus particles were formed within 10 to 15 minutes, rather than over a period of hours, as was the case in the early reassembly experiments in which protein had been used in the disaggregated form[6].

The notion that disks are involved in the natural biological process of initiation was strengthened by companion experiments[20] in which assembly was carried out with RNAs from different sources. These showed a preference, by several orders of magnitude, of disks for the viral RNA over foreign RNAs or synthetic polynucleotides of simple sequence. It is thus the disk state of the protein that is needed to achieve specificity in the interaction with the RNA. In the experiments cited earlier, in which virus-like rods were made containing TMV A-protein and foreign RNA[8], reactions were carried out at an acid pH, and under these artificial conditions the protein alone would tend to form helical rods and so could entrap any RNA present.

Besides this effect of disks on the rate of initiation, which had been predicted, we also found to our surprise that the disks appeared to enhance the rate of elongation, and we concluded that they must be therefore actively involved in growth. This result has been questioned by some other workers in the field and is still the subject of argument[21,22], but recent discoveries on the configuration of RNA during incorporation into a growing particle (see Section 2.5) have made the involvement of disks in the elongation, as well as in nucleation, much more intelligible.

The disk form of the protein therefore provided the elements which were missing from the simple reconstitution experiments using disaggregated protein, namely speed and specificity. We now knew what the disk did, the next question was how did it do it?

### 2.4. The Interaction of the Protein Disk with the Initiation Sequence on the RNA

Specificity in initiation ensures that only the viral RNA is picked out for coating by the viral protein. This must be brought about by the presence of a unique sequence on the viral RNA for interaction with the protein disk. *Zimmern* and *Butler* isolated the nucleation region containing this site by supplying limited quantities of disk protein, sufficient to allow nucleation to proceed, but not subsequent growth, then digesting away the uncoated RNA with nuclease[23,24]. With the varying protein : RNA ratios and different digestion conditions, they found they could isolate a series of RNA fragments, all of which contained a unique common core sequence with variable extents of elongation at either end. These fragments could be rebound to the coat protein when it was in the form of disks. Among this population of fragments was a fragment only about 60 nucleotides long—just over the length necessary to bind

round a single disk—and it appeared to represent the minimum protected core. Because of the strong rebinding of this fragment back to the disk, it seemed likely that it constituted the "origin of assembly", where the normal nucleation reaction began.

However, the work on the RNA produced, in turn, another puzzle: the obvious expectation that the nucleation region would be near one end of the RNA turned out to be wrong. The nucleation occurs about one sixth of the way along the RNA from the 3′ end[25], so that over 5000 nucleotides have to be coated in the major direction of elongation (3′—5′) and 1000 have to be coated in the opposite direction. Yet growing nucleoprotein rods observed in the electron microscope[20] were always found to have all the uncoated RNA only at one end: why were rods never seen with a tail at each end? The resolution of this conundrum came from considering the structure of the protein disk, to which I now turn.

Although the structure of the disk was solved in detail only in 1977, an earlier stage in the X-ray analysis gave the clue as to how it might interact with the RNA. At 5 Å resolution[26] the course of the polypeptide chain could be traced and the basic design of the disk established (cf. Fig. 4). The subunits of the upper ring of the disk lie in a plane perpendicular to the disk axis while those of the lower ring are tilted downward towards the centre, so that the two rings touch only towards the outside of the disk. In the neighbourhood of the central hole they are thus far apart, like an open pair of jaws which could, as it were, "bite" a stretch of RNA entering through the central hole. Moreover, entry through the centre would be facilitated because the inner region of the protein, from around the RNA binding site inward, was found to be disordered and not packed into a regular structure.

It therefore looked very much as though the disk was designed to permit the RNA to enter through the central hole, effectively enlarged by the flexibility of the inner loop of protein, and intercalate between its two layers. The RNA which would enter thus would of course be the nucleation sequence which lies rather far from an end of the RNA molecule. This could, however, be achieved if the RNA doubled back on itself at a point near the origin of assembly and so entered as a hairpin loop. Indeed, the smallest RNA fragment that is protected during nucleation has a base sequence which can fold into a weakly paired double-helical stem with a loop at the top, that is a hairpin (Fig. 6). This was proposed by *Zimmern*[24]. The loop and top of the stem have an unusual sequence, containing a repeating motif of three nucleotides, with guanine (G) in one specific position, and usually adenine (A) or sometimes uracil (U) in the other two. Since there are three nucleotide binding sites per protein subunit, such a triplet repeat pattern will place a specific base in a particular site on the protein molecule and could well lead to the recognition of the exposed RNA loop by the disk during the nucleation process.

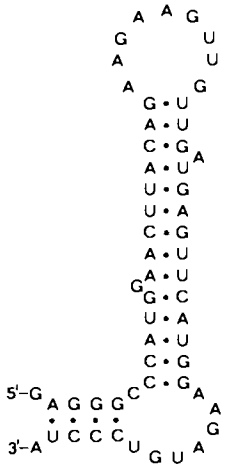

Fig. 6. Postulated secondary structure of the RNA in the nucleation region [24]. This gives a weakly bonded double-helical stem and a loop at the top which is probably the actual origin of assembly. The sequence at and near the top contains a repeating motif of three bases having G in the middle position and A, or U in the outer positions.

### 2.5. Nucleation and Growth

The hypothesis for nucleation[27] is then that the special RNA hairpin would insert through the central hole of the disk into the jaws formed by the two layers of protein subunits (Fig. 7). The dimensions are quite suitable for this to occur and the open loop could then bind to the RNA binding sites on the protein. More of the rather unstable double helical stem would melt out and be opened as more of the RNA was bound within the jaws of the nucleating disk. Some, as yet unknown, feature of this interaction would cause the disk to dislocate into a short helical segment, entrapping the RNA and, after the rapid addition of a few more disks[23], would provide the first stable nucleoprotein particle.

The subsequent events after nucleation can be called growth and as stated above there is a controversy about the particular way in which this proceeds. Our view is that elongation in the major direction of growth very likely takes place through the addition of further disks, as indeed our first reconstitution experiments drove us to conclude. The special configuration generated during the insertion of the loop into the middle of the disk must be perpetuated as the rod grows, by pulling further RNA up through the central hole. Thus, elongation could occur by a substantially similar mechanism to nucleation, only now, rather than requiring the specific nucleation loop of the RNA, it occurs by means of a "travelling loop" which can be inserted into the centre of the next incoming disk. This mechanism therefore overcomes the main difficulty in envisaging how a whole disk of protein subunits could interact with the RNA in the growing helix. There is now more evidence for growth by incorporation of blocks of subunits of roughly disk size[22], but the subject is still controversial and I will therefore not proceed further with it.

On the other hand, there is now clear experimental confirmation of our hypothesis for the mechanism of nucleation. This predicts (i) that two tails of the RNA will be left at one end of the growing nucleoprotein rod formed, and (ii) that one of these tails would project directly from one end but the other would be doubled back all the way from the active growing point at the far end of the rod down the central hole of the growing rod. Both of these predictions

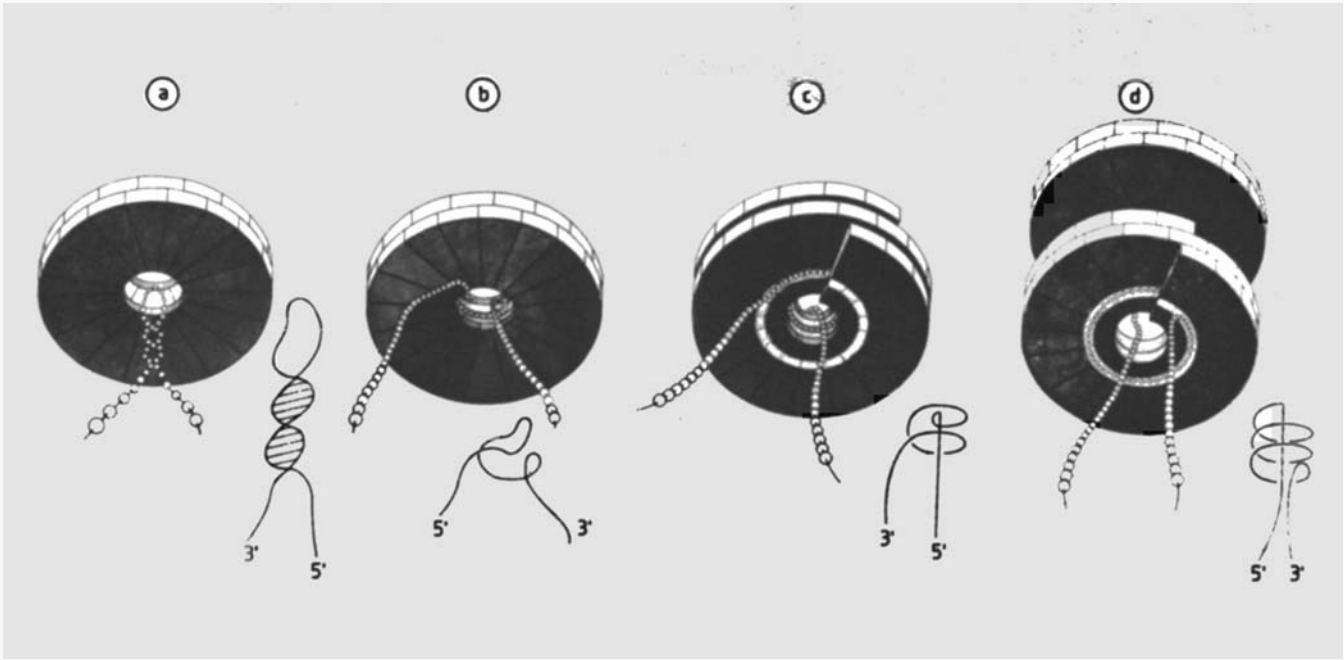

Fig. 7. Nucleation of virus assembly occurs by the insertion of a hairpin of RNA (see Fig. 6) into the central hole of the protein disk and between the two layers of subunits ⓐ. The loop at the top of the hairpin binds to form part of the first turn, opening up the base-paired stem as it does so ⓑ, and causes the disk to dislocate into a short helix ⓒ. This presumably "closes the jaws", entraining the RNA between the turns of protein subunits, and gives a start to the nucleoprotein helix (which can then elongate rapidly to some minimum stable size) ⓓ.

have now been confirmed. *Hirth*'s group in Strasbourg has obtained electron micrographs of growing rods in which the RNA is spread by partial denaturation, and many particles show two tails protruding from the same end[28]. In Cambridge my colleagues have used high resolution electron microscopy, in which the two ends of the rods can be identified by their shapes to show that it is indeed the longer tail that is doubled back through the growing rod[29]. Other experiments show that the RNA configuration has a substantial effect on the rate of assembly[29].

### 2.6. Design and Construction: Physical and Biological Requirements

We have seen that the protein disk is the key to the mechanism of the assembly of TMV. The protein subunit is designed not to form an endless helix, but a closed two-layer variant of it, the disk, which is stable and which can be readily converted into the lock-washer or helix-going form. The disk therefore represents an intermediate sub-assembly by means of which the entropically difficult problem of nucleating helical growth is overcome. At the same time the nucleation by the disk sub-assembly furnishes a mechanism for recognition of the homologous viral RNA (and rejection of foreign RNAs) by providing a long stretch of nucleotide binding sites for interaction with the special sequence of bases on the RNA. The disk is thus an obligatory intermediate in the assembly of the virus, which simultaneously fulfills the physical requirement for nucleating the growth of the helical particle and the biological requirement for specific recognition of the viral RNA. TMV is self-assembling, self-nucleating and self-checking.

There are a number of morals to be derived from the story of TMV assembly[1]. The first is that one must distinguish between the design of a structure and the construction process used to achieve it. That is, while TMV looks like a helical crystal and its design lends itself to a process of simple addition of subunits, its construction actually follows a more complex path that is highly controlled. It illustrates the point that function is inextricably linked with structure and how much can be done by one single protein. A most intricate structural mechanism has been evolved to give the assembly an efficiency and purposefulness whose basis we now understand. The general moral of all this is that not merely does nature once again confound our obvious preconceptions, but it has left enough clues for us to be able to puzzle out finally what is happening. As *Einstein* once put it, "Raffiniert ist der Herrgott, aber bösartig ist er nicht: The Lord is subtle, but he is not malicious".

## 3. Crystallographic or Fourier Electron Microscopy

In 1955, *Finch* and I in London, and *Caspar*, then in Cambridge, took up the X-ray analysis of crystals of spherical viruses. These had first been investigated by *Bernal* and his colleagues just before and after the war, using "powder" and "still" photography. *Finch* and I worked on Turnip Yellow Mosaic Virus (TYMV) and its associated empty shell, and *Caspar* on Tomato Bushy Stunt virus (TBSV). *Crick* and *Watson* had predicted that spherical viruses ought to have one of the forms of cubic symmetry, and we showed that both viruses had icosahedral symmetry. Later, when *Finch* and I showed that polio virus also had the same symmetry, we realised that there was some

underlying principle at work, and this eventually led *Caspar* and I to formulate our theory of virus shell structure[30].

When my research group moved to Cambridge in 1962, we turned to electron microscopy for the speed with which it enables one to tackle new subjects, and also because it produces a direct image, or so we thought. Armed with a theory of virus design and some X-ray data, we had some notion of how spherical shells of viruses might be constructed and thought we would be able to see the fine detail in electron micrographs. Thus, we knew what we were looking *for*, but we soon found that we did not understand what we were looking *at*: the micrographs did not present simple direct images of the specimens. We soon discovered the limitations of electron microscopy. First, there were preparation artefacts and also radiation damage during observation. Secondly, artificial means of contrast enhancement had to be used as the majority of atoms in biological specimens have an atomic number too low to give sufficient contrast on their own. Thirdly, the image formed depends on the operating conditions of the microscope and on the focussing conditions and aberrations present. Above all, because of the large depth of focus of the conventional microscope, all features along the direction of view are superimposed in the image. Finally, in the case of strongly scattering or thick specimens, there is multiple scattering within the specimen, which can destroy even this relation between object and image.

For these reasons, the detail one sees in a raw image is often unreliable and not easily interpretable without methods which correct for the operating conditions of the microscope and which can separate contributions to the image from different levels of the specimen. It is also important to be able to assess the degree of specimen preservation in each particular case. These procedures for image processing of electron micrographs were developed by myself and my colleagues over a period of about 10 years. Their aim is to extract from the information recorded in electron micrographs the maximum amount of reliable information about the two- or three-dimensional structures which are being examined. Some applications of these methods to various problems studied in the Medical Research Council Laboratory, Cambridge, over the first 15 years are given in Table 1. Electron microscopy combined with image reconstruction, supplemented wherever possible by X-ray studies on wet, intact material, has provided what are now generally accepted models of the structural organisation of a large number of biological systems such as those listed in Table 1. Here, I will describe only a limited number of examples which serve to demonstrate the power of various techniques and the nature of the results they can give. Fuller accounts of the methods and the theory are given elsewhere[2,3], but I would like to emphasize that these methods arose out of practical concerns and grew in the course of tackling concrete problems; nevertheless they have proved to be of wide application.

Table 1. Some applications of electron microscope image reconstruction in the MRC Laboratory of Molecular Biology, Cambridge, 1964–1979.

| Viruses | Organelles | Enzymes |
|---|---|---|
| Helical<br>TMV, TMV protein disk, Paramyxoviruses | Microtubules from flagellar doublets and brain; tubulin sheets | Haemocyanin<br>Glutamic dehydrogenase |
| Icosahedral<br>Polyoma, wart, TBSV, TYMV, R17, Nudaurelia, CPMV | Muscle filaments: actin; actin + tropomyosin; actin + myosin + tropomyosin (inhibited and relaxed) | Catalase; crystals and tubes<br>Sickle cell haemoglobin fibres |
| Adenovirus hexon<br>Aberrant hexagonal and pentagonal tubes of polyoma | Bacterial flagella;<br>Bacterial cell walls | Purple membrane (Bacteriorhodopsin) |
| Phage T2 and T4<br>Head and its tubular variants (polyheads)<br>Tail: sheath + core<br>Baseplate | Ribosome crystals<br>Chromatin: crystals of nucleosome cores; tubes of histone octamers<br>Gap junctions | Cytochrome oxidase |

### 3.1. Two-Dimensional Reconstruction: Digital Computer Image Processing

We began our studies on viruses, both spherical and helical, using the method of negative staining which had recently been introduced by *Huxley*, and by *Brenner* and *Horne*[31]. In this method the specimen is embedded in a thin amorphous layer of a heavy metal salt which simultaneously preserves and maps out the shape of the regions from which it is excluded. Much fine detail was to be seen, but one could not easily make sense of it in most cases. People simply thought that the specimens were being disordered, because it was assumed that the negative stain gave, as it were, a footprint of the particle. We gradually came to realise that the confusion arose, not so much because of the disorder that the stain produced, but because there was a superposition of detail from the front and back of the particle; *i.e.*, the stain was enveloping the whole particle, so forming a cast rather than a footprint. This interpretation was proved in two different ways which proceeded in parallel. First, in the case of the spherical viruses, one could build a model and compute or otherwise display it in projection and we found that this could account for many if not all of the previous uninterpretable images[32]. The uniqueness of the model could be proved by tilting experiments in which the specimens on the grid and the model were tilted in the same manner through large angles (cf. Fig. 10 and ref. [73]). The second approach was applied to helical structures, which are translationally periodic and therefore lend themselves to a direct image analysis, which I shall now illustrate.

Figure 8a shows an electron micrograph of a negatively stained specimen of a "polyhead", which is a variant of the head of T4 bacteriophage, consisting mainly of the major head protein. The particle has been flattened and so its original tubular form lost. The image clearly shows some structural periodicities, but these are difficult to discern and such interpretations used to be left to subjective judgement. I realised that the optical (Fraunhofer) diffraction pattern produced from such an image would allow an objective analysis of all the periodicities present to be made[33]. This is shown in Figure 8b. Here clear diffraction maxima can be seen: these fall into two sets which can be accounted for as arising respectively from the near and far

sides of the specimen. In this way it was established that the negative stain was producing a complete cast of the particle rather than a one-sided footprint of it[33]. Since this is a helically periodic structure, the diffraction maxima tend to lie on a lattice and so they pick out genuine repeating features within the structure. In this case the regular diffraction maxima extended to a spacing of about 20 Å which demonstrated that the long range order in the specimen was preserved to this resolution, which is indeed sufficient to resolve individual protein molecules.

The essence of image processing of this type is that it is a two-step procedure after the first image has been obtained. First the Fourier transform of the raw image is produced. Fourier coefficients are then manipulated or otherwise corrected and then transformed back again to reproduce the reconstructed image. These operations can be carried out most easily on a digital computer, and digital image-processing as first introduced by *DeRosier* and myself[36] allows a much greater flexibility than our original optical method and makes three-dimensional procedures possible.

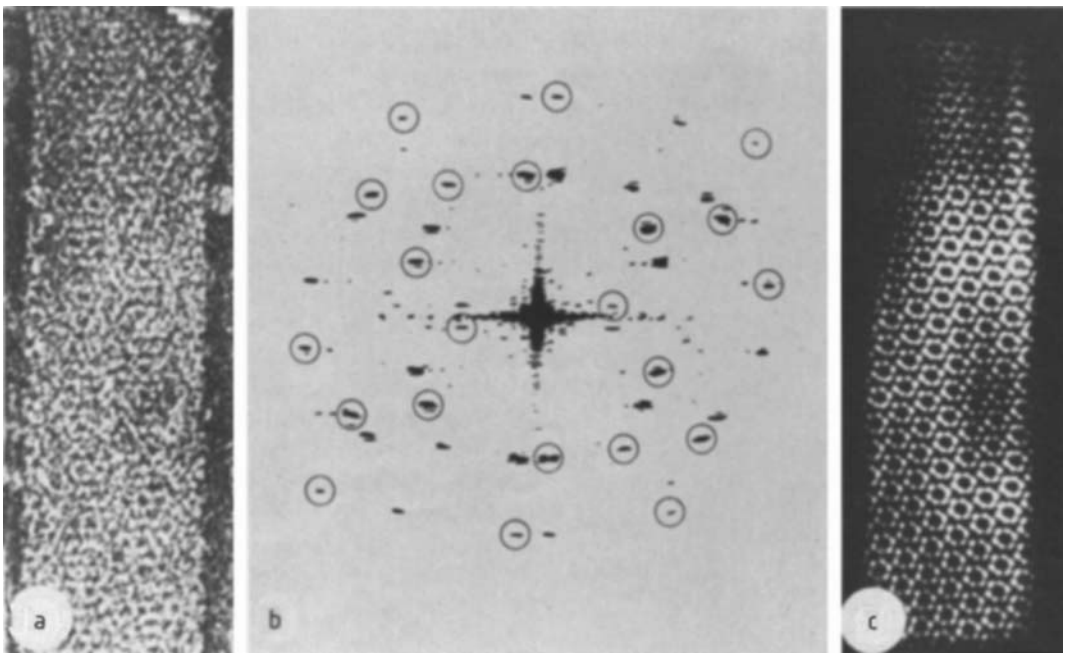

Fig. 8. Optical diffraction and image filtering of the tubular structures known as "polyheads", consisting of the major head protein of T4 bacteriophage [35]. ⓐ Electron micrograph of negatively stained flattened particle; magnification × 200000. ⓑ Optical diffraction pattern of ⓐ, with circles drawn around one set of diffraction peaks corresponding to one layer of the structure. ⓒ Filtered image of one layer in ⓐ using the diffraction mask shown in ⓑ. The apertures in the mask are chosen so that the averaging here extends locally only over a few unit cells. Individual molecules arranged in hexamers can be seen.

The confusion in the image is largely due to the superposition of the near and far sides of the particle, and any one such side can be filtered out in an optical system by a suitably positioned mask which transmits only the desired diffracted rays[34]. The filtered image, Figure 8c, is immediately interpretable in terms of a particular arrangement of protein molecules[35].

The clarity of the processed image derives also from the fact that the background noise in the diffraction pattern has been filtered out. This noise arises because of the individual variations between molecules in the specimen, *i.e.* the disorder, and these contribute randomly in all parts of the diffraction pattern. Indeed, what has been done is that the signal-to-noise ratio in the image has been enhanced by averaging over the copies of the molecules present in the arrangement. This idea of averaging over many copies of a repeated motif is central to the most powerful techniques developed so far for producing reliable images of biological specimens, and the three-dimensional procedures which I will describe later can also use this technique.

### 3.2. Three-Dimensional Image Reconstruction

The first example I have given (Fig. 8) is of a relatively simple case where the problem is essentially that of separating contributions from two overlapping crystalline layers and we have seen how the method of Fourier analysis resolves the superposition in real space into separated sets of contributions in Fourier space. It was, however, already clear from the simple analysis of spherical viruses that in order to get a unique or reliable picture of a three-dimensional structure one must be able to view the specimen from very many different directions[32]. These different views were often provided by specimens lying in different orientations but they can also be realised by tilting the specimen in the electron microscope (see Section 3.1). Originally, as described, the different views were interpreted by the building of models, but eventually I saw that a set of transmission images taken in different views could be combined objectively to give a reconstruction of a three-dimensional object.

This happened when *DeRosier* and I were studying the

tail of bacteriophage T4 and our analysis showed that there were contributions to the image from the internal structure as well as from the front and back surfaces[36]. To work in three dimensions a generalised form of the two-dimensional filtering process had to be found, and—by making a connection with X-ray analysis—I realised that what was required was a three-dimensional Fourier synthesis. In the analysis of the X-ray diffraction patterns of TMV, I had used the idea that a helical structure could be built up mathematically out of a set of cylindrical harmonic functions; there is a relation between the number of functions that could be obtained and the number of different views available. Each new view would give additional harmonics of higher spatial frequency, and so, if one had enough views, one could build up the complete structure. Later, we recognized[36] that this synthesis was only a special case of a general theorem known to crystallographers as the projection theorem.

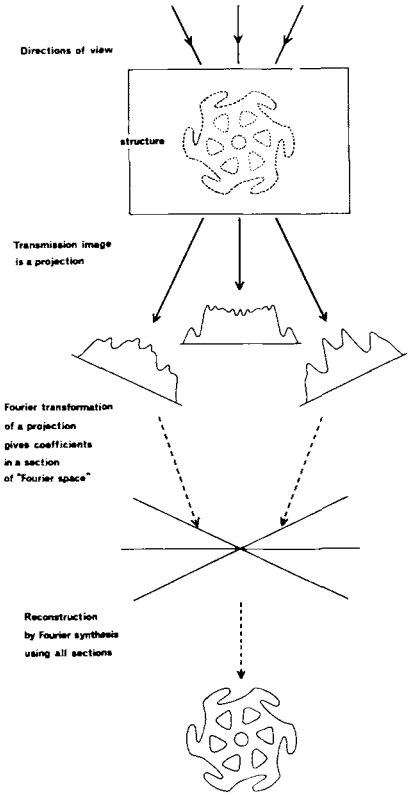

Fig. 9. General scheme for the process of 3-D reconstruction of an object from a set of 2-D projections [36].

The general method of reconstruction which we developed (Fig. 9) is based on the projection theorem, which states that the two-dimensional Fourier transform of a plane projection of a three-dimensional density distribution is identical to the corresponding central section of the three-dimensional transform normal to the direction of view. The three-dimensional transform can therefore be built up section by section using transforms of different views of the object, and the three-dimensional reconstruction then produced by Fourier inverstion. The important feature of the method is that it tells one how many different views are needed for a required resolution and how these are to be recombined into a three-dimensional map of the object[36,37]. The process is both quantitative and free from arbitrary assumptions. The approach is similar to conventional X-ray crystallography, except that the phases of the X-ray diffraction pattern cannot be measured directly, whereas here they can be computed from a digitised image. Were it not for radiation damage, the different views could be collected from a single particle by using a tilting stage in the microscope, but more realistically one must use several particles in different but identifiable orientations. In general, it is desirable to combine data from different particles so that imperfections can be averaged out.

The Fourier method is only one of several ways for solving the sets of mathematical equations which relate the unknown three-dimensional density distribution with known projections in different directions[37], but in fact no other reliable method has been shown to be superior and it is used in computer tomography. Moreover, the Fourier method has the advantage that because it is carried out in steps, *i.e.* formation of the two-dimensional transforms, and then recombination in three dimensions, it is possible as described above, to assess, select, and correct the data going into the final reconstruction.

Many applications have been made. The first application was in fact to the phage tail of T4, the problem in which it had arisen. Particles with helical symmetry are the most straightforward to reconstruct, because a reconstruction can be made from a single view of the whole particle, to a limited resolution, set by the helix symmetry. In physical terms, this is because a single image of a helical particle presents many different views of the repeating subunit, and it was this simplification that led us to use the phage tail as a first specimen for 3-D image reconsruction. Generally, more than one view is necessary, but any symmetry present will reduce the number required. Typically, for small icosahedral viruses, three or four views are sufficient, but many more specimens must be investigated before the appropriate number can be found and averaging carried out[38]. Figure 10 shows two electron micrographs and the three-dimensional reconstruction of human wart virus (HWV), which was investigated by *Crowther* and *Amos*[39].

### 3.3. Phase Contrast Microscopy

Electron microscopy, combined with some method of image analysis, when applied to negatively stained specimens, has proved ideal for determining the arrangement and shape of small protein subunits within natural or artificial arrays, including two-dimensional crystals and macromolecular assemblies such as viruses and microtubules[2]. The structural information obtainable has proved to be highly reliable with respect to detail down to about the 20 Å or 15 Å level. It became clear, however, that the degree of detail revealed was limited by the granularity of the negative stain and the fidelity with which it follows the surface of the specimen[40]. To obtain much higher resolution information, better than about 10 Å, one should dispense with the stain and view the protein itself. At high resolution, there is a second problem: irradiation damage. This

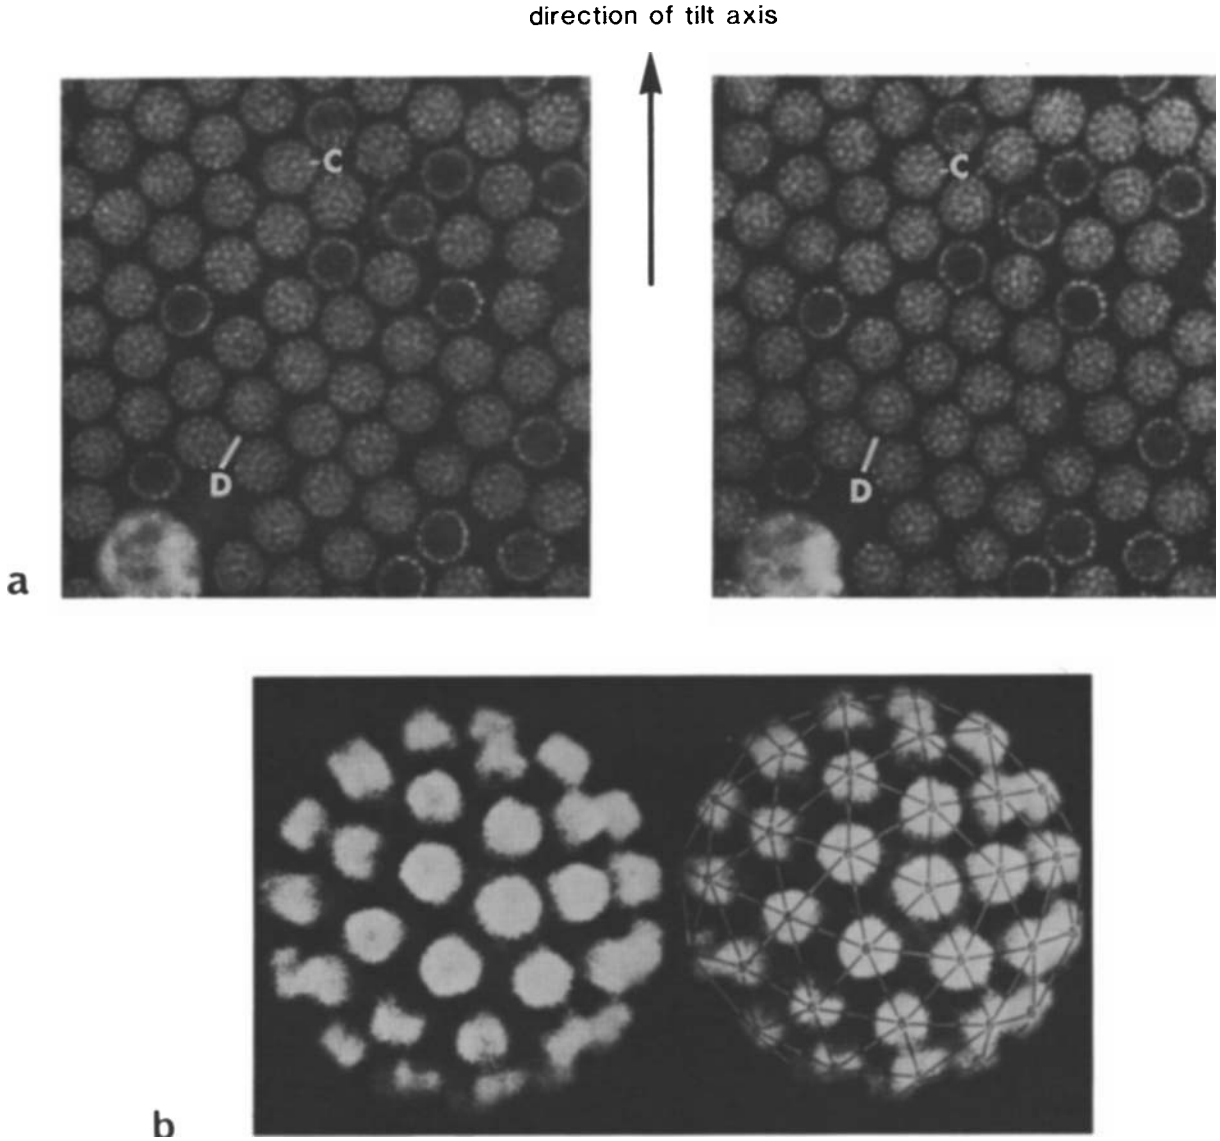

Fig. 10. ⓐ Electron micrographs of the same field of negatively-stained close-packed particles of human wart virus (HWV), (left) before, and (right) after tilting the specimen grid through an angle close to 18° [73]. × 140000. ⓑ A three-dimensional reconstructed image of human wart virus [39]. Alongside is shown the underlying icosahedral surface lattice [30] with the fivefold and sixfold symmetry axes marked.

can be reduced by cutting down the illuminating beam, but the statistical noise is then increased, and the raw image becomes less and less reliable. However, this difficulty can be overcome satisfactorily by imaging ordered arrays of molecules, so that the information from the different molecules can be averaged, as described above, to give a statistically significant picture. The first problem of replacing the negative stain, yet avoiding dehydration, can be solved in two ways. One, now being intensively studied, is to use frozen hydrated specimens[41]. The second, tried method is that of *Unwin* and *Henderson*, who, in their radical approach to determining the structure of unstained biological specimens by electron microscopy[42,43], used a dried-down solution of glucose to preserve the material.

The question then arose as to how this unstained specimen, effectively transparent to electrons, is to be visualised. In the light microscopy of transparent specimens the well-known Zernike phase contrast method is used. Here the phases of the scattered beams relative to the unscattered beam are shifted by means of a phase plate and then the scattered and unscattered beams are allowed to interfere in the image plane to produce an image. A successful electrostatic phase contrast device for electron microscopy, quite analogous to the phase plate used in light microscopy, was constructed by *Unwin*[44], but it is not easy to make or use. A practical way of producing phase contrast in the electron microscope is simply to record the image, with the objective lens underfocussed, and this was the method used by *Unwin* and *Henderson*.

The defocussing phase contrast method arose out of an academic study by *Erickson* and myself of image formation in the electron microscope[45]. This was undertaken because of a controversy that had developed concerning the nature of the raw image itself. When three-dimensional image reconstruction was introduced and applied to biological particles embedded in negative stain, objections were raised by various workers in the field of materials science, accustomed to dynamical effects in strongly scat-

tering materials, to the premise that the image essentially represented the simple projection of the distribution of stain. It was asked whether multiple or dynamical scattering might not vitiate this assumption. To investigate this question, *Erickson* and I undertook an experimental study of negatively stained thin crystals of catalase as a function of the depth of focussing[45]. We found that a linear or first order theory of image formation would explain almost entirely the changes in the Fourier transform of the image. We concluded that the direct image, using a suitable value of underfocus dependent on the frequency range of interest, is a valid picture of the projection of the object density. When greater values of underfocus were used to enhance the contrast, the image could be corrected to give a valid picture.

This study, although confined to the medium resolution range, included a practical demonstration that *a-posteriori* digital image processing could be used to measure and compensate for the effects of defocussing, and we suggested that this approach could be directly extended to high resolution to compensate for the effects of spherical aberration as well as defocussing. It also provided a convenient way of producing phase contrast in the electron microscope in the case of unstained specimens. The image is recorded with the objective lens underfocussed, so changing the phases of the scattered beams relative to the unscattered (or zero order) beam. Defocussing does not however act as a perfect phase plate analogous to that of *Zernike,* since the phases are not all changed by the same amount, and successive bands of spatial frequencies contribute to the image with alternately positive and negative contrast. In order to produce a "true" image, the electron image must be processed to correct for the phase contrast transfer of the microscope so that all spatial frequencies contribute with the same sign of contrast.

To produce their spectacular three-dimensional reconstructed image of the purple membrane of *Halobacterium* to a resolution of about 7 Å[44], *Henderson* and *Unwin* took a series of very low-dose images of different pieces of membrane tilted at different angles. The final map represented an average over some 100000 molecules. The small amount of contrast present in the individual micrographs was produced by underfocussing which was then compensated for in the computer reconstruction by the method described above. For the first time the internal structure of a protein molecule was "seen" by electron microscopy.

## 4. The Structure of Chromatin

The work on viruses has given results not only of intrinsic interest, but as indicated above, the difficulties in tackling large molecular aggregates led to the development of methods and techniques which could be applied to other systems. A recent example of this approach, and one which I think would not have gone so fast without our earlier experience, is that of the investigation of chromatin. Chromatin is the name given to the chromosomal material when extracted. It consists mainly of DNA, tightly associated with an equal weight of a small set of rather basic proteins called histones. We took up the study of chromatin in Cambridge about ten years ago when the protein chemists had shown that there were only five main types of histones, the apparent proliferation of species being due to post-synthetic modifications, so that the structural problem appeared tractable.

The DNA of the eukaryotic chromosome is probably a single molecule, amounting to several centimeters in length if laid out straight, and it must be highly folded to make the compact structure one can see in a chromosome. At the same time it is organised into separate genetic or functional units, and the manner in which this folding is achieved, genes organised and their expression controlled, is the subject of intense study throughout the world. The aim of our research group has been to try to understand the structural organisation of chromatin at various levels and to see what connections could be made with functional controls.

The high concentrations in which histones occur in the cell nucleus suggested that their role was structural, and it was shown over the years 1972—1975 that the four histones H2A, H2B, H3 and H4 are responsible for the first level of structural organisation in chromatin. They fold successive segments of the DNA about 200 base pairs long into compact bodies of about 100 Å in diameter, called nucleosomes. A string of nucleosomes or repeating units is thus created and when these are closely packed they form a filament about 100 Å in diameter. The role of the fifth histone H1 was at first not clear. It is much more variable in sequence than the other four, being species and tissue specific. In the years 1975—1976 we showed that H1 is concerned with the folding of the nucleosome filament into the next higher level of organisation, and later how it performed this role.

This is not the place to relate in detail how this picture of the basic organisation of chromatin emerged[4], but the idea of a nucleosome arose from the convergence of several different lines of work. The first indications for a regular structure came from X-ray diffraction studies on chromatin which showed that there must be some sort of repeating unit, albeit not well ordered, on the scale of about 100 Å[46,47]. The first biochemical evidence for regularity came from the work of *Hewish* and *Burgoyne*[48], who showed that an endogenous nuclease in rat liver could cut the DNA into multiples of a unit size, which was later shown by *Noll,* using a different enzyme, *Micrococcus* nuclease, to be about 200 base pairs[49]. The fact that the nuclease cuts the DNA of chromatin at regularly spaced sites, quite unlike its action on free DNA, is attributed to the fact that the DNA is folded in such a way as to make only short stretches of free DNA between these folded units available to the enzyme. The third piece of evidence which led to the idea of a nucleosome was the observation by *Kornberg* and *Thomas*[50] that the two highly conserved histones, H3 and H4, existed in solution as a specific oligomer, the tetramer $(H3)_2(H4)_2$, which behaved rather like an ordinary multi-subunit globular protein. On the basis of these different lines of evidence, *Kornberg* in 1974[51] proposed a definite model for the basic unit of chromatin as a bead of about 100 Å diameter, containing a stretch of DNA 200 base pairs long condensed around the protein core made out of eight histone molecules, namely the

$(H3)_2(H4)_2$ tetramer and two each of H2A and H2B. The fifth histone, H1, was somehow associated with the outside of each nucleosome. A quite unexpected feature of the model was that it was the DNA which "coated" the histones rather than the reverse.

However, in 1972, when *Kornberg* came to Cambridge, all this lay in the future. We began using X-ray diffraction to follow the reconstitution of histones and DNA, because the X-ray pattern given by nuclei, or by chromatin isolated from them, limited as it was, was the only assay then available to follow the ordered packaging of the DNA. These X-ray studies showed that almost 90% reconstitution could be achieved when the DNA was simply mixed with an unfractionated total histone preparation, but all attempts to reconstitute chromatin by mixing DNA with a set of all four purified single species of histone failed, as if the process whereby the histones were being separated were denaturing them. We therefore looked for milder methods of histone extraction and found that the native structure could be reformed readily if the four histones were kept together in two pairs, H3 and H4 together, and H2A and H2B together, but not once they had been taken apart. It was this work which led *Kornberg* to investigate further the physicochemical properties of the histones and to the discovery[50] of the histone tetramer $(H3)_2(H4)_2$, which in turn led him to the model of the nucleosome described above.

### 4.1. The Structure of the Nucleosome

Approaches such as nuclease digestion and X-ray scattering on unoriented specimens of chromatin or nucleosomes in solution could reveal certain features of the nucleosome, but a full description of the structure can only come from crystallographic analysis, which gives complete three-dimensional structural information. In the summer of 1975 my colleagues and I therefore set about trying to prepare nucleosomes in forms suitable for crystallization. Nucleosomes purified from the products of *Micrococcus* nuclease digestion contain an average of about 200 nucleotide pairs of DNA, but there is a rather wide distribution about the average, and such preparations are not homogeneous enough to crystallize. However, this variability in size can be eliminated by further digestion with *Micrococcus* nuclease. While the action of *Micrococcus* nuclease on chromatin is first to cleave between nucleosomes, it subsequently acts as an exonuclease on the excised nucleosome, shortening the DNA first to about 166 base pairs, where there is a brief pause in the digestion[52], and then to about 146 base pairs, where there is a clear plateau in the course of digestion, before more degradation occurs. During this last stage the histone H1 is released[52], leaving as a major metastable intermediate a particle containing 146 base pairs of DNA complexed with a set of eight histone molecules. This enzymatically reduced form of the nucleosome is called the core particle and its DNA content was found to be constant over many different species. The DNA removed by the prolonged digestion, which had previously joined one nucleosome to the next, is called the linker DNA.

A core particle therefore contains a well-defined length of DNA and is homogeneous in its protein composition. We naturally tried to crystallize preparations of core particles, but we were not at first successful, probably because of small traces of the fifth histone H1. Eventually my colleague *Leonard Lutter* found a way to produce exceptionally homogeneous preparations of nucleosome core particles, and these formed good single crystals[53]. The conditions for growing the crystals were based on our previous experience in crystallizing transfer-RNA, because we reasoned that a good part of the nucleosome core surface would consist of DNA. These experiments perhaps surprised biologists in showing dramatically that almost all the DNA in the nucleus is organised in a highly regular manner.

The derivation of a three-dimensional structure from a crystal of a large molecular complex is, as for the TMV disk, a process that can take many years. We have therefore concentrated on obtaining a picture of the nucleosome core particle at low resolution by a combination of X-ray diffraction and electron microscopy, supplemented where possible by biochemical and physicochemical studies. We first solved the packing in the crystals by analysing electron micrographs of thin crystals and then obtained projections of the electron density along the three principal axes of the crystals, using X-ray diffraction amplitudes and electron microscope phases[53, 54]. The nucleosome core particle turned out to be a flat disk-shaped object, about 110 Å by 110 Å by 57 Å, somewhat wedge-shaped, and strongly divided into two layers. We proposed a model in which the DNA was wound into about $1\frac{3}{4}$ turns of a shallow superhelix of pitch about 27 Å around the histone octamer. There are thus about 80 nucleotides in each turn of the superhelix. This model for the organisation of DNA in a nucleosome core also provided an explanation for the results of certain enzyme digestion studies on chromatin[53, 55], thus showing that what we had crystallized was essentially the native structure.

The first crystals we obtained were found to have the histone proteins within them partly proteolysed, but their physicochemical properties remained very similar to those of the intact particle. We have since grown crystals from intact nucleosome cores which diffract to a resolution of about 5 Å and a detailed analysis is in progress[56]. Over the years *Daniela Rhodes, Ray Brown,* and *Barbara Rushton* have grown crystals of core particles prepared from seven different organisms: all give essentially identical X-ray patterns testifying to the universality of nucleosomes. There is a dyad axis of symmetry within the particle, which is not surprising since the eight histones occur in pairs and DNA is studded with local dyad axes. High angle diffuse X-ray scattering from the crystals shows that the DNA of the core particle is in the B-form.

An electron density map of one of the principal projections of the crystal is shown in Figure 11a. This map gives the total density in the nucleosome, the density of the DNA not being distinguished from that of the protein. The contributions of protein and DNA can be distinguished by using neutron scattering combined with the method of contrast variation and such a study was therefore begun by *John Finch* and a group at the Laue-Langevin Institute, Grenoble, when sufficiently large crystals were available[57]. The obtained maps of the DNA and protein along

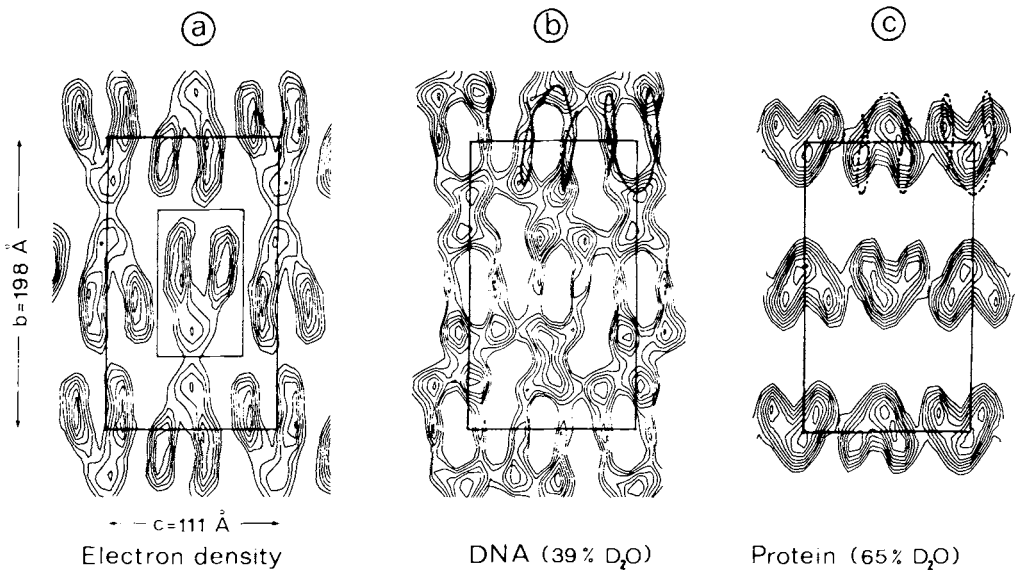

Fig. 11. Fourier projection maps of the nucleosome core particle. ⓐ Map calculated from X-ray data [56]; ⓑ and ⓒ calculated from neutron scattering data using contrast variation [57]. ⓑ The DNA component with the path of the superhelix drawn superimposed on the density. ⓒ The protein core component.

the three principal axes (see Figs. 11b and 11c). The map of the DNA is consistent with the projection of about $1\frac{3}{4}$ superhelical turns as proposed earlier, and the map of the protein shows that the histone octamer itself has a wedge shape.

### 4.2. Three-Dimensional Image Reconstruction of the Histone Octamer and the Spatial Arrangement of the Inner Histones

An alternative to separating the contributions of the DNA and the protein by neutron diffraction is to study the histone octamer directly. The histone octamer which forms the protein core of the nucleosome can exist in that form free in solution at high salt concentration, which displaces the DNA[58]. In the course of attempts to crystallize it, we obtained ordered aggregates—hollow tubular structures—which were investigated by electron microscopy[59]. The image reconstruction method described in Section 3.2 was used to produce a low resolution three-dimensional map and model of the octamer (Fig. 12a). As a check that the removal of DNA had not led to a change in the structure of the histone octamer, projections of this model were calculated and compared with the projections of the protein core of the nucleosome obtained from the neutron scattering study mentioned above. There was a good agreement between the three maps showing that the gross structure was not altered.

At the resolution of the analysis (20 Å) it was shown that the histone octamer possesses a two-fold axis of symmetry, just as the nucleosome core particle itself. Like the nucleosome core, the histone octamer is a wedge-shaped particle of bipartite character. Its periphery shows a system of ridges which form a more or less continuous helical ramp of external diameter 70 Å and pitch about 27 Å, exactly suitable for it to act as a spool on which could be wound about $1\frac{3}{4}$ turns of superhelix of DNA in the appropriate dimensions (Fig. 12b).

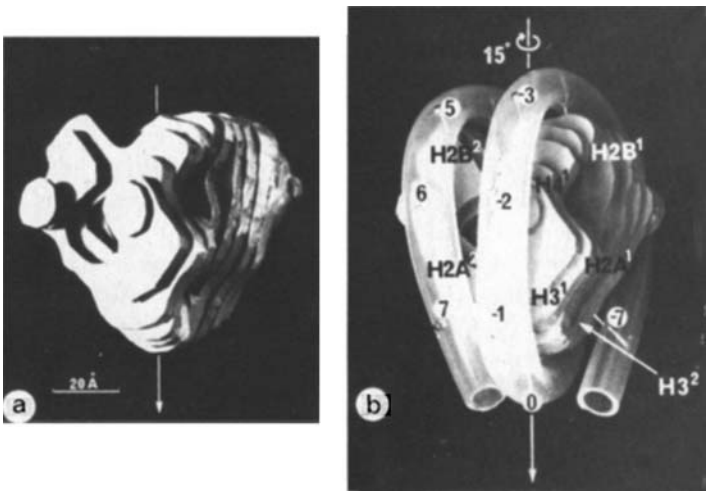

Fig. 12. ⓐ Model of the histone octamer obtained by three-dimensional image reconstruction from electron micrographs [59]. The dyad axis is marked. The ridges on the periphery of the model form a left-handed helical ramp on which $1\frac{3}{4}$ to 2 turns of a superhelix of DNA could be wound. ⓑ The histone octamer structure ⓐ with two turns of a DNA superhelix wound around it. (Note that for clarity, the diameter of the plastic tube has been chosen smaller than the true scale for DNA.) Distances along the DNA are indicated by the numbers $-7$ to $+7$, taking the dyad axis as origin, to mark the 14 repeats of the double helix contained in the 146 base pairs of the nucleosome core. The assignment of the individual histones to various locations on the model is described in the text.

The resolution of the octamer map is too low to define individual histone molecules, but we have exploited the relation of the octamer to the superhelix of DNA to interpret them in terms of individual histones[59]. This interpretation uses the results of *Mirzabekov* and his colleagues[60] on the chemical cross-linking of histones to nucleosomal DNA, and also information on histone/histone proximities given by protein cross-linking. This data cannot be interpreted

reliably without a three-dimensional model because a knowledge of the points of contact of histones along a strand of the DNA is not sufficient to fix a spatial arrangement of the histones in the nucleosome core. Furthermore, because the two superhelical turns of DNA are close together the pattern of histone/DNA cross-links need not directly reflect the linear order of histones along the DNA. The three-dimensional density map restricts the number of possibilities and enables choices to be made.

In the spatial arrangement proposed, the helical ramp of density in the octamer map is composed of a particular sequence of the eight histones, in the order H2A-H2B-H4-H3-H3-H4-H2B-H2A, with a dyad in the middle. The $(H3)_2(H4)_2$ tetramer has the shape of a dislocated disk or single turn of a helicoid, which defines the central turn of a DNA superhelix. The structure of the histone tetramer explains the findings of many workers, expanding on the original observations of *Felsenfeld*[61], that H3 and H4 alone, in the absence of H2A and H2B, can confer nucleosome-like properties on DNA, in particular supercoiling and resistance to *Micrococcus* nuclease digestion, whereas H2A and H2B alone cannot. It also explains the asymmetric dissociation of the histone octamer when the salt concentration is lowered: the octamer dissociates, through a hexameric intermediate, into a $(H3)_2(H4)_2$ tetramer and two H2A·H2B dimers[58,62].

### 4.3. The Role of Histone H1 and Higher Order Structures

These studies have given a fairly detailed picture of the internal structure of the nucleosome, but until 1975 there was still no clear idea of the relation of one nucleosome to another along the nucleosome chain or basic chromatin filament, nor of the next higher level of organisation. It had been known for some time that the thickness of fibres observed in electron microscopical studies of whole-mount chromosome specimens varied from about 100 to 250 Å in diameter, depending on whether chelating agents had been used or not in the preparation. Taking this as a clue, *Finch* and I carried out some experiments *in vitro* on short lengths of chromatin prepared by brief micrococcal digestion of nuclei[63]. In the presence of chelating agents this native chromatin appeared as fairly uniform filaments of 100 Å diameter. When $Mg^{2+}$ ions were added, these coiled up into thicker, knobbly fibres about 250–300 Å in diameter, which are transversely striated at intervals of about 120–150 Å, corresponding apparently to the turns of an ordered, but not perfectly regular helix or supercoil. Since the term "supercoil" had already been used in a different context, we called it a solenoid, because the turns were spaced close together. On the basis of these micrographs and companion X-ray studies[64], we suggested that the second level of folding of chromatin was achieved by the winding of the nucleosome filament into a helical fibre with about six nucleosomes per turn. Moreover, we found that when the same experiments were carried out on H1-depleted chromatin, only irregular clumps were formed, showing that the fifth histone H1 is needed for the formation or stabilisation of the ordered fibre structure.

These experiments told us the level at which H1 performs its function of condensing chromatin, but the way in which the H1 molecule mediates the coiling of the 100 Å filament into the 300 Å fibre only became clear later by putting together evidence from the biochemistry, from the crystallographic analysis, and from more refined electron microscopic observations.

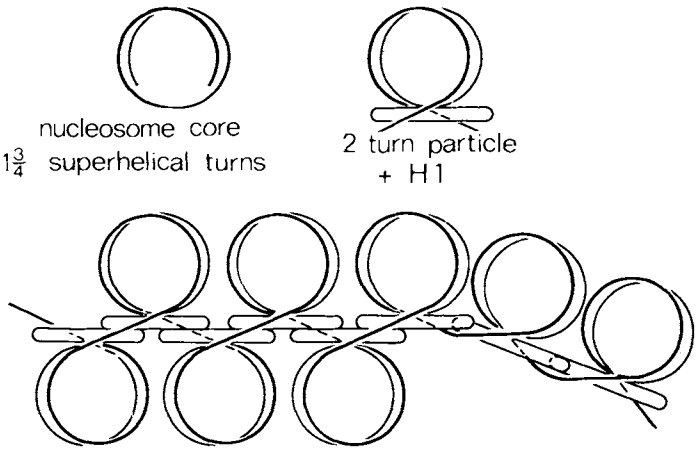

Fig. 13. (Top) If the 146 base pairs of DNA in the nucleosome core correspond to $1\frac{3}{4}$ superhelical turns, then the 166 base particle corresponds to about 2 full superhelical turns. Since the 166 base pair particle is the limit point for the retention of H1 [52], it must be located as shown. (Bottom) Schematic diagram of the nucleosome filament at low ionic strength, showing origin of the zigzag structure (cf. Fig. 14). At the right of the drawing is shown a variant of the zigzag structure which is often observed: this is formed by flipping a nucleosome by 180° about the filament axis.

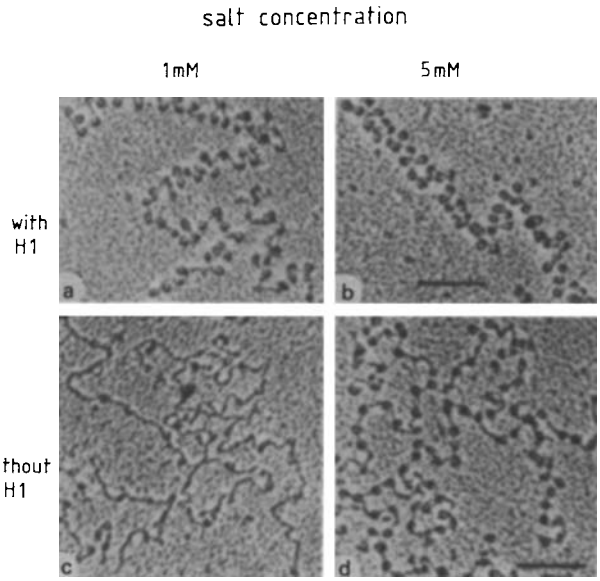

Fig. 14. The appearance of chromatin with and without H1 at low ionic strength [66]. When H1 is present the first recognizable ordered structure is ⓐ a loose zigzag in which the DNA enters and leaves the nucleosome at sites close together; at a somewhat higher salt concentration ⓑ the zigzag is tighter. In the absence of H1, there is no order in the sense of a defined filament direction. At the lower salt concentration ⓒ, nucleosome beads are no longer visible, the structure having opened to produce a fibre of DNA coated with histones. At somewhat higher salt concentration ⓓ, beads are again visible but the DNA enters and leaves the nucleosome more or less at random. The bar represents 100 nm.

From observations on the course of nuclease digestion, taken in conjunction with the known X-ray structure of the

nucleosome core, one can deduce where the H1 might be on the complete nucleosome. I have already mentioned in Section 4.1 that there is an intermediate in the digestion of chromatin by *Micrococcus* nuclease at about 166 base pairs of DNA and it is during this step from 166 to 146 base pairs that H1 is released[52]. Since the 146 base pairs of the particle correspond to $1\frac{3}{4}$ superhelical turns, we therefore suggested that the 166 base pair particle contains two full turns of DNA[53]. This brings the two ends of the DNA on the nucleosome close together so that both can be associated with the same single molecule of H1 (Fig. 13). A particle consisting of the histone octamer and 166 base pairs has been called the chromatosome[65] and has been suggested by us and others to constitute the basic structural element of chromatin. In this particle, the H1 would therefore be on the side of the nucleosome in the region of the entry and exit of the DNA superhelix.

This location follows in logic: but was histone H1 really there? Although H1 is too small a molecule to be seen directly by electron microscopy, its position in the nucleosome can be inferred from its effect on the appearance of chromatin, in the intermediate range of folding between the 100 Å nucleosome filament and the 300 Å solenoidal fibre. These intermediate stages were exposed in the course of a systematic study by *Thoma* and *Koller*[66], of the folding of chromatin with increasing ionic strength. By employing monovalent salts rather than divalent ones, they exposed a range of structures showing increasing degrees of compaction as the ionic strength was raised. Thus, from the filament of nucleosomes around 1 mM, the extent of structure increased through a family of intermediate helical structures until, by 60 mM, the compact 300 Å fibre structure was formed, in all respects identical to that originally observed by *Finch* and myself.

The location of H1 can be deduced by considering the difference between the structures observed in the range of ionic strength 1—5 mM in the presence or absence of H1 (Fig. 14). In chromatin containing H1, an ordered structure is seen in which the nucleosomes are arranged in a regular zigzag with their flat faces down on the supporting grid. The zigzag form arises because the DNA enters and leaves the nucleosome at sites close together, as one would expect from the combination of X-ray and biochemical evidence (Fig. 13). In chromatin depleted of H1, entrance and exit points are more or less on opposite sides and in any case randomly located. Indeed, at very low ionic strength, the nucleosomal structure unravels into a linearised form in which individual beads are no longer seen. When H1 is present this is prevented from happening. We therefore concluded that H1, or strictly part of it, must be located at, and stabilises, the region where DNA enters and leaves the nucleosome, as was predicted.

In the zigzag intermediates the H1 regions on adjacent nucleosomes appear to be close together or touching. We therefore suggested that, with increasing ionic strength, more of the H1 regions interact with one another, eventually aggregating into a helical polymer along the centre of the solenoid and thus accounting for its geometrical form. Polymers of H1 have indeed been shown to exist by chemical cross-linking experiments at both low and high ionic strength[61], but it remains to be shown that they are located in the centre of the fibre. The important point, however, is that it appears to be the aggregation of H1 which accompanies, and indeed may control, the formation of the 300 Å fibre.

### 4.4. The Roles of the Histones

From the spatial arrangements of molecules proposed for the histone octamer and from the location deduced for histone H1, one can see [59] the roles of the individual histones in folding the DNA on the nucleosome (Fig. 15). The $(H3)_2(H4)_2$ tetramer has the shape of roughly a single turn of a helicoid and this defines the central turn of the DNA superhelix. H2A and H2B add as two heterodimers,

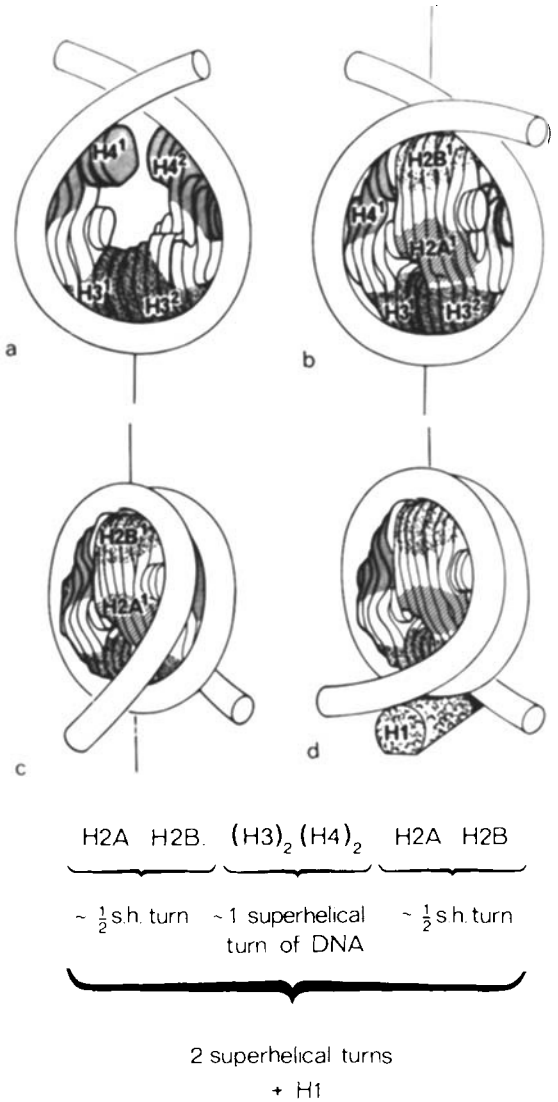

Fig. 15. "Exploded" views of the nucleosome, showing the roles of the constituent histones. The patches on the histone core indicate locations of individual histone molecules, but the boundaries between them are not known and are thus left unmarked. ⓐ the $(H3)_2(H4)_2$ tetramer has the shape of a lock-washer and can act as a spool for 70–80 base pairs of DNA, forming about one superhelical turn. ⓑ An H2A·H2B dimer associates with one face of the tetramer. ⓒ H2A·H2B dimers on opposite faces each bind 30—40 base pairs of DNA, or one-half a superhelical turn, to give a complete 2-turn particle. ⓓ The histone H1 interacts with the unique configuration of DNA at the entry and exit points to seal off the nucleosome.

H2A/H2B, one on each face of the H3-H4 tetramer, each binding one extra half-turn of the DNA, thereby completing the two-turn superhelix. Finally, H1 then binds to the unique region at the side of the two-turn particle where three segments of DNA come together, stabilising and "sealing off" the nucleosome, and also mediating the folding to the next level of organisation. Such a sequence of events in time would provide a structural rationale for the temporal order of assembly of histones onto newly replicated DNA[68-70].

We now have arrived at a moderately detailed model of the nucleosome and a description for the next higher level of folding. There is thus a firm structural and chemical framework in which to consider the dynamic processes which take place in chromatin in the cell, that is, transcription, replication and mitosis.

## 5. Concluding Remarks

I particularly wanted to outline the chromatin work because it may serve as a contemporary paradigm for structural studies which try to connect the cellular and the molecular. One studies a complex system by dissecting it out physically, chemically, or in this case enzymatically, and then tries to obtain a detailed picture of its parts by X-ray analysis and chemical studies, and an overall picture of the intact assembly by electron microscopy. There is, however, a sense in which viruses and chromatin, which I have described here, are still relatively simple systems. Much more complex systems, ribosomes, the mitotic apparatus, lie before us and future generations will recognise that their study is a formidable task, in some respects only just begun. I am glad to have had a hand in the beginnings of the foundation of structural molecular biology.

*It will be obvious that I could not have accomplished all that has been summarized here without the help of many highly able and valued colleagues and collaborators. After Rosalind Franklin's death, I was able to continue and extend the virus work with John Finch and Kenneth Holmes, who were then students, and who became colleagues. Over the years I have had a transatlantic association with Donald Caspar and have benefitted from his advice, criticism and insights. I can mention here only some of the names of my other collaborators in the several branches in which I have been involved: in the study of virus chemistry and assembly, Reuben Leberman, Tony Durham, Jo Butler and David Zimmern; in virus crystallography, William Longley, Peter Gilbert, John Champness, Gerard Bricogne and Anne Bloomer; in electron microscopy and image reconstruction, David DeRosier, Harold Erickson, Tony Crowther, Linda Amos, Jan Mellema, Nigel Unwin and, throughout, John Finch; in the structural studies on transfer RNA, Brian Clark, who provided the biochemical background without which the work could not have begun, Jon Robertus, Jane Ladner and Tony Jack; in chromatin, Roger Kornberg, whose skill and insight transformed a "messy" project into a clear problem, Markus Noll, Len Lutter, and also Daniela Rhodes and Ray Brown, who fruitfully transferred their experience from tRNA to nucleosomes, and finally Tim Richmond and John Finch who are engaged in the higher resolution X-ray studies now in progress.*

# Holographic Methods for the Investigation of Photochemical and Photophysical Properties of Molecules

**New analytical methods (23)**

**By Christoph Bräuchle* and Donald M. Burland***

Holography is most frequently thought of as a method of photography that results in three-dimensional images of the object being photographed. It is certainly true that this is the most visually spectacular aspect. But holography can also be used as a powerful tool for the investigation of a variety of photochemical and photophysical processes. These experimental techniques rely on the fact that small spatial modulations of a material's optical properties (index of refraction and absorption coefficient) can deflect an incident light beam into another direction. By following the growth or decay in intensity of this deflected beam, one can follow the underlying photochemical and photophysical processes producing the changes in optical properties. If a CW laser is used to produce the hologram one can use the technique to investigate solid state photochemistry. If a pulsed laser is used one can investigate a broad range of time dependent processes; energy transfer, diffusion, rotational relaxation, charge transport *etc.* Compared to conventional spectroscopic techniques the holographic method shows various advantages. So for example it is a highly sensitive zero-background technique and permits free choice of detection wavelength and detection beam intensity.

As a result of information obtained using the holographic technique as a scientific tool, one can also find new classes of materials for the recording of holograms. This is the way in which two-photon four-level systems for hologram recording in the infrared were discovered. Materials of this type are self-developing, can have the recording process gated on and off with an auxiliary source, and can be read with the infrared recording laser with no erasing of the hologram.

## 1. Introduction

Holography is most widely known as a technique for producing a three-dimensional picture. According to *Gabor*'s original idea[1], for which he received the Nobel prize in 1971, a picture or more generally information can be stored as an interference pattern generated from an object and reference wave. Although the production of a three-dimensional picture[2] was one of the most impressive initial results of holography[3–5], applications of the technique have since spread over a variety of different areas. For example, holographic interferometry[6,7] can be used to measure very small deformations of an object which is put under mechanical stress. In this way holography represents an important advance in nondestructive material testing. Medical and biomedical applications[8] are a growing field for holographic methods. A great amount of effort has also gone into the assessment of the potential usefulness of holograms in optical memories[9,10]. In this application holograms containing binary information are produced in a two- or three-dimensional array. Holograms can play an important role in coherent optical data processing[11,12].

Perhaps in the future holograms will be most widely used for the production of a variety of kinds of optical elements for focusing and deflecting light[13, 14]. Holographic optical elements are currently being considered for applications as passive devices in the fast growing area of integrated optics[15] and optical communication technologies[16].

In all of these cases the basic principle[3-5] is the same: An object wave which carries complete information about the object in the modulation of its intensity and phase is overlapped with a reference wave (see Fig. 1a) which is frequently a plane wave. If both waves are mutually *coherent* in space and time, *i.e.*, if there are fixed phase relationships between both waves during the recording period, a stationary interference pattern is produced. This pattern can be impressed photochemically into a photosensitive recording medium. The photochemically stored interference pattern is called the hologram. It consists of a complex pattern of irregularly arranged bright and dark regions of microscopic dimensions representing the interference fringes. Because of this irregularity such a hologram at first sight seems to contain no information at all. However, if it is illuminated with the reference wave only (see Fig. 1b), the recorded interference fringes diffract part of the reference wave in such a way that an image wave is reconstructed as an exact replica of the original object wave. Since not only the intensity (as in photography) but also the absolute value of the phase of the object wave is reconstructed correctly, the technique is called holography, originating from the Greek word "ὅλος" meaning "the whole". In a sense the whole pictorial information is stored in a hologram, permitting one to reconstruct a complete three-dimensional image of the original object.

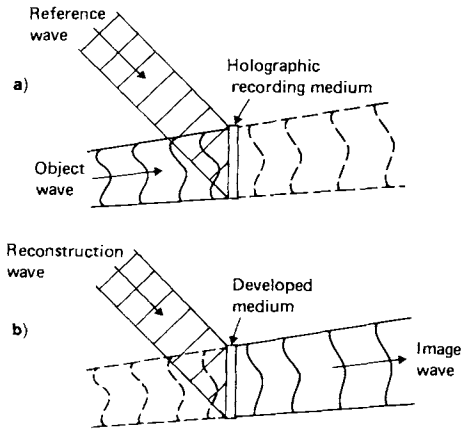

Fig. 1. Schematic representation (a) of the holographic recording and (b) reconstruction procedures.

From this brief description of holography it is obvious that *coherence* of the object and reference wave is a prerequisite. Therefore after the invention of holography[1] in 1948 its rapid development had to await the development of the laser[17] as a source of coherent light. The close relationship between laser technology and holographic development holds to the present day. So, for example, new lasers such as the semiconductor lasers[18] have stimulated a search for new holographic recording materials in the infrared.

In this review we will concentrate on two aspects of holography. First we want to discuss the application of holography as a powerful scientific tool for the investigation of photochemical and photophysical processes. Because the hologram recording process involves photochemical and photophysical changes of the photosensitive molecules in the recording medium, it is possible to use holography in order to follow these processes. In this way, holography can serve as an extremely sensitive tool for fundamental photochemical and photophysical investigations. The second aspect of holography that we wish to discuss is the search for new holographic recording materials. We will show how fundamental investigations using holographic photochemistry can yield new kinds of holographic recording materials. These new materials rely on a two-photon four-level (2P4L) photochemical reaction scheme and a comparison with conventional one-photon two-level (1P2L) photochemical recording systems will demonstrate that the 2P4L systems have many significant advantages. The use of these new materials in a range of holographic applications will be discussed.

## 2. The Use of Holography to Investigate Photochemical and Photophysical Processes

### 2.1. The Principle

In order to investigate photochemical and photophysical processes by holography it is reasonable to use the simplest of holograms, *i.e.*, a plane wave hologram[3-5]. This will avoid unnecessary complications. The production of such a plane wave hologram is shown in Figure 2. Two coherent waves (reference and object wave) with the intensities $I_R$ and $I_O$ and the same wavelength overlap at the holographic sample. Since both waves are plane waves the interference pattern is a simple cosine modulation of intensity $I(x)$ in the $x$-direction across the sample,

$$I(x)=(I_R+I_O)\left[1+V\cos\left(\frac{2\pi x}{\Lambda}\right)\right] \quad (1)$$

where $V=2\sqrt{I_R I_O}/(I_R+I_O)$ accounts for the contrast or fringe visibility and $\Lambda=\lambda/(2\sin\theta)$ gives the fringe spacing which is dependent on the wavelength $\lambda$ and the angle of incidence $\theta$. With both beams having the same intensity ($I_R=I_O$), $V$ equals unity and totally dark and maximally bright stripes occur in the interference pattern (cf. Fig. 2).

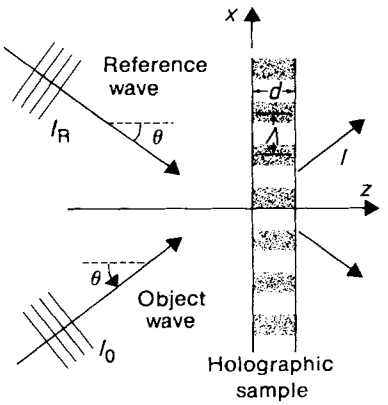

Fig. 2. The production of a plane wave hologram. For meanings of symbols see text.

If the holographic sample contains molecules that are photochemically or photophysically sensitive to the incident light they will change their chemical or physical properties. This change will be strongest in the brightest regions of the interference pattern and absent in the dark regions. In cases where these photochemical or photophysical changes are related to corresponding changes of the index of refraction $n$ or the absorption coefficient $a$ of the molecules, a spatial modulation of the index of refraction

$$n(x)=n_0+n_1\cos\left(\frac{2\pi x}{\Lambda}\right) \tag{2a}$$

and the absorption coefficient

$$a(x)=a_0+a_1\cos\left(\frac{2\pi x}{\Lambda}\right) \tag{2b}$$

will be produced by the interfering light beams. This modulation has the same periodic behavior as the intensity pattern $I(x)$ in Eq. (1). $n_0$ and $a_0$ in Eqs. (2) are the average values of the index of refraction and the absorption coefficient whereas $n_1$ and $a_1$ are the corresponding amplitudes of modulation. This photochemically or photophysically impressed variation of the index of refraction or the absorption coefficient of the holographic sample represents the process of plane wave hologram formation. Because of its regular spatial variation and its analogies to optical gratings it has also been called a holographic grating. When a reading beam strikes such a plane wave hologram along the direction of the reference wave, some of the light from this beam will be diffracted by the holographic grating and the absent object wave will be reconstructed.

A hologram can be characterized by its diffraction efficiency[3] which is defined as the intensity $I$ of the diffracted beam divided by the intensity $I_R$ of the reading beam. *Kogelnik*[19] has obtained an important expression for the diffraction efficiency $\eta$ of a plane wave hologram of thickness $d$:

$$\eta=\frac{I}{I_R}=\left[\sin^2\left(\frac{\pi n_1 d}{\lambda\cos\theta}\right)+\sinh^2\left(\frac{a_1 d}{2\cos\theta}\right)\right]\exp\left(-\frac{2a_0 d}{\cos\theta}\right) \tag{3a}$$

This expression was derived for thick or volume plane wave holograms for which the relation $d\gg\Lambda$ holds. Generally, in all cases treated in this review, thick holograms are obtained.

In order to give an interpretation of Eq. (3a) it is important to emphasize that the two terms inside the square bracket of Eq. (3a) represent two different mechanisms of hologram formation. The first term describes hologram formation as a result of changes in the index of refraction and connects the diffraction efficiency with the amplitude $n_1$ in Eq. (2a). Holograms of this type are called *phase holograms*[3] because the diffraction is caused by phase changes of the reading beam due to the modulation of the optical path lengths by $n(x)$. The second term describes holograms resulting from changes in the absorption according to Eq. (2b). These holograms are called *amplitude holograms*[3]. For these holograms the diffraction occurs because the reading beam sees a quasi-multislit grating produced by $a(x)$. The exponential factor in Eq. (3a) accounts for the absorption of the reconstruction wave as it passes through the sample. This factor is responsible for the low maximum theoretical diffraction efficiency[3] of 3.7% for a pure amplitude hologram. On the other hand, for pure phase holograms the efficiency may theoretically approach 100% if the reading wavelength $\lambda'$ is not absorbed ($a_0=0$, $a_1=0$). For photochemical reactions it can be shown[20] that even in cases where some absorption is present the effect of the phase hologram generally exceeds that of the amplitude hologram. For these cases, in a first approximation it is often possible to consider the phase holograms only.

Equation (3a) is the central formula for the holography described in this review. It is obvious from this equation that changes in the photochemical or photophysical properties of molecules in the holographic sample can cause changes in the diffraction efficiency $\eta$ if these properties are related to corresponding changes in the index of refraction or absorbance. In Sections 2.2–2.3 a new holographic method is described which measures the change of molecular parameters by following the change of the diffraction efficiency. Since, in most applications of this holographic technique, the total diffraction efficiency is small ($\eta\leq 0.01$) Eq. (3a) can be accurately approximated by Eq. (3b):

$$\eta=\left[\left(\frac{\pi n_1 d}{\lambda\cos\theta}\right)^2+\left(\frac{a_1 d}{2\cos\theta}\right)^2\right]\exp\left(-\frac{2a_0 d}{\cos\theta}\right) \tag{3b}$$

In these cases, $\eta$ is directly proportional to the *square* of the amplitudes $n_1$ and $a_1$.

## 2.2. The Holographic Method with Continuous Wave (CW) Lasers

### 2.2.1. Determination of Photochemical Rate Constants

If the holographic sample (Fig. 2) consists of photochemically active molecules dispersed in a polymer film or any other glassy or crystalline matrix these molecules will react in the brightly illuminated regions of the sample but not in the dark regions. As a result, a spatial variation of the photochemical product formation occurs which changes the index of refraction and the absorption coefficient of the sample. The change in the index of refraction can be obtained from the photochemical changes by using the Lorentz-Lorenz relation[21], which gives for the amplitude $n_1$ after some manipulations[20]:

$$n_1=\frac{(n_0^2+2)^2}{6000 n_0}\sum_i R_i\Delta C_i(t) \tag{4a}$$

where $R_i$ is the molar refraction and $\Delta C_i(t)$ gives the time dependent changes of the concentration at the maxima of the interference pattern. The subscript i runs over all components of the reaction. A similar formula can be obtained for the changes in the absorption coefficient caused by a photochemical reaction

$$a_1(\lambda)=2.30\sum_i \varepsilon_i(\lambda)\Delta C_i(t) \tag{4b}$$

where $\varepsilon_i(\lambda)$ is the molar extinction coefficient of the *i*th component of the reaction.

For a simple one-step reaction

$$A_1 \xrightarrow{k} A_2 \tag{5}$$

with the overall reaction rate $k$ the changes of the concentrations of $A_1$ and $A_2$ with time are well known from the kinetic rate equations[22]

$$C_1(t) = C_1(0)\,e^{-kt} \tag{6a}$$
$$C_2(t) = C_1(0) - C_1(0)\,e^{-kt} \tag{6b}$$

where $t$ equals time and $C_1(0)$ is the initial concentration of $A_1$. Considering a pure phase hologram and putting Eqs. (6) in (4a) and (4a) in (3) gives a relationship for the efficiency as a function of time[20,23–26]. For the early stages of the hologram formation, where $\eta$ is very low, Eq. (3b) can be used instead of Eq. (3a) giving the simple result[25]:

$$\eta = (F \cdot C \cdot k)^2 t^2. \tag{7}$$

In Eq. (7)

$$F = \frac{\pi d}{\lambda' \cos\theta} \quad \text{and} \quad C = \frac{(n_0^2+2)^2}{6000 n_0}(R_2 - R_1)C_1(0)$$

are constants representing geometrical and material specific parameters. From an experimental observation of $\eta$ as a function of time it can thus be seen that one can obtain the overall rate constant $k$. Curves showing $\eta$ as a function of time are called hologram growth curves. The remainder of this section will indicate how one can obtain important information about photochemical and photophysical processes from such curves.

### 2.2.2. Experimental Observation of Hologram Growth Curves

Experimentally, hologram growth curves are obtained with an apparatus[20,23–27] similar to the one shown in Figure 3. The light from a laser is split into reference and object waves which produce the interference pattern at the sample. The formation of the hologram can be observed in two ways. First the light from a second laser (most conveniently a HeNe laser) can be used to read the hologram. If the light of this second laser strikes the sample with the intensity $I_R$ it will be diffracted by the hologram. The intensity $I$ of the diffracted beam can be modulated, measured with a photodiode and recorded with a lock-in amplifier. It is directly proportional to the diffraction efficiency $\eta = I/I_R$ and provides a record of the hologram growth as a function of time. If one chooses the wavelength of this second laser so that it is not absorbed by the sample a pure phase hologram is observed. It has to be mentioned, however, that in cases where the reading wavelength $\lambda'$ differs from the writing wavelength $\lambda$ a different angle of incidence $\theta'$ for the reading beam must be used for the maximum intensity $I$. This angle should satisfy the Bragg relation[3]:

$$2\Lambda \sin\theta' = \lambda' \tag{8}$$

In Eq. (8) $\Lambda$ is fixed once the hologram is impressed.

A second method of detection is to use the light of the argon laser itself. In this case a chopper is used in the object beam. When the chopper blocks the object beam, only the reference wave strikes the sample. Then light of this wavelength is deflected into the direction of the object wave as the hologram grows and can be detected with a photodiode which is connected to a boxcar integrator. The reference of the chopper opens the gate of the signal input of the boxcar integrator only during the periods when the object beam is blocked so that hologram growth (open period of the chopper) and hologram detection (closed period) follow each other at the frequency of the chopper. In this way the Bragg relation is automatically satisfied.

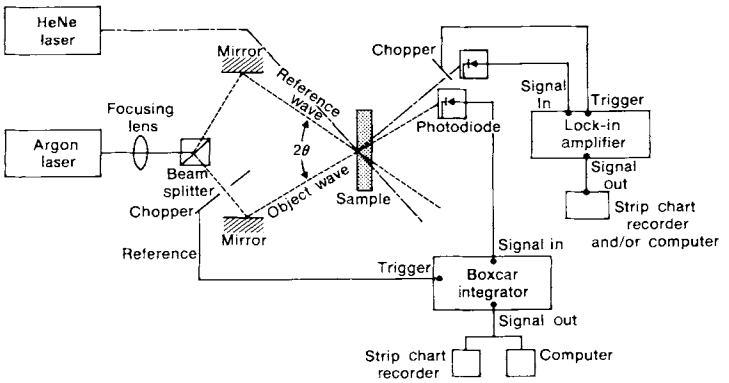

Fig. 3. A schematic representation of the apparatus for the recording of holographic growth curves. The detection method using a third HeNe laser is indicated by the dash-dotted line. The method using a chopper in the object beam is shown by the dashed line.

The setup in Figure 3 illustrates several advantages of the holographic technique. It is truly a zero-background technique. Until the hologram begins to form no light is received at the photodiode. If one uses a HeNe laser for detecting the hologram, scattered light from the writing laser can be reduced by placing a narrow band pass filter before the photodiode allowing only 632.8 nm light to reach the detection. The HeNe laser beam has very little divergence so that one can further eliminate interference from scattered light simply by moving the detector well away from the sample. With such an experimental arrangement hologram efficiencies of less than $10^{-9}$ can be detected.

### 2.2.3. Analysis of Hologram Growth Curves to Obtain Quantum Yields and the Number of Mechanistically Necessary Photons

With the experimental setup described above hologram growth curves[23–27] as shown in Figure 4 can be obtained. All curves show a quadratic time dependence in good agreement with Eq. (7). For each curve in the figure, *i.e.*, for each intensity of the hologram producing beams, an overall rate constant $k$ can be obtained according to Eq. (7).

The dependence of the overall rate constant $k$ on the intensity can be explained by referring to the energy level

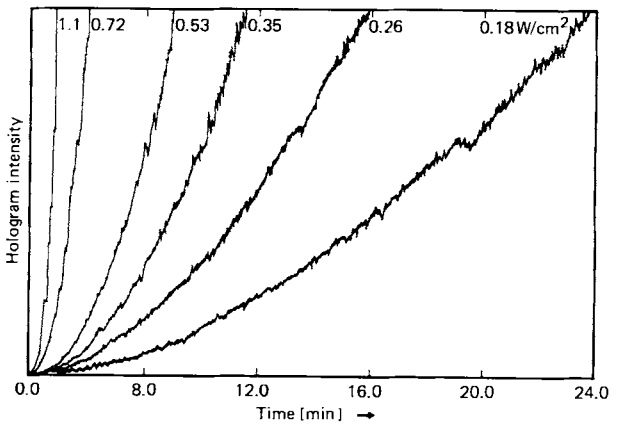

Fig. 4. Hologram growth curves for different intensities of the hologram forming beams. Only the early stages of the hologram growth are shown. These results were obtained with a sample of dimethyl-*s*-tetrazine in polyvinylcarbazole using the 514.5 nm line from an argon ion laser.

schemes in Figure 5. On the left side of Figure 5 a one-photon two-level (1P2L) process is shown. Here the absorption of one photon excites the molecule into the reactive state $A_1^*$. The right side of Figure 5 illustrates a two-photon four-level (2P4L) scheme indicating that two photons are necessary to reach the reactive state $A_2^*$. Since the rate constant $k$ obtained above describes only the overall reaction process ($A_1 \rightarrow A_2$ for the left side or $A_1 \rightarrow A_3$ for the right side of Fig. 5), it involves the intensity-dependent "absorption rates" $I_a$. In the steady state approximation it can be easily shown that $k$ is related to the intensity $I$ according to

$$k = \xi I^r \tag{9}$$

where $r$ gives the number of mechanistically necessary photons and $\xi$ contains all other photochemical and photophysical constants. For the one-photon process ($r = 1$) in Figure 5 one gets[23]

$$\xi = 2303 \cdot \varepsilon_1 \phi_p \tag{10a}$$

with $\varepsilon_1$ the molar extinction coefficient and $\phi_p$ the photochemical quantum yield, whereas for the two-photon process ($r = 2$)

$$\xi = (2303)^2 \cdot \varepsilon_1 \varepsilon_2 \tau_2 \phi_2 \phi_p \tag{10b}$$

with $\varepsilon_1$, $\varepsilon_2$ the molar extinction coefficients of the two absorption steps, $\tau_2$ the lifetime and $\phi_2$ the quantum yield for

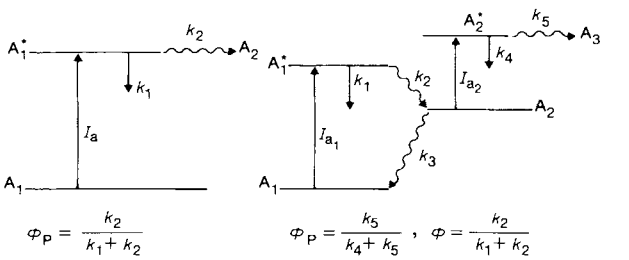

Fig. 5. Energy level diagrams for a one-photon two-level (left side) and a two-photon four-level (right side) photoreaction. The rate constants and the quantum yields for the kinetic processes are indicated as are expressions for the quantum yields.

population of state $A_2$. $\phi_p$ is the photochemical quantum yield.

A plot of $\log k$ as a function of $\log I$ gives $r$ as the slope and $\log \xi$ as the intercept according to Eq. (9). Such a plot is shown in Figure 6 for the holographically observed photoreaction of *o*-nitrobenzaldehyde (ONB)[25,28] dissolved in a polymethylmethacrylate (PMMA) film. Since $r = 1.04$ the use of Eq. (10a) with the easily obtained value of $\varepsilon_1$ gives the photochemical quantum yield $\phi_p = 0.17 \pm 0.05$ for this reaction in very good agreement with the value determined by optical absorption spectroscopy. Thus, the holographic method provides information about the overall photochemical reaction scheme (see Fig. 5) through the value of $r$, and provides information about the ratio between the rates of excited state photochemistry and photophysical relaxation processes through $\phi_p$. In Section 2.2.6 the advantages of the holographic technique are discussed in more detail; however, it is already obvious from this example that important parameters such as $r$ and $\phi_p$ can be obtained quite easily by this technique.

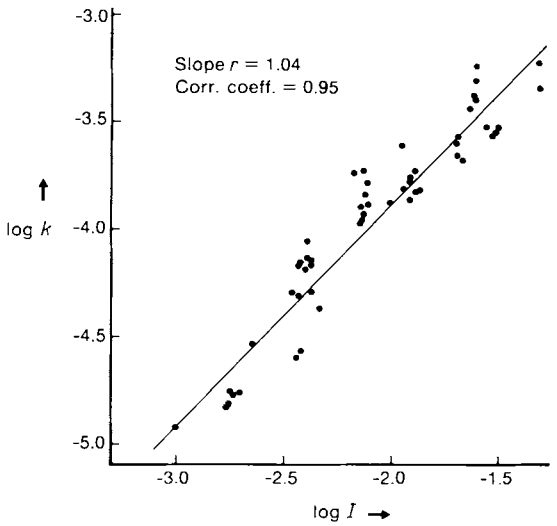

Fig. 6. A double logarithmic plot of the overall rate constant $k$ as a function of intensity $I$ for the holographically observed photoreaction of *o*-nitrobenzaldehyde.

Several other reactions have been investigated using the holographic technique sketched above. In the field of ketone photochemistry, hydrogen abstraction by benzophenone in a PMMA matrix has been studied[29]. It has been shown that a two-photon consecutive reaction is the major pathway in the solid (see also Section 2.2.4) in contrast to solution where this pathway is a minor one[30–32]. The reaction steps involve two photons probably because of a cage effect in the solid matrix[29,33]. Another example is the holographic investigation of dimethyl-*s*-tetrazine[23,24,34] which dissociates in a two-photon reaction[35,36]. A so far unidentified intermediate plays an important part in this reaction. There have been several attempts to characterize this intermediate[37–39]. The holographic method has shown[34] that the intermediate which is responsible for the two-photon nature of the reaction has an absorption in the same range as dimethyl-*s*-tetrazine itself (see also Section 2.2.5).

### 2.2.4. *Computer Modelling of Hologram Growth Curves*

Hologram growth curves can have different shapes[20,29] according to the reaction mechanism underlying the production of the hologram. It is instructive to compare calculated hologram growth curves with experimentally obtained ones, for one can obtain valuable information about reaction mechanisms in this way. The bases for such a calculation are Eqs. (3) and (4). Since these equations connect the time dependent change of the concentrations $\Delta C_i(t)$ of each component of the reaction with the hologram efficiency $\eta$ the hologram growth curves can be calculated for all types of kinetic rate equations. Therefore, having an expression for the kinetic rate equations of a particular reaction scheme, the appropriate growth curve can, in principle, be simulated.

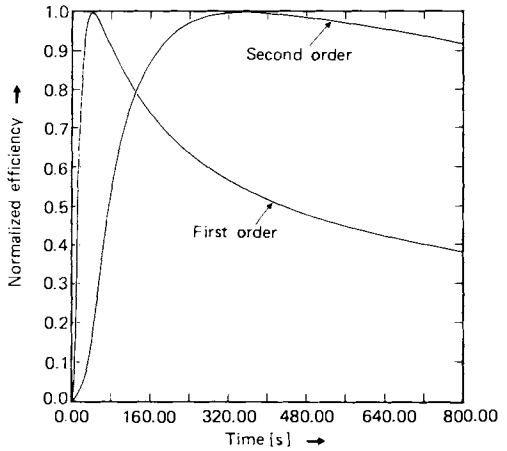

Fig. 7. Calculated hologram growth curves for first and second order holograms. Both curves have been normalized to maximum efficiencies of unity.

Figure 7 shows such calculated hologram growth curves for first and second order holograms of a simple one-step reaction $A_1 \rightarrow A_2$ as in Eq. (5)[20]. The second order hologram can be observed at an angle $2\theta$. It is weaker than the first order hologram and results primarily from the fact that after prolonged irradiation times the change of the index of refraction reaches saturation due to bleaching of the photoactive material in the bright parts of the interference pattern. This can be seen in Figure 8 where the change of the index of refraction is calculated for increasing reaction times. As a result of the bleaching process, $n(x)$ must be described by a Fourier expansion for longer reaction times instead of the simple two term expression in Eq. (2). Higher order holograms are then due to higher order coefficients of $n(x)$ in the Fourier expansion.

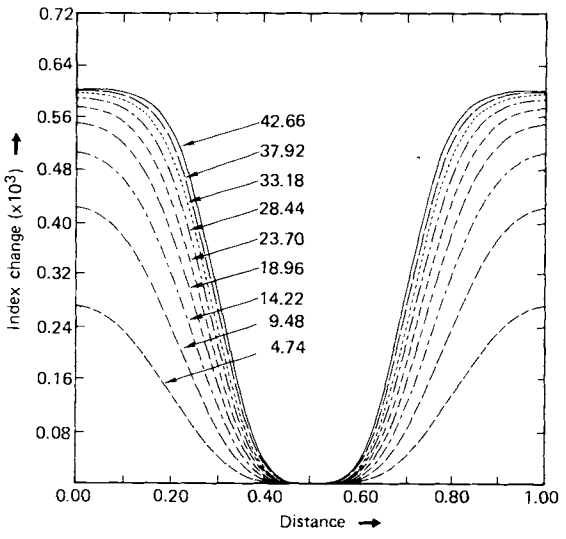

Fig. 8. The change in index of refraction across one period $\Lambda$ of the holographic grating for a one-step photoreaction for various illuminations times. (The distance is in units of $\Lambda$.)

The experimentally observed curves in Figure 4 for a one-step reaction are obtained only for the very first part of hologram growth well before saturation begins. If one expands the timescale in Figure 7, a clear quadratic time dependence is found for the early stages of hologram growth as observed experimentally and described by Eq. (7).

Hologram growth curves can be calculated for more complex kinetic schemes. For example, a consecutive reaction

$$A_1 \xrightarrow{k_1} A_2 \xrightarrow{k_2} A_3 \tag{11}$$

has been treated[20]. Results for such a calculation are shown in Figure 9. For the reaction scheme outlined in Eq. (11), one can, according to Eq. (4a), write

$$n_1 \sim \Delta C_2 R_2 + \Delta C_3 R_3 - (\Delta C_2 + \Delta C_3) R_1 . \tag{12}$$

For the case shown in Figure 9b, $R_1 > R_2 > R_3$; thus, $n_1$ is negative throughout the reaction. In this case we expect the hologram to grow initially at a rate characteristic of the $A_1 \rightarrow A_2$ reaction but eventually to grow with the $A_2 \rightarrow A_3$ rate. This is exactly what occurs, as shown in Figure 9b.

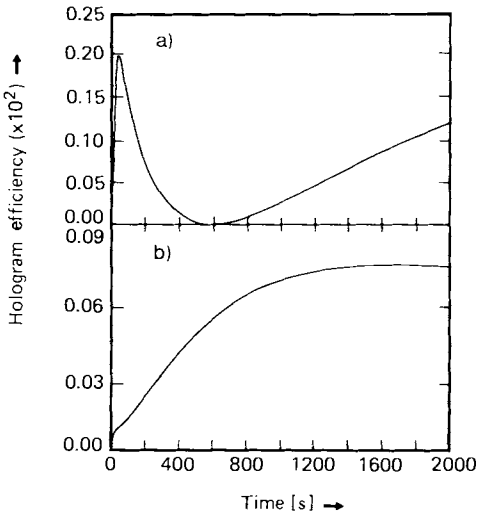

Fig. 9. Calculated hologram efficiency *versus* time for a consecutive reaction scheme $A_1 \rightarrow A_2 \rightarrow A_3$: (a) Subtractive and (b) additive behavior of the change in the index of refraction in the two reaction steps.

If, perhaps in another wavelength region, $R_2 > R_1 > R_3$ the result in Figure 9a is obtained. During the initial stage of the reaction while $A_1$ is being converted into $A_2$, the hologram grows at a rate characteristic of this reaction. But

as the reaction proceeds further $A_2$ is replaced by $A_3$ and since $R_3 < R_1$ this means that $n_1$ must eventually become negative. Following $n_1$ as a function of time, we find that $n_1$ begins to decrease during the second phase of the photochemistry, passing through zero and eventually becoming negative. Since the hologram efficiency depends only on the square of the quantity $n_1$, the expected hologram growth pattern is as shown in Figure 9a.

Such hologram growth curves have been observed for the consecutive photoreaction scheme of benzophenone in PMMA[20,29]. Results at two different wavelengths corresponding to the two cases discussed above (cf. Fig. 9) are shown in Figure 10.

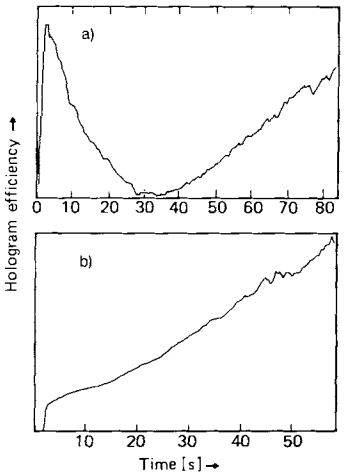

Fig. 10. Experimental hologram efficiency *versus* time for a 250-μm thick sample of 5% by weight benzophenone in PMMA. The hologram was produced using the UV-lines of an $Ar^+$ laser and read with (a) the UV lines and (b) the 514 nm line.

These examples show that characteristic shapes of hologram growth curves occur for different types of reactions. As long as expressions for the kinetic rate equations are available these shapes can be calculated and compared to the experimentally observed features. In this way they can help to prove the underlying reaction mechanism, and, in principle, a fit can give the kinetic parameters.

### 2.2.5. *Observation of a Photochemical Action Spectrum Using Holography*

As a final example of the use of the CW holographic technique in photochemical investigations the observation of a photochemical action spectrum will be discussed[29,34,40]. Many examples exist of photochemistry that occurs when a molecule in its lowest metastable triplet state is excited to a higher triplet state[41]. The holographic technique is particularly useful for studying such processes because it can be used even in cases where interfering reactions occur from the lowest triplet state.

To illustrate the use of holography in this context, we consider the first step in the benzophenone hydrogen abstraction process[29]. As discussed in Section 2.2.3, this process involves the consecutive absorption of two photons. The first photon at a frequency $\omega_1$ excites the $S_0 \rightarrow S_1$ absorption as shown in Figure 11. After intersystem crossing, the lowest triplet state $T_1$ is produced. Absorption of a second photon at $\omega_1$ produces $T_3$. As a result of photochemistry undergone by $T_3$, a product known as the light absorbing transient (LAT)[30-32] is produced.

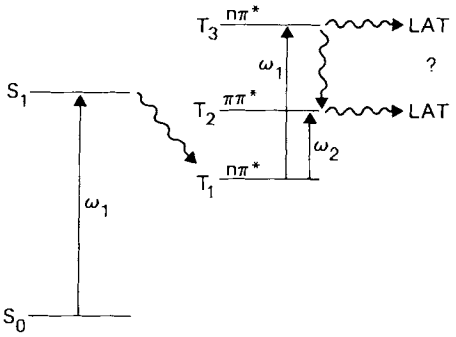

Fig. 11. The energy level diagram for the first step of the photoreaction of benzophenone to the light absorbing transient (LAT) involving the absorption of two photons. Two possible pathways to the LAT are suggested.

The question arises as to which excited states are responsible for the photochemical reaction, $T_3$ itself or an intermediate triplet state $T_2$ that is reached by radiationless relaxation from $T_3$. The holographic technique is ideally suited to answer questions like this. Figure 12 indicates how this might be done. A UV source that need not be coherent excites the benzophenone molecules at $\omega_1$ ultimately producing molecules in the $T_1$ state. Note that even if this irradiation results in photochemistry no hologram is produced since there is no interference pattern.

If two interfering beams at a frequency $\omega_2$ now strike the sample, they can excite the benzophenone molecules to a higher triplet state. If photochemistry occurs from this higher state, then a hologram will be formed. By varying the frequency $\omega_2$ and following the hologram growth rate, a photochemical action spectrum may be obtained. For benzophenone these results indicate that, referring to Figure 11, the nπ* state $T_3$ is reactive, but the ππ* $T_2$ is not.

Investigations using this technique have also been performed for the N–H bond cleavage reaction of carbazole[40] and the previously discussed photodissociation of dimethyl-*s*-tetrazine[34].

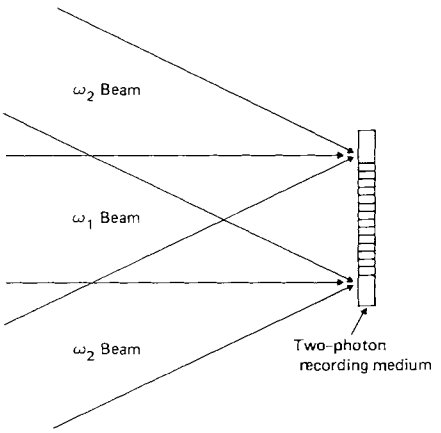

Fig. 12. A three-beam experiment using two different light sources. Only the beams at $\omega_2$ need to be coherent, and only these beams can produce a hologram.

### 2.2.6. *Comparison of the Holographic Method with Conventional Absorption Spectroscopy*

It is perhaps useful at this point to compare the holographic method with other spectroscopic methods, such as conventional optical absorption spectroscopy.

One advantage of the holographic technique is that only small sample areas are needed. Since the fringe spacing of the interference pattern are in the range of a few microns a sample area with a diameter of less than 100 μm contains more than enough fringes to give a well-defined diffraction pattern. Due to the low divergence of laser beams it is easy to focus the light onto such small sample areas. Thus, for materials which are available in small quantities or difficult to align on large surfaces (biological samples, crystals *etc.*) the holographic technique is very suitable.

Further, the holographic technique is sensitive to changes in *both* the index of refraction and absorption. Thus, this technique encompasses both *dispersion* and *absorption* spectroscopy. To illustrate this important point, Figure 13 shows the absorption curve $a(\omega)$ and the related dispersion curve $n(\omega)$ for an optical transition with a maximum at the frequency $\omega_0$[42]. It is obvious from Figure 13 that in the holographic technique the wavelength for the observation of a photochemical reaction is not restricted to the range of absorption but can, in principle, be chosen anywhere in the optical region. This free choice of the detection wavelength has the advantage that overlapping absorption bands do not prevent the investigation of the kinetics of a reaction. Complicated reaction schemes (*e.g.* $A \rightarrow B \rightarrow C \cdots$) can be observed at a *single* wavelength and *without* interruption even when the reaction components have totally different regions of absorption. Further, the detection wavelength can be chosen in a spectral range where the detection system has high sensitivity or where convenient laser sources are available.

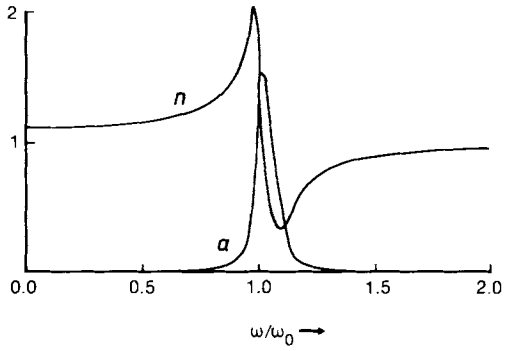

Fig. 13. The dispersion curve *n versus* $\omega$ and the absorption curve *a versus* $\omega$ for an optical transition at frequency $\omega_0$. The abscissa is in units of $\omega/\omega_0$.

If one considers a pure phase hologram the detection beam is *not* absorbed and one has the additional advantage of being able to choose the intensity of the detection beam. Using high power in this beam does not destroy the sample but can give highly improved sensitivity. It should be emphasized that the use of the phase hologram in the holographic technique adds a powerful dispersion method to the spectroscopic tools in the optical region. With the exception of optical rotatory dispersion spectroscopy[43] for optically active materials there exists no other useful dispersion technique.

As mentioned previously (cf. Section 2.2.2) the holographic technique is a zero-background technique, *i.e.* the hologram grows out of the dark. This is in contrast to conventional optical absorption spectroscopy where attenuations, *i.e.* differences in light intensities have to be measured. Since a weak attenuation of a light beam is always much more difficult to measure than the small absolute light intensity of a deflected beam itself the holographic technique is more sensitive than conventional absorption spectroscopy[44-47]. Index changes of $10^{-7}$ or optical absorption changes of $10^{-5}$ are sufficient to cause an easily detected diffracted beam[47].

In the examples of the holographic technique shown so far, the characteristics of the spatial orientation of the fringe pattern relative to a distinct spatial axis of the sample have not been used. However, it is easy to imagine that for anisotropic processes like lattice controlled photoreactions or diffusion processes the orientation of the fringe pattern can reveal the corresponding tensor components quite easily. In Section 2.3 some examples will be discussed. In conventional optical absorption spectroscopy such experiments are impossible.

The advantages discussed above for holography with continuous wave lasers can also be attributed to the pulsed holographic technique described in the following sections. However the limitations of the technique have to be mentioned too. Thus, for example, the observation of photochemical reactions using continuous wave irradiation is confined to reactions in the solid state and an identification of the photoproducts is not possible. Conventional absorption spectroscopy can, however, help to identify photoproducts if the products show characteristic absorption bands.

## 2.3. The Holographic Method with Pulsed Lasers – Transient Gratings

### 2.3.1. *Creation and Detection of Transient Gratings*

Lasers can be run not only in the continuous wave (CW) mode, but can also be used as pulsed light sources giving very short light pulses with a pulse width ranging from about a picosecond up to several nanoseconds[48]. These pulses can be selected as single pulses out of a pulse train or can be obtained at a high repetition rate. If such a laser pulse is split by a beam splitter, as indicated in Figure 3, then, provided the path lengths are equal, two laser pulses arrive at the sample simultaneously but from different directions. Because both pulses originate from the same laser and are thus coherent, an interference pattern is created at the sample which exists for a duration approximately equal to the pulse width. Due to photochemical or photophysical processes involving the molecules in the sample, a holographic grating is induced quasi-instantaneously. After the pulses have left the sample, this grating may decay because of relaxation processes in the sample.

This decay can easily be observed by using a probe pulse with variable time delay. The probe pulse will be diffracted by the grating and its diffracted intensity as a function of

delay time will give the time dependent decay of the grating. An experimental setup[45,49–52] with pulsed lasers can be run at a high repetition rate (*e.g.* 500 Hz) measuring the diffracted probe pulse intensity averaged over many pulses, while slowly varying the time delay between excitation and probe pulses. The time resolution of such an apparatus is given approximately by the pulse width of the laser pulses. The decay of such a grating can, of course, also be observed by a diffracted CW-detection beam whose time dependent intensity shows the decay of the grating. Since the above described holographic grating exists only for a short period of time the holographic method using pulsed lasers is often called the transient grating technique[45,49–51]. (The expression "Forced Rayleigh Scattering" is also used for this technique[52].)

Unlike the CW-holographic method, the transient grating technique is not restricted to investigations of molecules in the solid state but can also be used for molecules in the liquid phase. A wide variety of time dependent phenomena can be observed by this technique. Examples include processes like the relaxation of excited states[44,53,54], photoreactions from excited states, energy transfer across the fringe pattern[56], energy trapping[46], diffusion processes of molecules[44,47,54,57–59], carrier transport in semiconductors[50,60], optical generation and detection of ultrasonic waves[45], and thermal diffusion[44,51]. In the following sections, we will concentrate on a few examples of the technique.

### 2.3.2. *Excited State Dynamics: Lifetimes, Photoreactions and Energy Transfer*

In this section, we want to concentrate on transient gratings produced by time dependent phenomena involving excited states of molecules excluding any effect which may result from the diffusion of the molecules themselves. Thus, we are first restricting our discussion to transient grating effects involving molecules in the solid state or where the relaxation times of interest are much shorter than any observable molecular diffusion process. We will discuss three cases dealing with lifetimes of excited states, photoreactions and energy transfer.

If molecules in the holographic sample are excited by two interfering laser pulses to higher electronic or vibrational states, the index of refraction and the absorbance of the sample will change. The index changes are due to rearrangements in the electronic structure of the molecules[61] whereas the change in the absorption results from a partial depopulation of the ground state. Thus, a holographic grating will be produced in the same general manner as discussed in Section 2.1. Since the change in the index of refraction and absorption coefficient is proportional to the number of molecules excited, the diffraction efficiency $\eta$ depends on $(N_1)^2$, *i.e.*, the square of the number of the excited states at the grating peaks. Here, the simple Eq. (3b) has been used because of the low hologram efficiency produced by the excited states. In the absence of any other processes besides the relaxation of the excited states to the ground state, the time dependence of the intensity $I(t)$ of a diffracted probe beam will be determined by the excited state lifetime $\tau$:

$$I(t)=A\exp\left(-\frac{2}{\tau}t\right). \tag{13}$$

In Eq. (13), $A$ is a constant gathering together all time independent holographic parameters. A plot of $\log I(t)$ against time $t$ will give the decay rate $k=2/\tau$ as the slope and $A$ as the intercept. Thus, lifetimes of excited states can be obtained easily with the transient grating technique[45,50,53]. This can be important for states that decay without the emission of radiation and which cannot thus be investigated by optical emission techniques. Further, from the value of $A$ in Eq. (13), the differences of the molar refractions of the ground and excited states can be elucidated. This gives, in principle, the possibility of determining polarizabilities of excited molecules[62].

Besides the radiationless or radiative relaxation of excited states, a photoreaction can also occur from these transient states as discussed in Section 2.2. It is of interest to see if any complementary information can be obtained by the transient grating technique that cannot be obtained by the CW-holographic method. Without going into details and restricting ourselves to the simple case of a one-photon two-level reaction scheme (see Fig. 5), it can be shown that the time dependence of the diffraction efficiency should be given by [55]

$$\eta(t)=(K_1+K_2\exp[-(k_1+k_2)t])^2 \tag{14}$$

In this equation, $K_1$ and $K_2$ are time independent constants whereas $k_1$ and $k_2$ are rate constants for the decay of the excited state and the photochemical step respectively as indicated in Figure 5. Assuming that the population in the excited state is established instantaneously by the two interfering laser pulses, $k_1$ describes the decay of the transient grating while $k_2$ characterizes the time dependent increase of the modulation depth of the grating due to the creation of photochemical products. Thus, in this case, a photophysical hologram decays and a photochemical hologram grows. The sum of the rate constants for both processes $(k_1+k_2)$ can be obtained from the experimental measurements. The seperate rate constants $k_1$ and $k_2$ cannot be obtained from the pulsed holographic measurements alone. However, if this result is *combined* with the photochemical quantum yield $\phi_p=k_2/(k_1+k_2)$ obtained from the CW-holographic experiment the lifetime of the excited state $\tau=1/k_1$ and the rate constant $k_2$ of the photochemical step can be determined. Thus, a combination of both CW and pulsed holographic methods can provide a detailed picture of the photochemical reaction. It is also possible to obtain $k_1$ and $k_2$ from the application of one of the holographic methods and a spectroscopic lifetime measurement.

Starting again from the modulated pattern of excited states created by two interfering laser pulses, as a third example, one can describe the subsequent dynamics of an excited state not only by radiative and radiationless relaxation to the ground state but also by energy transfer[63,64] to neighboring molecules. For these processes, molecular crystals[65] provide an important example. Their energy transfer has been studied at least in part as a model for energy transfer in biological systems[66,67]. In molecular crys-

tals, energy transfer results from intermolecular interactions and can be thought of as a migration of an excited state by hopping from molecule to molecule in the time before relaxation to the ground state. Because intermolecular interactions are anisotropic, the transfer of energy is very often easier along some crystallographic directions than others. If a transient grating is created in such a crystal, its decay will thus depend on two processes: First the excited state lifetime $\tau$ will reduce the amplitude of the fringe pattern as discussed above and second, the migration of the excited states perpendicular to the fringes will wash out the modulation pattern. Assuming that the energy transport can be described as a diffusion process with a diffusion constant $D$, the observed signal intensity $I(t)$ of the diffracted probe beam should show an exponential decay as in Eq. (13); however, the decay rate $k$ must be modified by a second term describing the diffusion process[56]:

$$k = 2/\tau + (16\pi^2 D/\lambda^2)\theta^2. \qquad (15)$$

Since the effect of the diffusion process on the overall decay depends on $D$ and in addition on the fringe spacing $\Lambda$ (see Eq. (1)), the second term in Eq. (15) depends on $\lambda$ and $\theta$. Performing transient grating experiments with different fringe spacings, *i.e.*, by varying $\theta$, a set of decay constants $k$ can be measured. From the slope of a plot of $k$ as a function of $\theta^2$, the diffusion constant $D$ can be calculated, whereas the intercept of the plot yields the lifetime $\tau$. Thus, transient grating experiments with variable fringe distances are capable of *separating* lifetime and diffusion effects quite easily.

Such measurements have been done by several workers[50,56,68]. In Figure 14, the results of *Siegman et al.*[56] are shown. They investigated a single crystal of *p*-terphenyl doped with $10^{-3}$ mol/mol of pentacene. Obtaining $k$ from decay curves as in Figure 14a and plotting $k$ as a function of $\theta^2$ (see Fig. 14b), they obtained a diffusion constant $D = 2 \pm 0.1$ cm$^2$ s$^{-1}$ for the energy transfer along the crystallographic $b$ axis. The intercept $2/\tau$ was in good agreement with the independently measured lifetime of $\tau = 9.5 \pm 0.3$ nsec. Since such measurements can be done along different crystallographic directions by simply rotating the holographic sample the anisotropy of energy transfer and thus of intermolecular interactions can be studied in a very direct manner.

It should be emphasized that the transient grating technique with variable fringe distances is not just restricted to diffusion by energy transfer. In principle, any diffusive process that reduces the peaks and fills the nulls of the modulation pattern can be investigated. Thus, for example, transient gratings have been produced in *semiconductors*[50,60,69]. In these materials, the gratings are due to the formation of free carriers and the decay of the grating gives the characteristic diffusion constant for the movement of the free carriers. Other systems in which light induced charge transport is of great importance include *electro-optic crystals* such as $LiNbO_3$ and $LiTaO_3$ doped with transition metals. These materials have been considered as potential candidates for holographic information storage[10] and have a variety of other applications in modern optics. The photoinduced electron and hole transport in

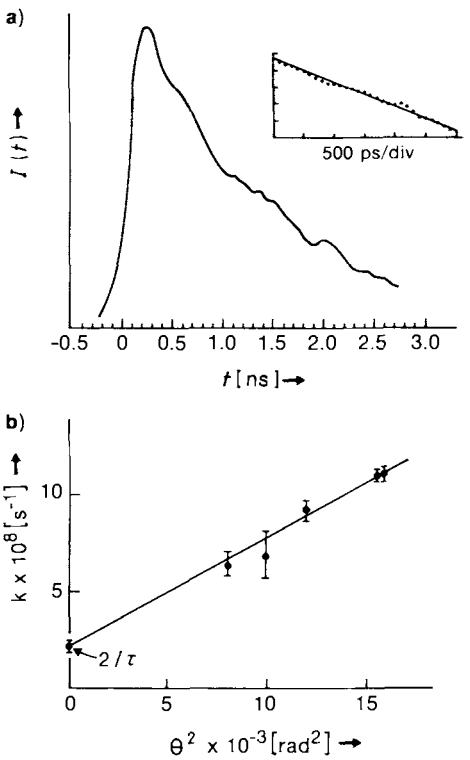

Fig. 14. (a) The decay of the diffracted probe pulse intensity *versus* probe pulse delay time. The inlay shows the logarithmic plot giving the decay rate $k$ as the slope. (b) The transient grating decay rate $k$ *versus* the square of the angle of incidence $\theta^2$ giving the diffusion constant $D$ as the slope and $2/\tau$ as the intercept. After [56].

these materials has been investigated by holographic methods[70]. So far, mainly CW-holographic methods have been used[71]; however, for systems with shorter decay times the transient grating method is suitable as well.

### 2.3.3. *Rotational and Translational Diffusion Processes in Liquid Solutions*

In the sections above, it was assumed that the molecules under investigation had fixed positions relative to the polarization of the exciting as well as the detecting light pulses because they were incorporated in an ordered or unordered way in a crystalline or glassy matrix. However, if the experiments are performed in liquid solution, the molecules can diffuse within the sample showing rotational as well as translational diffusion. Since laser light is linearly polarized, the two interfering light pulses will preferentially excite molecules with a transition moment parallel to the electric vector of the light waves. So not only a spatial modulation pattern of excited states is created by the interference of the two light pulses but also a photoselection of preferentially oriented molecules. For these molecules in a liquid solution, it is possible to follow rotational diffusion if the polarization of the delayed probe pulses relative to the exciting laser pulses is taken into account[44,54]. Since rotation of molecules in solution will occur much faster than noticeable diffusion of excited molecules from the peaks into the nulls of the grating, it is the rotational and not the translational diffusion which is observed first using linearly polarized laser light as a probe beam. As in time resolved fluorescence depolarization ex-

periments[72, 73] the decay of the transient grating is measured with two time dependent signals[54] $I_{\parallel}(t)$ and $I_{\perp}(t)$ which are obtained for parallel or perpendicular orientation of the polarization of the probe pulse relative to that of the excitation pulses. A detailed analysis[44, 54] of the time dependence of the signals $I_{\parallel}(t)$ and $I_{\perp}(t)$ shows that the sum $S(t)$ of both signals gives an exponential decay with a decay constant $k = 1/\tau$ where $\tau$ is the lifetime of the excited state. Computing the difference $D(t)$ of both signals $I_{\parallel}(t)$ and $I_{\perp}(t)$ and taking the ratio $R(t) = D(t)/S(t)$ it can be shown that $R(t)$ gives an exponential decay too; however, the decay constant $k_R = 1/\tau_R$ yields the rotational reorientation time $\tau_R$. So, by performing two time dependent measurements, $I_{\parallel}(t)$ and $I_{\perp}(t)$, it is possible to *separate* the lifetime effect from the reorientation of the molecules. In Figure 15a, the two time dependent signals $I_{\parallel}(t)$ and $I_{\perp}(t)$ are shown for a sample of Rhodamine B in *n*-propanol as obtained by *Fayer et al.*[54]. Figure 15b shows the corresponding logarithmic plot of $S(t)$ and $R(t)$ giving the excited state lifetime $\tau$ and the rotational reorientation time $\tau_R$, respectively.

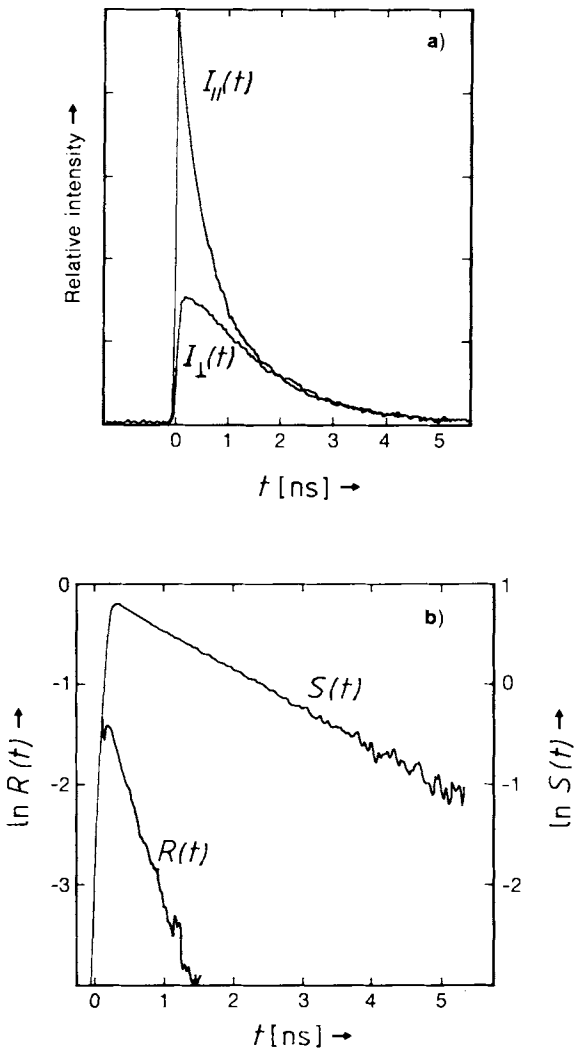

Fig. 15. (a) The decay of the transient grating signal with probe pulse polarization parallel to ($I_{\parallel}(t)$) and perpendicular to ($I_{\perp}(t)$) the excitation polarization for a sample of rhodamine B in *n*-propanol. (b) $S(t)$ and $R(t)$ curves calculated from the data presented in (a). The straight line fits yield values of the excited state lifetime $\tau$ and the orientational reorientation time $\tau_R$. After [54].

It is interesting to note that the above obtained excited state lifetime can be checked in a third experiment. Setting the polarization of the probe beam at 54.7° (the "magic angle") relative to the excitation polarization, it can be shown that the observed decay is independent of rotational dynamics. In this case, the exponential decay of the signal $I_M(t)$ gives directly the excited state lifetime $\tau$. So both independently obtained values for $\tau$ can be compared[44, 54].

In principle, diffusion of molecules perpendicular to the grating can also be observed in liquids. However, for this translational diffusion process the lifetime of the excited states of the molecules must be in the range of the diffusion time necessary to give noticeable equilibration between the peaks and the nulls of the grating. This limitation can be circumvented if the molecules are labeled by forming photoproducts[47, 74]. For the observation of very slow diffusion processes, as discussed in Section 2.3.4, this is of great importance.

The investigation of rotational reorientation and translational diffusion of molecules in liquid solvents is helpful in discussing solute conformations, solvent-solute interactions and local solvent structure[72–77]. In particular, the predictions of the Debye-Stokes-Einstein hydrodynamic theory[78] can be examined yielding the effective volume of the rotating molecule as a characteristic parameter. So far, such investigations have been done by applying time resolved absorption[79] or fluorescence depolarization spectroscopy[72, 73] in the picosecond time regime. With the transient grating technique, an additional, very accurate technique is available. If this technique is combined with fluorescence depolarization measurements differences in the excited state and ground state rotation times $\tau_R$ can be obtained. Values of up to 30% are estimated for these differences.

### 2.3.4. *Holographic Investigations of Polymers*

A recently very active field of research is the study of chain dynamics in polymer solutions or in pure polymers. It was pointed out that one has to distinguish carefully between individual and collective chain motions, *i.e.*, monomer motions respectively with or without relative displacement of the center of mass of the chains[80]. Whereas the collective motions can be observed quite well with, *e.g.* dynamic light scattering[81], for the individual chain motion described by a self-diffusion process no suitable technique has been available until recently. The reason was the very slow diffusion process with diffusion constants $D$ in the range of $10^{-7}$ to $10^{-11}$ cm$^2$ s$^{-1}$. Since the duration of the experiment is proportional to the square of the diffusion length, classical tracer techniques[82] using macroscopic diffusion distances (0.1–1 cm) imply extremely long detection times of the orders of several days or weeks. However, if the diffusion length is diminished to the microscopic fringe distances of an interference pattern (1–10 μm) the observation time will be reduced by up to 8 orders of magnitude. *Léger* and *Rondelez et al.*[47, 57, 58] have investigated successfully the self-diffusion of polystyrene chains in benzene with the holographic technique using a photochromic label on the polymer chains. After the holographic excitation pulses, the labels indicate the peaks and the nulls of the grating

which are then equilibrated by diffusion. Thus, *very slow* diffusion processes can be observed efficiently by the holographic technique. This is not only of interest for polymers in solution but also for, *e.g.*, diffusion of polymer chains—especially of low molecular weight additives like plasticizers—in a pure polymer network[59], or for biological processes such as protein diffusion on cell surfaces[83].

Another application of the holographic technique is the determination of the chain length of polymers. For example, the polymerization of butadiene single crystals has recently been observed with a holographic setup[84]. The disappearance of the hologram due to the growth of polymeric chains across the fringe pattern was investigated. So far, the chain length did not exceed the spatial resolution of the holographic grating so that only an upper limit on chain length could be determined. These investigations have been done using a CW holographic technique but could also have been done with the transient grating technique[62].

### 2.3.5. *Optical Generation of Ultrasonic Waves by Transient Gratings*

So far, local heating by the *absorption* of the two interfering light pulses has not been taken into account. With low laser power, this effect is negligible[44]. However, if high laser power is concentrated in short laser pulses considerable heating can occur in the sample[44,45,50,51,85–87]. Since this heating is due to radiationless relaxation processes of the excited molecules, it is concentrated at the local maxima of the transient interference pattern and causes a thermal expansion in this region of the sample. Thus, the density in the peaks of the grating is reduced whereas the density in the nulls is increased. As a result, a counterpropagating density wave (a standing density wave) is created, which is present even after the two exciting pulses have left the sample. In this way, an ultrasonic wave can be generated optically in the medium. It is obvious that the wavelength of this wave is determined by the fringe distance $\Lambda$. Since $\Lambda$ can be varied easily, in a broad range from about 1 mm to 0.1 μm (cf. Eq. (1)) tunable acoustic frequencies from about 3 MHz to 3 GHz can be generated by simply changing the angle of incidence $\theta$ [45]. Since the oscillating density changes of the ultrasonic wave cause oscillations of the amplitude $n_1$ of the index of refraction, the ultrasonic wave can be detected with diffracted time delayed probe pulses in the ordinary manner. Results are shown in Figure 16c for a $5 \times 10^{-5}$ M solution of malachite green in ethanol[45], where the excitation wavelength was chosen in the absorption region of malachite green.

Another mechanism for generating ultrasonic waves by transient gratings uses stimulated Brillouin scattering instead of absorption[88,89]. This mechanism is similar to stimulated Raman scattering. A higher frequency photon in one of the two interfering beams is cancelled and a lower frequency photon in the other beam is created. The result is an acoustic phonon with a frequency equal to the difference of the frequencies of the two photons. In addition to the conservation of energy, the conservation of momentum has to be satisfied. The spread in frequency in the two interfering pulses is always broad enough to allow efficient phonon generation at any angle of intersection of the two interfering beams. It has to be emphasized that in this mechanism, *no absorption* and therefore no heating occurs. There is a direct coupling of the optical electromagnetic field to the material acoustic field. Thus, this effect can be observed without absorption of the interfering beams as shown in Figure 16a for a solution of pure ethanol[45]. A more detailed description[45,88,89] of the heating effect and the stimulated Brillouin scattering shows that different time dependences of the diffracted signal arise which allow a separation of the two mechanisms. In Figure 16b, an intermediate case is shown where both mechanisms are visible because of the very low concentration of malachite green[45]. Both of the above mentioned mechanisms have to be taken into account when decaying signals of transient gratings as described in the foregoing sections show an oscillating behavior[56,85,87,89].

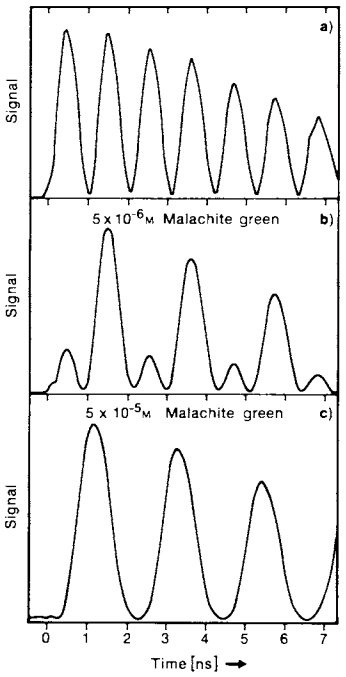

Fig. 16. Optically generated ultrasonic waves detected in (a) pure ethanol, (b) and (c) malachite green in ethanol (increasing concentrations). In pure ethanol the Brillouin scattering is responsible, whereas in concentrated solutions of malachite green, the heating effect due to absorption accounts for the generation of ultrasonic waves; (b) represents an intermediate case. After [45].

Since the ultrasonic waves can be optically generated in liquids and in solids, there are a wide variety of applications[45,50]. The technique can be used for nondestructive acoustic testing of materials, for measuring anisotropic elastic constants, acoustic attenuation, isotropic and anisotropic thermal diffusion, photoelastic constants, and a variety of other interesting material parameters.

## 3. New Materials for Holography

### 3.1. Conventional Holographic Materials

In the preceding discussion we have shown how the development and decay of a hologram can be used to obtain

information on a variety of chemical and physical processes. We will now turn this approach around and show how these studies of solid state chemistry can result in the development of new classes of holographic recording materials.

A variety of materials have been considered for holographic recording. Table 1 lists a few of these materials and the subject has been treated in a number of reviews[90,91]. One can list several desirable criteria for holographic materials. A reasonably high efficiency is desirable, but efficiencies approaching 100% are not necessary. The photosensitivity should be high, *i.e.*, the time required to reach maximum efficiency should be as short as possible. The recording material should be sensitive in wavelength regions accessible to commercially available lasers. The hologram must not be erased during reading, so some method of fixing the recorded interference pattern is necessary.

Table 1 illustrates the point that no material satisfies all of these requirements. On the other hand, a material like dichromated gelatin is perfectly adequate for many applications and has proven quite useful[92].

Table 1. Properties of some holographic recording materials.

| Material | Advantage | Disadvantage |
|---|---|---|
| dichromated gelatin | large $n_1$<br>high hologram efficiency<br>thin coatings | spectral sensitivity<br>recording speed<br>passivation<br>shelf life |
| photopolymer | light induced developing<br>no shrinkage<br>inert<br>coating ease | small $n_1$<br>thick coatings<br>spectral sensitivity<br>low hologram efficiency |
| photographic film | spectral sensitivity<br>chemical amplification<br>reproducibility | medium efficiency<br>substrate choices<br>resolution |
| photoresist | high hologram efficiency<br>coating ease<br>stability | spectral sensitivity<br>recording speed<br>linearity |
| thermoplastic | "self-developing"<br>high sensitivity<br>erasibility | spectral sensitivity<br>low hologram efficiency<br>resolution |

One severe limitation in all of the currently available materials is their spectral sensitivity. This sharply limits the number of possible laser sources that can be used directly. Dichromated gelatin, for example, cannot be used at wavelengths longer than 500 nm[92]. Responses to wavelengths as long as 748 nm have been obtained using photographic film such as Kodak 649F or 120-01[93]. Attempts to spectrally sensitize dichromated gelatin or holographic quality photographic film to longer wavelengths have so far produced unsatisfactory results. At present no single-photon volume holographic recording material with response at wavelengths longer than 750 nm exists. This is unfortunate because it means that there are no holographic materials compatible with the convenient and inexpensive injection diode lasers such as GaAlAs (800—900 nm) or GaInAsP (1.2—1.6 μm).

As a result of some of the photochemical investigations described in the first part of this paper, a new technique has been developed involving *two-photon four-level photochemistry* for the production of holograms in the red and infrared[94,95]. In addition to their spectral sensitivity, these materials have the advantage that they are self-developing and require no fixing step. Furthermore, the hologram can be gated off and on by utilizing an auxiliary light source.

### 3.2. Two-Photon Four-Level (2P4L) Photochemistry for Holographic Recording

Most holographic recording materials utilize photochemical reactions in which the rate of product formation depends linearly on laser light intensity. The corresponding 1P2L scheme has already been shown in Figure 5. Only two levels of the molecule $A_1$ are involved in the photochemistry. It can be shown[23] that the overall rate constant $k$ for product formation is proportional to the molar extinction coefficient $\varepsilon$ and is linear in laser intensity $I$ as previously indicated:

$$k \sim \varepsilon I. \tag{16}$$

Now consider using such a two-level medium for holographic recording. Such an experiment is shown schematically in Figures 1 and 5. Normally the reconstruction wave will be at the same wavelength as the object and reference waves. This means that the reconstruction wave itself can also produce photochemistry. This photochemistry will result in gradual erasure of the hologram. There are two ways of eliminating or minimizing the effect of erasure during reading for 1P2L materials. The first, and less satisfactory method, is simply to reduce the reading light intensity so that the photochemistry that occurs during reading is reduced to an acceptable level. This is, of course, impractical when the hologram is meant to be semi-permanent. The most commonly used method of eliminating erasure is to fix the holographic image permanently. This is done in dichromated gelatin and silver halide films by wet chemical processes.

Another disadvantage of 1P2L materials arises when one considers extending their sensitivity into the red and infrared regions. All of the energy used to produce photochemistry must come from *one* absorbed photon (cf. Fig. 5). Very few systems undergo efficient photochemistry in the red or infrared, and those few systems that do also tend to be thermally unstable. This point is illustrated in Table 2, where laser wavelengths and bond energies are compared. Both AIBN and hexaphenylethane shown in the table are thermally unstable.

It has been recognized by previous workers that many of the problems with the one-photon systems are either not present or are significantly reduced in importance when the hologram forming photochemical process involves the absorption of two or more photons[96,97]. These investigators employed a two-photon three-level (2P3L) system. The energy level diagram for such a system is similar to the four level scheme shown in Figure 5 with the difference that $A_1^*$ and $A_2$ have now been combined into a single level. In a three-level system, the recording medium is simul-

Table 2. Bond energy and related wavelengths of various lasers.

| Bond | Bond-Energy [a] [kJ/mol] | Wavelength [nm] | Laser | Wavelength range [nm] |
|---|---|---|---|---|
| C–H | 410 | 291.7 | | |
| C–C | 347.3 | 344.5 | $Ar^+$ (UV) | 334-364 |
| Cl–Cl | 239.3 | 499.9 | $Ar^+$ (VIS) | 458-529 |
| Br–Br | 189.1 | 632.8 | HeNe | 632.8 |
| | 140.6 | 850 | GaAlAs | 800-900 |
| AIBN | 129.7 | 992 | | |
| | 112.6 | 1064 | Nd-YAG<br>Nd-Glass | 1064 |
| $(C_6H_5)_3C-C(C_6H_5)_3$ | 50.2 | 1906 | | |

[a] Value for azobisisobutyronitrile (AIBN) from F. M. Lewis, M. S. Matheson, *J. Am. Chem. Soc. 71* (1949) 747. All other values from S. W. Benson, *J. Chem. Educ. 42* (1965) 503.

taneously exposed to radiation at two different optical frequencies $\omega_1$ and $\omega_2$ with intensities $I_1$ and $I_2$. The rate constant $k$ for product formation is now given by

$$k \propto \varepsilon_1 I_1 \varepsilon_2 I_2 \tau \tag{17}$$

where $\varepsilon_1$ and $\varepsilon_2$ are the respective molar extinction coefficients at the two frequencies $\omega_1$ and $\omega_2$. $\tau$ is the lifetime of the intermediate state.

Consider the simple case where $\omega_1 = \omega_2$. The photochemistry is then proportional to $I_1^2$. Any reduction in the laser intensity during reading would have its effect on hologram erasure reduced by the square of this factor. In addition, the energy to produce photochemistry is now supplied by two laser photons and it should not be difficult to find thermally stable two-photon systems that could be used with red or infrared radiation.

Perhaps a more interesting case is when $\omega_1 > \omega_2$, *i.e.* when the energy from the ground level to the intermediate level is greater than from the intermediate level to the final level. The medium is illuminated by reference and object beams at a frequency $\omega_2$, as well as by an additional uniform and not necessarily coherent beam at $\omega_1$. Note that we have treated this case in another context in the discussion associated with Figure 12. Holograms formed using this approach have several advantageous properties. As for the case where $\omega_1 = \omega_2$, these materials can be written with red or infrared lasers. Most of the energy needed to produce photochemistry is supplied by the $\omega_1$ photon which can be in the ultraviolet. Another important advantage is that the recording medium is sensitive to the $\omega_2$ radiation only when $\omega_1$ radiation is present. Thus, during the reconstruction of the image for readout no additional deleterious exposure of the recording medium takes place. Also, temporal or spatial gating of the recording can be achieved by masking or modulating the $\omega_1$ beam.

The first demonstrations of two-photon holographic recording were in $LiNbO_3$ and KTN ($KTa_xNb_{1-x}O_3$), where the recording process was the multi-photon photorefractive effect[96,97]. This effect involves the excitation of carriers within the crystal lattice to produce a macroscopic polarization change that induces a modulation of the index of refraction *via* the electro-optic effect. The major disadvantage of these materials is the lack of real intermediate energy levels between the ground and final states. Since a resonant enhancement from these intermediate levels is not present, the two-photon absorption processes are extremely weak and peak exposure intensities greater than 5 $MW/cm^2$ are necessary. A factor of 100 improvement in sensitivity was demonstrated by doping the $LiNbO_3$ crystal with $Cr^{3+}$, thereby converting the intermediate level from a virtual to a real level with a 500 ns lifetime[98]. The resulting sensitivity, however, was still several orders of magnitude too low for CW two-photon holography.

It can be shown[95] that *no* 2P3L system can be sensitive enough to be used for holographic recording with CW lasers. This can be seen qualitatively by considering the role played by the intermediate state. For optimum production of photochemical products one wants the population in this state to be as large as possible. This means that the extinction coefficient $\varepsilon_1$ should be large and the lifetime $\tau$ of this state should be long. However, these two quantities are not independent since lifetime and absorption strength are inversely proportional to each other. There is thus an upper limit to the rate $k$ that one can obtain for a 2P3L system.

To produce two-photon holographic systems that can be used with CW laser sources, one must circumvent these constraints. One way of doing this is to use the two-photon four-level system (Fig. 5). There are now two intermediate levels $A_1^*$ and $A_2$. Level $A_1^*$ may have a large oscillator strength with respect to transitions from the ground state, while level $A_2$ may have a long lifetime. It thus should be possible to find a two-photon four-level system with which one can produce holograms using only a few milliwatts of CW laser power.

A variety of organic materials have energy level systems arranged as shown in Figure 5. States $A_1$ and $A_1^*$ are the lowest ground state and an excited singlet state of the molecule, respectively. $A_2$ and $A_2^*$ may be ground and excited states of an isomeric form of the molecule or they can be excited triplet states. In fact, such systems are described in Section 2.2.5. In that earlier discussion we were interested in using holography to investigate excited state photochemistry. Here we note that benzophenone[29] and carbazole[94] can be used in two-photon four-level holographic recording materials.

The holographic system that has been most thoroughly investigated in this context is biacetyl dissolved in a polymer host matrix[95]. The relevant absorption spectra of biacetyl are shown in Figure 17. The initial photon excites the

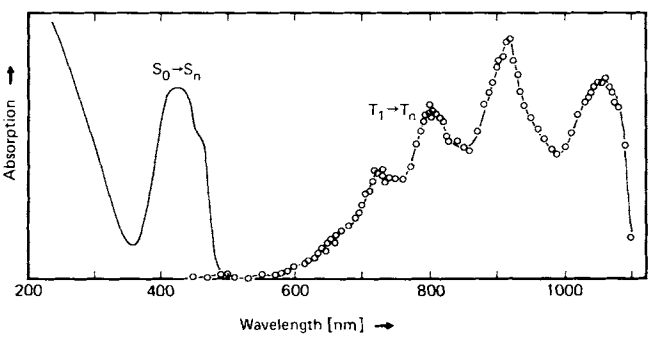

Fig. 17. The $S_0 \rightarrow S_n$ and $T_1 \rightarrow T_n$ absorption spectra for biacetyl. The $S_0 \rightarrow S_n$ absorption is for a 15% concentration of biacetyl in a 300-μm thick sample of polycyanoacrylate and the $T_1 \rightarrow T_n$ absorption is for a $3.9 \times 10^{-2}$ M solution of biacetyl in carbon tetrachloride.

biacetyl molecule from its ground state to an excited singlet state $S_n$. This can be done according to the figure, provided the exciting wavelength is shorter than 500 nm. The second photon produces the hologram by exciting the biacetyl from $T_1 \rightarrow T_n$. This occurs if the second wavelength is between 600 and 1100 nm. The hologram is produced as a result of a photochemical reaction that occurs from $T_n$. Hologram formation in biacetyl[95] is illustrated in Figure 18. The experimental arrangement was similar to the one

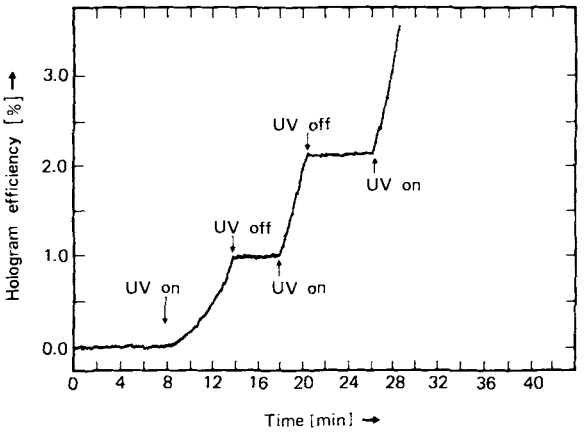

Fig. 18. Gating of a hologram in a 15% biacetyl in polycyanoacrylate sample.

sketched in Figure 12. The matrix in which the biacetyl was dissolved for these experiments was a polycyanoacrylate polymer. Irradiation at $\omega_1$ was provided in the UV by a medium pressure Hg-lamp. The infrared source at $\omega_2$ was a krypton laser operating at 752.5 nm. At time $t=0$ only the IR source illuminates the sample. Since this light is not absorbed by a ground state biacetyl molecule, no hologram is produced. When the UV source is turned on hologram formation begins. When it is turned off the hologram growth is gated off. Holograms formed in this way require no chemical development step. They are "developed" simply by turning off the UV source.

### 3.3. Applications of 2P4L Materials

In this section we will illustrate several applications of two-photon four-level infrared holographic materials. The most familiar application for materials of this type is in the production of three-dimensional images. The recording of an extended image using the biacetyl/polycyanoacrylate system is shown in Figure 19[99]. The hologram was produced and reconstructed at 752.5 nm. The advantage of recording extended holographic images in this way lies in the possibility of spatially or temporally gating the process. By spatially gating hologram formation one can imagine the production of holographic movies with frame to frame exposures gated on and off with the UV source. Temporal gating, of course, provides the potential for recording holograms at precisely well-defined instants in time.

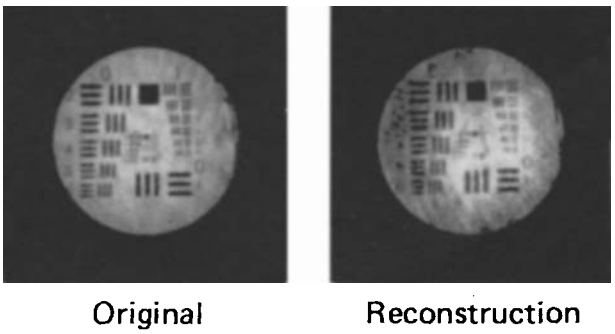

Fig. 19. Two-photon hologram of a resolution chart.

In the future holograms will probably be most widely used for the production of a variety of kinds of optical elements for the deflection and focusing of light. Holographic optical elements (HOEs) utilize the fact that a hologram is capable of transforming a family of incident waves. The simplest example of a HOE is the holographic grating formed by the interference of plane object and reference waves. This type of HOE was described in Section 2.1, and later its use for monitoring photochemistry was treated. Another example is the holographic lens that is formed by the interference of a spherical object wave with a spherical or plane reference wave. Figure 20 shows the recording geometry for the production of an off-axis holographic lens. A hologram is produced from the "real" glass lens. If this hologram is illuminated it will work like a lens; thus a copy of the lens is obtained. The properties and applications of HOEs have been the subject of several recent reviews[100].

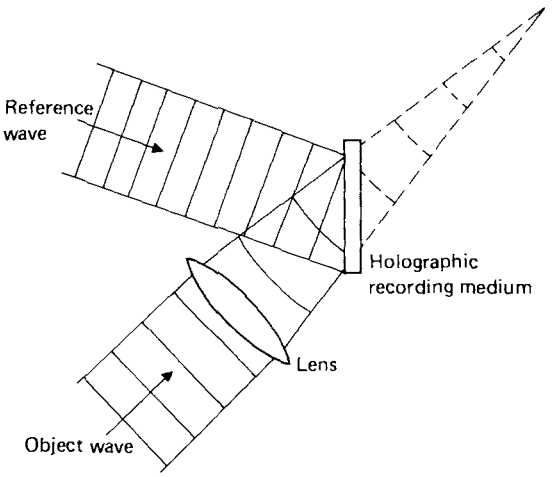

Fig. 20. The arrangement of the coherent light waves necessary to record the holographic image of a lens.

The fundamental advantage of HOEs is that a complex and expensive optical system can be replaced by a cheap and simply fabricated piece of plastic. This is a particularly important consideration when one wishes to use the HOE with an inexpensive injection diode laser.

As a final example of the use of the infrared hologram recording technique described above, we consider the fabrication of integrated optical devices[101]. The general principal of these devices is illustrated in Figure 21. The two interfering infrared beams intersect inside a narrow dielectric waveguide formed from a thin biacetyl/polycyanoacrylate layer between glass plates. Since the infrared beams are confined within a several micron thick dielectric layer, power densities can be quite high. Input powers of a few milliwatts can result in waveguide power densities of a few

kilowatts/cm$^2$. This is particularly important for the two-photon four-level materials that tend to have low recording sensitivities. Optical waveguide directional couplers have been produced in this way[102].

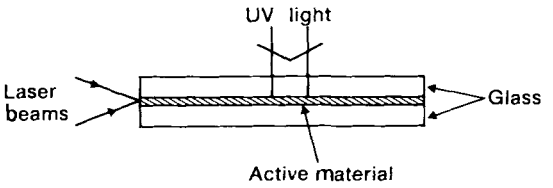

Fig. 21. Formation of a thin-film waveguide directional coupler, whose active material is suitable for two-photon four-level photochemistry.

## 4. Conclusion and Outlook

In this review we have discussed a variety of material parameters that can be studied using holographic grating techniques. Excited state photochemistry, energy transfer, rotational relaxation, charge transport and polymerization can all be conveniently studied by holography. One can use CW or pulsed versions of the technique.

The holographic technique has several distinct advantages over conventional spectroscopic methods. The CW technique is ideally suited for investigating solid state photochemical reactions such as photopolymerization, and photodegradation. Pulsed holography can be used to follow dynamic processes such as diffusion. Because extremely small sample areas are used for these measurements, the method can for example be used to follow energy transfer or diffusion in biological systems.

The holographic technique measures diffusion or energy transport in directions perpendicular to the fringe planes. Because this direction can be varied by varying the incident plane formed by the interfering beams, holography can be used in a variety of applications where diffusion or energy transport is anisotropic. The use of pulsed holography to produce ultrasonic waves permits one to obtain values for the elastic constants and acoustic attenuation. In this way holography can be used as a non-destructive testing method.

In addition to the above uses of holography for physical measurements, we have shown in this paper, how the fundamental holographic technique can be used to suggest new classes of holographic recording materials. This point has been illustrated by a discussion of infrared sensitive two-photon four-level holographic recording materials. Because the recording process in these materials can be gated on or off, they offer new possibilities for holographic information recording. In addition they are sensitive in the wavelength regime of the widely used semiconductor lasers. These new holographic materials can be used as passive elements in integrated optics and optical communication. Current two-photon four-level photochemical recording materials are not yet sensitive enough to be widely practical. Much work needs to be done to understand this two-photon recording process and to identify more sensitive materials.

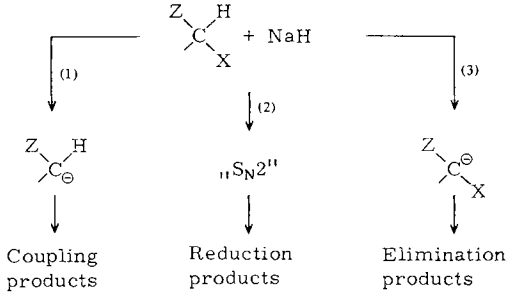
# Complex Reducing Agents (CRA's)— Versatile, Novel Ways of Using Sodium Hydride in Organic Synthesis

**New synthetic methods (39)**

By Paul Caubère*

Why do we hardly use the simplest and, at the same time, inexpensive reducing agent sodium hydride in organic chemistry? To this question the answer is invariably: "It is too basic". In this progress report we describe work we have performed aimed at controlling the basicity of NaH using sodium alcoholates and metal salts. The *c*omplex *r*educing *a*gents (CRA's) developed (symbolized NaH-RONa-$MX_n$) allow organic halides, alkenes, alkynes and ketones to be reduced selectively. Highly regioselective 1,4- and 1,2-reductions of α,β-unsaturated ketones are easily performed using appropriate metal salts. Modified CRA's have proved to be excellent hydrosilylating reagents for carbonyl groups, non-pyrophoric heterogeneous hydrogenation catalysts, coupling reagents for aryl and vinyl halides, and reagents for the carbonylation of organic halides under very mild conditions. The study of these reactions opened up the field to phase-transfer-catalyzed photostimulated carbonylations as well as to $S_{RN}1$ reactions of metalates.—Thus, starting from the simple sodium hydride a large number of useful reagents have become accessible.

## 1. Introduction



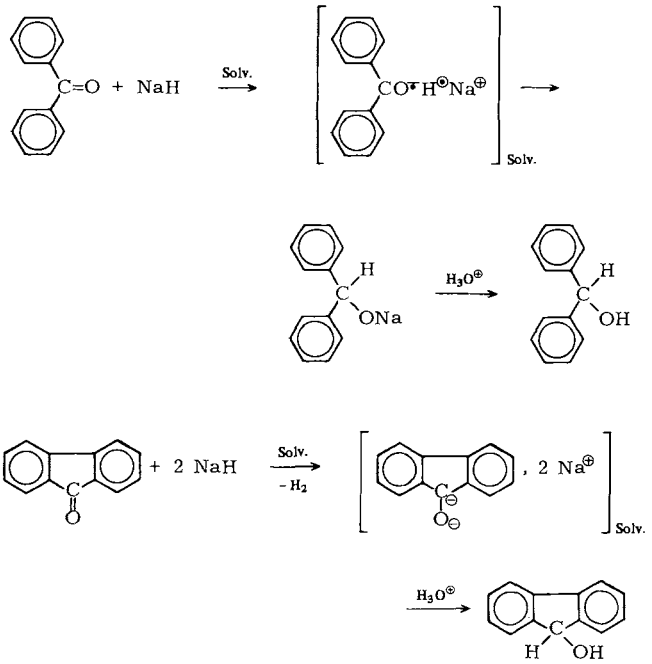
### 1.1. General Considerations

Sodium hydride is a long-known, inexpensive reagent easily prepared on a large scale from sodium and hydrogen. It is generally used in organic chemistry only as a base for proton abstraction[1]. Although a few substrates may be reduced by NaH, the reactions are often slow and the yields far from excellent[1,2]; nevertheless, these reductions indicate the potential reducing properties of NaH which, unfortunately, are masked by the basic ones.

Thus to be able to use this reagent for reductions the following have to be achieved: 1) its ability to undergo one-electron transfer must be increased and 2) its basic properties must be masked. In the present review we shall describe how these problems could be solved using a combination of observations, experiments, and intuition.

### 1.2. Reducing Properties of Sodium Hydride in Aprotic Solvents

During investigations on base-promoted eliminations in hexamethylphosphoric triamide (HMPA)[3] (Warning: suspected carcinogen[4]) it was observed that NaH reacted with benzyl bromide to give bibenzyl and a small amount of toluene (reduction product), instead of the expected *trans*-stilbene (elimination product). This unexpected reaction was thoroughly studied using substrates possessing, simultaneously, a reactive halogen and hydrogens of varying acidity. With less acidic hydrogens the soft base[5] $H^{\ominus}$ attacks the halogen atom (soft acid) and the halogen-substituted carbon atom, leading to couplings (reaction (1)) and reductions (reaction (2)), respectively. On the other hand, if sufficiently acidic hydrogens are present normal acid-base reactions occur (reaction (3))[6,7]. Mechanistic studies[6] led us to propose an ionic mechanism (Scheme 1).



Scheme 1. X = halogen.

One-electron transfer from $H^{\ominus}$ to the substrate is presumably the preliminary step to halide loss. To confirm this hypothesis we studied the reaction of NaH with *gem*-dihalocyclopropanes in HMPA: a reaction which has been well explored in connection with radical and "ionic" reductions[8]. We found[6,9] that dibromides could be reduced to monobromides and that the reductions could take place by way of radicals trapped in solvent cages. Support for one-electron transfer from $H^{\ominus}$ was provided by the reduction of carbonyl derivatives in aprotic solvents[10]. Indeed, ketyl radicals were detected by ESR spectroscopy in the reduction of benzophenone and fluorenone. Moreover, benzophenone incorporated an electron and a hydrogen atom from NaH, but fluorenone accepted two electrons to form a dianion. These experiments are concordant with the mechanism depicted in Scheme 2.

An extremely unusual observation convinced us of the propensity of NaH to undergo one-electron transfer reactions: careful addition of aqueous HMPA to a suspension of NaH (free from Na) in HMPA led to blue solutions of solvated electrons[6]. This indicates that in the presence of water solvated by HMPA hydride ions could lose electrons, which in turn are solvated by HMPA (for interpretation of this reaction, see Section 2.10).

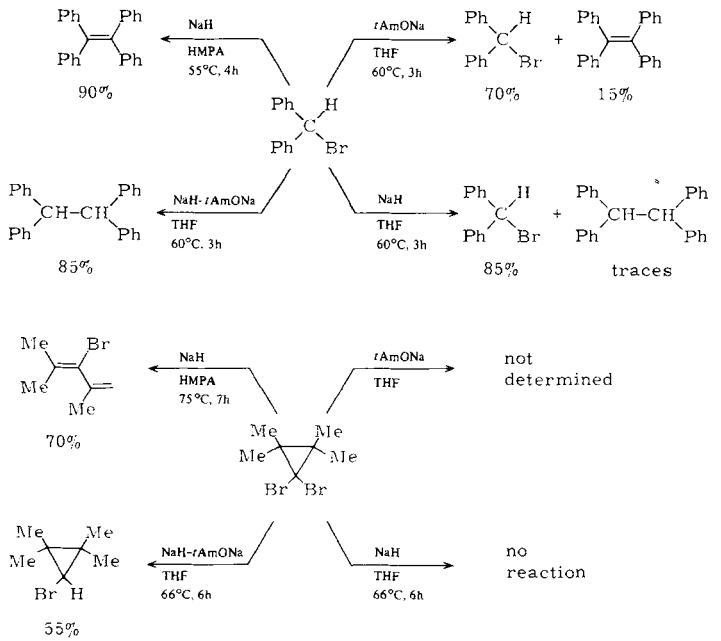


Scheme 2. Solv. = solvent = HMPA.

### 1.3. Activated Sodium Hydride "NaH-RONa"

In addition to investigating the reducing properties of NaH, we studied the system NaH-RONa (we term the alcoholate RONa an activating agent). Indeed, at that time we had already established the concept of the synergism of bases and had shown that $NaNH_2$-RONa ("complex bases"[11]) had properties remarkably different from those of the individual components. If such a synergism were to occur between NaH and RONa, a parallel increase of the basic or reducing properties would result.

Major differences appeared between the properties of activated NaH (NaH-RONa (2:1)), which is as readily prepared as complex bases[11], and those of NaH and

Scheme 3.

RONa. The following features emerged[7,9,10,12]: 1) sodium *tert*-amylalcoholate (*t*AmONa) was found to be an excellent activating agent; 2) in HMPA, NaH-*t*AmONa was a stronger base than either NaH or *t*AmONa; 3) although NaH was very weakly reactive in tetrahydrofuran (THF), NaH-*t*AmONa showed marked reducing properties (Scheme 3); 4) other things being equal, NaH-*t*AmONa in THF had comparable or even better reducing properties than NaH in HMPA (Scheme 3). Finally, since ketyl radicals were observed during the reduction of aromatic ketones by NaH-*t*AmONa in THF[10] we concluded that in THF one-electron transfer from NaH could be amplified by sodium alcoholates.

Unfortunately, all the results obtained up to this point, interesting though they were, did not give us any hope of finding general synthetic applications for the reagent; indeed, even in THF, NaH-RONa was still too basic. Fortunately, as we shall see later, a solution was found to this problem in the course of investigations directed towards a somewhat different target.

## 2. Complex Reducing Agents (CRA's) "NaH-RONa-$MX_n$" and Related Reagents

### 2.1. Introductory Remarks

In the hope of preparing transition-metal hydride derivatives, we studied the reactivity of NaH with Cu salts. The results were disappointing and difficult to reproduce. We therefore tested whether NaH-*t*AmONa could be used in place of NaH. Moreover, it was felt that the presence of alcoholates in the reagent might enhance its reducing properties.

This time we were not disappointed. First experiments[13] showed that addition of copper salts to NaH-*t*AmONa at 50–60 °C in THF reproducibly led to formation of brown-black reagents which slowly reduced aromatic halides. Since these first results the number of reagents and applications have grown considerably.

Nomenclature: *c*omplex *r*educing *a*gents will be abbreviated as CRA's or MCRA's (metal atom specified) or as RONa·MCRA's (alcoholate and metal atom specified); if necessary, we symbolize RONa·MCRA as NaH-RONa-$MX_n$, although, of course, $MX_n$ is not present as such in the reagent. The abbreviation RONa·MCRA(x/y/z) indicates that NaH/RONa/$MX_n$ (in that order) is equal to the molar ratio x/y/z. This ratio refers to the ratios of the starting reagents and has nothing to do with the actual constitution of the CRA (see Section 2.10).

### 2.2. Main Characteristics of CRA's

CRA's are readily prepared from commercial reagents. Thus, it is sufficient to add, in the chosen solvent, anhydrous $MX_n$ to NaH-RONa, or to add the alcohol to the suspension obtained by mixing NaH and $MX_n$. After warming, the reagents are ready for use[14]. CRA's are heterogeneous reagents, whose reactive moiety seems, generally, to be located in the solid fraction. Their reactivity is a function of the solvent; the ratio of the reagents; the na-

ture of the alcoholate; and, above all, the nature of the metal salt. Advantage may be reaped from this: a palette of reducing agents with graduated properties can be obtained. Considering the large number of metal salts which led to CRA's and their various areas of application, we are presently far from having exhausted all the possibilities. The properties of CRA's[14-17] are briefly summarized below.

CRA's can be prepared starting from the halides or acetates of Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, Zr, Mo, Pd, and W. Using the chosen test reaction, the reduction of 1-bromonaphthalene, we observed that, besides naphthalene, noticeable amounts of 1,1'-binaphtyl were formed with Fe-, Cu-, Cd-, and ZnCRA's.

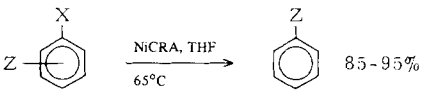
The influence of the solvent is not easy to predict; however it may be stated that dimethoxyethane (DME) usually leads to more reactive CRA's than THF. In general, it appears that the reducing properties decrease with the polarity of the solvent (from DME, THF to benzene and cyclohexane).

When metal complexes are used as starting materials instead of salts, the ligands seem to have a strong influence on the properties of CRA's. For example, the CRA prepared from NaH, *t*AmONa, and $NiCl_2$ reacted poorly with 1-bromonaphthalene, whereas the reagent obtained from $(Ph_3P)_2NiCl_2$ led to very good yields of naphthalene and binaphtyl. The formation of large amounts of binaphtyl was surprising, since all other reagents prepared from Ni salts, such as $Ni(OAc)_2$, only afforded naphthalene. The following interpretation is proposed: during preparation of CRA from Ni salts, low oxidation-state Ni species are formed which occur as reducing species later in the reaction. On the other hand, in the presence of $Ph_3P$ [from $(Ph_3P)_2NiCl_2$] a fraction of the low oxidation-state metal species must be trapped as complexes capable of coupling with organic halides. Thus, in the presence of sufficient amounts of appropriate ligands formation of CRA's could lead to formation of new reagents possessing properties other than reducing. This hypothesis has been verified experimentally (see Sections 2.4 and 2.9).

We must now underline a very important point concerning the complexes thus obtained. Even if they are well-known complexes it must be borne in mind that they are generated in a somewhat unusual environment! Thus, completely unexpected properties may occur. For an example see Section 2.9.

For CRA's themselves, the influence of reactant ratios has been determined experimentally for each type of reaction. Presently we are only at the initial stages of their interpretation (Section 2.10).

For alcoholates a short study showed that the variation of activating properties follows a trend which resembles that found for complex bases[11]. Thus *t*AmONa, *t*BuONa, *i*PrONa, and $Et(OCH_2CH_2)_2ONa$ exhibit excellent activating properties. Most of the reactions studied were performed using tertiary alcoholates to avoid possible redox side reactions.



Interestingly, a number of CRA's reactions may be performed catalytically or semi-catalytically.

Finally, it should be noted that the basicity of CRA's appears to be weakened—a very important point for synthetic uses.

### 2.3. Reduction of Organic Halides by CRA's

All reagents used in this section were prepared from *t*AmONa.

NiCRA(4/2/1) (NaH, *t*AmONa, and $Ni(OAc)_2$ in molar ratio 4:2:1) reduced aromatic iodides, bromides, chlorides, and even fluorides under mild conditions and in good yields (Scheme 4)[15]. CoCRA (4/2/1) did not reduce fluorides and reduced chlorides slowly, although in good yields.

| X | Z | *t* [h] | X | Z | *t* [h] |
|---|---|---|---|---|---|
| F | H | 6 | Br | 4-Me | 1 |
| F | 4-MeO | 12 | Br | 2-MeO | 1 |
| Cl | 2-Me | 1 | Br | 4-MeO | 1 |
| Cl | 3-Me | 1 | Br | 2-COOH | 1-2 |
| Cl | 4-Me | 1.5 | Br | 3-COOH | 1-2 |
| | | | Br | 4-COOH | 12-18 |

Scheme 4. Reaction times *t* are for comparable amounts of substrate.

*gem*-Dibromocyclopropanes were easily reduced to the corresponding monobromo derivatives by NiCRA and CoCRA. Even the reduction of 7,7-dichloronorcarane took place under mild conditions with NiCRA (4/2/1)[16]. The values of the *cis/trans*-ratios of 7-bromonorcaranes obtained from 7,7-dibromonorcarane varied between 2.3 and 3, indicating the intervention of free radicals[8] in the reductions. It was also shown that these reductions could be performed with catalytic amounts of metal salts (yields were *ca.* 400% with Co and *ca.* 500% with Ni).

Finally, the reduction and selective reduction of alkyl, vinyl, benzyl, and allyl halides[17,18] were examined in more detail. The following salient features emerged:

Of the CRA's capable of reducing alkyl halides under mild conditions (particularly CRA's containing V, Fe, Co, Ni, Zn, and Cd), NiCRA(4/2/1) and ZnCRA(4/2/1) were selected: the reactions were performed in THF or DME.

| R | X | *T* [°C] | *t* [h] | Yield [%] |
|---|---|---|---|---|
| 1-Octyl | Br | 20 | 0.5 | 90-95 |

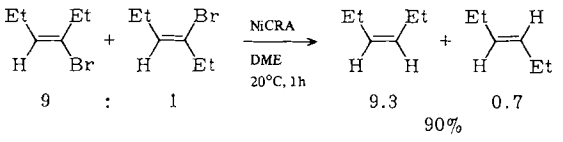
| 2-Cyclohexenyl | Br | −40 | 0.08 | 90 |

[a] In addition, 30-40% 1-methylcyclohexene is formed. [b] Reduction with ZnCRA in THF.

Scheme 5. Reaction times *t* are for comparable amounts of substrate.

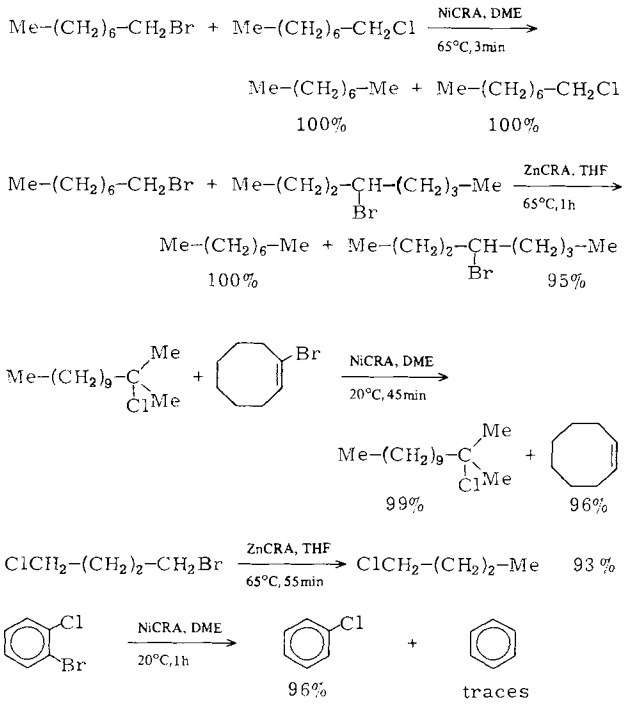
With NiCRA, the general reactivity followed the trends RI > RBr > RCl and primary, secondary > tertiary. It is noteworthy that even tertiary halides were reduced under rather mild conditions. ZnCRA reduced only primary halides, following the trend RI > RBr ≫ RCl.



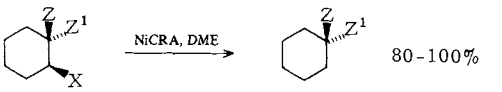
Benzyl and allyl halides were reduced by NiCRA and ZnCRA. In Scheme 5 some significant examples are given.

Vinyl chlorides and bromides were reduced highly stereoselectively under extremely mild conditions in excellent yields by NiCRA (Scheme 6).

Reductions could be performed with NiCRA but not with ZnCRA in the presence of catalytic amounts of metal salts.



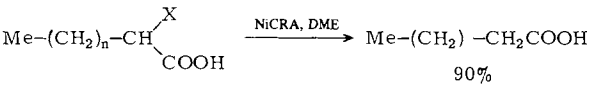
| R | X | n | $T$ [°C] | $t$ [min] |
|---|---|---|---|---|
| H | Br | 2 | 20 | 30 |
| H | Br | 3 | 20 | 60 |
| H | Cl | 2 | 45 | 25 |
| 4-Me | Cl | 2 | 45 | 10 |



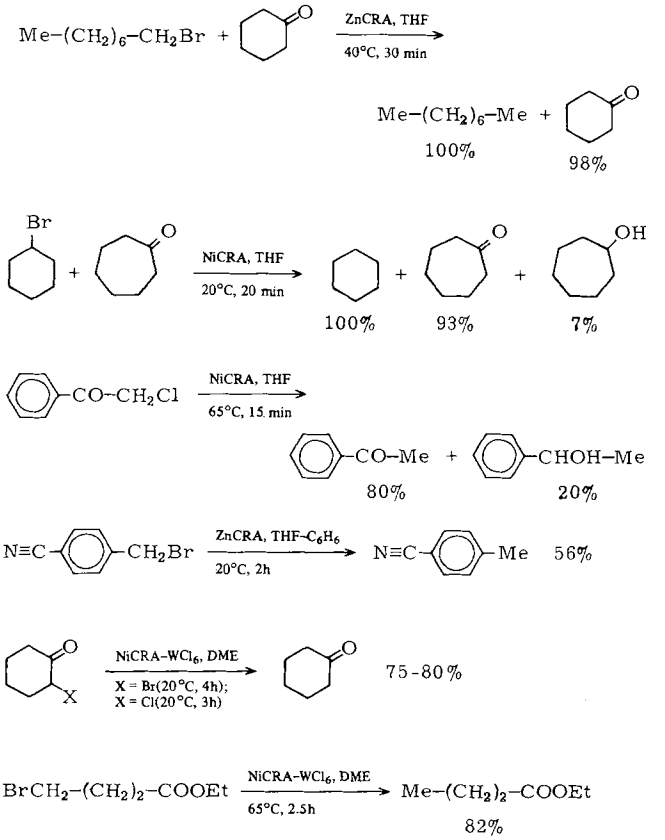
Scheme 6.

The differences in reactivity between the various halides were sufficient to permit selective reductions (Scheme 7). Particularly striking was the reduction of *o*-bromochlorobenzene to chlorobenzene, which took place readily without formation of benzyne.

Scheme 7.



Finally, the unique reactivity of NiCRA and ZnCRA with organic halides is such that carbon-halogen bonds can be selectively reduced in the presence of numerous functional groups (Scheme 8).



| X | Z | Z¹ | $T$ [°C] | $t$ [min] |
|---|---|---|---|---|

|---|---|---|---|
| Br | 8 | 20 | 2 |
| Cl | 1 | 20 | 30 |

Scheme 8. Reaction times $t$ are for comparable amounts of substrate.

It is notable that no eliminations were observed in the reduction of β-haloethers and α-haloketals. A number of α-haloketones and γ-haloesters were too sensitive to be reduced by the usual CRA's; addition of $WCl_6$ to NiCRA enabled "normal" reductions to be performed (cf. the last two equations of Scheme 8), but the role played by $WCl_6$ remains obscure.

How should CRA's be classified among other known reducing agents?

Considerable effort has been devoted to the use of metal hydrides as reducing agents for organic halides[19a]; alkali metal aluminum hydrides have been extensively studied[19]. $LiAlH_4$ itself readily reduces reactive halides and, less readily, secondary bromides, *e.g.* bromocyclohexane is particularly resistant to reduction. Tertiary, aromatic, and alkenyl halides are reduced with difficulty, unless they are iodides. More efficient are a number of alkoxyaluminum hydrides[19a, i, n], but these are of limited value for the reduction of tertiary, vinyl, and aromatic halides.

Finally, the ability of aluminum hydrides to reduce numerous functional groups limits their use for the selective removal of halogen atoms.

The less reactive borohydrides $LiBH_4$ and $NaBH_4$[19a, b, g-i] are more selective, but more drastic conditions are often necessary[19a, h, 20a-c]. Note that with these reagents "indirect reduction" (dehydrohalogenation-hydroboration) may be observed[19a, h]; these hydrides lead to low yields of reduction products with a number of bromides, chlorides and, above all, with aromatic and alkenyl halides.

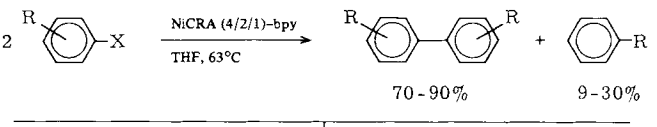
Modification of simple borohydrides leads to more efficient reducing agents such as $M[BH_3CN]$ (M = Na, K, $Bu_4N$), 9-BBNCN (9-cyano-9-hydrido-9-borabicyclo[3.3.1]nonane), or $Li[BHEt_3]$ (superhydride).

In HMPA[4] benzyl, allyl, as well as primary and secondary halides are reduced by an excess of cyanoborohydrides[20e] (treatment for 24 h at 70–100 °C is necessary with the less reactive halides). These hydrides are much less successful in reducing alkenyl, aromatic, and a number of tertiary halides. On the other hand, they are selective, since most other functional groups do not react under the conditions used.

Note that reducing agents such as the ate-complex prepared from 9-borabicyclo[3.3.1]nonane selectively reduce benzyl, allyl, and tertiary halides. There is evidence to suggest formation of a carbocation intermediate[20f]. $Li[BHEt_3]$[19a, g-i] is a convenient reagent for the reduction of reactive halides. Tertiary halides are reduced slowly, since elimination can be a competing reaction and vinyl or aryl halides are inert.

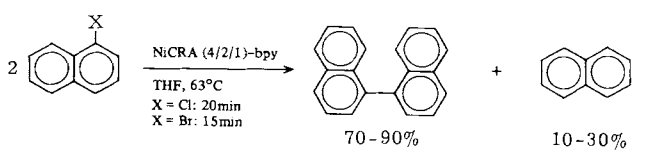
$Cr^{II}$ salts[19a, 21] and organotin hydrides[19a, 22] are valuable reagents for the selective reduction of aliphatic and reactive halides, but are much less reactive with alkenyl and aromatic halides. Moreover, a number of $Cr^{II}$ salts are unstable and use of tin hydrides often necessitates high reduction temperatures. Also, some problems can arise in disposing of the tin residues (see the comments given in [19f]).

The results given in Schemes 4–8 show that CRA's compare favorably with the above reducing agents. Generally, our reagents are more efficient with less reactive halides; in their selectivity they appear, with a few exceptions, to be as selective as other reducing agents.



A large number of transition-metal species have also been reported to reduce organic halides[19a, 23]; among these the reagents obtained by addition of metal salts to aluminum hydrides or borohydrides are directly comparable to CRA's.

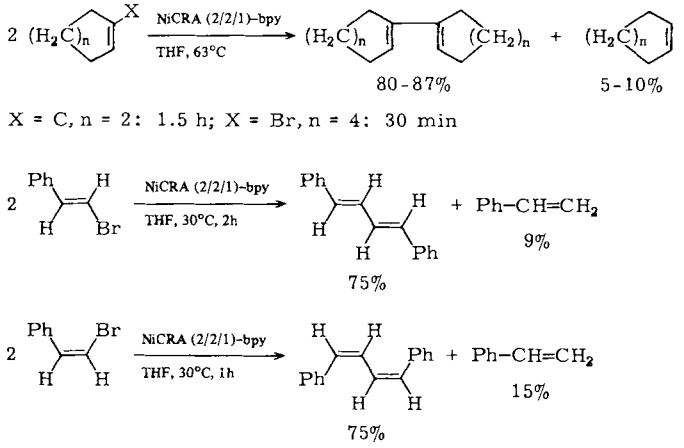
Lithium copper hydrides $Li_nCuH_{n+1}$ (from MeLi, CuI, and $LiAlH_4$)[24a] exhibit different reactivities. $Li_4CuH_5$ (the most reactive) reduces cyclohexyl, vinyl, and aryl chlorides poorly at room temperature, even after 24 h. The reagents obtained by addition of a series of transition-metal salts to $LiAlH_4$[24b, c] reduce aliphatic as well as aromatic halides, including chlorides; however, unreactive halides necessitate long reaction times, and no selective reductions have been studied. The reagent prepared from $Li[AlH(OMe)_3]$ and CuI[24d] essentially reduces organic bromides. Parallel experiments have been performed with $NaBH_4$[19a, 25]. The most reactive reagents were obtained with $Ni^0$[25b] and, above all, Pd derivatives[25a]; however, weakly reactive halides, such as arenes, require a very large excess of $NaBH_4$ and reaction conditions conducive to the decomposition of the borohydride[25a]. More reactive is the reagent obtained from $K[BHsBu_3]$ and CuI[25e]; however, it must be used in large excess with aromatic chlorides and also reduces keto and ester groups.



Here too, it seems that CRA's compare favorably with the last mentioned reagents. As a general comment it must be underlined that CRA's can be prepared readily from commercial starting materials and are, on the whole, less expensive than most other reducing agents.

### 2.4. Use of Ligand-Modified MCRA's (MCRAL's) to Couple Organic Halides

Stimulated by the reactions observed with $(Ph_3P)_2NiCl_2$ (Section 2.2), we first prepared *t*AmONa · NiCRA(4/2/1) in the presence of $Ph_3P$. The addition of 1-bromonaphthalene to the reagent thus obtained led to 70% of 1,1'-binaphthyl and to only 25% of naphthalene[17]. In order to avoid side reactions, such as transfer of phenyl from $Ph_3P$, the latter was replaced by 2,2'-bipyridine, leading to satisfying results (Scheme 9)[17, 26].



| X | R | *t* [h] | X | R | *t* [h] |
|---|---|---|---|---|---|
| Br | H | 0.5 | Cl | H | 2.5 |
| Br | 2-MeO | 0.5 | Cl | 2-Me | 8 |
| Br | 3-MeO | 0.5 | Cl | 3-Me | 8 |
| Br | 4-MeO | 0.5 | Cl | 4-Me | 8 |

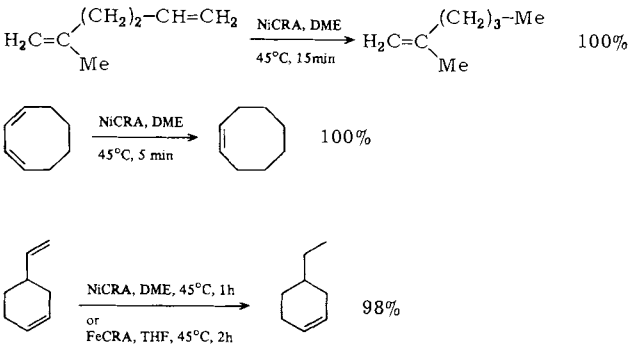
Scheme 9. Reaction times *t* are for comparable amounts of substrate.

A comparison of Schemes 4 and 9 underlines the substantial difference between CRA's and the new reagents, which we term MCRAL (L = ligand).

Some problems arose with NiCRAL and their reactions with vinyl halides: NiCRA is too powerful a reducing agent. Since NiCRA (4/2/1) contains NaH (see Section 2.10) but NiCRA (2/2/1) does not, we used the latter reagent and succeeded in performing coupling reactions (Scheme 10)[26b].

Scheme 10.

It is noteworthy that the reactions took place without isomerization.

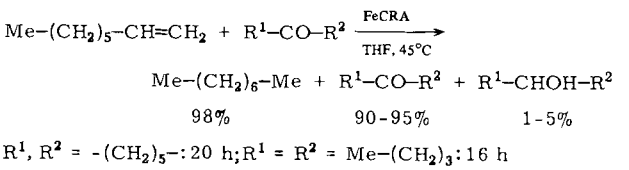


Although our studies of coupling reactions are only just beginning, comparison with the literature is very encouraging. Coupling of aryl or vinyl halides by $Ni^0$ complexes or $Ni^0$ species generated *in situ* has been described (see *e.g.* [27]). Not only are NiCRAL's much more thermally stable and less air-sensitive than conventional $Ni^0$ complexes, but they are also more efficient in coupling bromides and, above all, chlorides. Moreover, the coupling of simple alkenyl bromides appears to be stereospecific with NiCRAL but not with $Ni^0$ complexes[27d].

### 2.5. Reduction of Alkynes and Alkenes by CRA's

Here we shall elaborate only upon those results which throw light on the nature of CRA's. Mono- and disubstituted alkynes are smoothly reduced to the corresponding alkanes by *t*AmONa·NiCRA (4/2/1) and *t*BuONa·FeCRA (4/2/1) (from $FeCl_3$) in THF or anisole[28]. Moreover, the use of FeCRA avoids the inconvenience presented by NaH-$FeCl_3$, which necessitates a large excess of NaH and of $FeCl_3$ and causes oligomerization of monosubstituted alkynes[29a]. This result emphasizes the improvement wrought by addition of alcoholates.

Interestingly, using appropriate conditions NiCRA allows the reduction of alkynes to alkenes. The alkenes obtained from disubstituted alkynes were predominantly *cis*, corresponding to a *syn*-addition of the reagent. With monosubstituted alkynes small amounts of 2-alkenes arising from isomerization of 1-alkenes were detected. These observations strongly suggest the presence of nickel hydride species[30].



NiCRA and FeCRA also reduce alkenes[28]. Depending on the environment of the double bond they behave differently, thus permitting selective reductions (Scheme 11)[28b,31a].

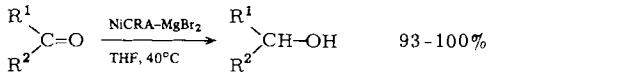
Scheme 11.

Careful study of the reaction with NiCRA led to an intriguing observation: reductions of alkenes are catalytic with respect to Ni only if stoichiometric amounts of the alcoholate and alkene are used; they are catalytic with respect to alcoholate only if stoichiometric amounts of Ni and alkene are used[31b].

Finally, even though NaH-$FeCl_3$ reduces ketones[29b], FeCRA does not: this permits selective reductions (Scheme 12)[28b].

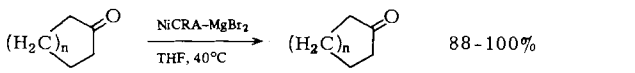
Scheme 12.

CRA's are as efficient as reagents containing $LiAlH_4$ or $NaBH_4$ and a metal salt [216, 32]. Their selectivity in competitive reduction of alkenes is also comparable. On the other hand, CRA's as well as $LiAlH_4$-containing systems[32a] are more selective than $NaBH_4$-containing reagents[32b] in the reduction of alkynes to alkenes. Finally CRA's are much more efficient than LiH-metal salt systems in which the very reactive and pyrophoric LiH is prepared from *t*BuLi and hydrogen[2e].



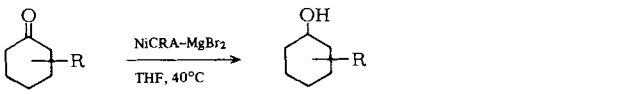
### 2.6. Reduction of Ketones and Aldehydes and Regioselective Reduction of α,β-Unsaturated Ketones by CRA's

Ketones and aldehydes, whose reductions are of synthetic interest, constitute ideal substrates to ascertain whether the basic properties of CRA's really have been controlled.

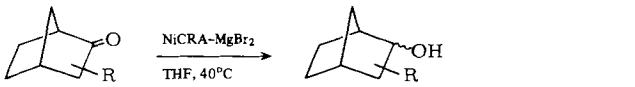


Exploratory experiments performed with *t*AmONa·NiCRA (4/1/1)[28a] showed that enolizable ketones might be reduced; however, these reductions suffer from long reaction times, only moderate yields with some substrates, and retro-reactions of varying rate (reoxidation of the alcoholate produced). We were able to show[33] that reoxidation was due to decomposition of transition-metal alcoholates[23,34] (formed in addition to sodium alcoholate), leading to ketones and metal hydrides. These results suggested that the addition of alkali metal or alkaline earth cations could increase the reduction rates by electrophilic assist-

ance; moreover, these cations might efficiently compete with $Ni^{II}$ for complexation at the oxygen atom, hence, helping to limit reoxidation. Among others, Li and Mg halides were found to be particularly suited for this purpose. They allowed fast NiCRA reduction of ketones in excellent yields, and dramatically retarded the reoxidation process (Scheme 13). Among other CRA's examined under the same conditions, *t*AmONa·CdCRA (4/1/1) and, particularly, *t*AmONa·ZnCRA (4/1/1), were found to be very efficient reducing agents for ketones.



Reduction of aromatic or α-alkylated aliphatic aldehydes by NiCRA (with Li or Mg salts) presented no difficulties, but low yields of reduction products were obtained with primary aliphatic aldehydes. In these cases, satisfying results were obtained using ZnCRA in the absence of added salts (Scheme 13)[33].



| $R^1$ | $R^2$ | *t* [h] | $R^1$ | $R^2$ | *t* [h] |

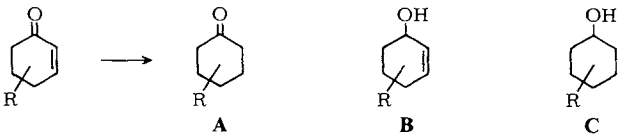
| Cyclohexyl | NiCRA–$MgBr_2$ | 1 | 98 |
| Hexyl | ZnCRA | 3 | 60 |

Scheme 13. Reaction times *t* are for comparable amounts of substrate.

It was also shown that reductions performed with NiCRA could be catalytic with respect to Ni, *t*AmONa, and $MgBr_2$[33]. On the other hand, with ZnCRA yields were never higher than 180% relative to Zn[31b].



Among the myriad of reagents able to reduce ketones and aldehydes [see *e.g.* [19b, h, n, 20d, 21b]] CRA's occupy a consolidated position among those species capable of operating at not too low a temperature. However, their stereoselectivity has to be improved. We already know that it is possible to modify the stereochemistry of the reduction by varying the nature of the alcoholate, and this, therefore, constitutes one of the ways we have at our disposal to improve the performance of these reagents.

It should be noted that CRA's are much more efficient than NaH-$FeCl_2$, NaH-$FeCl_3$[29b], or LiH-transition-metal salt systems[2e]; moreover, commercial NaH is much less

Scheme 14. Reaction times *t* are for comparable amounts of substrate.

expensive and easier to handle than the very reactive, highly pyrophoric LiH used by *Ashby et al.*

The results obtained in reducing alkenes and saturated ketones encouraged us to attempt the regioselective reduction of α,β-unsaturated ketones. Under the conditions found to be satisfactory for saturated ketones it was discovered that highly regioselective reductions could be performed using NiCRA, leading to saturated ketones, and with ZnCRA leading to allylic alcohols (Scheme 14)[35].

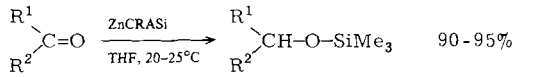
It is noteworthy that, with two exceptions, saturated alcohols are formed, if at all, only in trace amounts.

Broadly speaking, reagents which reduce α,β-unsaturated carbonyl compounds may be divided into three groups:

The first contains reducing agents which mainly or exclusively lead to saturated carbonyl compounds in moderate to excellent yields: among them are $M^{\oplus}[HFe(CO)_4]^{\ominus}$ or $M^{\oplus}[HFe_2(CO)_8]^{\ominus}$ (see *e.g.* literature cited in [19b] and [23]), $R_3SiH$-$F_3CCOOH$[36], $NaBH_4$-pyridine[37], NaHTe (from tellurium powder and $NaBH_4$)[38], $LiBHEt_3$[19h], RCuHLi[39], or $LiAlH_4$-CuI[40].

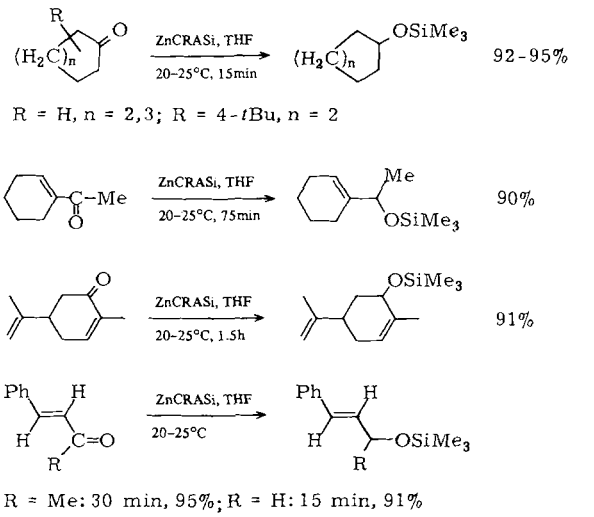
The second group contains reagents which give excellent yields of allyl alcohols. Here are found reagents such as 9-BBN[41] or $NaBH_4$-lanthanoid chlorides[42].

The third group comprises reagents which regioselectively reduce α,β-unsaturated carbonyl derivatives to varying extents and/or whose regioselectivity depends on the structure of the carbonyl compound, on the experimental conditions, or on the nature of the reagent. In this group are a number of aluminum hydrides and borohydrides, either with or without transition-metal salts[19b,n,23,41,43–46], as well as alkylaluminums[47], $Li_nCuH_{n+1}$[24a], NaH-$Fe^{II}$ or NaH-$Fe^{II}$[29a].



Comparison of the results shown in Scheme 14 with the data given in the above cited literature references indicates that 1) the regioselectivity of the inexpensive NiCRA and ZnCRA reagents is such that they may be classified among the best reducing agents of the first and the second groups, respectively, and 2) that, on average, the overall yields with CRA's must be considered as very good.

### 2.7. Hydrosilylation of Carbonyl Groups in Saturated and α,β-Unsaturated Ketones and Aldehydes by $Me_3SiCl$-Modified MCRA's (MCRASi's)



Condensation of three equivalents of $Me_3SiCl$ with *t*AmONa·ZnCRA (4/1/1) led to a new reagent (ZnCRASi) which hydrosilylated carbonyl groups[48]. The active silicon component appears to be bound to the reactive aggregates. ZnCRASi, an inexpensive reagent, rapidly reduces ketones and aldehydes to give excellent yields of trimethylsilyl ethers. This reagent specifically reduces carbonyl groups and does not reduce or isomerize CC double bonds (Scheme 15).

These results indicate that ZnCRASi is one of the best reducing reagent for the selective reduction of the carbonyl group of α,β-unsaturated carbonyl derivatives.

The most general method of hydrosilylating carbonyl groups is the reaction of alkyl, aryl or alkoxysilanes[49] catalyzed by group VIII metal derivatives. The common drawbacks of these reactions lie in the use of generally ex-

| $R^1$ | $R^2$ | *t* [min] |

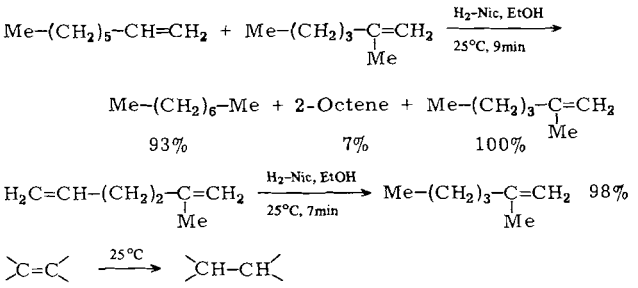
Scheme 15. Reaction times *t* refer to comparable amounts of substrate.

pensive reagents, of frequently high reaction temperatures, and the lack of selectivity towards CC double bonds in unsaturated carbonyl derivatives. Recently[49b] an interesting highly regioselective hydrosilylation of α,β-unsaturated carbonyl compounds has been described: with $R_3SiH$–$(Ph_3P)_3RhCl$ 1,4-addition products are formed and with $R_2SiH_2$–$(Ph_3P)_3RhCl$ 1,2-addition products. ZnCRASi compares favorably with the second system and is much less expensive.

### 2.8. Use of MCRA's in the Preparation of Selective Catalysts (Mc's) for Heterogeneous Hydrogenation

Our results suggest that CRA's could behave like metal hydride species (see Section 2.5). Considering that M–H bond formation is one of the postulated key steps in numerous catalytic hydrogenations[34b], it might be anticipated that CRA's could be sources of new hydrogenation catalysts: exploratory experiments[50] performed with *t*AmONa·NiCRA (4/2/1) were successful. Catalysts obtained from CRA's are abbreviated "Mc's" (M = metal).



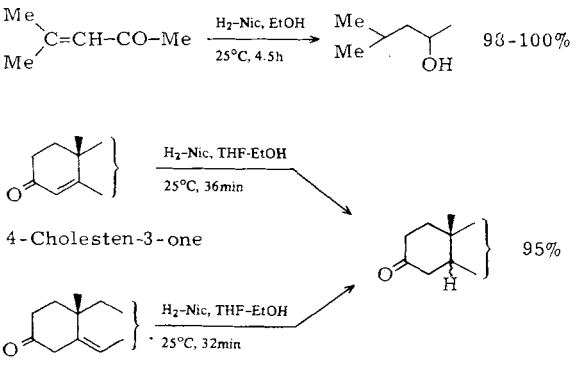
Nic's are NiCRA's (4/2/1) prepared at temperatures lower than usual, in which residual NaH has been neutralized[51]. In special cases, soluble alcoholates may be removed easily by washing ($Nic_w$).

Even when dry, Nic's are not pyrophoric. Nickel constitutes 60 to 70% (by weight) of the ethanol-washed catalyst. Thus alcoholates, on which the efficiency of Nic's depends, could be included as part of the catalyst framework. Nic's may be used in protic (MeOH, EtOH, *etc.*) or aprotic

(AcOEt, THF, toluene, *etc.*) solvents. Interestingly, they are only very slightly sensitive to catalyst poisoning and lead to good results with Ni/substrate ratios varying from 1:20 to 1:200. Finally, in the presence of NaH and under an inert atmosphere they are stable for long periods.

### 2.8.1. Hydrogenation of CC Double Bonds by tAmONa Containing Nic at Standard Pressure[51,52]

Nic is very sensitive to the environment of the alkene double bond, and selective hydrogenations are easily performed. Moreover, hydrogenation of CC double bonds can be performed without difficulty in the presence of various functional groups (Scheme 16). It is noteworthy that although carbonyl groups may be reduced by Nic (see Section 2.8.3), its affinity for the CC double bond is strong enough to allow selective hydrogenation of α,β-unsaturated ketones.



| Educt | Reagent | *t* [min] | Product | Yiled [%] |

| COOH | $H_2$–$Nic_w$ or Nic, EtOH | 58 | 97 |

Scheme 16. Reaction times *t* refer to comparable amounts of substrate.

### 2.8.2. Partial Hydrogenation of CC Triple Bonds by tAmONa Containing Nic at Standard Pressure[51,52]

Complete hydrogenation of mono- and disubstituted alkynes is readily performed using Nic. The reaction proceeds in two steps; the catalyst preferentially complexes the alkyne[53]. Taking advantage of this, partial hydrogenations of alkyne derivatives can be performed in excellent yields in the presence of quinoline (Scheme 17).

| $R^1$ | $R^2$ | Reagent | Yield [%] | Purity [%] |
|---|---|---|---|---|
| Pr | Me | $H_2$–$Nic_w$, MeOH | 82 | 96 |
| Et | Et | $H_2$–$Nic_w$, MeOH | 80 | 97 |
| Ph | Me | $H_2$–$Nic_w$, EtOH | 80 | 90 |

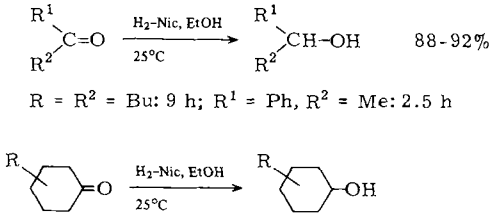
| Et–C(OH)(Me) | H | $H_2$–Nic, EtOH | 90 | 81 |
| 1-cyclohexenyl | H | $H_2$–Nic, EtOH | 84 | 80 |

Scheme 17. In most cases the impurity was the saturated product.

Taking into account that the yields in Scheme 17 refer to isolated products, it should be noted that a number of results obtained with Nic (particularly with 1,4-butynediol[54] and 1-ethynylcyclohexene[55]) compare favorably with those obtained with Lindlar palladium. Nic is superior to Raney nickel[55b].

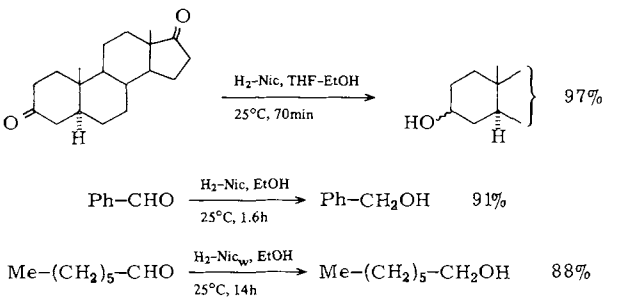


### 2.8.3. Hydrogenation of CO Double Bonds by tAmONa Containing Nic at Standard Pressure[51,52]

It is well known that only a few nickel catalysts allow the reduction of carbonyl compounds under mild conditions[56]. Among the more efficient are $W_7$-, $W_6$- and modified $W_4$-Raney nickels; however, $W_7$- and $W_6$-Raney nickels have very poor storage stability, $W_6$-Raney nickel appears to be hazardous[56], and the modifications of $W_4$-Raney nickel needed for hydrogenations of carbonyl groups are not simple to prepare[57].

Nic does not suffer from these drawbacks and is able to reduce carbonyl groups under mild conditions, frequently regioselectively (Scheme 18).

### 2.8.4. Comparison of Mc's with other Hydrogenation Catalysts



Nic's are easily and reproducibly prepared, are non-pyrophoric, can be stored, and are nonhazardous; they allow selective reduction of double bonds, partial hydrogenation of triple bonds and hydrogenation of carbonyl groups under ambient conditions. The affinity of Nic's for CC double bonds and carbonyl groups is sufficiently different, on

| R | t [h] | Yield [%] |
|---|---|---|
| 2-Me | 4.5 | 83 |
| 3-Me | 4.2 | 82 |
| 4-Me | 3.8 | 82 |
| 4-*t*Bu | 4 | 92 |
| 2-cyclohexyl | 20 | 94 |
| 2,6-$Me_2$ | 16 | 85 |
| 3,3,5-$Me_3$ | 6 | 88 |
| 3,3,5,5-$Me_4$ | 16 | 90 |

Scheme 18. Reaction times *t* refer to comparable amounts of substrate.

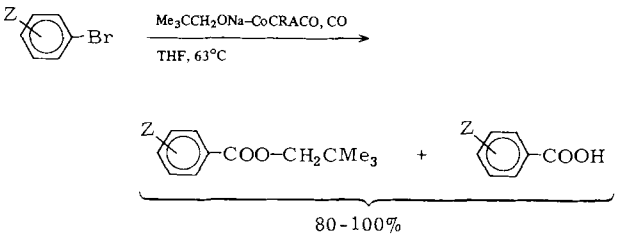
the whole, to allow selective hydrogenation of the CC double bonds of unsaturated ketones or aldehydes.

As far as efficiency, selectivity and handling are concerned, Nic's are more interesting than Raney nickels. The properties of Nic's are more directly comparable with those of *Brown*'s $P_1$- and $P_2$-nickel[56c,58], although their compositions are completely different (P-nickels contain large amounts of nickel boride[59]). In fact, to a certain degree, they are complementary; P-nickels and Nic's are very sensitive to the environment of the double bond, show rather low propensity toward isomerization or hydrogenolysis, and are not subject to poisoning by amines[59,60]. Use of $P_2$-nickel, however, allows hydrogenation of unsaturated nitriles to saturated ones[60], whereas use of Nic's does not[61]. In contrast, carboxyl groups (as sodium salts) do not prevent hydrogenations by Nic's, whereas cinnamic acid cannot be reduced using $P_2$-nickel[62].

P-nickels[56c,58,59,63] and Nic's permit selective hydrogenation of alkenes, but their respective selectivity toward cycloalkenes is different. On the other hand, unlike $P_2$-nickel[56c], Nic's do not have a propensity to disproportionate.

Partial hydrogenation of acetylenes can be performed highly selectively. However, in the presence of ethylenediamine $P_2$-nickel[64] could be slightly better for hydrogenating disubstituted alkynes, whereas Nic's could be slightly better with 1-alkynes.

P-nickels promote hydrogenation of carbonyl groups only very slowly[59,65], whereas Nic's do so fairly rapidly, thereby allowing carbonyl hydrogenations to be performed under mild conditions. Nic's promote, even in difficult cases, selective hydrogenation of the CC double bond of unsaturated ketones; however, perhaps $P_2$-nickel is more selective in special cases.

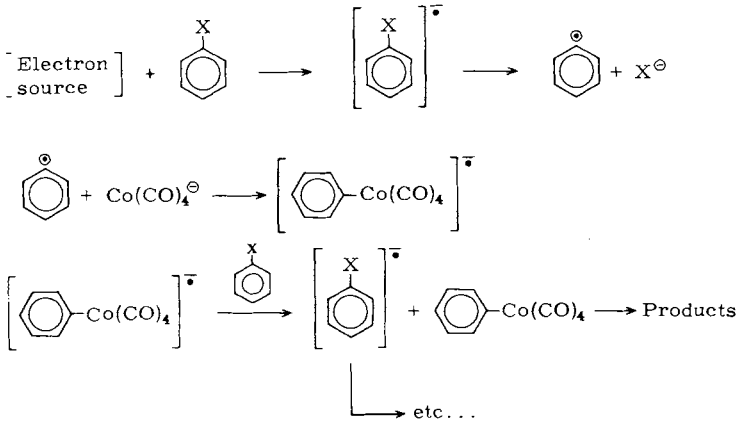


Since Nic's are prepared from NaH-RONa, their properties can be varied simply by changing the activating alcoholates. Moreover, many other catalysts may be prepared in a similar manner to Nic, and some of them (Coc, Pdc[52]) appear to be very promising for selective hydrogenations.

## 2.9. Carbonylation of Halogen Derivatives with CO-Modified MCRA's (MCRACO's) at Standard Pressure

### *2.9.1. Carbonylation of Aryl Halides with CoCRACO — Consequences for Phase Transfer Catalyzed Carbonylations*

Starting from the same ideas as in Section 2.4, we examined the preparation of CRA's using CO at atmospheric pressure. For the following reasons we chose to study the possible preparation of carbonylcobalt compounds and their ability to carbonylate aromatic halides: 1) the preparation of carbonylcobalt compounds from Co salts in aprotic media under mild conditions was rare in the literature[66a]; 2) contrary to an erroneous statement[66b], extreme reaction conditions are required for carbonylation of aryl halides in the presence of Co species[66c].



After careful systematic study[67] we succeeded in preparing a series of reagents (termed CoCRACO's) from CoCRA's (4/2/1), which reproducibly carbonylated aryl halides at atmospheric pressure of CO (Scheme 19). In the presence of amines, amides were obtained in moderate to good yields, and the carbonylations were found to be catalytic with respect to Co.

Z = H: 10 h; 2-Me: 25 h; 3-Me: 20 h; 4-Me: 20 h; 2-MeO: 15 h; 3-MeO: 15 h; 4-MeO: 15 h; 4-F: 20 h; 4-MeCO: 25 h

Scheme 19. Reaction times *t* refer to comparable amounts of substrates.

Investigations of the constitution of CoCRACO's led to the following conclusions: 1) *ca.* 90% of the cobalt was in solution; 2) only a fraction (*ca.* 13%) of the soluble cobalt was present as a carbonyl species; 3) the only carbonylcobalt species present was $NaCo(CO)_4$[68]. However, this anion alone does not carbonylate aryl halides under mild conditions[69]. We showed that this apparent contradiction was due to an $S_{RN}1$[70]-initiated process (one-electron transfer from $H^{\ominus}$). This result was confirmed when we were able to photostimulate the carbonylation of aryl halides in the presence of $NaCo(CO)_4$-*t*AmONa[68]. From these results, reactions involving CoCRACO's should proceed as depicted in Scheme 20.

Scheme 20.

The ability of $Co(CO)_4^{\ominus}$ to react *via* an $S_{RN}1$ process has an interesting consequence. It is known that $Co(CO)_4^{\ominus}$ might be generated from $Co_2(CO)_8$ in a PTC process[71]; however, under these conditions only organic halides which are particularly reactive in $S_N2$ processes can be carbonylated. These results led us to think that simple irradiation of such systems might allow the carbonylation of aryl and vinyl halides. This was in fact the case, and we can now perform numerous reactions of this type (Scheme 21) by irradiating a PTC system in a pyrex reaction flask with a simple commercial "sun lamp"[72]!

RX ⟶ RCOOH

| R | X | Reagent and conditions | $t$ [h] | Yield [%] |

Scheme 21.

### 2.9.2. *Carbonylation of Organic Halides with FeCRACO*

FeCRACO is prepared from *t*AmONa·FeCRA (4/2/1) using CO at 1 bar pressure. The soluble fraction contains mainly $Na_2Fe(CO)_4$ and some $Na_2Fe_2(CO)_8$[73]. Interestingly, this $Na_2Fe(CO)_4$ behaves very differently to pure $Na_2Fe(CO)_4$, which has been thoroughly studied by *Collman et al.*[23,74]. Thus, using FeCRACO primary, secondary, and even tertiary bromides and chlorides can be carbonylated, whereas under normal conditions $Na_2Fe(CO)_4$ is moderately reactive with secondary halides; however, no reaction is observed with 1-bromoadamantane after 9 days. Although these carbonylations have to be improved, some excellent results have already been obtained (Scheme 22)[73]. It should be noted that the carbonylations of primary and secondary halides are catalytic with respect to the metal[73].

$$RX \xrightarrow[DME,\ then\ H_3O^{\oplus}]{FeCRACO,\ CO} \underset{\mathbf{A}}{RCOOH} + \underset{\mathbf{B}}{RCOOtAm} + \underset{\mathbf{C}}{RCHO}$$

| R | X | $T$ [°C] | $t$ [h] | Yield [%] |
|---|---|---|---|---|
| $Me-(CH_2)_7$ | Br | 20 | 20 | 75 [a] |
| $Me-CH(-(CH_2)_5-Me)$ | Br | 20 | 53 | 68 [a] |
| $Me-CH(-(CH_2)_5-Me)$ | Cl | 65–70 | 13 | 60 [a] |

| Cyclohexyl | Cl | 65–70 | 36 | 75 [b] |
| 1-Adamantyl | Br | 40 | 84 | 88 [b] |
| 1-Adamantyl | Cl | 65–70 | 80 | 80 [b] |

[a] Relative yields **A** + **B** 58–90%, **C** 38–10%. [b] Only **A** + **B** are formed.

Scheme 22. Reaction times $t$ refer to comparable amounts of substrate.

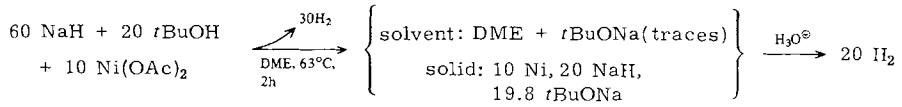
Of course, a radical mechanism must be suspected for most of these carbonylations. This is supported by the carbonylation of $C_6H_5Br$ by FeCRACO under CO (40% yield), the first example of carbonylation of bromobenzene by $Na_2Fe(CO)_4$.

### 2.10. Structure and Mode of Action of CRA's

The determination of the constitution of CRA's is a very difficult task. However, interesting data have been obtained for *t*BuONa·NiCRA (4/2/1) and *t*AmONa·ZnCRA (4/1/1)[75].

An analysis of the gas evolved during preparation of CRA's and their hydrolyses, and of the phase distribution of their main constituents yielded important information, which is briefly summarized in Scheme 23; the notation defined in Section 2.1 is used. In both cases, the amount of hydrogen evolved during the preparation was 10 mmol in excess of that expected for the reaction of NaH and ROH.

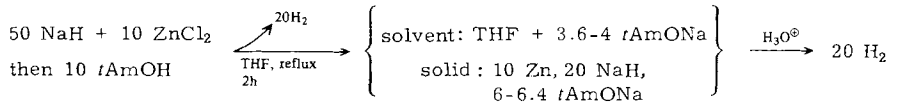
For NiCRA the excess of $H_2$ arises from the reaction



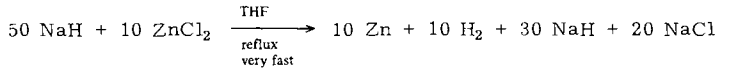
$$2H^{\ominus} + Ni^{II} \longrightarrow Ni^0 + H_2$$

No reduction took place without alcoholate. The crucial part played by the alcoholate may have two explanations: 1) activation of NaH (Section 1.3), and/or 2) formation of nickel alcoholates with concomitant favorable shift of the $Ni^{II}$ reduction potential[76], or electron relay between $H^{\ominus}$ and $M^{n\oplus}$. Both phenomena probably occur. Indeed, the addition of NaH to $RONa-Ni(OAc)_2$ in THF or DME leads to a reagent similar to NiCRA, but the rate of formation is lower[31b]. Likewise, *t*AmONa–$Co(OAc)_2$ reacts with NaH and CO to give $NaCo(CO)_4$; in contrast, $Co(OAc)_2$ does not[68].

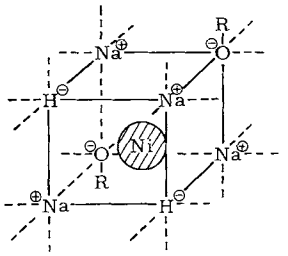
The amount of hydrogen evolved in the hydrolysis of NiCRA is consistent with that expected from the "free" hydride. It is, further, noteworthy that *t*BuONa was found only in the solid fraction despite its high solubility in DME.



Comparison of X-ray powder patterns of the solid fractions with those of the possible constituents or precursors leads to the following conclusions[75]: 1) at least some NiCRA (if not all) is crystalline; 2) NiCRA consists of new



NiCRA (4/2/1)



ZnCRA (4/1/1)

Scheme 23. Above: the NiCRA (4/2/1) shown here consists of NaH, *t*BuONa, and $Ni(OAc)_2$ in the molar ratio 4:2:1.—Below: the ZnCRA (4/1/1) shown here consists of NaH, *t*AmONa, and $ZnCl_2$ in the molar ratio 4:1:1 (numerical values in scheme: mmol).

species in which each constituent (or precursor) has lost its own characteristics and participates in the formation of new structures. From the data, NiCRA appears to be constituted of aggregates formed by association of matrices (see Scheme 24) consisting of Ni atoms surrounded by $Na^{\oplus}$, $H^{\ominus}$, $tBuO^{\ominus}$, and perhaps $AcO^{\ominus}$.

Scheme 24.

The results for ZnCRA[75] are interesting. The excess of $H_2$ observed in the preparation (Scheme 23) arises from the reaction:

$$2H^{\ominus} + Zn^{II} \longrightarrow Zn^{0} + H_2$$

consistent with the results of *Ashby et al.*[77]. Since ZnCRA may be obtained by addition of *t*AmOH to the suspension obtained after $ZnCl_2$ has been allowed to react with excess of NaH, this suggests that ZnCRA is formed by the reaction of *t*AmOH with Zn–NaH! Moreover, *t*AmOH does not react with Zn (prepared from NaH and $ZnCl_2$), and the metal was found in the solid fraction. In contrast to *t*BuONa with NiCRA about one third of *t*AmONa remained in solution with ZnCRA.

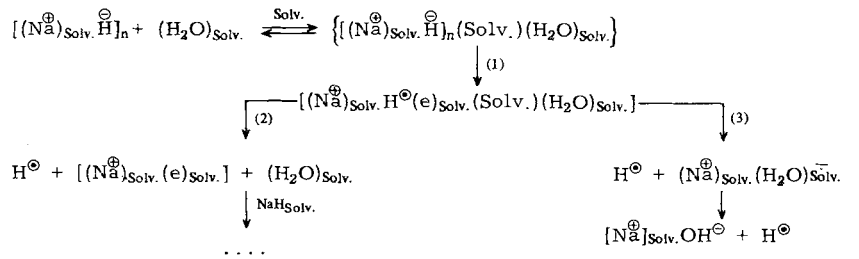
Analysis of the X-ray powder patterns study led to the following conclusions: 1) most of the NaH and about 30% of Zn are present as such; 2) the remaining Zn and *t*AmONa form new species. In other words, ZnCRA has to be considered as an association of Zn metal, NaH, and species tentatively formulated as $[(tAmO)_xZnNa_x]_n$. Why should this mixture be so efficient in reducing substrates such as carbonyl compounds? In trying to answer this question we noted the following observations[75]: 1) "$[(tAmO)_xZnNa_x]_n$" obtained from NaH-*t*AmONa-$ZnCl_2$ (3/1/1) does not reduce ketones; 2) Zn prepared from $ZnCl_2$–NaH (1/2) does not reduce ketones either; 3) curiously, Zn–NaH obtained from $ZnCl_2$–NaH (1/5) slowly reduces ketones such as cyclohexanone, but is much less efficient than ZnCRA.

From these observations it appears that ZnCRA could be tentatively considered as a mixture of NaH, $[(tAmO)_xZn(Na)_x]_n$, a small amount of $[(tAmO)_y(H)_zZn(Na)_{y+z}]_n$ (the active part), and some Zn metal. Reductions would take place at the active part, which could be regenerated from NaH and $[(tAmO)_xZnNa_x]_n$.

For chemists not intimately concerned with it, the work described in this review may appear to be more akin to alchemy than chemistry. This is not completely true. In fact, a unifying principle has directed the greater part of the research on complex bases and on CRA's, and I shall attempt to rationalize this beginning with complex bases.

The activation of ionic bases or nucleophiles by alcoholates must arise from formation of aggregates of the type $(-M^{\oplus}-Nu^{\ominus}-M^{\oplus}-\overset{\ominus}{O}R-)_n$. Of course, $Nu^{\ominus}M^{\oplus}$ also activates $RO^{\ominus}M^{\oplus}$, and once the aggregates are formed they must be viewed as a single entity. I postulate that these "supermolecules" presumably possess structures with marked electron delocalization and strong one-electron transfer tendencies. More generally, if $Nu^{\ominus}M^{\oplus}$ is a potential one-electron transfer reagent, an aggregation with appropriate ion pairs (or with itself) would lead to new species with much higher one-electron transfer abilities. It should be noted that one-electron transfer from $NaNH_2$–*t*BuONa has been recently demonstrated[78].

The active part of CRA's must also be viewed as consisting of NaH-RONa supermolecules, whose framework contains low oxidation-state metal cores. The metal species must be stabilized by the surrounding ionic framework and amplify the one-electron transfer ability of the whole.



Moreover, they must also participate in anchoring the substrates during the electron transfer process.

If this description is accepted, CRA's appear to be complex polymeric hydrides with strong one-electron transfer abilities. The reduction steps could then be: 1) fixation to the "polymer"; 2) one-electron transfer; 3) hydrogen abstraction. The hydrogen source for the last step is of particular interest. The low yields of coupled products in the reductions support the conclusion that free radicals are not very abundant. However, some current experiments show that some of the hydrogen fixed on the reduced substrates must be supplied by the solvent. The absence of coupling could indicate that the radicals formed on the aggregates are still strongly bound to the reagent until the hydrogen abstraction step.

Thus, it appears plausible that in the reduction of substrates by CRA's radical species are formed on the polymer. A small fraction of these radicals may be liberated, resulting in coupling reactions and abstraction of hydrogen from the solvent. Other radicals strongly bound to the reagent abstract hydrogen from the polymeric hydride. The remaining fraction, consisting of more loosely bound radicals, abstracts hydrogen from the solvent. Presumably the lower the amount of free NaH, the greater the degree of solvent participation.

In view of what is known about reactions between organic substrates and low oxidation-state metal species[79], together with the recent results obtained by *Ashby et al.* on electron transfer from hydrides (and other reagents)[19l, 80], the view of CRA's presented above appears to be a good rationale.

Finally, in Section 1.2 we mentioned the generation of solvated electrons in HMPA in the reaction between NaH and water (or alcohols). This reaction, in my opinion, may be related to the activation hypothesis. Indeed, in HMPA the active part of NaH must take the form $(H^{\ominus}\text{--}Na^{\oplus}\text{--}\overset{\ominus}{O}\text{--}\overset{\oplus}{P}\!\!<)_n$ (which resembles the aggregates in complex bases or activated NaH), whose one-electron transfer ability is increased. Electron transfer through HMPA from active NaH towards a protic substrate (bound to HMPA) must be the first step of the reaction (step 1, Scheme 25). HMPA, a good electron stabilizing solvent[81], may trap some of the electrons (step (2)), while the others follow the normal pathway (step (3)).

Scheme 25. Solv. = solvent = HMPA.

To generalize this view, it is proposed that in an appropriate medium radical formation as well as numerous "ionic reactions" could be initiated by an electron transfer through electron-transmitting, separated nucleophile-electrophile ion pairs.

## 3. Conclusions

Before examining possible future developments of CRA's, some remarks must be made.

After we had published our first results on CRA's[15], some work appeared describing reducing agents involving NaH-metal salt systems. Thus, *Fujisawa et al.*[29] showed that NaH–$FeCl_2$ and NaH–$FeCl_3$ were able to reduce CC double bonds and carboxy groups. However, long reaction times and a considerable excess of reagents had to be used. On the other hand, *Ashby et al.*[2e], who attempted to reduce 1-octene with NaH in the presence of a series of metal salts, concluded their work with the following sentence: "It was somewhat disappointing that NaH did not produce yields of octane larger than 5%, since NaH is much less expensive than LiH and is easier to handle". It must be noted that even the highly reactive LiH did not lead to very efficient reducing agents.

In fact, in the course of the hundred or so control experiments we performed with the NaH-metal salts systems we also observed unsatisfactory reactivity in most cases; however, with some substrates high yields of reduction products were obtained. Nevertheless, the reactions were not very reproducible, and above all, substitution of the substrate by a similar one led to very low, or to no, yields of reduction product.

It, therefore, appears that NaH alone can donate its electrons, but its proton affinity impedes it with a few exceptions; activated by alcoholates or some metal salts its tendency to electron transfer becomes better but erratic. Moreover, the basicity of NaH-RONa still constitutes a formidable drawback.

In CRA's NaH, RONa and metal species occur together, and a synergism between the constituents seems to arise which concentrates their efforts toward a goal: to donate electrons to organic substrates.

In the future some work which should be performed is dictated by these observations. I am convinced that the study of physical properties of solid CRA's, such as conductivity and magnetic behavior, should lead to important information and perhaps show that they constitute a new class of electronic materials. Moreover, it is not unreasonable to assume that CRA's could be the first members of a new generation of electron or hydrogen reservoirs.

Of course, the initial studies on the constitution of CRA's, which we have performed on NiCRA and ZnCRA, must be extended.

The role played by the activating agents is so important that it appears of paramount importance to continue the

study of the influence of alcoholates on the properties of CRA's. Above all, activating agents with heteroatoms other than oxygen should be studied. Presumably elements such as sulfur, for example, should be excellent electron regulators. The use of "chelating" and polymeric activating agents would also lead to new CRA's.

A further point must be raised. We showed in Section 2.6 that CRA's containing two different metals have interesting properties. It is clear that the association of two (or more?) complementary metals should open new possibilities for application of CRA's. Use of these multimetal-containing CRA's to obtain new catalysts should also be investigated.

For elucidating the mechanism of reduction by CRA's, reactions with NaD should be very informative. Currently, the greatest problem is to find pure NaD. Sodium deuteride is very expensive since it has few uses. If deuteration were possible with CRA's, NaD would become less expensive than other deuterides. It should also be noted that NaH, which is relatively cheap, would become still less expensive if proper packaging were available to facilitate its use in industry, and extend its use as a reducing agent.

Among the problems which must still be considered is the investigation of the possibilities offered by CRA's to oligomerize or polymerize vinyl or dienyl monomers[17]. The use of asymmetric activating agents would also be of interest to induce asymmetric reductions as well as asymmetric coupling reactions or carbonylations.

Carbonylations must also be developed further in aprotic media and under phase transfer catalysis conditions. Specifically the concept of $S_{RN}1$-condensation of metalates should be extended.

To conclude it can said that the study of CRA's and related reagents is far from completion. If all the working hypotheses expressed in the work covered in this review are correct, then we have achieved the expected results in a designed way. If, on the contrary they are wrong, then we have been very lucky!

*I express my sincere appreciation to my coworkers who are individually identified in the references, particularly to J. J. Brunet. I am indebted to them for their experimental as well as intellectual contributions. Our work has been financially aided by the Centre National de la Recherche Scientifique, as E.R.A., DGRST (Proscom), Hoechst France, and Société Nationale Elf Aquitaine (Production). I am very grateful to Professor K. G. Taylor, visiting Professor in Nancy University, for helpful discussions.*

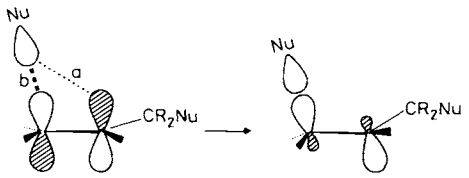
## On the Stereochemistry of the $S_N2'$ Reaction

By *Wolf-Dieter Stohrer**

In bimolecular nucleophilic substitution with allyl rearrangement ($S_N2'$ reaction) the entering and the leaving nucleophile (Nu) can be oriented antiplanar (*anti*-reaction *via* the transition state **1**) or synplanar (*syn*-reaction *via* the transition state **2**). Of the $S_N2'$ reactions so far investigated stereochemically the overwhelming majority proceeded with high *syn*-preference[1].

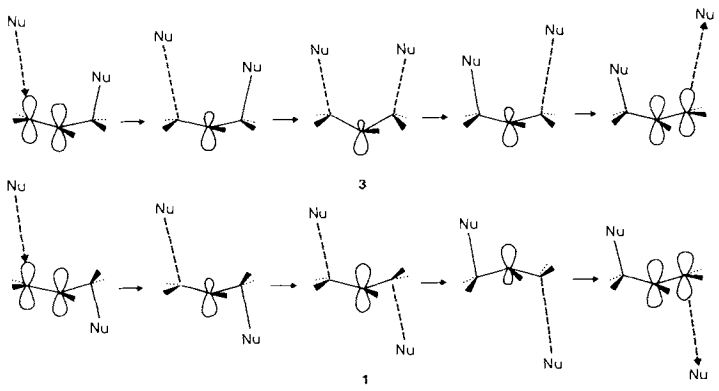


In most of the theoretical investigations[2] on the stereochemistry of the $S_N2'$ reaction this *syn*-preference is rationalized, in that the quasi-cyclic transition state **2** (as a Hückel arene) is sufficiently favored stereoelectronically compared to the non-cyclic transition state **1**, although

[*] Prof. Dr. W.-D. Stohrer
Fachbereich 2, Studiengang Chemie der Universität
Postfach, D-2800 Bremen 33 (Germany)

MO calculations[3] strengthen the obvious suspicion that the greater steric—and in the case of (negatively) charged transition states also electrostatic—repulsion between the two nucleophiles in **2** compared to in **1** compensates the stereoelectronic stabilization.

In this communication attention is drawn to a further stereoelectronic factor favoring the *syn*-reaction which has hitherto never been taken into consideration[4]. The central C atom, which does not directly participate in the reaction, and which in the transition state—regardless if charged or not—accumulates *more or less negative charge*, is planar in the *anti*-transition state **1** (as shown), *i.e.* $sp^2$-hybridized, but (other than previously assumed and other than shown in **2**) non-planar in the *syn*-transition state, and—because of the *partial negative charge on this C atom energetically more favorably*—$sp^n$ hybridized ($2<n<3$). The bigger of the two orbital lobes lies (as shown in **3**) on the side opposite to that of the two nucleophiles.



These different hybridizations at the central C atom (C-2) of the two transition states can be readily explained in terms of the frontier orbital model: the entering nucleophile interacts with maximal stabilization with the LUMO of the double bond, *i.e.* for optimization of the direct bonding interaction b and for minimization of the antibonding interaction a the nuclear framework distorts itself such that the bigger orbital lobe of the $sp^n$-hybridized central C atom develops on the side opposite to that of the entering nucleophile.

Based on the principle of microscopic reversibility, this correspondingly also applies to the leaving nucleophile, *i.e.*:

—in the *syn*-reaction (*via* **3**) the bigger orbital lobe on C-2 remains on the same side of the molecule along the whole reaction coordinate;

—in the *anti*-reaction (*via* **1**) the bigger orbital lobe on C-2 must change "sides" during the reaction, *i.e.* an energetically more or less unfavorable inversion must take place at the central atom, which is partially negatively charged during the reaction.

This inversion barrier reduces *a priori* the chance of the *anti*-reaction all the more with increasing accumulation of negative charge at C-2 in the transition state, *i.e.* the longer the 'bond breaking' of the leaving nucleophile lags behind the 'bond forming' of the entering nucleophile; and *vice versa!* Thus, other things being equal, a difficultly cleavable nucleophile should favor the *syn*-reaction, an easily cleavable nucleophile the *anti*-reaction. The height of this barrier, which depends on the nature of the nucleophiles, can still be increased (in favor of the *syn*-reaction) or lowered (in favor of the *anti*-reaction) by commonly known steric and/or electronic factors.

[4] The model presented here differs fundamentally from the, at first glance, apparently similar "Orbital Distortion Model" of C. L. Liotta, *Tetrahedron Lett. 1975*, 523. Liotta uses the statistical distortion of the LUMO to predict the preferred nucleophilic attack; in the model presented here the dynamic distortion of the nuclear framework along the reaction coordinate is investigated.

## Probing the Environment of Al Atoms in Noncrystalline Solids: $Al_2O_3$–$SiO_2$ Gels, Soda Glass, and Mullite Precursors**

By *John M. Thomas**, *Jacek Klinowski*, *Paul A. Wright*, and *Rustum Roy*

Very few techniques are available for ascertaining the coordination of atoms within amorphous or quasi-crystalline solids. One recently developed approach is based on magic-angle spinning NMR (MAS-NMR) which, especially in crystalline specimens[1], can readily identify the immediate environment of atoms. Tetra- and hexacoordinated Al and Si are directly distinguishable in various minerals and their synthetic analogues using $^{27}Al$ and $^{29}Si$ MAS-NMR spectroscopy. Moreover, tri- and tetracoordinated B in borosilicate glasses[2a]; different kinds of tetracoordinated Si in silica gels[2b] and cements[2c] have been characterized.

A disadvantage of $^{29}Si$ MAS-NMR for nuclei having spin 1/2 in amorphous solids are long spin-lattice relaxation times, which we have found to be of the order of several hours in some high-purity glasses[3]. Relaxation of quadrupolar nuclei, such as $^{27}Al$ with spin 5/2, proceeds by a different mechanism from those with spin 1/2 and is generally very fast. Recycle times of 0.1 sec give quantitatively reliable spectra; another important advantage of $^{27}Al$ is its 100% isotopic abundance, which makes $^{27}Al$-NMR a very sensitive probe. Al atoms can, for example, be

University Park, PA 16802 (USA)

[**] We wish to thank the University of Cambridge for support and experimental assistance, Prof. C. A. Fyfe (Ontario) for recording the $^{27}Al$-MAS-NMR spectra, Dr. S. R. Elliott for preparing the soda glass, and Dr. W. E. Hull and Dr. D. Müller for their experimental help. We are grateful for the support of the Science and Engineering Research Council and B.P. Co. Ltd. The Sol-gel research of Rustum Roy is supported by NSF Grant No. DMR-8110476.

quantitatively detected[4] even in materials with Si/Al ratios as large as 10000. $^{27}$Al-MAS-NMR can be used to distinguish four- and six-coordinated Al, the former resonating at $\delta \approx 50$—90 ppm, and the latter at 0—20 ppm (relative to $Al(H_2O)_6^{3+}$). It is advantageous to employ high magnetic field strengths, since the second-order quadrupolar interaction is inversely proportional to the field strength. $^{27}$Al-MAS-NMR spectra were recorded at 104.22 MHz and 130.32 MHz using Bruker WH-400 and AM-500 spectrometers; the latter instrument uses the highest currently available persistent magnetic field. Delrin rotors were spun at rates up to 4 kHz.

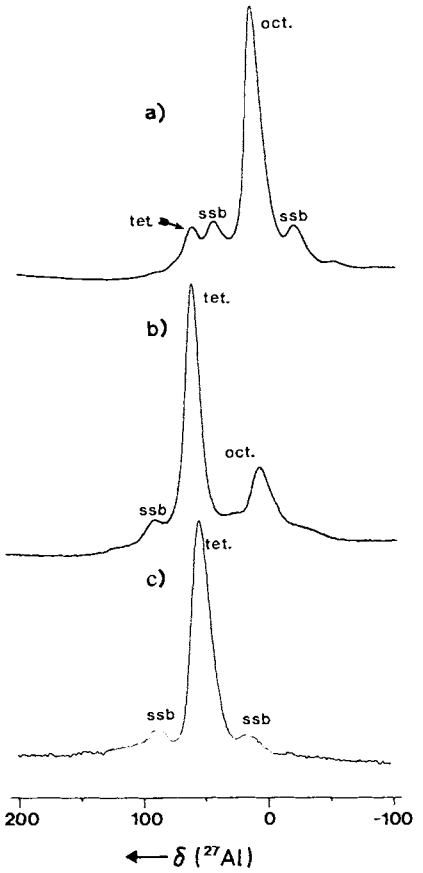

Fig. 1. $^{27}$Al-MAS-NMR spectra at 104.22 MHz: a) $Al_2O_3$—$SiO_2$ gel with 75% $Al_2O_3$; b) $Al_2O_3$—$SiO_2$ gel with 28% $Al_2O_3$; c) Soda glass (15% $Na_2O$ + 85% $SiO_2$) containing only traces of $Al_2O_3$: ssb = spinning of sidebands, oct. = octahedral, tet. = tetrahedral.

In the gel containing *ca.* 28% $Al_2O_3$ most Al atoms are tetracoordinated, while in the gel with *ca.* 75% $Al_2O_3$ most Al is hexacoordinated (octahedral); indeed, the spectrum of this gel is almost indistinguishable from that of commercial $Al_2O_3$. Figure 1(c) shows the spectrum of soda glass containing 15% $Na_2O$, 85% $SiO_2$ and only traces of Al: all the Al atoms in soda glass are tetrahedrally bound. This is also the case in borosilicate glass containing traces of $Al_2O_3$. In all cases the NMR signals are relatively broad, indicating that Al is present in a variety of environments, *i.e.* is disordered. It appears that Al functions as an "environmental probe", in that it adopts the preferred coordination of the dominant component of the gel.

We have used $^{27}$Al-MAS-NMR to study the crystallization of mullite from a $SiO_2$—$Al_2O_3$ xerogel precursor. Mullite (nominally $3Al_2O_3 \cdot 2SiO_2$, with a variable composition close to Al : Si = 3 : 1) is a very stable phase, whose structure has not yet been unambiguously established, but is loosely based on the ordered sillimanite structure involving chains of Al octahedra parallel to the z-axis, cross-linked by tetrahedra containing both Si and Al[5]. By analogy with Al-substituted sillimanite we would expect that two unit cells of mullite contain twelve sites, four of which are octahedral and eight tetrahedral. Since in mullite Si is tetracoordinated it follows that two unit cells of mullite (with the ideal composition) contain four octahedral and five tetrahedral Al atoms, and three tetrahedral Si atoms. Mullite xerogel precursor was prepared by mixing 15 g of $Al(NO_3)_3 \cdot 9H_2O$, 10 mL of ethanol, 5 mL of water, and 2.2 mL of $Si(OC_2H_5)_4$. The gel (amorphous to X-rays) was warmed in a water bath (4 h, 75 °C), subsequently air dried for 15 d, and finally heated to 450 °C. Crystallization of mullite was monitored by heating the gel to various temperatures in the range 1000 to 1400 °C and recording X-ray diffractograms and $^{27}$Al-MAS-NMR spectra (Fig. 2) of the products.

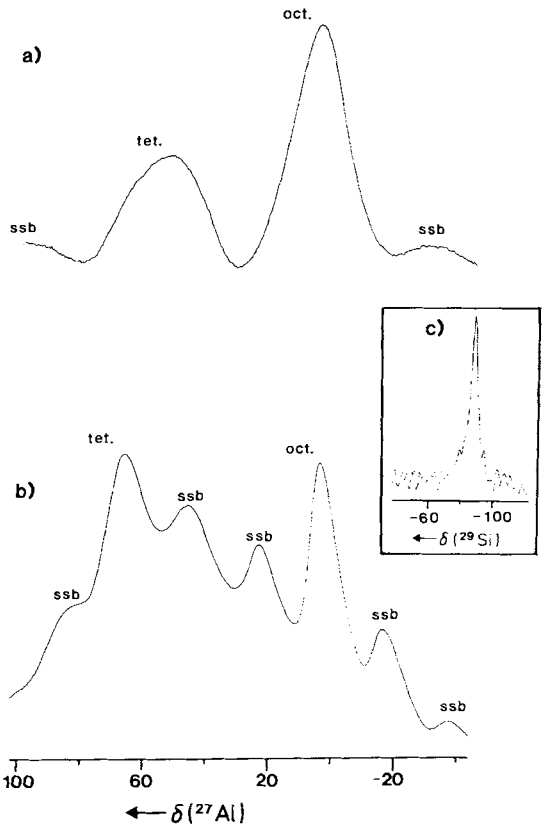

Fig. 2. $^{27}$Al-MAS-NMR spectra at 130.32 MHz; a) mullite xerogel; b) crystalline mullite; c) $^{29}$Si-MAS-NMR spectrum of crystalline mullite at 59.60 MHz.

The $^{27}$Al spectrum of the parent xerogel (Fig. 2a) is well resolved and yields a ratio of tetrahedral to octahedral Al of 0.63, in good agreement with the spectra in Figures 1a and 1b. Since the corresponding ratio in mullite is 1.25 (see above) its crystallization from the gel must involve extensive conversion of hexacoordinated to tetracoordinated Al. This was indeed observed by $^{27}$Al-MAS-NMR. X-ray diffraction studies identify $\gamma$-$Al_2O_3$ as an intermediate product in samples heated to lower than 1400 °C. The $^{29}$Si-MAS-NMR spectrum of crystalline mullite (Fig. 2a; $T_1$ in the order of several seconds) features a *single* signal at $\delta = -86.0 \pm 1$ (rel. to TMS), indicating that all Si atoms are in an identical intracrystalline environment. The assign-

ment of the resonance to Si(4Al) is consistent with the structural model described above.

## Surfactants with Novel Structural Characteristics**

By *Edwin Weber**

A typical surfactant molecule consists of a lipophilic and hydrophilic part[1]. Here we report on surfactants having a novel construction principle which at the same time exhibits the characteristics of neutral ligands[2]. The oligotopic crown ethers **1**—**11** attracted our attention because of their remarkable solubility behavior. Unexpectedly, the six-armed (**1**, **2**) and some trisubstituted species (**5**, **8**, **9**) (cf. Table 1) are highly soluble in water and other polar solvents (methanol, ethanol, dimethylformamide, dimethyl sulfoxide), but as a rule only possess limited solubility in less polar solvents (including chloroform). Aqueous solutions of these compounds readily wet a contiguous glass wall (*e.g.* $\gamma = 47$ mN/m for **1**, 42 for **8**, each in $5 \times 10^{-4}$ M solution, $T = 23$ °C). Upon concentrating the solutions the viscosity and the foaming ability increase markedly until a reversible opaque and almost immobile gel results. The surfactant character is illustrated even more clearly by the occurrence of cloud points in water[1,3] (Table 1), which are directly related to the molecular structure: the cloud point decreases with increasing conformational flexibility of the molecular framework and *vice versa* (cf. **1** with **2**, **8** with **9**, **9** with **11**). A typical characteristic of these compounds is that upon evenly warming samples of these compounds in glass vessels the clouding always starts at the glass/water/air interface.

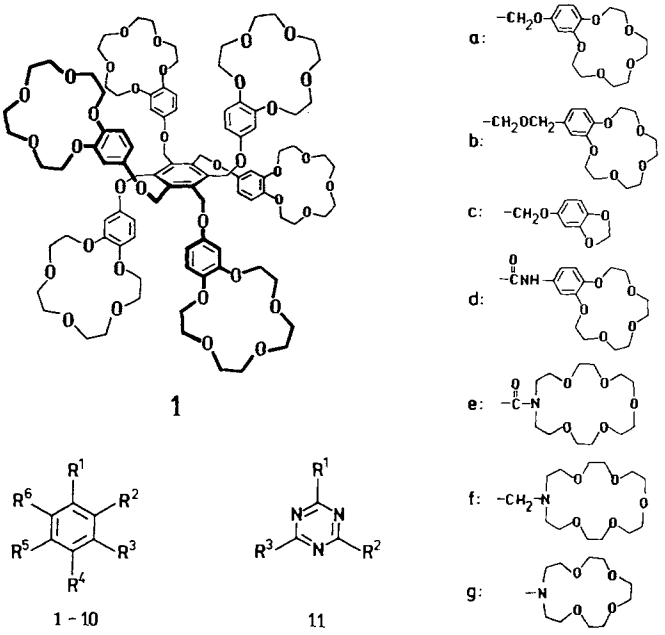

Table 1. Selected data for the synthesized compounds [a].

| No. | $R^1$—$R^6$ | M.p. [°C] | CP [°C] [b] |

| 10 | $R^1$, $R^3$ = **a**; $R^2$, $R^4$, $R^5$, $R^6$ = H | (glassy) | [c] |
| 11 | $R^1$—$R^3$ = **g** | 107—108 | 83—85 |

[a] Elemental analyses and spectroscopic data are consistent with the given structures; melting points are not corrected. [b] Cloud point in water, $10^{-3}$ M solution. [c] Low soluble in water. [d] No clouding up to 100 °C.

The clouding phenomenon described above indicates that in the chosen concentration range micellar solutions are present[3]. Using light scattering methods, critical concentrations for micelle formation of $1.3 \times 10^{4}$ and $5.4 \times 10^{-4}$ mol/L were determined for **1** and **9**, respectively ($T = 23$ °C)—values which are typical for non-ionic surfactants[3]. The aggregation number of the micelles of **8** at $c = 5 \times 10^{-4}$ mol/L is 76; for **1** the value is 50, which seems to correspond to the increased number of ligand arms.

Solvent- and temperature-specific short-range order data of the dissolved surfactants can also be gathered from the $^1$H-NMR spectra[4].

Since numerous biological reactions proceed and/or are catalyzed in aqueous (lyotropic) systems, and because of the enzyme model character of crown ethers[5], the novel surfactant structures should provide highly promising starting points for biomimetic catalysis. The interactions of complexing agents with surfactants are also decisive in the washing process[1b].

## A New Phytohormone from *Mimosa pudica L.***

By *Hermann Schildknecht** and *Wolfgang Bender*

The extract of *M. pudica L.* contains, aside from 4-*O*-(6-*O*-sulfo-β-D-glucopyranosyl)gallic acid **1** (M-LMF4)[1], a further leaf movement factor called M-LMF5. Preliminary UV and $^1$H-NMR spectroscopic investigations on small amounts of sample immediately showed a high degree of similarity in the arene- and sugar-moieties of the two mimosa hormones. However, subsequent comparative TLC and HPLC studies revealed distinct differences in the polarity and chemical behavior of the two compounds. It followed from these investigations that the sugar moiety of M-LMF5 must contain an acid group whose p$K_a$ value compares with that of acetic acid. An improvement in the previously used separation technique enabled isolation of sufficient amounts of the compound for elucidation of the structure.

The IR spectrum of M-LMF5 (KBr microdisk) shows a pronounced band between 1660 and 1730 cm$^{-1}$, which is caused by superposition of two carbonyl absorptions: that of the gallic acid CO group and that of an aliphatic CO group. The $^{13}$C-resonances at $\delta = -175.7$ (C-6′) and $-172.3$ (C-7) confirm the presence of the acid groups in the molecule. Both groups must be free since large downfield shifts occurred in the dipotassium salt. The signals observed between $\delta = -110$ and $-160$ could be assigned to the ring atoms of gallic acid (3,4,5-trihydroxybenzoic acid). The singlet of H-2,6 at $\delta = 7.07$ in the $^1$H-NMR spectrum points to symmetrical substitution of the aglycone moiety. The $^{13}$C-NMR signal at $\delta = -106.8$ is characteristic for C-1′ of a β-D-*O*-glucosidically linked pyranose. The large coupling constant of $J_{1,2} = 7.5$ Hz observed for the anomeric doublet in the $^1$H-NMR spectrum confirms the β-pyranose configuration, the chemical shift of H-1′ ($\delta = 5.08$) the 1′-*O*-glycosidic linkage. Separated from the multiplet of three protons ($\delta = 3.69$), there appears a doublet from H-5′ at $\delta = 3.97$ ($J_{4,5} = 8.5$ Hz), typical for hexauronic acids. Since also this signal is split by diaxial coupling, the β-D-glucopyranosiduronic acid in M-LMF5 must be 1′-*O*-glucosidically linked with the 4-OH group of the gallic acid.

The structures of the sugar and aglycone of the phytohormone could be confirmed by GC and GC/MS analysis after acid hydrolysis and silylation. All the mass spectra (EI and CI) were identical with those of the authentic reference substances trimethylsilyl 3,4,5-tris(trimethylsiloxy)benzoate and tris(trimethylsilyl)-α,β-glucurono-3,6-lactone. The data obtained on mass spectrometric investigation of the unhydrolyzed molecule were also consistent with the proposed structure. The low-resolution FAB (fast atom bombardment) measurement shows *m/z* 345 for $M-1$ in the spectrum of the negative ions. In the high-resolution MS of persilylated M-LMF 5 we have obtained $M-CH_3$ as highest mass (*m/z* 835.3065, $C_{33}H_{67}O_{11}Si_7$, error 0.3 mmu). The 4-*O*-(β-D-glucopyranosiduronyl)gallic acid **2** synthesized by us in a modified Koenigs-Knorr reaction was identical with natural M-LMF5 in all chromatographic and spectroscopic properties. The compound, which occurs only in hormonal amounts in the mimosa, still triggers the specific stimulation reaction at a concentration of $3 \times 10^{-6}$ mol/L, and is a further low-molecular phytohormone.

**1**, R = $CH_2OSO_3H$ (M-LMF 4)
**2**, R = COOH (M-LMF 5)

This new leaf movement factor of the mimosa (M-LMF5, **2**) is only apparently similar to the already known factors such as **1**[1, 13], since its chemical and biological behavior are largely determined by the carboxy group in the sugar moiety, which is much less weakly acidic than the sulfuric acid ester group. It would be interesting to know whether this second natural structural variation of the leaf movement substances also occurs in other plants or is only to be found in *M. pudica L.*

## *p*-(*o*,*p*)-*o*-Tribenzene and *p*-(*o*,*p*)-(*o*,*o*)-*p*-Tetrabenzene, Diels-Alder Oligomers of Benzene

By *Wolfram Grimme** and *Gerd Reinhardt*

Benzene comprises both functionalities necessary for a Diels-Alder reaction—a diene and an ene—and, like other difunctional compounds, should, therefore, be capable of forming oligomeric and polymeric structures. The direct cycloaddition of benzene is precluded by its high resonance energy, which on the other hand causes the ready decomposition of adducts obtained *via* indirect pathways. Hence, *p*-*o*-dibenzene, **1a**, is only known as a ligand in a tricarbonyliron complex[1], which decomposes at $-20$ °C upon removal of the iron. This readiness to undergo retrocleavage reactions should not be so pronounced in the higher homologues of the series **1**, since now only one of the cleavage products exhibits aromatic resonance. We now report on *p*-(*o*,*p*)-*o*-tribenzene, **1b**, which is stable at room temperature and is suitable for the addition of further benzene moieties.

**1a**, n = 0; **1b**, n = 1

Institut für Organische Chemie der Universität
Greinstrasse 4, D-5000 Köln 41 (Germany)

The cycloadduct **2**[2] of *p*-benzoquinone and cyclooctatetraene can be transformed by standard methods (reduction of the carbonyl-flanked double bond with zinc in acetic acid, and deoxygenation *via* the bistosylhydrazone[3]) into the benzene adduct **3** of cyclooctatetraene. Compound **3** decomposes at 132 °C into its components and cannot, therefore, be transformed by a thermal Diels-Alder reaction into its dimer **4**. In contrast, in the presence of 12 mol% tris(*p*-bromophenyl)ammoniumyl hexachloroantimonate as catalyst the reaction proceeds in $CHCl_3$ at room temperature within 20 min[4]. In **4** both cyclobutene rings can be simultaneously removed by double cycloaddition of *o*-chloranil and subsequent photolysis to afford **5**, CO, and tetrachlorobenzene[5]. The heptacycle **5** is a tetrabenzene $(CH)_{24}$ in which, in contrast to the principle of construction of the series **1**, the cyclohexadiene ring of the part structure **1b** functions as a dienophile towards benzene. On heating the *p*-(*o*,*p*)-(*o*,*o*)-*p*-tetrabenzene **5** for 12 h at 50 °C, the "wrongly" associated benzene ring is selectively cleaved off, leading to the *p*-(*o*,*p*)-*o*-tribenzene, **1b**. The assignment of the *endo*-configuration to both rings annelated to the central bicyclooctene moiety is based on the chemical shifts of the protons at the ring junctions in **1b** and in the model compounds **7** and **8** (Table 1).

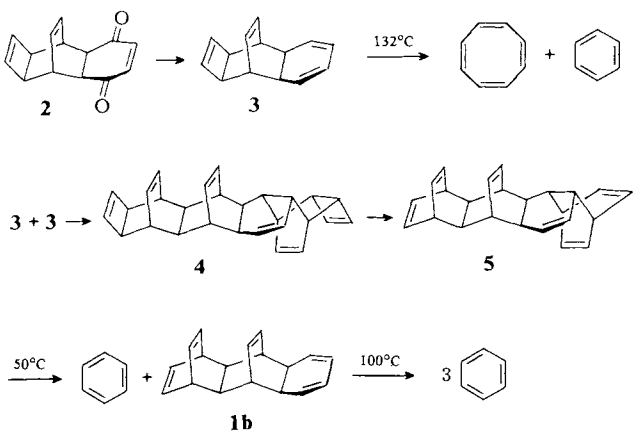

Table 1. Physical data for compounds **1b** and **3**—**8**. $^1$H-NMR spectra ($\delta$-values) were recorded at 90 MHz in $CCl_4$.

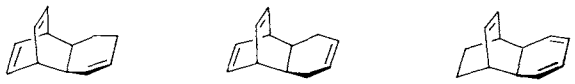
**1b**, m.p. = 95 °C; $^1$H-NMR: 6.62 (m, 2H), 5.77 (m, 4H), 5.27 (AA'BB', 4H), 3.25 (m, 2H), 2.73 (s, 2H), 2.33 (m, 2H), 1.98 (s, 2H)

**3**, m.p. = 77 °C; $^1$H-NMR: 5.93 (m, 2H), 5.79 (s, 2H), 5.38 (AA'BB', 4H), 2.67 (m, 2H), 2.63 (s, 2H), 2.52 (m, 2H)

**4**, m.p. = 180 °C; $^1$H-NMR: 6.1—5.4 (12H), 2.8—1.4 (16H); MS: *m/z* 364 ($M^+$), 260 ($M^+ - C_8H_8$), 104 ($C_8H_8^+$, 100%), 78 ($C_6H_6^+$, 25)



**5**, m.p. = 96 °C (decomp.); $^1$H-NMR: 6.3—6.0 (m, 6H), 5.8—5.2 (m, 6H), 3.35 (m, 4H), 2.8—1.2 (m, 8H)

**6**, $^1$H-NMR: 6.30 (t, 2H), 6.20 (t, 2H), 5.67 (AB, $J$ = 9.5 Hz, 2H), 3.45 (m, 2H), 1.85 (m, 5H), 1.12 (m, 1H)

**7**, $^1$H-NMR: $\delta$ = 6.36 (m, 4H), 5.73 (m, 2H), 3.28 (quint, 2H), 1.93 (m, 6H)

**8**, m.p. = 58 °C; $^1$H-NMR: 6.28 (m, 2H), 5.28 (AA'BB', 4H), 2.82 (s, 2H), 2.42 (m, 2H), 1.40 (AA'BB', 4H)

The tribenzene, **1b**, decomposes at 100 °C into its components; the obligatory dibenzene intermediate, **1a**, cannot be detected. The question at which end of the cyclooligomeric benzenes of type **1** the retro-cleavage occurs can be answered by means of the model adducts **6** to **8**: **6** and **7**, in which benzene is the diene-component, decompose more rapidly than **8**, in which benzene is the ene-component. Furthermore, as comparison of **6** and **7** indicates, the conjugated ene-component 1,3-cyclohexadiene is more readily removed from the cycloadducts with *p*-bonded benzene than its 1,4-isomer (Table 2). On the one hand this leads to an explanation of the selective cleavage of the "wrongly" attached benzene ring of the tetrabenzene **5**, since in this case a conjugated diene is cleaved from a *p*-bonded benzene. On the other hand it is clear that in the decomposition of **1b** the *p*-bonded benzene is removed first.

6 7 8

Table 2. Free energies of activation for the thermal cycloreversion.

| | | *p*-bonded benzene | | | *o*-bonded benzene | |
|---|---|---|---|---|---|---|
| Cpd. | **1b** | **5** | **6** | **7** | **3** | **8** |
| $\Delta G^+$ [kcal/mol] [a] | 29.3 [b] | 25.1 [c] | 26.9 [c] | 28.5 [b] | 31.8 [b] | 35.8 [d] |

[a] At 110.8 °C; error limit ≤ 1.0 kcal/mol. [b] In $CCl_4$. [c] In *n*-dodecane. [d] In $C_2D_2Cl_4$.

For the higher members of the series **1**, it is expected that the *p*-bonded benzene units are cleaved off stepwise with equal activation energies and that the heat of reaction of *ca.* 6 kcal/mol for each benzene extrusion might raise the reaction rate to the explosion limit.

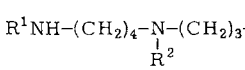
## Synthesis of Acylpolyamines: Acetylspermidines and $C_{12:0}$-Acarnidine**



By *John Boukouvalas, Bernard T. Golding*, Richard W. McCabe,* and *Pritpal K. Slaich*

Naturally occurring acylpolyamines [*e.g.* the $N^8$- and $N^1$-acetylspermidines **1a** and **1b**[1], the alkaloid maytenine, **1c**, the siderophore parabactin **1d**, and the acarnidines, **2a**—**2c**, from the sponge *Acarnus erithacus*[4]] have potential clinical applications. Efficient synthetic routes to these compounds and their analogues are, therefore, required[5]. We describe a general, convergent route to acylpolyamines, which is illustrated by the syntheses of **1a** and **1b** and of the $C_{12:0}$-acarnidine **2a**. In the synthesis of **2a** the value

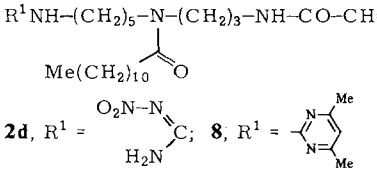
of reductive, electrolytic de-protection of a nitroguanidine is demonstrated.

$R^1NH-(CH_2)_4-N(R^2)-(CH_2)_3-NHR^3$ **1**

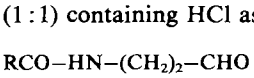
**1a**, $R^1$ = MeCO, $R^2$ = $R^3$ = H; **1b**, $R^1$ = $R^2$ = H, $R^3$ = MeCO



**1c**, $R^1$ = $R^3$ = PhCH=$^{E}$=CHCO, $R^2$ = H

**2a–c**

**2a**, $R^4$ = $Me(CH_2)_{10}$; **2b**, $R^4$ = $Me(CH_2)_5CH=^{Z}=CH(CH_2)_3$

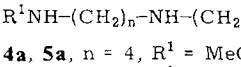


**2c**, $R^4$ = $EtCH=^{Z}=CHCH_2CH=^{Z}=CH(CH_2)_2CH=^{Z}=CH(CH_2)_2$

$R^1NH-(CH_2)_5-N(Me(CH_2)_{10}CO)-(CH_2)_3-NH-CO-CH=CMe_2$ **2d**, **8**

**2d**, $R^1$ = $O_2N-N=C(NH_2)-$; **8**, $R^1$ = 1,4,6-trimethylpyrimidin-2-yl

The propanals **3a—3c** were prepared [yields: *e.g.* 77% for **3b**] by acylating 3,3-diethoxypropylamine and hydrolyzing the resulting acylamidoacetal with aqueous dioxane (1 : 1) containing HCl as catalyst.

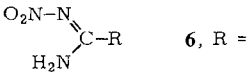


$RCO-HN-(CH_2)_2-CHO$ **3**

**3a**, R = $PhCH_2O$; **3b**, R = Me; **3c**, R = $Me_2C=CH$

*Synthesis of 1a and 1b:* Condensation of **3a** with *N*-(4-aminobutyl)acetamide (molar ratio 1 : 1) in $CH_2Cl_2$ gave the Schiff base **4a**, which was immediately reduced with $NaBH_4$ to afford amine **5a** [47% relative to **3a**]. Hydrogenolysis of **5a** gave **1a** (70%), which was isolated as its dihydrochloride. A similar strategy was used to prepare the dihydrochloride of **1b** [41% relative to **3b**].

$R^1NH-(CH_2)_n-N=CH-(CH_2)_2-NHR^3$ **4**



$R^1NH-(CH_2)_n-NH-(CH_2)_3-NHR^3$ **5**

**4a**, **5a**, n = 4, $R^1$ = MeCO, $R^3$ = $PhCH_2OCO$

**4b**, **5b**, n = 4, $R^1$ = $PhCH_2OCO$, $R^3$ = MeCO

**4c**, **5c**, n = 5, $R^1$ = $O_2N-N=C(NH_2)-$, $R^3$ = $Me_2C=CHCO$

*$C_{12:0}$-Acarnidine, 2a: Blunt et al.*[13] have recently described a synthesis of acarnidine **2a** and analogous structures. In our approach to acarnidine **2a** we protected the guanidino function by an *N*-nitro group. This strategy removes the troublesome basicity of the guanidino group, and has also been used to protect arginine residues in peptides[14]. Furthermore, the de-protection, for which many methods employing either reducing agents or acidic reagents have been described, is conveniently the last step of the synthesis.

$O_2N-N=C(NH_2)-R$ **6**, R = 1,4,6-trimethylpyrimidin-2-yl; **7**, R = $NH-(CH_2)_5-NH_2$

We found that dropwise addition of a solution of amine **6** in dioxane (molar ratio 1 : 1) to 1,5-diaminopentane in dioxane gave *N*-(5-aminopentyl)-*N'*-nitroguanidine **7**, which precipitated directly from the reaction mixture (5.5 h, 20 °C) in 64% yield. Condensation of **7** with aldehyde **3c** (molar ratio 1 : 1) in $CH_2Cl_2$ gave, after 1.5 h at 20 °C, the imine **4c**. This was immediately reduced (excess $NaBH_4$ in MeOH) to amine **5c** (50% relative to **3c**), which was acylated with *p*-nitrophenyl laurate and 1-hydroxybenzotriazole (molar ratio 1 : 1 : 2) in dimethylformamide to give nitro-substituted $C_{12:0}$-acarnidine **2d** [80%]. Attempts to remove the nitro group from **2d** using either $SnCl_2$ or $TiCl_3$ failed. We avoided strong acidic reagents (*e.g.* HF) or catalytic hydrogenation for this de-protection, since these reactions would probably affect the dimethylacryloyl residue of acarnidines and/or the unsaturated fatty acyl groups of acarnidines **2b** and **2c**. In a model experiment we determined that *N*-benzyl-*N'*-nitroguanidine was cleanly converted into *N*-benzylguanidine (isolated as its hydrogen carbonate in 52% yield) when reduced at a mercury cathode (−0.9 V *vs.* SCE) in tetrahydrofuran/0.5 M aq. $H_2SO_4$ (1 : 1).

Application of this method to nitro compound **2d** gave $C_{12:0}$-acarnidine, **2a**, which was isolated as its sulphate by removing THF from the electrolyzed solution. The product contained an impurity (*ca.* 20%), which was removed by preparative layer chromatography.

Reaction of $C_{12:0}$-acarnidine, **2a**, with acetylacetone gave pyrimidine, **8**, isolated as a colorless oil in 55% yield. Its $^1$H-NMR spectrum is consistent with the assigned structure, and its EI mass spectrum exhibits all the structurally significant peaks reported in [4].

Warming solutions of **2d** and **2a** from 294 to 333 K results in the collapse of several of the $^1$H-NMR resonances. We ascribe this behavior to the existence of rotamers about the tertiary *N*-lauroyl bond for compounds **2a** and **2d**.

leads to formation of the 1-(arylcarbonyloxy)alkyltriphenylphosphonium salts **5**[2], which can be converted by reaction with strong bases [sodium bis(trimethylsilyl)amide **6a**[3a], lithium diisopropylamide **6b**[3b]] into the corresponding 1-(arylcarbonyloxy)alkylidenetriphenylphosphoranes **7**. The highly reactive ylides **7** (they undergo Wittig reactions even at $-50\,^{\circ}C$) have surprising properties: when their solutions are heated from $-60\,^{\circ}C$ to room temperature, the unsymmetrically substituted 1,2-diketones **9** and triphenylphosphane **4** are obtained.

We presume that the carbanionic center initially reacts with the acyl moiety in **7** with formation of the zwitterions **8**, which split off **4** to give the diketones **9** (ylide diketone rearrangement). The results of a crossover experiment are consistent with the formation of **8** and, thus, with an *intra*molecular reaction: an equimolar mixture of the salts **5a** and **5b** (Table 1) leads, according to the general procedure for **9**[4] to formation of the diketones **9a** and **9b**. The amount of crossover product **9c** expected from conceivable intermolecular reaction mechanisms is at most 1%[5]. Since the salts **5** are obtainable in good yields for a wide variety of the aromatic moieties $R^1$ and $R^2$[1], the synthetic route presented here constitutes a novel method for the preparation of unsymmetrically substituted 1,2-diketones.

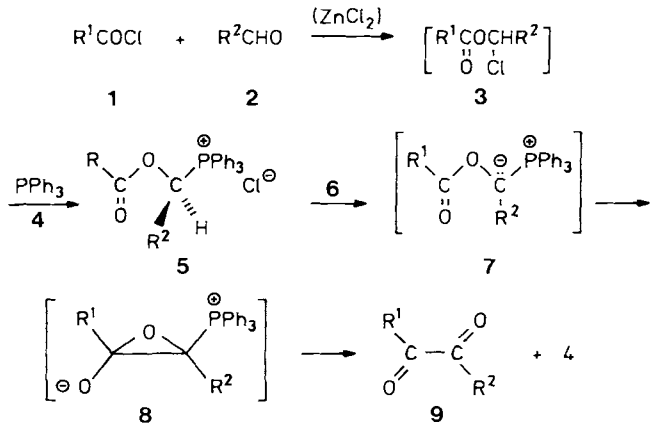

Table 1. 1,2-Diketones **9** from **5**.

| 9 | $R^1$ | $R^2$ | Yield [%] [a] | M.p. [°C] | |
|---|---|---|---|---|---|
| **a** | $C_6H_5$ | $C_6H_5$ | 51, 50 [b] | 92 | (92–96 [6a]) |
| **b** | $p$-$CH_3C_6H_4$ | $p$-$CH_3C_6H_4$ | 35 | 99–100 | (102 [6a]) |
| **c** | $C_6H_5$ | $p$-$CH_3C_6H_4$ | 39, 53 [c] | 31–32 | (31 [6b]) |
| **d** | $p$-$CH_3C_6H_4$ | $p$-$ClC_6H_4$ | 34 | 116–117 | — |
| **e** | $C_6H_5$ | 1-Naphthyl | 31, 51 [c] | 97–98 | (102.5–103 [6c]) |
| **f** | $C_6H_5$ | 1-Thienyl | 34 | 57–58 | (59–60 [6d]) |

[a] The yields have not been optimized; all compounds gave correct elemental analyses. [b] Reaction with **6b**. [c] Results when working at greater dilution (here: 500 mL THF/13.5 mmol **5** [4], otherwise: 200 mL THF/40 mmol **5**, cf. [1]) after 6 h at $-30\,^{\circ}C$.

## $\eta^6$-Bonded Alkylbenzenes as Novel Bridging Ligands in Dinuclear Complexes of Iron and Cobalt

By *Klaus Jonas**, *Gerd Koepe*, *Ludwig Schieferstein*, *Richard Mynott*, *Carl Krüger*, and *Yi-Hung Tsay*

We have recently prepared $(CpVH)_2C_6H_6$ as well as $(CpV)_2C_6H_6$, $(CpV)_2C_6H_5CH_3$, $(CpV)_2C_6H_5C_3H_7$, and $(CpV)_2C_6H_3(CH_3)_3$ ($Cp = \eta^5$-$C_5H_5$), a series of novel dinuclear complexes that are the first reported examples in which $\eta^6$-arene ligands are bonded to two metal centers[1]. While the two vanadium atoms in the hydrido vanadium compound $(CpVH)_2C_6H_6$ are located on the same side of a non-planar $C_6H_6$ ring (Fig. 1a), in the other four complexes the six-membered rings are planar with the metal atoms on opposite sides (Fig. 1b).

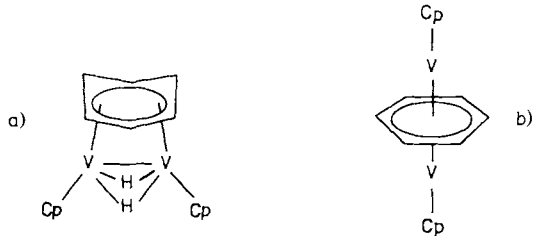

Fig. 1. The compounds (a) $(CpVH)_2C_6H_6$ and (b) $(CpV)_2C_6H_6$ (and analogous alkylbenzene complexes).

A common feature of these vanadium complexes is that their six-membered ring bridging ligands contain six equal or approximately equal CC bond lengths. We now report the iron complexes **2a**, **2b**, and the cobalt complex **4**, all of which contain six-membered ring ligands with unequal CC bond lengths. These bridging ligands are non-planar, as found in $(CpVH)_2C_6H_6$.

Starting material for the synthesis of the iron complexes **2** is CpFe(cod) **1** (cod = 1,5-cyclooctadiene), a monomeric 17-electron metal complex with an unpaired electron, which was prepared from Li[CpFe(cod)] and trityl chlo-

ride[2]. **1** reacts with 2-butyne or 3-hexyne in the molar ratio 2:3 in ether or pentane at 0 °C to give **2a** (Fig. 2) or **2b**,

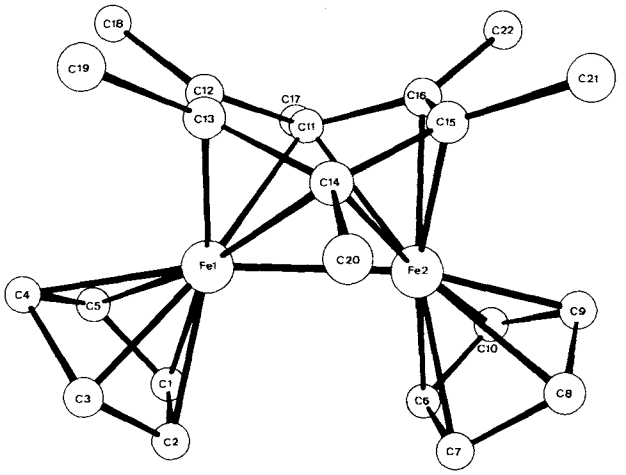

Fig. 2. Molecular structure of **2a** in the crystal [5, 10].

respectively. **2a** and **2b** are fluxional and display antiferromagnetic behavior.

$$2\,\mathrm{CpFe(cod)} + 3\,C_2R_2 \longrightarrow (\mathrm{CpFe})_2C_6R_6 + 2\,\mathrm{cod}$$

**1** — **2a**: R = $CH_3$; **2b**: R = $C_2H_5$

The mononuclear cobalt complex **3**, prepared by hydrocobaltation of *p*-xylene[8], was used as starting material for the synthesis of the dinuclear cobalt complex **4** (Fig. 4).

$$2\,(Cy_2PC_2H_4PCy_2)Co[\eta^5\text{-}C_6H_5(CH_3)_2] \xrightarrow[20\,^\circ C]{-\,C_6H_4(CH_3)_2,\ -\,2\,H^\oplus} [(Cy_2PC_2H_4PCy_2)Co]_2[C_6H_4(CH_3)_2]$$

**3** — **4**

Cy = Cyclohexyl; $[\eta^5\text{-}C_6H_5(CH_3)_2]$ = Dimethylcyclohexadienyl

When a solution of **3** in *p*-xylene is diluted with *n*-hexane and then allowed to stand at room temperature, **4** precipitates as dark red crystals.

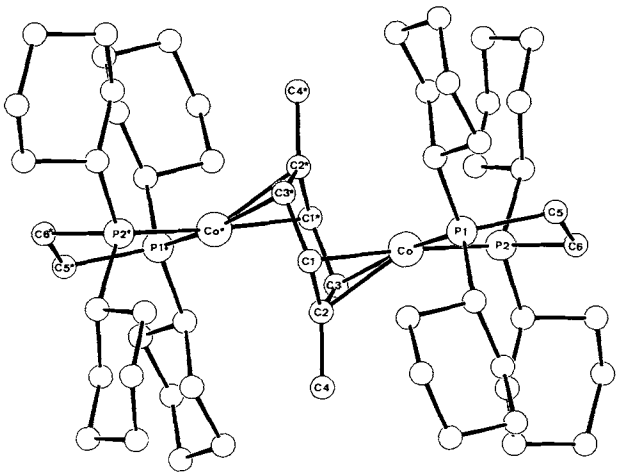

Fig. 4. Molecular structure of **4** in the crystal [9, 10].

The synthesis and structures of these new dinuclear complexes of vanadium, iron, and cobalt, demonstrate that $\eta^6$-arene bridging ligands are capable of bonding two metal centers in at least four different ways.

## The One-Electron Oxidation of Diazasilacyclopentenes**

By *Onno Graalmann, Michael Hesse, Uwe Klingebiel*, William Clegg, Martin Haase,* and *George M. Sheldrick**

*Dedicated to Professor Ulrich Wannagat on the occasion of his 60th birthday*

Following our reports on substitution and elimination reactions at the reactive centers of diazasilacyclopentenes[1,6]—the silyl and the methylene groups—we now turn to the one-electron oxidation of the ring system[7]. As oxidizing agent we chose $AlCl_3/CH_2Cl_2$, which oxidizes compounds with vertical first oxidation potentials of < 8 eV in solution to radical cations[7].

2-*tert*-Butyl-3,3,5-trimethyl-1,2-diaza-3-sila-5-cyclopentene **1** reacts with $AlCl_3/CH_2Cl_2$ with cleavage of 1,2-dichloroethane to give a colorless solid **2**; no ESR signal was found for **2**. The cryoscopic determination of the molar mass of **2** indicated dimerization of an initially formed radical cation. Since a radical cation with bulky substituents should not dimerize so readily we synthesized **3** and oxidized it analogously.

**1, 3** — **2, 4**

**1, 2**, R = R' = Me, **3, 4**, R = $CHMe_2$, R' = $CMe_3$

Colorless crystals of **4** were isolated. Its constitution as a salt of a radical cation was established, *inter alia*, by sig-

nals in a complicated ESR spectrum and by a crystal structure analysis (Fig. 1).

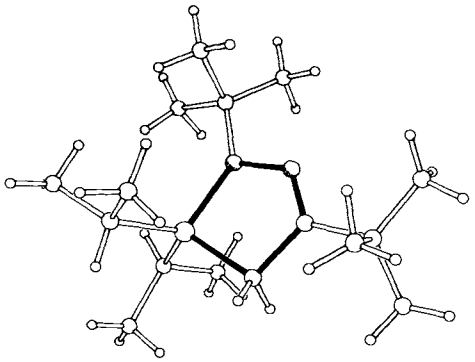

Fig. 1. Structure of the cation of **4** in the crystal. Bond lengths [pm] and bond angles [°] in the inner ring: NN 142.4(12), NSi 178.1(9), SiC 188.6(12), CC 152.3(15), CN 124.5(14); NNSi 108.1(6), NSiC 91.4(5), SiCC 102.7(7), CCN 116.3(9); CNN 119.6(9).

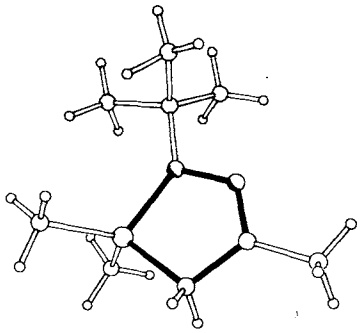

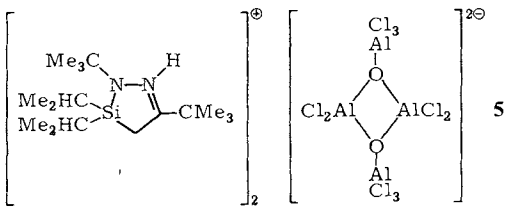

Fig. 2. Structure of the cation of **2** in the crystal.

A change in conformation during the transition from neutral compounds to radical cation was not observed. According to a subsequent X-ray structure analysis, **2** also contains a monomeric cation in the crystal (Fig. 2). **2** and **4** are very sensitive to hydrolysis. During repeated recrystallization of **4**, the formation of a partially hydrolyzed product **5** could not be avoided. X-ray structure analysis shows

that **5** is a protonated diazasilylcyclopentene with a recently described chlorooxoaluminate as counterion[9].

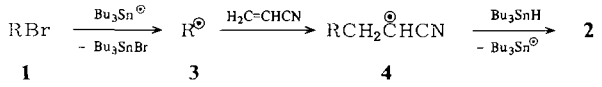
## Diastereoselective Syntheses of *C*-Glycopyranosides**

By *Bernd Giese** and *Jacques Dupuis*

*Dedicated to Professor Sir Derek Barton on the occasion of his 65th birthday*

*C*-Glycosides occur as subunits of natural products[1a] and as enzyme inhibitors[1b], and are of great preparative interest as potential, chiral synthetic building blocks[2a]. The linking of the axial CC bond in the formation of *C*-glycopyranosides such as, *e.g.*, in palytoxin is of special interest[2b]. We have now elaborated a diastereoselective one-pot synthesis of the axial *C*-glycopyranosides **2a–c**, starting from α-D-glycopyranosyl bromides **1a–c**.

10% solutions of **1a–c** with tributyltin hydride (molar ratio 1.0 : 1.0–1.5) and acrylonitrile (10- to 20-fold excess) in boiling ether were photolyzed for 6–12 h. The *C*-glycopyranoside **2a** crystallized out directly in 72% yield (m.p. 120–121 °C). For isolation of the *C*-galactopyranoside **2b** (yield 70%; m.p. 79–80 °C) and of the *C*-mannopyranoside **2c** (yield 65%; oil) the tin salts were precipitated with potassium fluoride and the oily residues chromatographed. The structure assignment can be unequivocally resolved from the $^1$H-NMR spectra[3]. The coupling constants decrease from 6.8–8.5 Hz for diaxial, through 3.1–5.2 Hz for axial/equatorial, to 1.7 Hz for diequatorial arrangements of the vicinal H-atoms on the tetrahydropyran ring.



The NMR spectra contain no indication of the occurrence of equatorial *C*-glycopyranosides; consequently these CC-coupling reactions must proceed very selectively.

As in the reduction of halides with tributyltin hydride[4a], alkyl radicals **3** should also be formed on reaction of gly-

[*] Prof. Dr. B. Giese, J. Dupuis
Institut für Organische Chemie und Biochemie
der Technischen Hochschule
Petersenstrasse 22, D-6100 Darmstadt (Germany)

[**] This work was supported by the Fonds der Chemischen Industrie.

cosyl bromides **1**. These radicals react with acrylonitrile[4c] in competition with H-trapping[4b] to give the adduct radicals **4**. H-Transfer yields the *C*-glycosides **2** and the chain-carrying trialkylstannyl radical.

**1** **3** **4**

The formation of the sterically unfavored α-anomers **2** indicates that either an anomeric effect is effective in the radical CC-bond formation or that σ-radicals are formed which are trapped before their inversion by acrylonitrile. Because of the large variety of possible CC-bond formations *via* radical additions to alkenes[5], this diastereoselective synthesis opens up a wide entry to variously substituted *C*-glycosides with axial alkyl groups on C-1.

## Photocycloaddition of 6-Oxopurines and Thymine to Products with Cyclobutane Part Structures

By *Grażyna Wenska, Stefan Paszyc**, and *Bohdan Skalski*

Previously, it has generally been accepted that among purine and pyrimidine constituents of nucleic acids only the latter can undergo photochemical cycloaddition reactions[1a]. Using dinucleotide analogues in which various purines are linked to pyrimidine by a trimethylene chain, we have observed novel photocycloadducts in which the purine residue is covalently bonded to pyrimidine[1b]. We wish to report here the hitherto unknown, thermally stable cyclobutane photoproducts isolated from low-pressure mercury lamp irradiation of aqueous solutions of **1a** and **1b** ($10^{-3}$ M, ca. 30% conversion of starting materials, 10 min)[2]. Photoproducts **2a** and **2b**[3] were isolated in 80–90% yields (based on amount of **1a** and **1b** consumed).

The absence of CC double bonds in **2a** and **2b** is indicated by their UV and 90 MHz $^1$H-NMR spectra. As expected, only two signals, arising, respectively, from one H, are observed in the low-field region after treating the samples with $D_2O$. The opening of the pyrimidine ring in the purine moiety is also clearly indicated by $^1$H-NMR spectroscopy. Thus, as demanded by the structure of **2a**, one of the N–$CH_3$ resonances appears as a doublet due to coupling with an additional proton at nitrogen.

**1** **2**

**1a** **3a** **2a**

**a**, R=$CH_3$ ; **b**, R=H

Photoproducts **2a** and **2b** undergo a reversible photochemical reaction. Irradiation with light of wavelength $\lambda=254$ nm cleaves a cyclobutane ring. The identity of the resulting product, **3a**, is based on its spectral properties[3] and is further confirmed by comparison with a sample synthesized independently from **1a** by mild alkaline hydrolysis. Irradiation of **3a** with light of wavelength $\lambda>290$ nm gives **2a** as the sole product.

Careful inspection of Dreiding models suggests *cis-syn* geometry for **2a** and **2b** due to the shortness of the trimethylene chain[4].

The formation of **2** could be accounted for by initial photocycloaddition of the CC double bonds $C^5=C^6$ of the thymine and $C^4=C^5$ of the hypoxanthine moiety. In a subsequent dark reaction a water molecule adds to the C=N bond of the 4,5-dihydropyrimidine moiety of hypoxanthine, followed by a ring opening reaction[5]. The reverse sequence

does not occur here since no reaction has been observed upon irradiation of aqueous solutions of 9-propylhypoxanthine with light of wavelength $\lambda=254$ nm.

## Solution-Phase Metal Atom Preparation of Catalytically Active Zeolite-Encapsulated Metal Clusters; Characterization and Application to the Selective Reduction of CO to Butene**

By *Linda F. Nazar, Geoffrey A. Ozin*, François Hugues, John Godber,* and *Denis Rancourt*

Here, we wish to report a new, versatile technique for the preparation of zeolite-encapsulated, zerovalent metal clusters under extremely mild conditions: the method relies on the *in situ* formation of a highly labile organometallic in solution (solvated metal-atom reagents) using rotary metal-vapor, solution-phase synthetic techniques, and is applicable to a wide variety of metals. The choice of the organometallic species that acts as the metal atom carrier is governed by the dimensions and stability of the molecule, which must be sufficiently small to permit access to the α-cage of the zeolite through the outer window (this "opening" is 7.4 Å in diameter for NaY), and must also be sufficiently labile to allow facile dissociation of the organic ligand at or below room temperature. These requirements are fulfilled by the bis(toluene)metal(0) complexes of iron and cobalt, whose dimensions are approximately 7 Å along the longest axis, and which decompose at *ca.* −30 and −50 °C, respectively[1].

The Mössbauer spectra of a representative freshly prepared sample of $Fe_n^0$/NaY with $^{57}Fe$ enrichment, and of a deliberately oxidized sample show that Fe is no longer present as bis(toluene)iron(0)[2], that no oxidation has occurred during the preparation of the sample, that the average size of the $Fe_n^0$ particles is quite small, and that they are superparamagnetic. The Mössbauer doublets for $Fe_n^0$/NaY show different line intensities and line widths, and can adequately be fitted assuming only a distribution of isomer shifts and quadrupole splittings, although relaxation and Gol'Danskii-Karyagin effects cannot be discounted as contributing towards the observed line asymmetry.

The diameters of the iron clusters were calculated from the magnetization curves of the various $Fe_n^0$/NaY samples, using the low field ($d_{LF}$) and high field ($d_{HF}$) approximations of the Langevin function for superparamagnetic particles. The $\bar{d}_{LF}$ and $\bar{d}_{HF}$ diameters of the superparamagnetic $Fe_n^0$ clusters lie between 4 and 11 Å, with an average value of $\bar{d} \approx 6-7$ Å. Furthermore, from the Mössbauer spectra it can be estimated that *ca.* 80–90% of the iron is present in the form of these very small iron clusters. It is also interesting that most of the $Fe_n^0$ clusters formed by the bis(toluene)iron(0) method have diameters less than 12 Å, the diameter of the supercage of zeolite Y. Although this cannot be taken as proof that the iron clusters lie within the zeolite α-cages, the very large quadrupole splittings observed in the Mössbauer spectra strongly suggest that this is indeed the case.

Metal analysis of $Fe_n^0$/NaY and $Co_n^0$/NaY samples showed that there is a decided preference by a factor of about 5 for adsorption of the organometallic in the α-cage over that of the toluene; we presume that this originates from the greater interaction between the $Na^+$ cations of the zeolite and complexed toluene rings rather than with free toluene[12].

Preliminary results on samples of $Fe_n^0$/NaY and $Co_n^0$/NaY containing *ca.* 0.5% Fe and 2.4% Co by weight, respectively, indicated they were catalytically active for the Fischer-Tropsch synthesis (above 230 °C, 1 atm pressure, flow microreactor/on-line gas chromatograph system).

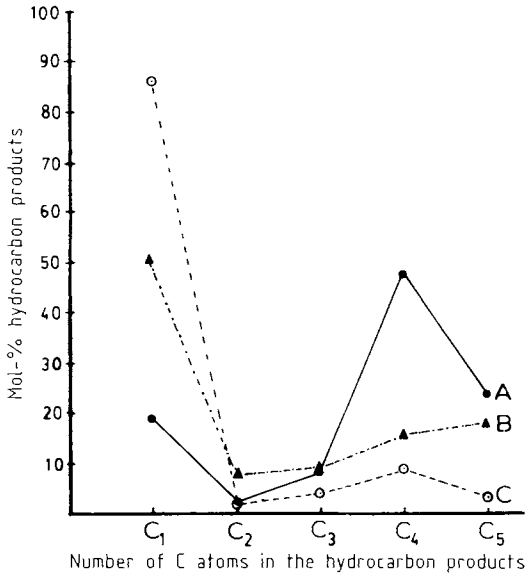

Fig. 4 I. Distribution of products in the Fischer-Tropsch synthesis with $Fe_n^0$/NaY catalysts. A) Normal sample (see Supplement), 250 °C, $CO/H_2 = 1:2$, 0.15% conversion; 1-butene: 10.4 mol-%, isobutene: 5.0%, *trans*-2-butene: 16.2%, *cis*-2-butene: 15.4%. B) Normal sample, 300 °C, $CO/H_2 = 1:2$, 0.10% conversion. C) Sample P, 250 °C, $CO/H_2 = 1:2$, 0.02% conversion.

The resultant hydrocarbon distribution with $Fe_n^0$/NaY and $Co_n^0$/NaY samples at *ca.* 250 °C do not follow Schulz-Flory (SF) behavior[13]. A high selectivity for $C_4$ hydrocarbons is evident, corresponding to *ca.* 50 and 70 mol% of the total hydrocarbons for the iron and cobalt catalysts, respectively, with little $CH_4$ being formed (Fig. 4 I A and 4 II A). When the reaction was carried out at *ca.* 290–300 °C, however, the fraction of $CH_4$ increased, less $C_4$ hydrocarbon was formed, and selectivity decreased (Fig. 4 I B and Fig. 4 II B). Furthermore, a zeolite sample which had been specifically prepared to contain large clusters of iron on the external zeolite surface, by allowing the bis(toluene)iron(0)/zeolite slurry to warm to RT during filtration (sample P), showed very high levels of $CH_4$ at 250 °C and a small amount of $C_4$ hydrocarbon (Fig. 4 I C). The data at *ca.* 250 °C are consistent with the presence of very small $Fe_n^0$ and $Co_n^0$ clusters in the zeolite super-cages, giving rise to the observed product selectivity. As the temperature is raised, migration and sintering of metal clusters occurs, resulting in larger clusters, probably on the zeolite external surface and, hence, in higher levels of $CH_4$.

Daniels*, Toronto, for the use of their magnetic and Mössbauer equipment and for their invaluable advice.

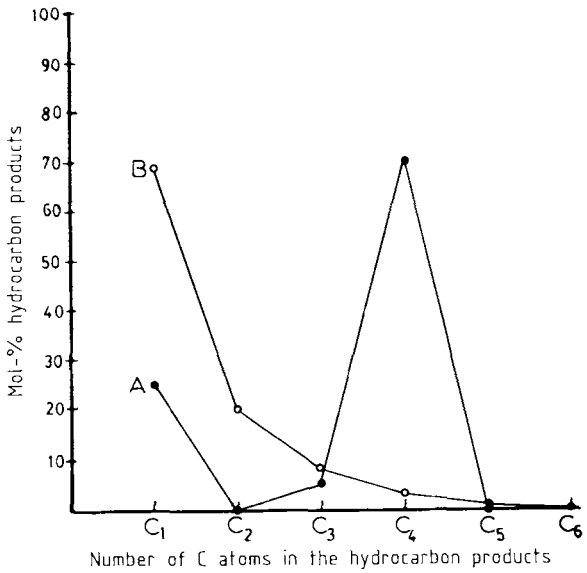

Fig. 4 II. Distribution of products in the Fischer-Tropsch synthesis with $Co_n^0/NaY$ catalysts. A) Normal sample, 247 °C, $CO/H_2 = 1:2$, 0.02% conversion, 1-butene: 33 mol-%, isobutene: 3%, *trans*-2-butene: 18.5%, *cis*-2-butene: 15.5%. B) Normal sample, 290 °C, $CO/H_2 = 1:2$, 0.04% conversion.

In summary, $Fe_n^0/NaY$ and $Co_n^0/NaY$ clusters encapsulated in zeolites have proven to be interesting catalysts for the conversion of $CO/H_2$ mixtures into low carbon number olefins with a propensity towards $C_4$ products. The results reinforce the hypothesis of *Jacob et al.*[15] that Fischer-Tropsch product distributions are directly dependent on metal particle size.

## Detonation of Benzyl(triethyl)ammonium Permanganate

By *Jürgen Graefe* and *Roland Rienäcker**

Although several groups have already reported on the danger of benzyl(triethyl)ammonium permanganate[1-3], a recent incident in our laboratory gives cause for a renewed warning that utmost care must be taken when handling this compound.

[*] Dr. R. Rienäcker, Dr. J. Graefe
Max-Planck-Institut für Kohlenforschung
Kaiser-Wilhelm-Platz 1, D-4330 Mülheim a. d. Ruhr (Germany)

Crystalline benzyl(triethyl)ammonium permanganate (*ca.* 50 g) was prepared from benzyl(triethyl)ammonium chloride and potassium permanganate according to the method described by *Schäfer et al.*[4], but instead of drying the crystals as prescribed, *i.e.* at 40 °C in a vacuum drier[5], they were dried in a high vacuum at 20 °C over 36 h. On pouring these dried crystals from a wide-necked Erlenmeyer flask into another vessel, they ignited explosively with formation of a flame about 1 m in length.

Thus, contrary to previous reports, benzyl(triethyl)ammonium permanganate can decompose explosively even at room temperature, so very strict safety measures should be taken when using this oxidizing agent in the dry state.

[5] H. J. Schäfer *et al.* have been using this compound, even in large amounts (200 g), in their work over the past 6 years and have never observed a detonation when drying the reagent in a vacuum drier (max. 40 °C, *ca.* 20 torr) or a dessicator (RT, 15 torr, Sicapent) (private communication).

## Kinetics of the Reaction of Electron Deficient Olefins with Nitrile Ylides Generated by Laser Flash Photolysis of Substituted Azirines**

By *Nicholas J. Turro**, *David A. Hrovat*, *Ian R. Gould*, *Albert Padwa*, *William Dent*, and *Robert J. Rosenthal*

*Dedicated to Professor G. O. Schenck on the occasion of his 70th birthday*

In view of the traditional importance of nitrile ylides as intermediates in azirine photochemistry[1] and the new attention that these species have acquired as possible intermediates in carbene chemistry[2], we have initiated a pulsed laser transient absorption study of a series of azirines **1**—**3**. The nitrile ylides derived from these azirines have been characterized both in terms of their optical absorption spectra and absolute rates of reactivity, and as possible intermediates in carbene chemistry.

[**] The authors at Columbia thank the Air Force Office of Scientific Research and the National Science Foundation for their generous support of this research. The authors at Emory acknowledge the support of the National Science Foundation.

Pulsed laser photolysis of Ar-purged isooctane solutions of **1**—**3** at 25 °C resulted in the production of intense, long-lived ($\tau > 100$ μs) absorptions over the range 250—400 nm. Absorption spectra taken *ca.* 5 μs after the laser pulse are in excellent agreement with those obtained at 77 K (Table 1). While laser photolysis of azirines **1** and **3** gave rise to absorptions attributable to nitrile ylides only, azirine **2** yielded a signal of an additional short-lived intermediate in the range 300—320 nm. This species, unlike the ylides, was quenched by $O_2$ ($k_q = 2 \times 10^9$ M$^{-1}$ s$^{-1}$), thus allowing us to obtain the spectrum of the ylide alone. Subtraction of the $O_2$-purged spectrum from the Ar-purged spectrum (after normalization at 370 nm) resulted in a spectrum of the short-lived intermediate with $\lambda_{max} = ca.$ 305 nm; this corresponds well with that of diphenyl carbene produced by other routes[3]. It is important that the ylide absorption obtained from azirine **2** is not observed upon pulsed laser photolysis of diphenyl carbene precursors in acetonitrile solvent. This is in contrast to the observation of an ylide, formed by addition of the free carbene to the nitrile solvent, upon laser flash photolysis of 9-diazofluorene in acetonitrile[2]. Evidently, the rate constant for reaction of acetonitrile with diphenyl carbene is significantly smaller than that of acetonitrile with fluorenylidene.

Table 1. Absorption maxima and rate constants of the subsequent reactions of the primary photolysis products of azirines **1**—**3**.

| Azirine | $\lambda_{max}$ (77 K) [nm] [a] | $\lambda_{max}$ (298 K) [nm] [b] | $k_q$ [d] (acrylonitrile) [M$^{-1}$ s$^{-1}$] | $k_q$ [d] (fumaronitrile) [M$^{-1}$ s$^{-1}$] | $k_{rel}$ (acrylonitrile, fumaronitrile) |
|---|---|---|---|---|---|
| **1** | 346 | 345 | $(1.22 \pm 0.03) \times 10^6$ | $(1.09 \pm 0.07) \times 10^9$ | $890 \pm 100$ |
| **2** | 368 | 305 [c], 360 | $(1.0 \pm 0.3) \times 10^6$ | $(5.4 \pm 0.3) \times 10^8$ | $540 \pm 200$ |
| **3** | 277 | 280 | $(5.4 \pm 0.3) \times 10^6$ | $(7.4 \pm 0.8) \times 10^9$ | $1370 \pm 200$ |

[a] Steady-state photolysis (1000 W Xe/Hg arc lamp equipped with a high intensity monochromator; $\lambda_{ex} = 248 \pm 10$ nm) of *ca.* $10^{-5}$ M azirine in Ar-purged 3-methylpentane. [b] Laser flash photolysis (Lambda Physik EMG 101 Excimer Laser, 248 nm, 15 ns pulse width) of *ca.* $10^{-5}$ M azirine in Ar-purged isooctane. [c] This absorption is quenched by $O_2$ (see text). [d] Conditions are the same as in [b], except that azirine, **1**, was excited at 308 nm (20 ns pulse width).

In the absence of quenchers the observed transient decays for each ylide exhibit both first and second order components; however, pulsed laser photolysis of azirines **1**—**3** in the presence of electron deficient olefins in $O_2$-saturated isooctane solution resulted in quenching of the transient absorption. At sufficiently high olefin concentrations, the decay of the transient obeyed clean first-order kinetics. Under these experimental conditions, plots of the observed first-order rate for ylide decay as a function of olefin concentration were linear, and their slopes gave the bimolecular quenching rate constant, $k_q$. The rate constants for quenching by acrylonitrile and fumaronitrile are listed in Table 1. For azirine **1** the relative quenching rates of fumaronitrile and acrylonitrile have been reported in the literature from steady-state trapping experiments[4]. This value ($1070 \pm 100$) is the same, within experimental error, as that obtained from our absolute rate constants ($890 \pm 100$).

The rate constants $k_q$ for the reaction of the nitrile ylide derived from **1** with methyl acrylate and diethyl fumarate were studied as a function of temperature. The resulting Arrhenius plots after correction for solvent contraction indicate that $k_q$ for methyl acrylate is essentially insensitive to temperature ($E_a \approx 0$ kcal/mol), while the quenching rate constant for diethyl fumarate initially increases with decreasing temperature ($E_a \approx -1.5$ kcal/mol) and begins to decrease at temperatures below *ca.* −65 °C. This type of Arrhenius behavior has been observed previously for the quenching of phosphorescence from ketones, carbenes, and singlet oxygen[5]. A kinetic scheme which fits this behavior is given in eq. (a), where NY is the nitrile ylide and NY/olefin is a nitrile ylide/olefin complex:

$$\text{NY} + \text{olefin} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{NY/olefin} \xrightarrow{k_2} \text{product} \qquad \text{(a)}$$

Assuming steady-state kinetic behavior for the complex, the observed first-order quenching rate constant, $k_q$, can be expressed in terms of the above rate constants to give eq. (b):

$$k_q = \frac{k_1 k_2}{k_{-1} + k_2} \qquad \text{(b)}$$

Rearrangement of this equation gives the ratio of the rates for dissociation and collapse to product for the ylide/olefin complex [eq. (c)]. Assuming that complex formation is diffusion controlled (*i.e.*, $k_1 = k_{diff}$), calculation of the diffusion rate constant at the temperatures at which $k_q$ was obtained yields values for the ratio $k_{-1}/k_2$ from eq. (c):

$$k_{-1}/k_2 = \frac{k_1 - k_q}{k_q} \qquad \text{(c)}$$

A plot of $\lg k_{-1}/k_2$ *versus* 1/T was found to yield a straight line (Fig. 1), whose slope yields the difference in the activation parameters for product formation and dissociation of the complex (*i.e.*, $\Delta\Delta G^{\neq} = \Delta G^{\neq}_{prod} - \Delta G^{\neq}_{diss}$). As expected, the free energy requirement for reaction *versus* dissociation is greater for the slower quencher methyl acrylate

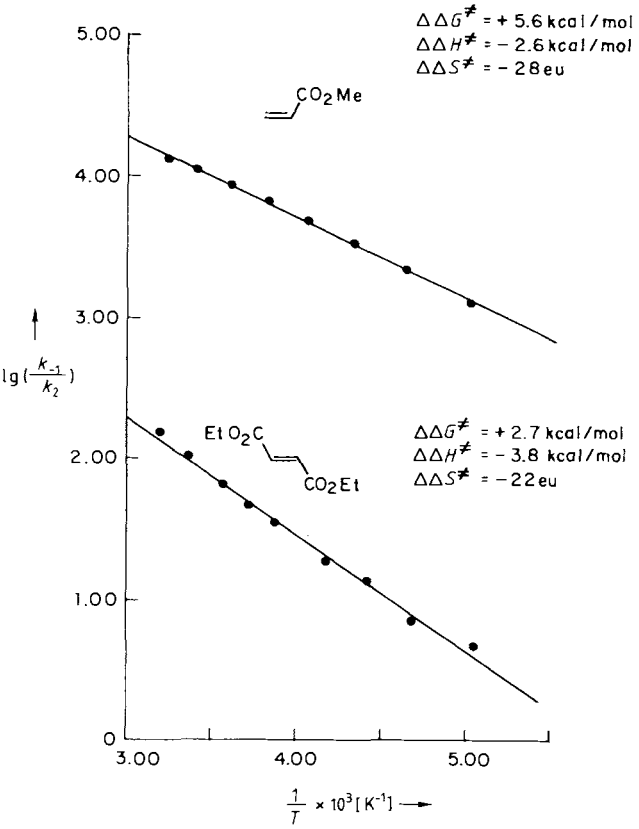

Fig. 1. Plot of $\lg(k_{-1}/k_2)$ against $1/T$ ($\Delta\Delta G^{\neq}$ calculated at $T = 298$ K).

 © Verlag Chemie GmbH, 6940 Weinheim, 1983 0570-0833/83/0808-0626 $ 02.50/0 

than for the faster quencher, diethyl fumarate; however, it is noteworthy that the bulk of this free energy difference, $\Delta\Delta G^{+}$, results from differences in the activation entropy rather than enthalpy.

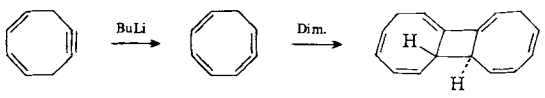
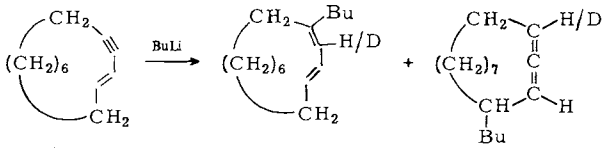
## Base-Induced Isomerization of Cycloalkenynes in Competition with Addition Reactions**

By *Johannes Zountsas, Matthias Kreuzer,* and *Herbert Meier**



The recently discovered group of substances the cycloalkenynes, such as **1**[3,4], offer interesting possibilities for reaction with bases. Besides isomerization to cyclic allenes **2**, with bases—such as alkyllithium compounds—addition reactions must also be considered; here, the regioselectivity is decisive for preparative applications. Isotopic labeling with deuterium has proved of value in elucidating the course of the reaction.

Bu = *n*-$C_4H_9$, *t*-$C_4H_9$
**1a**, **3a**, **4a**: n = 4
**1c**,**c'**, **2c**, *trans*-**3c**, **8c**: n = 8



All variants of the eight-membered ring system **1** lower the geometrical ring-strain energy $E_g$. 1,2-Addition to the triple bond is thermodynamically most favorable, since only in **3** and **4** is $E_g = 0$. 1-Cycloocten-3-yne, **1a**, adds to butyllithium, used in *ca.* threefold excess, to afford exclusively **3a** and **4a**. Here, in contrast to *cycloadditions* of **1a**, a regioselectivity in favor of **3a** is observed (*n*BuLi, **3a** + **4a** = 80%, **3a** : **4a** = 80 : 20, *t*BuLi, **3a** + **4a** = 80%, **3a** : **4a** = 76 : 24). This orientation corresponds to the distribution of charge estimated from the $^{13}$C-NMR signals. Thus, in **1a** the electron density at C-4 is smaller than at C-3; the $C_4H_9^{\ominus}$ ion therefore favors addition at C-4.

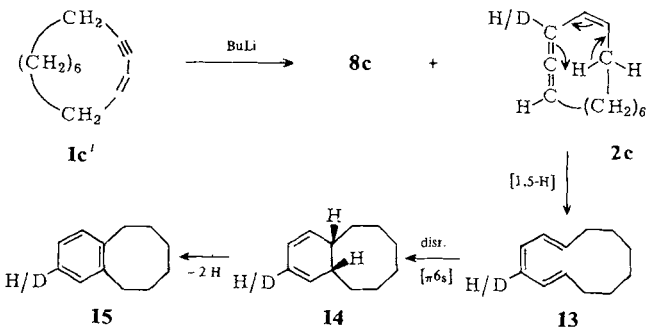
1,3-Cyclooctadien-6-yne, **1b**, behaves differently. Base-catalyzed isomerization results first in 1,2,4,6-cyclooctatetraene, **2b**, which dimerizes regio- and stereospecifically to afford **9** (yield with *n*BuLi and *t*BuLi, 72%)[6]. The stereochemistry of the addition was determined from the 4-phenyl-1,2,4-triazolin-3,5-dione adducts.

**1b** **2b** **9**

The two highly strained eight-membered ring alkynes **1a** and **1b**, therefore, behave quite differently with butyllithium. For comparison we examined the strained twelve-membered ring *trans*-enyne, **1c**, and its *cis*-isomer, **1c'**, with $E_g = 0$[4]. Although in analogy to **1a**, **1c** forms the 1,2-adduct **3c** (30%), the main reaction is, nevertheless, a regiospecific 1,4-addition to give **8c** (57%).

**1c** **3c** **8c**

In contrast, only 13% **8c** is formed from **1c'**; isomerization to **2c** (54%) is preferred. At room temperature, **2c** rearranges by suprafacial [1,5-H]-shift to afford the (*E,Z,E*)-1,3,5-cyclododecatriene, **13**, which undergoes thermally allowed, disrotatory ring closure to yield the bicycle **14**. The isomerization **2c** → **13** → **14** proceeds quantitatively; at room temperature which of the three products is isolated depends only on the reaction time. Heating **14** for several hours lead to its dehydrogenation and to formation of **15** (60%).



The four modes of reaction of the cycloalkenynes (**1a**, **b**, **c**, **c'**) with butyllithium should serve to indicate the synthetic potential of the reactions.—Open-chain enynes are less reactive[10].

High-field measurements and double resonance experiments permit the products described here to be characterized from their $^1$H- and $^{13}$C-NMR data.

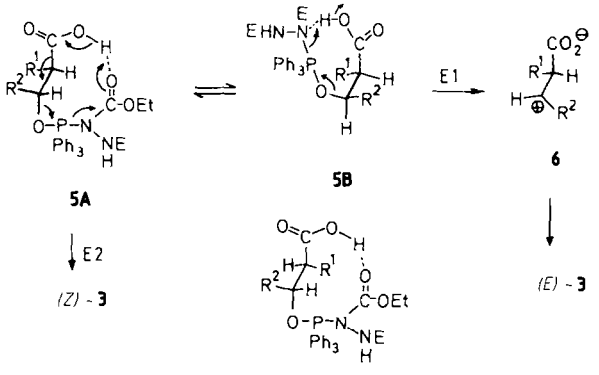
## Olefins from β-Hydroxycarboxylic Acids—Synthesis of Isomerically Pure α- and β-Asarone**

By *Johann Mulzer** and *Ortrud Lammer*

The dehydrative decarboxylation of β-hydroxycarboxylic acids (**1**, **4**) with the adduct **2** has proven useful for the synthesis of olefins[7b]. We report here on the steric course of the reaction, and, as an application, we describe the synthesis of isomerically pure α- and β-asarone (**11** and **13**, respectively).

**1** *(threo)* *(Z)*-**3** *(E)*-**3**



**4** *(erythro)*

In the *threo* series[8] (Table 1) the isomeric distribution shifts with increasing +M effect of $R^2$ from pure (*Z*)-**3** to pure (*E*)-**3**. The residue $R^2$ can be catagorized into three groups. I: $R^2$ with small +M effect. In these cases pure (>98%) (*Z*)-**3** is formed. II: $R^2$ with medium +M effect. (*Z*)- and (*E*)-**3** are both formed in varying amounts. III: $R^2$ with large +M effect. Up to >98% (*E*) is obtained. Compared to $R^2$, $R^1$ is of minor significance and merely shows an influence on the acids in group II. The *erythro* acids **4a—c**, **h—m** (notation analogous to **1**, see Table 1) always afford >98% (*E*)-**3** in yields of 80—95%, independent of the nature of $R^1$ and $R^2$.

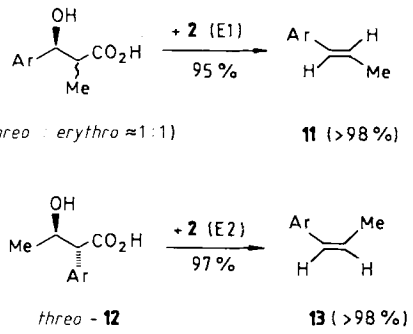
Table 1. Steric course of the reaction of **1** with **2** (tetrahydrofuran, 22°C, 5 min). Presumed mechanism: group I: E2; group II: E2 and E1; group III: E1.

| **1** | $R^1$ | $R^2$ | **3** *Z* : *E* [a] | Yield [b] | Group |
|---|---|---|---|---|---|
| **a** | Ph | Me | >98 : 2 | 73 | |
| **b** | Ph | Et | >98 : 2 | 82 | |
| **c** | Ph | *i*Pr | >98 : 2 | 92 | I |
| **d** | *t*Bu | Et | >98 : 2 | 60 | |
| **e** | OPh | Et | >98 : 2 | 85 | |
| **f** | OPh | *n*Pr | >98 : 2 | 84 | |
| **g** | Ph | Vinyl | 94 : 6 | 91 | |
| **h** | Me | Ph | 85 : 15 | 82 | |
| **i** | Et | Ph | 73 : 27 | 87 | |
| **j** | Ph | Ph | 55 : 45 | 82 | II |
| **k** | *i*Pr | Ph | 24 : 76 | 81 | |
| **l** | *t*Bu | Ph | < 2 : 98 | 82 | |
| **m** | | | | | |
| **n** | Ph | 2-Furyl | < 2 : 98 | 96 | |
| **o** | Ph | 4-$MeOC_6H_4$ | < 2 : 98 | 87 | III |
| **p** | Ph | 4-$Me_2NC_6H_4$ | < 2 : 98 | 92 | |

[a] **a—m**: Determined by GC; **n—p**: determined by $^1$H-NMR (60 MHz, $CDCl_3$). [b] Aside from **3**, *ca.* 10% β-lactone is also formed from **1a—d**, **h—m**.

**5A** **5B** **6** **7**

Scheme 1. E = $CO_2Et$.



These results find a mechanistic rationalization in the hydroxy-activated intermediates **5** (from **1**) and **7** (from **4**), which decompose *via* E2- or E1-fragmentation, depending on the electron supply from $R^2$ (Scheme 1). In the *threo* series these two mechanisms lead to sterically different products. The E2-reaction is coupled with the *anti*-conformation **5A** and furnishes (*Z*)-**3**. The E1-route, on the other hand, proceeds *via* the conformer **5B**, sterically favored by the larger $R^1$—$R^2$ distance, and **6** to (*E*)-**3**. Thus, the data in Table 1 can be interpreted to the effect that group I is operated by the E2-mechanism and group III by the E1-mechanism. In group II, on the other hand, both mechanisms depend on the position of equilibrium **5A** ⇌ **5B**; the E1-decomposition being favored more and more with increasing bulkiness of $R^1$ (**h—m**). In the *erythro* series the all-*anti* arrangement **7** is the optimal intermediate for both mechanism; hence, (*E*)-**3** becomes the sole possible isomer.

*Synthesis of α- and β-asarone 11 and 13*, respectively: Asarone **13**, a constituent of calamus oil, was first recognized in 1977 as a novel chemosterilizing insecticide[11]. The activity

is connected with the (*Z*)-geometry[11]. **11** and **13** cannot be prepared in isomerically pure form by Wittig reaction[12], and they are almost unseparable even by TLC.

Scheme 2. Ar = 2,4,5-trimethylphenyl.

As an easy access to **11** and **13** we chose the reaction of **10** and **12** with **2** (Scheme 2). The electron-rich aryl group ($R^2$) in **10** enforces the E1 elimination and, quite consistently, **11** is formed from **10** in >98% yield. In the case of **12**, on the other hand, the methyl group induces an E2-mechanism; up to >98% of **13** is isolated. The transition from **10** to **12** corresponds to an interchange of substituents $R^1$ and $R^2$ with largely differing +M effects. The character of elimination is—in complete agreement with our interpretation—thereby completely shifted from E1 to E2.

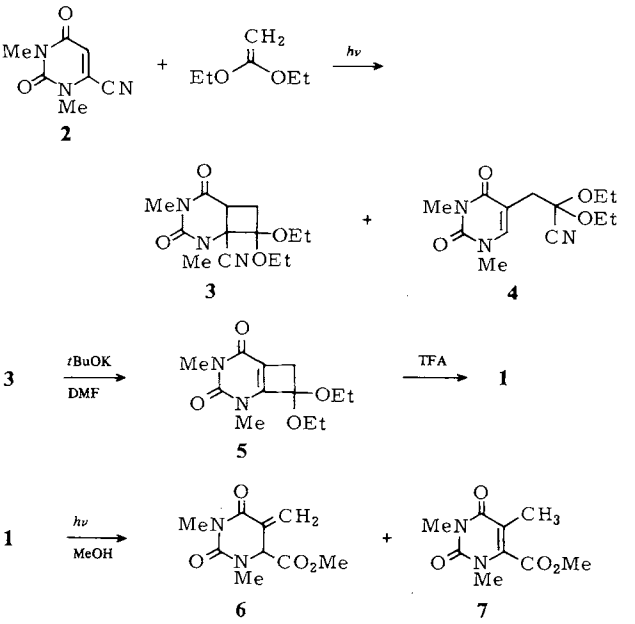
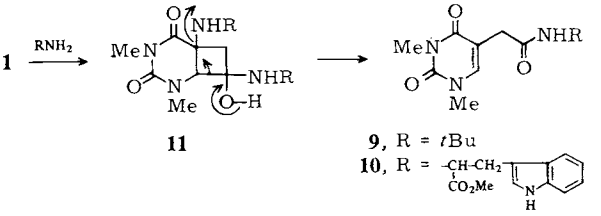
## Photocycloaddition of 6-Cyanouracil to Ketene Diethyl Acetal: Synthesis of a Uracil Derivative Possessing a Cyclobutenone Framework



By *Isao Saito*, Fuyuhiko Kubota, Koji Shimozono,* and *Teruo Matsuura**

*Dedicated to Professor G. O. Schenck on the occasion of his 70th birthday*



The synthesis of highly photochemically reactive pyrimidine bases is of special importance for photochemical modification of nucleic acids[1]. Upon irradiation, pyrimidine bases possessing cyclobutenone frameworks are expected to exhibit high reactivity toward nucleophiles, since photochemical ring-opening of cyclobutenone may produce highly reactive vinylketene derivatives[2]. We describe here the synthesis of 2,4-diazabicyclo[4.2.0]oct-1(6)-en-3,5,8-trione **1**, the first uracil derivative possessing a cyclobutenone framework, utilizing photocycloaddition as a key step.

Irradiation of 6-cyano-1,3-dimethyluracil, **2**, and excess ketene diethyl acetal in acetonitrile at −25 °C using a high-pressure mercury lamp (Pyrex filter) gave cycloadduct **3** (40%) and rearranged product **4** (23%). The formation of rearranged adducts such as **4** has previously been shown to occur in the photoaddition of **2** to other olefins[4]. Conversion of **3** into **5** (80%) was readily accomplished by reaction with potassium *t*-butoxide in dimethylformamide. Treatment of acetal **5** with 90% trifluoroacetic acid (TFA) gave cyclobutenone **1** (77%) [m.p. = 108—110 °C; $^1$H-NMR ($CDCl_3$): $\delta$ = 3.38 (s, 3H), 3.40 (s, 3H), 3.67 (s, 2H)].

Cyclobutenone **1** is stable at ambient temperature in the usual organic solvents, including alcohols; however, irradiation of methanolic solutions of **1** resulted in rapid formation of **6** (55%) and **7** (21%). **7** also formed by prolonged irradiation of **6**, whereas the latter probably originates from the trapping of vinylketene **8** by methanol.

Unexpectedly, cyclobutenone **1** reacts smoothly with primary amines without irradiation at ambient temperature to give 5-substituted uracil derivatives in high yields. For example, treatment of **1** with *t*-butylamine gave **9** quantitatively. When a solution of **1** and tryptophan methyl ester

[*] Prof. Dr. I. Saito, F. Kubota, K. Shimozono, Prof. Dr. T. Matsuura
Department of Synthetic Chemistry, Faculty of Engineering
Kyoto University, Kyoto 606 (Japan)

in acetonitrile was stirred at room temperature, the adduct **10** precipitated (76%). Thus the cyclobutenone **1** can be used as a synthon for the preparation of 5-substituted uracil derivatives under neutral conditions. In view of the high reactivity of the CC double bond of cyclobutenones toward nucleophiles[2], **9** is assumed to arise from ring-opening of the amine adduct **11**[5].

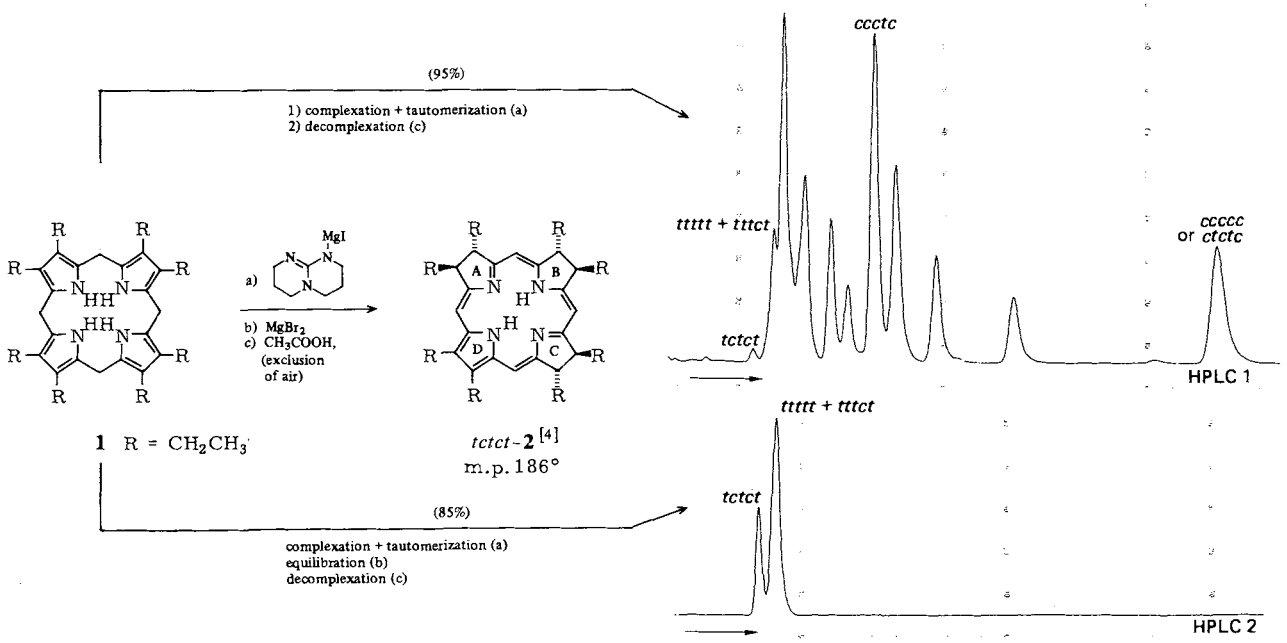
## The Chemistry of Pyrrocorphins: Stereoselectivity in the Porphyrinogen→Pyrrocorphin Tautomerization**

By *Rudolf Waditschatka* and *Albert Eschenmoser**

As originally surmised[1], and recently demonstrated[2], the corphinoids play a central role in the biosynthesis of vitamin $B_{12}$. We report here new findings on the chemistry of the pyrrocorphins[3].



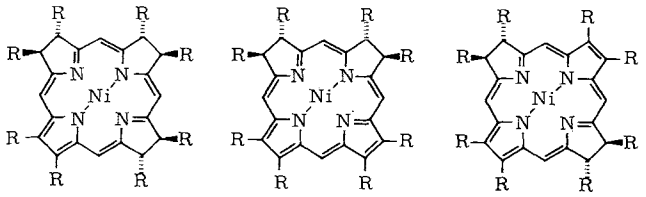
Pyrrocorphin[3]

Corphin[1]

Optimized reaction conditions have now been found for the previously reported[3a] porphyrinogen→pyrrocorphin tautomerization. Thus, treatment of octaethylporphyrinogen **1** with the MgI salt of 1,5,7-triazabicyclo[4.4.0]-dec-5-ene (TBD) directly followed by decomplexation with acetic acid (see legend to Scheme 1), provided a mixture of diastereomers of the octaethylpyrrocorphins **2** in practically quantitative yield. This endergonic isomerization proceeds *via* the non-isolated mixture of diastereomeric Mg pyrrocorphinate complexes (assumed to be decomplexed under conditions of kinetic control)[3a]. HPLC of the non-equilibrated mixture of pyrrocorphins resulted in detection of at least 12 of the 20 possible diastereomers (UV/VIS, HPLC 1), the configurations of three of which have been assigned. Normally, the *cctc* isomer[3a,4] makes up the main part (15–20%) of such mixtures.

If the mixture is allowed to equilibrate between the tautomerization and the decomplexation steps, or the 12-component mixture is subjected to such conditions, a mixture of diastereomers is obtained in 85% yield, HPLC of which now shows only two fractions (HPLC 2). The first fraction (*ca.* 30% of the total mixture) is the readily crystallized

Scheme 1. R = Et. a) $8 \times 10^{-3}$ M **1** in xylene, 15 equiv. TBD, 5 equiv. EtMgI, 16 h, 85°, under $N_2$. Work-up with saturated NaCl/$H_2O$ (or c directly). b) $2 \times 10^{-3}$ M Mg-complex of **2** in wet benzene, 12 equiv. $MgBr_2$, RT, 15 min. c) 10% $CH_3COOH$ in saturated NaCl/$H_2O$, 1 min, *ca.* 20°C. All operations conducted in glove box (< 5 ppm $O_2$). HPLC Partisil 5; pentane + 1.5 vol.-% $Et_3N$, detection 340 nm. For experimental details see *R. Waditschatka*, Dissertation ETH Zürich (in preparation), and [5c].



isomer *tctct*-**2** (m.p. = 186°C). The second fraction is a binary (not crystallized) mixture of isomers *ttttt*-**2** (*ca.* 25%) and *tttct*-**2** (*ca.* 45%). Thus, *tctct*-**2**, a crystalline representative having the pyrrocorphin structure, can be prepared in 20–25% yield directly from octaethylporphyrinogen.

The configurational assignment of *tctct*-**2** rests on the complexation with nickel(II) acetate (acetic acid, 110°C, 5

[*] Prof. Dr. A. Eschenmoser, R. Waditschatka
Laboratorium für Organische Chemie der
Eidgenössischen Technischen Hochschule, ETH-Zentrum
Universitätstrasse 16, CH-8092 Zürich (Switzerland)

[**] This work was supported by the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung. We thank Dr. *D. Livingston* for translating the German manuscript and Dr. *E. Zass* for his assistance in the preparation of the final version.

min), which gives the known[3a] nickel(II) pyrrocorphinate *tctct*-**3** as the sole product (HPLC, $^1$H-NMR, UV/VIS). Incorporation of nickel into the second fraction of HPLC 2 gives, in contrast, two nickel pyrrocorphinates, easily separable by HPLC. Dehydrogenation in air (4 d, RT, hexane) transforms one of these into a binary mixture (1 : 2.5), composed of the known[5] nickel(II) isobacteriochlorinate, *ttt*-**4**, and the known[5c] nickel(II) bacteriochlorinate, *ttt*-**5**, (UV/VIS, HPLC). Analogous dehydrogenation of the other nickel pyrrocorphinate provides a mixture of the known isobacteriochlorinates *tct*-**4**[5] and *ttt*-**4**[5] (3.5 : 1), together with small amounts of a nickel bacteriochlorinate. The second pyrrocorphin fraction from HPLC 2 is, therefore, composed of the diastereomers *ttttt*-**2** and *tttct*-**2**.

*tctct*-**3** *tct*-**4** *ttt*-**5**

The three diastereomers present in the equilibrated mixture of pyrrocorphins **2** have a trans arrangement for each of the vicinal sets of ethyl groups. The equilibration occurs at the stage of the magnesium complexes, which are assumed to be mutually interconverted by protonation and deprotonation of the corresponding magnesium corphinates[3c].

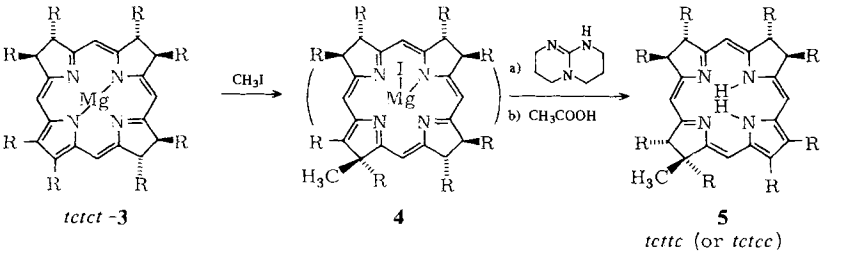
## The Chemistry of Pyrrocorphins: *C*-Methylation of Pyrrocorphinates at the Ligand Periphery**

By *Rudolf Waditschatka, Eva Diener,* and *Albert Eschenmoser**

The pyrrocorphin **1** and corphin **2** chromophores can be interconverted by protonation and deprotonation, respectively[1]. We report here that *the magnesium and zinc pyrrocorphin complexes are C-methylated selectively at the ligand periphery with methyl iodide to give the corphin complexes.* Thus, the pyrrocorphin ligand system promises to provide an entry to the (long sought[2]) biomimetic introduction of methyl groups into the construction of peripherically methylated porphinoids and corrinoids.



Upon treatment with excess EtMgI in tetrahydrofuran (THF) (70 °C, 10 min), *tctct*-octaethylpyrrocorphin[1a] is transformed into the (extremely oxygen-sensitive) magnesium complex **3** (Scheme 1; $\lambda_{max}$ = 354 (rel. int. = 1.00), 392 (0.66), 408 (0.84), 533 (0.10), 593 (0.18), 646 nm (0.66) in hexane). Brief heating of rigorously dried **3** in benzene/$CH_3I$ (2 : 1), followed by work-up with $H_2O$/NaCl gives the magnesium corphinates **4** (mixture of diastereomers, $\lambda_{max}$ = 308 (0.78), 363 (1.00), 540 (0.20), 566 (0.20) in hexane). Deprotonation with 1,5,7-triazabicyclo[4.4.0]dec-5-ene[1c] in benzene (5 min, RT), followed immediately by decomplexation (dilute acetic acid, a few min at RT) provides a mixture of monomethylated pyrrocorphins of constitution **5**, **6**, and **7** (combined yield *ca.* 90%)[3]. Of the three main fractions detected by HPLC, one could be isolated and characterized as isomer **5** (*tcttc* or *tctcc*)[4]. Its structural assignment, **5**, stems from its characteristic pyrrocorphinoid UV/VIS spectrum (cf. [1]), its $^1$H-NMR spectrum (4 vinyl proton signals at $\delta$ = 6.06, 6.12, 6.61, 6.73, 300 MHz, $CS_2/C_6D_6$ 9 : 1), and its mass spectrum ($m/z$ = 554 (100%, $M^+$); its nuclear Overhauser effect (NOE) $^1$H-NMR difference spectrum shows a strong NOE from the singlet of the angular methyl group ($\delta$ = 1.48) to the vinyl proton singlet at $\delta$ = 6.61, which fixes the position of the pyrrole ring relative to the methyl group. The *cis*-configuration of the ethyl groups on the methylated ring[4] is apparent from a strong NOE between the methyl singlet and a methine multiplet centered around $\delta$ = 3.0, and is confirmed by conversion of **5** into the nickel(II) *cis*-chlorinate **8b**. The remaining two HPLC main fractions (spectra recorded as a mixture; $M^+$, $m/z$ = 554 (100%); UV/VIS as **5**) contain three pyrrocorphins of constitution **6** and **7**[4]. The $^1$H-NMR spectrum shows three methyl singlets ($\delta$ = 1.149, 1.154, 1.271, *ca.* 3 : 1 : 4, 300 MHz in $C_6D_6$) and three groups of four (partially overlapping) vinyl proton signals. The possibility that these pyrrocorphins are diastereomers of **5** is precluded by NOE's observed from the methyl signals to three upfield vinyl proton signals.

Direct complexation of the crude methylation mixture from **3** with nickel acetate ($CH_3COOH$, 105 °C, 5 min) gives four main fractions readily separated by HPLC: a (38%), b (23%), c (15%), and d (19%). Fractions b, c, and d are UV/VIS and $^1$H-NMR spectroscopically uniform nickel(II) pyrrocorphinates of constitution **7**, **5**, and **6** (c identical with the Ni complex from pure **5**); fraction a contains two components (2.5 : 1), the main component being a *cis*-isomer of **7**[4]. Upon autoxidation in air, c and d produce the UV/VIS spectrum of a nickel(II) bacteriochlorinate/isobacteriochlorinate mixture; in contrast, a and b produce

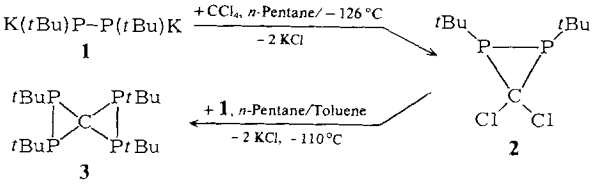
a clean isobacteriochlorinate spectrum. Upon dehydrogenation (*o*-chloranil, hexane-ether, RT), b and d give the *trans*-chlorinate **8a**, and a and c the *cis*-chlorinate **8b** (UV/VIS, HPLC).

In exploratory investigations with the total mixture of diastereomers **3**, described in [1c], we observed that zinc pyrrocorphinates react analogously with methyl iodide (THF, 80°C, $ZnI_2$). Here, the methylation products were identified by deprotonation, decomplexation ($CF_3COOH$, $CH_3CN$, RT), dehydrogenation (*o*-chloranil, benzene, RT), and chromatography to give the monomethylated chlorins **9a** (m.p. = 193°) and **9b** (m.p. = 203°)[5].



The peripheral *C*-methylation of pyrrocorphins extends the conjugation of the *bis*-vinamidine system of the starting chromophore (cf. **1**) to a corrinoid *tris*-vinamidine system (cf. **2**). We presume that this is the reason for the occurrence of peripheral *C*-methylation. The methylation step and the pyrrocorphinate-regenerating deprotonation step (**3**→**4**→**5**) are separable. This should stimulate attempts to perform sequential methylations of pyrrocorphins starting from porphyrinogens, as well as to explore the regio- and stereoselectivity problems thereby presented.

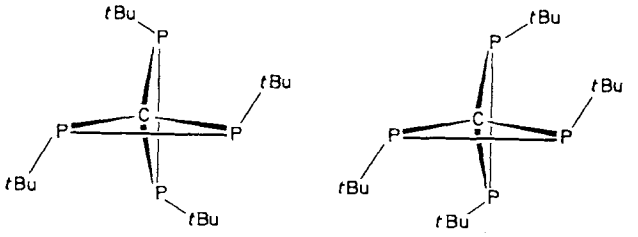
## $(tBuP)_2C(tBuP)_2$— The First Tetraphosphaspiro[2.2]pentane**



By *Marianne Baudler** and *Wolfgang Leonhardt*

[2+1]-Cyclocondensation of 1,2-dipotassium 1,2-di-*tert*-butyldiphosphide **1** with geminal dihaloalkanes leads to formation of diphosphiranes $(tBuP)_2CR_2$[1]. Reaction of the phosphide with silicon tetrachloride (2:0.9) furnishes the tetraphosphasilaspiro[2.2]pentane $(tBuP)_2Si(tBuP)_2$[2]. We report here on the reaction of **1** with tetrachloromethane, in which, aside from polymeric solids and *tert*-butylcyclophosphanes $(tBuP)_n$ (n = 4, 3), the novel phosphorus three-membered ring compounds 1,2-di-*tert*-butyl-3,3-dichlorodiphosphirane **2** and tetra-*tert*-butyltetraphosphaspiro[2.2]pentane **3** are formed.

**1** **2** **3**

The spirocycle **3**, the proportion of which in the soluble products amounts to *ca.* 5 mol-%[3], is formed as a mixture of the isomers **3a** and **3b** (85:15), which differ from each

[3] All reactions and work-ups were carried out in a glove box under nitrogen (< 5 ppm $O_2$).

[4] The configuration of the angular methyl group relative to the ethyl groups on the unmethylated rings has not been established.

[5] $^1$H-NMR (300 MHz, $C_6D_6$): *s*, the $CH_3$ from **9a**: $\delta = 2.03$, from **9b**: $\delta = 1.96$. $^{13}$C-NMR (75 MHz, $C_6D_6$); *q* the angular $CH_3$ group of **9a**: $\delta = 22.21$, from **9b**: $\delta = 28.11$.

other in the relative arrangement of the *trans*-oriented *tert*-butyl groups at the two three-membered rings. Whereas **3a** could be isolated as colorless stable crystals (m.p. 141–143 °C, reversible)[5], **3b** slowly rearranges at room temperature to **3a**. Owing to its thermal decomposability, the diphosphirane **2** could be enriched to only 80 mol-%.

**3a,b** and **2** were identified by their molecular masses (MS: **3a,b**: *m/z* 364; **2**: *m/z* 258) and nuclear magnetic resonance spectra[4], and, in the case of **3a**, also by elemental analysis. Proof of the structure of **3a,b** and **2** is provided by the $^{31}$P-NMR signals observed in the high-field region characteristic for phosphorus three-membered ring compounds[2b]. The spirocyclic molecular framework of **3** follows from the $^{13}C\{^1H\}$-NMR spectrum of **3a**, which, as a result of C,P-coupling, shows two triplets of triplets for the *tert*-butyl groups and a quintet with $^1J(CP) = 80.6$ Hz for the spiro carbon atom. Of the two singlets in the $^{31}P\{^1H\}$-NMR spectrum of **3**, the downfield signal of lower intensity is ascribable to the isomer **3b**, since here the transannular steric interaction of the *tert*-butyl substituents leads to a downfield shift as a result of widening of the exocyclic C–P–C bond angles.

Remarkable in the case of **3a** is its low sensitivity towards air and moisture, and the finding that the $P_4C$ ring skeleton does not fragment during the mass spectrometric investigation, even at 70 eV.

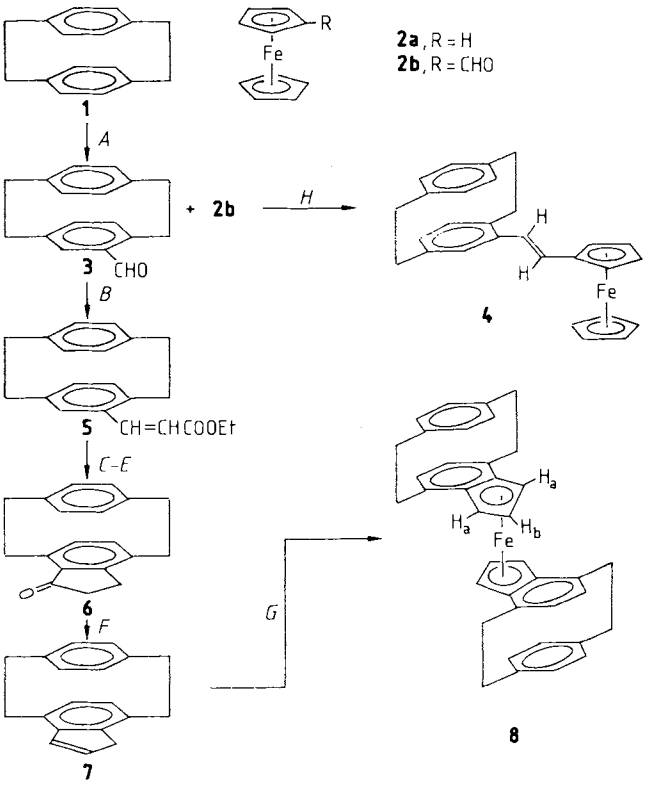
[4] $^{31}P\{^1H\}$-NMR: **2** (purity 80%, *n*-pentane): $\delta = -76.1$ (s, 2P); **3a** (*n*-hexane): $\delta = -132.0$ (s, 4P); **3b** (mixture with **3a** and $(t\text{BuP})_n$, *n*-hexane): $\delta = -109.7$ (s, 4P).—$^{13}C\{^1H,^{31}P\}$-NMR: **3a** (benzene/[D$_6$]-benzene): $\delta = 30.42$ (s, 4C, PC), 29.89 (s, 12C, PCC), 24.46 (s, 1C, $P_4C$).—$^1H\{^{31}P\}$-NMR: **3a** (benzene/[D$_6$]-benzene): $\delta = 1.25$ (s, 36H).



[5] *One-pot reaction for* **3a**: A solution of tetrachloromethane (10.3 g, 67 mmol) in toluene (60 mL) is cooled to −78 °C and added dropwise (2–4 drops/s) to a stirred suspension of **1** (17.6 g, 60 mmol) in 150 mL of *n*-pentane/toluene (1 : 1) at −110 °C. The mixture is stirred for a further 5 h at −78 °C, after which time the precipitate is filtered off under suction in the cold and then washed three times each with 20 mL toluene. The combined filtrates are evaporated down at room temperature and the black-brown viscous residue is chromatographed on $Al_2O_3$ (heated *in vacuo*) with *n*-hexane. The fractions with the highest content of **3** are combined, the solvent is removed by evaporation, and the residue successively recrystallized from *n*-hexane (*ca.* 9 times), dioxane (*ca.* 3 times), and methanol (*ca.* 2 times) with concomitant $^{31}$P-NMR spectroscopic monitoring; yield 0.19 g (2%) **3a**, purity >99% (trace of $(t\text{BuP})_4$, $^{31}$P-NMR).

## New Link between Cyclophane and Ferrocene Chemistry**

By *Sayed El-Tamany, Friedrich-Wilhelm Raulfs,* and *Henning Hopf**

[2.2]Paracyclophane **1** and ferrocene **2a** are prototypes of multilayered organic and organometallic molecules, respectively. We were interested in whether multilayer systems consisting of alternating organic and organometallic components can be synthesized from these two sandwich compounds. In order to achieve the greatest electronic interaction between "layers" it is recommendable to link **1** and **2** either by unsaturated structural units or by direct annelation[1].

A coupling of the first type may be achieved by reacting the commercially available product **2b** with the aldehyde **3**, which is readily obtainable from **1** by Rieche formylation[2], using the coupling method described by *McMurry* (Lenoir variant)[3]. Besides the main product **4** (33%, brown-red needles from ethanol/chloroform, m.p. 175–177 °C), dimers of **3** (7%) and **2b** (24%) are also formed, which, however, can be easily separated from **4** by chromatography. The $^1$H-coupling constant between the two olefinic protons ($\delta = 6.77$ and 6.56) of 16.0 Hz is consistent with the *E*-configuration[4].

*A:* $Cl_2CHOCH_3/TiCl_4$, $CH_2Cl_2$ (92%); *B:* $(EtO)_2P(O)CH_2CO_2Et$/NaH, tetrahydrofuran (THF) (85%); *C:* 1. NaOH, 2. HCl (91%); *D:* Pd/C, $H_2$, ethyl acetate (91%); *E:* polyphosphoric acid, 120 °C (79%); *F:* 1. $H_2NNHTs$, $H^+$, EtOH (86%), 2. Na, $HOCH_2CH_2OH$, reflux (79%); *G:* 1. Na (suspension), THF, 2. $FeCl_2$, THF (14%); *H:* $TiCl_4$/Zn, pyridine/THF (33%).

**3** can also be used as starting material for the second type of coupling: The aldehyde is converted by Wittig-Horner reaction into the unsaturated ester **5**, which can be cyclized by conventional methods to the five-membered ring ketone **6**. Bamford-Stevens elimination affords the olefin **7**, which is subsequently allowed to react in analogy to a synthesis of bisindenyliron to give **8**[5]. Proof of the structure of this four-layered molecule, which on sublimation (200–220 °C/$10^{-3}$ torr) yields dark-violet crystals, is based on spectroscopic data[4]. Noteworthy is the chemical shift of the five-membered ring protons $H_b$ and $H_a$ in **8** compared to that observed in the model substance bisindenyliron[5]: Whereas $H_b$ in both ferrocene derivatives ab-

[1] The complexation of cyclophanes with the ($\eta^5$-cyclopentadienyl)iron unit is well-known: A. R. Koray, *J. Organomet. Chem. 232* (1982) 345, and references cited therein, particularly E. D. Laganis, R. G. Finke, V. Boekelheide, *Proc. Natl. Acad. Sci. USA 78* (1981) 2657. The 1:1 and 1:2 adducts that are formed, however, no longer contain intact ferrocene units. Moreover, in the 2:1 products the surfaces of the cyclophanes capable of complexation are complexed, so that there is no direct possibility for the construction of oligomeric structures. This limitation does not exist in the case of the coupling possibilities presented here; the requisite dialdehydes of **1** and [2.2]indenophane have already been prepared (S. Ehrhardt, F.-W. Raulfs, H. Hopf, unpublished results).

# BOOK REVIEWS

**World Energy Supply: Resources, Technologies, Perspectives.** By *Manfred Grathwohl*. Walter de Gruyter & Co., Berlin 1982. 450 pp., bound, DM 120.00.

This book needs to be read selectively. Portions of it are well thought out and convey useful information in a useful way. Other portions are close to unreadable; they consist of an accumulation of information from dozens of sources, frequently selected and reproduced with little discrimination, and presented to the reader with scarcely more input by the author than goes into compiling a telephone directory. This is a pity, for the book bears all the evidence of very hard work over a prolonged period.

The task is, of course, enormous. It calls for an ability to deal intelligently with the major aspects of fossil energy, nuclear, solar and everything in between. It would be a big job for a committee. It is apt to overwhelm a single author, and I am afraid in this instance it has almost done that. Over and over the author is reduced to merely citing the literature. I have not made a count, but the number of sentences that begin with "According to ..." is large. What emerges is a hybrid between a reproduction of statistics and diagrams, a physics textbook, a geography textbook, and an occasional policy recommendation that expresses more the author's own philosophy or moral suasion than a conclusion from the data presented.

The book is meticulously organized along logical lines. It proceeds from a brief, largely introductory chapter, entitled "Primary sources and world economics" to a discussion of the world's energy potential (which contains segments on each of the primary sources) to a very extensive chapter on energy supply systems, by which are meant basically the non-primary sources—nuclear, solar, electricity, synthetic fuels, etc. It next deals with question of the environment and with safety and closes with a brief chapter in which conclusions are drawn.

Of these chapters, by far the best are those dealing with energy supply systems, or what I would call "secondary sources". Here one has the feeling that the author is at home, comfortable with the subject matter and far less inclined to lean, often uncritically, on the literature as his main support. Within this area, nuclear matters are especially well discussed, and so is solar energy.

Had the author been less ambitious and just published the second half of the book, he would merit high marks. Unfortunately, the first half in no way measures up to the second. Some of the reasons are inherent in his self-imposed limitation to supply. They are inherent in that it is very hard, if not unproductive, to deal merely with the supply side. Indeed, one senses that the authors feels the same way, for he finds himself compelled to bring in demand if only for the purpose of assessing adequacy of resources. But, of course, he cannot usefully do that without discussing price. Adequacy or inadequacy exists only at a stipulated price. Without it there cannot be too much or too little. Yet, demand and price are treated, if at all, in a highly incidental fashion. This removes much of the discussion from reality. If I may mention the four most discussed energy books that were published in the United States in 1979 and 1980: *Energy in America's Future, Energy Future, Energy: The Next Twenty Years,* and *Energy in Transition* (only one of which, incidentally, is mentioned in the author's references, as best I can tell), they dealt, without exception, equally with supply and demand and with price as the link.

Still, as I have said, demand sneaks in. So do discussions of population growth, income differences among countries, famine, and the like – none of these themes being developed and discussed with the authority that stems from knowledge. They are obviously subjects that fascinate him, but self-discipline should have kept him from (as an old editor-friend of mine used to say) chasing too many rabbits at the same time. Too many *obiter dicta*.

Concept and structure of the book apart, much of the first half or so of the book (chapters 2 and 3) is, moreover, quite unsatisfactory on its own merit. Two points stick out. First, there is the author's above-mentioned indiscriminate use of sources, a practice that proves only that he had access to a wide range of books and articles. What is missing is evaluation. They are presented as, or turned into, tables and graphs, regardless of the time the data were first published, or without revealing to the reader the background of the data, so that he has to take them on faith, and second-hand at that. This is particularly distressing when most of these data are not hard facts but estimates, so that

the assumptions behind them are at least as interesting and certainly as important to understanding as the data themselves. Here the author simply lets the reader down. If I want to read a new book on energy, I am interested in what the author makes of this vast arsenal of numbers. Otherwise I go to the original source.

What adds to the discomfort is that much of the material is badly, at times fatally, out of date. To be sure, there are reasons: the time it takes to translate such a long, complex volume, the speed with which the energy scene is changing, the slowness with which some of the data become available. But it goes beyond that. For example, most of the production and consumption data on the United States—the area I am most familiar with—are drawn from publications that are four and five years old. One of these is, for example, a 1977 report by the Congressional Research Service, a compilation of separate articles by some twenty authors. How far out of date it is, can be seen when we look at the U. S. energy consumption and oil import projections for 1985—then seven years in the future—and compare them with the 1982 reality. Consumption, then conjectured to rise from 74 quads in 1976 to 95 quads in 1985 had instead dropped to 71 quads in 1982! No reason to believe it will reach even 80 by 1985. Oil imports then projected to rise from 8.1 million barrels per day in 1976 to 11.8 million berrels per day in 1985 have instead declined to 5 million barrels per day in 1982. These are hardly small differences, nor is this an atypical example. Nuclear energy projections, for instance, and with them uranium requirements, are taken from sources prior to the beginning of the big slide in plans and construction of new plants.

In the face of an abundance of timely data from governmental, industrial and academic sources this is not excusable. As a result, recent trends and projections are for the most part not just useless but misleading. Though less so, obsolescence also penetrates the technology portion. To cite an especially glaring example, the author reports plans for a U. S. scheme to produce shale oil through the explosion of nuclear devices. Puzzled what he had in mind I consulted the source reference at the back of the book: an article in a German journal written in 1965! Surely, it would not have been difficult to track the relevance of that statement and above all not to present it as though this was a contemporary plan. Again, this is not an isolated instance. The Energy Research and Development Administration (ERDA) which was dissolved in 1978, figures as a live agency. Its estimates, now several years old, are presented as valid now. This is especially disturbing when a projection of solar energy reaching 25 percent of total U. S. energy in 2000 is ascribed to that organization (this was a one-time "goal" put forward by President Carter in early 1977), followed by the observation that "recent projections are even higher". Recent, when? The oil price did not quadruple in two years after 1973, but in one year (p. 59). Coal slurry pipelines are not in the "research and pilot" stage in the U. S. (p. 90). One, carrying coal from Arizona to California, has been operating for several years, and an earlier one, in Ohio, carried coal for some 160 km for many years, before it succumbed to competition from the railroad. A 1400 mile line will begin to be built in 1984 and is expected to go into operation in 1986. Expectations for steady increases in enhanced oil recovery have been steadily declining and reliance on non-conventional sources of natural gas has been relegated to a more distant horizon.

Various experts' or organizations' cost estimates for new sources or processes are based on costs and prices long exceeded, and much of the time it is not clear whether we are dealing in current or constant monetary units. The word "presently" used frequently remains generally undefined.

Some peculiarities may be due to language difficulties. For example, anthracite is a small portion of U. S. coal, yet it is repeatedly used to characterize all U. S. coal. Indeed, for some reason anthracite and bituminous coal are at times treated as synonymous. That there are "vast" coal fields available for strip-mining in the Middle West is equally confusing. They are in the *West*, not the *Middle* West, nor is there any anthracite in Kentucky (p. 54). The *imbalance* between production and consumption is persistently referred to as *discrepancy*, a term that threw me off until I sensed the error.

Given the enormous effort that must have gone into writing this book, the care with which the glossary, the index and the referencing has been done, it is indeed a pity that the outcome is not more useful. It would be my advice to take with a large pinch of salt the offerings in chapter 2 and 3 and concentrate on the balance of the book, even though here too, caution is advised.

*Hans H. Landsberg* [NB 593 IE]

**Electrons in Chemical Reactions; First Principles.** By *L. Salem*. Wiley-Interscience, Chichester 1982. xii, 260 pp., bound, £ 27.25.

Anyone who has read and followed *Lionel Salem's* numerous, original and pioneering publications will note with disbelief and regret that he has turned his back on chemistry, in order to devote himself in future to banking. The present volume is thus—if another U turn does not follow—something of a going-away present to his colleages and a summary of current thinking concerning the electronic theory of chemical reactions as seen by a scientist, who has made fruitful contributions to the field.

The text is written from a lofty standpoint and assumes a solid background in theoretical chemistry on the part of the reader, at least enough that he can recognize the importance of and complete the numerous, almost impressionistically sketched definitions. This is in no way the introduction at an elementary level that the subtitle "First Principles" seems to suggest.

The choice and treatment of the individual themes (energy hypersurfaces; the electronic structure of excited molecules and intermediates; orbital and state symmetries; reaction paths; the role of electron spin; solvent effects) distinctly bear the stamp of the predilections and style of an author who likes to work out the solution of a problem using a theoretical-chemical "catch as catch can" technique, which extends from the use of naive, resonance considerations to the use of quantum-chemical methods of considerable sophistication. The result is a sometimes uneven but demanding text, that is always stimulating and readable but which challenges contradiction on occasions. Furthermore, since the text leans on the interests and work of the author, there are necessarily gaps which some readers will deplore. The few trivial errors, such as the wrong quadricyclane or benzvalene formulas on p. 113 and 122 will scarcely cause misunderstanding.

Taken as a whole this book constitutes an exceedingly stimulating piece of work that is suited as a "mise au point" as well as a basis and source of information for postgraduate seminars and discussions at a higher level. From the latter point of view its rather personal approach is an added attraction.

*Edgar Heilbronner* [NB 589 IE]

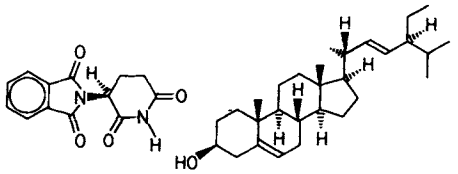
# Stereoselective Synthesis of Enantiomerically Pure Natural Products—Estrone as Example**

By Gerhard Quinkert* and Herbert Stark



*Dedicated to Sir Derek Barton on the occasion of his 65th birthday*

Natural products have been synthesized for billions of years in animals, plants, and microorganisms. As a rule they occur enantiomerically pure. Their chiral character corroborates their use in metabolism or as biologically active agents. Natural products may be insufficient in quality or quantity. They have recently begun to become accessible, either unchanged or modified, by biological synthesis; here, too, they are obtained enantiomerically pure. In the last twenty years chemical synthesis has become a major concern of organic chemists. Their target compounds are primarily enantiomerically pure natural products or biologically active variants thereof.

## 1. Current Problems in the Chemical Synthesis of Natural Products

### 1.1. The Fundamentally Different Routes to Enantiomerically Pure Target Compounds

At the threshold of synthetic biology[3] one of the main challenges of synthetic chemistry is to find routes which satisfy the demands of industrial applicability to enantiomerically pure compounds with biologically important properties. As the "thalidomide case"[5] shows, the application of enantiomerically pure active agents is no matter for esoteric players of the "glass-bead game"[***]. According to recent investigations, only (*S*)-(−)-thalidomide **1** behaves teratogenically when administered intraperitoneally to mice and rats; it is claimed that (*R*)-(+)-thalidomide (*ent*-**1**), even at the highest doses, causes no deformity in animals used in the experiments[6].

**1** **2**

Scheme 1. (*S*)-(−)-thalidomide **1** and stigmasterol, (3β,22*E*)-5,22-stigmastadien-3-ol **2**.

Enantiomerically pure target compounds are now accessible by three routes *via* chemical synthesis. Whenever possible, the synthetic chemist resorts to optically active natural products as starting materials[7]. By conducting a synthesis intelligently, use can be made of the evolutionary preference for one enantiomer in the selection operations yet to be performed, so that on introduction of further centers of chirality a choice between two diastereomers, and never one between two enantiomers is involved.

It is left very much to the imagination of the synthetic chemist to decide what natural products are suitable starting materials in a particular instance. Previously, in natural product synthesis it was generally attempted to select both starting material and target molecule from the same class of compounds. Thus, for example, the Mexican barbas-

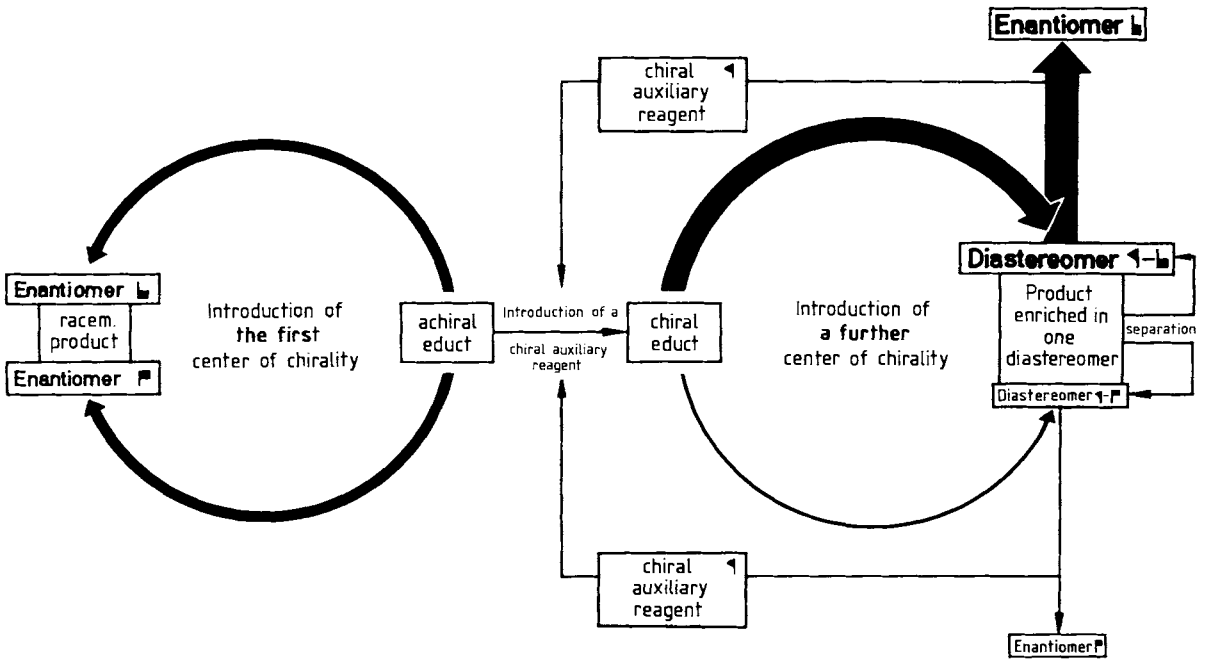
co[9], which contains diosgenin **3**, was used for some time as the raw material for the partial synthesis of steroids with the C-17 side chain shortened or even absent, as in the naturally occurring hormone estrone **8a** or the synthetically produced progestin fraction of the oral contraceptive norethindrone **7**. In the meantime, sitosterol **4** or stigmasterol **2** have supplanted **3**. This substitution was provoked by politico-economic circumstances[11] and made possible by recent technological progress[12].



Scheme 2. Partial synthesis of pharmacologically interesting 19-norsteroids such as norethindrone **7** or estrone **8a** from diosgenin **3** or sitosterinol = (3β)-5-stigmasten-3-ol **4**.

The trend is moving towards the use as starting materials of those natural products that, as far as possible, are available from cultivated plants or microorganisms; examples are (+)-glucose **9**[14], (+)-tartaric acid **10**[16], (+)-lactic acid **11**[18], and (+)-camphor **12**[20]. Their structural relationship with the target compounds is generally obvious only at a second glance. It is not enough that they are available cheaply; in addition they must fit into a synthetic scheme which preserves the introduced optical activity and guarantees the desired sense of chirality. Yet only rarely do natural products directly correspond to the starting materials. Generally, structural modifications are necessary; here the result of stereoselection, which occurred in the course of biosynthesis without the chemist's cooperation and culminated in the actual absolute configuration produced, must not be spoiled.

Scheme 3. (+)-Glucose **9**, (2*R*,3*R*)-(+)-tartaric acid **10**, (*S*)-(+)-lactic acid **11**, or (1*R*)-(+)-camphor **12**; important optically active natural products that are possible chiral starting materials, either directly or after structural modification.

From the early days, the conventional method for chemists to obtain enantiomerically pure target compounds has been the resolution of racemates[22]. To separate enantiomers at the end of a multistep synthesis is almost fatal; indeed more than 50% of a laboriously constructed synthetic product is thus lost. Resolution of a racemate at the start of a synthesis is much more acceptable, certainly in those cases when the other enantiomer can either be used in the

Scheme 4. Mode of action of a chiral auxiliary reagent, which converts an achiral into a chiral educt; instead of a racemic product, a diastereomerically enriched product is obtained. This can be converted into pure enantiomers by separation of the diastereomers and recovery of the chiral auxiliary reagent. The flag symbols (see [17]) are two-dimensionally chiral figures.

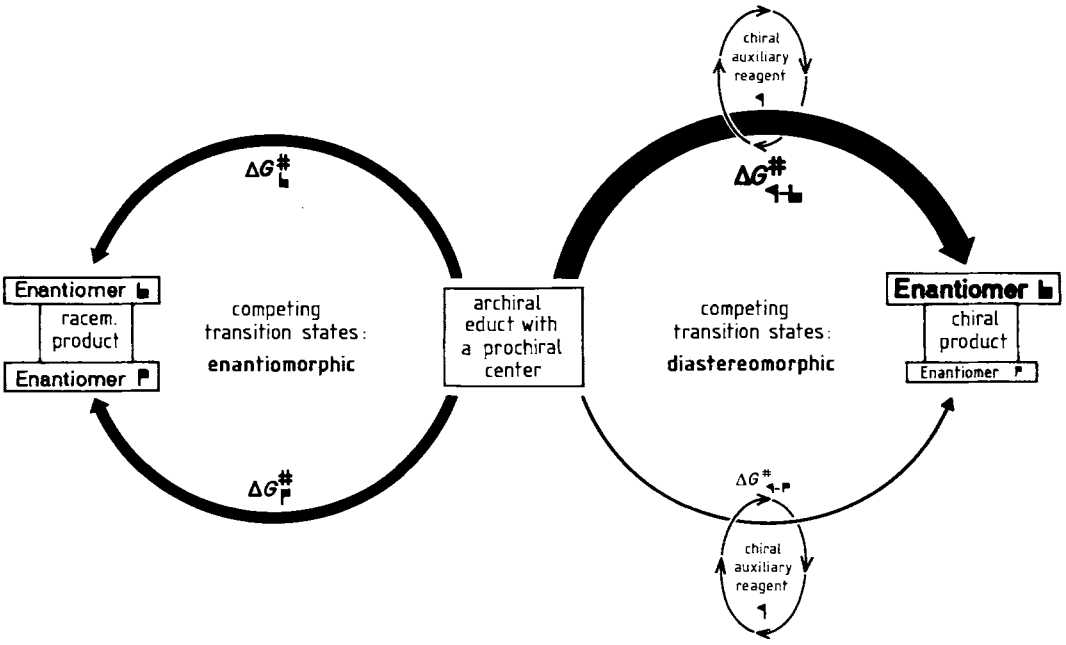
synthesis or converted into the synthetically useful isomer[26]. In the past, many chemists have regarded their synthesis as accomplished when a racemic mixture was obtained, only half of which consists of the target compound. This may well have contributed to the fact that it has too often been ignored that the enantiomers of active agents can differ in their biological activity.

The forward-looking approach to enantiomerically pure compounds makes use of kinetic stereoselection and includes a so-called asymmetric step in the synthesis. Such a plan is based on the insight that each reaction step in which a center of chirality is formed produces two stereoisomers (Scheme 4). On introduction of the first center of chirality two reaction paths having the same width lead from the achiral educt to two enantiomeric product components, whereas on introduction of every further center of chirality two reaction paths having different widths connect the now chiral educt to two diastereomeric product components. Therefore, formation of the first center of chirality must be avoided under all circumstances. The *imperative of asymmetric synthesis* expresses this requirement in its classical form (see Scheme 5).

Imperative of asymmetric synthesis

Whenever stereo-isomers arise, avoid enantiomers!

Scheme 5. "Imperative of asymmetric synthesis" which, in its classical form, goes back to *Emil Fischer* [27].



The problem thus imposed is, therefore, to ensure that a chiral auxiliary reagent is incorporated into the achiral educt (see Scheme 4). Any center of chirality formed in a subsequent reaction cannot be the first one, of course, and the resulting two diastereomers, which usually are produced in different amounts, can generally readily be separated. After recovery of the chiral auxiliary reagent (which can be used again for stereoselection), the product enantiomers are available in a pure state. "In this way optical activity is propagated from molecule to molecule as life is passed on from cell to cell". In 1894, Emil Fischer used these words[27] to comment on the principle of asymmetric synthesis which he had formulated. Since then our understanding of the course of chemical reactions has grown, and stereoselection is understood as the preference for one of two transition states which compete with one another. In its updated version the *imperative of asymmetric synthesis* (see Scheme 6) demands:

Imperative of asymmetric synthesis

Select enantiomers via diastereomorphic transition states!

Scheme 6. "Imperative of asymmetric synthesis" in its updated form.

If the chiral auxiliary reagent is only transiently incorporated into the competing transition states and, furthermore, is perhaps only needed in catalytic quantities, then the ideal version of asymmetric synthesis has been achieved:

Scheme 7. Possible mode of action of a chiral auxiliary reagent (if catalytically effective) which transforms competing enantiomorphic into diastereomorphic transition states. Instead of a racemic product, an enantiomer-enriched product results. The flag symbols (see [17]) are two-dimensionally chiral figures.

An achiral educt with a prochiral center gives rise, *via* two competing diastereomorphic transition states, to a chiral product in which one of the two enantiomers predominates. The degree of selectivity is determined by the difference in the free energies of activation $\Delta G^{\ddagger}_{\blacksquare} - \Delta G^{\ddagger}_{\blacksquare}$ (see Scheme 7). To achieve, for example, an enantiomeric excess of 92% (*i.e.* a ratio of ■ to ■ of 96 : 4) this difference need only to amount to 1.5 kcal/mol.

### 1.2. The Classification of Natural Product Total Syntheses

Today, selectivity is the watchword of the synthetic chemist. Indeed the progress of synthetic chemistry can be judged by the precision with which a single, quite definite, chemical species can be synthesized among the many possible isomers, in particular the many possible stereoisomers. If the accumulated fund of natural product total syntheses of the last 50 years is considered, it follows that the criterion of *stereoselection* enables a sensible classification of natural product synthesis.

*Category I*

Little or no stereoselectivity on the introduction of centers of chirality

Time-consuming separations, including racemate resolution

Scheme 8. Typical pre-1950 natural product syntheses: low selectivity of the absolute configuration of the target compound.

To *Category I* (Scheme 8) belong those syntheses which are characterized by little or no stereoselectivity in the introduction of the required centers of chirality. They are associated with time-consuming separations, including racemate resolution, and on this account are of little practical use. The natural product syntheses known in the first half of this century are practically without exception to be included in this category.

*Category II*

High stereoselectivity on introduction of every center of chirality, except the first

Racemate resolution at any rate

Scheme 9. Natural product total syntheses in the third quarter of this century: high selectivity for the relative configuration of the synthetic target compound.

Then syntheses appeared on the scene which were distinguished by high stereoselectivity on introduction of each center of chirality, with the exception of the first one. In many cases the cost of separation could be so far reduced that practical application began to be considered. The representatives of *Category II* (see Scheme 9) are handicapped by the fact that the envisaged target compounds can only be obtained with the correct relative configuration and, hence, an enantiomer separation still has to conclude the synthesis.

*Category III*

High stereoselectivity on introduction of center of chirality, including the first

Limited effort on separation-no racemate resolution

Scheme 10. Natural product total syntheses as they ought to be today with high selectivity for the absolute configuration of the synthetic target compound.

*Category III* (Scheme 10) comprises total syntheses that before 1970 at best existed only on paper: syntheses of enantiomerically pure target compounds without a subsequent racemate resolution. To this class belong all total syntheses that begin with an optically active starting material or in which an optically active intermediate occurs as early as possible in the synthesis. Those syntheses in which the chiral building blocks arise from asymmetry inducing reactions are worthy of special note.

### 1.3. The Unambiguous Use of Configurational Formulas in Characterizing Enantiomers and Enantiomeric Mixtures

Reaction steps in which asymmetry is introduced lead either directly (see Scheme 7) or, *via* initially resulting diastereomers (Scheme 4), to mixtures in which two enantiomers can appear in any arbitrary ratio. In order to work out the factors of stereoselection in different cases, a simple and unambiguous notation is needed. The indiscriminate use of one and the same configurational formula for different configurational problems makes it more difficult for chemists to understand one another and turns out to be a considerable barrier in discussing stereochemical problems with non-chemists. Thus accounts of syntheses can be found in which a particular configurational formula not only characterizes the absolute configuration depicted by the formula, but also that of its enantiomer and/or mixtures of both enantiomers. Therefore in the following we shall take the literal meaning of a configurational formula,

even with respect to the absolute configuration, and use the Arabic numeral representing the chemical formula in the text only for that enantiomer expressed by the configurational formula.

**12** **13**

**13** ≡ *ent*-**12**

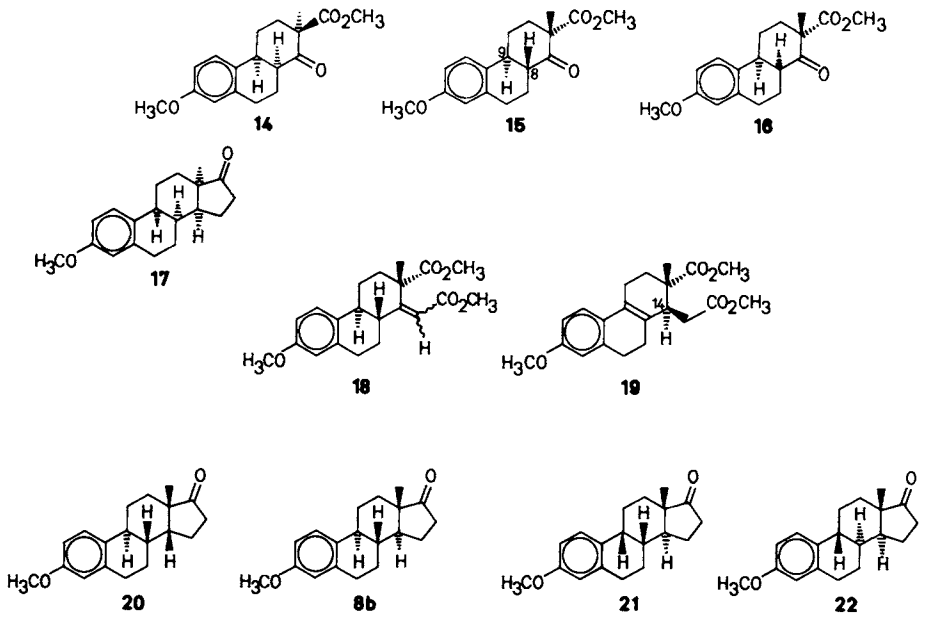
**12**/*ent*-**12** = 1:1 ≡ *rac*-**12**

Scheme 11. Systematic use of configurational formulas. **12** describes only the dextrorotatory enantiomer of camphor. If the other camphor enantiomer is being dealt with, the mirror image formula **13** is not shown and *ent*-**12** is written instead of **13**. Mixtures of both enantiomers are easily and unambiguously described. In the case of the racemate, the expression *rac*-**12** is used.

If instead of a chiral compound, whose configurational formula has been depicted, its enantiomer is being discussed, we shall omit the formula of the latter (see Scheme 11). To indicate that enantiomer, the Arabic numeral, a synonym of the depicted configurational formula, is prefixed by *ent*. Mixtures in which one enantiomer prevails are specified by the unprefixed Arabic numeral and by the same numeral prefixed by *ent*. Thus it is easy to distinguish those cases in which the ratio of the enantiomers is not known (but $\neq 1$), those for which it is simply known what enantiomer predominates ($>1$ or $<1$), and those in which the numerical ratio could be determined precisely [(100 − n) : n]. For the frequently encountered special case in which the enantiomers are present in exactly the same proportion, the prefix *rac* is placed before the Arabic numeral synonymous with the configurational formula that represents one of the enantiomers. This emphasizes the special position that racemic mixtures occupy among mixtures of enantiomers.

If in a flow chart describing a natural product synthesis, not only the enantiomer whose absolute configuration is correctly depicted appears but also the corresponding racemic mixture, the latter is not characterized by a chemical formula. Instead, an Arabic number prefixed by *rac* is used which has previously been assigned to a chemical formula outside the flow chart (see, *e.g.*, Scheme 28). Before the foregoing proposal for notation is dismissed by the perplexed reader, it should be recalled that less than 25 years ago *Fieser*[28], in publications in *J. Am. Chem. Soc.*, suggested the use of boldface Arabic, in place of the previously usual Roman numerals as convenient "representatives" of chemical compounds. What far-sighted editors allowed experimentally in those days could not be dispensed with today by authors and readers of chemical publications.

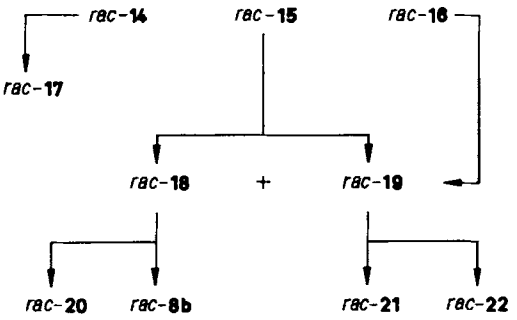
From the development of stereochemical nomenclature it can be clearly seen how chemists have delved ever deeper into more and more complex stereochemical problems. At the beginning of organic chemistry it was *steric factors* that determined the ground state. Then followed a phase in which *stereoelectronic factors* that influenced transition states were postulated. Today *factors of stereoselection*, either of steric, electronic, or stereoelectronic origin, loom large in considerations of chemical synthesis of natural products.



## 2. The Development of Natural Product Synthesis Exemplified by Estrone

The development of chemical syntheses of natural products is best clarified using selected target compounds. Here we shall avail ourselves of the synthesis of estrone as example: the synthesis of estrone, in general, and the *photochemical* synthesis of estrone (see Section 3), in particular. Numerous variations on the theme of "estrone synthesis" have been devised and realized in university and industrial laboratories over the last forty years. A systematic grouping of such syntheses does not correspond to the historical development. Much more useful is the classification of natural product total syntheses in terms of the *criterion of stereoselection* referred to in Section 1.2.

### 2.1. Category I Estrone Syntheses

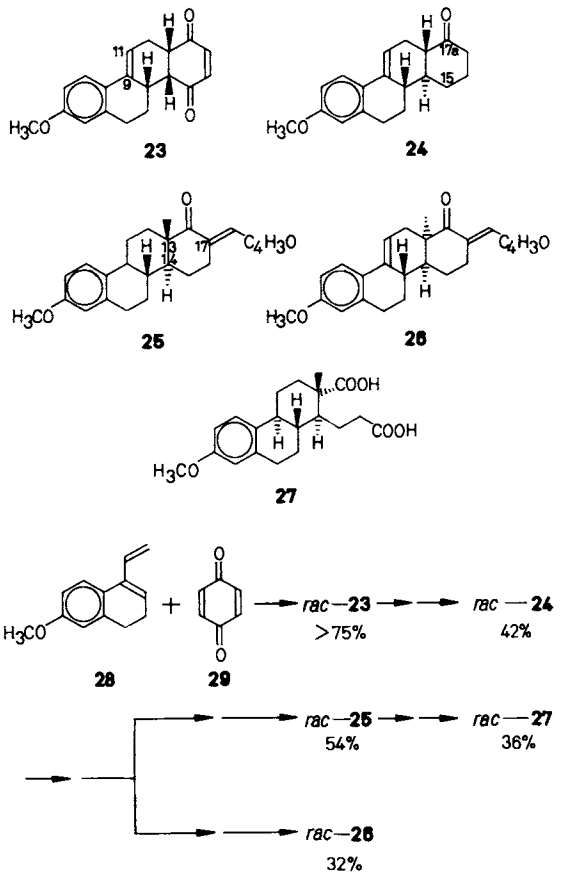


The first total synthesis of estrone was published in 1948 by *Anner* and *Miescher*[30]. It follows the A→AB→ABC →ABCD construction principle. Here, *rac*-**15** (see Scheme 12) plays a key role. This racemate is one of four possible racemates, three of which were in fact isolated (*rac*-**14**, *rac*-**15**, and *rac*-**16**). It was obtained through a series of reactions based on preliminary work by *Robinson et al.*[31] and *Bachmann et al.*[32]. In the mixture of stereoisomeric racemates *rac*-**15** is the main component and is easily separated from the others by fractional crystallization. The subsequent route to estrone makes quite clear the problems of selection that appear in category I syntheses. As if it were not enough that the selectivity upon introduction of the fourth asymmetric center was very low, even the stereochemical information already present was partly lost under the reaction conditions used.

From the outset, the configuration at C-8, labile under basic conditions, cannot be maintained. After Reformatzky reaction and subsequent elimination of water, a mixture of both unsaturated esters *rac*-**18** and *rac*-**19** was isolated. The formation of *rac*-**19** indicates a complex reaction path involving epimerization of C-8 and also places the stereostructural information at C-9 in question. Thus a large part of the selection achieved in *rac*-**15** is destroyed. The primary elimination product with an endocyclic double bond is isomerized to the thermodynamically more stable styrene derivative *rac*-**19**. Hydrogenation of *rac*-**18** leads, as expected, to two esters, epimeric at C-14, which could be separated by fractional crystallization. Under the same conditions *rac*-**19** also affords two saturated esters, the formation of only one of which can be explained by a further double bond shift. The relative configuration was finally established by hydrogenation of the unsaturated esters *rac*-**18** and *rac*-**19**. Arndt-Eistert homologation of the acetic acid side chains of the four products of hydrogenation, followed by cyclization of the resultant dicarboxylic acids in the presence of $Pb(CO_3)_2$, and subsequent decarboxylation of the cyclization product finally gave four racemates having the constitution of the methyl ether of estrone: *rac*-**8b**,

Scheme 12. Total synthesis of estrone after *Anner* and *Miescher* [30] (see Scheme 13).

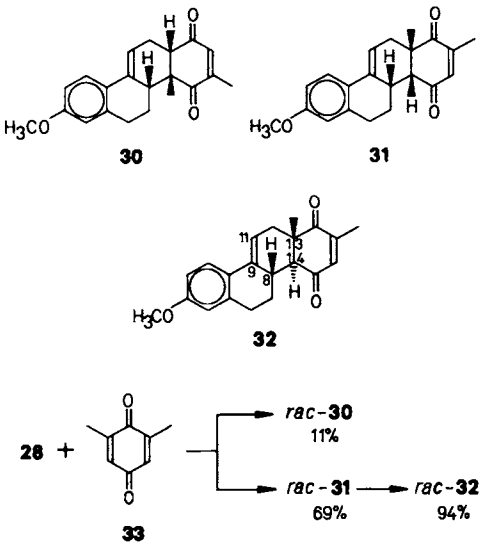
*rac*-**20**, *rac*-**21**, and *rac*-**22**. Resolution of the corresponding menthyloxyacetates of *rac*-**8b** gave a pure enantiomer, whose melting point and optical rotation were identical to those of natural **8a**. The absolute configuration of the synthetic product was, thus, substantiated. The relative configurations of the three remaining racemates having the estrone constitution were not definitely determined until 1958 by *Johnson* et al.[33], after all eight possible racemates had been synthesized.



Scheme 13. Flow chart for the total synthesis of estrone after *Anner* and *Miescher* [30] (see Scheme 12).

## 2.2. Category II Estrone Syntheses

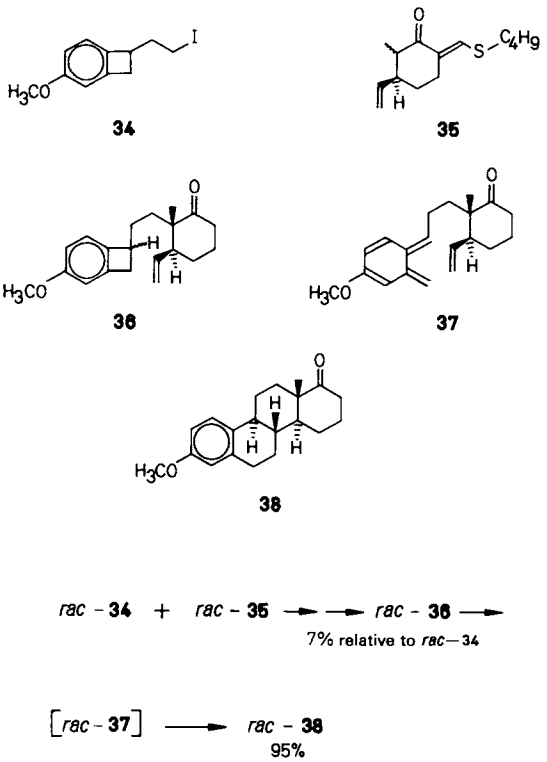
The estrone synthesis of *Johnson et al.*[34] belongs to category II (see Scheme 9). It follows the AB + D → ABCD construction principle and in order to achieve the necessary *trans*-fusion of the rings C and D leads first to a D-homoestrone derivative. An intermolecular Diels-Alder reaction serves as the key step (see Scheme 14).



The achiral AB unit **28** reacts with *p*-benzoquinone **29** to give the tetracyclic adduct *rac*-**23**. Of the three possible racemates only the one with the relative *syn*/*cis* configuration was formed. Since **29** was chosen as a constitutionally symmetric dienophile, no regioisomers occurred. After hydrogenation of the ring D double bond of *rac*-**23** and selective reduction of the 17a-keto group to the alcohol, the desired *anti* arrangement of the hydrogen atoms on C-8 and C-14 occurs under the basic reaction conditions necessary for deoxygenation of the 15-keto group, and *rac*-**24** was obtained by subsequent oxidation of the 17a-OH group.

Scheme 14. Synthesis of *rac*-estrone, *rac*-**8a** after *Johnson*, *Walker* et al. [34].

The selective introduction of the angular methyl group at C-13 proved somewhat puzzling; studies by *Johnson* and *Allen* on model compounds[35] had shown that if a C-9,C-11 double bond is present, predominantly *trans* alkylation is to be expected. To avoid formation of regioisomeric methyl ketones, the 17-position in ring D of *rac*-**24** was blocked by condensation with furfural. In fact, on methylation of the resulting furfurylidene ketone with potassium *tert*-butoxide/methyl iodide the 13β-methyl compound was predominantly obtained. However, the β/α selectivity of 3 : 2 is still relatively small. Reduction of the 9,11-double bond of *rac*-**26** with sodium in liquid ammonia led in high stereoselectivity to the thermodynamically more stable *trans* arrangement of rings B and C. The usual reaction sequence to contract ring D completed the synthesis of *rac*-**8a**.

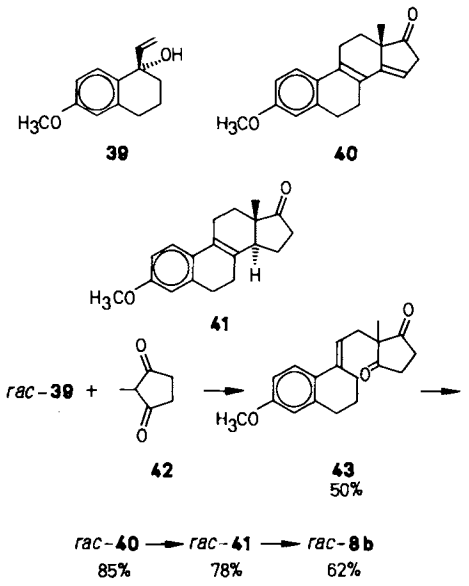


The improvement in the selective construction of the C-8, C-9, and C-14 centers of chirality is striking compared to category I syntheses. The introduction of the angular methyl group still leaves something to be desired. This shortcoming has been remedied in a variant by *Valenta et al.*[36] (see Scheme 15): they managed to exploit the synthetic potential of the Diels-Alder reaction even better than *Johnson et al.* As dienophile they used **33**, which already bears the methyl group later to be incorporated at C-13. On the assumption that the cycloaddition follows the *endo*-rule, the relative *syn/cis* configuration would arise at the future C-8, C-14, and C-13 centers but would later be modified to the relative *anti/trans* configuration. In the past, the realization of such a plan had failed: the Diels-Alder reaction of **28** with **33** had indeed led to the "wrong" constitutional isomer, *rac*-**30**. *Valenta et al.*[36] were now able to show that this cycloaddition proceeds regioselectively in the presence of Lewis acids. With 1.3 equivalents of $BF_3$-ether at −15 °C, the desired regioisomer predominates (*rac*-**31** : *rac*-**30** = 6 : 1). Base-catalyzed epimerization at C-14 and catalytic hydrogenation of the 9(11)-double bond of *rac*-**32** (palladium/calcium carbonate) established the relative configuration of the remaining asymmetric centers in the desired sense. A new procedure for ring contraction led finally to *rac*-**8a**. This total synthesis satisfies to a large measure the demands for selection of category II. It is unsatisfactory only in that to establish the *trans*-fusion of rings C and D the multistep detour via the D-homosteroid skeleton has to be undertaken.

Scheme 15. Synthesis of *rac*-estrone (*rac*-**8a**) after *Valenta et al.* [36].

Yet the synthetic potential of the Diels-Alder reaction is still not exhausted; the intramolecular variant allows the construction of the carbon skeleton in a straightforward manner with optimal control of the stereochemistry. Constitutional isomers do not occur on completion of the steroid skeleton because the short linkage between diene and dienophile moieties precludes incorrect orientations, only formally possible.

Since then, numerous syntheses of 19-norsteroids have been published which follow the particularly clear-cut A + D → AD → ABCD construction principle using kinetically unstable *o*-quinodimethanes[37]. They are impressive, above all, for the ease with which the relative *trans/anti/trans*-configuration at the C-9, C-8, C-14, and C-13 centers can be achieved.

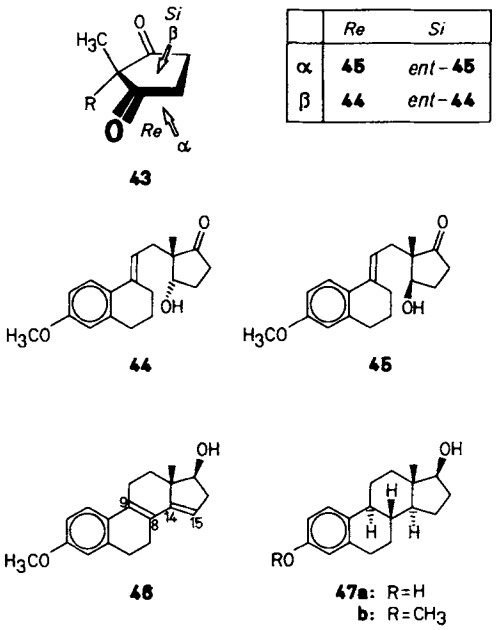


Scheme 16. Synthesis of *rac*-D-homoestrone methyl ether (*rac*-**38**) after *Kametani et al.* [38].

For *Kametani et al.*[38], *rac*-**36** functioned as a latent *o*-quinodimethanoid derivative. It was accessible by alkylating the enolate of *rac*-**35** with *rac*-**34**. To achieve the regioselective coupling of the ring A and ring D units, a protecting group was temporarily introduced, which otherwise has no further function. One must commiserate with the Japanese authors that they did not succeed in the corresponding conversion with the five-membered homologue of *rac*-**35** (later a ring A unit was alkylated, as an achiral α-nitrile anion, with a five-membered, chiral ring D unit (see Section 2.3)). The heat-induced isomerization of *rac*-**36** *via* *rac*-**37** to *rac*-**38** occurred in high chemical yield. Since *rac*-**38** had already been converted into *rac*-**8a**, the sequence of

reactions sketched out in Scheme 16 constitutes a formal total synthesis of *rac*-**8a**.

The total syntheses developed in the laboratories of *Johnson, Valenta,* and *Kametani* have enormous didactic value. They teach that it pays to develop systematically the key reaction of a synthetic scheme—here the Diels-Alder reaction. *Kametani*'s synthesis, moreover, illustrates an all too common case: the efficiency of the key reaction is impressively demonstrated, yet the other conversions are not optimized with the same care. A total synthesis that in terms of composition and execution can serve as a model must satisfy the requirement that it be fully developed.



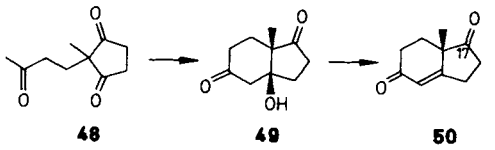
Scheme 17. Synthesis of *rac*-estrone (*rac*-**8a**) after *Torgov, Ananchenko et al.* [39].

The synthetic target compound can be attained without detours using the concept outlined by *Torgov et al.*[39] in 1963. This follows the AB+D→ABD→ABCD construction pattern (see Scheme 17); the AB unit, *rac*-**39**, obtained by treating 6-methoxytetralone with vinylmagnesium halide, reacts under acid catalysis with 2-methyl-1,3-cyclopentanedione **42** to give the achiral diketone **43**. *Kuo, Taub,* and *Wendler*[40] found that the acidity of **42** alone is sufficient to bring about the condensation. **43** cyclizes in the presence of *p*-toluenesulfonic acid to give *rac*-**40**. The tetracyclic reaction product already contains the complete steroid skeleton but only one of the necessary asymmetric C atoms. The three remaining centers of asymmetry are easily introduced along with the *trans*-fusion of rings C and D (*rac*-**41**) or the *trans/anti/trans* configuration of the BCD ring system (*rac*-**8b**) by catalytic hydrogenation of *rac*-**40** from the less hindered side using palladium/calcium carbonate, or by reducing *rac*-**41** with potassium and aniline in liquid ammonia *via* the thermodynamically more stable radical anion transients.

The synthetic concept proposed by *Torgov et al.* has, even today, lost none of its startling simplicity. It would play a significant role among the estrone syntheses of category III if **40** instead of *rac*-**40** were produced.

### 2.3. Category III Estrone Syntheses

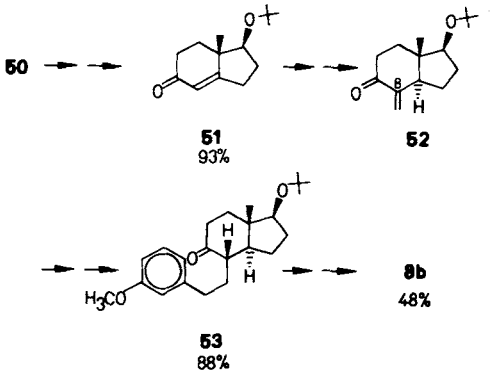
The first total synthesis of enantiomerically pure estrone without racemate resolution draws, as expected, on *Torgov*'s concept (see Scheme 17). It sets out from the diketone **43**, achiral but equipped with a prochiral center, which is the source compound for the four stereoisomeric hydroxyketones **44**, *ent*-**44**, **45**, and *ent*-**45** (see Scheme 18). If an achiral hydrogenating agent attacks one of the two enantiotopic carbonyl groups from both diastereotopic sides of the molecule [see **43**], then, albeit with different probabilities of formation, *rac*-**44** and *rac*-**45** will result simultaneously. In fact, the bulky lithium *tert*-butoxyaluminum hydride attacked selectively from the less hindered β-side, on which the methyl group lies, to afford the partially hydrogenated product *rac*-**44** in 85–90% yield[40].



Scheme 18. Microbiological reduction of the diketone **43** (R=2-(6-methoxy-1,2,3,4-tetrahydronaphthylidene)ethyl]) and the conversion into (+)-17β-estradiol **47a** [41].

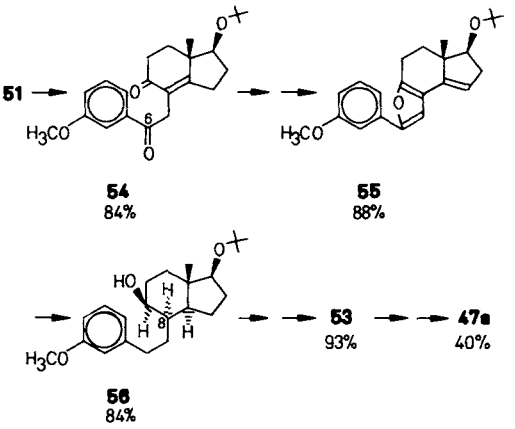
To avoid a racemate, a chiral hydrogenating agent had to be employed which, furthermore, selectively reacted with only one of the two carbonyl groups. Hydrogenating enzymes or microorganisms that contain such reductases were considered. Since the conformation of the enzyme-bound substrate not only can differ from case to case, but, moreover, is known in no single example, model studies were required. It turned out that of 160 microorganisms—bacteria, yeasts or fungi—that were tested in preliminary investigations[41], most were capable of partially hydrogenating **43**, and 37 of these came in for closer consideration; one group produced principally **44**, another group afforded mainly *ent*-**45**, and, finally, a third group resulted in a mixture of both diastereomers. With *Saccharomyces uvarum (CBS 1508) ent*-**45** could be obtained on a technical scale in 74% yield[41]; its subsequent cyclization (with HCl in methanol) led to **46** (see Scheme 18). Catalytic hydrogenation ($Pd/CaCO_3$) of the C-14,C-15 double bond of the resulting cyclisation product, followed by chemical reduc-

tion (K and aniline in liquid $NH_3$) of the generated dihydro product afforded 3-methoxy-1,3,5(10)-estratrien-17-ol **47b** in 37% overall yield (based on *ent*-**45**)[42,43].



The remarkable total synthesis of 19-norsteroids with a microbiological key step was to be outdone shortly after its realization through the exclusive application of cheaper reagents of known structure. Two industrial laboratories that had mounted a joint research program independently discovered a simple route to the optically active synthetic building block **50** (see Scheme 19)[44]: they observed that the triketone **48**, achiral but fitted out with a prochiral center, cyclized to the aldol in the presence of (*S*)-(−)-proline (3 mol%) with a high preference for **49** over *ent*-**49**. On subsequent dehydration **50** was obtained in over 90% chemical and optical yields.

Scheme 19. Preparation of the optically active CD building block **50** by asymmetric cyclization of the triketone **49**, catalyzed by (−)-(*S*)-proline [44].

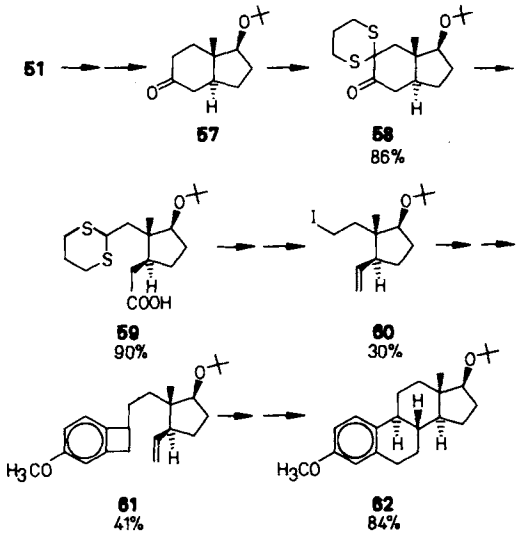


In spite of profound mechanistic considerations and adroit manipulation of the experimental parameters the parties involved[44–46] have not yet succeeded in deciphering the structure of the competing diastereomorphic transition states (cf. Scheme 7). The remarkable finding[45] that in the presence of (*S*)-(−)-proline **48** cyclizes preferentially to **49**, whereas in the presence of (*S*)-(+)-homoproline (side-chain lengthened by one $CH_2$ group) it cyclizes preferentially to *ent*-**49**, has since become the touchstone for every attempt to interpret the asymmetry-inducing aldol addition.

The total syntheses of 19-norsteroids starting from **50** follow the A+CD→ACD→ABCD construction pattern. The estrone synthesis developed by Hoffmann-La Roche (Basel and Nutley, NJ, USA)[47] (see Scheme 20) proceeds *via* the α-methylene ketone **52**. First the 17-keto group of **50** was reduced and the resultant alcohol converted into the *tert*-butyl ether. Methylmagnesium carbonate was used

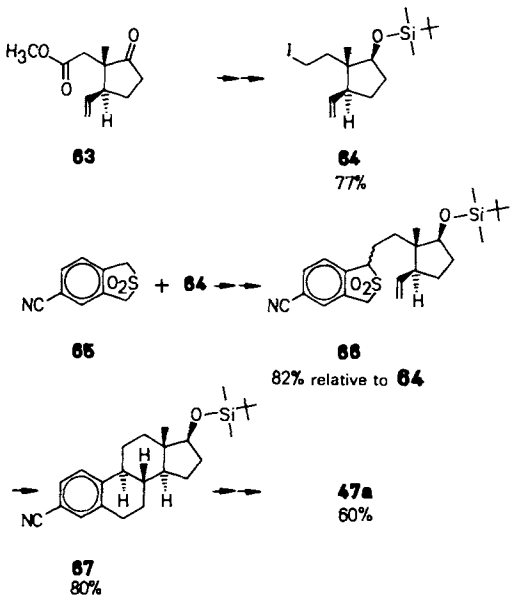
Scheme 20. Synthesis of (+)-estrone methyl ether **8b** developed by chemists from Hoffmann-La Roche [47]. No yields were given for the conversion **51**→**52**.

to introduce a carboxyl group at C-8. On hydrogenation of the β-keto acid, which has been opened out by hydrogen bonding, stereoselective attack of the catalyst from the sterically less hindered α-side is observed; at any rate, in the dihydro product the rings are fused *trans* to one another. **52** was finally reached by a decarboxylating Mannich condensation. From here, **53** is obtained by 1,4-addition of *m*-methoxybenzylmagnesium chloride and stereochemical correction of the primary reaction product. Ring B was closed by cyclodehydration. The resultant mixture of olefins contains as its main component the 9,11-unsaturated steroid. The latter can be catalytically hydrogenated with the customary high stereoselectivity. Cleavage of the *tert*-butyl ether and oxidation of the now unprotected hydroxy group finally afforded **8b**.



Scheme 21. Synthesis of (+)-17β-estradiol **47a** by chemists from Schering AG [48].

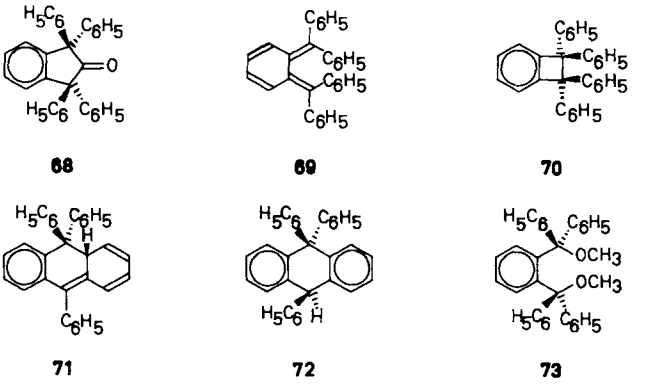
The route worked out by *Wiechert et al.* (Schering AG Berlin)[48] to 17β-estradiol **47a** (see Scheme 21) avoids the detour from **51** to **52**. Instead **51** was directly alkylated to **54** with *m*-methoxyphenacyl bromide. Treatment of the dimethyl ketal obtained by selective conversion of the C-6 keto group with *p*-toluenesulfonic acid furnished the furan derivative **55**. Catalytic hydrogenation of **55** generated **56** with *trans*-fused rings C and D; Jones oxidation and subsequent correction of configuration at C-8 led to the previously known compound **53** (see Scheme 20) and thus to **47a** or, if desired, to **8a**.



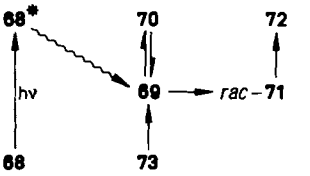
With the syntheses of enantiomerically pure 19-norsteroids (see Schemes 20 and 21) the chemists of the Roche and Schering groups changed the synthetic panorama in more than one respect: they overcame a psychological barrier that, more or less consciously, had stood in the way of the cultivation of asymmetric synthesis. With **50** they, moreover, enriched the pool of versatile chiral synthetic building blocks[49].

As shown in Scheme 22, *Kametani et al.*[51] have applied the synthetic unit **51**, easily generated from **50**, to the construction of **61**. The benzocyclobutene derivative **61** is better suited than *rac*-**36** (see Scheme 16) to function as a latent *o*-quinodimethane derivative: firstly because it occurs as the enantiomer with the necessary absolute configuration and secondly because it already contains the five-membered ring D.

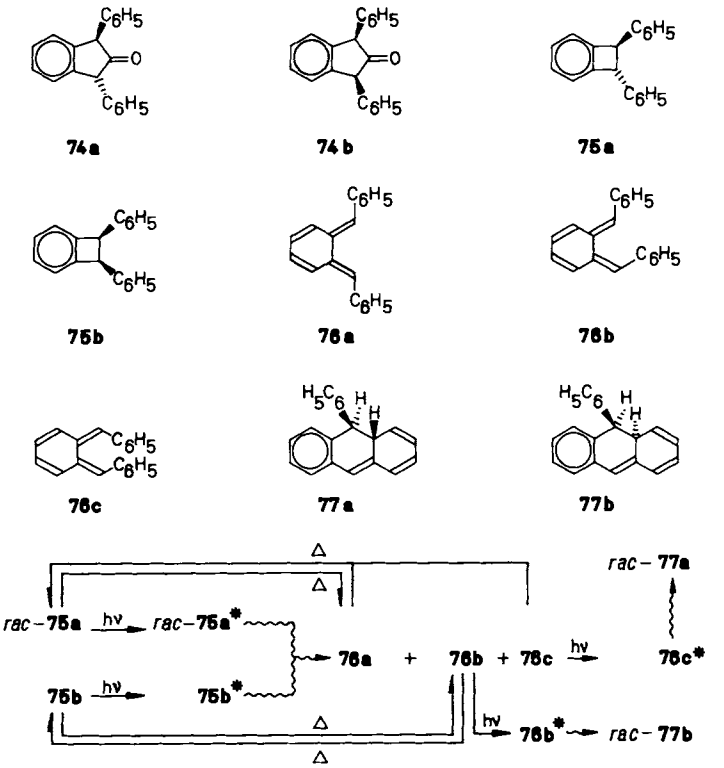
Scheme 22. The synthesis of (+)-17β-estradiol **47a** from the optically active CD building block **51** (see Scheme 20) after *Kametani et al.* [51]. No yields were given for the conversion **51**→**57**.



Of course, the route from **51** to **60** is much too long for practical purposes. It is somewhat better to rely on the route (see Scheme 23) developed by *Oppolzer et al.*[52], even though a racemate resolution must be accomplished, fortunately quite early in the synthesis.

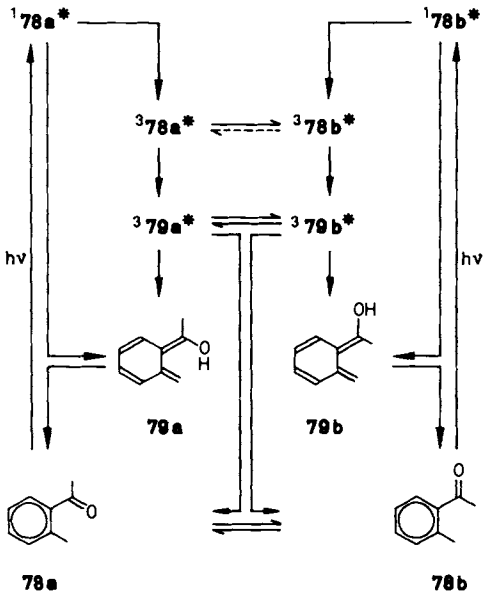


Scheme 23. Synthesis of (+)-17β-estradiol **47a** after *Oppolzer et al.* [52].



## 3. The Photochemical Synthesis of Estrone

Work in our laboratory has the aim of developing photochemical reactions to the point where they can be considered as key reactions in natural product total syntheses. Precisely why photochemical conversions should interest us is quickly explained: light is a clean "reagent", whose intensity and energy content can be finely controlled and which makes kinetically unstable transients with great synthetic potential from many conveniently accessible key compounds.



Scheme 24. Preparation of tetraphenyl-*o*-quinodimethane **69** by photodecarbonylation [53a] of **68** [53b]: characterized by electron absorption spectroscopy at low temperature [53c, d] or by kinetic spectrophotometry [53e] at room temperature. **69** cyclizes to the kinetically favored benzocyclobutene derivative **70** or to the thermodynamically favored isodihydroanthracene derivative *rac*-**71** [53d, e, 54].

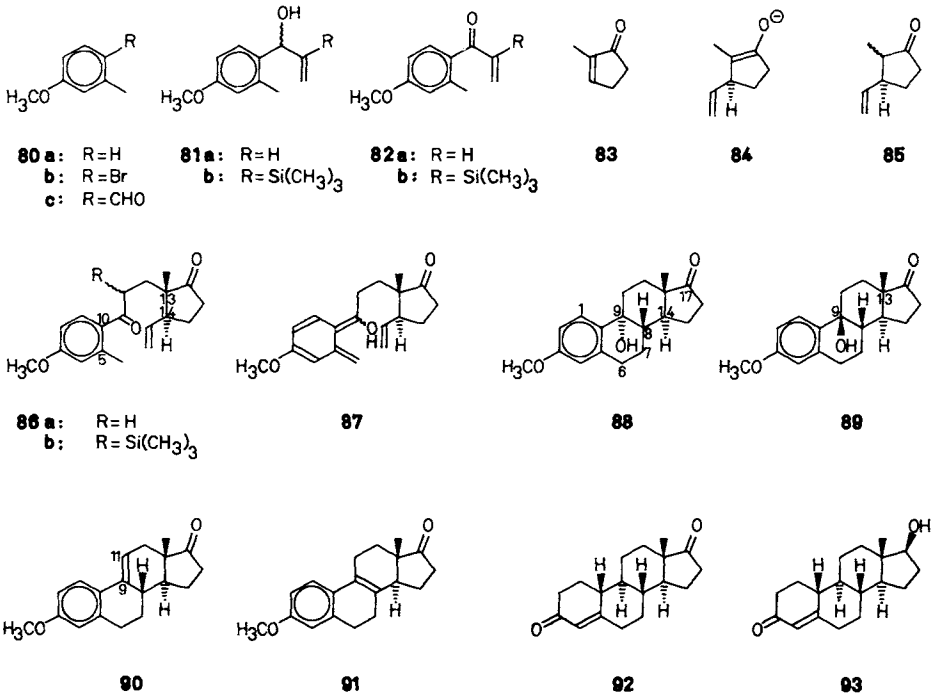
Scheme 25. Preparation of **76a** and **76c** by photodecarbonylation [53a] of *rac*-**74a** or **74b** [56a—d]: characterized by electron absorption spectroscopy at low temperature [56e] or by kinetic spectrophotometry at room temperature [53e]. Intermolecular Diels-Alder reaction [56b] and cyclization of **76a** or **76c** or **76b** to give *rac*-**75a** or **75b** [56b, e], and of **76b** or **76c** to afford *rac*-**77b** or *rac*-**77a** [56e].

The decision to construct the carbon skeleton of 19-norsteroids by intramolecular Diels-Alder reaction of a suitably substituted vinyl group with a photochemically generated *o*-quinodimethane derivative *(vide infra)* was preceded by years of study of *o*-quinodimethane derivatives. Schemes 24 and 25 summarize the experience gained.

*o*-Quinodimethanes with a hydroxyl group in the chromophore system, often also described indiscriminately as photoenols, are accessible from *o*-alkyl substituted acetophenone derivatives by light induced isomerism. Scheme 26 shows the complex relationships that exist between the

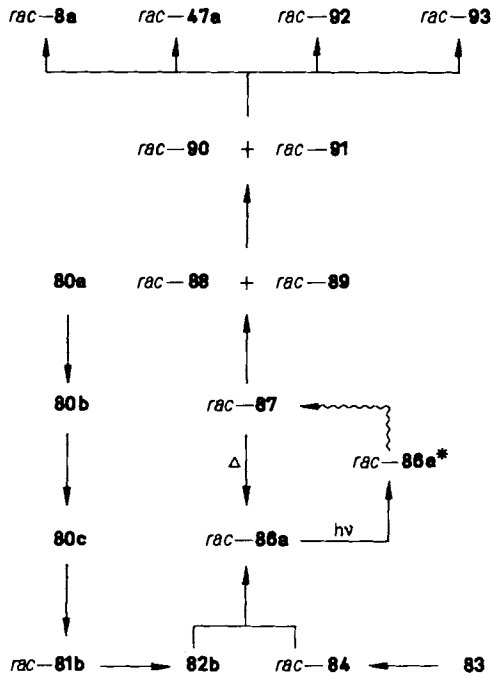
Scheme 26. Thermally reversible [59] adiabatic photoenolization [57] of *o*-methyl-substituted acetophenone derivatives **78a** ⇌ **78b** after *Haag, Wirz,* and *Wagner* [60].

educt conformers **78a** or **78b** and the transient configurations **79a** or **79b**.



Since *o*-quinodimethanoid phototransients appear in both cases as mixtures of stereoisomers, pragmatic reasons selected photoenolization of **86a** (see Scheme 27) and not the light-induced ring opening *e.g.* of **61** (see Scheme 22): the acetophenone derivative is more readily accessible and, because of its absorption at longer wavelength, more conveniently photoactivated than the benzocyclobutene derivative.

### 3.1. Racemic Target Compounds[58]



The synthesis of 19-norsteroids proceeding *via* an *o*-quinodimethanoid phototransient and which follows the A + D → AD → ABCD construction pattern (see Section 2.2) is convergent in its initial phase and typified by the separate production of both ring A and ring D units.

The ring A unit **82b** is formed in an overall 56% yield by a conventional reaction sequence which begins with *m*-cresol methyl ether **80a** (see Scheme 28); **80a** can be converted into **80b** with bromine in carbon tetrachloride below 0°C in the presence of iron filings. The Grignard reagent formed from **80b** affords the aldehyde **80c** on reaction with *N,N*-dimethylformamide in tetrahydrofuran at temperatures below −20°C. Reaction of the Grignard reagent from (1-bromovinyl)trimethylsilane with **80c** in tetrahydrofuran below room temperature gives *rac*-**81b**, which on subsequent chromic acid oxidation in the water/ether two phase system affords the achiral Michael acceptor **82b**.

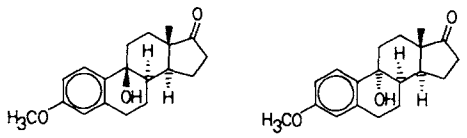
The corresponding Michael donor, *rac*-**84**, which plays the part of the ring D unit, is formed directly by $Cu^{III}$-catalyzed, 1,4-addition of vinyllithium to **83**[63] and reacts *in situ* with **82b**. In the racemic series a problem of stereosel-

Scheme 27. Total synthesis of 19-norsteroids using a photochemical key reaction [50, 58].

Scheme 28. The total synthesis of racemic 19-norsteroids (cf. Scheme 27; a thermally reversible photoisomerization system [61] plays a key role [58].

ection is encountered for the first time with the Michael addition: the newly formed C-12,C-13 bond lies either on the same or on the opposite side of the vinyl group at C-14. The AD adduct *rac*-**86a**, of course, is the desired one, for which not only the indicated constitution but also the specified relative configuration are correct. This racemate would already contain a five-membered ring D and would have the methyl group at C-13 oriented *trans*, once and for all, to the H atom at C-14.

In fact, *rac*-**86a** was successfully isolated, free of isomers, in 70% yield[65]. The trimethylsilyl group, which is removed from the primary Michael adduct *rac*-**86b** on acid work-up, amplifies the effect of selection which occurs in any case. **82b** approaches **84** from the less hindered side to an even greater extent than **82a**, and possibly the Michael addition, reversible when **82a** is used, becomes irreversible if **82b** is the starting material (see Section 2 of [50]). The relative configuration of *rac*-**86a** was determined by NMR spectroscopy by comparison of the chemical shifts either of the protons of the angular methyl group or of C-13 and C-14 with the corresponding data for suitable reference compounds[66].



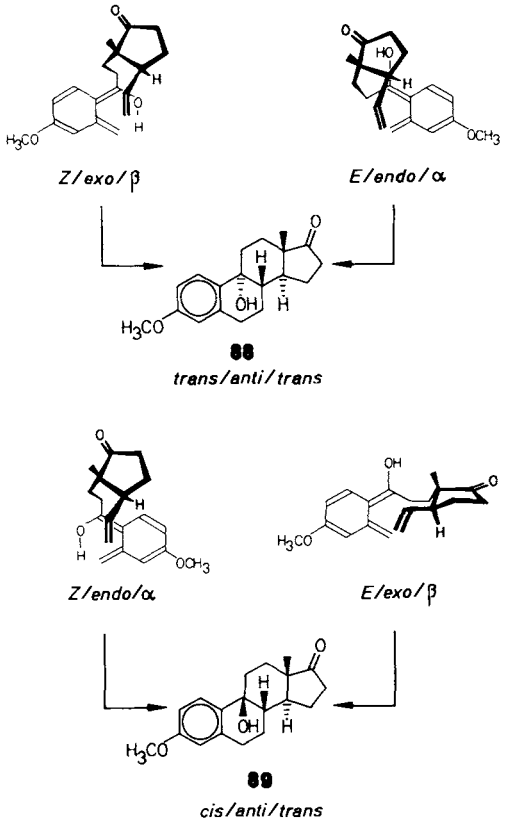
The disecosteroidal Michael adduct *rac*-**86a** already possesses all the carbon atoms of the future 19-norsteroids; as yet the bonds between C-6 and C-7 and between C-8 and C-9 are absent. To complete the carbon skeleton of the target compound, the AD adduct *rac*-**86a** was isomerized to an *o*-quinodimethanoid photo-transient, *rac*-**87**, and the latter to an ABCD cycloadduct. In our steroid synthesis (see Scheme 28) a key role is played by a thermally reversible photoisomerization system with a trappable intermediate[61] (here by intramolecular Diels-Alder reaction). The reketonization of the photoenol *rac*-**87** seems at first sight rather undesirable since it reduces the quantum yield of the photochemically initiated overall reaction. However, on optimization of the reaction conditions, which at the end sounded rather alchemical, it turned out to be very useful precisely for the case when the generated phototransient cannot be trapped by intramolecular Diels-Alder reaction, and the desired cycloadduct cannot, therefore, be isolated. When on UV irradiation of *rac*-**86a** in a mixture of $C_6D_6$ and $CD_3OD$ the $CH_3$-group at C-5 was converted to a $CD_3$ group, it was concluded that the acidic photoenol definitely must have been present as an intermediate.

In the elaborated version of the synthesis, the Michael adduct *rac*-**86a** is converted into a mixture of constitutionally isomeric styrene derivatives, *rac*-**90**/*rac*-**91**, in 65% overall yield. It turned out to be expedient not to isolate the kinetically unstable components of the ABCD cycloadduct with the constitution 9-hydroxy-3-methoxy-1,3,5(10)-estratrien-17-one, but rather to dehydrate it using oxalic acid in dry benzene.

The irradiation was eventually carried out

- in methylcyclohexane (optically transparent with boiling point 100.9 °C) at 95 °C
- with light of wavelength >340 nm (to avoid absorption by the nonconjugated keto group and resultant loss of stereochemical integrity at C-13)
- in the presence of 2,6-di- or 2,4,6-trimethylphenol (to protect the initially formed ABCD cycloadduct from light-induced decomposition) as well as
- in the presence of pyridine (which raises the barrier to reketonization and, hence, the lifetime of the (*Z*)-photoenol)

Photoenolization of the AD adduct was followed by thermal cyclization of the resulting phototransient of an ABCD cycloadduct. The latter was converted without purification into a mixture of 95% *rac*-**90** and 5% *rac*-**91**[69].



**94** **95**

Scheme 29. **94** and **95**, the other members, beside **88** and **89** (see Scheme 27), of the group of 9-hydroxy-3-methoxy-1,3,5(10)-estratrien-17-ones stereoisomeric at C-8 and C-9.

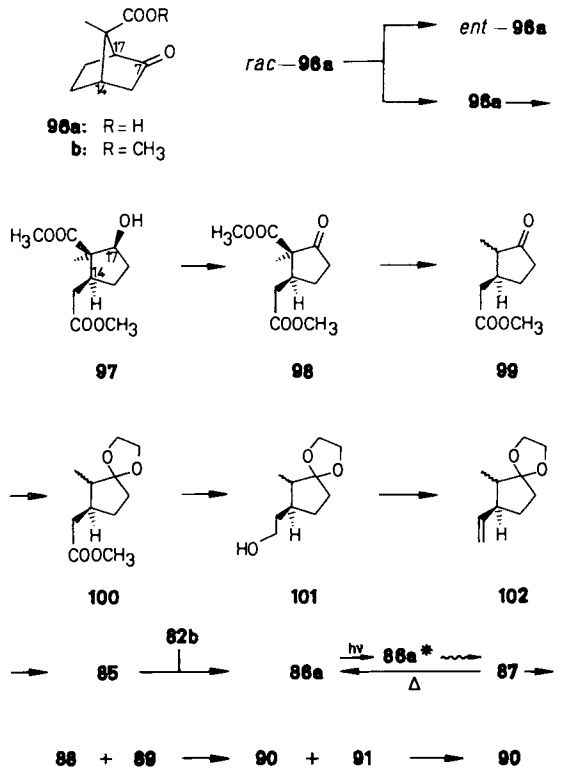
In the racemic series of compounds the conversion of the AD adduct into the ABCD cycloadduct poses, for the second time, a problem of stereoselection: since the *trans* fusion of the rings C and D is present already in *rac*-**86a**, altogether four relative configurations are feasible: *trans/anti/trans rac*-**88**, *cis/anti/trans rac*-**89**, *trans/syn/trans rac*-**94**, or *cis/syn/trans rac*-**95** (see Scheme 29). To establish their structures both cycloadduct components were isolated, albeit in low yield. All the chemical shifts and coupling constants were determined by two-dimensional FT-NMR analysis for the major isomer[70]. In the latter the *trans* diaxial coupling between H-14α and H-8β (11.5 Hz) and between H-7α and H-8β (12.6 Hz) indicates the desired *trans/anti/trans*-configuration, *rac*-**88**. This relative confi-

guration can only have resulted from the least strained of all possible transition states: the vinyl group approaches the diene, whose enolic double bond has the *Z*-configuration, from the β-side and with an *exo*-orientation (see Scheme 30). The alternative approach of the vinyl group from the α-side but *endo*-orientated to the diene with the enolic double bond in the *E*-configuration is much too strained to be considered seriously.

Scheme 30. How *rac*-**87** reacts to give the ABCD cycloadducts *rac*-**88** and *rac*-**89**; *rac*-**88** indeed arises from the least strained of all possible transition structures with the enolic CC double bond *Z*-orientated and *exo* approach of the dienophile region to the diene moiety from the α-side. Whether *rac*-**89** arises from the transition state in which the enolic CC double bond is *Z*-orientated and the dienophile region *endo*-approaches the diene moiety from the α-side or from the transition state with *E*-orientation of the enolic CC double bond and *exo*-approach of the dienophilic region to the diene moiety from the β-side cannot be decided from mere inspection of molecular models [58].

The minor isomer has the relative configuration *cis/anti/trans* of *rac*-**89**. Under conditions that admittedly lead to a mixture of *rac*-**90** and *rac*-**91**, but not to an equilibrium mixture[69], *rac*-**89**, and for that matter *rac*-**88** also, dehydrates to the styrene derivative *rac*-**90**. *rac*-**90** contains a double bond between C-9 and C-11 and the original *anti/trans*-configuration is still intact.

For *rac*-**89** it is not so easy to imagine the structure of the appropriate transition state. Certainly, regioselectivity favoring the constitution of the steroid skeleton is exceedingly high: in the conversion of the AD adduct into the ABCD cycloadduct the short bridge between C-9 and C-13 allows CC bond formation only between C-9 and C-8 and between C-6 and C-7. Whether the vinyl group, a poor nucleophile, approaches the *Z*-configurated *o*-quinodimethane from the α-side in an *endo*-orientation and/or the *E*-configurated *o*-quinodimethane from the β-side in an *exo*-orientation cannot be reliably estimated merely by inspection of molecular models. It should be recalled that in the synthetic routine the AD adduct *rac*-**86a** is converted in remarkable overall yield into a mixture of the styrene derivatives *rac*-**90**/*rac*-**91**. Intermediates need not be isolated and the resulting olefinic mixture need not be separated. Due to the pioneering investigations of *H. Smith et al.*[71], those reduction conditions which lead from a mixture of *rac*-**90**/*rac*-**91** optionally to *rac*-**8a**, *rac*-**47a**, *rac*-**92** or *rac*-**93** are precisely known[72].



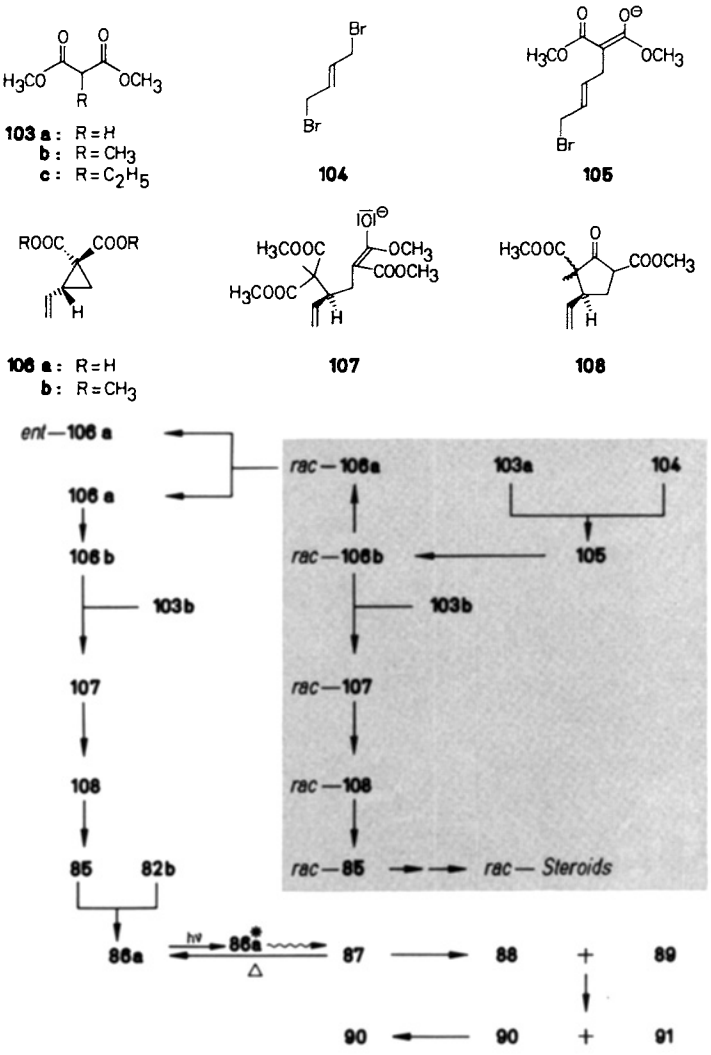
Since efficient syntheses to give access to enantiomerically pure compounds with biologically important properties have been demanded *(vide supra)*, the photochemical synthesis of estrone must not stop with racemic products. Further development has to commence at that point in the course of the synthesis where a racemic synthetic building block is introduced for the first time (see Scheme 28): in our case with the ring D unit. Enantiomerically pure 19-norsteroids would be accessible if, instead of *rac*-**84**, the enantiometer **84** were available.

### 3.2. Enantiomerically Pure Target Compounds

#### *3.2.1. The Chiral Ring D Building Block by Racemate Resolution of a Synthetic Precursor*[73]

A possible route to the enantiomerically pure ring D component **85** and thence to the enantiomerically pure steroid **90** (see Scheme 31) starts with the readily available[74] keto carboxylic acid *rac*-**96a**, the resolution of whose racemate has been thoroughly studied[75].

Which of the two separated enantiomers must be represented by **96a**, and which by *ent*-**96a** has been determined by trial and error[77]. The constitutional relationship between **96a** and **85** becomes obvious as soon as the C-17,C-7 bond is opened (numbering of the C atoms in **96a**, **b** reflects their position in the steroid eventually formed) by Baeyer-Villiger oxidation and hydrolysis of the initially formed lactone. The hydroxyl group at C-17 thus produced may be oxidized to a keto group. The desired vinyl group is obtained from the acetic acid side chain at C-14 by a standard procedure[78] without damaging the stereostructural integrity of the chiral center at C-14 (see Scheme 31). **85** represents a mixture of diastereomers; this was converted into the enolate **84**, as in the racemic series, and then into a mixture of the styrene derivatives **90** and **91**. The main components of **85**, which has the methyl group at C-13 *trans*-orientated to the H atom of C-14, and of **90**/**91**, which has the double bond between C-9 and C-11, were purified by chromatography and characterized by their chiroptical data. Since **90** is accessible from natural (+)-estrone by etherification and dehydration[79], natural and synthetic samples could be compared; the values of the optical rotations and the CD spectra leave no doubt that the samples are identical, and thus that C-14 of **96a** has (*S*)-chirality. It was precisely this last point that had prompted the synthesis of 3-methoxy-1,3,5(10),9(11)-estratetraen-17-one **90** shown in Scheme 31: authentic samples of **85**, **86a**, and **90**[73] would then be available to stereostructurally control the total synthesis of enantiomerically pure 19-norsteroids which uses a chiral ring D building

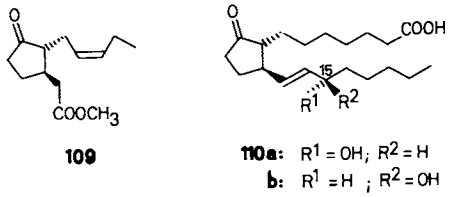


Scheme 31. Synthesis of the enantiomerically pure estrone derivative **90**; after racemate resolution of *rac*-**96a**, **96b** is converted into the mixture of enantiomerically pure diastereomers of type **85** [75]; **90** is obtained from **85** [76].

block obtained by asymmetric induction (see Section 3.2.2). Before this total synthesis, which dispenses with resolution of racemates, is more closely examined, the ring D unit should be logistically safeguarded.

*Perkin*[81], *Linstead*[82], and *Danishefsky*[83] and their respective co-workers have established the conditions whereby dimethyl *rac*-2-vinylcyclopropane-1,1-dicarboxylate *rac*-**106b** is

- conveniently accessible by intermolecular alkylation of the enolate of **103a** with (*E*)-1,4-dibromo-2-butene **104** and subsequent $S_{eN'}$ reaction (cyclization by vinylogous nucleophilic substitution)[84] of the intermediate enolate **105** (see Scheme 32),
- ring opened on nucleophilic substitution of the vinyl-substituted C atom by the enolate anion of dimethyl methylmalonate **103b**, whereupon the resultant enolate *rac*-**107** cyclizes in a Dieckmann condensation, and the β keto diester *rac*-**108** arising from alkoxide-initiated elimination of dimethyl carbonate gives *rac*-**85** after hydrolysis and decarboxylation (see Scheme 32).



If the dextrorotatory enantiomer **106b** is substituted for *rac*-**106b** in the synthetic sequence, the enantiomerically pure steroid **90** can be obtained *via* the chiral ring D unit **85** and the optically active AD adduct **86a**. It will be remembered that the compounds specified, in as far as they contain a five-membered ring, have already been prepared as reference compounds; there are, thus, three test points in the synthesis at which the enantiomeric purity of intermediates can be checked. The result[80] is convincing; no-

Scheme 32. Synthesis of *rac*-**8a**, *rac*-**47a**, *rac*-**92**, or *rac*-**93** from **103a**, **104** and **103b** via *rac*-**85**; area in grey [85]; synthesis of **90** via **85** from **106a**, after the resolution of *rac*-**106a** with (−)-brucine [66b, 86]: area not in grey; see [87].

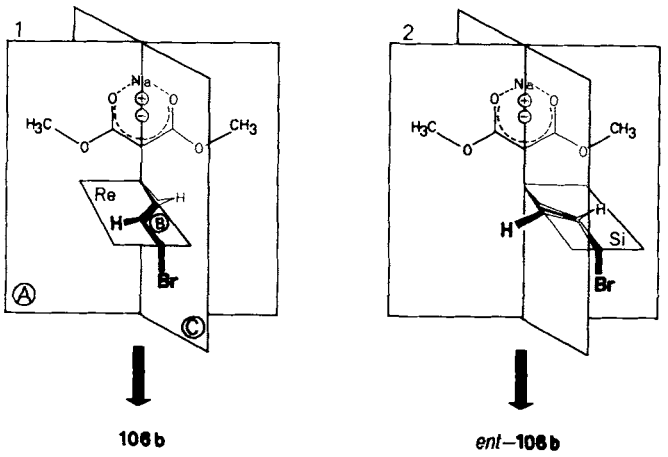
where—including the conversion of **106b** to **85**—is stereostructural information lost: *ent*-**106b**[88] is transformed into enantiomerically pure methyl jasmonate **109**[90,91] or (−)-11-deoxyprostaglandin $E_1$ **110a**, or (−)-15-*epi*-11-deoxyprostaglandin $E_1$ **110b**[89]. In all these cases (see Scheme 33) it is assumed that inversion[92] of configuration at the center of substitution occurs simultaneously with opening of the cyclopropane ring.

With the four chiral reference compounds **106**, **85**, **86a**, and **90** in hand, the preparations for a total synthesis of

Scheme 33. Enantiomerically pure target compounds whose synthesis began with *ent*-**106b** [88] as chiral starting material; for **109** see [90] and for **110a** and **110b** see [89].

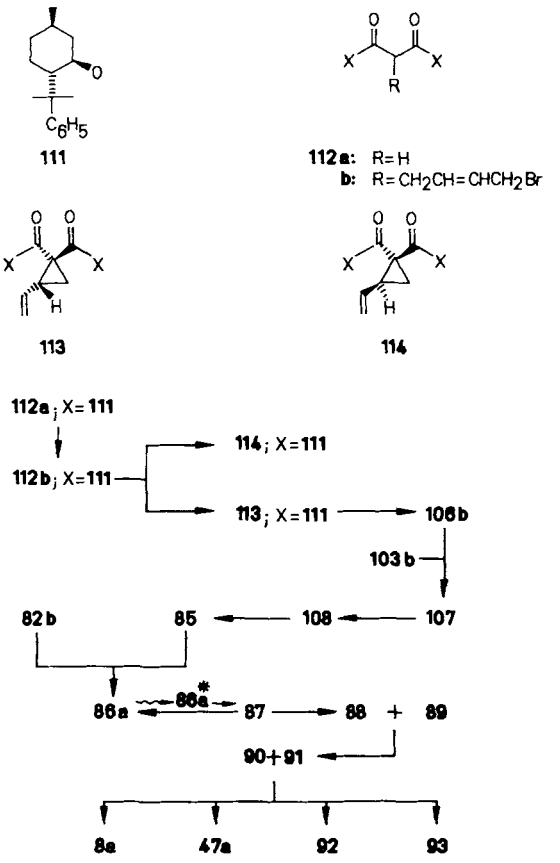
19-norsteroids were complete. What was still missing was the preparation of the enantiomerically pure synthetic building block **106b** by an asymmetry-inducing step.

### *3.2.2. The Chiral Ring D Unit by Application of an Asymmetry-Inducing Step*



The enolate of the monosubstituted dimethyl malonate **105** (see Scheme 32) reacts *via* an $S_{cN'}$ reaction[84] to give *rac*-**106b**. The formation of a cyclopropane ring can also be rationalized as an intramolecular addition of a nucleophile to an electrophile, arising from elimination and concomitant allylic rearrangement. The central C atom of **105** functions here as a nucleophilic center; the halogen-distant C atom with coordination number 3 from the haloallyl group as an electrophilic center. At **105** the reaction path branches and separate routes lead to the two enantiomers **106b** and *ent*-**106b**. The corresponding transition states are at least enantiomorphic. Yet what detailed structure lies behind them? An analysis of the course of the reaction requires that conformational flexibility of **105** be limited. Scheme 34 sketches the reacting compound and lays stress equally on the malonate moiety, on the region of the halogen-containing substituent, and on their mutual orientation.

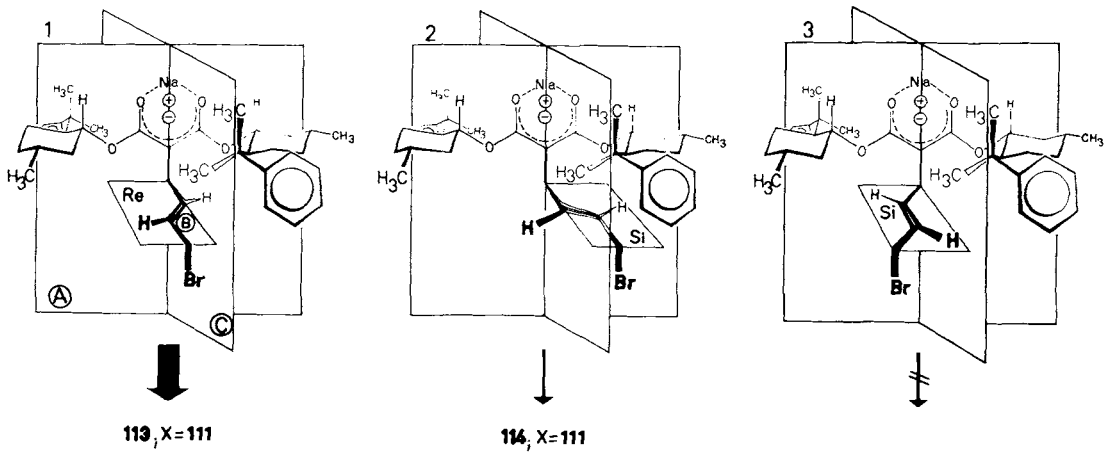
As a bidentate ligand, the enolate of a malonate diester is able to chelate a suitable cation[93]. By this means this structural element, which is otherwise "floppy", is tightly locked in a U-shaped conformation: the chelate ring and both methoxy groups lie more or less in a single plane (plane Ⓐ in Scheme 34)[94].



In the halogen-containing substituent the carbon atoms of the CC double bond and the central atoms of their ligands are likewise oriented in a plane (plane Ⓑ). In the transition state of the $S_{cN'}$ reaction, the two parts of the molecule are so mutually oriented that optimal overlap of the orbitals is achieved. This is the case when the axes of the anionic donor orbital and the olefinic acceptor orbital lie in the plane (plane Ⓒ) which also contains the centers of the future three-membered ring. In short: the conformations depicted in Schemes 34.1 and 34.2 satisfy the stereoelectronic requirements of the $S_{cN'}$ reaction.

The formation of the cyclopropane ring occurs in one of the two half-spaces into which plane B has divided three-dimensional space (see Scheme 34). If it occurs in the *Re* half-space[96] the (*R*)-enantiomer **106b** results, and if in the *Si* half-space the (*S*)-enantiomer *ent*-**106b** is obtained. Since the conformations of the competing transition states are enantiomorphic and, hence, have the same potential energy, the racemate *rac*-**106b** is formed. In order to obtain three-membered ring diastereomers, which are easier to separate than the three-membered ring enantiomers (see Scheme 4), the *imperative of asymmetric synthesis* may be invoked (see Scheme 5) and a chiral auxiliary reagent introduced into the hitherto achiral educt **105**, *e.g.* by using the alkoxide residue of a chiral alcohol instead of the methoxide residue. In the following discussion (−)-8-phenylmenthol (hydride of **111**) plays the role of the optically active auxiliary reagent. This alcohol is accessible from (+)-pulegone[97], can be esterified with malonic acid, and can be recovered from the corresponding ester of **106a**[50]. It is, as will be shown, superbly suited to assist in the generation of enantiomerically pure dimethyl 2-vinylcyclopropane-1,1-dicarboxylate **106b** (see Scheme 35).

Scheme 36 shows at a glance that the representations 36.1 and 36.2 are diastereomorphic[96]. The reaction paths that branch from **112a** (X = **111**; see Schemes 4 and 7) dif-

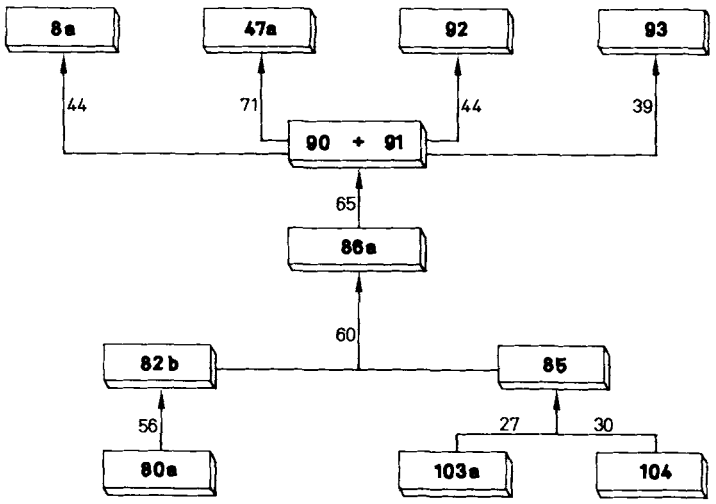


Scheme 34. $S_{cN'}$ reaction via enantiomorphic transition states of the same potential energy gives *rac*-**106b** (see Scheme 32). Cyclopropyl ring formation in the *Re* half-space (Scheme 34.1) gives **106b**, whereas cyclization in the *Si* half-space (Scheme 34.2) gives *ent*-**106b**.

Scheme 35. Asymmetric synthesis of **8a**, **47a**, **92** or **93** from **104** (see Scheme 32) or the corresponding dichloro compound and **112a** (X = **111**). After optimization [98] enantiomerically pure **113** (X = **111**) was obtained in 67% yield and thence—with recovery of the chiral alcohol (the hydride of **111**)—**106b** was isolated in 65% yield [99].

fer in width and provide unequal amounts of **113** (X = **111**) or **114** (X = 111). The chemical yield of **113** (X = **111**) should be higher than that of its epimer **114** (X = **111**), thanks to the steric hindrance between the dimethylbenzyl group of the chiral alcohol moiety and the $C_4H_6Br$ ligand. This interaction exists practically only in the transition state between **112b** (X = **111**) and **114** (X = **111**) (see Scheme 36.2), not, however, in the transition state between **112b** (X = **111**) and **113** (X = **111**) (see Scheme 36.1).

Scheme 36. $S_{cN'}$ reaction via diastereomorphic transition states of unequal potential energy gives predominantly **113** (X = **111**) and only a very limited amount of **114** (X = **111**) (see Scheme 35). **113** arises from cyclopropane ring formation in the *Re* half-space (Scheme 36.1), whereas **114** (X = **111**) arises from cyclization in the *Si* half-space (Scheme 36.2 but not 36.3).

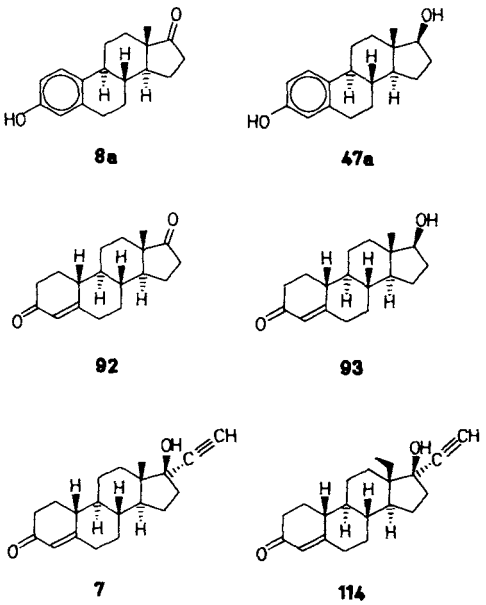


If the representations 36.2 and 36.3 are compared, it is immediately seen that the bromine-containing ligand can very easily flip over from the congested (see Scheme 36.2) to the empty quadrant (see Scheme 36.3) by rotation of both parts of the **112b** molecule around the central CC single bond. Thus it might be expected that the three-membered ring closure would also be possible in the *Si* half-space without significant steric hindrance, and in consequence, that substantial molecular selection would be questionable. Such a conclusion, however, disregards the stereoelectronic requirements of the $S_{cN'}$ reaction. Ultimately, cyclization in the *Si* half-space to afford diastereomer **114** (X = **111**) with a newly created center of (*S*)-chirality is handicapped compared to cyclopropanation in the *Re* half-space. Before the experimental results are reported, a word about a hitherto neglected detail of the $S_{cN'}$ reaction mechanism is in order: Opinions still differ[100] as to whether the nucleophilic center and the leaving group in the transition-state structure of an $S_{cN'}$ reaction are orientated *syn* or *anti* to one another. The antiplanar conformation is shown in Schemes 34 and 36 simply for the sake of convenience of representation. It is to be expected, however, that the synperiplanar orientation dominates[101]. The arguments developed above in favor of **113** (X = **111**) and against **114** (X = **111**) (Scheme 36) would then carry even more weight.

If **112a** (X = **111**) (see Scheme 35) is treated with (*E*)-1,4-dihalobutene in the presence of tricaprylammonium chloride in the *n*-hexane/50% aqueous sodium hydroxide two phase system at room temperature, enantiomerically pure **113** (X = **111**) is obtained in 67% yield after HPLC purification. Vigorous hydrolysis (KOH/MeOH/$H_2O$) and treatment of the resultant crude acid with excess $CH_2N_2$ gave **106b** (see Scheme 35) in 65% yield.

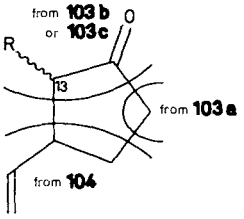
This is an example in which stereoselection has been successfully directed during introduction of the first center of chirality. In order to draw the correct conclusions for analogous cases in the future, the essential points of this stereoselection should be summarized: For a compound to fulfill the task of selection, it must, within a definite type of conformation, adopt one of two competing diastereomorphic conformations. The type of conformation is determined in each case by stereoelectronic factors which are specific for the reaction in question. In the present case the chelate effect exerts an additional influence. Selection in favor of one of two competing diastereomorphic transition states arises from involvement of a chiral auxiliary reagent. Which enantiomer of the latter should be used, follows from a comparative conformational analysis in which the least possible steric hindrance between different parts of the molecule is decisive.

To proceed beyond a mere formal synthesis, the three-membered ring compound **106b**, obtained by an asymmetry-inducing step, was converted by ring expansion into the ring D building block **85** (see Scheme 35), which was then transformed *via* Michael adduct **86a** and a mixture of constitutionally isomeric steroids **90** and **91** into the various target compounds **8a**, **47a**, **92**, or **93** (see Scheme 35)[50]. Scheme 37 presents an overview and details the chemical yields of the individual sections of the synthesis.



Thus, the aim of preparing enantiomerically pure 19-norsteroids stereoselectively has been achieved by a total synthesis that uses a photochemical key reaction and cheap industrial chemicals, dispenses with racemate resolution, and does not depend on the tedious use of protective groups.

Scheme 37. At a glance: the chemical yields for the individual sections of the asymmetric total synthesis of diverse enantiomerically pure 19-norsteroids from *m*-cresol methyl ether **80a** (see Fig. 27), dimethyl malonate **103a** and (*E*)-1,4-dibromo-2-butene **104** (see Scheme 32) via a photochemical key reaction.



Depending on preference, the photochemical synthesis of estrone leads

- to 19-norsteroidal natural products which contain a benzenoid ring A (**8a**, **47a**; see Fig. 38) and exhibit estrogenic activity;
- to 19-norsteroidal gestagens having no benzenoid ring A (**92**, **93**, **7**; see Scheme 38) which, while themselves not natural products, can easily be prepared from them;
- to 19-norsteroidal gestagens which are methylated at C-18 (norgestrol **115**; see Scheme 38) and are more readily obtained by total synthesis from cheap industrial chemicals than by partial synthesis from available natural products.

Scheme 38. Biologically active 19-norsteroids which are accessible via the photochemical synthesis of estrone. While for **7**, **8a**, **47a**, **92** or **93** partial and total syntheses compete, for **115** total synthesis is clearly favored.

The last-cited case reveals the flexibility of the photochemical synthesis of estrone. If the synthesis of the ring D building block **85** from three components is recalled (see Scheme 39), the structural scope for target compounds of topical interest becomes clear; if instead of **103b** the homologous compound **103c** is used along with **103a** and **104**, steroidal derivatives with an ethyl, rather than a methyl, group at C-13 are obtained[102].

Scheme 39. The ring D building block with $R=CH_3$ or with $R=C_2H_5$ arises from the components **103a**, **104** and either **103b** or **103c**.

The chiral ring D building block **85** could also be used for total syntheses that follow the A+D→AD→ABCD construction principle and include thermally induced *o*-quinodimethanes. These syntheses, developed in other laboratories, have, hitherto, led only to racemic 19-norsteroids[103].

Natural products are one of the few *de novo* sources of drug discovery and the target compounds of chemical synthesis. In an area where research is carried out to cultivate synthetic methodology and to study structure-activity relationship, industrial chemists on the whole are more interested in new products, whereas chemists in the academic world for the most part are more interested in new synthetic methods. The development of the total synthesis of 19-norsteroids illustrates what a "concerted effort" can achive for the stereoselective synthesis of enantiomerically pure natural products.

These days, the art of synthesis is linked to a productive technology of synthesizing. One after another, synthetic methods are refined until they correspond to *Emil Fischer's* concept of asymmetric synthesis. In view of the results expected from biological synthesis, the conspicuous growth in potential of chemical synthesis has occurred just in time. Chemical synthesis will certainly profit from competition with developing recombinant DNA technology.

*Wolf-Dietrich Weber, Ulrich Schwartz, Herbert Stark, Friedhelm Adam, Helmut Baier, Stefan Gross, and Gudrun Frank were involved as undergraduates, postgraduates, or postdoctorals in the synthetic work in our laboratory mentioned here. Gerd Dürner has many years experience of analytical and preparative HPLC. His cooperation, supported by Marlies Dürr and Gabriele Stracke, has lent our statements the degree of security they enjoy. Prof. D. Rehm and Priv.-Doz. Dr. F. P. Montforts performed online-dialog computer search in data banks. As always, Helga Zimmermann took care of the illustrations, and Anneliese Dlabal was responsible for the many versions up to the final manuscript. Our work has been generously supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie, and promoted by donations of valuable samples, numer-*

*ous chemicals and considerable quantities of solvents from the chemical industry in this country. The above-mentioned ladies and gentlemen and the institutions referred to all deserve our sincere gratitude.*

[14] D-(+)-glucose **9**, free or bound, is the most abundant of all organic compounds on our planet. This sugar is readily accessible and is a renewable resource. Thanks to its accumulation of functional groups and chiral centers it is a convenient starting material for the synthesis of many enantiomerically pure target compounds; [15] is a leading reference.

[23] Eschenmoser's synthesis of cobyric acid is also a teaching model in this respect; it comprises 37 steps [24]; a racemic Diels/Alder adduct is obtained at the second step and the two isomers separated using (+)- or (−)-phenylethylamine. While the dextrorotatory isomer was developed into suitable A, B or C ring units, the chiral ring D unit arose from the levorotatory enantiomer [25].

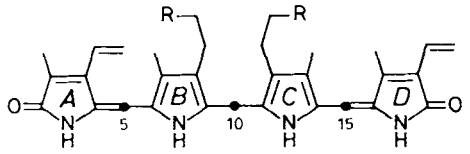
# Solution Conformations, Photophysics, and Photochemistry of Bile Pigments; Bilirubin and Biliverdin Dimethyl Esters and Related Linear Tetrapyrroles

**By Silvia E. Braslavsky, Alfred R. Holzwarth, and Kurt Schaffner***

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

Bilirubin and biliverdin dimethyl esters (BRE and BVE, respectively) and related linear tetrapyrroles have been studied using a combination of photochemical and spectroscopic techniques, the latter including absorption, fluorescence, fluorescence excitation, medium-induced circular dichroism, and proton magnetic resonance. Both types of tetrapyrroles form mixtures of different topological isomers in very dilute solutions. In the case of the bilirubins the heterogeneity of the solutions is caused by two coexisting conformers with different orientations of the A/B and C/D pyrromethenone moieties with respect to each other. The spectral properties of one conformer resemble the isolated parent pyrromethenone, whereas those of the other result from electronic coupling of the two subchromophores presumably held in a "ridge tile"-like orientation. C–C rotations at the C-5 and C-15 bridges substantially compete in both components with the photochemical channels ($E \rightarrow Z$ isomerization and lumirubin formation) for the radiationless deactivation of the excited singlet state. The more rigid "ridge tile" component additionally undergoes hydrogen bond-mediated deactivation, and it photoisomerizes more efficiently. The situation is markedly more complex with the biliverdins. In order to obtain a more detailed insight into the mechanisms of the radiationless excited-state processes, time-resolved optoacoustic spectroscopy and ultrafast absorption (pump-probe) and fluorescence detection (single-photon-timing) techniques were used to supplement the stationary methods. The solution mixtures are composed of a (family of) helically coiled all-*Z*,all-*syn* species, and of species differing from the former by stretched arrangements of the rings B and C around the central C-10 bridge (*E-anti, E-syn,* and *Z-anti*). Two excited singlet states with picosecond lifetimes are attributed to either one or two coiled ground-state forms, and two remarkably long-lived nanosecond excited states arise each from a stretched ground state. The radiationless deactivation of the shorter-lived of the picosecond states is brought about by ultrafast intramolecular proton transfer between the B/C nitrogen atoms, in addition to the C–C rotational modes operative in both. $Z \rightarrow E$ photoisomerization is also an appreciable deactivation channel of excited biliverdin dimethyl ester. It is confined to the central C-10 double bond and selectively affords a stretched isomer (10*E-anti*), which thermally reforms the coiled starting material at room temperature *via* a sequence of tautomerization and C–C rotation. Heating or ultrasonic treatment can reverse this sequence and drive it farther to populate another stretched isomer (10*E-syn*) which is thermally stable at room temperature. This stretched form aggregates (presumably to dimers) already at concentrations at which the coiled species still appears to be fully monomeric.

## 1. Introduction[**]



Linear, open-chain tetrapyrroles (cf. Scheme 1) are synthesized in nature from δ-aminolevulinic acid *via* the porphyrins which are oxidatively cleaved at either of two (α and γ) of the four methine linkages[1]. While in higher organisms iron has to be removed prior to the cleavage, the porphyrins of plants and lower algae are cleaved directly. Linear tetrapyrroles are found in nature as catabolic products (*e.g.*, the neurotoxic bilirubin in the bile fluid), as the chromophores of biliproteins performing important photobiological functions, and as pigments in lepidopters (*e.g.*, biliverdin IXγ = pterobilin).

The linear tetrapyrroles also attract attention for several other reasons. They are chromophores of remarkably high flexibility, and they may potentially adopt a large number of configurational, conformational, and tautomeric forms. Some interconversions of such forms can be expected to occur exclusively in the photoexcited state, in particular

the $E \rightleftharpoons Z$ isomerizations of the exocyclic double bonds. Others such as rotations around C–C single bonds are characteristic ground-state processes, and still others such as intramolecular transfers of protons or hydrogens are *a priori* possible in either state. In the fully conjugated BVE, furthermore, proton transfers between the two central rings B and C would merely lead to a temporary shift of the ground-state equilibrium between two very similar tautomers—a change in population of only two in a mixture of possibly several more components which would be very difficult to directly differentiate spectroscopically. Rather, demonstration of such a proton transfer possibly would remain restricted to experimental detection as a non-radiative deactivation channel.

In view of the structural features, which are of quite general interest, and the biological relevance of the linear tetrapyrroles, their photophysics and photochemistry have been widely studied in recent years[2]. For example, the $Z \rightarrow E$ photoisomerization of BR has been found to be the crucial step in the phototherapy used routinely in hospitals for treating the jaundice of the newly-born (neonatal hyperbilirubinemia)[3], and BVE has roused interest as a model chromophore for the photochromic plant chromoprotein phytochrome and for the light-harvesting (antennae) pigments of cyanobacteria, red algae, and cryptophyceae.

This article will focus on our investigations of recent years into the solution conformation, the photophysics and photochemistry of BRE, BVE and related compounds. At room temperature in liquid solution, fully conjugated linear tetrapyrroles such as BVE appear to be photochemically unreactive at first sight, and the luminescence[4–6] and intersystem crossing[5,7,8] quantum yields are very small. Radiationless deactivation processes ("energy wasting") must therefore be of particular importance in this type of molecules. It is appropriate at this juncture to recall that radiationless deactivation of an electronically excited molecule can occur by intersystem crossing, which is a transition between states of different spin multiplicities (*e.g.*, triplet excited to ground state), by internal conversion, which is a transition between states of the same spin multiplicity (*e.g.*, excited singlet to ground state), and/or by photochemical reaction. "Energy wasting" channels are pathways by which ground-state starting compounds are regenerated after photoexcitation. Photochemical reactions meet with this requirement only when the photoproduct is thermally labile and returns to the starting material. The problems posed in the investigation of such processes together with the finding that the linear compounds in solution quite generally exist as mixtures of several forms with different photophysical and photochemical properties, rendered the studies particularly challenging and exciting. The final goal of this investigation is the understanding of the factors controlling specific relaxation processes, *i.e.*, the routing of the excitation energy into radiative, radiationless, and photochemical channels.

## 2. The Rubins

### 2.1. Spectroscopy of Bilirubin Dimethyl Ester in Solution. Coexistence of Different Forms

A combination of absorption, luminescence, SICD and $^1$H-NMR studies has established that BRE can adopt various forms of aggregation and of monomeric species such as conformers and/or tautomers depending on concentration, solvent and temperature[9]. BR and its dianion appear to behave qualitatively in a similar way, as judged from their solvatochromic and thermochromic properties in absorption and fluorescence[9–12]. For dilute solutions of BRE (*ca.* $10^{-5}$ M) the situation is exemplified in Figures 1–3 which clearly indicate the presence of at least two species[9]. Either or both of these species may in fact represent groups, each of which is composed of several components similar in spectral and conformational respects. For the sake of simplicity we shall continue here, nevertheless, to use the expressions "two species" or "two forms".

The absorption bands of BRE in different solvents at room temperature exhibit quite different intensity ratios. For example, in ethanol there is a maximum at 448 nm with a shoulder at 408 nm, and in 2-methyltetrahydrofuran a maximum at 397 nm with a shoulder at 445 nm (Fig. 1B). However, the fluorescence spectra in these solvents at the same temperature are still very similar (Figs. 1A and 1B). The emission of one species—with $\lambda_{max}^{exc} = 450$ nm at room temperature and 481 nm at 77 K—strongly predominates in ethanol over the entire temperature range. While the other species—with $\lambda_{max}^{exc} = 395$ and 420 nm, respectively—is detected in ethanol only at 77 K as a very small fraction (Fig. 2), appreciable contributions of both species to the fluorescence are observed in ethyl lactate at room temperature (Fig. 1C and 1C′) and in 2-methyltetrahydrofuran at 77 K (Fig. 2)[9].

When evaluating the quantitative aspects of fluorescence, it is important to recall that *the ground-state fraction*

[*] Trivial names are used throughout this article. In accordance with the IUPAC nomenclature suggested for the bile pigments [*Pure Appl. Chem. 51* (1979) 2251] the Fischer IXα notation for the carbon skeletons of BR, BRE and BVE is omitted while the full Fischer nomenclature is retained for the constitutional isomers. Furthermore, all-*Z*,all-*syn* conformations are not specified. Only diastereoisomers with at least one *E* double bond and/or *anti* arrangement of the nitrogen atoms are designated as such.

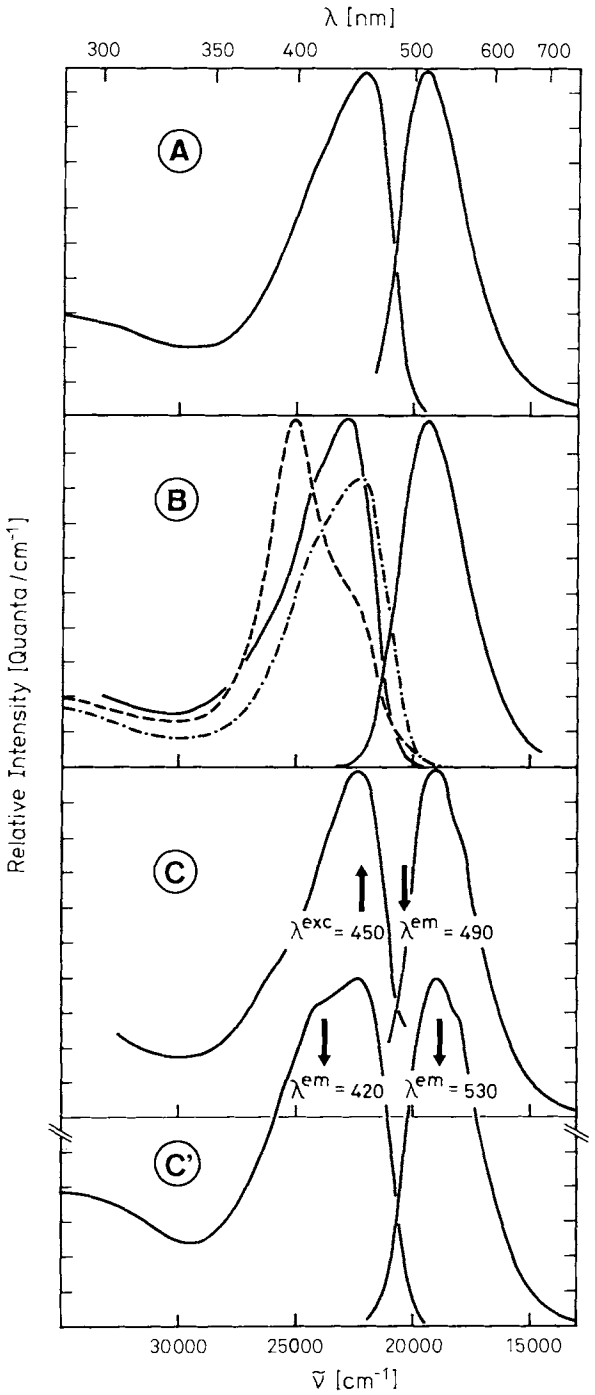

Fig. 1. Corrected room temperature fluorescence and fluorescence excitation spectra of BRE in ethanol (A), 2-methyltetrahydrofuran (B), and ethyl lactate (C and C). While in A and B the spectra are essentially independent of $\lambda^{exc}$ and $\lambda^{em}$, they clearly arise from different components of a mixture in C and C where $\lambda^{exc}$ and $\lambda^{em}$ were varied. The room temperature absorption spectra in ethanol (---) and in 2-methyltetrahydrofuran (----) are also given in B for comparison [9].

*of a fluorescing component in a mixture, i. e., the molar fraction $X_i$, is often difficult to determine.* Since the relative fluorescence intensity is proportional to the product of $X_i$ times individual fluorescence quantum yield, $\Phi_{f(i)}$, the comparison of the fluorescence bands therefore does not give a direct measure of $X_i$ unless $\Phi_{f(i)}$ is known as well. In investigations such as discussed here, however, the measurement of $\Phi_{f(i)}$ values is normally difficult if at all possible.

Fluorescence lifetime and SICD measurements in optically active solvents confirm the presence of two BRE species[9]. For example, in ethanol at 77 K fluorescence lifetimes of 1.9 ns for the predominant "450 nm" and 11.9 ns

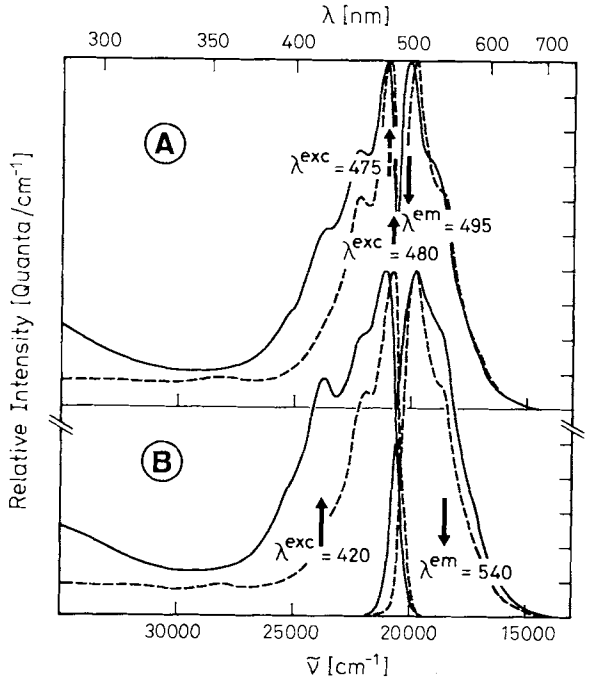

Fig. 2. Corrected 77 K fluorescence and fluorescence excitation spectra of BRE in ethanol (---) and in 2-methyltetrahydrofuran (—). A: $\lambda^{exc}$ = 475 (ethanol) and 480 nm (2-methyltetrahydrofuran), $\lambda^{em}$ = 495 nm (both solvents); B: $\lambda^{exc}$ = 420 nm, $\lambda^{em}$ = 540 nm (both solvents) [9].

for the minor "395 nm" component of the dual emission were obtained. The relative lifetimes are reversed at room temperature. Thus, from the room temperature data (Table 1) a *circa* tenfold lower fluorescence quantum yield, and hence a correspondingly shorter lifetime has been estimated for the minor species than was measured for the major component. The BR form which spectrally corresponds to the "450 nm" BRE species, was found to have a lifetime of about 20 ps in organic solvents at room temperature[13, 14]. Lifetimes in the nanosecond range, found for BR in various media and initially attributed to the *E,Z* photoisomers[15], now appear more likely to belong to secondary photoproducts such as lumirubin and isolumirubin (see Section 2.3 and Schemes 3 and 4). The *E,Z* isomers have much lower fluorescence quantum yields[14] and hence should possess correspondingly shorter lifetimes than BR.

In ethyl (*S*)-(−)-lactate and (*R,R*)-(−)-2,3-butanediol at room temperature, where the absorptions of BRE lie between the two extremes shown in Figure 1B, the SICD spectrum exhibits two bands of opposite signs in the Vis region (Figs. 3A and 3B). While the wavelength positions of the SICD maxima are almost independent of the solvent, their relative intensities and signs respond to solvent changes. The most simple explanation for this behavior is to attribute the two bands to different species. However, one cannot rule out the alternative that one of the BRE

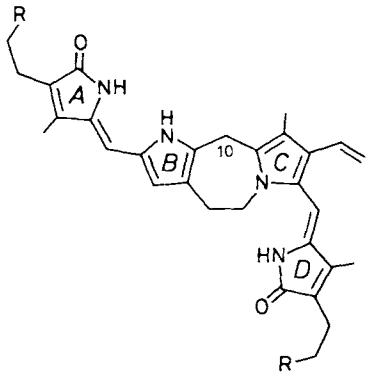
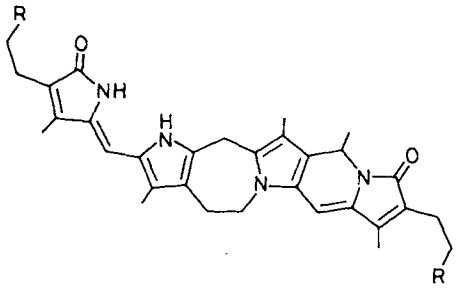
forms has an intrinsic bisignate Cotton effect[*] owing to exciton coupling, and that this spectrum is superimposed by an additional single CD band belonging to the second BRE form. The two Cotton effects of SA-bound BR, again of opposite signs, can be ascribed either to a bisignate effect due to exciton coupling as proposed previously[16], or to a conformational inhomogeneity of BR. The latter perhaps is complexed only with one half of the molecule so that much of it might still be able to adopt different conformations[11]. This last point, however, is still under debate[17]. The former alternative finds some support in the fact that the BR populations in solution and when bound to SA, as judged from the absorption spectra, appear to be more homogeneous than are those of BRE in various solvents[9].



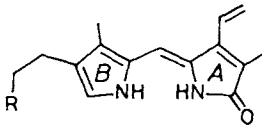
### 2.2. The Nature of the Coexisting Ground-State Forms. Phorcarubin and Isophorcarubin Dimethyl Esters

For an evaluation of the nature of the two prevailing forms of BRE in dilute solutions it is best to first consider analogous results obtained for PRE and IPRE (Scheme 2)[18]. Both isomers possess more rigid tetrapyrrole backbones than does the parent BRE. The fusion of the central rings B and C forces the two pyrromethenone partial structures into a stretched (though not necessarily planar) alignment with the nitrogens in an *anti* arrangement. While in PRE the pyrromethenones are still conformationally and configurationally flexible around the C-5–C-6 and C-14–C-15 bonds, the constraints are greater in IPRE, with one of the pyrromethenones (rings C/D) fixed by intramolecular cyclization in the *Z-anti* form. Coalescence of the C-10 methylene proton signals in the NMR spectra of PRE and IPRE at room temperature shows that the central seven-membered ring has retained some degree of conformational mobility in both compounds. In contrast, the fused tricyclic C/D chromophore of IPRE must be more rigid, and only the A/B part is as flexible as in BRE and the parent pyrromethenone 1.



This rigidity is reflected for IPRE, on the one hand, in some structure of the UV absorption even at ambient temperature, whereas the coexistence of several conformers of the more flexible bilirubins gives rise to broad and unstructured bands. On the other hand, it is even more clearly reflected in the fluorescence quantum yields of the rubins and of 1 in fluid solution (Table 1). IPRE exhibits by far the highest fluorescence efficiency of all. This can be attributed to the C/D chromophore and its lack of conformational mobility. Such mobility is known to provide an efficient mode for radiationless deactivation in other chromophoric systems[19] (see also the verdins, Section 3[4]).

The absorption, fluorescence and fluorescence excitation properties of both PRE and IPRE qualitatively resemble those of BRE. In each case, they again clearly arise



[*] An intrinsic bisignate Cotton effect is a couplet, *i.e.*, two close-lying Cotton effects with opposite signs. Such couplets are observed in the CD of coupled oscillators with sufficiently large electrical transition moments; cf. [82].

**PRE** Phorcarubin dimethyl ester

**IPRE** Isophorcarubin dimethyl ester

from at least two species, and the composition again strongly depends on concentration, solvent and temperature[9, 18]. The nature of the two forms prevailing at low concentrations has not yet been rigorously elucidated, but a conformational isomerism is the most likely. A lactam-lactim tautomerism, which has been ruled out for BRE[22, 23], seems less probable, and aggregation, preferred in apolar solvents at sufficiently high concentrations[23], had been excluded for the low-concentration experiments with BRE, PRE, and IPRE[9, 18]. In view of the similarity in fluorescence and fluorescence excitation it was suggested[18] that the origin of the spectral heterogeneity is also common to all three compounds. It is attributed to different relative orientations of the A/B and C/D subchromophores around the central C-10 methylene carbon which in PRE and IPRE is contained in the still flexible seven-membered ring (see above). The alternative would be that the different forms arise from different orientations of the individual rings with respect to each other, *i.e.*, within the A/B and C/D pyrromethenone moieties. This possibility is ruled out by the negligible contribution at room temperature of the non-cyclized pyrromethenone moiety to the total emission of IPRE. An important general conclusion then is that *the major contribution to the heterogeneity in fluorescence comes from the different orientations of the A/B and C/D pyrromethenone moieties with respect to each other.*

It is in accord with this conclusion that the spectral properties of the "395 nm" species of BRE, on the one hand, resemble those of the isolated parent chromophore **1**[24, 25]. A geometry with minimum electronic interaction between the two halves of the BRE molecule was consequently assigned to this species[25]. On the other hand, the spectrum of the "450 nm" form cannot be extrapolated straightforwardly from the spectra of the separate partial chromophores. Rather, it must arise from an electronic coupling of the two subchromophoric moieties of BRE, presumably owing to a particular geometric orientation. Analogous assignments can also be made for the two forms of BR.

Calculations on the BR-SA complex[16] using CD and the absorption data which essentially correspond to those of the "450 nm" species predicted a conformation similar to the "ridge tile" arrangement (Scheme 3) found subsequently for the BR crystal structure[26]. We shall see in Section 2.4 that this is also the most likely arrangement for the electronically coupled "450 nm" forms of BR and BRE in organic solvents.

Scheme 3. Intramolecularly hydrogen-bonded "ridge tile" conformation of BR in the crystal structure [26]. The "450 nm" forms of BR and BRE in organic solvents presumably possess a similar conformation.

### 2.3. The Photochemistry of Bilirubin and Bilirubin Dimethyl Ester

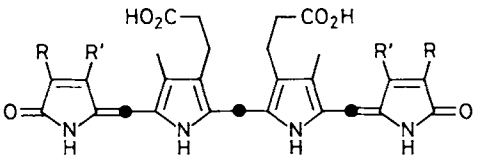
Under anaerobic conditions, two types of photoisomerizations have been encountered[20, 27-33]: A rapid configurational $Z \rightarrow E$ isomerization of either of the exocyclic C=C double bonds has been found with BR and BRE, as well as with similar tetrapyrroles and model compounds[34], and BR has also been shown to undergo a less efficient cyclization to form lumiproducts. Other photoreactions such as addition reactions, formation of positional isomers, and oxidative degradation of BR do not noticeably interfere with $Z \rightarrow E$ isomerization and lumiproduct formation, since

they proceed with quantum yields that are at most a tenth of that of the predominant isomerization near room temperature. The oxidation reactions, moreover, require aerated solutions[35].

Several studies show that the $Z \rightarrow E$ double bond photoisomerization occurs in the lowest excited singlet state of BR. The evidence can be summarized as follows:

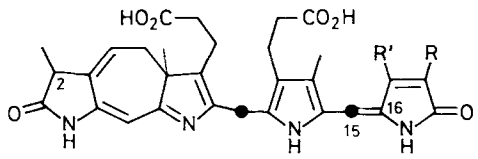
1) The quantum yields of fluorescence and $Z \rightarrow E$ isomerization of SA-bound BR exhibit a reciprocal relation as the temperature is varied. The fluorescence yield increases from about 0.0002 at room temperature to 0.44 at 77 K, while the isomerization yield drops from 0.20 to $\leq 0.01$[14].

2) The yield of triplet state BR near room temperature strongly varies with the nature of the solvent, but it consistently is lower than the isomerization yield[5,7,8]. The fluorescence yields under the same conditions are about ten times lower[5,14], indicating that electronic relaxation of excited singlet BR at this temperature proceeds predominantly *via* radiationless pathways other than intersystem crossing to the triplet state.



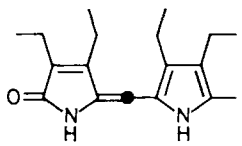
3) In organic and aqueous solvents, in vesicles and when bound to SA the $S_1$ state of BR with a lifetime in the range of 12—70 ps was observed at 295 K by fluorescence ($\lambda^{em} = 525$ nm)[13] and absorption detection[14]. Similar lifetimes were also obtained for BR-IIIα and the pyrromethenone **2** (Scheme 4)[13]. The assignment of the absorption decay to the $S_1$ state is confirmed for BR-SA by the parallel temperature dependence of this decay and of the fluorescence quantum yield[14].

The three configurational photoisomers of BR[31,32] and BRE[28,29,36] are unstable and revert to the (4*Z*,15*Z*)-isomer, both photochemically and thermally. Equation (a) summarizes these interconversions[31]:



$$4Z,15Z \rightleftharpoons (4E,15Z + 4Z,15E) \rightleftharpoons 4E,15E \qquad \text{(a)}$$

The anaerobic photochemical transformations of BR, both in solution and bound to human and rat SA, have been studied in some detail. The results did not differ qualitatively. While the symmetrical BR-IIIα rapidly reaches a photostationary equilibrium with its (*E*,*Z*) and (*E*,*E*) isomers[31], the $Z \rightarrow E$ isomerization of BR and BR-XIIIα is accompanied in each case by the slower photocyclization to the C(-2)-epimeric lumirubins LR and ILR[33] (Scheme 4). On further irradiation of the lumirubins an $E \rightleftharpoons Z$ equilibrium at the C-15=C-16 double bond is established without detectable reversion to the parent bilirubins. Since the lumirubin formation is not inhibited by molecular oxygen, it was suggested that the reaction occurs also from the excited singlet state. It appears, furthermore, that the cyclization is a single-photon process *not* requiring the (*E*,*Z*)-bilirubins as intermediates[33].



It is not surprising in the light of the heterogeneous composition of BRE solutions (Sections 2.1 and 2.2) that the anaerobic photochemistry proved dependent on the excitation wavelength[36]. The "395 nm" species has a lower quantum yield of photoisomerization than the "450 nm" conformer. Moreover, the distributions of the products formed, at very low conversions, from the two components and their reactivities in the secondary phototransformations are different. The results can be summarized by extending the reaction scheme (a) to (b) which represents a *minimum* scheme for the $E \rightleftharpoons Z$ isomerizations of the "395 nm" and "450 nm" solution forms of BRE. Additional transformations not included in this scheme (*e.g.*, conversions diagonally across the scheme (b) such as *Z,Z*-BRE′ $\rightleftharpoons$ *Z,E*-BRE″ *etc.*) are also conceivable provided that the preferences for the reaction pathways are maintained.

### 2.4. Radiationless Deactivation (Internal Conversion)

Rotation modes around the C—C and C=C bonds at C-5 and C-15 play a substantial role in the direct deactivation of the first singlet excited state of BR and BRE at room temperature. This conclusion is based on the overall quantum efficiency associated with the $Z \rightarrow E$ photoisomerization (*i.e.*, with the relaxation by $k_1$ and $k_2$ of the twisted excited singlet state, $^1S_1$, to both the *Z,Z* and *E,Z* isomers;

see Fig. 4), which is probably not much greater than 0.4 in solution (see below)[27,37,38], and the fact that an important part of the wasting channels for the remainder (almost 0.6, with emission being negligible) is turned into fluorescence upon lowering the temperature or upon embedding the molecule in a solid matrix at room temperature (Table 1). This points to substantial energy dissipation in fluid media at room temperature by rotations around C–C single bonds, which are strongly inhibited in solid matrices. The rotations are restricted to the C-5 and C-15 bridges, *i.e.*, to within the pyrromethenone subchromophores. The evidence has already been partially given in Sections 2.1 and 2.2. It comprises the behavior of the emission with temperature or viscosity, the comparison with PRE and IPRE, and the increase of fluorescence[39], singlet lifetime, and singlet yield[15] upon disruption of the intramolecular hydrogen bonds. Such bonds, between the carbomethoxy carbonyls and the pyrrole nitrogens similar to those found in the crystal structure of BR[26] (Scheme 3), are presumably attained also in organic solvents[12,40–42]. Results with SA-bound BR confirm this assignment. At room temperature, the fluorescence yield increases upon binding by a factor of about 25 over that in chloroform solution, while the photoisomerization remains essentially unaffected[14,28]. Although the fluorescence yield of the BR-SA system at room temperature reaches only about a fifth of the yield at 77 K in ethanol, the trends followed upon binding to SA and upon cooling are parallel. Moreover, the photoisomerization is obviously not subject to the same environmental control. An analogous situation is also indicated for the pyrromethenone **1**, the fluorescence of which increases by a similar margin upon binding to SA[17].

These considerations refer particularly to the electronically coupled "450 nm" species since it is the predominant form of BR and BRE under the conditions studied. The relative fluorescence quantum yields of the two BRE species (low for the "395 nm" and high for the "450 nm" form at room temperature) and their opposite trends with the lowering of temperature indicate that the latter is the more rigid one. The greater rigidity may derive, in BR, from a conformational fixation through intramolecular hydrogen bonds, *i.e.*, the "450 nm" form of BR may correspond to an arrangement as shown in Scheme 4. According to NMR measurements, the activation barrier associated with the unzipping of the six hydrogen bonds of BR is *ca.* 75 kJ/mol in chloroform[42]. The internal bonding restricts the rotational freedom of the molecule, and it slows down the excited-state twisting towards the $Z \rightarrow E$ photoisomerization[20,28], with a barrier of *ca.* 30 kJ/mol[43]. In SA-bound BR which lacks the hydrogen bridging between the two halves of the pigment, the barrier is lowered to 23 kJ/mol[20].

The "450 nm" species of BRE may well be subject to similar constraints, albeit less important since there are fewer hydrogen bonds involved in the diester. Thus, the overall rate of isomerization of BRE is faster than that of BR in the same solvent[28]. Reversible intramolecular proton transfer processes remain available for alternative channels of energy wasting. This deactivation mode should be less affected thermally and by viscosity than that induced by the C–C rotation modes, and it should thus assume a more important role at low temperature. The more flexible "395 nm" species presumably lacks similar intramolecular hydrogen bridges, and it consequently is more readily subjected to deactivation induced by rotations around C–C bonds and less so to hydrogen bond-mediated deactivation.

In conclusion we may extend somewhat the kinetic scheme of an earlier[14] diagram of the potential energy levels and deactivation routes of BR and BRE (Fig. 4). The sums of rotational and hydrogen bridge-mediated deactivation rate constants, $k_{d(1)}$ and $k_{d(2)}$, of the $S_1$ states of BR, BRE and the *E,Z* photoisomers are included as an important competition to fluorescence. In the BR-SA system the $Z \rightarrow E$ isomerization quantum yield and the proportion of the *E,Z* isomer in the photoequilibrium at room temperature are about equal (*ca.* 0.2) when excited at the isosbestic point of 465 nm[14,30]. In terms of the rate constants $k_{d(1,2)}$, $k_{I,II}$ and $k_{1,2}$ two limiting situations can be envisaged. On the one hand, it has been suggested[20] that the twisted singlet state, $^tS_1$, is formed with nearly total efficiency from both the *E,Z* and *Z,Z* $S_1$ states ($k_I/k_{II}$ at $\lambda^{irr} = 465$ nm). This assumption would result in a $k_1/k_2$ ratio of *ca.* 4 and would leave no room for direct radiationless deactivation to the ground state. It should be pointed out that the rate constants of all C–C and C=C rotational modes, $k_I$, $k_{II}$, $k_{d(1)}$, and $k_{d(2)}$ can be expected to be strongly viscosity and/or temperature dependent, for they involve large-amplitude intramolecular motions (cf. also Section 3). The *a priori* assumption in [20] that $k_d$ is *independent* of temperature and/or viscosity is lacking experimental verification. The reciprocal relation between the yields of fluorescence and photoisomerization are insufficient evidence for establishing constancy of $k_d$. Our arguments are further supported by the finding that in frozen matrix $Z \rightarrow E$ photoi-

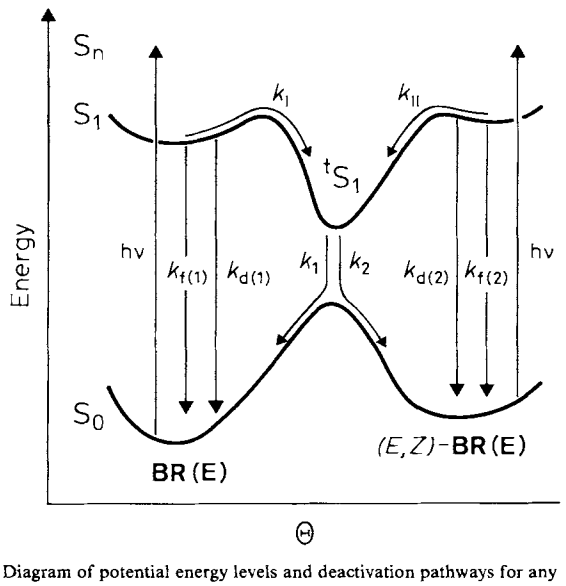

Fig. 4. Diagram of potential energy levels and deactivation pathways for any given conformer of BR and BRE and their *E,Z* photoisomers. $\Theta$ designates the twist angle about one of the exocyclic double bonds, $k_{d(1)}$ and $k_{d(2)}$ are the sums of the rate constants for deactivation by C–C rotation and hydrogen bridge-mediated processes, $k_{f(1)}$ and $k_{f(2)}$ are the rate constants for fluorescence, $k_I$ and $k_{II}$ for twisting around a double bond, and $k_1$ and $k_2$ for relaxation of the twisted excited state, $^tS_1$, to starting material and photoproduct, respectively. The activation energies required for $k_{d(1)}$ and $k_{d(2)}$ and the reaction paths for the cyclization to the LR's and ILR's, the mechanism of which is still under debate, are not depicted (cf. [14]).

somerization is negligible and yet the fluorescence quantum yield does not reach unity. We therefore prefer an alternative situation approaching the other extreme in which the ratio $k_I/k_2$ is close to 1. This implies that the efficiency of $^1S_1$ formation is considerably less than unity and different for the two $S_1$ states (*i.e.*, $k_I/k_{II}$ *ca.* 4:1 at $\lambda^{irr}=465$ nm). The remainder would thus be available for direct deactivation of the $S_1$ states *via* $k_{d(1)}$ and $k_{d(2)}$, respectively, as discussed above. The second model also fully accommodates the above-mentioned different responses of fluorescence and photoisomerization of BR upon complexation with SA.

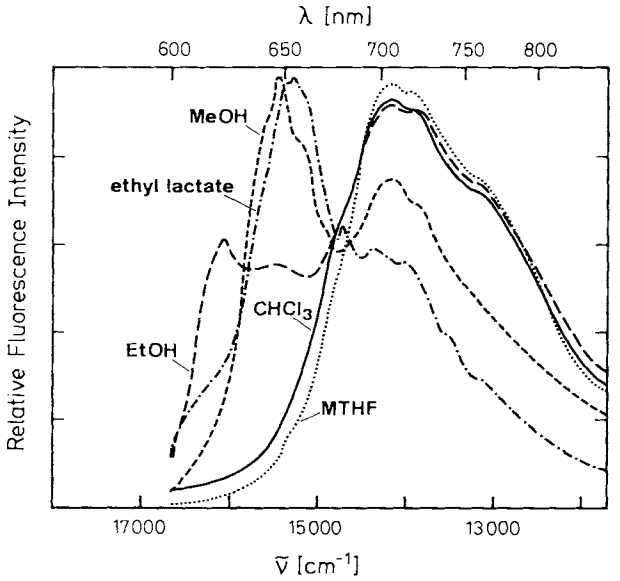
## 3. The Verdins

### 3.1. Spectroscopy of Biliverdin Dimethyl Ester in Solution. Coexistence of Helically Coiled and Stretched C-10 Isomers

A combination of stationary spectroscopic techniques similar to that used for BRE served also for the initial investigation of BVE. It was subsequently supplemented by time-resolved methods (LIOAS, PP, SPT) which afford a better insight into the relationship between structure and radiationless processes of individual species.

The solution spectra of BVE, at low concentrations, also exhibit distinct thermochromic and solvatochromic properties which again have been interpreted in terms of predominantly two forms coexisting in solution (as an illustration see Fig. 5)[4,44,45]. Aggregation at low concentrations (*e.g.*, $\leq 10^{-5}$ M in ethanol; for a discussion of aggregation see Section 3.5) and lactam-lactim tautomerism can be discarded[46]. The intensity ratio of the two first emission bands varies quite appreciably in the various solvents. In methanol and ethyl lactate the absolute maximum is at *ca.* 660 nm, and in ethanol, chloroform and 2-methyltetrahydrofuran at around 710 nm.

The "660 nm" form, with its relatively small values for the SICD Cotton effect, the Stokes shift and the $D_{UV}/D_{Vis}$ ratio in the fluorescence excitation spectrum has been assigned a stretched form[4,44,47]. Furthermore, the stretched partial structure can be localized around the C-10 bridge (Scheme 5)[47,48] (see Section 3.4 for the evidence). Although our term "form" may, as for the rubins, just as well cover members of families of closely related spatial arrangements rather than individual forms, the vibrationally



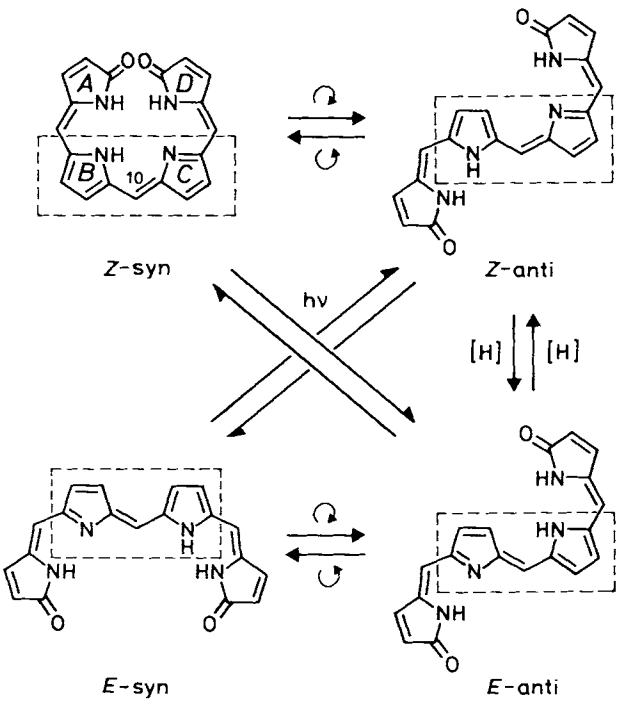


Fig. 5. Corrected fluorescence spectra of BVE in different solvents at room temperature; $\lambda^{exc}=580$ nm; concentration $1\times10^{-5}$ M [47]. MTHF = 2-methyltetrahydrofuran. Prior to the measurement, the solutions were subjected to a *short* ultrasonic treatment in order to ensure better reproducibility. There are slight quantitative differences in composition between the sonicated and the corresponding non-sonicated solutions (cf. Section 3.3).

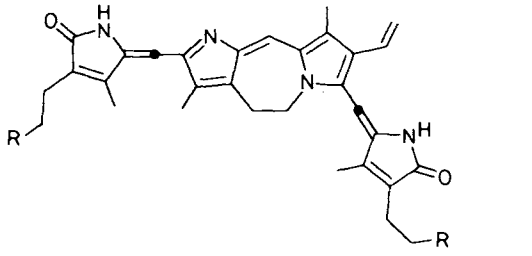
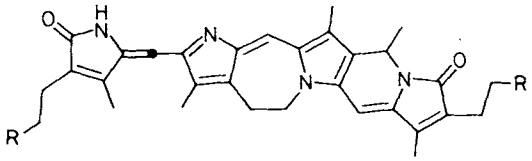
Scheme 5. The helically coiled all-*Z*,all-*syn* and the three stretched *E-anti*, *E-syn* and *Z-anti* forms of bilatriene with interconversion paths involving proton transfer processes (tautomerizations) between the B/C nitrogens ([H]) and rotation around the C-9–C-10 single bond (⌒) in the electronic ground state, and $E \rightleftharpoons Z$ isomerization of the C-10=C-11 double bond in the excited state (*hν*). Given the unsymmetric IXα substitution pattern of BVE, the overall number of these forms doubles to eight [*] (cf. Scheme 9).



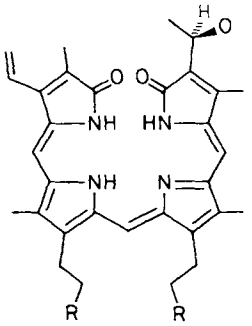
[*] In order to simplify the nomenclature in this article, we shall use generally applicable terms such as "form" and "species" in the discussion of the possible spatial arrangements of BVE, in lieu of "conformation" as a general topological definition or "conformation" and "configuration" as energetically distinguished terms for rotational isomerism. Scheme 5 lists the forms of the constitutionally symmetrical bilatriene, which are still possible after motions within the A/B and C/D halves of the molecule have been excluded. A justification of this restriction in the context of this article is given in Section 3.4. The diverse forms, which equilibrate only slowly at room temperature, can be divided into two categories: the *Z-syn* form on the one hand, and the three stretched forms *E-anti*, *E-syn* and *Z-anti* on the other hand. These species form two pairs of configurational isomers (*E-anti*/*Z-syn* and *E-syn*/*Z-anti*), the components of which are formally interconvertible. Such interconversions can be effected in both a one-step $E\rightarrow Z$ isomerization of the C-10=C-11 double bond and in two steps comprising a rotation around the C-9–C-10 single bond and a proton transfer between the B and C nitrogen atoms. The two-step transformation proceeds, in each case, *via* the *anti* component of the alternate pair (cf. Scheme 5). When the unsymmetrical IXα substitution of rings A and D is introduced, each of the forms of Scheme 5 is supplemented by a further constitutional isomer (tautomer) as shown in Scheme 9.

structured narrow bands of the "660 nm" species (cf. Figs. 5 and 10C) point to a well defined unique species.



The "710 nm" form, with a longer-wavelength emission, a broader first excitation band, and larger values for rotational strength, Stokes shift and $D_{UV}/D_{Vis}$ ratio, was identified as a helically coiled all-*syn*-type orientation similar to the conformation found in the crystal lattice[49]. This form is quite generally the more abundant in organic solvents[44,45,50]. A thermal barrier of 42 kJ/mol was measured, in a $^1$H-NMR kinetic study of the centrochiral methanol adduct **3** (Scheme 6)[51], for the interconversion of the two diastereoisomeric bilatriene all-*syn* helices.

The conformational assignment is based on a detailed $^1$H-NMR study of the all-*syn* form in chloroform solution[45], and it is in accord with the prediction of semiempirical calculations that the ratio $D_{UV}/D_{Vis}$ of the two main absorption bands of the verdins is a function of molecular extension. A decrease of this ratio indicates a change from a helically coiled to a more stretched form[16,52-57]. This trend analysis is supported by the fact that the conformationally rigid stretched verdins BVE-IXδ (Scheme 8), PBE and IPBE (Scheme 6)[58-60] have a very much smaller UV absorption band than BVE.



SICD measurements in optically active solvents corroborate the conclusions drawn from the emission results. Structurally related compounds such as tetraphenylporphyrin, protoporphyrin, and dipyrromethenes do not exhibit any such SICD. The observed effects therefore reflect mainly an inherent chiral property of BVE. At room temperature, the positions of the two main absorption bands, and particularly the position of the Vis maximum, are solvent-dependent, whereas the SICD bands invariably appear at the same wavelength. They either coincide with the absorption, which is an envelope of the individual absorptions of the various forms, or they are red-shifted (Fig. 6A). Such red shifts are due to the fact that the most abundant species in most solvents is the coiled form which absorbs at the longer wavelengths. These findings confirm the

coexistence of at least two forms. Their relative populations vary with the nature of the solvent, and they differ in their contributions to rotational strength, absorption, and fluorescence. The SICD spectrum of BVE-H$^+$, which exhibits the same general spectroscopic characteristics as BVE (Table 1), reveals even more clearly the composite nature of the solution. Only one component of BVE-H$^+$ similar to the "660 nm" species of BVE is seen by fluorescence at

room temperature in ethyl lactate. Nevertheless, the visible SICD is shifted to longer wavelengths relative to the corresponding absorption (Fig. 6B), and the rotational strengths of both bands are markedly lower than those of BVE. Furthermore, the visible SICD shows two Cotton effects of opposite signs. The interpretation necessarily is as ambiguous as it is in the case of BR (Section 2.1). Rather than attributing the phenomenon to exciton splitting alone, we prefer again to attribute it to a composed SICD split either into two single-band components of opposite signs or into one single-band component superimposed onto another one which is bisignate. The shorter-wavelength component is assigned to the predominant stretched species possessing an intrinsically small rotational strength. The red-shifted SICD component then is of the coiled form with an intrinsically larger rotational strength which is present in too small an amount for absorption and fluorescence detection.

### 3.2. Picosecond Kinetics of Excited State Relaxation in Biliverdin Dimethyl Ester

The study of detailed aspects of the radiationless relaxation processes by fluorescence quantum yield determinations and LIOAS (see below) has been particularly impaired by the considerable overlap of the absorption and fluorescence spectra of the individual BVE forms. These difficulties have recently been overcome by an investigation[47] which combined picosecond absorption and fluorescence detection using the PP and SPT techniques, respectively, and a synchronously pumped mode-locked dye laser system[61]. It proved much superior to previous single-shot picosecond measurements of etiobiliverdin with transient absorption and fluorescence detection[62]. The results obtained are supplementary to the data obtained by the stationary (absorption, fluorescence, SICD) and limited-time resolution methods (LIOAS) which have previously led to the postulate of the coexistence of two (families of) BVE ground-state forms in solution.

In general, a greater number of decay components could be found by the SPT technique (Table 2, Fig. 7 and Fig. 8) than by transient absorption spectroscopy (PP, Table 3). This is due to the considerably larger dynamic range covered by the former (>3 orders of magnitude) than by the latter (*ca.* 1—2 orders of magnitudes). Apart from this, the results obtained by the two techniques are in excellent agreement. They show that, in fact, the situation is even more complex for dissolved BVE than previously recognized. *Up to four fluorescing species, two short-lived (picosecond range) and two long-lived ones (nanosecond range), are detected (Tables 2 and 3). These four excited states can be attributed to either three or four ground-state species.*

The nanosecond decay components $\tau_3$ and $\tau_4$ originate from the stretched "660 nm" form(s). Lifetimes in the nanosecond range are remarkably long for BVE in liquid solution. In accordance with the narrow fluorescence and excitation bands, their partially resolved vibrational structure, and the small Stokes shift these long lifetimes indicate that the species should possess a relatively rigid and uniform conformation and a high fluorescence quantum

Fig. 7. [a] Concentration $1 \times 10^{-5}$ M in all measurements; MTHF, 2-methyltetrahydrofuran. [b] The $\tau$ values correspond to the $T$ values given in the insets of Figs. 7 and 8. The ordering $\tau_1 \ldots \tau_n$ (increasing lifetimes) does not correspond to the ordering $T_1 \ldots T_n$. Errors in lifetimes are ±10% or ±5 ps, whichever is larger, except for the single-exponential analysis in which the error is ±1%. For components with a relative yield of less than 5% the errors in lifetime may be up to ±20%. [c] See Fig. 7A. [d] See Fig. 7B. [e] See Fig. 8A. [f] See Fig. 8B.

yield. The long lifetime and the high fluorescence yield are best compatible with an arrangement of rings B and C which prevents rapid deactivation by intramolecular proton transfer between the central nitrogen atoms. While any other than the *Z-syn* form would satisfy this condition alone (cf. Scheme 5), the rigidity appears feasible only by intramolecular hydrogen bonding in a fashion similar to the "ridge tile"-type stabilization (Scheme 3) of BRE, which requires an *anti* arrangement of the B/C nitrogen atoms. As will be shown in Section 3.4, this conclusion is strongly and independently supported by the photochemical results with BVE-IXγ and -IXδ[48].

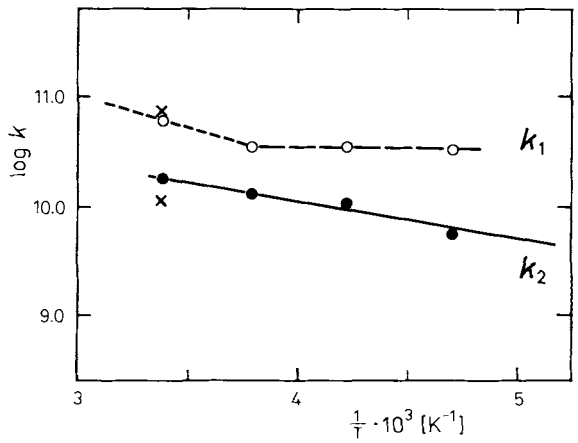
[a] Concentration $3\text{-}7 \times 10^{-4}$ M in all measurements; MTHF, 2-methyltetrahydrofuran. [b] Maximum errors ± 10%. [c] Cf. data point x in Fig. 9. [d] This lifetime possibly represents an average value of two components. [e] Lower limit to the actual lifetime of a nanosecond component. [f] $\tau_2/\tau_3$.

The spectral properties of stretched BVE are quite reminiscent of those of native phytochrome and phycobiliproteins, especially the phycocyanines. The chromophores of these proteins have also been assigned stretched conformations[2a] in analogy to previous conclusions about BVE[44] and to the absorptions of PBE and IPBE[63]. Inasmuch as analogies between the biliprotein chromophores and BVE are valid, it is of a general photobiological interest to note that BVE can adopt an *inherently rigid* stretched conformation even at room temperature in solution. Intramolecular stabilizing forces evidently suffice. Stabilizing interaction with the protein is, therefore, not necessarily an *a priori* condition for the conformational rigidity of BVE-like tetrapyrroles in biliproteins, in contrast to the generally accepted previous view.

The picosecond decay components are related to the coiled "710 nm" species. The different responses of their decay rates to temperature (Fig. 9) indicates that two mechanisms are responsible for the ultrarapid radiationless deactivation. Relaxation induced by rotation around the single bonds of the methine bridges is presumed to be common to both components. Intramolecular proton transfer, most probably between the central B and C nitrogen atoms as predicted also for *Z-syn*-dipyrroles[64], contributes additionally to the deactivation of the faster ($\tau_1$) of the two decay components. Thus, the relaxation data of the shorter-lived picosecond species are independent of temperature below *ca.* 260 K in $EtO^2H$. The $\log k_1$ *vs.* $1/T$ function consequently is a sum of temperature-dependent and -independent processes, *i.e.*, rotations around C–C bonds and proton transfer, respectively. The latter (long dashes in Fig. 9) brings about radiationless deactivation at a rate of $3.5 \times 10^{10}\ s^{-1}$, and it parallels the temperature-(or rather, viscosity-)dependent relaxation induced by C–C rotations (short dashes). The activation energy for the rotations is in the range of the solvent viscosity activation energy, with an estimated lower limit of *ca.* 12 kJ/mol.



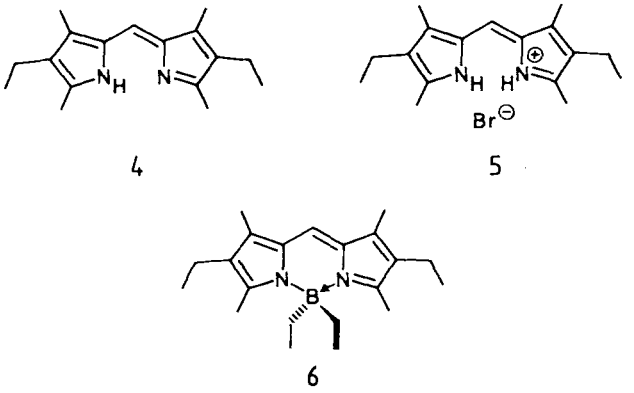


Fig. 9. Temperature dependence of the picosecond decay rate constants $k_1$ and $k_2$ of the BVE transients $\tau_1$ and $\tau_2$, respectively, in $EtO^2H$, determined by the PP technique; $\lambda^d$ = 643 nm. ○: short-lived component $\tau_1$; ●: long-lived component $\tau_2$; ×: room temperature data in EtOH (see Table 3). The short dashes denominate the temperature-(viscosity-)dependent part of the decay of $\tau_1$, and the longer dashes denominate the temperature-independent proton transfer in the $\tau_1$ component [47].

The temperature dependence of the longer-lived component, $\tau_2$, can be smoothly fitted to a straight line (cf. $k_2$ in Fig. 9). Ultrafast intramolecular proton transfer plays no role in the relaxation of this state, and the small activation energy of about 6 kJ/mol must solely be due to intramolecular barriers to other relaxation modes through, *e.g.*, C–C rotation.

Scheme 7. Models used as reference compounds in the evaluation of the deactivation modes induced by C–C rotations and intramolecular proton transfer.

The comparison of the fluorescence quantum yields of BVE at 77 K and room temperature with those of ZnBVE, BVE-$H^+$ and compounds **4**–**6** (Scheme 7 and Table 1) suggests that intramolecular proton transfer between the nitrogens (of rings B and C in the verdins) and C–C rotations are important in inducing the radiationless deactivation of BVE. An appreciable N–H/$^2$H isotope effect on the fluorescence yield was therefore expected. However, no such effect, even at 77 K[4], could be observed in EtOH/EtO$^2$H. The model of picosecond relaxation mechanisms now also offers a rationale for the failure of these attempts. At room temperature the radiationless decay rate of the $\tau_1$ component, and thus also its fluorescence yield, is still largely determined by the conformational relaxation rather than by the proton transfer. At very low temperatures the increase in the overall fluorescence yield may be mostly due to an increase in fluorescence yield of the longer-lived components ($\tau_2 - \tau_4$) which are not affected by the proton transfer. This argument presumes that the unproportionally large increase in fluorescence yield overrides the partial loss of stretched species incurring upon cooling. Therefore, the contribution of the proton transfer to the fluorescence yield is relatively small at the two temperature extremes, evidently ranging within the experimental error of the continuous excitation method.

Our results clearly show that in solution, depending on the conditions, at least three species of BVE can occur in the electronic ground state. They include two stretched forms with long-lived $S_1$ states ($\tau_3$, $\tau_4$). The results give no straightforward indication, however, as to whether the two picosecond decays ($\tau_1$, $\tau_2$) are related to only one or to several ground state species. From a conformational viewpoint the first possibility appears more plausible. However, one may expect anyway, in accordance with Ramachandran[56,65], force field[66] and MO calculations[53,55-57], the potential energy minima to be quite flat and the separating activation barriers small in comparison with the thermal energy.

The fluorescence lifetimes now provide also a rough estimate of the relative fluorescence quantum yields of coiled and stretched BVE in solution. The absorption coefficient of the long-wavelength band, which was excited in the lifetime determinations, is only about four times larger for the stretched than for the coiled form. The fluorescence yield is consequently about two orders of magnitude larger for the former.

### 3.3. The Thermal Interconversion of the Helically Coiled and Stretched Forms of Biliverdin Dimethyl Ester. Influence of the Medium

The differences between the static spectra of the two forms of BVE are best illustrated by the observations—using fluorescence, fluorescence excitation, and SICD in optically active membranes—upon the incorporation of BVE into the lipophilic part of the bilayer of liposome membranes[67].

When the incubation of intact liposomes with BVE is carried out at room temperature without ultrasonic or thermal perturbation, the fluorescence of the helically coiled form initially predominates in all cases. It persists in the gel-type liposomes, *e.g.*, in DPL membranes, the phase transition of which is above room temperature (315 K; Fig. 10A). It changes, however, to the emission of the stretched species on standing when incorporated in more fluid liquid-crystalline liposomes (*e.g.*, in EYL which has a phase transition temperature of 268 K). The same irreversible change can also be effected by heating the BVE-DPL liposomes to a temperature above the phase transition, and by sonication of the BVE-containing liposomes (Fig. 10B). Stretched species consequently are the only form(s) demonstrable by fluorescence in liposomes which have been prepared by cosonication of BVE and lipid (Fig. 10C). These findings show that the population of stretched species of BVE is favored in the membranes and that, however, a minimum fluidity of the local environment is prerequisite for spontaneous stretching in the membranes.

Again, SICD measurements—in the optically active EYL membrane—confirm the emission-based conclusions about the BVE forms in liposomes. The development of the CD band at 650 nm with time—its increase in intensity during the first phase after incubation, followed by gradual disappearance—and its dependence on the method of incorporation parallel those of the emission.

The stretching of coiled BVE in the liquid-crystalline membranes is facilitated by the ordered medium as long as it is not too rigid. A similar *stretching in solution at room temperature occurs only very slowly*[48,68]. Dimethyl sulfoxide, even in catalytic amounts, provides for the lowest activation energy observed so far. In other solvents stretching requires activation energies in the order of about 20 kJ/mol, which is in the range of solvent viscosity activation. It can only be effected upon sonication or heating of such solutions, up to a limit which is determined by the

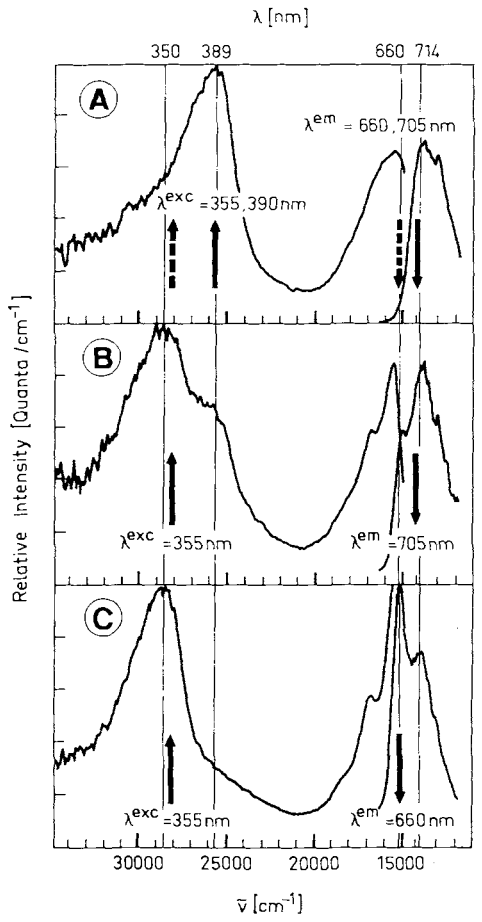

Fig. 10. Corrected fluorescence and fluorescence excitation spectra of BVE-DPL liposomes at 298 K, Ⓐ from a sample prepared by incubation of preformed DPL liposomes with BVE, Ⓑ after subsequent *short* sonication, and Ⓒ from liposomes prepared by cosonication of BVE and DPL. The spectra Ⓐ, which were wavelength independent in emission and excitation, are those of the coiled "710 nm" species, Ⓑ shows the grow-in of the stretched "660 nm" form on ultrasonic perturbation, and Ⓒ exhibits the "660 nm" spectra essentially uncontaminated with the "710 nm" species. Note that $\lambda^{em}$ of the "710 nm" species is shifted in DPL to *ca.* 730 nm [67].

maximum temperature reached, the rate of cooling, and the solvent nature. The largest populations of the stretched form have been obtained so far in dimethyl sulfoxide, somewhat smaller ones in protic solvents (alcohols), and the smallest in aromatic hydrocarbons[68]. It is interesting to note that, by comparison, the barrier between the two conformers of BRE (the "395 nm" and "450 nm" forms; Section 2) must be substantially lower.

The results of fluorescence and LIOAS during the first hours after incubation of the liposomes with BVE afford some insight into the process of incorporation into the membranes and the nonradiative energy dissipation of BVE in these media[67]. The fluorescence quantum yields of coiled and stretched BVE in the EYL and DPL liposomes are all similar and about 5—8 times higher than $\Phi_f$ of stretched BVE in ethanol at room temperature (Table 1). This increase evidently reflects the greater constraints exerted by the more rigid membranes on the vibrational and rotational degrees of freedom, *i.e.*, the overall rate of radiationless relaxation processes of incorporated BVE is reduced. One may therefore expect a concomitant decrease of the LIOAS signal which is a measure of all nonradiative nonphotochemical decay modes[69]. In the case of BVE-DPL such a decrease is indeed observed. It is 2/3 or less of the minimum "prompt" heat dissipation yield $\alpha$ (which is defined as the fraction of absorbed energy converted into the acoustic wave)[70, 71] measured for BVE in ethanol (Fig. 13)[67, 71].

The LIOAS study of the incorporation of BVE into liposome membranes revealed also a facet of a more direct photochemical interest[67]. In the case of DPL the LIOAS intensity decreased during the first 20 hours after incubation (Fig. 11B), finally reaching *ca.* 30% of the initial value. One should have anticipated, *a priori*, a correspondingly large increase in fluorescence yield. However, a mere 5—20% increase is observed (Fig. 11A). Moreover, the time scales of the two observations are different, with only two hours to reach a constant $\Phi_f$ value. The portion of decrease in LIOAS, which correlates with the increase in $\Phi_f$, is obviously overridden by a similar but much larger effect. The origin for this large LIOAS deficit is likely to be photochemistry. Since no permanent photochemical change is observed in BVE-DPL, such a photoreaction of BVE must

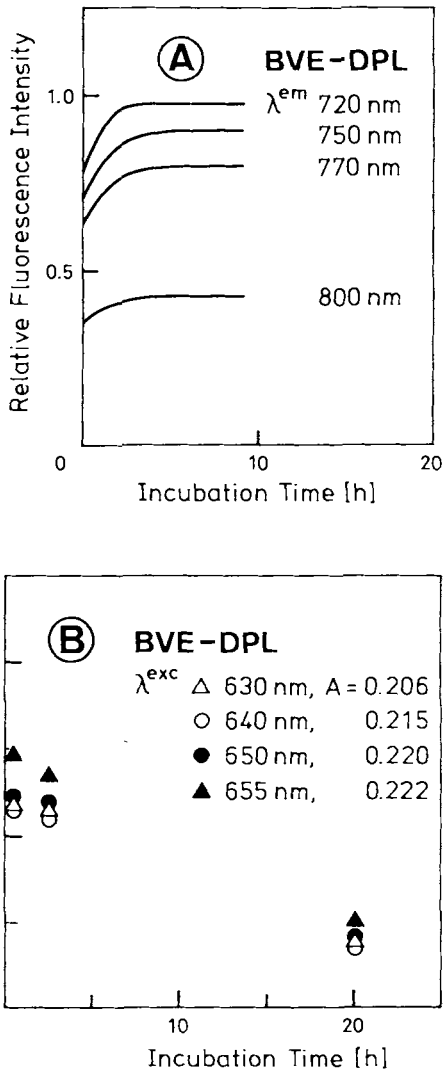

Fig. 11. Incubation of preformed DPL liposomes with BVE: Ⓐ Increase of fluorescence intensity at several emission wavelengths, and Ⓑ decrease of the LIOAS signal intensity (measured 9 μs after the laser pulse) at several excitation wavelengths, both as a function of the time elapsed after incubation [67b].

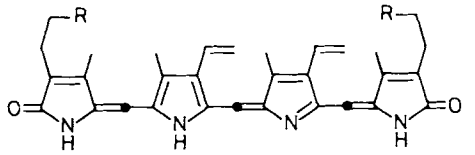
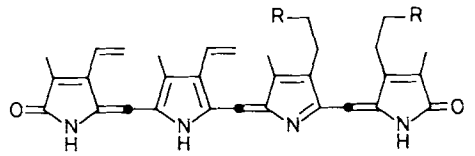
revert thermally on a time scale too long ($>1$ μs) to be registered by LIOAS. The lower limit for the lifetime of the photoproduct is given by the time required for generating the acoustic wave.



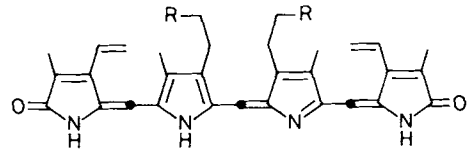
The fluorescence increase after the incubation of the EYL liposomes with BVE is of similar magnitude as that observed for DPL (Table 1), but the LIOAS intensity does not change significantly in this instance. A photochemical $Z \rightarrow E$ isomerization and thermal reversion—although not directly in evidence—is again consistent with these observations. They would require that in the "soft" EYL membranes the thermal reversion of the photoproduct is faster ($<1$ μs) than in the more rigid DPL liposomes, which is plausible.

One of the possible ways to visualize the events upon the incubation of liposomes with BVE is now as follows. When added in a concentrated tetrahydrofuran solution to the aqueous liposome dispersion, the BVE is deposited on the membrane surface in an aggregated form (cf. Section 3.5). In the process of intrusion into the membrane the aggregates will split into the monomers, which then are finally found as the preferentially coiled or stretched species depending on the lipid viscosity. The concomitant increase in fluorescence intensity possibly reflects a somewhat less efficient radiationless deactivation of the monomers, unless it is not simply a concentration effect caused by the deposition of aggregates on the membrane surface. In any event, the monomers undergo the—thermally reversible—photoisomerization significantly more efficiently as indicated by the increase in LIOAS deficit.



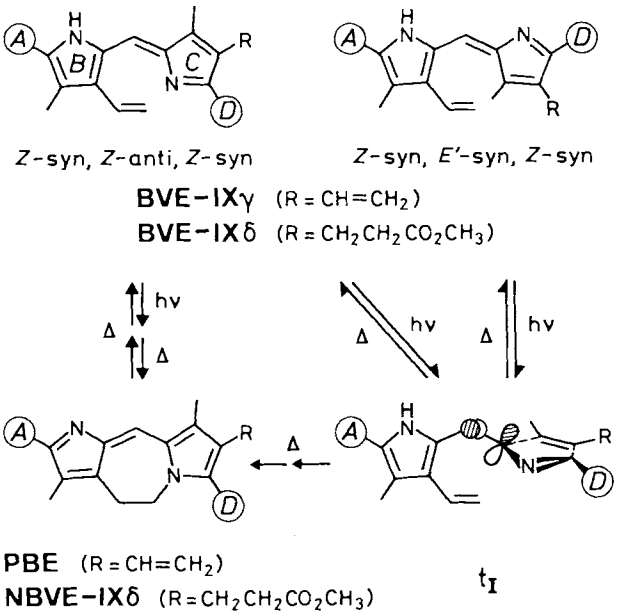
### 3.4. The Photochemistry of Biliverdin Dimethyl Ester. The Conformation-Selective Photocyclization of the Biliverdin IXγ and IXδ Dimethyl Esters

Inspection of molecular models suggests that the coiled all-*Z*,all-*syn* BVE molecule can be transformed into many different stretched forms by rotations around any of the C-5, C-10 and/or C-15 single and double bonds. No specific differentiation in regard of this multiple choice of stretched forms has yet been made in the preceding Sections, except for Scheme 5 and the footnote on p. 663 where it was assumed that the difference between the coiled and stretched forms is exclusively localized within the ring B/C partial structure, *i.e.*, that rotations are limited to the bonds of the central bridge C-10. In the following, arguments supporting this assignment shall be derived from the photochemical results obtained with BVE and its XIIIα, IXγ, and IXδ isomers (Scheme 8).



Since the constitutional isomers BVE, BVE-IXγ, BVE-IXδ and BVE-XIIIα exhibit generally similar spectral properties, it is reasonable to assume that their electronic ground and excited states are also similar rather than being drastically affected by the different substitution patterns. Furthermore, the individual sets of dual fluorescence and fluorescence excitation spectra indicate that the solutions of all these biliverdins are heterogeneous and have similar compositions, with the coiled all-*Z*,all-*syn* forms emitting at the longer wavelengths and the stretched forms emitting at the shorter wavelengths. The spectral similarity suggests,

**BVE-IXγ** Biliverdin IXγ dimethyl ester



**BVE-IXδ** Biliverdin IXδ dimethyl ester

**BVE-XIIIα** Biliverdin XIIIα dimethyl ester

$R = CO_2CH_3$

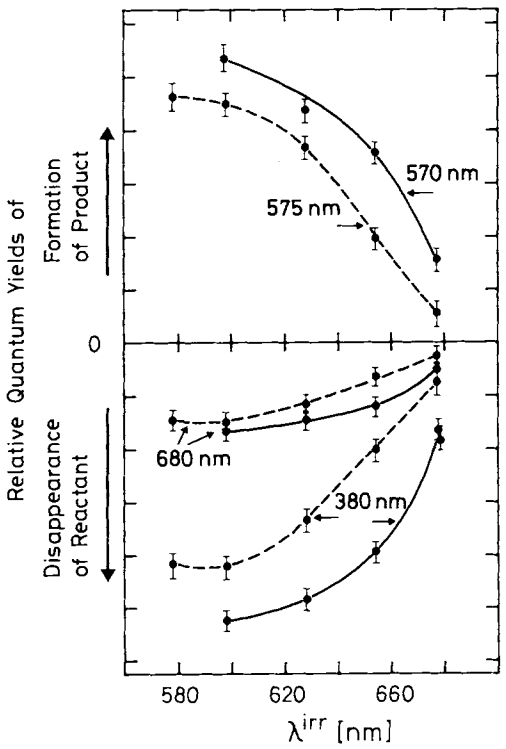
Scheme 8. Constitutional formulas of BVE-IXγ, BVE-IXδ, and BVE-XIIIα.

Scheme 9. Possible primary steps of the photocyclization of stretched forms of BVE-IXγ and BVE-IXδ to PBE and NBVE-IXδ, respectively. Ⓐ and Ⓓ stand for the correspondingly IXγ- and IXδ-substituted partial structures. For the *E'-syn* notation cf. Scheme 10.

moreover, that the stretched forms have similar arrangements around all three methine bridges.

BVE-IXγ and BVE-IXδ cyclize thermally and photochemically to PBE and NBVE-IXδ, respectively (Scheme 9)[58,60]. An analogous ring closure across one of the lateral

bridges (C-5 and C-15) is not observed, neither in BVE-IXγ and BVE-IXδ as an alternative to the closure in the central part, nor in BVE and BVE-XIIIα which have one and two vinyl groups, respectively, exclusively adjacent to lateral bridges. One may expect on the basis of structural and mechanistic considerations that the cyclization can occur in several possible ways, which all should exhibit a distinct selectivity for the stretched conformation of the starting material. For example, the ring closure may be effected directly from the twisted excited state intermediate, $^t$I, of the photochemical interconversion of the *E'-syn* and *Z-anti* isomers (cf. Scheme 10), in competition to relaxation to either (Scheme 9). Excited state processes other than twisting, *e.g.*, a direct electrocyclic ring closure, may also be visualized as responsible for the primary photochemical step. In either case the formation of the final product will require some sort of a hydrogen relocation subsequent to the cyclization. A stretched conformation is prerequisite for any of these or alternative primary reactions to occur in BVE-IXγ and BVE-IXδ. And indeed, a marked dependence of the quantum yields of the photoreaction on the irradiation wavelength strongly suggests a distinct selectivity favoring reaction in one particular conformation[48]. Thus, the highest quantum yields are achieved with irradiation wavelengths in the region of 575–600 nm where absorption by the stretched forms is relatively important. Above this range, where the relative importance of the absorption by the coiled form increases, the reaction efficiency declines sharply (Fig. 12).



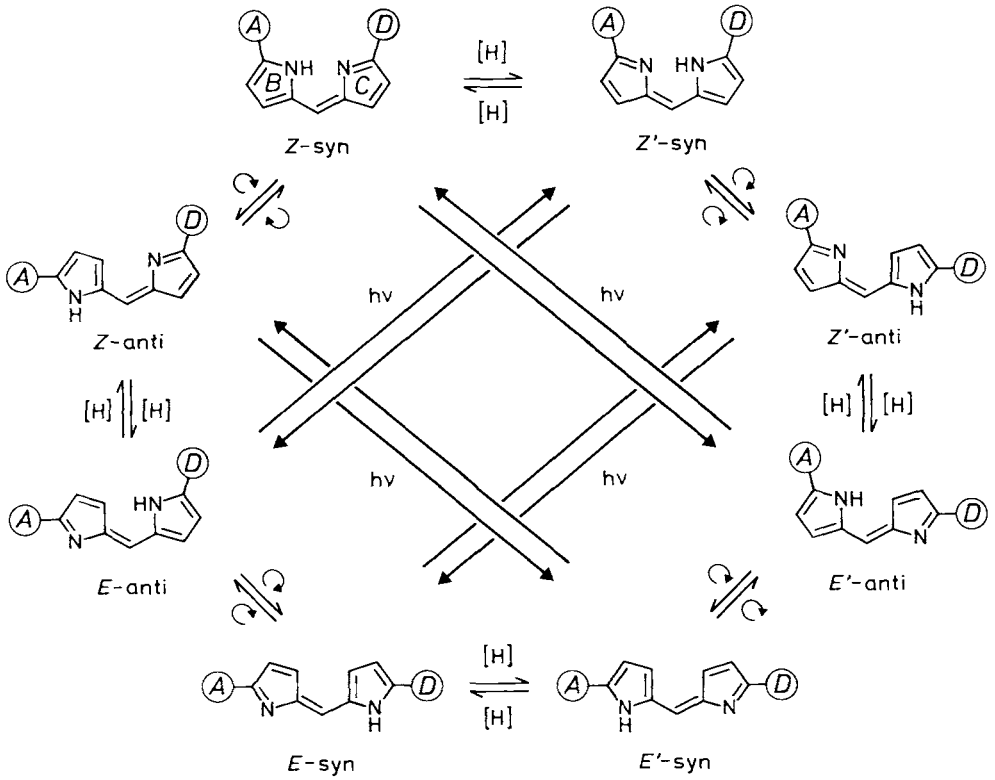


Fig. 12. Relative quantum yields, plotted as a function of irradiation wavelength, of the disappearance of BVE-IXγ (—) and BVE-IXδ (---) (bottom), and of the cyclization to PBE (—) and NBVE-IXδ (---) (top), respectively. For each transformation, the measurements were carried out at the wavelengths of the three extrema in the difference spectrum obtained upon irradiation in dimethyl sulfoxide. The initial concentrations of BVE-IXγ and BVE-IXδ were in the order of $10^{-5}$ M [48].

For a better understanding of the above arguments based on the absorption properties of the diverse species, we should reiterate that the Stokes shifts are large for the coiled and small for the stretched forms. This means that the absorption of the stretched form is relatively narrow (560–660 nm in ethanol) and superimposed onto the short-wavelength flank of the much broader absorption band of the coiled species. In fact, the absorption of the coiled species is adequately represented by the normal absorption spectrum, since this species is the more abundant in most solvents, apparently independent of concentration (see Section 3.5). The absorption of the stretched species is only accessible in the excitation spectrum of the short-wavelength fluorescence.

The photochemical results obtained with the four isomers can be rationalized comprehensively when it is assumed that in each case *the stretching of the coiled form is confined to thermal and photochemical transformations within the B/C moiety, while the Z-syn geometry of the A/B and C/D partial structures is retained as shown in Scheme 5.* An inspection of the eight possible C(10)-isomeric forms of an unsymmetrically substituted biliverdin reveals that one can discern three topologically different groups, comprising: 1) two coiled $Z^{(\prime)}$-*syn* forms, 2) two stretched $E^{(\prime)}$-*syn* forms, and 3) four stretched *anti* forms (Scheme 10). The coiled ($Z^{(\prime)}$-*syn*) and the stretched $E^{(\prime)}$-*anti* forms selectively interconvert by direct $E \rightleftharpoons Z$ photoisomerization, whereas the four other stretched isomers cannot directly photoisomerize to the coiled forms, and vice versa.

Irradiation of BVE in ethanol at 173 K ($\lambda^{irr} = 560$ and 700 nm) affords a photostationary equilibrium in which the composition is shifted towards a larger population of stretched forms[44]. The initial ground state-controlled composition is reestablished when the irradiated solution is warmed up to room temperature, where neither a similarly lasting photochemical change[44,60,71] nor any transient absorptions in the microsecond range[7,72] can be detected. However, a LIOAS study[71] has revealed that BVE does in fact undergo photoisomerization also under these conditions. Considerable losses of "prompt" heat dissipation, $\alpha$, are registered upon irradiation of low BVE concentrations ($10^{-6}$ M; see Fig. 13), which give a measure of the formation of a photoproduct reverting back to BVE on the microsecond time scale. Analogous findings have already been described for BVE incorporated in the liposomes (Section 3.3). It is also interesting to note that the *E,Z,Z* and *Z,Z,E* isomers[46] give $\alpha$ values larger than 1 (*e.g.*, $\alpha = 1.3$ at $\lambda^{irr}$ 640 nm)[71] indicating an immediate heat release upon photoisomerization to the all-*Z* BVE. The net energy release of this overall exothermic process is thus *ca.* 40 kJ/mol.

The thermal stabilities of stretched BVE formed from the coiled form upon heating or ultrasonic perturbation (Section 3.3) and of that formed photochemically are evidently different. The interconversion paths shown in Scheme 10 suggest an explanation of this apparent discrepancy. The photochemical stretching of the coiled BVE affords directly the $E^{(\prime)}$-*anti* forms, whereas the thermal treatments of the coiled species may drive the transformations farther and populate also the stretched $E^{(\prime)}$-*syn* conformations. The implication then is that C–C rotation in

Scheme 10. Interconversions which link the eight possible C-10 isomers of BVE, involving proton transfer processes ([H]), rotation around the C-9–C-10 single bond (↷), and $E \rightleftarrows Z$ isomerization of the C-10=C-11 double bond ($h\nu$). This Scheme derives from Scheme 5 upon the introduction of the asymmetrical IXα substitution pattern of rings A and D, again not allowing for a change in geometry within the A/B and C/D partial structures.

the latter is the rate determining step for the reformation of coiled BVE. We should note in this context that it cannot yet be predicted which of the two C–C rotations involved will be the rate determining activation barrier in the reverse direction, *i.e.* the thermal stretching of coiled BVE to the $E^{(\prime)}$-*syn* form.

In view of the photochemical behavior of BVE and its IXγ and IXδ isomers it appears plausible to expect that *10E→10Z photoisomerization may play an appreciable role as a deactivation channel of excited BVE.* It is important in this connection to recall two collateral aspects of bilatriene photochemistry. One concerns the remarkable change in the photochemical behavior of BVE either when adsorbed on alumina[46,73] or in solution in the presence of strong electron donors[74]. Under these conditions 'bilirubin-type" processes are in fact observed. Reaction now occurs selectively at C-4 and C-15, and the *E,Z,Z* and *Z,Z,E* isomers are formed. These isomers are more stable thermally than the *Z,E,Z* isomers and, if formed, they would not have escaped detection after the irradiations in inert solvents. The striking difference in the photochemistry has been ascribed to strong interaction by a donor with C-10 or even to the intervening addition of a nucleophile to this position. It is brought about by the extensive delocalization through the symmetrical hydrogen bridge between the nitrogens in rings B and C[76], which renders C-10 the lowest-electron density carbon in the biliverdins and susceptible to such nucleophilic attacks[4,75]. The resulting bilirubin-type intermediates are capable of undergoing the observed photoreactions at C-5 and C-15 and, being much more efficient emitters than the verdins at low temperatures (cf. Table 1), they have also been recognized[4] as the trace sources of the so-called "blue" or "anomalous" fluorescence of BVE[4,77] and of phytochrome[25]. The step sequence has been confirmed for the parent 2,3-dihydrobilatriene model chromophore of phytochrome. After the deliberate addition of 2-mercaptoethanol to C-10 the dipyrromethenone partial structure could be selectively $Z \rightarrow E$ photoisomerized[46], whereas the irradiation of the intact 2,3-dihydrobilatriene in the presence of iodine (as an oxidant) and pyridine effects addition of the latter to C-5[78].

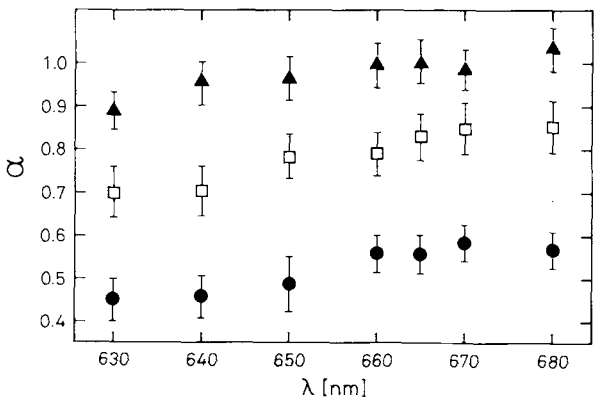

Fig. 13. LIOAS of BVE in ethanol: "prompt" heat dissipation fractions $\alpha$; ● = $1.0 \times 10^{-6}$ M, □ = $2.0 \times 10^{-6}$ M, ▲ = $1.3 \times 10^{-5}$ M [71].

The second aspect concerns the question why in the absence of medium-induced processes the *E-Z* photoisomerization of BVE is confined to C-10. On the basis of calculations and studies of appropriate model compounds[79] it

has been concluded that the excited-state twisting preferentially involves the double bond with the greatest out-of-plane distortion in the ground state. This is demonstrated, *e.g.*, by results with etiobiliverdins which are *N*-methylated in rings A and/or D. Steric crowding by the methyl substituents forces the rings out of the dipyrromethenone plane and destabilizes the subchromophores. As a consequence, $Z \rightarrow E$ photoisomerization occurs, already in inert solvents, selectively about the double bond adjacent to the substituted ring in the monomethylated, and about either of the two double bonds in the dimethylated derivative[79].

### 3.5. The Formation of Aggregates

The tendency of BVE to aggregate, already referred to in Section 3.1, can manifest itself in various ways. One is to form strong adducts of varying stoichiometry with solvents such as tetrahydrofuran, acetonitrile, and ethyl lactate[80]. Another one is shown by the LIOAS results in Figure 13. Static inhibition of the formation of the *Z,E,Z* photoisomers through some sort of association of an unidentified quencher with ground-state BVE was proposed[71] to cause the concentration dependence of $\alpha$, without noticeably effecting a deviation from the Lambert-Beer law in the long-wavelength absorption. It could only recently be demonstrated that the association in fact involves like BVE molecules[68]. As seen in Figure 14, the emission maximum at $10^{-4}$ M in methanol is around 735 nm. On dilution its intensity drops, and there is a shift towards shorter wavelengths, accompanied by the growing-in of a band at around 650 nm. At concentrations of $10^{-6}$ M the long-wavelength emission has disappeared, while bands around 650 and 700 nm are persisting. The quantitative evaluation of the three emission bands was associated with large errors since the measurements were approaching the limits of instrumental sensitivity. Nevertheless, the fluorescence band at *ca.* 700 nm, which is that of the coiled monomer, proved largely independent of concentration. On the other hand, the emission intensities of the stretched form at 650 nm and of the 735 nm band followed opposite trends

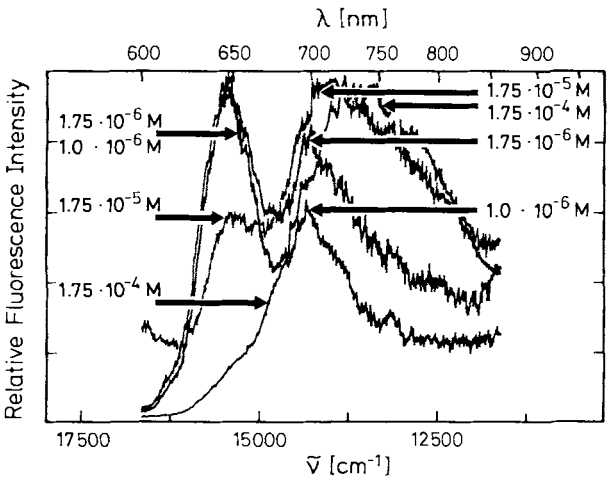

Fig. 14. Concentration dependence of the fluorescence of BVE in methanol at room temperature; $\lambda^{irr} = 580$ nm. The stock solution ($1.75 \times 10^{-4}$ M) had been prepared without warming or sonication. The maximum of each spectrum is normalized [68].

with the changing of concentration. In other words, the association selectively involves the dimerization of the stretched *Z-syn,E(ʹ)-anti,Z-syn* forms. In accord with this conclusion, the excitation spectra of the emissions of Figure 14 exhibit with increasing concentration a distinct broadening of both bands, together with a hypsochromic shift of the Vis maximum from 635 nm to about 600 nm, and a bathochromic shift of the UV maximum from 345 nm to about 380 nm.

## 4. Conclusions and Outlook

The present knowledge of the rather complex picture of the ground- and excited-state behavior of BRE and BVE is based on a large array of diverse experimental and theoretical studies, all of which could not adequately be incorporated into this article[81]. The variety of coexisting forms in organic solvents as well as the variable responses of the individual components—in their electronic ground and first excited singlet states—to medium, temperature and concentration are, generally speaking, common to BRE and BVE, even though important differences may be found with regard to certain aspects. It should also be reiterated in this connection that not all details are yet fully understood. The hitherto most elaborate investigation has been carried out with BVE, owing to the supplementing of the static spectroscopic methods with methods of limited (LIOAS) and highest possible time resolution (PP, SPT). It has afforded a far-reaching insight into the structural and dynamic properties of the diverse components, their selective interconversions upon photochemical and thermal excitation, and the deactivation channels of the individual singlet excited states.

It has already been pointed out in Section 1 that the *in vitro* physical and (photo)chemical properties of the linear tetrapyrroles alone would justify the relatively expensive spectroscopic study of these compounds and the concurrent instrumental and methodological developments (see, *e.g.*,[61,71]). Beyond this, however, the expectation has been amply confirmed that the resulting knowledge constitutes an essential contribution to the studies of the molecular foundations of biological systems containing such pigments. The elucidation of the anaerobic photochemistry of BR in connection with neonatal jaundice, and the further development of the phototherapy was of great importance. The significance, for the biliproteins, of the conclusions drawn from the picosecond kinetics and photochemical studies of BVE has already been alluded to in Sections 3.2 and 3.4. Undoubtedly, other such results will still be forthcoming[81] and lend further support in the even more exacting investigations of the processes in biological systems. This is to be expected in particular from studies with linear tetrapyrroles of the dihydrobilindione type, which are even more closely related in structure to the biliproteinic chromophores, and with the native chromophores linked to oligopeptidic residues as accessible from partial degradation of the proteins. A further approach towards *in vivo* conditions is seen in experiments modelled after the experiences with BVE in solution but carried out in combination with biologically more relevant media (*e.g.*, membranes). In ad-

dition, decisive advances in the *in vivo* studies appear feasible with the application of spectroscopic methods which have been developed, *inter alia*, in connection with studies of the tetrapyrrole models (*e.g.*, laser-induced optoacoustic spectroscopy and single-photon-timing with multi-component resolution capacity in a dynamic range over >3 orders of magnitude).

*Our work described here greatly profited from collaboration with friends and colleagues of other laboratories, notably with Dr. W. Kufer and Professor H. Scheer of the Universität München, Dr. A. A. Lamola of Bell Laboratories, Murray Hill, Professor D. A. Lightner of the University of Nevada, Reno, and Dr. V. Sundström, Mr. Å. Sandström, and Dr. T. Gillbro of the University of Umeå. It would not have been possible at all, however, without the efforts of the team at the Mülheim institute, the first director of which this article is dedicated to. The team includes, among others, the scientists Dr. H. Al-Ekabi, Dr. S. Culshaw, Dr. R. M. Ellul, Dr. H. Lehner, Dr. J. I. Matthews, Professor C. Nicolau, Dr. C. Pétrier, Dr. I.-M. Tegmo-Larsson, Professor R. G. Weiss (while on leave from Georgetown University), and Mr. J. Wendler, the technical staff members Mr. H.-J. Herbert, Miss A. Keil, Miss G. Koc, Miss D. Kreft, Mr. W. Riemer, Mr. W. Schuster, Mr. V. Seeling, and Mrs. G. Wojciechowski, the staff of the computer center, and that of the electronic and mechanical workshops.*

# Ligand-Free Metal Clusters

**By Geoffrey A. Ozin* and Steven A. Mitchell**

Recent advances in the synthesis and spectroscopic characterization of ligand-free metal clusters immobilized in cryogenic rare gas matrices have contributed greatly to the understanding of electronic, geometric, dynamic, and chemical bonding properties of a wide range of uni- and bimetallic clusters as a function of nuclearity and metal type. The knowledge accumulated on molecular metal aggregates devoid of ligands and isolated on various supports will form an important data base for gauging the reliability of quantum chemical calculations on metal clusters, as well as for comprehending certain aspects of chemisorption on, and catalysis by, supported metal clusters. It can be envisaged that information on ligand-free metal clusters entrapped in a wide range of matrix environments in conjunction with the data for these same metal clusters in the gas phase and in molecular beams will probably contribute towards understanding metal-support interactions and to the designed synthesis of a new breed of high-technology heterogeneous catalysts in the not too distant future.

## 1. Introduction to Zerovalent "Naked" Metal Clusters

In a recent review of the structure and diversity of metal clusters[1], the smallest group by far consisted of neutral metal clusters devoid of ligands. On the other hand, the theory of cluster models is usually applied to just such kinds of "ligand-free" metal aggregates, because they are thought to represent the most chemically and physically realistic bridge between isolated metal atoms and the extended arrays of metal atoms found in bulk metals[2]. Not surprisingly, therefore, theoretical studies of the size dependence of electronic, magnetic, structural, bonding, and reactivity properties of ligand-free metal clusters currently far outnumber experimental work, mainly because of the considerable technical difficulties in preparing sufficient quantities of representative metal clusters. However, this situation is changing rapidly, and the main purpose of this

review article is to examine the current status of experimental work on naked metal clusters. Attention will be directed mainly towards the technique of matrix isolation, with only a cursory glance at the corresponding gas phase data and at the theory of cluster models. Because of the burgeoning activity in the area over the past five years, an exhaustive coverage of naked metal cluster research is beyond the scope of this article, and only key experiments and underlying principles will be illustrated.

Over the past decade, experimental techniques for preparing and spectroscopically probing specific naked metal clusters of nuclearities spanning the range from atom to the bulk solid have increasingly attracted the attentions of a multidisciplinary group of scientists. Molecular beam and matrix isolation methods have emerged as the methods of choice to study ligand-free metal clusters in the gas and condensed phases, respectivity[3]. In the ideal, collision-free environment of a molecular beam, the metal cluster can be considered to be truly isolated from cluster-substrate interactions. Therefore, it can be argued that spectroscopic methods capable of selectively extracting information from molecular beams of metal clusters hold great promise for studying diverse size-dependent properties of aggregates of metal atoms in their equilibrium configurations. Co-condensation of metal atoms and/or metal clusters and rare gases from either jets or beams at cryogenic temperatures represents the other main approach for observing nucleation phenomena from isolated metal atoms to bulk metal agglomerates in a weakly interacting solid support. In this way, the metal dispersion as well as the thermal and photolytic behavior of particular metal atomic and cluster species can be evaluated spectroscopically. The spectra obtained reflect not only the properties of the cluster "guests" but also their interaction with the host[10]. Because the size requirement of up to *ca.* ten metal atoms is of great practical significance to the spectroscopic, chemical and catalytic properties of supported metal clusters in both weakly and strongly interacting environments[4], it is important to study very small metal clusters both in various types of substrates and in the gas phase. In this way, it is hoped to be able to develop a scale of metal-support effects (guest-host interactions) and to evaluate the role that they play in diverse phenomena[5].

In this overview, we shall concentrate on some of the more recent experimental advances in the field of naked metal clusters immobilized in rare gas solid supports. Although such experiments are certainly of a fairly recent vintage, they can be considered to have evolved as a natural extension of the original matrix isolation method. A brief introduction to matrix isolation will, therefore, be discussed in the following section.

## 2. The Cryogenic Matrix Trapping Experiment

Matrix isolation is a technique whereby solids formed at low-temperature are used as media for stabilizing reactive chemical species for the purpose of spectroscopic study. The modern practice of matrix isolation, involving the use of monatomic rare gases as matrix materials in the temperature range 4–20 K, was pioneered by *Pimentel et al.*[6] in the early 1950's. The experimental technique typically involves condensation of gaseous atomic or molecular species together with a large excess of an inert gas matrix on a suitable substrate at cryogenic temperatures. A very attractive feature of this method is that normally unstable or highly reactive species may be isolated for long periods of time, allowing relatively leisurely spectroscopic investigation. It is often the case that the interaction between the guest species and the host matrix is sufficiently weak that electronic, vibrational, and ESR spectra differ only slightly from those expected from a simple model of a nonrotating, but otherwise unperturbed, gaseous species having internal degrees of freedom (apart from rotation) in equilibrium at the temperature of the matrix. Thus the low temperature of the solid matrix serves not only to stabilize the species of interest but also to simplify its spectra. The number of species which can be studied spectroscopically by matrix isolation techniques is very large, being limited only by the requirement that the species itself or a suitable photolytic precursor can be produced initially in the gaseous state. Fruitful areas of application include free radicals, molecular ions, and high-temperature species found in the vapor above refractory materials such as metal oxides, carbides, nitrides, halides, and the metals themselves. The most commonly used probes are IR, Raman, UV/VIS, laser-induced fluorescence, and ESR spectroscopy[7–11].

Chemical applications of matrix isolation began to be investigated following their early development by *Skell et al.*[12] and *Timms*[13]. An early example of an application of low-temperature condensation of high-temperature species as a synthetic technique is the work of *Skell* and *Wescott*[12] on reactions of carbon species with organic compounds on a surface cooled with liquid nitrogen. The first example of the use of matrix isolation for *in situ* spectroscopic characterization of reaction products formed by co-condensation of gaseous reactants and a rare gas diluent at a temperature below 77 K is a study by *Andrews* and *Pimentel*[14] of the reaction of Li atoms and NO to form LiON in an argon matrix. Matrix cryochemistry has since undergone extensive development, with applications in inorganic, organometallic, and organic chemistry[15–18]. An especially fruitful area has been the chemistry of elemental vapors, in particular of metal vapors[15–17]. The reaction of main group and transition-metal atoms with small inorganic and organic molecules in inert gas matrices have been extensively investigated, and in many cases detailed vibrational and electronic spectroscopic studies of the products carried out. In addition to providing information on the reactivity and general chemical properties of metal vapors, and on the structures and electronic properties of many new and interesting metal-containing molecular species, these studies are often relevant to problems in chemical synthesis and homogeneous and heterogeneous catalysis[15, 19].

An important consideration in certain matrix isolation experiments is to what extent the gaseous species of interest becomes isolated and free from interactions with other guest molecules in the host matrix. In many applications it is desirable to minimize guest-guest interactions, but, since the species of interest are often thermodynamically unstable with respect to dimerization or polymerization, significant quantities of polymers are also often isolated in the

matrix along with the monomer. Measures which may be taken to minimize this effect include the use of very low temperatures and very high dilution with inert gas. Whereas the formation of aggregates is frequently an undesirable side effect, the resultant species are often interesting in their own right; it then becomes of interest to take steps to control the aggregation process and, hence, produce specific cluster species for spectroscopic characterization. This technique of "designed relaxation" of matrix isolation conditions has been used to obtain vibrational spectra of clusters such as $(H_2O)_n$ $(n=1-4)$[20]; $(SiO)_n$ $(n=1-3)$[21]; and $(MX)_n$ (M = Cu or Ag; X = Cl or Br; $n=1-8$)[22]. In addition, there are many examples of matrix isolation spectroscopic studies of metal cluster species: a selection of these forms the subject of this progress report.

## 3. Metal Atom Clusters

A remarkable feature of the structure of metals is the role played by the extended crystal lattice in determining the overall electronic properties and stability of the bulk phase. The question of how the physical and chemical properties of metals change in the limit of very small particle sizes has recently become the focus of increasing investigation[3,4,23,24]. This interdisciplinary area of research is motivated by both fundamental and applied interests. Very small metal particles are employed as catalysts in a broad range of industrially and commercially important chemical processes[25]. The nature of the catalysts used in these systems is often only poorly understood, and it is hoped that experimental and theoretical studies directed at elucidating the general properties of highly dispersed metals will provide a basis for the more rational selection and testing of catalysts. Metal clusters containing only a few metal atoms are particularly interesting from a fundamental viewpoint, since at this level one may expect the most marked deviations from the properties of the bulk phase. A striking experimental demonstration of this is the study by *Montano* and *Dyson*[124] of the evolution of iron clusters from atom to bulk metal using Mössbauer matrix spectroscopy. The dependence of the isomer shift on cluster size for $Fe_n$ $(n=1$ to 8) is shown in Figure 1. Here, it is seen that the isomer shift undergoes a large change on proceeding from a single iron atom to the dimer; the maximum value of the isomer shift occurs at the dimer and trimer level, and then gradually diminishes to the value of α-iron for a cluster of eight iron atoms. Concomitant reductions in the magnitude of the quadrupole splitting with cluster size are also observed (see Section 8.7).

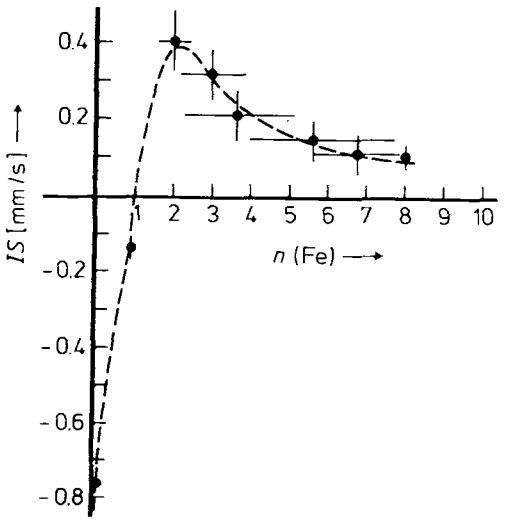

Fig. 1. Variation of isomer shift in the Mössbauer spectra of $Fe_n$ clusters in solid Ar at 4.2 K with the number of nearest-neighbor Fe atoms [124].

A large number of reports dealing with theoretical studies of the evolution of the electronic structure of uni- and bimetallic metal clusters to that of the bulk metal have also appeared[2,3,23,24]. Studies of this type should aid in understanding the structure and properties of metals and alloys and in elucidating the electronic properties of highly dispersed metallic clusters.

## 4. Metal Clusters in the Gas Phase

Experimental investigations of metal clusters with low numbers of atoms have been actively pursued along a number of different directions. The equilibrium vapors above heated metals are in most cases predominantly atomic, as, for example, metals of the first transition series; mass spectrometric studies have shown that their vapors consist of more than 99% atoms[26]. Detection of the diatomic molecules of these metals under equilibrium conditions has, nevertheless, permitted measurements of the diatomic bond dissociation energies[26]: this technique has been extended to include measurements of the atomization energies of certain metal cluster species[3], including $Cu_3$ and $Ag_3$[27]. Recently, a number of methods have been used to produce metal vapors which contain higher proportions of clusters than occur in the pure equilibrium vapors: these include; 1) bombardment of solid metals with energetic rare gas ions (sputtering techniques)[29,29]; 2) vapor phase nucleation of the metal in the presence of a relatively high pressure of inert gas at low temperature (gas evaporation methods)[30,31]; 3) supersonic expansion of either the pure metal vapor[32–35] or of an inert gas to which a small amount of the metal vapor has been added[36]; 4) pulsed laser vaporization of metals[37]; and 5) laser-induced decomposition of organometallic complexes of metal clusters[38,39]. The role of the low-temperature inert gas in the above techniques is to cool the metal vapor and, hence, to produce a condition of supersaturation, thus promoting formation of clusters. For the methods involving supersonic expansion, the cooling is achieved by adiabatic expansion of the vapor from a high pressure region through a small orifice into a vacuum. Although the usefulness of these methods for producing metal clusters has been demonstrated by means of mass spectrometric measurements, to date, only very few spectroscopic studies of metal clusters in the gas phase have been performed. *Sontag* and *Weber*[132a] have studied $Sb_2$ isotopomers by laser-induced fluorescence and determined the spectroscopic constants in various molecular states. *Schumacher et al.*[34] have reported the formation of pure and mixed alkali metal clusters of the type $Na_n$ $(n \leq 16)$, $K_n$ $(n \leq 12)$, and

$K_nNa_m$ ($n+m \leqq 6$) in experiments involving supersonic expansion of the metal vapors. These workers used a single photon photoionization technique in conjunction with mass spectrometric detection to measure ionization potentials of the clusters, and reported data for each of the individual members of the series $Na_n$ ($n \leqq 14$) and $K_n$ ($n \leqq 8$): at the time, these data represented the longest continuous series of any cluster property yet known. These studies have more recently been extended to include seeded beam expansions of high-temperature sodium vapor in He, Ne, Ar, Kr, and $N_2$ carrier gases[36]. In contrast to conventional supersonic expansions, which display an exponential decrease of the abundance of clusters with nuclearity up to $Na_{16}$, the seeded sodium beams produce much larger clusters; at least up to $Na_{65}$ (the upper detection limit of the mass spectrometer) with unprecedented mass abundancies at $Na_8$, $Na_{19}$, $Na_{38}$: these possibly correspond to particularly stable sodium clusters or to an artifact of the cluster growth process. Using a technique involving two-color laser photoionization of sodium clusters in a supersonic sodium beam[*] and mass-selective detection of $Na_3^+$, *Schumacher et al.*[40] were able to generate a spectrum which is in certain respects equivalent to an electronic absorption spectrum of $Na_3$.

A most significant series of experiments has recently been reported for transition-metal molecular beams by *Smalley et al.*[36a,68c]. Here, transition-metals were vaporized with a pulsed laser (Q-switched Nd: YAG second harmonic, 532 nm) and combined with a pulsed supersonic helium expansion. In this way (pulsed supersonic nozzle), large concentrations of ultracold clusters were produced (cf. Fig. 2), including even those of the most refractory metals such as molybdenum and tungsten containing up to 25 atoms[68c]. Very recently *Kaldor et al.*[38] have generated beams of $Fe_n$($n=2$–$23$) and $Ni_n$, ($n=2$–$25$) clusters in a similar manner. From the dependence of the ionizing laser intensity of the time-of-flight mass spectrometric signals, it was found that the cluster ionization potentials exhibited oscillations as a function of cluster size, rather than a monotonic decrease towards the bulk metal work function. Moreover, even for clusters as large as $Fe_{23}$ and $Ni_{25}$ the values had not converged to the work function of the bulk metal. Oscillatory structures of this type had previously been observed in the mass spectra of alkali and group Ib metal clusters and were attributed to the paired/unpaired nature of the S-band. Such a simple explanation cannot, however, be invoked to rationalize the situation for the more complex Fe($3d^64s^2$) and Ni($3d^84s^2$) metals. Thus, the structure has been construed as evidence for unique geometrical and/or electronic porperties for $Fe_n$ and $Ni_n$ clusters and suggests chemical properties which may differ vastly from those of the bulk metal. These results indicate a promising future for the application of supersonic beam and laser spectroscopic techniques to gas-phase metal cluster studies. However, it must be recognized that the requirement for rather complicated experimental techniques is a significant factor which may well retard the expected progress.

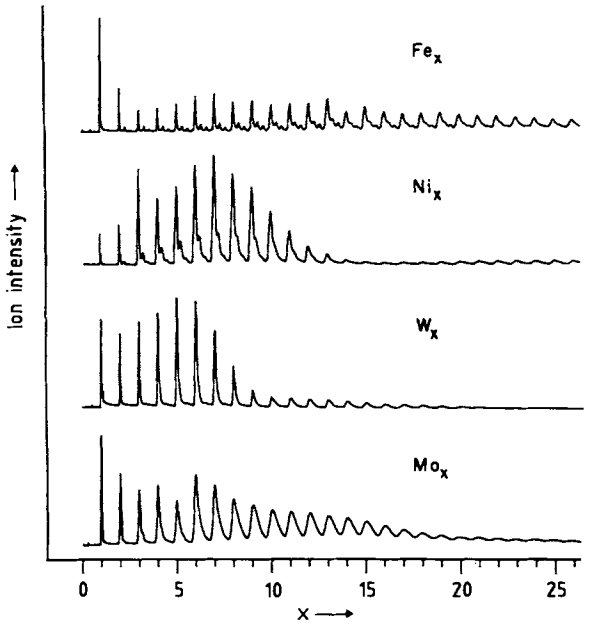

Fig. 2. Time-of-flight mass spectra illustrating cluster size distributions obtained for beams of iron, nickel, tungsten, and molybdenum. Ions were produced by photoionization using an ArF (193 nm) excimer laser with a brightness of *ca.* 1 mJ/cm$^2$. The nozzle backing pressure was 8 bar He, which expanded through a 1 mm orifice. The mass spectra of $Fe_x$ and $Ni_x$ contain additional features due to metal oxides $M_xO_y$. The features in the $Mo_x$ mass spectrum are broadened by the various isotopomers arising from the seven naturally occurring molybdenum isotopes [68c].

## 5. Supported Metal Clusters

The use of refractory solids, such as alumina or silica, or porous materials, such as zeolites, to stabilize metal clusters and small metal particles is widespread and forms the basis of much of the current practice in heterogeneous catalysis by metals[25]. Physical methods of analysis such as X-ray scattering, electron microscopy, magnetization measurements, Mössbauer, photoelectron, ESR and more recently solid-state metal NMR spectroscopy have been used extensively in conjunction with chemisorption studies to characterize supported metal particle arrays. Many examples of such studies may be found in the proceedings of several recent international conferences on the growth and properties of metal clusters[3,4,23,24]. A recent development in this rapidly growing area is the introduction of a new technique which is useful for examining the structures of supported metal particles: this involves analysis of the fine structure extending beyond an X-ray absorption edge, EXAFS (extended X-ray absorption fine structure)[*]. As discussed by *Teo*[41], the fine structure is sensitive to the immediate environment of the atom absorbing the X-ray irradiation, and yields information on the number, type, and distances of the atoms in the first few coordination spheres of the absorber. An example of an interesting application of this method is the comparison of the interatomic distances in bulk platinum metal and zeolite-entrapped pla-

[*] The term "supersonic molecular beam" gives no information about the velocities involved. Under certain conditions (pressure differences of approximately 10 torr, geometry of the jet) phenomena can occur in gas expansion experiments of this type which can formally be accounted by those of ultrasound.

[*] 50 years ago it was observed that the fine structure of an absorption edge extended over a region *ca.* 1000 eV beyond that of an edge.

tinum particles of about 10 Å diameter (corresponding to less than 100 metal atoms per particle) by *Moraweck et al.*[42]. The characteristic interatomic distance for the platinum particles was found to be *ca.* 4% less than the corresponding distance in the bulk metal. The combination of EXAFS and high-resolution electron microscopy (with a resolution of better than 2.5 Å)[43] should enable the size distribution and morphology of supported metal particles to be characterized in considerable detail. Considering that certain features of electronic structure are amenable to study by photoelectron, Mössbauer, and fluorescence spectroscopy, and that chemical properties may be probed by chemisorption and catalytic studies, it is apparent that considerable potential exists for examining trends in cluster properties as a function of particle size, shape, and the nature of the support. The metal clusters which are accessible by preparative methods using solid supports at room temperature typically contain more than one hundred metal atoms, and these systems are most often studied using the above techniques. As discussed below, matrix isolation is a widely applicable method for stabilizing clusters of fewer than ten metal atoms in a form suitable for investigation by a variety of spectroscopic methods.

## 6. Metal Clusters in Rare Gas Matrices—How It All Began

From early studies of the electronic absorption spectra of metal atoms such as Hg, Cd, Mg, and Na isolated in rare gas matrices, it was recognized that under certain conditions significant quantities of homonuclear diatomic metal molecules were co-isolated in the solid matrix with the metal atoms and exhibited distinct UV/VIS bands[44]. Subsequent investigations showed that the extent to which diatomic metal molecules were formed depended in a very sensitive way on the dilution ratio of the metal atom/rare gas atom; the choice of rare gas; and the temperature of the cold substrate during the deposition process[45–48]. It was suggested that the formation of metal dimers and polymers occurred because the metal atoms are highly mobile before they dissipate their kinetic energy in the newly condensing surface layers of the matrix; thereby, aggregation processes can occur for a brief period before solidification of the new layers and immobilization of the metal atoms. This idea has recently been put into the form of a simple kinetic model for the metal atom aggregation processes[49–51]. The model predicts that for a constant inert gas deposition rate the ratio of the absorbance of a metal molecule with n atoms to that of the metal atom should be proportional to the $(n-1)$th power of the metal deposition rate. By means of a quartz crystal microbalance to accurately monitor metal deposition rates, experimental data were obtained which were in accord with this prediction[51,52]. This development contributed to a growing interest in the cryochemical synthesis of diatomic and polyatomic metal molecules: matrix-absorption spectra have been reported for a variety of homo- and heteronuclear diatomic transition-metal molecules, including several whose corresponding gas phase spectra are not available[51–54]. Matrix-isolated metal cluster species whose UV/VIS absorption spectra have been reported include $Na_{3,4}$[55,56], $Mg_{3,4}$[57], $Co_3$[58], $Ni_3$[59], $Cu_{3,4}$[60], $Cr_3$, $Mo_3$, $Cr_nMo_{3-n}$[61a], $Ag_{3-6}$[62,63], and $Cr_nAg_m$[61b].

## 7. Bridging the Gap between Naked Metal Clusters in the Gas Phase and in Matrices

The generation of a distribution of metal clusters in a molecular beam, followed by selective separation of a cluster of specific nuclearity and its subsequent trapping in a rare gas matrix for spectroscopic observation have recently been realized in an elegant experiment by *Schumacher et al.*[127]. In essence, this was achieved by incorporating a Stern-Gerlach magnet into an experimental set-up designed to immobilize pre-formed, spectrally and mass spectrometrically analyzed cluster beams in an inert gas matrix at 4 K. For $Na_x$ ($x = 1, 2, 3$) beams, it was possible to separate paramagnetic $Na_1$ and $Na_3$ magnetically from diamagnetic $Na_2$ and, hence, obtain the UV/VIS spectrum of high purity $Na_2$ dimers in a krypton matrix. Furthermore, by cocondensing the separated partial beam through a mask with Kr onto a cooled sapphire target, it was also possible to obtain the optical spectrum of low density $Na_3$ in solid krypton.

It has recently been demonstrated by *Scoles et al.*[139] that rare-gas cluster hosts containing a single guest molecule can be produced using free-jet expansions and molecular beam techniques. For example, Ar clusters containing a single $SF_6$ or $CH_3F$ molecule have been generated using nozzles with very small orifices and high-dilution mixtures of gases. Using this method it has proved possible to spectroscopically study the seeded molecule as a function of cluster size and temperature. In the limit of large cluster size, this form of spectroscopy in the gas phase would become equivalent to normal matrix spectroscopy. In this way, *Scoles et al.*[139] succeeded in proving that the IR spectra obtained in the limit of large clusters for $(Ar)_nSF_6$ and $(Ar)_nCH_3F$ were remarkably similar to the infrared spectra of the same molecules deposited in an Ar matrix. Clearly the extension of this technique to $(Ar)_nM_x$ as a function of n and x would be a rather elegant way of determining line-shifts and -shapes, and, hence, would be a new method of probing metal-support interactions (cf. Sections 9, 12, and 13).

It seems clear from these pioneering experiments that the combination of size-specific absorption spectroscopy in metal cluster beams with mass-selective separation and techniques of collecting rare-gas solids offers exciting possibilities for in-depth study of the properties of individual particles in mixtures of metal clusters using both gas and matrix phase spectroscopy: the method, thus, offers a new way of studying the perturbation of metal cluster properties by a host support.

## 8. Spectroscopic Methods of Studying Naked Metal Clusters in Solids at Low Temperatures

A variety of spectroscopic methods have been employed to study metal clusters in rare gas matrices. A brief survey of the most important results is presented in the following sections.

### 8.1. Laser-Induced Fluorescence, Raman, and Resonance Raman Spectroscopy

Characteristically, in the electronic absorption spectra of many matrix-isolated metal atomic species the absorption bands are quite broad, with half-widths in the range 100—500 $cm^{-1}$[64]. The UV/VIS absorption bands observed for matrix-isolated diatomic metal molecules are often similarly broad, and in many cases the vibrational structure of the electronic absorption bands is either poorly resolved or not detected[45,48,51,54]. The technique of laser-induced fluorescence (LIF) offers some important advantages in studying the electronic spectra of these systems. The narrow band width and high intensity of the stimulating radiation enable high-resolution spectra to be recorded. In those cases where absorption bands are inhomogeneously broadened due to the occurrence of a multiplicity of slightly different matrix trapping sites, laser excitation may selectively pick out one or a narrow distribution of trapping sites, and thereby produce fluorescence spectra with greatly diminished line-broadening. Laser-induced fluorescence techniques have recently been used to measure the ground-state vibrational frequencies and first anharmonicity constants of molecules such as $Ti_2$, $V_2$[65], $Ni_2$[66], $Fe_2$[67], and $Mo_2$[68] isolated in rare gas matrices. Studies of the electronic absorption spectra of these systems have provided information on certain excited-state vibrational frequencies and on the electronic energy levels[52–54]. Experimental measurements of vibrational frequencies and electronic transition energies are valuable for comparisons with theoretical predictions, and useful insights into the nature of the chemical bonding may be gained by examining trends in these data, especially in conjunction with related data such as bond dissociation energies[65].

With the new LIF data for $Mo_2$[68a] and $Cr_2$[68b] in cryoscopic matrices, and a recent report of resonant two-photon ionization spectra for these same species in a rotationally cold supersonic beam of metal clusters[68c], the topical issue of metal-metal multiple bonding[68d] in these dimers has taken on a new perspective. This began in 1974 with the report by *Efremov et al.*[68e] of a rotationally resolved transient absorption around 460 nm produced by flash photolysis of gaseous $Cr(CO)_6$, and assigned to $Cr_2$ with an "amazingly" short bond length of 1.68 Å in the electronic ground state ($v=0$). Support for this assignment came first in 1975 from the work of *Ozin et al.*[68f], who used quantitative concentration studies of Cr atoms in an argon matrix to identify $Cr_2$ absorptions at 455 and 260 nm. This report was followed in 1977 by the first definitive characterization of UV/VIS transitions of $Mo_2$ and CrMo in rare gas matrices[68g]. At this time *Ozin et al.*[68h] and *Gray et al.*[68i], on the basis of semiempirical MO calculations, independently proposed that the high spin $3d^54s^1$ and $4d^55s^1(^7S)$ ground states of Cr and Mo atoms, respectively, could be considered to be bonded through two single 4sσ and 3dσ bonds, and two 3dπ and two 3dσ bonds, yielding tightly bound, closed shell $^1\Sigma_g^+$ electronic ground states for both $Cr_2$ and $Mo_2$. The proposal of a sextuple metal-metal bond in the $Cr_2$ and $Mo_2$ dimers stimulated a number of *ab initio* calculations[68j] which produced effective bond orders ranging from 0 to >4. Hence, it was highly significant that the LIF matrix studies of *Gruen et al.*[68a] on $Mo_2$, and *Moskovits et al.*[68b] on $Cr_2$ yielded very high vibrational frequencies (475.7 $cm^{-1}$ and 427.5 $cm^{-1}$, respectively) with exceedingly short empirically estimated bond lengths (1.9 Å and 1.7 Å, respectively). For $Mo_2$, *Gruen et al.*[68a] observed time-resolved LIF spectra for this species isolated in argon and krypton matrices (Fig. 3). Here, two separate vibrational progressions were observed, each having long (m sec) but distinct lifetimes (exponential and biexponential, respectively), with spacings $\omega_e = 475.7 \pm 4.5$ $cm^{-1}$; these originate from $Mo_2$ in two slightly different matrix sites. Minimal perturbation of the vibrational states of $Mo_2$ by the surrounding rare gas atoms was indicated by the invariance of $\omega_e$ in Ar and Kr.

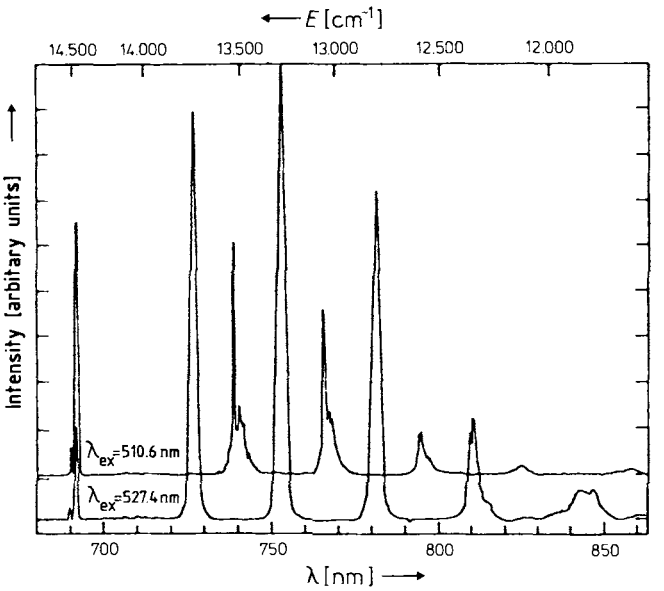

Fig. 3. Emission spectrum of $Mo_2$ in solid krypton. The upper curve is observed for 510.6 nm excitation and the lower for 527.1 nm excitation [68a].

A pivotal experiment, which provided a direct determination of the metal-metal bond length and electronic ground state in $Cr_2$ and $Mo_2$, has recently been reported by *Smalley et al.*[68a]. They used a pulsed-laser metal vaporization source to produce supersonic beams of chromium and molybdenum clusters. With resonant two-photon ionization, mass-selective detection techniques, rotationally resolved absorptions at *ca.* 460 nm and 530 nm were observed for $Cr_2$ and $Mo_2$ isotopomers, respectively. The rotational structure found for each species was that expected for a $^1\Sigma_u^+ \leftarrow {}^1\Sigma_g^+$ transition. Rotational constants yielded bond lengths of 1.68 Å and 1.94 Å for $Cr_2$ and $Mo_2$, respectively, in the v = 0 level of the $^1\Sigma_g^+$ state[68]. Moreover, the vibronic analysis indicates that $Cr_2$ and $Mo_2$ have the same electronic structure. The available experimental data can, therefore, be considered to vindicate the original proposal by *Efremov et al.*[68e] of a short bond for gas phase $Cr_2$, as well as the conclusion by *Ozin et al.* of similar electronic and bonding properties for $Cr_2$, CrMo, and $Mo_2$ isolated in rare gas matrices[68g,h]. Since naked $Cr_2$, with its internuclear separation of 1.68 Å, now boasts the shortest homonuclear bond of any element (Cr bulk, 2.5 Å, $Cr_2^{4+}$ complexes, 1.83 Å[68k]), the controversial issue of the existence

of effective metal-metal bond orders of $>4$ can be considered to have received new fuel.

*Miller* and *Andrews* have made extensive studies of the electronic absorption and LIF spectra of homonuclear and heteronuclear group IIa and IIb diatomic metal molecules isolated in rare gas matrices[69]. The advantages of combining matrix and gas phase studies of the electronic spectra of molecules such as $Pb_2$, $Cu_2$ and $Bi_2$ has been demonstrated by *Bondybey et al.*[70a], *Gole et al.*[70b], and *Nixon et al.*[71].

Recently, Raman and resonance Raman data have been published on tri- and multi-atomic metal clusters, exemplified by $Cr_3$, $Ni_3$, $Cu_3$, $Ag_3$, $Pb_3$, $Sb_3$, $Sb_4$, and $Pb_4$ in rare gas matrices[72,74,133,134]. On the basis of analysis of the isotopic fine structure of laser-excited emissions of $Ni_3$ molecules isolated in an argon matrix (Fig. 4), *Moskovits* and *DiLella*[72] proposed that this species has a bent structure with an apex angle of between 90° and 100°. The frequency of the symmetric stretching vibration of $Ni_3$ was reported to be 232 $cm^{-1}$; the comparable value for $Ni_2$ is 381 $cm^{-1}$[66].

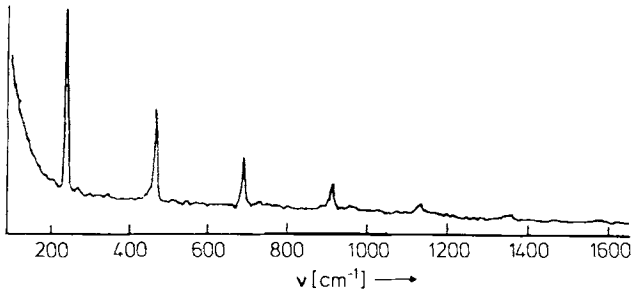

Fig. 4. Resonance Raman spectrum of a solid argon matrix containing nickel excited with 488 nm $Ar^+$ laser radiation, and assigned to $Ni_3$ [72].

Raman and resonance Raman spectra have recently been obtained for $Cr_3$ in argon matrices, and a bent structure with an estimated apex angle of *ca.* 60° was proposed[72]. The resonance Raman spectrum of $Cu_3$ in solid Ar (excitation center *ca.* 16810 $cm^{-1}$) has been found to display an irregularly spaced progression of lines (major series 355, 710, 1063, 1430 $cm^{-1}$; minor series 404, 760, 1115 $cm^{-1}$) with vibrational components possessing an unexpected form of isotopic structure thought to be diagnostic of a pseudorotating $Cu_3$ molecule[133] (see calculations on $Li_3$[88] and ESR data[129]). Briefly, the assignment of fluxionality to $Cu_3$ was based, in part, on the observation of vibrational features arising only from $^{63}Cu_3$ and $^{65}Cu_3$, but not from $^{63}Cu_2{}^{65}Cu$ and $^{63}Cu^{65}Cu_2$ isotopomers. This was explained by proposing that the degenerate vibrational ground (and possibly excited) state of $D_{3h}$ ($^2E'$) of $^{63}Cu_3$ is removed in $C_{2v}$ ($^2B_2 + {}^2A_1$), $^{63}Cu_2{}^{65}Cu$. Such splittings could possibly put the $^{63}Cu_2{}^{65}Cu$ isotopomer out of resonance with the exciting laser frequency. Also, changes in selection rules could make the dipole-allowed electronic excitation in $^{63}Cu_3$ forbidden in $^{63}Cu_2{}^{65}Cu$. Either or both of these effects could lead to the absence of $^{63}Cu_2{}^{65}Cu/{}^{63}Cu^{65}Cu_2$ vibronic components in the resonance Raman spectrum of the $Cu_3$ molecule undergoing dynamic Jahn-Teller distorsions[133].

For the first time, a complete vibrational spectrum of $Sb_4$ has been observed in rare gas matrices by non-resonant Raman scattering[132b]. Samples were prepared by quenching antimony vapor (deposited under Langmuir evaporation conditions, which favor $Sb_4$ as the major component) with, for example, Ar at *ca.* 13 K. The Raman spectra shown in Figure 5 were obtained using visible laser

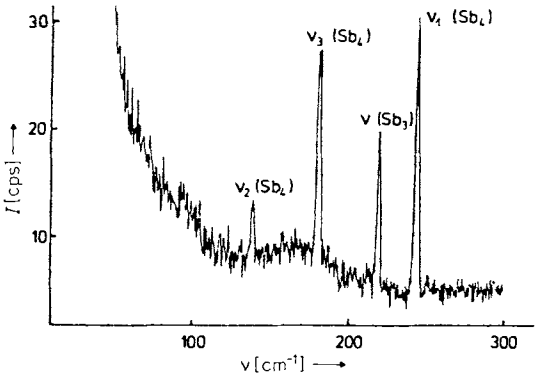

Fig. 5. Raman spectrum of $Sb_4$ in argon at 13 K. A resonance Raman line assigned to $Sb_3$ is also present in this sample, as well as a broad background around 160 $cm^{-1}$ assigned to larger $Sb_n$ clusters [132].

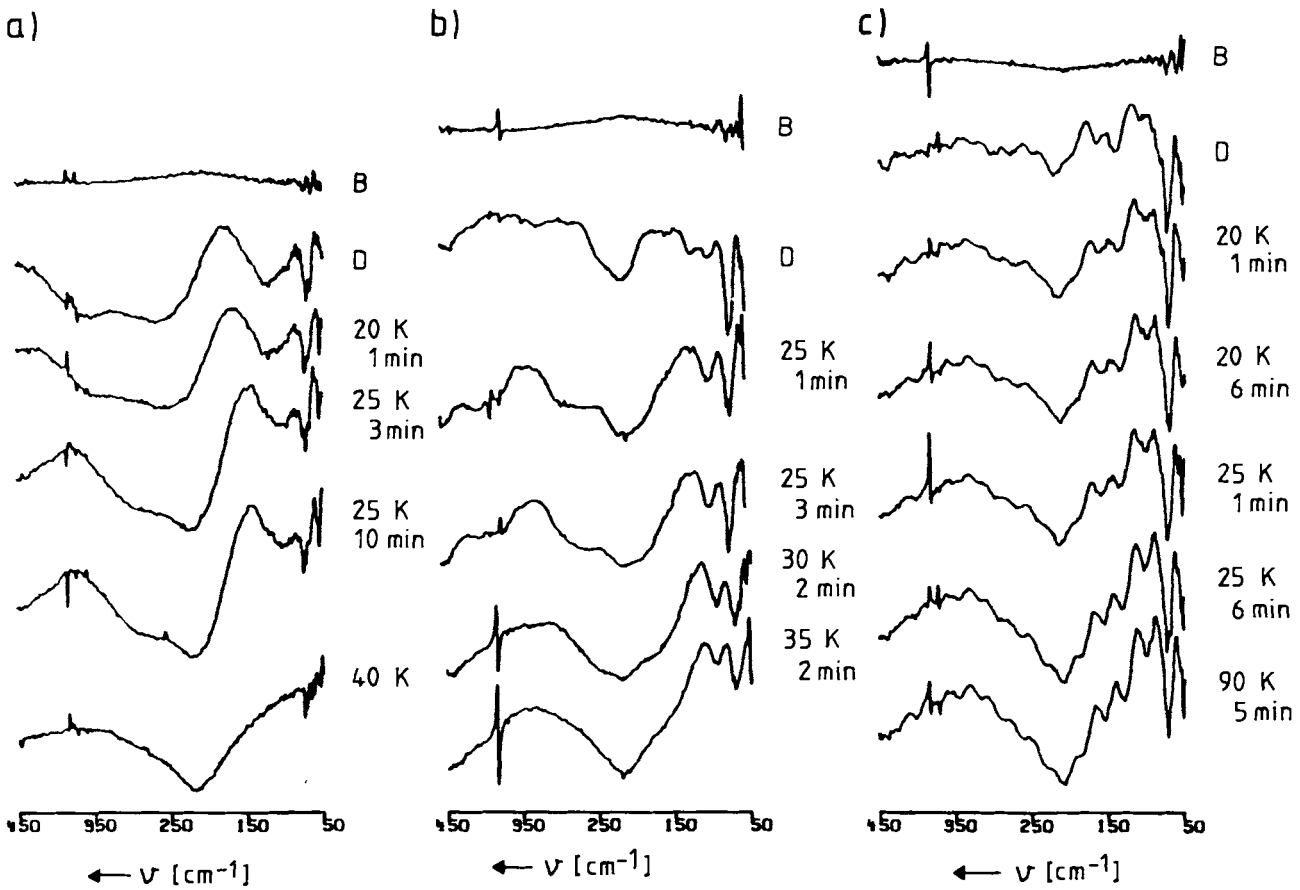
excitation. The observation of three vibrational modes at 241.5, 178.5 and 137.1 $cm^{-1}$, the first being strongly polarized, the second and third being completely depolarized (all lines displaying only $\omega^4$ intensity variation without enhancement), is consistent with the symmetry assignment $\nu_1(A_1)$, $\nu_3(T_2)$, and $\nu_2(E)$, respectively, for an $Sb_4$ molecule with $T_d$ symmetry; none of the modes is subject to resonance enhancement. A resonance Raman spectrum of an antimony cluster ascribed to $Sb_3$ was also observed in this study; however, no structural conclusions could be drawn.

Laser-excited emissions attributable to tetrahedral $Bi_4$ in a neon matrix have been observed by *Bondybey* and *English*[73], who were able to extract all three fundamental vibrational frequencies of this molecule from their data. *Stranz* and *Khanna*[74] reported vibrational frequencies from emission spectra which they tentatively assigned to a trigonal ($D_{3h}$) $Pb_3$ molecule isolated in a xenon matrix.

## 8.2. Fourier Transform Far-Infrared (FT-FarIR) Spectroscopy

Whereas Raman and resonance Raman methods alone may establish cluster geometry, ambiguities can arise from scattering or resonance enhancement by only specific isotopomers and/or structural isomers, as well as non-observation of inactive or weakly active Raman or resonance Raman bands. Uncertainties of this type can, in principle, be clarified by complementary low frequency IR spectroscopic data. Very recently, we devised an experiment in which metal clusters isolated in a rare gas were generated directly inside a far-FIR vacuum interferometer[75]. In this way, the first IR spectroscopic data for ligand-free metal triatomics were obtained. The results for $Cr_3$ immobilized in argon and xenon matrices have revealed that, depending on the metal concentration and thermal treatment condi-



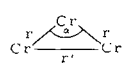


Fig. 6. FT far-IR spectra for Cr/Ar ratios of a) $\approx 1/10^3$, b) $\approx 2.5/10^4$, c) $\approx 1/10^4$ deposited at 12 K and annealed at the temperatures indicated. Peak to peak noise at 200 $cm^{-1}$ *ca.* 0.5% [75].

Table 1. Observed and calculated far-IR active vibrational modes of $Cr_3$ [a, b].

| Calculated [c, d] | | | | | | | | | | | Observed [e] | Assignment [f] |
|---|---|---|---|---|---|---|---|---|---|---|---|---|

| | | | | | | | | | 46 | | | |
| | | | | | | | | | | 27 | | |

[a] All frequency units in $cm^{-1}$. [b] Frequencies refer to argon matrices. [c] Stretching force constants and interaction constants in mdyn $Å^{-1}$, where $f_r = 1.00, f_{rr} = 0.05$, $f_r = 1.00\gamma, f_{rr} = 0.05\gamma$; $\gamma = (180 - \alpha)/120$. [d] Frequencies in parenthesis denote Raman-only active modes. [e] Summary of data from a collection of concentration and annealing experiments (Cr/Ar $\approx 1/10^4$ to $1/10^3$ and 12–40 K, respectively), which are conducive to the formation of $Cr_3$. A sharp absorption observed around 75 $cm^{-1}$ for Cr/Ar and 60 $cm^{-1}$ for Cr/Xe matrices is thought to originate from a localized Cr atom-rare gas cage vibration, rather than a chromium cluster vibration. [f] Numbers in parenthesis refer to the bond angle $\alpha$.

tions, molecular geometries ranging from that of an equilateral triangle to that of an almost linear triatomic molecule can be trapped and identified (cf. Fig. 6 and Table 1).

It is evident from these data that the $Cr_3$ cluster must have a rather shallow potential energy surface for the framework deformation and that, for a particular selection

of experimental conditions, extremely subtle perturbations can profoundly influence cluster geometry. These results are significant because they underscore that even a "weak" metal-support interaction can markedly influence the electronic, vibrational, and geometrical properties of a supported metal cluster. It is clear from these results that FT far-IR spectroscopic data will form a valuable adjunct to the complementary information emerging from laser Raman, resonance Raman, and resonance fluorescence spectroscopy.

### 8.3. Magnetic Circular Dichroism (MCD) Spectroscopy

Magnetic circular dichroism (MCD) spectroscopy has recently been applied to study the electronic absorption spectra of $Cu_{2,3}$, $Ag_{2,3}$, $Mg_{2,3,4}$, $Ca_2$, $Sr_2$, $Mn_2$, and $Ni_n$ isolated in rare gas matrices[57,76,117,118]. This technique involves measurement of the differential absorption of left and right circularly polarized light propagating along the direction of an externally applied magnetic field, and yields information on the degeneracy of the electronic states involved in optical transitions. The MCD spectra of certain paramagnetic molecules exhibit a characteristic temperature dependence which is diagnostic of the presence of unpaired electron spins. *Grinter et al.*[76] reported temperature-dependent MCD spectra for an absorption band at 246 nm (cf. Fig. 7) which had previously been assigned to paramagnetic $Ag_3$ in an argon matrix, thus supporting the previous assignment[109]. Their results were also suggestive of orbital degeneracy in the excited electronic state, consistent with a $^2\Pi \leftarrow ^2\Sigma$ assignment for the electronic transition and, therefore, indicating a linear $Ag_3$ molecule: this is also consistent with the results of a recent Raman spectroscopic study of $Ag_3$ molecules isolated in a krypton matrix[77]. *Miller et al.*[57] have reported the MCD spectra of $Mg_3$ and $Mg_4$ clusters isolated in argon matrices: a detailed analysis of these spectra provided evidence for a triangular ($D_{3h}$) structure for $Mg_3$ and a tetrahedral structure for $Mg_4$.

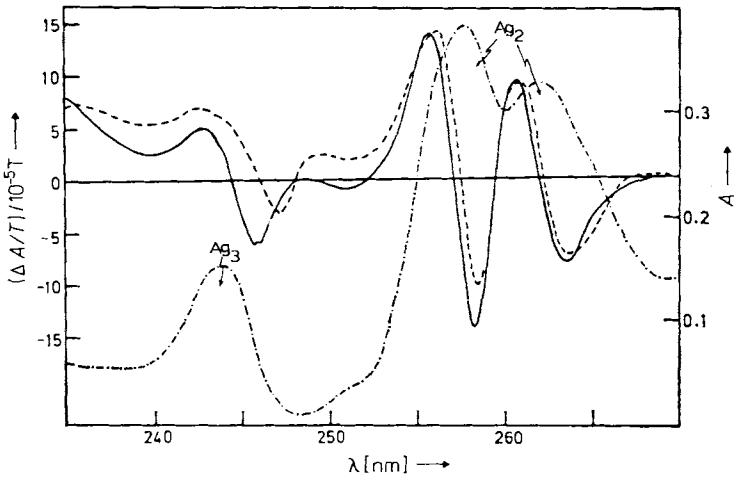

Fig. 7. Absorption and MCD spectra of silver in an argon matrix. Features in the region of 246 nm and 254–270 nm are assigned to $Ag_3$ and $Ag_2$ molecules, respectively. The MCD spectra were measured at a field of 6 T. Absorption spectrum at 10 K (-·-·-·); MCD spectrum at 10 K (——) and 20 K (– – –) [76].

In an early study of Ni atoms in an argon matrix[119], it was reported that 325 nm excitation of one of the $3d^84s^2 \rightarrow 3d^84s^14p^1$ Ni atomic resonance absorptions causes aggregation to $Ni_2$ and $Ni_3$ clusters, which absorb in the range 350–530 nm[119]. Prolonged photolysis caused these bands to disappear and be replaced by new absorptions at *ca.* 240 nm, which were ascribed to $Ni_n$ clusters ($n>3$). In a recent MCD study of Ni/Kr matrices subjected to prolonged atomic photolysis, absorption by a $Ni_n$ cluster was observed at *ca.* 235 nm[118]. This probably corresponds to the same $Ni_n$ cluster observed in an argon matrix at *ca.* 240 nm. Further work will be required to establish the value of n. In this context, it should be noted that recent matrix vacuum-UV/VIS studies of Ni atoms in rare gas solids have shown that the electronic ground-state configuration of the isolated Ni atom can be changed by the matrix; for example it is $3d^84s^2$ in Ne and in the gas phase, but $3d^94s^1$ in Ar, Kr, and Xe. The important point is that repulsive matrix-dopant interactions in Ar, Kr, and Xe are sufficiently lowered in the $3d^94s^1$ configuration of Ni to overcompensate for the 205 $cm^{-1}$ energy difference by which the $3d^94s^1$ level lies above the $3d^84s^2$ level in Ne an in the free atom[136].

Temperature-dependent transitions (347 and 331 nm) in the optical absorption and MCD spectra of Mn atoms in argon matrices over the range 13–27 K have been assigned recently to the $Mn_2$ molecule[117]. The data confirm the earlier theoretical proposal by *Nesbet*[89] that $Mn_2$ should be a weakly bound, antiferromagnetic molecule with a $^1\Sigma_g^+$ ground state. The exchange energy for ground state $Mn_2$ was determined to be $-10.3 \pm 0.6$ $cm^{-1}$, which is identical to the value[86] obtained by *Weltner et al.* from ESR measurements (cf. Section 8.5), and is consistent with the calculated value of $-4$ $cm^{-1}$[89].

### 8.4. UV-Photoelectron Spectroscopy (UPS)

*Jacobi et al.* have recently shown that UV-photoelectron spectroscopy is a highly useful technique for the study of matrix isolated species[78], such as atoms and clusters of Ni and Cu. Rare gas matrices of 50 Å thickness were deposited onto a thin film of Ga on a flat copper block as cryosurface, taking advantage of the featureless UPS of gallium in the energy range of interest. At binding energies below 8 eV, He($II_\beta$) excitation of Cu/Kr $\approx 1/10^3$ produced a new peak at 5.1 eV, which is not observed in a pure krypton matrix (Fig. 8a), and which is ascribed to atomic Cu (Fig. 8b): all bond energies are relative to the Fermi level of the gallium substrate. For Cu/Kr $\approx 1/10^2$, a broad emission at *ca.* 4 eV is assigned to matrix entrapped $Cu_n$ clusters (Fig. 8c). These data are quite distinct from those of bulk Cu (Fig. 8d). Both the invariant Cu atom emission at *ca.* 5.1 eV in various matrices (Ar, Kr, and Xe), assigned to a $3d^94s^1$ final state, and the corresponding gas to matrix relaxation shifts of 1.3 eV confirm that the ground state of Cu atoms in the matrix is the same as in the gas phase, namely $4d^{10}4s^1$; furthermore, the mechanism of relaxation in the matrix is solely intra-atomic, being determined by the Cu 4s electron. The discrepancy between the emissions of small $Cu_n$ clusters at *ca.* 4 eV and that of bulk Cu at *ca.* 2.5 eV is at variance with some electronic structure calcula-

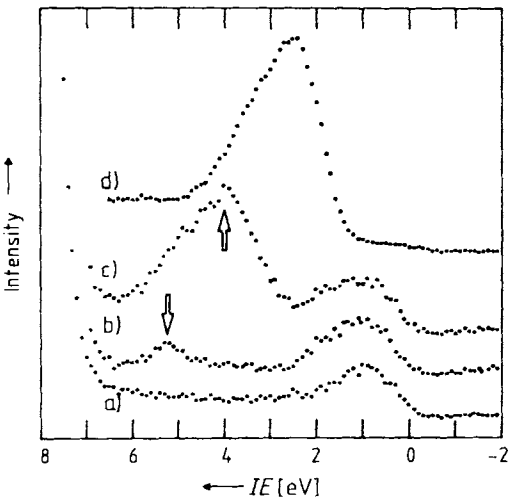

Fig. 8. UPS of a) a pure krypton matrix, b) Cu atoms isolated in krypton and c) Cu clusters isolated in krypton. For comparison the spectrum of bulk Cu is also shown in d). Excitation: $He(II_\beta)$; $T = 7$ K [78].

tions[79] which indicate that copper clusters with as few as 6 to 13 atoms display d-band energies similar to those of bulk Cu. The UPS data imply that to achieve acceptable convergence of metal cluster electronic properties and those of the bulk metal, nuclearities higher than those previously treated by theory will probably have to be considered. It is interesting to note that although the emission spectra of Cu and $Cu_n$ are independent of the matrix gas, emission from the np orbitals of the rare gas host atoms was markedly modified by the copper guests; for example, two kinds of Xe $5p_{1/2,3/2}$ emissions are observed in $Cu_n$/Xe matrices, one of which is identical with that of pure Xe and the other, whose intensity is dependent on the concentration of Cu, is red-shifted by 0.8 eV. The data imply that the atomic relaxation process for an Xe atom in the proximity of a Cu or $Cu_n$ guest is dominated by relaxation effects in the metal rather than in the surrounding Xe atoms. In this sense the UPS data of Cu-doped rare gas solids are similar to those observed for physisorbed rare gases[80].

More recently, *Jacobi et al.* have extended their UPS studies of $Cu_n$ and $Ni_n$ clusters isolated in rare gas matrices to include reactive matrices such as CO and $O_2$[120]. In these experiments they compared the adsorption of CO and $O_2$ on Cu and Ni films with that on small $Cu_n$ and $Ni_n$ clusters and, hence, introduced a novel method of studying chemisorption and catalysis by small metal particles. For $Cu_n$ in CO, for example, a new emission was observed at 1.5 eV, which was not present in the UPS of $Cu_n$ isolated in rare gas matrices. This new signal was assigned to a photoemission from the $2\pi^*$ orbital of CO, which is unoccupied in the free molecule, but partly occupied by charge transfer from $Cu_n$. A similar peak is observed for CO adsorbed on Cu films and surfaces, and has been taken to be diagnostic of $Cu \rightarrow CO(2\pi^*)$ charge transfer; an interaction which plays a central role in Cu–CO bond formation.

### 8.5. Electron Spin Resonance (ESR) Spectroscopy

Matrix-isolated diatomic metal molecules such as $Mn_2$, $Sc_2$, CrCu, and clusters such as $Li_3$, $Na_3$, $K_3$, $Ag_3$, $Cu_3$, CuAgCu, $Cu_5$, $Mn_5$, $Ag_5$, $Na_7$, and $K_7$ have been studied by electron spin resonance (ESR) spectroscopy[81–87, 121, 129, 130, 140].

The ESR spectra reported by *Lindsay et al.*[81–83] for $Na_3$ and $K_3$ isolated in argon matrices indicated linear or slightly bent structures for these systems, and provided direct evidence for covalent rather than ionic or van der Waals' bonding in $M_3$ molecules. In addition, evidence was found for a second form of $K_3$ exhibiting a dynamic structure which fluctuates between three equivalent bent forms of the molecule; the three potassium atoms alternatively occupying the apical position. Fluxionality of this type has been predicted theoretically for the $Li_3$ molecule by *Gerber* and *Schumacher*[88].

Subsequently, ESR spectra assigned to pseudorotating $^6Li_3$ and $^7Li_3$ molecules were observed[129] following photoaggregation at 30 K of $^6Li$ and $^7Li$ atoms, respectively, which were isolated initially in argon matrices at 4.2 K. A typical spectrum for $^6Li_3$ in solid argon is shown in Figure 9. Unlike matrix-isolated $Na_3$ and $K_3$[81–83], the ESR spectra of $Li_3$ showed no alternating line-width behavior in the range 30–40 K, and no stationary $Li_3$ spectra were found between 4.2–40 K. Instead, the observation of seven equally spaced hyperfine transitions with measured intensities close to 1:3:6:7:6:3:1 is consistent with the coupling of the unpaired electron with three equivalent $I = 1$ nuclei and, hence, with assignment to pseudorotating $^6Li_3$ (Fig. 9). The observation of a ten line ESR spectrum (with two components obscured) in the analogous $^7Li$/Ar photoaggregation experiment is in accord with that expected for three equivalent $I = 3/2$ nuclei in a pseudorotating $^7Li_3$ molecule[129]. The absence of a stationary ESR spectrum of the trimer was taken as evidence that $Li_3$ has a relatively "non-localized" ground vibronic state. An average isotropic spin population in $Li_3$ of $\bar{\rho} = 0.225$ was obtained from the ESR data: this value is in excellent accord with *ab initio* calculations for $Li_3$[131]. Moreover, the total isotropic spin population of $3\bar{\rho} \approx 0.68$ indicates approximately 30% p-character in the unpaired electron wavefunction and, hence, significant sp hybridization in the $Li_3$ molecule. In general, the ESR spectra of $Li_3$ are consistent with a $(E' \times e')$ vibronic ground state having $^2E'$ symmetry. On the ESR time scale, the trimer appears to pseudorotate, for example, by tunneling between three equivalent electronic potential energy wells of $^2B_2$ symmetry which are insufficiently deep to support a vibrational level; that is, a completely fluxional $Li_3$ molecule as originally predicted theoretically by *Gerber et al.*[88].

In this same vein, *Lindsay et al.* have recently reported ESR spectra for $Na_7$ and $K_7$ septemers. These spectra display large isotropic hyperfine splittings from two equivalent alkali nuclei plus a much smaller splitting from at least five additional equivalent nuclei. The most likely structure for these $M_7$ clusters appears to be a pentagonal bipyramid; the most compact geometry for seven interacting spheres.

A recent report by *Howard et al.* described the ESR spectrum of $Ag_3$ molecules isolated in solid benzene[84]. The spectrum was interpreted as indicating a slightly bent structure for $Ag_3$. These same authors have recently obtained ESR spectra for $Cu_3$, CuAgCu, and $Cu_5$ trapped in various organic matrices[121]; for example, $^{63}Cu_3$ was trap-

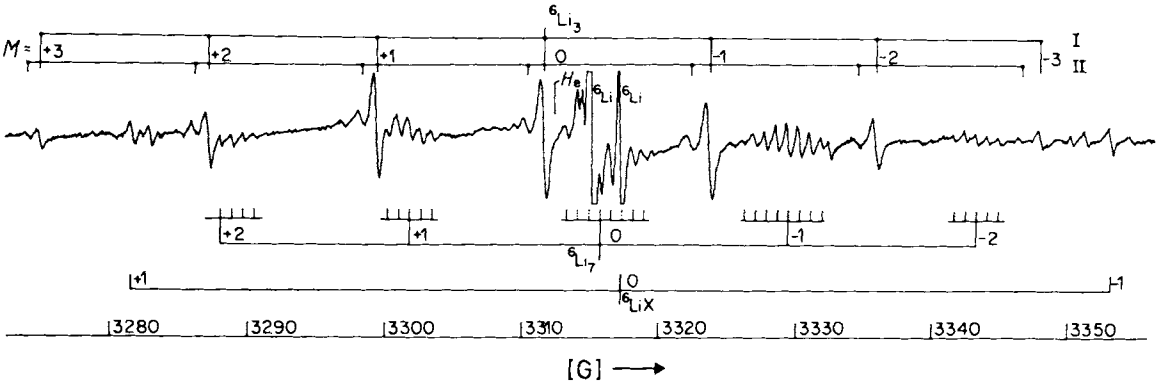

Fig. 9. ESR spectrum of pseudorotating $^6Li_3$ in an argon matrix at 28.5 K. Roman numerals designate matrix sites. Also shown are atomic lithium, $^6Li_7$, and a radical, designated $^6LiX$ [129].

ped in an adamantane matrix at 77 K. Its ESR spectrum displayed 16 sets of quartets with $a_2 = 625.5$, $a_1 = 55.6$ G and $\langle g \rangle = 1.9925$ (obtained from an exact solution of the isotropic spin Hamiltonian using the Breit-Rabi equation). The spectrum was ascribed to a single unpaired electron having equal and large isotropic hyperfine interactions with two equivalent $^{63}Cu$ atoms and a further small interaction with a third $^{63}Cu$ atom. By analogy to that of $Ag_3$ in solid benzene[84], it was suggested that the structure of $Cu_3$ was slightly bent with a $^2B_2$ electronic ground state. Using $^{63}Cu/^{107}Ag/C_6D_6$ codepositions at 77 K, *Howard et al.* observed an ESR spectrum consisting of sixteen doublets with a large hyperfine splitting from two equivalent $^{63}Cu$ nuclei ($I = 3/2$, $a_2 = 880.5$ G) and a smaller hyperfine splitting from one $^{107}Ag$ nucleus ($I = 1/2$, $a_1 = 35.5$ G), with $\langle g \rangle = 1.962$. Analysis of the data led to assignment to the mixed triatomic cluster $^{63}Cu^{107}Ag^{63}Cu$, which probably has an obtuse triangular structure with a $^2B_2$ electronic ground state. In a related study, *Howard et al.*[121] co-condensed $^{63}Cu$ and $C_6D_{12}$ with simultaneous *in situ* photochemical excitation at $\lambda > 320$ nm. The ESR spectrum of the sample at 77 K was highly impressive, displaying a 16 line pattern, each component of which was subsplit into a 13 line multiplet. The unequally spaced 16 lines were assigned to a large hyperfine splitting from two equivalent $^{63}Cu$ atoms and were fitted with the Breit-Rabi equation. This yielded an $a_2$ value of 608 G and a $\langle g \rangle$ value of 2.055. Each of the large lines was further split into 13 lines with an intensity distribution close to that expected for two equivalent Cu atoms with a hyperfine interaction of 15 G and a third Cu atom having twice this interaction. An assignment to $Cu_5$ was clearly indicated. Of the five structures considered by *Howard*[121] for $Cu_5$: linear $D_{\infty h}$; trigonal bipyramidal $D_{3h}$; square pyramidal $C_{4v}$; body centered square $D_{4h}$; and pentagonal $D_{5h}$ the final three species are immediately precluded since they do not contain three distinct types of Cu atom as required by the ESR data. The linear structure is predicted to have the highest spin density on the central Cu atom followed closely by that on the two terminal Cu atoms, with the two intermediate Cu atoms having much smaller values. Since the ESR spectra of $Cu_5$ showed two equivalent Cu atoms with large hyperfine splittings and three with small, the $D_{3h}$ trigonal bipyramidal structure was favored[121]. Molecular orbital calculations on $Cu_5$ suggest that the unpaired electron occupies an e′ orbital formed by a linear combination of equatorial Cu orbitals[97,98]. The $^2E'$ electronic ground state of $Cu_5$ is, therefore, degenerate; however, Jahn-Teller distortion is expected to remove this degeneracy and, thereby, lower the total energy. The distorted $Cu_5$ structures that result are described as $C_{2v}$ "compressed" and $C_{2v}$ "opened". Quite different electron spin distributions are expected for the relevant $a_1$ and $b_2$ HOMO's of the respective $Cu_5$ ($C_{2v}$) clusters which correlate with the degenerate e′ HOMO of the $Cu_5$ ($D_{3h}$) cluster. Proceeding in this way the ESR spectra of $Cu_5$ were interpreted in terms of a trigonal bipyramidal skeleton with a Jahn-Teller distortion towards the $C_{2v}$ "open" arrangement of five copper atoms.

Similar results have also recently been obtained by *Howard et al.*[121] for the neutral cluster $^{107}Ag_5$, generated at 77 K from $^{107}Ag$ by photolysis during deposition in $C_6D_{12}$, followed by careful annealing to remove the transitions belonging to $^{107}Ag$ and $^{107}Ag_3$ from the overall spectrum; what remains is a reasonably clean ESR spectrum which is assigned to $^{107}Ag_5$ (Fig. 10). The signal intensity shows reversible temperature dependence, suggesting either dynamic behavior or a matrix orientation effect. The spectrum consists principally of a triplet of multiplets, indicating two equivalent $^{107}Ag$ nuclei ($I = 1/2$) with $a_2 = 204.6$ G and $\langle g \rangle = 2.081$. The sub-splittings associated with each line of the triplet were best fitted by proposing coupling to three additional $^{107}Ag$ atoms, two being equivalent with $a_2 = 5.5$ G, and the third having $a_1 = 11$ G. In this way the ESR spectrum shown in Figure 10 was assigned. By analogy to the reasoning described previously for $Cu_5$, the

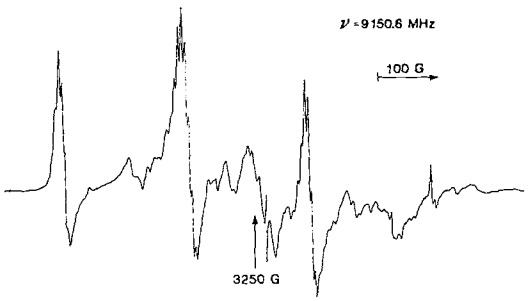

Fig. 10. ESR spectrum of $^{107}Ag_5$ in $C_6D_{12}$ at 77 K following careful annealing to remove most of the $^{107}Ag$ and $^{107}Ag_3$ [121].

trigonal bipyramidal structure with Jahn-Teller distortion was assigned to $^{107}Ag_5$. Using $^{107}Ag$ one-electron parameters, the isotropic hyperfine interactions in $^{107}Ag_5$ yielded the following unpaired spin populations: 62% for two equatorial $^{107}Ag$ nuclei; 1.7% for the unique equatorial $^{107}Ag$; and 0.8% for the remaining two axial $^{107}Ag$ nuclei. These are similar in magnitude to the spin-populations on the copper nuclei of $Cu_5$. The data imply that in $^{107}Ag_5$ *ca.* 60% of the unpaired spin-population resides in 5s orbitals, with as much as 40% spin density in p and/or d orbitals.

The interesting diatomic molecules CrCu[85], $Sc_2$[140], and $Mn_2$[86] have been prepared in rare gas matrices and studied by ESR spectroscopy by *Weltner et al.*: for $Sc_2$ and CrCu high spin $^5\Sigma$ and $^6\Sigma$ ground states, respectively, were suggested. Although a diamagnetic ground state was indicated for $Mn_2$, in agreement with an earlier theoretical prediction[89], evidence was found for a series of regularly spaced higher spin states, some of which were found to be thermally accessible for $Mn_2$ in a krypton matrix at 50 K (Fig. 11). For example, in krypton at 4.2 K only Mn atom signals were observed, displaying six lines of equal intensity centered at *ca.* 3350 G of hyperfine splitting *ca.* 28 G. At 10 K an 11 line pattern of intensity ratio 1:2:3:4:5:6:5:4:3:2:1 and hyperfine splitting 15 G begins to emerge at 2511 G (Fig. 11). The observed ESR

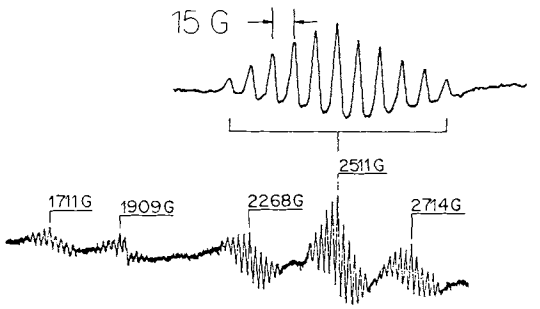

Fig. 11. ESR spectrum of the $Mn_2$ antiferromagnetically exchange-coupled dimer isolated in a Kr matrix at a temperature of *ca.* 50 K, $\nu = 9.3840$ GHz [86].

spectra and their temperature dependence identified lines at 1711, 2511, 4305 G with $S = 2$ and 1909, 2268, 2714, 4050 G with $S = 3$ total spin states; these were analyzed assuming a spin Hamiltonian of the form

$$\mathscr{H} = \beta H \cdot g \cdot S - (J/2)[S(S+1) - S_i(S_i+1) - S_j(S_j+1)] + D_z[S_z^2 - 1/3\,S(S+1)] + (A/2)S \cdot (I_i + I_j)$$

where $J$ is the isotropic exchange energy; $S = S_i + S_j$ is the total spin with values $S_i + S_j$, $S_i + S_j - 1, \ldots 0$; $A$ is the hyperfine interaction constant for the isolated atom; and $D_z$ is an effective zero-field splitting parameter expected to be dependent on the $S$ value. The ESR spectra of $Mn_2$ are thus analyzed in terms of an antiferromagnetically exchange-coupled dimer which takes on thermally accessible and increasing values of $S$ as the temperature increases from 4.2 to 50 K. Support for this fascinating proposal would stem from the observation of the $S = 4$ signals, which are expected to evolve at *ca.* 65 K, a temperature which was unfortunately inaccessible in *Weltner*'s study[86]. The temperature variation of the absorption and MCD

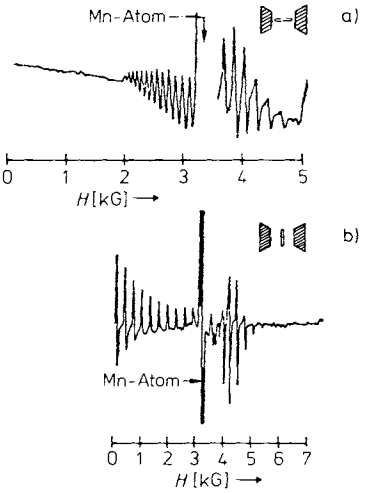

Fig. 12. ESR spectrum of the $Mn_5$ molecule in solid krypton at 4 K ($\nu = 9.378$ GHz). Strong preferential orientation of the $Mn_5$ molecules is indicated by the different spectra observed when the flat face of the sapphire rod is parallel (top spectrum) and perpendicular (bottom spectrum) to the magnetic field direction [87].

spectra of $Mn_2$ in solid argon described in earlier work[117] are consistent with the conclusions drawn from the ESR study of $Mn_2$ in solid krypton[86].

Finally, an interesting example of a metal cluster in a high spin state is $Mn_5$, for which a recent matrix-isolation ESR study[87] suggested a total electronic spin $S = 25/2$ (corresponding to five unpaired spins on each Mn atom) and a pentagonal planar geometry (Fig. 12).

### 8.6. X-Ray (EXAFS) Spectroscopy

The presence of incompletely filled atomic d orbitals in transition metals gives rise to a rather dense manifold of low-lying electronic states for diatomic metal molecules. The relative stabilities of these low-lying electronic states are a matter of considerable interest to problems involving the electronic structures of metals and the electronic configurations and bonding capabilities of the diatomic metal subunits of binuclear metal complexes with neutral or ionic ligands. The chemistry and catalytic activity of many of these binuclear metal complexes are currently being actively investigated[90]. Several recent theoretical studies of diatomic transition-metal molecules point out the difficulties associated with treating electron correlation and exchange effects adequately[91–99]. It is clear that experimental results on these systems are crucial for the development of reliable theoretical treatments. Of particular importance are the properties of the ground electronic state, including, in addition to the vibrational frequency and dissociation energy, the internuclear distance, spin multiplicity, and orbital state symmetry. The recent EXAFS[100] and Mössbauer spectroscopic studies[101] of $Fe_2$ in argon matrices by *Montano et al.* may be noted in this connection. From the EXAFS data a bond distance of 1.87 Å was deduced for $Fe_2$ in argon, and the Mössbauer results were indicative of a $^7\Sigma$ electronic ground state. Similar Mössbauer studies have been reported for the heteronuclear diatomics FeNi, FeMn, FeCu, and FeCo[101]. Currently available experi-

mental and theoretical results suggest stable states of high spin multiplicity for diatomic transition-metal molecules.

In a recent study, *Montano et al.* obtained EXAFS and XANES (X-ray absorption near edge structure) data for small $Fe_n$ molecules in neon matrices (Fig. 13) over a wide range of Fe concentrations[102]. By averaging the Fe–Fe distances over a narrow range of $Fe_n$ multimers, a significant contraction of the Fe–Fe distance was observed: 2.48 Å for α-Fe; 2.30 Å for $Fe_n(n>5)$; 2.05 Å for $Fe_2$, $Fe_3$, and $Fe_4$; and 2.02 Å at extreme dilutions, for mainly $Fe_2$. It is fascinating to note that similar nuclearity-dependent metal-metal interatomic distances are beginning to emerge from related studies of metal clusters on more strongly interacting supports, such as those reported by *Moraweck et al.*[42] ($Pt_n$/zeolites) and *Apai et al.*[103] ($Cu_n$ and $Ni_n$ on carbon and oxides, respectively). The XANES spectra of $Fe_n$/Ne solids also show considerable metal concentration dependence near edge structures (Fig. 13b). A K-edge shift of $3\pm1$ eV for Fe atoms compared to that of bulk Fe is consistent with the expected higher binding energies for $3d^64s^2$ Fe monomers compared to the $3d^74s$ configuration of the bulk metal[102]. The near edge absorptions observed for $Fe_n$ multimers were tentatively assigned to

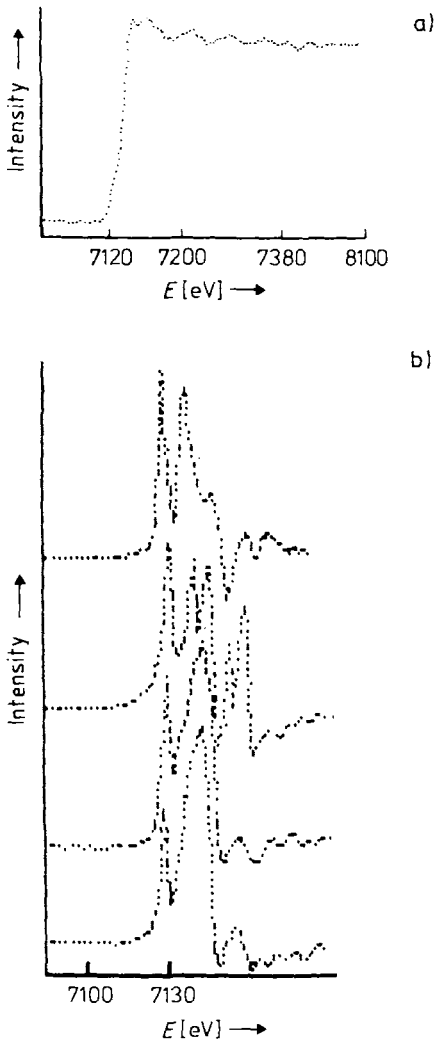

Fig. 13. a) X-ray absorption spectrum (EXAFS) of a sample containing 0.4 at-% Fe in Ne at 4.2 K. b) Derivative of the XANES spectra of (a) Fe foil; (b) 1.5 at% Fe in Ne; (c) 0.5 at% Fe in Ne; and (d) 0.4 at% Fe in Ne at 4.2 K [102].

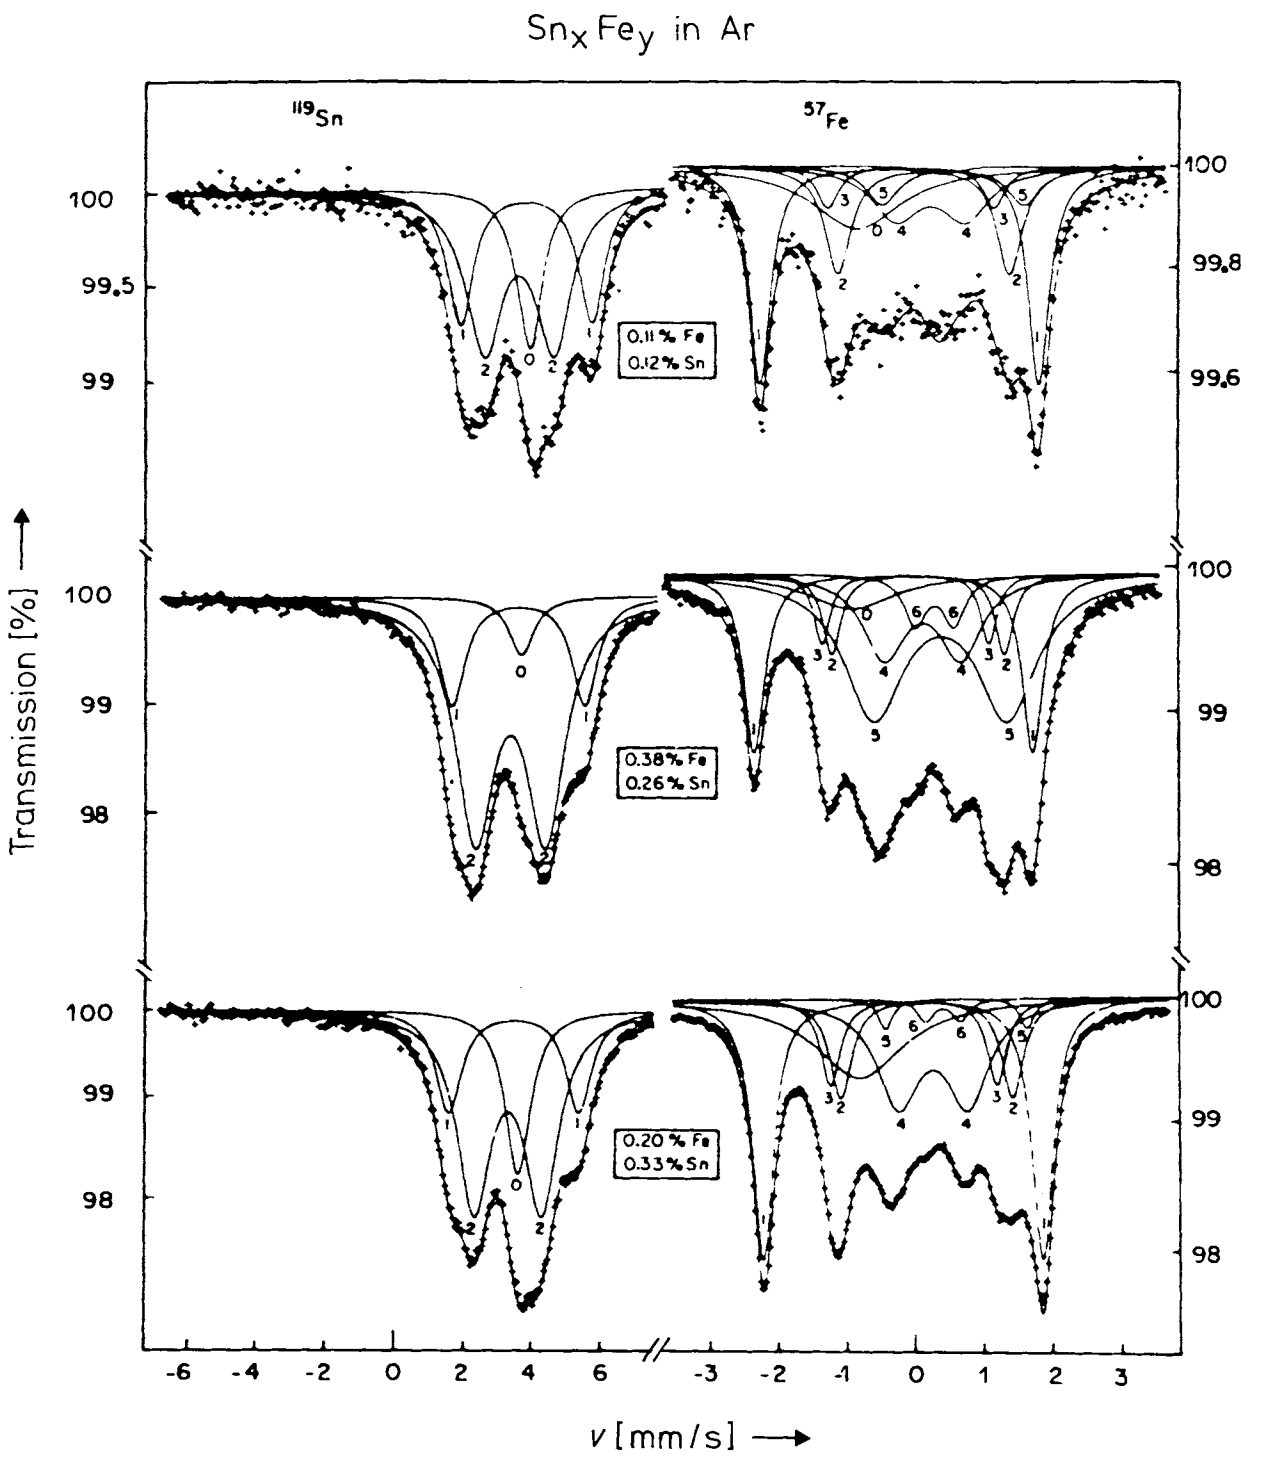
1s→3d,4s,4p,np transitions. However, a firmer theoretical understanding of XANES will be necessary to quantify metal cluster data of the above type.

### 8.7. Mössbauer Spectroscopy

Mössbauer spectra of matrix-isolated $Fe_xCo_y$ molecules have recently been obtained[122]. A number of samples were investigated with metal concentrations varying from 0.1 to 25 at-%. From symmetry considerations and the magnitude of the electric field gradient, the electronic ground state of the FeCo molecule was found to be $^6\Sigma$. In addition to FeCo, the trimeric clusters $Fe_2Co$ and $FeCo_2$ were identified and their Mössbauer parameters determined[122]. Definitive conclusions on the structure of these triatomic, bimetallic clusters were not made in this study; however, using higher metal concentrations and Monte Carlo methods to estimate the cluster size and composition, the variation of the isomer shift of Fe with the number of cobalt nearest neighors in $Fe_xCo_y$ clusters could be established[122]. Similar kinds of experiments have been performed for $Fe_n$[124]. It was found that the isomer shift approached the value obtained for iron in a cobalt matrix for about twelve Co nearest neighbors. For one Co nearest neighbor a maximum in the isomer shift of Fe was observed, indicating a change in the configuration of the iron atom with a subsequent decrease of the s electron density at the $^{57}$Fe nucleus. As the number of surrounding Co atoms increased, the isomer shift was observed to decrease from this maximum value, suggesting an increase in the s electron density at the nucleus arising from 3d electron delocalization effects. It is interesting that the Mössbauer spectra obtained for a metal concentration of 5 at-% with Fe : Co = 1 : 3 already showed the six lines characteristic of magnetic hyperfine splitting[122]. Monte Carlo analysis of these samples predicts the formation of clusters containing only four to five metal atoms: $Fe_2Co_2$, $FeCo_3$, $FeCo_4$, $Fe_3Co_2$, and $Fe_2Co_3$. At 25 at-% the observed magnetic hyperfine field was the same as that observed for disordered iron-cobalt alloys of the same composition.

From this brief look at the Mössbauer spectroscopic investigation of the Fe/Co matrix (as well as the $Fe_n$ study described previously, cf. Fig. 1) it can be deduced that such studies have great potential for probing subtle electronic and bonding interactions between metal atoms, and provide a means of following the evolution of bulk metallic properties from those of the metal atom to those of the small metal cluster.

Very recently, $^{119}$Sn and $^{57}$Fe Mössbauer spectra (Fig. 14) have been employed to study small bimetallic clusters of $Fe_xSn_y$ in solid argon[104, 123]. The use of two γ-resonance probes in a single sample of clusters, and self-consistent assignment of isomer shifts, quadrupole splittings, line widths, and relative intensities of the $^{119}$Sn and $^{57}$Fe lines led to identification of FeSn, $Fe_2Sn$, $Fe_2Sn_2$, $FeSn_3$, $Fe_2Sn_3$ and $FeSn_4$ molecules; provided geometrical clues concerning the mixed trimers; gave relative reactivity information for Fe and Sn atoms and dimers in nucleation processes occurring during matrix condensation; and enabled some conclusions to be drawn about the Fe–Sn bond in ligand-free $Fe_xSn_y$ clusters.



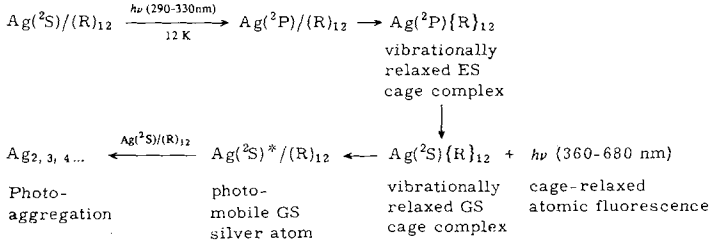


Fig. 14. Two γ-resonance $^{57}$Fe and $^{119}$Sn Mössbauer absorption spectra for various metal to argon ratios at 4.5 K. The solid lines are a least squares fit of the experimental spectra. Six and three components were characterized for $^{57}$Fe and $^{119}$Sn, respectively. Notation: 0 = $Fe^0$, 1 = $Fe_2$, 2 = FeSn, 3 = $FeSn_2$, 4 = SnFeSn, 5 = $Fe_2Sn$, 6 = $Fe_3$ and 0 = $Sn^0$, 1 = $Sn_2$, 3 = $Sn_xFe_y$ [104].

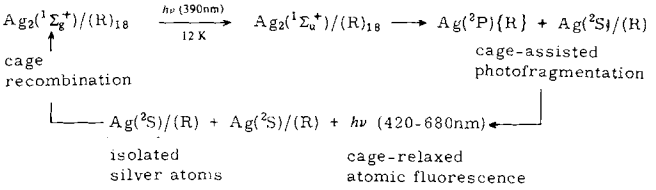
### 8.8. UV/VIS Absorption and Emission Spectroscopy

Experimental studies of metal clusters are subject to an inherent difficulty, since it is generally not feasible to selectively produce specific cluster species. Conditions leading to formation of significant quantities of any given cluster may, in general, be expected to lead also to formation of comparable quantities of both larger and smaller clusters. In the absence of methods to selectively excite or detect one cluster, therefore, it is generally necessary to deconvolute spectroscopic data into contributions from several clusters. It is, thus, highly desirable to work with well characterized cluster distributions, and to be able to easily change the cluster distribution in a designed way. As noted earlier, the general mechanism of metal cluster formation in cryoscopic matrices is aggregation of the metal atoms in the mobile surface layers of the matrix during the deposition process. The degree of aggregation is controlled by

factors such as the metal atom/rare gas atom dilution ratio, the temperature of the cold substrate, and the atomic weight of the matrix gas; all of which may be varied to optimize the cluster distribution. Further agglomeration of the metal species in the deposited matrix may, in certain cases, be induced by thermal annealing[63]. UV/VIS absorption measurements provide a convenient and fairly sensitive means of detecting entrapped metal clusters. Matrix-isolated metal atoms typically exhibit very intense UV/VIS absorption bands; hence, it is not unexpected that diatomic metal molecules and small clusters also show absorptions in this region. Under conditions of carefully controlled metal atom aggregation, quantitative metal deposition techniques may be used in conjunction with optical absorption measurements to estimate relative extinction coefficients of isolated atoms and of diatomic and triatomic metal molecules[49]. Measurements of this type are very useful, since they serve to define the experimental conditions under which at least partly understood metal cluster distributions may be produced.

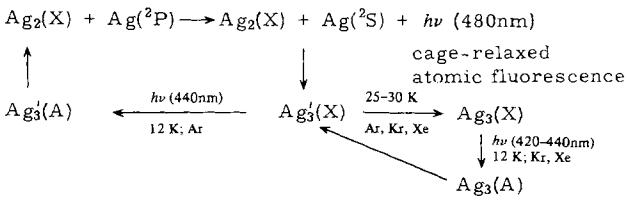
A new method for producing silver clusters in rare gas matrices has recently been reported by *Ozin* and *Huber*[63]. This involves photoinduced diffusion and aggregation of entrapped silver atoms promoted by narrow-band illumination of the matrix at a wavelength corresponding to the strong resonance absorption band of the silver atoms. Similar metal atom photoaggregation effects have been observed for matrix-isolated sodium, nickel, copper, chromium, molybdenum, and rhodium atoms[19, 58, 61, 105, 118, 125]. In this context, the fluorescence emission and excitation spectra of metal atoms and small clusters immobilized in cryogenic matrices exhibit a specificity which, for sometime, has been recognized as a sensitive probe of the microscopic environment of the entrapped guest signalling subtle changes in its surroundings as well as specific guest-host interactions in its ground and excited states[105–108, 128]. Here, a striking resemblence between the optical spectra of silver atoms isolated in rare gases and faujasite zeolites, and those of small clusters of silver atoms has been noted and interpreted in terms of a weak metal-support interaction for the silver guests in the zeolitic host[5].



Scheme 1. Photoprocesses of silver atoms isolated in rare gas matrices. $(R)_{12}$ represents the twelve nearest-neighbor rare gas atoms (R = Ar, Kr, Xe) around a cubooctahedral, substitutional Ag atom trapping site.

Studies of the energetics and dynamics of Ag, $Ag_2$, $Ag_3$, Cu, and $Cu_2$ in rare gas solids have been undertaken[63, 105–111]. The absorption and fluorescence spectra are indicative of strong guest-host interactions in the low lying excited states of these species. A summary of the observed radiative and non-radiative relaxation processes of VIS- and UV-photoexcited Ag, $Ag_2$ and $Ag_3$ in rare gas solids is shown in Schemes 1–3.

The most pertinent feature of the spectroscopy and photoprocesses of Ag atoms isolated in rare gas matrices are the strong guest-host interactions in the optically excited, vibronically active $^2P$ state of Ag, which results in fast vibrational relaxation of the rare gas cage atoms surrounding the Ag($^2$P) atom followed by cage-relaxed (strongly red-shifted) atomic fluorescence. It is thought that the destabilization caused by formation of a Ag($^2$S) ground state in the vibrationally relaxed excited state cage-configuration provides the driving force for photoinduced diffusion of the Ag atom leading to photoaggregation[63, 107].



The optical absorption and fluorescence spectra of $Ag_2$ in rare gas solids[108] are also clearly indicative of strong guest-host interactions involving the A ($^1\Sigma_u^+$) and C ($^1\Pi_u$) states of $Ag_2$ (cf. Scheme 2).

Scheme 2. Photoprocesses of silver dimers isolated in rare gas matrices. $(R)_{18}$ represents the eighteeen nearest-neighbor rare gas atoms (R = Ar, Kr, Xe) around a $D_{2h}$ disubstitutional $Ag_2$ trapping site.

The atomic emission spectrum produced by A←X excitation of $Ag_2$ at 390 nm in argon, krypton, and xenon matrices is interpreted in terms of dissociation of an excited state of $Ag_2$. This involves strong destabilization of the A state of $Ag_2$ (bound in the gas phase) and strong stabilization of the Ag($^2$P) + Ag($^2$S) fragments by matrix-cage relaxation effects (cf. Scheme 2). The net "cage-assisted" photofragmentation yield is only *ca.* 10%[110] due to the short-range repulsive constraints of the matrix cage, which result in efficient recombination of the ground state Ag fragments (Scheme 1).

The optical absorption and fluorescence spectra and photochemical properties of $Ag_3$ provide clear evidence for the occurrence of two distinct forms of $Ag_3$ in each of the three rare gas matrices[5, 106, 109, 111]. These observations show that the matrix environment stabilizes distinct isomeric forms of this species. It appears that the normal form of $Ag_3$ is produced in argon, krypton and xenon matrices, and a structurally distinct yet normal form, denoted $Ag_3'$, by photoinduced aggregation of Ag in argon matrices and by 420–440 nm photoisomerization of $Ag_3$ in krypton and xenon matrices[111]. The results available for $Ag_3$ and $Ag_3'$ in rare gas solids are summarized in Scheme 3.

Scheme 3. Photoprocesses of silver trimers isolated in rare gas matrices.

For the $Ag_3'$ isomer in solid argon, the spectroscopic and photochemical results indicate that an efficient photodissociative-recombination process $Ag_3 \rightleftharpoons Ag_2 + Ag$ occurs in the matrix cage. However, for the $Ag_3$ isomer in solid krypton and xenon, the available data lean heavily in favor of a photoisomerization to the $Ag_3'$ structural form within a deformable matrix cage, rather than a photodissociation or photoionization process.

## 9. Matrix Effects on the Spectroscopic Properties and Structure of Naked Metal Clusters

As described previously, isomeric forms have been proposed for $Ni_3$[72], $Cr_3$[75], and $FeSn_2$[104] in rare gas solids. Recently, three forms of $Cu_3$ have been identified in solid xenon[60b]. These are significant discoveries because they represent direct experimental evidence that the environment in a rare gas solid can exert a decisive influence on the energetic, dynamic, and structural properties of entrapped molecular metal clusters. Thus, in certain cases it may not be appropriate to directly compare the results of spectroscopic and structural studies of immobilized metal clusters with predictions based on calculations on the corresponding clusters in the gas phase. Of course, a great deal of very useful and interesting information can be obtained from such spectroscopic studies, even if the clusters are significantly perturbed by the matrix support, because such interactions are expected to be of importance in most experiments involving metal clusters, especially those involving chemical or catalytic processes. It is perhaps not surprising that such matrix interactions are important for $Ag_3$ because, on the basis of accurate SCF-CI-MO calculations on the $Ag_3$ molecule, *Basch*[112] has concluded that the energy difference between a linear and strongly bent form of $Ag_3$ is only 0.14 eV (3.2 kcal·mol$^{-1}$). This energy difference is of the same order of magnitude as the spectral shift of the $Ag_3$ absorption bands on changing from argon to xenon matrices, and can be taken as a rough measure of the magnitude of the $Ag_3$-rare gas interaction energy. Similar MO calculations have shown an energy difference of only 0.04 eV between the linear, obtuse, and acute forms of $Cu_3$[137]. Thus, even a weak metal-support effect can exert a significant influence on the energetic, structural, and dynamic properties of entrapped cluster guests. It is thus of paramount importance to evaluate the metal-support interactions for a range of metal clusters in a wide variety of supports.

## 10. Loosely Coupled Groups of Metal Atoms and Clusters

The UV/VIS absorption, fluorescence emission, and excitation spectra of Cu atoms in xenon matrices[115] have recently revealed the existence of a weakly coupled copper dimer ($Cu_2''$) which co-exists with the "normal" diatomic copper molecule ($Cu_2'$) (Fig. 15a). Kinetic and spectroscopic studies (Fig. 15b) have shown that photoexcitation of $Cu_2''$ with visible light induces an irreversible first-order transformation to form the normal dicopper molecule,

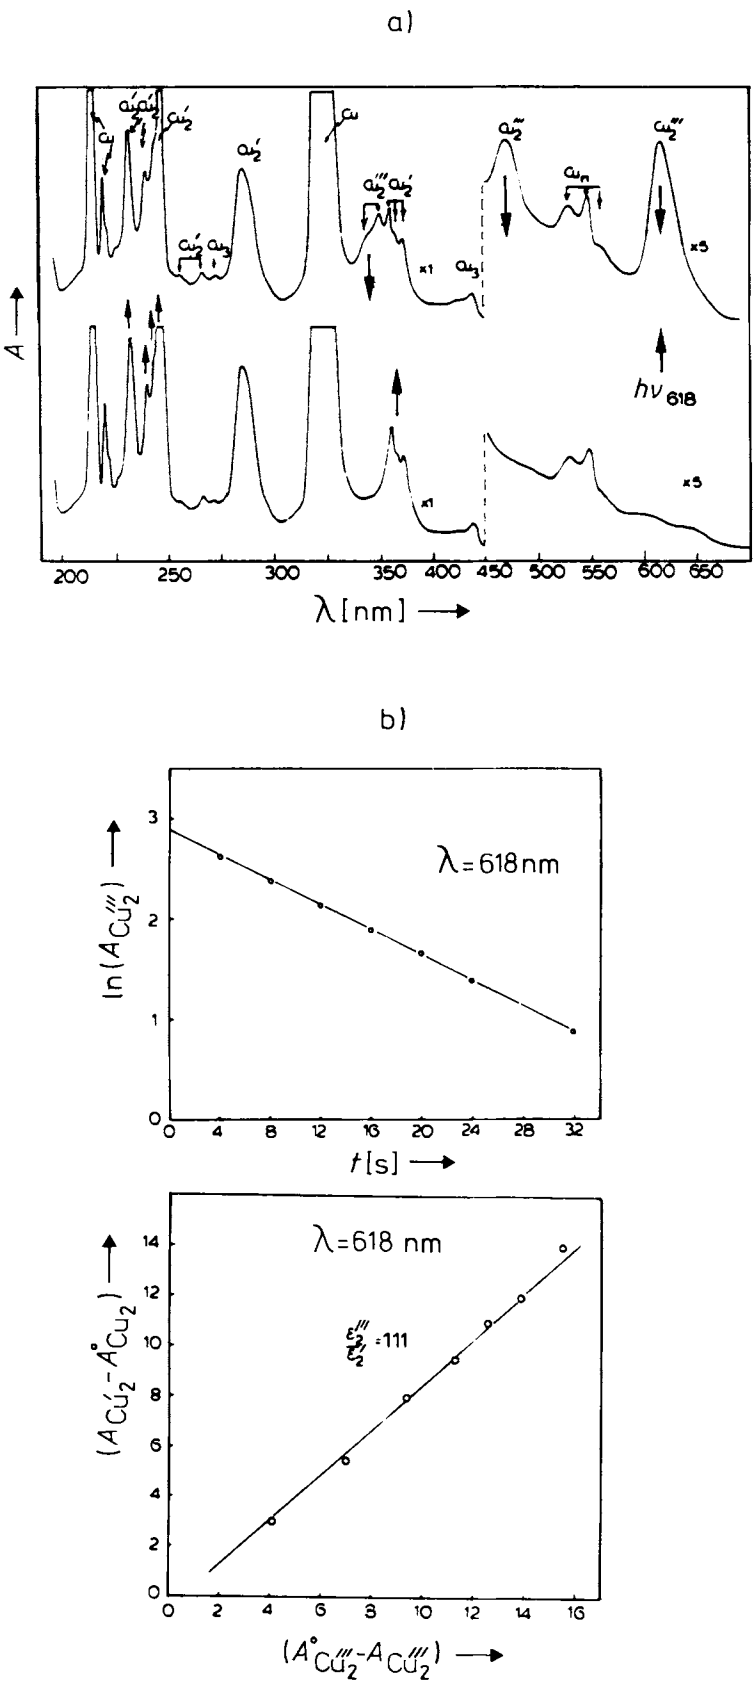


Fig. 15. a) Top: UV/VIS absorption spectrum of Cu/Xe ≈ 1/10$^3$ at 10–12 K; Bottom: Following photoexcitation at 618 nm for 5 min showing photoconversion of the weakly coupled $Cu_2''$ molecule to the normal $Cu_2'$ molecule. Similar effects are observed for the 474 nm absorption of $Cu_2''$.

b) Photoconversion $Cu_2'' \xrightarrow{h\nu(618\,nm)} Cu_2'$ showing well behaved first-order kinetics (top) and direct proportionality to the growth of $Cu_2'$ (bottom). The latter yields a value of the extinction coefficient ratio $\varepsilon_2''/\varepsilon_2'$ of *ca.* 1 [115].

$Cu_2'$. SCF-Xα-SW-MO calculations of the spectroscopic properties of copper dimers, modelled to fit the nearest-neighbor and next nearest-neighbor disubstitutional vacancy sites of solid xenon, were compared with the experimental observations[115]. These calculations suggest that the weakly coupled copper dimer can be considered to have arisen from the trapping and stabilization of copper atoms in next nearest-neighbor disubstitutional vacancy sites as the $D_{4h}$, $Cu_2''''\{Xe\}_{20}$ "cage-complex" (Fig. 16a), which is unique to the xenon lattice and has no detectable counterparts in solid argon or krypton[105]. Photochemical or thermal excitation of $Cu_2''''\{Xe\}_{20}$ binuclear species produces the normal $D_{2h}$, $Cu_2'\{Xe\}_{18}$ dimer (Fig. 16b), containing copper atoms trapped in nearest-neighbor disubstitutional vacancy sites, separated by the gas-phase $Cu_2$ internuclear distance.

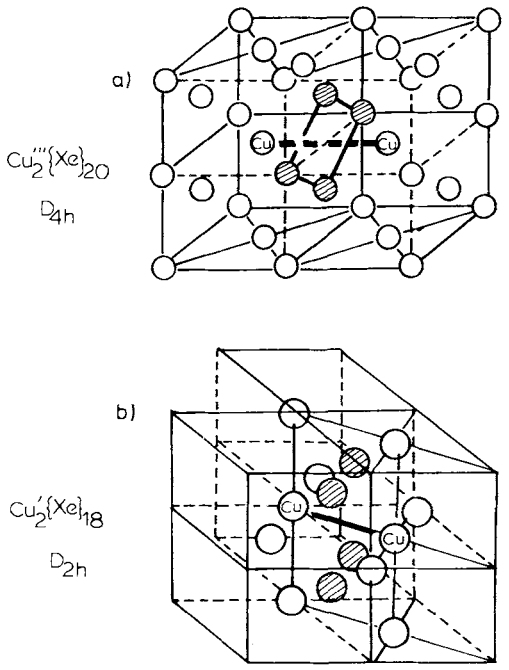

Fig. 16. Illustration of a) the weakly-coupled $D_{4h}$, $Cu_2''''\{Xe\}_{20}$ copper dimer cage-complex and b) the normal $D_{2h}$, $Cu_2'\{Xe\}_{18}$ copper dimer cage-complex, isolated in the fcc lattice of xenon at 12 K [115].

In view of the discovery of weakly coupled copper atom pairs in solid xenon, it is now clear that extreme care must be exercised in analyzing spectroscopic, photochemical and kinetic studies of metal clusters immobilized in weakly and strongly interacting supports. It seems highly likely that unexplained lines and effects observed in the spectra and reactions of entrapped metal clusters, which might have been presumed to originate from metal aggregates bound in a "normal" covalent fashion, may instead arise from loosely coupled groups of metal atoms (and clusters). These concepts should be kept firmly in mind in future work on metal clusters. It is believed that the loosely coupled "cage-complex", $Cu_2''''\{Xe\}_{20}$, may be analogous to the $F_2$ color-center in alkali halides, which comprises two neighboring anionic vacancies, each containing a single trapped electron. The alkali halide $F_2$ color center is well-known and is of considerable interest for broadly tunable, optically pumped, "dye-like", continuous wave, solid-state lasers[116]. Immobilized metal atoms and clusters may, therefore, find an application in lasers in the near future.

## 11. Surface Effects in Raman Spectroscopy (SERS)

Finally, the highly popular but not yet fully understood technique of surface enhanced Raman spectroscopy (SERS) will be briefly examined from the point of view of matrix-isolation metal cluster spectroscopy. Since the first observation of highly intense Raman emissions from adsorbents on rough silver surfaces[113a], many experiments and much theoretical work have been directed towards exploring the origin of the effect. Three recent reviews have been written on the subject[113b]. Two theoretical models appear to have attracted most attention: One involves coupling with surface plasmons, the other considers coupling to localized electronic states induced by chemisorption. Both consider the role played by the size and shape of the adsorbate on the Raman enhancement. Experiments using well-defined single crystal grating surfaces, colloidal metal particles, and molecular metal clusters as model substrates have been designed to evaluate these effects[113b]. Matrix isolation methods are, therefore, useful in evaluating SERS, since the technique of matrix trapping is useful for generating and stabilizing size- and shape-controlled metal agglomerates with dimensions varying from atomic, to molecular, to colloidal, to that of the bulk microcrystal.

Most of the Raman studies of molecules on or near colloidal metal surfaces have involved CO, pyridine, $C_2H_2$, or $C_2H_4$ and silver. These experiments have demonstrated that SERS depends on the excitation of surface plasmons involving only the first layer of adsorbed molecules chemically bonded to the surface. In essence, the excitation profile of the enhancement appears, in a general, to follow the spectral behavior of the surface plasmon. This has been interpreted in terms of a model in which the adsorbent vibrations couple with the conduction-electron surface plasmon mode by charge-transfer between the adsorbent and the metal, synchronous with the vibration[113b].

Recently, Raman enhancement studies due to chemical effects alone have been studied on the silver clusters $Ag_2$ and $Ag_3$ entrapped in rare gas solid films in the presence and absence of pyridine[114a]. Complementary IR studies have also subsequently appeared[114b]. Interestingly, both the ligand and $\nu$(Ag–N) stretching regions were found to be quite similar to those of pyridine chemisorbed on silver electrodes. Although the luminescence of naked silver clusters[106–108, 128] was found to be markedly perturbed by the presence of pyridine, neither the vibration frequencies of the pyridine ring nor those of the $\nu$(Ag–Ag) stretching modes of $Ag_2$ or $Ag_3$[77] were significantly shifted. It would appear, therefore, that the last word has not yet been spoken on the major effects contributing to the surface enhancement mechanism. Nevertheless, matrix isolation of metal cluster and colloidal metal particles, either with or without a reactive ligand, is important for the study of SERS as well as other spectroscopic and chemical phenomena which depend on the nuclearity of the metal[106].

## 12. Limitations and Strengths of the Matrix Isolation Technique

When assessing the spectroscopic data for naked metal clusters embedded in low temperature matrix supports, it is advisable to bear in mind the difficulties involved in generating well defined cluster distributions as well as those characteristics arising from the solid state, both of which can influence, complicate, and confuse spectroscopic analyses.

On the positive side, the matrix isolation method enables high concentrations of metal clusters, even those of refractory metals, to be stabilized in a low temperature environment for leisurely spectroscopic study. As described previously in this article, the technique has been extensively used to investigate a wide range of transition-metal dimers as well as higher uni- and bimetallic clusters. Thermal excitation of low-lying excited electronic states is usually quenched at cryogenic temperatures, thereby simplifying the absorption spectra of metal dimers and clusters compared those expected at the temperatures needed to vaporize the metals. These low temperatures are conducive to detailed rotational analysis of metal clusters in, for example, the collision-free environment of a supersonic molecular beam. However, isolation of the clusters in a solid support generally results in loss of rotational structure, thereby imposing certain limits on the spectroscopic determination of, for example, electronic symmetry species and bond lengths and geometries. On the other hand, these "frozen gas" cluster samples can display pronounced band sharpening, enhancement of vibrational structure and metal isotope bands, as well as a rich hyperfine structure. From this information, the guest can be identified, permitting evaluation of vibrational frequencies; first anharmonicity constants; estimates of bond dissociation energies; and even structural determination of the metal cluster carrier. Furthermore, in an isotropic frozen solid the randomly oriented, rigidly held cluster also permits fruitful exploitation of photoselection techniques and polarization spectroscopy, which have great value for cluster identification and in the assignment of electronic and vibrational symmetry species.

The advantages offered by the "frozen gas" are somewhat offset by loss of some of the finer details of spectroscopic structure due to inhomogeneous broadening and perturbations induced by the matrix host. The latter effects may be manifest as gas to matrix spectral shifts (as much as 1000 $cm^{-1}$, depending on the spectroscopic technique), and as band shape and intensity changes; they generally depend on the host matrix. Effects of this type do, however, carry useful information on guest-host interaction potentials in the ground and excited states of entrapped clusters, which are of increasing interest for studies of metal-support effects important in catalysis.

Splittings of spectral lines can arise from a myriad of solid state and electronic effects; the most commonly encountered being multiple trapping sites, low site symmetries, metal isotopes in natural abundance, crystal field perturbations, phonon, spin-orbit and vibronic coupling, as well as extraneous impurity centers. In many instances, multiple trapping site effects may either arise from different host cage geometries or guest structures or a combination thereof.

A thorough spectroscopic analysis of an immobilized naked metal cluster, therefore, requires a judicious choice of control experiments to assess the importance of matrix perturbations and effects mentioned above. These commonly involve variations of the host substrate, its temperature and of the metal concentration in combination with metal isotope enrichment studies, impurity doping experiments (usually atmospheric and typical high temperature metal source contaminants such as $O_2$, $N_2$, CO, $CO_2$, $CH_4$, and $H_2O$) and possibly photochemical treatment. In this way, authentic band splittings can be distinguished from extraneous matrix effects, thereby greatly enhancing the value of matrix isolation data for the characterization of ligand-free metal clusters.

In the matrix isolation experiment it is important to bear in mind that the identification of metal clusters of specific nuclearity, produced either by co-condensing metal atoms and matrix gases, or by photoaggregating metal atoms in solid matrices, relies heavily on the use of approximate statistical models and nucleation kinetic techniques designed to describe the metal cluster growth processes and resulting metal cluster distributions for a particular set of experimental conditions. (Cluster distributions can be subsequently manipulated by thermal annealing and photochemical methods, and certainly aid in identifying species and in spectral interpretation.) These "indirect" methods for defining metal cluster nuclearity and cluster concentrations are limited to about 1–5 at-% of metal, which is equivalent to a cluster of about six metal atoms. This approach is clearly less straightforward than "direct" mass spectrometric observation of a cluster distribution, as is commonly used in the characterization of gas phase cluster samples. It is worth noting that cryogenic secondary-ion mass spectroscopy (SIMS), recently pioneered by *Michl et al.*, is likely to help in alleviating this particular weakness of the matrix isolation experiment[126]. Clearly, the entrappment of metal clusters in solid supports is not a panacea for the characterization of arrays of metal atoms. Matrix isolation studies have their place together with gas phase molecular beam studies. Useful information can be gleaned from each method, and both are interesting in their own right.

For the matrix trapping experiment one can conclude by saying that when metal and matrix gas depositions are precisely controlled using *in situ* mass monitors, mass flow meters and/or laser interference film thickness devices, a quantitative metal concentration and/or photoaggregation experiment can be used in conjunction with statistical and kinetic cluster growth models to pinpoint, with a fair degree of certainty, the identity and concentration of the metal cluster species present. The increasing number of cryogenic matrix studies of naked metal clusters using different spectroscopic probes, the results of which support each other, attests to the reliability and value of the method and establishes a permanent place and ongoing role for matrix isolation spectroscopy as one of the two methods of choice for understanding the physicochemical properties of ligand-free metal clusters.

## 13. Future Prospects

Over the last few years an impressive array of new synthetic techniques and powerful spectroscopic probes have been applied to the study of ligand-free metal clusters in rare gas matrices. The spectroscopic methods used in these investigations now include ESR, MCD, UPS, EXAFS, XANES, Mössbauer, FT far-IR, Raman, resonance Raman and LIF spectroscopy: A list of acronyms almost as impressive as those found in surface science! These studies are yielding a wealth of new electronic, vibrational, structural and bonding information for what can be regarded as the simplest, yet theoretically most challenging form of metal aggregate. With these kinds of data, the characterization of certain physical and chemical properties of a wide range of metal clusters in different solid supports is now a realistic goal. In conjunction with emerging gas phase data for ligand-free metal clusters, a unique opportunity now exists for assessing the strength of metal-support interactions and for monitoring subtle alterations in electronic charge density and structure at the anchoring site of a supported metal cluster.

Experimental and theoretical breakthroughs that are much needed in the field of ligand-free metal clusters and which one can look forward to in the near future include:

a) The development of new techniques and improvement of existing methods for the size-selective generation of $M_n$ molecules in the gas phase and in the matrix, as well as in solid inorganic and organic supports of relevance to heterogeneous catalysis.
b) The perfection of sources and separation devices for generating well defined, high nuclearity metal clusters ($6 \leqq n \leqq 500$) for elucidating the effect of cluster size on physical properties on proceeding from molecular metal clusters to bulk metals, and to study size effects in small metal clusters.
c) The development of higher sensitivity and better resolved spectroscopic probes for elucidating molecular electronic, geometrical, and bonding details of naked metal clusters in both the gas phase and solid supports; these methods could permit an evaluation of metal-support interactions of great importance in chemisorption and catalytic phenomena.
d) Continuing improvement of molecular electronic structure calculations including configuration, interaction, and relativistic effects of small $M_n$ clusters of the 1st to 3rd transition series. This would develop an interplay with available experimental data, enabling extensions to larger $M_n$ clusters. Calculations of this type are of great interest because they provide ideal test cases of metal-metal bonding free from the complexities introduced by metal-ligand and intraligand bonding.
e) The application of increasingly sophisticated experimental and theoretical methods to the study of precisely defined $M_n$ clusters interacting with ligands of interest in surface chemistry. In this way, the interface between "supercoordinately" unsaturated $M_nL$ complexes and L chemisorbed on the bulk metal can be explored, thereby enhancing our understanding of chemisorption phenomena and, possibly, of surface catalytic processes.
f) More detailed studies of heteronuclear metal aggregates as a function of size and composition. These studies are relevant to bimetallic cluster catalysis, to examinations of the evolution of the chemical and physical properties of bulk alloys from those of molecular "alloy" clusters, and for the study of metal atom components classified in the bulk phase diagram as miscible or immiscible.
g) Further investigations of static and dynamic Jahn-Teller effects of the type observed for $Li_3$, $Na_3$, $K_3$, and $Cu_3$, and predicted theoretically for $Li_3$. Studies of this type are valuable because they contribute to our understanding of potential energy surfaces and the symmetry of the distortions of non-rigid naked metal clusters. They should also serve as a stringent testing ground for relaxation theories of fluxional metal clusters in disparate time scales, and should enable differentiation of localized vibronic ground states with quantum mechanical tunneling from completely fluxional schemes. The concepts derived from studies of fluxional, ligand-free metal clusters of low nuclearity will aid our comprehension of larger non-rigid metal clusters. This in turn is relevant to dynamic effects of metal surfaces, as well as to non-rigidity in other classes of metal clusters containing ligands; for example, carbonylmetal clusters, organometallic complexes containing multiple metal-metal bonds, and compounds containing metal-metal bonds involving metals in high oxidation states.

*Financial assistance from the Natural Sciences and Engineering Research Council of Canada's Strategic Energy Programme, and a Special Research Grant from the Connaught Foundation of the University of Toronto are both greatly appreciated. S. A. M. acknowledges NSERC and Noranda for graduate scholarships at various times during his research at the University of Toronto. We should like to express our gratitude to V. E. Bondybey, P. A. Montano, R. Grinter, J. A. Howard, D. M. Lindsay, A. Kaldor, and R. E. Smalley for helpful comments on this manuscript and for preprints of their recent research in this field.*

# Turgorins, Hormones of the Endogeneous Daily Rhythms of Higher Organized Plants— Detection, Isolation, Structure, Synthesis, and Activity**

By Hermann Schildknecht*

*Dedicated to Professor Adolf Butenandt on the occasion of his 80th birthday*

Probably the most fascinating biological phenomenon is the movement which is so impressively observed in higher organized plants when, *e.g.*, in a sort of "quick retreat", the sensitive plant apparently vanishes on touching, or when all the pinnules of an acacia fold together pairwise at dusk, as though the whole tree were going to "sleep". Such plants and trees do not possess muscles for the movement of their organs; instead of the contraction of a "still primitive" actomyosin system, in this movement the hydrostatic internal pressure of the vacuoles—the turgor—in the parenchymal cells of the motile organs is often drastically and unilaterally reduced. After preception of an external stimulus there follows a gradual or sudden change in the semipermeability of the boundary plasma layers, and, mediated by a stimulus conduction, also of all the symplasts of a multicellular plant organism. The phytohormones which form the molecular basis of the physiology of movement discussed here have now been isolated and structurally elucidated. The chemical agonists of phytodynamics, referred to as turgorins, elicit leaf movement; moreover, they very probably also regulate—perhaps together with other phytohormones—the mechanism of change of aperture in stomatal transpiration. Hence, the turgorins facilitate not only a regulation of temperature, but even their own transport in the sap of the whole plant body.

## 1. Introduction

*Alexander the Great,* amidst all military enterprises, paid great regard to the spread of civilization by the furtherance of literary and scientific research. During his campaigns to subjugate the Persian empire—a task left to him by his father, *Philip of Macedon*—he ordered his generals on their respective expeditions to carefully record the local "histories", *i.e.* to write accounts of the flora and fauna *etc.* at the places they visited—or the "ιστορίαι" as they were called by the Ionians some centuries previously. Afterwards, all these records were collected in the imperial archive at Babylon, intended by Alexander to be the principal city on the founding of the new empire. It was here also that compedia important for the learned world were prepared which later stimulated *Theophrastus* to write his excellent "Plant Geography"[2], in which he comprehensively and expertly compiled the botanical accounts of Alexander the Great's expeditions, and outlined for the first time the "physiognomy" and "behavior" of all the flora of the orient. *Theophrastus* paid particular attention to the trees bearing pinnate leaves—with their scanty shade—and described these with the word τό πτερυγῶδες[3].

*Mimosa asperata L.*, the sensitive plant of the Ancients, has leaves of the same shape—even twofold, *i.e.* bipinnate leaves. As *Theophrastus* aptly said, "...and it is thus possible for the wonderful Mimosa of Memphis to collapse on being touched—it wilts! But after a while it recovers in all its grandeur"[4].

Thus, *Theophrastus* had for the very first time described plant mimicry, further examples of which have since been found in the orchids and the insect attracting plants[5].

That even the ancient Greeks, who are known to have been excellent observers, associated the closing and opening of leaves with the relaxation of cell pressure—of the turgor—and renewed tension of the cell sap is borne out by the expression "ἀφαυαινόμενα" (dying or parched with thirst)[4].

From this pre-Christian era to the present the sensitive plant has been the object of investigation and experiment for generations of naturalists of the western world, who have hoped to throw light on the phenomenon of the turgor movement of fixed plants.

## 2. Ecological Plant Physiology

The objective of this relatively young scientific discipline[6] is to explain the existence of a plant and its adaptation to the environment in physiological and biological terms in such a way that all aspects, even at the molecular level, are taken into account, and thus, in particular, that the *active principles* of "chemical plant ecology" are taken into consideration.

It is now known that the growth and development processes of higher plants are influenced by photohormones[7]. Like the hormones in human and animal organisms they can be formed in certain tissues and then translocated to the active centers, *i.e.* to the target organs. But this is not always so. There are several examples where the so-called

[*] Prof. Dr. H. Schildknecht

[**] Plant Defense Substances, Part 21.—Part 20: [56].

 © *Verlag Chemie GmbH, 6940 Weinheim, 1983* *0570-0833/83/0909-0695 $ 02.50/0* 

hormones are also active "on the spot", *i.e.* where they are released. One could compare such "tissue hormones" with the prostaglandins of the animal organism. However, because of the ambiguity of the term hormone, it would be incorrect to designate these phytohormones as effectors, since this would include herbicides, which can also react hormonally but do not occur in nature, as *e.g.* the synthetic growth regulator 2,4-dichlorophenoxyacetic acid.

### 2.1. Phytohormones

Unlike the animal hormones, plant hormones are less specific, and many physiological processes are influenced at one and the same time by several hormones. For an overview of the complex hormonal system of higher plants one distinguishes four important classes of hormones on the basis of their structure and activity, namely the auxins, gibberellins, cytokinins, and abscisins (cf. Table 5). Aside from these, however, the chemically most simple growth factor, ethylene, must also be mentioned. Ethylene occupies a special position insofar as it not only influences growth processes but also the germination of seeds, the formation of buds, flowers, and roots, and the ripening of fruit—in intimate interaction with the aforementioned hormones.

All phytohormones have a common physiological property: they act on and *via* plasma membranes. This holds true in particular for the hormones responsible for the rapid movement of fixed plants; the chemical structure of these hormones was, however, unknown until just a few years ago. This is virtually unbelievable when one considers that their activity has been known for centuries.

### 2.2. Phytodynamics

According to the historian *Julius Sachs*[8], the climax in the development of phytodynamics was reached with "A treatise by Ernst Wilhelm Brücke on the movement of mimosa leaves (1848), which has become an accepted model for all further investigations in this field". Methodologically important for an explanation of the phytodynamics involved in plant movement was a clear interpretation of the potential set up between the vascular bundle and the turgescent parenchymal sheath, and ascription of the periodically stimulated movements to movement of water in the parenchyma.

The movements observed in fixed higher plants can only arise by movement of water and the accompanying changes in pressure in the motile organs, since the muscular system typically found in animals is missing.

Actually, contractile proteins have been isolated from motile organs[9], but these do not exhibit the same biochemical properties as the proteins isolated from muscles. Also our attempts[10] to detect cytochemically contractile elements with fluorescein-stained phalloidin and cytochalasin B using the method of *Th. Wieland et al.*[11] gave inconclusive results, probably because the reagents are unable to penetrate into the plant cells.

There are thus osmotic forces which lead to the plant turgor- or variation-movements through changes in cell turgidity.

#### 2.2.1. *Turgor Movements*

An increase or decrease of the turgor alone leads to shortening or lengthening of the cells, *i.e.* to cell movement. In fact, the turgor merely needs to change on one side of an organ to bring about movement. In stomatal movement, which is vital for plant life, an increase of turgor leads to flexion, a decrease of turgor to stretching of the guard cells.

Visible leaf movements have been and still are of special importance for studies on the physiology of plant movements. Such movements are made possible through pulvini or leaf joints (hinge effect), whose anatomical structure determines the pattern of movement—independently of the stimulus direction. In this case one speaks of a nastic movement, which is variously designated depending upon the type of stimulus triggering the movement: seismonastic (shaking), thigmonastic (touching), traumatonastic (wounding), photonastic (light), and thermonastic (heat).

#### 2.2.2. *The Pulvinus—The Motor Organ of Leaf Movements*

After *Brücke* had recognized[12] that the movement of the leaf's joints—the pulvini (cf. Figs. 3 and 4)—was caused by a change of turgor, the observed relaxation of the highly turgescent abaxial and adaxial motile tissue by exudation of cell fluid into the intercellular space prior to the movement was explained[13]. The sudden loss of turgor in all excitable cells of the pulvinus causes a measurable shortening of the thin-walled abaxial motor tissue. The essentially thicker adaxial tissue, on the other hand, hardly experiences any change in length and functions as a sort of hinge joint[14] (cf. Fig. 4).

On the *Physiology of the Motile Cells in the Pulvini:* The motile cells contain a tannin vacuole and a central vacuole[15]. During movement, *i.e.* change of shape of the two vacuoles, a migration of $Ca^{2+}$ takes place[16]. At the same time large amounts of $K^+$ and $Cl^-$ ions are released into the intercellular space and give rise to an action potential[17]. In the following reconstitution phase the tannin vacuole assumes its original spherical shape. The refractory period for the rest potential lies between 2 and 3 minutes[14], while up to 20 minutes can elapse before the pulvini have regained their normal daily position.

As long ago as 1912, *Pfeffer* proposed that rapid loss of turgor is caused by an active contraction of the protoplasts, coupled with a simultaneous increase in membrane permeability. Several authors have therefore tried to demonstrate a participation of the ATP-ATPase system in leaf movement after the fashion of muscle contraction in animals[19]. *Driessche*[20] observed a closing of the pinnules on application of mersalyl, an ATPase blocking agent, to opened primary leaves. This rather indicates, however, an energy-consuming system, which is necessary for the maintenance of the turgor and, thus, of the opened daily position.

#### 2.2.3. *Stimulus Conduction in* Mimosa pudica L.

The mechanism of rapid stimulus conduction is still a controversial topic in Mimosa research.

As already pointed out, differences in the turgor between guard cells and their companion cells determine the degree of opening or the aperture of the stomata. One may assume that turgor differences propagate in vast dimensions. Thus, even before the turn of the century it was assumed by various authors[21] that the stimulus, in the form of a change of pressure in a network of "tube cells"[22] traversing the phloem[*], is transmitted throughout the whole plant body. However, this theory became untenable following the experiment carried out by *Macdougal*[42], who connected the basal ends of cut shoots to a pressure pump and observed no reaction at all on suddenly changing the pressure.

As the electrophysiologist *Bose*[23] of Calcutta showed—when experimenting with *M. pudica L.* and other sensitive and non-sensitive plants—the propagation of differences in electric potential is a further possibility for communication between cells or organs. *Bose* found that the irritation is accompanied by an action potential, which is rapidly transmitted through stem and leaf stalk. He thus came to the conclusion that the stimulus is transmitted through plants in the same way as it is in the animal nervous system.

*Ricca*'s stimulus conduction theory for the transport of a "wound hormone" in the transpirational stream came under violent attack. *Herbert*[24] observed stimulus conduction in a primary leaf stalk, even though he had severed the xylem[*]; hence, the stimulus must have passed through the still intact phloem.

Even as early as 1908 *Linsbauer*[25] had been able to measure various rates of conduction on changing the intensity and type of stimulus; some rates even reached an order of magnitude of 10—40 cm/s. These values were later confirmed in further electrophysiological investigations carried out by *Bose*[23,26] and *Umrath*[27]. *Snow*[28,29], who determined the rates of chemonastic stimulus conduction with stained mimosa extracts, quoted highest values of 8 to 20 cm/min.

*Houwink* was undoubtedly the first to attempt to combine the chemical and electrical conduction of stimuli (chemo-electric sensory transduction)[30]. He found two sorts of stimulus conduction: a very rapid single action flow, which cannot continue in dead parts of tissue, and a stimulus flow, with a much slower rate, which even traverses dead zones of tissue. He called the latter "variation".

*Sibaoka*[31] confirmed the different rates of stimulus conduction and designated them the s-wave (slow wave, a few mm/s), the m-wave (middle wave, 5—40 mm/s), and the r-wave, already recognized by *Houwink* (r = rapid, 60 mm/s). It was also *Houwink* who described stimulus conduction in the following way: The stimulant transported in the xylem sap stream elicits a response in the neighboring tissue in the form of a variation potential (s-wave). Either the signal substance itself or the variation potential generated by it triggers a rapid action potential (m- or r-wave), which can travel ahead of the slower variation potential.

[*] The phloem is the sieve part, the xylem the woody part of the vascular bundle.

## 3. The Sleep Movements of Plants

Perhaps the most wondrous observation ever made in plant physiology was that by Alexander the Great's admiral, *Androsthenes* of Thasos, on the Bahrein island Tylos in 325 BC: He noticed the nyctitropic movements of the pinnules of *Tamarindus indica L.* (Fig. 1)[32]. *Androsthenes* was deeply impressed by the fact that even plants can move, and, even more so, by the observation that the pinnate leaves of a large tree, directed by some still unknown inner life, can gently fold together from dusk until dawn, such that one can say that the tree sleeps: καθεύδει.

Fig. 1. *Tamarindus indica L.* during the day (left) and at night (right).

When *Androsthenes,* like his predecessor *Archias of Pella,* decided not to attempt circumnavigation of the treacherous, surf buffeted Cape Musandam and nearby dangerous rocky islands in the Persian Gulf with a thirty-oar galley, he instead examined, with outstanding scientific interest, the flora of an until then unknown coast in the wonderland of Arabia. For two thousand years, his report remained the sole scientific record of the flora of this paradisaic group of islands. Unfortunately, the original report was lost at a very early date, but we find an excellent transcript of it in *Theophrastus'* Plant Geography[4].

*Androsthenes* outlined the daily periodic movement of the pinnate leaves of the tamarind in their four stages so masterfully that his description of this plant movement phenomenon has never been surpassed. It is the first documentary record of plant sleep, which only some two thousand years later was to become generally known through the behavior of *M. pudica L.,* when, fittingly enough, the astronomer *de Mairan* in 1729 observed that the daily periodic movements of leaves do not implicitly comply with changes in daylight.

### 3.1. The Physiological Clock

As *de Mairan* found out by experiment, the sensitive plant *M. pudica L.* closes and opens its pinnules at the usual time, even in continuous darkness. According to a communique by *du Fay*[33] in the Histoire de L'Academie Royal des Sciences Paris, "The sensitive feel the sun even without seeing it". And thus, the "inner clock" of the plant

kingdom was "brought to light"; the regular rotation of our planet in the course of evolution has so impressed itself upon plants that its day-night rhythm, now inherited by them, is autonomously simulated.

30 years later, in 1759, *Zinn*[34], with his experiments on the bean, and then, in 1832, *de Condolle*[35] with his experiments on *Mimosa, Oxalis,* and *Phaseolus,* confirmed that periodic leaf movements can also take place in continous daylight. The interest of almost all eminent plant physiologists of the second half of the nineteenth century—*Darwin, Dutrochet, Hofmeister, Sachs,* and *Pfeffer*[8]—was now aroused in the patterns of motion of pinnate leaves. These scientists were concerned with how movements were executed, but also with why they existed and what caused their periodicity.

It was to be expected that this basic research work would also lead to discoveries of fundamental importance. Thus, in his experiments on the sensitivity of mimosa leaves, *Pfeffer* discovered that a "remarkably high hydrostatic pressure was involved", and this prompted him to explore the physical causes of such a phenomenon, which he outlined in his famous "Osmotic Studies" in 1877. Even the very first of *Pfeffer*'s models of the cell, never missing in elementary scientific lectures, subsequently formed the basis of *van't Hoffs* theory of solutions.

#### *3.1.1. Circadian Rhythms*

"Circadian rhythms" was the expression suggested by *Halberg*[36] to define the endogenous or autonomous daily rhythms of plants, for these rhythms are observed to continue under constant conditions, especially constant temperature, in continuous light or continuous darkness, but with a periodicity of only approximately 24 hours (*circa* = approximately, *diem* = day; hence circadian).

Interest in these rhythms has increased tremendously in the last few years, since it was recognized that the phenomena are of importance not only in biology. Numerous biological observations of such rhythms have been made, as can be gathered from the book "Die physiologische Uhr" by *Bünning,* one of the pioneers in this field[37]. However, the final active principle of endogenous rhythms remains, as before, unknown.

### 3.2. Endogenous Chemonasty

When *Linné* in 1755 was studying the periodic movement of leaves it sufficed him when describing this phenomenon, which he observed in numerous types of plants, to call it simply "plant sleep". *Pfeffer* in 1875 summed up the same phenomena under the heading "nyctinasty" and suggested that "even chemical stimuli play a prominent role in the autoregulatory control of internal sensory transmission and, thus, also of autonomous (endogenous) movement". His tutor, *Sachs,* had already surmised the participation of "internal factors" in visible plant rhythms as early as 1863. We may therefore speak of an "endogenous chemonasty" when a movement, uninfluenced in its direction, is induced by active principles that are generated in the plant itself.

This gave us very good reason some 30 years ago to search for the presumed endogenous active principle—later designated as the "Leaf Movement Factor" (LMF)—or perhaps even a new phytohormone. Such active principles could possibly be the chemical initiators of many plant movements.

#### *3.2.1. Bioassay of the Active Principles of Seismonasty and Nyctinasty*

It was *Ricca*[38], who in 1916 first attempted to detect stimulants in *Mimosa pudica L.* in his well-known glass tube experiments. He connected the two parts of a cut shoot of mimosa *via* a small glass tube filled with a salt solution or water. According to *Ricca* a stimulation of one part of the shoot is transduced and conducted as stimulant through the solution and into the other part of the shoot, where it triggers the well-known movement reaction of the pinnules.

We have repeatedly tried over the past ten years to reproduce *Ricca*'s pioneering experiment, but have never met with success. However, the glass tube experiment at least served as a model for a bioassay of turgor active movement factors which is still in use today. From the point of view of a natural products chemist it cannot be overemphasized that the demonstration of an active principle is characteristically influenced by the choice of bioassay. Nature is being interrogated—sometimes in a biased way—and the sort of answer we get is already asserted by the disposition of a given object in the test. Moreover, as quoted by *Dörfflings*[7], "hormones are chemical signals to which the living system responds in various ways depending on the disposition of the system or depending on how strong the signal is or from which direction it comes". We believe that the bioassay chosen by us, *i.e.* the bioassay of a single leaf, enables one to detect the sought after phytohormones with regards to function just as well if not better than with a whole plant. Two criteria important for the hormone activity are combined—transport to the target organ and visible triggering of the physiological effect at the target organ.

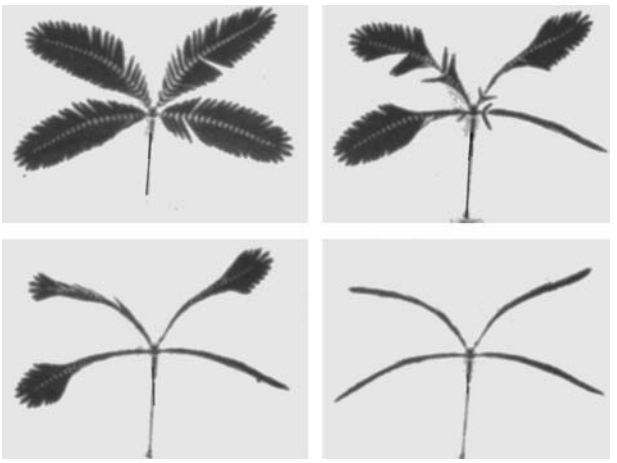

Fig. 2. Bioassay for the detection of turgor active phytohormones. The supposed active principle is placed in a small glass vase and is drawn up by the rachis of the *M. pudica L.* leaf. After a short time the pinnules fold together.

When a leaf is separated from the mimosa plant, and, after restoration, is placed in a solution of the supposed active principle (Fig. 2), the sap stream, influenced to some extent by the external temperature and pressure, transports the phytohormone to the active site, *i.e.* to the pulvini, where (Fig. 3) the biomembranes respond so strongly that each pair of pinnules rapidly fold up through visible turgor changes until the whole leaf has assumed the typical irritated posture.

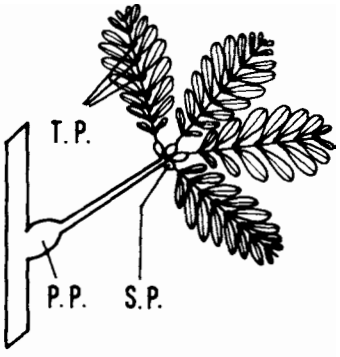

Fig. 3. Schematic drawing of a mimosa leaf showing the primary (P.P.), secondary (S.P.) and tertiary pulvini (T.P.).

The primary as well as the tertiary pulvini are irritated by these substances. The response of the primary pulvinus is manifested by a drooping of the whole leaf stalk (Fig. 4). We have also observed that the pulvini usually react one after the other corresponding to their position and the acropetal progress of the chemonastic stimulus (cf. Fig. 5 and 6). The dilution at which the stimulatory action is still evident may be regarded as a further criterium for the hormonal character of the irritant. As long ago as 1936 *Fitting* reported[39] that an extract of 1 g fresh mimosa leaves, dissolved in 500 g, or even in 5000 g of water under optimal conditions, triggers the specific mimosa reaction in the leaf-test. Accordingly, the movements recognizable in the test are by no means the result of an all-or-nothing reaction; *Fitting* actually reported a usable relationship between strength of stimulus and response. In the movement reactions observed by us we have even demonstrated a quantitative relationship between degree of stimulation and response. On recording a dose-response curve (Fig. 7)

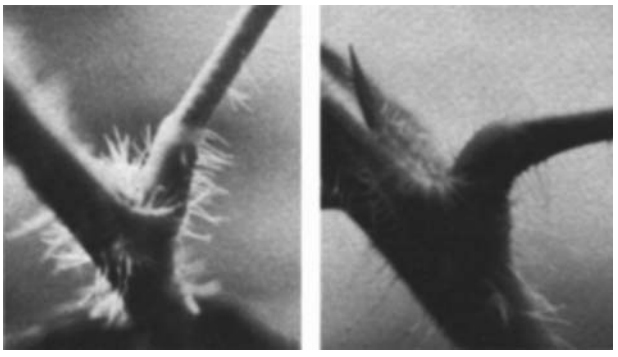

Fig. 4. Primary pulvinus on a mimosa shoot, before (left) and after (right) irritation.

Fig. 5. Test situation with a mimosa shoot

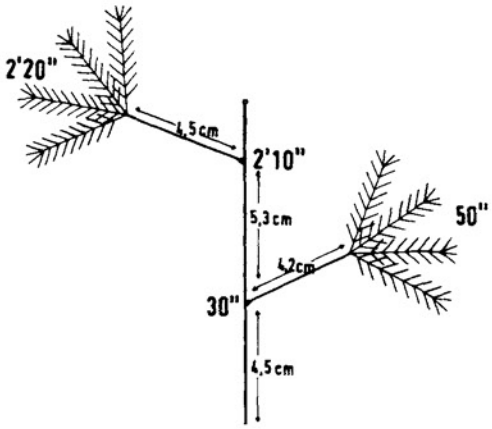

Fig. 6. Rate of stimulus conduction in a leafed shoot of *M. pudica L.* after a chemonastic irritation.

we were able to confirm the hyperbolic dependence of the response time on the concentration of mimosa extract reported by *Sibaoka*[40], and have successfully applied it to the control of fractionation and enrichment in the isolation of the natural product. The exposure time of the pinnate

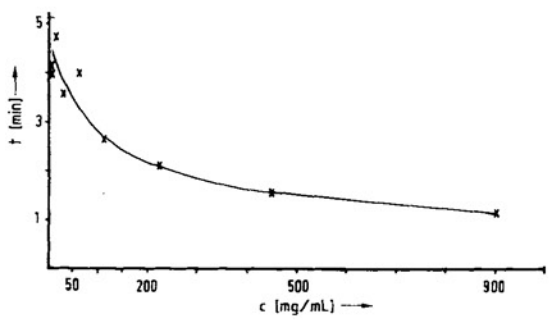

Fig. 7. Dose-response curve of a crude extract of *M. pudica L*

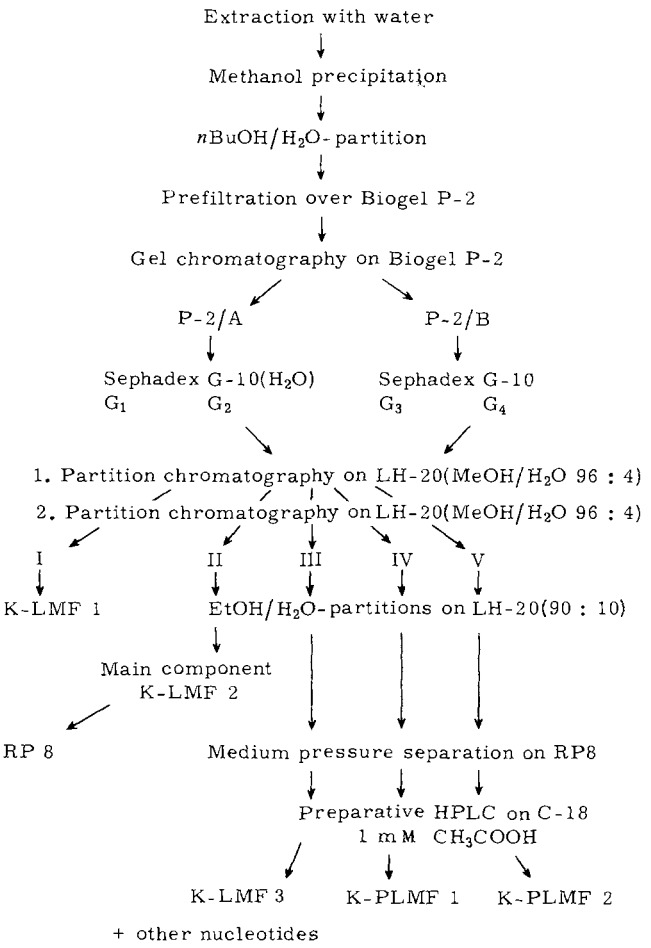
leaves is often several minutes, so that the recorded curve not only reflects the intensity of the stimulation but also the duration of activity (amount of stimulation = intensity × time)[41].

### 3.2.2. *The First Irritants from M. pudica L.*

*Umrath*[27] was the first to point out that the same class of chemical compounds occur in several types of mimosaceae active principles. *Fitting*[43] tested more than 1000 substances regarding their chemonastic activity in the sensitive plant. His most important finding was that some amino acids and anthraquinone derivatives are stimulative down to a concentration of $10^{-3}$ to $10^{-4}$ mol/L, while a mimosa extract is still active at a dilution of 1:5000.

Despite extensive attempts at purification, the results of *Fitting*[39] as well as those of *Soltys* and *Umrath et al.*[44] were only modestly informative: the supposed active principle had to be a "perhaps nitrogen-containing, and probably monobasic oxyacid with a molecular weight of between 300 and 500". Resigned, *Fitting* remarked, "further efforts to isolate the mimosa hormone in pure form must, in my opinion, be carried out by chemists, for they alone have the appropriate aids at their command and can master the modern methods of separation that are obviously required"[39].



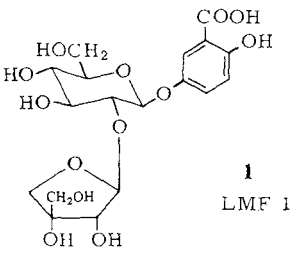
The challenge was accepted. But progress was slow, and it was not until 1980 that the supposed phytohormones could be isolated in pure form by highly developed Tswett column chromatography and their structures elucidated by modern instrumental techniques of analysis.

## 4. Leaf Movement Factors (LMFs)

When a plant with pinnate leaves exhibits the abovementioned "sleep movement", and its pinnules are joined to the stalk by pulvini, the leaf extract will most certainly react chemonastically in the aforementioned bioassay. This holds true especially in the case of acacia plants, even though they may only react nyctinastically and not seismonastically.

The South African plant *Acacia karroo* is not "sensitive", but even it folds its leaves together pairwise when it reacts nyctinastically, or even only thermonastically; and it then looks just like a "sleeping" mimosa plant (Fig. 8).

After having collected convincing evidence that the hormones found in the mimosa plant also occur in the extract from *A. karroo*[45,46]—and probably in substantially higher concentration than in the mimosa—we concentrated our efforts on developing a method of separation which would ensure isolation of the active substances in pure form (cf. Scheme 1)[46].

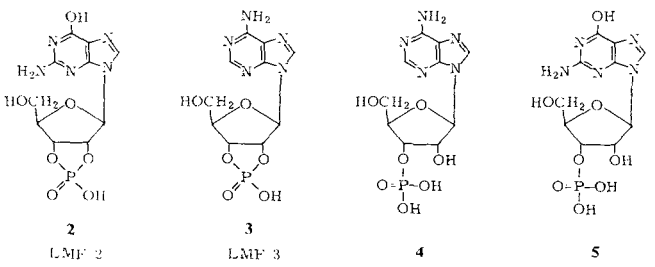


Scheme 1. Separation process for isolation of the chemonastically active hormones from *Acacia karroo* (cf. Figs. 9 and 10). Separation by medium pressure reverse phase chromatography.

Fig. 8. *A. karroo*; the pinnate leaves of one branch are partly irritated thermonastically (Stellenbosch, South Africa).

The results obtained on using this multistep and painstaking method of separation confirm that the complex phenomenon of movement in plants involves a chain of stimuli with participation of various active substances. On working up the crude extract from *A. karroo* we obtained five, almost pure, active fractions (I to V). However, despite the high degree of purity, on further chromatographic separation only substances of limited activity could be isolated, apart from the much more highly active factors K-PLMF 1 and 2.

We should only mention here the Leaf Movement Factor isolated from *M. pudica L.* (M-LMF 1) **1** and its synthesis[47,48], for we are still unable to state its position in a chain of stimuli, even though we have isolated it again as K-LMF1 from *A. karroo*.



1
LMF 1

### 4.1. Nucleotides as Leaf Movement Cofactors

On purifying a dry crude extract from 4.5 kg of *M. pudica L.* by dissolution/precipitation with methanol, ion-exchange chromatography and filtration over polyacrylamide we obtained a solution of active substances free of amino acids, from which, after further purification by chromatography on Sephadex LH 20, we were able to isolate crystalline M-LMF 2 and 3[49]. Preliminary analysis of these active substances pointed to cyclic nucleotides, which were first detected in plant tissue only a few years ago. This finding called for an intensive spectroscopic analysis of the substances. The absorption maxima at 254 and 275 nm and the positive Cotton effect already showed M-LMF 2 to be a guanosine derivative, which was identified by a detailed IR investigation and PFT-$^1$H-NMR spectroscopy as 2',3'-guanosine cyclomonophosphate **2**. M-LMF 3 correspondingly proved to be 2',3'-adenosine cyclomonophosphate **3**. From a highly active fraction obtained on separation of the *A. karroo* extract (cf. Scheme 1) we isolated the pure substances K-LMF 2 and 3. On the basis of their $^1$H-NMR spectra alone it was evident that these were the same cyclic nucleotides found in *M. pudica L.*

An extended and thorough analysis of all movement factors, *i.e.* also of cofactors, revealed two further nucleotides in the region typical for the above nucleotides (HPLC), which according to the UV, IR, and $^1$H-NMR spectra could only be 3'-adenosine monophosphate **4** and 3'-guanosine monophosphate **5** (cf. Table 1).

2 LMF 2 | 3 LMF 3 | 4 | 5

Table 1. Comparison of the retention times (HPLC) of the nucleotides from *M. pudica L.* and *A. karroo*. Column: 25 × 0.8 cm, Nucleosil C-18, 5 μm, 1 mM $CH_3COOH$, 165 bar, 5 mL/min. UV: $\lambda = 254$ nm.

| | Nucleotides | Authentic substances $t_r$ [min] | *M. pudica* | *A. karroo* |
|---|---|---|---|---|
| 3 | 2',3'-cAMP | 10.3 | 10.4 | 10.3 |
| 4 | 3'-AMP | 8.6 | 8.7 | 8.7 |
| 2 | 2',3'-cGMP | 4.25 | 4.3 | 4.3 |
| 5 | 3'-GMP | 3.6 | 3.65 | 3.6 |

### 4.2. Periodic Leaf Movement Factors (PLMFs) from *A. karroo* (K-PLMF)

The latter-mentioned components found in a mixture of active principles of the nyctinastically reacting African plant *A. karroo* flank factors which in purest form are also chemonastically active. We have designated them as Periodic Leaf Movement Factors (PLMF), so as to point out, using the same nomenclature, that they are the endogenous factors of the daily periodic leaf movements—of a plant not irritable by touching or shaking.

As shown in Scheme 1, the fractions I to V obtained by partition chromatography led, on further separation by medium pressure reverse phase chromatography, to the factors K-PLMF 1 and 2 in almost pure form. However, without any impurities K-PLMF 1, *e.g.*, can only be isolated by HPLC on C-18-alkylated silica gel (cf. Fig. 9).

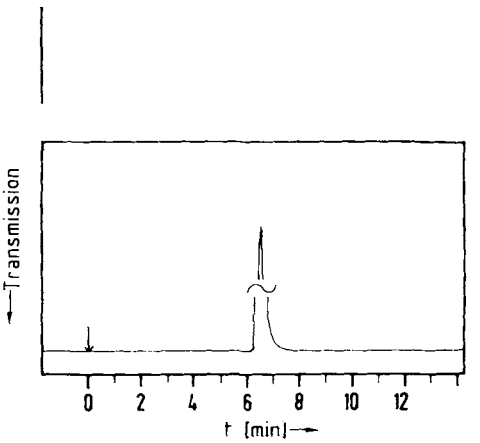


Fig. 9. HPLC diagram of K-PLMF 1 on Nucleosil C-18, 5 μm; column 25 × 0.8 cm, 1 mM $CH_3COOH$, 165 bar, 5 mL/min. Ordinate: transmission at $\lambda = 210$ nm.

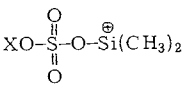
#### *4.2.1. Structure Analysis of K-PLMF 1 and 2*



The first relevant information on the structure of these factors was provided by the UV absorption spectrum, which indicated the presence of a gallic acid derivative. The analysis of barely visible amounts of the active principle with a high resolution mass spectrometer confirmed the presence of gallic acid by virtue of the recorded $m/z$ values 79, 107, 125, 126, 153, and 170. Of special significance, however, was the fragment $m/z = 63.9609$—which corresponds to the $SO_2^+$ ion—since this is the first time that an $SO_2$-group has been detected in a molecule of active principle, alongside glucose and the aforementioned aglycone (cf. Table 2).

An extensive mass spectrometric analysis of the trimethylsilyl derivative of K-PLMF 1 provided a clear insight into its structure (cf. Fig. 10). The replacement of the organic sulfate by the derivatizing agent was especially informative.

The fragment with $m/z = 227.0229$ (standard deviation 0.8 mmu) contains a complete sulfate group. In this connection the fragment with $m/z = 573.2371$ ($C_{24}H_{45}O_7Si_4$) is of special interest, since it indicates presence of a free carboxy group in the molecule.

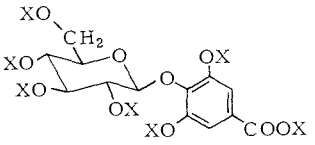


Table 2. Mass spectrometry of K-PLMF 1. Direct inlet, sample temperature 300 °C, ZAB 2F high resolution mass spectrometer.

| *m/z* | Exact mass | Elemental composition | Standard deviation (mmu) |
|---|---|---|---|
| 64 | 63.9609 | $SO_2$ | +1.0 |
| 79 | 79.0178 | $C_5H_3O$ | +0.6 |
| 80 | 80.0266 | $C_5H_4O$ | −0.4 |
| 95 | 95.0105 | $C_5H_3O_2$ | +2.8 |
| 97 | 97.0276 | $C_5H_5O_2$ | +1.3 |
| 107 | 107.0131 | $C_6H_3O_2$ | +0.2 |
| 108 | 108.0219 | $C_6H_4O_2$ | −0.8 |
| 110 | 110.0371 | $C_6H_6O_2$ | −0.3 |
| 125 | 125.0242 | $C_6H_5O_3$ | −0.3 |
| 126 | 126.0337 | $C_6H_6O_3$ | −2.0 |
| 153 | 153.0199 | $C_7H_5O_4$ | −1.1 |

*M* 836

alcohols. We thus had indication of a sugar sulfate, which, however, was first detected by FAB (fast atomic bombardment) mass spectrometry with negative ions[50]. The key fragment $m/z = 411$ (Fig. 11) points to the presumed sulfate of a gallic acid glucoside, the fragment $m/z = 241$ to the glucose sulfate moiety, and the fragment $m/z = 169$ to gallic acid. Such fragments are not found in an FAB spectrum of a mixture of glucose and potassium hydrogen sulfate.

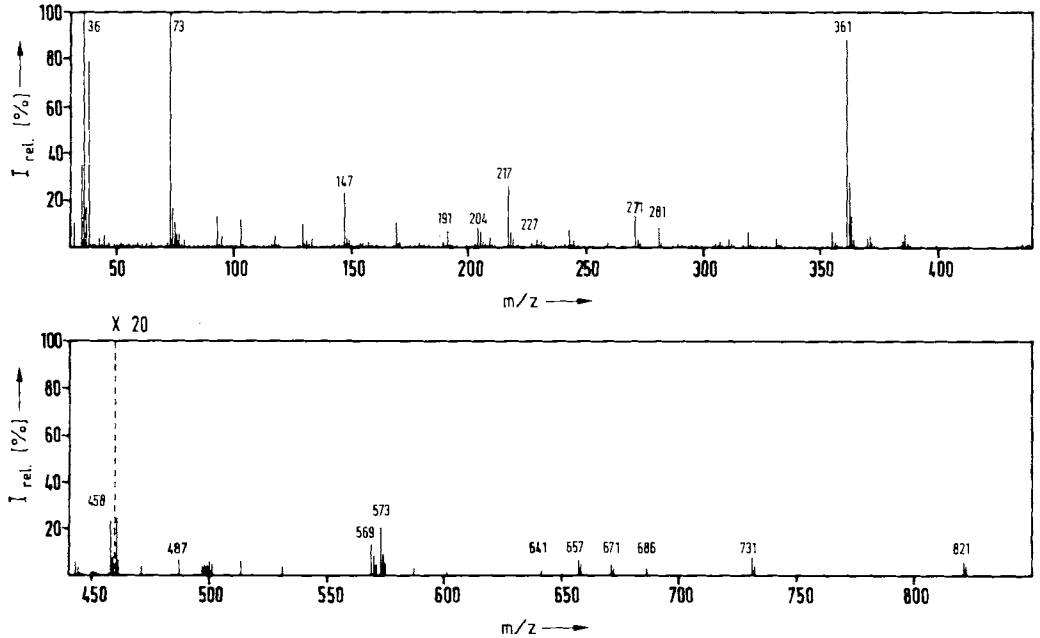

Fig. 10. EI mass spectrum of persilylated K-PLMF 1; direct inlet.

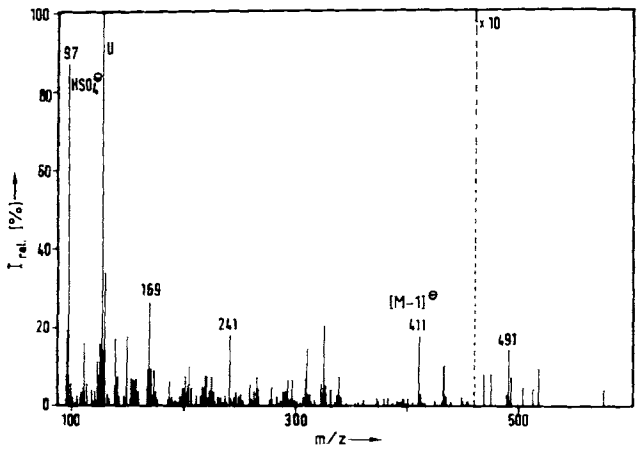
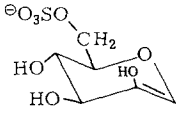
Consistent with the mass spectrometric finding, the IR absorption spectrum of K-PLMF 1 shows a band at 1284 $cm^{-1}$ for an S=O stretching vibration and one at 818 $cm^{-1}$ (γC–O–S), which is characteristic for sulfates of primary





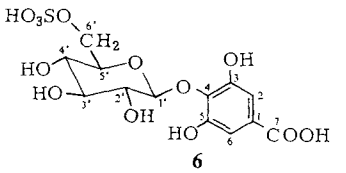


Fig. 11. FAB mass spectrum of K-PLMF 1, obtained with negative ions.

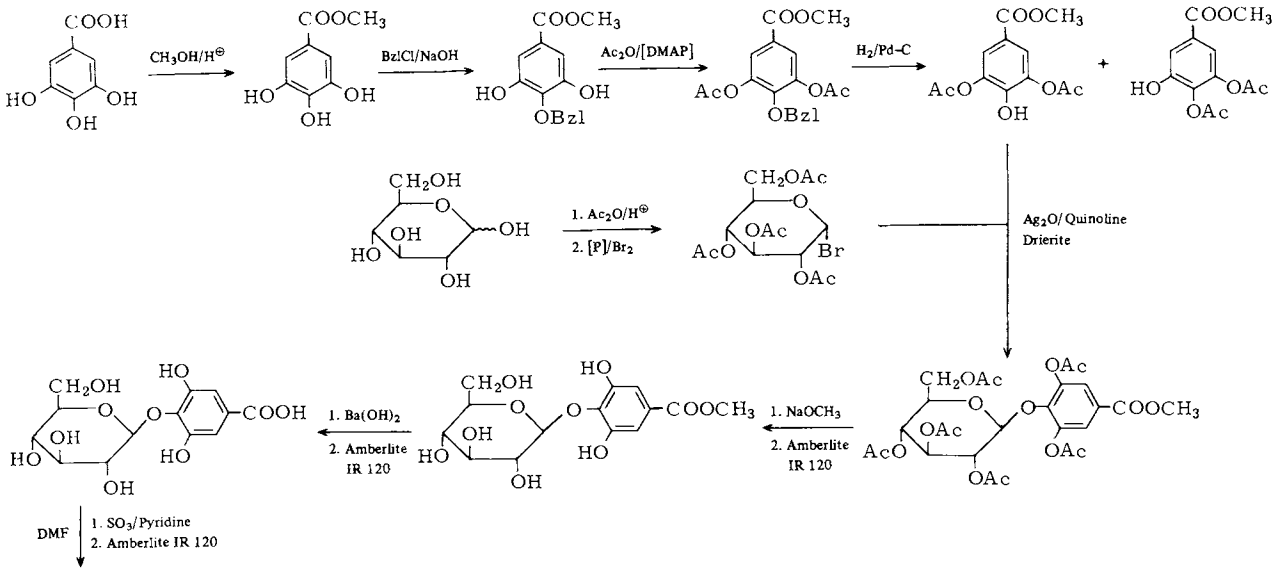
The structure of a 4-*O*-(6-*O*-sulfo-β-D-glucopyranosyl)gallic acid **6** for K-PLMF 1 could be unequivocally confirmed by $^{13}$C-NMR spectroscopy (Fig. 12). It is well-known that the downfield shift of the $^{13}$C-NMR signal of

*m/z* 241



**6**

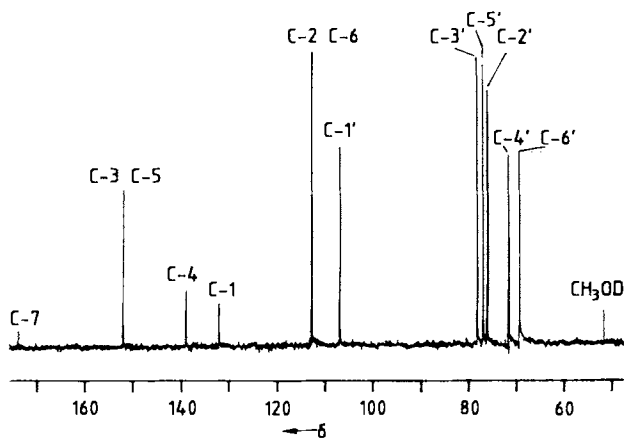
K-PLMF 1

C-6′ by about $\Delta\delta = 6$ clearly points to esterification of the primary alcoholic group of the glucose. We therefore expected the corresponding signal of K-PLMF 1 between $\delta = 68$ and 70. Consistent with this we found a triplet at $\delta = 69.4$ in the off-resonance spectrum.

Elucidation of the structure of K-PLMF 2 was aided by this finding[51]. Even its IR absorption spectrum was quite

similar to that of K-PLMF 1. Gallic acid and glucose could also be detected gas-chromatographically in the hydrolyzates of both movement factors. As in the case of K-PLMF 1 it was possible, after hydrolysis of K-PLMF 2 with 2 N hydrochloric acid, to collect the sulfate as barium sulfate in substance and to identify it by the Debye-Scherrer diagram.

The first indication that K-PLMF 2 could contain two sulfate groups was revealed by high-pressure liquid chromatography, according to which K-PLMF 2 appears to be



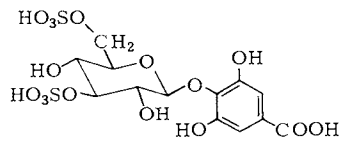


Fig. 12. 75.46-MHz $^{13}$C-NMR spectrum of K-PLMF 1 in $D_2O$ (480000 scans); techique: broad band coupling; reference signal: $CH_3OD$.

much more polar than K-PLMF 1. The highly resolved spectrum of silylated K-PLMF 2 shows all ions corresponding to those of silylated 4-*O*-glucosylgallic acid. But only the $^{13}$C-NMR spectrum confirmed that the hydroxy groups on C-6′ and C-3′ are each esterified by a sulfate group, thus giving K-PLMF 2 the structure **7**.

7
K-PLMF 2

### 4.2.2. *Synthesis and Biological Activity of K-PLMF 1*

The synthesis of K-PLMF 1 was not only important as a final proof of structure; we also wanted to check the biological activity of the synthetic active substance. At the same time, however, the synthetic route should serve as a model example for the preparation of other similar compounds, in order to investigate structure-activity relationships.

We have glucosidized gallic acid as methyl 3,5-di-*O*-acetylgallate, which had been prepared in a four-step reaction sequence. The protected aglycone was reacted with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide, silver oxide and quinoline in a "classical" Koenigs-Knorr reaction to give the peracetylated methyl glucosylgallate. Cleavage of the acetyl groups and hydrolysis of the ester group affords free 4-*O*-(β-D-glucopyranosyl)gallic acid, which is reacted with $SO_3$/pyridine complex to give the sulfate. Sulfation at the unprotected glucoside to give the 6′-sulfate is facilitated by the increased reactivity of the primary 6′-OH group compared to the remaining secondary OH-groups.

In this way, a natural leaf movement factor has been prepared by *Milde* for the first time in a laboratory[52]. Not

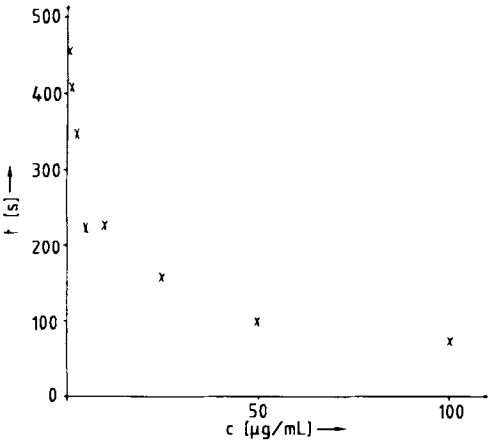

Fig. 13. Dose-response curve of synthetic K-PLMF 1 (**6**); cf. Fig. 7.

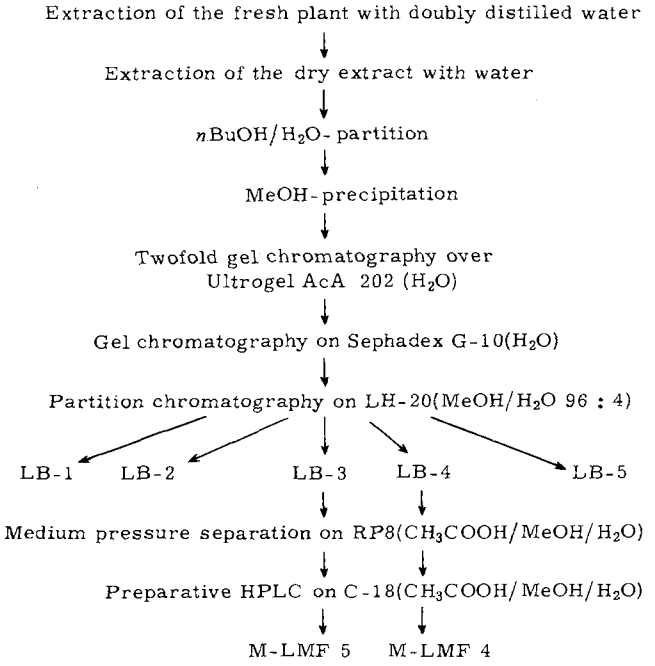
only all the spectroscopic properties, but also the biological properties of the synthetic product are in excellent agreement with those of the natural substance. Thus, in the bioassay (cf. Fig. 2) we obtained the same dose-response curves (cf. Fig. 7) as we had determined for the acid extract of the sensitive plant. The 6′-sulfate **6** which was synthesized also elicited the previously described leaf movement response, even at a concentration of $2 \times 10^{-7}$ mol/L.

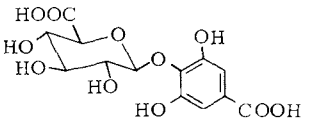


### 4.3. Detection of LMFs in Several Families of Plants

Despite all the intensive work on the non-sensitive *A. karroo*, the sensitive plant *M. pudica L.* still remains an important object for our research work on the movement phenomena of plants.

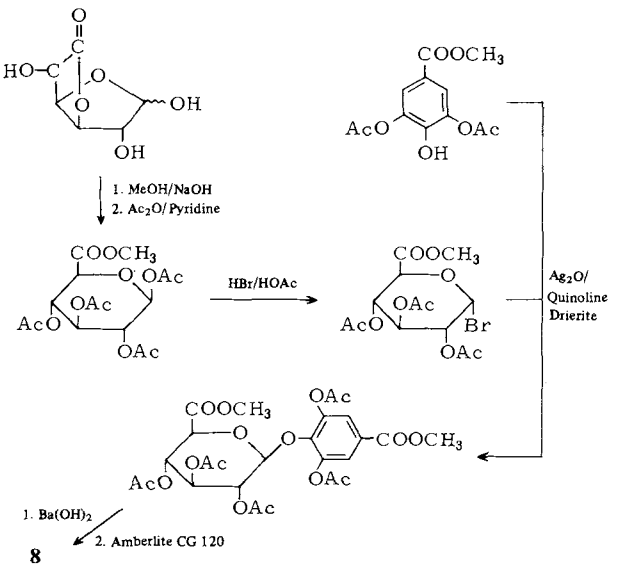
#### *4.3.1. LMFs from* M. pudica L.

By an unavoidably lengthy, yet rational separation process (Scheme 2), we were able to isolate from 23 kg of fresh mimosa from our plantation at Hainsbachweg in Heidelberg 0.8 mg of a compound which, in its pure state, also exhibited a considerable nastic activity[53]. Preliminary chromatographic and spectroscopic studies indicated that the active substance of mimosa was very probably identical with **6**, the K-PLMF 1 isolated from *Acacia karroo*. The structure was finally proven by an NMR spectroscopic analysis.



The extract of *M. pudica L.* contains, aside from 4-*O*-(6-*O*-sulfo-β-D-glucopyranosyl)gallic acid **6** (M-LMF 4), a further movement factor called M-LMF 5[1,54]. UV and $^1$H-NMR spectroscopic investigations on small amounts of the new compound already showed a high degree of similarity in the arene and sugar moieties of the two mimosa

Scheme 2. Isolation of the LMF from *M. pudica L.* Separation by medium pressure reverse phase chromatography on Merck Lithoprep RP8, HPLC separation on Polygosil C-18.5 μm.



hormones. Subsequent comparative TLC and HPLC studies, however, revealed marked differences in the polarity and chemical properties of the two compounds. All the data indicated that M-LMF 5 must contain an acid group in the sugar moiety of its molecule whose $pK_s$ value is comparable to that of acetic acid.

Decisive for the proposed structure of the new leaf movement factor from the sensitive plant were the NMR spectroscopic data. The acid groups of the molecule are confirmed by the $^{13}$C-resonances at $\delta = 175.7$ (C-6′) and 172.3 (C-7). Both groups must be free, since marked downfield shifts occur in the dipotassium salt. The signals between $\delta = 110$ and 160 could be assigned to the ring atoms of the gallic acid. The signal at $\delta = 106.8$ is characteristic for C-1′ of a β-D-glucosidically linked pyranose. In the $^1$H-NMR spectrum, the singlet of the two protons H-2,6 at $\delta = 7.07$ suggests symmetric substitution of the aglycone. The large coupling constant of $J_{1,2} = 7.5$ Hz in the anomeric doublet confirms the β-pyranose configuration, the chemical shift of H-1′ ($\delta = 5.08$) the 1′-glucosidic linkage. Separated from the multiplet of three protons ($\delta = 3.69$) there appears at $\delta = 3.97$ the doublet of H-5′ ($J_{4,5} = 8.5$ Hz) typical for hexuronic acids. Since this signal is also split by diaxial coupling, the β-D-glucopyranosideuronic acid in M-LMF 5 must be 1′-glucosidically linked with the 4-OH group of the gallic acid.

**8**
M-LMF 5

All the chromatographic and spectroscopic data of the 4-*O*-(β-D-glucopyranosideuronyl)gallic acid **8** synthesized by us by a modified Koenigs-Knorr reaction[1] were identical with those of natural M-LMF 5. The compound, which occurs only in hormonal amounts in mimosa, still triggers the specific stimulation reaction at a concentration of $3 \times 10^{-6}$ mol/L and is thus a further, low-molecular leaf movement factor.

**8**
M-LMF 5

M-LMF 5 **8** is only apparently similar to the leaf movement factors K-PLMF 1 and 2 (**6** and **7**, respectively); the chemical and biological behavior of the active substance **8** are determined by the carboxy function in the C-6′ position, which is much less acidic than the sulfuric acid ester function. It would be interesting to know whether this second variation of the structure of natural leaf movement substances also occurs in other plants or is only to be found in *M. pudica L.*

### 4.3.2. *A Leaf Movement Factor from a Malvaceae*

Not only after we had isolated, structurally identified, and synthesized the first biologically very active leaf movement factor from *A. karroo* did we ask ourselves whether or not there were other fixed, higher organized plants which react nyctinastically, using the same or a chemically similar active principle. Thus, we had already also observed the movements of *Abutilon grandiflorum*, whose leaves were found to fold together and its leaf stalks droop downwards, even at midday (Fig. 14).

Fig. 14. *Abutilon grandiflorum* in the midday heat at Hainsbachweg in Heidelberg.

Table 3. Occurrence of K-PLMF 1 in *Fabaceae, Oxalidaceae,* and *Malvaceae; t* = reaction time of on extract. K-PLMF 1 **6** is identical with M-LMF 4 and with S-PLMF 1 (see Section 4.3.3).

| Plant | *t* [s] | K-PLMF 1 | Ref. |
|---|---|---|---|
| *Mimosa pudica L.* | 25 | + | [54] |
| *Acacia karroo* | 30 | + | [51] |
| *Acacia dealbata* | 40 | + | [68] |
| *Albizia julibrissin* | 50 | + | [58] |
| *Gleditsia triacanthos* | 60 | + | [69] |
| *Robinia pseudacacia* | 60 | + | [70] |
| *Oxalis acetosella* | 50 | ? | [67] |
| *Oxalis stricta* | 40 | + | [56] |
| *Oxalis deppei* | 40 | + | [67] |
| *Abutilon grandiflorum* | 25 | + | [55] |

We were, however, astounded at also being able to isolate K-PLMF 1 from this flowering plant of the family *Malvaceae*[55], but not surprised to find it also in plants of the family *Fabaceae* (Table 3).

### 4.3.3. *LMFs of the Oxalidaceae*

It has been known since *Pliny the elder*'s time that oxalis-type plants also behave nyctinastically, and under certain circumstances even react thigmonastically or seismonastically. This is observed particularly nicely in the case of *Oxalis deppei,* the four-leaf clover, which folds its four leaves together like an umbrella, not only at night but also in full sunshine (Fig. 15).

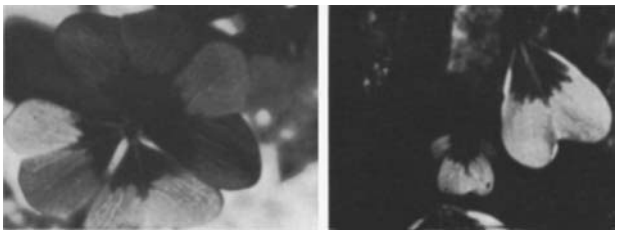


Fig. 15. *Oxalis deppei* at 16.07 (left) and at 21.14 hours (right) on July 11, 1982.

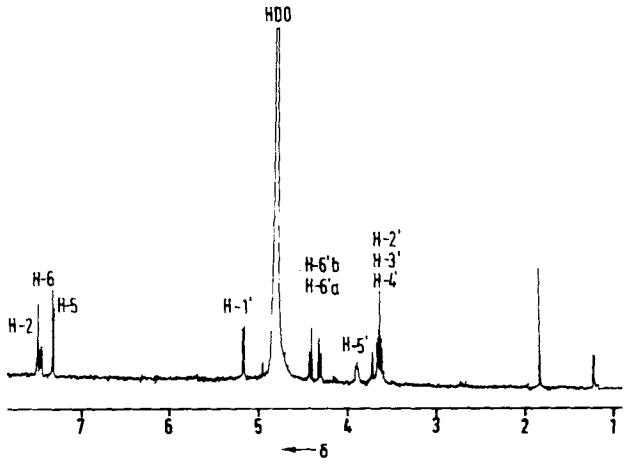
The first attempts made in the search for LMF in this family of plants, which are quite different from the *Fabaceae,* have revealed that here also the chemical principles underlying nyctinastic movement are compounds at least related to the already known factors.

Thus, it is not surprising that we have isolated a leaf movement factor S-PLMF 1 from *Oxalis stricta,* the sorrel, which is identical with K-PLMF 1[56]. A second factor S-PLMF 2, which could be isolated by the usual methods of enrichment, exhibited in a bioassay the well-known leaf movement reaction, and, following preliminary spectroscopic studies, it could be concluded that it was likewise chemically related to the previously described LMFs (cf. also Table 4).

Table 4. Comparison of the retention times (HPLC) of diverse PLMFs. Column: 25 × 0.8 cm Nucleosil C-18, 5 μm; detection: $\lambda = 210$ nm; System I: 20% $CH_3OH$/0.05% $CH_3COOH$; 3 mL/min; System II: 1 mM $CH_3COOH$; 5 mL/min.

| | | $t_r$ [min] System I | $t_r$ [min] System II |
|---|---|---|---|
| **6** | S-PLMF 1 | 15.1 | 5.8 |
| **6** | K-PLMF 1 | 15.3 | 5.9 |
| **9** | S-PLMF 2 | 11.9 | 4.3 |
| **7** | K-PLMF 2 | 42.2 | 3.1 |

By means of GC-MS investigations on the silylated hydrolyzate we found that the aglycone of S-PLMF 2 was not gallic acid but protocatechuic acid, with one less hydroxy group. Glucose was also found to be a structural unit of S-PLMF 2. As in the case of the other LMFs, the total structure of S-PLMF 2 has been determined NMR spectroscopically (cf. Fig. 16). Typical coupling patterns of a 1,3,4-substituted arene are recognizable in the downfield region of the spectrum: two doublets and the doublet of doublets.



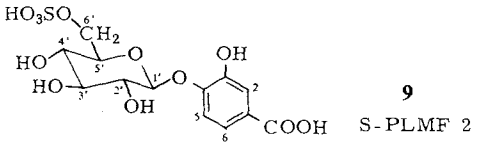


Fig. 16. 500-MHz $^1$H-NMR spectrum of S-PLMF 2 in $D_2O$ (500 scans), calibration: HDO = 4.77 ppm.

The splitting of the H-5 signal at $\delta = 7.2$ ($J = 8.1$ Hz) is brought about by the *ortho*-coupling with H-6. This in turn additionally couples with the *meta* H-2 ($J = 2.0$ Hz). Since the methyl protons of the glucopyranoside have experienced a significant downfield shift of about $\Delta\delta = 0.5$ compared to unsubstituted glucosides it must be concluded that an electron-attracting substituent is located on C-6'. According to data in the literature, and our proton resonance spectroscopic findings on LMFs that have already been identified, especially K-PLMF 1, the polar group could be a sulfate ester. Unequivocal proof of this was not possible, even from the $^{13}$C-NMR spectrum, since a total of not more than 0.8 mg of the active substance was available for all the analytical and spectroscopic investigations. Hence, here once again the synthesis served as a means for proof of the structure; the end product, 4-*O*-(6-*O*-sulfo-β-D-glucopyranosyl)protocatechuic acid **9**, proved to be identical with the natural substance, both spectroscopically and in the bioassay[56].

**9** S-PLMF 2

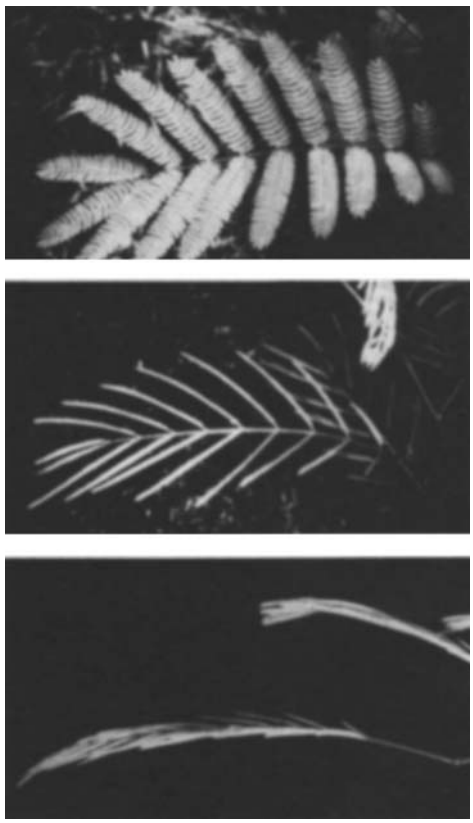
This structural variant of K-PLMF 1 exhibited specific activity at a concentration of 0.001 to 0.005 mg/L in the biological test system (Fig. 2); the absence of an hydroxy group in the aglycone obviously leads to a reduction of the activity by a factor of more than 10.

### 4.4. Phenomena-Oriented Consideration of the LMFs

Studies on the day-night periodicity of leaf movements led to the discovery of the circadian rhythms of plants[57]. The movements are caused by a change in the turgescent tension in the tissues of the motile organs made up of parenchymic cells. We may assume that the change of turgor is the consequence of changes in the water permeability of boundary plasma layers, caused by turgor active endogenous factors, the leaf movement factors.

#### *4.4.1. PLMFs as Final Active Principles of the "Circadian Rhythms" of* Albizia lophanta

*Hein*[58] was able to demonstrate on the pinnate leaves of *A. lophanta*, whose daily periodic movements are illustrated quite vividly in Figure 17, that leaves placed in an aqueous solution of K-PLMF 1 **6** (0.05 mM) "sleep" earlier than the control plants.



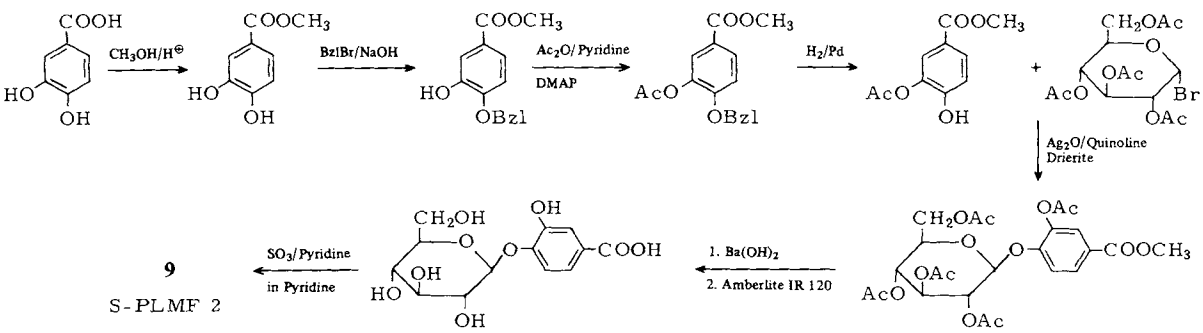


Fig. 17. Pinnate leaf of *A. lophanta*, photographed at 19.23 (top), 21.53 (center), and about 22.22 hours CET (bottom) on July 15, 1981.

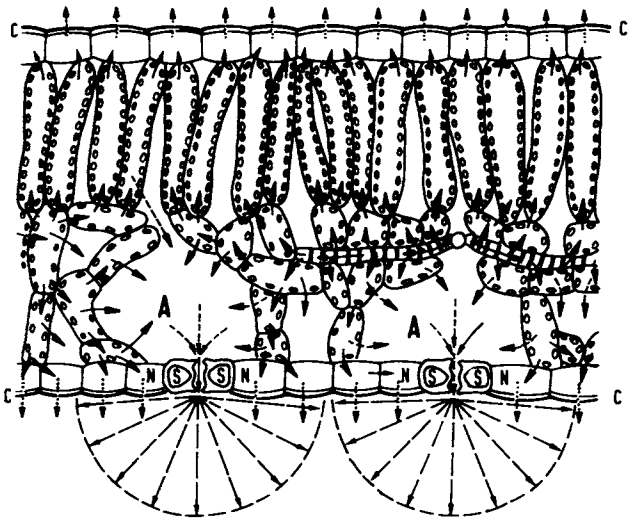
An unexpected finding was that the pinnules close together later under the influence of 2′,3′-*c*AMP **3** and 2′,3′-*c*GMP **2** (3 mM). Furthermore, the cyclic nucleotides remarkably influence the time of opening of the pinnules after four hours' action in the morning. The activity of all three factors also depends on the time of the day. Thus, earlier as well as later "sleeping" of the test leaves can be initiated by combination of the PLMF with the cyclic nucleotides.

#### *4.4.2. PLMFs as Final Active Principles of the Nastic Movements of Stomatal Opening*

Stomatal opening on the underside of the leaves of higher organized plants regulates transpiration and gas exchange as a result of the turgor movement of their guard cells. Stomatal opening (Fig. 18) provides communication



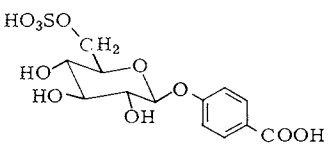


Fig. 18. Stomatal and cuticular transpiration of a leaf, altered after *Nultsch* [41]; S = guard cells, N = companion cells, A = breathing holes (stomatal openings), C = cuticula; arrows indicate the direction of flow of water.

between the external air and the intercellular system of the subepidermal tissue. It has long been known that each increase in the turgor of the guard cells relative to the companion cells leads to opening of the stomatal slit, each decrease in turgor to closing of the stomatal slit[59]. Although turgor changes can come about in various ways, we may, following our experiences with LMFs, assume that here also PLMF 1 **6** is the final active principle.

In fact it has emerged from experiments carried out by *H. Ziegler et al.*[60] that M-LMF 5 **8**, synthetic 4-*O*-(6-*O*-sulfo-β-D-glucopyranosyl-*p*-hydroxybenzoic acid **10**[61], and, above all, K-PLMF 1 and 2 (**6** and **7**, respectively) can make guard cell protoplasts of broad beans *(Vicia faba)* rapidly shrink after previously being brought to

**10**

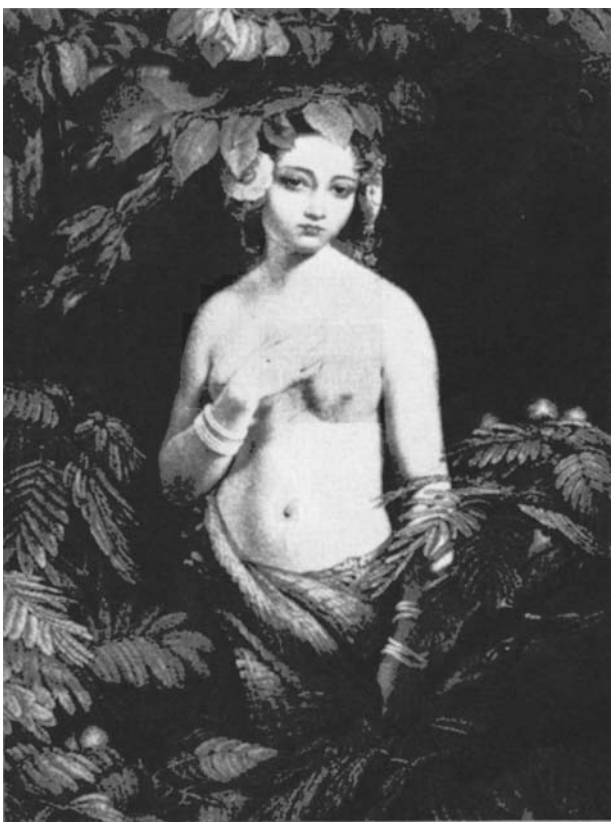
swelling with $K^+$ ions. This means that the sulfate-containing turgorins, in particular, rapidly increase the permeability of the plasma membrane. As a rule, they have a closing effect on the guard cells in isolated but intact Vicia leaf epiderma. This observation by *Ziegler* and *Schnabl* is in agreement with the experimental results obtained by *Jung*[62]: in a barley leaf segment bioassay on the influence of leaf ageing and stomatal movement, K-LMF 1 promotes leaf senescence and stomatal closure.

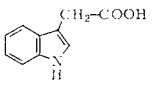
## 5. Turgorins—A New Class of Phytohormones

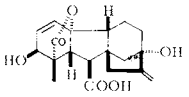
It was already pointed out in Section 2 that the first four classes of phytohormones listed in Table 5, like the superhormone ethylene, are important agonists in ecological plant physiology. Following the identification of K-LMF 1—exactly 50 years after the discovery of the first phytohormone by *Kögl* in 1931[7]—we must extend the list.

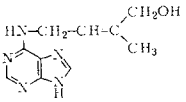
Like all phytohormones, the trugorins are transported from the place where they are formed through the sap stream to the target organ, where they depolarize a biomembrane and so alter its permeability that the turgor diminishes. The pinnate leaves close and open and the whole mimosa tree goes to "sleep" and "wakes up" again—together with a likewise hormone-regulated "Venus pudica", who, in an allegoric portrayal by an unknown artist, takes a look at a new day (Fig. 19).

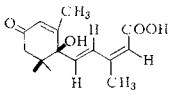
Her beauty is due in part to a phenol, which of course K-PLMF 1 also is. But, more by good luck than good management the artist has cunningly represented the mutuality of hormone-regulated life forms—a human person and a











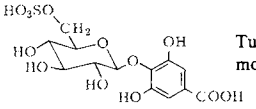


Fig. 19. "Venus pudica" in the mimosa jungle—xylograph of a picture of the late, romantic cum classic period [63].

Table 5. The most important classes of hormones in higher organized plants.

| Hormone Class | Structure | Activity | Discovery |
|---|---|---|---|
| Auxins<br>Example:<br>3-Indolyl-acetic acid |  | Longitudinal growth | 1931 |
| Gibberellins<br>Example:<br>Gibberellin-acid $GA_3$ |  | Longitudinal growth | 1935 |
| Cytokinins<br>Example:<br>Zeatin |  | Cell division - Cytokinesis | 1955 |
| Abscisins<br>Example:<br>(+)-Abscinic acid |  | Abscission - Stomatal opening movement | 1970 |
| Turgorins<br>Example:<br>K-PLMF 1 **6** |  | Turgor movement | 1981 |

plant. The female sexual hormone estradiol promotes *inter alia,* a growth movement of the breast glands, the turgorin K-PLMF 1 promotes the sleep movement of a mimosa.

## 6. Discussion and Outlook

In his "Plant Geography"—a work such as has never been surpassed in antiquity—the Greek philosopher *Theophrastus* already compared the phenomenon of "plant sleep" with the phenomenon of movement of the sensitive plant, and thus, unknowingly presented mimosa as the index plant for all later research work (Fig. 20) on the power of movement in plants (after *Darwin*[64]). Thus, one can understand that *Pfeffer*'s warning remained for a long time unheeded. In § 3 of the "Nature of Stimulation Processes" in his Pflanzenphysiologie[65] he says: "Accordingly, even in special cases, *e.g.* sudden stimulation reactions (such as the folding together of the leaves of the sensitive plant), are of little general significance compared to the army of slow and continually effective reactions and regulations".

This claim was—so far as the stimuli of sleep movements are concerned—first given justice in 1981, when we isolated and elucidated the structure of the first turgorin from *Acacia karroo,* a non-sensitive plant[51].

### 6.1. Dissemination of the Turgorins

The relatively wide dissemination of the turgorins is now recognized (cf. Table 3). But we are still tormented by the question of whether all nyctinastically responsive plants have essentially only K-PLMF 1 **6** at their disposal, or whether or not compounds other than turgorins can be effective.

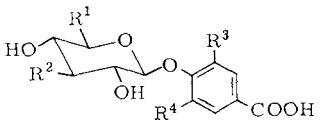
We must first wait for the analytical results obtained on the rain tree (*Pithecolobium saman,* Fabaceae), the flame tree (*Delonix regia,* Ceasalpinaceae), the calliandra (*C. fulgens* and *C. Haematocephala,* Mimosaceae), and the bauhinia (*Bauhinia* spec., Caesalpinaceae). *Hein*[58] has, already found that K-PLMF 1 does in fact occur in *Albizia julibrissin* (cf. Table 3), but not in a near relative, *Albizia lophanta*. From *A. julibrissin* we isolated a complex mixture of over 20 saponins, which were obtained in pure form by HPLC. These saponins consist of a pentacyclic triterpenic acid, linked to two sugar chains containing up to seven monosaccharide units. Almost all of these saponins are also coupled in an ester-like fashion with two α,β-unsaturated monoterpenic acids. Small variations in the triterpene, sugar, or monosaccharide moieties of the molecules give rise to numerous possible structures. Although, in principle, they are very similar in structure it was surprising that only two of the individual components proved to be highly active in the bioassay. In the most favorable case 3 mg/L sufficed, at a molecular weight of *ca.* 2000, to stimulate a leaf movement. By a detailed NMR spectroscopic analysis of the individual components, in which 2D-techniques have proven especially valuable, it has been shown

Fig. 20. *M. pudica L.*, photographed in the mimosa plantation, Heidelberg-Hainsbachweg, during the day (left), at night (center), and after touching (right).

that even a small change in one of the monoterpenes can lead to a drop in the activity by a factor of about 1000. Thus, the activity is in no way a general property of the saponin; rather, it is coupled with definite structural requirements in which the monoterpenes play an important role.

Also surprising are the results which *Koch*[66] obtained with the leaves of *Glycine max.*, the soya bean: derivatives of *p*-hydroxycinnamic acid occur, which appear to be esterified with a sugar acid.

Of importance for an overview of the new class of hormones are also the investigations with oxalidaceae, not only because they represent other families than the Fabaceae, but also because an extract from the bulb of the four-leaf clover *(Oxalis deppei)*—which in all probability contains K-PLMF 1—stimulates the leaves of some plants to "sleep". *Backfisch*[67] found a new chemonastically active factor in the South African plants *Oxalis compressa* and *O. obtusa*, which according to their chromatographic behavior must be substantially more polar then K-PLMF 1. Because of the inducible variation in potential in the vine, *Vitus gongylodes*, *Houwink*[30] assumed that a stimulating substance was also effective here, as in the mimosa. Whether in this case the turgorins described by us are involved will be clarified by a bioassay.



### 6.2. Mechanism of Stimulus Perception and Its Inductive Character

At the slightest touch, the sensitive hairs on the pulvini of *M. pudica L.* stimulate movement of the hinge cells in the leaf joints. We may assume that the first step of the physiological process is the—perhaps enzymatic—activation of the turgorins.

#### *6.2.1. Stimulation Reactions at the Biomembrane*

As agonists of turgor bending and thus of the associated changes in permeability of the biomembranes, the turgorins provide the causal connection between irritation and movement. As in the case of acetylcholine, the neurotransmitter in animal synapses, a receptor also participates in plant stimulation phenomena; this was previously recognized by us by the fact that the turgorins exhibit a distinct structure-activity relationship (cf. Table 6). The activity decreases when the free phenolic OH-groups are absent.

Table 6. Structure-activity relationship of the turgorins.

| | Turgorin | Structure $R^1$ | $R^2$ | $R^3$ | $R^4$ | Activity min. Conc. [g/L] |
|---|---|---|---|---|---|---|
| **6** | K-PLMF 1 [a] | $CH_2OSO_3H$ | OH | OH | OH | $10^{-4}$ |
| **7** | K-PLMF 2 | $CH_2OSO_3H$ | $OSO_3H$ | OH | OH | $10^{-4}$ |
| **9** | S-PLMF 2 | $CH_2OSO_3H$ | OH | OH | H | $10^{-3}$ |
| **8** | M-LMF 5 | COOH | OH | OH | OH | $10^{-3}$ |
| | PLMF-synth. | $CH_2OSO_3H$ | OH | H | H | $10^{-2}$ |
| | LMF-synth. | COOH | OH | H | H | $5 \times 10^{-1}$ |

[a] Identical with M-LMF 4 and S-PLMF 1.

However, alone on the basis of investigations on the role of 3′,5′-*c*AMP in plant "sleep"[71], the PLMFs must still be discussed together with the aforementioned cyclic nucleotides as additional members of a stimulation chain.

Perhaps, with the endogenous cofactors 2′,3′-*c*AMP and 2′,3′-*c*GMP (**3** and **2**, respectively, Table 1), we have further "second messengers" of the higher plants.

#### *6.2.2. Stimulation Conduction*

The above-mentioned, easily controlled turgorin syntheses will enable us to study both the receptor as well as stimulus conduction with the aid of $^{13}C$-labeled active substances.

The inductive effect of a stimulus on movement is nowhere more conspicuous than in hormone-carrying stimulus conduction. Provisionally, we can only corroborate *Houwink*'s hypothesis[30], according to which a specific irritant—in our way of thinking a turgorin—is transported in the channels from the induced vacuole to the typically structured target organ. In this process a variation potential (10 cm/min) occurs. In principle, we make no distinction between the endogenous movements controlled by external stimulation and those controlled by an internal mechanism, *e.g.* the sleep movements, which obey a physiological clock.

## 7. Epilogue

> *Das logische Wissen kann wahr nur sein, wenn es allumfassend ist.*
>
> *K. Jaspers, Von der Wahrheit*[73]

Although trees, for the very sake of their unsurpassable size have remained fixed, they are not on this count wholly immovable; just like the plants with regard to their external appearance and the mechanics of their movements they demonstrate incomparably greater diversity than animals—despite the absence of a developed musculator.

But how can a fixed plant manage its highly systemized organic structure, or even alone its circulation, without muscles and thus without a heart? Actually, only by a subtle control of the turgor in the motor and guard cells (cf. also Figs. 18 and 21). In end effect, it is thus the "water balance" of the whole plant organism which controls, *via* biomembranes and thus by turgorins, the temperature regulation in the plant body and makes its firmness possible.

If one was previously of the opinion that cuticular exchange (Fig. 18) is not regulatable[41], then one should again reflect on turgor-controlled movement, at least of the papilionaceous plants with their daily periodic leaf movements.

Alone the idea of a common chemical basis for all turgor-controlled movements suggests that cuticular as well as stomatal transpiration is influenced by the sleep movements of the leaves, *i.e.* likewise hormonally controlled.

In the comparison just drawn between plants and animals we presume a similar, even though primitive actomyosin system in the ancient forms of both types of life, from

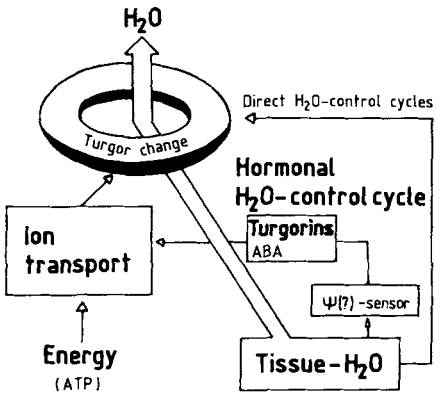


Fig. 21. Regulatory mechanism of the water balance of higher terrestial plants; simplified according to *Haupt* [72]. The guard cells are depicted schematically above. ABA signifies abscissinic acid; ψ-sensor signifies sensor for the water potential (ψ) in a tissue.

which the animal muscles could have developed. But we are still lacking the appropriate analogue to the animal nervous system in the plants, in which *e.g.* one even misses the synapses. The neutrotransmitter, however, should now be compared with the turgorins, or perhaps also with new phytohormones not yet chemically identified beyond doubt.

*When, as is the case here, the author has been granted the privilege, after thirty years of research, to present a comprehensive account of such a fascinating area of phytochemistry – framed by historical, artistic and philosophical considerations – then he owes his gratitude to an unusually large number of highly able and valued colleagues and collaborators, both technical and scientific. They have shown a high degree of skill and expertise at manipulating barely visible amounts of natural products in the quest to interpret a natural phenomenon on a sound chemical basis. This has naturally entailed a resort to modern and sophisticated instrumental analysis, the apparatus for which, like many other things, could not have been acquired or realized without appreciative and generous financial support from the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. I am deeply indebted to Brigitte Schmich for the layout of the diagrams and to Patricia Bock, my secretary, for her remarkable engagement in the preparation of the manuscript. And last but not least I also wish to thank Dr. Karl Friedrich (Brazil) and Prof. U. Burger (South Africa) for their continued help in placing tropical plants at my disposal.*

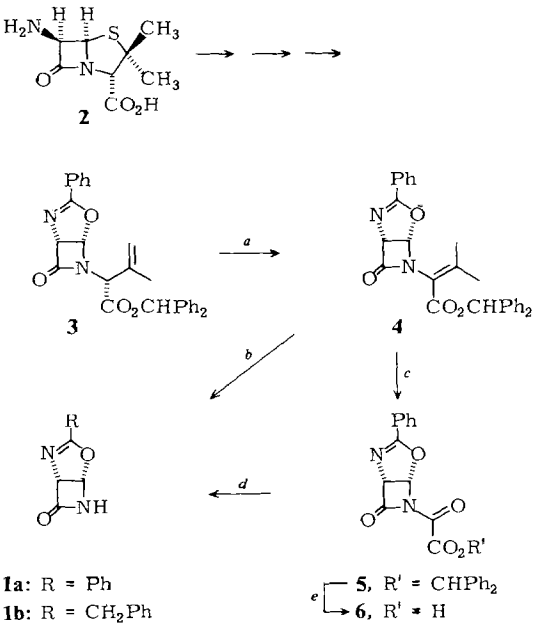
## Synthesis of the Chiral Synthetic Building Block (1*R*,5*S*)-3-Phenyl-4-oxa-2,6-diazabicyclo[3.2.0]hept-2-en-7-one from 6-Aminopenicillanic Acid

By *Dieter Häbich**

The isolation and determination of the structure of thienamycin together with the discovery of the monobactam antibiotics gave renewed impetus to the synthesis of β-lactams.

The previously unknown oxazolines **1**, which have no substituents at N-6, should be particularly useful building blocks for syntheses of this type and be accessible by analogy to the corresponding thiazolines[5]. The synthetic potential of compounds **1** has already been recognized. For example, *Stoodley* reported the unsuccessful attempt to isolate the enantiomer of **1b** using another route[7].



*Aoki et al.* used the stereoselective intramolecular ring-opening of *N*-substituted annelated oxazolines to synthesize oxacephems[8]. *Woodward et al.* employed the reaction of free azetidinones with electrophiles in the total synthesis of cephalosporin C[9]. Oxazolines **1** should permit reactions of both types.

We have now synthesized (1*R*,5*S*)-3-phenyl-4-oxa-2,6-diazabicyclo[3.2.0]hept-2-en-7-one **1a** (alternatively: 2-phenyl-3a,5a-dihydroazet[3,2-*d*]oxazol-5-one) as well as some of its *N*-substituted derivatives (Scheme 1).

The *epi*-secopenicillin **3**, accessible in four steps from 6-aminopenicillanic acid **2**, can be isomerized to **4** using the base-catalyzed method described by *Maki et al.*[11]. Oxidative cleavage of the side chain to afford **1a** proceeds directly with potassium permanganate[5]. Higher yields can be obtained using the route *via* **5**, obtained by ozonolysis of **4**. Methanolysis of **5** in the presence of silica gel or sodium methoxide as catalyst yields the crystalline oxazoline **1a**, $[\alpha]_D^{20} = -114.8$ (0.836% in acetone).

Surprisingly, acid **6** can be formed from ester **5**, although its IR band at 1832 $cm^{-1}$ suggests a highly reactive β-lactam ring.

Crystalline **6** is stable [m.p. = 148–150 °C (decomp.)]; however, in solution (DMSO-$D_2O$-$NaHCO_3$) it rapidly decomposes at 37 °C. Neither **6** nor **1a** exhibit antibiotic activity or inhibit β-lactamases.

Scheme 1. *a:* cat. $NEt_3$, $CH_2Cl_2$, 6 h RT (84%). *b:* $KMnO_4$-acetone-water, pH 7 (19%). *c:* $O_3$, $CH_2Cl_2$ −70 °C; $Me_2S$ (70%). *d:* $SiO_2$, $CH_3HO$, 8 min RT (62%) *or* cat. $NaOCH_3$, $HOCH_3$, 15 min RT (46%). *e:* $CF_3COOH$, anisole, $CH_2Cl_2$, 20 min 0 °C (68%).

## The Photooxygenation of Estrogens: a New Synthesis of 19-Norsteroids

By *Pilar Lupón, José Gómez,* and *Juan-Julio Bonet**

*Dedicated to Professor Günther O. Schenck on the occasion of his 70th birthday*

Since the pioneering work of *G. O. Schenck*, photooxygenation has been widely used as the key step of many organic syntheses[3], some of which have been conducted

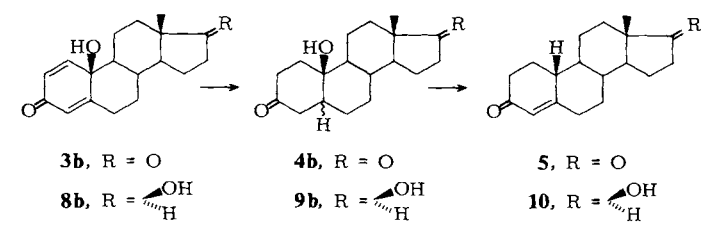
even on a technical scale. Classical examples are the synthesis of the anthelmintic ascaridole by 1,4-cycloaddition of singlet oxygen to α-terpinene[5], and the ene-reaction between citronellol and singlet oxygen to form rose oxide[6].



We now report a new application of photooxygenation to the synthesis of 19-norsteroids. These compounds, of considerable importance due to their biological activity, have been traditionally prepared by Birch reduction of estradiol derivatives[8]—a very remarkable procedure that, nevertheless, has some limitations[8].

Our procedure is based on the known photooxygenation of *p*-substituted phenols to the corresponding 4-hydroperoxy-2,5-cyclohexadienones[12], which we have applied to the synthesis of estrogens. The main advantages of this reaction are that it can be carried out directly with the free phenols; that no solubility problems arise; that keto groups remain unchanged; and that the operation is simple, affording the required products in good yield.

Scheme 1.

The photosensitized oxygenation of estrone **1** in methanol using rose bengal as sensitizer led to a mixture of hydroperoxide **2** and alcohol **3** (Scheme 1), which was separated by silica gel chromatography: estradiol **6** was photooxygenated under the same conditions to give **7** and **8**. The isolated hydroperoxides **2** and **7** are white crystalline solids which decompose slowly at room temperature; the alcohols **3** and **8** are stable white crystalline solids. Reduction of the crude mixtures of the photooxygenation of **1** and **6** with iodine in methanol yielded, preferentially, the alcohols **3b** (76%) and **8b** (78%), respectively; with **1** the less stable 10α-isomer **3a** (2.5%) was also isolated as a minor component. Yields are not optimized.

Scheme 2.

Transformation of the unsaturated alcohols into 19-norsteroids was carried out in two steps (Scheme 2). Catalytic hydrogenation ($PtO_2$) of **3b** and **8b** afforded in practically quantitative yield the saturated alcohols **4b** and **9b**, respectively. Dehydration of solutions of **4b** and **9b** in methanol was carried out in the presence of perchloric acid (70%) as catalyst on silica gel at 90°C. In this way, 19-nor-4-androstene-3,17-dione **5** and 19-nortestosterone **10** were obtained in 51% and 60% yield, respectively (not optimized).

## The *endo*-3,10-Dimethyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3,10-diyl Dication, A Novel Bishomoaromatic/Allylic Dication and its Rearrangement to the Symmetrical *cis-anti-cis*-3,10-Dimethyltricyclo[5.3.0.$0^{2,6}$]deca-4,8-dien-3,10-diyl Dication**

By *George A. Olah**, *Massoud Arvanaghi*, and *G. K. Surya Prakash*

Although the chemistry of carbocations has largely been confined to the study of carbomonocations, interest in carbodications is growing rapidly. Several intriguing experimental and theoretical studies have been undertaken on carbodications, including classical carbodications with three-coordinate C atoms and non-classical carbodications with hexacoordinate C atoms[1].

In our continued interest in carbodications, we now report the generation and NMR spectroscopic study of *endo*-3,10-dimethyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-dien-3,10-diyl dication **2**, a novel bishomoaromatic, allylic dication.

Dissolution of a slurry of 3-*exo*-10-*syn*-dimethyltricyclo[5.2.1.$0^{2,6}$]deca-4,8-diene-3,10-diol **1**[2] in $SO_2ClF$ in $FSO_3H:SbF_5/SO_2ClF$ at −120°C (liquid nitrogen/ethanol slush bath) resulted in a dark orange solution.

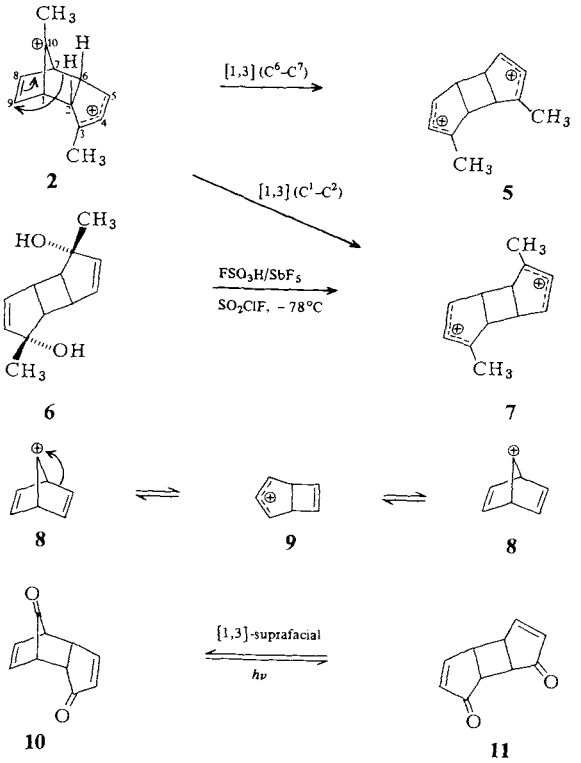
[**] Stable Carbocations. Part 248. Support of our work by the National Science Foundation and the National Institutes of Health is gratefully acknowledged. Presented at the 185th National Meeting of American Chemical Society, Organic Division, Seattle, WA, March 1983.

The $^{13}$C-NMR spectrum of the resulting solution exhibited twelve major absorptions (Table 1). Based on the chemical shifts and multiplicities the ion is unequivocally assigned the dicationic structure **2**. The dication has a bishomoaromatic/allylic dication framework, and the observed chemical shifts correspond closely to those of the monocations **3**[3a] and **4**[3b]; however, the bishomoaromatic moiety in **2** is unsymmetrical. The observed $^1$H-NMR spectrum is also compatible with structure **2** (Table 1). **2** is stable only below $-100\,^\circ$C; at higher temperatures it slowly rearranges irreversibly to a new species.

**3**

**4**



Warming a solution of **2** to $-40\,^\circ$C results in formation of a species with only six absorptions in the $^{13}$C-NMR spectrum, indicating the formation of a very symmetrical dicationic system. The observed chemical shifts and multiplicities suggest formation of a tertiary bisallylic dication. The $^1$H-NMR chemical shifts in the allylic region at $\delta = 9.25$ and 8.12 also corroborate this structure. The rearrangement of the unsymmetrical dication **2** to a symmetrical new dicationic system can occur *via* a 1,3-sigmatropic shift. In fact, a 1,3-shift of either the $C^6$–$C^7$ bond or the $C^1$–$C^2$ bond results in two symmetrical bisallylic tertiary dicationic systems **5** or **7**. The structure of the rearranged species is unequivocally assigned to the *cis-anti-cis*-3,10-dimethyltricyclo[5.3.0.0$^{2,6}$]deca-4,8-dien-3,10-diyl dication **5**: formation of *cis-anti-anti*-dication **7** was excluded by its independent synthesis involving ionization of the 3,8-diol **6**[4] in $FSO_3H/SO_2ClF$ at $-78\,^\circ$C. It appears that the $C^6$–$C^7$ bond migrates preferentially since it is farther from the tertiary allylic cationic center than the $C^1$–$C^2$ bond. There is precedence for similar rearrangements in the literature: the 7-norbornadienyl cation **8** undergoes rapid 1,2-sigmatropic shift (through the intermediacy of bicyclo[3.2.0]heptadienyl cation **9**), resulting in scrambling of carbon and hydrogen atoms[5a]. The photochemical conversion of tricyclic diendione **10** into *cis-anti-cis*-tricyclic dienedione **11** has also been reported[5b], although we were unable to reproduce this result satisfactorily.

Dications **5** and **7** show similar $^{13}$C-NMR chemical shifts, although there are some apparent differences in the chemical shifts of the allylic carbon atoms. This is as a consequence of the separation of the tertiary cationic centers by only two C atoms in **5**, compared to three C atoms in **7**.

Table 1. $^{13}$C- and $^1$H-NMR spectroscopic data of the tricyclic carbodications **2**, **5**, and **7** [a].

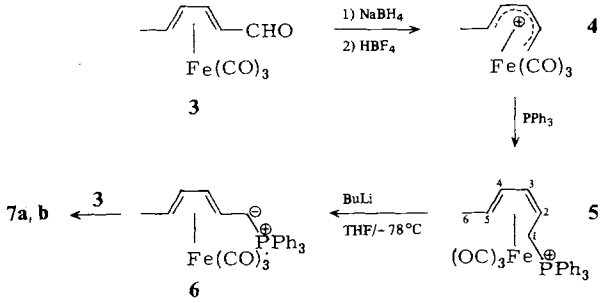
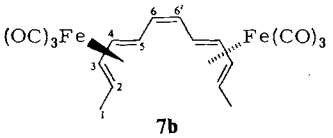
[**] Reactions with Metal-Coordinated Olefins, Part 2.—Part 1: [2b].



phosphonium derivatives of type **2**[2a], which are hardly accessible by other routes, are formed quantitatively.

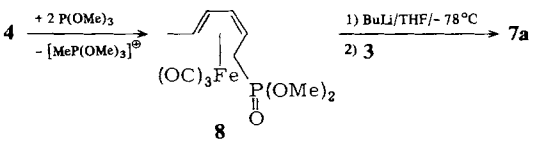
**1** **2**



They can be oxidatively decomplexed[2b]; **2** itself cannot be converted into a stable ylide[2a]. This occurs only when dimethyl(phenyl)phosphane is used[2c].

Our investigations now indicate that reaction of acyclic dienyl systems such as **4**[1] with triphenylphosphane and subsequent deprotonation with n-butyllithium lead to formation of stable deep-red solutions of ylide complex **6**, which smoothly undergo a Wittig reaction with **3**[3] to form the two isomeric polyene complexes **7a** and **7b** in the ratio 1:3[4].

**3** **6**



The products **7a** and **7b** have the empirical formula $C_{12}H_{16}Fe_2(CO)_6$; their $^{13}$C-NMR spectra are consistent with symmetrical structures with four coordinated and one non-coordinated double bond[4]. Because of the symmetry and the fixed (*E,E*)-configuration of **3**, they can, therefore, only differ in configuration at C-6, C-6′. On the basis of the coupling $^3J$(*C*-5, *H*C-6′), obtained from selectively {$^1$H}-decoupled $^{13}$C-INEPT spectra, we assign an (*E*)-configuration to **7a** and, in contrast, a (*Z*)-configuration to **7b** for the middle double bond.

**7b**

Both molecules have two (degenerate) chiral moieties; they therefore occur as an enantiomeric pair or as a *meso*-form. No stereochemical assignment can be made from the spectroscopic data of **7a** and **7b**; however, it appears that both molecules most probably have a *transoid* arrangement of the two $Fe(CO)_3$ groups. This is confirmed for **7a** by X-ray structure analysis (Fig. 1). The polyene chain is almost planar, but exhibits the usual slight distorsion of the terminal CC bonds of complexed *s-cis*-dienes.

Compounds **7a** and **7b** are, on the whole, air-stable and even at higher temperatures are configurationally stable.

**8**

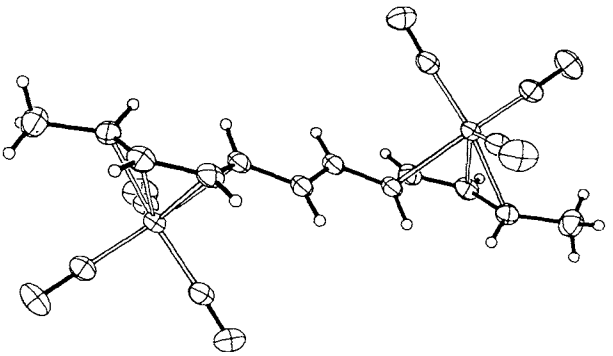


Fig. 1. Molecular structure of complex **7a** in the crystal. Structural data (at ca. −140 °C): $P2_1/c$; $a = 7.389(1)$, $b = 12.230(1)$, $c = 11.923(1)$ Å, $\beta = 117.83(1)°$, $Z = 2$; 3448 symmetry-independent reflections; $(\sin\theta)/\lambda \leq 0.76$ Å$^{-1}$; $R = 0.036$, no absorption correction. Further details on the crystal structure investigation can be obtained from the Fachinformationszentrum Energie Physik Mathematik, D-7514 Eggenstein-Leopoldshafen by quoting the depository number CSD 50485, the names of the authors, and the journal citation.

They are moderately soluble in aliphatic solvents, but readily soluble in toluene or $CHCl_3$. Deprotonation of **5** with potassium *tert*-butoxide affords **7a**, exclusively, just as in the Wittig-Horner variant, which upon reaction of **4** with trimethyl phosphite and subsequent spontaneous Michaelis-Arbuzov reaction of the primary adduct leads to **8**.

The Wittig carbonyl olefination is a key reaction in preparative organic polyene chemistry[5a,b], but is also occasionally used to extend the chain length of diene-$Fe(CO)_3$ complexes[5c]. The reactions described here differ from conventional methods in three ways:

1. The reaction of cationic dienyl-$Fe(CO)_3$ complexes with triphenylphosphane or trimethylphosphite affords in regeiospecific addition otherwise only difficultly accessible dienylphosphonium salts or dienylphosphonates.
2. The *cisoid*-ylides formed initially upon deprotonation of **5** or **8** are apparently unstable; they isomerize completely at C-2. In fact, **5** rearranges to the isomeric (*E,E*)-phosphonium complex with deuteration at C-1 in the presence of catalytic amounts of $CD_3ONa$ in $CD_3OD$[2b]. Cyclic systems such as **2** do not have this stabilization possibility and cannot, therefore, be converted into stable ylides at the complex.
3. Formation of the ylide from **5** using *n*BuLi and subsequent reaction with **3** do not lead to the high (*E*)-selectivity normally observed, but to the preferred formation of the (*Z*)-isomer. Use of *t*BuOK as described by *Schlosser*[5d], in turn unexpectedly affords exclusively the (*E*)-isomer **7a**. In contrast, the Wittig-Horner reaction displays the normal (*E*)-selectivity[5b].

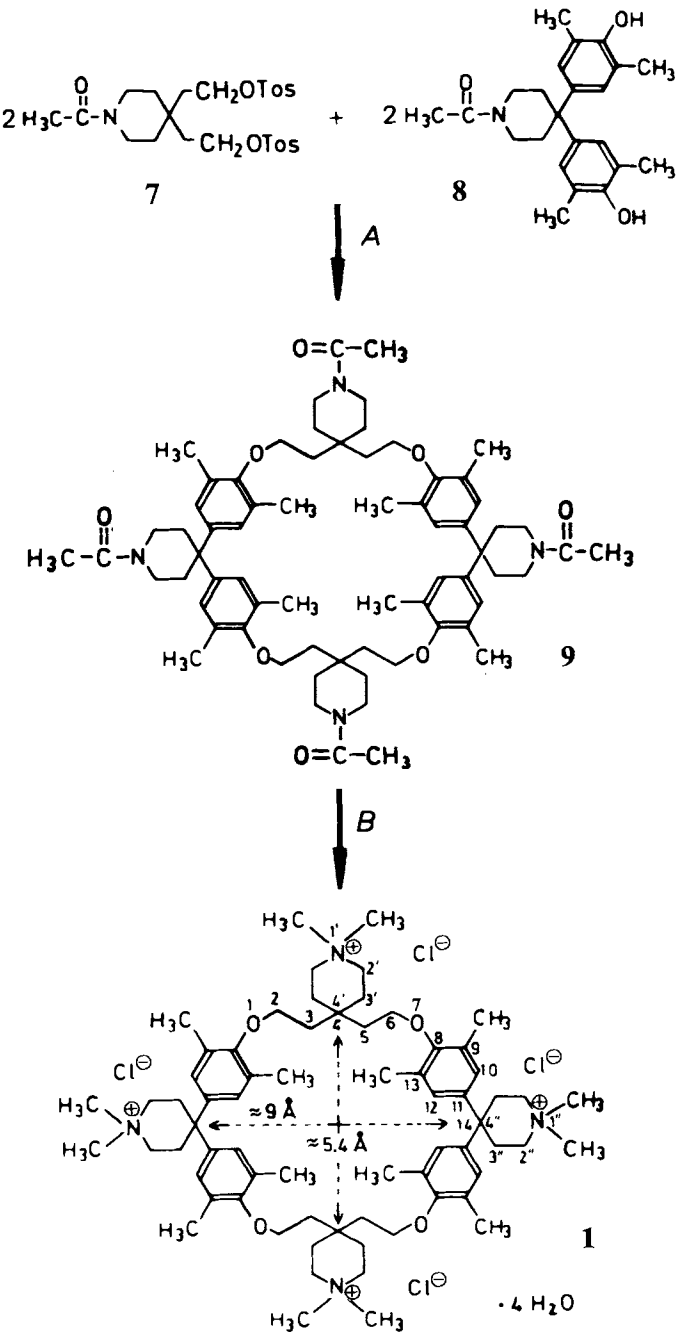
## Inclusion Complexes between a Macrocyclic Host Molecule and Aromatic Hydrocarbons in Aqueous Solution

By *François Diederich** and *Klaus Dick*

We are interested in cyclophane-like macrocycles which possess a hydrophobic cavity of definite size and which permit the formation of stoichiometric inclusion complexes with apolar substrates in aqueous solution at room temperature at pH ≈ 7[2]. The key reaction in the synthesis of the novel host molecule **1** is the cyclization of two equivalents each of **7** and **8** to the macrocycle **9**, which proceeds in 18% yield; **1** is obtained in good yield after four subsequent steps[3]. Over the range $2\times10^{-4}$—$7\times10^{-3}$ M, the $^1$H-NMR signals of **1** in $D_2O$ (303 K, see Table 1) are independent of concentration and are highly resolved. The critical micellar concentration (CMC) of **1** in water was found to be $7.5\times10^{-3}$ M by $^1$H-NMR spectroscopy.



If a suspension of solid pyrene prepared by ultrasonification is stirred or shaken with a $2\times10^{-5}$ M aqueous solution of **1** and then centrifuged and filtered, the solution exhibits the intense fluorescence of monomeric pyrene.

In this solid-liquid extraction an inclusion complex between pyrene and **1**, which possesses a hydrophobic cavity of complementary size, is formed. A solution of **13** (with smaller cavity) is considerably less effective. A $2\times10^{-5}$ M solution of γ-cyclodextrin has an even weaker effect, and a $2\times10^{-4}$ M solution of **12** produces no increase in fluorescence intensity compared to the extraction with water.

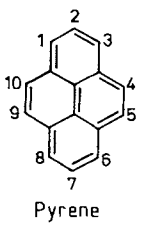
Aqueous solutions of the complex of **1**-pyrene can also be prepared by liquid-liquid extraction: *e.g.* a $10^{-2}$ M solution of pyrene in *n*-heptane is shaken with a $2\times10^{-5}$ M aqueous solution of **1**.

Multiple extraction of an aqueous solution of the **1**-pyrene complex with *n*-hexane results in quantitative transfer of pyrene into the organic phase; the concentration of **1** before complex formation can be determined from the absorption spectrum of the aqueous phase. The concentration of the complex is obtained from the concentration of pyrene in the organic phase on consideration of the solubility of pyrene in water[10]. Using a $5.5\times10^{-3}$ M solution of **1**, a concentration of complex of $2.9\times10^{-3}$ M was achieved.

Evidence for the 1:1-stoichiometry and information about the geometry of the **1**-pyrene complex in aqueous solution were obtained by $^1$H-NMR spectroscopy (Table 1). The large difference in chemical shift between the solution of the complex and the solutions of the components can best be explained by the following favored geometry of the complex: the long pyrene $C_2$-axis through C(2) and C(7) lies along the direction of the $C_2$-axis passing through the cavity of **1** perpendicular to the mean molecular plane.

*A:* KOH, [18]crown-6, tetrahydrofuran, 48 h, 65°C, 18%; *B:* 1) NaOH, $CH_3OCH_2CH_2OH$, 124°C, 85%; 2) HCHO, HCOOH, 100°C, 91%; 3) $FSO_3CH_3$, $CHCl_3$, 25°C, 82%; 4) Dowex 1×8 $Cl^\ominus$, 79%.

Pyrene only then fits completely into the cavity if its short $C_2$-axis, which intersects the C(4)—C(5) and C(9)—C(10) bonds, runs in the direction of the $C_2$-axis of **1** through the spiro carbon atoms of the two diphenylmethane moieties. In this way, H-2,7 of pyrene project out of the cavity and are shifted to the smallest extent; in contrast, H-1,3,6,8 and H-4,5,9,10 are directed towards the diphenylmethane moieties and are shifted markedly to high field.



The proposed geometry for the complex is corroborated by the low-field shift of the protons of **1** in the pyrene molecular plane and by the high-field shift of the protons perpendicular to this plane. The unexpected high-field shift of H-2′ and N(1′)—$CH_3$ can be explained by the conformational mobility of the $C_5$ bridges bearing the piperidinium

**13**

rings which, favored by additional hydrophobic interactions, can approach the pyrene. In contrast to the highly resolved pyrene signals between 273 and 353 K, the signals of **1** in the complex are very broad below 333 K. This probably arises from the exchange of pyrene on the $^1$H-NMR time scale with the host molecules present in excess[16].

By analogy, inclusion complexes were prepared from **1** and water-insoluble aromatic hydrocarbons such as perylene, fluoranthene, naphthalene, and durene. $^1$H-NMR and optical spectra confirm the results obtained from the complexation of pyrene.

[3] Correct analytical results and appropriate spectra were obtained for these compounds.
[10] A $8 \times 10^{-7}$ M (0.162 mg/L) aqueous solution of pyrene can be prepared at room temperature using the method described; this value, obtained photometrically, is completely consistent with the literature data: H. B. Klevens, *J. Phys. Chem. 54* (1950) 283; W. W. Davis, M. E. Krahl, G. H. A. Clowes, *J. Am. Chem. Soc. 64* (1942) 108.
[16] The $^1$H-NMR experiment was performed using a similar concentration ratio [**1**]:[pyrene] and a concentration of complex of $5.5 \times 10^{-5}$ M (303 K); here, almost identical chemical shifts (e.g. of the pyrene protons at $\delta$ = 7.57, 7.19, and 6.95) and similar line widths for the signals of **1** are obtained—an important piece of evidence for the same complex form at concentrations below the CMC of **1**.

## Synthesis and Reactions of $\eta^5$-Cyclopentadienylbis(ethene)cobalt

By *Klaus Jonas**, *Etienne Deffense*, and *Dietrich Habermann*

Metallocenes react with alkali metals and olefins, with elimination of alkali-metal cyclopentadienides, to give transition metal-olefin or alkali metal-transition metal-olefin complexes[3]. Thus, reaction of cobaltocene ($Cp_2Co$) with potassium and ethene in diethyl ether leads to formation of the bis(ethene) complex **1**.

$$Cp_2Co + K + 2C_2H_4 \xrightarrow[-20 \text{ to } 0\,^\circ C]{Et_2O} \underset{\mathbf{1}}{CpCo(C_2H_4)_2} + KCp$$

This unusually facile entry to **1** (one-step synthesis, yield 85%), whose ethene ligands are readily replaceable, makes **1** a very useful starting material in organometallic chemistry (*cf.* Supplement). Of particular interest are the reactions of **1** with alkynes or nitriles since, with $CpCo(CO)_2$ or $CpCo(C_8H_{12})$ at temperatures $>100\,^\circ C$, cobalt-catalyzed alkyne cyclotrimerization[25] or cocyclization of alkynes and nitriles to afford pyridine derivatives occurs[26].

At $-10\,^\circ C$, **1** reacts with 2-butyne in *n*-hexane to afford a new deep-red complex, which can be recrystallized from boiling *n*-hexane, and which, according to the elemental analysis and mass spectrum, has the composition **9**.

$$\underset{\mathbf{1}}{CpCo(C_2H_4)_2} + 3\,C_2(CH_3)_2 \xrightarrow[-10\,^\circ C]{n\text{-}C_6H_{14}} \underset{\mathbf{9}}{CpCo\{C_6(CH_3)_6\}} + 2C_2H_4$$

The product **9** (yield 46%) was investigated crystallographically but, because of disorder in the crystal lattice, an accurate description of the molecular geometry could not be obtained. However, these results indicate that the cobalt atom in **9** is sandwiched between a cyclopentadienyl ring and a hexamethylbenzene ring[18]. The magnetic moment, $\mu_{eff} = 2.85\,\mu_B$, of solid **9** is almost exactly that expected for two unpaired electrons according to the spin-only formula. We assume, therefore, that **9** exists as $\eta^5$-$C_5H_5Co$-$\eta^6$-$C_6(CH_3)_6$, which is isoelectronic with the cation of $[\{C_6(CH_3)_6\}_2Co]PF_6$[27], and in which the krypton electronic configuration is exceeded by two electrons. This probably accounts for the ease of displacement of the hexamethylbenzene ligand, *e.g.*, with CO, and why **9** is the first reported $(C_5H_5)Co$-compound that can catalyze the cyclotrimerization of alkynes and cocyclization of alkynes and nitriles at *room temperature*.

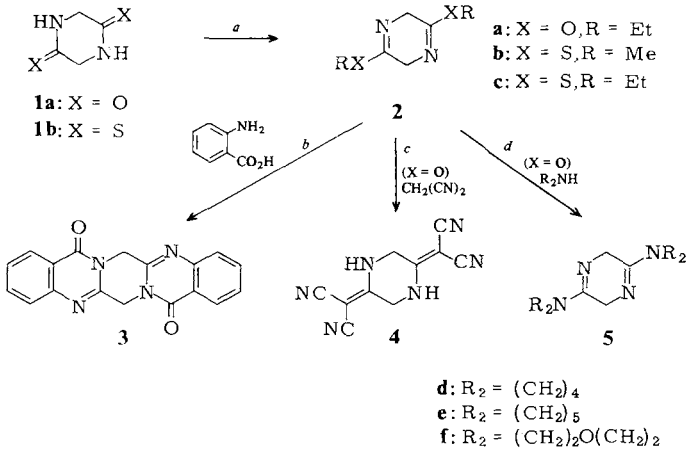
## Diazaquinodimethanes, Donor-Substituted Pyrazines, and Dihydropyrazines**

By *Rudolf Gompper** and *Walter Breitschaft*



*Dedicated to Professor Harald Jensen on the occasion of his 60th birthday*

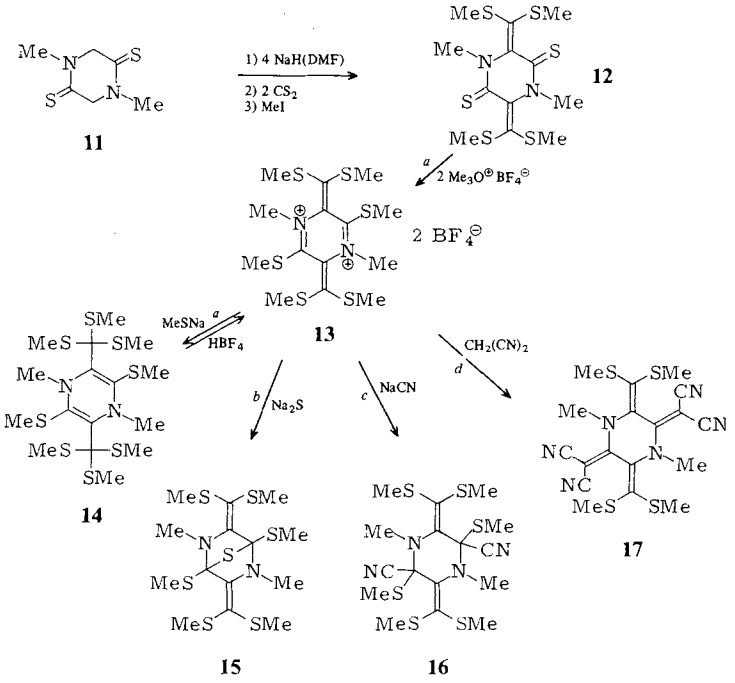
Previously, the influence of ring N-atoms on the properties of quinodimethanes has only been studied with azaquinodimethanes[1a]. With one exception[2a], diazaquinodimethanes have not yet been described. Since diethoxydihydropyrazines can be converted into carbanions[2b], it might be expected that compounds of this type and aryl- and pyridylmalononitriles[1] would react with cyclic carbenium salts to afford diazoquinodimethanes.

The syntheses start from the dihydropyrazines **2** [by analogy to the formation of **2a** from **1a**[3], **2b,c** can be prepared from **1b**; **2b**: yield 77%, m.p. = 103–104 °C; **2c**: 63%, b.p. = 150 °C/0.01 torr, m.p. = 30–32 °C]. The diaminodihydropyrazines **5** are formed from **2a** on reaction with secondary amines [**5d**: 78%, m.p. = 143–144 °C (decomp.); **5e**: 52%, decomp. above 126 °C; **5f**: 48%, m.p. = 165.5 °C (decomp.)]. In the presence of anthranilic acid as the amine component the sparingly soluble 7,15-dihydropyrazino[2,1-*b*:5,4-*b'*]-diquinazoline-5,13-dione **3** [54%, ocher-colored platelets, m.p. = 298 °C] is obtained from **2a,b**. The structure type **3** also occurs in the piperazine derivative **4** (m.p. > 300 °C), which forms almost quantitatively from **2a** and malononitrile. The desired diazaquinodimethanes **6**, which correspond to the bis(ethylenedithio)-*p*-quinodimethanes[4], are formed by reaction of **2** with 2-methylthio-1,3-dithiolanylium methyl sulfate [**6a**: 43%, yellow needles, m.p. = 218–219 °C; **6b**: 21%, orange needles, m.p. = 285 °C (decomp.)]. — Addition of tetrafluoroboric acid-ether to **6a** yields the bis(tetrafluoroborate) of **6a** as a brick-red powder.

*a*: AcOH-pyridine, Δ, 30 min; *b*: 1) 2*n*BuLi, THF, −78 °C, 2) $CS_2$, 3) MeI, −78→25 °C; *c*: chloranil, toluene, Δ, 3 h; *d*: 1) *n*BuLi, THF, −78 °C, 2) PhCHO, 3) AcOH, −78→25 °C, 4) 150 °C/0.01 bar or benzene, TosOH, Δ; *e*: 130 °C, 1 h.

*a*: 1) $R_3O^{\oplus}BF_4^{\ominus}$, $CH_2Cl_2$, Δ, 3 d, 2) $Na_2HPO_4/NaH_2PO_4$, $H_2O$; *b*: 150–200 °C, 1 h; *c*: 120 °C, 1 h; *d*: $CHCl_3$, toluene or xylene, Δ, 15–60 h.

3-Dimethylaminomethyl-2,5-bis(methylthio)pyrazine **10** [42%, yellow oil, b.p. = 170/0.01 torr] is formed upon heating **2b** with *N,N*-dimethylformamide diethyl acetal in dimethylformamide. Apparently, the CH-acidity of **10** is insufficient to cause further reaction to a quinodimethane such as **6**. Also the action of carbon disulfide on the Li salt of **2b** results only in formation of a monoadduct. Methylation of the latter affords 3-[bis(methylthio)methyl]-2,5-bis(methylthio)pyrazine **7** [39%, m.p. = 77–78 °C]. Reaction of the Li salt of **2b** with benzaldehyde proceeds similarly. The 1:1-adduct (not isolated, cf.[3]) formed after hydrolysis can be converted into 3-benzyl-2,5-bis(methylthio)pyrazine **9** (44%, m.p. = 56.5–58.5 °C).



The new compounds **7**, **9**, and **10** are to be considered as electron-rich pyrazines. Further compounds of the general type **8** can be prepared, by analogy to the oxidation of **2a**[3], by heating **2b** and **5d–f** with chloranil in toluene [**8b**: 42%, pale yellow needles, m.p. = 105–107 °C; **8d**: 52%, m.p. = 172.5–173 °C; **8e**: 16%, m.p. = 123–123.5 °C; **8f**: 70%, m.p. = 182–182.5 °C].

The electron acceptor properties of **6** should be increased by twofold quaternization. **6**, however, does not react with alkylating agents. We, therefore, prepared the ketene thioacetal **12** [59%, orange rhomohedra,

Institut für Organische Chemie der Universität
Karlstrasse 23, D-8000 München 2 (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemische Industrie.

m.p. = 123—125 °C] from **11**. **12** reacts with trimethyloxonium tetrafluoroborate to yield 3,6-bis[bis(methylthio)methylene]-1,4-dimethyl-2,5-bis(methylthio)3,6-dihydropyrazindium bis(tetrafluoroborate) **13** [83%, orange needles, blackens above 225 °C; UV/VIS ($CH_3CN$): $\lambda_{max}$ (lg $\varepsilon$) = 205 (4.15), 300 (sh, 4.09), 447 nm (4.21)].

*a*: $CH_2Cl_2$, 25 °C, 15 h; *b*: $CH_2Cl_2/H_2O$, 25 °C, 2 h; *c*: $CH_3CN$, 25 °C, 15 h; *d*: pyridine, Δ, 1 h.

**13** contains two ambifunctional azaallyl cation moieties. Heating with malononitrile in pyridine gives the tetrakis(methylene)piperazine derivative **17** [80%, yellow needles, m.p. = 189.5—191 °C; UV/VIS ($CH_3CN$): $\lambda_{max}$ (lg $\varepsilon$) = 225 (4.10), 274 (4.30), 360 nm (4.40)], and this is the product expected from the charge distribution in **13**. The site at which malononitrile attacks the C atom of the C=N bonds is confirmed by the fact that the salt obtained from **12** and triethyloxonium fluoroborate also reacts with malononitrile to afford **17**. In the same way, **13** reacts with sodium cyanide and sodium sulfide to yield **16** [29%, m.p. = 162.5—163 °C] and the episulfide **15** [57%, m.p. = 170.5—171 °C (decomp.)], respectively, which is interesting *inter alia* because of its structural relationship with the 3,6-epithio-2,5-piperazinediones (cf.[5]).

Remarkably, sodium methanethiolate reacts with **13** to give the dihydropyrazine **14** [66%, pale yellow parallelepipeds (from hexane), m.p. = 136—137.5 °C]. In view of the formal antiaromaticity of **14** (cf.[6]), which represents a novel type of stable dihydropyrazines, its great tendency to form is striking. Addition of tetrafluoroboric acid-ether to a solution of **14** in dichloromethane leads to re-formation of **13**.

## Photochemistry of Previtamin $D_3$ at 92 K: Formation of an Unstable Tachysterol$_3$ Rotamer**

By *Paul A. Maessen, Harry J. C. Jacobs*, Jan Cornelisse,* and *Egbert Havinga*

*Dedicated to Professor G. O. Schenck on the occasion of his 70th birthday*

The principle of non-equilibration of excited rotamers (NEER)[2] predicts that on irradiation of previtamin $D_3$(P) (at least) two species are generated, *tZc*-P* and *cZc*-P*, each of which yields its specific assortment of photoproducts. As products of *cis/trans*-isomerization, one expects the formation of the *tEc* and *cEc* rotamers of tachysterol$_3$ (T) from *tZc*-P* and *cZc*-P*, respectively (Fig. 1+2).

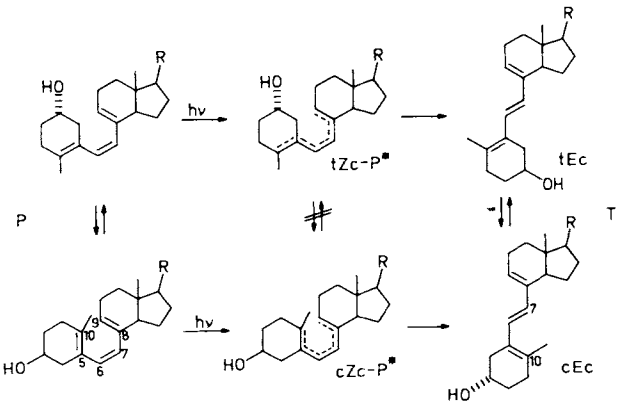

Fig. 1+2 (extract). Non-equilibration of excited rotamers (P*) and photochemical *cis/trans* isomerization of previtamin $D_3$(P) and tachysterol$_3$ (T). R = $CH(CH_3)(CH_2)_3CH(CH_3)_2$.

The *cEc* rotamer, which is destabilized by steric interaction between 10-$CH_3$ and 7-H, can be observed only when the conversion into the more stable *tEc* and *tEt* rotamers is impeded. We, therefore, turned our attention to low-temperature irradiation, and monitored the reaction by UV and CD spectroscopy.

At temperatures down to 125 K the irradiation of previtamin $D_3$ appears to proceed essentially as observed at room temperature, the rapid formation of tachysterol$_3$ being indicated by the characteristic UV[5] and CD absorption spectra. A different behavior is manifest when the ir-

[*] Dr. H. J. C. Jacobs, Dr. P. A. Maessen, Prof. Dr. J. Cornelisse, Prof. Dr. E. Havinga

[**] Studies of Vitamin D and Related Compounds, Part 30.—Part 29: [1].

radiation is conducted at 92 K. Irradiation in ether/isopentane/alcohol 5:5:1 (EPA) solution (Fig. 4) produces a species exhibiting a broad, almost structureless absorption band that is red-shifted relative to the absorption of previtamin $D_3$ and tachysterol$_3$. The Cotton effect is large and negative.

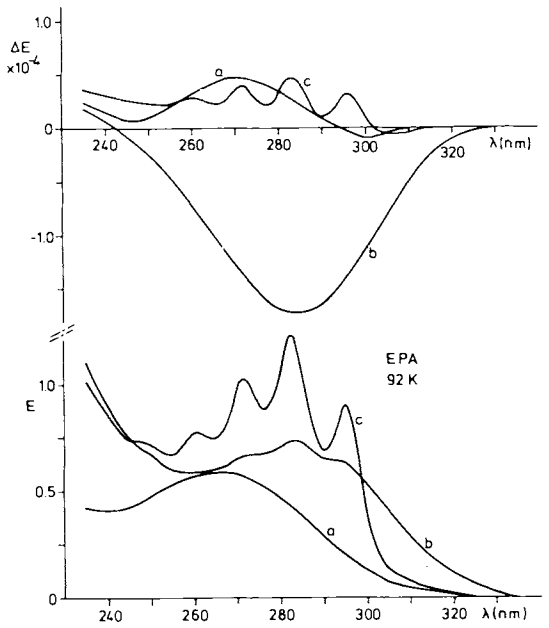

Fig. 4. UV and CD spectra of previtamin $D_3$ (EPA, 92 K). a) Before irradiation; b) after irradiation for 1 to 3 min; c) after irradiation for 1 to 3 min the mixture is warmed to 105 K and then cooled to 92 K.

The spectra remain the same as long as the solution is kept at 92 K in the dark; however, on warming the sample to 100—105 K in the dark, the spectra slowly change and take on the appearance of those of tachysterol$_3$ obtained by irradiation at 125 K. Irradiation at 92 K in the less viscous methylcyclohexane/isopentane 1:5 (MIP) solution proceeds similarly, but the intermediate is less stable and is gradually converted into tachysterol$_3$ upon standing in the dark at 92 K. From the rate of disappearance a free energy of activation of 27 kJ mol$^{-1}$ (6.5 kcal mol$^{-1}$) ± 10% is calculated for the decay process.

The intensity and $\lambda_{max}$ of the UV and CD spectra suggest a conjugated triene; the configuration of the central double bond must be *trans*, since only a low energy barrier separates the intermediate from the *E*-triene tachysterol$_3$. We therefore identify the transient species with the higher-energy *cEc* rotamer of tachysterol$_3$. The activation energy includes a viscosity-dependent contribution, whose value is an upper limit for the intrinsic barrier to twisting about the single bond. It compares favorably with the energy barrier separating s-*cis*- from s-*trans*-butadiene (3.9 kcal mol$^{-1}$)[9]. Similarly, the difference in the UV absorption curves b and c (Fig. 4) corresponds to the change observed upon conversion of s-*cis*- to s-*trans*-butadiene[9].

We note that apart from cyclization *cis/trans* isomerization apparently is an important pathway of relaxation for an excited *cZc* triene. Furthermore, the formation of the *cEc* rotamer as a primary photoproduct in the *cis/trans* isomerization nicely illustrates the operation of the NEER principle in the photochemistry of conjugated polyenes.

## Regiocontrolled Prenylations and Alkylations of Furans: Preparation of Rosefuran and Novel Analogues**

By *Zeinhom M. Ismail* and *H. M. R. Hoffmann**

Friedel-Crafts alkylation is one of the most important reactions undergone by aromatic rings. In contrast, heteroaromatic systems have been studied less. We have previously obtained a variety of 2-allylfurans by silver-ion promoted heterolysis of allylic iodides in the presence of furans[2], and related work has been reported by other groups[3]. Using improved methodology for generating electrophilic carbon intermediates[4], we now describe novel alkylations of furans **1a**, **b**. It turns out that prenylation[5] of 3-methylfuran **1a** is feasible in one step without polymerization to give rosefuran **3** and the previously unknown isomer **4** (Table 1).

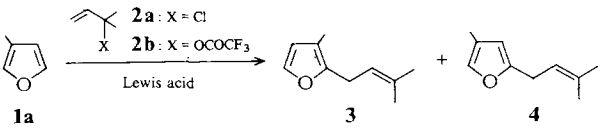

Table 1. Preparation of rosefuran **3** and its isomer (**4**) *via* prenylation of 3-methylfuran **1a**.

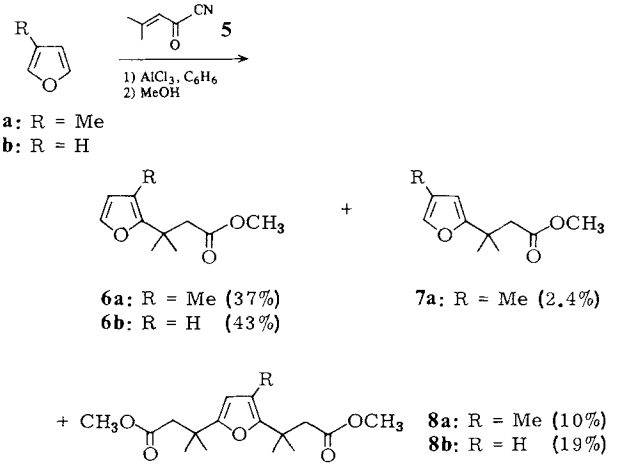
| No. | Experimental Conditions | Ratio 3 : 4 | Yield [%] 3 + 4 |
|---|---|---|---|
| 1 | **2a** [a], $AgOCOCF_3$, pentane, RT, 17 h | 80 : 20 | 5 [b] |
| 2 | **2a**, $ZnCl_2 \cdot Et_2O$ [c], $CH_2Cl_2$, −40 °C, 1 h | 80 : 20 | 30 [d] |
| 3 | **2b**, $ZnI_2$, $CH_2Cl_2$, reflux, 2 h | 74 : 26 [e] | 73 |
| 4 | **2b**, $ZnI_2$, $CH_2Cl_2$, RT, 18 h | 89 : 11 [e] | 73 |

[a] A. J. Ultée, *J. Chem. Soc. 1948*, 530. [b] Conversion of 3-methylfuran **1a** was very low, and most of **1a** was recovered. Polymerization of products was not observed. [c] See [5a]. [d] Unidentified products with longer GC retention time were formed also. When the reaction was carried out at room temperature for 10 min, the conversion (**3** + **4**) was 17% (GC). Longer reaction times gave tarry material. [e] Product ratios determined by GC and, independently, by $^1$H-NMR.



Initial experiments with **2a** and silver trifluoroacetate led to **3** and **4** in low yields (5% after 17 h; cf. Table 1, No.
